The carbon-13 NMR spectra of *n*-pentane were measured by means of a Japan Electron Optics Laboratory JEOL PS-100-type spectrometer at 25.15 MHz, at −60 and 22°C, using a 8 mm sample tube and the multiple-scan-average technique. Cyclohexane was used as the external referencee.

Calculation

From the molecular orbital theory[3-5] of nuclear spin-spin coupling constants, it can be shown that, if the Fermi contact term dominates the spin-spin coupling interaction, the magnitude of the coupling constant between directly-bonded nuclei should show a direct dependence on the amount of *s* character in the bond between them as follows:

$$J_{C-H} = \left(\frac{4}{3}\right)^2 h\beta^2\gamma_C\gamma_H(\Delta E)^{-1}(1s_H|\delta|1s_H)(2s_C|\delta|2s_C)P^2_{C-H} \quad (1)$$

where β is the Bohr magneton; γ_X, the nuclear magnetogyric ratio of the X atom; ΔE, the average excitation energy; $(1s_H|\delta|1s_H)$ and $(2s_C|\delta|2s_C)$, the one-electron integrals at the hydrogen and carbon nuclei respectively, and P_{C-H}, the carbon 2*s*-hydrogen 1*s* element of the bond-order matrix. Moreover, when 0.550 and 2.767 a.u.[22] are used as $(1s_H|\delta|1s_H)$ and $(2s_C|\delta|2s_C)$ respectively, Eq. (1) can be simply rewritten as follows:

$$J_{C-H} = 7885(\Delta E)^{-1}P^2_{C-H}\,(\text{Hz}) \quad (2)$$

If the value of ΔE is a constant for each carbon of *n*-pentane, J_{C-H} should be proportional to P^2_{C-H}. Here, the bond orders were calculated using the CNDO/2 method.

Among the nine rotational isomers, *n*-pentane can take seven preferred rotational isomers, the TT, TG, TG′, GT, G′T, GG, and G′G′ forms, but for the GG′ and G′G forms, which are at any rate, negligible because of their steric hindrances. The rotational isomeric states of *trans* (T) and *gauche* (G and G′) are defined as occurring at the rotational angles of 0, 120, and 240° respectively by means of the clockwise rotation around the C–C bond expressed in the Newman projection.

We numbered the carbon atoms in pentane as follows:

$$CH_3(1)\text{-}CH_2(2)\text{-}CH_2(3)\text{-}CH_2(2)\text{-}CH_3(1)$$

The C–C and C–H bond lengths are set as 1.54 Å and 1.10 Å respectively, and both the C–C–C and C–C–H bond angles are set at 109°28′.[23]

The numerical calculations were carried out by means of the HITAC-5020E of the Computer Center of the University of Tokyo.

Results and Discussion

The carbon-13 NMR spectrum of *n*-pentane observed at 22°C is shown in Fig. 1, where a quartet and two triplets are identified as $CH_3(1)$, $CH_2(2)$, and $CH_2(3)$ carbons respectively with a decrease in the field. Then, the directly-bonded carbon-hydrogen coupling constants (J_{C-H}) were obtained; they are shown in Table 1, including those values observed at −60°C. From these results, it was found that the J_{C-H} value of the $CH_3(1)$ is larger than that of the $CH_2(2)$ or $CH_2(3)$, and that the $CH_2(2)$ is slightly larger than the $CH_2(3)$, but no value of J_{C-H} depends upon the temperature.

Next, the calculated values of P^2_{C-H} of seven rotational isomers in *n*-pentane are shown in Table 2, which also gives those values averaged by the populations of these rotational isomers using the following formula:

$$P^2_{C-H_{AV}} = \sum_{i=1}^{7} X_i P^2_{C-H_i} \quad (3)$$

where;

$$X_i = e^{-\Delta E_i/RT} \Big/ \sum_{i=1}^{7} e^{-\Delta E_i/RT} \quad (4)$$

Calculated[b]			
ΔE=10 eV			
−60°C	189.5	184.6	182.0
22°C	189.5	184.6	182.1
ΔE=14.8 eV			
−60°C	127.8	124.7	122.9
22°C	127.8	124.7	123.1

a) Averaged using the four data.
b) Calculated using 570 cal/mol as ΔEg.

Table 2. The calculated values of P^2_{C-H} in the preferred isomers and those averaged over the isomers in *n*- pentane

Conformations	P^2_{C-H}		
	$CH_3(1)$	$CH_2(2)$	$CH_2(3)$
TT	0.240	0.232	0.232
TG	0.240	0.231	0.230
TG′	0.240	0.231	0.230
GT	0.240	0.242	0.231
G′T	0.240	0.242	0.231
GG	0.240	0.229	0.228
G′G′	0.240	0.229	0.228
Averaged			
(a)	0.240	0.234_0	0.230_8
(b)	0.240	0.234_1	0.231_0

a) Averaged using 570 cal/mol as ΔE at −60°C.
b) Averaged using 570 cal/mol as ΔE at 22°C.

Here, $P^2_{C-H_i}$ is the square of the carbon 2*s*-hydrogen 1*S* element of the bond-order matrix, X_i, the fraction of the *i*-th isomer: ΔE_i, the energy difference between the TT and the *i*-th isomer; *R*, the gas constant, and

22) N. Muller and D. T. Carr, *J. Phys. Chem.*, **67**, 112 (1963).
23) L. Pauling, "Nature of Chemical Bond," Cornell University Press (1960).

T, the absolute temperature. Then, from Eqs. (2) and (3), the spin-spin coupling constant ($J_{C-H_{Av}}$) averaged by the populations of the rotational isomers is expressed as follows:

$$J_{C-H_{Av}} = \sum_{i=1}^{7} X_i J_{C-H_i}$$

$$= \frac{7885}{\Delta E} \sum X_i P^2_{C-H_i}$$

$$= \frac{7885}{\Delta E} \cdot P^2_{C-H_{Av}} \text{ (Hz)} \quad (5)$$

where J_{C-H_i} is the spin-spin coupling constant of the i-th isomer. We have reported that the observed temperature dependence of the proton chemical shift of n-pentane can be better interpreted by 570 cal/mol as the energy difference (ΔEg) between the *trans* and *gauche* conformations.[24] Thus, 570 cal/mol was used as the ΔEg value of used in our calculations.[25]

The values of $J_{C-H_{Av}}$ calculated using 570 cal/mol as ΔEg are shown in Table 1. Since there is no definite value for the average excitation energy (ΔE) for n-pentane, we at first tried to use 10 eV for ΔE; this value was originally used by Pople[26] in the calculation of the C-13 chemical shift of ethane. The calculations were found to give much larger values than those observed. Then, as the observed values scarcely seem to depend upon the temperature, we determined ΔE using the method of least squares in such a way that the best agreement was between the calculated and observed values of J_{C-H} at -60 and 22°C; we found it to be 14.8 ± 0.06 eV. By substituting this value into Eq. (5), $J_{C-H_{Av}}$ is expresses as:

$$J_{C-H_{Av}} = 533 P^2_{C-H_{Av}} \quad (6)$$

The plots of the observed J_{C-H} value against $P^2_{C-H_{Av}}$ are shown in Fig. 2. It was found that the J_{C-H} values of $CH_3(1)$, $CH_2(2)$, and $CH_2(3)$ are well proportional to those of P^2_{C-H}, calculated using 14.8 eV as ΔE. The solid line is the theoretical one obtained from Eq. (6). The scattering of the observed values from the theoretical line is found to be very small.

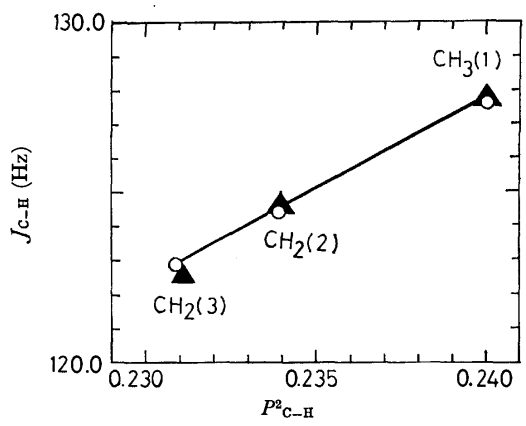

Fig. 2. The plots of the observed J_{C-H} against the $P_{C-H}{}^2$ in n-pentane. The solid line was calculated using Eq. (6). ○: observed at −60°C, ▲: observed at 22°C

As shown in Table 1, the temperature dependence of the values of J_{C-H} is not significant. Also, the calculated values of J_{C-H} depend scarcely at all upon the temperature, because the averaged values of P^2_{C-H} are not so sensitive to the temperature. However, this do not mean that it is not necessary to take the preferred conformations into account in the calculation of J_{C-H}. If the *trans* form is assumed to be the only conformation of n-pentane, the P^2_{C-H} values the $CH_2(2)$ and $CH_2(3)$ groups become equal to each other; therefore, the calculated and observed values of J_{C-H} do not agree with each other (the proportionality between J_{C-H} and P^2_{C-H} does not hold.). Thus, it is necessary to take the rotational isomers into account in order to obtain a better agreement with the observed and calculated results.

As has been described above, the same value, 14.8 eV, was used as ΔE for all the calculations of the J_{C-H} values of the methyl and methylene carbons in the preferred isomers; it was found to explain the experimental values reasonably well. However, there is a possibility that the ΔE values among the preferred isomer and among the carbons in a isomer differ from one another. Thus there remains some question about concluding 14.8 eV to be the ΔE of n-pentane. We will later treat with this problem in association with the carbon-13 chemical shifts of n-pentane.

Far-infrared Spectra of Zinc Halide Complexes with Acetonitrile

Tomoichi KAMO and Masao KIMURA

Department of Chemistry, Faculty of Science Hokkaido University, Sapporo

(Received February 28, 1972)

The infrared spectra of zinc halide complexes with acetonitrile, $ZnX_2 \cdot 2CH_3CN$ (X=Cl, Br, I), in the solid state were recorded in the region from 4000 to 96 cm^{-1}. The Zn–N stretching bands for the chloride and bromide were observed, at 210 and 212 cm^{-1} respectively, as composite bands of the A_1 and B_1 species. For the iodide, the Zn–N stretching band of the B_1 species was observed at 219 cm^{-1}, while the A_1 mode was coupled with the Zn–I stretching mode and was absorbed at 252 and 179 cm^{-1}. The N–Zn–N bending bands were observed at 163, 162, and 153 cm^{-1} and the Zn–N≡C bending bands, at 125, 128, and 132 cm^{-1}, for the chloride, bromide, and iodide respectively. The normal coordinate analysis was carried out by the use of the Urey-Bradley force field, and the Zn–N stretching force constant was obtained as 0.56 mdyn/Å. The force constant is much smaller than the corresponding ones in complexes containing nitrogen donors in the sp^3 and the sp^2 valency states.

It has been known that nitriles react with many metal halides to form σ-complexes by donating the lone-pair electron of the nitrogen atom.[1] The metal-nitrogen bonds in these complexes have generally been considered to be very weak, since the electron-donating ability of the nitrogen atoms in alkyl cyanides is weaker than that in amines or imines.[1] Many investigators have been interested in the strength of these coordinate bonds and have studied the infrared spectra of nitrile complexes with metal halides.[1,2] However, the number of studies in which metal-nitrogen stretching bands are observed is rather limited.

Infrared studies suggesting weak metal-nitrogen bonds have been published of the complexes of acetonitrile with $SnCl_4$,[1,3-5] $ZnCl_2$,[6] and NbX_5 and TaX_5 (X= Cl and Br).[7] In these studies, the metal-nitrogen stretching vibrations, ν_{MN}, have been assigned bands below 225 cm^{-1}.[8] Besides, the spectra of acetonitrile complexes with Pd(II), Pt(II), and Rh(II) halides have been reported to have no band above 200 cm^{-1} which can be assigned unambiguously to ν_{MN}.[9]

In contrast to the studies mentioned above, relatively high frequencies for ν_{MN}, 650—400 cm^{-1}, have been reported for such cyanide complexes as $M(CO)_3 \cdot 3CH_3CN$ (M=Cr, Mo, and W),[10] $BX_3 \cdot CH_3CN$ (X= Cl, Br, and F),[11,12] $AlCl_3ClCN$,[13] and cyanopyridine·$MClO_4$ (M=Cu(I), Ag(I), and Au(I)).[14] However, these high frequencies may be considered to reflect the M–N bonds strengthened by the high electron affinities of the metals characteristic of the IIIb-element halides and the metal carbonyls,[10,11] or by the increased electron-donating ability of the ligand nitrogen due to the contribution of an ionic resonance structure.[14]

Thus, ordinary metal halide-alkyl cyanide complexes appear to have very weak coordinate bonds and to give rise to M–N stretching bands around 200 cm^{-1}. Yet, our information on the coordination of this type cannot be said to be sufficient. Although the spectrum of $ZnCl_2 \cdot 2CH_3CN$ in a CH_3CN solution has already been studied,[6,15] the spectra associated with the skeletal modes have not been analysed completely. In addition, a band at 174 cm^{-1} assigned to the ν_{MN} by Evans and Lo[6] has not been observed in the Raman spectrum by Addison *et al.*[15] In order to get a clear vision of the M–N bonds in nitrile complexes, it was thought necessary to reexamine the far-infrared spectra of $ZnX_2 \cdot 2CH_3CN$.

Experimental

The complexes, $ZnX_2 \cdot 2CH_3CN$ (X=Cl, Br, and I), were prepared in the following manner. A saturated solution of 99% pure zinc halide in dry acetonitrile was prepared in a dry box filled with dry nitrogen gas. After the undissolved portions had then been filtered off, the solvent was evaporated moderately with an aspirator until white crystals appeared. The crystals were then collected and dried over P_2O_5 for two days. The complexes were considerably stable in dry air, but they were readily decomposed by atmospheric water vapour.

Found for the chloride: Cl, 31.79%. Calcd for $ZnCl_2 \cdot 2CH_3CN$: Cl, 32.47%. Found for the bromide: Br, 52.32%. Calcd for $ZnBr_2 \cdot 2CH_3CN$: Br, 52.01%. Found for the iodide: I, 63.16%. Calcd for $ZnI_2 \cdot 2CH_3CN$: I, 63.25%.

The infrared spectra ranging from 4000 to 400 cm^{-1} for liquid acetonitrile and the complexes were observed with KBr plates on a JASCO IR-G infrared spectrophotometer while the spectra in the low-frequency region from 500 to 96 cm^{-1} were observed with polyethylene plates on a Hitachi

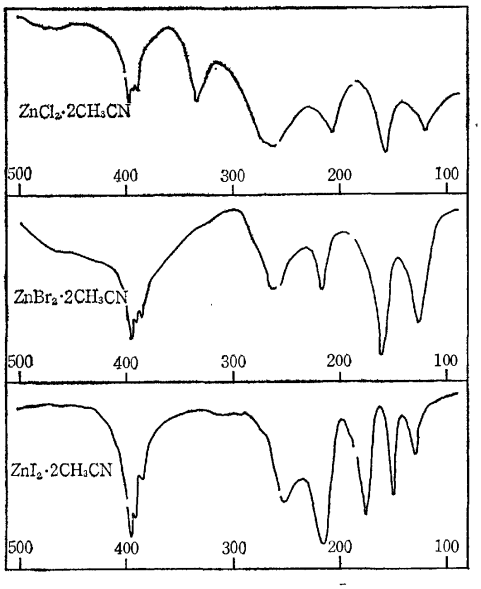

Fig. 1. Observed spectra of the complexes below 500 cm^{-1}.

FIS-21 far-infrared spectrophotometer. The mull method was empolyed for the solid samples. The observed frequencies associated with the ligand acetonitrile and the skeleton about the Zn atom are listed in Tables 1 and 2 respectively, while the spectra below 500 cm^{-1} are reproduced in Fig. 1.

Assignments

By considering the compositions of the samples and by referring to the structures of various zinc complexes previously determined,[16] it was assumed that these complexes have C_{2v} symmetry,[17] as other workers have done.[6,15] The infrared data for the complexes may be divided into intra-ligand and skeletal vibrational modes, which will be discussed separately.

Ligand Vibrations. The spectra of the complexed nitriles are very similar to one another and correspond very well with the spectra for uncomplexed acetonitrile except for the splittings of bands observed in the 2250, 1440, 1370, 920, and 380 cm^{-1} regions. If we consider that these splittings are caused by interaction between the two coordinated nitriles, the assignments of the observed bands to the intra-ligand vibrations can easily be made, as is shown in Table 1, by analogy with those for the free acetonitrile, which have been established

16) L. E. Sutton, "Tables of Interatomic Distances and Configuration in Molecules and Ions," the Chemical Society, London (1965).

17) According to the crystal structure analysis of $ZnCl_2 \cdot 2CH_3CN$ carried out by I. V. Isakov and Z. V. Zvonkova, *Doklady Akad. Nauk U. S. S. R.*, **145**, 801 (1962), this molecule has a distorted tetrahedral structure about the Zn atom with a symmetry very close to C_{2v}. The structure parameters calculated from the given atomic coordinates are as follows: $\angle$N≡C–CH_3 180°, $\angle$Zn–N≡C 111°, $\angle$ClZnCl 131°, $\angle$NZnN 101°, Zn–N 1.95 Å, Zn–Cl 2.18 Å, C–C 1.51 Å, and C≡N 1.12 Å.

by several workers.[15,18,19]

The similarities between the frequencies for the free and complexed acetonitriles suggest that these complexes are formed by a weak σ-bonding through the lone-pair electrons. The band splittings observed over the entire spectra of the complexes, especially the splitting of the C–C≡N bending vibration into three bands, are consistent with the presumed symmetry.

The C–C stretching, ν_{CC}, and the C–C≡N bending frequencies were observed higher by as much as 4—22 cm^{-1} and 23—33 cm^{-1} respectively than those observed for the free ligand. These high frequency shifts may be caused by the coupling of the ligand vibrations with the skeletal mode of the complexes. This interpretation is supported by the normal coordinate analysis, which will be described in a later section. The lowest frequency band in the region of the C≡N stretching vibration, ν_{CN}, for the complexes was observed as low as the C≡N stretching frequency for the free nitrile. Despite the fact that a high frequency shift of ν_{CN} is generally characteristic of coordination through the lone-pair electrons on the nitrogen atoms of nitriles,[1,20] we assigned the lowest frequency band to one of the two expected ν_{CN} bands and the highest frequency band at about 2300 cm^{-1} to a combination band. These assignments are different from the assignments made by Evans and Lo,[6] but they are in accordance with those made by Addison *et al.* except for the assignment of the 2250 cm^{-1} band.[15] This apparently unshifted absorption can be interpreted as being due to the Fermi resonance occurring between the ν_{CN} and the combination band of the symmetric CH_3 deformation, $s\delta_{CH_3}$, and ν_{CC}, as was suggested in the previous studies of the spectra for the free nitrile.[15,18,21] The combination band, *e.g.*, the $1375+918=2293$ cm^{-1} band for the chloride, is located at a higher frequency than the ν_{CN} for the free molecule. When the ν_{CN} is shifted towards a higher frequency upon coordination and approaches more closely to the combination band, the two bands may suffer the effect of the Fermi resonance more strongly. As a result, the combination band may be raised, and the stretching band may be lowered in frequency, more in the complexed state than in the free state.

In addition to the assignment of the ν_{CN} band, the present interpretation is also somewhat different with regard to the splitting bands from those reported by previous workers, who studied the Raman and infrared spectra of a zinc chloride solution in CH_3CN.[6,15] They attributed the observed splitting bands to the fundamental vibrations belonging to the complexed and the free nitrile. However, similar splittings, as observed even in the spectra of the crystalline sample, indicate that the splittings observed in the solution spectra can not simply be ascribed to the vibrations of the sample in different states.

Skeletal Vibrations of Complexes. For the sekleton, L_2ZnX_2, of these complexes, fifteen normal modes of vibration, $4A_1+4A_2+3B_1+4B_2$, can be expected, including the librational modes of the ligands, L. Here, the subscripts 1 and 2 are used with reference to the LZnL plane. Among them, the two normal modes corresponding to methyl torsions, A_2+B_2, will not be observed in infrared spectra. It follows that a total of ten fundamental bands are to be assigned. In view of the similarity in the ligand vibrations, it may be considered that these complexes are in similar electronic states, and that the force constants of the internal potentials have similar magnitudes for all the complexes. Accordingly, each of the vibrational modes associated with the nitrogen atoms can be expected to absorb at nearly the same frequency, independent of the particular halogen atoms, while the other modes involving the halogen atoms absorb at different frequencies from one complex to another. For the chloride and bromide, one can easily identify two groups of bands; the first is a group of the zinc-halogen stretching vibrations, which decrease in frequency as the halogen atoms change from Cl to Br, while the second group consists of three bands, at about 210, 160, and 130 cm^{-1}, which are unaltered in position by the substituents. The observed bands at 333 and 265 cm^{-1} for the chloride undoubtedly belong to the first group and were assigned to the antisymmetric and symmetric Zn–Cl stretching modes, $a\nu_{ZnCl}$ and $s\nu_{ZnCl}$, respectively. The corresponding band for the bromide is that observed at about 260 cm^{-1}, where the two modes seem to overlap. The bands belonging to the second group are related to the coordinated nitrogen atoms. The band at 210 cm^{-1} may be assigned to the Zn–N stretching modes, ν_{ZnN}, which belong to the A_1 and B_1 species. Of the two bands at about 160 and 130 cm^{-1}, the higher was assigned to the N–Zn–N bending mode, δ_{NZnN}, and the lower, to the Zn–N≡C bending mode, δ_{ZnNC}, since the latter mode corresponds to the librational mode of the ligand and is expected to absorb at a lower frequency. There exist three infrared active librational modes of the ligands. Of them, the two modes of the B_1 and B_2 species were considered to overlap at about 130 cm^{-1}, and the A_1 mode, to lie below the observed frequency limit. These assignments were ascertained by the normal coordinate treatment, which will be described later. The present assignment of ν_{ZnN} differs from that made by Evans and Lo. We found no band at 174 cm^{-1}, but observed a band at 163 cm^{-1} (see Fig. 1). This band was then assigned to the δ_{NZnN}, as has been mentioned above.

The identification of bands for the iodide is not so clear as that for the chloride and bromide. However, the spectra of the iodide may be explained as follows. Generally, bands related to the Zn–I stretching modes, ν_{ZnI}, in various zinc iodide complexes are known to be observed at about 220 cm^{-1},[22,23] a frequency nearly equal to those assigned to ν_{ZnN} for the chloride and

bromide. If this is the case for the present iodide, the ν_{ZnN} and ν_{ZnI} of the A_1 species would couple strongly with each other to result in a comparatively large splitting. Thus, we considered that the ν_{ZnN} and ν_{ZnI} of the A_1 species were split into bands at 252 and 179 cm^{-1}, while the B_1 and B_2 modes remained overlapped at 219 cm^{-1}, as is illustrated in Fig. 2. The band at 153 cm^{-1} for the iodide is slightly lower in position than the corresponding bands for the chloride and bromide, at 163 and 162 cm^{-1} respectively, which were assigned to δ_{NZnN}. This slight lowering in frequency for the iodide is probably due to a coupling of this bending mode with the ν_{ZnI} of the A_1 species. All the bands for $ZnI_2 \cdot 2CH_3CN$ can thus be interpreted successfully by assigning the bands near 210 cm^{-1} to the ν_{ZnN} of the chloride and bromide, and by considering the iodide to have a similar Zn-N coordinate bond. The assignments made for the skeletal modes are shown in Table 2.

Normal Coordinate Analysis

The normal coordinate analyses by the *G-F* matrix method were carried out in order to confirm these assignments and estimate the bond strength between the zinc atom and the ligand. The structure of $ZnCl_2 \cdot 2CH_3CN$ has been reported by Isakov and Zvonkova to have a distorted tetrahedral structure about the Zn atom, with a linear C-C≡N frame and specifically with a Zn-N≡C angle of 111°, a value considerably less than 180°.[17] The nonlinearity of a metal-N≡C system has been reported for the addition compounds of $CuCl_2$ and CH_3CN ($\angle CuNC = 160°$),[24] while the linearity of some metal-N≡C-C systems has been confirmed by X-ray structure analyses for nitrile complexes, such as $SnCl_5 \cdot CH_3CN$[25] and $BX_3 \cdot CH_3CN$.[26] It is probable that the metal-N≡C system is not linear in the crystalline state. However, whether or not such an angle as small as 111° is real in $ZnCl_2 \cdot 2CH_3CN$ will require further investigation. Since all the spectral evidence supports the idea that the C≡N triple bond, advantageous to forming a linear linkage, is virtually retained in the present complexes, in our calculations we did not adopt the results of the crystal structure analysis, but, rather, preferred the following assumed molecular geometry. The structure of a free nitrile as determined by microwave spectroscopy was employed for the ligands.[27] The Zn-N≡C angle was assumed to be 180°, as in previous normal coordinate analyses of nitrile complexes,[6,7,13] and the other valency angles about the Zn atom were assumed to be tetrahedral angles, 109.5°. The Zn-N distance was assumed to be 2.00 Å, and the Zn-X distances, to be 2.30, 2.38, and 2.48 Å for Cl, Br, and I respectively, referring to the literature on several zinc halide complexes.[16]

The complexes are expected to undergo thirty-nine normal modes of vibration, $13A_1+7A_2+11B_1+8B_2$, among which the two torsional vibrations of the methyl groups, A_2+B_2, were not treated because the torsional force constant could be considered to be nearly zero.

A force field of the modified Urey-Bradley type was used:

$$2V = \sum_{ij} K_{ij}(\Delta r_{ij})^2 + \sum_{ij} H_{ij} r_i^0 r_j^0 (\Delta\alpha_{ij})^2 + \sum_{ij} F_{ij}(\Delta q_{ij})^2 + \sum_{ij} F'_{ij} q_{ij}^0 (\Delta q_{ij}) + \kappa(\text{methyl}) + f(\Delta\alpha_{ZnNC} \cdot \Delta\alpha_{NCC})$$

where κ is the force constant for the internal tension of the valence angles of the methyl group and where f is the force constant for the interaction between the Zn-N≡C bending and the C-C≡N bending. The internal tension about the Zn atom was not introduced into the force field, since the bands corresponding to the skeletal deformation modes were not observed. The force constants for the ligand were determined so as to reproduce the observed frequencies for the liquid acetonitrile listed in Table 1, by starting with the force constants of the Urey-Bradley force field determined for free acetonitrile by Nakagawa and Shimanouchi.[18] The force constants thus obtained are shown in Table 3.[28] By transferring them to the complexes, the force constants related to the skeletal modes were then determined by a brute-force method. In the calculations, the force constants, H_{XZnX}, H_{NZnX}, F_{XX}, and F_{NX}, were assumed at plausible values. Since the three complexes have nearly identical coordinate bonds identical force constants associated with the nitrogen atom were chosen for the three complexes, and they were determined so as to reproduce best the observed frequencies belonging to the B_1 species rather than

those belonging to the other species, for the B_1 modes were considered to have no appreciable mode mixings with one another. Among the Zn-X force constants, the K_{ZnI} was determined by using mainly the observed frequencies belonging to the B_2 species in order to see clearly the influence of the mode mixing in the A_1 species. The resulting force constants of the skeleton are listed in Table 4. Table 5 compares the observed and calculated frequencies in the low-frequency region. The non-zero force constant, $f(\Delta\alpha_{ZnNC} \cdot \Delta\alpha_{NCC})$, had to be used in order to obtain calculated C-C≡N bending frequencies in agreement with the observed ones. By introducing this interaction term, the splitting into three bands and the high-frequency shift by about 30 cm^{-1} observed for the δ_{CCN} were accounted for satisfactorily. It must be noted that the calculated Zn-N≡C bending frequencies of the A_1 species were not brought into a frequency region higher than 70 cm^{-1} even if such a cross term was taken into consideration. The spectra in the Zn-I and Zn-N stretching frequency region were previously explained qualitatively in the section of the assignments. This now becomes clearer, as may be seen in Table 5; that is, Table 5 justifies the interpretation that the specific features in the spectra of the iodide are caused by the mode mixings, which were enhanced by the lowering of the Zn-X stretching frequency due mainly to an increase in the mass of the halogen atom. However, since the potential energy distribution for the bands at 252 and 179 cm^{-1} is changed delicately by a slight change in the force constants, the dominant contributor to each band can not be specified definitely. If the Zn-N≡C system is nonlinear, then some force constants necessarily change from the values listed in Table 4. However, it was assured by normal coordinate treatments for bent systems that the K_{ZnN} was substantially unchanged unless the Zn-N≡C angle was extremely small, such as below 150°.

It seems necessary here to comment on the high frequency shifts of the C≡N and C-C stretching frequencies upon coordination. The calculated frequencies for the ν_{CC} were 934 cm^{-1} for the A_1 species and 930 cm^{-1} for the B_2 species. This indicates that a fairly large high-frequency shift occurs in complexing without altering the K_{CC} value. In contrast, the high-frequency shift of the ν_{CN} cannot be explained without assuming an increase in the K_{CN} value, as has been pointed out previously.[1,20] If one wishes a better agreement with the observed frequencies, 2273, 2285, and 2274 cm^{-1} for the chloride, bromide, and iodide respectively, the K_{CN} values must be increased by 0.30, 0.42, and 0.30 mdyn/Å respectively.

Zn-N Force Constant

Table 6 shows the observed frequencies related to the Zn-N stretching mode for several complexes of zinc halides with ligands containing nitrogen as a donor atom. It can be seen in Table 6 that, while the bands for the amine complexes are located at 500—400 cm^{-1}, those for the imine and nitrile complexes lie in a much lower frequency region, 250—200 cm^{-1}. In order to show the strength of the coordinate bonds, Table 7 shows the K_{ZnN} values for $ZnX_2 \cdot 2NH_3$,[30,31] $ZnX_2 \cdot 2CH_3CN$ and $ZnX_2 \cdot 2$ (imidazole),[32] which represent the three types of coordination. The Zn-N force constants for all the complexes listed in Table 6 were not available, and we did not try complete normal coordinate analyses for all these complexes. However, the K_{ZnN}'s in pyridine and thiazole complexes, which have ring systems similar to imidazole, may be considered to have the same order of magnitude as that for the imidazole complexes. The relatively low frequency for the imidazole complex results from the mass effect of the imidazole ring. Thus, the K_{ZnN} values for the nitrile complexes can be said to be much smaller than those for the amine and imine complexes. Ozin

and Walton have found that a value of 0.4 mdyn/Å is best for the metal-nitrogen stretching force constants of the 1:1 complexes of $NbCl_5$ and $TaCl_5$ with acetonitrile.[7] This value is of about the same order as that obtained by us. Pd(II) and Pt(II) halide-acetonitrile complexes must also have a similar force constant in view of their low stretching frequencies as suggested by Walton.[9] On the other hand, much larger force constants, 2.5—3.5 mdyn/Å for $BX_3 \cdot CH_3CN$ molecules and 2.0—3.0 mdyn/Å for $XCN \cdot AlCl_3$, have been reported by Shriver and Swanson[11] and by Kawai and Kanesaka[13] respectively. On surveying these data, it may be noted that the coordinate bonds of ordinary metal halide-alkyl cyanide complexes have force constants of 0.6—0.4 mdyn/Å, giving rise to absorption bands around 200 cm^{-1}, unless some other causes for strengthening the M-N bonds are present. It seems that the strength of the M-N coordinate bond is dependent largely on the valency state or the hybridized state of the nitrogen atom, but is independent of the substituents, and that the order is $sp^3 \geq sp^2 > sp$. Furthermore, the approximate force constants and stretching frequencies of Zn-N coordinate bonds may be predicted from the valency state of the nitrogen atom involved.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3314—3320 (1972)

Electrical Conduction in TCNQ Anion Radical Salts

Nobuko SAKAI, Ichimin SHIROTANI, and Shigeru MINOMURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo, 106

(Received March 7, 1972)

The temperature dependence of the electrical resistivity of single crystals of TCNQ anion radical salts with alkali metal, quinolinium, and triethylammonium cations has been investigated at temperatures between 300 and 540°K. It has been observed in these salts that the activation energy increases in the region of higher temperatures. In the cases of Na- and K(TCNQ) crystals, the reversal of the sign of the thermo-e.m.f. from the *p*-type to the *n*-type has been observed around the temperatures at which the activation energy increases. An interpretation of the experimental results is presented.

The salts based on the anion-radical of 7,7,8,8-tetracyanoquinodimethane (TCNQ) exhibit room-temperature electrical conductivities ranging from 10^2 to about $10^{-5}\ \Omega^{-1}\cdot cm^{-1}$.[1-3] The magnitude of the electrical conductivities depends strongly on the nature of the cation. For example, the salts with metal cations generally show low to intermediate conductivities (10^{-5}—$10^{-2}\ \Omega^{-1}\cdot cm^{-1}$), while the salts with cations of planar aromatic heterocyclic molecules show high conductivities ($\sim 10^2\ \Omega^{-1}\cdot cm^{-1}$). It has been reported that several TCNQ salts with aromatic cations show metallic behavior of temperature-independent conductivities as high as $10^2\ \Omega^{-1}\cdot cm^{-1}$ and temperature-independent paramagnetic susceptibilities which can

be interpreted by assuming that the charge carriers are degenerate, as in a metal.[2,4] Recently, it has been found, contrary to the results of Kepler, that the highly conductive salts behave as typical semiconductors; that is, they have an electrical conductivity and a magnetic susceptibility which depend slightly on the temperature, and also absorption edge at about 40 cm^{-1}.[5] The electrical conduction mechanism of these $TCNQ^-$ anion radical salts has subsequently been discussed by several authors.[5-12] On the other hand, only a few studies have been made in connection with the electrical conduction in less conductive simple salts with metal cations.[13,14] The mechanism of electrical conduction in the $TCNQ^-$ anion radical salts seems to be yet unclear in spite of many investigations.

It has been suggested in another paper[15] that the electrical conduction near room temperature in alkali metal cation-TCNQ anion radical simple salts may be due to such extrinsic properties as impurities or defects. This suggestion is based on the scattered values of the activation energy and the pressure coefficient of resistivity from crystal to crystal. In this paper, electrical measurements in the high-temperature region will be reported in more detail.

Experimental

Crystals of alkali metal cation-TCNQ anion radical salts were prepared by the method described in Ref. 15. Crystals of quinolinium$(TCNQ)_2$[Q$(TCNQ)_2$] and triethylammonium$(TCNQ)_2$[TEA$(TCNQ)_2$] which had been synthesized according to the method developed by the du Pont group[1] were provided by Kondow.

The electrical measurement was made along the needle axis in most crystals by the potential-drop method, with two electrode probes in about 10^{-2} Torr. Electrical contacts to the crystal were made with du Pont #4817 silver paste.

A qualitative analysis of the Seebeck effect was carried out in the following manner. Some temperature difference was created during a short time between two junction to the needle crystal, one end of which was fixed vertically on the alumina base connected to a heater. The thermo-e.m.f. appeared transiently in the absence of an applied voltage between the two junctions, the sign of the cold junction being the sign of the Seebeck coefficient.

sponds to the positive carrier, *p*-type. The behavior of these curves is very complicated. The minimum and the maximum points in the resistivity and an increase in the activation energy were observed in the high-temperature region, above 400°K. The electrical resistivity, ρ, and the activation energy, *E*, obtained from the expression: $\rho=\rho_0\exp(E/kT)$ varied from crystal to crystal. The activation energy of Na (TCNQ) is between 0.23 and 0.32 eV near room temperature and between 0.6 and 1.1 eV in the high-temperature region. The sign of the thermo-e.m.f. is reversed from the *p*-type to the *n*-type above the temperature around which the activation energy increases.

Figures 3 and 4 show similar data for several specimens of K(TCNQ) crystal. The minimum and the maximum points in the resistivity, an increase in the activation energy, and the reversal of the sign of the thermo-e.m.f. from the *p*-type to the *n*-type were observed in the higher-temperature region, passing

through the phase-transition point similarly to the case of Na(TCNQ). The activation energy of K-(TCNQ) is between 0.15 and 0.45 eV in the lower-temperature region and between 0.4 and 0.6 eV in the high-temperature region. The temperature at which the sign of the thermo-e.m.f. was reversed fell remarkably upon the second thermal cycling in the measurement of the same specimen.

Figure 5 shows the temperature dependence of the resistivity in several specimens of dark purple Rb-(TCNQ) crystals. The activation energy was observed to depend on the temperature, and to increase in the higher-temperature region, similarly to the cases of Na(TCNQ) and K(TCNQ). However, the reversal of the sign of the thermo-e.m.f. was not observed. The sign is positive, *p*-type, over all the temperature range measured. The activation energy of dark purple Rb-(TCNQ) is between 0.16 and 0.22 eV near room temperature and between 0.22 and 0.4 eV in the high-temperature region. The abrupt increase in the resistivity at high temperatures is due to the decomposition of this salt. On the other hand, the dark purple Rb(TCNQ) crystal in the form of a prism obtained from the same batch reveals a temperature dependence of the resistivity different from the above-exhibited results on that in the form of needle, as is shown in Fig. 6. The relation of log ρ *versus* the reciprocal temperature is not linear over the temperature range measured, and it is monotonous, without any discontinuity in activation energy, at high temperatures. The resistivity and the activation energy at room temperature of dark purple Rb(TCNQ) prisms ($\rho_{25}\sim10^4$ Ω·cm and $E\sim0.34$ eV) are larger than those of needles ($\rho_{25}\sim10^2$ Ω·cm and $E\sim0.16$ eV). It has not yet been investigated whether or not the two kinds of dark purple Rb(TCNQ) have an identical crystal structure.

Polymorphism has been shown in Rb(TCNQ) crystals.[16] The reddish-purple Rb(TCNQ) crystal with a crystal structure different from that of the dark purple Rb(TCNQ) crystal shows a larger resistivity

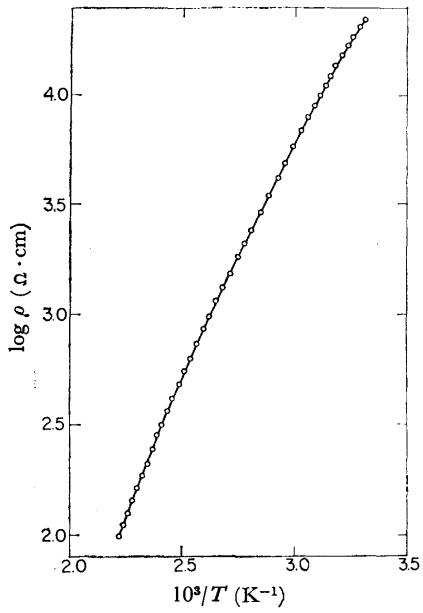

Fig. 6. Temperature depencence of the resistivity for dark purple Rb(TCNQ) with the form of prism.

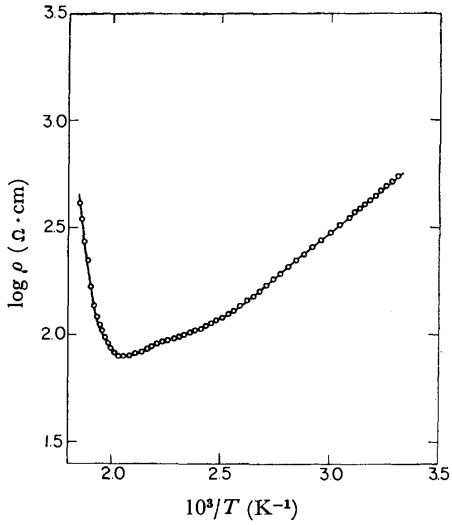

Fig. 7. Temperature dependence of the resistivity for Cs-(TCNQ) crystal.

and activation energy than those of the dark purple Rb(TCNQ) crystal ($\rho_{25}\sim10^5\,\Omega\cdot$cm and $E\sim0.51$ eV). Since most of the reddish-purple Rb(TCNQ) crystals broke down at the phase transition point of 374°K, accurate measurements could not be made in the higher-temperature region. The thermo-e.m.f. shows a positive sign below the phase-transition temperature.

Figure 7 shows the temperature dependence of the resistivity of the Cs(TCNQ) crystal. The outside appearance of this salt resembles that of the dark purple needles Rb(TCNQ). The resistivity changes almost monotonously with the temperature. The abrupt increase in the resistivity at high temperature is due to the decomposition of the compound. The resistivity at room temperature is about $6\times10^2\,\Omega\cdot$cm. The activation energy is about 0.16 eV in the region from room temperature to about 400°K. The sign of

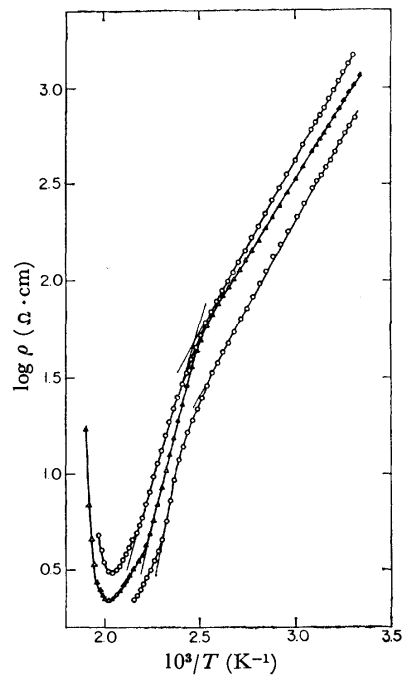

Fig. 8. Electrical resistivity as a function of reciprocal temperature of three $Cs_2(TCNQ)_3$ crystals.

the thermo-e.m.f. is positive over the temperature range measured.

Moreover, the temperature dependence of the resistivity of some salts of the $M^+(TCNQ)_n^-$ type with a value of n higher than one was measured in order to investigate the electrical conduction mechanism in connection with the case of alkali metal cation-TCNQ anion simple salts. Figure 8 shows the resistivity as a function of the reciprocal temperature of three specimens of $Cs_2(TCNQ)_3$ crystals. The discontinuity in the activation energy was observed in the high-temperature region. In one specimen the discontinuity in the activation energy occurred at about 397°K, below and above which the activation energies were 0.32 and 0.78 eV respectively. The sign of the thermo-e.m.f. is negative over the temperature range measured. The abrupt increase in the resistivity at high-tempera-

tures is due to the decomposition of the compound.

Figure 9 shows the resistivity as a function of the reciprocal temperature of the $Q(TCNQ)_2$ and TEA-$(TCNQ)_2$ crystals. It was measured perpendicularly to the needle in the single crystal of $Q(TCNQ)_2$. An anomaly in resistivity was also observed in these complex salts. The activation energy near room temperature is about 0.10 eV, and the activation energy in the narrow temperature region from about 370°K to the decomposition temperature of about 395°K is about 0.18 eV, in the case of the $Q(TCNQ)_2$ crystal. The room-temperature resistivity and the activation energy measured here are larger than those generally reported.[1,2,8,25] It should be noted that the temperature dependence of the conductivity is markedly different from those in the direction of the needle reported in Ref. 8 and 25. The room-temperature resistivity and the activation energy of the TEA$(TCNQ)_2$ crystal along the needle axis are about 1.0 $\Omega\cdot$cm and about 0.13 eV respectively. Also in this crystal, the narrow temperature region where the resistivity decreased with an increase in the temperature with the activation energy of about 0.56 eV was observed before the decomposition occured. No qualitative measurement of the thermo-e.m.f. was carried out. At present, the electrical measurement are not sufficient.

The semiconductivity data of several TCNQ anion radical salts are summarized in Table 1, along with data generally reported.

Discussion

The experimental results described above, particularly the observation of the changes in the sign of the thermo-e.m.f. as a function of the temperature and in the activation energy on Na(TCNQ) and K(TCNQ) crystals, suggest that two carrier effects play important roles in the electrical-conduction process in the crystals of the alkali metal cation-TCNQ anion radical simple salts treated in this work. Alkali metal cation-TCNQ anion radical simple salts are considered to be extrinsic semiconductors in the low-temperature region. This has been expected from the scattered values of the activation energy near room temperature and those of the pressure coefficient of resistivity from crystal to crystal.[15] It was observed that some crystals of K(TCNQ) revealed a resistance increasing with an increase in the pressure, while some revealed the reverse. It has also been reported that the pressure coefficients of the ionization energies of impurities in silicon and germanium vary considerably with the kind of impurity.[17] The simplest scheme of energy levels in the *p*-type extrinsic semiconductors contains an acceptor level. Oxygen may act as an acceptor impurity in alkali metal cation-TCNQ simple salts.

The ionic conduction, on the other hand, may be expected to contribute to the electrical conductivity in these salts. That is, alkali cations may be supposed to move in crystals of these TCNQ salts through lattice defects, such as Frenkel or Schottky defects, and vacancies created by the impurity of divalent metal cations substituted for monovalent alkali metal cations, which are well-known in ionic crystals.[18] The ionic conductivity is known to decrease with an increase in the pressure.[19]

The observed conductivities in alkali metal cation-TCNQ anion radical simple salts were off Ohm's law from the low-electric field; for example, they were off about 40 volts/cm in the K(TCNQ) crystal, and at

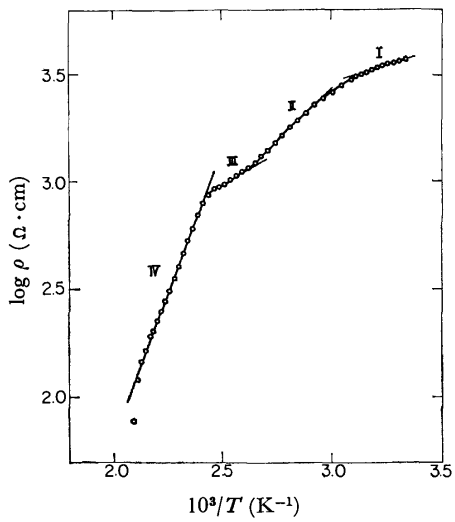

Fig. 10. Temperature dependence of the resistivity for K(TCNQ) crystal containing Ba^{2+} ions of about 0.5 atom%.

higher fields the current increased more than linearly. The negative pressure coefficient of the conductivity, $d\sigma/dP<0$, was observed in some specimens of the K(TCNQ) crystal.[15] These experimental observations seem to show that the contribution of the ionic conduction to the electrical conduction is not negligible. The temperature dependence of the resistvity was measured on the crystal of K(TCNQ) containing Ba^{2+} ions. Since the ionic radius of the Ba^{2+} ion (1.36 Å) is almost equivalent to that of the K^+ ion (1.33 Å), it is expected that the vacancies of the K^+ ion are added in crystal by the substitution of Ba^{2+} ions for the lattice points of K^+ ions. The samples were prepared by the use of a mixture of KI and BaI_2 as the cation source. The electrical resistivity as a function of the reciprocal temperature for the K(TCNQ) crystal containing Ba^{2+} ions of about 0.5 atom% is shown in Fig. 10. As is shown in this crystal, the curves of log ρ *versus* $1/T$ for K(TCNQ) crystals containing Ba^{2+} ions seem to consist of four parts, each with a different activation energy. The activation energy near room temperature, which was about 0.08 eV in the case of the sample shown in Fig. 10, was observed to be dependent on the concentration of Ba^{2+} ions; that is, it decreases with an increase in the concentration of Ba^{2+} ions. The ionic conduction may play some part in the electrical conduction in the narrow temperature region near room temperature in the K(TCNQ) crystal. Though the minimum and the maximum points in the resistivity were not observed in crystals of K(TCNQ) containing Ba^{2+} ions, an increase in the activation energy and a change in the sign of the thermo-e.m.f. were observed in the high-temperature region. The high-temperature region, where the activation energy is larger than in the lower temperature region and where the sings of the carriers are negative, seems to be the intrinsic region of the electrical conduction.

It is reasonable that, in the case of $TCNQ^-$ anion radical salts, the electrical conductivity in the intrinsic region arises from the motion of the odd π electrons among the TCNQ sites. LeBlanc[10] has proposed a model in which the odd electrons are localized and occupy highly-ordered positions so as to minimize their mutual Coulomb repulsions in non-conducting states and conducting states arise from the introduction of defects into the ordered ground-state configuration. According to this model, for the smiple salt an odd electron is removed from one $TCNQ^-$, leaving a $TCNQ^0$, and added to a distant $TCNQ^-$ to give a $TCNQ^{2-}$. The "electron" ($TCNQ^{2-}$) and "hole" ($TCNQ^0$), which are independently mobile, can occupy states in a band with the width Δ. The activation energy for conductivity, E, is given as:

$$2E = C - \Delta$$

where C is an increase in the electrostatic energy by the formation of $TCNQ^0$ and $TCNQ^{2-}$.

The above mechanism may also be applied to the dark purple Rb(TCNQ) crystal, where the $TCNQ^-$ anions pack in a columnar manner with an equivalent interplanar spacing of 3.28 Å at room temperature.[16] In this salt, the absorption band at 6.5 kK, as is shown in Fig. 11, can be assigned to the charge-transfer band between the $TCNQ^-$ anions, which is located in a lower energy region than that of reddish-purple Rb(TCNQ) at 8.6 kK. In the case of the dark purple Rb(TCNQ), the charge-transfer band can be expected to participate in the intrinsic electrical conduction with, for example, the charge-transfer excited state being the conducting state.

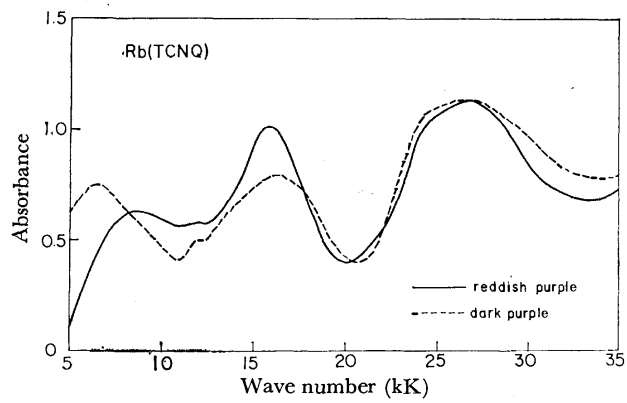

Fig. 11. Electronic absorption spectra of reddish and dark purple Rb(TCNQ).

On the other hand, it has been reported that the TCNQ units in reddish-purple Rb(TCNQ) are stacked in a columnar manner, with alternate interplanar spacings of 3.159 and 3.484 Å at −160°C.[20] It is certain that there is a bimolecular association of TCNQ anion radicals in the column. Although the crystal structures of Na(TCNQ) and K(TCNQ) have not been reported in detail, these salts seem to have a crystal structure similar to that of reddish-purple Rb(TCNQ). It may be considered that the crystalline state of these alkali metal cation-TCNQ anion radical salts is made out of "quasi-molecules" of $(TCNQ)_2^{2-}$, and that the charge-transfer band (Na(TCNQ): 8.6 kK, K(TCNQ): 8.3 kK) is characteristic

20) A. Hoekstra, T. Spoelder, and A. Vos, *Acta Crystallogr.*, *B*, **28**, 14 (1972).

of the intra-quasi-molecular excitation process, in which the electrons are localized in the quasi-molecules. If this is plausible, charge carriers in the intrinsic electrical conduction seem to be produced by the following reaction, in which the electronic state represented is separated by a great distance in the crystal:

$$(TCNQ)_2^{2-} + (TCNQ)_2^{2-} \rightleftharpoons (TCNQ)_2^{-} + (TCNQ)_2^{3-}.$$

The energy for the charge transfer in the above reaction would be larger than the energy of charge-transfer band around 8 kK.

It has been reported that the TCNQ molecules are arranged with repeating units of three molecules and four molecules in $Cs_2(TCNQ)_3$ and $TEA(TCNQ)_2$ respectively, and that an odd π electron is localized at the definite TCNQ molecular site.[21,22] It is expected for $Cs_2(TCNQ)_3$ that the charge transfer will occur between the adjacent pair of $TCNQ^0$ and $TCNQ^-$ and between the adjacent $TCNQ^-$ ions. The absorption bands around 11.7 kK (1.4 eV) and <5 kK (0.6 eV) may be assigned to the charge-transfer band between $TCNQ^-$ ions and to that between $TCNQ^0$ and $TCNQ^-$.[23,24] The activation energy for the electrical conduction of about 0.3 eV below 400°K and that of about 0.7 eV above 400°K seem to be related to the charge-transfer band between $TCNQ^-$ ions and that between $TCNQ^0$ and $TCNQ^-$ respectively. This inference would mean that the discontinuity of activation energy in $Cs_2(TCNQ)_3$ is due to the existence of different conducting states rather than to the existence of an extrinsic electrical conduction arising from impurities or defects. An analogous mechanism may be considered also for other complex TCNQ salts. However, at the present time, the experimental data are not sufficient for us to examine the explanation presented here.

Recently, Farges *et al.* have reported a successful measurement of the Hall effect in single crystals of $TEA(TCNQ)_2$ at room temperature.[12] From the experimental results of the positive Hall constant and Seebeck coefficient along the *a*-axis, and of the negative Seebeck coefficient along the *c*-axis of highest conductivity, it has been reported that two-carrier effects play a role in the conduction process in $TEA(TCNQ)_2$. Furthermore, the small activation energy of 0.065 eV calculated from the expression $\rho = \rho_0 \exp(E/kT)$ has been reported in the case of samples with evaporated silver contacts. This value of the activation energy is much smaller than the generally-reported values and the value obtained in the present work. Farges *et al.* have also described the introduction of impurities which act as acceptros in their samples.

In the present work, the increase in the activation energy was observed in the higher temperature region for single crystals of $TEA(TCNQ)_2$ and $Q(TCNQ)_2$. This also suggests that the high electrical conductivity of these salts is due to the impurity conduction.

Further work is required to make clear the electrical properties in TCNQ anion radical salts. The anisotropy in electrical conductivity and the effect of the pressure on the conductivity in the single crystal of $Q(TCNQ)_2$ will then be investigated in turn.

The authors would like to thank Dr. Tamotsu Kondow for supplying the samples.

Phase Transition of Alkali Metal Cation-TCNQ Anion Radical Simple Salts

Nobuko SAKAI, Ichimin SHIROTANI, and Shigeru MINOMURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo, 106

(Received March 7, 1972)

The phase transition at 1 bar has been observed in alkali metal cation-TCNQ anion radical simple salts by means of measurements of the electrical resistivity of their single crystals. The temperature dependence of the resistivity under high hydrostatic pressures has been studied in order to investigate the effect of the pressure on this phase transition. The nature of this phase transition has been discussed. The pressure-induced new phase has also been found in these TCNQ salts at room temperature; thus, more than three phases (α, β, $\gamma\cdots$) are considered to exist in the solid phase of these TCNQ salts.

It has been shown, from the measurement of the volume change under high pressures by Bridgman, that several molecular organic solids exhibit pressure-induced phase transitions.[1] He has described that it appears that polymorphism is an even more common phenomenon among organic than among inorganic compounds in the temperature range of solid CO_2 temperatures up to 200°C and up to about 50 kbar; this can be expected, because it has appeared that the chance that a substance will exhibit polymorphism is roughly greater the lower the melting point, and, in general, the melting points of organic substances are lower than those of inorganics. The molecular interactions in the crystals of organic substances which he had studied are principally van der Waals interactions.

Ion radical salts, which have attracted interest because of their peculiar electrical and magnetic properties, and which have been studied extensively,[2,3] contain complicated molecular interactions, such as the Coulomb forces, the van der Waals forces and the charge-transfer forces. These molecular interactions have different effects on the inter-molecular distances, so that pressure-induced phase transitions, whose mechanism would be different from that in the organic neutral molecular crystals, may be expected to occur in the ion radical salts.

Recently, McConnell and his co-workers[4] have determined the pressure-induced phase transitions in triphenylmethylarsonium$(TCNQ)_2$ (TCNQ: 7,7,8,8-tetracyanoquinodimethane) from the pressure dependence of the exciton magnetic resonance. They have explained the observed P-T phase diagram in terms of a simple theory of non-interacting triplet excitons, contrary to Chesnut's theory,[5] where the phase transition is attributed to attractive exciton-exciton interactions.

In this paper we will report on the effect of pressure on the phase transitions of the crystalline $M^+(TCNQ)^-$ salts (M^+=alkali metal cation) occurring at 1 bar, which have been found by Vegter *et al.*,[6] and the new pressure-induced phase transitions found in these crystals from the pressure dependence of the electrical resistivity at room temperature.

Experimental

Preparation of Single Crystals. Crystals of Na(TCNQ), K(TCNQ), and Rb(TCNQ) were prepared at room temperature by a diffusion process in a solution of commercially-available metal-iodide and TCNQ purified by recrystallization from acetonitrile distilled from phosphorus pentoxide and by sublimation *in vacuo*.[7] An apparatus different from that described by Pott and Kommandeur[8] was used for crystal growing; a test tube of a suitable length within metal-iodide crystals was left standing in a 200 m*l* Erlenmeyer flask within TCNQ crystals; in both of them acetonitrile was poured, and then the flask was covered and allowed to stand two or three weeks at room temperature. Crystals of Cs(TCNQ) were prepared by the metathesis of CsCl with Li(TCNQ) in water using above-mentioned apparatus. The crystals had various sizes; for example, $0.7\times0.3\times0.1$ mm^3—$0.4\times0.3\times0.2$ mm^3 for Na(TCNQ) and $15.0\times1.0\times1.0$ mm^3—$2.0\times0.3\times0.3$ mm^3 for K(TCNQ). Crystals of Li(TCNQ) have not been available large enough for single-crystal measurements in this way. The polycrystalline powder samples of Li(TCNQ) and K(TCNQ) were prepared by mixing boiling acetonitrile solutions of TCNQ and metal iodide.[7]

Electrical Measurements. The electrical resistivity was measured by means of the direct-current method, with two-electrode probes, because of the high resistance of small crystals. Electrical contacts to the crystals were made with silver paste. A high-pressure cylinder with an inside diameter of 30 mm and a piston distance of 80 mm was used. The maximum attainable pressure is 15000 kg/cm^2 in this cylinder. Silicone oil of low viscosity was used as the pressure-transmitting medium. The pressure was measured with a manganin gauge. The high-pressure apparatus and the high-pressure plug, with a sample mounting and a heater, are shown in Fig. 1.

Only one end of the crystal, in the form of a needle, was fixed vertically on the bakelite base with silver paste in order to prevent the crystal from breaking from the difference

in the compressibilities of the crystal and the base when pressure was raised.

The nichrome wire heater around the alumina cylinder, the outside of which was fixed by cement, was used for heating the samples. The temperature was measured by means of a copper-constantan thermocouple placed near the crystal.

Optical Measurements. The measurement of the electronic absorption spectra was carried out using a Cary recording spectrophotometer, Model 14M. The temperature dependence of the absorption spectra was measured on samples rubbed on glass plates using a high-temperature optical cell in about 10^{-2} Torr, the temperature being measured by means of a copper-constantan thermocouple.

Results and Discussion

A. Effect of Pressure on the Phase Transition. The $M^+(TCNQ)^-$ crystals available here for electrical measurements are almost like the twinning crystals. In the case of Rb(TCNQ), two kinds of crystals, whose external appearances are different, were prepared in the same batch by the method described above. One is a reddish-purple needle similar to K(TCNQ), and the other is a dark purple needle similar to Cs(TCNQ) or the prism. The yield of reddish-purple crystals constitutes a small percentage of the total yield of Rb(TCNQ) crystals. The physicochemical properties are remarkably different between the two crystals.[9] For example, the electrical resistivity, ρ, at room temperature is about $10^5\,\Omega\cdot$cm and $10^2\,\Omega\cdot$cm, and the activation energy, E_a, obtained from the expression $\rho=\rho_0\exp(E_a/kT)$ is between 0.41 and 0.53 eV and between 0.16 and 0.19 eV for the reddish-purple Rb(TCNQ) and the dark purple one respectively. The electronic absorption spectra are also different, as has been shown in Fig. 2.

9) Recently, by means of X-ray analysis, the difference of the crystal structure between reddish-purple Rb(TCNQ) and dark purple one was made clear. I. Shirotani, H. Kobayashi, N. Sakai, and Y. Saito, This Bulletin, to be published.

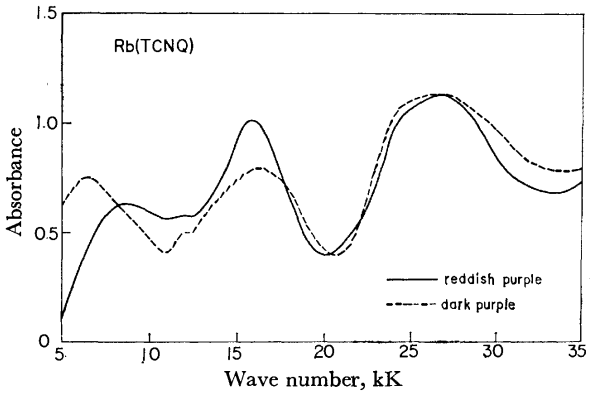

Fig. 2. Electronic absorption spectra of reddish and dark purple Rb(TCNQ).

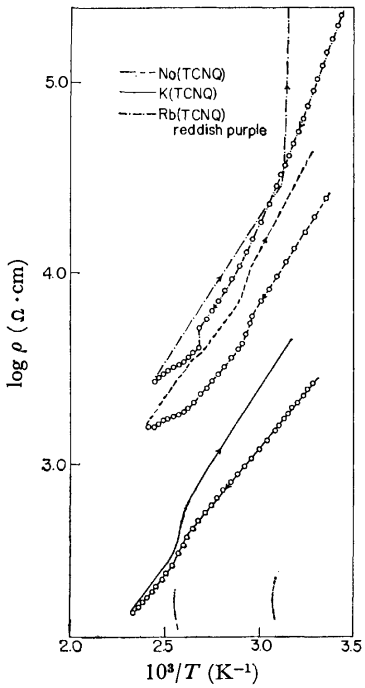

Fig. 3. Electrical resistivity as a function of reciprocal temperature of Na(TCNQ), K(TCNQ), and reddish-purple Rb(TCNQ) in 10^{-2} Torr.

Figure 3 shows the electrical resistivity of $M^+(TCNQ)^-$ crystals as a function of the reciprocal temperature. This measurement was carried out in about 10^{-2} Torr. The presence of the anomalies in resistivity was observed at about 338, 391, and 374°K for Na-, K-, and reddish-purple Rb(TCNQ) respectively. The resistivity, ρ, and the activation energy, E_a, of these $M^+(TCNQ)^-$ crystals varied from crystal to crystal.

The activation energy of Na(TCNQ) is from 0.23 to 0.32 eV below the transition temperature and from 0.16 to 0.22 eV above. The resistivity decreases by a factor of about 0.8 at the transition point. In thermal cycles for the same crystal, the resistivity during cooling is higher than that during the initial heating and the room-temperature resistivity in the second thermal cycle is higher than the initial value by a factor of about 1.2. However, the agreement of the transition temperature among several specimens, among heating

and cooling processes, and among repeated measurements of the same crystal is excellent. The heat of transition of Na(TCNQ) is very small, but it was distinctly observed by the preliminary measurements by means of a differential scanning calorimeter, this is in contrast with the case reported by Vegter *et al.*[6]

The activation energy of K(TCNQ) is from 0.23 to 0.45 eV below the transition point and from 0.15 to 0.31 eV above. In this salt, the resistivity changes slowly over a 5 to 8°K interval before a linear log ρ *versus* $1/T$ relationship in the region of the low activation energy is obtained. The amount of the change in the resistivity at the reverse transition on cooling is larger than that at the transition on heating. The agreement of the transition temperature among the several specimens is within ±6°K.

In the case of reddish-purple Rb(TCNQ), the activation energy is from 0.41 to 0.53 eV below the transition point and from 0.28 to 0.37 eV above. The abrupt decrease in the resistivity by a factor of about 0.6 was observed at the transition, but most of the crystals break down at the transition point, and so it is difficult to obtain accurate measurements of the transport behavior in the high-temperature phase. A large hysteresis in the transition temperature was observed. The transition point is 374±1°K upon heating and 323±4°K upon cooling.

A similar abrupt change in resistivity was observed at about 231 and 254°K for the dark purple Rb(TCNQ) crystals and Cs(TCNQ) crystals respectively. The amount of the change in resistivity at the transition point is very small, and no change in the activation energy was observed above and below the transition point for these salts.

Table 1. Transition temperature and heat of transition for $M^+(TCNQ)^-$ salts

	Transition temperature (°K)		
	Present work	After Vegter *et al.*[a]	Heat of transition[a] ΔH (cal/mol)
Na(TCNQ)	338	348	unobservable
K(TCNQ)	391	395	60
Rb(TCNQ)			
reddish-purple	374	381	1010
dark purple	231	—	—
Cs(TCNQ)	254	210	unobservable

a) Ref. 6)

The transition temperatures observed in the present electrical measurements for various salts are summarized in Table 1, along with the data reported in Ref. 6. The disagreement of the transition temperatures may be due to differences in the methods of measurement or to the differences in the purity of the samples. The scattering values of the activation energy among several specimens seem to be mainly due to the influence of impurities on the electrical conduction.[10]

10) N. Sakai, I. Shirotani, and S. Minomura, *ibid.*, **45**, 3314 (1972).

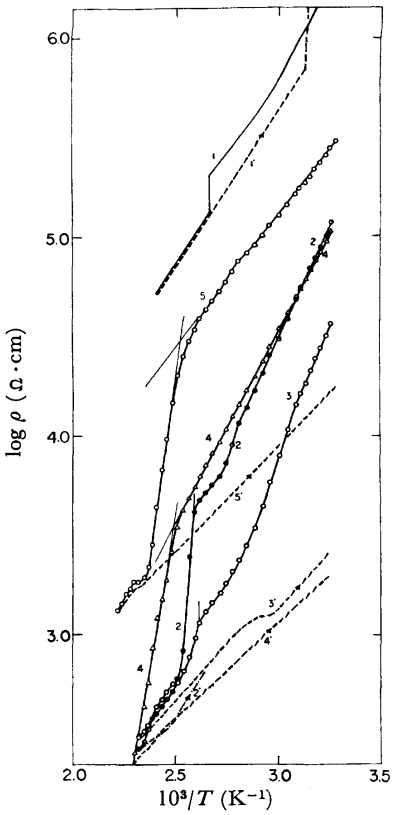

Fig. 4. Electrical resistivity as a function of reciprocal temperature under several constant high pressures of reddish purple Rb(TCNQ).
curve 1: 0 kbar, 2: 2.2 kbar, 3: 4.2 kbar, 4: 8.3 kbar, 5: 10.4 kbar.

The effect of the hydrostatic pressure on the transition temperature was studied in order to obtain information about the nature of the phase transition in $M^+(TCNQ)^-$. Figure 4 shows the resistivity as a function of the reciprocal temperature under several constant high pressures for the reddish-purple Rb(TCNQ) crystal. The transition temperature of 374°K at 1 bar rises with an increase in the pressure. The transition seems to be sluggish under high pressures. The curves of log ρ *versus* $1/T$ under high pressures seem to be complicated because of the appearance of the new pressure-induced phase transition to be described in the next section, B. Although the breakdown of crystals at the transition point occurring at one atmosphere did not occur under high pressures, different crystals were used for each run because of the possibility of the high-temperature phase being quenched at room temperature under high pressures. The activation energy in the low-temperature phase decreased with an increase in the pressure ($dE_a/dP \sim -0.01$ eV/kbar). The pressure dependence of the activation energy in the high-temperature phase was not well known because of the limited temperature region.

Figure 5 shows a phase diagram of the reddish-purple Rb(TCNQ). The slope obtained from the curve is calculated to be:

$$dP/dT = +0.36 \text{ kbar/deg.} \quad (1)$$

The discontinuity in volume at the transition may be calculated from the Clausius-Clapeyron relation for

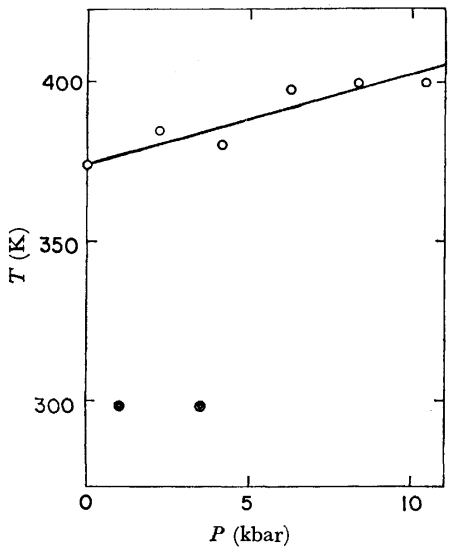

Fig. 5. Phase diagram of reddish-purple Rb(TCNQ). Pressure-induced phase transition points (see the text) are also written in at room temperature.

the first-order transition:

$$dP/dT = \Delta S/\Delta V, \quad (2)$$

where ΔS is the total change in entropy between the two phases. ΔS is evaluated from the latent heat of transition. The ΔS for the reddish-purple Rb(TCNQ) is about 2.65 cal/mol·deg, judging from the data in Table 1; consequently, ΔV is 0.31 cm^3/mol.

The temperature dependence of the resistivity under several constant high pressures was measured also for Na- and K(TCNQ). In these salts, the small amount of change in the resistivity at the transition point became obscurer with an increase in the pressure, and so it was difficult to obtain the pressure coefficients for the transition temperature over a wide region of pressures. The preliminary value of dP/dT for Na(TCNQ) is +0.014 kbar/deg up to about 4 kbar. Data concerning the phase transition for various ion radical salts are summarized in Table 2.

Table 2. Data concerning the phase transition for various ion radical salts

	dP/dT (kbar/deg)	ΔS (cal/mol·deg)	ΔV (cm^3/mol)
Rb(TCNQ)	+0.36	2.65[a]	+0.31
W.B.P.	+0.1[b]	2.19[c]	+0.91[b]
$[(C_6H_5)_3PCH_3]^+$-$(TCNQ)_2^-$	negative	1.72[d]	$\sim$−2
$[(C_6H_5)_3AsCH_3]^+$-$(TCNQ)_2^-$	negative	—	$\sim$−3.51[e]

a) Ref. 6, b) Ref. 11, c) Ref. 12, d) Ref. 13, e) Ref. 4.

The ΔV at the transition of $[(C_6H_5)_3AsCH_3]^+$-$(TCNQ)_2^-$ has been obtained by the following treatment, proposed by McConnell and his co-workers.[4]

The condition for phase equilibrium —that the Gibbs free energies, including the spin-exchange free energy for a strongly-alternating linear array without any exciton-exciton interaction of the two phases, be equal at the transition point— leads to the following equation for the P-T phase separation curve:

$$P = -(\Delta E^0/\Delta V^0) + (kT/\Delta V^0)\ln[(1-\rho_I)/(1-\rho_{II})] \quad (3)$$

where the quantity ρ is the triplet excitation density as defined by the equation of the molar paramagnetic susceptibility as:

$$\chi_p = \rho N_0 g^2\beta^2/3kT, \quad (4)$$

and is related to the energy separation between the thermally-accessible triplet state and the ground state by the following equation:

$$\rho = 3[3+\exp(J/kT)]^{-1}. \quad (5)$$

When Eq. (3) is led, it has been assumed that the two crystal forms have very similar crystal structures, and that the phonon heat capacities of the two phases are equal and are essentially independent of the pressure, and, further, that the thermal coefficients of the volume expansion of both phases are small, nearly equal, and independent of the pressure.

The value of ΔV^0 of $[(C_6H_5)_3AsCH_3]^+(TCNQ)_2^-$ has been determined to be −11.7 Å^3/spin pair from the measurement of P, T, ρ_I, and ρ_{II} at the transition point. The ΔV value of the negative sign indicates a decrease in the crystal volume at the transition to the high-temperature phase, which is the high-pressure phase for $[(C_6H_5)_3AsCH_3]^+(TCNQ)_2^-$.

The total change in entropy between the two phases is composed of electronic terms, lattice terms, and spin-ordering terms:

$$\Delta S = \Delta S_{electronic} + \Delta S_{lattice} + \Delta S_{spin}. \quad (6)$$

The electronic entropy change may be neglected in these ion radical salts because of the small number of carriers. Although, in the case of $[(C_6H_5)_3AsCH_3]^+$-$(TCNQ)_2^-$, the $\Delta S_{lattice}$ has been neglected in the treatment by McConnell and his co-workers, the $\Delta S_{lattice}$ seems to be the main factor in the entropy change in the reddish-purple Rb(TCNQ). The contribution of ΔS_{spin} to ΔS will be several percent in the reddish-purple Rb(TCNQ), as in the cases of Würster's Blue Perchlorate (W.B.P.) and $[(C_6H_5)_3PCH_3]^+$-$(TCNQ)_2^-$. This was estimated from the data of K(TCNQ).[6] For the case of the reddish-purple Rb(TCNQ), the following equation[11] for the phase-separation line may be used instead of Eq. (3):

$$P = -(\Delta E/\Delta V) + T\Delta S_{lattice}/\Delta V + (kT/\Delta V)\ln[(1-\rho_I)/(1-\rho_{II})]. \quad (7)$$

The ΔV values of the positive sign in the reddish-purple Rb(TCNQ) and W.B.P. indicate an increase in the crystal volume at the transition to the high-temperature phase. Recently, the structure determination of the reddish-purple Rb(TCNQ) has been carried out by means of an X-ray diffraction study at a low temperature (−160°C) by Hoekstra, Spoelder, and Vos.[14] The crystal of the reddish-purple Rb-

14) A. Hoekstra, T. Spoelder, and A. Vos, *Acta Crystallogr., B*, **28**, 14 (1972).

(TCNQ) belongs to the monoclinic symmetry of the $P2_1/c$ space group, with lattice constants of $a=7.187$, $b=12.347$, $c=13.081$ Å, and $\beta=98.88°$ at $-160°C$, and with those of $a=7.30$, $b=12.40$, $c=13.13$ Å, and $\beta=98.8°$ (which are preliminary values) at room temperature, including four molecules in a unit cell.

The room-temperature W.B.P. is orthorhombic, the space group is Pn2n or Pnmn, with a unit cell of dimensions $a=5.98$, $b=10.21$, and $c=10.23$ Å, which includes two molecules in a unit cell; at ~77°K through the phase transition at 186°K, it changes to a monoclinic symmetry with lattice constants of $a=11.70$, $b=20.22$, $c=10.17$ Å, and $\gamma=92.7°$.[15]

According to these crystal data, the rates of the volume change to the molar volume at the transition point are about 0.5% and about 0.17% in W.B.P. and the reddish-purple Rb(TCNQ) respectively. The volume change in Rb(TCNQ) must considerably smaller than that in W.B.P.

Figure 6 shows the temperature dependence of the electronic absorption spectra of the reddish-purple Rb(TCNQ).

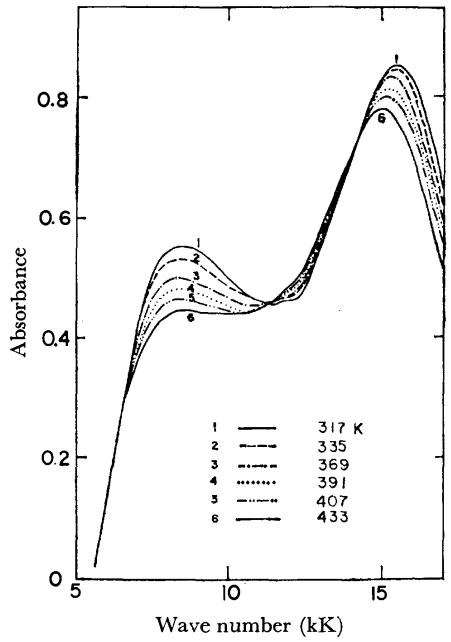

Fig. 6. Temperature dependence of the electronic absorption spectra of reddish-purple Rb(TCNQ).

Figure 7 shows the absorbance of two absorption peaks and the energy of the peak in the higher-energy region as a function of the temperature for the reddish-purple Rb(TCNQ), K(TCNQ), and Na(TCNQ). The absorption spectra of these crystalline TCNQ salts are similar to those of the dimer of the TCNQ anion radical in an aqueous solution.[16–19]

It has been reported that the TCNQ units in the reddish-purple Rb(TCNQ) are stacked in a plane-to-plane manner and that the interplanar spacings of 3.159 and 3.484 Å alternate within a row, and the Rb^+ ions also form rows along the a axis, with alternating distances of 3.483 and 3.726 Å between the ions at $-160°C$.[14] It is certain that there is a bimolecular association of TCNQ anion radicals in the column in the reddish-purple Rb(TCNQ) crystal. The preliminary structure determination of K(TCNQ) by Anderson and Fritchie[20] has shown that the TCNQ anions are stacked plane-to-plane in the column, but it is not certain whether or not there is a bimolecular association of TCNQ anions in the column.

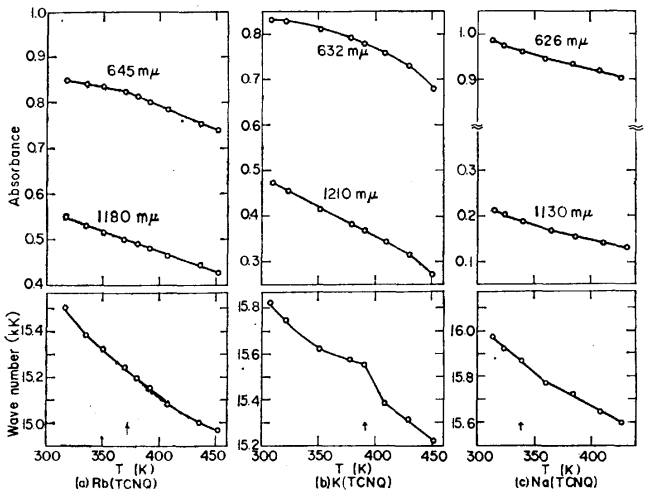

Fig. 7. Absorbance of two absorption peaks and the energy of the peak in the higher energy region as a function of temperature.
(a) reddish-purple Rb(TCNQ) (b) K(TCNQ) (c) Na(TCNQ)

If the phase transition observed in $M^+(TCNQ)^-$ is similar to that at about 190°K in W.B.P., the mechanism of which has been explained by the dimerization scheme, that is, the presence of dimerized Würster's Blue species at low temperatures,[12,15,21,22] it may be expected to occur at the transition point where the absorbance of the charge-transfer absorption band in the near-infrared region changes abruptly, and the peak positions may be expected to shift considerably so that the spectra correspond to those of the TCNQ anion monomer. However, as has been shown in Figs. 6 and 7, the absorbance and the peak energy decrease almost monotonously with an increase in the temperature, and no abrupt change or shift at the transition point was observed except for the small peak shift in K(TCNQ). The spectra seem to be similar to those of the dimer of the TCNQ anion radical above the transition temperature. A little shift of the isosbestic points was observed above and below the transition point.

Although any inequality of interaction between neighboring TCNQ anions in the column would become smaller in the high-temperature phase, the

bimolecular association of TCNQ anion radicals seems to be preserved in the high temperature phase in the reddish-purple Rb(TCNQ). The phase transition may be principally the result of the change in the manner of packing between the Rb^+ ions and the $TCNQ^-$ column, because the crystals fractured at the transition point in spite of the slight change in the arrangement of TCNQ anions and the small volume change.

On the other hand, only a slight change in the $TCNQ^-$ column would be expected in the case of $M^+(TCNQ)^-$ salts except for the reddish-purple Rb-(TCNQ).

B. New Pressure-induced Phase. In $M^+(TCNQ)^-$ salts anomalies in the pressure dependence of resistivity were found at room temperature; they seem to be attributable to the new pressure-induced phase transition. This is analogous with the fact that a number of inorganic substances show anomalies in the electrical resistivity at their pressure-induced phase transition.[23,24]

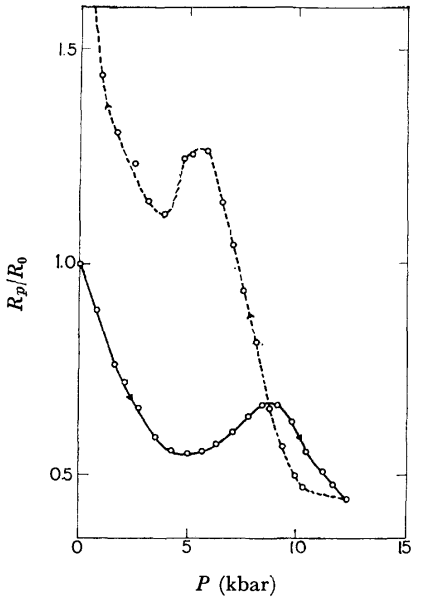

Fig. 8. Relative resistance as a function of pressure at room temperature in the pellet of polycrystalline Li(TCNQ).

Figure 8 shows the relative resistance as a function of the pressure at room temperature in Li(TCNQ). Four high-pressure runs were made on the polycrystalline powder samples pressed into pellets with a pressure of 7 kbar. The main features were identical in all the runs. The resistance decreases up to about 5 kbar, and then it increases, attaining its maximum at about 8.5 kbar and then again decreasing. As the pressure decreases, the minimum and the maximum of resistance shift to about 4 and 5.5 kbar respectively. It is likely that the phase transition occurs around 5 kbar, and that it is complete by about 8 kbar. The phase transition in Li(TCNQ) has not been observed in the temperature range from −150°C to +230°C at one atmosphere.[6] Therefore, the transition found here must be a pressure-induced phase transition.

It has been reported that the resistance decreases monotonously under very high pressures in the range from 28 to 170 kbar.[25] In that pressure region, the pressure dependence of the resistance in the new high pressure phase seems to be shown.

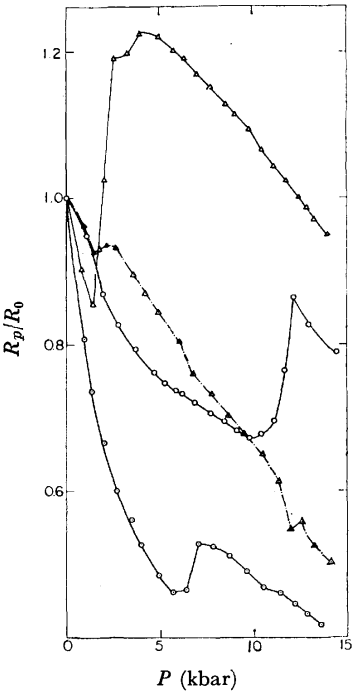

Fig. 9. Relative resistance as a function of pressure at room temperature in several Na(TCNQ) crystals.
-○- and -⊙-: $\rho_a//$, -△- and -◬-: $\rho_b//$.

Figure 9 shows the pressure dependence of the relative resistance at room temperature in several Na(TCNQ) crystals. The crystal axis along which the resistance had been measured was assigned on the basis of a prelimianry X-ray analysis by Konno *et al.*,[26] according to which columns of $TCNQ^-$ ions are parallel to the *a* axis. The anomalies in the resistance were found in all the crystals. However, the pressures at which the anomalies were observed were somewhat different from crystal to crystal. Further, the manner of the anomalies varies; for example, some crystals show a discontinuous rise in resistance, while other crystals show only a change in the slope in the curve of the relative resistance *versus* the pressure around the equal pressure. It is likely that the manner of the anomaly differs with different crystal axes. Probably the phase transitions occur about 1.5, 6, and 10—11 kbar.

Figures 10, 11, and 12 show three typical results in eight measurement runs of the pressure dependence of the resistance in K(TCNQ) crystals. The measurements of the resistance were carried out along the needle axis. K(TCNQ) crystals exhibited a strange behavior in the pressure dependence of the resistance.

26) M. Konno and Y. Saito, private communication.

That is, in spite of all the crystals having a similar outside appearance, some crystals revealed that the resistance increased with an increase in the pressure, while others revealed the reverse. It was also observed in some crystals that the pressure dependency of the resistance in the course of the first increase in pressure was remarkably different from that in the course of the second increase in pressure after the release of the pressure on the same crystal, as has been shown in Fig. 12. The crystals seemed not to be damaged after the second measurement. The anomalies in the resistance were observed around 2, 5, and 9 kbar.

The pressure dependence of the resistance was measured on polycrystalline powder samples of K(TCNQ)

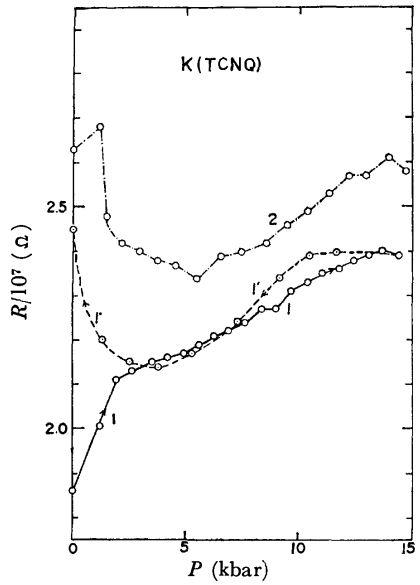

Fig. 10. Resistance as a function of pressure at room temperature in K(TCNQ) crystal A. (1) the first increasing pressure run, (1′) release of pressure run, (2) the second increasing pressure run.

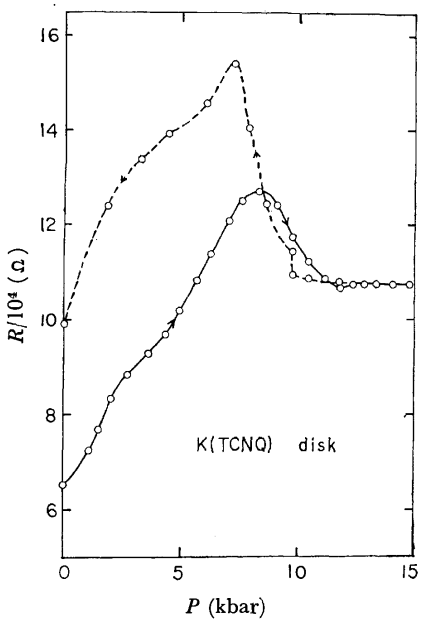

Fig. 13. Resistance as a function of pressure at room temperature in the pellet of polycrystalline K(TCNQ).

pressed into pellets with a pressure of 7 kbar; this was done in order to investigate whether or not the variation in the pressure dependency in crystals was due to the difference in methods of sample preparation; the results are shown in Fig. 13. Four runs were made. The main features were identical in all the runs. The resistance increased up to about 8.2 kbar, and then decreased with an increase in the pressure. The reason for this disagreement in the powder sample and the crystal samples is not clear at present. However, because any imperfection, such as a chemical impurity

or a lattice defect, has an influence on the electrical conduction, it is probable that the slight difference in the imperfection was reflected in the pressure dependence of the resistance. It is possible that each crystal prepared simultaneously by a diffusion process has a different imperfection.

The change in the slope at about 2.2 kbar and the maximum of resistance at about 8.2 kbar in the powder sample seem to correspond to the anomalies around 2 and 5 or 9 kbar respectively observed in the crystal sample. The pressure-induced phase transition must have occurred at those pressures.

Recently, a preliminary experiment was carried out concerning the pressure dependence of the lattice constants of K(TCNQ) by means of X-ray powder diffraction analysis under hydrostatic high pressures.[27] No marked changes in the diffraction pattern were observed up to 4.5 kbar. Therefore, the transformation of the crystal structure at those pressure-induced phase transition points, if any, would be very slight.

The effect of a very high pressure on the resistance of the powder K(TCNQ) has been studied in the pressure region from ~20 to ~500 kbar, and it has been reported that there is a distinct break in the slope of the resistance-pressure curve at 250—300 kbar.[28] However, no explanation for this phenomenon has yet been provided.

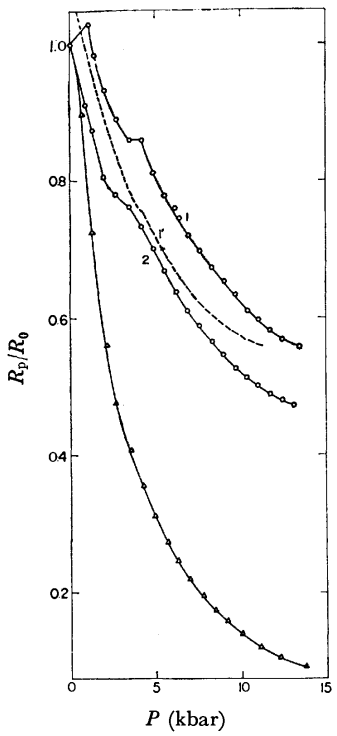

Fig. 14. Relative resistance as a function of pressure at room temperature in Rb(TCNQ).
—○—: reddish-purple crystal (1) the first increasing pressure run, (1′) release of pressure run, (2) the second increasing pressure run, —△—: dark purple crystal.

Figure 14 shows the pressure dependence of the relative resistance in both the reddish- and dark purple Rb(TCNQ) crystals. The anomalies were found at about 1 and 3.5 kbar, at which the new pressure-induced phase transition occurs, in the reddish-purple Rb(TCNQ). These new pressure-induced phase transition points are written in the phase diagram as has been shown earlier in Fig. 5. More than three phases ($\alpha,\beta,\gamma,\cdots$) are considered to exist in the solid phase of Rb(TCNQ); consequently, it is possible that the boundary line shown in Fig. 5 is due to the transition from the new pressure-induced phase to the high-temperature phase in the region of higher pressures. The anomaly at about 1 kbar disappeared in the course of the first release of pressure and the second increase in pressure. In the case of the dark purple Rb(TCNQ), on the other hand, the resistance decreased monotonously with an increase in the pressure, and no anomalies in resistance corresponding to those in the reddish-purple Rb(TCNQ) were observed up to 13.5 kbar. Whether or not the pressure-induced phase transition occurs in the dark purple Rb(TCNQ) is not yet clear.

The effect of pressures up to 7 kbar on the electronic absorption spectra of these $M^+(TCNQ)^-$ salts has been studied.[18] No marked change in the absorption spectra has been observed in the pressure region above and below the transition pressure found here.

For the present, the nature of the new pressure-induced phase transition found in $M^+(TCNQ)^-$ salts is not known. The TCNQ ions are arranged with some periodicity in the column in the $TCNQ^-$ anion radical salts. It would be expected that the phase transition arises from a change in the periodicity in the $TCNQ^-$ column. Even a slight change in the external condition would affect the stabilization of the crystal lattice in the ion radical salts because of the complicated molecular interaction in them. The phenomena of the presence of numerous modifications over a wide region of pressure and temperature would appear to be rather general in the ion-radical salts.

The authors would like to thank Miss Michiko Konno for performing the X-ray diffraction experiment.

The Isomerization of *n*-Butenes over Acidic Ion-exchange Resin

Takayoshi UEMATSU*

Department of Chemical Engineering, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo

(Received March 13, 1972)

The isomerization of *n*-butenes and the polymerization of propylene were studied in a gas-phase reaction on a sulfonic acid-type resin catalyst. These reactions were considered to proceed *via* the carbonium ion formation on the functional groups, and a strong correlation was found between the activities in these two reactions. The acidity and the acid strength of the resin catalyst were measured by means of amine titration in a nonpolar solvent using Hammett indicators. The value of the acidity obtained at $pK_a=6.8$ seemed to correspond to the number of the ion-exchangeable hydrogen on the functional groups. The effects of poisoning by ion exchange with Na^+, Mg^{2+} or by adsorption of NH_3 were also studied. The decrease in the activity for the isomerization was not proportional to the amount of cations exchanged. The catalytic activities of the protonic hydrogen seemed not to be equal as was suggested by the result of resin catalysts in polar solvents. The possible heterogeneity of the active sites on the resin catalyst was discussed. The six relative rate constants were calculated on the basis of the mutual interconversion among the three isomers of *n*-butene. The apparent energy of activation for the double-bond migration of 1-butene was found to be 17 kcal/mol on the H-form resin, but it was changed by ion exchange with Na^+. The selectivities were characteristic of solid acid catalysts of the protonic type.

Many types of acidic oxide catalysts have been studied in hydrocarbon reactions. However, these catalysts have been found to show a very complicated behavior, reflecting their coexisting various acidic properties of the active sites. The catalyses have been accounted for by the surface-acid sites, which are usually classified into two typical acid types: protonic (Brönsted) acid and non-protonic (Lewis) acid site.[1-3] In some cases, they were extended to oxidative sites to form a cation radical complex on the surface.[4-6] Furthermore, these acid sites have a widespread distribution in terms of acid strength and activity.[7] Thus, a typical solid acid with a single type of acid and homogeneous activity has been expected to be studied.

Attempts have been made to use acidic ion-exchange resins of a conventional gel-type structure in solution[8-10] or in the vapor phase of polar reactants.[11,12] These catalyses have been considered to be similar to those by homogeneous acid catalysts, such as hydrochloric acid or sulfuric acid.[13] An acidic resin of the macroreticular-type was used in the gas-phase reaction.[14] Manassen and his co-worker prepared a sulfonated and a phosphonated polyphenyl resin catalyst which were stable up to 350°C, and observed no special surface effects over them.[15] In the dehydration of alcohol on an acidic resin catalyst, the homogeneous catalytic activities of the functional groups have been reported,[16] while the heterogeneity of the active sites has also been suggested by the different results regarding the poisoning effect by Na^+ and Li^+.[17]

In the present investigation, the catalytic behavior of a sulfonated styrene–divinylbenzene copolymer was studied in terms of olefin reactions, which can give more information about resin catalysts in a gas-phase reaction. The heterogeneity of the resin catalyst will be discussed also.

Experimental

Materials. The sulfonated styrene–divinylbenzene copolymer with a macroreticular structure was prepared from commercial ion-exchange resin Amberlyst-15. The resin was washed with methanol and then with decationized water to remove any extraneous materials. It was converted to the Na-form by treating it with a 1N NaOH solution according to the conventional column method, and was again reversed to H-form (AMH standard) with a 1N HCl solution. After washing with decationized water, it was treated with methanol and dried under reduced pressure. The Na-poisoned catalysts (AMHNa series) were prepared by soaking AMH in a NaOH solution containing the desired quantity of Na^+ ions for 2 weeks at room temperature. They were then washed and dried in a manner similar to that for AMH. The purity of the reactant gases was above 99.8%. They were repeatedly distilled at −196°C prior to use.

Procedures. The ion-exchange capacity of AMH was determined by titration with a NaOH solution. The surface area was measured by the BET method of N_2 adsorption. The isomerization and the polymerization reaction were carried out in a closed circulating system. The catalysts were evacuated first at room temperature and then at 110°C

for 2 hr. The products were analyzed by means of a gas chromatography, using a propylene carbonate–alumina column at 0°C. The isomerization reaction of 1-butene was also studied in a flow-type reactor, using N_2 as the carrier gas. The catalysts were pretreated in a N_2 stream at 110°C for 2 hr.

Results

Ion-exchange Capacity and BET Surface Area. The titration curve obtained with the powdered AMH is shown in Fig. 1. This result shows behavior characteristic of a strong electrolyte and quite resembles that of the sulfonated polyphenyl resin.[15] The total amount of NaOH added up to the neutral point of pH 7.0 was 3.79 meq/g of dry resin, while 4.03 meq/g was needed up to pH 11.0, above which no more pH change was detected upon the further addition of NaOH. The latter value was in good agreement with the ion-exchange capacity for the evacuated AMH (4.02 meq/g), but was slightly smaller than that of the standard AMH (4.32 meq/g).

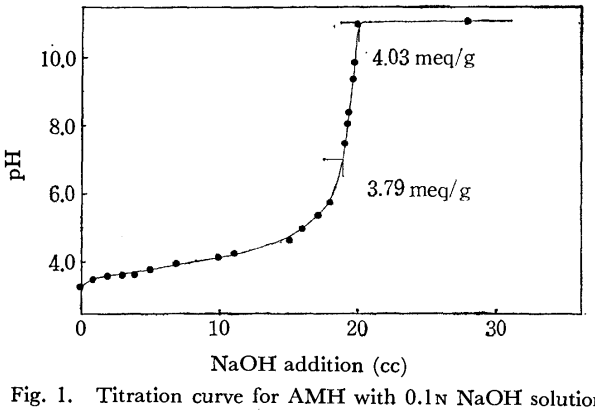

Fig. 1. Titration curve for AMH with 0.1N NaOH solution.

The BET surface areas obtained with the resin catalysts evacuated at 110°C for 2 hr were: 86 m^2/g (AMH), 57 m^2/g (AMHNa05), 74 m^2/g (AMHNa10), 67 m^2/g (AMHNa20), 54 m^2/g (AMHNa40), and 65 m^2/g (AMNa). These results appear not to show any systematic tendency in the effect of cation-exchange on the surface area. The decrease in the surface area of AMH was very small, even after evacuation at temperatures below 140°C. This suggests that the change in the substrate by the ion exchange or the pretreatment of evacuation at 110°C were negligible.

DTA and TGA Observations. The sulfonated styrene–divinylbenzene copolymer catalyst is expected to contain some water in the macro-pores or the channels in the resin matrix. A part of them may be in a hydrated sate to the functional groups. It was found from the DTA and TGA observations that the water of this kind can easily be removed by heating under atmospheric pressure. The total weight losses up to 150°C, above which the DTA and TGA curves showed no more changes, were 34.2 wt-% (AMH) and 22.0 wt-% (AMNa). These results correspond to losses of 4.7 $H_2O/-SO_3H$ and 2.9 $H_2O/-SO_3Na$ respectively, in good agreement with the hydration numbers of the polystyrene sulfonic acid-type resin reported in the literature: 3.9 (to H^+)+0.9 (to $-SO_3^-$) and 1.5 (to Na^+)+0.9 (to $-SO_3^-$).[18] When AMH and AMNa were evacuated at 110°C for 2 hr, the water content decreased remarkably, and the further weight loss by heating up to 140°C was less than 3—5%, and above that temperature desulfonation took place.

Polymerization of Propylene. The polymerization of ethylene was not promoted by AMH, but propylene and *n*-butene were catalyzed under the present experimental conditions below 100°C. The time course of the total pressure decrease could not be explained by Tamele's equation,[19] which is very often applied to the polymerization reaction of propylene over solid acid catalysts. A Langmuir-type rate expression (1) was found to be appicable, as is shown in Fig. 2;

$$r = -\mathrm{d}P/\mathrm{d}t = kP/1 + KP \qquad (1)$$

P: total pressure, t: time, k: rate constant, K: constant of the equilibrium factor, r: rate of the reaction.

The apparent energy of activation for the polymerization on AMH was found to be 10 kcal/mol in the range of temperatures higher than 84°C and 3.5 kcal/mol in the lower range.

Isomerization of n-*Butenes.* Under the reaction conditions used for the isomerization of *n*-butenes, the polymerization reaction detected was negligible. Starting from any isomers of *n*-butene, only products from the double-bond migration and the *cis-trans* isomerization were observed. Thus, the reaction system can be approximately expressed by a three-component kinetic system of the Pines type.[20] The change in the relative compositions of the gas-phase products is illustrated by the ternary system as shown in Fig. 3. Starting from each isomer of *n*-butenes, the same equilibrium composition, the point E, was approached after prolonged reaction times, and the curve are nearly linear up to much higher conversions. These facts suggest that the selectivity of the catalyst did not change during the reaction, at least not during the early stage of the conversion. Selectivities expressed by the initial product ratios; ${}_{c}S_{t}^{t}$, ${}_{1}S_{c}^{t}$, ${}_{c}S_{1}^{c}$, were obtained from the tangents of the curves at zero conversion. There were several characteristic features of the behavior, especially in the stereo-selectivities; the double-bond migration of 1-butene showed a strong kinetic preference for the formation of *trans*-2-butene, though the relative ratio of the products, *trans*-2-butene/*cis*-2-butene, was less than that of the thermodynamic equiliblium. In the isomerization of *cis*-2-butene, the relative amounts of the products, *trans*-2-/1-butene, were nearly that of the equilibrium from the very low conversion, while the products from *trans*-2-butene favored the formation of *cis*-2-butene than that of 1-butene.

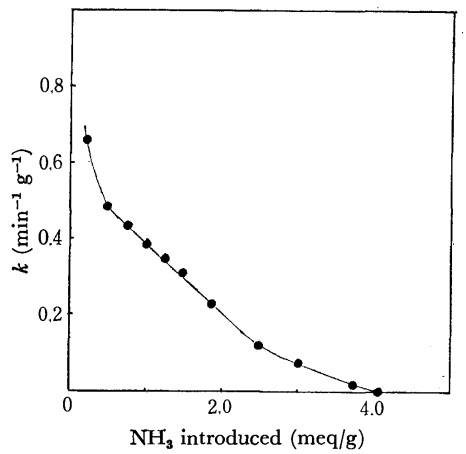

Fig. 4. Poisoning effect by NH_3 on the activity of AMH in flow system. AMH 100 mg. Carrier gas N_2 17.8 cc/min. 1-butene 1.08 cc/min. Temperature 70°C. NH_3 was introduced simultaneously into the carrier gas.

Assuming a mutual interconversion among the three *n*-butenes according to the first-order rate law, the six relative values of the rate constants were calculated from the initial selectivities and the equiliblium constants. They are listed in Table 2, together with the reported values for solid acid catalysts.

Ammonia Titration during the Reaction in the Flow System. The change in the activity by the poisoning of the adsorbed NH_3 was also observed, as is shown in Fig. 4. It can be noticed that, in the poisoning curve, the decrease in the activity was not so abrupt, but was rather proportional to the amount of NH_3 added. The total amount of the NH_3 required to poison the activity completely was 4.03 meq/g. This coincided with the effective ion-exchange capacity measured by Na^+ (4.02 meq/g). The double-bond migration of 1-butene was investigated on a series of partially ion-exchanged resin catalyst, AMHNa or AMHMg. The kinetic parameters are listed in Table 1. This behavior is quite different from that of the simultaneous poisoning by NH_3 adsorption. The selectivity, ${}_{1}S_{c}^{t}$, expressed by the initial ratio of the products, *trans*-2-/*cis*-2-, had a slight tendency to decrease upon cation exchange by Na^+ or Mg^{2+}.

Table 1. Kinetic parameters for 1-butene isomerization over AMHNa series catalysts

Catalyst	$k_1 \times 10^3$ (min^{-1} g^{-1})	${}_{1}S_{c}^{t}$	E (kcal/mol)	log A
AMH	45.6	1.35	17.0	9.8
AMHNa05	26.7	1.19	17.0	9.6

Discussion

The catalytic activities of the sulfonated resin catalysts can presumably be attributed to the acidic properties of the hydrogens of the sulfonic acid groups. This was easily established by the fact that neither the substrate resin with no functional groups nor the Na-form resin showed any catalytic activities. This was consistent with the observations over the surface of *para*-toluenesulfonic acid and other various substituted benzenesulfonic acid.[21] It has been reported that deuterium adoption was observed in the course of isomerization of *n*-butenes over deuterated sulfonic

acid resin catalysts[22] and deuterated *para*-toluenesulfonic acid crystals.[23] Thus, from this point of view, the catalysis over the acidic ion-exchange resin can be considered to be that of a typical type of solid acid catalyst with a protonic character.

The titration curve in Fig. 1 shows that the hydrogens of $-SO_3H$ or AMH were dissociated to some extent to give pH 3.4—3.5 in decationized water. At the neutral point, pH 7.0, some of the exchangeable hydrogens survived. Manassen found that the number of exchangeable acidic groups calculated by the titration method was smaller than that obtained from the chemical analysis.[15] However, these two values do not necessarily correspond to the effective sulfonic acid groups in the working state of the gas-phase catalysis. The coincidence of the number of adsorbed NH_3 with that of the exchangeable hydrogens suggests that almost all the ion-exchangeable hydrogens are effectively active in the isomerization of *n*-butenes, even in the gas phase. The amount of NH_3, 4.03 meq/g, which was required for poisoning the activity correspond to the population of $H^+/3.1$ A^2. This means that the sulfonic groups become close enough for them to interact with each other or with adsorbed species. If there were some hydrated water, the probability of the interaction would increase.

The acid strength of *para*-toluenesulfonic acid and benzenesulfonic acid in an aqueous solution is said to be $pK_a=0.6$.[24] However, the acid strength of the sulfonic acid resin has not been obtained directly. Using Hammett indicators, the acid strength of AMH was observed as strong as $pK_a=-3.0$——-5.6 at the minimum. The acidities measured by means of *n*-butylamine titration in cyclohexane proved to be 3.9 meq/g ($pK_a=6.8$), 2.6 meq/g ($pK_a=1.5$), and 1.0 meq/g ($pK_a=-3.0$). It should be noticed that the value of 3.9 meq/g, which include rather weak acid sites agrees with the total number of ion-exchangeable hydrogen, and that there is an apparent heterogeneity in acid strength among the functional groups on the resin catalyst. In contrast to the phosphonated polyphenyl-type resin,[15] the titration curve for AMH showed no step-by-step ion exchange in a NaOH solution. When the conventional resin catalyst was used in a polar solvent, the heterogeneity of the activity of the functional groups has been considered to have negligibly small effect on the nature of the acid catalysts.[17] In polar solvents, the hydrogens of the sulfonic acid groups on the resin would dissociate into protons and they would be loosely bonded to the counter ion, $-SO_3^-$, much as in a highly concentrated polyelectrolyte solution.[25,26] In the evacuated state, the protonic hydrogens are probably bonded more tightly to the counter groups and thus their activities are more affected by the properties of the substrate. An inhomogeneous structure of the substrate resin is known to be produced in the processes of the polymerization, the crosslinking, and the sulfonation.[25]

On the other hand, the possibility of an induced heterogeneity can not be neglected. Considering the population of the functional groups, which corresponds to one sulfonic group for each phenyl groups, the following interactions can be anticipated: 1) between adjacent sulfonic groups,[25] 2) between adsorbed species and neighboring sulfonic acid groups,[27,28] and 3) between adsorbed species and substrate resin. If these interactions can not be neglected, the catalysis and the poisoning effect will be complicated in a detailed mechanism. The differences between the behavior of the gradual poisoning caused by NH_3 adsorption in the flow system and that caused by Na^+ ion exchange are difficult to explain. However, in the former case, NH_3 molecules may be randomly adsorbed onto the active sites and the front of the poisoned area in the catalyst bed may advance linearly with the addition of NH_3, while in the latter case, the ion exchange proceeds in the static system, where the equilibrium is accomplished progressively from the stronger sites to the weaker sites, so that the activity decreases remarkably on the addition of only a small amount of NaOH. In this case, both the intrinsic and the induced heterogeneities may be responsible for the curvature in the poisoning curve.

The effectiveness of the poisoning per ion by Na^+ and Mg^{2+} are nearly equal irrespective of the different compositions. This fact indicates that the divalent cation, Mg^{2+}, may block only one counter ion, like the monovalent cation Na^+, and that the surface complexes, such as $-SO_3MgCl$ and/or $-SO_3Mg(OH)$, may probably exist on the resin.

A compensation effect seemed to exist between the

pre-exponential factors and the apparent energies of activation for the double-bond migration of 1-butene over AMHNa-series catalysts. A similar relation was reported in the decomposition of alcohol over the Dowex-50-Na and -Li series.[17] These facts suggest that the ion exchange provokes the effects on both the enthalpy and the entropy terms of the activated system. The observed change in the selectivities is due to the same causes. The apparent energy of activation for 1-butene isomerization on AMH, 17 kcal/mol, is a little different from the reported value for the 1-butene adsorption forming the carbonium ion on the resin surface, 13.8 kcal/mol.[29]

29) D. Kallo, I. Preszler, and Schay, *Acta Chim. Acad. Sci. Hung.*, **64**, 211 (1970).

The relative values of the first-order rate constants based on the phenomenological ternary system are notably different from the results on the other solid acid catalysts, such as alumina, silica-alumina, and zeolites. The rate constants for *cis-trans* isomerization, k_{ct} and k_{tc}, are relatively large, and the selectivity from 1-butene, k_{1t}/k_{1c}, is more than unity. These findings are different from those for alumina or silica-alumina, as is shown in Table 2. It was found in the previous study that there was an inclination for Lewis-type acid sites to have smaller selectivities for the *trans*-2-butene formation than protonic acid sites on the several solid acid catalysts.[30] The relative values listed are consistent with this view.

The selectivity change during the strong fouling or as a result of poisoning was very samll. The isomerization of *n*-butenes over AMH can probably be explained by the mechanism *via* a common intermediate of the *sec*-butyl carbonium ion, as has already been proposed for similar acid catalysts.[20,31,32] The parallelism found between the catalytic activity for the polymerization of propylene and the double-bond migration can be said to support this idea.

The author wishes to express his thanks to Professor Emeritus Dr. Tadao Shiba for his valuable advice throughout the study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3333—3342 (1972)

The Vibrational Assignment and Force Constants of Halogenomethylsilanes and Their Germanium Analogues: $ClCH_2SiH_3$, $ClCH_2SiD_3$, $BrCH_2SiH_3$, $BrCH_2SiD_3$, $ClCH_2GeH_3$, and $ClCH_2GeD_3$

Keiichi OHNO and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received March 14, 1972)

The infrared spectra of $ClCH_2SiH_3$, $ClCH_2SiD_3$, $BrCH_2SiH_3$, $BrCH_2SiD_3$, $ClCH_2GeH_3$, and $ClCH_2GeD_3$ for both the gaseous and solid states in the 250—4000 cm^{-1} region have been obtained. All the fundamental vibrations except for the skeletal bending and $YH_3(-D_3)$ (Y=Si, Ge) torsional vibrations have been observed and assigned. The normal vibration calculation has been carried out using a modified Urey-Bradley force field. The transferability of the force constants has also been investigated.

In order to get information about the vibrational assignments and the molecular forms of the rotational isomerism from normal vibration calculations, a set of force constants in a modified Urey-Bradley force field for the group of molecules containing silicon or germanium atoms will be obtained.

The force constants of X_nYH_{4-n} (X=Cl, Br; Y=Si, Ge; n=1—4)[1] and $(CH_3)_4Si$[2] in an Urey-Bradley force field have been reported. Vibrational assignments for

$Cl^{35}CH_2Ge^{74}D_3$	30.59	247.92	262.63	−0.9839	11.6

CH_3YH_3,[3] $CH_3CH_2YH_3$,[4] and $(CH_3)_2SiH_2$[5] (Y=Si, Ge) have also been made.

We will now report the vibrational assignment and force constants of $ClCH_2SiH_3$, $ClCH_2SiD_3$, $BrCH_2SiH_3$, $BrCH_2SiD_3$, $ClCH_2GeH_3$, and $ClCH_2GeD_3$.

These assignments and force constants will be compared with those of the corresponding ethyl halides. These force constants will be transferred to the molecules concerning the rotational isomerism, such as chloromethylmethylsilane.

Experimental

The samples were prepared from tetrahalogenosilanes. The tetrahalogenosilanes were treated by diazomethane, and the resultant halogenomethyltrihalogenosilanes were reduced by $LiAlH_4$ or $LiAlD_4$ in *n*-butyl ether in a vacuum.[6] The crude samples were purified by repeated distillation in a vacuum. The germanium samples were prepared by a similar procedure.

The infrared spectra for the gaseous and solid states were recorded on a Perkin-Elmer model 621 infrared spectrophotometer. 10 cm and 1 m gas cells fitted with KBr or CsI windows were used for the gas measurements. The spectra for the solid states were obtained by condensing the gaseous samples on a CsI window cooled with liquid nitrogen.

Results and Discussion

Band Contours. Chloromethylsilane has been shown by microwave study to have the C_s symmetry and to have a slightly prolate asymmetric top.[7] For $XCH_2YH_3(-D_3)$ (X=Cl, Br; Y=Si, Ge), the principal moments of inertia and Ray's asymmetry parameters given in Table 1 were calculated from the following parameters: C-Cl=1.788 Å, C-Br=1.950 Å, C-Si=1.889 Å, C-Ge=1.945 Å, C-H=1.096 Å, Si-H=1.477 Å, Ge-H=1.529 Å, Y-C-X=109.3°, Y-C-H=109.3°, H-Y-H=110.6°, and H-C-H=107.5°. The bond angles given above have been assumed to be equal to the values for chloromethylsilane. Ray's asymmetry parameters indicate that these molecules may be approximated as a prolate symmetric top. The expected P-R spacing of parallel bands given in Table 1 was calculated by the use of the formulae of Gerhard and Dennison, using $(I_b+I_c)/2$ for I_x.[8] The observed P-R spacing is given in Tables 8—10.

Vibrational Assignments. Halogenomethylsilanes and halogenomethylgermane may have the C_s symmetry. The 18 normal vibrations are reduced to 11 vibrations of the A′ species and 7 of A″, both of which are infrared active. The *a* and *b* internal axes are in the plane of symmetry, while the *c* axis is perpendicular to it. The A′ vibrations may have either *a*-, *b*-, or *ab*-type infrared band contours in the asymmetric top case. The A″ vibrations, on the other hand, have *c*-type infrared band contours. Vibrational assignments of the CH_2 group may be made with reference to the band contours and assignments for CH_2Cl_2,[9] which has magnitudes of rotational constants and asymmetry parameters similar to those for $XCH_2YH_3(-D_3)$. Also, vibrational assignments are made with reference to those of $CH_3YH_3(-D_3)$[3] and $CH_3CH_2YH_3(-D_3)$.[4] The observed frequencies and their assignments are summarized in Tables 2—7. The fundamental vibrations are given in Tables 8—10, together with the intensities, band types, and P-R spacings.

Vibrations of the CH_2 Group. The CH_2 stretching vibrations are expected near 3000 cm^{-1}. In this region, almost all higher bands were of the *c*-type, while the lower bands were of the *ab*- or *b*-type, indicating that the former bands should be assigned to the CH_2 antisymmetric stretching vibration and the latter to this symmetric vibration. These two bands were observed at slightly higher frequencies for molecules with heavier atoms or groups attached to the CH_2 group.

The CH_2 deformation vibrations are expected in the 700—1500 cm^{-1} region. For these molecules, the CH_2 scissors, wagging, twisting, and rocking vibrations were observed as *a*- or *ab*-type bands at about 1400 cm^{-1}, as *ab*- or *b*-type bands at 1100—1200 cm^{-1}, as *c*-type bands at 1050—1120 cm^{-1}, and as *c*-type bands at about 800 cm^{-1}. It is noted that the CH_2 twisting vibrations for $XCH_2YH_3(-D_3)$ are observed clearly as *c*-type bands, similar to those for CH_2X_2(X=Cl, Br),[9] and unlike those for $CH_3CH_2YH_3(-D_3)$[4] and CH_3CH_2X,[10] whose CH_2 twisting vibrations are not well separated from the CH_2 wagging vibrations.

The broad absorptions observed in the gaseous state at 1000—1200 cm^{-1} may be assigned to the vibrations for decomposed compounds, because no corresponding absorptions are observed in the solid state.

Vibrations of the $YH_2(-D_3)$ (Y=Si, Ge) Group. For $CH_3YH_3(-D_3)$, $CH_3CH_2YH_3(-D_3)$, and $XCH_2YH_3(-D_3)$, the corresponding vibrations of $YH_3(-D_3)$ group are expected in the same frequency region and give rise to a similar type of bands in the gaseous state. A very strong *c*-type band assigned to the SiH_3 asymmetric stretching vibrations of both *A′* and *A″* species and an *ab*-type band assigned to the symmetric stretching vibration were observed at 2197 and 2168 cm^{-1} for $ClCH_2SiH_3$, and at 2197 and 2164 cm^{-1} for $BrCH_2SiH_3$, respectively. The separations between the SiH_3 asymmetric and symmetric stretching vibrations for CH_3YH_3 and $CH_3CH_2YH_3$ have been reported to be smaller than 6 cm^{-1}. On the other hand, a larger separation of about 30 cm^{-1} was observed for XCH_2YH_3. However, as no other fundamental vibrations are expected in this region, mixing with the other vibrations cannot be considered. As the YD_3 stretching vibrations were observed in the 1500—1600 cm^{-1} region, mixing with a nearby vibration such as the CH_2 scissors at about 1400 cm^{-1} was expected. The separations for CH_3YD_3 and $CH_3CH_2YD_3$ have been reported to be about 20 cm^{-1}. For XCH_2YD_3, these separations and also a splitting between *A′* and *A″* species of the YD_3 asymmetric stretching vibrations were observed.

The SiH_3 asymmetric deformation of *A′* and *A″* vibrations were assigned to the strong *c*-type band at 950 cm^{-1} for $ClCH_2SiH_3$ and at 944 cm^{-1} for $BrCH_2SiH_3$. This symmetric vibration was assigned to the very strong *b*-type band at 925 cm^{-1} for both $ClCH_2SiH_3$ and $BrCH_2SiH_3$. For $ClCH_2SiD_3$, the strong bands at 700 (*c*-type) and 676 cm^{-1} were assigned to the SiD_3 asymmetric vibrations of the *A″* and the *A′*

10) T. Shimanouchi, Tables of Molecular Vibrational Frequencies, Part I, Bulletin NSRDSNBS 6, p. 40—41, NBS 6, Washington, D. C. (1967) and F. A. Miller and F. E. Kiviat, *Spectrochim. Acta*, **25A**, 1363 (1969).

species respectively. However, this symmetric vibration is considered to mix with the C–Si stretching vibration. Also, for $BrCH_2SiD_3$, the assignments of four bands due to the C–Si, C–Br stretchings, and SiD_3 deformations vibrations with the same symmetry may be complicated, since these vibrations are expected in the same frequency region. These vibrations were assigned on the basis of a normal vibration calculation. For $ClCH_2GeH_3$ and $BrCH_2SiH_3$, both the A' and A'' vibrations of the YH_3 rocking were assigned to the strong *ab*- or *b*-type bands near 500 cm^{-1}. However, for $ClCH_2SiH_3$, a weak *c*-type band assigned to the A'' vibration of the SiH_3 rocking was observed at 509 cm^{-1}. This A' vibration was assigned to the strong *ab*-type band at 557 cm^{-1}. The YD_3 rocking vibrations were observed as strong *b*-type bands (A') at about 400 cm^{-1} and as medium-intensity bands (A'') on the lower frequency side of the former bands.

The vibrational assignments for $ClCH_2GeH_3(-D_3)$ were made similarly; they are given in Tables 6 and 7.

The splittings of the $YH_3(-D_3)$ rocking vibrations ($(\nu_{10}—\nu_{17})$ in Tables 8—10) can be compared for related molecules: 87 cm^{-1} (72 cm^{-1}) for $CH_3CH_2SiH_3(-D_3)$>48 cm^{-1} (46 cm^{-1}) for $ClCH_2SiH_3(-D_3)$> 0 cm^{-1} (14 cm^{-1}) for $BrCH_2SiH_3(-D_3)$ and 29 cm^{-1} (35 cm^{-1}) for $CH_3CH_2GeH_3(-D_3)$>0 cm^{-1} (14 cm^{-1})

a, b, c, d, e) See a), b, c), d), and e) of Table 8.

for $ClCH_2GeH_3(-D_3)$. It is expected that the skeletal bending vibrations go away from the $YH_3(-D_3)$ rocking vibration gradually in this order: C-C-Y<Cl-C-Y< Br-C-Y. The splittings decrease in the same order. Moreover, the ratio $((\nu_{10}-\nu_{17})/\nu_{17}$ in Tables 8—10) for the YH_3 rocking vibration is smaller than that for the YD_3 rocking vibration. This shows that the splittings increase when the frequencies of the $YH_3(-D_3)$ rocking and the skeletal bending vibrations become closely spaced together. It seems that the $YH_3(-D_3)$ rocking vibration is affected by the skeletal bending vibration.

Skeletal Vibrations. The $XCH_2YH_3(-D_3)$ molecules have four skeletal vibrations: the C–Y stretching, C–X stretching, X–C–Y bending, and $YH_3(-D_3)$ torsional vibrations. The latter two vibrations were expected in the region below 300 cm^{-1}, which were not observed in the present study. The C–Y and C–X stretching vibrations have the same symmetry, and their bands are expected to appear in the same spectral region of 600—800 cm^{-1}, mixing with each other. Two strong or medium *b*-type bands were observed in this region. These vibrations were assigned on the basis of a comparison of the infrared spectra of $ClCH_2SiH_3(-D_3)$, $BrCH_2SiH_3(-D_3)$, and $ClCH_2GeH_3(-D_3)$ and the normal vibration calculations.

Overtone and Combination Vibrations. The assignments of some overtone and combination vibrations are given in Tables 2—7. For all of the $XCH_2YH_3(-D_3)$, the CH_2 scissors and CH_2 wagging combination vibrations were observed as *b*-type bands near 2500 cm^{-1}. The unassigned weak absorptions may be due to the combination or overtone vibrations for the X–C–Y bending and the $YH_3(-D_3)$ torsion, or to the difference vibrations for fundamentals.

Normal Vibration Calculation

In order to get information about the vibrational assignments and the molecular forms for the rotational isomerism, a set of force constants of the molecules containing silicon or germanium atoms are investigated. The Urey-Bradley force field may be the most effective force field for this purpose.[11] We have attempted to establish the transferability of the set of force constants for similar molecules.

At first, the force constants for CH_3YH_3 were transferred from those for XYH_3[1] and $(CH_3)_4Si$.[2] The force constants of H(C–Y–H), H(Y-C–H), F(C·Y·H), and F(Y·C·H) were, then, obtained by adjusting the calculated frequencies towards the observed.

Secondly, the force constants for CH_3YH_3 and XCH_2-CH_2X[12] were transferred to those for XCH_2YH_3, where the structural parameters were of the same values used in the calculation of the moments of inertia, but assuming tetrahedral angles. Symmetry coordinates are the usual, commonly-used ones.[3,9]

As no X–C–Y bending vibrations were observed in the present study, the force constants of H(X–C–Y) and F(X·C·Y) could not be determined. For them we used the values for XCH_2CH_2X.

In the simple Urey-Bradley force field, the $YH_3(-D_3)$ rocking, CH_2 rocking, and CH_2 twisting frequencies of the *A''* species strongly suggest the necessity of some modification of the force field. Therefore, *trans* coupling, *t*, and *gauche* coupling, *g*, were added, assuming the *gauche* coupling to be $g=-0.5\,t$.[13] When all the transferred force constants of bending and repulsion were used, the mean errors of the calculated and observed frequencies for these molecules could not be made smaller than 2%. The assumption was made that some bending force constants were variable for each molecule and that the repulsion force constants were transferable.

The set of force constants obtained is listed in Table

in Tables 12—14. The distribution of the potential energy (PED) among the modes shows that the concept of characteristic group frequencies can be applied to all the halogenomethylsilanes and to halogenomethylgermane except for some modes. It may also be seen that the CH_2 rocking, YH_3 rocking, and YH_3 asymmetric deformation modes of the A'' species, and the C-X stretching and YH_3 rocking modes of the A' species, show a considerable amount of mixing for $XCH_2YH_3(-D_3)$ (PED, 5—30%). Especially in $ClCH_2GeH_3(-D_3)$, the Ge-C-Cl bending and $GeH_3(-D_3)$ rocking modes show a mixing of about 20% (PED). It seems that the *trans* coupling, t_1, largely contributed to this, because this value for $ClCH_2GeH_3$ is significantly larger than that for XCH_2SiH_3.

The authors wish to thank Associate Professor Michiro Hayashi of Hiroshima University for his helpful discussions and advice throughout the experiments and Mr. Yasuhiro Takeda and Mr. Kazuki Hamo for their help in the syntheses of the initial samples. The authors also wish to thank Dr. Hiromu Sugeta of Osaka University for the use of his computer programs.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3342—3345 (1972)

Fractionation of Tritiated Water in Potassium Chromium Sulfate Dodecahydrate

Haruhiko TANAKA,* Tsutomu KADO, and Hisao NEGITA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received March 21, 1972)

A considerable dilution of tritiated water in the water of crystallization was observed in the crystal-growth process of $KCr(SO_4)_2 \cdot 12H_2O$ from a slightly supersaturated aqueous solution. This was explained in terms of an ionic process in aqueous solution and a surface-diffusion mechanism of crystal growth. It was also found that the tritium content in the hexahydrate was appreciably smaller than that in the liberated water during the course of reaction;

$$KCr(SO_4)_2 \cdot 12H_2O \xrightarrow[in\ vacuo]{40^\circ C} KCr(SO_4)_2 \cdot 6H_2O + 6H_2O.$$

It seems that the stepwise dehydration supports the dehydration mechanism proposed by Garner.

It has been reported that an examination of the fractionation of tritiated water in the crystallization of some hydrated salts from an aqueous solution helps clarifying the crystal-growth mechanism and/or the behavior of water during the course of crystallization.[1] We might expect that examination of the possible fractionation of tritiated water during the course of stepwise dehydration also leads to understanding of the dehydration mechanism. Though various studies have been carried out on the dehydration processes, not much has been done to clarify its mechanism. So far such an elucidation does not seem to have been made in the light of the fractionation of tritiated water.

Recently, the hydration of ions in an aqueous solution has been studied extensively by various methods, the life-time of a hydrated cation being determined.[2] Eigen stated from the relaxation technique that alkali metal ions are very weakly hydrated in aqueous solutions, *i.e.*, the life-time of the hydrated cations is *ca.* 10^{-9} sec.[3]

On the contrary, it is well-known that the water of hydration of a chromium ion is very rigidly held in the sphere, *i.e.*, the life-time of the Cr^{3+} ion is *ca.* 10^5—10^6 sec.[4]

The crystal growth of a few salts from very slightly supersaturated solutions has been studied extensively by Bennema.[5] He concluded from his study that the crystal growth may occur by means of the surface-diffusion mechanism originally proposed by Burton *et al.*

Hepburn and Phillips reported that the water coordinated to the univalent cation is primarily dissociated *in vacuo* in the case of alum:[6]

$$[M^+(OH_2)_6][M^{3+}(OH_2)_6](SO_4)_2 \longrightarrow M^+[M^{3+}(OH_2)_6](SO_4)_2 + 6H_2O$$

On the contrary, Garner suggested that the exchange of the water coordinated to each cation in alum occurs during the course of stepwise dehydration, the excess water being dissociated to give the hexahydrate.[7] A study from a new view point is desirable for the elucidation of the mechanisms of the crystal growth and dehydration. It seems to be of interest to examine the possible fractionation of tritiated water in alum which would be caused by the crystal growth from a solution and stepwise dehydration.

For this purpose, potassium chromium sulfate dodecahydrate, $KCr(SO_4)_2 \cdot 12H_2O$, was chosen.

Experimental

Commercial potassium chromium sulfate dodecahydrate was purified by recrystallization. Twice-distilled water containing a trace amount of tritiated water (HTO) was used as a solvent. The single crystal of $KCr(SO_4)_2 \cdot 12H_2O$ was grown from a slightly supersaturated tritiated aqueous solution at 20.2°C by evaporating the solvent gradually.

Half of the water of crystallization was removed from the single crystal at 40°C *in vacuo*. Another half of the water was dehydrated completely by heating at 350°C. Water from the dodecahydrate was also recovered by heating at 350°C until no further dehydration was observed. The recovery of water is shown in Fig. 1.

The tritium contents were compared by analyzing the activity of tritium. Measurements were carried out with a liquid scintillation counter, a Packard Model 2002 Tri-Carb Scintillation Spectrometer. As a scintillant we used a solution composed of toluene, ethylene glycol monomethyl ether, 2,5-diphenyloxazole (PPO) and 1,4-bis-2′-(5′-phenyloxazolyl) benzene (POPOP).

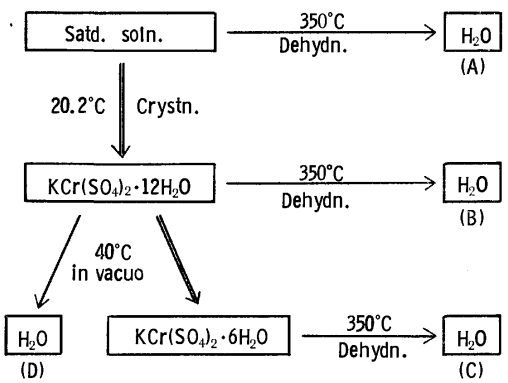

Fig. 1. The scheme for the recovery of water.

Results and Discussion

The separation factor S_1 of HTO for the crystal growth of a hydrated salt from a slightly supersaturated aqueous solution has been defined as $S_1 = N_s/N_l$, where N_s and N_l are the mole fractions of HTO in the solid and liquid phases, respectively.[8] On the contrary, the separation factor S_2 for the dehydration $KCr(SO_4)_2 \cdot 12H_2O \longrightarrow KCr(SO_4)_2 \cdot 6H_2O + 6H_2O$ can be defined as the ratio of the mole fraction of HTO in the hexahydrate to that in the dodecahydrate. The separation factor S_3 can thus be given by the ratio of HTO content in the primarily liberated water to that in the dodecahydrate.

Table 1. Separation factor of HTO in $KCr(SO_4)_2 \cdot 12H_2O$

Comparison of watr	Ratio of cpm[a]	Separation factor
(B)/(A)	(17469±170)/(18191±83)	$S_1 = 0.960 \pm 0.007$
(C)/(B)	(17222± 71)/(17469±170)	$S_2 = 0.986 \pm 0.007$
(D)/(B)	(17895±173)/(17469±170)	$S_3 = 1.024 \pm 0.009$

a) Mean of 5–6 measurements with a counter of 35% efficiency.

Table 1 shows the observed fractionation of tritiated water. (A), (B), (C), and (D) denote the kinds of water shown in Fig. 1. The average net counts per minute (cpm) for 0.1 g of water and the values of the separation factor which are equal to the ratios of cpm are given, each cpm being in proportion to the mole fraction of HTO.

We see from the S_1 value 0.960 that tritiated water is considerably diluted in the dodecahydrate during the course of crystallization from its aqueous solution. It is found from the S_2 value 0.986 that tritiated water is appreciably diluted in the hexahydrate during the course of stepwise dehydration; $KCr(SO_4)_2 \cdot 12H_2O \xrightarrow[in\ vacuo]{40°C} KCr(SO_4)_2 \cdot 6H_2O + 6H_2O$. The dilution in the hexahydrate can also be seen from the S_3 value 1.024.

Tritium Fractionation on the Crystal Growth of $KCr(SO_4)_2 \cdot 12H_2O$. It has been reported that the S_1 value is found to be nearly equal to unity if the crystal grows according to a volume-diffusion mechanism; there is a direct integration of the growth unit from the solution into the kink without any surface diffusion.[9] On the contrary, tritiated water may be diluted in the water of crystallization, if a surface-diffusion mechanism in which the growth unit diffuses over a wide range of the crystal surface before integrating into the kink, controls the crystal growth from a solution.[1]

It has been shown in the crystal growth of potassium aluminum sulfate dodecahydrate $KAl(SO_4)_2 \cdot 12H_2O$ that HTO can be diluted in the water of hydration of

the K^+ ion in the crystal and the fractionation may not actually take place for the hydration water of the Al^{3+} ion in the crystal.[1] The R_{HTO}/R_{H_2O} ratio has been obtained for the free water on the crystal growth of the hydrated salt *via* surface diffusion:

$$R_{HTO}/R_{H_2O} = (m_{H_2O}/m_{HTO})^{1/2} = 0.949, \quad (1)$$

where R_{HTO}/R_{H_2O} is the ratio of the integration of HTO into the crystal to that of H_2O, and m_{H_2O}/m_{HTO} the mass ratio of H_2O to HTO.

Although the hydration number of an ion in an aqueous solution can not be defined in a strict sense, it may be conveniently taken as the number of water molecules directly coordinated to the central ion, for example, six for the Cr^{3+} ion.[10] The hydration water of the K^+ ion may, as is the case for $KAl(SO_4)_2 \cdot 12H_2O$, be assumed to become free to be integrated into the crystal from a solution, since the life-time of the hydrated cation is extremely short; *ca.* 10^{-9} sec.[3] This seems to be in line with the suggestion of Samoilov that the K^+ ion diffuses in an aqueous solution practically without any hydration water.[11]

It is well-known that the water is strongly bound to the Cr^{3+} ion as compared with the Al^{3+} ion, *i.e.*, the life-time of $Cr(OH_2)_6^{3+}$ and $Al(OH_2)_6^{3+}$ is 10^5—10^6 sec[4] and 1—10 sec,[12] respectively. Thus, the Cr^{3+} ion can be assumed to enter the crystal accompanying the hydration water, since such a behavior may be the case with Al^{3+} ion.[1] As for the sulfate ion, hydration may be negligibly weak in that the ion may be integrated into the crystal practically without accompanying hydration water as is the case for the K^+ ion.

Accordingly, it appears that half of the water in $KCr(SO_4)_2 \cdot 12H_2O$, *i.e.*, the water of crystallization coordinated to the K^+ ion, comes from the free water and another half from the hydration water of the Cr^{3+} ion in the solution. It can be assumed that HTO is diluted in $K(OH_2)_6^+$ of the dodecahydrate according to Eq. (1) and that no practical fractionation takes place in $Cr(OH_2)_6^{3+}$ of the crystal, if we neglect the possible slight enrichment of HTO in the hydration water of the Cr^{3+} ion in the solution.[13]

Although the calculated value of S_1 deviates a little from the observed one, the considerable dilution of HTO in the crystal is explained not by the volume-diffusion but surface-diffusion mechanism and the ionic process.

Validity of the Calculation of S *in Relation to the Data with HDO.* Studies have been carried out on the fractionation of deuterated water (HDO) in the crystallization of hydrated salts from solutions and some important data have been given.[14-16] The data by Barrer and Denny[14] include the S value of HDO less than the lower limiting value of 0.973 which is obtained if the present assumption for the calculation of S of HTO is applied to that of HDO.

Johansson and Holmberg[15] found that HDO is slightly enriched in some hydrated crystals. The enrichment of heavy water in the crystal can not be explained well by the present treatment, *i.e.*, the maximum S value may be estimated to be unity in the case of the volume-diffusion mechanism.[9]

The discrepancy may be due to the following factors: (1) The S value should depend on experimental conditions, especially on the crystallization rate and temperature. (2) Strictly speaking, the fractionation of heavy water in the hydration water is not always negligible in the aqueous solution. (3) The S value might also be influenced by the bond character of the water of crystallization in the crystal.

Factor (1) seems to be the most important at this stage since the well developed single crystal we obtained was grown from a very slightly supersaturated solution under strictly controlled conditions, where the theory of crystal growth can be applied.

Tritium Fractionation on the Dehydration of $KCr(SO_4)_2 \cdot 12H_2O$. Studies have been carried out on the dehydration of hydrated salts *in vacuo*.[17] Numerous examples reveal that an interfacial mechanism is frequently operative during the course of dehydration. It is also assumed generally that water molecules dissociate from the surface of a hydrated crystal to cause a partially dehydrated structure which then leads to a partly amorphous state. A further rearrangement then occurs giving crystalline nuclei of a new phase.

Hepburn and Phillips suggested that (1) the water coordinated to the univalent ion is primarily dissociated *in vacuo* in the case of alum without any exchange of the water with the hydration water of the trivalent ion, and (2) the hexahydrated crystal is then formed in which the structure differs from that of the original dodecahydrate.[6]

It has been suggested that tritiated water is diluted in the hydration water of the K^+ ion in the crystal of the dodecahydrate during the course of crystallization from a solution. Thus, the S_2 and S_3 values can be estimated to be larger and smaller than unity, respectively, if the mechanism proposed by Hepburn and Phillips is the case in the dehydration process.

However, contrary to expectation, the S_2 and S_3 values were found to be 0.986 and 1.024, respectively, implying that the dehydration does not proceed by means of the above mechanism. Thus it can be expected that an alternative mechanism controls the stepwise dehydration of $KCr(SO_4)_2 \cdot 12H_2O$ *in vacuo*.

The dehydration process of $KCr(SO_4)_2 \cdot 12H_2O$ to $KCr(SO_4)_2 \cdot 6H_2O$ is assumed to be followed by three steps.[7] (1) Collapse of the lattice of the dodecahydrate to give an amorphous intermediate and gradual growth of the nuclei of the hexahydrate, (2) diffusion of the dissociated water through the product, and (3) evaporation of the water from the surface of the product. A diagram of the dehydration mechanism is given in Fig. 2. Such a dehydration process implies that the ex-

change of the hydration water of the Cr^{3+} ion with the other water molecules occurs during the course of dehydration. Such an exchange seems to be supported by the work of Okazaki *et al.*[18]

We believe that Garner's suggestion is appropriate and can be used to account qualitatively for the separation factors, S_2 and S_3. Under the present experimental conditions, the dodecahydrate seems to decompose to give an amorphous intermediate with the adsorbed water molecules on the surface as well as in the interior. The dilution of tritiated water in the hexahydrate may occur in the succeeding rearrangement, since the hydration water of the Cr^{3+} ion is interchangeable with that of the K^+ ion. That is, the hexahydrate may recrystallize from the amorphous state, when the dilution occurs in a similar manner to that in the crystallization of a hydrate from an aqueous solution by means of a surface-diffusion mechanism.

It can be concluded that the dehydration, $KCr(SO_4)_2 \cdot 12H_2O \xrightarrow[in\ vacuo]{40°C} KCr(SO_4)_2 \cdot 6H_2O + 6H_2O$, proceeds by the mechanism of Garner and not by that of Hepburn and Phillips.

The authors express their thanks to Dr. Osamu Yamamoto for his help in measuring the activity of tritium.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3345—3349 (1972)

The Diffuse Reflection Spectra of 1-Arylazo-2-naphthols Deposited on Various Synthetic Fibers

Yoshio MATSUNAGA and Nobuhiko MIYAJIMA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo
(Received March 23, 1972)

The diffuse reflection spectra of sixteen 1-arylazo-2-naphthols deposited on polypropylene, polyacrylonitrile, polyethylene terephthalate, and Nylon-6,6 were recorded in the range from 350 to 700 nm. The spectra indicate the coexistence of the azo and hydrazone tautomers in these systems. By a comparison with the absorption spectra of the compounds dissolved in *n*-hexane, acetonitrile, methyl benzoate, and formamide, it was concluded that the nature of the fibers is the major factor determining the tautomeric equilibria. The effect of moisture on the spectra was found to be rather small except in the cases of the *p*-OH and *p*-MeO derivatives deposited on polyacrylonitrile.

In earlier work, evidence from diffuse reflection spectra was presented for the existence of an azo-hydrazone tautomerism of 1-arylazo-2-naphthols[1] diluted with sodium chloride.[2] The spectra were found, in many cases, to be temperature-dependent. The direction of the change is governed by the kind and position of the substituents; *e.g.*, the change is towards the hydrazone tautomer when the temperature is elevated in the cases of the *p*-Cl and *o*-NO_2 derivatives. Furthermore, the equilibrium was found to move by dilution towards the hydrazone tautomer in all cases. As more and more molecules of the compound are dispersed by dilution, the trend observed was attributed to the stabilization of the hydrazone tautomer by the highly polar surface of the alkali halide. This conclusion has been confirmed by recent measurements of the fluorescence of the same samples.[3] On the other hand, the equilibrium in solution was well established by Burawoy *et al.* about twenty years ago.[4] The relative stability of the hydrazone tautomer was reported to increase in this order of solvents: *n*-hexane<ethanol<chloroform<water. On the basis of these observations, we would expect the tautomeric composition of the azo dyestuff to be much affected by the nature of the substrate on which the compound is deposited.

Our previous work on the diffuse reflection spectra of filter papers dyed with 1-arylazo-2-naphthols revealed that the two tautomeric forms coexist in this state.[5]

1) This designation is used throughout this paper for convenience; it is not intended to define the structure of the compounds.

In addition, the appreciable changes in the hue of the dyed papers caused by moisture could be explained by the deviation from the Kubelka-Munk theory due to the increased regular reflection and, in many cases, by the movement of the equilibrium. In order to demonstrate clearly the effect of substrates on the equilibrium, it would seem to be convenient to employ substrates less hygroscopic than cellulose. Therefore, we selected for this study four synthetic fibers—namely, polypropylene, polyacrylonitrile, polyethylene terephthalate, and Nylon-6,6. To check whether or not the equilibria are essentially determined by the interaction with the substrate, the absorption spectra of 1-arylazo-2-naphthols dissolved in the following solvents were also examined: *n*-hexane, acetonitrile, methyl benzoate, and formamide. These solvents will be considered as model compounds of the synthetic fibers employed.

Experimental

Materials. The samples of 1-arylazo-2-naphthols were the same as those used in our previous work.[5] The derivatives carried one of the following substituents in the *o*-, *m*-, and *p*-positions on the phenyl rings: methyl, chloro, hydroxyl, methoxy, or nitro group.

Fabrics made of polypropylene, polyacrylonitrile, polyethylene terephthalate, and Nylon-6,6 were kindly provided by the Japan Exlan Co. and the Toyo Spinning Co.

Measurements. Fabrics cut into squares, 5 cm×5 cm, were wetted as uniformly as possible with an acetone solution of one of the 1-arylazo-2-naphthols, dropped from a 1 m*l* pipette with graduations. The amount of the compound was then adjusted to about 6 μg per cm^2. The procedure in the diffuse-reflectance measurements was similar to that described in our previous paper.[5] The spectra were plotted using the Kubelka-Munk function, $f(R)=(1-R)^2/2R$, where R is the reflectance. Both the reflection and absorption spectra are presented by taking the maxima arbitrarily as 1.00 in all the figures.

Results and Discussion

1-Phenylazo-2-naphthol (Figs. 1 and 2). The absorption spectra in the four solvents are shown in Fig. 1. For example, the spectrum in *n*-hexane shows two strong bands at about 420 and 460 nm, and a weak one around 500 nm, whereas in formamide the intensity of the first band is relatively reduced and those of the second and third are considerably increased. The band at 420 nm is known to be due to the azo tautomer, and the rest, to the hydrazone tautomer. A comparison of the spectra in Fig. 1 and those recorded in our related works indicates that the concentration of the azo tautomer of 1-phenylazo-2-naphthol decreases in this order of solvents: *n*-hexane (1.890)>acetonitrile (37.5)>ethanol (24.30)>methyl benzoate (6.59)>chloroform (4.806)>formamide (109.5)>50% ethanol. The numbers in parentheses are the dielectric constants of the respective solvents.[6] Burawoy and Thompson noted that the order of solvents obtained by them is approximately in line with the increasing dielectric constant.[7] However, the above-mentioned order, where acetonitrile, methyl benzoate, and formamide were newly added, does not support their suggestion.

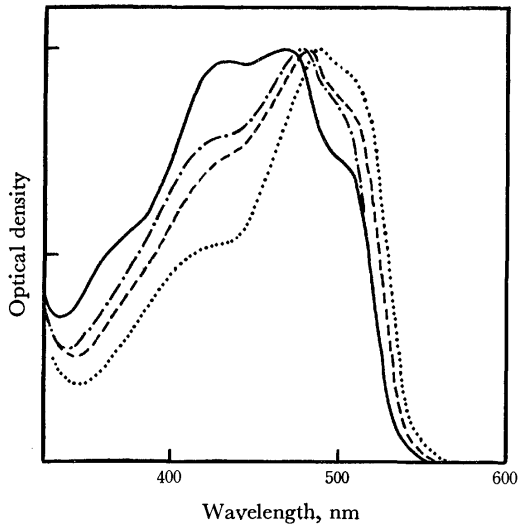

Fig. 1. Absorption spectra of 1-phenylazo-2-naphthol dissolved in *n*-hexane (——), acetonitrile (-·-·), methyl benzoate (----), and formamide (·····).

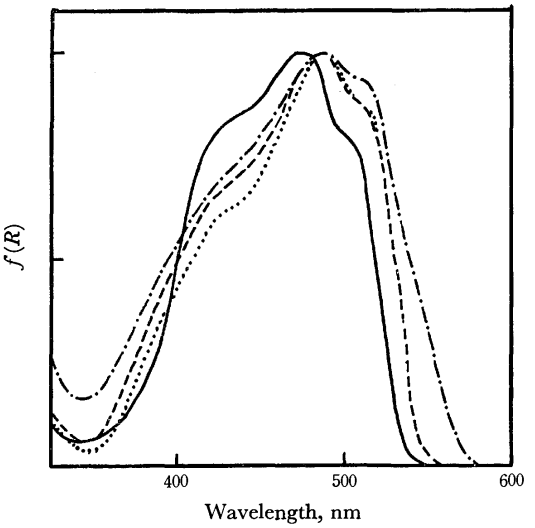

Fig. 2. Reflection spectra of 1-phenylazo-2-naphthol deposited on polypropylene (——), polyacrylonitrile (-·-·), polyethylene terephthalate (----), and Nylon-6,6 (·····).

Figure 2 presents the diffuse reflection spectra of the 1-phenylazo-2-naphthol deposited on the four synthetic fibers. The relative intensity of the 420 nm band due to the azo tautomer decreases in this order of substrates: polypropylene>polyacrylonitrile>polyethylene terephthalate>Nylon-6,6, an order which corresponds well to the order of solvents. Therefore, it seems to be certain that the nature of the fibers is the major factor determining the equilibrium. Unfortunately, the relative intensity of the band appearing around 500 nm and assignable to the hydrazone tautomer is not quite consistent with that of the band at 420 nm. As will be mentioned, the disagreement seems to arise from the anomalous behavior of the compound deposited on polyacrylonitrile.

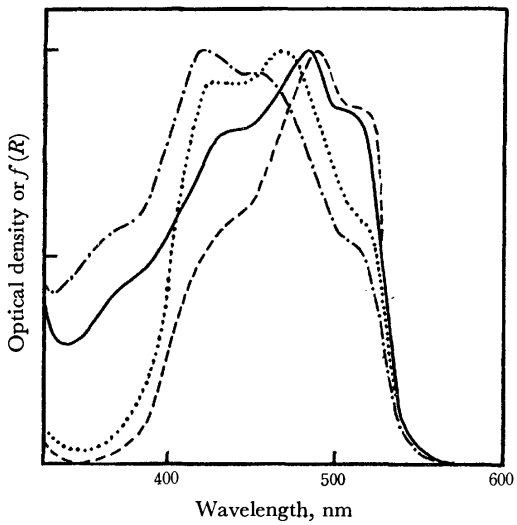

Fig. 3. Absorption spectra of 1-(*o*-tolylazo)-2-naphthol (——) and 1-(*p*-tolylazo)-2-naphthol (-·-·) dissolved in *n*-hexane and reflection spectra of the former compound (——) and the latter (·····) deposited on polypropylene.

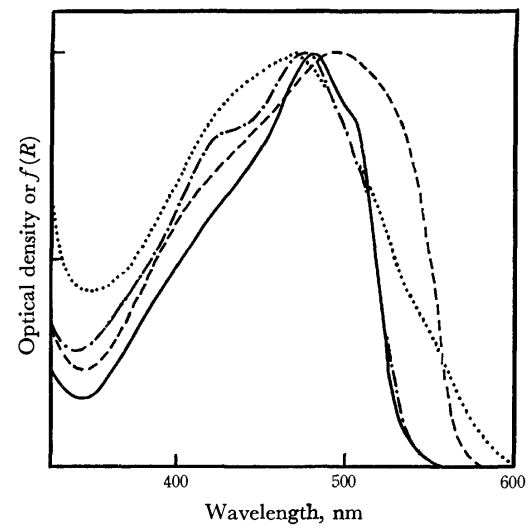

Fig. 4. Absorption spectra of 1-(*o*-chlorophenylazo)-2-naphthol (——) and 1-(*p*-chlorophenylazo)-2-naphthol (-·-·) dissolved in acetonitrile and reflection spectra of the former compound (——) and the latter (·····) deposited on polyacrylonitrile.

1-Tolylazo-2-naphthols (Fig. 3). Burawoy *et al.* reported that the intensity of the absorption band due to the azo tautomer in an ethanolic solution increases in this order of substituents: *o*-Me<*m*-Me~H<*p*-Me.[4] As an example, the absorption spectra of the *o*- and *p*-Me derivatives in *n*-hexane are compared with the reflection spectra of the same compounds deposited on polypropylene in Fig. 3. In accordance with the order of substituents reported by Burawoy *et al.*, the concentration of the azo tautomer in *n*-hexane appears to be higher in the *p*-Me derivative than in the *o*-Me derivative. The same tendency is also found in the reflection spectra. However, it may be noted that the hydrazone tautomer is a little more stabilized by polypropylene than by *n*-hexane. The spectrum of the *p*-Me derivative is the most markedly dependent on not only the solvent, but also on the substrate, among the 1-tolylazo-2-naphthols. The relative intensity of the band due to the azo tautomer around 420 nm was found to decrease in this order: polyacrylonitrile> polypropylene>polyethylene terephthalate>Nylon-6,6. Here again, polyacrylonitrile is not located in the expected position. On the other hand, the intensity of the band due to the hydrazone tautomer at about 520 nm increases in the order to be expected from the nature of the substrates.

1-Chlorophenylazo-2-naphthols (Fig. 4). The relative intensity of the band due to the azo tautomer in solution increases in the following order: *o*-Cl<*m*-Cl< *p*-Cl, as has been reported by Burawoy *et al.*[4] The solution spectra of the last derivative are nearly the same as those of 1-phenylazo-2-naphthol. In the other two cases, the hydrazone tautomers are so favored that their spectra are rather insensitive to the change in solvents. In accordance with this observation, their reflection spectra are not much modified by the substrates. In Fig. 4, the absorption spectra of the *o*- and *p*-Cl derivatives in acetonitrile are compared with the reflection spectra of the compounds deposited on polyacrylonitrile. The structures observed in the former spectra are not detectable in the latter; however, it is not difficult to see that the reflection spectrum bears a similarity to the respective absorption spectrum.

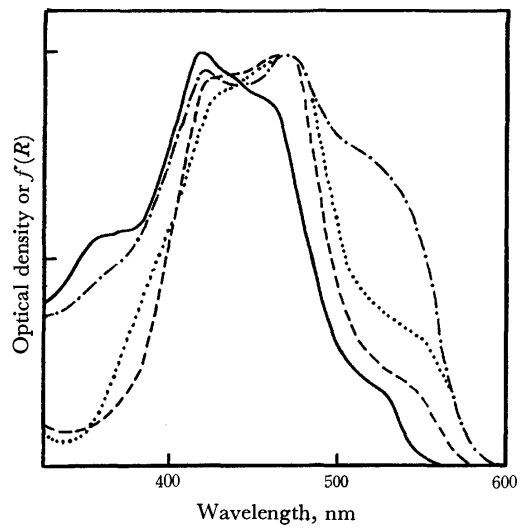

Fig. 5. Absorption spectra of 1-(*p*-hydroxyphenylazo)-2-naphthol dissolved in *n*-hexane (——) and formamide (-·-·) and reflection spectra of the same compound deposited on polypropylene (----) and Nylon-6,6 (·····).

1-Hydroxyphenylazo-2-naphthols (Fig. 5). On the basis of the relative intensity of the band at 420 nm, the concentration of the azo tautomer may be concluded to increase in this order of substituents: *o*-OH< *m*-OH<H<*p*-OH. Consequently, the most pronounced solvent effect on the spectrum can be observed with the *p*-OH derivative. The two extremes of the spectra, that is, those in *n*-hexane and formamide, are shown in Fig. 5. In the former solution, the band at 420 nm, assignable to the azo tautomer, is the strongest. On the other hand, the band due to the hydrazone

tautomer located at 470 nm is much intensified in the latter solution. In addition, it must be noted that the shoulder around 525 nm is appreciably enhanced. The solvent effect on the tautomeric equilibrium is not exactly the same as that found for 1-phenylazo-2-naphthol, suggesting the presence of some specific interaction between the solute and solvents. In the order of solvents for the *p*-OH derivative, methyl benzoate comes before ethanol. As is represented by the spectra of the *p*-OH derivative deposited on polypropylene and Nylon, the effect of substrates on the reflection spectra is much less than that of solvents on the absorption spectra. The tautomeric equilibrium is shifted more towards the hydrazone tautomer compared with that in the model-compound solution. Nevertheless, the spectral change by the substrates is in the expected direction. In the other two derivatives, the effects of the solvents and also of the substrates are generally not appreciable. The only exception is the combination of the *m*-OH derivative and polyacrylonitrile, where a blue shift as much as 25 nm is found.

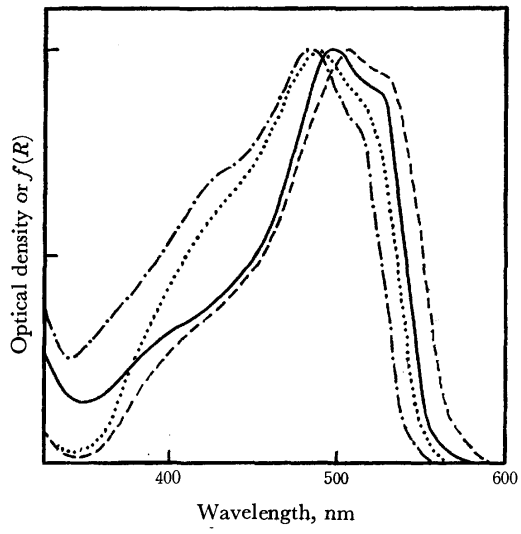

Fig. 6. Absorption spectra of 1-(*o*-anisylazo)-2-naphthol (——) and 1-(*m*-anisylazo)-2-naphthol (-·-·) dissolved in methyl benzoate and reflection spectra of the former compound (——) and the latter (·····) deposited on polyethylene terephthalate.

1-Anisylazo-2-naphthols (Fig. 6). The solution spectra are similar to those of the corresponding hydroxy derivatives. However, the solvent effect on the former spectra is a little more pronounced than that on the latter. In the cases of the *o*- and *m*-MeO derivatives, the order of solvents is modified in the same way as is found with the *p*-OH derivative. In Fig. 6, the absorption spectra of the *o*- and *m*-MeO derivatives in methyl benzoate are compared with the reflection spectra on polyethylene terephthalate. The excellent correspondence between the absorption and reflection spectra supports the hypothesis that the interaction between the compound and the substrate is responsible for the determination of the tautomeric compositions on polyethylene terephthalate. The order of the relative intensities of the band due to the azo tautomer is quite normal in the reflection spectra of the *m*-MeO derivative. However, some anomalies are observed with the other two derivatives deposited on polyacrylonitrile; that is, a red shift of the whole spectrum as much as 30 nm was observed with the *o*-MeO derivative, and an intensification of the bands above 500 nm was noted in both the derivatives.

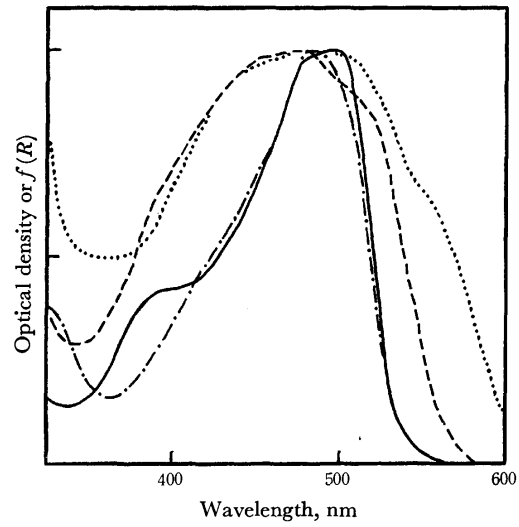

Fig. 7. Absorption spectra of 1-(*o*-nitrophenylazo)-2-naphthol (——) and 1-(*p*-nitrophenylazo)-2-naphthol (-·-·) dissolved in acetonitrile and reflection spectra of the former compound (----) and the latter (·····) deposited on polyacrylonitrile.

1-Nitrophenylazo-2-naphthols (Fig. 7). Except in the case of the *m*-NO_2 derivative, the band to be assigned to the azo tautomer is hardly observable in the solution spectra. As may be expected from this observation, no clear solvent effect is found in these cases. Nonetheless, the reflection spectra of the *o*- and *p*-NO_2 derivatives on polyacrylonitrile were found to be very different from the absorption spectra measured in acetonitrile (see Fig. 7). The reflection spectra are much broader than the absorption spectra and resemble the solid-state spectra reported in our previous works.[2,3] These two compounds appear not to be well dispersed on polyacrylonitrile. As a result, the tautomeric equilibria are shifted to the azo tautomer. It must be added that a similar situation has previously been found in the moistened filter papers dyed with these nitro derivatives.[5]

The moisture regains of the synthetic fibers are known to be as follows: polypropylene, 0%; polyacrylonitrile, 1.3%; polyethylene terephthalate, 0.4%; and Nylon-6,6, 4.5%.[8] In accordance with the low values for polypropylene and polyethylene terephthalate, the reflection spectra do not respond to the addition of moisture. The only exceptions are the *m*-OH and *o*-MeO derivatives deposited on polyethylene terephthalate. In the former case, a blue shift of the absorption maximum by 10 nm is observed. The spectrum of the latter derivative is dominated by the bands located at 505 and 530 nm. The intensity ratio

8) H. Sofue, "Gosei-sen'i (Synthetic Fibers)," Dai-nippon Tosho, Tokyo (1968), p. 167.

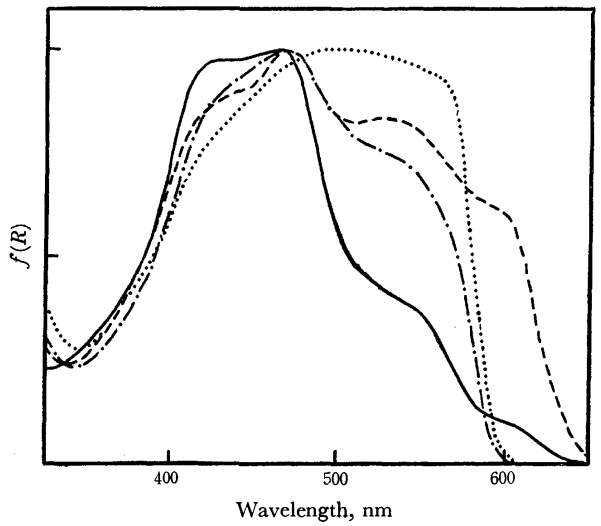

Fig. 8. Reflection spectra of 1-(*p*-hydroxyphenylazo)-2-naphthol deposited on polyacrylonitrile; dried (——) and moistened (– – –), and those of 1-(*p*-anisylazo)-2-naphthol deposited on the same substrate; dried (–·–·) and moistened (·····).

of these two bands is 1.00: 0.95 when dried, but 0.99: 1.00 when moistened, indicating a slight movement of the tautomeric equilibrium towards the hydrazone tautomer on moistening.

The spectra of the *p*-OH and *p*-MeO derivatives deposited on polyacrylonitrile were found to be drastically modified by moistening (see Fig. 8). By a comparison with the spectra recorded in *n*-hexane and formamide (shown in Fig. 5), the change in the spectrum of the *p*-OH derivative can be attributed to the movement of the equilibrium towards the hydrazone tautomer. The spectral change exhibited by the *p*-MeO derivative can also be explained by the movement in the same direction. The latter spectrum after moistening is rather similar to that recorded with a solid sample diluted with sodium chloride.[2] However, the coincidence cannot be considered as an indication that the dye molecules are segregated upon moistening, because the movement is not in the direction to be expected in such a case. In addition, it must be noted that no marked decrease in the absorption intensity due to the segregation is observed here. Therefore, the movement of the tautomeric equilibrium appears to be caused solely by the change in the medium. A less pronounced but definite change in the spectrum was observed with some other derivatives. The results are summarized in Table 1. The intensity ratio of the absorption maximum in the spectrum of a moistened sample to that in the spectrum of the corresponding dried sample is also presented in this table. The latter is the average of the measurements made before moistening and after drying again. The flattening of the spectrum by moisture observed with polyacrylonitrile is found to be rather small if compared with the flattening observed with filter paper.

Table 1. The intensity ratio of the absorption maximum in the spectrum of 1-arylazo-2-naphthol deposited on moistened polyacrylonitrile to that deposited on the dried substrate and the direction of the movement of the equilibrium by moisture; towards the azo tautomer (+) or the hydrazone tautomer (−)

Substituent	Positon		
	ortho	*meta*	*para*
None		0.5 (−)	
Methyl	0.6 (±)	0.9 (−)	0.5 (−)
Chloro	0.9 (±)	1.1 (−)	0.8 (±)
Hydroxy	0.5 (+)	0.7 (±)	0.3 (−)
Methoxy	1.0 (±)	0.8 (−)	0.8 (−)
Nitro	0.8 (±)	0.8 (−)	1.0 (±)

Although the highest moisture regain is shown by Nylon, the effect on the spectra is not very appreciable. The equilibrium was found to move, if at all observable, slightly towards the hydrazone form. As has been mentioned earlier, formamide, the model compound of this substrate, is located next to 50% ethanol in the order of solvents. Therefore, it is not surprising to see that the tautomeric composition in 1-arylazo-2-naphthols deposited on Nylon is not much affected by moisture.

A Computer Simulation of the Oxidation Mechanism. The Liquid-phase Oxidation of Cumene Catalyzed by Triphenylsulfonium Chloride

Katsutoshi OHKUBO and Tohru HASHIMOTO

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto

(Received March 24, 1972)

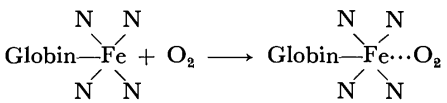
The mechanism of the liquid-phase oxidation of cumene (RH) catalyzed by triphenylsulfonium chloride was investigated by the computer simulation on the basis of the kinetic analysis. We will discuss particularly the initial short stage of the reaction through the time-conversions of the concentrations of components produced or consumed: R·, RO_2·, ROOH, a complex between the catalyst and O_2 (Cat.-O_2), *etc.* We determined the values of the rate constants appearing in the reaction steps with a good analytic fit to the experimental results, together with the activation energies of all the reaction steps. The following relationships were found between the initial rate of the component formation, r_i (component), and the initial concentration of reactants ($(Cat.)_i$, $(RH)_i$, and $(O_2)_i$):

$$r_i(Cat.\text{-}O_2) \simeq 1.243 \times 10^{-2}(Cat.)_i^{0.970}(RH)_i^{0.0}(O_2)_i^{0.964} \quad mol/l\cdot min$$
$$r_i(R\cdot) \simeq 4.705 \times 10^{-12}(Cat.)_i^{0.648}(RH)_i^{1.886}(O_2)_i^{-0.422} \quad mol/l\cdot min$$
$$r_i(RO_2\cdot) \simeq 5.837 \times 10^{-12}(Cat.)_i^{0.316}(RH)_i^{0.509}(O_2)_i^{0.737} \quad mol/l\cdot min$$
$$r_i(ROOH) \simeq 4.860 \times 10^{-4}(Cat.)_i^{0.436}(RH)_i^{1.842}(O_2)_i^{0.850} \quad mol/l\cdot min$$

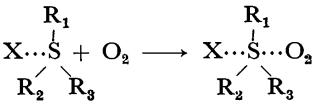
It is well known that, in the liquid-phase oxidation of hydrocarbons, some chelate compounds such as copper phthalocyanine[1] participate in the catalytic activation of the ground state, $^3\Sigma_g^-O_2$, as:

$$Cu\text{-}pc + O_2 \longrightarrow Cu\text{-}pc^{\delta+}\cdots O_2^{\delta-} \qquad (1)$$

where Cu-pc denotes copper phthalocyanine. With respect to the catalytic activation of the $^3\Sigma_g^-O_2$, other types of catalysts, such as hemoglobin[2] and sulfonium compounds,[3] can also activate the $^3\Sigma_g^-O_2$:



(2)



(3)

(R_1, R_2, R_3=alkyl or aryl group)

The complex expressed in Eq. (3) has been previously demonstrated in our kinetic study[4] of the mechanism of cumene oxidation catalyzed by triphenylsulfonium chloride. Such an interaction between sulfonium compounds and the $^3\Sigma_g^-O_2$ has also been confirmed by UV spectroscopic[5] and MO-theoretical studies.[6]

Judging from the fact that a sulfonium catalyst plays an important role in the catalytic activation of the ground state $^3\Sigma_g^-O_2$, the first step can be said to consist of the formation of a complex, Cat.-O_2, as:

$$Cat. + O_2 \underset{k_{t'}}{\overset{k_t}{\rightleftharpoons}} Cat.\text{-}O_2 \qquad (4a)$$

where Cat. denotes a sulfonium compound. Such a complex, Cat.-O_2, then abstracts an active hydrogen from hydrocarbon (RH) to produce an alkyl radical (R·):

$$Cat.\text{-}O_2 + RH \xrightarrow{k_1} R\cdot + Cat. + \cdot O_2H \qquad (4b)$$

This is followed by the usual propagation steps:

$$R\cdot + O_2 \xrightarrow{k_p} RO_2\cdot \qquad (4c)$$

$$RO_2\cdot + RH \xrightarrow{k_2} ROOH + R\cdot \qquad (4d)$$

The termination steps are:

$$2RO_2\cdot \xrightarrow{k_t} \text{inactive products} \qquad (4e)$$

$$Cat. \xrightarrow{k_d} \text{inactive form} \qquad (4f)$$

The deactivation of the catalyst is taken into consideration by Eq. (4f), and the possibility of the radical recombination of other types (R·+R· or R·+RO_2·) is discarded under the present reaction conditions, *i.e.*, an oxygen pressure above 200 mm of mercury.[7] In addition, the decomposition reaction of hydroperoxide is neglected in this paper, because the quantity of O_2 consumed by RH (mol) corresponds to that of hydroperoxide formed (mol) during the initial short stage of the reaction.

The present study has been undertaken in an attempt to elucidate the oxidation mechanism, especially that during the initial short stage of the reaction, by the use of a simulation analysis on a high-speed computer, with attention given to the time-conversions of unstable

7) The effect of the O_2 pressure on the reaction rate does not generally appear above an O_2 pressure of 200 mmHg.

intermediates, oxidants, and reactants; this initial short stage holds the key to the reaction, though chemical and physical studies of the alkyl radical formation are in an early stage of development.

Procedure of Simulation

Normal reaction sequences can be expressed by the following general form:

$$R_1 + R_2 + \cdots + R_n \xrightarrow{k} P_1 + P_2 + \cdots + P_m \quad (5)$$

where R_i are reactants, P_i are products, and k is the rate constant. The reaction increments (or decrements) D are shown, with dt representing a very short time interval, as follows:

$$D = k\prod_{i=1}^{n}(R_i)dt \quad (6)$$

During such a very short time interval, dt, such increments (or decrements) at the reaction time t, D_t, can be expressed by:

$$D_t = \frac{D_{t+dt} + D_{t-dt}}{2} \quad (7)$$

where D_{t+dt} and D_{t-dt} are the reaction increments (or decrements) at the reaction times of $t+dt$ and $t-dt$ respectively ($D_{-dt}=D_0$). The average increments (or decrements), D_{av}, are, then, defined by:

$$D_{av} = \frac{D_t + D_{t+dt}}{2} \quad (8)$$

From Eqs. (7) and (8),

$$D_{av} = 1.5D_t - 0.5D_{t-dt} \quad (9)$$

The concentrations of reactants (R_i) and products (P_i) are, then, changed with D_{av}:

$$(R_i)_t = (R_i)_{t-dt} - D_{av} = (R_i)_{t-dt} - (1.5D_t - 0.5D_{t-dt}) \quad (10a)$$

$$(P_i)_t = (P_i)_{t-dt} + D_{av} = (P_i)_{t-dt} + (1.5D_t - 0.5D_{t-dt}) \quad (10b)$$

This calculation method gives a trapezoidal averaging which is superior to simple decrementing, and this form of calculation is superior to the Runge-Kutta integration.[8] The present simulations on the oxidation mechanism without the ROOH decomposition were carried out in the following way. A series of increments ($D(i)$, $i=1$—7) are defined by the following terms on the basis of the reaction schemes presented previously (see Introduction):

$$D(1) = k_i(O_2)(\text{Cat.})dt \quad (11a)$$

$$D(2) = k_i'(\text{Cat.-}O_2)dt \quad (11b)$$

$$D(3) = k_1(\text{RH})(\text{Cat.-}O_2)dt \quad (11c)$$

$$D(4) = k_p(O_2)(R\cdot)dt \quad (11d)$$

$$D(5) = k_2(\text{RH})(RO_2\cdot)dt \quad (11e)$$

$$D(6) = k_t(RO_2\cdot)^2dt \quad (11f)$$

$$D(7) = k_d(\text{Cat.})dt \quad (11g)$$

For each chemical equation, there is a corresponding differential term:

$$d(\text{Cat.})/dt = k_1(\text{RH})(\text{Cat.-}O_2) + k_1'(\text{Cat.-}O_2) - k_i(O_2)(\text{Cat.}) - k_d(\text{Cat.}) \quad (12a)$$

$$d(\text{Cat.-}O_2)/dt = k_i(O_2)(\text{Cat.}) - k_1(\text{RH})(\text{Cat.-}O_2) - k_i'(\text{Cat.-}O_2) \quad (12b)$$

$$d(R\cdot)/dt = k_1(\text{RH})(\text{Cat.-}O_2) + k_2(\text{RH})(RO_2\cdot) - k_p(O_2)(R\cdot) \quad (12c)$$

$$d(RO_2\cdot)/dt = k_p(O_2)(R\cdot) - k_2(\text{RH})(RO_2\cdot) - k_t(RO_2\cdot)^2 \quad (12d)$$

$$d(\text{ROOH})/dt = k_2(\text{RH})(RO_2\cdot) \quad (12e)$$

$$d(\cdot O_2H)/dt = k_1(\text{RH})(\text{Cat.-}O_2) \quad (12f)$$

$$d(\text{inactive product})/dt = k_t(RO_2\cdot)^2 \quad (12g)$$

$$d(\text{inactive form})/dt = k_d(\text{Cat.}) \quad (12h)$$

From Eqs. (11a—g) and (12a—h), the following relationships can be derived:

$$D(\text{Cat.})_{av} = D(2)_{av} + D(3)_{av} - D(1)_{av} - D(7)_{av} \quad (13a)$$

$$D(\text{Cat.-}O_2)_{av} = D(1)_{av} - D(2)_{av} - D(3)_{av} \quad (13b)$$

$$D(R\cdot)_{av} = D(3)_{av} + D(5)_{av} - D(4)_{av} \quad (13c)$$

$$D(RO_2\cdot)_{av} = D(4)_{av} - D(5)_{av} - D(6)_{av} \quad (13d)$$

$$D(\text{ROOH})_{av} = D(5)_{av} \quad (13e)$$

$$D(\cdot O_2H)_{av} = D(3)_{av} \quad (13f)$$

$$D(\text{inactive product})_{av} = D(6)_{av} \quad (13g)$$

$$D(\text{inactive form})_{av} = D(7)_{av} \quad (13h)$$

The desired concentrations of a component C (reactant, intermediate, or product), $(C)_t$, at the reaction time, t, can be determined by:

$$(C)_t = (C)_i + \int_0^t D(C)_{av}dt \quad (14)$$

where $(C)_i$ and $D(C)_{av}$ are, respectively, the initial concentrations of the components, C, and the over-all increments (or decrements) changing with t. In this paper, the $(C)_t$ values were evaluated every 0.1 sec.

Simulation Results and Discussion

Determination of Rate Constants. Mention should first be made of some characteristic features of the liquid-phase oxidation of cumene (RH) catalyzed by triphenylsulfonium chloride. The oxidation proceeds without any appreciable incubation period; its reaction rate soon reaches its maximum after the start of the reaction (usually up to 600 sec) and then gradually decreases to its stationary state. Moreover, the decomposition of the cumene hydroperoxide (ROOH) accumulated can be neglected for *ca.* 1 hr after the start under the usual reaction conditions.[4] In the previous kinetic study[4] of this cumene oxidation, some values of the rate constants in Eqs. (4a—f) have been determined at 65°C as below:

$$k_i = 2.23\times10^{-2}\ \text{mol}^{-1}\cdot l\cdot\text{sec}^{-1};\quad k_i' = 0.82\times10^{-3}\ \text{sec}^{-1};$$

$$k_1 = 0.794\times10^{-3}\ \text{mol}^{-1}\cdot l\cdot\text{sec}^{-1};\quad k_d = 1.39\times10^{-3}\ \text{sec}^{-1}.$$

With respect to the rate constant of the termination

8) E. Whitaker and A. Robinson, "The Calculation of Observations," Blackie and Son, London (1944), p. 132; H. Margenau and G. H. Murphy, "The Mathematics of Physics and Chemistry," D. van Nostrand, New York (1943), p. 450; R. W. Southwork and S. L. Deleeuw, "Digital Computation and Numerical Methods," McGraw Hill, New York (1965), p. 420.

reaction (Eq. (4e)) Melville and Richards[9] have reported $k_t=3.3\times10^4$ mol$^{-2}\cdot l^2\cdot$sec^{-1} at 65°C in the cumene oxidation. We will here determine the k_p and k_2 values, with a good analytic fit for the simulation analyses. Figure 1 indicates the dependence of the ROOH concentration, (ROOH), upon various k_p and k_2 values (from $k_p(O_2)_i$[10]$=\sim10^6$ to $k_p(O_2)_i=\sim10^2$ with a factor of ten); the time-conversion curves are not directly influenced by the settled k_p values, but are directly changed by k_2 values. Bearing in mind that k_p values usually fall in the range from $\sim10^6$ to $\sim10^7$,[11] the k_p value for the cumene oxidation at 65°C can be set at 1.185×10^7 ($k_p(O_2)_i=5.0\times10^5$).

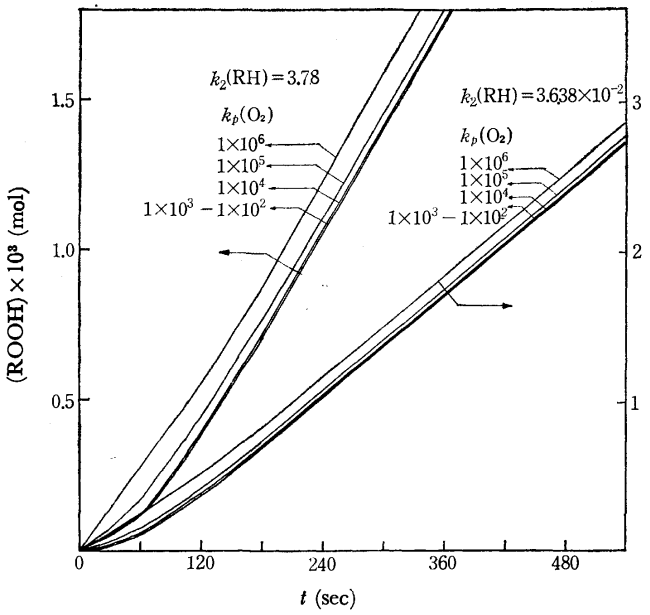

Fig. 1. Variation in time-conversion of (ROOH) with $k_p(O_2)$ and k_2(RH) values.
Initial condition: (Cat.)$_i=3.35\times10^{-4}$mol/l; (RH)$_i$=6.75 mol/l; (O$_2$)$_i=4.22\times10^{-2}$ mol/l.

Next, let us determine the k_2 value, which usually falls in the range of 10^{-1}—10^{-2} as a factor of ten in the autoxidation of cumene, tetralin, or ethyl linoleate at 25—65°C.[14] Figure 2 shows the time-conversion curves of (ROOH) at various k_2 values, together with the experimental curve obtained from cumene (6.75 mol/l) oxidation catalyzed by triphenylsulfonium chloride (3.35×10^{-4} mol/l) at 65°C under atmospheric pressure. As can be seen from Fig. 2, (ROOH) varies in parallel with the k_2(RH) value at a fixed $k_p(O_2)$ value, and the k_2 value of 9.63×10^{-2} mol$^{-1}\cdot l\cdot$sec^{-1} (k_2(RH)$_i$=0.65) can be taken as the most preferable

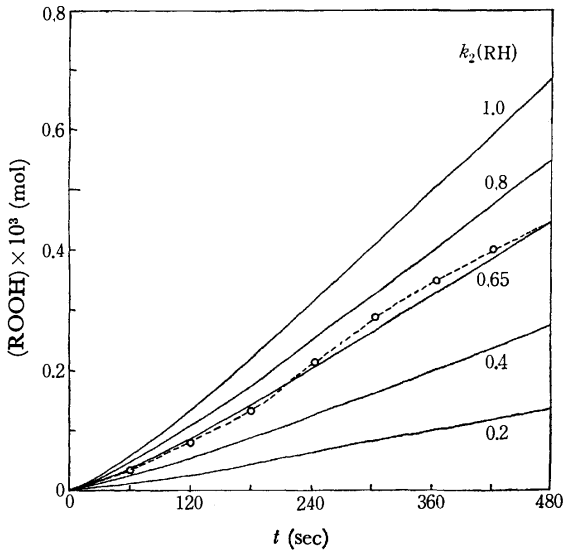

Fig. 2. Variation in time-conversion of (ROOH) with k_2(RH) values. (Dotted curve indicates the experimental result.)
Initial condition: (Cat.)$_i=3.35\times10^{-4}$ mol/l; (RH)$_i$=6.75 mol/l; (O$_2$)$_i=4.22\times10^{-2}$ mol/l.

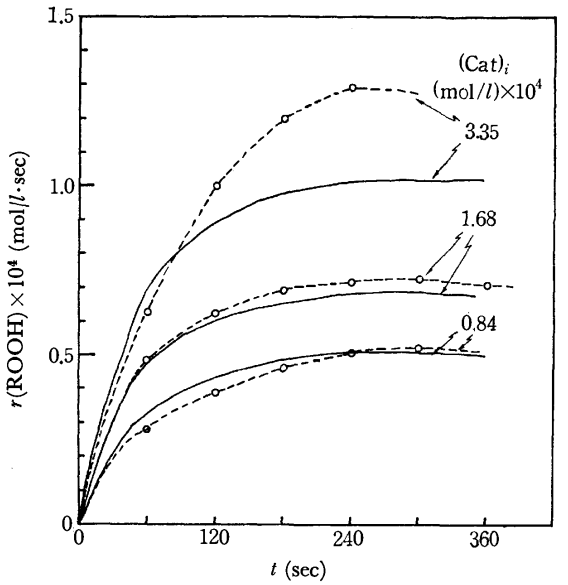

Fig. 3. Variations in time-conversion of ROOH concentration with initial concentration of Cat. (Solid and dotted curves indicate simulation and experimental results respectively.)
Initial condition: (Cat.)$_i$=variable; (RH)$_i$=6.75 mol/l; (O$_2$)$_i=4.22\times10^{-2}$ mol/l.

value with a good analytic fit. Tests of the fitness of k_2 value (9.63×10^{-2} mol$^{-1}\cdot l\cdot$sec^{-1}) for the simulation analyses well made. The results of these tests are shown in Fig. 3, where the variations in the time-conversion of the rate of ROOH formation (r(ROOH)) with (Cat.)$_i$ are illustrated, together with the experimental data.[15] From Fig. 3, $k_2=9.63\times10^{-2}$ mol$^{-1}\cdot l\cdot$sec^{-1} is considered to be fit for the present simulations

9) H. W. Melville and S. Richards, *J. Chem. Soc.*, **1954**, 944,
10) (O$_2$)$_i$ means the initial concentration of O$_2$. Hereafter, the initial concentrations of the components, (C), will be expressed by (C)$_i$; for instance, (RH)$_i$, (Cat.)$_i$, (R·)$_i$, *etc.*
11) For example, k_t(mol$^{-1}\cdot l\cdot$sec^{-1}) at 25°C=6.76×10^7,[12] 1.0×10^7,[13] and 1.0×10^6 [13] for tetralin, ethyl linoleate, and digeranyl respectively.

14) C. Walling, "Free Radicals in Solution," John Wiley, New York (1957), p. 422.
15) The experimental rate curves can be reproduced with a good analytic fit by $r=k$(RH)$_i^{1.27}$(O$_2$)$_i^{0.68}$(Cat.)$_i$($e^{-at}-e^{-bt}$), where k, a, and b are constants the values of which have been reported in Ref. 4.

of the initial short stage of the oxidation, within the range of observational and calculational errors.[16] Here, the time-conversions of the concentrations of reactants, intermediates, and a product, (Cat.), (Cat.-O_2), ($\cdot O_2H$), (R$\cdot$), ($RO_2\cdot$), and (ROOH), are shown in Fig. 4 for the sake of understanding the reaction system; (Cat.-O_2), ($RO_2\cdot$), and (R$\cdot$) soon arrived at their maxima (t=300 sec) and then gradually lowered to their apparent stationary concentrations. Their distributions were, for instance, at 300 sec, roughly expressed by:

$$(\text{Cat.-O}_2):(\text{R}\cdot):(\text{RO}_2\cdot):(\text{ROOH}) \simeq 1:7\times10^{-8}:5\times10^{-2}:10$$

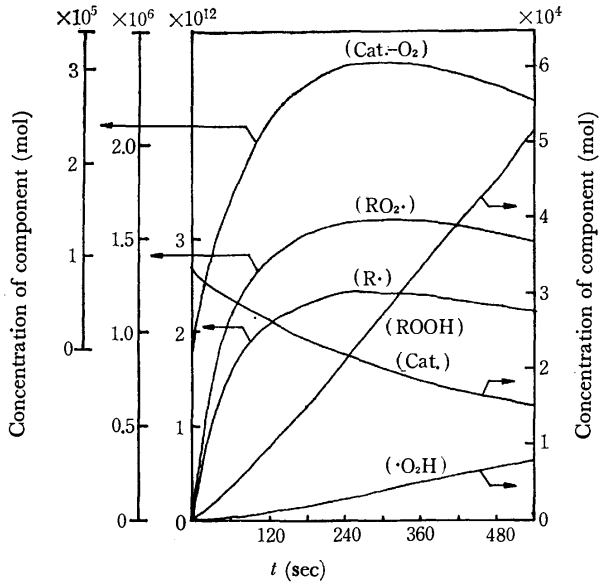

Fig. 4. Time-conversion curves of concentrations of components produced or consumed.
Initial condition: $(\text{Cat.})_i=3.35\times10^{-4}$ mol/l; $(\text{RH})_i=6.75$ mol/l; $(\text{O}_2)_i=4.22\times10^{-2}$ mol/l.

Time Conversion of the Complex, Cat.-O_2. Some remarks should be made before discussing the simulation results. Cat. (*viz.* triphenylsulfonium chloride) interacts with O_2 to form a complex,[5,6] Cat.-O_2, in which the distance between the central S and the center of the O-O bond axis is 2.5—3.0 Å,[6] and in whcih the O-O bond is stretched to a value above 1.30 Å (from 1.2072 Å of the $^3\Sigma_g^-O_2$). In regard to (Cat.-O_2), the simulation results gave at first the time conversions of (Cat.-O_2). The variations in the time conversions of (Cat.-O_2) with $(\text{Cat.})_i$, $(\text{O}_2)_i$, and $(\text{RH})_i$ are shown in Fig. 5. Figure 5 indicates that (Cat.-O_2) possessing the maximum ascends with an increase in $(\text{Cat.})_i$ or $(\text{O}_2)_i$, whilst, interestingly, $(\text{RH})_i$ has little influence on (Cat.-O_2) during the very short stage up to 60 sec. The latter phenomenon may be ascribed to a constant enhancement of the intermolecular interaction between Cat.-O_2 and RH during the above-mentioned period. It is of interest here to pay attention to the dependence of the initial rate of Cat.-O_2 formation, r_i(Cat.-O_2), on $(\text{Cat.})_i$, $(\text{O}_2)_i$, or $(\text{RH})_i$. As shown in Fig. 6, log r_i (Cat.-O_2) *vs.* log $(\text{Cat.})_i$, log $(\text{O}_2)_i$, and/or log$\cdot(\text{RH})_i$ plots gave straight lines and the following relationships can be obtained:

$$r_i(\text{Cat.-O}_2) \propto (\text{Cat.})_i^{0.970} \quad (15a)$$

$$r_i(\text{Cat.-O}_2) \propto (\text{O}_2)_i^{0.964} \quad (15b)$$

$$r_i(\text{Cat.-O}_2) \propto (\text{RH})_i^{0.0} \quad (15c)$$

Eqs. (15a—c) can be rewritten as:

$$r_i(\text{Cat.-O}_2) \simeq 1.243\times10^{-2}(\text{Cat.})_i^{0.970}(\text{O}_2)_i^{0.964}(\text{RH})_i^{0.0} \text{ mol/}l\cdot\text{min} \quad (16)$$

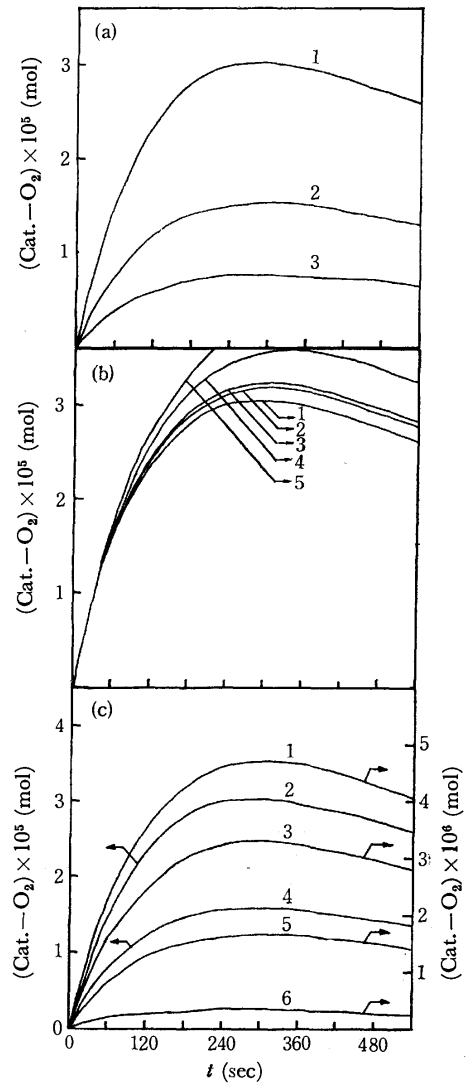

Fig. 5. Variation in time-conversion of (Cat.—O_2) with initial concentrations of Cat., RH, and O_2.
(a) Initial condition
$(\text{RH})_i=6.75$ mol/l; $(\text{O}_2)_i=4.22\times10^{-2}$ mol/l.
$(\text{Cat.})_i$ 1: 3.35×10^{-4} mol/l, 2: 1.68×10^{-4} mol/l, 3: 0.84×10^{-4} mol/l.
(b) Initial condition
$(\text{Cat.})_i=3.35\times10^{-4}$ mol/l, $(\text{O}_2)_i=4.22\times10^{-2}$ mol/l.
$(\text{RH})_i$ 1:6.75 mol/l, 2: 6.31 mol/l, 3: 6.12 mol/l, 4: 5.03 mol/l, 5: 3.80 mol/l.
(c) Initial condition
$(\text{Cat.})_i=3.35\times10^{-4}$ mol/l; $(\text{RH})_i=6.75$ mol/l;
$(\text{O}_2)_i$ 1: 6.03×10^{-3} mol/l, 2: 4.22×10^{-2} mol/l, 3: 4.22×10^{-3} mol/l, 4: 2.11×10^{-2} mol/l, 5: 2.11×10^{-3} mol/l 6: 4.22×10^{-4} mol/l.

16) The experimental data were obtained by the graphic differentiation of the time-conversion curve of (ROOH), this procedure brought about observational errors.

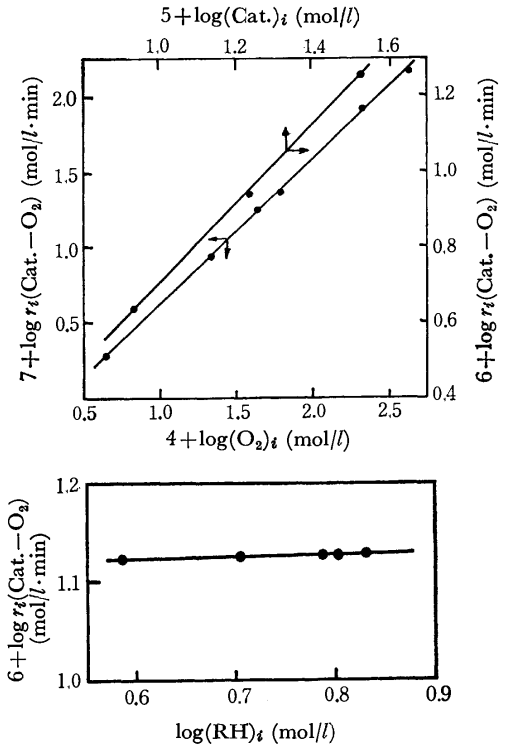

Fig. 6. Plots of log r_i (Cat.—O$_2$)$_i$ *vs.* log(Cat.)$_i$, log(O$_2$)$_i$, and log(RH)$_i$.

Time Conversion of Alkyl Radicals, R·. The process of the R· formation plays an important role in the oxidation reaction, specifically during the initial stage, since the R radical itself acts as a source for the propagating radical chains (Eqs. (4c) and (4d)). Figure 7 indicates the variations in the time conversion of (R·) with (Cat.)$_i$, (O$_2$)$_i$, and (RH)$_i$. As can be seen from Fig. 7, the higher (Cat.)$_i$ and (RH)$_i$ become, the larger becomes the amount of (R·), whilst (O$_2$)$_i$ depresses the R· formation, perhaps because of its predominant consumption of R· through Eq. (4c). The Linear relationships of log r_i (R·) *vs.* log (Cat.)$_i$, log (RH)$_i$, and/or log (O$_2$)$_i$ were rewritten as:

$$r_i(\mathrm{R}\cdot) \propto (\mathrm{Cat.})_i^{0.648} \quad (17a)$$

$$r_i(\mathrm{R}\cdot) \propto (\mathrm{RH})_i^{1.856} \quad (17b)$$

$$r_i(\mathrm{R}\cdot) \propto (\mathrm{O_2})_i^{-0.422} \quad (17c)$$

Eqs. (17a—c) can be rearranged as:

$$r_i(\mathrm{R}\cdot) \simeq 4.705\times10^{-12}(\mathrm{Cat.})_i^{0.648}(\mathrm{RH})_i^{1.886}(\mathrm{O_2})_i^{-0.422} \quad \mathrm{mol}/l\cdot\mathrm{min} \quad (18)$$

Time Conversion of Alkylperoxy Radicals, RO_2·. Considering that (RO_2·) directly controls the rate of ROOH formation through Reaction (4d), the RO_2 radical must also play an impotant role in the oxidation reaction. We will, then, adjust the simulation results as to (RO_2·) similarly to the cases of (Cat.-O$_2$) and (R·). The variations in the time conversion of (RO_2·) with (Cat.)$_i$, (RH)$_i$, and (O$_2$)$_i$, and the plots of log r_i (RO_2·) *vs.* log (Cat.)$_i$, log (RH)$_i$, and log (O$_2$)$_i$ gave the following relationships:

$$r_i(\mathrm{RO_2}\cdot) \propto (\mathrm{Cat.})_i^{0.316} \quad (19a)$$

$$r_i(\mathrm{RO_2}\cdot) \propto (\mathrm{RH})_i^{0.509} \quad (19b)$$

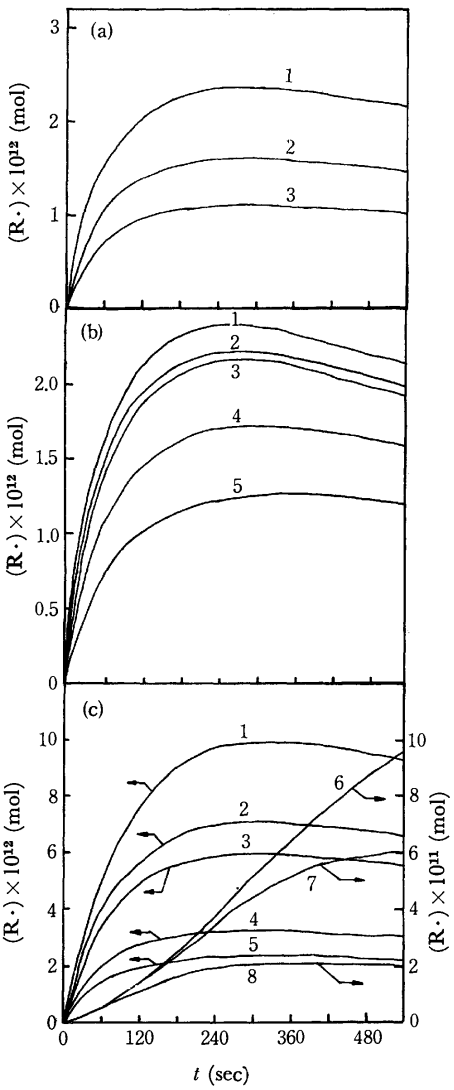

Fig. 7. Variations in time-conversion of (R·) with initial concentrations of Cat., RH, and O$_2$.
(a) Initial condition
(RH)$_i$=6.75 mol/l; (O$_2$)$_i$=4.22×10^{-2} mol/l.
(Cat.)$_i$ 1: 3.35×10^{-4} mol/l, 2: 1.68×10^{-4} mol/l, 3: 0.84×10^{-4} mol/l.
(b) Initial condition
(Cat.)$_i$=3.35×10^{-4} mol/l; (O$_2$)$_i$=4.22×10^{-2} mol/l.
(RH)$_i$ 1: 6.75 mol/l, 2: 6.31 mol/l, 3: 6.12 mol/l, 4: 5.03 mol/l, 5: 3.80 mol/l.
(c) Initial condition
(Cat.)$_i$=3.35×10^{-4} mol/l; (RH)$_i$=6.75 mol/l.
(O$_2$)$_i$ 1: 2.11×10^{-3} mol/l, 2: 4.22×10^{-3} mol/l, 3: 6.03×10^{-3} mol/l, 4: 2.11×10^{-2} mol/l, 5: 4.22×10^{-2} mol/l, 6: 4.22×10^{-6} mol/l, 7: 4.22×10^{-5} mol/l, 8: 4.22×10^{-4} mol/l.

$$r_i(\mathrm{RO_2}\cdot) \propto (\mathrm{O_2})_i^{0.737} \quad (19c)$$

Then,

$$r_i(\mathrm{RO_2}\cdot) \simeq 5.837\times10^{-12}(\mathrm{Cat.})_i^{0.316}(\mathrm{RH})_i^{0.509}(\mathrm{O_2})_i^{0.737} \quad \mathrm{mol}/l\cdot\mathrm{min} \quad (20)$$

Time Conversion of Hydroperoxide, ROOH. In the liquid-phase oxidation of hydrocarbons catalyzed by transition-metal catalysts, it is generally believed that the reaction can proceed after the decomposition of ROOH accumulated during the incubation period (the so-called induction period). The phenomena of ROOH

TABLE 1. ACTIVATION ENERGIES AND RATE CONSTANTS OF REACTION STEPS

Reaction number	Reaction	d_{12} (Å)	$\mu\times10^{23}$ (g)	E (kcal/mol)	Rate constant
(1)	Cat.$+O_2\rightarrow$ Cat.$-O_2$	4.284	4.80	19.93	$9.389\times10^{9}\sqrt{T}\ e^{-19.93/RT}$ mol$^{-1}\cdot l\cdot$sec^{-1}
(2)	Cat.$-O_2\rightarrow$ Cat.$+O_2$	7.36	54.9	21.37	$2.898\times10^{9}\sqrt{T}\ e^{-21.37/RT}$ sec^{-1}
(3)	Cat.$-O_2+$RH$\rightarrow$R$\cdot$+Cat.$+\cdot O_2$H	7.03	14.6	22.46	$1.447\times10^{10}\sqrt{T}\ e^{-22.46/RT}$ mol$^{-1}\cdot l\cdot$sec^{-1}
(4)	R$\cdot+O_2\rightarrow RO_2\cdot$	3.95	4.19	6.38	$8.538\times10^{9}\sqrt{T}\ e^{-6.38/RT}$ mol$^{-1}\cdot l\cdot$sec^{-1}
(5)	$RO_2\cdot+$RH$\rightarrow$ROOH+R$\cdot$	6.88	11.1	19.30	$1.592\times10^{10}\sqrt{T}\ e^{-19.30/RT}$ mol$^{-1}\cdot l\cdot$sec^{-1}
(6)	$RO_2\cdot+RO_2\cdot\rightarrow$ inactive product	7.07	12.55	10.74	$1.582\times10^{10}\sqrt{T}\ e^{-10.74/RT}$ mol$^{-1}\cdot l\cdot$sec^{-1}

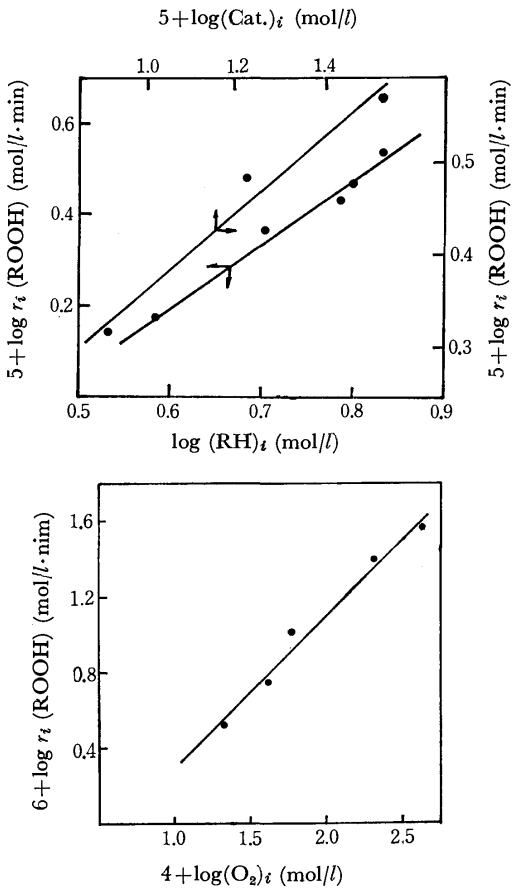

Fig. 8. Plots of log r_i(ROOH) *vs.* log(Cat.)$_i$, log(RH)$_i$, and log(O$_2$)$_i$.

decomposition have been already given in detail,[17-19] but those of ROOH formation during the initial short stage still remain obscure. It is more than of interest —it is necessary— to discuss the dependence of the time conversions of (ROOH) during the above-mentioned period upon the fresh catalyst and the fresh reactants. The plots of log r_i (ROOH) *vs.* log (Cat.)$_i$ and/or log (reactant)$_i$ indicated linear relationships, and we obtained the following equation from the straight lines in Fig. 8:

$$r_i(\mathrm{ROOH}) \simeq 4.860\times10^{-4}(\mathrm{Cat.})_i^{0.436}(\mathrm{RH})_i^{1.842}(\mathrm{O_2})_i^{0.850}\ \mathrm{mol}/l\cdot\mathrm{min} \quad (21)$$

Equation (21) demonstrates that the initial formation of ROOH will be approximately controlled by the square root of (Cat.)$_i$. This implies that we should take into consideration the radical recombination reaction, $RO_2\cdot+RO_2\cdot\longrightarrow$inactive products, even during the initial short stage.

Activation Energies of Reaction Steps. Now, we will estimate the activation energies of the reaction steps (Eqs. (4a—e)) on the basis of the collision theory.[20] The rate constant of the bimolecular reaction, k_{12}, is usually produced by a kinetic theory expression:

$$k_{12}(\mathrm{mol^{-1}}\cdot l\cdot\mathrm{sec^{-1}}) = \pi N d_{12}^2(8kT/\pi\mu)^{1/2}\mathrm{e}^{-E/RT}\times10^{-3} \quad (22)$$

where N, k, d_{12}, and μ stand for the Avogadro number, the Boltzmann constant, the molecular diameter, and the reduced mass respectively. The activation energies evaluated are tabulated in Table 1, together with the rate constants; the formation of Cat.$-O_2$ is an thermic reaction and, suprisingly, the radical recombinations of Eqs. (4c) and (4e) need appreciable activation energies. The latter phenomena must bedue to the reaction of bulky reactants.

In conclusion, more precise discussions of the oxidation mechanism will be undertaken in a succeeding paper on the basis of such favorable methods as the Monte Carlo simulation.

The calculations were carried out on a FACOM 230-60 computer at the Computation Center of Kyushu University.

20) In the present reaction system without solvents (the effect of polar oxidation products can be disregarded during the very initial short stage), we can easily establish the Maxwell-Boltzmann distribution, considering that the ascending of collisions in the liquid-phase accompanies the increase in the rates of activation and the deactivation of activated complexes.

Deuteron Magnetic Resonance Studies of Structures and Phase Transitions in the Tantalum-Deuterium System

Keikichi NAKAMURA

National Research Institute for Metals, Nakameguro, Meguro-ku, Tokyo

(Received March 28, 1972)

The deuteron magnetic resonance in the tantalum-deuterium system has been measured as a function of the composition (0.45 to 0.198 D/Ta) and of the temperature (90 to −179°C), and the results has been discussed in relation to the neutron diffraction and the heat capacity data. The most probable arrangement of the deuteriums in the polymorphic varieties has been proposed. For the low temperature form (β_1 form), it has an ordered structure which belongs to the space group $A222$, with the four tantalums at the $4K$ positions and the two deuteriums at the $2a$ positions. Since the deuterium positions are described by a single Z' principal axis direction, which coincides with the c axis, the quadrupole coupling constant is not averaged by the rapid diffusion of the deuteriums. For the intermediate temperature form (β_2 form), a structure constructed with four types of domains has been proposed. In this structure, the space group is the same as that of the β_1 form, and the deuterium positions in the domains are $2a$, $2b$, $2c$, and $2d$ respectively. For the high temperature form (α form), the observed quadrupole coupling constant, which is averaged to zero, can be accounted for if the deuteriums are randomly distributed over all the available tetrahedral sites. However, the calculated configurational entropy based on this assumption is larger than the measured value.

It is a well known phenomenon that many transition metals absorb hydrogen under appropriate conditions.[1] As for the tantalum, the solubility extends to about 44 atomic percent at 200°C and under a 1 atomosphere. However, when the temperature decreases below 60°C, a new phase (β phase) based on the composition Ta_2H is formed.[2,3]

According to the X-ray diffraction study,[2] the high temperature phase (α phase) possesses a body centered cubic structure of elementary tantalum, while the low temperature phase (β phase) is a body centered tetragonal with an axial ratio of $c/a=1.008$. Saba, Wallace, Sandmo, and Craig have measured the heat capacity of Ta_2H[4] from 12 to 555°K and have found three λ points, indicating that the following four forms exist; β_1 below 306°K, β_2 between 306 to 332.5°K, β_3 from 332.5 to 333.5°K, and α above 333.5°K. They have also estimated the configurational entropies. They were zero, 0.7, 3.3, and 4.9 e.u.mol^{-1} for β_1, β_2, β_3, and α respectively. Since there are 12 tetrahedral sites available for each hydrogen atom, they attributed the λ points to the rearrangement of hydrogen among these sites.

The neutron diffraction study by Wallace[5] has shown that the β_1 form is pseudocubic, with $a=2a_0=6.74$ Å, where a_0 is a lattice constant for the β_2 form. He proposed three configurations which satisfied the neutron diffraction intensities for the β_1 form. One of the structures, which he denoted structure A, belongs to the space group $I4$, with half deuteriums located at the general positions of 1/4 1/8 0 and 5/8 0 1/4. To account for the contradiction between the proposed structure and the vanishing residual entropy for the β_1 form, he proposed a structure with a high local order in domains which are not large enough to give rise to superstructure diffractions.

To solve the above contradiction, this problem in the ordered structure of Ta_2D has been discussed in a series of paper.[6-8] Among the three proposed structures, however, the superlattice diffraction reliability factors of the first two structures[6,7] are appreciably worse than that of Wallace's disordered structure. The best agreement with the experimental results was obtained by Petrunin, Somenkov, Shil'shtein, and Chertkov (hereafter abbreviated as PSSC), who took into account the displacement of the Ta atom. This structure is orthorhombic and belongs to the space group $A222$, with $a\approx b\approx\sqrt{2}\,a_0$ and $c\approx a_0$. The four Ta atoms are located at the 4K positions ($-x$ 0 0, 1/2+x 1/2 0, $-x$ 1/2 1/2, 1/2+x 0 1/2), and the two deuterium atoms at the $2a$ positions (1/4 1/4 1/4, 1/4 3/4 3/4). The displacement parameter, x, which was so determined as to minimize the reliability factor, was 0.012, while the minimized reliability factor, for the superlattice diffraction was 0.107.

Among the four proposed structures cited above, the reliability factor for the PSSC ordered model with the displacement of Ta is the smallest, and that for Wallace's model is next. However, one may obtain additional information from the deuteron magnetic resonance. The main purpose of this paper is to obtain additional information on the arrangement of deuteriums in the polymorphic varieties of Ta_2D through studying the deuteron magnetic resonance, which is very sensitive to the position and the translational motion of the deuteriums.

0.45 to 0.198 D/Ta were prepared by a direct reaction of a known amount of deuterium gas with a known amount of Ta metal powder.

The deuteron magnetic resonance measurements were made using a Varian VF-16 wide line spectrometer operating at 6.53 MHz. The temperatures of the samples from −180 to +90°C were obtained with a Varian variable-temperature accessory.

Results

Deuteron Resonance at Room Temperature. At room temperature, the deuteron resonance of the powdered TaD_n (n=0.45, 0.43, 0.375) consists of two parts; one is at the center of the Larmor frequency, and the other consists of a pair of lines located symmetrically around the Larmor frequency (Fig. 1). The intensity ratio of the central line relative to the two satellite lines increased with a decrease in the deuterium concentration. Since the line width of the satellite lines was broad and the intensity was weak, the satellite lines could not be observed for the samples with deuterium concentrations lower than 0.33/Ta. The integrated intensities of the two components are shown in Fig. 2. The extrapolated intensity of the satellite lines to the lower D/Ta value becomes zero at a D/Ta value between 0.2 to 0.15. If we take into consideration the experimental facts that the solubility of hydrogen in Ta metal is about 20%, and that above this concentration the β Ta_2H phase develops,[2,3] the central line can be assigned to the deuteron resonance of the α Ta, and the satellite lines, to that of the β Ta_2D. The theoretical powder pattern line shape in the presence of quadrupole interaction due to nuclei with I=1 has been calculated.[9,10] We have thus smoothed the theoretical line shape with the Gaussian distribution of various values of the root mean square line width (σ). The results are shown in Fig. 1-(A); a more detailed analysis of the powder pattern for an asymmetric field gradient is shown in the Appendix. From the method described in the Appendix, the quadrupole coupling constant, e^2qQ/h, 33.9 KHz, and the asymmetry parameter, η, 0.15 to 0.25, were obtained.

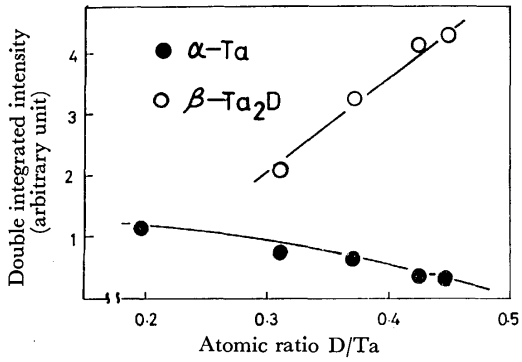

Fig. 2. Concentration dependence of double integrated signal intensity of deuteriums in α Ta and β Ta_2D.

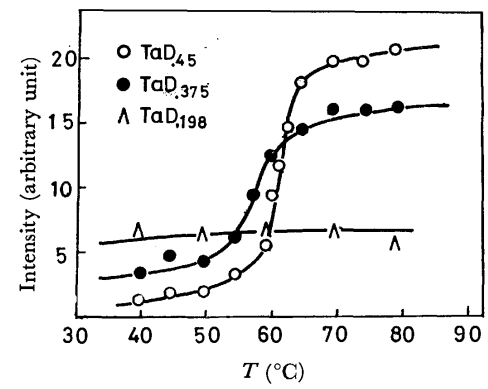

Fig. 3. Temperature dependence of signal intensity of deuteriums in α Ta.

Deuteron Resonance and Phase Transition above Room Temperature. When the TaD_n (n=0.45, 0.43, 0.375) was warmed from room temperature, the deuteron resonance signal intensity of the α Ta began to increase, and that of the β form began to decrease. The signal intensity of the former continued to increase even after that of the β Ta_2D was vanishingly small, but finally it became constant. As shown in Fig. 3, the temperature range where the phase transition proceeded was about 10°C for the $TaD_{0.45}$ sample. The phase transition temperature, which we define as the middle point of the temperature-signal intensity curve, depended on the composition of the sample. As the deuterium concentration decreased, the temperature range of the phase transition became broad and the phase transition temperature became obscure. For the $TaD_{0.198}$ sample, the signal intensity of the α form did not change over the temperature range from +90 to −50°C. For this composition, therefore, most of the deuteriums dissolve in the α Ta metal.

Deuteron Resonance below Room Temperature. As the temperature of the samples decreased, the deuteron signal intensity of the α Ta decreased until it vanished in the temperature range from −30 to −70°C. The

temperature at which the signal vanished depended on the sample composition; *i.e.*, it was about $-30°C$ for $n=0.45$ and about $-70°C$ for $n=0.198$. As the temperature decreased, the line width of the β Ta_2D became broad. However, even at $-180°C$, the line shape corresponds to that which has nearly the same quadrupole coupling constant smoothed with a broad Gaussian distribution (Fig. 1-(C)).

Discussion

Deuterium Arrangement in β_1 Ta_2D. To account for the experimental results, it is necessary to calculate the electric field gradient (EFG) at the interstitial deuterium atoms. No precise calculation of EFG at interstitial atoms has yet been made. Bloembergen and Rowland[11] have used a Thomas-Fermi approximation by Mott and Jones[12] and have calculated the EFG at monovalent solvent Cu atoms in Cu–Zn substitutional alloy, where the EFG is produced by the extra positive charge of the divalent solute Zn. A similar treatment has been made by Schreiber and Cott[13] for the calculation of EFG at La in the La–H interstitial system. Coogan and Gutowsky[14] applied this approximation in their calculation of the potential energy for hydrogen diffusion in the Ti–H system. Our problem in the EFG calculation is similar to that of the last case. However, in order to know the arrangement of deuteriums, it is not necessary to know the exact solution of the EFG calculation. What it is desirable to know is the relative sign, the relative magnitude, the principal axis direction, and the asymmetry parameter of the EFG tensor. These parameters, fortunately, are determined only by the array of Ta and deuterium ions and are almost independent of the method of estimation of the conduction electron contribution.[15] In this section, we used Mott's screened potential. By using this, we do not expect to have a completely exact solution of the principal value of the EFG tensor, but can obtain the relative magnitude, the relative sign, the principal axis direction, and the asymmetry parameter of the EFG tensor.

Here we choose a set of orthogonal axes, X', Y', and Z' as the principal axes; the Z' axis lies along the direction of the maximum component, and X' along that of the minimum component. The maximum component, eq, at the i-th deuterium atom may be expressed as;

$$eq = \frac{\partial^2 V}{\partial Z'^2} = \sum_j V''(r_{ij}) \frac{(3\cos^2\theta_{ij} - 1)}{2} \qquad (1)$$

where $V''(r_{ij})$ is the field gradient along the ij direction and is given by;

$$V''(r_{ij}) = \frac{2Z_j e}{r_{ij}^3}(1 + Kr_{ij} + (Kr_{ij}/2)^2)\exp(-Kr_{ij}) \qquad (2)$$

where r_{ij} is the distance between the i-th deuterium and the surrounding j-th ion, θ_{ij} is the angle between the Z' axis and the ij direction, $Z_j e$ is the charge on the j-th ion, and the summation is made over the j-th ions. When the crystal is cubic the EFG at each site is axially symmetric. However, since the low temperature form (β form) is a slightly distorted cubic form, with $c/a = 1+\Delta$, where Δ is a small quantity compared with 1, the EFG is not axially symmetric.

Next, we will calculate the EFG for the deuterium arrangement proposed by Wallace.[5] Structure A, which he assumed to be most reasonable,[16] belongs to the $I4$ space group ($a = 2a_0 = 6.74$ Å) with half deuteriums located at the general positions of 1/4 1/8 0 and 5/8 0 1/4. We denote the 8 positions at 1/4 1/8 0, 7/8 1/4 0, 3/4 7/8 0, 1/8 3/4 0, 5/8 0 1/4, 3/8 0 1/4, 0 3/8 1/4, and 0 5/8 1/4 as TA1, TA2, ·····, TA8, the other 8 positions are, of course, at $+1/2$ 1/2 1/2 translation. Due to r_{ij}^{-3} and $\exp(-Kr_{ij})$ terms in Eq. (2), the EFG due to ions other than the nearest neighbor Ta ions can be disregarded. Then, eq and the asymmetry parameter are;

$$eq = -\frac{2}{5}V''(R_1) - \frac{2}{5}V''(R_2) - \frac{12}{25}\Delta V''(R_2) \qquad (3)$$

$$\eta = 3(1 - V''(R_2)/V''(R_1)) - \frac{6}{5}\Delta < 3(1 - (R_1/R_2)^3) - \frac{6}{5}\Delta \qquad (4)$$

where $R_1 = \sqrt{5}\, a_0/4$ and $R_2 = \sqrt{5}\, a_0\ (1 + 4\Delta/5)/4$ are the deuterium–tantalum distances, and the principal axis directions are;

$Z' \| a$, $Y' \| b$ and $X' \| c$ axes for TA2, TA4, TA5, and TA6

$Z' \| b$, $Y' \| a$ and $X' \| c$ axes for TA1, TA3, TA7, and TA8

From the above considerations, one may draw the following conclusion. When the temperature increases and the jump frequency becomes larger than the quadrupole coupling constant of the deuterium atom, each deuterium atom will experience two sites with different principal axis directions and the quadrupole coupling constant will be averaged. Consequently, the following predictions will be realized; (1) the largest principal component will be $eq(1-\eta)/2 \approx eq/2$; (2) the direction of the largest principal component will become parallel to the c axis, and (3) the asymmetry parameter will become zero. Therefore, the quadrupole coupling constant at a low temperature must be twice that at a high temperature as long as the above situation holds.

The ordered deuterium arrangement proposed by PSSC is shown in Fig. 4. It can easily be seen from the $2a$ positions of the deuteriums and the pseudo-tetragonality of the cell that, in the absence of a displacement of the Ta atoms, the EFG at the deuteriums in this ordered arrangement is axially symmetric with respect to the c axis. However, if we consider the fact that the displacement of Ta atoms at $\pm x$ improves the neutron diffraction reliability factor, the EFG is thought to be distorted from the axial symmetry. The maximum principal component, eq, and the asymmetry parameter, η, calculated from the nearest neighbor

16) The other two structures which Wallace denoted as Structure B and C give the same result as Structure A.

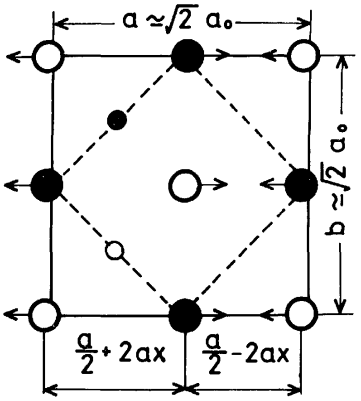

Fig. 4. Projections onto 001 plane of β_1 Ta_2D (PSSC model) Ta's are at $z=0$ (large opened circles) and at $z=1/2$ (large closed circles). D's are at $z=1/4$ (small opened circles) and $z=3/4$ (small closed circles).

four Ta atoms are;

$$eq \approx \left(-\frac{4}{5}+\frac{48}{25}+\frac{96}{25}x\right)V''(R_3) \quad (5)$$

$$\eta \approx 24x \quad (6)$$

where $R_3=\sqrt{5}a_0(1+(8x+\Delta)/5)/4$. Since the deuteriums in this ordered structure are situated in a special position, whose Z' direction is parallel to the c axis, the quadrupole coupling constant is not averaged by the rapid diffusion of the deuteriums; that is, the quadrupole coupling constant at a low temperature must be the same as that at a high temperature. Therefore, in order to determine which of the proposed structures is consistent with the deuteron magnetic resonance results, it is sufficient to know; (1) whether the asymmetry parameter at a high temperature is zero or larger than zero ($\approx 24x$), or (2) whether the quadrupole coupling constant at a low temperature, where the deuterium diffusion is negligible, is twice that at a high temperature.

In the previous section, we have shown that the asymmetry parameter at room temperature lies between 0.15 to 0.25, appreciably larger than zero. In order to examine (2), it is necessary to know the correlation time for deuterium diffusion at −179°C. We obtained the correlation times for hydrogen diffusion at −180°C by an extrapolation method by using the proton magnetic resonance data of the TaH_n interstitial system.[17] These times are 10^{-4} and 1.4×10^{-4} sec for $n=0.66$ and 0.1 respectively. The correlation time for deuterium diffusion is expected to be longer than that for hydrogen diffusion due to the isotope effect. Therefore, we assume that $1/\tau_c \ll e^2qQ/\hbar$. As is shown in Fig. 1, the observed spectrum at −179°C can not be expressed as having twice as large quadrupole coupling constant as that at room temperature. It is better expressed as having approximately the same quadrupole coupling constant as that at room temperature, and it is smoothed with a broad Gaussian distribution. From these considerations, it seems that the ordered arrangement proposed by PSSC is the most probable structure for the β_1 form. The calculated eq, asymmetry parameters and configurational entropies for the other two structures,[6,7] together with the above two, are listed in Table 1.

Deuterium Arrangement in β_2 Ta_2D. According to the neutron diffraction study by Wallace,[5] the unit cell of this form ($a=a_0=3.37$ Å) is the same as the X-ray unit cell, which contains one deuterium and two tantalums. There are 12 tetrahedral sites in a unit cell. According to Wallace's notation, these are T_1, T_2, ⋯, T_6 at 1/2 1/4 0, 1/2 3/4 0, 1/4 1/2 0, 3/4 1/2 0, 0 1/2 1/4 , and 1/2 0 1/4, while the other 6 sites are T'_1, T'_2, ⋯, T'_6 at a +1/2 1/2 1/2 translation. If the crystal is cubic, these 12 sites are structually equivalent. However, since the β_2 is a slightly distorted cubic form, these 12 sites may be divided into S and L groups,[5] S group contains T_5, T_6, T'_5, and T'_6, while L contains the other 8 sites. There are only three arrangements, random distribution in the S sites, in the L sites, and in all the sites. The calculated neutron diffraction intensities for these three arrangements showed an excellent agreement with the experimental results.[5]

The EFG of these 12 sites may be calculated by means of Eqs. (3) and (4) and by substituting $x=0$ in Eqs. (5) and (6). The resulting Z' direction are shown in Table 2. By using consideration similar to that used previously, one may easily reach the following conclusions;

(1) If the deuteriums are distributed over all the tetrahedral sites with equal probability and with a rapid translational motion, the resultant quadrupole coupling constant will be averaged and will become zero (for b. c. c.) or below the level of detection (for b. c. t.)

Table 1. Calculated eq, η and configurational entropies(S_c) for the various proposed β_1 Ta_2D structures

	Space group	Deuterium positions	R[a]	$(eq)_H/(eq)_L$[b]	η[c]	S_c (e.u. mol^{-1})
Wallace[5]	$I4$	$8G$(1/4 1/8 0) $8G$(5/8 0 1/4)	0.17	1/2	c)	2.7
Palenik[6]	$I\bar{4}$	$8G$(0 1/4 1/8)	0.29	1	0	0
Somenkov *et al.*[7]	$Pnnn$	a(1/4 1/4 1/4) b(1/4 3/4 3/4)	0.30	1	0	0
Petrunin *et al.*[8]	$A222$	$2a$ (1/4 1/4 1/4)	0.107	1	$\approx 24x$[d]	0

a) Superlattice diffraction reliability factor.
b) Ratio of eq at a high temperature to that at a low temperature.
c) At a high temperature; $\eta=0$ and, at a low temperature; η is given by Eq. (4).
d) $x=0.012$ at a room temperature, $x=0.017$ at a liquid nitrogen temperature.

TABLE 2. CALCULATED Z′ AXIS DIRECTION FOR EACH OF THE 12 TETRAHEDRAL SITES OF THE β_2 FORM

Group		Z' axis direction
L	T_1, T_2, T_1', T_2'	$Z'\|\|$ b axis
	T_3, T_4, T_3', T_4'	$Z'\|\|$ a axis
S	T_5, T_6, T_5', T_6'	$Z'\|\|$ c axis

(2) If the deuteriums are distributed over the L sites, the resultant quadrupole coupling constant will be a half of that at a low temperature where the rapid translational motion is absent.

(3) Since the Z' direction of the tetrahedral sites in the S group is parallel to the c axis, the quadrupole coupling constant will not be averaged by the rapid translational motion of the deuteriums. Consequently, the quadrupole coupling constant is approximately the same as that for the ordered β_1 form.

TABLE 3. CALCULATED eq, η AND CONFIGURATIONAL ENTROPIES FOR THE VARIOUS PROPOSED β_2 Ta_2D STRUCTURES

	$eq_{\beta 2}/eq_{\beta 1}$ [a]	η	S_c(e.u. mol^{-1})
L [b]	1/2	0	5.97
S [c]	1	0	4.20
L and S [d]	0	—	6.82

a) $eq_{\beta 1}$ is given by Eq. (5).
b) Random distribution in the L sites.
c) Random distribution in the S sites.
d) Random distribution in all sites.

The calculated eq, the asymmetry parameters, and the configurational entropies for the three proposed structures are shown in Table 3. It should be noted that the observed deuteron resonance line shape exhibits no quadrupole coupling constant change upon the $\beta_1 \rightarrow \beta_2$ phase transition, and that the most probable structure for the β_1 form is the PSSC ordered model. Then, from an inspection of the table, one can see that the distribution in the S sites seems to be the probable structure for the β_2 form. However, the calculated configurational entropy is far larger than the observed value, 0.7 e.u. mol^{-1}. In order to account for the large difference between the calculated and observed entropies, we must take some kinds of local order into consideration.

Local Order in the β_2 Form. The locally ordered structure which we will discuss in this section must satisfy the following three conditions; (1) the deuteron quadrupole coupling constant and asymmetry parameter of the β_2 form must be of the same order as the β_1 form; (2) in spite of the above condition, there must be no superlattice diffraction in the β_2 form, and (3) the configurational entropy of the β_2 form must be only 0.7 e.u. mol^{-1}. From condition (1), we see that the arrangement of Ta atoms around the deuterium atom is the same as that of the β_1 form. This means that the symmetry of the β_2 form must be orthorhombic. From condition (2), we see that the deuteriums must be distributed over all the tetrahedral sites in the S group with a quarter occupancy. This means that the symmetry of the β_2 form must be tetragonal. However, this tetragonality contradicts condition (1), while a quarter occupancy contradicts condition (3).

Let us try to account for the above contradiction. In the A222 space group, without considering the displacement of Ta ($4K$ positions), the $2a$(1/4 1/4 1/4, 1/4 3/4 3/4), $2b$(1/4 1/4 3/4, 1/4 3/4 1/4), $2c$(3/4 1/4 3/4, 3/4 3/4 1/4), and $2d$(3/4 1/4 1/4, 3/4 3/4 3/4) positions are all equivalent. In the ordered structure, the deuteriums are at the $2a$ positions and the Ta are displaced by $\pm x$. However, as the temperature increases, the preservation of the mutual positions of the deuteriums becomes difficult and probability of finding deuteriums in the $2b$, $2c$, and $2d$ positions becomes progressively larger. However, before the deuteriums are found to be statistically distributed over these sites, one may find a locally ordered structure. This consideration yields a concept of a domain structure which is constructed with four types of domains. The deuteriums in the domains are, of course, at the $2a$, $2b$, $2c$, and $2d$ positions. Since the domains are perfectly ordered internally, the configurational entropy is merely the entropy of the mixing of the domains. For one mole of Ta_2D, the number of domains is $N/(2r^3)$, where N is the Avogadro number, where r is a repeat number of a unit lattice per domain, and the number of complexions is $(N/(2r^3))!/((N/(8r^3))!)^4$ and $S_c = R\ln 4/(2r^3)$. The probable value of r, which is determined so that the calculated value coincides with the experimental value of 0.7 e.u. mol^{-1} is 1.4. For such small domains, as Wallace[5] has pointed out, sharp superlattice diffractions do not develop and the diffraction pattern closely resembles that in which deuteriums are randomly distributed over the S sites. Therefore, we can assume that the above domain structure satisfies the three conditions simultaneously and seems to be the most probable structure. An example of the domain structure projected onto 100 plane is shown in Fig. 5.

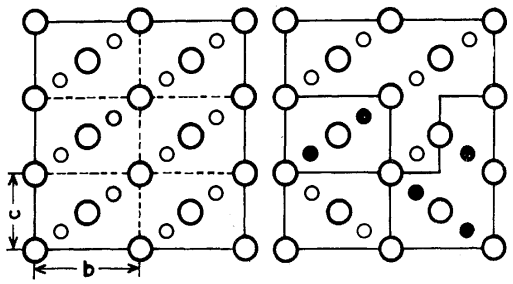

Fig. 5. Projection onto 100 plane of the ordered β_1 (left) and locally ordered β_2 form (right). Only Ta's at $x=0$ (opened large circles) are shown. D's are at $x=1/4$(small opened circles) and $x=3/4$ (small closed circles).

Deuterium Arrangement in α Ta_2D. The quadrupole coupling constant of this form is too small to be detected. This fact can be accounted for if the deuteriums are undergoing a rapid translational motion over all available tetrahedral sites (L and S sites). The configurational entropy calculated from this structure is 6.82 e.u. mol^{-1}. On the other hand, Saba *et al.*[4] have shown that the configurational entropy of this form is 4.9 e.u. mol^{-1}, which does not change even at 573°K. This indicates that the deuteriums are not randomly distributed over all the tetrahedral sites, but are dis-

tributed in a manner which retains some kinds of local order. However, in considering such a locally ordered structure, it should be taken into account that (1) the crystal is cubic and (2) the quadrupole coupling constant is averaged to zero. These conditions require that, in a locally ordered domain, there must be three different equally abundant sites, whose Z' directions are parallel to the a, b, and c axes respecitvely. It is possible to imagine such a domain structure without a loss of crystal symmetry. However, since it is difficult to interpret why such domain structure is energetically stable, we will not discuss further this problem.

Electric Field Gradient Calculation. In the previous section, we have used a simple electrostatic model in which the electric potential from the ions is screened by the conduction electrons around the ions. However, we have left the constant, K, and the electric charge on the ions underemined. In this section, we will discuss these parameters.

It has been shown that when a hydrogen enters the metal, it loses most of its electron cloud to the conduction band or to the metal ions. The ^{139}La magnetic resonance study of La-H[13] system has shown that the EFG at the La ion due to the defect of hydrogen ions can best be calculated by the assumption of a positive charge on the hydrogen ion. However, the relatively large negative proton Knight shift in the Ti-H system[18] has shown that the hydrogen does not lose its electron completely in this system. Schreiber and Graham[19] have suggested, from the zero proton Knight shift in the Ta-H, Nb-H, and V-H systems, the existence of bare protons in these systems. The proton relaxation times of Ta-H[17] and Nb-H[20] systems have shown no contribution of conduction electrons to their relaxation mechanisms. Therefore, the assumption of a positive charge on the interstitial deuterium ions is a good approximation.

In compensation for a positive charge on hydrogen ions, a negatively ionized metal ion model has been presented.[14] However, this assumption is inconsistent in its use of a screened potential and also contradicts the pulsed NMR result[21] that the hydrogen diffusion activation energy is independent of the hydrogen concentration. We assume that the effect of electrons removed from the interstitial hydrogen atoms is merely to change the conduction electron density slightly and that this effect has no influence on the net charge of the Ta ions.

The values of K for Cu, Ag, and Al have been calculated to be 1.72 to 1.81×10^8 cm^{-1}. Due to the r_{ij}^{-3} and $\exp(-Kr_{ij})$ terms in Eq. (2), the summation in Eq. (1) easily converges. The computation has been made over 68 Ta and 29 deuterium ions within the sphere of radius of $R=\sqrt{69}\,a_0/4$. With $a_0=3.37$, $c/a=1.008$, and displacement parameter $x=0.012$, some combinations of K and Z_{Ta} which have been so determined as to the calculated quadrupole coupling constants agree with the observed value, 33.9 KHz, are as follows;

Z_{Ta}	K	η
5	1.75×10^8 cm^{-1}	0.235
4	1.54×10^8 cm^{-1}	0.186
3	1.47×10^8 cm^{-1}	0.128

The dependence of η on Z_{Ta}, of course, comes from the contribution on the Ta ion to the EFG. Since the observed asymmetry parameter lies between 0.25 to 0.15, 4 to 5 charge on the Ta ion seems to be plausible. However, if the deuteriums do not lose their electron cloud completely, a +5 charge on the Ta ion may be more realistic.

The author wishes to express his thanks to Professor Shizuo Fujiwara for his continuing interest and encouragement. Thanks are also given to Drs. Masatoshi Okada and Takeo Yamamoto, who read the manuscript and made some useful comments.

The first-order powder pattern of one satellite for asymmetric field gradient, $P_\eta(x)$, is defined in Ref. (9) page 342. If the individual lines are assumed to be the form as,

$$f(x) = \exp\left[-(x-x')^2/2\sigma^2\right] \tag{1'}$$

where $x=(\nu-\nu_0)/(3\,e^2qQ/4h)$. The resultant shape function, $G'_\eta(x)$ (derivative), is given

$$G'\eta(x) = \int_{-1}^{1}(x-x')[P(x')+P(-x')]\exp\left[-(x-x')^2/2\sigma^2\right]dx' \tag{2'}$$

Examples for $\eta=0.23$ are shown in Fig. 6. We define x_1, $x_3(x_3', x_3'')$ and x_4 as derivative maxima (minimum) and x_2 as derivative zero. As shown in Fig. 7, x_1 and x_2 are very sensitive to η, x_1 and x_2 may be used to obtain η. Quadrupole coupling constant is most accurately determined by measuring x_4 which is very insensitive to η and σ. When η is large enough or σ is small enough to be able to observe the separation between x_3' and x_3'', η may be very easily obtained by comparing $(x_3''-x_3')/(x_4-x_3'')$ against η as shown in Fig. 8.

Electron Spin Resonance Studies of the Carbon Dioxide Anion Radical Adsorbed on X-Type Zeolites

Kunihisa SOGABE, Akinori HASEGAWA, Yoshio YAMADA,* and Masaji MIURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received April 3, 1972)

The hindered motion and the structure of the CO_2^- radical adsorbed on various zeolites were investigated by means of ESR spectroscopy. The adsorbed CO_2^- radical was obtained by the γ-irradiation of zeolites with carbon dioxide labeled with ^{13}C. The results show that the interaction of the CO_2^- radical with the zeolite surface changes with the electrostatic field on the surface. The motion and the structure of the adsorbed CO_2^- radical are affected by the properties of the zeolite surfaces; the former is also influenced by the extent of exchange of the cation on zeolite, regardless of the time of irradiation, before or after the introduction of carbon dioxide. The formation of the CO_2^- radical on zeolites was interpreted on the basis of such a mechanism that electrons are initially trapped by the surface of zeolite upon the irradiation and then transferred to carbon dioxide molecules. The results also show that the process of the electron transfer depends on the kind of cation.

The application of ESR spectroscopy to adsorbed molecules has been of considerable interest, since it permits detailed studies of their adsorbed state. Several works have been reported on the formation of the CO_2^- radical on an insulator, such as SiO_2 or MgO.[1-4] However, very little information has been obtained on the interaction between the radical and the solid surface.

Sharp and Symons[5] have recently investigated the CO_2^- radicals formed in various formates and shown that the ESR parameters for the CO_2^- radical depend markedly upon the nature of the host lattice. According to their results, the crystal field, which increases as the cation's charge increases or its radius decreases, causes a profound perturbation in the CO_2^- radical. Kasai[6] has studied the crystal-field interaction between an adsorbed paramagnetic species, O_2^-, and Y-type zeolites, and shown that the splitting of energy levels of the O_2^- is exactly twice as large with BaY as with NaY.

In this work, we will attempt to represent the crystal-field interaction in terms of the hindered motion and the structural variation in the CO_2^- radical adsorbed on zeolites.

Experimental

The X-type zeolite was furnished in the sodium form (Linde Lot No. 1380019). Ion-exchanged zeolites were prepared by exchanging the sodium ions with other kinds of

cations in their chloride solutions by the conventional method.[7] The exchange process was then repeated in order to achieve a high degree of replacement. The exchanged zeolites were washed with distilled water in order to remove the excess chloride ions. Thus, Li-, K-, Mg-, Ca-, and BaX were obtained. The degree of ion-exchange was determined by measuring the amount of the exchanged sodium ions by means of atomic-absorption spectroscopy.

After the exchanged zeolite had been evacuated for 5 hr in a vacuum of 10^{-5} Torr at 500°C, it was slowly cooled to room temperature and transferred into an ESR sample tube. Carbon dioxide containing 59.1 atom% ^{13}C, which had been obtained from Merck Sharp & Dohme of Canada, Ltd., was used in order to observe the ^{13}C hyperfine structure. The carbon dioxide was introduced into the sample tube through a breakable seal at room temperature. After the zeolite had been exposed to the carbon dioxide gas of 20 Torr for 30 min, the physically-adsorbed carbon dioxide was removed by means of a liquid nitrogen trap. The ESR sample tube was sealed off *in vacuo* and then irradiated with ^{60}Co γ-rays (6×10^5 R/hr) for 30 min at 77°K.

The ESR spectra were measured at various temperatures by a spectrometer described elsewhere.[8] In order to study the mechanism of the formation of the adsorbed CO_2^- radical, a pre-irradiation process was also adopted.

Results and Discussion

The percentages of exchanged ions are shown in Table 1. In the case of MgX, only 59.6% of Na^+ was exchanged even when the exchange process was repeated; this seems to be due to the large hydration radius of Mg^{2+}.[9]

Formation and Identification of the CO_2^- Radical. The shapes of the hyperfine structures of ^{13}C in the spectra obtained for the zeolite exchanged by the Li^+ ion and the bivalent cation are very close to that of the $^{13}CO_2^-$ radical adsorbed on silica gel.[2] Each spectrum consists of a central line originating from the $^{12}CO_2^-$ radical and of two additional outer lines due to the $^{13}CO_2^-$ radical. However, no ESR spectrum of the CO_2^- radical adsorbed on NaX or KX was observed under the same experimental conditions as were used for the other zeolites. The CO_2^- radical on NaX or KX was obtained when these zeolites were irradiated for 16 hr at room temperature in the presence of carbon dioxide at 100 Torr. The formation of the radical on the NaX or KX may be interpreted as follows: the irradiation at room temperature enabled electrons to transfer from the surface to adsorbed carbon dioxide. The g-values evaluated from the hyperfine structure of ^{13}C are summarized in Table 1.

Structure of the CO_2^- Radical. Ovenall and Whiffen[10] have observed the ESR spectrum of the CO_2^- radical produced in γ-irradiated sodium formate and determined the structure of the radical by analyses of the g-values and the ^{13}C coupling constants. According to the molecular orbital theory, the unpaired 17th electron occupies the $4a_1$ molecular orbital:[10,11]

$$(4a_1) = c_1C(s) + c_2C(p) + c_3O(P_{z1}+P_{z2}) + c_4O(P_{y1}-P_{y2}) + c_5O(s_1+s_2) \quad (1)$$

Actually, the ^{13}C coupling constants of the $^{13}CO_2^-$ radical are used for the estimation of the atomic orbital coefficient of Eq. (1).

$$A_{iso} = C_1^2A_s, \quad A_{//} - A_{iso} = C_2^2A_p \quad (2)$$

where A_s and A_p are the coupling constants for the electrons in the pure carbon $2s$ and $2p$ orbitals, 1189 and 42.9 G[10,12] respectively, and where C_1^2 and C_2^2 are the spin densities in the carbon $2s$ and $2p$ orbitals respectively, which give information on the hybridization of the orbitals.

The OCO angle of the CO_2^- radical, θ, has been derived in terms of the hybridization:[13]

$$\cos\theta = -\frac{\lambda^2}{\lambda^2+2} \quad (3)$$

where λ^2 is the ratio of hybridization, C_2^2/C_1^2. The anisotropic hyperfine structure of the $^{13}CO_2^-$ radical

observed at 77°K was analyzed in order to determine the OCO angle. The values of C_1^2, C_2^2, and λ^2 estimated from the spectra of the CO_2^- radicals adsorbed on the various zeolites are given in Table 1. The results on MgO[1] and SiO_2[2] are also listed in the table. The change in the value of θ, namely, the structural variation in the CO_2^- radical, has been ascribed to the difference in cation radius.[2] The charge of the cation as well as its radius, however, seems to affect the structure of the CO_2^- radical, as can be seen in Table 1.

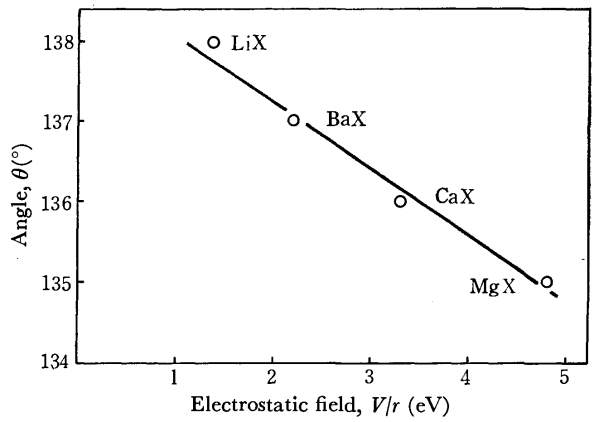

Fig. 1. Relationship between OCO angle of CO_2^- radical and electrostatic field on zeolites.

One aim of the present study is to investigate the interaction between the CO_2^- radical and the zeolite surface through the structural variation in the CO_2^- radical brought about by the change in the kind of cation on zeolite. Rabo *et al.*[14] have calculated the electrostatic fields characteristic of the cations on the zeolite surfaces. In Fig. 1, a good linear relationship can be seen between the electrostatic field on the zeolite surface and the OCO angle of the CO_2^- radical adsorbed on the zeolite. This means that the structure of the adsorbed CO_2^- radical is strongly affected by the electrostatic field; the OCO angle of the CO_2^- radical decreases as the charge of the cation increases or as its radius decreases. These results are consistent with those obtained by ESR studies of the CO_2^- radical trapped in formates.[5] However, the perturbation on the structure of the CO_2^- radical observed in this study is more remarkable than that in formates.

Motion of the CO_2^- Radical. In order to obtain some information on the interaction between the adsorbed CO_2^- radical and the zeolite surface, the motional behavior of the radical was investigated through the observation of the temperature variation in the spectrum of the $^{13}CO_2^-$ radical. It was found that the spectra of the radical on NaX and KX are isotropic even at 77°K, as can be seen in Figs. 2(a) and (b). There is little difference in these spectra, and their ^{13}C hyperfine coupling constants are both equal to 133G. Therefore, the CO_2^- radical on NaX and KX may be free from the cations on the zeolites and may still rotate or vibrate on the surfaces even at this

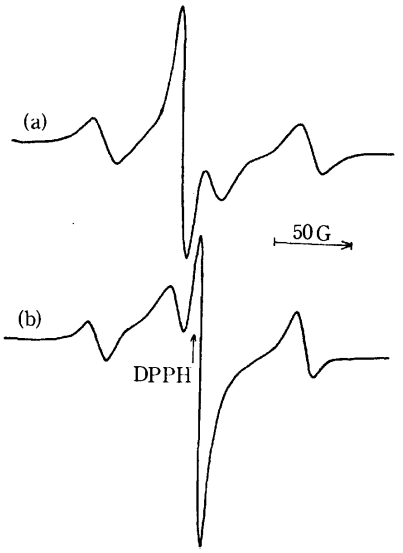

Fig. 2. ESR spectra of CO_2^- radical on (a) NaX and (b) KX at 77°K.

temperature.[15] As may be seen in the figures, a signal having $\Delta H=10$G and $g=2.012$ appeared. The same signal was observed when these zeolites were irradiated at 77°K in the absence of carbon dioxide. This may be ascribed to the hole generated by γ-irradiation, similarly to the cases of NaY reported by Stamires and Turkevich[16] and by Wang and Lunsford.[17] As regards LiX, the CO_2^- radical, as can be seen in Fig. 3, may weakly interact with the surface at 77°K.

