There have been published several reports in which the polarizability has been investigated theoretically.[1-6] The variational-perturbation method has been applied to calculate the polarizability by several investigators. From the results of this treatment using the LCAO–MO functions of the Roothaan type for the zero-order wave functions, O'Hare and Hurst[1] suggested that the calculated polarizability can be used to determine whether or not the wave functions are appropriate, since the theoretical polarizability is sensitive to the zero-order wave functions. Liebmann and Moskowitz[2] discussed the results of the calculations for the polarizabilities of many compounds by this method. They compared the polarizabilities calculated by the use of different types (Slater- and Gaussian-types) of atomic orbitals with each other. Also, Sadlej[3] calculated the polarizability by the variational-perturbation method, using the complete neglect of differential overlap (CNDO) version, and compared the results of his calculations with those of the non-empirical calculations. He concluded that the CNDO version can be adapted for the calculation of the polarizability.

Davies[4] discussed the theoretical polarizability calculated from the first-order perturbed wave functions in the self-consistent perturbation theory within the framework of the CNDO approximation. From a comparison between the results of calculations in which the 2p orbitals of the hydrogen atom are and are not considered, he concluded that the valence orbital basis set, which is generally used in the LCAO–MO method, was inadequate for the representation of the perturbed wave functions. In the method described above, the perturbing term in the molecular Hamiltonian which arises from the interaction between the molecule and the uniform electric field, **E**, is $H' = -e\sum_i \mathbf{r}_i \cdot \mathbf{E}$, where $\mathbf{r}_i$ is the position vector of the i-th electron.

The finite perturbation theory has been used by Hush and Williams[5,6] to investigate the polarizability and the anisotropy. In this method, the SCF calculation was performed for an appropriate system including an molecule plus a fixed charge on the molecular axis.

Although the polarizability is dependent upon the frequency of the incident light, all the theoretical treatments described above do not take the contribution of the frequency of the incident light into account. In this work, however, an approximate method which is dependent upon the frequency of the incident light has been used to calculate the polarizability of several small molecules. The total wave function used to calculate the polarizability has been obtained by the CNDO method,[7-11] involving the configuration interaction treatment. The dependence of the values of the polarizability and the anisotropy on the frequency of the incident light has been discussed. Moreover, the effect of the parametrization in the CNDO method on the calculated polarizability has been discussed. Furthermore, for example, this approximate method has been used to estimate the dependence of the polarizability derivatives, $(\partial\alpha/\partial S_i)_0$ and $(\partial^2\alpha/\partial S_i^2)_0$, on the frequency of the incident light, where α is the molecular polarizability, and S_i, an appropriate symmetry coordinate.

Methods of Calculation

The Molecular Polarizability. The perturbed wave function (Ψ_a) of the system in the electromagnetic field is represented by the wave functions (Ψ^0's) of the system in the absence of the field:[12]

$$\Psi_a = \Psi_a^0 + \sum_b C_b \Psi_b^0, \tag{1}$$

where, if the energy of the incident light is $\varepsilon(=h\nu)$, the C_b is given by the relation:

$$C_b = \frac{iE_{ba}}{2c\hbar}\mathbf{A}_0^0 \cdot \langle \Psi_b^0 | e\sum_i \mathbf{r}_i | \Psi_a^0 \rangle \left\{ \frac{\exp(i(E_{ba}+\varepsilon)t/\hbar)}{E_{ba}+\varepsilon} + \frac{\exp(i(E_{ba}-\varepsilon)t/\hbar)}{E_{ba}-\varepsilon} \right\} + \text{constant}, \tag{2}$$

12) H. Eyring, J. Walter, and G. E. Kimball, "Quantum Chemistry," John Wiley & Sons, New York (1944), p. 118.

where $E_{ba}=E_b-E_a$ $(=h\nu_{ba})$ and where $\mathbf{A}_0^0$ is the vector relating to the electric field, $\mathbf{E}_0$: $\mathbf{E}_0=\varepsilon/c\hbar\ \mathbf{A}_0^0 \sin \varepsilon/h\ t$.

The dipole moment ($\mathbf{R}_a$) associated with the Ψ_a state as a function of the electric field is:

$$\mathbf{R}_a = \langle\Psi_a^0|e\sum_i \mathbf{r}_i|\Psi_a^0\rangle + \frac{2}{h}\sum_b \frac{\nu_{ba}}{\nu_{ba}^2-\nu^2}\langle\Psi_a^0|e\sum_i \mathbf{r}_i|\Psi_b^0\rangle\langle\Psi_b^0|e\sum_i \mathbf{r}_i|\Psi_a^0\rangle\cdot\boldsymbol{E}_0. \quad (3)$$

The first term on the right-hand side in Eq. (3) is the permanent dipole moment of the system. By averaging the vector quantities over all the orientations of the system with respect to the field, the second term can be rewritten as follows:

$$\frac{2}{3h}\sum_b \frac{\nu_{ba}|\langle\Psi_a^0|e\sum_i \mathbf{r}_i|\Psi_b^0\rangle|^2}{\nu_{ba}^2-\nu^2}\mathbf{E}_0 = \alpha\mathbf{E}_0. \quad (4)$$

Thus, the polarizability, α, can be calculated from the quantum-mechanical expression, Eq. (4).

The Molecular Anisotropy. The molecular anisotropy, κ, which determines the depolarization of light scattered by the molecule, is expressed by the components of the polarizability tensor as follows:

$$\kappa^2 = \{(\alpha-\alpha_1)^2+(\alpha-\alpha_2)^2+(\alpha-\alpha_3)^2\}/6\alpha^2, \quad (5)$$

where α_1, α_2, and α_3 are the principal polarizabilities of the molecule. In the case of linear molecules, Eq. (5) can be simplified as follows:

$$\kappa = (\alpha_{//}-\alpha_\perp)/3\alpha = \Delta\alpha/3\alpha, \quad (6)$$

where $\alpha_{//}=\alpha_1$, $\alpha_\perp=\alpha_2=\alpha_3$.

The Molecular Wave Functions. In this calculation, the molecular wave functions, Ψ^0's, in Eq. (1) are described as the antisymmetrized products of one-electron functions and the excited state, Ψ_b^0, is described as a linear combination of the excited configurations (Φ_{i-k}) obtained by the configuration interaction (CI) treatment. The wave functions and energies of the excited states were improved by these CI treatments, but the improvement of the ground state by considering doubly-excited configurations was abridged to avoid tedious computations.

The one-electron wave functions were determined by means of the CNDO method, that is, the approximate self-consistent molecular orbital method with complete neglect of differential overlap. In an effort to determine the effect of the parametrization in the CNDO method on the theoretical polarizability and anisotropy three different types of calculations were performed.

Method I. The calculation followed the original CNDO/2 method proposed by Pople *et al.*[7-9]

Method II. The calculation was performed according to the modified CNDO method proposed by Bene and Jaffé.[10,11]

Method III. In this method, the calculation was performed under the same approximation as Method II except for the evaluation of the bonding parameter. The distinction in estimating the bonding parameters for the pi-type and for sigma-type interaction was avoided, and the bonding parameter referring to the sigma-type interaction was approximated by the adoption of the method for the pi-type interaction. The numerical values of the parameters are indicated in Table 1.

Table 1. Parameter values (eV)

	Atom	H	C	N	O
β_A^0 [a]	Method I	−9	−21	−25	−31
	Method II	−12	−17	−26	−45
γ_{AA} [b]	Method I[c]	20.40	16.06	19.27	22.48
	Method II[d]	12.85	11.11	12.01	13.00

a) Bonding parameter.
b) One-center electron-repulsion integral.
c) Calculated as a Coulomb repulsion integral over Slater's functions. (Z': H(1s) 1.2, C(2s) 3.25, N(2s) 3.9 and O(2s) 4.55).
d) Calculated as a difference between the ionization potential and electron affinity of 1s for H atom and of 2p for C, N, and O atoms.

In order to obtain the excited states, Ψ_b^0's, required to describe the perturbed wave function by means of Eq. (1), the SCF calculations described above were followed by CI treatment. In the CI treatment, all singly-excited configurations were considered. By the use of the coefficients ($c^{(b)}$'s) of the configurations and the transition moment between the ground state and each excited configuration, the integral in Eq. (4) could be calculated as follows:

$$\langle\Psi_a^0|e\sum_i \mathbf{r}_i|\Psi_b^0\rangle = \sum_i^{occ}\sum_k^{unocc} c_{(i-k)}^{(b)}\langle\Psi_a^0|e\sum_i \mathbf{r}_i|\Phi_{i-k}\rangle. \quad (7)$$

The X-component of the integral on the right-hand side of the above equation is expressed by:

$$\langle\Psi_a^0|e\sum_i X_i|\Phi_{i-k}\rangle = -\sqrt{2}\sum_A\{2.5416X_A\sum_\mu d_{i\mu}^{(A)}d_{k\mu}^{(A)} + 7.3370(d_{i(2s)}^{(A)}d_{k(2p_x)}^{(A)}+d_{i(2p_x)}^{(A)}d_{k(2s)}^{(A)})/Z_A'\} \text{ (Debye)}, \quad (8)$$

where $d_{i\mu}^{(A)}$ is the coefficient of the atomic orbital, χ_μ, on the A atom in the molecular orbital, φ_i; where X_A is the X-component of the position vector (atomic unit) of the atom A, and where Z_A' is the orbital exponent of the A atom. The Y- and Z-components of the integral can be obtained in the same manner by replacing $d_{i(2P_X)}$ in Eq. (8) with $d_{i(2P_Y)}$ and with $d_{i(2P_Z)}$ respectively, and by replacing X_A with Y_A and with Z_A respectively.

The Polarizability Derivatives. The molecular polarizabilities were calculated for the molecule distorted in the manner dictated by the appropriate symmetry coordinate. The desired values were obtained by fitting the calculated polarizabilities to a cubic function with respect to the symmetry coordinate and by taking the first and second derivatives.

Results and Discussion

The calculated polarizabilities are, in Table 2, listed and compared with the theoretical and observed values reported by other investigators. The values calculated by Method I were similar in magnitude to those calculated by Hush[5] and Davies.[4] Generally, they were smaller than the experimental results. The calculated polarizabilities were improved by the use of Methods II and III. From a comparison between the results of different calculations, it has been found that the transition energies and transition moments along the

bond axis vary widely from method to method, while the transition moments perpendicular to the bond axis remain unaltered. Moreover, it seems reasonable to conclude that a direct basic cause of the results for the theoretical polarizabilities being different from those found by different approximate methods is the differences between energy levels which are affected by the bonding parameter in the CNDO calculation.

a), b), c), d), and e) References to footnotes are the same as those in Table 2.
f) The anisotropy was calculated from Eq. (5).

The calculated anisotropies are summarized in Table 3. Generally, they were larger than the experimental results. However, the order of magnitude in the theoretical values for the molecules was in satisfactory agreement with that obtained from the observed results, such as $CO_2 > C_2H_2 > N_2 > CO > C_2H_6$. The values calculated by Method I were slightly improved as compared to those from Methods II and III. Of course, the values of the $\Delta\alpha$'s showed the same tendencies. However, Method II was adapted for the calculation of the polarizability, as has been stated above. This change in the results can be explained by the facts that the $\alpha_{//}$'s calculated by Method II increased remarkably in comparison with those from Method I, but there was not very much change for the values of $\alpha_{\perp}$'s in these different types of calculations. Thus, an approximate method which provides appropriate values for both the α and $\Delta\alpha$ must be found. Furthermore, the effect of the inner-shell electrons and the consideration of the atomic vacant orbitals, such as the 2p orbital for hydrogen introduced by Davies,[4] remain subjects for future study.

The approximate method for the polarizability calculation in this work is characterized by the introduction of the frequency of the incident light. As an example of the application of this method, variations in the polarizability and anisotropy with the frequency of the incident light were calculated. The results of the calculations are shown in Figs. 1 and 2. These figures show that the calculated values vary with the decrease in the difference between the energy of the incident light and the calculated energy for the first absorption band which is allowed for the electron transition. Furthermore, the polarizability derivatives, $\alpha' = (\partial\alpha/\partial S_i)_0$ and $\alpha'' = (\partial^2\alpha/\partial S_i^2)_0$, with respect to the symmetric stretching coordinate, S_i, were calculated for NH_3 and CO_2 by the use of the wave functions and energies calculated by Method I. The variations in

12	34.304	459.015		

a) $\alpha'=\left(\frac{\partial\alpha}{\partial S_i}\right)_0$, and $\alpha''=\left(\frac{\partial^2\alpha}{\partial S_i^2}\right)_0$.

where $S_i=\frac{1}{\sqrt{2}}(\Delta r'_{CO}+\Delta r''_{CO})$ for CO_2,

and $S_i=\frac{1}{\sqrt{3}}(\Delta r'_{NH}+\Delta r''_{NH}+\Delta r'''_{NH})$ for NH_3.

b) Calculated energyies for the first absorption bands were 12.78 eV and 9.98 eV for CO_2 and NH_3 respectively.

the polarizability derivatives with the energy of the incident light were also calculated; they are indicated in Table 4. The α''/α' ratio was calculated as a function with respect to the energy of the incident light; it is shown in Fig. 3. Such a treatment as has been described above can be used for the analysis of the resonance and pre-resonance Raman intensities[14,15] in a manner similar to that used in the infrared region: the dipole-moment derivative, $(\partial\mu/\partial S_i)_0$ and $(\partial^2\mu/\partial S_i^2)_0$, obtained by the CNDO calculation are effective for the theoretical calculation of the infrared absorption intensity of the vibration band.[16–18]

Conclusion

The dipole polarizabilities, α's, and the anisotropies, κ's, of small linear molecules were calculated according to a formula derived from the time-dependent perturbation theory. The method of the calculation in this work is characterized by the introduction of the frequency of the incident light. The calculated polarizabilities were generally smaller than the experimental results. However, the calculated anisotropies and $\Delta\alpha$'s were larger than the observed results. These results of the calculations were discussed on the basis of the values of $\alpha_{//}$ and $\alpha_{\perp}$ calculated with different parametrizations. As an example of the application of this method, the variations in the polarizability and anisotropy with the frequency of the incident light were calculated. Moreover, the polarizability derivatives, $(\partial\alpha/\partial S_i)_0$ and $(\partial^2\alpha/\partial S_i^2)_0$, with respect to the symmetric stretching coordinate, S_i, were calculated for NH_3 and CO_2. Furthermore, the variations in the polarizability derivatives with the energy of the incident light were calculated.

Arylation and Vinylation Reactions of Benzo[*b*]furan *via* Organopalladium Intermediates

Akira KASAHARA,* Taeko IZUMI, Minoru YODONO,** Ryu-ichi SAITO, Toru TAKEDA, and Toshiaki SUGAWARA***

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa-shi, Yamagata 992

(Received June 8, 1972)

The Heck reaction of benzo[*b*]furan with arylpalladium chloride leads to the formation of 2-arylbenzo[*b*]-furan derivatives. In the presence of palladium acetate, benzo[*b*]furan reacts in benzene to give 2,2′-bibenzo-[*b*]furyl, accompanied by 2-arylbenzo[*b*]furan. In the phenylation of [2-^{2}H]benzo[*b*]furan with phenylpalladium salts, it was confirmed that no hydride shift takes place in the reaction. In the presence of palladium acetate, benzo[*b*]furan also reacts with olefin to produce benzo[*b*]furyl-substituted olefins, accompanied by a small amount of 2,2′-bibenzo[*b*]furyl, and from the reaction of [β,β-$^2H_2$]styrene and benzo[*b*]furan in the presence of palladium acetate it was confirmed that no hydride shift occurs in the reaction.

It is considered that furan possesses a considerable aromatic character arising from the delocalization of four carbon π-electrons and two paired electrons donated by the oxygen atom. However, furan still has a character which clearly resembles a conjugated diene or enol ether. In order to study whether or not the Heck arylation[1] occurs in the reaction of benzo[*b*]-furan (I) with arylpalladium compounds, the reaction of I with arylmercuric compounds (II) was performed in the presence of palladium salts. This report also contains the results of a study of the reaction of I and olefins in the presence of palladium acetate.

Results and Discussion

In the presence of palladium salts, I was allowed to react with II in polar solvents, such as ethanol. The substitution reaction on the C_2 of I has been observed to lead to the formation of 2-arylbenzo[*b*]furan (III), accompanied by a small amount of biaryl (IV). The reactions carried out are summarized in Table 1. The properties of the products are given in Table 2. Furthermore, in order to study whether or not a hydride shift takes place between the C_2 and C_3 of I in the Heck reaction of I, the reaction of [2-^{2}H]-benzo[*b*]furan (V) with arylpalladium compounds was performed in ethanol at room temperature. The results are summarized in Table II. If the reaction of V with arylpalladium compounds proceeds *via* a hydride shift, the reaction will produce product (III) containing some deuterium on the C_3. However, in the presence of palladium salts, the reactions of V with phenylmercuric

b) The deuterium-content of the products was calculated from the mass spectra analyses results.
c) The 60 MHz NMR spectra showed also an absence of *D* in the C_3.

acetate, *p*-tolylmercuric chloride, and *p*-anisylmercuric chloride all result in the formation of III; this indicates that the deuterium content is not at all different from the case of the hydride shift. This clearly shows that no hydride shift occurs in the reaction.

Davidson and Trigg[2] have recently reported that reactions between aryl compounds and palladium salts give arylpalladium complexes, and a biaryl-formation reaction by palladium salts has also been reported.[3] We were interested in whether or not the arylation reaction of I also occurs in the reaction of I, benzene, and palladium acetate, and so the reaction of I with palladium acetate was performed in a solution of acetic acid and benzene for 6 hr. The reactions carried out are summarized in Table 4. Interestingly, in the case of the reaction with benzene, 2,2′-bibenzo[*b*]furyls (VI, homocoupling products) rather than III was formed as the major product, suggesting that the reactivity of I towards palladium acetate is far higher than that of benzene and that I is highly activated by palladium

Table 4. The reactions of benzo[*b*]furans (I) with benzene

Benzo[*b*]furans	Products	Yield %[a]
Benzo[*b*]furan	Biphenyl	4
	III-1	12
	2,2′-Bibenzo[*b*]furyl (VI-1)[b]	68
5-Methylbenzo[*b*]-furan	Biphenyl	5
	III-5	10
	5,5′-Dimethyl-2,2′-bibenzo[*b*]-furyl (VI-2)[c]	70
[2-^{2}H]-Benzo[*b*]-furan	Biphenyl	5
	III-1[d]	11
	VI-1[e]	70

a) Yields are based upon the used benzo[*b*]furans.
b) Mp 194—195°C, (lit.[f] mp 194.5—195.5°C).
c) Mp 217—218°C, IR spectrum: 883 cm^{-1}. NMR spectrum: δ 2.43 s (6) $-CH_3$, 7.01 s (2) furan ring protons, 7.12—7.44 ppm m (6). Found: C, 82.48; H, 5.41%; mol wt 255 (Rast). Calcd for $C_{18}H_{14}O_2$: C, 82.48; H, 5.34%; mol wt 262.
d, e) Deuterium contents of both compounds were 0 % from the mass spectra analyses results and the 60 MHz NMR spectra also showed an absence of D in the furan ring.

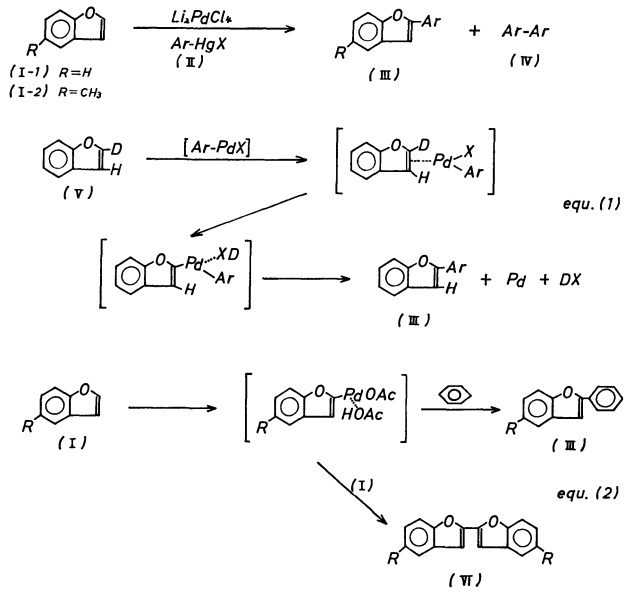

Fig. 1.

salts, thus forming benzo[*b*]furylpalladium salts. The reaction can be explained by Eq. (2) of Fig. 1. Furthermore, the reaction of V and benzene was carried out in the presence of palladium acetate and acetic acid. The deuterium analyses of the products clearly show that no hydride shift occurs in the formation of either VI or III.

On the other hand, Fujiwara *et al.*[4] have described that a reaction mixture of palladium acetate, olefins, benzene derivatives, and acetic acid gives arylation products of olefins. Therefore, in order to investigate the reactivity of I towards olefins, the reaction of I, olefin, and palladium acetate was performed.[5] When a solution of I and olefin in acetic acid was heated at reflux in the presence of palladium acetate, benzo[*b*]furyl-substituted olefin (VII) was obtained as the major product, accompanied by VI. Neither the acetoxylation products of I nor those of olefins were obtained. The results of the reaction are summarized in Table 5. The products were identified by the observation of the IR and NMR spectra (Table 6). For example, the reaction of I-1 with styrene resulted in

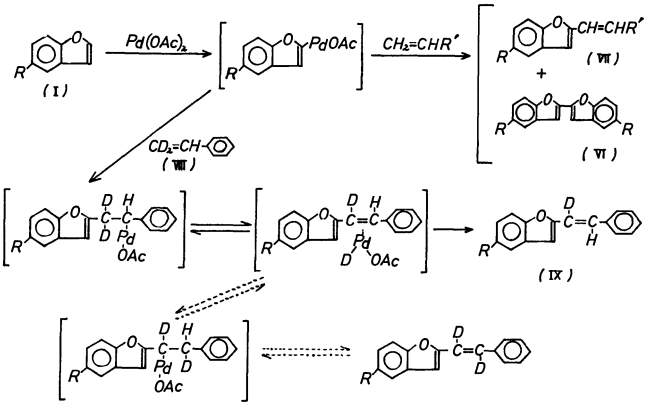

Fig. 2.

5) Recently, it has been reported briefly that the reaction of furan and styrene in the presence of palladium acetate resulted in the formation of 2-styrylfuran and 2,5-distyrylfuran: I. Moritani, R. Asano, Y. Fujiwara, and S. Teranishi, Abstracts of Papers Presented at the 26th Annual Meeting of the Chemical Society of Japan (1972), II, p. 1033.

the formation of 2-styrylbenzo[*b*]furan (VII-1), accompanied by a small amount of VI-1. These results indicate that this substitution reaction occurs on the C_2 atom of I and the β-carbon atom of styrene, and also that the reactivity of the benzo[*b*]furylpalladium compounds is far higher toward olefin than toward I. As with Fujiwara's arylation of olefin, it appears that an electron-donating group on olefinic carbon stoms decreases the yields.

Moreover, in order to study whether or not the reaction of I, olefins, and palladium acetate proceeds *via* a hydride shift, the reaction of I with [β,β-$^2H_2$]-styrenes (VIII) was performed in the presence of palladium acetate and acetic acid. If the hydride shift occurs in the reaction of I with VIII, the reaction will produce a mixture of mono- and di-deuterio-derivative of VII. However, the reaction of I with VIII resulted in the formation of monodeuterio-styrylbenzo-[*b*]furans (IX), indicating that the deuterium content is completely different from the case of the hydride shift (D-content=150%). The reaction of V and undeuteriated styrene also produced VII-1, which was free from deuterium. Furthermore, the reaction of V and VIII resulted in the formation of IX. All these results clearly confirmed that no hydride shift takes place in the reaction, and suggested that a loss of hydrido-palladium species from the benzo[*b*]furylpalladium compound-olefin adduct involves the intermediate formation of a hydride-palladium π-complex and is much more likely than the readdition in the reverse direction.

Experimental

Analysis and Materials. All the melting points and boiling points are uncorrected. The infrared spectra were recorded by means of a Hitachi EPI-S IR spectrometer, while the NMR spectra were obtained by a Hitachi H-60 NMR spectrometer at 60 MHz in $CDCl_3$, using tetramethylsilane as the internal standard. Their chemical shifts are recorded as parts per million downfield from tetramethylsilane on the scale, together with the splitting pattern and the relative integrated area: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; d-d, double-doublet. The mass spectra were obtained on a Hitachi RMU-6d mass spectrometer, using a direct inlet and an ionization energy of 70 eV.

The palladium acetate was prepared according to the procedure of Wilkinson.[6] The [β,β-$^2H_2$]-styrene (VIII) was prepared from ethyl phenylacetate according to the method described by Schubert and Lamm.[7] The following compounds were synthesized by the methods described in the literature: benzo[*b*]furan[8] (I-1), bp 173—174°C; 5-methylbenzo[*b*]furan[9] (I-2) bp 197—199°C; *p*-tolylmercuric chloride,[10] mp 232—233°C; *p*-anisylmercuric chloride,[11] mp 173—174°C; *m*-nitrophenylmercuric chloride,[12] mp 218—221°C. The phenylmercuric acetate and the starting olefins were of a commercial grade.

Preparation of [2-^2H]-Benzo[b]furan (V). 2-Bromobenzo[*b*]furan was prepared from 2,3-dibromobenzo[*b*]furan in an 80% yield by the method described by Stoermer and Kahlert.[13] 2-Bromobenzo[*b*]furan (4.5 g, 0.179 mol) was reduced with lithium aluminum deuteride (4.5 g, 0.107 mol) in anhydrous tetrahydrofuran to [2-^{2}H]benzo[*b*]furan (V) (bp 173—174°C); 65% yield. NMR spectrum: δ 6.49 (s) H on the C_3; 7.06—7.51 (m) aromatic ring protons. The 60 MHz NMR spectrum showed the absence of H on the C_2, and a mass-spectral analysis indicated that the isotopic purity was 98.5%.

Found: C, 80.78; H, 5.97%. Calcd for C_8H_5DO: C, 80.57; H, 5.90%.

General Procedure for the Arylation of Benzo[b]furans (I). A lithium chloropalladite solution was prepared by stirring 0.84 g (0.02 mol) of anhydrous lithium chloride and 1.77 g (0.01 mol) of anhydrous palladium chloride overnight at room temperature in 100 ml of ethanol. To this lithium chloropalladite solution, a mixture of 0.01 mol of arylmercuric compound (II) and 0.02 mol of I was added, after which the mixture was stirred at room temperature for 12 hr. The products were isolated by filtration to remove a precipitated palladium and by distillation under reduced pressure to remove the solvent. The residue was dissolved in benzene and chromatographed on alumina. The first elution with benzene and recrystallization from ethanol afforded colorless crystals, which were identified as biphenyl derivatives by a mixed-melting-point determination. Further elution with benzene or chloroform and recrystallization from ethanol afforded the respective arylation product (III). The structures of the products were confirmed by a mixed-melting-point determination with an authentic sample and by the observation of the IR and NMR spectra. The results are summarized in Table 1, while the analytical results and the properties of the products are listed in Table 2.

General Procedure for the Arylation of [2-^2H]-Benzo[b]furan (V). In an ethanol (80 ml) solution of lithium chloropalladite (0.01 mol), a mixture of 0.01 mol of an arylmercuric compound (II) and 0.02 mol of V was stirred for 12 hr at room temperature. After the separation of the precipitated palladium, and after the evaporation of the solvent, the residual oil was separated by alumina chromatography. The 2-arylated benzo[*b*]furan thus produced was recrystallized from ethanol. The deuterium-content of the purified products was calculated from a mass-spectra analysis. (see Table 3).

General Procedure for the Reaction of Benzo[b]furans (I) with Benzene. In a solution of dry benzene (100 ml) and acetic acid (40 ml), was dissolved palladium acetate (2.24 g, 0.01 mol) and an equivalent amount of I. The mixture was heated gently under reflux at 80°C with stirring for 6 hr. After the separation of the precipitated palladium, the mixture was poured into water. The organic layer was separated, the aqueous layer was extracted with benzene, and the combined extracts were neutralized, washed, and dried ($MgSO_4$). After the evaporation of the solvent, the residue was dissolved in benzene and chromatographed on alumina. The first elution with benzene afforded colorless crystals which were identified as biphenyl by a mixed-melting-point determination. The second elution with benzene and recrystallization from ethanol afforded the 2-phenylbenzo[*b*]furans (III). Further elution with benzene or chloroform and

*) The deuterium-content of the products was calculated from the mass-spectral analyses results, and on the basis that D-content of product containing one olefinic deuterium is 100%.

a) Neither of the 60 NMR nmr spectra of the products showed also evidence of D in the β-carbon of styryl group.

recrystallization from ethanol afforded colorless crystals which were identified as 2,2′-bibenzo[*b*]furyls (VI). The results are summarized in Table 4.

The Reaction of [2-^2H]-Benzo[b]*furan (V) with Benzene.* In the presence of palladium acetate, the reaction of V, benzene, and acetic acid was carried out by the same procedure as that used in the reaction of I with benzene. The products were purified by chromatography on alumina and recrystallization from ethanol. The results are summarized in Table 4. The isotopic purity of the products was calculated on the basis of a mass-spectral analysis and from the NMR results.

General Procedure for the Reaction of Benzo[b]*furan (I) with Olefins.* A mixture of palladium acetate (10 mmol), olefin (10 mmol), and I (10 mmol) was stirred in acetic acid (100 ml) for 6 hr at reflux. The resulting mixture was filtered to remove palladium metal, and, after the evaporation of the solvent under reduced pressure, the residue was poured into water. The organic layer was extracted with ether, and the ether layer was treated with an aqueous sodium bicarbonate solution, washed with water to free it from acetic acid, and then dried over anhydrous magnesium sulfate. After the evaporation of the solvent, the products were isolated by column chromatography. The first elution with benzene and the subsequent recrystallization from ethanol afforded colorless crystals which were identified as the 2-benzo[*b*]furyl-substituted olefin derivative (VII). Further elution with chloroform and recrystallization from ethanol afforded VI. The structures of the products were confirmed by means of the IR and NMR spectra. The results are summarized in Table 5, while the analytical results and the properties of the products are listed in Table 6.

The reactions of I with VIII, of V with styrene, and of V with VIII proceeded in a manner similar to that described above. The isotopic purity of the products was calculated on the basis of a mass-spectral analysis and from the NMR results. The results are summarized in Table 7.

The authors would like to express their thanks to Professor Yoshio Kitahara of Tohoku University for the measurements of the mass spectra, to Assistant Professor Kaoru Hanaya and Mr. Hideaki Kudo of Yamagata University for the measurements of the NMR spectra, and to the Kawaken Fine Chemical Co., Ltd., for its gift of palladium chloride.

Determination of Catalytic Rate Constants in the Reaction of Lysozyme and Oligosaccharide by Computer Simulation Analysis

Hiroko TADA and Toshiaki KAKITANI*

Department of Physics, Kyoto University, Kyoto 606

**Research Institute for Fundamental Physics, Kyoto University, Kyoto 606*

(Received July 20, 1972)

We have developed Chipman's kinetic study on a reaction of lysozyme and oligosaccharide. That is, we have analyzed how each catalytic rate constant affects the pattern of time-course graphs of oligomer concentrations in the reaction. By fitting computer simulation curves to three experimental time-course graphs, values of the catalytic rate constants for the bond-cleavage, transglycosylation and hydration are determined step by step. Also some binding constants are evaluated.

Recently Chipman formulated a kinetic model for the reaction of lysozyme and oligosaccharides including reaction mechanisms of hydrolysis and transglycosylation.[1] The kinetic equations became much complicated, far from that of Michaelis-Menten type. Numerically solving them by computer, he rather well simulated experimental data[2] of the time-course graphs of oligomer concentrations in the reaction. Performing the least-squares fit to one of the experimental data, he evaluated the rate constant of bond-cleavage and the ratio between the rate constant of transglycosylation and that of hydration as 1.75 sec^{-1} and $2.77\times10^{3}M^{-1}$, respectively. This study is much valuable because a kinetic scheme which includes the transfer reaction is formulated in a simple form, and the value of the rate constant of bond-cleavage is given for the first time. In this paper, we intend to develop his study and determine the values of the rate constants of transglycosylation and hydration which are not determined by him. We do this by analyzing the role of each catalytic rate constant in the pattern of the time-course graph. In the next section, we briefly formulate our kinetic model which differs a little from Chipman's.

Kinetic Model

Lysozyme has six binding sites for the substrate $(GlcNAc\text{-}MurNAc)_n$[3] named A, B, C, D, E, and F, and it cleaves the glycosyl bond locating between the D and E sites of the bound substrate.[4] As MurNAc cannot be bound at the A, C, and E sites, the oligomer is cleaved only between MurNAc and GlcNAc.[5] Therefore, in the kinetic treatment, we can consider the disaccharide GlcNAc-MurNAc as a unit. Then, six species of binding forms are allowed. In Fig. 1 we show our kinetic model. The notation is as follows: D_n is the oligomer $(GlcNAc\text{-}MurNAc)_n$, $C_{n,i}$ the complex of D_n and the enzyme E where the i-th susceptible

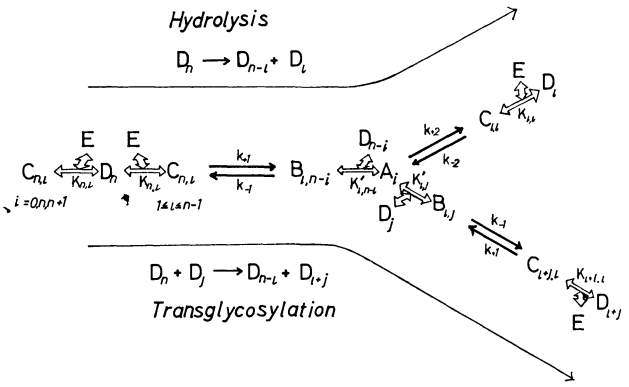

Fig. 1. Kinetic scheme of the lysozyme-catalyzed reaction. The notation is explained in the text.

bond from the non-reducing terminus of the oligosaccharide is at the catalytic site, A_i the "enzyme-carbonium ion intermediate" complex,[4] and $B_{i,n}$ the complex of A_i and D_n in which the non-reducing terminus of D_n is bound at the EF site of A_i. The complexes $C_{n,i}$ for $i=0$, n, $n+1$ are the non-productive ones, and $C_{n,i}$ for $1\leq i\leq n-1$ are the productive ones. Catalytic rate-constants, k_{+1}, k_{-1}, k_{+2}, and k_{-2} are those of bond-cleavage, bond-formation, hydration and its reverse process, respectively. These catalytic rate constants are assumed to be same for both poor and good substrates. The arrow $\overset{\nearrow}{\underset{\searrow}{\Longleftrightarrow}}$ represents a binding process, in which we assume an equilibrium is attained. The binding constant is written beside the arrow. These binding constants are explicitly written as follows:

$$\left.\begin{aligned} &K_{1,0}=K_{EF},\ K_{1,1}=K_{CD},\ K_{1,2}=K_{AB}\\ &K_{n,0}=K_{EF},\ K_{n,1}=K_{C\sim F},\ K_{n,n}=K_{A\sim D},\ K_{n,n+1}=K_{AB}\\ &\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\text{for } n\geq 2\\ &K_{n,i}=K_{A\sim F}\qquad\qquad\text{for } n\geq 3,\ \leq 2i\leq n-1\\ &K'_{n,j}=K_{EF}\qquad\qquad\text{for all } j \text{ and } n. \end{aligned}\right\}\quad(1)$$

This kinetic model is much simplified by considering the following group S_n of the substrates and group I_j of the intermediates within which all species are combined to each other by the binding equilibrium processes:

$$[S_n]=[D_n]+\sum_i[C_{n,i}]+\sum_j[B_{j,n}],\quad(n=1,2,\cdots)\quad(2)$$

$$[I_j]=[A_j]+\sum_n[B_{j,n}].\quad(j=1,2,\cdots)\quad(3)$$

The kinetic equations for these groups are written as

$$\frac{d[S_1]}{dt} = k_{+2}[A_1] - k_{-1}K_{EF}[D_1]\sum_j[A_j] + k_{+1}K_{C\sim F}[D_2][E] + k_{+1}K_{A\sim F}[E]\sum_{l>2}[D_l], \quad (4)$$

$$\frac{d[S_n]}{dt} = k_{+2}[A_n] - k_{+1}\{K_{C\sim F}+(n-2)K_{A\sim F}\}[D_n][E] - k_{-1}K_{EF}[D_n]\sum_j[A_j] + k_{+1}K_{C\sim F}[D_{n+1}][E] + k_{+1}K_{A\sim F}[E]\sum_{l>n+1}[D_l] + k_{-1}K_{EF}\sum_{m<n}[A_m][D_{n-m}], \quad \text{for } n\geq 2 \quad (5)$$

$$\frac{d[I_j]}{dt} = -k_{+2}[A_j] + k_{+1}K_j'[E]\sum_{l>j}[D_l] - k_{-1}K_{EF}[A_j]\sum_n[D_n], \quad (j=1, 2, \cdots) \quad (6)$$

where

$$[D_n] = [S_n]/(1+K_n[E]+K_{EF}\sum_j[A_j]) \quad (7)$$

$$[A_j] = [I_j]/(1+K_{EF}\sum_n[D_n]) \quad (8)$$

$$[E] = ([E]_0-\sum_j[I_j])/(1+\sum_n K_n[D_n]) \quad (9)$$

$$K_j' = \begin{cases} K_{C\sim F} & \text{for } j=1 \\ K_{A\sim F} & \text{for } j=2, \end{cases} \quad (10)$$

$$K_n = \sum_{i=0}^{n+1}K_{n,i} = \begin{cases} K_{EF}+K_{CD}+K_{AB} & \text{for } n=1 \\ K_{EF}+K_{C\sim F}+(n-2)K_{A\sim F}+K_{A\sim D}+K_{AB}. & \text{for } n\geq 2 \end{cases} \quad (11)$$

In the above $[E]_0$ is the total enzyme concentration.

Here we mension about the difference between our model and Chipman's. Although our model is based on the consideration of the equilibrium at the binding process also for intermediates, Chipman's model is based on the scheme of the two-step enzymic reaction similar to α-chymotrypsin.[6] That is, he neglected, in Fig. 1, all species of B and the complexes C at the exits of the catalytic processes. But this difference is trivial. Indeed, observed quantities of the time-course graphs are the percent radioactivity P_n defined by

$$P_n = 100n[S_n]/\sum_l l[D_l]_0, \quad (12)$$

where $l[D_l]_0$ is the initial substrate concentration of the l-mer measured by GlcNAc-MurNAc unit. Thus, the time-course graph perfectly coincides between both models if our $k_{-1}K_{EF}$ is put equal to Chipman's rate constant of transglycosylation k_T. If either the experiment by which one can detect the species of C or B, or the calculation without the equilibrium-assumption for the binding is made, small difference between the two models will appear.