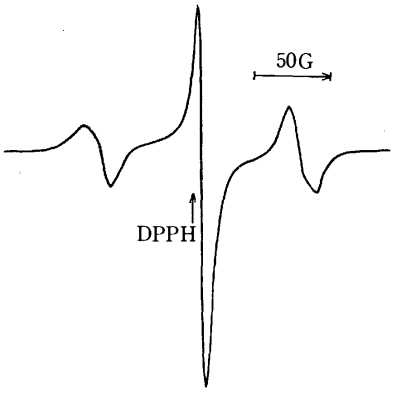

Fig. 3. ESR spectrum of CO_2^- radical on LiX at 77°K.

A distinct difference in the motion appeared on the zeolite exchanged with bivalent cations. The spectrum of the $^{13}CO_2^-$ radical on the MgX (59.6%) shown in Fig. 4 is anisotropic at 77°K. It was found, indeed, that the radical begins to rotate freely at about 200°K. When the sample was cooled down again from 298 to 77°K, the anisotropic spectrum was observed again; the spectral change is completely reversible with respect to the temperature variation. Also, the motion of the

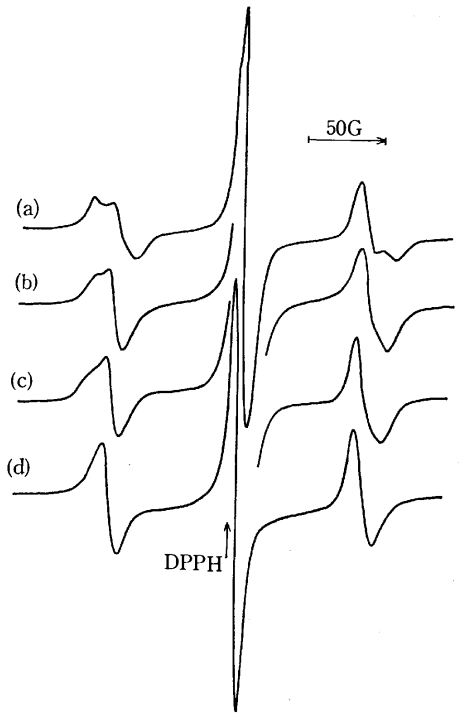

Fig. 4. ESR spectra of CO_2^- radical on MgX at (a) 77°K, (b) 180°K, (c) 190°K, and (d) 200°K.

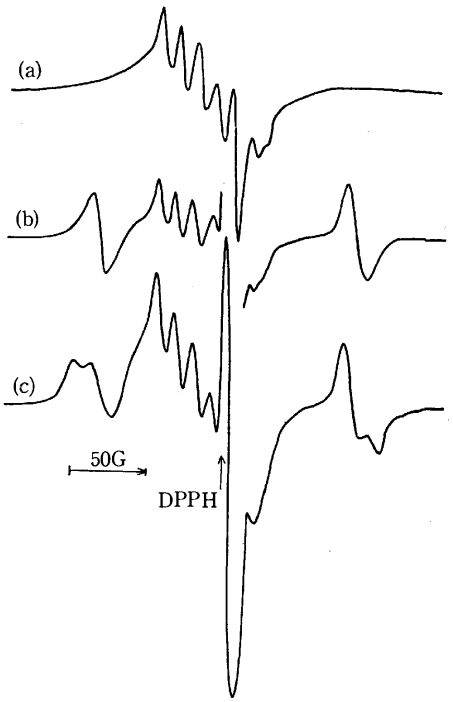

Fig. 5. (a) ESR spectrum of MgX irradiated for 2 hr at 77°K. (b) Spectrum of CO_2^- radical on pre-irradiated MgX at 298°K and (c) that at 77°K.

CO_2^- radical on pre-irradiated MgX was the same as that on post-irradiated MgX, as can be seen in Fig. 5. This indicates that the motional behavior of the CO_2^- radical on the zeolite is independent of the irradiation process.

The CO_2^- radical on the MgX was stable at room temperature for a few days, but bleached at about

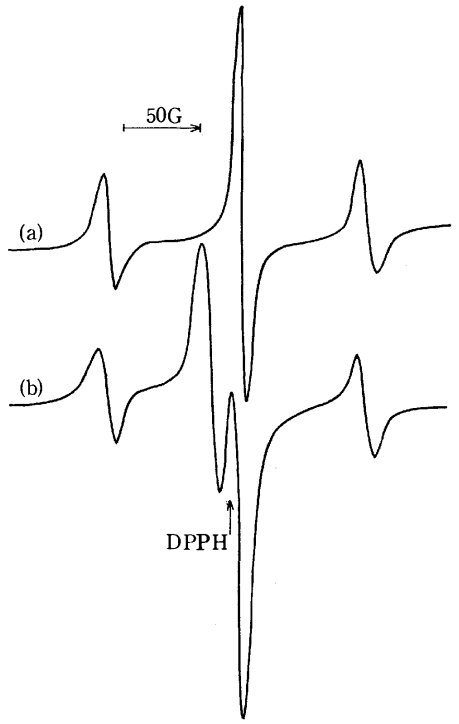

Fig. 6. ESR spectra of CO_2^- radical on MgX (a) at 298°K and (b) after standing for 48 hr at room temperature.

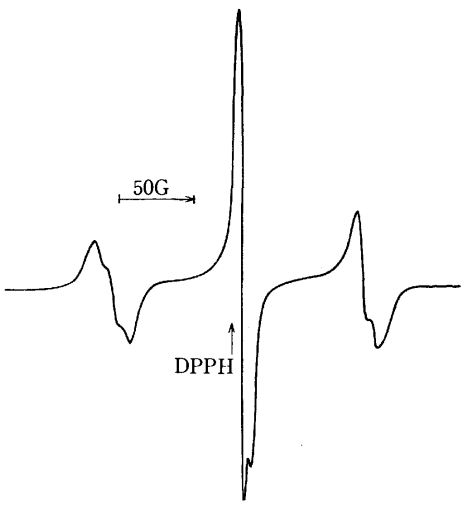

Fig. 7. ESR spectrum of CO_2^- radical on CaX (96.4%) at 77°K.

420°K. However, an additional line ($g=2.012$) appeared after 48 hr at room temperature (Fig. 6(b)); the intensity of this line increased with a decrease in the intensity of the spectrum for the CO_2^- radical while it stood. This additional line may be due to the hole, as in the case of the zeolite irradiated in the absence of carbon dioxide, as has been described above. This increase in the amount of the hole may be accounted for by the electron capture of the CO_2^- radical in the process of the degradation of the radical. The anisotropic spectrum of the $^{13}CO_2^-$ radical on the CaX (96.4%) (Fig. 7) hardly changed between 77 and 420°K. This spectrum was still observed at 77°K even after the sample had been heated to 600°K in

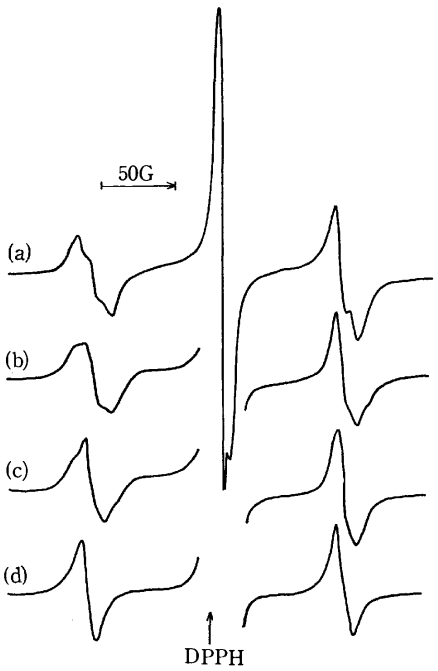

Fig. 8. ESR spectra of CO_2^- radical on CaX (78.5%) at (a) 77°K, (b) 127°K, (c) 150°K, and (d) 163°K.

a furnace. The same result was obtained in the case of BaX. This suggests that the adsorbed CO_2^- radical strongly interacts with the zeolite surfaces and is stabilized on them. Such a stable anisotropic spectrum as obtained on the CaX or BaX could not be observed on the MgX, though the electrostatic field caused by the Mg^{2+} ion is generally expected to be stronger than that caused by the Ca^{2+} or Ba^{2+} ion.[14,18,19] This contradiction may be interpreted in terms of the very low degree of ion exchange on MgX, compared with that on CaX or BaX.

In this view, a series of zeolites differently exchanged by bivalent cations were investigated. For instance, the motional behavior of the radical adsorbed on CaX (78.5%) can be deduced from Figs. 8(a)—(d). The $^{13}CO_2^-$ radical on a zeolite with a lower degree of cation exchange shows almost the same spectrum as that on the zeolite with a higher exchange degree at 77°K, but the temperature at which the radical begins to move or bleach depends remarkably upon the exchange degree, as can be seen in Table 2. That is, an almost complete exchange with a cation such as Ca^{2+} or Ba^{2+} greatly restricts the motion of the radical. All the radicals adsorbed on zeolites of lower degrees of exchange bleach below room temperature. It can be

a) Pre-irradiation for 2 hr at 77°K.

deduced from these phenomena that the electrostatic field influences the motion of the CO_2^- radicals more effectively than the perturbation on the structure of the CO_2^- radicals.

The Reaction of Carbon Dioxide with γ-Irradiated Zeolites. Wang and Willard[3] have reported that the addition of carbon dioxide to γ-irradiated silica gel results in the formation of the O_2^- radical, though the CO_2^- radical is formed on the post-irradiated gel, while Yamada *et al.*[2] have found that the latter radical is formed on the pre-irradiated gel. In the present study, the CO_2^- radical was generated on both post- and pre-irradiated zeolites. The results obtained in the case of MgX (59.6%) are shown in Figs. 4 and 5. On the other hand, a hyperfine structure attributed to the interaction of the trapped electron with the aluminum nucleus[16,17] was observed on irradiated MgX in the absence of carbon dioxide, as is shown in Fig. 5(a). However, when the MgX was irradiated in the presence of carbon dioxide, the hyperfine structure due to the ^{27}Al nucleus could not be observed. This can be interpreted as follows: the electrons formed during the irradiation are preferentially captured by the carbon dioxide molecule because this molecule traps electrons more deeply than aluminum does. Thus, the CO_2^- radical may be formed relatively easily on the surface of irradiated zeolite. In the cases of NaX and KX, no CO_2^- radical was observed when they were irradiated at 77°K, but it was generated by irradiation at room temperature. It may be deduced from these observations that the amount of trapped electrons formed during the irradiation is small, or that the ability to transfer the trapped electron to the carbon dioxide molecule is weak, at 77°K. Upon irradiation for 16 hr at room temperature, the amounts of sites sufficient to form the radicals may be obtained. Further work will be needed in order to discuss these sites.

The Mechanism of Decomposition of Hydrogen Peroxide by Iodine in Acid Solutions. The Rates of Associated Reactions

Isao MATSUZAKI,[1] Radmilo SIMIC,[2] and Herman A. LIEBHAFSKY

Department of Chemistry, Texas A & M University, College Station, Texas 77843, U. S. A.

(Received April 4, 1972)

For the purpose of isolating elementary reactions responsible for the decomposition of hydrogen peroxide by iodine and its compounds, the reaction at 50°C of acid solutions containing I_2, I^-, HIO, *etc.* with $[I^-]$ and $[I_2]$ controlled by use of TlI(s) and I_2(s) was studied. The rates of the evolution of oxygen, consumption of hydrogen peroxide and production of H^+ were subjected to measurement and led to a formulation of a complex mechanism consisting of the following reactions: $HIO_2+H_2O_2\longrightarrow HIO+H_2O+O_2$; $H_2OI^++H_2O_2\longrightarrow HIO_2+H^++H_2O$; $HIO+H_2O_2\longrightarrow H^++I^-+H_2O+O_2$; $HIO_2+H^++I^-\longrightarrow 2HIO$; $H_2OI^+\rightleftharpoons HIO+H^+$; $I^-+H^++H_2O_2\longrightarrow HIO+H_2O$; and $I_2+H_2O\rightleftharpoons HIO+H^++I^-$. Absolute or relative rate constants for the first four reactions were evaluated by using equilibrium and rate constants of the others.

A series of preliminary investigations[3–6] has been made at 50°C toward clarifying the mechanism of the decomposition of hydrogen peroxide by iodine and its compounds, the only known completely inorganic oscillating reaction. It has been suggested that the following step might have much to do with the oxygen evolution in the pulses:

Step 10: $HIO + H_2O_2 \longrightarrow H^+ + I^- + H_2O + O_2$[7]

The purpose of the present investigation is to determine the value of the rate constant, which would help us understand to what degree Step 10 contributes to the pulsed oxygen evolution. The step is found to be responsible for most oxygen produced when hydrogen peroxide is oxidized by iodine at 25°C in acid solutions[8] in the virtual absence of iodate ion, which should be present to achieve oscillating decomposition.

Step 10 is difficult to study even in acid solutions because it is always accompanied by other reactions such as

Step 11: $I^- + H^+ + H_2O_2 \longrightarrow HIO + H_2O$

Step 13: $IO^- + H_2O_2 \longrightarrow I^- + H_2O + O_2$

$$I_2 + 5H_2O_2 = 2IO_3^- + 2H^+ + 4H_2O \quad (1)$$

$$3I_2 + 3H_2O = IO_3^- + 5I^- + 6H^+ \quad (2)$$

By using TlI(s) to control the iodide concentration, Liebhafsky[8] accomplished what appeared to be a satisfactory isolation of Step 10 at 25°C in acid solutions saturated with iodine so that oxygen evolution could be measured *as a constant rate* and its rate law deduced. Under these conditions, the overall reaction was assumed to be

$$I_2(s) + 2Tl^+ + H_2O_2 = 2TlI(s) + 2H^+ + O_2 \quad (3)$$

The rate of oxygen evolution at 50°C was studied by the method outlined above. Under certain conditions, the amount of H_2O_2 consumed was considerably greater than that called for by the stoichiometry of (3), and the H^+ produced was considerably less. It accordingly became necessary to investigate the additional reactions. They have been confirmed, and the result will contribute to the eventual understanding of the oscillating decomposition.

Experimental

Materials and Apparatus. Hydrogen peroxide of 30% content without inhibitor from J. T. Baker Chemical Co. and from Mallinckrodt Chemical Works was determined iodometrically before each experiment as follows. After dilution of 0.2 m*l* 30% H_2O_2 to 25 m*l*, 20 m*l* of 2N H_2SO_4, 2 g KI and 3 drops of 3% $(NH_4)_6Mo_7O_{24}$ (to expedite reaction) were successively added. After 3 min, the liberated iodine was titrated with 0.1M $Na_2S_2O_3$, starch indicator being added near the end of the titration.

Perchloric acid of analytical grade (J. T. Baker Chemical Co., 60 or 70% by weight) was used in preparing dilute (0.1N and less) solutions standardized against Na_2CO_3 with bromocresol green as indicator.

Iodine of analytical grade (J. T. Baker Chemical Co.) was pulverized before use.

A stick of highly pure thallium (Fisher Scientific Co.) was shaved as needed for the preparation of thallous perchlorate. The shavings were dissolved in excess strong perchloric acid at 105°C. The precipitated perchlorate was filtered and washed at 5°C with water until the washings were neutral.

Thallous nitrate of analytical grade (K & K Laboratories and Fisher Scientific Co.) was used in the reaction mixtures and also to prepare the slightly soluble thallous iodide by addition of potassium iodide. The precipitate was thoroughly washed with water.

The reaction vessel (Fig. 1), a 125 m*l* Erlenmeyer flask, sharply indented to promote mixing, had a rubber-capped side arm for the addition of reagents and for the withdrawing

of samples by means of a syringe. It was connected to a 100 m*l* gas buret for the measurement of evolved oxygen.

Procedure. Water pre-saturated with oxygen, perchloric acid, 0.05 g of TlI(s), thallous perchlorate solution and 2 g of I_2(s) were added successively to the reaction vessel at room temperature to make a liquid volume near 60 m*l*. After thermal equilibrium was reached in the thermostat at 50°C, the prescribed amount of hydrogen peroxide at thermostat temperature was injected from the syringe to start the reaction (t=0). Two minutes later the first sample (1.6 m*l*) was withdrawn. Further samples, the same in volume, were taken at recorded intervals of time. Gas-buret readings were made every 2 or 3 min. From these, rates of oxygen evolution were calculated, correction for the partial pressure of water vapor being made for 25°C, the assumed gas temperature.

The reaction was stopped in the samples as follows. From the 1.6 m*l* of reaction mixture in a 50 m*l* beaker, 1 m*l* was withdrawn with a pipet and discharged into 2 m*l* of carbon tetrachloride and 25 m*l* of water. The mixture was then shaken vigorously to extract iodine. Acid was then determined on one 10 m*l* portion of the aqueous phase by titration with NaOH, and H_2O_2 iodometrically on another by titration with thiosulfate. Blank tests showed that the formation of TlI and of TlI_3, which occurred on the addition of KI prior to titration, did not interfere with the iodine determination. Values of $\Delta[H_2O_2]$ and $\Delta[H^+]$ were calculated for the

a) Subscripts 0 in $[H^+]_0$, $(d[H^+]/dt)_0$, *etc.*, specify quantities at time=0.
b) The value of 3.08×10^{-3} M is the solubility of I_2 at 50°C. Two grams of I_2, *i.e.*, 7.9×10^{-3} mol, was added to saturate the reaction mixtures (60 m*l* before the first sampling), so that it may be regarded as saturated with I_2.
c) The value of $[Tl^+]_0$ was obtained by multiplying the amount in mole of $TlClO_4$ added to the reaction mixture (60 m*l*) by 1000/60.
d) The solubility product for TlI is 4.2×10^{-7} M[2] at 50°C as determined by interpolation of the data[9]; this value, on division by $[Tl^+]_0$, gives $[I^-]_0$. Experimentally, in order to ensure the establishment of the dissolution equilibrium of TlI, 0.05 g (=1.5×10^{-4} mol) of TlI was added to each reaction mixture (60 m*l* before the first sampling).
e) The values shown were obtained by extrapolating the concentrations of the withdrawn samples to time=0. They were practically in agreement with those calculated for the amounts of reagents mixed.
f) Lower limit.

1 ml of reaction mixture by taking the volume ratio 26/10 into account.

At the end of the reaction, information on TlI(s) and $TlIO_3$(s), both sparingly soluble, was obtained from the weighed, filtered residue after removal of I_2(s) by sublimation. Cubic thallous iodide is red at sublimation temperature and changes to a yellow, rhombic form as it is cooled to room temperature. The iodate is white and its presence was confirmed qualitatively by iodine liberation in Experiment 3 (Table 1). No iodate was formed in Experiments 1 and 2 (Table 1).

Results of Comprehensive Experiments. We begin by examining the relative importance of several reactions in this system.

For V_{13}, we have[10]

$$V_{13} \equiv dO_2/dt = -d[H_2O_2]/dt = k_{13}[H_2O_2][IO^-] = k'_{13}[H_2O_2][I_2]/[H^+]^2[I^-] \quad (4)$$

with $k'_{13}=5.62\times10^{-11}$(M²/min) according to Fig. 1, Ref. 10. This corresponds to $(V_{13})_0=1.09\times10^{-6}$, 2.64×10^{-7}, and 6.35×10^{-8}M/min for Experiments 1, 2, and 3, respectively. Comparison with the measured rates in Table 1 shows that V_{13} can be neglected.

For V_{11}, we have[11]

$$V_{11} \equiv -d[H_2O_2]/dt = -d[H^+]/dt = k_{11}[H_2O_2][I^-] + k'_{11}[H_2O_2][I^-][H^+]$$

$$k_{11} = 4.91\times10^9\ e^{-13400/RT}(M^{-1}\cdot min^{-1})$$

$$k'_{11} = 4.58\times10^8\ e^{-10450/RT}(M^{-2}\cdot min^{-1})$$

from which we obtain at 50°C

$$V_{11}(M/min) = (4.18+38.9[H^+])[I^-][H_2O_2] \quad (5)$$

For a comparison with the measured rates in Table 1 as above, we calculate $(V_{11})_0=0.042\times10^{-4}$, 0.182×10^{-4}, and 0.891×10^{-4}M/min for Experiments 1, 2, and 3, respectively. These rates are not negligible relative to the corresponding rates in Table 1.

Formation of I_3^- was neglected in computing $[I^-]_0$ values for Table 1. We have for the tri-iodide equilibrium

$$K_{15} = [I_2][I^-]/[I_3^-] = 2.67\times10^{-3}M$$

the numerical value having been obtained by extrapolating experimental data.[12] For the conditions of Table 1, the equilibrium value of $[I_3^-]$ is 1.28×10^{-7}mol, which is negligible relative to the amount (0.05 g or 1.5×10^{-4}mol) of TlI added and justifies the calculation of $[I^-]_0$ as made.

$TlIO_3$ was formed only in Experiment 3 and in a negligible amount. Reactions (1) and (2) may therefore be disregarded in discussing mechanism.

Schematic Representation of Mechanism: We formulated and tested various mechanisms for their capability of accounting for the results. Of these a plausible one has been found. Because of its complexity the mechanism is shown schematically (Fig. 2). The figure shows only the interaction of the various iodine species. Steps are represented by single arrows; equilibria, by double arrows; H_2O_2, H^+, and H_2O are omitted. The complete equations are

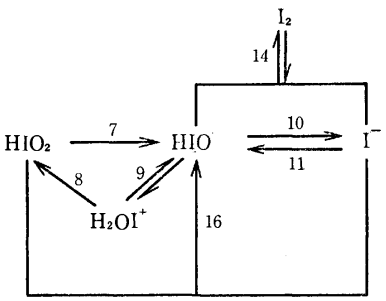

Fig. 2. Schematic representation of the mechanism.

Step 7	$HIO_2 + H_2O_2 \longrightarrow HIO + H_2O + O_2$
Step 8	$H_2OI^+ + H_2O_2 \longrightarrow HIO_2 + H^+ + H_2O$
Equilibrium 9	$H_2OI^+ \overset{K_9}{\rightleftharpoons} HIO + H^+$
Step 10	$HIO + H_2O_2 \longrightarrow H^+ + I^- + H_2O + O_2$
Step 11	$I^- + H^+ + H_2O_2 \longrightarrow HIO + H_2O$
Equilibrium 14	$I_2 + H_2O \overset{K_{14}}{\rightleftharpoons} HIO + H^+ + I^-$
Step 16	$HIO_2 + H^+ + I^- \longrightarrow 2HIO$

The solubility equilibria for I_2(s) and TlI(s) have not been included. Of the intermediate iodine species, HIO and H_2OI^+ exist at equilibrium concentrations; HIO_2 is at a steady-state concentration and is amenable to treatment by the Bodenstein steady-state approximation. The use of this approximation is on a firm basis as the rates in the reaction system are constant.

Analyses of Results According to the Mechanism: The steady-state approximation gives

$$d[HIO_2]/dt = V_8 - V_7 - V_{16} = (k_8/K_9)[HIO][H^+][H_2O_2] - k_7[HIO_2][H_2O_2] - k_{16}[HIO_2][H^+][I^-] = 0 \quad (6)$$

and hence

$$[HIO_2] = (k_8/K_9)[HIO][H^+][H_2O_2]/(k_7[H_2O_2] + k_{16}[H^+][I^-]) \quad (7)$$

The rate of oxygen evolution is

$$dO_2/dt = V_{10} + V_7 = k_{10}[HIO][H_2O_2] + k_7[HIO_2][H_2O_2] \quad (8)$$

By insertion of K_{14} and of $[HIO_2]$, Eq. (8) is transformed into

$$(dO_2/dt)([H^+][I^-]/[I_2][H_2O_2]) = k_{10}K_{14} + (k_8/K_9)K_{14}[H^+]/\{1+(k_{16}/k_7) \times ([I^-][H^+]/[H_2O_2])\} \quad (9)$$

For the sake of brevity the left side of Eq. (9) will be denoted by A, and the right side by A′.

The quantity A is convenient for obtaining k_{10}, k_8/K_9, and k_{16}/k_7 from the experimental results. Let us plot A as a function of $[H^+]$ as abscissa for the experiments in Table 1, in which $[I^-]$ is constant, and denote the intercept on the ordinate axis by A^0. Then, we have by Eq. (9)

$$A^0 = k_{10}K_{14} \quad (10)$$

$$(dA/d[H^+])_{[H^+]=0} = (k_8/K_9)K_{14} \quad (11)$$

The products of constants shown above can be evaluated graphically from the experimentally established variation of A with $[H^+]$. By use[13] of $K_{14}=4.12\times10^{-12}M^2$ and $K_9=6\times10^2$M at 50°C, and of the graphically evaluated results, the following constants were calculated:

$$\left.\begin{aligned} k_{10} &= 2.68\times10^{-8}/4.12\times10^{-12} = 6.5\times10^3(M^{-1}\cdot min^{-1}) \\ k_8/K_9 &= 9.4\times10^{-8}/4.12\times10^{-12} = 2.28\times10^4(M^{-2}\cdot min^{-1}) \\ k_8 &= 2.28\times10^4\times6\times10^2 = 1.37\times10^7(M^{-1}\cdot min^{-1}) \\ k_{16}/k_7 &= 2.14\times10^5(M^{-1}) \end{aligned}\right\} \quad (12)$$

10) H. A. Liebhafsky, *Chem. Rev.*, **17**, No. 1, August, 89 (1935).
11) H. A. Liebhafsky and A. Mohammad, *J. Amer. Chem. Soc.*, **55**, 3977 (1933).
12) A. D. Awtrey and R. E. Connick, *ibid.*, **73**, 1842 (1951).
13) J. D. Burger and H. A. Liebhafsky, unpublished work.

The value of k_{16}/k_7 was calculated from Eq. (9). That the results listed above are satisfactory for all experiments in Table 1 is evident from a comparison of the following values of A and A':

$A \times 10^8$ (mol/l) ··· 3.82(Exp. 1), 5.76(Exp. 2), 9.36(Exp. 3)

$A' \times 10^8$ (mol/l) ··· 3.82(Exp. 1), 5.45(Exp. 2), 10.12(Exp. 3)

The specific rates in Eq. (12) are based on values of dO_2/dt only. A severe test of their reliability is to see whether a mechanism that uses these specific rates can yield the three experimentally determined rate quotients listed in Table 1. For this purpose, the rates V_7, V_8, V_{10}, V_{11}, and V_{16} must be expressed in suitable form.

We begin with

$$V_8 = k_8[H_2OI^+][H_2O_2] = (k_8/K_9)[HIO][H^+][H_2O_2]$$
$$= (k_8/K_9)(K_{14}[I_2]/[H^+][I^-])[H^+][H_2O_2]$$
$$= (k_8/K_9)K_{14}([I_2][H_2O_2]/[I^-]) \quad (13)$$

We then proceed to obtain V_7, V_{10}, and V_{16} by the relations

$$V_{10}/V_8 = k_{10}[HIO][H_2O_2]/(k_8/K_9)[HIO][H^+][H_2O_2]$$
$$= k_{10}/(k_8/K_9)[H^+]$$
$$\therefore \quad V_{10} = \{k_{10}/(k_8/K_9)[H^+]\} \times V_8 \quad (14)$$
$$V_7/V_{16} = k_7[HIO_2][H_2O_2]/k_{16}[HIO_2][H^+][I^-]$$
$$= (k_7/k_{16})([H_2O_2]/[H^+][I^-])$$
$$V_7 + V_{16} = V_8$$

the last of which is derived from the Bodenstein steady-state approximation applied to HIO_2.

By solving the last two equations simultaneously, we find

$$V_{16} = V_8/\{(k_7/k_{16})([H_2O_2]/[H^+][I^-]) + 1\} \quad (15)$$

which leads to V_7 because

$$V_7 = V_8 - V_{16} \quad (16)$$

Expressed in terms of the individual rates, the three rate quotients in Table 1 are

$$-dO_2/d[H_2O_2] = (dO_2/dt)/(-d[H_2O_2]/dt)$$
$$= (V_7 + V_{10})/(V_7 + V_{10} + V_8 + V_{11}) \quad (17)$$
$$-d[H^+]/d[H_2O_2] = (d[H^+]/dt)/(-d[H_2O_2]/dt)$$
$$= \frac{(V_{10} + V_8 - V_{16} - V_{11}) - (V_{11} + 2V_{16} + V_7 - V_{10} - V_8)}{V_7 + V_{10} + V_8 + V_{11}}$$ [14]
$$= (2V_{10} + 2V_8 - 3V_{16} - 2V_{11} - V_7)/(V_7 + V_{10} + V_8 + V_{11}) \quad (18)$$

$$\Delta TlI/\Delta O_2 \doteqdot dTlI/dO_2$$
$$= \{(V_{10} - V_{16} - V_{11}) - (V_{11} + 2V_{16} + V_7 - V_{10} - V_8)\}$$ [15]$$/(V_7 + V_{10})$$
$$= (2V_{10} - 2V_{11} - 3V_{16} - V_7 + V_8)/(V_7 + V_{10}) \quad (19)$$

14) Under the experimental conditions, Equilibrium 14 is maintained, and $[H^+]$, $[Tl^+]$ —and hence $[I^-]$— are virtually constant; consequently so is [HIO]. Therefore, the net rate of HIO production in the reaction system must equal the net rate of HIO consumption in the reverse reaction in Equilibrium 14. This net rate of HIO production is given by the terms in the second parentheses; owing to Equilibrium 9, H_2OI^+ counts as HIO. As one H^+ is consumed for each HIO in the reverse reaction of Equilibrium 14, the terms in the parentheses in question also give the rate of H^+ consumption in this reverse reaction. The terms in the first parentheses give the net rate of H^+ production in all reactions other than the forward reaction of Equilibrium 14.

15) The reasoning here parallels that given in 14) except that I^- (or TlI) and not H^+ is involved.

TABLE 2. COMPARISON OF CALCULATED RATE QUOTIENTS WITH EXPERIMENTAL RATE QUOTIENTS FROM TABLE 1

Exp't No.	1	2	3
$V_7 \times 10^5$ (M/min)	2.92	5.59	9.93
$V_8 \times 10^5$ (M/min)	3.62	7.50	14.80
$V_{10} \times 10^5$ (M/min)	7.35	5.18	3.58
$V_{11} \times 10^5$ (M/min)	0.42	1.82	8.91
$V_{16} \times 10^5$ (M/min)	0.698	1.90	4.87
$(-dO_2/d[H_2O_2])_0$ [a]	0.717 (0.85)	0.536 (0.49)	0.363 (0.29)
$(-d[H^+]/d[H_2O_2])_0$ [a]	1.12 (1.0)	0.519 (0.61)	−0.151 (0.18)
$(dTlI/dO_2)_0$ [b]	1.21 (1.31)	0.272 (0.893)	−1.51 (−0.071)

a) Experimental values from Table 1 in parentheses, the inaccuracies of which are estimated to be less than ±2.5%.

b) Experimental values for $\Delta TlI/\Delta O_2$ from Table 1 in parentheses.

A comparison of experimental and calculated rate quotients is given in Table 2. In light of the complexity of the reaction system and the difficulty of analytical work, we consider the comparison satisfactory.

TABLE 3. DATA FOR SUPPORTING MEASUREMENTS AT 50°C OF OXYGEN EVOLUTION RATE

Exp't No.	4	5	6	7

Supporting Measurements of Oxygen Evolution Rate. To confirm the validity of Eq. (9), and to establish a basis for estimating the reliability of the various specific rates, measurements of the rate of oxygen evolution were carried out at various $[I^-]$ and $[H^+]$. Values of A and A' for these experiments are listed in Table 3. The agreement between each A and the corresponding A' is good enough, in view of the complexity of Eq. (9).

Relation to Previous Work

What began as a simple temperature-coefficient measurement for a reaction previously investigated[8] at 25°C had to be expanded into a complete kinetic investigation because evidence was obtained at 50°C to show that Eq. (3), assumed by Liebhafsky,[8] did not describe what actually took place. An attempt was made to interpret his results at 25°C in terms of the new mechanism. The attempt was partially successful. It gave consistent results and showed in particular that his value of k_{10} must be too high. Because his rate measurements were for calculated *average* (not *initial*) concentrations, they must be repeated if reliable values of the specific rates at 25°C are to be obtained.

The new work has a bearing on the *reduction*[16] of hydrogen peroxide by iodine. One difficulty with this

16) H. A. Liebhafsky, *J. Amer. Chem. Soc.*, **53**, 2074 (1931).

reaction was the need to find some species related to iodine that could *reduce* H_2O_2. HIO seemed to be excluded because it oxidizes H_2O_2 in Step 10. The existence of $H_2I_2O_3$ was consequently postulated. Subsequently Bell and Gelles[17] proved the existence of H_2OI^+, which makes the assumption of Step 8 seem a better way out of the difficulty.

The complexity of the new results shows that the present reaction system is closely related to that in which the oscillating decomposition of peroxide occurs; an important difference is that $[IO_3^-]$ is appreciable in the second system. The new specific rates (k_8, k_{10}, and the ratio k_{16}/k_7) should eventually be useful for describing the oscillating decomposition.

In the previous work, it was assumed that HIO_2 reduces H_2O_2 to form IO_3^-, which contradicts Step 7 if HIO_2 can react with H_2O_2 in only one way. Unfortunately, HIO_2 cannot be isolated under our conditions for a direct test of its reactivity with H_2O_2. The evidence for Step 7 is as strong as indirect evidence of this kind can be.

17) R. P. Bell and E. Gelles, *J. Chem. Soc.*, **1951**, 2734.

Summary

An investigation of the oxidation by iodine of hydrogen peroxide in acid solutions at 50°C has shown the reaction to be more complex than had been expected.

Comprehensive experiments in which $[I^-]$ was controlled by use of TlI(s) gave a mechanism in which the four steps

Step 7 $HIO_2 + H_2O_2 \longrightarrow HIO + H_2O + O_2$

Step 8 $H_2OI^+ + H_2O_2 \longrightarrow HIO_2 + H^+ + H_2O$

Step 10 $HIO + H_2O_2 \longrightarrow H^+ + I^- + O_2 + H_2O$

Step 16 $HIO_2 + H^+ + I^- \longrightarrow 2HIO$

are involved as constituent elementary steps. Numerical values for 50°C: $k_8 = 1.37 \times 10^7 M^{-1} \cdot min^{-1}$; $k_{10} = 6.5 \times 10^3 M^{-1} \cdot min^{-1}$; $k_{16}/k_7 = 2.14 \times 10^5 M^{-1}$. The last two specific rates appear as a ratio because $[HIO_2]$ is unknown.

We are grateful to the Robert A. Welch Foundation for supporting this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3371—3375 (1972)

The Estimation of the Surface Properties of Metal Oxides by the Use of TCNQ Adsorption. II. The Electron-donor Property of Silica-Alumina, Silica-Titania, and Alumina-Titania System Surfaces

Hiroshi HOSAKA, Norimichi KAWASHIMA, and Kenjiro MEGURO

Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received April 11, 1972)

The electron-donor property of silica–alumina, silica–titania, and alumina–titania system surfaces was investigated by means of TCNQ adsorption. When TCNQ was adsorbed on the surfaces of the metal oxide systems from its acetonitrile solution, the surfaces of the metal oxides acquired the coloration characteristic of each oxide. The coloration was caused by the formation of TCNQ anion radicals on the metal oxide surfaces. The presence of the TCNQ anion radicals was confirmed by studying the ESR absorption and the electronic spectrum. The silica–alumina, silica–titania, and alumina–titania systems showed lower radical-ion-forming activity (electron-donating power) than the parent oxides-silica, alumina, and titania. The change in the activity with the composition was characteristic of each metal oxide system.

The presence of electron-transfer sites on the surface of certain metal oxides is well known.[1-6] Recently, it has been reported that the formation of TCNQ anion radicals takes place on some metal oxide surfaces, and that the electron-donor property of metal oxides can be estimated by the use of 7,7,8,8-tetracyanoquinodimethane (TCNQ) adsorption.[6]

The present paper will describe the electron-donor property of silica–alumina, silica–titania, and alumina–titania systems as studied by means of TCNQ adsorption.

Experimental

Materials. The samples of the silica–alumina, silica–titania, and alumina–titania systems were prepared by the co-hydrolysis of silicon ethoxide and aluminium butoxide mixtures, silicon ethoxide and titanium butoxide mixtures, and aluminium butoxide and titanium butoxide mixtures, respectively, in different molar ratios. Excess aqueous ethanol was vigorously stirred into the alcoholic solution of alkoxides. Stirring was continued for 10 hr at a temperature near the boiling point. The precipitate was then separated by

centrifuging, thoroughly washed with water and methanol, finely ground, and then evacuated at 100°C until the residual pressure was less than 10^{-5} Torr. The complete hydrolysis of these alkoxides was confirmed by studying the infrared spectra. The dried products were calcined for 2 hr at 500°C.

The composition of the metal oxide systems was measured with a Rigaku Denki X-ray vacuum spectrograph by means of X-ray fluorometry. The abbreviations used are as follows: S, silica; A, alumina; T, titania; 4SA, SA, and S4A, silica-aluminas containing 35, 64, and 81% alumina; 4ST, ST, and S4T, silica-titanias containing 21, 55, and 83% titania; 4AT, AT, and A4T, alumina-titanias containing 28, 62, and 83% titania, respectively.

The crystal features as determined by X-ray diffractometry, and the surface areas as determined by studying the nitrogen adsorption of the metal oxides, are set out in Table 1.

TCNQ was synthesized from the condensation product of 1,4-cyclohexanedione and malononitrile.[7] This was purified by repeated recrystallization. The purity was checked by elemental analysis, by the measurement of the melting point, and by spectrophotometry.[6]

Apparatus and Procedure. The metal oxide was placed in a flask which was attached to a high-vacuum line and outgassed at 10^{-5} Torr for 1 hr at 100°C, and then cooled to 25°C *in vacuo* prior to the TCNQ adsorption. A solution of TCNQ in acetonitrile (10 mM) was then poured into the flask through a stop cock. Subsequently, the contents of the flask were transferred into an L-type test tube and then shaken for 2 hr at 25°C. After this shaking, the metal oxide was collected by centrifuging and dried at room temperature *in vacuo*. The dried sample was used for the measurement of the electronic spectrum and was evacuated at 10^{-5} Torr for the ESR measurement.

The ESR spectra were measured by means of a Japan Electrons Optics Laboratory JES-3BS-Xtype ESR spectrometer operating at a cavity resonance frequency of 9400 Hz with 100 kHz modulation. The *g*-value was obtained by comparison with the value for Mn^{2+}. The radical concentration (spin conc.) was estimated by comparing the peak-to-peak height on the first derivative curves with that of an internal-standard Mn^{2+} sample.

The electronic spectra of the samples were measured by means of a diffuse-reflectance spectrophotometer.

Results and Discussion

When TCNQ was adsorbed on the surfaces of the silica-alumina, silica-titania, and alumina-titania from its acetonitrile solution at room temperature, the surfaces of the metal oxides acquired the colorations characteristic of each oxide, as is shown in Table 1. The same colorations were observed when the metal oxides were ground with TCNQ crystal. The colorations of the metal oxide surfaces suggest that new adsorbed species are formed on the surfaces. This suggestion was confirmed by the evidence that the colored metal oxides showed ESR absorptions, indicating the presence of free radical species. The spectra are unresolved (Figs. 1—2; *g*-values, 2.011), which can be explained by the fact that the anisotropy of the hyperfine structure arises from the lack of motional degrees of freedom. The state of the adsorbed species was studied by means of the electronic spectra in addition to the ESR spectra. The electronic spectra of the colored samples are illustrated in Figs. 3—5. The bands appearing below 400 mμ are common to all the metal oxides and may be supposed to correspond to the physically-adsorbed state of neutral TCNQ, which has its absorption band at 395 mμ.[8] In the case of the silica-titania and alumina-titania systems, this assignment does not hold completely because the titania has its characteristic band in the same region. The absorption bands in the visible region observed in the cases of the silica-alumina, silica-titania, and

alumina-titania systems can be attributed to neither TCNQ nor the metal oxides. The bands near 600 mμ probably stem from the dimer TCNQ anion radical, which absorbs light at 643 mμ.[9] They are very broad and have not been assigned with certainty, but support is given by the characteristic features that neutral TCNQ absorbs only at 395 mμ, that TCNQ has a high electron affinity, and that the TCNQ anion radical derivatives are stable even at room temperature.[10-13]

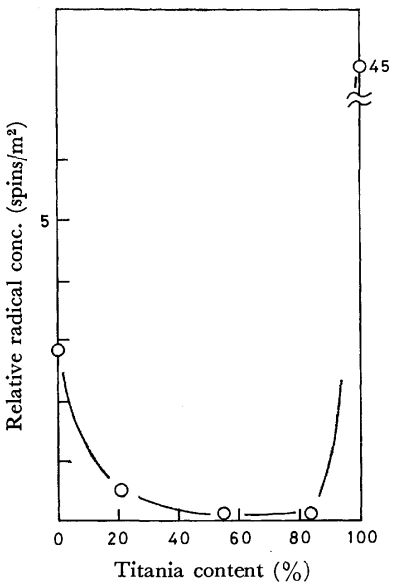

Fig. 7. The change in TCNQ anion radical forming activity of the silica–titania systems with composition.

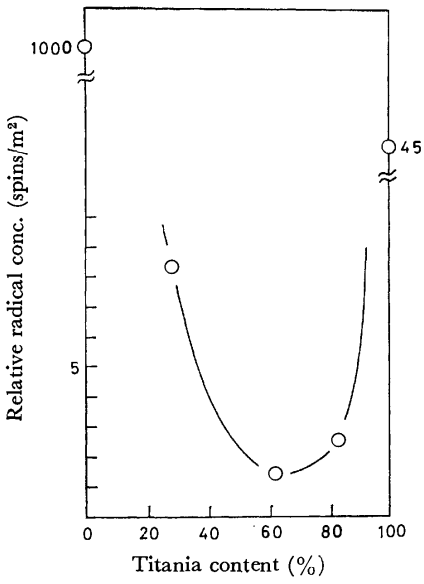

Fig. 8. The change in TCNQ anion radical forming activity of the alumina–titania systems with composition.

In view of the ESR and the electronic spectra, it is confirmed that radical ions are formed from TCNQ on the metal oxide surfaces as a result of electron transfer to TCNQ from the metal oxide surfaces.

The TCNQ anion-radical-forming activity of the metal oxide surfaces is shown in Table 1 and Figs. 6—8. The activity is reflected in the saturation of the color of TCNQ on the metal-oxide surfaces and the increase in absorbance at C-T band. The activity sequence and the color of the samples were found to be: S4A (greenish light grey)>SA (light brown)>4SA (brown tinged white); 4ST (pink)>S4T (brown tinged white)>ST (colorless); 4AT (orange)>A4T (deep pink)>AT (red brown).

The silica–alumina, silica–titania, and alumina–titania systems showed much less activity than the parent oxides-silica, alumina, and titania. The systems exhibit surface properties (surface area, heat of immersion, hydrophilicity, and surface acidity) which would not be qualitatively predicted from a consideration of the independent properties of the parent oxides.[14-16]

Flockhart *et al.*[5] have reported that typical silica–alumina cracking catalysts have negligible reducing (electron donating) power and that silica–aluminas of a higher alumina content possess an appreciable reducing activity, but this may be associated with the presence, in the conglomerate, of a pure alumina phase. It is well known that the -Si-O-Al- structure forms a strong acid site,[17-28] but the formation of an electron-donor site can not be expected. In the present work, all of the silica–alumina systems (4SA, SA, and S4A) showed appreciable radical-forming activity and the activity increased with an increase in the alumina content. However, the silica–alumina systems had much less activity than the alumina. The steep fall in the activity between the silica–alumina system and the alumina suggests that the pure alumina phase is present only a little on the silica–alumina surfaces. The activity increases gradually between 4SA and SA, and then increases steeply between SA and S4A. This suggests the existence of a small part of a pure alumina phase on the surface of S4A. The existence of the pure alumina phase is confirmed by the appearance of the weak band at about 650 mμ in S4A corresponding to the C-T band of TCNQ adsorbed on the alumina.

The surface hydroxyl ion may be one of the electron-donor sites.[5,6] Hall *et al.*[29] reported that the greater part of surface hydroxyls on silica–alumina catalyst consisted of SiOH. SiOH is much more stable than AlOH,[30] and shows little radical-forming activity.[6] The low activity of the silica–alumina systems agreed with Hall's results.

The change in the activity of the silica–alumina systems with the alumina content was approximately inverse to that of the surface acidity.[15]

The silica–titania systems had negligible radical-

Table 1. Summary of the TCNQ adsorption

Sample	Composition	Crystal features by X-ray diffraction	Surface area (m^2/g)	The color of the metal oxide surface after TCNQ adsorption	The relative radical concentration (radical conc./m^2)
silica		amorphous	600	yellow	2.8
alumina		weak γ-Al_2O_3 lines	263	blue green	1000
titania		weak anatase lines	64	violet	45
4SA	35% Al_2O_3	amorphous	263	brown tinged white	1.3
SA	64% Al_2O_3	amorphous	279	light brown	7.2
S4A	81% Al_2O_3	amorphous	367	greenish light grey	70
4ST	21% TiO_2	amorphous	348	pink	0.5
ST	55% TiO_2	amorphous	343	colorless	0.14
S4T	83% TiO_2	weak anatase lines	239	brown tinged white	0.2
4AT	28% TiO_2	amorphous	331	orange	8.3
AT	62% TiO_2	amorphous	377	red brown	1.4
A4T	83% TiO_2	weak anatase lines	195	deep pink	2.5

forming activity, and the C-T band scarcely appeared at all. This result suggests that the pure titania phase is present only a little on the silica-titania surfaces. It is noteworthy that a weak anatase line in the X-ray diffraction pattern of the S4T suggests the presence, in the conglomerate, of a pure titania phase, but the S4T had negligible radical-forming activity.

The alumina-titania systems showed much less radical-forming activity than the parent oxides-alumina and titania. The TCNQ adsorbed on the alumina-titania systems showed the C-T band at about 500 mμ corresponding to the TCNQ adsorbed on the titania. This observation suggests the presence of a pure titania phase and the absence of a pure alumina phase on the alumina-titania system surfaces. The radical-forming activity decreases steeply between the alumina and 4AT, decreases gradually between 4AT and AT, increases between AT and A4T, and increases markedly between A4T and the titania. The AT has showed the most characteristic surface properties among the alumina-titania systems.[14]

The TCNQ anion radical-forming activity has been proposed as a convenient method for estimating the electron-donor property of metal oxide surfaces.[6] In the present paper, the electron-donor property of silica-alumina, silica-titania, and alumina-titania systems has been revealed and information regarding the surface structure of the mixed-oxide systems has been obtained by means of studying the radical-forming activity and the wavelength of the C-T band.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3375—3379 (1972)

Electrical and Optical Properties of the Iodine Complexes of Phenoxazine, Phenoselenazine, and Benzophenothiazines[1]

Yoshio MATSUNAGA and Yukio SUZUKI*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received April 26, 1972)

The electrical resistivities and Seebeck coefficients of the 2: 3 iodine complexes of phenoxazine, phenoselenazine, and benzophenothiazines were measured as a function of the temperature. They have resistivity values at 20°C ranging from 10 ohm·cm for the phenoxazine complex to 34 ohm·cm for the benzo[*a*]phenothiazine complex. Employing the equation of Johnson and Lark-Horowitz for the Seebeck coefficient of an intrinsic semiconductor, the ratio of the electron-to-hole mobility in the phenoselenazine complex was found to be 1.07 and the electron mobility was estimated as 0.26 cm^2/V sec. By an examination of the vibrational spectra, the expected cation-radical character was confirmed for the complexes of phenoselenazine and benzophenothiazines. The presence of a broad electronic absorption band in the rock-salt region characteristic of low-resistivity organic semiconductors was noted in every case.

The phenothiazine-iodine complex, the formation of which was reported by Pummerer and Gassner as early as 1913,[2] was found to exhibit a relatively low electrical resistivity about a decade ago.[3] Further studies of the electrical resistivity of this complex have

* Present address: Tokyo Shibaura Electric Co., Kawasaki.

1) Presented at the 24th Annual Meeting of the Chemical Society of Japan, Suita, April 1971.

3) Y. Matsunaga, *Helv. Phys. Acta*, **36**, 800 (1963).

been published by several workers.[4-7] More recently, measurements have been made of the Seebeck coefficient as a function of the temperature by Sano *et al.*[7] In addition, the electrical properties of the iodine complexes of the *N*-methyl and *N*-ethyl derivatives have been compared with those of the above-mentioned complex.[3,7,8] The electronic absorption spectrum in the visible region has been examined by Bhat and Rao, and the diffuse reflection spectrum in both the visible and near-infrared regions, by Matsunaga and Shono.[5,6] The presence of an electronic absorption maximum at 5.5 kK was shown by the latter workers. In the initial report on the resistivity, it was demonstrated that the vibrational spectrum of the phenothiazine-iodine complex is quite different from that of the parent organic compound, but practically the same as that of semiquinoid phenothiazine bromide.[3] On the basis of this observation, which was subsequently confirmed by a more detailed work,[6] it was postulated that every phenothiazine molecule in the solid complex bears an approximately unit-positive charge.

Thus, considerable interest has been shown in the phenothiazine-iodine complex; however, little work has been carried out on the complexes of structurally related compounds. One of the present authors has previously measured the electrical resistivities of the complexes of benzo[*a*]- and benzo[*c*]-phenothiazines.[3] Contrary to the introduction of the *N*-alkyl group, the extra ring does not appreciably affect the resistivity. No attention has been paid to their optical properties. On the other hand, nothing is known about the iodine complexes of phenoxazine and phenoselenazine. Pursuing an inquiry into the effect of the organic component on the electrical and optical properties of the iodine complexes, these four compounds have been taken up in comparison with phenothiazine.

Experimental

Materials. The phenoxazine was prepared by the condensation of *o*-aminophenol in the presence of iodine.[9] The crude product extracted with toluene was recrystallized from ethanol. The reaction between diphenylamine and selenium monochloride was carried out in chloroform, as has been described by Müller *et al.*, instead of the benzene originally used by Cornelius.[10] This compound was recrystallized from ligroin. The selenium monochloride needed for the synthesis of phenoselenazine was made by the addition of concentrated sulfuric acid to a mixture of selenium, selenium dioxide, and concentrated hydrochloric acid, following the procedure of Lenher and Kao.[11] The benzo[*a*]- and benzo[*c*]-phenothiazines were obtained by the reaction of sulfur on α- and β-phenylnaphthylamines respectively, using a small amount of iodine as the catalyst.[12] Both of them were purified by recrystallization from ligroin. The preparation of the semiquinoid bromides was carried out by the oxidation of the organic compounds with bromine, as has been reported for phenothiazine bromide by Kehrmann and Diserens.[13] The iodine complexes were precipitated when the organic component and iodine, separately dissolved in benzene, were mixed.

Measurements. The electrical resistivities and Seebeck coefficients were recorded as a function of the temperature by the methods described in the paper by Kan and Matsunaga.[8] Measurements of the vibrational and electronic spectra were made as have been reported elsewhere.[6]

Results and Discussion

The iodine contents presented in Table 1 indicate that all the complexes consist of two molecules of the organic component and three of iodine. They are all black polycrystalline powder except for the phenoxazine complex, which is in the form of needles with metallic luster.

Table 1. Composition of the iodine complexes

Organic component	Iodine content (%)	
	Calcd for 2:3	Found
Phenoxazine	67.6	67.7
Phenothiazine	65.7	65.6
Phenoselenazine	60.7	60.9
Benzo[*a*]phenothiazine	60.5	61.4
Benzo[*c*]phenothiazine	60.5	61.3

Electrical Properties. The resistivity of the complexes under study shows a temperature dependence which follows the typical semiconductor behavior:

$$\rho = \rho_0 \exp(E/kT) \quad (1)$$

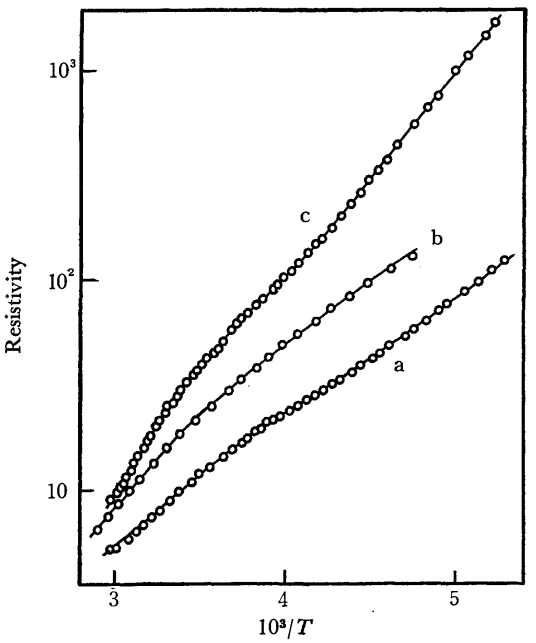

Fig. 1. Electrical resistivities of the iodine complexes of a) phenoxazine, b) phenothiazine, and c) phenoselenazine.

Table 2. Electrical properties of the iodine complexes in the higher temperature region

Organic component	ρ at 20°C (ohm cm)	E (eV)	μ_e/μ_h	m_e/m_h	Ref.
Phenoxazine	10	0.14	2.11	1/40	This work
Phenothiazine	20	0.17	—	—	3
Phenothiazine	13	0.19	—	—	6
Phenothiazine	17	0.164	*ca.* 0.7	—	7
Phenothiazine	19	0.19	<1	—	This work
Phenoselenazine	32	0.28	1.07	1/2	This work
Benzo[*a*]phenothiazine	20	0.19	—	—	3
Benzo[*a*]phenothiazine	34	0.16	>1	—	This work
Benzo[*c*]phenothiazine	20	0.20	—	—	3
Benzo[*c*]phenothiazine	18	0.14	>1	—	This work

For example, the logarithm of the resistivity of the complexes of phenoxazine, phenothiazine, and phenoselenazine is plotted against the reciprocal temperature in Fig. 1. The presence of a break near or a little below room temperature is noted in these three cases. The values of the resistivity (ρ) at 20°C and the activation energy (E) in the higher temperature region are summarized in Table 2, where literature values are also included for the sake of comparison. Except for the case of the benzo[*a*]phenothiazine complex, the present results are in fair agreement with the available data. Both the resistivity and activation energy increase in this order of organic components: phenoxazine<phenothiazine<phenoselenazine.

The plot for the benzophenothiazine complexes does not show a break in the temperature range measured. We confirmed the earlier observation that the presence of an extra benzene nucleus —in other words, a more widespread electron delocalization in the organic component— modifies only a little the electrical properties of the iodine complex. This conclusion is in marked contrast with the appreciable effect of the size of an alkyl group on the nitrogen atom of phenothiazine on the electrical resistivity of the iodine complex.[8]

Single crystals of the low-resistivity tetracyanoquinodimethane (TCNQ) anion-radical salts have been known to be highly anisotropic.[14–16] The resistivity value observed along the long-needle axis of crystal of the simple *N*-methylphenazinium salt, 0.007 ohm·cm, is the lowest ever recorded for any organic compound. This value is much lower than the resistivity determined on the polycrystalline compaction of the same salt, 0.5 ohm·cm.[16] Similar results have been reported for the complex *N*-methylquinolinium salt, 0.01 ohm·cm in the long axis direction and 0.5 ohm·cm with a compacted sample. In addition, the activation energy measured with the single crystal is known also to be lower than that obtained with a compaction: <0.01 eV *vs.* 0.07 eV.[15] As was mentioned above, the phenoxazine-iodine complex is obtainable in the form of needles. Therefore, it seemed worthwhile to attempt measurements of the resistivity along the long needle axis of this iodine complex as a function of the temperature. Surprisingly, the resistivity at 20°C was found to be 8 ohm·cm, which must be considered in good agreement with the value observed with a compaction if one takes into consideration the errors involved in the geometrical measurements of small crystals. Moreover, the activation energy estimated by the measurements in the range from −65 to 20°C is 0.14 eV. Here again, the agreement with the value given in Table 2 is excellent.

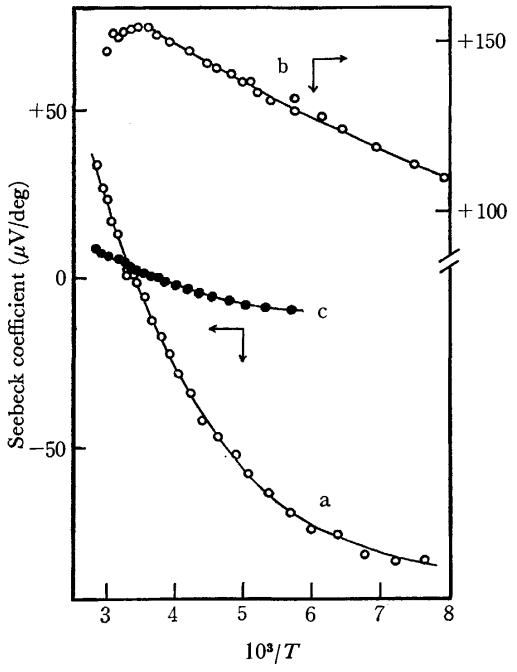

Fig. 2. Seebeck coefficients of the iodine complexes of a) phenoxazine, b) phenothiazine, and c) phenoselenazine.

The temperature dependence of the Seebeck coefficient (Q) is shown in Fig. 2 for the iodine complexes of phenoxazine, phenothiazine, and phenoselenazine. At 20°C, the values are as follows: +5 μV/deg for the oxazine complex, +153 μV/deg for the thiazine complex, and +4 μV/deg for the selenazine complex. Our value for the second complex agrees well with that reported by Sano *et al.*[7] Although a tendency for the better conducting materials to have smaller Seebeck

14) L. R. Melby, R. J. Harder, W. R. Hertler, W. Mahler, R. E. Benson, and W. E. Mochel, *J. Amer. Chem. Soc.*, **84**, 3374 (1962).
15) W. J. Siemons, P. E. Bierstedt, and R. G. Kepler, *J. Chem. Phys.*, **39**, 3523 (1963).
16) L. R. Melby, *Can. J. Chem.*, **43**, 1448 (1965).

coefficients, and *vice versa*, has often been noted,[17] the present complexes do not follow it. The higher-temperature region of the curve is nearly straight in the cases of the first and third complexes. To this region, one may apply the expression for the thermoelectric motive force of an intrinsic semiconductor:[18,19]

$$Q = -\frac{k}{e}\left[\frac{b-1}{b+1}\left(\frac{E_G}{2kT}+2\right)+\frac{3}{4}\ln\frac{m_e}{m_h}\right] \quad (2)$$

where b is the ratio of the electron-to-hole mobility, μ_e/μ_h, E_G is the width of the forbidden band, and m_e and m_h are the effective masses of the electron and the hole respectively. On the assumption that E_G is twice the activation energy given in Table 2, b is evaluated as 2.11 for the oxazine complex and as 1.07 for the selenazine complex. With the values of temperature where the sign of the coefficient changes, the ratio of the effective masses was estimated to be as is shown in the table. The Seebeck coefficients of the benzo[*a*]- and benzo[*c*]-phenothiazine complexes are −47 and −57 μV/deg respectively at 20°C. The curves are nearly parallel to that for the selenazine complex; however, the linear parts are too short to fit Eq. (2).

The conductivity (σ) is given by:

$$\sigma = \frac{1}{\rho} = e\mu_e\left(\frac{b+1}{b}\right)N\exp(-E/kT) \quad (3)$$

On the basis of the density determined from the compactions, N is estimated to be 2.54×10^{22} phenoxazine molecules or 2.50×10^{22} phenoselenazine molecules per cm^3 of the complex. Employing the resistivity and activation energy listed in Table 2, the electron mobility in the selenazine complex is calculated to be 0.26 cm^2/V sec. This value is close to that estimated for the electron in the *N*-methylphenothiazine-iodine complex by the same method,[8] and is of the same order as the only known Hall mobility observed with iodine complexes.[20] On the other hand, the electron mobility estimated for the oxazine complex, 0.004 cm^2/V sec, rules out the application of a band model to this iodine complex. The present organic components are structurally related, and the electrical resistivities of the iodine complexes are of the same order as each other. Nevertheless, the results indicate that the conduction mechanism in the complexes is very sensitive to a minor modification of the component molecule.

An alternative explanation for the behavior shown in Fig. 2 may be proposed on the basis of a hopping model. The Seebeck coefficient for hopping electrons is given by:

$$Q = -\frac{k}{e}\left[(1-2\beta)\frac{E}{kT}+\ln\frac{c_0-c}{c}\right] \quad (4)$$

where c is the charge carrier concentration and where c_0 is the total concentration of accessible sites.[21,22] It may be supposed that the site initially containing the electron requires a fraction, β, of the activation energy. By comparison with the terms in Eq. (2), β is estimated as 0.41 for the oxazine complex and as 0.49 for the selenazine complex; that is, the motional energy is divided into a ratio of about 2:3 between the two sites in the former complex and nearly equally between the two in the latter. The c/c_0 ratios are approximately 0.9 and 0.6 respectively; however, their meaning in the present complexes is still unknown.

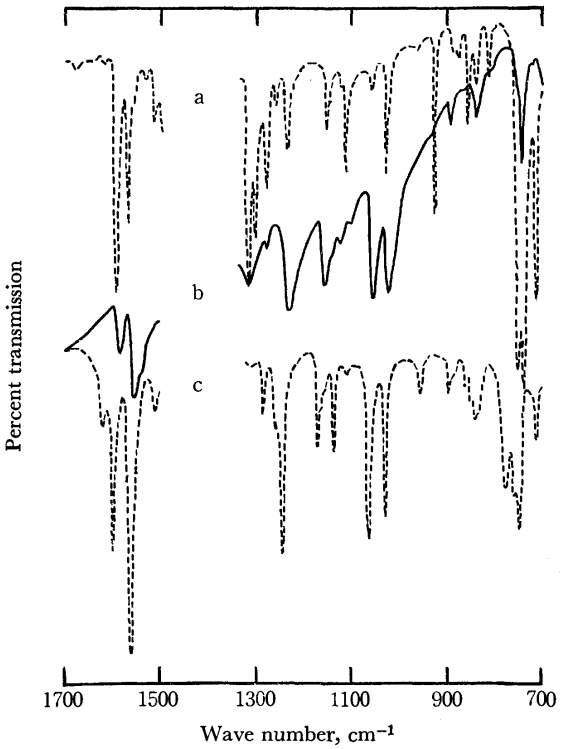

Fig. 3. Vibrational spectra of a) phenoselenazine, b) the iodine complex, and c) the semiquinoid bromide.

Optical Properties. As the phenoxazine complex is difficult to be pulverized, only a spectrum with a very poor resolution could be recorded. Therefore, the vibrational spectra of the other three iodine complexes will be considered in this paper. In Fig. 3 the spectrum of the phenoselenazine-iodine complex in the region from 700 to 1700 cm^{-1} is compared with those of the parent compound and the semiquinoid bromide. Of course, iodine is not active in this spectral region. Each spectrum bears a resemblance to that of the corresponding phenothiazine compound reported earlier.[6] The relative intensity and location of the two bands in the iodine complex appearing in the region from 1550 to 1600 cm^{-1} resemble those of the two in the bromide, but not those in the selenazine itself. Furthermore, the strong bands located at 1025, 1055, and 1235 cm^{-1} can be well compared with the three in the bromide located at 1030, 1060, and 1345 cm^{-1}. Thus, the main feature in the above-mentioned region seems to agree with that of the cation-radical. However, the following differences must be noted. The band to be compared with the one at 1330 cm^{-1} in the iodine complex can be found only in the parent

compound. Neither the selenazine nor the bromide shows the band corresponding to that 1160 cm^{-1} in the iodine complex. It must be added that a strong band appearing at 925 cm^{-1} in the selenazine is not observed in the spectrum of the complex. On the basis of these observations, it is very likely that the positive charge on the selenazine molecule in the complex is fairly large, if not a unit.

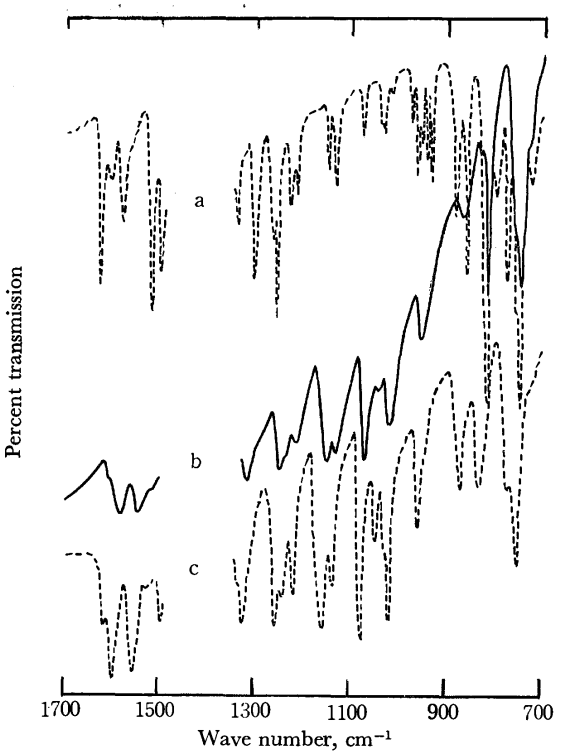

Fig. 4. Vibrational spectra of a) benzo[*c*]phenothiazine, b) the iodine complex, and c) the semiquinoid bromide.

The vibrational spectra of benzo[*c*]phenothiazine, the iodine complex, and the semiquinoid bromide are presented in Fig. 4. The pattern shown by the complex is in essential agreement with that of the bromide, confirming the expected ion-radical character of the iodine complex. The similarity of the iodine complex and the bromide of benzo[*a*]phenothiazine is also found in the vibrational pattern.

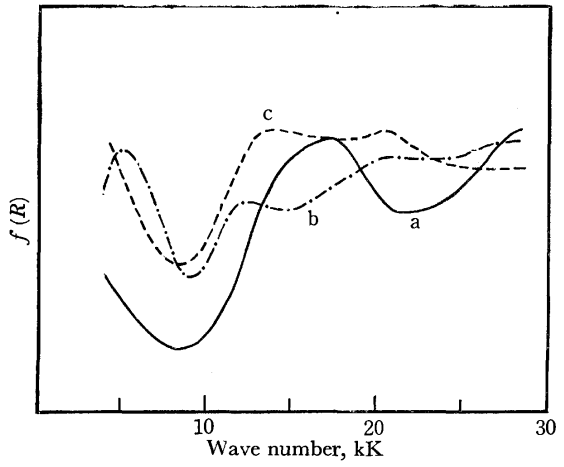

Fig. 5. Diffuse reflection spectra of the iodine complexes of a) phenoxazine, b) phenothiazine, and c) phenoselenazine.

In Fig. 5 the electronic spectra, as measured by the diffuse reflectance method, are shown for the iodine complexes of phenoxazine, phenothiazine, and phenoselenazine. The maximum of the low-energy band in the thiazine complex is found at 5.2 kK, while it was found at 5.5 kK in our previous work.[6] On the other hand, those of the other two complexes are expected to be below 4 kK, the limit of the spectrophotometer employed. This is the reason why a strong back-ground absorption is seen in the vibrational spectrum of the selenazine complex presented in Fig. 3. The appearance of a low-energy absorption band attributable to an electronic transition is common to low-resistivity organic semiconductors, *e.g.*, the TCNQ anion-radical salts and some ionic molecular complexes.[14,17,23–25] However, the location of its maximum is not necessarily correlated with the resistivity, as has been pointed out in our paper on the TCDQ and TBDQ anion-radical salts.[26] In the present complexes, it may be noted that the location of the maximum cannot be correlated with the magnitude of the activation energy (see Table 2).

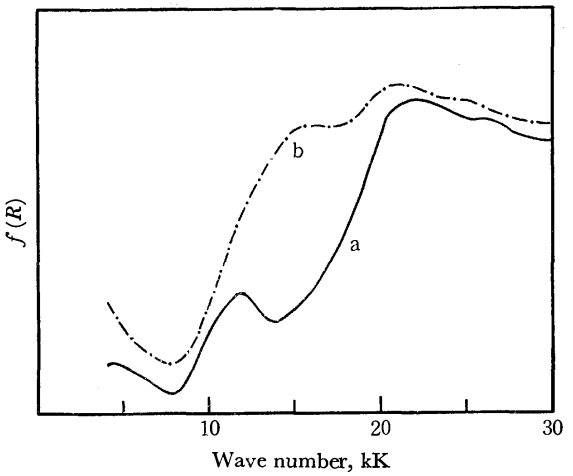

Fig. 6. Diffuse reflection spectra of the iodine complexes of a) benzo[*a*]phenothiazine and b) benzo[*c*]phenothiazine.

The reflection spectra of the benzophenothiazine complexes are given in Fig. 6. In contrast with the complexes in Fig. 5, the low-energy bands are appreciably weaker than those in the visible region. Nevertheless, these two complexes are as conductive as the other three. The maximum is located at 4.4 kK in the case of the benzo[*a*]phenothiazine complex, but below 4 kK in the other. This difference can be noted in the vibrational spectra, too. The recording of the spectrum of the former complex is much easier than that of the latter because of the absence of a strong back-ground absorption, which tends to produce distortions and a lack of resolution in the vibrational spectrum.

Electron Spin Resonance Study of Amino Acid Radicals Produced by Fenton's Reagent[1]

Hitoshi TANIGUCHI,* Hideyo HASUMI, and Hiroyuki HATANO
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received April 26, 1972)

Free-radical intermediates in the reaction of the hydroxyl radical with amino acids and structurally related compounds such as alcohols, amine, and carboxylic acids have been studied by ESR spectroscopy using a continuous-flow method. The hydroxyl radical is generated by a ferrous ion-hydrogen peroxide system (Fenton's reagent). ESR spectra with fairly good signal-to-noise ratios are obtained for the first time in a Fenton's reagent system from glycine, valine, leucine, glutamic acid, lysine, methionine, tyrosine, ethylamine, acetic acid, propionic acid, *n*-butyric acid, and succinic acid. Structures, *g*-values, and hyperfine coupling constants of these radicals are tabulated. The analysis of ESR spectra shows that the same radical species are produced mainly in a Fenton's reagent system as in a titanous chloride-hydrogen peroxide system. This is consistent with the existence of the hydroxyl radical in both systems. The observed ratio of C_2–H to C_1–H proton hyperfine coupling constants[2] gives information concerning steric conformations, freedom in the internal rotations, and *s*-character of the intermediate radicals.

The hydroxyl radical, generated by a ferrous (Fe^{2+}) ion-hydrogen peroxide (H_2O_2) system (Fenton's reagent),[3] has been found to oxidize a variety of organic substrates.[4,5] A kinetic examination and product analysis have elucidated the various mechanisms of these oxidations of aliphatic[4] and aromatic[5] compounds. Unstable organic radicals produced by Fenton's reagent have been detected successfully by electron spin resonance (ESR) spectroscopy using a continuous-flow method. Much is already known about the unstable radicals from alcohols,[6] aliphatic ethers,[7] alicyclic compounds,[7] and furans.[8] However, little is known about the free radicals obtained by Fenton's reagent from biomolecules other than the amino acids such as α-alanine,[2] β-alanine,[2] serine, aspartic acid, cystine, and cysteine.[9,10]

In the course of investigations on the oxidation of biomolecules, intermediate radicals in the reaction of the hydroxyl radical generated by a titanous (Ti^{3+}) chloride–hydrogen peroxide system with amino acids,[10] amino acid derivatives,[11] nitrogen heterocyclic compounds,[12] and dialkylsulfoxides[13] were reported in previous papers. Our experimental study of the oxidation involving the hydroxyl radical has now been extended in the present work to include also the oxidation by Fenton's reagent.

Since the hydroxyl radical is one of the main products of water radiolysis,[14] a chemical reaction system generating the hydroxyl radical could be used to simulate the effects of ionizing radiation on aqueous organic solutions. Recently, Neta and Fessenden[15] reported an ESR spectrum of $NH_2\dot{C}HCOOH$ radical from aqueous acidic solution of glycine irradiated directly in the ESR cavity with high-energy electrons, and the structure of glycine radical is identical with that obtained in this work. Therefore, a Fenton's reagent system might be a good model system of the radiolysis of aqueous solutions of biomolecules.

Experimental

The experimental arrangements and procedures for the observation of intermediate radicals produced in a Fenton's reagent system were essentially the same as described previously in a Ti^{3+}–H_2O_2 system.[10-13] The ESR spectra of intermediate radicals were recorded on an X-band spectrometer (JEOL, Model JES-ME-3X) at room temperature within 7 to 13 msec after mixing two reactants. The hyperfine (hf) coupling constants and *g*-values were calibrated by comparison with a sample of potassium peroxylamine disulfonate in aqueous sodium carbonate solution (nitrogen hf splitting, 13.0 ± 0.1 G; $g=2.00550\pm0.00005$).[16] Probable errors in hf coupling constants and *g*-values are 0.1 G and 0.0001, respectively.

All materials were obtained commercially and used without further purification. The concentrations of ferrous sulfate ($FeSO_4\cdot7H_2O$) and hydrogen peroxide were 0.005M and 0.1M, respectively. Organic substrates were added to both reactants usually in 0.1 to 1.0M concentration according to their reactivity and solubility. Reactant solutions of cystine and

aspartic acid with comparatively low solubility at room temperature were prepared and flowed through the cavity of ESR spectrometer at 40 to 50°C. Both reactant solutions were acidified to about pH 2 with dilute sulfuric acid and deoxygenated by bubbling nitrogen gas in order to prevent the oxidation of ferrous ion. In the experiment conducted within a pH region of approximate neutrality, the pH of each reactant solution being adjusted with sodium hydroxide, ethylenediaminetetraacetic acid was added to the reactant solution of ferrous sulfate so as to avoid the precipitation of ferric salt.

Results and Discussion

Identification of the Intermediate Radicals. ESR spectra with sufficient signal-to-noise ratios were obtained from glycine, α-alanine, valine, leucine, aspartic acid, glutamic acid, lysine, cystine, methionine, tyrosine, methyl alcohol, ethyl alcohol, isopropyl alcohol, ethylamine, acetic acid, propionic acid, *n*-butyric acid, and succinic acid. The structures of amino acid radicals deduced from the analysis of the spectra, and the

estimated g-values and hf coupling constants are summarized in Table 1; g-values and hf coupling data of β-alanine, serine, and cysteine radicals obtained by Armstrong and Humphreys[9] are also shown in parentheses. For comparison, structures, g-values, and hf coupling constants of radicals from organic substrates structurally related to amino acids are tabulated in Table 2. The concentration ratio is also given for the substrates where two or three kinds of radicals were observed, although the ratio might depend upon the kinetic conditions. Radicals from twelve substrates listed in the synopsis section were not previously studied by ESR spectroscopy in a Fenton's reagent system. ESR spectra of the intermediate radicals from glutamic acid and tyrosine are reproduced in Figs. 1 and 2. L-Phenylalanine gave an ESR signal with poor signal-to-noise ratio.

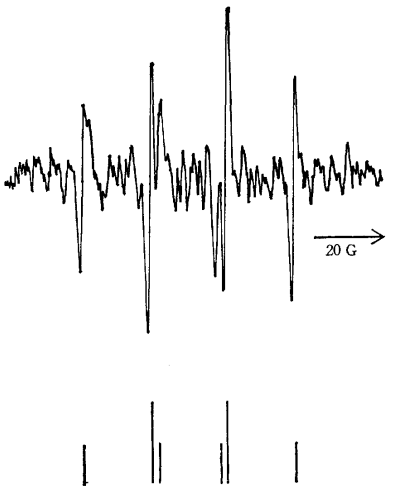

Fig. 1. Electron spin resonance spectrum of the intermediate radical from 0.15M L-glutamic acid with reconstruction. Microwave power, 20 mW; pH, 2.2.

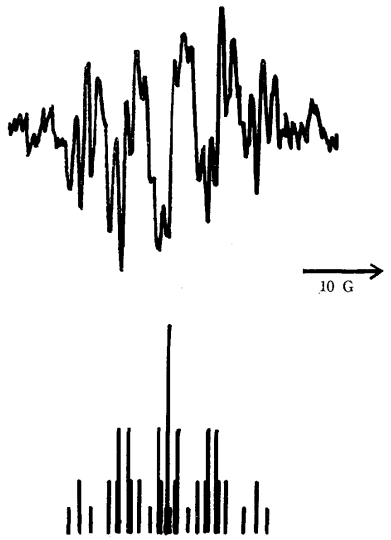

Fig. 2. Electron spin resonance spectrum of the intermediate radical from 0.015M L-tyrosine with reconstruction. Microwave power, 20 mW; pH, 1.7.

Almost all substrates, except aspartic acid, glutamic acid, lysine, and tyrosine which had not been examined in an acidic Ti^{3+}–H_2O_2 system, were found to give the same radical species as those formed in a Ti^{3+}–H_2O_2 system.[9,10,13,17,18] This supports the view that the hydroxyl radical is the active species formed in both Fe^{2+}–H_2O_2 and Ti^{3+}–H_2O_2 systems. However, there were some differences in ESR spectra between the two systems; minor component of α-alanine radicals, $NH_2\dot{C}(CH_3)COOH$,[19] α-hydroxy[2] radical of isopropyl alcohol,[17] methyl radical from acetic acid,[20] and $\dot{C}H_2$-CH_2COOH radical from propionic acid[10] which were observed in a Ti^{3+}–H_2O_2 system, were not recorded in a Fenton's reagent system, while β-hydroxy[2] radical of ethyl alcohol with poor signal-to-noise ratio in a Ti^{3+}–H_2O_2 system and an unidentified component of propionic acid radicals consisting apparently of quartet (splitting, 20.0 G) of triplet (22.7 G) were observed in this Fenton's reagent system.

From ethyl alcohol, Shiga[6] detected only the β-hydroxy radical in a Fenton's reagent system. In contrast, he detected only the α-hydroxy radical from ethyl alcohol oxidized with a Ti^{3+}–H_2O_2 system. He claimed that the active species in Fenton's reagent had different character from that in a Ti^{3+}–H_2O_2 system. We also reexamined intermediate radicals in the reaction of Fenton's reagent with ethyl alcohol, and an ESR spectrum due to two kinds of radicals was observed, in which the hydroxyl radical abstracted a hydrogen atom from different C–H bonds; *i.e.*, from C_α–H and C_β–H bonds.[2] The apparent concentration ratio of α- to β-hydroxy radicals was 1 : 1.3. Consequently, there is no essential difference in reactivities between the Fenton's reagent and a Ti^{3+}–H_2O_2 system, and it is supposed that the active species is the hydroxyl radical in both systems. The relative concentrations of the various organic radicals would depend on the one-electron oxidation of the resulting radicals by both metal ions and hydrogen peroxide as Norman and West[21] stated and recently Czapski *et al.*[22] confirmed; *i.e.*, ferric (Fe^{3+}) ion is a much stronger oxidizing agent than titanic (Ti^{4+}) ion for organic radicals, and the α-hydroxy radical is supposed to be oxidized more readily than the β-hydroxy radical with Fe^{3+} ion. This is applicable to the case of isopropyl alcohol in which an α-hydroxy radical was not observed in a Fenton's reagent system. Walling and Kato[4] developed a new kinetic analysis for the oxidation of ethyl alcohol with Fenton's reagent. They showed also that the hydroxyl radical attacked both α- and β-hydrogens of ethyl alcohol, and the β-hydroxy radical was not oxidized by Fe^{3+} ion but dimerized, while the α-hydroxy radical was oxidized.

The g-values of radicals with C_1–OH and C_1–COOH groups such as methyl alcohol, ethyl alcohol, acetic acid, glutamic acid, propionic acid, n-butyric acid, and

glycine, and those of radicals from tyrosine, cystine, and cysteine are higher than the g-values of other radicals and in the range of 2.0032—2.0108. This shows that those radicals are π electron radicals in which an unpaired electron is delocalized on oxygen or sulfur atom which has a fairly large spin-orbit coupling constant and lone pairs of electrons.

ESR spectra with good signal-to-noise ratios were obtained from 0.01M cystine and 0.015M tyrosine, whose concentrations were much lower than in the case of the other organic substrates. It is suggested that the reaction mechanism and reactivity of the hydroxyl radical with cystine and tyrosine are different from those with other amino acids. As for tyrosine, the ESR spectrum of the corresponding phenoxy radical was the only one observed as shown in Fig. 2. It was not observed in the absence of ferrous ion. Therefore, tyrosine radical is postulated to be formed in the reaction with the hydroxyl radical and/or ferric ion, either abstracting a hydrogen atom from the hydroxyl group or removing an electron from tyrosine itself. The coupling constants of ring protons in the tyrosine radical are in good agreement with those of p-cresol radical obtained by the oxidation with Ce^{4+} ion.[23] Cystine radical might be formed by the addition of the hydroxyl radical to sulfur atom and consequent cleavage of sulfur-sulfur bond. This is a similar mechanism to the case of methionine radicals. From methionine, ethyl type radical and methyl radical were observed resulting from the cleavage of carbon-sulfur bond, as is the case in a Ti^{3+}–H_2O_2 system.[13]

In the case of lysine, ESR spectrum was obtained at pH 4, which was similar to that observed at pH 2. Since two protonated amino groups deactivate adjacent C-H bonds towards the electrophilic hydroxyl radical,[10] the hydrogen abstraction with the hydroxyl radical is thought to occur mainly at the C_γ–H bond in the side chain.

Hyperfine Coupling Constants. It is well established that the C_1–H coupling constant, a_{C_1-H}, of a π electron radical with a planar configuration of bonding orbitals around the C_1 carbon atom is proportional to the unpaired spin density on the C_1 atom, ρ_{C_1}.[24] The

$$a_{C_1-H} = Q_{C_1-H}\rho_{C_1} \quad (1)$$

C_2–H coupling arises from the hyperconjugative interaction between the unpaired $2p_z$ orbital and the C_2–$H_{3-n}R_n$ group, and the semi-empirical relationship (2) has been used to correlate the C_2–H coupling constant, a_{C_2-H}, with the conformation of free radicals.[25]

$$a_{C_1-H} = \rho_{C_1}(B_0 + B_2\cos^2\theta) \quad (2)$$

The angle θ is the dihedral one between the p-orbital containing the unpaired electron and the C_1–C_2–H plane. In most cases,[26] B_0 is assumed to be negligible relative to B_2.

$$a_{C_1-H} = \rho_{C_1}B_2\cos^2\theta \quad (2)'$$

From the above Eqs. (1) and (2)′, the ratio of C_2–H to C_1–H coupling constants is expressed as Eq. (3).

$$a_{C_2-H}/a_{C_1-H} = B_2\cos^2\theta/Q_{C_1-H} \quad (3)$$

The value of $|B_2/Q_{C_1-H}|$ for an aliphatic π electron radical is estimated experimentally to be 1.20 based on the proton hf coupling constants of the ethyl radical[26] in which the methyl group rotates freely around the C_1–C_2 bond so that $\cos^2\theta = 1/2$. Therefore, the radical with the ratio of a_{C_2-H} to a_{C_1-H} deviating much from 1.20 is supposed to take a restricted conformation in which the internal rotation of the C_2–H bond around the C_1–C_2 axis is hindered much, or is assumed to have some s-character in the orbital of an unpaired electron on C_1 atom.

The ratios of a_{C_2-H} to a_{C_1-H} obtained in the present investigation are shown in column 6 of Tables 1 and 2. Looking at the structures of radicals with ratios more than 1.32 or less than 1.08, we notice that in a group consisting of radicals from aspartic acid (ratio, 0.69), glutamic acid (0.91), n-butyric acid (1.00), isopropyl alcohol (1.00), leucine (1.00), and valine (1.38), the bulky methyl groups, a protonated amino group, and a carboxyl group will severely restrict the internal rotation of C_2–H bond around the C_1–C_2 axis. In the α-hydroxy radical of ethyl alcohol (ratio, 1.48), a large value of the ratio may be ascribed to a somewhat nonplanar configuration around C_1 and the consequent s-character giving small C_1–H coupling constant.[27] For the serine radical (ratio, 0.51), a small value of the ratio might be due to the hindered internal rotation probably because of the formation of an intramolecular hydrogen bond between the hydroxy group and NH_3^+ and/or COOH.

Thus, the ratio of a_{C_2-H} to a_{C_1-H} is expected to become an additional measure concerning steric conformations, freedom in the internal rotations, and planarities of organic radicals.

(Received May 11, 1972)

The resonance Raman spectra were observed from dilute aqueous solutions of the poly (vinyl alcohol)-iodine complex, using the He–Ne 632.8 nm and Ar^+ ion 488.0 nm lines for excitation. Two kinds of poly (vinyl alcohol) were used; one (A) had the degree of polymerization of 500, and the other, (B) 2000. For both samples, the resonance Raman spectra taken with the 632.8 nm line are similar to that of the starch-iodine complex, the intensity of the Raman band at 155 cm^{-1} being strongly enhanced. This band is assigned to the antisymmetric stretching vibration of the I_3^- ion aligned in the helical poly(viny alcohol) molecule. On the other hand, the intensity of the Raman band at 106 cm^{-1} is enhanced for Sample A when the 488.0 nm line is used for excitation. This band is assigned to the symmetric stretching vibration of the I_3^- ion. Its overtones were observed until the sixth. It is clear that the enhancement of the intensities of the 155 and 106 cm^{-1} bands is closely connected with the absorption bands at 670 and 490 nm respectively.

Much work was done on the resonance Raman effect in the pre-laser period.[1] With the recent development of laser-Raman spectroscopy, renewed interest in the resonance Raman effect has been growing both experimentally and theoretically. It seemed that it would be attractive to apply this effect to the study of the molecular structure of trace amounts of colored substances in solution. As the concentration of a colored substance detectable by the resonance Raman effect is very low (*ca.* 10^{-4} mol/*l*) compared with the ordinary Raman effect or the infrared absorption, this method will find various applications not only in physical chemistry, but also in analytical and biological chemistry.

One of the present authors (MT) has studied the resonance Raman spectra observed from dilute aqueous solutions of the starch-iodine complex.[2] The observed Raman bands have been assigned to the vibrations of the I_3^- ions aligned linearly in the cylindrical cavity inside the helical starch molecule. Since poly(vinyl alcohol) (PVA) is known to form a blue complex with iodine, just as starch does, we have taken up this complex in order to check whether or not it is structurally similar to the starch-iodine complex. The results show that the PVA-iodine complex gives a spectrum similar to that of the starch-iodine complex. Under certain conditions, however, a completely different spectrum is observed for the PVA-iodine complex. The details will be reported in the present paper.

Experimental

Sample. Two kinds of PVA samples were used. One (Sample A) had the average degree of polymerization of 500, and the other (Sample B), 2000. Both samples were purchased from the Wako Chemical Co. and were used without further treatment. The tacticities of these polymers are not precisely known. The other reagents were also obtained commercially. The iodine was purified by sublimation.

Each sample solution of the PVA-iodine complex was prepared as follows: 1 cc of a mixed solution of iodine (0.0029 mol/*l*) and potassium iodide (0.12 mol/*l*) was added to 5 cc of a 0.2 wt% aqueous solution of PVA and then the mixture was diluted to 25 cc with boric acid solutions of various concentrations (0.05—0.30 mol/*l*).[3]

In Table 1, the numbering of the sample solutions is given. The concentration of iodine in each sample was 1.1520×10^{-4} mol/*l* as I_2.

TABLE 1. THE NUMBERING OF SOLUTIONS[a]

PVA	H_3BO_3[b] 0.05	0.10	0.15	0.20	0.25	0.30
DP=500	A-1	A-2	A-3	A-4	A-5	A-6
DP=2000	B-1	B-2	B-3	B-4	B-5	B-6

a) For each solution, the PVA and iodine concentrations are 2.0 wt% and 1.152×10^{-4} mol/*l*, respectively.
b) The concentration of boric acid is expressed in mol/*l*.

Spectral Measurements. The Raman spectra were recorded using a He–Ne laser (632.8 nm) and an Ar^+ ion laser (488.0 nm) for excitation. When the He–Ne laser was used, a spectrometer was employed which consisted of a Spex 1401 double monochromator, a photomultiplier, a phase-sensitive detector, and a recorder.[4] Also, a Raman spectrometer constructed by the Kawaguchi Denki Co. and a JEOL JRS-U1 spectrometer were used, both with an Ar^+ ion laser. The Raman scattering was observed at right angles to the exciting laser beam, which radiates the sample very close to the quartz-cell wall.

Hitachi EPS-3 and 124 spectrophotometers were used to measure the absorption spectrum in the ultraviolet and visible regions.

Results and Discussion

Figure 1 shows an example of the Raman spectrum

* Present address: Department of Biophysics and Biochemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo.

2) M. Tasumi, *Chem. Lett.*, **1972**, 75.

3) It might be more reasonable to regard the complex as a ternary one consisting of PVA, iodine, and boric acid. However, we keep the tradionally-used name of PVA-iodine complex. Actually, the complex is formed even without boric acid after the mixed solution of PVA and iodine is left for a long time.

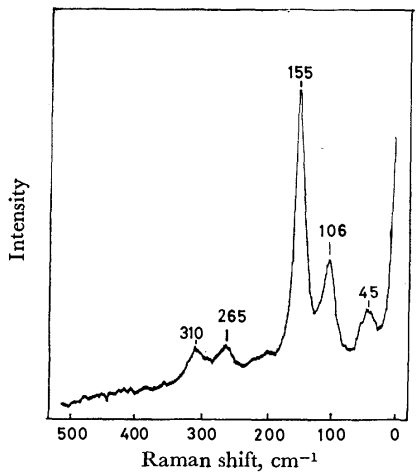

Fig. 1. The Raman spectrum of the solution B-3 taken with the 632.8 nm excitation.

of the PVA-iodine complex obtained with the 632.8 nm line of the He-Ne laser. A close resemblance is found between this and the spectrum reported previously for the starch-iodine complex.[2] It seems reasonable, therefore, to presume that the structure of the PVA-iodine complex is similar to that of the starch iodine complex. In other words, the present result is compatible with the model structure of the PVA-iodine complex proposed by Zwick[5] that a linear polyiodide chain is enclosed by a helical PVA molecule and that the latter, in turn, is surrounded by borates which maintain the PVA helix by forming the -C-O-B-O-C- bridge.

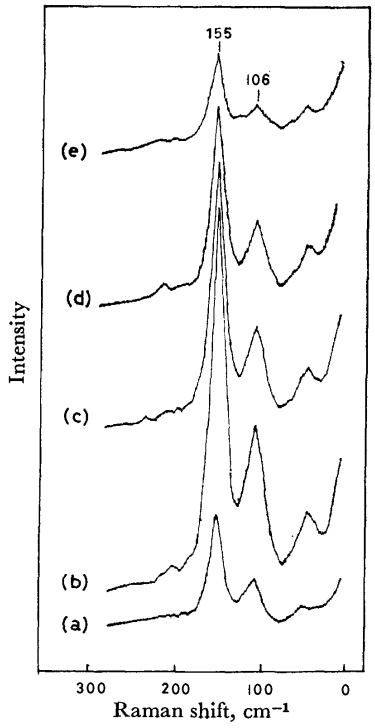

Fig. 2. The Raman spectra of Sample B taken with the 632.8 nm excitation. Iodine concentrations are as I_2:
(a) 2.09×10^{-4} mol/l; (b) 1.05×10^{-4} mol/l;
(c) 0.52×10^{-4} mol/l; (d) 0.26×10^{-4} mol/l;
(e) 0.13×10^{-4} mol/l.

5) M. M. Zwick, *J. Appl. Polym. Sci.*, **9**, 2393 (1965).

By analogy with the starch-iodine case, the three bands at 45, 106, and 155 cm^{-1} in Fig. 1 may be assigned, respectively, to the bending, symmetric stretching, and antisymmetric stretching vibrations of the I_3^- ion. The other two, at 265 and 310 cm^{-1}, may be assigned to a combination tone ($265\approx106+155$) and an overtone ($310\approx155\times2$).

In the following part we will discuss various spectral characteristics observed under different conditions.

(1) Effect of the Concentration on the Raman Intensities. Figure 2 shows the dependence of the Raman intensities on the iodine concentration observed for Sample B. The apparent Raman intensity reaches its maximum at the iodine concentration of 1.0488×10^{-4} mol/l. A similar tendency was also observed in the solution of Sample A.

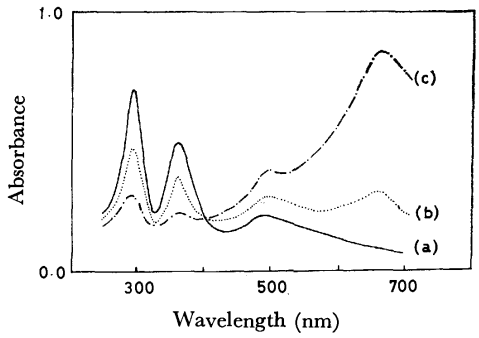

Fig. 3. The absorption spectrum of Sample A in the ultraviolet and visible regions. The solutions used are:
(a), A-1; (b), A-3; (c), A-5.

(2) Correlation between the Absorption and the Raman Spectra. (a) Ultraviolet and Visible Absorption Spectra: The absorption spectrum of Sample A in the ultraviolet and visible regions is shown in Fig. 3. The color of the complex varied from red to blue as the concentration of boric acid was increased. The absorption bands at 290 nm and 350 nm are due to the I_3^- ion. The band at 490 nm is close to the absorption wavelength of the I_2 molecule. However, only a small amount of the I_2 molecule would remain in the solutions treated here because of the presence of excess potassium iodide. As the extinction coefficient of the I_2 molecule is small ($\varepsilon=746$ $l$mol^{-1}cm^{-1}), it is unlikely that the 490 nm band in Fig. 3 arises from I_2. Therefore, this band should be assigned to the PVA(Sample

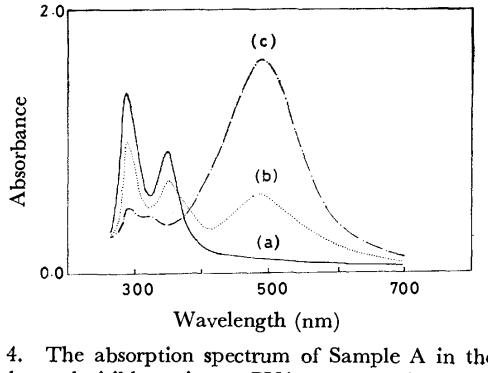

Fig. 4. The absorption spectrum of Sample A in the ultraviolet and visible regions. PVA concentrations are:
(a), 0.04 wt%; (b), 0.2 wt%; (c), 1.0 wt%. No boric acid was added.

A)-iodine complex. This is supported also by the observation that the intensity of this band increases with an increase in the PVA concentration, while, on the other hand, the intensities of the 290 and 350 nm bands of the I_3^- ion decrease, as is shown in Fig. 4. The band at 670 nm appears very strongly when the boric acid concentration is high.

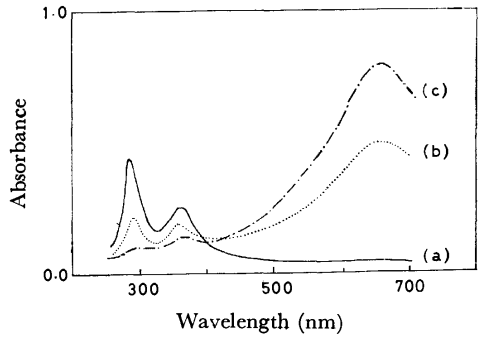

Fig. 5. The absorption spectrum of Sample B in the ultraviolet and visible regions. Boric acid concentrations are: (a), B-1; (b), B-3; (c), B-5.

Figure 5 shows the absorption spectra of the B solution series. The color of the B-1 solution (yellow) was exactly the same as that of the solution of iodine and potassium iodide. This would mean that Sample B does not make a complex with iodine at low boric acid concentrations. At higher boric acid concentrations, Sample B also shows a strong band at 670 nm.

It is noted that the 490 nm band found in the spectra of Sample A is not observed in any of the spectra of Sample B. This difference gives rise to an important effect in the Raman spectra, as will be discussed later.

(b) The Raman Spectra Observed with the 632.8 nm Excitation: The Raman spectra of the A and B solution series are shown in Figs. 6 and 7 respectively; they were obtained with the 632.8 nm line of the He-Ne

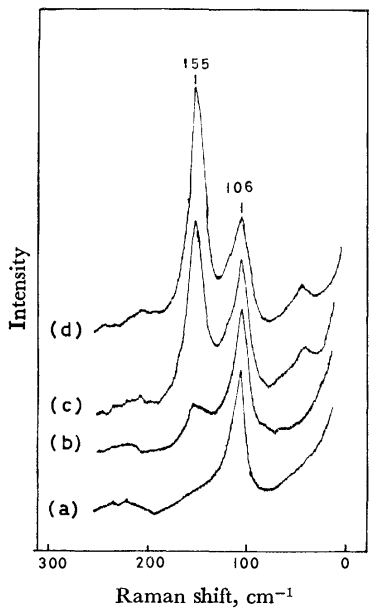

Fig. 6. The Raman spectra of the solution series A taken with the 632.8 nm excitation.
(a), A-1; (b), A-2; (c), A-3; (d), A-5.

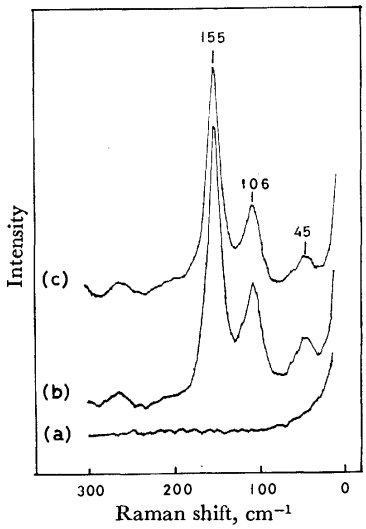

Fig. 7. The Raman spectra of the solution series B taken with the 632.8 nm excitation.
(a), B-1; (b), B-3; (c), B-5.

laser. A marked change may be seen in the spectra of the A solution series. The Raman band at 155 cm^{-1} (the antisymmetric stretching mode) is not observed in the reddish solution A-1. When the color of the complex becomes blue, this band is strongly enhanced. In contrast with this, the intensity of the 106 cm^{-1} band (symmetric stretching mode) remains nearly constant throughout the A solution series, independent of the color of the complex.

No Raman bands are observed for the yellow solution B-1. However, as the color becomes increasingly blue upon the addition of the boric acid, strong Raman bands appear for the B-3, B-4, and B-5 solutions.

(c) The Raman Spectra observed with the 488.0 nm Excitation: Figure 8 shows the spectrum of the A-4 solution obtained with the 488.0 nm line of the Ar^+ ion laser. It can be noted that the Raman band at 106 cm^{-1} is strongly enhanced and that overtones may be observed until the sixth. The Raman line at 155 cm^{-1} is observed only as a weak shoulder. This is in contrast with Fig. 1, in which the band at 155 cm^{-1}

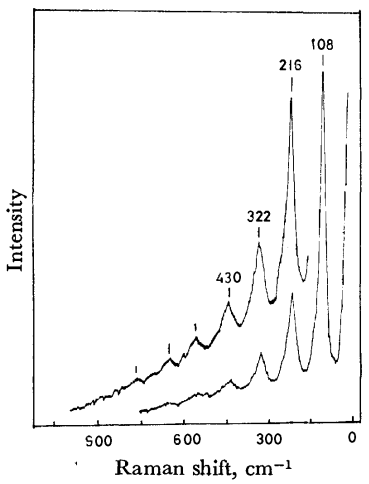

Fig. 8. The Raman spectrum of the solution A-4 with the 488.0 nm line excitation. The solution A-2 gives essentially the same spectrum.

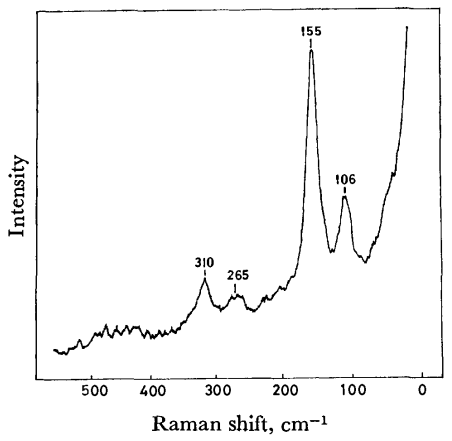

Fig. 9. The Raman spectrum of the solution B-3 taken with the 488.0 nm line excitation.

is much stronger than the band at 106 cm^{-1}.

For Sample B, on the other hand, essentially the same spectra were observed as those obtained with the He-Ne 632.8 nm line (Fig. 9).

The different spectral behavior between Sample A and Sample B with respect to the 488.0 nm excitation seems to be associated with the fact that Sample A has the 490 nm band, which is resonant with the exciting line, whereas Sample B has no such band.

TABLE 2. SUMMARY OF THE RESONANCE EFFECT[a)]

Exciting line	Sample: PVA-iodine A red	A blue	B yellow	B blue	Starch-iodine[b)]	Free I_3^-
632.8 nm	s	s,A	none	s,A	s,A	s
488.0 nm	S	S	none	s,A	s,A	s

a) The capital letters S and A indicate that the intensities of the I_3^- *symmetric* and *antisymmetric* modes are, respectively, enhanced greatly. The small symbol s means that the intensity of the I_3^- *symmetric* stretching is enhanced, but not as greatly as the case indicated by the capital letter.

b) Taken from Ref. 2.

The results obtained above are summarized in Table 2, together with those for the starch-iodine complex and the free I_3^- ion. The Raman spectra of the free I_3^- ion in an aqueous solution are shown in Fig. 10. The measurements were made under much higher I_3^- concentrations than those used in the Raman measurements of the complexes. This indicates that the resonance effect is much weaker for the free I_3^- ion than for I_3^- in the complexes, reflecting the experimental conditions that the exciting wavelengths used are outside the absorption bands of the free I_3^- ion found at 350 and 290 nm (preresonance case).

The following points in Table 2 are most noteworthy: (i) The intensity of the I_3^- antisymmetric stretching mode is strongly enhanced in the complex state under some conditions, whereas it is only weakly observed in the free state. This is undoubtedly due to the presence of the absorption band of the complex at 670 nm (PVA-iodine) or *ca.* 600 nm (starch-iodine).

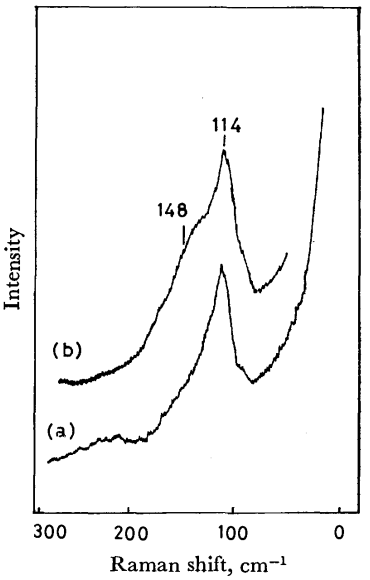

Fig. 10. The Raman spectra of aqueous solutions of potassium iodide.
(a), excited with the 488.0 nm line; (b), excited with the 632.8 nm line.

(ii) The intensity of the I_3^- symmetric stretching mode is enhanced in the free I_3^- spectra. It is strongly enhanced also in the complex-state spectra, instead of the antisymmetric mode, if the exciting wavelength is resonant with the absorption band at 490 nm.

These results clearly show that the alternative enhancement of different Raman bands can be achieved by using the resonance effect. As far as we know, such a clear example of alternative enhancement has not yet been reported. The mechanism which gives rise to the alternative enhancement must be rather complicated. However, we propose a very simple working hypotheses which might be of some value in understanding such a resonance effect: if the direction of a vibrational transition moment of a non-centrosymmetric molecule coincides with that of the electronic transition moment responsible for the resonance effect, the Raman intensity of the relevant vibrations has a chance of being selectively enhanced. As has been discussed in a previous paper,[2)] the transition moment of the 600 nm band of the starch-iodine complex is directed parallel to the linear chain of the I_3^- ion. Therefore, the Raman intensity of the I_3^- antisymmetric stretching mode is enhanced if the 600 nm band is resonant with the exciting wavelength. It seems quite reasonable to expect that the situation is the same for the enhancement of the I_3^- antisymmetric stretching mode of the PVA-iodine complex, though the direction of the transition moment of the 670 nm band of the PVA-iodine complex has not been determined experimentally. On the other hand, the 490 nm band would have its transition moment directed perpendicular to the I_3^- chain, if the working hypothesis described above be true. It is highly probable that the I_3^- ion in the complex deviates slightly from the linear centrosymmetric structure[6)] and, as a result, the transition moment

6) A. G. Maki and R. Forneris, *Spectrochim. Acta.*, **23A**, 867 (1967).

of the I_3^- symmetric stretching mode is directed perpendicularly to the I_3^- chain. In this case, the Raman intensity of this mode may be selectively enhanced by the resonance between the 490 nm band and the 488.0 nm Ar^+ line. However, it should be mentioned that the origin of the 490 nm band is not very clear as yet. It is conceivable that this band is associated with either the tacticity of the polymer or the chain end, since this band is observable only in the spectrum of Sample A. This problem can be clarified only through experiments which utilize well-characterized polymer samples. Also, the validity of that working hypothesis should be tested by choosing suitable molecules, for which not only the molecular structures but also the assignment of the vibrational and electronic spectra are firmly established.

The Crystal Structure of the Polymerization Catalyst of Acetaldehyde and Its Derivatives. II.[1] The Crystal and Molecular Structure of the Trimethylamine Oxide Adduct of Dimethylaluminum *N*-Phenylbenzimidate, $[(CH_3)_2Al\cdot O\cdot C(C_6H_5):N(C_6H_5),\ ON(CH_3)_3]$

Yasushi KAI, Noritake YASUOKA, Nobutami KASAI, and Masao KAKUDO*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka, 565

**Institute for Protein Research, Osaka University, Yamadakami, Suita, Osaka, 565*

(Received May 13, 1972)

The molecular structure of a stereospecific (*isotactic*) polymerization catalyst of the acetaldehyde-Lewis base adduct $[Me_2Al\cdot O\cdot CPh:NPh,ONMe_3]$ has been determined from three-dimensional X-ray data collected on a single crystal diffractometer. The crystal belongs to the triclinic system (space group $P\bar{1}$), with two formula units in a cell with dimensions of; $a=8.517\pm0.004$, $b=10.096\pm0.005$, $c=12.256\pm0.005$ Å, $\alpha=104.67\pm0.04$, $\beta=106.97\pm0.04$, and $\gamma=98.10\pm0.04°$. The structure was solved by the symbolic addition method and refined by the block-diagonal, least-squares procedure. The molecule is monomeric, and both amide and $ONMe_3$ groups are connected to the aluminum atom through oxygen atoms. The amide moiety has an imino-ether type structure and two adjacent benzene rings take *trans* configuration about the N–C bond. The co-ordinated $ONMe_3$ group has a structure similar to that of the free molecule.

This work is a part of a series of molecular-structural studies[1–5] of the stereospecific polymerization catalysis of acetaldehyde. In recent years, Tani and his co-workers have found that, among the catalytic systems of the stereospecific polymerization reaction of aldehydes, the reaction products of trialkylaluminums and acid amides show excellent catalytic activities for the *isotactic* polymerization of acetaldehyde and methylmethacrylate.[6–9]

This catalytic system has attractive features which facilitate stereochemical investigations. First, the catalytic system contains few side reactions and gives a very high yield of the stereospecific polymer. Therefore, a rather simple reaction mechanism can be expected. Second, the polymerization reaction is mild, and many interesting complexes can be isolated in a pure crystalline form.

The series of complexes selected for molecular-structural studies in this catalytic system are:

(I) $[Me_2Al\cdot O\cdot CPh:NPh]_2$,[10]

(II) $[Me_2Al\cdot O\cdot CPh:NPh,\ MeCHO]_2$,

(III) $[Me_2Al\cdot O\cdot CPh:NPh,\ MeCHO,\ AlMe_3]$, and

(IV) $[Me_2Al\cdot O\cdot CPh:NPh,\ ONMe_3]$.

The complex I is a highly stereospecific polymerization catalyst of acetaldehyde obtained from an equimolar reaction of trimethylaluminum and benzanilide; its molecular structure has been reported previously.[1,2] The polymerization catalyst-monomer complex II shows the same catalytic activities as I. The co-ordinated aldehyde can be replaced by a free aldehyde present in the solution, but it can not be replaced by other electron donors, such as pyridine or tetrahydrofuran. Using the complex III, a Lewis acid adduct of II, as a catalyst, an *atactic* polymer of acetaldehyde is obtained.

The complex IV is a strong Lewis base adduct of

the polymerization catalyst; it is obtained from an equimolar mixture of I and $ONMe_3$ in benzene at room temperature:

$$[Me_2Al\cdot O\cdot CPh{:}NPh]_2 \xrightarrow[\text{in benzene at room temperature}]{+ONMe_3} [Me_2Al\cdot O\cdot CPh{:}NPh,\ ONMe_3]$$

I IV

This complex is the most stable one in argon among the four complexes mentioned above. However, it does not show any catalytic activities, and significant differences can be expected between the molecular structures of the polymerization catalyst, $[Me_2Al\cdot O\cdot CPh{:}NPh]_2$ and this complex. The structure determination was undertaken by means of X-ray diffraction. The preliminary results were communicated earlier.[5]

Experimental

The colorless, prismatic crystals were prepared and supplied by Tani and Yasuda of this University. As the crystals decompose immediately in the air, they were sealed in thin-walled glass capillary tubes in argon.

Nickel-filtered Cu$K\alpha$ radiation was used for the preliminary X-ray experiments. Oscillation and Weissenberg photographs showed that the crystal has no crystallographic symmetry, and the space group is $P\bar{1}$ or $P1$.

Both the determination of the unit-cell dimensions and the collection of the intensity data were carried out on a Rigaku on-line controlled, four-circle, single crystal diffractometer. Zirconium-filtered Mo$K\alpha$ radiation was used. The setting angles of each reflection were computed by the Busing-Levy method[11] on an Aicom-C2 computer attached to the diffractometer. The method requires precise values of the centering angles, 2θ, ω, χ, and ϕ, of three linearly-independent reflections of known indices in order for us to determine the orientation of the crystal and the dimensions of the unit cell. The reflections chosen were 500, 030, 007, $0\bar{3}0$, and $00\bar{7}$. During the intensity measurement of each quadrant of the reciprocal lattice, three of the five chosen reflections included in the quadrant were used. The crystal data are listed in Table 1. The accuracies of the cell parameters were estimated from the reproducibilities of the cell parameters as calculated from different sets of reflections. The crystal density was determined by the flotation method in a mixed solution of carbon tetrachloride and *n*-hexane. Intensity measurements were carried out at room temperature by using the ω–2θ scan technique with a β-filter. The scan range, $\Delta(2\theta)$ of each reflection was computed by this equation:

$$\Delta(2\theta) = 2.0° + 0.7° \tan\theta_c.$$

The starting angle of the scan is $(2\theta_c - 1.0°)$, where θ_c is the calculated value of the Bragg angle using the $\lambda(\text{Mo}K\alpha_1)$ (=0.70926 Å), and the scanning speed of the scintillation counter was 4.0°/min. Sheets of nickel foil with graded thicknesses were used as intensity attenuators. Before scanning a reflection, a short, fixed-time (one second) intensity measurement was taken at the $2\theta_c$ position, and an appropriate attenuator was selected and was inserted in order to control the intensity in the optimum range (below 7000 cps in this experiment). The background scattering was measured for five seconds at both ends of the scan range by means of the stationary-crystal stationary-counter technique. The intensities were corrected for the background scattering and for the usual Lorentz and polarization effects. Each structure factor, along with its standard deviation, as estimated by the counting statistics, was calculated and printed out before the measurement of the next reflection. The absorption correction was ignored (μ=1.3 cm^{-1} for Mo$K\alpha$). The intensity of the 300 reflection was chosen as the standard and was measured every 25 reflections. The crystal used had dimensions of about 0.5×0.3×0.3 mm. The collimator was 1.0 mm in diameter. During the intensity measurements, the intensity of the standard reflection gradually decreased. The structure factor magnitudes, therefore, decreased approximately linearly up to $(\sin\theta)/\lambda$=0.458. After this, they showed a sudden decrease. Probably the crystal decomposed completely. Then another crystal of an approximately equal size was chosen and further intensity measurements were carried out up to $(\sin\theta)/\lambda$=0.539. The intensities of about 200 reflections ($(\sin\theta)/\lambda$=0.235) were also remeasured for the second crystal, and the structure factor magnitudes were compared with those obtained from the first crystal. No special anisotropy due to the absorption was found. Then the scalings of the two kinds of data, including the intra- and inter-crystal scaling, were undertaken linearly based on the observed changes in the structure factor magnitudes of the standard reflection. A total of 2399 independent reflections were obtained, among which 2048 were non-zero reflections.

V=948.5 Å^3	

Structure Determination and Refinement

The crystal structure was solved by obtaining phases directly from the structure factor magnitudes by means of the symbolic addition procedure.[12] The structure factors reduced previously were placed on an absolute scale by means of a three-dimensional Wilson plot, and the structure factor magnitudes, $|F|$, and the normalized structure factor magnitudes, $|E|$, were computed by means of SIGMA program[13] on a FACOM 230-60 computer at Kyoto University. The distribution of the normalized structure factor magnitudes, $|E|$, and their statistical averages are given in Table 2. On the basis of these statistics, the space group was determined to be $P\bar{1}$, which was confirmed at the later stage of the structure determination. The SIGMA program was also utilized to list the $\sum_2$ relationships for each reflection and to calculate the associated probabilities. The probabilities were determined by

13) T. Ashida, SIGMA, The Universal Crystallographic Computing System (I), edited by T. Sakurai, p. 43, Japanese Crystallographic Association, 1967.

means of the equation:

$$P_+(E_h) = \frac{1}{2} + \frac{1}{2}\tanh(\sigma_3\sigma_2^{-3/2}|E_h|\sum E_k E_{h-k}),$$

and their lower limit was set at 0.97.

Positive signs were assigned to three linearly-independent reflections in order to define the origin of the unit cell. The signs of the five other reflections were then all determined to be + from the $\sum_2$ relationships among the origin-defining reflections. Four additional reflections were chosen, and their phases were designated by the letters *a*, *b*, *c*, and *d* in order to facilitate the symbolic addition procedure. Starting from the phases of these 12 reflections (Table 3), 99 signs out of 103 reflections whose $|E|$ values are greater than 2.0 were determined as functions of *a*, *b*, *c*, and *d* by using the SORT-SIGMA 2 program.[14] Through the application of the $\sum_2$ formula, it was found, from the relationships among the symbols, that $a=c=d$ and $b=+$.

As the + signs were assumed for the three origin-fixing reflections, the − sign was never introduced into these reflections in the course of the application of the $\sum_2$ formula for the space group $P\bar{1}$. It was then necessarily concluded that the signs of *a*, *c*, and *d* are all − ; otherwise, a trivial solution would have resulted. On the basis of these 99 phases, the application of the $\sum_2$ relationship was extended over 303 reflections with $|E|\geqq 1.50$ and the phases of 203 additional reflections were determined. At this stage, one of the 99 phases changed its sign to the correct one.

From the *E*-map (Fig. 1), the locations of all of the 23 nonhydrogen atoms were found easily. On the basis of these atomic locations, block-diagonal least-squares refinement was carried out by means of the HBLS IV program.[15] The atomic scattering factors used in the calculation were taken from those of Hanson and his co-workers.[16] After 5 cycles refinement using the isotropic temperature factors, the *R* index was found to be 0.17 for non-zero reflections. This rather large *R* value was considered to have resulted from the large differences between $|F_o|$ and $|F_c|$ values, especially for small $|F_o|$'s. Therefore, all the $|F_o|$'s smaller than $3\sigma(F_o)$ were excluded from the further refinement. Anisotropic temperature factors were then introduced for all the nonhydrogen atoms and the refinement was continued. After 4 cycles, the *R* value was reduced to 0.097 for 1359 non-zero reflections. From the difference Fourier map computed by means of SFFR program[17] and from the model examination, all of the hydrogen atoms were located. Considering these hydrogen atoms and using a weighting scheme to be described later, the final refinement was undertaken and the *R* index decreased to 0.068 for non-zero reflections. The weighting scheme applied was;

$$|F_o| < F_{\min}: w = F_{wt}$$
$$F_{\min} \leqq |F_o| \leqq F_{\max}: w = 1.0$$
$$F_{\max} < |F_o|: w = F_{\max}/|F_o|$$

where $F_{\max}=20.0$, $F_{\min}=0.0$, and $F_{wt}=0.0$. The weighted *R* index defined as $\{\sum w\cdot(|F_o|-|F_c|)^2/\sum w\cdot(F_o)^2\}^{1/2}$ is 0.082.

TABLE 2. DISTRIBUTION OF THE NORMALIZED STRUCTURE FACTOR MAGNITUDE AND STATISTICAL AVERAGES

	Distribution of $\|E\|$ %		Number of reflections
	Theoretical (Centrosymmetric)	Experimental	
$\|E\|\geqq 3.0$	0.3	0.38	9
$\|E\|\geqq 2.0$	5.0	4.3	103
$\|E\|\geqq 1.0$	32.0	33.0	792
			2399 (total)

	Experimental	Theoretical	
		Centrosymmetric	Noncentrosymmetric
$<\|E^2\|>$	1.000	1.000	1.000
$<\|E\|>$	0.790	0.798	0.886
$<\|E^2-1\|>$	0.946	0.968	0.739

Results and Discussion

The molecular structure, with the numbering of atoms, as viewed along the b axis is shown in Fig. 2. The interatomic bond distances and angles calculated using the DAPH program[18] are listed in Tables 8 and 9 respectively.

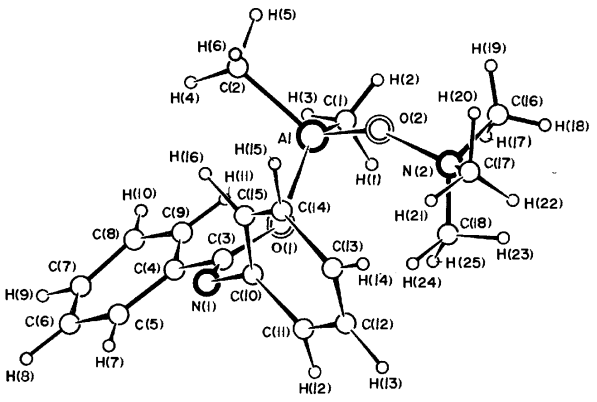

Fig. 2. Molecular structure.

Molecular Structure. The molecule is monomeric. The amide and $ONMe_3$ groups are both connected to the aluminum atom through oxygen atoms. The aluminum atom has a slightly distorted tetrahedral

geometry. The C(1)-Al-C(2) bond angle (117.3(0.5)°) is equal to that of the polymerization catalyst [$Me_2Al\cdot O\cdot CPh{:}NPh]_2$ (117.6(0.5)°), but it shows a large deviation from the typical tetrahedral bond angle of 109.5°. Such a rather large bond angle of C(methyl)-Al-C(methyl) is often found associated with tetrahedrally co-ordinated aluminum atoms in some organoaluminum compounds.[19-22]

The interatomic bond distances between the aluminum atom and the oxygen of the amide moiety, Al-O(1), is 1.770(6) Å, which is a little shorter than the corresponding distances of the related complexes: 1.805(6) Å in [$Me_2Al\cdot O\cdot CPh{:}NPh]_2$, 2.045(7) Å in [$Me_2Al\cdot O\cdot CPh{:}NPh$,MeCHO]$_2$, and 1.846(7) Å in [$Me_2Al\cdot O\cdot CPh{:}NPh$,MeCHO,$AlMe_3$]. The O(1)-C(3) bond distance of 1.330(9) Å is intermediate between typical single and double bond distances. The C(3)-N(1) distance is 1.263(11) Å. The carbon and nitrogen double bond distance has been given as 1.265 Å by Pauling[23] and as 1.28 Å by Cox and his co-workers.[24] The C-N bond in oximes, >C=N-OH, is generally assumed to be a localized double bond, the distance of which lies between 1.225 and 1.33 Å.[25] From these facts, it can be concluded that the C(3)-N(1) in the present complex is an almost-localized double bond. Five atoms, O(1), C(3), N(1), C(4), and C(10), are co-planar within a deviation of 0.01 Å. The most interesting feature is that, unlike those in [$Me_2Al\cdot O\cdot CPh{:}NPh$, MeCHO]$_2$ and [$Me_2Al\cdot O\cdot CPh{:}NPh$,MeCHO,$AlMe_3$], the two adjacent benzene rings take the more stable, *trans* configuration about the C(3)-N(1) bond, the internal rotation angle being 178.9°. The dihedral angle between the best plane

of the two benzene rings is 80.5°. The average values of the C-C and C-H distances in benzene rings are 1.381 and 1.09 Å respectively.

The $ONMe_3$ moiety is attached to the aluminum atom by the co-ordination of the oxygen atom. The Al-O(2) bond distance, 1.826(6) Å, takes a reasonable value compared with those found in the related organoaluminum compounds.[1-4] The crystal structure of $[Me_3NO,HCl]$ was determined by Rérat[26] and had since been refined by Caron and his co-workers[27] in the course of the crystal structure analysis of $ONMe_3$.[28] The corresponding bond distances and angles in these complexes are compared with those in the $ONMe_3$ moiety of the present complex (Table 10). The O(2)-N(2) bond distance (1.402(9) Å) is intermediate between those in $[Me_3N^+-O^-]$ and $[Me_3N^+OH\cdot Cl^-]$.

26) P. C. Rérat, *Acta Crystallogr.*, **13**, 63 (1960).
27) A. Caron and J. Donohue, *ibid.*, **15**, 1052 (1962).
28) A. Caron, G. J. Palenik, E. Goldish, and J. Donohue, *ibid.*, **17**, 102 (1964).

Caron and his co-workers considered that the opposite formal charge affects the O–N bond distance in the structure of $ONMe_3$. According to this theory, the negative formal charge on the oxygen atom of the $ONMe_3$ moiety in the present complex may be weakened by the co-ordination to the electron-deficient aluminum atom. The aluminum atom is not so strong a Lewis acid as the proton; however, it may be that the co-ordination of oxygen does not completely cancel the charge on the oxygen atom, as in the case of the proton in [$Me_3N^+OH\cdot Cl^-$]. This can reasonably explain the fact that the O(2)–N(2) distance lies between the corresponding distances in [$Me_3N^+–O^-$] and [Me_3N^+-$OH\cdot Cl^-$]. The average values of the two C–N bond distances are 1.478 ± 0.011 Å in [$Me_3N^+OH\cdot Cl^-$] and 1.477 ± 0.006 Å in [$Me_3N^+–O^-$]. The N(2)–C(16) and N(2)–C(18) bond distances have values equal to those found in the above two compounds. The N(2)–C(17) bond is slightly longer than the other N(2)–C bonds, though the difference is not very significant. The geometry around the N(2) atom is a little distorted tetrahedron. Such a geometry around the nitrogen atom is also found in [$Me_3N^+–O^-$].

Table 10. Comparison of the interatomic distances and angles in the $ONMe_3$ groups

Atoms	[Me_3N^+-OH, Cl^-][a] (Ref. 26)	[$Me_3N^+–O^-$][a] (Ref. 27)	Me_3NO moiety in the present complex

a) The crystal structure of these compounds has a mirror symmetry and only two carbon atoms of three methyl carbons are independent.

The molecular structures of the polymerization catalyst I and of the present complex IV are compared in Fig. 3 and Table 11. In Fig. 3 both molecules are projected onto the O–C–N plane of the amide moiety, which is present in both compounds. The amide moiety is connected to the electron-deficient aluminum atom by both oxygen and nitrogen atoms in I, but only by oxygen in IV. The nitrogen atom in IV is, therefore, liberated from bonding to the aluminum. The C(3)–N(1) bond distance in IV is a little shorter than that in I. The C(3)–O(1) distance in IV is,

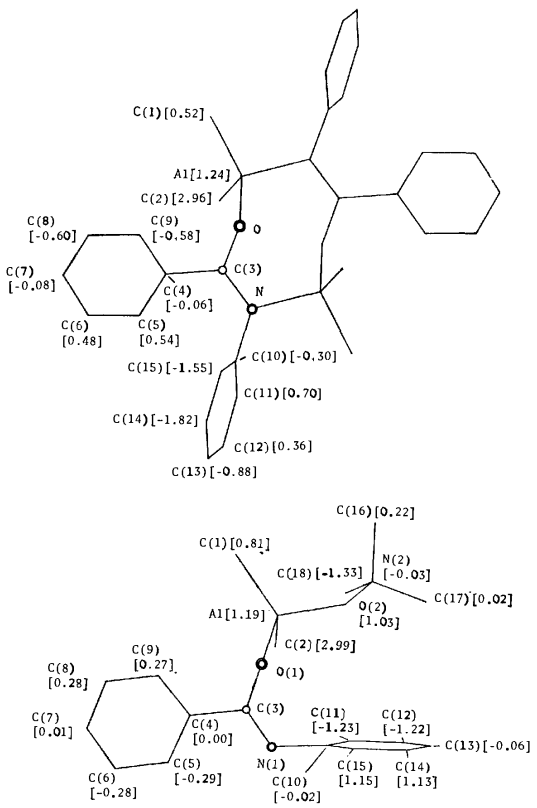

Fig. 3. Comparison of the molecular structure of [$Me_2Al\cdot O\cdot CPh{:}\ NPh]_2$ (*top*) and [$Me_2Al\cdot O\cdot CPh{:}$ NPh, $ONMe_3$] (*bottom*). Both are projected onto the plane of the –O–C–N– skeletons which are contained commonly in both molecules. Deviations from the plane (in Å) are given in brackets.

Table 11. Comparison of the selected interatomic distances and angles and dihedral angles between some planes[a] in the amide moieties of complexes (I) and (IV)

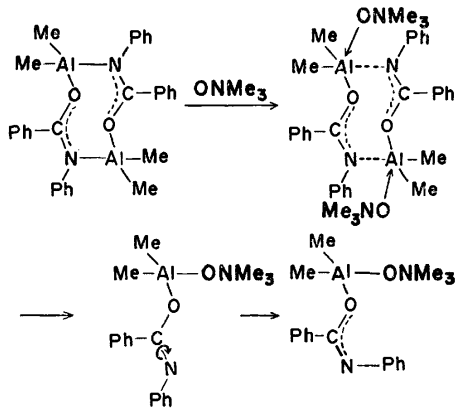
	(I)	(IV)
Al–O(1)	1.805(6) Å	1.770(6) Å
O(1)–C(3)	1.277(10)	1.330(9)
C(3)–N(1)	1.305(11)	1.263(11)
C(3)–C(4)	1.501(12)	1.490(11)
N(1)–C(10)	1.447(12)	1.419(11)
Al–O(1)–C(3)	133.6(0.6)°	137.7(0.5)°
Plane 1–Plane 2	2.9°	0.03°
Plane 1–Plane 3	14.3	1.0
Plane 1–Plane 4	27.6	13.5
Plane 1–Plane 5	75.5	86.2
Plane 2–Plane 3	11.4	1.1
Plane 4–Plane 5	70.3	80.5

a) These planes are consisted of the atoms of;
Plane 1; O(1), C(3), N(1)
Plane 2; N(1), C(3), C(4)
Plane 3; C(3), N(1), C(10)
Plane 4; Least-squares plane of benzene ring (C(4)-C(9))
Plane 5; Least-squares plane of benzene ring (C(10)-C(15))

on the contrary, a little longer than that in I. Such differences in the C–N and C–O bond distances are probably due to the difference in C–N bond character: that is, there a delocalized double bond in I, but an

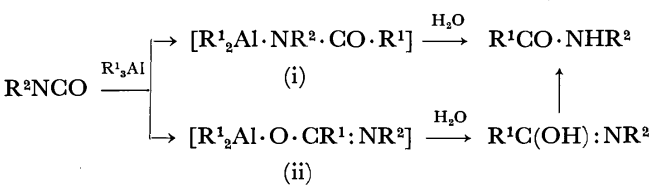
almost localized double bond in IV. The most remarkable configurational difference in the amide moieties is that the two benzene rings are *cis* in I, but *trans* in IV.

The isolation of the present complex [$Me_2Al\cdot O\cdot CPh$: NPh,$ONMe_3$] in a stable crystalline form and its molecular structure throw some interesting aspects on the chemical reactions of this catalytic system. One is concerned with the reaction from I to IV, the reaction which has been formulated before. When the dimeric complex of I is treated with a strong Lewis base, $ONMe_3$, an nucleophilic attack of the oxygen of $ONMe_3$ on the aluminum occurs. This promotes the cleavage of the Al–N bond, but not that of the Al–O bond. After the bond fission, the benzene ring attached to the nitrogen atom takes the more stable *trans* configuration. This is schematically shown below.



The second is related to the co-ordination scheme in the molecular structure of [$Me_2Al\cdot O\cdot CPh$: NPh]$_2$. The reaction of trialkylaluminum, R^1_3Al, and related compounds with isocyanate, R^2NCO, has been reported;[29,30] the products of this reaction gave *N*-substituted acid amides, R^1CONHR^2, on hydrolysis. Two intermediate compounds have been proposed in this reaction, depending on whether the insertion of isocyanate to an R^1–Al bond occurs by means of the C=N or C=O bond. In the insertion of isocyanate into the Et–Al bond,[31] the reaction products have been proposed to have the eight-membered ring structures of (iii) and (iv), which correspond to the dimeric structures of (i) and (ii) respectively.

Jennings and his co-workers studied the reaction



between trialkylaluminum and various *N*-substituted acid amides,[32] and they proposed that the reaction products had eight-membered ring structures like (iii) and (iv). We recently determined the molecular structure of [$Me_2Al\cdot O\cdot CPh$: NPh]$_2$.[1,2] The molecule has a centrosymmetrical eight-membered ring structure, and the bond distances show the molecule to have a hybrid structure of the two canonical forms, (iii) and (iv). On the other hand, the molecular structure of the present complex, [$Me_2Al\cdot O\cdot CPh$: NPh,$ONMe_3$], shows that the Al–O bond is more stable than the Al–N bond towards attack by a strong Lewis base on the aluminum atom. In other words, this result shows that the Al–N bond has much more of a co-ordination-bond character than the Al–O bond. On the basis of this fact, we can assume that the canonical form, (iv), is predominant in the dimeric structure of [$R_2Al\cdot O\cdot CR'$: $NR'']_2$.

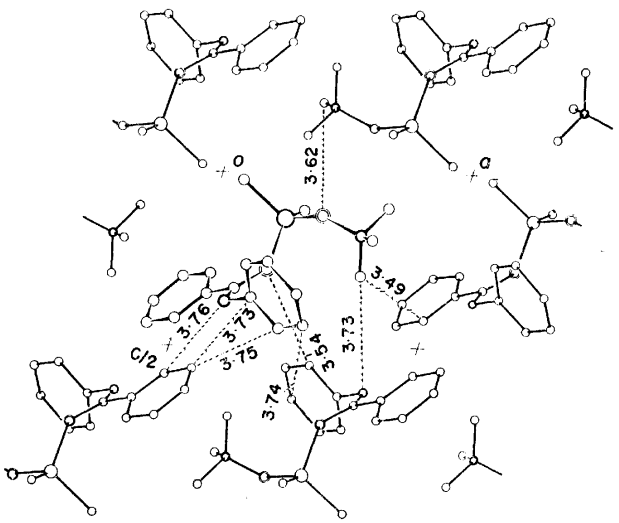


Fig. 4. Crystal structure viewed along the *b* axis.

Crystal Structure. Figure 4 shows the molecular packing projected along the *b* axis. The intermolecular atomic contacts less than 3.8 Å are shown by broken lines. None of them is significantly shorter than the normal van der Waals' contact.

The authors wish to express their deep thanks to Professor Hisaya Tani and Dr. Hajime Yasuda of Osaka University for their kindness in supplying the sample and for their helpful discussions.

(Received May 13, 1972)

The molecular structure of a stereospecific (*isotactic*) polymerization catalyst of the acetaldehyde-monomer complex, $[Me_2Al\cdot O\cdot CPh:NPh,MeCHO]_2$, has been determined on the basis of three-dimensional X-ray data collected photographically. The crystal belongs to the orthorhombic system (space group *Pcca*) with four dimer formula units in a cell with the dimensions of: $a=15.83(3)$, $b=12.61(1)$, and $c=17.66(1)$ Å. The structure was established by the heavy-atom method and refined by block-diagonal, least-squares procedure. The molecule is dimeric and has a C_2-2 symmetry. A monomer molecule, acetaldehyde, is inserted in the Al–N bond of the original polymerization catalyst. The oxygen atom bridges both aluminum atoms, Al–O=1.858(6) and 1.985(6) Å. The α-carbon atom of acetaldehyde bonds to the nitrogen atom of the amide moiety, C–N=1.469(12) Å. The aluminum atom is penta-co-ordinated and has a trigonal bipyramidal conformation.

We have been carried out a series of molecular-structural studies of the trimethylaluminum–benzanilide system, a catalytic system of the *isotactic* polymerization of acetaldehyde, by means of X-ray diffraction. Four complexes in the series are assumed to be the key substances for obtaining useful informations about the stereospecific polymerization mechanism of acetaldehyde. They are; (I) the polymerization catalyst, $[Me_2Al\cdot O\cdot CPh:NPh]_2$;[1] (II) the polymerization catalyst-monomer complex, $[Me_2Al\cdot O\cdot CPh:NPh,MeCHO]_2$; (III) the polymerization catalyst-monomer-Lewis acid complex, $[Me_2Al\cdot O\cdot CPh:NPh,MeCHO, AlMe_3]$; and (IV) the polymerization catalyst–Lewis base complex, $[Me_2Al\cdot O\cdot CPh:NPh,ONMe_3]$.

We have already communicated the preliminary results on these four complexes[2-5] and also reported the molecular structures of complexes I[6] and IV[7] in detail. The complex I is dimeric and has a centro-symmetric eight-membered ring, where the amide moieties make bridges between two aluminum atoms by the –O–C–N– skeletons. The complex IV is composed of a monomeric unit of I and a strong Lewis base, $ONMe_3$. The amide moiety in IV takes a stable *trans* configuration, unlike that in I (*cis*).

In this paper we will describe the crystal and molecular structure of the polymerization catalyst–monomer complex, $[Me_2Al\cdot O\cdot CPh:NPh, MeCHO]_2$, which is considered to be essentially the polymerization intermediate of this catalytic system. The main purpose of this work is to clarify the co-ordination state of acetaldehyde to the polymerization catalyst.

Experimental

The crystals of $[Me_2Al\cdot O\cdot CPh:NPh, MeCHO]_2$ were prepared and supplied by Tani and Yasuda of this University. They were far more unstable than the polymerization catalyst, $[Me_2Al\cdot O\cdot CPh:NPh]_2$. Besides being very air-sensitive, they decomposed at temperatures above 20°C. A large number of well-looking crystals were taken from the mother solution; they were sealed in thin-walled glass capillary tubes in argon. During the X-ray experiment, the Weissenberg camera was placed and operated in a cool chamber. As the chamber was temporary, the temperature inside the chamber was controlled only within about 10°C.

Nickel-filtered Cu$K\alpha$ radiation ($\lambda=1.5418$ Å) was used throughout the X-ray experiments. The unit cell dimensions were determined from two zero-level Weissenberg photographs along the *a* and *c* axes. Debye powder lines of tungsten were superposed on the Weissenberg photographs for calibration, and the cell parameters were determined by the least-squares procedure. The space group was determined to be D_{2h}^{8}–*Pcca* (No. 54) on the basis of the extinctions of reflections ($l\neq 2n$ for $0kl$, $l\neq 2n$ for $h0l$, and $h\neq 2n$ for $hk0$). The crystal data are listed in Table 1. These data impose a C_i–$\bar{1}$ or C_2–2 symmetry on the dimeric molecule.

The intensity data were collected by means of multiple-film equi-inclination Weissenberg photographs along the *a* and *c* axes. As the crystal was unstable even in argon at about 10°C, four crystals of a similar size (about 0.4×0.4×1.0 mm) were used (three along the *a* axis and one along the *c* axis). 2053 reflections from $0kl$ through $1l,k,l$, and 515 reflections from

*hk*0 through *hk*2 were collected. Their intensities were estimated visually, and they were corrected for the usual Lorentz and polarization factors and also for the spot-shape effect. The absorption correction was ignored ($\mu=11$ cm^{-1} for Cu$K\alpha$). A total of 2185 independent reflections were obtained, among which 451 reflections were too weak to be measured.

Structure Determination and Refinement

The structure was established by the heavy-atom method. The initial co-ordinates of the aluminum atom were determined from the three-dimensional Patterson maps. The computations of the minimum function and a Fourier synthesis were carried out, both based on the location of the aluminum atom.[8] From these maps, three reasonable atomic locations were found close to the aluminum atom, but none of them could be identified as carbon, nitrogen, or oxygen. The atomic scattering factors of the nitrogen atoms were, therefore, assumed for these atoms in the succeeding Fourier synthesis, and 17 atomic positions out of 21 nonhydrogen atoms could be located. The remaining 4 atomic locations were determined from the successive Fourier synthesis.

Starting from the locations of these nonhydrogen atoms, the block-diagonal least-squares refinement was done, using the HBLS IV program[8] on a FACOM 230-60 computer at Kyoto University. The function minimized was $\sum w(\Delta F)^2$, and at the initial stage w was taken as unity for all reflections. The atomic scattering factors used were taken from those of Hanson and his co-workers.[9] Using the isotropic temperature factors for all the nonhydrogen atoms, the usual R index converged to 0.20 after 3 cycles. The difference Fourier map was computed, and all the hydrogen atoms could be located approximately. The refinement proceeded including these hydrogen atoms and applying the anisotropic temperature factors for nonhydrogen atoms. The weighting scheme described later was also included in the refinement. The R index was improved to 0.15 after 2 cycles. In this refinement, the locations of atoms bearing the hydrogen, especially that of the α-carbon atom in the acetaldehyde moiety, were much improved. The difference Fourier map was again computed based on the new locations of the nonhydrogen atoms, and the positions of hydrogen atoms were determined again. The final refinement was carried out considering the redetermined hydrogen atoms; the final R value is 0.143 for non-zero reflections ($R=0.191$ for all reflections). The weighting scheme applied in the final refinement is: $|F_o|<F_{min}$; $w=F_{wt}$, $F_{min}\leqq|F_o|\leqq F_{max}$; $w=1$, $F_{max}<|F_o|$; $w=(F_{max}/|F_o|)^2$, where $F_{max}=20.0$, $F_{min}=4.0$, and $F_{wt}=0.20$.

The final atomic co-ordinates of the nonhydrogen atoms, along with their estimated standard deviations, and the anisotropic temperature factors are listed in Tables 2 and 3 respectively. The atomic co-ordinates and isotropic temperature factors of the hydrogen atoms are listed in Table 4. Table 5 lists the observed and

As may be seen in Fig. 1, the molecule is dimeric and has a C_2-2 symmetry instead of the C_i-$\bar{1}$ which was found in the catalyst, $[Me_2Al\cdot O\cdot CPh{:}NPh]_2$. The most interesting feature is that the aldehyde molecule is inserted between the aluminum and nitrogen atoms of the catalyst and is connected to the catalyst by two sites, O(2) and C(16). The O(2) co-ordinates to the aluminum (Al), and the C(16) bonds to the nitrogen atom of the amide moiety. These facts show that the relative position of the aldehyde molecule and the catalyst skeleton is uniquely fixed in the solid state. Such a co-ordination might be a main feature, even in the solution.

The oxygen (O(2)) of the aldehyde moiety co-ordinates to the other aluminum atom (Al′) and makes an oxonium ion-type bonding. Three bonds from the O(2) lie on the same plane (within 0.02 Å). The difference between the two Al-O(2) bond distances, (Al-O(2)=1.858(6) Å and Al′-O(2)=1.985(6) Å), is significant. The cryoscopic measurement of the molecular weight suggests that the dimeric molecule dissociates in the dilute solution under the polymerization conditions. For the dissociation, the cleavage of the Al′-O(2) bond is necessary. The rather long distance of Al′-O(2) suggests the possible fission of this bond. This was recently proved to be true by the isolation and structural determination of $[Me_2Al\cdot O\cdot CPh{:}NPh, MeCHO, AlMe_3]$.[4]

The α-carbon atom, C(16) of the aldehyde moiety shows an sp^3 hybridization; all the bond angles around the C(16) are tetrahedral (Table 7), and the bond distances, C(16)-O(2) (1.418(11) Å), C(16)-N (1.469 (12) Å), and C(16)-C(17) (1.559(17) Å), show the

normal values of the single covalent bond.

The most remarkable features are that the aluminum atom is penta-co-ordinated, and that a distorted trigonal-bipyramid is formed. The geometry around the aluminum atom is shown in Fig. 2. The aluminum atom lies exactly on the C(1)–C(2)–O(2) plane (within 0.01 Å), and the three bond angles around the aluminum in this basal plane show little deviation from 120°, the value expected for the typical trigonal bipyramid. The O(1) atom is just beneath the aluminum atom, and the three bond angles, O(1)–Al–C(1), O(1)–Al–C(2), and O(1)–Al–O(2), show a relatively good coincidence with the expected value of 90°. The interatomic vector, O(1)–Al, makes an angle of 84.6° with the basal plane, while the angle between the O(2′)–Al vector and the basal plane is 73.7°. The latter shows a great deviation from 90°. The distortion of the geometry around the aluminum atom from the trigonal bipyramid may be attributed to the formation of an additional four-membered ring, Al$\begin{matrix}\diagup O(2')\diagdown \\ \diagdown O(2)\diagup\end{matrix}$Al′.

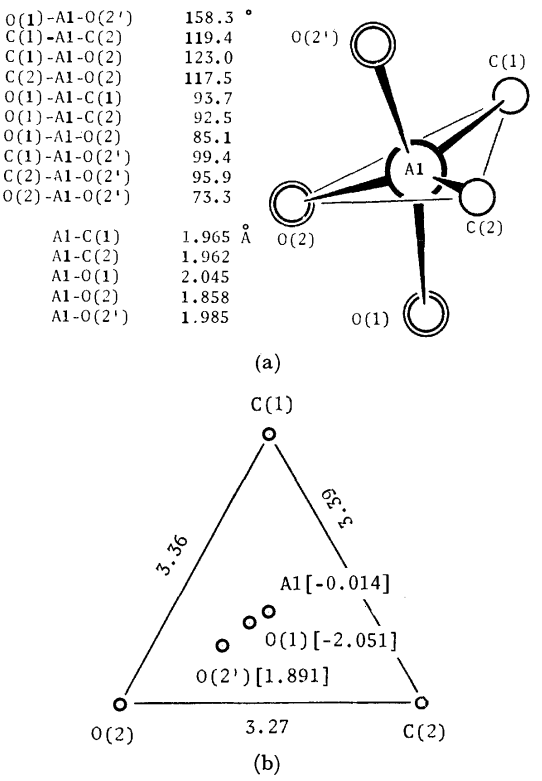

Fig. 2. The co-ordination geometry around the penta-co-ordinated aluminum atom. (a) Bond distances and angles. (b) Projection onto the basal plane (deviation from the plane are given in the brackets in Å unit).

The geometry around the penta-co-ordinated aluminum atom is summarized in Table 8. In [AlH_3, $2NMe_3$],[11] the aluminum atom lies on the crystallographic center of symmetry and two nitrogen and one aluminum atoms lie on a straight line. Because of the disorder, the presence of the six half-hydrogen atoms was assumed on the plane perpendicular to the N–Al–N axis in the hexagonal array. In the infinite-chain molecule with the molecular unit of [Me_2N–CH_2–CH_2–NMe_2]–AlH_3,[12] two aluminum atoms of the asymmetric unit do not lie at any crystallographic special positions. Two nitrogen atoms from two different diamine molecules occupy the apical positions of the trigonal bipyramid, with N–Al–N angles of 178.0° and 176.5°. The three hydrogen atoms around the aluminum atom, which were located by the difference Fourier synthesis, lie on an equatorial plane with an approximate three-fold symmetry. μ-Oxo-di[bis(2-methyl-8-quinolinolato-

aluminum(III)][13] also contains two penta-co-ordinated, slightly distorted trigonal bipyramidal, aluminum atoms in an asymmetric unit. Three oxygen and one aluminum atoms lie on the equatorial plane, and two nitrogen atoms occupy the apical positions. The average value of the N-Al-N is 163°. On the other hand, in the present complex, two carbon and one oxygen atoms lie on the equatorial plane and two oxygen atoms occupy the apical positions. The O-Al-O angle is 158°; much distortion is seen. In $C_8H_{24}Al_3Br_5O_6Si_4$,[14] each aluminum atom is co-ordinated by four oxygen and one bromine atoms, but the distortion is too large to interpret the geometry as either a trigonal bipyramid or a square pyramid.

Crystal Structure. Figure 3 shows the crystal structure projected along the *b* axis. Intermolecular atomic contacts of less than 3.8 Å are shown by broken lines. They are all considered as normal van der Waals' contacts.

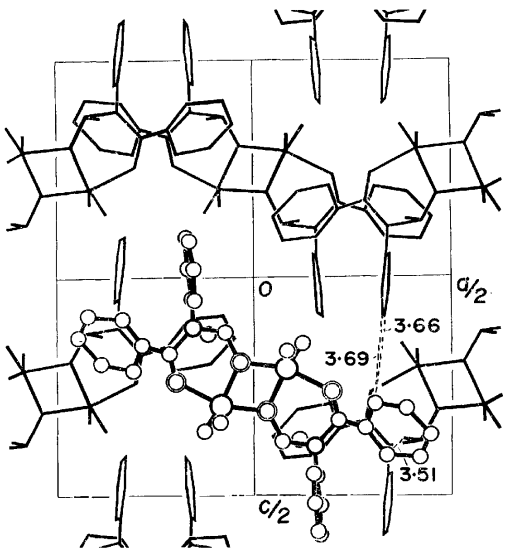

Fig. 3. The crystal structure projected along the *b*-axis.

Some Reactions about the Present Complex. From among the reactions of the trimethylaluminum-benzanilide catalyst system, some important reactions related with the present complex are shown in Fig. 4. In a previous paper,[7] the reaction from complex I to IV was discussed from a molecular-structural point of view. Very recently, Tani and his co-workers discovered that complex IV can also be obtained from complex II (the present complex) and $ONMe_3$ under conditions similar to those above. The complex II is obtained from complex I and MeCHO as has been described before. From these facts, the reaction scheme can be redrawn as is in Fig. 4 by drawing the molecular structures of these complexes.

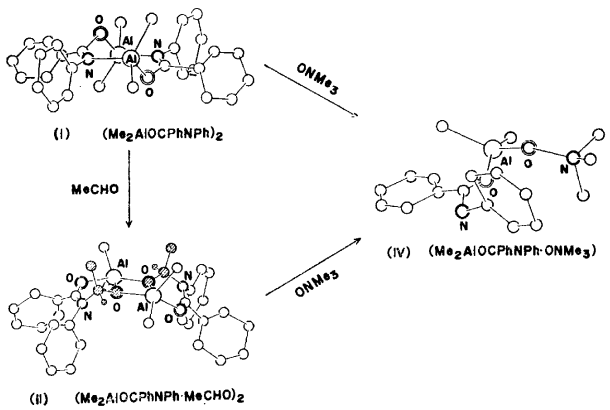

Fig. 4. Reactions related with the present complex (IV).

It is interesting to make some stereochemical consideration of how the polymerization catalyst I reacts with acetaldehyde to form a catalyst-monomer complex II, which is assumed to be essentially the polymerization intermediate. Both of the oxygen atoms of $ONMe_3$ and MeCHO react as the Lewis base, but $ONMe_3$ is much stronger than MeCHO. The most significant difference between these two bases is that $ONMe_3$ is unifunctional, whereas MeCHO is bifunctional; when the oxygen atom of MeCHO acts as a Lewis base, the α-carbon can act like Lewis acid. In Fig. 5, the postulated molecule (ii) may, therefore, not be so stable as (i), which is identical with the complex IV (IV in Fig. 4), even though the amide moiety takes a stable *trans* configuration. The interaction between the electron-deficient α-carbon atom of acetaldehyde and the electron-rich nitrogen atom of the amide moiety can be expected. The subsequent configurational change of the amide moiety from *trans* to *cis* is required to make the interaction possible. This is shown by the postulated molecule (i) in Fig. 6. An additional rotation about the Al-O bond (Fig. 6 (ii)) is necessary to strengthen the interaction. Another rotation about the O-C bond (Fig. 6 (iii)) completes the formation of a half of the complex II (Fig. 6 (iv)). The present complex, (II) is then formed by the association of these two halves.

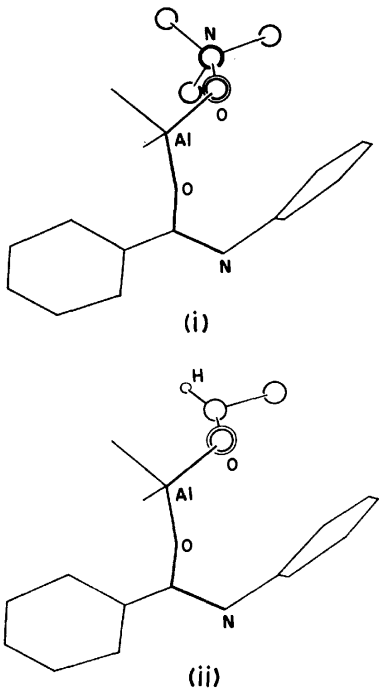

Fig. 5. The comparison of the molecular structure of [Me_2Al·O·CPh: NPh, $ONMe_3$] (i) and a postulated molecule [Me_2Al·O·CPh: NPh, MeCHO] (ii).

The molecular-structural change in the reaction of the complex II with $ONMe_3$ (Fig. 4) can also be discussed in a similar manner, but in the reverse direction. The stronger Lewis base $ONMe_3$ attacks and replaces the aldehyde moiety of a half of the dissociated complex II to form the complex IV.

The α-carbon atom of the acetaldehyde moiety in the complex II is an asymmetric carbon. Since the molecule has a crystallographic C_2-2 symmetry, there are two asymmetric carbon atoms of the same configuration in a molecule. The space group belongs to a centrosymmetric *Pcca*, and there are an equal number of optical isomers in the crystal. The absolute configuration of these asymmetric carbon is, therefore, S–S or R–R. A hypothetical molecule, which has a C_i-$\bar{1}$ symmetry instead of C_2-2, is shown in Fig. 7; the absolute configuration of the asymmetric carbon atoms is S–R or R–S. In the postulated molecule, if the geometry around the aluminum atom is kept significantly unchanged from that of the actual molecule, a rather short contact C(2)···C(17′), 3.3 Å, results between the two methyl groups in a molecule (one attached to the aluminum atom and the other from the aldehyde moiety). Such a steric hindrance probably make it difficult for the molecule of C_i-$\bar{1}$ symmetry to exist or at least makes the molecule unstable.

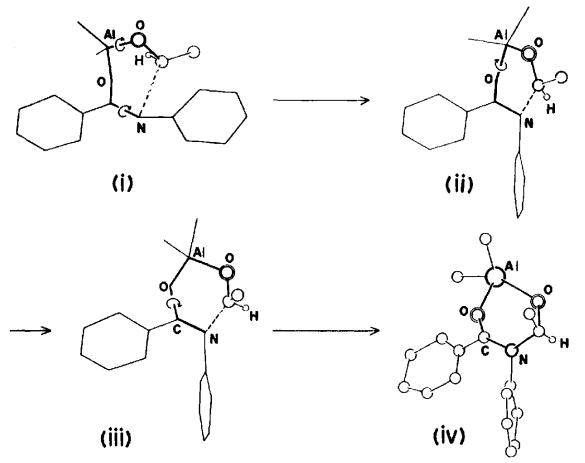

Fig. 6. Schematic representation of a conversion of the postulated molecule, [Me_2Al·O·CPh: NPh, MeCHO] into the real structure, which is a half of the [Me_2Al·O·CPh: NPh, $MeCHO]_2$ molecule.

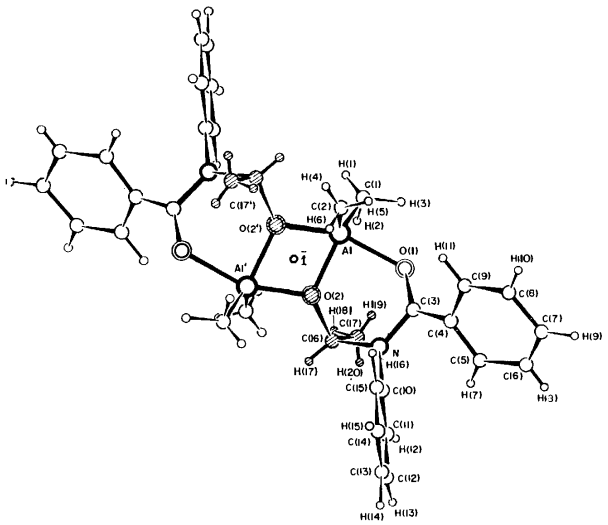

Fig. 7. A hypothetical molecule for [Me_2Al·O·CPh: NPh, $MeCHO]_2$ with C_i-$\bar{1}$ symmetry instead of C_2-2.

The authors wish to express their deep thanks to Professor Hisaya Tani and Dr. Hajime Yasuda of Osaka University for their kindness in supplying samples and for their helpful discussions.

The Crystal Structure of the Polymerization Catalyst of Acetaldehyde and Its Derivatives. IV. The Crystal and Molecular Structure of Dimethylaluminum *N*-Phenylbenzimidate-*O*-(Trimethylaluminum)-Acetaldehyde Complex, $[(CH_3)_2Al\cdot O\cdot C(C_6H_5):N(C_6H_5), CH_3CHO, Al(CH_3)_3]$

(Received May 13, 1972)

The molecular structure of a stereospecific (*isotactic*) polymerization catalyst of the acetaldehyde-monomer-Lewis acid complex, $[Me_2Al\cdot O\cdot CPh: NPh,MeCHO,AlMe_3]$, has been determined from three-dimensional X-ray-diffraction data collected photographically. The crystal belongs to the monoclinic system (space group $P2_1/n$), with four formula units in a cell with dimensions of: $a=13.60(3)$, $b=13.74(2)$, $c=12.40(2)$ Å, $\beta=95.9(2)°$. The structure was solved by the heavy-atom method and was refined by the block-diagonal, least-squares procedure. The trimethylaluminum forms a bond with the electron-rich oxygen atom of acetaldehyde through the electron-deficient aluminum atom. The polymerization mechanism can reasonably be concluded to be the "co-ordinated cationic polymerization".

During the organochemical investigations of the stereospecific polymerization catalysis of aldehydes, Tani and his co-workers prepared many interesting substances and isolated them in the form of crystals.[1-4] The catalytic system of trialkylaluminum-acid amide gave highly stereospecific polyaldehydes almost quantitatively. The reaction with this catalytic system is mild and has few accompanied side reactions. Therefore, the exact structure determinations of the key substances may reveal much important information about the stereospecific polymerization mechanism. Four compounds were chosen as the key substances in the trimethylaluminum-benzanilide catalyst system; (I) the polymerization catalyst $[Me_2Al\cdot O\cdot CPh: NPh]_2$, (II) the catalyst-monomer complex $[Me_2Al\cdot O\cdot CPh: NPh,MeCHO]_2$, (III) the catalyst-monomer-Lewis acid complex $[Me_2Al\cdot O\cdot CPh: NPh,MeCHO,AlMe_3]$, and (IV) the catalyst-Lewis base complex $[Me_2Al\cdot O\cdot CPh: NPh,ONMe_3]$. Among these, the molecular structures of I, II, and IV were already reported in detail.[5-7] The complex III, the last one in this series, which is prepared by the equimolar reaction of II and trimethylaluminum in *n*-hexane at 0°C, acts also as the polymerization catalyst of aldehydes, but gives an *atactic* polymer. In this article we will describe the molecular and crystal structure of III. The preliminary results of the structural analysis were communicated earlier.[8] The polymerization mechanism of acetaldehyde has been investigated from the stereochemical point of view on the basis of the molecular structures of these four key substances, together with the organochemical information.

Experimental

The crystals of $[Me_2Al\cdot O\cdot CPh:NPh, MeCHO, AlMe_3]$ were prepared and supplied by Tani snd Yasuda of this University. The compound is very air-sensitive, and the crystal was sealed in a thin-walled glass capillary tube in argon. Two kinds of crystals with different habits were obtained. One of them grows along the *a* axis, and the other, along the *b* axis. Both are colorless, long, and prismatic. The latter crystal examined always had a twinned structure. Figure 1 shows the twinning in the $h0l$ reciprocal lattice plane. The subscript I or II shows to which component each unit cell belongs. The planes containing the $b^*(=b)$ axis and the reciprocal lattice point rows, $h0\bar{h}_I$ and $h0\bar{h}_{II}$, are the twin planes. If the $h0\bar{h}_I$ is taken as c^*_I and the $h0\bar{h}_{II}$ as c^*_{II}, the space group and the twin plane can be described as $P2_1/c$ and the b^*-c^* plane respectively: the same kind of twinning

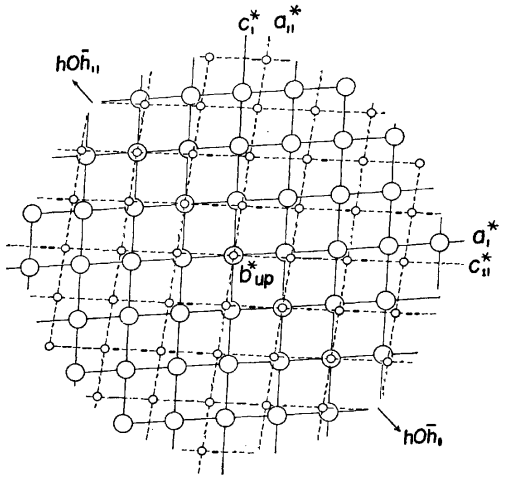

Fig. 1. One reciprocal lattice plane in the twinning crystal of $[Me_2Al\cdot O\cdot CPh: NPh,MeCHO,AlMe_3]$.

is found in $[Me_2Al\cdot O\cdot CPh: NPh]_2$.[5] The cell dimensions were determined by a least-squares fitting using the theta values obtained from $0kl$ and $h0l$ Weissenberg photographs. The space group was uniquely determined as $P2_1/n$ from the systematic absence of reflections ($h0l$: $h+l\neq 2n$, and $0k0$: $k\neq 2n$). The crystal data are listed in Table 1. The nickel-filtered Cu$K\alpha$ radiation ($\lambda=1.5418$ Å) was used throughout the X-ray experiments. The crystal density was measured by the flotation method in a mixed solution of carbon tetrachloride and *n*-hexane.

TABLE 1. CRYSTAL DATA OF $[(CH_3)_2Al\cdot O\cdot C(C_6H_5): N(C_6H_5), CH_3CHO, Al(CH_3)_3]$

Monoclinic	$C_{20}H_{29}O_2NAl_2$
$a=13.60(3)$ Å	$M=369.4$
$b=13.74(2)$ Å	$Z=4$
$c=12.40(2)$ Å	$d_m=1.07$ g·cm^{-3}
$\beta=95.9(2)°$	$d_x=1.064$ g·cm^{-3}
$V=2304.8$ Å^3	Space group $P2_1/n$
	$\mu=13.0$cm^{-1}(for Cu$K\alpha$)

The intensity data were collected by multiple-film equi-inclination Weissenberg photographs along the *a* axis only. The intensities were measured visually, and were corrected for the usual Lorentz and polarization factors, as well as for the spot-shape effect. Two independent crystals of a similar size (about $1.0\times 0.3\times 0.3$ mm) were used. In the layers from $0kl$ through $9kl$, 2891 independent reflections were observed, among which 2336 were non-zero reflections. The interlayer scales were first set proportional to the exposure times and improved in the course of the least-squares refinements with isotropic temperature factors for nonhydrogen atoms.

Structure Determination and Refinement

The structure was established by the heavy-atom method. From a Patterson map, two independent aluminum atoms were easily located. Two successive Fourier maps gave the locations of all the nonhydrogen atoms. The refinement of the structure was done by the method of block-diagonal least-squares. Computations were carried out using the HBLS IV program[9] on a FACOM 230-60 computer at Kyoto University. The function minimized was $\sum w(\Delta F)^2$, and at the intial stage w was taken as unity for all the reflections. The atomic scattering factors used were taken from those of Hanson and his co-workers.[10] Three cycles of the refinement with isotropic temperature factors for non-hydrogen atoms gave the R index of 0.18. Interlayer scales were improved during this refinement and then fixed. Further refinement was followed with anisotropic temperature factors for heavy atoms, and a weighting scheme to be described later was applied. After 2 cycles, the R index was 0.15. At this stage, a difference Fourier synthesis was computed and all the

9) Most of the programs used in the calculations were taken from "The Universal Crystallographic Computing System (I), edited by T. Sakurai, Japanese Crystallographic Association, 1967," and the other programs were cited in our previous paper.[7]

hydrogen atoms were located. By including these hydrogen atoms with the isotropic temperature factors, the refinement was done and the R index was reduced to 0.13 after 2 cycles. The difference Fourier map was again computed to obtain improved hydrogen locations. The final refinement gave an R index of 0.124 for non-zero reflections and one of 0.16 for all the reflections. The weighting scheme applied was; $|F_o|<F_{min}$; $w=F_{wt}$, $F_{min}\leqq|F_o|\leqq F_{max}$; $w=1.0$, and $F_{max}<|F_o|$; $w=(F_{max}/|F_o|)^2$, where F_{min}, F_{max}, and F_{wt} were, each changed during the refinements to balance the $\sum w(\Delta F)^2$ over the whole range of $|F_o|$ and $(\sin\theta)/\lambda$. Those values applied at the final refinement were $F_{min}=2.57$, $F_{max}=12.85$, and $F_{wt}=0.15$ respectively.

The final atomic co-ordinates of the heavy atoms, and their estimated standard deviations and the anisotropic temperature factors, are listed in Tables 2 and 3 respectively. The atomic co-ordinates and the isotropic temperature factors of the hydrogen atoms are listed in Table 4. The observed and calculated structure factors are given in Table 5.[11]

11) Table 5 has been submitted to, and is kept as Document No. 7211 by, the office of the Chemical Society of Japan, 1-5 Kanda Surugadai, Chiyoda-ku, Tokyo. A copy may be secured by citing the Document number and by remitting, in advance, ¥ 300 for photo prints. Pay by check or money order payable to: Chemical Society of Japan.

Results and Discussion

Molecular Structure. Figure 2 shows the molecular structure projected along the *a* axis. The seven atoms of the acetaldehyde moiety are shown as hatched circles. The bond distances and angles were calculated using the DAPH program;[9] they are listed in Tables 6 and 7 respectively.

The trimethylaluminum connects with [$Me_2Al\cdot O\cdot CPh{:}NPh$,MeCHO], one half of the polymerization catalyst-monomer complex, by co-ordination between

the electron-deficient aluminum atom and the electron-rich oxygen atom of the acetaldehyde moiety. In the molecular structure of [dioxane, $(AlMe_3)_2$], a similar co-ordination of $AlMe_3$ to the oxygen atom is found.[12] The Al(2)-O(2) distance of 1.928(6) Å is shorter than the corresponding distance of 2.02(2) Å in [dioxane, $(AlMe_3)_2$]. The geometry of the Al(2) atom is a slightly distorted tetrahedron. The average value of the O(2)-Al(2)-C(methyl) angles of 103.8(0.5)° is a little smaller than that of C(methyl)-Al(2)-C(methyl), 114.5(0.6)°. The average bond distance between Al(2) and three methyl carbons is 1.977(14) Å. The Al(1) atom has a much more distorted tetrahedral geometry than Al(2). The maximum and minimum bond angles around the Al(1) atom are 121.6(0.6)° of C(1)-Al(1)-C(2) and 94.1(0.3)° of O(1)-Al(1)-O(2) respectively.

The molecular structure of this compound, except for the trimethylaluminum moiety, is very similar to that of one-half of the polymerization catalyst-monomer complex II. Table 8 compares the selected interatomic bond distances and angles in the present complex, [$Me_2Al\cdot O\cdot CPh:NPh$,MeCHO,$AlMe_3$] (III), with those of the corresponding parts in [$Me_2Al\cdot O\cdot CPh:NPh$,MeCHO]$_2$ (II). In Fig. 3 are compared the molecular structures of II and III projected onto the O-C-N plane of the amide moiety, which is present in both complexes. The numbers in brackets show the deviations of each atom from the O-C-N plane (in Å units).

The Al(1)-O(1) distance in II is much longer than that in III. This may be due to the difference in the co-ordination geometries of aluminum atoms. In the complex II the aluminum atom is penta-co-ordinated, it has a trigonal-bipyramidal geometry, and the oxygen atom of the amide moiety, O(1), occupies the apical position. The Al(1)-O(2) bond distances, on the contrary, show a good agreement in these two compounds. The C-O bond distance in the co-ordinated aldehyde moiety in III, C(16)-O(2)=1.378(11) Å, is a little shorter than the normal C-O single bond distance, though not significantly so. The C(16)-C(17) (1.523 (15) Å) and N-C(16) (1.489(11) Å) distances agree well with the respective expected single-bond distances.

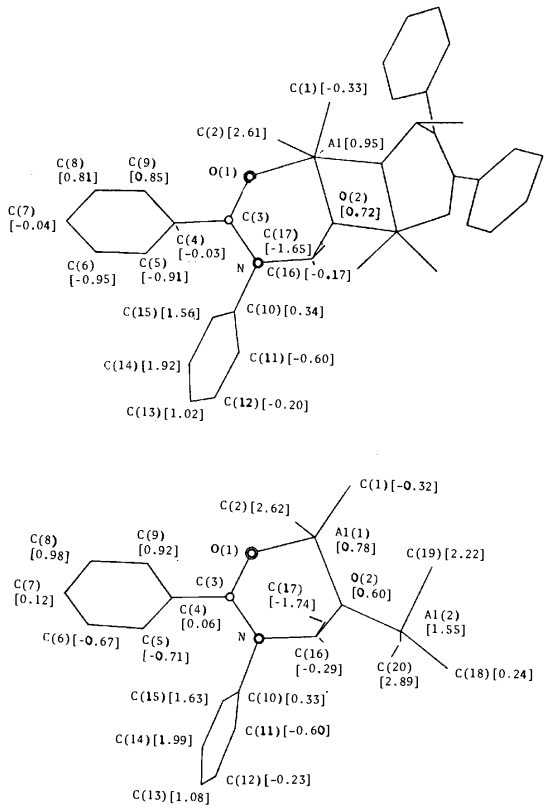

Fig. 3. Comparison of the molecular structure of [$Me_2Al \cdot O \cdot CPh:NPh$,MeCHO]$_2$ (*top*) and [$Me_2Al \cdot O \cdot CPh:NPh$, MeCHO,$AlMe_3$] (*bottom*). Both are projected onto the plane of the -O-C-N- skeletons which are contained commonly in both molecules. Deviations from the plane (in Å) are given in brackets.

The two adjacent benzene rings in the amide moiety in III have a *cis* configuration, and the internal rotation angle around the C(3)–N bond is 12.7°. The dihedral angle between the best planes of these rings is 67.4°.

Crystal Structure. Figure 4 shows the molecular packing in the unit cell. The intermolecular atomic contacts shorter than 3.8 Å are shown by the broken lines. These are the usual van der Waals' contact distances.

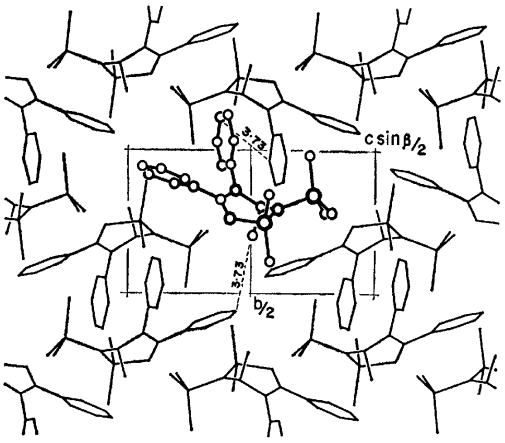

Fig. 4. Crystal structure viewed along the *a* axis.

Polymerization Mechanism in This Catalytic System

In the catalytic system of the highly stereospecific polymerization of acetaldehyde, we have previously undertaken the X-ray structure analysis of the following four key substances in an attempt to clarify the reaction mechanism. They are;

(I) [$Me_2Al \cdot O \cdot CPh:NPh]_2$

(II) [$Me_2Al \cdot O \cdot CPh:NPh$, $MeCHO]_2$

(III) [$Me_2Al \cdot O \cdot CPh:NPh$, MeCHO, $AlMe_3$]

(IV) [$Me_2Al \cdot O \cdot CPh:NPh$, $ONMe_3$]

The molecular geometries of these four complexes and the organochemical backgrounds have already been reported.[1-8] Figure 5 shows the molecular structures of these complexes viewed along arbitrary orientations, for an easy understanding of them (the numbers from I to IV correspond to the above complexes).

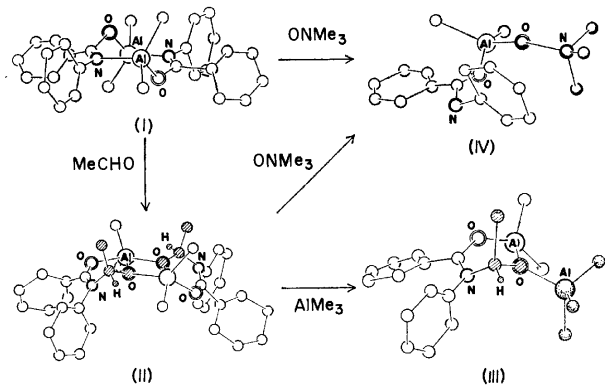

Fig. 5. Moleculer structures and their reactions of four key substances in the catalytic system of trimethylaluminum-benzanilide.

The dimeric catalyst I takes an imino-ether-type structure: a centro-symmetrical eight-membered ring is composed of the -O-C-N- bridges of amide moieties between two aluminum atoms. The complex IV is monomeric and *catalytically inactive.* The Al-O-C-N moiety takes the same configuration as the monomeric unit of the catalyst I, except that two benzene rings adopt a *trans* configuration.

The catalyst-monomer complex II has a dimeric structure related by the two-fold axis. The aldehyde moiety is maintained by the catalyst at the sites of both oxygen and α-carbon atoms. The oxygen atom co-ordinates to the two aluminum atoms, and the α-carbon atom bonds to the nitrogen of the amide moiety. However, the Al-O-C-N moiety takes a different configuration from that in I or IV. In the structure of III, the configuration of the monomeric unit of II is exactly maintained. The typical Lewis acid, $AlMe_3$, attacks and co-ordinates to the aldehyde oxygen atom, but not to the amide oxygen. This suggests that the aldehyde oxygen atom is more active than the amide oxygen in response to the attack of the electrophilic reagent.

Besides the above-mentioned molecular geometries, much chemical evidence has been accumulated.[1-4]

They are: (a) both catalysts, I and II, lose their activities when they are absolutely dried; a small amount of water behaves as the co-catalyst in this system, and both the yield of polymer and the stereospecificity of the polymerization reach their maxima at the optimum water concentration (1/30 mole per mole of the catalyst I, *i.e.*, *ca.* 1×10^{-4} mol% of the aldehyde); and (b) the polymerization is hindered by the existence of the strong electron donor. These two facts show that the polymerization system belongs to the cationic type; we will call the present polymerization the "co-ordinated cationic polymerization". Other important evidences are: (c) the aldehyde moiety of II can be easily replaced by a free aldehyde present in the solution; and (d) the water which is a co-catalyst in this system does not affect the exchange reaction of aldehyde.

In the reaction from I to II, we can postulate the following steps: (1) the fission of the Al–N bond in I induced by the co-ordination of the acetaldehyde to the aluminum atom by its oxygen, as in the co-ordination of $ONMe_3$ in IV; (2) the formation of an imino-ether-type intermediate, in which two benzene rings take a stable *trans* configuration; (3) bond formation between the nitrogen atom (in amide) and α-carbon (in aldehyde), followed by the configurational change of benzene rings from *trans* to *cis*, and (4) dimeric association. The association reaction is placed last because the cryoscopic measurement of the molecular weight of II shows the compound is likely to be monomeric in such a dilute solution as in the present polymerization conditions; this may be supposed on the basis of the long Al–O (aldehyde oxygen) distance of 1.985(6) Å. The formation of the monomeric complex III also supports the dissociation of the II in the dilute solution. The configurational change from (1) to (4) was examined by using a molecular model reported elsewhere.[7]

From the knowledge of the molecular structures given by the chemical evidence, a plausible mechanism of *isotactic* polymerization is proposed; it is shown in Fig. 6 (Schemes V to VII).

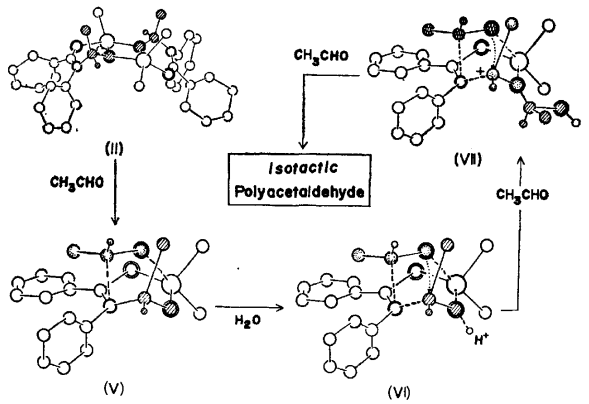

Fig. 6. Proposed mechanism for stereospecific polymerization of acetaldehyde.

The scheme V is constructed as an intermediate complex both for the aldehyde exchange reaction and for the initiation of the polymerization reaction. The broken lines show the postulated weak bonds caused by the co-ordination of the aldehyde. Model examination shows that the steric hindrance gives little possibility of taking a co-ordination other than that drawn in the scheme V. This fact probably contributes to the stereospecificity of the polymerization. In the exchange reaction, the aldehyde moiety in the catalyst is replaced by the weakly co-ordinated second aldehyde and there is no further change.

In the polymerization initiation, the formation of a chemical bond takes place between these two aldehyde molecules. This case is shown in scheme VI. First, a proton (probably from the water, the co-catalyst) attacks the oxygen atom of the initially-co-ordinated aldehyde, as the trimethylaluminum attacks the corresponding aldehyde oxygen in II. Then the cationic character of the proton transfers to the oxygen to form an oxonium cation, which weakens the co-ordination bond between the oxygen and aluminum atoms. After that, the cationic character moves to the α-carbon atom and generates a carbonium cation, which increases the affinity to the oxygen atom of the secondary co-ordinated aldehyde and at the same time weakens the bonding to the nitrogen atom. The secondary co-ordinated aldehyde now adds to the initially-co-ordinated one, and the aldehyde dimer thus formed replaces the initially co-ordinated aldehyde. The replacement is accompanied by the stimulation of the co-ordination of a new, third aldehyde. This is shown in scheme VII. The new aldehyde adds to the dimer, and the newly-formed trimer replaces the dimer in its co-ordination. The succession of these reactions produces the linear *isotactic* polymer of acetaldehyde.

As has been reported, the polymerization of acetaldehyde by the catalysis of complex III gives an *atactic* polymer. This fact can be explained by the dissociation of trimethylaluminum from III. The trimethylaluminum itself also acts as a polymerization catalyst and gives an *atactic* polyaldehyde under the conditions of the polymerization reaction by the complex III.[4] The polymerization reaction by the I or II catalyst is very mild compared with the reaction by the trimethylaluminum itself. Therefore, if the complex III is placed under the polymerization conditions, the dissociation of trimethylaluminum from this complex occurs. The dissociated trimethylaluminum acts predominantly as a polymerization catalyst and gives an *atactic* polymer.

The authors wish to express their deep thanks to Professor Hisaya Tani and Dr. Hajime Yasuda of Osaka University for their kindness in supplying the samples and for many their helpful discussion.

Measurements of Acid-strength Distribution beyond $H_0=-8.2$ of Sillca-Alumina Catalysts by UV-Spectrophotometric *n*-Butylamine Titration Method[1)]

Jun-ichiro TAKE, Tetsuo TSURUYA,[2)] Tetsuo SATO,[3)] and Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 29, 1972)

A new UV-spectrophotometric *n*-butylamine titration method was proposed for measuring acid-strength distribution of acid sites on solid acid catalysts. The method can provide information on acid-strength distribution of acid sites beyond $H_0=-8.2$, which can not be obtained by the conventional visual *n*-butylamine titration method. Acid-strength distributions were measured for a series of silica-alimina catalysts differing in sodium content, using 4-benzeneazodiphenylamine ($pK_a=1.5$), *trans*-benzalacetophenone ($pK_a=-5.6$), 4-nitrotoluene ($pK_a=-10.5$), and 2,4-dinitrotoluene ($pK_a=-12.8$) as indicators. The results revealed that about one-half of the acid sites on an unpoisoned silica-alumina catalyst lay in the H_0 region from -10.5 to -12.8, and the strongest ones in the H_0 region beyond -12.8. The strong acid sites were eliminated with the modification of acid-strength distribution as the catalyst was poisoned with sodium ions. UV spectra of the above indicators in adsorbed state were discussed.

Various methods have been developed for the measurement of acid-strength distributions of solid surfaces. The method frequently referred to as the Benesi or *n*-butylamine titration method[4,5)] has been widely employed. In this method, solids suspended in a nonpolar solvent such as benzene are titrated with *n*-butylamine and a series of visible H_0 indicators, the end-point being determined by the naked eye. Benesi[5)] revealed, using this method, that most of the acid sites on silica-alumina lay in the region $H_0 \leq -8.2$. Information on acid-strength distributions in this region is indispensable for the study of solid acid catalysis. No such information, however, can be provided by the conventional *n*-butylamine titration method, since anthraquinone is the least basic ($pK_a=-8.2$) of well-known visible H_0 indicators. Available H_0 indicators having a pK_a lower than -8.2 change color in the ultraviolet region, and thus UV-spectrophotometric titration becomes essential. Moreover, such titration is superior to the conventional method by the naked eye in determining the end-point.

From the viewpoint of homogeneity of acid sites in acid strength, Kobayashi[6)] has recently analyzed the data on silica-alumina that were obtained by UV-spectrophotometric titration using visible dimethyl yellow ($pK_a=3.3$) or methyl red ($pK_a=4.8$) as an indicator. Durshel and Sommers[7)] showed ultraviolet and visible absorption spectra of several visible H_0 indicators in adsorbed state in order to examine their suitability for the conventional titration of surface acidity.

We have applied UV-spectrophotometry to the conventional method using 4-benzeneazodiphenylamine, the use of which was recommended by Drushel and Sommers.[7)] The method was then extended to titration using other indicators, especially 4-nitrotoluene ($pK_a=-10.5$) and 2,4-dinitrotoluene ($pK_a=-12.8$), both of which respond to very strong acid sites with color change in the ultraviolet region. The use of these indicators furnished new information on acid-strength distributions in the H_0 region beyond -8.2 of acid sites on silica-alumina catalysts.

Experimental

Materials. The silica-alumina catalysts listed in Table 1 were taken from batches used in previous studies,[8)] and were calcined at 550°C for 8 hr in atmosphere. Silica gel (WAKOGEL Q-12 for chromatography) was also used. The indicators, 4-benzeneazodiphenylamine (BADA), *trans*-benzalacetophenone (BAP), 4-nitrotoluene (NT), and 2,4-dinitrotoluene (DNT), were of EP or GR grade and were dissolved in decaline after repeated recrystallization. Their pK_a values are 1.5 for BADA, -5.6 for BAP, -10.5 for NT, and -12.8 for DNT.[9)] A 0.1 N decaline solution of *n*-butylamine, purified by distillation, was used as a titrant. Decaline used as a nonpolar solvent was passed through two chromatographic columns containing freshly activated silica gel and alumina[10)] in order to remove water, aromatics and other impurities. The water content was reduced to below 10 ppm.

Titration Procedure. The catalyst sample was activated at 450°C overnight in a vacuum. After ten to twenty 20 m*l* conical flasks with ground glass stoppers had been weighed, roughly one gram of the sample was placed in each in a dry box replaced with dried nitrogen. The tightly stoppered flasks were reweighed, and about 10 m*l* of decaline was then added to each in the dry box. A solution of *n*-butylamine was introduced into the sample slurries so that they differed in amine content. After vigorous shaking, the tightly stoppered sample slurries were placed in a desiccator at 30°C for two days for equilibration, and then an indicator was added to each. They were put to stand in the desiccator for additional three or four days for reaction of the indicator. The result-

a) Measured by the BET method with N_2.

ing sample slurry was transferred to a conventional 10 mm absorption cell with a 9 mm quartz spacer to provide a light-path length of 1 mm.

No indicators were detected in the supernatant layer of decaline. The following amounts of indicators were used: 0.3 for BADA, 1 for BAP, and 1.5 to 2.0 for NT and DNT, in μmol/g-catalyst.

Evaluation of Molar Absorptivities. Ultraviolet and visible absorption spectra were recorded against reference cell containing fresh sample slurries (not treated with amine) on Hitachi Recording Spectrophotometer (Model EPS-2). The molar absorptivity ε of an adsorbed indicator was evaluated by the equation

$$\varepsilon = \frac{Av}{mwl}, \qquad (1)$$

where A is absorbance, v the volume of a sample slurry in an absorption cell (liter), m the amount of an adsorbed indicator (mol/g-catalyst), w the amount of a sample in an absorption cell (g), determined after decaline has been removed by evaporation, l the light-path length (cm).

Results and Discussion

The relevant UV absorption spectra of the indicators are summarized in Table 2.

4-Benzeneazodiphenylamine (BADA). A decaline solution of BADA (yellow) shows absorption at 390 mμ. This is slightly red-shifted (415 mμ) in a polar solvent such as ethanol because of the interaction between indicator and solvent. An absorption band at 535 mμ (purple) in acidified aqueous solution is evidently due to the conjugate acid of BADA. Adsorption of BADA on every fresh silica-alumina catalyst gave a band at 550 mμ alone, in good agreement with the spectrum obtained by Drushel and Sommers,[7] showing that all the adsorbed molecules were in the conjugate-acid form. As the level of neutralization of the surface was raised, the band decreased in intensity with the development of an absorption band near 450 mμ due to the physically adsorbed neutral indicator, and finally only the band near 450 mμ remained. The slight red-shift to 450 mμ from 440 mμ for silica gel seems to be due to a stronger physical adsorption of the indicator. The presence of an isosbestic point was also observed in a series of spectra, each being determined for a catalyst at a different level of neutralization, indicating that none other than the simple acid-base reaction took place on the solid surface.[11] The above behavior is very similar to that observed in a series of aqueous sulfuric acid solutions, each having a different acidity.

TABLE 2. ABSORPTION SPECTRA OF INDICATORS[a]

Indicator	In solution		On solid surface		
	Acidic	Neutral	Fresh SA-1	Neutralized SA-1	Silica gel
BADA	535	415	550	450	440
BAP	320 (w) 400—430 (s)	315	320 (sh) ~400	320	315
NT	380	310	300 (w,sh) 340 (s) ~500 (w)	300	295
DNT	280 (m) 340 (s)	260	260 (s) 320 (sh) ~500 (w)	260	255

a) λ in mμ; (s), strong; (m);, medium (w), weak; (sh), shoulder.

Changes in the level of neutralization of solid surfaces may therefore be followed quantitatively by observing the concentration of BADA adsorbed either in tht conjugate-acid form c_A or in the neutral form c_P. Spectrophotometric determination of the concentration requires data on the following molar absorptivities: (1) ε, the molar absorptivity at a selected wavelength of the adsorbed indicator, generally containing both the conjugate-acid species and the neutral one, (2) ε_A and ε_P, the molar absorptivity at the same wavelength of the pure species adsorbed in the conjugate-acid form and that in the neutral form, respectively. These are connected with c_A or c_P by the equation

$$\frac{c_A}{c_0} = \frac{\varepsilon-\varepsilon_P}{\varepsilon_A-\varepsilon_P} \text{ or } \frac{c_P}{c_0} = \frac{\varepsilon-\varepsilon_A}{\varepsilon_P-\varepsilon_A} \qquad (2)$$

only when $c_A+c_P=c_0$, where c_0 is the total concentration of the adsorbed indicator and can be determined from the amount of addition. Since the relation, $c_A+c_P=c_0$, holds evidently for adsorbed BADA, a titration curve can be obtained by plotting the color change ratio $x_A=c_A/c_0$ or $x_P=c_P/c_0$ of BADA against

the amount of *n*-butylamine added.

The ε values at 550 mμ are given in Table 3, each being for a different level of neutralization of each silica-alumina catalyst. The reproducibility of the ε values is considerably good when it is taken into account that a specimen for spectral measurement is in slurry form.

We see that each fresh catalyst provides the same ε value within experimental error, and also that a few fresh catalysts including SA-1 remain practically unchanged even upon addition of the 0.05 or 0.1 meq/g-catalyst of *n*-butylamine. Thus the ε value for each fresh catalyst can be taken as the ε_A value of the indicator. This is also in line with the fact that a band appears only at 550 mμ on each fresh catalyst. The average ε_A value, $(4.3\pm0.4)\times10^4$, is in accordance with that (3.8×10^4) determined from a linear relationship between the absorbance at 550 mμ of adsorbed BADA and its amount with a thin wafer of SA-1.[12] It is lower than that in an aqueous sulfuric acid solution, 5.88×10^4 at the maximum peak position of 535 mμ, by a factor of about 1.4. A similar observation was reported for dimethyl yellow and methyl red adsorbed on silica-alumina catalyst by Kobayashi.[13] Molar absorptivity ε for each catalyst sufficiently neutralized corresponds to ε_P. It can be neglected since its value is very small compared with the ε_A value.

Titration curves are shown in Fig. 1. In the calculation of the color change ratio, ε for each fresh catalyst was taken as ε_A for the corresponding one. The color change of an indicator is visually observed when the surface concentrations of the neutral and the conjugate-acid species become equal. The point of color change or the end-point therefore corresponds to the intersection of a titration curve with a horizontal line at $x_A=0.5$.

According to Benesi,[5] acid strength of solid surfaces can be expressed with the Hammett and Deyrup H_0 function

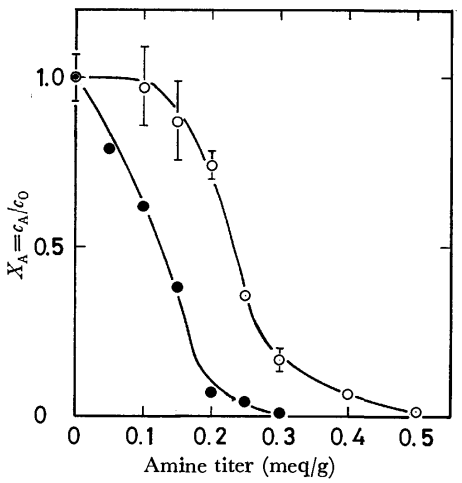

Fig. 1. Titration curves with BADA for SA-1(○) and SA-1-Na-3 (●).

$$H_0 = -\log(a_{H^+}f_B/f_{BH^+}) = pK_a + \log(c_B/c_{BH^+}). \quad (3)$$

The value of abscissa of the intersection therefore gives the amount of acid sites having an H_0 equal to or lower (stronger) than the pK_a of the indicator used. The amount of acid sites so determined for each silica-alumina catalyst is shown in Table 4. The acid content ($H_0\leq1.5$) of SA-1 decreases to about two-thirds of its original value on treatment with aqueous sodium hydroxide solution, but those for the set of the SA-1-Na and SA-Na catalysts scarcely differ from each other.

a) Quantity in parentheses is the relative deviation. b) Number of separate spectral measurements.

Thus UV-spectrophotometric titration is useful for measuring an acid-strength distribution of acid sites on catalyst surfaces.

trans-*Benzalacetophenone (BAP).* A protonated BAP molecule in a concentrated sulfuric acid solution exhibits a strong band at 400—430 mμ depending upon acidity of the solution and a weak one near 320 mμ, as shown by Noyce and Jorgenson.[14] The former decreases in intensity with the development of the latter as acidity of the solution is reduced, and finally disappears.

The spectrum of BAP adsorbed on fresh SA-1, where a strong band near 400 mμ and a weak one near 320 mμ (shoulder) appear, shows that the conjugate-acid species is formed on the fresh surface of SA-1. Recent workers[7] observed that BAP adsorbed on silica-alumina gave a strong band at 390 mμ and a weak one at 310 mμ. They attributed the former mainly to the strongly adsorbed neutral species, presumably, on the basis of the difference between the wavelength of absorption on the silica-alumina (390 mμ) and that in concentrated sulfuric acid solution (430 mμ). Our assignment is also based on the fact that the intensity of the strong band near 400 mμ decreases as *n*-butylamine is added. The spectra in the ultraviolet region below 340 mμ varied in a somewhat complicated manner upon titration. No isosbestic point was observed. This suggests that some reactions besides the simple acid-base reaction take place in the system under investigation. When the complicated behavior of the spectra is ignored, an increase in the extent of neutralization of solid surfaces may be followed by observing a decrease in the intensity of the band near 400 mμ, as was the case in the titration using BADA.

The ε values at 400 mμ are summarized for different levels of neutralization of SA-1 in Table 5, and their variations with fresh catalysts in Table 6. They decrease with increasing amount of *n*-butylamine. Reproducibility is fair but not so good as that for adsorbed BADA. The value for fresh SA-1 does not change upon addition of the 0.05 meq/g-catalyst of *n*-butylamine (Table 5). This is also the case for SA-1-Na-1. The ε values for the fresh catalysts other than SA-Na-HAcO do not differ within experimental error (Table 6). These findings support the conclusion that the ε_A value of BAP corresponds to the ε value for each fresh catalyst except for SA-Na-HAcO. All the ε values for catalysts sufficiently neutralized, on which only the physically adsorbed neutral species is probably present, are very small compared with the ε_A value. Accordingly, in the calculation of the color change ratio, the ε_P was neglected for all the catalysts, and ε for each fresh catalyst was taken as ε_A for the corresponding one, except for SA-Na-HAcO. For the latter, the average ε value for other fresh catalysts, $(11.5 \pm 1.2) \times 10^3$, was taken as the ε_A value. The value is lower than that in an aqueous sulfuric acid solution of $H_0 = -7.3$ by a factor of about 3.4. The decrease in absorption intensity exceeds that observed for BADA.

14) D. S. Noyce and M. J. Jorgensen, *J. Amer. Chem. Soc.*, **84**, 4312 (1962).

Further study has revealed that this remarkable decrease in absorption intensity resulted from contamination with the *cis*-isomer produced by light-induced *trans-cis* isomerization of BAP either in adsorbed state or in solvent, and that the ε_A value of the *trans*-isomer adsorbed on SA-1 corresponded to about 56% of that in a sulfuric acid solution of $H_0=-7.3$.[15] Since the *cis*-isomer is almost as basic as the *trans*-isomer,[14] the use of the spectral data obtained without consideration for contamination with the *cis*-isomer are not likely to lead to a serious error.

A typical titration curve is shown in Fig. 2. Such a curve furnishes the amount of acid sites having an H_0 equal to or lower than -5.6 (Table 4). The acid contents ($H_0 \leq -5.6$) decrease with an increase in sodium content.

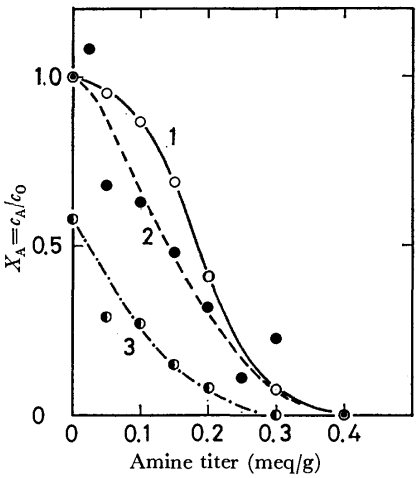

Fig. 2. Titration curves with (1) BAP, (2) NT, and (3) DNT for SA-1.

4-Nitrotoluene (NT). In dilute oleum protonated NT molecules show strong absorption only at 380 mμ. On successive dilution, the band decreases in intensity with the development of a band at 310 mμ due to the solvated neutral molecules, and finally disappears. In the spectrum of NT adsorbed on fresh SA-1, three bands appear near 300, 340, and 500 mμ. In most cases, the band near 300 mμ behaved in a complicated manner upon successive titration: that is, its absorption intensity decreased in an early stage and subsequently increased. On silica gel and silica-alumina catalysts sufficiently neutralized, NT gives only a band at 300 mμ. Thus it is apparent that the physically adsorbed molecules show absorption near 300 mμ, but it is difficult to conclude that the band is due only to the physically adsorbed molecules because of its complicated behavior during the course of titration. On the other hand, the strong band near 340 mμ, with a similar wavelength of absorption to that in acidic solutions, decreased in intensity without exception upon successive titration. This indicates that the band near 340 mμ is due to the species adsorbed in the conjugate-acid form. The very weak band near 500 mμ, which disappears on addition of excess *n*-butylamine, can be attributed to the anion radical of NT.

The absorbance of the band near 340 mμ was determined at 357 mμ, slightly longer than the wavelength of absorption maximum, in order to reduce the contribution from the band around 300 mμ (see Table 5 and 6). The ε value for fresh SA-1 appears to decrease slightly on addition of the 0.05 meq/g-catalyst of *n*-butylamine even when experimental error is considered (Table 5). The ε values for the fresh catalysts vary with catalyst (Table 6), showing that the fresh silica-alumina catalysts differ in their ability to adsorb NT molecules in the conjugate-acid form. Both facts imply that a new criterion is required for the determination of the ε_A value of the indicator.

Neither non-empirical nor empirical methods have been established for the estimation of the molar absorptivity of a certain species in adsorbed state from that in solution. With BADA and BAP, the molar absorptivity of the adsorbed conjugate-acid species has proved to fall to about 70% and to about 56% of that in acidic solution, respectively. If these correlations hold for NT, ε_A will be estimated to be 10.7×10^3 (60%) to 12.5×10^3 (70%) for the adsorbed conjugate-acid species of NT. These values are equal to the ε value observed for fresh SA-1 within experimental error. The assumption may be reasonable in view of the fact that the ε value for fresh SA-1 is substantially constant even on addition of the 0.025 meq/g-catalyst of *n*-butylamine (Table 5). The ε value for fresh SA-1 was therefore taken as the ε_A value for all the silica-alumina catalysts. As the ε_P value for each catalyst, the ε value for the corresponding one neutralized sufficiently with the 0.35—0.4 meq/g-catalyst of *n*-butylamine was taken, since it was not negligible as compared with the ε_A value.

In the calculation of the color change ratio, the complicated behavior of the band near 300 mμ was ignored as in the case of BAP (see Fig. 2 and Table 4). The acid contents ($H_0 \leq -10.5$) decrease with ε for fresh catalyst. The difference of acidity between SA-1-Na-3, SA-Na-HCl, and SA-Na-HAcO may become apparent by using an indicator slightly more basic than NT.

2,4-Dinitrotoluene (DNT). The spectral data in solutions were taken from literature.[16] Protonated DNT absorbs strongly at 340 mμ and moderately near 280 mμ. A band due to strongly solvated neutral DNT appears near 260 mμ. In the spectrum of DNT adsorbed on fresh SA-1, three bands appear: a strong one near 260 mμ, and weak ones near 320 (shoulder) and 500 mμ. On silica gel and SA-1 poisoned sufficiently with *n*-butylamine, DNT shows absorption only near 260 mμ. The intensity of the band near 320 mμ decreased upon successive titration, indicating that it was due to the adsorbed conjugate-acid species, while the band 260 mμ behaved in a similar manner to one near 300 mμ of adsorbed NT. Thus no isosbestic point was observed. The very weak band near 500 mμ can be attributed to the anion radical of DNT.

The absorbance of the band near 320 mμ was deter-

15) Presented at the 19th Annual Meeting of the Chemical Society of Japan, Yokohama, April 1966.

16) J. C. D. Brand, W. C. Horing, and M. B. Thornley, *J. Chem. Soc.*, **1952**, 1374.

mined at 340 mμ in order to reduce the contribution from the band near 260 mμ (see Tables 5 and 6). We see from these tables that an assumption is required for the calculation of the color change ratio of DNT as in the case of NT. The ε_A value for each catalyst was estimated to be 8.2×10^3, which corresponded to 60% of the value in oleum (1.37×10^4),[16] according to the criterion used for NT. The ε value for each catalyst sufficiently neutralized was taken as the ε_P value for the corresponding one (see Fig. 2 and Table 4).

Acid-strength Distribution. The acid strength distributions of acid sites on all of the silica-alumina catalysts are shown in Table 7. They are obtained from Table 4 as the difference of acid contents with two adjacent indicators.

TABLE 7. ACID-STRENGTH DISTRIBUTION[a),17]

Catalyst	H_0			
	1.5 to −5.6	−5.6 to −10.5	−10.5 to −12.8	≤−12.8
SA-1	0.05	0.05	0.11	0.02
SA-1-Na-1	0.04	0.09	0.03	0
SA-1-Na-2	0.05	0.09	0.01_5	0
SA-1-Na-3	0.04_5	0.08	0	0
SA-Na-HCl	0.05	0.10	0	0
SA-Na-HAcO	0.11	0.07	0	0

a) In meq/g catalyst.

The original unpoisoned silica-alumina catalyst SA-1 has the largest amount of strong acid sites ($-12.8< H_0\leq-10.5$) along with relatively small amounts of the strongest ones ($H_0\leq-12.8$), moderately strong ones ($-10.5<H_0\leq-5.6$), and weak ones ($-5.6<H_0\leq1.5$). This is qualitatively in line with the results of Benesi,[5] who found that the strength of most acid sites on synthetic silica-alumina lies beyond an H_0 of −8.2. Apparently strong acid sites ($H_0\leq-10.5$) on SA-1 are eliminated as it is poisoned with sodium ions. The effect of alkali-treatment on surface acidity, however, is not a mere disappearance of acid sites but a modification of acid-strength distribution where strong acid sites are eliminated and replaced in some manner with sites of lower acid strength. A similar effect was found for more severely alkali-poisoned silica-alumina by Hirschler[18] using H_R indicators.

Anion Radicals. Reducing ability of alumina and silica-alumina catalysts has recently been demonstrated with tetracyanoethylene[19] and various aromatic nitrocompounds.[20] For example, the latter compounds formed stable anion radicals on these catalysts, giving a three-line ESR spectrum insensitive to molecular oxygen. Adsorption of NT and DNT on fresh SA-1 gave ESR spectra (g value=2.004) similar to that of the adsorbed trinitrobenzene anion radical[20] and insensitive to molecular oxygen. This indicates that stable NT anion radical is formed on the catalyst surface. There seems to be no publication on UV spectra of NT anion radical. Comparison of the UV and ESR data on two different kinds of "free radicals" produced from NT in strongly basic solution[21] with another publication on ESR data[22] shows that one absorption at 538 mμ may be due to the anion radical (the other, 517 mμ). In the light of this and the fact that the surface of alumina became reddish-purple when it adsorbed trinitrobenzene,[20] the very weak bands near 500 mμ for NT and DNT (Table 2) can be attributed to their anion radicals. Accordingly, the wavelength employed for analysis of adsorbed NT or DNT is free from the band due to its anion radical. The concentration of reducing sites on the surface of SA-1 with alumina content of 13% is estimated to be 1×10^{-5} meq/g-catalyst from literature,[20] corresponding to about 1% of that of NT or DNT added. It is therefore concluded that the material balance, $c_A+c_P=c_0$, for each indicator is hardly affected by ignoring the formation of its anion radical. This is also given at least qualitative support by the fact that a reduction of absorptivity observed for the adsorbed conjugate-acid species of NT is not unusual.

The authors thank Dr. Y. Saito and Dr. H. Arai for their helpful discussions.

Topological Index and Thermodynamic Properties. I. Empirical Rules on the Boiling Point of Saturated Hydrocarbons

Haruo HOSOYA, Keiko KAWASAKI,* and Kimiko MIZUTANI**
Department of Chemistry, Ochanomizu University, Bunkyo-ku, Tokyo
(Received June 10, 1972)

Empirical relations are proposed for the boiling point (bp) and the topological index (Z_G) of a saturated hydrocarbon as

$bp = a \log Z_G + b$

or $bp = (a \log Z_G + c)/\sqrt{N} + b$,

where N is the number of the carbon atoms. A number of compounds with or without ring(s) are plotted for these relations. Correlation is generally better for cyclic compounds than for chain compounds. Sterically hindered paraffins deviate appreciably. Several empirical rules on the isomeric lowering of the boiling point of saturated hydrocarbons are presented and most of them are shown to be consistent with the above relations. Several empirical formulae for the boiling point of normal paraffins are compared and discussed.

Topological index Z_G has been defined for a non-directed graph G, or the carbon atom sekeleton of a saturated hydrocarbon.[1-3] In relation to the mathematical treatment on Z_G many interesting properties were found. A graphical method for enumerating the coefficients of the characteristic or secular polynomial of the Hückel molecular orbital was proposed.[4] It was also pointed out that Z_G is correlated well with several of the thermodynamic quantities of molecules such as the boiling point.[1]

In this paper relations between the topological index and the boiling point of saturated hydrocarbons are analyzed in detail and several empirical rules on the boiling point are presented and discussed.

Topological Index

The definition and enumerating method of the topological index are summarized below.[1-4]

A non-adjacent number $p(G,k)$ for graph G is the number of ways in which such k bonds are so chosen from G that no two of them are connected, $p(G,0)$ being unity and $p(G,1)$ the number of bonds.

The topological index Z_G for G is defined as the sum of $p(G,k)$'s,

$$Z_G = \sum_{k=0}^{m} p(G, k). \quad (1)$$

For example Z_G's for the two graphs I and II are obtained as follows:[5]

$$Z_I = 1 + 6 + 8 + 2 = 17$$
$$Z_{II} = 1 + 6 + 5 = 12.$$

For larger graphs Z_G can be obtained using either

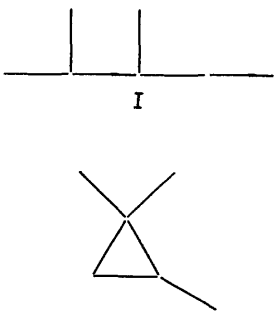

Chart 1

of the two composition principles, CPI and CPII. With the notations adopted in Fig. 1 we have

$$\text{CPI: } Z_G = Z_L Z_M + Z_A Z_B Z_C Z_D Z_E Z_F \quad (2)$$

$$\text{CPII: } Z_G = Z_A Z_B Z_C Z_M + Z_D Z_E Z_F Z_L - Z_A Z_B Z_C Z_D Z_E Z_F \quad (3)$$

Application of CPI and CPII, respectively, to graphs I and II is illustrated in Fig. 2.

Tables of the $p(G,k)$ numbers and Z_G values for smaller tree graphs and non-tree graphs are respectively given in Refs. 2 and 3.

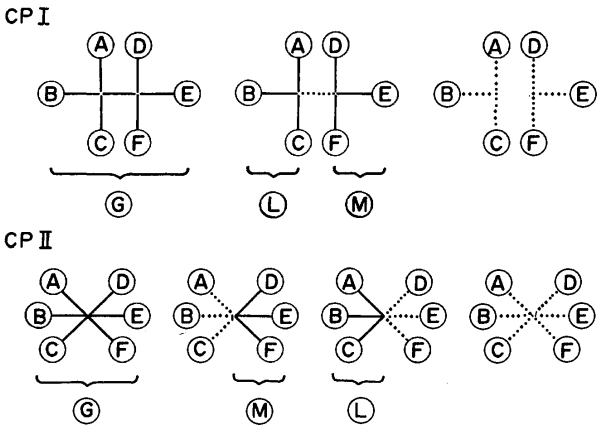

Fig. 1. Illustration for the two composition principles. A, B,···F, L, and M are subgraphs of graph G. Cutting of a bond is represented by a dotted line.

Note the shift in the ordinate. The numbers in circles represent the numbers of rings. The small numbers 1, 2, and 3 are referred to the text.

General Aspects of Correlation

Figure 3 gives plots of the boiling points against $\log Z_G$ for chain, monocyclic, bicyclic, and tricyclic saturated hydrocarbons. The boiling point data were taken from the API report[6] and supplemented by the Beilstein Handbuch.[7] There exist serveral geometrical isomers which can not be discriminated by the topological index, *e.g.*, 1,*cis*- and 1,*trans*-2-dimethylcyclopropanes. An averaged value is plotted for a group of such isomers.

Although there are observed several scattered points,[8] the boiling point for a series of compounds with similar structures rises roughly linear to $\log Z_G$, namely,

$$bp = a \log Z_G + b. \quad (4)$$

For all the groups of compounds studied, the slope a is almost the same and the value b decreases with an increase in the number of rings. In other words, if two saturated hydrocarbons with the same Z_G value but with different numbers of rings are compared, the more the rings the lower the boiling point.

Strictly speaking, the slope a slowly decreases with $\log Z_G$ and the plots can be straightened up by taking $\log(Z_G-3)$ as the abscissa. However, it must be emphasized here that, contrary to the attempts by many authors,[10-13] our standpoint is not to find out the best-fit empirical formula but to understand the topological aspects of the boiling point with as few parameters as possible. Further, it may be noted that several thermodynamic quantities such as critical temperature, heat of vaporization, absolute entropy, vapor pressures at various temperatures are also correlated with the topology of a molecule,[14] and that the boiling point is chosen here as the most typical of them.

Let us see the relation (4) in more detail. The plot bp—$\log Z_G$ for the chain isomers C_7H_{16} and the plot

bp—Z_G for the monocyclic isomers C_6H_{12} are shown, respectively, in Figs. 4 and 5. The boiling points are fairly well correlated with Z_G or log Z_G both for chain and cyclic compounds. This is the case for other lower members of hydrocarbons. However, as molecules become larger the plots for chain compounds are getting scattered as seen in Fig. 3. Most points deviating appreciably are those of sterically crowded compounds such as 2,2,3,3-tetramethylbutane (marked with 1 in Fig. 3), 2,2,3,3-tetramethylpentane (2) and 2,2,3,3,4-pentamethylpentane (3).

On the other hand, for higher members of cyclic compounds the correlation is as good as the smaller molecules. Surprisingly, the plots for the known family of cyclenes ($C_{10}H_{16}$ and $C_{11}H_{18}$) with three fused rings are lined up as seen in Fig. 6. Thus let us consider the problem separately for chain and cyclic compounds.

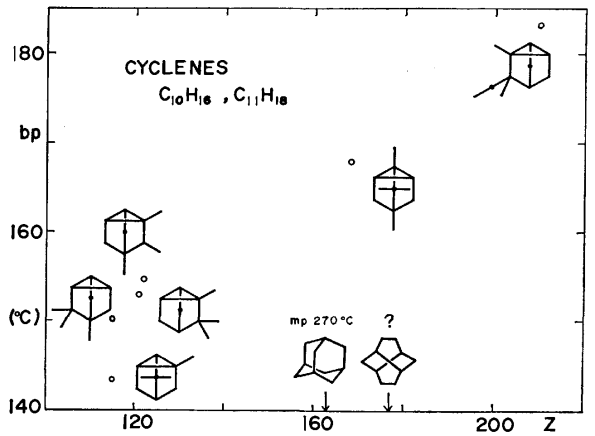

Fig. 6. Boiling point-topological index plot of the cyclene isomers $C_{10}H_{16}$ and $C_{11}H_{18}$.

Chain Paraffins

Since the effect of the branching of the topological index is analyzed elsewhere,[1] discussion will be given here of phenomenological point of view.

Empirical Formula. During an attempt in straightening up of the relation (4) for normal paraffins it was found that the plot of $\sqrt{N}(bp-a)$ of branched chain paraffins with N carbon atoms against log Z_G gives an interesting pattern as shown in Fig. 7. The points for normal paraffins lie perfectly on a line passing the origin, while isomeric paraffins lie on "branches" stemming from the points of the corresponding normal paraffins. The slopes of the branches seem to be almost the same. Although many points still deviate in this plot, the points for a series of compounds with similar structures such as 2-methyl isomers are found to lie on a line parallel to that of the normal paraffins. Thus we get

$$bp = (a \log Z_G + c)/\sqrt{N} + b. \quad (5)$$

The values of a and b are constant for a series of compounds either with the same N or with similar structures and are given in Table 1. Accuracy of Eq. (5) for normal paraffins will be compared in Appendix with a variety of hitherto proposed empirical formulae.

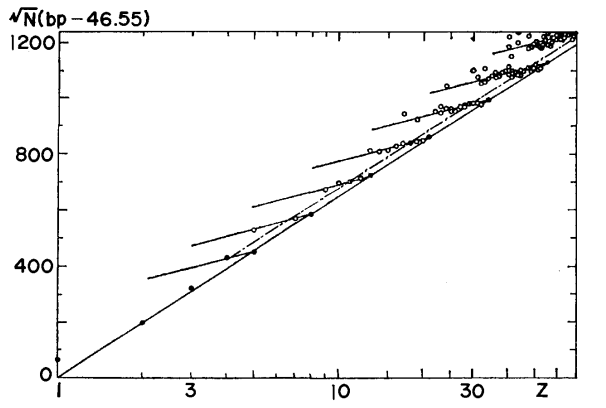

Fig. 7. Plots of $\sqrt{N}(bp-46.55)$ against log Z for chain saturated hydrocarbons. Boiling points are in °K.
●: normal paraffins, ◑: 2-methyl isomers and ○: other isomers.

Table 1. The values of the constants in the boiling point-topological index relation[a)]

Category	a	b	c
Normal paraffins	650.3	46.55	0
Compounds with similar structures[b)]	650.3	46.55	Dependent on the type
Compounds with the same N[c)]	310.0	46.55	Dependent on N

a) The boiling point (in °K) can be obtained from the relation $bp=(a \log Z_G+c)/\sqrt{N}+b$.
b) Obtained from the least squares calculation for the compounds with N from 2 to 10.
c) Obtained from the least squares calculation for the heptane isomers by omitting 3-ethylpentane and 2,2,3-trimethylbutane. N is the number of the carbon atoms.

Empirical Rules. From Eq. (5) the boiling point lowering (Δbp) of an isomer is expected to be

$$\Delta bp = bp(\text{normal}) - bp(\text{isomer}) \quad (6)$$

$$= a \log (Z_{\text{normal}}/Z_{\text{isomer}})/\sqrt{N}. \quad (7)$$

In Tables 2 and 3 observed and calculated values are compared for six different series of paraffin isomers.

	—C(—)(—)—...			—C(—)(—)—...			—C(—)(—)—...		

a) See the footnote of Table 2.

In some series of compounds the values for the lowest members deviate appreciably as is reasonably expected and may be omitted from the consideration. We get several empirical rules on the boiling points of chain paraffins. The topological index is shown to be in parallel with the boiling point change through Eq. (5).

Rule 1) Of all the isomeric paraffins the normal compound has the highest boiling point.

Rule 2) A monomethyl substitution lowers the boiling point by about 7 ± 1°C. (See Series A, B, and C in Table 2).

Rule 3) A *geminal*-dimethyl substitution lowers the boiling point by about 2 ± 1°C more than the double of a monomethyl substitution. (Compare pairs of Series A and D, B and E, and C and F in Tables 2 and 3).

Rule 4) The magnitude of the boiling point lowering by a monomethyl or *geminal*-dimethyl substitution alternates as the site of the substitution runs from the terminal towards insides. (See Series A, B,···F).

No exception has long been observed for Rule 1). It is proved in Ref. 1 as Theorem 4 that the topological index of the normal compound is the largest of all the isomeric structures.

Rule 4) deserves to be noted. As evident from Table 2, 2-methyl and 4-methyl substitutions lower the boiling point by about the same amount, which is larger than the contribution by a 3-methyl substitution. This is also the case for *geminal*-dimethyl substitutions. In both cases the boiling point lowering by further inner substitutions converges rapidly to a limit. This behavior reminds one of the zig-zag change of melting points of chain compounds with the increase of the chain length. That the topological index has just the same property can be shown as follows.

Let the topological index of a normal paraffin with N carbon atoms (n-N-ane) be $Z_{\bar{N}}$. For a 2-methyl substituted isomer (2-Me-(N-1)-ane) the topological index $Z_{2\text{-Me}}$ is expressed as

$$Z_{2\text{-Me}} = Z_{\bar{N-1}} + Z_{\bar{N-3}}$$

by using the composition principle. (Eq. (15) of Ref. 1) For larger N's the value $Z_{\bar{N}}$ increases asymptotically as $\alpha^{N+1}/\sqrt{5}$,[15)] with $\alpha=(1+\sqrt{5})/2$. Thus the ratio

	8.4 (6.2)	5.5 (4.8)	 −0.7 (2.7)

a) Numerals in parentheses are calculated from Eq. (7).

$Z_{\bar{N}}/Z_{2\text{-Me}}$ converges to a limit $(5+3\sqrt{5})/10=1.171$ with increasing N's. Similarly we get

$Z_{\bar{N}}/Z_{3\text{-Me}} \to 1.099$, $Z_{\bar{N}}/Z_{4\text{-Me}} \to 1.125$,
$Z_{\bar{N}}/Z_{5\text{-Me}} \to 1.115$ and finally
$\lim_{m\to\infty} (Z_{\bar{N}}/Z_{m\text{-Me}}) \to \sqrt{5}/2 = 1.118$.

In order to check the additivity of the lowering of the boiling point by branching, the lowering of the boiling point, $\Delta\Delta bp$, of disubstituted paraffins with respect to a reference mono-substituted compound was studied. Some of the results are shown in Tables 4—6.

Let us consider the octane isomers as an example. The boiling point of 2,5-dimethylhexane is lower than that of 2-methylheptane by 8.5°C (Series G in Table 4), which is very close to the value 8.1°C (Series A) of the lowering of the latter with respect to *n*-octane. These values are estimated from the topological index through Eq. (5) or (7) to be 7.6 and 7.1°C, respectively. Both for the observed and calculated values, good agreement is observed between Δbp's of Series A and $\Delta\Delta bp$'s of Series G. The $\Delta\Delta bp$ values for Series H and J represent other examples of the boiling point lowering by 2-methyl substitution. Rule 2) seems to be obeyed for Series G, H, and J. However, the boiling point lowerings of 2,3-dimethylated butane, pentane, and hexane are as small as about 2°C with respect to 2-methylpentane, 3-methylhexane, and 4-methylheptane (not shown), respectively. Sterically hindered substitution seems to raise the boiling point appreciably.

Series K, L, and M in Table 5 give the boiling point lowering by *geminal*-dimethyl substitutions. In Table 6 observed and calculated boiling point lowerings (Δbp and $\Delta\Delta bp$) of 2-, 3-, and 4-methyl subsitutions for dodecane isomers are demonstrated. Thus we get

Rule 5) If two substituents are well separated from each other, the lowering of the boiling point is additive.

Rule 6) Too much crowded substitution does not lower the boiling point effectively.

If one admits the relation (5), all these empirical rules except for Rule 6) can be predicted. Qualitatively the same conclusions can be obtained from the simpler relation (4). It has been known that the boiling point is well correlated with the absolute entropy of a molecule in gaseous state and we have found that the absolute entropy of saturated hydrocarbons are linearly dependent on log Z_G fairly well.[14] Thus it can be said that the topological index is a good index for the topological properties of molecules and is useful for rough estimation of some thermodynamic quantities. By the term "topological properties" we mean such quantities that may be related with the entropy or the number of the degree of freedom for

Table 7. Isomers of the smallest topological index and those with the lowest boiling points

N	Smallest Z	Lowest bp 1	Lowest bp 2
5			6			7			8			
9			10			11			12			
internal rotations of a molecule.

Steric effect seems to be one of the most important factors that could improve the empirical relations (4) and (5). This point has already been discussed by Platt[9] that the polarity number or the number of "steric pairs" p[16] proposed by Wiener[10] is the best parameter for evaluating this effect. Thus the isomer with the lowest boiling point is not necessarily the one with the smallest topological index. This is seen in Table 7.

Cyclic Paraffins

Figure 5 for the plot of all the possible isomers of monocyclic C_6H_{12} hydrocarbons is instructive to realize the effect of branching on the boiling point of cyclic compounds. Plots of other series, though not complete, show similar trend and we get

Rule 7) Among all the isomers of monocyclic saturated hydrocarbons (C_NH_{2N}) the isomer with no branch (cyclo-N-ane) has the highest boiling point.

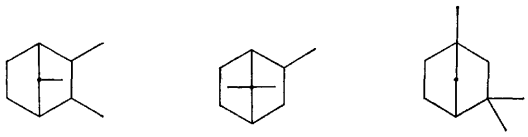
Rule 8) For polycyclic saturated hydrocarbons isomers without branches have generally higher boiling points than those with branches.

Rule 9) For cyclic compounds with the same ring skeleton, the longer the longest branch the higher the boiling point.

Rule 10) For cyclic compounds with the same ring skeleton, the more the quarternary carbon atoms, the lower the boiling point.

Rule 7) is analogous to Rule 1), that is, the normal paraffin has the highest boiling point among the isomers of chain saturated hydrocarbons. The remaining Rules 8)—10) are consistent with the general aspects of the topological index.[3] As an application of these Rules let us consider some interesting topics.

We can predict that among the possible twenty bornane isomers, *i.e.*, trimethylbicyclo[2.2.1]heptanes, 2,3,7-trimethyl derivative III and 1,3,3-trimethyl derivative V, respectively, give the highest (*ca.* 170°C) and lowest (*ca.* 150°C) boiling points, while bornane, 2,7,7-trimethyl isomer IV boils at 160°C.



III $Z=116$ IV $Z=102$ V $Z=88$

It is also predicted that among the possible isomers of $C_{10}H_{16}$ cyclenes, the isomers VI and VII respectively give the highest (*ca.* 160°C) and lowest (*ca.* 145°C) boiling points (See Fig. 7).

VI $Z=138$ VII $Z=106$

Adamantane is known to be volatile but to melt at as high as 270°C. The topological index is calculated as 163 and the boiling point is estimated as below as 165°C from the interpolation of the plots of tricyclic compounds (Fig. 7). A paradoxical result is also obtained for twistane with $Z=177$. So we must say that for highly fused ring compounds the topological index alone cannot account for the boiling point.

Appendix

Comparison of Several Empirical Relations of the Boiling Points of Normal Paraffins. Empirical formulae of the boiling points of the lower members of normal paraffins have been proposed by many authors. Typical of them are as follows:

Table 8. Comparison of the empirical formulae for the boiling point of normal paraffins[a)]

N	Exp. bp (°K)	Error=calcd−obsd (°K)					
		(8)	(9)	(10)	(11)	(12)	(13)

100	988.2	100.3	−25.1	−237.2	104.3	−0.3	408.2

a) The number in parentheses indicates the equation number in text.

$$bp = 745.42 \log (N+4.4) - 416.31 \quad (8)^{17)}$$

$$bp = 1209.59 - 1162.9/(1+0.074189N^{0.85}) \quad (9)^{18)}$$

$$bp = \{(21720N-11820)/(1+0.000283N^2)\}^{1/2} \quad (10)^{19)}$$

$$bp = 127.55N^{2/3}/(1+0.07033N^{2/3}) \quad (11)^{20)}$$

$$\log (1078-bp) = 3.0319 - 0.04999N^{2/3} \quad (12)^{21)}$$

16) The number p is defined as the number of pairs of carbon atoms which are separated by three carbon-carbon bonds.

17) G. Egloff, J. Sherman, and R. B. Dull, *J. Phys. Chem.*, **44**, 730 (1940).

18) J. R. Platt, *J. Chem. Phys.*, **15**, 419 (1947).

19) Y. Varshni, *J. Ind. Chem. Soc.*, **28**, 535 (1951).

20) K. Nakanishi, M. Kurata, and M. Tamura, *J. Chem. Eng. Data*, **5**, 210 (1960).

21) A. Kreglewski and B. J. Zwolinski, *J. Phys. Chem.*, **65**, 1050 1961).

Boiling points are in °K and N is the number of carbon atoms. Expressions with many parameters or of complicated forms are not chosen here.[12,13)] Now let us add our Eq. (5).

$$bp = 650.3 \log Z_{\bar{N}}/\sqrt{N} + 46.55 \quad (13)$$

By using the asymptotical form of $Z_{\bar{N}}$ we get

$$bp = 135.90\sqrt{N} + 46.55 - 91.37/\sqrt{N}. \quad (14)$$

for larger N.

Although the forms of these formulae are quite different from each other they give fairly good values for paraffins with N from 2 to 10 as shown in Table 8. Since all these relations were obtained so as to fit the lower members of the series most of them including our relations (13) and (14) are in poor agreement with experiments for higher members of the series up to $N=100$. However, the relation (12) gives surprisingly good results.

Conditions Favorable for the Formation of γ-FeOOH by Aerial Oxidation in an Acidic Suspension of Iron Metal Powder

Masao KIYAMA, Toshikazu AKITA, Shigeki SHIMIZU,*
Yoshiro OKUDA,* and Toshio TAKADA
Institute for Chemical Research, Kyoto University, Kyoto
(Received December 2, 1971)

Dilute solutions of ferrous sulfate, sulfuric acid, hydrochloric acid, nitric acid and acetic acid in which iron powders are dispersed have been oxidized at below 80°C by blowing air into them. The resulting precipitates have been examined by means of X-ray diffraction, chemical analysis and optical and electron microscopy. When the iron powder is well dispersed, γ-FeOOH is formed with or without α-FeOOH, α-Fe_2O_3, or Fe_3O_4. The mode of formation depends on such factors as particle size, amount of iron powder, kind of anion present and temperature. Particle size greatly influences the formation of γ-FeOOH in the sulfate system, but not in the other systems.

Clarification of conditions for the formation of ferric oxyhydrate (FeOOH) would be significant with respect to the theory of mechanism of corrosion of iron. Ferric oxyhydrate has four modifications: α-, β-, γ-, and δ-forms. The first three are nonferromagnetic[1-3] and the last is ferromagnetic.[4,5] By dehydration of γ-FeOOH, which is isomorphous with boehmite γ-AlOOH, ferromagnetic ferric oxide γ-Fe_2O_3 is formed.[6,7] This drew the attention of many chemists who investigated conditions favorable for its formation. γ-FeOOH can be obtained by slow oxidation of a suspension of ferrous compound precipitated by adding alkali to excess ferrous salt solution under certain conditions.[8-10] By oxidation γ-FeOOH is always formed *via* a dark green compound called green rust I or II. Presence of the green rust has been considered to be indispensable for the formation of γ-FeOOH. However, we have found that γ-FeOOH can also be formed directly from aqueous solutions of ferrous salt ($FeBr_2$ or a mixture of $FeCl_2$ and excess NaI solutions).[11] In order to clarify the mechanism of formation of γ-FeOOH more systematical experiments are needed.

In the present paper experimental conditions favorable for the formation of γ-FeOOH in acidic suspensions of iron powder are given.

Experimental

Materials. Chemical reagents of analytical grade were used. Crushed electrolytic iron powders of 270, 240, 140, 117, 104, 74, 61, and 43μ in particle size were prepared by use of 50, 60, 100, 120, 150, 200, 250, and 325 mesh sieves, respectively. Air for stirring and oxidizing the solution containing iron powder was passed through washing vessels containing KOH solution to remove dust and organic elements.

Apparatus. An ordinary reaction vessel was found to be unsuitable, since with such a vessel the rate of precipitate formation is very low because of aggregation of the iron particles. For the sake of uniform stirring and oxidation we used a hard glass vessel 7 cm in internal diameter and 80 cm in height as shown in Fig. 1. The vessel is composed of a cylindrical tube A, a perforated plate B 0.1 cm in thickness with small holes of 0.1 cm in diameter arranged at equal distances of about 0.8 cm, and a gas holder C. The vessel is closed with a rubber D into which are inserted a temperature regulator E, a thermometer F, a quartz tube containing nichrome heater G and a water condenser H. The temperature regulator consists of a spiral bimetal dipped in oil in a glass tube.

Procedure. Compressed air was bubbled into the vessel from the bottom through the perforated plate at a rate of 100 *l*/hr by operating a cock. One liter of each acidic solution was poured into the vessel from the top, but it was scarcely observed to fall into the gas holder. The iron powder was poured into the solution and the air flow rate was increased to a certain degree. The solution in which the iron powder was dispersed was quickly heated by the nichrome heater and kept at a certain temperature. After being separated from the remaining iron particles by decantation, the precipitate was filtered, washed with water, and then dried at about 105°C. pH measurements were carried out with a Horiba electrode pH meter.

Identification. The sample thus prepared were examined by means of chemical analysis and X-ray diffraction using Fe*Kα* radiation, and observed under optical and electron microscopes. The content of γ-FeOOH (*R*) was determined from the equation $R=I_\gamma/I_\gamma+I_\alpha$, where I_γ and I_α are the relative intensities of the X-ray diffraction lines of γ-EeOOH (*d*(020)6.32 Å) and α-FeOOH (*d*(110) 4.21 Å), respectively.

Results and Discussion

Precipitation in Sulfate Suspensions. Experiments were carried out by use of the iron powder with size distributions: 140—104=1.0, 104—74=8.4, 74—61=10.4, 61—43=15.8, below 43μ=64.4 wt%. Air was blown at the rate of 650 *l*/hr for 10 hr into 0.5M-$FeSO_4$ and 0.2M-$FeSO_4$ solutions containing 20 g (0.36 mol) of the iron powder. These suspensions were kept at 70°C. 0.2M-H_2SO_4 solution containing 31 g (0.56 mol) of the iron powder was also subjected to the same treatment. These sulfate suspensions changed gradually from grayish black to brownish yellow, as the reaction proceeded. In order to know the relation between the pH of the suspensions and the remaining iron particles, a part of each suspension (about 50 m*l*) was taken out for examination during the course of oxidation. The pH values are plotted against time in the logarithmic scale in Fig. 2. The pH value increased to about 7 by addition of the iron powder to the solution, and then decreased to about 4. It remained at about 4 while the iron powder was present in the solution. When the iron powder disappeared completely, the pH dropped to below 3. It is believed that precipitation takes place when the iron powder is dissolved and the ferrous ions are oxidized as follows.

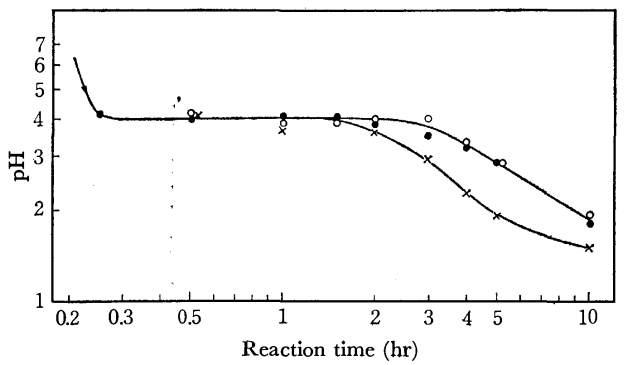

Fig. 2. pH of suspension at various time intervals: × =0.5M-$FeSO_4$, ○=0.2M-$FeSO_4$, ●=0.2M-H_2SO_4 as the starting solution.

$$2Fe(metal) + 4H^+ = 2Fe^{2+} + 2H_2(gas)$$

$$2Fe^{2+} + 3H_2O + \frac{1}{2}O_2 = 2FeOOH + 4H^+$$

When the iron powder is uniformly dispersed, the ferrous ions consumed by oxidation to form a precipitate are replenished by neutralization between the acid formed and the iron powder. This might be the reason that the pH remained at about 4. The solubility products of iron hydroxides are: $(Fe^{2+})(OH)^2=10^{-14}$ and $(Fe^{3+})(OH)^3=10^{-36}$. In these suspensions, no ferrous precipitate can exist but ferric ions which are to be precipitated.

The samples thus obtained (Found: Fe_2O_3 87.5—88.6 wt%, Calcd for $Fe_2O_3\cdot H_2O$, Fe_2O_3 89.9 wt%) were mixtures of α-FeOOH and γ-FeOOH. Their γ-FeOOH content R progressively increased to about 0.3 in the samples prepared from 0.5M-$FeSO_4$ (sample A), 0.2M-$FeSO_4$ (B) and 0.2M-H_2SO_4 (C) which were the starting solutions. Optical micrographs of these samples show that acicular particles are present with granular ones (Fig. 3). Their shapes and sizes depend

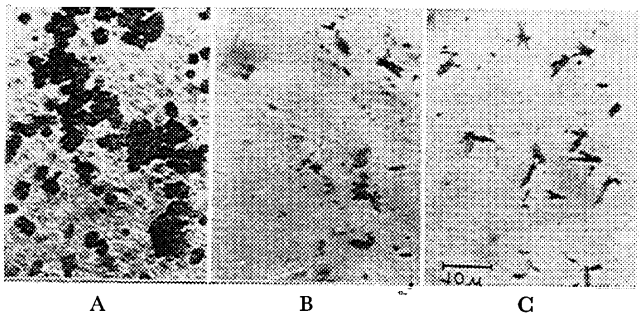

Fig. 3. Optical microscope photographs of FeOOH particles: A=0.5M-$FeSO_4$, B=0.2M-$FeSO_4$, C=0.2M-H_2SO_4 used as the starting solution.

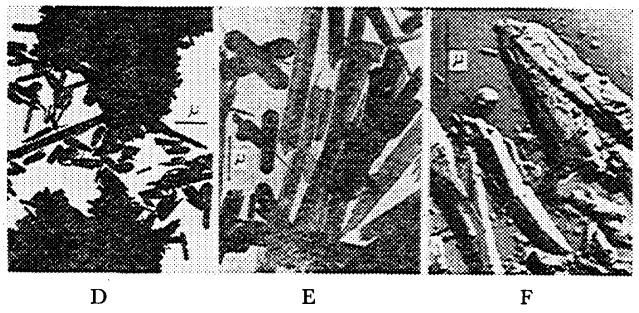

Fig. 4. Electron micrographs of typical shapes of particles prepared from the sulfate suspension.

on the concentration of ferrous ions in the starting solution. Electron micrographs of typical particles are given in Fig. 4 (D) and (E) and that of twin particles observed by carbon replica method in Fig. 4 (F). Very elongated and big bur-like particles can be seen together with X-, Y-, and tablet-shaped ones. According to electron microdiffraction, the very elongated particles were γ-FeOOH and the other ones α-FeOOH. The X- and Y- shaped ones as well as the big bur-like ones did not overlap one another. The former had a re-entrant angle of about 60°.

In order to find the favorable conditions for the formation of γ-FeOOH, experiments were carried out by use of the same iron powder. Oxidation was continued for 6 hr under various conditions, such as the flow rate of air blown, concentration of sulfuric acid, amount of the iron powder added and reaction temperature.

Table 1. Iron compounds formed by oxidation of iron powder ($<140\,\mu$) present in sulfuric acid solutions under various conditions

0.20	3.27	70	650	α-H

a) Abbreviations: α-H=α-FeOOH, γ-H=γ-FeOOH.

The results are summarized in Table 1. With the increase of air flow rate the iron powder becomes more uniformly dispersed, the formation of γ-FeOOH being accelerated. In water the rate of precipitation was very slow and the oxidation product contained not γ-FeOOH but a mixture of α-FeOOH and Fe_3O_4 (or γ-Fe_2O_3). The formation of γ-FeOOH depends strongly on the amount of iron powder, γ-FeOOH being always formed together with α-FeOOH.

In order to examine the effects of particle size and amount of iron powder experiments were carried out as follows. Four iron powders with different particle sizes (270—240 μ, 140—117 μ, 74—61 μ, and below 43 μ) were used and different amounts of each iron powder were added to 0.2M-H_2SO_4 solutions. The suspensions were oxidized for 8 hr at 65°C by blowing air into them at 1000 l/hr.

The γ-FeOOH contents R for different iron particle sizes are plotted against the amount of iron powder in Fig. 5. After 8 hr, the solutions to which 80 g (1.43 mol/l) and 200 g (3.58 mol/l) of the iron powder with 117—140 μ in particle size and 20 g or more of the iron powder with 240—270 μ had been added, had a pH of about 4 and still retained the iron powder. For a given amount of iron powder the larger the particle size, the higher the R, the maximum of R on each curve depending on particle size. This indicates that the particle size of iron powder is more effective for γ-FeOOH formation than its total surface area which is the product of its amount and particle size at the initial stage of oxidation.

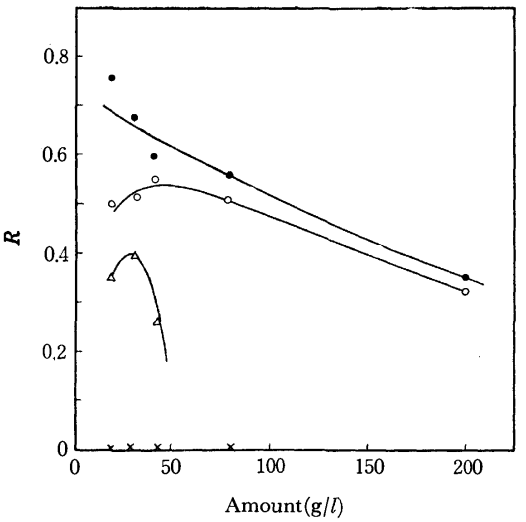

Fig. 5. Effects of the size and amount of the iron powder on the γ-FeOOH content R.
●: 270—240 μ, ○: 140—117 μ, △: 74—61 μ, ×: —43 μ

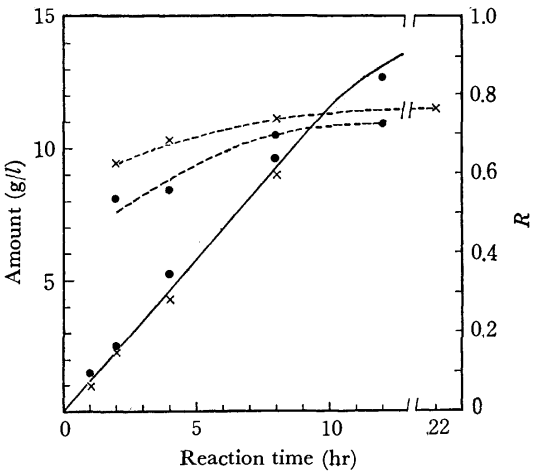

Fig. 6. Amount of precipitates formed and R(γ-FeOOH content) at various periods. Iron powder with particle size of 240—270 μ, 20 g=×, 40 g=●. ——: Amount, ----: R

In order to increase R, the following experiments were carried out. 0.35 mol (20 g) and 0.70 mol of iron powder (240—270 μ) were added to 0.2M-H_2SO_4 solution. The suspensions were oxidized at 65°C for different periods by blowing air into them at a rate of 1500 l/hr. The amount of precipitate formed and R are plotted against time in Fig. 6. Neither depends strongly on the amount of iron powder added and R hardly varies with time.

Precipitation in Other Suspensions. Since a single phase of γ-FeOOH was hardly formed in the sulfate suspensions, experiments were carried out with hydrochloric, nitric and acetic acids in order to examine the effect of anions on the formation of γ-FeOOH.

33 g (0.675 mol/l) of iron powder (104—140 μ) was added to each of the solutions 0.25M-HCl, CH_3COOH and HNO_3. The suspensions were oxidized at 40, 55, 70, and 80°C for 8 hr by blowing air at the rate 1000 l/hr. When the iron powder was added to the acetic acid solution, foaming occurred so heavily that at first

Table 2. Iron compounds formed by oxidation of iron powder (140—104 μ) in chloride, nitrate and acetate solutions (0.25 M in acid) at various temperatures

Temp. (°C)	Chloride	Nitrate	Acetate
40	γ-H>α-H	α-H>γ-H>Sp	α-H
55	γ-H>α-H	γ-H>α-H>Sp	γ-H>α-H
70	γ-H≫α-H	α-H≈Sp>γ-H ≈α-O	γ-H≫α-H
80	γ-H>α-H ≈α-O	α-H≈α-O>γ-H ≈Sp	α-O>γ-H

α-H=α-FeOOH, γ-H=γ-FeOOH, α-O=α-Fe_2O_3, Sp=Fe_3O_4 or γ-Fe_2O_3.

air had to be jetted from the top of the vessel into the suspension to subdue the farm. No iron particles remained in the chloride suspensions oxidized at 70 and 80°C, and the acetate suspensions oxidized at 55, 70, and 80°C. The pH of the chloride suspensions remained at about 4 while iron particles were present, whereas the pH of the acetate suspensions was about 4 regardless of the presence of iron particles. In the nitrate suspensions oxidized at temperatures between 40 and 80°C, iron particles were present. The remaining iron particles in the nitrate suspensions oxidized at 70 and 80°C were coated with black material (probably Fe_3O_4), the rate of precipitation being slow. The kinds of precipitates obtained from each suspension at various temperatures are given in Table 2. γ-FeOOH is formed below 70°C together with α-FeOOH in the chloride and acetate suspensions. α-Fe_2O_3 begins to be formed at 70°C in the nitrate suspension and is formed with other precipitates in all the suspensions at 80°C.

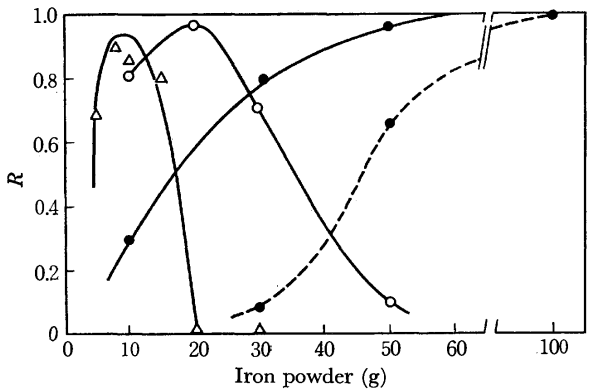

Fig. 7. Effects of the particle size and amount of iron powders added to acetate solution (0.5 *l*) on *R*: △=<43 μ, ●=117—140 μ, ○=240—270 μ.
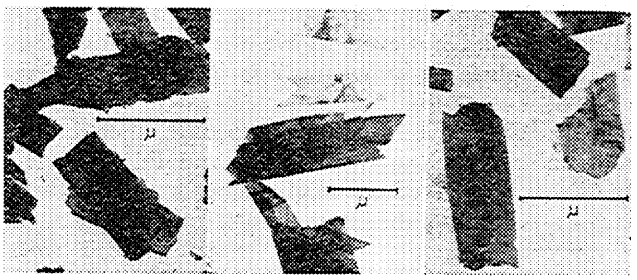
Solid curves: at 70°C, air flow rate 1500 *l*/hr,
Dotted curve: at 55°C, 1000 *l*/hr.

In order to examine the effect of the air flow rate on *R* at temperatures where α-Fe_2O_3 is hardly formed, the same suspensions were oxidized for 8 hr at different air flow rates between 500 and 1500 *l*/hr at 70°C for the chloride and acetate and at 55°C for the nitrate. The *R* value for acetate increased with the increase of air flow rate. It reached 1.0 at the rate of 1500 *l*/hr. The *R* values for the other suspensions did not depend strongly on the air flow rate. It was about 0.8 for the chloride and 0.4 for the nitrate.

The effects of the particle size and the amount of iron powder on *R* were examined. Three kinds of iron powders with different particle sizes (<43, 117—140 and 240—270 μ) were added to acidic solutions containing 0.25M-acid, their amounts being between 10 and 200 g (0.358 and 3.58 mol/*l*), and each suspension was oxidized at 70°C for 6 hr by blowing air into it at 1500 *l*/hr. Of the three suspensions the total volume of the acetate suspension decreased to 1/2 liter, since foaming became heavier with the increase of surface area of the iron powder. With the acetate suspension, *R* depends on both the amount and particle size of the iron powder (Fig. 7). It increases with the increase or decrease in the amount of iron powder, depending on the particle size, *viz.*, it depends on the total surface area of the iron powder present at the initial stage. The surface area favorable for the formation of γ-FeOOH changes with reaction condition as can be seen by the dotted curve in Fig. 7 (reaction temperature: 55°C, air flow rate: 1000 *l*/hr, the other conditions the same as above). When the suspensions containing more than 30 g (0.54 mol/*l*) of iron powder with particle size of below 43 μ was oxidized at 70°C, fine particles of Fe_3O_4 (about 0.1 μ) were formed.

Table 3. Conditions favorable for the formation of γ-FeOOH from 0.25N-acid solutions containing iron powder
(air flow rate=1500 *l*/hr, time=6 hr)

	Acid	Iron powder		Temp. (°C)	γ-FeOOH content *R*
		size (μ)	amount (mol/*l*)		
No. 1	CH_3COOH	104—140	1.75	70	1.00
No. 2	HCl	104—140	1.75	70	0.97
No. 3	HNO_3	74—61	2.53	55	1.00



(No. 1) (No. 2) (No. 3)

Fig. 8. Electron micrographs of γ-FeOOH particles formed in acetate (No. 1), chloride (No. 2) and nitrate suspensions (No. 3) as in Table 3.

The effects of particle size and amount of iron powder on *R* for chloride and nitrate were less marked than for acetate suspension. γ-FeOOH was obtained in the chloride and nitrate suspensions under proper conditions, iron particles remaining. Fine particles of Fe_3O_4 (about 0.1 μ) were also formed in the surface layer of iron particles in nitrate suspension containing more than 30 g of the iron powder (<43 μ) and in chloride suspension containing more than 60 g of iron powder (<43 μ). The conditions favorable for the formation of γ-FeOOH are summarized in Table 3

and electron micrographs of the γ-FeOOH particles separated from the remaining iron particles are shown in Fig. 8. The γ-FeOOH particles evidently differ from the very elongated ones prepared from sulfate.

The presence of green rust has been considered to be indispensable for γ-FeOOH formation, and it has been suggested that γ-FeOOH is formed by its surface oxidation. However, the shape of γ-FeOOH particles (acicular) prepared *via* the green rust does not resemble that of the particles of green rust (hexagonal plate-like). γ-FeOOH can also be formed by oxidizing ferrous salt solutions or suspensions of iron powder not *via* the green rust. It is thus proposed that γ-FeOOH may be formed not by surface oxidation of the green rust but by oxidation of hydroxo iron (II) complex formed by dissolution of either the green rust or iron powder.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3426—3429 (1972)

The Preparation and Some Reactions of Platinum(II) and Palladium(II) Complexes of Vinyl Ethers[1)]

Yasuo WAKATSUKI,* Shun-ichi NOZAKURA, and Shunsuke MURAHASHI
Faculty of Science, Osaka University, Toyonaka, Osaka

(Received December 18, 1971)

Stable complexes with the general formula $[Cl_2ML]_2$ (M=Pt, Pd; L=vinyl ethers, propenyl ethers, 1,2-dimethoxyethylene) have been prepared. The IR spectra of $[Cl_2Pt(trans\text{-}CH_3CH{=}CHOCH_3)]_2$ showed a change which was attributed to the *trans—cis* isomerization of the coordinated olefin. A similar *cis—trans* isomerization was also suggested for the other propenyl ether and 1,2-dimethoxyethylene complexes. The palladium complex of vinyl *t*-butyl ether was found to react with aqueous NaOH in a way similar to the Wacker process.

Although many transition metal–olefin complexes are known, few reports have appeared concerning complexes of olefins with strong electron-releasing substituents such as vinyl ethers; indeed, it has only been known that Fe(0) forms a very unstable complex with vinyl ethyl ether.[2)] Such olefins will form unstable complexes with low valent transition metals because they have a strong σ-donating ability, but a poor π-accepting ability. In Pt(II) and Pd(II) complexes of ethylene, the contribution of the back donation has been emphasized, as in the case of the Zeise salt.[3)] A detailed study of IR spectra has, however, shown that σ-donation from the olefin plays an important role in these complexes, while back-donation from the metal is of little importance.[4)] Vinyl ethers can be expected, therefore, to form stable complexes with Pt(II) and Pd(II). Also, coordinated vinyl ethers might show an unusual behavior as a result of the interaction of lone-pair electrons of the oxygen atom with the metal. In this work, Pt(II) and Pd(II) complexes of vinyl ethers and their derivatives will be prepared, and the properties of the novel complexes will be studied by means of IR spectroscopy.

Results and Discussion

The analytical data and some physical properties of the novel complexes obtained by the following reactions are listed in Tables 1 and 2.

$$[Cl_2PtC_2H_4]_2 + 2\text{olefin} \longrightarrow [Cl_2P\text{tolefin}]_2 + 2C_2H_4$$

$$2Cl_2Pd(PhCN)_2 + 2\text{olefin} \longrightarrow [Cl_2Pd\text{olefin}]_2 + 4PhCN$$

As expected, all the complexes are moderately stable in air at room temperature except for the vinyl trimethylsilyl ether complex, which is moisture-sensitive.[5)] They can be stored at −20°C for months.

The last columns in Tables 1 and 2 show the configuration of the coordinated olefin, as determined by IR spectroscopy.

Figure 1 shows the IR spectra of the platinum complex of propenyl methyl ether. The spectrum of the freshly-prepared complex of *trans*-propenyl methyl ether (I) is shown at the top (a). When the solid sample, I, was allowed to stand under argon at 70°C for 48 hr, the spectrum changed to (b), indicating that the change takes place even in a solid state, while the sample I dissolved in toluene at 70°C for several hours showed the spectrum at the bottom (c). The spectrum (c) was also obtained when the complex (II) was prepared from the *cis*-isomer. The dotted line in Fig. 1-(c) shows the spectrum of the palladium analog (III); it was virtually identical with that of the platinum complex. As will be described later, the decomposition of the sample III with pyridine yielded almost pure *cis*-propenyl methyl ether. These facts indicate that the sample I was a mixture of *cis*- and *trans*-olefin complexes,

whereas the sample II was a pure *cis*-olefin complex and coordinated propenyl methyl ether was isomerized from *trans* to *cis*.

In the case of the 1,2-dimethoxyethylene coordinated to platinum, a similar isomerization in a solid state was followed by studying the IR spectra; however, the isomerization was from *cis* to *trans* in this case.

The platinum complex of propenyl trimethylsilyl ether and palladium complexes of propenyl methyl ether and 1,2-dimethoxyethylene all showed one kind of IR spectrum independent of the olefin isomers used. The configuration of the coodinated olefins in these complexes was determined by comparing the IR spectra with those of platinum complexes.

To compare these olefins with those having no oxygen atoms among their substituents, platinum complexes of *cis*- and *trans*-2-butene and *cis*- and *trans*-β-methylstyrene were prepared; however, they did not show any isomerization. The results with the 2-butene complex are in agreement with those reported by Jonassen and Kirsch.[6] The fact that coordinated propenyl ethers and 1,2-dimethoxyethylene isomerized readily under the conditions under which coordinated 2-butene and β-methylstyrene did not isomerize at all suggests that the contribution of the oxygen atom in the vinyl ether derivatives is essential for the isomerization. The most probable explanation may be some kind of interaction of the oxygen atom with the metal, thus stabilizing the transition state.

cis-Propenyl methyl ether coordinated to palladium or platinum was displaced with pyridine, and the propenyl methyl ether thus liberated was analyzed by glc. Propenyl methyl ether of the *cis*/*trans* ratio of 45 : 1 was liberated from the palladium complex, but the ratio was 3.1 : 1 when it was displaced from the platinum complex, indicating that a considerable amount of the *trans*-isomer was formed in the course of the displacement reaction. Orchin and his co-workers suggested that the displacement of coordinated ethylene by pyridine may proceed by a prior $\pi \rightarrow \sigma$ rearrangement:[7]

$$\begin{matrix} CH_2 & Cl \\ \| & | \\ CH_2 & Pt\text{–}NC_5H_5 \end{matrix} \overset{C_5H_5N}{\rightleftharpoons} C_5H_5N\rightarrow CH_2\text{–}CH_2\text{–}\underset{\displaystyle Cl}{\overset{\displaystyle Cl}{\underset{|}{\overset{|}{Pt}}}}\leftarrow NC_5H_5$$

An analogous σ-bonded intermediate may account for the observation that the *trans*-isomer is formed during the *cis*-propenyl ether displacement by pyridine:

$$Pt\cdots\begin{matrix} CH & CH_3 \\ \| & \\ CH & OCH_3 \end{matrix} \xrightarrow{C_5H_5N} C_5H_5N\rightarrow Pt\text{–}\underset{\displaystyle CH_3}{CH}\text{–}\underset{\displaystyle OCH_3}{CH}\leftarrow NC_5H_5$$

$$\Updownarrow$$

$$C_5H_5N\rightarrow Pt\text{–}\underset{\displaystyle CH_3}{CH}\text{–}\underset{\displaystyle OCH_3}{CH}\leftarrow NC_5H_5 \longrightarrow C_5H_5NPt + \underset{\displaystyle CH_3}{\overset{\displaystyle OCH_3}{CH{=}CH}}$$

If the olefin molecule, which is about to leave the metal, spends enough time in the σ-complex state to allow rotation around the C–C bond, the *cis*/*trans* ratio of the liberated olefin will be controlled by the conformations of the σ-complex as well as by relative rate of its decomposition.

The palladium complex of vinyl *t*-butyl ether was treated with an aqueous hydrogen fluoride and with an aqueous sodium hydroxide. The complex was recovered unchanged from a suspension in 45% aqueous hydrogen fluoride; this is in contrast to the fact that free vinyl ethers are readily hydrolyzed into aldehyde and alcohol in an acid. On the other hand, the complex reacted vigorously with a 45% aqueous sodium hydroxide to yield palladium metal and a quantitative amount of the acetate ion; furthermore, about 84% of the theoretical amount of *t*-butyl alcohol was detected by glc. By analogy with the Wacker process, the reaction may be described as follows:

$$\frac{1}{2}[Cl_2Pd(CH_2{=}CHOCMe_3)]_2 \xrightarrow{OH^-} CH_3COOCMe_3 + Pd^0 + HCl + Cl^-$$

$$CH_3COOCMe_3 \xrightarrow{OH^-} CH_3COO^- + Me_3COH$$

Experimental

Solvents. The toluene and petroleum ether (bp 30—50°C) were purified by the ordinary method and were dried by refluxing over sodium for several days. They were freshly distilled before use.

Olefins. The vinyl methyl ether, vinyl 2-chloroethyl

6) H. B. Jonassen and W. B. Kirsch, *J. Amer. Chem. Soc.*, **79**, 1279 (1957).

7) P. D. Kaplan, S. Schmist, and M. Orchin, *ibid.*, **90**, 4175 (1968).

ether, vinyl 2,2,2-trifluoroethyl ether, and 2-butene were commercial reagents. The other olefins were prepared by the known methods.[9-12] The *cis*- and *trans*-isomers of propenyl ethers were separated by fractional distillation and were confirmed by studying their NMR coupling constants. The *cis*- and *trans*-isomers of 1,2-dimethoxyethylene were separated by fractional distillation and were identified by dipole-moment measurements in benzene (*cis*, 2.00D; *trans*, 1.83D).

[Cl_2Ptolefin]$_2$. This complex was prepared simply by the addition of an olefin to a suspension of $[Cl_2PtC_2H_4]_2$ in toluene. The complexes of vinyl 2,2,2-trifluoroethyl ether, 1,2-dimethoxyethylene, and β-methylstyrene were prepared at room temperature, but the reactions of the other olefins were carried out at low temperatures in order to prevent side reactions. The preparation of the propenyl methyl ether complex will be described as an example; about a 100 mg portion of $[Cl_2PtC_2H_4]_2$ was suspended in 10 m*l* of toluene under a nitrogen atmosphere, and then the suspension was cooled in a dry ice–methanol bath. About 0.2 m*l* of propenyl methyl ether was added, and the mixture was stirred for about 1 hr. The heterogeneous mixture gradually turned homogeneous as the reaction proceeded. The toluene and the excess of propenyl methyl ether were evaporated at −35°C under reduced pressure. The resulting yellow powder of the complex was recrystallized, if necessary, from hot toluene–petroleum ether.

[Cl_2Pdolefin]$_2$. This complex was prepared by the reaction of $Cl_2Pd(PhCN)_2$ and an olefin according to Kharasch's method.[13] The reaction was carried out in toluene at room temperature. The preparation of 1,2-dimethoxyethylene complex was as follows: about a 200 mg portion of $Cl_2Pd(PhCN)_2$ was dissolved in 20 m*l* of toluene under a nitrogen atmosphere, after which the undissolved material was removed by filtration. To this filtrate, 0.05 m*l* of 1,2-dimethoxyethylene was added, and then the solution was continuously stirred. The precipitation of the desired complex occurred within 1 hr. The supernatant solution was removed by decantation, and the precipitate was washed with toluene several times.

Decomposition of the Complexes with Pyridine. The platinum and palladium complexes of propenyl methyl ether were decomposed with pyridine, thus liberating the original olefin without forming any by-product. For example, to 200 mg of $[Cl_2Pt$ *cis*-$CH_3CH{=}CHOCH_3]_2$ we added 1 m*l* of toluene containing a calculated amount of pyridine. The complex dissolved immediately, and there precipitated within 1 hr white crystals which appeared to be $[Pt\ Py_4]Cl_2$. The supernatant solution was analyzed by glc (tricresyl phosphate, 1.5 m, 40°C).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3429—3433 (1972)

Determination of the Formation Constants of Actinoid and Lanthanoid Lactate Complexes by Means of Electrophoresis

Masanobu SAKANOUE and Mitsuo NAKATANI

Radiochemical Laboratory, Faculty of Science, Kanazawa University, Kanazawa

(Received February 14, 1972)

Determination of the complex formation constant of actinides (Am, Cm) and lanthanides (Pm, Eu, Lu) with lactic acid was carried out by means of the electrophoretic method. "Cellogel", a gelatinized cellulose acetate was used as the supporting medium for electrophoresis at 10°C. Electrolyte solutions of various pH at an ionic strength of 1.5 were prepared from 0.5M lactic acid solution for electrophoresis at various pH values. The migration zones of α- and β-emitter were determined by α track on cellulose nitrate and autoradiographic image on X-ray film, respectively. The mobility of each nuclide at different pH was analyzed to obtain the formation constants of lactate complex of each element with reference to dissociation equilibrium. The β_1 values thus obtained were consistent with those obtained by other methods. The method was found to be especially useful for determining the complex formation constants of *trans*-uranium elements with only tracer amounts of these elements.

Electrophoresis has been used not only for the separation of various ions, but also for the study of coordination compounds or ion pairs in certain solution systems. Since it is possible to get information on the presence of the functional groups in a given solution system from the relationship[1-4] $U=aZ/\sqrt{M}$ (U: the zone mobility of the migrating substances, Z: their charge, M: the molecular weight), studies[5-10] have

been carried out on the determination of formation constants of complex compounds. The method is suitable and effective for radioactive elements, especially *trans*-uranium elements, since their radioactivities can be easily measured by various methods including autoradiography even in tracer amounts of these elements.

Basic factors concerning electromigration mobility have been studied and the formation constants of some actinide and lanthanide element complexes with lactic acid have been estimated radiochemically, the results of which are reported in this paper.

Theoretical Consideration

In order to estimate the formation constants from electrophoretic mobility data, the following theoretical consideration can be made. Since the trivalent metal ions of lanthanide and actinide elements do not form polynuclear complexes,[11] the consecutive equilibria of mononuclear complexes ML, ML_1, $\cdots ML_N$ and the corresponding equilibrium constants are given by the following equations.

$$\left.\begin{aligned} &M^{3+} + L = ML^{2+};\ K_1 = \frac{[ML]}{[M][L]} \\ &ML^{2+} + L = ML_2^{+};\ K_2 = \frac{[ML_2]}{[ML][L]} \\ &ML_{N-1}^{3-(N-1)} + L = (ML_N)^{3-N};\ K_N = \frac{[ML_N]}{[ML_{N-1}][L]} \end{aligned}\right\} \quad (1)$$

In the method of Bjerrum to arrive at the values of K_N, the stability or formation constant, the underlying principle is the unambiguous relationship between the average number $\bar{n}$ of anionic ligands bound to a metal ion in an equilibrium mixture and the total anion concentration.

$\bar{n}$ can be expressed as

$$\bar{n} = \frac{[ML] + 2[ML_2] + \cdots + N[ML_N]}{[M] + [ML] + [ML_2] + \cdots + [ML_N]} \quad (2)$$

The concentrations of complexes in this equation can be substituted by the expression derived from Eq. (1). Eliminating [M] in both the numerator and denominator, we have

$$\bar{n} = \frac{(K_1[L]) + 2(K_1K_2[L]^2) + \cdots + N(K_1K_2\cdots K_N[L]^N)}{1 + (K_1[L]) + (K_1K_2[L]) + \cdots + (K_1K_2\cdots K_N[L]^N)} \quad (3)$$

Introducing the complex product defined by

$$\beta_n = \frac{[ML_N]}{[M][L]^n} = \prod_{i=1}^{N} K_i \quad (4)$$

Eq. (3) can be written in a more concise form:

$$\bar{n} = \frac{\sum_{n=1}^{N} n\beta_n[L]^n}{1 + \sum_{n=1}^{N} \beta_n[L]^n} \quad (5)$$

If the average charge of a complex of trivalent metal ion with n of anion ligands is represented by $\bar{Z}$, the zone mobility U_c is expressed by

$$U_c = a\frac{\bar{Z}}{\sqrt{M}} = \frac{a}{\sqrt{M}}(3-\bar{n}) = U_k - a\frac{\bar{n}}{\sqrt{M}} \quad (6)$$

where the mobility of non-coordinated trivalent metal ions is given by $U_k = a\ 3/\sqrt{M}$.

Substituting $\bar{n}$ of Eq. (5) into Eq. (6), we get

$$\begin{aligned} U_c &= U_k - \frac{a}{\sqrt{M}} \cdot \frac{\sum_{n=1}^{N} n\beta_n[L]^n}{1 + \sum_{n=1}^{N} \beta_n[L]^n} \\ &= \frac{U_k + \sum_{n=1}^{N} \left(U_k - a\frac{n}{\sqrt{M}}\right)\beta_n[L]^n}{1 + \sum_{n=1}^{N} \beta_n[L]^n} \\ &= \frac{U_k + \sum_{n=1}^{N} U_n\beta_n[L]^n}{1 + \sum_{n=1}^{N} \beta_n[L]^n} \end{aligned} \quad (7)$$

where U_n is the mobility of a complex of trivalent metal ion coordinated with n univalent anion ligands (n: integer) and can be represented by the following equation from the relation $U_k = a\ 3/\sqrt{M}$.

$$U_n = a\frac{(3-n)}{\sqrt{M}} = a\frac{3}{\sqrt{M}} - a\frac{n}{\sqrt{M}} = U_k - \frac{n}{\sqrt{M}} \quad (8)$$

In Eq. (7), the values of U_k, U_n, and β_n are constant under the same experimental conditions, whereas U_c varies with [L].

To determine β_n from U_c and U_n, mobility U_c should be obtained for different organic ligand concentrations. As the functional groups of the organic acid accept or donate protons, the dissociation constant of the equilibrium ($H_nL \rightleftarrows H_{n-1}L + H^+$) is determined by the pH value. The ligand concentration $[H_{n-1}L]$ is then obtained as a function of the pH values. Thus solutions with different ligand concentrations can be prepared from those with identical concentrations of the organic acid by changing pH value. The relationship between the dissociation degree α of univalent organic acid and pH value is given by

$$\alpha = \frac{1}{1 + 10^{-(pH - pK)}} \quad (9)$$

where pK is $-\log K_d$, K_d being the dissociation constant of the organic acid. The ligand concentration can be determined by multiplying the dissociation degree by the normality of the organic acid. The formation constant β_n can then be determined from the relationship between the experimental mobility U_c and the defined pH value.

In Eq. (7), $\sum_{n=2}^{N} \beta_n[L]^n$ can be neglected at low ligand concentrations because it is much smaller than $\beta_1[L]$. Thus, at low ligand concentrations, β_1 can be calculated by

$$U_c = \frac{U_k + U_1\beta_1[L]}{1 + \beta_1[L]} \quad (10)$$

from which we get

$$\beta_1 = \frac{U_k - U_c}{U_c - U_1} \cdot \frac{1}{[L]} \quad (11)$$

Therefore

11) K. Buchtela, "Isotopenpraxis" 3, Jahrgang. Heft 12 (1967).

$$\log \frac{U_k - U_c}{U_c - U_1} = \log \beta_1 - p[\mathrm{L}] \quad (12)$$

Thus the plot of $\log (U_k - U_c)/(U_c - U_1)$ *vs.* $p[\mathrm{L}]$ should give a straight line with slope 1. The intercept of this line with the abscissa is $\log \beta_1$.

The β_2 value can be calculated from the following equations.

$$U_c = \frac{U_k + U_1\beta_1[\mathrm{L}] + U_2\beta_2[\mathrm{L}]^2}{1 + \beta_1[\mathrm{L}] + \beta_2[\mathrm{L}]^2} \quad (13)$$

$$\beta_1 = \frac{\beta_1[\mathrm{L}](U_1 - U_c) + (U_k - U_c)}{[\mathrm{L}]^2(U_c - U_2)} \quad (14)$$

Experimental

Materials and Apparatus. The supporting medium is "Cellogel," the gelatinized cellulose acetate provided from Chemetron-Milano, Italy. It was found by preliminary electrophoretic studies[12] of ^{147}Pm and ^{177}Lu on various supporting materials, that, except for "Cellogel," metal ions were liable to be adsorbed on filter papers usually used for electrophoresis. The "Cellogel" strips preserved in 40% methanol solution were rinsed and stored in distilled water for a few days to remove methanol.

Electrophoresis was carried out by mean of the apparatus provided by Mamino Industry Co. The supporting medium was placed in carbon tetrachloride bath cooled by circulating water of constant temperature (10±0.1°C) in order to avoid heat caused by electric current. The background electrolyte solution was 0.5M lactic acid and its ionic strength was adjusted to 1.5 with potassium chloride, since mobility is affected by ionic strength (Fig. 1) through the change of either resistance or complex formation constants.

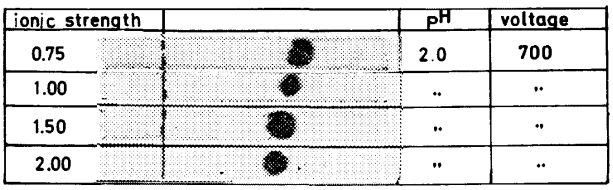

Fig. 1. Autoradiograms of promethium at different ionic strength.

The radioisotopes used were ^{147}Pm, ^{152}Eu, ^{177}Lu, ^{241}Am, and ^{242}Cm. ^{152}Eu and ^{177}Lu having high specific activity were prepared by neutron irradiation of europium and lutetium target in KUR reactor. ^{242}Cm was obtained in carrier-free state after the radiochemical separation of neutron irradiated ^{241}Am target.[13]

The reagents used were all extra pure ones supplied from Wako Pure Chem Ind. Ltd. The stock solutions (1—3N HCl solution) of radioactive nuclides were evaporated to dryness dissolved into electrolyte solutions of various pH and allowed to stand for one day.

The electrolyte solutions were prepared as follows. Lactic acid solution (about 1N) was prepared and its concentration was determined by titration with 0.1N sodium hydroxide. Solutions of NaOH(2N) and $HClO_4$(2N) were prepared and each was mixed with 1N lactic acid in the volume ratio 1:1. This gave two solutions; 0.5M lactic acid—1N NaOH, 0.5M lactic acid—1N $HClO_4$. They were mixed together in various ratios to obtain solution of desired pH.

Procedure. The "Cellogel" strips were dipped at first in the solutions of the background electrolyte (pH 3, 7, and 10) and then in the solutions with various pH used for migration. The excess electrolyte on the "Cellogel" strips was removed with filter paper and then about 1—2 μl of the radioactive sample solution was placed at the starting point marked on the strip. The diameter of the sample spot was about 3 mm. After the "Cellogel" strip had been placed in the migration chamber, a constant voltage was applied between the two electrodes.

After the migration, the "Cellogel" strip was dried in air and fixed to a thick paper. The migration zones of the β-emitter were determined by autoradiograph with X-ray films (Fuji medical X-ray Film), and that of α-emitters by the α-track method[14] with a cellulose nitrate film. The cellulose nitrate film was etched with a 6N sodium hydroxide solution at 60°C for 10 minutes to reveal the α tracks, and was then observed with a microscope.

Results and Discussion

The autoradiogram of ^{147}Pm and the α-track electrophoregram of ^{241}Am are shown in Figs. 2 and 3, respectively.

The relationship between the mobility of ^{147}Pm and the pH value of the electrolyte solution (lactic acid) is shown in Fig. 4. The mobility decreases remarkably with increasing pH in the pH range 0—4, and is almost independent of the pH in the range 5—8. The mobility also decreases above pH 8.

The dissociation of lactic acid at different pH values is shown in Fig. 5 according to the data $pK=3.6$ for lactic acid by means of Eq. (9). It can be seen that the ligand concentration changes remarkably in the pH region 2—5, and is almost constant above pH 6.

The first drop in mobility in the pH range 0—4 (Fig. 4) depends on the decrease of the average charge

of the complex due to the increase of the number of anionic ligands coordinated to promethium. The constancy of mobility in the pH range 5—8 can be understood to be due to the constancy of ligand concentration of lactic acid in this pH region. The decrease of mobility above pH 8 might be due to the formation of complexes with both hydroxy and lactate ions as ligands, since the concentration of hydroxy ion is rather high. This, together with the existence of a plateau at the pH range 4—8 suggests that the effect of hydroxy ion is negligible over the pH range 0—4.

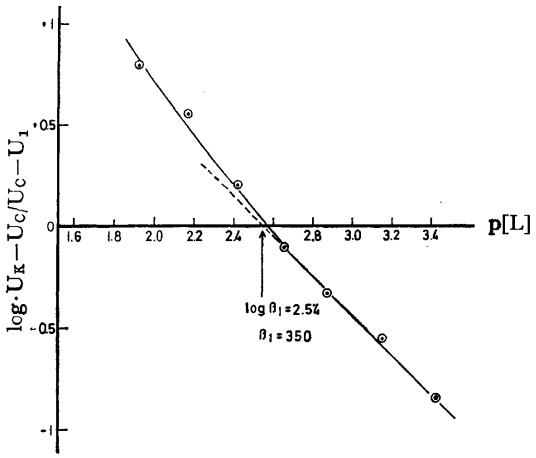

Fig. 6. The analysis for β_1 value from electrophoretic data of promethium in the lactate solution.

By estimating the value of U_k and U_1 from the mobility-pH curves (Fig. 4), we obtain the graphical plot of Eq. (12) for promethium (Fig. 6). The slope of this straight line is 1 in the range of large p[L] value, *i.e.*, of small [L] values due to small values of pH. However, in the range of small p[L] value, the gradient

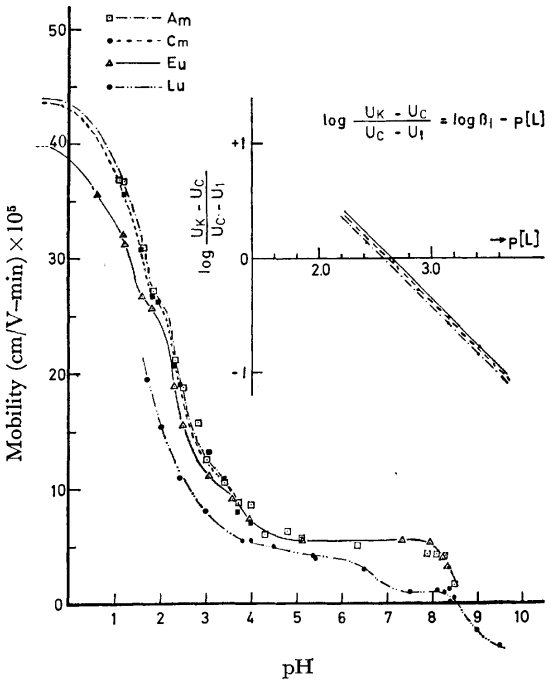

Fig. 7. Mobility — pH curves of Eu, Lu, Am, and Cm lactates and the analysis for β_1 values.

is slightly larger than 1. The reason might be that $\beta_2[L]^2$ is not negligible any more in this case, because of the formation of PmL_2 complexes. As shown in Fig. 6, the value for β_1 should be read from the intercept at the point $p[L]=2.54$, giving the value 350.

The mobility-pH curves for Eu, Lu, Am, and Cm are shown in Fig. 7. They are similar to those for promethium and can be analyzed in the same manner as before.

At any pH, the smaller the mobility, the larger the tendency of complex formation. Therefore, it is shown qualitatively that the formation constants increase in the order Am<Cm<Eu<Lu.

The difference in the formation constants of Am and Cm is very small. The maximum number of coordinated lactate ions may be estimated to be about 2.4 for Lu, but about 2.5 for Eu, Am, and Cm under the conditions employed.

The plots of $\log (U_k-U_c)/(U_c-U_1)$ *vs.* $p[L]$ are also shown (upper right, Fig. 7). The gradients are approximately 1 for all these elements. The curve for Lu is not given since no data are available for the low pH range.

The logarithms of β_1, β_2, and β_3 values are summarized in Table 1 with the previous data. The stability constants β_1 of the lactate complexes of the rare earth elements have been found to decrease with increasing ionic strength.[15,16] The β_1 values we obtained agree fairly well with those obtained by the different methods if the effect of ionic strength on β_1 values is considered. Each $\log \beta_1$ value we obtained may include an error of about 1% (absolute value) as in other works.[8,9] However, under the same conditions, a comparison of $\log \beta_1$ can be made more strictly for Am, Cm, and Eu (Fig. 7). The β_2 values determined are slightly samller than those previously reported, though a larger error (about 10% of $\log \beta_2$ value) may be included in the estimation of β_2.

Table 1. Logarithms of stability constants of Pm, Eu, Am, and Cm lactates

Element	Method	Temp. (C°)	Ionic strengh	$\log \beta_1$	$\log \beta_2$	$\log \beta_3$	Ref.

	(a)	10	1.5	2.59	4.29		this work

Method: (a) electrophoresis, (b) potentiometric titration, (c) distribution measurement, (d) ion exchange.

The electrophoretic method requires only small amounts of samples to determine stability constants. Since the difference in β_1 values of each element becomes small at high ionic strength, it is recommended that separation of elements should be carried out at low ionic strength, as the separation factor of two elements is proportional to the ratio of their stability constants.

Potentiometric Titration of Iron(III) with Hydrazine Sulphate at Room Temperature

G. Gopala Rao, P. V. Krishna Rao, and G. Bala Bhaskara Rao
Department of Chemistry, Andhra University, Waltair, India
(Received May 13, 1971)

Conditions have now been developed for a direct potentiometric titration of iron(III) with hydrazine sulphate at room temperature. Osmium tetroxide markedly catalyses the reaction in medium of 2.0—3.0 pH. Under the conditions prescribed four moles of iron(III) are reduced per every mole of hydrazine oxidised. Application of the new method to the assay of iron(III) in an alloy is also considered.

Hydrazine sulphate, $N_2H_4 \cdot H_2SO_4$ is now readily available at the purity required of a primary standard. It is non-hygroscopic and has a long shelf life. Aqueous hydrazine sulphate solutions are reported to be stable even for a long period of two months.[1] In view of these considerations it has been proposed as a primary standard in acid-base titrimetry[2] and in redox titrimetry.[3] The use of the hydrazine sulphate as a reducing agent has been reviewed by Berka, Vulterin, and Zyka.[4] A survey of the literature shows that the reagent has not been used till now for the detremination of iron(III). Many years ago Kirk and Browne[5] propounded an interesting hypothesis that one electron oxidising agents react with hydrazine to give nitrogen and ammonia according to the equation:

$$N_2H_4 - e \longrightarrow \frac{1}{2}N_2 + NH_3 \qquad (1)$$

and with two electron oxidising agents giving only nitrogen according to the overall equation

$$N_2H_4 - 4e \longrightarrow N_2 + 4H^+ \qquad (2)$$

The stoichiometry of four equivalents of oxidising agent per mole of hydrazine required by Eq. (2) is found to be followed by reactions of hydrazine with iodine, bromine, iodine monochloride and thallic chloride. With one electron oxidising agents like iron(III), manganese(III), and cerium(IV) the number of equivalents of oxidising agent per mole of hydrazine was never found to be one as required by Eq. (1) but was found to be lying between 1 and 2. For the reaction with cerium(IV) in sulphuric acid medium Benrath and Ruland,[6] and Gopala Rao, Subramanyam, and Krishna Rao[7] obtained values of 1.221 and 1.224 respectively for the value of the equivalents of cerium-(IV) reacted with one mole of hydrazine at 80—90°C. The latter workers showed that a direct titration of hydrazine in 1N sulphuric acid medium can be made at 50° with a potentiometric end-point in the presence of manganous sulphate as a catalyst. It was observed that manganese(II) not only affected a considerable acceleration of the reaction but also brought down the stoichiometry of the reaction from 1.224 to 1.016. The value of 1.016 is closer to 1.0 as required by the hypothesis of Kirk and Browne and this improvement in stoichiometry could be understood in terms of the hypothesis because manganese(II) acts as a catalyst through a one-electron mechanism by its oscillation between the +2 and the +3 oxidation states. A more striking change in the stoichiometry was observed by Gopala Rao and Krishna Rao[8] in their titration of hydrazine hydrochloride in hydrochloric acid medium with cerium(IV) nitrate at room temperature in the presence of potassium bromide as a mediator. In this case there is a swing in the stoichiometry of the reaction in the other direction, changing from 1.224 to 4.0. The reaction of hydrazine with cerium(IV) in the presence of potassium bromide undoubtedly occurs through bromine as per Eq. (2) above. Having thus achieved the change of type in the case of hydrazine-cerium(IV) reaction from a mixed type to an accurately stoichiometric 2-electron type with the use of bromide as a mediator or from a mixed type to a very nearly 1-electron type with the use of manganese(II) as a catalyst, we undertook an investigation to see if the iron(III)-hydrazine reaction can also be made to conform to an accurate integral stoichiometry of any one type. Studying the reaction of iron(III) with hydrazine in sulphuric acid medium at 80—90° under varying conditions of acidity and ratio of the reactants but always keeping iron(III) in excess, Cuy[9] found that the stoichiometry varied in the limits 1.32—1.92. A few representative results are listed in Table 1.

It would thus appear that iron(III) functions both as a one-electron type and a two-electron type oxidising

Table 1. Stoichiometry of the iron (III) hydrazine reaction

Acidity	Initial Fe(III) / N_2H_4	Stoichiometry no. of moles of iron(III) consumed per mole of N_2H_4
2N	66	1.32
2.6N	200	1.45
0.12N	66	1.74
0.11N	200	1.92

agent for hydrazine, with regard to the type classification of Kirk and Browne. This classification has been adopted by many kineticists[10-12] in their studies of the hydrazine-iron(III) reaction. A close look at the results of Cuy shows that the two-electron type of oxidation increasingly manifests itself with decreasing acidity and with increasing proportion of iron(III). This may be understood in terms of hydrolysis of iron(III) and its dimerisation. Remy[13] states that the exchange of OH^- group for ClO_4^- in aqueous iron(III) perchlorate solution is associated with a simultaneous condensation process of the type

$$2Fe(ClO_4)_3 + H_2O \rightleftharpoons [(ClO_4)_2Fe\text{-}O\text{-}Fe(ClO_4)_2] + 2HClO_4$$

Millburn and Vosburgh,[14] from a spectrophotometric study of 0.01—0.001M iron(III) perchlorate solutions, suggested the dimerisation of the first hydrolysis product by the following scheme.

$$Fe^{3+} + H_2O \longrightarrow [Fe(OH)]^{2+} + H^+$$

$$2Fe(OH)^{2+} \longrightarrow [Fe(OH)_2Fe]^{4+}$$

Whatever may be the formula of the dimeric species, it will be noted that the dimeric species functions as a two-electron oxidiser. Even at the low acidity of 0.11N sulphuric acid, there is still a good deal of one electron type of oxidation of hydrazine because the maximum stoichiometry obtained was only 1.92 and not 4. Moreover the rate of oxidation of hydrazine by iron(III) in this acidity range is not fast enough at room temperature or even at 80 or 90° to facilitate a direct titration. We have now made the interesting observation that the use of osmium tetroxide in trace amounts profoundly accelerates the reaction besides regulating the reaction type to accurately conform to a stoichiometry of 4.0. The details of a potentiometric titration of iron(III) with hydrazine sulphate are presented below. A visual titration was not found possible using the redox indicators, methylene blue, thionine, and variamine blue.

Experimental

Reagents. *Hydrazine Sulphate Solution*: A 0.1M stock solution was prepared from AR, BDH hydrazine sulphate, $N_2H_4\text{-}H_2SO_4$, which was dried at 150°C for one hour. The weight purity agreed within ±0.2% with the purity determined by the bromate method of Kurtenacker and Wagner[15] as modified by Kolthoff.[16] This stock solution was suitably diluted with distilled water when required.

Iron(III) Solution: A 0.1M solution is prepared from AR, BDH ferric ammonium sulphate in 0.2N sulphuric acid. The solution was standardised by photochemical reduction with oxalic acid and subsequent titration with sodium vanadate following the method of Gopala Rao and Madhusudana Rao,[17] and also by the standard procedure of reduction in the Jone's reductor and titration of the reduced solution with standard dichromate solution.

Osmium Tetroxide Solution: A 0.2% solution of osmium tetroxide was prepared in 0.1N sulphuric acid from a sample supplied by M/s. Johnson Mathey, England.

All other chemicals employed in this investigation are of analytical reagent grade. The pH of the titration mixtures was adjusted with a 10% solution of sodium bicarbonate with the aid of strips of indicator-paper supplied by M/s. British Drug House (India) Ltd.

Apparatus. The potentiometric titration assembly employed in this investigation comprises of a Junior potentiometer, a Taut suspension galvonometer (both supplied by M/s. W. G. Pye & Co., England), a bright platinum rod as indicator electrode, and a saturated calomel electrode as a reference electrode. Contact between test potential and the reference electrode has been established by means of a porous plate-end salt bridge filled with a saturated solution of potassium sulphate. The titration vessel consists of a 150 ml Pyrex beaker fitted with a five-holed rubber stopper. The holes accomodate respectively a salt bridge, an indicator electrode, the nozzle of a microburette, and the inlet and outlet tubes for nitrogen.

Our preliminary experiments have shown (i) that the reduction of iron(III) with hydrazine sulphate in an acid solution is extremely slow at room temperature (ii) the speed of reduction increases with decreasing acidity of the medium (iii) even in a medium of pH 2.0—3.0 the reaction is too slow for a potentiometric titration to be carried out at room temperature. (iv) At higher temperatures the iron-(III) solution undergoes rapid hydrolysis in this pH range and precipitates as the hydroxide. However we made the interesting observation that when traces of osmium tetroxide are added to the reaction mixture, the reaction is markedly accelerated at room temperature in this pH range and this catalysed reaction can be utilised for a direct potentiometric titration of iron(III) with hydrazine sulphate.

Effect of Varying the pH *of the Medium.* The influence of pH on the shape of the *E-V* curve is shown in Fig. 1. When the pH of the iron(III) solution is 1.0 the potentials attain stable values in about two min in the early stages of the titration, but a wait of 10—12 min is required near the equivalence point. Moreover, at this pH, the potential break at the equivalence point was not quite satisfactory being about 15 mV for 0.04 ml of the titrant. At pH 2.5—3.0, the potentials attain stable values within one minute in the early stages of the titration, in about 2—3 min near the equivalence point and in about 5 min at the equivalence point. The potential break at the equivalence is about 60—70 mV per 0.04 ml of 0.025M hydrazine sulphate. In titrations with a 0.1M solution of hydrazine sulphate, the break in potential at the equivalence point is about 90 mV per 0.04 ml of the titrant.

Effect of Oxygen of the Air. Titrations conducted in presence of atmospheric oxygen gave results which agree with those conducted in an inert atmosphere. This shows that nitrogen evolved in the reaction is sufficient to act as a blanket against the interference of the oxygen of the air.

Stoichiometry. Under the conditions prescribed, it has been found that four moles of iron(III) are reduced per mole of hydrazine oxidised, in accordance with the equation

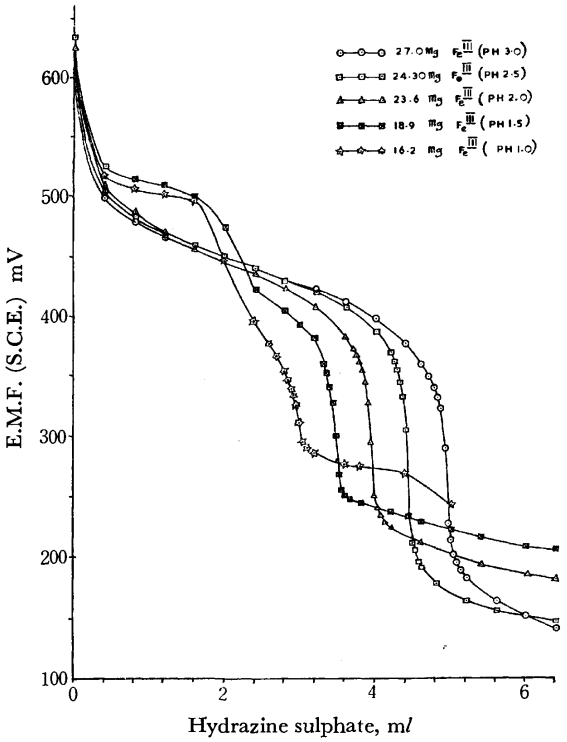

Fig. 1. Effect of pH on the potential break at the equivalence point in the titration of iron(III) with 0.025M hydrazine sulphate.

$$N_2H_5^+ + 4Fe^{3+} \longrightarrow N_2 + 4Fe^{2+} + 5H^+.$$

Effect of Varying Osmium Tetroxide Concentration. Our experiments with varying amounts of osmium tetroxide have shown that a minimum of 0.2 m*l* of a 0.2% solution of the catalyst is needed for a satisfactory potentiometric titration while quantities beyond 0.5 m*l* result in slightly higher titers.

Recommended Procedure. The pH of an aliquot of the iron(III) solution taken in a titration vessel is carefully adjusted with the aid of strips of pH indicator paper to lie between 2.5 and 3.0 using a 10% solution of sodium bicarbonate. Then 0.2 m*l* of a 0.2% solution of osmium tetroxide is added, the mixture diluted to 50 m*l* and then titrated with a 0.025—0.1M hydrazine solution to a potentiometric endpoint using the titration assembly described above. The potential values were recorded with a wait of one minute after the addition of each drop of the titrant in the initial stages of the titration, and after a wait of 2 min near the equivalence point. During the titration a drop or two of bicarbonate solution is added from time to time to neutralise the acid formed in the reaction. The potential reading at the equivalence point is noted after a wait of 5 min. After the equivalence point the potentials again attain stable values within a minute after the addition of the titrant. Some representative results of titrations carried out according to the new procedure are recorded in Table 2.

Table 2. Recovery of iron(III) by potentiometric titration with hydrazine sulphate

Amount of iron(III), mmol	
Taken	Found
0.0634	0.0636
0.1105	0.1096
0.3120	0.3125
0.4199	0.4200
0.9287	0.9265
1.3950	1.3910
2.0410	2.0530

Titrations of dilute solutions of iron(III) with hydrazine sulfate are not possible when the over all concentration of iron(III) is below 10^{-2} mol/*l*. Reverse titrations of hydrazine sulphate with iron(III) are not feasible under the pH and catalyst conditions stated above. It was observed that when osmium tetroxide was added to the hydrazine sulphate solution, it was reduced to a black colloidal mass which was not reoxidised by the iron(III) solution dropped from the burette.

Interferences. Vanadium(V) and chromium(VI) interfere by simultaneously reacting with hydrazine sulphate under the experimental conditions. Molybdenum(VI) interferes at higher concentrations (when Mo(VI)/Fe(III) is 20) by formation of an insoluble white precipitate, presumably iron(III) molybdate. Molybdenum(VI) also interferes at low concentrations (1.85×10^{-2} mg/50 m*l*) through formation of molybdenum blue presumably by reduction of molybdenum(VI) by the iron(II) formed in the reaction. In the presence of titanium(IV) the titration of iron(III) is not possible, probably due to hydrolysis of titanium(IV) at the prescribed pH and deposition of the hydrolysed product on the platinum electrode.

Uranium(VI), vanadium(IV), copper(II), nickel(II), cobalt(II), chromium(III), and manganese(II) do not interfere. Sulphate and perchlorate also do not interfere. Chloride interferes at a final concentration greater than 35 mg/50 m*l* by lowering the potential break. In the presence of complexing anions like phosphate, fluoride, salicylate, and thiocyanate the titration of iron(III) is not possible.

Application of the New Procedure for the Determination of Iron(III) in Alloys

Analysis of an Alloy. An accurately weighed sample (*ca.* 1.0 g) of the alloy (soft iron nail) is treated with 25 m*l* of 1:1 (vol/vol) nitrogen free sulphuric acid in a 250 m*l* beaker covered with a watch glass and heated on a hot plate till it completely dissolves. The resulting solution which contained a few black floating particles (carbon) is filtered after dilution with water through a Whatman No. 42 filter paper into a 500 m*l* Pyrex beaker and treated dropwise with 0.1N solution of potassium permanganate until a very pale pink colour of $KMnO_4$ persists. The excess of permanganate is destroyed by adding one or two drops of a 10% (vol/vol) hydrogen peroxide solution. The resulting solution is gently heated to boiling on a hot plate to destroy the excess hydrogen peroxide. It is then cooled to room temperature, quantitatively transferred to a 500 m*l* volumetric flask and made up to the mark.

Table 3. Assay of iron(III) in an iron nail

Wt. of the sample analysed, g	Iron(III) found, g		
	Present method, g	Jone's reduction method, g	Photochemical reduction method, g
1.3058	1.3020	1.3031	1.3017
1.1810	1.1776	1.1780	1.1767
0.9894	0.9876	0.9877	0.9877

Aliquots of this solution are titrated with 0.025M hydrazine sulphate solution to a potentiometric end-point according to the recommended procedure. The results are compared with those obtained by titration with a standard solution of potassium dichromate after reduction in a Jone's reductor, and also with those obtained by the photochemical reduction method of Gopala Rao *et al.*[17] The data in Table 3 show that the results obtained by the new procedure are in excellent agreement with those obtained by the standard procedures.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3437—3439 (1972)

Titrimetric Determination of Iron(II), Molybdenum(V), and Thallium(I) with Potassium Chlorate Using Redox Indicators

G. Gopala Rao and C. Radhakrishnamurty*
Department, of Chemistry Andhra University, Waltair, India

(Received May 17, 1971)

Accurate and convenient procedures have now been devised for the titrimetric determination of iron(II), molybdenum(V), and thallium(I) with potassium chlorate using visual indicators. These procedures are more advantageous than the procedures involving bromate. Further, chlorate is to be preferred as it is more inexpensive than bromate or iodate. Potassium chlorate is now obtainable at the purity required of a primary standard at a nominal cost. The chlorate titration procedure for iron(II) works satisfactorily even in the presence of organic materials such as oxalic acid, tartaric acid, and citric acid, so that it can be used for the determination of ferrous iron in pharmaceutical preparations or of ferric iron after reduction. It has been observed by us that oxygen of the air interferes in the titration of iron(II) in 6—7M hydrochloric acid medium using naphthol blue black or methyl orange as a redox indicator but not in the titration of iron(II) in sulphuric acid medium using ferroin as an indicator. An inert atmosphere is not necessary for the titration of molybdenum(V) and thallium(I) in hydrochloric acid medium.

Although potassium chlorate is available at the purity required of a primary standard, it has not been very much used as a titrimetric reagent. Potassium chlorate may function in acid solution either as a five electron oxidant giving chlorine or as a six electron oxidant giving chloride as the end product. The calculated redox potentials for these two reactions are 1.47 and 1.45 V respectively, comparable to those of cerium(IV) sulphate and potassium permanganate. Inspite of these high redox potentials potassium chlorate is comparatively inert in dilute acid solution. Its comparative chemical inertness is explicable from kinetic considerations. The rates of reactions of potassium chlorate even with substances of very low redox potentials like tin(II) and titanium(III) are very slow. Recent studies on the kinetics of reactions involving chlorate have shown that the reaction rates increase with increasing hydrogen ion concentration. Since resonance stabilisation is large for oxyanions, it is necessary to overcome this stability in order that a chemical reaction takes place. On the addition of hydrogen ions at high concentration the oxyanions are converted into less stable forms which can easily react with other chemical species. Taking advantage of the kinetic results we have been able to establish conditions under which potassium chlorate can be used as an oxidimetric reagent for the direct titration of iron(II), molybdenum(V), and thallium(I) at room temperature using suitable redox indicators.

* Department of Chemical Engineering, Andhra University, Waltair, India.

Experimental

Preparation of Solutions. A 0.1N solution of potassium chlorate is prepared from "Pro Analysi" reagent supplied by E. Merck and its purity is checked by the method prescribed by Vogel.[1] The assayed purity agreed with the weight purity.

A 0.1N solution of iron(II) was prepared from Analar reagent grade Mohr's salt supplied by British Drug Houses. The final concentration of sulphuric acid in the solution is 1.0N. The solution is standardised against potassium dichromate.

A 0.1N solution of molybdenum(V) was prepared from Analar reagent grade ammonium molybdate which was reduced in 3M hydrochloric acid in a mercury reductor according to the instructions of Furman and Murray[2] and standardised against standard cerium(IV) sulphate by the procedure of Gopala Rao and Suryanarayana.[3]

A 0.1N thallium(I) sulphate solution was prepared from Analar reagent grade thallous sulphate and standardised against potassium dichromate according to the procedure of Erdey, Vigh, and Buzas.[4]

All other chemicals used in the investigation are of chemically pure grade.

Visual Titration of Iron(II) with Potassium Chlorate. From preliminary studies it was observed that ferroin is rapidly oxidised only in a medium containing sulphuric acid and phosphoric acid at final concentrations of 8—9 and 2M respectively. The oxidised indicator is, however, reduced rapidly by iron(II) under all conditions of acidity. In 9 and 10M sulphuric acid alone titrations cannot be conducted because ferroin decomposes as the end-point is approached. Phosphoric acid not only stabilises the indicator but also catalyses the oxidation of indicator by chlorate. In view of these considerations the following procedure is recommended for the titrimetric determination of iron(II) with potassium chlorate.

Recommended Procedures for the Titration of Iron(II).

Procedure 1: A known volume of 12M sulphuric acid is taken in a 150 m*l* pyrex titration cell and enough distilled water added to give an overall acidity of 8—9M when diluted to 50 m*l*. The mixture is cooled to the room temperature and then an aliquot of iron(II) solution is added followed by 5 m*l* of 85% syrupy phosphoric acid. Stirring the mixture well, add 0.1 m*l* of 0.01M ferroin and titrate with 0.1N solution of potassium chlorate. The titration is to be made dropwise towards the end, giving a wait of 10 seconds between successive additions. At the end-point the colour change is from red to pale blue. The indicator correction is 0.07 m*l* of 0.1N chlorate solution to be deducted from the titer. The average relative error of determination of iron(II) is ±0.2%.

Procedure 2: The addition of 1—2 m*l* of 0.1N of vanadium(IV) sulphate in place of phosphoric acid also catalyses the reaction at overall acidity of 7—8M sulphuric acid using 0.1 m*l* ferroin as an indicator. The average relative error of determination of iron(II) is ±0.2%.

Procedure 3: Titrations of iron(II) with potassium chlorate have been found possible in 6—7M hydrochloric acid medium in an inert atmosphere, using 0.1 m*l* of 0.2% naphthol blue black or 0.1 m*l* of 0.1% methyl orange as a redox indicator. The colour changes at the end-point are from green to yellow with naphthol blue black and red to yellow with methyl orange. The indicator correction amounts to 0.06 m*l* of 0.1N potassium chlorate per 0.1 m*l* of any of the two indicator solutions, to be deducted from the experimental titre. For titrations of iron(II) in 6—7M hydrochloric acid medium an inert atmosphere is necessary, because iron(II) will be oxidised by oxygen of the air due to lowering of the iron(III)/iron(II) potential in hydrochloric acid medium.

Interferences: Five hundred milligram of oxalic acid, 75 mg of tartaric acid, 525 mg of citric acid, 41 mg of cobalt(II), 53 mg of nickel(II), 13 mg of chromium(III), and 15 mg of vanadium(IV) do not interfere in a volume of 50 m*l*. Glucose interferes. Representative results are presented in Tables 1 and 2.

Table 1. Titration of iron(II) with potassium chlorate

Indicator	Amount of iron(II) in mmol	
	Taken	Found
Ferroin	0.3960	0.3950
8—9 M H_2SO_4	0.4384	0.4390
+	0.5245	0.5234
2 M H_3PO_4	0.7091	0.7111
Ferroin	0.2567	0.2572
7—8 M H_2SO_4	0.5200	0.5190
+	0.6200	0.6182
1—2 m*l* of 0.1 M vanadium(IV)	0.7316	0.7335

Table 2. Titration of iron(II) with potassium chlorate

Indicator	Amount of iron(II) in mmol	
	Taken	Found
Naphthol blue black	0.3570	0.3651
6—7 M HCl	0.4039	0.4048
	0.4529	0.4536
	0.6806	0.6794
Methyl orange	0.3468	0.3476
6—7M HCl	0.4487	0.4478
	0.5665	0.5670
	0.7018	0.7037

Visual Titration of Molybdenum(V). Satisfactory visual titrations of molybdenum(V) with potassium chlorate can be made in 5—7M hydrochloric acid medium with the addition of 1 m*l* of 0.01M iron(III) as a catalyst per 50 m*l* using 0.1 m*l* of 0.1% methyl orange or methyl red as an indicator. While using 0.1 m*l* of 0.2% napthol blue black as an indicator it is necessary to add 3 m*l* of the iron(III) solution as a catalyst. The titration is carried out rapidly in the beginning and slowly towards the equivalence point allowing 20—25 sec, after each addition of a drop of the reagent; with methyl orange or methyl red the end-point is denoted by the disappearance of red colour. In the case of naphthol blue black the colour change is from bluish green to yellow. The indicator correction with 0.1N chlorate solution is 0.06 m*l* per 0.1 m*l* of any of these indicator solutions. These indicators do not work in sulphuric acid medium. The average relative error of determination is ±0.2%. Our observations showed that an inert atmosphere is not necessary for the titration of molybdenum(V).

Interferences: Twenty six milligram of chromium(III) and 44 mg of vanadium(IV) do not interfere.

Some typical results are given in Table 3.

Table 3. Titration of molybdenum(V) with potassium chlorate

6—8M HCl	0.3175	0.3185
	0.3632	0.3621
	0.3936	0.3944

case of methyl orange and methyl red, 0.06 m*l* in the case of phenosafranine and neutral red and 0.04 m*l* in the case of naphthol blue black. The average relative error of determination is found to be $\pm 0.25\%$. Methyl red and methyl orange turn from red to yellow, naphthol blue black turns from blue to light pink at the end-point. Phenosafranine changes color from blue violet to colorless through pink, while neutral red gives a transition of violet to colorless through pink. It has been observed by us that titrations of thallium(I) gave identical results both in air and an inert atmosphere. This shows that thallium(I) is not oxidised by oxygen inspite of the lowering of the thallium(III)/thallium(I) potential.

Some typical results are given in Table 4.

Discussion

The procedure now developed for the determination of iron(II) with potassium chlorate is much more simple and convenient than the procedure with potassium bromate. Moreover potassium chlorate is more inexpensive than potassium bromate. Kolthoff and Belcher[5] state that in the titration of ferrous iron with bromate using methyl red or methyl orange as an indicator, the colour of the indicator disappears long before the equivalence point is reached, due to the slowness of the reaction between iron(II) and bromate. Smith and Bliss[6] recommended the addition of a copper salt as a catalyst. However, as the copper also catalyses the atmospheric oxidation of the ferrous iron, arsenate is proposed to be added. They also recommended the addition of phosphoric acid to lower the oxidation potential of the system.

It is noteworthy that in the potassium chlorate method now developed for the determination of iron(II), various organic materials such as oxalic acid, tartaric acid, and citric acid do not show any interference; whereas the permanganate and dichromate methods cannot be used in their presence. The chlorate method, therefore, holds out great promise for the determination of iron(II) in pharmaceutical preparations.

The titration method for thallium(I) now developed by us is also more advantageous than the bromate procedure as the latter requires heating to 50—60°C.

Substituent Effects on Suspected Phenonium Ion Reactions

Charles A. KINGSBURY and D. C. BEST
Department of Chemistry, University of Nebraska, Lincoln, Nebraska 68508, U.S.A.

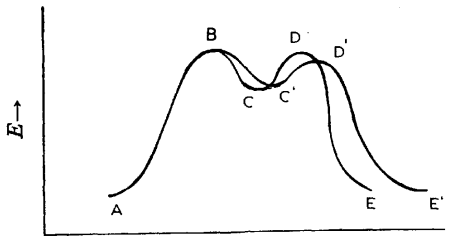
(Received May 15, 1971)

The stereochemistry of the various conversions in the 1,2-diphenyl-1-propyl system was measured as a function of aromatic substituent. For β-anisyl groups the reaction occurred with retention of configuration. For compounds with indifferent electron donating aryl groups, the conversions were stereoselective forming mostly *threo* product. For β-*p*-nitrophenyl groups the stereochemical course of the reaction was "racemization." The latter reactions were associated with the presence of open ions. In certain reactions, acetate products were formed in low yield with retention of configuration, irrespective of substituent. The kinetics of ethanolysis were consistent with (partial) bridged ion formation for the *threo* isomers and with extensive open ion formation for the *erythro* species.

The problem of the intermediacy of a phenonium ion species has occupied the attention of chemists for a considerable period.[1,2] In a sense, the question of whether or not a phenonium ion can exist has been answered by the direct spectral observation of Olah, Pittman, Namenworth, and Comisarow,[3] and in a related system, by Winstein and Baird.[4] The question remains whether the type of ion thus observed is similar to a solvolysis reaction intermediate.

The nature of the solvolysis intermediate has been inferred from stereochemical[5] and in other cases from kinetic data.[6] The inferences from stereochemical data are in actuality concerned with the relative rates of processes that give retention of configuration, (*e.g.* C→D→E of Scheme 1) and processes that give other stereochemical results (*e.g.* C′→D′→E′). These processes are sensitive not only to the nature of the intermediate (or intermediates) but also to the energy levels of the various possible transition states leading to products.[1c] Thus, product of a certain stereochemistry (*e.g.* E′) may not reflect the nature of the most stable intermediate (*e.g.* C), but merely the lowest energy pathway for conversion to products.

On the other hand, inferences from kinetic data depend on the relative energy levels A and B, and do not directly involve the intermediate C. The hope is that the energy level of B will parallel that of the first-formed intermediate C or C′. This expectation is perhaps reasonable if anchimeric assistance is present, that is where the β-aryl group pushes off the leaving group. Brown and co-workers[6,7] have advanced the existence of a large rate enhancement (over a standard compound) as the criterion for the presence of a phenonium ion intermediate. This criterion is not met in the solvolysis of 3-phenyl-2-butyl compounds, although certain β-anisyl substrates appear to fulfill this criterion.[6,7] However, in non-nucleophilic solvents such as trifluoroacetic acid, Nordlander and Deadman[8] have shown that ordinary β-phenyl substrates are indeed characterized by large rate enhancements. On the other hand, Lancelot and Schleyer believe that even a small rate enhancement may reflect the intermediacy of a bridged ion.[9]



Scheme 1.

The compounds of interest to this study are shown in Scheme 2. In these studies various of the groups Z were interposed. The question of interest is whether any evidence for participation by a β-aryl group can be detected, if the cationic center is stabilized by the effect of an α-aryl group. In a bicyclic system, Brown and co-workers have suggested that additional stabilization of a quite stable tertiary cation by participation would be unnecessary.[10] Winstein has questioned this conclusion.[11] The elegant tracer studies of Collins and Benjamin were discouraging in this regard, as there was no evidence for the existence of a bridged ion of the σ variety in the 1,2,2-triphenylethyl cation.[12] This work also showed that one must be cognizant of the fact that one of the prime pieces of evidence for participation, namely retention stereochemistry, may arise by other means. In this work, steric interference with the inversion pathway by a β-aryl group was

postulated.[13] On the other hand, the early work of Cram and Elhafez[14] on the 1,2-diphenyl-1-propyl system was interpreted in terms of β-aryl participation, although the nature of the intermediates perhaps needs to be recast in more modern terms.[14,15] In still other work, retention has been observed in solvolyses forming several types of α-aryl cations, in which no possibility of participation exists.[16-19] The leaving group may lead in the attacking solvent fragment producing retention, but, generally speaking, the mechanism of these processes requires further elaboration.

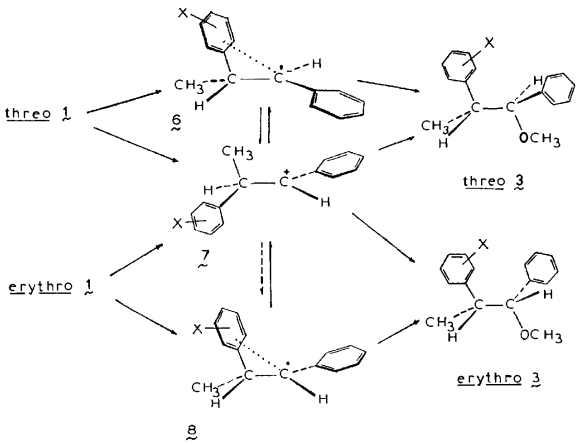
Scheme 2.

The solvolysis data are listed in Table 1. These data will be discussed in terms of the mechanism shown in Scheme 3, which is similar to that originally proposed by Cram and Elhafez.[14] The greater reactivity of the *threo* compounds could be explained by the greater stability of the bridged intermediate **6** than the analogous intermediate, **8**, which results from *erythro* **1**. The latter intermediate would be destabilized



Scheme 3.

by an unfavorable phenyl-methyl interaction. However, Cram and Elhafez also showed that the *threo* **1c** is more reactive than *erythro* **1c** in S_N2 reactions.[14,20] Thus, a sizable *threo*/*erythro* rate ratio would be expected for both β-aryl participation (k_Δ) and direct solvent attack (k_s).[2,9] Of more significance is the fact that a large *threo*/*erythro* ratio is observed for the *p*-methoxy compounds (*ca.* 28). Participation, if any, should be facilitated by this substituent.[9] Conversely, the *threo*/*erythro* ratio is minimum for the *p*-nitro compounds (2.9), which, most likely, form open ions.[21] The rate differences between *erythro* and *threo* isomers cannot be ascribed to differences in ground state energies. Equilibration of either pure *threo* or pure *erythro* **1c** produced 52±5% *erythro* and 48±5% *threo* **1c**, indicative of very similar stabilities.[20]

The absolute rates of reaction are also largest for the *p*-methoxy compounds and minimum for the *p*-nitro compounds. For the *threo* isomers, a linear ρ—σ^+ dependence is observed, in which ρ is −1.3. This value is rather low compared to certain model compounds which solvolyze by anchimerically assisted

paths (ρ near -3).[9,22,23]

For the *erythro* isomers, curved ρ—σ plots are observed (Fig. 1), which, in other cases, have been ascribed to a change in mechanism from the k_s route to the k_Δ route as the electron donating character of the substituent progressively improves.[9] However, for the *p*-nitro and *p*-chloro compounds, the ΔS^* values are generally higher than the value given by Winstein as indicative of nucleophilic assistance to ionization by solvent (-18 e.u.).[24] The cation, which is stabilized by the α-aryl group, requires less solvent stabilization.

TABLE 2. PER CENT *threo* OF AN *erythro*/*threo* MIXTURE IN THE REACTION **1**→**3** AT 56±3°C IN 90% AQUEOUS METHANOL

			% *Threo* **3**[e]

a) Total *threo* product (80% ether **3** plus 20% alcohol **2**).
b) No *erythro* product was observable.
c) Uncorrected for *ca.* 10% *erythro* inpurity.
d) At 75°C, 68% *threo* **3c** was observed.
e) The overall yield is 80±5% ethers **3** and 20% alcohols **2**.

Table 3 lists the bromide **1** to methyl ether **3**, and the bromide to acetate **4** conversions catalyzed by silver acetate. These conversions contrast the effects of acetic acid and the more nucleophilic solvent, methanol. Compared to the data in Table 2, a greater tendency for inversion is noted for these silver catalyzed reactions in methanol, particularly for electron withdrawing substituents. The effect of temperature for these conversions is quite pronounced. For example, *erythro* **1c** gave 86% *threo* methyl ether **3c** at room temperature, and 78% at 55°C. On the other hand, *erythro* **1a** gave 33% *threo* **3a** at 3°C, 40% at 34°C, and 54% at 55°C. Thus, the stereochemistry changed from retention to slight inversion.[17]

The loss of stereoselectivity[17] with increasing temperature is interpreted in terms of the greater importance of the open ion **7** (and possibly also of **6**). In acetic acid the **8**→**7**⇌**6** equilibration sequence also has a greater chance of becoming established, due to lower solvent nucleophilicity, and indeed *erythro* **1a** forms predominately *threo* products.

The product ratios in ethanol were difficult to establish by NMR due to overlapping of peaks. The stereochemistry of the solvolysis in 90% aqueous methanol was therefore determined, and the results are recorded in Table 2. The stereochemistry in methanol and in ethanol was qualitatively similar, however. The data shown in Table 2 were somewhat temperature dependent with lower stereoselectivity observed at higher temperatures.

The data in Tables 1 and 2 indicate a fairly good correlation between solvolysis rate and stereochemistry. For the anisyl compounds, which solvolyze the most rapidly, a high degree of retention is observed for the *threo* isomers, and somewhat less retention is observed for the *erythro* compound. In the latter case, formation of the open ion **7** is quite important due to steric strains present in the bridged ion **8**. We agree with Brown that π bridged intermediates,[15,24b] such as **6** and **8**, deserve serious consideration due to the absence of strong rate accelerations and the absence of high stereospecificity.

For the *p*-nitro compounds, which are unreactive, a slight overall inversion of configuration is noted, but the product ratios are close to the equilibrium *threo*/*erythro* ratio. The *erythro* unsubstituted and *p*-chloro compounds give predominately *threo* products. The bridged ion **8** (which would yield *erythro* product) is unimportant because the weak stabilizing character of the β-aryl group is not able to overcome steric repulsions. The predominate pathway is thought to be the formation of the open ion **7**, which forms products of mixed stereochemistry. Internal rotation may also occur in **7**, with concurrent formation of **6**, which yields *threo* products.

a) % *Threo* of an *erythro/threo* mixture.

In methanol, small amounts of acetates **4** are also formed in addition to the ethers **3**. Although the stereochemistry of **4** is difficult to measure accurately by NMR, predominate retention stereochemistry is evident. The acetates **4** formed from reactions in methanol may result from a four-center type of mechanism.[18]

In order to show the generality of the stereochemical changes, the conversions of the alcohols **2** to the chlorides **5** were studied. The reaction mixture was 4:1 acetic acid and concentrated hydrochloric acid. The products were not stable under the reaction conditions. Epimerization and olefin formation were evident upon long reaction times. The data listed in Table 4 were determined by trial and error variation of reaction times, in an attempt to achieve minimum olefin formation and maximum stereoselectivity. The stereochemistry of the chlorides is rather similar to that of the acetates in Table 3 and the ethers in Table 2. No conclusion is drawn from the acetate data in Table 4 due to the possibilities for Fischer esterification of the parent alcohol.

In conclusion, the stereochemical results are a function of the intrinsic characteristics of the molecules, and not functions of the reaction conditions except for certain minor variations as discussed above. We feel there is definite evidence for participation by β-anisyl groups (rapid solvolysis and generally retention stereochemistry). Participation by the β-phenyl group may be of importance through an ion such as **6**, but no evidence exists for the presence of the less stable ion **8**. While it is true that the α-aryl group reduces the demand for β-aryl participation, the necessity for solvent stabilization is also reduced, which gives the phenonium ion more of a chance.

The possibility exists that the predominate *threo* products, which occur from substrates **c** and **d**, result from a simple lower energy pathway from the open ion. However, the trend of the stereochemical data, as substituent progressively becomes more electron donating, is precisely what one would expect on the basis of reaction through a π-phenonium ion. These substituents should not affect the reaction pathways available to an open ion. As discussed in the Introduction, one cannot state that the bridged ion is more stable than the open ion, since relative product yields reflect the relative energies of the intermediate ions and the relative transition state energies leading to products. A second alternate explanation of the data, involving steric interference of groups at the β-carbon upon attack upon one of the two faces of the open ion, would predict predominately *erythro* product,[14] which is not observed. This work and related studies emphasize the importance of *both* open ions and bridged ions in a single reaction sequence,[2,9,14] rather than *either* an open ion[6] *or* a bridged ion mechanism.[5]

Table 4. Overall yield and stereochemical purity of the 2→4 and 2→5 conversion in acetic acid–con. HCl, 4:1 at 26±3°C

c) % *Threo* product of an *erythro/threo* mixture.

Experimental

The substrates **2** (except **2e**) were prepared by aryl Grignard addition to the appropriate 2-arylpropanals. The latter were usually prepared from the glycidic ester.[23] The following procedure is typical.[27] To 1-(4-chlorophenyl)-1-ethanone (77 g, 0.5 mol) and ethyl chloroacetate (56 g, 0.5 mol) plus 120 m*l* benzene in a 2 *l* three-necked flask, 0.5 mol of potassium *t*-butoxide was added in increments as a solid, and the mixture vigorously stirred for 24 hr. The resulting red solution was poured over ice and extracted with benzene. The organic layers were dried ($MgSO_4$), and the solvent evaporated. The glycidic ester was distilled, the fraction boiling at 121°C/0.75 mmHg was collected. This material was treated with sodium ethoxide (5.8 g sodium in *ca.* 100 m*l* ethanol) and after 2 hr the flask was cooled to 0°C and 8 m*l* of water was added. The sodium salt derived from the glycidic ester

27) A. I. Vogel, "Practical Organic Chemistry," 3rd Edition, Longmans, Green and Co., Ltd., London (1956), p. 907.

separated and was collected by filtration. The mother liquor yielded a second crop when cooled and diluted with ether, total 37 g. This salt was treated with dilute hydrochloric acid (28 m*l* conc. acid plus 150 m*l* water). The mixture was stirred for 2 hr and heated to *ca.* 80°C for 2 hr. The mixture was poured over ice and extracted with ether. The ether layer was washed with water, dil. sodium bicarbonate solution, dried over magnesium sulfate, and distilled; the fraction boiling from 78—80°C/10.7 mmHg was collected, 12.7 g.

The above aldehyde (17.3 g, 0.132 mol) was added dropwise to a solution of phenyl magnesium bromide prepared from 6.5 g magnesium plus 27.4 m*l* bromobenzene. The mixture was poured into ice/ammonium chloride. Hydrochloric acid was added until the aqueous layer was slightly acidic. The ether extract was washed with water, dil. sodium bicarbonate, and distilled, the fraction boiling from 148—150°C/0.7 mmHg (15.7 g) was taken (mixed *erythro* and mostly *threo* diastereomers **2d**).

To 3.14 g (0.0177 mol) of the above alcohol in 70 m*l* pyridine was added 3.5 g *p*-nitrobenzoyl chloride. This mixture was heated on a steam bath for 15 min and stirred for 0.5 hr. The mixture was poured onto ice, and extracted twice with 10% hydrochloric acid, water, twice with dil. sodium hydroxide, and twice with water. The ether layer was dried and evaporated yielding crystals, which were recrystallized from ethanol–water and from pentane–carbon tetrachloride. These were the *threo* **2d** *p*-nitrobenzoate mp 111.6—111.8°C. The *erythro* isomer was elusive in this case but could be prepared by oxidizing the alcohol to the ketone and reducing the ketone with lithium aluminum tri-*t*-butoxy hydride. In general the diastereomerically pure alcohols **2** were prepared by hydrolyzing the purified *p*-nitrobenzoates. Substrates **2c** however were prepared by the method of Cram and Elhafez.[14]

Mixed diastereomers **2e** were prepared from 2-(4-nitrophenyl)-1-phenyl-1-ethanone by the following reactions.[28] To 0.5 g (0.00207 mol) of the above ketone in 50 m*l* dry acetone, 5 g potassium carbonate and 5 m*l* iodomethane were added with rapid stirring. The resulting purple reaction mixture was refluxed 2 hr and poured into ice and extracted with ether. The ether layer was washed with water, dried and the solvent evaporated yielding an oil, whose NMR spectrum indicated predominantly 2-(4-nitrophenyl)-1-phenyl-1-propanone. The material from several runs (9.5 g 0.037 mol) was dissolved in anhydrous tetrahydrofuran and added dropwise to a suspension of 10.0 g (0.0394 mol) of lithium aluminum tri-*t*-butoxy hydride with rapid stirring. After stirring 2 hr the mixture was refluxed 4 hr cooled, treated with saturated potassium carbonate solution and poured onto ice. The mixture was extracted with ether, and the organic layer washed with water, dried solvent evaporated and the product chromatographed on silica gel. The benzene eluant was evaporated to yield yellow crystals, mp 102.8—103.1°C, *erythro* **2e**.

The bromides **1** were prepared from the alcohols by treatment with HBr. The following procedure is illustrative. To *erythro* **2c** (1.0 g, 0.0047 mol) dissolved in 20 m*l* CCl_4, cooled to 0°C, 50 m*l* of chilled conc. HBr and 39 g LiBr were added to the rapidly stirred mixture and the resulting mixture was stirred 4 hr and then allowed to come to room temperature.

The organic phase was separated, and the diluted aqueous phase was extracted with CH_2Cl_2. The combined organic layers were washed several times with distilled water, and then dried ($MgSO_4$). The filtered solution was concentrated by rotary evaporation. The resulting oil was *ca.* 80% *threo* **1c** and 20% *erythro* **1c**. Crystallization was induced by cooling. The isomers were separated by repeated recrystallization making use of the fact that the *erythro* isomer was not soluble in ethanol (for other compounds, **1a**, **b**, **d**, pentane was used). Of the 1.29 g (94% of theoretical) crude product usually about 0.2 g pure *erythro* **1c**, mp 157—159°C, and 0.6 g *threo* **1c**, mp 57—59°C, could be isolated in a pure state.

Erythro **1a** (X=*p*-CH_3O), mp 132—133°C, NMR ($CDCl_3$) δ 1.13 (d, 3, $C\underline{H}_3$), 3.43 (doublet of quartets, 1, $C\underline{H}$-CH_3), 3.78 (s, 3, $C\underline{H}_3O$), 5.00 (d, 1, J=9.2 Hz, $C\underline{H}$-Br), 6.84 (d, 2, $C_6\underline{H}_4$-OCH_3), 7.15 (d, 2, $C_6\underline{H}_4OCH_3$), 7.30 (s, 5, $C_6\underline{H}_5$).

Found: C, 62.83; H, 5.49%. Calcd for $C_{16}H_{17}BrO$: C, 62.96; H, 5.61%.

Erythro **1c** (X=H), mp 157—159°C, (lit,[14] mp 159—160°C); NMR ($CDCl_3$) δ 1.14 (d, 3, $C\underline{H}_3$), 3.49 (doublet of quartets, 1, $C\underline{H}$-CH_3), 5.07 (d, 1, J=9.7 Hz, $C\underline{H}$-Br), 7.30 (s, 5, Ar), and 7.35 (s, 5, Ar).

Erythro **1d** (X=*p*-Cl), mp 115—116°C; NMR ($CDCl_3$) δ 1.10 (d, 3, $C\underline{H}_3$), 3.45 (doublet of quartets, 1, $C\underline{H}$-CH_3), 4.98 (d, 1, J=9.6 Hz, $C\underline{H}$-Br), 7.20 (d, 2, $C_6\underline{H}_4Cl$), 7.30 (d, 2, $C_6\underline{H}_4Cl$), and 7.30 (s, 5, Ar).

Found: C, 58.18; H, 4.41%. Calcd for $C_{15}H_{14}ClBr$: C, 58.18; H, 4.56%.

Erythro **1e** (X=*p*-NO_2), mp 139—140°C; NMR ($CDCl_3$) δ 1.16 (d, 3, $C\underline{H}_3$), 3.62 (doublet of quartets, 1, $C\underline{H}$-CH_3), 5.03 (d, 1, J=9.7 Hz, $C\underline{H}$-Br), 7.35 (s, 5, Ar), 7.40 (d, 2, $C_6\underline{H}_4NO$), and 8.20 (d, 2, $C_6\underline{H}_4NO_2$).

Found: C, 56.30; H, 4.11%. Calcd for $C_{15}H_{14}BrNO_2$: C, 56.45; H, 4.11%.

Product Runs. A typical run is given (silver acetate catalyzed reaction of *threo* **2e** in methanol, Table 2). Approximately 150 mg of substrate was dissolved in 30 m*l* absolute methanol, and 150 mg silver acetate was added. The mixture was stirred at *ca.* 35°C for 6 hr. The mixture was filtered, and the liquid added to a separatory funnel containing ether and water. The aqueous layer was extracted with ether several times. The combined organic layers were extracted with water twice, and dried ($MgSO_4$). The solvent was removed by rotary evaporation and the product analyzed by NMR (Fig. 2).

Product Analyses. *Erythro* and *threo*-1,2-diphenyl-1-propyl bromides, chlorides, methyl ethers, and acetates were prepared which showed the literature physical constants in each case. Since the NMR resonances were only slightly affected by aromatic substituent, the above compounds sufficed as models for all compounds. The NMR analyses were possible because the methyl resonances of the *threo* isomers uniformly fell in the region δ 1.2—1.5, whereas the resonances of the *erythro* isomers fell upfield (δ 1.0—1.2).

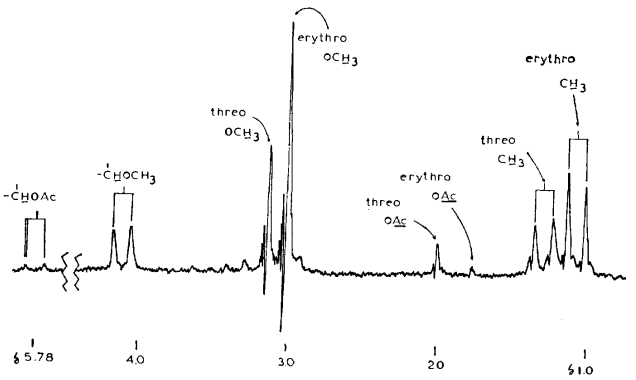

Fig. 2. Silver acetate catalyzed reaction product (**1e**→**3e**, **4e**).

The percentage of each isomer was determined from an average of 3—5 integrations. The methyl ethers also showed separate resonances for the *erythro* and *threo* isomers, an integration over the CH_3O peaks was always in good agreement with integration over the methyl resonances. The various conversions were very clean, with no apparent rearrangement, and little or no olefin formation (olefin formation was only apparent in the alcohol to chloride conversions, Table 4). The possible rearrangement products 2-methoxy-1,2-diphenylpropane and 3,3-diphenyl-2-propanol were synthesized. The distinctive resonances of these materials were never observed. Similarly *erythro*-1,2-diphenyl-1-deuterio-1-propanol was subjected to the **2**→**5** conversion. No deuterium scrambling was evident. Only in the case of the *o*-methoxy were small peaks observed, not associated with the normal products.

Kinetics. The rates of reaction were followed conductometrically. By making up known standards, it was proved that conductance was linear with hydrogen bromide concentration. Two cells were used, one with platinized electrodes, the other with plain platinum electrodes. These gave the same rates at low temperature although some divergence occurred at the higher temperatures. At the lower temperatures, due to the difference in surface area of the two cells, it is unlikely that the platinum surface was catalyzing the reaction. At higher temperatures the lower rates found with the plain cell were considered the most reliable. From sixteen to fifty-five points were taken. The rate plots were always linear over three and usually over four to five half-lives, with little scatter evident except in the latest stages of the reaction. The rates were determined graphically. The data given in Table 1 are the average of two to four runs. In one case **1c**, four-fold variation of concentration of the substrate produced very similar rate constants indicative of true first-order kinetics. Substrate concentration normally was *ca.* 10^{-4} to 10^{-5}M. The solvent (ρ=0.8403 at 25°C; 79.6% ethanol by weight) was prepared by mixing weighed amounts of redistilled ethanol with redistilled water. Activation parameters were obtained from least squares analysis of log rate *vs.* inverse temperature plots.

The Determination of Sulfide- and Sulfate-Sulfur in Igneous Rocks with Tin(II)-Strong Phosphoric Acid and Strong Phosphoric Acid[1)]

Shigeru NAGASHIMA, Minoru YOSHIDA, and Takejiro OZAWA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 15, 1972)

A method for the determination of minute amounts of sulfide- and sulfate-sulfur in igneous rocks was investigated. A rock sample is easily dissolved by heating with tin(II)-strong phosphoric acid or strong phosphoric acid. When the rock sample is dissolved with tin(II)-strong phosphoric acid, total-sulfur is evolved as hydrogen sulfide. With strong phosphoric acid, sulfide-sulfur is evolved as hydrogen sulfide, but sulfate-sulfur is not. The hydrogen sufide evolved is fixed as zinc sulfide, and then determined by the photometric method, using mercuric thiocyanate and ferric iron. The conditions for separating sulfide- and sulfate-sulfur in rocks were examined by using samples which had been prepared by mixing rock or silica (each of them, $<0.001\%$ S) with sulfides or sulfates. The application of the method to some igneous rock samples gave results with a coefficient of variation of about 5% for sulfur contents of 0.01—0.02%. The sulfur in samples with more than 0.001% can be determined by using about 0.1 g of samples. The sulfide- and sulfate-sulfur in two standard rock samples were also determined: W-1 (Total-S, 0.012%; Sulfide-S, 0.005%; Sulfate-S, 0.007%) and G-1 (Total-S, 0.004%, Sulfide-S, $<0.001\%$; Sulfate-S, 0.004%).

It has been said that sulfur in igneous rocks exists in the forms of sulfides and sulfates. The proportion of sulfide- and sulfate-sulfur, and their amounts, would reflect the conditions of igneous rocks at the time of formation. In 1960, Ricke[2)] determined the sulfide- and sulfate-sulfur content of rocks by two titrimetric methods. Recently, Schneider[3)] separated the sulfide- and sulfate-sulfur in basalts, and measured the isotope composition of each sulfur. However, their methods have some defects. In these methods, rock sample is treated with hydrochloric acid in the separation of sulfide- and sulfate-sulfur. The decomposition of rocks, however, requires a very long time (more than about 6 hr). Moreover, the rock sample is not perfectly dissolved with hydrochloric acid, and all the sulfide-sulfur in the sample may not be determined. Moreover, they did not check that sulfate-sulfur was not determined in the determination of sulfide-sulfur.

One of the present authors (T. O.) and others[4)] have previously reported a sensitive method for the determination of total-sulfur in igneous rocks. The method consists of decomposing a rock sample by heating it with tin(II)-strong phosphoric acid,[5)] releasing the sulfur as hydrogen sulfide, and finally determining it by the photometric method, using mercuric thiocyanate and ferric iron.[6)] A rock sample is easily dissolved with tin(II)-strong phosphoric acid or strong phosphoric acid. The present authors were aware that when the sample is dissolved with strong phosphoric acid without tin(II), sulfide-sulfur is evolved as hydrogen sulfide, while sulfate-sulfur is not.

It is not clearly known what forms of sulfur exist in usual igneous rocks, for the sulfur content is generally very low. However, many investigators[7-10)] have microscopically detected sulfides in igneous rocks with relatively high contents of sulfur, *e.g.* pyrite, pyrrhotite, chalcopyrite, pentlandite, bornite, cubanite, covellite, and digenite. Schneider[3)] forecast the sulfate-sulfur in basalts as follows: (a) as sulfate minerals, *e.g.* barite, anhydrite, nosean, and haüyne; (b) in the crystal lattice of silicates and apatite; (c) in fluid inclusions.

On the other hand, we expected pyrite, pyrrhotite, chalcopyrite, barium sulfate and calcium sulfate as typical sulfur compounds in igneous rocks. In order to examine the conditions for separating sulfide- and sulfate-sulfur, samples were prepared by mixing rock or silica with these sulfides or sulfates.

Experimental

Apparatus. The apparatus used in this study (Fig. 1 and 2) was mostly the same as that described by Arikawa *et al.*[4)]

The nitrogen flow rate was measured by a Kusano flowmeter KG-1 type.

A Hirama photoelectric-spectrophotometer type 6, and 10 mm cells were used to measure the absorbance.

Reagents. All the chemicals used were of an analytical reagent quality. Redistilled water was used for the reagent preparation and throughout the procedure.

Strong Phosphoric Acid: This reagent was prepared by heating 1000 g of orthophosphoric acid ($d=1.7$) in a round bottomed silica flask (Fig. 1) up to 250°C on a mantle heater.

Tin(II)-Strong Phosphoric Acid: This reagent was prepared by heating 78 g of stannous chloride dihydrate and the above obtained strong phosphoric acid in the round-bottomed silica flask up to 280°C on the mantle heater.

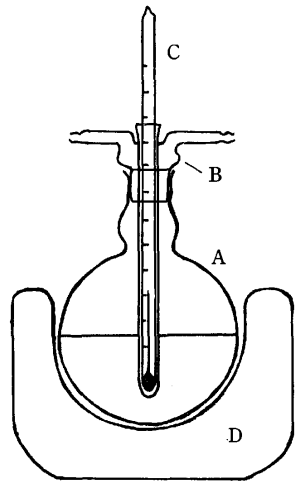

Fig. 1. Apparatus for the preparation of strong phosphoric acid and tin(II)-strong phosphoric acid.
A: Round-bottomed silica flask (1 *l*), B: Gas-delivery silica cap with thermometer-protecting tube, C: Thermometer (360°C), D: Mantle heater.

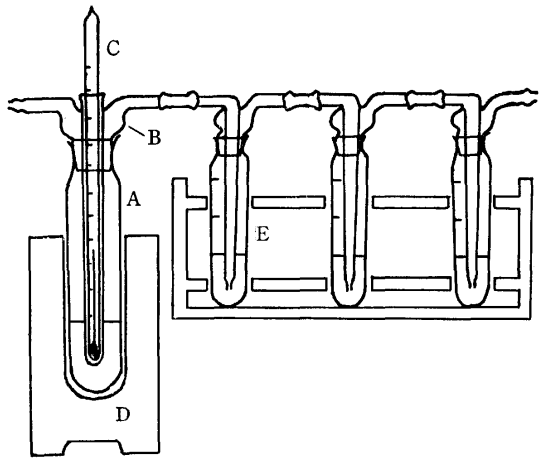

Fig. 2. Apparatus for the determination of total- and sulfide-sulfur.
A: Silica test tube (inner-diameter: 3.5 cm, length: 17 cm), B: The same as B in Fig. 1, C: Thermometer (360°C), D: Electric furnace, E: Absorption tube: centrifuge tube (15 m*l*) fitted with gas-delivery cap.

Standard Sodium Sulfate: Dissolve 4.43 g of dried sodium sulfate in water and dilute to exactly 1 *l*. The solution is standardized by the gravimetric method of the determination of sulfate as barium sulfate. It contains 1 mg of sulfur per m*l*. Prepare the working solution by diluting this solution adequately.

Saturated Barium Hydroxide Solution:

Zink Sulfate Solution (3%): Dissolve 5.3 g of zinc sulfate heptahydrate in water and dilute to 100 m*l*.

Sodium Hydroxide Solution (1M):

Acetic Acid Solution (1M):

Mercuric Thiocyanate Solution: Solid mercuric thiocyanate was prepared as has been described by Utsumi.[11] Dissolve 0.5 g of mercuric thiocyanate in 100 m*l* of methyl alcohol.

Ferric Nitrate-Perchloric Acid Solution: Dissolve 28.3 g of ferric nitrate in 100 m*l* of a 4M perchloric acid solution.

Sodium Carbonate Solution (1%):

Carbon Tetrachloride: *Nitrogen Gas*: Nitrogen from a commercial cylinder is purified with an alkaline pyrogallol solution, and then dried with solid calcium chloride.

Preparation of Mixed Samples. The mixed samples (Table 1) were prepared by the following procedure. For example, in the case of mixing rock with pyrite, 1 g of a finely-powdered rock and 0.03 g of pyrite were thoroughly mixed in an agate mortar with a pestle for one hour. They were mixed again with 2 m*l* of carbon tetrachloride for one hour. Next, 0.1 g of the mixed sample and 1 g of rock were mixed in the same manner. The procedure was repeated by using 0.1 g of this mixed sample and 1 g of rock. The other mixed samples were also prepared by the same procedure. These samples contained about 15 μg of sulfur per 100 mg. In the present study, basalt from Aokigahara, Mt. Fuji, Yamanashi Prefecture, silica (99.99%) from the Ko-Jundo-Kagaku Institute (their total-sulfur contents were less than 0.001%), pyrite from Udo Mine, Shimane Prefecture, pyrrhotite from Yanahara Mine, Okayama Prefecture, and chalcopyrite from Miyatamata Mine, Akita Prefecture, were used. The barium sulfate and the calcium sulfate were prepared from a barium chloride solution, a calcium chloride solution, and sulfuric acid.

Procedure and Calibration Curve. *Procedure (1) (the Determination of Total-Sulfur)*: In a silica test tube, place about 0.1 g of a finely-powdered rock sample and 15 m*l* of tin(II)-strong phosphoric acid. Mix them with a silica rod (length: about 18 cm). During the heating, keep this rod in the test tube. Into three absorption tubes, add 0.5 m*l* of a zinc sulfate solution (3%), 3 drops of a 1M sodium acetate solution, and about 4.5 m*l* of water respectively. Connect all the parts of the apparatus, as is shown in Fig. 2. Introducing nitrogen gas (flow rate, 50—180 m*l*/min), heat the silica test tube by an electric furnace (800W). When it reaches 280°C,[12] keep it at 280±3°C for 30 min by using a slide auto-transformer. Disconnect the absorption tubes from the apparatus, and rinse the inside of the first absorption tube's cap into the tube with a small quantity of water. To it add one drop of phenolphthalein as an indicator, and then 0.1M sodium hydroxide solution dropwise until the color changes. By this procedure, micro amounts of zinc sulfide coprecipitate with zinc hydroxide. After centrifugation, discard the supernatant liquid. Into the absorption tube, transfer the solution in the second absorption tube. Run the same procedure again, and then repeat it for the solution in the third absorption tube. In order to wash the precipitate, add 3 m*l* of a sodium carbonate solution (1%) and about 7 m*l* of water, shake vigorously, centrifuge, and discard the supernatant liquid. To the precipitate, add 0.5 m*l* of a 1M acetic acid solution, 1 m*l* of a mercuric thiocyanate solution, and 2 m*l* of a ferric nitrate-perchloric acid solution, in this order. After diluting to exactly 10 m*l* with water, in order to collect the mercuric sulfide, add 0.5 m*l* of carbon tetrachloride, shake vigorously, and centrifuge. Measure the absorbance of the supernatant liquid at 460 mμ, using water as the reference.

Procedure (2) (the Determination of Sulfide-Sulfur): Using the apparatus shown in Fig. 2, place about 0.1 g of a finely-powdered rock sample containing less than about 10 mg of ferrous iron as ferrous oxide and 15 m*l* of strong phosphoric acid. The subsequent procedure is the same as that described in (1).

Calibration Curve: The calibration curve (Fig. 3) was obtained by using a standard sodium sulfate solution (0—30 μg as S) and 2 drops of a saturated barium hydroxide solution,

11) S. Utsumi, *Nippon Kagaku Zasshi*, **73**, 835 (1952).

12) The time necessary to reach 280°C is about 20 min after the start of heating.

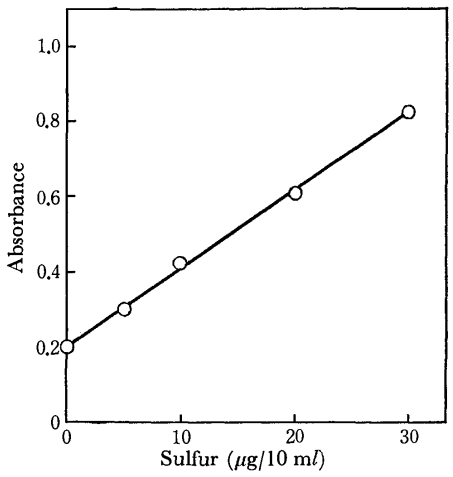

Fig. 3. Calibration curve.

which had been evaporated to dryness in a silica test tube; the sulfur was subsequently determined by Procedure (1).

Results and Discussion

The total-sulfur in igneous rocks was determined by the method of Arikawa *et al.*[4] With a slight modification of the method, several tests were carried out.

The Effect of the Heating Time on Procedure (1). The recovery of sulfur was examined by varying the heating time (5—40 min) using the standard sodium sulfate solution (30 μg as S). The heating time of 30 min was decided on the basis of the results (Fig. 4).

The Effect of the Nitrogen Flow Rate on Procedure (1).

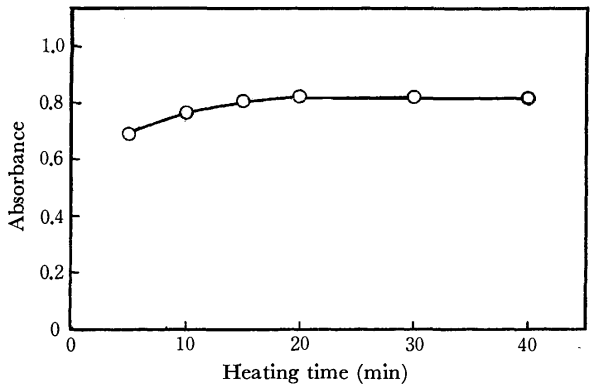

Fig. 4. Effect of the heating time on Procedure (1).

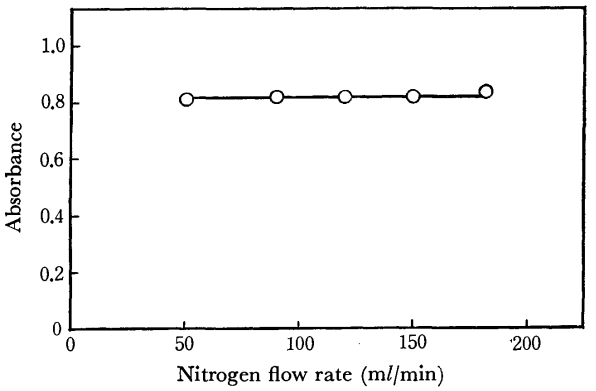

Fig. 5. Effect of the nitrogen flow rate on Procedure (1).

TABLE 1. DETERMINATION OF TOTAL-SULFUR IN THE MIXED SAMPLES BY PROCEDURE (1)

Sample	S (μg) added	found	difference	Relative deviation (%)
Rock+FeS_2	15.7	15.3	−0.4	2.5
	17.5	17.2	−0.3	1.7
	19.2	19.3	+0.1	0.5

	29.0	29.5	+0.5	1.7

Rock: Basalt (Mt. Fuji, S: ≪0.001%)

The recovery of sulfur was tested by varying the nitrogen flow rate (50—180 ml/min) using the standard sodium sulfate solution (30 μg as S). The results (Fig. 5) indicate that the nitrogen flow rate in this range has no effect on the recovery of sulfur.

Determination of Total- and Sulfide-Sulfur in Mixed Samples. The mixed samples previously described were analyzed by Procedure (1). As Table 1 shows, the results give values with a relative deviation of less than 5%. The total-sulfur in the forms of both sulfides and sulfates can be determined by Procedure (1). Therefore, if only the sulfide-sulfur in igneous rocks can be determined, the sulfate-sulfur content can be obtained from the difference between the total- and the sulfide-sulfur.

The condition of determining only the sulfide-sulfur with strong phosphoric acid was examined by using the mixed samples. At first, the mixed sample of rock-pyrite and that of rock-barium sulfate (each of them including about 15 μg of S) were used. The

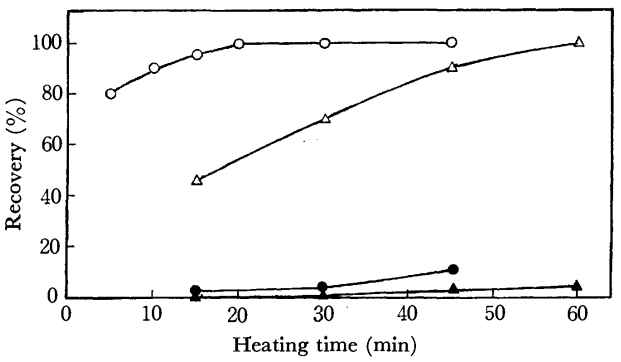

Fig. 6. Determination of sulfide-sulfur with strong phosphoric acid (1).
○ Rock+FeS_2 } at 280°C

△ Rock+FeS_2 } at 260°C
▲ Rock+$BaSO_4$ }
These samples contain about 15 μg as S.

temperature (260 and 280°C) and the heating time (5—60 min) were varied. The results are given in Fig. 6. At 280°C, the sulfur in the mixed sample of rock-pyrite is completely recovered in 30 min At the same temperature, the sulfur in the mixed sample of rock-barium sulfate is partly evolved as hydrogen sulfide. Within 30 min, the amount of sulfur is almost negligible (<5%), but in 45 min it grows appreciable (>10%). The sulfate-sulfur sppears to be reduced by the ferrous iron in the rock. This problem will be discussed later. At 260°C, the results of the heating time of 60 min seem to be the same as those of the heating time of 30 min at 280°C. However, the use of 260°C requires a longer time than does that of 280°C. Therefore, the heating time of 30 min at 280°C has been investigated further.

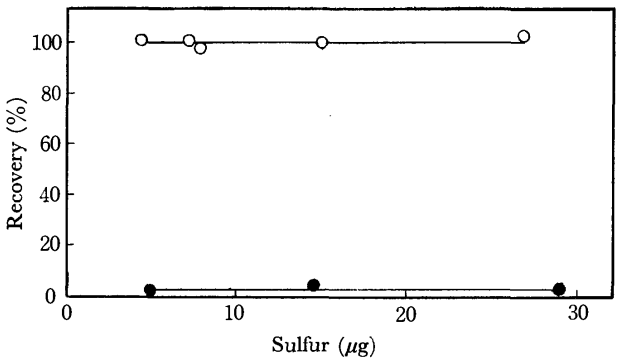

Fig. 7. Determination of sulfide-sulfur with strongs phosphoric acid (2).
○ Rock+FeS_2 } at 280°C
● Rock+$BaSO_4$ }
Heating time: 30 min

Under this conditions and using Procedure (2), recovery was tested using various amounts of the mixed sample of rock-pyrite and that of rock-barium sulfate. According to the results (Fig. 7), the sulfur in the mixed sample of rock-pyrite is completely recovered, and the evolution of sulfur in the mixed sample of rock-barium sulfate is almost negligible (<5%).

The results of the recovery tests by means of Procedure (2) and using various kinds of mixed samples are summarized in Table 2. They indicate that the separation of the sulfide- and the sulfate-sulfur is possible.

The Effect of Ferrous Iron on Procedure (2). As has already been mentioned, it has been thought that, in Procedure (2), the sulfate-sulfur is partly reduced by the ferrous iron in the rock. This point was checked by using the standard sodium sulfate solution (15 μg as S) and various amounts of iron oxide. As the ferrous oxide, wüstite (Found: FeO, 98%) was used; it had been synthesized as described by Darken and Gurry.[13] The ferric oxide was prepared from a ferric chloride solution and aqueous ammonia. The sulfur contents of these oxides were less than 0.001%. The results (Fig. 8) indicate that sulfate-sulfur is partly reduced in the presence of ferrous oxide. The evolution of sulfur is almost negligible (<5%) with less than about 10 mg of ferrous oxide. It is independent of the amount of ferric oxide in the range of 0—30 mg. Therefore, in analysis by Procedure (2), a rock sample which contains less than about 10mg of ferrous iron as ferrous oxide should be placed in a silica test tube.

The Determination of Sulfide- and Sulfate-Sulfur in Rock Samples. In order to confirm the reproducibility of the method, various igneous rock samples were analyzed by Procedures (1) and (2). These results (Table 3) show the coefficient of variation to be about 5% for sulfur contents of 0.01—0.02%.

The method was also checked by adding known amounts of sulfide- and sulfate-sulfur to the sample No. 3. The results (Table 4) are in good agreement with the values in Table 3.

The Analysis of Standard Rocks. The sulfide- and sulfate-sulfur in two standard rock samples, G-1 and W-1, prepared by the U. S. Geological Survey, were also determined by Procedures (1) and (2) (Table 5). The data reported previously for the two rock samples

(shown in Table 5) indicate a very wide scatter. According to the present analysis, for the total-sulfur our value of W-1 is in good agreement with the values of Ricke[2] and Frost *et al.*,[14] but our value of G-1 is lower than both of theirs, being nearer to the value of Frost *et al.* than to Ricke's. For the sulfide-sulfur, our values of W-1 and G-1 are significantly lower than those of Ricke.

a) The present data.

Conclusion

By the use of the present method, the determination of sulfide- and sulfate-sulfur in igneous rocks is possible with tin(II)-strong phosphoric acid and strong phosphoric acid. The method is excellent in that a rock sample can be easily dissolved by heating for a relatively brief time (30 min), and the sulfide- and sulfate-sulfur in rocks can be determined by using the above two reagents respectively in the same procedure. The application of this method to some igneous rock samples gave results with a coefficient of variation of about 5% for sulfur contents of 0.01—0.02%. The sulfur in samples with more than 0.001% can be determined by using about 0.1 g of samples. The time necessary to analyze one sample is about two hours.

The authors wish to thank Professor Iwazi Iwasaki of Toho University and Dr. Yoshiko Arikawa of Japan Women's University, for their hearty encouragement and suggestions during this study. Thanks are also due to Professor Takashi Katsura and Mr. Kenzo Kitayama of the Tokyo Institute of Technology, and Mr. Hiroshi Haramura of Tokyo University, for many discussions and for their kind supply of the standard rock samples, G-1 and W-1, and wüstite.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3451—3455 (1972)

Isomerism of the Metal Complexes Containing Multidentate Ligands. II. The Cobalt(III), Cobalt(II), and Nickel(II) Complexes of *N,N,N',N'*-Tetrakis(2-aminoethyl)ethylenediamine and -1,2-propanediamine and Their Absolute Configurations

Yuzo Yoshikawa, Ekyo Fujii, and Kazuo Yamasaki
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received May 1, 1972)

The cobalt(III), cobalt(II), and nickel(II) complexes of *N,N,N',N'*-tetrakis(2-aminoethyl)ethylenedianime and -1,2-propanediamine were prepared, and the cobalt(III) complex of the former ligand was resolved by fractional crystallization and column chromatography on SE-Sephadex. The absolute configurations of the cobalt(III) complexes were assigned on the basis of the stereospecificity of the latter ligand; they were later confirmed by the X-ray analysis. The electronic absorption, circular dichroism, and optical rotatory dispersion spectra of the complexes prepared were also measured.

The cobalt(III) complex of *N,N,N',N'*-tetrakis(2-aminoethyl)-ethylenediamine (abbreviated as penten) was first prepared by Emmenegger and Schwarzenbach;[1] it has been characterized by infrared and electronic spectral measurements and by stability studies in an aqueous solution. The absolute configuration of the complex was assigned from its rotatory dispersion[1] and its circular dichroism spectrum.[2] We have prepared nickel(II) and cobalt(II) complexes of penten in addition to the cobalt(III) complexes, and assigned the absolute configuration of the latter using the stereospecificity of *N,N,N',N'*-tetrakis(2-aminoethyl)-1,2-propanediamine (abbreviated as R-mepenten) and its cobalt(III) complex.

The absolute configuration thus tentatively assigned (Fig. 1) was enantiomeric to that of Emmenegger and Schwarzenbach,[1] and to that of Mason and Norman,[2]

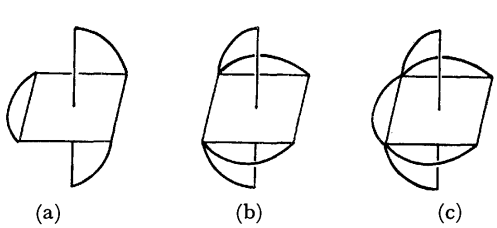

Fig. 1. Absolute configurations of (a): $(-)_{589}$-$[Co(en)_3]^{3+}$, (b): $(-)_{589}$-*u-facial*-$[Co(dien)_2]^{3+}$, and (c): $(-)_{589}$-$[Co(penten)]^{3+}$. The configurations are denoted by Δ, $\Delta\Delta\Delta$, and $\Delta\Lambda\Delta$ respectively. By summing the contribution from each skew chelate pair, the net contribution of the latter two will become Δ.

2) S. F. Mason and B. J. Norman, *Chem. Commun.*, **1965**, 73.

but the same as that of Gollogly and Hawkins.[3] The absolute configuration assigned by us was confirmed by the X-ray analysis of Saito *et al.*[4] Since only a brief preliminary report[5] has been published on these nickel and cobalt complexes of penten and R-mepenten, a detailed report will be published here.

Experimental

1. Ligands. The penten and laevorotatory R-mepenten were specially prepared by the Seikenkagaku Co., the latter being synthesized from R-propylenediamine. They were then further purified by vacuum distillation. Penten, bp 159—163°C (0.08—0.10 mmHg); R-mepenten, bp 147—153°C (0.10 mmHg).

2. Preparation of the Complexes. *2.1.* *[Co(penten)]Br_3·$2H_2O$*: *Method A*: One gram of penten and 2 g of finely ground $[CoBr(NH_3)_5]Br_2$ were mixed in a 100 m*l* round-bottomed flask; the flask was then gently heated over a flame until the color of the mixture became reddish-brown, ammonia having been evolved during the reaction. After the mixture had then been cooled to room temperature, a 2 m*l* portions of water was added and the unreacted $[CoBr(NH_3)_5]Br_2$ was filtered off. By adding ethanol to the filtrate, a red syrup was obtained; this syrup yielded red hexagonal crystals after repeated recrystallizations from water. Found: Co, 10.03; N, 14.14; C, 21.39; H, 5.44; Br, 42.56; H_2O, 6.39%. Calcd for $CoC_{10}H_{28}N_6Br_3\cdot 2H_2O$: Co, 10.39; N, 14.82; C, 21.18; H, 5.69; Br, 42.28; H_2O, 6.35%.

Method B: Two and half grams of $[CoBr(NH_3)_5]Br_2$, 1.3 g of penten, and 0.2 g of active charcoal were mixed with 30 m*l* of water, and the mixture was stirred for 11 hrs. After filtering off the charcoal, the filtrate was concentrated and the red syrup thus obtained was purified as Method A.

2.2. *$(-)_{589}$-[Co^{III}(R-mepenten)]$I_3\cdot H_2O$*: This complex was prepared in the same way as Method B. A hygroscopic reddish-brown powder obtained by adding ethanol to the reaction mixture was dissolved in water, and to this solution an aqueous solution of potassium hexacyanocobaltate(III) was added. The reddich-brown crystals of $(-)_{589}$-[Co(R-mepenten)][$Co(CN)_6$]·$3H_2O$ thus precipitated were purified by recrystallization. These crystals were suspended in water together with the ion-exchange resin (Dowex 1-X8, 20—50 mesh) in the bromide form, and the mixture was stirred for several hours. The filtrate was evaporated, and by the subsequent addition of potassium iodide, red crystals of $(-)_{589}$-[Co(R-mepenten)]$I_3\cdot H_2O$ were obtained. Found: Co, 8.62; N, 12.23; C, 19.07; H, 4.48; I, 53.86; H_2O, 2.38%. Calcd for $CoC_{11}H_{30}N_6I_3\cdot H_2O$: Co, 8.37; N, 11.94; C, 18.77; H, 4.58; I, 54.07; H_2O, 2.56%.

The molar rotation of this complex iodide is $[M]_{545}=-5150°$, $[M]_{485}=+9980°$. The complex iodide was converted to the chloride by passing it through a column of Dowex 1-X8 in the chloride form. The molar rotation of the chloride is $[M]_{546}=-5200°$, and $[M]_{485}=+10220°$.

2.3. *[Ni(penten)]$(ClO_4)_2$*: Two grams of nickel(II) perchlorate hexahydrate dissolved in 1 m*l* of water, and 1 g of penten dissolved in 1 m*l* of water were mixed; when the mixture was left standing, a reddish-violet syrup separated out. After the repeated recrystallization of this syrup from hot water, violet crystals were obtained. Found: Ni, 12.18; N, 17.09; C, 24.77; H, 5.85%. Calcd for $NiC_{10}H_{28}N_6O_8Cl_2$: Ni, 11.98; N, 17.15; C, 24.51; H, 5.76%.

2.4. *$(+)_{589}$-[Ni(R-mepenten)]$(ClO_4)_2\cdot 1/2H_2O$*: Five grams of nickel(II) perchlorate hexahydrate and 4 g of R-mepenten were dissolved in 20 m*l* of water. On evaporating the solution, violet crystals were obtained, and they were purified by recrystallization from water. Found: Ni, 11.57; N, 16.14; H_2O, 1.78%. Calcd for $NiC_{11}H_{30}N_6O_8Cl_2\cdot 1/2H_2O$: Ni, 11.44; N, 16.38; H_2O, 1.76%. The molar rotation is $[M]_{494}=+520°$.

2.5. *$[Co^{II}(penten)]^{2+}$ and $(+)_{589}$-$[Co^{II}$(R-mepenten)]$^{2+}$ Ions*: These complexes were not isolated in solid states, but were prepared only in aqueous solutions under nitrogen, since they were oxidized in air. About 74 mg of R-mepenten was dissolved in a small amount of water. Nitrogen was bubbled through this solution and also the solution of the equivalent amount of cobalt(II) chloride, and then both solutions were mixed in a vessel filled with nitrogen and connected to a quartz cell 1 cm thick for the spectral measurements. All the measurements were carried out in nitrogen to prevent oxidation.

The concentration of the complex was determined by chelatometric titration using a 0.01M EDTA solution after decomposing the complex with a mixture of perchloric and sulfuric acids. The complex ion $[Co^{II}(penten)]^{2+}$ was prepared in a manner similar to that described above.

3. Resolution of the Cobalt(III) Penten Complex. *Method A*: As the resolving agent, $(-)_{589}$-$K_3[Co(C_2O_4)]_3$ was used. When 1 g of [Co(penten)]$Br_3\cdot 2H_2O$ dissolved in 8 m*l* of water and 0.5 g of the resolving agent dissolved in 4 m*l* of water were mixed, a sparingly soluble diastereoisomer of $(+)_{589}$-[Co(penten)]$^{3+}$ was precipitated. To this diastereoisomer suspended in water, barium iodide was added. After removing barium trisoxalatocobaltate(III) by filtration, the filtrate was evaporated; $(+)_{589}$-[Co(penten)]$I_3\cdot H_2O$ was thus obtained. Found: Co, 8.39; N, 12.04; C, 17.49; H, 4.19; I, 54.99; H_2O, 2.56%. Calcd for $CoC_{10}H_{28}N_6I_3\cdot H_2O$: Co, 8.54; N, 12.18; C, 17.41; H, 4.38; I, 55.17; H_2O, 2.61%.

The enantiomer, $(-)_{589}$-iodide, was obtained from the mother liquor as the dihydrate. The molar rotation is $[M]_{542}=+5700°$ and $[M]_{481}=-9810°$ for the $(+)_{589}$-iodide, and $[M]_{542}=-5640°$ and $[M]_{481}=+9660°$ for the $(-)_{589}$-iodide.

Method B: A column chromatographic method on SE-Sephadex was used to resolve the complex; the details have been described previously.[6] Both enantiomers were completely separated on the column by the use of 0.3M sodium antimony $(+)_{589}$-tartrate as the eluent. First the $(-)_{589}$-isomer and then the $(+)_{589}$-isomer were eluted. Each effluent was diluted four to five times, and then again adsorbed on a P-cellulose column.

After washing the column with a large amount of 0.01N HCl, each enantiomer was eluted with 0.5N HCl. The enantiomers were further purified through the hexacyanocobaltate(III), which was reconverted to the chloride by passing it through a column of Dowex 1-X8 in the chloride form. The molar rotation for the $(+)_{589}$-chloride is $[M]_{542}=$

a) These values were obtained for the more soluble chloride.

+5920° and $[M]_{481}=-10280°$, while that for the $(-)_{589}$-chloride is $[M]_{542}=-5910°$ and $[M]_{481}=+10280°$. The active isomers resolved by Method A were further subjected to the chromatographic resolution, but no further increase in rotation occurred, indicating the complete resolution by the crystallization of the diastereoisomers.

4. Measurements. The electronic absorption(AB), and optical rotatory dispersion(ORD) spectra of aqueous solutions of the complexes were measured at 25°C by the use of a JASCO ORD/UV-5 recording spectrometer, using quartz cells 1 and 10 mm thick. The circular dichroism(CD) spectrum in the region 190—700 nm was measured with the same apparatus, and that in the region 700—1200 nm with a Shimadzu QV-50 spectrophotometer equipped with a CD attachment.

Results and Discussion

1. Co(III) Complexes. Table 1 lists the data of the AB and CD spectra of the complexes studied, and in Fig. 2 the AB, CD, and ORD spectra of $(-)_{589}$-$[Co(penten)]^{3+}$ and the CD spectrum of $(-)_{589}$-$[Co(R\text{-}mepenten)]^{3+}$ are shown. These two complexes, which have the same absolute configuration, as determined by the X-ray crystal analysis,[4] show almost the same AB and CD spectra.

Among the CoN_6-type complexes, $[Co(en)_3]^{3+}$ was most extensively studied for the AB, CD, and absolute configuration. It has been found that the sign of CD band at about 20000 cm^{-1}, which corresponds to the $^1A_1\rightarrow{}^1E_a$ transition of the first *d-d* absorption band in the D_3 symmetry, depends on the chirality around the central cobalt atom; that is, the Δ configuration[7] shows a minus sign and the Λ configuration, a plus sign.

When three complexes, $[Co(en)_3]^{3+}$,[8] *u-facial*-$[Co(dien)_2]^{3+}$,[6] and $[Co(penten)]^{3+}$,[4] whose absolute configurations have been determined by X-ray crystal analysis, are compared (Fig. 1), the complexes with the Δ configuration always show the same minus sign

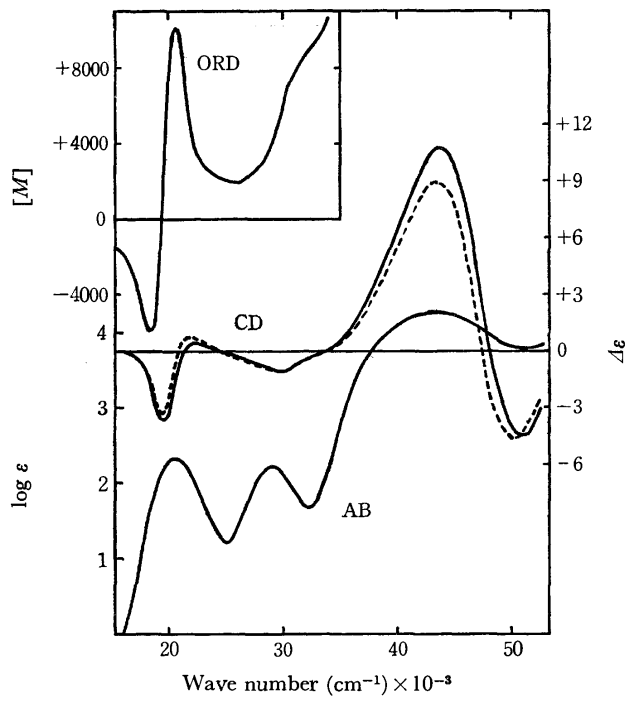

Fig. 2. The AB, CD, and ORD spectra of $(-)_{589}$-[Co(penten)]$Cl_3 \cdot H_2O$ (——) and the CD spectrum of $(-)_{589}$-[Co(R-mepenten)]$Cl_3 \cdot 2H_2O$ (----).

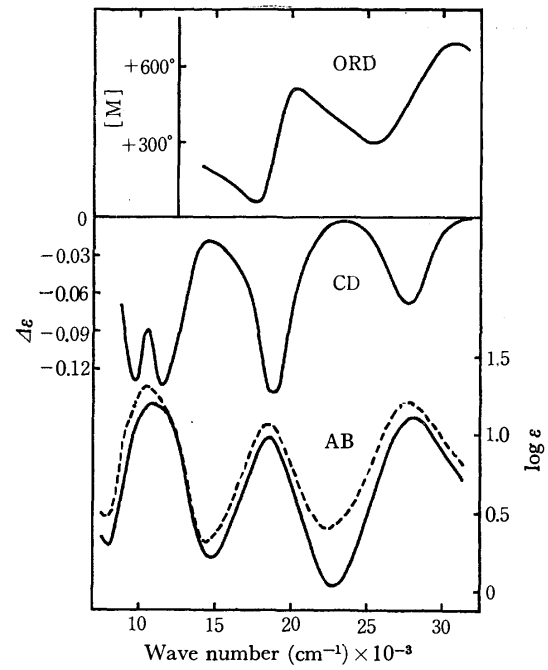

Fig. 3. The AB, CD, and ORD spectra of $(+)_{589}$- [Ni(R-mepenten)]$(ClO_4)_2$ (——) and the AB spectrum of [Ni-(penten)]$(ClO_4)_2$ (----).

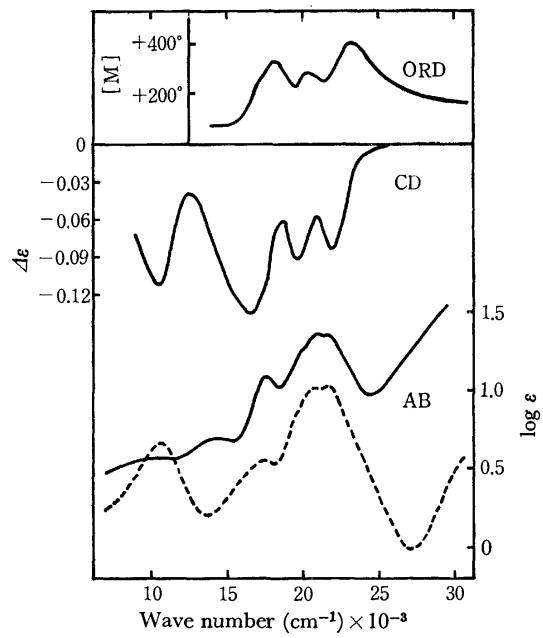

Fig. 4. The AB, CD, and ORD spectra of $(+)_{589}$-[Co(R-mepenten)]$^{2+}$ (——) and the AB spectrum of [Co(penten)]$^{2+}$ (----).

of the CD band at about 20000 cm^{-1}. Thus, for these complexes a close relationship exists between the absolute configuration and the sign of the CD band, and the absolute configuration tentatively assigned from the sign of the CD band is found to agree with those determined by the use of X-rays. In these three cases, the configurations derived from the octant rule[9] and the ring-pairing method[10] agree with those determined by the X-ray crystal analysis.

2. Co(II) Complexes. In Fig. 4, the AB, CD, and ORD spectra of $(+)_{589}$-[Co(R-mepenten)]$^{2+}$ and the AB spectrum of [Co(penten)]$^{2+}$ ions are shown. The first AB band of the former complex splits into two at 11000 and 14200 cm^{-1}; these bands may be assigned to the transition, $^4T_{1g}(^4F) \rightarrow {}^4T_{2g}(^4F)$ split in the lower symmetry. The signs of the CD bands are all minus.

3. Ni(II) Complexes. In Fig. 3, the AB, CD, and ORD spectra of $(+)_{589}$-[Ni(R-mepenten)]$(ClO_4)_2$ and the AB spectrum of [Ni(penten)]$(ClO_4)_2$ are shown. Three absorption bands of the former complex at 11000, 18600, and 28200 cm^{-1} are assigned to the transitions, $^3A_{2g}(^3F) \rightarrow {}^3T_{2g}(^3F)$, $^3A_{2g}(^3F) \rightarrow {}^3T_{1g}(^3F)$, and $^3A_{2g}(^3F) \rightarrow {}^3T_{1g}(^3P)$ respectively in the octahedral field. The signs of the CD bands are all minus.

4. Absolute Configuration of the Co(II) and Ni(II) Complexes. When R-mepenten coordinates to a metal in a six coordination, its methyl group takes an equatorial position, and the absolute configuration of the complex thus formed is stereospecifically determined. The configuration thus determined was confirmed by X-ray analysis of [Co(R-mepenten)]$^{3+}$. On the basis of the stereospecificity of R-mepenten thus confirmed it seems reasonable to assume that the cobalt(II) and nickel(II) complexes of R-mepenten have the same absolute configuration as the cobalt(III) complex of the same ligand.

The transitions of the first *d-d* absorption band of the octahedral cobalt(III), cobalt(II), and nickel(II) complexes are all magnetically allowed. Although the complexes of R-mepenten are not strictly octahedral, the sign of the CD band corresponding to the first

9) C. J. Hawkins and E. Larsen, *Acta Chem. Scand.*, **19**, 185 (1965).

10) J. I. Legg and B. E. Douglas, *J. Amer. Chem. Soc.*, **88**, 2967 (1966).

absorption band is minus for $(+)_{589}$-[Co(R-mepenten)]$^{2+}$ and for [Ni(R-mepenten)]$^{2+}$, that of $(-)_{589}$-[Co(R-mepenten)]$^{3+}$, corresponding to the $^1A_1 \rightarrow {}^1E_a$ transition, is also minus, indicating a close relationship between these signs and their absolute configurations.

In addition to the cobalt(III), cobalt(II), and nickel(II) complexes, we have tried to prepare the copper complexes of penten and R-mepenten from copper(II) perchlorate and the ligands. For both ligands, complexes with the approximately 1 : 1 composition were obtained as blue powders, but it was not possible to isolate them in chromatographically pure states and to characterize them.

We wish to thank Professor Y. Shimura of Osaka University and Dr. T. Yasui for permission to use their laboratory's Shimadzu spectrophotometer and its CD attachment.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3455—3457 (1972)

The Synthesis of 2,3-Dimethoxy-5-methyl-*p*-benzoquinone

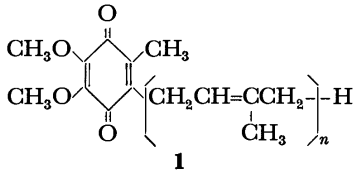
Kikumasa SATO, Seiichi INOUE, and Haruhito SATO

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Ooka, Minami-ku, Yokohama, 233

(Received December 28, 1971)

2,3-Dimethoxy-5-methylbenzoquinone, the key intermediate of the synthesis of coenzyme Q, was synthesized *via* two new routes. The methylation of 5-nitrovanillin gave 5-nitroveratraldehyde, which was then catalytically reduced to afford 5-aminohomoveratrol. The oxidation of 5-aminohomoveratrol gave 2,3-dimethoxy-5-methylbenzoquinone. 2,3,4-Trimethoxyphenol was obtained by the decarboxylation of 3,4,5-trimethoxysalicylic acid. This was converted *via* Mannich reaction to 2,3,4-trimethoxy-6-methylphenol, which was then easily oxidized to 2,3-dimethoxy-5-methylbenzoquinone.

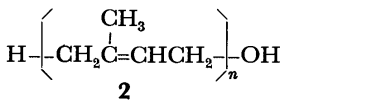
Coenzyme Q_n (n=1—12) (**1**),[1] the 2,3-dimethoxy-5-methylbenzoquinone containing the unsaturated isoprenoid substituent in the 6-position, was first discovered in rat liver and heart muscle as coenzyme Q_{10} in 1958 by Morton *et al.*,[2] who used the designation "ubiquinone (50)."



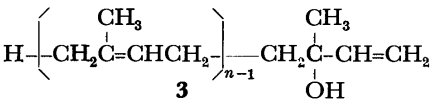
1

A subsequent search for other examples of this new class of isoprenoid benzoquinones revealed their widespread distribution in many kinds of animal tissue and bacteria.

Coenzyme Q has also been synthesized by the condensation of 2,3-dimethoxy-5-methylhydroquinone with polyprenyl alcohol (**2** or **3**), followed by the oxidation of the condensation product[3,4].



2



3

Several investigators have studied the synthesis of 2,3-dimethoxy-5-methylbenzoquinone (**4**) from vanillin[5–9] and gallic acid.[10–12] The present paper will describe convenient methods for the preparation of **4**.

From 5-Nitrovanillin. Anslow *et al.*[5] synthesized **4** from vanillin in five steps. If the reduction of both formyl and nitro groups of nitrovanillin is achieved in the same stage, all the reaction steps are much shortened.

Anhydrous potassium salt of 5-nitrovanillin (**5**),[13]

obtainable from vanillin, and dimethyl sulfate in refluxing xylene afforded 5-nitroveratraldehyde (**6**) in a moderate yield. 5-Nitrocreosol has been reported to be easily methylated to 5-nitrohomoveratrol.[5] The presence of a formyl substituent in **5**, on the contrary, seems to diminish the reactivity of the O-methylation.

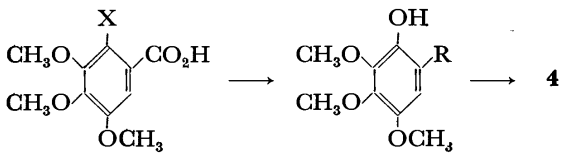
8, $R^1=CH_3$, $R^2=CH_3$, $R^3=NH_2$

The catalytic hydrogenation of **6** then gave 5-amino-3,4-dimethoxybenzyl alcohol (**7**), which could not be further reduced under the same reaction conditions because of the poisonous effects of the amino group on the catalyst. Therefore, the alcohol (**7**) was hydrogenated over palladium/charcoal in the form of its hydrochloride to afford **8**, which has been transformed to the quinone (**4**) by Anslow *et al.*[5]

From 3,4,5-Trimethoxysalicylic Acid. In 1956 Mayer and Fikentscher[14] found that 2-bromo-3,4,5-trimethoxybenzoic acid (**9**) underwent a relatively facile hydrolysis with the aid of cupric ions in an aqueous alkaline medium to give 3,4,5-trimethoxysalicylic acid (**10**). This acid (**10**) was then decarboxylated by heating in *N,N*-dimethylaniline to afford 2,3,4-trimethoxyphenol (**11**).

The transformation of **11** to 6-methyl-2,3,4-trimethoxyphenol (**13**) was successfully achieved by means of the Mannich reaction. When the phenol (**11**) was treated with dimethylamine and formaldehyde, the Mannich base, 6-(*N,N*-dimethylamino)methyl-2,3,4-trimethoxyphenol (**12a**), was obtained in a quantitative yield. The structure of this compound was apparent from its PMR spectrum, which had a singlet for the aminomethylene at δ 3.42, and another singlet at δ 2.26 for the aminomethyl groups, in the ratio of 1 : 3. The phenolic proton peak appeared far downfield at δ 8.90 because of hydrogen bonding with the amino-nitrogen. That the dimethylaminomethyl group was introduced at the *ortho* position to the hydroxy was also confirmed by the infrared spectrum, in which the O–H stretching absorption band was broadened and shifted to *ca.* 3000 cm^{-1} as a result of the chelation with the nitrogen atom. This Mannich base was then subjected to hydrogenolysis in the presence of copper chromite to give **13** in a moderate yield.



9, X=Br
10, X=OH

11, R=H
12a, $R=CH_2N(CH_3)_2$
b, $R=CH_2SCN(CH_3)_2$ (‖ S)
13, $R=CH_3$

On the other hand, recently Byck and Dawson[15] used a modified Mannich reaction in preparing 6-methylcatechol derivatives, where the methyl group was derived by the hydrogenolysis of the *N,N*-dimethyldithiocarbamoylmethyl group. When this procedure was applied to the present study, 6-(*N,N*-dimethyldithiocarbamoyl)methyl-2,3,4-trimethoxyphenol (**12b**), which had been obtained from **11**, gave **13** upon hydrogenolysis with Raney nickel W-7.

Finally, the phenol (**13**) was oxidized with potassium bichromate and hydrochloric acid to afford the desired quinone (**4**) quantitatively; this quinone was identica in all respects with an authentic material.

The former method of the synthesis of **4** has shorter reaction steps, but suffers from a low overall yield. On the other hand, the latter one consists of easily practicable reactions and **4** is obtained in a moderate overall yield.

Experimental

All the melting points and boiling points are uncorrected. The infrared (IR) spectra were recorded on a Hitachi EPI-S2 spectrophotometer as neat liquids or KBr pellets. The PMR spectra were obtained on a JEOL Model C-60 spectrometer in a carbon tetrachloride solution, with tetramethylsilane as the internal standard.

5-Nitroveratraldehyde (6). 5-Nitrovanillin (**5**)[13] was heated with an equivalent of 1N potassium hydroxide, and the resultant clear solution was allowed to cool. The precipitated material was collected and then dried at 110°C under reduced pressure. A mixture of well-dried 5-nitrovanillin potassium salt (6 g, 25.5 mmol), dimethyl sulfate (3.6 m*l*, 38.3 mmol), and xylene (60 m*l*) was stirred at 125°C for 8 hr. After the reaction mixture had then been cooled to room temperature, an aqueous 5% potassium hydroxide solution was added and the mixture was filtered. The ethereal extract of the filtrate was dried over anhydrous sodium sulfate and concentrated to afford crude 5-nitroveratraldehyde, which was then recrystallized from aqueous ethanol; mp 88—89°C (lit, mp 90—91°C).[13] Yield, 3.1 g (57%).

5-Amino-3,4-dimethoxybenzyl Alcohol (7). 5-Nitroveratraldehyde (**6**) (8 g, 37.8 mmol) was reduced in ethanol (45 m*l*) in the presence of 5% Pd/C (2 g) under a pressure of 100 atm of hydrogen at room temperature. The catalyst was then removed by filtration, and the solvent was distilled off. The distillation of the residual oil gave a pale brown liquid, bp 135°C/0.4 mmHg, which, on standing, gradually crystallized to colorless crystals. Yield, 4.35 g (63%); mp 64—65°C (from benzene—ligroin). IR: 3500, 3400, 1630, 1600, 1510, 1140, 1060, 840 cm^{-1}.

Found: C, 58.74; H, 7.51%. Calcd for $C_9H_{13}O_3N$: C, 59.00; H, 7.15%.

5-Aminohomoveratrol (8). A solution of 5-amino-3,4-dimethoxybenzyl alcohol (**7**) (28 g, 0.153 mol) in methanol (250 m*l*) and concentrated hydrochloric acid (16 m*l*) was shaken with 5% Pd/C (8 g) under an atomospheric pressure of hydrogen. When the absorption of hydrogen ceased, a second crop of the catalyst (3 g) was added, after which the mixture was shaken further until hydrogen was no more absorbed. After the catalyst and solvent had then been removed, the

15) J. S. Byck and C. R. Dawson, *J. Org. Chem.*, **33**, 2451 (1968).

residue was dissolved in dilute aqueous potassium hydroxide (200 ml) and extracted with ether. The ethereal extract was dried over potassium hydroxide; the subsequent evaporation of the solvent and distillation afforded **8**; bp 90—95°C/0.3 mmHg. Yield, 8.2 g (32%). *N*-Acetyl derivative, mp 89°C (lit, mp 89°C).[16]

2,3,4-Trimethoxyphenol (11). 3,4,5-Trimethoxysalicylic acid (**10**)[14] monohydrate (20 g) was dissolved in dimethylaniline (60 ml) and heated under reflux with vigorous stirring. After the evolution of carbon dioxide had ceased, and aqueous sodium hydroxide solution was added to the reaction mixture and dimethylaniline was separated from the aqueous layer. The aqueous alkaline layer, after several extractions with ether, was carefully acidified with hydrochloric acid and extracted with ether. The ethereal extract was then dried and distilled to afford **11** (6.0 g, 46%); bp 141°C/15 mmHg; mp 40—40.5°C (methylene chloride). IR: 3400, 1480, 1090 cm^{-1}. PMR: δ 3,67. 3.78, 3.81 (CH_3O), 5.65 (OH), and 6.45 ppm (aromatic H).

Found: C, 58.88; H, 6.73%. Calcd for $C_9H_{12}O_4$: C, 58.69; H, 6.57%.

6-(N,N-Dimethylamino)methyl-2,3,4-trimethoxyphenol (12a). To a solution of **11** (5.08 g, 27.6 mmol) in ethanol (20 ml), cooled in an ice-water bath, we added 40% aq. dimethylamine (3.26 g, 29 mmol) and then, drop by drop, 37% formalin (2.32 g, 28.6 mmol). The mixture was allowed to stand overnight and then heated under a gentle reflux for 2 hr. The solvents were evaporated under reduced pressure, leaving an oily material (6.2 g, 93% yield) which was shown not to contain any detectable contaminants *via* PMR spectroscopy and thin-layer chromatography on silica gel; n_D^{20} 1.5287. IR: 3000 (broad), 1480, 1127, and 1087 cm^{-1}. PMR: δ 2.26 (NCH_3), 3.42 (CH_2), 3.62, 3.68, 3.73 (OCH_3), 6.00 (aromatic H), and 8.90 ppm (OH).

Found: C, 59.31; H, 7.97%. Calcd for $C_{12}H_{19}O_4N$: C, 59.73; H, 7.94%.

6-(N,N-Dimethyldithiocarbamoyl)methyl-2,3,4-trimethoxyphenol (12b). To a solution of **11** (3.68 g, 20 mmol) in ethanol (20 ml), were added carbon disulfide (1.68 g, 22.1 mmol), 37% formalin (1.68 g, 20.7 mmol), and 40% aq. dimethylamine (2.36 g, 21.0 mmol), successively in this order. After being allowed to stand overnight, the mixture was heated under reflux for 2 hr and then concentrated *in vacuo* to give a crystalline mass which was subsequently purified by column chromatography on silica gel; 4.75 g (75%); mp 86.5—87°C (MeOH). IR: 3350 (OH), 1495, 1468, and 1075 cm^{-1}. PMR: δ 3.45 (NCH_3), 3.77, 3.80, 3.92 (OCH_3), 4.47 (CH_2), 5.53 (OH), and 6.73 (aromatic H).

Found: C, 49.01; H, 6.12%. Calcd for $C_{13}H_{19}O_4NS_2$: C, 49.18; H, 6.03%.

6-Methyl-2,3,4-trimethoxyphenol (13). *(a)* A solution of 6.2 g of the Mannich base (**12a**) in 200 ml of dry dioxane was put into an autoclave and hydrogenated at 160°C for 4 hr in the presence of Cu-CrO (6.0 g), with an initial hydrogen pressure of 140 kg/cm^2. The filtreed solution was then concentrated *in vacuo*. The residual oil was dissolved in 3N HCl (26 ml), saturated with sodium sulfate, and extracted three times with ether. The extract was dried over calcium chloride and distilled to afford **13** (2.5 g, 45.6%); bp 96—97°C/0.35 mmHg; mp 25.6—26.7°C. IR: 3440 (OH), 1470, 1123, and 1080 cm^{-1}. PMR: δ 2.13 (CH_3), 3.72, 3.77, 3.87 (CH_3O), and 6.32 ppm (aromatic H).

Found: C, 60.45; H, 7.44%. Calcd for $C_{10}H_{14}O_4$: C, 60.59; H, 7.12%.

(b) A solution of **12b** (obtained from 3.68 g of **11**) in dry dioxane (120 ml) was refluxed for 16 hr with Raney nickel W-7, prepared from 36.8 g of a nickel aluminum alloy. The filtered solution was diluted with ether (100 ml) and acidified with dilute hydrochloric acid. Two layers were separated, and the aqueous layer was extracted with ether. The combined organic layer was dried over magnesium sulfate and distilled to give **13** (1,5 g. 38% based on the phenol **11**); bp 140°C/14 mmHg. The IR and PMR spectra and the retention time on glpc were all identical with those of the sample of *(a)*.

2,3-Dimethoxy-5-methylbenzoquinone (4). *(a)* Aminohomoveratrol (**8**) was oxidized with sodium bichromate in dilute sulfuric acid, essentially according to the method of Anslow. The quinone (**4**) was thus obtained in 29% yield; mp 58—59°C (lit, mp 59°C).[5]

(b) To a solution of **13** (0.198 g, 1 mmol) in 5% sodium hydroxide (1 ml), were added a solution of potassium bichromate (0.147 g, 2 mmol) in water (10 ml) and then 1N hydrochloric acid (4 ml). The mixture was stirred for several minutes before it was extracted with ether. The extracts were dried and freed of any solvent to afford **4** (0.18 g, quantitative yield); mp and mixed mp 57—58°C.

The authors wish to express their gratitude to Mr. Takehiko Goshi for his capable technical assistance in these experiments.

The Stereochemistry and the Circular Dichroism of Several Pinane Derivatives[1]

Toshifumi HIRATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received November 4, 1971)

The optical rotatory dispersion and the circular dichroism curves were measured for some bicyclo[3.1.1]-heptane derivatives. The applicability of the octant rule to a bicyclo[3.1.1]heptane system was discussed in connection with its preferred conformation; the conformation was determined on the basis of nuclear magnetic resonance spectrum measurements.

Some questions[3-7] have arisen as to the application of the octant rule to the optical rotatory dispersion (ORD) and the circular dichroism (CD) measurements of a pinane system. A combination of the examination of molecular models and physico-chemical study has suggested[8-10] that the preferred conformation of pinane derivatives differ from the chair conformation of an unstrained cyclohexane ring because of the strain caused by the cyclobutane ring. From this point of view, the author now wishes to study the applicability of the octant rule to a bicyclo[3.1.1]heptane system, as well as the preferred conformation of several pinane derivatives.

Results and Discussion

The Preferred Conformation. The preferred conformations of several pinane derivatives were determined on the basis of the anisotropic effect[11-13] of the carbonyl group in the NMR spectrum by comparing the chemical shifts of the sample with those of the corresponding carbonyl-free compound. The conformers, **1a** and **1b**, are proposed as the preferred conformations for (−)-10β-pinan-3-one (**1**). A large upfield shift may be predicted for the C-9 methyl group of **1a**, whereas a downfield one may be predicted for that of **1b**, as is shown in Fig. 1. The signal of the C-9 methyl resonance shows the upfield shift of 0.12 ppm, when the chemical shift of the ketone (**1**) is substracted from that of 10β-pinane (**2**). This fact indicates that **1a** is

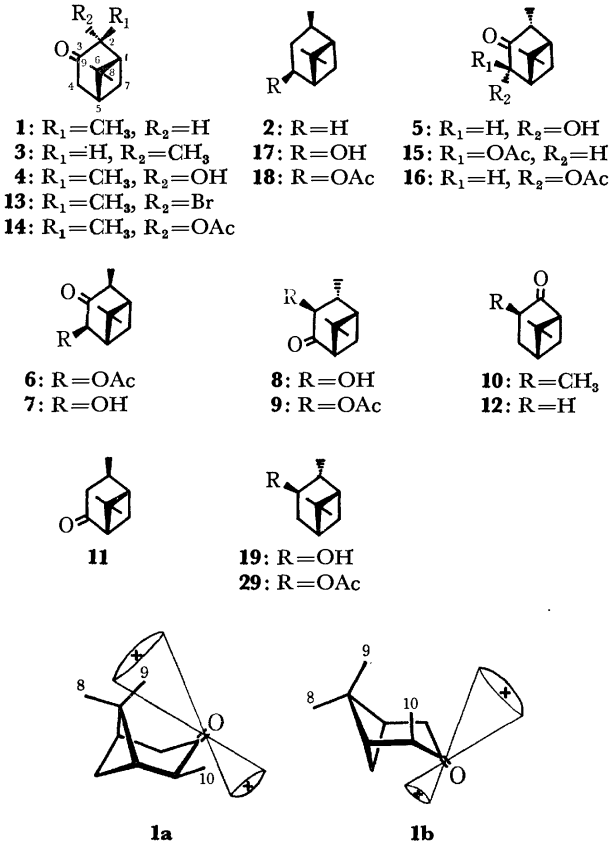

Fig. 1. Possible preferred conformations and predicted anisotropic effect of the carbonyl group for the ketone (**1**).

the preferred conformation of the ketone (**1**). Similarly, the anisotropic effect of the C-9 methyl resonance (Table 1) indicates that the preferred conformations of 10α-pinan-3-one (**3**), 2α-hydroxy-10β-pinan-3-one (**4**), 4α-hydroxy-10α-pinan-3-one (**5**), 4β-acetoxy-10β-pinan-4-one (**8**), 3β-acetoxy-10α-pinan-4-one (**9**), 3β-methylnopinone (**10**), 10β-pinan-4-one (**11**), and nopinone (**12**) are **3a**—**12a** respectively, as is shown in Figs. 2 and 3.

The proposed preferred conformations were further examined by studying the solvent effect[14-16] of the NMR spectrum. As a general rule, Δ values are positive for protons lying at the back of a reference plane and negative for protons lying in front of the

plane. The reference plane was supposed to go through the carbonyl carbon at right angles with the carbon-oxygen bond of the carbonyl group for a benzene-induced effect, and also through the α-position to the carbonyl group for a pyridine-induced effect. The C-10 methyl protons of ketones, **1**, **3**, **4**, **5**, **7**, **10**, and **13**, suffer only a small shift when the solvent is changed from carbon tetrachloride to benzene, and a downfield shift when a change of the solvent from carbon tetrachloride to pyridine (Table 2). These facts show that the C-10 methyl group of these compounds is equatorial. However, the preferred conformations of 4β-acetoxy-10β-pinan-3-one (**6**), 2α-acetoxy-10β-pinan-3-one (**14**), and 4β-acetoxy-10α-pinan-3-one (**15**) were not determined by means of the solvent effect only because of the disturbance caused by the acetoxyl group. The IR spectra of hydroxyketones, **5**, **7**, and **8**, showed, respectively, an intramolecularly hydrogen-bonded hydroxyl band at 3536, 3540, and 3514 cm^{-1}, assigned to the equatorial hydroxyl group. Although the preferred conformation of the acetate (**14**) was not assigned by these methods, the conformer (**14a**) may be proposed as the preferred conformation, because of the decrease in the steric hindrance of the C-10 methyl group and the stabilization by the dipole-moment of the acetoxyl and the carbonyl groups. In addition, since **4a** and **13a** are the preferred conformations for compounds **4** and **13**, respectively, similar to the compound (**14**), the conformer **14a** seems to be appropriate. On the other hand, conformations keeping the coplanarity of the C-1—C-5 atoms have been considered[6] to hold for pinane derivatives. The coplanar conformation can, however, be rejected on the grounds of the fact that the intramolecular hydrogen bonding is formed in the ketones, **5**, **7**, and **8**. No reason to consider the coplanar conformation for the other ketones has been given by the physico-chemical data.

The Application of the Octant Rule. In order to examine the applicability of the octant rule to a pinanone system, the present author prepared some pinane derivatives belonging to two groups as follows: (A) pinan-2- or 4-one, with the carbonyl group adjacent to the four-membered ring, and (B) pinan-3-one, with the carbonyl group at the symmetric position to the ring.

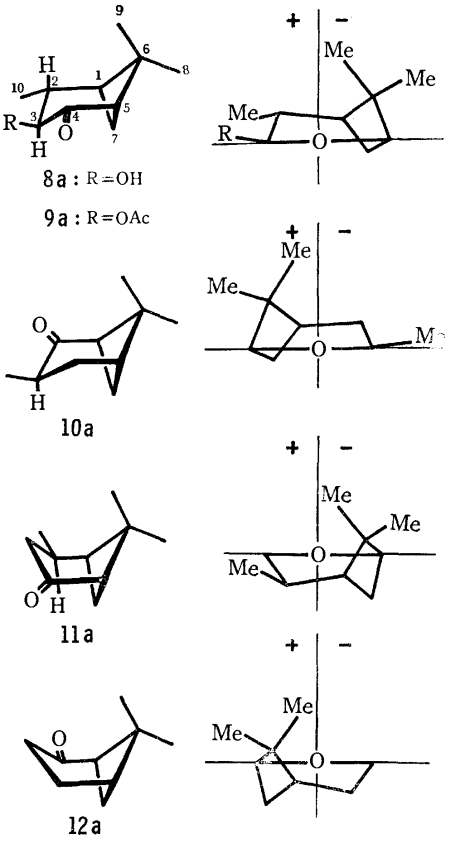

Fig. 2. Preferred conformations and octant projection diagrams for ketones (**8**), (**9**), (**10**), (**11**), and (**12**).

The compounds of the A group are the ketones, **8**, **9**, **10**, **11**, and **12**. Octant projection diagrams for the preferred conformation of these ketones are shown in Fig. 2. The diagrams indicate a large contribution of the C-6 *gem*-dimethyl group to the optical activity. The predicted Cotton effect is negative for **8a**, **9a**, and **11a**, but positive for **10a** and **12a**. Even if the preferred conformation of these compounds is coplanar, the same sign of a Cotton effect can be predicted.

17) A. F. Regan, *Tetrahedron*, **25**, 3801 (1969).
18) J. M. Coxon, E. Dansted, M. P. Hartshorn, and K. E. Richards, *Tetrahedron Lett.*, **1969**, 1149.

The ORD and the CD curves in both polar and nonpolar solvents showed a large, negative Cotton effect for **8**, **9**, and **11**, and a large, positive one for **10** and **12**. In addition, the same sign of a Cotton effect was observed for various-temperature CD curves in the EPA solvent[19] and in decalin. It was thus established that a Cotton effect for compounds of the A group is in good agreement with the predicted one obtained by applying the octant rule of the cyclohexanone pattern.

On the other hand, the direct application of the octant rule to the ketones of the B group presented complicated problems. Octant projection diagrams of the conformers, **1a**, **3a**, **4a**, **5a**, **6a**, **7a**, **13a**, and **14a**, are shown in Fig. 3. The predicted Cotton effect is positive for **1a**, but negative for **3a**, **4a**, **13a**, and **14a**. A Cotton effect for **5a**, **6a**, and **7a** cannot be predicted, since the contribution of the hydroxyl and the acetoxyl groups to the optical rotation can not be compared

with that of the methyl group. The compound **1** showed a negative Cotton effect, while compounds **4** and **14** showed a positive one. The observed Cotton effect of these samples was not identical with the prediction. The bromoketone (**13**), however, showed a negative Cotton effect which coincides with the prediction. The ketone **3** in the nonpolar solvent exhibited a positive Cotton effect at a shorter wavelength and a weak negative effect at a longer one. However, the negative effect diminished in the polar solvent (Fig. 4). The CD curve of the ketone **3** at lower temperatures (Fig. 7) showed an increase in the positive strength of the shorter wavelength band and a decrease in the negative strength of the longer one; it is temperature-dependent. This double-humped Cotton effect may result from a solvation, because the $n\rightarrow\pi^*$ absorption of a solvated ketone generally appears at a shorter wavelength than that of an unsolvated one. In addition, octant projection diagrams for the coplanar conformations, (**1b**), (**3b**), (**4b**), (**6b**), (**13b**), and (**14b**), may be possible for the ketones **1**, **3**, **4**, **6**, **13**, and **14** respectively, as is shown in Fig. 5. The predicted Cotton effect was positive for **1b** and negative for **3b**, while the signs for **4b**, **6b**, and **14b** could not be predicted, because the rotational strength of the hydroxyl and the acetoxyl groups could not be estimated. A negative Cotton effect, however, was predicted for **13b**, since the bromine atom contributes to a larger extent to the optical rotational strength than the methyl group does. The ketone **15** may be at the equilibrium among the conformers **15a**⇌**15b**⇌**15c**, but the preferred conformation was not implied even by any physico-chemical data. However, all these con-

These data are represented by the δ value in ppm.

formers are capable of predicting a negative Cotton effect, as is shown in Fig. 6. The ORD and CD curves of the compound **15** exhibited a positive Cotton effect; it is not identical with the prediction.

It was also observed that the amplitudes ([θ] *ca.* 300—2000 in methanol) of the CD curves for the B group are considerably small in comparison with those of the A group ([θ] *ca.* 3000—8000). This may be explained as follows: the symmetric skeleton of the compounds of the B group to their carbonyl group necessarily shows a relatively small contribution to the optical rotatory strength, whereas the *gem*-dimethyl bridge occupying unsymmetrically the compounds of the A group shows a large one. These facts suggest that the CD curves of the compounds of the B group are influenced easily by other factors, such as the temperature, the solvation, and the strain of the skeleton. Thus, these observations indicate the necessity of prudent care in the application of the octant rule to the pinan-3-one system.

Experimental

The NMR spectra were taken with a Varian Associates, HA-100 spectrometer, and a Hitachi Perkin-Elmer, R-20, High-resolution spectrometer on solutions in concentrations of 10 per cent, using tetramethylsilane as the internal standard. The signals of the C-8, C-9, and C-10 methyl protons of pinane derivatives are shown in Table 3. The ORD and the CD curves were measured on a Japan Spectroscopic Co., ORD/UV-5, Spectropolarimeter, equipped with a circular dichroism attachment, at 25°C. The variable-temperature CD curves were obtained by the use of the same spectrometer, using a low- and high-temperature cell. The IR spectra in the hydroxyl-stretching region were measured with a Perkin-Elmer, 621, Grating Infrared Spectrometer in a 0.002M carbon tetrachloride solution at a spectral slit-width of less than 2 cm^{-1} at 25°C, using a salt absorption cell 20 mm in length.

(−)-10β-Pinane-3-one (1). Following the procedure previously reported,[20] 20 g of (+)-isopinocamphenol (mp 55—57°C, $[\alpha]_D^{25}$ +31.6°) prepared from (−)-α-pinene ($[\alpha]_D^{25}$ −39.9°) through hydrobarotion[21] was oxidized with sodium dichromate to give 17.8 g of 10β-pinane-3-one (**1**): $[\alpha]_D^{25}$ −9.77° (neat) (lit,[21] $[\alpha]_D^{25}$ +10.3°, from (−)-isopinocamphenol); UV (MeOH) 291 nm (ε 17.6), (isooctane) 295 nm (ε 16.6); ORD (*c* 1.1, MeOH) $[\phi]_{400}$ −100, $[\phi]_{319}$ −889, $[\phi]_{276}$ +1200, $[\phi]_{248}$ +960, $[\phi]_{230}$ +1360, (*c* 0.25, isooctane) $[\phi]_{400}$ +30, $[\phi]_{320}$ −617, $[\phi]_{313}$ −440, $[\phi]_{309}$ −617, $[\phi]_{302}$ −65, $[\phi]_{298}$ −216, $[\phi]_{292}$ +277, $[\phi]_{288}$ +205, $[\phi]_{277}$ +617, $[\phi]_{245}$ +404, $[\phi]_{220}$ +645; CD (*c* 1.1, MeOH) $[\theta]_{338}$ 0, $[\theta]_{294}$ −1670, $[\theta]_{247}$ 0, (*c* 0.25, isooctane) $[\theta]_{331}$ 0, $[\theta]_{315}$ −365, $[\theta]_{305}$ −760, $[\theta]_{296}$ −832, $[\theta]_{285}$ −649, $[\theta]_{249}$ 0; variable temp. $[\theta]_{247}$ 0.

(−)-3β-Acetoxy-10α-pinan-4-one (9). The acetylation of the hydroxyketone (**8**) (100 mg) with acetic anhydride in pyridine gave the acetate (**9**) (95 mg): mp 38—39°C; $[\alpha]_D^{25}$ −135.2° (*c* 0.49, MeOH); UV (MeOH); 284 nm (ε 54.9), (isooctane) 290 nm (ε 63.0); ORD (*c* 0.14, MeOH) $[\phi]_{400}$ −1200, $[\phi]_{303}$ −7410, $[\phi]_{263}$ +5560, $[\phi]_{230}$ +1390, (*c* 0.20, isooctane) $[\phi]_{400}$ −685, $[\phi]_{308}$ −5000, $[\phi]_{267}$ +4660, $[\phi]_{230}$ +2330; CD (*c* 0.14, MeOH) $[\theta]_{322}$ 0, $[\theta]_{285}$ −6830, $[\theta]_{237}$ 0, (*c* 0.20, isooctane) $[\theta]_{326}$ 0, $[\theta]_{290}$ −4870, $[\theta]_{245}$ 0.

(+)-3β-Methylnopinone (10). To a stirred solution of potassium hydroxide (7.0 g) in methanol (20 m*l*), was added a sample of (−)-10β-pinan-2α,3α-diol monotosylate (6.2 g) which had been prepared in our previous work.[26] The solution was heated to 65°C for 3 hr had then kept further at room temperature overnight. The reaction mixture was extracted with ether to give an oily product (2.5 g), which was subsequently subjected to chromatography on a silica-gel column to isolate the ketone (**10**) in an 8.5% yield: $[\alpha]_D^{25}$ +59.7° (neat); UV (MeOH) 275 nm (ε 30.1); ORD (*c* 0.64, MeOH) $[\phi]_{400}$ +380, $[\phi]_{301}$ +3550, $[\phi]_{265}$ −3380, $[\phi]_{230}$ −1080, (*c* 0.77, isooctane) $[\phi]_{400}$ +157, $[\phi]_{304}$ +1490, $[\phi]_{268}$ −1530, $[\phi]_{230}$ −315; CD (*c* 0.64, MeOH) $[\theta]_{317}$ 0, $[\theta]_{285}$ +2740, $[\theta]_{240}$ 0, (*c* 0.77, isooctane) $[\theta]_{322}$ 0, $[\theta]_{290}$ +1240, $[\theta]_{238}$ 0; variable temp. CD (*c* 0.61, EPA) $[\theta]_{323}^{-192°}$ 0, $[\theta]_{289}$ +2940, $[\theta]_{248}$ 0, $[\theta]_{320}^{+25°}$ 0, $[\theta]_{283}$ +2410, $[\theta]_{250}$ 0, (*c* 0.59, decalin) $[\theta]_{317}^{-74°}$ 0, $[\theta]_{287}$ +2580, $[\theta]_{254}$ 0, $[\theta]_{316}^{+25°}$ 0, $[\theta]_{288}$ +1630, $[\theta]_{254}$ 0, $[\theta]_{317}^{+137°}$ 0, $[\theta]_{288}$ +1920, $[\theta]_{253}$ 0.

(−)-10β-Pinan-4-one (11). *a) Preparation of (−)-verbenone*: To a stirred sample of 100 g of (−)-α-pinene ($[\alpha]_D^{25}$ −39.9°), was added a *t*-butyl chromate solution, which had been prepared from chromiun trioxide (220.5 g), *t*-butyl alcohol (330 g), benzene (500 m*l*), glacial acetic acid (150 g), and acetic anhydride (150 g) following the method in the literature.[27] The mixture was stirred for 12 hr at room temperature in an atmosphere of nitrogen, and then it was treated with water and oxalic acid as usual.[27] The reaction product extracted with benzene was subjected to distillation and then to column chromatography to isolate (−)-verbenone (39.4 g); bp 80—84°C/9 mmHg, $[\alpha]_D^{25}$ −208.6° (neat).

b) Preparation of Ketone 11: (−)-verbenone (1.3 g) in ethanol was hydrogenated in the presence of palladium hydroxide on calcium carbonate, under an atmospheric pressure, to yield an oily product (1.2 g). The product was rectified by distillation under a reduced pressure to give the ketone (**11**) (1.0 g): bp 59—61°C/11 mmHg, $[\alpha]_D^{25}$ −47.8° (neat), d_D^{25} 0.9693, n_D^{25} 1.4751; UV (MeOH) 274 nm (ε 34.5), (isooctane) 285 nm (ε 20.2); ORD (*c* 0.15, MeOH) $[\phi]_{400}$ −250, $[\phi]_{305}$ −2620, $[\phi]_{266}$ +2720, $[\phi]_{235}$ +1250, (*c* 0.17, isooctane) $[\phi]_{400}$ −250, $[\phi]_{317}$ −1670, $[\phi]_{314}$ −1450, $[\phi]_{307}$ −1800, $[\phi]_{270}$ +1800, $[\phi]_{230}$ +710; CD (*c* 0.15, MeOH) $[\theta]_{320}$ 0, $[\theta]_{285}$ −3550, $[\theta]_{230}$ 0, (*c* 0.35, isooctane) $[\theta]_{324}$ 0, $[\theta]_{294}$ −2380, $[\theta]_{250}$ 0; variable temp. CD (*c* 0.20, EPA) and (*c* 0.27, decalin) (Fig. 9); the semicarbazone derivative, mp 222—223°C.

(+)-Nopinone (12). Into a solution of 5.0 g of (−)-β-pinene ($[\alpha]_D^{25}$ −21.8°) in 30 m*l* of dichloromethane, was passed ozonized oxygen at −60°C. The solution was subjected to steam distillation, and then extraction with chloroform to give 2.8 g of an oily product. The distillation of the product gave 14.5 g of (+)-nopinone (**12**): bp 76.5—77.5°C /7 mmHg, $[\alpha]_D^{25}$ +18.9° (neat), d_D^{25} 0.9786, n_D^{25} 1.4761; IR (liq.) 1713 cm^{-1} (C=O); UV (MeOH) 273 nm (ε 30.2),

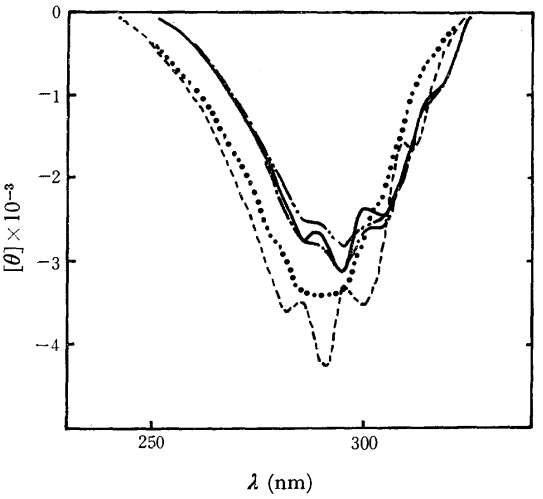

Fig. 9. CD curves of the ketone (**11**) in selected solvents at various temperatures: ——, —·—, and —··—, at −74, +20, and +138°C in decalin; ----- and ·····, at −192 and +25°C in EPA, respectively.

(−)-2α-Bromo-10β-pinan-3-one (13).[28] *a) Preparation of 3-Acetoxy-pin-2-ene*: Following the method in the reference,[3] the treatment of (−)-10β-pinan-3-one (**1**) with acetic anhydride in the presence of perchloric acid afforded (−)-3-acetoxy-pin-2-ene in a 76% yield: $[\alpha]_D^{25}$ −35.0° (*c* 0.29, MeOH) (lit,[3] $[\alpha]_D^{25}$ +36° (*c* 1.00), derived from (+)-10β-pinan-3-one).

b) Preparation of Bromoketone 13: Bromine (0.94 g) dissolved in carbon tetrachloride (4 m*l*) was added to a stirred suspension of (−)-3-acetoxy-pin-2-ene (1.08 g) and anhydrous sodium carbonate (1.00 g) in carbon tetrachloride (5 m*l*) over a 5 min period at 0°C. After stirring for a further 5 min, the ether extract gave 1.13 g of an oily product, which was composed of 84% of the bromoketone (**13**): $[\alpha]_D^{25}$ −101.8° (*c* 1.18, MeOH); IR (liq.) 1722 cm^{-1} (C=O); UV (MeOH) 313 nm (ε 135.3); ORD (*c* 1.18, MeOH) $[\phi]_{400}$ −638, $[\phi]_{335}$ −1620, $[\phi]_{305}$ −1080, $[\phi]_{250}$ −3430, $[\phi]_{230}$ −1720, (*c* 0.24, isooctane) $[\phi]_{400}$ −692, $[\phi]_{349}$ −1800, $[\phi]_{302}$ −143, $[\phi]_{250}$ −2240, $[\phi]_{230}$ −1190; CD (*c* 1.18, MeOH) $[\theta]_{365}$ 0, $[\theta]_{317}$ −1000, $[\theta]_{293}$ −227, $[\theta]_{258}$ −1000, (*c* 0.24, isooctane) $[\theta]_{364}$ 0, $[\theta]_{318}$ −1700, $[\theta]_{285}$ −315.

(−)-4β-Hydroxy-10β-pinane (17) and Its Acetate (18). A solution of 1.0 g of (−)-10β-pinan-4-one (**11**) in 20 m*l* of ether was stirred into a suspension of 0.3 g of lithium aluminum hydride in 50 m*l* of ether. The mixture was then refluxed for 2 hr. The reaction mixture, after having been treated in the usual manner, afforded 1.0 g of **17**. The subsequent acetylation of **17** (100 mg) with acetic anhydride in pyridine gave the acetate (**18**) (95 mg).

a) 4β-Hydroxy-10β-pinane (17): Mp 72—73°C, $[\alpha]_D^{25}$ −5.1° (*c* 4.0, benzene); NMR (CCl_4) δ 1.22 (s, C_8-3H), 1.16, (s, C_9-3H), 1.07 (d, J=7.0 Hz, C_{10}-3H), and 4.22 ppm (m,

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3464—3472 (1972)

Elektrochemische Untersuchungen über den Litheffekt

Tsuneo SUGA

Forschungslaboratorium der Konishiroku Photoindustrie AG., Sakura-machi, Hino, Tokio, 191

(Eingegangen am 18. April 1972)

Es wurde der Mechanismus des Litheffektes diskutiert. Um dieses Problem zu behandeln, wäre es nützlich, daß man sich den Litheffekt in Verbindung mit Lithemulsion und Lithentwickler überlegt. Nach Yule[1] beschleunigen die bei der Entwicklung entstandenen Oxydationsprodukte des Hydrochinons die Lithentwicklung. In der vorliegenden Arbeit wurde die Rolle der Oxydationsprodukte weiter vom Standpunkt der Oxydation aus elektrochemisch untersucht. Die Oxydationsprodukte beschleunigen die Entwicklung der stärker belichteten Körner durch die Herabsetzung des Ladungsbarriereeffektes und hemmen die Entwicklung der schwächer belichteten Körner durch die Oxydationsfähigkeit. Wenn diese beiden Faktoren miteinander ins Gleichgewicht gebracht werden, könnte man einen guten Litheffekt erhalten. Nach dieser Ansicht konnte man die Ursache für den guten Litheffekt einer Lithemulsion gut erklären.[2]

Der Lithentwickler, der oft als „Ansteckungsentwickler" bezeichnet wird, ist ein Hydrochinonentwickler, dessen Gehalt an Sulfit stark herabgesetzt ist. Wenn ein Lithfilm in diesem Entwickler behandelt wird, erhält man den Litheffekt, der eine ultraharte Gradation und eine steile Bildschärfe kennzeichnet.

Obwohl der Lithentwickler bis heute in der Reproduktionstechnik häufig verwendet worden ist, erschienen wenige Arbeiten darüber. Yule hat 1945 den Mechanismus der Lithentwicklung mitgeteilt und dieser Mechanismus ist bis heute von vielen Forschern wie Baines,[3] Vanreusel,[4] Wood,[5] Umberger,[6] Zwicky[7], und Frank[8] unterstützt worden. Nach der Meinung von Yule[1] beschleunigen die Oxydationsprodukte des Hydrochinons die Entwicklung der belichteten Körner. Wegen der niedrigen Konzentration von Sulfit bleiben die Oxydationsprodukte als Semichion oder Chinon, ohne sich durch Versetzen mit Sulfit zu Hydrochinonsulfonsäure zu verwandeln. Kürzlich ist die Entwicklungsaktivität des Semichinons bei der Lithentwicklung wieder von Eggers[9] und Zwicky[10] betont worden. Lu Valle[11,12] und Goldberg[12] diskutierten die Entwicklungsaktivität des Hydroxyhydrochinons. In alkalischer Lösung ist Chinon nicht beständig und geht durch die sogenannte Hydratationenolisation in Hydroxyhydrochinon über. James[13] zeigte die superadditive Aktivität der Reaktionsprodukte von Aminogruppen der Gelatine mit Chinon und deutete die oxydative Wirkung des entstehenden Chinons an. Auf Grund unserer Meinungen ist die

oxydative Wirkung des Chinons von großer Wichtigkeit. In einer neueren Arbeit hat Zwicky[10] aber keinen Oxydationseffekt bei der Lithentwicklung vertreten.

Da es nötig ist, daß der Litheffekt mit Lithemulsion und Lithentwickler in Zusammenhang steht, ist es ratsam, auf Grund der photographischen Eigenschaften von Emulsion über den Mechanismus der Lithentwicklung zu diskutieren. Soweit wir bisher festgestellt haben, erschienen aber solche Arbeiten selten. In der Zusammenfassung unserer Arbeiten[2,14-20] ist eine weitere Überlegung für den Litheffekt durch Einführen des Begriffes „Oxydation" wie folgt erlangt worden.

Experimentelles

Entwicklung und Sensitometrie. Die hinter einem Graukeil in einem Sensitometer vom Typ Konishiroku KS-7 belichteten Filmstreifen wurden im Entwickler bei 20°C behandelt. Der verwendete Lithentwickler[14,18] war ein normaler formaldehydbisulfithaltiger Hydrochinonentwickler. Dem Versuchsziel entsprechend wurde Natriumsulfit zugesetzt. Nach der Schwärzungsmessung trug man den Logarithmus der relativen Belichtungswerte (log rel. E) auf die Abszisse und die Schwärzungswerte (S) auf die Ordinate auf, um die sogenannte Schwärzungskurve zu erhalten. Die Bestimmung der Empfindlichkeit wurde aus der notwendigen Lichtmenge für eine Schwärzung von 1,0 durchgeführt.

Lithfilm. Der orthochromatische Lithfilm von Konishiroku Photoindustrie AG.

Emulsion. Benutzte Emulsionen wurden durch Doppeleinlauf hergestellt.[15] Als Lithemulsion diente eine Chlorbromsilberemulsion, deren Gehalt an AgBr 30 Mol % war. Die mit Inertgelatine hergestellten Emulsionen wurden mit verschiedenen Sensibilisatoren nachgereift. Die Zusatzmengen der Sensibilisatoren pro 1 Mol AgX waren $3{,}4\times10^{-5}$ Mol $Na_2S_2O_3$ für Schwefelsensibilisierung, 1×10^{-5} Mol $HAuCl_4$ für Goldsensibilisierung, und $3{,}4\times10^{-5}$ Mol $Na_2S_2O_3$ plus 1×10^{-5} Mol $HAuCl_4$ für Schwefelgoldsensibilisierung. Die nachgereiften Emulsionen wurden auf Unterlage gegossen und getrocknet.

Bleicher. Das Bleichen des latenten Bildes und des Makrosilbers wurde in 0,12%iger Chinonlösung bei 20°C durchgeführt.[18] Ihr pH-Wert wurde durch Metaborat kontrolliert.

Redoxpuffer. Das Redoxpotential des latenten Bildes wurde nach der Reinders'schen Methode gemessen. Als Redoxpuffer[18] wurden Fe^{3+}/Fe^{2+}-Lösungen [0,25 Mol $FeSO_4$-$(NH_4)_2SO_4 6H_2O/l$ plus 0,25 Mol $Fe_2(SO_4)_3(NH_4)_2SO_4 24H_2O$ /*l*] benutzt, deren Potential mit Natriumzitrat eingestellt war. Die Messung des Redoxpotentials wurde gegen eine gesättigte Kalomelelektrode durchgeführt. Alle Potentialzahlenwerte in dieser Arbeit sind aber auf die Normalwasserstoffelektrode bezogen.

Versuchsergebnisse

1. Litheffekt. Ein guter Litheffekt für die 2,5 Min. lithentwickelte schwefelsensibilisierte AgCl/Br-Emulsion ist in Abb. 1a dargestellt. Er ging aber in Anwesenheit des Sulfites verloren, so daß die Schwärzungskurve eine wesentlich weiche Gradation mit einer vorgerückten Schwelle hatte.

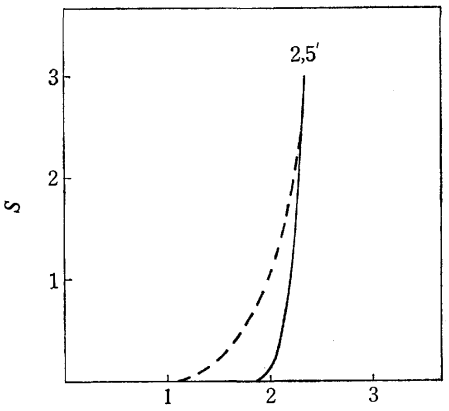

Abb. 1. (a) Schwärzungskurven der AgCl/Br-Lithemulsion, entwickelt in 2,5 Min.
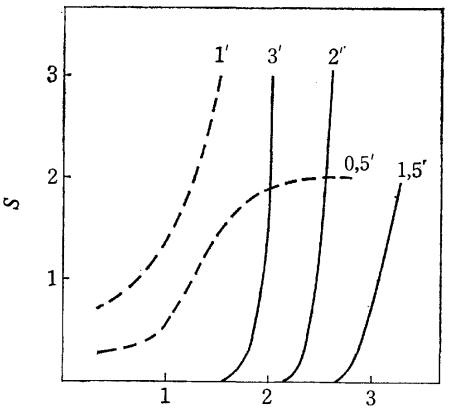
—— Lithentwickler
—— Lithentwickler + 60 g Na_2SO_3/l



(b) Zeitlicher Entwicklungsablauf der Lithemulsion.
—— Lithentwickler
---- Lithentwickler ohne Bromid
Die Zahlen an den Kurven geben die Entwicklungszeit in Minuten.

In Abb. 1b[14] rückten die Schwärzungskurven mit der fortschreitenden Lithentwicklungszeit vor, indem sie den Litheffekt zeigten. Ohne Bromid war der Litheffekt auch bei kürzerer Entwicklungszeit ganz verloren.

Substanzen,[2] die mit Ag^+-Ionen schwerlösliche Salze bilden, wurden in einer Hydrochinon-Alkali-Lösung zugesetzt. Wie aus Tabelle 1 ersichtlich ist, sind Br^--

Ionen für den Litheffekt sehr wichtig. SCN^--Ionen geben einen kleinen Litheffekt und die anderen Ionen scheinen eine geringe Rolle für den Litheffekt zu spielen.

2. *Bildausbreitung in der Lithentwicklung.*[16] Auf zwei mit Graukeil belichteten Filmschichten wurden Linien mit Feder und 0,1% iger $AgNO_3$-Lösung gezogen. Nach dem Trocknen wurden die eine mit dem Lithentwickler und die andere mit dem sulfithaltigen Entwickler 2,5 Min. behandelt. Bei der Lithentwicklung konnte man in Abb. 2 eine auffällige Bildausbreitung wahrnehmen. Mit der Schwärzungszunahme des Hintergrundes wurde die Linienbreite vergrößert, während keine Ausbreitung im Beisein des Sulfites stattfand.

Sobald eine AgCl-Emulsion unter geschmolzten Umständen dem Entwickler zugefügt wurde, schwärzte sie sich. Eine Minute nach der Emulsionszufügung wurden die belichteten Filmstreifen in den Entwickler getaucht. 1 Liter Entwickler enthielten 0,03 Mol AgCl und 9 g Gelatine. Zum Kontrolle-Entwickler wurden nur 9 g Gelatine addiert. Die zur Versuche gebrauchten Entwickler waren folgende. 1) Lithentwickler 2) Lithentwickler plus 120 g Na_2SO_3/l 3) Lithentwickler ohne KBr. In Abb. 3 ist der Verlauf der Empfindlichkeit als Funktion der Entwicklungszeit in drei Entwicklern dargestellt. Durch Zusatz von AgCl-Emulsion wurde eine nennenswerte Empfindlichkeitssteigerung im Fall des Lithentwicklers, fast keine im Fall der Anwesenheit von 120 g Sulfit/l erwiesen. Bei der Entwicklung ohne Bromid wirkte die Emulsionszufügung umgekehrt ein. Wie in Abb. 3 gezeigt, setzte sich die Empfindlichkeit herab.

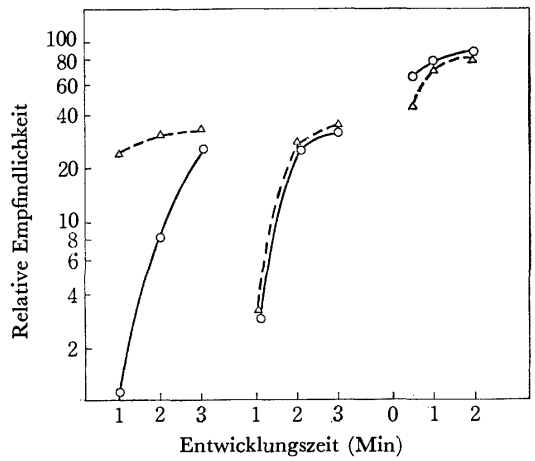

Abb. 3. Einfluß der AgCl-Emulsion zugefügten Entwickler (----) auf den Empfindlichkeitsverlauf im Vergleich zum Kontrolle-Entwickler (——).

mitten: Lithentwickler mit 120 g Na_2SO_3/l
rechts: Lithentwickler ohne KBr

3. *Oxydierbarkeit des Chinons.* Chinon wirkt oxydativ ein. Hier wurde die oxydative Wirkung desselben auf das Makrosilber[14] und das Mikrosilber des latenten Bildes[15,18] untersucht. Die entwickeltes Silberteilchen enthaltenen Filmstreifen wurden in Chinonlösungen (pH 3,6) getaucht. Nach Fixieren wurden die Schwärzungswerte gemessen. Das Silberteilchen in Filmstreifen wurde durch Chinon nicht oxydiert. Bei der Anwesenheit von Cl^--, SCN^--, und Br^--Ionen wurde Schwärzungsabnahme in dieser Reihenfolge

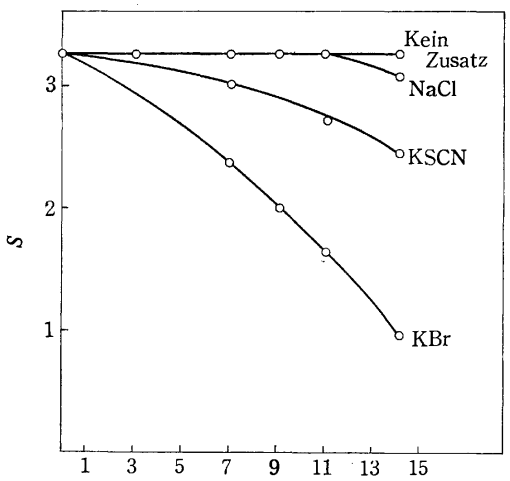

Abb. 4. Abhängigkeit der Zusätze (0.0168 Mol/l) von der Oxydation des Makrosilbers mit Chinonlösung (pH 3,6).

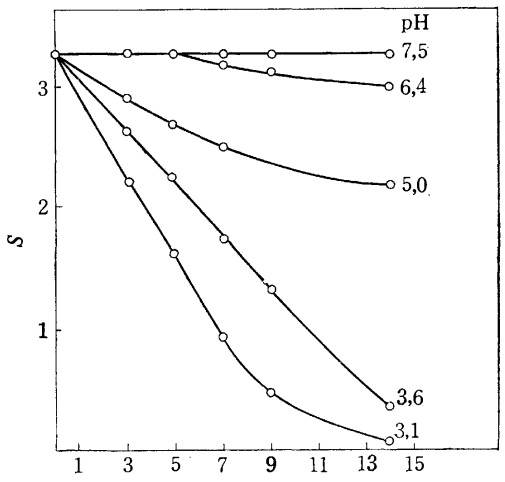

Abb. 5. Einfluß des pH-Wertes von Chinonlösungen auf die Oxydation des Makrosilbers.

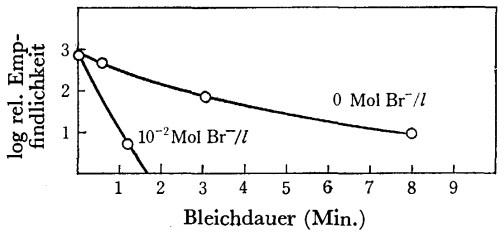

Abb. 6. Oxydierbarkeit des latenten Bildes der Lithemulsion als Funktion der Chinonbleichdauer.

30 Sek. vorbehandelt in Br⁻-Lösung (0,1 g KBr/*l*), dann 3 Min. lithentwicklt.
30 Sek. vorbehandelt in Chinon-Lösung (0,1 g KBr/*l* + 0,4 g Chinon/*l*), dann 3 Min. lithentwickelt.

größer. (Abb. 4) Der Einfluß des pH-Wertes von Chinonlösung auf die Oxydation des Silbers wurde in Abb. 5 dargestellt. Je niedriger der pH-Wert war, desto größer wurde die Schwärzungsabnahme.

Wenn man die belichteten Filmstreifen vor der Lithentwicklung in Chinonlösung behandelte, besonders im Beisein der Br⁻-Ionen, fand die Oxydation der latenten Bildkeime statt. (Abb. 6) Aus Schwärzungskurven in Abb. 7 kann man ersehen, daß eine größere Desensibilisierung und eine steilere Gradation durch Vorbehandlung mit Chinon-Br⁻-Bad im Vergleich mit Br⁻-Bad erzielt wurden. Durch Vorbehandlung in Chinonlösungen, deren pH-Werte variiert waren, konnte man, wie in Abb. 8 gezeigt, die Empfindlichkeitsabnahme unter pH-Wert von 7, die Empfindlichkeitssteigerung über pH-Wert von 7 beobachten.

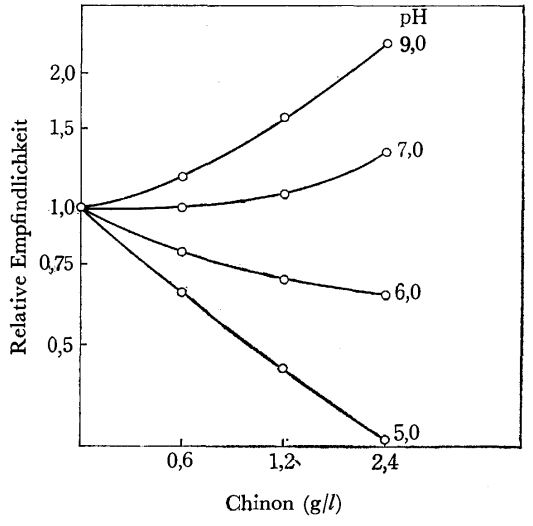

Abb. 8. Einfluß des pH-Wertes und Chinonkonzentration von Vorbehandlungsbad auf die Empfindlichkeit der Emulsion.

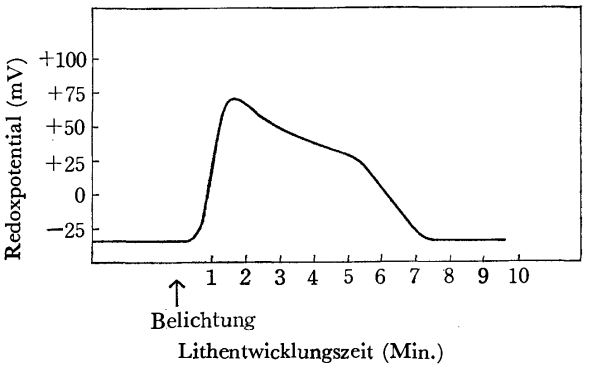

Abb. 9. Redoxpotentialänderung an der Unterseite der Emulsionschichten während der Lithentwicklung.

4. Redoxpotentialänderung während der Entwicklung. Die Redoxpotentialänderung in der Emulsionschicht wurde in Abhängigkeit von der Entwicklungszeit geprüft.[18] Die mit Thiosulfat gereifte Emulsion wurde auf die Oberfläche der Platinelektrode aufgetragen und bis zum Erstarren gekühlt. Die beschichtete Pt-Elektrode wurde im Lithentwickler getaucht, dann mit einer Birne bestrahlt. Die Potentialänderung wurde gegen eine gesättigte Kalomelelektrode gemessen. (Abb. 9) Bei einigen Versuchen lagen die Redoxpotentialsverschiebungen zwischen 80 und 100 mV. Die Redoxpotentialänderung an der Oberfläche des entwickelnden Lithfilms und dieselbe im Entwickler an der von der Emulsionsoberfläche den Abstand von 1 mm entfernten Stelle werden in Tabelle 2 beschrieben. Bei der Lithentwicklung war die Potentialänderung an der Oberfläche so groß wie die in der Emulsionschicht. Man konnte aber keine Potentialänderung im Lithentwickler, auch an der dem Film nahen Stelle finden. Sulfit verschob die Potentialänderung nach kleineren Werten, und diese kleine Potentialänderung wurde auch im Entwickler an der Filmschicht nahen Stelle deutlich bemerkt.

Tabelle 2. Redoxpotentialänderung im Entwickler auf und über den entwickelnden Lithemulsionschichten

Entwickler	auf der Emulsionschicht	1 mm über der Emulsionschicht
Lithentwickler	130 mV	0 mV
Lithentwickler + 60 g Na_2SO_3/*l*	40 mV	35 mV

5. Redoxpotential des latenten Bildes.[18] Die belichteten Filmstreifen wurde in Fe^{3+}/Fe^{2+}-Redoxlösungen 6 Stunden gebadet. Die zur Ausbildung eines stationären Zustandes benötigte Dauer waren 6 Stunden, wie sie auch Hillson[21] im Fall der AgCl-Emulsion gezeigt hat. Die Streifen wurden nachher mit 1% iger ÄDTE-

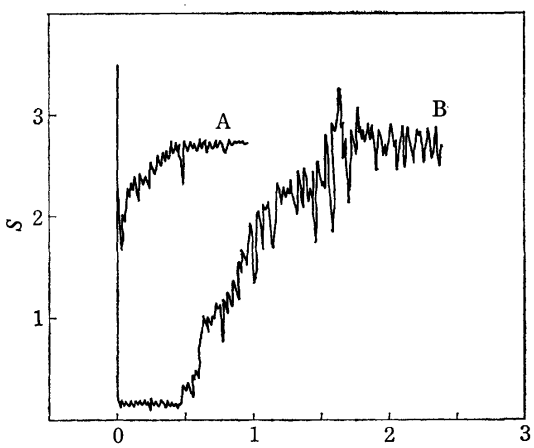
	10^{-2}	250	

Lösung zur Maskierung der Eisenionen gewaschen und dann entwickelt. Aus den Versuchsergebnissen wurde das kritische Potential, bei dem die Oxydation des latenten Bildes beginnt, im Vergleich mit Nullprobe in Tabelle 3 ermittelt.

6. Saumeffekt in der Lithentwicklung. An scharfen Grenzen zweier Bildfläche verschiedener Schwärzung tritt der Saumeffekt auf, der die Schwärzung am Rand der schwächer belichteten Fläche durch Diffusion von entwicklungshemmenden Reaktionsprodukten erniedrigt. Hier wurde der Saumeffekt des Lithfilms untersucht. Man belichtete den zuerst im Streulicht gelegenen Lithfilm wieder mit einer scharfen Kante. Der Schwärzungsverlauf beim Übergang von hohen zu niedrigen Schwärzungswerten wurde mit Hilfe des Mikrodensitometers durch unsere frühere Methode[20] in Abb. 10 registriert. Die Streulichtmengen wurden

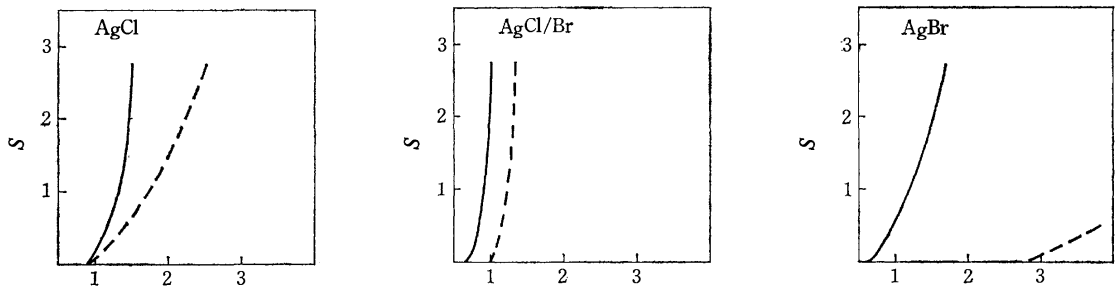


Abstand von der Grenze einer Kante (mm)

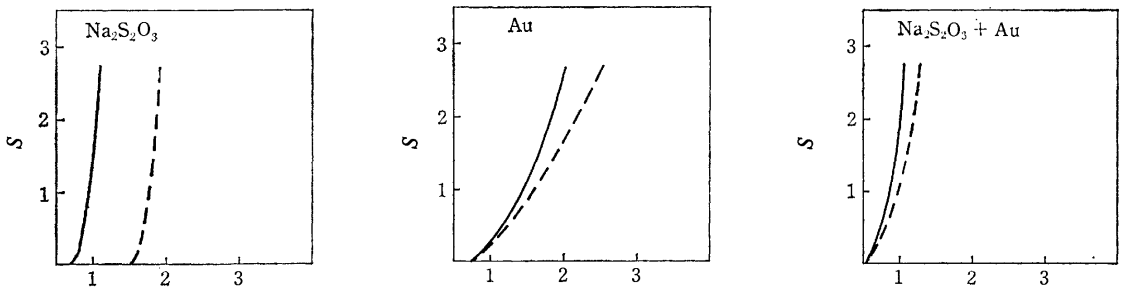
Abb. 10. Saumeffekt einer Lithemulsion an der scharfen Grenze zweier Flächen verschiedener Schwärzung.
Kurve A: stärker belichtet, 1,25 Min. entwickelt.
Kurve B: schwächer belichtet, 2,5 Min. entwickelt.

so kontrolliert, daß die Schwärzung Werten von 2,7 erreicht. Daher waren die Lichtmengen für Kurve A höher als für Kurve B. Der Saumeffekt für Kurve B (2,5 Min. entwickelt) war groß, während derselbe für Kurve A (1,25 Min. entwicklt) klein war. Durch Zusatz des Sulfites wurde der Saumeffekt stark verabsetzt.

7. Oxydierbarkeit, Entwickelbarkeit und Litheffekt der verschiedenen Emulsionen. Die Oxydierbarkeit des latenten Bildes der schwefelsensibilisierten AgCl-, AgCl/Br-, und AgBr-Emulsion[15] und der schwefel-, gold- und goldschwefel-sensibilisierten AgCl/Br-Emulsion[18] ist in Abb. 11 gegeben. Man behandelte die belichteten

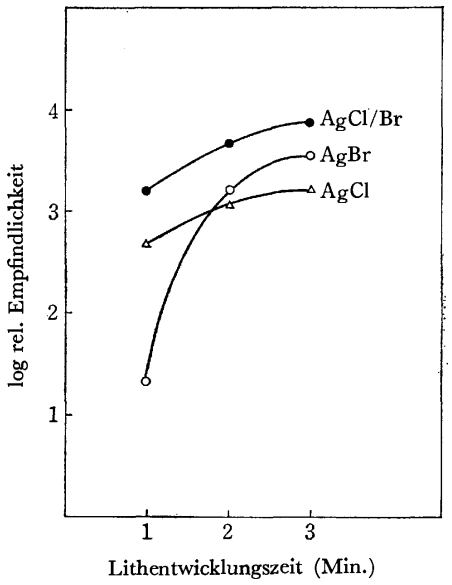


(a) Schwefelsensibilisierte AgCl-, AgCl/Br- und AgBr-Emulsion, 30 Sek. vorbehandelt mit Chinon (pH 5) dann lithentwickelt.

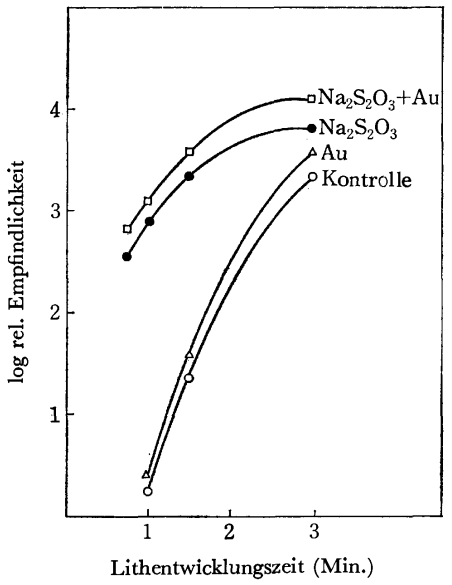


(b) AgCl/Br-Emulsion, die mit $Na_2S_2O_3$, $HAuCl_4$ und ($Na_2S_2O_3$ + $HAuCl_4$) gereift, 3 Min. vorbehandelt mit Chinon (pH 5), dann lithentwickelt.

Abb. 11. Oxydierbarkeit des latenten Bildes mit Chinonlösung (----) im Vergleich zu Originalkurven (——).



(a) Schwefelsensibilisierte AgCl-, AgCl/Br- und AgBr-Emulsion.



(b) AgCl/Br-Emulsionen, die mit $Na_2S_2O_3$, $HAuCl_4$ und ($Na_2S_2O_3$ + $HAuCl_4$) gereift wurden.

Abb. 12. Verlauf der Empfindlichkeit verschiedener Emulsionen als Funktion der Lithentwicklungszeit.

Filmstreifen vor der Entwicklung mit Chinonlösung, die 0,1 g KBr und 0,4 g Chinon pro Liter bei pH 5 behielt. Als Kontrolle diente KBr-Bad ohne Chinon. Unter den versuchten Emulsionen verschoben sich die Schwärzungskurven der AgCl/Br-Emulsion, besonders der schwefelsensibilisierten, durch Chinon parallel zu der Originalkurve. Die Gradation blieb trotz des Bleichens ungefähr konstant. Dies zeigt, daß die latenten Bildkeime dieser Emulsionen im Gebiet der schwächeren Belichtungen durch Chinon und Br^--Ionen leicht oxydiert sind, dagegen dieselben der anderen Emulsionen etwas schwieriger oxydiert sind.

Der Verlauf der Empfindlichkeitszunahme der oben genannten Emulsionen[15,17] in Abhängigkeit von der Entwicklungszeit ist in Abb. 12 gegeben. Unter diesen Emulsionen hatten die schwefelgereifte AgCl-, die schwefelgereifte AgCl/Br- und die goldschwefelgereifte AgCl/Br-Emulsion hohe Entwickelbarkeit an stärker belichteten Körnern durch Hydrochinon. Die gleiche Tendenz wie die in Abb. 12 gezeigt, wurde auch vom sulfithaltigen Hydrochinonentwickler erhalten.

Die schwefelsensibilisierte AgCl/Br-Emulsion zeigte einen guten Litheffekt, während man bei der AgCl-Emulsion etwas verringerten, bei der AgBr-Emulsion fast keinen Litheffekt fand.

Diskussion

Hydrochinon wird bei der Lithentwicklung ohne Sulfit über die radikalische Zwischenstufe des Semichinons in das Chinon verwandelt. Aus Hydrochinon und Chinon läßt sich Semichinon bilden. In der Lithentwicklung entstehen als erste Stufe die Oxydationsprodukte des Hydrochinons wie Semichinon und Chinon. Wegen der niedrigen Konzentration des Sulfites sammeln sich diese in der Gelatineschicht. In alkalischer Lösung geht Chinon durch Disproportionierung in Hydrochinon und Hydroxyhydrochinon über.[11,12] Nach Meinungen von Eigen und Matthies[22] liegt die Reaktionsgeschwindigkeitskonstante der Hydroxychinonbildung aus Chinon in alkalischer Lösung viel niedriger als die Bildungsgeschwindigkeit des Semichinons aus Hydrochinon und Chinon. Daher könnten die enolisierten Hydratationsprodukte des Chinons bei der Lithentwicklung eine kleine Rolle spielen. Nach Yule[1] verursachen die Oxydationsprodukte des Hydrochinons die Ansteckungsentwicklung, indem sie die Entwicklung benachbarter wenig belichteten Körner beschleunigen. Die Resultate in Abbildungen 2 und 3 beweisen die beschleunigende Wirkung der Oxydationsprodukte. Die Bildausbreitung in Abb. 2, mit anderen Worten, die ansteckende Schwärzungszunahme läßt sich wahrscheinlich von den Oxydationsprodukten ableiten. In der Gegenwart von Sulfit, welches diese Oxydationsprodukte unter Bildung von Hydrochinonsulfonsäure beiseite bringt, kann man wohl die auffallende Bildausbreitung in Abb. 2 und das Entwicklungsbeschleunigen in Abb. 3 nicht mehr beobachten. Das dem Entwickler zugefügte Chinon zeigte keine so große Beschleunigung wie die AgCl-Emulsion. Daher wirkt wahrscheinlich der naszierende Zustand der Oxydationsprodukte stärker ein. Dagegen wirkten die durch AgCl-Emulsion[16] entstandenen Oxydationsprodukte bei der Lithentwicklung ohne Bromid weniger beschleunigend als hemmend ein. Dies wird wohl von der James'schen Ladungsbarrieretheorie[23] wie folgt erklärt. Die sich um die Körner bildende Ladungsbarriere von Br^--Ionen überwindet das Herantreten der negativ geladenen Hydrochinonionen zu den Körnern, so daß sich die Entwicklungsgeschwindigkeit verringert. Nach Brauer und Staude[24] wird Chinon an belichtete Körner adsorbiert, das seinerseits imstande ist, zwei Moleküle Hydrochinon pro ein Molekül Chinon zu adsorbieren. Die Rolle der Oxydationsprodukte

22) M. Eigen und P. Matthies, *Chem. Ber.*, **94**, 3309 (1969).
23) T. H. James, *J. Phy. Chem.*, **43**, 701 (1939).
24) E. Brauer und H. Staude, *Z. Elektrochem.*, **58**, 129 (1954).

als der Entwicklungsbeschleuniger ist wohl dadurch erklärt, daß sie den durch die Ladungsbarriere hervorgerufenen Effekt verringern, um die Elektronenübertragung vom herantretenden Hydrochinon auf den Entwicklungskeim zu erleichtern. Hydrochinon ist vermutlich das stärkere Reduktionsmittel als Semichinon, so daß die Entwicklung ohne Bromid durch die entstandenen Oxydationsprodukte wie Abb. 3 gehemmt wird.

Die bisherigen Vorstellungen über die Lithentwicklung sind zwar passend für die Erklärung der oben angegebenen Resultate, aber können nicht genug beweisen, warum der Litheffekt bei der Entwicklung ohne Bromid nicht gewahr wurde. Dies zeigt, daß man weiterer Vorstellungen über die Lithentwicklung bedarf. Hierbei kann es als angemessen betrachtet werden, die Oxydation durch Chinon und deren Einfluß auf die Lithentwicklung zu bemerken.

Das Silberpotential ist wie Gleichung (1) beschrieben, wobei das Normalpotential des Silbers E°_{Ag} den Wert von 808 mV hat.

$$E_{Ag} = E^{0}_{Ag} + (RT/F) \ln [Ag^{+}] \quad (1)$$

Die in dieser Arbeit benutzte Chinonlösung hatte bei pH-Wert von 3,6 das Redoxpotential 526 mV. Unter diesen Bedingungen kann das Makrosilber durch Chinonlösung nicht oxydiert werden. Zusätze von NaCl, KSCN, und KBr zur Chinonlösung setzen den E_{Ag}-Wert herunter. Man rechnet die Silberpotentiale gemäß der Gleichung (1) mit Löslichkeitsprodukt in der oben angegebenen Reihenfolge als 333 mV, 208 mV, und 184 mV. Alle diese Werte zeigen eine elektrochemische Möglichkeit, das Makrosilber zu oxydieren, was in Abb. 4 verwirklicht ist. Das Redoxpotential der Chinonlösung beschreibt man gemäß der Gleichung (2).

$$E_{Q} = E^{0}_{Q} + (RT/2F) \ln ([Q][H^{+}]^{2}/[HQ]) \quad (2)$$

wo das Normalpotential E°_{Q} den Wert von 696 mV hat, und [ ] die Aktivität jeder Substanzen bedeutet. Die Potentialdifferenz zwischen E_{Ag} und E_{Q} ist eine treibende Kraft der Oxydation des Silbers. Die Ergebnisse in Abb. 4 entsprechen der Größe der Potentialdifferenz. Wie in Abb. 6 gezeigt, wurde dagegen das Mikrosilber des latenten Bildes durch Chinon oxydiert. Als Gründe kann man hier zwei Vorstellungen bezeichnen.

1. Nach der Thomson-Ostwald'schen Formel hat das Mikrosilber des latenten Bildes die größere Löslichkeit im Vergleich zum massiven Silber.

2. Die aus Silberhalogenidkristalle aufgelösten Halogenionen verschieben das Silberpotential des latenten Bildes zur negativeren Werten.

Beim Versuch der Abb. 4 konnte man eine erhebliche Schwärzungserniedrigung des Makrosilbers auch durch die mit AgCl gesättigte Chinonlösung nicht beobachten. Daher könnte der erste Grund eine Hauptrolle spielen.

Vorbehandlung mit der bromidhaltigen Chinonlösung gab die erhebliche Desensibilisierung, besonders am Fuß der Schwärzungskurve. (Abb. 7) Gleichung (2) beschreibt, daß die Oxydationskraft der Chinonlösung mit steigender Konzentration des Chinons und der H^{+}-Ionen stärker wird. Mit diesen Verhältnissen kann man die Abhängigkeit des pH-Wertes und der Chinonkonzentration auf das Bleichen des Silbers erklären. (Abb. 5 und 8) Bei den Vorbehandlungen mit Chinon im pH-Bereich über 7 wurde das Empfindlichkeitssteigen beobachtet. Beim höheren pH-Bereich wird sich die Oxydationskraft des Chinons verringern und geht Chinon ins Reduktionsmittel über, so daß dieses Mittel das latente Bild wahrscheinlich verstärkt. Dieses Resultat stimmt mit dem von Zwicky[10] überein, in dem der mit Lithentwickler vorbehandelte Lithfilm bei der nachfolgenden Entwicklung mit der phenidonhaltigen Hydrochinonlösung eine höhere Schwärzung zeigte. Daraus kommt ein Schluß, daß kein Oxydationseffekt bei der Lithentwicklung erfolgt. Es könnte aber schwer sein, die Oxydationskraft bei der Lithentwicklung nur mit der nachfolgenden anderen Entwicklung sichtbar nachzuweisen.

Das Redoxpotential der Hydrochinonlösungen wird, wie in Abb. 9 gezeigt, durch die Entstehung der Oxydationsprodukte und der H^{+}-Ionen, durch die Konzentrationsabnahme des Hydrochinons, nach positiveren Werten verschoben. Die Potentialänderungen der auf Pt-Elektrode beschichteten nassen Lithemulsion lagen während der Lithentwicklung zwischen 80 mV und 100 mV. Als man die Pt-Elektrode auf dem entwickelnden Lithfilm kontakt setzte, zeigten die Potentialverschiebungen noch größere Werte. Dies wird wohl auf den Unterschied der Quellung der zwei Emulsionschichten zurückgeführt. Die Potentialsteigerung konnte man in der Lithentwicklerlösung an der Stelle gar nicht finden, die nur 1 mm von der entwickelnden Emulsionschicht entfernt ist. Wie aus Tabelle 2 ersehen ist, setzte Sulfit die Potentialänderung auf der Emulsionschicht stark herab, während man in diesem Fall die gleiche Potentialänderung im Entwickler über der Schicht bemerkte. Das kommt wahrscheinlich auf die Oxydationsprodukte an, die, bei Anwesenheit des Sulfites leicht, bei Abwesenheit desselben schwer, aus der Schicht herausdiffundieren. Nach Meinungen von Frieser und Eger[25] können die Oxydationsprodukte im Fall des Bisulfitgehaltes auf weniger als 2 g pro Liter nicht leicht aus der Schicht herausdiffundieren und mit der Gelatine der Schicht zur Vernetzung reagieren.

Das gemessene Redoxpotential des latenten Bildes ist ein kritisches Potential, bei dem die Entwicklungsgeschwindigkeit Null ist und dann die Oxydation beginnt. Nach den Vorstellungen von Reinders,[26] Hillson[21], und Frei[27] ist das kritische Potential mit dem makroskopischen Silber-Gleichgewichtspotential nicht identisch, vielmehr liegt es um 100 mV bis 200 mV negativer. Matejec, Moisar[28] und Schmidt[29] zeigten, daß das Redoxpotential des latenten Bildes demselben des Makrosilbers nahe liegt. Nach Matejec und Moisar[28] treten Störungen in Messungen durch Fe^{3+}/Fe^{2+}-Lösungen auf, wird das Redoxpotential der verwendeten Fe^{3+}/Fe^{2+}-Lösungen durch Zugabe des Zitrates variiert, und verschieben die mit Silberhalogenid nicht

gesättigten Lösungen die gemessenen Werte zu negativeren Werten. Unserer Messung nach war die Verschiebung des Silberpotentials der mit AgCl gesättigten Lösung durch Zusatz von 1,5 bis 4,0 Mol Zitrat/l um 57 mV und in Gegenwart von 10^{-2} Mol NaCl/l nur um 7 mV. Mit diesen Werten wurde das gemessene Potential korrigiert. Das gemessene Redoxpotential der AgCl-Emulsion war 320 mV. Deshalb sind die korrigierte Werte 377 mV bei 0 Mol Cl^-/l, und 207 mV bei 10^{-2} Mol Cl^-/l. Diese Werte liegen um 136 mV bei 0 Mol Cl^-/l, um 137 mV bei 10^{-2} Mol Cl^-/l negativer als das aus der Thermodynamik berechnete Potential des Makrosilbers. Das Redoxpotential der AgCl/Br-Emulsion lag negativer als das der AgCl-Emulsion. Bei der Anwesenheit von Br^--Ionen würde es noch negativer liegen. Die exakte Messung ist schwer wegen der Konvertierung von AgCl durch Br^--Ionen. Das makroskopische Silberpotential bei 0,025 Mol Br^-/l liegt rechnerisch bei 172 mV. Unter Annahme der Erniedrigung um 140 mV im Fall des latenten Bildes würde der oxydative Abbau des latenten Bildes von AgCl/Br-Emulsion in der Nähe des Wertes von 30 mV beginnen. Eine merkliche Redoxpotentialsteigerung konnte man in der entwickelnden Schicht finden. Schließlich lag das Redoxpotential in der Schicht während der Lithentwicklung bei 60 mV oder über 60 mV. Auf Grund thermodynamischer Überlegungen könnte man unter diesen Bedingungen eine Oxydation der latenten Bildkeime durch die bei der Lithentwicklung entstandenen Oxydationsprodukte erwarten. Das Redoxpotential des latenten Bildes ist ein in reversiblen Systemen gemessenes Gleichgewichtspotential. Die chemische Entwicklung und der Abbau des latenten Bildes sind irreversibel, dabei spielt nicht der Gleichgewichtszustand, sondern die Reaktionsgeschwindigkeit eine große Rolle. Daher ist es fraglich, ob man nur durch Messung des Redoxpotentials die Eigenschaften der Entwicklung erfassen kann. Man könnte aber dadurch eine Möglichkeit der Oxydation des latenten Bildes in der Lithentwicklung diskutieren. Bei der Oxydation des latenten Bildes sind einige Fälle vorstellbar, d.h. der ganze Abbau, der partielle Abbau und die Entwicklungshemmung ohne Abbau des latenten Bildes. Den ersten Fall könnte man sich nicht vorstellen. Der ganze Abbau würde eine Empfindlichkeitssteigerung nach längerer Entwicklungszeit nicht hervorbringen. Eine Oxydation in der Lithentwicklung sollte man im zweiten oder im dritten Fall erwarten, obgleich sich diese zwei Fälle deutlich voneinander unterscheiden. Unseren Beobachtungen nach[19] wurde der an der Lithentwicklung teilnehmende Bildkeim viel leichter oxydiert als der an der üblichen Entwicklung teilnehmende. Ein kleiner partieller Abbau im zweiten Fall, der bei der Lithentwicklung nur eine geringe Empfindlichkeitsabnahme verursachen kann, würde keinen bemerklichen Effekt bei der üblichen Entwicklung erweisen. Der dritte Fall hängt an von der Verringerung der Werte zwischen den Potentialen des latenten Bildes und des umliegenden Entwicklers. Mit anderen Worten dürfte man erklären, daß die Oxydationsprodukte des Hydrochinons in der Lithentwicklung mit Hilfe von Br^- und H^+-Ionen oxydativ einwirken. Eine Ursache des Saumeffektes bei der Lithentwicklung wird auch wohl auf die oxydative Wirkung der aus der Stelle hoher Schwärzung diffundierenden Oxydationsprodukte zurückgeführt. Daher verringert Sulfit den Saumeffekt bei der Lithentwicklung durch Beseitigung der Oxydationsprodukte. In Abb. 10 ist gezeigt, daß der Saumeffekt von dem 2,5 Min. entwickelten Bild viel größer als der von dem 1,25 Min. ist. Daraus kann man annehmen, daß die oxydative Wirkung stärker auf die schwächer belichteten als auf die stärker belichteten ist. Nach Yule wird die Schwärzung durch Streulicht herabgesetzt, wenn man den Film zusammen mit Rasterpünkten entwickelt. Nach unserem Versuch war dieser Effekt desto stärker, je der Raum des Rasterpunktes größer war. Diese Resultate sind auch mit der oxydativen Wirkung diffundierender Oxydationsprodukte zu erklären.

Die Schärfe am Rand des Rasterpunktes hängt vermutlich in großem Maße von den diffundierenden Oxydationsprodukte ab. Bei der Entwicklung der mit Graukeil belichteten Schicht spielen die Wirkungen diffundierender Oxydationsprodukte auf den Fuß der Schwärzungskurve vermutlich keine große Rolle. Dies könnte der Grund sein, warum die Erzielung einer steilen Gradation im makroskopischen Bereich und eines scharfen Punktes im mikroskopischen Bereich nicht immer direkt miteinander gekoppelt sind.

Die latenten Bildkeime der Emulsion, die einen guten Litheffekt zeigt, sind in der schwächer belichteten Stelle leicht, in der stärker belichteten schwer oxydiert, wie es in Abb. 11, in Tabellen 4 und 5 gezeigt ist. Man sollte hier beobachten, daß das Verhalten des latenten Bildes einer Lithemulsion an der schwächer belichteten Stelle und der stärker belichteten merklich verschieden ist. Der Unterschied der beiden Schwärzungskurven in Abb. 1a ist der oxydativen Wirkung zuzuschreiben. Der Lithentwickler ohne Bromid zeigte auch in kürzerer Entwicklungszeit keinen Litheffekt. Eine wichtige Rolle der Br^--Ionen in der Lithentwicklung liegt wahrscheinlich darin, daß sich das Redoxpotential des latenten Bildes erniedrigt, um von den Oxydationsprodukten oxydativ beeinflußt werden zu können. Die anderen außer Br^--Ionen in Tabelle 1 können das Redoxpotential des latenten Bildes nicht genug erniedrigen, so daß man einen guten Litheffekt nicht erhalten kann. Im Beisein der SCN^--Ionen konnte man einen kleinen Litheffekt erhalten. Eine Erklärung dafür ist, daß die Erniedrigung des Redoxpotentials durch SCN^--Ionen kleiner als durch Br^--Ionen ist.

Der Mechanismus der Lithentwicklung ist zwar noch heute nicht genug klar,[30] aber aus obigen Tatsachen kommt eine erweiterte Ansicht wie folgt zum Schluß.

In der ersten Stufe wird der Ablauf der Entwicklung gehemmt, da die Oxydationsprodukte des Hydrochinons mit Hilfe von Br^-- und H^+-Ionen auf die latenten Bildkeime oxydativ einwirken. Dies entspricht der sehr niedrigen Schwärzung, die man bei kürzerer Lithentwicklungszeit kaum beobachten kann. Diese

30) H. Frieser, G. Haase, und E. Klein, „Die Grundlagen der photographischen Prozesse mit Silberhalogeniden," Bd. 2, herausgegeben von Akademische Verlagsgesellschaft, Frankfurt am Main (1968), S. 884.

oxydative Einwirkung geht aber in der Lösung mit Sulfit weg. Die oxydative Hemmung ist vor allem stark an der schwächer belichteten Stelle. Das latente Bild an der stärker belichteten Stelle widerstrebt der Oxydation und wird weiter entwickelt. Die entstandenen Oxydationsprodukte diffundieren einigen Abstand zu den umliegenden Körnern, teils um die Entwicklung der stärker belichteten Körner durch die Herabsetzung des Ladungsbarriereeffektes zu beschleunigen, teils um dieselbe der schwächer belichteten Körner durch den oxydativen Abbau des latenten Bildes oder durch die Hemmung der Entwicklung niederzuhalten.

Der Litheffekt ist abhängig von der Entwickelbarkeit der stärker belichteten Bildkeime und von der Oxydierbarkeit der schwächer belichteten. Wenn diese beiden Faktoren miteinander ins Gleichgewicht gebracht werden, könnte man einen guten Litheffekt erhalten. Mit anderen Worten, beruht der Litheffekt auf der Entwickelbarkeit der stärker belichteten Bildkeime durch Hydrochinon und der Oxydierbarkeit der schwächer belichteten durch Chinon. Der Litheffekt, die Entwickelbarkeit durch Hydrochinon und die Oxydierbarkeit durch Chinon, wie sie in Abbildungen 11 und 12 dargestellt, sind in Tabellen 4 und 5 wieder zusammengefaßt. Die AgCl/Br-Emulsion von drei Silberhalogenidemulsionen und die schwefelsensibilisierte Emulsion von drei chemisch sensibilisierten AgCl/Br-Emulsionen beweisen einen guten Litheffekt. Die Ursache dafür ist so erklärt, daß ihre latenten Bildkeime in der stärker belichteten Stelle durch Hydrochinon schnell entwickelt werden und dieselben in der schwächer belichteten Stelle durch Chinon leicht oxydiert werden. Der Litheffekt der AgBr-Emulsion ist schlecht, da die Entwicklbarkeit und die Oxydierbarkeit von AgBr-Emulsion miteinander nicht im Gleichgewicht sind. Wenn die latenten Bildkeime der AgCl-Emulsion noch etwas leichter oxydiert werden könnten, würde sie einen besseren Litheffekt beweisen.

TABELLE 4. ERKLÄRUNG DES LITHEFFEKTES VON DREI SILBERHALOGENIDEMULSIONEN

Oxydierbarkeit	$S \gg Au > S+Au$

Herrn Prof. Dr. K. Honda an der Universität Tokio möchte ich für die wertvolle Diskussion herzlich danken.

NOTES

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3473—3474 (1972)

A Study of Catalysis by Uranium Oxide and Its Mixed Catalysts. III.[1] A Comparison of the Uranium Oxide Catalyst with Vanadium Oxide, Molybdenum Oxide and Tungsten Oxide Catalysts for the Catalytic Oxidation of Carbon Monoxide

Fumio Nozaki and Keiichi Ohki

Department of Industrial Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba

(Received March 17, 1972)

The catalytic oxidation of carbon monoxide over various metal oxides has been studied by several workers discussing the order of oxidation activity.[2] However, there have been very few reports about the uranium oxide catalyst. The present authors have reported previously about the supported uranium oxide catalysts.[3] The purpose of this paper is to make a survey of the oxidation activity of U_3O_8, V_2O_5, MoO_3, and WO_3 catalysts, and to discuss the causative relationship between the catalytic activity and the thermodynamic properties of the oxides, such as the heat of formation or the heat of oxide-interconversion.

Experimental

Catalyst Samples. All of the catalysts were obtained by the usual method of preparation. U_3O_8 was prepared by the thermal decomposition of ammonium diuranate, $(NH_4)_2U_2O_7$, obtained from uranyl nitrate by precipitation with NH_4OH. The sample calcined at 450°C for 3 hr in an air stream was green-black in color and 20.8 m^2/g in B.E.T. surface area. The V_2O_5 catalyst was prepared from NH_4VO_3 by calcination. The sample calcined at 500°C for 3 hr in an air stream was tan-orange and 5.2 m^2/g in surface area. The MoO_3 catalyst was obtained by the calcination of the precipitate prepared from $(NH_4)_6Mo_7O_{24}$ and HNO_3. The sample calcined at 500°C for 2 hr in an air stream was white and 3.0 m^2/g in surface area. The WO_3 catalyst was obtained by the calcination of the precipitate prepared from $(NH_4)_{10}W_{12}O_{41}$ and HNO_3. After it had been calcined at 500°C for 2 hr, the sample was yellow and 12.1 m^2/g in surface area.

Catalytic Oxidation of Carbon Monoxide. The flow-type apparatus and the procedure for the rate measurements were the same as those previously reported.[3] All of the experiments were carried out under the following identical conditions: total flow rate of feed gas=100 ml (20°C)/min, feed ratio of $CO:O_2:N_2=3:3:4$, total pressure=1 atm. The amount of catalyst packed in the reactor was controlled in the range from 0.2 to 1.2 g according to the catalyst specimen in order to prevent the conversion of carbon monoxide from exceeding 20%. Under these experimental conditions, the observed conversion of carbon monoxide was proportional to the amount of catalyst used. The equation used in the calculation of the reaction rate was:

$$r = \frac{1}{S}\frac{y_0 x}{(W/F)} \quad (1)$$

where r: reaction rate per unit of surface area of the catalyst (mol/m^2 hr), y_0: CO mol fraction at the inlet of the catalyst bed (=0.3), S: surface area of the catalyst (m^2/g), W: amount of catalyst (g), F: total flow rate of feed gas (=0.268 mol/hr).

Results and Discussion

The conversion data as a function of the reaction temperature are shown in Fig. 1. We calculated the reaction rates by using Eq. (1) and plotted log (r) as a function of $1/T$ in Fig. 2. From Figs. 1 and 2, it is found that U_3O_8 is exceedingly high in oxidative activity and that the order of catalytic activity is as follows: $U_3O_8>V_2O_5>MoO_3>WO_3$. We estimated the reaction rates from Fig. 2 at a reaction temperature of 500°C and have illustrated the rate data as a function of the heat of formation, $(-\Delta H°_f)$[4] or of the heat of oxide-interconversion, $(\Delta H°_{MO_{x-1}} - \Delta H°_{MO_x})$[5]

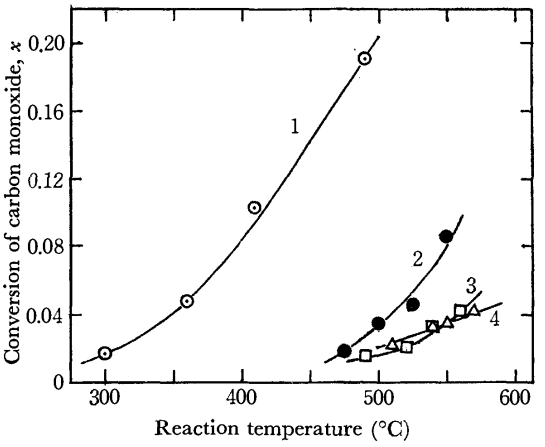

Fig. 1. Conversion of carbon monoxide as a function of reaction temperature.

3) F. Nozaki, M. Kobayashi, and S. Yoshida, *Nippon Kagaku Kaishi*, **1972**, 26.

4) This is the heat of formation per metal atom (kcal/metal atom). The data of $-\Delta H°_f$ are quoted from "Shokubai Kogaku Koza", Vol. 2 (ed. by Catalysis Soc. of Japan), p. 141 and "Chemistry of Uranium" (by Katz and Rabinowitch), p. 295.

5) The value of $(\Delta H°_{MO_{x-1}} - \Delta H°_{MO_x})$ corresponds to the heat of reaction of the following deoxygenation: $MO_x \rightarrow MO_{x-1} + 1/2\ O_2$, where MO_{x-1} means the next lower oxidized state of metal oxide, MO_x. In the present case, the chemical formulas of MO_{x-1} are U_3O_7, V_2O_4, MoO_2, and WO_2 respectively. The data of the heat of reaction are quoted from the books noted in Ref. 4).

4: WO_3 (E_a=16 kcal/mol)

in Fig. 3. In order to characterize the U_3O_8 catalyst, the available data or estimated values[6] of $r_{500°C}$ in the cases of NiO, ZnO, Cr_2O_3, and TiO_2 are also illustrated in Fig. 3 by quoting data from published papers.[7-9]

As is shown in Fig. 3, the correlation between $r_{500°C}$ and $-\Delta H°_f$ has a tendency to move towards a low activity with the increase in $-\Delta H°_f$; however, the activity of U_3O_8 is much higher, as would be expected from $-\Delta H°_f$, and is situated between the ZnO (or NiO) and Cr_2O_3 (or V_2O_5) catalysts. It should be emphasized in this study that U_3O_8 is considerably high in oxidative activity for an *n*-type semiconducting oxide catalyst. Within the limits of the catalyst species investigated in this study, the correlation between

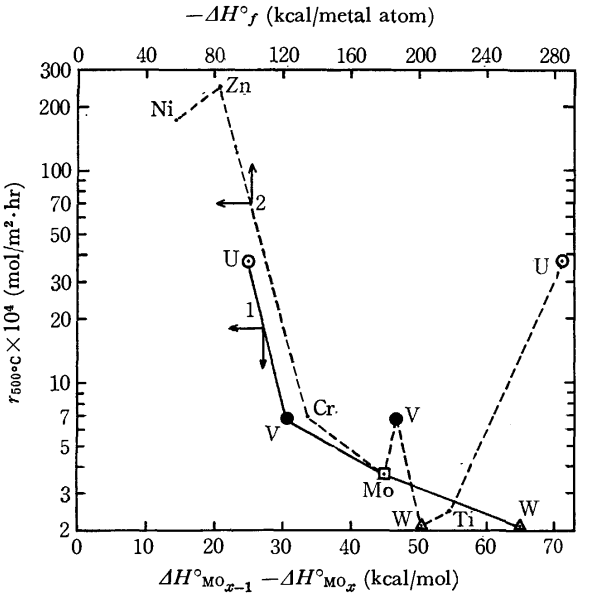

Fig. 3. Correlation between catalytic activity and thermodynamic property of catalyst oxides.
1: (solid line) reaction rate at 500°C *vs.* ($\Delta H°_{MO_{x-1}} - \Delta H°_{MO_x}$)
2: (dotted line) reaction rate at 500°C *vs.* $-\Delta H°_f$

$r_{500°C}$ and ($\Delta H°_{MO_{x-1}} - \Delta H°_{MO_x}$) is regular and shows a predictable variation with a change in ($\Delta H°_{MO_{x-1}} - \Delta H°_{MO_x}$). A probable explanation of why U_3O_8 is active in spite of the large heat of formation can be given on the basis of the fact that U_3O_8 is readily reduced with CO and reoxidized with O_2 because of the small heat of oxide-interconversion.[3] This finding suggests that all of the oxygen atoms in U_3O_8 are not on an equal footing and that some of the specified oxygen atoms showing a high reactivity are involved, as Tarama *et al.*[10] have already pointed out with regard to the V_2O_5 catalyst. We will attempt to obtain more detailed information on this aspect after we have investigated the physico-chemical structure of the uranium oxide catalyst.

6) The values of $r_{500°C}$ were computed or estimated from the rate equations or from the Arrhenius plots of the rate data for identical experimental conditions with this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3475—3476 (1972)

An MO-theoretical Account of the Catalytic Property of Transition-metal Carbides and Nitrides in Dehydrogenation Reactions

Katsutoshi OHKUBO, Hidetoshi SHIMADA, and Masahide OKADA

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto

(Received April 10, 1972)

Refractory compounds of transition-metal carbides and nitrides have been pronounced to be catalysts possessing high catalytic activity in the dehydrogenation of ethylbenzene,[1] cyclohexane,[2] *etc.*, while those of transition-metal borides have proved to be quite inactive.[2] The catalytic properties of refractory compounds, however, have not yet been strictly established on a molecular level. The present study was undertaken in an attempt to correlate the electronic states of transition-metal carbides and nitrides and their catalytic properties in the dehydrogenation reactions, using the all-valence-shell-electron extended Hückel MO (EHMO) method[3] involving metal *d*-orbitals. The FCC NaCl-type carbides and nitrides (named MC and MN respectively) of TiC, VC, ZrC, NbC, HfC, TaC, TiN, VN, CrN, ZrN, NbN, and HfN have been studied; a simple model of their solid states for the EHMO calculations is presented in Fig. 1 and in Table 1.

a) Taken from H. F. Mark, J. J. McKetta, Jr., and D. F. Othmer, "Encyclopedia of Chemical Technology," 2nd, Ed., Vol. 4, (1964), p. 13.

First, let us discuss the correlation between the atomic charges of M in MC or MN and the rate constants,[1] *k*, reflecting the catalytic activity in the dehydrogenation of ethylbenzene at 560 and 600°C. As Fig. 2 indicates, the MC series tested showed the formal charges of M in the range of *ca.* +0.3—3.5 and gave a maximum indicative of their catalytic activities near the tri-valent charge of M (transition metal).

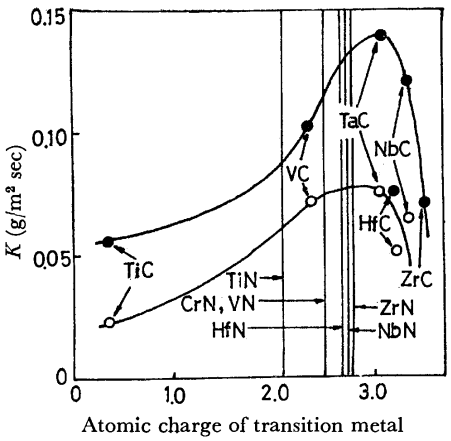

Fig. 2. Correlation between the catalytic activities of transition metal carbides and nitrides and the atomic charges of their metals.
○: 560°C; ●: 600°C

Next, a more precise discussion will be undertaken. The transition-metal carbides and nitrides are characterized by the lowest unoccupied (LU), triply-degenerate d_{xz}, d_{yz}, and d_{xy} metal-orbitals, and also by the LU+1, doubly-degenerate $d_{x^2-y^2}$ and d_{z^2} metal-orbitals. The net orbital populations of the *s* and *p* orbitals of metal and carbon (or nitrogen) atoms at the highest occupied (HO) or the LU level are neglegibly small. This implies that the *s* and *p* orbitals cannot participate directly in the electron donor-acceptor process between the catalyst and such reactants as ethylbenzene. Table 2 lists the orbital populations of the d_{xz}, d_{yz}, and d_{xy} orbitals on the metal at the triply-degenerate levels (denoted as $1/2N_{xz}$, $1/2N_{yz}$, and $1/2N_{xy}$ respectively)

Phys.*, **39**, 1397 (1963); *ibid.*, **40**, 2474 (1964): the ionization energies (eV unit) of the outer *s*, *p*, and *d* shells for Coulomb integrals of transition metals were taken from Moor's table (C. E. Moor, "Atomic Energy Levels," Natl. Bur. Std. Circ., No. 467 (1958), Vols. 1, 2, and 3) as follows: 10.33, 6.38, and 11.84 for Ti; 8.0, 6.0, and 10.0 for V; 8.0, 7.0, and 9.0 for Cr; 7.14, 4.78, and 7.14 for Zr; 7.58, 4.99, and 7.58 for Nb; 7.87, 5.87, and 7.87 for Hf; 8.14, 5.15, and 8.14 for Ta.

Table 2. Electronic states of transition metal carbides and nitrides

MC or MN	Bond population of M–C or M–N	Net orbital populations at degenerate levels	
		$1/2N_{xz}=1/2N_{yz}=1/2N_{xy}$	$1/2N_{x^2-y^2}=1/2N_{z^2}$
TiC	0.438	0.1421	0.0355
VC	0.438	0.2324	0.0252
ZrC	0.241	0.1449	0.0322
NbC	0.296	0.2397	0.0153
HfC	0.363	0.1351	0.0461
TaC	0.364	0.2389	0.0157
TiN	0.287	0.2432	0.0084
VN	0.217	0.2447	0.0075
ZrN	0.106	0.2453	0.0073
NbN	0.133	0.2455	0.0065
HfN	0.173	0.2444	0.0008
CrN	0.235	0.2109	0.0575

and of the $d_{x^2-y^2}$ and d_{z^2} orbitals at the doubly-degenerate levels (denoted as $1/2N_{x^2-y^2}$ and $1/2N_{z^2}$ respectively), together with the bond populations of the M–C and M–N. Bearing in mind the connection between the catalytic activity and the degree of incompleteness of the *d*-electron subshells in the dehydrogenation reactions,[4] the correlation between the activity and the values of $1/2N_{xz}$ (or $1/2N_{yz}$) and/or $1/2N_{xy}$ seems significant.[5] As can be seen from Fig. 3, there is a linear dependence between the *k* values and the above-mentioned populations of MC (M=Ti, V, Nb, Hf, and Ta); it can be concluded that the transition-metal carbides thus catalyze the dehydrogenation of ethylbenzene as an electron acceptor.

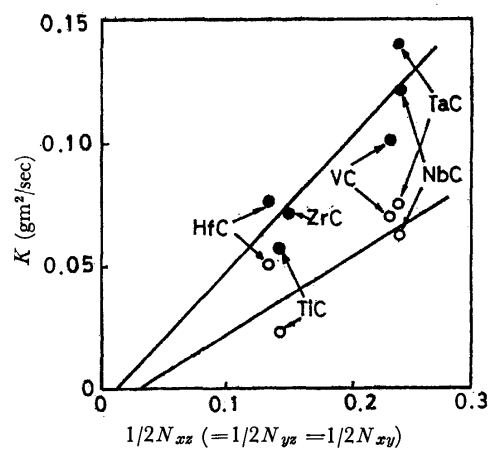

Fig. 3. Correlation between the catalytic activities of transition metal carbides and nitrides and the values of $1/2N_{xz}$ (or $1/2N_{yz}$) and /or $1/2N_{xy}$.
○: 560°C; ●: 600°C

Finally, it is worthy of emphasis, on the basis of the above consideration, that the transition-metal nitrides are not less active than the carbides thereof and that the catalytic activity follows the order: NbN≳ZrN> VN≳HfN≳CrN.

We wish to express our appreciation to the Data Processing Center of Kyushu University for the generous permission to use the FACOM 230-60 computer.

4) S. Z. Roignskii, *Zh. Fiz. Khim.*, **5**, 249 (1935).

5) An increase in the formal charge of M, which is almost directly related to the sum of net orbital populations of the d_{x^2}, d_{yz}, d_{xy}, $d_{x^2-y^2}$, and d_{z^2} orbitals at triply- and doubly-degenerate levels, does not always give a high catalytic activity (see Fig. 1); the relatively large values of $^1/_2N_{x^2-y^2}$ and/or $^1/_2N_{z^2}$ of such nitrides as ZrN and HfN diminish the values of $^1/_2N_{xz}$ (or $^1/_2N_{yz}$) and/or $^1/_2N_{xy}$ in spite of their large formal charges of M (+3.494 and +3.157 for Zr and Hf respectively). The net orbital populations of the d_{xz}, d_{yz}, and d_{xy} orbitals at the LU degenerate levels seem more significant than the formal charge of transition metal.

Colloidal Structure of Aluminum Soaps Dispersed in Organic Media

Yuhei Uzu and Michihiro Hattori

Chemical Institute, Faculty of Science, Shinshu University, Asahi, Matsumoto, Nagano

(Received April 19, 1972)

In connection with the structure of gels formed by metal soaps in organic media, aluminum soaps exhibit many interesting properties. Till now, the colloidal structures of many metal soaps have been widely studied by a variety of techniques. In particular, a perfect image of the soap fibers constituting the dispersed phase can be obtained by means of the electron microscope, provided that a portion of the liquid which masks the fibers is eliminated in a suitable manner.

Especially in the case of 12-hydroxystearic acid and its uni- and bivalent metal soaps, it is recoginized that the soap fibers are twisted in the form of aggregates.[1,2] However, no data on the trivalent metal soaps of 12 hydroxystearic acid have yet been shown, to say nothing of such a twisting structure. Its main causes seem to be its susceptibility to thermal decomposition and the difficulty of obtaining pure soaps.

To elucidate the mechanism of occurrence of such a twisting, various explanations have been proposed in the literature.[3,4,5] Above all, it seems reasonable to assume that the twisting is related to the conformation of the soap molecules, as has been suggested by

1) J. W. Wilson, NLGI *Spokesman*, **27**, 373 (1964).
2) T. Tachibana, K. Kayama, and H. Takeno, This Bulletin, **45**, 415 (1972).

5) G. Rooney and R. J. Bird, *Nature*, **190**, 337 (1961).

Tachibana.[2] The present work shows that similar twisted fibers were found in the aggregates of aluminum 12-hydroxystearate dispersed in such solvents as *n*-hexadecane and white mineral oil.

Aluminum 12-hydroxystearate was prepared by an aqueous metathesis similar to the manner described for the preparation of aluminum stearate.[6] The fatty acids of the commercial products used in this work were purified by repeated recrystallization from ethanol or acetone until those of over 99% purity were obtained, as established by gas-chromatographic analysis. The acids in aqueous ethanol were treated with a slight excess of a potassium hydroxide solution at 50—60°C to yield potassium soaps. The potassium soaps were, then, heated to dissolve them in water, and a hot solution of aluminum chloride at about 90°C was added slowly until the precipitation was complete. The aluminum soaps thus obtained were filtered and thoroughly washed with distilled water and acetone to remove the residue contained in the soaps. Finally, they were dried over P_2O_5 *in vacuo* at 60°C.

The infrared absorption spectra for aluminum stearate and aluminum 12-hydroxystearate were almost identical. Moreover, a comparison of the spectra of the corresponding fatty acids with those of these aluminum soaps showed that the major distinction was the complete absence of the band at 1695 cm^{-1} due to the presence of free fatty acid in the latter, which contains little or no extractable fatty acid. In addition, the thermal analysis confirmed the absence of the transition peak of the free fatty acid. The soaps have a strong band at 983 cm^{-1}, one which is possibly due to an Al–O– covalent and coordinate type of band, as has been reported of aluminum stearate.[6] Also, two absorption bands are displayed at about 1450 and 1590 cm^{-1} which are due to the symmetric and assymmetric stretching vibrations respectively of the carboxylate group. The splitting of the latter band expected in the hydrated forms did not appear. Besides, the elementary analysis indicated that the str./Al and 12 hydroxystr./Al ratio of these soaps were about 2.0 and 1.8 respectively. On the basis of these data, the aluminum 12-hydroxystearate prepared is considered to be a mixture which consists of a disoap plus a small quantity of a monosoap.

A series of studies of the colloidal structures of these soaps has made parallel to one of the gelling properties of these soaps for various organic media. Considerable care was taken in the preparation of the specimen for examination by means of the electron microscope in order to prevent the deformation of the soap thickner structure. In order to make a specimen for electron microscopy, a small amount of the gel or gel-like precipitates was spread in a thin layer on the electron microscope's specimen grids covered with a thin film of carbon, which are then placed on a filter paper. After deoiling by wetting the paper slowly with *n*-hexane, the specimens were chromium-shadowed and examined in the electron microscope.[7] Figures 1 and 2 depict typical electron micrographs of fibers of aluminum 12-hydroxystearate dispersed in *n*-hexadecane and highly-refined mineral oil at 110°C. Further, the similar twisted shapes were obtained in such other organic media as amyl acetate, octyl acetate, and decyl alcohol.

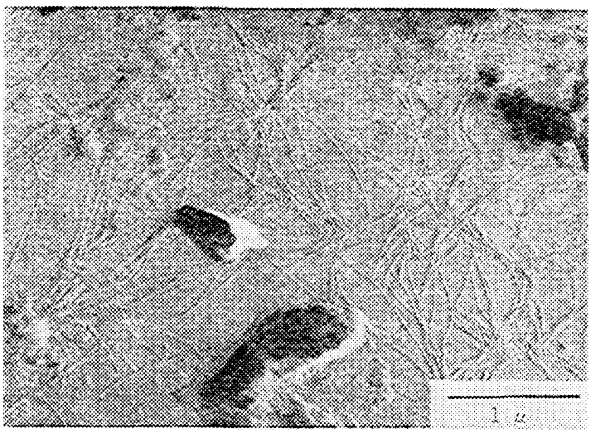

Fig. 1. Electron micrograph of twisted fiber of almuinum 12-hydroxystearate dispersed in *n*-hexadecane at 110°C.

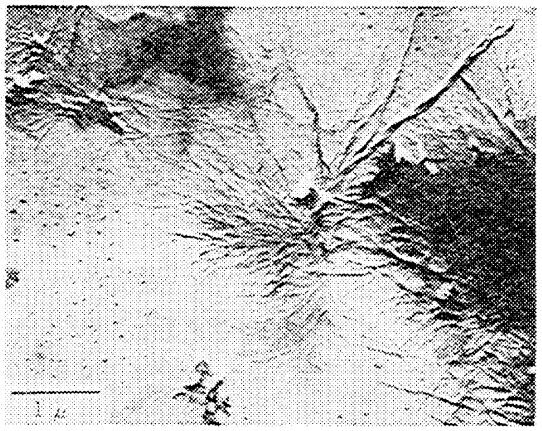

Fig. 2. Electron micrograph of aluminum 12-hydroxystearate dispersed in mineral oil at 110°C.

Out of a fear of decomposition and a release of their free acid with a rise in the temperature, the IR spectra were examined and thermal analysis was carried out

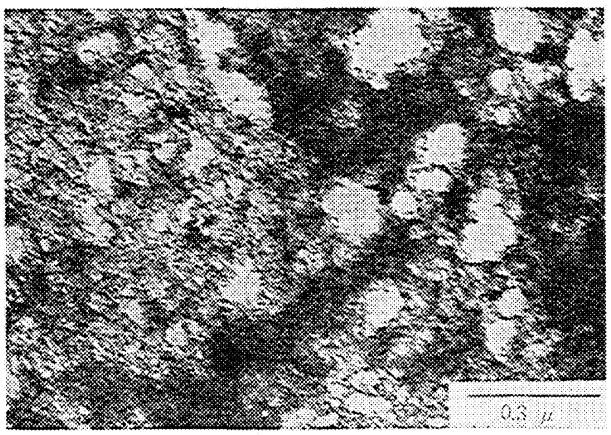

Fig. 3. Electron micrograph of aluminum stearate dispersed in mineral oil at 110°C.

for specimens which has been treated thermally at 90 and 110°C. There was no evidence of the release of free fatty acid as a result of the decomposition. Accordingly, it is considered probable that the twisting structure is ascribable to that of aluminum 12-hydroxystearate.

Figure 3 shows a dense honey-combed structure formed in the aggregates of aluminum stearate. It seems to indicate that such a network structure of aluminum stearate is not so easy to break as in other metal soaps in the deoiling process. This supports the view that it is due to the polymerization of aluminum stearate, as has been reported elsewhere.[8] Furthermore, this idea may be associated, in some manner, with the abnormal low long spacing value of 40.9 Å derived from the X-ray diffraction patterns of aluminum stearate. On the other hand, the large value of 47.8 Å of the aluminum 12-hydroxystearate closely approximates the long spacing values of bivalent soaps.[9] It is suggested that these remarkable differences of the long spacing value, together with the electron-microscopic work, may be interpreted as additional evidence supporting the difference in the degree of gelatization.

Charge-transfer and Proton-transfer in the Formation of Molecular Complexes. III.[1] 2,4-Dinitrophenol Complexes with Various Anilines

Nobuaki INOUE and Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received April 22, 1972)

When picric acid is combined with a number of the derivatives of aniline, the acid-base interaction generally predominates in both the solid and molten states. However, we found earlier that the complexes with the following four anilines can be essentially of the charge-transfer type above the melting points: *o*-chloroaniline, *m*-nitroaniline, 3-nitro-4-methylaniline, and *N,N*-dimethylamino-*p*-benzaldehyde.[2] Their pK_a values are rather low, in the range between 1.6 and 3.0.

2,4-Dinitrophenol is weaker than picric acid as a proton-donor; that is, the pK_a value of the former phenol is higher, at least by 3, than that of the latter. If the range of pK_a values of anilines, in which the phenomenon of complex isomerization by melting is observable, is essentially determined by the balance between the pK_a value of a polynitrophenol and those of anilines, one would expect the range observable with 2,4-dinitrophenol to be shifted higher by approximately the above-mentioned amount than that found with picric acid. Hertel's observation that this dinitrophenol forms a yellow complex with *o*-anisidine (pK_a= 4.52) and a red one with *p*-bromoaniline (pK_a=3.86) seems not to be inconsistent with this anticipation.[3]

We attempted to prepare molecular complexes of 2,4-dinitrophenol with about thirty derivatives of anilines. The complexes dissolve well into most organic solvents. Chloroform was often found to be suited for the isolation. The solid complexes were obtained, with the nineteen anilines arranged in the order of decreasing pK_a value as is shown in Table 1.[4] Ten anilines from *p*-anisidine to *m*-anisidine, the pK_a values of which are above 4.20, were found to form yellow-colored complexes with 2,4-dinitrophenol. The presence of a NH_3^+ pattern in their vibrational spectra indicates that they are salts formed by means of proton-transfer from the phenol to the anilines. All of them turn orange or red upon melting. The isomerization was confirmed by measuring the vibrational and electronic spectra above the melting points. For example, Fig. 1 presents the vibrational spectra in the region from 2000 to 4000 cm^{-1} of the *p*- and *m*-anisidine complexes in the solid and molten states. By a comparison with the spectra of the corresponding anilinium chloride, two broad bands appearing at about 2600 and 2900 cm^{-1} in the spectra of the solid complexes were assigned to the NH_3^+ group. This pattern has been well known to be typical of picrates of primary amines.[5] Upon melting, the above-mentioned broad bands disappear and several sharp bands are observed in the region from 2850 to 3450 cm^{-1} (see Curves b and d). The bands at 2840, 2950, 3350, and 3450 cm^{-1} arise from the aniline, and those at 3100 and 3250 cm^{-1}, from the phenol. The two located at 3350 and 3450 cm^{-1} can be assigned to the NH_2 group. These solid complexes exhibit electronic absorptions only below 500 nm; however, the appearance of an absorption band in the

p-Nitroaniline	0.99	Yellow	96.5	Yellow

a) 78—79°C by Hertel, Ref. 3. b) Reported by Hertel, Ref. 3.