Numerical Calculation

Experimentally it is shown that k_{-2} is much small compared with all other reaction rate constants.[2] Thus we neglect its process in the numerical calculation. The binding constants $K_{A\sim F}$, $K_{A\sim D}$, and K_{AB} will be equalized with the apparent binding constants experimentally obtained for the hexamer, tetramer, and dimer, respectively. Those values are 3.5×10^4, 2.0×10^3, and 20 M^{-1}, respectively.[7] If we use the additivity-assumption of the binding energy, $K_{C\sim F}$, K_{CD}, and K_{EF} are calculated from the above binding constants as 28, 1.6, and 0.3 M^{-1}, respectively. However, the validity of the additivity-assumption has been proved neither experimentally nor theoretically. Therefore, we treat $K_{C\sim F}$, K_{CD}, and K_{EF} as unknown parameters together with k_{+1}, k_{-1}, and k_{+2}. In the following, we call a reaction, where the $2m$-mer is initially mixed with

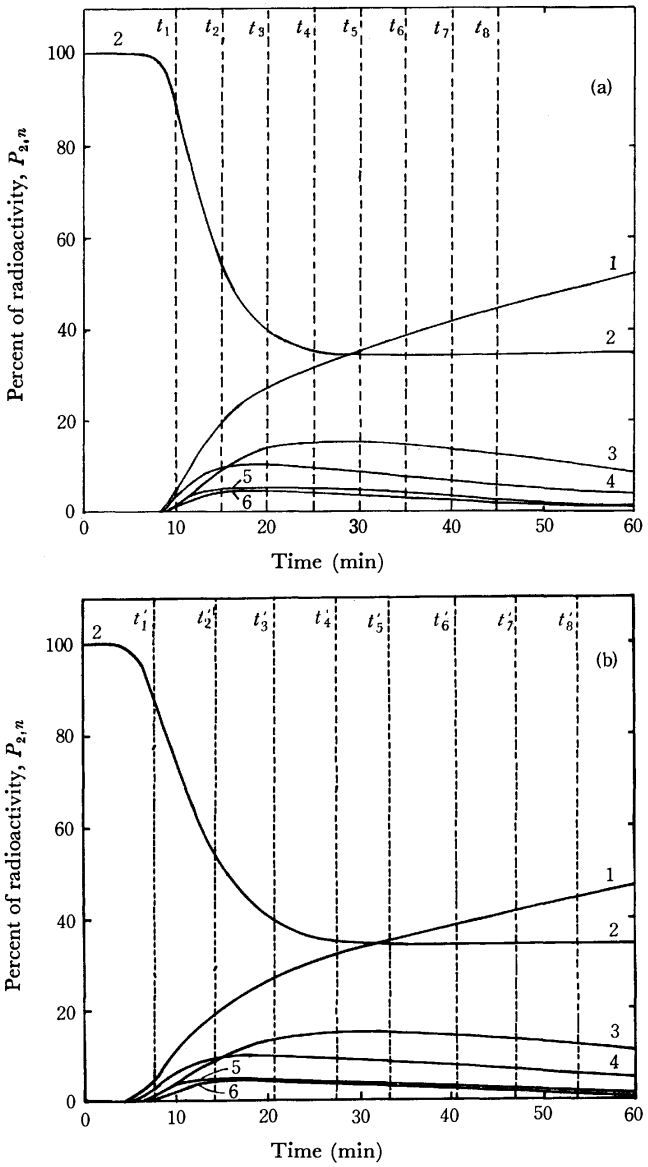

Fig. 2. Comparison of two time-course graphs in the tetramer-reaction between which the value of a is the same but those of the other kinetic constants are not. (a): $k_{+1}=2.0\ sec^{-1}$, $k_{-1}=1.8\times10^3\ sec^{-1}$, $k_{+1}=0.62\ sec^{-1}$, $K_{C\sim F}=2\times10^{-4}M^{-1}$, $K_{CD}=1.6\ M^{-1}$ and $K_{EF}=1.0\ M^{-1}$. (b): $k_{+1}=1.7\ sec^{-1}$, $k_{-1}=3.3\times10^2\ sec^{-1}$. $k_{+2}=0.33\ sec^{-1}$, $K_{C\sim F}=5.0\ M^{-1}$ $K_{CD}=1.6\ M^{-1}$ and $K_{EF}=3.0\ M^{-1}$. The value of a is $3.0\times10^3M^{-1}$ for both (a) and (b). The initial condition is $[D_2]_0=7.5\times10^{-3}M$, $[E]_0=2.1\times10^{-5}M$. The number beside each curve is the value of n.

lysozyme, as the $2m$-mer reaction. In our numerical calculation, the maximum length of the oligomer is put to be 18-mer. However, for example, in the tetramer-reaction, the largest oligomer given in the experimental curves is $P_{2,6}$. In such a case, we put $P_{2,6}=\sum_{n=6}^{9}P_{2,n}$ in our calculation. For the hexamerand octamer-reactions, we employed the similar procedure.

From the inspection of many time-course graphs with different values of the parameters, we have found the following important properties in this kinetic model. (i) In Fig. 2, we plotted two graphs of the tetramer-reaction, between which the ratio $a=k_{-1}K_{EF}/k_{+2}$ is same but the values of k_{+1}, k_{+2}, $K_{C\sim F}$, and K_{CD} are not same. In Fig. 2(a), we pick up an arbitrary set of times $\{t_i\}$ $(i=1, 2, \cdots, N)$, and obtain $\{P^{a}_{2,n}(t_i)\}$, where $P^{a}_{2,n}(t_i)$ denotes $P_{2,n}$ at time t_i in Fig. 2(a). Then, we find a set of times $\{t_i'\}$ which nicely satisfy the equation

$$P^{b}_{2,n}(t_i') = P^{a}_{2,n}(t_i) \tag{13}$$

for all n in Fig. 2(b) irrespectively of the values of the other parameters. This means that the ratio a is an essential factor which determines the distribution of the oligomer concentrations. This property holds also in the hexamer- and octamer-reactions. In the next section, we shall qualitatively explain this important property of our kinetic model. (ii) The time scale of the reaction is determined mainly by the catalytic rate con stants k_{+1} and k_{+2}. But they do not necessarily change the time scale uniformly. (iii) As shown in Fig. 3, the binding constant $K_{C\sim F}$ plays a role only in the initial stage called "time-lag-region" of the tetramer-reaction and little affects the time-course graphs of the hexamer- and octamer-reactions. This property comes from the fact that the tetramer is a poor substrate although the higher oligomer is a good substrate.[2] (iv) The binding constant K_{EF} affects the time-course graphs only through the form of $k_{-1}K_{EF}$ except when k_{EF} is much larger than K_{AB}. This is easily understood from the fact that K_{EF} enters into the kinetic equations mainly by the form of $k_{-1}K_{EF}$. This property states that we cannot simply determine the value of k_{-1} and K_{EF} independently. (v) The binding constant K_{CD} does not affect our time-course graphs unless K_{CD} is much larger than K_{AB}.

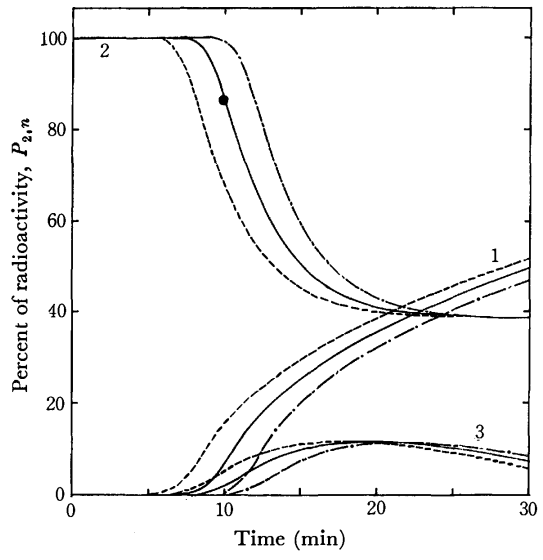

Fig. 3. Time-course graphs of the tetramer-reaction where the value of $K_{C\sim F}$ is varied. ------: $K_{C\sim F}=10^{-5}M^{-1}$, ——: $K_{C\sim F}=10^{-7}M^{-1}$, —·—: $K_{C\sim F}=10^{-9}M^{-1}$. The other parameters are $k_{+1}=3.3$ sec^{-1}, $k_{-1}=9.8\times10^{2}$sec^{-1}, $k_{+2}=0.58$ sec^{-1}, $K_{CD}=1.6$ M^{-1} and $K_{EF}=1.0$ M^{-1}. The initial concentrations of D_2 and E are the same as those in Fig. 2. The black circle is the experimental value of $P_{2,2}$ at 10 min.[2] The number beside each curve is the value of n. Curves of oligomers higher than hexamer are not written in this graph.

Determination of the Ratio $a=k_{-1}K_{EF}/k_{+2}$. In fitting of the theoretical curves to the experiments, we use the experimental values in the early stage of the reaction, because our kinetic model may not be good in the latter stage of the reaction as we discuss later. In the following numerical calculation, we used the times $t_1=10$ min and $t_2=17$ min for the tetramer-reaction, and $t_1=1$ min and $t_2=4$ min for the hexamer- and octamer-reactions.

Using the property (i), we can determine the value of the parameter a by best fitting the theoretical curve to the experimental values $P^{E}_{m.n}(t_1)$ and $P^{E}_{m.n}(t_2)$ for all n in the three reactions, where the superscript E denotes the experiment. We describe below the method of our calculation. First we fix the value of a. Suitably choosing the other parameters, we obtain t_1''s and t_2''s which satisfy the equation

$$P_{m,m}(t_i') = P^{E}_{m,m}(t_i), \qquad (i=1, 2) \tag{14}$$

for the tetramer-, hexamer-, and octamer-reactions, respectively. Then we calculate the following error function:

$$f_{m,i}(a) = \sum\{P_{m,n}(t_i')-P^{E}_{m,n}(t_i)\}^2, \qquad (i=1, 2) \tag{15}$$

Error functions thus obtained depend on a and are plotted in Fig. 4. The sum of these six error functions becomes minimum at $a=1.7\times10^{3}$ M^{-1}. This minimum point is derermined mainly by the three $f_{m,2}$'s. But we should not trust this value so firmly, because the minimum points in error function largely differ from each other. It will be right to say that the value of a is roughly in the region 1.2×10^{3} M$^{-1}<a<4.0\times10^{3}$ M^{-1}.

Determination of k_{+1} *and* k_{+2}. The values of k_{+1} and k_{+2} are not determined uniquely from the fitting procedure to a single kind of reaction, but only a functional relationship between them is obtained. Using the property (ii), we intend to obtain sets of k_{+1} and k_{+2} in each reaction for the fixed value of a. In the tetramer-reaction, the set of k_{+1} and k_{+2} are obtained by the procedure that t_1' and t_2', which are obtained from Eq. (14), may satisfy $t_2'-t_1'=t_2-t_1=7$ min. For the hexamer- and octamer-reactions, they are determined as the average of those which satify $t_1'=t_1=1$ min and $t_2'=t_2=4$ min, respectively. The obtained values k_{+1} and k_{+2} are shown in Fig. 5 for two values of a. Our expectation was that the three curves should cross at a point, which determines the real values of k_{+1} and k_{+2}. Indeed, it is well realized. From this graph, we obtain $k_{+1}=3.3$ sec^{-1} and $k_{+2}=0.58$ sec^{-1} for $a=1.7\times10^{3}$ M^{-1}, and $k_{+1}=2.0$ sec^{-1} and $k_{+2}=0.62$ sec^{-1}

Table 1. Values of the kinetic constants

The free energy of the catalytic rate constant is calculated from the equation $\Delta F^{*}_{x} = -RT \ln (k_x h/\kappa T)$. The cooperative energy E_c is also listed.

Kinetic constants	Ours $a=1.7\times10^{3}M^{-1}$	Ours $a=3.0\times10^{3}M^{-1}$	Chipman's[1] $a=2.77\times10^{3}M^{-1}$
k_{+1} (sec^{-1})	3.3	2.0	1.75
$k_{-1}K_{EF}$ ($M^{-1}sec^{-1}$)	9.8×10^{2}	1.8×10^{3}	Unknown (9.2×10^{4})
k_{+2} (sec^{-1})	0.58	0.62	Unknown (1.0×10^{2})
$K_{C\sim F}$ (M^{-1})	10^{-7}	2×10^{-4}	$\leq 6.3\times10^{-4}$
K_{CD} (M^{-1})	5.7×10^{-8}	1.2×10^{-5}	(0.5)
K_{EF} (M^{-1})	Unknown	Unknown	Unknown
ΔF^{*}_{+1} (kcal/mol)	17.0	17.2	17.4
$\Delta F^{*}_{-1}+\Delta F_{EF}$ (kcal/mol)	13.5	13.1	(10.8)
ΔF^{*}_{+2} (kcal/mol)	18.0	17.9	(14.9)
$\Delta F_{C\sim F}$ (kcal/mol)	9.7	5.1	≥ 4.4
ΔF_{CD} (kcal/mol)	10.0	6.8	(0.4)
E_c (kcal/mol)	11.8	7.2	≥ 6.5

The values in the parentheses are the standard values of Chipman.

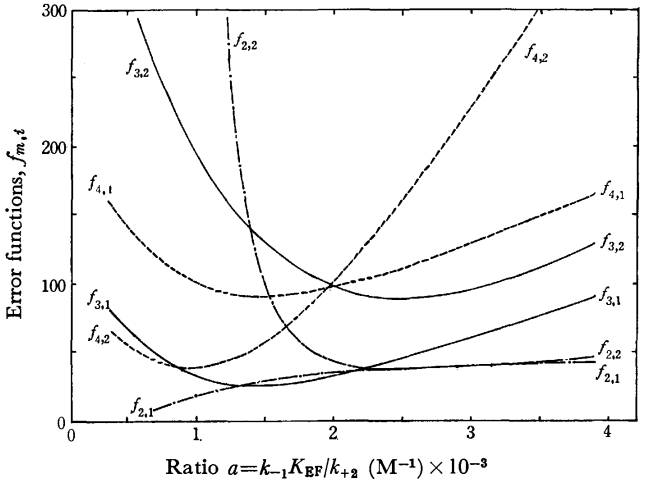

Fig. 4. Graphs of error-functions. -·-·-: tetramer-reaction, ——: hexamer-reaction and ------: octamer-reaction. The intial conditions used for our calculation are as follows: In the tetramer-reaction $[D_2]_0=7.5\times10^{-3}M$ and $[E]_0=2.1\times10^{-5}M$. In the hexamer-reaction $[D_3]_0=2.9\times10^{-4}M$ and $[E]_0=2.0\times10^{-6}M$. In the octamer-reaction $[D_4]_0=2.4\times10^{-4}M$ and $[E]_0=2.0\times10^{-6}M$.

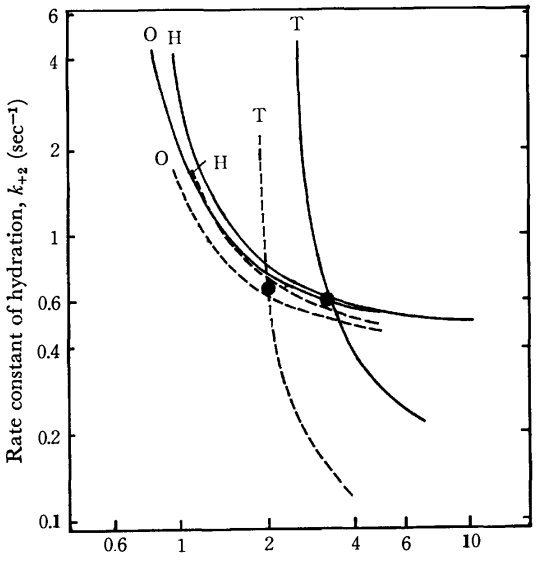

Fig. 5. Graphs of the sets of k_{+1} and k_{+2}. ——: $a=1.7\times10^{3}M^{-1}$ and ------: $a=3.0\times10^{3}M^{-1}$. The letters T, H, and O denote the tetramer–, hexamer– and octamer-reactions, respectively. The black circles are our obtained points through which three curves pass.

for $a=3.0\times10^{3}\ M^{-1}$.

Determination of $K_{C\sim F}$. We use the property (iii). As shown in Fig. 3, we determine the value of $K_{C\sim F}$ in such a way that $P_{2,2}$ may pass $P^{E}_{2,2}(t_1)$, fixing all the other parameters, where $t_1=10$ min. Some theoretical curves for the case of $a=1.7\times10^{3}\ M^{-1}$ are plotted in Fig. 3. From this, we get $K_{C\sim F}=10^{-7}\ M^{-1}$. In the same way, we get $K_{C\sim F}=2\times10^{-4}\ M^{-1}$ for the case of $a=3.0\times10^{3}\ M^{-1}$.

In Table 1, we summarized our results, together with the value of Chipman.[1] The method to get the value of K_{CD} is written in the following section. In Fig. 6, theoretical curves of ours are drawn and compared with the experiment.

Theoretical Analysis and Discussion

At first, we consider the important qualitative characteristics of our kinetic model. The most important one is the property (i), *i.e.*, the distribution of oligomers is almost uniquely determined by the ratio $a=k_{-1}K_{EF}/k_{+2}$. The reduced scheme of the reaction-path of this kinetic model is represented by the groups of the substrates and the intermediates as in Fig. 7, which is called as Path(n,i) henceforth. In the Path(n,i), if the step X(n,i) is rate-determining, the intermediate is rapidly converted to each product through the step Y(i). Then, on a given iteration step, a decrease of ΔC moles in S_n through the Path(n,i) produces the change ΔS_m in S_m. From Eqs. (5) and (6) it is given by

$$\Delta S_m = d_m - d_{i+m} + (\delta_{m,n-i}-\delta_{m,n})\cdot\Delta C, \quad (m=1, 2, \cdots) \qquad (16)$$

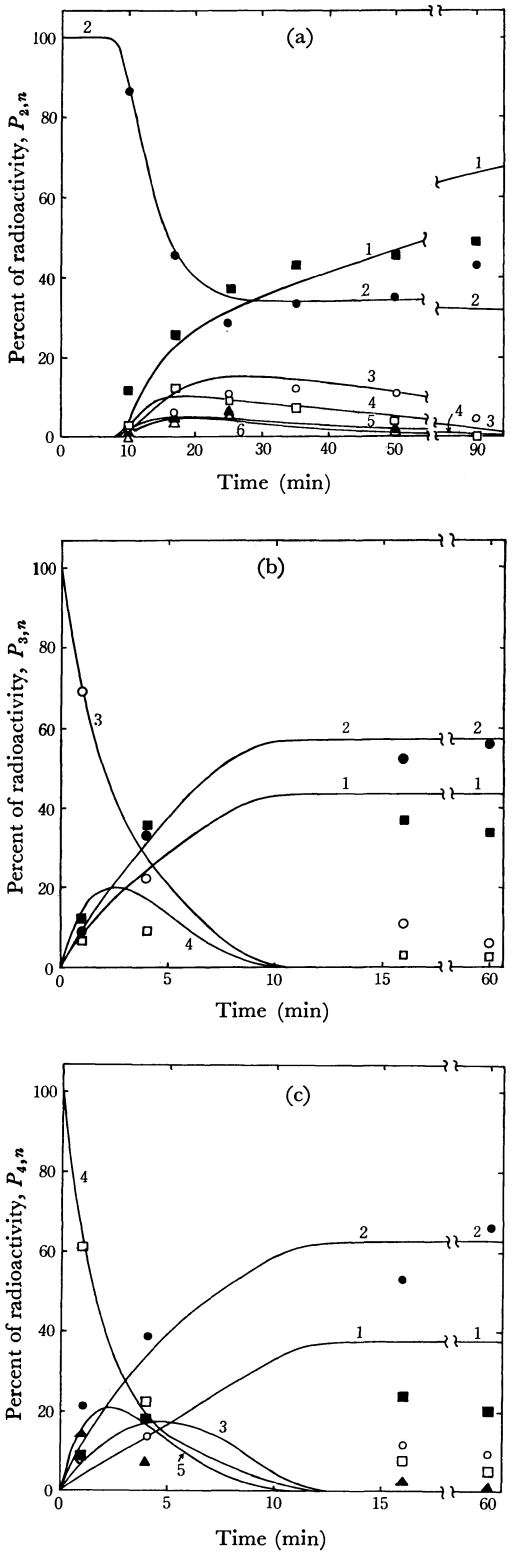

Fig. 6. Theoretical time-course graphs compared with the experiment. (a), (b), and (c) are the graphs of the tetramer-, hexamer- and octamer-reactions. The kinetic constants are as follows: $k_{+1}=2.0\,\mathrm{sec}^{-1}$, $k_{-1}=1.8\times10^{3}\,\mathrm{sec}^{-1}$, $k_{+2}=0.62\,\mathrm{sec}^{-1}$, $K_{C\sim F}=2\times10^{-4}\mathrm{M}^{-1}$, $K_{CD}=1.6\,\mathrm{M}^{-1}$ and $K_{EF}=1.0\,\mathrm{M}^{-1}$. The initial concentrations of the oligomer and the enzyme are same as those in the figure legend of Fig. 4. The experimental points[2] are shown by the following symbols; ■: dimer, ●: tetramer, ○: hexamer, □: octamer, ▲: 10-mer, △: 12-mer. The number beside each curve is the value of n.

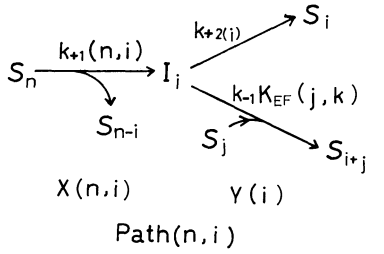

Fig. 7. The reduced scheme of the reaction-path. The step $X(n,i)$ is the process of the bond-cleavage of the $2n$-mer in the productive i-th binding form and the step $Y(i)$ is the process where the carbonium intermediate is converted to an oligomer of different kind depending on the species of the acceptor. The reduced catalytic rate constants in this figure are defined by $k_{+1}(n,i)=k_{+1}K_{n,i}[E]/(1+K_n[E]+K_{EF}\sum_l[A_l])$, $k_{+2}(i)=k_{+2}/(1+K_{EF}\sum_l[D_l])$ and $k_{-1}K_{EF}(i,j)=k_{-1}K_{EF}/\{(1+K_{EF}\sum_l[D_l])(1+K_j[E]+K_{EF}\sum_l[A_l])\}$.

where

$$d_m=\begin{cases}0 & \text{for } m<i\\ \Delta C/(1+a\sum_l[D_l]) & \text{for } m=i\\ \Delta C\cdot a\cdot[D_{m-i}]/(1+a\sum_l[D_l]) & \text{for } m>i\end{cases} \tag{17}$$

and $\delta_{i,j}$ is the Kronecker's delta function. In Eqs. (16) and (17), as $\{[D_l]\}$ are given from the previous step of the iteration procedure, ΔS_m is uniquely determined by a. Since the total reaction is obtained as the sum of this Path(n,i) over n and i, the total change on this iteration step is also uniquely determined by a. The time-course graphs are obtained by accumulating these iteration steps. Thus the pattern of the distribution is uniquely determined by a. When the step $Y(i)$ is rate-determining, the situation is more complicated. Among the groups $\{S_m\}$ $(m=i,\ i+1,\ \cdots)$ directly produced by the step $Y(i)$, the productive complexes $\{C_{m,l}\}$ $(m=i,\ i+1,\ \cdots;\ l=1,\ 2,\ \cdots,\ m-1)$ are immediately converted to $\{S_{m-l}\}$ and $\{I_l\}$ through the steps $\{X(m,l)\}$, and further these products $\{S_{m-l}\}$ pass the same procedure as $\{S_m\}$. Then the changes in S_m and I_m due to a decrease of ΔC moles in I_i through the step $Y(i)$ is obtained, accumulating also the effects of these sequential steps, as follows:

$$\Delta S_m=-d_{i+m}+Z_m\{d_m+d_{m+1}Z_{m+1,m}+\sum_{n>m+1}d_n(Z_{n,m}+\sum_{k=1}^{n-m-1}\sum_{\{n>l_1>l_2>\cdots>l_k>m\}}Z_{n,l_1}Z_{l_1,l_2}\cdots Z_{l_k,m})\} \tag{18}$$

$$\Delta I_m=-\delta_{i,m}\Delta C+\sum_{n>m}d_n[Z_{n,n-m}+(1-\delta_{n,m+1})\times\sum_{k=1}^{n-m-1}Z_{k+m,k}\{Z_{n,k+m}+(1-\delta_{k,n-m-1})\times\sum_{j=1}^{n-k-m-1}\sum_{\{n>l_1>l_2>\cdots>l_j>k+m\}}Z_{n,l_1}Z_{l_1,l_2}\cdots Z_{l_j,k+m}\}], \tag{19}$$

where

$$Z_m=\{1+(K_{EF}+K_{m,m}+K_{m,m+1})[E]+K_{EF}\sum_l[A_l]/(1+K_m[E]+K_{EF}\sum_l[A_l])\}$$

$$Z_{m,j}=K_{m,m-j}[E]/(1+K_m[E]+K_{EF}\sum_l[A_l]) \tag{20}$$

and $\{d_m\}$ are the same as Eq. (17). The sum of $\{n>l_1>l_2>\cdots>l_k>m\}$ denotes to sum up for all the set of l_1, l_2, $\cdots$, l_k satisfying the relation in the parentheses. In Eq. (20), $[E]$ and $\{[A_l]\}$ are given from the previous step of the iteration procedure. Then, also in this case, the distribution of oligomers is uniquely determined by a. When both the steps $X(n,i)$ and $Y(i)$ are rate-determining, the same conclusion may be obtained approximately although the exact explanation is impossible. The other important qualitative characteristic of our model is that; the time scale of the time-course graphs is determined only by the rate constants of the rate-determining steps independently of the other rate constants. When every step is rate-determining, it is dependent on all rate constants. Then, as shown in Fig. 5, the values of k_{+1} and k_{+2} with which the calculated graphs fit to a single time-course graph of the experiment are of the hyperbolic-like relation. These two conclusions are the general qualitative aspects in the endocatenase-catalyzed reaction of oligomers involving the transfer-reaction.

Next we compare our calculation with that of Chipman.[1] Using the method of the least-squares fit to 24 data points of the tetramer-reaction, he obtained the following results: (a) k_{+1} is rate-determining and its value is (1.75 ± 0.17) sec^{-1}, (b) the value of a is $(2.77\pm0.3)\times10^3$ M^{-1}, (c) $k_{-1}K_{EF}$ and k_{+2} are not rate-determining, thus those values are not obtained, and (d) the value of $K_{C\sim F}$ is less than $(6.3\pm12.4)\times10^{-4}$ M^{-1}. His values of a and k_{+1} are rather in agreement with ours. But, his results, (b) and (c), do not seem to be correct judging from our graph of Fig. 5. That is, the tetramer curve in Fig. 5 is almost perpendicular at $k_{+1}\cong1.8$ sec^{-1} and bends to the right as the value of k_{+1} becomes larger than 2.0 sec^{-1}. Thus, k_{+1} is not rate-determining except the perpendicular region of the curve. This means that one cannot determine the values of k_{+1} or k_{+2} but obtain a relation between them from the data of the tetramer-reaction only.[10] In our calculation, we used other two data, *i.e.*, time-course graphs of the hexamer- and octamer-reactions. Finding the cross points among these three curves, we succeeded in determining the values of k_{+1} and k_{+2}. The point corresponding to his standard values lies near the upper-extrapolated tetramer curve, but far above the hexamer and octamer curves in Fig. 5. There may be an argument that the experiments of the hexamer- and octamer-reactions are not so correct.[8] If it is really so, our results will also be corrected. But, our procedure to determine the values of the catalytic rate constants using graphs similar to Fig. 5 is useful whenever other reliable experiments appear. As to the value of $K_{C\sim F}$, our result is consistent with his.

Summarizing the above results and using the value of the free-energy of the hydrolysis of maltose,[9] which is similar to that of MurNAc–GlcNAc, we give in

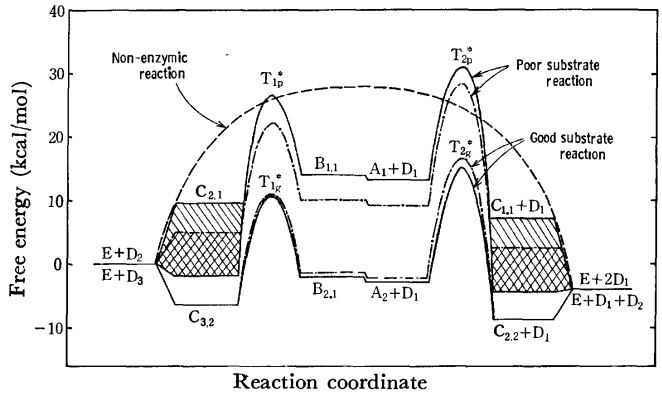

Fig. 8. Free-energy scheme in the lysozyme-catalyzed reaction. The graphs of the tetramer- and hexamer-reactions are written together by fitting the initial energy levels to zero. ——: $a=1.7\times10^3$M^{-1}, -·-·-: $a=3.0\times10^3$M^{-1}. The energy levels of $C_{2,1}$ and $C_{1,1}+D_1$ have uncertainty. The highest levels of them are those obtained from the assumption that the catalytic rate constants are same for both the good and poor substrates. The lowest levels are those obtained from the additivity-assumption of the binding energy. The real energy levels will be between those of the two extreme cases. These graphs are written assuming $K_{EF}=0.3$ M^{-1}. When this value is altered, the energy levels of $B_{1,1}$ and $B_{2,1}$ shift by $-RT\ln(K_{EF}/0.3)$ kcal/mol, keeping all the other energy levels unchanged. T_{1p}^*, T_{2p}^*, T_{1g}^*, T_{2g}^* represent transition states for the poor and good substrates reactions. The energy level of the non-enzymic reaction is also written for comparison.

Fig. 8 a schematic model for the free-energy potential of lysozyme reaction. From the case of the good substrates in Fig. 8, the value of k_{-2} is estimated as about 10^{-4} sec^{-1}, which is much smaller than the other catalytic rate constants as expected. Furthermore, the unknown binding constant K_{CD} is estimated by the difference between the energy height of T_{2p}* from the line $E+2D_1$ and that of T_{2g}* from the line $C_{2,2}+D_1$, as 1.2×10^{-5} M^{-1} and 5.7×10^{-8} M^{-1} for $a=3.0\times10^3$ M^{-1} and 1.7×10^3 M^{-1}, respectively. The non-enzymic case is also drawn in Fig. 8 for comparison, using Piszkiewicz and Bruice's data on the di-*N*-acetylchitobiose.[11] The transition state for the poor substrates has almost the same height as the non-enzymic one, but, for the good substrates, it is largely lowered by as much as 12—13 kcal/mol, which makes the overall rate constant by about 10^9 times larger. This large stabilization of the transition-state is produced by the cooperative binding effect between the AB and C∼F sites. Its cooperative energy is calculated as

$$E_c = -RT\ln(K_{AB}K_{C\sim F}/K_{A\sim F}) - \Delta F_m \qquad (21)$$

where ΔF_m, which is due to the mixing entropy, is about 2.4 kcal/mol. Here, if the additivity-assumption of the binding energy holds, E_c becomes zero. Our value of E_c is 11.8 kcal/mol and 7.2 kcal/mol for $a=1.7\times10^3$ M^{-1} and 3.0×10^3 M^{-1}, respectively. This large value means that the sites A and B play an important role to stabilize the distorted conformation at the D site in the reaction of the good substrates, although the mechanism of it is yet unknown.

9) R. A. Dedonder, *Ann. Rev. Biochem.*, **30**, 347 (1961).

10) Examining reactions of higher oligosaccharides under low concentration conditions, Chipman seems to have estimated that k_{+2} should be at least of the order of 0.5 sec^{-1}. If it is assumed, his results (b) and (c) are derived.

11) D. Piszkiewicz and T. C. Bruice, *J. Amer. Chem. Soc.*, **90**, 5844 (1968).

It may be also considered, however, that the real reaction of the bond-cleavage of the poor substrates proceeds in the more loosely bound form with less strain (*i.e.* much larger value of $K_{C\sim F}$), and by much smaller value of k_{+1}, maintaining the value of $k_{+1}K_{C\sim F}$ as constant (in the kinetic equations (4)—(9), $K_{C\sim F}$ appears mainly in the form $k_{+1}K_{C\sim F}$). The real energy level of this loosely bound complex may be located somewhere in the hatched region of Fig. 8. Similar consideration may be applied to K_{CD} and k_{-2} for the dimer.

The observable effect of the transglycosylation does not appear until the ratio a becomes so large that the value of $k_{-1}K_{EF}[D]$ becomes comparable to that of k_{+2}. It is reasonable that the order of our obtained value of a is 10^3 M^{-1}, since the substrate concentration is order of 10^{-3}—10^{-4}M in the experiments we used. This result means that the rate constant of the transfer-reaction may be rather large even for the case of other enzyme-catalyzed reactions, in which an effective transfer-reaction had not been detected experimentally. It may be detected, if the suitable initial concentration of the substrate is used, so that the transfer-reaction process becomes comparable to the competitive process.

Recently, using the transient NMR[12] and T-jump method,[13] the forward binding rate constants k_{+b} for GlcNAc, $(GlcNAc)_2$, and $(GlcNAc)_3$ are obtained as 3.5×10^5 $M^{-1}sec^{-1}$, 3.6×10^6 $M^{-1}sec^{-1}$, and 4.44×10^6 $M^{-1}sec^{-1}$, respectively. We find that the binding rate $k_{+b}[D_n][E]$ is not necessarily much larger than the reaction rate $k_{+1}[C_{i,j}]$. Therefore, the equilibrium-assumption about the binding process may not be so good. In the following we shortly examine how our kinetic schemes and simulated time-course graphs are altered if the dynamical process of the binding is effective. The binding constants of the above oligomers are 20—50 M^{-1}, 5×10^3 M^{-1}, and 1.0×10^5 M^{-1}, respectively.[14] Therefore, we find that the binding rate constant does not become large so much as the binding constant does as the oligomer becomes large. This tendency will also apply to the higher oligomers. In addition, binding rate constant of the productive binding may become very small because the D site of the complex must be distorted. From these, it is well expected that the number of the productive complex is much smaller than that calculated from the equilibrium-assumption when considerable numbers of small oligomers coexist. Then, the reaction proceeds much slowly. In the latter stage of the hexamer- and octamer-reactions where dimer and tetramer are considerably produced, the above case might be applied. In the experimental result, this seems to have happened (considerable amounts of the hexamer and octamer remain even at 15 min). In the earlier stage of the reaction, the dynamical binding effect, if exists, might be small.

We think that our kinetic model and treatment based on its qualitative characteristics described in this paper are a useful general method to determine the catalytic rate constants of the endocatenase-catalyzed reaction of oligomer including the transfer-reaction.

The authors wish to express their sincere thanks to Dr. H. Fukutome for valuable discussions and improving this manuscript. They also thank to Prof. D. M. Chipman for the critical comments.

The Reaction of *O,O'*-Diethyl α-Lithiomethylphosphonate with Organic Dihalides

Koichiro OSHIMA, Tamio SHIRAFUJI, Hisashi YAMAMOTO, and Hitosi NOZAKI

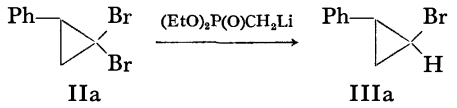
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606

(Received July 28, 1972)

The reactions of the α-lithio derivative of diethyl methylphosphonate with various organic halides are described. The half-reduction of *gem*-dihalocyclopropanes has been achieved with this reagent. The same reagent gives bibenzyl and tetraphenylethane from benzyl bromide and benzhydryl chloride respectively. The deprotonation-metallation process is observed in the reactions of cinnamyl chloride and of *trans*-β-bromostyrene, in which 3-chloro-1,6-diphenyl-1,5-hexadiene and 1,4-diphenyl-3-buten-1-yne are produced respectively.

The half-reduction of olefin-dihalocarbene adducts by organometallic reagents[1] is a useful method for obtaining monohalocyclopropanes, but it has been limited in scope due to competing reactions arising from the intermediary α-halocyclopropylmetal compounds. We have found that the α-lithio derivative of diethyl methylphosphonate appears to be an excellent reagent for the half-reduction of dihalocyclopropanes under mild conditions. This reagent showed promise of largely circumventing the side reactions encountered with other organometallic reagents.

O,O'-Diethyl α-lithiomethylphosphonate (I), prepared simply from *O,O'*-diethyl methylphosphonate and *n*-butyllithium at −78°C,[2] reacted with 1,1-dibromo-2-phenylcyclopropane (IIa) to give the expected 1-bromo-2-phenylcyclopropane (IIIa) as a predominant product



IIa IIIa

(68%). In contrast, the reaction of methylsulfinylcarbanion[3] with the dibromide, IIa, resulted in a polymeric mixture in which the desired bromide, IIIa, was absent. The anion, I, produced 9-bromo-*cis*-bicyclo[6.1.0]nonane (IIIb) from 9,9-dibromo-*cis*-bicyclo[6.1.0]nonane (IIb) in a 66% yield, while with *n*-butyllithium the latter afforded 1,2-cyclononadiene (IV) as the major product.[4]

A variety of *gem*-dihalocyclopropanes have been successfully reduced to the respective monobromides using the phosphonate reagent, as is indicated in Table 1. Most noteworthy is the preferential formation of thermodynamically more stable *trans*- or *exo*-monobromocyclopropanes, which might originate from the *endo-exo* isomerization of the initially-formed halocyclopropyllithium.[5]

TABLE 1. REACTION OF *gem*-DIBROMOCYCLOPROPANES WITH I IN THF

Substrate		Product[a]		
	Code		*exo* (*trans*)	*endo* (*cis*)
Code, R_1, R_2		Yield[b] (%)

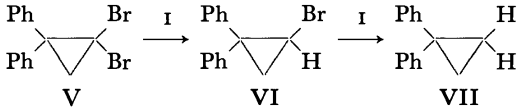
a) Products were identified by IR, NMR, and MS spectra with authentic samples.[1a]
b) Analyzed by glc.
c) Allene was also obtained in 9% yield and was identified by comparison with an authentic sample.

The preparation of the totally reduced cyclopropane derivative was also attained with this reagent. When *ca.* three equivalents of the anion, I, were allowed to react with 1,1-dibromo-2,2-diphenylcyclopropane (V), a mixture of 1-bromo-2,2-diphenylcyclopropane (VI), and 1,1-diphenylcyclopropane (VII) was obtained. The cyclopropane, VII, was obtained as the sole product (62%) when a large excess of the anion, I, was used for this reaction (>6 equiv).



V VI VII

The similarity of the anion, I, to methylsulfinylcarbanion prompted us to examine the reaction of I with other organic halides. Corey and Chaykovski have reported[6] that the treatment of benzyl chloride and benzhydryl chloride with methylsulfinylcarbanion furnished stilbene and tetraphenylethylene respectively.