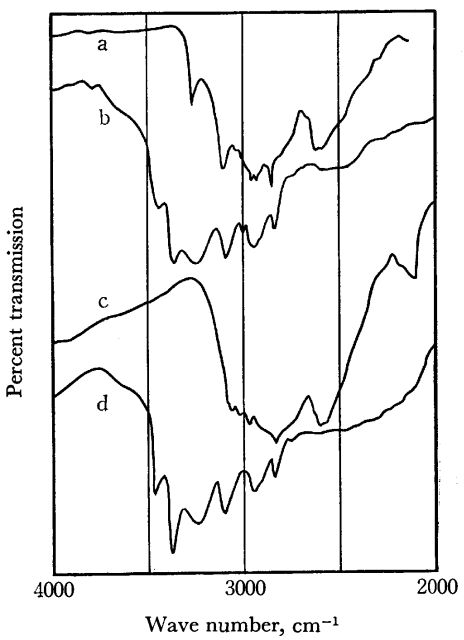

Fig. 1. Vibrational spectra, a) the *p*-anisidine-2,4-dinitrophenol at room temperature, b) the same above the melting point, c) the *m*-anisidine-2,4-dinitrophenol at room temperature, and d) the same above the melting point.

region from 500 to 600 nm was noted in the melts. The corresponding *m*-dinitrobenzene complex could be isolated only with unsubstituted aniline. The similarity in spectrum between the molten 2,4-dinitrophenol complex and the *m*-dinitrobenzene complex suggests that the band appearing upon melting is due to the intermolecular charge-transfer interaction. No change in color was observed upon the melting of the rest of the solid complexes. Their vibrational spectra indicate the absence of proton-transfer either in the solid state or in the molten state. These nine complexes may be supposed to be of the charge-transfer type.

The lower limit of the pK_a range where the phenomenon of complex isomerization by melting is observable appears to be very close to the pK_a of 2,4-dinitrophenol, 4.09.[6] The results given in Table 1 show that a complex is of the proton-transfer type when the pK_a value of aniline is higher than this and that a complex is of the charge-transfer type when the pK_a value of aniline is lower. It must be added that such a coincidence is not necessarily seen with other phenols. On the basis of the vibrational spectrum, the *p*-nitroaniline-picric acid complex was found to be of the charge-transfer type. Although the pK_a values reported for picric acid are rather scattered, ranging from 0.22 to 0.708,[6] *p*-nitroaniline has a pK_a value higher than they.

On the other hand, the upper limit of the pK_a range could not be established with the present phenol. Possibly, it is located higher than the upper limit observed with picric acid, the 2.96 of 3-nitro-4-methylaniline, by approximately the difference between the pK_a values of these two phenols.

(Received May 4, 1972)

A vibrational treatment of methyl isopropyl sulfide was made by McCullough *et al.*,[1] who suggested the existence of two rotational isomers, C_1 (G) and C_S (T), on the basis of their vibrational data; they claimed that the C_1 form is stable in the solid state. Lately, Scott and El-Sabban[2] carried out a normal coordinate treatment of this sulfide using a valence force field, and concluded that only the C_1 conformation exists, while the C_S conformation must have too high energy to exist even in the liquid state. In this paper, in order to overcome the above-mentioned disagreement among the conformational analyses of methyl isopropyl sulfide, and in order to obtain complete infrared data, we newly recorded the infrared spectra in the gaseous, liquid, and solid states; we have then tentatively assigned the observed bands.

Results and Discussion

The obtained infrared data of methyl isopropyl sulfide are summarized in Table 1. In the C–H stretching, the CH_3 degenerate deformation, and the CH_3 symmetrical deformation, the spectra obtained are well-resolved. In the 1500—1400 cm^{-1} region the CH_3 degenerate deformation, in the 1400—1300 cm^{-1} region, the CH_3 symmetrical deformation, and in the 1300—800 cm^{-1} region, the C–H in-plane and out-of-plane bending, CH_3 rocking, and C–C stretching bands are expected. In the last region, there are some bands which disappear in the crystalline state. Most of the bands which disappear in the crystalline state may be due to the less stable conformation. Here, the existence of the rotational isomers can be suggested for this sulfide. The existence of the rotational isomers, however, is more clearly shown in the C–S stretching and skeletal deformation regions. Methyl isopropyl sulfide has two C–S stretching vibrational freedoms for one comformation. In the liquid state, four bands appear; two bands remain in the solid state. In the skeletal deformation region, 500—200 cm^{-1}, about five bands, including two torsional bands, are expected for one conformation. In this region, eleven bands appear

in the liquid state and five bands remain in the annealed state. Thus, in the liquid or gaseous spectra in the C–S stretching and skeletal deformation regions, there are bands which correspond to two forms. In the annealed state, this sulfide may exist in one form.

In order to confirm the existence of the rotational isomers, we attempted to make an experiment on the solvent effects. We took up the bands at 637 and 610 cm^{-1} and used cyclohexane and acetone as the solvents. In this species, however, it seems that the difference in the dipole moment between the two conformations, C_S and C_1, is not very much. In the observed spectra, we cannot see any clear difference. We have, then, tried to determine the temperature dependence of the liquid bands at temperatures of 27—50°C. Figure 1 shows the plots of log D_S/D_N *vs.* $1/T\times10^3$ of the three liquid-band pairs. In Fig. 1, D_S means the stable forms and D_N means the less stable forms. The origin of log D_S/D_N is different in each case. The pairs of bands at 1244/1263, 725/610, and at 637/610 cm^{-1} show nearly the same temperature dependence. From these slopes, we can see the enthalpy difference between two rotational isomers; the order of ΔH is evaluated to be *ca.* 1—1.5 kcal/mol. We cannot, however, determine an exact value, since our obtained data are not sufficient.

From the obtained infrared data, therefore, we can postulate for this sulfide that: a) two conformations coexist in the liquid and gaseous states (energy difference $\Delta H\fallingdotseq1$—1.5 kcal/mol), and b) one form exists in the crystalline state.

Experimental

The methyl isopropyl sulfide was prepared by the method of McAllan *et al.*,[3] bp 84—85°C/760 mmHg (reported bp[3] 84.8°C/760 mmHg). The purity of this sulfide was checked by means of gas chromatography. The methods of infrared recording and instrument used were described previously.[4]

Reaction Rates in the Monomer-Dimer Equilibrium of TCNQ Anion Radicals as Studied by the Temperature-Jump Method

Akihiko YAMAGISHI, Yôichi IIDA, and Masatoshi FUJIMOTO
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo
(Received May 13, 1972)

In spite of electrostatic repulsion, various ion-radical molecules are known to dimerize in solution. There have been a number of investigations concerning the equilibrium constants and the heats of dimerization in the reversible monomer-dimer equilibria of ion radicals.[1-5] Up to now, however, no attempt has been made to measure the reaction rate constants for such systems.

Boyd and Phillips found a reversible monomer-dimer equilibrium of the 7,7,8,8-tetracyanoquinodimethane (TCNQ) anion radicals in an aqueous solution. The equilibrium constant for dimerization at 25°C and the heat of dimerization were determined to be $2.5\times10^{3}\text{M}^{-1}$ and -10.4 kcal/mol·dimer respectively.[2] In the present paper, the temperature-jump technique was applied to this equilibrium in order to investigate the kinetics of the formation and dissociation of the TCNQ anion radical dimers. The intermolecular interaction between the ion radicals in solution will be discussed on the basis of these experimental results.

Experimental

The kinetic measurements were performed on a temperature-jump apparatus, Messanlagen Studiengesellschaft. A Teflon cell was constructed so that the measurements could be made under deaerated conditions. The temperature rise was attained by Joule heating. For this cell, the time constant of the abrupt temperature rise was estimated by using

the acid hydrolysis of *p*-nitrophenol, in which the rate constant is of the order of 10^{10} M^{-1} sec^{-1}.[6] In its aqueous solution with an ionic strength of 0.23, the time constant required for a 90% rise of about 2°C was found to be 4 μsec at a 30 kV discharge. An aqueous solution of Li^+ $TCNQ^-$ containing 0.2M $LiClO_4$ as a supporting electrolyte was prepared *in vacuo* and was then admitted into the cell without any exposure to air. The measurements were made after nitrogen gas (1 atm) had been introduced into the cell.

Results and Discussion

First, the monomer-dimer equilibrium of theTCNQ anion radicals in 0.2M aqueous $LiClO_4$ solution, as expressed by Eq. (1), was examined by measuring the absorption spectrum and its concentration dependence:

$$2TCNQ^- \rightleftharpoons (TCNQ^-)_2. \quad (1)$$

The concentrations of the monomer, [$TCNQ^-$], and the dimer, [$(TCNQ^-)_2$], in the equilibrium state were determined by using the values for their molar extinction coefficients at 660 and 740 nm respectively in a pure aqueous solution reported by Boyd and Phillips.[2] The equilibrium constant:

$$K = \frac{[(TCNQ^-)_2]}{[TCNQ^-]^2} \quad (2)$$

was thus estimated to be 1.2×10^4M^{-1} at 14°C in a 0.2M $LiClO_4$ aqueous solution. This value was found to be rather larger than that of 4.9×10^3M^{-1} at 14°C in a pure aqueous solution reported by Boyd and Phillips.[2] This means that the ionic atmosphere of the solvent favors the dimer form in the equilibrium of Eq. (1).

For the equilibrium of Eq. (1) in a 0.2M $LiClO_4$ aqueous solution at 14°C, the temperature-jump relaxation measurements were made by observing the time dependence of the optical absorption and its concentration dependence. When the temperature was abruptly raised, we found a decrease in the absorbance in the region of 450—540 nm, where the dimer of the TCNQ anion radicals mostly absorbs.[2] The observed decrease in the absorbance is, then, attributable to the decrease in the dimer concentration in Eq. (1); that is, the equilibrium expressed by Eq. (1) is shifted to the left when the temperature is raised. For example, the solution of [$TCNQ^-$]$=5.7\times10^{-5}$M at 20°C is given in Fig. 1. Figure 2 shows experimental plots of the reciprocal value of the observed relaxation time, τ^{-1}, *versus* the concentration of [$TCNQ^-$] for various solutions.

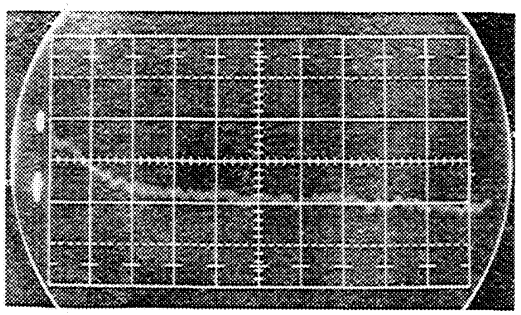

Fig. 1. The decrease of the absorbance observed by the temperature-jump method in the monomer-dimer equilibrium of Eq. (1) at 20°C; λ=525 nm, 5 μsec/division, [$TCNQ^-$]$=5.7\times10^{-5}$M.

In the monomer-dimer equilibrium of Eq. (1) let the rate constants for the dimerization and the dissociation be $\vec{k}$ and $\overleftarrow{k}$ respectively. In this case, we have the following relation:

$$\tau^{-1} = 4\vec{k}[TCNQ^-] + \overleftarrow{k}. \quad (3)$$

If we put the average τ value in the experimental results into this equation, we obtain the following values for $\vec{k}$ and $\overleftarrow{k}$:

$$\vec{k} = 3.5\times10^8 \text{ M}^{-1} \text{ sec}^{-1}, \quad (4)$$

$$\overleftarrow{k} = 9\times10^4 \text{ sec}^{-1}. \quad (5)$$

We can relate these values to the monomer-dimer equilibrium constant as $K=\vec{k}/\overleftarrow{k}$. The K value thus estimated, 4×10^3M^{-1}, is consistent with that previously estimated from the static measurement of the absorption spectra. The τ value, however, may be almost independent of [$TCNQ^-$], because the observed τ values in Fig. 2 include some uncertainty. In this case, the

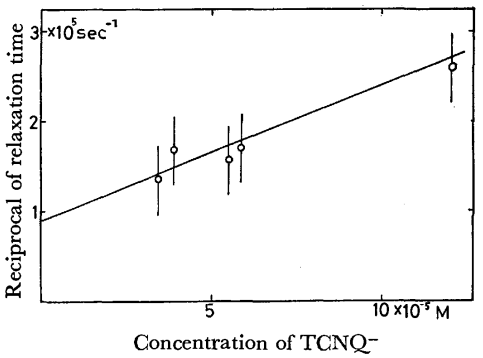

Fig. 2. The dependence of a relaxation time τ^{-1} on [$TCNQ^-$] in the monomer-dimer equilibrium of Eq. (1) at 15°C.

observed τ values practically coincide with the cell constant of the apparatus, and the $\vec{k}$ and $\overleftarrow{k}$ values may be larger than those for Eqs. (4) and (5) respectively. Although more accurate measurements are desirable for the determination of the τ values, we can consider, at present, that the values in Eqs. (4) and (5) give the lower limits of the intrinsic $\vec{k}$ and $\overleftarrow{k}$ values respectively.

On the other hand, if the reaction rate for the dimerization of the TCNQ anion radicals in an aqueous solution can be described by a diffusion-controlled process for charged particles, the theoretical reaction rate at the temperature, T, can be represented by:[7]

$$\vec{k}(\text{calc}) = \frac{4\pi q^2 N D(N/1000)}{\varepsilon R T[\exp(q^2 N/\varepsilon R T\sigma) - 1]} \quad (6)$$

where q is the charge of a particle; N, Avogadro's number; D, the diffusion coefficient of a particle; ε, the dielectric constant of a medium, and R, the gas constant. σ represents the diameter of a particle, which is assumed to be a sphere. Putting the reasonable values of $D=1.8\times10^{-5}$ cm^2 sec^{-1} and $\sigma=4.0\times$

6) M. Eigen and K. Kustin, *J. Amer. Chem. Soc.*, **82**, 5952 (1960).

7) A. A. Frost and R. G. Pearson, "Kinetics and Mechanism," John Wiley and Sons, New York (1961), p. 271.

10^{-8} cm into Eq. (6), we obtain, at 15°C:

$$\vec{k}(\text{calc}) = 1.8 \times 10^{9}\ \text{M}^{-1}\ \text{sec}^{-1}. \quad (7)$$

The observed $\vec{k}$ value in Eq. (4) was found to agree with the $\vec{k}$(calc) value. Therefore, the reaction rate for the dimerization of the TCNQ anion radicals in an aqueous solution can be understood in terms of the diffusion-controlled process.

On the Phase Transition of *N*-Methylchloroacetamide

Hideaki CHIHARA, Tokutsuka KIICHI,* and Nobuo NAKAMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received July 13, 1972)

N-Methylchloroacetamide is one of model compounds of peptide. The infrared and dielectric studies were carried out on the molecular conformation in solution in 1956.[1] Recently Miyazawa has found a phase transition at 38°C by his infrared measurements.[2] He considered that this phase transition is accompanied with the change in the molecular conformation from one of the '*gauche*' type in the low temperature phase (Phase II) to the '*trans*' type in the high temperature phase (Phase I). Later it was found by an X-ray structural study[3] that there are two different kinds of molecules in a monoclinic unit cell of $P2_1/n$ in Phase II: The molecules of one kind assume a planar structure but the others are non-planar. Each kind of molecules assumes '*cis*'-conformation instead of *gauche* form as suggested by previous workers. The N-H···O type hydrogen-bond network exists between the same kind of molecules and extends along the crystalline *c*-axis. The present Note describes the results of the differential thermal analysis (DTA), dielectric measurements, and ^{35}Cl nuclear quadrupole resonance (NQR) studies in an attempt to obtain detailed information with respect to the phase transition.

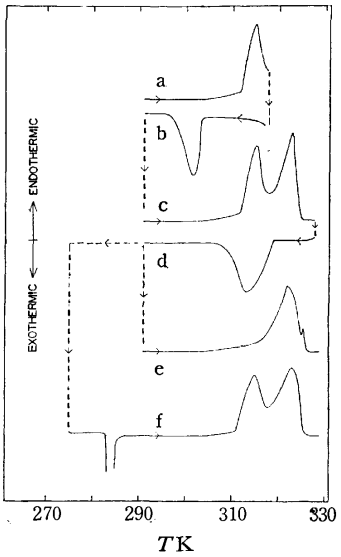

Fig. 1. Differential thermal analysis curves.

The specimen was prepared according to the literature[4] and purified by sublimation under reduced pressure. (mp 45.8±0.2°C; literature value 46°C[1]). Figure 1 shows the DTA curves of the samples having different thermal history. It was found that (1) the specimen which has never been melted or has been stored at room temperature for a long time after melting and freezing undergoes a typical first-order phase transition at 311.6 K which is reversible with a thermal hysteresis effect (curves a, b, and c in Fig. 1), (2) when the specimen is cooled from the melt no phase transition occurs both in cooling and heating directions (curves d and e). The solid phase (Phase III) obtained by cooling the liquid is probably the same as Phase I because their mp and shape and magnitude of the thermal anomaly coincide with each other, (3) Phase

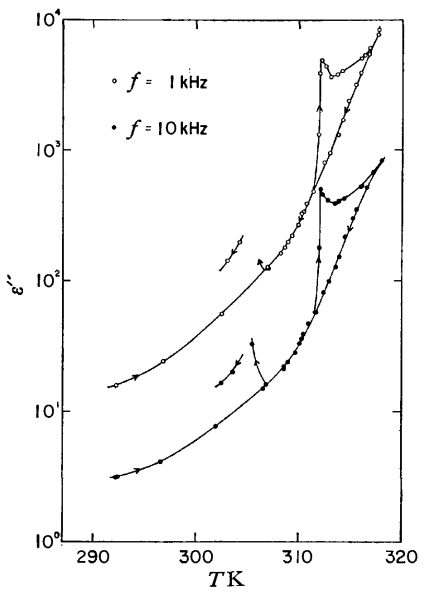

Fig. 3. Dielectric loss factor ε'' at 1 kHz (○) and 10 kHz (●).

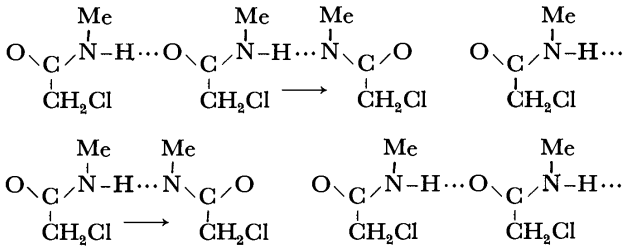
III can exist at room temperature as a metastable phase for a few days but it transforms gradually to Phase II at room temperature, and (4) a sharp transformation of Phase III to Phase II occurs at about 283 K when Phase III is heated from a low temperature with an exothermic phenomenon as shown in the curve f in Fig. 1.

Two ^{35}Cl NQR lines were observed only in Phase II. The resonance frequencies are $\nu_1=34.658\pm0.003$ and $\nu_2=34.783\pm0.001$ MHz at 24.2 K, which decreased monotonously and merged into a single line above 304 K ($\nu_1=\nu_2=33.381$ MHz at 310.2 K). The ^{35}Cl spin-lattice relaxation time T_1 changes slightly from 30 ms at 170 K to 7 ms at 309 K. This fact shows that the internal rotation of molecules is not seen until the transition point T_c is reached. Because the resonance lines are not observable in Phase I, it is considered to be a disordered phase probably with respect to the molecular conformation.

On the other hand, dielectric constant and the loss factor ($\varepsilon'=9.72$, $\varepsilon''=15.9$ at 292 K, $f=1$ kHz) increase gradually with increasing temperature and discontinuous jump occurs at T_c as shown in Figs. 2 and 3.

From ε'' we calculated the DC conductivity σ according to the equation $\sigma=(1/2)\varepsilon''f$. The values of σ (in 10^{-8} ohm^{-1}cm^{-1}) were 0.79 (292 K), 9.4 (309 K), 77 (312 K), and 264 (316 K).

The very high conductivity in Phase I may be interpreted in terms of the proton transfer mediated by the internal rotation of $-CONHCH_3$ group about the C–C bonds as follows:



This mechanism is similar to that proposed for the conduction in imidazole crystal.[5]

Syntheses of 1,ω-Bis(5-ethyl-8-hydroxy-7-quinolyl)-alkanes and Their Copper(II) Complexes

Kiyoshi TOBINAGA,[1] Masakuni MUKAINO,[2] Takahiko INAZU,* and Tamotsu YOSHINO

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka

(Received February 7, 1972)

It is of interest to synthesize compounds in which two molecules of 8-quinolinol are connected by a polymethylene bridge in their 7-positions, and also to examine their complexes as formed with metal ions, because the structure of the complex is expected to be one of three types: mono-, di-, or poly-nuclear metal complexes—that is, A, B, and C in Fig. 1, depending on the chain length of the polymethylene bridge.

The synthetic routes are shown in Scheme 1. The III_n compounds (n=6, 8, and 10) were synthesized by the Friedel-Crafts acylation of 5-ethyl-8-quinolinol[3] with polymethylenedicarbonyl chlorides of different chain lengths. In order to cause the acylation exclusively at the 7-position, the 5-position of 8-quinolinol was blocked by an ethyl group. The IV_n compounds were obtained by the Huang-Minlon modification of the Wolff-Kischner reduction of the corresponding III_n compounds. The copper(II) complexes were obtained by the addition of an ethanolic solution of copper(II) acetate monohydrate to a solution of the corresponding IV_n compounds in ethanol (n=6 and 10) or dioxane (n=8).

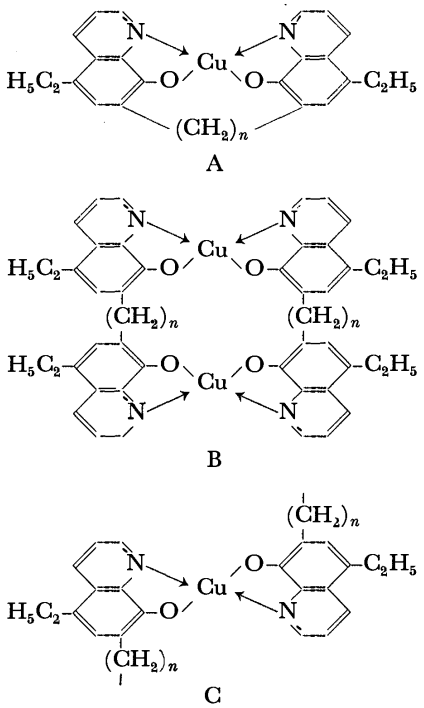

Fig. 1

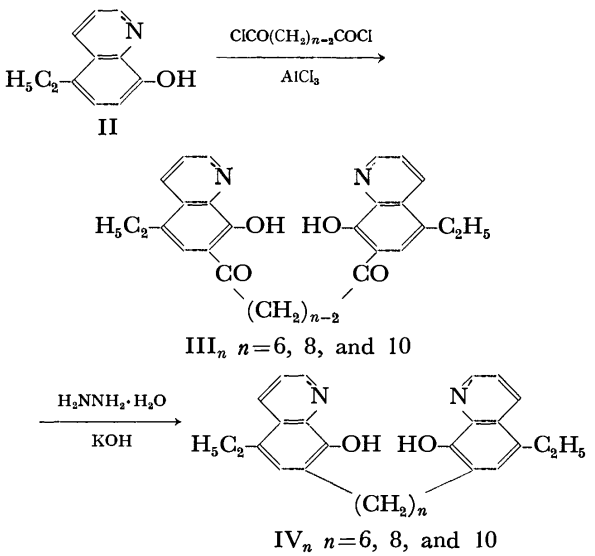

Scheme 1.

The physical properties and analytical data are shown in Table 1. The results of the molecular-weight determination indicate that the benzene-soluble copper(II) complex of the IV_6 compound is dimeric. For the copper(II) complexes of the IV_8 and IV_{10} compounds, the molecular weight could not be determined owing to the extremely low solubility in the solvents suitable for molecular weight determination. Bis(5-ethyl-8-quinolinolato)copper(II) is considered to have a *trans*-planar configuration, as does the well-known bis(8-quinolinolato)copper(II),[4] and to have an absorption maximum at 693 mμ in chloroform, as is shown in Table 2. The copper(II) complexes of the IV_8 and IV_{10} compounds also showed an absorption maximum at a similar position. Therefore, these complexes are inferred to have probably a polymeric, *trans*-planar structure either C in Fig. 1 or a similar structure. In the case of the copper(II) complex of the IV_6 compound, however, the absorption maximum is slightly different from those of the complexes of 5-ethyl-8-quinolinol as well as those of the IV_8 and IV_{10} compounds. From

Table 2. Absorption maxima of copper(II) complexes of II, IV_6, IV_8, and IV_{10} in chloroform

	λ_{max}	ε_{max}
II-Cu	693	52
IV_6-Cu	715	46
IV_8-Cu	690	a)
IV_{10}-Cu	690	a)

a) Accurate measurements of extinction coefficients could not be obtained in chloroform, owing to extremely low solubility of the compounds in this solvents.

4) R. C. Hoy and R. H. Morris, *Acta Crystallogr.*, **22**, 476 (1967).

the fact that the absorption maximum differed from those of the *trans*-structure and the fact that the molecular weight coincided with that of the dimer, as has been described above, the benzene-soluble copper(II) complex of the IV_6 compound may be concluded probably to have such a dinuclear *cis*- or near-*cis*-structure as B in Fig. 1.

Experimental

The melting points are uncorrected. The infrared spectra were obtained on a Hitachi EPI-S2 spectrophotometer in a KBr disk. The electronic spectra were measured in chloroform on a Hitachi EPI-3T spectrophotometer. The molecular weight was determined on a Hitachi Perkin-Elmer molecular-weight-determination apparatus, using benzene as the solvent.

1,6-Bis(5-ethyl-8-hydroxy-7-quinolyl)hexane-1,6-dione. III_6. To a stirred solution of 5-ethyl-8-quinolinol[3] (5 g) in tetrachloroethane (140 m*l*), adipyl chloride (2 g) was added. The then separated yellow precipitate was dissolved during the portion-by-portion addition of anhydrous aluminum chloride (15.5 g). The resulting yellow solution was kept at about 70°C for 15 hr to separate a green precipitate. After being cooled, the mixture was poured onto ice to precipitate hydrochloride of the III_6 compound, which was collected, washed with benzene, and boiled with water to change it into the corresponding free base. The base was then crystallized to give pale yellow needles by extraction with methylene chloride using a Soxhlet extractor. $\nu_{C=O}$, 1628 cm^{-1}.

1,8-Bis(5-ethyl-8-hydroxy-7-quinolyl)octane-1,8-dione. III_8. A mixture of 15 g of 5-ethyl-8-quinolinol, 9 g of suberyl chloride, 33 g of anhydrous aluminum chloride, and 150 m*l* of tetrachloroethane was heated at 65—68°C for 15 hr. The reaction mixture was poured onto crushed ice. The tetrachloroethane was removed by steam distillation. A precipitate of III_8 hydrochloride was filtered and suspended in water. The free base, III_8, was obtained by the neutralization of III_8 hydrochloride with sodium hydroxide. $\nu_{C=O}$, 1658 cm^{-1}.

1,10-Bis(5-ethyl-8-hydroxy-7-quinolyl)decane-1,10-dione. III_{10}. A mixture of 10 g of 5-ethyl-8-quinolinol, 6.8 g of sebacyl chloride, 31.5 g of anhydrous aluminum chloride, and 120 m*l* of tetrachloroethane was heated at 65—70°C for 20 hr. After the subsequent removal of the tetrachloroethane by steam distillation, a separated precipitate of the III_{10} hydrochloride was filtered and then suspended in water. The free base, III_{10}, was obtained by the neutralization of the III_{10} hydrochloride with sodium hydroxide. $\nu_{C=O}$, 1662 cm^{-1}.

1,6-Bis(5-ethyl-8-hydroxy-7-quinolyl)hexane. IV_6. A mixture of the III_6 compound (2 g), hydrazine hydrate (20 m*l*), and potassium hydroxide (15 g) in triethylene glycol (75 m*l*) was heated at 200—220°C for 1 hr until gas evolution ceased. The resulting red solution was poured into water and neutralized with hydrochloric acid to give a yellow precipitate, which was then collected and dried. The crude product was dissolved in benzene and chromatographed on silica gel to afford colorless needles.

1,8-Bis(5-ethyl-8-hydroxy-7-quinolyl)octane. IV_8. A mixture of 1 g of the III_8 diketone, 15 m*l* of hydrazine hydrate, 10 g of potassium hydroxide, and 60 m*l* of diethylene glycol was heated at 200—230°C for 1.5 hr. After being cooled, the reaction mixture was poured into water and then neutralized with hydrochloric acid to give a precipitate. The precipitate was collected by filtration and dried. The crude product was dissolved in chloroform and chromatographed on silica gel to afford colorless crystals.

1,10-Bis(5-ethyl-8-hydroxy-7-quinolyl)decane. IV_{10}. A mixture of 1 g of the III_{10} diketone, 13 m*l* of hydrazine hydrate, 10 g of potassium hydroxide, and 80 m*l* of triethylene glycol was heated at 220°C for 1.5 hr. The crude product was dissolved in benzene and chromatographed on silica gel to afford colorless needles.

Copper(II) Complex of the Compound IV_6. $B(n=6)$. A solution of copper(II) acetate monohydrate (100.8 mg) in ethanol (100 m*l*) was vigorously stirred, drop by drop over a 20 min period, into a warm solution of the IV_6 compound (214 mg) in ethanol (150 m*l*) to give reddish-brown leaflets. About 1 mg of the complex is soluble in 1 m*l* of benzene.

Copper(II) Complex of the Compound IV_8. $B(n=8)$. A solution of 20.1 mg of copper(II) acetate monohydrate in 15 m*l* of ethanol was added to a solution of 45.8 mg of IV_8 in 30 m*l* of dioxane. The solution turned dark yellow, and after it had stand overnight the orange precipitate was separated. It was insoluble in benzene and chloroform.

Copper(II) Complex of the Compound IV_{10}. $B(n=10)$. A solution of 100.7 mg of copper(II) acetate monohydrate in 100 m*l* of ethanol was added, drop by drop to a solution of 21.7 mg of VI_{10} in 150 m*l* of ethanol. The mixture turned yellow and the orange precipitate was separated. It was very slightly soluble in chloroform and soluble in pyridine, but the pyridine solution gave no precipitate when concentrated and cooled.

An ESR Study of the 1:2 Complexes of Copper(II) with Optically-active and Racemic α-Amino Acids

Hiroshi Yokoi, Mitsuru Sai, and Taro Isobe

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai

(Received February 10, 1972)

Any of the crystal structures of the metal complexes of amino acids are unpredictably unique because of their characteristic hydrogen-bonding behavior.[1,2] Various properties of the complexes in crystal have been studied by the IR,[3-6] visible absorption,[6,7] and ESR[8] methods. Special attention has been given to stereospecific effects in complexes of metals with optically-active ligands.[9] The purpose of this paper is briefly to communicate the ESR results of the 1:2 complexes of copper(II) with various optically-active and racemic α-amino acids in various states.

Experimental

Materials. The copper(II) complexes employed here are listed in Table 1, together with their abbreviations. They all were prepared according to the usual methods,[6,10] using commercial G.R.-grade α-amino acids, and were recrystallized from water. $[Cu(L\text{-}Ala)_2]$ and $[Cu(L\text{-}Val)_2]$ were prepared by heating the corresponding hydrates *in vacuo* at about 160°C. All the complexes were identified by elemental analysis.

Measurements. The X-band and K-band ESR spectra of the complexes were measured in a polycrystalline state at room temperature and in a frozen solution at the temperature of liquid nitrogen with a Hitachi ESR spectrometer, Model MES-4001. The sample solutions contained the complexes in concentrations of 10^{-3}—10^{-2}M, where an equivolume mixture of water and methanol was used as the solvent. The visible absorption spectra of the complexes in a polycrystalline state were measured by the so-called opal glass method with a Cary model 14 spectrometer.[11]

Table 1. Experimental data

Ligand	Copper (II) complex[a]	Polycrystals[b] g_1	g_2	g_3	λ_{max}[d] (nm)	Frozen solution[c] $g_{//}$[e]	$g_\perp$[f]	$\lvert A_{//}\rvert$[g] $\times 10^4$ (cm^{-1})	λ_{max}[h] (nm)

Results and Discussion

Powder ESR Spectra. All the powder K-band ESR spectra are shown in Fig. 1; they were analyzed by the use of the approximation of Kneubühl.[12] The results are listed in Table 1, together with the visible absorption data. It has been suggested that there may be no such strong spin-exchange interactions as affect the g values in most crystals of the *trans* 1:2 complexes of copper (II) with amino acids.[8,13]

The ESR line shape of $[Cu(DL\text{-}Ala)_2]\cdot H_2O$ was quite different from that of $[Cu(L\text{-}Ala)_2]$. The dehydration of $[Cu(DL\text{-}Ala)_2]\cdot H_2O$ caused a drastic change in the ESR spectrum; the resulting spectrum resembled that of $[Cu(L\text{-}Ala)_2]$. This fact indicates that the water molecule of $[Cu(DL\text{-}Ala)_2]\cdot H_2O$ in a crystal is influential in determining the copper(II)-ion environment. The ESR line shapes of $[Cu(DL\text{-}Val)_2]$ and $[Cu(DL\text{-}Ser)_2]$ were also similar to that of $[Cu(L\text{-}Ala)_2]$. Their optically-active isomers, however. were quite different in line shape from $[Cu(L\text{-}Ala)_2]$, The spectra of both $[Cu(L\text{-}Val)_2]$ and its hydrate, whose g values were almost the same, indicate an elongated-tetragonal copper(II)-ion environment; therefore, the water molecule of this hydrate is of little importance to the copper(II)-ion environment. On the other hand, $[Cu(L\text{-}Ser)_2]$ showed a so-called reverse ESR spectrum ($g_{//}<g_{\perp}$) as well as $[Cu(L\text{-}Pro)_2]\cdot 2H_2O$. $[Cu(L\text{-}Ser)_2]$ is known to adopt a *cis*-configuration,[14] and it has been inferred from IR measurements that $[Cu(L\text{-}Pro)_2]\cdot 2H_2O$ also adopts a *cis*-geometry.[5] The crystal of $[Cu(L\text{-}Ser)_2]$ is quite different from those of the other *trans* complexes in the packing of crystallographically non-equivalent molecular pairs,[1,8,14] and it seems likely that the reverse ESR spectrum is caused by a spin-exchange interaction which is effective on the crystal structure of the *cis* complex. In a word, all the above-mentioned experimental facts clearly indicate that a sensitive detection and investigation of the stereospecificity in a metal complex in a crystylline solid can be carried out by the ESR method.

Solution ESR Spectra. All the ESR line shapes observed for the complexes in a frozen aqueous-methanolic solution were quite similar to each other; this fact is in striking contrast with the results in a crystalline solid. The K-band ESR line shapes indicate especially clearly that the copper(II) ions are present in a tetragonal field, as the example shown in Fig. 2 shows. This behavior of the complexes in solution may be regarded as a general property of the planar copper (II) complexes.[15]

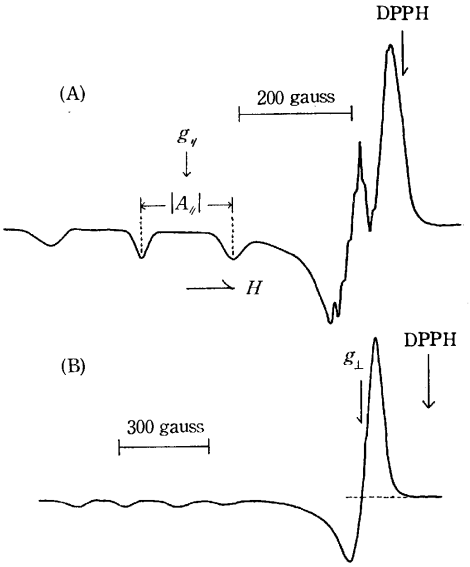

Fig. 2. The ESR spectra of $[Cu(L\text{-}Val)_2]\cdot H_2O$ in aqueous-methanolic solution at 77°K.
(A): X-band, (B): K-band.

Each of the data of $g_{//}$ and $|A_{//}|$ in Table 1 was obtained as the average of 5—8 experiments. These data clearly indicate that there is a small but significant difference in the copper(II)-ion environment between the optical isomers in frozen solutions. Interestingly, the ORD experiments for analogous samples in aqueous solutions showed that the conformation of the chelate ring influences the apical coordination of water molecules.[16] In this work, however, the observed difference between the isomers is too small to reveal what structural difference there is practically. A racemic copper(II) complex in solution is distributed among the three isomers, $[Cu(L\text{-}A)_2]$, $[Cu(D\text{-}A)_2]$, and $[Cu(L\text{-}A)(D\text{-}A)]$,

O-Alkylation of Phenols by Esters

Taketoshi KITO, Norimichi YANAI, and Ichiro HIRAO

Laboratory of Industrial Chemistry, Department of Chemical Engineering, Kyushu Institute of Technology, Tobata-ku, Kita-kyushu

(Received March 10, 1972)

We have reported that methyl *p*-hydroxybenzoate adds to acrylonitirle and methyl acrylate in the presence of triton B or metal sodium to give compounds with cyanoethyl and methoxycarbonylethyl groups respectively.[1] In these reactions, good results were obtained below 150°C. However, when methyl methacrylate was used in place of acrylonitrile or methyl acrylate, no product was obtained under the conditions employed in the above reactions. Therefore, we carried out the reaction of potassium salt of methyl *p*-hydroxybenzoate with methyl methacrylate at 200°C, and the resulting mixture was analyzed by gas chromatography. As a result, the mixture was found to contain methyl *p*-anisiate and a dimer of methyl methacrylate. The latter is methyl 2-methyl-5-methoxycarbonyl-5-hexenoate [CH_2=C($COOCH_3$)$CH_2CH_2CH(CH_3)COOCH_3$], whose structure was confirmed by instrumental analysis. This reaction is interesting as an *O*-alkylation of phenols.

This reaction was then also applied to other phenols, and good results were obtained there. Moreover, alkyl esters of acrylic acid and acetic acid were also found to be effective alkylating agents. The present paper will deal with the *O*-alkylation of phenols by esters.

Experimental

The NMR spectra were obtained on a Japan Electron Optics Laboratory spectrometer (JNM C-60HL), with TMS used as the internal standard. The mass spectra were obtained on a Hitachi mass spectrometer (RMU-6L), using an electron-accelerating voltage of 70eV. The IR spectrum was measured with a Japan Spectroscopic spectrometer (IRA-2). The gas chromatography was performed with a Yanagimoto apparatus (G80T).

Reaction of Potassium Salt of Methyl p-*Hydroxybenzoate with Methyl Methacrylate.* In a 300 m*l* autoclave, with an electro-magnetic stirrer, we placed 0.07 mol of potassium salt of methyl *p*-hydroxybenzoate and 0.7 mol (70.0 g) of methyl methacrylate containing 0.1 wt% of hydroquinone. After the air had been replaced by nitrogen, the mixture was heated to the prescribed temperature (it took about 30 min) and kept there for 5 hr. After cooling, the insoluble product was filtered off and the filtrate was washed with an aqueous alkaline solution and water. The mixture was found by gas chromatography to contain two main components (I and II).

The another reactions were carried out under the same conditions.

The components, I and II, were separated by gas chromatography and were analyzed by NMR, MS, IR, and elementary analysis. The results were as follows. Component I: NMR ($CHCl_3$); τ 2.98 (a part of the AB system, 2H, J=9.0 Hz), 3.07 (a part of the AB system, 2H, J=9.0 Hz), 6.07 (s, 3H), and 6.12 (s, 3H). Mass; *m/e* 168 (1.2%), 167 (9.9), 166 (M^+, 93.7), 136 (27.0), 135 (100), 107 (37.1), 92 (45.2), 77 (65.5), 64 (31.5), 63 (28.0), 50 (15.5), and 15 (12.6). Found: C, 65.18; H, 6.35%. Calcd for $C_9H_{10}O_3$: C, 65.05; H, 6.07%. Component II: NMR (neat); τ 3.92 (d, 1H, J=1.4 Hz), 4.45 (d, 1H, J=1.4 Hz), 6.29 (s, 3H), 6.38 (s, 3H), 7.5—7.9 (m, 3H), 8.1—8.5 (m, 2H), and 8.87 (d, 3H, J=7.3 Hz). Mass; *m/e* 200 (M^+, 1.0%), 141 (33.9), 140 (55.3), 126 (63.0), 125 (37.6), 109 (44.7), 88 (100), 81 (94.2), 59 (52.4), 57 (36.9), 56 (33.2), 53 (32.5), 41 (57.3), 39 (38.6), and 15 (57.6). IR (cm^{-1}); 1727 (s, broad), 1633 (m), and 945 (m). Found: C, 59.83; H, 8.15%. Calcd for $C_{10}H_{16}O_4$: C, 59.98; H, 8.05% On the basis of these data, these components, I and II, were identified as methyl *p*-anisiate and CH_2=C($COOCH_3$)-$CH_2CH_2CH(CH_3)COOCH_3$ respectively.

Determination of Products. All the products were determined by gas chromatography, using dimethylaniline or nitrobenzene as the internal standard. The conditions were as follows: column, PEG 20M or Apiezone Grease L 2.25 m; temp. 200°C; He, 10 m*l*/min. Authentic samples of *O*-methyl products (anisole derivatives), if necessary, were prepared from phenols and dimethyl sulfate in aqueous alkali. Phenyl butyl ether was prepared by Williamson ether synthesis.

Results and Discussion

The reaction of alkali phenoxides with methyl methacrylate was carried out at 150, 200, and 250°C for 5 hr. In the gas chromatograms of those reaction mixtures, no products with retention times longer than that of methyl methacrylate were found, or if any were found, they were all minor products except for the *O*-methyl product and the dimer. Therefore, the resulting *O*-methyl product and dimer were determined by gas chromatography. The results are summarized in Table 1.

d) Yields are based on MMA used.
e) NMR, MS, and IR data are present in the experimental section.
f) MMA was heated in the absence of phenoxides.

Similar reactions were carried out in methyl acetate and acrylate in place of methyl methacrylate. *O*-methyl products were also obtained from both reactions, but an appreciable amount of polymer was formed in the latter and this complicated the post-treatment of the reaction mixture. The yields from both reactions were lower than those from the reactions in methyl methacrylate under comparable conditions, but the yield of the *O*-methyl product was not appreciably affected by the reaction temperature.

From the reactions of potassium phenoxide with ethyl methacrylate, acrylate, and acetate at 200°C for 5 hr, phenetole was obtained. Similarly, from the reaction of potassium phenoxide with butyl methacrylate and acetate, phenyl butyl ether was obtained. These results are listed in Table 2.

Patai and his co-worker reported that 2-alkoxynaphthalene was formed in the reaction of 2-naphthol (0.04 mol) with the ester (0.08 mol), in which methyl methacrylate, methyl acetate, ethyl acetate, and ethyl butyrate were included, in the presence of concentrated sulfuric acid (0.1 m*l*) at the reflux temperature.[2] The yield of 2-methoxynaphtalene from methyl acetate was 20—25%, that from methyl methacrylate was 45—50%, that of 2-ethoxynaphthalene from ethyl acetate was 40—45%, and that from ethyl butyrate, 20—25%. These results suggest that the alkylation was caused by the alkyl hydrogen sulfate formed from the ester and sulfuric acid.

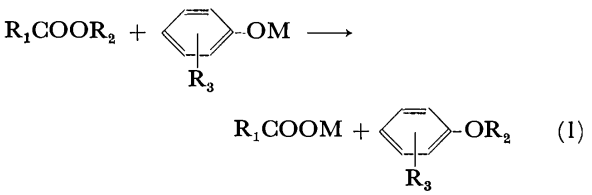
b) Reaction time; 5 hr.
c) Yields are based on phenols used.
d) The structure was confirmed by NMR and IR.

Pierce and his co-worker reported that anisole was formed in the reaction of sodium phenoxide with methyl trichloroacetate at room temperature in carbon tetrachloride, although the reaction of sodium phenoxide with ethyl trifluoroacetate gave no phenetole, but only phenyl trifluoroacetate.[3]

The reaction process treated in this paper may be expressed as in Eq. (1), where R_1 is isopropenyl, ethenyl or methyl, where R_2 is methyl, ethyl, or butyl, where



(1)

R_3 is a substituent on a phenyl nucleus, and where M is sodium or potassium. If the oxygen atom of phenol attacks the carbonyl carbon atom of the ester, the resulting product would be the phenyl ester; this is the reaction of sodium phenoxide with ethyl trifluoroacetate reported by Pierce and his co-worker.[3] However, in the present reactions, the oxygen atom of phenoxides must attack the alkyl carbon atom adjacent to the ether linkage and the alkyl-oxygen cleavage must occur. This mechanism is supported by the formation of phenetole and phenyl butyl ether described above. The reactions will be favored, thus, by a greater charge separation between oxygen and alkali atoms of alkali phenoxides. Therefore, the potassium salts must give better results than the sodium salts. On the contrary, the reaction will not be favored by an electron-attracting group, such as chloro and

methoxycarbonyl groups, as an *ortho* substituent. Higher alkyl esters, such as butyl and ethyl esters, will also reduce the yield of the *O*-alkyl product. The results listed in Tables 1 and 2 are almost all consistent with the above idea.

The reaction with methyl methacrylate proceeded in two directions, the one being an *O*-methylating reaction, and the other, a dimerization of methyl methacrylate. The latter reaction has been reported by Albisetti and his co-workers; they determined the structure of the resulting dimer by a chemical technique.[4] The yield of the dimer was not affected by the molar ratio of methyl methacrylate: phenoxides (Table 1), suggesting that the two reactions—that is, an *O*-alkylation and a dimerization of methacrylate (methyl, ethyl, or butyl ester)—proceed independently of one other.

Thanks are due to Mr. Takatomo Funamoto for his assistance in the experimental work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3492—3493 (1972)

Studies of Organosulfur Compounds. VII. The Preparation and Reaction of Some Crystalline Piperidinium Salts of Aliphatic Dithio Acid

Shinzi KATO and Masateru MIZUTA
Faculty of Engineering, Gifu University, Kagamihara, Gifu

(Received March 21, 1972)

Although the syntheses of aliphatic dithio acid derivatives have been carried out, no isolation of the salts (almost entirely metal salts), which are very important as intermediates in the preparation of derivatives, have been reported as yet. In the course of the studies of the reactions bis(thioaroyl)disulfides with amines, it was found that the crystals of amine salts of aromatic dithio acid were very stable[1] and could easily be obtained from the corresponding aromatic dithio acids and various secondary or tertiary amines.[2] In this paper, we wish to report the successful preparation of some crystalline piperidinium salts of aliphatic dithio acid.

Results and Discussion

The reaction of dithiopropionic acid in ethyl acetate with an equimolar amount of piperidine gave piperidinium salts (IIa) of dithiopropionic acid in a 67% yield as glistering yellow crystals. The structure of IIa was identified by elemental analysis and by studying the IR and UV spectra. In the IR spectrum, strong broad absorption bands due to amine salts were observed in the range of 3000—2500 cm^{-1}, while the UV spectrum showed its maximum band at 455 mμ (ε 39). Furthermore, the structure of IIa was supported by the quantitative formation of the methylester through the action of methyl iodide. An analogous treatment of dithioisobutyric, dithiopentanoic, dithiohexanoic, and dithiocyclohexanecarboxylic acid with the piperidine gave the corresponding piperidinium salts (IIb—e) in good yields. The results are summarized in Table 1.

All the piperidinium salts obtained, except for that of dithiopropionic acid, were fairly stable in solid states at room temperature, and did not change when left standing for 3 days, but the salts gradually decomposed over 50°C, with the evolution of hydrogen sulfide. On the other hand, the salts of dithiopropionic acid

were unstable, and after one week even at 0°C completely changed from solid to oily material, with the evolution of hydrogen sulfide.

The salts were only slightly soluble in ether, benzene, and acetonitrile, but were easily soluble in dichloromethane, chloroform, acetone, and ethanol. The salts readily reacted with alkyl bromides or iodides in dichloromethane to give the corresponding alkyl esters in almost quantitative yields, but the reactions with t-butyl bromide or alkyl chlorides with no electron withdrawing group on their α-position did not occur, even under more severe conditions (Table 2).

Spectral Data. *a) IR Spectra*: Mecke and Spiesecke[3] assigned $\nu_{C=S}$ to 1216 cm^{-1} for dithioacetic acid. However, there has been only one recent report on the subject; in it Lindner and Kunze[4] assigned $\nu_{C=S}$ for 1242 cm^{-1} for silver and lead trifluorodithioacetates. We reported that $\nu_{C=S}$ for the amine salts of aromatic dithio acids was observed near 1000 cm^{-1}.[2] In the amine salts, very intensive absorption bands seemingly due to $\nu_{C=S}$ of the dithiocarboxylate group were observed in the 1000—925 cm^{-1} range without any exceptions (Table 1). This results fits with those of the amine salts of aromatic dithio acids, and also with the assignment given for metal salts of dialkyldithiocarbamates (near 982 cm^{-1})[5] and xanthates (1040 and 1080 cm^{-1}),[6] and for trialkylphosphonidithioformulate ($R_3P^+CSS^-$, near 1050 cm^{-1}).[7]

b) UV Spectra: Table 1 lists the absorption maxima (λ max) in mμ and the molecular extinction coefficients (ε) at each maximum. As is shown in Table 1, the amine salts (II) showed two characteristic maximum band, 339 (ε 16000—18000) and 455 mμ (ε 30—40), without any exceptions, indicating that the former bands are due to $\pi\rightarrow\pi^*$, and the latter, due to $n\rightarrow\pi^*$.

Attempts at the isolation of the amine salts of dithioacetic and dithio-2-methyl-isobutyric acids, and the crystallization of secondary or tertiary amine salts other than the piperidinium salts were unsuccessful.

Experimental[8]

Materials. Aliphatic dithio acids were prepared in dry THF by the method of Houben.[9]

Some typical procedures are shown, and the detailed data are summarized in Table 1.

Piperidinium Salts (IIb) of Dithioisobutyric Acid. A solution of 1.7 g (0.02 mol) of piperidine in ethyl acetate (2 m*l*) was added to ethyl acetate (10 m*l*) containing 4.1 g (0.02 mol) of dithioisobutyric acid at 5°C and allowed to stand for overnight below −20°C. The precipitates were filtered and recrystallized from dichloromethane-n-hexane to give 3.9 g of IIb as plate crystals.

Reaction of the Piperidinium Salts (IIa) of Dithiopropionic Acid with Methyl Iodide. A solution of IIa (0.03 mol) and methyl iodide (0.04 mol) in dichloromethane (10 m*l*) was stirred at room temperature for 1 hr. After evaporating the solvent and the excess of methyl iodide, a small portion of petroleum ether (bp below 40°C) was added to the residue and insoluble parts (piperidinium iodide) were filtered off. Vacuum distillation of the filtrate gave 3.4 g (94%) of methyl dithiopropionate: bp 46—47°C/10—11 mmHg; IR (neat): $\nu_{C=S}$ 1190 cm^{-1}. The boiling point, and the IR spectrum were identical with those of an authentic sample prepared by the method of Houben and Shultze.[9]

The authors wish to thank Professor Yoshio Hirabayashi and Mr. Hideharu Ishihara of Gifu University for discussion.

Dimorphic Forms of 2-Amino-4-(*N*-methylanilino)-6-isopropenyl-*s*-triazine

Yasuo YUKI, Tadao TAIKA, and Masamitsu NAGANO

Department of Fiber and Polymer, Nagoya Institute of Technology, Gokiso, Showa-ku, Nagoya

(Received April 11, 1972)

2-Amino-4-(*N*-methylanilino)-6-isopropenyl-*s*-triazine (AMIT) was prepared by the reaction of N^1-methyl-N^1-phenylbiguanide with methyl methacrylate, as has previously reported.[1] In this paper, it has been found that AMIT has dimorphic forms. In the case of the recrystallization of AMIT from methanol, two different crystals were obtained. The sample immediately crystallized was named AMIT-β, while that slowly crystallized was named AMIT-α. AMIT-β melted at 104°C and immediately solidified into a crystal that melted at 118°C. AMIT-α melted at 118°C. When the acetone solution of AMIT-α was poured into water, AMIT-β was precipitated. AMIT-α was also obtained by the crystallization of AMIT-β or an AMIT-α and β mixture from benzene. AMIT-α and β were easily changeable by crystallization by different procedures.

TABLE 1. ELEMENTARY ANALYSES AND NMR DATA OF AMIT

Sample	Elementary analyses C%	H%	N%	NMR data (DMSO-d_6, 35°C) (ppm)
AMIT-α	64.60	6.06	29.84	H_a, CH_3 H_a, 5.40(q)
AMIT-β	64.81	6.19	29.67	C=C H_b, 6.22(d)
Calcd for $C_{13}H_{15}N_5$	64.71	6.27	29.02	H_b, CH_3, 2.00(s) N-CH_3, 3.45(s) NH_2, 6.79(s) C_6H_5, 7.32(s)

The results of the elementary analyses and the NMR data of AMIT-α and β are shown in Table 1. The elementary analytical results were identical with the calculated value of AMIT. The NMR data in DMSO-d_6 were also identical with each other. The ultraviolet spectra of AMIT-α and β in ethanol, water, or cyclohexane were identical. From the above results, it was found that AMIT-α and β were the same compound.

The existence of two crystal forms has been confirmed by the entirely different X-ray powder diagrams for AMIT-α and β. Some absorptions of the infrared spectra of AMIT-α and β were different when the infrared spectra was measured in the crystal state in potassium bromide disks. The differences were shown in the absorptions of amino groups and isopropenyl groups. The N-H stretching absorptions were at 3325 (small), 3290, and 3190 cm^{-1} for AMIT-α, but they were at 3450, 3280, 3180 cm^{-1} for AMIT-β. The NH_2 bending absorptions of AMIT-α were at 1642 and 640 cm^{-1}, while that of AMIT-β were at 1620 and 655 cm^{-1}. The bending absorption of the isopropenyl group was at 940 cm^{-1} for AMIT-α and at 918 cm^{-1} for AMIT-β. The absorptions of the phenyl (760 and 695 cm^{-1}) and *s*-triazinyl (825 cm^{-1}) groups were identical with each other. From the above results, it was assumed that there was a different interaction between the proton of the amino group and the π electrons of the isopropenyl group of AMIT in crystals.

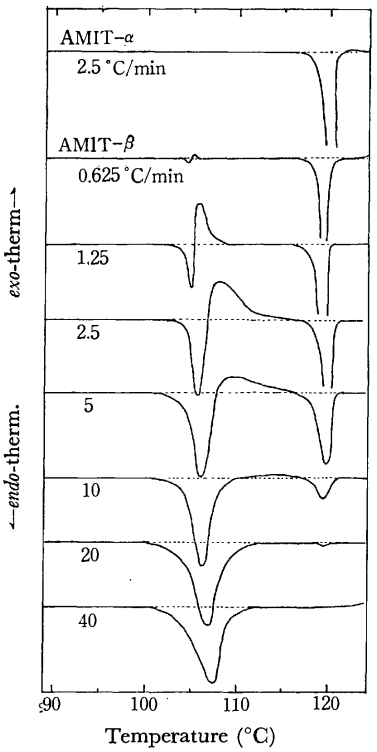

Fig. 1. DSC curves of AMIT-α and AMIT-β.

TABLE 2. ΔH OF AMIT-α AND β

Sample	Heating rate (°C/min)	ΔH_β	ΔH_{cr}	ΔH_α (kcal/mol)	$\Delta H_\beta'$
AMIT-α	2.6	—	—	6.6	—
AMIT-β	0.625	0.1	0.1	6.8	6.8
	1.25	2.8	2.5	6.9	7.2
	2.5	4.3	4.2	5.7	5.8
	5	6.0	2.6	3.4	6.8
	10	6.5	0.3	0.7	6.9
	20	6.4	—	0.1	6.5
	40	6.7	—	—	6.7

The thermal behavior of samples was examined by the technique of a differential scanning calorimeter (DSC). The results are shown in Fig. 1. AMIT-α showed only an endothermic peak at 118°C by fusion, and the heat of fusion of AMIT-α was 6.6 kcal/mol. On the other hand, AMIT-β showed two endothermic peaks, at 104 and 118°C, by fusion, and one exothermic peak between the two endothermic peaks. This exotherm was caused by crystallization. The heat of

1) Y. Yuki, T. Kakurai, and T. Noguchi, This Bulletin, **43**, 2123 (1970).

fusion at 104°C (ΔH_β), the heat of fusion at 118°C (ΔH_α) and the heat of crystallization (ΔH_{cr}) of AMIT-β are summed up in Table 2. These heats depended on the heating rate. ΔH_β was increased as the heating rate became faster. On the other hand, ΔH_α decreased as the heating rate became faster. ΔH_α was 6.8 kcal/mol at a heating rate of 0.625°C/min. This value was almost equal to the ΔH of AMIT-α. This is thought to be because the heat of fusion of AMIT-β is compensated for by the heat of crystallization. The theoretical heat of fusion of AMIT-β ($\Delta H_\beta'$) was obtained from Eq. (1):

$$\Delta H_\beta' = \Delta H_\beta + \Delta H_\alpha - \Delta H_{cr} \quad (1)$$

The values of $\Delta H_\beta'$ are also described in Table 2, and the mean value of $\Delta H_\beta'$ was 6.8 kcal/mol.

The infrared spectra of the sample that was heated at 115°C was identical with that of AMIT-α. From the above results, AMIT-β can be said to be the thermodynamically unstable crystal form compared with AMIT-α, and it can be seen that AMIT-β crystallizes after melting at 104°C into the stable form, AMIT-α.

The Determination of the Enantiomeric Purity of Methyl *p*-Tolyl Sulfoxide by Means of an NMR Shift Reagent

Hitosi NOZAKI, Kimiaki YOSHINO, Koichiro OSHIMA, Yasusi YAMAMOTO

Department of Industrial Chemistry, Kyoto University, Yoshida, Sakyo-ku, Kyoto, 606

(Received April 17, 1972)

The NMR method for determining the enantiomeric excess of amines and alcohols employs a chiral complex of europium, tris[3-(*tert*-butylhydroxymethylene)-*d*-camphorato]europium(III) (**1**).[1] The NMR shift of oxiranes and sulfoxides has also been recorded.[2-4] We have independently been engaged in the same subject of research and wish to record the NMR shifts of optically-resolved sulfoxides as well as the analytical practice, neither of which has yet been described. A modified method of preparing **1** is also described.

Figure 1a shows a spectrum of a carbon tetrachloride solution of (±)-methyl *p*-tolyl sulfoxide (**2**) and **1** (3.0: 1.0 mol ratio). The separation of the enantiotopic methyl singlets was 0.14 ppm. A mixture of the optically-pure (+)-(R)-methyl *p*-tolyl sulfoxide (**2**) ($[\alpha]_D$ +145.5°, *c* 0.40, acetone) and **1** (3.5: 1.0 mol ratio) exhibited the NMR spectrum shown in Fig. 1b, only one S-methyl singlet being observed. The NMR spectrum of partially-resolved sulfoxide **2** ($[\alpha]_D$ +47.9°, *c* 1.06, acetone, 33% calculated optical purity) in the presence of **1** is given in Fig. 1c. Obviously, the S-methyl protons of (R)-**2** resonate at a higher field than their counterparts in (S)-**2**. The overlapping methyl peak areas in Fig. 1c were separated by means of the Brace method.[5] Each peak was cut out and weighed. The values gave an enantiomeric ratio of 1.0/2.0 or a 33% enantiomeric excess. The absolute rotation of methyl *p*-tolyl sulfoxide was calculated to be

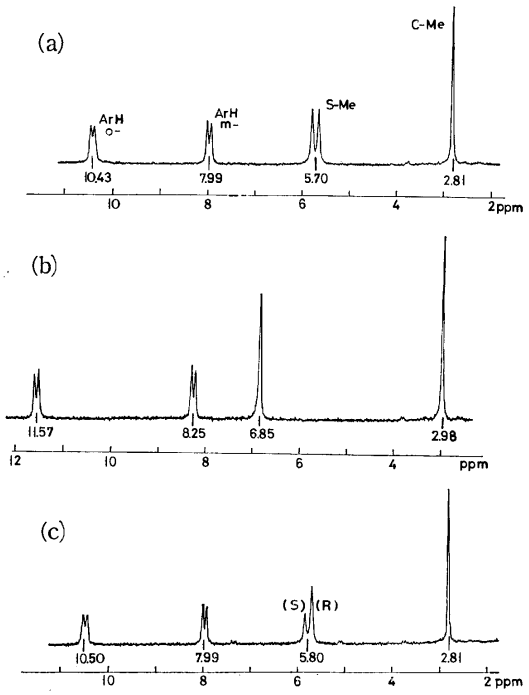

Fig. 1. Spectra of (a) (±)-methyl *p*-tolyl sulfoxide (**2**) (0.091 mmol) in CCl_4 (0.4 m*l*) containing the shift reagent, **1** (0.030 mmol), (b) (+)-(R)-**2** (0.91 mmol), CCl_4 (0.4 m*l*), **1** (0.026 mmol), and (c) partially resolved sulfoxide, **2** (1.04 mmol), CCl_4 (0.5 m*l*), **1** (0.032 mmol).

144° (lit. 145.5° [6a]).

The NMR method is naturally applicable to further sulfoxides. The S-methyl singlet of methyl phenyl sulfoxide resonating at the higher field in a carbon tetrachloride solution has been shown to arise from

the isomer of the R-configuration. In a chloroform solution, however, this method proved unsuccessful, as no difference between the methyl protons of enantiomers was observed. The attempted application of the present method to the methyl ester of a *p*-tolylsulfinic acid failed because of the samll separation of the enantiomeric signals.

Experimental

The NMR spectra were obtained on a 100 MHz instrument (Varian HA-100), using TMS as the internal standard. The optically-active sulfoxides were prepared from (−)-menthyl arylsulfinate and methylmagnesium iodide by the known method.[6] The optically-active complex **1** was obtained from *tert*-butylhydroxymethylene-*d*-camphor and europium(III) nitrate in the presence of sodium hydroxide.[1,7] The diketone was prepared from camphor and pivaloyl chloride by the following modified method.

A mixture of camphor (24 g, 0.16 mol) and sodium hydride (3.8 g, 0.16 mol) in hexamethylphosphoric triamide (150 m*l*) under N_2 was stirred at 70°C for 5 hr to give a dark brown carbanion solution. This solution was diluted with THF (30 m*l*), and then a solution of pivaloyl chloride (8.8 g, 0.08 mol) in THF (10 m*l*) was added under ice-cooling. The reaction mixture was then stirred at room temperature for 12 hr, poured into water (500 m*l*), acidified with 10% hydrochloric acid (50 m*l*), and extracted with benzene. The product was purified by chromatography on a silica-gel column, followed by distillation; bp 130°C/2 mmHg. The 3-*t*-butylhydroxymethylene-*d*-camphor thus obtained (11%) formed white crystals; mp 65—67°C. We could find no suitable recrystallization solvent. The IR, NMR, the mass spectrum, and the analyses supported the structure.

The financial support from the Ministry of Education, the Japanese Government, and from the Toray Science Foundation is acknowledged with pleasure.

Synthetic Studies of Carbohydrate Derivatives with Photochemical Reaction. III.[1] Solvent Effects on the Photocycloaddition of Acetone to 3,4,6-Tri-*O*-acetyl-D-glucal

Kazuo MATSUURA, Younosuke ARAKI, and Yoshiharu ISHIDO

Department of Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo

(Received April 26, 1972)

In a previous paper,[2] the present authors reported the photochemical reaction of mercaptans or 1,3-dioxolane with enoses in the presence of acetone (**1**) as a photosensitizer. In the present paper, we wish to report the photocycloaddition of **1** to 3,4,6-tri-*O*-acetyl-D-glucal (**2**); this resulted in the formation of an oxetane derivative, *i.e.*, 5,6,8-tri-*O*-acetyl-2,4;3,7-dianhydro-1-deoxy-2-*C*-methyl-D-*glycero*-D-*ido*-octitol (**3**), and there were interesting solvent effects on the reaction. According to a recent paper,[3] incidentally, the photocycloaddition of **1** to **2** without the utilization of any solvent gave **3** in a 33% yield; this yield was calculated on the basis of the amount of **2** consumed (recovery yield=47%), and the structure of **3** was deduced by deriving **3** into some derivatives.

Results and Discussion

The irradiation of **2** in **1**—2-propanol (100: 1) with an ultraviolet lamp under nitrogen at room temperature for 100 hr gave **3** in a good yield. The structure of **3**, especially with respect to the stereochemistry in the mutual fusion of its pyranose and oxetane rings at C-3 and C-4 of **3**, was examined as follows.

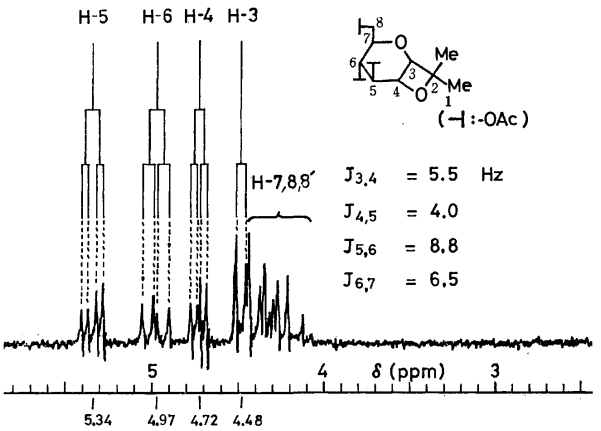

Fig. 1. 100 MHz NMR spectrum of 5,6,8-tri-*O*-acetyl-2,4; 3,7-dianhydro-1-deoxy-2-*C*-methyl-D-*glycero*-D-*ido*-octitol (**3**) in $CDCl_3$ with TMS as the internal standard. (δ 2.5—5.8 ppm)

i) The NMR spectrum of **3**, whose signals were assigned by the double-resonance technique, shows (*cf.* Fig. 1) that the H-3 and H-4 signals give a doublet at δ 4.48 ($J_{3,4}$=5.5 Hz) and a quartet at 4.72 ppm ($J_{4,5}$=4.0 Hz), respectively. Consequently, the facts lead to the conclusion that the carbonyl oxygen of **1** links to C-2, and the carbonyl carbon to C-1 of the

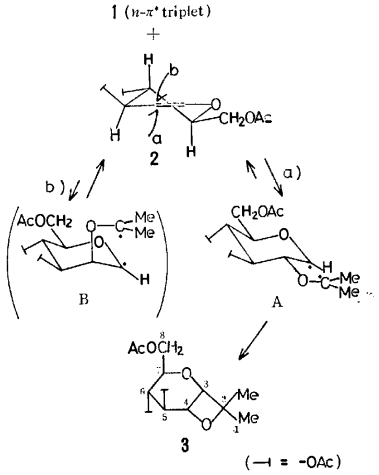
pyranose ring of **2**.[4] The coupling constants of H-6—H-7 (6.5 Hz) and H-5—H-6 (8.8 Hz) indicate that H-6 and H-7 are not in a true diaxial *trans* correlation; hence, the pyranose ring of **3** can be considered to be strained to some extent.

ii) The addition of piperylene as a quencher to the system resulted in no formation of **3**, and the reaction was confirmed to involve the addition of the n—π^* triplet acetone to **2**. It is well known[5] that the carbonyl oxygen in the n—π^* triplet state is electron-deficient. Thus, the attack of the carbonyl oxygen should take place at the more electron-sufficient C-2 of **2**, and the resultant radical at C-1 should be stabilized by the resonance with the pyranose ring oxygen. Moreover, the general mode of the oxetane ring formation in the photochemistry is considered to involve the biradical intermediate.[6] On the basis of the above considerations, the mechanism of this reaction may be formulated as below. The selective formation of **3**



with the chirality of *S* at C-4 may be explained by comparing the stereochemical stability between the biradical intermediates, A and B. This conclusion agrees with that reported by Ong and Whistler.[3]

Subsequently, the solvent effects on this reaction were examined; the results are summarized in Table 1. Interestingly, the addition of solvents (about 1%) to **1** promoted the formation of **3**, whereas the addition of 100 times of a solvent to **1** brought about no formation of **3** and a quantitative recovery of **2**; this is in contrast with the addition of 2-propanol, which resulted in the formation of two new products detected gas-chromatographically with retention volumes of 2.5 and 2.6 (observed as a shoulder on the preceding peak), and the recovery of **2** in a 5% yield.[7]

Table 1. The examination of sovent effects on the photocycloaddition reacion[a]

Solvent added[b]	Yield of the Octitol (**3**), %[c]
2-Propanol	99
2-Propanol-Piperylene[d]	0
Ethanol	70
Diethyl Ether	46
Tetrahydrofuran	30
1,4-Dioxane	87
Cyclohexane	25
Benzene	26
Toluene	52
Pyridine	24

a) All the reactions were carried out by the use of **2** (35 mg), acetone (10 m*l*) under nitrogen at room temperature by the irradiation with an ultraviolet lamp (450 W) for 32 hr.
b) Zero point one m*l* of the solvents were added, respectively, and, on the other hand, the addition of a large excess amount of them other than 2-propanol resulted in no reaction.
c) All the yields were calculated from glc. *cf.* Without any solvent, the reaction gave the product in 17% yield.[3]
d) The addition of piperylene (0.5 and 0.1 m*l*, respectively) resulted in quntitative recoveries of **2**.

Similar phenomena were found in the same reactions of the other enoses; those investigations are now in progress in our laboratory.

Experimental

The solvents applied in the experiments were purified in the usual manner before use. Irradiations were carried out with a high-pressure mercury lamp (450W) of Ushio Electric, Inc., in a Pyrex-glass test tube at the distance of about 5 cm. The TLC was carried out by the use of Wakogel B-5 and the solvent system of benzene–methanol (9: 1 v/v) for the development. The NMR spectra were taken with Varian XL-100 in $CDCl_3$ by the use of tetramethylsilane (TMS) as the internal standard, while a mixture of $CDCl_3$-CD_3CN (1: 1) was used for the improvement of the resolution of the spectrum. The glc was done with a Hitachi K-53 apparatus; column: 1% of SE-30 on Chromosolb W(60—80 mesh), carrier gas: N_2 under 1.5 atm, oven temperature: 200°C, and injection temperature: 300°C. MS was taken with a Hitachi RMU-6E apparatus.

*Irradiation of 3,4,6-Tri-*O*-acetyl-*D*-glucal (2) with Acetone (1).* A solution of **2** (1.00 g) in a mixture of **1** (10 m*l*) and 2-propanol (0.1 m*l*) was irradiated under a nitrogen atmosphere at room temperature for 100 hr, and then the volatiles were evaporated *in vacuo*. The residue was subsequently chromatographed on a silica gel column by the use of benzene–acetone (19: 1 v/v) as an eluting solvent system; this gave a chromatographically-pure syrup of **3** (330 mg, 27% yield[9]). $[\alpha]_D^{25}$ +49.5° (*c* 1.0 Me_2CO) $[\alpha]_D^{25}$ +54.1° (*c* 1.0, $CHCl_3$)[3]. NMR ($CDCl_3$) δ 4.48 (H-3, d, $J_{3,4}$=5.5 Hz), 4.72 (H-4, q, $J_{4,5}$=4.0 Hz), 5.34 (H-5, q, $J_{5,6}$=8.8 Hz), 4.97 (H-6, q, $J_{6,7}$=6.5 Hz), 4.4—4.1 (H-7,8,8′, m), 1.43 and 1.45 ($2CH_3$), and 2.06, 2.08, and 2.11 ppm ($3CH_3CO$), and NMR ($CDCl_3$-CD_3CN=1: 1) δ 4.47 (H-3), 4.69 (H-4), 5.30 (H-5), 4.93 (H-6), 4.45—4.10 (H-7,8,8′), 1.40 and 1.43 ($2CH_3$), and

The Stereochemistry of Hydrogenation with Tris(triphenylphosphine)chlororhodium

Yasuhisa SENDA,* Sekio MITSUI, Hiroshi SUGIYAMA,** and Shuichi SETO**

Department of Applied Science, Tohoku University, Sendai

***Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai*

(Received May 17, 1972)

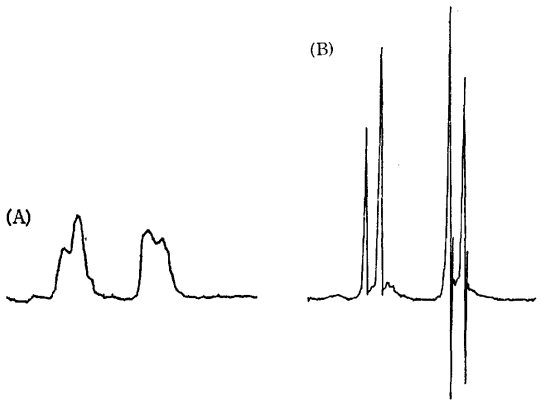
Wilkinson and his co-workers have shown that tris(triphenylphosphine)chlororhodium is an efficient catalyst for the hydrogenation of alkenes and alkynes.[1] The stereochemistry of the addition of hydrogen to the olefinic bond has been investigated only by Wilkinson and his co-workers[1] and by Birch and Walker.[2] Wilkinson and his co-workers confirmed, by a study of the IR spectrum, that the deuteration of maleic acid proceeded to give mainly *meso*-1,2-dideuterosuccinic acid; this means that the hydrogenation occurs with the *cis* addition of hydrogen to the double bond. Birch and Walker found that the deuteration of 22-dihydroergosteryl acetate occurred in a *cis* fashion.

In order to obtain further evidence on the stereochemistry of the addition of hydrogen, several olefinic compounds were deuterated and the steric configuration of the products were examined by the NMR procedure. The following olefins were used as substrates; *trans*-benzalacetophenone, *trans*-benzalpinacolone, methyl *trans*-cinnamate, *trans*-crotononitrile, and *trans*-cinnamonitrile. Deuteration was performed in benzene at an ordinary pressure and temperature. The products were separated from the complex catalyst by alumina chromatography and were subjected to NMR.

The NMR spectrum of methyl β-phenylpropionate-d_2, the reduction product from methyl *trans*-cinnamate, showed that its ethylene moiety resonated at δ: 2.55 and 2.93 as a broad doublet. The vicinal coupling constant, J_{HH}, was approximately 6.5 Hz. In order to confirm the coupling constant, the double resonance of the deuterium atom was performed. The spectrum of -CHD-CHD- obtained was a sharp AB-type doublet whose coupling constant was 5.46 Hz. The spectra were shown in Fig. 1. In the NMR spectrum of phenylpropionitrile-d_2 from *trans*-cinnamonitrile, the signal of the ethylene moiety appeared at δ: 2.33 and 2.71; in shape it was a broad doublet, and their vicinal coupling constant was 6.60 Hz.

TABLE 1. CHEMICAL SHIFT AND COUPLING CONSTANT OF DEUTERATION PRODUCTS WITH $RhCl(PPh_3)_3$

trans-Olefin	d_2-Product	-CHD-CHD- δ (ppm)	-CHD-CHD- J (Hz)
Methyl Cinnamate	Methyl β-Phenylpropionate	2.55 2.93	5.46
Benzalacetophenone	Diphenylpropanone	3.04 3.17	4.86
Benzalpinacolone	Dimethylphenylpentanone	2.67 2.79	5.11
Cinnamonitrile	Phenylpropionitrile	2.33 2.71	6.60
Crotononitrile	Butyronitrile	1.57 2.24	6.56



(A) Undecoupled Spectrum (B) Deuterium Decoupled Spectrum

Fig. 1. The NMR spectra of ethylene part of methyl β-phenylpropionate-d_2.

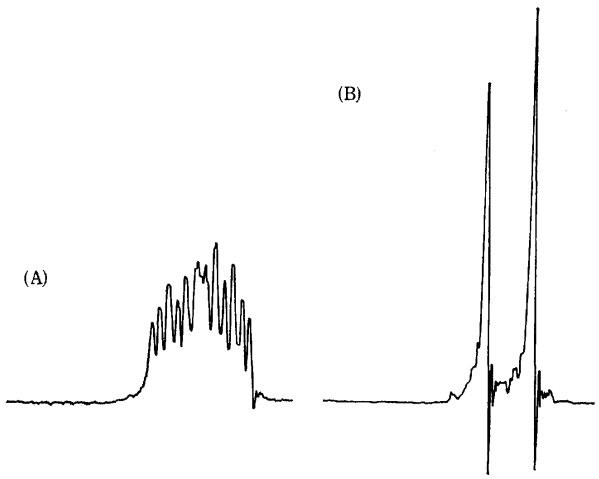
In spite of our expectation that the spectra of the ethylene parts of diphenylpropanone-d_2, the reduction product from *trans*-benzalacetophenone, and of dimethylphenylpentanone-d_2, from *trans*-benzalpinacolone, being an AB-type signal, the former compound showed the signal at around δ: 3.00, and the latter, at around 2.75 as a multiplet. In order to examine these spectra in detail, the double resonance of the deuterium atoms of these compounds was performed. As a consequence,

1) J. A. Osborn, F. H. Jardine, J. F. Young, and G. Wilkinson, *J. Chem. Soc., A*, **1966**, 1711; F. H. Jardine, J. A. Osborn, and G. Wilkinson, *ibid., A*, **1967**, 1574.

2) A. J. Birch and K. A. M. Walker, *Tetrahedron Lett.*, **1966**, 4939.

we obtained the coupling constants of these AB-type signals as 4.86 Hz in diphenylpropanone-d_2 and 5.11 Hz in dimethylphenylpentanone-d_2 accompanying the unidentified peaks.

The deuterium decoupling of the complicated spectra of butyronitrile-d_2 obtained from *trans*-crotononitrile showed signals which were a sharp doublet at δ: 2.24 and an A_3B-type octet at 1.57. The coupling constant of the signal at δ: 2.24, which corresponds to the methine proton, α to the cyano group, was 6.56 Hz. The spectra are shown in Fig. 2.



(A) Undecoupled spectrum (B) Deuterium decoupled spectrum

Fig. 2. The NMR spectra of methylene proton α to the cyano group of butyronitrile

The NMR spectra of methyl β-phenylpropionate-d_2 and phenylpropionitrile-d_2 were also measured at low and high temperatures. When the temperature was decreased to -55, -70, -80, and -90°C, the spectra showed no significant change in the shape of the signals as the coupling constant of the protons of the ethylene moiety. On the other hand, when the spectra of methyl β-phenylpropionate-d_2 were measured at a high temperature, those signals became broad at 100°C, but again became sharp at 150°C. In this case, no significant change in the coupling constant of the methylene protons of the ethylene moiety was observed.

Jackmann reported[3] that the vicinal coupling constants of the *erythro* and the *threo* isomers of *p*-methoxycinnamic acid dibromides were found to be 11.6 and 9.9 Hz respectively. He also reported that in a typical case it could perhaps be assumed that the J_{AB} in the *erythro* isomer is essentially in the range above 10 Hz, while that in the *threo* isomer is essentially in the range below 5 Hz.

Whitesides and his co-workers[4] confirmed, from a measurement study of dimethylbutane derivatives, that J_{trans} is normally 10—14 Hz and that J_{gauche} is 4—6 Hz.

When the spectra of methyl β-phenylpropionate-d_2 were measured at several points of the temperature, the width of the signal of the ethylene protons showed a temperature dependence at high temperatures. The signal became broader at 100°C than at room temperature. A further increase of the temperature made the signal sharp. This fact shows that the compounds used in the present study seem to take a fixed conformation at room temperature. As the temperature is elevated, a restricted rotation around the carbon-carbon single bond may occur; a high rate of interconversion is inferred at 150°C.

These results show that all of the diastereoisomers of open-chain compounds which were obtained in the present study by deuteration with tris(triphenylphosphine)chlororhodium may be assumed to be *threo* isomers. Therefore, deuteration occurs to the olefinic double bond in a *cis* fashion, supporting the results of Wilkinson and his co-workers and of Birch and Walker.

Experimental

Materials. The methyl *trans*-cinnamate was prepared from commercial *trans*-cinnamic acid by esterification. The *trans*-benzalacetophenone was prepared by the Claisen-Schmidt condensation of benzaldehyde and acetophenone with a 1.7 mol solution of sodium hydroxide in aqueous ethanol.[5] The *trans*-benzalpinacolone was obtained from benzaldehyde and pinacolone as the above unsaturated ketone.[6] The *trans*-crotononitrile was separated from commercial isomeric mixture by preparative gas chromatography. The *trans*-cinnamonitrile was prepared by the dehydration of cinnamaldoxime in boiling acetic anhydride.[7] All the olefinic compounds agreed in physical constants with the samples earlier prepared and were checked by studying their NMR and IR spectra.

Hydrogenation. In a typical experiment, a 80 mg portion of tris(triphenylphosphine)chlororhodium in 5.0 m*l* of benzene was presaturated with deuterium for 2 hr, and then the substrate (0.01 mol) in 5.0 m*l* of benzene was added, through a side-arm entry port, to the reaction flask. After the reaction flask had been stirred for 24 hr, the complex catalyst was removed by alumina-column chromatography and the solvent was distilled off.

NMR Spectra. The NMR spectra were measured with a JNM-C-60HL apparatus at 60 MHz and a JNM-PS-100 apparatus at 100 MHz. Simultaneous decoupling was accomplished at 14.349152 MHz using JNM-PS-100. The samples were examined at approximately 20% (w/v) in CCl_4. TMS was used as the internal standard. The low-temperature NMR was measured at approximately 5% (w/v) in CS_2 while at high temperatures the samples were in a neat condition.

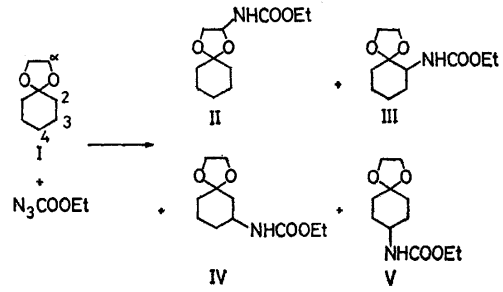
The Photochemical and Thermal Reaction of Ethyl Azidoformate with Cyclohexanone Ethylene Acetal

Tamejiro HIYAMA, Shinsaku FUJITA, and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto

(Received May 19, 1972)

Ethoxycarbonylnitrene reacts regioselectively with cyclic ethers to afford α-C–H insertion products.[1] Radical species and/or oxygen-imine intermediates have been proposed[1,2] as the explanation of the selectivity. In order to obtain further information on this problem, we have examined the reactions of ethoxycarbonylnitrene with cyclohexanone ethylene acetal (I) which has four kinds of methylene groups.

Ethyl azidoformate in I was decomposed photochemically or thermally; the products shown in Scheme 1 were then collected by distillation and preparative gas chromatography (GC). Since the separation of II by preparative GC was not satisfactory, the isomer was isolated by the selective acid hydrolysis of the crude products and by subsequent preparative GC. The regioisomers, III, IV, and V, were identified by comparing them with authentic samples prepared by the acetalization of the corresponding amino ketone. *N*-Ethoxycarbonyl-2-aminocyclohexanone (VI) was obtained by the DMSO-oxidation of 7-ethoxycarbonyl-7-azanorcarane.[3] *N*-Ethoxycarbonyl-3-,[4] and 4-aminocyclohexanone (VIII and X) were prepared by the hydrogenation of ethyl 3- and 4-hydroxycarbanilate, followed by chromic oxidation.



Scheme 1

The reaction conditions and product distributions are summarized in Table 1. The direct photolysis[5] gave a fair amount of V. This may be ascribed to the transition state XIc, arising from the boat-form conformation of an oxygen-imine XI, or simply to the singlet nitrene. Meanwhile, the formation of III and IV can be understood in terms of the intermediacy of the oxygen-imine reaction *via* the two transition states of XIa and XIb. The yield of II increased both in the dilution experiment and, more especially, in the acetophenone-sensitized photolysis. This suggests that a triplet nitrene or a triplet azide attacks the α-methylene of the acetal in a radical sense, producing II *via* a hydrogen abstraction-recombination mechanism. The thermolytic decomposition gave a comparable yield of II, which was, however, absent among the products in the dilution experiment. This may be explained similarly as in the reaction of cyanogen azide with ether.[6] Thus, the acetal oxygen may attack the azide group bimolecularly to form an oxygen-imine intermediate (XI), which may subsequently produce the α-insertion product (II). The dilution

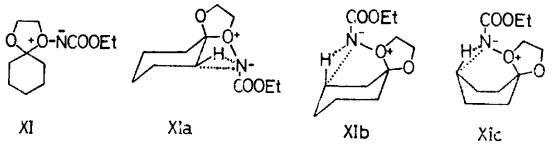
with dibromoethane disfavors the formation of the oxygen-imine (XI) and, consequently, that of II.



XI XIa XIb XIc

Experimental

Table 2 lists the physical properties of the new compounds.

Photolysis of Ethyl Azidoormate in I. Ethyl azidoformate (2.60 g, 22.6 mmol) and cyclohexanone ethylene acetal (44 m*l*) were irradiated for 20 hr. The recovery of the excess acetal, followed by distillation at 122—143°C/0.18 mmHg, gave a mixture of II, III, IV, and V (0.99 g). The isolation of IV and V was effected by preparative GC (Silicone SE 30, 30%, 6 mm×1 m, 150°C.)

Isolation of II. A mixture (3.6 g) of the products obtained as has been described above was dissolved in ether (150 m*l*), and the solution was shaken with 10% hydrochloric acid (140 m*l*) for 5 min, washed with water, neutralized with aqueous sodium bicarbonate, and dried over anhydrous sodium sulfate. Concentration and distillation then yielded crude II (0.69 g). The hydrolysis was repeated, and the pure sample was obtained by preparative GC.

Thermolysis of Ethyl Azidoformate in I. A mixture of ethyl azidoformate (1.05 g, 9.1 mmol) and I (5 m*l*) was added, drop by drop (over 40 min), to I (15 m*l*) at 120°C under a nitrogen atmosphere, and thereafter heating was continued for 3 hr. Concentration and distillation gave a mixture of II, III, IV, and V (1.16 g). The separation of each component was effected as has been described above.

N-Ethoxycarbonyl-3-aminocyclohexanone (VIII). Ethyl 3-hydroxycarbanilate (10.7 g, 59 mmol), Raney nickel (W-2) (3 g), and ethanol (150 m*l*) were heated at 175—190°C in an autoclave under a hydrogen atmosphere (110 kg/cm^2) for 2 days. The subsequent filtration of the catalyst and evaporation of the solvent yielded VII as a viscous oil (9.8 g, 89%). IR (neat): 3300, 1690, 1540 cm^{-1}. MS: *m/e* 187 (M^+).

A mixture of sodium dichromate dihydrate (6.0 g), concentrated sulfuric acid (5 m*l*), and water (30 m*l*) was added, drop by drop, to a solution of VII (9.8 g) in ether (50 m*l*) at 0°C, and subsequently 20% sulfuric acid (5 m*l*) was added. After stirring for 2 hr, the ether layer was separated, washed with water, and dried (sodium sulfate). Concentration and distillation gave VIII[4] (3.13 g, 32%).

The hydrogenation of ethyl 4-hydroxycarbanilate was performed as has been described above to afford IX in a quantitative yield. IR (Nujol): 3330, 1695, 1540 cm^{-1}. The chromic oxidation of IX, followed by distillation, gave X (27% yield).

Acetalization of VI. A mixture of VI (0.24 g), ethylene glycol (2.0 m*l*), boron trifluoride etherate (0.5 m*l*), and dichloromethane (5 m*l*) was stirred at room temperature for a day. The mixture was then poured into water (100 m*l*), extracted with ether, washed with aqueous sodium bicarbonate, and dried over anhydrous sodium sulfate. Concentration and preparative layer chromatography on silica gel (benzene) gave III (0.113 g, 38%).

The acetalization of VIII and X afforded IV and V in 25 and 44% yields respectively.

Financial support from the Ministry of Education, the Japanese Government, is acknowledged with pleasure.

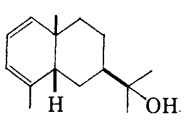
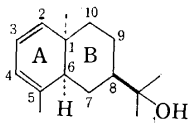
(Received June 3, 1972)

(+)-Occidentalol, an eudalene-type sesquiterpene alcohol isolated from the heartwood of *Thuja occidentalis* L., has been shown[1] to possess *cis* ring-fusion[2] and a 1,3-diene system. The optical rotatory dispersion



1

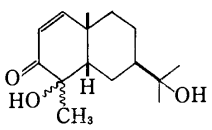


2

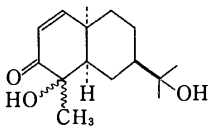
(ORD) study[3,4] of its related compounds has led to the acceptance of structure **1** of two structures **1** and **2** possible for (+)-occidentalol. However, recently the structure has been revised to **2** on the basis of nuclear magnetic resonance (NMR) spin-decoupling[5] and synthesis[6] of the antipode of (+)-occidentalol from α-santonin. We now wish to present additional evidence supporting absolute configuration (**2**), and to describe the conformational study of (+)-occidentalol and its dehydration products (**5**) and (**6**) by circular dichroism (CD) measurements at various temperatures.

Results and Discussion

Further Support for the Absolute Configuration of (+)-Occidentalol. According to Mislow's suggestion,[3]

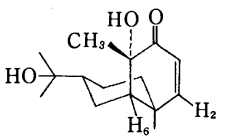


3

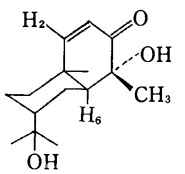


4

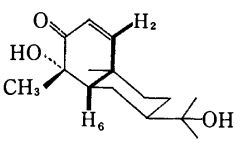
the structure possible for (+)-5-hydroxy-8-(1-hydroxy-1-methylethyl)-1,5-dimethylbicyclo-[4.4.0]-2-decen-4-one[7] derived from (+)-occidentalol may be **3** or **4**, each of which can take two possible conformations **3a** and **3b**, and **4a** and **4b**. The infrared spectrum of the α'-hydroxy-α,β-unsaturated ketone in the hydroxyl-stretching region indicated four absorption bands at 3635 (ε 34), 3622 (ε 66), 3592 (ε 80), and 3490 cm^{-1} (ε 6) in 0.0042M carbon tetrachloride solution. The two high-frequency bands can be attributed to free hydroxyl stretching due to the hydroxyisopropyl group and the hydroxyl group at C-5. The third band was assigned to the OH···π intramolecularly-interacted hydroxyl group and the fourth to the OH···O interacted hydroxyl group adjacent to the carbonyl group.[8] Since the A-ring of the four conformers has been postulated to exist in the most stable half chair conformation,[9] the hydroxyl group at C-5 should be in the axial orientation and will easily form the OH···π hydrogen bond. Accordingly, in the conformational equilibrium between **3a** and **3b** and between **4a** and **4b**, conformers **3a** and **4a** may be expected to predominate because they suffer the less 1,3-diaxial interaction.



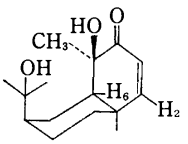
3a



3b



4a



4b

Long range coupling of the W or the M type[10] between H-2 and H-6 may be expected for **4a**, since the H-2, C-2, C-1, C-6, and H-6 portion of this conformer is in a coplanar zigzag spatial arrangement; this is not the case for the conformer (**3a**). The NMR spectrum (60 MHz) of compound **4** showed the characteristic resonance pattern for olefinic protons of H-2 and H-3 at 6.59 and 5.95 ppm respectively. Upon irradiation of the signal due to H-6 at 1.82 ppm, the spin-coupling pattern due to H-2 at 6.59 ppm (dd, $J_{2,3}$=10.5 Hz and $J_{2,6}$=2.0 Hz) was transformed to a doublet ($J_{2,3}$=10.5 Hz). This observation of the long range coupling ($J_{2,6}$=2.0 Hz) indicates that the compound (**4**) exists in the preferred conformation (**4a**).

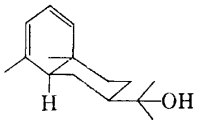
Table 1. The percentage change of molecular ellipticity of compounds **2**, **5**, and **6** in the MI solvent and decalin

Compds.	MI solvent[a]			Decalin		
	$[\theta](\lambda_{max})\times10^{-4}$ at 25°C (T_2)	$[\theta]$ $(\lambda_{max})\times10^{-4}$ at -180 ± 2°C (T_1)	$I^{T_2}_{T_1}$	$[\theta]$ $(\lambda_{max})\times10^{-4}$ at 143 ± 1°C (T_2)	$[\theta]$ $(\lambda_{max})\times10^{-4}$ at 25°C (T_2)	$I^{T_2}_{T_1}$
2	6.10	6.65	− 8.3	6.21	6.61	− 6.1
5	5.16	6.19	−16.6	4.53	5.60	−19.1
6	7.49	8.81	−15.0	6.32	7.76	−18.6

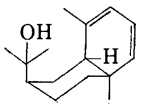
a) The MI solvent is composed of methylcyclohexane–isopentane in the ratio 1:3 by volume.

This further supports the revised absolute configuration of (+)-occidentalol (**2**).

The Conformation of (+)-Occidentalol (2) and Its Dehydration Products (5) and (6). (+)-Occidentalol (**2**) may take two possible preferred conformations (**2a**)



2a

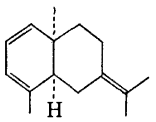


2b

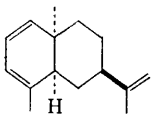
and (**2b**). The diene system of the conformer (**2a**) is skewed in the sense of a right-handed helix, whereas the system of **2b** in the sense of a left-handed helix. The helicity rule[11] predicts a positive Cotton effect for the conformer (**2a**) and a negative one for the conformer (**2b**). The CD curve of **2** exhibited a positive Cotton effect at 25°C, keeping the sign with the same rotational strength as above in a range of +140 to −180°C. The percentage change of molecular ellipticity[12] expressed as $I^{T_2}_{T_1}=([\theta](T_2)-[\theta](T_1))\times100\%/[\theta](T_1)$ is small, being almost within the deviation (6.1%) (Table 1). The result indicates the predominance of the conformer (**2a**). Furthermore, the population of the conformer (**2a**) is deduced to be more than 99% at room temperature,[13] because the difference between the conformational energies of **2a** and **2b** is more than 3.85 kcal/mol, as estimated by summation of the conformational energies of the methyl (1.70 kcal/mol)[14] and the isopropyl (2.15 kcal/mol)[14] groups.

Additional evidence in favor of the stability of the conformer (**2a**) was obtained by means of the NMR spectrum of the three olefinic protons H-2 (5.21 ppm), H-3 (5.74 ppm), and H-4 (5.49 ppm), and the H-6 proton (1.65 ppm), at various temperatures. The spectrum showed the same spin-coupling pattern[5] at +50, −10, and even −60°C in deuterochloroform.

The dehydration products, (**5**) and (**6**), of occidentalol can exist in two interconvertible conformations (**5a**) and

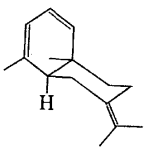


5

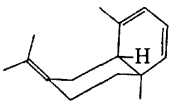


6

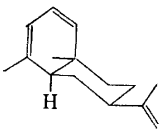
(**5b**), and (**6a**) and (**6b**), respectively, where the A-ring of the conformers (**5a**) and (**6a**) has a skewed diene system in the sense of a right-handed helix, whereas the diene system of the conformers (**5b**) and (**6b**) is skewed in a left-handed helix. The temperature-dependence of the CD curve of these compounds (Table 1) showed the presence of the conformational equilibrium between **5a** and **5b** and between **6a** and **6b**, since the



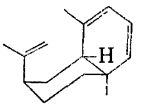
5a



5b



6a



6b

percentage change of the molecular ellipticity for these compounds are about two times as large as that of **2**. The increase in the positive rotational strength with a lowering of the temperature indicated the predominance of the conformers (**5a**) and (**6a**).

Experimental

(+)-Occidentalol (2). The same sample of (+)-occidentalol as described in the previous report[2] was used.

Dehydration of (+)-Occidentalol (2). 8-Isopropylidene-1,5-dimethylbicyclo[4.4.0]-2,4-decadiene (5): To the solution of 0.3 g of (+)-occidentalol in 6 ml of pyridine was added dropwise phosphorus oxychloride (0.6 ml), and the mixture was left to stand at 5—10°C for 5 hrs and then treated in the usual way. The oily product (0.23 g) obtained was separated into two fractions by column-chromatography on silica-gel (Merck Kieselgel G, less than 0.08 mm) impregnated with 20% (w/w) silver nitrate. The first fraction gave the dehydration product (**5**) as a viscous oil: $[\alpha]_D^{25}$ +698° (*c* 0.034, EtOH); λ_{max} (EtOH) 269 nm (ε 4720); δ ($CDCl_3$) 0.82 (s, 3H, methyl), 1.63 (s, 6H, two vinylic methyls), 1.76 (s, 3H, vinylic methyl), 5.32 (d, J=9.0 Hz, 1H, vinyl), 5.55 (b, 1H, vinyl), and 5.85 ppm (dd, J=9.0 and 5.0 Hz, 1H, vinyl).

8-Isopropenyl-1,5-dimethylbicyclo[4.4.0]-2,4-decadiene (6): The second fraction gave the dehydration product (**6**) as a viscous oil: $[\alpha]_D^{25}$ +674° (*c* 0.036, EtOH); ν_{max} (liq. film) 3100, 1645, 1586, 892, and 735 (vinyl) cm^{-1}; λ_{max} (EtOH) 265 nm (ε 4920); δ ($CDCl_3$) 0.84 (s, 3H, methyl), 1.63 (d, J=1.0 Hz, 3H, vinylic methyl), 1.74 (d, J=1.0 Hz, vinylic methyl), 4.63 (s, 2H, vinyl), 5.25 (d, J=9.0 Hz, 1H, vinyl), 5.55 (b, 1H, vinyl), and 5.80 ppm (dd, J=9.0 and 5.0 Hz, 1H, vinyl).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3504—3505 (1972)

Reactions of Benzenediazonium-2-carboxylate with Arylimino- and Acylmethylenetriphenylphosphoranes

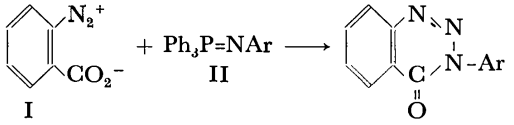
Takayuki KAWASHIMA and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 18, 1972)

There is no report on the reaction of benzenediazonium-2-carboxylate (I) with arylimino- (II) or acylmethylenetriphenylphosphoranes (III).

The reactions of I with II gave 3-aryl-3,4-dihydrobenzo[*e*][1,2,3]triazin-4-ones (IV), *N*-arylbenzamides (V), *N*,*N*′-diarylureas (VI) and triphenylphosphine oxide (VII) in dichloromethane at room temperature, their yields being dependent upon aryl group of II (Table 1).



I + Ph_3P=NAr (II) → IV + PhCONHAr (V) + $(ArNH)_2CO$ (VI) + Ph_3PO (VII)

a: Ar=Ph
b: Ar=*p*-MeC_6H_4
c: Ar=*p*-ClC_6H_4

Table 1. Reactions of benzenediazonium-2-carboxylate (I) with aryliminotriphenylphosphoranes (II)[a)]

II	Ar	IV(%)	V(%)	VI(%)	VII(%)
a	Ph	13.4	9.6	—	81.5
b	*p*-MeC_6H_4	20.0	—	4.4	90.0
c	*p*-ClC_6H_4	—	20.2	3.8	91.1

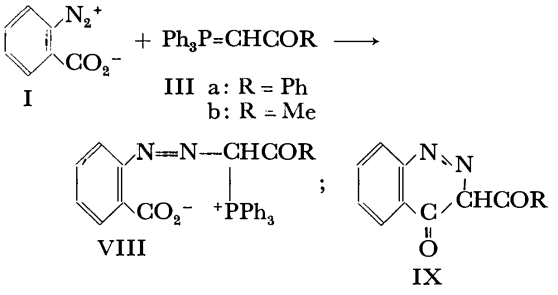
a) Yields were calculated on the basis of the amount of II used.

The products were identified by the comparison of the melting points and IR spectra with those of authentic samples and on the basis of the MS spectra.

The formation of IV is explicable by the attack of the diazonium group of I to the imino nitrogen atom of II, followed by the elimination of VII. Separate experiments indicated that benzanilide (Va) was not produced from IVa but produced quantitatively by the reaction of IIa with benzoic acid,[1)] which is produced by the decomposition of I,[2)] under the same condition. Urea (VI) is considered to be formed by the reaction of II with carbon dioxide, which was produced by decomposition of I, followed by the hydrolysis of isocyanate or carbodiimide thus produced during the isolation.

Variation in the yields of IV, V, and VI is attributable to a competition of the reaction between I and II with the decomposition of I to benzoic acid and carbon dioxide. For example, the absence of IVc in the case of IIc is attributable to a low nucleophilicity of the imino nitrogen in IIc because of the presence of electron-attractive *p*-chlorine atom.

Next, the reactions of I with acylmethylenetriphenylphosphoranes (III) were carried out in dichloromethane at room temperature. The products were phosphonium betaines (VIII) instead of expected IX.



I + Ph_3P=CHCOR (III a: R = Ph, b: R = Me) → VIII ; IX

The structure of VIII was determined by the elemental analyses, the IR, ^{1}H-, and ^{31}P-NMR spectra. The ^{31}P-NMR spectra (δ −4.5 (in $CHCl_3$) and −3.8 (in $C_2H_4Cl_2$) from 85% phosphoric acid as external standard for VIIIa and VIIIb, respectively) support the structure of alkylidenephosphorane or phosphonium salt.[3)] The IR spectra showed the absence of carboxyl group and the presence of carboxylate group (I: 1630 and 1360; VIIIa: 1595 and 1360; VIIIb: 1625 and 1360 cm^{-1}). From these data, another possible structures were ruled out.

Thermal decomposition of VIII gave VII and tarry material containing carboxyl group, instead of IX.

A reason why IX is not formed is attributable to a lack of nucleophilicity of α-carbon atom in VIII.

N-Benzoylimino- and α-benzoylbenzylidenetriphenylphosphoranes did not react with I under the same condition.

Experimental

Materials. The following compounds were prepared by the methods described in literatures: benzenediazonium-2-carboxylate (I);[4] phenylimino- (IIa),[5] mp 128—131°C; *p*-tolylimino- (IIb),[6] mp 133—136°C; *p*-chlorophenylimino- (IIc),[6] mp 116—118°C; benzoylmethylene- (IIIa),[7] mp 181—183°C; and acetylmethylenetriphenylphosphoranes (IIIb),[8] mp 203—205°C.

Reactions of I. *a) With Phenyliminotriphenylphosphorane (IIa)*: To an excess amount of I in dichloromethane was added 4.47 g (12.7 mmol) of IIa in dichloromethane under nitrogen and the mixture was stirred at 10°C overnight. After filtration of unchanged I and removal of the solvent *in vacuo*, the residue was chromatographed on alumina to afford 0.38 g (13.4%) of IVa (with benzene–chloroform), mp 149—150°C (from benzene) (lit,[9] 150—151°C), $\nu_{C=O}$ 1660 cm^{-1}, *m/e* 223 (M^+), 2.87 g (81.5%) of triphenylphosphine oxide (VII) (with chloroform), 0.24 g (9.6%) of benzanilide (with chloroform–ether), mp 159—160°C (from methanol), and 1.274 g of red tarry material (with ethanol).

b) With p-*Tolyliminotriphenylphosphorane (IIb)*: A similar reaction using 3.66 g (10 mmol) of IIb for 5 hr gave 0.47 g (20%) of IVb, mp 142—143°C (from benzene) (lit,[10] 143°C), $\nu_{C=O}$ 1680 cm^{-1}, *m/e* 237 (M^+), 2.50 g (90%) of VII and 0.21 g (4.4%) of VIb, mp 250°C (from ethanol) (lit,[11] 256°C).

c) With p-*Chlorophenyliminotriphenylphosphorane (IIc)*: The reaction was carried out using 4.23 g (10.9 mmol) of IIc. The reaction was slow and the presence of unchanged IIc was observed even after stirring overnight. Similar treatment gave 0.51 g (20.2%) of *N*-*p*-chlorophenylbenzamide, mp 192—193°C (from benzene) (lit,[12] 187—187.5°C), 2.76 g (91.1%) of VII and 0.23 g (3.8%) of VIc, mp 300°C from ethanol) (lit,[13] 310°C).

d) With Benzoylmethylenetriphenylphosphorane (IIIa): A similar reaction was carried out using 1.3 g (3.4 mmol) of IIIa at 0°C until the presence of unchanged IIIa was not observed by tlc. After filtration of unchanged I, the solvent was removed *in vacuo* to afford 1.1 g (61.2%) of brown crystals, mp 196—197°C (decomp.) (from ethyl acetate); IR (KBr disk): 1690, 1595, 1360, and 1105 cm^{-1}; $\lambda_{max}^{CH_2Cl_2}$: 262 (ε 23,000) and 409 nm (32,000); ^{1}H-NMR ($CDCl_3$): δ 7.3—8.2 (m); ^{31}P-NMR ($CHCl_3$): δ −4.5; *m/e*: 277 (10%), 262 (39), 184 (11), 183 (37), 108 (26), 105 (100), 77 (59), and 51 (11).

Found: C, 74.84; H, 4.71; N, 5.29%. Calcd for $C_{33}H_{25}N_2O_3P$: C, 74.99, H, 4.77; N, 5.30%.

e) With Acetylmethylenetriphenylphosphorane (IIIb): Reaction of 9.3 g (29.2 mmol) of IIIb with excess amount of I finished after 15 min at 0°C. Similar treatment gave 13.0 g (95.5%) of yellow crystals, mp 192—194°C (decomp.) (from ethyl acetate); IR (KBr disk): 1695, 1625, 1360, and 1110 cm^{-1}; $\lambda_{max}^{CH_2Cl_2}$: 258 (ε 18,000) and 398 nm (25,000); ^{1}H-NMR ($CDCl_3$): δ 2.61 (3H, s, $COCH_3$) and 7.0—7.8 (20H, m, Ph, and $-CH\langle$); ^{31}P-NMR ($C_2H_4Cl_2$): δ −3.8; *m/e*: 277 (10%), 263 (14), 262 (84), 261 (20), 185 (10), 184 (27). 183 (100), 152 (16), 133 (20), 108 (70), 107 (27), 77 (45), 52 (43), 51 (45), and 43 (39).

Found: C, 72.05; H, 4.83; N, 6.02%. Calcd for $C_{28}H_{23}N_2O_3P$: C, 72.10; H, 4.97; N, 6.01%.

SHORT COMMUNICATION

Reduction of Carbonyl Compounds with Various Hydrosilane-Rhodium(I) Complex Combinations

(Received September 5, 1972)

It has been known that the hydrosilation of carbonyl compounds can be effected by various catalytic systems such as metal halides *e.g.* $ZnCl_2$[1] and H_2PtCl_6,[2] and UV light.[3] Among them, metal or metal halide catalyst systems have been used within the limit of monohydrosilanes, mainly due to the fact that the disproportionation of polyhydrosilane is also catalyzed by these substances.[4] Gilman and Wittenberg[5] found that diphenylsilane adds to benzophenone at temperature of 220—270°C, but the reaction conditions are too drastic to allow the use of a wide variety of carbonyl compounds in solution. We found that tris(triphenylphosphine)chlororhodium (**1**) is an extremely effective catalyst for the hydrosilation of carbonyl compounds in comparison with other knwon catalysts. Now we wish to report the effective hydrosilation of carbonyl compounds, which is equivalent to hydrogenation after hydrolysis, using a variety of hydrosilane-rhodium(I) complex **1** combinations. The hydrosilation with monohydrosilanes was found to take place under very mild conditions to give the expected products. Further, the rate of the reaction was found to increase when dihydro- and trihydrosilanes were employed, and the disproportionation of these hydrosilanes were virturally negligible.

A typical procedure is described for the hydrosilation of cyclohexanone by diphenylsilane: To a mixture of 0.98 g (10 mmol) of cyclohexanone and 1.84 g (10 mmol) of diphenylsilane, 9.5 mg (0.1 mol%) of $(Ph_3P)_3RhCl$ (**1**) was added, and the mixture was stirred at ice-cold temperature, and the hydrosilation was completed within 10 min. *n*-Hexane (50 m*l*) was added to the reaction mixture, the resulting precipitate filtered off, the solvent was evaporated, and the residual solution was distilled under reduced pressure, and 2.78 g (98%) of cyclohexyloxydiphenylsilane (**2 g**) was obtained. The silylether **2 g** thus obtained was smoothly hydrolyzed by MeOH–KOH–H_2O solution to afford cyclohexanol quantitatively. Results of the hydrosilation using various hydrosilanes, ketones and aldehydes are summarised in Table 1.

The hydrosilation of α,β-unsaturated ketones and aldehydes also proceeded smoothly under mild conditions to give the adducts in fairly high yield. In these cases, the reaction proceeded in a manner of 1,4-addition, and afforded silylenolethers **3**, which were easily hydrolyzed to saturated ketones or aldehydes by acetone–MeOH–H_2O–K_2CO_3 quantitatively. These findings clearly indicate that the reaction using hydrosilane-rhodium(I) complex combinations with α,β-unsaturated carbonyl compounds may open a new route to selective hydrogenation of the carbon-carbon double bond in α,β-unsaturated carbonyl compounds, and also open an important route to the preparation of silylenolethers, which are much interested as a synthetic intermediate. Results are listed in Table 2.

Though a hydrosilane has been known as a reducing agent for certain ketones, the scope of those reactions is limited to a very narrow area as quoted before. However, many carbonyl systems became able to be reduced by hydrosilane-rhodium(I) complex combinations taking advantage of easily hydrolyzable character of silylethers. Application of this reducing method to other systems and the mechanism of the reaction are now under active investigation. We believe that this reducing method has a wide potential utility as hydroboration.

A Deuteron Magnetic Resonance Study of the Motion of Ligands in $[Co(ND_3)_5(D_2O)](ClO_4)_3$

Takeshi Ito

Department of Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yakohama

(Received February 18, 1972)

The deuteron magnetic resonance of single crystals of aquopentamminecobalt(III) perchlorate was measured at various temperatures. The observed quadrupole coupling shows that $[Co(ND_3)_5(D_2O)]^{3+}$ ions execute a rapid isotropic reorientation at high temperatures (above 320°K), while only a C_3 axis reorientation of the ligand ND_3 groups is present at low temperatures (below 290°K). No anisotropic uniaxial reorientation was observed about the C_4 axis parallel to the Co–(D_2O) direction. At temperatures between 310°K and 320°K, the spectrum of a fast exchange limit was observed, together with the spectrum of a slow exchange limit. This anomaly may be explained by the classical rotation of the D_2O ligand.

When clusters of atomic groups rotate in crystals, there are several possibilities with regard to the symmetry of the crystal and the cluster. If both the symmetry of the crystal and that of the cluster are cubic, the reorientational motion of such a cluster may be isotropic because there is no preferential axis of reorientation. On the other hand, in the case of the crystal whose symmetry is lower than cubic, the possibility of some anisotropy in such a motion exists because of the effect of the crystal field even if the cluster has cubic symmetry. In fact, reorientational motion about a single C_3 or C_4 axis is observed in a suitable temperature range for a few compounds.[1-3] In the case of a cluster symmetry lower than cubic, such as *trans*-MA_4X_2 and MA_5X-type complex ions, the M–X bond is the preferential axis for reorientational motions because the motions about all the C_3 axes or C_4 axes except the M–X bond cause an exchange of the A ligand for a different ligand, X, and the motion is usually anisotropic. By proton magnetic resonance studies of cobalt ammine complexes, motional narrowing has been observed in several pentammine and tetrammine complexes at temperatures lower than room temperature, but the second moment of these complexes at room temperature are twice or more as large as those of hexammine complexes.[4-6] This presumably suggests that only the anisotropic uniaxial motion about a C_4 axis parallel to the Co-X bond direction is excited.

In the present work, the deuteron magnetic resonance of single crystals of aquopentamminecobalt(III) perchlorate is studied as one of the singular cases mentioned above. About this crystal it has been reported that the symmetry of the crystal is cubic, while that of the $[Co(NH_3)_5(H_2O)]^{3+}$ ion is lower than cubic, and that the cluster ions are statistically oriented in three possible orientations in the crystal.[7,8] Therefore, it is very interesting to know whether the motion of this tetragonal cluster ion is anisotropic or not in the cubic crystal field.

Experimental

The sample was prepared by the standard method.[9] Deuteration was performed by the repeated isotope exchange of $[Co(NH_3)_5(H_2O)](ClO_4)_3$ with D_2O. The single crystals were obtained by the slow cooling of a saturated solution of $[Co(ND_3)_5(D_2O)](ClO_4)_3$ in D_2O. The crystals exhibit {111} faces. The typical sample used was about $10\times10\times10$ mm^3. The measurements were carried out at 10 MHz using a Robinson-type oscillator detector with field sweep and field modulation (230 cps). The field calibration was performed by means of a D_2O signal at various frequencies, as measured by means of an electronic counter. Temperature control was accomplished by using an electric heater wound outside the probe.

Results and Discussion

The observed spectrum at room temperature consists of three pairs of lines (hereafter, these will be denoted

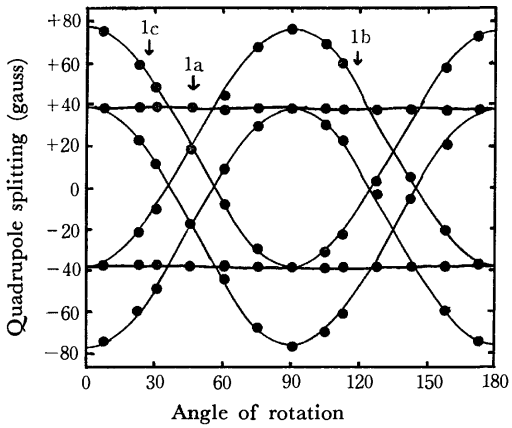

Fig. 1. Rotation pattern of deuteron magnetic resonance of $[Co(ND_3)_5(D_2O)](ClO_4)_3$ at room temperature, for the rotation about one of the crystal axes. θ is the angle between the applied external magnetic field H_0 and the crystal axis.

as lines 1a, 1b, and 1c). The rotation pattern of this spectrum is shown in Fig. 1. In most of the metal ammine complexes, the $ND_3(NH_3)$ ligand makes a rapid C_3-axis reorientation even at 77°K. In this case, the averaged electric field gradient at deuterons in ND_3 is in the direction of the Co-N bond. Therefore, assuming the axially symmetric field gradient about the Co-N bonds, we obtain the deuteron quadrupole coupling constant of $e^2qQ/h=67.1$ kHz. This value seems reasonable when compared with the deuteron quadrupole coupling constant, which is about 180 kHz for the rigid ND_4^+[10,11] and which is estimated to be about 60 kHz by averaging the C_3-axis reorientation of ND_3. The spectrum at 77°K is almost identical except that the splittings are about two percent greater than those at room temperature. This may be due to the difference between the amplitudes of torsional vibrations at 77°K and those at room temperature. No D_2O signal was observed over the temperature range from 77°K to room temperature. The intensity of the D_2O signal should be one- and two-fifteenth as large as that of the ND_3 signal for stationary and rapid 180°-flipping D_2O respectively. Possibly, the failure to detect the D_2O signal is due to the lack of sensitivity in the apparatus.

The features of the absorption lines at temperatures higher than room temperature are more interesting. The intensity of the absorption lines, 1a, 1b, and 1c, gradually decreases with an increase in the temperature. A new absorption line (line 2) at the Larmor frequency appeared at high temperatures, as is shown in Fig. 2. The line broadening and reappearing must be due to the reorientation of the $[Co(ND_3)_5(D_2O)]^{3+}$ ion. Since the quadrupole splitting of the high-temperature line is almost zero, it is evident that this reorientational motion is not uniaxial but isotropic. However, as can clearly be seen in Fig. 2, both the low-temperature lines (1a, 1b) and the high-temperature line (2) are simultaneously observed at some temperatures. Such an anomalous phenomenon of the coexistence of spectra of a slow exchange limit and of a fast exchange limit can be explained by only the theory of simple motional averaging. In tracing the motional broadening of deuteron resonance lines, there is commonly a range of temperature where the spectrum is completely washed out and unobservable between the two limitting ranges. Therefore, the 1 and 2 lines must be due to the different origins. To explain these facts, we should examine the following three possibilities:

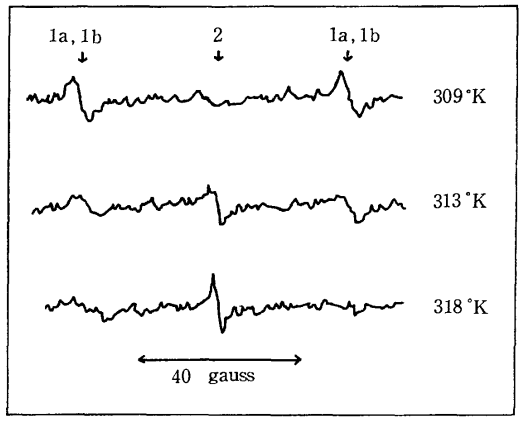

Fig. 2. Line broadening at 309°K, 313°K and 318°K. The magnetic field is applied parallel to the crystal axis.

(A) Although there is only one equivalent site in this crystal, the crystal fields acting on the individual complex cations may be slighly different from each other because the complex cations are randomly oriented in the crystal.[7,8] As a result, the rates of the reorientation of complex cations may not all be the same. Therefore, the 1 and 2 lines may be signals from the cations with a slower rate of reorientation and with a faster rate of reorientation respectively.

(B) In this crystal, the order-disorder phase transition was reported at 314°K.[7] If the rate of reorientation is slow in the ordered phase and fast in the disordered phase, the 1 and 2 lines may originate from the complex cations in the ordered phase and the disordered phase respectively, because both phases usually coexist near the transition temperature.

(C) In contrast with (A) and (B), the 1 and 2 lines may be due to the same type of complex cations, not different types. In this case, the 1 and 2 lines may be considered to originate from ND_3 and D_2O respectively.

Of course, the propriety of these interpretations should be examined by taking the experimental results of the proton second moment, the spin-lattice relaxation time in the laboratory frame (T_1), and that in the rotating frame ($T_{1\rho}$) into consideration. For this compound, the second moment decreases smoothly as the temperature increases in the range from 290°K to 340°K. The spin-lattice relaxation times, T_1 and $T_{1\rho}$, have no discontinuity over the temperature range studied. $T_{1\rho}$ has a sharp minimum at 333°K.[12]

In the case of Model (A), either a very broad linewidth transition of a proton resonance or a shallow minimum in a spin-lattice-relaxation-time-*versus*-temperature curve should appear, because various correlation times of reorientation can be expected. However, the experimental results are contradictory. Therefore, this model may be inadequate. In the case of Model (B), the correlation time of reorientation should exhibit a discontinuity at the temperature of phase transition. In fact, the broadening of the 1 lines and the narrowing of the 2 line occur more quickly at temperatures near the transition point. Therefore, it is certain that the phase transition is accompanied by a discontinuity in the correlation time of reorientation. However, if the signals due to the stationary and rotating ions are observed in the ordered and disordered phase respectively, the difference between the correlation times in the two phases must be considerably large. As a result, the spin-lattice relaxation time should have a clear discontinuity at the transition temperature. However, the experimental results do not exhibit such a discontinuity.

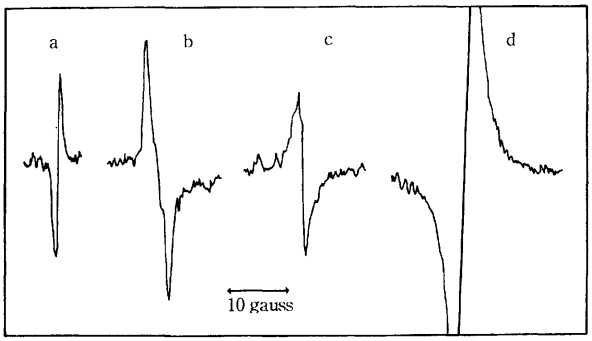

Fig. 3. Deuteron magnetic resonance spectra of $[Co(ND_3)_5(D_2O)](ClO_4)_3$ at 365°K. (a): $\theta=0°$, with small modulation; (b): $\theta=0°$, with large modulation; (c): $\theta=45°$, with small modulation; (d): $\theta=45°$, with large modulation. θ is the angle between the external magnetic field H_0 and the crystal axis.

Moreover, in order to test the possibility of Model(B), the following experiment was made at a temperature sufficiently above the transition point (365°K), as is shown in Fig. 3. If the external magnetic field, H_0, is applied parallel to the crystal axis (θ=0°), a sharp line is observed when the modulation width is small (Fig. 3a), and the peak intensity of this line scarcely changes with an increase in the modulation width (Fig. 3b). On the other hand, if H_0 is applied parallel to the bisector of the crystal axes (θ=45°), a somewhat broad line is observed when the modulation width is small (Fig. 3c). The peak intensity of this line is markedly increased with an increase in the modulation width (Fig. 3d). This suggests that the absorption line consists of a sharp and a broad component at this temperature, and that the latter component is too broad to be observed when H_0 is applied parallel to the crystal axis. Since only one phase should exist at this temperature, Model (B) may be inadequate to explain these experimental results, in which case only Model (C) is possible.

The line widths due to the motion, $\Delta\nu_M$, at the limit of slow and rapid exchange rates have been derived from the general formula as follows:[13,14]

slow exchange limit: $$\Delta\nu_M = \frac{1}{4\pi\tau_c} \quad \text{(inside lines 1a, 1b)} \tag{1}$$

and $$\Delta\nu_M = \frac{1}{2\pi\tau_c} \quad \text{(outside line 1c)} \tag{2}$$

rapid exchange limit: $$\Delta\nu_M = \frac{4}{9}(\nu_1^2 + \nu_2^2 + \nu_3^2)\,\tau_c, \tag{3}$$

where τ_c is the correlation time of this motion and where ν_i is the frequency difference at the site i from the center of gravity of the spectra (*i. e.*, $\nu_1+\nu_2+\nu_3=0$). As a result, the width of the motional averaged line is strongly dependent on the initial splitting. That is, the lines with a small splitting are averaged more effectively than the lines with a large splitting by motion. In the present case, if the motion of the D_2O ligand is a usual 180°-flip reorientation, the deuteron quadrupole splitting of D_2O is larger than that of the ND_3 under a rapid C_3-axis reorientation. However, if the motion of the D_2O ligand is a classical rotation about the Co–O bond axis and if its rate is sufficiently fast at this temperature, the averaged deuteron quadrupole splitting is very small because the bond angle of D_2O is close to the tetrahedral angle. Assuming that the bond angle of D_2O is 105°[15] and that the quadrupole coupling constant of stationary coordinated D_2O is 240 kHz,[14] we obtain the quadrupole coupling constant of D_2O averaged by such motion as 13.4 kHz. Therefore, the following explanation is possible: the 1 and 2 lines are the stationary signals of ND_3 and the motional averaged signal of the D_2O ligand respectively. Here we use the words "stationary" and "motional averaged" with respect to the motion of the whole complex cation. The stationary D_2O signal may not be observed because of its weakness, and the averaged ND_3 signal may be the broad component of the high-temperature spectrum. On the basis of this model, the correlation times of the motion of the complex ion are calculated from the line width due to the motion, $\Delta\nu_M$, which is itself estimated from the observed signal intensity by an apporoximate procedure.[16] The results thus obtained are shown in Fig. 4, together with those obtained from the proton second moment and the spin-lattice relaxation time in the rotating frame ($T_{1\rho}$). Although a considerable difference is observed between the correlation times derived from the deuteron resonance and those from the second moment or $T_{1\rho}$, the qualitative features of line broadening and reappearing may be explained by Model (C). This discrepancy may be due to the effect of the overmodulation. In the procedure of Chiba and Kakiuchi[16] the signal is as-

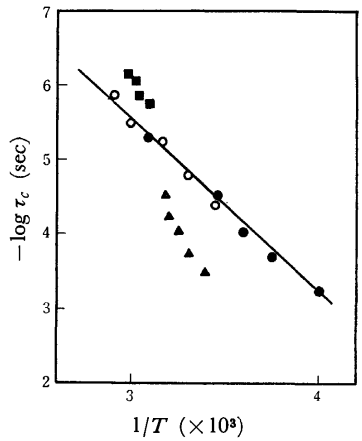

Fig. 4. Correlation times of the motion of aquopentammine-cobalt(III) ion calculated from the deuteron resonance, from the proton second moments and from the proton spin-lattice relaxation times in the rotating frame, $T_{1\rho}$. ○ from proton second moments; ● from proton $T_{1\rho}$; ▲ from deuteron resonance of ND_3; ■ from deuteron resonance of D_2O.

sumed to be a first derivative; that is, the modulation width is assumed to be infinitely small. In the present experiment, however, a fairly large modulation was used, especially for the motional broadening lines, since the intensities of the lines are weak. As a result, the decrease in intensity due to the line broadening is smaller than that estimated by the procedure of Chiba and Kakiuchi.[16] Therefore, the correlation times derived from the motional narrowing lines of D_2O (■ in Fig. 4) may be smaller, and the motional broadening lines of ND_3 (▲ in Fig. 4) may be larger, than the respective true value. Using Eq. (3) and τ_c derived from the second moment and $T_{1\rho}$, we obtained the line width due to the motion as 3.93 kHz and 0.99 kHz in the cases of $\theta=0°$ and 45° respectively, for the signals of ND_3 at 365°K. These results do not contradict the experimental finding that the broad component of the absorption lines at 365°K is not observed in the case of $\theta=0°$, while it is observed in the case of $\theta=45°$, since the observable limit of line width due to the motion is estimated to be about 3 kHz.

For the crystal treated here, no anisotropy was found in the motion of the cluster, and the motion of the D_2O ligand may be similar to the reorientation of the ND_3 about a C_3 axis rather than the usual 180°-flip one. This suggests that the D_2O and ND_3 ligands are essentially undistinguishable in this crystal. This conclusion seems reasonable in view of the fact that the symmetry of the crystal is cubic in contrast with the lower symmetry of the cluster.

The author would like to thank Professor Takehiko Chiba of Nihon University and Professor Jiro Higuchi of Yokohama National University for their valuable comments and criticism on the manuscript. Also, he wishes to thank Professor Chiba for the use of his facilities.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3510—3514 (1972)

A Consideration of Orbital Interaction in the Reaction of $^1\Delta_g$ Molecular Oxygen with Ethylene Derivatives

Satoshi INAGAKI, Shinichi YAMABE, Hiroshi FUJIMOTO, and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Kyoto

(Received March 27, 1972)

The stereochemical path of the reaction between the $^1\Delta_g$ oxygen molecule and ethylene was examined in terms of orbital interaction. The results here obtained suggest that a path *via* the perepoxide intermediate or *via* a perepoxide-like transition state should be carefully examined in discussing not only the steric path to dioxetane, but also the mechanism of hydroperoxide formation.

Extensive studies[1] of the reactions of the $^1\Delta_g$ oxygen molecule with olefinic bonds have revealed the existence of cycloaddition products (both $2+2$[2] and $4+2$ cycloadducts[3-5]), allylic hydroperoxides,[4,6] and fragmentation products — that is, carbonyl compounds. The fact that a single species, the singlet oxygen, gives both $2+2$[2a] and $4+2$[1] cycloadducts, with the configuration of olefin retained, provides us with an interesting problem to be examined from the viewpoint of molecular orbital symmetry. In addition, there are now heated controversies[1] regarding the mechanism of the reactions between the singlet oxygen and ethylene derivatives, especially concerning the existence of the perepoxide intermediate or the perepoxide-like transition state. Here, the following questions come to mind. Is the 1,2-cycloadduct, namely, dioxetane, formed as a primary product or as a rearranged compound of an initially-formed intermediate, perepoxide? Furthermore, does a concerted "ene" reaction occur in fact, or does an allylic hydroperoxide have any precursor? If any, what is the precursor?

In order to obtain some information about the detailed reaction path, Kearns,[1,7] using correlation diagrams, recently examined three different models for the concerted addition of the singlet oxygen to ethylene, IA, IIA, and IIIA, and suggested that IA and IIA are generally allowed, while IIIA is allowed only for the olefins with particularly low π ionization potentials. These results, obtained from the correlation diagrams, are not necessarily satisfactory in our attempt to ascertain the stereochemistry of the reaction paths, for there remains the important problem of whether dioxetane, previously detected,[2] is a primary product or a rearranged product of perepoxide. Hence, another discussion from a different standpoint, that of particular orbital interaction,[8] is worth being presented.

Choice of Models

In discussing the mechanisms of both dioxetane and allyic hydroperoxide formations, perepoxide has been

recommended as a feasible intermediate,[1] but this recommendation still remains without any theoretical are experimental conclusive evidence for or against it. As typical models of perepoxide, IA and IB are chosen in this study. In IA, one oxygen is placed in the plane determined by the carbons of ethylene and the other oxygen, while one oxygen is located vertically away from the coplane in IB. IB is our originally-chosen model.

On the other hand, some concerted processes, namely, the $2\pi_s+2\pi_a$ and $2\pi_s+2\pi_s$ cycloadditions represented by the models IIA and IIIA respectively, have naturally been proposed[1] in analogy to ethylene dimerization.[9] It should be noted that the frontier orbitals to interact with each other are orthogonal; therefore, the overlapping between them is zero in IIA. Hence, the IIB model in which the plane containing the C_2 axis and O-O bond axis and the one containing the C_2 axis and the C-C bond axis intersect with the 30° angle, was examined in order to evaluate the actual effectiveness of IIA.

The last model, IIIB, will be used to examine the possibility of an unsymmetrical ionic or biradical-like transition state. The deformation from the symmetrical structure was introduced by rotating the O-O bond in the plane by an arbitrary angle (5°).

Consideration of the Particular Orbital Interaction

From numerous instances of actual chemical reactions, it is now well-established that a majority of chemical reactions take place at the position, and in the direction, where the overlapping between the highest occupied (HO) molecular orbital (MO) and the lowest unoccupied (LU) MO is most favored.[8] Accordingly, it is first necessary to look into the nodal properties of the frontier orbitals of $^1\Delta_g$ oxygen in order to determine the most probable reaction path in terms of particular orbital interaction.

The electronic configuration of $^1\Delta_g$ molecular oxygen is $(1\sigma_g)^2(1\sigma_u)^2(2\sigma_g)^2(2\sigma_u)^2(1\pi_u)^4(3\sigma_g)^2(1\pi_{gyz})^2(1\pi_{gzx})^0$ taking the O-O axis along the Z-axis. The MO's π_{gyz} and π_{gzx} have two nodal planes, one involving the O-O axis and the other perpendicular to this axis (Fig. 1). It follows that the singlet oxygen has the HOMO and the LUMO of the same symmetry property, extending in two planes perpendicular to each other.

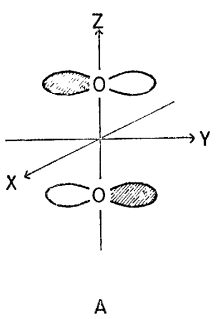

Fig. 1. The nodal property and the direction of the extension of the HOMO (A) and the LUMO (B) of $^1\Delta_g$ molecular oxygen.

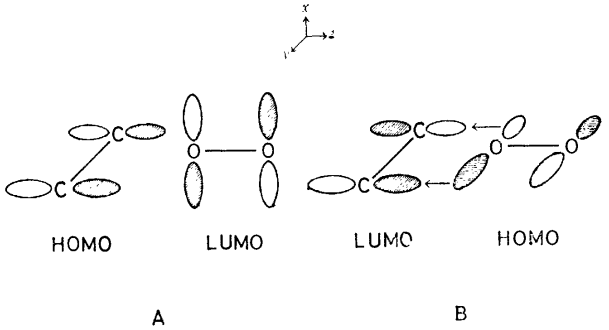

Fig. 2. The modes of HOMO-LUMO interactions between $^1\Delta_g$ molecular oxygen and ethylene in the model IA;
(A) intreraction between the HOMO of ethylene and the LUMO of $^1\Delta_g$ molecular oxygen;
(B) interaction between the LUMO of the former and the HOMO of the latter.

The IA model will first be considered here in terms of orbital interaction, which has been examined by means of a correlation diagram and which has been shown to represent an allowed process from the viewpoint of the conservation of orbital symmetry.[1] Suppose that the molecular plane and the C-C bond axis of ethylene are fixed parallel to the XY-plane and the Y-axis respectively, and $^1\Delta_g$ molecular oxygen is on the Z-axis (Fig. 2). Then, it can readily be found from the requirement of orbital symmetry that the HOMO of ethylene and the LUMO of the oxygen do not overlap at all, irrespective of any rotation of oxygen about the Z-axis (Fig. 2A). On the other hand, the LUMO of ethylene can overlap with the HOMO of the singlet oxygen because they have the same symmetry property with respect to reflection in the ZX-plane (Fig. 2B). This mode of orbital interaction may, however, be less important, since it means a charge-transfer from oxygen to ethylene; this mode of electron delocalization contradicts the generally-accepted electronegativity order. Accordingly, the model IA is not expected to represent the most favorable reaction path.

In the model IB, both modes of frontier orbital interactions which imply the charge-transfer from ethylene to oxygen, and the reverse, are favorable. The HOMO of ethylene can effectively interact with the terminus of the LUMO of the singlet oxygen (Fig. 3A), while the HOMO of oxygen, with its maxi-

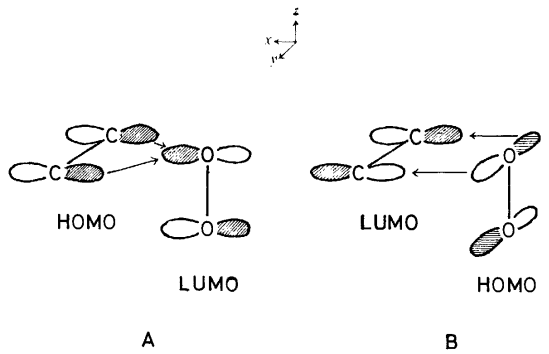

Fig. 3. The modes of HOMO-LUMO interactions between $^1\Delta_g$ molecular oxygen and ethylene in the model IB;
(A) interaction between the HOMO of ethylene and the LUMO of $^1\Delta_g$ molecular oxygen;
(B) interaction between the LUMO of the former and the HOMO of the latter.

mum extension in the direction parallel to the C–C bond, can also interact with the LUMO of ethylene (Fig. 3B), because these interacting MO's have the same symmetry with respect to the bisecting plane of the combined system (ZX-plane). Accordingly, the model IB may be supposed to be the most promising candidate for the actual reacting system.

A concerted mechanism can be alternative interpretation of the formation of 1,2-cycloadduct dioxetane. The characteristic of such a reaction path is that the way of approach of oxygen to ethylene maintains a certain symmetry, at lowest, the C_2 element. In these cases, there are two typical modes of frontier orbital interaction. One of them is a suprafacial-antarafacial interaction between the HOMO of the ethylenic π orbital and the LUMO of the singlet oxygen $1\pi_{gzx}$, as is illustrated in Fig. 4A (ethylene approaches oxygen along the Y-axis, with the π orbital in the XY-plane). This interaction mode, which corresponds to the IIA or IIB model, would not be so favored by the geometry as to eventuate in the stabilizing of the transition state. The other significant interaction is a suprafacial-suprafacial interaction between the LUMO of ethylene and the HOMO of the singlet oxygen (Fig. 4B, model IIIA). This mode of interaction is geometrically most feasible, but again it results in an unfavorable charge-transfer from the singlet oxygen to ethylene.

The last model, IIIA, cannot be discussed here by taking only the orbital symmetry into consideration, for this model does not have any particular symmetry. Accordingly, the estimation of the IIIB model will be made by the MO calculation to be described in the following section.

As a result, $^1\Delta_g$ molecular oxygen is expected to approach a double bond of olefins, most probably forming trigonal ring composed of two carbons and an oxygen atom, and tailed by the other oxygen, which drops out of the plane of the ring.

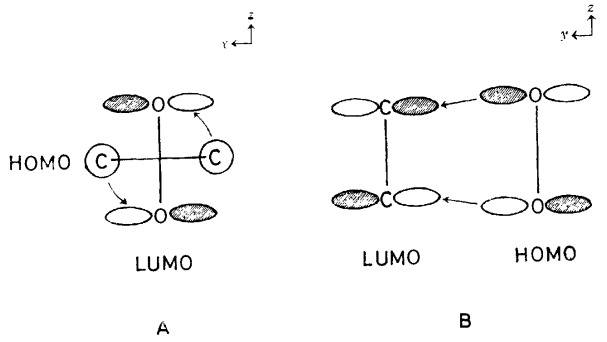

Fig. 4. The modes of HOMO-LUMO interactions between $^1\Delta_g$ molecular oxygen and ethylene in the model IIA and IIIA; (A) the interaction between the HOMO of ethylene (suprafacial) and the LUMO of the singlet oxygen (antarafacial) and (B) that between the LUMO of the former (suprafacial) and the HOMO of the latter (suprafacial).

Calculation

The chemical interaction at the early stage of a reaction was discussed by dividing the interaction energy, ΔW, into Coulomb (E_Q), exchange (E_K), delocalization (D), and polarization (Π) terms by the use of the configuration-interaction method (Eq. (1)):[10]

$$\Delta W = E_Q + E_K - D - \Pi. \quad (1)$$

E_Q is the quantity which reflects the charge distribution of the two independent reactants. E_K has a positive value with regard to the reactions between two closed-shell molecules, serving as a repulsive term. D is the stabilization energy due to the mixing-in of the charge-transferred states, in which one electron of an occupied MO of one molecule is transferred into an unoccupied MO of the other molecule. The last term, Π, contributes to the stabilization resulting from the involvement of the local excited states within one molecule under the influence of the approach of the other. The most preferable reaction path may be defined as the one which makes ΔW the smallest.

In Table 1, the results of the calculation are given with regard to some assumed models of the reaction of the singlet oxygen with ethylene derivatives. By comparing the terms in Table 1, we can see, first, that E_Q is zero, for the singlet oxygen has no net charge on both nuclei and Π is also small. The superiority or the inferiority of an assumed reaction path to others is determined essentially by the terms E_K and D. That is, the reaction may favorably proceed through a geometry capable of enlarging the D term and of depressing the E_K term. Accordingly, IA and IB can be expected to be more favorable than others. It is, however, noteworthy that the model IIIB has a re-

latively low ΔW, implying a tendency toward a biradical-like character of the reactions.

In order to examine E_K and D in detail, it is worthwhile to look into the overlap integrals between the MO's of oxygen and ethylene (given in Table 2), since both the energy terms, E_K and D, are overlap-dependent quantities. Roughly speaking, E_K is parallel to the overlap integrals between the occupied MO's of oxygen and the occupied MO's of ethylene, while D increases as the magnitueds of the overlap integrals increase between the occupied MO's and the unoccupied MO's of the two species. With this as well as the orbital symmetry in mind, we will compare the values of the overlaps, especially with regard to two different models, IB and IIIA.

Among the overlaps, some larger values are found, in which the HOMO, denoted by π, of ethylene, participates. This π orbital, having a large extension in the direction of the singlet oxygen, can overlap with the MO's of the oxygen with a suitable symmetry property, that is, σ_g and π_u in the model IIIA, and all the MO's in the model IB except for $1\pi_u$ and $1\pi_g$ having an extension of the lobes perpendicular to the π orbital of ethylene. The overlap integrals between the π MO of ethylene and $2\sigma_u$, $1\pi_u$, and $3\sigma_g$ of the singlet oxygen in the model IIIA are larger than the corresponding ones in the model IB. This presumably results from the difference in the geometry of the assumed models. In the model IIIA, the relevant orbital lobes extend face to face with each other, while, in the model IB, only a terminus of singlet oxygen can be effectively involved in the orbital overlapping. It follows that, though the π of ethylene can overlap with more MO's of the singlet oxygen in IB than in IIIA, the absolute values are smaller. In addition, since, in the model IIIA, there are considerably large overlap integrals between σ_2 of ethylene and the σ_u and π_g of the singlet oxygen, as well as the accumulating contributions of the other modes of exchange interaction, a larger value of E_K results in IIIA compared with that in the IB model. The sum of the squares of the overlap integrals between the occupied MO's of ethylene and the occupied MO's of the singlet oxygen was calculated to be 1.31×10^{-3} in the model IB and 1.84×10^{-3} in the model IIIA. Therefore, the preference of the model IB to the model IIIA is partly attributable to the smaller occupied-occupied MO interactions, resulting in the smaller exchange energy E_K.

Table 2 gives other valuable information about the orbital interaction between the occupied MO's of one molecule and the unoccupied MO's of the other, that interaction contributing to the stabilization of the system through the delocalization energy, D. That the overlap integral is zero between the LUMO $1\pi_g$ of the singlet oxygen and the HOMO π of ethylene in the IIIA model indicates numerically that this orbital interaction is symmetry-forbidden, as has been described in the previous section of considering orbital interaction. On the other hand, the orbital interaction between the LUMO of ethylene and the HOMO of oxygen is symmetry-allowed. In the model IB, both the HOMO-LUMO interactions are allowed. Although the overlap integral between ethylene π^* and oxygen π_g is a larger value, 0.014, in the model IIIA as compared with the others, this charge-transfer state is located too high ($\sim$9.4 eV) above the initial state. Therefore, this interaction does not contribute very effectively to the stabilization of the reacting system, since the delocalization energy is in inverse proportion to the energy difference. On the contrary, the interaction between the HOMO of ethylene and the LUMO of oxygen is favorable because of the smaller energy difference between this charge-transfer state and the initial state (2.6 eV). As a result, in spite of the smaller value of the overlap integral in the model IB (0.008), this HOMO-LUMO interaction, in which ethylene acts as an electron-donor and the oxygen serves as an electron-acceptor, yields a larger stabilization in the model IB than the HOMO-LUMO interaction in the model IIIA as mentioned above. Thus, the examination of the exchange and delocalization energies in terms of MO overlap integrals reveals the reason for the superiority or inferiority of one assumed reaction path to another.

The HOMO-LUMO interaction reflected by the D term is now found to be most favored in the geometry of the model IB among all the models examined here. On the contrary, the smaller value of E_K for the model IA than for IB reserves the possibility of the preference of IA. Any attempt to reach a conclusive statement about the preference of IA or of IB is futile, since it depends on the subtle balance between D and E_K terms. The most favorable geometry of the transition state can probably be expected

TABLE 3. TOTAL ENERGY EVALUATED BY CNDO METHOD

to assume a nuclear configuration intermediate between IA and IB.

A CNDO[11] calculation was carried out with respect to the six models (IA, IB, IIA, IIB, IIIA, and IIIB) in order to affirm the conclusion drawn from the consideration and the calculation of orbital interaction. As the numerical values in Table 3 show, the nuclear configurations represented by the models IA and IB have lower total energies than the other, corresponding models.[12] In addition, these two models are less destabilized than the others as the two reactants approach further from R=3Å to R=2Å, as is shown in Table 3.[12] This result is in conformity with the prediction of the previous calculation of intermolecular interactions.

Conclusion

The speculative consideration of particular orbital interaction between the frontier orbitals supplies us with some information concerning the modes of interaction between $^1\Delta_g$ molecular oxygen and ethylene derivatives. The finding that the nuclear configuration represented by the model I is energetically favorable for the early-stage interaction between $^1\Delta_g$ molecular oxygen and ethylene is interesting since the way of the approach of a diatomic molecule with the HOMO and the LUMO of the same symmetry to ethylene has now been examined for the first time.

Our present study seems to suggest the presence of a perepoxide intermediate (which may or may not be stable) on the route to the corresponding dioxetane,[14] which is then readily subjected to decomposition into carbonyl compounds.[16] It is also probable that a perepoxide intermediate may be rearranged to allylic hydroperoxide.[17] Alternatively, it is likely that the allylic hydroperoxides are formed through a perepoxide-like transition state.

It may be true that there is some room for reviewing the choices of the models, especially in connection with the intermolecular distances and the changes in the nuclear configurations with the progress of the reaction to be compared, but the essential features of the reactions of $^1\Delta_g$ molecular oxygen with ethylene derivatives, which are derived here from our considerations and from the calculation of the orbital interaction, could not be very much changed by choosing the assumed models. With all the features here revealed, we can say with some certainty that a suprafacial-antarafacial interaction, as in the case of thermal dimerization of ethylene derivatives, is directly inapplicable to the reaction path to dioxetane formation, and that a path *via* a perepoxide intermediate or a perepoxide-like transition state should be carefully examined in discussing not only the steric path to dioxetane, but also the mechanism of hydroperoxide formation.

Electron Spin Resonance during Photolysis of *p*-Benzoquinone and Its Derivatives in Ethanol

Hiroshi YOSHIDA, Koichiro HAYASHI, and Tetsuo WARASHINA*

Faculty of Engineering, Hokkaido University, Sapporo

**Research Reactor Institute, Kyoto University, Kumatori-cho, Osaka*

(Received April 22, 1972)

Electron spin resonance measurements were carried out at room temperature during photolysis of solutions containing *p*-benzoquinone, 2-methyl-*p*-benzoquinone, 2,5-dimethyl-*p*-benzoquinone and 1,4-naphthoquinone in ethanol. From all quinones, the semiquinone radicals and semiquinone anions are found to form simultaneously. When the solution is made acidic, the semiquinone anion transforms into the semiquinone radical, so that the spectrum of the latter is easily determined. For benzoquinone, the semiquinone radical is formed efficiently by light of $\lambda \approx 300$ nm, and has a life of about 0.05 sec. The semiquinone anion is formed by light of $\lambda \approx 460$ nm and is rather long-lived (about 0.5 sec). These results suggest that the semiquinone anion may be formed mostly by photodissociation of charge-transfer complex between benzoquinone and alcohols. Observed proton hyperfine coupling constants were subjected to the molecular orbital treatment. The coupling constants in all the semiquinone anions examined are well interpreted by McLachlan's approximate SCF-MO method and Colpa-Bolton's relation with $Q=27$ G and $K=12.8$ G. However, good agreement is not attained between the observed coupling constants and the calculated ones for the semiquinone radicals.

Semiquinone anions and semiquinone radicals are well known to be involved in both reduction and oxidation processes between quinones and hydroquinones. Since Venkataraman and Fraenkel's pioneering work of detecting electron spin resonance (ESR) spectra of semiquinone anions by oxidizing hydroquinone and durohydroquinone in alkaline solution with oxygen,[1] ESR studies have been extensively made on semiquinone anions formed by oxidizing hydroquiones,[2,3] and by reducing quinones with glucose or sodium dithionite,[3] or electrochemically[4,5] in alkaline solutions. Semiquinone anion was also observed by photolysing duroquinone in the presence of excess alkoxide ion in the solution.[6]

Observed hyperfine structure due to protons in semiquinone anions were first examined with reference to the spin densities calculated from the simple Hückel molecular orbital treatment combined with the McConnell relation.[7] Their observed values agreed rather well with the theoretically expected ones, except for methyl-substituted benzosemiquinone anions.[3,8] The hyperfine coupling constants were found to be affected, more or less depending on the position of proton, by solvent,[4] which was interpreted as due to the complexing between the oxygen atoms in the semiquinone anion and the solvent molecules, using the approximate SCF-MO method developed by McLachlan[9] to estimate the spin densities with the Coulomb integral of oxygen atoms and the resonance integral of C–O bond as adjustable parameters.[5,10] Later, this solvent effect was elucidated from the hyperfine structure due to ^{13}C nuclei.[11,12]

By means of flash photolysis, Bridge and Porter first observed semiquinone anions and radicals as intermediate entities formed in the solutions of many quinones.[13] Photolysis was found to be a convenient and useful way to form semiquinone radicals for ESR studies. Gough and Symons detected ESR spectra of *p*-benzosemiquinone[14] and durosemiquinone radicals[6,15] and described the dependence of their hyperfine structure upon the nature of the solvent by the valence-bond treatment. They reported that the semiquinone radicals or anions were observable depending on pH of the solutions. Recently, Wilson[16] examined the hyperfine structure of his spectrum of *p*-benzosemiquinone radical in photolyzed dimethoxyethane solution in reference with the McLachlan's SCF-MO calculation of spin densities and excess charges and Colpa and Bolton's relation[17] instead of the McConnell's.

The present authors studied the kinetical behavior of free radicals formed during photolysis of benzophenone solution in alcohols by using a flow-technique combined with ESR.[18] Here, this study is extended to solutions of *p*-benzoquinone and its derivatives in alcohols, mainly ethanol, and it is found that both semiquinone radicals and anions are formed simultaneously in neutral solution. The mechanism of

their formation is examined in detail for *p*-benzoquinone. The observed hyperfine structure due to protons is discussed for all quinones examined in terms of the McLachlan's MO treatment and the Colpa and Bolton's relation.

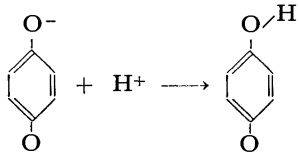
Experimental

The apparatus used has been described in detail previously.[18] ESR measurements were carried out with a conventional X-band spectrometer (Varian, E-3) during photolysis with a super-high pressure mercury arc (Philips, SP 500) of solutions from which dissolved oxygen was removed by bubling helium gas beforehand. The effective volume of a quartz flat cell was $7 \times 0.2 \times 32$ mm.

All chemicals were analytical grade and used as received without further purification, except where otherwise stated.

Results and Discussion

Formation and Decay of p-*Benzosemiquinone Anions and Radicals.* When the solution of *p*-benzoquinone in ethanol is photolyzed, the ESR signal as shown in Fig. 1a is observed. Apparently, the signal is composed of an quintet spectrum and that of triple double-triplet. The former is attributed to *p*-benzosemiquinone anion with four equivalent protons, while the latter is due to *p*-benzosemiquinone radical (monoprotonated benzosemiquinone). If the solution is made acidic by adding a small amount of acetic acid, almost all of the semiquinone anion transforms into the semiquinone radicals as expected from the observation in the flash photolysis study,[13] through the protonation reaction,



(1)

though a weak spectrum of the semiquinone anion is still observable (see Fig. 1b). The observed concentration of the semiquinones is of the order of 10^{-6} M. The half-life is found, by shutting off and flashing the photolyzing light rapidly, to be a few hundreds milliseconds for the semiquinone anion and less than one hundred milliseconds (the response time of the spectrometer) for the semiquinone radicals in the absence of acetic acid.

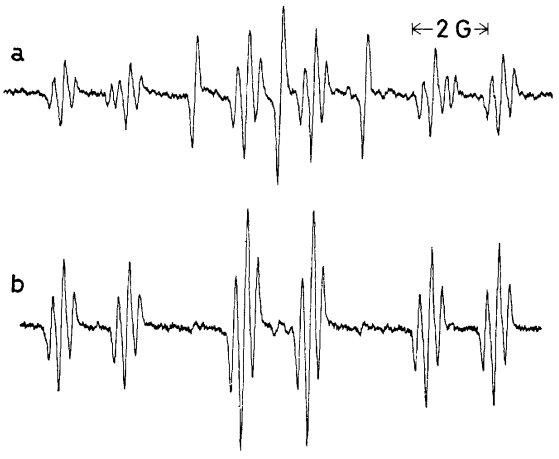


Fig. 1. ESR spectra observed during photolysis of *p*-benzoquinone solution in ethanol (5.5 mM). (a) Spectra due to benzosemiquinone radical (triple double-triplets) and due to benzosemiquinone anion (quintet) formed in neutral solution. (b) Spectrum due to benzosemiquinone radical in acidic solution containing 30 mM of acetic acid.

The temperature dependence of the yield was examined for both anion and radical at a fixed flow rate of solution, and the results are shown in Fig. 2 for methanol and in Fig. 3 for ethanol as solvent. The yield of anion decreases with increasing temperature, while that of radical remains almost unchanged. The dependence of yield upon the resident time of solution in the cell (the effective volume of the cell/the flow rate) is examined for the solution in methanol, as shown in Fig. 4. As the solution is heated during photolysis, its temperature varys depending on the flow rate. In Fig. 4, the observed values are plotted after correcting the temperature effect by using the relationship between the yield and the temperature shown in Fig. 2. The observed yield of anion increases remarkably with increasing the resident time of solution, reaching at a plateau value. This suggests that the life time of

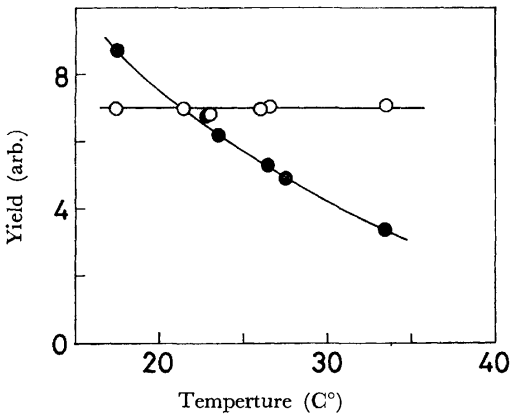

Fig. 2. Observed yield of benzosemiquinone radical (○) and benzosemiquinone anion (●) formed during photolysis of *p*-benzoquinone solution in methanol (5.5 mM) as a function of temperature. Resident time of flowing solution in the cell: 1.1 sec.

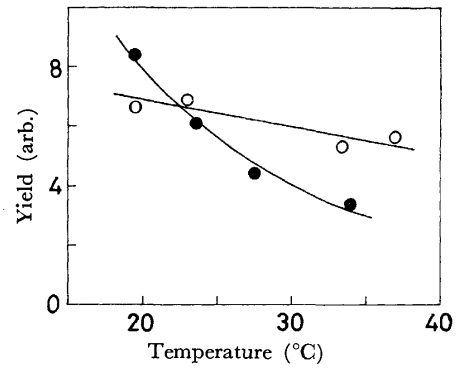

Fig. 3. Observed yield of benzosemiquinone radical (○) and benzosemiquinone anion (●) formed during photolysis of *p*-benzoquinone solution in ethanol (5.5 mM) as a function of temperature. Resident time of flowing solution in the cell: 1.5 sec.

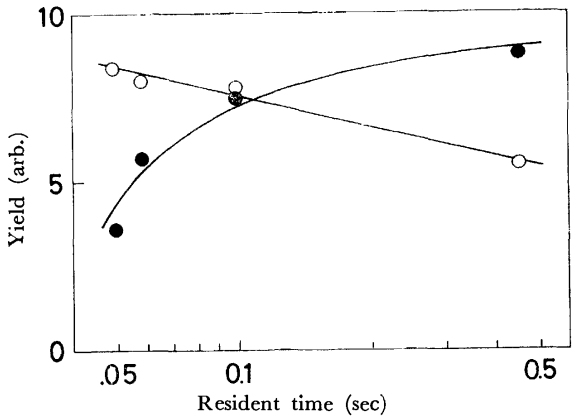

Fig. 4. Dependence of the yield of benzosemiquinone radical (○) and benzosemiquinone anion (●) formed during photolysis of *p*-benzoquinone solution in ethanol (5.5 mM) upon resident time of flowing solution in the cell. Observed values were plotted after the correction of temperature effect.

the anion is rather long (~0.5 sec) and that a fraction of the anions flow out of the cell before their chemical decay. On the other hand, the radical yield decreases with increasing resident time, and the reason is not known at the moment. This trend indicates, at least, that the radical formed disappears in the cell and that its life time is less than 0.05 sec. The above observation of the yields may indicate that the fate of anion, from its formation till disappearance, is independent of the radical in neutral solutions.

In order to elucidate the above argument, the effect of wavelength of the light on the formation of anion and radical was examined by inserting a cut-off filter in the light path. The results are shown in Fig. 5, where the abscissa indicates the wavelength of 50% transmission of filters used and the plots at 270 nm represent the observed yield for the photolysis without filter. The free radical is formed efficiently with light of $\lambda<300$ nm, whereas the anion is formed with light of $\lambda\approx460$ nm. The initial faint decrease in the yield of anion at $\lambda=270-310$ nm may be interpreted by the process,

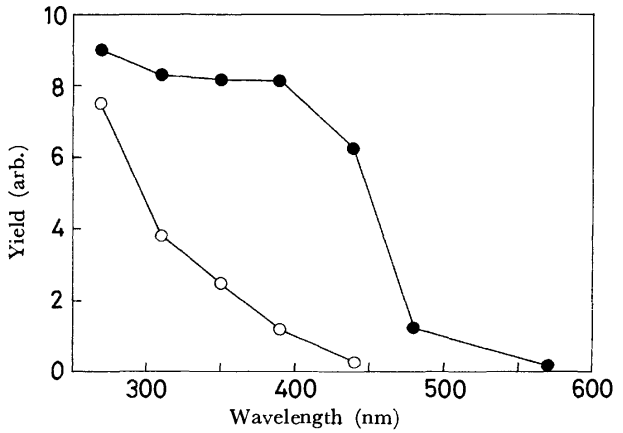

Fig. 5. Dependence of the yield of benzosemiquinone radical (○) and benzosemiquinone anion (●) formed during photolysis of *p*-benzoquinone solution in ethanol (5.5 mM) upon the wavelength of light.

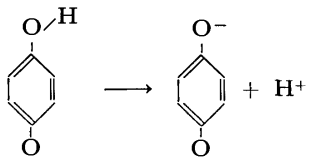

(2)

However, the anion forms mostly for the wavelength appreciably longer than that for the formation of the radical.

The previous results of the flash photolysis study indicated that the primary process in the photolysis of duroquinone was the hydrogen abstraction of the singlet excited quinone to form semiquinone radical. However, in ethanol solution, formation of the semiquinone anion other than in process (2) was also suggested to occur.[13] In the present ESR study, the semiquinone anion is found not to form through the semiquinone radical, by using a selective wavelength of photolyzing light.

If electron transfer occurs directly from the solvent to *p*-benzoquinone under the light of $\lambda\approx460$ nm, the charge transfer interaction between *p*-benzoquinone and the solvent is necessarily involved so that the photo-excited electron donor and acceptor complex dissociates into ions. The efficiency of semiquinone anion formation did not change, though the ethanol was purified by distilling with concentrated sulfuric acid, refluxing with silver nitrate and sodium hydroxide and distilling again. Using dichloromethane as a solvent, the semiquinone radical is observed but the semiquinone anion is not. According to these results, the photo-excited quinone-alcohol complex probably dissociates to form the semiquinone anion, though the possibility cannot be excluded at this moment that some impurities in ethanol play an important role in the formation of the semiquinone anion.

An alternative interpretation is that the *p*-benzohydroquinone formed by disproportionation of the semiquinone radical[13] photo-dissociates to form the semiquinone anion. As a matter of fact, when the solution of *p*-benzohydroquinone in ethanol is photolyzed, an intense ESR spectrum of *p*-benzosemiquinone anion is observed, while the spectrum of semiquinone radical is so weak that it may be ignored. In this case, the question still remains as to why the hydroquinone dissociates to form the anion rather than to form the radical.

For all quinones examined, 2-methylbenzoquinone, 2,5-dimethylbenzoquinone and 1,5-naphthoquinone, corresponding semiquinone anions are observed in addition to semiquinone radicals.

Observed Hyperfine Coupling Constants. Proton hyperfine coupling constants in *p*-benzosemiquinone anion have been reported by several workers[1,2,19] in protic solvent, and the reported values are all very close to 2.368 determined by Venkataraman *et al.*[2] As it is independent of temperature in the range examined (18—36°C), this value was taken as a reference to determine hyperfine coupling constants in other semiquinones studied in the present investigation.

19) D. C. Reitz, F. Dravnieks, and J. E. Wetz, *J. Chem. Phys.*, **33**, 1880 (1960).

Table 1. Observed proton hyperfine coupling constants of *p*-benzosemiquinone radical

Solvent	Temperature	Hyperfine coupling constant (G)		
		2 Ring protons	2 Ring protons	Hydroxy proton
Ethanol	19°C	0.29	5.09	1.86
	26°C	0.31	5.11	1.84
	36°C	0.34	5.21	1.81
Dichloromethane	34°C	0.85	5.64	1.40

Observed hyperfine coupling constants for the benzosemiquinone radical are summarized in Table 1. Their values in ethanol are compared with the values reported by Gough.[14] They are found to be a little dependent on temperature; the coupling constants of ring protons increase with increasing temperature, whereas that of the hydroxy proton decreases. Such a trend agrees with what was observed by Wilson[16] for the radical in dimethoxyethane as solvent.

Figure 6a and 6b show the ESR signals observed from neutral and acidic solution of 2-methylbenzosemiquinone in ethanol, respectively. Evidently, 2-methylbenzosemiquinone anion and some free radical are formed simultaneously in neutral solution, as in solution of *p*-benzoquinone. Venkataraman *et al.* reported hyperfine coupling constants of 2.462, 2.537 and 1.764 G for the ring protons and 2.045 G for the methyl protons, for 2-methylbenzosemiquinone anion.[2] Although the signal in Fig. 6a is complex because of overlapping spectra, almost all hyperfine lines of the anion spectrum are seen at the position expected from the reported coupling constants. Separation between the outer most line (indicated by arrows) is measured to be 12.9 G, which agrees very well with 12.898 G, the sum of all hyperfine separation.

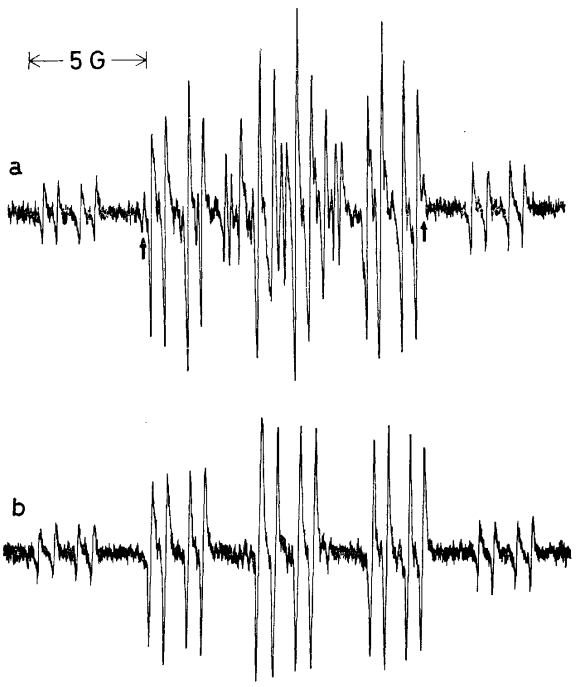

Fig. 6. ESR spectra observed during photolysis of 2-methyl-*p*-benzoquinone solution in ethanol (4.9 mM) (a) in the absence and (b) in the presence of 30 mM of acetic acid.

If the solution is made acidic, the signal becomes much simpler and only a spectrum of the quintet of double-doublet is observed. It may be ascribed to a neutral free radical. However, the number of protons involved is six, which indicates that the spectrum is not due to the semiquinone radical (monoprotonated 2-methylbenzosemiquinone). Although this interpretation has not yet been made, the observed hyperfine coupling constants are 5.00 (4 protons), 1.72 and 0.71 G at 24°C.

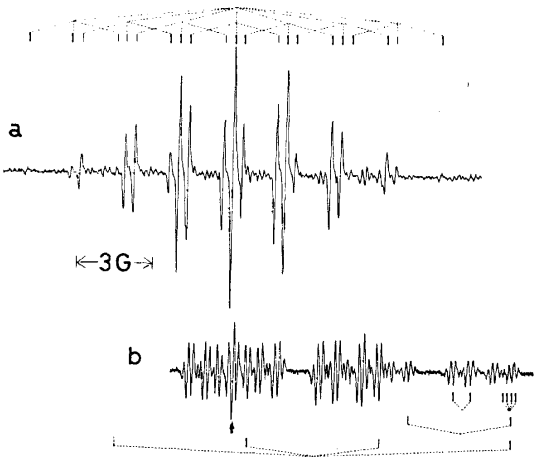

Fig. 7. ESR spectra observed during photolysis of 2,5-dimethyl-*p*-benzoquinone solution in ethanol (4.4 mM) (a) in the absence and (b) in the presence of 30 mM of acetic acid.

The ESR signal observed from the neutral solution of 2,5-dimethylbenzoquinone is shown in Fig. 7a. In addition to a very weak spectrum, the spectrum of septet of triplet (indicated by sticks) is observed and reasonably attributed to 2,5-dimethylbenzosemiquinone anion. The observed hyperfine coupling constant of 1.83 G due to the ring protons and that of 2.25 G due to the methyl protons are in good agreement with the values reported previously.[2] Figure 7b shows the spectrum observed from the acidic solution, which has hyperfine structure due to three unequivalent protons (4.32, 1.70 and 0.71 G) and two kinds of methyl protons (5.18 and 0.20 G at 18°C) attributable to the 2,5-dimethylbenzosemiquinone. The weak background spectrum in Fig. 7a looks like the spectrum due to the semiquinone radical. Therefore, both the semiquinone radical and anion are also formed simultaneously in the neutral solution of 2,5-dimethylbenzoquinone.

ESR signals observed from 1,4-naphthoquinone show a rather complex feature, because they are sometimes recorded as emission lines depending on the measuring conditions and will be reported in detail elsewhere.[20] In this case, the 1,4-naphthosemiquinone radical and anion are also formed simultaneously in neutral solution, but their spectra are separable by referring to the spectrum from the acidic solution.

Wertz and Vivo[21], and Adams *et al.*[22] reported poor resolved spectra of the nephthosemiquinone anion, and later Venkataraman *et al.* suceeded in observing its spectrum with well resolved hyperfine structure.[2] The present observation (see Table 2) is in good agreement with those previously reported. The observed hyperfine coupling constants for the naphthosemiquinone radical are 6.80, 1.63 (2 protons), 1.50, 0.34 and 0.17 G (2 protons) at 34°C.

Molecular Orbital Calculation. The observed spectra of semiquinone anions and semiquinone radicals indicate well resolved hyperfine structure and, therefore, may be compared to molecular orbital calculations. Vincow and Fraenkel examined the observed hyperfine coupling constants of semiquinone anions with reference to the simple Hückel MO calculations and obtained a good agreement between the observed coupling constants and expected ones.[3] However, Brandon and Lucken claimed that the agreement was obtained not only for a unique pair but also for several pairs of parameters, the Coulomb integral of the oxygen atom and the resonance integral of the carbon-oxygen bond, in the frame of the simple Hückel MO calculations.[23] In the present investigation, McLachlan's approximate SCF-MO method[9] with a value of 1.2 for λ was used to calculate spin densities, ρ_i, and excess charge densities, ε_i. Colpa and Bolton[17] suggested the dependence of isotropic hyperfine coupling constants in hydrocarbon radical anions and cations upon the excess charge density, and postulated the relation, $a_i^H=(Q+K\varepsilon_i)\rho_i$. According to the observed spectra of radical ions of anthracene, Bolton and Fraenkel suggested −27 and −12.8 G for Q and K,[24,25] which were used in the present investigation. Calculations were made with FACOM 230—60 computer of Hokkaido University Computing Center.

For *p*-benzosemiquinone and 1,4-naphthosemiquinone anions, computations were carried out with adjustable parameters γ_{CO} and δ_O ($\alpha_O=\alpha+\delta_O\beta$ and $\beta_{CO}=\gamma_{CO}\beta$ where α and β are the Coulomb and resonance integral for carbon atoms and carbon-carbon bond) for the carbonyl group. In the range of 0.3—3.0 and 0.3—2.0 for δ_O and γ_{CO} (with the interval of 0.05 units), respectively, the best agreement is obtained between the observed hyperfine coupling constants and calculated ones with the values of $\delta_O=1.2$ and $\gamma_O=1.3$, as shown in Table 2.

Gendell *et al.*[10] obtained the best agreement with $\delta_O=1.6$, $\gamma_{CO}=1.55$ and $\lambda=1.2$, using the simple McConell relation, $a_i^H=-23.7\rho_i$. Therefore, it is indicated that the smaller parameters are more suitable for the Colpa-Bolton's relationship than for McConell's. Das and Fraenkel examined the proton and ^{14}C splittings of *p*-benzosemiquinone and anthrasemiquinone anions with the McLachlan's method of calculating spin densities and the simple McConell's relationship, and found that unique pair of δ_O and γ_{CO} did not interpret well the hyperfine splittings of these semiquinone anions simultaneously.[12] The present results suggest that a unique pair of parameters may interpret the hyperfine splittings of *p*-benzosemiquinone derivatives.

For the methyl substituted benzosemiquinone anions, a conjugative model C-C′-H_3 was considered, and the previously used parameters,[26] $\delta_{H_3}=-0.5$, $\delta_{C'}=-0.1$,

26) R. Wilson, *Can. J. Chem.* **44**, 551 (1966).

$\gamma_{C'-H_3}=2.5$ and $\gamma_{C'-C}=0.9$, were used. The calculated coupling constants of the ring protons agree rather well with the observed ones for dimethyl-*p*-benzosemiquinone and methyl-*p*-benzosemiquinone anions.

For semiquinone radicals, the agreement between experimental results and the molecular orbital calculations has not been attained satisfactorily. Any combinations of the parameters for hydroxy group ($\delta_O=$ 0.3—3.0 and $\gamma_{CO}=0.3$—1.7) do not account for the observed proton hyperfine coupling constants in the *p*-benzosemiquinone radical and those in the naphthosemiquinone radical simultaneously, if the parameters for the carbonyl group are fixed to the values determined above for the semiquinone anions. The replacement of one of the carbonyl groups in the semiquinone anions with a hydroxy group may cause the decrease in the electronic charge on the other carbonyl group, which requires a set of parameters for the carbonyl group in the semiquinone radicals different from that in the semiquinone anions. This may be one of the possible reasons why the satisfactory resutls have not been obtained in the MO calculations for the semiquinone radicals.

Conclusion

Photolyzing the solutions of *p*-benzoquinone, 1,4-naphthoquinone, 2-methyl-*p*-benzoquinone and 2,5-dimethyl-*p*-benzoquinone in alcohol at room temperature, the short-lived semiquinone anions and radicals were observed simultaneously by ESR measurements, combined with a flow technique. Although a fraction of the semiquinone radicals possibly transforms into the semiquinone anion, the latter is mostly formed directly from the solute.

The proton hyperfine coupling constants were determined for the semiquinone anions and radicals except for those from 2-methyl-*p*-benzoquinone. For the semiquinone anions, the observed coupling constants agree well with those computed from the McLachlan's approximate SCF-MO method and the Colpa-Bolton's relationship between the coupling constants and the spin densities and excess charge densities.

The authors express their sincere thanks to Prof. T. Higashimura for giving the opportunity to use the experimental facilities.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3520—3526 (1972)

Positive Charge Distribution of Secondary Alkylamines and Its Correlation with the Bond-Scission Probability Appearing in Their Mass Spectra[1]

Masao YAMAMOTO, Iwao FUJITA,* Michiyasu ITOH,*,[2] and Kozo HIROTA*,[3]

(Received April 24, 1972)

With respect to the correlation between scission probabilities and positive charge distributions on the skeletal bonds of amines appearing in their mass spectra, further research is reported on four secondary amines (diethylamine, dipropylamine, dibutylamine and methylbutylamine). In each secondary alkylamine the fragment ions formed by the scission of α–CC bond are the most abundant experimentally, *i. e.*, the scission probability of α–CC bond is the largest in monoamines as well. Agreement between experiments and LCBO-MO calculations on four secondary alkylamines is found to be satisfactory as in the case of propylamine, using the same semi-empirical parameters as those of monoamines in the calculation. It is shown that from detailed calculations of diethylamine by CNDO method the scission of α–CC bond is also easy due to concentration of the positive charge at the bond, theoretically in accordance with the semi-empirical calculation. Change of mass spectra *vs.* ionizing voltage is explained on a generalized scheme, which combines two existing theories of fragmentation (QET and MOT).

We have shown that the molecular orbital theory (MOT) for mass spectra can explain quantitatively the skeletal fragmentation of compounds such as normal[4] and cyclic alkanes,[5] ketones,[6] amines,[7] ethers,[8] esters[9] and aminoacid esters.[10] In MOT it is assumed that relative scission probability of each skeletal bond of of the electron-bombarded molecule is proportional to the positive charge distribution of the highest occupied molecular orbital (HO-MO) at the corresponding bond of its molecular ion, where the positive charge distribution means the distribution of the positive hole formed by losing an electron from the HO-MO of the neutral molecule. Thereby, knowledge of the con-

stants characteristic to each functional group is required for calculation of the HO-MO, except for normal and cyclic alkanes.

As far as the mass spectra of the normal and cyclic alkanes are concerned, the above assumption seems to be acceptable.[11] Several comments have been given on the use of the assumption for predicting the mass spectra of the compounds containing heteroatoms. Lorquet et al.[12] criticized the use of calculated results of alkylamines based on the LCBO-MO approximation in our attempt to extend the research to normal alkylamines, *i. e.*, although the positive charge densities at the CN bond and lone pair are 16% and 71% of the total, respectively, only that at the CC bond is taken in discussing the scission probability. In the LCBO-MO approximation, however, the positive charge distribution of the lone pair is included implicitly in that of the CN bond, so that net charge distribution at the CN bond might occupy only a small fraction of the total and be even smaller than that of the α-CC bond adjacent to it. We therefore adopted in our previous work on ethylamine and propylamine[13] the CNDO (the complete neglect of differential overlap) method of LCAO-MO-SCF proposed by Pople *et al.*[14] The results were found to be favorable.

In our research[6] on propyl-, butyl-, amyl-, hexyl- and heptylamine, calculation was carried out by the LCBO-MO method, and two parameters concerned with amino group were determined empirically from the observed values of propylamine and butylamine. The parameters were found transferable also in the calculation of alkyldiamines from C_4 to C_7[7b] and aminoacid esters.[10]

We report herewith that a good agreement can be found for four secondary alkylamines between the calculated values obtained by the LCBO-MO method and the observed from mass spectra by use of the two parameters of the primary amines, and also diethylamine by use of the calculated positive charge obtained by the CNDO method.

Calculations

LCBO-MO Method. According to the assumption, the scission probability of the skeletal bonds is proportional to the positive charge densities of the HO-MO of the molecular ion. In actual calculation, the charge densities are assumed to be equal to the electron densities of the corresponding neutral molecule, calculated by the LCBO-MO method. The MO belonging to the skeletal bond Φ is given by

$$\Phi = \sum_{i=1}^{n} c_i \phi_i, \qquad (1)$$

where ϕ_i is the bond-orbital of the i-th skeletal bond. The summation is carried out on all the bond adopting the united atom approximation.[15]

The secular equation of a molecule is

$$|e_{ij} - \delta_{ij}E| = 0, \qquad (2)$$

where e_{ij} denotes the matrix element and E the energy of the molecular orbital. All the interactions except for those adjacent group bonds are assumed to be zero. The required parameters in the calculation are the Coulomb integrals of CN and α-CC bond and resonance integral of CN bond as follows.

$$\alpha_{C-N} = \alpha_0 + 0.5\beta_0,\ \alpha_{C-CN} = \alpha_0 - 2.0\beta_0,\ \beta_{C-N} = \beta_0 \qquad (3)$$

where α_0 and β_0 are the Coulomb integral and the resonance integral of normal alkane, respectively. The parameters in Eq. (3) were determined from the experimental values of propylamine and butylamine.[7a]

CNDO Method. The CNDO method is a semi-empirical LCAO-MO-SCF method calculating molecular orbitals and is known to be applicable to π electrons and lone pair electrons as well as σ electrons. Nine possible conformations of diethylamine and three of methylethylamine were calculated. Atomic distances of both amines were adopted as follows: C-C, 1.540 Å; C-N, 1.474Å; C-H, 1.085Å; N-H, 1.012Å.

Table 1. Matrix elements $U_{\mu\mu}$ (in electron volts)

	H	C	N
s orbital	−7.176	−14.051	−19.316
p orbital	—	−5.572	−7.275

$U_{\mu\mu} = (\mu|-\frac{1}{2}\nabla^2 - Z_A/r_{1A}|\mu)$

All the bond angles were taken to be 109°28′. Atomic integrals necessary in the calculation were the same as in the paper of Pople and Segal[14] (Table 1). In the calculation of electron densities, $2s$, $2p_x$, $2p_y$, $2p_z$, orbitals of nitrogen and carbon atoms were adopted as the basis set of orbitals, which were transformed into sp^3-hybrid orbitals after the calculation.

Experimental

The mass spectra were measured on a high resolution type apparatus (Hitachi RMU-7HR), its resolution being *ca.* 5000, and on an ordinary one (Hitachi RMU-5B) installed at Osaka University. Ionization voltage (V_i) was varied in several steps from 10 to 80 volts, the repeller voltage being fixed at 3 volts. The gas-reservoir temperature was maintained at about the boiling point of each sample during the course of measurement. The compounds studied were diethylamine, dipropylamine, dibutylamine and methylbutylamine.

Results

Mass Spectra of Secondary Amines. The mass spectra of four secondary amines at V_i=80 and 20 volts and abundance ratios of the ions in the main peaks from the high resolution measurement are shown in Tables 2 and 3, respectively.

	$(C_3H_6)^+$			21	31				
43	$(C_2NH_5)^+$			17	4	81	78	86	86
	$(C_3H_7)^+$			83	96	19	22	14	14

The largest peak of each amine arose from the ion formed by the scission of α-CC bond as in primary amines, *i. e.*, diethylamine, *m/e* 58 $(C_2H_5NHCH_2)^+$; dipropylamine, *m/e* 72 $(C_3H_7NHCH_2)^+$; dibutylamine, *m/e* 86 $(C_4H_9NHCH_2)^+$; methylbutylamine, *m/e* 44 $(CH_3NHCH_2)^+$.

From the high resolution mass spectra (Table 3), ions of *m/e* 43 of dipropylamine are found to consist of $(C_2NH_5)^+$ (20%) and $(C_3H_7)^+$ (80%), while in dibutylamine and methylbutylamine the ratios of both ions in *m/e* 43 are the reverse. The differences are caused by the processes giving $(C_3H_7)^+$ such that scission at the CN bond occurs in dipropylamine while at the α-CC bond in the latter two amines.

The peaks derived from the metastable ions and the fragmentation processes are shown in Table 4. The metastable peaks were fairly large (Fig. 1). In primary amines they could not be observed. We see from Table 4 that the ions of *m/e* 30 and *m/e* 44 are assigned to be those formed by secondary scission (except for *m/e* 44 of methylbutylamine). In the case of dipropylamine, after the ion of *m/e* 72 was first formed by the

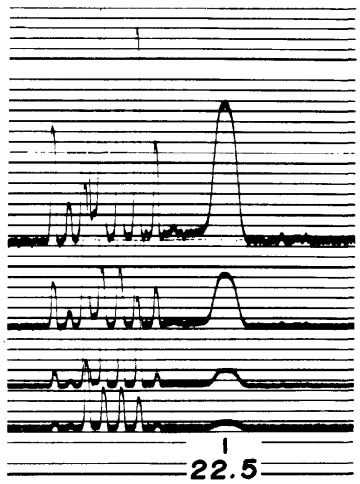

Fig. 1. Metastable peak of dibutylamine.

scission of α-CC bond, the scission at the residual α-CC bond produced the m/e 44 and the successive scission at CN bond produced the m/e 30. Both ions were the rearrangement ions. They did not decrease practically by lowering the ionizing voltage. Thus the phenomenon differs from the case of primary amines.

Scission Probabilities. The observed scission probabilities were evaluated by using ordinary mass spectra and the individual high resolution mass spectra for the necessary ions. As an example, in the case of dipropylamine, it was considered that since the ions of m/e 30 and m/e 44 were formed by the secondary scission of the m/e 72, the ion formed by the scission at the α-CC bond was the sum of the ions of m/e 72, m/e 30 and m/e 44. In the case of methylbutylamine, it was also possible that the ion of m/e 30 was formed by the scission at the CN bond of butyl group. The m/e 30 ion through process A is produced by the primary scission at the CN bond of butyl group (Bond 1) and that through process B is produced by the secondary scission of m/e 72 ion (Bond 1′ and 2).

$$CH_3\overset{1'}{-}NH\overset{1}{-}CH_2\overset{2}{-}CH_2\overset{3}{-}CH_2\overset{4}{-}CH_3$$

$$\nearrow\ (CNH_4)^+\ m/e\ 30 \qquad (A)$$

$$\searrow\ (NHCH_2CH_2CH_3)^+\ m/e\ 72 \rightarrow (CNH_4)^+\ m/e\ 30 \qquad (B)$$

Since the origin of these ions cannot be distinguished experimentally yet, the amount of the ion through process A and that through process B were estimated to be half, assuming that these two processes were brought about in a simillar proportion. The observed values thus estimated are shown in Table 5 in comparison with those calculated by the LCBO-MO method.

The calculated values by the CNDO method are given in Table 6. The subscripts for each carbon atom are the same as those in Fig. 2. The positive charge distributions of the HO-MO of each conformation are shown in %, where the mean value was evaluated on the assumption that the contribution was equal. About 40% of the positive charge is located at the lone pair orbitals. From the table, the positive charge distributions of the HO-MO at the skeletal bonds were calculated by summing up those of the atomic orbitals which constituted the skeletal bonds and normalizing these values. The positive charge distributions concerned with the skeletal bonds are indicated in Fig. 3. The positive charge distribution of the α-CC bond contains about 60% of the total charge, and the expected tendency of easy scission at the α-CC bond is realized experimentally.

Discussion

The Quasi-Equilibrium Theory (QET)[16] and the molecular orbital theory (MOT) for mass spectra deal with an explanation of the production processes of the ions appearing in mass spectra. According to QET, the ions are produced by the thermal unimolecular decomposition of molecular ions in high vibrational excited states by the electron bombardment. According to MOT, they are produced by the autoionization from molecules in the superexcited states by the electron bombardment. As shown by the investigations of Platzman[17] and Hatano *et al.*[18], the ion production from the superexcited state is predominant at the bombarding voltage V_i higher by several volts or above than the ionization potential, while the radical production from the superexcited state is predominant at V_i near the ionization potential. Thus, at lower V_i the ions are produced mostly by the unimolecular decomposition explaned by QET, but at higher V_i they are produced *via* the superexcited state explained by MOT in addition to that by QET.

A comparison of the 30V and 80V-mass spectra shows that the fraction of fragment ion peaks losing many hydrogen atoms such as $(C_2H_3)^+$ and $(C_3H_3)^+$ is large in the 80V-mass spectrum, but there is little in the main peaks of both spectra. From the comparison of 30V and 80V-mass spectra, it is indicated that bombarded molecules absorb energy of about 30 eV, while the difference between 20V and 80V-mass spectra is very large as shown in Table 2, the mass spectra changing markedly for making 30eV the border. This is in line with the result in radiation chemistry whose mean total energy accepted by the molecules bombarded with high energy radiation is about 30 eV. As V_i approaches the ionization potential, the selective scission of the bonds obeying the scheme of QET becomes more predominant, making that of MOT less on the contrary. At higher V_i the scission obeying the schemes of MOT and QET takes place simultaneously, but it might be explained mainly by MOT, its interpretation agreeing with the mass spectra of amines. It can thus be concluded that at V_i near the ionization potential most of the ions are produced by the scheme of QET; the higher V_i, the larger the contribution of the scheme of MOT to production of the ions.

The scission probability calculated by the LCBO-MO method and the experimental results (V_i=80V and 20V) in Table 5 are compared in Fig. 4. The parameters used in the calculation by LCBO-MO method were determined empirically from the mass spectra of propylamine and butylamine. Agreement between calculation and experiment is satisfactory. These findings indicate that the parameters can be transferred to secondary amines. Their transferability is also given in the explanation of aminoacid esters.[10] The present results of diethylamine obtained by the

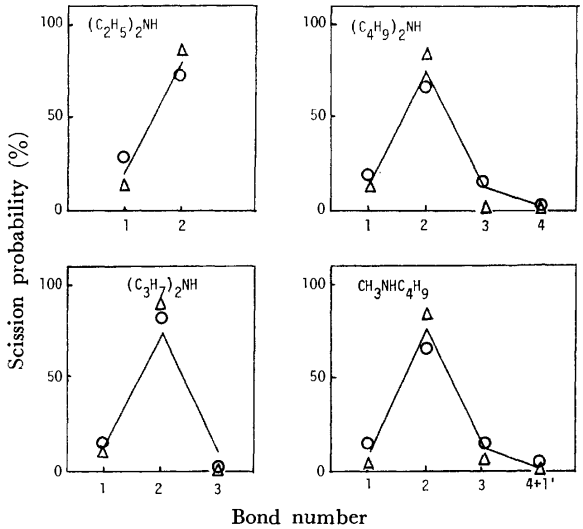

Fig. 4. Scission probability of the skeletal bonds of secondary amines.
○: V_i=80 V., △: V_i=20 V., —: Calcd.

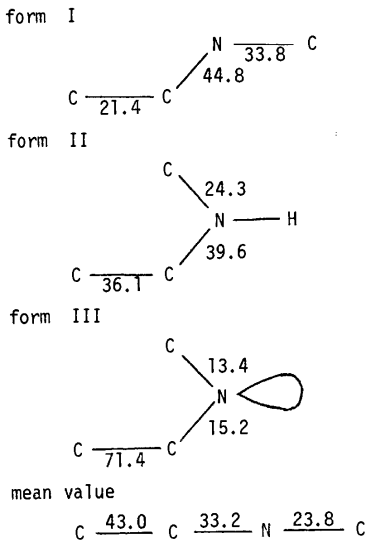

Fig. 5. Positive charge distribution of the HO orbital on the skeletal bond (%).

calculation of the CNDO method offers a good support to the semi-empirical result. Moreover, in the CNDO-calculation of methylethylamine their mean charge density concerning the skeletal bonds is the largest at the α-CC bond (Fig. 5).

Agreement between calculation and experiment is better at higher V_i than at lower V_i in the cases of secondary amines, and the degree of agreement is superior to the case of propylamine. The fragment ions produced by QET and by MOT are observed simultaneouly in mass spectra. The alkanes produce many fragment ions at higher V_i, especially the ions of small carbon numbers such as $(C_2H_4)^+$, $(C_2H_5)^+$, $(C_3H_5)^+$, $(C_3H_7)^+$ which occupy most of the fragment ions. They might be considered to be secondary fragment ions produced by QET. On the other hand, changes of mass spectra against the variation of bombarded voltages are relatively small in these amines. This

suggests that the secondary scission originating successively from the first scission might be very few.

With respect to the production of fragment ions of lower hydrocarbons at the skeletal scission, Stevenson concluded that the fragment with the higher carbon number of the two fragments produced from the molecular ion becomes an ion, while the other becomes a radical.[19] Saito et al.[20] indicated that good correlations existed between the amount of the fragmentions and the positive charge in them for the higher hydrocarbons. Most of the peaks appearing in the mass spectra of amines are originated from the ions containing N-atoms such as *m/e* 30 $(CNH_4)^+$, *m/e* 44 $(C_2NH_6)^+$, *m/e* 86 $(C_3NH_{12})^+$. Positive charges of each group containing those of CH bond, NH bond and lone pair obtained by CNDO-calculations, are given in Fig. 6. When the α-CC bond is broken the positive charge of the fragments containing N-atom occupies 80% in propylamine and 87% in diethylamine. From the experimental results total amount of the fragment ions containing N-atom formed by the scission of α-CC bond occupies 92% in propylamine and 99% in diethylamine. Though the correlation of positive charge *vs.* amount of ions with amines is not so good as with hydrocarbons, it is suggested that the fragment having more charge of the two fragments is liable to become an ion.

Zero-point Average Structure of a Molecule Containing Two Symmetric Internal Rotors. Acetone

Takao Iijima

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received May 18, 1972)

The theory of vibrational correction to the observed moments of inertia of a molecule which contains an internal rotor has been extended to the case of two symmetric internal rotors, and applied to the analysis of the structure of acetone. The zero-point average structure has been determined by using the moments of inertia obtained by microwave spectroscopy and the bond distances from gas electron diffraction. The zero-point average parameters have been determined as follows: C–C 1.517±0.003 Å; C=O 1.210±0.004 Å; C–H 1.091±0.003 Å; ∠HCH 108° 30′±30′; ∠CCC 116° 0′±15′. The isotope effects in the structure parameters have also been observed in terms of the increase caused by deuteration to be δ(DCD) +10′±12′; δ(CCC) −17′±2′. The tilt angle of the methyl top was determined to be 2° 0′±30′.

Large amplitude intramolecular motions give rise to additional complexity in the method of vibrational correction to the rotational constants. This was discussed in some detail in a previous paper, where the theory for a molecule with internal torsion was presented.[1] However, the scope was restricted to the molecule containing only one internal top. In view of ever increasing interest in the accurate structure parameters of many simple molecules which have two internal rotors, the method has been extended to the two-top case, and the zero-point average structure of acetone has been determined. The present study is to replace the previous one on the average structure of acetone,[2] where the torsional motion was treated as a vibrational one.

The treatment is based on a specified condition that the molecule has at least one symmetry plane by which the two tops are exchanged with each other. The restriction is compensated by the simplicity of numerical procedure and the applicability to many two-top molecules.

Theory for the One-top Case[1]

First, a brief survey of the theory for the one-top case seems to be necessary. The essential part of the procedure for vibrational correction is to calculate the effective values of the rotational constants $\sigma_{\alpha\beta}$ which are supposed to differ from the rigid values due to vibrational motions. The theoretical expression for the vibrational correction is therefore characterized by matrices l and n which specify the relations between the normal coordinate Q_s, torsional velocity $\dot{\gamma}$, Cartesian displacement $\boldsymbol{\rho}_i$ and velocity vector $\mathbf{v}_i$ of each atom in the molecule. The relations are

$$\sqrt{m_i}\,\boldsymbol{\rho}_i = \sum_s l_{is} Q_s \tag{1}$$

$$\sqrt{m_i}\,\mathbf{v}_i = \sum_s l_{is}\dot{Q}_s + \sum_s \dot{\gamma} n_{is} Q_s \tag{2}$$

where m_i is the mass of the i-th atom. The components of $\boldsymbol{\rho}_i$ and $\mathbf{v}_i$ are given as projected onto the frame-fixed coordinate axes, the matrix element n_{is} vanishing for the atoms belonging to the frame.

The four dimensional moments of inertia tensor, for three angular velocities of overall rotation and an additional one of the torsional motion, are calculated in terms of l and n for an instantaneous situation where only the s-th normal coordinate Q_s has a non-zero value. It may be denoted by $I(Q_s)$. A slightly modified inertia tensor I' is set up as

$$I'(Q_s)_{\alpha\beta} = I(Q_s)_{\alpha\beta} - \sum_{s'} \zeta^{(\alpha)}_{ss'}\zeta^{(\beta)}_{ss'}Q_s^2 \tag{3}$$

in order to make conversion of the velocity representation of the kinetic energy into the momentum representation.[3] The zeroth and first order term of the rotational constants can be obtained by taking the inverse of I'. The averaging over the ground vibrational state and appropriate repetition of the process over all normal coordinates are performed according to the equations

$$\sigma_{\alpha\beta} = \sigma^{(0)}_{\alpha\beta} + \sigma^{(1)}_{\alpha\beta} + \sigma^{(2)}_{\alpha\beta} \tag{4}$$

$$\sigma^{(0)}_{\alpha\beta} + \sigma^{(1)}_{\alpha\beta} = \sum_s \frac{1}{2}\{\mu_{\alpha\beta}(D_s) + \mu_{\alpha\beta}(-D_s)\} \tag{5}$$

$$\sigma^{(2)}_{\alpha\beta} = -\sum_{ss'}\frac{D_s^2}{2}\cdot\frac{(\omega_s-\omega_{s'})^2}{\omega_{s'}(\omega_s+\omega_{s'})} \times \sum_{\alpha'\beta'}\zeta^{(\alpha')}_{ss'}\zeta^{(\beta')}_{ss'}\mu^0_{\alpha\alpha'}\mu^0_{\beta\beta'} \tag{6}$$
$$(a, \beta, \alpha', \beta' = x, y, z, \gamma)$$

where D_s is the root mean square value of Q_s and μ is the inverse of I'.

The elements of I and ζ for the principal axis components are given by ordinary expressions, and the γ-components are given by the following.[1]

$$I_{\tau\tau} = J_{\tau\tau} + \sum_i (n_{is}\cdot n_{is})Q_s^2 + 2\boldsymbol{\lambda}\cdot\sum_i(\Lambda_{is}\times n_{is})Q_s^2 \tag{7}$$

$$I_{\tau\alpha} = \lambda_\alpha J_{\tau\tau} + \sum_i (l_{is}\times n_{is})_\alpha Q_s^2 - (\boldsymbol{\lambda}\times L_{R's})_\alpha Q_s \tag{8}$$
$$(\alpha = x, y, z)$$

$$\zeta^{(\tau)}_{ss'} = \boldsymbol{\lambda}\cdot\sum_i(\Lambda_{is}\times l_{is'}) + \sum_i n_{is}\cdot l_{is'} \tag{9}$$

where all notations follow Ref. 1, and the subscript i runs over the atoms belonging to the top. $J_{\tau\tau}$ is the geometrical moment of inertia of the top around its axis where the vibrational displacement of each atom due to Q_s is taken into account; $L_{R's}$ is the L matrix which relates the symmetry coordinate of the infinitesimal rotation of the top to the Q_s and Λ_{is} is the l-matrix relative to the center of gravity of the top.

Extension of the Method to the Two-top Case

The angular velocity vector ω for a two-top molecule consists of five components, three for the overall rotation and two for the torsinal motions. Accordingly the tensors of moments of inertia and rotational constants are (5×5) dimensional ones. The $\zeta_{ss'}$ also has five components.

Eq. (1) is still valid for the relation between the frame-fixed Cartesian displacement $\boldsymbol{\rho}_i$ and Q_s, and so is the time derivative Eq. (2). It is obvious that the $\mathbf{v}_i$ for an atom of top 1 is independent of the torsional velocity of top 2, and *vice versa*. It is thus concluded that the elements of I-tensor and ζ are given by exactly the same expressions as Eqs. (7), (8) and (9), if the numbering of atoms i covers top 1 for the $\gamma_1\alpha$-components and top 2 for the $\gamma_2\alpha$-components. The $\gamma_1\gamma_2$-term of I does not appear.

The (4×4) part of the (5×5) I-tensor can therefore be obtained by making full use of the routine procedure for the one-top case, where one of the two tops, *e. g.* top 2, is included in the frame group, both γ_2 and $\dot{\gamma}_2$ being put equal to zero. The remaining $\gamma_2\alpha$-components can be obtained by simple symmetry consideration.

Top 1 is transferred to top 2 by symmetry operation σ_h. If atom i_1 of top 1 is transferred to atom i_2 of top 2 by σ_h, every component of $l_{i2,s}$ projected onto the principal axes x, y, and z is equivalent either to that of $l_{i1,s}$ or $-l_{i1,s}$ depending on the symmetry of the s-th normal coordinate. Consistency between the direction of torsinal motion for positive γ and the direction of the unit vector λ should be maintained within each top in such a manner that clockwise rotation around λ facing towards its direction is the motion corresponding to positive γ. However, arbitrary choice is allowed for the symmetry property of one of them in relation to the transference between the two tops. In the present treatment, λ is taken to be symmetric to σ_h. Then γ becomes anti-symmetric with respect to σ_h. By choosing the yz-plane to be the plane of symmetry and the x-axis perpendicular to it, the symmetry property of l_{is} and that of n_{is} *etc.* are easily obtained as summarized in Table 1. The entry $-$, for example, in column (x) for l_{is} means that $l^{(x)}_{i2,s}$ is equal to $-l^{(x)}_{i1,s}$, and so on.

Table 1. Symmetry properties of l_{is}, Λ_{is}, n_{is} and $L_{R's}$

	l_{is} and Λ_{is}			n_{is} and $L_{R's}$		
	(x)	(y)	(z)	(x)	(y)	(z)
$s\subset A'$	$-$	$+$	$+$	$+$	$-$	$-$
$s\subset A''$	$+$	$-$	$-$	$-$	$+$	$+$

By means of Eqs. (7), (8) and Table 1, the $\gamma_2\alpha$-components of I-tensor can be related to those of $\gamma_1\alpha$-components, simply as

$$I(Q_s)_{\tau 2,x} = -I(Q_s)_{\tau 1,x} \tag{10}$$

$$I(Q_s)_{\tau 2,\alpha} = I(Q_s)_{\tau 1,\alpha} \quad \text{for } \alpha = y \text{ and } z, \tag{11}$$

and

$$I(Q_s)_{\tau 2,\tau 2} = I(Q_s)_{\tau 1,\tau 1} \tag{12}$$

if Q_s belongs to the symmetry species A' which is symmetric with respect to σ_h. If Q_s belongs to A'', the Q_s on the right-hand side of the above equations should be replaced by $-Q_s$. Changing the sign of Q_s is relevant to the term linear in Q_s and also to $J_{\tau\tau}$ and λ_α which implicitly contain terms linearly dependent on Q_s.

3) E. B. Wilson, Jr. and J. B. Howard, *J. Chem. Phys.*, **4**, 260 (1936).

Similarly, $\zeta_{ss'}^{(\gamma 2)}$ is given by

$$\zeta_{ss'}^{(\gamma 2)} = \zeta_{ss'}^{(\gamma 1)}, \text{ if } s \subset A', s' \subset A'' \text{ and } \textit{vice versa} \quad (13)$$

and

$$\zeta_{ss'}^{(\gamma 2)} = -\zeta_{ss'}^{(\gamma 1)}, \text{ if } s \subset A', s' \subset A' \text{ or } s \subset A'', s' \subset A'' \quad (14)$$

The second term of Eq. (3) and $\sigma_{\alpha\beta}^{(2)}$ of Eq. (6) are thus easily calculated in terms of $\zeta_{ss'}^{(\gamma 1)}$ and the above symmetry rule.

The symmetry property of $\zeta_{ss'}^{(\gamma)}$, combined with the non-vanishing conditions (Table 2) leads to the symmetry properties of the second term of Eq. (3) and that of $\sigma_{\alpha\beta}^{(2)}$ of Eq. (6). The result is simply that the sign should be changed only for the x-components and otherwise equivalent to the corresponding $\gamma_1\alpha$-terms. The $\gamma_1\gamma_2$-term of I' is not necessarily zero in contrast to that of I.

Table 2. Non-vanishing conditions for $\zeta_{ss'}^{(\alpha)}$

(x)		(y)		(z)		(γ)	
s	s'	s	s'	s	s'	s	s'
A'	A'	A'	A''	A'	A''	A' or A''	A' or A''
or							
A''	A''		*vice versa*				

The whole symmetry consideration may be stated in a more compact way as follows. The γ_2-components of I' and $\sigma_{\alpha\beta}^{(2)}$ tensors are obtained by applying a symmetry operation σ_h to the γ_1-components. The symmetry operation σ_h implies change of the sign of Q_s, if Q_s, is anti-symmetric to σ_h and change of the sign of γx-components. Naturally the new cross terms, $\gamma_1\gamma_2$-elements, can not be covered by this symmetry operation.

Zero-point Average Structure of Acetone

Zero-point Moments of Inertia and Angle between the two Top-axes. The formulation was applied to the determination of the zero-point average structure of acetone which has two internal rotors. The microwave spectra of this molecule and those of isotopic species were investigated by Nelson and Pierce.[4] The spectra of the d_6-species were observed by Swalen and Costain.[5]

The vibrational correction was calculated by assuming an appropriate set of structure parameters and by use of the force constants determined by Cossee and Schachtschneider.[6] The observed moments of inertia, the corrections for the vibrational effect and the zero-point values are listed in Table 3 for the normal and the d_6-species. The microwave data of $(^{13}CH_3)_2CO$ and $(CH_3)_2C^{18}O$ were also used. The vibrational corrections for these species were almost equivalent to those of the normal species.

The direction cosines of the top-axes λ_a and λ_b were determined from the parameters α and β reported by Nelson and Pierce.[4] The effective values of λ_a and

Table 3. Effective and zero-point moments of inertia of acetone. (in amu Å^2 units)

		I^{eff} a)	ΔI	$I^{(z)}$

	γ	(6.398) b)	−0.094	6.304

a) Determined by Nelson and Pierce.[4]
b) Estimated from $I_\gamma^{(z)}$.

λ_b were obtained by the relation

$$\frac{\beta}{\alpha} = \frac{\lambda_b I_a}{\lambda_a I_b} \quad (15)$$

which is derived from the definitions of α and β, and the constraint $\lambda_a^2+\lambda_b^2=1.0530$ for the normal species and 1.0352 for the d_6-species. The ratio β/α was used as an experimental value, since it is independent of I_τ, the effective moment of inertia of methyl top around its axis, and might be free from possible systematic errors introduced in the course of the barrier height analysis.

The effective values were then converted into the zero-point values by corrections which were evaluated by the model calculation for the vibrational effect. The zero-point value of the angle between the two top-axes $2\theta_z$ was then evaluated to be $120.0\pm0.4°$ for both normal and d_6-species. The two values of $2\theta_z$ obtained from λ_a and λ_b were in excellent agreement with each other within 0.1°.

Adjustment of Structure Parameters. The r_z-parameters were determined from the $I^{(z)}$ values and C–C and C=O r_z-distances obtained by means of electron diffraction[2,7,8] in a way quite parallel to that for acetaldehyde.[1] The isotope effect on the C–H and C–D distances was evaluated by $\langle \Delta z \rangle_0$ or the mean displacement projected along the equilibrium bond direction, by use of the calculated values of the parallel and perpendicular mean amplitudes[9] and the Morse anharmonicity parameter a. Two values were assumed for a, 2.0 Å^{-1} and 2.6 Å^{-1}, which are supposed to be the possible extremes of the a value for a C–H bond.[10] The difference between r_z values for the C–H bond was 0.001 Å and 0.002 Å for the two extremes.

7) C. Kato, S. Konaka, T. Iijima, and M. Kimura, This Bulletin, **42**, 2148 (1969).
8) The centrifugal stretchings of C–C and C–O distances were assumed to be 0.0002 Å in the previous study. Resently Dr. Hilderbrandt calculated them rigorously and obtained 0.0006 Å and 0.0002 Å for C–C and C–O, respectively. (Private communication *via* Professor R. A. Bonham.) There is no important change in the r_z(ED) values even with these exact numbers.
9) Dr. S. J. Cyvin kindly informed the author of his calculated values of the mean amplitudes of the normal species. His results are in excellent agreement with the author's. It should be noted, however, that the mean amplitudes should not include the contribution from the torsional motions in the present scheme of analysis.
10) K. Kuchitsu, *J. Chem. Phys.*, **49**, 4456 (1968).

The mean value 0.0015Å was then assumed to be the difference r_z(C-H)$-r_z$(C-D) in the following analysis.

A large shortening of r_z from the equilibrium bond length, obtained as a result of the calculation in the preceding paper,[2] originated from a large perpendicular amplitude due to the torsional motion of the methyl tops. In the present treatment, however, the torsional motion is separated out of the vibrational motions and the r_z(C-H) becomes the average value on the vibrational ground state not including the torsional motion. The methyl tops undergo the torsional motion while performing vibrational harmonic motions about the structure expressed in terms of the zero-point structure parameters.

The adjusted structure parameters were r_z(C=O), r_z(C-C), r_z(C-H). α_z(CCC) and α_z(HCH). In addition to these, α_z(CCC) and α_z(DCD) of the d_6-species were included as independent parameters. The $2\theta_z$ values were fixed to the value obtained in the preceding section. The trial values of r_z(C=O) and r_z(C-C) were varied within the error limits of electron diffraction values. For each set of these two parameters, the remaining parameters were so adjusted that the calculated moments of inertia might best fit the observed zero-point values.

In a scheme where the diffraction values are utilized as much as in the present treatment, the contribution from the isotopically substituted species, especially the ^{13}C and ^{18}O species, to the structure parameters is rather small and the final result would have been substantially the same if the parameters had been adjusted by use of the normal species only. This was pointed out by Kuchitsu *et al.*[11] Inclusion of the deuterated species would produce no more than additional ambiguity if the possible isotope effects in the structure parameters were assumed to be estimated values, unless the estimates are somehow known accurately enough. In the present treatment the isotope effects in the α_z(CCC) and α_z(DCD) were regarded as adjustable, or in other words, unknown parameters. As a result, the spectroscopic moments of the deuterated species had a role not only of affording additional information on the overall structure parameters but also of giving experimental evidence of the isotope effects on the less known parameters such as bond angles. The assumption that there is no appreciable isotope effect in the C-C and C=O distances seems to be reasonable.

Although the addition of two more independent parameters for the deuterated species seems to reduce the usefulness of the d_6-data as supplementary information, it actually turns out that the d_6-data are still very useful in alleviating strong mutual correlation existing between the structure parameters of the molecule.

The best fit values of the parameters are listed in Table 4 together with the ranges indicating the uncertainties, which were estimated by criteria discussed in Ref. 1. The corresponding r_g-values are also shown in Table 4. The allowable amounts of deviations of the parameters are not independent of, but related to, each other by the mutual correlation. Since it is difficult to show the correlation scheme in the Table, the listed values simply indicate the widest possible deviations which could be allowed by an appropriate combination of the values of the parameters. The zero-point moments of inertia calculated by use of these best fit values of the parameters are in agreement with the observed values within 0.01 amu. Å^2 for all of the twelve $I^{(z)}$ of the four species. The consistency between spectroscopic and diffraction data is almost perfect.

Isotope Effects in Deuterated Species. We see from Table 4 that appreciable isotope effects due to deuterium substitution were observed in the zero-point average values of CCC and HCH angles. The CCC angle of the d_6-species is less than that of the normal species by 17′. A similar amount 18′ was obtained and discussed in a previous paper,[2] where it was interpreted to be caused by anharmonicity in the symmetric rocking motion of the two methyl tops. The same argument holds in the present case, although there seems to be no sound reason to exclude intramethyl HCH bending from the possible source of anharmonicity, because there has also been an isotope effect observed in the DCD angle.

However, the fact that the DCD angle is not smaller but larger than HCH by 10′ strongly suggests that a repulsive force between the two methyl tops might be the major source of anharmonicity. Such a force would push the two tops so that the three hydrogens are bent closer to each other, and the zero-point vibration would suffer such anharmonicity as to make it harder for the methyl tripod to open than to close. This is the type of anharmonicity which lead to a larger DCD angle than HCH, and be predominant in the cubic term of the symmetric rocking mode.

The same manipulation as was applied to the CCC angle[2] was also applied to the HCH angle, and the $\langle\Delta\alpha\rangle_0$ value of HCH was evaluated to be −38′ assuming that the anharmonicity is mainly due to the methyl rocking.

The direction of tilt is also consistent with the presence of repulsive interaction between the two tops.

11) K. Kuchitsu, T. Fukuyama and Y. Morino, *J. Mol. Structure*, **4**, 41 (1969).

However, according to the microwave studies by Pierce and co-workers on several molecules, the existence of tilted methyl tops is closely related to the presence of an unsaturated carbon atom adjacent to the methyl top.[12] The tilt in acetone is probably caused by superposed effect of both repulsive interaction and the electronic state of the central carbon. More exact pinning down of the origin of the tilting is still left to future investigations.

Approximate equilibrium values of the structure parameters can be estimated from the zero-point average values and $\langle \Delta z \rangle_0$ and $\langle \Delta \alpha \rangle_0$. The estimated values for C–H, $\angle$CCC and $\angle$HCH are shown also in Table 4. r_e(C–H) 1.08_3 Å is fairly reasonable as compared with some reported values of C–H, *viz.*, 1.08_7 Å of CH_3CHO[1] and 1.085 Å of CH_4.[13] As for the equilibrium values of the bond angles, no data are available for comparison. It is interesting, however, to note that the equilibrium angle of HCH in the methyl top seems to be very close to that of acetaldehyde 108°42′, while the zero-point average values are apart from each other because of the opposite direction of the effect of anharmonicity.

Determination of the barrier height by use of the effective value of the moment of inertia of the methyl top and the non-unity constraint of $\lambda^2_a + \lambda^2_b$ would be interesting, if it were possible to follow the sophisticated procedure of the barrier height analysis by Nelson and Pierce.

The author wishes to thank Professor Masao Kimura for his encouragement, and Dr. Shigehiro Konaka for his helpful comments. Numerical computations were performed on a FACOM 230—60 of the Hokkaido University Computing Center and also on a FACOM 270—20 at the laboratory of Professor Kimio Ohno, to whom the author's thanks are also due.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3530—3534 (1972)

Nuclear Quadrupole Resonance Study of Chloral Hydrate

Hideaki CHIHARA and Nobuo NAKAMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, 560

(Received June 5, 1972)

Three nuclear quadrupole resonance lines were observed in chloral hydrate at temperatures 20—300K, the frequencies being 38.2863±0.0004 MHz(ν_1), 39.5415±0.0002(ν_2), and 39.6252±0.0002(ν_3) at 20.3K. Their temperature dependence was measured below 77K, showing monotonous decrease with increasing temperature. The difference in frequency between ν_1 and ν_2(or ν_3) is probably due to a crystal field effect rather than OH···Cl hydrogen bonding as has been suggested. The spin-lattice relaxation time for all the lines, determined by pulse techniques, coincides with each other and tends to decrease rapidly above 250K. The decrease was interpreted as arising from hindered internal rotation of the CCl_3 group with the activation energy of 8.8 kcal mol^{-1}.

It is known that O-H···Cl type hydrogen bond exists in a few crystalline solids.[1] Chloral hydrate has been considered to have this type of hydrogen bond. Existence of the hydrogen bond was first predicted by Kondo and Nitta on the basis of their X-ray crystal structure analysis.[2] Allen found that one of the three ^{35}Cl nuclear quadrupole resonance (NQR) lines was much lower in frequency than the other two and interpreted the low frequency in terms of a hydrogen bond between an O-H group and the chlorine atom.[3] The crystal structure of chloral hydrate was later redetermined by Ogawa by an X-ray method and the possibility of a bifurcated hydrogen bond of the type O–H$\langle^{Cl}_{O}$ was suggested on the basis of the short intermolecular O-Cl and O-O distances.[4]

The structural data of Ogawa was further refined and all the hydrogen atoms were located with a neutron diffraction method by Brown.[5] The hydrogen atoms of the two crystallographically non-equivalent hydroxyl groups were found between two oxygen atoms of different molecules, O–H···O type hydrogen bonds being rather long in the crystallographic *ac*-plane.

Recently a question was raised by Biedenkapp and Weiss[6] as to whether or not the large NQR frequency shift is due really to the hydrogen bonding to chlorine. They examined the temperature range 77—323K and found that only a small change occurs in the ^{35}Cl NQR spectra upon deuteration; the observation led them to conclude that the "crystal field effects" rather than the OH···Cl hydrogen bond could account for the spectra.

The purpose of the present paper is to examine the existence and nature of the possible O–H···Cl hydrogen

bonding in chloral hydrate by means of the single crystal NQR method.

Experimental

Chloral hydrate (Merck) was recrystallized from chloroform solution by evaporation at 25°C. A single crystal (approximately $1\times1\times0.7$ cm^3) was grown also in the chloroform solution.

The ^{35}Cl NQR frequencies were measured at temperatures 20—80K by using a Dean-type super-regenerative spectrometer on a powdered specimen. Single crystal Zeeman effect experiment was carried out at liquid nitrogen temperature. The spin-lattice relaxation times were measured by the 180°—90° method[7] at 77—300K using a pulsed spectrometer. Details of the experimental methods were described elsewhere.[8]

Results and Discussion

Description of Crystal Structure. Chloral hydrate crystallizes in a monoclinic system with the space group $P2_1/c$ and contains four molecules in a unit cell. Figure 1 shows the crystal structure which was determined by Brown.[5] There are two relatively long O–H···O hydrogen bonds (H···O=1.908 and 1.933 Å). There is a somewhat short H···Cl distance of 2.643 Å between the hydrogen H_1 and the chlorine Cl_1 to be compared with the sum of the van der Waals radii of H and Cl atoms (3.0 Å).

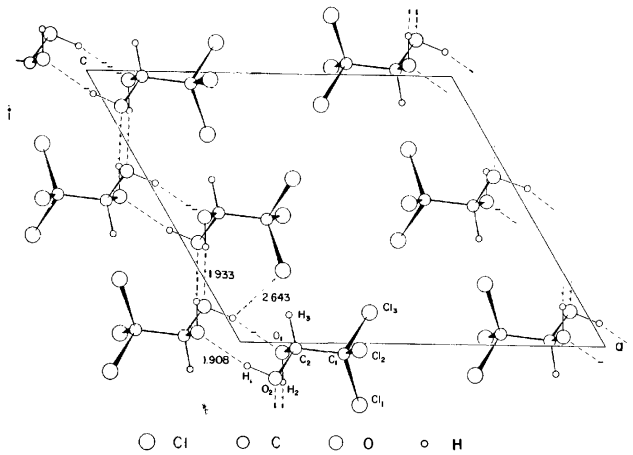

Fig. 1. Crystal structure of chloral hydrate projected along the crystalline *b* axis. (Ref. 5)

Figure 2 shows the position of the zero-splitting loci for four of the six independent C–Cl bond directions in a laboratory coordinate system. The direction of principal *Z*-axis and the asymmetry parameter η of the electric field gradient of ^{35}Cl in each C–Cl bond were calculated by using a NEAC-2200 computer from the observed zero-splitting loci by means of the relation[9]

$$\sin^2\theta = 2/(3-\eta\cos 2\varphi),$$

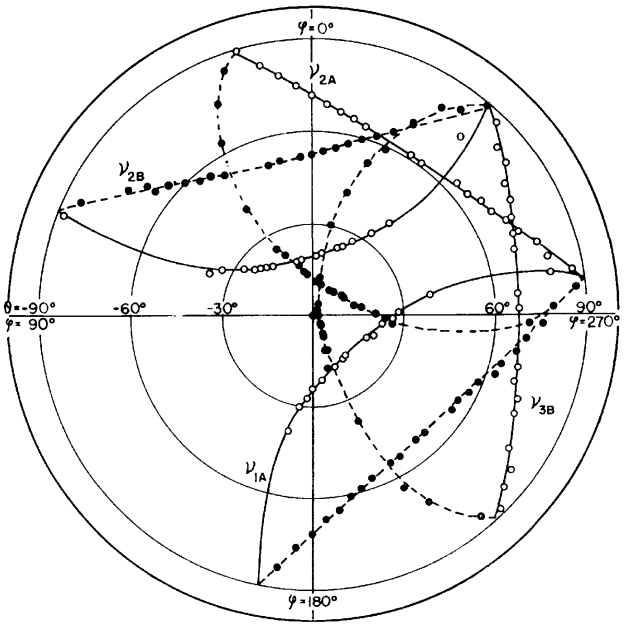

Fig. 2. Zero-splitting loci of four C–Cl bonds at 77K.
—○— locus projection from above the plane of paper,
--●-- locus projection from below the plane of paper.

where θ and φ are respectively the polar and azimuthal angles of the Zeeman field direction that gives zero splitting in the coordinate system fixed to the principal EFG tensor axes. The number of data collected was 40 for Cl_{1A}, 40 for Cl_{2A}, 43 for Cl_{2B} and 46 for Cl_{3B}. The results are given in Table 1, with the direction cosines of the other two unobserved cones[10] (Cl_{1B} and Cl_{3A}), which were calculated by utilizing the fact that there is a glide plane perpendicular to the crystalline *b*-axis. From an examination of the relative directions of the six C–Cl bonds (assumed to coincide with the *Z*-axes of EFG) we can unambiguously assign each NQR frequency to a particular chlorine atom in Fig. 1, *viz.*, ν_1, ν_2, and ν_3 correspond to Cl_1, Cl_3 and Cl_2, respectively. It is noticeable that ν_1, which is anomalously lower than the other two, corresponds to the Cl_1 atom which has a close hydrogen neighbor.

Interactions between Chlorine Cl_1 and Other Atoms. We now attempt to find the possible interactions that make the ν_1 frequency lower than ν_2 or ν_3. The geometry of the CCl_3 group as determined by diffraction methods is quite normal in that every C–Cl distance (1.760 to 1.765 Å) is typical of a single bond length and that the angles between the three C–Cl bonds are close to the tetrahedral angle (see Table 2). Thus there seems to be no interaction of intramolecular origin through σ bonds that will be responsible for the difference between ν_1 and ν_2 (or ν_3). The fact that the asymmetry parameters for the three chlorines are small and about the same in magnitude also supports such a view.

Of the intermolecular interactions, the hydrogen

bonding between O_2-H_1 and Cl_1 is an obvious possibility which could account for the NQR frequency of Cl_1. Two models of hydrogen bond, electrostatic and charge-transfer, will now be studied in turn.

In an electrostatic model, we consider that a net positive charge δ is produced on the proton H_1 as a result of the formation of the hydrogen bond O_2-H$\cdots$ O_1 and this charge interacts with the effective negative charge on Cl_1. The additional electrostatic interaction makes the system more stable. This model corresponds to the bifurcated hydrogen bond O-H$\langle^{Cl}_{O}$ suggested by Ogawa[4]. An excess EFG Δq should be produced by the charge δ, at the position of the Cl_1 nucleus. This is given by

$$\Delta q = \delta\left(\frac{3\cos^2\theta-1}{r^3}\right)(1-R),$$

where θ is the angle between the C-Cl_1 axis and the Cl$\cdots$H direction, r the Cl$\cdots$H distance and R the shielding or antishielding coefficient of covalently bonded chlorine atom. If we put $\delta=+0.1e$,[11] $\theta=122.5°$, and $r=2.64$ Å, R is required to be as large as 10^3 in order to explain $\Delta\nu=1.3$ MHz. This is mainly because the angle θ is close to the magic angle (54°44′ or 125°16′), and therefore the electrostatic part of the hydrogen bond alone, if any, is not sufficient to account for $\Delta\nu$.

According to a simple charge-transfer theory of hydrogen bond[12] a fraction of $3p$ electrons in a Cl lone pair orbital has to be transferred to a vacant antibonding orbital of the O-H group.[13] In this case the EFG tensor components can be analyzed by using the p-electron population numbers U_x, U_y, and U_z on the Cl atom.[14] Here U_z is the population number in the C-Cl bonding orbital, U_x and U_y are those in the lone pair orbitals in the absence of charge transfer. If U_x is assumed to change to U_x' by the charge transfer interaction, the decrease in EFG Δq is given by

$$\Delta q = \frac{1}{2}(U_x-U_x')q_{at}$$

or, in terms of the frequency shift $\Delta\nu$,

$$\Delta\nu = \frac{1}{2}(U_x-U_x')\nu_{at}, \quad \nu_{at} = \frac{1}{2}e^2Qq_{at}$$

where q_{at} is the EFG in the atomic chlorine. The change in η is approximately given by

$$\Delta\eta \doteqdot \frac{3}{2}\frac{\nu_{at}}{\nu}(U_x'-U_x).$$

$\Delta\eta$ can be either positive or negative according to the sign of (U_x-U_y) in the molecule without the charge transfer.

We can estimate the quantity U_x-U_y and then η by assuming that $\Delta\nu$ is produced only by charge transfer: On substitution of $\Delta\nu=+1.29$ MHz and

13) The overlap integral between the hydrogen 1s and chlorine 3p lone pair orbital amounts to 0.07 if the Slater-type atomic orbitals are used.
14) T. P. Das and E. L. Hahn, "Nuclear Quadrupole Resonance Spectroscopy," Academic Press, New York (1958): H. Chihara and N. Nakamura, This Bulletin, **44**, 2676 (1971).

$\nu_{at}=+54.87$ MHz, we obtain $U_x-U_x'=0.046$ and $\Delta\eta=-0.096$. While the value of U_x-U_x' is not of an unacceptable magnitude, the difference in the experimental asymmetry parameter on different chlorine atoms is trivial as shown in Table 1.

The charge-transfer model does not satisfactorily account for observation.

We are now left with what is generally called a crystal field effect. From the crystal structure as depicted in Fig. 1, we find that both the Cl_2 and Cl_3 atoms have Cl···Cl intermolecular contacts whereas the Cl_1 atom has as close neighbors two oxygen atoms of the same molecule and two oxygen atoms of the neighboring molecules. In particular, the intramolecular Cl···O distances are short (3.06 and 3.09 Å) and the orientation of hydroxyl groups is such that the polarization of oxygen $2p$ lone-pair orbitals would affect the EFG at the Cl_1 site to some extent. The fact that the temperature coefficient of the three NQR lines are similar to each other (Fig. 3) also suggests that the intermolecular (including non-bonded intramolecular) interactions in which the chlorine atoms participate are of long range.

Molecular Motion. The temperature dependence of the NQR frequencies below 80K is shown in Fig. 3. NQR frequencies at 79K were in agreement with published results.[3,6] The resonance frequencies at 20.3K are ν_1, 38.2863±0.0004; ν_2 39.5415±0.0002; and ν_3, 39.6252±0.0002 MHz. These values are rather larger than those for the frequencies at 0K predicted by Biedenkapp and Weiss.[6] It is apparent that ν_1 shows no anomalous temperature dependence as is usually expected in the solid where intermolecular charge transfer exists.[15,16] This has already been discussed by Biedenkapp and Weiss on the experimental data above 77K. The normal behavior of ν_1 above 20K supports the view that the resonance frequency shift originates mainly from the polarization of lone pair orbitals of oxygen.

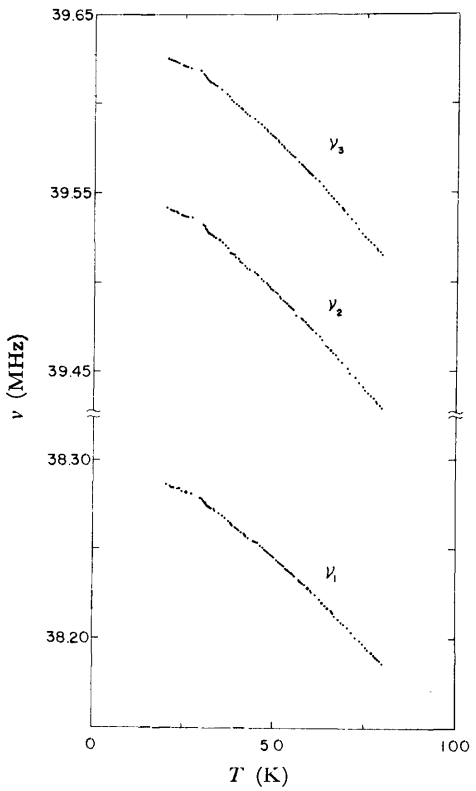

Fig. 3. Temperature dependence of ^{35}Cl nuclear quadrupole resonance frequencies.

The result of measurements of the spin-lattice relaxation time T_1 is shown in Fig. 4. Values of T_1 of ν_1, ν_2 and ν_3 coincide with each other within experimental error over the entire temperature range examined.

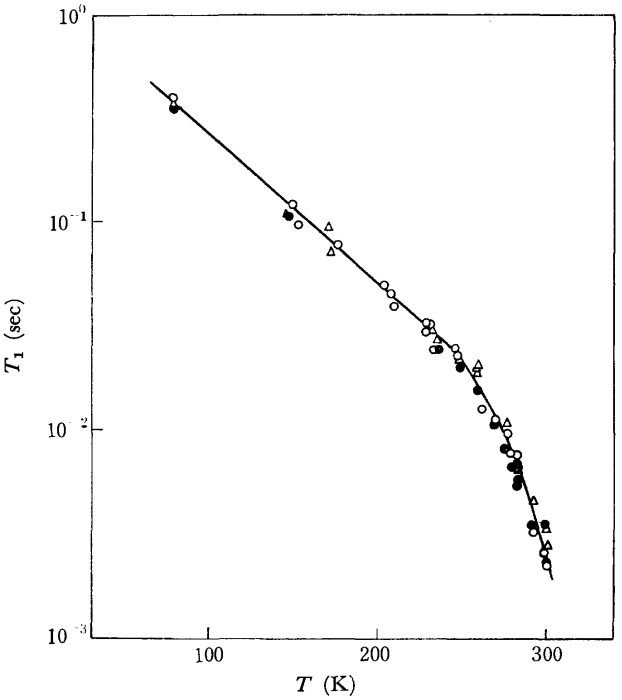

Fig. 4. Nuclear quadrupole spin-lattice relaxation time.
○: ν_1, ●: ν_2, △: ν_3

This suggests that there exists no excess electric quadrupolar or magnetic dipolar interaction between Cl_1 and its environment.

The T_1 value decreases rapidly above 250K. This phenomenon is interpreted as due to the excitation of the internal rotation of the CCl_3 group about the molecular C-C axis. The plot of $\ln 1/T_1$ against $1/T$ gives a straight line; thus, the relation $1/T_1=Ae^{-E_a/RT}$ holds. The slope of the line gives the activation energy $E_a=8.8+0.8$ kcal/mol.[17] This value is much larger than 4 kcal/mol for CCl_3COOH.[19] It may be reasonable to consider that the high potential barrier in chloral hydrate is attributed to large

Photolysis of Nitromethane in Gas Phase at 313 nm

Koichi HONDA,* Hitoshi MIKUNI, and Makoto TAKAHASI

Department of Pure and Applied Sciences, College of Gerneal Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received June 8, 1972)

Photolysis of nitromethane in gas phase at 313.0 nm was studied at 55°C. Methyl nitrite, formaldehyde, nitrosomethane and NO were obtained as main products, their quantum yields being determined to be $\phi_{CH_3ONO}=0.22$, $\phi_{HCHO}=0.20$, $\phi_{CH_3NO}=0.06$ and $\phi_{NO}=0.10$. The dependence of the quantum yields on the pressure of quenching gases such as ethylene, *cis*-2-butene, CO_2 and NO were investigated. The quantum yields of products except formaldehyde decrease with increase in pressure of ethylene or *cis*-2-butene. The sensitized isomerization of 2-butene was also observed. The quantum yield of triplet nitromethane was determined by the Cundall method and compared with that by product analysis. Both give the identical value 0.6. Since ϕ_{HCHO} is not affected by any quencher, it is concluded that formaldehyde is formed directly from singlet excited nitromethane.

Numerous investigations have been carried out on the decomposition of nitromethane. They have revealed that the main primary process is the rupture of C–N bond as shown by (I) under various conditions, *i.e.*, continuous photolysis,[1-6] flash photolysis.[7-9] radiolysis,[4,10,11] and pyrolysis.[12]

$$CH_3NO_2 \rightarrow CH_3 + NO_2 \quad (I)$$

In the case of pyrolysis, the main reaction subsequent to (I) is hydrogen atom abstraction by methyl radical from nitromethane, but in the case of photolysis, the recombination reaction between methyl radical and nitrogen dioxide is dominant, because hydrogen atom abstraction requires an activation energy of more than several kcal/mol. Thus, the final products in photolysis differ markedly from those in pyrolysis in spite of the same primary process. The diversity of the decomposition products of the compound suggests the complexity of secondary successive reactions.

The fact that reaction (I) is the main primary process of photolysis of nitromethane was shown by several authors. McGarvey and McGrath,[8] and Napier and Norrish[9] observed the strong absorption spectrum of methyl radical immediately after flashing nitromethane. Bielski and Timmons[6] detected the ESR spectra of methyl radical and of nitrogen dioxide during photolysis of nitromethane at 77°K. However, Christie *et al.*[3] suggested that a molecular elimination process (II), first proposed by Hirschlaff and Norrish,[1] was involved in the primary processes of photolysis of nitromethane from the fact that the yield of formaldehyde was unaffected by the addition of nitric oxide.

$$CH_3NO_2 \rightarrow CH_2O + HNO \quad (II)$$

Moreover, Cundall *et al.*[4] suggested that in the liquid phase photolysis of nitromethane at 253.7 nm an oxygen atom elimination process (III) might be involved in the primary processes, as in the case of aromatic nitrocompounds, because so much formation of nitrosomethane cannot be explained by a cage reaction between methyl radical and nitrogen dioxide.

$$CH_3NO_2 \rightarrow CH_3NO + O \quad (III)$$

There seems to be little doubt that the decomposition proceeds at least partly from an initial dissociation into methyl radical and nitrogen dioxide, as shown in (I), but a contribution of (II) and/or (III) also appears to be possible according to the results of the above workers.

Rebbert and Slagg[2] suggested that two excited states would be related to photo-decomposition of

liquid nitromethane, in order to explain the fact that the quantum yield of methyl nitrite was larger at 253.7 nm than at 313.0 nm.

Cundall *et al.*[4] pointed out that the two excited states might be a triplet π–π^* and triplet n–π^* state respectively from the reduction of the quantum yield of methyl nitrite in the presence of oxygen and wavelength effect in the photolysis of liquid nitromethane. However, it is still open to question whether the decomposition process really occurs from the triplet state and if so, how much the quantum yield of the triplet state is.

We have thus attempted to obtain more information on the following problems in the photolysis of nitromethane in gas phase, when the n–π^* band is irradiated.

(i) The possibility of processes other than (I).

(ii) The triplet quantum yield of nitromethane by applying the so called "Cundall method."[3]

Experimental

Materials. Commercial nitromethane (Tokyo-Kasei and Wako-Junyaku) was purified by distilling with rejection of large amounts of initial and final fractions, after dissolved nitrogen dioxide was removed by refluxing for several hours with flushing nitrogen. The pure material was stored in a 500 ml flask *in vacuo* after being dried by anhydrous sodium sulfate and distilled into high vacuum apparatus as required. All the gases were of high purity and obtained from Takachiho Kagaku. *cis*-2-Butene contained 0.44% *trans*-isomer as an impurity, but was used without further purification. Ethylene still contained 0.03% methane and 0.08% ethane after bulb-to-bulb distillation. Nitric oxide was used every time after fresh distillation to avoid contamination of nitrogen dioxide. Carbon dioxide was used without further purifications.

Apparatus and Method. The light source was an Ushio 250 D super high pressure mercury arc lamp with a Pyrex filter to eliminate light shorter than about 300 nm and with a quartz lens, diameter 5 cm and focas length 5 cm to make the incident light parallel.

Under these conditions, the light effectively absorbed by nitromethane was mainly in the 313.0 nm region. This region is the tail part of the n–π^* band, and the contamination of the effect of the π–π^* band adjacent to the n–π^* band is considered to be eliminated. As the molar extinction coefficient of the region is very small ($\varepsilon<4$), strong light intensity is necessary to perform experiments during the relatively short irradiation time. We did not elaborate further optical arrangements to monochromatize the incident light.

The reaction cell was a quartz cylinder with a small cold finger tip, 5 cm in diameter and 20 cm in length with a volume of 410 m*l*. The cell part was held in an electric furnace with quartz window and a stirring fan to keep constant temperature within ± 1°C during the course of an experiment. It was separated from other parts by a greaseless valve.

The vacuum system was the conventional one, being set up completely mercury free to avoid the reaction of nitrogen dioxide with mercury. Sample gas was introduced into a constant volume vessel (410 m*l*). The pressure was measured by a calibrated Bourdon gauge, and the gas in the vessel was trapped into the cold finger of reaction cell with a liquid nitrogen bath. When a mixture of nitromethane with other gas was required, these procedures were repeated for each gas. The mixture prepared was kept at a reaction temperature for complete mixing at least one hour before irradiation. The usual experiments were carried out at 28 Torr (at 25°C) of nitromethane and at reaction temperature 55°C.

Actinometry. Rebbert and Slagg[2] showed that the quantum yield of ethylene formed from nitroethane is 0.074 in gaseous photolysis at 313.0 nm. Since the absorption spectrum of nitromethane was almost the same as that of nitroethane,[14] the quantum yields of products of nitromethane were easily determined. The amount of incident light in the reaction cell is determined to be 1.7×10^{17} photon/sec.

Analysis. The products were collected in a series of traps; the first was a U type tube, the second and the third were removable tubes each containing completely degassed water (about 2 m*l*) and a detachable large volume bulb (about 3 *l*). The analytical procedure was as follows.

(i) The first trap was cooled by a liquid nitrogen bath, and non-condensable gases (H_2, N_2, CO, CH_4 and most of NO) were collected in a large bulb by diffusion after the occluded gases in frozen materials were removed with freeze-melt cycles. The bulb was then detached and jointed to a Toepler pump-gas buret system. The gases were analysed by gas-chromatography (molecular sieve 5 A column, 1 m, room temp., He carrier), but the amount of NO was estimated by subtracting the moles of the other products from the total amount of noncondensable gases, because NO could not be analysed by gas-chromatography with good reproducibility. The analytical error of NO was thus larger than that of other non-condensable gases. In a very small conversion experiment, the first trap was cooled by ethyl bromide slush bath (—120°C) and gases (H_2, N_2, CO, CH_4, NO, N_2O, and C_2H_6) noncondensable at —120°C were analysed by mass-spectrometry.

(ii) The valve to the second trap cooled by a liquid nitrogen bath was opened, and the water soluble products (mainly formaldehyde and methyl nitrite) and nitromethane were dissolved in water. The aqueous solutions prepared were diluted to a constant volume and were used for quantitative analysis of formaldehyde and methyl nitrite. When both could not be measured simultaneously, they were measured separately by repeating the experiment twice.

(iii) Nitrosomethane was known to dimerize almost completely when condensed; it deposited as a white powder on the wall of the first trap together with formaldehyde polymer after procedure (ii). The materials were then vaporized by warming up to about 100°C with an electric oil bath and were condensed into the third trap cooled by a liquid nitrogen bath and dissolved into water. The analytical methods were the same as those for the second trap. The total quantity of formaldehyde was determined as the sum obtained in procedures (ii) and (iii).

The analytical methods of methyl nitrite, formaldehyde and nitrosomethane: Parker's method[15] (quantitative formation of diazo-dye by the reaction of α-naphthylamine with the nitrite ions produced by hydrolysis of methyl nitrite), Bricker's method[16] (dye formation by the reaction

of chromotropic acid with formaldehyde in the presence of concd sulfuric acid) and UV-spectroscopy of *cis*-nitrosomethane dimer[17] (λ_{max}; 265 mn, ε_{max}; 1.0×10^4). It was confirmed that these methods were not affected by nitromethane and added gases except nitric oxide. If nitric oxide is present, Briker's method cannot be applied, but the amount of formaldehyde in the first trap is a solid polymer. The total amount of formaldehyde in the presence of nitric oxide was then estimated assuming the ratio of total amount to partial amount in the first trap is the same as the ratio in the absence of nitric oxide. Moreover, since Parker's method is also affected remarkably by dissolved nitric oxide, the analysis of methyl nitrite was carried out after the nitric oxide dissolved in the second trap solution was expelled completely by flushing with nitrogen for several hours.

The original impurity content as well as the isomerization product content of *cis*-2-butene were determined by gas chromatographic analysis (active alumina with 2% squalane column, 2 m, 100°C, N_2 carrier, FID).

Miner products not analysed were checked also by gas chromatography (DOP, 2 m, 100°C, He carrier, TCD).

Analytical methods described above were modified in some cases.

Results

(I) Quantum Yields of Products at Small Conversions. In the gas phase photolysis of nitromethane (55°C, 28 Torr at 25°C), the products of quantum yields more than 0.05 at small conversions were methyl nitrite, formaldehyde, nitric oxide, nitrosomethane and nitrous oxide, their amounts decreasing in this order. When irradiation was prolonged, CO joined the main products (up to $\phi_{CO}=0.13$ at 90 min. irradiation) and the quantum yields of main products (methyl nitrite, formaldehyde and nitric oxide) decreased with the irradiation time (up to $\phi_{CH_3ONO}=0.07$, $\phi_{CH_2O}=0.10$ at 90 min. irradiation).

Minor products analysed quantitatively were methane, hydrogen, carbon monoxide and nitrogen. Other minor products detected in gas-chromatograph were ethane, methanol, water, methyl nitrate and carbon dioxide. Nitrogen dioxide was not detected in the final products (at least at small conversions) by mass spectroscopic analysis. This agreed with the results of earlier workers,[2,4] although the possibility of loss during the course of pumping gaseous products with a Toepler-pump was not completely excluded, since nitrogen dioxide is very reactive with mercury.

As shown in Fig. 1, formaldehyde is the main product even at such a small conversion as 0.3% (at 1 min irradiation), differing from the result of Rebbert and Slagg.[2] Process (III), if it exists at all, would not be so important at least under the experimental condition, since the quantum yield of nitrosomethane is so small.

The quantum yields of products larger than 0.05 are summarized in Table 1.

The quantum yields of minor products determined by mass spectroscopy at small conversions (1 min. and 2 min. irradiations) were $\phi_{H_2}=0.02$; $\phi_{CH_4}=0.02$; $\phi_{N_2+CO}=0.05$, and except CO, they decreased to one tenth, when irradiated longer than 15 min.

b) Obtained from mass spectral results from 1 and 2 min. irradiation products.

(II) Effects of Added Gases. The variations of quantum yield of methyl nitrite, formaldehyde and nitric oxide with the pressures of added gases, *i.e.*, ethylene, *cis*-2-butene, NO or CO_2 are shown in Fig. 2a, 2b, 2c and 2d.

The quantum yield of formaldehyde is almost independent of the added gases, ethylene or *cis*-2-butene, while those of methyl nitrite and nitric oxide decrease with increase in the pressure of olefins (Fig. 2a and 2b). In other words, the formation of methyl nitrite and nitric oxide are suppressed by the presence of olefins, but that of formaldehyde is little affected. In the case of addition of *cis*-2-butene, isomerization of *cis*-2-butene to *trans*-isomer occurred simultaneously.

Minor products also decreased with increasing pressures of olefins, and at pressures above several tens of Torr, methane and hydrogen were below detectable limit. To know whether the decrease of the quantum yield of methyl nitrite might be due to the scavenging action of methyl radicals by the olefins, the amount of methyl radicals produced in the excess of ethylene was estimated from the yield of hydrocarbons (CH_4, C_2H_6, C_3H_6, C_3H_8, C_4H_{10}). It was found that the quantum yield of methyl radical is at most 0.01, if excess ethylene exists.

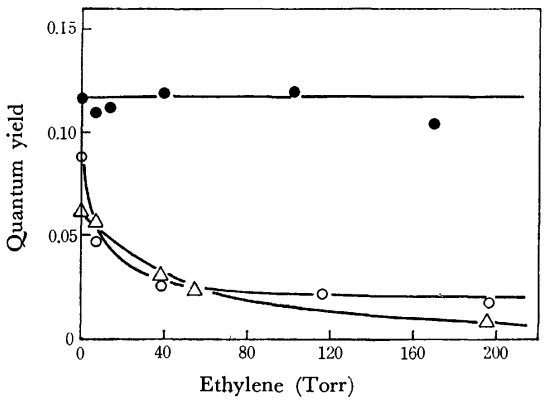

Fig. 2a. The quantum yields of methyl nitrite, formaldehyde and nitric oxide against the press. of ethylene. Irradiation time; 60 min.
○; methyl nitrite, ●; formaldehyde, △; nitric oxide

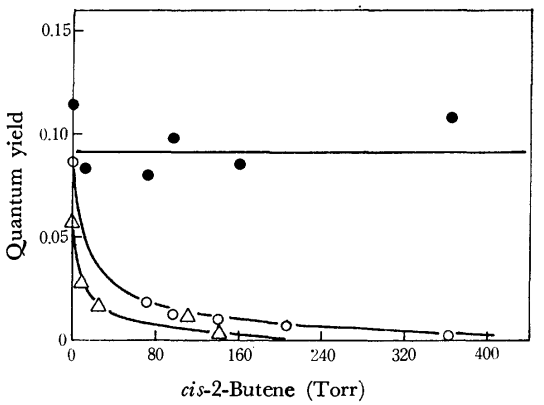

Fig. 2b. The quantum yields of methyl nitrite, formaldehyde and nitric oxide against the press. of *cis*-2-butene. Irradiation time; 60 min.
○; methyl nitrite, ●; formaldehyde, △; nitric oxide

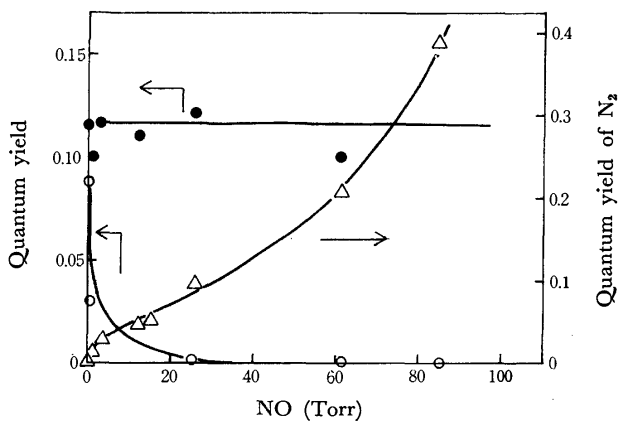

Fig. 2c. The quantum yields of methyl nitrite, formaldehyde and nitrogen against the press. of nitric oxide. Irradiation time; 60 min.
○; methyl nitrite, ●; formaldehyde, △; nitrogen

The quantum yield of methyl nitrite decreased sharply in the presence of nitric oxide and became almost zero above 25 Torr of nitric oxide (Fig. 2c). In this case, methane was not detectable at all and on the contrary, nitrogen increased remarkably with nitric oxide pressure.

As established by many workers, nitrogen formation

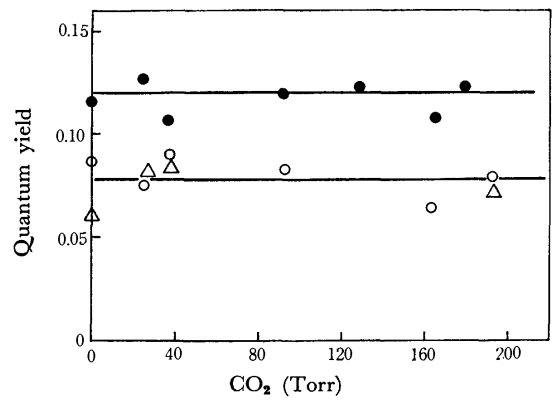

Fig. 2d. The quantum yields of methyl nitrite, formaldehyde and nitric oxide against the press. of CO_2. Irradiation time; 60 min.
○; methyl nitrite, ●; formaldehyde, △; nitric oxide

from nitric oxide is caused by disproportionation ($4NO \rightarrow N_2+2NO_2$) under the catalytic action of methyl radical. The sharp increase of nitrogen and the failure of methane formation therefore supports the view that process (I) to form methyl radical is involved in the primary processes of nitromethane photo-decomposition.

That the yield of formaldehyde was not affected by the addition of nitric oxide suggests that almost all the formaldehyde should be formed by the molecular elimination process like (II).[3]

The effect of added CO_2 was not noticeable either in the main products formation as shown in Fig. 2d or in minor products formation. Hence, the vibrationally excited states quenchable by added CO_2 is not supposed to be involved in the photo-decomposition of nitromethane.

(III) Effect of Reaction Temperature. In order to know the temperature effect of the primary processes of nitromethane photolysis, the quantum yields of methyl nitrite and formaldehyde were measured in the temperature range 25—200°C. The results shown in Fig. 3 indicate that methyl nitrite formation was

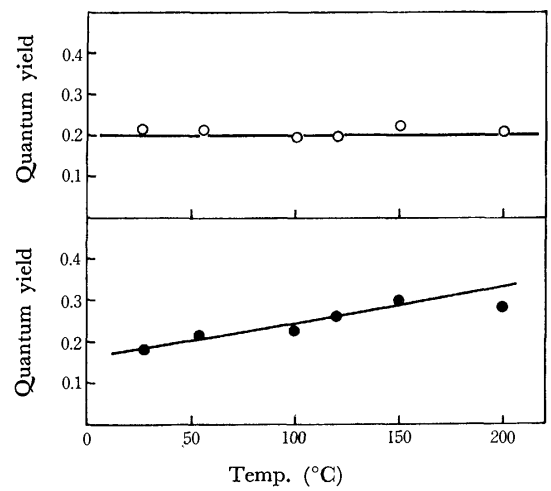

Fig. 3. Temperature dependence of the quantum yields of methyl nitrite, and formaldehyde. Irradiation time 1 min.
○; methyl nitrite, ●; formaldehyde

nearly temperature independent, whereas formaldehyde formation increased with increasing temperature. The increase of formaldehyde with reaction temperature cannot be ascribed to the pyrolytic formation of formaldehyde by the degradation of $\cdot CH_2NO_2$ radicals. If this is the case, the consumption of methyl radical by the abstraction reaction with nitromethane would be expected with increase of reaction temperature, resulting in a decrease of methyl nitrite with temperature. The activation energy of formaldehyde formation was estimated to be 0.7 kcal/mol.

Discussion

(I) Reaction Mechanism. The effect of added gases in the photolysis of nitromethane was shown to be as follows.

(i) Addition of *cis*-2-butene caused a decrease of the quantum yield of methyl nitrite and nitric oxide. A part of *cis*-2-butene was simultaneously isomerized to *trans* form, whereas it little affected formaldehyde formation. This implies that the processes to yield methyl nitrite and nitric oxide proceed through a triplet state of nitromethane, but not those for formaldehyde formation, since the isomerization of *cis*-2-butene is thought to take place through triplet 2-butene formed by the photosensitization of a triplet nitromethane.

(ii) Ethylene acts in the same way as *cis*-2-butene, although less effectively, suggesting that ethylene also can quench the triplet state of nitromethane. Thus the lowest triplet energy of nitromethane is supposed to be greater than that of ethylene (about 78 kcal/mol).

(iii) The rate of methyl nitrite and methane formation decreased to zero while nitrogen formation increased remarkably on addition of nitric oxide, showing that the main primary process is the C–N bond fission (I), and methyl radical formed is scavenged by nitric oxide to give nitrosomethane, which reacts further with nitric oxide to produce nitrogen.

Since nitric oxide does not affect the rate of formaldehyde formation, formaldehyde is not formed by a radical reaction but by a molecular elimination reaction like process (II).

The above results suggest that process (I) takes place from the lowest triplet state of nitromethane, $T_{n-\pi^*}$, and process (II) takes place from such a very short lived state as not quenched by added gases, probably the lowest excited singlet state $S_{n-\pi^*}$.

The proposed reaction mechanism is as follows, where elementary reactions supposed to be important at a small conversion are underlined. Rate constants determined recently by several authors are shown in Table 2.

$$N \xrightarrow{h\nu} N_S$$

(1) $N_S(+M) \rightarrow N + (M)$

(2) $N_S \rightarrow N + h\nu_f$ (actually not observed)

(3) $N_S \rightarrow N_T$

Table 2. Summary of rate constants used in our calculations[a)]

Rate const	l/mol, sec
k_{9a}	4.1×10^{9} [18,19,b)]
k_{9b}	7.9×10^{9} [18,19,b)]
k_{9c}	$\ll k_{9a}, k_{9b}$ [19,c)]
k_{10a}	1.8×10^{8} [20)]
k_{10b}	2.4×10^{9} [18)]
k_{10c}	1.0×10^{8} [18,19)]
k_{10d}	2.3×10^{7} [20)]
k_{10e}	3.0×10^{10} [20)]
k_{10f}	1.2×10^{10} [c)20,d)]
k_{10g}	$4.8—14.4\times10^{6}$ [20)]

a) Rate const of (9a), (9b) and (10c) are based on the data at 90°C, and the others at 25°C. However, they can be all applied to the present case at 55°C, since activation energies of the reactions are nearly zero.
b) Calculated values from the ratio of k_{9a}, k_{9b} and k_{10c} to k_{10b} determined by Phillips and Shaw, and the value of k_{10b} obtained by Basco *et al.*
c) Reaction (9c) is not important in gaseous reactions, since CH_3O-NO bond undergoes rupture easily.
d) A tentative value determined by McGraw *et al.*

(4) $N_S \rightarrow CH_2O + HNO$

(5) $N_T \rightarrow CH_3\cdot + NO_2$

(6) $N_T(+M) \rightarrow N + (M)$

(7) $N_T \rightarrow N + h\nu_p$ (actually not observed)

(8) $N_T + Q \rightarrow N + Q_T$

(9a) $CH_3\cdot + NO_2 \rightarrow CH_3NO_2$

(9b) $CH_3\cdot + NO_2 \rightarrow CH_3O\cdot + NO$

(9c) $CH_3\cdot + NO_2 \rightarrow CH_3ONO$

(10a) $CH_3O\cdot + NO \rightarrow CH_3ONO$

(10b) $CH_3\cdot + NO \rightarrow CH_3NO$

(10c) $CH_3O\cdot + NO_2 \rightarrow CH_3ONO_2$

(10d) $CH_3O\cdot + NO \rightarrow CH_2O + HNO$

(10e) $CH_3O\cdot + HNO \rightarrow CH_3OH + NO$

(10f) $CH_3O\cdot + CH_3O\cdot \rightarrow CH_3OH + CH_2O$

(10g) $HNO + HNO \rightarrow H_2O + N_2O$

(10h) $CH_3\cdot + CH_3O\cdot \rightarrow CH_4 + CH_2O$

where N_S denotes the lowest excited singlet stage, N_T the lowest triplet state, N the ground state nitromethane and Q the triplet quenchers, respectively.

On the basis of the proposed reaction scheme, we can estimate the quantum yield of reaction (5), ϕ_5, to be 0.6 from the sum of quantum yields of the products at small conversions (Table 1) with the help of rate constants (k_{9a} and k_{9b}) reported by Philips and Show,[19] *viz.*, the quantum yield of reaction (9b), ϕ_{9b}, sum of ϕ_{CH_3ONO}, ϕ_{CH_3NO} and ϕ_{NO} is no less than 0.4, because these products are formed only from the sub-

18) N. Basco, D. J. L. James, and R. D. Suart, *Int. J. Chem. Kinet.*, II, 215 (1970).
19) L. Phillips and R. Shaw, Symp. Combust, 10th, Univ. Cambridge, England, 1964, pp. 453—461 (1965).
20) G. E. McGraw and H. S. Johnston, *Int. J. Chem. Kinet.*, I, 89 (1969).

sequent reactions of (9b), keeping in mind that reaction (9c) is negligible; the quantum yield of reaction (9a), ϕ_{9a}, is estimated to be about 0.2 on the basis of the ratio of the rate constants obtained by Phillips and Shaw;[19] Thus, ϕ_5 is estimated to be about 0.6.

The primary quantum yield of reaction (4), ϕ_4, the observed quantum yield of formaldehyde at small conversions, is about 0.2. The contribution of (10d), (10f) and (10h) is considered to be small for the production of formaldehyde.

The mechanism of CO formation might be complex; CO seems to be formed by the secondary photolysis of methyl nitrite and formaldehyde and/or by oxidation reaction of oxygen atom formed by the photolysis of nitrogen dioxide since CO formation is appreciable only on being irradiated for a long time.

Hydrogen may be formed also by the secondary photolysis of formaldehyde. Formation of small amounts of methanol, water, nitrous oxide and methyl nitrate is explained by the reactions (10e), (10f), (10g) and (10c).

In the case of nitric oxide addition, reaction (5) is followed by the chain reactions described below as established by several researchers.[3,9,21,22]

(10b) $CH_3\cdot + NO \rightarrow CH_3NO$

(11) $CH_3NO + 2NO \rightleftharpoons CH_3\text{-}\underset{\underset{NO}{|}}{N}\text{-}O\text{-}NO \rightarrow CH_3N_2NO_3$

(12a) $CH_3N_2NO_3 \rightarrow CH_3\cdot + NO_3 + N_2$

(12b) $CH_3N_2NO_3 \rightarrow CH_3NO_3 + N_2$

(13) $NO_3 + NO \rightarrow 2NO_2$

(14) $CH_3NO \rightarrow CH_2{=}NOH$

(15) $2CH_3NO \rightarrow (CH_3NO)_2$

(16) $CH_3NO + NO_2 \rightarrow CH_3NO_2 + NO$

Although reaction (9a) and reactions subsequent to (9b) might act as chain termination reactions to some extent, (14), (15) and (16) may become dominant as pressure of nitric oxide is increased, since we cannot detect methyl nitrite if nitric oxide is present in more than several Torr.

Formation of a trace of nitrogen without addition of nitric oxide may be interpreted also in terms of the above reactions. Since it was confirmed that HNO radical and methoxy radical have no ability to act as a chain carrier in the above disproportionation reactions of nitric oxide,[3] the anomalous increase of nitrogen in the presence of nitric oxide should be caused by (10b) and the successive reactions.

We confirmed that the plot of the quantum yield of nitrogen against the second power of nitric oxide pressure satisfied the linear relationship above several Torr of the pressure (not shown in the figure). This suggests that (12) is the rate determining step of these nitrogen formation reactions.

(II) Sensitized Isomerization of cis-2-*Butene by Nitromethane and Photostationary State.* It is generally accepted that the quantum yield of triplet state can be determined by the "Cundall method."[13] However, in order to apply this method, it should be confirmed that the isomerization does not occur through radical mechanism (Schenck mechanismm).[23]

Main radicals formed by the decomposition of nitromethane are methyl, methoxy, nitrogen dioxide, nitric oxide and HNO radical. Cundall and Davies[24,25] confirmed in their study of the photolysis of acetone and acetaldehyde that methyl radical does not cause the isomerization of 2-butenes. It is known that nitrogen dioxide and nitric oxide act as a catalyst of the thermal isomerization of 2-butenes and they reduce the activation energy from 63 kcal/mol to 12 kcal/mol[26] and 26 kcal/mol[27] respectively. However, under our experimental conditions (50°C), isomerization by either species must be negligible, because the calculated rate of isomerization is at least ten times slower than our experimental result. HNO radical may react with *cis*-2-butene in the same way as formyl radical to form secondary butyl radical and nitric oxide, but the secondary butyl radical is expected to decompose into methyl radical and propylene but not to reproduce 2-butenes. Although there seems to be no data on reactions of methoxy radical with olefins, our experimental results where the quantum yield of *trans*-2-butene increased with increasing *cis*-2-butene pressure in spite of the decrease of the quantum yield of methyl nitrite suggest that isomerization by methoxy radicals is less probable.

Another possibility may be isomerization through butenyl radical which may be formed by the abstraction of hydrogen atom from 2-butene by some radical. However, this is also less likely under our experimental conditions, since it requires activation energy of more than several kcal.

If the possibilities of isomerization through radical mechanism can be neglected, sensitized-isomerization by triplet nitromethane should be considered. For photosensitized isomerization to be possible, triplet energy of sensitizer should be larger or at least not much less than that of 2-butene. So far neither phosphorescence[28] nor S–T absorption spectrum has been observed, and we cannot predict from spectroscopic data whether the sensitized isomerization of 2-butene by nitromethane is possible or not. However, when we see that sensitized isomerization actually takes place, we can presume that the triplet level of nitromethane lies above that of 2-butene (76 kcal)[29] or ethylene (78 kcal).[29]

We shall discuss the sensitized isomerization of 2-

28) Dr. Kuboyama, The National Chemical Laboratory For Industry, kindly attmepted to measure the phosphorescence of nitromethane, but it could not be observed at least in the sensitivity range of the instrument.

butene by nitromethane more in detail. Completely in the same way as Cundall et al.[30] and Lee *et al.*,[31] the following reaction scheme is assumed for sensitized isomerization.

$$\begin{aligned}
&(8a) && N_T + B_{cis} \rightarrow N + B_{T\,cis}\\
&(8b) && N_T + B_{trans} \rightarrow N + B_{T\,trans}\\
&(17a) && B_{T\,cis} \rightarrow B_{T\,trans}\\
&(17b) && B_{T\,trans} \rightarrow B_{T\,cis}\\
&(18a) && B_{T\,trans} \rightarrow B_{trans}\\
&(18b) && B_{T\,cis} \rightarrow B_{cis}
\end{aligned}$$

where N_T denote triplet nitromethane, B_{cis} and B_{trans} *cis* and *trans*-2-butene, $B_{T\,cis}$ and $B_{T\,trans}$ triplet of 2-butene in *cis* and *trans* form respectively. The following rate expressions are derived in the usual way, under steady state conditions. The initial rate of isomerization of *cis*-2-butene to *trans* form, $R_{c\rightarrow t}$, under a fixed pressure of nitromethane and light intensity and in the absence of *trans*-2-butene, is given below.

$$R_{c\rightarrow t} = \left(\frac{I_a}{k_1+k_2[M]+k_3+k_4}\right) \times \left(\frac{k_{17a}k_{18a}}{k_{17a}k_{18a}+k_{17b}k_{18b}+k_{18a}k_{18b}}\right) \times \left(\frac{k_{8a}[B_{cis}]}{k_5+k_6[N]+k_7+k_{8a}[B_{cis}]}\right) \quad (1)$$

An analogous equation can be derived for reversed isomerization, and the ratio $R_{c\rightarrow t}/R_{t\rightarrow c}$ is expressed simply as follows.

$$R_{c\rightarrow t}/R_{t\rightarrow c} = k_{17a}k_{18a}/k_{17b}k_{18b} \quad (2)$$

In addition, in the photostationary state (abbreviated as pss), the ratio $([B_{trans}]/[B_{cis}])_{pss}$ can be expressed as follows.

$$([B_{trans}]/[B_{cis}])_{pss} = \frac{k_{8a}k_{17a}k_{18a}}{k_{8b}k_{17b}k_{18b}} = \frac{k_{8a}R_{c\rightarrow t}}{k_{8b}R_{t\rightarrow c}} \quad (3)$$

In the benzene-sensitized isomerization of 2-butene, Cundall *et al.*[30] reported the value of 1.37 for $R_{c\rightarrow t}/R_{t\rightarrow c}$, but later Lee et al.[31] obtained the value of 1.02. At the same time, for the value of $([B_{trans}]/[B_{cis}])_{pss}$, Cundall and his co-workers gave the value of 1.37, assuming that k_{8a}/k_{8b} is unity (no difference between *cis*- and *trans*-2-butene) on the basis of their observation that several efficient quenchers have identical quenching cross sections for triplet benzene but this observation seems to be supported neither by Tanaka *et al.*[32] nor Lee's group. In order to determine the exact value of $([B_{trans}]/[B_{cis}])_{pss}$, it is preferable to carry out the isomerization experiment starting from a mixture of *cis*- and *trans*-2-butene whose initial composition is already near the stationary state. Lee *et al.*[31] obtained the value of 0.92 by this method. Applying this technique to nitromethane-sensitized isomerization, we obtained the value of 0.90, irradiating a sample containing 28 Torr of nitromethane and 8.7 Torr of a mixture of *cis*- and *trans*-2-butene in an equal amount (Table 3). For the sake of comparison, the pss ratios for several sensitizers are given in Table 5. It is interesting that the organic sensitizers investigated so far give the value of around 0.9 for the pss ratio except Cundall's value for benzene. Larger quenching cross section of *trans*-2-butene to these organic sensitizers may be interpreted either in terms of the small difference in triplet energy of *cis*- and *trans*-2-butene or the difference in the ease of collision complex formation between the sensitizer and the quencher, but no well-established explanation has been given yet.

Table 3. Variation of *trans/cis* with irradiation time[a)]

Time (hr)	0	0.5	1.0	1.5	2.0	2.5	3.0	3.5	4.0
trans/cis	1.01	0.99	0.98	0.96	0.94	0.92	0.90	0.90	0.90

a) Nitromethane press.; 28 Torr, *trans*-, *cis*- mixture press.; 8.7 Torr, photolysis temp.: 55°C.

(III) Quantum Yield of Triplet Nitromethane by the Cundall Method and by Product Analysis. We determined the quantum yield of triplet nitromethane according to the ordinary procedure of the Cundall method. A good linear relationship is obtained between $1/\phi_{Bc\rightarrow t}$ and $1/[B_{cis}]$ (Fig. 4) where $\phi_{Bc\rightarrow t}$ is the quantum yield of *trans*-2-butene from *cis*-form in the absence of *trans* form, *viz.*, $\phi_{Bc\rightarrow t}=R_{c\rightarrow t}/I_a$.

The linear relationship is consistent with the following equation which is derived from equation (1).

$$1/R_{c\rightarrow t} = \frac{k_1+k_2[M]+k_3+k_4}{k_3I_a} \times \left(\frac{k_{17a}k_{18a}+k_{17b}k_{18b}+k_{18a}k_{18b}}{k_{17a}k_{18a}}\right) \times \left(\frac{k_5+k_6[N]+k_7}{k_{8a}[B_{cis}]}+1\right) \quad (4)$$

As shown in Fig. 4, the reciprocal of intercept gives the value of 0.3 which corresponds to $\phi_{c\rightarrow t}$ at an infinitely high pressure of *cis*-butene. Although we did not measure the ratio $R_{c\rightarrow t}/R_{t\rightarrow c}$ for nitromethane, we may assume that it is approximately unity as Haninger determined for benzene-sensitization, if we assume that

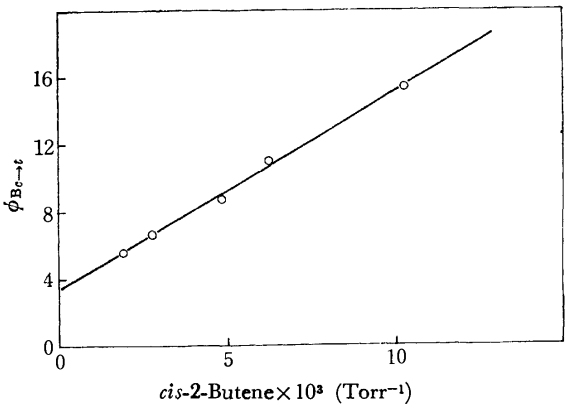

Fig. 4. Reciprocal-reciprocal plot of the quantum yields of triplet 2-butene and the press. of *cis*-2-butene.

29) M. W. Schmidt and E. K. C. Lee, *J. Amer. Chem. Soc.*, **92**, 3579 (1970).
30) R. B. Cundall, F. J. Fletcher, and D. G. Milne, *Trans. Faraday Soc.*, **60**, 1146 (1964).
31) E. K. C. Lee, H. O. Denschlar, and G. A. Haninger, *J. Chem. Phys.*, **48**, 4547 (1968).
32) M. Tanaka, T. Terao, and S. Sato, This Bulletin, **38**, 1645 (1965).

the ratio is independent of the triplet energy of sensitizer. In addition, we may assume that k_{17a} and k_{17b} are much larger than k_{18a} and k_{18b}, although Haninger pointed out there is some doubt as to this assumption. Thus, we obtain the following relationship.

$$\phi_3 = \phi_{N_T} = \phi^{\infty}_{B_T} = (\phi^{\infty}_{B_{c\to t}} + \phi^{\infty}_{B_{t\to c}}) = \phi_{B_{c\to t}}(R_{c\to t}+R_{t\to c})/R_{c\to t} \doteqdot 2R_{c\to t}/I_a = 2\phi_{B_{c\to t}} = 0.6 \quad (5)$$

Using the obtained values ϕ_3 and ϕ_4, we can estimate the value of ϕ_1 to be 0.2 as the difference $(1-\phi_3-\phi_4)$, neglecting the fluorescence process.

We showed that the quantum yield ϕ_5 is 0.6 which is calculated from the product analysis. Therefore, ϕ_{NT} obtained by the Cundall method is consistent with ϕ_5 obtained by product analysis, indicating that the non-radiative process (6) and radiative process (7) are not important, even though they exist. The quantum yields of reactions (1)—(7) are summarized in Table 4. Equation (4) can be made simpler as follows.

Table 4. Summary of the quantum yields of reactions (1)—(5)

ϕ_1	0.2
(ϕ_2	0)
$\phi_3(\phi_T)$	0.6
ϕ_4	0.2
ϕ_5	0.6
(ϕ_6	0)
(ϕ_7	0)

$$1/\phi_{B_T} = \left(\frac{k_1+k_3+k_4}{k_3}\right)\left(\frac{k_5}{k_{8a}[B_{cis}]}+1\right) \quad (6)$$

From the ratio of slope to intercept in Fig. 4, the ratio of rate constant for the dissociation to that for energy transfer, k_5/k_{8a}, is calculated to be 1.7×10^{-2} mol/l at 55°C. Since nitro compounds resemble carbonyl compounds in the behaviors of their absorption and phosphorescence spectra of n-π^* transition and 2-butene isomerization, it may be interesting to compare triplet quantum yield ϕ_T, and the rate constants k_5 and k_{8a}, as given in Table 4. We could not measure k_{8a} directly, unlike the case of carbonyl compounds, so that we can only compare the ratio k_5/k_{8a}, but if we could assume tentatively that k_{8a} of nitromethane is equal to that of acetaldehyde, k_5 would be 3.4×10^6 sec^{-1}.

We investigated the change of quantum yield of methyl nitrite with the increase in the pressure of

Table 5. Summary of photostationary state ratio

Sensitizer	E_T (kcal/mol)	$([B_{trans}]/[B_{cis}])_{pss}$
Hg($^3P_1$)	112.7	1.0[33]
Benzene	84.4	1.37[30]
Benzene	84.4	0.92[31,32]
Acetone	79—82	0.94[34]
Nitromethane	80	0.90

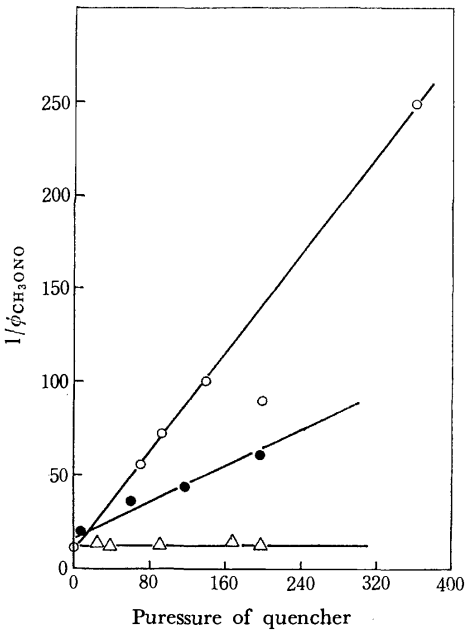

Fig. 5. Stern-Volmer plots of the quantum yield of methyl nitrite against the press. of quenchers.
○; *cis*-2-butene, ●; ethylene, △; CO_2

cis-2-butene. The Stern-Volmer plot of $1/\phi_{CH_3ONO}$ against ethylene and *cis*-2-butene gives a good linear relationship (Fig. 5). The result is consistent with the following equation derived on the basis of the reaction mechanism we proposed.

$$\frac{1}{\phi_{CH_3ONO}} = \frac{1}{\phi_T}\left(\frac{k_{9a}+k_{9b}}{k_{9b}}\right)\left(1+\frac{k_8[Q]}{k_5}\right) \quad (7)$$

The ratio k_5/k_8 is again calculated from the slope with the values of ϕ_T, and $(k_{9a}+k_{9b})/k_{9b}$, giving the value 2.0×10^{-2} mol/l for *cis*-2-butene and 5.8×10^{-2} mol/l for ethylene, respectively. The value for *cis*-2-butene is about 20% larger than that derived by the Cundall method from isomerization data. When the assumption and experimental errors are taken into account, both values may be in good agreement.

The Resonance Raman Effect of Azobenzene and *p*-Aminoazobenzene

Shiro KOIDE, Yasuo UDAGAWA, Naohiko MIKAMI, Koji KAYA, and Mitsuo ITO
Department of Chemistry, Faculty of Science, Tohoku University, Sendai
(Received July 12, 1972)

The resonance Raman spectra of azobenzene and *p*-aminoazobenzene were measured precisely at various excitation wavelengths. It was found that the π–π^* excited state played a dominant role in the Raman intensities but not the n–π^* excited state and that there was no correlation between the Raman intensity and the absorption coefficient at excitation wavelength.

Resonance Raman effect (RRE) is observed[1,2] when the frequency of Raman exciting light falls in the electronic absorption. One of the characteristic aspects of RRE is enormous enhancement of Raman intensity. In general, aromatic molecule has more than two absorptions in the visible and ultra-violet regions. Thus, it is interesting to see what difference occurs in the intensity enhancement when the excitations are made at different wavelengths which coincide with the absorptions of different electronic transitions of the molecule.

Azobenzene is suitable for such an experiment. It has two different electronic absorption bands centered at 450 and 320 nm (Fig. 1), which are assigned to n-π^* and π–π^* transitions, respectively[3,4]. Moreover, two different lasers whose lasing wavelengths fall in the above absorptions are now available.

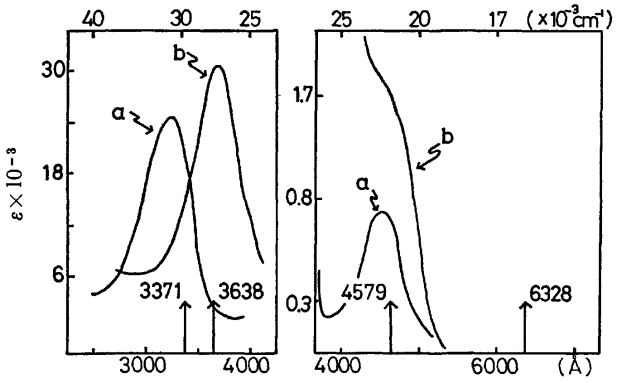

Fig. 1. The electronic absorption spectra of azobenzene and *p*-aminoazobenzene in the visible and ultraviolet regions.
a: Azobenzene in carbon tetrachloride.
b: *p*-Aminoazobenzene in carbon tetrachloride.

The Raman spectra of azobenzene and its derivatives excited by visible Hg lines have been reported by Brandmuller and Hacker,[5] who observed the intensity enchancement of several Raman lines in resonant condition with the n-π^* excited state.

We have studied the wavelength dependence of the Raman intensities of azobenzene and *p*-aminoazobenzene with various kinds of lasers covering from visible to near ultraviolet regions. It was concluded from the results that the excited electronic states corresponding to π–π^* absorptions were primarily important in RRE.

Experimental

Experimental details for taking Raman spectra have been described.[6] The exciting light sources used were a 6328 Å He–Ne laser, a 4579 Å Ar ion laser and a 3371 Å nitrogen pulsed laser. The 3638 Å lasing line of the Ar ion laser was also used.

The sample solution was prepared by dissolving the stock solution of benzene containing known amounts of the sample in an appropriate solvent (carbon tetrachloride or chloroform). Depending on the excitation wavelengths used, the concentration of the solution was so adjusted as to obtain the maximum efficiency. The concentrations appropriate to 6328, 4579, 3638 and 3371 Å excitations are about 10^{-1}, 10^{-4}, 10^{-4} and 10^{-5} mol/*l*, respectively. The intensities of the Raman lines of the sample were determined relative to the 992 cm^{-1} Raman line of benzene which was used as an internal standard for intensity.

The observed intensities of the individual Raman lines should be corrected for absorption of the sample to obtain the original intensities. The correction was made by $I=I_{obs}\times 10^{\varepsilon cx}$, where I is the original Raman intensity, I_{obs} is the intensity observed after passing the sample solution of concentration c and path length x, and ε is the absorption coefficient at the wavelength of the Raman line concerned. x represents the distance between the incident laser beam and the wall of the sample cell through which the Raman scattering is observed. Since c and x were determined from the experimental conditions and ε was also known by the electronic absorption measurement, the original intensity I was determined from I_{obs}. Corrections for the wavelength dependence of the detection system as well as for polarization character of the monochromator were also carried out.

Results and Discussion

The intensities of several main Raman lines of the sample relative to the intensity of the 992 cm^{-1} line of benzene were evaluated from the integrated areas of the individual Raman line of the recorded spectral chart and the corrections described above were made to the observed intensities. The corrected relative intensities normalized for the intensities at 6328 Å excitation are given in Table 1 for various excitation wavelengths. Errors in the values are also listed. The

TABLE 1. THE WAVELENGTH DEPENDENCES OF RAMAN INTENSITIES[a)]

Excitation wavelength		6328Å	4579Å	3638Å	3371Å
Azobenzene	1140 cm^{-1}	1	4	30	60
	1182 cm^{-1}	1	6	—[b)]	80
	1440 cm^{-1}	1	4	60	90
p-Amino-azobenzene	1139 cm^{-1}	1	10	100	100
	1184 cm^{-1}	1	9	—[b)]	200
	1422 cm^{-1}	1	20	200	300

a) The corrected relative Raman intensities of azobenzene and *p*-aminoazobenzene are normalized for the intensities at 6328Å excitation. Experimental errors at 4579 Å, 3638Å and 3371Å are ±20%, ±30% and ±30%, respectively.

b) The Raman line around 1180 cm^{-1} at 3638Å excitation is far weaker than the other Raman lines, so that it is not possible to obtain the quantitative value.

errors are due to the low signal to noise ratio and the relatively small magnitude of the signals. In spite of the large errors, the following discussions are possible through repeated measurements. The Raman line of 1440 cm^{-1} of azobenzene as well as the 1422 cm^{-1} line of *p*-aminoazobenzene has been assigned as due mainly to the N=N stretching vibration.[7-9] The vibrational modes of the other Raman lines around 1140 and 1180 cm^{-1} are not well established.

As seen in Table 1, the N=N stretching vibration undergoes more or less stronger enhancement than the other two Raman lines under rigorous resonant conditions (3638 and 3371 Å excitation). This indicates the close connection between the nature of the enhanced vibration and the electronic absorption band (the intramolecular charge transfer from benzene to the N=N group). It is concluded from the measurements at the two excitation wavelengths (3638 and 3371 Å) falling in the same π-π^* transition band that there is no correlation between the enhanced degree of the Raman line and the absorption coefficient at the excitation wavelength. This is clearly seen in the case of azobenzene. The degrees of enhancement differ at most twice in spite of the enormous distinction of the absorption coefficients at the two wavelengths (the molar absorption coefficients are 4.6×10^2 at 3638 Å and 2.0×10^4 at 3371 Å, respectively).

Mortensen[10] reported that the enhanced degree of Raman line was proportional to the square of the absorption coefficient at the excitation wavelength. Kiefer and Bernstein[11] asserted linear proportionality between these two quantities. Our result does not fit with either of these and further consideration is required.

For the RRE in the n-π^* absorption region by 4579 Å excitation, the relative intensities at the 4579 Å excitation (Table 1) do not seem to be as large as expected from the rigorous resonant condition. They seem to be of an order of magnitude anticipated from the preresonance effect contributed from the higher excited state. In order to see this, the wavelength dependences of the relative intensities of the Raman lines of azobenzene were calculated by means of the equation given by Albrecht and Hutley.[12] Assuming only the π-π^* excited state of azobenzene corresponding to the 320 nm absorption to be responsible to the preresonance effect, the relative intensities[13] at 4579 Å excitation were calculated to be about four times the intensity at 6328 Å, in which the wavelength dependence of the reference Raman line of benzene was taken into account by postulating the excited state corresponding to the 180 nm band of benzene as an active intermediate state.[12] The calculated value is of about the same order of magnitude as the observed values given in Table 1. The fairly large observed intensities at 4579 Å excitation for *p*-aminoazobenzene can also be explained by the closer preresonant condition achieved by the shift of the π-π^* absorption toward longer wavelength (the maximum peak of the π-π^* absorption of *p*-aminoazobenzene is located at 370 nm).

Thus it may be concluded qualitatively that the π-π^* excited states of azobenzene and *p*-aminoazobenzene play a dominant role in the Raman intensities but not n-π^* excited state.

Characterization of the Geometrical Isomers of the Carbonato(or oxalato)-aminoacidatodiammine Complexes of Cobalt(III)[1]

Kiyoshi NAKAI, Shuji KANAZAWA, and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received April 12, 1972)

Three geometrical isomers of the $[CoCO_3(aa)(NH_3)_2]$-type complex (aa stands for the α-alaninate, β-alaninate or valinate ion)—the *mer*(*cis*-diammine)-, *mer*(*trans*-diammine)- and *fac*-isomers—have been prepared. Three similar isomers of the $[Co\ ox(gly)(NH_3)_2]$ and $[Co\ ox(\beta\text{-ala})(NH_3)_2]$ complexes have been obtained by reactions of the corresponding carbonato complexes with an oxalate. In addition, the corresponding three isomers of a related $[Co(gly)(NH_3)_2(OH_2)_2]^{2+}$ complex have been prepared. The isomers thus obtained have been characterized by their absorption, PMR, and IR spectra. Of the *mer*(*trans*) isomers of the present complexes, those of the carbonato-α-alaninato and carbonatovalinato complexes revealed clear shoulders in their second absorption bands. Through the present study, some relationships between the appearance of such a shoulder in the *mer*(*trans*-diammine) isomer and the ring size of chelates have been deduced.

In a previous paper,[2] we reported that three possible geometrical isomers of the $[CoCO_3(gly)(NH_3)_2]$ complex could be isolated from a reaction mixture of the *cis*-$[Co(CO_3)_2(NH_3)_2]^-$ complex with glycine, and that an isomer characterized as the *mer(trans)* form showed an interesting absorption spectrum with a clear shoulder in the second absorption band. Here, *mer(trans)* represents the isomer which has two NH_3 groups in the *trans* positions and three N (or O) atoms in the *cis-trans* positions (Fig. 1).

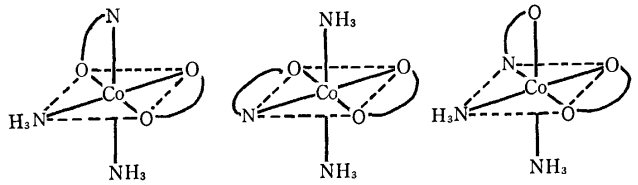

Fig. 1. Possible geometrical isomers.

The present work was first undertaken in order to obtain complexes by using α-alanine, valine, and β-alanine instead of the glycine used in the previous work. Then the work was proceeded in obtaining the related glycinatodiammine and β-alaninatodiammine complexes containing oxalate ion in place of the carbonate ion. In each preparation three geometrical isomers of a desired complex were obtained. In addition, three isomers of the $[Co(gly)(NH_3)_2(OH_2)_2]^{2+}$ complex were obtained through the acid hydrolysis of each isomer of the corresponding carbonato complex.

As to the *mer(trans)* isomers, the absorption spectra of the carbonato-α-alaninato and carbonatovalinato complexes showed a shoulder such as that observed for the previous glycinato complex, while the spectra for the carbonato-β-alaninato, oxalatoglycinato, and oxalato-β-alaninato complexes revealed no shoulder. On the other hand, a shoulder was observed on the shorter-wave-length-side of the first band for the oxalato-β-alaninato and diaquoglycinato complexes.

1) Presented at the 26th Annual Meeting of the Chemical Society of Japan, April 3rd, 1972, Hiratsuka.

Experimental

Preparation. The procedure for the preparation of the $[CoCO_3(aa)(NH_3)_2]$-type complexes (where aa stands for the α-alaninate, β-alaninate, or valinate ion) was essentially the same as that for the glycinato complex previously reported.[2] In that preparation of the glycinato complex, the *mer(trans)* isomer was precipitated during the reaction between the *cis*-$[Co(CO_3)_2(NH_3)_2]^-$ and glycine, while no precipitate was obtained in the present preparation. The reacted solution, therefore, was directly chromatographed in order to separate geometrical isomers of a desired complex.

The formation ratio among the three isomers for the carbonato complexes, *mer(cis)* : *mer(trans)* : *fac*, was determined spectrophotometrically with the fractions obtained in chromatographic separation. The results obtained were: 4.4 : 1.0 : 1.5 for the α-alaninato complex, 5.1 : 1.0 : 1.4 for the valinato complex, and 6.0 : 1.0 : 0.6 for the β-alaninato complex.

The $[Co\ ox(gly)(NH_3)_2]$ complex was prepared as follows. To a suspension of the *mer(trans)*-$[CoCO_3(gly)(NH_3)_2]$ complex (1.5 g, 0.005 mol) in water (20 ml), we added 60% perchloric acid (ca. 1 ml) under an iced condition; the mixture was then stirred for about 30 min under the same conditions in order to complete the acid hydrolysis. Then, potassium oxalate (2 g, 0.01 mol) was added to the solution, and it was neutralized with an aqueous solution of potassium hydroxide, whereby potassium perchlorate was precipitated. After the removal of the precipitates by filtration, the filtrate was stirred for 30 minutes at room temperature. The resulting solution was then chromatographed in the same manner as the carbonato complexes. During the addition of water to a column of Dowex 50W-X8 (Na-form), three bands were separated. After each band had been collected in a fraction, the fraction was concentrated and kept in a refrigerator. Very fine crystals were obtained from each concentrate.

The oxalato-β-alaninato complex could be obtained by a similar preparation, using the carbonato-β-alaninato complex as the starting material.

When an isomer of the carbonatoglycinato complex was treated with a saturated solution of oxalic acid, very fine crystals were deposited. This compound was the corresponding isomer of the $[Co(gly)(NH_3)_2(OH_2)_2]^{2+}$ complex.

The results of the elemental analyses for the complexes obtained in the present work are given in Table 1.

proton magnetic resonance (PMR) spectra were measured with the same instruments as were used in a previous work.[2] Since it had been reported in the previous paper that the geometrical configuration of an isomer of the carbonato complex was retained in the process of acid hydrolysis, the PMR spectra were measured in a mixture of D_2O and D_2SO_4 (1 : 1 v/v), using sodium 3-(trimethylsilyl)-propanesulfonate as the internal or external reference.

Results and Discussion

Characterization of Isomers. The absorption spectra of the three isomers for each complex are shown in Figs. 2—7, while the numerical data are listed in Table 2, in which the data for the known $[CoCO_3(gly)(NH_3)_2]$ complex are also included for the sake of comparison.

In the cases of α-alaninato and valinato complexes, the isomers obtained from the first fractions in

their chromatographic separations exhibit absorption spectra very similar to that for the *mer(cis)* isomer of the glycinato complex. The same situation holds between the isomers of the third fractions of the present complexes and the *fac* isomer of the glycinato complex. Each spectrum for the isomers of the second fractions

a) $\times 10^{13}\ sec^{-1}$

clearly shows a shoulder in the second absorption band, similar to the spectrum for the *mer(trans)* isomer of the glycinato complex. However, the intensity of the second band of the α-alaninato complex is rather larger than that of the first band, contrary to the cases of the corresponding isomers of the glycinato and valinato complexes (Figs. 2 and 3). From these similarities in absorption spectra, *mer(cis)*, *mer(trans)*, and *fac* structures (Fig. 1) could be assigned to the isomers isolated, according to the order of elution.

For the carbonato-β-alaninato complex, the *mer* and *fac* assignments to the isomers can easily be done from the shapes of the first absorption bands, but *cis* and *trans* assignments for the two *mer*-isomers are difficult because their spectra resemble each other very much (Fig. 4). However, from the order of elution, it may be assumed that the *mer(cis)* isomer is the compound obtained from the first fraction. Further confirmation is provided by PMR spectral studies to be described later.

As to the oxalatoglycinatodiammine complex, the isomer obtained from the second fraction shows its first and second absorption maxima at considerably shorter wavelengths compared with the isomer obtained from the first fraction (Fig. 5). Apart from the

disappearance of a shoulder, this hypsochromic shift of the absorption bands in the former isomer corresponds well to that in the *mer(trans)* isomers of the carbonato-α-aminoacidato complexes. Thus, the *mer* isomer of the second fraction may be regarded as the *mer(trans)* isomer.

As to the oxalato-β-alaninato complex, the two *mer* isomers show similar spectra; it is impossible to determine their geometrical configurations by means of the electronic spectra (Fig. 6). Therefore, the confirmation is based on the PMR spectral data.

In the previous paper, it was reported that the configuration of each isomer of the carbonatoglycinato complex was retained during acid hydrolysis. The electronic spectrum of each isomer of the aquo complex isolated as an oxalate in the present work is consistent with the previous observation (Fig. 7).[2)]

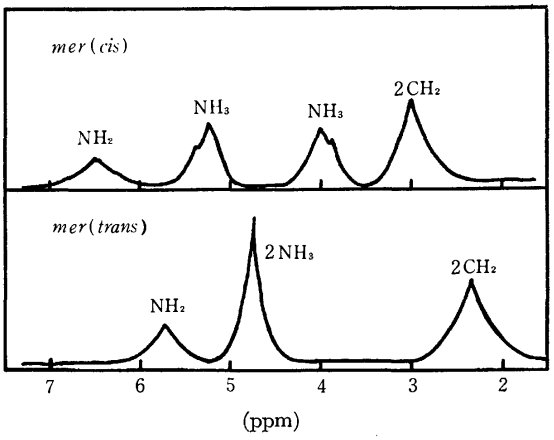

Fig. 8. PMR spectra of the *mer*-isomers of the $[Co(CO_3)(\beta\text{-ala})(NH_3)_2]$ in D_2O/D_2SO_4.

The PMR spectra of the two *mer* isomers of the carbonato-β-alaninato complex are shown in Fig. 8. The isomer tentatively identified as the *cis* isomer, based on the order of elution, shows four peaks, at 6.5, 5.3, 4.0, and 3.0 ppm, with an integrated ratio of ca. 2 : 3 : 3 : 4. As is indicated in the figure, this ratio corresponds to the NH_2 group of the chelated β-alaninate, the two NH_3 groups in different environments, and the two CH_2 groups of the β-alaninate undistinguishable from each other. On the other hand, the isomer assigned tentatively to the *trans* isomer shows three peaks, at 5.7, 4.8, and 2.7 ppm, with a ratio of ca. 2 : 6 : 4. This ratio corresponds to the NH_2 group, the two NH_3 groups in equivalent environments, and the two CH_2 groups respectively. From these results, the previous assignments are now ascertained.

The PMR spectra of the two *mer*-isomers of the oxalatoglycinato complex are shown in Fig. 9. The spectrum of the isomer assumed to be *cis* exhibits four peaks; the one observed at 5.7 ppm is due to the NH_2 group of the chelated glycinate, while the other three peaks, close together between 3.5 and 4.5 ppm, are due to the complexed NH_3 groups and the CH_2 group of the glycinate. The integrated ratio of these peaks is estimated to be ca. 2 : 3 : 2 : 3, ranging from lower to higher fields. Provided that the two peaks at 4.3

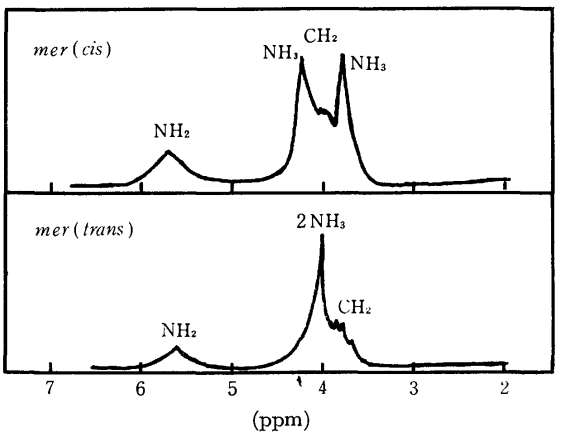

Fig. 9. PMR spectra of the *mer*-isomers of the $[Co(ox)(gly)(NH_3)_2]$ in D_2O/D_2SO_4.

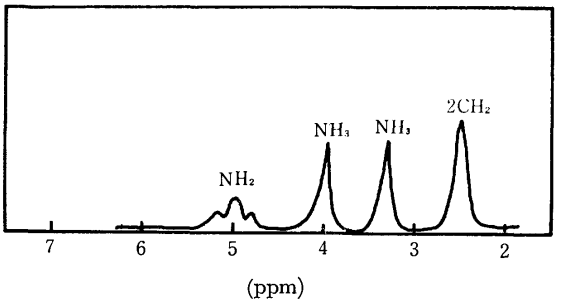

Fig. 10. PMR spectrum of the *mer(cis)*-$[Co(ox)(\beta\text{-ala})(NH_3)_2]$.

and 3.8 ppm are due to the NH_3 groups in different environments, the above ratio corresponds to the proton numbers concerned. Thus, the PMR results also support the assignment of the *cis* configuration to this isomer. On the other hand, the spectrum of the other *mer* isomer exhibits three peaks, at 5.6, 4.0, and 3.8 ppm, with a ratio of ca. 2 : 6 : 2. Since the middle peak, with the highest value, is attributable to the two NH_3 groups in equivalent situations, the *mer(trans)* configuration is assigned to this isomer.

The PMR spectrum of the *mer*-isomer of the oxalato-β-alaninato complex obtained from the first fraction is shown in Fig. 10. The isomer exhibits four peaks, at 5.2, 4.0, 3.3, and 2.5 ppm, with a ratio of ca. 2 : 3 : 3 : 4. This result suggests that the two coordinated NH_3 groups are in different environments and that, therefore, this isomer may be assigned the *mer(cis)* configuration. Though the PMR spectrum of the other *mer*-isomer was not measured, it is certain from the above-mentioned analogue of the configurational determination that this isomer has the *mer(trans)* configuration.

The PMR spectrum of each isomer for the present diaquo complex is essentially the same as that in the previous work.[2)]

The evidence for the chelation of a carbonate ion in the β-alaninato complex was supported by the IR spectral data—that is, by the observation of the bands near 1600 (ν_s(C=O)), 1270 (ν_s(C-O)+δ(O-C=O)), 1030 (ν_s(C-O)), and 760 cm^{-1} (in-plane def. of

CO_3^{2-}).[3] The evidence for the chelation of an oxalate ion in the oxalato complexes was also supported by the observation of characteristic bands at 1710 and 1680 (ν_{as}(C=O)), 900 (ν_s(C–O)+δ(O–C=O)), 1400 (ν_s(C–O)+ν(C–C)), and 1260 cm^{-1} (ν_s(C–O)+δ(O–C=O)).[3] In the IR spectra of the aquo-complex, the existence of an oxalate ion as the counterion was also supported by the absorption near 1700 cm^{-1}; the band of oxalic acid of crystallization is also observed in this region.

Mer(trans) *Isomers.* As has been mentioned in the foregoing discussion, the absorption spectra of the *mer(trans)* isomers for the α-alaninato and valinato complexes, like that for the glycinato complex, show shoulders in their second absorption bands. A similar shoulder in the second absorption band has been found in a few complexes: Jørgensen[4] cited the spectra for the [Co edta(OH)]$^{2-}$ and [Cr edta(OH)]$^{2-}$ species. Furlani *et al.*[5] stated that such effects upon the second absorption band for the [Cr edta(OH)]$^{2-}$ species could be due to a lower symmetry caused by a distortion of the octahedron. Emmenegger and Schwarzenbach[6] reported a similar splitting in the spectrum of the [Co penten(OH)]$^{2+}$ complex (penten=*N,N,N',N'-tetrakis*(α-aminoethyl)ethylenediamine). Recently, Igi *et al.*[7] have reported that the second absorption bands for the [Co(guH)(en)$_2$]$^{3+}$ and [Co(gu)(en)$_2$]$^{2+}$ complexes (guH stands for a guanylurea) split into two components.

It should be noticed that even though the second absorption band exhibits a remarkable splitting for the present *mer(trans)* isomer, the first absorption band shows nothing remarkable. In addition, it is a noteworthy fact that the half-width of the first band for the *mer(trans)* isomer of a carbonato-α-aminoacidato complex is less than that for the *mer(cis)* isomer of the same complex (Table 1).

For the *mer(trans)* isomer of the carbonato-β-alaninato complex, both the first and second absorption maxima are at considerably lower wavelengths than those for the same isomer of a carbonato-α-aminoacidato complex. Moreover, no shoulder is found in the second band region for this isomer of the β-alaninato complex.

When the absorption spectral data are compared between the *mer(trans)* isomers of the carbonatoglycinato and oxalatoglycinato complexes, their maxima are at almost the same positions, though the carbonato ligand lies in a lower position in the spectrochemical series than the oxalato ligand, and no shoulder is observed for the isomer of the oxalato complex. When the same comparison is made between the *mer(cis)* and *mer(trans)* isomers of the oxalato complex, a considerable hypsochromic shift is observed in the latter isomer. This feature is the same as in the case of the corresponding carbonato complex.

As to the absorption spectrum of the *mer(trans)* isomer of the oxalato-β-alaninato complex, both the first and second bands are observed at rather longer wavelengths than those of the corresponding oxalatoglycinato complex, and a shoulder appears in the shorter wavelength-side of the first absorption band. Comparing this spectrum with that of the *mer(cis)* isomer, both the first and second bands are observed at almost the same positions.

From an X-ray study of the $[CoCO_3(NH_3)_4]^+$ complex,[8] it has been pointed out that the bond lengths between the complexed NH_3 groups lying at the *trans* positions to the carbonate chelate and the central cobalt are longer than those between the other NH_3 groups lying at the *cis* positions, and that the ∠NCoN with N atoms of the NH_3 groups in the *trans* positions is larger than the other N–Co–N angles. Thus, we can now expect that the two NH_3 groups lying at the *trans* positions to the carbonate chelate behave as weaker ligands than the NH_3 groups at the *cis* positions. Moreover, such an effect will more strongly appear when a rigid five-membered chelate ring is in a co-plane with the carbonate chelate ring. Thus, it can be expected in regard to the present carbonato-α-aminoacidato complex, that the α-aminoacidate chelate lying on a co-plane with the carbonate chelate behaves as a somewhat weaker ligand than the same chelate forming a spiral with the carbonate chelate. The remarkable differences in absorption spectrum between a *mer(trans)* and the corresponding *mer(cis)* isomer may be related to the different effects of the carbonate chelates upon the α-aminoacidate chelates. The absorption spectrum of the *mer(cis)* isomer of a carbonato-α-amino acidato complex can be understood with the aid of a ligand field theory, such as in Yamatera's prediction,[9] but the spectrum of the *mer(trans)* isomer of the same complex can not be interpreted at present.

As a result of the present work, we can say the following thing: 1) An octahedral cobalt(III) complex consisting of a five-membered α-aminoacidate ring, two ammonia groups in *trans* positions, and a four-membered carbonate ring reveals a shoulder which is considered to be one component of the split second absorption band, while, when the five-membered aminoacidate ring is replaced by a six-membered one, or when the four-membered carbonate ring is replaced by a five-membered oxalate ring, no such shoulder appears. 2) The half-width of the first absorption band of the *mer(trans)* is less than that of the *mer(cis)* isomer for a carbonato-α-aminoacidato complex. 3) A *mer(trans)* isomer containing a five-membered aminoacidate and a carbonate or an oxalate chelate ring shows its first and second absorption maxima at shorter wavelengths than the *mer(cis)* isomer of the same complex.

Determination of the Stability Constants of the Bis(selenocyanato)mercury(II) and Tris(selenocyanato)mercurate(II) Complexes by a Polarographic Method

Teisuke MURAYAMA and Akio TAKAYANAGI

Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu

(Received May 1, 1972)

Selenocyanate ions give an anodic polarographic wave with a half-wave potential of 0.033 V (*vs.* SCE) at 25°C and 0.044 V at 35°C for a 1 mM solution. The electrode process is: $Hg \rightleftarrows Hg^{2+} + 2e$, $Hg^{2+} + 2SeCN^- \rightleftarrows Hg(SeCN)_2$, $Hg^{2+} + 3SeCN^- \rightleftarrows Hg(SeCN)_3^-$. By means of an equation which gives the relation between the anodic current and electrode potential, stability constants of the bis(selenocyanato)mercury(II) and tris(selenocyanato)-mercurate(II) complexes (β_2 and β_3, respectively) were calculated from the polarograms. Values of log β_2 and log β_3 at ionic strength 0.3 are, respectively, 21.4_3 and 25.6_6 at 25°C, and 20.4_4 and 24.4_8 at 35°C.

We reported in previous papers on the determination of stability constants of mercuric cyanide, the tri- and tetra-cyanomercurate(II) ions, and the tris(thiosulfato)mercurate(II) ion by a polarographic method.[1,2] This paper describes the determination of stability constants of the bis(selenocyanato)mercury(II) and tris(selenocyanato)mercurate(II) complexes by the same method. The constant of the tris complex was given by Toropova,[3] but that of the bis complex does not seem to have been reported.

Experimental

Commercial potassium selenocyanate (Koso Kagaku-Yakuhin) was used without purification. The concentration of the potassium selenocyanate stock solution was determined by argentometric titration.[4]

The stock solution of mercuric chloride was prepared by dissolving a weighed amount of the reagent of guaranteed grade.

The supporting electrolyte was 0.3 M potassium nitrate. For the amperometric titration of mercuric chloride, 0.002% Triton X-100 was added as a maximum suppressor.

All solutions were prepared with redistilled water.

The dropping mercury electrode had the following characteristics (in 0.3 M potassium nitrate solution at zero applied potential *vs.* SCE and at 25°C): the rate of flow of mercury (m), 1.978 mg/sec; the drop time (τ), 4.13 sec; $m^{2/3}\tau^{1/6} = 2.00$.

The cell and the salt bridge were described previously.[2] To prevent interaction between the oxidation product and the mercury accumulated on the bottom of the cell, it was necessary to start measurements of the anodic wave as soon as the dropping mercury electrode was introduced into test solutions which had been degassed with nitrogen. The measurements were made at 25.0 and 35.0±0.1°C. All potentials were corrected for the internal resistance (*iR* drop) across the cell.

Polarograms were measured by a Yanagimoto PA-102 polarograph operated manually. The bridge of the polarograph was calibrated by a precise potentiometer.

Results and Discussion

Fig. 1 shows anodic waves of the selenocyanate ion. The half-wave potential is 0.033 V *vs.* SCE at 25°C and 0.044 V at 35°C when the concentration of selenocyanate ions is 1 mM. The limiting current measured at a potential of 0.300 V *vs.* SCE is directly proportional to the concentration of selenocyanate ions, as shown in Fig. 2. The temperature coefficient of the limiting current is 1.2%.

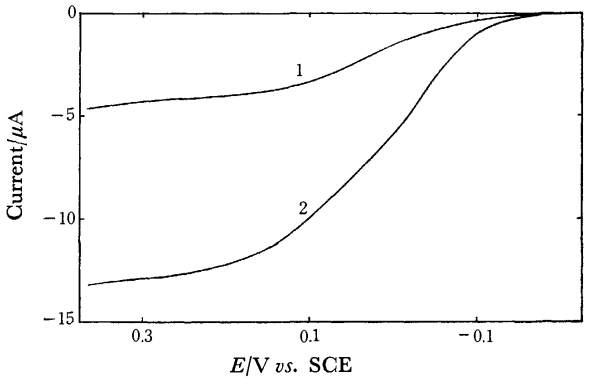

Fig. 1. Polarograms of the selenocyanate ion at 25°C. Corrected for the residual current. Supporting electrolyte, 0.3 M potassium nitrate. Concentration of potassium selenocyanate: 1; 1.142 mM, 2; 3.42_6 mM.

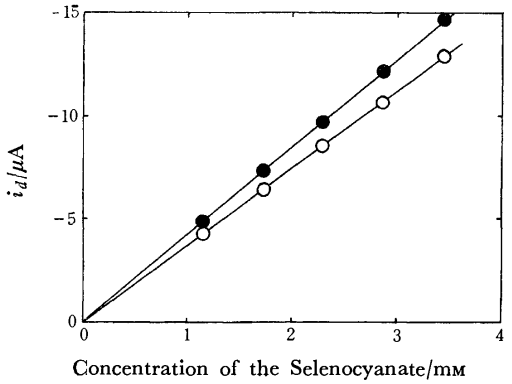

Fig. 2. Dependence of the diffusion current on the concentration of the selenocyanate. Temperature: ○; 25°C, ●; 35°C.

By analogy with other anodic processes in which mercuric complexes are produced,[1,2,5] the overall electrode process of the selenocyanate ion may be

considered to be composed of an electron transfer step

$$Hg = Hg^{2+} + 2e \quad (1)$$

and complex formation reactions:

$$Hg^{2+} + 2SeCN^- = Hg(SeCN)_2 \quad (2)$$

$$Hg^{2+} + 3SeCN^- = Hg(SeCN)_3^- \quad (3)$$

Reactions (1), (2), and (3) are assumed to be reversible. The formation of $Hg(SeCN)_4^{2-}$ and higher complexes are not considered here, because the polarographic behavior of the anodic wave is fully explained with reactions (1), (2), and (3) as shown in the following.

The potential E of the dropping mercury electrode is given by

$$E = E^0 + \frac{2.303RT}{2F}\log\frac{2\gamma_1\kappa_4}{\beta_2\kappa_2} + \frac{2.303RT}{2F}\log\frac{10^{-3}y}{(1+rx)x^2} + \frac{6.909RT}{2F} \quad (4)$$

where E^0 is the standard potential of mercuric-mercury electrode, R the gas constant, T the absolute temperature, F the Faraday constant, γ_1 the activity coefficient of the mercuric ion, β_2 the stability constant of the bis(selenocyanato)mercury(II) complex, κ_2 the Ilkovič constant for the same complex, κ_4 the Ilkovič constant for the selenocyanate ion, x the concentration of selenocyanate ions at the surface of the dropping mercury electrode, and

$$r = \frac{\beta_3\kappa_3}{\beta_2\kappa_2} \quad (5)$$

$$y = \frac{i}{2\kappa_4} \quad (6)$$

Here β_3 and κ_3 are, respectively, the stability and Ilkovic constants of the tris(selenocyanato)mercurate-(II) ion, and i is the anodic current. The value of x is calculated by

$$x = \frac{r(x_0-3y)-1+\sqrt{r^2(x_0-3y)^2+2r(x_0-y)+1}}{2r} \quad (7)$$

where $x_0 = i_d/\kappa_4$.[2] The value of κ_4 is 3.75 μA/mM at 25°C and 4.22 μA/mM at 35°C.

If the correct value of r is used, the logarithmic plot construced according to Eq. (4) should produce a straight line with a reciprocal slope equal to 2.303 $RT/(2F)$. By the method of trial and error the best value of r was determined to be 1.7×10^4 at 25°C, and 1.1×10^4 at 35°C. Figure 3 shows the logarithmic plot constructed from polarograms observed at 25°C. Table 1 shows the reciprocal slope of the plot constructed with these values of r and the potential e_0 where $\log 10^{-3}y(1+rx)^{-1}x^{-2}$ becomes zero. Fair agreement among the values in the respective columns is considered as evidence in support of the assumption that reactions (1), (2), and (3) are responsible for the anodic wave and that $Hg(SeCN)_4^{2-}$ and higher complexes do not participate.

Values of β_2 and β_3 can be calculated from r and e_0, if E^0, γ_1, κ_2, and κ_3 are known. The standard electrode potential E^0 at 25°C was given as 0.8500 V *vs.* SHE (=0.6056 V *vs.* SCE) by Hietanen and Sillén.[6]

	average	0.042
Temperature, 35°C; r=1.1×10⁴		
1.142	31	0.050
1.713	31	0.051
2.28_4	31	0.050
2.85_5	30	0.053
3.42_6	30	0.051
	average	0.051

a) The potential where $\log 10^{-3}y(1+rx)^{-1}x^{-2}$ becomes zero.

The value at 35°C was calculated to be 0.6040 V *vs.* SCE from this and the entropy change of reaction (1) at 25°C.[7]

The activity coefficient of the mercuric ion was estimated through the Debye and Hückel equation without the extended term.[8]

$$\log\gamma_i = -\frac{Az_i^2(2I)^{1/2}}{1+Ba_i(2I)^{1/2}} \quad (8)$$

7) W. M. Latimer, "Oxidation Potentials," Prentice-Hall, New York, N. Y. (1952), p. 30 and p. 176.

8) G. N. Lewis, M. Randall, K. S. Pitzer, and L. Brewer, "Thermodynamics," McGraw-Hill Book Co., New York, N. Y. (1961), p. 344.

In this equation γ_i, z_i, and a_i are the activity coefficient, the charge number, and the ionic size parameter, respectively, of the ion i, I is the ionic strength of the solution, and A and B are constants at a given temperature.[9] The value of a_i was assumed to be 5 Å for the mercuric ion.[10] The value of γ_1 was calculated to be 0.261 at 25°C and 0.255 at 35°C.

For the determination of κ_2 and κ_3, 25 m*l* of 0.260 mM mercuric chloride was titrated amperometrically with 11.42 mM potassium selenocyanate at a potential of −0.50 V *vs.* SCE. Figure 4 shows the titration curves. At first an approximate value of β_2 was estimated to be $10^{21.8}$ from Eq. (4) by introduction of the average value of e_0 at 25°C and of an approximate relation $\kappa_2=2\kappa_4$. From this and stability constants of chloro complexes of mercury(II),[11] it was concluded that the formation of the bis(selenocyanato)mercury(II) complex is quantitative if the total concentration of the selenocyanate is below 0.52 mM. The same holds at 35°C. Hence, 99% of the total mercury in the solution exists as bis(selenocyanato)mercury(II) when 1.13 m*l* of 11.42 mM potassium selenocyanate solution is added. From the diffusion current observed in the solution of this composition, the value of κ_2 was calculated to be 8.38 μA/mM at 25°C and 9.85 μA/mM at 35°C. Further addition of the selenocyanate causes little change in the diffusion current. This indicates that κ_3 is nearly equal to κ_2. In the following the ratio κ_3/κ_2 is assumed to be equal to unity. (At 35°C the ratio is not exactly equal to unity, but the discrepancy does not alter the result).

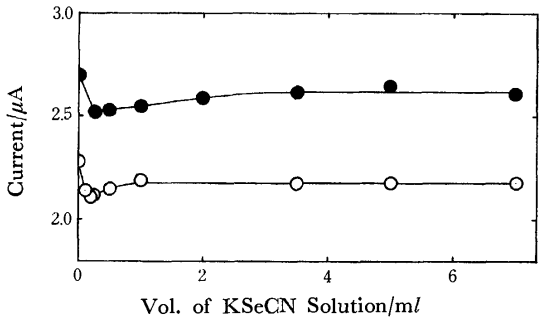

Fig. 4. Titration of 25 m*l* of 0.260 mM mercuric chloride with 11.42 mM potassium selenocyanate. Titrated at $E=-0.50$ V *vs.* SCE. Temperature: ○; 25°C, ●; 35°C.

By introduction of e_0 and other values given in the above into Eq. (4), the exact value of log β_2 was calculated to be 21.4_3 at 25°C and 20.4_4 at 35°C. From r, log β_2, and the relation $\kappa_3/\kappa_2=1$, the value of log β_3 was found to be 25.6_6 at 25°C and 24.4_8 at 35°C. Toropova gave 26.40 for log β_3 at 25°C.[3] Her value is greater than the value given in this study by about 0.7, the reason being not clear at present.

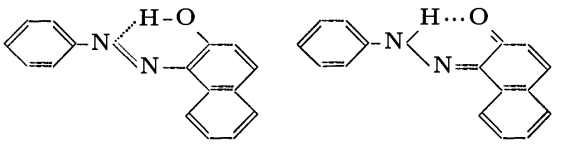
Mass Spectrometry of 1-Phenylazo-2-naphthols

Kousuke KOBAYASHI, Kenji KURIHARA, and Kazutoyo HIROSE
Dai-Nippon Ink Institute of Chemical Research, Kamikizaki, Urawa-shi, Saitama

(Received January 14, 1972)

In order to examine the azo-hydrazone tautomerism of substituted 1-phenylazo-2-naphthols and to estimate the effect of substituents on the equilibrium, mono-substituted 1-phenylazo-2-naphthols were synthesized and the spectra were compared with those of the respective acetylated derivatives and β-naphthoquinone-methylphenylhydrazone as references of the azo and hydrazone forms respectively. The spectra of acetylated derivatives show the same pattern as those of the original samples except for the molecular ion and ion at *m/e*: 43. Moreover, β-naphthoquinone-methylphenylhydrazone displays a different fragmentation process, the cleavage of the N–N bond. In conclusion, the substituted 1-phenylazo-2-naphthols exist in the gaseous state as only the azo form; this is different from the results in the liquid and solid states. The fragmentation processes, in which the reactions of $M^+ \rightarrow (m/e: 171)^+ \rightarrow (m/e: 143)^+ \rightarrow (m/e: 115)^+$ mainly occur, are clarified on the basis of these results. The effect of substituents on the reaction rate of the formation of ions at *m/e*: 171 from molecular ions is examined. The correlation with the Hammett σ constants is $\rho = 0.078$ for meta substituents, and the plots for para substituents lie under the line, which means that the reaction rate for para substituents is slow. This is explained on the basis of the resonance effect.

Many studies have been carried out in an attempt elucidate the structure of 1-phenylazo-2-naphthols (PAN), which may exist as a true azo form (I) or as a hydrazone form (II).[1)]



(I) (II)

1) H. Zollinger, "Azo and Diazo Chemistry," Interscience, New York (1961), p. 322.

Over thirty years ago, Hendricks and his co-workers[2] and Kuhn[3] discussed how they exist as a resonance hybride or a tautomeric mixture. Later Burawoy and his co-workers, based on the electronic spectra in various solvents, clearly demonstrated that they exist in solution as tautomeric equilibria.[4] Further evidence for the presence of tautomerism in both solid and solution of PAN has been provided by many techniques, such as measurements of the electronic spectra,[5-8] the infrared spectra,[9] the chemical shift of ^{14}N in NMR,[10] the diamagnetic susceptibility,[11] and the fluorescence.[12] Recently Bansho and his co-workers[7] studied these phenomena quantitatively, and concluded that 50—70% of the molecules exist as the hydrazone form whatever the state, a solid in KBr disk or a solution in a polar (ethanol) or non-polar solvent (cyclohexane), by a comparison of the extinctions in the regions of 410—420 mμ and 480—500 mμ. They also pointed out that there is no linear relation between the percentage of the hydrazone form and the Hammett σ constants.

Unfortunately, the tautomeric equilibria of PAN in the gaseous state have not been studied. Recently, it has become apparent that no keto-enol tautomerism takes place after electron bombardment in a mass spectrometer.[13] Thus, we tried to elucidate the tautomeric equilibria in the gaseous state and the effect of substituents by using a mass spectrometer.

Experimental

Measurement of the Mass Spectra. The spectra were obtained by the use of a JMS-01SG double-focusing mass spectrometer (Japan Electron Optics Laboratory Co., Ltd.). Using 75 eV electrons at a regulated emission current of 200 μA, all the experiments were made by the electrical detection method under low resolution conditions, several samples were also examined by the photo-plate detection method under high resolution conitions (*ca.* 20000) in order to confirm the elemental compositions. Samples were introduced through the direct sample inlet system under the condition of an ion-source temperature of 200—210°C and a sample-vaporizing temperature of 50—110°C (selected for each sample). The metastable ion was detected by the accelerating-voltage-scan method.[14] The pattern coefficients were measured at the maximum of the beam current by using a rapid scan to avoid any change in the ion beam.

Samples. The samples used were 15 PAN (Table 1), 7 PAN acetates (Table 2), and β-naphthoquinonemethylphenylhydrazone (NQH). The PAN were synthesized by the usual coupling reaction between β-naphthol and substituted anilines, were purified three times by recrystallization, and were confirmed by studying the melting point and the mass spectrum. The PAN acetates were synthesized by the usual acetylation of PAN using pyridine and acetic anhydride. They were also purified and confirmed in the same manner. NQH was synthesized by a reaction of β-

naphthoquinone and methylphenylhydrazinesulfate,[15] and was purified by crystallizing it three times from benzene-ligroin. The sample thus obtained consisted of long, flat, amethyst-colored crystals and melted at 118°C.

Results and Discussion

Mass Spectra of PAN. The characteristic ions observed in the spectra of PAN are $M^{+\cdot}$, $(M-1)^+$, $(m/e : 171)^+$, $(m/e : 143)^+$, $(m/e : 115)^+$, a substituted phenyl ion, and a further decomposed ion of the substituted phenyl ion, as is shown in Table 1. The main reaction is $M^{+\cdot} \rightarrow (m/e : 171)^+ \rightarrow (m/e : 143)^+ \rightarrow (m/e : 115)^+$, which is confirmed by the measurement of the metastable ions. The reaction is similar to that of azobenzenes.[16] It is, however, very dangerous to decide that PAN exist in the gaseous state as the azo form, since there is some possibility that the hydrazone form would react in the same manner.

Recently, some organic compounds which possess keto-enol tautomerism have been studied by means of mass spectrometer.[13,17] As has been mentioned above, no movement of tautomeric equilibria was observed after electron impact. This means that the mass spectra reflect the state of tautomeric equilibria in the gaseous state. Using this phenomenon, Zamir and his co-workers discussed the effect of the inlet temperature on the keto-enol equilibria of the acetylacetone.[18]

It is, at any rate, necessary to determine the state of tautomeric equilibria in order to make the fragmentation process clear.

Azo-hydrazone Tautomerism. It was revealed that the (M-42) ion radical, observed in the mass spectra of acetylated derivatives of compounds which possess keto-enol tautomeric equilibria, corresponds to the enol form of original compounds.[19,20] The acetylated derivatives of PAN were synthesized and measured by means of the mass spectrometer. The spectra obtained were then compared with those of the original PAN (See Figs. 1, 2, and 3). The spectra of PAN and their acetates resemble each other except for a few differences in intensity. That the relative intensities of $(M\text{-}42)^+$ to $(m/e : 171)^+$ and/or $(m/e :$

$143)^+$ in the spectra of acetylated derivatives are somewhat larger than those of M^+ to $(m/e : 171)^+$ and/or $(m/e : 143)^+$ in the spectra of original ones, can be reasonably explained by the energy loss at a de-ketene reaction. Actually, the spectra of PAN electron-bombarded at 50 eV are more similar even in intensity to those of acetylated derivatives electron-bombarded at 75 eV. An examination of the metastable ions generated in the first field-free region showed that the fragmentation processes were all same except for $(M\text{-}43)^+$. Also, the metastable ions generated in the second field-free region were found to be equal in shape and in relative abundance to the precursor ions; this means that the structure of the precursor ions in the spectra of both PAN and their acetates are the same.[21] These facts also support the theory that PAN exist in the gaseous state as the azo form, but they are insufficient to clarify the tautomeric equilibria, because the fragmentation processes of the hydrazone form remain undissolved. As it is impossible to measure the mass spectrum of PAN in the hydrazone form, we synthesized *β*-naphthoquinone-methylphenylhydrazone (NQH) as a model compound for the hydrazone form and measured its mass spectrum, which is shown in Fig. 4. The fragmentation process,

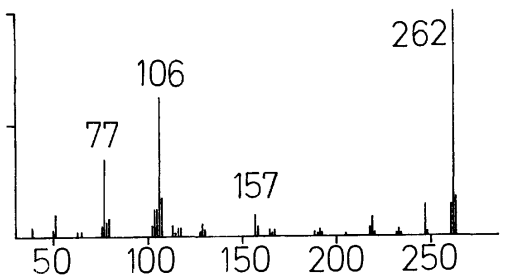

Fig. 4. Mass spectrum of *β*-naphthoquinonemethylphenylhydrazone.

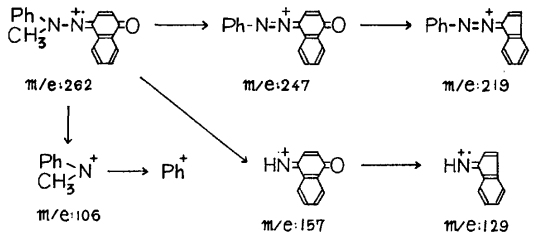
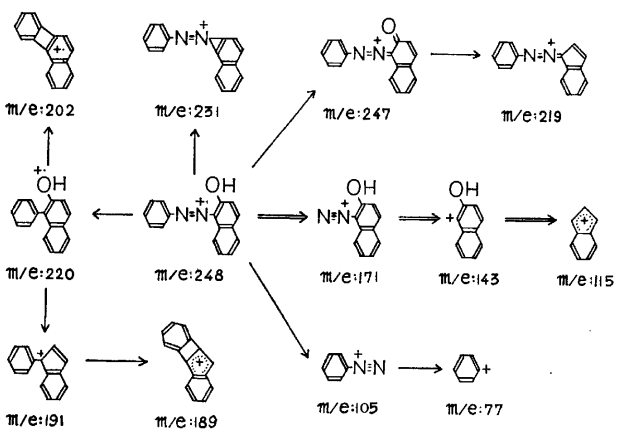


Scheme 1

as determined by the measurements of the precise mass and the metastable ions, is shown in Scheme 1. The main reaction can be understood as a cleavage of $M^{+\cdot}$ to $(m/e : 106)^+$, which corresponds to an ion designated as $(X\text{-}Ph\text{-}NH)^+$ in the spectra of PAN. The reaction of $M^{+\cdot} \rightarrow (m/e : 247)^+ \rightarrow (m/e : 219)^+$ in the spectrum of NQH corresponds to that of $M^{+\cdot} \rightarrow (M-1)^+ \rightarrow (M-1-28)^+$ in the spectra of PAN. These observations do not always support the existence of the hydrazone form in PAN, because there is some possibility that the azo form reacts in the same manner. That $(M\text{-}CH_3)^+$ is observed, while $(M\text{-}Ph)^+$ is not, means that the hydrazone form of PAN will produce $(M-1)^+$ rather than $(M\text{-}Ph)^+$. This also supports the theory that PAN exists as the azo form. The ion radical at $m/e : 157$ in the spectrum of NQH would be produced by the cleavage of the N-N bond with hydrogen transfer from CH_3, so the reaction does not give any information about the tautomerism of PAN. The fact that the $(X\text{-}Ph\text{-}NH)^+$ ion, which should come from the hydrazone form, is not observed supports the idea that PAN exist in the gaseous state as the azo form. In the spectrum o f PAN-13 (p-OCH_3), an ion at $m/e : 122$ corresponding to $(X\text{-}Ph\text{-}NH)^+$ was observed as a 9% intensity of the base peak. This fact indicates some coexistence of the hydrazone form.

It can be concluded, for the foregoing reasons, that PAN exist in the gaseous state at the measured temperature as the azo form, except for the para methoxy derivative, in which a little hydrazone form coexists.

Fragmentation Process of PAN. The fragmentation process of PAN-1 is determined on the basis of the azo form by measurements of the precise mass and the metastable ions (see Scheme 2). The other PAN

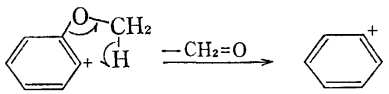


Scheme 2

are explained by the same process. The scission of both sides of the azo group is a main reaction which resembles that of azobenzenes.[16] The cleavage of $M^{+\cdot}$ to $(m/e : 171)^+$ is more liable to occur than that to $(m/e : 105)^+$, for the naphthol ring is a stronger electron donor than the phenyl ring.[22] The $(Ph-X)^+$ ion becomes stronger with an increase in the electron-donating power of the substituents (see Table 1).

The common ions with intensities of less than several percent are $(M-1)^+$, $(M-17)^+$, $(M-28)^+$, $(M-29)^+$, $(m/e : 218)^+$, and $(m/e : 189)^+$. The $(M-28)^+$ contains reaction products of the elimination of a nitrogen molecule and a carbonyl group.

When a substituent is attached to the ortho position, characteristic reactions have been observed by the mass spectrometer; this has been called the "ortho effect".[23] In the spectra of PAN, the ortho nitro group shows typical effect compared with the meta and para positions-i.e., the very weak $(M-1)^+$, strong $(M-17)^+$, and strong $(M-47)^+$ corresponding to $(M-OH-NO)^+$. As for the methoxy group, the ortho derivative shows the weak $(M-1)^+$, strong $(M-15)^+$, strong $(M-31)^+$, weak $(m/e : 107)^+$, and strong $(m/e : 77)^+$ relative to the meta and para derivatives. The last two cases can be explained in terms of the low-energy barrier of a reaction as follows:



m/e : 107 m/e : 77

In the case of chloro and methyl groups, the typical ortho effect was not observed.

Effects of Substituents on the Rate of Reaction from $M^{+\cdot}$ to Ion at m/e : 171. Bursey and his co-workers[24-26] have examined the kinetic approach to the reaction of acetophenones and benzophenones in a mass spectrometer. They have stated that electron-impact fragmentations may be related to ground-states processes, since the relative abundances of acetyl $(m/e : 43)$ and benzoyl $(m/e : 105)$ cations in various spectra are quantitatively related to the Hammett σ constants. Bowie and his co-worker observed the same correlations for the $(Ph-N=N)^+$ ion in the monosubstituted azobenzenes ($\rho=1.05$).[16] In our experiments, the effect of substituents on the reaction from M^+ to $(m/e : 171)^+$ were examined. The results obtained are shown in Fig. 5, where Z and Z_0 indicate the relative intensities of $(m/e : 171)^+$ to $M^{+\cdot}$ in the spectra of PAN and PAN-1 respectively. The same treatment of the reaction from $(M-42)^+$ to $(m/e : 171)^+$ was done upon the acetylated derivatives; the log (Z/Z_0) thus obtained was consistent with that of the original samples within the range of experimental error. In Fig. 5 the meta substituents correlate with each other by means

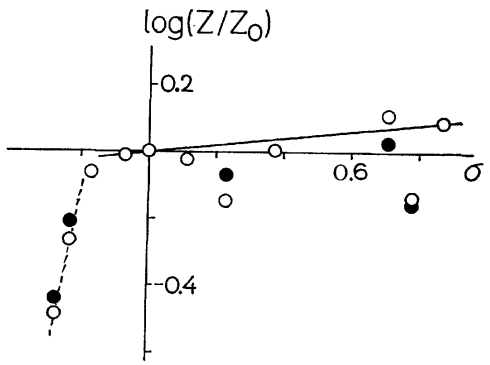


Fig. 5. Correlation of the intensities of ion at m/e: 171 with Hammett σ.
○: PAN, ●: PAN acetates

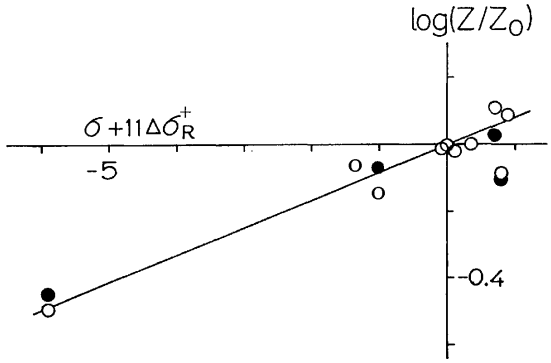

Fig. 6. Improved correlation of the intensities of ion at m/e: 171 with Hammett σ by using Yukawa-Tsuno equation.
○: PAN, ●: PAN acetates

of Hammett σ constants, but some deviations are observed with regard to the para substituents. Such poor correlations have so far been observed.[27] In order to solve this problem, Johnstone and his co-worker have proposed a concept of the participation of excited-state reactions, where good Hammett correlations are found for para but not meta substituents.[28] In our case, however, the results may indicate that the reaction proceeds through a ground state rather than through an excited state, since good Hammett correlations are found for meta but not para substituents. Moreover, the correlations are improved by an application of the Yukawa-Tsuno equation[29] except for the para nitro derivative, as is shown in Fig. 6; the vafues obtained are $\sigma=0.08$ and $r=11$ (r is a parameter of the relative strength of the resonance effect.). The small ρ-value, which is very different from that of azobenzenes, is probably dependent on a relaxation effect of the hydrogen bond.

The authors express their thanks to Mr. M. Sawai of Teikoku Hormone MFG. Co., Ltd. for generous support of this work and to Prof. T. Takeuchi of Nagoya University for his constant interest and encouragement.

The Stereoselective Reactivities of DL-Amino Acid *N*-Carboxyanhydrides for (−)-Menthol

Tadao HAYAKAWA, Hiroyuki YAMAMOTO, Yukiko MURAKAMI, Yoshihiro YOBIKO, and Shunji MITANI

Institute of High Polymer Research, Faculty of Textile Science and Technology, Shinshu University, Ueda

(Received January 31, 1972)

The stereoselective reactivities of some neutral DL-amino acid *N*-carboxyanhydrides for (−)-menthol were studied by varying the concentration of hydrogen chloride as a catalyst and the reaction temperature. From the results of gas-liquid-chromatographic analyses, the esterification rates of D-amino acids were shown to be higher than those of L-amino acids in all cases. The highest ratio of the esterification rate, V_D/V_L, is 2.37. The recovered unreacted amino acids were always enriched in the L-form. The stereoselective reactivities were influenced by the catalyst concentration and not influenced by the reaction temperature.

In the previous papers, (−)-menthyl esters of α-amino acids have been synthesized from amino acids and (−)-menthol by the use of the azeotropic distillation method[1] and the amino acid *N*-carboxyanhydride (NCA) method.[2] In these reactions, D-form amino acid (−)-menthyl esters gave better yields than L-form esters. This suggests that the reactions proceed through different esterification rates of the two enantiomers.

In the present study, the stereoselective reactivity of amino acid enantiomers for (−)-menthol and the optical purity of the recovered unreacted amino acids were studied. The experimental conditions were as follows. Racemic amino acid NCAs of alanine, valine, and phenylalanine were reacted with one half a molar equivalent of (−)-menthol in dioxane, while the hydrogen chloride concentration and the reaction temperature were varied. After the unreacted NCA has then been hydrolyzed and removed, the amino acid (−)-menthyl esters were acetylated. The amounts of two diastereomers were determined from the gas-liquid-chromatographic (glc) analyses[3] by correcting them with the calibration curves made by authentic amino acid (−)-menthyl esters. From the results obtained under several experimental conditions, the stereoselective reactivities can be said to be influenced by the concentration of hydrogen chloride as a catalyst and not to be influenced by the reaction temperature. We consider that, at high catalyst concentrations, the NCA ring changes to the acid chloride, which easily accepts the steric effect of (−)-menthol.

Experimental

Preparation of Amino Acid (−)-Menthyl Ester Hydrochlorides. The (−)-menthyl ester hydrochlorides of L- and D-alanine, L- and D-valine, and L- and D-phenylalanine were synthesized by azeotropic distillation using *p*-toluenesulfonic acid, as has been described previously.[1]

Acylation of Amino Acid (−)-Menthyl Ester Hydrochlorides. Acetylation: To a solution of L- and D-amino acid (−)-menthyl ester hydrochloride in 10 m*l* of ethyl acetate, a 2 molar equivalent of a 1 N sodium carbonate solution and a 1.5 molar equivalent of acetic anhydride were added at 0°C. After stirring for 1 hr at 0°C and then for 2 hr at room temperature, the organic layer was washed successively with water, a 0.5 N sodium bicarbonate solution, water, 0.5 N hydrochloric acid, and water; dried over sodium sulfate, and evaporated to dryness *in vacuo*. The product was treated with *n*-hexane, filtered, and dried; the yield was, on the average, 90—95%.

Benzoylation: To a solution of L- and D-amino acid (−)-menthyl ester hydrochloride in 5 m*l* of ethanol containing a 2 molar equivalent of sodium ethoxide, a 1.2 molar equivalent of benzoyl chloride was added at 10°C. After stirring for 3 hr, the solution was evaporated to dryness *in vacuo*. The product was extracted with ethyl acetate, and the organic layer was successively washed with water, a 0.5 N sodium bicarbonate solution, water, 0.5 N hydrochloric acid, and water; dried over sodium sulfate, and evaporated to dryness *in vacuo*. The residue was treated with *n*-hexane, filtered, and dried; the yield was, on the average, 80—88%.

Retention Times of Standard Samples. The retention times of standard samples, as determined by glc, are shown in Table 1. As is shown in Table 1, the acetyl derivatives were well and rapidly separated. We carried out all the glc analyses using acetyl amino acid (−)-menthyl esters.

Table 1. Gas chromatographic separation of acyl-α-amino acid menthyl esters

Amino acid menthyl ester	Column temp. (°C)	Retention time of diastereomers (min)		t_D/t_L
		t_D[a]	t_L[b]	
Acetyl Ala	175	27	24	1.13
Benzoyl Ala	220	38	33.5	1.13

Benzoyl Val	220	31	27.5	1.13
Acetyl Phe	220	39.5	37	1.07
Benzoyl Phe	220	21.5	19.5	1.10

a) Retention time of acyl-D-amino acid-(−)-menthyl ester.
b) Retention time of acyl-L-amino acid-(−)-menthyl ester.

DL-Amino Acid NCA's. The NCA's were synthesized by the phosgene method.[4] All the NCA's were recrystallized from ethyl acetate and *n*-hexane.

N-Acetyl Amino Acid (−)-Menthyl Esters. To a solution of (−)-menthol (0.01 mol) in 100 m*l* of dioxane containing 1N, 2N, 4N, and 5.8N (saturated) hydrogen chloride as catalysts, DL-amino acid NCA (0.02 mol) was added, then the mixture was reacted with stirring at 10, 20, and 30°C. At regular time intervals, 10-m*l* portions of the reaction mixture were taken out, and then 10 m*l* of water was added to it. The unreacted NCA was hydrolyzed by heating in a boiling-

water bath for 2 min. The dioxane was removed *in vacuo*. The aqueous layer was made alkaline by the addition of a sodium bicarbonate solution. The amino acid (−)-menthyl ester was extracted with 25 m*l* of ethyl acetate. This organic layer was acetylated with acetic anhydride and sodium carbonate in the same way as above. The acetyl amino acid (−)-menthyl ester in ethyl acetate was directly analyzed by glc.

The Test of the Stereoselective Hydrolysis. In order to check the stereoselective hydrolysis of the amino acid menthyl esters in a hydrochloric acid solution in the above experiments, the following experiments were designed. To a solution of DL-alanine menthyl ester (0.0002 mol) in 1.0 m*l* of dioxane, 1.0-m*l* portions of 1N, 2N, 4N, and 6N hydrochloric acid were added separately. Then the mixture was heated in the boiling-water bath for 2 min. After the reaction mixture has been treated in the same way as above, the recovery of the L- and D-alanine menthyl esters was determined by glc. The results are shown in Table 2.

Table 2. Recovery of amino acid menthyl esters by hydrolysis

HCl concn. (N)	Recovery, %	
	L-Alanine deriv.	D-Alanine deriv.
1	100.0	100.0
2	98.8	100.0
4	92.4	94.1
6	88.7	90.6

As is shown in Table 2, the hydrolysis of the ester was little affected by heating in 1N and 2N hydrochloric acid. In higher concentrations of hydrochloric acid, the stereoselective hydrolysis was observed slightly in two diastereomers. The recovery ratio of the two diastereomers (D/L) was 1.02 in 6N hydrochloric acid. This ratio suggests that the stereoselective hydrolysis has little influence on the stereoselective reactivity of DL-NCA for (−)-menthol.

Recovery of Unreacted Amino Acid. Amino acid NCA (0.002 mol) and a one-half molar equivalent of (−)-menthol (0.001 mol) in 10 m*l* of 4N HCl/dioxane were reacted at 20°C for 12 hr. After the same treatment as has been described above, the aqueous layer was made alkaline by sodium bicarbonate. The amino acid (−)-menthyl ester was extracted with ethyl acetate. To this basic aqueous solution, 2,4-dinitrofluorobenzene (DNFB, 0.0018 mol) was added, and the mixture was stirred at 40°C until a clear solution was obtained. The unreacted DNFB was extracted with ether. The aqueous layer was acidified to Congo Red with 6N hydrochloric acid and extracted with 50 m*l* of ether. The ethereal layer was washed with water, dried over sodium sulfate, and then passed through a cellite column treated with a pH-6.5 phosphate buffer[5] to purify it. The organic solvent was evaporated to dryness *in vacuo*, and the residue was redissolved in 1N sodium hydroxide. From the absorbance of the ultraviolet absorption at nearly 360 mμ of this solution, the yields of DNP-amino acids were calculated. The yields and $[\alpha]_D$ are shown in Table 3. From the $[\alpha]_D$ values of the DNP-amino acids shown in Table 3, each amino acid is L-form rich. This suggests that the (−)-menthyl esterification of DL-amino acid prefers the D-form to the L-form.

Table 3. Recovery of unreacted α-amino acid

DNP-Amino acid	Recovery[a] %	$[\alpha]_D$ 1N NaOH	Confign.	Optical purity,[b] %
Ala	41.0	+8.6°	L	5.9
Val	26.1	+4.2°	L	3.9
Phe	49.1	−3.8°	L	4.1

a) Recoveries were calculated from starting DL-amino acid NCA. b) Defined as ($[\alpha]_D$ obsd/$[\alpha]_D$ lit)×100. DNP-L-Ala, $[\alpha]_D$ +143.9° (1N NaOH); DNP-L-Val, $[\alpha]_D$ +109.2° (1N NaOH); DNP-L-Phe, $[\alpha]_D$ −93.6° (1N NaOH).

Method. Glc analyses were carried out on a Hitachi K 53 gas chromatograph with a flame ionization detector, using a 1 m×3 mm glass column (60/80 mesh 20% poly-neopenthyl glycol succinate on chromosorb W AW DMCS) and with a nitrogen flow rate of 30 m*l*/min.

Results and Discussion

The Reaction Rates and Their Ratios of the Esterification of Two Enantiomers. The yields of the diastereomers obtained by the reaction of DL-alanine NCA and (−)-menthol at 20°C using 4 N HCl/dioxane are shown in Fig. 1 as a function of the time. This suggests that the esterification rate of D-amino acid, V_D, is larger than that of L-amino acids, V_L. At their initial stages, a linear relationship exists between the yields of the amino acid (−)-menthyl esters and the reaction time. At a prolonged reaction time, though the increments of both yields per unit of time decreased, constant (V_D/V_L) ratios were observed. The dependences on the temperature and the concentration of the hydrogen chloride catalyst for stereoselective reactivity of each amino acid NCA are shown in Table 4. From these results, the ratios of the reactivity of the diastereomers were calculated. As is shown in Table 4, V_D and V_L increase with an increase in the temperature and in the concentration of a catalyst under each set of conditions. In all cases, V_D is larger than V_L. This suggests that the ratio of stereoselective reactivity, V_D/V_L, is not influenced by the reaction temperature, but is influenced by the concentration, of a catalyst.

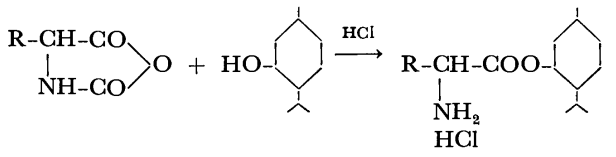
	5.8	0.55	0.32	1.72						

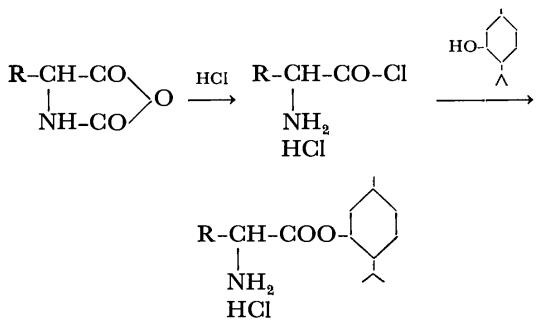
a) Reaction rate of D-amino acid NCA (mg/m*l*·hr).
b) Reaction rate of L-amino acid NCA (mg/m*l*·hr).

Moreover, the maximum ratios of stereoselectivity were observed when the reaction was carried out using saturated hydrogen chloride as a catalyst in three amino acids. As is shown in Table 3, the recovered unreacted amino acids are always L-form rich.

Reaction Mechanism. It was found that the stereoselective reactivity of DL-amino acid NCA for (−)-menthol is not influenced by the reaction temperature in the range from 10 to 30°C, but is influenced by the catalyst concentration of hydrogen chloride. This suggests that the reaction may proceed by the route of scheme 1 or 2.



(1)



(2)

At low hydrogen chloride concentrations, the reaction may proceed mainly by the route of scheme 1 and the stereoselective reactivity is small. On the other hand, at high hydrogen chloride concentrations, the reaction may proceed by the route of scheme 2 and large stereoselectivities are obtained.

TABLE 5. REACTION RATES AND RATIOS FOR (−)-MENTHOL AFTER REACTED WITH DL-VALINE NCA AND HYDROGEN CHLORIDE

Reaction time (hr)	V_D[a]	V_L[b]	V_D/V_L
0	0.025	0.021	1.19
1	0.035	0.027	1.30
2	0.041	0.029	1.41
3	0.044	0.030	1.47

Solvent: 2N HCl/dioxane, Temp: 20°C
a) Reaction rate of D-amino acid NCA (mg/m*l*·hr).
b) Reaction rate of L-amino acid NCA (mg/m*l*·hr).

In order for the reaction to proceed *via* the route of scheme 2 exclusively, DL-valine NCA was reacted with 2 N HCl/dioxane for 1, 2, and 3 hr at 20°C, and then (−)-menthol was added to the solution. This mixture was allowed to react for 2.5 hr. The valine (−)-menthyl ester thus obtained was analyzed by glc in order to determine the yield of each diastereomer by the method described above. The results are shown in Table 5. As is shown in Table 5, the higher stereoselectivity was observed when the NCA and hydrogen chloride were kept for a long time before the addition of (−)-menthol. Therefore, it is considered that, at high hydrogen chloride concentrations, the NCA changes to the acid chloride, which is more susceptible to the steric effect of (−)-menthol. Such a difference may cause the higher stereoselective reactivity.

The authors wish to express their thanks to Dr. K. Harada of the University of Miami for his helpful discussions and encouragement.

The Thermal Reaction of 3-Benzoylguaiazulene and Methyl Guaiazulene-3-carboxylate

Shinji KUROKAWA, Mamoru HASHIMOTO,* and Shûichi HAYASHI

Department of Chemistry, Faculty of Education, Saga University, Honjo-machi, Saga

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received January 31, 1972)

3-Benzoylguaiazulene (I) and methyl guaiazulene-3-carboxylate (XI) were heated at 250—260°C. From 3-benzoylguaiazulene we obtained, besides S-guaiazulene (II), three new azulenoids, which were established to be 2-benzoylguaiazulene (III), 1-benzoyl-7-isopropyl-3,4-dimethylazulene (IVa) and 2-benzylguaiazulene (V). On the other hand, the products yielded from methyl guaiazulene-3-carboxylate, together with S-guaiazulene, were elucidated to be methyl 7-isopropyl-3,4-dimethylazulene-1-carboxylate (XII) and methyl guaiazulene-2-carboxylate (XIII). In addition to the loss and the migration of the acyl group, the exchange of acyl and methyl groups in the five-membered ring took place in both acylguaiazulenes, as well as in the case of 3-acetylguaiazulene reported earlier. Moreover, the reduction of the acyl group was also observed in 3-benzoylguaiazulene.

In an earlier paper[1] dealing with the thermal reaction of 3-acetylguaiazulene at 200°C, it was shown that S-guaiazulene (II) and 2-acetylguaiazulene (VI) were formed by the loss or the migration of the acetyl group. In the same reaction, 1-acetyl-7-isopropyl-3,4-dimethylazulene (XIV) was also found to be formed by the exchange of acetyl and methyl groups in the five-membered ring of the azulene nucleus.[2] The present investigation was undertaken to see if this kind of reaction could occur in another acylguaiazulene having an acyl group such as benzoyl or methoxycarbonyl.

Results and Discussion

The Thermal Reaction of 3-Benzoylguaiazulene (I). When 3-benzoylguaiazulene (I) was heated at 250—260°C for 2 hr, three new compounds were obtained in addition to the S-guaiazulene (II) formed by the loss of the benzoyl group.

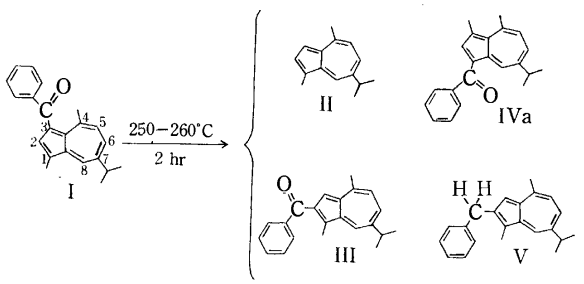


Chart 1.

a) 2-Benzoylguaiazulene (III). The green crystalline substance (mp 87.5—88.5°C) which was isolated as the major product in this reaction had the same molecular formula, $C_{22}H_{22}O$, as the I used as the starting material. The existence of a benzoyl group in this compound was known from the appearance of the $\nu_{C=O}$ band at 1633 cm^{-1} in its IR spectrum and from the presence of the notable ions at *m/e* 197 and 105 respectively, ascribed to $(M-C_6H_5CO)^+$ and $C_6H_5^+$ in the mass spectrum.

In the NMR spectrum of the compound taken in a deuterochloroform solution (*cf.* Experimental section) we observed, besides five aromatic proton signals ascribed to the benzoyl group, signals due to one isopropyl-, two aromatic methyl-, and four aromatic ring-protons corresponding to the guaiazulene moiety. These chemical shifts and coupling constants ($J_{5,6}$= 10.1 Hz, $J_{6,8}$=1.5 Hz) were quite close to those of 3-benzoylguaiazulene. Thus, the compound may be thought to be an isomer which differs from 3-benzoylguaiazulene in the position of the benzoyl group.

On the other hand, the NMR spectrum taken in a trifluoroacetic acid solution lacked the H_2 signal which was observed in the spectrum of I (7.50 ppm). This agreed well with the fact that the Me_1 and C_3-methylene signals[3] appeared as a triplet and a quartet (2.45 and 4.59 ppm, J=2.0 Hz) respectively because of the absence of the H_2 proton. The compound may, therefore, be concluded to hold the benzoyl group at the 2-position.

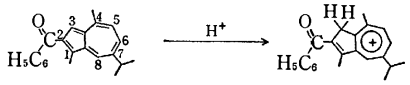
In order to confirm the above deductions, we attempted to synthesize 2-benzoylguaiazulene (III) starting from 2-acetylguaiazulene (VI), whose structure had previously been established.[1] As the first step, we attempted to prepare the carbinol (X) by the reaction of VI and a Grignard reagent derived from bromobenzene. The product, however, consisted of two kinds of blue oil. On the basis of the NMR data (*cf.* Experimental section), these compounds were elucidated to be 2-(1-phenylethenyl)guaiazulene (VII) and 2-(1-phenylethyl)guaiazulene (VIII), which would be formed from carbinol (X) through dehydration or hydrogenation, respectively. Successively, the olefin

* Present address: Department of Industrial Chemistry, Kyushu Technical University, Sensui-machi, Tobata-ku, Kitakyushu.

1) S. Kurokawa, This Bulletin, **43**, 509 (1970).

2) S. Kurokawa, *Tetrahedron Lett.*, **1969**, 3567.

3) For instance, the protonation occurs in 2-benzoylguaiazulene as follows. All the compounds in this paper except the 1-benzoyl compound (IVa) take this type of conjugate acid form, in which protonation occurs at the 3-position:



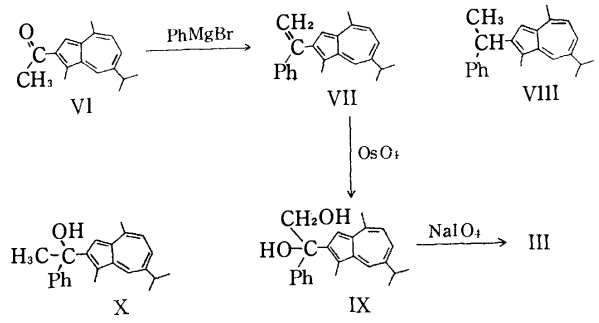


Chart 2.

(VII) was oxidized with osmium tetroxide[4] to give glycol (IX), which was then further oxidized with periodate to afford III. The green crystalline substance obtained in the thermal reaction of I was identical with the synthesized product; thus, it was concluded to be 2-benzoylguaiazulene (III).

b) 1-Benzoyl-7-isopropyl-3,4-dimethylazulene (IVa). A purple oil with a molecular formula of $C_{22}H_{22}O$ was isolated from a benzene-eluted fraction in the elution chromatography of the reaction products. This compound exhibited a $\nu_{C=O}$ band at 1606 cm^{-1} in the IR spectrum and gave 2,4-dinitrophenylhydrazone (mp 249—251°C). Moreover, the *m/e* 105 ion, the base peak in the mass spectrum, was attributed to $C_6H_5CO^+$. Thus, it is certain that the compound also contains a benzoyl group.

Furthermore, all the signals observed in the NMR spectrum (Fig. 1A) corresponded well to those in the spectra of the starting material (I) and 2-benzoylguaiazulene (III). This compound may, therefore, be thought to be an isomer which differs from I and III only in the positions of the substituents.

The two doublet signals of 9.78 (d, 1H, J=2.1 Hz) and 7.17 ppm (d, 1H, J=10.5 Hz) seen in the aromatic-proton region of the NMR spectrum can reasonably be assigned to H_8 and H_5 respectively, for their coupling constants and coupling pattern agree very closely with those of S-guaiazulene (II) and I. The H_6 proton, though unrecognizable due to the overlap of the benzene-ring protons, must exist, because no other proton can be a coupling partner of the above two protons. Consequently, the seven-membered ring of this compound has the same 4,7-disubstitution as that of the starting material.

Among these signals, the signal of the H_8 proton (9.78 ppm) moves downfield by 1.73 ppm relative to that of S-guaiazulene. Such a remarkable shift is characteristic of the acylazulenes with an acyl group at the peri position (1-position) [*cf.* 1-acetylazulene; 9.89 ppm.[5] 1-acetyl-7-isopropyl-3,4-dimethylazulene; 10.28 ppm[2]]. Thus, the compound has the benzoyl group at the 1-position.

The methyl doublet of 2.79 ppm with J=1.0 Hz (Me_3) observed in the NMR spectrum taken in a trifluoroacetic acid solution (Fig. 1B) may be attributed to the methyl protons of the five-membered ring spin-coupled with an adjacent olefinic proton

4) J. B. Brown, H. B. Henbest, and E. R. H. Jones, *J. Chem. Soc.*, **1952**, 3172.

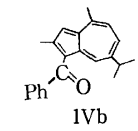

Chart 3.

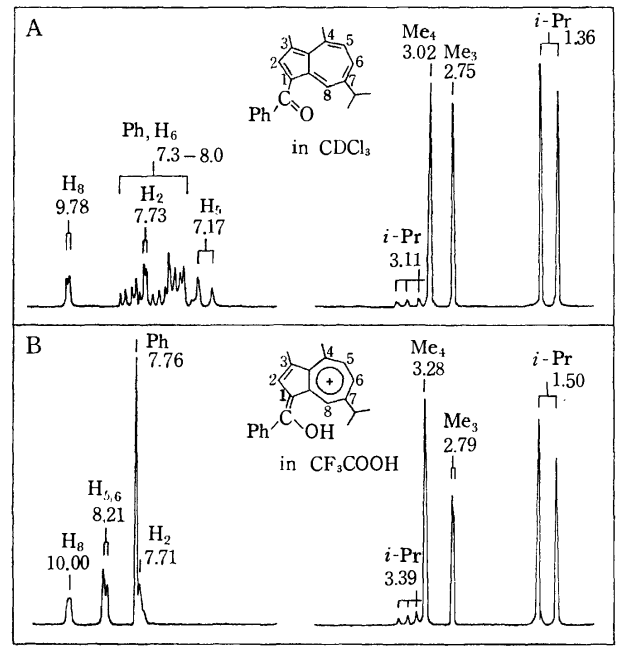


δ, ppm

Fig. 1. NMR spectra of 1-benzoyl-7-isopropyl-3,4-dimethylazulene (A) and its conjugate acid (B).

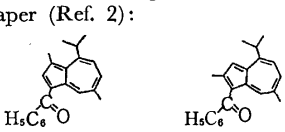
(7.71 ppm; H_2). One of the methyl groups should, therefore, be located at either the 2- or 3-position. From the above data, the two formulae of IVa and IVb become possible for this compound.[6] However, the compound represented by IVb has already been reported by Treibs *et al.* to be the benzoylation product of Se-guaiazulene,[7] and it is evidently different from the present compound. The present compound must, therefore, be 1-benzoyl-7-isopropyl-3,4-dimethylazulene (IVa).

c) 2-Benzylguaiazulene (V). A blue oily substance, which had a molecular formula of $C_{22}H_{24}$ and which gave a dark brown picrate (mp 106—108°C), was separated by the *n*-hexane-silica-gel elution chromatography of the reaction products.

In the NMR spectrum of the compound taken in a deuterochloroform solution (*cf.* Experimental section) we observed a sharp singlet (4.29 ppm, 2H) assigned to the protons of a methylene group, in addition to the

5) D. Meuche, D. Dreyer, K. Hafner and E. Heilbronner, *Helv. Chim. Acta.* **50**, 1178 (1967).

6) Strictly speaking, the following formulae are also possible for this compound. The examination on these formulae is, however, abbreviated in this paper for they, accompanying the changes in the seven-membered ring, have already been discussed in a preceding paper (Ref. 2):



7) W. Treibs, Ch. Vollard, and M. Reimann, *Ann.*, **648**, 164.

signals due to a benzene ring and a guaiazulene moiety. Thus, the compound may be thought to have a benzyl group formed through the reduction of the benzoyl group in the starting material (I).

When a visible absorption maximum (592 nm) of the compound is analyzed according to the Plattner rule,[8] three positions, 2, 6, and 8, are possible for the benzyl group. Of these positions, the 2-position is selected, since the signal attributable to H_2 is not observed in the NMR spectrum of the compound taken in a trifluoroacetic acid solution (*cf.* Experimental section); this is in accordance with the appearance of the C_3-methylene and Me_1 signals as a quartet and a triplet respectively (3.89 and 2.52 ppm respectively; $J=1.8$ Hz).

Based on the above knowledge, this compound was synthesized through the Huang-Minlon reduction of 2-benzoylguaiazulene (III), whose structure had been established before (*cf.* a); thus, it was determined to be 2-benzylguaiazulene (V).

The Thermal Reaction of Methyl Guaiazulene-3-carboxylate (XI). The heating of the methyl ester (XI) at 250°C for 1 hr produced two kinds of ester compounds besides S-guaiazulene.

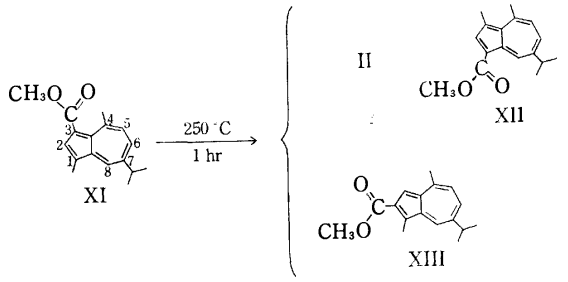


Chart 4.

a) Methyl 7-Isopropyl-3,4-dimethylazulene-1-carboxylate (XII). A purple oily substance, the major product of the reaction, had a molecular formula of $C_{17}H_{20}O_2$, the same as XI. This compound showed a $\nu_{C=O}$ band at 1688 cm^{-1} in its IR spectrum, and it exhibited a sharp methyl singlet (3.91 ppm) in its NMR spectrum (Fig. 2A) which was assigned to a methoxy group. Moreover, the *m/e* 225 peak seen in the mass spectrum was attributed to the $(M-OCH_3)^+$ ion. Thus, the compound is a methyl ester similar to the starting material. A doublet signal of an aromatic-ring proton (9.78 ppm, 1H, $J=2.0$ Hz), observed at the lowest field in the NMR spectrum (Fig. 2A), was ascribed to the H_8 proton by comparison with the spectra of other azulenes. The chemical shift of this proton was, however, of an extremely downfield nature, which is the characteristic of the acylazulenes having an acyl group at the peri position [*cf.* 1-benzoyl compound (IVa)]. Accordingly, the compound may be thought to hold a methoxycarbonyl group at the 1-position.

Furthermore, the NMR spectrum of a conjugate acid (Fig. 2B) showed a methyl singal (1.62 ppm, d, $J=7.2$ Hz; Me_3) and a methine signal (4.48 ppm, double quartet, $J=7.2$ and 1.8 Hz; H_3), spin-coupled to one another. On the other hand, as only the 3-position is known to be possible for the protonation in an azulene nucleus,[3] the above methyl group apparently exists at the 3-position.

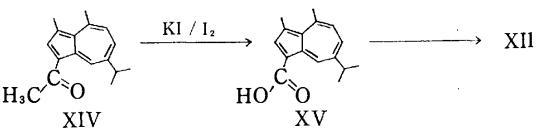

Chart 5.

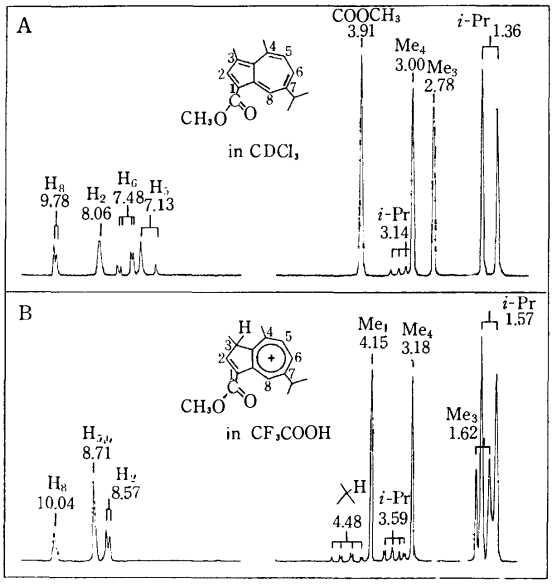

δ, ppm

Fig. 2. NMR spectra of methyl 7-isopropyl-3,4-dimethylazulene-1-carboxylate (A) and its conjugate acid (B).

These data suggest that the compound has the structure of methyl 7-isopropyl-3,4-dimethylazulene-1-carboxylate (XII). On the basis of this deduction, the structure was established as follows: 1-Acetyl-7-isopropyl-3,4-dimethylazulene (XIV), elucidated earlier,[2] was oxidized with hypoiodite to give the carboxylic acid (XV), which was then treated with diazomethane to afford the same methyl ester (XII) as was obtained from XI.

b) Methyl Guaiazulene-2-carboxylate (XIII). Trace amounts of a blue oil isolated from the reaction products were found to be XIII by comparison with an authentic specimen.[1]

Sequence of the Reaction. Table 1 lists the yields (%) of the reaction products formed from the three

Table 1. The yield (%) of the thermal isomerization products

Products	Acyl groups		
	CH_3CO[1,2]	C_6H_5CO	CH_3OCO
S-Guaiazulene	1.4	1.8	0.8
2-Acylguaiazulene	16.4	11.3	0.08
1-Acyl-7-isopropyl-3,4-dimethylazulene	7.0	5.7	5.3
2-Benzylguaiazulene	—	2.5	—

3-acylguaiazulenes studied thus for.

As is obvious from Table 1, all of the 3-acylguaiazulenes gave reaction products of the common type, *viz.*, those formed through the loss of the acyl group, through the migration of the same group from the 3- to the 2-position, and through the exchange between acyl- and methyl-groups in the five-membered ring of the azulene nucleus. However, some discrepancy among the reactions due to the differences in the acyl substituents is also observed: the main reaction in ketone is the migration of the acyl group, while that in the methyl ester is the exchange of acyl- and methyl-groups in the five-membered moiety, and the reduction of acyl group is noted only in the benzoyl compound. How these differences in the reactivity occur is not apparent at present, but we are continuing to make our best efforts to solve this problem in our laboratory.

Experimental

All the melting points in this paper are uncorrected. The UV and visible absorption spectra were taken in a cyclohexane solution. The IR spectra were obtained using liquid films or KBr disks, and the mass spectra (MS), at 70 eV. The NMR spectra were measured at 60 MHz, and the chemical shifts are given by ppm, using TMS as the internal standard. The thin-layer chromatography (tlc) was conducted by the use of silica gel-G (Merck).

3-Benzoylguaiazulene (I). This compound was synthesized by the reaction of S-guaiazulene (II) and benzoyl chloride in the presence of an aluminium chloride catalyst.[9] The recrystallization of the product from *n*-hexane-ethanol (1 : 1) gave green prisms [mp 122.8—123.2°C (mp 121.5°C,[9] mp 120—121°C[10])], which showed a single brown spot (R_f, 0.20) in tlc using benzene. IR: 1606 cm^{-1} (C=O) [1637 cm^{-1} in nujol mull[10]]. UV: nm (log ε), 244.5 (4.51), 280sh (4.30), 290 (4.42), 309 (4.08), 323.5 (4.10), 401 (3.91) [249, 289, 314, and 319 nm respectively[10]]. Visible absorption spectrum: nm (ε), 586 (443), 639sh (329) [583 nm[10]]. NMR ($CDCl_3$): 2.55 (s, 3H; Me_1), 7.55 (S, 1H; H_2), 2.71 (s, 3H; Me_4), 7.12 (d, 1H, J=11.0 Hz; H_5), 1.37/3.09 (d, 6H/m, 1H, J=6.0 Hz; i-Pr), 8.20 (d, 1H, J=1.8 Hz; H_8), 7.3—8.0 (m, 6H; Ph, H_6). NMR (CF_3COOH)[3]: 2.51 (q, 3H; Me_1), 7.50 (m, 1H; H_2), 6.44 (m, 1H; H_3), 2.96 (s, 3H; Me_4), 8.78 (s, 2H; $H_{5,6}$), 1.62/3.61 (d, 6H/m, 1H, J=6.8 Hz; *i*-Pr), 8.84 (s, 1H; H_8), 7.7—8.5 (m, 5H; Ph). MS: *m/e* 302 (M, $C_{22}H_{22}O$; 1.7%), *m/e* 287 (M-CH_3; 46.5%), *m/e* 105 (C_6H_5CO; 25.8%), *m/e* 77 (C_6H_5; 90%).

Thermal Reaction of 3-Benzoylguaiazulene (I). 3-Benzoylguaiazulene (2.00 g) was heated at 250—260°C in a sealed tube for 2 hr. The reaction mixture, after being dissolved in a small amount of benzene, was eluted through a silica-gel column with benzene, and separated into the following four fractions, depending upon the color:[11]

Fr. 1 blue oil (654.9 mg)··· {S-guaiazulene (II) (35.3 mg) / 2-benzylguaiazulene (V) (50.0 mg)}

Fr. 2 green oil (338.6 mg)···2-benzoylguaiazulene (III) (225.9 mg)

Fr. 3 purple oil (340.1 mg)···1-benzoyl-7-isopropyl-3,4-dimethylazulene (IVa) (113.4 mg)

Fr. 4 brown oil (715.2 mg)···3-benzoylguaiazulene (I) (recovered)

2-Benzylguaiazulene (V). The blue oil of Fr. 1 showed two blue spots (R_f, 0.36 and 0.16) in tlc with *n*-hexane. By means of *n*-hexane-silica-gel elution chromatography, it was separated into two components, corresponding to the two spots in tlc. The oil of R_f, 0.36 was identical with the authentic specimen of II in tlc. V was obtained as a blue oil with an R_f of 0.16, and it gave a dark brown picrate upon treatment by the usual method. After being recrystallized from ethanol, it showed a mp of 106—108°C. UV: nm (log ε), 247.6 (4.38), 291 (4.75), 297 (4.80), 309 (4.23), 341 (3.65), 355 (3.76), 382 (3.26), 390sh (2.74). Visible absorption spectrum: nm (ε), 550sh (313), 592 (422), 632sh (368). NMR ($CDCl_3$): 2.53 (s, 3H; Me_1), 4.29 (s, 2H; CH_2), 7.20 (s, 5H; Ph), 2.75 (s, 3H; Me_4), 1.34/2.95 (d, 6H/m, 1H, J=6.8 Hz; *i*-Pr), 8.16 (d, 1H, J=1.8 Hz; H_8), 6.8—7.7 (m, 3H; $H_{3,5,6}$). NMR (CF_3COOH)[3]: 2.52 (t, 3H, J=1.8 Hz; Me_1), 4.20 (s, 2H; CH_2), 7.34 (s, 5H; Ph), 3.89 (q, 2H, J=1.8 Hz; $2H_3$), 2.92 (s, 3H; Me_4), 8.47 (s, 2H; $H_{5,6}$), 1.55/3.53 (d, 6H/m, 1H, J=6.8 Hz; i-Pr), 8.67 (s, 1H; H_8). MS: *m/e* 288 (M, $C_{22}H_{24}$; 14.3%), *m/e* 273 (M-CH_3; 11.4%), *m/e* 197 (M-$C_6H_5CH_2$; 11.2%), *m/e* 91 (C_7H_7; base peak).

Huang-Minlon Reduction of 2-Benzoylguaiazulene (III). By reference to the procedure of Treibs,[12] a solution of III (104.9 mg) and 100% hydrazine hydrate (0.2 m*l*) in triethylene glycol (2 m*l*) was heated under reflux for 1 hr. To this hot solution, powdered potassium hydroxide (100 mg) was slowly added; the mixture was then gradually brought to room temperature, during which time a vigorous evolution of nitrogen gas was observed and the color of the mixture changed from green to blue. A blue-colored fraction was collected by distilling, under reduced pressure, a mixture of triethylene glycol diluted with water, and the colored material was extracted repeatedly with benzene to give a blue oil (70.7 mg). By means of successive petroleum ether-silica-gel elution chromatography, 2-benzylguaiazulene (V) was separated as a blue oil (36.8 mg) which showed a single spot (R_f, 0.16) in tlc with *n*-hexane.

2-Benzoylguaiazulene (III). The green oil of Fr. 2 was purified by repeated benzene-silica-gel elution chromatography to afford green crystals which showed, after recrystallization from ethanol, a mp of 87.5—88.5°C. It exhibited a single spot (R_f, 0.42) in tlc with benzene. IR: 1633 cm^{-1} (C=O). UV: nm (log ε), 252.5 (4.45), 302 (4.73), 307.5sh (4.67), 345 (3.82), 356 (3.81). Visible absorption spectrum: nm (ε), 645 (598), 736sh (258). NMR ($CDCl_3$): 2.69 (s, 3H; Me_1), 2.74 (s, 3H; Me_4), 6.94 (d, 1H, J=10.1 Hz; H_5), 1.35/3.04 (d, 6H/m, 1H, J=6.4 Hz; *i*-Pr), 8.27 (d, 1H, J=1.5 Hz; H_8), 7.2—8.0 (m, 7H; Ph, $H_{3,6}$). NMR (CF_3COOH)[3]: 2.45 (t, 3H, J=2.0 Hz; Me_1), 4.59 (q, 2H, J=2.0 Hz; $2H_3$), 3.18 (s, 3H; Me_4), 8.91 (s, 2H; $H_{5,6}$), 1.63/3.54 (d, 6H/m, 1H, J=7.0Hz; *i*-Pr), 9.03 (s, 1H; H_8), 7.6—8.2 (m, 5H; Ph). MS: *m/e* 302 (M, $C_{22}H_{22}O$; base peak), *m/e* 287 (M-CH_3; 69.1%), *m/e* 259 (M-C_3H_7; 8.4%), *m/e* 197 (M-C_6H_5CO; 19.1%), *m/e* 105 (C_6H_5CO; 76.2%), *m/e* 77 (C_6H_5; 83.8%).

The Grignard Reaction of 2-Acetylguaiazulene (VI) with Bromobenzene. To an ethereal solution of a Grignard reagent prepared from bromobenzene (8.4 g) in the usual manner,

9) W. Treibs, *Chem. Ber.*, **90**, 761 (1957).

10) D. H. Reid, W. H. Stafford, and W. L. Staffored, *J. Chem. Soc.*, **1958**, 1118.

11) Next to the dotted lines are shown the compounds obtained from each fraction after it had been further purified by means of elution chromatography or recrystallization.

12) W. Treibs, H.-J. Neupert, and J. Hiebsch, *Chem. Ber.*, **92**, 141 (1959).

under water cooling, another solution of VI (1.9 g) in ether (20 ml) was added, drop by drop, over a 10-min period. After the mixture had then been allowed to stand at room temperature for 7 hr, the excess reagent was decomposed with methanol (25 ml) and subsequently with a dilute aqueous solution of ammonium hydroxide. From the ether layer, a green resinous material was obtained; it was separated into two components by the use of petroleum ether-silica-gel elution chromatography. The olefin (VII) was obtained from the quickly-eluted fraction as a blue oil (169.0 mg) which showed a single spot (R_f, 0.68) in tlc with petroleum ether. NMR ($CDCl_3$): 2.37 (s, 3H; Me_1), 5.74/5.35 (d, 1H/d, 1H, J=2.0 Hz; $=CH_2$), 7.16 (s, 5H; Ph), 2.72 (s, 3H; Me_4), 6.84 (d, 1H, J=10.5 Hz; H_5), 1.28/3.02 (d, 6H/m, 1H, J=7.2 Hz; *i*-Pr), 8.04 (d, 1H, J=1.8 Hz; H_8), 7.0—7.4 m, 2H; $H_{3,6}$).

From the slowly-eluted fraction, the reduced product (VIII) was obtained as a blue oil (269.3 mg), which exhibited a single spot (R_f, 0.58) in tlc with petroleum ether. NMR ($CDCl_3$): 2.40 (s, 3H; Me_1), 1.74/4.45 (d, 3H/q, 1H, J=7.5 Hz; $-CH-CH_3$), 7.05 (s, 5H; Ph), 2.76 (s, 3H; Me_4), 6.80 (d, 1H, J=10.5 Hz; H_5), 1.30/2.98 (d, 6H/m, 1H, J=6.8 Hz; *i*-Pr), 7.97 (d, 1H, J=2.0 Hz; H_8), 7.0—7.3 (m, 2H; $H_{3,6}$).

The Oxidation of 2-(1-Phenylethenyl)guaiazulene (VII) with Osmium Tetroxide. The olefin (VII) (169.0 mg) thus obtained was dissolved in a mixed solvent of pyridine (0.14 ml) and ether (5 ml), and then the solution was added, under dry ice-ethanol cooling (*ca.* −53°C), to a solution of osmium tetroxide (136 mg) in ether (15 ml). The mixture, when cooled for a further hour and then left to stand for a few hrs at room temperature, yielded green crystals; these crystals were separated by filtration and combined with those resulting from the filtrate by letting them stand a further hour at room temperature. The combined crystals were taken up into chloroform (20 ml), and the solution was shaken for 10 min with an aqueous solution (20 ml) containing mannitol (2.1 g) and potassium hydroxide (0.2 g). The subsequent removal of the solvent yielded rough glycol (IX) as a dark green oil (293.2 mg).

Periodate Oxidation of 1-Phenyl-1-(2-guaiazulenyl)ethanediol-1,2 (IX). The rough glycol (IX) dissolved, without further purification, in methanol (29 ml) was oxidized with a 0.05M aqueous solution of sodium metaperiodate by stirring the mixture at room temperature for 40 min under a nitrogen atmosphere. The reaction mixture was then poured into a saturated aqueous solution of sodium chloride, and the precipitate was extracted with ether to give a green mass (372.9 mg). This mass was chromatographed on silica gel with benzene, and then separated into blue crystals (1.9 mg, II) and green crystals (3.1 mg) of 2-benzoylguaiazulene (III).

1-Benzoyl-7-isopropyl-3,4-dimethylazulene (IVa). The purple oil of Fr 3 was further purified with benzene - silica-gel-elution chromatography to give IVa as a purple oil which showed a single spot (R_f, 0.24) in tlc with benzene. IR: 1606 cm^{-1} (C=O). UV: nm (log ε), 250 (4.43), 292 (4.34), 316 (4.38), 393 (4.01), 408sh (3.94). Visible absorption spectrum: nm (ε), 532sh (648), 565 (722), 600sh (576).

The 2,4-dinitrophenylhydrazone of this compound was obtained by using a mixed solvent of ethanol and phosphoric acid[13] as a reddish-brown powder. After being recrystallized with a mixed solvent of ethanol and ethyl acetate, it showed a mp of 249—251°C.

Found: C, 68.97; H, 5.56; N, 11.56%. Calcd for $C_{28}H_{26}N_4O_4$: C, 69.69; H, 5.43; N, 11.61%.

Methyl Guaiazulene-3-carboxylate (XI). This compound was synthesized by treating II with phosgene, followed by the treatment of acid chloride with methanol.[14] It was obtained as a purple oil which showed a single spot (R_f, 0.33) in tlc with benzene. IR: 1699 cm^{-1} (C=O). UV: nm (log ε), 228.5 (4.72), 238 (4.47), 239.5 (4.47), 243.5 (4.57), 249 (4.65), 255 (4.61), 261 (4.37), 264sh (4.00), 267.5 (4.00), 273sh (4.17), 280sh (4.40), 292sh (4.60), 298.5 (4.61), 314sh (4.39), 382 (3.86). Visible absorption spectrum: nm (ε), 544sh (462), 575 (552), 617sh (454) [572 nm[15]]. NMR ($CDCl_3$): 2.55 (s, 3H; Me_1), 7.94 (s, 1H; H_2), 3.87 (s, 3H; MeO), 2.91 (s, 3H; Me_4), 7.19 (d, 1H, J=10.8 Hz; H_5), 7.50 (dd, 1H, J=10.8 and 1.8 Hz; H_6), 1.34/3.07 (d, 6H/m, 1H, J=5.8 Hz; *i*-Pr), 8.23 (d, 1H, J=1.8 Hz; H_8). NMR (CF_3COOH)[3]: 2.46 (t, 3H, J=1.8 Hz; Me_1), 7.37 (m, 1H; H_2), 3.91 (s, 3H; MeO), 5.16 (m, 1H; H_3), 3.01 (s, 3H; Me_4), 1.56/3.44 (d, 6H/m, 1H, J=6.6 Hz; *i*-Pr), 8.68 (s, 3H; $H_{5,6,8}$). MS: *m/e* 256 (M, $C_{17}H_{20}O_2$; base peak), *m/e* 241 (M-CH_3; 25.5%), *m/e* 225 (M-OCH_3; 31.8%).

Thermal Reaction of Methyl Guaiazulene-3-carboxylate (XI). XI (1.66 g) was heated in a sealed tube at 250°C for 1 hr. The reaction mixture was chromatographed on silica gel with benzene, and then separated into the following fractions:

Fr. 1 S-guaiazulene (II) (13.2 mg)
Fr. 2 methyl guaiazulene-2-carboxylate (XIII) (1.3 mg)[1]
Fr. 3 methyl 7-isopropyl-3,4-dimethylazulene-1-carboxylate (XII) (87.3 mg)
Fr. 4 methyl guaiazulene-3-carboxylate (XI) (1.22 g) (recovered)

Methyl 7-Isopropyl-3,4-dimethylazulene-1-carboxylate (XII). In order to prevent contamination by a non-azulenic component or an acidic material, the purple oil of Fr. 3 (30.2 mg) was dissolved in a mixed solvent of benzene (1 ml) and petroleum ether (100 ml), after which the solution was extracted twice with 85% phosphoric acid (50 ml). An orange-colored phosphoric acid layer was washed repeatedly with petroleum ether and diluted with ice-water, and purple oil thus isolated was taken up into petroleum ether. After the removal of the solvent, XII was obtained as a purple oil (29.9 mg) which exhibited a single spot (R_f, 0.34) in tlc with benzene. IR: 1688 cm^{-1} (C=O). UV: nm (log ε), 228.5sh (4.23), 234sh (4.34), 240.5sh (4.47), 243.5 (4.56), 249 (4.63), 254.5 (4.54), 261 (4.22), 264 (3.71), 267.5 (3.69), 299.5 (4.68), 306.5 (4.66), 312 (4.51), 350 (3.73), 367 (3.93), 385 (4.08). Visible absorption spectrum: nm (ε), 532sh (540), 571 (720), 615.5 (594). MS: *m/e* 256 (M, $C_{17}H_{20}O_2$; base peak), *m/e* 241 (M-CH_3; 70.2%), *m/e* 225 (M-OCH_3; 23.6%).

Found: C, 78.96; H, 7.72%. Calcd for $C_{17}H_{20}O_2$: C, 79.65; H, 7.86%.

Hypoiodate Oxidation of 1-Acetyl-7-isopropyl-3,4-dimethylazulene (XIV). A solution of XIV (169.0 mg) in dioxane (22 ml) was mixed with a 10% aqueous solution of sodium hydroxide (23 ml) with stirring at 80°C. To this mixture, kept at 80°C, we added, drop by drop over a 20-min period, another aqueous solution (8.2 ml) of iodine (820 mg) and potassium iodide (1.64 g). After the mixture had been stirred for a further 10 min, the excess iodine was reduced by adding a few drops of a saturated sodium hydrogen sulfite

13) G. D. Johnson, *J. Amer. Chem. Soc.*, **73**, 5888 (1951).

14) W. Treibs, H.-J. Neupert and J. Hiebsch, *Chem. Ber.*, **92**, 1216 (1959).

solution, the mixture was cooled to room temperature, and the reddish-brown iodoform thus precipitated was filtered off. The filtrate was diluted with water (30 ml), the solution was washed repeatedly with chloroform and acidified with 2N hydrochloric acid, and a crude acidic material was taken up into ether. A rough carboxylic acid (XV) was thus obtained as a brown oil (82.7 mg).

Preparation of Methyl Ester of 7-Isopropyl-3,4-dimethylazulene-1-carboxylic Acid (XV). To a solution of crude carboxylic acid (XV) (82.7 mg) in ether, we added an ethereal solution of diazomethane prepared from nitrosomethylurethane (4 g); the solution was then kept at room temperature for 8 hr. The reaction mixture was, after being treated in the usual manner, submitted to benzene - silica-gel elution chromatography to afford methyl 7-isopropyl-3,4-dimethylazulene-1-carboxylate (XII) as a purple oil (8.1 mg).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3564—3566 (1972)

The Synthesis of 3′-Phosphate and 2′,3′-Cyclic Phosphate of 2-Amino-4-hydroxy-6-(1′,2′,3′-trihydroxypropyl)pteridine

Katsura SUGIURA, Haruhiro YAMASHITA, and Miki GOTO

Department of Chemistry, Gakushuin University, Toshima-ku, Tokyo

(Received February 9, 1972)

2-Amino-4-hydroxy-6-(D-*erythro*-1′,2′,3′-trihydroxypropyl)pteridine 3′-phosphate and 2′,3′-cyclic phosphate, important intermediates of pteridine biosynthesis, were prepared by simple methods. D-*erythro*-, L-*erythro*-, D-*threo*-, and L-*threo*-isomers of 2-amino-4-hydroxy-6-(1′,2′,3′-trihydroxypropyl)pteridine, prepared by the method of Viscontini, were phosphorylated with a mixture of phosphorus pentoxide and phosphoric acid. The products were separated by chromatography on a DEAE-cellulose column. The main phosphorylated compounds were 3′-phosphates; small amounts of 2′,3′-diphosphates were also produced. On treatment with DCC, the 3′-phosphate gave 2′,3′-cyclic phosphate.

In 1961, Goto and Forrest isolated a new phosphorylated pteridine from *E. coli*; the structure of 2-amino-4-hydroxy-6-(1′,2′,3′-trihydroxypropyl)pteridine-3′-phosphate was proposed for this compound.[1] The pteridine was synthesized in a very low yield by the condensation of 2,4,5-triamino-6-hydroxypyrimidine with D-ribose-5-phosphate[1,2] and by the reaction of 2-amino-4-hydroxy-6-(D-*erythro*-1′,2′,3′-trihydroxypropyl)pteridine (neopterin) with 2-cyanoethyl phosphate, followed by mild alkaline hydrolysis.[3] The biological function of this compound (neopterin-3′-phosphate) was proved to be that of a key compound in the biosynthesis of folic acid and the biopterin group of co-factors.[4-6] The occurrence of L-*threo*-neopterin (monapterin), and possibly its 2′,3′-cyclic phosphate, in nature has been reported.[7-9] Recently, the enzymic transformation of D-*erythro*-neopterin to D-*threo*-neopterin has been demonstrated.[10]

For the study of the biosynthesis of pteridines, we have synthesized the 3′-phosphates of D-*erythro*-, L-*erythro*-, D-*threo*-, and L-*threo*-neopterins by simplified methods; we used the phosphorylation procedure usually applied to nucleosides.[11] The neopterins were prepared by the method of Viscontini *et al.*[12] and were phosphorylated with a mixture of phosphorus pentoxide and phosphoric acid. The products were separated by chromatography on a DEAE-cellulose column. The main phosphorylated compounds were 3′-phosphates (I); small amounts of 2′,3′-diphosphates were also produced. Furthermore, the 2′,3′-cyclic phosphate of D-*erythro*-neopterin was synthesized by the action of DCC on D-*erythro*-neopterin-3′-phosphate.[13] The cyclic phosphate of D- or L-*erythro*-neopterin was recently isolated from *Photobacterium phosphoreum* (Suzuki and Goto, unpublished).

The biochemical function of the pteridines thus synthesized will be discussed elsewhere.

ethanol were added) were refluxed for 3.5 hr under nitrogen. The reaction mixture was then concentrated to dryness *in vacuo*, the residue was dissolved in water (1600 m*l*), and the solution was neutralized with a 5% sodium bicarbonate solution. After aeration for 18 hr, the solution was acidified with acetic acid to pH 3—4 and acetone (30 m*l*) was added. The precipitate was collected by centrifugation and washed, in succession, with ice water, ethanol, acetone, and ether. The crude product was then dissolved in ammonia (pH 8.0) and purified by a conventional chromatographic method using a Dowex 1X8 column ($HCOO^-$, 7.5×24.0 cm) and a 0.03M ammonium formate buffer; the pH of the developer was changed continuously from 8 to 7. The reaction mixture was then separated into three fluorescent bands. The eluate of the second band was concentrated to 1 *l*, and the solution was kept in a refrigerator to give 3.0 g (37%) of D-*erythro*-neopterin. Recrystallization from water gave 1.1 g of needles.

Similarly, L-*erythro*-, D-*threo*-, and L-*threo*-neopterins were prepared by the condensation of 2,4,5-triamino-6-hydroxypyrimidine with L-arabinose-, D-xylose-, and L-xylose-phenylhydrazones respectively. The analyses, yields, and optical rotations of the products are summarized in Table 1.

Phosphorylation. D-*erythro*-Neopterin (1 mmol), 85% phosphoric acid (6 g) and phosphorus pentoxide (4 g) were mixed at 0°C, after which the mixture was stirred at 40—45°C for 1 hr. Water (60 m*l*) was added and heated for 30 min at 95—100°C. The compounds were adsorbed on charcoal (5 g); the charcoal was then washed well with water and eluted with a solution containing 50% ethanol and 4% ammonia (1 : 1). The eluted solution was concentrated to a small bulk at below 40°C; then it was put on the top of a DEAE-cellulose column (3.0×15.0 cm), which was then washed successively with 0.001N hydrochloric acid, 0.003N hydrochloric acid-0.01M lithium chloride, and 0.003N hydrochloric acid-0.1 M lithium chloride. Neopterin was eluted

by the first solvent, the 3′-phosphate, by the second, and the 2′,3′-diphosphate, by the third solvent. Each eluted fraction was treated with charcoal as has been described above, and the crude material thus obtained was recrystallized from 50% ethanol. The product was obtained as ammonium salt. Likewise, the phosphorylation was carried out for L-*erythro*-, D-*threo*-, and L-*threo*-neopterin. The yields are given by total optical density (TOD), and the analytical values of the products are summarized in Tables 2 and 3.

Neopterin-3′-phosphate. On treatment with potassium metaperiodate in a 0.1 M potassium carbonate solution for 24 hr, this compound gave 2-amino-4-hydroxypteridine-6-carboxylic acid quantitatively. The phosphate (*ca.* 0.3 mg), magnesium acetate (0.005 mM), and alkaline phosphatase (10 units, from calf mucosa) in a 0.1 M tris-buffer (pH 9.5) were incubated at 37°C for 30 min; it was then hydrolyzed to neopterin theoretically. The phosphate was identical with the neopterin-3′-phosphate prepared by the condensation of 2,4,5-triamino-6-hydroxypyrimidine and D-ribose-5-phosphate; the comparison was carried out by chromatographic and electrophoretic methods.

Neopterin-2′,3′-diphosphate. On treatment with potassium periodate in a 0.1 M potassium carbonate solution for 24 hr at room temperature, neopterin-2′,3′-diphosphate remained unchanged. On treatment with alkaline phosphates, this compound gave neopterin quantitatively. This evidence indicates that the conversion of the 2′-phosphate to the 3′-phosphate occurred during the incubation process.

D-erythro-*Neopterin-2′,3′-cyclic phosphate.* Free D-*erythro*-neopterin-3′-phosphate was obtained by passing the ammonium salt (74 mg, 0.2 mM) through a Dowex 50 (H^+) column (developer: water). The effluent was evaporated to dryness *in vacuo* at below 30°C. The residue was dissolved in a mixture of triethylamine (0.03 m*l*, 0.2 mM) and water (2 m*l*). Methanol (15 m*l*) and DCC (1.03 g, 5 mM) were added, and the whole was refluxed for 30 min and evaporated to dryness. The residue was dissolved in a mixture of water (100 m*l*) and ether (50 m*l*) by shaking, and the insoluble portion was removed by filtration. The aqueous layer was evaporated to dryness *in vacuo*. The crude material thus obtained was purified further by chromatography using cellulose columns (5.0×25.0 cm) and the following developers: A, 2-propanol, 1% ammonia (2 : 1), and B, water. Recrystallization from a little water gave the faint yellow cyclic phosphate (yield, 44 mg).

Found: C, 33.30; H, 3.38; N, 20.02; P, 8.92%. Calcd for $C_9H_{10}O_6N_5P \cdot H_2O$: C, 32.43; H, 3.60; N, 21.02; P, 9.31%.

The sample was dried at 70—80°C and 0.01 mmHg for 12 hr over P_2O_5 for analysis. On treatment with 0.1 N hydrochloric acid at 95—100°C for 15 min, the cyclic phosphate gave only D-*erythro*-neopterin-3′-phosphate; this was identified by determining the optical rotation of the hydrolysis product (alkaline phosphatase). On treatment with a large excess of potassium metaperiodate in a 1 M sodium carbonate solution at room temperature for 12 hr, it remained unchanged.

The R_f-values of the pteridines are given in Table 4.

(Received February 29, 1972)

The photolysis of ethoxalyl azide gives ethoxalylnitrene and ethoxycarbonyl isocyanate. The nitrene adds to C=C double bonds and is inserted into O-H and C-H bonds. At high ethanol concentrations, where the singlet nitrene predominates, the O-H insertion product is formed dominantly. At low ethanol concentrations, where much of the nitrene changes to the triplet state, the hydrogen-abstraction product is preferred. The reactivity of the nitrene toward the C-H bonds of 2-methylbutane is more selective than that of ethoxycarbonylnitrene.

In a preliminary communication,[1] we reported that thermolysis of ethoxalyl azide in alcohols gave ethoxycarbonylurethanes *via* ethoxycarbonyl isocyanate, the Curtius rearrangement product, whereas the photolysis of the azide in alcohols or hydrocarbons yielded *N*-alkoxy- or *N*-alkyl-ethoxalamides, whose formation could be explained by the assumption of ethoxalylnitrene as an intermediate. This paper will deal cheifly with the reactions of ethoxalylnitrene with alcohols and hydrocarbons, and with the reactivities of the nitrene toward C-H bonds of hydrocarbons studied in further detail.

Results and Discussion

All experiments on the photolysis of ethoxalyl azide were carried out in dichloromethane, since the neat azide was explosive.

Photolysis of Ethoxalyl Azide in Alcohols and in Hydrocarbons. Ethoxalyl azide (I) was decomposed by the light (mainly 2537 Å) of a low-pressure mercury arc in a mixture of dichloromethane with alcohols at —78°C in an atmosphere of nitrogen. The reaction gave ethoxalamide (IV) and *N*-alkoxyethoxalamides (V), accompanied by *N*-alkoxycarbonylurethanes (III) and the dehydrogenation products of the alcohols employed.

Similarly, the photolysis of I with hydrocarbons yielded *N*-alkyl- or *N*-cycloalkyl-ethoxalamides (VI) and ethoxalamide (IV), in addition to ethoxycarbonyl isocyanate (II). The yields of the products are listed in Table 1.

As is shown in Table 1, the yields of isocyanate (II) were almost the same in all cases, while those of the amides (IV and V, IV and VI) varied with the substrate employed. The results suggest that the mechanism for the formation of isocyanate is different from that for the formation of amides; the rearrangement of I into II seems to proceed *via* a concerted mechanism, whose transition state is expressed by I', as has been

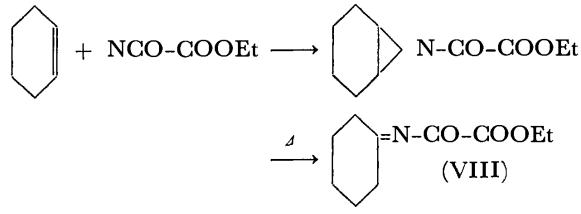
Scheme 2.

pointed out in the Curtius rearrangement of pivaloyl azide[2,3] (Scheme 1).

On the contrary, the formation of IV, V, and VI can be explained by assuming the intermediacy of a carbonylnitrene, ethoxalylnitrene (VII), in a manner similar to that of the photolyses of ethyl azidoformate[4] and pivaloyl azide[3] in hydrocarbons (Scheme 2).

In the reaction with alcohols, no insertion products of ethoxalylnitrene into C-H bonds of alcohols were recognized in the reaction products (Table 1). This shows that ethoxalylnitrene is inserted preferentially into O-H bonds rather than C-H bonds, suggesting the electrophilic character of the nitrene, in analogy with ethoxycarbonylnitrene[5,6] and benzoylnitrene[7].

In the reaction with hydrocarbons, however, products (VI) from the insertion of ethoxalylnitrene into different types of C-H bonds were formed, excepting the case of cyclohexene (Table 1). The decomposition of I in cyclohexene gave a 20% yield of *N*-ethoxalylcyclohexanonimine (VIII) in place of insertion products. The product (VIII) may be formed by the addition of ethoxalylnitrene to the double bond of cyclohexene, followed by isomerization during gas chromatography at a column temperature.



Dilution Effect. If it is assumed that the nitrene is formed in the singlet state and that part of the nitrene then changes into triplet nitrene before reacting with substrates, the lower the substrate concentration, the greater should be the quantity of triplet nitrene, leading to an increase in the formation of hydrogen-abstraction product (IV). This expectation led us to investigate the effect of the ethanol concentration on the distribution of ethoxamide (IV) and *N*-ethoxyethoxalamide (Va) in the product mixture. Table 2 shows the results of the photolyses of ethoxalyl azide in ethanol-dichloromethane mixtures, employing a 4 : 10 molar ratio of azide to ethanol. The ratio of the yield of IV to that of Va increased with the decrease in the ethanol concentration in dichloromethane. A similar tendency has been observed in the photolyses of ethyl azidoformate in isoprene-dichoromethane mixtures[8] and of pivaloyl azide in cyclopentane-neopentane (solvent) mixtures.[2]

TABLE 2. DISTRIBUTION OF IV AND Va IN THE PHOTOLYSIS OF ETHOXALYL AZIDE AT VARIOUS ETHANOL CONCENTRATION

Mole % of ethanol in CH_2Cl_2	Yield of IV[a] (%)	Yield of Va[a] (%)	Ratio of IV:Va
64	9.8	26	0.38
15	7.6	8.1	0.94
12	7.8	6.4	1.2
10	13	4.0	3.3
7.9	14	3.8	3.7
5.4	13	3.5	3.7
4.1	14	3.3	4.2
0	2.8	—	

a) The yields are calculated based on the amount of azide.

The results indicate that the singlet ethoxalylnitrene is inserted into the O-H bond of ethanol to give Va, while the triplet nitrene abstracts hydrogen atoms from ethanol to afford IV.

Reactivities of Ethoxalylnitrene toward the C-H Bonds in 2-Methylbutane. When ethoxalyl azide was photolyzed in a dichloromethane solution of 2-methylbutane, four isomeric insertion products (VIa—VId) were formed in a total yield of 21%.

The division of their yields by the number of hydrogen atoms of each type available gives the relative reactivities of the various sites on 2-methylbutane. The two different sites of primary C-H bonds had nearly the same reactivity, within the limits of the accuracy of our measurements. The reactivities of ethoxalylnitrene toward primary (1°), secondary (2°), and tertiary (3°) C-H bonds of 2-methylbutane are summarized in Table 3, those of ethoxycarbonylnitrene[9] and pivaloylnitrene[2] toward the same C-H bonds are also cited there for the sake of comparison.

Table 3. Reactivities of ethoxalylnitrene and other carbonylnitrenes toward the C-H bonds in 2-methylbutane

Carbonylnitrene (from photolysis of azide)	Type of C-H bond		
	1°	2°	3°
N-CO-COOEt	1	6.6(±11%)[a]	43(±14%)
N-CO-OEt	1	9 (±10%)	34(±5%)
N-CO-C(CH_3)$_3$	1	8.6(±10%)	160(±25%)

a) The relative errors appear in parentheses.

The results indicate that the reactivity of ethoxalylnitrene is more selective than that of ethoxycarbonylnitrene, because of the larger resonance stabilization of the former.

Experimental

The IR spectra were recorded on a Hitachi EP-S spectrophotometer, and the NMR spectra were taken on a Hitachi R-20 instrument, using tetramethylsilane as the internal standard. Gas chromatography (vpc) was done on Yanagimoto GCG-3DH and GCG-5DH units, employing the following adsorbents: A, 10% Dioctyl phthalate on Neopak 1A (40~60 mesh); B, 15% Polyethylene glycol succinate on Neopak 1A (40~60 mesh). Quantitative analyses by vpc were carried out by calibrating the detector response for the compound in question by injecting known volumes of standard solutions and aliquots of the reaction mixture. Tests for the decomposition of samples during vpc analysis were made by collecting all the effluent in a dry ice-methanol trap, and by reinjecting. If no new vpc peaks appeared and no significant change was observed in the relative size and height of the peaks, decomposition was regarded as being absent.

Materials. Ethoxlyl azide (I) has been described in the literature[10], but the preparation of I from sodium azide and ethoxalyl chloride is much superior to the method reported in Ref. 10. Ethoxalyl chloride (29 g, 0.2 mol) dissolved in 60 g of dichloromethane was dropped, over a period of 0.5 hr, into a vigorously stirred solution of sodium azide (16 g, 0.24 mol) in 90 ml of water at −5~0°C. After the mixture had been stirred at 0°C for another 3 hr, the layers were separated, the aqueous layer was extracted with 20 ml of cold dichloromethane, and the combined dichloromethane solution was washed twice with a 10% sodium carbonate solution and water as soon as possible. The dichloromethane solution was dried repeatedly over anhydrous sodium sulfate at the dry ice-methanol temperature until a clear solution was obtained. Since free ethoxalyl azide, like other carbonyl azides of a low molecular weight, was predicted to be explosive at room temperature, the formation of ethoxalyl azide in the solution was confirmed by the reaction with ethanol at 35°C to give *N*-ethoxycarbonylurethane (IIIa), the yield of azide was observed to be 50—60% by the measurement of nitrogen evolved during the reaction. The dichloromethane solution of azide may be preserved for a couple of days at the dry ice-methanol temperature.

The alcohols and hydrocarbons, except for cyclohexene, were purified according to published directions[11]. Cyclohexene was prepared from cyclohexanol[12] and was then purified. The purities of the substrates and solvents were sufficiently proved by vpc.

Photolysis of I in Alcohols. About 50 g of a dichloromethane solution of I (about 0.04 mol), prepared by the reaction of 9.6 g (0.07 mol) of ethoxalyl chloride with 5.3 g (0.08 mol) of sodium azide, was placed in an irradiation vessel immersed in a dry ice-methanol mixture, and then 1.0 mol of an alcohol was added to the solution with stirring. After being flushed with dry nitrogen, the mixture was irradiated. When the evolution of nitrogen was over, the solvent was removed at room temperature under a 1-mmHg pressure, and the residue was distilled at 30—150°C under a 1×10^{-2}-mmHg pressure. The distillate was analyzed by vpc using the A adsorbent, the structures of the products were determined by means of elemental analyses and by measurements of IR and NMR spectra.

In the photolysis of I (6 g, 0.042 mol) in ethanol, *N*-ethoxycarbonylurethane (IIIa), ethoxalamide (IV), and *N*-ethoxyethoxalamide (Va) were obtained in yields of 3.0 g (45%), 0.48 g (9.8%), and 1.8 g (26%) respectively. In the photolysis of I (5.6 g, 0.039 mol) in 2-propanol, *N*-isopropoxycarbonylurethane (IIIb), IV, and *N*-isopropoxyethoxalamide (Vb) were isolated in yields of 3.1 g (45%), 0.73 g (16%), and 1.5 g (22%) respectively. These products showed the following physical properties.

N-Ethoxycarbonylurethane (IIIa): mp: 49—50°C. IR (KBr, cm^{-1}): 3220 (NH); 1750 (C=O); 1210 (C-O). NMR (CCl_4, τ): 1.83 (NH, bs); 5.79 (C-CH_2, 4H, q); 8.70 (CH_3, 6H, t). Found: C, 44.71; H, 6.88; N, 8.69%. Calcd for $C_6H_{11}O_4N$: C, 44.90; H, 7.13; N, 8.60%.

Photolysis of I in Cyclic Hydrocarbons. To about 50 g of a dichloromethane solution of I (about 0.04 mol), prepared from ethoxalyl chloride (9.6 g, 0.07 mol) with sodium azide (5.3 g, 0.08 mol), we added a mixture of a cyclic hydrocarbon (ten times the molar quantity of the I employed) and about 60 g of dichloromethane (the total amount of dichloromethane was adjusted to thirty times the molar quantity of the I), and then the photolysis was carried out as has previously been described. The isocyanate (II) thus produced was trapped at room temperature under a 1-mmHg pressure in a vessel, cooled by dry ice-methanol, and refluxed for two hr with an adequate amount of ethanol in order to convert it into *N*-ethoxycarbonylurethane (IIIa). The yield of II was estimated from that of IIIa, since the conversion of II into IIIa proceeded quantitatively.

The other products contained in the distillation residue were collected at 30—200°C under a 1×10^{-2}-mmHg pressure and were analyzed by vpc using the B adsorbent and the corresponding urethanes as standard materials.

In the photolysis (I: 5.4 g, 0.0378 mol) in cyclohexane, *N*-cyclohexylethoxalamide (VI-1), IV, and II were obtained in yields of 1.2 g (16%), 0.17 g (3.7%), and 2.5 g (41%) respectively. In the photolysis (I: 5.7 g, 0.04 mol) in cyclopentane, *N*-cyclopentylethoxalamide (VI-2), IV, and II were obtained in yields of 1.3 g (17%); 0.17 g (3.7%), and 2.9 g (45%) respectively. In the photolysis (I: 6.0 g, 0.042 mol) in benzene, *N*-phenylethoxalamide (VI-3), IV, and II were isolated in yields of 0.9 g (11%), 0.19 g (3.8%), and 3.3 g (48%) respectively. In the photolysis (I: 6.4 g, 0.045 mol) in cyclohexene, however, 1.8 g (20 %) of *N*-ethoxalylcyclohexanonimine (VIII) was obtained, accompanied by 0.28 g (5.3%) of IV, 2.2 g (43%) of II, and 3 g of an unidentified tarry substance.

The physical properties of VI-1, VI-2, VI-3, and VIII are shown below.

N-Cyclohexylethoxalamide (VI-1): mp: 145°C. IR (KBr, cm^{-1}): 3300 (NH); 1735, 1655 (C=O); 1205 (C-O). NMR (CCl_4, τ): 2.81 (NH, bs); 5.80 (C-CH_2, q); 6.33 (N-CH, m); 8.65 (CH_3, t). Found: C, 60.01; H, 8.37; N, 7.01%. Calcd for $C_{10}H_{17}O_3N$: C, 60.28; H, 8.60; N, 7.03%.

N-Cyclopentylethoxalamide (VI-2): IR (CCl_4, cm^{-1}): 3250 (NH); 1730, 1675 (C=O); 1210 (C-O). NMR (CCl_4, τ): 2.65 (NH, bs); 5.3—6.0 (N-CH, m); 5.74 (O-CH_2, q); 7.7—8.8 (ring CH_2, 8H, m); 8.63 (CH_3, t). Found: C, 58.20; H, 8.20; N, 7.60%. Calcd for $C_9H_{15}O_3N$: C, 58.36; H, 8.10; N, 7.56%.

N-Phenylethoxalamide (VI-3): mp: 66°C. IR (KBr, cm^{-1}): 3325 (NH); 3100, 1595 (arom. CH); 1710, 1695 (C=O). NMR (CCl_4, τ): 0.74 (NH, bs); 2.2—2.4, 2.55—3.0 (ring CH, 5H, m); 5.76 (O-CH_2, q); 8.72 (CH_3, t). Found: C, 62.02; H, 5.68; N, 7.22%. Calcd for $C_{10}H_{11}O_3N$: C, 62.16; H, 5.74; N, 7.25%.

N-Ethoxalylcyclohexanonimine (VIII): IR (CCl_4, cm^{-1}): 1745, 1700 (C=O); 1670 (C=N); 1200 (C-O). No bands of NH and olefinic CH were observed. NMR (CCl_4, τ): 5.68 (O-CH_2, q); 8.60 (CH_3, t); 7.9—8.8 (ring CH_2, 10H, m). No signals expected at the aziridine[4] and oxazoline[13] rings were recognized. Found: C, 60.61; H, 7.78; N, 7.21%. Calcd for $C_{10}H_{15}O_3N$: C, 60.89; H,

Dilution Effect. Dilution experiments were carried out, keeping the molar ratio of azide to ethanol at 4 : 10 (0.084 : 0.20 mol) and using dichloromethane as the diluent. For the quantitative determination of the products, the crude reaction mixture was injected into the vpc apparatus.

Photolysis of I in 2-Methylbutane (Reactivities of Ethoxalylnitrene toward C–H Bonds). A solution of 2-methylbutane (72 g, 1.0 mol) in 85 g of dichloromethane was added to 115 g of a dichloromethane solution of I (about 0.12 mol) on cooling, after which the mixture was irradiated as has been described. The reaction products were fractionated into two portions, as has been described in the case of cyclic hydrocarbons. The one fraction obtained under a 1-mmHg pressure gave 9.1 g (47%) of II. The other fraction, obtained under a 1×10^{-2}-mmHg pressure, was analyzed by vpc on a column containing the B adsorbent at 160°C, using *N*-cyclohexylethoxalamide as the standard material.

Four isomeric ethoxalamides, VIa—VId, were obtained in a total yield of 21%, besides 1.3 g (9.3%) of IV. The yields of the four isomers were determined by assuming that the detector response is nearly the same for VIa—VId, and were taken as the bases for the calculation of the relative reactivities in Table 3. The results are arranged on Table 4, while the physical and analytical data of VIa—VId are shown in Tables 5, 6, and 7.

Studies of Dithiobiurets. III. The Preparation and Properties of 3,5-Disubstituted 3*H*-1,2,4-Dithiazoles

Isao IWATAKI

Chemical Research Laboratory, Nippon Soda Co., Ltd., Kozu, Odawara

(Received March 2, 1972)

3,5-Disubstituted 3*H*-1,2,4-dithiazoles were prepared by the oxidation of dithiobiurets, *S*-benzylisodithiobiurets, and alkyl trithioallophanates, and then 3-acyl or carbamoylimino derivatives were obtained by the direct acylation or carbamoylation of the dithiazole salts. From the spectral data of these compounds, it is concluded that the carbonyl group affects the pseudoaromatic character of the dithiazole ring system.

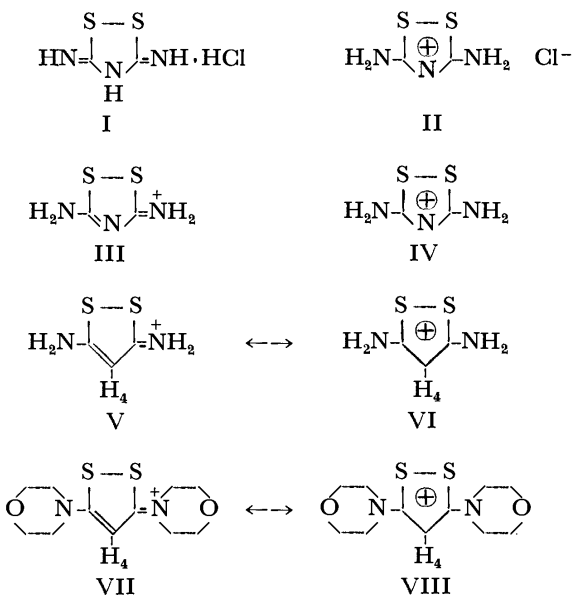
We previously reported that 2-acetylimino-5-dimethylamino-3*H*-1,2,4-dithiazole hydrothiocyanate was obtained by the thermal decomposition of 1,1-dimethyl-5-acetyldithiobiuret.[1] The free base which was prepared by the neutralization with potassium carbonate did not show any carbonyl absorption in the infrared spectrum in spite of the existence of the acetyl group, while its hydrochloride or sulfate showed a strong carbonyl absorption band at 1690 cm^{-1}.

In this investigation, we prepared many related compounds and obtained new information concerning their pseudoaromatic chartacteristics from their spectral properties. Indeed, 3-acylimino or carbamoylimino dithiazole derivatives showed the same behavior as 2-acetylimino-5-dimethylamino-3*H*-1,2,4-dithiazole, except in a few cases.

Dithiazole derivatives, prepared by the oxidation of dithiobiurets, are well known as thiurets. Their structure had been studied by mean of IR, UV, X-ray, *etc.*, and their pseudoaromatic ring system has been confirmed by many workers. Unsubstituted thiuret, prepared by the oxidation of dithiobiuret with hydrogen peroxide in hydrochloric acid, was first formulated as having a hydrochloride of diiminodithiazole structure I,[2] but this compound formed salt with only one equivalent of acid; therefore, Jensen, Baccaro and Buchardt[3] considered that the basic ion was the diaminodithiazolyl ion, II. Furthermore, they described that 1,2,4-dithiazole derivatives showed an strong infrared band at 1510—1540 cm^{-1} which is due to the aromatic ring system.

Foss and Tjomsland[4] obtained data denying the I structure by X-ray methods, but they suggested that the conjugation does not extend over the S–S bond, unlike the cases of 3-alkyl or phenyl-1,2-dithiolium salts.[5]

Hordvik and Sundsfjord[6] concluded, from their structural investigations of the hydrobromide and the hydrochloride, that the relative weight of the resonance form containing the S–S double bond should be smaller in the 3,5-diamino-1,2-dithiolium ion than in the unsubstituted 1,2-dithiolium ion. Prinzbach and Futterer[7] described, with regard to the ion structure of 1,2 and 1,3-dithiolium salts, that the positive charge is largely locarized on the exocyclic nitrogen atom; they concluded this from the chemical shift of the proton at the 4 position in the nmr spectra. That is, the chemical shifts for H-4 in the cases of the 3,5-diamino VI and dimorpholino VIII derivatives appear in a high field (6.52 and 6.46 ppm) in comparison with the substituted 1,2-dithiolium salts (8—9 ppm). Thus, it is clear that the 3,5-diamino-1,2,4-dithiazole salts are of the III structure because they have the same properties as 3,5-diaminodithiolium salts. This fact has already been confirmed by Jensen, Baccaro, and Buchardt.[3] On the other hand, a preliminary result of a X-ray structural determination of 3,5-diacetamino-1,2-dithiolium iodide[8] indicates that a partial bonding between sulfur and oxygen leads to a shortening of the S–S bond; consequently, the stability of the dithiolium cation increases upon acetylation.



Results and Discussion

Preparation of the Starting 3H-1,2,4-Dithiazole Salts. 1-Mono or disubstituted 2,4-dithiobiurets, which were the starting materials of this study, were prepared by known methods. The first of these is by the fusion of

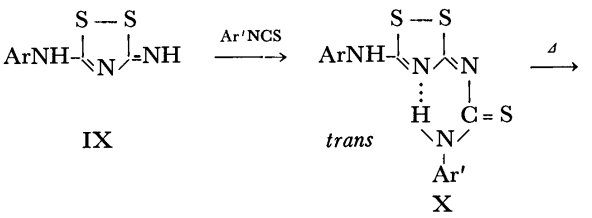
arylamines with perthiocyanic acid.[9] The second method is that of Dixit[10] whereby perthiocyanic acid is treated with aliphatic amines in water. He described that 1-alkyl-2,4-dithiobiurets were obtained in good yields at an ordinary temperature, but most of the 1,1-disubstituted derivatives could not be obtained by this method. The third method is the action of amines on methyl trithioallophanate. Bousquet obtained 1-aryl-2,4-dithiobiurets by the reaction of potassium trithioallophanate with anilines.[11] Aliphatic amines reacted with it, but no pure product could be obtained. On the other hand, methyl trithioallophanate which has been prepared from the potassium salt with dimethyl sulfate reacted with dialkylamines at an ordinary temperature to give 1,1-dialkyl-2,4-dithiobiurets. 1,1,5-Trisubstituted-2,4-dithiobiurets were also obtained from dialkylthiocarbamoylisothiocyanates.[12] The dithiobiurets thus prepared were oxidized with chlorine in an alcohol or chloroform solution to give the corresponding 3*H*-1,2,4-dithiazole hydrochlorides in good yields.

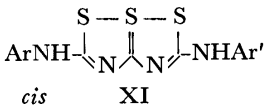
5-Alkylamino-*3*-imino or *5*-alkylamino-*3*-alkylimino dithiazole salts were prepared by Dixit's method[13] by means of the oxidative debenzylation of S-benzylisodithiobiurets which had previously been obtained by the reaction of S-benzylisothioureas and alkylisothiocyanates without going through dithiobiurets. Generally, free bases of 5-substituted amino-3-iminodithiazole salts are unstable and decompose to substituted cyanothioureas under alkaline conditions, even at low temperatures,[14] but 3-alkylimino derivatives are stable and can be isolated as free bases.[13]

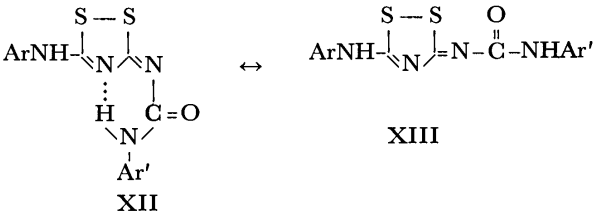
Acylation of the Imino Group. Salts of the dithiazole derivatives react with acid anhydride in acetone or benzene at ordinary temperatures in the presence of 2 mole equivalents of tertiary amines to give the corresponding 3-acylimino derivatives. Higher fatty acid anhydrides, such as capric or palmitic anhydride, are less reactive and require heating. Acid halides also react with the salts, but the yields are always very low. In these cases, the acylation will occur on sulfur atoms and results in ring opening and decomposition. Acetic and propionic anhydrides react with them without tertiary amines, and keeping only at room temperature gives the corresponding acetylated or propionylated derivatives in good yields. 3-Acyliminodithiazoles are thermally unstable under alkaline conditions. When the reaction is carried out at a higher temperature, the primary product is formed first, but it is decomposed later by excess tertiary amine.

*Preparation of 3-acylimino-5-alkylthio-3*H*-1,2,4-dithiazoles.* Hydroiodides of 5-alkylthio derivatives were prepared by the method of Allen and Shelton from alkyl trithioallophanates.[15] The subsequent treatment of these salts with acid anhydrides, as described above, afforded the corresponding acylated compounds.

Spectral Properties. The dithiazole derivatives which were prepared by the above methods showed characteristic behavior in the infrared spectra. The frequencies of the carbonyl and C=N stretching bands of the related compounds are shown in Table 1. Most of the free bases of the 3-acylimino or carbamoylimino derivatives do not show carbonyl absorption in the region normally expected for amide groups, but a pair of absorptions appears at 1550—1600 cm^{-1}. These two bands have equal intensities, and one of them may be assigned to the C=N stretching band. All the 3-acylimino derivatives form salts with mineral acids, and the infrared spectra of the corresponding salts show an carbonyl absorption in the ordinary region, like mesoionic compounds (cf. Table 2).







Behringer and Weber[16] obtained a trans form of 5-anilino-3-(N-phenyl)thiocarbamoylimino-3H-1,2,4-dithiazole X when IX was treated with phenylisothiocyanate, then it was converted to the *cis* form XI by heating. They confirmed those structures by studying the UV spectra. On the other hand, they also prepared carbamoyl derivatives; in those cases, they presumed that the carbamoyl groups were present in the tautomeric form, as is shown (XII and XIII). However, 5-dimethylamino-3-carbamoylimino derivatives showed an infrared absorption band of the carbonyl group in a region similar to that of the corresponding acyl derivatives, unlike the cases of 5-alkylamino or anilino-3-carbamoylimino derivatives. The difference between 5-dimethylamino and 5-monoalkyl or arylamino derivatives was further confirmed by studying the UV spectra. The UV spectra of the related compounds are shown in Table 3 and Fig. 1—3. Fig. 1 shows the spectra of the starting dithiazole

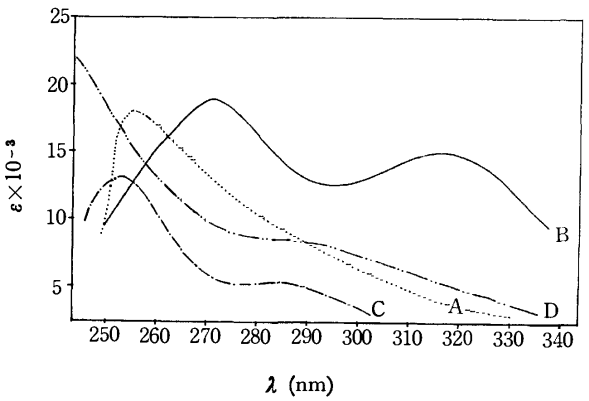

Fig. 1. UV spectra of 5-alkylamino or anilino-3-imino-3H-1,2,4-dithiazole salts.
A ····· 5-dimethylamino-3-imino-, hydrochloride.
B ——— 5-anilino-3-imino-, hydrochloride.
C —·—· 5-methylamino-3-imino-, hydrobromide.
D —··— 5-anilino-3-imino-.

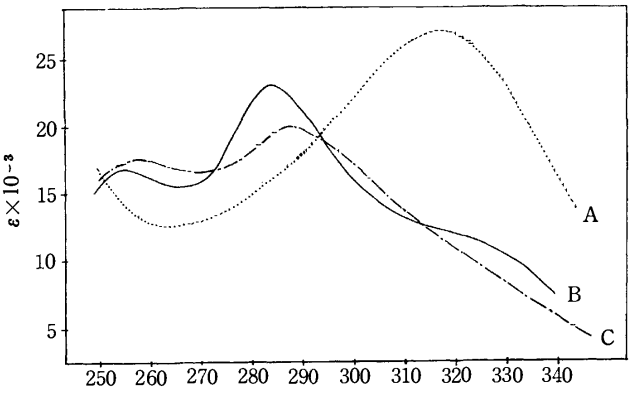

Fig. 2. UV spectra of 5-anilino or dimethylamino-3-(N-phenyl)carbamoylimino or benzoylimino-3*H*-1,2,4-dithiazoles.
A ····· 5-anilino-3-(*N*-phenyl)carbamoylimino-.
B ——— 5-dimethylamino-3-benzoylimino-.
C —·—· 5-dimethylamino-3-(*N*-phenyl)carbamoylimino-.

salts. The spectrum of 5-dimethylamino-3-(N-phenyl)carbamoylimino derivative is very similar to the corresponding 3-benzoylimino derivative and differs a little from the spectrum of the 5-anilino-3-(N-phenyl)carbamoylimino derivative. From this fact, it is obvious that the carbamoyl group of the 5-dimethylamino compound has the same conformation as the corresponding acyl derivatives and is located at the *cis* position, because the interaction between S and O can occur only at the *cis* form. Actually, all the acylimino derivatives will be in the *cis* form, because the intramolecular hydrogen bonding can not arise in the acyl series. The spectra of 3-(*N*-methyl)-carbamoylimino-5-substituted amino dithiazoles are shown in Fig. 3. The 5-monoalkylamino and 5-anilino derivatives gave similar spectra. They contain two amino protons, namely, *a* and *b*; the *a* proton is able to shift to the imino nitrogen at the 3 position by resonance, as is shown in XV, and then XV isomerizes to the trans structure, such as XVI or XVII.

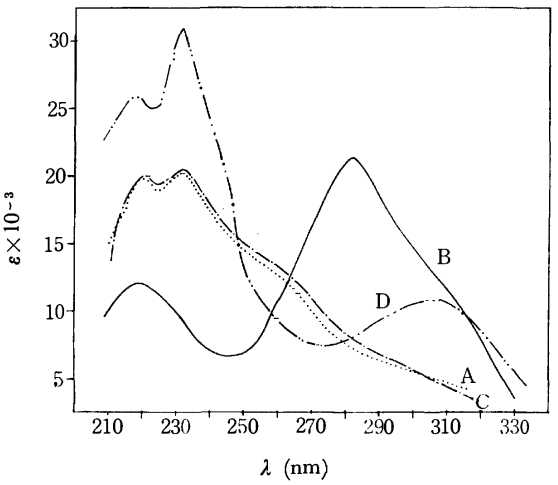

Fig. 3. UV spectra of 3-(*N*-methyl)carbamoylimino-3*H*-1,2,4-dithiazole derivatives.
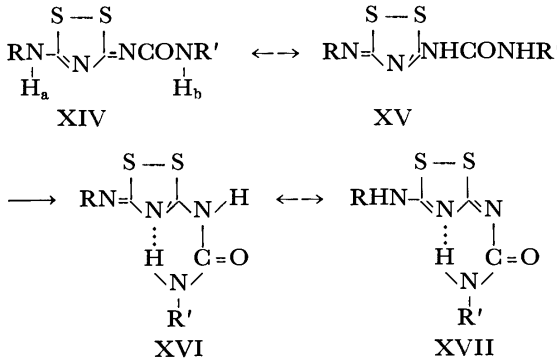
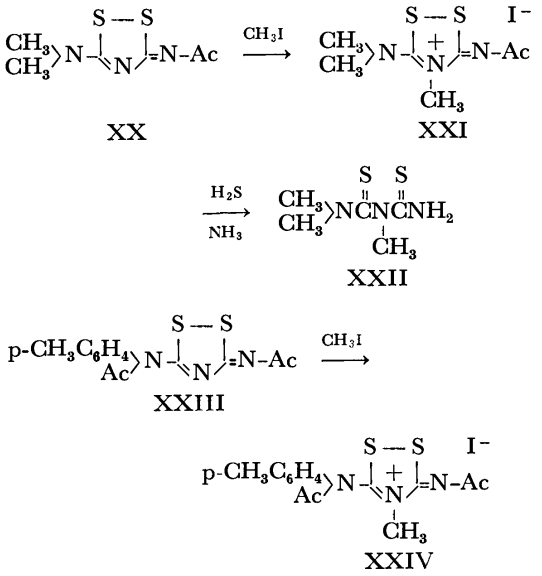
A ····· 5-methylamino-.
B ———— 5-dimethylamino-.
C —·—· 5-ethylamino-.
D —··— 5-anilino-.

The presence of the *b* proton facilitates the formation of the stable *trans* conformation by intramolecular hydrogen bonding. On the other hand, as the 5-dimethylamino derivative does not contain the *a* proton, the resonance between XIV and XV does not occur and the *cis* compound is formed as in the cases of the acylation.



All the acylimino derivatives showed an absorption at about 290 mμ similar to the *N*-acyl sydnonimines,[19] and their salts showed a charge separation between the dithiazole ring and the exocyclic acylimido group.

A carbonyl group which combines with the 3-imino group facilitates the formation of a dithiazolyl cation, as is shown by XVIII and XIX; as a result, the dithiazole ring may be stable, like other heteroaromatic compounds.



5-Alkyl or arylamino-3-acyliminodithiazoles were easily reacted with methyl iodide to give the methiodides in good yields. In these cases, the methylation occurred at the 4 position because, by the treatment of an alcoholic solution of a dithiazole with alkaline sulfide, it is smoothly reduced to a 3-methylated dithiobiuret. For instance, XX reacted with methyl iodide to form XXI, when kept at only room temperature, and was then reduced to XXII with hydrogen sulfide and ammonia in a hot ethanolic solution. Diacetyl derivatives such as XXIII also reacted with methyl iodide to give the corresponding methiodide XXIV. The methiodides thus obtained showed an infrared absorption band of the carbonyl group at 1670 cm^{-1}, and they decomposed upon treatment with alkali, even with sodium bicarbonate. These results suggest that the positive charge may be localized on the nitrogen atom at the 4 position and that the dithiazole ring may be unstable.

Experimental

The melting points are uncorrected. The ultraviolet spectra were recorded on a Shimadzu model MPS-50L apparatus. The infrared spectra were recorded on a JASCO model IR-G spectrophotometer in Nujol mull.

Formation of 1-Substituted 2,4-Dithiobiuret from Amines and Methyl Trithioallophanate. To a suspended solution of methyl trithioallophanate (0.1 mol) in 50 m*l* of ethanol, the amine (0.2 mol) was added at an ordinary temperature. When the reaction mixture was warmed with stirring, the methyltrithioallophanate gradually went into the solution. The resulting solution was stirred for 1 hr at 30—40°C and poured into 300 m*l* of 1 N-hydrochloric acid. The precipitate was then filtered off and recrystallized from ethanol. In this manner, the following dithiobiurets were prepared.

Di-*n*-propyl, di-*i*-propyl and di-*n*-butyl amines all failed to react with methyl trithioallophanate.

Formation of 3,5-Disubstituted 3H-*1,2,4-Dithiazoles, Oxidation of 1,1-Disubstituted 2,4-Dithiobiurets.* 2,4-Dithiobiurets were easily oxidized to the related dithiazole salts with many oxidizing reagents, for example, iodine, bromine, hydrogen peroxide, ferric chloride and sodium hypochlorite in an acidic medium.

	43	137—138*	$C_5H_{11}N_3OS_2$	21.49	21.72	33.34	33.16

a) Decomp.

A small quantity (0.1 mol) of the dithiobiuret was dissolved in 50 m*l* of chloroform or ethanol, and an excess of chlorine gas was passed through the solution with stirring at an ordinary temperature. The hydrochloride thus precipitated was filtered and washed with acetone. It was almost pure and could be used in the next reaction without recrystallization. All of the 1,1-disubstituted 2,4-dithiobiurets were oxidized in a similar manner.

*Oxidation of 1-Alkyl-4*S*-benzyliso-2,4-dithiobiurets.* 5-Methylamino, 5-isopropylamino, and 5-*n*-butylamino-3*H*-1,2,4-dithiazole hydrobromides were prepared by Dixit's method.[13)]

The isodithiobiuret (0.1 mol) was dissolved in 50 m*l* of chloroform, and then bromine (0.11 mol) was stirred in 40°C. The precipitate was filtered and washed with acetone. The yield was 80—90%: 5-methylamino-3-imino-3*H*-1,2,4-dithiazole hydrobromide, mp 232—233°C (decomp.) (Ref. 13, mp 228°C), 5-isopropylamino-3-imino-, mp 215—218°C (decomp), 5-*n*-butylamino-3-imino-, mp 189—193°C (decomp.).

Formation of 1,1,5-Trisubstituted 2,4-Dithiobiurets. Freshly-prepared dimethylthiocarbamoyl isothiocyanate[12)] (0.1 mol) was dissolved in 50 m*l* of acetone, and then the amine (0.1 mol) was added at an ordinary temperature. The solution was stirred for 1 hr, the solvent was removed *in vacuo*, and the crystalline residue was recrystallized from ethanol. The yield was almost quantitative. In this manner, the following new dithiobiurets were prepared:
1,1-dimethyl-5-*t*-butyl-2,4-dithiobiuret, mp 102—103°C. Found: C, 43.84; H, 7.76; N, 19.18; S, 29.22%. Required for $C_8H_{17}N_3S_2$: C, 43.55; H, 7.76; N, 18.84; S, 28.88%.
1,1-dimethyl-5-phenyl-, mp 83—84°C. Found: C, 50.21; H, 5.44; N, 17.57; S, 26.78%. Required for $C_{10}H_{13}N_3S_2$; C, 50.08; H, 5.81; N, 17.37; S, 26.88%.

*Formation of 1,1-Dimethyl-5-t-butylimino-*3H*-1,2,4-dithiazole.* 1,1-Dimethyl-5-*t*-butyl-2,4-dithiobiuret (11 g, 0.05 mol) was dissolved in 50 m*l* of ethanol, and then bromine (8 g) was added at 0°C. The precipitate was filtered and dissolved in 300 m*l* of water; subsequent neutralization with potassium carbonate gave 10 g (91%) of the dithiazole. The substance was recrystallized from ethanol as pale yellow prisms. Mp 76—77°C. Found: C, 43.94; H, 6.61; N, 19.10; S, 29.54%. Required for $C_8H_{15}N_3S_2$: C, 44.24; H, 6.91; N, 19.35; S, 29.49%.

1,1-Dimethyl-5-phenylimino-3*H*-1,2,4-dithiazole was prepared by the same procedure. Mp 89—90°C. Found: C, 50.33; H, 4.58; N, 17.81; S, 26.86%. Required for $C_{10}H_{11}N_3S_2$: C, 50.63; H, 4.64; N, 17.72; S, 27.00%.

*Formation of 5-Alkylthio-3-imino-*3H*-1,2,4-dithiazole Hydroiodide.* Alkyl trithioallophanate were oxidized by the known method.[15)] The yield was always quantitative, and the following hydroiodides were thus prepared: 5-methylthio-3-imino-3H-1,2,4-dithiazole hydroiodide, mp 161—163°C (Ref. mp 157°C), 5-ethylthio-, mp 143—144°C (Ref. mp 143—145°C), 5-benzylthio-, mp 133—134°C. Found: C, 29.61; H, 2.34; N, 7.53; S, 26.38; I, 34.55%. Required for $C_9H_9IN_2S_3$: C, 29.32; H, 2.45; N, 7.61; S, 26.09; I, 34.51%.

*Acylation of 5-Substituted Amino or Alkylthio-3-imino-*3H*-1,2,4-dithiazole Salts.* *(A) With Tertiary Amine*: The dithiazole salt (0.05 mol) and the required acid anhydride (0.1 mol) were mixed in 50 m*l* of acetone, and then triethylamine (0.1 mol) was stirred in at room temperature. The exothermic reaction was observed, and the temperature was raised to 30—40°C. The mixture was stirred for 1 hr at this temperature, and then poured into water and made alkaline with potassium carbonate. The resulting precipitate was filtered off, washed with water, and recrystallized from methanol or ethanol.

(B) Without Tertiary Amine: The dithiazole salt (0.05 mol) and the acid anhydride (0.2 mol) were heated at 50—60°C for 1 hr with stirring; the mixture was then poured into water, and the precipitate was filtered off, washed with water, and recrystallized from methanol or ethanol.

(C) With Acyl Halides Instead of Acid Anhydrides: Into a mixture of the dithiazole salt (0.05 mol) and the acyl halide (0.05 mol) in 50 m*l* of acetone, pyridine (0.05 mol) was stirred at room temperature, that temperature was maintend for 20 min. The mixture was then poured into water, and the precipitate was collected and then recrystallized from alcohol, acetone, *n*-hexane, *etc.* The results are summarized in Table 5.

*Formation of 5-Anilino-3-acetylimino-*3H*-1,2,4-dithiazole.* A mixture of 5-anilino-3-imino-3*H*-1,2,4-dithiazole (1.1 g) and 1-acetylimidazole (0.6 g) in 10 m*l* of tetrahydrofuran was allowed to stand for 1 week at room temperature. The solution was then poured into water, and the precipitate was collected. Recrystallization from alcohol gave 1 g of yellow needles, melting at 191—192°C with decomposition. Found: C, 47.92; H, 3.51; N, 16.64; S, 25.72%. Re-

quired for $C_{10}H_9N_3OS_2$: C, 47.81; H, 3.59; N, 16.73; S, 25.50%. This substance was converted to a diacetyl derivative with acetic anhydride and pyridine. The melting points and infrared spectra were identical.

*Formation of 3-Acetylimino-5-dimethylamino-4-methyl-*3H-*1,2,4-dithiazolium Iodide, XX.* 3-Acetylimino-5-dimethylamino-3H-1,2,4-dithiazole (3 g) and methyl iodide (10 m*l*) were refluxed in acetone (20 m*l*) for 1 hr and then allowed to stand at room temperature for 2 days. The resulting precipitate was filtered off, washed with acetone, and recrystallized from ethanol, affording the methiodide (4.2 g, 85%) as pale yellow needles. Mp 208—209°C with decomposition. Found: C, 24.36; H, 3.52; I, 36.73; N, 12.32; S, 18.89%. Required for $C_7H_{12}IN_3OS_2$: C, 24.35; H, 3.48; I, 36.81; N, 12.17; S, 18.55%. IR: 1670 cm^{-1} (C=O).

3-Acetylimino-4-methyl-5-(*N-p*-tolyl)acetamido-3*H*-1,2,4-dithiazolium iodide XXIII was prepared by the same procedure as a yellow powder. The yield was 65%. Mp 190—191°C with decomposition. Found: C, 35.91; H, 3.10; I, 28.95; N, 9.42; S, 14.85%. Required for $C_{13}H_{14}IN_3O_2S_2$: C, 35.86; H, 3.22; I, 29.20; N, 9.66; S, 14.71%. IR: 1690, 1680 cm^{-1} (C-O).

*Reduction of 3-Acetylimino-5-dimethylamino-4-methyl-*3H-*1,2,4-dithiazolium Iodide, XXII.* Into a suspended solution of the methiodide (2.8 g) in 10 m*l* of ethanol and 20 m*l* of 28%-aqueous ammonia, hydrogen sulfide was passed for 1 hr

a) Decomp. b) Diacetyl compound could not be obtained.

at 40°C. The methiodide was then gradually fed into the solution, which thereby turned yellow. The solution was then cooled and acidified with concentrated hydrochloric acid. The white solid was filtered off, washed with water, and recrystallized from ethanol. Thus, 1,1,3-trimethyl-2,4-dithiobiuret (0.65 g) was obtained, while from the mother liquor, 1,1,3-trimethyl-5-acetyl-2,4-dithiobiuret (0.09 g) was obtained. The latter compound was obtained by the acetylation of the dithiobiuret. Their IR, tlc, and mp were identical. 1,1,3-trimethyl-2,4-dithiobiuret: mp 100—102°C. Found: C, 33.60; H, 6.11; N, 23.39; S, 36.48%. Required for $C_5H_{11}N_3S_2$: C, 33.90; H, 6.21; N, 23.73; S, 36.16%. 1,1,3-triemethyl-5-acetyl-2,4-dithiobiuret: mp 161—162°C. IR: 1720 cm^{-1} (C=O).

Formation of 5-*Methylamino*-3-*(N-methyl)carbamoylimino*-3H-1,2,4-*dithiazole.* To a suspended solution of 3-imino-5-methylamino-3H-1,2,4-dithiazole hydrobromide (2.3 g) and methyl isocyanate (0.6 g) in 20 m*l* of tetrahydrofuran, triethylamine (1 g) was added at room temperature. The solution was stirred for 1 hr, and poured into water, and then the precipitate was filtered off. Recrystallization from dimethylformamide gave 1 g of white crystals, melting at 229—230°C. Found: C, 29.38; H, 3.99; N, 27.23; S, 31.49%. Required for $C_5H_8N_4OS_2$: C, 29.41; H, 3.92; N, 27.45; S, 31.37%. IR: 1670 cm^{-1} (C=O). The following new 3-(*N*-substituted)carbamoyliminodithiazoles were prepared by the same method. 5-Ethylamino-3-(*N*-methyl)carbamoylimino-: mp 223—224°C. Found: C, 29.81; H, 4.62; N, 25.38; S, 29.39%. Required for $C_6H_{10}N_4OS_2$: C, 33.03; H, 4.59; N, 25.69; S, 29.36%. IR: 1680 cm^{-1} (C=O). 5-Anilino-3-(*N*-methyl)carbamoylimino-: mp 162—163°C with decomposition. Found: C, 45.23; H, 3.85; N, 20.91; S, 24.02%. Required for $C_{19}H_{10}N_4OS_2$: C, 45.11; H, 3.76; N, 21.05; S, 24.06%. 5-Dimethylamino-3-(*N*-methyl)carbamoylimino-: mp 218°C with decomposition. Found: C, 33.15; H, 4.92; N, 25.68; S, 29.57%. Required for $C_6H_{10}N_4OS_2$: C, 33.03; H, 4.59; N, 25.69; S, 29.36%. 5-Dimethylamino-3-(*N*-phenyl)carbamoylimino-: mp 183.5°C with decomposition. Found: C, 46.88; H, 4.57; N, 20.05; S, 22.46%. Required for $C_{11}H_{12}N_4OS_2$: C, 47.17; H, 4.29; N, 20.00; S, 22.86%.

Solvent Effects under High Pressures. IV.[1] A Procedure for the Estimation of Solvation in the Transition State

Yasuhiko KONDO, Masaru OHNISHI, and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received March 3, 1972)

The rate constants and activation parameters were measured for the reaction of pyridine with benzyl bromide in various solvents. The rate constants were better correlated to the activation volumes than to the activation entropies. The linear free-energy relationships were observed in the plots of the log k values of some Menschutkin reactions *vs.* the log k values of the present reaction in various solvents. Corresponding to their good correlations between the values of log k and of their pressure derivatives for the present reaction, the values of $(z \cdot \Delta P)$, which are the slopes of the plots of $\Delta V_0^{\neq}$ *vs.* KV^0, increased with the increase in the slopes of the above linear free-energy relationships. The activation volumes in various solvents are linearly correlated to their pressure derivatives. An equation which predicts the relationship has been derived. Using this equation, the solvation number in the activated complex and the average pressure within its cosphere have been estimated to be *ca.* 4 and 910 (kg. cm^{-2}) respectively. Based on these results, discussions have been given on the solvation in the transition state for the present reaction.

In the works of this series,[1,2] the Menschutkin reaction of triethylamine with ethyl iodide has been chosen as the standard system in order to investigate the mechanisms of the solute-solvent interaction in the transition state. As the work continued, we needed a system sensitive to the change in the medium. As an example of such a system, the reaction of pyridine with benzyl bromide was chosen.

On the other hand, this system has long been referred to as the standard example of conforming to the Kirkwood theory.[3,4] However, contributions from the specific interaction between a solute and solvents have been suggested to play a significant role in the solvent effect in typical Menschutkin reactions.[5-7]

Therefore, the detailed analysis of the present system will throw some light on the origin of these interactions.

In this paper, the activation parameters of the reaction will be analyzed by empirical procedures, and then we will discuss the pressure dependence of

the activation volumes.

Experimental

Materials. Pyridine, a special-grade reagent, was refluxed over potassium hydroxide for a few days and then distilled. The middle fraction was stored over barium oxide and redistilled before use. Benzyl bromide, another special-grade reagent, was dried over anhydrous potassium carbonate and distilled twice under reduced pressure. The other solvents were commercial reagent-grade reagents and were purified by procedures described elsewhere.[8-11]

Kinetic Procedure. Separate solutions of pyridine and the bromide in a solvent were prepared by weight (usually the concentrations of the reagents were *ca.* 0.01—0.05 M in the reaction mixture). The solutions were mixed in polyethylene ampoules. These ampoules were sealed quickly, shaken vigorously, and immersed into a glass test tube containing mercury which was maintained at the reaction temperature. The test tube was then immersed into the oil of the pressure vessel in a thermostat bath. After a given period, the reaction mixture was partitioned between light petroleum and water. The aqueous layer was potentiometrically titrated with a silver nitrate solution.

Usually reactions were carried out at six fixed pressures (1, 300, 600, 900, 1,200, and 1,500 kg cm^{-2}) and at four fixed temperatures (20.0, 30.0, 40.0, and 50.0°C).

The Rate Law in Alcohols. In methanol and 2-propanol, a spontaneous solvolysis has been observed for the bromide. Therefore, the total rate law can be written as follows:

$$\frac{dx}{dt} = k_2(a-x)(b-x) + k_1(a-x) \quad (1)$$

where a, b, x stand for the initial mole fractions of benzyl bromide and of pyridine, and the mole fraction of the bromide ion at the time, t; respectively.

The second-order rate constants (k_2) for the Menschutkin reaction were calculated by means of Eq. (1) after the corrections of the first-order solvolysis rate (k_1), which was measured independently under the same reaction conditions.

Results

All the reaction rates followed second-order kinetics except in alcohols, where both the first order- and second order-rate constants were calculated by the procedure mentioned above. All the second order-rate constants, k_x, are expressed in a mole fraction unit (sec^{-1}), which is related to the rate constants in a molar unit, k_M ($l \cdot mol^{-1} \cdot sec^{-1}$), by the equation: $k_x = k_M V_s^{-1}$, where V_s stands for the molar volume of the solvent (in l) at the reaction temperature. For most of the reaction conditions, the measurements were repeated more than twice. The rate constants thus obtained under hydrostatic pressures were first scrutinized by the procedure developed by the present authors,[2] and then the pressure-dependence parameters were calculated by the least-squares method based on the following equations:

$$\ln k = A + BP + CP^2 \quad (2)$$

$$\Delta V_0^{\neq} = -RTB \quad (3)$$

$$(\partial \Delta V^{\neq}/\partial P)_0 = -2RTC \quad (4)$$

The least-squares calculations were also performed for the temperature-dependence parameters on the basis of the following equations:

$$\ln (k_x/T) = A'/T + B' \quad (5)$$

$$\Delta H^{\neq} = -RA' \quad (6)$$

$$\Delta S^{\neq} = R(B' - \ln k_b/h) \quad (7)$$

where k_b and h stand for the Boltzmann and the Plank constants.

These calculations were done using a NEAC 2200—500 computer. The results thus obtained are collected in Table 1.

The estimated errors are as follows: k_x; ±1.7%, $\Delta V_0^{\neq}$; ±1.3 (cm^3·mol^{-1}), $(\partial \Delta V^{\neq}/\partial P)_0$; ±0.002 (cm^5·mol^{-1}·kg^{-1}), $\Delta H^{\neq}$; ±0.2 (kcal·mol^{-1}), $\Delta S^{\neq}$;

Discussion

Empirical Analysis of Activation Parameters. Figure 1 shows the relation between these parameters and the solvent characteristics.

An interesting feature of the plot is that the activation volumes are fairly well correlated to the rate constants, except for a few solvents, the molar volumes of which are fairly smaller than those of the correlative solvents; *i.e.*, for the former solvents they are *ca.* 40—75 ml·mol^{-1}, and for the latter, 100—110 ml·mol^{-1}. However, the sign of the slope suggests, if we use the theory of the absolute reaction rates[3] as a base, that the reaction systems are under a negative pressure. This unreasonable conclusion indicates that the solvent characteristics manifest themselves on the rate constant through the form of an enthalpy and of an entropy, but not directly in the form of a volume.

The numbers refer to the Table 1.

As far as the activation entropy is concerned, there seem to be two series of solvents, each grouped around a line; it follows that there exist two negative isokinetic temperatures with regard to the solvent variations. The accuracy of our measurements may be discerned by the nearly complete correlation with a slope greater than unity (Fig. 2). As will be described in the next discussion, the activation volumes of the present reaction show the largest sensitivity to environmental changes. Therefore, the above observation on the activation entropies is in contrast to the behavior of the activation volumes.

Up till now, as for the Menschutkin reaction four systems have been reported in connection with the systematic studies of the solvent effects on their reaction rates under high pressure.[2,12–15] These results are plotted against those of the present system in Fig. 3. It should be noted that over a fairly wide range of rate constants there are very good correlations among them.

The slope of the plot serves as a measure of the sensitivity of the relevant system to the environmental change.

TABLE 2. COMPARISONS OF TWO TYPES OF SLOPES

	$\Delta\log k/(\Delta\log k)_{\text{Benzyl Br+Py}}$	$(z\cdot\Delta P)$[kg·cm^{-2}]
Benzyl bromide + Pyridine	1.0	3.45×10^3
Ethyl iodide + Triethylamine	0.84	2.6×10^3
Methyl iodide + Pyridine	0.82	2.6×10^3
ω-Bromoacetophenone + α-Picoline	0.68	1.9×10^3

In our previous papers, the activation volume has been reported to have a linear relation with the product of the compressibility and the molar volume of the solvent, KV^0. According to our model, the slope of the plot should give the value of $(z\cdot\Delta P)$, which is supposed to act as a measure of sensitivity to the solvent variation, as may partly be inferred from the observations in Fig. 1. These two types of slopes, *i.e.*, the slopes of the plots of Figs. 3 and 4, are collected in Table 2 (the listed values of $(z\cdot\Delta P)$ indicate the least-squared values as calculated by means of Eq. (12)).

Based on the values of Table 2, it would be possible to classify the systems into three groups—(pyridine+benzyl bromide), (Et_3N+EtI and pyridine+MeI), and (α-picoline+ω-bromoacetophenone). The sensitivity difference between the first two groups may be ascribed to the nature of the benzyl bromide, since the C–Br bond of the bromide is expected to be more labile than that of the aliphatic halides, and, as a result, all the reacting systems, *i.e.*, both the reactants and the activated complex, will be more sensitive to the environmental change. On the contrary, the difference between the last two groups may be understood by taking into account the steric hindrance due to both α-methyl and carbonyl groups to solvation at the cationic center.

Another interesting feature shown by Fig. 3 is that the rate constants in methanol show a marked deviation from the correlating lines. This deviation should be ascribed to the extra acceleration of the pyridine-benzyl bromide system by methanol compared to that of the aliphatic alkyl iodide systems, as can partly be anticipated from the fact that the benzyl bromide solvolyses fairly easily in methanol compared to the other halides shown in Table 2.

In another respect, this effect may be responsible for the discrepancy pointed out by Heydtmann and Buttner[16] that, for benzyl bromide, the rate constants in ethanol-benzene mixtures satisfy the Kirkwood relationship, whereas for the reaction of methyl iodide with pyridine in the same mixture, they do not.

Glew and Moelwyn-Hughes studied the base-catalyzed and uncatalyzed hydrolyses of methyl halides in water and found that the activation energies for the latter process are greater by *ca.* 3.5 (kcal·mol^{-1}) than those of the former.[17,18] The situation is quite similar to the present case. However, the absolute magnitudes of the activation parameters are not particularly helpful in leading to a conclusion as to the type of mechanism.

A linear relation between $\Delta S^{\neq}$ and $\Delta V^{\neq}$ has been observed by Laidler *et al.* for miscellaneous reactions in aqueous solvent,[19,20] and has been supposed to be evidence for the electrostriction theory. For the present case and the other quaternization reactions, no simple relations between the two quantities could be observed. This fact is not unexpected from the figures described above.

As can partly be inferred from the above discussion, these facts suggest that the major factors which give rise to perturbations on the activation entropy are not necessarily the same as those influencing the activation volumes, especially for the Menschutkin reaction.

Activation Volumes and Its Pressure Dependence. In a previous publication,[2] an equation which is helpful for correlating the activation volume with the solvent characteristics has been developed. In discussing the pressure dependence of the activation volumes, a slight modification is necessary.

Based on a concept similar to that used in the previous publication,[2] the total volume, V_t, of a solution composed of N moles of the pure solvents and n moles of the solute at a certain pressure, P, would be given by:

$$V_t = (N-nz)V_p^0 + nV_s + nzV' \tag{8}$$

where V_p^0, V_s, V', and z are the molar volumes of a pure solvent, of a pure solute and of a solvated solvent, and the solvation number of the solute, respectively.

In this case, the partial molar volume of the solute, V_s^0, is given by:

$$\overline{V}_s^0 = (\partial V_t/\partial n)_N = V_s + z(V'-V_p^0) \tag{9}$$

As for the Menschutkin reaction, it has been suggested that the polarity of the activated complex is considerably larger than those of the reactants,[3,14] and that the change in the activation volume by solvents is mainly controlled by the interaction between the activated complex and solvent molecules.[14]

On the basis of these facts, the activation volume at an external pressure P, $\Delta V_p^{\neq}$, would be given by this equation, applying Eq. (9) only to an activated complex:[1]

$$\Delta V_p^{\neq} = (\overline{V}_{\neq}^0-(\overline{V}_a^0+\overline{V}_b^0)) = (V_{\neq}-(\overline{V}_a^0+\overline{V}_b^0)) + z(V'-V_p^0) \tag{10}$$

Using the definition of the compressibility of the solvent, the activation volume at zero external pressure, $\Delta V_0^{\neq}$, is expressed as follows:

$$K = -\frac{1}{V}(\partial V/\partial P)_T \tag{11}$$

$$\Delta V_0^{\neq} = (V^{\neq}-(\overline{V}_a^0+\overline{V}_b^0)) - (z\cdot\Delta P)KV^0 \tag{12}$$

where V^0 and ΔP stand for the molar volume of a pure solvent and the difference between the average pressure in the cosphere of the activated complex and

16) H. Heydtmann and D. Buttner, *ibid.*, **63**, 39 (1969).
17) E. A. Moelwyn-Hughes, *Proc. Roy. Soc. Ser. A*, **164**, 295 (1938).
18) D. N. Glew and E. A. Moelwyn-Hughes, *ibid.*, **211**, 254 (1952).
19) D. Chen and K. J. Laidler, *Trans. Faraday Soc.*, **54**, 1026 (1958).
20) K. J. Laidler and R. Martin, *Int. J. Chem. Kinet.*, **1**, 113 (1969).

the atmosphere.

As for the pressure dependence of $\Delta V^{\neq}$, by the differentiation of Eq. (10) with respect to a pressure:

$$(\partial \Delta V^{\neq}/\partial P) = (\partial/\partial P)\{V_{\neq} - (\overline{V}_a{}^0 + \overline{V}_b{}^0) + zV'\} - z(\partial V_p{}^0/\partial P) \quad (13)$$

Since, for the discussions of the solvent dependence of the activation volume and its pressure derivative, the first term of Eq. (13) would be taken as a constant, the pressure derivative of the activation volume at zero external pressure, $(\partial \Delta V^{\neq}/\partial P)_0$, is given by:

$$(\partial \Delta V^{\neq}/\partial P)_0 = \text{const.} + zKV^0 \quad (14)$$

By the cancellation of the KV^0 term from Eqs. (12) and (14):

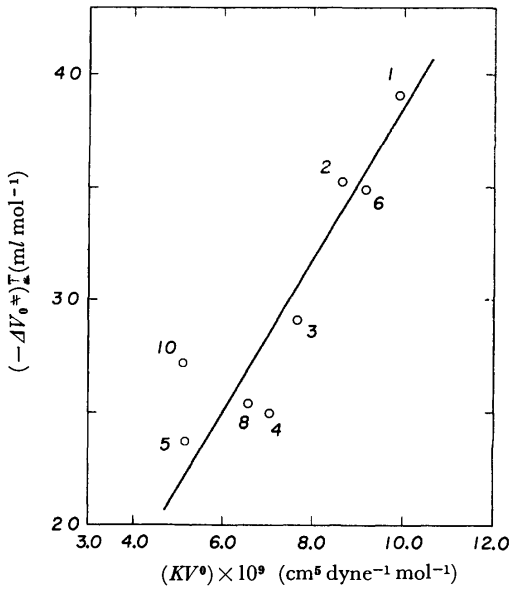

Fig. 4. Plots of $(-\Delta V_0^{\neq})$ *vs.* KV^0 for the reaction of pyridine and benzyl bromide at 30°C.
The numbers refer to the Table 1.

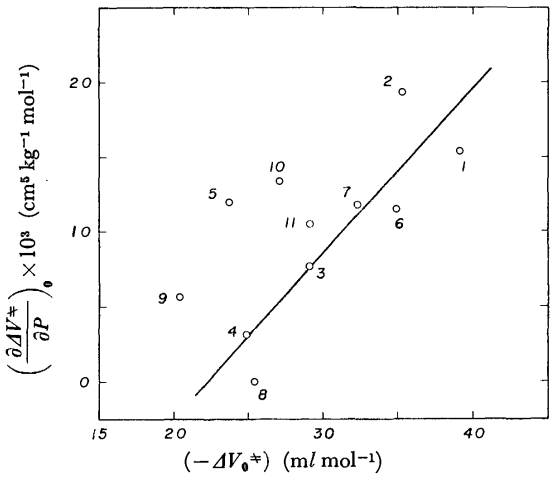

Fig. 5. Plots of $(\partial \Delta V^{\neq}/\partial P)_0$ *vs.* $(-\Delta V_0^{\neq})$ for the reaction of the pyridine and benzyl bromide at 30°C.
The numbers refer to the Table 1.

$$(\partial \Delta V^{\neq}/\partial P)_0 = \text{const.} + (1/\Delta P)(-\Delta V_0^{\neq}) \quad (15)$$

Two types of plots, *i.e.*, Eqs. (12) and (15), are shown in Figs. 4 and 5. In Fig. 5, the regression line is drawn with the exception of three solvents-*i.e.*, nitrobenzene methanol, and 2-propanol, which show larger deviations than would be expected from the experimental errors.

From these slopes, the solvation number of the activated complex is estimated to be *ca.* 4 (*i.e.*, $(z\cdot\Delta P)/\Delta P = (3.8\times 10^3)/(9.1\times 10^2) \fallingdotseq 4$), and the average pressure within the cosphere of the activated complex, to be 9.1×10^2 (kg·cm^{-2}).

Although it is difficult to estimate the uncertainties to be associated with those values, at least three factors should be taken into account in doing so.

First, the fundamental ideas on the reaction systems are based on the discrete model, which might give only a qualitative description of the reaction system. Further, the linear assumptions used in deriving these equations would be the second factor restricting the conclusions reached. Finally, for evaluating the solvation number in the transition state, it is necessary to calculate the second derivatives of the rate constant with respect to the pressure.

Linear relations have been found between ΔV^0 and $(\partial \Delta V^0/\partial P)$ for the dissociation of weak acids in water.[21,22] These slopes correspond to *ca.* 4.7×10^3 (kg·cm^{-2}). Similar values have been estimated for the ionization in water by a different procedure.[23]

According to our model, these values indicate the effective pressures in the vicinity of the ion. A comparison of the two slopes is quite interesting, leading to the view that the charge development in the transition state of the Menschutkin reaction is about one-fifth of the ionization reaction.

As has been described above, the reference works were carried out in aqueous solvents,[19-23] while the present works were done in non-aqueous solvents. Many recent works have clearly shown the marked differences in solvent characteristics between aqueous and non-aqueous solvents. Some uncertainties might be introduced into the above conclusion as a result of having avoided the factor in our model.[24]

Although qualitative, the above estimation of the charge development in the transition state is not unexpected, for the transition state has been suggested to be not so highly ionic as quaternary ammonium halides.[25] The incomplete charge development in the transition state might be responsible for the lack of linear relationships between $\Delta S^{\neq}$ and $\Delta V_0^{\neq}$ for the present reaction.

Oxidative Dimerization of Pyrrole Derivatives. III. Studies on the 3-Carbonyl Substituted Pyrryl Radicals.[1,2]

Kuniyuki TOMITA and Norio YOSHIDA

Central Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo

(Received March 15, 1972)

The thermochromic properties of the dimers in solution, obtained by oxidation of 3-carbonyl substituted pyrroles, was determined as being due to the reversible dissociation into pyrryl radicals. The structure and character of the pyrryl radicals are discussed on the basis of substituent effect on thermochromism and ESR studies.

In previous papers,[3),4)] we reported the oxidative dimerization of some pyrroles and the structures of the resulting dimers. This paper describes the radical mechanism for the thermochromic properteis of some dimers and discusses the structures and characters of the pyrryl radicals.

Results and Discussion

Thermochromism in Solution. When a colorless benzene solution of dimer I, bis[3-ethoxycarbonyl-4,5-bis(*p*-methoxyphenyl)-2-methylpyrryl], is heated, a slightly reddish purple color (λ_{max} 555 mμ) and ESR signal are observed at about 60°C, the intensities being enhanced with the rise in temperature. On cooling, the colour disappears reversibly with diminution of the ESR signal intensity. This indicates that the thermochromic property is caused by reversible radical dissociation of the dimer.

It is well-known that the dissociation of such dimers is enhanced by the resonance stabilization of the radicals formed. We examined the properties of other dimers, II–XI, to clarify the substituent effects on the stabilizing ability of the resulting pyrryl radicals. The results are listed in Table 1.

The difference in behavior between dimer I and III makes it clear that a carbonyl substituents in the 3-position is essential for thermochromism. This suggests that the carbonyl groups have a potential radical stabilizing ability presumably due to resonance and the carbonyl function should lie in the same plane as the pyrryls.[5)]

Table 1 also shows that the 3-carbonyl substituted dimers dissociate only when they have a radical stabilizing *p*-anisyl group at 5-position, the 4-substituents being less important. Therefore, it seems that these radicals have a similar steric structure to the original dimers,[3)] in which the phenyl ring at 4-position is bent out of the pyrryl radical plane differing from that at 5-position. The hyperfine splitting of the ESR spectra also supports this view.

The substituent effects are in line with those observed in the dimerization reaction and the rate of interconversion of the dimers,[4)] supporting the intermediacy of identical radical species in these reactions.

ESR Spectra of the Pyrryl Radicals. Figure 1a

5) An analogous radical stabilizability of carbonyl groups, including their steric requirement, was reported in the case of pyridinyl radicals. M. Ito and S. Nagakura, This Bulletin, **39**, 369 (1966).

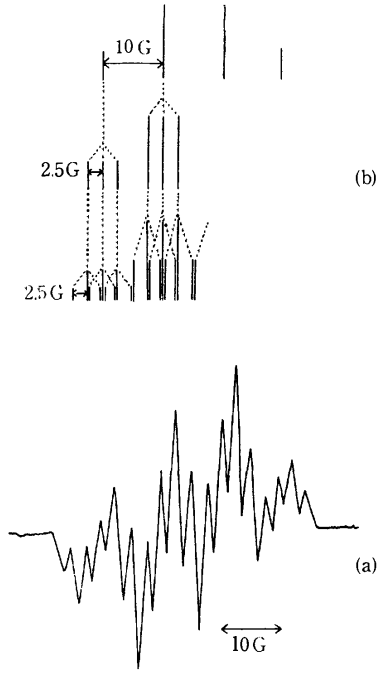

Fig. 1. ESR spectrum from I in degassed toluene at 110°C. (a) Observed spectrum. (b) Stick diagram.

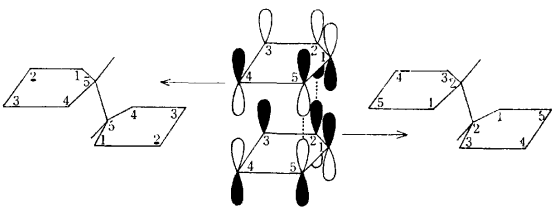
shows the ESR spectra observed for a solution of I in toluene at 110°C. At large amplitude of magnetic modulation, the spectrum showed broad quintet lines (1 : 3 : 3 : 1, a=10G). The ESR spectrum from dimer IV (2-ethyl) exhibited triplet lines (1 : 2 : 1, a=10G) and further subsplittings in each component of the triplet just like those observed in I. It is clear, therefore, that the largest splitting (10G) is caused by the α-protons of the 2-alkyl substituents.

On the other hand, the absence of any interaction of the unpaired electron with protons of the 3-ester group was confirmed by the fact that the radical from dimer II(3-acetyl) gave the same spectrum as that from I. Little participation of the 4-phenyl ring protons was also suggested by the observation of identical spectra from dimer VI(4-phenyl) and I.[6]

The subsplittings should therefore be caused by the nitrogen and the protons(ortho) of the 5-phenyl ring. The isotope labelled dimer XII(^{15}N labelled I) and XIII (I deuterated at an ortho proton of 5-phenyl ring) were prepared and ESR spectra of the corresponding radicals were recorded, as shown in Figs. 2 and 3.

From a comparison of the spectra shown in Figs. 1a, 2 and 3, hyperfine splitting of the pyrryl radical from I could be assigned as follows[7]: a_H=10G(2-alkyl protons); a_H=2.5G (ortho protons of 5-phenyl ring): a_{14N}=2.5G(a_{15N}=3.3G), as illustrated in Fig. 1b.

The ESR data suggest the occurrence of the large spin densities at 2, 5 and 1(N) positions and consequently a high probability of dimerization of the radicals at these positions, which is consistent with the preferential formation of 2,2′- and 5,5′-dimers.[3),4)] The lack of N,N′ bonding can be attributed to steric hindrance which makes recombination of the radical difficult or weakens the bond of the dimer, if formed at all. It is uncertain why no unsymmetrical dimer, 2,5′, was formed. One possible explanation is that the dimerization proceeds by symmetry-controlled secondary orbital interactions.[8)] Thus, the highest overlap of the molecular orbitals could become possible in the assumed transition state leading to the symmetrical dimers, as illustrated in the following scheme.[9)]



Experimental

Melting points are uncorrected. The IR spectra were determined by means of Nujol mulls with a Hitachi EPI-S2 spectrophotometer. The NMR spectra were obtained using a Varian A-60 NMR spectrometer, using tetramethylsilane as the internal standard at 32°C. The mass spectra were

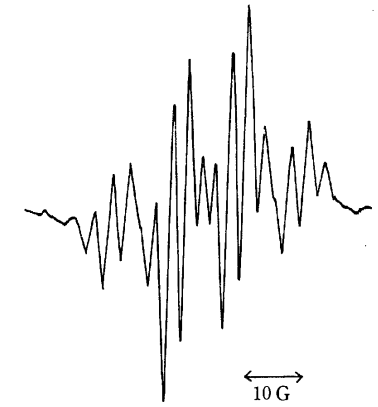


Fig. 2. ESR spectrum from XII in degassed toluene at 110°C.

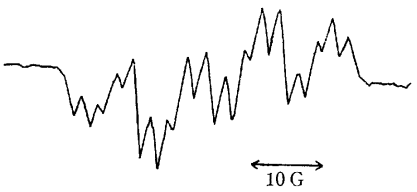

Fig. 3. ESR spectrum from XIII in degassed toluene at 110°C.

6) This also shows that the 4-phenyl ring is twisted from the plane of the pyrryl radical and supports the given steric structure.

7) Partial disagreement in intensities with the theoretical spectrum may be attributed to the difficulty in finding optimum conditions for ESR measurement of these pyrryl radicals.

8) R. Hoffman and R. B. Woodward, *J. Amer. Chem. Soc.*, **87**, 4388 (1965).

9) The diagram of the orbital occupied with an odd electron was obtained from HMO calculation. The calculated spin density of the radical is appreciably in accord with that predicted from ESR results.

obtained using a JEOL-JMS-OIS mass spectrometer. The ESR measurements were carried out in *ca.* 10% deaerated solution with a Hitachi MES 4001 type X-band spectrometer, with MES 4701 Thermocontroller, and the splitting constants were measured relative to aqueous solution of Fremy's salt. Visible spectra were obtained using a Cary-14, with Coolnics Circulator CTE-IA.

*Bis[4,5-bis(*p*-methoxyphenyl)-2-methylpyrryl] (III).* By a similar procedure as described for the preparation of I, II, IV—XI,[3),4)] III was obtained quantitatively from 4,5-bis(*p*-methoxyphenyl)-2-methylpyrrole as colorless powder, which was recrystallized from acetone to give colorless prisms, mp 142—145°C(decomp.). Found: C, 78.26; H, 6.25; N, 4.78%. Calcd for $C_{38}H_{36}O_4N_2$: C, 78.06; H, 6.21; N, 4.79. Mass spectrum: M^+ 584.

*Bis[3-ethoxycarbonyl-4,5-bis(*p*-methoxyphenyl)-2-methylpyrryl-^{15}N] (XII).* *a)*: After $^{15}NH_3$ gas, generated from $^{15}NH_4Cl$(1.0 g) and 15% aqueous NaOH(10 m*l*), was introduced into acetic acid(50 m*l*), 1.3 g of anisoin and 1.0 g of ethyl acetoacetate were added and the mixture was refluxed for 2 hr. The reaction mixture was poured into ice water and the resulting precipitate was separated by filtration, washed with water and dried *in vacuo* to give 1.65 g of ethyl 4,5-bis(*p*-methoxyphenyl)-2-methylpyrrole-3-carboxylate-^{15}N, mp 131—134°C(benzene-petroleum ether). IR(cm^{-1}): ν_{NH} 3370, $\nu_{C=O}$ 1675. Mass spectrum: M^+ 366.

b): Oxidation of pyrrole-^{15}N afforded dimer XII, quantitatively. mp 138—140°C(decomp.). IR(cm^{-1}): $\nu_{C=O}$ 1725. Mass spectrum: M^+ 730.

*Bis[4,5-bis(*o*-deuterio-*p*-methoxyphenyl)-3-ethoxycarbonyl-2-methyl-pyrryl] (XIII).* *a)*: A mixture of 6.4 g of *o*-bromo-*p*-methoxybenzaldehyde,[10)] 2.5 g of 10% palladium on carbon, 4.0 g of sodium acetate and 100 m*l* of methanol was shaken with deuterium under atmospheric pressure at room temperature until uptake ceased (about 20 min). After the mixture was filtered and concentrated below 50°C under reduced pressure, the residue was extracted with ether and the solution was washed with water and dried. After evaporation of ether, the resulting oil was distilled (at 250°C, bath temp.) to give 3.7 g of anisaldehyde-2-*d*. Mass spectrum: M^+ 137. NMR spectrum (ppm in CCl_4): 3.90 (3H, singlet), 6.90—7.87 (3H, multiplet), 9.87(1H, singlet).

b): Anisaldehyde-2-*d* gave anisoin-2,2'-d_2 by the usual benzoin condensation method. Mp 104—107°C. Mass spectrum: M^+ 274.

c): Reaction of 0.25 g of anisoin-2,2'-d_2 and 0.4 g of ethyl acetoacetate in the presence of 1.0 g of ammonium acetate in 20 m*l* of acetic acid afforded 0.20 g of ethyl 4,5-bis(*o*-deuterio-*p*-methoxyphenyl)-2-methylpyrrole-3-carboxylate, mp 131—133°C, by a similar procedure as described for the preparation of pyrrole-^{15}N. NMR spectrum (ppm in $CDCl_3$): 6.70—7.40(6H, multiplet). Mass spectrum: M^+ 367.

d): Oxidation of pyrrole-d_2 gave dimer XIII quantitatively. Mp 136—138°C(decomp.). IR(cm^{-1}): $\nu_{C=O}$ 1725. Mass spectrum: M^+ 732.

The authors would like to thank Dr. Genshun Sunagawa, the director of these laboratories, for his encouragement and Drs. K. Murayama and T. Toda for the ESR spectra measurement and helpful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3586—3590 (1972)

Sulfilimine. XVII. Syntheses and Reactions of *N*-Carbamoylsulfilimines

Shigeru OAE, Toshiaki MASUDA, Kenji TSUJIHARA, and Naomichi FURUKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received March 18, 1972)

The physical and chemical properties of several new sulfilimines, *N*-carbamoylsulfilimines, and their syntheses were studied. The sulfilimines were prepared by the action of *N*-chlorourea on appropriate sulfides in acetonitrile, and their IR and NMR spectra were obtained. Thermolysis, hydrolysis and reactions with thiophenol and sodium nitrite were carried out and the results were discussed.

Sulfilimines with the general structural formula R'RS→NR'' were first prepared by Nicolet and Willard[1] in 1921. Recently, Whitfield *et al.*[2] reported the syntheses of a new class of sulfilimines, dimethyl and diethyl *N*-ethoxycarbonylsulfilimines from the corresponding sulfides and *N*-chloroethyl carbamate.

We have found that *N*-chlorourea[3] also reacts with sulfides giving the corresponding sulfilimines, *N*-carbamoylsulfilimines. Their syntheses and reactions are reported.

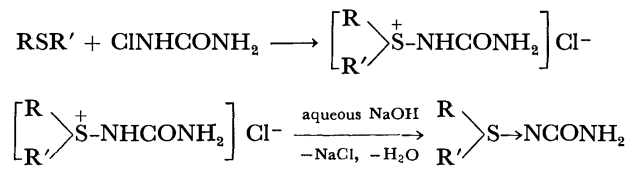
Results and Discussion

Syntheses and Spectroscopic Data. Syntheses of *N*-carbamoylsulfilimines are shown in Scheme 1.



[R: aryl, R': alkyl]

Scheme 1.

Alkyl aryl sulfides were treated with *N*-chlorourea in acetonitrile to afford the corresponding *N*-carbamoyliminosulfonium chlorides. They were treated directly with an aqueous alkaline solution without being isolated. *N*-carbamoylsulfilimines were obtained as white solids in 40—70% yield, after the aqueous alkaline solution had been extracted with chloroform. No diaryl sulfilimines were obtained under the same conditions. The sulfilimines were recrystallized from chloroform, acetone-alcohol or benzene-alcohol. The products and their yields are shown in Table 1.

Table 1. Products and yields

$$\left[\begin{matrix}R\\R'\end{matrix}\!\!>\!S\rightarrow NCONH_2\right]$$

R	R′	Mp, °C	Yield, %
Ph	Me	175—6	64
p-MeC_6H_4	Me	168—9	55
p-ClC_6H_4	Me	150—1	42

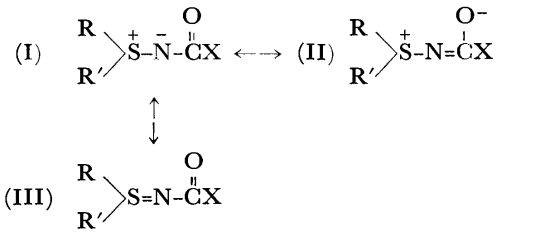
Ph	*i*-Pr	122—3	67
Ph	*n*-Bu	101—2	66

Kucsman *et al.*[4] and Whitfield *et al.*[2] reported that the C=O and S=N IR absorption bands of *N*-dihaloacetyl- or *N*-ethoxycarbonylsulfilimine appear at 1620—1640 cm^{-1} (C-O), and 810—820 cm^{-1}(S-N), respectively. They proposed that the structure of the compound can best be represented by betaine form (II). However, the strong C=O stretching absorption band of *N*-carbamoylsulfilimines appears at 1640—1685 cm^{-1} and is similar to that of urea, but the S-N band is at 960—1040 cm^{-1}. Thus, the major contributing form of the *N*-carbamoylsulfilimines is not always form (II) but either form (I) or (II) depending on the kind of sulfilimine.

The methyl protons of the NMR spectra of the methyl phenyl *N*-carbamoylsulfilimine appear as a singlet at δ 2.97 ppm, and the chemical shift appears about 0.3 ppm and 0.1 ppm downfield from those of the corresponding sulfoxide and dimethyl *N*-ethoxycarbonylsulfilimine,[2] respectively. Thus, the S(IV) atom in the methyl phenyl *N*-carbamoylsulfilimine is considered to have a more positive charge than that of the corresponding sulfoxide or dimethyl *N*-ethoxycarbonylsulfilimine, and the shift is analogous to that of the methyl protons of methyl phenyl *N*-*p*-tolylsulfonylsulfilimine.

Thus the canonical form (I) appears to be the major contributor to the *N*-carbamoylsulfilimine structure.

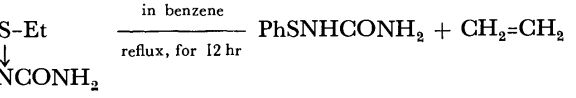
Reactions. We have carried out extensive studies on the reactions of sulfilimines, particularly *N*-sulfonylsulfilimines.[5-10] In order to compare the chemical behaviors of *N*-carbamoylsulfilimine with those of the *N*-sulfonyl derivative, we treated the new sulfilimine under similar reaction conditions as those of the *N*-*p*-tolylsulfonyl derivative.



[X: $CHCl_2$, $CHBr_2$, OEt, NH_2]

Scheme 2.

1) Thermolysis: *N*-*p*-Tolylsulfonylsulfilimines with β-proton have recently been found to give olefins in high yields.[6] When ethyl phenyl *N*-carbamoylsulfilimine was heated in benzene, sulfenamide and ethylene were similarly found to be obtained in good yields.



Scheme 3.

The mechanism of the reaction is not clear but the reaction is considered to proceed *via* an Ei mechanism involving a five membered cyclic transition state as in the case of *N*-*p*-tolylsulfonylsulfilimines.[6),10] When thermolysis was carried out in methanol solution, the sulfide, α-methoxy sulfide and urea were obtained as shown in Scheme 4.

		(A)	(B)	(C)
		A	B	C
R′	H	75%	14%	~100%
	Me	73%	17%	~100%

Scheme 4.

The reaction with this type of sulfilimine is unique since the *N*-*p*-tolylsulfonyl derivatives do not react under the same conditions. An analogous reaction was observed when alkoxysulfonium salt[11] or *N*-*p*-tolylsulfonylsulfilimine[12] was treated with a base such as alkoxide or hydroxide in alcohol solution. As in the case of the sulfonium salt or *N*-*p*-tolylsulfonylsul-

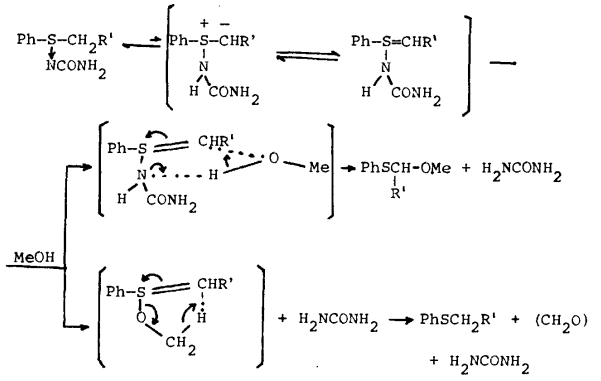
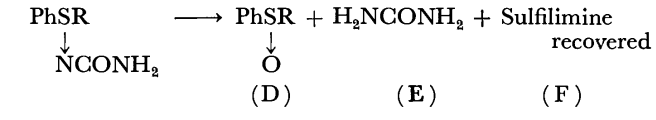
12) H. Kobayashi, N. Furukawa, T. Aida, K. Tsujihara, and S. Oae, *Tetrahedron Lett.*, **1971**, 3109.



Scheme 5.

filimine, the reaction seems to proceed through the initial proton transfer from C atom to N atom to form an intermediate which upon addition of methanol affords the α-alkoxy sulfide and the sulfide.

2) Hydrolysis: Treatment of methyl phenyl *N*-carbamoylsulfilimine with 5% aqueous alkaline solution, water or 5% aqueous hydrogen chloride solution at 55°C for 8 hr gave phenyl methyl sulfoxide.

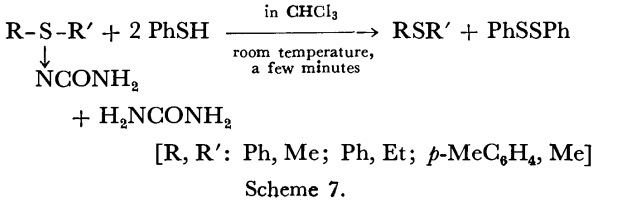


R	Reaction conditions	D	E	F
Me	5% KOH-H_2O	98%	not detd.	0%
	H_2O	99%	not detd.	0%
	5% HCl-H_2O	56%	not detd.	37%
Et	5% KOH-H_2O	98%	not detd.	0%

Scheme 6.

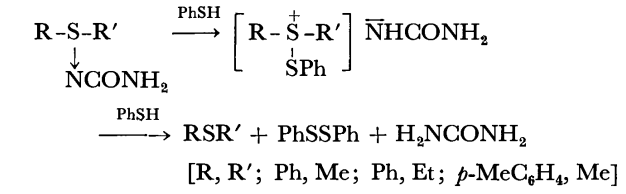
Thus, methyl phenyl *N*-carbamoylsulfilimine easily hydrolyzes in water as well as in aqueous alkaline solution. However, it hydrolyzed slowly in aqueous hydrogen chloride solution since the attack of hydroxide anion on the S(IV) atom is considered to lead to the hydrolysis product. A similar treatment of ethyl phenyl *N*-carbamoylsulfilimine with 5% aqueous alkaline solution at 60°C for 6 hr gave ethyl phenyl sulfoxide.

3) Reaction with Thiophenol: When the *N*-carbamoylsulfilimine was treated with thiophenol, it was easily reduced at room temperature within a few minutes to the corresponding sulfide (Scheme 7). Besides the sulfide, both urea and diphenyl disulfide were obtained quantitatively. For the reduction of one equivalent mole of sulfilimine two equivalent moles of thiophenol were required stoichiometrically.



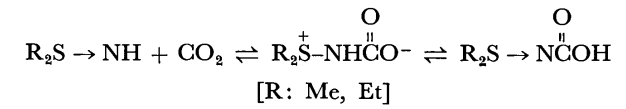
Scheme 7.

This reaction is analogous to that of sulfoxide or *N*-*p*-tolylsulfonylsulfilimine with thiophenol or *O,O*-dialkyl dithiophosphoric acid.[8] Thus the mechanism is considered to involve the initial nucleophilic attack by thiophenolate ion on S(IV) atom forming the sulfonium salt as an intermediate.



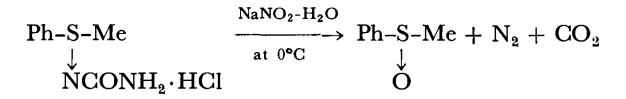
Scheme 8.

4) Reaction with Sodium Nitrite: It was reported by Appel and Buechner[13] that treatment of dialkyl sulfilimine with carbon dioxide gives the compound $R_2SNH \cdot CO_2$.



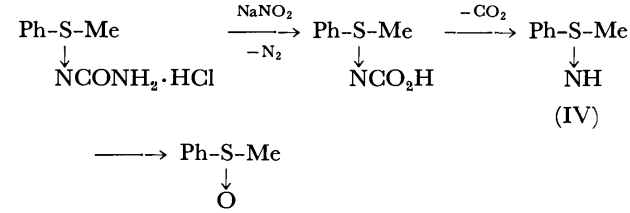
Scheme 9.

We therefore carried out the diazo-decomposition of *N*-carbamoylsulfilimine in the hope of obtaining the alkyl aryl sulfilimine. However, treatment of *N*-carbamoylsulfilimine hydrochloride with sodium nitrite at 0°C in water led to the evolution of N_2 and CO_2 gases, and the product obtained was found to be only the sulfoxide, no free sulfilimine derivative being obtained.



Scheme 10.

Although free sulfilimine (IV) was not actually isolated, its formation as an intermediate during the diazo-decomposition of *N*-carbamoylsulfilimine might be expected, since decarboxylation was observed as by Appel *et al.* The mechanism is considered as shown in Scheme 11.



Scheme 11.

Experimental

Materials. All the solvents, *i.e.*, benzene, methanol and chloroform were purified by standard procedures.[14] The others used were of chemical grade. Aqueous hydrogen chloride, sodium nitrite and sodium hydroxide were of special

a) The chemical shifts (ppm) were measured with a Hitachi Perkin-Elmer R-20 High Resolution NMR Spectrometer (60 MHz) using TMS as an internal standard (δ=0.00) in $CDCl_3$. The multiplicity of the signal is given by s=singlet, d=doublet, t=triplet, q=quartet and m=unresolved multiplet.

0.08 mol of sulfides in 50 ml of acetonitrile was dropped with stirring into the above mentioned *N*-chlorourea solution maintained at 15—20°C by external cooling. After the addition, the temperature was raised to 60—70°C for 1 hr. A 10% aqueous solution of sodium hydroxide was added dropwise for about 30 min until the solution became alkaline. *N*-Carbamoylsulfilimine was then extracted with chloroform from alkaline solution. The compound was recrystallized as white solid from chloroform, acetone-alcohol or benzene-alcohol. Yield, 40—70%. IR and NMR spectra of *N*-carbamoylsulfilimine are summarized in Tables 2 and 3.

Thermolysis of Ethyl Phenyl N-*Carbamoylsulfilimine in Benzene.* About 0.004 mol (0.88 g) of ethyl phenyl *N*-carbamoyl-sulfilimine was heated in refluxing benzene (10 ml) for 10 hr under nitrogen stream. Ethylene was produced in 60% yield by this reaction and was converted into 1,2-dibromoethylene. This was confimed by comparing its glc behavior with that of the authentic compound. Benzene was removed from the residue and *N*-phenylthiourea, mp 163°C, was isolated in 95% yield. IR spectra: (ν_{N-H} 3440, 3200, $\nu_{C=O}$ 1677), NMR spectra: (δ 7.43, 5-Ar-H (multiplet), δ 8.19, 1-H (singlet), δ 6.54, 2-H (singlet)). The NMR spectra were measured with TMS internal standards (δ=0.00) as a reference peak in DMSO-d_6.

Found: C, 49.20; H, 16.35: N, 16.42%. Calcd. for $PhSNHCONH_2$: C, 49.99; H, 16.68; N, 16.65%.

Thermolysis of Methyl Phenyl N-*Carbamoylsulfilimine in Methanol.* About 0.005 mol (0.88 g) of methyl phenyl *N*-carbamoyl-sulfilimine was heated in refluxing methanol (10 ml) for 10 hr. The products obtained were separated by column chromatography and identified by comparing their IR and NMR spectra with those of the authentic compounds. Yields of sulfide, α-methoxy sulfide and urea were 0.44 g (75%), 0.12 g (14%) and about 0.30 g (100%), respectively.

Thermolysis of Ethyl Phenyl N-*Carbamoylsulfilimine in Methanol.* About 0.004 mol (0.88 g) of ethyl phenyl *N*-carbamoyl-sulfilimine was heated in refluxing methanol (10 ml) for 6 hr as well as methyl *p*-tolyl *N*-carbamoylsulfilimine. The products were determined by comparing their IR and NMR spectra with those of the authentic compounds. Yields of sulfide, α-methoxy sulfide and urea were 0.43 g (73%), 0.13 g (17%) and about 0.30 g (100%), respectively.

Hydrolysis of Methyl Phenyl and Ethyl Phenyl N-*Carbamoylsulfilimine.* Methyl phenyl *N*-carbamoylsulfilimine 0.002 mol (0.363 g) was heated at 55°C for 8 hr in 5 ml of 5% aqueous potassium hydroxide solution, water or 5% aqueous hydrogen chloride solution. The reaction solution was then acidified with a 10% aqueous hydrogen chloride solution and reactants were extracted with chloroform. The solution was then made alkaline by a 10% aqueous sodium hydroxide solution and the reactants were again extracted with chloroform. The products were identified by comparing their IR, NMR spectra with those of the authentic samples. Yield of sulfoxide was 0.24 g (98%), 0.25 g (99%) and 0.14 g (56%), respectively. Yields of the sulfilimine recovered were 0%, 0% and 37%, respectively.

Ethyl phenyl *N*-carbamoylsulfilimine (0.002 mol) was hydrolyzed by the same method, to the corresponding sulfoxide (98% yield) at 60°C for 6 hr in 5 ml of 5% aqueous potassium hydroxide solution. The product was identified by comparing its IR, NMR spectra with those of the authentic compound.

Reaction of N-*Carbamoylsulfilimine with Thiophenol.* A 10% solution of thiophenol in chloroform was dropped with stirring into a solution of about 0.005 mol of *N*-carbamoylsulfilimines (methyl phenyl, methyl *p*-tolyl or ethyl phenyl *N*-carbamoylsulfilimine) in 10 ml of chloroform at room temperature. After the addition, the solution was maintained at room temperature for a few minutes. Thiophenol (0.01 mol) was required to complete the reaction. The products, sulfide, disulfide and urea were separated by column chromatography and were identified by comparing their IR, NMR spectra with those of the authentic compounds.

Reaction of Methyl Phenyl N-*Carbamoylsulfilimine with Sodium Nitrite.* Two drops of a 35% aqueous hydrogen chloride solution was added to a solution of about 0.002 mol (0.37 g) of methyl phenyl *N*-carbamoylsulfilimine in 3 ml of water. Into this was dropped a solution of about 0.003 mol (0.20 g) of sodium nitrite in 2 ml of water, the temperature being maintained at 0°C with an ice bath. The solution was stirred overnight at 0°C, and the products were then extracted with chloroform. Methyl phenyl sulfoxide was obtained in 28% yield (0.08 g) and identified by comparing its IR and and NMR spectra with those of the authentic compound. Methyl phenyl *N*-carbamoylsulfilimine was recovered in 63% yield.

Studies of Acyl and Thioacyl Isocyanates. X.[1] The Cycloaddition Reaction of Benzoyl and Thiobenzoyl Isocyanates with Benzaldazines

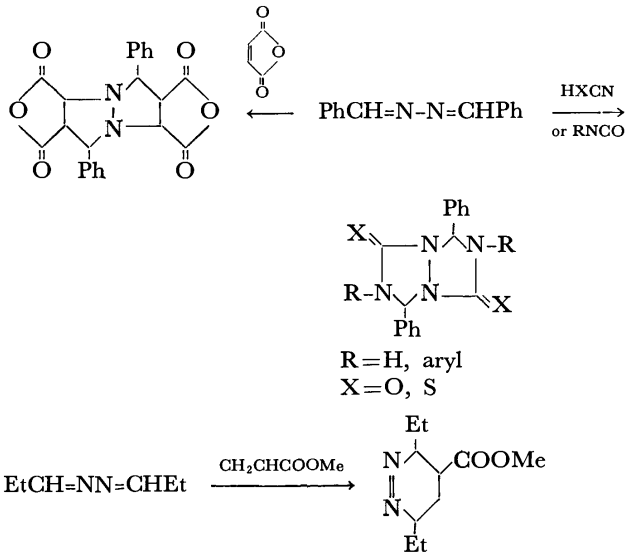
Otohiko TSUGE and Shuji KANEMASA

Research Institute of Industrial Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka, 812

(Received March 11, 1972)

Although benzoyl isocyanates do not react with benzaldazines at room temperature, the criss-cross cycloadducts are formed if the reaction is carried out in refluxing xylene. On the other hand, thiobenzoyl isocyanate behaves quite differently toward the same azines. It reacts easily with azines at room temperature to afford to mono- or the bis(4+2) cycloadducts depending on the nature of the substituent in the azines. We found that the mono (4+2) cycloadduct can be thermally dissociated into its components. Neither benzoyl isocyanate nor thiobenzoyl isocyanate react with aromatic ketazines.

Azines having the conjugated system C=N-N=C exhibit a curious behavior toward cycloaddition reactions. Benzaldazines react with cyanic acid,[2] thiocyanic acid,[2,3] isocyanates,[3] maleic anhydride[4,5] and methyl acrylate[6] to form the corresponding criss-cross cycloadducts. On the other hand, the reaction of propionaldazine with methyl acrylate affords a Diels-Alder type adduct;[6] in this case the aldazine behaves as a diene (Scheme 1).



Scheme 1

Benzoyl (I) and thiobenzoyl isocyanates (II) react with the C=N bonds of anils[7,8] and carbodiimides[9] to give the (4+2) and/or (2+2) cycloadducts. Accordingly, in the reaction of acyl isocyanate with azines, we might expect the formation of a criss-cross cycloadduct or Diels-Alder adduct, besides mono- or bis(4+2) or (2+2) cycloadduct of C=N bonds of azines. However, no study has been reported on the addition of acyl isocyanate to azines. As part of the investigation of the chemistry of I and II with compounds having a C=N bond, their reaction with aromatic azines was studied.

Results and Discussion

Reaction of Benzoyl Isocyanates with Benzaldazines. Although no reaction of benzoyl isocyanate (Ia) with benzaldazine (IIIa) took place at room temperature, Ia reacted with IIIa in refluxing xylene to afford a 2 : 1 adduct IVa in 58% yield. The IR spectrum of IVa showed bands ascribable to $\nu_{C=O}$ at 1760 and 1680 cm^{-1}. The NMR spectrum in deuteriochloroform ($CDCl_3$) exhibited a singlet (2H) assignable to two equivalent methine protons at δ 7.20 ppm, besides signals of aromatic protons. The mass spectrum showed the parent peak (M^+) at *m/e* 502, together with major peaks at *m/e* 397 (M^+—PhCO), 355 (M^+—PhCONCO), 278 (355$^+$—Ph), 250 (278$^+$—CO), 208 ([Ph–CH=N-N=CH-Ph]$^+$), 147 ([PhCONCO]$^+$) and 105 ([PhCO]$^+$).

Hydrolysis of IVa with hydrochloric acid afforded hydrazodicarbonamide (V) and benzaldehyde. The structure of V was confirmed by spectral data and elemental analysis as well as by comparison with an authentic sample prepared from urea and hydrazine hydrate;[10] benzaldehyde was identified as its 2,4-dinitrophenylhydrazone (Scheme 2). It is thus deduced that the most reasonable structure for IVa of the possible 2 : 1 cycloadducts, including bis (2+2), (4+2) and mixed cycloadducts, is the criss-cross cycloadduct.