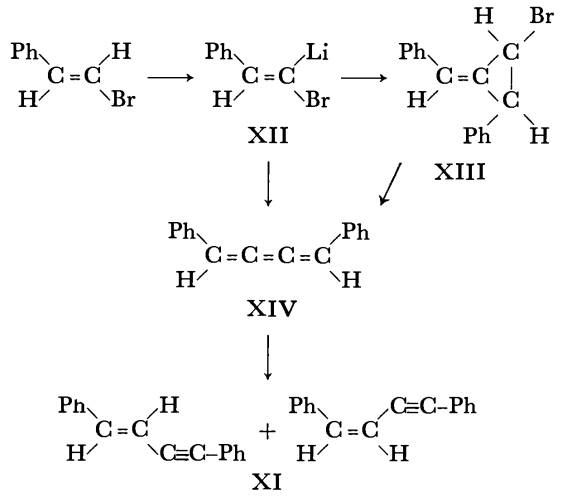
In contrast to these results, the anion, I, gave bibenzyl (VIII) and tetraphenylethane (IX) from benzyl bromide and benzhydryl chloride respectively. We suppose that this novel condensation reaction involves an unstable arylated carbanion, which affords the final product upon reaction with another halide.

Although the above-mentioned reactions are to be ascribed to the dehalogenation-metallation process, the deprotonation-metallation process has also been observed in some cases. Cinnamyl chloride gave 3-chloro-1,6-diphenylhexadiene-1,5 (X), whereas *trans*-β-bromostyrene afforded 1,4-diphenyl-3-buten-1-yne (XI). The latter reaction might involve an intermediary vinylcarbenoid, XII, which reacts with β-bromostyrene to form the methylenecyclopropane, XIII, followed by isomerization to XI through the cumulene derivative, XIV. An alternative pathway might be the direct dimerization of the vinylcarbenoid, XII, to form the cumulene, XIV.[7] The possibility of the formation of



phenylacetylene as an intermediate was excluded by the following experiment. When the solution of I was successively treated with phenylacetylene at −78°C and then with β-bromostyrene, no trace of XI could be detected among the products.

Experimental

All the bps are uncorrected. The microanalyses were performed at the Elemental Analyses Center of Kyoto University and by Mrs. Kiyoko Fujimoto. The NMR spectra were taken with a JEOL C-60H spectrometer and the chemical shifts are reported in δ values relative to the TMS internal standard. The mass spectra were obtained on a Hitachi RMU 6D spectrometer. The glc analyses or separations were performed using a 1 m column of SE-30 (30%) on Chromosorb W and He as the carrier gases.

General Procedure of the Reactions of Organic Halides with O,O'-Diethyl α-Lithiomethylphosphonate (I). In a nitrogen atmosphere, diethyl methylphosphonate was dissolved in freshly-distilled (over LAH) THF so as to give *ca.* a 0.5M solution. The solution was cooled to −78°C on a methanol–dry ice bath, and *n*-butyllithium (1.2 equiv) was added to this solution with stirring. After 15 min, a solution (*ca.* 1M) of organic halide was slowly added at −78°C. The ratio of the bromide to I was taken to be 1: 1.5 unless otherwise stated. The mixture was allowed to stand overnight at room temperature, treated with ice-cold water, and extracted with ether three times. The combined ethereal extracts was concentrated *in vacuo*. The products were separated and identified as usual. The following descriptions refer to cases which are not sufficiently covered by Table 1.

*Reaction of 13,13-Dibromo-*cis*-bicyclo[10.1.0]tridecane (IId).* The dibromide, IId (600 mg, 1.75 mmol), was treated with the anion, I (3.00 mmol), in dry THF (15 ml) at −78°C. A glc analysis of the crude reaction mixture showed the presence of *exo*-IIId (54%), *endo*-IIId (11%), and 1,2-cyclotridecadiene (9%). The bromide, IIId, was separated by preparative glc.

13-Bromo-*cis*-bicyclo[10.1.0]tridecane (IIId): bp 100°C (bath temp.)/0.05 mmHg; IR (neat) 1469, 1447, 1250, 1238, 1225 cm^{-1}; MS *m/e* (relative abundance) 260 (9), 258 (9), 175 (21), 79 (100). The NMR analysis did not reveal the methine proton absorption.

Found: C, 60.5; H, 8.9%. Calcd for $C_{13}H_{23}Br$: C, 60.2; H, 8.9%.

*Reaction of 13,13-Dibromo-*trans*-bicyclo[10.1.0]tridecane (IIg).* The halide, IIg (600 mg, 1.75 mmol), was treated with the anion, I (3.00 mmol), in dry THF (15 ml) at −78°C. The reaction mixture showed the presence of 13-bromo-*trans*-bicyclo[10.1.0]tridecane (IIIg, 72%) and 1,2-cyclotridecadiene (8%) upon glc assay. The bromide, IIIg, was separated by preparative glc.

IIIg: bp 100°C (bath temp.)/0.05 mmHg; IR (neat) 1465, 1443, 1270, 1248, 1237, 1222 cm^{-1}; NMR (CCl_4) δ 0.85 (b, 2), 1.42 (b, 2), 2.72 (q, 1, J_{cis}=7.2 Hz, J_{trans}=3.5 Hz) ppm; MS *m/e* (relative abundance) 260 (12), 258 (12), 179 (10), 135 (18), 109 (31), 95 (100).

Found: C, 60.2; H, 9.1%. Calcd for $C_{13}H_{23}Br$: C, 60.2; H, 8.9%.

Reaction of 7,7-Dibromobicyclo[4.1.0]heptene-3 (IIe). A solution of IIe (850 mg, 3.37 mmol) in THF (2 ml) was added to a solution of I (6.00 mmol) in dry THF (7 ml) at −78°C. The reaction mixture was then worked up as usual. The glc analysis of the resulting oil showed the presence of *exo*-IIIe (63%) and *endo*-IIIe (12%); each component was separated by preparative glc.

exo-7-Bromobicyclo[4.1.0]heptene-3 (*exo*-IIIe): bp 60°C/18 mmHg; IR (neat) 3050, 1655, 1220 cm^{-1}; NMR (CCl_4) δ 5.47 (b, 2), 2.74 (t, 1, J_{trans}=3.1 Hz), 2.37 (b, 4), 1.45 (b, 2) ppm; MS *m/e* (relative abundance) 174 (12), 172 (12), 131 (11), 117 (11), 93 (100).

Found: C, 48.9; H, 5.5%. Calcd for C_7H_9Br: C, 49.2; H, 5.2%.

endo-IIIe: bp 65°C/18 mmHg; IR (neat) 3050, 1668, 1252 cm^{-1}; NMR (CCl_4) δ 3.29 (t, 1, J_{cis}=7.4 Hz) ppm.

Reaction of 1,1-Dibromo-2,2-diphenylcyclopropane (V). The dibromide, V (700 mg, 2.00 mmol), was treated with the anion, I (3.00 mmol), in THF. The glc analysis of the crude reaction mixture showed the presence of 1-bromo-2,2-diphenylcyclopropane (VI, 73%), which was separated by preparative glc.

VI: bp 140°C (bath temp.)/0.05 mmHg; IR (neat) 1252 cm^{-1}; NMR (CCl_4) δ 7.15 (d, 1), 3.56 (t, 1, J=6.5 Hz), 1.73 (d, 2) ppm; MS *m/e* (relative abundance) 274 (3), 272 (3), 194 (41), 193 (100), 115 (100).

When V (350 mg, 1.00 mmol) was treated with I (3.00 mmol), 1,1-diphenylcyclopropane (VII, 40% by glc assay) was obtained in addition to VI (28% by glc assay). When V (60 mg, 0.17 mmol) was treated with I (1.00 mmol), the cyclopropane, VII (62% by glc assay), was obtained as the

sole product.

Reaction of Benzyl Bromide. Benzyl bromide (340 mg, 2.00 mmol) was treated with the anion, I (3.00 mmol), in THF (15 ml) at −78°C. The preparative tlc separation of the crude reaction mixture then gave VIII (127 mg, 70%) as the sole product; it was identical in all respects with an authentic sample.

Reaction of Benzhydryl Chloride. Benzhydryl chloride (200 mg, 1.00 mmol) was treated with the anion, I (1.50 mmol), in THF (7 ml) at −78°C. After the concentration of the dried extracts *in vacuo*, a white solid was obtained. Recrystallization from benzene–hexane (1:1) gave pure IX (125 mg, 75%) as colorless crystals; the IX was identical in all respects with an authentic sample.

Reaction of Cinnamyl Chloride. Cinnamyl chloride (500 mg, 3.30 mmol) was added to a solution of the anion, I (5.00 mmol), in THF (20 ml) at −78°C. The subsequent glc analysis of the reaction mixture showed the presence of 3-chloro-1,6-diphenyl-1,5-diene (X, 71%), which was then separated by preparative glc.

X: bp 160°C (bath temp.)/0.08 mmHg; IR (neat) 1625, 1594, 959, 740, 692 cm^{-1}; NMR (CCl_4) δ 7.13 (b, 10), 6.0 (m, 5), 2.55 (t, 2) ppm; MS *m/e* (relative abundance) 270 (0.51), 268 (0.96), 232 (2.4), 151 (17), 117 (100), 115 (61).

Found: C, 80.3; H, 6.6%. Calcd for $C_{18}H_{17}Cl$: C, 80.4; H, 6.4%.

Reaction of trans-*β-Bromostyrene.* *trans-β*-Bromostyrene (600 mg, 3.30 mmol) was added to a solution of I (4.90 mmol) in THF at −78°C. The usual work up, followed by glc separation, afforded *cis*-XI (79 mg, 39%) and *trans*-XI (15 mg, 8%).

1,4-Diphenyl-*cis*-3-buten-1-yne (*cis*-XI): bp 80°C/0.05 mmHg; IR (neat) 2200, 780 cm^{-1}; NMR (CCl_4) δ 7.73 (m, 2), 7.21 (m, 8), 6.56 and 5.76 (AB q, 1 each, $J_{AB}=15$ Hz); MS *m/e* (relative abundance) 204 (100), 203 (88), 202 (82), 103 (14), 101 (29).

1,4-Diphenyl-*trans*-3-buten-1-yne (*trans*-XI): mp 94—95°C (lit, 95.5—96°C[8]); IR (KBr) 945 cm^{-1}; NMR (CCl_4) δ 7.23 (m, 5), 6.96 and 6.26 (AB q, 1 each, $J_{AB}=12$ Hz) ppm; MS *m/e* (relative abundance) 204 (100), 203 (85), 202 (77), 103 (13), 101 (27).

The authors are grateful to Professor Keiiti Sisido for his generous help and to Dr. Yasusi Yamamoto for his discussions. The financial support from the Ministry of Education, the Japanese Government, and from the Toray Science Foundation is also acknowledged with pleasure.

Studies on Reactions of the *N*-Phosphonium Salts of Pyridines. I. A New Method for the Activation of Carboxylic Acids *via* the *N*-Phosphonium Salts by Means of the Oxidation of Tri- and Di-esters of Phosphorous Acid in the Presence of Tertiary Amines

Noboru YAMAZAKI and Fukuji HIGASHI

Department of Polymer Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received September 8, 1972)

Carboxylic acids were found to be activated by an oxidation mixture prepared from tri- and di-esters of phosphorous acid and mercuric chloride in a pyridine solution; they yielded the corresponding anilides upon treatment with aniline, together with a nearly quantitative yield of metallic mercury. The yield of the anilides was affected by the alkyl groups in the esters and by the tertiary amines. Only a small effect of the steric factor of carboxylic acids upon the reaction was seen in the cases of the diesters, and none at all was observed in the triesters. The reaction was proposed to proceed *via* the *N*-phosphonium salts of pyridines, which were not purely isolated, but which were assumed on the basis of the IR spectra.

Though various methods[1] have been reported for the phosphorylation of alcohols by means of the esters of phosphorous acid, there are few which are effective for the phosphorylation of carboxylic acids.[2] Mukaiyama *et al.*[3] have reported obtaining diethyl acyl phosphates by means of the oxidation of triethyl phosphite and monobromocyanoacetamide in the presence of carboxylic acids. They have also shown that mercuric salts such as mercuric chloride are useful oxidizing agents for the oxidation of phosphorous acid in the course of the preparation of monoalkyl phosphates.[4] In the oxidation of trialkyl phosphite with *N*-chlorosuccinimide, an *N*-phosphonium salt[5] have been suggested to be involved.

In a previous paper,[6] we ourselves reported briefly a convenient method for the synthesis of carboxylic amides and esters *via* the *N*-phosphonium salts of pyridine prepared by the oxidation of phosphorous acid and its esters with mercuric chloride in pyridine, and showed that pyridine played an important role in this reaction.

This paper will present the detailed results of the oxidation of various tri- and di-esters of phosphorous acid in tertiary amines, especially in pyridine, resulting in the *N*-phosphonium salts of pyridine, and of the activation of carboxylic acids to give the corresponding amides by means of the salts.

Results and Discussion

Through the studies of this series of reactions, aniline was chosen as the amine component of the amides, because anilides are readily isolated and the yield of the activated carboxylic acids can be estimated almost quantitatively from the amount of the anilides obtained.

When tri- and di-isopropyl esters of phosphorous acid were brought into reaction with mercuric chloride in refluxing pyridine, followed by treatment with an equimolar amount of acetic acid and then with aniline, acetanilide was obtained in 73 and 94% yields respectively, together with a nearly quantitative yield of metallic mercury. In a similar manner, various anilides were successfully synthesized from various phosphites (see Tables 1 and 2). However, no detectable amount of the anilide was obtained when a mixture of acetic acid and aniline was heated in pyridine under reflux in the absence of these phosphorous compounds.

The reaction may be summarized as follows:

$$P(OR)_3 \text{ (or } H\text{-}P(O)(OR)_2) + HgCl_2 \xrightarrow{Py} \text{I (or IV)} + Hg^0$$

$$\xrightarrow{R^1COOH} \text{II (or V)} \xrightarrow{R^2NH_2} R^1CO\text{-}NHR^2 + Py\cdot HCl$$

$$+ O{=}P(OR)_3 \text{ (or } HO\text{-}P(O)(OR)_2)$$

Compounds I, II, IV, and V have been assumed to be the *N*-phosphonium salts of pyridines.[6] The phosphorous compounds may be considered to participate not catalytically but stoichiometrically in this reaction from the fact that the yield of the anilide was reduced with a decrease in the amount of the phosphites in pyridine.

The effect of the alkyl group in the phosphites on this reaction was examined by using various phosphites under identical conditions. From the yield of acetanilide (Table 1), the reactivities of trialkyl phosphites are determined to be in the following order: trimethyl< tri-*n*-butyl≈triethyl<triisopropyl. In the cases of the diesters of phosphorous acid, the order of reactivities was similar to that of the triesters; dimethyl<di-*n*-butyl≈diethyl<diisopropyl. Triphenyl phosphite was not oxidized in this system, whereas diphenyl phosphite gave acetanilide in a 93% yield.

There was expected a side reaction in which alkyl groups of the phosphites were attacked by acids to afford the acid esters. Actually, a small amount of ethyl acetate was detected by the gas-chromatographic analysis of the reaction mixture from acetic acid and the oxidation product (I) of triethyl phosphite, besides a 53% yield of acetanilide. Since a separate experiment gave only a small amount of acetanilide upon the reaction of ethyl acetate with aniline under identical conditions, the amide by the present method was not formed through the reaction of the esters thus obtained with aniline.

The steric requirement of I and IV upon carboxylic acids was not observed in the cases of the triesters, whereas only a small effect was observed in the cases of the diesters, when the carboxylic residues were quite large (see Table 2). These results suggested that the reaction of I and IV with carboxylic acids was a replacement of the chlorine atom by the acyloxy groups instead of an addition of the acyloxy groups to the phosphorus-oxygen double bond in IV, as will be discussed in this paper.

Table 1. The preparation of acetanilide using various phosphites and mercuric chloride in pyridine

Phosphite	Acetanilide, Yield, %
Trimethyl	0
Triethyl	53
Triisopropyl	73
Tri-*n*-butyl	50
Dimethyl	56
Diethyl	77
Diisopropyl	94
Di-*n*-butyl	74
Diphenyl	93

Table 2. The preparation of various anilides using tri- and di-isopropyl phosphites and mercuric chloride in pyridine

Anilides	Triisopropyl phosphite, Yield, %	Diisopropyl phosphite, Yield, %
Acetanilide	73	94
n-Butyranilide	77	98
Isobutyranilide	74	97
Pivalanilide	61	70
Benzanilide	79	78

Tertiary amines influenced the yield of the anilide. Of the amines examined, pyridine was most effective for the reactions of phosphorous acid and its mono- and di-esters. In the case of triisopropyl phosphite, α-picoline among the pyridine derivatives gave the best results; even in 2,6-lutidine acetanilide was obtained in a 59% yield (Table 3). These results indicated that the basicity of the amine was rather more influential than its steric effect on the yield of the anilide. Triethylamine did not yield acetanilide. This may be caused by the instability of the I and/or II obtained from the amine. On the contrary, in the case of diisopropyl phosphite, pyridine gave a better result (a 94% yield of acetanilide) than α-picoline (77% yield).

Table 3. The preparation of acetanilide in various tertiary amines using triisopropyl phosphite

Amines	pK_a	Acetanilide[a], Yield, %
Pyridine	5.23	73
α-Picoline	5.97	83
2,6-Lutidine	6.99	59
Triethylamine	10.87	0

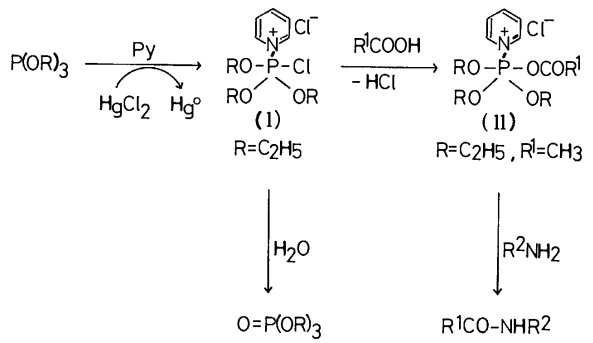
a) The reaction was carried out in refluxing pyridine or 115 °C in other pyridines. In the case of triethylamine refluxing acetonitrile was used as solvent.

The difference in the effect between tri- and di-isopropyl phosphites may be caused by the stability and reactivity of I and IV to carboxylic acids and/or amines like aniline.

In order to confirm the proposed mechanism described in a previous paper,[6] we have attempted to isolate the intermediate compounds, I and II, but with only limited success.

The *N*-phosphonium salt of pyridine (I) was separated as an ether-insoluble pale brown syrup from an oxidation mixture of triethyl phosphite. When I or the oxidation mixture, without the separation of I, was treated with carboxylic acids, the *N*-phosphonium salt of pyridine carrying acyloxy groups (II) was obtained. On further treatment of II with aniline, the anilides were obtained in good yields.

The over-all route of the reaction is summarized in Scheme 1:



Scheme 1.

These salts, I and II, have not been purely isolated because they were difficult to crystallize and because II was contaminated with pyridine hydrochloride. They were very stable in pyridine and in other aprotic solvents, but unstable in protonic solvents. On the treatment of I with water, triethyl phosphate was obtained in a 45% yield. I could activate alcohols and amines as well as carboxylic acids.[6] II carrying active acyloxy groups gave the corresponding carboxylic amides and esters by aminolysis and alcoholysis respectively.

Generally, trialkyl phosphites are dealkylated when oxidized with halogens. However, the fact that triethyl phosphate was obtained instead of diethyl phosphate when I was treated with water indicated that dealkylation seemed to be exclusive and that the phosphorus compound in I was in the form of a triester.

The IR spectrum of I showed strong absorption bands at 1630 and 1485 cm^{-1} and a weak band at 1580 cm^{-1}. These bands are assumed to be due to $\nu_{C=N^+}$ in the *N*-phosphonium salt of pyridine, judging from the fact that the *N*-phosphoryl pyridines[7] have characteristic bands near 1650 cm^{-1}. Although pyridinium halides and *N*-alkyl-pyridinium halides also have bands[8] around 1630 cm^{-1} which are also attributable to $\nu_{C=N^+}$, the absence of dealkylation on I as has been mentioned above, ruled out the possibility that I was the pyridinium salt. The band at 565 cm^{-1}, which disappeared upon the reaction of acetic acid with I may be due to ν_{P-Cl}.[9]

The UV spectrum of I exhibited the characteristic bands around 260 nm due to a pyridine moiety. The results of the quantitative analysis of chlorine in I by the use of silver nitrate; and of the acid-base titration of I showed that I contained one mole of pyridine and two chlorine atoms.

The proposed chemical structure of I is shown in Scheme 1; it will here be called the *N*-phosphonium salt of pyridine, taking into account its types of reactions, though it might also be named the pyridinium salt.

The band at 1710 cm^{-1} in the IR spectrum of II is due to $\nu_{C=O}$; it is quite similar to that of acetic acid and different from that of diethyl acetyl phosphate[10] at 1780 cm^{-1}. The characteristic bands at 1630, 1580, and 1485 cm^{-1} are due to the $\nu_{C=N^+}$ caused by the *N*-phosphonium salt of a pyridine like I. Though these bands overlapped with those of pyridine hydrochloride, the latter contribution to these bands was not very significant, judging from the weak intensity of the bands at 1535 and 1430 cm^{-1} due to the hydrochloride.

The result of the acid-base titration of II indicated that about equimolar amounts of acetic acid and pyridine were involved in II, assuming that II was contaminated with an equimolar amount of pyridine hydrochloride.

As has been described above, pyridine hydrochloride, which was not observed in I, appeared in this step of the formation of II. This shows that the chlorine atom (or chloride ion) on I may be replaced by the acetoxy group, resulting in II. This explanation is in good agreement with the aforementioned findings on the steric effect of carboxylic acids.

On the basis of these results, II is proposed to be the acyloxy *N*-phosphonium salt of pyridine (Scheme 1). The band due to $\nu_{C=O}$ in II, which was expected to shift to a higher wave number, had a relatively low wave number. This would account for the insufficient migration of electrons on the carbonyl carbon of the acyloxy groups to the phosphorus atom, as has been discussed by Cramer.[10]

In a similar manner, by using the diethyl ester of phosphorous acid, IV and V in Scheme 2 were obtained.

The IR spectrum of IV showed the bands due to $\nu_{C=N^+}$ caused by the *N*-phosphonium salt of pyridine;

7) M. Wakselman and E. Jampel, *Tetrahedron Lett.*, **1970**, 1521.
8) B. Witkop, *Experimentia*, **10**, 420 (1954).

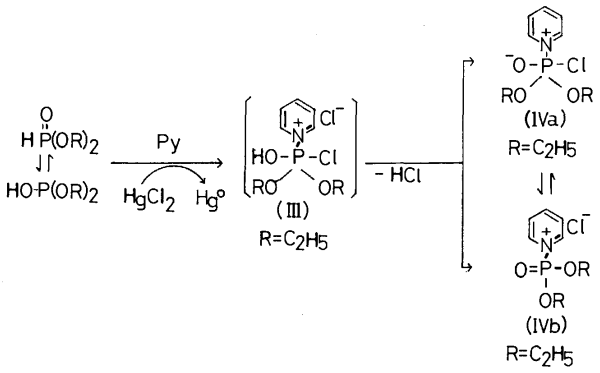
10) F. Cramer and K. G. Gärtner, *Chem. Ber.*, **91**, 704 (1958).

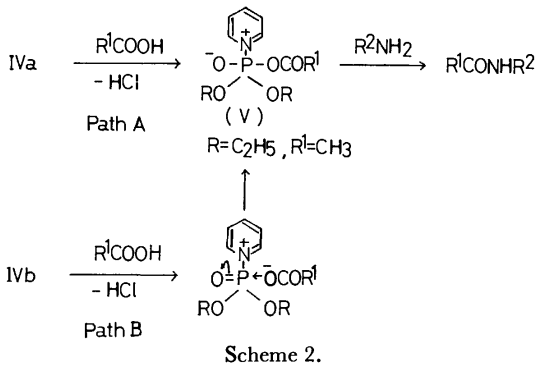
also those of pyridine hydrochloride were observed. Therefore, in the case of the diester, an intermediate similar to I was formed initially and then it was changed into IVa and IVb by releasing hydrogen chloride in two possible ways. The loss of the chloride anion from pyridinium salt (III) gave IVa, which included a phosphorus-chlorine bond. On the other hand, a phosphorus-oxygen double bond was formed by releasing the chlorine atom on the phosphorus, resulting in IVb. IVa seemed to be more plausible because there was no substantial change in the bands except for the $\nu_{C=O}$ band of acetic acid during the reaction of IV with acetic acid, and it is unlikely that V has the structure corresponding to IVb.

The steric requirement of IV upon carboxylic acids was observed, though it was not very large (see Table 2). This can not be expected from the structure of IVa alone because of the simple replacement of the chlorine atom of IVa by acyloxy groups in the reaction of IVa with the acids, such as was observed on I (Path A in Scheme 2). This fact may be accounted for by the minor participation of IVb, whose reaction with the acids would be a direct attack of the acyloxy anions on the phosphorus atom and would be affected by the steric effect (Path B).

From these results it may be considered that both structures, IVa and its isomer IVb, were involved in this system, and that the former appeared preferably to participate in this reaction.

In the spectrum of V, the bands due to the $\nu_{C=N^+}$ caused by the *N*-phosphonium salt (as in IV) and due to the $\nu_{C=O}$ of the acetoxy group as appeared in II were observed, indicating that V was an *N*-phosphonium salt, like IV (see Scheme 2).





Scheme 2.

Experimental

The infrared spectra were recorded on a Jasco IR-G spectrometer. The syrupy samples were placed between sodium chloride cells or between polyethylene films for low wave numbers (400 to 700 cm^{-1}). The ultraviolet spectrum was taken in ethanol on a Shimadzu RS-27 spectrometer.

The mercuric chloride, tertiary amines, and diphenyl phosphite were obtained from commercial sources. The trialkyl and dialkyl phosphites were prepared according to the literature.[11]

Separation of I and IV. A mixture of equivalent amounts of triethyl phosphite (2.1 g, 12.5 mmol) and mercuric chloride (3.5 g) was refluxed for 1 hr in 20 ml of pyridine. After cooling, the mixture was separated from the liberated metallic mercury and extracted with ether. The separated ether-insoluble syrup (I) was washed with ether to remove the unchanged phosphite and pyridine and was then evaporated under reduced pressure. I was obtained as a pale brown syrup. In the same way, IV was obtained by the reaction of diethyl phosphite (1.8 g, 12.5 mmol) and mercuric chloride (3.5 g) in 20 ml of pyridine.

Separation of II and V. A mixture of equivalent amounts of triethyl phosphite (2.1 g, 12.5 mmol) and mercuric chloride (3.5 g) was refluxed in 20 ml of pyridine. After 1 hr, acetic acid (0.8 g, 12.5 mmol) was added and the mixture was refluxed for an additional hour. By the same procedure as has been described above, II was obtained as a green syrup. Similarly, V was obtained by using diethyl phosphite, mercuric chloride, and acetic acid in pyridine.

Preparation of Anilides using Various Phosphites. The anilides were prepared by the method described in our previous paper.[6] These showed the IR spectra and melting points to be identical with those of authentic samples. Acetanilide was prepared in various tertiary amines in refluxing pyridine or at 115°C in other pyridine derivatives. In the case of triethylamine (4 equiv), the reaction was conducted for 2 hr under reflux in acetonitrile.

Studies on Reactions of the *N*-Phosphonium Salts of Pyridines. II. A New Method for the Activation of Carboxylic Acids *via* the *N*-Phosphonium Salts by Means of the Oxidation of Phosphorous Acid and Its Monoesters in the Presence of Tertiary Amines

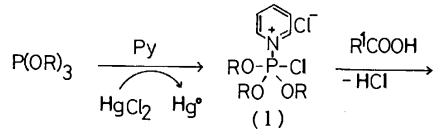
Noboru YAMAZAKI and Fukuji HIGASHI

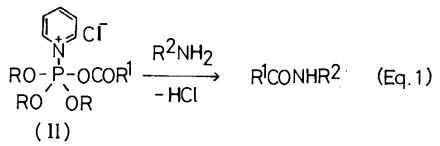
Department of Polymer Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received July 31, 1972)

The oxidation of phosphorous acid and its monoesters with mercuric chloride was carried out in pyridine; they were then treated with carboxylic acids and with aniline. The oxidation reaction was conducted also in the presence of carboxylic acids, after which the mixture was treated with aniline. By both procedures, the corresponding anilides were obtained in good yields. The influence of the steric factors of carboxylic acids, their acidity, and the tertiary amines were observed in the reaction. Phosphorous acid provided a better result than the monoesters. In addition, the chain length of carboxylic acids in the case of the esters influenced the yields of the anilides, which decreased with an increase in the chain length. The structural effect of tertiary amines was studied on pyridine derivatives. The ester residues also affected the yield, and of the esters examined the monophenyl ester was more favorable than the alkyl esters. Other mercuric halides and mercuric acetate were also found effective as oxidizing agents. The reaction was proposed to proceed *via* the *N*-phosphonium salts of pyridines.

In our previous papers,[1,2] we have shown that carboxylic acids could be activated *via* the *N*-phosphonium salt (I) obtained by means of the oxidation of tri- and di-esters of phosphorous acid with mercuric chloride in tertiary amines like pyridine. Salt I is turned into II by the successive reaction with carboxylic acids. Salt II of the acids gives the corresponding amides upon further treatment with amines (Eq. (1)):





In this paper, we will describe a successful extension of this method to the reaction using phosphorous acid and its monoesters in the place of the tri- and di-esters.

Results and Discussion

The oxidation of phosphorous acid and its monoesters (ammonium salt) with mercuric chloride was carried out in pyridine under reflux in two ways, in the absence and in the presence of carboxylic acids. In Method A, the oxidation was carried out in the absence of the acids in a way similar to those described in previous papers.[1,2] A mixture of equimolar amounts of the ethyl ester and mercuric chloride was refluxed in pyridine for 1 hr and then treated with carboxylic acid for an additional hour of refluxing, followed by further reaction with aniline for 2 hr. The corresponding anilides were obtained in good yields; the yields are listed in Table 1. In Method B, in the presence of carboxylic acids, *e.g.*, when a mixture of equimolar amounts of phosphorous acid or the monoesters, mercuric chloride and acetic acid was refluxed for 1 hr, and then treated with aniline for an additional 2 hr of refluxing, acetanilide was obtained in 92 and 80% yields respectively. In the same way, the anilides of various carboxylic acids were obtained in the yields shown in Tables 1 and 2.

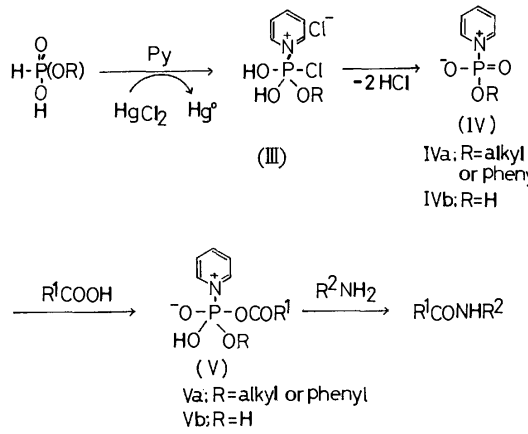
2) N. Yamazaki and F. Higashi, Part 1: This Bulletin, **46**, 1235 (1973).

The reaction can be explained in a manner similar to those in previous papers. In the first stage the *N*-phosphonium salt (III) was formed through the oxidation of phosphorous acid and its monoesters with mercuric chloride in pyridine. In this study, however, salt III was unstable in pyridine and was changed into IV by releasing hydrogen chloride. It is conceivable that IV does not contain any chlorine atoms and forms a zwitter-ion structure, since phosphorous acid and its monoesters have more than two hydrogen atoms capable of forming hydrogen chloride. Salt IV is then converted into V by the reaction with carboxylic acid. The aminolysis of V with aniline yielded the amides as is shown in Scheme 1.



Scheme 1

In order to confirm the proposed mechanism, IV and V were separated through the procedure described in the previous paper and were analyzed by the IR-spectroscopic method, though they were difficult to isolate in pure forms because of contamination with pyridine hydrochloride.

The IR spectra of IVa and IVb showed characteristic absorption bands at 1630 and 1485 cm^{-1}. These bands, which were almost identical with those given by the *N*-phosphonium salts derived from the tri- and di-esters of phosphorous acid, were attributed to the $\nu_{C=N^+}$ in the phosphonium salts of pyridine. Bands due to pyridine hydrochloride were also observed. Since phosphorous acid and its monoesters have two or three hydrogen atoms, they would afford two moles of the hydrochloride. From these results, the structure of IV was proposed, as is shown in Scheme 1.

The characteristic bands appearing at 1630, 1485, and 1710 cm^{-1} in the spectra of Va and Vb were almost identical with those provided by the reaction products from the tri- and di-esters of phosphorous acid and acetic acid. The former two bands were attributed to the $\nu_{C=N^+}$ of the *N*-phosphonium salt, and the latter, to the $\nu_{C=O}$ of the acetoxy group. Therefore, the structure of V was proposed to be the *N*-phosphonium salt carrying the acetoxy group, as is shown in Scheme 1.

In the reaction of the monoethyl ester, it was found that the yield of acetanilide increased from the 80% of Method B to the 92% of Method A. Prolonged heating for an additional hour of aminolysis (from 2 to 3 hr) also improved the yield to 94%. For the improvement of the yield, three explanations are possible: the incomplete oxidation of the ester, the slow nucleophilic reaction with the carboxylate anions, and the insufficient aminolysis of Va. Since the aminolysis with aniline has proceeded almost completely within 2 hr, as will be discussed later, and since metallic mercury was obtained in a nearly quantitative yield within 1 hr under the conditions of Method B, however, insufficient oxidation and aminolysis can be excluded in elucidating the improvement. As a consequence, the rate-determining step in the reactions turned out to be the conversion of IVa to Va by the attack of the carboxylate anions.

On the contrary, these improvements were not observed in the reaction using phosphorous acid. This must be the result of an intramolecular hydrogen bonding in IVb, which will be discussed later in this paper.

The results presented above suggest that the reaction of IV with carboxylic acids to yield V involves a direct nucleophilic attack of the anions on IV. Hence, the reaction might be influenced by the acidity and the steric effect of the acids, and by the electrophilic nature of the phosphorus atom in IV. The electrophilicity would be governed by the electronic nature of the ester residues and by the basicity of the tertiary amines involved in the *N*-phosphonium salt (IV).

The effects of the acidity and the steric factor of carboxylic acids upon the yield of the anilides were studied by using the monoethyl ester (ammonium salt), various carboxylic acids, and mercuric chloride in pyridine (Method B); the results are summarized in Table 1. Sterically hindered carboxylic acids, such as isobutyric and benzoic acids, gave their anilides in yields only about a half of that of acetanilide. The reaction was also influenced by the acidity of the acids. This was evident from the fact that trifluoroacetic acid, with a high pK_a value of 1.26, gave trifluoroacetanilide in 87% yield, although less than a 50% yield would be expected from a consideration of its steric effect alone. Furthermore, the reaction was affected by the chain length of the acids. Among the acids with similar pK_a values, the yields of the corresponding anilides decreased with an increase in the chain length of the acids. For example, acetic, propionic, and *n*-butyric acids, which have their pK_a values in the range of 4.7 to 4.8, gave anilides in 80, 70, and 59% yields respectively. Analogous phenomena were observed in the reaction using the other monoalkyl esters as well (see Table 3).

As has been expected, the reaction would be in-

Table 3. The preparation of anilides using various monoesters of phosphorous acid and mercuric chloride in pyridine (Method B)

Monoester	Anilide, yield, %

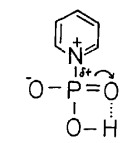
Ethyl	80	59
Isopropyl	74	59
Phenyl	94	87

fluenced by the electrophilicity of the phosphorus atom in IV, which itself chiefly depends on the electronic character of the ester residues in the monoesters. The effect of the ester residues upon the reaction was studied in terms of the yield of the isolated anilides by using various monoesters (ammonium salt) by Method B (see Table 3). The facts that no effect of the bulkiness of the residues in the alkyl esters was observed, and that the monophenyl ester, inspite of having a more bulky group, gave better results than the monoalkyl esters, indicated that the reaction was not influenced by the bulkiness of the ester residues. In addition, no such substantial decrease in the yields was seen in the monophenyl ester with an increase in the chain length of carboxylic acids as was observed in the monoalkyl esters. These results led us to consider that the presence of electron-attracting groups like the phenyl group decreased the electron density on the phosphorus atom in IVa and facilitated the nucleophilic attack of the carboxylate anions on IVa, not causing a substantial decrease in the yields with an increase in the chain lengths of the acids. On the other hand, the electron-donating groups like the isopropyl group increased the electron density and slowed down the reaction, resulting in a decrease in the yields with an increase in the length.

In the reaction of phosphorous acid, a similar steric effect of the acids upon the yields was observed, though it was not so serious as that observed in the monoesters. The effect of the chain length of the acids was not seen in this case. This might be caused by the intramolecular hydrogen bonding involving in IVb, which facilitates the reaction of IVb with the acids.

In the reaction of IV with carboxylic acids, several differences were observed between IVa (monoesters) and IVb (phosphorous acid). The results of the steric effect, mentioned above, indicated that the nucleophilic attack of carboxylate anions on IVb (R=H) was preferable to that on IVa (R=alkyl or phenyl). As a rule, phenyl and alkyl groups are more electro-positive and electronegative respectively than the hydrogen atom. If the reactivity of IV to the anions is caused by the electron deficiency on the phosphorus atom in IV, which itself depends chiefly on the inductive effect of the ester residues, the relative reactivity of IV might be in the order of IVa (R=phenyl)>IVb (R=H)> IVa (R=alkyl). However, the order obtained in this study was, unexpectedly, IVb (R=H)>IVa (R= phenyl)>IVa (R=alkyl).

This conflict can be explained by considering an intramolecular hydrogen bonding in IVb, as is shown below. Because of this bonding, the phosphorus atom became electron-deficient through the migration of the electrons at the phosphorus-oxygen bond to the oxygen; consequently, the nucleophilic attack of the anions on IVb was facilitated. On the other hand, in the case of the monoesters such a hydrogen bonding was unlikely to be involved in IVa. Therefore, the reactivity of IVa was governed mainly by the inductive effect of the ester residues, since the relative reactivity obtained in this study was IVa (R=phenyl)>IVa (R=alkyl), compatible with the order of the effect.



(IVb)

Tertiary amines were expected to play an important role, through the phosphorus-nitrogen bond of IV and V, in affecting the electrophilic nature of the phosphorus atom. Using phosphorous acid, the effect of tertiary amines upon the reaction (the yield of acetanilide) was investigated by varying the substituents in the pyridine nucleus (Table 4). The effects were not in agreement with those obtained by using triesters. In the reaction using the triesters, α-picoline gave a better result than pyridine, and even in 2,6-lutidine acetanilide was obtained in 59% yield. However, in this case pyridine was more favorable than α-picoline, and in 2,6-lutidine the anilide was not formed. The yield in γ-picoline, which was nearly the same as in α-picoline, was worse than that in β-picoline, indicating that the steric effect of the amines was not profound. Though the yield decreased with an increase in the basicity of amine among pyridine derivatives, the effect was inexplicable solely by the basicity, because triethylamine of a high pK_a value in acetonitrile gave acetanilide in 17% yield. The effect of amines appeared to be caused by the stability and reactivity of IV and/or V to carboxylic acids and aniline.

The aminolysis of V with aniline was investigated in reactions using phosphorous acid under various conditions (Table 5). The results showed that the acetoxy group carried by Vb was not so active, and that more than 2 hr of refluxing were required for the complete aminolysis of Vb with aniline. This fact provided additional evidence that V was not in the form of active acetyl phosphates.

Table 4. The preparation of acetanilide in various tertiary amines

All of the oxidizing agents used in this study, such as mercuric halides and its acetate, were found to be effective for this reaction (see Table 2).

Experimental

The mercuric chloride, tertiary amines, and phosphorous acid were obtained from commercial sources. The monoesters of phosphorous acid were prepared according to the literature.[3]

Separation of IVa (R=Et) and IVb. A mixture of equivalent amounts of the monoethyl ester (ammonium salt) of phosphorous acid (1.60 g, 12.5 mmol) and mercuric chloride (3.5 g) was refluxed for 1 hr in 20 ml of pyridine. After the separation of the liberated metallic mercury and ammonium chloride, IVa was obtained by the procedure described in the previous paper. Similarly, IVb was obtained by the reaction of phosphorous acid (1.03 g, 12.5 mmol) and mercuric chloride (3.5 g) in 20 ml of pyridine.

Separation of Va (R=Et) and Vb. A mixture of equivalent amounts of the monoethyl ester (ammonium salt) of phosphorous acid (1.60 g, 12.5 mmol) or phosphorous acid (1.03 g, 12.5 mmol) and mercuric chloride (3.5 g) was refluxed for 1 hr in 20 ml of pyridine. The reaction mixture was then treated with acetic acid (0.8 g, 12.5 mmol) under reflux for an additional hour. By the aforementioned procedures, Va and Vb were obtained. They were also obtained by the reaction of the monoethyl ester (ammonium salt) or phosphorous acid and mercuric chloride in the presence of acetic acid under reflux for 1 hr in pyridine.

Preparation of Anilides using Phosphorous Acid and Its Monoesters. The anilides were prepared by two methods.

Method A: The oxidation was carried out in the way described above. The reaction mixture was treated with an equivalent carboxylic acid under reflux for 1 hr, and then with a 10% excess of aniline for an additional 2 hr.

Method B: The oxidation was carried out under reflux for 1 hr in the presence of a carboxylic acid, and then treated with aniline for 2 hr under reflux. The product was isolated accoding to the procedure described in a previous paper.[1] The anilides thus obtained showed IR spectra and melting points identical with those of authentic samples.

Preparation of Acetanilide in Various Tertiary Amines. The reactions were carried out by Method B using phosphorous acid in refluxing pyridine or at 115°C in other pyridine derivatives. In the case of triethylamine (4 equiv.), the reaction was conducted in refluxing acetonitrile.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1242—1246 (1973)

Stereospecific Addition Reaction between Butadiene and Amines

Tadashi NARITA, Nobuyoshi IMAI, and Teiji TSURUTA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received August 1, 1972)

The reaction of butadiene with secondary amines initiated by *n*-butyllithium was found to proceed selectively to produce 1-dialkylamino-*cis*-butene-2 under appropriate reaction conditions. For instance, diethylamine produced 1-diethylamino-*cis*-butene-2 in a 98—99% purity. By kinetic and spectroscopic studies, it was concluded that the lithium dialkylamide–dialkylamine (1:2) complex plays an important role in this addition reaction. The second-order rate constants of the reaction are 0.85×10^{-3} l/mol sec for diethylamine and 2.4×10^{-3} l/mol sec for diisobutylamine.

It was previously reported that the reactivity of lithium alkyl was drastically influenced by coupling with lithium 2-alkoxyethoxide.[1-5] Since it seemed worthwhile to examine the influence of lithium 2-alkoxyethoxide upon the reactivity of lithium amide, reactions between butadiene and lithium dialkylamides were studied in the presence of the 2-alkoxyethoxide. Contrary to the case of lithium alkyl, the reactivity of the lithium amide was not significantly influenced by the 2-alkoxyethoxide. However, it was unexpectedly found that lithium dialkylamide was activated in a specific fashion by the stoichiometric quantity of the parent dialkylamine.

This paper will present the results of a study of the reaction of butadiene and dialkylamine initiated by *n*-butyllithium and producing 1-dialkylaminobutene derivatives. A preliminary report of the results was published elsewhere.[6]

Experimental

Most of the experiments were carried out under purified nitrogen to preclude oxygen and atmospheric moisture.

Reagents. Cyclohexane, butadiene, and amines were purified by the usual method. *n*-Butyllithium was prepared from *n*-butyl chloride and lithium metal in purified petroleum ether and was used as a cyclohexane solution.

Synthesis of 1-Dialkylaminobutene Derivatives. The addi-

tion products of dialkylamine to butadiene were isolated as follows. A 200 ml flask was equipped with a reflux condenser with a dry ice-methanol refrigerant and a KOH drying column. A 100 mmol portion of butadiene vapor was introduced through the KOH column for two hours into a magnetically-stirred cyclohexane solution at 50 °C, into which dialkylamine (100 mmol) and *n*-butyllithium (5 mmol) were added. After the mixture has been stirred another three hours at 50°C, the reaction was stopped by the addition of a small amount of methanol. The products were isolated by fractional distillation and by preparative vapor phase chromatography (vpc). The analyses of the products were performed by NMR, IR, and mass spectrometry. The analytical data are shown in Table 1 and Fig. 1.

Metalation of Amines. A cyclohexane solution of *n*-butyllithium was added to a solution of secondary amine at 0 °C by means of a syringe. After five minutes stirring, an excess of carbon tetrachloride was added in order to decompose the residual *n*-butyllithium; then the mixture was treated with water. *n*-Butane present in the oil layer was analyzed by vpc.

Kinetics of the Addition Reaction. Into a round-bottomed flask equipped with a three-way stop cock, butadiene and cyclohexane were introduced. A solution of the lithium dialkylamide-dialkylamine complex was then added into the flask. The reaction was quenched after various time intervals by sampling a portion of the solution and adding it to an ether solution of methanol. The products were analyzed by vpc.

Results and Discussion

Synthesis of 1-Dialkylaminobutene Derivatives. The results of the addition reaction of dialkylamines to butadiene initiated by a catalytic amount of *n*-butyllithium are summarized in Table 2. The yields of the butenylation products were all about 85% except for the case of diisopropylamine. Higher-molecular-weight compounds than the simple butenylation products were not detected by vpc under these reaction conditions.

Kinetic Studies of the Addition Reaction. The addition reaction of dialkylamine to butadiene in the presence of *n*-butyllithium was assumed to proceed through the following three steps:

$$R_2NH + n\text{-}C_4H_9Li \longrightarrow R_2NLi + n\text{-}C_4H_{10} \quad (1)$$

$$R_2NLi + CH_2{=}CH{-}CH{=}CH_2 \xrightarrow{k_b} R_2NC_4H_6Li \quad (2)$$

$$R_2NC_4H_6Li + R_2NH \xrightarrow{k_t} R_2NC_4H_7 + R_2NLi \quad (3)$$

At first, the metalation of dialkylamine with *n*-butyllithium, Eq. (1), was examined in cyclohexane. After the dialkylamine had been reacted with *n*-butyllithium, the cyclohexane solution was treated with carbon tetrachloride and then with water. The mol of *n*-butane recovered by vpc should be equal to that of the lithium amide formed, since the non-reacting *n*-butyllithium should have been decomposed by CCl_4. The results shown in Table 3 clearly indicate that the reaction of dialkylamine and *n*-butyllithium proceeds stoichiometrically at 0 °C within 5 min to produce lithium dialkylamide.

The dependence of the butadiene concentration on

a) Reaction temp.: 0 °C, reaction time: 5 min.

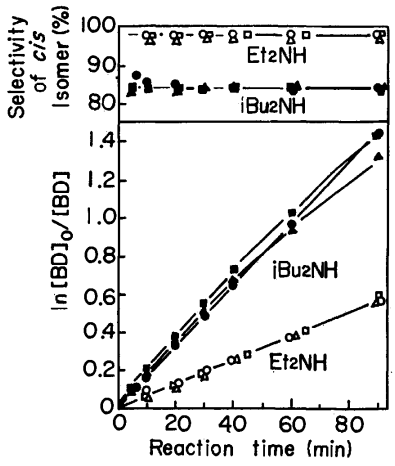

Fig. 2. Dependence of butadiene concentration on addition reaction rate.
[Butadiene]$_0$/[R_2NLi]$_0$ Value, ●○: 1.0, ■□: 2.0, ▲△: 3.0. [R_2NH]$_0$=0.375 M, [R_2NLi]$_0$=0.125 M. Solvent: cyclohexane, reaction temp.: 50 °C

the reaction rate was examined with the ratio of initial concentrations, [R_2NH]$_0$: [R_2NLi]$_0$, being three to one, where R were ethyl and isobutyl. The straight lines in Fig. 2 show that the reaction is in a first-order dependence on the butadiene concentration below the 60% conversion.

The rate, v, of the addition is expressed by Eq. (4):

$$v = k'[\text{butadiene}] \quad (4)$$

The relationship between k' and the initial concentration of lithium dialkylamide at the concentration of [R_2NH]$_0$: [R_2NLi]$_0$=3: 1 is shown in Fig. 3. Pseudo first-order rate constants, k', were found to be proportional to the concentration of lithium dialkylamide

$$k' = k[R_2NLi] \quad (5)$$

where k is the rate constant of the reaction.

The results presented above seem to mean that the rate of the addition reaction varies as the first-order of the concentrations of butadiene and lithium dialkylamide respectively. In the absence of dialkylamine, however, no addition reaction proceeded in cyclohexane, as is shown in Table 4. Addition products were not detected even in such polar solvents as triethylamine or *N,N,N',N'*-tetramethylethylenediamine, which are known to form associated complexes with organolithium compounds. These results suggest that the role of amino-hydrogen is different from that of the usual polar solvents.

In order to get some more information on the species, infrared spectroscopic analyses were carried out with

a mixture of lithium diisobutylamide and diisobutylamine. As is shown in Fig. 4(A), the absorption at 650 cm^{-1} was assignable to the free N–Li stretching frequency, because the characteristic absorptions of C–Li and O–Li were known to appear at 548 and 577 cm^{-1} respectively. The absorption at 650 cm^{-1} decreased as the ratio of the diisobutylamine concentration to the lithium diisobutylamide concentration increased. The absorption disappeared when the ratio exceeded 2.0. At [NH]/[NLi]=2.0 and 3.0 a new peak was observed at 595 cm^{-1}; this peak was detected in the spectrum of neither diisobutylamine nor lithium diisobutylamide. Therefore, this new peak was assigned to a complex of lithium diisobutylamide with diisobutylamine. With the aid of the calibration curve, the concentration of the complex present in the system was calculated from the absorbance of the peak at 650 cm^{-1}. The complex formation of lithium dialkyl-

a) Solvent: cyclohexane.

suggested by the NMR spectra shown in Fig. 4(B), in which an inflection point was observed at [NH]/[NLi]=2.0. As the proton-exchange reaction between *i*-Bu_2NH and *i*-Bu_2NLi is fast at room temperature, the methylene NMR signals of the complex are observed at the average value of the corresponding signals for its components. Furthermore, an exchange reaction should also be possible between the complex and free *i*-Bu_2NH when more than two times as much of the latter is present as *i*-Bu_2NLi. Another exchange reaction, on the other hand, is operative in the reaction between the complex and free *i*-Bu_2NLi in the region to the left of the inflection point in Fig. 4(B).

The overall scheme of the addition reaction may be drawn as follows:

$$R_2NLi + 2R_2NH \longrightarrow R_2NLi\cdot 2R_2NH \quad (6)$$

$$R_2NLi\cdot 2R_2NH + CH_2{=}CH{-}CH{=}CH_2 \xrightarrow{k_b} R_2NC_4H_6Li\cdot 2R_2NH \quad (7)$$

$$R_2NC_4H_6Li\cdot 2R_2NH + R_2NH \xrightarrow{k_t} R_2NCH_2CH{=}CHCH_3 + R_2NLi\cdot 2R_2NH \quad (8)$$

Since the butenylation, Eq. (7), should be the rate-determining step of the addition reaction, the rate can be expressed as follows:

$$v = k_b[\text{complex}][\text{butadiene}] \quad (9)$$

In the region of $[R_2NH]/[R_2NLi]>2$, the concentration of the complex is controlled by the concentration of lithium amide, so that Eq. (9) can be reduced to Eq. (10):

$$v = k_b[R_2NLi][\text{butadiene}] \quad (10)$$

Equation (10) well explains the results of Fig. 2. On the contrary, in the region of $[R_2NH]/[R_2NLi]\leqq 2$, the concentration of the complex should be controlled by the concentration of dialkylamine, so that Eq. (9) can be reduced to Eq. (11):

$$v = \frac{1}{2}k_b[R_2NH][\text{butadiene}] \quad (11)$$

As a matter of fact, Eq. (11) can be used in the analyses of the addition reaction in the region of $[R_2NH]/[R_2NLi]\leqq 2$, as is shown in Fig. 5.

The rate constants of the reactions calculated from Eq. (9) are summarized in Table 6.

Diisopropylamine did not react with butadiene. No infrared peak assignable to a complex of amine and lithium amide was observed. The steric hindrance of the isopropyl group is presumably the reason for the low reactivity of diisopropylamine.

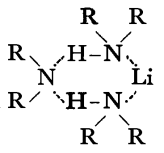
$(CH_3)_2CHCH_2$	2.4	80	80

The selectivity of the reaction to produce the *cis* isomer decreased when the $[R_2NH]/[R_2NLi]$ value increased (*cf.* Tables 2, 4, and Fig. 2). The selectivity is also affected by the structures of the alkyl groups of dialkylamine, as is shown in Tables 2 and 4. It can safely be concluded that di-*n*-alkylamine produces the *cis* isomer in high purity. Especially, diethylamine gives the *cis* isomer in a 98—99% purity.

Although the structure of the complex has not been clearly elucidated, we wish to propose the following structure on the basis of NMR, IR, and the reactivity of the complex:



This structure can probably explain the finding that *N,N,N',N'*-tetramethylethylenediamine and triethylamine do not have any positive effects on the reaction of lithium dialkylamide.

Derivatives of Cyclic Disulfides. II.[1] Alkaline Hydrolysis of 1,2-Dithiaacenaphthene *S*-Oxide

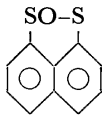
Seizo TAMAGAKI, Hiroo HIROTA, and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

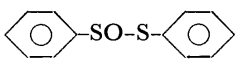
(Received August 24, 1972)

The alkaline hydrolysis of 1,2-Dithiaacenaphthene *S*-oxide has been investigated kinetically, its reactivity being compared with that of its open-chain analog, phenyl benzenethiolsulfinate. The rate was found to be of first order with respect to both hydroxide and the ester. 1,2-Dithiaacenaphthene *S*-oxide was found to be hydrolyzed 10^3 times more slowly than the open-chain analog in an alkaline medium. The reduced reactivity was interpreted on the basis of structural rigidity.

Aromatic five-membered cyclic sulfates and sulfonates are known to be hydrolyzed in alkaline solution 10^6—10^7 times faster than the corresponding open-chain esters,[2] and the main driving force for the remarkable rate enhancement in the hydrolytic reactivities of these five-membered cyclic esters has been believed to be due to the ring strain. The small values of the internal ring angle around the sulfur atom reflect the strain present in these five-membered rings. The hydrolysis of these esters is considered to proceed *via* an intermediate or transition complex which has a structure of approximately trigonal-bipyramid, in which the ring angle around the sulfur atom is close to 90° and the five-membered ring spans apical and equatorial positions. Since the ring angle around the sulfur in the five-membered cyclic esters is close to 90° even in the ground state, the compound can readily assume trigonal-bipyramidal geometry. However, in contrast to the alkaline hydrolysis of five-membered cyclic esters, that of an analogous five-membered cyclic compound containing sulfur-linkage has not been explored despite its inherent importance in biological systems.[3] Thus, we have synthesized 1,2-dithiaacenaphthene *S*-oxide (I) as a model compound, and subjected it to alkaline hydrolysis and compared its reactivity with that of phenyl benzenethiolsulfinate (II).



(I)

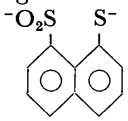


(II)

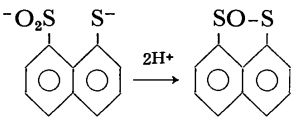
Although both sulfur atoms are confined rigidly at two peri-positions of naphthalene ring, 1,2-dithiaacenaphthene *S*-oxide is considered to be less strained than the corresponding oxygen-analogs, for the bond length of *S*–*S* linkage is considered to be nearly the same as the non-bonding distance between two peri-positions. However, since the two sulfur atoms in compound (I) are fixed rigidly at peri-positions of naphthalene nucleus, the kinetic behavior of this compound may not be similar to that of the five-membered sulfates or sulfonates.

Results and Discussion

Upon alkaline hydrolysis of I, the product could be separated into two parts; one soluble in ordinary organic solvents such as ether or chloroform, the other insoluble in common organic solvents but very soluble in water. 1,2-Dithiaacenaphthene, *i.e.*, reduced product, was obtained from the organic layer (37%). The latter water-soluble salts were neutralized with hydrochloric acid to afford 1,2-dithiaacenaphthene *S*, *S*-dioxide (8%) and 1,2-dithiaacenaphthene *S*-oxide (23%). A careful analysis of the UV spectra of an alkaline aqueous ethanol solution of 1,2-dithiaacenaphthene *S*-oxide indicates that the characteristic band due to the initial 1,2-dithiaacenaphthene *S*-oxide (247 nm) disappears, and a new band (265 nm) appears as the reaction proceeds. On completion of hydrolysis, the 265 nm band also begins to disappear at a relatively slower rate. The UV spectra and the product analysis suggest that the first stage of the reaction is the formation of a sodium salt of



because the attacking site for hydroxide ion in the initial step seems to be the sulfinyl sulfur. The starting material was regenerated in a considerable amount only after neutralization.



(III) (I)

There are two possible attacking sites for hydroxide in the initial step of the reaction, *i.e.*, the sulfinyl sulfur and the divalent sulfenyl sulfur. According to the HSAB principle,[4] the attack on the sulfinyl sulfur is more favorable than that on the sulfenyl sulfur, since hydroxide ion is a hard base. It is known that in alkaline hydrolysis of aryl arenethiolsulfinate, no hy-

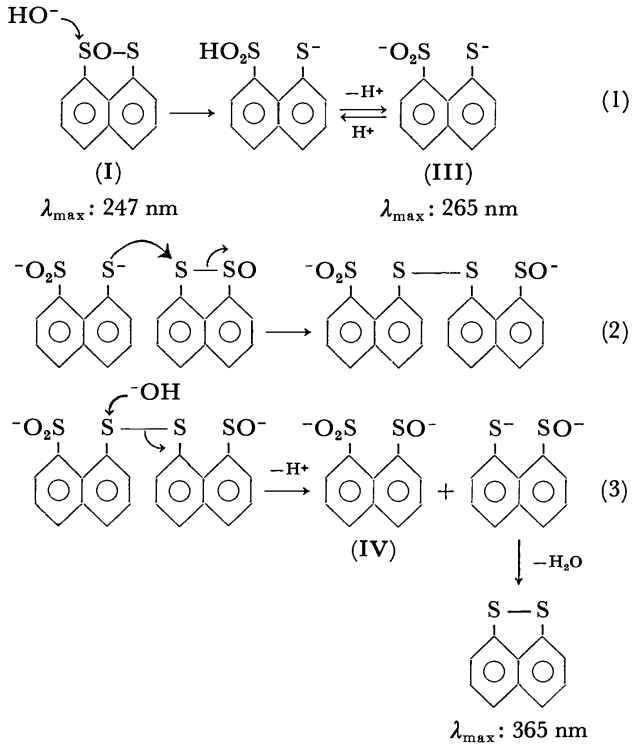
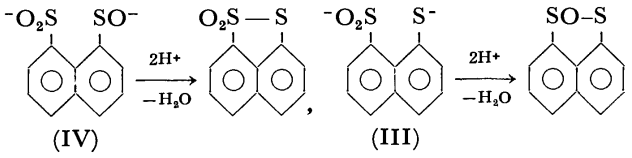
droxide ion attacks the sulfenyl sulfur in accordance with the HSAB principle.[5] We suggest that the most probable mechanism for this reaction is as follows.



After neutralization



In order to clarify the structural effect on the rate of hydrolysis, we carried out kinetic measurements in a weakly alkaline 60% ethanol–water solvent, keeping the concentration of the ester around 10^{-5} M. Measurements were carried out by observing spectrometrically the disappearance of the chracteristic UV absorption band of 247 nm due to 1,2-dithiaacenaphthene *S*-oxide. The first-order dependence of rate on the initial concentration of the ester was observed. The rate constants are listed in Table 1. The first-order dependence of k_{obs} on the hydroxide ion concentration is also shown in Table 2. The fact that the initial rate was found to be exactly proportional to the initial concentration of both the ester and hydroxide ion indicates that in the first step of the reaction the rate depends only on the concentration of both hydroxide ion and the ester and that the attack of hydroxide ion on sulfinyl sulfur occurs exclusively. We can thus conclude that no subsequent reaction takes place at all in the initial step of the reaction. The initial rate method was found to be approriate for kinetic measurements of the alkaline hydrolysis of 1,2-dithiaacenaphthene *S*-oxide. The second-order constants were easily calculated from the

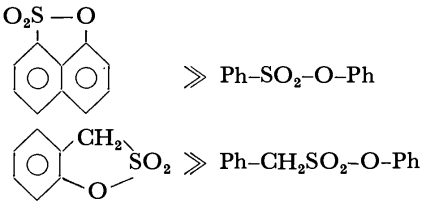
values of k_{obs} by dividing them by the initial concentration of hydroxide ion (Table 3). A kinetic experiment on the alkaline hydrolysis of phenyl benzenethiolsulfinate was also carried out in a pH-controlled buffer solution because the reaction was found to be very fast. The buffer chosen was potassium phosphate monobasic (KH_2PO_4)–sodium phosphate dibasic (Na_2HPO_4) system. The alkaline hydrolysis of 1,2-dithiaacenaphthene *S*-oxide was carried out in a medium of the same ionic strength as in the case of phenyl benzenethiolsulfinate.

In the alkaline hydrolysis of aromatic sulfonates and sulfates, the rates of the five-membered cyclic esters were reported to be 10^6—10^7 times faster than those of the corresponding open-chain analogs.[6]



However, five-membered cyclic thiolsulfinate (I) was found to be hydrolyzed 1.5×10^3 times more slowly than the corresponding acylic ester.

The activation energy for the five-membered thiolsulfinate is markedly low, *i.e.*, $\Delta H^{\ddagger}=8.8$ kcal mol^{-1}, while the activation entropy is more negative, *i.e.*, $\Delta S^{\ddagger}=-32$ e.u., than that of phenyl benzenethiolsulfinate. These activation parameters suggest that the markedly small rate of the cyclic thiolsulfinate is mainly caused by the entropy term of free energy of activation. Thus, the surprisingly reduced reactivity of five-membered thiolsulfinate ester as compared with the case of sulfate ester can be rationalized on the basis of the following special nature of 1,2-dithiaacenaphthene skeleton; in 1,2-dithiaacenaphthene *S*-oxide two sulfur atoms are bound rigidly to fit just at the two peri-positions of naphthalene nucleus, *i.e.*, the bond length of *S*–*S* linkage being 2.1 Å according to the atomic radii

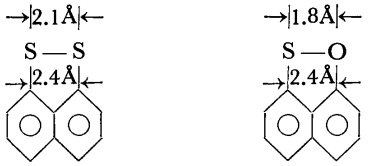
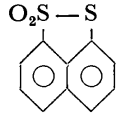
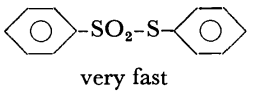
given by Pauling, close to the distance between two peri-positions (2.4 Å). It is evident that the five-membered ring is much less strained than the oxygen analog which is highly strained because of the shorter bond length of S–O linkage (1.8 Å). Therefore the



C–S–S angle is supposed to be very close to 90°. This seems to be adequate for the formation of a trigonal bipyramidal transition complex or intermediate of sp^3d configuration in which the ring angle around the sulfur atom is close to 90° and the five-membered ring spans apical and equatorial positions to accomodate the incoming nucleophile, *i.e.*, OH^- ion, giving rise to a lower value of activation enthalpy. The large negative activation entropy of the 1,2-dithiaacenaphthene *S*-oxide as compared with that for the open-chain analog indicates that due to the confinement at the peri-positions the S–S bond cannot be cleaved easily by the attack of the hydroxide ion on the sulfinyl sulfur unless its C–S bond is bent off the normal bond angle of a peri-substituent. A similar rate-retardation should be found in the alkaline hydrolysis of the five-membered cyclic 1,2-dithiaacenaphthene *S*,*S*-dioxide as compared to that of the open-chain benzenethiolsulfonate. The open-chain thiolsulfonate was hydrolyzed overwhelmingly faster than that of the thiosulfonate bearing the naphthalene ring (Table 3).



no reaction



very fast

Experimental

Materials. 1,2-Dithiaacenaphthene was prepared according to the method of Zweig and Hoffmann.[7] 1,2-Dithiaacenaphthene *S*-oxide was obtained by the oxidation of 1,2-dithiaacenaphthene with sodium metaperiodate in dioxane–water or by selective deoxygenation of thiolsulfonate with trimethyl phosphite. The procedure is as follows. 1,2-Dithiaacenaphthene 3.1 g (16.1 mmol) was dissolved in 90 ml of dioxane into which a solution of 6.8 g (30.5 mmol) of sodium metaperiodate in 60 ml of water was added. The resulting solution was kept at room temperature for 12 hr, and then extracted with benzene. The solvent was evaporated and the residue was recrystallized from *n*-hexane–benzene to afford yellow needles, mp 82.5—83.5°C. Another procedure is as follows. Upon refluxing the mixture of 1,2-dithiaacenaphthene *S*,*S*-dioxide 220 mg (1.0 mmol) and trimethyl phosphite 310 mg (2.5 mmol) in 100 ml of benzene for 3 hr, a nearly quantitative amount of 1,2-dithiaacenaphthene *S*-oxide and a trace of 1,2-dithiaacenaphthene were obtained. The reaction mixture was evaporated and the residue was separated by column chromatography. The compound showed an IR stretching band at 1080 cm^{-1} characteristic of the S–O group. UV: max 247 nm (ε: 25700 in 60% EtOH–H_2O) Mass spectrum showed the conversion from *m/e* 206 to *m/e* 178. Found: C, 58.20; H, 2.98%. Calcd for $C_{10}H_6OS_2$: C, 58.27; H, 2.88%. Kinetics: A solution of 1 ml of 1,2-dithiaacenaphthene *S*-oxide (1.2×10^{-3}M) in absolute ethanol was added to a mixture of 29 ml of ethanol and 20 ml of 4.0×10^{-4}M KOH water solution, the latter mixture being kept in a constant temperature bath prior to addition of the ester. An aliquot of the reaction mixture was withdrawn to a UV cell and its optical density near 247 nm was recorded with a Hitachi EPS-3T recording spectrophotometer. Since the reaction was expected to be complicated as illustrated in equations (1)—(3), only the initial rate was used for calculation of the rate constant. The initial slope obtained graphically was found to be proportional to the initial rate of the reaction:

$$-d[ester]/dt = -d(O.D)/dt \times 1/\varepsilon$$
$$= k_{obs}[E_0] = k_{OH}[OH^-][E_0]$$

The plot of the rates against the initial concentration of the ester gave a straight line. (Table 2)

Product. 1,2-Dithiaacenaphthene *S*-oxide (1.84 g, 8.9 mmol) and KOH (0.76 g, 14 mmol) were dissolved in methanol. After being left at room temperature for 12 hr, the solution was evaporated and the residue was extracted with ether and chloroform. Concentration of the extract afforded 1,2-dithiaacenaphthene (583 mg, 37%). The inorganic layer which did not dissolve either in ether or chloroform was neutralized with hydrochloric acid and then extracted with ether and chloroform. After the solvent was removed the residue was separated by column chromatography into 1,2-dithiaacenaphthene *S*-oxide (425 mg, 23%) and 1,2-dithiaacenaphthene *S*,*S*-dioxide (108 mg, 6%).

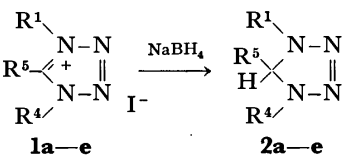
(Received September 12, 1972)

The sodium borohydride reduction of azolium iodides containing two, three, or four nitrogen atoms in the ring was studied. 1,4,5-Trisubstituted tetrazolium iodides gave Δ^2-tetrazolines, whereas 1,3,5-trisubstituted tetrazolium iodide yielded no reduction product. 1,3,4,5-Tetrasubstituted 1,2,4-triazolium iodides and 1,2-disubstituted 1,2,3-triazolium fluorosulfonate were reduced to Δ^2-1,2,4-triazolines and Δ^3-1,2,3-triazoline respectively, but 1,3,4,5-tetrasubstituted 1,2,3-triazolium iodides were not reduced at all. Both pyrazolium and imidazolium salts gave the corresponding azolidines. These results can be explained in terms of the characteristics of sodium borohydride, which reduces selectively the immonium moiety in azolium salts.

The reduction of pyridinium salts and these benzo-derivatives with sodium borohydride has been well-established and utilized as a synthetic tool useful in obtaining hydrogenated heterocycles.[1] With regard to the reduction of azolium salts, thiazolium halides[2,3] and pyrazolium perchlorate[4] give thiazolidines and pyrazolidine respectively in a protic solvent, and benzoisooxazolium[5] and benzoimidazolium salts[6] yield the corresponding benzoazolines. Imidazolium iodides are, however, reduced to ring-cleaved products, *N,N,N'*-trialkylethylene diamines.[7] These confused results prompted us to investigate the unknown behavior of triazolium and tetrazolium salts in the sodium borohydride reduction and to attempt to ascertain the common properties of azolium salts.

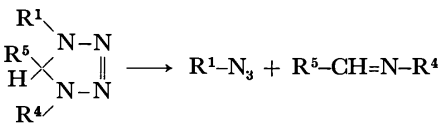
In general, azolium salts were treated with excess sodium borohydride in 95% ethanol at room temperature for several hours; the sole products were afforded in good yields when the reduction occurred. The reduction of 1,4,5-trisubstituted tetrazolium iodides (**1**) gave the corresponding Δ^2-tetrazolines (**2**). The analytically-pure Δ^2-tetrazoline (**2a—d**) could be isolated from the ethereal extract of the product without further purification.

The structure of the novel type of Δ^2-tetrazoline was elucidated by means of NMR and elementary analyses. The NMR spectra of **2a—c** displayed a singlet peak at around δ 4.61 ppm associated with the C^5-proton, while that of **2d** showed a quartet at δ 4.15 ppm and a doublet at δ 1.52 ppm assigned to the C^5-proton and the 5-methyl protons respectively. **2a** and **2d** are comparatively unstable to heat and are decomposed completely at 120°C in only a few minutes to give alkyl azides and Schiff's bases, whereas **2b** and **2c** are more stable and are scarcely decomposed at all on heating at 150°C. The formation of Schiff's bases was observed in the mass spectra of these tetrazolines.



1a—e **2a—e**

	a	**b**	**c**	**d**	**e**
R^1:	CH_3	CH_3	C_2H_5	CH_3	CH_3
R^4:	CH_3	C_2H_5	C_2H_5	C_6H_5	CH_3
R^5:	C_6H_5	C_6H_5	C_6H_5	CH_3	CH_3



In the reduction of 1,4,5-trimethyltetrazolium iodide (**1e**), the attempted isolation of the product, **2e**, was unsuccessful; however, the formation of **2e** was confirmed by the NMR spectrum of an aqueous solution of the reaction mixture. The spectrum revealed only two kinds of peaks, consisting of a singlet at δ 2.93 ppm and a doublet at δ 1.40 ppm. (A third peak might be hidden behind the absorption peak of water.) The peak at δ 2.93 ppm and the peak at δ 1.40 ppm can be assigned to, respectively, the *N*-methyl and 5-methyl protons of **2e** on the basis of the integral ratio and the chemical shifts, but the 5-methyl protons of the unreacted tetrazolium iodide, **1e**, also have a singlet peak at δ 2.93 ppm. For the further assignment of these peaks a similar reduction of **1e** was attempted in deuterium oxide; the reduced product, **5**, showed only a singlet peak at δ 2.93 ppm. Our previous report has revealed that the rapid hydrogen-deuterium exchange of the 5-methyl protons in 1,4,5-trimethyltetrazolium iodide, **1e**, occurred in a deuterium oxide solution, but no exchange of the 1- and 4-*N*-methyl protons was observed even under strongly basic conditions.[8] Therefore, the singlet peak at δ 2.93 ppm of **5** should be assigned to the 1- and 4-*N*-methyl protons. Similarly, the singlet peak at δ 2.93 ppm of **2e** should be associated not with the 5-methyl protons of the

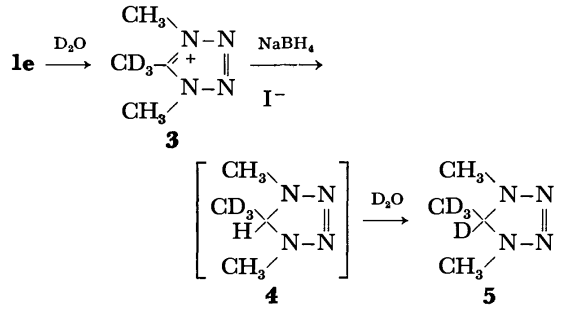
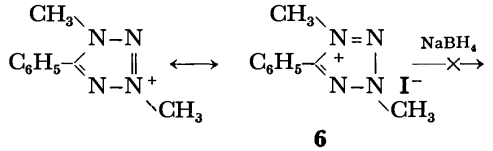
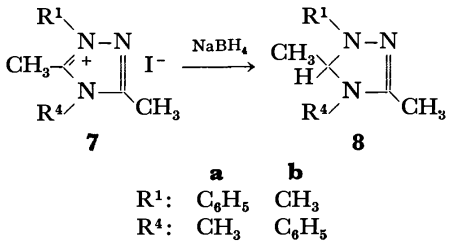
unreacted **1e**, but with the *N*-methyl protons of **2e**. The splitting of the peak of the 5-methyl protons of **2e** into a doublet suggested the presence of a C^5-proton peak hidden behind the absorption peak of water.



Our previous report[9] has shown that the reaction of 1-methyl-5-phenyltetrazole with methyl iodide gave a mixture of 1,3-dimethyl- and 1,4-dimethyl-5-phenyltetrazolium iodide (**6** and **1a**) at room temperature when the reaction continued for a long time. When a mixture of **1a** and **6**[10] was treated with sodium borohydride, the 1,4-dimethyl salt, **1a**, was reduced to 1,4-dimethyl-Δ^2-tetrazoline, **2a**, but the 1,3-dimethyl salt, **6**, remained unchanged.

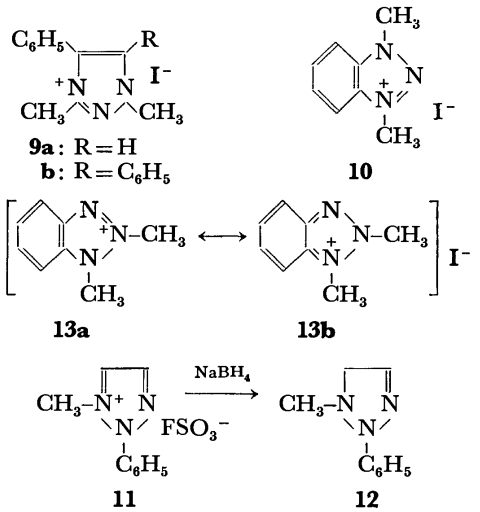


In the reduction of 1,3,4,5-tetrasubstituted 1,2,4-triazolium iodides (**7**),[11] the more electron-deficient 5-carbon atom was attacked by the hydride ion from sodium borohydride. The Δ^2-1,2,4-triazolines (**8**) thus formed showed the presence of the quartet peak of the C^5-proton and the doublet peak assigned to the 5-methyl protons in the NMR spectra.

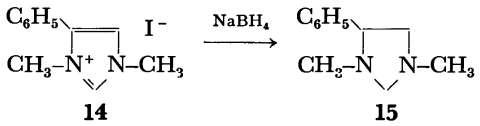


By contrast, the reaction of 4-phenyl- and 4,5-diphenyl-1,3-dimethyl-1,2,3-triazolium iodides (**9**),[12] or 1,3-dimethylbenzotriazolium iodide (**10**)[13] with sodium borohydride gave no reduction product, and each starting iodide was recovered.

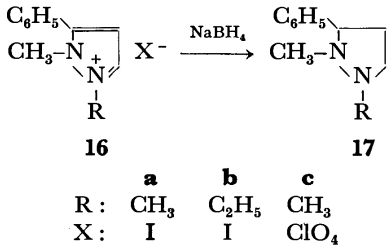
1-Methyl-2-phenyl-1,2,3-triazolium fluorosulfonate (**11**)[14] was reduced to the corresponding Δ^3-triazoline (**12**), which was identified by the NMR spectrum and elemental analysis. However, 1,2-dimethylbenzotriazolium iodide (**13**)[13] yielded no reduction product.



Under conditions similar to those of the above reduction, the treatment of 1,3-dimethyl-4-phenylimidazolium iodide (**14**) gave only one product, 1,3-dimethyl-4-phenyl-imidazolidine (**15**), although Godefroi[7] reported the formation of a ring-cleaved product in the reduction of 1-benzyl-3-alkylimidazolium iodides.