Benzoylation of the criss-cross cycloadduct VI[2] prepared from IIIa and cyanic acid, with benzoyl chloride in pyridine afforded perhydro-2,6-dibenzoyl-1,5-diphenyltriazolo[1,2-a]triazole-3,7-dione (IVa), as shown in Scheme 2.

Similar reactions of benzoyl isocyanates (Ia-Id) with benzaldazines (IIIa—IIIe) gave the corresponding criss-cross cycloadducts IV. The yields, physical properties and results of elemental analyses of IV are summarized in Table 1.

We see that the yield of IV is affected by the nature of the substituents R^1 and R^2. The stronger the

a) All the compounds are colorless prisms. b) Reaction temperature: 140°C. Reaction of Ia with IIIe (24 hr) and of Ib with IIIa (48 hr) did not take place.

electron-donating nature of substituent R^2 in III, the higher the yield of IV, while the effect of substituent R^1 in I on the yield is the reverse: although Ia and Ib did not react with IIIe and IIIa, respectively, the reactions of Ia with IIIb and of Id with IIIa gave excellent yields of IV. On the other hand, I did not react with aromatic ketazines such as acetophenone and benzophenone azines under similar conditions.

Reaction of Thiobenzoyl Isocyanate with Benzaldazines. In contrast with benzoyl isocyanates (I), thiobenzoyl isocyanate (II) reacted easily with benzaldazine (IIIa) at room temperature to afford a quantitative yield of the 1 : 1 adduct VIIa. The IR spectrum of VIIa showed no bands assignable to ν_{NH}, but displayed bands of $\nu_{C=O}$ and $\nu_{C=N}$ at 1680, 1660 and 1650 cm^{-1} respectively; it is very similar to that of the (4+2) cycloadduct[8)] of II to benzylidenaniline. In the NMR spectrum ($CDCl_3$) singlets appeared at δ 6.42 (1H, >C**H**) and 9.48 ppm (1H, -C**H**=N-), besides signals of aromatic protons.

Thus, VIIa was deduced to be 3-benzylidenamino-2,6-diphenyl-2*H*-1,3,5-thiadiazin-4(3*H*)-one, whose structure corresponds to the (4+2) cycloadduct of II to one C=N bond of IIIa.

a) All the compounds are colorless needles. b) NMR δ ppm: 6.41 (1H, singlet, $\rangle$C**H**), 9.52 (1H, singlet, -C**H**=N-) in $CDCl_3$; 7.07 (1H, singlet, $\rangle$C**H**), 8.75 (1H, singlet, -C**H**=N-) in CF_3COOH.

In similar reactions of II with azines IIIb—IIId, a 1 : 1 or a 2 : 1 adduct was formed, depending on the nature of substituent R^2 in III. When R^2 is electron-donating such as methoxy or methyl, the 2 : 1 adduct VIII was obtained, while the 1 : 1 adduct VIId was only formed if R^2 is electron-withdrawing such as chlorine. However, the reaction with IIIe having nitro groups did not take place even under forced conditions. The results are summarized in Table 2.

The structures of 1 : 1 adduct VIId, and of 2 : 1 adducts VIIIb and VIIIc were confirmed to be those of the corresponding mono(4+2) and bis(4+2) cycloadducts of II to one and both C=N bonds in III on the basis of spectral studies. In spite of having a second C=N bond to which to add, II did not react further with the 1 : 1 adduct VII under more forced conditions (at 50°C for 5 min and then at room temperature for 3 hr); instead the unchanged 1 : 1 adduct was recovered almost quantitatively.

The NMR spectrum of VIIIc indicated that its configuration is symmetrical; singlets attributable to two equivalent methyl and methine protons appeared at δ 2.25 and 6.22 ppm in $CDCl_3$, and at δ 2.35 and 6.79 ppm in trifluoroacetic acid (CF_3–COOH), respectively.

On the other hand, two stereoisomers VIIIb-1 and VIIIb-2 were obtained in the reaction with IIIb. Their NMR spectra could not be measured in the same solvent, because VIIIb-1 is insoluble in $CDCl_3$ and VIIIb-2 decomposed in CF_3COOH. The NMR spectrum of VIIIb-1 in CF_3COOH showed two singlets at δ 3.89 (6H, O**C**$\mathbf{H}_3$) and 6.81 ppm (2H, $\rangle$C**H**), while four singnlets appeared at δ 3.77, 3.81 (each 3H, O**C**$\mathbf{H}_3$) and 5.35, 6.59 ppm (each 1H, $\rangle$C**H**) in the NMR spectrum of VIIIb-2 ($CDCl_3$). This indicates that the configuration of VIIIb-1 is symmetrical, while that of VIIIb-2 is asymmetrical.

Dreiding models of VIII show that the free rotation of N^3–$N^{3'}$ bond is hindered by the steric interaction between the 2- or 2′-aryl group and 4′- or 4-carbonyl group. Thus, two isomers resulting from the configurations of 2- and 2′-aryl groups are possible for symmetrical 2 : 1 adduct VIIIb-1 or VIIIc: one (VIII-A) in which both 2- and 2′-aryl groups are quasi-axial,

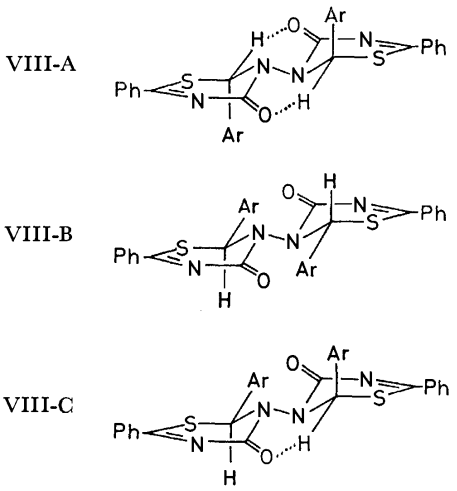

Fig. 1.

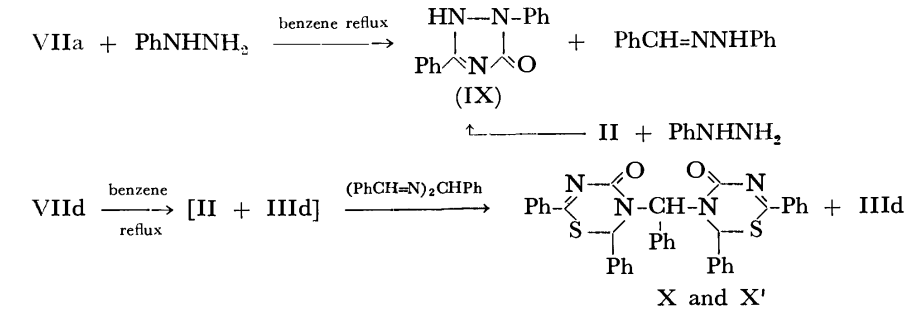
and the other (VIII-B) in which they are quasi-equatorial. However, it is conceivable that VIII-A is more favorable since there is a significant repulsion between 2- or 2′-aryl group and 4′- or 4-carbonyl group in VIII-B (Fig. 1).

On the other hand, the configuration VIII-C in which 2- and 2′-aryl groups are quasi-equatorial and quasi-axial, respectively, is only possible for asymmetrical 2 : 1 adduct VIIIb-2. In this case, there is a steric interaction between 2-aryl group and 4′-carbonyl group, and the rotation of N^3–$N^{3'}$ bond should occur to attain minimum steric hindrance.

The singlet of methine protons of VIIIc is shifted to a lower field by about 0.6 ppm, in changing from $CDCl_3$ to CF_3COOH. If the value of the shift is applied to the methine protons of VIIIb-1, a singlet should appear at δ ca. 6.2 ppm in $CDCl_3$. Consequently, the singlets at 5.35 and 6.59 ppm in VIIIb-2 could be assigned to the 2-quasi-axial and 2′-quasi-equatorial hydrogens, respectively. The shift of equatorial hydrogens to a lower field can be explained in terms of hydrogen bonding with the carbonyl group in the adjacent ring as shown in Fig. 1. Isolation of the 2 : 1 adduct of type VIIIb-2 was unsuccessful, probably owing to its instability.



Scheme 3.

It is of interest to note that II behaves quite differently from I toward benzaldazines, although just as in the case of I, no reaction took place with aromatic ketazines.

Thermal Dissociation of Mono(4+2) Cycloadducts VII. The 1 : 1 adducts VII decomposed at their melting points and changed to reddish violet substances. When a solution of VII in dry benzene was heated to reflux, it gradually turned red. Upon cooling, the red color disappeared, the solution becoming colorless. This suggests that VII could be thermally dissociated into its components, since the benzene solution of II is reddish violet. We established thermal dissociation by the following experiments.

Phenylhydrazine reacted with VIIa in refluxing benzene to give 2,3-dihydro-2,5-diphenyl-1,2,4-triazol-3(1*H*)-one (IX) and the phenylhydrazone of benzaldehyde,[11] although hardly any reaction took place at room temperature. The structure of IX was confirmed by comparison with an authentic sample prepared from II and phenylhydrazine.[12] When VIId was treated with hydrobenzamide in refluxing benzene, two isomeric bis(4+2) cycloadducts X and X'[8] of II to hydrobenzamide and *p*-chlorobenzaldazine IIId were obtained (Scheme 3).

Experimental

All melting points are uncorrected. The IR spectra were measured as KBr pellets on a JASCO IR-S spectrophotometer; the NMR spectra were determined at 60 MHz on a Hitachi R-20 NMR spectrometer with TMS as an internal reference. The mass spectra were obtained on a Hitachi RMS-4 mass spectrometer with a direct inlet and an ionization energy of 70 eV. Elemental analyses were carried out by Miss M. Akita.

Materials. Benzoyl isocyanates (Ia–Id) were prepared by the method reported previously.[13] Thiobenzoyl isocyanate (II):[12] a solution of 1.0 g of 2-phenylthiazoline-2,4-dione[14] in 10 m*l* of xylene was heated at 120°C, producing a reddish violet solution of II. This is referred as the standard solution of II. Benzaldazines were prepared from the corresponding aldehydes and hydrazine hydrate in acetic acid. Benzaldazine (IIIa), mp 93°C (lit,[15] mp 93°C); *p*-methoxy- (IIIb), mp 169—170°C (lit,[16] mp 170—172°C); *p*-methyl- (IIIc), mp 153°C (lit,[17] mp 153°C); *p*-chloro- (IIId), mp 207—208°C (lit,[16] mp 208°C); *p*-nitrobenzaldazine (IIIe), mp 296—297°C (lit,[18] mp 297—298°C).

Reaction of Benzoyl Isocyanates (I) with Benzaldazines (III). The procedure is illustrated by a reaction of benzoyl isocyanate (Ia) with benzaldazine (IIIa).

A solution of 2.0 g of Ia and 1.4 g of IIIa in 15 m*l* of dry xylene was refluxed in an atmosphere of nitrogen for 23 hr, and the reaction mixture was allowed to stand at room temperature for 2 days, during which time crystals deposited. Filtration gave 1.18 g of colorless crystals. The filtrate was evaporated *in vacuo* to leave resinous materials, which solidified on trituration with petroleum ether to yield 0.78 g of crystals. Recrystallization of the combined crystals (1.96 g (58%)) from petroleum ether (bp 45—65°C) gave perhydro-2,6-dibenzoyl-1,5-diphenyltriazolo[1,2-b]triazole-3,7-dione (IVa), mp 130.5—131°C (decomp.), as colorless prisms.

Similarly, the reaction of benzoyl isocyanates (Ia—Id) with benzaldazines (IIIa—IIIe) gave the corresponding criss-cross cycloadduct IV. However, Ia and Ib did not react with IIIe and IIIa, respectively. The reaction conditions and yields, physical porperties and results of elemental analyses are summarized in Table 1.

Hydrolysis of Criss-cross Cycloadduct IVa. A suspension of 0.4 g of IVa in 20 m*l* of concentrated hydrochloric acid was stirred at 100°C for 3 hr. After cooling, it was filtered to recover 0.17 g (40%) of unreacted IVa. Evaporation of the filtrate *in vacuo* left a residue, which was washed with a small amount of water and then recrystallized from water to afford 55 mg (58%) of hydrazodicarbonamide (V), mp 255.5°C (decomp.) (lit,[10] mp 244—245°C (decomp.)), as colorless prisms. The compound was identical with an authentic sample prepared from hydrazine hydrate and urea.[10]

Found: C, 20.10; H, 4.90; N, 47.71%. Calcd for $C_2H_6N_4O_2$: C, 20.34; H, 5.12; N, 47.44%.

From the washings, benzaldehyde was identified to be its 2,4-dinitrophenylhydrazone.

Preparation of IVa. To a stirred solution of 4.5 g of IIIa in 30 m*l* of acetic acid was added 5.25 g of sodium cyanate at room temperature over a period of 15 min. After the reaction mixture had been stirred for 30 min at the same temperature, it was then poured into 100 m*l* of water. Filtration gave 4.8 g (76%) of perhydro-1,5-diphenyltriazolo-[1,2-a]triazole-3,7-dione (VI), mp 235°C (decomp.) (lit,[2]

11) The formation of the hydrazone indicates that benzaldazine IIIa generated by dissociation was hydrolyzed to benzaldehyde.

mp 234°C (decomp.)), as pale yellow prisms. A mixture of 0.5 m*l* of benzoyl chloride and 0.5 g of VI in 10 m*l* of pyridine was stirred at room temperature for 18 hr. It was then poured into water to precipitate a colorless solid, which on recrystallization from petroleum ether (bp 45—65°C) afforded 0.85 g (99.5%) of IVa, mp 130.5—131°C (decomp.).

Reaction of Thiobenzoyl Isocyanate (II) with p-*Methoxybenzaldazine (IIIb).* The standard solution of II was stirred with 0.7 g of IIIb at 50°C for 30 min. Filtration gave 0.78 g (50%) of bis(4+2) cycloadduct VIIIb-1. The analytical sample was prepared by recrystallization from xylene.

The filtrate was evaporated *in vacuo* to leave isomeric bis(4+2) cycloadduct VIIIb-2, which was recrystallized from benzene-petroleum ether (bp 45—65°C).

Similarly, the reaction of II with IIIa, IIIc and IIId gave the corresponding mono(4+2) cycloadducts VIIa, VIId and bis(4+2) cycloadduct VIIIc, respectively, while II did not react with IIIe. The yields, physical properties and results of elemental analyses of VII and VIII are given in Table 2.

Reaction of VIIa with Phenylhydrazine. A solution of 0.1 g of VIIa and 5 drops of phenylhydrazine in 10 m*l* of dry benzene was refluxed for 30 min, during which time 40 mg (63%) of 2,3-dihydro-2,5-diphenyl-1,2,4-triazol-3(1*H*)-one (IX), mp 230—231°C, precipitated. Compound IX was identical with an authentic sample, mp 230–231°C,[12] prepared from II and phenylhydrazine. The filtrate was concentrated *in valuo* to give 0.11 g (95%) of phenylhydrazone of benzaldehyde, identical with an authentic sample.

Reaction of VIId with Hydrobenzamide. A solution of 0.2 g of VIId and 0.1 g of hydrobenzamide in 15 m*l* of dry benzene was refluxed for 1 hr. The crystalline precipitate was filtered and washed with hot benzene to leave 80 mg (30%) of bis(4+2) cycloadduct X, mp 208—209°C (decomp.).[8] The filtrate was evaporated *in vacuo* to give a mixture of 40 mg of azine IIId and 80 mg (30%) of isomeric bis(4+2) cycloadduct X', mp 186°C,[8] which were separated by extraction with carbon tetrachloride. Evaporation of benzene washings afforded 50 mg of azine IIId; the total yield of azine IIId is 90 mg (72%).

This work was partially supported by a grant from the Ministry of Education. The authors would like to express their thanks to Professor J.-P. Anselme, University of Massachusetts, Boston, for reading the manuscript.

(Received March 28, 1972)

Synthetic studies on ethyl α,β-unsaturated β-nitrocarboxylates (IV) through two routes are described. Ethyl α-hydroxy-β-nitrocarboxylates (II) obtained by the reactions of ethyl α,β-unsaturated carboxylates with fuming nitric acid or by those of nitroparafins with ethyl glyoxylate, were treated with acetic anhydride to afford ethyl α-acetoxy-β-nitrocarboxylates (III), which were subsequently converted into IV by treatment with bases used as catalysts. On the other hand, IV was also obtained from ethyl α-chloro-β-nitrocarboxylates derived from the reactions of ethyl α,β-unsaturated carboxylates with nitryl or nitrosyl chloride. The structural assignments of IV were made on the basis of elementary analysis, infrared spectra and its conversion into the corresponding α-methoxy derivatives.

General methods for the syntheses of ethyl α,β-unsaturated α-nitrocarboxylates (I) are found in literature. They can be classified into two methods; (a) by elimination of the corresponding β-hydroxycarboxylates obtained from appropriate aldehydes and ethyl nitroacetate, *via* the acetoxy derivatives,[2-5] and (b) by nitration of ethyl α,β-unsaturated carboxylates with nitric acid or dinitrogen trioxide.[6-9]

However, there are no reports on the general synthesis ethyl α,β-unsaturated β-nitrocarboxylates (IV) except for that of β-nitroacrylic acids by the elimination of α-halo-β-nitropropionic acids.[10-12]

In a previous paper,[1] one of the authors (C. S.) reported on the direct synthesis of I and ethyl α-hydroxy-β-nitrocarboxylates (II) by treatment of ethyl α,β-unsaturated carboxylates with fuming nitric acid.

In this paper, we report detailed studies on the preparation of IV through two synthetic routes.

Results

Synthesis of IV from Nitroparaffins and Ethyl Glyoxylate. Condensation of appropriate nitroparaffins and ethyl glyoxylate[13] obtained by lead tetraacetate oxidation of ethyl tartrate in benzene gave II in about 50% yield (Table 1). The absorption patterns and boiling points of these nitro alcohols (II) are identical with those II prepared from the olefinic esters and fuming nitric acid.[1]

Acetylation of II with acetic anhydride under reflux for 1.5 hr afforded ethyl α-acetoxy-β-nitrocarboxylates (III) in good yields (Table 2). When III was treated with a small amount of inorganic or organic bases as catalysts in the absence of solvent by shaking for 15 minutes at 80—120°C, the expected ethyl α,β-unsaturated β-nitrocarboxylates (IV) were obtained (Table 3).

Formation of ethyl α-nitroolefin carboxylates (I) by elimination of β-acetoxy group from ethyl β-acetoxy-α-nitrocarboxylates was carried out by using sodium carbonate as a catalyst in benzene.[5] However, in the case of elimination of α-acetoxy group from III, it was found that sodium hydrogen carbonate without solvent was superior to sodium carbonate in benzene.

Synthesis of IV from Ethyl α,β-Unsaturated Carboxylates. When olefinic esters were treated with nitryl chloride in ether below 0°C for 5 hr, ethyl α-chloro-β-nitrocarboxylates (V) were obtained as the main products, together with ethyl α,β-dichlorocarboxylates (VI), a small amount of higher-boiling product and polymerized reddish residue. The higher-boiling product was identified as ethyl α-nitrito-β-nitrocarboxylates (VII) from the fact that it showed an infrared absorption band of an intense nitrito group in the 1620—1630 cm^{-1} region and that it was converted into II by boiling in water.[9] Nitration by nitrosyl chloride under similar conditions also gave the same products (V and VI), but the formation of VII and the residue was found to be less than in the case of nitryl chloride. Other products such as ethyl α,β-dinitrito- and β-nitrito-α-nitrocarboxylates could not be detected. The elimination reaction of V with triethylamine afforded IV in about 50% yield.

In order to confirm its structure, compound IV was converted into the corresponding α-methoxy deriva-

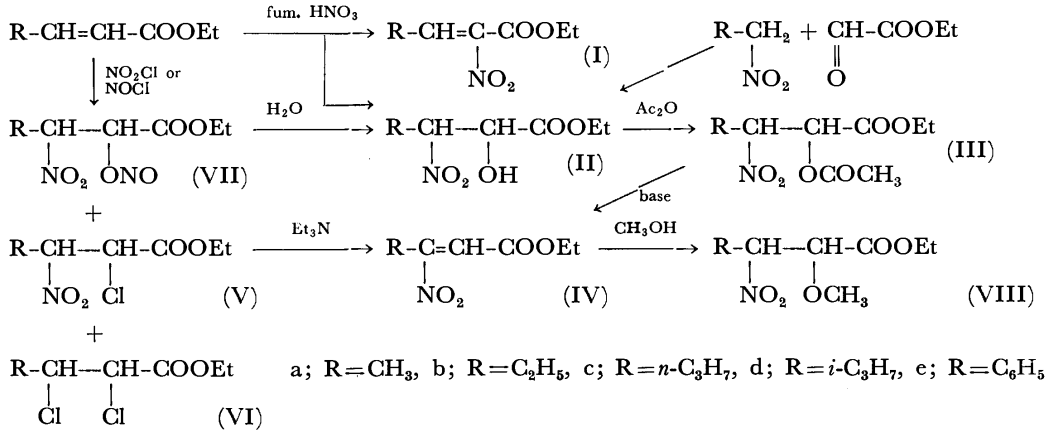

Scheme 1.

tives. When IV was treated with methanol in the presence of sodium methoxide below −10°C, the expected ethyl α-methoxy-β-nitrocarboxylates (VIII) were obtained. The disappearance of carbon-carbon double bond absorption in the 1640—1680 cm^{-1} region of the infrared spectrum of IV indicates the formation of VIII.

Experimental

All boiling and melting points are uncorrected. The IR spectra were recorded with a Hitachi EPI-G2 Spectrometer.

Reaction of Nitroparaffin with Ethyl Glyoxylate Derived from Ethyl Tartrate and Lead Tetraacetate. Lead tetraacetate (0.048 mol) was added portionwise with stirring to a cooled solution of ethyl tartrate (0.048 mol) in dry benzene (50 m*l*). After stirring for 1.5 hr at room temperature, separated crystals were filtered off and washed well with dry benzene. The filtrate and the washings were combined (about 100 m*l*). Appropriate nitroparaffin (0.098 mol) and 6% ethanolic solution of sodium ethoxide (from 2.4 g of sodium in ethanol (40 m*l*)) were added to the combined solution, with vigorous stirring. The weak alkaline solution was allowed to stand overnight with stirring at room temperature. After concentration of the solution, the residual oil was added to a mixture of benzene (100 m*l*) and water (50 m*l*). The solution was then acidified with 3 N hydrochloric acid. After removal of the precipitated crystals, the solution was washed with water twice (each 30 m*l*), and then dried over anhydrous magnesium sulfate and evaporated. Distillation of the residual oil afforded ethyl β-hydroxy-α-nitrocarboxylates (II), which were confirmed to be the same as the specimens prepared from ethyl α,β-unsaturated carboxylates and fuming nitric acid from their boiling points and IR spectra. The results are summarized in Table 1.

Acetylation of Ethyl α-Hydroxy-β-nitrocarboxylates (II) with Acetic Anhydride. A mixture of II (0.05 mol) in acetic anhydride (0.1 mol) was refluxed for 1.5 hr. Subsequent distillation of the reaction product under reduced pressure afforded an almost colorless oil, which was identified as ethyl α-acetoxy-β-nitrocarboxylates (III). However, ethyl 2-acetoxy-3-nitro-3-phenylpropionate (IIIe) could not be isolated in pure state and directly converted into ethyl 3-nitro-3-phenyl-2-propenoate (IVe) during the course of distillation. The results are summarized in Table 3.

Reaction of α,β-Unsaturated Carboxylic Esters with Nitryl Chloride (Procedure A). Nitryl chloride (0.48 mol) was added drop by drop, with vigorous stirring, to a solution of ethyl α,β-unsaturated carboxylates (0.32 mol) in dry benzene (60 m*l*) cooled below 0°C with an ice-salt bath. After being stirred for 5 hr at 0°C, the reaction mixture was

allowed to attain room temperature and to stand for 3 days. The benzene solution was washed successively with ice water (60 ml), 5% aqueous solution of sodium carbonate and finally twice with water. The solution was dried over anhydrous sodium sulfate and then evaporated. Distillation of the residual oil afforded three fractions, two of which were identified as ethyl α-chloro-β-nitrocarboxylates (V) and ethyl α,β-dichlorocarboxylates (VI). The highest boiling fraction was identified as ethyl α-nitrito-β-nitrocarboxylates (VII), though it could not be obtained in a pure state. The results are summarized in Tables 4 and 5.

Reaction of α,β-Unsaturated Carboxylic Esters with Nitrosyl Chloride (Procedure B). Nitrosyl chloride (0.5 mol) was added in a stream to a solution of ethyl α,β-unsaturated carboxylates (0.3 mol) in dry benzene (100 ml) cooled below 0°C with an ice-salt bath. After being stirred for 3 hr at 0°C, the reaction mixture was allowed to attain room temperature and to stand for 5 days. The benzene solution was washed with 5% aqueous solution of sodium carbonate and with water, and then dried over anhydrous sodium sulfate and evaporated. Distillation of the residual oil afforded V and VI. The results are summarized in Tables 4 and 5.

Conversion of Ethyl 4-Methyl-2-nitrito-3-nitrovalerate (VIIId) into Ethyl 2-Hydroxy-4-methyl-3-nitrovalerate (IId). A mixture of the crude VIId (5 g, bp 128—160°C/2 mmHg) in water (20 ml) was refluxed for 5.5 hr, and the resulting yellow solution was extracted three times with ether. The ethereal solution was washed with water, and dried over magnesium sulfate. After the evaporation of ether, the residue was distilled to give an almost colorless oil (IId; 1.5 g, 34.0%), bp 125—127°C/4 mmHg.

Analogous treatment of ethyl 2-nitrito-3-nitrobutyrate (VIIa; 7 g, bp 130—160°C/3 mmHg) with boiling water afforded the corresponding hydroxy compound (IIa; 2.6 g, 60.1%), bp 108—112°C/5 mmHg.

Elimination Reaction of Ethyl α-Chloro-β-nitrocarboxylates(V) with Triethylamine (Procedure C). Dry triethylamine (0.05 mol) was added drop by drop, with shaking, to a solution of V (0.05 mol) in dry benzene (30 ml) at room temperature. After stirring for 1 hr, water (30 ml) was added to the reaction solution and then the mixture was extracted three times with benzene. The combined benzene extracts were washed with water and then dried over anhydrous sodium sulfate. After concentrating the benzene extract, distillation of the residual oil afforded a yellow oil which was identified as ethyl α,β-unsaturated β-nitrocarboxylates (IV). The results are summarized in Table 6.

Elimination Reaction of Ethyl α-Acetoxy-β-nitrocarboxylates (III) with Sodium Acetate in the Absence of Solvent (Procedure D). Compound III (0.043 mol) was heated in the presence of sodium acetate (0.06 g) with shaking for 15 min at 110—120°C and subsequent distillation of the reaction product under reduced pressure afforded IV together with a small quantity of acetic acid. The results are summarized in Table 6.

Elimination Reaction of Ethyl 2-Acetoxy-4-methyl-3-nitrovalerate (IIId) with Several Bases. Compound IIId (0.1 mol) was heated in the presence of various bases (7×10^{-4} mol) with shaking for 5—15 min at 80—120°C. Subsequent distillation of the reaction product under reduced pressure afforded ethyl 4-methyl-2-nitro-2-valerate (IVd) together with a small quantity of acetic acid. The results are summarized in Table 3.

Methoxylation of Ethyl α,β-Unsaturated β-Nitrocarboxylates (IV) with Methanol. A solution of IV (0.07 mol) in methanol (80 ml) was added, with vigorous stirring, to a 5% methanolic solution of sodium methoxide (from 3.5 g of sodium in methanol (70 ml)) cooled below −10°C. The temperature of the reaction mixture rose up to about 15°C, at which stirring was continued for 1 hr. A small amount of of crushed dry ice was then added portionwise. The cooled mixture was poured into water (500 ml), and the resulting solution was acidified with glacial acetic acid, whereby an oily product separated out. The product was extracted several times with ether. The combined ethereal extracts were washed with water, dried over anhydrous magnesium sulfate and evaporated. Distillation of the residual oil afforded ethyl α-methoxy-β-nitrocarboxylates (X) as an almost colorless oil. The results are summarized in Table 7.

A Theoretical Aspect on the Mechanism of Thermal Dimerization of Cyclooctatetraene[1]

Hiizu IWAMURA and Kazuhiko MORIO

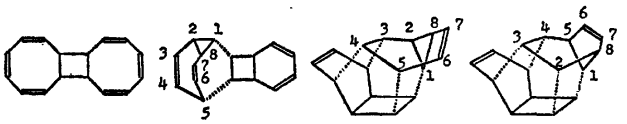
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo

(Received March 31, 1972)

Thermal isomerization of cyclooctatetraene to semibullvalene **6** has been studied theoretically by the MINDO methods. The reaction is predicted to be exothermic by comparison of the calculated heats of formation and to be allowed as a concerted cyclization by constructing a complete MO correlatiom diagram. These findings together with the knowledge of thermal interconversion of cyclooctatetraene and bicyclo[4.2.0]octa-2,4,7-triene **5** suggest a tentative mechanism for thermal dimerization of cyclooctatetraene in which dimers **2**, **3**, and **4** are formed by coupling of the two isomers **5** and **6** of cyclooctatetraene.

It has been shown by Reppe *et al.*,[2] Jones,[3] and Schröder[4] that cyclooctatetraene forms several dimers on heating under various reaction conditions. A mixture of isomers **1**, mp 53°C, and **2**, mp 76°C, for example, is obtained by heating neat cyclooctatetraene at 100° in a sealed tube. Refluxing in *o*-dichlorobenzene and *N,N*-diethylaniline as the diluents results in formation of dimers **3**, mp 41.5°C, and **4**, mp 18.5°C, respectively. In spite of their fascinating structures and utility as the excellent intermediates for synthetic works highlighted by preparation of bullvalene,[5] little study has been done on the mechansim of formation of these dimers **1**~**4**.

We notice by simple inspection of the molecular framework of these dimers that structural units of bicyclo[4.2.0]-octa-2,4,7-triene **5** and semibullvalene **6** are incorporated in **2**, **3** and **4** as shown in Chart 1, and are led to propose a hypothesis that these dimers could be formed by coupling of **5** and **6** which in turn might be produced by thermal valence isomerization of cyclooctatetraene. While thermal interconversion of cyclooctatetraene and **5** has been unambiguously established,[6] the thermal conversion of the former to **6** has been the subject of considerable controversy. Thus **6** can be formed by the acetone sensitized photolysis of cyclooctatetraene.[7] In the case of 1,3,5,7-tetramethylcyclooctatetraene, it is a pyrolytic condition of heating at 250°C for 15 hr rather than irradiation under various conditions which gives the corresponding semibullvalene.[7] Criegee and Askani reported efficient conversion at elevated temperature of octamethylcyclooctatetraene to the semibullvalene.[8]

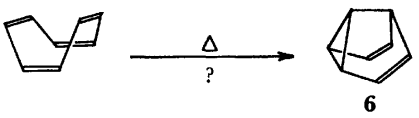


1 **2** **3** **4**

Chart 1. Molecular framework of dimers **1**~**4** of cyclooctatetraene.

With all the findings mentioned above which are suggestive of a possible thermal transformation of cyclooctatetraene to **6**, experimental efforts to detect the latter in the gaseous and condensed phase pyrolysates of the former have proved to be totally unsuccessful. The products are usually styrene and dihydropentalene as well as benzene and acetylene.[9,10] Formal application of the orbital symmetry rule is also controversial; the same 1,3 ; 2,6 concerted multicyclization of cyclooctatetraene has been predicted as an allowed process in the ground state by a group of authors[11] while others reasoned the allowedness in the excited state.[12]

With no operational test available, we began theoretical approach to the problem and present here the analyses of the electronic structure of the molecular reorganization reaction represented by the equation;



6 (1)

Methods of Theoretical Calculation

The theoretical methods employed here are to construct a quantitative molecular orbitals correlation diagram between cyclooctatetraene and semibullvalene **6**, and to see if the occupied MO levels are correlated between the two species. Since the experimental data concerning the geometry of **6** are not available, the theoretical geometry has to be sought by minimizing the molecular energy with respect to all the bond lengths and angles in the molecule. Out of several versions of the semi-empirical SCF MO theories, the MINDO/2

method[13] proposed by Dewar *et al.* is considered to reproduce the best geometry; the geometry which gave the minimum value of total energy by the MINDO/2 method was taken as the equilibrium geometry of the actual molecule. For the sake of consistency of comparison, the optimized geometry of cyclooctatetraene was also employed in the present study.

Correlation between the MO's of the species in either side of Eq. (1) is not straightforward because cyclooctatetraene and **6** lack any common symmetry element. It is, however, rendered possible to find the MO correlation by imposing in the reaction coordinate close to the end product the intermediate which corresponds to the transition state structure for the degenerate Cope rearrangement of **6**.[1] The C_2 symmetry operation is kept for the first half of the reaction, and the C_s symmetry element holds throughout the last half of the reaction coordinate (see Chart 2). Since the activation energy for the Cope rearrangement is known to be exceptionally low,[14] the above specification of the reaction as passing through this intermediate does not necessarily mean the restriction of the course of the reaction to a stepwise reaction; the intermediate and **6** are energetically too close to be separated on the entire potential energy surface interrelating the $(CH)_8$ isomers.

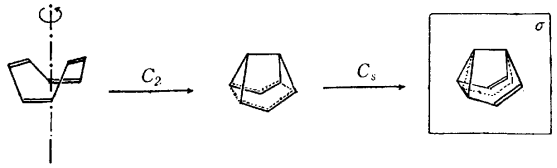

Chart 2. Symmetry elements along the reaction coordinates.

Estimation of heats of formation of cyclooctatetraene and **6** is considered to be illuminative as a measure of the exothermicity of the forward reaction of Eq. (1). The MINDO/2 approximation is reputed to underestimate heats of formation of the cyclopropane ring by about 10 kcal/mol.[13] In this respect, it is worthwhile to recourse to the original version (MINDO/1) of the approximation which, although artificially parametrized, gives best results of the theoretical heats of formation with the use of the standard bond lengths; even a seriously strained cyclobutene deviates only by 3.4 kcal/mol from the experimental value.[15] Therefore more reliable estimation of heats of formation of cyclooctatetraene and **6** was made by the MINDO/1 calculations in which the optimal lengths reached by the MINDO/2 approximations were replaced by the standard bond lengths of Baird and Dewar.[15] Heats of formation are by definition given by total bonding energies minus heats of formation of the free atoms in the molecule in the standard state. The total bonding energies are in turn calculated by subtracting the sum of isolated atom energies from the total valence shell energies.

Partitioning of the total valence shell energy (E) of a molecule into the terms due to one-center (E_A) and two-center (E_{AB}) was performed at the level of MINDO approximations analogously to the method elaborated by Gordon in the CNDO/2.[16]

$$E = \sum_{A} E_A + \sum_{A<B}\sum E_{AB} \tag{2}$$

The one-center terms can be expressed in terms of standard integrals as

$$E_A = \sum_{\mu}^{A}\left[P_{\mu\mu}U_{\mu\mu} + \frac{1}{2}P_{\mu\mu}^2\langle\mu\mu|\mu\mu\rangle\right] + \sum_{\nu\neq\mu}^{A}\sum^{A}\left\{P_{\mu\mu}P_{\nu\nu}\left[\langle\mu\mu|\nu\nu\rangle - \frac{1}{2}\langle\mu\nu|\mu\nu\rangle\right] + P_{\mu\nu}^2\left[\frac{3}{2}\langle\mu\nu|\mu\nu\rangle - \frac{1}{2}\langle\mu\mu|\nu\nu\rangle\right]\right\} \tag{3}$$

Full expression for the bi-centric terms (E_{AB}) are

$$E_{AB} = E_{AB}^{R} + E_{AB}^{X} + E_{AB}^{E} \tag{4}$$

where:

$$E_{AB}^{R} = 2\sum_{\mu}^{A}\sum_{\nu}^{B}P_{\mu\nu}\beta_{\mu\nu} \tag{5}$$

$$E_{AB}^{X} = -\frac{1}{2}\sum_{\mu}^{A}\sum_{\nu}^{B}P_{\mu\nu}^2\gamma_{AB} \tag{6}$$

$$E_{AB}^{E} = (P_AP_B - P_AZ_B - P_BZ_A)\gamma_{AB} + Z_AZ_BR_{AB}^{-1} \tag{7}$$

and E_{AB}^{R}, E_{AB}^{X}, and E_{AB}^{E} represent the resonance, exchange and electrostatic energies, respectively.

Results and Discussion

In Fig. 1 is summarized the MO correlation diagram obtained by application of symmetry operation and the noncrossing rule to the final MO's. We notice that the occupied MO levels are satisfactorily correlated between the starting cyclooctatetraene and product **6**.

The second clear-cut criterion obtained in the present study which supports the thermal route of Eq. (1) is, as shown in Table 1, that the heats of formation of cyclooctatetraene is higher than that of **6** by 13.4 kcal/mol; the forward reaction is predicted to be exothermic.

Turning now to the consideration of the driving force of the exothermic reaction, we note that the MO numbers 1, 8 and 20 of cyclooctatetraene are mostly responsible for lowering the electronic energy as the reaction proceeds. Nature of these levels is not obvious at a glance over the eigen vectors of the all-valence-electron SCF MO method, since separation of the σ and π character of a given MO is not clear. In this respect, it is instructive to go back to the correlation diagram constructed on the π-orbital approximation. Starting from cyclooctatetraene in which the occupied levels are made of four ethylene groups weakly overlapped through σ-bonds, we end up, as illustrated in Fig. 2, with two σ- and two π-orbitals of **6** with the aid of the bonding levels of two interacting allylic orbitals of the intermediate. In reality all

these levels split further on coupling with a combination of σ-orbitals of the same symmetry. As a result, none of the MO's in Fig. 1 can be exactly equivalent to any one MO in Fig. 2. Closer inspection of the MO coefficents reveals, however, that the 8th and 20th MO's of cyclooctatetraene in Fig. 1 are most reasonably approximated by the A_4 orbital in Fig. 2.[17] The behavior of the two MO's of cyclooctatetraene during the course of the reaction indicates that 1,3 ; 2,6 interaction of the π-orbitals of cyclooctatetraene is of bonding in nature. The reaction may figuratively be regarded as an intramolecular Diels-Alder ($2_\pi + 4_\pi$) reaction between the C-1, C-2 ene unit and the diene C-3~C-6. Instead of suprafacial overlap between the front lobes of C-2 and C-3, and C-1 and C-6 which leads to **5**, the opposite lobes of the p-orbitals on C-1 and C-2 are involved to form the new σ-bonds of **6** with the bottom lobe of C-3 and the top p-lobe of C-6, respectively (Chart 3).

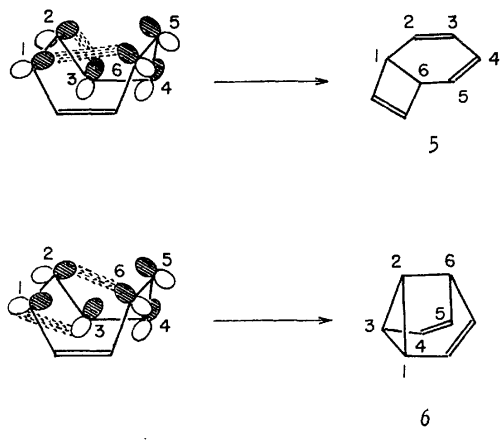

Chart 3. Two modes of thermally allowed closure.

Another aspect of the origin of the driving force for the reaction of Eq. (1) can be found in Table 1. In terms of resonance energy, the transition state structure of the Cope rearrangement of **6** is most favored (−155.16 eV) by the aromaticity of the Hückel type array of the 6π electrons. Cyclooctatetraene (−153.40 eV) is presumably destabilized to some extent by its anti-aromaticity due to cyclic array of 8π electrons. It is also interesting to note that contribution of the non-bonded interaction to the bi-centric resonance energy in cyclooctatetraene is −0.0074, −0.0038, and +0.3485 eV for the atomic pair of C_1~C_6, C_2~C_6, and C_1~C_3, respectively; a nagative value for E_{AB} implies bonding between atoms A and B while a positive value implies an anti-bonding interaction. It is also apparent in Table 1 that the one center terms are largely responsible for the total energy difference between cyclooctatetraene and **6**. The main contribution comes from the terms for C_2, $C_4(C_8)$, and C_5-(C_7) of **6**, and the effect appears to be associated with an increase in electron density and consequently one-center core binding energy of these carbon atoms. Of special importance is the high p_y electron density at C_2 of **6** which characterizes the electronic structure of this molecule (the y axis is taken parallel to the C_1—C_3 bond. The numbering system is given for **6** in Chart 3 only to clarify the original positions of atoms in the precursor, and does not conform to the IUPAC rules).

It is now conclusive on the theoretical bases that the reaction of Eq. (1) is an allowed process as a concerted cyclization in the ground state. Prediction to the contrary in Ref. 12 is found to be due to wrong drawing of the orbitals in which ring closure should lead to unrealistic semibullvalene with the cyclopropane ring fused trans (Chart 4).

Chart 4. Double cyclization of cyclooctatetraene according to the drawings in Ref. 12.

So far is rationalization of the thermally allowed conversion of cyclooctatetraene to semibullvalene. We are now halfway to give full theoretical account for the hypothesis that dimers **2**~**4** could be formed by way of coupling between **5** and **6**. In Chart 5 are shown one of the conceivable modes in which the coupling takes place. By application of the mnemonics of

17) The highest occupied orbital A_4 in Fig. 2, for example, appears to split into the MO's 20, 13, and 8 in Fig. 1 by mixing with a combination of σ orbitals in the ethylenic double bonds which has A symmetry for C_2 operation.

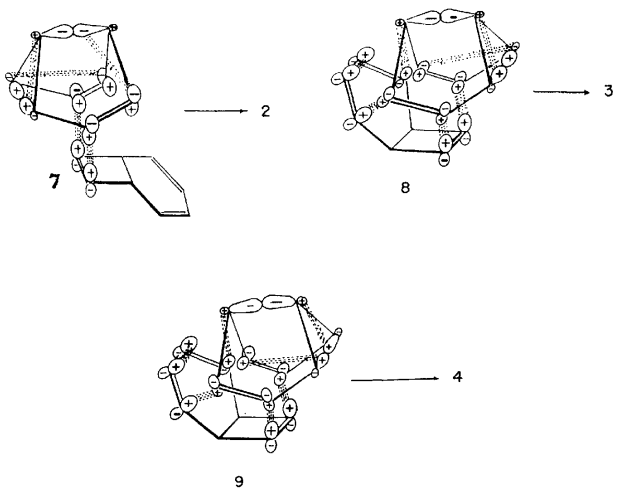

Chart 5. Mechanism I of the dimer formation of cyclooctatetraene from **5** and **6**.

Zimmerman for determining the allowedness or forbiddenness of symmetry controlled reactions, **7** is described as containing a cyclic array of ten atomic orbitals in which there are zero or even numbers of sign inversion resulting from plus-minus overlaps.[7,18] The type of the system is classified as Hückel and the process is predicted to be symmetry allowed in a ground state reaction. In the terminology of Woodward and Hoffmann,[11] the process can be described as $[{}_{\pi}2_s+{}_{\pi}2_a+{}_{\sigma}2_a+{}_{\sigma}2_a+{}_{\pi}2_a]$ processes. In **8** and **9** there are 14 AO's overlapping next to each other to form a cyclic array of orbitals. Irrespective of the choices of the sign of the basis set AO's, the total number of sign inversion resulting from plus-minus overlaps is zero or even. The Hückel system is again predicted to be allowed. Thus the modes of closure given in Chart 5 are proposed as a tentative mechanism for thermal dimerization of cyclooctatetraene.

In view of the multi-center interaction between **5** and **6** in the transition states **7**~**9** the proposed mechanism should require a large negative entropy of activation. Although no quantitative study has yet been carried out, the fact that the dimers are formed only in condensed phases and that in neat or moderately concentrated solution is in accord with the expectation.[2-4] When the entropy requirement of mechanism I is seriously taken as a disadvantage, an alternative mechanism of the intermediacy of **10** followed by intramolecular closure to give **1**~**4** may be considered as another candidate (Chart 6). The first step is a typical Diels-Alder reaction— the $[{}_{\pi}4_s+{}_{\pi}2_s]$ cycloaddition. The routes to **3** and **4** include internal closure of the cyclooctatriene moiety to the dihydrosemibullvalene. The theoretical argument developed in the first half of the present paper can similarly be applied to predict the allowedness of this part of the reactions.[7] Thus mechanisms I and II differ only in the chronology of the ring closure and can not be differentiated from the standpoint of orbital symmetry control of electrocyclic reactions.

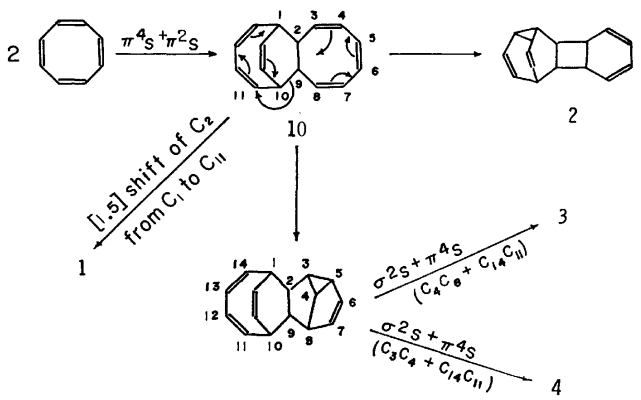

Chart 6. Mechanism II of the dimer formation of cyclooctatetraene.[19]

19) Dimers **1** and **2** formed at relatively low temperatures are not precursors of **3** and **4**. Prolonged heating of **2** has been shown to give a tetramer instead of an isomeric dimer.[4]

Synthetic Reactions by Complex Catalysts XXVIII. Reaction of β-Propiolactone with Alkyl Halide Caused by Cu_2O-Isonitrile Complex

Takeo SAEGUSA, Ichiki MURASE, Michio NAKAI, and Yoshihiko ITO

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto

(Received April 24, 1972)

Oligomerization of β-propiolactone (BPL) caused by the Cu_2O-isonitrile complex in the presence of alkyl halide was studied, and an oligomeric mixture of acrylate derivatives **3** ($n=1$, 2 and 3 in Eq. (3)) was isolated in fairly high yields. The complex catalyst showed a distinguished catalytic activity for the oligomerization of BPL. The reaction mechanism involving an intermediate of organocopper(I) isonitrile **4**, which is converted into copper(I) acrylate isonitrile complex **5** was presented.

In our continuing studies on the reactions caused by the Cu_2O-isonitrile complex, it has been established[1,2] that the Cu_2O-isonitrile complex abstracts hydrogen atom from the so-called active methylene compound to produce organocopper(I) isonitrile complex **1** which plays a key role as an intermediate in the respective reaction.

$$\begin{matrix}X\\Z\end{matrix}\!\!>\!CH_2 + Cu_2O + n\text{RNC} \rightarrow \begin{matrix}X\\Z\end{matrix}\!\!>\!CHCu(\text{RNC})_n \quad (1)$$

1

In the present study, β-propiolactone (BPL) was employed as an active hydrogen compound, which was subjected to the reaction with the Cu_2O-isonitrile complex in the presence of alkyl halide. It was found that the Cu_2O-isonitrile complex readily caused oligomerization of BPL, in which oligomers having an acrylic carbon-carbon double bond as the terminal group were selectively produced. It might be of interest to compare with the usual base-catalyzed oligomerization of BPL.[3] For the present oligomerization, a scheme involving an intermediate of organocopper(I) isonitrile complex **2** is presented.

$$\begin{matrix}CH_2\text{—}CH_2\\ |\quad\ |\\ O\text{——}C{=}O\end{matrix} \xrightarrow{Cu_2O,\ m\text{RNC}} \begin{matrix}Cu(\text{RNC})_m\\ |\\ CH_2\text{—}CH\\ |\quad\ |\\ O\text{——}C{=}O\end{matrix} \quad (2)$$

2

Results and Discussion

BPL was heated at 80°C with Cu_2O-*t*-butyl isocyanide as a catalyst in the presence of alkyl halide to produce an oligomer mixture of acrylate derivatives **3** ($n=1,2$ and 3 in Eq. (3)) in fairly high yields. Each product was isolated by glpc and was identified by NMR and IR spectra as well as elemental analysis. No higher oligomer ($n\geq 4$ of **3**) was detected by glpc analysis.

$$n\begin{matrix}CH_2\text{—}CH_2\\ |\quad\ |\\ O\text{——}C{=}O\end{matrix} + \text{RX} \xrightarrow{Cu_2O\cdot R'NC} CH_2{=}CHCOO(CH_2CH_2COO)_{n-1}\text{-R} \quad (3)$$

3

Some representative reactions are summarized in Table 1.

The reaction of BPL with primary and secondary alkyl halides caused by the Cu_2O-isonitrile system gave the corresponding ester **3**. However, the reaction

with *t*-butyl bromide was unsuccessful, since it underwent elimination virtually exclusively under the present reaction conditions, producing isobutene. The reaction with aromatic halide gave no ester derivative.

The Cu_2O-pyridine system also gave rise to oligomerization, although it was somewhat less effective than the Cu_2O-isonitrile system, as seen in Table 2. The presence of Cu_2O was essential. Without Cu_2O, isonitrile alone caused no reaction under the present conditions.

The activities of some copper and silver compounds were examined (Table 3). Cu_2O and Ag_2O in combination with isonitrile showed distinguished results.

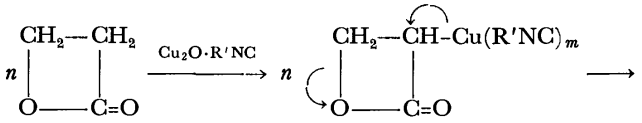
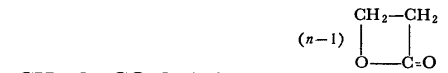
The following scheme explains several experimental findings.

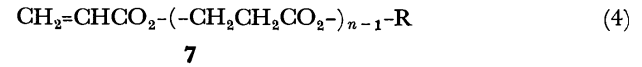


4



5

6



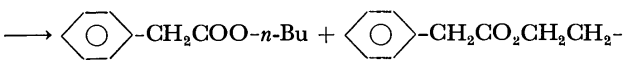
(4)

7

First, the α-hydrogen of BPL is abstracted by the Cu_2O-isonitrile system to form an organocopper(I) isonitrile complex **4**, which is converted into copper(I) acrylate isonitrile complex **5** through the ring-opening of **4**. The nucleophilic attack of **5** to the second molecule of BPL and the subsequent propagation of the BPL ring-opening will lead to the formation of the oligomeric copper(I) carboxylate **6**. Copper(I) salt complexes of acrylate and oligomeric carboxylates react with alkyl halide to produce the corresponding esters.

Several findings support the above scheme of the reactions. The nucleophilic attack of copper(I) carboxylate isonitrile complex to BPL was verified by an experiment in which BPL was treated with a complex of copper(I) phenylacetate *t*-butyl isocyanide **8** at 80°C in the presence of *n*-butyl bromide. The products were as follows.

8



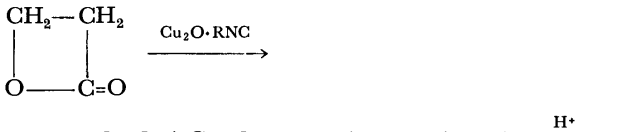
9 27% **10**

COO-*n*-Bu + $CH_2=CHCOO(CH_2CH_2COO)_{n-1}$-*n*-Bu (5)

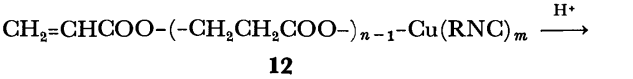
63% 5% ($n=1$ and 2)

Butyl phenylacetate **9** is formed by the direct reaction of **8** with butyl bromide, and **10** is produced by the sequence of reactions of ring-opening of BPL and esterification. The esterification of carboxylic acid with alkyl halide caused by the Cu_2O-isonitrile system has recently been found[4] and may have various applications.

When BPL was treated with the Cu_2O-isonitrile complex in the absence of alkyl halide, a mixture of oligomeric acids ($n=1$, 2 and 3 of **11**) was obtained after work-up with acidic water.



12



(6)

11

A mixture of the oligomeric copper(I) carboxylate **12** obtained in Eq. (6) was treated with ethyl bromide to give an oligomer mixture of acrylate derivatives, in which the oligomer distribution was roughly the same as that in the Cu_2O-isonitrile induced oligomerization of BPL in the presence of ethyl bromide.

Experimental

Reagents. Commercial analytical Cu salts and Ag salts were dried under N_2 before use. *t*-Butyl isocyanide was prepared according to Ugi's procedure.[5] Commercial BPL was purified by distillation under nitrogen after being dried over molecular sieves 3A. Commercial alkyl and aryl halides were purified by distillation under nitrogen. Commercial phenylacetic acid of extra pure grade was used.

(20 mmol) of BPL and 2.74 g (20 mmol) of *n*-BuBr in 5 m*l* of benzene was heated under nitrogen with stirring at 80°C for 7 hr. 20 m*l* of petroleum ether was then added and undissolved Cu_2O and precipitated complex were separated by filtration. The filtrate was subjected to distillation, collecting a fraction of 80°C/760 mmHg—110°C/6 mmHg. Each product was purified by means of preparative glpc. Structures of the products were determined by IR and NMR spectra and elemental analysis. The results are summarized in Table 4.

In the case of the other alkyl halides, the reactions were carried out by a similar procedure to that of the reaction with *n*-BuBr under the conditions shown in Tables 1, 2, and 3. The identification data of products are summarized in Table 4.

Reaction of BPL with Copper(I) Phenylacetate t-*Butyl Isocyanide Complex (**8**) in the Presence of* n-*Butyl Bromide.* A mixture of 1.43 g (10 mmol) of Cu_2O, 2.72 g (20 mmol) of phenylacetic acid, and 2.08 g (25 mmol) of *t*-butyl isocyanide in 15 m*l* of benzene was heated at 80°C for 3 hr. Formation of water was observed during the course of the reaction. The reaction mixture was subjected to filtration under nitrogen, and the filtrate was evaporated to remove benzene and water. Cu(I) phenylacetate-*t*-butyl isocyanide complex remained and was dried at 80°C in a vacuum (2 mmHg) for 3 hr. Cu(I) phenylacetate-*t*-butyl isocyanide complex was used for the following reaction without further purification. To this Cu(I) carboxylate *t*-butyl isocyanide complex was added 15 m*l* of benzene and 1.45 g (20 mmol) of BPL and the mixture was heated at 80°C for 3 hr under nitrogen. 20 mmol of *n*-butyl bromide was then added, and the reaction mixture was heated at 80°C for 6 hr. After 20 m*l* of *n*-pentane was added, precipitated CuBr-isonitrile complex was separated. The organic layer was subjected to distillation. *n*-Butyl phenylacetate (**9**) and **10** were obtained in yields of 27% and 63%, respectively. **9**: Found: C, 74.82; H, 8.14%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%. NMR ($CDCl_3$): τ 2.70 (5H), 6.40 (2H), **10**: Found: C, 68.33; H, 7.65%. Calcd for $C_{15}H_{20}O_4$: C, 68.16; H, 7.63%. NMR ($CDCl_3$): τ 2.71 (5H), 5.69 (2H), 6.39 (2H), 7.38 (2H).

Only small amounts (less than 5%) of acrylate derivatives were identified by comparison of the glpc retention time and the IR spectrum with that of the authentic sample.

*Reaction of Oligomeric Copper(I) Carboxylate (**12**) with Ethyl Bromide.* A mixture of 2.15 g (15 mmol) of Cu_2O, 3.85 g (45 mmol) of *t*-butyl isocyanide and 2.18 g (30 mmol) of BPL in 7.5 m*l* of benzene was heated at 80°C for 5 hr. After the reaction mixture was cooled to room temperature, 4.32 g (40 mmol) of ethyl bromide was added, and the mixture was stirred for 2 hr at room temperature. *n*-Pentane was then added and CuBr-isonitrile complex was separated. The organic layer was subjected to distillation, and the products were purified by preparative glpc. $CH_2=CHCOO(CH_2CH_2COO)_{n-1}C_2H_5$ ($n=1$ (10%), $n=2$ (21%), $n=3$ (16%)) was obtained in a total yield of 47%.

When BPL (30 mmol), ethyl bromide (40 mmol), *t*-butyl isocyanide (45 mmol) and Cu_2O (15 mmol) were all mixed together and the mixture was heated at 80°C for 7 hr, almost the same result as above was obtained. The product yields were as follows. $CH_2=CHCOO(CH_2CH_2COO)_{n-1}C_2H_5$: $n=1$ (10%), $n=2$ (17%), $n=3$ (8%); Total yield was 35%. Data for the identification of these products are summarized in Table 4.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3607—3611 (1972)

Preparations and Reactions of *N*-Benzoyl- and *N*-Ethoxycarbonylcarbodiimides

Oyo MITSUNOBU, Masazumi TOMARI, Hiroo MORIMOTO, Toshio SATO, and Michio SUDO

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo

(Received April 27, 1972)

The reaction of *N*-benzoyl-*N'*-*t*-butylthiourea with either diethyl azodicarboxylate or azodibenzoyl resulted in the formation of benzoyl-*t*-butylcarbodiimide in 84% and 48% yields, respectively. Dehydrosulfurization of various thioureas was also effected with mercuribenzamide. Benzoyl- or ethoxycarbonylcarbodiimides were obtained in over 80% yields. The reaction of benzoyl-*t*-butylcarbodiimide with one equivalent each of *N*-benzoylglycine and glycine ethyl ester led to the formation of N^1-benzoyl-N^2-*t*-butyl-N^3-(ethoxycarbonyl)methylguanidine in a good yield, no *N*-benzoylglycylglycine ethyl ester being isolated. When benzoyl-*t*-butylcarbodiimide was allowed to react with benzoic acid, dibenzimide and *t*-butyl isocyanate were formed. Similarly, *N*-ethoxycarbonylbenzamide and *N*-benzoylglycine(*N'*-ethoxycarbonyl)amide were prepared in good yields.

Carbodiimides have been used as versatile reagents in organic synthesis. For the preparation of peptides and nucleotides, dicyclohexylcarbodiimide (DCC) has been extensively used.[1] The reactivity of DCC, however, decreases in the presence of strong bases.[2] Thus, it is desirable to prepare more reactive carbodiimides such as *N*-acylcarbodiimides. α,β-Unsaturated carbonyl compounds undergo base catalyzed addition (Michael reaction)[3] and *N*-acylcarbodiimides are expected to show a similar reaction.

Some *N*-acyl-, *N*-ethoxycarbonyl- and *N*-sulfonylcarbodiimides have been synthesized but with low

yields.[4] In this report we present convenient methods for the preparation of *N*-benzoyl- and *N*-ethoxycarbonylcarbodiimides and some reactions of the carbodiimides.

Preparation of N-*Benzoylcarbodiimides by Means of either Diethyl Azodicarboxylate or Azodibenzoyl and Triphenylphosphine.* The reaction of *N*, *N'*-disubstituted thioureas (I) with diethyl azodicarboxylate (IIa) followed by treatment with triphenylphosphine resulted in the formation of the corresponding disubstituted carbodiimides in good yields.[5] Since the reaction proceeds in a neutral medium without any formation of reactive compounds such as water or strong acids, the process might be applied to preparation of more reactive carbodiimides.

When *N*-benzoyl-*N'*-*t*-butylthiourea (Ie) was allowed to react with an equimolar amount of IIa in tetrahydrofuran(THF) at room temperature, orange red of IIa faded in 3 days. After treatment with triphenylphosphine, benzoyl-*t*-butylcarbodiimide (IIIe), diethyl hydrazodicarboxylate and triphenylphosphine sulfide were obtained in 84%, 79%, and 71% yields, respectively.

We might assume that the reactivity of azo compounds depends on electron affinity of the nitrogen-nitrogen double bond. Thus, azodibenzoyl (IIb) was used in place of IIa in the above reaction.

The reaction of Ia, Ib, or Id with IIb in THF at room temperature led to the formation of the corresponding carbodiimide (IIIa, IIIb, or IIId) and *N,N'*-dibenzoylhydrazine in nearly quantitative yields. Thin layer chromatography (tlc) of the reaction mixture revealed the presence of sulfur. Unlike the reaction of I with IIa,[5] no 1 : 1 adduct of I with IIb could be isolated. When *N*-benzoyl-*N'*-*t*-butylthiourea (Ie) was treated with an equimolar amount of IIb at room temperature, the orange red of IIb disappeared within 4 hr and IIIe was isolated in a 47% yield. In order to facilitate the purification of the carbodiimide, an equimolar amount of triphenylphosphine was added before working up. An attempt to isolate benzoylcyclohexylcarbodiimide (IIIf) by distillation, however, was unsuccessful, presumably due to limited stability against moisture. Thus, the reaction mixture resulting from the reaction of *N*-benzoyl-*N'*-cyclohexylthiourea (If) with IIb was treated with water and *N*-benzoyl-

N'-cyclohexylurea was obtained in a 46% yield.

Preparation of Disubstituted Carbodiimides by Means of Mercuribenzamide. The above reaction is coupled to a redox system, *i. e.*, the hydrogen atoms in thiourea are abstracted by azo compounds and the sulfur atom in it is eliminated by the formation of triphenylphosphine sulfide. Other reagents capable of abstracting hydrogen and sulfur atoms may therefore be used for the preparation of carbodiimides. Mercuribenzamide (IV) was chosen for this purpose.

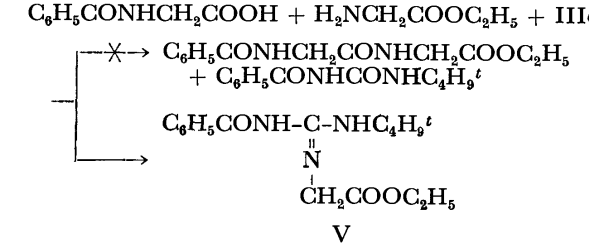
Mercuribenzamide was allowed to react with an equimolar amount of Ia, Ic, or Id in benzene at room temperature for 2 hr. After removal of mercuric sulfide, IIIa, IIIc, or IIId was obtained in nearly quantitative yields.

Similarly, some *N*-benzoyl- and *N*-ethoxycarbonylcarbodiimides (IIIe—h) were prepared in over 80% yields. The results are summarized in Table 1.

Reaction of N-*Benzoyl*-N'-t-*butylcarbodiimide and* N-*Ethoxycarbonyl*-N'-t-*butylcarbodiimide.* A special merit asociated with the use of DCC in the preparation of peptides is ease in manipulation. However, under certain conditions, *O*-acylisoureas initially formed from DCC and *N*-protected amino acids exhibit a marked propensity to undergo ready rearrangement of the acyl group giving *N*-acylureas.[1c]

The reaction of IIIe with an *N*-protected amino acid may also lead to the formation of corresponding *O*-acylisourea, in which the electron density of the nitrogen atom having a benzoyl group is reduced and another nitrogen atom is crowded by *t*-butyl group. Thus we might expect that the rearrangement to an *N*-acylurea *via* acyl transfer is prevented.

The reaction of IIIe with one equivalent each of *N*-benzoylglycine and glycine ethyl ester in dichloromethane at room temperature unexpectedly resulted in the formation of N^1-benzoyl-N^2-*t*-butyl-N^3-ethoxycarbonylmethylguanidine (V) in a 76% yield, 77% of *N*-benzoylglycine being recovered. *N*-Benzoyl-*N'*-*t*-butylurea was obtained in an 18% yield, but no *N*-benzoylglycylglycine ethyl ester was isolated. Similarly, V was prepared in a 71% yield when the reaction was carried out in THF.



In general, DCC reacts with the carboxyl function of amino acids even when both amine and carboxylic acid reactants exist. Thus, the reactivity of IIIe is quite different from that of DCC and closely resembles that of isocyanates.

The reaction of IIIe with benzoic acid was attempted in order to test its reaction with carboxylic acid. Benzoic acid was allowed to react with an equimolar amount of IIIe in dichloromethane at room temperature

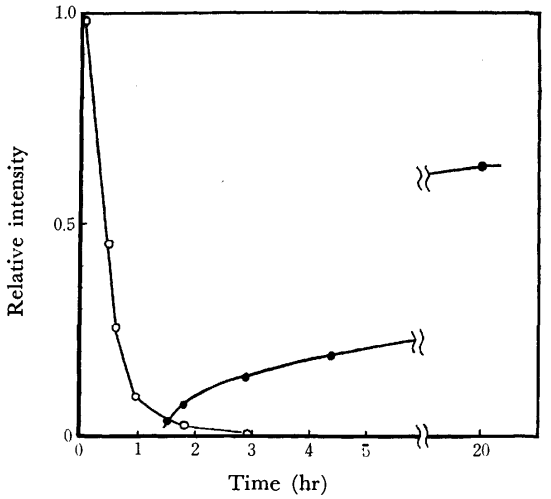


Fig. 1. Relative intensity of absorptions at 2150 and 2250 cm^{-1}.
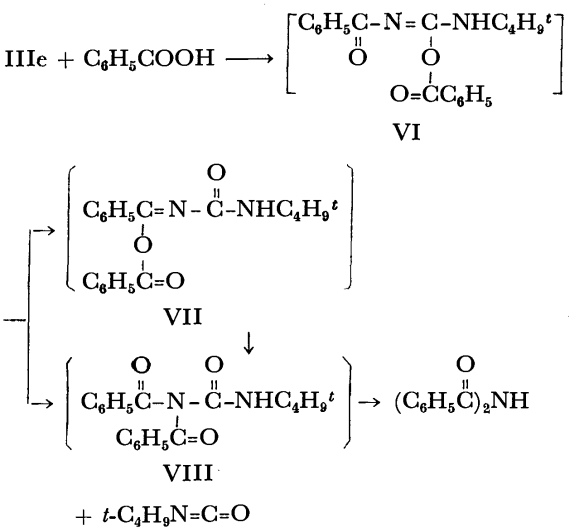
—○— : Absorption at 2150 cm^{-1}
—●— : Absorption at 2250 cm^{-1}

and the reaction was followed by IR spectrum. The absorption at 2150 cm^{-1} attributed to the -N=C=N- bond virtually disappeared in 2 hr, and a new absorption at 2250 cm^{-1} appeared in 1.5 hr. Intensity of the new absorption became constant after 20 hr and dibenzimide was isolated in a 72% yield from the reaction mixture (Fig. 1). When IIIe was allowed to react with benzoic acid for 20 hr followed by treatment with aniline, *N*-phenyl-*N'*-*t*-butylurea was obtained in an 87% yield. This unexpected result may be explained as follows: *O*-benzoyl-isourea (VI) formed from IIIe and benzoic acid is converted into *N*-dibenzoyl-*N'*-*t*-butylurea (VIII). VIII subsequently is decomposed to dibenzimide and *t*-butyl isocyanate by intramolecular hydrogen transfer. The possibility of initial formation of an imidoyl benzoate (VII) prior to VIII could not be ruled out.

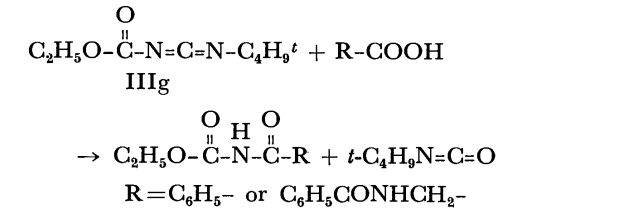


That the transfer of the benzoyl group took place rapidly was proved by the following experiment. When IIIe was treated with benzoic acid for 2 hr at room temperature and then aniline was added, benzanilide was obtained only in a 33% yield along with *N*-benzoyl-

N'-t-butylurea, *N*-phenyl-*N'-t*-butylurea, and benzamide.

When the reaction of IIIe with benzoic acid was carried out in the presence of a catalytic amount of triethylamine and the reaction was followed by IR spectrum as above, it took over 5 hr for the carbodiimide to disappear. On the other hand, a new absorption at 2250 cm^{-1} appeared in 30 min.

Similarly, the reaction of ethoxycarbonyl-*t*-butylcarbodiimide (IIIg) with an equimolar amount of benzoic acid or *N*-benzoylglycine resulted in the formation of *N*-ethoxycarbonylbenzamide and *N*-benzoylglycine(*N'*-ethoxycarbonyl)amide in fairly good yields.



$C_2H_5O-\overset{O}{\overset{\|}{C}}-N=C=N-C_4H_9^t$ + R-COOH

IIIg

$\rightarrow C_2H_5O-\overset{O}{\overset{\|}{C}}-\overset{H}{N}-\overset{O}{\overset{\|}{C}}-R + t\text{-}C_4H_9N=C=O$

$R = C_6H_5-$ or $C_6H_5CONHCH_2-$

Experimental

The IR spectra were measured on a Nippon Bunko IR-G spectrophotometer. The NMR spectra were obtained on a Hitachi Perkin-Elmer R-20 high resolution spectrometer at 60 MHz, using tetramethylsilane as an internal standard. Thin layer chromatography (tlc) was carried out on Merck PF_{254} or Wako Gel B-5.

Reagents. Diethyl azodicarboxylate,[6] azodibenzoyl,[7] and mercuribenzamide[8] were prepared by the usual procedures. *N*-Benzoyl- and *N*-ethoxycarbonyl thioureas were prepared from an amine and either benzoyl or ethoxycarbonyl thioisocyanate. The solvents were purified by ordinary procedures.

Preparation of Benzoyl-t-butylcarbodiimide by the Reaction of N-Benzoyl-N'-t-butylthiourea with an Azo Compound and Triphenylphosphine. a) Using Diethyl Azodicarboxylate. A solution of diethyl azodicarboxylate (1.74 g, 10 mmol) in THF (3 m*l*) was added dropwise to a solution of *N*-benzoyl-*N'-t*-butylthiourea (2.36 g, 10 mmol) in THF (10 m*l*) with stirring at room temperature. After the solution was kept standing at room temperature for 2 days, triphenylphosphine (2.62 g, 10 mmol) in THF (6 m*l*) was added, The solution was stirred for 1 hr and concentrated *in vacuo*. The residue was extracted with petroleum ether (30—60°C) to separate soluble material from the remainder. The extract was concentrated and distilled to give benzoyl-*t*-butylcarbodiimide, bp 110°C/0.55 mmHg, 1.65 g (84%), IR (neat): 2150 (-N=C=N-) and 1660 cm^{-1} (>C=O). NMR (CCl_4): δ 1.40 (s, 9H, $-C(CH_3)_3$), 7.30 and 7.90 (m, 3H and 2H, aromatic protons). The material, insoluble in petroleum ether, was applied to a column (2.5×25 cm) of alumina in benzene. The column was eluted first with benzene and then with methanol. Triphenyl phosphine sulfide (71%) was obtained from the benzene fraction and diethyl hydrazodicarboxylate (79%) was obtained from the methanol fraction.

b) Using Azodibenzoyl. A solution of azodibenzoyl (1.19 g, 5 mmol) in benzene (35 m*l*) was added dropwise to a solution of *N*-benzoyl-*N'-t*-butylthiourea (1.18 g, 5 mmol) in benzene with stirring at room temperature. After the mixture was stirred for 5 hr, dibenzoylhydrazine (mp 245—248°C, 1.12 g, 93%) was filtered off. Triphenylphosphine (1.31 g, 5 mmol) in benzene (10 m*l*) was then added to the filtrate and a white precipitate formed was removed by filtration. The filtrate was concentrated *in vacuo* and the residue was extracted with petroleum ether (30—60°C) to separate soluble material from the remainder. The extract was concentrated and distilled to give IIIe, bp 71—74°C/0.08 mmHg, 482 mg (48%). The material, insoluble in petroleum ether, was triphenylphosphine sulfide, mp 155—162°C, 1.14 g (78%).

Reaction of N-Benzoyl-N'-cyclohexylthiourea with Azodibenzoyl. A solution of IIb (238 mg, 1 mmol) in benzene (1 m*l*) was added dropwise to a solution of **If** (262 mg, 1 mmol) in benzene (2 m*l*) with stirring at room temperature. After the mixture was stirred for 4 hr, dibenzoylhydrazine (mp 244—245°C, 195 mg, 81%) was removed by filtration. The IR spectrum of the filtrate showed strong absorption at 2150 cm^{-1} (-N=C=N-). The filtrate was treated with water (1 m*l*), the product being separated by preparative tlc (dichloromethane, benzene-THF (1 : 1), and benzene) to give sulfur (20 mg, 63%) and *N*-benzoyl-*N'*-cyclohexylurea, mp 161—162°C, 57 mg (46%). IR (KBr): 3250 (>N-H), 1690 (>C=O), and 1600 cm^{-1} (C_6H_5-). NMR (CCl_4): δ 1.8 (m, 11H, *cyclo*-$C_6H_{11}-$), 3.75 (broad s, 1H, >N-H), 7.5 and 8.15 (m, 3H and 2H, aromatic protons), and 9.0 (1H, >N-H).

Preparation of N-Benzoyl- and N-Ethoxycarbonylcarbodiimides from Thioureas and Mercuribenzamide. Equimolar amounts (20 mmol) of *N*-benzoyl- or *N*-ethoxycarbonylthiourea (I) and IV were suspended in benzene (100 m*l*) and the mixture was stirred for 3 hr at room temperature. After mercuric sulfide was removed by filtration, the filtrate was evaporated and the residue was extracted with petroleum ether. The corresponding carbodiimide was obtained by distillation from the extracts. The results are summarized in Table 1.

Reaction of N-Benzoyl-N'-t-butylcarbodiimide with N-Benzoylglycine and Glycine Ethyl Ester. A suspension of *N*-benzoylglycine (179 mg, 1 mmol) and IIIe (202 mg, 1 mmol) in dichloromethane (6 m*l*) was stirred for 20 min at room temperature. A solution of glycine ethyl ester (103 mg, 1 mmol) in dichloromethane was then added dropwise in 20 min to the suspension. After the mixture was kept standing overnight, *N*-benzoylglycine was separated by filtration, mp 187—191°C, 137 mg (77%). The filtrate was applied to silica gel plates which were developed in chloroform. The main band was further separated by tlc (ether) giving *N*-benzoyl-*N'-t*-butylurea, 40 mg, 18%, mp 144—145°C (from ethanol): Found: C, 65.46; H, 7.34%. Calcd for $C_{12}H_{16}N_2O_2$: C, 65.43; H, 7.32%. NMR (CCl_4): δ 1.5 (s, 9H, $-C(CH_3)_3$), 7.4—8.15 (m, 5H, aromatic protons), 9.1 (1H, >N-H), and 10.9 (1H, >N-H), and N^1-benzoyl-N^2-*t*-butyl-N^3-carboethoxymethylguanidine (232 mg, 76%, mp 96—98°C (from petroleum ether). Found: C, 62.98; H, 7.59; N, 13.74%. Calcd for $C_{16}H_{23}N_3O_3$: C, 62.93; H, 7.59; N, 13.76%. IR (KBr): 1750 cm^{-1} (>C=O). NMR (CCl_4): δ 1.25 (t, 3H, $-O-\overset{|}{C}-CH_3$), 1.5 (s, 9H, $-C(CH_3)_3$), 2.5 (1H, >N-H), 4.25 (m, 4H, $>NCH_2CO_2CH_2\overset{|}{C}-$), 7.4 and 8.15 (m, 5H, aromatic protons), and 10.4 (1H, >N-H).

When the reaction was carried out in THF, the guanidine was obtained in a 71% (215 mg) yield.

Reaction of N-Benzoyl-N'-t-butylcarbodiimide with Aniline. A solution of aniline (93 mg, 1 mmol) in dichloromethane (1.5 m*l*) was added dropwise to a solution of IIIe (202 mg, 1 mmol) in dichloromethane (1.5 m*l*) with stirring at room temperature. After about 1 hr, the tlc of the solution re-

6) N. Rabjohn, "Organic Syntheses," Coll. Vol. III, p 375 (1955).

vealed a new spot while no starting materials remained. The solution was kept standing overnight and the solvent was removed under reduced pressure giving N^1-benzoyl-N^2-*t*-butyl-N^3-phenylguanidine, mp 100—101°C, 286 mg (97%). The guanidine was recrystallized from petroleum ether, mp 102°C. NMR (CCl_4): δ 1.5 (s, 9H, $-C(CH_3)_3$), 4.8 (1H, >N-H), 7.25 and 8.15 (m, 10H, aromatic protones), and 12.4 (1H, >N-H).

*Reaction of Benzoyl-*t*-butylcarbodiimide with Benzoic Acid. a) Measurement of IR Spectrum of the Reaction Mixture.* A solution of IIIe (202 mg, 1 mmol) and benzoic acid (122 mg, 1 mmol) in dichloromethane (3 m*l*) was placed in 0.05 cm matched cell (NaCl) and the reaction was followed by means of IR spectrum at room temperature. Figure 1 shows relative intensity of absorption at 2150 and 2250 cm^{-1}.

b) Treatment of the Reaction Mixture with Aniline. A solution of IIIe (202 mg, 1 mmol) and benzoic acid (122 mg, 1 mmol) in dichloromethane (4.5 m*l*) was stirred at room temperature for 2 hr. Aniline (93 mg, 1 mmol) in dichloromethane (3 m*l*) was then added and the solution was stirred for additional 5 hr. After the solution was kept standing overnight, the products were isolated by preparative tlc (1,2-dichloroethane–ether (30 : 1) and 1,2-dichloroethane–ether (15 : 1)) giving benzanilide (mp 163—164°C, 64 mg, 33%), *N*-benzoyl-*N'*-*t*-butylurea (mp 140—142°C), *N*-phenyl-*N'*-*t*-butylurea (mp 164—165°C) and benzamide.

In a separate experiment in which the mixture obtained as above was stirred for 20 hr, followed by treatment with aniline (93 mg, 1 mmol) in dichloromethane (3 m*l*), benzanilide (mp 162—163°C, 44 mg, 22%), benzamide (mp 127—128°C, 23 mg, 19%) and *N*-phenyl-*N'*-*t*-butylurea (mp 166—168°C, 167 mg, 87%) were obtained.

c) Treatment of the Reaction Mixture with Water. A mixture obtained as above was stirred for 20 hr at room temperature followed by addition of water (0.1 m*l*). After the solution was kept standing overnight, dibenzimide was obtained by preparative tlc using dichloromethane–ether (10 : 1) in a 72% yield, mp 150—151°C (from ethanol–water, 1 : 1). Satisfactory analytical and spectra data were obtained.

Reaction of N-*Ethoxycarbonyl*-N'-t-*butylcarbodiimide with Benzoic Acid.* A solution of IIIg (85 mg, 0.5 mmol) and benzoic acid (61 mg, 0.5 mmol) in THF (1.5 m*l*) was refluxed for 3.5 hr and kept standing overnight. After removal of the solvent under reduced pressure, a quantitative amount of *N*-ethoxycarbonylbenzamide (mp 108—109°C) was obtained which was recrystallized from ethanol, mp 113°C. The product was shown to be identical with the authentic sample by comparison of IR spectra.

*Reaction of Ethoxycarbonyl-*t*-butylcarbodiimide with* N-*Benzoylglycine.* A solution of IIIg (85 mg, 0.5 mmol) and *N*-benzoyl glycine (89 mg, 0.5 mmol) in THF (8 m*l*) was refluxed for 3 hr. After the solution was kept standing overnight at room temperature, the solvent was removed under reduced pressure. The residue was applied to silica gel plates developed in 1,2-dichloroethane–ether (5 : 1). *N*-Benzoylglycine(*N'*-ethoxycarbonyl)amide was thus isolated in a 73% (91 mg) yield, mp 152—154°C. Recrystallization from ethanol gave an analytical sample which gave satisfactory analytical and IR data.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3611—3614 (1972)

Studies on Amino-hexoses. XV. Synthesis of Deoxy-*N*-acetyl-muramic Acid

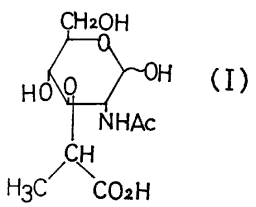
Hitoshi ARITA, Kiyofumi FUKUKAWA, and Yoshio MATSUSHIMA

Department of Chemistry, Osaka University College of Science, Toyonaka

(Received February 9, 1972)

Benzyl 2-acetamido-6-*O*-acetyl-4-chloro-2,4-dideoxy-3-*O*-[D-1-(methyl carboxylate)ethyl]-α-D-galactopyranoside and benzyl 2-acetamido-4,6-dichloro-2,4,6-trideoxy-3-*O*-[D-1-(methyl carboxylate)ethyl]-α-D-galactopyranoside were prepared by the reaction of sulfuryl chloride on *N*-acetyl-muramic acid derivatives. 2-Acetamido-2,4-dideoxy-3-*O*-(D-1-carboxyethyl)-D-xylohexo-pyranose (*N*-acetyl-4-deoxy-muramic acid) and 2-acetamido-2,4,6-trideoxy-3-*O*-(D-1-carboxyethyl)-D-xylohexo-pyranose (*N*-acetyl-4,6-dideoxy-muramic acid) were prepared by the reduction of these chlorodeoxy derivatives with tri-*n*-butyltin hydride.

N-Acetyl-muramic acid (Formula 1), now known to be a constituent of the cell walls of both gram-positive and gram-negative bacteria, was isolated at first as a nucleotide derivative that plays the role of precursor in cell wall biosynthesis.[1] Lindberg and Agback prepared some analogues of muramic acid with variations of the lactic side chain for the purpose of inspecting antibacterial activity.[2] Diana synthesized 6-deoxy analogues of muramic acid for the same purpose.[3] As is well-known, *N*-acetyl-muramic acid is glycosidically bound at C-4 with *N*-acetyl-D-glucomine in the bacterial cell wall mucopeptides, and the



(I)

Formula 1

hydroxyl group at C-4 of muramic acid seems to be indispensable for cell wall biosynthesis. We attempted to prepare 4-deoxy- and 4,6-dideoxy-*N*-acetyl-muramic acid on the basis of the stereospecific synthesis of muramic acid reported by Matsushima and Park.[4] Introduction of chlorodeoxy group at C-4 or C-6 of

2) B. Lindberg and H. Agbach, *Acta Chem. Scand.*, **18**, 185 (1964).

3) G. D. Diana, *J. Org. Chem.*, **35**, 1910 (1970).

4) Y. Matsushima and J. T. Park, *ibid.*, **27**, 3581 (1962).

N-acetyl-muramic acid was performed by the reaction with sulfuryl chloride in pyridine.[8] The chlorodeoxy sugars were successfully reduced by tri-*n*-butyltin hydride and α-α'-azobisisobutyronitrile as an initiator of the radical reaction.

Results and Discussion

The route of the synthesis is shown in the Scheme 1. Intermediate **1** was prepared according to the method of Flowers and Jeanloz.[5] Partial acetylation giving 6-*O*-acetyl compound of **1** was successful, its structure being confirmed by NMR spectrometry. Two methyl signals appeared in the region δ 2.0—2.1, one being assigned as *N*-acetyl (δ 2.03) and the other as 6-*O*-acetyl (δ 2.0). No signal for 4-*O*-acetyl was observed. Complete selectivity of acetylation between C-6 and C-4 may be due to the influence of a lactyl side chain at C-3. We found no such selectivity between primary and secondary hydroxyl groups under the same reaction conditions.[6,7] Treatment of **1** and **2a** with sulfuryl chloride resulted in chlorodeoxy compounds **4a** and **3b**. The chloro groups were introduced most probably through the intermediates **3a** and **2b**. The configuration of the chloro group at C-4 of both **4a** and **3b** was inferred to be galacto-type on the basis of the data presented by Jennings and Jones.[8] Reduction of **4a** with tri-*n*-butyltin hydride proceeded without producing any by-product under mild conditions, but reduction of **3b** required refluxing overnight to complete the reaction. As in the case of reduction of chlorodeoxy neutral sugars, no reaction occurred without co-existence of a small amount of α,α'-azobis-isobutyronitrile.[7] Compounds **5a** and **4b** were deacetylated with sodium hydroxide and debenzylated by catalytic reduction with palladium on charcoal. The structures of the synthetic substances were confirmed by NMR spectrometry. The NMR assignment of compound **5a** is as follows (Fig. 1). Irradiation at δ 1.40 caused the quartet of $CH_3\underline{CH}$-$COOCH_3$ at δ 4.10 to collapse to a singlet. Conversely, irradiation at δ 4.10 caused the doublet at δ 1.40 to collapse to a singlet. Irradiation of H-2 at δ 3.60 caused the doublet of H-1 at δ 5.38 to collapse to a singlet. Integration suggested that H-4e existed in the region δ 1.8-2.3 overlapping the signal of the *N*-acetyl group. Similarly H-4a existed in the region δ 1.2—1.8 overlapping the signal of $\underline{CH_3}$-$CHCOOCH_3$. Furthermore, integration suggested that H-3 and H-5 existed in the region δ 3.7—4.1 overlapping CH_3-$CHCOO\underline{CH_3}$. The spectrum of compound **4b** is shown in Figs. 2 and 3. Irradiation at δ 1.37 caused the quartet of $CH_3\underline{CH}COOCH_3$ at δ 4.10 to collapse to a singlet. Irradiation of H-5 at δ 3.98 caused the doublet of CH_3-5 at δ 1.16 to collapse to a singlet. Irradiation of H-2 at δ 3.65 also caused the doublet of H-1 at δ 5.30 to collapse to a singlet. Integration suggested that H-3 existed in the region δ 3.7—4.1, which overlapped the signal of $CH_3CHCOO\underline{CH_3}$.

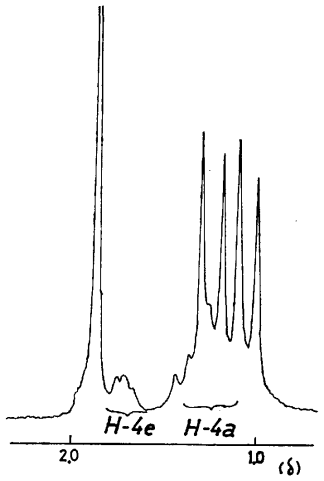

Fig. 3. The NMR spectrum of **4b** in $CDCl_3$+Benzene-d_6.

Integration also suggested that H-4e, H-4a existed in the region δ 1.8—2.3 and δ1.1—1.7 overlapping the signals of C-5 CH_3 and $\underline{CH_3}CHCOOCH_3$, respectively. The assignment of H-4e was confirmed by the addition of benzene-d_6 to the solution of **4b** in $CDCl_3$ (Fig. 3). The signal of H-4e appeared in a higher field.

Experimental

General Methods. All the melting points were uncorrected. Nuclear magnetic resonance spectra were recorded using the specimens dissolved in chloroform-*d* with tetramethylsilane as an internal standard. A Varian T-60 spectrometer was employed. Thin layer chromatagraphy (tlc) was performed with silica gel G (Merck). The spots were detected by spraying with 5% sulfuric acid in methanol and heating at 150°C. Tri-*n*-butyltin hydride was prepared by thermal decomposition of tri-*n*-butyltin formate according to the method of Okawara and Ohara.[9]

*Benzyl 2-Acetamido-2-deoxy-3-O-[D-1-(methyl carboxylate)ethyl]-α-D-glucopyranoside (**1**).* Compound (**1**) was prepared from benzyl 2-acetamido-4,6-*O*-benzylidene-3-*O*-[D-1-methyl carboxylate ethyl]-2-deoxy-α-D-glucopyranoside by treatment in a 80% aqueous acetic acid at 60°C for 2 hr.[5] $[\alpha]_D^{46}$+127° (*c* 1.08, in chloroform)

*Benzyl 2-Acetamido-6-O-acetyl-2-deoxy-3-[D-1-(methyl carboxylate)ethyl]-α-D-glucopyranoside(**2a**).* Compound **1** (13 g) was dissolved in a mixture of anhydrous chloroform (50 m*l*) and pyridine (50 m*l*), and the solution was cooled in a dry ice-acetone bath. Acetic anhydride (3.75 m*l*) was added dropwise to the solution, and the reaction solution was kept at −20°C for 40 hr. A few drops of water was added to destroy residual acetic anhydride and the solution was dried up *in vacuo*. The residual syrup was extracted with chloroform and the extract was washed with water several times. The chloroform layer was dried up *in vacuo* to give a slightly colored syrup (13.5 g), which showed a single spot on tlc with the solvent system *n*-BuOH-EtOH-H_2O (3 : 1 : 1). $[\alpha]_D^{20}$+91.2° (*c* 1.25, in chloroform) NMR (in $CDCl_3$); δ 1.4 (3H d; *J* 7 Hz $\underline{CH_3}CHCOOCH_3$) 2.10 (3H s, OAc) 2.04 (3H s, NAc) 2.34 (1H s, OH) 3.74 (3H s, $-CO_2CH_3$) 5.33 (1H d, *J* 3 Hz H-1) 7.6 (1H d, *J* 5 Hz NH)

*Benzyl 2-Acetamido-6-O-acetyl-4-chloro-2,4-dideoxy-3-O-[D-1-(methylcarboxylate) ethyl]-α-D-galactopyranoside(**4a**).* Compound **2a** (13 g) was dissolved in anhydrous pyridine (30 m*l*) and the solution was cooled in an ice-water bath. Sulfuryl chloride (2.9 m*l*) was added dropwise, and the solution was kept in a refrigerator overnight and then kept at room temperature for 3 hr. The reddish reaction solution was extracted with chloroform and the extract was washed with water several times. Evaporation *in vacuo* gave a syrup which was co-distilled with toluene until residual pyridine was completely removed. Rapid crystallization occurred, and recrystallization with 2-propanol gave colorless needles (8.4 g) which melted at 139—140°C and had $[\alpha]_D^{20}$+182° (*c* 1.0 in chloroform) Found: C, 55.10; H, 6.20; N, 3.12; Cl, 7.59%. Calcd for $C_{21}H_{28}O_8NCl$: C, 55.07; H, 6.16; N, 3.06; Cl, 7.74%. NMR (in $CDCl_3$) δ 1.42 (3H d, *J* 7 Hz $\underline{CH_3}CHCOOCH_3$) 2.0 (3H s, OAc) 2.03 (3H, s, NAc) 3.72 (3H s, $COOCH_3$) 4.0 (1H unresolved. H-2) 4.03 (1H q, *J* 7 Hz $\underline{CH_3}CHCOOCH_3$) 5.43 (1H d, *J* 3 Hz H-1) 7.1 (1H d, *J* 5 Hz NH)

*Benzyl 2-Acetamido-6-O-acetyl-2,4-dideoxy-3-O-[D-1-(methyl carboxylate) ethyl]-α-D-xylohexopyranoside(**5a**).* Six grams of **4a** was dissolved in anhydrous toluene under nitrogen atmosphere. Tri-*n*-butyltin hydride (5 m*l*) and α,α′-azobisisobutyronitrile (10 mg) were added to the solution. The mixture was heated at 80°C under stirring for 2 hr. Evaporation *in vacuo* gave a syrup, which was chromatographed on silica gel column with ethyl acetate-toluene (1 : 1) as an eluant. A colorless syrup (4.5 g) was obtained, which failed to crystallize. The syrup was re-chromatographed on a silica gel column with the same solvent. $[\alpha]_D^{20}$+154° (*c* 1.57 in chloroform) Found: C, 58.71; H, 6.72; N, 3.29%. Calcd for $C_{21}H_{29}O_8N$: C, 59.56; H, 6.90; N, 3.31%. NMR (in $CDCl_3$) δ 1.4 (3H d, *J* 7 Hz $\underline{CH_3}CHCOOCH_3$) *ca.* 1.5 (1H H-4a) *ca.* 2.2 (1H H-4e) 2.01 (3H s, OAc) 2.04 (3H s, NAc) *ca.* 3.6 (1H unresolved H-2) 3.74 (3H s, CO_2CH_3) 4.10 (1H q, *J* 7 Hz $\underline{HC}(CH_3)COOCH_3$) 5.38 (1H d, *J* 3 Hz H-1) 7.1 (1H d, 5 Hz NH)

*2-Acetamido-2,4-dideoxy-3-O-(D-1-carboxyethyl)-D-xylohexopyranose (**7a**).* Two grams of **5a** was dissolved in a mixture of methanol (25 m*l*) and 2N aqueous sodium hydroxide (2 m*l*), and the solution was kept at room temperature for 40 hr. It showed no color reaction of ester,[10] and was neutralized with glacial acetic acid. Reduction with hydrogen over 10% palladium on charcoal was carried out at room temperature. The reduction was complete within 24 hr. Palladium charcoal were filtered off, and the filtrate was passed through a column of Dowex-50X8 (H^+) to remove sodium ion and then dried up *in vacuo* to a colorless syrup (1.2 g), which failed to crystallize. The syrup was further purified on a Bio-gel P-2 column (3.0×200 cm) with 0.02 M acetic acid as an eluant. $[\alpha]_D^{20}$+71° (*c* 1.22 in water) Found: C, 47.32; H, 6.85; N, 4.78%. Calcd for $C_{11}H_{19}O_7N$: C, 47.65; H, 6.91; N, 5.05%. NMR (in D_2O) δ 1.4 (3H d, *J* 7 Hz $\underline{CH_3}COOCH_3$) *ca.* 1.68 (1H H-4a) 2.05 (3H s, NAc) *ca.* 2.3 (1H H-4e) 5.34 (1H d, *J* 3 Hz H-1).

*Benzyl 2-Acetamido-4,6-dichloro-2,4,6-trideoxy-3-O-[D-1-(methyl carboxylate)ethyl]-α-D-galactopyranoside(**3b**).* Four grams of **1** was dissolved in anhydrous pyridine (40 m*l*) and the solution was cooled in an ice-water bath. Sulfuryl chloride (2.0 m*l*) was then added to the solution, which was kept in a refrigerator overnight and then kept at room temperature for 3 hr. The reaction solution was extracted with chloroform and the extract was washed several times with water.

9) R. Okawara and M. Ohara, *J. Organometal. Chem.*, **3**, 484 (1965).

10) N. Abdel-Akher and F. Smith, *J. Amer. Chem. Soc.*, **73**, 5869 (1951).

The chloroform extract was evaporated *in vacuo* to a syrup, which was extracted with toluene–ligroin (3 : 1) several times on a boiling water bath. The extracts were collected and dried up *in vacuo*. Crystals appearing in methanol were recrystallized with the same solvent to give colorless needles (2.5 g) melting at 131—135°C and had $[\alpha]_D^{20}+103°$ (*c* 1.0, in chloroform). Found, C, 52.52, H, 5.69; N, 3.26; Cl, 15.94%. Calcd for $C_{19}H_{25}O_6NCl_2$: C, 52.54; H, 5.80; N, 3.23; Cl, 16.33%.

*Benzyl 2-Acetamido-2,4,6-trideoxy-3-O-[D-1-(methyl carboxylate)ethyl]-α-D-xylohexopyranoside(**4b**).* Two grams of **3b** was dissolved in anhydrous toluene (50 m*l*) under nitrogen atmosphere and tri-*n*-butyltin hydride (3 m*l*) and α,α'-azobisisobutyronitrile (*ca.* 10 mg) were added. The solution was refluxed for 24 hr. The slightly yellow solution was passed through silica gel column with a solvent mixture of ethylacetate and toluene (1 : 1) as an eluant. The syrup obtained was pure as judged by tlc (ethylacetate–toluene 1 : 1), its Beilstein test being negative. $[\alpha]_D^{20}+177°$ (*c* 1.0, in chloroform) Found: C, 63.01; H, 7.38; N, 3.81%. Calcd for $C_{19}H_{27}O_6N$: C, 62.45; H, 7.45; N, 3.83%.

NMR (in $CDCl_3$) δ 1.16 (3H d, *J* 7 Hz CH_3-5) 1.37 (3H d, *J* 7 Hz $\underline{CH_3}CHCOOCH_3$) *ca.* 1.5 (1H H-4a) 2.0 (3H s, NAc) *ca.* 2.1 (1H H-4e) *ca.* 3.65 (1H H-2) 3.73 (3H s, CO_2-CH_3) 4.1 (1H q, *J* 7 Hz $CH_3CHCOOCH_3$) 3.98 (1H q, *J* 7 Hz H-5) 5.31 (1H d, *J* 3 Hz H-1) 7.15 (1H d, *J* 5 Hz NH).

*2-Acetamido-2,4,6-trideoxy-3-O-(D-1-carboxyethyl)-D-glucopyranose (**5b**).* Compound **4b** (800 mg) was dissolved in 10 m*l* of methanol, and 2 N aqueous sodium hydroxide (1 m*l*) was added. The solution was kept at room temperature for 40 hr and then neutralized with glacial acetic acid. Evaporation *in vacuo* gave a syrup which was dissolved in 2-propanol (50 m*l*) and reduced with hydrogen over palladium charcoal at room temperature. The reaction was complete after 24 hr. The charcoal was filtered off and the filtrate dried up *in vacuo*. The residual syrup was dissolved in 3 m*l* of water and the solution was passed through a column of Dowex-50X8 (H^+) to remove sodium ion. Although the product showed a single spot on tlc (BuOH–EtOH–water 3 : 1 : 1), it failed to crystallize. $[\alpha]_D^{20}+63°$ (*c* 1.7, in water) Found: C, 49.75; H, 7.32; N, 5.24%. Calcd for $C_{11}H_{19}O_6N$: C, 50.56; H, 7.33; N, 5.36%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3614—3619 (1972)

Studies on Amino-hexoses. XVI. Synthesis of Deoxy-analogues of *N*-Acetyl-D-glucosamine

Hitoshi ARITA, Kiyofumi FUKUKAWA, and Yoshio MATSUSHIMA

Department of Chemistry, Osaka University College of Science, Toyonaka

(Received May 10, 1972)

For deoxy analogues of *N*-acetyl-D-glucosamine and three deoxy-analogues of phenyl *N*-acetyl-β-D-glucosaminide were synthesized by means of chlorination with sulfuryl chloride and reduction of the chlorides with tri-*n*-butyltin hydride. The free sugars thus obtained failed to crystallize except for 6-deoxy and 4,6-dideoxy compounds. Phenyl glycosides were mostly crystalline. The yield of chlorination and reduction was generally high.

As is well-known, many bacteria contain in their cell walls a polysaccharide composed of alternate *N*-acetyl-D-glucosamine and *N*-acetyl-muramic acid residues.[1] It is a substrate for the bacteriolytic enzymes of various origins among which hen egg white lysozyme is known to bind at its active site the substrate, some of the constituent monosaccharide units of which form hydrogen bondings with appropriate portions of the peptide bonds of the enzyme.[2] For a study of the mode of binding between the enzyme and the substrate, it may be interesting to use deoxy-analogues of the substrate as an inhibitor or a model substrate where the definite position of the saccharide is incapable of forming hydrogen bonding. Deoxy-analogues of *N*-acetyl-D-glucosamine are not known except for 6-deoxy-*N*-acetyl-D-glucosamine which was synthesized by Morel[3] and isolated later by Smith[4] from a bacterial polysaccharide. In the following the syntheses of 3-, 4-, 6-deoxy-, and 4,6-dideoxy-*N*-acetyl-D-glucosamine and phenyl glycosides of the former three compounds are described.

Results and Discussion

The routes of the synthesis are shown in Scheme 1 and 2. Partial acetylation of compound II gave compound III in a good yield, and its structure was confirmed by NMR spectrometry. The NMR spectra showed that one OH group (δ 2.87) and three acetyl groups(δ 1.9—2.2) existed. Threatment of II and III with sulfuryl chloride gave the respective chlorodeoxy derivatives. Jennings and Jones reported that 3-chlorodeoxy derivative could not be prepared by the reaction of sulfuryl chloride with alkyl 4,6-*O*-benzylidene-α-glucoside on account of 1,3-diaxial interaction between C-1 axial alkyl group and chloride ion attacking C-3 from an axial direction.[5] The rule held also for the derivatives of *N*-acetyl-glucosaminide, although it had neiboring *trans* acetamide group. Thus, benzyl 2-acetamido-2-deoxy-β-D-glu-

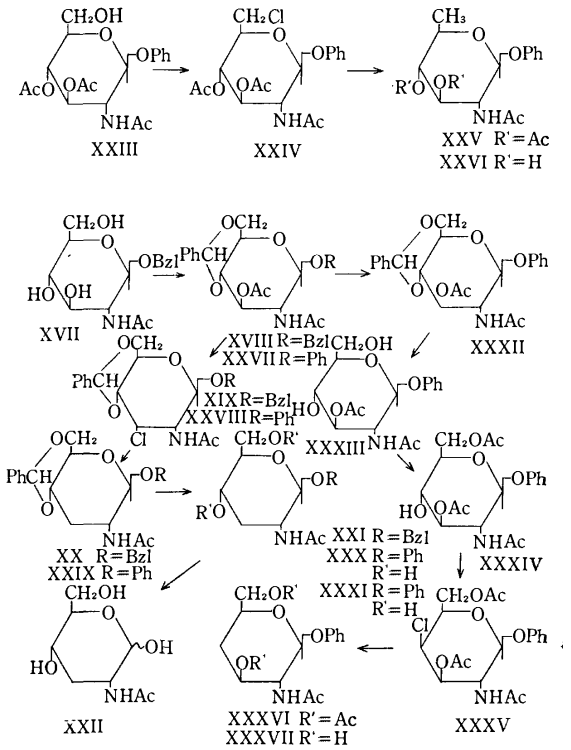

Scheme 2.

copyranoside(XVII) reacted with sulfuryl chloride to give the chlorodeoxy derivative, but benzyl 2-acetamido-2-deoxy-α-D-glucopyranoside did not give the expected product. Hannesian was successful in obtaining 6-bromo-6-deoxy derivative by the cleavage of 4,6-*O*-benzylidene group with *N*-bromosuccinimide (NBS).[6] This reaction was applied for obtaining XIII from I. Reduction of the deoxyhaloderivatives was successfully performed with tri-*n*-butyltin hydride and α,α'-azobisisobutyronitrile(AIBN). Selectivity between primary and secondary halides of the reduction with tri-*n*-butyltin hydride was observed previously.[7] VIII was then selectively reduced at C-4 under appropriate reaction conditions. NMR spectrometry of XII showed that primary halogen was hardly reduced. The structures of the reduced substances were confirmed by NMR spectrometry (Figs. 1 and 2).

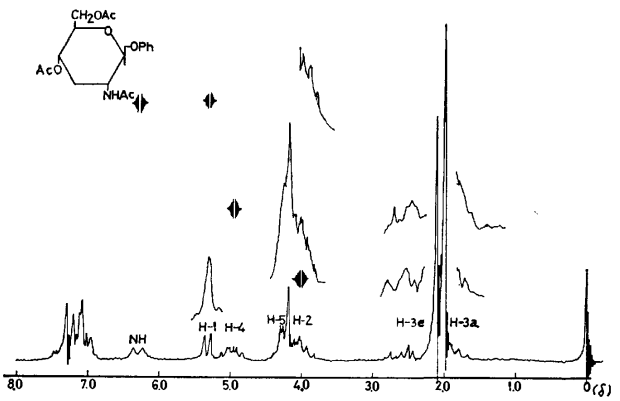

Fig. 1. The NMR spectrum of XXXI in $CDCl_3$.

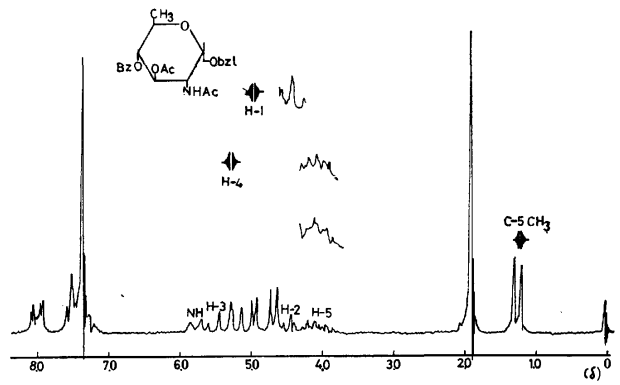

Fig. 2. The NMR spectrum of XIV in $CDCl_3$.

NMR spectra of XIV was assigned as follows. Irradiation at δ 1.20(C-5 CH_3) caused the octet of H-5 at δ 4.10 to collapse to a doublet. Irradiation at δ 5.20(H-4) caused it to collapse to a quartet. Irradiation at δ 4.86(H-1) simplified the region δ 4.35—4.5, which was expected to be H-2 proton signal. NMR spectra of XXXI were assigned as follows. Irradiation at δ 5.0(H-4) simplified the region δ 4.2—4.4 and δ 1.7—2.8. The former was assigned as a H-5 proton signal and the latter as H-3a, H-3e from the irradiation and decoupling data. Irradiation at δ 6.35(NH) and δ 5.35(H-1) simplified the region δ 3.8—4.2, which was expected to be H-2 proton singal. Irradiation at δ 4.10(H-2) caused the doublet of H-1 at δ 5.35 to collapse to a singlet.

Experimental

General Methods. All the melting points were uncorrected. Nuclear magnetic resonance spectra were recorded with a Varian T-60 spectrometer. The specimens were dissolved in chloroform-d with tetramethylsilane as an internal standard. Thin layer chromatography (tlc) was carried out with Silica gel G(Merck). The spots were detected by spraying with 5% sulfuric acid in methanol and heating. As detection of the 3-deoxy derivatives of *N*-acetyl-D-glucosamine could not be made by this method, they were detected on a plate treated with fluorescein(DC-Fertigplatten Kieselgel F 254). Silica gel column chromatography was carried out with silicic acid (100 mesh, Mallinckrodt) with a solvent system toluene-ethyl acetate(1 : 1) as an eluant. Tri-*n*-butyltin hydride was prepared by the thermal decomposition of tri-*n*-butyltin formate.[8]

Benzyl 2-Acetamido-3-O-acetyl-4,6-O-benzylidene-2-deoxy-α-D-glucopyranoside(I) Benzyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside(20 g)[9] was dissolved in a mixture of pyridine(150 m*l*) and acetic anhydride(20 m*l*). The solution was kept at room temperature overnight. The solvent was evaporated *in vacuo*, and the residual pyridine was removed by co-distillation with dry toluene. Crystallization took place in ethanol, and recrystallization in the same solvent gave colorless needles(18.5 g), mp 215—216°C. Found: C, 65.35; H, 6.08; N, 3.24%. Calcd for $C_{24}H_{27}O_7N$: C, 65.29; H, 6.16; N, 3.17%.

Benzyl 2-Acetamido-3-O-acetyl-2-deoxy-α-D-glucopyranoside(II). Compound I (16.0 g) was dissolved in 80% aqueous acetic acid (600 m*l*) and the solution was kept at 65—70°C for 2 hr. Evaporation of the solvent *in vacuo* gave a syrup. The residual solvent in the syrup was co-distilled several times with dry toluene. The crystals appeared in toluene (9.0 g), mp 113—116°C. Found: C, 57.79; H, 6.51; N, 3.96%. Calcd for $C_{17}H_{23}O_7N$: C, 57.78; H, 6.56; N, 3.93%.

Benzyl 2-Acetamido-3,6-di-O-acetyl-2-deoxy-α-D-glucopyranoside (III) Compound II (15.0 g) was dissolved in a mixture of pyridine(30 m*l*) and chloroform(50 m*l*). The solution was cooled in a dry ice-acetone bath, and acetic anhydride (2.7 m*l*) was added to the solution. The reaction was continued at −20°C for 48 hr. Evaporation *in vacuo* gave a syrup which was subsequently passed through a column of silica gel. The fractions which contained compound III were collected and dried *in vacuo* to give a syrupy product (9.8 g). $[\alpha]_D^{20}$+80° (*c* 1.0, chloroform) Found: C, 59.12; H, 6.42; N, 3.43%. Calcd for $C_{19}H_{25}O_8N$: C, 57.71; H, 6.37; N, 3.54%. NMR (in $CDCl_3$) δ2.87(1H, s, OH) 4.92 (1H, d, *J* 3Hz H-1) 5.85 (1H d, *J* 8Hz NH) 2.12 (3H s, NAc) 1.98(3H s, 3-O-Ac) 2.08(3H s, 6-O-Ac)

Benzyl 2-Acetamido-3,6-di-O-acetyl-4-chloro-2,4-dideoxy-α-D-galactopyranoside(IV). Compound III (9.4 g) was dissolved in pyridine (50 m*l*) and the solution was cooled in an ice-water bath. Sulfuryl chloride(2.4 m*l*) was then added to the solution, and the mixture was kept in a refrigerator overnight and then kept at room temperature for 3 hr. Excess solvent was removed by evaporation *in vacuo*, and the residue was extracted with chloroform and the extract was washed with water several times. The chloroform layer was collected and dried *in vacuo* to a syrup which crystallized in toluene. Recrystallization in the same solvent gave colorless crystals(5.5 g); mp 132—133°C, $[\alpha]_D^{20}$+159° (*c* 1.03, chloroform). Found: C, 55.32; H, 5.85; N, 3.38; Cl, 8.76%. Calcd for $C_{19}H_{24}O_7NCl$: C, 55.14; H, 5.85; N, 3.38; Cl, 8.57%.

Benzyl 2-Acetamido-3,6-di-O-acetyl-2,4-dideoxy-α-D-xylohexopyranoside(V) Compound IV (2.5 g) was dissolved in dry toluene(30 m*l*) under nitrogen atmosphere. To this solution were added tri-*n*-butyltin hydride(3.0 m*l*) and AIBN (*ca.* 30 mg). The reaction was continued for 2 hr at 80—90°C under stirring. The solution was dried *in vacuo* to give a syrup, which was passed through a column of silica gel with a solvent system (toluene-ethyl acetate 1 : 1) as an eluant. The product was crystallized in ethanol. Recrystallization in the same solvent gave needles(1.9 g); mp 105—107°C, $[\alpha]_D^{20}$+101° (*c* 0.87, chloroform). Found: C, 59.80; H, 6.59; N, 3.63%. Calcd for $C_{15}H_{21}O_5N$: C, 60.14; H, 6.64; N, 3.63%. NMR (in $CDCl_3$) δ4.93 (1H d, *J* 3 Hz H-1) 5.70 (1H d, NH) 1.4—2.1(H-4a,e) 2.05 (3H s, NAc) 1.95 (3H s, 6-OAc) 1.84(3H s, 3-OAc).

Benzyl 2-Acetamido-2,4-dideoxy-α-D-xylohexopyranoside (VI). Compound V(1.23 g) was deacetylated with 0.1 M sodium methoxide in methanol, and the solution was treated with Dowex 50×8 (H^+) to remove sodium ion. Evaporation of methanol *in vacuo* gave crystals, which were recrystallized in ethanol giving 700 mg of a colorless specimen. Mp 170.5—171°C. Found: C, 60.87; H, 7.16; N, 4.68%. Calcd for $C_{15}H_{21}O_5N$: C, 61.00; H, 7.17; N, 4.74%.

2-Acetamido-2,4-dideoxy-D-xylohexopyranose (VII). Compound VI (650 mg) was dissolved in ethanol (50 m*l*) and 10% palladium on charcoal (2.0 g) was added to the solution. Hydrogen was passed through the solution for three days at room temperature. The charcoal was filtered off, and the filtrate was dried *in vacuo* to give 300 mg of a syrup which did not crystallize. $[\alpha]_D^{20}$+78° (*c* 1.58, water). Found: C, 46.71; H, 7.43; N, 6.57%. Calcd for $C_8H_{15}O_5N$: C, 46.82; H, 7.37; N, 6.83%.

Benzyl 2-Acetamido-3-O-acetyl-4,6-dichloro-2,4,6-trideoxy-α-D-galactopyranoside (VIII). Compound II (4.0 g) was dissolved in pyridine (30 m*l*) and the solution was cooled in an ice-water bath. Sulfuryl chloride(2.3 m*l*) was then added dropwise to the solution. The reaction solution was kept in a refrigerator overnight and then kept at room temperature for 3 hr. Excess pyridine was removed by evaporation. The residue was extracted with chloroform and the extract washed with water several times. The chloroform layer was dried *in vacuo*. The residue was extracted with boiling toluene several times, and the extracts were dried *in vacuo*. Recrystallization in ethanol gave colorless needles(2.8 g); mp 158—160°C, $[\alpha]_D^{20}$+128° (*c* 1.0, chloroform). Found: C, 52.49; H, 5.44; N, 3.61; Cl, 18.13%. Calcd for $C_{17}H_{21}O_5NCl_2$: C, 52.32; H, 5.42; N, 3.59; Cl, 18.17%. NMR (in $CDCl_3$) δ4.93 (1H, d, *J* 3 Hz H-1)) 5.70 (1H d, NH) 2.05 (3H s, NAc) 1.87 (3H s, 3-O-Ac)

Benzyl 2-Acetamido-3-O-acetyl-2,4,6-trideoxy-α-D-xylohexopyranoside (IX). Compound VIII (1.8 g) was dissolved in dry toluene (30 m*l*) under nitrogen atmosphere. To this solution was added tri-*n*-butyltin hydride (2.0 m*l*) and AIBN (*ca.* 20 mg). The reaction mixture was refluxed for 24 hr. The solution was then dried *in vacuo*. The residual sirup was dissolved in ligroin (10 m*l*) and the solution was kept in a refrigerator overnight. Crystals were obtained and washed with cold ligroin and recrystallized in the same solvent giving 1.5 g of the specimen. Mp 122—123°C, $[\alpha]_D^{20}$+106° (*c* 1.15, chloroform). Found: C, 62.18; H, 7.06; N, 4.29%. Calcd for $C_{17}H_{23}O_5N$: C, 63.53; H, 7.21; N, 4.36%. NMR (in $CDCl_3$) δ4.93 (1H d, *J* 3 Hz H-1) 1.75—2.2 (1H H-4e) 1.3—1.6 (1H H-4a) 3.7—4.1 (1H m, H-5) 5.83 (1H d, NH) 2.0 (3H s, NAc) 1.9 (3H 3-O-Ac) 1.28 (3H d, *J* 6 Hz CH_3-5).

Benzyl 2-Acetamido-2,4,6-trideoxy-D-xylohexopyranoside (X). Compound IX (500 mg) was deacetylated with *ca.* 0.1 M sodium methoxide in methanol by the same manner as described for VI. Recrystallization in ethanol gave colorless crystals; mp 183—185°C, $[\alpha]_D^{20}+107°$ (*c* 1.03, methanol). Found: C, 63.96; H, 7.56; N, 4.98%. Calcd for $C_{15}H_{24}O_4N$: C, 64.49; H, 7.58; N, 5.01%.

2-Acetamido-2,4,6-trideoxy-xylohexopyranose (XI). Compound X (300 mg) in 2-propanol (50 ml) was reduced with hydrogen over 10% palladium on charcoal (1.5 g) at room temperature. The reaction was complete within 20 hr and charcoal was filtered off, the filtrate being dried *in vacuo*. Crystallization took place in ethanol-ethyl acetate, and recrystallization in the same solvent gave colorless needles; mp 147—150°C, $[\alpha]_D^{20}+88°$ (*c* 0.43, water). Found: C, 47.17; H, 8.07; N, 6.82%. Calcd for $C_8H_{15}O_4N\cdot H_2O$: C, 46.37; H, 8.27; N, 6.76%.

Benzyl 2-Acetamido-3-O-acetyl-6-chloro-2,4,6-trideoxy-α-D-xylohexopyranoside (XII). Compound VIII (1.3 g) was dissolved in dry toluene (30 ml) under nitrogen atmosphere, and to the solution were added tri-*n*-butyltin hydride (1 ml) and AIBN. The reaction was continued for 1 hr at 80—90°C under stirring. Evaporation *in vacuo* gave a product which was washed with cold ligroin several times. Recrystallization in ethanol gave colorless needles (800 mg); mp 121—126°C, $[\alpha]_D^{20}+136°$ (*c* 1.0, chloroform). Found: C, 58.27; H, 6.32; N, 4.04; Cl, 8.83%. Calcd for $C_{17}H_{22}O_5NCl$: C, 57.55; H, 6.25; N, 3.95; Cl, 9.71%.

Benzyl 2-Acetamido-3-O-acetyl-4-O-benzoyl-6-bromo-2,6-dideoxy-α-D-glucopyranoside (XIII). Compound I (5.0 g) was dissolved in a mixture of carbon tetrachloride (100 ml) and tetrachloroethane (40 ml). To this solution were added NBS (2.25 g) and barium carbonate (10 g). The reaction mixture was refluxed for 1.5 hr. Insoluble substances were filtered off, the brown filtrate was extracted with chloroform and the extract washed with water several times. The solvent was evaporated *in vacuo* to a syrup. The product was found in tlc to be contaminated with the starting material (compound I). The syrup was thus treated with 80% aqueous acetic acid at 70°C for 2 hr to remove benzylidene group from the remaining compound I. Evaporation *in vacuo* gave a syrup, which was subsequently placed on a silica gel column and eluated with a solvent system (ethyl-acetate–toluene 1 : 1). The product (1.4 g) did not crystallize, although it was shown on tlc to be highly pure. $[\alpha]_D^{20}+27°$ (*c* 0.99, chloroform). Found: C, 55.77; H, 5.26; Br, 13.71%. Calcd for $C_{24}H_{26}O_7NBr$: C, 55.41; H, 5.04; Br, 15.36%.

Benzyl 2-Acetamido-3-O-acetyl-4-O-benzoyl-2,6-dideoxy-α-D-glucopyranoside (XIV). Compound XIII (800 mg) was dissolved in dry toluene under nitrogen atmosphere, and to this solution were added tri-*n*-butyltin hydride (1 ml) and AIBN (*ca.* 20 mg). The reaction mixture was refluxed overnight, and the solution was dried in vacuo. The residual syrup was dissolved in ligroin (5 ml) and the solution was kept in a refrigerator overnight. Crystals were obtained and were washed with cold ligroin several times. Purity of the crystals did not improve by recrystallization, and they were subjected to silica gel column chromatography. Colorless crystals were obtained (440 mg); mp 144—146°C, $[\alpha]_D^{20}+57°$ (*c* 0.90, chloroform). Found: C, 65.49; H, 6.23; N, 3.23%. Calcd for $C_{24}H_{27}O_7N$: C, 65.29; H, 6.16; N, 3.17%. NMR (in $CDCl_3$) δ 4.86 (1H d, *J* 3 Hz H-1) 4.3—4.5 (1H unresolved H-2) 5.4 (1H unresolved H-3) 5.3 (H-4) 4.1 (H-5) 1.20 (3H d, *J* 6 Hz CH_3-5) 1.88 (3H s, NAc) 1.88 (3H s, 3-OAc) 5.78 (1H d, NH)

2-Acetamido-2,6-dideoxy-glucopyranose (XVI). Compound XIV (400 mg) was treated with *ca.* 0.1 M sodium methoxide in methanol, and the solution was neutralized with acetic acid. Ten percent palladium on charcoal (1.0 g) was added to this solution, and hydrogen was led in for 24 hr at room temperature. The charcoal was filtered off, and the filtrate was passed through a column of Dowex 50X 8 (H^+). The eluant was dried *in vacuo*, and the residue crystallized immediately; mp 207—210°C, $[\alpha]_D^{20}+26.4°$ (*c* 1.0, water). Found: C, 47.01; H, 7.42; N, 6.76%. Calcd for $C_8H_{15}O_5N$: C, 46.82; H, 7.37; N, 6.83%. NMR (in D_2O) δ5.05 (1H d, *J* 3 Hz H-1) 1.25 (3H d, *J* 6 Hz CH_3-5) 2.0 (3H s, NAc)

Benzyl 2-Acetamido-2-Deoxy-β-D-glucopyranoside (XVII).[10] Pentaacetyl glucosamine (20.0 g) was dissolved in glacial acetic acid saturated with HBr (100 ml) and the solution was kept at room temperature overnight under stirring. The solution was extracted with chloroform and the extract was washed with water and aqueous sodium bicarbonate several times.[11] The chloroform layer was dried over sodium sulfate. To this solution was added benzyl alcohol (15 ml), Drierite (20 g) and silver carbonate (15 g), and the mixture was kept at room temperature in the dark under vigorous stirring. The insoluble substances were filtered off, and the filtrate was dried *in vacuo* to a syrup. Crystallization took place in ethanol. Recrystallization in the same solvent gave colorless needles (12.5 g); mp 162—164°C, $[\alpha]_D^{20}-54°$ (*c* 1.23, chloroform). The specimen was subsequently deacetylated with *ca.* 0.1 M sodium methoxide in methanol. Recrystallization in 2-propanol gave colorless needles (6.5 g); mp 191—192°C $[\alpha]_D^{20}-29°$ (*c* 0.93, water). Found: C, 57.83; H, 6.80; N, 4.52%. Calcd for $C_{15}H_{21}O_6N$: C, 57.86; H, 6.80; N, 4.50%.

Benzyl 2-Acetamido-4,6-O-benzylidene-2-deoxy-β-D-glucopyranoside (XVIII). Compound XVII (6.5 g) was mixed with benzaldehyde (50 ml). To this was added zinc chloride (6.5 g), and the mixture was shaken at room temperature overnight. The homogeneous solution thus obtained was poured into ice-water and the precipitates were washed with water and ligroin several times. Recrystallization in ethanol gave a crystalline product (6.7 g) which decomposed over 200°C. Found: C, 63.13; H, 6.64; N, 3.59%. Calcd for $C_{22}H_{25}O_6N$: C, 66.15; H, 6.31; N, 3.51%. Though the specimen was crystalline, its benzylidene residue gradually split for some unknown reason even in the solid state. As a result the analytical value of carbon was far less than the theoretical one.

Benzyl 2-Acetamido-3-chloro-4,6-O-benzylidene-2,3-dideoxy-β-D-allopyranoside (XIX). Compound XVIII (6.0 g) was dissolved in pyridine (150 ml) and the solution was cooled in an ice-water bath. Sulfuryl chloride (1.6 ml) was added to the solution, and the reaction mixture was kept in a refrigerator for 2 hr and then at room temperature overnight. Excess pyridine was removed by evaporation. The residue was extracted with chloroform and the extract was washed with water several times. The chloroform layer was dried *in vacuo* to a syrup, which was immediately crystallized in ethanol. Recrystallization in the same solvent gave colorless crystals (2.0 g); mp 205°C (decomp.), $[\alpha]_D^{20}-87°$ (*c* 0.87, chloroform). Found: C, 63.38; H, 5.85; N, 3.39; Cl, 8.17%. Calcd for $C_{22}H_{24}O_5NCl$: C, 63.23; H, 5.79; N, 3.35; Cl, 8.48%.

Benzyl 2-Acetamido-4,6-O-benzylidene-2,3-dideoxy-β-D-ribo-hexopyranoside (XX). Compound XIX (700 mg) was dissolved in dry toluene under nitrogen atmosphere. To this solution were added tri-*n*-butyltin hydride (1.0 ml) and

AIBN (*ca.* 20 mg). The reaction was complete within 15 min, and the product obtained immediately as white needles was collected and washed with ligroin several times. Recrystallization in methanol gave colorless needles (620 mg); mp 246°C (decomp.) Found: C, 68.73; H, 6.59; N, 3.72%. Calcd for $C_{22}H_{25}O_5N$: C, 68.91; H, 6.57; N, 3.65%.

2-Acetamido-2,3-dideoxy-ribohexopyranose (XXII). Compound XX (50 mg) was dissolved in 80% aqueous acetic acid (300 ml) and the solution was kept at 65—70°C for 2 hr. The clear solution was evaporated *in vacuo* to a syrup, which was dissolved in cold water (5 ml). Insoluble substances were filtered off. To the filtrate was added 10% palladium on charcoal (1.5 g) and hydrogen was passed into the solution at room temperature. The reduction was complete within 24 hr, and charcoal was removed. The filtrate was dried *in vacuo* to a syrup, which did not crystallize. $[\alpha]_D^{20}$ −6.5° (*c* 2.15, H_2O). Found: C, 45.36; H, 7.32; N, 6.73; Calcd for $C_8H_{15}O_5N$: C, 46.82; H, 7.37; N, 6.83.

Phenyl 2-Acetamido-3,4-di-O-acetyl-2-deoxy-β-D-glucopyranoside (XXIII). Compound XXIII was prepared from phenyl 2-acetamido-6-*O*-trityl-3,4-di-*O*-acetyl-2-deoxy-β-D-glucopyranoside according to the method of Mega *et al.*[12] Mp 228—229°C $[\alpha]_D$ −10.8° (*c* 0.5, chloroform).

Phenyl 2-Acetamido-3,4-di-O-acetyl-6-chloro-2,6-dideoxy-β-D-glucopyranoside (XXIV). Compound XXIII (2.0 g) was dissolved in pyridine (20 ml) and the solution was cooled in an ice-water bath. To this solution was added sulfuryl chloride (0.56 ml) and the reaction mixture was kept in a refrigerator overnight and then at room temperature for 3 hr. Excess pyridine was removed by evaporation *in vacuo*, and the residue was extracted with chloroform and the extract washed with water several times. Chloroform layer was dried *in vacuo* to a syrup. The syrup crystallized in ethanol, and recrystallization in the same solvent gave colorless needles; (800 mg); mp 190°C (decomp.), $[\alpha]_D^{20}$ −15° (*c* 0.93, chloroform). Found: C, 53.55; H, 5.55; N, 3.53; Cl, 8.71%. Calcd for $C_{18}H_{22}O_7NCl$: C, 54.07; H, 5.55; N, 3.50; Cl, 8.87%.

Phenyl 2-Acetamido-3,4-di-O-acetyl-2,6-dideoxy-β-D-glucopyranoside (XXV). Compound XXIV (750 mg) was dissolved in dry toluene (50 ml). To this were added tri-*n*-butyltin hydride (0.8 ml) and AIBN (*ca.* 20 mg). The reaction was continued overnight at 80—90°C with stirring. The solvent was evaporated *in vacuo* to a syrup, which crystallized immediately. Recrystallization in ethanol gave a colorless product (700 mg); mp 200°C (decomp.), $[\alpha]_D^{20}$ +48° (*c* 1.03, chloroform). Found: C, 58.08; H, 6.23; N, 3.68%. Calcd for $C_{18}H_{23}O_7N$: C, 59.18; H, 6.33; N, 3.83%.

Phenyl 2-Acetamido-2,6-dideoxy-β-D-glucopyranoside (XXVI). Compound XXV (510 mg) was deacetylated with sodium methoxide by the same method as described for VI. Recrystallization in 2-propanol gave colorless needles (1.34 mg); mp 210°C (decomp.), $[\alpha]_D^{20}$ −16° (*c* 0.7, methanol). Found: C, 58.31; H, 6.53; N, 4.96%. Calcd for $C_{14}H_{19}O_5N$: C, 58.77; H, 6.81; N, 4.98%.

Phenyl 2-Acetamido-4,6-O-benzylidene-2-deoxy-β-D-glucopyranoside (XXVII).[13] Phenyl 2-acetamido-2-deoxy-β-D-glucopyranoside (5.0 g)[14] was reacted with benzaldehyde (30 ml) and zinc chloride (5.0 g) at room temperature overnight. The solution was poured into ice-water and the precipitates were washed with water and ligroin several times. Recrystallization in ethanol gave colorless needles (5.5 g) which decomposed at 250°C. Found: C, 65.32; H, 6.00; N, 3.61%. Calcd for $C_{21}H_{23}O_6N$: C, 65.44; H, 6.02; N, 3.63%.

Phenyl 2-Acetamido-3-chloro-4,6-O-benzylidene-2,3-dideoxy-β-D-allopyranoside (XXVIII). Compound XXVII (4.0 g) was dissolved in pyridine (150 ml). To this solution was added sulfuryl chloride (1.0 ml) under cooling in an ice-water bath. The reaction solution was kept in a refrigerator overnight and then at room temperature for 10 hr. The solvent was removed by evaporation *in vacuo* and the residue was extracted with chloroform and the extract washed with water several times. The chloroform layer was separated and dried *in vacuo*, and the residue was crystallized in methanol–water (4 : 1). Recrystallization in the same solvent mixture gave colorless needles (1.2 g); mp 184°C (decomp.), $[\alpha]_D^{20}$ −24° (*c* 1.0, chloroform). Found: C, 62.20; H, 5.50; N, 3.49; Cl, 8.85. Calcd for $C_{21}H_{22}O_5NCl$: C, 62.45; H, 5.49; N, 3.47; Cl, 8.87.

Phenyl 2-Acetamido-4,6-O-benzylidene-2,3-dideoxy-β-D-ribohexopyranoside (XXIX). Compound XXVIII (516 mg) was dissolved in dry toluene (100 ml). To the solution were added tri-*n*-butyltin hydride (0.5 ml) and AIBN (*ca.* 20 mg) at 90°C under stirring. The reaction was complete within 10 min. White precipitates were obtained and were filtered off and washed with ligroin several times. Recrystallization in methanol gave colorless needles (476 mg); mp 250°C. Found: C, 67.46; H, 6.24; N, 3.75%. Calcd for $C_{21}H_{23}O_5N$: C, 68.28; H, 6.28; N, 3.79%.

Phenyl 2-Acetamido-2,3-dideoxy-β-D-ribohexopyranoside (XXX). Compound XXIX (470 mg) was dissolved in 80% aqueous acetic acid (300 ml) and the solution was kept at 65—70°C for 2 hr. The solution was evaporated *in vacuo*, and the residual syrup was dissolved in water (5 ml). Insoluble substances were removed by filtration, and the filtrate was dried *in vacuo*. Crystallization took place in 2-propanol. Recrystallization in the same solvent gave colorless needles (170 mg); mp 178—180°C, $[\alpha]_D^{20}$ −33° (*c* 0.8, methanol). Found: C, 59.06; H, 6.80; N, 4.91%. Calcd for $C_{14}H_{19}O_5N$: C, 59.77; H, 6.81; N, 4.98%.

Phenyl 2-Acetamido-4,6-di-O-acetyl-2,3-dideoxy-β-D-ribohexopyranoside (XXXI). Compound XXX (50 mg) was dissolved in a mixture of pyridine (5.0 ml) and acetic anhydride (2.5 ml), and the solution was kept at room temperature overnight. Evaporation *in vacuo* gave a syrup, and the contaminating reagents were co-distilled with toluene. Crystallization took place in ethanol. Recrystallization in the same solvent gave colorless needles (43 mg); mp 138—139°C. Found: C, 58.62; H, 6.33; N, 3.89%. Calcd for $C_{18}H_{23}O_7N$: C, 59.18; H, 6.33; N, 3.83%. NMR (in $CDCl_3$) δ5.32 (1H d, *J* 7 Hz H-1) 4.00 (1H unresolved H-2) 2.50 (1H unresolved H-3e) 1.80 (1H unresolved H-3a) 4.95 (1H octet H-4) 2.15 (3H s, NAc) 2.00 (6H s, OAc) 6.25 (1H d, NH).

Phenyl 2-Acetamido-3-O-acetyl-4,6-O-benzylidene-2-deoxy-β-D-glucopyranoside (XXXII). Compound XXVII (5.0 g) was acetylated with acetic anhydride (10 ml) in pyridine (200 ml). Recrystallization in ethanol gave colorless needles (5.0 g). Found: C, 63.91; H, 5.71; N, 3.27%. Calcd for $C_{23}H_{25}O_7N$: C, 64.62; H, 5.90; N, 3.28%.

Phenyl 2-Acetamido-3-O-acetyl-2-deoxy-β-D-glucopyranoside (XXXIII). Compound XXXII (5.0 g) was dissolved in hot glacial acetic acid (500 ml). To this solution was added water (100 ml) dropwise under shaking in a water bath kept at 65°C. The reaction was continued for 2 hr at 65—70°C. Evaporation of the solvent *in vacuo* gave crystals which were washed with ether several times. Recrystallization in ether gave white powder (3.5 g). Found: C, 56.53; H, 6.21; N, 4.10%. Calcd for $C_{16}H_{21}O_7N$: C,

56.63; H, 6.24; N, 4.13%.

Phenyl 2-Acetamido-3,6-di-O-acetyl-2-deoxy-β-D-glucopyranoside (XXXIV). Compound XXXIII (3.0 g) was dissolved in a mixture of pyridine (20 ml) and chloroform (10 ml), and the solution was cooled in a dry ice-acetone bath. Acetic anhydride (0.93 ml) was then added to the solution, and the reaction mixture was kept at −20°C for 48 hr. The solvent was evaporated *in vacuo*, and the residual syrup was crystallized in 2-propanol. Recrystallization in the same solvent gave colorless crystals (2.2 g); mp 180—185°C, $[\alpha]_D^{20}$ −22° (*c* 1.2, chloroform). Found: C, 56.59; H, 6.30; N, 3.62%. Calcd for $C_{18}H_{23}O_8N$: C, 56.68; H, 6.08; N, 3.67%.

Phenyl 2-Acetamido-3,6-di-O-acetyl-4-chloro-2,4-dideoxy-β-D-galactopyranoside (XXXV). Compound XXXIV (1.5 g) was dissolved in pyridine (20 ml). To this solution was added sulfuryl chloride (0.45 ml). The reaction solution was kept in a refrigerator overnight and then at room temperature for 3 hr. Excess pyridine was removed by evaporation *in vacuo*, and the residue was extracted with chloroform and the extract was washed with water several times. Chloroform was evaporated *in vacuo*. Crystals appeared in 2-propanol, and recrystallization in the same solvent gave colorless needles (1.1 g); mp 216°C (decomp.), $[\alpha]_D^{20}$ +21° (*c* 1.25, chloroform). Found: C, 54.05; H, 5.53; N, 3.54; Cl, 9.22. Calcd for $C_{18}H_{22}O_7NCl$: C, 54.07; H, 5.54; N, 3.50; Cl, 8.87.

Phenyl 2-Acetamido-3,6-di-O-acetyl-2,4-dideoxy-β-D-xylohexopyranoside (XXXVI). Compound XXXV (500 mg) was dissolved in toluene (20 ml) and reacted with tri-*n*-butyltin hydride (0.5 ml) in the presence of AIBN (*ca.* 20 mg) at 80—90°C for 2 hr. Crystals were obtained on evaporation of the solvent *in vacuo*. Recrystallization in 2-propanol gave colorless needles (300 mg); mp 168.5—170°C, $[\alpha]_D^{20}$ −47° (*c* 0.57, chloroform). Found: C, 59.07; H, 6.29; N, 3.92%. Calcd for $C_{18}H_{23}O_7N$: C, 59.17; H, 6.34; N, 3.83%.

Phenyl 2-Acetamido-2,4-dideoxy-β-D-xylohexopyranoside (XXXVII). Compound XXXVI (200 mg) was deacetylated with sodium methoxide in methanol. Recrystallization in water gave colorless needles (80 mg); mp 201—203°C, $[\alpha]_D^{18}$ −6.5° (*c* 0.65, water). Found: C, 59.71; H, 6.78; N, 4.92%. Calcd for $C_{14}H_{19}O_5N$: C, 59.77; H, 6.81; N, 4.98%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3619—3624 (1972)

Studies on Aminosugars. XXXI. Synthesis of 3,4-Dideoxy-3-enosides and the Corresponding 3,4-Dideoxysugars[1)]

Sumio UMEZAWA, Yasushi OKAZAKI, and Tsutomu TSUCHIYA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi-cho, Kohoku-ku, Yokohama

(Received May 11, 1972)

As model experiments to prepare unsaturated and deoxy variants of complex aminoglycosidic antibiotics, methyl 3,4-dideoxy-α-D-*erythro*-hexopyranoside (**8**) and methyl 2,6-diamino-2,3,4,6-tetradeoxy-α-D-*erythro*-hexopyranoside (**15**) have been synthesized through the corresponding 3,4-unsaturated glycosides (**6**, **12**), which were prepared from the corresponding 3,4-di-*O*-mesyl derivatives (**5**, **11**) by treatment with sodium iodide and zinc dust in high yields. These are rare examples of 3,4-dideoxy and 3,4-unsaturated sugars.

Unsaturated sugars are drawing attention in recent years from biological point of view. However, 3,4-unsaturated sugars were rarely reported. Recently, we described the synthesis of 3′,4′-dideoxykanamycin B[2)] which is active against drug-resistant bacteria, by utilizing a 3,4-unsaturated intermediate. The present synthesis was undertaken as a fundamental experiment to see if a practical method could be worked out for converting aminoglycosidic antibiotics into their unsaturated and dehydroxylated derivatives.

Cyclic sugars having one double bond and no substituents on the unsaturated carbons can be classified into four groups, namely, 1,2- (glycals), 2,3-, 3,4- (in pyranoses) and 5,6-double bonded (in furanoses) sugars. Among them, glycals are most popular and 2,3-dideoxy-2-enoses are prepared mostly by the double bond migration of glycals. Terminal 5-enoses are also prepared fairly easily from mother sugars by applying the methods adopted to open-chain sugars. In order to introduce 2,3-unsaturation into cyclic sugars 2,3-epoxide,[3)] 2,3-episulfide,[4)] 2,3-epimine,[5)] 2,3-iodotosylates,[6)] azidotosylate,[7)] 2,3-iodoacetates,[8)] 2,3-iodohydrin,[9)] 2,3-carbonate,[10)] 2,3-thionocarbonate,[11)] 2,3-disulfonates[11)] and compounds having a deoxy group at 2 or 3 position[12)] are utilized as an intermediate.

As for the examples of 3,4-unsaturated sugars, Bock and Pedersen[13] prepared a 3,4-dideoxy-3-enopyranoside by reduction of the corresponding 3,4-dideoxy-3-eno-2-keto precursor which was prepared by double bond migration of a glycal. Ferrier and Vethaviyaser[14] prepared 3,4-dideoxy-3-enopyranosides by 1,3-azido or 1,3-thiocyano migration of the corresponding 2,3-unsaturated precursors. Hains[15] prepared benzyl 2-*O*-benzyl-3,4-dideoxy-3-eno-α-D-*glycero*-pentoside from benzyl 2-*O*-benzyl-β-L-arabinopyranoside 3,4-thionocarbonate by utilizing Corey-Winter method.[16] In this paper, we wish to describe the syntheses of the 2,6-di-*O*-benzoyl derivative (**6**) of methyl 3,4-dideoxy-α-D-*erythro*-hex-3-enopyranoside, methyl 2,6-diamino-2,3,4,6-tetradeoxy-α-D-*erythro*-hex-3-enopyranoside (**13**) and their hydrogenation products, namely, methyl 3,4-dideoxy-α-D-*erythro*-hexopyranoside (**8**) and methyl 2,6-diamino-2,3,4,6-tetradeoxy-α-D-*erythro*-hexopyranoside (**15**).

We intended to prepare some unsaturated and deoxy derivatives of 2,6-diamino-2,6-dideoxy-D-glycose because an appreciable number of useful antibiotics (kanamycin B,[17] neomycin B, C, vistamycin, butyrosin A, B *etc.*) contain the sugar as one of their constituents. Since the deoxy derivatives of aminosugars are rarely known, we initiated the synthesis of an unsaturated derivative of methyl α-D-galactopyranoside (**1**) as a model experiment, taking into consideration the presence of 3,4-*cis*-diol group in it.

Methyl 3,4-*O*-isopropylidene-α-D-galactopyranoside (**2**) prepared from **1** in a high yield was benzoylated and the isopropylidene group of the di-*O*-benzoyl derivative (**3**) was removed by 75% acetic acid to yield methyl 2,6-di-*O*-benzoyl-α-D-galactopyranoside (**4**) quantitatively.

Tipson-Cohen method,[18] which utilized vicinal disulfonic ester groups for making an unsaturated bond was then applied to this product, because the method had been proved to be applicable to cyclic sugars having *trans*-diequatorial sulfonyloxy groups by Horton *et al.*[11] Mesylation of **4**, giving a di-*O*-mesyl derivative (**5**) was followed by treatment with sodium iodide and zinc dust at 130—150°C for 1.5 hr in DMF to give a 3,4-unsaturated derivative, namely, methyl 2,6-di-*O*-benzoyl-3,4-dideoxy-α-D-*erythro*-hex-3-enopyranoside (**6**) in a yield of 93%, syrup, $[\alpha]_D^{22}$ −17.3° (*c* 1, chloroform). The high yield is noteworthy in contrast with that (~50%) from[11] methyl 4,6-*O*-benzylidene-2,3-di-*O*-sulfonyl-α-D-glucopyranosides, and may suggest that the initial nucleophilic attack of iodide ion might occur at C-4 of **5** much more easily[19] than that at C-3 or C-2 of the above-mentioned sugar

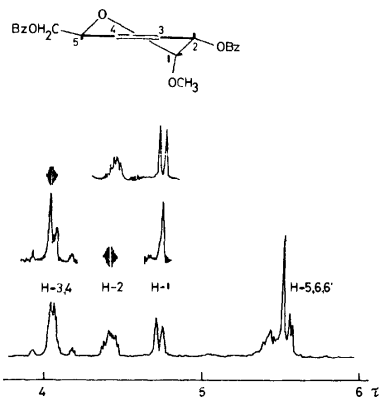

Fig. 1. The NMR spectrum of **6** in $CDCl_3$ at 100 MHz.

derivatives, though details of the mechanism of the reaction remain equivocal. The structure of **6**, was confirmed by the NMR spectrum (Fig. 1); Irradiation of a multiplet at τ 4.42 caused the H-1 doublet (τ 4.73, J~4 Hz) to collapse to a singlet, and consequently it was assigned to H-2. At the same time, 2-proton deformed AB quartet centered at τ 4.06 was assigned to double bond protons at C-3 and 4; the τ-value and the signal pattern ($J_{3,4}$~11 Hz) agreed with the structure. Irradiation of H-3,4 caused H-2 multiplet to collapse to a quartet ($J_{1,2}$ 4 Hz and ~2.5 Hz), the latter coupling being assigned to $J_{2,5}$. The magnitude of this homoallylic coupling[20] showed that H-2 and 5 stand nearly axially to the plane including the C_2–C_3=C_4–C_5 bond and the result shows that **6** is a derivative having 3,4-unsaturated α-D-*erythro* structure in the half-chair conformation. The conformation is reasonable also in view of anomeric effect.

Compound **6** was hydrogenated in an usual manner to give a 3,4-dideoxy derivative (**7**).[21] In its NMR spectrum, a 4-proton multiplet appeared at τ 7.6—8.5, indicating the presence of a ethylene protons. Removal of the protecting groups from **7** gave methyl 3,4-dideoxy-α-D-*erythro*-hexopyranoside (**8**), $[\alpha]_D^{22}$+126° (*c* 1.1, water)

Next, an analogous sequence of reactions were applied to methyl 2,6-dideoxy-2,6-dimethoxycarbonylamino-α-D-glucopyranoside (**10**) which was prepared by methanolysis of tetra-*N*-methoxycarbonylneamine (**9**), and the di-*O*-mesyl derivative (**11**) of **10** was treated likewise as described in the preparation of **6**. Treatment of **11** with sodium iodide and zinc dust in DMF at 98°C for 3 hr gave the 3,4-unsaturated derivative (**12**), $[\alpha]_D^{20}$−35° (*c* 0.7, methanol), in a yield of 90%. Since **11** has vicinally situated *trans*-diequatorial sulfonic ester groups, this reaction will be the first example that *trans*-diequatorial sulfonic ester groups went to unsaturation smoothly in a high yield. The smooth reaction will in part be attributable to the presence of a C-4 sulfonyloxy group, which is suscep-

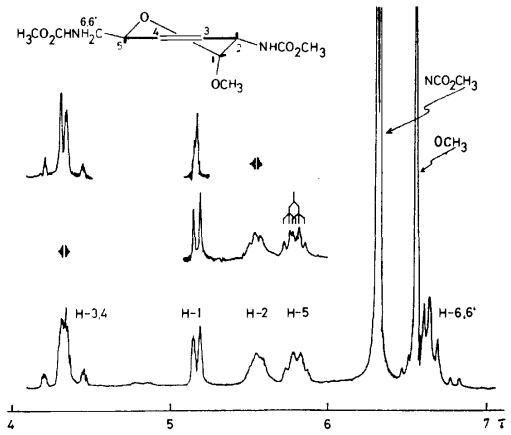

Fig. 2. The NMR spectrum of **12** in $CDCl_3$–D_2O at 100 MHz.

tible to an attack by a nucleophilic reagent, but neighboring group assistance by methoxycarbonylamino groups at C-2 and 6 should also be considered. The structure of **12** was confirmed by its NMR spectrum (Fig. 2) and double irradiation experiments (see Experimental). The coupling constants $J_{1,2}$ 4.2 Hz, $J_{3,4}$ 11 Hz, $J_{2,5}$~4 Hz (homoallylic), $J_{5,6}$ 5.3 Hz and $J_{5,6'}$ 4 Hz were confirmed. Small couplings ($J<1$ Hz) were also observed between H-3,4 and H-1, between H-3,4 and H-2, and between H-3,4 and H-5. These values indicated that **12** is in a half-chair conformation as depicted in Fig. 2.

Removal of the protecting groups from **12** gave the desired 3,4-unsaturated glycoside (**13**) as needles of monosulfate hemihydrate, $[\alpha]_D^{22}+26°$ (*c* 1, water). The NMR experiments of **13** (Fig. 3) again showed the coupling constants, $J_{1,2}$ 4.2 Hz, $J_{3,4}$ 11 Hz, $J_{2,5}$ 3.5 Hz, $J_{5,6}$ 6 Hz and $J_{5,6'}$ 4 Hz, being consistent with the half-chair conformation.

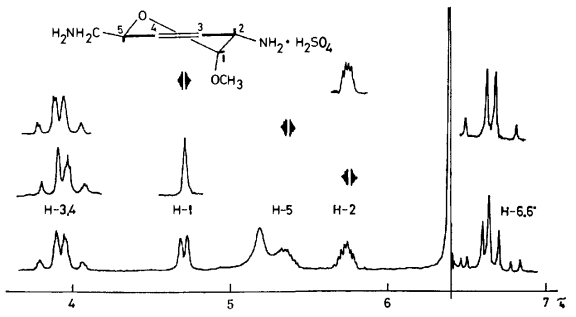

Fig. 3. The NMR spectrum of **13** in D_2O at 100 MHz.

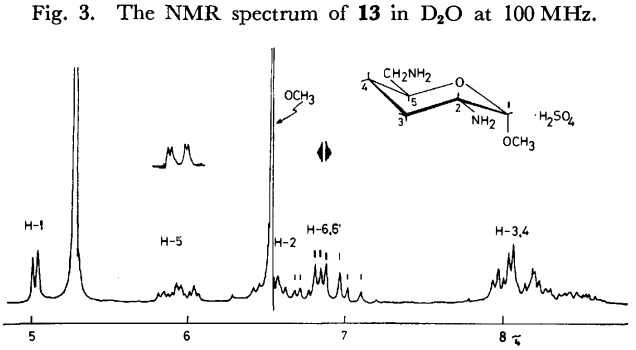

Fig. 4. The NMR spectrum of **15** in D_2O at 100 MHz.

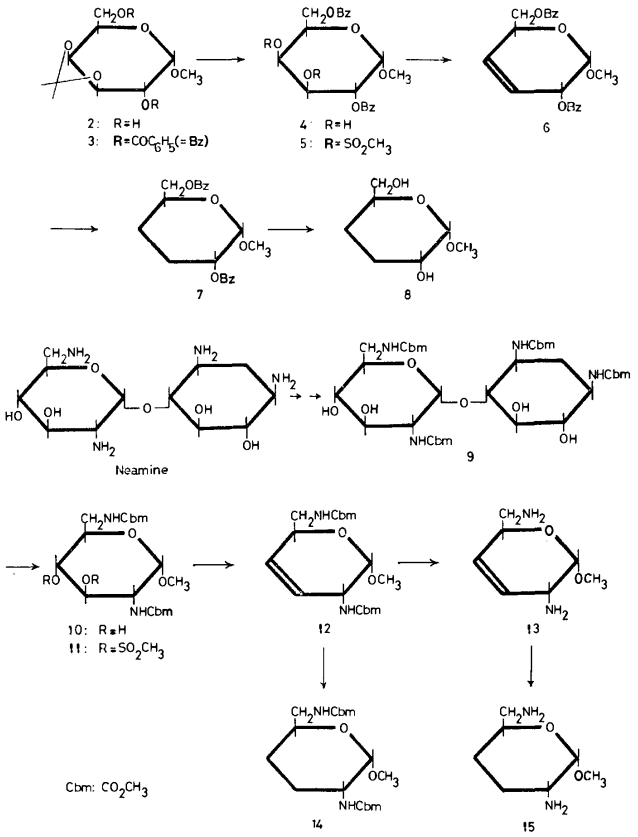

Chart 1.

Hydrogenation of **12** gave a tetradeoxy derivative (**14**), $[\alpha]_D^{19}+126°$ (*c* 0.7, methanol). Removal of the protecting groups then gave the 3,4-saturated glycoside (**15**) as needles of monosulfate hydrate, $[\alpha]_D^{22}+128°$ (*c* 1, water). The NMR spectrum was shown in Fig. 4.

Experimental

The NMR spectra were measured with a Varian A-60D or a Varian HA-100(at 100 MHz) spectrometer. Tetramethylsilane (for the solution of deuteriochloroform) and sodium 4,4-dimethyl-4-silapentane-1-sulfonate (for the solution of deuterium oxide) were used as the internal standards. Thin layer chromatography (tlc) was carried out on microscope slides coated with silica gel, and the spots were visualized with sulfuric acid.

Methyl α-D-Galactopyranoside (1). A suspension of D-galactose (5 g) in 4% hydrogen chloride in methanol (200 m*l*) was refluxed for 7 hr. Tlc (chloroform–methanol 5 : 2) of the reaction mixture showed that the starting material (R_f 0.30) disappeared and methyl α-D-galactofuranoside (R_f 0.63) and methyl α and β-D-galactopyranosides (R_f 0.47) appeared. Basic lead carbonate (30 g) was added and, after vigorous stirring, the suspension was centrifuged. The supernatant layer was evaporated to give a syrup (6 g). The syrup (22 g) was passed through a short column of Dowex 1×2 (OH form, 80 m*l*) with aid of water and the fraction containing galactopyranosides were evaporated. The resultant syrup (18.5 g) was dissolved in water and ethanol (12 m*l*) was added to cause crystallization of **1**, 7.15 g, mp ~97°C (not sharp), $[\alpha]_D^{20}+180°$ (*c* 1, water) (lit,[22] 111—

22) D. F. Mowery, Jr. and G. R. Ferrante, *J. Amer. Chem. Soc.*, **76**, 4103 (1954).

115°C, $[\alpha]_D^{20}+178°$). From the mother liquor another crop (2.73 g) was obtained. Total yield was 46%.

Found: C, 39.85; H, 7.90%. Calcd for $C_7H_{14}O_6 \cdot H_2O$· C, 39.62; H, 7.60%.

Methyl 3,4-O-Isopropylidene-α-D-galactopyranoside (2). Compound **1** was treated likewise as described by Buchanan and Saunders[23] and the crude product was extracted with ethyl acetate instead of acetone.[23] The solution was evaporated to give a syrup, which was chromatographed on a column of silica gel with ethyl acetate. From the earlier eluate, **2** was obtained in a yield of 64% (lit,[23] 47%), mp 103—105°C, $[\alpha]_D^{20}+163°$ (*c* 1.8, water) (lit,[23] 103—104°C, $[\alpha]_D^{22}+161°$ in chloroform). From the late eluate the 4,6-*O*-isopropylidene derivative was obtained in a yield of 17%.

Methyl 2,6-Di-O-benzoyl-3,4-O-isopropylidene-α-D-galactopyranoside (3). To a solution of **2** (3.0 g) in dry pyridine (60 m*l*), benzoyl chloride (4.5 m*l*) was added and the solution was allowed to stand for 30 min. After addition of water (0.8 m*l*), the solution was concentrated to approximately 10 m*l*, and to the concentrate, chloroform (200 m*l*) was added. After stirring, the organic layer was washed successively with potassium hydrogen sulfate solution, sodium hydrogen carbonate solution and water, dried over sodium sulfate and evaporated to give a syrup, 5.5 g (97%), $[\alpha]_D^{21}+134°$ (*c* 2.3, methanol); IR: 1725, 1260, 1110, 1070; 1043, 1023, 1010 (w), 995, 958 (w), 915, 865, 840, 800, 773 (w), 708 (s) cm^{-1}.

Found: 65.02; H, 6.11%. Calcd for $C_{24}H_{26}O_8$: C, 65.14; H, 5.92%.

NMR (in $CDCl_3$): τ 8.62 and 8.41 (both 3H singlets, isopropylidene), 6.60 (3H s, OCH_3), 5.2—5.7 (5H m), 4.92 (1H d, J 3.5 Hz, H-1), 4.75 (1H q, J 3.5 and 7.3 Hz, H-2), 2.3—2.7 (6H) and 1.75—2.0 (4H)(each multiplet, typical for benzoyl protons); $J_{1,2}$ 3.5 Hz, $J_{2,3}$ 7.3 Hz.

Methyl 2,6-Di-O-benzoyl-α-D-galactopyranoside (4). A solution of **3** (1.19 g) in 75% aqueous acetic acid (10 m*l*) was heated at 90°C for 15 min. The solution was evaporated and coevaporated with toluene to give a syrup. The syrup was dissolved in ethyl acetate and the solution was washed with sodium hydrogen carbonate solution and water, dried over sodium sulfate and evaporated to give a syrup, 1.05 g (97%), which crystallized on seeding. Recrystallization was carried out from methyl ethyl ketone-petroleum ether, mp 125—127°C, $[\alpha]_D^{22}+107°$ (*c* 1, chloroform); IR (KBr): 1720, 1275, 1115, 1095; 1040, 1023, 1010 (w), 995 (w), 970, 935 (w), 915, 890, 840 (w), 800, 780, 707 (s) cm^{-1}.

Found: C, 62.92; H, 5.65%. Calcd for $C_{21}H_{22}O_8$: C, 62.68; H, 5.51%.

Methyl 2,6-Di-O-benzoyl-3,4-di-O-mesyl-α-D-galactopyranoside (5). A solution of **4** (3.09 g) and methanesulfonyl chloride (2.7 g) in pyridine (78 m*l*) was allowed to stand at room temperature overnight. On tlc with benzene-ethyl acetate (10 : 1), **4**, (R_f 0.04) and initially appeared mono-*O*-mesyl derivative (R_f 0.15) disappeared and **5** (R_f 0.40) appeared as the final product. Water (0.8 m*l*) was added and the solution was evaporated to give a syrup, which was dissolved in chloroform. The solution was washed with sodium hydrogen carbonate solution and with water, dried over sodium sulfate and evaporated to give a thick syrup, 4.21 g (98%), $[\alpha]_D^{25}+136°$ (*c* 1.3, chloroform); IR (KBr): 1725, 1360 (ν_{as} SO_2), 1270, 1175, (ν_s SO_2), 1110; 1025, 965, 930 (sh), 915 (s), 850 (s), 805, 777, 760, 710 (s).

Found: C, 49.41; H, 4.84; S, 11.43%. Calcd for $C_{23}H_{26}O_{12}S_2$: C, 49.45; H, 4.69; S, 11.48%.

NMR (in $CDCl_3$): τ 6.93 and 6.76 (both 3H singlets, SO_2CH_3), 6.57 (3H s, OCH_3), 5.2—5.75 (3H m), 4.67—4.80 (1H m), 4.55 (3H, singlet-like pattern, width at half-height was 3.5 Hz); 2.3—2.7 (6H) and 1.7—1.95 (4H) (benzoyl protons).

Methyl 2,6-Di-O-benzoyl-3,4-dideoxy-α-D-erythro-hex-3-enopyranoside (6). To a solution of **5** (2.07 g) in dry DMF (40 m*l*, dried over CaH_2), dry sodium iodide (10 g) and zinc dust (4 g) were added and the mixture was heated in an oil bath (130—150°C) with vigorous stirring for 1.5 hr. Hot chloroform was added and the mixture was filtered while hot and the solution was evaporated *in vacuo* with subsequent coevaporation with toluene. The residue obtained was extracted with chloroform and the solution was washed successively with water, sodium thiosulfate solution and with water again, dried over sodium sulfate and evaporated to give a syrup, 1.27 g (93%). On tlc with benzene-ethyl acetate (10 : 1), the syrup showed a single spot (R_f 0.66). The syrup was distilled under vacuum (0.0005 mm) on an oil bath (180—190°C) to give a liquid, $[\alpha]_D^{22}-17.3°$ (*c* 1, chloroform); IR: 1725; no peaks in 1610—1700; 1265, 1100, 707 cm^{-1}.

Found: C, 68.36; H, 5.72%. Calcd for $C_{21}H_{20}O_6$: C, 68.47; H, 5.47%.

NMR (in $CDCl_3$ at 100 MHz)(Fig. 1): τ 6.25 (3H s, OCH_3), 5.35—5.6 (3H m, H-5,6,6'), 4.73 (1H d with small splittings, J~4 Hz, H-1), 4.42 (1H m, H-2); 4.06 (2H multiplet, which is a deformed AB quartet (J_{AB}~11 Hz), H-3,4); 2.35—2.70 (6H m.) and 1.85—2.0 (4H m) (benzoyl protons).

Methyl 2,6-Di-O-benzoyl-3,4-dideoxy-α-D-erythro-hexopyranoside (7). A solution of **6** (1.36 g) in methanol (5 m*l*) was hydrogenated with palladium black and hydrogen under pressure (50 lbs/sq. inch) at room temperature for 5 hr. The reaction mixture was filtered and the solution was evaporated to give syrup, 1.22 g (88%), which crystallized on standing. This was recrystallized from ethanol, mp 70—71°C, $[\alpha]_D^{22}+56.7°$ (*c* 1, chloroform); IR (KBr): 1720, 1715, 1270, 1095; 1038, 1025, 1010, 995, 955, 900, 875, 860, 705 (s), 680 cm^{-1}.

Found: C, 68.34; H, 6.13%. Calcd for $C_{21}H_{22}O_6$: C, 68.09; H, 5.99%.

NMR (in $CDCl_3$): τ 7.6—8.6 (4H m, H-3,3', 4,4'), 6.54 (3H s, OCH_3), 5.5—6.0 (3H m, H-5,6,6'), 4.7—5.1 (2H m, H-1 and 2), 2.3—2.7 (6H) and 1.75—2.05 (4H) (benzoyl protons).

Methyl 3,4-Dideoxy-α-D-erythro-hexopyranoside (8). To a solution of **7** (4.73 g) in methanol (40 m*l*), 3 M sodium methoxide in methanol (1.4 m*l*) was added and the solution was allowed to stand for 10 min. After addition of a small amount of Amberlite IR-120 (H^+ form), the solution was filtered and evaporated to give a syrup. The aqueous solution (500 m*l*) of the syrup was shaken with a small amount of ether and the aqueous layer separated was evaporated to give a syrup, 1.84 g (89%), $[\alpha]_D^{22}+126°$ (*c* 1.1, water); IR (KBr): 1450, 1050 (s), 985 (sh), 963, 925, 900, 845, 785 (w) cm^{-1}.

NMR (in D_2O): τ 7.9—8.6 (4H m, H-3,3',4,4'), 6.53 (3H s, OCH_3), 6.05—6.5 (4H m., H-2,5,6,6'), 5.29 (1H d, $J_{1,2}$ 3.5 Hz, H-1).

Methyl 2,6-Dideoxy-2,6-dimethoxycarbonylamino-α-D-glucopyranoside (10). To a mixture of neamine tetrahydrochloride[24] (1.02 g) and basic lead carbonate (7 g) in aqueous acetone (1 : 1, 20 m*l*), methoxycarbonyl chloride (1.01 g) was added dropwise with stirring at room temperature, and stirring was continued for 3 hr. Tlc (ethyl acetate-methanol 5 : 1) of

23) J. G. Buchanan and R. M. Saunders, *J. Chem. Soc.*, **1964**, 1796.

24) K. Tatsuta, E. Kitazawa, and S. Umezawa, This Bulletin, **40**, 2371 (1967).

the reaction mixture showed that neamine (R_f 0) disappeared and the tetra-*N*-methoxycarbonyl derivative (**9**, R_f 0.45) appeared. The reaction mixture was filtered, and the mass separated was washed with hot water several times. Filtrate and the washings were combined and concentrated to a small volume. Dowex 1×2 (OH form) resin (1.5 m*l*) was added and the mixture was shaken for a while whereupon some precipitates were liberated. The mixture was filtered and the solution was evaporated and then coevaporated with benzene to give a solid (1.07 g)[25], which still contained some inorganic salts. The crude **9** (4 g) obtained above was suspended in 8% hydrogen chloride in methanol (80 m*l*) and the mixture was refluxed for 40 hr. Tlc (ethyl acetate–ethanol 8 : 1) of the resulting solution showed three spots of R_f 0.56 (**10**), 0.40 (β-anomer of **10** ?) and 0.09 (probably *N,N'*-dimethoxycarbonyl-2-deoxystreptamine; the color appeared on strong heating after spraying sulfuric acid; when the crude isolated product was treated with hot basic solution, the product liberated 2-deoxystreptamine). The pale-brown solution was neutralized with anhydrous sodium carbonate (13.5 g) under stirring and the inorganic salts precipitated were removed by centrifuging. The supernatant layer was evaporated and coevaporated with toluene and the residue obtained was extracted with *p*-dioxane (30 m*l*×3). The solution, which contained **10** and a small amount of 2-deoxystreptamine derivative described above but was free from inorganic salts, was evaporated. The methanol solution (10 m*l*) of the residue (2.3 g) was charged on a short column of alumina (50 g, Woelm acidic) and developed with ethyl acetate–methanol (1 : 1). The eluate containing **10** was evaporated to give a solid (1.54 g), which was proved to contain only a slight amount of the 2-deoxystreptamine derivative. The solid was then recrystallized from methanol to give **10** (0.79 g). The mother liquor, after evaporation, was chromatographed with methanol on a column of Dowex 1×2 (OH form, 100 m*l*), pretreated with methanol. Compound **10**, the 2-deoxystreptamine derivative (R_f 0.09) and a by-product (R_f 0.40) were eluted in this order. The fraction containing **10** was evaporated to give a solid (0.37 g). Total yield of **10** was 1.16 g (52%). The combined product was finally recrystallized from a hot mixture of methanol–acetone (1 : 4), mp 175—177°C, $[\alpha]_D^{21}$ +108° (*c* 0.7, water); IR (KBr): 1690 (s, broad), 1550, 1440, 1290, 1275, 1060; 978, 947, 925 (w), 900 (w), 835 (w), 785, 770 (w), 760 (w), 710 cm^{-1}.

Found: C, 42.60; H, 6.76; N, 8.88%. Calcd for $C_{11}H_{20}N_2O_8$: C, 42.86; H, 6.54; N, 9.09%.

NMR (in D_2O): τ 6.63 (3H s, OCH_3), 6.31 (6H s, $NHCO_2C\underline{H}_3$), 6.2—7.2 (6H), 5.23 (1H d, $J_{1,2}$ 2.3 Hz, H-1).

The fraction containing the product of R_f 0.40 was evaporated to give a solid (125 mg), $[\alpha]_D^{21}$ −9.8° (*c* 0.7, water).

*Methyl 2,6-Dideoxy-3,4-di-*O*-mesyl-2,6-dimethoxycarbonylamino-α-*D*-glucopyranoside (**11**).* To a solution of **10** (615 mg) in pyridine (12 m*l*), methanesulfonyl chloride (600 mg) was added and the solution was allowed to stand overnight. Tlc (benzene–ethyl acetate 1 : 3) showed that **10** (R_f 0.14) and a monomesyl derivative (R_f 0.47), which appeared in an early stage, disappeared, and **11** (R_f 0.59) appeared as the final product. Similar treatment of the solution with that described in the preparation of **5** gave a solid, 840 mg (92%), which was recrystallized from ethanol, mp 193—195 °C, $[\alpha]_D^{23}$ +94° (*c* 1.5, chloroform); IR (KBr): 1710 (sharp), 1545, 1355 (ν_{as} SO_2), 1277, 1175 (ν_s SO_2); 1055, 1030, 975, 965, 930, 908, 852, 842, 820, 777, 755, 722 cm^{-1}.

25) This experiment was performed by Yasushi Takagi of our laboratory.

Found: C, 33.84; H, 5.03; N, 6.04; S, 13.99%, Calcd for $C_{13}H_{24}N_2O_{12}S_2$: C, 33.62; H, 5.21; N, 6.03; S, 13.81%.

NMR (in $CDCl_3$): τ 6.90 and 6.77 (both 3H singlets, SO_2CH_3), 6.59 (3H s, OCH_3), 6.29 (6H s, $NHCO_2C\underline{H}_3$), 5.36 and 5.06 (both 1H triplets, J 9 Hz, H-3 and 4), 5.22 (1H d, $J_{1,2}$ 3.2 Hz, H-1); $J_{2,3}=J_{3,4}=J_{4,5}$ 9 Hz.

*Methyl 2,3,4,6-Tetradeoxy-2,6-dimethoxycarbonylamino-α-*D*-erythro-hex-3-enopyranoside (**12**).* To a solution of **11** (503 mg) in dry DMF (10 m*l*), dry sodium iodide (5.5 g) and zinc dust (2.5 g) were added and the mixture was heated in an oil bath (98±1°C) for 3 hr with vigorous stirring. On tlc with benzene–ethyl acetate (1 : 2), **11** (R_f 0.39) disappeared and a product (R_f 0.52) appeared. Hot chloroform (60 m*l*) was added and the reaction mixture was filtered. The solution was washed successively with water (60 m*l*), saturated sodium thiosulfate solution (30 m*l*) and with water (60 m*l*×2), dried over sodium sulfate and evaporated to give a syrup, 268 mg (90%), which crystallized on standing and recrystallized from ethanol, mp 157—159°C, $[\alpha]_D^{20}$ −35° (*c* 0.7, methanol); IR (KBr): 1695, 1540, 1250, 1105, 1055, 1008; 955 (w), 942, 915, 843, 803, 784, 733, 700 cm^{-1}.

Found: C, 48.20; H, 6.43; N, 10.02%. Calcd for $C_{11}H_{18}N_2O_6$: C, 48.17; H, 6.61; N, 10.21%.

NMR: To a solution of **12** in deuteriochloroform, deuterium oxide was added and, after storage for one day, the solution was measured at 100 MHz (Fig. 2): τ 6.69 (1H q, *J* 5.3 and 14 Hz, H-6), 6.59 (1H q, *J* 4 and 14 Hz, H-6'), 5.80 (1H incomplete quartet, H-5), 5.55 (1H m, H-2), 5.17 (1H d, H-1), 4.17—4.48 (2H m, H-3,4).

Irradiation at τ 4.32 (H-3,4) caused the H-5 multiplet to become double triplets (*J* 4, 4 and 5.3 Hz), the H-2 multiplet to become an incomplete triplet (*J*∼4 Hz) and H-1 doublet to become a sharp doublet (*J* 4.2 Hz). Irradiation at τ 5.55 (H-2) caused the H-1 doublet to collapse to a singlet and H-3,4 multiplet to collapse to an AB quartet (J_{AB} 11 Hz); as for the AB quartet, the pair in the lower field became more sharpened than that in the higher field. Irradiation at τ 5.80 (H-5) caused the H-6,6' octet to collapse to an AB quartet (*J* 4 Hz).

*Methyl 2,6-Diamino-2,3,4,6-tetradeoxy-α-*D*-erythro-hex-3-enopyranoside (**13**).* To a solution of **12** (179 mg) in aqueous methanol (5 : 1, 3 m*l*), barium hydroxide octahydrate (600 mg) was added and the mixture was refluxed for 4 hr. On tlc with *n*-butanol–pyridine–water–acetic acid (6 : 4 : 3 : 1), the reaction mixture showed two spots of R_f 0.25 and 0.69 (very weak). Carbon dioxide was introduced and the resulting precipitates were removed by centrifuging. The supernatant layer was evaporated to give a residue, which was neutralized with 1 N sulfuric acid and after treatment with charcoal, the mixture (pH∼3) was concentrated to approximately 0.5 m*l*. Addition of acetone gave needles, 146 mg (85% as **13** sulfate hemihydrate), mp: gradually decomposed over than 180°C, $[\alpha]_D^{22}$ +26° (*c* 1, water).

Found: C, 31.96; H, 6.63; N, 9.94; S, 11.84%. Calcd for $C_7H_{14}N_2O_2\cdot H_2SO_4\cdot 1/2H_2O$: C, 31.69; H, 6.46; N, 10.56; S, 12.09%.

NMR (in D_2O at 100 MHz)(Fig. 3): τ 6.69 (1H q, *J* 6 and 14 Hz, H-6), 6.61 (1H q, *J* 4 and 14 Hz, H-6'), 5.74 (1H m, H-2), 5.35 (1H m, H-5), 4.70 (1H d, *J* 4.2 Hz, H-1), 3.92 (2H m, H-3,4).

Irradiation of H-1 caused the H-2 multiplet to collapse to a quartet (*J*∼1.5 and 3.5 Hz).

*Methyl 2,3,4,6-Tetradeoxy-2,6-dimethoxycarbonylamino-α-*D*-erythro-hexopyranoside (**14**).* A solution of **12** (416 mg) in aqueous methanol (1 : 4, 5 m*l*) was hydrogenated with palladium black and hydrogen under pressure (50 lbs/sq. inch) at 35°C overnight. On tlc with benzene–ethyl acetate (1 : 2),

both the starting material (**12**) and the product (**14**) gave the same R_f-value (0.52), however, they were distinguished each other by their coloration with anisaldehyde-sulfuric acid[26]: **12** colored orange initially and then turned brown after 1 hr and **14** colored blueviolet to yellow (after 1 hr). The mixture was filtered and evaporated to give a thick syrup, 400 mg (95%), $[\alpha]_D^{19}+126°$ (*c* 0.7, methanol); IR (KBr): 1700, 1540, 1275, 1260; 1050, 1027, 1020, 980, 948, 915, 890 (w), 784, 715 (w) cm^{-1}.

Found: C, 48.10; H, 7.42; N, 10.21%, Calcd for $C_{11}H_{20}N_2O_6$: C, 47.82; H, 7.30; N, 10.14%.

NMR (in $CDCl_3$): τ 8.0—8.6 (4H m, H-3,3',4,4'), 6.62 (3H s, OCH_3),6.31 (6H s, $NHCO_2C\underline{H}_3$), 5.35 (1H d, $J_{1,2}$ 3.5 Hz, H-1).

*Methyl 2,6-Diamino-2,3,4,6-tetradeoxy-α-*D*-erythro-hexopyranoside (**15**).* To a solution of **14** (414 mg) in aqueous methanol (5 : 1, 6 m*l*), barium hydroxide octahydrate (1.2 g) was added and the mixture was refluxed under stirring for 3 hr. Carbon dioxide was introduced and the mixture was treated as described in the preparation of **13** to give **15**, needles, 288 mg (94% as sulfate monohydrate). Mp: gradually decomposed over than 180°C (slightly changed at ~135°C), $[\alpha]_D^{22}+128°$ (*c* 1, water).

Found: C, 30.45; H, 7.04; N, 9.85; S, 11.62%. Calcd for $C_7H_{16}N_2O_2\cdot H_2SO_4\cdot H_2O$: C, 30.43: H, 7.30; N, 10.14; S, 11.60%.

NMR (in D_2O at 100 MHz)(Fig. 4): τ 7.9—8.7 (4H m, H-3,3',4,4'); 6.96 (1H q, *J* 8.7 and 13.5 Hz, H-6) and 6.80 (1H q, *J* 3.5 and 13.5 Hz, H-6'); these signals formed the AB part of an ABX system; 6.53 (3H s, OCH_3), 6.52 (1H m, H-2), 5.94 (1H m, H-5), 5.03 (1H d, *J* 3.3 Hz, H-1).

Irradiation at τ 6.52 (H-2) caused the H-1 doublet to collapse to a singlet and the multiplet at τ 7.9—8.7 to change. Irradiation at τ 6.87 caused the H-5 multiplet to collapse to a quartet (*J* 2 and 10.5 Hz); $J_{1,2}$ 3.3 Hz, $J_{4ax,5}$ 10.5 Hz, $J_{4eq,5}$ 2 Hz, $J_{5,6}$ 8.7 Hz, $J_{5,6'}$ 3.5 Hz, $J_{6,6'}$ 13.5 Hz.

The authors wish to thank Dr. Hiroshi Naganawa of the Institute of Microbial Chemistry for carrying out decouplings in the NMR spectra and to Mr. Saburo Nakada for the elemental analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3624—3628 (1972)

Studies on Aminosugars. XXXII. Synthesis of 3′, 4′-Dideoxykanamycin B[1]

Sumio UMEZAWA,* Hamao UMEZAWA,** Yasushi OKAZAKI,* and Tsutomu TSUCHIYA*

* *Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi-cho, Kohoku-ku, Yokohama*

** *Institute of Microbial Chemistry, Shinagawa-ku, Tokyo*

(Received May 11, 1972)

Penta-*N*-ethoxycarbonylkanamycin B (**1**) prepared from kanamycin B was treated with 2,2-dimethoxypropane in DMF to give a 3′,4′;4″,6″-di-*O*-isopropylidene derivative (**3**). Subsequent benzoylation afforded a 2″-*O*-benzoyl derivative (**4**), Removal of the isopropylidene groups from **4** followed by controlled isopropylidenation afforded the corresponding 4″,6″-*O*-isopropylidene derivative (**5**), which was then transformed to a 3′,4′-di-*O*-mesyl derivative (**6**). Treatment of **6** with sodium iodide and zinc dust in DMF gave the desired 3′,4′-unsaturated derivative (**7**). Hydrogenation and removal of the protecting groups gave the title compound. The 3′,4′-dideoxykanamycin B expectedly showed remarkable activity against kanamycin-resistant bacteria as well as sensitive strains.

As described in the preceding papers, the 3′-deoxykanamycin[2] exhibited antibiotic activity in the same strength as the parent antibiotic and, moreover, it showed strong inhibition against resistant bacteria such as *E. coli* carrying R factor, resistant *Staphylococci* and *Pseudomonas*, whereas 3′-*O*-methylkanamycin[3] is inactive. On the other hand, we have found that 3,4-unsaturation of glycopyranosides smoothly proceeded by treatment of their 3,4-di-*O*-mesyl derivatives with iodide and zinc dust in dimethylformamide (DMF) as described in the foregoing paper.[4] The interest in this particular method of dehydroxylation is first that unsaturation occurs at C-3,4 position of an aminosugar and, fortunately, the yield of the reaction is excellent. Secondly, the reaction opens the possibility for us to synthesize a 3′,4′-dideoxy derivatives of kanamycin and allied antibiotics, though the structures of such antibiotics are much more complex. We were interested in the 3′,4′-dehydroxylation of kanamycin B because the antibiotic contains 2,6-diamino-2,6-dideoxy-D-glucose on which experience of 3,4-dehydroxylation has been gained.[4] Thus, the synthesis of 3′,4′-dideoxykanamycin B was undertaken.

The amino groups of kanamycin B were protected by ethoxycarbonyl chloride in aqueous acetone in the presence of sodium carbonate to give penta-*N*-ethoxycarbonylkanamycin B (**1**). The reason for the use of ethoxycarbonyl groups instead of benzyloxycarbonyl

1) A part of this paper was read by S. Umezawa at Symposium of New Natural Product Syntheses, 23rd International Congress of Pure and Applied Chemistry at Boston, U. S. A., July 28, 1971. or acyl (acetyl or benzoyl) groups are that the benzyloxycarbonyl group seemed to have no special advantage over the ethoxycarbonyl group in the present synthesis and that the acyl protection of the amino groups in kanamycins renders the kanamycin-derivatives scarcely soluble in usual organic solvents. The product (**1**) was acetonated with 2,2-dimethoxypropane in DMF in the presence of *p*-toluenesulfonic acid giving 4″,6″-mono-*O*-isopropylidene derivative (**2**) in a yield of 95%. Its NMR spectrum in dimethyl sulfoxide-d_6 showed that the isopropylidene methyls resonated separately at τ 8.60 and 8.72, indicating[3] that the isopropylidene group was attached to C-4 and 6 of the 3-amino-3-deoxy-D-glucose moiety of the derivative (**2**). Compound **2** was again treated with 2,2-dimethoxypropane to give 3′,4′;4″6″-di-*O*-isopropylidene derivative (**3**), $[\alpha]_D^{20}+87°$ (*c* 1, DMF) in approximately 30% yield. Since the *N*-protected 4,5;4″,6″-di-*O*-isopropylidene derivative[3] of 6-*O*-(3-amino-3-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine was obtained from the corresponding precursor in a yield of 84%, the above low yield may be ascribable to the molecular complexity of the kanamycin derivative (**2**). However, when dimethoxycyclohexane was used instead of dimethoxypropane and the reaction was performed under diminished pressure,[5] **1** gave the corresponding di-*O*-cyclohexylidene derivative in a high yield (90%), on which details will be published elswhere. Benzoylation of **3** gave 2″-*O*-benzoyl derivative (**4**), $[\alpha]_D^{21}+114°$ (*c* 1, DMF). Increase in optical rotation ($[\alpha]_D+87°$(in **3**)⟶$+114°$ (in **4**)) showed that the benzoylation occurred at the hydroxyl group on C-2″ but not on C-5 where is optically least sensitive and is sterically hindered. The inactivity of the hydroxyl group at C-5 to acylation was also encountered in the synthesis of kanamycin-6″-uronic acid.[6] Removal of the isopropylidene groups of **4** followed by controlled isopropylidenation gave the 2″-*O*-benzoyl-4″,6″-*O*-isopropylidene derivative (**5**) in a 73% yield. The positions selectively isopropylidenated were confirmed by its NMR spectrum.

Mesylation of **5** with mesyl chloride in pyridine gave the 3′,4′-di-*O*-mesyl derivative (**6**). 3′,4′-Unsaturation of **6** was performed by treatment[7] with sodium iodide and zinc dust in DMF as described in the previous paper.[4] 2″-*O*-Benzoyl-3′,4′-dideoxy-3′-eno-penta-*N*-ethoxycarbonyl-4″,6″-*O*-isopropylidenekanamycin B (**7**), $[\alpha]_D^{21}+36°$ (*c* 4, DMF), was obtained in a yield of 38%. Since methyl 2,6-di-*O*-benzoyl-3,4-dideoxy-α-D-*erythro*-hex-3-enopyranoside[4] (93%), methyl 2,3,4,6-tetradeoxy-2,6-dimethoxycarbonylamino-α-D-*erythro*-hex-3-enopyranoside[4] (90%) and 5,6-*O*-cyclohexylidene-3′,4′-dideoxy-3′-eno-tetra-*N*-methoxycarbonylneamine[8] (70%) were obtained from the corresponding precursors in high yields, the comparatively low

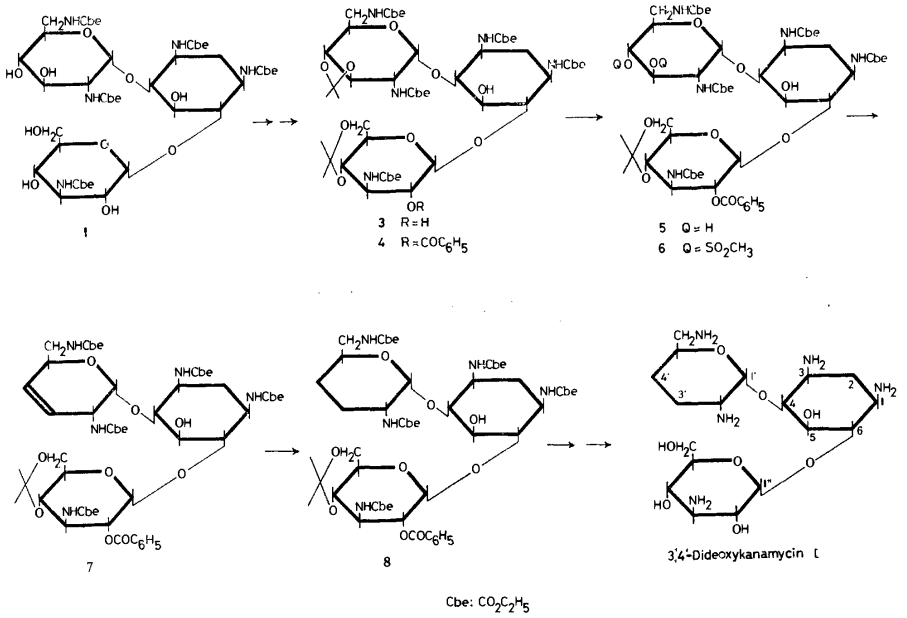

Chart 1.

yield of **7** may be due to some unfavorable influence of the free hydroxyl group of C-5 in **6**. 3',4'-Unsaturation of **7** was confirmed by its NMR spectrum (Fig. 1): a two proton singlet appeared at τ 4.04 characteristic to 3,4-alkene protons.[8] The low optical rotation (+36°) of **7** also required the above structure. As the hydrogenated product (**8**) described below had $[\alpha]_D$+93.5° (in DMF), the difference in molecular rotation between **7** and **8** is calculated to be (36—93.5°)×954 (MW of **7**)≃−55000°. The value, which will be the net contribution of the 3,4-unsaturation bond to the rotation of the α-D-*erythro*-hexopyranoside, is in good accord with that of structurally related compound **12** and **14** described in the preceding paper,[4] although methanol was used as the medium: (−35—126°)×274 (MW of **12**)≃−45000°.

Compound **7** was then catalytically hydrogenated to a dideoxy derivative (**8**), $[\alpha]_D^{22}$+93.5° (*c* 0.4 DMF). In the NMR spectrum (Fig. 2), a broadened signal corresponding to ethylene protons appeared (τ 7.8—8.5). Hydrolysis of **8** with aqueous acetic acid gave a deacetonation product (**9**), which, on removal of the other protecting groups with barium hydroxide, gave 3',4'-dideoxykanamycin B. The elemental analysis, the NMR spectrum (Fig. 3) and the result of hydrolysis of the product with 6 N hydrochloric acid confirmed the structure of the product as expected. It is worth describing that, in the NMR spectra, one of the doublets (J 3.5 Hz) of anomeric protons of 3',4'-dideoxykanamycin B base markedly shifts to down field (τ 4.80→4.08) on addition of sulfuric acid. The similar effect is also observed in the case of kanamycin B base (τ 4.66→4.12).

The semisynthetic 3',4'-dideoxykanamycin B exhibited the desired antibacterial spectrum. Microbiological studies[1] showed that resistant bacteria including various strains of *E. coli* carrying R factor, resistant *Staphylococci* isolated from patients, and *Pseudomonas aeruginisa* are remarkably sensitive to the antibiotic derivative.

Experimental

General. The general methods used were the same as those given in a previous paper.[4] Paper chromatography was performed on Toyo Roshi paper No. 50 with *n*-butanol-pyridine-water-acetic acid (6 : 4 : 3 : 1) and the spots were detected with 0.5% ninhydrin in pyridine and heating to 110°C. Frequently used solvent systems for TLC were as follows: benzene-methanol (4 : 1) (Solvent A) and chloroform-ethanol (12 : 1) (Solvent B).

*Penta-*N-*ethoxycarbonylkanamycin B (**1**).* To a mixture of kanamycin B base (1.0 g) and anhydrous sodium carbonate (0.9 g) in aqueous acetone (1 : 1, 20 m*l*), ethoxycarbonyl chloride (1.16 g) was added dropwise and the mixture was agitated for 1 hr at room temperature and then allowed to stand overnight. After the resulting slurry was neutralized with 1 N hydrochloric acid, the mixture was filtered, and the solid was washed with water, dried (1.46 g, 84%), and recrystallized from aqueous methanol (2 : 3), mp 304—306°C, $[\alpha]_D^{22}$+93.5° (*c* 0.3, DMF); R_f 0.34 (TLC with Solvent A); IR (KBr): 1700 (sh), 1690 (s), 1540 (s); 1040 (s), 975 (sh), 932 (w), 875 (m), 778 cm^{-1}. NMR (in dimethyl sulfoxide-d_6): τ 8.85 and 8.82 (each triplet, 15H in total, J 6.7 Hz, $NHCO_2CH_2\underline{CH_3}$).

Found: C, 47.03; H, 6.89; N, 8.32%. Calcd for $C_{33}H_{57}N_5O_{20}$: C, 46.97; H, 6.81; N, 8.30%.

*Penta-*N-*ethoxycarbonyl-4″,6″-*O-*isopropylidenekanamycin B (**2**).* To a mixture of **1** (1.05 g, 1.19 mmol) and anhydrous *p*-toluenesulfonic acid (29 mg, dried at 80°C *in vacuo*) in dry DMF (20 m*l* dried over CaH_2), 2,2-dimethoxypropane (0.43 g, 4.1 mmol) was added and the mixture was allowed to stand at 37°C for 1.5 hr. The starting material (R_f 0.29 on tlc with Solvent A) disappeared and the product (**2**, R_f 0.47) appeared with a slight amount of diisopropylidene product (**3**, R_f 0.76). A small amount of Amberlite IRA 400 (OH form) was added, and after filtration, the solution was concentrated *in vacuo* to a syrup, which was poured into water. The resulting solid was filtered and washed thoroughly with benzene, 1.05 g (95%). The solid was dissolved in dioxane and reprecipitated by the addition of water, mp>300°C,

$[\alpha]_D^{22}$+84° (*c* 0.5, DMF); IR (KBr): 1700 (s, broad), 1675 (sh), 1540; 1040 (broad), 945 (w), 907 (vw), 877, (w), 850 (w), 780 cm^{-1}.

Found: C, 48.62; H, 7.10; N, 8.02%. Calcd for $C_{36}H_{61}N_5O_{20}$: C, 48.92; H, 6.96; N, 7.92%.

NMR (in dimethyl sulfoxide-d_6): τ 8.84 (15H t, *J* 6.7 Hz, $NHCO_2CH_2C\underline{H}_3$), 8.72 and 8.60 (both 3H sinlgets, isopropylidene), 6.00 (10H q, *J* 6.7 Hz, $NHCO_2C\underline{H}_2CH_3$).

Penta-N-*ethoxycarbonyl-3′,4′;4″,6″-di*-O-*isopropylidenekanamycin B* (**3**). To a solution of **2** (13.7 g) and anhydrous *p*-toluenesulfonic acid (0.35 g) in dry DMF (70 m*l*), 2,2-dimethoxypropane (18.8 g) was added and the solution was heated at 65°C for 30 min. After concentration to approximately 60 m*l*, another 2,2-dimethoxypropane (35 g) and anhydrous *p*-toluenesulfonic acid (0.15 g) were added and the solution was again heated at 65°C for 30 min. After triethylamine (6 m*l*) was added, the solution was poured into a mixture of benzene (500 m*l*) and water (600 m*l*) with stirring. Resulting precipitates, which were suspended between aqueous and organic layers, were filtered, washed with benzene and dried to give a solid (6.5 g). This was proved to be the starting material unchanged (**2**, R_f 0.12 on tlc with Solvent B) and was again used in another run. The organic layer and the benzene washings were allowed to stand overnight, and some precipitates appeared were removed by filtration. The solution was evaporated to give solid (**3**), having an R_f 0.32 on tlc with Solvent B. The solid was dissolved in dioxane and reprecipitated by the addition of water, yielding 4.2 g (25.3%) of **3**, mp 236—237°C, $[\alpha]_D^{20}$ +87° (*c* 1, DMF); IR (KBr): 1735, 1705 (s), 1535; 1040, 1025, 985 (sh), 947 (w), 880 (w), 850 (w), 780 cm^{-1}.

Found: C, 50.54; H, 7.30; N, 7.59%. Calcd for $C_{39}H_{65}N_5O_{20}$: C, 50.70; H, 7.09; N, 7.58%.

NMR (in pyridine-d_5): τ 8.86 (15H t, *J* 6.7 Hz, $NHCO_2CH_2C\underline{H}_3$), 8.60 (12H a slightly broadened singlet, isopropylidene), 5.4—6.5 (27H multiplet, skeleton protons and $NHCO_2C\underline{H}_2$ CH_3).

2″-O-*Benzoyl-penta*-N-*ethoxycarbonyl-3′,4′;4″,6″-di*-O-*isopropylidenekanamycin B* (**4**). To a solution of **3** (3.24 g) in pyridine (48 m*l*), benzoyl chloride (1.68 g) was added and the solution was allowed to stand for 1 hr. After addition of water (0.4 m*l*), the solution was evaporated to give a syrup, which was dissolved in chloroform (200 mg). The solution was washed with sodium hydrogencarbonate solution and with water, dried over sodium sulfate and concentrated to approximately 20 m*l*. Addition of *n*-hexane (140 m*l*) to the solution gave a solid, 3.35 g (96%), mp 205—209°C, $[\alpha]_D^{21}$ +114° (*c* 1, DMF); IR (KBr): 1735—1700, 1535; 1030, 985 (sh), 950 (w), 877 (sh), 865 (w), 850 (w), 780, 715 cm^{-1}.

Found: C, 54.01; H, 7.11; N, 6.66%. Calcd for $C_{46}H_{69}N_5O_{21}$: C, 53.74; H, 6.77; N, 6.81%.

2″-O-*Benzoyl-penta*-N-*ethoxycarbonyl-4″,6″*-O-*isopropylidenekanamycin B* (**5**). A solution of **4** (282 mg) in aqueous acetic acid (1 : 3, 4 m*l*) was heated at 95°C for 1 hr. A deacetonated product (R_f 0.06 on tlc with Solvent B) appeared. The solution was coevaporated with toluene to give a solid, which was washed with water and dried (258 mg, 99%). To a solution of the deacetonated product (935 mg) in dry DMF (6 m*l*), 2,2-dimethoxypropane (230 m*l*) and anhydrous *p*-toluenesulfonic acid (20 mg) were added and the solution was allowed to stand at 30°C for 1 hr. On tlc with Solvent, B, a spot (R_f 0.36) appeared together with two minor spots of R_f 0.49 (**4**) and R_f 0.06. Another portion of 2,2-dimethoxypropane (96 mg) was added and the solution was allowed to stand for 1 hr at room temperature, the deacetonated substance (R_f 0.06) disappearing. Triethylamine (0.2 m*l*) was added and solution was poured into cold water (100 m*l*). The resulting precipitates were filtered, washed with water and dried. The solid, after washing with benzene, was dissolved in dioxane and reprecipitated by the addition of water, 722 mg (73% based on **4**), mp 305—307°C, $[\alpha]_D^{21}$ +105° (*c* 1, DMF); IR (KBr): 1735—1690, 1540; 1035, 985 (sh), 950 (w), 877 (w), 865 (w), 850 (w), 782, 713 cm^{-1}.

Found: C, 52.52; H, 6.67; N, 7.31%. Calcd for $C_{43}H_{65}N_5O_{21}$: C, 52.27; H, 6.63; N, 7.09%.

NMR (in dimethyl sulfoxide-d_6): τ 9.10, 8.86 and 8.83 (6H, 3H and 6H triplet, respectively, *J* 6.7 Hz, $NHCO_2CH_2C\underline{H}_3$), 8.70 and 8.56 (both 3H singlets, isopropylidene), 2.0—2.6 (5H multiplet, typical for benzoyl protons).

2″-O-*Benzoyl-penta*-N-*ethoxycarbonyl-4″,6″*-O-*isopropylidene-3′,4′-di*-O-*mesylkanamycin B* (**6**). To a solution of **5** (1.18 g) in pyridine (15 m*l*), methanesulfonyl chloride (0.56 g) was added and the solution was allowed to stand at room temperature for 1.5 hr. On tlc with chloroform–ethanol (12 : 1), a spot (R_f 0.30, mono-*O*-mesyl derivative) which appeared in an early stage of the reaction disappeared and a spot (R_f 0.35) appeared. After addition of water (0.1 m*l*), the solution was concentrated *in vacuo* to one-third volume and poured into water. Resulting precipitates were filtered, washed with water and dried yielding 1.32 g (96%), mp 198°C, $[\alpha]_D^{22}$ +107° (*c* 1.5, DMF); IR (KBr): 1735, 1720, 1700, 1540, 1350 (broad), 1175 (νSO_2); 1035, 965, 930 (sh), 877 (w), 865 (w), 850, 827, 782, 757 (w), 712 cm^{-1}.

Found: C, 47.36; H, 6.06; N, 5.38; S, 5.57%. Calcd for $C_{45}H_{69}N_5O_{25}S_2$: C, 47.24; H, 6.08; N, 6.12; S, 5.60%.

NMR (in pyridine-d_5): τ 8.95, 8.91 and 8.78 (3H, 6H and 6H triplet, respectively, *J* 6.7 Hz, $NHCO_2CH_2C\underline{H}_3$), 8.66 and 8.55 (both 3H singlets, isopropylidene).

2″-O-*Benzoyl-3′,4′-dideoxy-3′-eno-penta*-N-*ethoxycarbonyl-4″,6″*-O-*isopropylidenekanamycin B* (**7**). To a solution of **6** (100 mg) in dry DMF (2 m*l*), dry sodium iodide (1.1 g) and zinc dust (500 mg) were added and the mixture was heated in an oil bath (95±1°C) for 1 hr under vigorous stirring. A hot mixture of chloroform (10 m*l*) and water (10 m*l*) were added and, after stirring for a while, the mixture was filtered and the solid separated was washed with a mixture of chloroform–methanol (1 : 1, 2 m*l*×2). The filtrate and the washings were combined and the organic layer was washed successively with water, sodium thiosulfate solution and with water again, dried over sodium sulfate and evaporated to give a solid (94 mg). On tlc with benzene–ethyl acetate (1 : 3), the solid showed four spots of R_f 0.53 (**6**), 0.43 (**7**), 0.32 and 0.22 (major). The undesirable products (R_f 0.53, 0.32 and 0.22) were successfully removed from the solid by extraction with ethyl acetate several times. The residue (32 mg, 38%) was dissolved in a mixture of methanol (0.1 m*l*) and chloroform (0.2 m*l*) and to the solution, ethyl acetate (0.7 m*l*) was added. **7** gradually crystallized, mp 282—284°C, $[\alpha]_D^{21}$ +36° (*c* 4, DMF); IR (KBr): 1735, 1700 (s, sharp), 1540; 1040, 1030, 987, 950 (w), 925 (vw), 867 (w), 850 (w), 783, 745 (w), 714 cm^{-1}.

Found: C, 54.00; H, 6.71; N, 7.52%. Calcd for $C_{43}H_{63}N_5O_{19}$: C, 54.14; H, 6.66; N, 7.34%.

NMR (in pyridine-d_5): τ 8.97, 8.85, 8.81 and 8.78 (6H, 3H, 3H and 3H triplet, respectively, *J* 6.7 Hz, $NHCO_2CH_2C\underline{H}_3$), 8.56 and 8.51 (both 3H singlets, isopropylidene), 4.04 (2H s, H-3′,4′).

The major product (R_f 0.22) was proved not to be a deacetonation product of **7**; the structure is now under study.

2″-O-*Benzoyl-3′,4′-dideoxy-penta*-N-*ethoxycarbonyl-4″,6″*-O-*isopropylidenekanamycin B* (**8**). To a solution of **7** (115 mg) in a mixture of dioxane (4.5 m*l*), methanol (2.5 m*l*) and water (2.5 m*l*), platinum oxide (40 mg, preactivated with hydrogen) was added and the mixture was hydrogenated under

pressure (50 lbs/sq. inch) for 5 hr. The solution was filtered and the filtrate was evaporated to give a colorless solid (110 mg, 96%), which was dissolved in dioxane, and recrystallized by the addition of water, mp 271—272°C, $[\alpha]_D^{22}$ +93.5° (*c* 0.4, DMF).

Found: C, 54.15; H, 6.75; N, 7.64%. Calcd for $C_{43}H_{65}N_5O_{19}$: C, 54.02; H, 6.85; N, 7.33%.

NMR (in pyridine-d_5): τ 9.08, 8.97, 8.83 and 8.79 (3H, 3H, 3H and 6H triplet, respectively, *J* 6.7 Hz, $NHCO_2CH_2\text{-}C\underline{H}_3$), 8.60 and 8.51 (both 3H singlets, isopropylidene), 7.8—8.5 (~4H unresolved broadened signals, CH_2CH_2 at C-3′ and 4′), 5.5—6.5 (~24H m, skeleton protons and $NHCO_2C\underline{H}_2CH_3$), 4.42 and 3.93 (each 1H d, *J* 3 Hz, H-1′, 1″).

*2″-O-Benzoyl-3′,4′-dideoxy-penta-N-ethoxycarbonylkanamycin B (**9**).* A solution of **8** (98 mg) in a mixture of water (0.5 m*l*) and acetic acid (0.8 m*l*) was heated in a boiling water bath for 5 min and the solution was allowed to stand at room temperature to give crystalline **9**. The mixture was stored in a refrigerator for several hours and the crystals were filtered, washed with cold water and dried to yield 73 mg (78%), mp 247—249°C, $[\alpha]_D^{24}$ +89° (*c* 2.7, DMF); IR (KBr): 1735 (sharp), 1700 (sharp), 1540; 1035, 1015 (sh), 990, 945 (w), 905 (w), 880 (w), 782, 720 cm^{-1}.

Found: C, 52.41; H, 6.54; N, 7.92%. Calcd for $C_{40}H_{61}N_5O_{19}$: C 52.45; H, 6.71; N, 7.65%.

*3′,4′-Dideoxykanamycin B (**10**).* A mixture of **9** (30 mg) and barium hydroxide octahydrate (250 mg) in aqueous dioxane (1 and 0.8 m*l*) was heated in a boiling water bath for 4.5 hr. Carbon dioxide was introduced, and the resulting suspension was heated for a while and centrifuged. The supernatant layer and the washings combined were evaporated to give a residue, which on paper chromatogram showed two spots of $R_{f\,\text{kanamycin B}}$ 1.3 (major, **10**) and 2 (minor); on tlc with the same solvent system, the residue also showed two spots of R_f 0.13 (major) and 0.26. The residue was charged on a column of Amberlite IRC-50 (NH_4 form) and, after washing with water, developed with 0.1—0.5 N ammonia with gradual increase of concentration. The minor substance (R_f 0.26 on tlc) was eluted with 0.3 N ammonia and the major with 0.5 N ammonia. The latter fraction was evaporated to give a solid, 9.6 mg (65%), $[\alpha]_D^{20}$ +132° (*c* 0.65, water).

Found: C, 48.05; H, 8.49; N, 15.54%. Calcd for $C_{18}H_{37}N_5O_8$: C, 47.88; H, 8.26; N, 15.51%.

Hydrolysis of 3′,4′-Dideoxykanamycin B. A solution of 3′,4′-dideoxykanamycin B in **6** N hydrochloric acid was heated at 95°C for 2 hr. Paper chromatogram of the resulting solution showed three spots of $R_{f\,\text{deoxystreptamine}}$ 1 (2-deoxystreptamine), 3 (3-amino-3-deoxy-D-glucose) and 2. The latest was assigned to be the spot of 2,6-diamino-2,3,4,6-tetradeoxyerythrose, which was obtained from the hydrolysis of methyl 2,6-diamino-2,3,4,6-tetradeoxy-α-D-erythropyranoside.[4]

The authors wish to thank Mr. Saburo Nakada for the elemental analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3628—3633 (1972)

Crystal and Molecular Structure of ω-Amino Acids, ω-Aminosulfonic Acids and Their Derivatives. I. The Crystal and Molecular Structure of γ-Guanidinobutyric Acid Hydrochloride and Hydrobromide

Tomie MAEDA, Takaji FUJIWARA, and Ken-ichi TOMITA

Faculty of Pharmaceutical Sciences, Osaka University, Toneyama, Toyonaka, Osaka

(Received May 12, 1972)

The crystals of γ-guanidinobutyric acid (GGBA) hydrochloride and hydrobromide, $C_5H_{12}O_2N_3Cl$ and $C_5H_{12}O_2N_3Br$, are both triclinic, space group $P\bar{1}$, with two molecules in a unit cell with the following dimensions; hydrochloride: $a=7.41$, $b=9.12$, $c=7.25$ Å, $\alpha=101.5°$, $\beta=112.4°$, $\gamma=65.2°$; hydrobromide: $a=7.94$, $b=9.36$, $c=7.78$ Å, $\alpha=103.2°$, $\beta=115.5°$, $\gamma=61.5°$. The X-ray structure analysis was carried out by the application of heavy atom method and refined by three dimensional least-squares method. Since GGBA hydrochloride and hydrobromide are isomorphous, the structure analysis was started by using of X-ray data of the hydrobromide to determine the rough atomic coordinates of its molecule, and the data of hydrochloride were used for the further refinement. The positions of the involved twelve hydrogen atoms were located by a three dimensional difference Fourier analysis. GGBA cation, $^{+}NH_2(NH_2)CNH(CH_2)_3COOH$, and Cl^- ion were almost perfectly on the $(20\bar{1})$ plane and formed a pararell sheet structure with six hydrogen bonds. The possible resonance structures were also discussed.

γ-Guanidinobutyric acid (GGBA) is one of the amino acids related to γ-aminobutyric acid (GABA), which was first discovered in mammalian brain by Roberts and Frenkel[1] and others,[2-3] and was also found in *Crustacea* as a depressive transmitter by Elliott *et al.*,[4,5] or in cerebral cortex of mammalian brain as an anti-convulsive substance by Hayashi and Nagai.[6] Since then, the significance of GABA has been widely studied from the physiological and biological standpoints. On the other hand, GGBA has been found in

1) E. Roberts and S. Frenkel, *J. Biol. Chem.*, **187**, 55 (1950).
2) J. Awapara, A. J. Landau, R. Everet, and B. Seale, *ibid.*, **187**, 35 (1950).
3) S. Udenfriend, *ibid.*, **187**, 65 (1950).
4) A. Bazemore, K. A. C. Elliott, and E. Florey, *Nature*, **178**, 1052 (1956).
5) K. A. C. Elliott and E. Florey, *J. Neurochem.*, **1**, 181 (1956).
6) T. Hayashi and K. Nagaki, Abstr. XX Inst. Physiol. Congr. 410 (1956).

brain as a complex of GABA with basic amino acid,[7,8] and it acts as a depressive substance in peripheral nervous system of *Crustacea*,[9] as a stimulant in mammalian brain,[10,11] and as a convulsive substance in cerebrum of rabbit.[12]

The crystal and molecular structure of GGBA, therefore, is of most interest in order to elucidate the correlation between its structural specificity and pharmacological action of GABA, GGBA and other related ω-amino acids. Preliminary structural feature of these compounds has been discussed,[13] and this paper deals with the precise structure analysis of GGBA hydrochloride and hydrobromide.

Experimental

GGBA was synthesized from GABA and methyl-isothiourea sulfate, confirmed by Sakaguchi's and ninhydrin reactions, and recrystallized from aqueous solution at room temperature.

The crystals of GGBA were dissolved in concentrated solution of hydrochloric acid or hydrobromic acid and the crystals of GGBA hydrochloride or hydrobromide were obtained after staying for about three days. They are both colorless needles and the marked cleavage plane is parallel to $(20\bar{1})$. Intensity data were collected by the multiplefilm method of the equi-inclination Weissenberg photographs with Ni-filtered Cu-$K\alpha$ radiation and estimated by visual comparison with a calibrated scale. Lorentz-polarization and spot-shape correction were applied, but no correction for absorption.

Weissenberg photographs around the *a*- and *b*- axes demonstrated that almost all the crystals of hydrochloride and hydrobromide were twins consisting of two components, in which *a**- and *b**- axes have the opposite directions for each component in the reciprocal lattice.

The two-dimensional intensity data for (*h*0*l*) and (0*kl*) reflections of hydrobromide were collected, in which almost all the reflections of each component were separable except a few overlapped reflections. A single crystal of hydrochloride was incidentally obtained and the three-dimensional intensity data around the *a*- and *b*- axes were collected and totally 1435 independent reflections were used for the refinement.

Unit cell parameters of GGBA hydrochloride and hydrobromide were determined by Weissenberg and precession photographs and the space group $P\bar{1}$ was confirmed by statistical method. Densities were measured by floatation method with benzene and carbon tetrachloride mixture. Crystallographic data so obtained are listed in Table 1.

Structure Determination

GGBA hydrochloride and hydrobromide seem to be isomorphous, as shown in Table 1. The Patterson projections on (010) and (100) planes of hydrochloride and hydrobromide are similar and, therefore, the molecular structure and packing in the crystal lattice should be similar in both crystals.

The structure determination was carried out by the usual heavy atom method. To determine the coordinates of heavy atoms, bromine and chlorine, in the unit cell, the Patterson projections along the *a*- and *b*-axes were calculated. The coordinates of light atoms except hydrogen atoms in GGBA hydrobromide could be determined from the Fourier projections on (010) and (100) planes of GGBA hydrobromide with the phase based on the coordinate of heavy atom.

In the following stage, the three-dimensional full data of hydrochloride were used. Since GGBA molecule itself has pseudo center of symmetry at the midpoint of C_β–C_γ bond and the both end groups of the molecule occupied by oxygen or nitrogen atoms have similar scattering power for X-ray, it is difficult to distinguish which end group is carboxyl or guanidyl group.

In Fig. 1, model (1) shows the Fourier map calculated with one chlorine and ten carbon atoms on the supposition that GGBA molecule is constituted by carbon atom alone, and model (2) and (3) give both Fourier maps calculated from two models in which the former has guanidyl group as the left terminal group and the latter as the right terminal group of GGBA molecular chain. From these Fourier maps, overall feature of peak heights in (1) is similar to that in (2) and the peak corresponding to N(3) in (2) has reasonable height but the peak in (3) is too high to assume it as a carbon atom. Therefore, Fourier map by the model (2) was thought to show the most probable electron density distribution of this compound, and it was also confirmed by the following least-squares refinement.

Table 2 lists up the isotropic temperature factors for each atoms, the scale factors for F_o, k, and R-index, $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$, for two models, (2) and (3), after five cycles of block-diagonal least-squares refinement. In this table, several features will be

TABLE 2. THE ISOTROPIC TEMPERATURE FACTORS ($Å^{-2}$)

Model (2)		Model (3)	
Cl^-	3.13	Cl^-	3.15
N(1)	3.22	O(1)	5.34
N(2)	3.00	O(2)	5.09
C(1)	2.72	C(1)	2.31
N(3)	2.72	C(2)	1.33
C(2)	3.77	C(3)	3.38
C(3)	3.46	C(4)	3.59
C(4)	3.72	N(1)	4.88
C(5)	3.72	C(5)	3.02
O(1)	3.53	N(2)	1.87
O(2)	4.24	N(3)	2.75
$R=0.299$		$R=0.324$	
$k=0.961$		$k=0.974$	

noted. For example, in comparison of N(1) in model (2) with O(1) in model(3), the temperature factor of O(1) is found to be larger than that of N(1). Considering that all atoms of GGBA molecule are covalently bonded with each other, it seems reasonable that the temperature factors of all atoms might be nearly equal as found in model (2) in Table 2. Therefore, if the resultant scale factor, k, is equal for two models and the model(2) is correct, the temperature factor of the oxygen atom assigned improperly in model(3) might become larger and that of nitrogen atom should be much smaller for the minimizing of the difference between $|F_o|$ and $|F_c|$.

The block-diagonal least-squares refinement was then carried out on the structure corresponding to the model (2). After five cycles of refinement with isotropic temperature factors to all the non-hydrogen atoms, the R-index value reduced to 0.254. Further five cycles of refinement with anisotropic temperature factor to chlorine atom and isotropic temperature factors to other ten atoms dropped the R-index to 0.195.

At this stage, a difference Fourier synthesis was computed in order to find the hydrogen atoms and all twelve hydrogen atoms could be located. After several cycles of refinement with anisotropic temperature factors to all non-hydrogen atoms, the R-index dropped to 0.153. One more refinement with all the twenty-three atoms including hydrogen atoms with isotropic temperature factors was performed to reduce the R-factor to 0.143 (0.129 except $F_o=0$). The agreement between the observed and calculated struc-

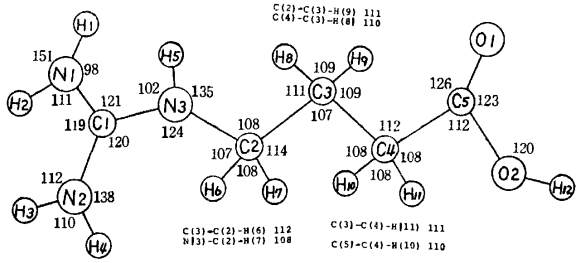

Fig. 4. (b) Bond angles (in degree) of GGBA hydrochloride.

mated standard deviations.

In guanidyl group, the average of three C–N bond lengths; 1.32, 1.32 and 1.34 Å, is 1.33 Å. These values are very similar to those reported so far in other compounds[15-19] with guanidyl group. However, these C–N bond distances are halfway between the normal C–N single bond length (1.47 Å) and the pure double bond distance (1.24 Å) proposed by Shomaker *et al.*[20]

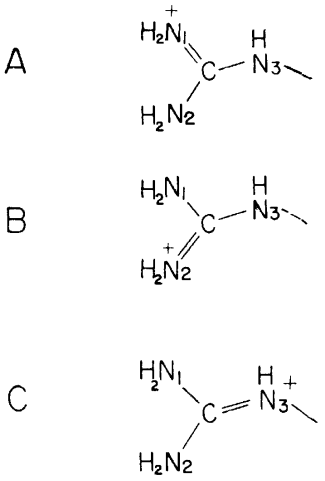

Fig. 5. Resonance of the guanidyl group in GGBA molecule.

Therefore, three C–N bonds of GGBA molecule have somewhat double bond character and the calculation by Pauling's method[21] indicated that the double bond characters of C(1)–N(1), C(1)–N(2) and C(1)–N(3) bonds are about 35%, 29% and 36% respectively. The major three resonance structures, A, B and C of the guanidyl group in GGBA cation, are shown in Fig. 5.

Three N–C–N angles, 119°, 120° and 121°, are not different with each other within the standard deviation. Similar bond angles are reported in guanidium chloride[17] and L-arginine dihydrate.[19]

The guanidyl group is attached to the carbon chain by a normal C–N bond of 1.48 Å. The average of the three C–C bond lengths is 1.53 Å and the C(3)–C(4)–C(5) angle of 112° is significantly larger than the other two angles, 107° and 108°.

The skeletal conformation of GGBA molecule is the 'trans-zigzag' form which is also found in GABA hydrochloride.[22]

In carboxyl group, C(5)–O(1) and C(5)–O(2) bond lengths are 1.17 and 1.32 Å respectively, and the three angles around the C(5) atom are 123°, 125° and 112° respectively. These values are not particularly different from those reported for α-amino acids so far investigated. However, C(5)–O(1) bond length is significantly shorter than C(5)–O(2) bond distance, and the angle of C(4)–C(5)–O(2) is smaller than that of C(4)–C(5)–O(1). Therefore, a hydrogen atom attaches to O(2) atom, which is confirmed by the difference Fourier synthesis, and GGBA hydrochloride is of the form, $^{+}NH_2(NH_2)CNH(CH_2)_3COOH \cdot Cl^{-}$, and GGBA molecule has probably zwitter-ion structure in free state. A similar conclusion is also reported in GABA hydrochloride[22] and L-leucine hydrobromide.[23]

The molecule of GGBA hydrochloride is almost perfectly planar and lies nearly on the (20$\bar{1}$) plane as shown in Fig. 6. The deviations of individual atoms from a least-squares plane are listed in Table 6. Six hydrogen atoms attached to nitrogen and oxygen

atoms lie also on the plane, but the other six hydrogen atoms attaching to the carbon atoms are situated above and below this plane.

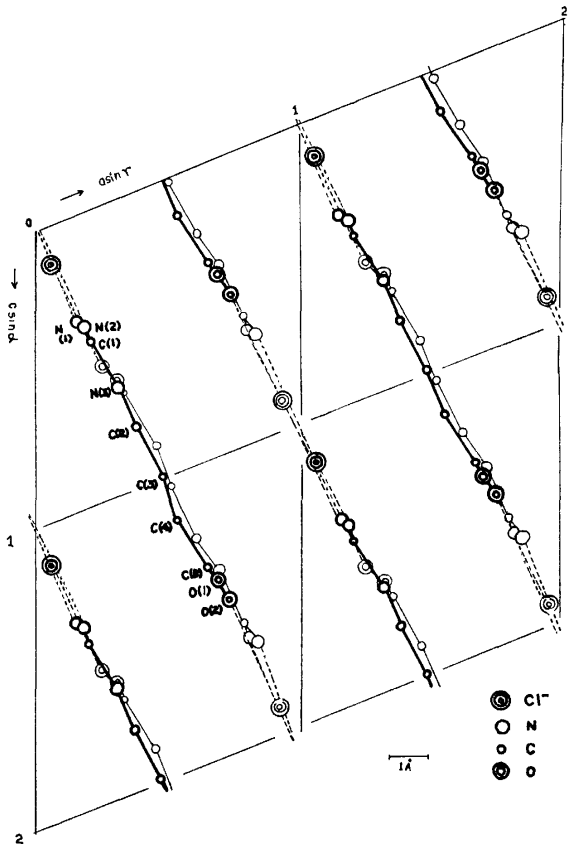

Fig. 6. A drawing of the structure of GGBA hydrochloride viewed down along the *b*-axis. The dashed lines indicate the hydrogen bonding.

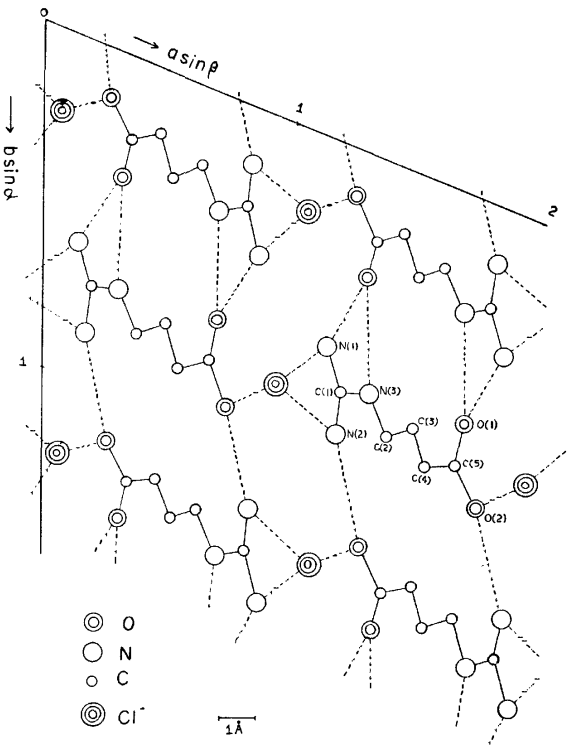

Fig. 7. A drawing of the structure of GGBA hydrochloride viewed down along the *c*-axis. The dashed lines indicate the hydrogen bonding.

The structure as viewed down the *c*-axis is shown in Fig. 7 and the hydrogen bond lengths are listed in Table 7. In guanidyl group, five hydrogen atoms attached to nitrogen atoms are used to form three N-H···O hydrogen bonds, 2.78 Å, 2.93 Å and 2.97 Å, and two N-H···Cl^- hydrogen bonds, 3.21 Å and 3.27 Å. One hydrogen atom attached to O(2) forms O-H···Cl^- hydrogen bond, 2.95 Å in length. Similar hydrogen bond lengths are reported in L-arginine dihydrate[19], L-tryptophan hydrochloride[24] and L-cystine hydrochloride.[25] All hydrogen bonds hold molecules together to form parallel sheets along $(20\bar{1})$ plane and no interaction except van der Waals force acts between the adjacent molecular planes as shown in Fig. 6 which is viewed down along the *b*-axis. This result explains the existence of the marked cleavage on $(20\bar{1})$ plane in the crystal.

This investigation was partly supported by the research grant from the Ministry of Education, Japan. We wish to express our sincere thanks for this support.

Crystal and Molecular Structure of ω-Amino Acids, ω-Amino Sulfonic Acids and Their Derivatives. II. The Crystal and Molecular Structure of α-Form of 3-Aminopropane Sulfonic Acid, Homotaurine

Sumiko UEOKA,* Takaji FUJIWARA, and Ken-ichi TOMITA

Faculty of Pharmaceutical Sciences, Osaka University, Toneyama, Toyonaka, Osaka

(Received May 12, 1972)

From ethanol aqueous solution, two forms of crystals of 3-aminopropane sulfonic acid (homotaurine) have been obtained in different crystal systems. The α-form is orthorhombic, space group $Pmn2_1$, with two molecules in a unit cell of the dimensions; $a=7.059$, $b=5.492$ and $c=7.428$ Å. The X-ray structure analysis was carried out by the application of usual heavy atom method and refined by three dimensional least-squares procedure. The final R-value is 0.059. In the crystalline state, homotaurine molecule has the zwitterionic structure, $NH_3^+-CH_2-CH_2-CH_2-SO_3^-$, with *trans-zigzag* skeletal configuration, and non-hydrogen atoms except two oxygen atoms lie exactly on a mirror plane. Each molecule in the crystal is connected by three dimensional network of three NH···O hydrogen bonds.

As described in previous papers,[1-3] we have been interested in the relationship between molecular conformation and physiological action of ω-amino acids and ω-amino sulfonic acids. 3-Aminopropane sulfonic acid, homotaurine, is a structural analogue of γ-aminobutyric acid (GABA), and it has one more methylene group than taurine, 2-aminoethane sulfonic acid. As a specific inhibitor of impulse transmission in the central nervous system, the pharmacological properties and possible physiological role of GABA have been recently reviewed in detail,[4] and it has been reported that homotaurine has more potent inhibitory effect than those of taurine[4-7] and also has a hypotensive and a cardiotonic effect.[8-10] As the detailed structure of taurine was reported by Okaya,[11] we describe here the crystal and molecular structure of homotaurine, comparing its molecular conformation with that of taurine.

Experimental

The powder sample of homotaurine was kindly supplied by Prof. S. Tsunoo, School of Medicine, Showa University, Tokyo. Dissolving this sample into hot ethanol aqueous solution, it was kept cool for crystallization. We have obtained two crystallographically different crystals, α- and β-form; the former is crystallized by cooling slowly and the latter by rapid cooling. The structure analysis of β-form is now in progress and as a part of our investigation on the molecular conformation of ω-amino sulfonic acid, the report will be published in near future. Therefore, we wish to discuss here just the detailed crystal and molecular structure of the α-form.

The cell dimensions were obtained on a Rigaku Denki four circles diffractometer with Mo-$K\alpha$ radiation, and they were given in Table 1. According to the systematic absences of reflections ($h0l$; $h+l=2n+1$, $h00$; $h=2n+1$, $00l$; $l=2n+1$), the orthorhombic space groups, $P2_122_1$, $Pmnm$ and $Pmn2_1$, are all possible. In consequence of the density measurement by floatation in carbon tetrachloride and ethylene bromide mixture, the number of molecule in a unit cell is two. On the other hand, homotaurine molecule itself has no two-fold symmetry. Therefore, the space group of the crystal is determined to be $Pmn2_1$.

TABLE 1. CRYSTAL DATA OF 3-AMINOPROPANE-SULFONIC ACID (HOMOTAURINE)

Crystal system:	orthorhombic
Cell constants:	$a=7.059\pm0.005$ Å
	$b=5.492\pm0.006$ Å
	$c=7.428\pm0.004$ Å
Space group:	$Pmn2_1$
Density (obsd):	$D_o=1.610\pm0.002$ g/cm³
(calcd):	$D_c=1.605$ g/cm³

The prismatic crystal was cut down to be approximately $0.2\times0.2\times0.2$ mm for intensity measurement. The intensity data were collected on the Rigaku Denki computer controlled automatic four-circles diffractometer. The $\omega/2\theta$ scan technique using Zr-filtered Mo-$K\alpha$ radiation was employed. A total of 1143 independent reflections in the range of $\sin\theta/\lambda=0.95$ Å^{-1} were collected and these observed structure factors were converted into absolute values by a program for Wilson's statistics.

Structure Determination

As expected from the fact that the space group of the α-form is $Pmn2_1$ and the unit cell contains two molecules, homotaurine molecule should be located on a mirror plane.

The coordinate of sulfur atom was determined by vector relation on three Harker sections of the sharpened Patterson synthesis with coefficient of $|F_o|^2_{\text{mod.}}=$

Table 2(b). The final temperature factors and their standard deviations ($\times 10^4$)
The anisotropic temperature factors are in the form of $\exp[-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+\beta_{12}hk+\beta_{13}hl+\beta_{23}kl)]$

$|F_o|^2 \exp[2\beta(\sin\theta/\lambda)^2]$. All positions of the non-hydrogen atoms were easily determined by a Fourier synthesis with phases based on the sulfur atom. After successive Fourier refinements, the discrepancy factor, $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$, decreased to 0.20.

Further refinement was carried out by the block-diagonal least-squares method. After five cycles of refinement with isotropic temperature factors ($R=$ 0.12) and further five cycles with anisotropic temperature factors for all non-hydrogen atoms ($R=0.066$), a difference Fourier synthesis was calculated to determine the locations of hydrogen atoms. Six hydrogen atoms bound to carbon atoms and two hydrogen atoms connected on the nitrogen atom were satisfactorily located with reasonable peak heights. However, peak height for the last one which was thought to be bound to the nitrogen atom was about half of others. There was also no peak to be assigned as a hydrogen atom near the sulfonic oxygen atoms on the difference map. Further five cycles least-squares refinement of positional parameters with anisotropic temperature factors for non-hydrogen atoms and isotropic for hydrogen atoms reduced the R factor to 0.059 (0.054 for $F_o \neq 0$).

The final atomic coordinates and temperature factors together with their estimated standard deviations are given in Table 2. The observed and calculated structure factors are listed in Table 3.

All the numerical calculations were carried out on a NEAC 2200—500 in the computing center of this University, a FACOM 230—60 in the data processing center at the Kyoto University and a HITAC 5020E in the computing center at University of Tokyo, using the programs written by Dr. Tamaichi Ashida and by

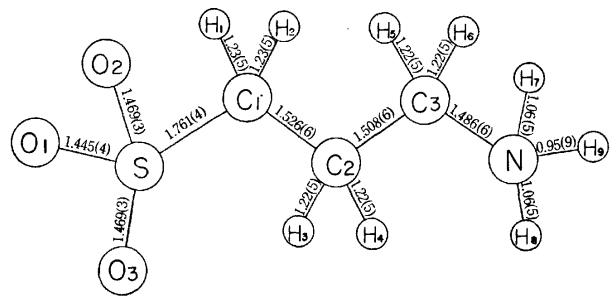
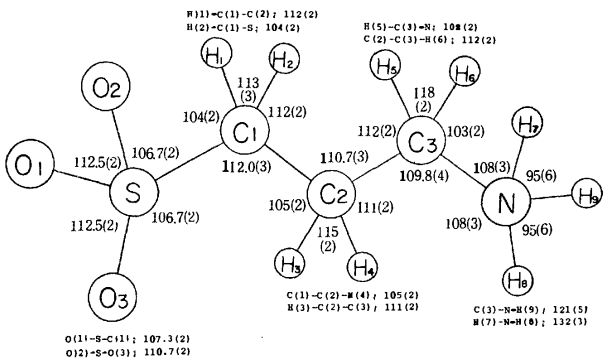
Results and Discussion

The bond distances and angles are shown in Fig. 1 (a) and (b).



(a)



(b)

Fig. 1. (a) Bond distances and their standard deviations in parentheses (in Å).
(b) Bond angles and their standard deviations in parentheses (in degree).

In crystal of the α-form, homotaurine molecule has the zwitterionic structure NH_3^+–CH_2–CH_2–CH_2–SO_3^-, and the seven atoms, O(1), S, C(1), C(2), C(3), N and H(9), in a molecule are exactly on a mirror plane and these atoms preserve the planar *trans-zigzag* configuration, while the same zwitterionic molecule of taurine has the *gauche* configuration around the central methylene linkage. A hydrogen atom, H(9), the location of which is still obscure, should be on the mirror plane and has to be *trans* configuration to C(2) atom with respect to C(3)–N bond, participating in NH···O hydrogen bond formation with the adjacent molecule on the same mirror plane.

It is still unknown about the general feature of molecular conformation of ω-amino sulfonic acid, but such *trans-zigzag* configuration in the homotaurine molecule is also found in GABA hydrochloride[12] and γ-guanidinobutyric acid (GGBA) hydrochloride and hydrobromide,[3] which are particularly interesting substances for the investigation on the relation between their molecular conformations and their characteristic physiological actions.

The configuration of the sulfonic group is considerably interesting. O(2) and O(3) oxygen atoms in a molecule are related by the mirror plane symmetry, and have exactly equal S–O distances of 1.469 Å, whereas O(1) atom exhibits a smaller separation of 1.445 Å. Considering the fact cited above and the longer O(1)···HN hydrogen bond distance of 2.892 Å, O(1) atom might be loosely interacted with an amino group, and it may reflect the ambiguity of H(9) position. Larger C(1)–S–O bond angle was found in the shorter S–O bonds, and it was also observed in taurine.

The C(1)–S distance of 1.761 Å is very similar to that of taurine molecule.[11] Taurine is a structural analogue of homotaurine, and as shown in Table 4 one significant deviation is found in bond angle C–C–N, 109.8° in homotaurine and 112.6° in taurine, while the corresponding angle in ω-amino acids is 111.2° in GABA[13] and 108.4° in β-alanine.[14]

The intramolecular distances between sulfonic group and amino group of ω-amino sulfonic acid are shown in Table 5. Considering the fact that taurine is less active than homotaurine on depression of cortical responses.[4-7] the conformational difference between these compounds might be substantial in these physiological significances. Another interesting feature to be noted here is that NH_3^+–$\underset{|}{CH}$–CH_2–SO_3^- configuration of taurine is same as that of L-cysteic acid,[15] which is active on excitation of cortical responses,[5] and furthermore homocysteic acid which possesses NH_3^+–$\underset{|}{CH}$–CH_2–CH_2–SO_3^- group as homotaurine, has much stronger excitatory action than cysteic acid. The configuration of homocysteic acid might be same as that of homotaurine.

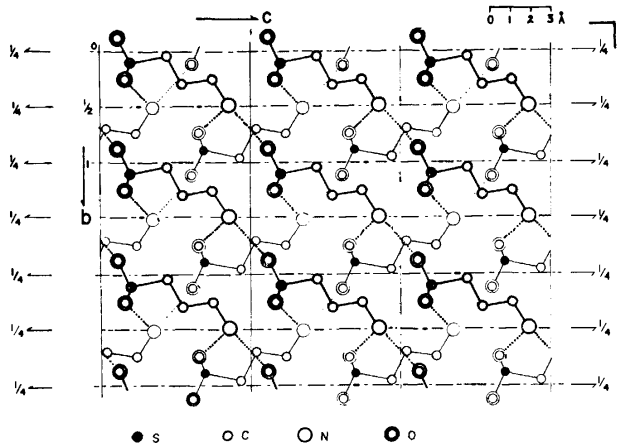

Fig. 2. (a) The crystal structure of homotaurine viewed down along the *a*-axis.

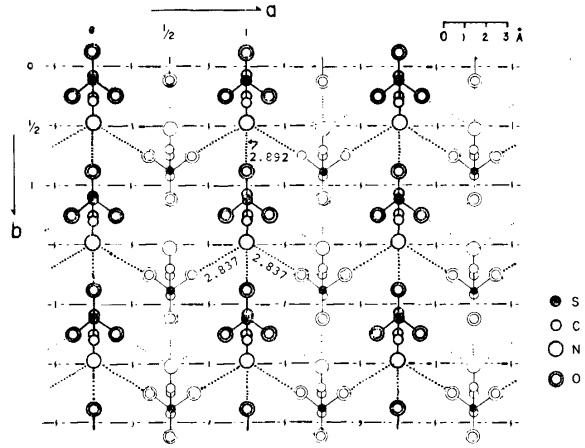

Fig. 2. (b) The crystal structure of homotaurine viewed down along the *c*-axis.

Figure 2 (a) and 2 (b) show the packing of molecules in crystal lattice projected along the *a*- and *c*-axis respectively, where the dotted lines indicate the hydrogen bonds. Homotaurine molecules are jointed to each other with three NH···O hydrogen bonds (2.837, 2.837 and 2.892 Å) to form three dimensional network structure, whereas in taurine structure, there are three NH···O intermolecular hydrogen bonds of 2.793, 2.893, and 2.939 Å, and one intramolecular hydrogen bonding of 2.926 Å. The intermolecular contacts between adjacent molecules are kept by normal van der Waals distances, of which the shortest one between N and C(2) atoms related by two-fold screw axis is 3.906 Å.

Linear Conjugated Systems Bearing Aromatic Terminal Groups. X.[1] Syntheses and Electronic Spectra of α,ω-Di-1-naphthyl- and α,ω-Di-2-naphthylpolyenes

Akio YASUHARA, Shuzo AKIYAMA, and Masazumi NAKAGAWA

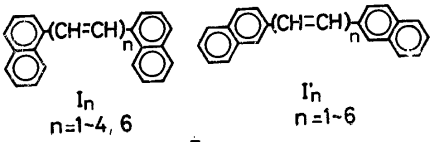
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka, 560

(Received May 12, 1972)

Syntheses of di-1-naphthyl- and di-2-naphthylpolyenes (I_n, $n=1$—4,6 and I_n', $n=1$—6) have been carried out by the Wittig reaction. Naphthaldehydes (III and III'), 3-naphthyl-2-propenals (V and V'), 5-naphthyl-2,4-pentadienals (VI and VI') and muconic aldehyde were used as carbonyl components. Naphthylmethyltriphenylphosphonium halides (IV and IV'), 3-naphthyl-2-propenyltriphenylphosphonium bromides (XI and XI') and 5-(2-naphthyl)-2,4-pentadienyltriphenylphosphonium bromide (XII') were synthesized and converted into the corresponding phosphoranes by reaction with phenyllithium. The reaction of carbonyl moiety with phosphorane by a proper combination afforded dinaphthylpolyenes (I_n and I_n'). The electronic spectra of di-1-naphthylpolyenes (I_n) showed broad and structureless absorption curves. In contrast, the absorption curves of di-2-naphthylpolyenes (I_n') exhibited a distinct vibrational fine structure. It was found that the bathochromic shift of the longest-wavelength peak (λ_{max}) along with the increase of the number of double bond (n) can be expressed by the following empirical formula:

$$\lambda_{max}=45.4n^{0.7}+302 \text{ (nm in tetrahydrofuran)}$$

The electronic spectra of α,ω-di-1-anthrylpolyenes[1] suggest that the aromatic terminal groups exert an appreciable effect on the electronic excitation of polyene chromophore. However, the spectral regularity of dianthrylpolyenes could not be discussed in detail owing to the broad and structureless bands in the longest-wavelength region. Preparation of other di-

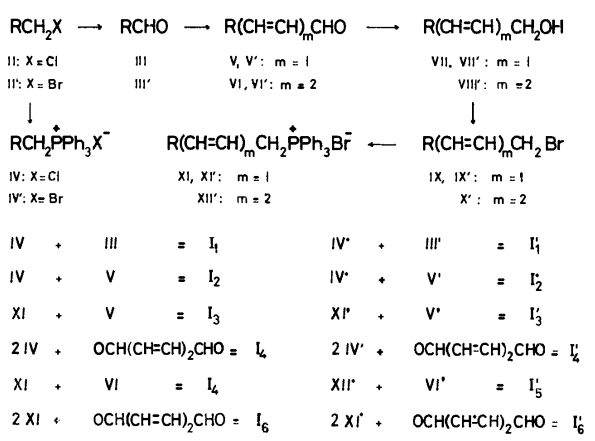


I_n n=1~4, 6 I_n' n=1~6

1) Part IX of this series: Y. Takeuchi, S. Akiyama, and M. Nakagawa, This Bulletin, **45**, 3183 (1972).

arylpolyenes was desirable to get further information on the role of aromatic terminal groups in spectral regularity. This paper deals with the syntheses and electronic spectral properties of di-1-naphthyl- and di-2-naphthylpolyenes (I_n and I_n'), and the spectral regularity of the latter.

Syntheses. Syntheses of di-1-naphthyl- and di-2-naphthylpolyenes (I_n and I_n') have been carried out according to the reaction sequence outlined in the Scheme. 1-Chloromethyl-[2] and 2-bromomethylnaphthalenes were converted into the corresponding naphthylmethyltriphenylphosphonium halides (IV and IV'). 3-(1-Naphthyl)-2-propenal (V) was prepared by the Meyer-Schuster rearrangement of 1-naphthylethynylcarbinol.[3] 2-Naphthaldehyde (III') prepared from 2-hydroxymethylnaphthalene was converted into 3-(2-naphthyl)-2-propenal (V') by a modified J. F. Arens and van Dorp method,[4] since the Meyer-Schuster rearrangement of 2-naphthylethynylcarbinol gave less satisfactory results. Naphthyl-2-propen-1-ols



Scheme. Syntheses of dinaphthylpolyenes (I_n and I_n'). R means a 1- or 2-naphthyl group, and the prime on the Roman figure indicates that R is 2-naphthyl group.

(VII and VII') obtained by the reduction of naphthyl-2-propenals (V and V') by means of sodium borohydride were converted into unstable allylic bromides (IX and IX'). IX and IX' afforded naphthylpropenyltriphenylphosphonium bromides (XI and XI') on treatment with triphenylphosphine. The reaction of Grignard derivative of methoxybutenyne[5] with 1- or 2-naphthaldehyde (III or III') followed by reduction with lithium aluminum hydride and treatment with acid yielded 5-(1-naphthyl)- or 5-(2-naphthyl)-2,4-pentadienal (VI or VI'). 5-(2-Naphthyl)-2,4-pentadien-1-ol (VIII') was prepared by the reduction of 2-naphthylpentadienal (VI') with sodium borohydride. 5-(2-Naphthyl)-pentadienyltriphenylphosphonium bromide (XII') was obtained from 2-naphthylpentadienol (VIII) *via* bromide (X').

The Wittig reaction between the aldehyde component (III, III', V, V', VI, and VI') and the phosphorane moiety obtained from phosphonium halide (IV, IV', XI, XI', and XII') according to the combination shown in the Scheme gave α,ω-dinaphthylpolyenes (I_{1-4}, I'_{1-3} and I'_5). The reaction of muconic aldehyde with phosphoranes derived from IV, IV', XI, and XI' afforded dinaphthyloctatetraenes (I_4 and I'_4) and dinaphthyldodecahexaenes (I_6 and I'_6), respectively. The 2-naphthyl series gave a lower yield than the 1-naphthyl series in the Wittig reaction (Table 1). Di-1-naphthylpolyenes (I_{1-4} and I_6) were found to be stable against heat and light and showed definite melting points. Di-2-naphthylpolyenes (I'_{1-6}) exhibited much higher melting points than those of 1-naphthyl analogues. Some of them decomposed on attempted melting point determination. Di-1-naphthylpolyenes (I_n) were found more soluble than di-2-naphthylpolyenes (I_n') in organic solvents. Decrease of solubility due to increase in the length of polyene chain was observed in both series. The color of crystals, melting points and the wave number of IR absorption in the region of C–H out-of-plane defor-

mation (δ) of *trans*-double bond are given in Table 1.

Electronic Spectra. The absorption curves and numerical data of electronic spectra of both series of dinaphthylpolyenes (I_n and I_n') are shown in Figs. 1 and 2 and Tables 2 and 3. Di-1-naphthylpolyenes (I_n) show broad and structureless intense bands in the long-wavelength region indicating the presence of steric interference between hydrogen atoms of ethylenic bonds and those of *peri*- and *o*-positions of naphthalene nuclei. The intense absorption bands in the

An asterisk indicates shoulder.

long-wavelength region in the electronic spectra of di-2-naphthylpolyenes (I_n') show a well-defined vibrational fine structure (Fig. 2). The long-wavelength band can be considered to arise from an interaction of ^1L_a band of naphthalene with polyene chromophore. The shoulder at longest-wavelength (357 nm) observed in the spectrum of di-2-naphthylethylene (I_1') seems to be related to the ^1L_b band of naphthalene nucleus. In the higher members (I'_{2-6}), the band related to ^1L_b seems to be submerged under intense ^1L_a bands. The spacings between the longest-wavelength subbands (λ_I) and the next longest-wavelength subbands (λ_{II}) are found to be 1400—1500 cm^{-1} except for di-2-naphthylethylene (I'_1) (Table 4).

Table 4. Spacing of vibrational fine structure of I'_n (cm^{-1})

n	1	2	3	4	5	6
	1210	1560	1450	1420	1420	1440

Regularity of the electronic spectra of di-1-naphthylpolyenes (I_n) could not be discussed owing to the broad and structureless features of the longest-wavelength bands. On the other hand, well-developed sub-peaks in the spectra of I_n' made it possible to determine the exact location of maxima at long-wavelength region. We consider the longest-wavelength bands of diarylpolyenes to shift linearly with the x-th power of the number of double bond (n), and the wavelength of maxima (λ_I and λ_{II}) might be expressed by the empirical formula

$$\lambda = A_n{}^x + B$$

just as in the case of diarylpoly-ynes. The plots of λ_I and λ_{II} *versus* $n^{0.7}$ gave good straight lines (Fig. 3).

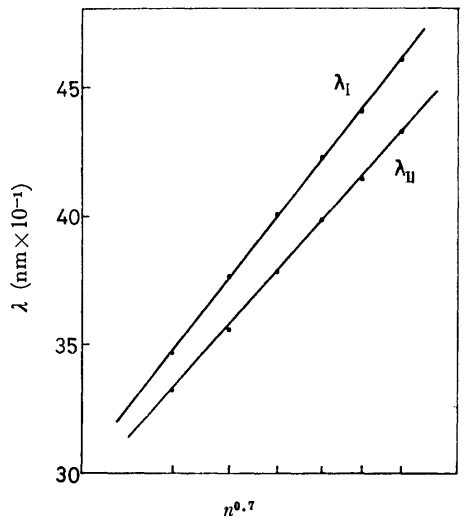

Fig. 3. Plot of λ_{max} *vs.* $n^{0.7}$ for di-2-naphthylpolyenes (I_n').
λ_I: longest-wavelength maxima
λ_{II}: second-longest-wavelength maxima

6) K. Nakasuji, S. Akiyama, K. Akashi, and M. Nakagawa, This Bulletin, **43**, 3567 (1970).
7) M. Nakagawa, S. Akiyama, K. Nakasuji, and K. Nishimoto, *Tetrahedron*, **27**, 5401 (1971).

The linear relationships can be expressed by the following empirical formulas:

$\lambda_I = 45.4\ n^{0.7} + 302$ (nm in tetrahydrofuran)
$\lambda_{II} = 40.0\ n^{0.7} + 292$ (nm in tetrahydrofuran)

The calculated values show excellent agreement with the observed values (Table 5). The spectral regularity

Table 5. Observed and calculated λ_I and λ_{II} of I_n'

	n	1	2	3	4	4	6
λ_I	Calcd	347	377	401	423	441	462

of 2,2'-dinaphthylpoly-ynes, acetylenic analogues of I_n', could be expressed by the empirical formula, $\lambda = 15.5\ n^{1.3} + 319$ (nm in tetrahydrofuran).[6,7] It should be noted that the B-values of both series are found to be nearly the same. However, the coefficient A of di-2-naphthylpolyenes (I_n') is much larger than that of 2,2'-dinaphthylpoly-yens.

Experimental

All the melting points are uncorrected. The electronic spectra were measured with a Hitachi EPS-3T spectrophotometer at room temperature employing a well-matched pair of 1-cm quartz cells, otherwise stated. The IR spectra were obtained on a Hitachi EPI-2 infrared spectrophotometer by the KBr-disk method. Evaporation of solvent was performed under reduced pressure.

1-Naphthylmethyltriphenylphosphonium Chloride (IV). A solution of 1-chloromethylnaphthalene[2] (II, 12.3 g, 0.07 mol) and triphenylphosphine (20.2 g, 0.077 mol) in xylene (100 m*l*) was refluxed to yield a colorless precipitate. The precipitate was filtered and washed with benzene, yielding colorless crystalline powder (33.1 g, quantitative). The material was recrystallized from ethanol to afford IV as colorless plates, mp 292—301°C (decomp.).