Analogously, the reduction of 1-alkyl-2-methyl-3-phenylpyrazolium iodide (**16**) yielded 1-alkyl-2-methyl-3-phenylpyrazolidine (**17**). This finding is consistent with the finding of El'tsov in the reduction of pyrazolium perchlorate (**16c**).[4]



We can summarize the results of the sodium borohydride reduction of azolium iodides as follows. In the case of the tetrazolium iodides, the positions of the substituents at the nitrogen atoms of the tetrazole ring determined whether or not reduction occurred, as is shown by the fact that 1,4,5-trisubstituted tetrazolium iodides (**1**) yielded the partially-reduced Δ^2-tetrazolines, while 1,3,5-trisubstituted tetrazolium iodide (**6**) gave no reduction product. The reduction was more complicated in the cases of triazolium salts and benzotriazolium iodides. 1,2,4-Triazolium iodides (**7**) were

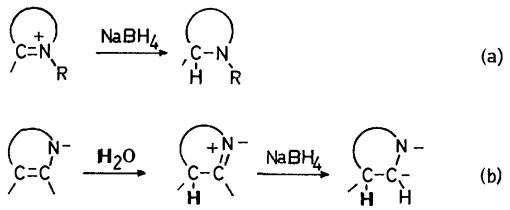
14) M. Begtrup and K. V. Poulson, *Acta Chem. Scand.*, **25**, 2087 (1971): The quarterization of 1-substituted triazole with alkyl iodide gave only 1,3-dialkyltriazolium iodide,[12] and 2-substituted triazole gave no quarternary iodide with alkyl iodide.

readily reduced, and the occurrence of the reduction of 1,2,3-triazolium salts depended on the positions of the substituents at the nitrogen atoms, much as in the case of tetrazolium iodides. Δ^3-1,2,3-Triazoline was derived from 1,2-disubstituted 1,2,3-triazolium salt (**11**), whereas 1,3-disubstituted derivative (**9**) was unchanged. No reduction occurred in two kinds of benzotriazolium iodides (**10** and **13**). Both pyrazolium and imidazolium iodides (**14** and **16**) gave the corresponding diazolidine.

Many investigations of the sodium borohydride reduction of pyridinium salts[15] have revealed the mechanism for the formation of the tetrahydropyridines; Clark and Sykes proposed a similar pathway for the reduction of the thiazolium salts to thiazolidines.[3]

An analogous pathway could be applied to the sodium borohydride reduction of the azolium iodides. All of the azolium salts which can be reduced contain an immonium-ion moiety in the formula of the mesomerism, as is shown by the examples of **1**, **7**, **11**, **14**, and **16**. The other azolium salts (**6** and **9**) which cannot be reduced, by contrast, involve no immonium-ion moiety in the formula. The hydride ion derived from sodium borohydride attacks an electron-deficient carbon of the immonium-ion system in an azolium salt to form an azoline (Reaction a). When there remains an enamine moiety in the structure of a formed azoline, the enamine system re-forms an immonium-ion system with protonation by the protic solvent and is subsequently reduced to azolidine as the final product (Reaction b). The further reduction of both pyrazoline and imidazoline gave the corresponding diazolidines, but neither Δ^2-1,2,4- and Δ^3-1,2,3-triazolines nor Δ^2-tetrazolines could be reduced due to the lack of an enamine moiety in each ring system. The above pathway may be applied to the cases of benzoazolium salts, though the partial reduction product (benzoazoline) was not further reduced, because the C=C



double bond in the benzoazoline is included in the resonance system of the benzene ring and cannot be attacked by sodium borohydride in a protic solvent, much as in the case of dimethylaniline. These examples are typical of the reduction of benzoisooxazolium[5] and benzoimidazolium salts,[6] which gave the corresponding dihydrobenzoazoles. The fruitless reduction of 1,3-disubstituted benzotriazolium iodide (**10**) can be explained by the lack of the immonium-ion moiety in its canonical formula, so that it was not reduced with sodium borohydride and was recovered. One of the canonical formulae (**13b**) of 1,2-disubstituted benzotriazolium iodide (**13**) involves an immonium-ion moiety, but the absence of any reduction of **13** suggests that **13b** may contribute to its resonance in the salt scarcely at all.

Experimental

The melting points were taken on Yanagimoto Seisakusho Micro Melting Point Apparatus, Serial No. 1417. The NMR spectra were obtained on a Japan Electron Optics C-60-H Spectrometer, operating at 60 MHz and with TMS (in $CDCl_3$) or DSS (in D_2O) as the internal reference. The UV spectra were measured in ethanol on a Shimadzu-MPS Spectrophotometer. The elemental analyses were performed by Mrs. K. Fujimoto of this labaratory on a Yanagimoto Autoanalyzer CHN Corder MT-1. The mass spectra were obtained on a Hitachi RMS-4 Mass Spectrometer.

*Reduction of 1,4-Dimethyl-5-phenyltetrazolium Iodide (**1a**) with Sodium Borohydride ($NaBH_4$).* To a solution of 395 mg (1.27 mmol) of **1a**[9] in 10 ml of 95% ethanol at room temperature, we added, portion by portion, 241 mg (6.35 mmol) of $NaBH_4$. After the mixture had ceased foaming, it was heated under reflux for 2 hr (or stirred for 5 hr at room temperature). The solvent was then removed *in vacuo*, and 10 ml of water was added to the residue. The aqueous layer was extracted twice with 20 ml portions of ether; the ether was then evaporated off to dryness *in vacuo* without heating to give 1,4-dimethyl-5-phenyltetrazoline (**2a**) as colorless crystals; 200 mg (89.5%); mp 53.0—53.5°C, NMR ($CDCl_3$) δ 7.46 (s, 5H, 5-phenyl), 4.48 (s, 1H, C^5-proton), 2.86 ppm (s, 6H, *N*-methyl).

Found: C, 61.49; H, 6.82; N, 31.57%. Calcd for $C_9H_{12}N_4$: C, 61.34; H, 6.86; N, 31.80%.

UV (EtOH) λ_{max} 281 nm (ε_{max} 1160).

The heating of **2a** at 120°C for 5 min in a sealed tube gave *N*-benzalmethylamine quantitatively; it was identified by comparison with an authentic sample.[16] The evolved gas was determined to be methyl azide by means of presence in its mass spectrum of a parent ion at *m/e* 57. Similarly, the thermolysis of **2d** gave *N*-ethylideneaniline and methyl azide.

*Reduction of 1-Ethyl-4-methyl-5-phenyltetrazolium Iodide (**1b**).* An analogous treatment of **1b**[9] gave a liquid, **2b**, in a 66.8% yield. Tlc (silica gel) analyses displayed one spot; R_f= 0.50, 9:1 *n*-hexane–ethyl acetate. NMR ($CDCl_3$) δ 7.50 (m, 5H, 5-phenyl), 4.65 (s, 1H, C^5-proton), 3.15 and 1.17 (q and t, 2H and 3H, 1-ethyl), 2.85 ppm (s, 3H, 4-methyl).

Found: C, 63.36; H, 7.36; N, 29.28%. Calcd for $C_{10}H_{14}N_4$: C, 63.13; H, 7.42; N, 29.45%.

*Reduction of 1,4-Diethyl-5-phenyltetrazolium Iodide (**1c**).* An analogous treatment of **1c**[9] gave a liquid, **2c** (R_f=0.56, 9:1 *n*-hexane–ethyl acetate), in a 60.5% yield. NMR ($CDCl_3$) δ 7.45 (m, 5H, 5-phenyl), 4.80 (s, 1H, C^5-proton), 3.11 and 1.13 ppm (q and t, 4H and 6H, *N*-ethyl).

Found: C, 64.27; H, 8.18; N, 27.55%. Calcd for $C_{11}H_{16}N_4$: C, 64.67; H, 7.90; N, 27.43%.

*Preparation of 1,5-Dimethyl-4-phenyltetrazolium Iodide (**1d**).* The reaction of 2 g of 5-methyl-1-phenyltetrazole[17] with an excess of methyl iodide in a sealed glass tube at 100°C for 5 hr gave **1d**;[18] mp 205—206°C.

Found: C, 35.62; H, 3.53; N, 18.68%. Calcd for $C_9H_{11}N_4I$: C, 35.78; H, 3.67; N, 18.55%.

NMR (D_2O) δ 7.80 (s, 5H, 4-phenyl), 4.45 (s, 3H, 1-methyl), 3.00 ppm (s, 3H, 5-methyl).

16) R. B. Moffett, "Organic Syntheses," Vol. 34, 1954, p. 64.

18) G. F. Duffin, J. D. Kendall, and H. R. J. Waddington, *Chem. Ind.* (London), **1955**, 1355.

*Reduction of 1,5-Dimethyl-4-phenyltetrazolium Iodide (**1d**).* An analogous treatment of **1d** gave a liquid, **2d** (R_f=0.45, 9:1 *n*-hexane–ethyl acetate), in a quantitative yield. NMR ($CDCl_3$) δ 7.35—6.95 (m, 5H, 4-phenyl), 4.15 (q, 1H, C^5-proton), 3.05 (s, 3H, 1-methyl), 1.52 ppm (d, 3H, 5-methyl). UV (EtOH) λ_{max} 304 nm (ε_{max} 3910), 222 nm (2980).

Found: C, 61.57; H, 6.89; N, 31.64%. Calcd for $C_9H_{12}N_4$: C, 61.34; H, 6.86; N, 31.80%.

*Reduction of 1,4,5-Trimethyltetrazolium Iodide (**1e**) in H_2O and D_2O.* The reaction of **1e** with $NaBH_4$ was carried out at room temperature in an NMR tube. After 2 hr, the NMR spectrum showed two kinds of peaks, at δ 2.93 (s) and 1.40 ppm (d); their integral ratio was 2:1.

A solution of **1e** in D_2O was kept at room temperature in an NMR tube. After one week, the singlet at δ 2.93 ppm disappeared. To the above solution we then added $NaBH_4$, and it was kept at room temperature. After 2 hr, the remaining singlet at δ 4.30 ppm disappeared and the singlet at δ 2.93 ppm reappeared.

*Reaction of the Mixture of 1,4-Dimethyl and 1,3-Dimethyl-5-phenyltetrazolium Iodide (**1a** and **6**) with $NaBH_4$ in $CDCl_3$.* A mixture of **1a** and **6**[10] was treated with $NaBH_4$ in $CDCl_3$. After 5 hr, the peak at δ 4.28 ppm disappeared, and instead two peaks, at δ 4.48 and 2.87 ppm (1:6), of **2a** appeared. However, the two peaks at δ 4.75 and 4.52 ppm assigned to the 1- and 3-methyl protons of **6** remained.

*Preparation of 1-Phenyl-3,4,5-trimethyl-1,2,4-triazolium Iodide (**7a**).*[11] We obtained **7a** by heating a solution of 1-phenyl-3,5-dimethyl-1,2,4-triazole in excess methyl iodide in a sealed glass bottle at 100°C for 32 hr. After cooling, the reaction mixture was washed with benzene. The residue was dissolved in minimum acetone, and to the acetone solution we added hexane to precipitate crystals. By the additional precipitation procedure we obtained yellow crystals (mp 169—172°C) in a quantitative yield. NMR ($CDCl_3$) δ 7.67 (m, 5H, *N*-phenyl), 3.84 (s, 3H, 4-methyl), 2.74 (s, 3H, 5-methyl), 2.64 ppm (s, 3H, 3-methyl).[19]

Found: C, 41.96; H, 4.45; N, 12.89%. Calcd for $C_{11}H_{14}N_3I$: C, 41.92; H, 4.48; N, 13.33%.

*Reduction of **7a**.* The treatment of **7a** with $NaBH_4$ gave, in a 70% yield, an unstable liquid whose structure was determined to be 1-phenyl-3,4,5-trimethyl-1,2,4-triazoline (**8a**) by studying its NMR spectrum; δ 7.6—6.8 (m, 5H, 1-phenyl), 4.88 (q, 1H, C^5-proton), 2.73 (s, 3H, 4-methyl), 1.97 (s, 3H, 3-methyl), 1.52 ppm (d, 3H, 5-methyl), and the mass spectrum: a parent ion at *m/e* 189.

*Preparation of 1,3,5-Trimethyl-4-phenyl-1,2,4-triazolium Iodide (**7b**).* The treatment of 3,5-dimethyl-4-phenyl-1,2,4-triazole[20] with excess methyl iodide in a sealed glass bottle at 100°C for 24 hr gave colorless crystals; mp 106—107°C. NMR (D_2O) δ 2.37 (s, 3H, 3-methyl), 2.58 (s, 3H, 5-methyl), 4.07 (s, 3H, 1-methyl), 7.5—8.0 ppm (m, 5H, 4-phenyl).[21]

Found: C, 41.40; H, 4.51; N, 12.99%. Calcd for $C_{11}H_{14}N_3I$: C, 41.92; H, 4.48; N, 13.33%.

*Reduction of **7b**.* Similarly, an unstable liquid (86%) was obtained from **7b**. Its structure was determined to be 1,3,5-trimethyl-4-phenyl-1,2,4-triazoline (**8b**) by studying its NMR spectrum; δ 1.37 (d, 3H, 5-methyl), 1.80 (s, 3H, 3-methyl), 2.72 (s, 3H, 1-methyl), 4.45 (q, 1H, C^5-proton), 7.0—7.5 ppm (m, 5H, 4-phenyl), and the mass spectrum: a parent ion at *m/e* 189.

Attempts at the elemental analysis of **8a** and **8b** were given up because of their instability even at room temperature.

*Reduction of 1-Methyl-2-phenyl-1,2,3-triazolium Fluorosulfonate (**11**).*[14] The reaction of 120 mg (0.463 mmol) of **11** with 30 mg of $NaBH_4$ was also carried out at room temperature in 95% methanol. The conventional treatment of the reaction product gave a viscous liquid (R_f=0.85, 9:1 methylene chloride–ethyl acetate), which was identified as 1-methyl-2-phenyl-1,2,3-triazoline-Δ^3; 69 mg (92.2%); n_{26}^D 1.5738. NMR ($CDCl_3$) δ 2.67 (s, 3H, *N*-methyl), 3.76 (s, 2H, C^5-protons), 6.7—7.5 ppm (m, 6H, C^4-proton and *N*-phenyl).

Found: C, 67.00; H, 6.94; N, 26.06%. Calcd for $C_9H_{11}N_3$: C, 67.05; H, 6.88; N, 26.07%.

*Reduction of 1,3-Dimethyl-4-phenylimidazolium Iodide (**14**).* The treatment of **14** with excess $NaBH_4$ (for 5 hr at room temperature or for 2 hr under reflux) gave a thermally stable liquid. It was distilled at 120°C/20 mmHg (76.9%), and its structure was determined to be 1,3-dimethyl-4-phenylimidazolidine (**15**) by studying its NMR spectrum ($CDCl_3$); δ 7.30 (s, 5H, 4-phenyl), 2.40 (s, 3H, *N*-methyl), 2.20 (s, 3H, *N*-methyl), 2.40—3.90 ppm (m, 5H, ring protons) and the mass spectrum *m/e* 176 (M^+). Its picrate was recrystallized from ethanol; mp 165—167°C.

Found: C, 50.77; H, 4.99; N, 17.31%. Calcd for $C_{17}H_{19}N_5O_7$: C, 50.37; H, 4.72; N, 17.28%.

*Reduction of 1,2-Dimethyl-3-phenylpyrazolium Iodide (**16a**).* By an analogous treatment of **16a**, 1,2-dimethyl-3-phenylpyrazolidine (**17a**) (73.1%) was obtained; bp 140°C/21 mmHg (lit,[22] 80°C/1.2 mmHg); mass spectrum *m/e* 176 (M^+). The recrystallization of its picrate from ethanol gave yellow crystals; mp 178—180°C (lit,[22] 177—179°C).

19) In deuterium oxide solution of **7a**, the rate of H/D exchange reaction of methyl protons at δ 2.74 ppm was faster than that at δ 2.64 ppm, so that the former is assigned to the more electron-deficient 5-methyl protons and the latter is to the 3-methyl protons.

20) R. Meyer, Ger. 579944 (1933): *Chem. Abstr.*, **27**, 4541 (1933).

21) The assignment of the peaks was determined as similarly as **7a**.

Dehydration in Liquid Sulfur Dioxide. I. Acid Amide and Acid Anhydride Synthesis in an Iodine-Pyridine-Sulfur Dioxide System

Masatomo NOJIMA, Shigeru HASEGAWA, and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received September 25, 1972)

A novel dehydrating reagent consisting of the I_2–pyridine–liq. SO_2 system has been examined in order to obtain acid amides from carboxylic acids and amines in liq. SO_2. Among the amines, aniline gave the most satisfactory results. A fairly good yield was also achieved when the SO_2Cl_2–Py–SO_2 system was used in place of the I_2–Py–SO_2 system. Various amines in the absence of acids in this system gave *N,N'*-disubstituted diaminosulfone derivatives in good yields. Benzoic acid itself in the absence of amines gave benzoic acid anhydride in this system slowly.

Liquid sulfur dioxide has been used as an unique solvent for the carbonium-ion reaction. It is an acidic dipolar aprotic solvent with a considerably small dielectric constant, 12.35 (22°C). The cationic reaction in this solvent is excellently favored. The organic reactions with negative ρ values can be successfully carried out in this solvent with unusual rapidity.[1]

The complex formations between various compounds bearing lone pairs and sulfur dioxide have been studied extensively.[2–5] Amines[2,3] and alcohols[4,5] are known to form 1:1 complexes with sulfur dioxide.

A chemical material called the Karl Fischer reagent,[6,7] consisting of iodine, pyridine, and sulfur dioxide in a 1:10:3 molar ratio, has been widely employed since 1935 for the convenient and quantitative analysis of water content in various substances in which the dehydration reaction of the organic compound is not proceeding.

The present authors have taken up a new liq. SO_2 system, consisting of iodine, pyridine, and sulfur dioxide in 1:3:100 molar ratio, or of sulfuryl chloride, pyridine and sulfur dioxide in the same ratio, in order to develop a new dehydrating reagent for organic chemistry.

Iodine is assumed to be dissociated in this system as:[8]

$$2\text{pyridine} + I_2 \rightleftarrows [\text{Py}\cdot\text{I}\cdot\text{Py}]^+ + I^- \quad (1)$$

Py = pyridine

and water is quantitatively determined as in the following equation:

$$H_2O + I_2 + 3\text{Py} + SO_2 \longrightarrow 2\text{HI}\cdot\text{Py} + SO_3\cdot\text{Py} \quad (2)$$

The dehydrating reaction of the organic compounds seems to proceed through a similar reaction series:

$$\text{RCOOH} + \text{R'NH}_2 + I_2 + 3\text{Py} + SO_2(\text{excess}) \longrightarrow \text{RCONHR'} + 2\text{HI}\cdot\text{Py} + SO_3\cdot\text{Py} \quad (3)$$

Results and Discussion

Amide Synthesis in the I_2–Py–Liq.SO_2 System. Acetic, propionic, and benzoic acids were reacted with several amines such as *n*-propyl amine and aniline. The results are listed in Table 1.

The results indicate that *n*-propyl amine is less reactive than aniline. The reaction might be accounted for by the lesser basicity of aniline as compared to that of *n*-propyl amine, the latter being solvated or complexes with sulfur dioxide to depress the reactivity of the amine greatly.[9]

$$\text{RNH}_2 + SO_2 \overset{K}{\rightleftarrows} \text{RNH}_2\cdot SO_2 \quad (4)$$

$$\text{RCOOH} + \text{R'NH}_2 \longrightarrow \text{RCOO}^-\text{NH}_3^+\text{R'} \xrightarrow[I_2\text{-Py-liq. } SO_2]{-H_2O} \text{RCONHR'} \quad (5)$$

The equilibrium constant, *K*, of the complex formation will be increased as the basicity of RNH_2 becomes larger, and the effective concentration of the amine in the solution will be decreased according to Eq. (4).

Secondly, the reaction of aniline with tetraethyl-

Table 2. Reaction products of benzoic acid and tetraethyl ammonium benzoate with aniline in the I_2–Py–Liq.SO_2 system

Starting material	Product	
$C_6H_5COOH+C_6H_5NH_2$	$C_6H_5CONHC_6H_5$ (85)	$C_6H_5NHSO_2NHC_6H_5$ (15)
$C_6H_5COON(Et)_4+C_6H_5NH_2$	$C_6H_5CONHC_6H_5$ (18)	$C_6H_5NHSO_2NHC_6H_5$ (24)
	$C_6H_5COOCOC_6H_5$ (14)	

ammonium benzoate in the same system was carried out in order to examine the role of the benzoate ion as the attacking reagent, depicted as follows:

$$C_6H_5COON(Et)_4 \rightleftharpoons C_6H_5COO^- + {}^+N(Et)_4 \quad (6)$$

$$C_6H_5COO^- + SO_2 \rightleftharpoons C_6H_5COO^-\cdot SO_2 \quad (7)$$

$$C_6H_5NH_2 + SO_2 \rightleftharpoons C_6H_5NH_2\cdot SO_2 \quad (8)$$

$$C_6H_5COO^- + {}^+N(Et)_4 + C_6H_5NH_2 + I_2 + Py\text{–}SO_2 \longrightarrow HI\cdot Py + SO_3\cdot Py + I^-N^+(Et)_4 + C_6H_5CONHC_6H_5 \quad (9)$$

However, the possibility of a reaction path through the benzoate anion can be disproved since the distributions of products formed from the two series of reactions are entirely different from each other, as may be seen in Table 2.

The yield of the acid amide is very small in the latter case. Moreover, benzoic acid anhydride was found in the reaction mixture of the reaction between tetraethylammonium benzoate and aniline. These results suggest that the intermediate $(C_6H_5COO)^-$ $(NH_3C_6H_5)^+$ is the most plausible one. The dehydration of benzoic acid itself has been examined in the same system. Benzoic acid is dehydrated to benzoic acid anhydride very gradually, as is shown in Table 3.

Table 3. The dehydration of benzoic acid in the I_2–Py–Liq.SO_2 system

Reaction period	Product (%)
1 hr	No reaction
24 hrs	$C_6H_5COOCOC_6H_5$ (50)
7 days	$C_6H_5COOCOC_6H_5$ (49)

The rate of the acid anhydride formation is very slow compared to that of the formation of the benzanilide; this suggests the path to the acid amide through the reaction of benzoic anhydride and aniline should also be rejected.

The authors also examined the reaction of the amine in this I_2–Py–SO_2 system.

Table 4. Reaction of amines in the I_2–Py–Liq.SO_2 system

Amine	Reaction period	Product	Yield %
Aniline	24	$C_6H_5NHSO_2NHC_6H_5$	50
Aniline+NaOTs	24	$C_6H_5NHSO_2NHC_6H_5$	81
$CH_3CH_2CH_2NH_2$	24	$C_3H_7NHSO_3NHC_3H_7$	10
Aniline	1	$C_6H_5NHSO_2NHC_6H_5$	84
Aniline+NaOTs	1	$C_6H_5NHSO_2NHC_6H_5$	95
Aniline (degassed)	1	$C_6H_5NHSO_2NHC_6H_5$	79

An inspection of Table 4 will show the following point: 1) *n*-Propyl amine gave a much smaller yield of diamino sulfone (10%) than aniline. 2) *N,N'*-Diphenyldiamino sulfone was obtained in a remarkably good yield in the presence of a catalytic amount of sodium toluenesulfonate. 3) Moreover, the yield was decreased when the reaction was prolonged for 24 hr, suggesting that an equilibrium condition will decrease the yield of the diamino sulfone. 4) The degassing of the reaction solution has little effect on the yield of the *N,N'*-diphenyldiamino sulfone. These phenomena suggest that the diamino sulfone formation in the liq. SO_2–I_2–Py system is an iodine-catalyzed dehydrogenation. The mechanism will be discussed further elsewhere.

Lastly, sulfuryl chloride was used in place of iodine in this system. A fair yield was achieved, as is shown in Table 5.

Table 5. Dehydration reaction in the SO_2Cl_2–Py–Liq.SO_2 system

Starting material	Product (yield %)
$C_6H_5COOH+C_6H_5NH_2$	$C_6H_5CONHC_6H_5$ (75)
$CH_3CH_2COOH+C_6H_5NH_2$	$CH_3CH_2CONHC_6H_5$ (27)
$C_6H_5NH_2$	$C_6H_5CHSO_2NHC_6H_5$ (70)

These results are very similar to those for the I_2–Py–liq. SO_2 system, and suggest the following intermediate, $(RCOO)^-(NH_3C_6H_5)^+$, in the reaction course. The overall reaction mechanism may be supposed to be as follows:

$$(RCOO)^-(NH_3C_6H_5)^+ + I^+ + I^- + Py\text{–}SO_2 \longrightarrow RCONHC_6H_5 + 2HI\text{–}Py + SO_3\text{–}Py \quad (10)$$

SO_2Cl_2–Py–liq.SO_2 system:

$$(RCOO)^-(NH_3C_6H_5)^+ + Cl^+ + SO_2Cl^- + Py\text{–}SO_2 \longrightarrow RCONHC_6H_5 + 2HCl\text{–}Py + SO_3\text{–}Py \quad (11)$$

Experimental

Materials. The liquid sulfur dioxide was dried over phosphorus pentoxide and distilled two times. Commercially-sold iodine, benzoic acid, and sodium *p*-toluenesulfonate of a reagent grade were used without further purification. The acetic acid, propionic acid, pyridine, and *n*-propylamine were all purified by the ordinary methods and distilled. A constant middle fraction was collected for use in the preparation.

Preparation of Tetraethylammonium Benzoate. Fowler's method was adopted.[10] Fresh silver oxide was obtained by mixing aqueous silver nitrate and aqueous sodium hydroxide solutions and was washed with water several times. Then silver oxide was added to the aqueous solution of tetraethylammonium iodide. After the removal of the precipitated silver iodide, equivalent moles of benzoic acid were added. By evaporating the water *in vacuo*, tetraethylammonium benzoate was obtained as a white crystal, which was then

10) D. L. Fowler, *J. Amer. Chem. Soc.*, **62**, 1140 (1940).

dried and stored in a dessicator.

IR (KBr) cm^{-1}: 1592, 1550, 1448, 1363, 1160, 990, and 710 cm^{-1}.

The Synthesis of an Amide in the Iodide–PyridineL–iquid SO_2 System. Into 30 ml of liq. SO_2 in a high-pressure glass vessel, 0.015 mol of iodine, 0.045 mol of pyridine, 0.015 mol of a carboxylic acid, and 0.030 mol of an amine were added at −70°C. The reaction mixture was then kept at 30°C for 1 hr. After the reaction, the reaction mixture was chille and poured into an ice-cooled aqueous solution of aboutd 1.5 molar sodium hydroxide and made alkaline. The amide was extracted by ether from the basic reaction mixture. The ethereal solution was washed with a saturated salt solution repeatedly dried over anhydrous sodium sulfate. After the evaporation of the ether, the product was purified by recrystallization and identified as an amide. The residue after the extraction was made acidic again by adding concd hydrochloric acid and was then extracted by ether. From the extract, a small amount of a diamino sulfone was obtained by a similar procedure.

Acetanilide: The reaction of acetic acid (0.9 g) and aniline (2.7 g) gave acetanilide (2.0 g, 80%, recrystallized from benzene). Mp and mixed mp with authentic specimen, 112—114°C;[11] IR (KBr) cm^{-1}: 1658(s), 1597(s), 1560(m), 1439 (m), 1325(m).

N-n-*Propylpropionamide*: The reaction of propionic acid (1.17 g) and *n*-propylamine (1.77 g) gave 0.4 g (27%) of a liquid; bp 64—65°C (0.4 Torr);[12] IR (KBr) cm^{-1}; 3250(m), 1640(s), 1560(s), 1472(s). NMR ($CDCl_3$) τ; 9.1(multiplet), 8.5(sextet), 7.8(quartet), 6.9(quartet), 2.9(singlet).

Propionanilide: The reaction of propionic acid (1.17 g) and aniline (2.70 g) gave 0.8 g (36%) of propionanilide (from benzene). Mass $m/e=149$ (M^+); mp and mixed mp, 104—106°C;[11] IR ($CDCl_3$) cm^{-1}: 1657(s), 1600(s), 1440(s), 745(m), 682(m).

N-n-*Ppropylbenzamide*: The reaction of benzoic acid (1.83 g) and *n*-propylamine (1.77 g) gave 1.2 g of a crystal (49%) (from ethanol–water); mp and mixed mp 83—85°C;[13] IR (KBr) cm^{-1}: 3250(m), 1628(s), 1540(s), 1450(s), 1370(s), NMR ($CDCl_3$) τ: 9.05(t), 8.4(sex), 6.6(q), 2.4(m), 3.15(s).

Benzanilide: The reaction of benzoic acid (1.83 g) and aniline (2.70 g) gave white crystals (from ethanol–water); 2.7 g (85%); mp and mixed mp, 158—161°C;[14] IR (KBr) cm^{-1}: 1650(s), 1530(s), 1439(s), 750(m), 682(m).

The Reaction of an Amine in the Iodide–Pyridine–Liq. SO_2 System. The reaction conditions and the procedure used were the same as those used for the amide synthesis. The molar ratio of the reagents was as follows: amine: iodine: pyridine: liq. $SO_2=2:1:3:100$.

N,N′-*Diphenyldiamino Sulfone*: Aniline (2.70 g) gave crystals (recrystallized from benzene); 3.1 g (84%); mp and mixed mp 111—113.[15] Mass, $m/e=248$ (M^+), 92.64. IR (KBr) cm^{-1}: 3225(m), 1595(m), 1140(m), 930(m), 740(m), 690(m).

N,N′-*Di*-n-*propyldiamino Sulfone*: *n*-Propylamine (1.77 g) gave white crystals (0.3 g, 10%; recrystallized from benzene). Mp and mixed mp 118—120°C.[15] Mass, $m/e=180$ (M^+), 151.58; IR (KBr) cm^{-1}; 3250(m), 1587(m), 1446(m), 1315(s), 1135(s), NMR ($CDCl_3$), τ: 9.0(t), 8.4(sex), 7.0(q), 2.7(s).

The Dehydration Reaction in the SO_2Cl_2–Pyridine–Liq. SO_2 System. We have examined the dehydration reaction of carboxylic acid and amine using sulfuryl chloride instead of iodine. The ratio of the reagents and the reaction conditions were the same as those used in the amide synthesis in the iodine–pyridine–liq. SO_2 system.

The Synthesis of Carboxylic acid Anhydride in the Iodine–pyridine–liq. SO_2 System. The reaction conditions used for the carboxylic acid anhydride synthesis were as follows: carboxylic acid (0.030 mol), iodine (0.015 mol), and pyridine (0.045 mol) were reacted in liq. sulfur dioxide (1.50 mol) for 24 hr at 30°C. The reaction mixture was then treated as has been described in the case of amide synthesis.

Benzoic Anhydride: Benzoic acid (3.66 g) gave 1.2 g of white crystals (yield 49%); mp and mixed mp,[16] 40—42°C. IR (KBr) cm^{-1}; 1785(s), 1720(s), 1600(m), 1450(m), 1210(m), 778(m), 675(s).

The Reaction of Tetraethylammonium Benzoate in the Iodine–Pyridine–Liq.SO_2 System. Into a mixture of pyridine (0.045 mol), iodine (0.015 mol), and aniline (0.030 mol) in liq. SO_2 (1.50 mol), we added 0.015 mol of tetraethylammonium benzoate; the mixture was then reacted for one hour at 30°C. The products were isolated and separated by the usual procedure.

The Photochemical Reaction of Diphenylacetylene with Enamines[1]

Norioki MIYAMOTO and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606

(Received September 28, 1972)

The irradiation of a mixture of diphenylacetylene (I) and the enamine of the diethyl ketone (II) or of cyclopentanone (IV) gives two β,γ-unsaturated ketones, III and X respectively, in which the diphenylacetylene moiety is formally inserted into the respective enamine double bond under hydrogen migration. The reaction with the enamine of cyclohexanone (V) affords 2-(1,2-diphenylvinyl)cyclohexanone (XIII) as the major product in addition to the cycloadduct (XV). In each case, the formation of photodimers of I has been observed. The reaction is quenched by the addition of pyrene, is sensitized by triphenylene, and is supposed to proceed by way of a triplet path. The different routes of the enamine reactions can be explained by considering the geometry of the intermediate diradicals.

Little is known about photochemical reactions in which an enamine[2] is attacked by photochemically-excited species. Foote and Wei-Ping reported the oxidative fission of the enamine double bond by singlet oxygen photochemically produced.[3] We ourselves have been interested in the reaction of photoexcited benzophenone with enamines, in which the oxetane formation competes with the hydrogen abstraction at the allylic position,[4] and also in the photoreaction of diphenylacetylene with enaminoesters.[5]

In continuation of previous studies along this line, we have investigated the photoreaction of diphenylacetylene with several types of enamines; the results will be described in this paper.

TABLE 1. PHOTOREACTION OF I WITH ENAMINES IN ETHANOL AND ACETONITRILE

Enamine	solvent	Product (yield[9] in %)
II[6]	EtOH	dimers[7] of I (13), III (10)
	CH_3CN	dimers[7] of I (16), III (18)
IV[6]	EtOH	dimers[7] of I (10), X (15)
	CH_3CN	dimers[7] of I (6.2), X (20)
V[6]	EtOH	dimers[7] of I (10), XIII (11), XV[6] (2.3)
	CH_3CN	dimers[7] of I (15), XIII (15), XV[6] (3.1)

When a benzene or *n*-hexane solution of diphenylacetylene (I) and 3-morpholinopent-2-ene (II)[6] was irradiated, the photodimers of I as described by Büchi *et al.*[7] and Bryce-Smith and Lodge[8] were obtained in a 10% yield.[9] In addition to this, β,γ-unsaturated ketone (III) was isolated as a viscous liquid in a 16% yield[9] upon silica gel-column chromatography (Scheme 1). The assigned structure for III was consistent with the IR, NMR, and UV spectra (see Experimental Section), and the semicarbazone gave correct analyses.

A similar reaction with 1-morpholinocyclopentene (IV) gave a cyclic β,γ-unsaturated ketone (X) as an oil in a 23% yield,[9] along with the photodimers[7] of I (Scheme 2). The structure of X was consistent with the spectroscopic data and was further proven by an alternative chemical method. When X was treated upon activated alumina as has been described by Heap and Whitham,[10] isomerization to an α,β-unsaturated ketone, 2,3-diphenylcyclohept-2-enone (XI), took place readily. The structure of XI was confirmed by the spectra and especially by the NMR, in which the absence of the vinyl-proton signal strongly supported the assigned structure. The precursor of X must be dienamine, IX. The presence of IX in the crude reaction mixture was directly ascertained by observing a characteristic triplet at δ 6.70 ppm (vinyl proton)[11] upon the NMR analysis of the residue obtained by the removal of the unchanged enamine from the irradiation mixture *in vacuo*. It may be noted that the reactions of both II and IV possibly proceed *via* such cyclobutenes as VIII and the dienamines to afford β,γ-unsaturated ketones, III and X, in which the diphenylacetylene moiety has been incorporated formally at the enamine double-bond site under hydrogen migration. Thermal reactions in a similar sense have been recorded exclusively with electronegatively-substituted acetylenes.[12,13] The attempted reaction of I with enamines completely failed to occur thermally in the dark.

When the photochemical reaction of 1-morpholinocyclohexene (V)[6] was effected similarly, a cyclohexanone derivative (XIII) and a minor amount of the adduct (XV) were isolated in 17 and 3.1% yields[9] respectively (Scheme 2).

The structure of XIII was elucidated by studying its

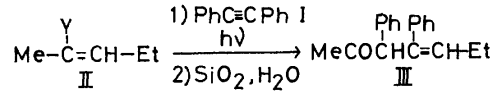


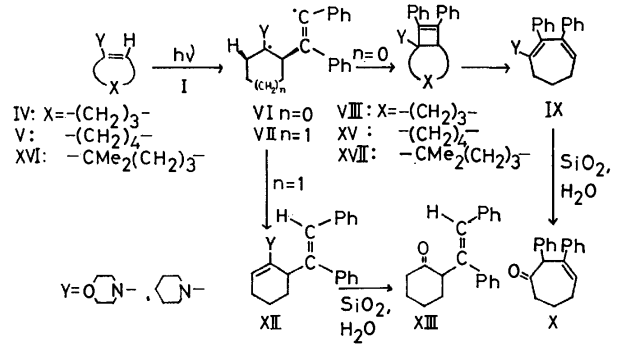
Scheme 1.

spectral data and by elemental analysis as well as by chemical degradation. The oxidation of XIII by Rudloff's method[14] gave 2-benzoylcyclohexanone (XIV), which was identical with the authentic specimen[15] prepared by the benzoylation of the enamine V.

TABLE 2. PHOTOREACTION OF I WITH PIPERIDINOENAMINES IN *n*-HEXANE

Enamine	Product (yield[9] in %)
II[16]	dimers[7] of I (8.2), III (20)
IV[16]	dimers[7] of I (10), X (25)
V[16]	dimers[7] of I (10), XIII (20), XV[16] (2.3)

The structure of the minor product, XV,[6] is mainly based on the spectral evidence. The UV showed the *cis*-stilbene chromophore, and the mass spectrum had eminent peaks at *m/e* 345 (M^+) and 167 (M^+-178). In addition, XV[6] remained unchanged upon chromatographic treatment.



Scheme 2.

The analogous reaction of an enamine[6] of 2,2-dimethylcyclohexanone (XVI) gave only a cycloadduct (XVII)[6] in a 2.0% yield[9] (Scheme 2). The structure was deduced from the spectral data.

Finally, the photoreaction of I with piperidinoenamines[16] of the diethyl ketone, cyclopentanone, and cyclohexanone proceeded much as with the corresponding morpholinoenamines (see Experimental Section).

Discussion

The photodimerization of I has been reported to proceed by way of a triplet path;[7] the same path was also assumed in the 2+2 photoaddition of I on 2,3-dihydropyran.[17] Ample evidence seems to support the idea that the π-π^* triplet pathway of I is important in the addition to enamines. Thus, the addition of pyrene[18] to a mixture of I[19] and enamines resulted in the complete suppression of either the cycloaddition or the dimerization of I.[20] Equimolar concentrations of I and pyrene were used. Since their molar extinction coefficients are approximately equal at the excitation wavelength (log ε=4.1 at 254 nm), the quenching effect of pyrene must be ascribed to the triplet energy transfer rather than to the absorption of the exciting light by itself. Meanwhile, the reaction conducted in a Pyrex vessel under irradiation with light filtered through aqueous 10% $CuSO_4$ was successfully sensitized by triphenylene (E_T=66.6 kcal/mol[18]). The photolysis in the absence of the sensitizer did not occur under the above conditions.