Found: C, 79.62; H, 5.38; Cl, 8.15%. Calcd for $C_{29}H_{24}PCl$: C, 79.35; H, 5.51; Cl, 8.08%.

3-(1-Naphthyl)-2-propen-1-ol (VII). A solution of sodium borohydride (1.5 g, 0.04 mol) and 3-(1-naphthyl)-2-propenal (V, 4.0 g, 0.022 mol) prepared by the Meyer-Schuster rearrangement of 1-(1-naphthyl)-2-propyn-1-ol,[3] in 2-propanol (200 m*l*) was refluxed for 2 hr. The residue obtained by concentration of the reaction mixture was treated with dilute hydrochloric acid and extracted with ether. After washing and drying, the extract was evaporated to yield crude VII (3.08 g, 76.2%) as a brown liquid. The crude alcohol (VII) was subjected to the following reaction.

3-(1-Naphthyl)-2-propenyl Bromide (IX). To a solution of the crude alcohol (VII, 3.08 g, 0.017 mol) in chloroform (50 m*l*) containing 10 drops of pyridine was added a solution of phosphorus tribromide (2.16 g, 0.008 mol) in chloroform (20 m*l*) over a 30-min period. After stirring for 20 hr, cracked ice was added to the chilled reaction mixture and then the mixture was poured onto ice-water. The aqueous layer was extracted with chloroform. The extract was successively washed with water, a saturated sodium hydrogencarbonate solution and water, and dried. The residue obtained by evaporation of the extract was dissolved in carbon

tetrachloride and filtered. The crystals deposited on concentration of the filtrate were washed with the same solvent to afford IX as brownish yellow crystals, mp 56—59°C, 4.09 g (quantitative).

3-(1-Naphthyl)-2-propenyltriphenylphosphonium Bromide (XI). A solution of bromide (IX, 4.09 g, 0.021 mol) and triphenylphosphine (5.56 g, 0.021 mol) in toluene (70 ml) was refluxed for 17 hr. Pale yellow solid deposited was collected by filtration and washed with toluene. The crude material 8.21 g, 98.1%) was recrystallized twice from ethanol to give pure phosphonium bromide (XI), mp 238—240°C,

Found: C, 73.28; H, 5.25; Br, 15.29%. Calcd for $C_{31}H_{26}PBr$: C, 73.09; H, 5.14; Br, 15.68%.

5-(1-Naphthyl)-2,4-pentadienal (VI). To a stirred solution of 4-methoxy-3-buten-1-yne (1.58 g, 0.019 mol) in tetrahydrofuran (10 ml) maintained at 38—40°C was added over a 30-min period a solution of ethylmagnesium bromide in the same solvent (20 ml) [prepared from ethyl bromide, 2.8 g (0.026 mol) and magnesium, 0.31 g (0.013 g-atom)] under nitrogen atmosphere. After stirring for further 30 min at room temperature, the mixture was chilled in an ice-salt bath and a solution of 1-naphthaldehyde (III, 1.0 g, 0.0064 mol) in tetrahydrofuran (20 ml) was added over a 25-min period. Stirring was continued overnight. A saturated solution of ammonium chloride (50 ml) was added to the reaction mixture under cooling with an ice-salt bath. The aqueous layer was extracted with ether. The combined organic layer was dried and evaporated to give a red liquid. Crude 1-(1-naphthyl)-5-methoxy-4-penten-2-yn-1-ol thus obtained was dissolved in ether (20 ml). The ethereal solution was added over a 40-min period to a stirred solution of lithium aluminum hydride (0.72 g, 0.019 mol) in ether (20 ml) under cooling in an ice-salt bath. After further stirring for 6.5 hr at room temperature, a mixture of ethyl acetate (5 ml) and ether (6 ml) and then ethyl acetate (3.5 ml), water (3 ml) and 4 N sulfuric acid (27 ml) were added successively to the ice-cooled reaction mixture. After being stirred overnight at room temperature, the aqueous layer was extracted with ether. The combined ethereal solution was washed successively with a solution of sodium hydrogencarbonate and water, and dried. Crude 1-naphthylpentadienal (VI, 1.108 g) was obtained as brownish liquid on evaporation of the solvent. This material was subjected to chromatography on silica gel and used in the subsequent reaction.

2-Hydroxymethylnaphthalene. To a refluxing solution of lithium aluminum hydride (6.50 g, 0.171 mol) in ether (200 ml) was added a solution of methyl 2-naphthoate (32.8 g, 0.171 mol) in ether (200 ml) and tetrahydrofuran (50 ml) over a period of 30 min. After the mixture had been stirred for 3 hr under reflux, methanol (60 ml) was added under cooling in an ice-bath and stirring was continued overnight. A saturated solution of ammonium chloride containing hydrochloric acid was added to the reaction mixture. The aqueous layer was extracted with ether. The combined organic layer was washed successively with aqueous sodium carbonate solution and water, and dried. Colorless crystals (27.1 g, 97.1%) obtained by evaporating the solvent were recrystalized from ethanol to give pure 2-hydroxymethylnaphthalene, mp 80—82°C (lit,[8] mp 80—80.5°C).

2-Naphthaldehyde (III'). A solution of 2-hydroxymethylnaphthalene (15.8 g, 0.10 mol) in pyridine (40 ml) was added to an ice-cooled suspension of chromium trioxide-pyridine complex in pyridine [prepared from chromium trioxide, (31.5 g, 0.30 mol) and pyridine (350 ml)] and kept at the same temperature for 1 hr. The reaction mixture was then allowed to stand at room temperature for 2 hr, and poured onto water and extracted with ether (1.5 l). The extract was washed successively with 10% hydrochloric acid, water, 10% aqueous sodium carbonate solution and water, and dried. Colorless crystals (14.8 g, 94.9%) obtained by evaporation of the solvent were recrystallized from carbon tetrachloride and then from ethanol, yielding pure III', mp 60—61°C (lit,[9] 59—60°C).

2-Bromomethylnaphthalene (II'). To an ice-cooled and stirred solution of 2-hydroxymethylnaphthalene (5.0 g, 0.032 mol) in chloroform (70 ml) containing 1 ml of pyridine was added dropwise a solution of phosphorus tribromide (9.6 g, 0.035 mol) in chloroform (15 ml). After stirring for 1 hr at room temperature, crushed ice was added to the reaction mixture under ice-cooling and the mixture was then poured onto ice-water. The aqueous layer was extracted with chloroform. The combined chloroform layer was washed successively with sodium hydrogencarbonate solution and water, and dried. Evaporation of the solvent afforded colorless crystals, 6.1 g (87.1%) which were recrystallized from ethanol to give pure II', mp 53—55°C (lit, 48°C[10], 53—56°C[11]).

2-Naphthylmethyltriphenylphosphonium Bromide (IV'). A solution of triphenylphosphine (6.71 g, 0.0256 mol) in benzene (100 ml) was added to a solution of 2-bromomethylnaphthalene (II', 5.60 g, 0.0253 mol) in benzene (100 ml). After the mixture had been stirred under reflux for 4.5 hr, the solid deposited was collected and washed with benzene, yielding colorless crystals, 11.4 g (93.4%). Recrystallization of the crystals from ethanol yielded pure IV', mp 251—252°C lit,[12] mp 248—251°C (decomp.)).

3-(2-Naphthyl)-2-propenal (V'). *(a) By the Meyer-Schuster Rearrangement*: To an ice-cooled and stirred solution of ethynylmagnesium bromide in tetrahydrofuran (70 ml) [prepared from ethyl bromide, 7.0 g (0.064 mol), magnesium, 1.2 g (0.05 g-atom) and excess acetylene][13] was added a solution of 2-naphthaldehyde (III', 5.0 g, 0.032 mol) in the same solvent (10 ml). The mixture was stirred overnight under cooling in an ice-bath. The reaction mixture was poured onto a saturated solution of ammonium chloride (150 ml). The aqueous layer was extracted with ether (200 ml). The combined organic layer was dried and evaporated. The residue was dissolved in benzene and passed through a short column of alumina (10 g). 1-(2-Naphthyl)-2-propyn-1-ol was obtained as pale yellow crystals (6.1 g) on concentration of the filtrate. The crude carbinol was dissolved in a mixture of dioxane (150 ml), water (25 ml) and concentrated sulfuric acid (3 ml) and the mixture was refluxed for 30 hr. The mixture was then poured onto water (280 ml) and extracted with benzene (300 ml). The extract was washed successively with 10% aqueous solution of sodium hydrogencarbonate (50 ml) and water (100 ml) and dried. Brown crystals obtained by evaporation of the solvent were dissolved in ether-benzene and the solution was stirred with a saturated solution of sodium hydrogensulfite for 3 hr to give sulfite adduct of V'. The adduct deposited was collected and decomposed with a dilute sodium hydroxide solu-

tion. 2-Naphthylpropenal (V′) liberated was taken up in benzene. After washing and drying, the benzene solution was evaporated. The residue redissolved in benzene (50 ml) was passed through a thin layer of alumina (4 g). Evaporation of the filtrate gave pure V′ as pale yellow crystals, mp 119—122°C, 1.26 g (21.6%).

(b) By the Modified Arens and van Dorp Method: To a stirred solution of lithium amide [from lithium (2.1 g, 0.303 g-atom)] in liquid ammonia (160 ml) was added over a 20-min period a solution of 2-chlorovinyl ethyl ether (16.52 g, 0.16 mol) in tetrahydrofuran (15 ml) under cooling in a dry ice-ethanol bath, and the mixture was stirred for further 1.5 hr at −60°C. To a solution of lithium ethoxyacetylide thus prepared was added a solution of 2-naphthaldehyde (III′, 5.95 g, 0.038 mol) in tetrahydrofuran (50 ml) over a period of 30 min. After the mixture had been stirred overnight at −40—30°C, ammonium chloride (18 g) was added to the mixture under cooling in a dry ice-ethanol bath. Stirring was continued for 15 min at −60°C. Ammonia was then allowed to evaporate. The residue was mixed with a saturated ammonium chloride solution (200 ml) and the organic layer was separated. The aqueous layer was extracted with ether (500 ml). The combined organic layer was dried and evaporated to yield a red liquid. A benzene solution of the red liquid was passed through a short column of alumina (5 g). The reddish liquid obtained by evaporation of the filtrate was dissolved in ether (30 ml). The ethereal solution was added to an ice-cooled solution of lithium aluminum hydride (2.01 g, 0.053 mol) in ether (70 ml) and stirring was continued overnight at room temperature. Ethyl acetate (10 ml) and 6 N sulfuric acid (100 ml) were then added dropwise in the ice-cooled reaction mixture and stirring was continued for 7 hr at room temperature. The organic layer was separated and the aqueous layer was extracted with ether and then with benzene. After washing and drying, the combined organic layer gave orange yellow crystals on evaporation of the solvent. The filtrate obtained by percolation of a benzene solution of the crude crystals through a column of alumina (15 g) was concentrated to yield 2-naphthylpropenal (V′, 4.5 g, 64.8%) which was recrystallized from ethanol to yield pure V′, pale yellow crystals, mp 122—124°C (lit, mp 118—119°C[14]; mp 125°C[15]).

3-(2-Naphthyl)-2-propen-1-ol (VII′). To a solution of 2-naphthylpropenal (V′, 1.91 g, 0.0105 mol) in tetrahydrofuran (50 ml) was added sodium borohydride (0.48 g, 0.0127 mol) and the mixture was refluxed for 1 hr under stirring. The reaction mixture was concentrated, treated with dilute hydrochloric acid and extracted with benzene. After washing and drying, the extract was evaporated to yield yellow crystals, 1.83 g (94.8%) which were recrystallized from carbon tetrachloride, thus affording pure VII′, mp 103—105°C.

Found: C, 84.43; H, 6.44%. Calcd for $C_{13}H_{12}O$: C, 84.75; H, 6.57%.

3-(2-Naphthyl)-2-propenyl Bromide (IX′). To an ice-cooled solution of 2-naphthylpropenol (VII′, 0.96 g, 0.0052 mol) in chloroform (30 ml) containing pyridine (1 ml) was added dropwise a solution of phosphorus tribromide (1.42 g, 0.0052 mol) in chloroform (10 ml). The mixture was stirred for 1 hr at 10°C. Cracked ice was then added to the reaction mixture under ice-cooling. After most of the organic solvent has been removed, the mixture was poured onto water and extracted with benzene. The extract, after washing and drying, was concentrated to afford IX′ as colorless crystals, 0.9 g (70%). This material was used without further purification in the following reaction.

3-(2-Naphthyl)-2-propenyltriphenylphosphonium Bromide (XI′). A solution of 2-naphthylpropenyl bromide (IX′, 0.9 g, 0.0036 mol) and triphenylphosphine (0.91 g, 0.0037 mol) in benzene (50 ml) was stirred for 48 hr at room temperature. Colorless crystals deposited (1.478 g, 80.0%) were recrystallized from aqueous ethanol to give colorless plates, mp 235—236°C. An analytical specimen was prepared on drying the crystals at 130°C for 6 hr *in vacuo*.

Found: C, 73.50; H, 5.31; Br, 15.54%. Calcd for $C_{31}H_{26}BrP$: C, 73.09; H, 5.14; Br, 15.69%.

5-(2-Naphthyl)-2,4-pentadienal (VI′). To a solution of ethylmagnesium bromide (0.04 mol) in tetrahydrofuran (40 ml) was added a solution of 4-methoxy-3-buten-1-yne (4.45 g, 0.054 mol) in the same solvent (30 ml) under nitrogen atmosphere at 40°C. After the evolution of ethane subsided, 2-naphthaldehyde (III′, 5.0 g, 0.032 mol) in tetrahydrofuran (30 ml) was added dropwise to the ice-cooled reaction mixture. After stirring overnight, the reaction mixture was poured onto an ice-cooled saturated solution of ammonium chloride (150 ml). The aqueous layer was extracted with ether. The extract was combined with the organic layer and dried. The residue obtained by evaporation of the solvent was dissolved in benzene and passed through a short column of alumina. Evaporation of the filtrate gave a reddish liquid which was dissolved in ether (50 ml). The ethereal solution was added dropwise to an ice-cooled and stirred solution of lithium aluminum hydride (1.53 g, 0.0404 mol) in ether (100 ml) and the mixture was stirred for 2 hr at 18°C. To this were added ethyl acetate (20 ml, 0.20 mol) and, after 30 min, 9 N sulfuric acid (90 ml). After being stirred overnight, the aqueous layer was extracted with benzene. The combined organic layer was worked up according to the usual manner and evaporated to give yellowish brown crystals, 3.64 g (54.6%). The crystals were recrystallized from carbon tetrachloride to yield pure 2-naphthylpentadienal (VI′), mp 135—137°C.

Found: C, 86.11; H, 5.78%. Calcd for $C_{15}H_{12}O$: C, 86.51; H, 5.81%.

5-(2-Naphthyl)-2,4-pentadien-1-ol (VIII′). To a suspension of finely powdered sodium borohydride (0.36 g, 0.0096 mol) in a mixture of tetrahydrofuran (90 ml) and ethanol (10 ml) was added a solution of 2-naphthylpentadienal (VI′, 2.0 g, 0.0096 mol) in tetrahydrofuran (30 ml). After the mixture had been refluxed for 1 hr, stirring was continued for 1 hr at room temperature. The reaction mixture was concentrated to one-third its original volume and mixed with dilute hydrochloric acid. The aqueous layer was extracted with benzene. After washing and drying, the combined organic layer was evaporated to give VIII′ as yellow crystals, 1.98 g (98.1%). Slightly crude VIII′ was used in the following reaction without further purification.

5-(2-Naphthyl)-2,4-pentadienyl Bromide (X′). To an ice-cooled and stirred mixture of 2-naphthylpentadienol (VIII′, 1.98 g, 0.0094 mol), tetrahydrofuran (40 ml) and pyridine (2 ml) was added dropwise a solution of phosphorus tribromide (2.55 g, 0.0094 mol) in tetrahydrofuran (10 ml). After stirring for 1.5 hr at room temperature, cracked ice was added to the reaction mixture under ice-cooling. The aqueous layer obtained by evaporation of the organic solvent was extracted with benzene. After the usual washing and drying, the extract was concentrated to afford X′ as yellow crystals, 1.57 g (61.0%). This material was subjected directly to the following reaction.

5-(2-Naphthyl)-2,4-pentadienyltriphenylphosphonium Bromide (XII′). A solution of X′ (1.57 g, 0.00575 mol) and triphenylphosphine (2.10 g, 0.00802 mol) in benzene (60 ml)

14) S. Israelashvili, Y. Gottlieb, M. Imber, and A. Habas, *J. Org. Chem.*, **16**, 1519 (1951).

was refluxed to yield colorless crystalline precipitate. The precipitate was filtered and washed with benzene to give yellow fine crystals, 2.255 g (73.3%). The crystals were recrystallized three times from ethanol, yielding pure phosphonium bromide (XII'), mp 217.7—219.1°C (decomp.).

Found: C, 73.51; H, 5.30; Br, 15.15%. Calcd for $C_{33}H_{28}PBr$: C, 74.02; H, 5.27; Br, 14.92%.

1,2-Di(1-naphthyl)ethylene (I_1). To a stirred suspension of 1-naphthylmethyltriphenylphosphonium chloride (IV, 8.8 g, 0.020 mol) in benzene (65 m*l*) was added an ethereal solution of phenyllithium (0.98 N, 20.5 m*l*, 0.020 mol) under nitrogem atmosphere. After the resulting deep red solution had been stirred for 30 min, a solution of 1-naphthaldehyde (III, 3.4 g, 0.020 mol) in benzene (10 m*l*) was added and the mixture was stirred for 111 hr at room temperature. Yellowish red precipitate deposited was collected and washed with benzene. Ethanol was added to a hot solution of the precipitate in benzene to give a pale yellow precipitate (1.5 g, 34%). The material was recrystallized three times from ethanol and dissolved in benzene. The benzene solution was passed through a short column of alumina (10 g). The crystals obtained on concentrating the filtrate were recrystallized from cyclohexane to give pure I_1 as pale yellow crystals, mp 160—162°C (lit,[16] 161°C).

Found: C, 94.55; H, 5.79%. Calcd for $C_{22}H_{16}$: C, 94.25; H, 5.75%.

1,4-Di(1-naphthyl)-1,3-butadiene (I_2). To a stirred solution of 1-naphthylmethylidenetriphenylphsophorane prepared from 1-naphthylmethyltriphenylphsophonium chloride (IV, 1.38 g, 0.0032 mol) in benzene (20 m*l*) and an ethereal solution of phenyllithium (5 m*l*, 0.0032 mol) was added under nitrogen atmosphere a solution of 3-(1-naphthyl)propenal (V, 0.568 g, 0.0031 mol) in benzene (10 m*l*). Stirring was continued for 20 hr to cause deposition of a yellow precipitate. The precipitate was washed with toluene and digested with the same solvent. The extract was concentrated to yield bright yellow needles, 0.678 g (71.1%). A benzene solution of the crystals was treated with active charcoal and the filtrate was passed through a thin layer of alumina. The crystals obtained from the filtrate were recrystallized three times from acetic acid to afford pure I_2 as yellow crystals, mp 173—173.5°C (lit,[14] mp 170°C).

Found: C, 94.37; H, 5.98%. Calcd for $C_{24}H_{18}$: C, 94.08; H, 5.92%.

1,6-Di(1-naphthyl)-1,3,5-hexatriene (I_3). A solution of 3-(1-naphthyl)-2-propen-1-ylidenetriphenylphosphorane was prepared by the reaction of phosphonium bromide (XI, 3.08 g, 0.006 mol) in benzene (40 m*l*) with an ethereal solution of phenyllithium (7.72 m*l*, 0.006 mol) under nitrogen atmosphere. After the resulting deep red solution had been stirred for 30 min, a solution of 3-(1-naphthyl)propenal (V, 1.0 g, 0.0055 mol) in benzene (20 m*l*) was added over a 20-min period under cooling. Stirring was continued for 15 hr. The yellow precipitate formed was digested with hot toluene. Concentration of the extract gave yellow crystals, 1.503 g (82.4%) which were dissolved in benzene and passed twice through a thin layer of alumina. The crystals obtained from the filtrate were recrystallized three times from benzene to afford pure I_3, mp 217—219°C.

Found: C, 93.93; H, 6.33%. Calcd for $C_{26}H_{20}$: C, 93.94; H, 6.06%.

1,8-Di(1-naphthyl)-1,3,5,7-octatetraene (I_4). *(a) From 1-Naphthylmethyltriphenylphosphonium Chloride and Muconaldehyde.* A mixture of 1-naphthylmethyltriphenylphosphonium chloride (IV, 1.317 g, 0.003 mol) in benzene (40 m*l*) and an ethereal solution of phenyllithium (5.8 m*l*, 0.003 mol) was stirred for 40 min under nitrogen atmosphere. To the resulting deep red solution of phosphorane was added rapidly a solution of muconaldehyde (0.110 g, 0.001 mol) in benzene (10 m*l*). After stirring overnight a crystalline precipitate was formed. This was filtered and the filtrate was concentrated to yield a second crop. The combined precipitate was digested with hot benzene. The extract was filtered and the filtrate gave yellow crystals (0.360 g, quantitative) on concentration. After the crystals had been recrystallized three times from benzene, a benzene solution of the crystals was percolated through a short column of alumina. Pure I_4, mp 225.7—225.8°C was obtained from the filtrate.

Found: C, 93.84; H, 6.13%. Calcd for $C_{28}H_{22}$: C, 93.81; H, 6.19%.

(b) From 5-(1-Naphthyl)-2,4-pentadienal (VI). To a stirred suspension of 3-(1-naphthyl)-2-propen-1-yltriphenylphosphonium bromide (XI, 1.28 g, 0.0025 mol) in benzene (20 m*l*) was added over a 10-min period an ethereal solution of phenyllithium (10 m*l*, 0.0025 mol) under nitrogen atmosphere to give a deep red solution of phosphorane. After 35 min, a solution of slightly crude 5-(1-naphthyl)-2,4-pentadienal (VI, 0.455 g, 0.0022 mol) in benzene (10 m*l*) was added over a period of 15 min to the solution of phosphorane. After stirring for 24 hr, the orange red precipitate formed was filtered and washed with benzene. The precipitate was digested with hot benzene and toluene and the combined extract was concentrated to half its original volume and treated with alumina (2 g). The concentrated solution was passed through a short column of alumina (5 g). Yellow crystals (0.505 g, 64.5%) obtained by concentration of the filtrate were recrystallized from toluene to give pure I_4, 222.4—225.1°C.

Found: C, 93.88; H, 6.38%. Calcd for $C_{28}H_{22}$: C, 93.81; H, 6.19%.

1,12-Di(1-naphthyl)-1,3,5,7,9,11-dodecahexaene (I_6). A solution of 3-(1-naphthyl)-2-propenylidenetriphenylphosphorane was prepared from 3-(1-naphthyl)propenyltriphenylphosphonium bromide (XI, 1.528 g, 0.003 mol) in benzene (40 m*l*) and an ethereal solution of phenyllithium (5.8 m*l*, 0.003 mol) under nitrogen atmosphere. To this was added repidly a solution of muconaldehyde (0.11 g, 0.001 mol) in benzene (10 m*l*) and the mixture was stirred for 48 hr at room temperature. Crystalline solid deposited was collected by filtration and the filtrate was evaporated to give second crop of crystalline solid. The combined material was extracted with hot benzene (total 500 m*l*). Brown crystals (0.563 g, quantitative) obtained by evaporation of the extract were recrystallized from toluene. Crude I_6 thus obtained was dissolved in hot toluene and passed through a thin layer of alumina (1.5 g). The crystals obtained by concentration of the filtrate were recrystallized twice from the same solvent, yielding pure I_6 as orange crystals, mp 240—242°C.

Found: C, 93.44; H, 6.32%. Calcd for $C_{32}H_{26}$: C, 93.62; H, 6.38%.

1,2-Di(2-naphthyl)ethylene (I_1'). To a stirred suspension of 2-naphthylmethyltriphenylphosphonium bromide (IV', 2.321 g, 0.0048 mol) in benzene (40 m*l*) was added an ethereal solution of phenyllithium (0.635 N, 7.5 m*l*, 0.0048 mol). After stirring for 1 hr, a solution of 2-naphthaldehyde (III', 0.726 g, 0.0047 mol) in benzene (15 m*l*) was added dropwise to the deep red solution of phosphorane and the mixture was stirred overnight. Crystalline solid deposited was digested with hot benzene and the hot extract was percolated through a short column of alumina. The crystals obtained from the filtrate were recrystallized from benzene

16) J. H. Wood, J. A. Bacon, A. W. Meibohm, W. H. Throckmorton, and G. P. Turner, *J. Amer. Chem. Soc.*, **63**, 1334 (1941).

to afford pure I_1' as pale yellow crystals, 0.968 g (74.3%), mp 258—259°C (lit, 257—258°C,[12] 255°C[16]).

1,4-Di(2-naphthyl)-1,3-butadiene (I_2'). A solution of 2-naphthylmethylidenetriphenylphosphorane was prepared by the reaction of phosphonium bromide (IV′, 1.049 g, 0.00217 mol) in benzene (40 m*l*) with an ethereal solution of phenyllithium (0.53 N, 4.05 m*l*, 0.00215 mol) under nitrogen atmosphere. To this was added a solution of 3-(2-naphthyl)-propenal (V′, 0.383 g, 0.0021 mol) in benzene (15 m*l*) and the mixture was stirred overnight. The residue obtained by evaporation of the solvent was digested with hot toluene. Crude crystals deposited on concentration of the filtrate were recrystallized from toluene, and the crystals were dissolved in the same solvent. The toluene solution was refluxed for several min with alumina (2 g) and filtered. The crystals deposited on cooling the filtrate were recrystallized from toluene, yielding pure I_2' as pale yellow needles, 0.208 g (32.3%), mp 271—273°C (lit,[14]: 268°C).

Found: C, 94.32; H, 5.90%. Calcd for $C_{24}H_{18}$: C, 94.08; H, 5.92%.

1,6-Di(2-naphthyl)-1,3,5-hexatriene (I_3'). To a stirred suspension of 3-(2-naphthyl)-2-propenyltriphenylphosphonium bromide (XI′, 0.764 g, 0.0015 mol) in benzene (50 m*l*) was added under nitrogen atmosphere an ethereal solution of phenyllithium (0.336 N, 4.5 m*l*, 0.0015 mol). After stirring for 30 min, 3-(2-naphthyl)propenal (V′, 0.182 g, 0.0010 mol) in benzene (20 m*l*) was added to the resulting deep red solution of phosphorane and the mixture was stirred overnight. The precipitate formed was digested with hot benzene and toluene. The combined extract was passed through a short column of alumina. The crystals obtained by evaporation of the filtrate were recrystallized from toluene to yield pure I_3' as yellow crystals, 0.121 g, (36.4%), mp 251—262°C (decomp.).

Found: C, 93.82; H, 5.99%. Calcd for $C_{26}H_{20}$: C, 93.94; H, 6.06%.

1,8-Di(2-naphthyl)-1,3,5,7-octatetraene (I_4'). To a stirred solution of 2-naphthylidenetriphenylphosphorane prepared from phosphonium bromide (IV′, 1.450 g, 0.003 mol) and phenyllithium (0.003 mol) according to the procedure for the preparation of I_1' and I_2' was added a solution of muconaldehyde (0.110 g, 0.001 mol) in benzene (12 m*l*) and the mixture was stirred overnight. Yellow crystalline solid deposited was digested with hot benzene. The filtrate obtained by percolation of the extract through a short column of alumina (5 g) was evaporated to yield yellow crystals. Recrystallization of the crystals from toluene afforded pure I_4' as yellow crystals, 0.330 g, (92.1%), mp 266—267°C.

Found: C, 93.47; H, 6.11%. Calcd for $C_{28}H_{22}$: C, 93.81; H, 6.19%.

1,10-Di(2-naphthyl)-1,3,5,7,9-decapentaene (I_5'). An ethereal solution of phenyllithium (0.277 N, 9.0 m*l*, 0.0025 mol) was added under nitrogen atmosphere to a stirred suspension of 5-(2-naphthyl)-2,4-pentadienyltriphenylphosphonium bromide (XII′, 1.338 g, 0.0025 mol) in benzene (40 m*l*) to give a deep red solution of phosphorane. To this was added after stirring for 30 min a solution of 5-(2-naphthyl)-2,4-pentadienal (VI′, 0.416 g, 0.0020 mol) in benzene (60 m*l*). After the mixture had been stirred overnight, the solid deposited was digested with hot benzene and toluene. The filtrate obtained by percolation of the combined extract through a thin layer of alumina (5 g) was concentrated to yield crystals. The crystals were recrystallized from toluene to give pure I_5' as yellowish orange needles, 0.252 g (32.8%), mp 268—269°C (decomp.).

Found: C, 93.66; H, 6.38%. Calcd for $C_{30}H_{24}$: C, 93.71; H, 6.29%.

1,12-Di(2-naphthyl)-1,3,5,7,9,11-dodecahexaene (I_6'). A solution of 3-(2-naphthyl)-2-propenylidenetriphenylphosphorane was prepared under nitrogen atmosphere from 3-(2-naphthyl)-2-propenyltriphenylphosphonium bromide (XI′, 1.273 g, 0.0025 mol) in benzene (50 m*l*) and an ethereal solution of phenyllithium (0.336 N, 7.45 m*l*, 0.0025 mol). To the resulting deep red solution was added a solution of muconic aldehyde (0.110 g, 0.001 mol) in benzene (20 m*l*). After the mixture had been stirred overnight at room temperature, the precipitate formed was digested with hot benzene and toluene. The extract was passed through a short column alumina. The crystals obtained by concentration of the filtrate were recrystallized from toluene to afford pure I_6' as orange crystals, 0.142 g (34.5%), mp 265—273°C decomp.), rate of temperature increase: 10°C/min).

Found: C, 93.64; H, 6.25%. Calcd for $C_{32}H_{26}$: C, 93.62; H, 6.38%.

Optically Active Triptycenes. II.[1] Synthesis of Optically Active 7-Substituted 2,5-Dimethoxytriptycenes

Fumio OGURA, Yoshiteru SAKATA, and Masazumi NAKAGAWA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka, 560

(Received May 16, 1972)

A series of optically active 7-substituted 2,5-dimethoxytriptycenes has been prepared from (+)-2,5-diacetoxy-7-carboxytriptycene (I) as suitable model compounds for a study of the relationship between their structure and optical rotatory properties. The single crystal of 2,5-dimethoxy-7-dimethylaminotriptycene hydrobromide (VII) thus prepared was subjected to X-ray crystallographic analysis and proved to have 1*R*, 6*S* absolute configuration. Consequently, it became clear that all compounds of this series have the same 1*R*, 6*S* configuration. They showed without exception positive optical rotation in visible wavelength region.

Triptycene is a highly symmetrical cage compound and has a definite and rigid molecular structure confirmed by reactivities,[2] various spectroscopic properties,[3] electric dipole moments,[4] and X-ray crystallographic analysis.[5,6]

Triptycene derivatives bearing different substituent groups in two of the three benzene rings can be resolved into optical antipodes. We reported on the synthesis and optical resolution of 2,5-diacetoxy-7-carboxytriptycene (I).[1] The optically active triptycene may be regarded as one of the most appropriate substances for studying the relation between structure and rotatory properties for the following reasons.

1. The difinite and rigid molecular structure should exclude the influence of complicated effects arising from the flexibility of the molecule.
2. The structural transformation necessary for the investigation can be accomplished without causing recemization and Walden inversion.
3. Theoretical approach to the analysis of the ORD and CD properties might be possible by utilizing the results of investigations on the electronic spectra of benzenoid chromophore.

We wish to report on the preparation of a series of 7-substituted 2,5-dimethoxytriptycenes with identical absolute configuration starting from (+)-2,5-diacetoxy-7-carboxytriptycene (I).[1] The general scheme of the transformation is summarized in Fig. 1. Hydrolysis of I by means of aqueous acetic acid containing hydrogen bromide afforded 2,5-dihydroxy-7-carboxytriptycene (II). Methylation of II with dimethyl sulfate in acetone in the presence of anhydrous potassium carbonate resulted in the formation of 2,5-dimethoxy-7-methoxycarbonyltriptycene (III).[7] 2,5-Dimethoxy-7-carboxytriptycene (IV) was obtained by hydrolysis of III in aqueous acetic acid containing sulfuric acid.[8]

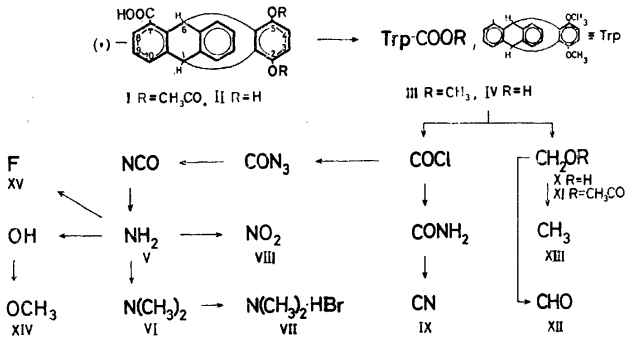

Fig. 1. General scheme of preparation of optically active triptycenes.

Treatment of IV in tetrahydrofuran with thionyl chloride yielded acid chloride, which was subjected to the Curtius reaction *via* acid azide and isocyanate to give 2,5-dimethoxy-7-aminotriptycene (V).

Methylation of V with trimethyl phosphate yielded 2,5-dimethoxy-7-dimethylaminotriptycene (VI).[9]

Amine (V) was oxidized to 2,5-dimethoxy-7-nitrotriptycene (VIII) by peracetic acid in chloroform.[10]

The above-mentioned acid chloride was treated with ammonia in tetrahydrofuran to yield acid amide. Dehydration of the amide by thionyl chloride in dimethylformamide afforded 2,5-dimethoxy-7-cyanotriptycene (IX).

Reduction of the ester (III) with lithium aluminum hydride in tetrahydrofuran gave 2,5-dimethoxy-7-hydroxymethyltriptycene (X), which was converted into 2,5-dimethoxy-7-acetoxymethyltriptycene (XI) on treatment with acetic anhydride.

Oxidation of carbinol (X) with chromium trioxide-pyridine complex in pyridine yielded 2,5-dimethoxy-7-formyltriptycene (XII).[11]

Chloromethyl derivative obtained by the reaction of X with thionyl chloride was reduced to 2,5-dimethoxy-7-methyltriptycene (XIII) with lithium aluminum hydride in refluxing tetrahydrofuran.[12]

Amine (V) was diazotized with sodium nitrite in acetic acid. Diazonium compound thus obtained was hydrolyzed in dilute boiling sulfuric acid to afford phenol derivative.[13] The crude phenol was methylated with dimethyl sulfate in acetone in the presence of anhydrous potassium carbonate to yield methyl ether (XIV).

Fluoro derivative (XV) was obtained from amine (V) by the Schiemann reaction.

All the new compounds described above gave satisfactory data of elemental analyses and their structures were confirmed by means of IR, UV, and NMR spectra.

X-Ray crystallographic analysis performed on the single crystal of (+)-2,5-dimethoxy-7-dimethylaminotriptycene hydrobromide (VII) demonstrated that the absolute configuration of VII was 1*R*,6*S* as shown in Fig. 2.[5] Consequently, all the compounds shown in Fig. 1 were proved to have the same 1*R*,6*S* configuration. All the compounds of this series showed dextro optical rotation regardless of the change of nature of substituent group at 7-position.

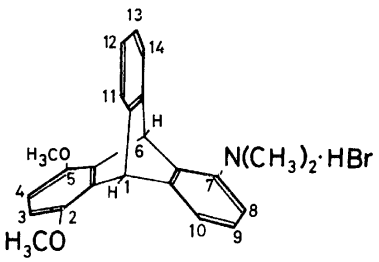

Fig. 2. The absolute configuration of (+)-2,5-dimethoxy-7-dimethylaminotriptycene hydrobromide.

Experimental

All the melting points were not corrected. The experimental procedures refer to the optically active substances, and purified anhydrous solvents were used throughout the experiments unless otherwise stated. Ligroin boiling at 60—80°C was used. The IR spectra were measured with a Hitachi EPI-2 and a JASCO DS-301 spectrophotometer. The NMR spectra in deuteriochloroform solution were obtained with a Varian A-60 spectrometer using TMS as an internal standard. Chemical shifts are recorded in δ unit. The electronic spectra were obtained with a Hitachi EPS-3T and a Zeiss PMQIIM4QIIId spectrometer. The optical rotations were measured with a Rudolf Model 200S-80 and a Yanagimoto ORD-185 spectropolarimeter. The circular dichroism spectra were measured with a Roussel-Jouan dichrograph B, II-CD-185 and JASCO J-20 spectropolarimeter with CD attachments. The inflections and shoulders are indicated with an asterisk. The optical rotations were measured at 20°C throughout the present research unless otherwise stated. Ethanol (99%) containing 0.1 N aqueous hydrochloric acid (2 m*l* of the hydrochloric acid was made up to 20 m*l* solution with the ethanol) was used as a solvent of measurement and abbreviated as 99% EtOH-HCl.

2,5-Dihydroxy-7-carboxytriptycene (II). To a hot solution of (+)-2,5-diacetoxy-7-carboxytriptycene (I, 1.436 g) was added hydrobromic acid (47%, 3.3 m*l*). The mixture was refluxed for 6 hr and allowed to cool to room temperature to precipitate fairly pure II (light brown leaflets, sintered at *ca.* 220°C and melted at *ca.* 300°C, 0.999 g, 94.5%) which could be used directly for the preparation of derivatives. Recrystallization of this material from acetic acid-water gave pure II, mp 332—335°C (decomp.). Elemental analyses of this substance gave no satisfactory results presumably owing to its nature of incomplete combustibility. IR (Nujol mull): 3700—2500 (ν_{O-H}, -COOH, -OH), 1689 (ν_{C-O}, -COOH) cm^{-1}. UV: $\lambda_{max}^{99\%EtOH}$ (ε) 261 (4160) 269 (4200), 294 (8330) nm. ORD: $[M]_{5791}^{18°C}$+189.4°, $[M]_{5461}^{18°C}$+215.9°, $[M]_{4358}^{18°C}$+412.2°, $[M]_{4047}^{18°C}$+535.5°, $[M]_{3650}^{18°C}$+849.0° (*c*, 0.4356, dioxane).

Hydrolysis of *dl*-I was carried out under somewhat different conditions. Racemic I (20 g) was dissolved in hot acetic acid (20 m*l*). A mixture of water (30 m*l*) and hydrobromic acid (47%, 4 m*l*) was added to the solution and refluxed for 7 hr. Racemic II was obtained as faint pink plates (1.3 g, 84.5%) on cooling the reaction mixture, mp 325°C (decomp.). Racemate exhibited a slightly different IR spectrum.

2,5-Dimethoxy-7-methoxycarbonyltriptycene (III). A mixture of II (0.60 g), dimethyl sulfate (1.1 g), anhydrous potassium carbonate (3.0 g), and acetone (40 m*l*) was refluxed for 8 hr under stirring. After cooling, the reaction mixture was poured onto water (*ca.* 300 m*l*) and extracted 3 times with benzene. The crude crystalline product obtained from the extract was dissolved in benzene and purified by passing through a short column of alumina (25 g). Colorless crystals (0.6 g) were obtained on evaporating the first 500 m*l* fraction. Recrystallization from a small amount of benzene gave pure III, mp 261.5—262.5°C (racemate, mp 227—228.5°C). IR (KBr-disk): 2830 (ν_{C-H}, $-OCH_3$), 1715 ($\nu_{C=O}$, $-COOCH_3$) cm^{-1}. NMR: 3.83 (6H, s, $-OCH_3$), 4.02 (3H, s, $-COOCH_3$), 5.95 (1H, s, C_1-H), 6.56 (2H, aromatic at C_{3-4}), 6.97—7.71 (8H, m, aromatic at C_{8-14} and C_6-H).[14] UV: $\lambda_{max}^{99\%EtOH}$ (ε) 294 (8220), 270 (3450), 262 (2790), 208 (63600), 195 (52500) nm. $\lambda_{max}^{dioxane}$ (ε) 295 (8200), 270 (3230), 262 (2500) nm. ORD: $[M]_{5791}^{25°C}$+91.6°, $[M]_{5461}^{25°C}$+104.6°, $[M]_{4358}^{25°C}$+195.9°, $[M]_{4047}^{25°C}$+248.8°, $[M]_{3650}^{25°C}$+386.2° (*c*, 0.7475, dioxane). 2,5-Dimethoxy-7-aminotriptycene (V). Carboxylic acid (IV, 0.410 g) was dissolved in tetrahydrofuran (25 m*l*) and treated with thionyl chloride (2 m*l*) under reflux for 3 hr. The solvent was removed under reduced pressure to give colorless crystals. The acid chloride obtained was fairly pure and could be used directly in the following reaction [IR (Nujol mull): 1755 ($\nu_{C=O}$, −COCl) cm^{-1}]. A solution of sodium azide (0.140 g) in water (3 m*l*) was added to an ice-cooled solution of the acid chloride (0.458 g) in tetrahydrofuran (35 m*l*). The reaction mixture was stirred for 2 hr and poured onto 300 m*l* of cold water. Colorless precipitate was collected by filtration and washed with water and dried. The acid azide is fairly stable and can be handled safely at room temperature, though spontaneous rearrangement to isocyanate occurred in part even under room temperature [IR (Nujol mull): 2150 ($\nu_{N=N=N}$, $-CON_3$), 1695 ($\nu_{C=O}$, $-CON_3$) cm^{-1}. Weak absorption band at 2270 cm^{-1} indicated the presence of a minor amount of isocyanate]. The well-dried acid azide (0.429 g) was spread over the bottom of a 300 m*l* Erlenmeyer flask and heated slowly up to 130°C and maintained at this temperature for 3 hr yielding light brown crystalline powder (0.385 g) with evolution of nitrogen [IR (Nujol mull): 2270 ($\nu_{N=C=O}$) cm^{-1}]. A mixture of the isocyanate (0.249 g), 99% ethanol (40 m*l*) and water (10 m*l*) was refluxed for 8 hr. Crystals deposited were collected by filtration and washed with 50% ethanol and water, successively, to give V as faintly pink leaflets (0.191 g). The filtrate and washings were combined and poured water(300 m*l*) and extracted 4 times with benzene. The combined extracts were washed with water and dried (sodium sulfate). Evaporation of the solvent afforded further 0.036 g of the amine (total yield 93% based on IV). Colorless pure crystals of V [mp 259—261°C (decomp.) in a sealed tube] were obtained by repeated sublimation under reduced pressure (bath temp. 200—220°C/3 mmHg). IR (KBr disk): 3495, 3470 (ν_{N-H}, $-NH_2$), 1623 (δ_{N-H}, $-NH_2$), 2845 (ν_{C-H}, $-OCH_3$) cm^{-1}. 2,5-Dimethoxy-7-dimethylaminotriptycene Hydrobromide (VII). The dimethylamine (VI, 0.038 g) dissolved in 99% ethanol (22 m*l*) was mixed with 47% aqueous hydrobromic acid (3 m*l*) and water (3 m*l*). Clear and homogeneous solution obtained on warming and filtration was placed in a loosely stoppered ground joint vessel and kept in the dark. Beautiful rhomboidal single crystals of VII developed gradually on storing the solution over a period of two or three months. Sometimes VII crystallized in needles. In such cases the solution had to be warmed to dissolve the needles and filtered again to get rhomboidal crystals. The crystals began to sublime at *ca.* 240°C and partly melted at the same time. It crystallized again in needles and perfectly decomposed to red oil at 250°C, IR (KBr disk): 2845 (ν_{C-H}, $-OCH_3$), 2785 (ν_{C-H}, $-N-CH_3$), 2700—2000 (ν_{N-H}, $-\overset{+}{N}H(CH_3)_2$) cm^{-1}. UV: $\lambda_{max}^{99\%EtOH}$ (ε) 297 (4490), 278.5 (4320), 269.5 (4460), 262 (4870), 255* (5100), 210 (55900), 196.5 (68700) nm. 2,5-Dimethoxy-7-nitrotriptycene (VIII). Ninety percent hydrogen peroxide (0.083 m*l*) and a small drop of concentrated sulfuric acid were added to ice-cooled chloroform (0.36 m*l*). Acetic anhydride (0.4 g) was then added to the mixture. The cooling bath was removed and the mixture was stirred for 15 min. After further addition of chloroform (0.24 m*l*) the mixture was heated to reflux under stirring. The heating bath was removed and a solution of V (0.196 g) in chloroform (20 m*l*) was added dropwise to the hot oxidizing mixture. Deposition of pale yellow crystals from the yellow reaction mixture was observed. The reaction mixture was refluxed under stirring. The resulting brown reaction mixture was poured onto water (100 m*l*) and extracted 3 times with chloroform. The combined extracts were washed successively with 10% aqueous potassium hydroxide, 10% aqueous hydrochloric acid and water, and dried (sodium sulfate). Brown yellow solid (0.203 g) obtained on evaporating the solvent under reduced pressure was dissolved in benzene and passed through a short column alumina (15 g). Yellow crystals (0.135 g) were obtained on concentrating the first 300 m*l* fraction eluted. The crude material was recrystallized 3 times from a mixture of ethyl acetate and ethanol, and then sublimed under reduced pressure (bath temp. 250°C/3 mmHg) to afford faintly yellow crystals. This material did not melt up to 300°C. IR (KBr disk): 2840 (ν_{C-H}, $-OCH_3$), 1525 ($\nu_{N-O\ asym}$, $-NO_2$), 1350

($\nu_{N-O\ sym}$, $-NO_2$) cm^{-1}. NMR: 3.83 (6H, s, $-OCH_3$) 5.98 (1H, s, bridgehead proton at C_1), 6.55 (2H, s, aromatic at C_{3-4}), 6.97—7.70 (8H, m, aromatic st C_{8-14} and C_6-H). The signal of bridgehead proton at C_6 is shifted to down-field owing to the anisotropic effect of the nitro group. Careful combustion of a mixture of VIII (2.019 mg) and sucrose (1.295 mg) gave the above results.

Racemate was recrystallized from benzene-ligroin, mp 270—274°C (decomp.). It showed no tendency to sublime.

2,5-Dimetoxy-7-cyanotriptycene (IX). Acid chloride (0.680 g) obtained by the reaction of IV with thionyl chloride according to the above procedure was dissolved in tetrahydrofuran (40 m*l*). Aqueous ammonia (28%, 5 m*l*) was added to the solution and the resulting clear two-layer mixture was allowed to stand overnight at room temperature. Colorless crystals of amide (0.353 g) deposited were filtered and washed with tetrahydrofuran. The combined filtrate and washings were concentrated under reduced pressure, yielding a second crop of the amide (0.257 g). The combined crystals were recrystallized from methyl acetate-methanol to yield pure amide, mp 305—320°C (decomp.). IR (Nujol mull): 3400, 3300, 3250, 3140 (ν_{N-H}, $-CONH_2$), 1680 ($\nu_{C=O}$, $-CONH_2$) cm^{-1}.

The amide (0.454 g) was dissolved in warm dimethylformamide (15 m*l*) and mixed with thionyl chloride (9 m*l*). Immediate development of red color and generation of heat were observed. As soon as the mixture was heated on a water-bath (80—90°C), deposition of a considerable amount of colorless solid was observed. Most of the solid again dissolved in the solution in a period of 10 min with evolution of sulfur dioxide and hydrogen chloride. The reaction mixture was kept at 80—90°C for 20 hr and then chilled in an ice-bath. Crystals of sulfur (0.125 g) deposited were removed by filtration and washed with dimethylformamide. The combined filtrate and washings were poured into water (300 m*l*). Red brown oil separated under evolution of gas was extracted 3 times with ether and once with benzene. The combined extracts were washed with water and dried over sodium sulfate. Yellow solid (0.554 g) obtained on evaporating the solvent under reduced pressure was dissolved in benzene and passed through a short column of alumina (25 g). IX was obtained as colorless crystals (0.270 g) on drying up the first 500 m*l* fraction eluted. It crystallized in fine needles from 99% ethanol. IX sublimed on heating *ca.* 200°C, mp 263—265°C. IR (KBr disk): 2840 (ν_{C-H}, $-OCH_3$), 2225 ($\nu_{C\equiv N}$) cm^{-1}. UV: $\lambda_{max}^{99\%EtOH}$ (ε) 296.5 (8880), 268.5 (3180), 262 (2190), 206 (73000), 194* (46500) nm. $\lambda_{max}^{dioxane}$ (ε) 297 (9200), 268.5 (3190), 261 (2180), 215.5 (45900) nm. Racemate was recrystallized from *n*-propyl alcohol and purified on sublimation at *ca.* 220°C, mp 246—248°C.

2,5-Dimethoxy-7-methyltriptycene (XIII). A solution of carbinol (X, 0.195 g) in benzene (25 m*l*) was mixed with thionyl chloride (2 m*l*). The mixture was stirred for 4 hr at room temperature and then refluxed for 30 min. Light brown solid [mp 160—180°C (decomp.)] obtained by evaporating the solvent and volatile material under reduced pressure gave no absorption of hydroxyl group in its IR spectrum. Owing to the unstable nature of the halide, the crude material was used directly in the following reaction. A solution of the crude chloride (0.213 g) in tetrahydrofuran (25 m*l*) was added dropwise to a mixture of lithium aluminum hydride (0.4 g) in the same solvent (20 m*l*) which had been stirred previously for 30 min at room temperature. After the mixture had been refluxed under stirring for 4 hr, it was cooled on an ice-bath and treated with methyl acetate, water and 6 N sulfuric acid, successively. The acidified mixture was poured onto water (200 m*l*) and extracted with ether. The combined extracts were washed with 5% aqueous sodium hydroxide and water, successively, and dried (sodium sulfate). Colorless solid obtained on evaporating the solvent under reduced pressure was dissolved in benzene and passed through a short column of alumina (20 g). Colorless crystals were obtained from the first fraction (300 m*l*). The crystals were recrystallized from methanol–methyl acetate to afford pure XIII, mp 207—209°C. IR (KBr disk): 2845 (ν_{C-H}, $-OCH_3$) cm^{-1}. Found: C, 84.08; H, 6.05%. Calcd for $C_{23}H_{20}O_2$: C, 84.12; H, 6.14%.

The racemate was prepared as follows. Racemate of X (1.310 g) dissolved in a mixture of ether (50 m*l*) and tetrahydrofuran (25 m*l*) was mixed with a sodium hydride suspension (content 50%, 0.229 g). The mixture was refluxed for 2 hr under vigorous agitation and allowed to stand overnight at room temperature. An additional sodium hydride suspension (0.236 g) was added and the mixture was refluxed for further 2 hr under vigorous agitation. *p*-Toluenesulfonyl chloride (0.728 g) in tetrahydrofuran (15 m*l*) was added under ice-cooling and the mixture was stirred for 48 hr. The mixture was filtered under careful protection from moisture. The filtrate was concentrated under reduced pressure to give crude tosylate as a solid.[16] The presence of unreacted X was clearly indicated by its IR spectrum. As the purification by recrystallization or by chromatography on alumina was not feasible owing to its unstable nature, the crude tosylate was subjected directly to the following reaction. A solution of the crude tosylate in tetrahydrofuran was added to a mixture of lithium aluminum hydride (0.250 g) in the same solvent (15 m*l*) which had been stirred for 30 min at room temperature. The mixture was refluxed for 7 hr. After being put to stand overnight at room temperature, methyl acetate, water, and 6 N sulfuric acid were successively added to the reaction mixture. The mixture was poured onto a saturated aqueous sodium chloride solution and extracted with ether. The combined ethereal extracts were washed with water and dried (sodium sulfate). Colorless solid obtained on evaporating the solvent was dissolved in benzene and passed through a short column of alumina (25 g). From the first fraction (300 m*l*), colorless crystals contaminated with mineral oil were obtained. It was digested with boiling ligroin for a short period and recrystallized from methanol–methyl acetate (2 : 3), mp 228—230°C.

Found: C, 83.90; H, 6.08%. Calcd for $C_{23}H_{20}O_2$: C, 84.12; H, 6.14%.

2,5,7-Trimethoxytriptycene (XIV). The amine (V, 6.953 g) was dissolved in acetic acid (307 m*l*) on warming and the resulting clear pink solution was cooled to 12—14°C. Sodium nitrite (1.468 g) in water (41.6 m*l*) was added dropwise to the solution under stirring in a period of 1.5 hr. To the resulting red brown solution was added acetic acid (100 m*l*) and stirring was continued for further 30 min at 12—14°C. Strongly cooled red brown solution of the diazonium compound was added dropwise to refluxing 6 N sulfuric acid (918 m*l*) to yield phenolic derivative. The resulting light brown solution containing brown precipitate was extracted 3 times with benzene. The combined extracts were washed with water and dried over sodium sulfate. Crude phenol derivative (6.440 g, 92.4%) was obtained as light brown solid on evaporating the solvent. A solution of the phenol (100.0 mg) in acetone (15 m*l*) was refluxed with dimethyl sulfate (0.1 g) in the presence of anhydrous potassium carbonate (1 g) for 2 hr. After being put to stand overnight at room temperature, the reaction mixture was poured onto cold water (150 m*l*) and extracted 3 times with benzene. The combined extracts were washed with water and dried over sodium sulfate. Light brown solid obtained on evaporating the solvent was dissolved in benzene and passed through a short column of alumina (30 g) and eluted with the same solvent. Light yellow crystals obtained from the first eluate (300 m*l*) were dissolved in carbon tetrachloride and passed again through a short column of alumina (30 g). Colorless crystals obtained in a quantitative yield on evaporating the first eluate (300 m*l*) were recrystallized twice from a mixture of methanol and methyl acetate to give pure XIV, mp 273—275°C. IR (KBr disk): 2840 (ν_{C-H}, $-OCH_3$), 1265 (ν_{C-O}, Ar–O–CH_3) cm^{-1}. UV: $\lambda_{max}^{99\%EtOH}$ (ε) 293 (4360), 276 (3440), 267.5 (3750), 216 (63900), 195 (46400) nm. 2,5-Dimethoxy-7-fluorotriptycene (XV). To a red brown solution of diazonium compound, prepared from V (0.187 g) according to the procedure used in the case of XIV, was

16) Tosylate of *d*-X could not be obtained by the reaction of *d*-X with *p*-toluenesulfonyl chloride in the presence of pyridine. In this case an unidentified solid bearing carbonyl group was obtained.

added a solution of sodium fluoroborate (0.1 g) in water (2 m*l*). The resulting reaction mixture was poured into a nearly saturated aqueous solution of sodium fluoroborate (15 g in 30 m*l* of water) to obtain the diazonium fluoroborate as red brown precipitate. The precipitate was collected by filtration and washed throughly with a small amount of cold water and dried exhaustively under reduced pressure. The dried fluoroborate (0.201 g) was spread over the bottom of a 300 m*l* Erlenmeyer flask and heated slowly up to 150 °C. The temperature of the flask was maintained at 150—160°C for 1.5 hr. The fluoroborate decomposed under evolution of nitrogen, yielding purple red crystalline powder. The reaction mixture was mixed with water (150 m*l*) and extracted with benzene. The combined extracts were washed with water and dried over sodium sulfate. The crude fluoro derivative obtained on evaporating the solvent was dissolved in benzene and passed through a short column of alumina (30 g). Concentration of the first benzene eluate (300 m*l*) gave the fluoro derivative as faintly yellow crystals (0.0816 g, 43.3%). The crystals were further purified by passing through a short column of alumina using carbon tetrachloride as a solvent. Colorless crystals (0.076 g) obtained from the first eluate (300 m*l*) were recrystallized twice from methanol give pure XV, mp 253.5—256.5°C (racemate, mp 248—249.5°C). UV: $\lambda_{max}^{99\%EtOH}$ (ε) 294 (4290), 276 (2570), 269 (1980), 261 (2010), 212.5 (70900), 195 (51800) nm. Reaction of Organoaluminum Coordination Compound with Carbon Dioxide

Shohei INOUE and Yoshiharu YOKOO

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 16, 1972)

The reaction of trialkylaluminum with carbon dioxide was suppressed by the presence of *N,N,N',N'*-tetramethylethylenediamine, 2,2'-dipyridyl, *N*-methylimidazole (MIm), and diethyl ether. On the other hand, the insertion reaction of carbon dioxide into the Al–N bond of diethylaluminum diethylamide was accelerated by the presence of MIm, *N*-methylbenzimidazole, and pyridine. The complexing agents are considered to play two different roles, *i. e.*, affecting the nucleophilicity of Al–C or Al–N bond and the ability of aluminum atom to accomodate carbon dioxide.

We have studied the reaction of organozinc coordination compound with secondary amines,[1,2] acidic hydrocarbons,[3] and carbon dioxide.[4] In these reactions, the complexes of dialkylzinc with *N,N,N',N'*-tetramethylethylenediamine (TMEDA), 2,2'-dipyridyl (Dipy), and *N*-methylimidazole (MIm) exhibit much enhanced reactivity when compared with dialkylzinc itself. The remarkable effect of MIm in the reaction with carbon dioxide was discussed in relation to the action of carbonic anhydrase, a zinc enzyme.[4]

Differently from dialkylzinc, trialkylaluminum is known to react readily with carbon dioxide at ordinary temperature and pressure.[5] In the present paper is reported the effect of the complex formation of organoaluminum compound with the above-mentioned complexing agents in the reaction toward carbon dioxide.

Results and Discussions

Reaction of Trialkylaluminum and Carbon Dioxide. The reaction of triisobutylaluminum with an atmos-

pheric pressure of carbon dioxide was examined at 0°C in toluene. As seen in Fig. 1, one of the isobutylaluminum linkages reacted rapidly and quantitatively with carbon dioxide, as determined by the absorption of carbon dioxide as well as by the formation of isovaleric acid. In the presence of an equimolar amount to triisobutylaluminum of TMEDA, Dipy, and MIm, the reaction was much suppressed, in contrast to the case of dialkylzinc. Even diethyl ether, which shows no effect on the reactivity of dialkylzinc, behaved similarly to TMEDA, etc. in the reaction of triisobutylaluminum.

When the reaction of triethylaluminum with carbon dioxide was carried out at 20°C, the absorption of carbon dioxide stopped at a quantity corresponding to 66% conversion of one ethyl-aluminum bond, and as the reaction products triethylcarbinol was detected together with propionic acid, indicating the fact that reaction (1) is accompanied by reactions (2) and (3).[5]

$$R_3Al + CO_2 \rightarrow RCOOAlR_2 \quad (1)$$

$$RCOOAlR_2 + R_3Al \rightarrow R_2CO + R_2AlOAlR_2 \quad (2)$$

$$R_2CO + R_3Al \rightarrow R_3COAlR_2 \quad (3)$$

In this case also, the absorption of carbon dioxide was much supperssed by the presence of TMEDA, MIm, diethyl ether; Dipy showed less suppressing effect.

Reaction of Diethylaluminum Diethylamide and Carbon Dioxide. As shown in Fig. 2, diethylaluminum diethylamide exhibited very low reactivity towards carbon dioxide even at 60°C. In the presence of some complexing agents, however, the absorption of carbon dioxide was accelerated, in contrast to the case of trialkylaluminum. In the infrared spectrum of the reaction mixture of diethylaluminum diethylamide-MIm (1 : 2) system with carbon dioxide, strong and broad IR bands were observed around 1490—1580 cm^{-1}, while diethylaluminum propionate shows corresponding band at 1550—1630 cm^{-1}. Upon acid hydrolysis of the reaction mixture, no propionic acid was detected. These facts indicate the formation of aluminum carbamate group, *i. e.*, the insertion of carbon dioxide to Al-N, but not to Al-C bond.

$$Et_2N\text{-}AlEt_2 + CO_2 \xrightarrow{\text{Complexing Agent}} Et_2N\text{-}COO\text{-}AlEt_2 \quad (4)$$

As seen in Fig. 2, aromatic monodentate complexing agents such as MIm, *N*-methylbenzimidazole, and pyridine were effective. Dipy exhibited only slight accelerating effect. The effect of MIm was very remarkable and the reaction took place readily even at 20°C. Furthermore, Al-N bond of diethylaluminum diethylamide reacted quantitatively with carbon dioxide even in the presence of a half mole ratio of MIm to the aluminum compound, indicating that MIm was effective as a catalyst (curve No. 9 of Fig. 2).

Factors affecting the reactivity. Triethylaluminum is dimeric with Al-C bridges[6] while triisobutylaluminum is monomeric, and triethylaluminum is known to form complexes such as $Et_3Al\cdot Dipy$ (1 : 1),[7] $Et_3Al\cdot TMEDA$ (2 : 1),[7] and $Et_3Al\cdot O(C_2H_5)_2$ (1 : 1). Triisobutylaluminum probably forms similar complexes. Then the decrease in the reactivity of trialkylaluminum towards carbon dioxide in the presence of the complexing agents may be ascribed to low reactivity of such complexes. Although the nucleophilicity of C-Al linkage will be increased by the coordination with Lewis base, the coordination of the reacting carbon dioxide to the aluminum atom is considered to be hindered by the complex formation of trialkylaluminum. The reactivity is thus much lowered.

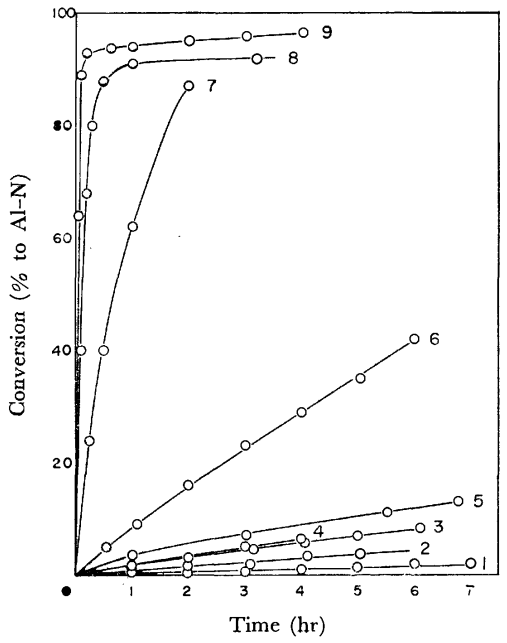

Fig. 2. Reaction of diethylaluminum diethylamide and carbon dioxide, in *p*-xylene at 60°C.
$[Et_2AlNEt_2]_0$, 0.5 M; CO_2, 1 atm; complexing agent (molar ratio to Al): 1: none, 2: tetrahydrofuran(2), 3: Dipy(1), 4: triethylamine(2), 5: TMEDA(1), 6: pyridine(2), 7: *N*-methylbenzimidazole(2), 8: MIm(2), 9: MIm(0.5).

In this respect, apparently reverse effect of the complexing agents on the reactivity of diethylaluminum diethylamide is interesting. Diethylaluminum diethylamide exists in a dimeric form with Al-N bridges.[8] In the presence of some of the complexing agents, it will probably become monomeric by the complex formation. In this monomeric complex the nucleophilicity of Al-N bond, freed from the bridge, is further enhanced by the coordination with Lewis base. But, as in the case of trialkylaluminum, the coordination of the reacting carbon dioxide to the aluminum atom is considered unfavorable in the complex. However, the nuclophilicity of Al-N is much higher than Al-C bond, as exemplified by the fact that the reaction of diethylaluminum diethylamide with carbon dioxide took place at Al-N but not at Al-C linkage. Therefore, the nucleophilicity of Al-N bond is considered so much enhanced by the complex formation that the coordination of the reacting carbon dioxide is not important

for the reactivity of diethylaluminum diethylamide in the presence of the complexing agent.

Thus, by the present study we may conclude that the complexing agents studied here play two different roles, *i. e.*, affecting the nucleophilicity of Al–C or Al–N bond and affecting the ability of Al atom to accommodate carbon dioxide. It should be noted here that the observed reactivity is also dependent on the stability of the complex, *i. e.*, the effective concentration of the complex.

The reverse effect of the complexing agents on the reactivity of trialkylaluminum and of dialkylzinc[4] might be understood by different contribution of the above-mentioned factors in the Al and the Zn compounds. The contribution of *d*-orbitals (filled in Zn, but not in Al) might also be considered, but no conclusion may be made from the results so far obtained.

Experimental

Materials. Triethylaluminum was purified by distillation in a nitrogen atmosphere, bp 97°C/10 mmHg. Triisobutylaluminum was also purified by distillation, bp 86°C/10 mmHg. Diethylaluminum diethylamide[8] was prepared by refluxing a *p*-xylene solution (200 m*l*) containing triethylaluminum (0.2 mol) and diethylamine (0.2 mol) for 6 hr. After the removal of *p*-xylene under reduced pressure, the product was obtained by distillation, bp 125°C/0.5 mmHg.

Carbon dioxide was purified by passing through a series of columns packed with cupric sulfate, potassium bicarbonate, reduced copper, phosphorus pentoxide, actived cupric oxide.

TMEDA was refluxed over calcium hydride and distilled, bp 121°C. Dipy was recrystallized from *n*-hexane, mp 69—70°C. MIm was prepared from imidazole, sodium and methyl iodide in liquid ammonia,[9] bp 115°C/54 mmHg. *N*-methylbenzimidazole was prepared from benzimidazole (obtained by the reaction of *o*-phenylenediamine and formic acid[10]) by the same method as MIm, mp 60°C. Pyridine and triethylamine were purified by distillation over barium oxide.

Benzene, toluene, *p*-xylene, diethyl ether, and tetrahydrofuran were purified by usual methods, refluxed over methallic sodium, and distilled.

Procedure. A mercury-sealed gas burette was connected with a 50 m*l* reaction flask by a three-way stopcock, the system was substituted by carbon dioxide, complexing agent and solvent was added, and the solution was saturated by carbon dioxide, The organoaluminum compound was added, and the absorption of carbon dioxide was followed by keeping the gas burette at the atmospheric pressure. The volume absorbed was corrected for temperature, atmospheric pressure and the partial pressure of the solvent. In order to determine carboxylic acid as the product, a definite amount of the reaction mixture was taken out, added by conc. hydrochloric acid, and subjected to gas chromatography using *p*-cymene as internal standard.

The authors wish to express their thanks to Professor Teiji Tsuruta for his valuable discussion.

Studies of Organosulfur Compounds. VI. The Preparation of Carbamoyl Esters of Aromatic Dithio Acids and Their Spectral Properties

Shinzi KATO, Tsuyoshi MITANI, and Masateru MIZUTA
Faculty of Engineering, Gifu University, Kagamihara, Gifu

(Received March 22, 1972)

It was found that aromatic dithio acids readily reacted with aryl isocyanate at room temperature to give the corresponding mixed thioanhydrides with the general formula of (ArCS·S·CONHAr) in excellent yields as stable crystals. The mixed thioanhydrides reacted with primary amines at room temperature to give the corresponding thioamides and asymmetric ureas, while the reaction with secondary amines gave the corresponging amine salts and asymmetric ureas in good yields. The spectral properties of the mixed thioanhydrides were discussed.

Although a few studies of the preparation of the mixed anhydrides (I[1], II[1e], *etc.*) and asymmetric thioanhydrides (III)[2] have been reported, there has been no report on the preparation of the mixed thioanhydrides of Structure (IV) except for the unsuccessful attempt by Houben and Schultze[3] to prepare

the anhydrides (IV, Ar; C_6H_5, R'; C_6H_5, CH_3) of dithio and carboxylic acid from magnesium halogenide salts of aromatic dithio acids and acid chlorides or anhydrides. Dithio acids in general are stronger acids[4] than the corresponding carboxylic acid or thio acid, and it is expected that dithio acids react with heterocumulenes (isocyanates, ketenes, *etc.*) to give the corresponding mixed thioanhydrides. In a previous work,[5] it was found that bis(thioacyl)disulfide was readily reacted with secondary amines to give their amine salts in good yields, and the use of the amine salts for the purification of aromatic dithio acids was more effective than that of the metal salts. In this paper, we will describe the preparation of the mixed thioanhydride with the general formula of VII from aromatic dithio acids and aryl isocyanates (Eq. (1)) and an investigation of some aspect of their chemistry.

$$\underset{\text{V}}{\text{ArCS}_2\text{H}} + \underset{\text{VI}}{p\text{-XC}_6\text{H}_4\text{NCO}} \rightarrow \underset{\text{VII}}{\text{ArCS-CNHC}_6\text{H}_4\text{-X-}p} \quad (1)$$

Results and Discussion

When *p*-methyldithiobenzoic acid in an ethyl acetate–ether (1 : 1) mixture was treated with an equimolar amount of phenyl isocyanate, phenylcarbamoyl *p*-methyldithiobenzoate (VIIg) was easily obtained in an 86% yield as reddish yellow crystals. The structure VIIg was identified by means of elemental analysis and by studying the spectral data. In the IR spectrum, very intensive absorption bands at 1708 cm^{-1} due to carbonyl stretching and at 1540 cm^{-1} due to amide II band stretching were observed. The NMR spectrum showed peaks at τ 7.70 (CH_3, s, 3H), 2.00—2.90 (aromatic, 9H), and −2.31 (NH, s, 1H). On the other hand, the absorption band at 499 mμ (ε 113) due to the $n \rightarrow \pi^*$ transition of the thiocarbonyl group was observed in the visible region. By an analogous treatment of other aromatic dithio acids with *para*-substituted phenyl isocyanates, the corresponding mixed thioanhydrides (VII) were prepared in good yields. The results are summarized in Table 1.

The mixed thioanhydrides (VII) thus obtained, except for VIIu, VIIv, and VIIw, were fairly stable crystals, and did not change in atmosphere for over two months. However, the heating of VII over their melting points decomposed VII to give the corresponding isocyanates, together with dark brown, intractable oil. Similar formations of the isocyanates on the heating of alkyl thiocarbamates have been described in German Patents.[6,7] On the other hand, the carbamoyl α-dithionaphthoates (VIIu, VIIv, and VIIw), except for VIIx which contains a *p*-nitro substituted carbamoyl group, were dark brown oil and gradually decomposed on standing in the atmosphere or in a solution (ethyl acetate or dichloromethane) at room temperature to give bis(α-thionaphthoyl)disulfide and the corresponding ureas in almost quantitative yields. These formations can be explained by the following scheme 1:[8]

$$\text{VIIu-w} \xrightarrow{rt} [\alpha\text{-}C_{10}H_7CS_2H] + [p\text{-X-}C_6H_4NCO]$$

$$\downarrow O_2 \qquad \downarrow H_2O$$

$$\alpha\text{-}(\text{-}C_{10}H_7CS_2)_2 \qquad (p\text{-X-}C_6H_4NH)_2CO$$

Scheme 1.

One of the interesting points about in the mixed thioanhydrides is their reaction with nucleophilic reagents because of their multi-reaction center, shown with the arrows a, b, and c, in Fig. 1. When the mixed

thioanhydride was treated with a two-molar amount of *p*-toluidine in dichloromethane at room temperature, *N*-*p*-tolylthiobenzamide (VIII) and phenyl-*p*-tolylurea (IX) were obtained in 94 and 95% yields, and also hydrogen sulfide evolved (Eq. (2)). Unlike *p*-toluidine, a similar treatment of VIIi with piperidine afforded piperidinium dithiobenzoate (X)[9] and the asymmetric urea (XI) in quantitative yields, and no evolution of hydrogen sulfide was observed (Eq. 3).

$$\underset{\text{VIIi}}{C_6H_5C(=S)\text{-}S\text{-}C(=O)\text{-}NHC_6H_5} + 2p\text{-}CH_3C_6H_4NH_2 \xrightarrow[CH_2Cl_2]{rt} H_2S$$

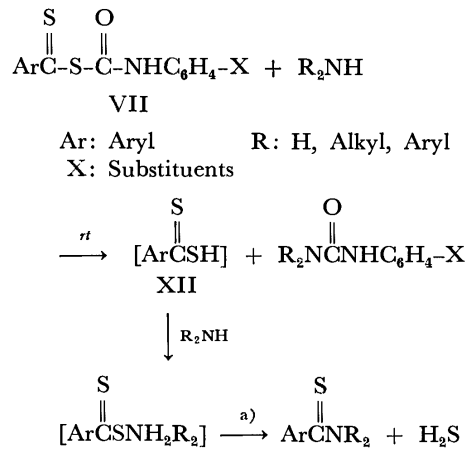
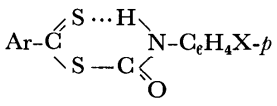
conditions gave the asymmetric ureas (IX or XI) in yields of over 60%. These results indicate the possibility of the nucleophilic attack of amines on the carbonyl carbon of the mixed thioanhydrides and the formation of the corresponding dithio acid (XII) as an intermediate (Scheme 2).



a) in the case of primary amines.

Scheme 2.

Spectral Data. *a) IR Spectra*: The IR spectra of all these anhydrides, without any exception, surprisingly showed no N–H stretching absorption band in the expected range (3100—3400 cm^{-1}); instead, we observed new absorption bands near 2900 cm^{-1} considered to be due to the N–H stretching band. Such an unusual shift in νN–H suggests a structure (XIII) containing an intramolecular hydrogen bond between sulfur and hydrogen. The NMR spectrum (NH near -2.30τ) further supported the XIII structure.



XIII

Ar: Aryl X: Substituents

The location of C=S group frequencies in organosulfur compounds has been a matter of considerable discussion. Bak *et al.*[10] reported that the two frequencies (ν C=S and C–S) obtained by a simplified force-constant calculation must be looked for in the vicinity of 1200 cm^{-1} (C=S) and 700 cm^{-1} (C–S), and the locations of the C=S in a series of twenty-one carboxymethyl dithio esters were observed between 1190 and 1225 cm^{-1}. Lately, Bellamy and Rogasch[11] have confirmed those results using solvent effects, and also suggested in a recent review[12] that ν C=S lies between 1225 and 1190 cm^{-1} in the dithio esters. The arylcarbamoyl dithio esters obtained, almost without exceptions, showed two fairly intensive absorption bands at near 1250 and 1050 cm^{-1}. However, it is difficult to assign the lower-frequency band to the C=S because that of amine salts of aromatic dithio acids was observed between 990 and 1020 cm^{-1}. Therefore, it seemed reasonable that the intensive absorption bands at near 1250 cm^{-1} are due to the C=S stretching bands in arylcarbamoyl dithioesters (VII). This also fits well with the assignment given by Bak *et al.*[10] and Bellamy.[11]

b) UV and Visible Spectra: Table 1 lists the absorption maxima in mμ and the molecular extinction coefficients at each maximum. As is shown in Table 1, all the mixed anhydrides (VII), showed two characteristic maximum absorption bands near 300 mμ (ε 15000—25000) and 500 mμ (ε 100—130). It may be considered that the former absorption bands are due to $\pi\rightarrow\pi^*$, and the latter, to the $n\rightarrow\pi^*$ transition of the thiocarbonyl group. The location of $n\rightarrow\pi^*$ fits well with the assignment given by Fabian *et al.*[13] for the methyl esters of aromatic dithio acids.

Experimental[14]

Materials. The aromatic dithio acids were prepared by the method described in a previous report[5], using THF as the solvent. Phenyl isocyanate was of a commercial grade and was distilled before use. The other aryl isocyanates were prepared, following the directions of the literature,[15] from the corresponding amines and phosgen; *p*-methoxyphenyl isocyanate, bp 105—106°C/8 mmHg *p*-tolyl isocyanate, bp 52—53°C/5 mmHg; *p*-nitrophenyl isocyanate: mp 55—57°C. The *p*-toluidine and piperidine were of a commercial grade and were purified by distillation or recrystallization before use. The solvents were dried and distilled.

Reactions were carried out under nitrogen. Some typical procedures will be described below, while the detailed data are summarized in Table 1.

Reaction of p-*Methyldithiobenzoic Acid with Phenyl Isocyanate.* An equimolar amount of phenyl isocyanate was added to a solution of *p*-methyldithiobenzoic acid (1.68 g, 0.01 mol) in 10-m*l* of ether-ethyl acetate (1 : 1), and the mixture was stirred for 30 min, at room temperature. The evaporation of the solvent from the reaction mixture below 20°C *in vacuo*, the recrystallization of the residue from ethyl acetate–petroleum ether (bp below 50°C, 1 : 3) gave 2.45 g of phenylcarbamoyl *p*-methyldithiobenzoate (VIIg).

Thermolysis of Phenylcarbamoyl Dithiobenzoate (VIIk). Phenylcarbamoyl dithiobenzoate (VIIk), 5.30 g, 0.02 mol) in a glass ampoule under nitrogen was heated for 30 min at 120°C. The distillation of the decomposition mixture gave 1.5 g (63%, based on the VIIk used) of phenyl isocyanate.

Decomposition of Phenylcarbamoyl α-Dithionaphthoate (VIIv) on Standing in an Atmosphere. A solution of 1.6 g (0.005 mol) of VIIv in ethyl acetate (20 m*l*) was allowed to stand in the atmosphere at room temperature. After 7 days, the color of the solution completely changed from dark brown to pink, and the precipitates appeared. After the removal of the solvent, the fractional crystallization of the residue from di-

13) J. Fabian, St. Scheithauer, and R. Mayer, *J. Prakt. Chem.*, **311**, 45 (1969).

14) All melting points were not corrected. The IR spectra were measured on a JASCO Grating Infrared Spectrophotometer IR-G. The UV spectra were recorded on Hitachi 124 Spectrophotometer. The NMR spectra were taken on a JEOL H-60 apparatus.

15) R. J. Slocombe, E. E. Hardy, T. H. Saunder, and R. L. Jenkins, *J. Amer. Chem. Soc.*, **72**, 1888 (1950).

chloromethane-ether gave 0.82 g (80%) of bis(α-thionaphthoyl)disulfide (mp 169—170°C[16]) and 0.55 g (91%) of diphenylurea (mp 60—70°C), which were identified by a comparision of their melting points and IR spectrum with those of an authentic sample.

Reaction of Phenylcarbamoyl Dithiobenzoate (VIIk) with p-Toluidine or Piperidine. *a*): *p*-Toluidine (1.07 g, 0.01 mol) was added to a solution of 1.36 g (0.005 mol) of VIIk in dichloromethane (10 m*l*) and stirred for 8 hr at room temperature. After the vacuum evaporation of the solvent from the reaction mixture, the residue was extracted with a small portion of ether. After the evaporation of the ether from the extracts, the recrystallization of the residue gave 1.2 g of *N*-*p*-tolylthiobenzamide (mp 126—127°C). On the other hand, the recrystallization of the ether-insoluble parts from dichloromethane gave 1.05 g of phenyl-*p*-tolylurea (mp (196—197°C). The thiobenzamide and the urea were identified by a comparision of the melting points and IR spectrum with those of authentic samples.[17]

b): The reaction of VIIk (0.05 mol) and piperidine (0.01 mol) under the same conditions as in a) gave 1.08 g (86%) of piperidinium dithiobenzoate (mp 112—114°C) and 0.97 g (96%) of phenylpiperidylurea (mp 165—166°C). The melting points and the IR spectra of the amine salts and the urea coincided exactly with those of authentic samples.

c) Competitive Reaction: A similar treatment of a mixture of dithiobenzoic acid (0.01 mol) and VIIk (0.01 mol) in dichloromethane (15 m*l*) with 0.01 mol of *p*-toluidine gave 1.43 g (63%, based on the *p*-toluidine used) of *N*-*p*-tolylphenylurea and 0.59 g (26%, based on the *p*-toluidine used) of *N*-*p*-tolylthiobenzamide.

d): A similar treatment of a mixture of dithiobenzoic acid (0.01 mol) and VIIk (0.01 mol) in dichloromethane (15 m*l*) with piperidine (0.01 mol) gave 1.47 g (72%, based on the piperidine used) of phenylpiperidylurea and 0.37 g (13%, based on the piperidine used) of piperidinium dithiobenzoate.

The authors wish to thank Professor Yoshio Hirabayashi and Mr. Hideharu Ishihara for their discussions.

Studies of Acenaphthene Derivatives. XXVI.[1] The Thermal Cycloaddition of 2-Diazoacenaphthenone to Isocyanates

Otohiko Tsuge,[2] Ichiro Shinaki, and Masahiro Koga

Research Institute of Industrial Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka, 812

(Received May 19, 1972)

Although 2-diazoacenaphthenone did not react with phenyl isocyanate or phenyl isothiocyanate on prolonged reflux in toluene, it reacted with strongly electrophilic benzoyl and *p*-chlorobenzoyl isocyanates and thiobenzoyl isocyanate to give the corresponding spiro[acenaphthenone-2,5′-oxazolin-4′-one] and the spiro-thiazolin-4′-one in good yields. On the other hand, the reaction of the α-diazoketone with benzoyl isothiocyanate gave 8-benzoylacenaphtho[1,2-*d*]isoxazolin-9-thione, which on catalytic hydrogenolysis over PtO_2 gave the dihydro compound corresponding to reductive cleavage of N–O bond of the isoxazoline ring. Furthermore, the reaction of the α-diazoketone with benzenesulfonyl isocyanate gave two stereoisomeric bis-spiro-azetidinones. The mechanisms of these reactions are proposed.

In an earlier publication,[3] it was reported that the reaction of 2-diazoacenaphthenone (**1**) with olefins gave diastereoisomeric spiro-cyclopropanes under mild conditions. In contrast, acetylenes yielded spiro-3*H*-pyrazoles. The reaction of α-diazoketones has been extensively studied by Ried and his co-workers,[4] and it has been shown that the reactions of α-diazoketones with multiple bonds form 1,3-[5] or 1,5-cycloaddition products under rather mild conditions (Scheme 1). For example, the reaction of α-diazoketones with isothiocyanate[6] or thiophosgene[7] gave thiazoles. Recently, in order to prepare medium-sized heterocycles,

the addition of 1,5-dipoles such as vinyldiazomethane,[8] vinylazide,[9] and other similar compounds,[10] has been investigated. However, the 1,5-dipoles cyclized intramolecularly to yield stable five-membered heterocycles rather than 1,5-cycloadducts.

Only the reaction of *o*-quinonediazide with ketenes[11] and ketenimines[12] resulted in 1,5-cycloaddition to yield the oxadiazepines. It would be expected that **1** might add to heterocumulene such as isocyanate to give the (2+5) cycloadduct, oxatriazepine. Since little information about the thermal cycloaddition reaction of **1** with isocyanates is available, we have investigated the reaction of **1** with several isocyanates under mild conditions, and now report our findings in this area.

Results and Discussion

It was previously reported[3] that thermolysis of α-diazoketone **1** did not take place in boiling toluene and the ketocarbene from **1** is not formed under such conditions. It has now been found that **1** did not react with phenyl isocyanate or isothiocyanate on prolonged reflux in toluene; **1** was recovered quantitatively. However, when a toluene solution of **1** and benzoyl isocyanate (**2a**) was refluxed for 30 hr, a 38.5% yield of **3a** was obtained as colorless needles, in addition to recovered **1**. The results of microanalysis and mass spectrum of **3a** fitted the molecular formula $C_{20}H_{11}NO_3$, which would arise from the elimination of nitrogen from a 1 : 1 adduct of **1** and **2a**. The IR spectrum of **3a** showed bands ascribable to carbonyl groups at 1762 and 1729 cm^{-1}. On the basis of the above observations, it may be deduced that **3a** is 2′-phenyl-spiro[acenaphthenone-2,5′-oxazolin-4′-one].

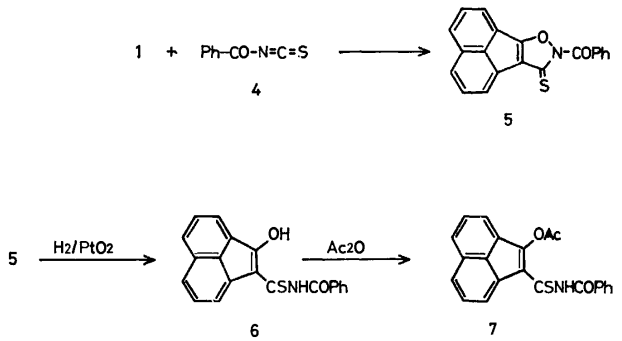
Under similar conditions, *p*-chlorobenzoyl (**2b**) and thiobenzoyl isocyanate (**2c**) gave the corresponding spiro-oxazolin-4′-one (**3b**) and spiro-thiazolin-4′-one (**3c**). The mass spectra of **3a**—**3c** were also compatible with the proposed structures.

It has been reported[13] that the C=N bond of isocyanate reacts easily with 1,3-dipoles, whereas the C–S bond of isothiocyanate is attacked predominantly. In order to compare with the reactivity of acyl isocyanates, the reaction of **1** with benzoyl isothiocyanate (**4**) was investigated.

When a toluene solution of **1** and **4** was refluxed for 10 hr, a 31% yield of a product **5** was obtained as yellow needles. The microanalysis and mass spectral data were in agreement with the molecular formula $C_{20}H_{11}NO_2S$ (M^+ m/e 329). Its IV spectrum exhibited a single carbonyl absorption at 1632 cm^{-1}. The thiocarbonyl test[14] was positive.

The hydrogenolysis of **5** over PtO_2 in dioxane at room temperature afforded a dihydro compound **6** as yellow needles. The IR spectrum of **6** showed the band ascribable to amide I absorption at 1645 cm^{-1}, and the NMR spectrum in carbon tetrachloride exhibited signals at δ 10.18 (1H, singlet, OH) and 14.15 ppm (1H, singlet, NH) besides aromatic protons. Treatment of the compound **6** with acetic anhydride afforded the *O*-acetylated derivative **7** as golden yellow needles.



Scheme 2.

On the basis of these observations, **5** and **6** were assigned as 8-benzoyl-acenaphtho[1,2-*d*]-Δ^4-isoxazolin-9-thione and 2-benzoylthiocarbamoyl-1-acenaphthylenol, respectively (Scheme 2).

Confirmatory evidence for the structure of **5** was provided by the mass spectrum; the spectrum of **5** showed no peak at *m/e* 226 which would arise by the elimination of benzonitrile from parent peak (M^+ *m/e* 329), while the fragment peaks (M^+— ArCN) appeared in the spectra of **3a**—**3c**.

These results show clearly that a ketocarbene intermediate was not involved. We view these reactions as depicted in Scheme 3. α-Diazoketone **1** would react with **2** to form intermediate **A** (X=Y=O or X=S, Y=O) which would cyclize to the triazoline, followed by the elimination of nitrogen and cyclization to **3**.

In contrast, the negative charge in the intermediate **A** (X=O, Y=S) formed from the reaction with **4** would be located on the sulfur atom, since diazomethane,[6] ketocarbenes[15] and epoxides[16] react predominantly

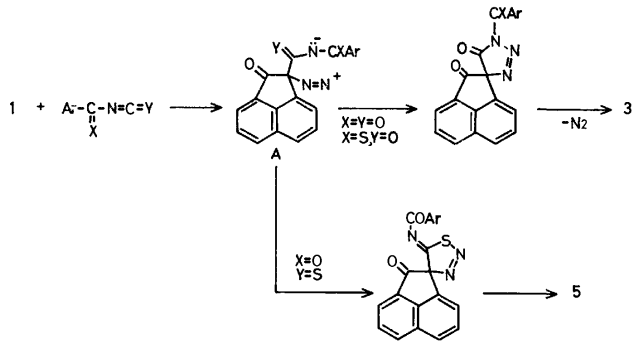
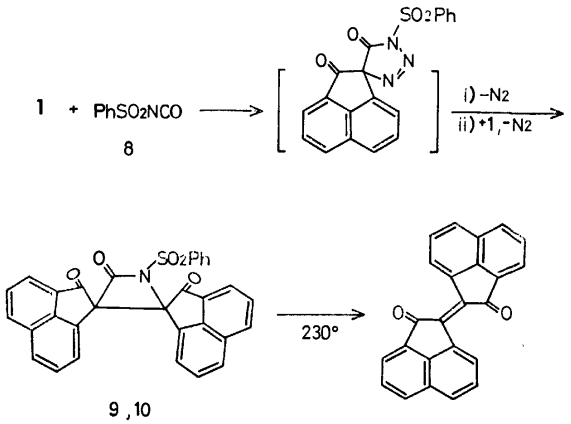


Scheme 3.

with the C=S bond of phenyl isothiocyanate. It would thus seem reasonable to assume that the betaine **A** would cyclize to the exo-double bonded thiadiazoline, followed by the elimination of nitrogen and ring closure to **5**.[17]

Since the sulfonyl group does not enter into conjugative effects,[18] products analogous to **3** would thus not be expected from the reaction of **1** with benzenesulfonyl isocyanate (**8**). The reaction of **1** with **8** in benzene at room temperature for 72 hr yielded two products **9** and **10** in 16 and 28.2% yields, respectively. Microanalyses of both **9** and **10** agreed with the molecular formula ($C_{31}H_{17}NO_5S$) derived from a 2 : 1 adduct of **1** and **8** with the elimination of nitrogen. The IR spectra of both **9** and **10** showed carbonyl bands at about 1800 cm^{-1}, which are assignable to carbonyl group in four-membered rings.[19] Thermal decomposition of both **9** and **10** at 230°C gave biacenedione in 77.6 and 31% yields, respectively.

From a consideration of the high carbonyl frequency and the result of the thermal decomposition to biacenedione, **9** and **10** may be considered as stereoisomeric



Scheme 4.

bis-spiro-azetidinone. However, their configurations have not been clarified (Scheme 4).

Recently, it has been reported that sulfonyl isocyanate reacted with diazofluorene to give bis-spiro-azetidinone which was converted thermally to bis-fluorenylidene.[20] We also reported that biacenedione was obtained by thermal decomposition of *N*-phenyl-bis-spiro-pyrrolidine formed from the 1,3-dipolar cycloaddition of 2-benzylidenacenaphthenone to azomethine oxide.[2]

On the basis of these results, it can be concluded that **1** does not react as a 1,5-dipole but rather as a 1,3-dipole incycloaddition to isocyanate, followed by cyclization to spiro-heterocycles.

Experimental

All melting points are uncorrected. The IR spectra were measured as KBr pellets and the NMR spectra were determined at 60 MHz with Hitachi R-20 NMR spectrometer using TMS as an internal reference. The mass spectra were obtained on a Hitachi RMS-4 mass spectrometer using a direct inlet and an ionization energy of 70 eV.

Materials. 2-Diazoacenaphthenone (**1**) was prepared by the reported method[22] and purified by chromatography (alumina), mp 93—94°C (lit,[22] mp 94°C); benzoyl (**2a**),[23] *p*-chlorobenzoyl (**2b**),[23] thiobenzoyl (**2c**),[24] benzenesulfonyl isocyanate (**8**),[25] and benzoyl isothiocyanate (**4**)[26] were prepared by the methods described in the literatures respectively.

*Reaction of **1** with Isocyanates (2).* The general procedure used is illustrated with the reaction of **1** with **2a**.

A solution of 780 mg (4.0 mmol) of **1** and 730 mg (5.0 mmol) of **2a** in 30 m*l* of toluene was refluxed for 30 hr, the reaction mixture was then cooled and filtered to give crystals, which on recrystallization from benzene-petroleum benzine (bp 42—60°C) afforded 360 mg (38.5%) of 2′-phenyl-spiro [acenaphthenone-2,5′-oxazolin-4′-one] (**3a**), mp 246—247°C, as colorless needles.

Found: C, 76.48; H, 3.61; N, 4.52%. Calcd for $C_{20}H_{11}NO_3$: C, 76.67; H, 3.54; N, 4.47%. IR cm^{-1}: $\nu_{C=O}$ 1729, 1762.

Mass spectrum *m/e* (rel. intensity): 313 (M^+, 54.5), 210 (M^+—PhCN, 37.8), 182 (210$^+$—CO, 75.5) 154 (182$^+$—CO, 100), 126 (154$^+$—CO, 63.6).

The toluene filtrate was concentrated *in vacuo* and the residue was purified by chromatography on alumina to yield 480 mg (61.5%) of unreacted **1**.

Similarly, the reaction of **1** with **2b** and **2c** for 30 and 12 hr respectively afforded the corresponding spiro-oxazolin-4′-one **3b** and spiro-thiazolin-4′-one **3c**.

3b: mp 269—271°C, colorless prisms (benzene). Yield, 59%.

Found: C, 69.17; H, 2.71; N, 4.04%. Calcd for $C_{20}H_{10}NO_3Cl$: C, 69.06; H, 2.88; N, 4.03%. IR cm^{-1}: $\nu_{C=O}$ 1730, 1766.

17) This reaction seems to be the same type as the decomposition of 4-acyltriazolones to form isoxazolines (K. H. Oehring, *Monatsch. Chem.*, **89**, 588 (1958)).

Mass spectrum *m/e* (rel. intensity): 349 (33.2), 347 (100) (M^+), 210 (M^+—Cl-  -CN, 57.5), 182 (210$^+$—CO, 44), 154 (210$^+$—CO, 88), 126 (154$^+$—CO, 36.4).

3c: mp 239—240°C, pale yellow prisms (benzene). Yield, 28%.

Found: C, 73.24; H, 3.29; N, 4.41%. Calcd for $C_{20}H_{11}NO_2S$: C, 72.94; H, 3.37; N, 4.25%. IR cm^{-1}: $\nu_{C=O}$ 1710, 1736.

Mass spectrum *m/e* (rel. intensity): 329 (M^+, 14), 226 (M^+—PhCN, 55), 198 (226$^+$—CO, 75), 170 (198$^+$—CO, 100), 126 (170$^+$—CS, 25.6).

In a similar fashion, 8-benzoylacenaphthol[1,2-*d*]-Δ^4-isoxazoline-9-thione (**5**), mp 215—217°C, was obtained in a 31% yield as yellow needles (from ligroin (bp 80—110°C)); a 33% yield of **1** was recovered.

Found: C, 73.14; H, 3.24; N, 4.15%. Calcd for $C_{20}H_{11}NO_2S$: C, 72.94; H, 3.37; N, 4.25%. IR cm^{-1}: $\nu_{C=O}$ 1632.

Mass spectrum *m/e* (rel. intensity): 329 (M^+. 100), 288 (8), 210 (288$^+$—CS, 4.4), 192 (6.6), 120 (5.2), 105 ($PhCO^+$, 66).

Catalytic Hydrogenation of ***5***. Hydrogenation of 200 mg of 5 in 30 m*l* of dioxane with 100 mg of PtO_2 resulted in smooth absorption of one equivalent of hydrogen in about 5 hr at room temperature. The reaction mixture was filtered and the catalyst was washed with 5 m*l* of dioxane. Concentration of the filtrate *in vacuo* left a residue which on trituration with petroleum benzine (20 m*l*) gave 160 mg of yellow crystals. The crystals were recrystallized from acetonitrile to give 2-benzoylthiocarbamoyl-1-acenaphthylenol (**6**), mp 155—157°C, as yellow needles.

Found: C, 72.57; H, 3.81; N, 4.21%. Calcd for $C_{20}H_{13}NO_2S$: C, 72.50; H, 3.96; N, 4.23%. IR cm^{-1}: $\nu_{C=O}$ 1645.

NMR (in CCl_4) δ ppm: 7.4—8.3 (11**H**, multiplet, aromatic protons), 10.18, (1H, singlet, O**H**), 14.15 (1H, singlet, N**H**).

Mass spectrum *m/e*: 331 (M^+).

A solution of **6** in methanol containing trace amounts of pyridine was treated with acetic anhydride at room temperature for 10 min to give a quantitative yield of yellow crystals, which on recrystallization from benzene–petroleum benzine yielded *O*-acetyl derivative **7**, mp 152—153°C decomp.), as golden yellow needles.

Found: C, 70.76; H, 3.80; N, 3.91%. Calcd for $C_{22}H_{15}NO_3S$: C, 70.77; H, 4.05; N, 3.75%. IR cm^{-1}: $\nu_{C=O}$ 1693, 1715.

NMR (in $CDCl_3$) δ ppm: 2.63 (3H, singlet, $COCH_3$), 7.39—8.3 (11**H**, multiplet, aromatic protons), 13.36 (1H, singlet, N**H**).

Mass spectrum *m/e*: 373 (M^+).

Reaction of ***1*** *with* ***8***. A solution of 1.55 g (8.0 mmol) of **1** and 1.83 g (10.0 mmol) of **8** in 50 m*l* of benzene was stirred for 72 hr at room temperature. The precipitated crystals were fractionally recrystallized several times from benzene to afford 190 mg (15%) of biacenedione, mp 294°C, identical with an authentic sample prepared from acenaphthenequinone and acenaphthenone, and 330 mg (16%) of bis-spiro-azetidinone **9**, mp 228—230°C (decomp.), as colorless prisms.

Found: C, 72.34; H, 3.71; N, 2.71%. Calcd for $C_{31}H_{17}NO_5S$: C, 72.23; H, 3.30; N, 2.72%. IR cm^{-1}: $\nu_{C=O}$ 1807, 1746, 1720.

The benzene filtrate was concentrated *in vacuo*; recrystallization of the residue from benzene–petroleum benzine gave 580 mg (28.2%) of isomeric bis-spiro-azetidinone **10**, mp 213—216°C (decomp.), as pale yellow needles.

Found: C, 72.09; H, 3.86; N, 2.54%. Calcd for $C_{31}H_{17}NO_5S$: C, 72.23; H, 3.30; N, 2.72%. IR cm^{-1}: $\nu_{C=O}$ 1806, 1738, 1710.

Thermal Decomposition of ***9***. Forty miligrams of **9** were heated at 230°C for 5 min without solvent. After cooling, the resulting semicrystalline residue was chromatographed on alumina. Elution with chloroform afforded 20 mg (77.6%) of biacenedione, mp 294°C. Similarly, thermolysis of **10** at 230°C gave a 31% yield of biacenedione.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3660—3667 (1972)

Inositol Derivatives. V. Selective Benzoylation of 1,2-*O*-Cyclohexylidene-*myo*-inositol and Preparation of New *O*-*p*-Tolylsulfonyl-*myo*-inositols

Tetsuo SUAMI, Seiichiro OGAWA, Kumiko OHASHI, and Shuichi OKI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama

(Received May 30, 1972)

The reaction of 1,2-*O*-cyclohexylidene-*myo*-inositol (**1a**) with 1.5 equiv. of benzoyl chloride below 0°C gave 3-*O*-benzoate (**2a**) predominantly in 40% yield, together with easily separable 3,6-di-*O*-benzoate (**3a**) in 2.5% yield. Selective sulfonylation of **2a** gave three new *O*-*p*-tolylsulfonyl-*myo*-inositols (the 4,6- (**8a**), 4,5- (**9a**), and 4,5,6-*p*-toluenesulfonates (**10**)). From **3a**, two *O*-*p*-tolylsulfonyl derivatives (5- (**15a**) and 4,5-*p*-toluenesulfonates (**16**)) were obtained. The relative reactivities, toward benzoylation, of the hydroxyl groups of **1a** were shown to be almost similar to those observed in tosylation. The *p*-tolylsulfonyloxy function on C-5 of **10** was found to be readily displaced preferentially by chloride ion.

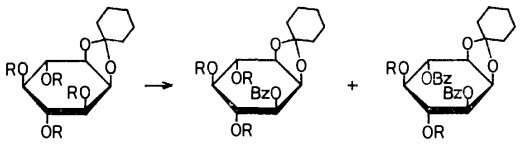
As the continuation to a program[1] to elucidate relative reactivities of hydroxyl groups of cyclitols toward esterification, a selective benzoylation of 1,2-*O*-cyclohexylidene-*myo*-inositol (**1a**)[2] was studied. We wish to report on the preparation of two benzoates by selective benzoylation of **1a**, from which four new *p*-toluenesulfonates of *myo*-inositol were obtained by

1) T. Suami, S. Ogawa, T. Tanaka, and T. Otake, This Bulletin, **44**, 835 (1971); T. Suami, S. Ogawa, and S. Oki, *ibid.*, **44**, 2820, 2824 (1971).

2) S. J. Angyal, M. E. Tate, and S. D. Gero, *J. Chem. Soc.*, **1961**, 4116.

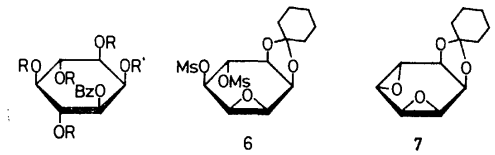
sulfonylation. Preferential replacement of the *p*-tolylsulfonyloxy function with chlorine atom in dry pyridine in the presence of pyridine hydrochloride was observed at elevated temperature.

The reaction of **1a** with 1.5 equiv. of benzoyl chloride in dry pyridine at −5—0°C for 3 days gave, in 40% yield, the 3-*O*-benzoate (**2a**) as the sole crystalline monobenzoate together with a considerable proportion of a mixture of the di- and tri-benzoates, from which the 3,6-di-*O*-benzoate (**3a**) was readily isolated in 2.5% yield by fractional crystallization. Acetylation of **2a** and **3a** in the usual way afforded the acetates (**2b**) and (**3b**), and mesylation gave the tri-*O*-mesyl derivative (**2c**) and di-*O*-mesyl derivative (**3c**), respectively.



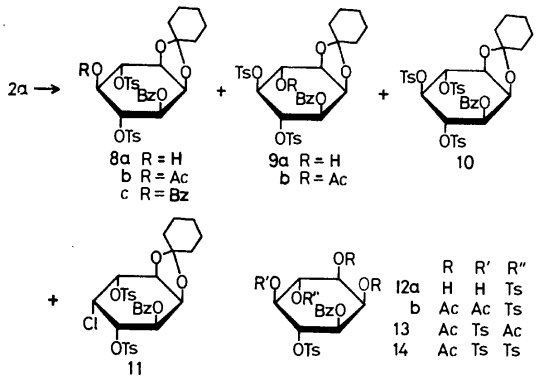
The structures of **2a** and **3a** were established by the following evidences. In analogy to the tosylation of **1a**,[1] the hydroxyl group at C-3 was also expected to be the most active toward benzoylation. Removal of the cyclohexylidene group from **2a** with boiling 80% aqueous acetic acid, followed by acetylation, gave 1-*O*-benzoyl-*myo*-inositol pentaacetate (**4**), which was proved to be identical with the compound derived from 1,4,5,6-tetra-*O*-acetyl-3-*O*-benzoyl-*myo*-inositol (**5**).[3] The proposed structure of **2a** was thus confirmed.

The reaction of **2a** with 3 equiv. of benzoyl chloride at 30°C was monitored by thin layer chromatography (tlc). After 2 days, the result was almost the same as that obtained in the reaction of **1a** with 4 equiv. of benzoyl chloride. Thus, it was clear that **3a** was formed from **2a** by further benzoylation and that an ester group was located at C-3.



When **3c** was treated with a slight excess of sodium methoxide in a mixture of chloroform and methanol, 1,2: 5,6-dianhydro-3,4-*O*-cyclohexylidene-*allo*-inositol (**7**)[4] was obtained. Since **7** can be formed from either 3,6- or 4,5-disulfonate, the structure of **3a** could be assigned to 3,6-dibenzoate. By similar treatment with sodium methoxide, **2c** afforded 2,3-anhydro-4,5-*O*-cyclohexylidene-1,6-di-*O*-methylsulfonyl-*epi*-inositol (**6**), whose proton magnetic resonance (PMR) spectrum in dimethyl sulfoxide-d_6 (DMSO-d_6) was consistent with the proposed structure, namely, the signal due to H-2 and H-3 appeared as a broad singlet at τ 6.29, and H-6 double doublet and H-1 doublet at τ 5.34 and 4.69, respectively. The up-field shift of H-6 signal might be interpreted by assuming the shielding effect above a plane of the epoxide ring in a skew conformation.[5] It is of interest to note that, in the PMR spectrum of the corresponding di-*p*-toluenesulfonate,[4] the complex multiplet (τ 6.45) due to H-2 and H-3, and H-5 triplet (τ 5.90) were only upshifted by *ca.* 0.20 ppm, as compared with those of **6**, due to the shielding effect of tosyloxy aromatic rings.

Compound **2a** may be a versatile intermediate in the synthesis of a number of inositol derivatives of biological interest. Selective sulfonylation of **2a** was carried out in order to synthesize new *O*-*p*-tolylsulfonyl-*myo*-inositols. The reaction of **2a** with 7 equiv. of *p*-toluenesulfonyl chloride in dry pyridine at room temperature (20—25°C) was monitored by tlc. After 4 days, formation of two di- and one tri-*p*-toluenesulfonates was shown by tlc. The crude mixture was then fractionated by crystallization to give 4,6-di- (**8a**) and 4,5,6-tri-*p*-toluenesulfonates (**10**) in 22 and 5% isolated yields, respectively. The oily 4,5-diester (**9a**) could be characterized by being converted into crystalline acetate (**9b**) (20% yield).



When the same reaction was carried out at 30°C for 3 days, compounds **8a**, **9b** and **10** were isolated in 30, 7, and 12% yields, respectively. Thus in view of the relative yields of the *p*-toluenesulfonates, it might be deduced that **9a** reacts with the acylating agent more rapidly than **8a** to yield **10** smoothly.

On the other hand, when the same reaction was carried out at 80—85°C, formation of an unidentified faster-moving product was observed. After 12 hr, fractionation of the crude reaction mixture by crystallization gave an unknown compound (**11**) in 9% yield, together with a mixture of **8a** and **10** (*ca.* 20%), **9b** (8%), and **10** (30%).

The acetate (**8b**) and benzoate (**8c**) were prepared in the usual way from **8a**. Removal of cyclohexylidene group from **8a** gave 1-*O*-benzoyl-4,6-di-*O*-*p*-tolylsulfonyl-*myo*-inositol (**12a**), which was converted into the triacetate (**12b**). Similarly, 1,2,6-tri-*O*-acetyl-3-

a) Measured at 60 MHz in $CDCl_3$, unless otherwise stated. Chemical shifts are given in τ-values. Abbreviations: d (doublet); t (triplet); dd (double doublet). First order coupling constant (Hz) are expressed. For convenience, all the compounds listed are named as derivatives of 1,2-*O*-cyclohexylidene-*myo*-inositol. b) Measured at 100 MHz. c) The signal appeared on deuteration. d) Broad doublet. e) Singlet for two methyl protons. f) Broad singlet for four methyl protons. g) Preparation of **21**, **22**, **23**, and **24** is given in Experimental.

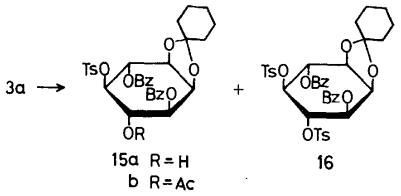
O-benzoyl-4,5-di- (**13**) and 1,2-di-*O*-acetyl-3-*O*-benzoyl-4,5,6-tri-*O*-*p*-tolylsulfonyl-*myo*-inositol (**14**) were prepared from **9b** and **10**, respectively.

Determination of the positions of the *p*-tolylsulfonyloxy groups was accomplished by means of PMR spectroscopy. In the PMR spectrum of **8a** in $CDCl_3$ (Table 1), two double doublets due to H-4 and H-6 appeared at τ 4.84 and 5.10, respectively, while H-5 triplet was observed at τ 6.12 upon addition of deuterium oxide, indicating the location of two sulfonyloxy groups at C-4 and C-6. The PMR spectrum of **9b** (Table 1) revealed the double doublet at τ 4.55, which could be assigned to H-6 signal, showing that the acetoxy group was attached at C-6.

Treatment of **9b** with excess methanolic sodium methoxide afforded **7**, excluding the 5,6-disulfonate structure of **9b**. Both the proposed structures of **8a** and **9b** were thus assigned unequivocally.

Selective sulfonylation of **3a** was conducted. The reaction of **3a** with 3 equiv. of *p*-toluenesulfonyl chloride at room temperature was monitored by tlc. After 3 days, **3a** disappeared and two mono- and one di-

p-toluenesulfonates were formed. Fractionation of the crude mixture by crystallization gave the 5-*O*- (**15a**) and 4,5-di-*O*-*p*-tolylsulfonyl derivatives (**16**) in 12 and 20% isolated yields, respectively. The faster-moving disulfonate, presumably 4-*O*-*p*-toluenesulfonate, could not be obtained in a crystalline form. However, judging from tlc, two monosulfonates seem to have been formed nearly in the same proportion.



In the PMR spectrum of the acetate (**15b**) derived from **15a**, the triplet due to H-5 appeared at higher-field (τ 5.00) as compared with H-4 double doublet (τ 4.05), indicating that the sulfonyloxy group was located at C-5.

Structural elucidation of **11** was carried out in the following way. Removal of cyclohexylidene group from **11** gave the dihydroxyl derivative (**17a**), which was transformed into the diacetate (**17b**). It was shown by elemental analyses of **11**, **17a** and **17b** that one of the tosyloxy functions of **10** was replaced by a chlorine atom. In the PMR spectrum of **11** (Fig. 1), two double doublets appeared at τ 4.73 and 4.23, having J=3.0 and 10.0 Hz, and J=4.0 and 10.0 Hz, respectively. From the coupling constants and their shapes they were clearly coupled to each other. Therefore, the former should be ascribed to the signal of the proton attached to the carbon atom bearing the tosyloxy group and the latter to that of 3-proton since it must be at the lowest field. Thus H-2, H-3, H-4, and H-5 were shown to be in equatorial, axial, axial, and equatorial arrangement, respectively. Consequently, the presence of the chlorine atom at C-5, its configuration being inverted, might only account for the above spectral data. The structure of **11** was tentatively assigned to 3-*O*-benzoyl-5-chloro-1,2-*O*-cyclohexylidene-5-deoxy-4,6-di-*O*-*p*-tolylsulfonyl-*neo*-inositol.

Mechanistically, a direct S_N2 attack of chloride ion

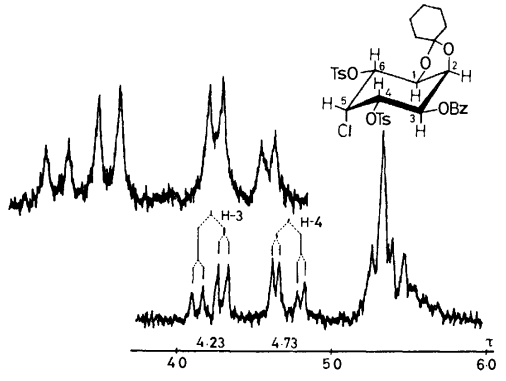


Fig. 1. Partial PMR spectrum of 3-*O*-benzoyl-5-chloro-1,2-*O*-cyclohexylidene-5-deoxy-4,6-di-*O*-*p*-tolylsulfonyl-*neo*-inositol (**11**) in $CDCl_3$ at 60 MHz. An amplified (magnification, 2) spectrum is shown above.

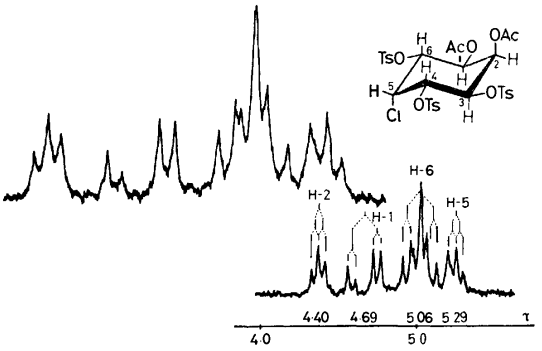

Fig. 2. Partial PMR spectrum of 1,2-di-*O*-acetyl-5-chloro-5-deoxy-3,4,6-tri-*O*-*p*-tolylsulfonyl-*neo*-inositol (**20b**) in $CDCl_3$ at 60 MHz. An amplified (magnification, 2) spectrum is shown above.

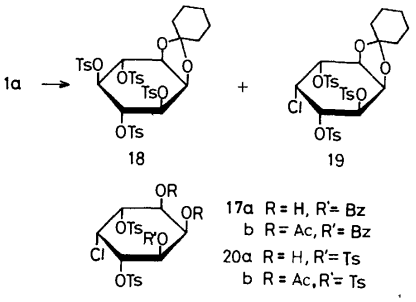
generated from pyridine hydrochloride formed might be postulated to occur at C-5 of **10**. This was supported by the following results: treatment of **10** with excess pyridine hydrochloride in dry pyridine at 90—95°C gave **11**, although in a poor yield (3.5%), but **11** could not be formed by a similar treatment of **8a**. As an analogous example, Hess and Stenzel[6] reported a facile replacement of C-6 and C-4 tosyloxy functions of methyl α-D-glucoside by treatment in dry pyridine with 6 equiv. of *p*-toluenesulfonyl chloride at 85°C.



In order to examine the proposed reaction mechanism, **1a** was subjected to similar reaction conditions yielding **11**. The expected chlorodeoxy compound (**19**) was obtained in 10% yield, together with the tetra-*O*-*p*-toluenesulfonate (**18**) (isolated yield 30%). Removal of the cyclohexylidene group from **19** gave the dihydroxyl derivative (**20a**), which was converted into diacetate (**20b**). Assuming that the displacement reaction occurred at C-5 of **18**, **19** might be formulated as 5-chloro-1,2-*O*-cyclohexylidene-5-deoxy-3,4,6-tri-*O*-*p*-tolylsulfonyl-*neo*-inositol. In the PMR spectrum of **20b** (Fig. 2), two narrow triplets appeared at τ 5.28 and 4.39, having J=2.5 and J=3.0 Hz, respectively, which were attributed to the signals of two equatorial protons (H-5 and H-2). The H-1 and H-6 signals appeared as double doublets at τ 4.69 and 5.05, having J=2.5 and 10.0, and J=3.0 and 10.0 Hz, respectively, indicating that the chlorine atom was situated axially orientated at C-5. The proposed structure was thus confirmed.

Consequently, it was demonstrated that C-5 *p*-tolylsulfonyloxy function of *p*-toluenesulfonic esters

6) K. Hess and H. Stenzel, *Ber.*, **68**, 981 (1935).

of 1,2-*O*-cyclohexylidene-*myo*-inositol was most readily replaced by chloride ion among four functions. The result is of interest in contrast to its lower reactivity toward esterification.

PMR spectra——The PMR spectra of the benzoates and sulfonates together with those of some related compounds are given in Table 1. The signals due to H-1 and H-2 could be readily assigned because they occurred up-field and were sufficiently separated from those of the protons on the remaining carbon atoms. Comparing the chemical shifts of the ring protons for **1c** with those for **1b**, the deshielding effect was observed in **1c** due to the benzoyl carbonyl group at C-3; namely, the signals for H-4, H-5, and H-6 were shifted down-field by 0.17, 0.12, and 0.13 ppm, respectively. In **3b**, H-4 and H-5 signals showed considerable down-field shifts (0.30 and 0.32 ppm) due to two ester groups at C-3 and C-6.

Interesting shielding effects on methyl signals of *p*-tolylsulfonyloxy groups were observed. The methyl protons of all the *p*-toluenesulfonates of *myo*-inositol derivatives so far reported[1] resonate in the range τ 7.54—7.59. For instance, the methyl signals of four *p*-tolylsulfonyl groups of **18** appeared at τ 7.55 as a slightly broadened singlet, whereas the introduction of benzoyl groups at vicinal positions to the *p*-tolylsulfonyloxy groups was found to cause intense up-field shifts for the methyl signals of the latter. That is, when the equatorial *p*-tolylsulfonyl group is flanked by an equatorial benzoyloxy group, the methyl signal upshifts by 0.14—0.24 ppm, and, when flanked by two, by 0.35—0.39 ppm.

It is well established that protons situated in the space above or below a benzene ring are subjected to shielding effects. The effects observed show that the benzoyloxy group adopts a conformation in which the aromatic ring is in a position at right angles to the plane of the ring of the ester group restricted of free rotation. The above effect may be applied adequately for the structural assignment of **8a** and **9b**. Thus, one of the signals of the tosyloxy methyl groups was shifted up-field by 0.20 and 0.19 ppm, respectively, showing that they were situated adjacent to the benzoyloxy group at C-3.

Experimental

Melting points were determined on a Mitamura Riken micro hot stage and are uncorrected. PMR spectra were measured on a Varian Associates A-60D (60 MHz) spectrometer at a concentration of *ca.* 10% deuteriochloroform or dimethyl sulfoxide-d_6 with tetramethylsilane as an internal standard. Chemical shifts are expressed in τ-values and signals are denoted by s (singlet), t (triplet), dd (double doublet), and m (complex multiplet). Values given for coupling constants are of first-order. Tlc was performed with silica gel (Wakogel B-10, Wako pure chemical industries Ltd.) using toluene–methyl ethyl ketone (4 : 1 or 3 : 1 volume) as the the solvent system. The compounds were detected by exposing the plate to iodine vapor or by heating after spraying 50% sulfuric acid. All solutions were concentrated by a rotary evaporator at 40—50°C under reduced pressure. All the compounds described in this paper are racemic.

3,4,5,6-Tetra-O-*benzoyl-1,2*-O-*cyclohexylidene*-myo-*inositol* (**1c**). To a solution of 1,2-*O*-cyclohexylidene-*myo*-inositol (**1a**)[2] (1.00 g) in dry pyridine (15 m*l*) was added 6 equiv. of benzoyl chloride (2.04 m*l*) under ice cooling and the mixture was kept in a refrigerator for 3 days. The solution was then poured into ice and water, and the precipitates were collected; yield 2.34 g, mp 227—241°C. By tlc, the crude crystals were shown to be contaminated with several minor components. Recrystallization from chloroform–ethanol gave colorless crystals (0.64 g, 25%) of **1c**, mp 241—243°C.

Found: C, 70.51; H, 5.05%. Calcd for $C_{40}H_{36}O_{10}$: C, 70.99; H, 5.36%.

3-O-*Benzoyl-1,2*-O-*cyclohexylidene*-myo-*inositol* (**2a**) *and 3,6-di*-O-*benzoyl-1,2*-O-*cyclohexylidene*-myo-*inositol* (**3a**). a) To a solution of **1a** (13.0 g) in dry pyridine (200 m*l*) was added, under cooling (−5—0°C), 1.5 equiv. of benzoyl chloride (8.7 m*l*) dropwise for 10 min. After being kept in a refrigerator overnight, the mixture was poured into ice and water (1 *l*). The resulting white precipitates were collected and washed thoroughly with water. The crude product (2.1 g) was recrystallized twice from methyl ethyl ketone to give colorless needles (0.58 g, 2.5%) of **3a**, mp 234—237°C. Tlc of the mother liquor indicated at least five spots: **3a**, three dibenzoates, and one tribenzoate.

Found: C, 66.85; H, 6.02%. Calcd for $C_{26}H_{28}O_8$: C, 66.65; H, 6.02%.

Evaporation of the water layer gave white crystals (5.60 g), which were recrystallized from methanol to give colorless needles (4.66 g, 39.5%) of **2a**, mp 203—205°C. From the mother liquor, an additional crop of **2a** (0.82 g) was obtained, which contained a small amount of **3a**, mp 199—205°C. Recrystallization from methanol afforded an analytical sample, mp 203.5—205°C.

Found: C, 62.87; H, 6.72%. Calcd for $C_{19}H_{24}O_7$: C, 62.62; H, 6.64%.

b) Compound **1a** (1.30 g) was treated with 1.0 equiv. of benzoyl chloride (0.58 m*l*) in dry pyridine (20 m*l*) overnight in a refrigerator, and an additional portion of benzoyl chloride (0.58 m*l*) was then added to the mixture. After being kept in a refrigerator overnight, the reaction mixture was processed as described above to give **3a** (102 mg, 4.4%), mp 234—237°C, and **2a** (569 mg, 31%), mp 200—203°C.

4,5,6-Tri-O-*acetyl-3*-O-*benzoyl-1,2*-O-*cyclohexylidene*-myo-*inositol* (**2b**). Compound **2a** (305 mg) was acetylated with acetic anhydride (4 m*l*) and pyridine (4 m*l*) overnight at room temperature. The reaction mixture was then poured into water and the crude crystals (402 mg, mp 175—177°C) were collected by suction, and then recrystallized from ethanol to afford colorless needles (344 mg, 85%) of **2b**, mp 176—178°C.

Found: C, 61.79; H, 6.27%. Calcd for $C_{25}H_{30}O_{10}$: C, 61.21; H, 6.17%.

3-O-*Benzoyl-1,2*-O-*cyclohexylidene-4,5,6-tri*-O-*methylsulfonyl*-myo-*inositol* (**2c**). To a solution of **2a** (202 mg) in dry pyridine (5 m*l*) was added methanesulfonyl chloride (0.21 m*l*, 5 equiv.) at 0°C. After being kept in a refrigerator for 2 days, the reaction mixture was poured into ice and water, and the resulting crystals (307 mg) were recrystallized from ethanol to give thin needles (239 mg, 72%) of **2c**, mp 208—210°C. An analytical sample was obtained by recrystallization from chloroform–ethanol, mp 208.5—211°C.

Found: C, 44.39; H, 5.05; S, 16.23%. Calcd for $C_{22}H_{30}O_{13}S_3$: C, 44.15; H, 5.05; S, 16.07%.

4,5-Di-O-*acetyl-3,6-di*-O-*benzoyl-1,2*-O-*cyclohexylidene*-myo-*inositol* (**3b**). Compound **3a** (195 mg) was acetylated in the same way as for **2b** to give a crude product (221 mg, mp 189—191°C), which was recrystallized from chloroform–ethanol to afford colorless rods (190 mg, 83%) of **3b**, mp 189—

192°C. Recrystallization from the same solvent gave an analytical sample, mp 192—193°C.

Found: C, 65.35; H, 6.16%. Calcd for $C_{30}H_{32}O_{10}$: C, 65.21; H, 5.84%.

*3,6-Di-O-benzoyl-1,2-O-cyclohexylidene-4,5-methylsulfonyl-myo-inositol (**3c**).* Compound **3a** (199 mg) was treated with methanesulfonyl chloride (0.17 ml, 5 equiv.) in dry pyridine (5 ml) in a similar way as for **2c** to give crude mesylate, which was recrystallized from chloroform–ethanol to give pure needles (181 mg, 68%) of **3c**, mp 244.5—245°C.

Found: C, 54.08; H, 5.45; S, 10.23%. Calcd for $C_{28}H_{32}O_{12}S_2$: C, 53.82; H, 5.17; S, 10.27%.

*1-O-Benzoyl-myo-inositol pentaacetate (**4**).* a) Compound **2a** (205 mg) was treated with boiling 80% aqueous acetic acid (10 ml) for 2 hr. The mixture was then evaporated to dryness, and the crystalline residue was acetylated with acetic anhydride and pyridine in the usual way to give a crude product (238 mg, mp 171—175°C), which was recrystallized from ethanol to afford colorless prisms (176 mg, 63%) of **4**, mp 176—180°C. An analytical sample was obtained by recrystallization from ethanol, mp 178—179°C.

Found: C, 56.27; H, 5.46%. Calcd for $C_{23}H_{26}O_{12}$: C, 55.87; H, 5.30%.

b) 1,4,5,6-Tetra-*O*-acetyl-3-*O*-benzoyl-*myo*-inositol (**5**)[3] (1.0 g) was acetylated, in the same way as for **2b**, to give crude crystals (1.02 g, mp 170—173°C), which were recrystallized from ethanol to afford pure crystals (886 mg, 81%) of **4**, mp 176—178.5°C. It was identical with the compound obtained in (a).

*2,3-Anhydro-4,5-O-cyclohexylidene-1,6-di-O-methylsulfonyl-epi-inositol (**6**).* To a solution of **2c** (82 mg) in a mixture of methanol (2 ml) and 2-methoxyethanol (2 ml) was added methanolic sodium methoxide (0.28 ml, equiv.) at room temperature. After 30 min, the mixture was evaporated to dryness and the residue was extracted with hot ethyl acetate. Evaporation of the extracts gave a crystalline residue which was triturated with petroleum ether and collected by suction: yield 34 mg (78%), mp 205—207°C. Recrystallization from 2-methoxyethanol afforded an analytical sample of **6**, mp 205.5—207°C.

Found: C, 42.66; H, 5.76; S, 16.43%. Calcd for $C_{14}H_{22}O_9S_2$: C, 42.20; H, 5.57; S, 16.10%.

*1,2 : 5,6-Dianhydro-3,4-O-cyclohexylidene-allo-inositol (**7**).* a) To a solution of **3c** (285 mg) in chloroform (7 ml) was added 1 equiv. of methanolic sodium methoxide (0.465 ml) and the mixture was kept in a refrigerator for 2 days. Tlc indicated one major spot together with two minor ones. The solution was then evaporated to dryness and the residue was extracted several times with hot ethyl acetate. The extracts were evaporated to give a crystalline residue, which was recrystallized from chloroform–ethanol to give colorless plates (39 mg, 38%) of **7**, mp 141—142°C. It was shown to be identical with an authentic sample.[4]

b) Compound **9b** (158 mg) was treated with 5 equiv. of methanolic sodium methoxide in a similar way to that described above to give crystals (40 mg, 87%) of **7**, mp 138—142°C.

p-*Toluenesulfonylation of **2a**. Preparation of 3-O-benzoyl-1,2-O-cyclohexylidene-4,6-di-O-p-tolylsulfonyl-myo-inositol (**8a**), 3-O-benzoyl-1,2-O-cyclohexylidene-4,5,6-tri-O-p-tolylsulfonyl-myo-inositol (**10**), and 6-O-acetyl-3-O-benzoyl-1,2-O-cyclohexylidene-4,5-di-O-p-tolylsulfonyl-myo-inositol (**9b**).* a) To a solution of **2a** (3.00 g) in dry pyridine (45 ml) was added 7 equiv. of *p*-toluenesulfonyl chloride (11.0 g) and the mixture was kept at room temperature for 4 days (20—25°C). The mixture was then poured into water (200 ml) and the resulting oily product was collected by decantation. It was dissolved in chloroform (100 ml) and washed successively with 10% aqueous sodium carbonate, N hydrochloric acid and water. After drying over anhydrous sodium sulfate, the solution was evaporated to give an oily product, which was crystallized from chloroform–ethanol to afford crystals (2.6 g). Tlc showed two major spots (**8a** and **10**). Fractional crystallization from the same solvent gave practically pure rods (1.66 g, 30%) of **8a**, mp 184—187°C, and needles (0.51 g, 7.6%) of **10**, mp 163—167°C. Analytical pure samples were obtained by recrystallization twice from the same solvent: **8a** (1.20 g, 21.6%), mp 186—188°C; **10** (0.30 g, 4.5%), mp 169—172°C.

8a: Found: C, 59.01; H, 5.32; S, 9.30%. Calcd for $C_{33}H_{36}O_{11}S_2$: C, 58.91; H, 5.39; S, 9.53%.

10: Found: C, 57.97; H, 5.17; S, 11.23%. Calcd for $C_{40}H_{42}O_{13}S_3$: C, 58.09; H, 5.12; S, 11.63%.

The mother liquor of the crude mixture was evaporated and dried by co-distillation with toluene to give a glassy product (2.11 g). A 970 mg-portion of the product was acetylated with acetic anhydride and pyridine in the usual way to give crude crystals, which were recrystallized from ethanol–toluene, affording needles (0.54 g, 19.8%) of **9b**, mp 181—184°C. Recrystallization from chloroform–ethanol gave an analytical sample, mp 182—184.5°C.

Found: C, 58.67; H, 5.33; S, 8.58%. Calcd for $C_{35}H_{41}O_{12}S_2$: C, 58.55; H, 5.76; S, 8.93%.

A 958 mg-portion of the glassy product was treated with boiling 80% aqueous acetic acid for 2 hr and the reaction mixture was evaporated to dryness, and the residue was crystallized from ethanol to give crystals (413 mg), whose tlc indicated the presence of two components. Recrystallization from ethanol–methyl ethyl ketone gave chromatographically pure crystals (55.9 mg), mp 227—228.5°C. An attempt to elucidate its structure failed. The mother liquor was evaporated to dryness and the residue was acetylated in the usual way to afford crude crystals which were recrystallized from chloroform–ethanol to give crystals (257 mg, 12%) of **13**, mp 202—205°C. This compound was identified with the compound derived from **9b**.

b) Compound **2a** (2.98 g) was treated with 7 equiv. of *p*-toluenesulfonyl chloride (11.0 g) at room temperature for 5 days. The reaction mixture was treated in a similar way to that described in (a) to give crude crystalline mixture (3.5 g) of **8a** and **10**. Fractional crystallization from chloroform–ethanol gave **8a** (0.58 g, 12.5%) and **10** (1.17 g, 17.3%) purely. The mother liquor of the crude crystals was evaporated, and, similarly, acetylated to give **9b** (1.15 g, 23%).

c) Compound **2a** (10.0 g) was treated with 7 equiv. of *p*-toluenesulfonyl chloride (36.7 g) at 30°C for 3 days. The reaction mixture was processed as described above to give crude crystalline mixture (14.9 g), from which **8a** (5.53 g, 29.8%) and **10** (2.67 g, 11.7%) were obtained by fractional crystallization. Compound **9b** (1.38 g, 7.0%) was obtained by acetylation from mother liquor.

p-*Toluenesulfonylation of **2a** at Elevated Temperature. Preparation of 3-O-benzoyl-5-chloro-1,2-O-cyclohexylidene-5-deoxy-4,6-di-O-p-tolylsulfonyl-neo-inositol (**11**).* a) Compound **2a** (2.95 g) was treated with 7 equiv. of *p*-toluenesulfonyl chloride at room temperature for 4 days and the reaction mixture was kept at 80—85°C for 12 hr. The mixture was poured into water and the resulting crystals (6.46 g) were collected by suction. Tlc indicated the presence of a faster-moving component together with **8a** and **10**. The mixture was fractionated by recrystallization from chloroform–ethanol to give pure crystals (1.98 g, 29.8%) of **10**, and cubic crystals (0.46 g, 9.4%) of **11**, mp 180—181°C. PMR ($CDCl_3$): τ 7.53,

7.67 (3, s, OTs C-CH_3).

Found: C, 57.56; H, 5.00%. Calcd for $C_{33}H_{35}O_{10}S_2Cl$: C, 57.34; H, 5.10%.

A crystalline mixture of **8a** and **10** (1.5 g), and **8a** (0.38 g, 8%) were isolated from the mother liquor.

b) Compound **2a** (3.03 g) was treated with 7 equiv. of *p*-toluenesulfonyl chloride at room temperature as described in (a) and the mixture was heated for 45 hr at 90—95°C. Fractional crystallization of the crude product afforded **10** (1.83 g, 31.7%), and **11** (1.03 g, 15.2%) purely.

5-O-Acetyl-3-O-benzoyl-1,2-O-cyclohexylidene-4,6-di-O-p-tolylsulfonyl-myo-*inositol* (***8b***). Compound **8a** (102 mg) was acetylated as in the preparation of **2b** to give an oily product, which was crystallized from chloroform–ethanol to afford crystals (69.4 mg, 65.2%) of **8b**, mp 124—126°C.

Found: C, 58.36; H, 5.42; S, 8.58%. Calcd for $C_{35}H_{38}O_{12}S_2$: C, 58.55; H, 5.76; S, 8.93%.

3,5-Di-O-benzoyl-1,2-O-cyclohexylidene-4,6-di-O-p-tolylsulfonyl-myo-*inositol* (***8c***). To a solution of **8a** (605 mg) in dry pyridine (11 m*l*) was added 6 equiv. of benzoyl chloride (0.63 m*l*) and the mixture was kept for 5 days at 80°C. The mixture was then poured into water and the resulting crystals (672 mg) were recrystallized from chloroform–ethanol to give colorless needles (583 mg, 84%) of **8c**, mp 195.5—198.5°C. Recrystallization from the same solvent afforded an analytical sample, mp 197—199°C.

Found: C, 61.45; H, 4.88; S, 8.57%. Calcd for $C_{40}H_{40}O_{12}S_2$: C, 61.83; H, 5.19; S, 8.26%.

1-O-Benzoyl-4,6-di-O-tolylsulfonyl-myo-*inositol* (***12a***). A mixture of **8a** (1.00 g) and 80% aqueous acetic acid (50 m*l*) was refluxed for 80 min. After being kept standing at room temperature overnight, the resulting precipitates were collected by suction: yield 0.625 g (71.0%), mp 221.5—223°C. An analytical sample was obtained by recrystallization from 2-methoxyethanol, mp 225—228°C.

Found: C, 54.53; H, 4.70; S, 10.53%. Calcd for $C_{27}H_{28}O_{11}S_2$: C, 54.72; H, 4.76; S, 10.53%.

1,2,5-Tri-O-acetyl-3-O-benzoyl-4,6-di-O-p-tolylsulfonyl-myo-*inositol* (***12b***). A mixture of **8a** (1.00 g) and 80% aqueous acetic acid (50 m*l*) was refluxed for 80 min, and then evaporated to dryness. The residue was acetylated with acetic anhydride (5 m*l*) and pyridine (5 m*l*) at 85°C for 40 min to give an oily product, which was crystallized from methanol, affording colorless plates (0.86 g, 86%) of **12b**, mp 197.5—198.5°C. An analytical sample was obtained by recrystallization from chloroform–ethanol, mp 189.5—200°C. PMR ($CDCl_3$): τ 7.55, 7.74 (3, s, OTs C-CH_3), 7.74, 8.06, 8.10 (3, s, OAc).

Found: C, 55.15; H, 4.71; S, 8.72%. Calcd for $C_{33}H_{34}O_{14}S_2$: C, 55.14; H, 4.74; S, 8.92%.

1,2,6-Tri-O-acetyl-3-O-benzoyl-4,5-di-O-p-tolylsulfonyl-myo-*inositol* (***13***). A mixture of **9b** (145 mg) and 80% aqueous acetic acid (10 m*l*) was refluxed for 3.5 hr and then evaporated to dryness. Tlc showed that **9b** disappeared and at least two major components were contained in the crude mixture. The residue was acetylated in the usual way to give an oily product which was crystallized from ethanol, affording colorless needles (22.3 mg, 15%) of **13**, mp 202.5—205°C. Recrystallization from chloroform–ethanol gave an analytical sample, mp 206—209°C. PMR ($CDCl_3$): τ 7.56, 7.83 (3, s, OTs C-CH_3), 7.85, 8.01, 8.02 (3, s, OAc).

Found: C, 55.13; H, 4.46; S, 8.65%. Calcd for $C_{33}H_{34}O_{14}S_2$: C, 55.14; H, 4.74; S, 8.92%.

1,2-Di-O-acetyl-3-O-benzoyl-4,5,6-tri-O-p-tolylsulfonyl-myo-*inositol* (***14***). A mixture of **10** (500 mg) and 80% aqueous acetic acid (25 m*l*) was refluxed for 2 hr and then evaporated to dryness. Tlc showed two spots together with a trace of **14**. The residue was digested with ethanol–pyridine to give a crude mixture (292 mg), mp 125—145°C. A 100 mg-portion of the mixture was acetylated with acetic anhydride (1 m*l*) and pyridine (1 m*l*) at 85°C for 1 hr and the solution was evaporated to dryness. Crystallization from chloroform–ethanol gave crystals (102 mg, 59%) of **14**, mp 174—177.5°C. An analytical sample recrystallized showed the same melting point. PMR ($CDCl_3$): τ 7.56 (6, s, 2OTs C-CH_3), 7.77 (3, s, OTs C-CH_3), 7.85, 8.16 (3, s, OAc).

Found: C, 54.81; H, 4.55; S, 11.46%. Calcd for $C_{38}H_{38}O_{15}S_3$: C, 54.93; H, 4.61; S, 11.58%.

p-*Toluenesulfonylation of* ***3a***. *Preparation of 3,6-di-O-benzoyl-1,2-O-cyclohexylidene-5-O-p-tolylsulfonyl*-myo-*inositol* (***15a***) *and 3,6-di-O-benzoyl-1,2-O-cyclohexylidene-4,5-di-O-p-tolylsulfonyl*-myo-*inositol* (***16***). a) To a solution of **3a** (1.00 g) in dry pyridine (12 m*l*) was added, under ice cooling, 7 equiv. of *p*-toluenesulfonyl chloride (2.85 g) and the reaction mixture was allowed to stand at room temperature for 3 days. The mixture was then poured into water and the resulting crystals were collected. The crude mixture weighed 1.10 g, its tlc showing three components. Recrystallization of the crude mixture from chloroform gave thin needles (378 mg, mp 201—203°C) of **16**. An analytically pure sample of **16** was obtained by recrystallization from chloroform–ethanol: plates (335 mg, 20.2%), mp 203—205°C. From the mother liquor of crude **16**, by crystallization from chloroform, practically pure crystals (238 mg) of **15a**, and a mixture of **15a** and **16** (181 mg) were obtained. Further recrystallization from chloroform–ethanol afforded prisms (162 mg, 12%) of **15a**, mp 196—198°C.

15a: Found: C, 63.13; H, 5.39; S, 5.46%. Calcd for $C_{33}H_{34}O_{10}S$: C, 63.65; H, 5.50; S, 5.15%.

16: Found: C, 61.83; H, 5.27; S, 8.35%. Calcd for $C_{40}H_{40}O_{12}S_2$: C, 61.83; H, 5.19; H, 8.26%.

b) Compound **3a** (1.00 g) was treated with 3 equiv. of *p*-toluenesulfonyl chloride (1.22 g) in dry pyridine (10 m*l*) at room temperature for 2 days. The reaction mixture was processed as in (a) to give crude crystals which were recrystallized from chloroform–ethanol, giving pure crystals (413 mg, 31%) mp 196.5—198.5°C. By tlc, it was shown to be contaminated with a trace of **16**.

A 50 mg-portion of the compound was acetylated as in the preparation of **14** to give crystals (50 mg, 94%) of the acetate (**15b**) mp 194—197°C. Recrystallization from chloroform–ethanol afforded an analytical sample, mp 197.5—199.5°C.

Found: C, 62.84; H, 5.25; S, 5.41%. Calcd for $C_{35}H_{36}O_{11}S$: C, 63.24; H, 5.46; S, 4.82%.

1-O-Benzoyl-5-chloro-5-deoxy-4,6-di-O-p-tolylsulfonyl-neo-*inositol* (***17a***). A mixture of **11** (0.50 g) and 80% aqueous acetic acid (25 ml) was refluxed for 100 min, and the mixture was evaporated to dryness to give a crystalline residue. It was recrystallized from ethanol to give colorless rods (351 mg, 80%) of **17a**, mp 186—188°C. Recrystallization from ethanol afforded an analytical sample with the same melting point.

Found: C, 53.12; H, 4.44%. Calcd for $C_{27}H_{27}O_{10}S_2Cl$: C, 53.07; H, 4.45%.

1,2-Di-O-acetyl-3-O-benzoyl-5-chloro-5-deoxy-4,6-di-O-p-tolylsulfonyl-neo-*inositol* (***17b***). Compound **17a** (190 mg) was acetylated as in the preparation of **12b** to give crystals (223 mg, 100%) of **17b**, mp 197—203°C. Recrystallization from chloroform–ethanol gave an analytical sample, mp 198—200°C. PMR ($CDCl_3$): τ 5.20 (1, t, H-5, J=3.0 Hz), 7.51, 7.64 (3, s, OTs C-CH_3), 7.88, 8.14 (3, s, OAc).

Found: C, 53.21; H, 4.33%. Calcd for $C_{31}H_{31}O_{12}S_2Cl$: C, 53.54; H, 4.50%.

Reaction of ***10*** *with Pyridine Hydrochloride.* A mixture

of **10** (1.04 g) and pyridine hydrochloride (1.20 g) was heated in a sealed tube at 105—110°C for 45 hr. The brown mixture was then poured into water and the resulting oily product was extracted with chloroform. The extract was washed successively with 10% aqueous sodium carbonate, N hydrochloric acid and water, and dried over anhydrous sodium sulfate. Evaporation of the solution gave an oily product which was crystallized from ethanol to afford a mixture of **10** and **11** (100 mg), and **11** (34.5 mg, 3.9%), mp 182—183°C.

Compound **8a** was subjected to the same reaction condition as described above, but, no formation of **11** could be observed.

p-*Toluenesulfonylation of* ***1a*** *at Elevated Temperature. Preparation of 1,2-O-Cyclohexylidene-3,4,5,6-tetra-*O-p-*tolylsulfonyl-*myo-*inositol (****18****) and 5-Chloro-1,2-O-cyclohexylidene-5-deoxy-3,4,6-tri-*O-p-*tolylsulfonyl-*neo-*inosotol (****19****).* To a solution of **1a** (10.0 g) in dry pyridine (100 m*l*) was added *p*-toluenesulfonyl chloride (51 g, 7 equiv.), and the mixture was kept at room temperature for 2 days and then at 90—95°C for 10 hr. The mixture was then poured into ice and water and the resulting oily product crystallized gradually. The precipitates were dissolved in chloroform (100 m*l*) and the solution was washed successively with 10% aqueous sodium carbonate, N hydrochloric acid and water, and dried over anhydrous sodium sulfate. Removal of the solvent gave an oily product which was crystallized from chloroform–ethanol to give crystals (3.9 g, 12%) of **19**, mp 175—179°C. Recrystallization from the same solvent afforded an analytical sample, mp 182—183.5°C. PMR ($CDCl_3$): τ 7.54 (9, s, OTs C-CH_3).

Found: C, 53.68; H, 5.30%. Calcd for $C_{33}H_{37}O_{11}S_3Cl$: C, 53.45; H, 5.00%.

From the mother liquor of **19**, **18** (9.4 g, 28%) was obtained by crystallization from ethanol and methyl ethyl ketone. Recrystallization from the same solvent gave an analytical sample, mp 127.5—130.5°C.

Found: C, 55.22; H, 5.20; S, 14.66%. Calcd for $C_{40}H_{44}O_{14}S_4$: C, 54.78; H, 5.06; S, 14.62%.

*2-Chloro-2-deoxy-1,3,4-tri-*O-p-*tolylsulfonyl-*neo-*inositol* (***20a***). A mixture of **19** (535 mg) and 80% aqueous acetic acid (20 m*l*) was refluxed for 2 hr and then evaporated to dryness. The residue was recrystallized from ethanol to give crystals (462 mg, 96%) of **20a**, mp 187—188°C. Recrystallization from ethanol–methyl ethyl ketone gave an analytical sample mp 187—189°C.

Found: C, 49.32; H, 4.39%. Calcd for $C_{27}H_{29}O_{11}S_3Cl$: C, 49.04; H, 4.42%.

*1,2-Di-*O-*acetyl-5-chloro-5-deoxy-3,4,6-tri-*O-p-*tolylsulfonyl-*neo-*inositol* (***20b***). Crude **20a** obtained from **19** (0.53 g) by the above procedure was acetylated with acetic anhydride (5 m*l*) and pyridine (10 m*l*) overnight at room temperature. Evaporation of excess reagent gave an oily product which was crystallized from ethanol to afford needles (0.52 g, 100%) of **20b**, mp 149—152°C. Recrystallization from ethanol–methyl ethyl ketone gave plates or needles (0.17 g, 35%), mp 175—176°C (after sintering at 150°C. PMR ($CDCl_3$): τ 7.53 (6, s, OTs C-CH_3), 7.57 (3, s, OTs C-CH_3), 7.88, 8.14 (3, s, OAc).

Found: C, 50.24; H, 4.57%. Calcd for $C_{31}H_{33}O_{13}S_3Cl$: C, 50.05; H, 4.44%.

*4,5-Di-*O-*benzoyl-1,2-*O-*cyclohexylidene-3,6-di-*O-p-*tolylsulfonyl-*myo-*inositol* (***21***). To a solution of 1,2-*O*-cyclohexylidene-3,6-di-*O*-*p*-tolylsulfonyl-*myo*-inositol[1] (200 mg) in dry pyridine (2 m*l*) was added benzoyl chloride (0.16 m*l*, 4 equiv.) under ice cooling and the solution was allowed to stand in a refrigerator overnight. The mixture was then poured into water and the resulting crystals (289 mg) were recrystallized from chloroform–ethanol to give pure needles (266 mg, 97%) of **21**, mp 217—218°C.

Found: C, 62.02; H, 5.08; S, 8.28%. Calcd for $C_{40}H_{40}O_{12}S_2$: C, 61.83; H, 5.19; S, 8.26%.

*4,6-Di-*O-*benzoyl-1,2-*O-*cyclohexylidene-3,5-di-*O-p-*tolylsulfonyl-*myo-*inositol* (***22***). 1,2-*O*-Cyclohexylidene-3,5-di-*O*-*p*-tolylsulfonyl-*myo*-inositol[1] (203 mg) was similarly treated with benzoyl chloride (0.20 m*l*, 5 equiv.) to give needles (228 mg, 82%) of **22**, mp 212—214°C. Recrystallization from chloroform–ethanol gave an analytical sample, mp 216—216.5°C.

Found: C, 62.12; H, 5.07; S, 8.03%. Calcd for $C_{40}H_{40}O_{12}S_2$: C, 61.83; H, 5.19; S, 8.26%.

*5,6-Di-*O-*benzoyl-1,2-*O-*cyclohexylidene-3,4-di-*O-p-*tolylsulfonyl-*myo-*inositol* (***23***). 1,2-*O*-Cyclohexylidene-3,4-di-*O*-*p*-tolylsulfonyl-*myo*-inositol[1] (200 mg) was treated with benzoyl chloride (0.16 m*l*, 4 equiv.) in the same way described for **21** to give needles (218 mg, 81%) of **23**, mp 152—154°C. An analytical sample was obtained by recrystallization from chloroform–ethanol, mp 153—154°C.

Found: C, 62.18; H, 5.12; S, 8.35%. Calcd for $C_{40}H_{40}O_{12}S_2$: C, 61.83; H, 5.19; S, 8.26%.

*4,5,6-Tri-*O-*benzoyl-1,2-*O-*cyclohexylidene-3-*O-p-*tolylsulfonyl-*myo-*inositol* (***24***). 1,2-*O*-Cyclohexylidene-3-*O*-*p*-tolylsulfonyl-*myo*-inositol[1] (1.00 g) was treated with benzoyl chloride (1.13 m*l*, 4 equiv.) in a refrigerator for 3 days. The reaction mixture was treated in the same way as for **21** to give crystals (1.61 g, 92%) of **24**, mp 198—200°C. Recrystallization from chloroform–ethanol gave an analytical sample with the same melting point.

Found: C, 66.82; H, 5.52; S, 3.96%. Calcd for $C_{40}H_{38}O_{11}S$: C, 66.11; H, 5.27; S, 4.41%.

The authors are grateful to Professor Sumio Umezawa for his kind advice, and to Mr. Saburo Nakada for carrying out the elementary analyses. Financial support from the Ministry of Education for this work is gratefully acknowledged.

Chemical Studies on Tuberactinomycin. IV.[1] The Chemical Structure of γ-Hydroxy-β-lysine, A New Amino Acid Isolated from Tuberactinomycin A and N[2]

Tateaki WAKAMIYA, Tetsuo SHIBA, and Takeo KANEKO*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received July 5, 1972)

γ-Hydroxy-β-lysine is a new basic amino acid isolated from the hydrolyzates of antitubercular peptides, tuberactinomycin A and N as one of the composite amino acids. The chemical structure and stereochemistry of the amino acid were established on the basis of chemical reactions and physical measurements, *i.e.*, IR, NMR, and ORD. One stereoisomer obtained in hydrochloric acid hydrolysis was determined as *threo*-γ-hydroxy-L-β-lysine (Ia), while the other one obtained in concentrated sulfuric acid hydrolysis as an *erythro* isomer (Ib).

Tuberactinomycin is a family of peptide antibiotics effective against tubercular bacilli.[3] Tuberactinomycin A and B were isolated from the broth filtrate of *Streptomyces griseoverticillatus* var. *tuberacticus*[4] and a mutant of the original microorganism produced tuberactinomycin N and O.[5]

Tuberactinomycin A is composed of following five amino acids, *i. e.*, L-serine, L-α,β-diaminopropionic acid, 3-ureidodehydroalanine,[6] L-tuberactidine,[7] and a new basic amino acid (I) with the molecular ratio of 2 : 1 : 1 : 1 : 1, while tuberactinomycin N contains capreomycidine[8] instead of tuberactidine and the other amino acids are common to those of tuberactinomycin A.[9]

Acid hydrolyzate of tuberactinomycin A or N was separated by ion-exchange column chromatography, using pyridine–formic acid buffer as an eluent. Serine, α,β-diaminopropionic acid, tuberactidine[10] (capreomycidine, in the case of tuberactinomycin N) and finally a new amino acid Ia were eluted from the column in this order. However, 3-ureidodehydroalanine was not obtained because of ease of decomposition to NH_3 and CO_2 during acid hydrolysis.

From the final fraction, the new basic amino acid was secured as hydrochloride. It had a molecular formula of $C_6H_{14}O_2N_2Cl_2$ (IIa·2HCl) and showed γ-lactone absorption at 1780 cm^{-1} in IR spectrum. A spot of IIa on thin-layer chromatogram was not identical with the original one in the eluate. This indicated that Ia is a basic γ-hydroxy amino acid and was converted to the γ-lactone IIa in the course of isolation procedure after column chromatography.

Taking advantage of the easy formation of γ-lactone from Ia as mentioned above and of insolubility of its derivatives, we attempted the direct and sole isolation of this amino acid from the tuberactinomycin hydrolyzate as acyl derivatives of the lactone. Thus, the acid hydrolyzate of tuberactinomycin A was benzyloxycarbonylated. The oily product formed even in alkaline medium was extracted and then purified by silica gel column chromatography. In this way the expected benzyloxycarbonyl lactone derivative $C_{22}H_{24}O_6N_2$ (IIIa) was obtained. This compound was identical with the benzyloxycarbonyl derivative of IIa. The compound IIIa thus obtained was debenzyloxycarbonylated with 30% hydrogen bromide in glacial acetic acid and the lactone IIa was prepared as dihydrobromide without difficulty.

For the purpose of structural determination of the amino acid Ia, the lactone IIa was saponified to prepare a hydroxy acid which was then reduced with hydriodic acid and red phosphorus. When the product was 2,4-dinitrophenylated, a small amount of di-DNP-β-lysine[11] was obtained together with di-DNP-IIa. Secondly, when the saponified product was oxidized with periodic acid followed by potassium permanganate treatment, β-alanine was detected by thin-layer chromatography as a single product of positive ninhydrin reaction. From these results, the structure of the new basic amino acid Ia could be assigned to γ-hydroxy-β-lysine unequivocally as shown in Scheme 1.

Furthermore, this structure was confirmed by NMR spectrum of dibenzyloxycarbonyl derivative IIIa in $CDCl_3$ as follows; α-CH_2 (d,d at δ 2.36 and 2.82 ppm), β-CH and γ-CH (overlapped at 4.50 ppm), δ-CH_2 (q at 1.80 ppm), ε-CH_2 (q at 3.30 ppm, changed to a triplet in addition of D_2O), β-NH and ε-NH (d at 6.2 ppm and t at 5.4 ppm, both disappeared in addition of D_2O).[12]

When tuberactinomycin A or N was 2,4-dinitrophenylated and then hydrolyzed, no other DNP amino acids than di-DNP-γ-hydroxy-β-lysine lactone (IVa) were detected. Therefore, γ-hydroxy-β-lysine is a sole N-terminal amino acid in the molecules of tuberac-

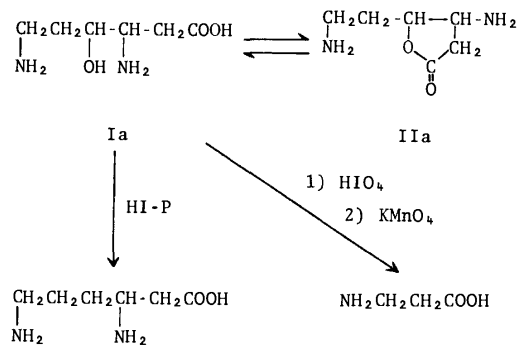
10) It was obtained as a mixture with viomycidine.

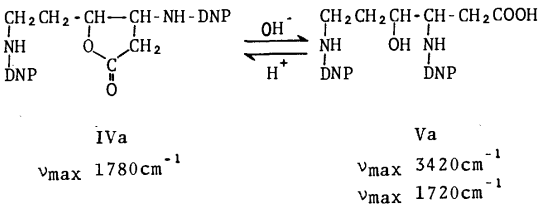
11) DNP stands for 2,4-dinitrophenyl.

12) The terms of d, t, and q show doublet, triplet, and quartet respectively.



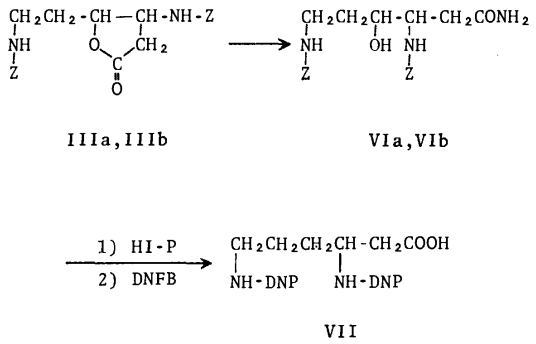
Scheme 1.

tinomycin A and N. The DNP derivative IVa showed the absorption band characteristic to γ-lactone at 1780 cm^{-1} likely as that of the lactone IIa. The lactone IVa was saponified with 1 N NaOH to prepare the corresponding hydroxy acid Va. Reversely, Va was easily converted to IVa by acid treatment.



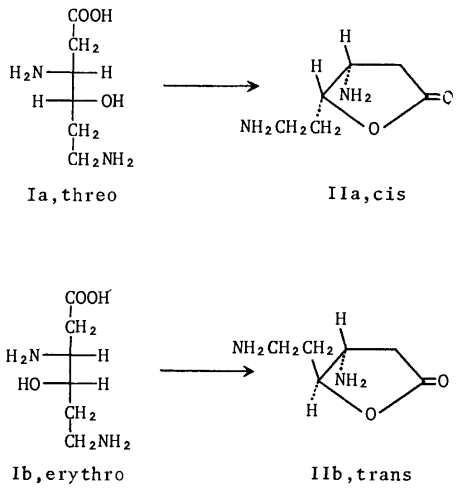
Interestingly, we have obtained a diastereoisomer of the amino acid Ia mentioned above as its lactone derivatives, when tuberactinomycin A was treated with concentrated sulfuric acid with the intention of carrying out N,O-migration reaction. It was benzyloxycarbonylated or 2,4-dinitrophenylated to prepare the corresponding derivatives, IIIb and IVb respectively, both of them showing the γ-lactone absorption in IR spectrum. Though these compounds IIIb and IVb were certainly the derivatives of γ-hydroxy-β-lysine lactone, they were not identical with IIIa and IVa obtained above in respects of IR spectrum, thin-layer chromatogram and melting point. Moreover, debenzyloxycarbonylated products IIa and IIb dihydrobromide prepared respectively from IIIa and IIIb evidently differed each other in thin-layer chromatogram, paper electrophoresis, $[\alpha]_D$, IR, NMR spectra and so on. Thus it was concluded that IIIb and IVb should be the diastereoisomers of IIIa and IVa respectively.

Concerning the stereochemistry of the amino acid I, it was first attempted to determine the configuration of β-carbon atom by the reduction of γ-hydroxyl group to drive to β-lysine. When γ-hydroxy-β-lysine I itself was used for the reduction, always the lactone was obtained as a main product indicating that the lactone formation proceeded much faster than the reduction. Therefore, dibenzyloxycarbonyl-γ-hydroxy-β-lysine amide VIa and VIb prepared by ammonolysis of IIIa and IIIb were used for this purpose. VIa and VIb were reduced with hydriodic acid and red phosphorus, and then 2,4-dinitrophenylated respectively. From the products of dinitrophenylation, di-DNP-β-lysine was separated and purified by preparative thin-layer chromatography and found to be completely identical with the authentic di-DNP-L-β-lysine (VII) in its ORD spectrum in both cases. In this respect, both isomers of γ-hydroxy-β-lysine must belong to L-series at β-carbon atom configurations.



On the other hand, the configurations of γ-carbon atoms of Ia and Ib were assigned by extended application of Hudson's lactone rule[13] as in the case of γ-hydroxylysine.[14] Thus, the lactone IIa and IIb were saponified with silver acetate to the corresponding hydroxy acids Ia and Ib respectively. Although these acids could not be isolated in pure states, mutarotations of them were measured in acidic solutions. From the facts that the rotation of Ia showed the positive shift in the course of time, while that of Ib indicated negative shift (Fig. 1), the configuration of γ-carbon atom was determined as D_g in Ia and L_g in Ib. In these cases, D_g should correspond to *R* and L_g to *S* configuration.

Consequently, it was concluded that Ia must be assigned to *threo*-γ-hydroxy-L-β-lysine and Ib to *erythro*-γ-hydroxy-L-β-lysine. This conclusion was supported by the following investigations. First, in the NMR spectra of IIa and IIb as shown in Fig. 2 and 3, coupl-



13) B. Witkop, *Experientia*, **12**, 372 (1956). Hudson's lactone rule says that γ- or δ-sugar lactones in which the carbon atom carrying the hydroxyl group contributed to the lactone linkage is related to D-glyceraldehyde show positive value of $[\alpha]_D$ (lactone) − $[\alpha]_D$ (acid) and those to L-glyceraldehyde give negative one.

14) N. Izumiya, Y. Fujita, F. Irreverre, and B. Witkop, *Biochemistry*, **4**, 2501 (1965).

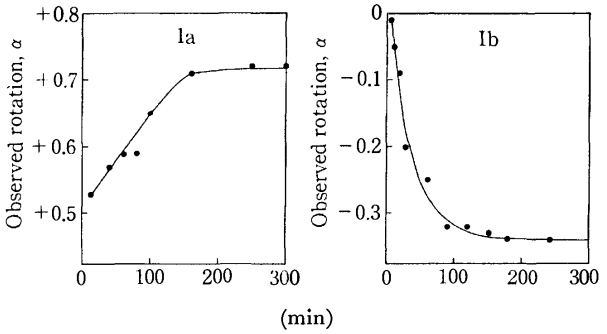


Fig. 1. Mutarotations of Ia and Ib.

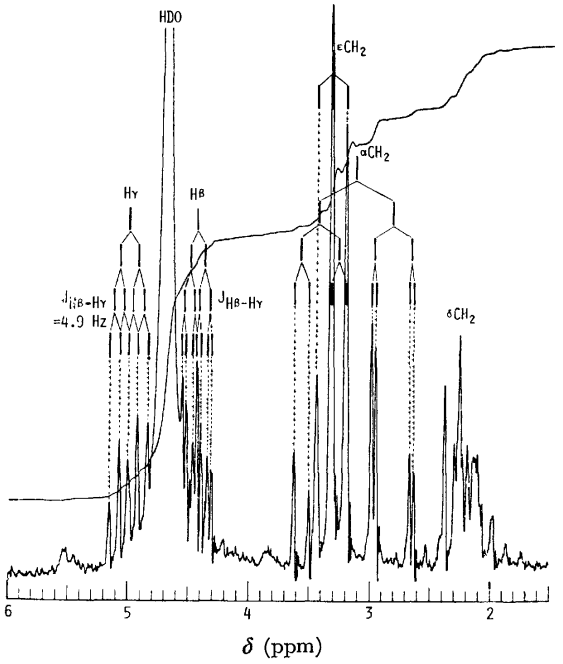

Fig. 2. NMR spectrum of IIa in D_2O.

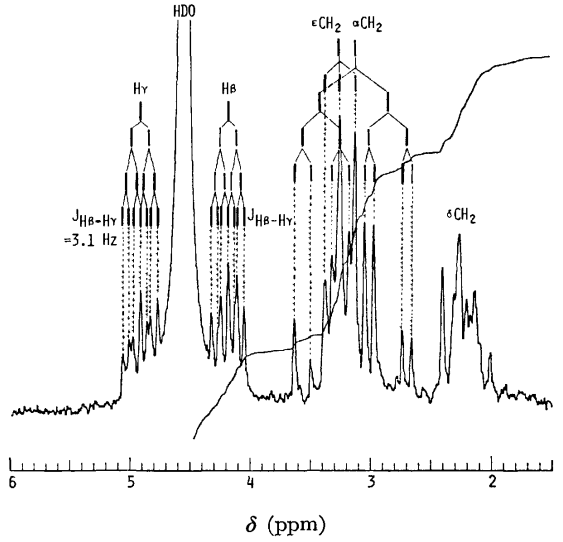

Fig. 3. NMR spectrum of IIb in D_2O.

ing constants between β and γ protons, of 4.9 Hz in the former and 3.1 Hz in the latter, indicated that vicinal protons in the lacton ring of IIa has a *cis* configuration and that of IIb a *trans* configuration, since dihedral angle consisting of vicinal protons in the five-membered lactone ring is near to 0° in *cis* form and to 120° in *trans* form, and therefore the coupling constant of *cis* configuration must be larger than that of of *trans* configuration. This assignment is consistent with the expectation that *threo*-γ-hydroxy-L-β-lysine forms *cis* γ-lactone ring and *erythro*-γ-hydroxy-L-β-lysine forms *trans* γ-lactone ring.

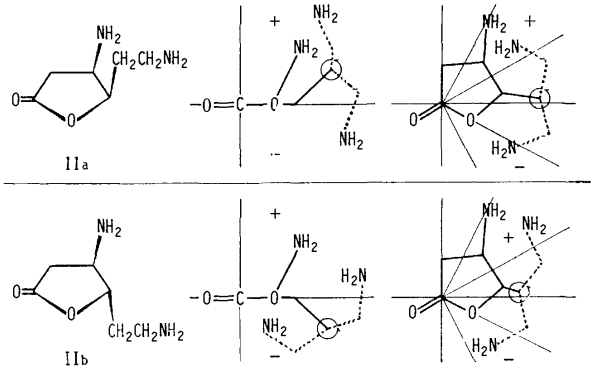

Fig. 4. Estimate of Cotton effects of IIa and IIb.

The above conclusion concerning the configurations of asymmetric carbon atoms in γ-hydroxy-β-lysine was also supported by ORD curve on the basis of Klyne's lactone sector rule.[15] According to this rule, it is expected that the ORD curves of *threo*- and *erythro*-γ-hydroxy-β-lysine lactone will show the positive Cotton effects as illustrated in Fig. 4, if they have β-L-configurations. There may exist negative contribution due to free rotations at δ-carbon atoms, which is, however, overcome by positive contribution as a whole. In fact, both ORD curves of IIa and IIb, in the range of 350 nm to 210 nm, showed positive plain curves indicating presences of positive Cotton effects at lower wavelength than 210 nm.

Recently, we carried out the synthetic work for this amino acid. Synthetic *erythro*-γ-hydroxy-DL-β-lysine in a form of lactone dihydrobromide was identical with that of *erythro* form of the natural amino acid.[16] Therefore, the conclusion of our study on chemical structure and stereochemistry of the new basic amino acid isolated from the antibiotics tuberactinomycin A and N was confirmed unequivocally.

Finally a problem remains, whether *threo* or *erythro* form of this amino acid is original one in the molecule of tuberactinomycin A or N and which is the artificial one converted during the acid treatment. At present, this subject is not yet clarified and must be left to a future investigation.

Experimental

All melting points are uncorrected. The infrared spectrum was obtained in nujol mull with a Nihon Bunko IR-S spectro-

16) T. Wakamiya, T. Teshima, and T. Shiba, Presented at the 26th Annual Meeting of the Chemical Society of Japan, Hiratsuka, April, 1972; p. 1275.

photometer. The NMR spectrum was obtained with a Hitachi NMR R-20 spectrometer and Nihon Denshi C-60 spectrometer. Tetramethylsilane (TMS) was used as an internal reference in deuterochloroform solution, and sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as an external reference in the case of deuterium oxide solution. The chemical shifts are expressed as ppm from TMS or DSS. The ORD curve was obtained with a Yanagimoto ORD-185 spectropolarimeter in 1N hydrochloric acid and in methanol. The specific rotation was obtained with a Perkin-Elmer 141 polarimeter in water and in dimethylformamide. Thin-layer chromatography was carried out by the ascending method on silica gel G and preparative thin-layer chromatography on silica gel H.

Isolation of threo-*γ-Hydroxy*-L-*β-lysine Lactone (IIa) Dihydrochloride.* A solution of 20 g of tuberactinomycin A hydrochloride in 180 m*l* of 6N hydrochloric acid was heated at 100°C in a sealed tube or under reflux for 24 hr. Hydrochloric acid was evaporated *in vacuo* and the residue was dissolved in water. The evaporation was repeated three times. The solution of the residue thus obtained in a small amount of water was applied on a column (2.5×65 cm) of Dowex 50W×2 ion-exchange resin which was previously equilibriated with a buffer solution of 0.2 M pyridine and formic acid (pH 3.1). In the elution using 5.5 *l* of the same buffer solution (pH 3.1), serine, α, β-diaminopropionic acid and a mixture of tuberactidine and viomycidine were eluted successively. When the buffer solution was changed to a mixture of 2 M pyridine and formic acid (pH 5.2), γ-hydroxy-β-lysine was eluted. Fractions containing γ-hydroxy-β-lysine were collected and evaporated *in vacuo*. The residue was dissolved in hydrochloric acid and evaporated again. Crystalline residue was dissolved in ethanol and allowed to stand in refrigerator. Colorless prisms obtained were recrystallized from water-ethanol, mp 250—252°C (decomp.), $[\alpha]_D^{25}+65°$ (*c* 0.5, H_2O).

Found: C, 33.04; H, 6.54; N, 12.85; Cl, 32.65%. Calcd for $C_6H_{14}O_2N_2Cl_2$: C, 33.19; H, 6.50; N, 12.90; Cl, 32.66%.

N^{β},N^{ϵ}-*Dibenzyloxycarbonyl*-threo-*γ-hydroxy*-L-*β-lysine Lactone (IIIa).* Hydrolysis of each 10 g of tuberactinomycin A or N hydrochloride was carried out under the similar condition to that mentioned above and hydrolyzate was evaporated *in vacuo*. Residue was dissolved in 100 m*l* of water and neutralized with sodium carbonate on cooling. The neutralized hydrolyzate was benzyloxycarbonylated by the usual method using 50 g of benzyloxycarbonylchloride and 100 m*l* of 2N sodium hydroxide. Oily substance formed before acidification was extracted with ethyl acetate and the extract was washed with aqueous sodium carbonate solution and then water thoroughly. The organic layer was dried over anhydrous sodium sulfate and then evaporated *in vacuo*. Oily residue obtained was purified by silica gel (Merck, 0.05—0.20 mm mesh) column chromatography. Chloroform (500 m*l*) and then chloroform-methanol (100 : 1, 1500 m*l*; 100 : 1.5, 200 m*l*) were passed through the column. Benzyl carbamate was eluted first, followed by the desired N^{β},N^{ϵ}-dibenzyloxycarbonyl-*threo*-γ-hydroxy-L-β-lysine lactone (IIIa). Recrystallization of 2.5 g of crude IIIa from ethyl acetate gave colorless needles, yield 2.1 g, mp 149.5°C, $[\alpha]_D^{20}+48.0°$ (*c* 0.4, DMF).

Found: C, 64.02; H, 5.73; N, 6.84%. Calcd for $C_{22}H_{24}O_6N_2$: C, 64.06; H, 5.87; N, 6.79%.

Finally, when a mixture of chloroform-methanol (100 : 4, 1200 m*l*) was used as an elution solvent, N^{α},N^{β}-dibenzyloxycarbonyl-L-α,β-diaminopropionamide was eluted.

Reduction of γ-Hydroxy-β-lysine to β-Lysine. In 2 m*l* of 1N sodium hydroxide, 50 mg of IIa dihydrochloride was dissolved, and allowed to stand at room temperature. After 2 hr, the reaction mixture was neutralized with 1N hydrochloric acid and concentrated *in vacuo*. The residue was dissolved in 5 m*l* of hydriodic acid, and 50 mg of red phosphorus was added. After heating for 3 hr under reflux at 135°C, the solution was evaporated *in vacuo*. The residue was dissolved in water and evaporation was repeated several times. To the solution of the residue in water was added silver oxide and the suspension was stirred for a half hour. Insoluble materials were filtered off and the filtrate was acidified with 1N hydrochloric acid. After filtration of silver chloride, the filtrate was neutralized with aqueous sodium hydrogencarbonate. To this solution was added 100 mg of 2,4-dinitrofluorobenzene in 5 m*l* of acetone and the pH of the solution was controlled always in alkaline side by further additions of sodium carbonate. After stirring at room temperature for 5 hr, it was acidified with diluted hydrochloric acid and the reaction mixture was extracted with ethyl acetate. Di-DNP-β-lysine was detected in the extract on thin-layer chromatogram using developing solvents of chloroform-methanol-acetic acid (95 : 5 : 1) and benzene-pyridine-acetic acid (40 : 10 : 1).

Periodic Acid Oxidation of γ-Hydroxy-β-lysine. To a solution of 50 mg of IIa dihydrochloride in 5 m*l* of 0.5N sodium hydroxide, 50 mg of crystalline periodic acid were added. After allowing to stand at room temperature for 2 hr, diluted potassium permanganate solution was added dropwise to the reaction mixture until the color of the solution remained. In the reaction mixture, β-alanine was detected by thin-layer chromatography. The reaction mixture was subjected to 2,4-dinitrophenylation. Thus, formation of DNP-β-alanine was confirmed also by thin-layer chromatography.

N^{β},N^{ϵ}-*Di-2,4-dinitrophenyl*-threo-*γ-hydroxy*-L-*β-lysine Lactone (IVa).* To a solution of 15 g of tuberactinomycin A hydrochloride in 400 m*l* of water, 15 g of 2,4-dinitrofluorobenzene in 400 m*l* of acetone was added. A mixture was stirred for 20 hr magnetically. It was evaporated *in vacuo* to remove acetone. Precipitate was filtered and washed with water, ethanol, and ether successively. DNP-Tuberactinomycin A obtained was reprecipitated from dimethylformamide-ether, yield 10.2 g. When 7.0 g of DNP-peptide prepared as above was suspended in 350 m*l* of 6N hydrochloric acid and heated under reflux for 24 hr, dark green insoluble material formed. It was filtered and recrystallized from dimethylformamide-ether to give 2.2 g of yellowish needles of N^{β},N^{ϵ}-di-DNP-*threo*-γ-hydroxy-L-β-lysine lactone (IVa), mp 245—246°C (decomp.), $[\alpha]_D^{22}-63.9°$ (*c* 0.5, DMF).

Found: C, 45.47; H, 3.50; N, 17.66%. Calcd for $C_{18}H_{16}O_{10}N_6$: C, 45.38; H, 3.39; N, 17.64%.

N^{β},N^{ϵ}-*Di-2,4-dinitrophenyl*-threo-*γ-hydroxy*-L-*β-lysine (Va).* A suspension of 600 mg of IVa in 6 m*l* of 1N sodium hydroxide was warmed at 90°C. After IVa was dissolved, the reaction mixture was immediately cooled and neutralized with 6 m*l* of 1N hydrochloric acid. Oily product formed was extracted with ethyl acetate and washed with water. Organic layer was dried over anhydrous sodium sulfate. It was concentrated *in vacuo* to give a crystalline residue which was then recrystallized from methanol, yield 0.4 g, mp 161—162°C (sint.) and 245°C (decomp.).

Found: C, 43.76; H, 3.86; N, 16.93%. Calcd for $C_{18}H_{18}O_{11}N_6$: C, 43.73; H, 3.67; N, 17.00%.

N^{β},N^{ϵ}-*Dibenzyloxycarbonyl*-erythro-*γ-hydroxy*-L-*β-lysine Lactone (IIIb).* A solution of 5.0 g of tuberactinomycin A hydrochloride in 140 m*l* of concentrated sulfuric acid was allowed to stand for five weeks in a sealed tube. The solution was poured into acetone on cooling with a freezing mixture.

A gel precipitated was filtered off, washed with acetone and ether, and then dried *in vacuo*. Dried precipitate was dissolved in 6N hydrochloric acid and allowed to stand at room temperature. After 18 hr, the acidic solution was neutralized with sodium hydrogencarbonate on cooling and benzyloxycarbonylation was carried out by the usual way. Oily product was extracted with ethyl acetate and washed with saturated aqueous sodium chloride solution. Organic layer was dried and concentrated *in vacuo*. Oily residue obtained was washed with petroleum ether and then made to powder by trituration with ether. The powder was extracted with ether using Soxhlet's extractor. Combined filtrate and extract were evaporated and residual oil was dissolved in ether. Crystals formed on addition of petroleum ether were filtered off and recrystallized from ethyl acetate and petroleum ether to afford 0.5 g of colorless needles, mp 96.5—97.5°C, $[\alpha]_D^{20}-9.0°$C (*c* 0.4, DMF).

Found: C, 64.07; H, 5.87; N, 6.81%. Calcd for $C_{22}H_{24}O_6N_2$: C, 64.06; H, 5.87; N, 6.79%.

N^{β},N^{ε}-*Di-2,4-dinitrophenyl*-erythro-*γ-hydroxy*-L-*β-lysine Lactone (IVb)*. Tuberactinomycin A was treated with concentrated sulfuric acid as described above and 500 mg of the product obtained was treated with 35 ml of 6N hydrochloric acid at room temperature for 20 hr. After the acid solution had been neutralized with sodium hydrogencarbonate, it was 2,4-dinitrophenylated by the usual manner. The reaction mixture was evaporated *in vacuo* to remove acetone and then insoluble materials were filtered off. The filtrate was extracted with ethyl acetate and washed with aqueous sodium hydrogencarbonate and water. Organic layer was dried and concentrated *in vacuo*. Crystalline residue was recrystallized from acetone and ether, yield 70 mg, mp 145°C (decomp. after sint.), $[\alpha]_D^{22}-177.8°$ (*c* 0.5, DMF).

Found: C, 45.39; H, 3.58; N, 17.77%. Calcd for $C_{18}H_{16}O_{10}N_6$: C, 45.38; H, 3.39; N, 17.64%.

N^{β},N^{ε}-*Dibenzyloxycarbonyl*-threo-*γ-hydroxy*-L-*β-lysine Amide (VIa)*. A solution of 500 mg of IIIa in methanol was saturated with ammonia. After allowing to stand at room temperature for a few days in a pressure bottle, methanol was evaporated under reduced pressure. Residual crystals were recrystallized from methanol to give colorless needles, yield 410 mg, mp 209°C, $[\alpha]_D^{20}+13.0°$ (*c* 0.4, DMF).

Found: C, 61.28; H, 6.34; N, 9.79%. Calcd for $C_{22}H_{27}O_6N_3$: C, 61.52; H, 6.34; N, 9.79%.

N^{β},N^{ε}-*Dibenzyloxycarbonyl*-erythro-*γ-hydroxy*-L-*β-lysine Amide (VIb)*. Colorless needles of VIb were prepared from 170 mg of IIIb as shown in VIa, yield 140 mg, mp 209—210°C, $[\alpha]_D^{20}-3.5°$ (*c* 0.4, DMF).

Found: C, 61.18; H, 6.24; N, 9.78%. Calcd for $C_{22}H_{27}O_6N_3$: C, 61.52; H, 6.34; N, 9.79%.

Reduction of VIa and VIb with Hydriodic Acid and Red Phosphorus. To a solution of 50 mg of VIa or VIb in 2 ml of 57% hydriodic acid, 80 mg of red phosphorus was added. After heating at 100°C for 20 hr in a sealed tube, excess red phosphorus was filtered off and the filtrate was evaporated *in vacuo*. The residue was dissolved in water. Hydriodic acid was decomposed with hydrogen peroxide. Iodine was filtered off and the filtrate was extracted with ethyl acetate. An aqueous layer was treated with 5% Pd-C to decompose excess hydrogen peroxide. After concentration, it was subjected to 2,4-dinitrophenylation. The product was purified by preparative thin-layer chromatography using developing solvent of chloroform-methanol-acetic acid (95 : 5 : 3). Di-DNP-*β*-lysine obtained was identified with an authentic sample by thin-layer chromatography. It was applied to the measurement of ORD curve.

Debenzyloxycarbonylation of IIIa to IIa dihydrobromide. A solution of 1 g of IIIa in 5 g of 30% hydrogen bromide in glacial acetic acid was kept at room temperature for 1 hr. When ether was added, IIa was precipitated as hydrobromide, yield 740 mg. Recrystallization from 94% ethanol gave prisms, mp 235—6°C (decomp.), $[\alpha]_D^{20}+48°$ (*c* 0.5, H_2O).

Found: C, 23.88; H, 4.53; N, 8.84; Br, 51.80%. Calcd for $C_6H_{12}O_2N_2\cdot 2HBr$: C, 23.54; H, 4.61; N, 9.16; Br, 52.23%.

Debenzyloxycarbonylation of IIIb to IIb Dihydrobromide. Removal of benzyloxycarbonyl group from 280 mg of IIIb was carried out as mentioned in the reaction of IIIa to IIa, to obtain IIb hydrobromide, yield 100 mg, mp 222—223°C (decomp.), $[\alpha]_D^{20}-18.0°$ (*c* 0.5, H_2O).

Found: C, 23.92; H, 4.62; N, 8.95; Br, 51.98%. Calcd for $C_6H_{12}O_2N_2\cdot 2HBr$: C, 23.54; H, 4.61; N, 9.16; Br, 52.23%.

Preparation of Hydroxy Acid Ia and Ib. To a solution of 200 mg of the lactone IIa or IIb hydrobromide in 5 ml of water, 1.0 g of silver acetate was added. Suspended solution was heated at 90°C with stirring for 2 hr. Silver bromide formed and excess silver acetate were filtered off. Filtrate was acidified to pH 3.5 with 1N hydrochloric acid. Precipitated silver chloride was filtered off and the filtrate was concentrated below the temperature of 30°C *in vacuo*. The hydroxy acids, Ia and Ib were obtained as oily products. These were applied to the measurement of mutarotation directly.

The authors wish to express their appreciations to Toyo Jozo Co. Ltd., for the supply of the samples of tuberactinomycins.

The Structural Elucidation of Sesquiterpene Lactones from *Petasites japonicus* Maxim[1]

Keizo NAYA, Mitsuo HAYASHI, Ichiro TAKAGI, Seisuke NAKAMURA, and Masakazu KOBAYASHI

Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Uegahara, Nishinomiya, Hyogo

(Received February 25, 1972)

The structures and absolute configurations of five new sesquiterpenic lactones—fukinolide (**1**), dihydrofukinolide (**2**), homofukinolide (**3**), S-fukinolide (**4**), and fukinanolide (**5**)—isolated from the flower stalks of *Petasites japonicus* Maxim. have been established by a combination of spectroscopic and chemical methods, and by correlation with the known fukinone (**25**).

In a preliminary communication,[2] we reported the isolation and the structural proofs of three new lactones,[3] fukinolide (**1**), S-fukinolide (**4**), and fukinanolide (**5**), obtained from the flower stalks of wild butterburs, *Petasites japonicus* Maxim. ("Fuki" in Japanese). Our subsequent work has led to the isolation of two new sesquiterpenic lactones, named dihydrofukinolide (**2**)[4] and homofukinolide (**3**),[4] from the wild plant. The present paper will describe the isolation and structural determination of these five lactones. All of them belong to the class of novel skeletal sesquiterpenoids of the fukinane (**6**) type,[5,6] and all are shown to be ester derivatives of fukinolidol (**8**), which is the common sesquiterpenic moiety of these lactones.

Fig. 1. Formulas **1**—**6**.

*Structure of Fukinolide (**1**).* Fukinolide (**1**) ($C_{22}H_{30}O_6$, mp 101.5—102.0°C, $[\alpha]_D^{22}$ −126°) is the most abundant constituent of the flower stalks of the wild strain. In the UV spectrum, **1** showed only an end absorption (ε, 11300 at 215 mμ). The functional groups of **1** were inferred from the IR(KBr) absorption bands to be as follows (Fig. 2): 1775 (γ-lactone), 1737, 1706, 1693, 1263, 1230 (esters), 3090, 1666, 1643, 917 cm^{-1} (double bonds).

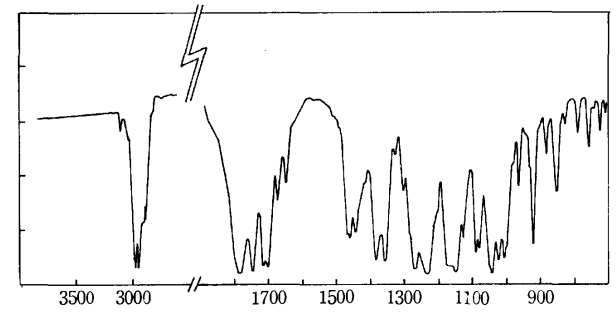

Fig. 2. IR spectra of fukinolide **1** and fukinolidol **8**.

The mild hydrolysis of fukinolide (**1**) with dilute hydrochloric acid gave deacetylfukinolide (**7**) ($C_{20}H_{28}O_5$, mp 167.0—167.5°C), which was then reconverted to **1** by acetylation with acetic anhydride-pyridine. The treatment of **1** with 2 N alcoholic potassium hydroxide afforded angelic acid,[7,8] and a doil, named fukinolidol (**8**) ($C_{15}H_{22}O_4$, mp 176.5—177.5°C). Thus, fukinolide (**1**) proved to be an acetate-angelate of fukinolidol (**8**).

The presence of a γ-lactone group in **1** was presumed from the reaction behavior of alkaline hydrolysis to **8**, as well as from its IR band at 1775 cm^{-1} (Fig. 2).

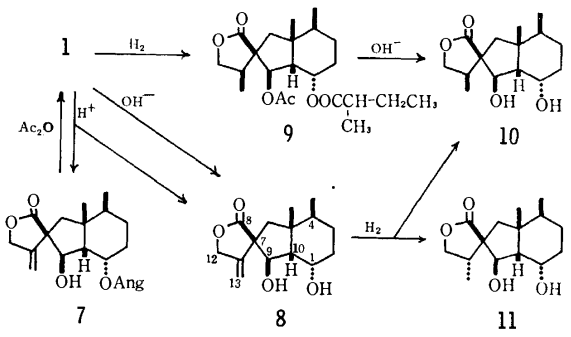

Fig. 3. Formulas **7**—**11**.

One of the two ethylenic double bonds clearly belongs to the angelyl group, as above, while the other seems to be an end-methylene group, judging from the IR bands at 3090, 1666, and 917 cm^{-1}. On hydrogenation with a platinum catalyst in acetic acid, **1** gave the tetrahydro derivative (**9**), which then afforded only dihydrofukinolidol (**10**) ($C_{15}H_{24}O_4$, mp 190.0—191.0 °C) on alkaline hydrolysis, while the similar hydrogenation of fukinolidol (**8**) gave dihydrofukinolidol (**10**) and its epimer, epidihydrofukinolidol (**11**) ($C_{15}H_{24}O_4$, mp 148.0—149.0°C). The IR spectra of **10** and **11** showed no band for an end-methylene group. It can readily be supposed that the above isomeric nature are caused by the hydrogenation of end-methylene groups by different steric environments depending on the existence of ester groups between fukinolide (**1**) and fukinolidol (**8**). The details of the stereochemistry will be described below.

The structure of fukinolidol (**8**) was established from the following evidence.

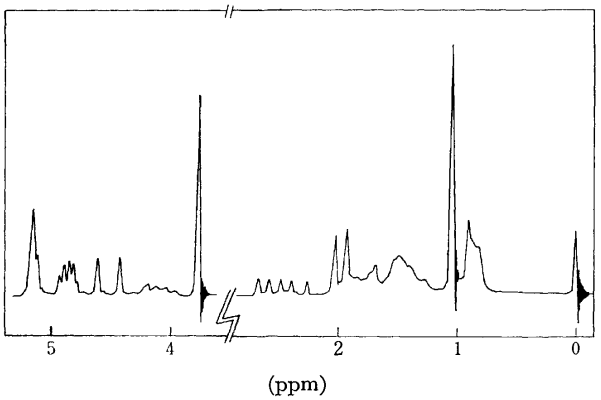

Fig. 4. NMR spectrum of fukinolidol **8**.

Spiro-lactone Group. Fukinolide (**1**) and fukinolidol (**8**) showed essentially similar NMR spectra,[9] except for the signals due to angelate and acetate groups in **1** (Fig. 4). The NMR spectra of **1** and **8** showed the presence of a $-O-CH_2-C=CH_2$ grouping with allyl coupling signals: *i. e.*, 5.20 (d, J=2.0 Hz, $-C=CH_2$) and 4.67 (t, J=1.5 Hz, $-O-CH_2-$) in **1**, and 5.12 (t, J=2.0 Hz, $-C=CH_2$) and 4.81 (m, $-O-CH_2-$) in **8**.

9) The NMR chart of fukinolide **1** was inserted in Ref. 2; NMR spectra in this paper were taken on a JEOL C-60 spectrometer with TMS as an internal reference. The values are reported in ppm.

The reduction of fukinolide (**1**) or fukinolidol diacetate (**12**) ($C_{19}H_{26}O_6$, mp 224.5—226.0°C) with lithium aluminum hydride afforded the same product, a tetrol (**13**) ($C_{15}H_{26}O_4$, mp 106.0—107.0°C), whose IR spectrum showed no C=O band, but the presence of an end-methylene group at 1649 and 906 cm^{-1}. The NMR spectrum of **13** exhibited the signals at 4.23 (slightly split s, 2H) and 5.28 (d, J=5.0 Hz, 2H) due to $HO-CH_2-$ and $-C=CH_2$ respectively, and newly-appeared signals at 3.84 and 3.51 (ABq, J=11.0 Hz, 2H) assignable to the $HO-CH_2-$ group, which was probably derived from the lithium aluminum hydride reduction of the lactone C=O group of **1** or **12**.

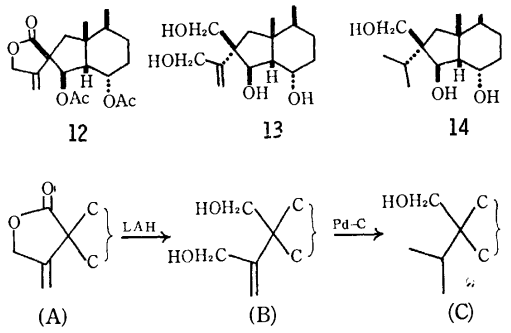

Fig. 5. Formulas **12**—**14**, Partial structure A, B and C.

The above data led to the conclusion that a partial structure (A) was present in **1**. The allylic hydroxyl group in the partial formula (B) was confirmed by the following chemical method.

On the hydrogenation of tetrol (**13**) with palladium charcoal in ethanol, the allylic hydroxyl group was eliminated by hydrogenolysis to yield a triol (**14**) ($C_{15}H_{28}O_3$, mp 88.5—89.5°C). The NMR spectrum of **14** showed signals at 0.97 and 1.07 (each d, J=6.5 Hz) due to a newly-introduced isopropyl group, as in the partial structure (C).

Carbon-ring System and 1,3-Diol Relationship. The NMR spectrum to fukinolidol (**8**) showed signals at 0.86 (d, J=5.0 Hz), 1.04 (s) assignable to a secondary methyl and a tertiary methyl respectively. Accordingly, considering the presence of a spiro-lactone group, two methyls, and the lack of saturation of fukinolidol (**8**) ($C_{15}H_{22}O_4$), the remaining nine carbon atoms seems to consist of a bicyclononane, most probably

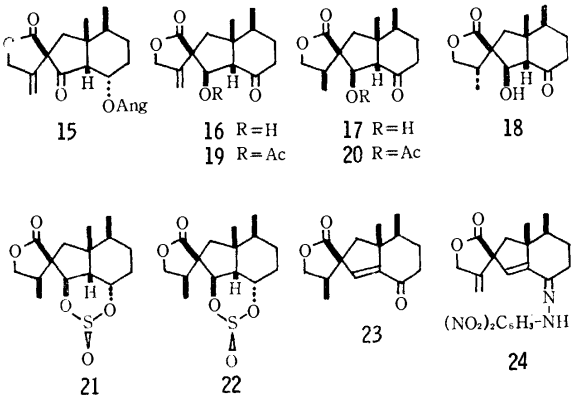

Fig. 6. Formulas **15**—**24**.

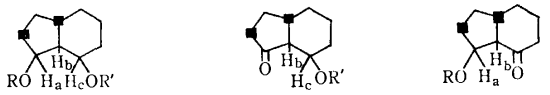
a 5-6 fused ring system. This assumption was verified chemically as follows.

The oxidation of deacetylfukinolide (**7**) with Jones' reagent gave a ketone (**15**) ($C_{20}H_{26}O_5$, mp 96.0—97.0°C), whose IR spectrum showed C=O bands for γ-lactone (1770 cm^{-1}), 5-membered ring ketone (1751 cm^{-1}), and α,β-unsaturated ester (1715, 1646, 1239 cm^{-1}). Similarly, Jones' oxidations of fukinolidol (**8**), dihydrofukinolidol (**10**), and epidihydrofukinolidol (**11**) gave three ketols, **16** ($C_{15}H_{20}O_4$, mp 141.5—142.0°C), **17** ($C_{15}H_{22}O_4$, mp 184.0—186.0°C), and **18** ($C_{15}H_{22}O_4$, mp 137.0—138.0°C) respectively, whose IR spectra showed bands at 3490 and 3365 (H-bonded OH), 1773 and 1755 (γ-lactone), and 1702sh and 1680 cm^{-1} (H-bonded 6-membered ring ketone) in **16**, at 3350 (H-bonded OH), 1767 (γ-lactone), and 1680 cm^{-1} (H-bonded 6-membered ring ketone) in **17**, and at 3470sh and 3405 (H-bonded OH), 1755 (γ-lactone), and 1680 cm^{-1} (H-bonded 6-membered ring ketone) in **18**. The IR spectra of both **16**-acetate (**19**) and **17**-acetate (**20**) showed C=O bands at *ca.* 1700 cm^{-1} attributable to 6-membered ring ketones, but no OH bands. Thus, the two hydroxyl functions of the above ketol derivatives are apparently located on the 5- and 6-membered ring respectively. Furthermore, the 1,3-relationship of the diols in fukinolidol (**8**) and dihydrofudkinoliol (**10**) was defined as will be described below.

The treatment of dihydrofukinolidol (**10**) with thionyl chloride-pyridine gave a mixture of two isomeric cyclic sulfites,[10] $C_{15}H_{22}O_5S$, which were separated by column chromatography to afford **21** (mp 190.5—191.5°C) and **22** (mp 187.5—188.5°C). These isomers were assigned to the **21** and **22** formulas from an examination of both the physical and chemical properties previously reported.[11] On the other hand, the treatment of the ketol **17** with phosphorus oxychloride-pyridine readily provided a dehydration product (**23**) ($C_{15}H_{20}O_3$, mp 103.0—103.5°C), whose IR, UV, and NMR spectra showed the presence of an α,β-unsaturated ketone; IR(KBr): 1681, 1629 cm^{-1}, λ_{max}^{EtOH} 250 mμ (ε, 7100), δ^{CDCl_3}: 6.07 (s) due to C-CH=C-CO. An alcoholic solution of the 2,4-dinitrophenylhydrazone of the **16** ketol was refluxed in the presence of a few drops of 85% phosphoric acid to give a dehydration product, **24** (mp 209.5—210.0°C), which showed the presence of a C-CH=C-C=N- grouping by the following data: λ_{max}^{EtOH} 373 mμ (ε, 31600),[12] δ^{CDCl_3}: 5.80 (s). The ease of dehydration suggests strongly that the **16** and **17** compounds both possess β-hydroxyketone groups. In the NMR spectra of **23** and **24**, the sharp singlets at both 6.07 and 5.80 indicate that the adjacent carbon atom of the ethylenic double bond bears no proton.

From the above results, all the two hydroxyl groups in fukinolidol (**8**), dihydrofukinolidol (**10**), and epidihydrofukinolidol (**11**) were confirmed to be in a 1,3-relationship. Subsequently, the outlines of H_a, H_b, and H_c in the 1,3-diol system, and the further expanded grouping $-CH_a(OH)-CH_b-CH_c(OH)-CH_2-$ in fukinolidol (**8**) could be drawn from the NMR data in Table 1.

Table 1. Chemical shifts (ppm as δ-values) of protons in 1,3-diol systems



D E F

■: bears no proton.

Compounds	H_a	H_b	H_c
Fukinolide **1**	5.79 d	2.82 dd	5.15 m
D: R=Ac R'=angelyl	J=10.5	J=5.0, 10.5	W ½=13.5
Deacetylfukinolide **7**	4.58 d	2.60 dd	5.20 m

Ketone **17**	4.36 d	2.90 d	
F: R=H	J=11.0	J=11.0	

In addition, the NMR spectra of fukinolide (**1**) and fukinolidol (**8**) showed a pair of signals at 2.26 and 1.93 (ABq, J=14 Hz, 2H) and at 2.14 and 1.84 (ABq, J=14.5 Hz, 2H) respectively, indicating the presence of an isolated methylene group. If fukinolide (**1**) is genetically derived from eremophilane derivatives as those of the main constituents isolated from the *Petasites* species,[13,14] the summary of the above evidence leads to the carbon-ring system of fukinolidol (**8**) and also implies its stereochemistry; *i. e.*, two methyls on the carbon-ring system should be situated at at C-4 and C-5 with β-configurations, and the 5-6 ring juncture should be a *cis*-fused ring system, as in Formulas **1** and **8**. Accordingly, the H_a, H_b, and H_c in **8** may be assignable to the α-, β-, and β-configurations respectively, as is shown in Formula **8** on the basis of the coupling constants, J_{ab}=11.0 Hz, and J_{bc}=5.0 Hz, in the NMR spectra of the **15**, **16**, and **17** ketones

(Table 1). Therefore, the configurations of the two hydroxyl groups in fukinolidol (**8**) can be assigned to the 1α(eq) and 9β orientations respectively. Further evidence of the stable 1α(eq) orientation was provided by the reduction of the ketol acetate (**20**) with sodium] borohydride, giving dihydrofukinolidol (**10**). The chemical shifts of the C-15 methyls in the NMR spectra of fukinolidol (**8**) ($CDCl_3$, 1.04; pyridine, 0.97) and dihydrofukinolidol (**10**) ($CDCl_3$, 1.03; benzene, 0.99) showed the anisotropic effect of of the spiro-lactone carbonyl group, suggesting that the lactone and 15β-methyl are located on the same side of the *cis*-fused 5-6 carbon-ring system. The ORD curves of the three ketones, **15**, **16**, and **17**, are in good agreement with the above stereochemistry (**15**: +Cotton; **16** and **17**: −Cotton effects).[15]

Thus, the above results lead to the stereoformulas of **8** and **1** for fukinolidol and fukinolide respectively.

The final evidence for the structure and stereochemistry of fukinolidol (**8**) was provided by the following chemical method for correlation to the known eremophilane derivative, fukinone (**25**),[13] *via* fukinan-8-ol (**26**).

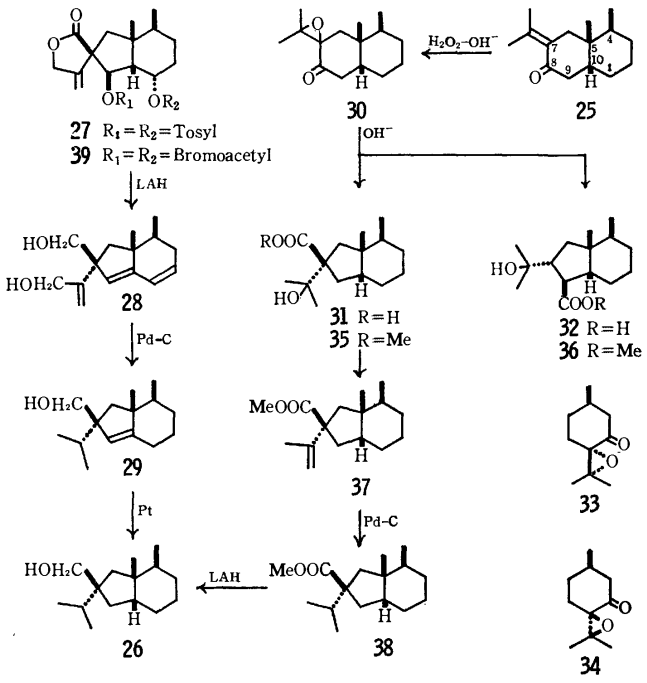

Fig. 7. Formulas **25**—**39**.

The treatment of fukinolidol ditosylate (**27**) (mp 179.5—180.0°C dec) with lithium aluminum hydride gave a diol, **28** ($C_{15}H_{22}O_2$, mp 119.5—120.0°C), whose spectra indicate the presence of a conjugated diene; λ_{max}^{EtOH} 237 mμ (ε, 18700); δ^{CDCl_3}: 6.21 (d, J=9.5 Hz, C-1 H), 5.75 (dt, J=9.5, 2.0 Hz, C-2 H) and 5.50 (s, C-9 H). The subsequent hydrogenation of **28** with palladium charcoal in ethanol afforded a product, **29**, by the hydrogenolysis of the allylic hydroxyl group, as has been described before. The IR and NMR spectra of **29** still showed the existence of an ethylenic bond; IR (film): 1662 cm^{-1}; δ^{CCl_4}: 4.95 (s, C-9 H). Subsequent hydrogenation with a platinum catalyst in acetic acid gave a saturated monol, fukinan-8-ol (**26**) ($C_{15}H_{28}O$, mp 38.0—39.0°C).

On the other hand, fukinan-8-ol (**26**) was prepared from the eremophilane-type, known fukinone (**25**), which is supposed to be a precursor for the genesis of fukinolide (**1**) and its homologues.

The treatment of a mixture of fukinone epoxides (**30**)[16] with an aqueous sodium hydroxide–ethanol solution gave mainly a mixture of a spiro-acid (**31**) and a nonspiro-acid (**32**), similar to the products of the Favorskii rearrangements of the two pulegone epoxides **33** and **34**.[17] The spiro-acid (**31**) was isolated as its ester, **35** ($C_{16}H_{28}O_3$, mp 63.5—64.5°C) by column chromatography. The stereochemistry of the spiro-acid can be properly described by Formula **31** in accordance with the known mechanism demonstrated for the rearrangement of the pulegone epoxides, **33** and **34**.[17] The spiro-ester (**35**) was dehydrated with phosphorus oxychloride-pyridine to afford an unsaturated ester (**37**); subsequent hydrogenation with 10% palladium charcoal in ethanol gave an oil (**38**). The reduction of the saturated alcohol (**38**) with lithium aluminum hydride gave a monol ($C_{15}H_{28}O$, mp 38.0—39.0°C), which was identical in all respects

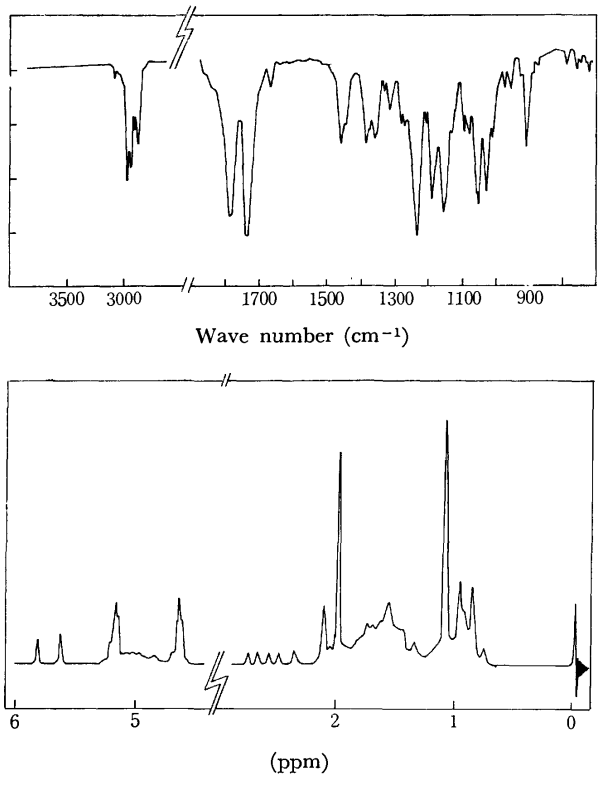

Fig. 8. IR and NMR spectra of dihydrofukinolide (**2**).

15) G. V. Baddeley, T. G. Halsall, and E. R. H. Jones, *J. Chem. Soc.*, **1960**, 1715; C. Djerassi, R. Riniker, and B. Riniker, *J. Amer. Chem. Soc.*, **78**, 6362 (1956); C. Djerassi, W. Closson, and E. Lippman, *ibid.*, **78**, 3163 (1956).

16) Recently α- and β-epoxides of fukinone have been separated and examined their stereospecific natures for Favorskii rearrangement. The details will be published soon.

17) G. W. K. Cavill and C. D. Hall, *Tetrahedron*, **23**, 1119 (1967); W. Reusch and P. Mattison, *ibid.*, **23**, 1953 (1967); S. A. A. Achmad and G. W. K. Cavill, *Aust. J. Chem.*, **16**, 858 (1963).

with the fukinan-8-ol (**26**) prepared from fukinolide (**1**).

At this stage, the structures and absolute configurations of fukinolidol and fukinolide can be represented as in Formulas **8** and **1**. In conjunction with this study, an X-ray analysis[18] has been performed with fukinolidol dibromoacetate (**39**); this also secured the molecular structure of fukinolidol (**8**).

Structure of Dihydrofukinolide (2). Dihydrofukinolide (**2**) ($C_{22}H_{32}O_6$, mp 125.0—126.0°C, $[\alpha]_D^{22}$ −105.5°) was named on the basis of having two hydrogens more than fukinolide (**1**) ($C_{22}H_{30}O_6$). Its IR and NMR spectra resemble those of fukinolide (**1**) except for the absorptions and signals attributable to the angelyl group[7] in **1**. Dihydrofukinolide (**2**) was deduced to be an ester of fukinolidol (**8**) from its IR spectrum; IR(KBr): 1788 (γ-lactone), 1734, 1236 (saturated ester), 3085, 1667, 909 cm^{-1} (end-methylene). In fact, the **2** compound afforded fukinolidol (**8**), acetic acid, and *d*-(S)-α-methylbutyric acid (**40**)[19] upon alkaline hydrolysis. These acids were identified as *p*-phenylphenacyl esters by comparison with authentic sample (tlc, mixed-melting-point determination, and IR spectra). Therefore, dihydrofukinolide (**2**) proved to be the acetate and *d*-(S)-α-methylbutyrate of fukinolidol (**8**).

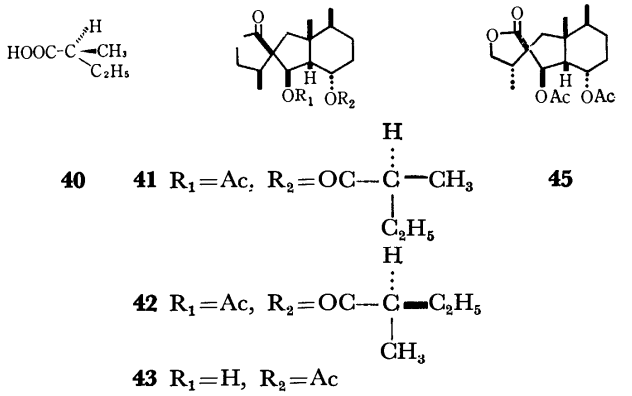

Fig. 9. Formulas **40**—**45**.

The final evidence for the structure of dihydrofukinolide (**2**) was obtained by the correlation with fukinolide (**1**) through its hydrogenated derivatives as follows.

The reduction of fukinolide (**1**) with a platinum catalyst in acetic acid afforded a mixture of two diastereomers, **41** and **42** ($C_{22}H_{34}O_6$), each of which was separated by repeated recrystallization with aqueous methanol, **41**, colorless needles, mp 112.0—113.0°C, $[\alpha]_D^{22}$ −52.25°; **42**, colorless prisms, mp 121.5—122.5°C, $[\alpha]_D^{22}$ −67.5°. The lower-melting isomer, **41**, was identical with tetrahydrofukinolide (mp 116.5—117.0°C, $[\alpha]_D^{22}$ −51.0°), which was obtained exclusively by the hydrogenation of dihydrofukinolide (**2**) with palladium charcoal in ethanol. On the other hand, the higher-melting isomer, **42**, showed a depression of the mixed-melting-point on admixture with tetrahydrofukinolide (**41**) prepared from dihydrofukinolide (**2**), and a different IR spectrum from that of **41**. The above diastereomers are only concerned with an asymmetric center derived from the hydrogenation of the angelyl moiety of fukinolide (**1**). This fact indicates that the addition of hydrogens to the end-methylene group of **1** proceeds preferentially from one side of the lactone ring, namely, from the opposite, less-hindered side to the attaching site of ester groups. The epimeric mixture of **41** and **42**, therefore, upon alkaline hydrolysis afforded only dihydrofukinolidol (**10**). On the other hand, the hydrogenation of fukinolidol (**8**) with palladium charcoal in ethanol gave two diastereomers connected with the configuration of C-13 methyl, $C_{15}H_{24}O_4$—namely, dihydrofukinolidol (**10**) (mp 190.0—191.0°C, $[\alpha]_D^{22}$ −14.5°) and epidihydrofukinolidol (**11**) (mp 148.0—149.0°C, $[\alpha]_D^{22}$ −69.5°), as has been described above. The above results apparently demonstrate that the the absence of ester groups facilitates the addition of hydrogens to the end-methylene group from both sides

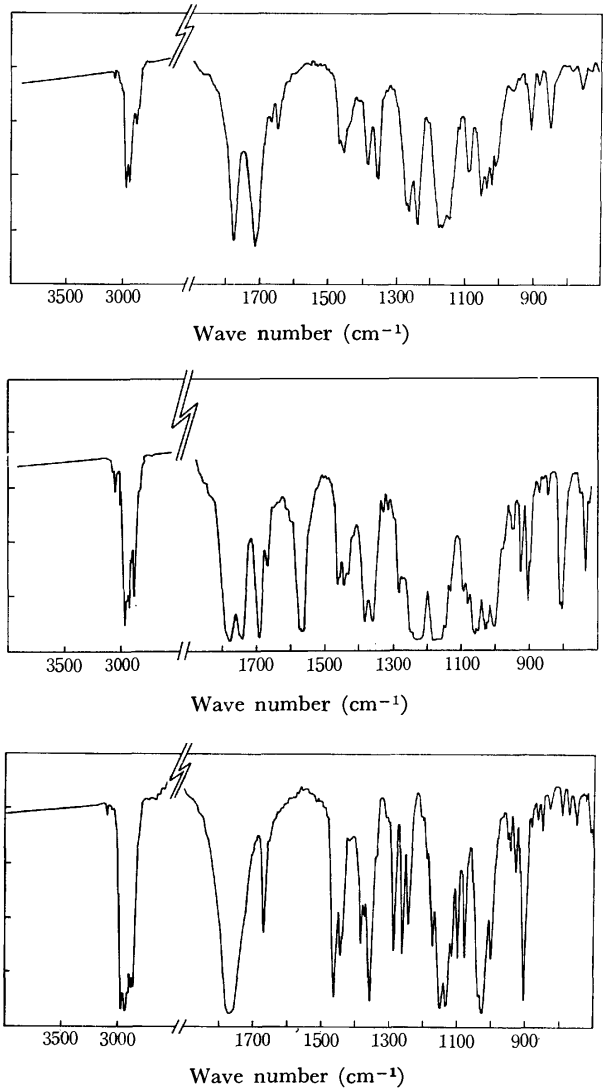

Fig. 10. IR spectra of homofukinolide **3**, S-fukinolide **4**, and fukinanolide **5**.

19) A. Yagi and T. Kawasaki, *Yakugaku Zasshi*, **82**, 210 (1962).

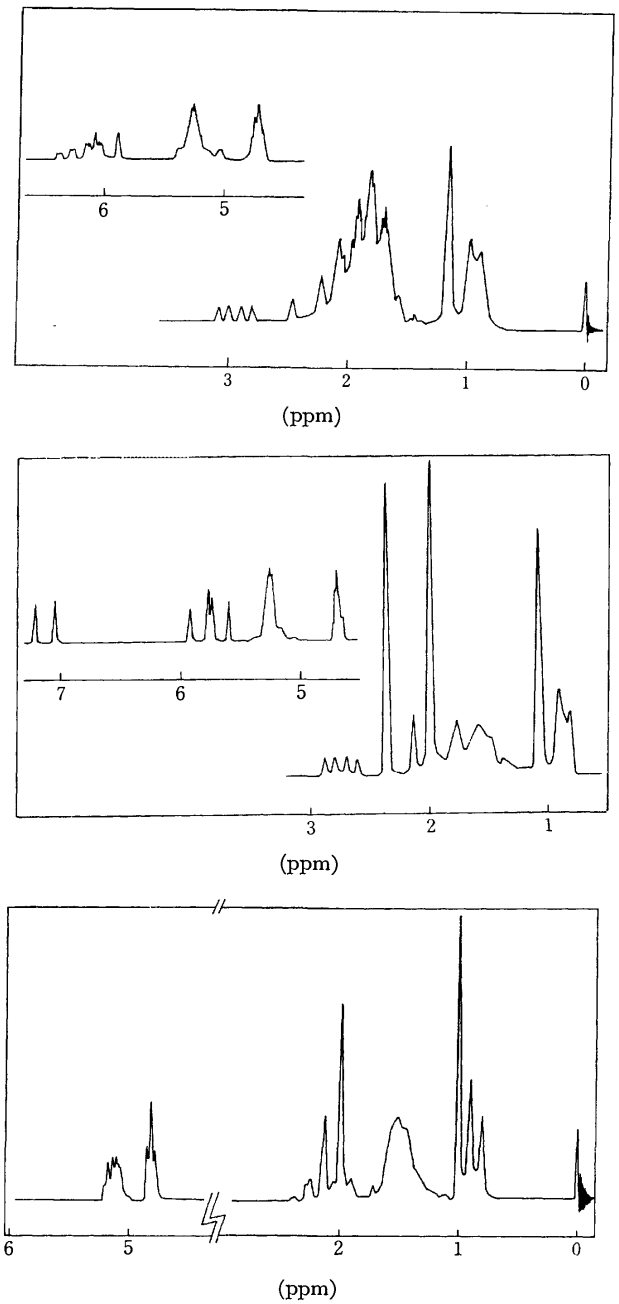

Fig. 11. NMR spectra of homofukinolide **3**, S-fukinolide **4**, and fukinanolide **5**.

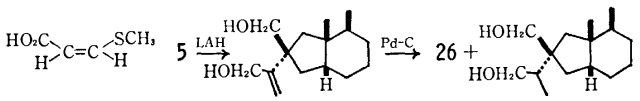
of the lactone ring. Thus, the epimer can be represented by Formula **11** in connection with Fomula **10**, with 13β-methyl for dihydrofukinolidol. This configurational postulation at the C-13 methyl group was also supported by the following chemical behavior in response to the steric hindrance caused by 13β-methyl: the acetylation of dihydrofukinolidol (**10**) containing 13β-methyl with acetic anhydride-pyridine gave a mixture of monoacetate (**43**) ($C_{17}H_{26}O_5$, mp 194.0—196.0°C) and diacetate (**44**) ($C_{19}H_{28}O_6$, mp 246.0—248.0°C, $[\alpha]_D^{22}$ −42.5°), while the acetylation of epidihydrofukinolidol (**11**) containing 13α-methyl under conditions similar to the above readily afforded only the diacetate (**45**) (mp 214.0—215.0°C, $[\alpha]_D^{22}$ −50.5°) quantitatively.

Homofukinolide (3). The spectroscopic absorption of homofukinolide (**3**) ($C_{25}H_{34}O_6$, mp 184.0—186.0°C, $[\alpha]_D^{22}$ −127°) were also similar to those of fukinolide (**1**). The NMR spectrum of **3** showed the signals at 6.13 attributable to two vinyl protons, and four vinyl methyl signals between 1.70—1.95 due to the two angelyl groups. The intensity of the UV maximum, ε, 23500 at 215 mμ supported the above assignment.[20] Homofukinolide (**3**) was hydrolysed with alcoholic potassium hydroxide to give fukinolidol (**8**) (mp 177.0—178.0°C) and angelic acid.[8] Those results led to the conclusion that homofukinolide (**3**) is the diangelate of fukinolidol (**8**).

S-Fukinolide (4). Compound **4** ($C_{21}H_{28}O_6S$, mp 200.0—201.0°C, $[\alpha]_D^{22}$ −161°) shows spectroscopic absorptions closely similar to those of fukinolide (**1**), except for the IR band at 1568 cm^{-1} and the NMR signals at 7.00 (d, J=9.5 Hz, 1H), 5.60 (d, J=9.5 Hz, 1H), 2.38 (s, 3H) instead of 5.96 (q, J=7.0 Hz, 1H), 1.80 (d, J=7.0 Hz, 3H) and 1.78 (s, 3H) due to the angelate group in **1**. Further, besides the above spectra, the UV spectra (λ_{max}^{EtOH} 287.5 mμ (ε, 15700)) suggest that Compound **4** may include an isolated disubstituted ethylenic acid residue containing a β-*S*-alkyl group. The hydrolysis of **4** with alcoholic potassium hydroxide gave fukinolidol (**8**) and *cis*-β-methylthioacrylic acid (**46**) ($C_4H_6O_2S$, mp 119.0—120.0°C).[8,21] Thus, S-fukinolide can be represented by Formula **4**.



46 **47** **48**

Fig. 12. Formulas **46**—**48**.

Fukinanolide (5). Fukinanolide (**5**) ($C_{15}H_{22}O_2$, mp 80.5—80.6°C, $[\alpha]_D^{22}$ +17.0°) showed IR bands indicating the presence of a γ-lactone (1770 cm^{-1}) and an end-methylene group (1665, 898 cm^{-1}). From a comparison of the NMR spectra of **5** and fukinolidol (**8**), this compound was readily inferred to possess the **5** structure.

The above conclusion was ascertained by the chemical method as follows.

The reduction of **5** with lithium aluminum hydride gave a diol, **47** ($C_{15}H_{26}O_2$, mp 81.5—82.0°C). Compound **47** was hydrogenated with 10% palladium charcoal to afford a monol ($C_{15}H_{28}O$) and another diol, **48** ($C_{15}H_{28}O_2$, mp 121.0—122.0°C). The monol is identical in all respects with fukinan-8-ol (**26**), as is to be expected.

Therefore, the structure and absolute configuration of fukinanolide can be represented by Formula **5**.

Fukinolide (**1**), *S*-fukinolide (**4**), and fukinanolide (**5**) have also been isolated from the flower stalks of *Petasites japonicus* subsp. *giganteus* Kitam. and named bakkenolide-B, -D, and -A respectively by Kitahara

and his colleagues. They have independently reached the same conclusions.[22]

Experimental

All the melting and boiling points are uncorrected. The IR spectra were recorded with a JASCO DS-402G spectrophotometer, and the UV spectra were obtained with a Cary Model 14 spectrophotometer. The optical rotations were measured with a Hitachi EPU-2A spectrophotometer, and the ORD curves were taken with a JASCO spectrophotometer, Model ORD-5. The mass spectra were measured with a Hitachi RMU-6 mass spectrometer. The analytical and preparative glc were performed with a Shimadzu GC-1C apparatus on a stainless steel column ($\phi=3$ mm). The tlc were run on silica gel (Merck Kieselgel G). The microanalyses were carried out in the microanalytical section of the Shionogi Research Laboratory, Shionogi and Co., Ltd.

*Isolation of Fukinolide (**1**), Dihydrofukinolide (**2**), Homofukinolide (**3**), S-Fukinolide (**4**), and Fukinanolide (**5**).* The dried flower stalks of *P. japonicus* Maxim. collected near the northern margin of Lake Biwa, at the foot of Mt. Ibuki, in Shiga Prefecture, and at Mt. Shirouma in Nagano Prefacture, were extracted in the cold with methanol for 20 days. The solvent was then removed under reduced pressure, and the residue was dissolved in benzene. The solution was washed with a saturated sodium hydrogen carbonate aqueous solution and then with water, dried over anhydrous sodium sulfate, and evaporated *in vacuo*, thus leaving a dark oil (95 g). This oil was repeatedly chromatographed on silica gel, and elution with benzene, benzene–ethyl acetate (50 : 1), or light petroleum–ethyl ether (50 : 1) gave fukinanolide (**5**) (tlc: R_f, 0.77, benzene–ethyl acetate, 15 : 1), homofukinolide (**3**) (R_f, 0.64), dihydrofukinolide (**2**) (R_f, 0.47), fukinolide (**1**) (25 g; R_f, 0.45), and S-fukinolide (**4**) (3 g; R_f, 0.34).

*Fukinolide (**1**)*: mp 101.5—102.0°C, colorless prisms (from light petroleum), $[\alpha]_D^{22}$ −126.0° (*c*, 1.0, MeOH), −117.5° (*c*, 1.0, $CHCl_3$); MS: *m/e* 390 M^+; IR (KBr): 1775 (γ-lactone), 1737, 1706, 1693, 1263, 1230 (ester), 3090, 1666, 1643, 917 cm^{-1} (double bond), (CCl_4): 1788 (γ-lactone), 1744, 1716, 1235 (ester), 3080, 1667, 1645, 900 cm^{-1} (double bond); NMR($CDCl_3$): 5.96 (q, $J=7.0$ Hz, =CH- in angelate), 5.79 (d, $J=10.5$ Hz, 9-CH), 5.20 (d, $J=2.0$ Hz, 13-CH_2), ca 5.15 (m, 1-CH), 4.67 (t, $J=1.5$ Hz, 12-CH_2), 2.82 (dd, $J=5.0$, 10.5 Hz, 10-CH), 2.26, 1.93 (ABq, $J=14.0$ Hz, 6-CH_2), 1.93 (s, AcO), 1.80 (d, $J=7.0$ Hz, β-CH_3 in angelate), 1.78 (s, α-CH_3 in angelate), 1.13 (s, 15-CH_3), 0.90 (d, $J=7.0$ Hz, 14-CH_3).

Found: C, 67.62; H, 7.83%. Calcd for $C_{22}H_{30}O_6$: C, 67.67; H, 7.74%.

*Dihydrofukinolide (**2**)*: mp 125.0—126.0°C, colorless prisms (from light petroleum), $[\alpha]_D^{22}$ −105.5° (*c*, 1.0, MeOH); IR-(KBr): 1788 (γ-lactone), 1734, 1236 (ester), 3085, 1667, 909 cm^{-1} (double bond); UV: λ_{max}^{EtOH} end absorption; NMR-($CDCl_3$): 5.80 (d, $J=11.5$ Hz, 9-CH), 5.20 (t, $J=1.0$ Hz, 13-CH_2), 5.09 (m, 1-CH), 4.69 (t, $J=2.0$ Hz, 12-CH_2), 2.66 (dd, $J=5.5$, 11.5 Hz, 10-CH), 2.30, 1.71 (ABq, $J=14.0$ Hz, 6-CH_2), 2.07 (s, AcO), 1.12 (s, 15-CH_3), 1.07 (d, $J=6.5$ Hz, 3H), 0.94 (d, $J=6.5$ Hz, 14-CH_3), ca 0.90 (m, 3H); (C_6H_6): 5.87 (d, $J=11.0$ Hz, 9-CH), 5.18 (m, 1-CH), 4.90 (t, $J=0.5$ Hz, 13-CH), 4.70 (t, $J=0.5$ Hz, 13-CH), 4.32 (m, 12-CH_2), 2.84 (dd, $J=5.5$, 11.0 Hz, 10-CH), 2.19, 1.66 (ABq, $J=14.0$ Hz, 6-CH_2), 1.83 (s, AcO), 1.05 (d, $J=6.5$ Hz, 3H), 0.91 (d, $J=6.5$ Hz, 14-CH_3), 0.84 (s, 15-CH_3), 0.62 (m, 3H).

Found: C, 67.20; H, 8.26%. Calcd for $C_{22}H_{32}O_6$: C, 67.32; H, 8.22%.

*Homofukinolide (**3**)*: mp 184.0—186.0°C, colorless needles (from light petroleum), $[\alpha]_D^{22}$ −127.0° (*c*, 1.0, $CHCl_3$); IR-(KBr): 1773 (γ-lactone), 1723sh, 1708, 1233 (ester), 3080, 1668, 1648, 905, 850 cm^{-1} (double bond); (CCl_4): 1785 (γ-lactone), 1717, 1235 (ester), 3080, 1670sh, 1645, 902, 845 cm^{-1} (double bond); UV: λ_{max}^{EtOH} 215 mμ (ε, 23500); NMR($CDCl_3$): 6.13 (q, $J=8.0$ Hz, 2H, β-CH in angelate), 5.90 (d, $J=11.5$ Hz, 9-CH), 5.20 (d, $J=2.5$ Hz, 13-CH_2), 5.16 (m, 1-CH), 4.65 (t, $J=2.0$ Hz, 12-CH_2), 2.92 (dd, $J=4.5$, 11.5 Hz, 10-CH), 2.35, 1.97 (ABq, $J=14.0$ Hz, 6-CH_2), 1.95—1.70 (4×CH_3), 1.18 (s, 15-CH_3), 0.96 (d, $J=5.5$ Hz, 14-CH_3).

Found: C, 69.68; H, 8.05%. Calcd for $C_{25}H_{34}O_6$: C, 69.74; H, 7.96%.

*S-Fukinolide (**4**)*: mp 200.0—201.0°C, colorless needles (from light petroleum), $[\alpha]_D^{22}$ −161.0° (*c*, 1.0, $CHCl_3$); IR-(KBr): 1778 (γ-lactone), 1743, 1693, 1234 (ester), 3090, 1668, 1568, 903, 803 cm^{-1} (double bond); UV: λ_{max}^{EtOH} 287.5 mμ (ε, 15700); NMR($CDCl_3$): 7.00 (d, $J=9.5$ Hz, β-CH in an acid residue), 5.73 (d, $J=11.0$ Hz, 9-CH), 5.60 (d, $J=9.5$ Hz, α-CH in an acid residue), 5.16 (d, $J=2.0$ Hz, 13-CH_2), 5.15 (m, 1-CH), 4.64 (t, $J=2.0$ Hz, 12-CH_2), 2.77 (dd, $J=4.5$, 11.0 Hz, 10-CH), 2.38 (s, S-CH_3), 2.28, 1.91 (ABq, $J=14.0$ Hz, 6-CH_2), 2.01 (s, AcO), 1.12 (s, 15-CH_3), 0.90 (d, $J=5.5$ Hz, 14-CH_3).

Found: C, 62.09; H, 6.99; S, 8.04%. Calcd for $C_{21}H_{28}O_6S$: C, 61.74; H, 6.91; S, 7.83%.

*Fukinanolide (**5**)*: mp 80.5—80.6°C, colorless leaflets (from light petroleum), $[\alpha]_D^{22}$ +17.0° (*c*, 1.0, MeOH); IR-(KBr): 1770 (γ-lactone), 1665, 898 cm^{-1} (end-methylene); NMR($CDCl_3$): 5.11 (dd, $J=2.0$, 2.0 Hz, 13-CH), 5.02 (dd, $J=2.0$, 2.0 Hz, 13-CH), 4.75 (ABq, $J=2.0$ Hz, 12-CH_2), 1.00 (s, 15-CH_3), 0.87 (d, $J=6.0$ Hz, 14-CH_3).

Found: C, 76.94; H, 9.53%. Calcd for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%.

*Acid Hydrolysis of Fukinolide (**1**).* A mixture of fukinolide (**1**) (1.0 g) in ethanol (10 m*l*) and a 6N hydrogen chloride solution (10 m*l*) was refluxed for 2.5 hr. The reaction mixture was then poured into water and extracted with ether. The ethereal extract was washed with a saturated sodium hydrogen carbonate solution and water, dried over anhydrous sodium sulfate, and evaporated to dryness. The residue (850 mg) was chromatographed on silica gel (25 g); subsequent elution with benzene–ethyl acetate (50 : 1) gave the crude deacetylfukinolide (**7**) (540 mg), which was then recrystallized from light petroleum as colorless needles, mp 167.0—167.5°C, $[\alpha]_D^{22}$ −144.0° (*c*, 1.0, MeOH); IR(KBr): 3530, 3440, 1752, 1709, 1695, 1669, 1642, 1233, 895 cm^{-1}; NMR ($CDCl_3$): 6.18 (q, $J=7.0$ Hz, β-CH in angelate), 5.17 (t, $J=2.0$ Hz, 13-CH_2), *ca.* 5.20 (m, 1-CH, partly superimposed with 13-methylene), 4.86 (m, 12-CH_2), 4.58 (d, $J=10.5$ Hz, 9-CH), 2.75 (OH), 2.60 (dd, $J=5.0$, 10.5 Hz, 10-CH), 2.25, 1.94 (ABq, $J=14.0$ Hz, 6-CH_2), 1.94 (d, $J=7.0$ Hz, β-CH_3 in angelate), 1.85 (s, α-CH_3 in angelate), 1.11 (s, 15-CH_3), 0.90 (d, $J=5.5$ Hz, 14-CH_3).

Found: C, 68.68; H, 8.11%. Calcd for $C_{20}H_{28}O_5$: C, 68.94; H, 8.10%.

Further elution with benzene–ethyl acetate (5 : 1) gave fukinolidol (**8**) (75 mg), which was recrystallized from ethyl acetate–light petroleum as colorless prisms; mp 174.0—176.0 °C, $[\alpha]_D^{22}$ −79.0° (*c*, 1.0, MeOH).

22) N. Abe, R. Onoda, K. Shirahata, T. Kato, M. C. Woods, and Y. Kitahara, *Tetrahedron Lett.*, **1968**, 369; 11th Symposium on the Chemistry of Natural Products, Symposium Paper (1967), p. 96; N. Abe, R. Onoda, K. Shirahata, T. Kato, M. C. Woods, Y. Kitahara, K. Ro, and T. Kurihara, *Tetrahedron Lett.*, **1968**, 1993.

Found: C, 67.81; H, 8.53%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%. This is identical with the specimen of fukinolidol (**8**) obtained by the alkaline hydrolysis of fukinolide (**1**), as determined by a mixed-melting-point determination and a comparison of the IR spectra.

*Regeneration of Fukinolide (**1**).* Deacetylfukinolide (**7**) (50 mg) was acetylated in the usual manner with acetic anhydride-pyridine. The product (47 mg) was recrystallized from light petroleum as colorless prisms; mp 101.5—102.0°C, $[\alpha]_D^{22}$ −137.0° (*c*, 1.0, MeOH).

Found: C, 67.94; H, 7.88%. Calcd for $C_{22}H_{30}O_6$: C, 67.67; H, 7.74%. This was found to be identical with an authentic sample of natural fukinolide (**1**) by a mixed-melting-point determination and by a comparison of the IR spectra.

*Alkaline Hydrolysis of Fukinolide (**1**).* Fukinolide (**1**) (3 g) was dissolved in 2N potassium hydroxide-menthanol (20 m*l*), and the mixture was allowed to stand at room temperature for 3 days. After the removal of the solvent and acidification with 2N sulfuric acid, the reaction mixture was extracted with ethyl acetate. The extract was washed with a saturated sodium hydrogen carbonate solution and water, and dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent gave fukinolidol (**8**) (1.54 g) (mp 176.5—177.5°C) as colorless prisms (from ethyl acetate-light petroleum). $[\alpha]_D^{22}$ −75.5° (*c*, 1.0, MeOH); IR(KBr): 3440 (OH), 1755 (γ-lactone), 3100, 1675, 910 cm^{-1} (double bond); NMR($CDCl_3$): 5.12 (t, *J*=2.0 Hz, 13-CH_2), 4.81 (m, 12-CH_2), 4.49 (d, *J*=11.0 Hz, 9-CH), 4.08 (m, 1-CH), 3.77 (2×OH), 2.55 (dd, *J*=5.5, 11.0 Hz, 10-CH), 2.14, 1.84 (ABq, *J*=14.5 Hz, 6-CH_2), 1.04 (s, 15-CH_3), 0.86 (d, *J*=5.0 Hz, 14-CH_3); (pyridine): 5.60 (s, 2H), 5.08 (d, *J*=3.0 Hz, 2H), 4.84 (m, 2H), 4.67 (d, *J*=11.0 Hz, 1H), ca 4.15 (m, 1H), 2.80 (dd, *J*=6.0, 11.0 Hz, 1H), 2.17, 1.81 (ABq, *J*=14.5 Hz, 2H), 0.97 (s, 3H), 0.77 (d, *J*=6.0 Hz, 3H).

Found: C, 67.42; H, 8.42%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%.

The above sodium hydrogen carbonate solution was acidified with 2N sulfuric acid and extracted with ether. The extract was washed with water and dried. The solvent was removed to give a residue (600 mg). The residue (200 mg) was then transformed to the *p*-phenylphenacyl ester in the usual manner, using *p*-phenylphenacyl bromide (356 mg). The product was chromatographed on silica gel (10 g); subsequent elution with light petroleum-ether (50 : 1) gave *p*-phenylphenacyl angelate (104 mg) (mp 89.5—90.5°C) as leaflets (from ethanol).

Found: C, 77.52; H, 6.19%. Calcd for $C_{19}H_{18}O_3$: C, 77.53; H, 6.16%.

The *p*-bromophenacyl ester of angelic acid was obtained in a similar manner (mp 64.0—66.0°C) as leaflets (from ethanol).

Found: C, 52.32; H, 4.34%. Calcd for $C_{13}H_{13}O_3Br$: C, 52.54; H, 4.41%.

*Acetylation of Fukinolidol (**8**).* Fukinolidol (**8**) (100 mg) was dissolved in acetic anhydride (1 m*l*) and pyridine (0.5 m*l*), and the mixture was left at room temperature for 48 hr. The reaction mixture was then worked up in the usual manner to give, quantitatively, crude diacetate (**12**) as an amorphous solid which was crystallized from ethanol as prisms; mp 224.5—226.0°C, $[\alpha]_D^{22}$ −120.0° (*c*, 1.0, $CHCl_3$); IR(KBr): 3080, 1773, 1746, 1741, 1668, 1241, 1231, 913 cm^{-1}; NMR($CDCl_3$): 5.78 (d, *J*=11.0 Hz, 9-CH), 5.20 (m, 13-CH_2), 5.00 (m, 1-CH), 4.68 (t, *J*=2.0 Hz, 12-CH_2), 2.71 (dd, *J*=5.0, 11.0 Hz, 10-CH), 2.27, 1.93 (ABq, *J*=14.0 Hz, 6-CH_2), 2.06 (s, AcO), 1.94 (s, AcO), 1.11 (s, 15-CH_3), 0.90 (d, *J*=5.5 Hz, 14-CH_3).

Found: C, 65.06; H, 7.50%. Calcd for $C_{19}H_{26}O_6$: C, 65.12; H, 7.48%.

*Dihydrofukinolidol (**10**).* A solution of fukinolide (**1**) (10.7 g) in acetic acid (30 m*l*) was hydrogenated with Adams' catalyst (626 mg) at room temperature. Hydrogen uptake (2 mol) ceased after 3 hr. After the filtration of the catalyst, the solvent was removed *in vacuo* to give crude tetrahydrofukinolide (**9**), which was used for the next step without any further purification. A solution of the above product in 2N potassium hydroxide-methanol was allowed to stand at room temperature for 2 days. The solvent was then removed, and the residue was diluted with water, and extracted with ether to take off the neutral part. The aqueous layer was acidified with 5N sulfuric acid and extracted with ethyl acetate. The extract was washed with a saturated sodium hydrogen carbonate solution and water, and then dried. The solvent was removed to give dihydrofukinolidol (**10**) (5.6 g); mp 190.0—191.0°C, colorless prisms (from ethyl acetate-light petroleum), $[\alpha]_D^{22}$ −14.5° (*c*, 1.0, MeOH); IR(KBr): 3525, 3445, 1766 cm^{-1}; NMR($CDCl_3$): 4.60 (d, *J*=11.0 Hz, 9-CH), 4.23 (t, *J*=8.5 Hz, 12-CH), 4.12 (m, 1-CH), 3.92 (dd, *J*=8.5, 10.0 Hz, 12-CH), 3.19 (s, 2×OH), 2.55 (dd, *J*=5.5, 11.0 Hz, 10-CH), 2.01, 1.49 (ABq, *J*=14.0 Hz, 6-CH_2), 1.13 (d, *J*=7.0 Hz, 13-CH_3), 1.03 (s, 15-CH_3), 0.80 (d, *J*=4.5 Hz, 14-CH_3); (C_6H_6): 4.54 (d, *J*=11.0 Hz, 1H), ca 4.0 (m, 1H), 3.92 (m, 2H), 3.78 (s, 2H), 2.79 (dd, *J*=5.5, 11.0 Hz, 1H), 1.97, 1.23 (ABq, *J*=14.0 Hz, 2H), 0.99 (s, 3H), 0.79 (d, *J*=7.0 Hz, 3H), 0.61 (d, *J*=5.0 Hz, 3H).

Found: C, 67.12; H, 9.20%. Calcd for $C_{15}H_{24}O_4$: C, 67.13; H, 9.02%.

*Reduction of Fukinolide (**1**) with Lithium Aluminum Hydride.* A solution of fukinolide (**1**) (600 mg) in dry ether (20 m*l*) was stirred, drop by drop, into a suspension of lithium aluminum hydride (280 mg) in dry ether (30 m*l*), and then the mixture was refluxed for 5 hr. The excess reagent was destroyed by the careful addition of ethyl acetate and water, followed by treatment with a saturated sodium sulfate solution. The organic layer was separated, and the aqueous layer was extracted with ether. The combined extracts were washed with water, and dried. The solvent was removed to leave an oily residue (543 mg), which was then chromatographed on silica gel (8 g). Elution with ethyl acetate-benzene (3 : 2) gave a tetrol (**13**) (300 mg); mp 106.0—107.0°C, $[\alpha]_D^{22}$ −14.0° (*c*, 1.0, MeOH); IR(KBr): 3390, 3275, 1649, 906 cm^{-1}; NMR($CDCl_3$): 5.28 (d, *J*=5.0 Hz, 13-CH_2), 4.86 (d, *J*=11.0 Hz, 9-CH), 4.23 (slightly split s, 12-CH_2), 4.00 (m, 1-CH), 3.84, 3.51 (ABq, *J*=11.0 Hz, 8-CH_2), 3.56 (s, 4×OH), 2.20 (dd, *J*=5.5, 11.0 Hz, 10-CH), 2.00, 1.34 (ABq, *J*=14.0 Hz, 6-CH_2), 0.91 (s, 15-CH_3), 0.76 (d, *J*=4.0 Hz, 14-CH_3); (pyridine): 0.87 (s, 15-CH_3), 0.67 (d, *J*=5.0 Hz, 14-CH_3).

Found: C, 66.96; H, 9.74%. Calcd for $C_{15}H_{26}O_4$: C, 66.63; H, 9.69%.

Tetrol-acetate. Tetrol (**13**) (65 mg) was acetylated with acetic anhydride (0.3 m*l*) and pyridine (0.2 m*l*) at room temperature for 40 hr. Working up in the usual manner gave the tetraacetate (95 mg) as a viscous oil; IR(film): 3090, 1742, 1642, 1245, 907 cm^{-1}; NMR($CDCl_3$): 6.10 (d, *J*=10.5 Hz, 9-CH), 5.38 (d, *J*=8.0 Hz, 13-CH_2), 5.05 (m, 1-CH), 4.10 (slightly split s, 12-CH_2), 4.20, 3.95 (ABq, *J*=11.5 Hz, 8-CH_2), 2.08 (s, 1×AcO), 2.03 (s, 2×AcO), 1.96 (s, 1×AcO), 1.00 (s, 15-CH_3), 0.80 (d, *J*=5.0 Hz, 14-CH_3).

*Reduction of Fukinolidol Diacetate (**11**) with Lithium Aluminum Hydride.* A solution of fukinolidol diacetate (**11**) (380 mg) in dry ether (45 m*l*) and dry benzene (5 m*l*) was stirred into a suspension of lithium aluminum hydride (310 mg) in dry ether (10 m*l*). After refluxing for 7 hr, working up as above afforded a crude tetrol (**13**) (84 mg). This was chro-

matographed on silica gel (5 g) and eluted with ethyl acetate-benzene (3 : 2). Mp 106.0—107.0°C, colorless leaflets (from ethyl acetate-light petroleum).

Found: C, 66.62; H, 9.51%. Calcd for $C_{15}H_{26}O_4$: C, 66.63; H, 9.69%.

This substance is identical with the tetrol (**13**) described above.

*Hydrogenation of Tetrol (**13**).* A solution of tetrol (**13**) (690 mg) in ethanol (5 m*l*) was shaken with hydrogen at room temperature in the presence of 10% palladium charcoal (68 mg) for 4 hr, until the hydrogen-uptake (1.37 mol) had ceased. After the subsequent filtration of the catalyst, the solvent was removed *in vacuo* to leave an oily residue (700 mg). The crude product was chromatographed on silica gel (20 g); elution with benzene-ethyl acetate (15 : 1) then gave triol (**14**); mp 88.5—89.5°C, colorless needles (from cyclohexane); $[\alpha]_D^{22}$ −5.5° (*c*, 1.0, MeOH); IR(KBr): 3430, 3330, 1386, 1370, 1088, 1047 cm^{-1}; NMR($CDCl_3$): 4.58 (d, J=11.0 Hz, 9-CH), 4.10 (m, 1-CH), 3.80, 3.54 (ABq, J=11.5 Hz, 8-CH_2), 3.30 (s, 3×OH), 2.78 (dd, J=5.5, 11.0 Hz, 10-CH), 1.88, 1.47 (ABq, J=10.5 Hz, 6-CH_2), 1.07 (d, J=6.5 Hz, 12- or 13-CH_3), 0.97 (d, J=6.5 Hz, 12- or 13-CH_3), 0.90 (s, 15-CH_3), 0.77 (d, J=5.0 Hz, 14-CH_3).

Found: C, 70.91; H, 11.25%. Calcd for $C_{15}H_{28}O_3$: C, 70.27; H, 11.01%.

*Oxidation of Deacetylfukinolide (**7**).* Jones' reagent (1.9 m*l*) was added to a solution of deacetylfukinolide (**7**) (1.0 g) in acetone (15 m*l*) under ice-salt cooling at −8— −12°C over a period of 3 hr with stirring. After stirring for a further 4 hr under the same conditions, the mixture was concentrated *in vacuo* and extracted with ether. The extract was washed with water and dried. The solvent was then removed to give a crude product (880 mg), which was subsequently crystallized from light petroleum to yield the pure ketone (**15**) (320 mg) as colorless needles; mp 96.0—97.0°C, $[\alpha]_D^{22}$ −110° (*c*, 1.0, MeOH), ORD (*c*, 0.1, MeOH): $[\alpha]_{589}$ −90°, $[\alpha]_{380}$ −220°, $[\alpha]_{342}$ 0°, $[\alpha]_{323}$ +1340°, $[\alpha]_{312}$ 0°; (*c*, 0 01, MeOH): $[\alpha]_{268}$ −5800°, $[\alpha]_{262}$ −5600°, $[\alpha]_{226}$ −12400°; IR(KBr): 3095, 1770, 1751, 1715, 1672, 1646, 1239, 902 cm^{-1}; NMR($CDCl_3$): 6.08 (q, J=7.0 Hz, β-CH in angelate), 5.22 (d, J=2.5 Hz, 13-CH), *ca.* 5.05 (m, 1-CH), 5.00 (d, J=2.5 Hz, 12-CH_2), 4.86 (d, J=2.5 Hz, 13-CH), 3.02 (d, J=5.0 Hz, 10-CH), 2.46, 2.17 (ABq, J=14.0 Hz, 6-CH_2), 1.96 (d, J=7.0 Hz, β-CH_3 in angelate), 1.90 (s, α-CH_3 in angelate), 1.23 (s, 15-CH_3), 0.98 (d, J=2.0 Hz, 14-CH_3).

Found: C, 69.47; H, 7.38%. Calcd for $C_{20}H_{26}O_5$: C, 69.34; H, 7.57%.