The mechanism of the cycloaddition of I to the IV enamine is considered to be as follows. The electrophilic nature of excited I has been demonstrated in the addition reaction to tetramethylethylene[21] and to 2,3-dihydropyran.[17] When the excited I in the triplet state is added to IV, the cycloadduct thus formed is the bicyclo[3.2.0]hept-6-ene derivative (VIII), which subsequently is isomerized to a cycloheptadiene, IX. The ring-opening of VIII might occur photochemically *via* a disrotatory mode,[22] but the true nature has not yet been determined.[23] The presence of the IX dienamine in the irradiation mixture, as evidenced by NMR spectroscopy, shows that the ring-opening proceeds prior to the hydrolysis upon silica gel.[24]

A priori, the formation of α-substituted cyclohexanone, XIII, may be explained in two ways. The first one is based on the hydrogen abstraction at the allylic position of the V enamine. The efficient abstraction of hydrogen has been observed both with the π-π^* excited state of olefins[25,26] as well as with that of acetylenes, as has been disclosed recently by Roberts *et al.*[27]

This route fails, however, to explain the fact that the reaction of II or of IV does not afford the products of a type such as XIII. Additionally, it should be noted that the hydrogen abstraction of cyclohexanone enamine occurs at the 3 position rather than at 6.[4]

An alternative mechanism (Scheme 2) is based on the facts that the reactive species is in the triplet state and that the reaction occurs independently of the

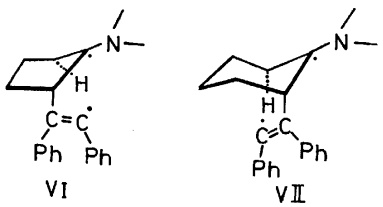
solvent polarity. The reaction of I with enamines in ethanol or acetonitrile gave results similar to those in *n*-hexane or benzene (see Experimental Section). We may reasonably assume that the attack of I on V proceeds step by step to give the diradical intermediate VII, first. Subsequent hydrogen abstraction takes place in VII through the six-membered transition state, thus producing an enamine, XII. The hydrogen abstraction caused by vinyl radicals has many precedents in the literature.[28] In sharp contrast, however, the cyclopentyl diradical, VI, gives the recombination product VIII predominantly, as has been stated previously. The difference may be explained as follows. Immediately after the attack of I on the π-bond in enamine, the stilbene moiety presumably occupies an axial position. Hydrogen abstraction takes place easily in such a conformation to give XII, while the less preferred radical recombination in VII forms XV in a far smaller yield. The corresponding intermediate diradical, VI, produced from the five-membered enamine, IV, must be less prone to hydrogen abstraction because of the disfavorable geometry. No hydrogen abstraction is observed, and the radical recombination product is formed exclusively (Scheme 3). The radical recombination was observed also with XVI, which has no removable hydrogen to afford the bicyclic product, XVII.[6]



Scheme 3.

Experimental

All the melting points and boiling points are uncorrected. The IR spectra were obtained on a Shimadzu IR-27-G spectrometer in a neat liquid film, unless stated otherwise. The NMR spectra were taken with a JEOL C-60-H spectrometer (60 MHz) with CCl_4 as the solvent, and the chemical shifts are recorded in δ values relative to TMS as the internal standard. The NMR data are given in the order of multiplicity (s=singlet, d=doublet, t=triplet, q=quartet, and m=unresolved multiplet), integration, and assignment. The UV spectra were taken in EtOH on a Hitachi EPS-2 recording spectrophotometer. The MS spectra were obtained with a Hitachi RM-61 spectrometer at 80 eV. The column chromatography was carried out on Mallinckrodt silicic acid (100 mesh). Plates of silica gel G were used for the tlc, and the spots were visualized with iodine vapor.

Irradiation of Diphenylacetylene (I) in the Presence of 3-Morpholinopent-2-ene (II).[6] A solution of I (1.0 g, 5.6 mmol) and II[6] (1.7 g, 11 mmol) in *n*-hexane or benzene (40 ml) was placed in a quartz vessel and irradiated externally by means of 200 W high-pressure mercury arc under a nitrogen atmosphere at room temperature for 48 hr. The progress of the reaction was followed by tlc analyses of aliquots. The reaction mixture was then concentrated *in vacuo*, and the residue was chromatographed over a silica gel-column. Elution with *n*-hexane gave unchanged I (500 mg). Further elution with the same solvent gave 1,2,3-triphenylnaphthalene (the photodimer[7] of I reported by Büchi) (120 mg, 6.1%[9]), which was obtained as colorless crystals; mp 150—152 °C (lit,[7] 151—153 °C), M^+ (356). Later fractions contained a blue crystalline mass, 1,2,3-triphenylazulene (the photodimer[7] of I) (78 mg, 3.8%[9]); mp 216—217 °C (lit,[7] 216—217 °C), M^+ (356). Elution with benzene gave 3,4-diphenylhept-4-en-2-one (III, 220 mg, 16%[9]), which was obtained as a colorless and viscous oil. IR (neat): 3100—3000, 1715, 1600, 700, and 680 cm^{-1}. UV: λ_{max}=245 nm (log ε=4.13). NMR: δ 0.90 (t, 3H, $-CH_2C\underline{H}_3$), 1.55 (d, 3H, $=CH-C\underline{H}_3$), 2.35 (q, 2H, $-C\underline{H}_2CH_3$), 4.65 (s, 1H, $-CPh\underline{H}-$), 5.35 (q, 1H, $=C\underline{H}-CH_3$), and 7.00—7.36 ppm (m, 10H, aromatic). No suitable recrystallization solvent has been found for further purification. Elemental analysis was performed by converting III to its semicarbazone; mp 201—203 °C (benzene–petroleum ether (bp 60—70 °C) (1:1)). (Found: C, 74.5; H, 7.7%. Calcd for $C_{20}H_{23}N_3O$: C, 74.7; H, 7.2%).

Irradiation of I in the Presence of 1-Morpholinocyclopent-1-ene (V).[6] A solution of I (1.0 g, 5.6 mmol) and IV[6] (1.7 g, 11 mmol) in *n*-hexane or benzene (40 ml) was irradiated for 48 hr quite analogously to the above method. The subsequent concentration of the reaction mixture *in vacuo* and elution of the residue adsorbed on a silica gel-column with *n*-hexane gave the unchanged I (430 mg) and the photodimers[7] (160 mg, 7.9%[9]). Elution with benzene gave 2,3-diphenylcyclohept-3-enone (X, 340 mg, 23%[9]), which was obtained as a colorless and viscous oil. IR (neat): 3100—3000, 1705, 1600, 750, and 700 cm^{-1}. UV: λ_{max}=245 nm (log ε=4.18). NMR: δ 1.50—1.90 (m, 2H, CH_2 attached to both sp^3 carbons), 2.20—2.70 (m, 4H, CH_2 adjacent to sp^2 carbons), 6.82 (s, 1H, $-CPh\underline{H}-$), 6.30 (t, 1H, vinyl) and 7.00—7.30 ppm (m, 10H, aromatic). No suitable recrystallization solvent has been found for further purification. Elemental analysis was performed by converting X to its semicarbazone, mp 209—212 °C (benzene–petroleum ether (1:1)). (Found: C, 75.0; H, 6.6%. Calcd for $C_{20}H_{21}N_3O$: C, 75.2; H, 6.6%).

Isomerization of 2,3-Diphenylcyclohept-3-enone (X) to 2,3-Diphenylcyclohept-2-enone (XI). The method was based on the one reported by Whitham[10] in the isomerization of cyclooct-3-enone to cyclooct-2-enone. A benzene solution of 2,3-diphenylcyclohept-3-enone (X, 100 mg, 0.38 mmol) was treated with alumina (5.0 g, Woelm neutral activity I) in a column for 24 hr. Elution with benzene furnished recovered X (20 mg). Further elution with benzene–ether (1:1) afforded 2,3-diphenylcyclohept-2-enone (XI, 65 mg, 65%), which was obtained as white crystals; mp 103—105 °C (*n*-hexane). IR (KBr): 3100—3000, 1680, 1650, 1600, 760, and 700 cm^{-1}. UV: λ_{max}=222 (log ε=4.25), 272 nm (4.10). NMR: δ 1.50—1.90 (m, 4H, CH_2 attached to both sp^3 carbons), 2.20—2.75 (m, 4H, CH_2 adjacent to sp^2 carbons) and 7.00—7.28 ppm (m, 10H, aromatic). (Found: C, 87.3; H, 6.8%. Calcd for $C_{19}H_{18}O$: C, 87.0; H, 6.9%).

Irradiation of I in the Presence of 1-Morpholinocyclohexene (V).[6] A solution of I (1.0 g, 5.6 mmol) and V[6] (1.9 g, 11 mmol) in *n*-hexane or benzene (40 ml) was irradiated for 48 hr in a manner similar to that above. The subsequent concentration of the reaction mixture and elution of the residue adsorbed on a silica gel-column with *n*-hexane gave the unchanged I (390 mg) and the photodimers[7] (98 mg, 4.9%[9]). Elution with benzene afforded 2-(1,2-diphenylvinyl)cyclohexanone (XIII, 231 mg, 15%[9]) as colorless crystals; mp

28) O. Shimamura, "Topics in Stereochemistry," Vol. 4, ed. by E. L. Eliel and N. L. Allinger, Wiley-Interscience, New York (1969), p. 1.

86—87 °C (petroleum ether). IR (KBr): 3050–3000, 1710, 1600, 760, and 700 cm^{-1}. UV: λ_{max}=220 (log ε=4.23), 270 nm (4.11). NMR: δ 1.50—2.06 (m, 6H, β and γ methylenes of the cyclohexanone ring), 2.00—2.50 (m, 2H, $-CH_2-C=O$), 3.30 (t, 1H, methine), 6.30 (s, 1H, vinyl) and 7.00—7.30 ppm (m, 10H, aromatic). (Found: C, 86.4; H, 7.5%. Calcd for $C_{20}H_{20}O$: C, 86.9; H, 7.3%).

Further elution with ether gave 1-morpholino-7,8-diphenylbicyclo[4.2.0]oct-7-ene (XV,[6] 59 mg, 3.1%[9]), which was obtained as colorless crystals; mp 85—86 °C (petroleum ether). IR (KBr): 3100—3000, 1600, 1120, 760, and 700 cm^{-1}. UV: λ_{max}=219 (log ε=4.20), 268 nm (4.10). NMR: δ 1.10—1.80 (m, 4H, CH_2 of the cyclohexane ring), 2.25 (t, 1H, methine), 2.40 (t, 4H, CH_2–N), 3.50 (t, 4H, CH_2–O), and 6.95—7.20 (m, 10H, aromatic). MS: 345 (M^+), 167 (M^+-178). (Found: C, 83.0; H, 8.0%. Calcd for $C_{24}H_{27}NO$: C, 83.0; H, 7.9%).

Oxidative Degradation of 2-(1,2-Diphenylvinyl)cyclohexanone (XVIII) to 2-Benzoylcyclohexanone (XIV). The method was based on that reported by Rudloff.[14] The stock oxidant solution[29] was placed in a flask, and into this was added slowly with stirring XVIII (500 mg, 1.8 mmol) dissolved in *t*-butylalcohol (5.0 ml). The solution was stirred for 3 hr at room temperature, and then the reaction mixture was extracted twice with ether. The combined extracts were washed with brine and then dried (Na_2SO_4). The solvent was evaporated, and the residue was chromatographed over silica gel. Elution with benzene–ether (1: 1) afforded 2-benzoylcyclohexanone (XIV, 240 mg, 65%), which was obtained as colorless crystals; mp 88—89 °C (*n*-hexane–benzene (2: 1)) (lit,[15] 88—89 °C). The authentic sample of XIV was prepared by the benzoylation of the V enamine.[15] The IR spectrum of XIV was superimpossible on that of the authentic specimen.

Irradiation of I in the Presence of 6,6-Dimethyl-1-morpholinocyclohexene (XVI).[6] A solution of I (1.0 g, 5.6 mmol) and XVI[6] (2.1 g, 11 mmol) in *n*-hexane or benzene (40 ml) was irradiated for 48 hr much as above. The subsequent concentration of the reaction mixture and column chromatography afforded 2,2-dimethyl-1-morpholino-7,8-diphenylbicyclo[4.2.0]oct-7-ene (XVII, 41 mg, 2.0%[9]), besides unchanged I (360 mg) and the photodimers[7] (300 mg, 15%[9]). The bicyclic product, XVII,[6] was obtained as colorless crystals; mp 95—96 °C (petroleum ether). IR (neat): 3050—3000, 1600, 1120, 760, and 700 cm^{-1}. NMR: δ 1.12 (s, 6H, CH_3), 1.20—1.80 (m, 6H, CH_2 of the cyclohexane ring), 2.20 (t, 1H, methine), 2.40 (t, 4H, CH_2–N), 3.50 (t, 4H, CH_2–O) and 6.87—7.00 ppm (m, 10H, aromatic). MS: 373 (M^+), 195 (M^+-178). (Found: C, 83.3; H, 8.5%. Calcd for $C_{26}H_{31}NO$: C, 83.6; H, 8.4%).

Quenching Studies in the Presence of Pyrene. A solution of I (300 mg, 1.7 mmol), II[6] (530 mg, 3.4 mmol), and pyrene (200 mg, 1.7 mmol) in *n*-hexane (20 ml) was placed in a quartz vessel and irradiated for 48 hr in a manner similar to that above. Tlc analyses showed that both the photochemical reaction of I with II[6] and the formation of the photodimers[7] of I were completely suppressed. Column chromatography (silica gel) gave totally recovered I (290 mg). The reaction of I with IV[6] or V[6] was similarly quenched by pyrene.

Sensitization by Triphenylene. (a): A solution of I (500 mg, 2.8 mmol), II[6] (870 mg, 5.6 mmol), and triphenylene (640 mg, 2.8 mmol) in benzene (20 ml) was irradiated externally for 48 hr with light filtered through aqueous 10% $CuSO_4$ (200 W high-pressure mercury arc). The subsequent concentration of the reaction mixture *in vacuo* and column chromatography (silica gel-column) afforded the photodimers[7] of I (140 mg, 14%[9]) and III (130 mg, 19%[9]) respectively.

(b): The photoreaction of I (500 mg, 2.8 mmol), IV[6] (860 mg, 5.6 mmol), and triphenylene (640 mg, 2.8 mmol) in benzene (20 ml) afforded the photodimers[7] of I (78 mg, 7.8%[9]) and X (73 mg, 10%[9]) under the same conditions as those described in (*a*).

(c): The photoreaction of I (500 mg, 2.8 mmol), V[6] (946 mg, 5.6 mmol), and triphenylene (640 mg, 2.8 mmol) in benzene (20 ml) afforded the photodimers[7] of I (130 mg, 13%[9]), XIII (130 mg, 17%[9]), and XV[6] (38 mg, 4.1%[9]) under the same conditions as in (*a*). In the absence of triphenylene, the reaction did not occur upon photolysis under the same conditions.

Photoreaction of I with Enamines[6] in Other Solvents. A solution of I (2.8 mmol) and an enamine[6] (5.6 mmol) in a solvent (20 ml) was irradiated in a quartz vessel for 48 hr (200 W high-pressure mercury arc). The results are summarized in Table 1.

Photoreaction of I with Piperidinoenamines.[16] A solution of I (2.8 mmol) and an enamine[16] (5.6 mmol) in *n*-hexane (20 ml) was irradiated for 48 hr much as above. The results are summarized in Table 2.

29) The stock oxidant solution consisted of sodium metaperiodate (20 g, 97 mmol) and potassium permanganate (390 mg, 2.5 mmol) in water (1 l).

Studies on Aminosugars. XXXIII. Syntheses of 4-Azido-2,3,6-tri-*O*-benzyl-4-deoxy- and 6-Azido-2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl Chloride

Yasushi TAKAGI, Tsutomu TSUCHIYA, and Sumio UMEZAWA

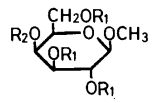
Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 222

(Received October 13, 1972)

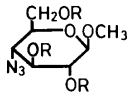
The titled compounds (**8** and **13**) have been prepared as synthetic intermediates.

As key intermediates for the syntheses of aminoglycosides, the titled compounds have been prepared.

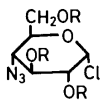
Methyl β-D-galactopyranoside (**1**) was converted into the 2,3,6-tri-*O*-benzoyl derivative (**2**) by means of the procedure of Reist *et al.*[1] utilizing the lower reactivity of C-4 axial hydroxyl group of D-galactose, and after mesylation of the remaining 4-hydroxyl group, the product (**3**) was transformed to methyl 4-azido-2,3,6-tri-*O*-benzoyl-4-deoxy-β-D-glucopyranoside (**4**). After removal of the benzoyl groups, the 4-azido-sugar (**5**) was benzylated to give **6**. Acidic hydrolysis of **6** gave 4-azido-2,3,6-tri-*O*-benzyl-4-deoxy-D-glucose (**7**), unavoidable removal of some of the benzyl groups being accompanied.[2] As for the hydrolysis of methyl glucosides of benzyl sugars, β-anomers generally give higher yields of free sugars than that of α-anomers, as reported by Austin *et al.*[3] The above yield of **7** (48%) was in accord with the above-mentioned view. Treatment of **7** with thionyl chloride gave the desired chloride (**8**). Its NMR spectrum indicated the α-configuration. The chloride was successfully used for the synthesis of 4-amino-4-deoxy-α-D-glucopyranosyl-2-deoxystreptamine.[4]



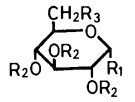
2: R_1=COC_6H_5, R_2=H
3: R_1=COC_6H_5, R_2=SO_2CH_3



4: R=COC_6H_5
5: R=H
6: R=$CH_2C_6H_5$



8: R=$CH_2C_6H_5$



9: R_1=OCH_3, R_2=H, R_3=OTs
10: R_1=OCH_3, R_2=H, R_3=N_3
11: R_1=OCH_3, R_2=$CH_2C_6H_5$, R_3=N_3
13: R_1=Cl, R_2=$CH_2C_6H_5$, R_3=N_3

Methyl 6-azido-6-deoxy-α-D-glucopyranoside (**10**) in a crude state has been prepared by Cramer *et al.*[5] We isolated it in a pure state and converted it into the tri-*O*-benzyl derivative (**11**). Acidic hydrolysis of **11** gave the 6-azido sugar (**12**) in a 37% yield. A similar chlorination as described in the preparation of **8** gave the desired compound (**13**).

The NMR spectrum of **13** indicated the α-configuration. The chloride was useful for the synthesis of 6-amino-6-deoxy-α-D-glucopyranosyl-2-deoxystreptamine.[6]

Experimental

Methyl 2,3,6-Tri-O-benzoyl-β-D-galactopyranoside (2). Mp 146—147 °C, $[\alpha]_D^{21}$ +53.5° (*c* 1, chloroform) (lit,[7] mp 143—144°C, $[\alpha]_D^{18}$ +56.1°).

Methyl 4-Azido-2,3,6-tri-O-benzoyl-β-D-glucopyranoside (4). To a solution of methyl 2,3,6-tri-*O*-benzoyl-4-*O*-mesyl-β-D-galactopyranoside[8] (**3**, 5.05 g) in dry dimethylformamide (DMF) (70 ml), powdered sodium azide (1.75 g) was added and the mixture was stirred at 130—140°C for 4.5 hr. On tlc with benzene–ether (20: 1), the solution showed two spots of R_f 0.6 (**4**, major) and 0.75. Evaporation followed by evaporation with toluene gave a brown residue, which was extracted with chloroform and the extract was washed with water, dried over sodium sulfate and evaporated to give a brown syrup. This was charged on a column of silica gel (150 g) and developed with the solvent system described above. The eluate containing **4** was evaporated to give a pale yellow solid (2.43 g, 53%), which was recrystallized from methanol, mp 124—125°C, $[\alpha]_D^{22}$ +120° (*c* 0.78, chloroform).

Found: C, 63.48; H, 4.78; N, 8.01%. Calcd for $C_{28}H_{25}N_3O_8$: C, 63.27; H, 4.74; N, 7.91%.

Methyl 4-Azido-4-deoxy-β-D-glucopyranoside (5). To a suspension of **4** (1.79 g) in dry methanol (20 ml), 2.4N sodium methylate (0.3 ml) was added and the suspension was stirred at room temperature overnight. The solution, after treatment with Amberlite IR 120 (H form), was evaporated to give a solid, which was washed with ether. Colorless solid obtained (0.70 g, 95%) was recrystallized from ethanol, mp 159.5—161°C, $[\alpha]_D^{22}$ +39° (*c* 0.66, water). NMR (in D_2O): τ 6.44 (3H, s, OCH_3), 5.65 (1H, d, $J_{1,2}$ 7.5 Hz, H-1).

Found: C, 38.63; H, 6.19; N, 19.23%. Calcd for $C_7H_{13}N_3O_5$: C, 38.35; H, 5.98; N, 19.17%.

Methyl 4-Azido-2,3,6-tri-O-benzyl-4-deoxy-β-D-glucopyranoside (6). A solution of **5** (770 mg) in DMF (10 ml) was treated with powdered potassium hydroxide (4.4 g) and benzyl chloride (4.5 g) similarly as described in the preparation of **11**, and chromatographed with benzene–ether (20: 1); colorless solid (1250 mg, 73%) was reprecipitated with benzene–petroleum ether, mp 64—65°C, $[\alpha]_D^{20}$ +80° (*c* 0.82, chloro-

form). IR (KBr): 2110 cm^{-1} (N_3).

Found: C, 68.93; H, 6.48; N, 8.79%. Calcd for $C_{28}H_{31}N_3O_5$: C, 68.69; H, 6.38; N, 8.58%.

4-Azido-2,3,6-tri-O-*benzyl-4-deoxy*-D-*glucose* (**7**). To a solution of **6** (409 mg) in acetic acid (16 ml), 2N hydrochloric acid (5 ml) was added and the solution was heated at 98°C for 4 hr. On tlc with benzene–ethyl acetate (5: 1), the solution showed four spots of R_f 0.80 (**6**, trace), 0.40 (**7**, major), 0.20, and 0.05. After addition of sodium hydrogen carbonate (1 g), the solvent was evaporated to give a residue. The residue was extracted with chloroform and the extrate was washed with sodium hydrogen carbonate solution and water, dried over sodium sulfate and evaporated to give a syrup. The syrup was charged on a column of silica gel (25 g) and developed with benzene–ethyl acetate (3: 1). The eluate containing **7** was evaporated to give a pale yellow solid (190 mg, 48%), which was recrystallized from benzene–petroleum ether, mp 84—85.5°C, $[\alpha]_D^{20}$ +75° (*c* 0.68, chloroform).

Found: C, 68.48; H, 5.84; N, 9.00%. Calcd for $C_{27}H_{29}N_3O_5$: C, 68.19; H, 6.15; N, 8.84%.

4-Azido-2,3,6-tri-O-*benzyl-4-deoxy*-α-D-*glucopyranosyl Chloride* (**8**). A solution of **7** (2.9 g) in thionyl chloride (90 ml) was allowed to stand at room temperature overnight. The solution was evaporated with toluene *in vacuo* to give a pale yellow syrup. The product was purified by passing a short column of silica gel (24 g) with dry benzene, and the portion (36—108 ml) containing the main product (tlc with benzene, R_f 0.73) was evaporated to give a syrup, 1.98 g (66%), $[\alpha]_D^{18}$ +200° (*c* 3.0, benzene); IR (KBr): 2100 (N_3), 1460, 1365, 740, 700 cm^{-1}; NMR ($CDCl_3$): τ 5.43 (2H, AB q, *J* 12 Hz, $OC\underline{H}_2C_6H_5$), 5.31 (2H, s, $OC\underline{H}_2C_6H_5$), 5.08 (2H, AB q, *J* 12 Hz, $OC\underline{H}_2C_6H_5$), 3.93 (1H, d, *J* 3 Hz, H-1), 2.68 (15H, s, $OCH_2C_6\underline{H}_5$).

Found: C, 65.75; H, 5.76; N, 8.37; Cl, 7.49%. Calcd for $C_{27}H_{28}N_3O_4Cl$: C, 65.65; H, 5.71; N, 8.51; Cl, 7.18%.

Methyl 6-Azido-6-deoxy-α-D-*glucopyranoside* (**10**). To a solution of methyl 6-deoxy-6-*O*-tosyl-α-D-glucopyranoside[5] (**9**) (9.51 g) in dry DMF (130 ml), powdered sodium azide (3.7 g) was added and the mixture was stirred under gentle boiling for 1 hr. Evaporation followed by evaporation with toluene gave a black residue, which was extracted with acetone. The solution, after treatment with charcoal, was evaporated to give a reddish brown syrup. This was charged on a short column of silica gel (40 g) and developed with ethyl acetate. The eluate was evaporated and the residue was dissolved in chloroform. Addition of *n*-hexane gave a thick syrup, 4.41 g (74%), $[\alpha]_D^{22}$ +122° (*c* 1, water); IR: 2100 cm^{-1} (N_3).

Found: C, 38.61; H, 6.03; N, 19.40%. Calcd for $C_7H_{13}N_3O_5$: C, 38.35; H, 5.98; N, 19.17%.

Methyl 6-Azido-2,3,4-tri-O-*benzyl-6-deoxy*-α-D-*glucopyranoside* (**11**). To a solution of **10** (7.41 g) in dry DMF (140 ml), powdered potassium hydroxide (44 g) was added and to the mixture, benzyl chloride (~40 ml) was added at intervals under stirring with occasional cooling. After completion of the reaction (*ca.* 2 hr), the organic layer was separated from an insoluble matter and the latter was washed with chloroform. The combined organic solution was evaporated with toluene to give a residue, which was extracted with chloroform and the extract was evaporated. The residual syrup was heated at 100°C *in vacuo* (~0.1 Torr) to remove volatile materials. The syrup was then dissolved in chloroform and the solution was washed with water, dried over sodium sulfate and evaporated to give a syrup, which was chromatographed on a short column of silica gel (50 g) with benzene–chloroform (1: 1). The eluate containing **11** was evaporated to give a pale-yellow syrup, 12.42 g (75%), $[\alpha]_D^{21}$ +48.2° (*c* 1, chloroform) (lit,[9] +53.1°).

Found: C, 68.73; H, 6.65; N, 8.79%. Calcd for $C_{28}H_{31}N_3O_5$: C, 68.69; H, 6.38; N, 8.58%.

6-Azido-2,3,4-tri-O-*benzyl-6-deoxy*-D-*glucose* (**12**). To a solution of **11** (9.68 g) in acetic acid (160 ml), 3N hydrochloric acid (40 ml) was added and the solution was heated at 90—95°C for 4 hr. On tlc (silica gel) with benzene–ether (10: 1), the solution showed three spots of R_f 0.80 (**11**), 0.35 (**12**, major) and 0, the last spot being strengthened on prolonged reaction. After addition of sodium hydrogen carbonate (8 g), the brown solution was treated with charcoal, and evaporated. The residue was dissolved in chloroform and the solution was washed with water, dried over sodium sulfate and evaporated. The resulting syrup was chromatographed on a column of silica gel (400 g) with benzene–ether (10: 1). The eluate containing **12** was evaporated to give a syrup, which crystallized on scratching, 3.44 g (37%). From the earlier eluate, **11** was recovered (1.80 g). Recrystallization from benzene–petroleum ether gave crystals, mp 78.5—80.5°C, $[\alpha]_D^{21}$ +65° (*c* 1, chloroform), IR (KBr): 3380, 2110 (N_3), 750, 735, 695 cm^{-1}.

Found: C, 68.06; H, 6.36; N, 8.95%. Calcd for $C_{27}H_{29}N_3O_5$: C, 68.19; H, 6.15; N, 8.84%.

6-Azido-2,3,4-tri-O-*benzyl-6-deoxy*-α-D-*glucopyranosyl Chloride* (**13**). A solution of **12** (1.42 g) in thionyl chloride (23 ml) was allowed to stand at 0°C for 2 hr and then at room temperature for 38 hr. On tlc with benzene, the solution gave a single spot at R_f 0.65. The solution was evaporated and then co-evaporated with toluene to give a syrup, which was further purified by column chromatography with silica gel (10 g) and dry benzene to give a pale yellow syrup, 0.95 g (65%), $[\alpha]_D^{24}$ +119° (*c* 0.94, chloroform): IR (liquid film): 2110 (N_3), 730, 695 cm^{-1}; NMR (in $CDCl_3$): τ 3.93 (1H, d, *J* 3.5 Hz, H-1).

Found: C, 65.44; H, 5.60; N, 8.65; Cl, 7.52%. Calcd for $C_{27}H_{28}N_3O_4Cl$: C, 65.65; H, 5.71; N, 8.51; Cl, 7.18%.

Studies on Aminosugars. XXXIV. Synthesis of 4-*O*- and 6-*O*-(4-amino-4-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine[1]

Yoshio NISHIMURA, Tsutomu TSUCHIYA, and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 222

(Received October 13, 1972)

Racemic *O*-isopropylidene derivative of *N,N'*-diethoxycarbonyl-2-deoxystreptamine was glycosidated with 4-azido-2,3,6-tri-*O*-benzyl-4-deoxy-α-D-glucopyranosyl chloride to afford two kinds of position isomers of α-glucoside, which was led to 4-*O*-(4-amino-4-deoxy-α-D-glucopyranosyl)- and 6-*O*-(4-amino-4-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine.

A series of aminosugar glycosides, namely, kanamycin A, B, C, and other related compounds have been synthesized in our laboratories. A group in them is monoglycosyl-2-deoxystreptamines, which are of interest in connection with the investigation of the relationship between chemical structure and antibacterial activity of aminoglycoside antibiotics. 4-*O*- and 6-*O*-α-D-glucopyranosyl-2-deoxystreptamine,[2] 4-*O*-,[3] 5-*O*-[4] and 6-*O*-α-D-glucosaminyl-2-deoxystreptamine,[3] 4-*O*- and 6-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxy streptamine[5] and 6-*O*-(3-amino-3-deoxy-D-glucosyl)-2-deoxystreptamine[6] have been prepared, and, it has been found that, among them, 4-*O*- and 5-*O*-(2-amino-2-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine[4,7] and 4-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine possess antibacterial activity. As an extension of the work, we describe here the syntheses of 4-amino-4-deoxy-α-D-glucopyranosyl-2-deoxystreptamines (**9**, **10**).

4-Azido-2,3,6-tri-*O*-benzyl-4-deoxy-α-D-glucopyranosyl chloride[8] (**1**) was condensed with a mixture (**2**) of racemic *N,N'*-diethoxycarbonyl-4,5- and 5,6-*O*-isopropylidene-2-deoxystreptamines[2] in dry benzene–dioxane in the presence of mercuric cyanide and Drierite (Chart 1). Separation of the products by column chromatography gave 4-*O*-(4-azido-2,3,6-tri-*O*-benzyl-4-deoxy-α-D-glucopyranosyl)-*N,N'*-diethoxycarbonyl-5,6-*O*-isopropylidene-2-deoxystreptamine (**3**) and 6-*O*-(4-azido-2,3,6-tri-*O*-benzyl-4-deoxy-α-D-glucopyranosyl)-*N,N'*-diethoxycarbonyl-4,5-*O*-isopropylidene-2-deoxy-

streptamine (**4**) in yields of 9.6 and 23%, respectively. Higher yield of 6-*O*-isomer was again here observed.[2,5]

After hydrolysis of **3** and **4** with aqueous acetic acid, the deisopropylidenated products (**5** and **6**) were reduced with Raney nickel and hydrogen to the corresponding amino-derivatives, which were then ethoxycarbonylated to give 4-*O*- and 6-*O*-(2,3,6-tri-*O*-benzyl-4-deoxy-4-ethoxycarbonylamino-α-D-glucopyranosyl)-*N*, *N'*-diethoxycarbonyl-2-deoxystreptamine (**7** and **8**), respectively. Debenzylation of **7** and **8** with palladium black and hydrogen followed by hydrolysis with hot barium hydroxide gave 4-*O*- and 6-*O*-(4-amino-4-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine (**9** and **10**), respectively. Simultaneous reduction of the azido group and debenzylation of **5** and **6** by use of palladium and hydrogen were not adopted by the same reason described in a previous paper.[5]

Respective assignment of 4-*O*- and 6-*O*-glycosidic linkage to **9** and **10** were established by the determination of the values of Δ[M] in tetraminecopper (II) sulfate solutions (TACu).[9] The Δ[M] values of **9** and **10** were +1540° and +165° respectively. The sign and the magnitude of the Δ[M] of **9** indicated that TACu formed complexes between C-1 NH_2 and C-6 OH in 2-deoxystreptamine moiety and between C-3 OH and C-4 NH_2 in the sugar moiety. On the other hand, in **10**, formations of complexes occurred between C-3 NH_2 and C-4 OH in 2-deoxystreptamine moiety and between C-3 OH and C-4 NH_2 in the sugar moiety giving the low Δ[M] value by counteraction of both complexes.

Both compounds, **9** and **10**, showed no antibacterial activity against organisms tested, showing that the position of the amino group in aminoglycosidic deoxystreptamines is one of the important factors in exibiting the antibacterial activity. Other biological activities of **9** and **10** are now under study.

Experimental

The NMR spectra were measured with a Varian A-60D spectrometer. Tetramethylsilane (for the solution other than deuterium oxide) and sodium 4,4-dimethyl-4-silapentane-1-sulfonate (for the solution of deuterium oxide) were used as the internal standards. Thin-layer chromatography (tlc)was carried out on microscope slides coated with silica gel, and the spots were visualized with sulfuric acid. Paper chromatography (ppc) was carried out on Toyo Roshi No. 50 paper.

4-O-(4-Azido-2,3,6-tri-O-benzyl-4-deoxy-α-D-glucopyranosyl)-N, N'-diethoxycarbonyl-5,6-O-isopropylidene-2-deoxystreptamine (3) and 6-O-(4-Azido-2,3,6-tri-O-benzyl-4-deoxy-α-D-glucopyranosyl)-N, N'-diethoxycarbonyl-4,5-O-isopropylidene-2-deoxystreptamine (4). A mixture of **1** (1.99 g, 2 mmol) and freshly prepared Drierite (1.75 g) in anhydrous benzene-dioxane (2:1, 27 ml) was heated at 60°C under stirring for 20 min and to the mixture, **2** (1.11 g, 3.2 mmol) and well dried mercuric cyanide (2.39 g) were added, and the mixture was refluxed for 10 hr under stirring. Mercuric cyanide (2.39 g) was added and the reaction was continued for another 10 hr. The mixture was filtered and the residue was washed with chloroform. The filtrate and the washings combined were evaporated to give a syrup which was dissolved in chloroform. The solution was washed with water, dried over sodium sulfate and evaporated to give a thick syrup (2.89 g). On tlc with chloroform–ethyl acetate (3:1), the syrup showed six spots of R_f 0.97 (starting material, **1**), 0.71, 0.65, 0.57, 0.49, 0.05 (starting material, **2**). The syrup was chromatographed on a column (48×850 mm) of silica gel (Wako Gel, 850 g) with chloroform–ethyl acetate (3:1), and the fractions of 3050—3200 ml and 3260—3490 ml containing the products of R_f 0.57 and R_f 0.49, respectively, were evaporated to give solids, **3** (0.31 g, 9.6% based on **2**) and **4** (0.74 g, 23% based on **2**). **4** was recrystallized from ether to give colorless crystals (0.73 g) but **3** could not be crystallized.

Compound **3**: mp 60—64°C, $[\alpha]_D^{17}$ +76° (*c* 1, chloroform); IR (KBr): 2100 (N_3), 1700 (amide I), 1535 (amide II); NMR ($CDCl_3$): τ 8.78 (6H, t, *J* 7 Hz, $CO_2CH_2C\underline{H}_3$), 8.62 and 8.58 (3H, s, each, isopropylidene), 5.89 (4H, q, *J* 7 Hz, $CO_2C\underline{H}_2CH_3$), 4.85—5.65 (6H, m, $OC\underline{H}_2C_6H_5$), 4.49 (1H, d, *J* ~3 Hz, H-1), 2.65 (15H, s, $OCH_2C_6\underline{H}_5$).

Found: C, 63.01; H, 7.00; N, 8.65%. Calcd for $C_{42}H_{53}N_5O_{11}$: C, 62.75; H, 6.64; N, 8.71%.

Compound **4**: mp 171.5—172.5°C; $[\alpha]_D^{17}$ +82.2° (*c* 1.8, chloroform); IR (KBr): 2100 (N_3), 1690 (amide I), 1535 (amide II); NMR ($CDCl_3$): τ 8.85 and 8.82 (3H, t, each, *J* 7 Hz, $CO_2CH_2C\underline{H}_3$), 8.66 (6H, s, isopropylidene), 5.94 and 5.91 (2H, q, each, *J* 7 Hz, $CO_2C\underline{H}_2CH_3$), 4.9—5.6 (6H, m, $OC\underline{H}_2C_6H_5$), 4.83 (1H, d, *J* ~3 Hz, H-1), 2.68 (15H, s, $OCH_2C_6\underline{H}_5$).

Found: C, 62.54; H, 6.45; N, 9.05%. Calcd for $C_{42}H_{53}N_5O_{11}$: C, 62.75; H, 6.64; N, 8.71%.

4-O-(4-Azido-2,3,6-tri-O-benzyl-4-deoxy-α-D-glucopyranosyl)-N, N'-diethoxycarbonyl-2-deoxystreptamine (5). A solution of **3** (290 mg) in 50% aqueous acetic acid (6.5 ml) was heated at 90°C for 30 min. The solution was poured into water and the resulting precipitate was filtered and washed thoroughly with water. The solid was recrystallized from aqueous acetone (5:1), 230 mg; mp 183—184°C; $[\alpha]_D^{17}$ +122° (*c* 1.5, pyridine); IR (KBr): 3400, 3300, 2100 (N_3), 1690 (amide I), 1540 (amide II); NMR (in pyridine-d_5 containing a small amount of D_2O): τ 8.88 and 8.75 (3H, t, each, *J* 7.3 Hz, $CO_2CH_2C\underline{H}_3$), 5.5—6.5 (15H, skelton protons and $CO_2C\underline{H}_2CH_3$), 4.8—5.6 (6H, m, $OC\underline{H}_2C_6H_5$), 3.80 (1H, d, *J* ~3 Hz, H-1), 2.3—2.9 (15H, m, $OCH_2C_6\underline{H}_5$).

Found: C, 61.02; H, 6.42; N, 8.88%. Calcd for $C_{39}H_{49}N_5O_{11}$: C, 61.33; H, 6.47; N, 9.17%.

6-O-(4-Azido-2,3,6-tri-O-benzyl-4-deoxy-α-D-glucopyranosyl)-N, N'-diethoxycarbonyl-2-deoxystreptamine (6). Compound **4** (720 mg) was treated likewise as described in the preparation of **5**. Crude solid obtained was crystallized from aqueous acetone (5:1), 630 mg (93%); mp 185.5—186°C; $[\alpha]_D^{18}$ +114° (*c* 1.5, pyridine); IR (KBr): 3440, 3300, 2100 (N_3), 1690 (amide I), 1540 (amide II); NMR (in pyridine-d_5 containing a small amount of D_2O): τ 8.88 and 8.85 (3H, t, each, *J* 7.0 Hz, $CO_2CH_2C\underline{H}_3$), 5.6—6.4 (15H, skeleton protons and $CO_2C\underline{H}_2CH_3$), 4.8—5.6 (6H, m, $OC\underline{H}_2C_6H_5$), 4.06 (1H, d, *J* ~3 Hz, H-1), 2.3—2.9 (15H, m, $OCH_2C_6\underline{H}_5$).

Found: C, 61.60; H, 6.48; N, 8.98%. Calcd for $C_{39}H_{49}N_5O_{11}$: C, 61.33; H, 6.47; N, 9.17%.