*Oxidation of Fukinolidol (**8**).* A solution of chromium trioxide (235 mg) in water (0.55 m*l*) and concentrated sulfuric acid (0.16 m*l*) was stirred, drop by drop over a 1-hr period, into a solution of fukinolidol (**8**) (560 mg) in acetone (3.5 m*l*) under a nitrogen atmosphere at 5°C. After stirring for a further 30 min, the reaction mixture was worked up as has been described above to yield a crude product (376 mg). Recrystallization from ethyl acetate-light petroleum gave monoketone (**16**) as colorless leaflets; mp 141.5—142.0°C, $[\alpha]_D^{22}$ −232° (*c*, 1.0, MeOH); ORD (*c*, 0.10, MeOH): $[\alpha]_{598}$ −170°, $[\alpha]_{315}$ −5000°, $[\alpha]_{296}$0°, $[\alpha]_{276}$+3670°, $[\alpha]_{250}$0°; (*c*, 0.005, MeOH): $[\alpha]_{228}$−8220°, $[\alpha]_{219}$0°; IR(KBr): 3490, 3365, 3085, 1773, 1755, 1680, 1675sh, 1666sh, 1190, 1162, 1096, 920, 913 cm^{-1}; NMR($CDCl_3$): 5.20 (t, J=2.0 Hz, 13-CH_2), 4.78 (m, 12-CH_2), 4.38 (d, J=11.0 Hz, 9-CH), *ca.* 3.5 (broad signal, OH), 2.86 (d, J=11.0 Hz, 10-CH), 1.00 (s, 15-CH_3), 0.97 (d, J=5.5 Hz, 14-CH_3).

Found: C, 68.20; H, 7.65%. Calcd for $C_{15}H_{20}O_4$: C, 68.16; H, 7.63%.

*Acetate (**19**).* The above monoketone (**16**) (50 mg) was acetylated with acetic anhydride (0.2 m*l*) and pyridine (0.2 m*l*) at room temperature for 50 hr. Working up in the usual manner gave an oil (42 mg), which was then chromatographed on silica gel (5 g); subsequent elution with benzene afforded the acetate (**19**) (24 mg), mp 132.5—133.0 °C, $[\alpha]_D^{24}$ −210° (*c*, 1.0, $CHCl_3$); IR(KBr): 1770, 1744, 1698, 918 cm^{-1}; NMR($CDCl_3$): 5.50 (d, J=11.0 Hz, 9-CH), 5.28 (d, J=2.7 Hz, 13-CH_2), 4.72 (t, J=3.0 Hz, 12-CH_2), 3.01 (d, J=11.0 Hz, 10-CH), 1.98 (s, AcO), 1.05 (s, 15-CH_3), 0.98 (d, J=6.0 Hz, 14-CH_3).

Found: C, 66.75; H, 7.31%. Calcd for $C_{17}H_{22}O_5$: C, 66.65; H, 7.24%.

*2,4-Dinitrophenylhydrazone of Monoketone (**16**).* The 2,4-dinitrophenylhydrazone was prepared by Brady's method and crystallized from aqueous ethanol as yellow needles; mp 220.0—221.0°C.

Found: C, 56.63; H, 5.45; N, 12.50%. Calcd for $C_{21}H_{24}O_7N_4$: C, 56.75; H, 5.44; N, 12.61%.

Dehydration of Monoketone 2,4-Dinitrophenylhydrazone. The above 2,4-dinitrophenylhydrazone (20 mg) in ethanol was refluxed with 85% phosphoric acid (3 drops) for 10 hr. The reaction mixture was concentrated *in vacuo*, poured into water, and extracted with ether. The extract was washed with a saturated sodium hydrogen carbonate solution and water, and dried. The subsequent evaporation of the solvent gave a crude product which was chromatographed on silica gel (3 g). Elution with benzene gave a dehydration product (**24**) (13 mg), which was then crystallized from ethanol as orange-red needles; mp 209.5—210.0°C; IR(KBr): 3090, 1775, 1673 cm^{-1}; NMR($CDCl_3$): 11.18 (m, 1H), 9.11 (d, J=2.5 Hz, 1H), 8.30 (dd, J=2.5, 9.5 Hz, 1H), 8.01 (d, J=9.5 Hz, 1H), 5.80 (s, 9-CH), 5.14 (m, 13-CH_2), 4.89 (t, J=2.0 Hz, 12-CH_2), 2.52, 1.95 (ABq, J=14.0 Hz, 6-CH_2), 1.28 (s, 15-CH_3), 0.97 (d, J=6.0 Hz, 14-CH_3).

Found: C, 59.02; H, 5.20%. Calcd for $C_{21}H_{22}O_6N_4$: C, 59.15; H, 5.20%.

*Oxidation of Dihydrofukinolidol (**10**).* A solution of chromium trioxide (1.44 g) in acetone (21 m*l*), water (3.3 m*l*) and concentrated sulfuric acid (1 m*l*) was stirred, drop by drop over 70 min under a nitrogen atmosphere at 3—5°C, into a solution of dihydrofukinolidol (**10**) (2.91 g) in acetone (35 m*l*). After stirring for a further 20 min, the excess reagent was decomposed with methanol (3 m*l*), diluted with water, and extracted with ether. The extract was washed with a 5% potassium hydroxide solution and then water, and dried. The removal of the solvent gave a crude product as a solid (2.4 g). The product was chromatographed on silica gel (80 g); subsequent elution with benzene-ethyl acetate (9 : 1) gave dihydromonoketone (**17**) (1.8 g); mp 184.0—186.0°C, colorless prisms (from acetone-light petroleum), $[\alpha]_D^{22}$ −79.0°(*c*, 1.0, MeOH); ORD (*c*, 0.1, MeOH): $[\alpha]_{589}$ −60°, $[\alpha]_{315}$ −2100°, $[\alpha]_{297}$0°, $[\alpha]_{275}$+2100°, $[\alpha]_{236}$+690°, $[\alpha]_{220}$+2100°; IR(KBr): 3350, 1767, 1680 cm^{-1}, (CCl_4): 3540, 1765, 1690 cm^{-1}; NMR($CDCl_3$): 4.36 (d, J=11.0 Hz, 9-CH), 4.33 (t, J=8.5 Hz, 12-CH), 4.02 (dd, J=8.5, 10.0 Hz, 12-CH), 2.90 (d, J=11.0 Hz, 10-CH), 2.80 (OH), 1.97, 1.61 (ABq, J=14.0 Hz, 6-CH_2), 1.21 (s, 15-CH_3), 1.15 (d, J=6.5 Hz, 13-CH_3), 0.93 (d, J=5.5 Hz, 14-CH_3).

Found: C, 67.71; H, 8.41%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%.

*Acetate (**20**).* Dihydromonoketone (**17**) (140 mg) in pyridine (0.4 m*l*) was treated with acetic anhydride (0.5 m*l*) at room temperature for 32 hr. Working up in the usual manner yielded the acetate (**20**) (120 mg); mp 158.5—159.5°C, colorless needles (from ethyl acetate-light petroleum), $[\alpha]_D^{22}$ −93° (*c*, 1.0, MeOH); IR(KBr): 1764, 1738, 1696 cm^{-1}; NMR($CDCl_3$): 5.67 (d, J=11.0 Hz, 9-CH), 4.38

(t, J=8.5 Hz, 12-CH), 3.73 (dd, J=8.5, 10.5 Hz, 12-CH), 2.94 (d, J=11.0 Hz, 10-CH), 1.98 (s, AcO), 1.16 (d, J=6.0 Hz, 13-CH_3), 1.07 (s, 15-CH_3), 0.97 (d, J=6.0 Hz, 14-CH_3).

Found: C, 65.93; H, 7.88%. Calcd for $C_{17}H_{24}O_5$: C, 66.21; H, 7.85%.

*Reduction of Dihydromonoketone Acetate (**20**) with Sodium Borohydride.* The acetate (**20**) (370 mg) in methanol (3 ml) was treated with sodium borohydride (200 mg) in methanol (7 ml) at room temperature for 19 hr. The reaction mixture was then diluted with water (3 ml) and allowed to stand at room temperature for 24 hr. Working up in the usual manner gave a solid (320 mg), which was subsequently crystallized from ethyl acetate; mp 190.0—191.0°C, colorless prisms, $[\alpha]_D^{22}$ −14.0° (*c*, 1.0, MeOH).

Found: C, 67.33; H, 9.01%. Calcd for $C_{15}H_{24}O_4$: C, 67.13; H, 9.02%.

The above substance was found to be identical in all respects with the dihydrofukinolidol (**10**) obtained from tetrahydrofukinolide (**9**) by mixed-melting-point determination and a comparison of the IR spectra.

*Oxidation of Epidihydrofukinolidol (**11**).* Jones' reagent (2.2 ml) was stirred, over a 45-min period at −15°C under a nitrogen atmosphere, into a solution of epidihydrofukinolidol (**11**) (1.0 g) in acetone (15 ml). After stirring for a further 30 min under the same conditions, the reaction mixture was treated with a little methanol and concentrated *in vacuo*. Extraction with chloroform gave ketone (**18**) (850 mg), which was then crystallized from ethyl acetate–light petroleum; mp 137.0—138.0°C, colorless needles, $[\alpha]_D^{22}$ −125° (*c*, 1.0, MeOH); ORD (*c*, 0.108, MeOH): $[\alpha]_{589}$ −140°, $[\alpha]_{400}$ −440°, $[\alpha]_{350}$ −880°, $[\alpha]_{311}$ −2580°, $[\alpha]_{293}$0°, $[\alpha]_{274}$+1680°, $[\alpha]_{232}$+690°, $[\alpha]_{220}$+790°; IR(KBr): 3470sh, 3405, 1755, 1714, 1689sh, 1680 cm^{-1}; NMR($CDCl_3$): 4.53 (dd, J=7.0, 8.5 Hz, 12-CH), 4.34 (dd, J=6.0, 11.0 Hz, 9-CH), 3.80 (dd, J=7.0, 9.5 Hz, 12-CH), 3.31 (d, J=6.0 Hz, OH), 2.87 (d, J=11.0 Hz, 10-CH), 1.99, 1.70 (ABq, J=14.0 Hz, 6-CH_2), 1.13 (s, 15-CH_3), 1.11 (d, J=7.0 Hz, 13-CH_3), 0.95 (d, J=6.0 Hz, 14-CH_3).

Found: C, 67.81; H, 8.46%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%.

*Dehydration of Dihydromonoketone (**17**).* The ketone (**17**) (120 mg) in pyridine (1.0 ml) was treated with phophorus oxychloride (0.4 ml) at room temperature for 30 hr. The reaction mixture was poured onto ice and extracted with ether. The extract was washed successively with dilute hydrochloric acid, a saturated sodium hydrogen carbonate solution and water, and dried. The removal of the solvent gave a crude product (90 mg) which was chromatographed on silica gel (5 g). Elution with benzene–ethyl acetate (50 : 1) afforded the dehydration product, **23** (80 mg); mp 103.0—103.5°C, colorless needles (from light petroleum); $[\alpha]_D^{22}$ −36° (*c*, 1.0, MeOH); ORD (*c*, 0.09, MeOH): $[\alpha]_{589}$ −70°, $[\alpha]_{360}$ −920°, $[\alpha]_{335}$0°, $[\alpha]_{310}$+1220°, $[\alpha]_{282}$0°; (*c*, 0.009, MeOH): $[\alpha]_{262}$ −1330°, $[\alpha]_{254}$0°, $[\alpha]_{232}$+20440°; IR(KBr): 1776, 1681, 1629 cm^{-1}; λ_{max}^{EtOH} 250 mμ (ε, 7100); NMR($CDCl_3$): 6.07 (s, 9-CH), 4.45 (dd, J=8.5, 9.5 Hz, 12-CH), 3.93 (t, J=9.5 Hz, 12-CH), 2.38, 1.79 (ABq, J=14.0 Hz, 6-CH_2), 1.24 (s, 15-CH_3), 1.00 (d, J=7.0 Hz, 13- and 14-CH_3).

Found: C, 72.54; H, 8.23%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

*Tosylation of Fukinolidol (**8**).* Fukinolidol (**8**) (2 g) was treated with *p*-toluenesulfonyl chloride (6.3 g) in pyridine (10 ml) and left for 72 hr at room temperature. The reaction mixture was diluted with water to deposit a solid. The collected precipitates (4.3 g) were chromatographed on silica gel (50 g); subsequent elution with benzene–ethyl acetate (30 : 1) gave ditosylate (**27**) (3.5 g); mp 179.5—180.0°C decomp., colorless prisms (from ethyl acetate–light petroleum); IR(KBr): 3060, 1774, 1673, 1600, 1498, 1179, 923 cm^{-1}.

Found: C, 60.65; H, 5.91; S, 11.19%. Calcd for $C_{29}H_{34}O_8S_2$: C, 60.60; H, 5.94; S, 11.16%.

*Reduction of Ditosylate (**27**) with Lithium Aluminum Hydride.* Ditosylate (**27**) (4.05 g) in dry tetrahydrofuran (30 ml) was added, drop by drop over a 2-hr period under refluxing, to a suspension of lithium aluminum hydride (3.0 g) in dry tetrahydrofuran (20 ml). After refluxing for 20 hr, the excess reagent was decomposed with tetrahydrofuran–water (1 : 1, 14 ml) and diluted with water (30 ml), and then 6N sulfuric acid (40 ml) was added. This mixture was extracted with ether to give an oily product (1.64 g). The chromatography of the product on silica gel (60 g) and elution with benzene–ethyl acetate (50 : 1) gave a fraction (422 mg) as the main product on tlc; this product was crystallized from light petroleum to afford diol (**28**); mp 119.5—120.0°C, colorless needles; IR(KBr): 3290, 1642, 1068, 1037, 1028, 901, 882 cm^{-1}; λ_{max}^{EtOH} 237 mμ (ε, 18700); NMR($CDCl_3$): 6.21 (d, J=9.5 Hz, 1-CH), 5.75 (dt, J=9.5, 2.0 Hz, 2-CH), 5.50 (s, 9-CH), 5.11 (d, J=9.0 Hz, 13-CH_2), 4.15 (s, 12-CH_2), 3.73 (s, 8-CH_2), 2.85 (2×OH), 2.02, 1.68 (ABq, J=11.0 Hz, 6-CH_2), 1.00 (s, 15-CH_3), 0.91 (d, J=6.0 Hz, 14-CH_3).

Found: C, 76.82; H, 9.52%. Calcd for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%.

*Hydrogenation of Diol (**28**).* A solution of diol (**28**) (631 mg) in ethanol was hydrogenated over 10% palladium charcoal (303 mg) at room temperature until the hydrogen-uptake had ceased (2.08 mol). After working up as usual, the chromatography of the crude product (509 mg) on silica gel (10 g) and elution with benzene–ethyl acetate (50 : 1) gave a fraction, an unsaturated monol (**29**) (110 mg) which showed the existence of an ethylenic linkage in the IR and NMR spectra; IR(film): 3330, 1662, 1380, 1365, 1038 cm^{-1}; NMR(CCl_4): 4.95 (s, 9-CH), 3.38 (s, 8-CH_2), 2.85 (s, OH), 0.93 (d, J=6.0 Hz, 12- and 13-CH_3), 0.88 (s, 15-CH_3), 0.82 (d, J=6.0 Hz, 14-CH_3).

The above sample in acetic acid (5.0 ml) was further hydrogenated with Adams' catalyst (20 mg) by the standard method. Working up as usual gave a monol, fukinan-8-ol (**26**), which was then purified by preparative glc (PEG 6000, 2.6 m; column temperature, 180°C; H_2, flow-rate, 150 ml/min), mp 38.0—39.0°C, $[\alpha]_D^{22}$+15.6° (*c*, 1.6, MeOH); IR(KBr): 3300, 1387, 1375, 1049, 1041, 1023 cm^{-1}; NMR(CCl_4): 3.37 (s, 8-CH_2), 2.71 (OH), 0.89 (d, J=6.0 Hz, 12- and 13-CH_3), 0.84 (s, 15-CH_3), 0.75 (d, J=6.5 Hz, 14-CH_3).

Found: C, 80.23; H, 12.66%. Calcd for $C_{15}H_{28}O$: C, 80.29; H, 12.58%.

*Favorskii Rearrangement of Fukinone Epoxide (**30**).* A solution of fukinone (**25**) (9.92 g) in methanol (300 ml) was treated with a mixture of 30% hydrogen peroxide (70 ml) and 2N sodium hydroxide–methanol (70 ml) at room temperature. After the removal of the solvent under reduced pressure, the mixture was diluted with water and extracted with ether to give a colorless oil, **30** (10.03 g); IR(film): 1722 cm^{-1}.

The above epoxide (**30**) in ethanol (42 ml) was refluxed with a 4N sodium hydroxide solution (34 ml) under a nitrogen atmosphere for 11 hr. The reddish-brown solution was then concentrated *in vacuo* and extracted with ether to remove the neutral part. The aqueous layer was acidified under ice-cooling with dilute sulfuric acid and then extracted with ether. The product was separated into neutral and acidic parts. The acidic part was treated with diazomethane-etherate overnight at room temperature, and then the reac-

tion mixture was evaporated to leave a yellow oil (8.12 g). Chromatography of the oil on silica gel (240 g) and elution with benzene-ethyl acetate (100 : 1) gave a spiro-ester, **35** (2.26 g, tlc: R_f, 0.37, benzene-ethyl acetate, 20 : 1); mp 63.5—64.5°C, colorless needles (from *n*-pentane), $[\alpha]_D^{22}$ +23.5° (*c*, 1.0, MeOH); IR(KBr): 3480, 1725, 1705, 1195, 1150 cm^{-1}; NMR(CCl_4): 3.68 (s, CH_3O-CO), 3.07 (s, OH), 1.13 (slightly split s, 12- and 13-CH_3), 0.88 (s, 15-CH_3), 0.77 (d, J=6.5 Hz, 14-CH_3).

Found: C, 80.23; H, 12.66%. Calcd for $C_{16}H_{28}O_3$: C, 80.29; H, 12.58%.

Further elution with the same solvent afforded a nonspiro-ester, **36**[16] (3.78 g, tlc: R_f, 0.18, benzene-ethyl acetate, 20 : 1), mp 52.0—54.0°C, colorless needles (from aqueous methanol), $[\alpha]_D^{22}$ +14.0° (*c*, 1.0, MeOH); IR(KBr): 3560, 3250, 1735, 1725, 1190 cm^{-1}.

*Dehydration of the **35** Ester.* A solution of the **35** ester (2.26 g) in dry pyridine (7 m*l*) was treated with phosphorus oxychloride (7.7 m*l*) under cooling and then left at room temperature for 46 hr. The mixture was subsequently poured onto ice and extracted with ether. After working up as usual, the product was chromatographed on silica gel (38 g); elution with light petroleum gave an unsaturated ester **37** (1.776 g); bp 87.0—95.0°C (bath temperature)/1 mmHg; IR(film): 1720, 1630 cm^{-1}; NMR(CCl_4): 4.77 (d, J=6.0 Hz, 12-CH_2), 3.59 (s, CH_3O-CO), 1.68 (s, 13-CH_3), 0.90 (s, 15-CH_3), 0.78 (d, J=6.0 Hz, 14-CH_3).

Found: C, 76.71; H, 10.57%. Calcd for $C_{16}H_{26}O_2$: C, 76.75; H, 10.47%.

*Hydrogenation of the Unsaturated Ester (**37**).* The above ester in ethanol (13 m*l*) was hydrogenated with 10% palladium charcoal (70 mg) at room temperature and atmospheric pressure to afford a saturated ester **38** as an oil; bp 66.0—86.0°C (bath temperature)/1 mmHg; $[\alpha]_D^{22}$ +23.8° (*c*, 1.51, MeOH); IR(film): 1720, 1235, 1180, 1141 cm^{-1}. The pure sample was obtained by glc (PEG 6000, 2.8 m; column temperature, 150°C; H_2-flow rate, 67 m*l*/min, retention time 10.7 min).

Found: C, 76.57; H, 11.16%. Calcd for $C_{16}H_{28}O_2$: C, 76.14; H, 11.18%.

*Reduction of the Saturated Ester (**38**) with Lithium Aluminum Hydride to Fukinan-8-ol (**26**).* The above ester (**38**) (1.7 g) in dry ether (15 m*l*) was stirred, drop by drop over a 50 min period at room temperature, to a suspension of lithium aluminum hydride (800 mg) in dry ether (20 m*l*), and then the mixture was refluxed for 2 hr. Working up as usual gave a colorless oil (1.51 g) which was subsequently purified by preparative glc (PEG 6000, 2.6 m; column temperature, 180°C; H_2-flow rate, 150 m*l*/min), mp 38.0—39.0°C, $[\alpha]_D^{22}$ +18.5° (*c*, 1.6, MeOH); MS: *m/e* 206 (M^+—18), 193 (base peak). This sample was identical in all respects with the fukinan-8-ol (**26**) prepared from fukinolide (**1**) and fukinanolide (**5**).

*Alkaline Hydrolysis of Dihydrofukinolide (**2**).* Dihydrofukinolide (**2**) (800 mg) was dissolved in 2 N potassium hydroxide-methanol (30 m*l*), and then the mixture was left for 90 hr at room temperature. After removal of the solvent and acidification with 2 N sulfuric acid, the reaction mixture was extracted with chloroform, and the extract washed with a saturated sodium hydrogen carbonate solution and then water. The dried extract was evaporated *in vacuo* to give fukinolidol (**8**) (340 mg); colorless prisms (from ethyl acetate), mp 177.0—178.0°C; $[\alpha]_D^{22}$ −83.0° (*c*, 1.0, MeOH).

Found: C, 67.74; H, 8.33%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%. This sample was identified with the authentic sample of fukinolidol (**8**) obtained from fukinolide (**1**) by a comparison of their IR spectra and by a mixed-melting-point determination.

The sodium hydrogen carbonate solution was acidified with dilute sulfuric acid and extracted with ether. The acidic extract was transformed to the *p*-phenylphenacyl esters in the usual way and gave a product. This was chromatographed on silica gel; subsequent elution with light petroleum-ether (50 : 1) afforded the *p*-phenylphenacyl ester of *d*-(S)-α-methylbutyric acid (**40**);[19] colorless needles, mp 71.0—72.0°C (from ethanol), $[\alpha]_D^{22}$ +16.5° (*c*, 1.0, $CHCl_3$); IR(KBr): 1746, 1694, 1605, 1244, 1183, 1158 cm^{-1}.

Found: C, 77.01; H, 6.84%. Calcd for $C_{19}H_{20}O_3$: C, 77.00; H, 6.80%.

*Hydrogenation of Dihydrofukinolide (**2**).* Dihydrofukinolide (**2**) (100 mg) was dissolved in ethanol (6 m*l*) and hydrogenated with 10% palladium charcoal (20 mg) at room temperature. After hydrogen-uptake (2 mol), the filtrate was evaporated *in vacuo* to furnish tetrahydrofukinolide (**41**) (95 mg); mp 116.5—117.0°C, colorless needles (from aqueous methanol); $[\alpha]_D^{22}$ −51.0° (*c*, 1.0, MeOH); IR(CCl_4): 1785 (γ-lactone), 1741, 1721sh, 1244 cm^{-1} (ester), (KBr): 1783 (γ-lactone), 1735, 1236 cm^{-1} (ester).

Found: C, 67.25; H, 8.65%. Calcd for $C_{22}H_{34}O_6$: C, 66.98; H, 8.69%. This sample was found to be identical with the lower-melting isomer (**41**) of tetrahydrofukinolide (**9**) obtained by the hydrogenation of fukinolide (**1**) by a mixed-melting-point determination and by a comparison of the IR spectra.

*Hydrogenation of Fukinolide (**1**).* Fukinolide (**1**) (200 mg) was hydrogenated with platinum oxide (20 mg) in acetic acid (10 m*l*) at room temperature. Hydrogen-uptake (25 m*l*, 2 mol) ceased after 45 min. The catalyst was then filtered off, and the solvent was evaporated *in vacuo* to afford a crystalline mass. The product was recrystallized from light petroleum to deposit a mixture of two crystals, each of which was separated mechanically and recrystallized from aqueous methanol.

One isomer (**41**) (50 mg) was in the form of colorless needles; mp 112.0—113.0°C, $[\alpha]_D^{24}$ −52.25° (*c*, 0.95, MeOH); IR(CCl_4): 1785 (γ-lactone), 1741, 1244 cm^{-1} (ester); (KBr): 1783 (γ-lactone), 1735, 1236 cm^{-1} (ester); NMR($CDCl_3$): 5.99 (d, J=11.5 Hz, 9-CH), 5.05 (m, 1-CH), 4.25 (t, J=8.5 Hz, 12-CH), 3.51 (dd, J=8.5, 10.5 Hz, 12-CH), 2.68 (dd, J=5.0, 11.5 Hz, 10-CH), 2.04 (s, AcO), 2.18, 1.62 (ABq, J=14.0 Hz, 6-CH_2), 1.23 (d, J=7.5 Hz, 13-CH_3), 1.10 (s, 15-CH_3), 1.08 (d, J=7.0 Hz, α-CH_3 in α-methylbutyrate), 0.88 (t, J=7.0 Hz, β-CH_3 in α-methylbutyrate), 0.85 (d, J=6.5 Hz, 14-CH_3).

Found: C, 66.89; H, 8.72%. Calcd for $C_{22}H_{34}O_6$: C, 66.98; H, 8.69%.

The other isomer (**42**) (70 mg) was in the form of colorless prisms; mp 121.5—122.5°C, $[\alpha]_D^{24}$ −67.5° (*c*, 1.0, MeOH); IR(CCl_4): 1785, 1741, 1244 cm^{-1}; (KBr): 1779, 1751, 1732, 1242 cm^{-1}.

Found: C, 66.79; H, 8.78%. Calcd for $C_{22}H_{34}O_6$: C, 66.98; H, 8.69%.

*Fukinolidol Dibromoacetate (**39**).* A mixture of dry benzene (25 m*l*), bromoacetyl bromide (2 m*l*), and fukinolidol (**8**) (500 mg) was refluxed for 5 hr. After working up as usual, the crude product (700 mg) was chromatographed on silica gel (11 g). Elution with benzene–ethyl acetate (80 : 1) gave dibromoacetate (**39**) (270 mg), which was then crystallized from ethyl acetate–light petroleum as colorless needles; mp 156.5—158.0°C, $[\alpha]_D^{22}$ −77.5° (*c*, 1.0, $CHCl_3$); IR(KBr): 1767, 1748, 1742sh, 1666, 1272, 910, 688, 604, 553, 530 cm^{-1}; NMR($CDCl_3$): 5.82 (d, J=11.0 Hz, 9-CH), 5.25 (t, J=2.0 Hz, 13-CH_2), *ca.* 5.1 (m, 1-CH), 4.75 (t, J=2.0 Hz, 12-CH_2), 3.87 (s, CH_2 in bromoacetate), 3.70

(s, CH_2 in bromoacetate), 2.82 (dd, J=5.0, 11.0 Hz, 10-CH), 2.32, 1.95 (ABq, J=14.0 Hz, 6-CH_2), 1.12 (s, 15-CH_3), 0.91 (d, J=5.0 Hz, 14-CH_3).

Found: C, 44.80; H, 4.77; Br, 31.25%. Calcd for $C_{19}H_{24}O_6Br_2$: C, 44.90; H, 4.75; Br, 31.45%.

Hydrogenation of Fukinolidol (8). Fukinolidol (**8**) (2.0 g) in ethanol (20 ml) was hydrogenated at room temperature and atmospheric pressure in the presence of 10% palladium charcoal (200 mg). After the absorption of hydrogen (195 ml), the catalyst was filtered and the solvent was evaporated *in vacuo*. The product was chromatographed over silica gel (50 g); subsequent elution with benzene–ethyl acetate (5 : 1) afforded dihydrofukinolidol (**10**) (1.20 g), which was then crystallized from ethyl acetate as colorless prisms; mp 190.0—191.0°C, $[\alpha]_D^{22}$ −14.5° (*c*, 1.0, MeOH). This was identical with the dihydrofukinolidol (**10**) obtained by the alkaline hydrolysis of tetrahydrofukinolide (**9**) (mixed-melting-point determination and a comparison of their IR spectra).

Further elution with the same solvent gave epidihydrofukinolidol (**11**) (600 mg), which was crystallized from ethyl acetate as colorless prisms; mp 148.0—149.0°C, $[\alpha]_D^{22}$ −69.5° (*c*, 1.0, MeOH); IR(KBr): 3365, 3330, 1758 cm^{-1}; NMR-($CDCl_3$): 4.52 (dd, J=7.0, 8.5 Hz, 12-CH), 4.47 (d, J= 10.5 Hz, 9-CH), 4.05 (OH), *ca.* 3.95 (m, 1-CH), 3.81 (dd, J=2.5, 8.5 Hz, 12-CH), 3.65 (OH), *ca.* 2.50 (m, 1H), 2.32 (dd, J=5.0, 10.5 Hz, 10-CH), 1.83 (s, 6-CH_2), 1.06 (d, J=6.0 Hz, 13-CH_3), 0.98 (s, 15-CH_3), 0.81 (d, J=3.5 Hz, 14-CH_3).

Found: C, 67.06; H, 9.03%. Calcd for $C_{15}H_{24}O_4$: C, 67.13; H, 9.02%.

Acetylation of Dihydrofukinolidol (10). Dihydrofukinolidol (**10**) (100 mg) was treated with acetic anhydride (0.5 ml) and pyridine (0.3 ml) at room temperature for 48 hr. The reaction mixture was then worked up in the usual manner. The crude product (130 mg) was chromatographed on silica gel (5 g); subsequent elution with benzene–ethyl acetate (80 : 1) gave diacetate (**44**) (70 mg), mp 246.0—248.0°C, colorless prisms (from ethyl acetate), $[\alpha]_D^{22}$ −42.5° (*c*, 1.0, $CHCl_3$); IR(KBr): 1769, 1738sh, 1733, 1241sh, 1233 cm^{-1}; NMR ($CDCl_3$): 5.95 (d, J=11.5 Hz, 9-CH), 5.00 (m, 1-CH), 4.24 (t, J=8.0 Hz, 12-CH), 3.50 (dd, J=8.0, 11.0 Hz, 12-CH), 2.68 (dd, J=5.5, 11.5 Hz, 10-CH), 2.15, 1.59 (ABq, J=14.0 Hz, 6-CH_2), 2.03 (s, AcO), 1.92 (s, AcO), 1.20 (d, J=7.0 Hz, 13-CH_3), 1.07 (s, 15-CH_3), 0.83 (d, J=4.5 Hz, 14-CH_3).

Found: C, 64.59; H, 8.04%. Calcd for $C_{19}H_{28}O_6$: C, 64.75; H, 8.01%. This was identical with the diacetate prepared by the hydrogenation of fukinolidol diacetate (**12**).

Further elution with the same solvent gave monoacetate (**43**) (30 mg); mp 194.0—196.0°C, colorless prisms (from ethyl acetate–light petroleum); IR(KBr): 3445, 1760, 1715sh, 1702, 1265 cm^{-1}.

Found: C, 66.00; H, 8.64%. Calcd for $C_{17}H_{26}O_5$: C, 65.78; H, 8.44%.

Acetylation of Epidihydrofukinolidol (11). Epidihydrofukinolidol (**11**) (150 mg) was acetylated under conditions similar to those above to furnish, quantitatively, diacetate (**45**) (190mg). The product was crystallized from ethyl acetate as colorless prisms; mp 214.0—215.0°C, $[\alpha]_D^{22}$ −50.5° (*c*, 1.0, $CHCl_3$); IR(KBr): 1768, 1731, 1235 cm^{-1}; NMR-($CDCl_3$): 5.75 (d, J=10.5 Hz, 9-CH), 5.02 (m, 1-CH), 4.27 (dd, J=6.5, 9.0 Hz, 12-CH), 3.82 (dd, J=2.5, 9.0 Hz, 12-CH), 2.50 (dd, J=5.5, 10.5 Hz, 10-CH), 2.04 (s, AcO), 1.98 (s, 6-CH_2), 1.92 (s, AcO), 1.06 (d, J=7.0 Hz, 13-CH_3), 1.05 (s, 15-CH_3), 0.88 (d, J=3.0 Hz, 14-CH_3).

Found: C, 65.00; H, 7.93%. Calcd for $C_{19}H_{28}O_6$: C, 64.75; H, 8.01%.

Hydrogenation of Fukinolidol Diacetate (12). Fukinolidol diacetate (**12**) (193 mg) in acetic acid (2 ml) was hydrogenated in the presence of platinum oxide (24.8 mg) at room temperature and atmospheric pressure. Working up in the usual manner afforded the dihydro compound (**44**); mp 246.0—248.0°C, colorless needles (from ethyl acetate–light petroleum).

Found: C, 64.48; H, 8.01%. Calcd for $C_{19}H_{28}O_6$: C, 64.75; H, 8.01%. This was identical with the dihydrofukinolidol diacetate (**44**) obtained by the acetylation of dihydrofukinolidol (**10**).

Hydrolysis of Homofukinolide (3). Homofukinolide (**3**) (0.4 g) was dissolved in 2 N alcoholic potassium hydroxide (20 ml), and then the mixture was left for 70 hr at room temperature. After the removal of the solvent and acidification with dilute sulfuric acid, the reaction mixture was extracted with chloroform. The extract was washed with a saturated sodium hydrogen carbonate solution and water, and dried. The subsequent evaporation of the solvent gave fukinolidol (**8**) (180 mg) as colorless prisms (from ethyl acetate); mp 177.0—180.0°C, $[\alpha]_D^{22}$ −79.5° (*c*, 1.0, MeOH).

Found: C, 67.78; H, 8.37%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%. This was identical with the sample of fukinolidol (**8**) obtained by the hydrolysis of fukinolide (**1**).

Acidification of the sodium hydrogen carbonate solution with dilute sulfuric acid and extraction with ether gave a crude acidic part (150 mg), which was then transformed into the *p*-phenylphenacyl ester in the usual manner. The product (450 mg) was chromatographed over silica gel (10 g) and eluted with light peroleum–ether (50 : 1) to afford *p*-phenylphenacyl angelate (130 mg) as colorless leaflets (from ethanol); mp 89.0—90.0°C.

Found: C, 77.54; H, 6.29%. Calcd for $C_{19}H_{18}O_3$: C, 77.53; H, 6.16%. This was identical with the authentic sample of *p*-phenylphenacyl angelate.

Hydrolysis of S-Fukinolide (4). S-Fukinolide (**4**) (300 mg) was dissolved in 2 N methanolic potassium hydroxide (10 ml), and then the mixture was left overnight at room temperature. The solvent was removed *in vacuo*, and the residue was acidified with dilute sulfuric acid and extracted with ether. The extract was washed with a saturated sodium hydrogen carbonate solution and water, and dried. The subsequent evaporation of the solvent gave a product (110 mg) which was crystallized from ethyl acetate as colorless prisms; mp 176.0—178.0°C, $[\alpha]_D^{22}$ −78.5° (*c*, 1.0, MeOH), −75.0° (*c*, 1.0, $CHCl_3$).

Found: C, 67.84; H, 8.42%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%. This was identical with the fukinolidol (**8**) obtained by the alkaline hydrolysis of fukinolide (**1**) according to a mixed-melting-point determination and a comparison of their IR spectra.

The sodium hydrogen carbonate solution was concentrated *in vacuo*, acidified with dilute sulfuric acid, and extracted with ether. The extract was washed with water and dried. After the removal of the solvent, the residue (100 mg) was crystallized from ethanol–cyclohexane to give an acid (**46**) as colorless prisms; mp 119.0—120.0°C, NMR($CDCl_3$): 11.10 (s, COOH), 7.20 (d, J=10.0 Hz, β-CH=), 5.85 (d, J=10.0 Hz, α-CH=), 2.39 (s, S-CH_3).

Found: C, 40.54; H, 5.19%. Calcd for $C_4H_6O_2S$: C, 40.66; H, 5.12%.

The above acid was transformed into the *p*-phenylphenacyl ester, which was then crystallized from ethanol as colorless needles; mp 132.5—133.5°C.

Found: C, 69.19; H, 5.20; S, 10.46%. Calcd for $C_{18}H_{16}O_3S$: C, 69.20; H, 5.16; S, 10.26%. The acid (**46**) was identified as *cis*-β-methylthioacrylic acid from the above

data.

*Reduction of Fukinanolide (**5**) with Lithium Aluminum Hydride.* A solution of fukinanolide (**5**) (662 mg) in dry ether (20 m*l*) was added, drop by drop, to a suspension of lithium aluminum hydride (264 mg) in dry ether (35 m*l*) at room temperature over a 1-hr period, and then the mixture was refluxed for 4hr. Working up as usual gave a crude diol (**47**) (657 mg), which was then crystallized from light petroleum; mp 81.5—82.0°C, colorless leaflets, $[\alpha]_D^{22}+22.0°$ (*c*, 1.0, MeOH); IR(KBr): 3280, 1638, 1063, 1040, 903 cm^{-1}.

Found: C, 75.61; H, 11.08%. Calcd for $C_{15}H_{26}O_2$: C, 75.84; H, 11.00%.

*Hydrogenation of Diol (**47**).* The diol (**47**) (410 mg) was hydrogenated with 10% palladium charcoal (70 mg) in ethanol (15 m*l*) at room temperature and atmospheric pressure. Working up in the usual manner gave a crude product (400 mg) which was subsequently chromatographed on silica gel (10 g). Elution with benzene afforded fukinan-8-ol (**26**) (78 mg); this was followed by purification on glc (PEG 6000, 2.6 m; column temperature, 180°C; H_2-flow rate, 150 m*l*/min; retention time, 29.5 min), mp 38.0—39.0°C, $[\alpha]_D^{22}+18.0°$ (*c*, 1.01, MeOH).

Found: C, 80.04; H, 12.52%. Calcd for $C_{15}H_{28}O$: C, 80.29; H, 12.58%. This was identical with the fukinan-8-ol (**26**) obtained from fukinone epoxide (**30**) and fukinolidol (**8**) as shown by a comparison of their IR spectra and by a mixed-melting-point determination.

Further elution with ethyl acetate afforded diol (**48**) (290 mg), which was subsequently crystallized from light petroleum; mp 121.0—122.0°C, colorless needles, $[\alpha]_D^{22}+11.7°$ (*c*, 0.94, MeOH); MS: *m/e* 240 M^+: IR(KBr): 3230, 1250, 1135, 1100, 1070, 1045 cm^{-1}.

The authors wish to thank Professor Yoshio Kitahara for his generous gift of lactone **5**, the staff of the Shionogi Research Laboratory, Shionogi and Co., Ltd., for the microanalysis, and the Institute of Food Chemistry for the measurement of the MS and NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3685—3692 (1972)

The Allylic Rearrangement. II.[1] Reactions of 5,5,5-Trichloro-3-penten-2-one with Nucleophiles[2]

Akira TAKEDA, Sadao TSUBOI, Takashi MORIWAKE, and Eiji HIRATA

Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama

(Received April 11, 1972)

Reactions of 5,5,5-trichloro-3-penten-2-one (**1**) with a number of nucleophiles have been carried out. It was found that the Grignard reagents (**5**) primarily attacked the carbonyl carbon of **1** yielding the corresponding tertiary alcohols (**7**). The reaction sequence of ethylmagnesium bromide (**5a**) is given as an example. The reaction of **5a** with **1** gave 6,6,6-trichloro-3-methyl-4-hexen-3-ol (**7a**) as the major constituent of the primary product. The hexenol **7a** readily underwent the allylic rearrangement by heating at distilling temperature (88—90°C/6 mmHg) to afford 4,6,6-trichloro-3-methyl-5-hexen-3-ol (**8a**), which was in turn converted into 6,6-dichloro-3-methyl-3,4-epoxy-5-hexene (**9a**) by treatment with sodium methoxide. The stereoselective synthesis of *dl-erythro*-4,6,6-trichloro-3-methyl-5-hexen-3-ol (**8a**-I) was achieved by using 3,5,5-trichloro-4-penten-2-one (**3**) as the starting material in place of **1**. *dl-trans*-6,6-Dichloro-3-methyl-3,4-epoxy-5-hexene (**9a**-I) was derived by the cyclization of **8a**-I with a base. The stereochemistry of **8a** and **9a** was discussed on the basis of NMR data. Nucleophiles such as methanol, hydrogen chloride, anilines, thiophenol, sodium acetate, sodium phenolate, and diethyl sodiomalonate gave the products of the conjugate addition (**15**). Ethyl sodioacetoacetate gave 2-chloro-3-acetonyl-4-ethoxycarbonyl-5-methylfuran (**17**).

As a class of compounds with polyfunctionality 3,3,3-trichloro-1-propenyl ketones have attracted the attention of several authors.[3a] Nevertheless, only a little is known of their chemical properties, and their behavior toward nucleophiles still remains uninvestigated. We have recently reported on the allylic rearrangement of 5,5,5-trichloro-3-penten-2-one (**1**) and phenyl 3,3,3-trichloro-1-propenyl ketone (**2**), and also some reactions of the rearranged products (**3**, and **4**) as an α-chloroketone.[1] To extend our knowledge of its chemical properties we carried out reactions of compound **1** with a number of nucleophiles such as ethylmagnesium bromide (**5a**), methylmagnesium iodide (**5b**), phenylmagnesium bromide (**5c**), diethyl sodiomalonate, ethyl sodioacetoacetate, methanol, and anilines. This paper will describe and discuss the results of these reactions.

$$CCl_3\text{-}CH{=}CH\text{-}\underset{\underset{O}{\|}}{C}\text{-}R \quad \rightleftarrows \quad Cl_2C{=}CH\text{-}\underset{\underset{Cl}{|}}{CH}\text{-}\underset{\underset{O}{\|}}{C}\text{-}R$$

1, R=CH_3 **3**, R=CH_3

2, R=C_6H_5 **4**, R=C_6H_5

It was found that the Grignard reagent (**5**) primarily attacked the carbonyl carbon of **1** yielding the corresponding tertiary alcohols (**7**). The reaction sequence of ethylmagnesium bromide (**5a**) is given in Scheme 1 as an example. When **5a** reacted with **1** at a lower temperature (−10——30°C), *trans*-6,6,6-trichloro-3-methyl-4-hexen-3-ol (**7a**) was formed as

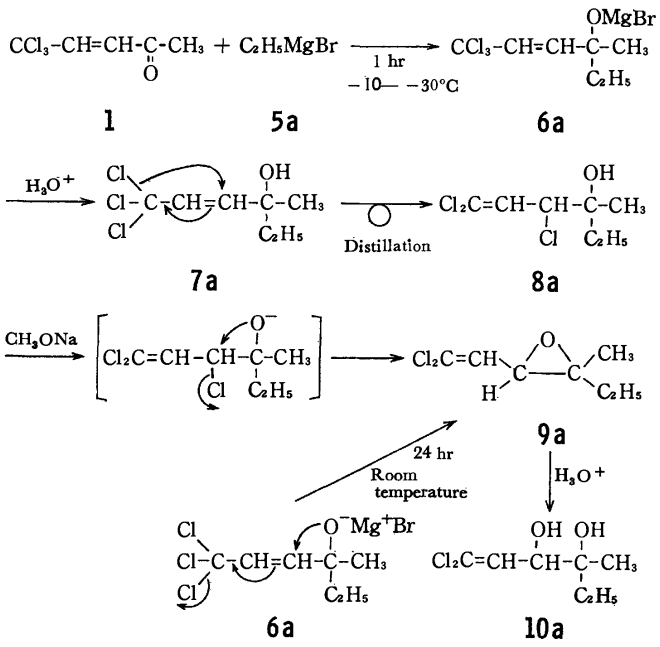
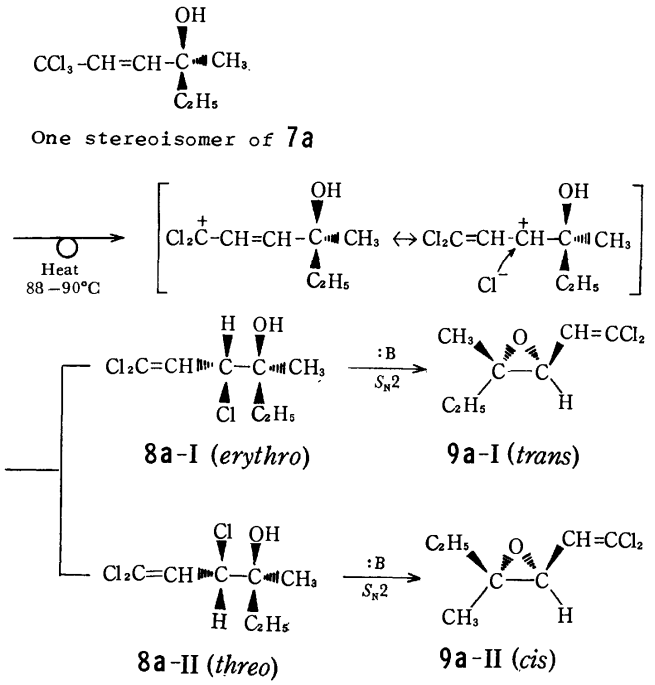
the sole primary product in a 53% yield together with a trace of 6,6-dichloro-3-methyl-3,4-epoxy-5-hexene (**9a**).[4] It is reasonable to consider that the highly electron-withdrawing group of trichloromethyl retards the transfer of the ethylenic electrons to the carbonyl carbon, thus preserving its reactivity to afford the 1,2-adduct rather than the 1,4-adduct, since the reaction of Grignard reagents with alkylideneacetone tends to result in the predominant formation of the 1,4-adducts.[5] Kohler[6] also reported that the 1,4-adduct, *i. e.* phenyl 3,3,3-trichloro-2-phenylpropyl ketone (**15j**) was the only product in the reaction of the ketone **2** with phenylmagnesium bromide (**5c**), but we confirmed that both the ketone **15j** and the 1,2-adduct, *i.e.* 4,4,4-trichloro-1,1-diphenyl-2-buten-1-ol (**7e**), were formed in a ratio of 3 : 4 in the same reaction.



Scheme 1.

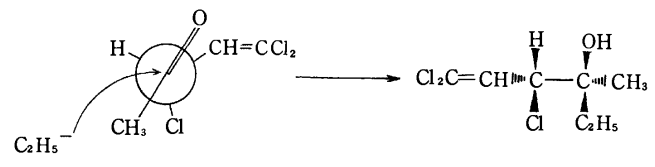
The chlorine atom of the hexenol **7a** is so labile on heating that it readily undergoes the allylic rearrangement to afford 4,6,6-trichloro-3-methyl-5-hexen-3-ol (**8a**) at distilling temperature (88—90°C/6 mmHg). The hexenol **8a** exists in two diastereomeric forms, *i.e. dl-erythro* (**8a**-I) and *dl-threo* (**8a**-II), which correspond to the peaks with the retention times[7] of 13.5 min (**8a**-I) and 14.5 min (**8a**-II) on glpc but were indistinguishable by means of either tlc[8] or by IR



Scheme 2.

spectrum. The planar structure of the intermediate carbonium ion enabled the chlorine atom of **7a** to migrate to its allylic position, from both sides of the plane with equal chances, yielding a mixture of nearly equal amounts of the diastereomers, **8a**-I and **8a**-II. The hexenol **8a** was further transformed into the epoxide **9a** in a 33% yield by treatment with a base in dry ether, which also consisted of two diastereomeric epoxides, **9a**-I and **9a**-II. The steric course of these reactions is illustrated in Scheme 2.

The stereoselective synthesis of **8a**-I was achieved by using the ketone **3** as the starting material in place of **1**. It is presumed from Cram's rule[9] that the reagent **5a** can attack the carbonyl carbon of the ketone **3** more readily from the opposite side of the 2,2-dichlorovinyl group as shown in Scheme 3. In fact the reaction of **5a** with **3** afforded only the hexenol **8a**-I in a 73% yield, which was then converted into *trans*-6,6-dichloro-3-methyl-3,4-epoxy-5-hexene (**9a**-I) in a 88% yield. The *trans* structure of **9a**-I was supported by NMR data, the signal due to the methyl protons appearing at a higher field (δ, s, 1.24 ppm) in **9a**-I than the



Scheme 3.

4) On March 30, 1971, we received a copy of the doctoral dissertation of Mr. François de Champs submitted to the Faculty of Science, the University of Paris, on October 31, 1970, entitled "Etude de la transposition allylique et de quelques proprietes de cetones α,β-ethyleniques γ,γ,γ-trichlorees". Champs obtained similar results. He suggested the possible formation of an epoxide in a small quantity.

8) Conditions of preparative tlc: support, silica gel G (E. Merck AG, Darmstadt), 0.8 mm; developer, *n*-hexane–acetone–chloroform (5 : 2 : 1, v/v); eluent, acetone.

9) D. J. Cram and F. A. Abd Elhafez, *J. Amer. Chem. Soc.*, **74**, 5828 (1952); D. J. Cram and K. R. Kopecky, *ibid.*, **81**, 2748 (1959); J. H. Stocker, P. Sidisunthorn, B. M. Benjamin, and C. J. Collins, *ibid.*, **82**, 3913 (1960).

methyl protons of the diastereomeric epoxide **9a**-II (δ, s, 1.30 ppm).[10] A similar differential shielding effect of the 2,2-dichlorovinyl group was also observed in 5,5-dichloro-2-methyl-2,3-epoxy-4-pentene (**9b**), which exhibited the signal due to the *cis* methyl protons at δ 1.28 ppm and the signal due to the *trans* methyl protons at δ 1.34 ppm. The prolonged reaction of **1** with **5a**, being conducted at room temperature, caused the cyclization of the intermediate **6a** to afford the epoxide **9a** in a 25% yield. It is assumed that the cyclization occurred in a concerted manner in which the oxyanion of **6a** attacks the carbon atom allylic to the chlorine of the trichloromethyl group as shown in Scheme 1. The treatment of the epoxide **9a** (**9a**-I/**9a**-II = *ca.* 1 : 1) with a 20% H_2SO_4 gave an epimeric mixture of 6,6-dichloro-3-methyl-5-hexene-3,4-diol (**10a**) in a 52% yield. The same treatment of the *trans* isomer (**9a**-I) gave *dl-erythro*-6,6-dichloro-3-methyl-5-hexene-3,4-diol (**10a**-I).

When the reagent **5a** was used in much excess in the Grignard reaction, 6-chloro-3-methyl-5-octene-3,4-diol (**12**) was obtained in addition to the compounds **8a** and **9a**. Small amounts of the by-products such as 5,5-dichloro-4-penten-2-one (**13**) and 6,6-dichloro-3-methyl-5-hexen-3-ol (**14**) were also isolated. The possible ways in which compounds **12**, **13**, and **14** were produced are shown in Schemes 4 and 5.[11] The pentenone **13** was prepared in a 29% yield in an alternative synthesis from **1** and magnesium.

The yields, properties, spectral data, and analyses of the tertiary alcohols **7**, the rearranged alcohols **8**, and the epoxides **9** obtained in analogous ways are listed in Tables 1, 2, and 3 respectively.

10) The substituents in heterocyclopropanes tend to cause methyl protons *cis* to them to appear at higher fields than those *trans* to them. *Cf.* L. M. Jackman and S. Sternhell, "Application of Nuclear Magnetic Resonance Spectroscopy in Organic Chemistry, 2nd Edition," Pergamon Press Ltd., London W. 1 (1969), p. 229.

11) Excess magnesium, which was present unreacted in the Grignard reagent, probably reacted with **1** to give pentenone **13**.

12) a) Champs (*loc. cit.*) described the formation of compounds **15a** (mp 25.5°C) and **15b** (bp 108—110°C/15 mmHg) as due to conjugate addition to **1** of methanol and hydrogen chloride, respectively. b) Champs detected the formation of 5,5,5-trichloro-4-diethylamino-2-pentanone in a 40% yield on NMR spectra.

a) Measured in CCl_4. b) Measured in $CDCl_3$. c) NMR spectrum indicates that this fraction consists of **7c** (27%) and **8c** (73%). d) Tlc analysis[17] of this fraction showed two spots at R_f values of 0.80 and 0.67 in the ratio 1 : 1. The 0.80 R_f component was separated by preparative tlc[18] and identified as phenyl 2-trichloromethylbutyl ketone (**15i**) by comparison of its IR spectrum with that of the authentitic sample. The 0.67 R_f component was separated by preparative tlc.[18] NMR spectrum showed it to be a mixture of **7d** and **8d** (3 : 5).

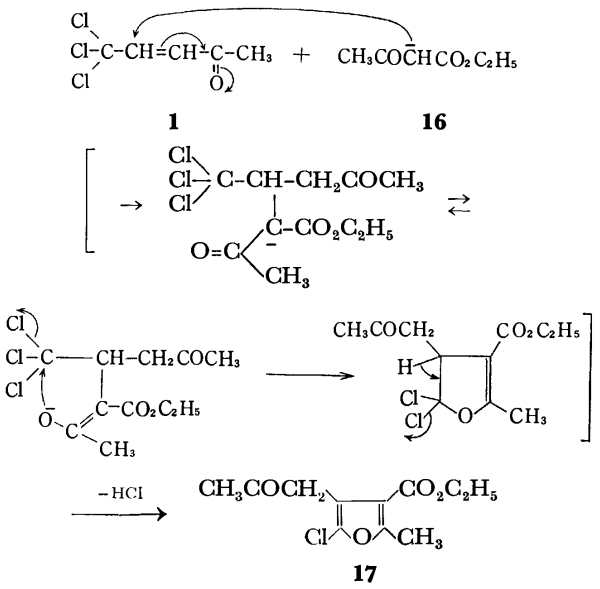
gate addition (**15**). Neither acetic acid nor phenol reacted with **1**, but a 90 wt% aqueous acetic acid caused hydration of **1** to give chloralacetone.[3b] On the contrary, both acetate and phenolate anions were found to be sufficiently nucleophilic to produce the compounds **15g** and **15h** when their conjugate acids were used as solvents. Diethyl sodiomalonate and **1** in dry ether afforded 5,5,5-trichloro-4-diethoxycarbonylmethyl-2-pentanone (**15f**) in a 70% yield indicating that the conjugate addition of the carbanion of sodiomalonate had occurred. These compounds, with the exception of **15h**, exhibited no IR absorption bands in the region of 1600—1700 cm^{-1}. On treatment of **1** with diethylamine in ether a resinous material was obtained with deposition of a large amount of diethylammonium chloride.[12b]

The reaction of **1** with ethyl sodioacetoacetate **16** gave exclusively a crystalline solid melting at 62°C in a 18% yield to which the structure 2-chloro-3-acetonyl-4-ethoxycarbonyl-5-methylfuran (**17**) was assigned on the basis of elemental analysis and spectral data. No other distillable products were obtained. Formation of the furan compound can be best interpreted by setting up a mechanism where the ambident anion of **16** attacks β and γ carbons of **1** as shown in Scheme 6, although no intermediate compounds have

been isolated as yet.



Scheme 6.

Experimental

The melting points and boiling points are uncorrected. Elemental analyses were carried out by Mr. Eiichiro Amano. Analytical determinations by glpc were performed on a Hitachi K-53 model gas chromatograph (3 mm o.d. × 1 m, 10% Apiezon Grease L on Chromosorb W), and the preparative isolations by glpc were performed on a Yanagimoto GCG-550T model gas chromatograph (3 mm o.d. × 2.25 m, 10% Apiezon Grease L on Chromosorb W). The mass spectra were obtained with a Hitachi RMS-4 model mass spectrometer. We are indebted to Mr. Hiroshi Ooyama, Hokko Chemical Industry Co., Ltd., and Mr. Heizan Kawamoto and Miss Hiromi Ootani for the NMR measurements. The microanalyses and spectral measurements were performed on the samples collected by glpc or tlc.

Ketones **1** and **3** were prepared by the methods reported previously.[1] Tertiary alcohols, **7c**, **7d**, and **7e**, listed in Table 1, were prepared in the same way as in the preparation of **7a**. Rearranged tertiary alcohols **8b**, **8c**, and **8d** were prepared by Procedure B. Epoxides **9b** and **9c** were obtained from **8b** and **8c** in the same ways as **9a**.

*trans-6,6,6-Trichloro-3-methyl-4-hexen-3-ol (**7a**).* Ethylmagnesium bromide (**5a**) was prepared from 5.5 g (0.05 mol) of ethyl bromide and 1.4 g (0.055 g atom) of magnesium in 20 m*l* of dry ether. The unreacted magnesium metal was recovered by decantation. To a solution of 7.5 g (0.04 mol) of **1** in 25 m*l* of dry ether was added dropwise the ethereal solution of **5a** with stirring at −30°C. The reaction mixture was stirred for additional 2 hr at −20—−10°C, and then acidified with 10% HCl. The ethereal layer was washed with water and dried over Na_2SO_4. Removal of the solvent gave 6.4 g (74% yield) of the residual oil containing **7a** as the major product. Tlc analysis[13] showed two spots at the R_f values 0.73 and 0.84, in a ratio of 9 : 1. Pure sample of **7a** with the R_f value of 0.73 was obtained by preparative tlc[14]: IR (cm^{-1}, liquid) 3425 (OH), 2980, 1620 (C=C), 735 (C–Cl); NMR (CCl_4) δ 0.91 (t, 3H, J=7.2 Hz, $-CH_2\underline{CH_3}$), 1.30 (s, 3H, $>C(OH)\underline{CH_3}$), 1.58 (q, 2H, J=7.2 Hz, $-\underline{CH_2}CH_3$), 2.02 (s, 1H, –OH), 6.08 and 6.38 (dd, 2H, J=14.5 Hz, *trans* $-\underline{CH}=\underline{CH}-$).

dl-erythro-*4,6,6-Trichloro-5-hexen-3-ol (**8a-I**).* The Grignard reagent **5a** was prepared from 4.9 g (0.045 mol) of ethyl bromide, 1.1 g (0.045 g atom) of magnesium in 30 m*l* of dry ether. The ethereal solution of **5a** was added dropwise to a solution of **3** (6 g, 0.032 mol) in 24 m*l* of dry ether with stirring at −30°C. The stirring was continued for additional 1 hr at −30——20°C. The reaction mixture was then acidified with 10% HCl. The ethreal layer was washed with water, dried over Na_2SO_4. The removal of the solvent gave 5.3 g (76%) of the crude product. Tlc analysis of this product showed two spots with the R_f values 0.61 and 0.72, in a ratio of the spot areas 20 : 1, corresponding to the R_f values of **8a** (R_f=0.61) and **3** (R_f=0.72).[15a] The analytical sample of **8a-1** was obtained by preparative tlc:[15b] IR (cm^{-1}, liquid) 3475 (OH), 3040, 2980, 1720, 1620 (C=C), 740 (C–Cl); NMR (CCl_4) δ 0.93 (t, 3H, J=7.2 Hz, $-CH_2\underline{CH_3}$), 1.27 (s, 3H, $>C(OH)-\underline{CH_3}$), 1.61 q, 2H, J=7.2 Hz, $-\underline{CH_2}CH_3$), 2.50 (s, 1H, –OH), 4.57 (d, 1H, J=9.0 Hz, $=CH-\underline{CH}Cl-$), 6.1 (d, 1H, J=9.0 Hz, $Cl_2C=\underline{CH}-$). Glpc analysis[7] of the purified sample indicated that it consisted of two components with the retention times, 13.5 min (**8a-II**, 1 part) and 14.6 min (**8a-I**, 9 parts).

Found: C, 38.58; H, 5.26%. Calcd for $C_7H_{11}Cl_3O$: C, 38.65; H, 5.10%.

*The Epimeric Mixture of 4,6,6-Trichloro-5-hexen-3-ol (**8a**).* *Procedure A*: Distillation of hexenol **7a** (5.4 g, 0.025 mol) afforded the crude product of **8a** (4.4 g, 81%), bp 88—90°C/6 mmHg; IR (cm^{-1}, liquid) 3475 (OH), 3040, 2980, 1720, 1620 (C=C), 920, 740 (C–Cl); NMR (CCl_4) δ 0.95 (t, 3H, J=7.2 Hz, $-CH_2\underline{CH_3}$), 1.14 (s, $>\underline{C}(OH)-\underline{CH_3}$, *threo*) and 1.27 (s, $>\underline{C}(OH)-\underline{CH_3}$, *erythro*) (epimeric mixture, 3H), 1.55 (q, 2H, J=7.2 Hz, $-\underline{CH_2}CH_3$), 1.95 (s, 1H, –OH), 4.59 (d, 1H, J=9.0 Hz, $=CH\underline{CH}Cl-$), 6.1 (d, 1H, J=9.0 Hz, $Cl_2C=CH-$). Glpc analysis[7] of this product showed three peaks. The components, retention times (min), and integrated percentages are as follows: 1, 4.7, 2%; 2, 13.5, 55%; 3, 14.6, 43%. Component 1 was identified as **9a** by comparison of its retention time with the authentic sample described in the next section.

Procedure B: The reaction of **5a** with **1** was carried out in the same way as the preparation of the hexenol **7a** using 15 g (0.08 mol) of **1** as the starting material. Distillation of the crude product gave 13.1 g of a clean oil, bp 78—100°C/4 mmHg. Glpc analysis[7] indicated that this fraction contained three components, which were fractionated by preparative glpc and identified by comparison of the IR spectra with those of the authentic samples; peaks (nos), compounds (nos), retention times (min), and the integrated peak areas are: 1, **9a**, 4.7, 14%; 2, **8a-II**, 13.5, 50%; 3, **8a-I**, 14.6, 36%.

Procedure C: The reaction of **5a** with **1** was conducted in a similar manner to Procedure B at room temperature for 24 hr, using 15 g (0.08 mol) of **1** as the starting material.

13) Conditions of tlc: support, silica gel GF_{254} (E. Merk AG, Darmstadt), 0.1 mm; developer, benzene-methanol (9 : 1 v/v); spray reagent, H_2SO_4–$KMnO_4$ (7 : 3 w/w). The spot of **1** on tlc appeared at R_f 0.84.

14) Conditions of preparative tlc: support, silica gel GF_{254} (E. Merk AG, Darmstadt), 1 mm; developer, benzene-methanol (9 : 1 v/v); eluent, acetone.

15) a) Conditions of tlc: support, silica gel GF_{254} (E. Merk AG, Darmstadt), 0.3 mm; developer, *n*-hexane-acetone-chloroform (5 : 1 : 1 v/v). b) The same support (1 mm) and the same developer as above were used. Eluent, acetone.

The ethereal extract of the crude product was distilled *in vacuo*. The results of the glpc analysis of each fractions are as follows:

Fractions (bp, °C/mmHg)	Weight (g)	Compounds detected by glpc[7] (retention times, min)			
		9a (4.7)	unknown (12.2)	**8a**-II (13.5)	**8a**-I (14.6)
I (59—69/12)	2.4	81	1	9	9
II (69—84/5)	3.3	45	20	21	14
III (84—90/5)	1.7	3.5	18	48	30
IV (>90/5)	1.0	—	—	—	—

The last fraction turned white crystals in a cooler. One recrystallization from petroleum ether (bp 45—55°C) gave 0.9 g of white crystals, to which the structure 6,6-dichloro-3-methyl-5-hexene-3,4-diol (**10**) was assigned: mp 81°C; IR (cm^{-1}, nujol) 3300 (OH), 1620 (C=C), 910, 800—650 (C–Cl); NMR ($CDCl_3$) δ 0.9 (t, 3H, J=6.8 Hz, $-CH_2\underline{CH_3}$), 1.20 (s, 3H, $>\overset{OH}{\underset{|}{C}}-\underline{CH_3}$), 1.43 (broad q, 2H, J=6.8 Hz, $-\underline{CH_2}-CH_3$), 2.01 (s, 2H, 2OH), 4.16 (d, 1H, J=9 Hz, $>\underline{CH}OH$), 6.02 (d, 1H, J=9 Hz, $Cl_2C=\underline{CH}-$).

Found: C, 42.40; H, 5.99%. Calcd for $C_7H_{12}Cl_2O_2$: C, 42.23; H, 6.08%.

Procedure D: The reaction of **5a** with **1** was carried out in a similar manner to Procedure C except that excess ethylmagnesium bromide (equivalent to 0.16 mol) was used on 18.7 g (0.1 mol) of **1**. The ethereal extract of the crude product was worked up as usual. The fraction distilling at 44—112°C/5 mmHg was collected and analyzed by glpc.[7] Peaks (nos), retention times (min), and the integrated peak areas are: 1, 2.9, 13%; 2, 4.7, 11%; 3, 7.9, 9%; 4, 10.1, 2%; 5, 12, 5%; 6, 13.5, 27%; 7, 14.6, 21%; 8, 16, 10%. Components 1, 2, 6, and 7 were identified as compounds **13**, **9a**, **8a**-II, and **8a**-I, by comparison of the IR spectra and retention times with those of the authentic samples. Components 3 and 8 were collected by preparative glpc and analyzed. The structure 6,6-dichloro-3-methyl-5-hexen-3-ol (**14**) was assigned to component 3 on the basis of the IR spectrum and analysis: IR (cm^{-1}, liquid) 3450 (OH), 2980, 1612 (C=C), 918, 700 (C–Cl).

Found: C, 46.41; H, 6.75%. Calcd for $C_7H_{12}Cl_2O$: C, 45.92; H, 6.61%.

The structure 6-chloro-3-methyl-5-octene-3,4-diol (**12**), was assigned to component 8: IR (cm^{-1}, liquid) 3400 (OH), 2980, 1615 (C=C), 1460, 904 (=C–H).

Found: C, 55.99; H, 8.59%. Calcd for $C_9H_{17}ClO_2$: C, 56.01; H, 8.89%.

*The Epimeric Mixture of 6,6-Dichloro-3-methyl-3,4-epoxy-5-hexene (**9a**).* Sodium methoxide (1.2 g, 0.022 mol) was added in several portions to a solution of 2.2 g (0.01 mol) of **8a** in 20 ml of dry ether at 0°C. The mixture was stirred at 0°C for 1 hr and then allowed to cool to room temperature. The mixture was poured into 20 ml of water and neutralized with dilute HCl. The ethereal layer was washed with water and dried over Na_2SO_4. After evaporation of the solvent the residual oil was distilled to yield 0.6 g (33%) of **9a**: bp 50—51°C/4 mmHg; IR (cm^{-1}, liquid) 3040 (=C–H and H–C(O)–C<), 2960—70, 1617 (C=C), 1250 (>C(O)–C<), 905, 865, 835, 812, 803, 690—660 (C–Cl); NMR (CCl_4) δ 0.97 (t, J=7.2 Hz, $-CH_2\underline{CH_3}$) and 1.0 (t, J=7.2 Hz, $-CH_2\underline{CH_3}$) (epimeric mixture, 3H), 1.24 (s, $>\overset{O}{\underset{\diagdown\diagup}{C}}-\underline{C}-\underline{CH_3}$, *cis* to $Cl_2C=CH-$) and 1.30 (s, $>\overset{O}{\underset{\diagdown\diagup}{C}}-\underline{C}-\underline{CH_3}$, *trans* to $Cl_2C=CH-$) (epimeric mixture, 3H), 1.35—1.90 (m, 2H, $-\underline{CH_2}CH_3$), 3.28 (d, 1H, J=7.5 Hz, H–C(O)–C<), 5.69 (d, 1H, J=7.5 Hz, $Cl_2C=\underline{CH}-$). Glpc analysis[7] of this product showed two very close peaks (the ratio of peak areas, 1 : 1) at the retention times (min), 4.5 and 4.7.

Found: C, 46.39; H, 5.88%. Calcd for $C_7H_{10}Cl_2O$: C, 46.44; H, 5.57%.

dl-*trans-6,6-Dichloro-3-methyl-3,4-epoxy-5-hexene (**9a**-I).* From 1 g (0.005 mol) of hexenol **8a**-I, treated with sodium methoxide in the same way as in the cyclization of the epimeric mixture (**8a**), 0.6 g (66%) of the glpc[7] pure product (**9a**-I) with the retention time (min) of 4.5 was obtained, oil: bp 62—64°C/6 mmHg; NMR (CCl_4) δ 0.97 (t, 3H, J=7.2 Hz, $-CH_2\underline{CH_3}$), 1.24 (s, 3H, $-\overset{O}{\underset{\diagdown\diagup}{C}}-\underline{C}-CH_3$, *cis* to $Cl_2C=\underline{CH}-$), 1.35—1.80 (broad q, 2H, J=7.2 Hz, $-\underline{CH_2}CH_3$, *trans* to $Cl_2C=\underline{CH}-$), 3.28 (d, 1H, J=7.5 Hz, $\underline{H}-\overset{O}{\underset{\diagdown\diagup}{C}}-\underline{C}-$), 5.69 (d, 1H, J=7.5 Hz, $Cl_2C=\underline{CH}-$). The IR spectrum of the purified sample (liquid) was identical with that of the epimeric mixture **9a**.

*The Epimeric Mixture of 6,6-Dichloro-3-methyl-5-hexene-3,4-diol (**10a**).* A mixture of 0.88 g (0.005 mol) of **9a** (**9a**-I/**9a**-II = *ca.* 1 : 1) and 50 ml of 20% H_2SO_4 was heated with stirring for 1 hr at 50°C. The ethereal extract of the reaction mixture was washed with water, and dried over Na_2SO_4. Removal of the solvent gave 0.5 g (52%) of white crystals (**10a**): mp 69—75°C (two recrystallizations from *n*-hexane); IR (cm^{-1}, nujol) 3300 (OH), 1620 (C=C), 910, 800—650 (C–Cl); NMR ($CDCl_3$) δ 0.94 (t, 3H, J=6.8 Hz, $-CH_2\underline{CH_3}$), 1.10 (s, 1.2H, $-CH_3$) and 1.20 (s, 1.8H, $-CH_3$) (epimeric mixture, 3H), 1.43 (broad q, 2H, J=6.8 Hz, $-\underline{CH_2}-CH_3$), 2.32 (s, 2H, 2-OH), 4.26 (d, 1H, J=9 Hz, $>\underline{CH}OH$), 8.02 (d, 1H, J=9 Hz, $Cl_2C=\underline{CH}-$).

dl-*erythro-6,6-Dichloro-3-methyl-5-hexene-3,4-diol (**10a**-I).* Hydrolysis of **9a**-I (0.57 g, 0.003 mol) carried out as above, afforded 0.34 g (55%) of white crystals exhibiting only one spot in tlc (R_f=0.17):[16] mp 75—82°C (two recrystallizations from *n*-hexane); IR (cm^{-1}, liquid) 3300 (OH), 1620 (C=C), 910, 800—650 (C–Cl); NMR ($CDCl_3$) δ 0.94 (t, 3H, J=6.8 Hz, $-CH_2\underline{CH_3}$), 1.20 (s, 3H, $-CH_3$), 1.43 (broad q, 2H, $-\underline{CH_2}CH_3$), 2.15 (s, 2H, 2OH), 4.26 (d, 1H, J=9 Hz, $>\underline{CH}-OH$), 6.02 (d, 1H, J=9 Hz, =CH–).

*5,5-Dichloro-4-penten-2-one (**13**).* A solution of 9.4 g (0.05 mol) of **1** in 30 ml of dry ether was added dropwise to 1.2 g (0.05 g atom) of magnesium at room temperature under the atmosphere of nitrogen. After being stirred for 2 hr, the mixture was acidified with 10% HCl. The ethereal layer was washed with water, dried over Na_2SO_4, and the solvent was then evaporated. The residual oil was distilled to give 2.2 g (29%) of **13**, oil: bp 51—55°C/5 mmHg; IR (cm^{-1}, liquid) 3050 (=C–H), 1720 (C=O), 1625 (C=C), 910; NMR (CCl_4) δ 2.20 (s, 3H, $-COCH_3$), 3.24 (d, 2H, J=6.75 Hz, $=CH-\underline{CH_2}-$), 6.03 (t, 1H, $=\underline{CH}-CH_2-$); mass spectrum (80 eV) *m/e* (relative intensity) 152 (31), 133 (14), 125 (35), 109 (53), 89 (42), 73 (44), 61 (38), 53 (34), 49 (39), 43 (100).

Found: C, 39,13; H, 3.89%. Calcd for $C_5H_6Cl_2O$: C, 39.25; H, 3.95%.

*Reaction of Ketone **2** with Grignard reagents **5a**, and **5c**.* Working up in the same ways as for **7a**, the reaction of ketone **2** (5 g, 0.02 mol) with **5a** (0.02 mol) gave 5.0 g of a

16) Conditions of tlc: support, Silica gel GF_{254} (E. Merk AG, Darmstadt), 0.2 mm; developer, *n*-hexane–acetone–chloroform (5 : 2 : 1 v/v); spray reagent, H_2SO_4-$KMnO_4$ (7 : 3 w/w).

light yellow oil. Tlc analysis[17] of this oil showed two spots at the R_f values 0.80 and 0.67, in the ratio 1 : 1. Pure sample of phenyl 2-trichloromethylbutyl ketone (**15i**) with the R_f value of 0.80 was separated by preparative tlc,[18] yield 45%; IR (cm^{-1}, liquid) 1692 (C=O), 1603 and 1586 (benzene ring); NMR (CCl_4) δ 0.98 (t, 3H, J=7.5 Hz, $-CH_2-C\underline{H}_3$). 2.0 (m, 2H, $-C\underline{H}_2CH_3$), 3.25 (m, 2H, $-C\underline{H}_2COC_6H_5$), 3.58 (m, 1H, $CCl_3C\underline{H}\langle$), 7.2—8.1 (m, 5H, $-C_6H_5$); mass spectrum (70 eV) (relative intensity) 278 (9, M^+, 3Cl), 206 (19), 120 (80), 105 (100), 77 (74).

Found: C, 51.37; H, 4.69%. Calcd for $C_{12}H_{13}Cl_3O$: C, 51.55; H, 4.69%.

The compound **7d** with the R_f value of 0.67 was similarly separated.

Ketone **2** *(5 g, 0.02 mol) and equimolar amount of* **5c**, worked up in the same ways as for **7a**, gave a mixture of light yellow needles (2.1 g) and a light brown oil (4.9 g). The crystals were separated by filtration and identified as compound **15j**: 125—126°C (from benzene); IR (cm^{-1}, liquid) 1680 (C=O), 1600 (benzene ring); NMR (CCl_4) δ 3.91 (d, 2H, J=6 Hz, $-CH_2CO$), 4.60 (t, 1H, J=6 Hz, $CCl_3C\underline{H}\langle$), 7.2—8.05 (m, 10H, $2C_6H_5$).

Found: C, 59.00; H, 4.12%. Calcd for $C_{16}H_{13}Cl_3O$: C, 58.66; H, 4.00%.

Tlc analysis[17] of the oily filtrate showed four spots at the R_f values 0.31, 0.52, 0.61, and 0.73, in the ratio 1 : 12 : 2 : 1. The spot of **15j** appeared at R_f 0.61. The component with the R_f value of 0.52 was separated by preparative tlc[18] and identified as **7e**.

*5,5,5-Trichloro-4-methoxy-2-pentanone (**15a**).* A solution of 5 g (0.027 mol) of **1** in 80 m*l* of dry methanol was refluxed for 9 hr. Excess methanol was removed *in vacuo*, and the residue, on distillation, gave 3.5 g (60%) of **15a**: bp 78°C/3 mmHg; IR (cm^{-1}, liquid) 1720 (ketone C=O); NMR (CCl_4) δ 2.19 (s, 3H, $-COCH_3$), 2.76 (dd, 1H, J=7.0 and 17.5 Hz, $-C\underline{H}_2COCH_3$), 3.10 (dd, 1H, J=3.7 and 17.5 Hz, $-C\underline{H}_2COCH_3$), 3.68 (s, 3H, $-OCH_3$), 4.24 (dd, 1H, J= 3.7 and 7.0 Hz, $\rangle C\underline{H}OCH_3$).

Found: C, 32.83; H, 4.07%. Calcd for $C_6H_9Cl_3O_2$: C, 32.83; H, 4.14%.

*4,5,5,5-Tetrachloro-2-pentanone (**15b**).* To a solution of 5 g (0.027 mol) of **1** in 30 m*l* of dry ether was passed dry hydrogen chloride gas at 0°C for 24 hr. The solvent was removed *in vacuo*, and the residue, on distillation, gave 5.9 g (98%) of **15b**: bp 87°C/3.5 mmHg; IR (cm^{-1}, liquid) 1720 (ketone C=O) and 790—770 (C–Cl); NMR ($CDCl_3$) δ 2.25 (s, 3H, $-CH_3$), 3.14 (dd, 1H, J=17.4 and 7.9 Hz, $-C\underline{H}_2-CO-$), 3.49 (dd, 1H, J=17.4 and 3.8 Hz, $-C\underline{H}_2CO-$), 4.97 (dd, 1H, J=7.9 and 3.8 Hz, $\rangle C\underline{H}Cl-$).

Found: C, 27.10; H, 2.91%. Calcd for $C_5H_6Cl_4O$: C, 26.82; H, 2.70%.

*5,5,5-Trichloro-4-anilino-2-pentanone (**15c**).* Fifteen grams (0.08 mol) of **1** and 7.4 g (0.08 mol) of aniline were dissolved in 10 m*l* of ether. The mixture was allowed to stand at room temperature for 10 hr, and then at 0°C—−5°C for 24 hr. The resulting solid was recrystallized from ether to afford 21.7 g (98%) of **15c**: mp 45°C; IR (cm^{-1}, nujol) 3320 (NH), 1703 (C=O), 1596 (benzene C=C), 768 and 750 (C–Cl).

Found: C, 47.40; H, 4.35; N, 4.90%. Calcd for $C_{11}H_{12}Cl_3NO$: C, 47.09; H, 4.31; N, 4.99%.

*5,5,5-Trichloro-4-(p-chloroanilino)-2-pentanone (**15d**).* A mixed solution of 15 g (0.08 mol) of **1** and 10.2 g (0.08 mol) of *p*-chloroaniline in 30 m*l* of ether similarly gave 22.8 g of a crude product, which was recrystallized from benzene to afford 21.6 g (90%) of **15d**: mp 115°C; IR (cm^{-1}, nujol) 3230 (NH), 1702 (C=O), 1590 (benzene C=C), 798 and 767 (C–Cl); NMR ($CDCl_3$) δ 2.2 (s, 3H, $-CH_3$), 2.85 (dd, 1H, J=16 and 8.0 Hz, $-C\underline{H}_2COCH_3$), 3.33 (dd, 1H, J=16 and 3.5 Hz, $-C\underline{H}_2COCH_3$), 4.87 (dd, 1H, $\rangle C\underline{H}CH_2COCH_3$), 6.65—7.22 (m, A_2B_2 with strong doublet centered at 6.93, 4H, aromatic).

Found: C, 41.92; H, 3.49; N, 4.13%. Calcd for $C_{11}H_{12}Cl_4NO$: C, 41.94; H, 3.52; N, 4.45%.

*5,5,5-Trichloro-4-phenylmercapto-2-pentanone (**15e**).* To a stirred solution of 10 g (0.053 mol) of **1** in 30 m*l* of benzene was added a solution of 6 g (0.053 mol) of thiophenol in 30 m*l* of benzene at 50°C. After the mixture was stirred at 50°C for 5 hr, the solvent was removed, and the residual solid was recrystallized from petroleum ether (bp 40—55°C) to afford 15 g (95%) of **15e**: mp 58°C; IR (cm^{-1}, nujol) 1720 (C=O), 1580 (benzene C=C), and 780—730 (C–Cl).

Found: C, 44.37; H, 3.56%. Calcd for $C_{11}H_{11}Cl_3OS$: C, 44.39; H, 3.73%.

*5,5,5-Trichloro-4-diethoxycarbonylmethyl-2-pentanone (**15f**).* To a stirred solution of 8.6 g (0.053 mol) of diethyl malonate in 80 m*l* of dry ether, 3.6 g (0.053 mol) of sodium ethoxide was added in several portions, and a solution of 10 g (0.053 mol) of **1** in 10 m*l* of dry ether was added dropwise at 0—5°C. The reaction mixture was stirred at 0°C for 1 hr, finally at room temperature for 1 hr, and then was made weakly acidic with dilute HCl (pH *ca.* 5). The ethereal extract of the organic layer was washed with water and dried over Na_2SO_4. Removal of the solvent left a yellow liquid which, on distillation, gave 13 g (70%) of **15f**: bp 155—157°C/5 mmHg; IR (cm^{-1}, liquid) 1745 and 1730 (C=O), and 790—760 (C–Cl).

Found: C, 41.74; H, 5.20%. Calcd for $C_{12}H_{17}Cl_3O_5$: C, 41.46; H, 4.93%.

*5,5,5-Trichloro-4-acetoxy-2-pentanone (**15g**).* A mixed solution of 1.5 g (0.018 mol) of sodium acetate and 3.4 g (0.018 mol) of **1** in 20 m*l* of acetic acid was refluxed for 30 min. It was diluted with 100 m*l* of water and then extracted with ether. The ethereal extract was washed with water and dried over Na_2SO_4. After recovery of the starting meterial at 94—96°C/20 mmHg, 0.4 g (9%) of the liquid distilling at a higher temperature was collected. Glpc analysis[7] showed it to contain 79% **15g**: IR (cm^{-1}, liquid) 2950, 1760 (acetoxy C=O), 1718 (ketone C=O), 770 (C–Cl).

Found: C, 33.72; H, 3.51%. Calcd for $C_7H_9Cl_3O_3$: C, 33.97; H, 3.66.

*5,5,5-Trichloro-4-phenoxy-2-pentanone (**15h**).* A mixed solution of 3.1 g (0.027 mol) of sodium phenoxide and 5 g (0.027 mol) of **1** in 45 m*l* of phenol was heated with stirring at 100°C for 4 hr. The reaction mixture was poured into a large amount of water and the organic layer was extracted with chloroform. The extract was washed with water and dried over Na_2SO_4. After recovery of chloroform and the starting materials, the fraction distilling at 123—125°C/3 mmHg was collected (1.4 g). Glpc analysis[19] showed it to contain 80% **15h** which was separated by preparative glpc: IR (cm^{-1}, liquid) 3050, 1723 (C=O), 1625 and 1593 (benzene ring), 770, 760, 700; NMR (CCl_4) δ 2.08 (s, 3H, $-COC\underline{H}_3$), 3.05 (m, 2H, $-C\underline{H}_2COCH_3$), 5.36 (dd, 1H, J=

*2-Chloro-3-acetonyl-4-ethoxycarbonyl-5-methylfuran (**17**).* Sodium (2.3 g, 0.1 g atom) was dissolved in 80 m*l* of absolute ethanol with moderate cooling. To the resulting solution was added 13 g (0.1 mol) of ethyl acetoacetate at room temperature with stirring. A solution of 18.7 g (0.1 mol) of **1** in 20 m*l* of absolute ethanol was then added dropwise at 0°C with stirring. After stirring was continued for additional 2 hr at room temperature, 200 m*l* of water was added with cooling. After being acidified with 10% HCl, the mixture was extracted with ether. The ethereal solution was washed with water, dried over Na_2SO_4 and evaporated. The residual oil was distilled at 100—125°C/0.05 mmHg to give 4.4 g (18% yield) of **17**: mp 62°C (*n*-hexane); IR (cm^{-1}, nujol) 1715 (C=O), 1610 and 1577 (furan C=C), 785 (C–Cl); NMR (CCl_4) δ 1.33 (t, 3H, $-CH_2C\underline{H}_3$), 2.12 (s, 3H, $-CO-C\underline{H}_3$), 2.55 (s, 3H, furan $-CH_3$), 3.61 (s, 2H, $-C\underline{H}_2CO-$), 4.29 (q, 2H, $-C\underline{H}_2CH_3$); mass spectrum (80 eV) *m/e* (relative intensity) 246 (4.3), 244 (13), 204 (11), 203 (33), 202 (33), 201 (83), 175 (17), 173 (47), 156 (46), 43 (100).

Found: C, 54.30; H, 5.39%. Calcd for $C_{11}H_{13}ClO_4$: C, 54.00; H, 5.35%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3692—3698 (1972)

The Acid-catalyzed Degradation of Methyl 2,3,4,5-Tetra-*O*-acetyl-α-L-xylo-2-hexulopyranosonate. A Model for the Degradation of L-xylo-Hexulosonic Acid[1]

Kazuaki GOSHIMA, Norihide MAEZONO, and Kanji TOKUYAMA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka, 553

(Received April 15, 1972)

The degradation reaction of L-xylo-hexulosonic acid (**1**) was studied, using methyl 2,3,4,5-tetra-*O*-acetyl-L-xylo-2-hexulopyranosonate (**11**) as a model compound. The degradation of **11** proceeded *via* two pathways, **11**→α,β-unsaturated ketone compound→a furan compound (path a) and **11**→a dihydropyrone compound→further decomposed products (not furans) (path b). The major pathway was path a in benzene and path b in water. The results supported the idea that the acid-catalyzed degradation of L-ascorbic acid (**2**) to furans would not proceed *via* **1**, but directly.

In spite of the long-standing interest in the degradation of L-ascorbic acid (**2**) in acidic solutions, the mechanism for the degradation under anaerobic conditions is still not well understood.[2-6] The reaction may be summarized in two major pathways. One involves the pathway of **2**→L-xylo-hexulosonic acid (**1**)→2-furaldehyde (**3**); the other involves the alternative one of **1**→**2**→**3**. The latter one seemed to have been established by kinetic studies,[5,6] whose validities were confirmed over wide ranges of acid concentration by our reinvestigation.[7] The former pathway, however, has recently received renewed attention because of the isolation of a new intermediate.[4] In this paper, we will attempt to study the behavior of **1** in acidic media when the conversion of **1** into **2** is inhibited. For this purpose, methyl 2,3,4,5-tetra-*O*-acetyl-α-L-xylo-hexulopyranosonate (**11**) was prepared as a starting material. If the pathway of **2**→**1**→**3** is probable, **11** can be converted into furan compounds.

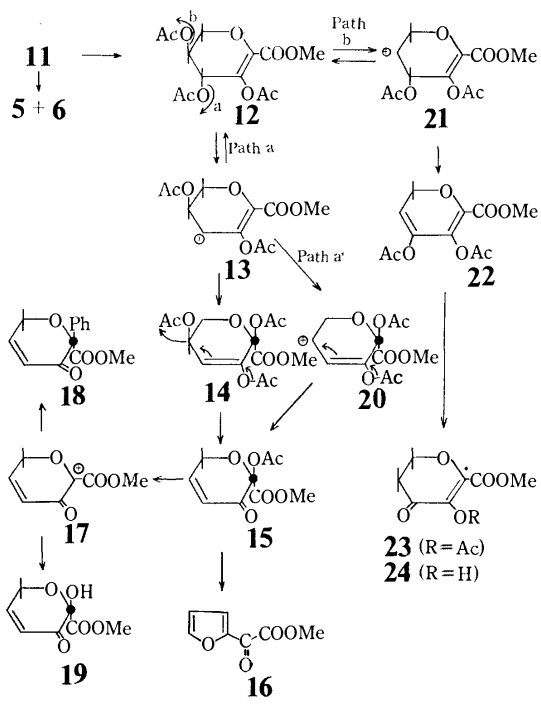

Chart 2.

structure of **11** was confirmed by the large coupling constants among ring-protons in the NMR spectrum.[9]

The heating of **11** in acetic acid–water (1 : 9, v/v) on a boiling-water bath gave no furan compounds. After 7 hr, four products, **5** and three unknown ones, were isolated by preparative thin-layer chromatography, along with the recovery of **11** to some extent. The elemental analysis of unknown products suggested them to be partially hydrolyzed derivatives of **11**; that is, one seemed to be the triacetate of **4** (**6**) and the others, to be diacetates. With **6**, the signals in the NMR spectrum were quite similar to those of **11**, but the multiplet due to H_5 shifted upfield. Therefore, the structure was determined to be methyl 2,3,4-tri-*O*-acetyl-L-xylo-hexulopyranosonate. The structures of diacetates were not determined, but the fact that the acetylation of them gave **11** suggested that they were hydrolyzed products of **11**. The results apparently showed that, in aqueous media, the degradation of **11** proceeded much slower than its hydrolysis; the studies under anhydrous conditions were clearly called for.

When **11** in dry benzene was treated with boron trifluoride-etherate, the reaction smoothly proceeded at a reflux temperature. The preparative thin-layer chromatography of the product gave three compounds **15**, **16**, and **18**, though trace amounts of other components were not isolated in pure states. The UV and IR spectra of **15** and **18** revealed bands indicative of α,β-unsaturated ketone and ester groups. The NMR spectra for ring-protons appeared as an ABXY system, which were similar to those previously reported for 1-*O*-acetyl-2-*O*-methyl-4,5-dideoxy-2,3-hexodiulopyranos-4,5-ene (**34**).[10] The spectra also suggested the presence of one acetoxyl group in **15** and one phenyl group in **18**. Therefore, **15** and **18** were identified as methyl 2-*O*-acetyl-4,5-dideoxy- and methyl 2-*C*-phenyl-2,4,5-trideoxy-2,3-hexodiulopyranosonate-4,5-ene respectively. Both compounds were racemates from optical rotations. The mass spectrum of **16** was identical with that of **3** except for the molecular ion peak (M^+)[11] and the IR spectrum showed the presence of ketone and ester groups. The structure of **16** was thus determined to be 2-methoxalylfuran. This structure was also supported by the NMR and UV spectra.

As **15** corresponded to the intermediates in the degradation of hexoses,[12] the degradation of **11** must proceed *via* the pathway of **11**→**15**→**16**. This idea was supported by the fact that the treatment of **15** in benzene containing boron trifluoride-etherate or in acetic acid–water gave **16**. As a small amount of **18** was also detected in the reaction of **15**, **18** must be formed *via* the pathway of **15**⇄**17**→**18**. The use of 1,2-dimethoxyethane as a solvent instead of benzene inhibited the formation of **18** and retarded the degradation rate. No further degradation of **18** was observed under the reaction conditions employed.

To elucidate the earlier stages of the degradation reaction in benzene, the reaction was performed under milder conditions. When **11** was treated at 60°C, the formation of **15** and a new compound was initially observed. The structure of the new compound was identified as the racemate of methyl 3,4,5-tri-*O*-acetyl-2-deoxy-L-threo-hexulopyranosonate-2,3-ene (**12**) by a comparison of its NMR and IR spectra with those of an authentic sample of **12**. The sample was prepared by a procedure similar to the preparation of 1,3,4,5-tetra-*O*-acetyl-2-deoxy-L-threo-hexulopyranos-2,3-ene (**33**)[10] to be described below. The aceto-bromination[13] of **4** gave a 2-bromo compound (**7**), while the dehydrobromination of **7** with mercuric cyanide in toluene yielded **12**, whose structure was confirmed by spectral data. Signals due to the ring protons of **12** appeared in an ABXY system quite similar to that of **33** in the NMR spectrum[10] and the characteristic band due to a double bond appeared in the IR. As the transformation of **33** to **34** under acidic conditions had already been established, the major pathway of the degradation of **11** was proposed to be **11**→**12**→**15**→**16**.

If the suggested pathway is reliable, the reaction rate (k_2) of **12**→**15** should be larger than that (k_1) of **11**→**12**, since the yield of **12** was very poor. Expectedly, the k_2/k_1 ratio given from the kinetic measurement of both reactions by following the decreases in the respective starting materials polarimetrically was about 15; consequently, it supported the pathway.

The fact that **11** was first isomerized to **12** prompted

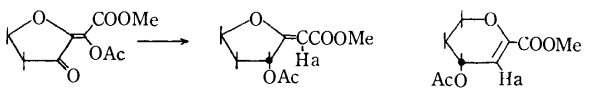
us to study the reaction of **12** as a starting material. First of all, reactions in benzene were examined. The treatment of **12** in boiling benzene containing boron trifluoride-etherate showed a tlc similar to that of the reaction of **11** under similar conditions. From the product, three major products, **15**, **18**, and **16**, and two minor ones were isolated. When the reaction was allowed to continue for longer periods of times, the amounts of **16** and **18** increased at the expense of **15**. This result also supported the existence of the above pathway of **12**→**15**→**16**.

The two minor products were identified, by a comparison of the tlc, as the minor components detected in the above-described reaction of **11** in benzene. One of them was also obtained by the mild hydrolysis of **15** and showed the characteristic bands due to hydroxyl and ester groups in the IR spectrum. Therefore, it was determined to be methyl 4,5-dideoxy-2,3-hexodiulopyranosonate-4,5-ene (**19**), which satisfied the NMR spectrum, too. As the mild hydrolysis of **15** yielded **19**, **19** must be formed by the hydrolysis of **15** during the reaction and/or preparative thin-layer chromatography.

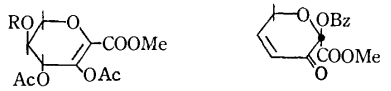


8 **10** **9**

Chart 3.

The other minor product showed the characteristic bands due to three kinds of carbonyl groups and a conjugate double bond in the IR spectrum. The NMR spectrum showed two 3-proton singlets due to one carbomethoxy and one acetoxyl and two 2-proton triplets, which constitute an A_2X_2 system. These spectral data suggested that this compound was a six-membered ring compound (**23**) or a five-membered ring one (**8**). The reduction of the compound with sodium borohydride in pyridine, followed by acetylation, gave a monoacetate. The combined data of spectral and elemental analyses, which showed the presence of one acetoxyl, one carbomethoxy and a double bond, suggested that the monoacetate was **9** or **10**. The signal due to Ha (see Chart 3) appeared as a doublet (J=5 Hz). As the Ha signal of **9** should appear as a doublet, and that of **10** as a singlet, the monoacetate was determined to be **9**; consequently, the parent compound must be **23**. The spectral data of analogus compounds also supported this conclusion.[14,15] The formation of **23** was very interesting. Although kojic acid and maltol are formed *via* enolone intermediates,[16] **23** was not derived from an enolone compound, **15**, and was not converted into furan derivatives on further acid treatments.

Chart 2 shows a summarized pathway of the reaction of **11**, which involves an initial 4→2 migration[10,17] of the acetoxyl group at C_4 of **12** (**11**→**12**→**13**→**14**→**15**→**16**, path a) and an initial elmination of the acetoxyl group at C_5 of **12** (**11**→**12**→**21**→**22**→**23**, path b). The racemization of **12** during the reaction supported the presence of the equilibrium among **12**, **13**, and **21**. In path a, the possibility of the 5→2 migration of the acetoxyl group (**11**→**12**→**13**→**20**→**15**→**16**, path a') could not be excluded, judging from the facts described below.



25: R=H
26: R=Bz

27

Chart 4.

The partial deacetylation of **12** under milder conditions, followed by benzoylation, gave 5-benzoate (**26**). The fact that the H_5 signal of a partially-deacetylated compound (**25**) appeared more in upfield than that of **12** supported the structures of **25** and **26**. The reaction of **26** under conditions similar to the above reaction afforded **15**, **16**, **18**, and **27**. The new product, **27**, was identified as the benzoyl analog of **15** by spectral and elemental analyses, and its formation suggested the existence of the 5→2 migration (path a').

It was difficult to study the degradation of **11** in aqueous media, since the hydrolysis of **11** was more rapid than the degradation. On the other hand, as **12** was established to be the initial intermediate in benzene, the reaction of **12** in acetic acid-water was carried out.

When **12** in water containing 10% acetic acid was heated on a boiling-water bath for 6 hr, multispots were detected in the tlc. From the chloroform extract of the product, three major components, **23**, **24**, and **25**, were isolated. Proof of the structure of the unknown compound, **24**, was provided by acetylation, which gave **23**. Among many minor components, **3** and **16** were successfully isolated. The water layer was evaporated to dryness. When the residue was dissolved in pyridine, the pyridine salt of oxalic acid was precipitated. After the removal of the salt by filtration, the pyridine solution was acetylated with acetic anhydride. The tlc of the product also showed many spots, from which relatively major component, **23**, and two unknown compounds, were isolated in pure states. The compound **23** isolated must naturally exist as **24** in the reaction medium. The NMR spectrum of the one of the unknown compounds showed one 3-proton singlet due to acetoxyl, one 1-proton singlet at a lower field and two 2-proton triplets, which constitute an A_2X_2 system. Therefore, its structure was identified as **32**. This structure was also supported by the UV and IR spectra. The other compound showed the characteristic band due to a carbonyl group in the IR spectrum, but no absorption

maximum in the UV. The NMR spectrum showed two 3-proton singlet due to acetoxyl groups, one 2-proton singlet, and two 2-proton triplets of A_2X_2 system. Its structure was thus determined to be the acetate of 3-deoxy-tetroulose (**30**).

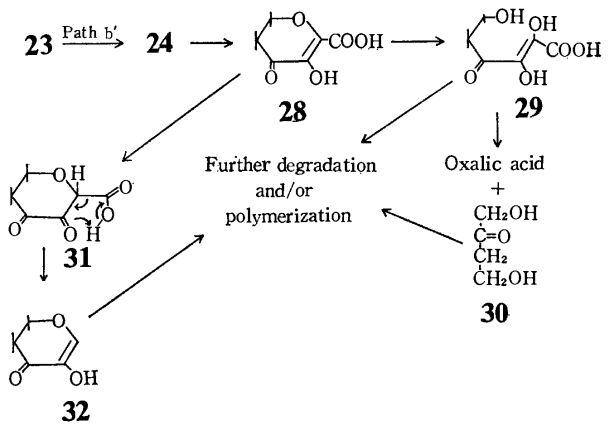

Chart 5.

Only a limited amount of 2-furaldehyde (**3**) was obtained from the degradation of **12** in water, contrary to that in benzene. The degradation in water must proceed mostly *via* path b (Chart 2), followed *via* path b′ (Chart 5). Some minor products were isolated, but their structures could not be determined. They must be further decomposed and/or polymerized products of the various intermediates shown in Chart 5. The possibility of path b′ was experimentally established; the treatment of **23** in acetic acid–water afforded oxalic acid, **30**, and **32**.

It is surprising that the pathway forming furans is not a major one in an aqueous solution. This fact suggested that **1** is not a probable intermediate in the acid-catalyzed degradation of **2**, as the kinetic data have previously presented.[5-7]

Experimental

All the melting points were recorded on a Kofler block and are uncorrected. The NMR spectra were taken in chloroform-*d* with a Varian A-60-A spectrometer using tetramethylsilane as the internal standard. The chemical shifts and coupling constants are expressed in τ unit and Hz respectively. The multiplicities of the signals are abbreviated as follows: s=singlet, d=doublet, t=triplet, q=quartet, and m=multiplet. The UV spectra were observed in 95% ethanol unless otherwise stated, and they are shown in nm. The IR spectra are expressed in cm^{-1}. The optical rotations were determined in a 10-cm microtube in chloroform containing 1% of ethanol, and the concentrations were recorded in percentages. Preparative thin-layer chromatography (ptc) and tlc were performed on a silica-gel plate. The solvent-systems (v/v) used were acetone and benzene (7 : 15, solvent A_1, and 1 : 4, solvent A_2), acetone and chloroform (1 : 9, solvent B), acetone and petroleum ether (1 : 3, solvent C), ether and benzene (7 : 15, solvent D_1, 1 : 3, solvent D_2, and 1 : 7, solvent D_3), ether and petroleum ether (4 : 1, solvent E_1, 7 : 3, solvent E_2, 3 : 2, solvent E_3, 1 : 1, solvent E_4, 2 : 3, solvent E_5, and 1 : 2, solvent E_6), and ether and chloroform (3 : 35, solvent F). The separated materials were developed with iodine vapor and the developed zones were extracted with acetone. Fraction 1 showed the fastest-moving components.

The evaporation of solvents used was carried out under reduced pressure.

*Methyl 3,4,5-Tri-O-acetyl-L-xylo-hexulopyranosonate (**5**).* To a solution of methyl L-xylo-hexulosonate (**4**)[8] (15 g) in pyridine (150 ml), we added, drop by drop, acetic anhydride (15 g) at −50°C. After stirring at the same temperature for 4 hr, the solution was evaporated to dryness. The residue was washed with petroleum ether and then recrystalized from ether, and then from a mixture of ethyl acetate and petroleum ether. The yield was 5.6 g, mp 109.6—112°C. $[\alpha]_D^{25.0}$ −27°(0.995). Found: C, 46.84; H, 5.47%; mol wt, 338. Calcd for $C_{13}H_{18}O_{10}$: C, 46.71; H, 5.43%; mol wt, 334.27.

*Methyl 2,3,4,5-Tetra-O-acetyl-α-L-xylo-hexulopyranosonate (**11**).* *(1) Synthesis*: A mixture of **5** (0.4 g), acetic anhydride (6 ml), and sodium acetate (0.4 g) was stirred at 70°C for 4 hr. The mixture was poured onto ice water, neutralized with sodium bicarbonate, and then extracted with chloroform. The chloroform solution was washed with water, and the chloroform was evaporated. The recrystallization of the residue from ether gave colorless columns; (0.32 g), mp 118—119°C. $[\alpha]_D^{25}$ −73.9° (0.973). NMR H_3, 4.48[d], ($J_{3,4}$ 10), H_4, 4.45[q] ($J_{4,5}$ 9.0), H_5, 4.89[m] ($J_{5,6}$, 6.0, $J_{5,6'}$, 10.5), H_6, 5.88[m] ($J_{6,6'}$, 11.5) $H_{6'}$, 6.46[m]. Found: C, 47.92; H, 5.37%; mol wt, 380. Calcd for $C_{15}H_{20}O_{11}$: C, 47.89; H, 5.36%; mol wt, 376.31.

(2) Reaction with Acetic Acid-water: A solution of **11** (2.0 g) in acetic acid–water (1 : 9, v/v) was heated for 7 hr on a boiling-water bath and then evaporated to dryness. The residual syrup was fractionated by ptc (solvent A_1). From Fraction 1, **11** (102 mg) was recovered. From Fractions 2, 3, and 4, **5** (53 mg), methyl 2,3,4-tri-*O*-acetyl-α-L-xylo-hexulopyranosonate (**6**) (328 mg) and a diacetate of **4** (92 mg) were obtained respectively. From Fraction 5 (the slowest-moving component), another diacetate of **4** (342 mg) was isolated. The acetylation of both the diacetates in a procedure similar to **5** gave **11**. **6**: mp 198—200°C. $[\alpha]_D^{25.0}$ −72.7° (1.019). NMR($CDCl_3$): H_5, 6.1[m]. Found: C, 46.95; H, 5.43%. Calcd for $C_{13}H_{18}O_{10}$: C, 46.71; H, 5.43%. Fraction 4 (a diacetate of **4**); Found: C, 45.02; H, 5.48%. Calcd for $C_{11}H_{16}O_9$: C, 45.21; H, 5.52%. Fraction 5 (a diacetate of **4**); Found: C, 45.22; H, 5.66%. Calcd for $C_{11}H_{16}O_9$: C, 45.21; H, 5.52%.

(3) Reaction in Benzene Containing Boron Trifluoride-etherate: (a) A solution of **11** (0.5 g) in dry benzene (5 ml) containing boron trifluoride-etherate (0.25 ml) was refluxed for 3 hr and then evaporated to dryness. The residual syrup was fractionated to two components by ptc (solvent D_1). The further ptc (solvent E_5) of the fast-moving component gave faster-moving 2-methoxalyfuran (**16**) (40 mg) and slower-moving **18** (4.5 mg). The purification of the slow-moving component by ptc (solvent D_1), followed by recrystallization from methanol, afforded **15** (41 mg). **15**: mp 95—96°C. $[\alpha]_{D.436}^{25.2}$ 0°. UV 226 (ε 9.8×10^3), 335 (ε 7.3×10). IR(KBr) 1762, 1700, 1629 (C=C, C=O). NMR H_4, 3.75[m] ($J_{4,5}$ 10.5, $J_{4,6}=J_{4,6'}$, 2), H_5, 2.88[m] ($J_{5,6}=J_{5,6'}$, 3), $H_{6,6'}$, 5.37[m]. Found: C, 50.65; H, 4.57%. Calcd for $C_9H_{10}O_6$: C, 50.47; H, 4.71%. **16**: mp 42—42.5°C (recryst. from ether and petroleum ether). UV 233 (ε 2.2×10^3), 291.5 (ε 1.2×10^4). IR(KBr) 1740, 1667 (C=C), 1557, 885 (furan).[18] NMR H_3, H_5, 2.2—2.35[m], H_4, 3.37[m] ($J_{3,5}$ 3.5, $J_{3,4}$ 1.5). Found: C, 54.59; H, 3.97%. Calcd for $C_7H_6O_4$: C, 54.55; H, 3.92%. **18**: syrup. $[\alpha]_D^{25.1}$ +2.0° (1.001). UV 296 (ε

18) A. R. Katritzky and L. M. Logowsky, *J. Chem. Soc.*, **1959**, 657.

3.5×10^2). IR(film) 1745, 1685, 1627 (C=O, C=C), 1548 (phenyl). NMR H_4, 3.78^m ($J_{4,5}$ 10.5, $J_{4,6}=J_{4,6'}$ 2.0), H_5, 3.03 ($J_{5,6}=J_{5,6'}$ 3.0) $H_{6,6'}$, 5.35^m, 5.60^m ($J_{6,6'}$ 19.5). Phenyl group (5H), 2.45—2.73^m. Found: C, 67.29; H, 5.45%; mol wt 243. Calcd for $C_{13}H_{12}O_4$: C, 67.23; H, 5.21%; mol wt 232.

(b) A solution of **11** (1.0 g) in dry benzene (10 ml) containing boron trifluoride-etherate (0.05 ml) was kept at 60°C for 10 hr, and then the solvent was removed. The residual syrup was fractionated by ptc (solvent E_1). Fractions 1, 2, 3 (a syrup, 101 mg), and **4** (a crystalline syrup, 692 mg) were obtained, but Fractions 1 and 2 could not be examined because of very limited amounts. The recrystallization of Fraction 3 gave **12** (5 mg), which was identified by a comparison of its IR and NMR spectra with those of an authentic sample (see below). However, the value of optical rotation was very small. [$[\alpha]^{25.0}$ 8° (1.00)]. The preparative thin-layer chromatography of Fraction 4 (solvent E_1) afforded **11** (529 mg) and **15** (40 mg).

Reaction of ***15****.* *(1) In the presence of Boron Trifluoride-etherate*: (a) A solution of **15** (20 mg) in dry benzene (0.5 ml) containing boron trifluoride-etherate (0.025 ml) was refluxed for 30 min and then evaporated to dryness. Preparative thin-layer chromatography (solvent E_1) of the residual syrup gave **16** (9 mg) and **18** (3 mg). (b) A solution of **15** (100 mg) in 1,2-dimethoxyethane (1 ml) containing boron trifluoride-etherate (0.05 ml) was stirred at 80°C for 20 hr and then evaporated to dryness. From the residue, a large part of the starting material was recovered, and **16** (36 mg) was isolated by ptc (solvent E_2).

(2) In Acetic Acid-water: A mixture of **15** (450 mg), acetic acid (0.5 ml) and water (4.5 ml) was heated on a boiling-water bath for 2 hr and then extracted with chloroform. The chloroform layer was evaporated to dryness and fractionated by ptc (solvent E_4). Forty-one miligrams of **16** and 7 mg of **15** were obtained. The water layer was also evaporated to dryness. The treatment of the residue with diazomethane, followed by purification by ptc (solvent E_4), gave **16** (26 mg).

(3) Hydrolysis: A solution of **15** (260 mg) in a mixture of methanol (2 ml), chloroform (2 ml) and one drop of hydrochloric acid was left to stand for 2 days at room temperature, and then the solvent was removed. The purification of the residue by ptc (solvent A_2) gave **19** (61 mg).

*Methyl 2-Deoxy-2-bromo-3,4,5-tri-*O*-acetyl-*L*-xylo-hexulopyranosonate* (***7***).* Acetic anhydride (260 ml) was cooled in an ice and water mixture, and then 60% perchloric acid (1.6 ml) was added, drop by drop. The solution was warmed to room temperature and **4** (64.5 g) was added to the stirred mixture at such a rate, over an about 30-min period, that the reaction temperature was kept between 30 and 40°C. The solution was then stirred at 0°C for 6 hr. Red phosphorus (19.4 g) was added slowly, and then bromine (116 g) was added at such a rate as to keep the reaction temperature below 20°C. Water (26 ml) was added, drop by drop, the continuously stirred and cooled mixture over an about 30-min period to pervent the temperature from rising above 20°C. The reaction mixture was kept for 10 hr at room temperature. Chloroform (60 ml) was added, and the mixture was filtered. The chloroform layer was washed with water, a saturated sodium bicarbonate solution and then water, subsequently it was dried, and the chloroform was removed. The recrystallization of the residue from ether gave needles of **7** (51 g), mp 107—109°C. $[\alpha]_D^{24.0}$ −134.8°(0.994). Found: C, 39.46; H, 4.35; Br, 20.41%; mol wt 400. Calcd for $C_{13}H_{17}O_9Br$: C, 39.28; H, 4.29; Br, 19.89%; mol wt 397.19.

*Methyl 3,4,5-Tri-*O*-acetyl-2-deoxy-*L*-threo-hexulopyranosonate-2,3-ene* (***12***).* *(1) Synthesis*: To a suspension of mercuric cyanide (13.7 g) in dry toluene (300 ml), a dry toluene solution (100 ml) of **7** (21 g) was added. Traces of water were removed by azeotropic distillation with toluene. After it had been refluxed for 10.5 hr with stirring, the reaction mixture was filtered and the filtrate was evaporated. The residue was extracted with chloroform (500 ml) and the chloroform was washed with a 30% potassium iodide solution and then water and dried. The subsequent removal of the chloroform gave a brown syrup. The repeated recrystallization of the syrup from ether gave needles of **12** (8 g), mp 109—111°C. $[\alpha]_D^{21.0}$ +236.9° (0.966). UV 243 (ε 7.6×10^3). IR(KBr) 1780—1720, 1655 (C=O, C=C). NMR H_4, 4.58^m, 5.02^m, H_6 5.60^m, $H_{6'}$ 5.97^m. Found: C, 49.41; H, 5.14%; mol wt 315. Calcd for $C_{13}H_{16}O_9$: C, 49.37; H, 5.10%; mol wt 316.26.

(2) Reaction in Benzene Containing Boron Trifluoride-etherate: A solution of **12** (1.0 g) in dry benzene (10 ml) containing boron trifluoride-etherate (0.5 ml) was refluxed with stirring, and then the solvent was removed. The residue was fractionated by ptc (solvent D_1). Fractions 1, 2, 3, 4, and 5 corresponded to **16**, **18**, **23**, **15**, and **19** respectively. The yields in mg are shown below:

Product	Reaction time			
	1 hr	3 hr	5 hr	13 hr[a]
15	194	157	27	56
18	31	32	41	—
16	22	47	131	115
23	54	46	22	32
19	trace	trace	trace	trace

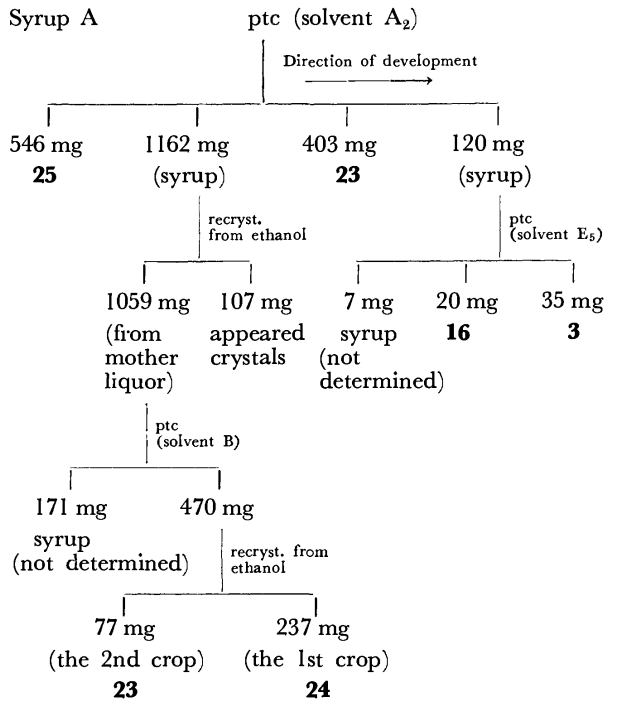
a) As a solvent, 1,2-dimethoxyethane was used instead of benzene.

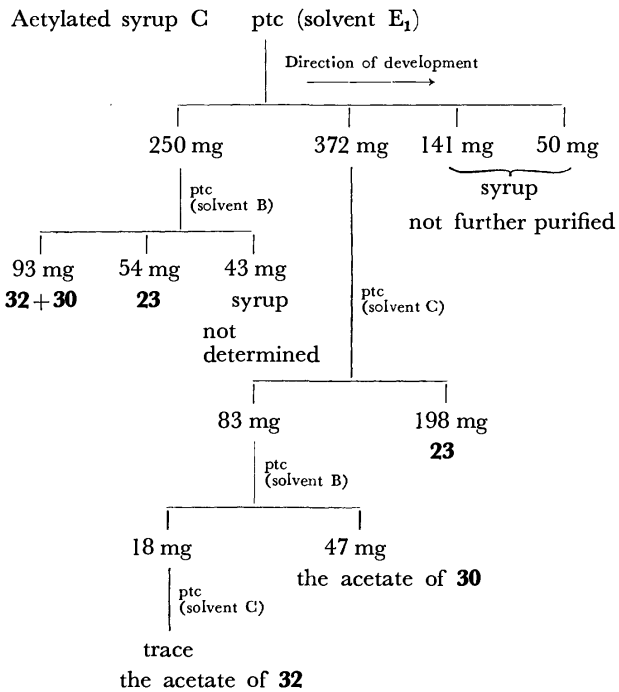
19: mp 48.49°C. $[\alpha]_D^{21.5}$ 0° (1.275). UV 226 (ε 9.9×10^3). IR(KBr) 3450 (OH), 1775, 1688, 1623 (C=O, C=C). NMR H_4, 3.75^m ($J_{4,5}$ 10.5, $J_{4,6}=J_{4,6'}$ 2), H_5 2.85^m ($J_{5,6}=J_{5,6'}$ 3), $J_{6,6'}$ 5.55^m, 5.25 ($J_{6,6'}=19$). Found: C, 48.96; H, 4.66%. Calcd for $C_7H_8O_5$: C, 48.84; H, 4.68%. **23**: mp 149—150°C (recryst. from methanol). UV 285 (ε 8.1×10^3), IR(nujol) 1765, 1739, 1689, 1620 (C=O, C=C). NMR $H_{5,5'}$, 5.22^t ($J_{5,6}$ 7), $H_{6,6'}$, 5.22^t. Found: C, 50.71; H, 4.77%; mol wt 218. Calcd for $C_9H_{10}O_6$: C, 50.47; H, 4.71%; mol wt 214.17.

(3) Reaction in Acetic Acid-Water: A solution of **12** (18 g) in acetic acid (18 ml) and water (162 ml) was heated on a boiling-water bath for 6 hr, and then, after cooling, extracted with chloroform (50 ml×4). The aqueous layer was evaporated to dryness. A syrup (5.9 g) was thus obtained (syrup C). The chloroform layer was washed with a 5% sodium carbonate solution (60 ml×2) and water, and dried, and then the chloroform was removed. An yellow syrup, (2.7 g) was thus obtained (syrup A). The sodium carbonate solution was made acid to pH 2 with hydrochloric acid, and extracted with chloroform, and then the chloroform was removed. Another syrup (520 mg) was thus obtained (syrup B). Syrup A was fractionated by ptc as follows:

The syrup B was purified by ptc (solvent B). Fifty-five milligrams of **24** were obtained.

The syrup C (2.0 g) was dissolved in dry pyridine (10 ml), and the pyridine salt of oxalic acid thus precipitated (424 mg) was collected by filtration. To the filtrate, we added acetic anhydride (10 ml). The solution was kept at room temperature for 2 days and then evaporated to dryness. The residue (2.4 g) was fractionated by ptc as follows:





24: mp 78—79°C. UV 325 (ε 8.3×10^3). Found: C, 48.65; H, 4.65%; mol wt 182. Calcd for $C_7H_8O_5$: C, 48.84; H, 4.68%; mol wt 172.13. **32** (acetate): syrup. UV(MeOH) 267 (ε 7.9×10^3). IR(film) 1760, 1670, 1620 (C=O, C=C). NMR H_1 2.62^s, $H_{4,4'}$ 7.31^q, $H_{5,5'}$ 5.47, CH_3COO 7.81^s (Satisfactory elementary analysis was not obtained). **30** (acetate): syrup. IR(film) 745 (OAc). NMR H_1 5.32^s, $H_{3,4}$ 7.25^t, 5.65^t, CH_3COO 7.85^s, 8.00. Found: C, 51.14; H, 6.35%. Calcd for $C_8H_{12}O_5$: C, 51.66; H, 6.43%.

Reduction of ***23***. To a solution of **23** (3.0 g) in pyridine (70 m*l*) we added finely powdered sodium borohydride (0.8 g) at 0°C under cooling. The solution was allowed to stand for 3 days in a refrigerator, made acidic with acetic acid and then evaporated to dryness. The residue was added to a mixture of acetic anhydride (75 m*l*) and pyridine (75 m*l*), left to stand in a refrigerator for 4 hr, and then evaporated to dryness. The residue was purified by ptc (R_f 0.75, solvent D_2), followed by ptc (R_f 0.31, solvent E_6). Eighty-one grams of **9** were thus obtained as a syrup. UV 240 (7.4×10^3). IR(KBr) 1740, 1640 (C=O, C=C). NMR ACO 7.95^s, COOMe 6.19, H_3 (Ha) 3.89^d ($J_{3,4}$ 5.0), H_4 4.75^m, $H_{5,5'}$ 7.43—8.17^m, $H_{6,6'}$ 5.46—6.14^m. Found: C, 53.40; H, 6.10%; mol wt 210. Calcd for $C_9H_{12}O_5$: C, 53.99; H, 6.04%; mol wt 200.12.

Reaction of ***23*** *in Acetic Acid–Water.* (1) A mixture of **23** (500 mg), acetic acid (0.5 m*l*), and water (4.5 m*l*) was heated on a boiling-water bath. After 3 hr, the reaction mixture was worked up in a manner similar to the one described above. The acetate of **30** (31 mg) was obtained.

(2) A mixture of **23** (2.5 g), acetic acid (2.5 ml) and water was heated on a boiling-water bath for 6 hr, and then worked up in a manner similar to the one described above. The pyridine salt of oxalic acid (10 mg), the acetate of **30** (15 mg), **24** (248 mg), and a mixture of the acetates of **30** and **32** (28 mg) were obtained.

*Methyl 3,4-Di-*O*-acetyl-*L*-*threo*-hexulopyranosonate-2,3-ene (****25****).* To a solution of **12** (4.0 g) in a mixture of dioxane (10 m*l*) and methanol (400 m*l*), we added a solution of potassium carbonate (2.0 g) in water (10 m*l*) below 5°C. After stirring for 30 min, the solution was neutralized by Amberlite IR 120 and then evaporated to dryness. The purification of the residue by ptc (solvent A_2) gave **25** (syrup, 0.68 g). $[\alpha]_D^{22}+222.1°$ (0.592). UV 247.5 (ε 1.47×10^4). IR(CCl_4) 3500 (OH). 1780, 1750, 1675 (C=O, C=C). NMR H_4 5.65^m, H_5 5.9—6.2^m. Found: C, 47.88; H, 5.35%; mol wt 295. Calcd for $C_{11}H_{14}O_8$: C, 48.14; H, 5.15%; mol wt, 274.32.

*Methyl 3,4-Di-*O*-acetyl-5-*O*-benzoyl-*L*-threo-hexulopyranosonate-2,3-ene (****26****).* *(1) Synthesis*: To a solution of **24** (1.0 g) in pyridine (10 ml), we added freshly distilled benzoyl chloride (1.0 g) under cooling, and then the mixture was left to stand overnight in a refrigerator. The solution was poured into water and extracted with chloroform. The chloroform was washed with 5% hydrochloric acid, a 5% sodium carbonate solution and then water, and dried, and the solvent was removed. The residual syrup was purified by ptc (solvent D_3). One gram of **26** was thus obtained, mp 120—121.5°C. $[\alpha]_D^{25.6}+256.7°$ (0.379). UV 233.5 (ε 2.0×10^4), 282 (ε 9.4×10^2). IR(KBr) 1777, 1743, 1727, (C=O, C=C). 1600 (phenyl). NMR H_4 4.41^m, H_5 4.75^m ($J_{4,5}$ 2.5), H_6 5.42^m ($J_{5,6}$ 3.0, $J_{4,6}$ 1.5), $H_{6'}$ 5.86^m ($J_{5,6}=J_{4,6}$ 1.5). Found: C, 57.29; H, 4.92%. Calcd for $C_{18}H_{18}O_9$: C, 57.14; H, 4.80%.

(2) Reaction in Benzene Containing Boron Trifluoride-etherate: A solution of **26** (750 mg) in dry benzene (7.5 m*l*) containing boron trifluoride-etherate (0.4 m*l*) was refluxed for 1 hr and then evaporated to dryness. The residue was fractionated into two fractions by ptc (solvent D_3). The slow-moving compound (270 mg) was **15**. The fast-moving fraction was further fractionated to two fractions and benzoic acid by ptc (solvent F). The fast-moving fraction (18 mg) contained **16** and **18**, and the slow-moving one, **27**. **27**: syrup. $[\alpha]_D^{25.6}$ 0.° UV 232.5 (ε 2.1×10^4), 276 (ε 1.2×10^3). IR (CCl_4) 1778, 1747, 1626 (C=O, C=C). Found: C, 60.99; H, 4.55%. Calcd for $C_{14}H_{12}O_6$: C, 60.87; H, 4.38%.

*Methyl 2-*O*-Benzoyl-4,5-dideoxy-2,3-hexodiulopyranosonate-4,5-ene (****27****).* To a solution of **19** (0.1 g) in pyridine (1 ml) we added benzoyl chloride (0.1 g), and then the mixture was left overnight in a refrigerator. The solution was poured into water and extracted with chloroform. The chloroform

was washed with 5% hydrochloric acid, a 5% sodium carbonate solution and then water; subsequently it was dried, and the solvent was removed. The residue was purified by ptc (solvent E_3), Pure **27** (0.1 g) was thus obtained.

*The Decrease Rates of **11** and **12**.* Kinetic measurements were made polarimetrically. About 0.025 mol of **11** (or **12**) was dissolved in an appropriate volume of benzene in a 250-m*l* volumetric flask at 50°C. Boron trifluoride-etherate (1 m*l*) was added to the solution, and the flask was filled exactly to the mark with benzene at 50°C. Samples (2 m*l*) was quickly transfered to a 5-m*l* volumetric flask containing triethylamine (0.1 m*l*); the flask was filled exactly with methanol at 25° for an optical rotation determination at 578 nm. The decreases in optical activities obeyed first-order kinetics. k_1 (decrease of **11**): 2.9×10^{-5} sec^{-1}; k_2 (decrease of **12**): 4.4×10^{-4} sec^{-1}.

(Received April 24, 1972)

Hydrogenation of 7-methylenebicyclo[3.3.1]nonan-3-one (**1**) over platinum oxide in acetic acid yielded 7α-methylbicyclo[3.3.1]nonan-3α-ol (**2**) as the sole product. Hydrogenation of (**1**) in ethyl acetate afforded 7α-methylbicyclo[3.3.1]nonan-3-one (**3**) as a reduced product and 7-methylbicyclo[3.3.1]non-6-en-3-one (**4**) as an isomerized product. Hydrogenation of **1** over palladium on carbon gave no reduced product but **4** in 100% conversion. Hydrogenation of 7-methylenebicyclo[3.3.1]nonan-3α-ol (**7**) and -3β-ol (**8**) over platinum oxide in acetic acid gave **2** and 7α-methylbicyclo[3.3.1]nonan-3β-ol (**5**), respectively. From studies based on NMR spectroscopy with use of a shift-reagent, it is concluded that the major conformer of **2** and **5** is of chair-boat form. By the equilibration experiment between **2** and **5** using aluminum isopropoxide in isopropyl alcohol at 110°C, the ΔG° value was found to be −2.2 kcal/mol.

In the bicyclo[3.3.1]nonane system, the preferred conformation is believed to possess a double chair form so long as the substitutents at C-3 and/or C-7 have β-configuration. Crystallographic investigation[1] has indicated that the preferred conformation of the bicyclo[3.3.1]nonane skeleton is of a double chair form in spite of the considerable interactions between the α-hydrogen atoms at C-3 and C-7. If this system takes predominantly such a preferred conformation, two interesting phenomena can be expected, a transannular reaction involving C-3 and C-7 and a steric effect toward the reagents. Examples of these phenomena have been given by many workers.[2] We have also reported on some novel transannular reactions.[3]

However, when a bulky substituent at C-3 has α-configuration, the substituted cyclohexane ring has been reported to exist in a boat conformation.[4-10] It has been reported that the symmetrically 3α,7α-disubstituted bicyclo[3.3.1]nonanes exist as an equilibrium mixture or in a double boat conformation owing to the bulkiness of the substituent.[11] The report prompted us to publish our study on the conformation of the compound unsymmetrically disubstituted at C-3 and C-7 both in α-configuration.

Catalytic hydrogenation of 7-methylenebicyclo[3.3.1]-nonan-3-one[12] (**1**) in acetic acid over platinum oxide gave exclusively 7α-methylbicyclo[3.3.1]nonan-3α-ol (**2**). However, hydrogenation in ethyl acetate gave 7α-methylbicyclo[3.3.1]nonan-3-one (**3**) and an isomerized product, 7-methylbicyclo[3.3.1]non-6-en-3-one (**4**). All the reductions gave stereospecifically α-substituted products. The geometry of the reduction product (**2**), in which both the hydroxyl and methyl groups have α-configuration, and that of the epimeric alcohol (**5**) were studied by NMR spectroscopy, analy-

sis of the patterns of the carbinyl protons, and with a shift-reagent developed for expansion of the chemical shift to analyze the signals.[13] The preferred conformations of **2** and **5** were concluded to be of boat-chair form. Equilibration between **2** and **5** with aluminum isopropoxide in isopropyl alcohol at 110°C gave a mixture consisting of 94.6% of **5**. The $\Delta G°$ value was calculated to be −2.18 kcal/mol. This could be considered as the gross energy difference between the two 1,3-diaxial hydroxyl-methylene interactions of the distorted cyclohexanol ring in **2** and the two 1,3-diaxial methylene-hydrogen interactions of the chair form in **5** providing that the methylcyclohexane ring takes a boat form.

Results and Discussion

We have reported two new transannular reactions of **1**; photoreduction[3b] leading to 7-methyl-3-noradamantanol (**6**) and diimide reduction[3d] giving the same compound in high yield. Our observations suggest that **1** might exist predominantly in a double chair form. In such a case, catalytic hydrogenation may be expected to occur exclusively from the less hindered β-face of the substrate (**1**). Actually, when hydrogenation of **1** over platinum oxide was conducted in acetic acid, 7α-methylbicyclo[3.3.1]nonan-3α-ol (**2**) was obtained quantitatively and stereospecifically. The compound was also obtained as a sole product by the hydrogenation of 7-methylene-bicyclo[3.3.1]nonan-3α-ol (**7**)[8] under the same conditions, whereas the same hydrogenation of 7-methylenebicyclo[3.3.1]nonan-3β-ol (**8**)[8] afforded 7α-methylbicyclo[3.3.1]nonan-3β-ol (**5**). Configuration-α of the methyl group in **2** and **5** was established by the oxidation of either **2** and **5** to give the same compound, 7α-methylbicyclo[3.3.1]nonan-3-one (**3**), the structure of which was confirmed by the fact that the compound (**3**) differs from the known 7β-methylbicyclo[3.3.1]nonan-3-one (**9**)[14] in all respects. The configurational assignments of the hydroxyl groups were not only obvious from the reaction schemes, but were also confirmed by the observation that lithium aluminum hydride reduction of **3** gave a mixture of **2** and **5** in the ratio 4 : 1, since the reagent preferably attacks from the sterically less hindered β-face.[15]

Hydrogenation of **1** over platinum oxide in ethyl acetate gave 7α-methyl ketone (**3**) as the reduced product together with **4** resulting from the migration of the double bond. When this reaction was allowed to proceed to completion, **4** was converted slowly but exclusively into **3**. When the amount of the catalyst was reduced (0.01 mol ratio), **3** and **4** were obtained in the ratio 3 : 2. The structure of **4** was assigned on the basis of IR, NMR, and elemental analysis. The reaction was followed by glc, which shows that at 50% hydrogenation, **4** was already formed together with **3**, and when the reaction was allowed to proceed further the amount of **3** increased at the expense of **4**. Pure sample of **4** afforded **3** when allowed to react for an extended period under the same conditions. This shows unamibiguously that hydrogenation and isomerization compete in the reaction of **1** under neutral conditions. When **1** was refluxed in ethanol under an atmosphere of nitrogen for 24 hrs, an isomeric mixture (**1** : **4**=2 : 1) was obtained. Attempted hydrogenation of **1** over palladium on carbon in ethanol failed and resulted in the complete isomerization into **4**.

Several workers[4-7] concluded from analysis of the NMR patterns corresponding to the carbinyl proton in the bicyclo[3.3.1]nonan-3-ols (**10**, **11**, **13**), that in the β-ols the major conformer is of a double chair form but in the α-ols the cyclohexanol ring exists in a boat form as a more stable conformer. In the same way, the conformation of the cyclohexanol rings of the two epimers (**2** and **5**) were studied by analysis of the patterns of the carbinyl protons by the first order approximation. The coupling constants obtained are shown in Table 1 with the values of the analogous compounds. The values for the β-ol (**5**); $J_{3,2\beta}$=11.4 and $J_{3,2\alpha}$=5.3 Hz indicate that the cyclohexanol ring exists in a normal chair form with an equatorial hydroxyl group as compared with the other β-ols. The values obtained for α-ol (**2**), $J_{3,2\beta}$=6.1 and $J_{3,2\alpha}$=1.1 Hz, differing from the other α-ols in the boat form, indicate that the cyclohexanol ring takes a chair ar-

14c	α,α	6.0	12.0	boat-boat	11

a) Time-averaged values for the boat-chair equilibrium.

rangement with an axial hydroxyl group. It was reported[16] that in ring A of steroids where the ring is known to be in a regular chair form, the vicinal coupling constants are $J_{3,2\beta}\cong 10$ and $J_{3,2\alpha}=5.5\pm1.0$ Hz for the axial carbinyl proton and $J_{3,2\beta}=J_{3,2\alpha}=2.0$—3.2 Hz for the equatorial carbinyl proton. If we take the above steroid system as a model, the chair form of the cyclohexanol ring of **2** might be supposed to undergo a considerable distortion[17] or make some contribution of the boat form to the conformational equilibrium, since flattening would increase one dihedral angle (between $H_{(3)}$ and $H_{(2)}$) and decrease the other from their initial values of 60°, which would lead to a somewhat smaller value for $J_{3,2\alpha}$ and a slightly larger value for $J_{3,2\beta}$.

The deduction that the cyclohexanol rings in **2** as well as **5** take chair conformations seems curious from the fact that the boat form is preferred in all α-ols (**10a**, **11a**, **13a**). To obtain information on the conformation, the NMR spectra of **2** and **5** were studied with NMR shift-reagent, $Eu(DPM)_3$, which complexes with a lone pair to induce shift mainly dependent on Eu–H distances.[13]

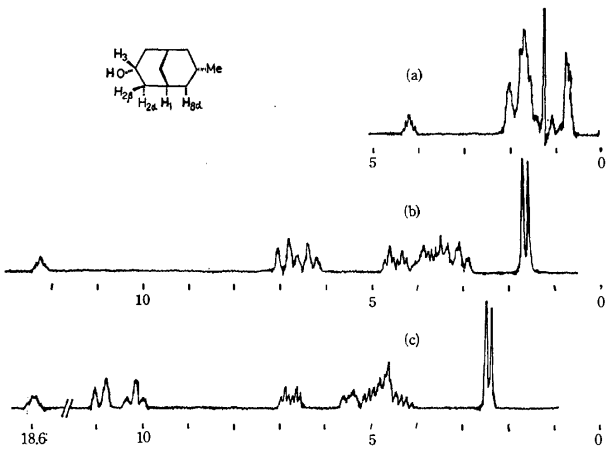

Fig. 1. 60 MHz NMR spectra of **2** in $CDCl_3$ containing $Eu(DPM)_3$ (a) 0, (b) 0.3 and (c) 0.5 in mole ratio.

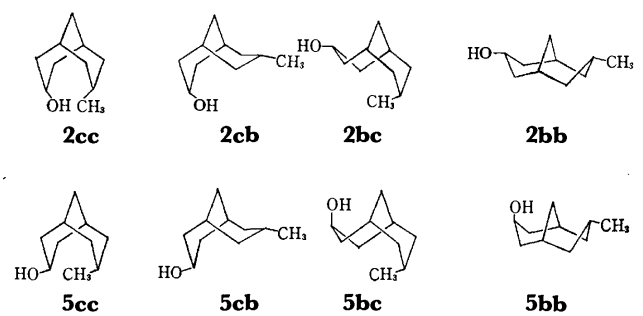
NMR spectra of **2** before and after addition of 0.3 and 0.5 molar ratio of $Eu(DPM)_3$ are shown in Fig. 1. In spectrum 1(b), the one-proton signal at the lowest field (δ 12.3) is assignable to the carbinyl proton from chemical shift. On irradiation at this signal position, the doublet of triplets (2H) centered at δ 4.60 collapsed into a two-line multiplet, indicating that the signal is assignable to $H_{(2\beta)}$. However, the assignment of β-configuration mainly rested in the generality[18] that the extent of deshielding to the protons located vicinally to a hydroxyl group appears to be dependent upon the magnitude of the dihedral angle between the hydroxyl group and the proton under consideration when $Eu(DPM)_3$ was used as the shift-reagent. The two-line multiplet (2H) centered at δ 6.96 is assigned to $H_{(2\alpha)}$ from the spacing of 15 Hz which is included also in the signal of $H_{(2\beta)}$ and from the mutual decoupling experiments (although imperfect) with the $H_{(2\beta)}$. From these signals in the spectra 1(b) and 1(c), the following coupling constants were obtained; $J_{3,2\beta}=6.0$, $J_{3,2\alpha}<1.5$, $J_{2\alpha,2\beta}=15$, $J_{1,2\beta}=4.5$ Hz. They are reasonably coincident with those obtained earlier. The three-line multiplet (2H) centered at δ 6.44 (Fig. 1 (b)) is assigned to $H_{(8\alpha)}$ because the signal collapsed into a two-line multiplet upon irradiation at the point where maximum coalescence of the three-proton



Formula 2.

16) L. M. Jackman and S. Sternhell, "Application of Nuclear Magnetic Resonance Spectroscopy in Organic Chemistry," 2nd Ed., Pergamon Press, Oxford (1969), p. 283.

17) As a rough approximation the deviation ($\Delta\Phi$) from the normal value (60°) was calculated as 22.5°, using the relationship $J=J_0\cos^2\Phi-C$(Ref. 16, p. 281) provided that $J=3.0$ Hz at $\Phi=60°$(taking the value for the equatorial carbinyl proton as a model (see text)), $J=6.1$ Hz at $\Phi=60°-\Delta\Phi$, and $J=1.1$ Hz at $\Phi=60°+\Delta\Phi$ were adopted.

18) P. V. Demarco, T. K. Elzey, R. B. Lewis, and E. Wenkert, *J. Amer. Chem. Soc.*, **92**, 5737, 5739 (1970).

doublet (δ 1.70) of the methyl protons could be obtained. It should be noted that the signal due to $H_{(8\alpha)}$ is more shifted than that of $H_{(2\beta)}$ indicating that $H_{(8\alpha)}$ proton is situated in the proximity of the hydroxyl group; this requires the cyclohexanol ring to be in the chair form and the methylcyclohexane ring in the boat form (2cb). The observation that the methyl protons are shifted much less than the other protons at both concentrations of $Eu(DPM)_3$ (1(b) and 1(c) in Fig. 1) suggests that the methyl group is located farthest from the hydroxyl group; this requires the methyl cyclohexane ring to be in a boat conformation since the cyclohexanol ring exists in a chair form.

NMR spectra of the epimeric alcohol (**5**) before and after addition of $Eu(DPM)_3$ in molar ratios 0.3 and 0.5 are shown in Fig. 2; the decoupling experiments and the assignments were made on spectrum 2(c).

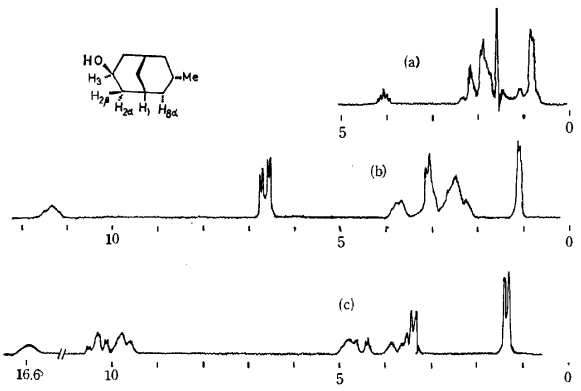


Fig. 2. 60 MHz NMR spectra of **5** in $CDCl_3$ containing $Eu(DPM)_3$ (a) 0, (b) 0.3 and (c) 0.5 in mole ratio.

From the change in pattern induced by the irradiation at the one-proton signal at δ 16.60 due to the carbinyl proton ($H_{(3)}$), the signals (each 2H) centered at δ 10.35 and 9.76 are assigned to $H_{(2\alpha)}$ and $H_{(2\beta)}$. Judging from these signals especially on the irradiation at the $H_{(1)}$ signal (the assignment is mentioned later), the following values are obtained; $J_{3,2\beta}=11$, $J_{3,2\alpha}=ca.$ 5, $J_{2\alpha,2\beta}=14$, $J_{1,2\beta}=3$ Hz. They indicate that the cyclohexanol ring is in a normal chair conformation with an equatorial hydroxyl group. In contrast to the case of **2**, the infiuence of the shift-reagent on the $H_{(8\alpha)}$ (tentatively assigned to the signal at δ 4.55) is much smaller. The smallest effect of the shift-reagent on the methyl protons implies that the methylcyclohexane ring takes a boat form since the cyclohexanol ring exists in the chair form.

Another assignable proton in **2** and **5** is the bridgehead proton ($H_{(1)}$) judging from the featureless broadening due to the six vicinal protons and from the decoupling experiments irradiated at the $H_{(2\beta)}$ signals. The signals have a half-height width of 18.1 Hz (δ5.5) in spectrum 1(c) for **2** and 18.5 Hz (δ4.8) in 2(c) for **5**.

The deduction that in **2** and **5** the methylcyclohexane ring exists in a boat conformation might be supported by the following fact. In the IR spectra of the bicyclo[3.3.1]nonane systems which exist predominantly in a double chair conformation, the stretching and bending bands are known to appear in the abnormally higher-frequency region (near 2990 and 1490 cm^{-1}, respectively.)[19] Both **2** and **5** show no such absorption. This indicates the relief of strain due to the double chair form.

In consequence, the actual preferred conformer for **2** is the boat-chair form (**2cb**) with a considerable flattening of the cyclohexanol ring or with a slight contribution of the double boat form (**2bb**) to the equilibrium.[20] In the case of **5** the boat-chair form (**5cb**) is predominantly preferred.

Two 1,3-diaxial methyl-methylene interactions may be estimated roughly to be 2×3.7 kcal/mol and two 1,3-diaxial hydroxyl-methylene interactions to be $2\times$ 2.4 kcal/mol.[21] This is why the methylcyclohexane ring (**2cb**), and not the cyclohexanol ring (**2bc**), takes the boat conformation in order to avoid the repulsion in the double chair form (**2cc**). A similar deduction is derived for **5** since the two 1,3-diaxial hydrogen-methylene interactions are estimated to be 2×0.85 kcal/mol.

The ΔG° values for the equilibration between **10a** and **10b**,[6] and **12a** and **12b**[9] have been reported to be -2.5 and -2.7 kcal/mol, respectively. Since the β-isomer exists predominantly in the double chair form and the α-isomer in the chair-boat form and the substituents in both cases have equatorial arrangement, the ΔG° values can be ascribed to the energy difference of the structural change between the double chair and chair-boat forms. It is thus interesting that in **2** the double boat conformation **2bb** is not preferred over **2cb** although the former does not possess the two 1,3-diaxial methylene-hydroxyl interactions which are present in the latter.

The ΔG° value for the equilibration between **2** and **5** was found to be -2.18 kcal/mol by the equilibration starting from either **2** or **5** with aluminum isopropoxide in isopropyl alcohol at 110°C. Since the cyclohexanol rings in **2** and **5** exist in the chair form, contrary to reported cases, this value can be supposed to be the free energy difference dependent on the axial-equatorial nature of the hydroxyl group. Since two 1,3-diaxial hydroxyl-methylene interactions may be estimated to be 2×2.4 kcal/mol or somewhat smaller and two hydrogen-methylene interactions as 2×0.85 kcal/mol,[21] the energy difference would be about 3.1 kcal/mol. Agreement with the experimental value is considered to be reasonably satisfactory.

Experimental

All the melting and boiling points are uncorrected. IR spectra were recorded on a Shimadzu IR-27C spectrometer, and NMR spectra were obtained with a JEOL C-60H spectrometer in $CDCl_3$ and CCl_4 solutions using tetramethyl-

silane as an internal standard. Mass spectra were recorded with a Hitachi RMS-4 mass spectrometer with a nominal ionizing energy of 70 eV and a source temperature of 150°C. Glc analyses and separation were carried out on a Shimadzu GC-4APT using a 3 mm×3 m column with 15% polyethylene glycol on Chromosorb W (60/80 mesh) operating at 150°C with helium flow rate 40 ml/min. Microanalyses were carried out by Mrs. K. Fujimoto.

7-Methylenebicyclo[3.3.1]nonan-3-one (**1**),[12] 7-methylenebicyclo[3.3.1]nonan-3α-ol (**7**)[14] and -3β-ol[14] were prepared according to the published methods. Tris(dipivalomethanato)europoium(III), Eu(DPM)$_3$, was prepared in a similar manner to the method of Eisentraut[22]; mp 189.5—190°C (lit,[23] mp 190—191°C).

Hydrogenation of ***1*** *over Platinum Oxide in Acetic Acid.* A solution of **1** (300 mg) in acetic acid (20 ml) was hydrogenated over platinum oxide (70 mg) for 20 hr. The catalyst was removed by filtration and the filtrate was neutralized with aqueous sodium bicarbonate solution and extracted with ether. The extract was dried (Na_2SO_4) and evaporated. The residue was purified by sublimation to give 293 mg (95%) of **2**, mp 101—102°C. Found: C, 77.70; H, 11.99%. Calcd for $C_{10}H_{18}O$: C, 77.86; H, 11.76%. IR (KBr): 3252, 2903, 1455, 1368, 1119 cm^{-1}; IR (CCl_4): 2908, 1461 cm^{-1}. NMR ($CDCl_3$): δ 0.85 (d, CH_3), 1.34 (s, OH), 4.15 (m, $H_{(3)}$). MS: *m/e* 154 (M^+).

Hydrogenation of ***7*** *over Platinum Oxide in Acetic Acid.* Platinum oxide (8 mg) in 3 ml of acetic acid was added to a solution of **7** (50 mg) in 3 ml of acetic acid, and the mixture was stirred under an atmosphere of hydrogen for 24 hr. After the same work-up as described above, 46 mg (92%) of **2** was obtained.

Hydrogenation of ***8*** *over Platinum Oxide in Acetic Acid.* A sample of **8** (45 mg) in acetic acid (6 ml) was hydrogenated for 16 hr over 10 mg of platinum oxide. After the usual work-up, sublimation of the residue *in vacuo* afforded 43 mg (95%) of **5**. Found: C, 77.97; H, 11.92%. Calcd for $C_{10}H_{18}O$: C, 77.86; H, 11.76%. IR (KBr): 3274, 2923, 1462, 1375, 1059 cm^{-1}; IR (CCl_4): 2925, 1466 cm^{-1}. NMR($CDCl_3$): δ 0.84 (d, CH_3), 1.59 (s, OH), 3.97 (m, $H_{(3)}$). MS: *m/e* 154 (M^+).

Oxidation of ***2*** *and* ***5*** *into* ***3***. To a solution of a complex prepared from chromic trioxide (600 mg) and pyridine (950 mg) in 20 ml of dichloromethane was added 100 mg of **2** in 3 ml of dichloromethane. The mixture was treated as described by Ratcliffe.[24] After the usual work-up, sublimation gave the ketone (**3**), mp 42.5—43.5°C in 90% yield. The same treatment of **5** also afforded **3** in almost the same yield. Found: C, 78.87; H, 10.77%. Calcd for $C_{10}H_{16}O$: C, 78.89; H, 10.59%. IR(KBr): 1704, 1379, 1354, 1087 cm^{-1}. MS: *m/e* 152 (M^+).

Hydrogenation of ***1*** *over Platinum Oxide in Ethyl Acetate.* A solution of **1** (100 mg) in 11 ml of ethyl acetate was hydrogenated for 2 days over 20 mg of platinum oxide. Removal of the catalyst and evaporation of the solvent gave a mixture of **3** and **4** in the ratio 4.5 : 1. Prolonged reaction (4 days) gave **3** exclusively. Hydrogenation of **1** (4.9 g) over a small amount of platinum oxide (100 mg) for 4 days gave a mixture of **3** and **4** in the ratio 3 : 2. Isolation of **3** and **4** was carried out by preparative glc, followed by sublimation and distillation, respectively. **3** was also isolated from the mixture by recrystallization three times from methanol at −65°C, mp 42.5—43.5°C. Ketone (**3**) was identical with the one obtained above by oxidation of **2** and **5** (spectroscopic data and mixed mp).

The analytical sample of **4**, bp 106—107°C/11 mmHg, showed single peak in glc analysis. Found: C, 79.69; H, 9.35%. Calcd for $C_{10}H_{14}O$: C, 79.69; H, 9.35%. IR (liquid): 3010, 1713, 1376, 1358 cm^{-1}. NMR(CCl_4): δ 1.64 (s, CH_3), 5.41 (d, =C–H). MS: *m/e* 150 (M^+).

Isomerization of ***1***. A solution of **1** (100 mg) in 8 ml of ethanol was stirred overnight over 20 mg of 5% palladium on charcoal under hydrogen atmosphere. Removal of the catalyst and evaporation of the solvent gave **4** in 100% conversion. A solution of **1** (100 mg) in 5 ml of ethanol was refluxed under vigorous stirring for 24 hr over 20 mg of platinum oxide under nitrogen atmosphere. After removal of the catalyst and evaporation of the solvent the residue was found to consist of 33% of **4** and 67% of **1** by glc analysis. A similar treatment over palladium on charcoal instead of platinum oxide gave no isomerization product and led to the recovery of the starting material.

Hydrogenation of ***4***. A solution of 60 mg of **4** in 5 ml of ethyl acetate was hydrogenated for 80 hr over 10 mg of platinum oxide. The usual work-up quantitatively gave **3** as the sole product.

Lithium Aluminum Hydride Reduction of ***3***. A solution of **3** (98 mg) in 6 ml of ether was added dropwise to a slurry of 32 mg of lithium aluminum hydride in 10 ml of ether under stirring. The reaction mixture was refluxed for 6 hr and then dilute hydrochloric acid was added to destroy the excess hydride. The ethereal layer was dried (Na_2SO_4) and evaporated. The residue was found to consist of **2** and **5** in the ratio 4 : 1 by glc analysis.

Equilibration. Reagents and solvents for equilibration were prepared according to the method described by Eliel.[25] The reaction was carried out in sealed tubes because of sublimation of the substrates.

Equilibration was performed on each 10 mg sample of the alcohols in a mixture of 12 mg of aluminum isopropoxide, 2 ml of acetone and 0.5 ml of isopropyl alcohol at 110°C. The reaction was quenched by pouring the mixture into 1 ml of 0.7 N hydrochloric acid and extracted with petroleum ether (bp 40—60°C). The extracts were dried (Na_2SO_4) and used for glc analysis which showed the equilibrium was established after 20 days. The results are summarized in Table 2.

TABLE 2. EQUILIBRATION BETWEEN **2** AND **5**

Run	Starting substrate	Time (days)	Composition **2** : **5**
1	2	7	9.1 : 90.9
2	2	20	5.4 : 94.6
3	5	7	2.0 : 98.0
4	5	23	5.3 : 94.7

We wish to thank Prof. H. Nozaki for his helpful discussions and encouragement.

Studies on Oxosulfonium Salts. I. Preparation and Physical Properties.[1]

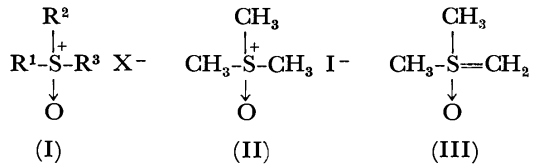
Michio KOBAYASHI, Kenji KAMIYAMA, Hiroshi MINATO, Yukio OISHI, Yoko TAKADA, and Yoshitaka HATTORI

Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo

(Received June, 1 1972)

Methods for preparation and physical properties of oxosulfonium salts have been discussed. Optically active ethylmethylphenyloxosulfonium salts have been prepared and their absolute configurations have been determined.

Very little has been reported on the oxosulfonium salts (I) except trimethyloxosulfonium iodide (II), which can easily be prepared by heating dimethyl sulfoxide and methyl iodide[2,3] and are used as a source of dimethyloxosulfonium ylid (III).



(I) (II) (III)

It seems of interest to investigate the methods for synthesizing oxosulfonium salts containing various substituents, especially the optically active salts containing three different substituents. The results of the investigation carried out in our laboratories will be described in this paper.

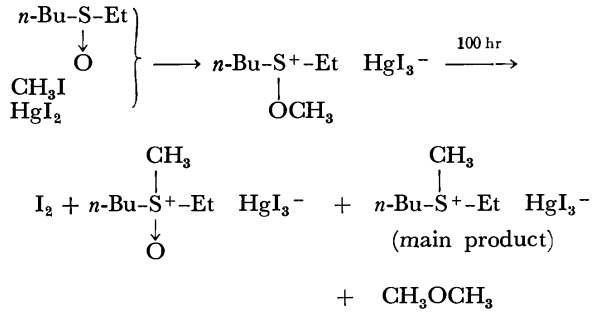
Results and Discussion

(I) Methods for Syntheses of Oxosulfonium Salts. As methods for synthesizing oxosulfonium salts, the following two approaches have been examined.

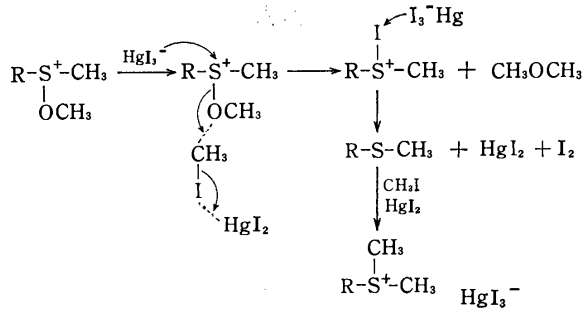
1) Oxidation of Sulfonium Salts: In the literature[4,5] oxidations of sulfonium salts to the corresponding oxosulfonium salts by use of hydrogen peroxide were described, but the products were not isolated as pure substances. In an attempt to examine this route as a possible method for synthesis of oxosulfonium salts, several sulfonium salts were treated with 30% H_2O_2, 87% H_2O_2-CF_3CO_2H, $PhCO_3H$-MeCN, NaOBr, HNO_3, Cl_2-CH_3CO_2H and PhIO under varied conditions, but no oxosulfonium salts were found. These results indicate that oxidation of sulfonium salts is not likely to be a general method for synthesizing oxosulfonium salts.

2) Alkylation or Arylation of Sulfoxides: In contrast with the very easy *S*-methylation of dimethyl sulfoxide, alkylation (alkyl groups larger than methyl) of dimethyl sulfoxide or methylation of dialkyl sulfoxides is very difficult. It was stated in the literature[6] that alkylations did not take place, but the reason why oxosulfonium salts were not formed was not discussed and what happened instead was not described.

When *n*-alkyl bromides or chlorides and sulfoxides were heated at 100°C for several days, no reaction took place. When a mixture of dialkyl sulfoxides or aryl sulfoxides and methyl iodide was refluxed for one day, almost no reaction took place. However, when mercury(II) iodide was added the reaction was greatly accelerated, but an NMR study indicated that the first step is the *O*-alkylation instead of the *S*-alkylation; the oxosulfonium salt must arise by subsequent rearrangement of the *O*-alkylated product or reaction of the unchanged sulfoxide with the *O*-alkylated product. At the same time a great amount of the corresponding sulfonium salt was always formed, and iodine and dimethyl ether were found as by-products. A typical example is shown below.



A plausible mechanism for the formation of the sulfonium salt is expressed as follows.



Since the solubilities of sulfonium salts and oxosulfonium salts are similar, their separation is difficult. However, repeated recrystallizations (more than a dozen times) from tetrahydrofuran-ether or alcohol can separate the two salts. Sulfonium salts are always the main product, and the yields of oxosulfonium salts are very low.

In the reaction between *p*-substituted phenyl methyl sulfoxides and methyl iodide-mercury iodide, considerable substituent effect was observed; the reaction was very slow with the sulfoxides containing electron-withdrawing substituents. With the *p*-bromophenyl

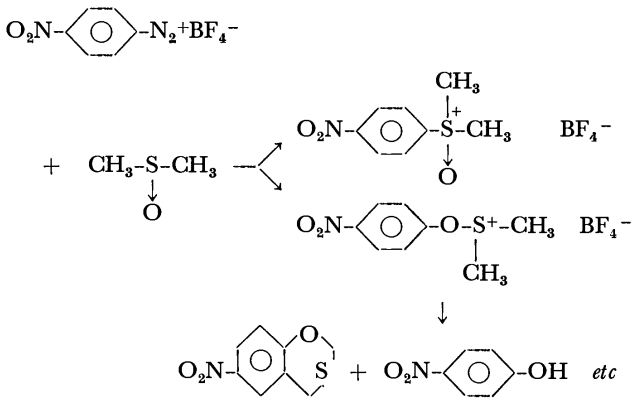
methyl sulfoxide, formation of the oxosulfonium salt was detected after 100 hr of refluxing. With the *p*-nitrophenyl methyl sulfoxide it was detected after 300 hr of refluxing, and the maximum yield after longer refluxing was below 1%.

When such powerful alkylating agent as trimethyl- or triethyloxonium tetrafluoroborate was used, only *O*-alkylation took place.[7]

Although sulfoxides generally do not react with aryl halides, heating a mixture of dimethyl sulfoxide and an anhydrous aryldiazonium salt results in the formation of an aryldimethyloxosulfonium salt,[8] but the main reaction was *O*-arylation and the maximum yield of oxosulfonium salts was 20%. Since substituted benzenediazonium salts are generally more stable than the non-substituted salt, higher temperature was used for their decomposition and the yields were lower (for the *p*-nitro salt, the yield was about 1%).



In the literature, it was described that the reaction among dimethyl sulfoxide, phenol and dicyclohexylcarbodiimide yields the *O*-phenylated dimethyl sulfoxide, which changes into 1,3-oxathian.[9]

(II) Physical Properties. 1) *Solubilities*: Oxosulfonium salts are soluble in acetone, acetonitrile, tetrahydrofuran, trifluoroacetic acid, hot methanol or hot ethanol, and insoluble in benzene, ether, chloroform, or carbon tetrachloride.

2) *Infrared Spectra*: Oxosulfonium salts show a strong absorption ($\varepsilon\sim300$) at 1220—1240 cm^{-1} due to their S–O stretching. The wave number of this absorption is approximately equal to the average of the wave numbers of the symmetric and asymmetric stretching of the S–O bond of the sulfones (1220 cm^{-1}) or that of the sulfoximines (1220—1240 cm^{-1}). This suggests that the double bond character of the S–O bond of oxosulfonium salts is similar to those of sulfones and sulfoximines, and much stronger than that of sulfoxides (1050 cm^{-1}).

The ν_{S-O} of *p*-substituted dimethyl phenyl oxosulfonium salts changes with the substituents, and a Hammett relationship was found to hold between $\Delta\nu$ and σ^+ values, as shown in Table 1.

TABLE 1. ν_{S-O} OF *p*-X-C_6H_4-$\overset{+}{S}(Me)_2$ HgI_3^- (O)

X	ν_{S-O} (in MeCN)
CH_3O	1238
CH_3	1240
H	1242
Br	1243
NO_2	1245

3) *NMR Spectra*: Oxosulfonium salts show the S^+—CH_3 signals at δ 4—4.5 and the S^+—CH_2—signals at δ 5. Since the corresponding methyl and methylene signals of sulfonium salts are observed at higher magnetic fields (by 0.5 ppm), these signals can be used for detection and quantitative determination of oxosulfonium and sulfonium salts. Changes of the methyl signals of *p*-substituted dimethylphenyloxosulfonium salts are shown in Table 2. A Hammett relationship was found to hold between $\Delta\nu$ and σ^+ values.

TABLE 2. NMR METHYL SIGNALS OF *p*-X-$C_6H_4\overset{+}{S}(Me)_2$ HgI_3^- AND *p*-X-$C_6H_4\overset{+}{S}(Me)_3$ HgI_3^- (O)

(in acetone-d_6)

X	Oxosulfonium Salts	Sulfonium Salts
CH_3O	δ 4.35	δ 3.50
CH_3	4.40	3.51
H	4.43	3.57
Br	4.47	3.59

(III) Reactions. 1) *Alkylation by Use of Oxosulfonium Salts*: Oxosulfonium salts can alkylate reactive anions. The reaction of dimethylphenyloxosulfonium ion with sodium *p*-toluenesulfinate gave methyl *p*-tolyl sulfone exclusively, and no methyl *p*-toluenesulfinate was found. When dimethylphenyloxosulfonium ion was heated with sodium iodide in acetone, the oxosulfonium ion was readily demethylated and converted to methyl phenyl sulfoxide.

The results of a detailed investigation on these S_N2 type reactions with nucleophiles will be described in a separate paper.

2) *Oxidation by Use of Oxosulfonium Salts*: Since an oxosulfonium ion contains an extra oxygen compared with a sulfonium ion, it may be expected to act as an oxidizing agent under some conditions. However, when a mixture of an oxosulfonium salt and benzyl alcohol, cyclohexanol, or *sec*-butyl alcohol was heated at 120—140°C, no oxidation to carbonyl compounds was observed. Neither hydroiodic acid nor zinc and hydrochloric acid reacted with oxosulfonium salts at room temperature. These findings indicate again that the S–O bond of an oxosulfonium salt is as strong as that of sulfones.

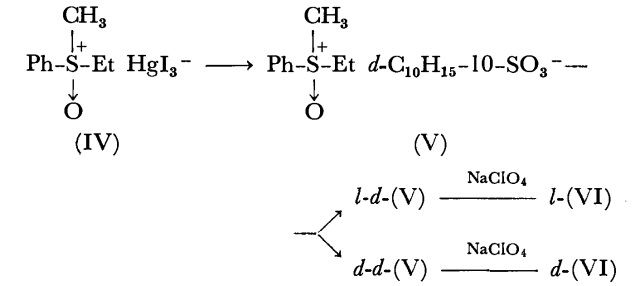
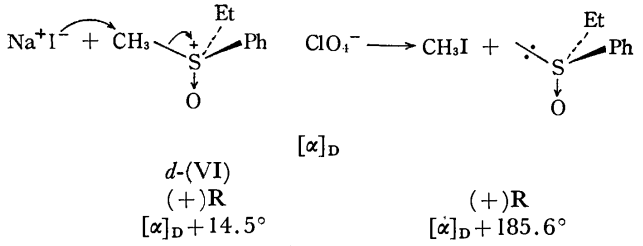
(IV) Optical Resolution.[10] Trimethyloxosulfonium ion was shown to possess a tetrahedral structure,[11] and the oxosulfonium ions containing three different substituents must be resolvable to a pair of enantiomers.

Ethylmethylphenyloxosulfonium mercuritriiodide (IV) was converted to its *d*-camphor-10-sulfonate (V), which was separated to *d-d* crystals (mp 142—143.5°C) and *l-d* crystals (mp 125—126°C) by repeated recrystallizations from acetone.



A solution of the *d-d*(V) or *l-d*(V) in acetone–water (1 : 1) was then passed through an anion-exchange resin which had been treated with aqueous sodium perchlorate solution. Recrystallization from ethanol yielded the *d*-perchlorate (VI) (mp 79.0—79.5°C, $[\alpha]_D^{32}+14.5°$, *c* 5.52, acetone) and the *l*-perchlorate (mp 79.0—79.5°C, $[\alpha]_D^{30}-14.3°$, *c* 4.61, acetone).

The absolute configuration of the *d*- and *l*-perchlorate (VI) were determined by conversion into the corresponding sulfoxides. From the *d*-perchlorate, the *d*-sulfoxide was obtained. Since Mislow and his co-workers have established that *d*-alkyl aryl sulfoxides possess the R-configuration,[12] the *d*-sulfoxide obtained here must also possess the R-configuration.



Since demethylation of the ethylmethylphenyloxosulfonium ion proceeds by S_N2 attack of iodide ion on the methyl group, not the sulfur atom, the stereochemistry of the sulfur atom must be retained during this demethylation. Therefore, the *d*-ethylmethylphenyloxosulfonium ion must also have the R-configuration.

These findings establish the following assignments for absolute configuration of the oxosulfonium ions.

Experimental

Materials. Ethyl phenyl sulfoxide was synthesized by oxidation of the corresponding sulfide with 30% H_2O_2 in acetone at 25—30°C for one week.[13] Bp 102—110°C/5 mmHg, IR, ν_{S-O} 1040 cm^{-1}.

Synthesis of Ethylmethylphenyloxosulfonium Mercuritriiodide (IV). After a mixture of mercury(II) iodide (11.0 g, 24.2 mmol) and methyl iodide (15 m*l*) was stirred in a 50 m*l* flask for 0.5 hr, ethyl phenyl sulfoxide (10.0 g, 64.6 mmol) was added. After nitrogen was bubbled through the mixture for 45 min, the mixture was refluxed under nitrogen for 65 hr. Then the excess methyl iodide was evaporated and the unchanged sulfoxide was removed with ether. When the reddish brown oil obtained was washed with ether several times, crude crystals were obtained, which gave yellow plates upon recrystallizations from methanol. Yield, 8.7 g (17.7%); mp 94—95°C; IR, 1240, 1210, 750 cm^{-1}; NMR, δ 1.54 (t, 3H), 4.37 (s, 3H), 4.58 (q, 2H), 8.10 (m, 5H).

In this reaction, a considerable amount of ethylmethylphenylsulfonium mercuritriiodide is formed. When the amount of methyl iodide relative to the amount of the sulfoxide is smaller, the yield of the sulfonium salt is greater. The reaction conditions described above are the optimum ones on the basis of the results of many experiments. When mercury(II) iodide was not added, no reaction takes place.

Optical Resolution. After *d*-10-camphorsulfonic acid (14.0 g, 60.0 mmol) and silver oxide (16.8 g) were let to react in acetonitrile (50 m*l*) for 7 hr, the excess silver oxide was filtered. To this acetonitrile solution of silver 10-camphorsulfonate, a solution of (IV) (45 g) in acetonitrile (60 m*l*) was added drop by drop at room temperature, and the AgI and HgI_2 were filtered. After the acetonitrile was removed under reduced pressure, water (100 m*l*) was added to the residue and the insoluble materials were filtered off. Complete removal of water from the aqueous layer by use of a vacuum pump gave colorless crystals of (V); Yield, 18.6 g (80.8%); $[\alpha]_D^{33}+25.6°$ (c 8.32, EtOH); IR, 1730, 1210, 1190, 1170 cm^{-1}; Anal. Calcd. for $C_{19}H_{28}O_5S_2$: C, 56.97; H, 7.05; Found: C, 56.64; H, 6.80%.

When fractional recrystallization of (V) (18.6 g) from acetone was repeated for 7 times, crystals of *d-d*-(V) were obtained; 3.1 g (33%); mp. 142—143.5°C; $[\alpha]_D^{33}+39.7°$ (c 2.90, EtOH). After the mother liquor was concentrated and the crystals initially formed were removed, the filtrate was further concentrated. When the crystals thus obtained were fractionally recrystallized six times, crystals of *l-d*-(V) were obtained; 1.07 g (12%); mp. 125—126°C; $[\alpha]_D^{32}+11.6°$ (c 4.66, EtOH).

Preparation of Ethylmethylphenyloxosulfonium Perchlorate (VI). After about 2 *l* of an aqueous sodium perchlorate solution was passed through a column of ion-exchange resin (Amberlite IRA 400), *d-d*-(V) (2.7 g) dissolved in a small amount of aqueous acetone was added to the column. Then a 1 : 1 mixture (by volume) of water and acetone was passed through the column. Evaporation of the eluate (about 1 *l*) under reduced pressure gave crystals, which were recrystallized from EtOH–ether; 1.52 g (84%); $[\alpha]_D^{32}+14.5°$ (*c* 5.52, acetone); mp. 79.0—79.5°C; IR, 1240, 1210, 1100 cm^{-1}; Anal. Calcd. for $C_9H_{13}O_5SCl$; C, 40.23; H, 4.88; Found: C, 40.21; H, 4.75%.

From *l-d*-(V) (1.07 g), *l*-(VI) was obtained in a similar manner; 0.63 g (87.2%); $[\alpha]_D^{30}-14.3°$ (c 4.61, acetone); mp. 79.0—79.5°C.

13) R. L. Shriner, H. C. Struck and J. Jorison, *ibid.*, **52**, 2066 (1930).

Reaction between Optically Active (VI) and Sodium Iodide. A mixture of *d*-(VI) (0.276 g, 1.09 mmol) and NaI (0.327 g, 2.18 mmol) in 5 m*l* of acetone was refluxed for 1 hr. Water was added to the mixture, and the sulfoxide was extracted with ether. When the ethereal extracts were dried over anhydrous magnesium sulfate and the ether was removed under reduced pressure, ethyl phenyl sulfoxide was obtained; 86.7 mg (51.3%); $[\alpha]_D^{33}+164.9°$ (*c* 1.7, acetone). When this sulfoxide was purified by column chromatography (Florisil), pure sulfoxide was obtained; $[\alpha]_D^{26}+185.6°$ (c 0.71, acetone); NMR, δ 1.14 (t, 3H), 2.70 (q, 2H), 7.49 (m, 5H). In a similar manner, *l*-(VI) (0.230 g, 0.86 mmol) gave *l*-sulfoxide; $[\alpha]_D^{35}-173.4°$ (c 0.89, acetone).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3706—3710 (1972)

Asymmetric Hydrogenation of the C=N Bond. A Study of the Controlling Factors on the Stereoselectivity

Takao YOSHIDA and Kaoru HARADA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka
**Institute for Molecular and Cellular Evolution, University of Miami, Coral Gables, Florida, U. S. A.*

(Received June 24, 1972)

Asymmetric catalytic hydrogenation of Schiff bases, *i. e.*, *N*-(methylbenzylidene)-α-methylbenzylamine and *N*-(ethylbenzylidene)-α-ethylbenzylamine, using 10% palladium hydroxide on charcoal was studied to elucidate the steric course of the reaction. Effects of temperature, solvent, pressure, the amount of the catalyst, and ratio of the *syn* and *anti* isomers on the asymmetric hydrogenation were investigated. Temperature, solvent, the amount of the catalyst were found to be factors which controlled the stereoselectivity of the reaction. The hydrogenation of *N*-(methylbenzylidene)-α-methylbenzylamine always gave a higher asymmetric yield than that of *N*-(ethylbenzylidene)-α-ethylbenzylamine. Lowering the reaction temperature, lowering the polarity of the solvent, and decreasing the amount of the catalyst gave higher stereoselectivities in the hydrogenation reactions.

Studies of the hydrogenolytic asymmetric transamination of Schiff bases between keto acids or their esters and optically active amines have been reported.[1] For the possible steric course of this type of asymmetric hydrogenation, a chelation hypothesis was postulated to explain the experimental results. Solvent and temperature effects were studied to support this hypothesis.[1d,e,f]

Prelog and Scherrer studied the asymmetric hydrogenation of optically active esters of β-methylcinnamic acid.[2] They discussed the relation between the conformations of substrates and the configurations of products. They applied the Prelog rule for the homogeneous reactions to explain the steric course of the heterogeneous hydrogenation. Since there are many other experimental results which can not be explained using the Prelog rule, the mechanism of the hydrogenation reaction was investigated. In order to investigate the reaction mechanism we carried out systematic studies of the asymmetric synthesis in which many parameters of the reaction were examined.

Overberger and his co-workers reported that the asymmetric hydrogenation of (*S*)(−)-*N*-(methylbenzylidene)-α-methylbenzylamine gave a product consisting of 88% (*S,S*) isomer and 12% (*S,R*) isomer.[3] They explained the observed result as follows. "There is a very facile equilibrium between the *syn* and *anti* forms and the *syn* isomer, being a higher energy state, is more easily reduced". However, there is no firm experimental basis for this explanation.

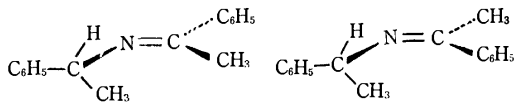

Fig. 1.

In this work *N*-(methylbenzylidene)-α-methylbenzylamine and *N*-(ethylbenzylidene)-α-ethylbenzylamine (I) were used as substrates. Effects of temperature, solvent, pressure, amount of the catalyst, and ratio of the *syn* and *anti* isomers of the substrate on the asymmetric hydrogenation of these substances were investigated.

3) C. G. Overberger, N. P. Marullo, and R. G. Hiskey, *J. Amer. Chem. Soc.*, **83**, 1374 (1961).

Ratios of two diastereoisomers in the products were determined by gas chromatographic separation using a column packed with 1.5% neopentylglycol succinate on chromosorb-W.

Temperature Effect. Temperature showed marked effect on the hydrogenation reaction. This effect is shown in Table 1 and Fig. 2 in which the percentage of DL isomers is plotted against temperature. As the reaction temperature decreased, the stereoselectivity of the reaction increased from 68% at 50°C to 89% at −20°C when R was CH_3 in I, and from 61% at 50°C to 81% at −20°C when R was C_2H_5 in I. The table shown below indicates the time required for the absorption of the equimolar amount of hydrogen. The rate of the hydrogenation reaction slowed down as the reaction temperature decreased from 30°C to −20°C, but at high temperatures the rate slowed down slightly.

React. temp. (°C)	50	40	30	20	10	0	−10	−20
React. time required (min)	14	10	8	8	10	10	22	60

Solvent Effect. Solvent effects are summarized in Table 2 and Fig. 3.

Pressure Effect. Pressure did not show any significant effect as shown in Table 3. Only a 5% increase in stereoselectivity was observed when the pressure was changed from 1 to 10 atm.

Effect of Amount of Catalyst. The amount of the catalyst was also found to be the one of the factors that controlled stereoselectivity. As the amount of the catalyst decreased, the DL-isomer ratio was increased as shown in Table 4.

Effect of syn-anti *Ratio of Substrate.* It was found that the ratio of the *syn* and *anti* forms of substrates was changed after redistillation. The *syn* and *anti* forms reached an equilibrium if they were allowed to stand for a few days at room temperature. In this experiment the substrates which had different ratios of *syn* and *anti* forms were hydrogenated in methanol and benzene. As shown in Table 5, the ratios of the products were not affected by the *syn* and *anti* ratios of the substrates.

In Table 6 the isomer ratio of the product during the reaction is shown. From the fact that the amine produced did not affect the stereoselectivity of the hydrogenation of the substrate secondarily during the reaction, it appears that the hydrogenated substrate desorbed rapidly from the active surface of the catalyst and exchanged with the unreacted substrate.

TABLE 1. TEMPERATURE EFFECT[a]

Substrate	C_6H_5–C(=N–CH(C_6H_5)–CH_3)–CH_3 (*S*)(−)		C_6H_5–C(=N–CH(C_6H_5)–C_2H_5)–C_2H_5 (±)

b) Ratios were determined by the gas chromatographic separation of two diastereoisomers.
c) Ratios were determined by measuring optical rotations of distilled products.

We propose the following reaction mechanism for the hydrogenation of this type of substrate. The substrate is isomerized rapidly by the catalyst bringing about an equilibration of the *syn* and *anti* isomers. Each isomer is then hydrogenated at a different rate from the least hindered side. This mechanism is supported by the fact that the ratio of the *syn* and *anti* isomers of the substrate does not affect the stereoselectivity of the hydrogenation. The conformation of the substrate on the catalyst which was proposed by

Overberger *et al.*, as shown in Fig. 1, cannot explain the experimental results obtained in this study. In other words the relatively high stereoselectivity would not be expected from the difference in the bulkiness of the hydrogen and methyl groups. If this is the case the stereoselectivity would increase when the methyl group is replaced by the ethyl group.

On the other hand, if we consider that the most populated conformation is the one in which hydrogen is located on the same plane of C_6H_5-C=N, and the

anti isomer (II), being a lower energy state, is readily hydrogenated from the least hindered side, that is, from the side of methyl and ethyl group, the difference in bulkiness of methyl (or ethyl) and phenyl group could induce the relatively high stereoselectivity. And also the lowering of stereoselectivity by replacing the methyl with the ethyl group is reasonable when this conformation is considered. This conformation is shown in Fig. 4.

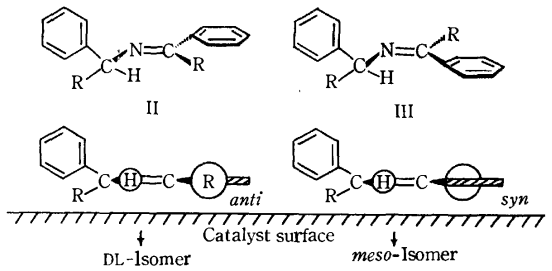

Fig. 4.

Recently the asymmetric reduction of Schiff bases, $R(CH_3)C{=}N{-}CH(CH_3){-}C_6H_5$ (R=Et, *i*-Pr, *t*-Bu), using $LiAlH_4$ and B_2H_6, and also the catalytic reduction using palladium hydroxide on charcoal were reported by Charles *et al.*[4] They discussed the steric course of the reaction and concluded that the conformation of the substrate at the transition state would be the one represented in Fig. 5. Interestingly their proposed substrate conformation on the catalyst is the same as we proposed.

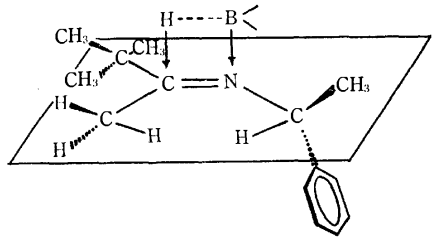

Fig. 5.

The temperature effect could be explained as follows. At low temperature the hydrogenation of the *anti* isomer (II), which is more stable in the preffered conformation, takes place much faster than that of the *syn* isomer (III), thereby resulting in high stereoselectivity. As the temperature increases, the difference of the hydrogenation rate for both isomers becomes smaller resulting in lower stereoselectivity.

The solvent effect could be explained as follows. When a polar solvent was used, the interaction between the solvent and the substrate is stronger and it causes the adsorptive strength of the substrate to be weaker. Therefore it is reasonable that the stereoselectivity of the reaction is lowered in polar solvents. However an increase in the stereoselectivity was not found in the less polar solvents, benzene and dioxane. The strong interaction between the solvent and the catalyst could possibly explain this result.

4) J. P. Charles, H. Christol, and G. Solladie, *Bull. Soc. Chim. Fr.*, **1970**, 4439.

The small effect of pressure is expected for this type of substrate, because the π-electrons of the C=N bond would conjugate with the π-electrons of the phenyl group. The π-benzyl group would then be adsorbed on the surface of the catalyst resulting in fast *cis*-addition of hydrogen.

The effect of the amount of the catalyst could also be rationalized by the competitive adsorption of the substrate. When the amount of catalyst is small, the more reactive *anti* isomer could be adsorbed faster than the *syn* isomer resulting in higher stereoselectivity.

In earlier work we found that solvents and temperatures could affect the stereoselectivity of the asymmetric hydrogenolytic transamination.[1e,f] For the reaction mechanism, it was proposed that two predominant conformations on the catalyst surface were possible, and under certain conditions, one conformation would prevail over the other. Since *N*-(methylbenzylidene)-α-methylbenzylamine and *N*-(ethylbenzylidene)-α-ethylbenzylamine have only one polar group to be hydrogenated, effects of temperatures and solvents could be expected to be smaller than that observed in earlier work.[1e,f] In fact, experimental results showed that these effects were smaller.

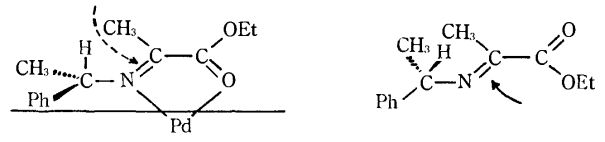

Fig. 6.

We conclude that the factors, which control the stereoselectivity of the asymmetric hydrogenation reaction, are mainly the structure of the molecule, temperature, solvent, and the amount of the catalyst.

Experimental

All melting points are uncorrected. IR and NMR were measured respectively by use of a Jasco IR-S and Varian A-60, T-60.

N-(Methylbenzylidene)-α-methylbenzylamine. This compound was prepared as described by Overberger.[3] bp 104—106°C/0.1 mmHg; (*S*)(−)-isomer, $[\alpha]_D^{25}$ −98.4° (*c* 5.59, benzene).

(S,S)(−)-α,α'-Dimethyldibenzylamine. The same procedure[3] was used to prepare this optically active amine. bp 110°C/1 mmHg $[\alpha]_D^{25}$ −197.3° (*c* 3.65, benzene). The hydrochloride did not melt at temperatures up to 300°C as described in literature. $[\alpha]_D^{25}$ −72.1° (*c* 2.94, ethanol).

N-(Ethylbenzylidene)-α-ethylbenzylamine. This compound was prepared in a similar manner, by using toluene as a solvent with a reaction time of 48 hr. Yield 74%, bp 123—124°C/2 mmHg.

Found: C, 85.57; H, 8.48; N, 5.43%. Calcd for $C_{18}H_{21}N$: C, 86.01; H, 8.42; N, 5.57%.

The optically active (*S*)(−)-isomer showed $[\alpha]_D^{25}$ −41.2° (*c* 4.31, benzene).

(S,S)(−)-α,α'-Diethylbenzylamine. (*S*)(−)-*N*-(Ethylbenzylidene)-α-ethylbenzylamine (3.6 g. 0.014 mol) in ethyl acetate (60 ml) was hydrogenated at room temperature under atmospheric pressure using 10% palladium hydroxide on charcoal as a catalyst. After one molar amount of

hydrogen was taken up, the catalyst was filtered off. The solvent was removed and the residual oil was distilled *in vacuo*. Yield, 2.7 g (74%), bp 115—118°C/1 mmHg.

Found: C, 84.94; H, 9.13; N, 5.63%. Calcd for $C_{18}H_{23}N$: C, 85.32; H, 9.15; N, 5.53%.

Amine obtained (2.7 g, 0.011 mol) was treated with 50 m*l* of 0.5 N hydrochloric acid to crystallize the hydrochloride. The hydrochloride (2.7 g) was collected and recrystallized from water three times. The pure (*S,S*)(−)-α,α′-diethyldibenzylamine hydrochloride melted at 210.5—211.5°C, $[\alpha]_D^{25}$−66.0 (*c* 1.91, ethanol).

Found: C, 74.55; H, 8.48; N, 4.85; Cl, 12.11%. Calcd for $C_{18}H_{24}NCl$: C, 74.59; H, 8.35; N, 4.83; Cl, 12.23%.

Optically pure (*S,S*)(−)-α,α′-diethyldibenzylamine was recovered from this hydrochloride by decomposition with aqueous sodium hydroxide. $[\alpha]_D^{25}$−203.1° (*c* 2.91, benzene).

Hydrogenation of Schiff Bases. Hydrogenation was carried out in a three-necked round bottom flask provided with a thermometer. Stirring was conducted with using a magnetic stirrer. In every reaction, the 10% palladium hydroxide on charcoal was all from the same lot that was prepared by a method described in the literature.[1)]

Temperature Effect. Schiff base (0.004 mol) in methanol (25 m*l*) was hydrogenated using 200 mg of 10% palladium hydroxide on charcoal under atmospheric pressure. Temperature was controlled by cooling the reaction flask in dry ice–methanol bath or by heating in a water bath. The experimental error of temperature was ±1°C in any reaction. The results obtained are listed in Table 1. The diastereoisomeric ratio of the reaction product was determined by gas chromatography directly instead of measuring the optical rotation of the distilled product to avoid possible fractionation during distillation. In fact the values obtained by the latter method did not correspond to the ones obtained by the gas chromatographic method.

Solvent Effect. Schiff bases (0.004 mol) in various solvents (25 m*l*) were hydrogenated using 200 mg of 10% palladium hydroxide on charcoal at 10° and 20° under atmospheric pressure. The results are listed in Table 2.

Pressure Effect. (*S*)(−)-*N*-(methylbenzylidene)-α-methylbenzylamine (0.002 mole) in methanol (25 m*l*) was hydrogenated using 100 mg of 10% palladium hydroxide on charcoal at 25° in a high pressure durable glass tube using a magnetic stirrer for agitation. The pressure was maintained by connecting the hydrogen cylinder at a fixed pressure to the reaction tube. The decrease of the pressure during reaction by consumption of hydrogen was negligible. The results are listed in Table 3.

Effect of Amount of Catalyst. (*S*)(−)-*N*-(methylbenzylidene)-α-methylbenzylamine (0.001 mol) in methanol (12 m*l*) was hydrogenated using 200, 100, 50, 30, and 10 mg of 10% palladium hydroxide on charcoal respectively at 25°C under atmospheric pressure. The results are listed in Table 4.

Effect of syn-anti *Ratio of Substrate.* (±)-*N*-(Ethylbenzylidene)-α-ethylbenzylamine (0.001 mol) in methanol or benzene (12 m*l*) was hydrogenated using 50 mg of 10% palladium hydroxide on charcoal at 14°C under atmospheric pressure. The ratio of *syn* to *anti* isomers of the substrate was calculated from the NMR spectrum in which the integral of the peaks at δ 4.05 (*syn*) and 4.53 (*anti*) ppm for a methine proton was used. The results are listed in Table 5.

Isomer Ratio of the Product during the Reaction. (*S*)(−)-*N*-(methylbenzylidene)-α-methylbenzylamine (0.004 mol) in methanol was hydrogenated using 200 mg of 10% palladium hydroxide on charcoal at 10°C under atmospheric pressure. The reactions were interrupted when the hydrogen consumption equaled 20, 40, 60, 80, and 100% of the theoretical amounts. The real percentages of the reaction completed were determined by the gas chromatographic method. The results are listed in Table 6.

Gas Chromatographic Separation of Diastereoisomers. The separation of (*S,S*)(−)-or (±)-α,α′-dimethyldibenzylamine from *meso* isomer, and (±)-α,α′-diethyldibenzylamine from *meso* isomer was carried out with the use of Shimadzu GC-3AF. Column length; 3 m, liquid phase; Neopentylglycol succinate 1.5% on Chromosorb-W, Column temperature; 155°C, Retention time; (*S,S*)(−)-and (±)-α,α′-dimethyldibenzylamine- 8.5 min, *meso*-α,α′-dimethyldibenzylamine-9.5 min, (*S,S*)(−)-and (±)-α,α′-diethyldibenzylamine- 8.7 min, *meso*-α,α′-diethyldibenzylamine-9.8 min, *N*-(methylbenzylidene)-α-methylbenzylamine-14.5 min, *N*-(ethylbenzylidene)-α-ethylbenzylamine-11.5 min.

The authors wish to express their thanks to Professor T. Shiba of the Department of Chemistry, Osaka University, for his valuable discussions and suggestions.

High Modulus Carbon Fibers from Pitch Materials[1)]

Sugio ŌTANI, Shoji WATANABE, Hosaku OGINO, Kazuo IIJIMA, and Teruyo KOITABASHI

Faculty of Technology, Gunma University, Kiryu, Gunma

(Received July 15, 1971)

Preparation of high modulus carbon fibers from pitch materials was attempted by two methods, stretch-graphitization and the use of a special pitch material composed of highly oriented constituent molecules. It was shown that carbon fiber of high tensile strength and of high modulus can be prepared by stretch-graphitization, and high modulus carbon fiber by heat treatment without stress from the pitch of tetrabenzophenazine. The property of precursor was found to have an important effect on the structure of the fiber.

Studies on the preparation and structure of high modulus carbon fibers have shown that they exhibit a high degree of preferred orientation of the constituent layer planes[2,3)] and heat treatment under stress

is essential for successful preparation.[4,5] Most of these investigations have dealt with PAN(polyacrylonitrile) or rayon precursors. Until 1968, pitch precursor had not been thought to be very suitable material for high modulus carbon fiber.[6] Since then some works[7–11] were reported on the preparation of high modulus carbon fiber from pitch precursor by stretch-graphitization. The results, however, were not so satisfactory as those for rayon or PAN precursors. We found that two kinds of pitch based carbon fibers of which mechanical properties are almost equal to PAN based high modulus or high strength carbon fibers could be prepared by stretch-graphitization using a larger stress and a higher temperature than in the preliminary works.[7–9]

During the course of investigation on carbonization of synthetic aromatic compounds, it was found that tetrabenzo(a,c,h,j)phenazine was converted by heating into a pitch-like material which had a high degree of preferred orientation of the constituent molecules. By use of this material, carbon fiber having a high degree of preferred orientation of constituent layer planes was prepared without stretch-graphitization.

This paper describes improved results obtained by stretch-graphitization method and the evaluation of new method.

Experimental

Carbon Fibers Prepared by Heat Treatment under Stress. Original carbon fibers was two kinds of commercial pitch based carbon fibers with the different purches time. Both fibers with diameters 8—12 μ, named (M) and (S) respectively, were prepared at 1000°C by the Kureha process.[12] No distinct difference was observed in their mechanical properties, X-ray diffraction profiles or densities.

Preparation. Improvement of the design of the furnace gave rise to successful application of higher temperature and greater stress than those in previous work.[7–9] The bundles (2000—3000 deniers) of the original carbon fibers were suspended along the central axis of graphite tube heater. A load (0.5—1.0 g per denier) was attached to the end of the bundle. The bundles were then heated in nitrogen atmosphere from room temperature up to 2800°C at a rate of 270±20°C per minute and then immediately cooled. There was a gradient of temperature along the fiber axis in the tube heater and the homogeneous region at maximum temperature was about 4 cm in length. A change in length of the carbon fibers was clearly observed at temperatures above 1800°C. The amount of change increased with the increase of applied stress.

Mechanical Properties. The preferred orientation of the basal planes in the fibers remarkably increased by the plastic deformation during the course of heating under stress. The diameter of the resulting fibers was 4—7 μ. Their tensile strength was closely related with their orientation parameters as shown in Fig. 1. The orientation parameters are represented by the definition of Brydges and Badami.[13] Mechanical properties were measured with a Tensilon using a cross-head speed of 2 mm/min and 2 cm guage length. The average values were calculated from 30—50 runs. The values of typical PAN based carbon fibers, Royal Aircraft Establishment(RAE) carbon fiber Type I (high modulus type) and Type II (high strength type), measured under the same conditions, are also plotted as control. We see that both pitch based carbon fibers have the same trend as regards relationship between tensile strength and orientation parameter. However, samples from the carbon fiber (M) generally have a higher Young's modulus at a given tensile strength than other samples (Fig. 2).

The carbon fiber with the highest modulus (G-1) has one of about 49×10^2 ton/cm^2. That with the highest tensile strength (G-2) and prepared from carbon fiber (S) has a strength of about 29 ton/cm^2. G-1 might be said to be a high modulus carbon fiber and G-2 a high strength carbon fiber. Other properties of G-1 and G-2 are listed in Table 1.

Carbon Fiber from Highly Oriented Pitch Materials. It is well-known[14,15] that a number of anisotropic spherules are formed in amorphous molten pitch materials by heating at 350—400°C. They grow with rising temperature and/or extending heating period. The mesophase anisotropic spherules are composed of highly oriented polycyclic aromatic plane molecules. Thus the pitch materials heated at 400—500°C generally consist of anisotropic spherules

and amorphous parts.

Tetrabenzo(a,c,h,j)phenazine ($C_{28}H_{16}N_2$) was converted into a pitch-like material by heating, which was optically anisotropic over the whole body (PZ pitch). It can thus be regarded as a typical highly oriented pitch material.

Preparation of Tetrabenzo(a,c,h,j)phenazine. Tetrabenzo-(a,c,h,j)phenazine was synthesized from diaminophenanthrene chlorohydrate and phenanthraquinone according to Schmidt and Söll.[16] The crystal purified by recrystallization from nitrobenzene solution is denoted by PZ-1. Since recrystallization was rather cumbersome, an attempt was made to omit final purification treatment by use of both raw materials purified before synthesis. The crystal thus prepared is denoted by PZ-2, which is essentially the same as PZ-1 except for the presence of about 1% of oxygen, appearance of a very weak absorption band around 1700 cm^{-1} in infrared spectrum and a low melting point of 462°C.

Conversion of Pitch Material from PZ Crystals. PZ-1 was fused into a yellowish brown liquid at 480°C and was converted gradually into a pitch-like material above 550°C and into a coke at 600°C. When PZ-1 was heated in a glass tube under nitrogen, the yields of the coke at 600°C and of PZ recrystallized through vapor phase in the cold part of the tube were respectively 65 and 33 wt%, gaseous product being about only 1 wt%. The spinnable pitch material was formed from PZ-1 by heating at 580°C for 60 min.

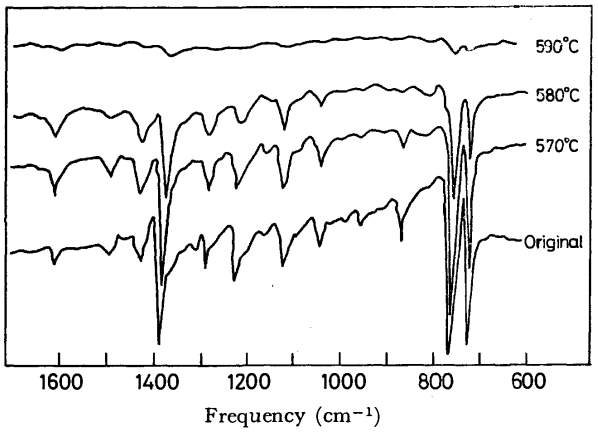

Fig. 3. Changes of IR spectra of PZ by heating under nitrogen.

Change of the infrared spectrum of PZ-1 by heating is shown in Fig. 3. We see that all bands, especially the two bands at 720 and 755 cm^{-1}, decreased remarkably at 580°C, a weak band appearing at 810 cm^{-1}.

Only the content of hydrogen decreased with temperature rise, from 34.8 to 32 atom% of sample treated at 580°C and 31.6 atom% treated at 600°C. Loss of a hydrogen up to 580°C and 600°C corresponds to 3—3.5 atoms of hydrogen per molecule. The content of nitrogen below 600°C remains almost the same as that of the original. Remarkable changes of X-ray diffraction profile were also observed at 580°C (Fig. 4). Below this temperature, the crystal structure of the original PZ is not greatly damaged, and 002 diffraction line appears at 580°C and grows with rising temperature.

The results of microscopic observation with crossed Nicols are shown in Fig. 5. The needle-like crystalline material

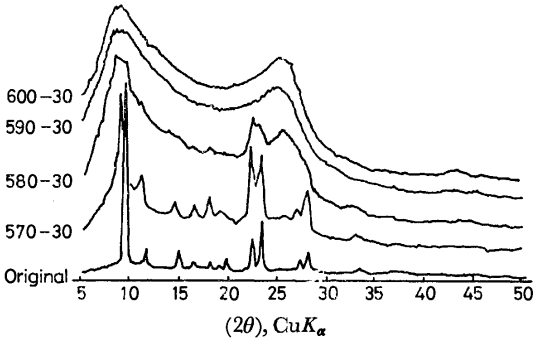

Fig. 4. Changes of X-ray diffraction profile with raising temperature. (Numbers show temperature (°C)—period (min)

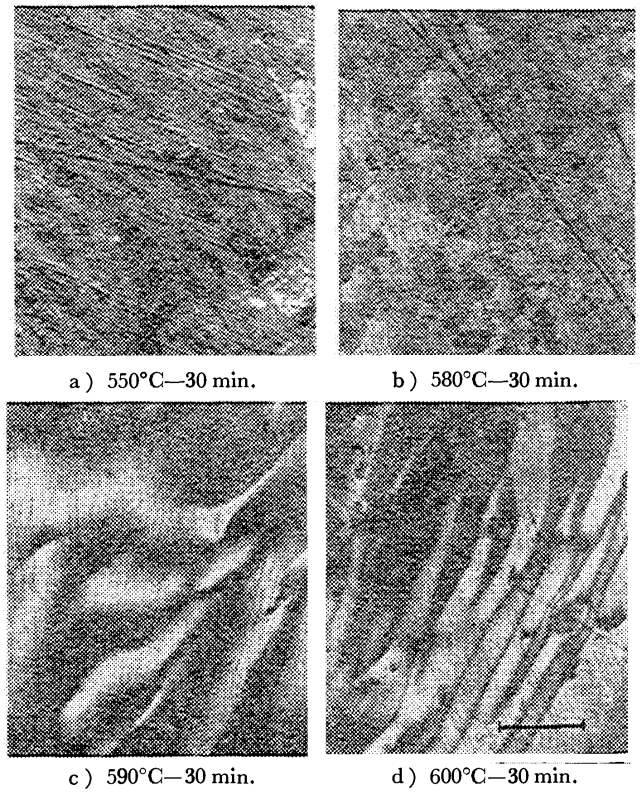

a) 550°C—30 min. b) 580°C—30 min.

Fig. 5. Microscopic photograph with crossed nicols (Scale is 50 μ)

16) J. Schmidt and J. Söll, *Ber.*, **40**, 2456 (1907).

(Fig. 5-a) appears to be converted into the oriented mesophase at 580°C (Fig. 5-c).

It has been found that pure PZ is converted into an anisotropic pitch-like material with a loss of about three hydrogen atoms per molecule. Since there are four overcrowed positions caused by four hydrogen atoms as shown in Fig. 6, the first step of dehydrogenation probably occurs at these positions and the plane dimer may be formed. Thus, it seems reasonable to consider that the pitch-like material formed at 580°C is mainly composed of a mixture of the monomer and the dimer, and the anisotropic structure caused by the interaction between these plane molecules.

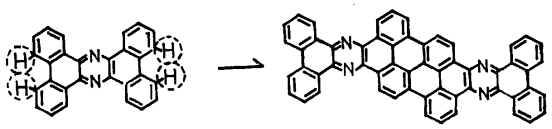

Fig. 6. Formation of dimer from PZ monomer.

PZ-2 crystal which contains some impurity gave the spinnable pitch-like material at lower heating temperature than that in the case of pure PZ-1 crystal. PZ-2 crystal was converted gradually into a black molten substance above 500°C. Spinnable pitch-like material was formed by heating under nitrogen at 530°C for 110 min. Various changes caused by heating in this case occurred during the process which was essentially the same as that for PZ-1.

Graphitizability of PZ Pitch. In order to determine the graphitizability of PZ pitch, the coke obtained was crushed and then heated under nitrogen at various temperatures below 2800°C. The coke made from PZ-1 pitch is a graphitizing carbon with interlayer distance d_{002} 3.361Å and crystallite thickness $Lc_{(002)}$ 850Å after 2800°C-treatment. PZ-2 pitch gave almost the same results as those of PZ-1 pitch.

Preparation of Carbon Fiber from PZ Pitch. The procedure was essentially the same as that previously reported.[12,17] In the case of PZ-2 pitch, the spinning temperature was 410—440°C and the spinning speed 300—400 m/min. It was better material than PZ-1 pitch from the viewpoint of spinnability and ability of conversion into an infusible fiber by oxidation. However, even in the case of PZ-2 pitch, its spinnability was not very satisfactory. The diameter of carbon fibers finally obtained was thus around 20 μ. This value is considerably greater than that of carbon fibers from petroleum asphalt, PVC pitch, and other pitch materials.[8,12,17] There was no difference between PZ-1 and PZ-2 pitch in the fundamental structure of the resulting carbon fibers. However, in mechanical properties, the carbon fiber from PZ-2 was better to some extent.

Carbonization was carried out under nitrogen up to the desired temperature below 2800°C. Heating rate was 5°C/min up to 1000°C and was 50°C/min above 1000°C. Throughout the process after spinning, heat treatment was carried out without mechanical stress.

Changes in Property with Heat Treatment. Changes in bulk density, electric resistivity and degree of preferred orientation of the basal planes are plotted in Fig. 7, and changes in crystal thickness(Lc), crystal size(La) and interlayer distance (d_{002}) in Fig. 8. It is noteworthy that the value of preferred orientation parameter is small. Even in the stage before heat treatment, it was only 23° and decreased to 6° with the rise in temperature. Since heat treatment was carried out with no stress, it is evident that the

Table 1. Characteristics of typical pitch-based carbon fibers

Characteristic	Pitch-based carbon fibers			PAN based carbon fiber
	Stretch-graphitized,		Non-stretch-graphitized PZ based fiber heated at 2800°C	RAE Type I
	G-1	G-2		
Orientation parameter (Z°)	9	8	6	8
Immersion density	1.85	1.75	2.08	2.01
Electrical resistance (ohm-cm)	5×10^{-4}	1×10^{-3}	4×10^{-4}	3×10^{-4}
Inter-layer distance (Å)	3.40	3.55	3.39	3.39
Crystal thickness (Å)	60	40	60	60
Young's modulus ($\times10^6$ psi)	70	45	20 (40)[a]	60
Tensile strength ($\times10^3$ psi)	300	420	120 (180)[a]	300

a) Maximum value.

the progress of orientation is due to the nature of the original pitch material.

The mechanical properties, tensile strength and Young's modulus are shown in Fig. 9. The maximum Young's modulus reaches about 280×10^8 g/cm^2(40×10^6 psi), but the maximum tensile strength is only 13×10^6 g/cm^2(180×10^3 psi). We see that Young's modulus increases with the rise in heat treatment temperature, the tensile strength having a minimum at around 2000°C.

Discussion

X-Ray diffraction parameters and the properties of the three typical carbon fibers are given in Table 1. PZ-pitch based carbon fiber heated at 2800°C and PAN based high modulus one are identical in their characteristics except for mechanical properties. Stretch-graphitized carbon fibers G-1 and G-2 are characterized by their low densities. From the data of interlayer distance, crystal thickness and electric resistance, it seems that the crystal growth in G-2 is restricted to some extent as compared with other fibers.

The mechanical properties of the pitch based carbon fibers were remarkably improved by means of stretch-graphitization using higher temperature and greater stress. From the data in Fig. 2, it is seen that two kinds of carbon fibers, high modulus and high strength, were prepared from pitch based carbon fibers by this method. Since the two carbon fiber M and S were heat treated under almost the same conditions, it seems reasonable that their formation is attributed mainly to the nature of the original carbon fibers. However, no distinct difference between the two original fibers was observed in their mechanical properties and structure. This seems to result from the lack of an effective method to detect the difference.

PZ pitch is less spinnable, and PZ pitch fiber has less ability to be converted into infusible fiber by oxidation as compared with PVC pitch and petroleum pitch.[17,18] PZ pitch based carbon fibers we obtained were somewhat rough, their diameter being around 20 μ. However, it has been found (Table 1) that the elemental nature, except for mechanical properties, of PZ pitch based carbon fiber is almost the same as that of PAN based high modulus fiber prepared by stretch-graphitization. Since PZ pitch based carbon fiber can be prepared without any stretching through the whole heating process, stretch-graphitization is not always necessary for preparing highly oriented carbon fiber, and thus the precursor nature has an essential effect on the structure of the fiber. Since Young's modulus of PZ pitch based fiber reaches 280×10^8 g/cm^2 (40×10^6 psi) in maximum value and 140×10^8 g/cm^2 (20×10^6 psi) in average value, one might say that PZ pitch based carbon fiber belongs to a high modulus, at least a middle modulus, carbon fiber. However, mechanical properties of the PZ pitch based carbon fibers are generally lower than those expected from their fundamental structure. It was shown that both Young's modulus and tensile strength were closely related to the diameter, increasing with decrease of the diameter.[17,18] When the diameter becomes smaller than 10 μ, the mechanical properties are remarkably improved. Thus, the lower mechanical properties of PZ based fiber is expected to improve remarkably, if the PZ based fiber having smaller diameter than 10 μ is prepared. For this purpose, it should be noted that PZ-2 pitch containing some amount of impurities was more spinnable and was more easily converted into the infusible fiber than PZ-1 pitch.

Little attention has been paid to finding a new procedure which does not require stretch-graphitization. The authors think there is a fair prospect that high modulus carbon fibers can be prepared by use of a graphitization process without stretching from pitch composed of highly oriented constituent molecules.

The authors are indebted to Dr. E. Ōta for supply of the PZ crystal and for helpful discussions.

NOTES

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3715—3716 (1972)

An SCF-MO-INDO Study of Isotropic and Anisotropic Hyperfine Coupling Constants for Sigma Radicals

Tetsuo MORIKAWA and Osamu KIKUCHI

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo

(Received November 25, 1971)

A knowledge of theoretically calculated hyperfine coupling constants (hfc) for a radical is helpful in interpreting its electronic structure and explaining the magnitudes and signs of the observed values. In the calculation of the isotropic hfc, the spin-polarization effect should be included.[1] The one-center dipolar interaction integrals mainly contribute to anisotropic hfc.[2] With these two factors taken into consideration, an improved SCF-MO function has been constructed and the isotropic and anisotropic hfc have been calculated.

The ground electron-configuration (Ψ_g) for a radical was obtained in terms of the approximate open-shell MO's of Longuet-Higgins and Pople using INDO approximation.[3] There are four types of one-electron-excited electron-configurations which are eigen functions (doublet) of S_z and S^2. When SCF-MO's are used, however, only one of them (Ψ_{ik}(II))[4] interacts with Ψ_g and the wave function Ψ_g can be improved by use of the first order perturbation: $\Psi=\Psi_g+\sum\lambda_{ik}\Psi_{ik}$ (II). The i, j components (i, $j=X$, Y, Z) of the anisotropic hfc, A^N_{ij}, and the isotropic hfc, a^N, for a nucleus N are:

$$A^N_{ij}=g\beta\hbar\gamma_N tr(\rho P),\ P_{rs}=\langle\chi_r|r_N{}^{-5}(3r_{Ni}r_{Nj}-r_N{}^2\delta_{ij})|\chi_s\rangle, \quad (1)$$

$$a^N=(8\pi/3)g\beta\hbar\gamma_N tr(\rho Q),\ Q_{rs}=\langle\chi_r|\delta(r_N)|\chi_s\rangle, \quad (2)$$

$$\rho_{rs}=C_{rm}C_{sm}+\sum_{i,k}(C_{ri}C_{sk}+C_{si}C_{rk})(mi|mk)/\Delta E_{ik}, \quad (3)$$

where C_{ri} are the LCAO coefficients ($\phi_i=\sum\chi_r C_{ri}$), ΔE_{ik} the energy differences between Ψ_{ik}(II) and Ψ_g, ρ_{rs} an element of the AO spin density matrix, and the other notations have their usual meaning. The second term in ρ_{rs} is what appears by spin-polarizarion. If AO's χ_r and χ_s belong to different atoms, dipolar interaction integrals P_{rs} are evaluated over the Slater type AO's[2] and one-center P_{rs} over the SCF-AO's expanded by Löwdin.[5] Q_{rs} are also evaluated over the Löwdin's SCF-AO's, only if both χ_r and χ_s are centered on the atom N.

The hfc of HCO, CO_2^-, CH_2=CH, HCN^-, and CH≡C were calculated. The results for HCO, a typical σ-radical, are described in some detail. The electronic structure of this radical has been reported.[3]

Table 1. Contribution of electron-configurations to hfc (MHz) of ^{1}HCO in the principal axes

Configuration	a	A_{xx}	A_{xy}	A_{yy}	A_{zz}
Ψ_g	243	23.2	−3.3	−6.3	−16.9
$1\sigma\rightarrow6\sigma$	1	−0.1	0.2	0.0	0.1
$2\sigma\rightarrow6\sigma$	31	−3.3	2.1	1.3	2.0
$2\sigma\rightarrow7\sigma$	5	−1.0	−0.4	0.6	0.4
$3\sigma\rightarrow6\sigma$	9	−1.1	0.9	0.4	0.7
$3\sigma\rightarrow7\sigma$	2	−0.4	0.1	0.3	0.2
$1\pi\rightarrow2\pi$	0	0.6	−0.1	−0.6	0.0
$4\sigma\rightarrow7\sigma$	−3	0.8	0.5	−0.5	−0.4
Sum of $i\rightarrow k$	45	−4.6	3.3	1.5	3.1
Total	288	18.7	0.0	−4.8	−13.9

Table 2. Contribution of each atom to the anisotropic hfc (MHz) of H^{13}CO in the principal axes

Atom		A_{xx}	A_{xy}	A_{yy}	A_{zz}
C	$2p_x{}^2$	−4.3	0	2.2	2.2
	$2p_y{}^2$	−27.4	0	54.8	−27.4
	$2p_z{}^2$	−1.5	0	−1.5	2.9
	Others	0	−0.1	0	0
	Total of C	−33.2	−0.1	55.5	−22.3
H		3.1	2.9	−0.8	−2.3
O		4.6	−2.8	−1.3	−3.3
	H+O	7.7	0.1	−2.1	−5.6
Total		−25.5	0	53.4	−28.0

The contribution of each electron-configuration to hfc for the proton is shown in Table 1. We see that the most important contribution is C-H $\sigma\rightarrow\sigma^*$ ($2\sigma\rightarrow6\sigma$). Spin-polarization should be included in the calculation of anisotropic hfc as for the isotropic hfc.

Each atom of HCO contributes to hfc of ^{13}C (Table 2). Holmberg[6] resolved the experimentally observed hfc (MHz) of ^{13}C into two axial parts: (A_{xx}, A_{yy}, A_{zz})=(−48, 72, −24)=(−40, 80, −40)$_{2py}$+(−8, −8, 16)$_{2pz}$. The second term shows the contribution of the carbon $2p_z$ orbital normal to the molecular plane. Table 2 suggests that the effect of neighbouring atoms is larger than that of C($2p_z$), and that the observed values can be resolved into those of $2p_x$ and $2p_y$. Direction cosines obtained show that the principal axis y of ^{1}H, ^{13}C, and ^{17}O rotate by 75°, 33°, and 16° from the C-O bond, respectively. The results for HCO are compared with available experimental data in Table 3. Satisfactory agreement was found for both

the isotropic and the anisotropic hfc. The present results are slightly better than the previous ones,[2] *e. g.*, for the anisotropic hfc (MHz) of ^{13}C, from (−17, 47, −30) to (−25, 53, −28). The isotropic and anisotropic hfc of other σ-radicals calculated by the present method, some of which are given in Table 3, are useful for the analysis of complicated ESR spectra in solid solution.

Binuclear Structure of Copper(II) 2-Pyridinolate Complex

Shuji EMORI, Isamu OKANO, and Yoneichiro MUTO

Department of Chemistry, Faculty of Science and Engineering, Saga Univesity, Honjo-machi, Saga, 840

(Received June 1, 1972)

Copper(II) acetate monohydrate has a typical isolated binuclear structure.[1] The temperature dependence of its magnetic susceptibility was clearly interpreted by a simple singlet-triplet equilibrium.[2,3] However, there has been controversy over the coupling mechanism in the crystal; direct interaction by a metal-metal δ-bond or superexchange interaction *via* the acetate bridges. Dubicki and Martin[4] pointed out that the δ-bond in the crystals of copper(II) acetate monohydrate is virtually nonbonding and that the configuration of the binuclear clusters is maintained by four bridging acetate groups. Their view has been supported by the following experimental results. The Cu–Cu separation, 3.02 Å in dichlorobis(6-hydroxypurine)copper(II) monohydrate[5] is much greater than 2.66 Å in copper(II) acetate monohydrate, although their exchange integrals are nearly equal.[6] The exchange integral -305 cm^{-1} of $(CH_3)_4NCu(CH_3COO)_2(NCS)$ is much higher than -485 cm^{-1} of of $(CH_3)_4NCu(HCOO)_2(NCS)$, although their Cu–Cu distances are nearly equal.[7] Thus we see that the cause of the formation of binuclear clusters of the type of copper(II) acetate monohydrate is the relative position of two active sites in the bidentate ligand and the direction of lone pairs of the active sites. We have attempted a synthesis of the copper(II) complex with 2-pyridinol whose ligand has the same site-structure and directionality as acetic acid.

Copper(II) 2-pyridinolate mono(2-pyridinol) was prepared by adding freshly prepared copper(II) hydroxide to a solution of excess 2-pyridinol. The reactants were agitated vigorously for 15 min to ensure maximum contact between the reactants. From the resulting suspension, crystals of $Cu(pyO)_2\cdot pyOH$ (py denotes 2-pyridyl radical) were formed in a week. The remaining non-reacted copper(II) hydroxide was removed by decantation and the crystals of pyridinolate were washed by ethanol and dried over silica gel in a desiccator. The salt was also prepared by adding dropwise a solution of sodium hydroxide to a mixture of copper(II) chloride and 2-pyridinol solution. Crystals of $Cu(pyO)_2\cdot pyOH$ were obtained overnight from the dark green suspension. No difference was observed between the two samples in analytical and magnetic data. Found: C, 51.10; N, 11.86; H, 3.74; Cu, 18.29%. Calcd for $CuC_{15}N_3O_3H_{13}$: C, 51.95; N, 12.12; H, 3.78; Cu, 18.32%.

The molar magnetic susceptibility of the complex was determined to be 565 μemu/mol (18°C) by the Gouy method, the magnetic field strength amounting to about 8000 Oe. Corrections were made for diamagnetic contributions (in μemu/mol) from 2-pyridinol (-54) and copper(II) ion (-11).[8] The value for the ligand was calculated from Pascal's constants.[9] Bleaney and Bowers[2] proposed a theoretical equation for the susceptibility χ of copper(II) compounds having a binuclear structure.

$$\chi = \frac{Ng^2\beta^2}{3kT}\left(1+\frac{1}{3}e^{2J/kT}\right)^{-1} + N\alpha$$

where J is the exchange integral and $N\alpha$ the temperature independent paramagnetism assumed to be equal to 60 μemu/mol,[3] the other quantities having their usual meanings. The observed susceptibility of the compound agrees well with the theoretical curve (Fig. 1), indicating the existence of dimer molecule in crystals. We realized that the structure of bidentate ligand is a factor in the formation of the dimeric structure of the type of copper(II) acetate mono-

hydrate. This indicates that the spin interactions between copper atoms occur by superexchange *via* pyridinol groups. The exchange integral and g-value of $Cu(pyO)_2 \cdot pyOH$ are evaluated as $J/k = -245°K$, $g = 2.10$. The magnitude of superexchange interaction depends to a great extent on the electronic structure of bridging ligands. This was proved by the fact that magnetic interaction operates more strongly in bis(6-aminopurinato)copper(II) tetrahydrate.[6] Our result where the antiferromagnetic interaction operates more strongly in the complex of $Cu(pyO)_2 \cdot pyOH$ than in $Cu(CH_3COO)_2 \cdot H_2O$ can be explained by considering that 2-pyridinol promotes the migration of positive holes to a greater extent than acetate groups.

Decarboxylation of Sodium β-Phenylglycidate under Conditions of Kolbe Electrolysis

Akira TAKEDA, Tosio MORIWAKE, Sigeru TORII,* and Takehiko TAKAKI*

Department of Synthetic Chemistry, School of Engineering, Okayama University, Okayama

** Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama*

(Received May 16, 1972)

The anodic decarboxylation of glycidic acids has recently been reported by Waters and Witkop.[1] They found that the anodic oxidation of aromatic glycidate such as piperonal glycidate gave a low yield of neutral material consisting of numerous compounds which were not further investigated. As an extension of our previous work on the anodic reaction of aldehyde,[2),3)] ketone,[3)] cinnamic acid,[4)] 5-alkyl-2-furoic acids,[5)] and cyclopropanecarboxylic acids,[6)] we studied the anodic decarboxylation of aromatic glycidic acids in protic media and obtained some information on the primary and secondary products in the reaction.

The anodic reaction of sodium β-phenylglycidate (**1**) in a mixed solvent of acetic acid–methanol–water using smooth platinum electrodes gave a neutral mixture in 51—63% yields based on **1**. When the neutral mixture was extracted with an aqueous Girard P reagent, it was separated into active carbonyl component (26% in weight) and non-active carbonyl component (74%), which were further analyzed by glpc. The ratios of peak areas (%) of the constitutents in the active carbonyl and non-active carbonyl components are summaried in Table I. Compounds such as benzaldehyde (**2**), acetophenone (**3**), methyl benzoate (**4**), benzyl acetate (**5**), and 1-phenethyl alcohol (**6**) were detected as principal products by glpc.

The electrochemical reaction of benzaldehyde in an aqueous acetic acid–potassium hydroxide solution has been shown[2)] to afford compounds **3**, **4**, and benzyl alcohol (**7**) as principal products and 1-phenethyl alcohol (**8**), *p*-tolualdehyde (**8**), *p*-methylacetophenone (**9**), propiophenone (**10**), and methyl toluates as minor components. A similar electrochemical reaction of acetophenone gave a small amount of neutral mixture which contained **10** as a major constituent (see Experimental). Although the pathway in which these prin-

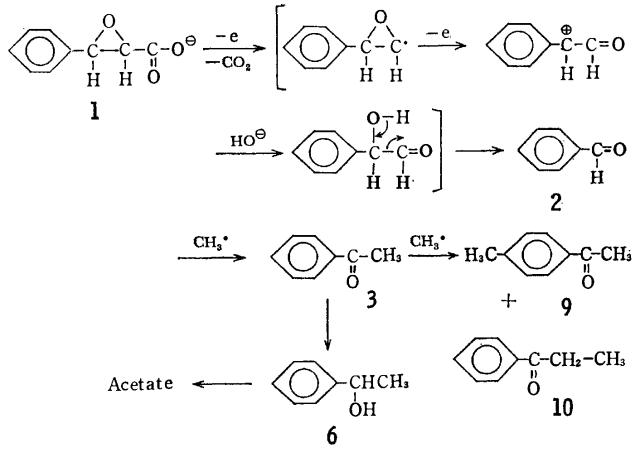
5) S. Torii, H. Tanaka, H. Ogo, and S. Yamasita, This Bulletin, **44**, 1079 (1971); S. Torii, H. Tanaka, and T. Okamoto, *ibid.*, **45**, 2783 (1972).
6) A. Takeda, S. Wada, and Y. Murakami, *ibid.*, **44**, 2730 (1971).



cipal products of the anodic reaction of **1** were formed is not certain at present, it seems that the mechanism proposed by Waters[1] for the electrochemical decarboxylation of α-methyl-α,β-epoxycyclohexylideneacetate and the related compounds can be applied to the formation of **2**. It can be suggested that benzaldehyde produced primarily underwent secondary reactions such as anodic methylation[2,3] to give **3**, and electrochemical reduction to give **7**. Compounds **8** and **9** may be interpreted as the products of ring methylation.[7] The anodic decarboxylation of sodium β-methyl-β-phenylglycidate (**11**) in an aqueous media afforded **3** as a predominant product when the reaction was carried out for a shorter period.

Experimental

All the boiling points are uncorrected. The products were analyzed by vapor-phase chromatography using a Hitachi F6-D instrument, Golay column (Z-45) coated with silicone oil (10%, SE-30). Electrolyses were carried out in the apparatus described previously.[2-4] The cell was immersed in a water-bath cooled with circulating cold water. The electrodes were two platinum foils (1.5×2.0 cm²) about 2 mm apart and the current direction was changed every 30 sec by means of a commutator.

Analytical grade acetic acid, methanol, acetophenone, and potassium hydroxide were used. Sodium β-phenylglycidate and sodium β-methyl-β-phenylglycidate were prepared by saponification of the corresponding ethyl esters[8] with sodium ethoxide. The following reference compounds were of commercial grade: benzaldehyde, benzyl alcohol, 1- and 2-phenethyl alcohols, benzoic acid, methyl benzyl ether, propiophenone, phenyl acetate, methyl *o*-toluate, methyl benzoate, *p*-tolualdehyde, *m*- and *p*-methylacetophenones, and methyl phenylacetate. The following acetates were prepared from the appropriate hydroxy compounds: benzyl acetate, bp 93°C/10 mmHg,[9] 2-phenethyl acetate, bp 118°C/13 mmHg,[10] *p*-methylbenzyl acetate, bp 95°C/13 mmHg,[11] phenacyl acetate, bp 150—164°C/2 mmHg,[12] *p*-acetoxyacetophenone, bp 165—170°C/19 mmHg.[13] Methyl *p*-toluate was prepared by treating *p*-toluic acid with diazomethane, bp 102—105°C/10 mmHg.[14] *o*-Methylacetophenone was also prepared: bp 110°C/14 mmHg.[15]

*Anodic Reaction of Sodium β-Phenylglycidate (**1**).* A mixture of **1** (18.6 g, 0.1 mol) with acetic acid (100 m*l*), methanol (50 m*l*), water (70 m*l*) and potassium hydroxide (4 g, 0.07 mol) was electrolyzed for 54 hr at 31—35°C with terminal voltage 10—13 V and a current of 0.8—0.9 A/cm². During the electrolysis a 40 m*l* portion of acetic acid was added every 8 hr. The reaction mixture was diluted with 300 m*l* of water and extracted with ether. The extract was washed with aqueous sodium chloride and sodium hydrogen carbonate, and was concentrated *in vacuo* to afford 9.5 g (51%) of neutral oil. 0.2 g of acidic product was obtained from the aqueous layer. After 5 g of the neutral mixture was treated with an excess (10 g) of Girard P reagent in ethanol at reflux temperature, 2.3 g of an oil consisting of non-active carbonyl components was recovered by extraction with ether. From the residual solution, 0.8 g of active carbonyl component was recovered by acid hydrolysis. The composition of the active carbonyl and the non-active carbonyl components analyzed by glpc is given in Table 1.

*Anodic Decarboxylation of Sodium β-Methyl-β-phenylglycidate (**11**).* A solution of 30 g (0.15 mol) of **11** in 150 m*l* of water was electrolyzed for 8 hr at 30—35°C with terminal voltage 11—12 V and a current of 0.9—1.0 A/cm². The reaction mixture was extracted with ether, washed with water and dried (Na_2SO_4). After evaporation of the solvent, 2.8 g of an oil was obtained which was chromatographed on silica gel and eluted with benzene (200 m*l*), ether (500 m*l*), and methanol (250 m*l*). From the fractions eluted by ether and methanol, 2.2 g of an oil was isolated. The IR spectrum of this oil was identical with that of an authentic sample of **3** and gave 2,4-DNP which was identified as that of **3** by mixed mp 235—237°C, IR spectrum, and microanalyses.

*Anodic Methylation of Acetophenone (**3**).* A mixture of **3** (12.1 g, 0.1 mol) with acetic acid (53 m*l*), methanol (67 m*l*), water (110 m*l*) and potassium hydroxide (4.0 g) was electrolyzed for 53 hr at 23—33° with terminal voltage 11—13 V and a current of 0.8—0.9 A/cm². During the course of electrolysis 30 m*l* of acetic acid was added every 7 hr. The reaction mixture was washed as usual and dried. After distilling off unreacted **3** with a Widmer column, 2.2 g of neutral oil was obtained from the reaction mixture. The glpc analysis of the mixture is given in Table 2.

Table 2. Composition of the products obtained in the anodic methylation of acetophenone

SHORT COMMUNICATIONS

A New Method for the Determination of the Volume Magnetic Susceptibility by NMR

Koichi HATADA, Yoshio TERAWAKI, and Hiroshi OKUDA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received September 7, 1972)

The determination of the volume magnetic susceptibility (χ_v) by NMR have been done by several workers using a special sample tube.[1-3] In the present work we have developed a new NMR method for determining the χ_v by the use of precision coaxial tubing (Wilmad Glass Co., inside diameters: inner tube, 1.3 mm; outer tube, 4.2 mm) and an NMR shift reagent.

The measurements were carried out on a JNM-4H-100 Spectrometer (100 MHz) at 22.5±0.2°C using an internal locking system. All the organic chemicals were obtained commercially, and they were purified and dried by the usual method. A solution of the shift reagent, $Eu(fod)_3$, in CCl_4 containing hexamethyldisiloxane (HMDS) was placed in the central capillary of the coaxial cell, and the sample of interest in the surrounding annulus. After optimizing the performance of the spectrometer and minimizing the intensity of the spinning sideband, the spectrum was measured using the HMDS signal from the inner tube as a lock signal. The signal of the sample in the outer tube is accompanied with fairly strong sidebands, as is illustrated in Fig. 1. The spacing of the bands is twice the spinning rate. The intensities of these sidebands increased with decreases in the spinning rate and in the χ_v of the sample in the surrounding annulus and with an increase in the concentration of $Eu(fod)_3$ in the central capillary. The peak height intensity of the first pair of sidebands(I) increased linearly with an increase in the reciprocal of the spinning rate (Fig. 2). When the intensities at a certain spinning rate

Fig. 1. NMR Spectrum of benzene in precision coaxial tubing.
Inner tube: 18.3(wt/vol%) solution of $Eu(fod)_3$ in CCl_4 and HMDS (1 : 1 vol/vol).
Outer tube: benzene.
Spinning rate: 23.2 Hz.

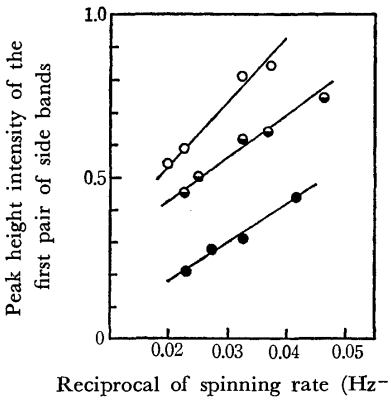

Fig. 2. The intensities of the first pair of sidebands at various spinning rates.
○: Bromoform, ◒: Chloroform, ●: Acetone

are deduced from the results shown in Fig. 2 and plotted against the known values of χ_v[4] for acetone, chloroform, and bromoform, a good linear relation is obtained. The relation at the spinning rate of 30 Hz is as follows:

$$I = -890000\,\chi_V - 0.068 \quad (1)$$

Using Eq. (1), the χ_v values of organic compounds can be determined. Some of our results ($-\chi_v \times 10^6$) are: acetonitrile, 0.540; *o*-xylene, 0.661; ethylbenzene, 0.639; benzene, 0.611. These values agree well with those recorded in the literature[4] (0.534, 0.644, 0.634, and 0.611 respectively). Similar results were obtained by placing a solution of $Pr(fod)_3$ or of cupric nitrate in the central capillary. However, on the Varian 220 MHz spectrometer, in which the direction of magnetic field was along the axis of sample spinning, such strong sidebands as are shown in Fig. 1 were not observed and the measurement of χ_v by this method could not be done.

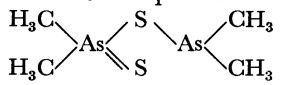
Novel Polymetallic Cobalt and Zinc Complexes formed with an Arsenic Sulphide Ligand. The X-Ray Structure Determination of Racemic Hexa-μ-dithiocacodylato-tetrazincsulphide $[SZn_4\{AsS_2(CH_3)_2\}_6]$

D. JOHNSTONE, J. E. FERGUSSON,* and Ward T. ROBINSON
Department of Chemistry, University of Canterbury, Christchurch, New Zealand
(Received October 31, 1972)

The reaction of the compound[1,2]



with $M(ClO_4)_2 \cdot 6H_2O$ (M=Co, Zn) in ethanol or acetone solution yields isomorphous hexagonal crystals, space group $P6_3$, unit cell dimensions (M=Co) $a=32.262$, $c=10.303$ Å, $D_m=2.05$ and stoichiometry (chemical and atomic absorption analyses) consistent with the formula $M_4As_6S_{13}C_{12}H_{36}$. Mixtures of the pure cobalt and zinc reactant or product molecules cause formation of isomorphous crystals with mixed metal stoichiometry. Recrystallization of the hexagonal crystals from dichloromethane solution yields isomorphous monoclinic crystals, space group $P2_1/n$, unit cell dimensions (M=Zn) $a=30.55$, $b=18.50$, $c=32.63$ Å; $\beta=95.7°$, $D_m=2.00$ and different stoichiometry. The title compound and its cobalt isomorph are minor recrystallization products.

The infrared spectra of all these compounds are strikingly similar in the range 1300—200 cm^{-1}, and similar to the spectra of dithiocacodylate complexes recently reported.[3] The NMR spectra of the zinc compounds confirm the expected retention by arsenic of the methyl groups coordinated to it in the free ligand.

Solution molecular weight determinations and numerous physical measurements indicate large polynuclear transition metal structures abound. For example one crystalline product containing zinc has hexagonal unit cell dimensions $a=15.42$, $c=34.65$ Å.

Electronic spectral measurements on the cobalt hexagonal crystals indicate a tetrahedral environment around the cobalt ions. The magnetic moment over the temperature range 193—93K drops from 3.49 to 2.16 BM per cobalt suggesting spin coupling between the metal ions in the polynuclear structure. The coupling is retained in solution, but can be reduced by forming mixed solutions with the isomorphous zinc complex. A compound with the composition $[Co\{AsS_2(CH_3)_2\}_2]$ is also reported to show spin coupling.[4]

The title compound was selected for initial X-ray analysis because it was ideally suited to locally available computing techniques.

Crystal Data. $Zn_4As_6S_{13}C_{12}H_{36}$, $M=1308.3$, Monoclinic, $a=11.586(8)$, $b=33.08(2)$, $c=11.996(8)$ Å, $\beta=117.39(1)°$, $U=4082$ Å^3, $D_m=2.12$ (by floatation), $Z=4$, $D_c=2.13$, $F(000)=2536$, Mo$K\alpha$ radiation, $\lambda=0.7107$ Å, μ(Mo$K\alpha$)=81.21 cm^{-1}. Space group $P2_1/c$. 4520 independent intensity data ($0<\theta\leqq21°$) were collected on a Hilger and Watts 4-circle automatic diffractometer. After correction for LP and absorption effects, 2637 intensities exceeded 3 times their estimated standard deviations. The structure was solved by the symbolic addition procedure then refined using these data and full-matrix least-squares methods until $R=0.058$.

The structure consists of well separated neutral molecules one of which is shown in the figure. All non-hydrogen atoms are in approximately tetrahedral coordination environments and bond lengths lie in the ranges normally expected for the atoms concerned. The structure has topological similarity to basic beryllium acetate. In each structure a central non-metallic atom (S,O) is bonded to four metal atoms (Zn, Be) located at the corners of a tetrahedron. The six edges of this tetrahedron are bridged by polyatomic anionic ligands ($\{AsS_2(CH_3)_2\}^-$, $(CH_3CO_2)^-$). However the high symmetry (T-23) exhibited by basic beryllium acetate, and related oxy- compounds, is not developed in this sulphide which has only ana pproximate C_3 axis of symmetry.[5] Figure 1 shows that the three six-membered SZnSAsSZn rings, which include the S and Zn atoms on the C_3 axis, have approximate chair conformations while the three which do not include the axial Zn atom have twist boat conformations. Models show no interactions precluding the existence of a molecule with the higher (T-23) symmetry and all twist boat ring conformations. This stereochemistry may be expected in some of the more complicated crystal modifications. Chirality of individual molecules has been demonstrated from the X-ray structural evidence, as well as studies of optical rotation.

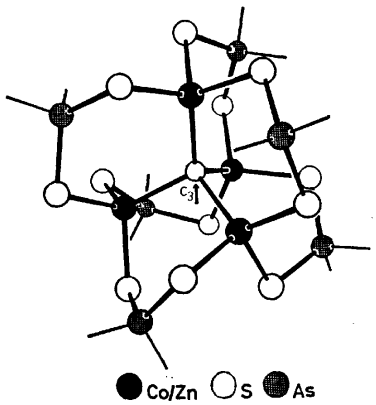


Fig. 1. Structure of $[SZn_4\{AsS_2(CH_3)_2\}_6]$
(Three top rings are chairs, three bottom rings are boats.)

Stereoselective Reduction of Ketones with Hydrosilane-Rhodium(I) Complex Combinations

Iwao OJIMA, Mitsuru NIHONYANAGI, and Yoichiro NAGAI*

Sagami Chemical Research Center, Onuma, Sagamihara 229

** Department of Chemistry, Gunma University, Kiryu, Gunma 376*

(Received September 5, 1972)

Aluminum hydrides,[1] aluminum alkoxides,[1,2] tin hydrides[3] and hydroboranes[5] can reduce ketones to alcohols stereoselectively and each reducing agent displays the respective characteristics of stereoselectivity. It is rather surprising that, in spite of the known capability of silicon hydrides to reduce ketones,[6] no attention has been so far drawn to stereochemistry in the reductions with these hydrides. Now, we wish to report here our preliminary results of the reduction of terpene ketones by hydrosilane-rhodium(I) complex combinations[4] which finds several marked differences in stereochemical selectivity from other reducing systems.

The reaction was carried out by stirring an equivalent mixture of a ketone and a hydrosilane at 0—80 °C in the presence of a catalytic amount of $(Ph_3P)_3$-RhCl. Alcohols were obtained by hydrolysis of the resulting silylethers. Yields of alcohols were nearly quantitative in all cases. Results of the hydrosilane reduction of camphor and menthone, representative terpene ketones, are listed in the Table. Included also in the Table are the reported selectivities achieved by other known reducing agents.

TABLE. STEREOSELECTIVITIES IN THE REDUCTION OF TERPENE KETONES BY HYDROSILANE-RHODIUM(I) COMPLEX COMBINATIONS (% less stable alcohol)

Reducing agent	Camphor	Menthone
$PhSiH_3$	90[a]	90[a]
Et_2SiH_2	91[a]	83[a]
$PhMeSiH_2$	75[a]	86[a]
Ph_2SiH_2	73[a]	85[a]
Et_3SiH	30[b]	64[c]
$PhMe_2SiH$	—[d]	0[c]
$LiAlH_4$	91[e]	29[f]
$Al(OPr\text{-}i)_3$		70[g]
$NaBH_4$		51[g]

Disiamylborane	65[e]	
Dicyclohexylborane	93[e]	
Diisopinocamphenylborane	100[e]	
Ph_2SnH_2		52[g]

a) The reaction was performed without solvent using 0.1 mol% $(Ph_3P)_3RhCl$. b) 1.0 mol% $(Ph_3P)_3RhCl$ was used and *n*-hexane was employed as a solvent. c) 1.0 mol% $(Ph_3P)_3RhCl$ was used without solvent. d) Camphor was recovered without any hydrosilation. e) See Ref. 5a. f) A. K. Macbeth and J. S. Shannon, *J. Chem. Soc.*, **1952**, 2852. g) See Ref. 3.

As shown in the Table, the bulkiness of silanes exerts large influence on the stereochemical course of the reduction and a bulky hydrosilane favors the production of the more stable alcohols. This trend is quite unusual since it has been shown by Brown and Varma that, in the reduction of monocyclic and bicyclic ketones, the more bulky hydroborane produces the larger percentage of less stable of the two possible alcohols.[5a] The peculiarity found in the hydrosilane reduction catalyzed by rhodium(I) complex suggests that the transition state for the reaction cannot be accommodated with a simple four-centered type.[7] However, a possible explanation for the observed trend can be advanced by taking into account the intermediacy of the organorhodium complex III as shown below, the formation of which is quite reasonable[10] in view of the well-documented "soft-hard conception".[9] As the steric course would be governed only by the size of the silyl moiety,[10] it can be said that the bulkier the substituents on silicon, the more pronounced may be the formation of the complex IIIa which is a precursor of the more stable alcohol. A further work on the mechanism of the rhodium(I) complex catalyzed reductions is now under investigation.

7) For example, H. O. House, and J. E. Oliver, *J. Org. Chem.*, **33**, 929 (1968); H. C. Brown and H. R. Deck, *J. Amer. Chem. Soc.*, **87**, 5620 (1965).

8) The conversion of the complex II to III will be favored on the basis of the following two points; i) as the Rh^I complex I is a soft acid, the Rh^I-C bond may be stronger than the Rh^I-O bond. ii) the Si-O bond newly formed in the complex III is very strong.

9) R. G. Pearson, *J. Amer. Chem. Soc.*, **85**, 3533 (1963).

10) The only variable steric factor is the size of silyl group, and therefore the bulky silyloxy group may occupy the less hindered site when the silyloxy group becomes larger than the rhodium moiety which is kept constant in the complex III.

A Convenient Method for the Hydrolysis of Vinyl Sulfides to Ketones

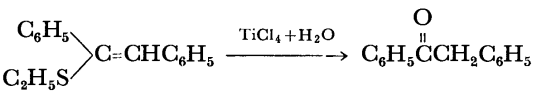
Teruaki MUKAIYAMA, Kunimasa KAMIO, Susumu KOBAYASHI, and Hisashi TAKEI

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 14, 1972)

In this communication, a convenient method for the hydrolysis of vinyl sulfides to ketones by the use of $TiCl_4$ is reported. In the previous paper,[1] it was shown that $AgClO_4$ is effective for the hydrolysis of thioketals or thioacetals. However, it was found that the $AgClO_4$-promoted hydrolysis of vinyl sulfide gave the hydrolyzed product in a low yield. Hydrolysis of vinyl sulfides has been generally performed under rather drastic acidic conditions[2] except the Hg(II)-promoted hydrolysis[3] reported by Corey *et al.*

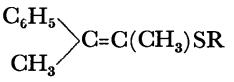
Based on the consideration that there are two possible ways of activation of vinyl sulfides towards hydrolysis, namely the activation of carbon-carbon double bond and carbon-sulfur bond, we examined the hydrolysis using various metal salts which might have strong affinity toward either double bond or sulfur atom. Finally, it was established that vinyl sulfides were easily hydrolyzed in the presence of 2 molar amounts of $TiCl_4$. For example, when α-ethylthiostilbene, **1**, was added to 2 molar amounts of $TiCl_4$ in acetonitrile at room temperature, the color of the solution changed from yellow to deep red. After stirring for about 20 min, 4 molar amounts of water was added and the reaction mixture was stirred at room temperature for an additional 4 hr. Then usual work-up afforded desoxybenzoin, **2**, in 78% yield and 21% of **1** was recovered. Further, it was found that,



1 **2**

when 2 molar amounts of $Pb_2O(OH)_2$ was added in the above reaction in order to remove ethanethiol formed at the same time, the increase of the yield was achieved and **2** was obtained in 92% yield and 8% of **1** was recovered. On the other hand, in the case of phenyl vinyl sulfide, there was no remarkable effect in the yield by the addition of $Pb_2O(OH)_2$.

In a similar manner, various vinyl sulfides were hydrolyzed to the corresponding ketones in high yields. For example, β-aryl substituted vinyl sulfide[4], **3**, was hydrolyzed quantitatively to 3-phenyl-2-butanone by the use of $TiCl_4$ in acetic acid. The results are shown in Table 1.



3 $R = C_2H_5$ or C_6H_5

In conclusion, it is noted that vinyl sulfides are easily hydrolyzed to the corresponding ketones in high yields without accompanying by-product under mild conditions by the action of $TiCl_4$. Further works are now in progress and will be reported at a later date.

TABLE 1. $R^1R^2C{=}CR^3(SR^4) \xrightarrow{2TiCl_4 + 4H_2O + n\ Pb_2O(OH)_2} R^1R^2CHCR^3$ (O)

A Convenient Method for Hydrolysis of 1,3-Dithiane Derivatives Using Cupric Chloride

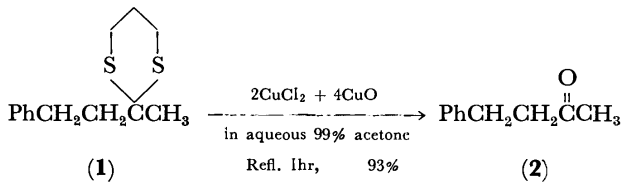
Koichi NARASAKA, Takeshi SAKASHITA, and Teruaki MUKAIYAMA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 19, 1972)

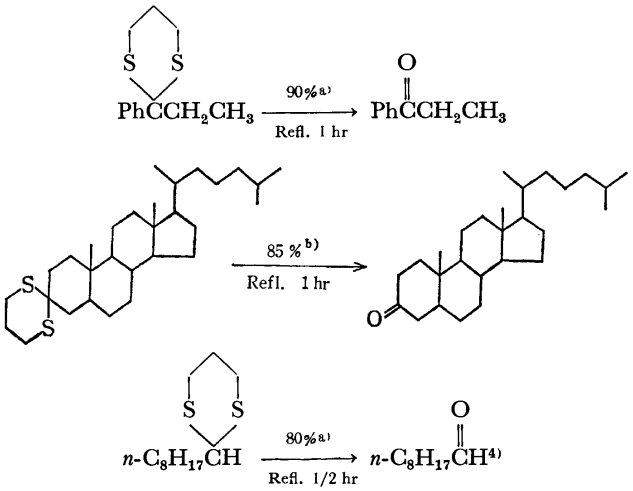
A variety of methods for generation of carbonyl compounds from 1,3-dithiane derivatives has been developed, however, none of these methods is general.[1] Therefore, in connection with the studies on the activation of carbon-sulfur bond with cupric chloride[2], we investigated the hydrolysis of 1,3-dithiane derivatives with cupric chloride.

The mixture of 5 mmol of 2-methyl-2-phenethyl-1,3-dithiane (**1**), 10 mmol of cupric chloride and 20 mmol of cupric oxide in 50 m*l* of aqueous 99% acetone[3] was refluxed for 1 hr. A precipitate was filtered off and the filtrate was condensed under reduced pressure. Ether was added to the residue and the resulting precipitate was filtered off. The filtrate, which was homogeneous by tlc and vpc, was distilled and benzylacetone (**2**) was obtained in 93% yield. When the reaction was carried out at room temperature for 2 hr, **2** was isolated in 83% yield.



(**1**) (**2**)

The hydrolysis of several other 1,3-dithiane derivatives was examined by the same procedure to test the generality of this method.



a) Yield of pure carbonyl compound isolated by distillation.
b) Yield of recrystallized product.

From the results shown in the above equations, it was confirmed that this method is applicable to hydrolysis of a wide variety of 1,3-dithiane derivatives and the corresponding carbonyl compounds were isolated in good yields by the simple procedure.

In addition, it was found that 2-*n*-octyl-1,3-dithiane is readily hydrolyzed with cupric chloride to the corresponding aldehyde in higher yield as compared with the cases of the hydrolyses of 2-monoalkyl-1,3-dithianes, such as 2-benzyl-1,3-dithiane and 2-*n*-hexyl-1,3-dithiane with mercuric chloride[1e,f], *n*-hexyl-1,3-dithiane with boron trifluoride–mercuric oxide[1f] and 2-*n*-octyl-1,3-dithiane with silver perchlorate.[5]

In conclusion, it is noted that this method affords a convenient method for hydrolysis of 1,3-dithiane derivatives, a useful synthetic intermediates, to carbonyl compounds. The further application is now in progress.

3) The reaction proceeds in various aqueous organic solvents (acetone, acetonitrile, methanol, and tetrahydrofuran), but it was noted that benzylacetone is obtained in the best yield in the case of aqueous 99% acetone.

4) In this case, the reaction was carried out under an argon atmosphere for 30 min.