4-O-(2,3,6-Tri-O-benzyl-4-deoxy-4-ethoxycarbonylamino-α-D-glucopyranosyl)-N,N'-diethoxycarbonyl-2-deoxystreptamine (7). Compound **5** (230 mg) was dissolved in aqueous dioxane (1:15, 3.2 ml) and the solution was hydrogenated with Raney nickel (T-4) and hydrogen under 50 p.s.i. at 42°C for 1 hr. On tlc with benzene–acetone (2:1), **5** (R_f 0.47) disappeared and a product (R_f 0.20) appeared. Filtration and evaporation of the solution gave a syrup (0.22 g), which was dissolved

9) S. Umezawa, T. Tsuchiya, and K. Tatsuta, This Bulletin, **39**, 1235 (1966).

in acetone (3.2 ml). To the solution, water (3.2 ml) was added under vigorous stirring. Anhydrous sodium carbonate (0.15 g) was added to the resulting suspension, and, after agitation for a while, ethoxycarbonyl chloride (0.063 g) was added slowly. Agitation was continued for 30 min. On tlc with the above-mentioned solvent system, the reaction mixture showed a major spot at R_f 0.40. The mixture was evaporated and the residue was dissolved in chloroform. The solution was washed with water, dried over sodium sulfate and evaporated to give a solid (0.23 g). Recrystallization from aqueous ethanol (1:2) gave a colorless solid, 199 mg (84%); mp 142—143°C, $[\alpha]_D^{17}$ +29.8° (*c* 1.4, chloroform); IR (KBr): 3400, 3300, 1695 (amide I), 1540 (amide II); NMR (in $CDCl_3$): τ 8.87, 8.81, and 8.78 (3H, t, each, *J* 7.2 Hz, $CO_2CH_2C\underline{H}_3$), 2.70 (15H, s, $OCH_2C_6\underline{H}_5$).

Found: C, 62.51; H, 7.23; N, 4.94%. Calcd for $C_{42}H_{55}N_3O_{13}$: C, 62.29; H, 6.85; N, 5.19%.

6-O-(2,3,6-Tri-O-benzyl-4-deoxy-4-ethoxycarbonylamino-α-D-glucopyranosyl)-N,N'-diethoxycarbonyl-2-deoxystreptamine (8). Compound **6** (629 mg) was dissolved in aqueous dioxane (1:8, 9 ml) and treated likewise as described above. The chloroform solution obtained after treatment with ethoxycarbonyl chloride was washed with water, dried over sodium sulfate and evaporated to give a residue (0.59 g), which was chromatographed on a column (14×280 mm) of silica gel (Wako Gel, 15 g) with benzene–acetone (2:1). The portion (36—46 ml) containing the major product (R_f 0.40 with benzene–acetone 2:1) was evaporated to give a solid (0.38 g). Recrystallization from aqueous ethanol gave a colorless solid, 315 mg (51%); mp 194—195.5°C, $[\alpha]_D^{17}$ +9.8° (*c* 1.5, chloroform); IR (KBr): 3400, 3300, 1690 (amide I), 1545 (amide II); NMR (in $CDCl_3$): τ 8.87, 8.83, and 8.81 (3H, t, each, *J* 7.0 Hz, $CO_2CH_2C\underline{H}_3$), 2.70 (15H, s, $OCH_2C_6\underline{H}_5$).

Found: C, 62.25; H, 6.73; N, 5.21%. Calcd for $C_{42}H_{55}N_3O_{13}$: C, 62.29; H, 6.85; N, 5.19%.

4-O-(4-Amino-4-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine (9). Compound **7** (200 mg) was dissolved in aqueous dioxane (3:20, 2.3 ml) by heating. A few drops of acetic acid were added and the solution was hydrogenated with freshly prepared palladium black and hydrogen under 50 p.s.i. at 40—45°C for 5 hr. On tlc with benzene–ethanol (4:1), **7** (R_f 0.8) disappeared and a product (R_f 0.2) appeared. Filtration and evaporation of the solution gave a solid (0.13 g), which was dissolved in 1N barium hydroxide (2 ml) and heated at 90°C for 8 hr. On paper chromatography with *n*-butyl-alcohol–pyridine–water–acetic acid (6:4:3:1), the solution showed a ninhydrin positive product ($R_{f\ 2\text{-deoxystreptamine}}$ 0.52). The solution was neutralized with carbon dioxide, and the resulting suspension was boiled for a while. After centrifuging, the upper layer was evaporated. After repeated extraction and evaporation of the residue with boiling water, the final residue was charged on a column (5×44 mm) of Amberlite IRC 50 (NH_4 form) and after washing the column with water, developed with 0.03N ammonia. The portion (70—180 ml) containing **9** was evaporated to give a solid (44 mg). An aqueous solution of the product was acidified with hydrochloric acid to pH 2 and evaporated to give a solid of trihydrochloride dihydrate of **9**, 61.4 mg (53%); $[\alpha]_D^{16}$ +67° (*c* 0.3, water), $[\alpha]_{436}^{16}$ +131° (*c* 0.3, water), $[\alpha]_{436\text{TACu}}^{16}$ +487° (*c* 0.3, TACu), $\Delta[M]_{TACu}^{16}$ +1540°; IR (KBr): 3400, 2920, 1600, 1500, 1100, 1050, 870, 770 cm^{-1}; NMR (in D_2O): τ 8.75 (1H, q, *J* ~13 Hz, H_{ax}-2), 7.87 (1H, double triplets, *J* ~4 Hz and ~13 Hz, H_{eq}-2), 4.67 (1H, d, *J* ~3 Hz, H-1).

Found: C, 30.55; H, 6.59; N, 9.09; Cl, 22.50%. Calcd for $C_{12}H_{25}N_3O_7 \cdot 3HCl \cdot 2H_2O$: C, 30.74; H, 6.88; N, 8.96; Cl, 22.69%.

6-O-(4-Amino-4-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine (10). Compound **8** (0.3 g) was treated similarly as described above. The base (71 mg) obtained was treated with hydrochloric acid to give trihydrochloride dihydrate of **10**, 88.6 mg (51%); $[\alpha]_D^{16}$ +69° (*c* 0.4, water), $[\alpha]_{436}^{16}$ +141° (*c* 0.4, water), $[\alpha]_{436\text{TACu}}^{16}$ +176° (*c* 0.4, TACu), $\Delta[M]_{TACu}^{16}$ +165°; $R_{f\ 2\text{-deoxystreptamine}}$ 0.48 (ppc with the same solvent system described above). The IR spectrum of the hydrochloride was quite similar to that of **9**. NMR (in D_2O): τ 8.74 (1H, q, *J* ~13 Hz, H_{ax}-2), 7.90 (1H, double triplets, *J* ~4 Hz and ~13 Hz, H_{eq}-2), 4.83 (1H, d, *J* ~3 Hz, H-1).

Found: C, 30.65; H, 6.80; N, 9.12; Cl, 22.41%. Calcd for $C_{12}H_{25}N_3O_7 \cdot 3HCl \cdot 2H_2O$: C, 30.74; H, 6.88; N, 8.96; Cl, 22.69%.

The authors wish to thank Dr. Hiroshi Naganawa of Institute of Microbial Chemistry for the measurements of the NMR spectra and Mr. Saburo Nakada for the elemental analysis. The authors also wish to thank Messrs. Toshio Sumida, Ryujiro Namba, and Takayuki Obata for their technical assistances.

Reaction between *p*-Toluenesulfinic Acid and Diphenyldiazomethane[1)]

Michio KOBAYASHI, Hiroshi MINATO, and Hideo FUKUDA

Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received October 23, 1972)

Reaction between *p*-toluenesulfinic acid and diphenyldiazomethane was investigated in several solvents. Reaction was faster in non-polar solvents and slower in polar solvents. Experiments with $CH_3C_6H_4SO_2D$ showed that protonation of diphenyldiazomethane is the rate-determining step. In non-polar solvents the main product was benzhydryl *p*-tolyl sulfone, whereas in polar solvents benzhydryl *p*-toluenesulfinate was the main product. In ethanol, benzhydryl ethyl ether was also produced. The mechanism of the reaction was discussed.

Although the formation of methyl sulfinates from sulfinic acids and diazomethane is known for a long time,[2)] no reactions of sulfinic acids with other aliphatic diazo compounds have been reported. Since sulfinate anions are ambident, alkylation may give rise to sulfinate esters and sulfones. Ordinary alkylating agents yield sulfones alone,[3)] whereas such powerful alkylating agents as triethyloxonium tetrafluoroborate give ethyl sulfinates as the main products.[4)] Relative yields of esters and sulfones are influenced by the solvent.[5)]

The kinetics and products of the reaction between *p*-toluenesulfinic acid and diphenyldiazomethane has been investigated, and the results are given in this paper.

Results and Discussion

Kinetic Studies. The rate of decrease of diphenyldiazomethane (I) was determined by use of the decrease of the absorption of I at 525 nm. The reaction was of first order in both *p*-toluenesulfinic acid (II) and I. Rates of the reaction were considerably different in various solvents; they were quite large in benzene or dichloromethane and much smaller in dioxane, alcohol or dimethyl sulfoxide. The rate constants in various solvents are shown in Table 1. When the logarithms of the rate constants determined at various temperatures were plotted against $1/T$, good straight lines were obtained. Activation parameters were calculated and are shown in Table 1.

	19.0	0.0328		

a) Reaction was rapid, and measurements were not so accurate.
b) By the rate of evolution of nitrogen.

Since the reaction between I and II yields nitrogen quantitatively, the rates of the reaction can be determined from the rates of evolution of nitrogen in the solvents in which the reaction rates are not so great. Although the measurements are not very accurate because of the rapidity of the reaction, the rate constant determined is in fair agreement with the value obtained spectrophotometrically.

The reaction between I and II is a three-step reaction, the first step being probably the rate-determining one.

$$ArSO_2H + Ph_2CN_2 \longrightarrow [Ph_2CHN_2^{\oplus}ArSO_2^{\ominus}] \quad (1)$$

$$[Ph_2CHN_2^{\oplus}ArSO_2^{\ominus}] \longrightarrow [Ph_2CH^{\oplus}ArSO_2^{\ominus}] + N_2 \quad (2)$$

$$[Ph_2CH^{\oplus}ArSO_2^{\ominus}] \longrightarrow Ph_2CHO_2SAr \quad (3)$$

The first step is the protonation of I. Since protonations are usually very rapid, it is doubtful whether or not step (1) is really the rate-determining step. Therefore, $CH_3C_6H_4SO_2D$ was synthesized. When the rate of the reaction between $CH_3C_6H_4SO_2D$ and I was determined in dioxane, measurements were not reproducible because the moisture in air dissolves into the dioxane and the H–D exchange takes place rapidly between $CH_3C_6H_4SO_2D$ and water. The measurements were therefore carried out in dioxane containing 2 vol% of heavy water (or ordinary water). The rates were determined by use of both the absorption at 525 nm and the volume of the nitrogen evolved. Table 2 shows that the rates with the deuterated com-

k_H/k_D {Volumetrically			3.2

pound are considerably smaller than those with the ordinary sulfinic acid. The kinetic isotope effects (Table 3) were about 3.0. These data show that protonation of I is the rate-determining step; that is, step (2) is faster than step (1). Step (2) proceeds very readily because it yields the resonance-stabilized diphenylmethyl cation.

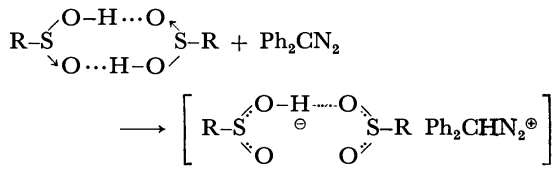
Rates of reaction in dioxane containing 2 vol% water are greater than those in anhydrous dioxane. This is probably due to the increase of the extent of ionization of II by the addition of water.

Reactions between carboxylic acids and aliphatic diazo compounds have been investigated extensively.[6] The reaction between benzoic acid and diphenyldiazomethane in ethanol is of second order, and k (20°C) is 6.6×10^{-3} $M^{-1}sec^{-1}$, $\Delta H^{\ddagger}=15.6$ kcal mol^{-1}, $\Delta S^{\ddagger}=-15$ e.u.[7] The rates with II shown in Table 1 are far greater than this value. This might be ascribed to the greater dissociation constant of II in comparison with that of benzoic acid.[8] Kinetic isotope effects were observed in the reaction between carboxylic acids and I (with benzoic acid, $k_H/k_D=3.6$ at 35.35°C in ethanol),[9] showing that protonation of I is the rate-determining step. It is of interest that the values of the kinetic isotope effects with carboxylic acids are approximately the same as those with II.

It was reported that the addition of water increased the rates of reaction between carboxylic acids and I in ethanol.[10]

As shown in Table 1, the reaction rates in non-polar solvents are much greater than those in polar solvents. Similar phenomena were observed in the rates of the reactions of carboxylic acids with I.[9]

The greater rates in non-polar solvents can be rationalized as follows. Infrared spectroscopy shows that sulfinic acids exist as dimers or polymers in non-polar solvents or in crystalline state.[11] When such dimeric sulfinic acids react with I, protonation takes place easily, because the sulfinate anion formed is stabilized by association with another sulfinic acid molecule.



In polar solvents, sulfinic acid molecules lose their dimeric structure and are solvated by solvent molecules. When such solvated molecules are to react with I, the bond between II and a solvent molecule must be cleaved first. This process requires extra energy, and therfore the reaction with I is slower.

Product Studies. In solvents other than alcohols, benzhydryl *p*-toluenesulfinate and benzhydryl *p*-tolyl sulfone were formed in 80—100% yields. The ratio between them varied with the solvent used. Amounts of the products were determined by use of infrared absorptions at 900 and 1140 cm^{-1} (ester) and 1310 cm^{-1} (sulfone) and NMR absorptions. In the reaction in ethanol, benzhydryl ethyl ether was found in addition to the sulfinate and sulfone. The molar ratios of the products in various solvents are shown in Table 4.

Table 4. Molar ratios of the products in various solvents

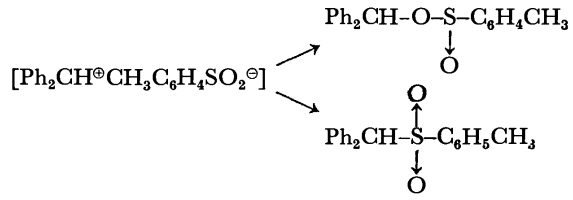
Solvent	Sulfinate[a]	Sulfone[b]	Ether[c]	Total yield (mol %)
CH_2Cl_2	0	100		80
Benzene	20	80		96
CH_3CN	81	19		100
Ethanol	60	14	26	100
Dioxane	83	17		100
DMSO	100	0		82

a) *p*-$CH_3C_6H_4SO_2CHPh_2$.
b) *p*-$CH_3C_6H_4SO_2CHPh_2$.
c) $C_2H_5OCHPh_2$.

In ethanol, the ratio (Sulfinate+Sulfone)/Ether was nearly constant when the concentrations of I and II were varied in the range $2.4—64.0\times10^{-3}$ M.

In DMSO, only benzhydryl *p*-toluenesulfinate was formed in the earlier period of the reaction, but the sulfinate slowly isomerized to sulfone, and the molar ratio of these two products was about 50:50 after 30 min at room temperature.

Reaction (3) is alkylation of the sulfinate anion by diphenylmethyl cation. Since the reactivity of resonance-stabilized diphenylmethyl cation is much less than that of a simple alkyl cation, not only the sulfinate ester but also the sulfone were formed.



Since sulfones are thermodynamically much more stable than the corresponding sulfinate esters, the above reaction is a kinetically-controlled reaction. In such polar solvents as DMSO, the benzhydryl ester once formed redissociates to an ion pair, which recombines, forming the sulfone. Thermal isomerization of a sulfinate ester to a sulfone has been reported on.[12] It is

also known that hydrolysis of benzhydryl sulfinate forms the corresponding sulfone as a byproduct.[13]

Table 4 shows that in polar solvents the yields of the sulfinate are greater whereas in non-polar solvents those of the sulfone are greater. This is probably related with the fact that rates of the reaction between I and II are smaller in polar solvents and greater in non-polar solvents. A plausible explanation for this phenomenon is as follows. As described above, sulfinic acids exist as dimers or polymers in non-polar solvents. When such dimeric acid reacts with I, the sulfinate anion formed exists in association with another sulfinic acid molecule. Since the negative charge on this dimer anion is not on a specific oxygen atom, combination of diphenylmethyl cation with the oxygen atom of the dimer anion takes place slowly, and consequently the combination with the sulfur atom takes place relatively rapidly.

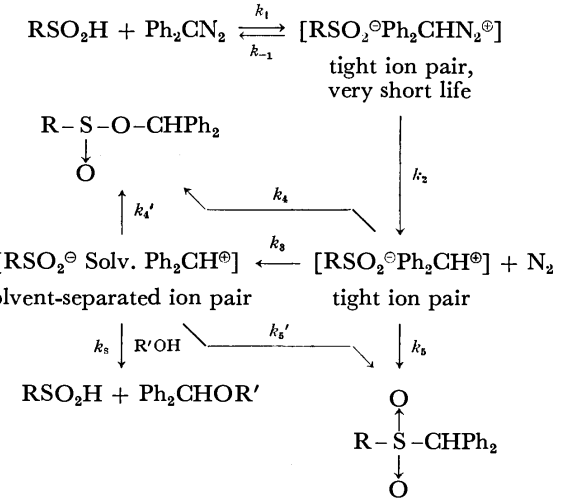
In such polar solvents as DMSO and dioxane, sulfinic acid molecules are hydrogen-bonded with solvent molecules and the reaction with I is slow. However, since the sulfinate anions formed are not much solvated, they quickly combine with cations at the negatively charged oxygen atoms, forming the thermodynamically less stable benzhydryl sulfinate as the main product.

In ethanol, benzhydryl ethyl ether was formed in a 26% yield which did not change much when the initial concentrations of I and II were varied. Formation of this ether can be ascribed to the attack of ethanol to the ion pair Ph_2CH^+–$O_2SC_7H_7$ or the solvent-separated ion pair.

When benzoic acid and I were let to react in ethanol, benzhydryl ethyl ether was found in a 45% yield.[10] When 2,4-dinitrophenol and I were let to react in ethanol, benzhydryl ethyl ether was found in a 39% yield.[14] The smaller yield of this ether in the reaction of I and II in ethanol means that the combination of $C_7H_7SO_2^-$ with Ph_2CH^+ is much faster than the combination of ethanol with Ph_2CH^+. This fact suggests that the ion pair Ph_2CH^+–$O_2SC_7H_7$ is tighter than Ph_2CH^+–O_2CR and that the sulfinate anion is more nucleophilic than carboxylate anions.

The reaction between I and II can be expressed in the following scheme.

The life time of the ion pair RSO_2^-–$Ph_2CHN_2^+$ must be very short, and a molecule of nitrogen is quickly lost from the tight ion pair. Probably k_1 is much smaller than k_2, and k_{-1} is also very small in comparison with k_2. The sulfinate and sulfone are formed mainly from the combination of the tight ion pair RSO_2^-–Ph_2CH^+, but part of them must arise from the combination of the solvent-separated ion pair, especially in polar solvents. In ethanol, part of the solvent-separated ion pair reacts with ethanol, forming benzhydryl ethyl ether.



Experimental

Materials. Diphenyldiazomethane, produced by oxidation of benzophenone hydrazone with mercuric oxide, was recrystallized from *n*-hexane; mp 31—32 °C.[15] Benzhydryl *p*-toluenesulfinate was synthesized by condensation of the corresponding acid and alcohol in the presence of dicyclohexylcarbodiimide;[16] mp 79 °C.

Kinetic Measurements. Reaction was followed by the decrease of the absorption of I at 525 nm with a Hitachi EPS-3T spectrophotometer. Neither II nor the reaction products had absorptions in this region. Rates of reaction were also determined volumetrically by use of a gas buret.

Reaction Products. The products of the reaction were separated by recrystallization or column chromatography, and identified by NMR and IR. The ratios of the products in the reaction mixture were determined by use of NMR (δ 3.65, $C_7H_7(SO)OCHPh_2$; δ 4.70, $C_7H_7(SO_2)CHPh_2$; δ 6.3—6.7, $CH_3CH_2OCHPh_2$), and IR (ν_{S-O} 1140 and ν_{C-O} 900 cm^{-1} of sulfinate; ν_{S-O} 1310 cm^{-1} of sulfone). Deuterated solvents (such as dimethyl sulfoxide-d_6) were used whenever necessary for NMR measurements.

New Agents for *t*-Butyloxycarbonylation and *p*-Methoxybenzyloxycarbonylation of Amino Acids

Takeshi NAGASAWA, Katsumasa KUROIWA, Kouichi NARITA, and Yoshikazu ISOWA*

Research Laboratory for Chemical Fibers, Nitto Boseki Company, Ltd., Fukuyama, Kōriyama, Fukushima
**Sagami Chemical Research Center, Ohnuma, Sagamihara, Kanagawa*

(Received October 30, 1972)

A new method for the preparation of *t*-butyloxycarbonyl amino acids and *p*-methoxybenzyloxycarbonyl amino acids has been devised. The former was obtained in satisfactory yields from amino acids and *t*-butyl *S*-4,6-dimethylpyrimid-2-ylthiocarbonate prepared from *t*-butyl alcohol and (4,6-dimethylpyrimid-2-ylthio)corbonyl chloride in dry pyridine, and the latter was also obtained from amino acids and *p*-methoxybenzyl *S*-4,6-dimethylpyrimid-2-ylthiocarbonate from *p*-methoxybenzyl alcohol and (*S*-4,6-dimethylpyrimid-2-ylthio)carbonyl chloride. These *t*-butyloxycarbonylation and *p*-methoxybenzyloxycarbonylation of amino acids are more convenient than the usual methods.

In recent years the *t*-butyloxycarbonyl (Boc) group[1] has found wide use for protecting the amino moiety of amino acids in peptide synthesis. Its merits are high selectivity and ease of removal by acidolysis (HCl in an inert solvent, or CF_3COOH), and at the same time resistance to hydrogenolysis, alkaline spilitting, hydrazinolysis, as well as absence of appreciable racemization.

The most widely employed reagents for the preparation of Boc-amino acids are Boc-azide,[2] Boc-Cl,[3] and *t*-butyl 2,4,5-trichlorophenyl carbonate,[4] which react with both the free amino acids and their esters in the presence of bases. But these methods suffer from various disadvantages, the strict control of reaction pH required in the case of Boc-azide, unstable property of Boc-Cl, and elaborate purification from 2,4,5-trichlorophenol of Boc-amino acids. A new water soluble agent (4-dimethylamino-1-*t*-butyloxycarbonylpyridinium chloride) for *t*-butyloxycarbonylation of amines was also reported.[5]

We wish to report a new, rapid and tidy method for the preparation of Boc-amino acids. Aminolysis of *t*-butyl *S*-4,6-dimethylpyrimid-2-ylthiocarbonate by the amino moiety of amino acids yields the corresponding Boc-amino acids in good yield; the 2-mercapto-4,6-dimethylpyrimidine liberated being acid soluble is easily separable from the Boc-amino acid, and the aminolysis is carried out at room temperature for 2—24 hr.

The *p*-methoxybenzyloxycarbonyl (Z(OMe))[6] group also has been widely used as a blocking substituent of the amino moiety of amino acids in peptide synthesis.[7] This group allows an easier removal by trifluoroacetic acid. The Z(OMe) group can be introduced with the use of *p*-methoxybenzyl 2,4,5-trichlorophenyl carbonate[8] or *p*-methoxybenzyloxycarbonyl azide.[9] These methods have been used in many cases, but the yields are not satisfactory. In the present investigation, *p*-methoxybenzyl *S*-4,6-dimethylpyrimid-2-ylthiocarbonate was very useful for the preparation of Z(OMe)-amino acids, too.

Results and Discussion

t-Butyl 4,6-Dimethylpyrimidyl-2-thiol Carbonate (IV) and p-Methoxybenzyl 4,6-Dimethylpyrimidyl-2-thiol Carbonate (V). 2-Mercapto-4,6-dimethylpyrimidine hydrochloride (I.HCl) was prepared from acetylacetone, thiourea, and concentrated hydrochloric acid in ethanol in the usual method.[10]

As was clear from the reaction schema shown below, the preparation of sodium 4,6-dimethylpyridine-2-thiolate (II) was described in experimental section in detail.

(4,6-Dimethylpyrimid-2-ylthio)carbonyl chloride(III) was prepared by adding a phosgene to the suspension of II in an inert solvent such as petroleum ether and toluene under cooling (−5——10°C). The resulting product was stable in a water free state at room temperature and solid below about 5°C, but decomposed at a temperature of about 100°C and hence could not be purified by distillation. In the sequent reaction, therefore, III was ordinarily used in a crude form. IV could be prepared readily from *t*-butyl alcohol and III in pyridine at room temperature and V also prepared from *p*-methoxybenzyl alcohol and III in the presence of pyridine in dry ether at room temperature. These reagents (IV and V) were considerably stable, pale yellow crystals and could be stored in a dark and cool place for six months without decomposition.

Boc-Amino Acids and Z(OMe)-Amino Acids. As a guide to model condition for the reaction between

amino acids and IV, the reaction between leucine and the active ester was first explored.

The effects of bases, solvents, reaction time, and reaction temperature were examined and the following results were found.

With aqueous dioxane as the solvent, the effect of five bases was examined and it was found that all except pyridine promoted the formation of Boc-leucine: the yield of product was greatest using triethylamine (quantitatively), sodium hydroxide (88%) or sodium carbonate (85%) and least using sodium hydrogen

carbonate (21%) shown in Table 1. Aqueous dioxane and dimethylformamide were rather more superior to other aqueous solvents, and a 10 hr reaction at 30—35°C gave the highest yield of the product shown in Table 2. As shown in Table 3, a five hours reaction gave 79% yield at a temperature of 15—20°C, 99% yield at 30—35°C.

On the bases of these experiences, the standard condition adopted for the reaction between amino acids and IV involved the use of triethylamine and aqueous dioxane or dimethylformamide at 30—35°C or room temperature for overnight. About twenty amino acids were examined and the yields of Boc-amino acids were consistently good as shown in Table 4.

Z(OMe)-amino acids were prepared from V and free amino acids by the same method as described for Boc-amino acids. The products obtained were shown in Table 5.

Experimental

Melting points were all determined in a Yanagimoto electric micromelting point apparatus and are uncorrected, and optical rotations were measured with a JASCO automatic polarimeter DIP-SL. All amino acids were L-configuration in this report.

4,6-Dimethylpyrimidyl-2-thiol Chloroformate (III). A solution of 128 g (3.2 mol) of sodium hydroxide in 600 ml of water was mixed with 420 g (3.0 mol) of I, and the resulting mixture was heated to completely dissolve the I and then allowed to cool. The resulting solution was charged into 15 l of acetone, whereby a sodium salt of I was precipitated. The precipitated sodium salt was recovered by filtration and then dried at 120°C for 24 hr to obtain 462 g (95%). Subsequently, 324 g (2.0 mol) of the above-mentioned sodium salt (II) was added as it was, *i.e.* in the form of solid to 1185 g of petroleum ether, and to the resulting suspension was added to 297 g of phosgene (3.0 mol) at −15——10°C, and the mixture was reacted with stirring at room temperature for 4 hr. After completion of the reaction, excess phosgene was removed by evaporation at 40—50°C while injecting nitrogene into the reaction liquid. Thereafter, the precipitate formed was filtered and then the petroleum ether was removed by evaporation *in vacuo*, to obtain about 365 g of III in crude yield of 90%.

t-*Butyl* S-*4,6-Dimethylpyrimidin-2-ylthiolcarbonate (IV).* Into a solution of 267 g (3.6 mol) of *t*-butyl alcohol in 752 g of pyridine was dropped under stirring and cooling to −5—0°C 364 g (1.9 mol) of the crude III, and the resulting mixture was reacted at 20—25°C for 3 hr. After completion of the reaction, deposited pyridine hydrochloride was separated by filtration, and the filtrate was charged with 2000 ml of water and then extracted 3 times each with 800 ml of petroleum ether. The petoleum ether layer was sufficiently washed with a cold 1N aqueous hydrochloric acid solution, washed twice with a saturated aqueous sodium chloride solution and dried over anhydrous sodium sulfate, and then the petroleum ether was evaporated under reduced pressure, wherby the crystal was obtained. The crystal was washed with a small amount of cold *n*-heptane and then dried to obtain 274—319 g (60—70%) of IV. Mp 50—51°C.

Found: C, 54.88; H, 6.64; N, 11.57; S, 13.29%. Calcd for $C_{11}H_{16}O_2N_2S$: C, 54.98; H, 6.71; N, 11.66; S, 13.34%.

p-*Methoxybenzyl* S-*4,6-Dimethylpyrimidin-2-ylthiolcarbonate (V).* 244 g (2.2 mol) of *p*-methoxybenzyl alcohol and 167 g (2.1 mol) of pyridine were dissolved in 2600 ml of ether. Into the resuting solution was dropped under stirring and cooling to −5—0°C 324 g of the crude III obtained in the above-mentioned procedure, and the resulting mixture was reacted at room temperature for 3 hr. After completion of the reaction, the reaction liquid was once with cold water, twice with a 1N aqueous citric acid solution or a 1N aqueous hydrochloric acid solution cooled to 0°C and a saturated aqueous sodium chloride solution, and dried over anhydrous sodium sulfate and then the ether was evaporated *in vacuo* to obtain 340—388 g (70—80%) of the pale yellow crystal of V. Mp 58—60°C (recrystallized from ether–petroleum ether).

Found: C, 58.98; H, 5.31; N, 9.22; S, 10.48%. Calcd for $C_{15}H_{16}O_3N_2S$: C, 59.19; H, 5.30; N, 9.20; S, 10.54%.

t-*Butyloxycarbonyl Amino Acids and* p-*Methoxybenzyloxycarbonyl Amino Acids (General Method).* 0.10 mol of amino acid

and 0.15 mol (21 ml) of triethylamine were added to 55 ml of water. To the resulting mixture of 0.11 mol of IV or V in 55 ml of dioxane or dimethylformamide, and then the mixture was reacted under stirring at room temperature for several hours. (2—24 hr) After completion of the reaction 150 ml of water was added to the reaction mixture, and unreacted carbonate was extracted twice with 200 ml of ethyl acetate. Subsequently, the aqueous layer was cooled to 0°C and adjusted to pH 2 by addition of a 5N aqueous hydrochloric acid cooled to 0°C, and then extracted once with 150 ml of ethyl acetate and twice with 80 ml of ethyl acetate. Thereafter, the ethyl acetate layers were united together, washed thrice with 100 ml of a 5% aqueous hydrochloric acid cooled to 0°C, and twice with 100 ml of a saturated aqueous sodium chloride solution and dried over anhydrous sodium sulfate (if necessary, using active carbon for decolorization.) and then the ethyl acetate was evaporated *in vacuo*, the resulting solid was recrystallized from the solvent indicated in Tables 4 and 5.

The preparations of Boc-aspagine, Boc-N^{im}-benzylhistidine, Boc-serine, and Boc-threonine were different from the general method in the following parts.

Boc-asparagine. In this procedure, an aqueous layer adjusted to pH 2 was allowed to stand overnight in a cold place (0—5°C) instead of extraction from ethyl acetate, whereby the crystal was deposited. The crystal was recovered by filtration and then washed with cold water to obtain 19.0 g (81.9%) of Boc-asparagine. Mp 175—177°C $[\alpha]_D^{20} = -7.2°$ (*c* 1, DMF).

*Boc-*N^{im}*-benzylhistidine.* This compound was similarly prepared in Boc-asparagine except the following part. In this procedure, pH of an aqueous layer was adjusted to pH 5.4 by acetic acid instead of adjusting pH 2 by a cooled 5N aqueous hydrochloric acid. Yield 33.9 g (98.3%). Mp 180—182°C. $[\alpha]_D^{20} = +24.8°$ (*c* 1, methanol).

Boc-serine. After the aqueous layer was adjusted to pH 2 by addition of a cooled 5N aqueous hydrochloric acid, sodium chloride was added to this mixture. Thereafter, the ethyl acetate layer were united together, washed thrice with 100 ml of a cooled 5% aqueous hydrochloric acid saturated by sodium chloride and dried over anhydrous sodium sulfate and decolorized with active carbon and evaporated *in vacuo* to obtain 17.3 g (84.6%). Mp 90—93°C. $[\alpha]_D^{20} = -4.9°$ (*c* 1, acetic acid).

Boc-threonine was similarly prepared in above described procedure.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1272—1275 (1973)

Quantitative Estimation of the Fehling Reaction of 1-*O*-Protected Uronic Acids

Juji YOSHIMURA, Jun-ichi HASHIMOTO, and Hiroaki ANDO

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 8, 1972)

Quantitative estimation of the Fehling reaction of 1-*O*-protected uronic acid derivatives showed that the reducing power of 1-*O*-protected hexofuranuronic acid derivatives corresponds to 23—37% of that of D-glucose. The presumption that the reducing ability might be attributed to the formation of unsaturated *aldehydo*-sugars by removal of the 1-*O*-protecting group through a cupric ion-catalyzed β-elimination was supported by the fact that 2,5-dimethoxy-6-oxo-2,4-hexadienoic acid was formed by alkaline β-elimination of methyl (methyl 2,3,5-tri-*O*-methyl-α-D-glucofuranosid)uronate.

Fehling-negative charactor of *O*-glycosides has been generally recognized in the carbohydrate chemistry for a long time, and only exceptionally, the positive[1-4] or negative[1,4-6] properties of several 1-*O*-protected-D-glucuronic acid derivatives were marked by several researchers. In a previous paper,[7] we have examined qualitatively the Fehling test of nineteen kinds of 1-*O*-protected uronic acid derivatives, and found that hexofuranuronic acids having a hydrogen atom at *C*-5 position were positive, while, pentofuranuronic, hexopyranuronic, and heptofuranuronic acids were negative. The formation of unsaturated aldehydes by removal of the 1-*O*-protecting groups through cupric ion-catalyzed β-elimination was deduced to be responsible for the exposed reducing ability. In this paper, the reducing power was quantitatively estimated and an evidence for the proposed β-elimination was obtained.

Results and Discussion

In addition to the reported thirteen examples,[7] following hexofuranuronic acid derivatives showed again the positive Fehling test: *i.e.*, 5-*O*-acetyl,[4] 5-*O*-tosyl,[8] and 5-bromo-5-deoxy[9] derivatives of 1,2-*O*-isopropyli-

a) These compounds were treated as the monomers.
b) Values in parentheses present that diminished the reducing power of the hydrazide moiety.

with the fact that the predominant anomer in the Fischer glycosidation of D-glucurono-6,3-lactone was β-form.[2] This anomerization implies the repulsion between C_1- and C_2-methoxy groups and an anomeric effect[18] in the α-furanose ring. The favorable conformation of **4** was deduced to be flattened T^2_3 from the NMR spectrum[19] (*cf.* Experimental section).

Quantitative estimation was carried out by the Bertrand method after refluxing for ten min, and the reducing powers were presented as oxidation-reduction equivalents (Table 1). These values of D-glucose and D-glucurono-6,3-lactone are reasonable compared with those reported.[20] Excepting fully *O*-methylated derivatives (**4** and **6**), all hexofuranuronic acid derivatives showed 23—37% reducing power of that of D-glucose. The facts that D-glucofuranuronic acid derivatives showed almost a constant reducing power and that there is an apparent difference between anomers (**4** and **5**) indicate that the reducing abilities depend on the configuration of the substrates. Lichtmyer and Hudson[21] reported that even enantiomers (D- and L-altrose) showed a different reducing power for the Fehling solution. Therefore, coordination of substrates to L-(+)-tartaric acid–Cu (II) complex will be the

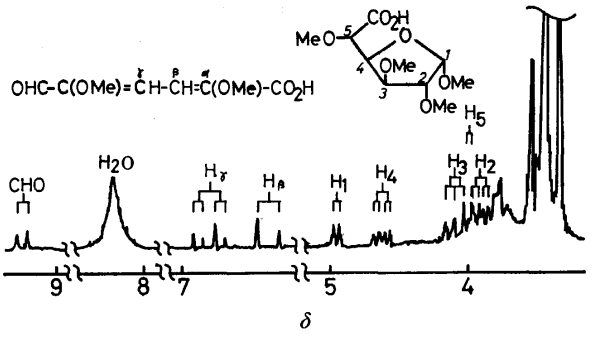

Fig. 1. NMR spectrum of the elimination products of **6** in $CDCl_3$.

first step in this oxidation-reduction, and then proceeds *via* two steps; *i.e.*, oxidation of the resulted complex with oxygen or the complex-catalyzed oxidation of substrate, as was depicted by Singh *et al.*[22]

On the other hand, no substantial change was observed in the NMR spectrum of 1,2-*O*-isopropylidene-α-D-glucofuranurono-6,3-lactone in 0.7M-sodium hydroxide at 55°C for 1 hr,[7] however, it is known that methyl (methyl α-D-glucopyranosid)uronates undergo *t*-butoxide-catalyzed β-elimination to give the corresponding 4-enoses, and the fully *O*-methylated derivative give a higher yield than others.[23] Examination of the product of such a β-elimination of **6** indicated the formation of 2,5-dimethoxy-6-oxo-2,4-hexadienoic acid in UV (λ_{max} 280 nm) and NMR (Fig. 1) spectra. The appearance of aldehyde proton (δ 9.15; d, J= 7.3 Hz) and two olefinic proton signals (δ 6.81; q, J=7.3 and 16 Hz, and δ 6.38; d, J=16 Hz) supported the structure and configuration of the product shown in Scheme 1. A similar examination of methyl 1,2-*O*-isopropylidene-3,5-di-*O*-methyl-α-D-glucofuranuronate showed λ_{max} 295 nm in UV and the appearance of one olefinic proton (δ 6.20; d, J=10.6 Hz) in NMR spectrum, but aldehyde proton signal could not be detected. Thus, it was proved that the β-elimination of hexofuranosiduronic acids gave unsaturated aldehydes, accompanying with liberation of 1-*O*-protecting groups.

On the reason for the weak reducibility of a few hexopyranuronic acids (**9**—**11**), examination of the Fehling test of 4-enoses might give some suggestions, and moreover, it will be worthy to note that the reaction is also stereospecific.

Experimental

All melting points are uncorrected. The solutions were evaporated under diminished pressure at a bath temperature not exceeding 45 °C. Specific rotations were measured in a 0.5-dm tube, with a Carl Zeiss LEP-A1 Polarimeter. The IR spectra were recorded with a Hitachi Model EPI-G2 grating IR spectrophotometer. The NMR spectra were taken in deuteriochloroform with a JNM-4H-100 MHz Spectrometer using tetramethylsilane as an internal standard. Chemical shifts and coupling constants were recorded in δ and Hz units, and frequencies in cm^{-1}.

1,2-O-Isopropylidene-α-D-glucofuranuronohydrazide (1). A solution of 1,2-*O*-isopropylidene-α-D-glucofuranurono-6,3-lactone (5.0 g) in hydrazine (5 ml) was refluxed for 1 hr, and evaporated to give a syrup which was crystallized from ethanol–petroleum ether. Yield, 3.2 g (56%); mp 143—146 °C; $[\alpha]_D^{23}$ −13.0° (*c* 1.08, water). IR: 3400—3300 (OH), 3220—3100 (NH), 1670 and 1520 (CONH), 1615 (NH_2), 1380—1370 (C-CH_3).

Found: C, 43.31; H, 6.17; N, 11.20%. Calcd for $C_9H_{16}N_2O_6$: C, 43.54; H, 6.50; N, 11.29%.

1,2-O-Isopropylidene-5-O-(p-tosyl)-α-D-glucofuranuronamide (2). To a suspended solution of 1,2-*O*-isopropylidene-5-*O*-(*p*-toluenesulfonyl)-α-D-glucofuranurono-6,3-lactone[7] (4.5 g) in methanol (100 ml) was added at −50 °C saturated methanolic ammonia (70 ml), and the resulted solution was kept at this temperature for 1.5 hr, neutralized with 60% acetic acid, evaporated to 15 ml, and then extracted with chloroform. Evaporation of the extracts gave a syrup from which crystals (250 mg, 5%) was obtained by standing the ether solution overnight in a refrigerator. Mp 155—157 °C; $[\alpha]_D^{23}$ +19.4° (*c* 0.99, acetone); IR: 3400 (OH), 3370—3180 (NH_2), 1680 and 1540 ($CONH_2$), 1585, 670, and 760 (benzene).

Found: C, 49.34; H, 5.21; N, 3.49; S, 8.36%. Calcd for $C_{16}H_{21}NO_8S$: C, 49.61; H, 5.47; N, 3.62; S, 8.28%.

(Methyl 2,5-di-O-methyl-β-D-glucofuranosid)urono-6,3-lactone (4). A solution of the α-anomer of **4**[6] (0.3 g) in methanolic hydrogen chloride (5%, 5 ml) was refluxed for 1 hr, and evaporated to give a syrup which was crystallized by standing overnight its methanol solution in a refrigerator. Yield, 46% (139 mg); mp 95.5—97 °C; $[\alpha]_D^{23}$ −19.1° (*c* 1.00, chloroform). IR: 1790 (lactone); NMR: 5.02 (H_1; s, $J_{1,2}\approx 0$), 4.99 (H_4; q, $J_{3,4}$=4.9, $J_{4,5}\approx$6.4), 4.85 (H_3; d, $J_{2,3}\approx 0$), 4.03 (H_5; d), 3.91 (H_2; s), 3.66 (OMe), 4.45 and 4.36 (2×C-CH_3).

Found: C, 49.25; H, 6.49%. Calcd for $C_9H_{14}O_6$: C, 49.54; H, 6.47%.

3-Acetamido-3-deoxy-1,2-O-isopropylidene-α-D-allofuranuronic acid (7). To a suspended solution of 3-acetamido-3-deoxy-1,2-*O*-isopropylidene-α-D-allofuranose[24] (4.8 g, 14 mmol) and platinum-charcoal (10%, 6 g) in water (150 ml) was bubbled oxygen in the rate of 10 ml/sec, under adjusting the pH at 7—7.8 with aqueous sodium bicarbonate (8%). When calculated amount of alkali was consumed, the solution was filtered, and the filtrate was evaporated to give a syrup. A solution of the syrup in acetone–water (1:1 in v/v, 300 ml) was treated four times with IR-120 (30 ml, H-form), and evaporated to give a syrupy product. Yield, 3.65 g (72%); $[\alpha]_D^{23}$ +48.8° (*c* 1.00, methanol); IR: 3350 (OH), 3100 (NH), 1725 (COOH), 1640 and 1550 (NHCO).

Found: C, 47.75; H, 6.40; N, 4.81%. Calcd for $C_{11}H_{17}NO_7$: C, 48.00; H, 6.23; N, 5.09%.

(Methyl 2,3,4-tri-O-acetyl-α-D-glucopyranosid)urononitrile (8). A solution of (methyl 2,3,4-tri-*O*-acetyl-α-D-glucopyranosid)-uronamide[25] (3.32 g, 10 mmol) and *p*-tosyl chloride (5.7 g, 30 mmol) in pyridine (15 ml) was heated at 80 °C for 3 hr, and then poured into ice-water. The precipitate was filtered and recrystallized from methanol. Yield, 70% (2.19 g); mp 156—157 °C; $[\alpha]_D^{23}$ +140° (*c* 0.4, methanol); IR: 1755 (ester).

Found: C, 49.38; H, 5.32; N, 4.37%. Calcd for $C_{13}H_{17}NO_8$: C, 49.52; H, 5.44; N, 4.44%.

This compound was directly obtained from D-glucurono-6,3-lactone in 17% yield, by successive glycosidation, amida-

tion, acetylation, and dehydration.

Quantitative Analysis. A mixture of the Fehling solution (A and B, each 25 ml) and sample (20 mg) was boiled for just 10 min, cooled with ice-water, and filtered (Toyoroshi No. 2 filter-paper). Cuprous oxide was dissolved in ferric sulfate solution with boiling, and then the solution was titrated with 0.1M-potassium permanganate. Analysis was repeated two or three times, and blank-test value was reduced from each mean value. Oxidation-reduction equivalent was calculated from the consumed potassium permanganate as follows;

$$\frac{(0.1\text{M-}KMnO_4,\ \text{ml}) \times \text{factor} \times \text{molecular weight}}{(\text{Sample weight, mg})}$$

*Elimination of Methyl (Methyl 2,3,5-tri-*O*-methyl-α-*D*-gluco-furanosid)uronate.* The following sample was used. Bp 63—73 °C/0.017 mmHg (bath temperature, 114—130 °C); $[\alpha]_D^{23}$ +109° (*c* 0.99, chloroform) [lit,[6] +122° (*c* 0.7, water)]; IR: 1740 (ester), 1450—1430 (C–CH_3); NMR: 4.92 (H_1; d, $J_{1,2}$=4.0), 4.52 (H_4; t, $J_{4,5}$=6.3), 4.02 (H_3; t, $J_{3,4}$=6.4), 3.94 (H_5; d), 3.88 (H_2; q, $J_{2,3}$=6.5), 3.77 (CO_2-CH_3), 3.47, 3.45, and 3.41 ($3\times OCH_3$).

A mixed solution of **7** (100 mg) in *t*-butyl alcohol (0.5 ml) and potassium (30 mg) in *t*-butyl alcohol (0.5 ml) was stood for 30 min at room temperature, neutralized with IR-120 (H^+), and evaporated to give a syrup, which was examined with UV and NMR spectrum, as mentioned in the before section.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1275—1278 (1973)

The Reaction of Nitriles with Phosgene. VII.[1] Synthesis of α,β-Unsaturated Isocyanates

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

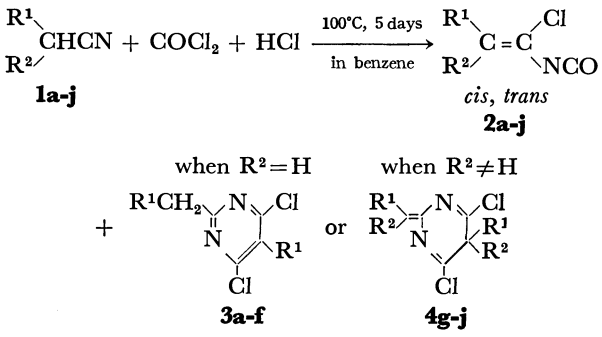
(Received December 5, 1972)

The reaction of nitriles with phosgene in the presence of hydrogen chloride was carried out for synthesizing α,β-unsaturated isocyanates. 3-Chloropropionitrile, 2,3-dichloropropionitrile, isobutyronirtile, and 2-chloromethylpropionitrile gave the corresponding α-chloro-α,β-unsaturated isocyanates in moderate yields (27—50%). Propionitrile, *n*-butyronitrile, and 3-phenylpropionitrile gave the corresponding pyrimidines as the major product. 3-Phenylpropionitrile, however, gave the isocyanate as the major product when the amount of benzene as a solvent increased. Reaction pathways to isocyanates and pyrimidines were discussed.

In a previous paper,[1] we reported a new synthesis of styryl isocyanates from arylacetonitriles with phosgene in the presence of hydrogen chloride. We have extended this isocyanate synthesis to variously substituted nitriles to determine its scope and utility for synthesizing α,β-unsaturated isocyanates.

Results and Discussion

Reactions were carried out at 100°C for 5 days in a 80 ml pyrex tube using benzene as a solvent.[2] A mixture of *cis*- and *trans*-α,β-unsaturated isocyanate **2** was formed along with pyrimidine derivative **3** or **4** (Scheme 1). Results are summarized in Table 1.



Scheme 1.

1,3-Dichloropropenyl isocyanate (**2e**) and 1,2,3-trichloropropenyl isocyanate (**2g**) were isolated by preparative glpc and were characterized by IR, NMR, and mass spectra and elemental analyses. Other isocyanates were characterized, without isolation, by IR and NMR spectra (Table 2). Their IR spectra showed an isocyanate band at 2255—2260 and a C=C stretching band at 1643—1675 cm^{-1}. Since the isocyanates were usually obtained as a mixture of the starting nitriles and benzene, it was difficult to isolate them by simple distillation. Thus, their yields were determined by NMR spectroscopic methods.

Pyrimidine derivatives **3** and **4** were identified by comparison with authentic samples except for **3c**,[3,4] which was identified by IR, NMR, and mass spectra. We reported that most of these pyrimidines were ob-

1) Part VI: M. Ohoka, S. Yanagida, and S. Komori, *J. Org. Chem.*, **36**, 3542 (1971).

2) Although other aromatic solvents such as toluene and chlorobenzene are preferable for the preparation of isocyanates with high boiling points, such high-boiling solvents are not advantageous for the reaction of a low-boiling nitrile, *e.g.* propionitrile. Thus, benzene was used as the solvent in this investigation.

3) S. Yanagida, T. Fujita, M. Ohoka, R. Kumagai, and S. Komori, This Bulletin, **46**, 299 (1973).

4) Since pyrimidine **4h** is very sensitive to moisture and an analytically pure sample was not obtained,[3] it was identified by its IR spectrum.

Table 1. Synthesis of unsaturated isocyanates[a)]

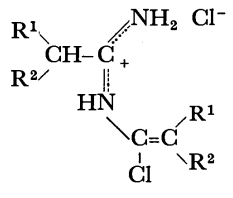
tainable in good yields from the reaction of nitrile-HCl 2:2 adducts **5** with phosgene.[3)]



5

3-Chloropropionitrile (**1e**), 2,3-dichloropropionitrile (**1g**), isobutyronitrile (**1h**), and 2-chloromethylpropionitrile (**1j**) gave expected isocyanates in moderate yields (27→50%). However, propionitrile (**1a**), *n*-butyronitrile (**1b**), and 3-phenylpropionitrile (**1f**, run 6) gave expected isocyanates in low yields together with moderate yields (38—60%) of the corresponding pyrimidines. On the other hand, 3-methylbutyronitrile (**1c**), 3,3-dimethylbutyronitrile (**1d**), and 2-ethylbutyronitrile (**1i**) afforded both isocyanates and pyrimidines in very low yields under most recovery of the starting nitriles.

The effect of reaction time and temperature on the yield of isocyanate **2e** was studied (Figs. 1 and 2). As shown in Fig. 1, the yield of **2e** reached a maximum value (*ca.* 40%) after around 5 days, then it gradually decreased and the amount of a resinous substance increased as the reaction time was prolonged. This indicates the existence of equilibria between isocyanate **2e** and starting materials (Scheme 2). The yield of **2e** increased nearly proportionally to temperature giving a maximum value (*ca.* 40%) at around 100°C and then gradually decreased (Fig. 2). Thus, the reaction is optimum at 100°C and for 5 days.

The possible reaction pathways to isocyanates are shown in Scheme 2. The existence of an equilibrium between imidoyl chloride **6** and α-chloroenamine **7** has been proposed by Simchen.[5,6)] In addition, he and his co-workers postulate that the α-chloroenamine rather

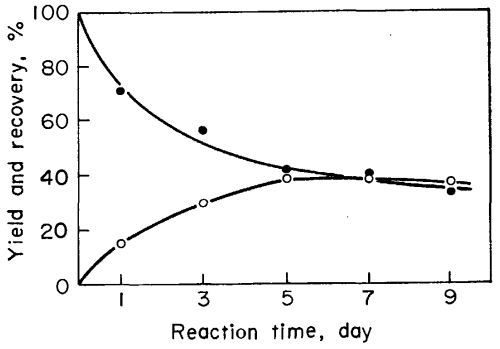


Fig. 1. Effect of reaction time on the yield of isocyanate **2e** and recovery of **1e**: yield of **2e**, ○; recovery of **1e**, ●. Reaction was carried out in 74 ml glass tube. Temperature 100 °C. Amounts of reactants: nitrile **2e** 3.1 g (35 mmol), HCl 0.5 g (14 mmol), $COCl_2$ 9.5 g (96 mmol), benzene 5 ml.

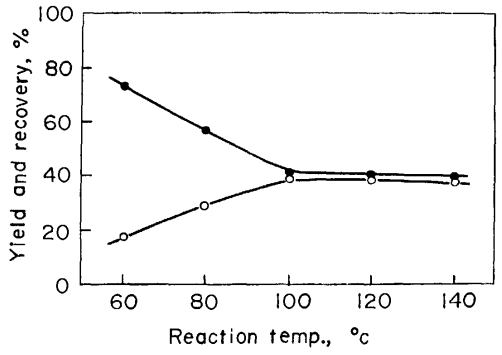

Fig. 2. Effect of reaction temperature on the yield of **2e** and recovery of **1e**: yield of **2e**, ○; recovery of **1e**, ●. Reaction was carried out in 75 ml glass tube. Amounts of reactants are the same as those shown in Fig. 1. Reaction time 5 days.

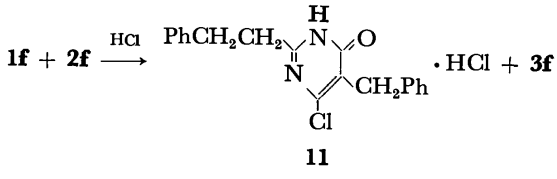
than the imidoyl chloride is acylated in the intramolecular cyclization of nitriles in the presence of hydrogen chloride.[5-7] However, the phosgenation of benzonitrile *via* imidoyl chloride to *N*-(α-chlorobenzylidene)-carbamoyl chloride **10** was found in our laboratory.[8] Therefore, in our case the phosgenation of both **6** and **7** probably takes place to give carbamoyl chlorides **8** and **9** as intermediates.

$$PhCN + COCl_2 \xrightarrow{HCl} PhC(Cl)=NC(=O)Cl$$

10

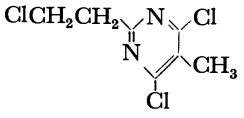
The following two paths (a and b) are possible routes to pyrimidines: path a involves a nitrile-HCl 2:2 adduct **5** as an intermediate and path b involves the secondary reactions of isocyanates. The pyrimidine formation *via* path b has been found in the reaction of α-chloro-*p*-nitrostyryl isocyanate with acetonitrile at 60°C in the presence of hydrogen chloride.[1] To clarify the possibility of path b, reactions of isocyanates **2e** and **2f** with some nitriles were carried out.

When **2f** was treated with **1f** in benzene at 100°C for 84 hr in the presence of hydrogen chloride, pyrimidone hydrochloride **11** was obtained in 39% yield along with pyrimidine **3f** (13%). The latter was apparently produced by chlorination of **11** with phosgene formed by the reverse reaction from **2f** (Scheme 2). This clearly indicates that pyrimidines can be formed *via* path b.



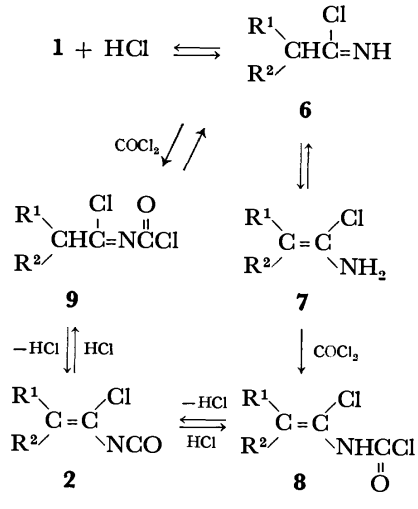
11

On the other hand, the reaction of **2e** with **1e** under similar conditions afforded only pyrimidine **3e** in 13% yield and a trace amount of **2e** was recovered. In addition, the reaction of **2e** with **1a** at 100°C for 3 days in the presence of phosgene and hydrogen chloride did not give **12**, but gave a mixture of **3a** and **3e** (mole ratio 88: 12) and 34% of **2e** was recovered. These facts suggest that the reactivity of isocyanate **2e** toward a nitrile in the presence of hydrogen chloride is lower than that of **2f**.



12

Nitrile-HCl 2:2 adducts **5** have been prepared by the reaction of nitriles with hydrogen chloride at 30—60°C using no solvents.[9] To examine whether **5** can also be formed under the reaction conditions or not, the reaction of **1a** with hydrogen chloride was carried out. The reaction at 100°C for 5 days resulted in the recovery of the starting materials. From these facts, pyrimidines are assumed to be formed mainly *via* path b. Since **5** might be formed as a labile intermediate even at 100°C, the pyrimidine formation *via* path a can not be neglected.



Scheme 2

The yields of isocyanates decreased as the number of β-hydrogens of nitriles decreased by methyl or chlorine substitution (run 3→4, 8→9, 8→10), especially 3,3-dimethylbutyronitrile (**1d**) having no β-hydrogens gave only a trace amount of isocyanate **2d**. This suggests that β-hydrogens stabilize the isocyanates by the hyperconjugation with the C=C bond of the isocyanates and shift the equilibria (Scheme 2) to the side of isocyanates. The stabilization of unsaturated isocyanates by the conjugation with aromatic rings has been observed in the synthesis of styryl isocyanates.[1] Since 2-ethylbutyronitrile (**1i**) has four β-hydrogens, it is expected to give good yield of isocyanate **2i**. However, the yield of **2i** as well as **4i** were low (run 9), indicating that the equilibria shifted to the side of the imidoyl chloride or the starting nitrile. The reason for this shift of the equilibria is not clear at present.

Whereas **1e** gave the isocyanate in good yield, **1a**, **1b**, and **1f** (run 6) gave the corresponding isocyanates in low

7) G. Simchen, *ibid.*, **103**, 389 (1970).

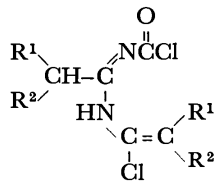
8) S. Yanagida, H. Hayama, M. Yokoe, and S. Komori, *J. Org. Chem.*, **34**, 4125 (1969).

9) S. Yanagida, T. Fujita, M. Ohoka, I. Katagiri, and S. Komori, This Bulletin, **46**, 292 (1973).

yields together with pyrimidines as the major products; this is explained by considering the difference in the reactivity of isocyanates toward nitriles. In the former case only a small amount of **2e** is consumed for the pyrimidine formation *via* path b because of its low reactivity and in the latter cases a considerable amount of the isocyanates is consumed for the pyrimidine formation.

When the amount of benzene as a solvent was increased (run 6→11→12), the yield of pyrimidine **3f** decreased dramatically and that of isocyanate **2f** increased as a result of suppression of path a or b by dilution.

The low yields of pyrimidines in run 7, 8, and 10 are reasonably ascribed to steric hindrance in the formation of **5** (path a) and **13** (path b).



13

As a conclusion, it is essential for obtaining isocyanates exclusively to substitute the nitriles by such substituents that not only stabilize the C=C bond of isocyanates but also suppress both the further reactions of once formed isocyanates and the dimerization of nitriles to **5**, or to dilute the reaction system by a solvent.

Experimental

NMR spectra were obtained using a JNM-G-60 spectrometer (Japan Electron Optics Laboratory Co.) with tetramethylsilane as an internal reference. IR spectra were recorded on a Japan Electronic IR-E spectrophotometer. Mass spectra were recorded on a Hitachi RMU-6E spectrometer. Preparative glpc was carried out with a Yanagimoto G-8 gas chromatograph.

General Procedure. In a 80 ml Pyrex tube was placed 35 mmol of a nitrile and 0.5 g (14 mmol) of anhydrous HCl was dissolved in it; then a solution of 9.5 g (96 mmol) of $COCl_2$ in 5 ml of benzene was added to the mixture. The tube was stoppered, chilled in dry ice–acetone and sealed carefully. It was placed in a 300 ml stainless autoclave containing 70 ml of *n*-hexane and heated at 100°C in an oil bath; *n*-hexane was added to avoid burst of the tube by exerting external pressure. After 5 days the tube was chilled in dry ice–acetone and opened carefully. After $COCl_2$ and HCl were purged, the reaction mixture was distilled at ordinary or under reduced pressure to give a mixture of the objective isocyanate, the starting nitrile, and benzene. The yield of isocyanate and the recovery of nitriles were determined by NMR. Pyrimidines were obtained by distillation or by extraction of the distillation residue of isocyanates with CCl_4.

*Isolation of Pure Isocyanate **2e** and **2g** by Preparative glpc.* Isolation of **2e** and **2g** was carried out using a column (14 mmϕ×150 cm) packed with dioctyl sebacate (7%) on Diasolid L (60—80 mesh) (column temp. 80°C, carrier gas H_2) and a column (14 mmϕ×75 cm) packed with dioctyl sebacate (7%) on Diasolid L (60—80 mesh) (column temp. 100°C, carrier gas H_2), respectively. 1,3-Dichloropropenyl isocyanate (**2e**), IR (liquid film), 2260 (NCO) and 1655 cm^{-1} (C=C); mass spectrum (70 eV) *m/e* (rel. intensity), 151 (17, M^+), 116 (100, M^+–Cl), 88 (8), 63 (38), and 52 (24). (Found: C, 31.62; H, 1.93; N, 9.05%. Calcd for $C_4H_3Cl_2NO$: C, 31.61; H, 1.99; N, 9.23%). 1,2,3-Trichloropropenyl isocyanate (**2g**), IR (liquid film), 2260 (NCO) and 1643 cm^{-1} (C=C); mass spectrum (70 eV) *m/e* (rel. intensity), 185 (23, M^+), 150 (100), 63 (56), and 49 (100). (Found: C, 25.86; H, 1.03; N, 7.79%. Calcd for $C_4H_2Cl_3NO$: C, 25.77; H, 1.03; N, 7.51%).

*4,6-Dichloro-1-isobutyl-5-isopropylpyrimidine (**3c**).* The distillation residue of run 3 was chromatographed on silica gel; *n*-hexane eluted **3c** (colorless liquid), IR (liquid film), 1548, 1500, 1408, 1297, and 800 cm^{-1}; NMR (CCl_4), δ 1.00 (d, 6H, J=6.4 Hz), 1.44 (d, 6H, J=6.8 Hz), 2.05—2.78 (m, 3H), and 3.47 (sep, 1H, J=6.8 Hz); mass spectrum (70 eV) *m/e* (rel. intensity), 246 (15, M^+), 231 (36), 204 (100), and 189 (48).

*Reaction of **2f** with **1f** in the Presence of HCl.* In a 30 ml glass tube was placed a mixture of **2f** (1.1 g, 5.7 mmol) and **1f** (1.4 g, 11 mmol), then anhydrous HCl (0.4 g, 11 mmol) was dissolved in it followed by addition of 2 ml of benzene. The tube was sealed and heated at 100°C for 84 hr. After HCl was purged, the precipitate formed was filtered, washed with a small amount of benzene, and dried *in vacuo* to give tan powder of pyrimid one hydrochloride **11** (0.78 g, 39%), IR (Nujol), 1710 and 1630 cm^{-1}. Its crystallization from EtOH gave colorless fine needles of the free base [6-chloro-5-benzyl-2(2-phenylethyl)-4(3*H*)-pyrimidone], mp 224—225°C, IR (Nujol), 1672 and 1595 cm^{-1}; NMR (CF_3COOH), δ 3.32 (complex, 6H), 4.03 (s, 2H), and 7.24 (m, 10H); mass spectrum (70 eV) *m/e* (rel. intensity), 326 (33, M^++2), 324 (100, M^+), 233 (69), and 91 (71). (Found: C, 70.31; H, 5.31; N, 8.46%. Calcd for $C_{19}H_{17}ClN_2O$: C, 70.26; H, 5.28; N, 8.62%).

The solvent was removed from the filtrate, the residual liquid being distilled under reduced pressure to give 1.1 g of **1f** (contained a trace amount of **2f**). The distillation residue was extracted with CCl_4, the solvent being removed to give **3f** (0.25 g, 13%).

*The Reaction of **2e** with **1e** in the Presence of HCl.* A mixture of **2e** (0.9 g, 5.9 mmol), **1e** (1.1 g, 12 mmol), HCl (0.4 g, 11 mmol), and benzene (2 ml) in a 30 ml glass tube was heated at 100°C for 84 hr. After HCl was purged, the resulting dark precipitate (intractable solid) was filtered off. The solvent was removed from the filtrate and the residual liquid was distilled under reduced pressure to give 0.9 g of **1e** (contained a trace amount of **2e**). The distillation residue was extracted with CCl_4, the solvent being removed under reduced pressure to give a yellow liquid of **3e** (0.2 g, 13%).

*Reaction of **2e** with **1a** in the Presence of $COCl_2$ and HCl.* In a 80 ml Pyrex tube were placed 2.0 g of a mixture of **2e** and **1e** [content of **2e**, 1.8 g (12 mmol)] and 1.3 g (24 mmol) of **1a**, then anhydrous HCl (0.8 g, 23 mmol) was allowed to be absorbed in it followed by addition of a solution of $COCl_2$ (7.2 g, 73 mmol) in 5 ml of benzene. The tube was sealed and heated at 100°C in an oil bath. After 3 days the tube was opened and $COCl_2$ and HCl were purged. The reaction mixture was distilled initially at ordinary pressure to give a mixture of **1a**, **2a**, and benzene, then under reduced pressure to give a mixture of **1e** (0.43 g) and **2e** (0.62 g, 34% recovery). The distillation residue contained 0.98 g of **3a** and 0.17 g of **3e**.

Total Syntheses of Antimycin A_3 and Its Diastereomer

Mitsuhiro KINOSHITA, Shinpei ABURAKI, Masao WADA, and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama, Kanagawa

(Received December 18, 1972)

Natural antimycin A_3 (**1A**) and its diastereomer (**1B**) were synthesized. By the syntheses, the correlations between configurations of the enantiomeric 2-butyl-4-hydroxy-3-isovaleryloxypentanoic acids present in the dilactone moieties of **1A** and **1B**, and those of natural (+)blastmycinone (+)**7a** and its enantiomer (−)**7a** were confirmed. The absolute configuration of **1B** was also determined.

In the recent papers we reported the total syntheses of dehexyl-deisovaleryloxy-antimycin A_1[1] as a prototype of antimycin A, and a diastereomeric mixture of antimycin A_3.[2] This paper presents the total syntheses of natural antimycin A_3 (**1A**) and its diastereomer (**1B**) (Fig. 1).

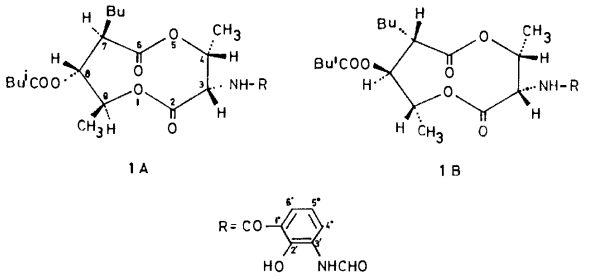


Fig. 1.

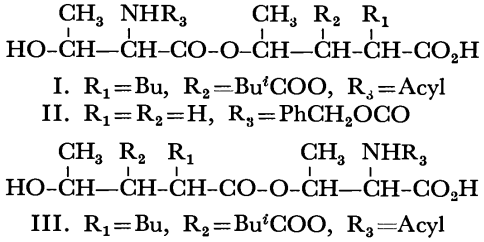
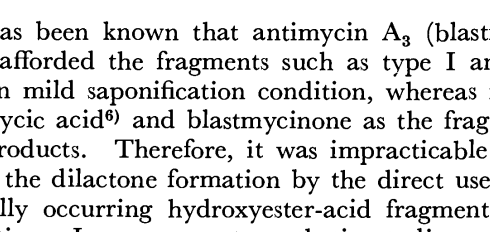
The primary structure of antimycin A_3 (blastmycin[3]) which is one of the major components of antimycin A complex was established by van Tamelen, *et al.*,[4] Birch, *et al.*,[5] and Yonehara, *et al.*[6] The absolute configuration for antimycin A_3 was first proposed by Endo and Yonehara[7] in 1967. In their configurational studies, consideration was given to a correlation between the configurations of blastmycin and optically active blastmycinone[6] obtained by saponification of the parent antibiotic and was based on the fact that lithium aluminum hydride reductions of blastmycin and blastmycinone afforded an almostly homogeneous 2-butylpentane-1,3,4-triol,[5] however, the experimental details were not given.

We were interested in the stereochemistry of the unique nine-membered dilactone ring which exists in antimycin A, and in its role playing in biological activity,[8] and attempted to synthesize the natural antimycin A_3 and its diastereomer. After publication of the preliminary report[9] of this paper, we have proposed the revised absolute configuration **1A** of antimycin A_3.[10]

The first important problem in the total synthesis of natural antimycin A_3 was the construction of the nine-membered dilactone ring having the same configuration as that of the natural product. Such a dilactone compound was considered to be obtainable by a lactonization of either type I or III of hydroxyester-acid which is a condensation product of the two kinds of hydroxy acid, *i.e.*, *N*-acyl-L-threonine and 2-butyl-4-hydroxy-3-isovaleryloxypentanoic acid possessing the same configuration as that of the corresponding moiety which exists in the molecule of antimycin A_3.



I. R_1=Bu, R_2=Bu^{t}COO, R_3=Acyl
II. R_1=R_2=H, R_3=$PhCH_2OCO$



III. R_1=Bu, R_2=Bu^{t}COO, R_3=Acyl

It has been known that antimycin A_3 (blastmycin) never afforded the fragments such as type I and III, even in mild saponification condition, whereas it gave blastmycic acid[6] and blastmycinone as the fragmentation products. Therefore, it was impracticable to examine the dilactone formation by the direct use of the naturally occurring hydroxyester-acid fragment or its derivative. In our recent synthetic studies on antimycins,[1,2] it has already been found that the lactonizations of the synthetic diastereomeric mixtures of the hydroxyester-acid, II and I (R_3=$PhCH_2OCO$), by heating with trifluoroacetic anhydride in benzene afforded the corresponding dilactone compounds in 33 and 6% yields, respectively, only this reagent and reaction condition being effective for these lactonizations. In such a lactonization reaction, the hydroxyester-acids of type I have been considered to be more favorable substrates rather than those of type III, because the absence of free terminal carboxyl group

in the *N*-acyl-L-threonine moiety of I will minimize any danger of the racemization which otherwise as in the case of III, may be caused on the α-carbon atom of the *N*-acylated amino acid unit by the activation of its carboxyl group with trifluoroacetic anhydride at higher temperature, even if α-amino group is protected by an urethan type acyl group such as benzyloxycarbonyl.

The next problem was the synthesis of the natural type of racemic diastereomer of 2-butyl-4-hydroxy-3-isovaleryloxypentanoic acid *t*-butyl ester, which was a useful intermediate for the synthesis of the hydroxy-ester-acids of type I. Of the four racemic diastereomers (**6a**—**6d**) which were prepared by the following synthetic route (Chart 1), the major isomer **6a** was the most promising intermediate, because it could be converted to the natural type (±) blastmycinone **7a**.

The starting material 2-benzyloxypropanal **2** was prepared from methyl 2-benzyloxypropanoate by reduction with diisobutylaluminum hydride.[11] The condensation of this compound with *t*-butyl 2-bromohexanoate **3** was effected smoothly by a modified Reformatsky reaction according to Moriwake[12] using magnesium instead of zinc to yield a mixture of four possible racemic diastereomers of *t*-butyl 4-benzyloxy-2-butyl-3-hydroxypentanoate (**4a**, **4b**, **4c**, and **4d**).

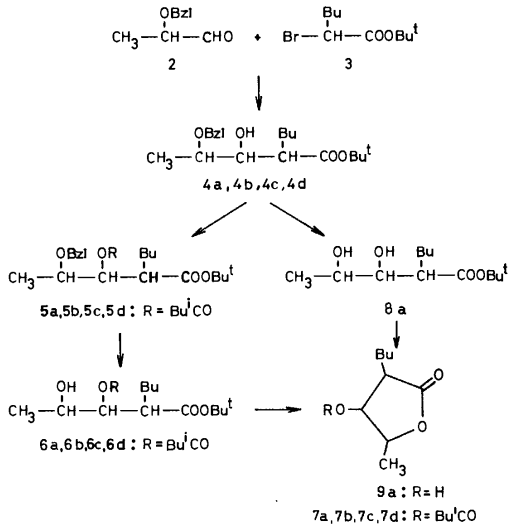

Chart 1.

Preparative isolation of these diastereomers was performed by silica gel column chromatography of the reaction product to give a mixture **4a**+**4b**, **4c**, and **4d** in yields of 43, 12.4, and 6.8% based on **2**, respectively. Repeated column chromatography of fractions containing **4a** and **4b** afforded in a small quantity a homogeneous sample of **4a** and a sample of **4b** contaminated by a trace of **4a**. The samples of **4a** and **4b** showed very similar R_f-values on tlc with several kinds of solvent system, however, their PMR spectra apparently differed in the chemical shifts of *t*-butyl and terminal methyl protons, and this difference was useful for inspection of homogeneity of these diastereomers. Since the preparative separation of **4a** from **4b** by column chromatography was impracticable in this stage, the diastereomeric separation had to be carried over to the next synthetic step.

The mixture **4a**+**4b** obtained above was treated with isovaleric anhydride in pyridine to afford a diastereomeric mixture of *t*-butyl 4-benzyloxy-2-butyl-3-isovaleryloxypentanoate **5a**+**5b**. Column chromatographic separation of the diastereomers was effectively carried out to give **5a** (75%) and **5b** (17%) in homogeneous states, which were identical with the *O*-isovalerylation products derived from the isolated samples of **4a** and **4b**, respectively. These results indicated that the above-mentioned Reformatsky reaction yielded the major diastereomer **4a** with a 56% stereoselectivity.

By the same way other diastereomers, **5c** and **5d** were obtained from **4c** and **4d**, respectively. The four diastereomers, **5a**, **5b**, **5c**, and **5d** were hydrogenolysed over palladium black to afford the corresponding diastereomeric *t*-butyl 2-butyl-4-hydroxy-3-isovaleryloxypentanoates, **6a**, **6b**, **6c**, and **6d**, respectively. In order to determine which diastereomer of the four (**6a**—**6d**) is the objective type of racemic 4-hydroxy-ester, they were converted to the corresponding stable 1,4-lactones, **7a**, **7b**, **7c**, and **7d** by treatment with 5N hydrogen chlorde in dioxane. The resulted structurally homogeneous diastereomeric lactones were readily distinguished by tlc and PMR. From comparison of these lactones with natural antimycin lactone based on tlc, glc, and PMR, it was concluded that the lactone **7a** derived from the major diastereomer **6a** was fortunately the natural type of racemic diastereomer, (±)blastmycinone.

The comparison was first carried out by tlc. The thin-layer chromatogram of natural antimycin lactone obtained from antimycin A complex with a solvent system petroleum ether–diisopropyl ether (7:4) showed a single spot having the same R_f-value as that of **7a**. The comparison by glc was somewhat complicated. The gas chromatogram of **7a** on a polyester succinate column showed a single peak having the same elution time as that of the major peak of natural blastmycinone, which was found in a gas chromatogram of the antimycin lactone. Recently, Yonehara, *et al.*[13] demonstrated by glc that natural blastmycinone is not homogeneous, but it consists of two isomers differing in the structure of the *O*-alkanoyl group. Consequently, our result could confirm that, in the gas chromatogram, the synthetic lactone **7a** shows the same peak with one of the two peaks of so-called blastmycinone and that the peak having longer retention time between the two, corresponds to the blastmycinone possessing isovaleryl group.

The chemical shifts and coupling constants of ring protons, ring methyl and 3-*O*-isovaleryl methyl protons of **7a** were identical with those of natural blastmycinone[14] and antimycin lactone, however, the PMR spectrum in $CDCl_3$ of **7a** showed no doublet at δ 1.15 present in that of the natural lactone. This signal may

14) The PMR chart was kindly provided by Prof. H. Yonehara.

be ascribed to the methyl protons of isomeric alkanoyl group in the blastmycinone subcomponent showing the glc peak of shorter retention time. This PMR observation was consisted with the above-mentioned result based on glc. Furthermore, it was confirmed that all the antimycin lactones obtained from antimycin A complex had the same stereochemistry in respect of their lactone rings.

The above stated structural relationship between **7a** and **4a** was also confirmed by an alternative route *via* (±)blastmycinolactol **9a**. Hydrogenolysis of **4a** over palladium black gave *t*-butyl 2-butyl-3,4-dihydroxypentanoate **8a**, which was treated with trifluoroacetic acid. The resulting crystalline hydroxylactone **9a** was *O*-isovalerylated with isovaleric anhydride in pyridine to afford a structurally homogeneous sample of (±)-blastmycinone **7a**. This synthetic route was applied in the syntheses of optically active (+)blastmycinone (+)**7a** and its enantiomer (−)**7a**.

The freshly prepared 4-hydroxyester **6a** was allowed to react with execss amount of *N*-benzyloxycarbonyl-*O*-*t*-butyl-L-threonine in the presence of dicyclohexylcarbodiimide (DCCI) and pyridine at 0°C, to afford a mixture of diastereomeric masked hydroxyester-acids (type I), which was chromatographed on a silica gel column to give optically active homogeneous diastereomers (+)**10A** and (−)**10B** in 29 and 27.7% yields based on **6a**, respectively. It is noteworthy that this step is substantially an optical resolution of the racemic 4-hydroxyester **6a**.

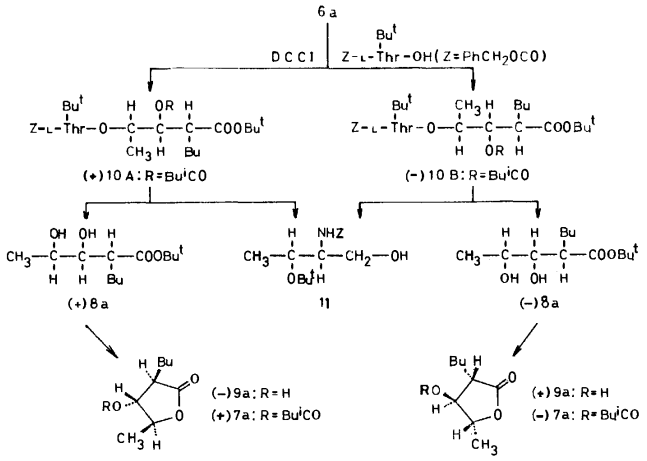

Chart 2.

The configurational assignments of the resolved hydroxyesters present in (+)**10A** and (−)**10B** were undertaken by the following procedure (Chart 2). Selective reduction of (+)**10A** with lithium aluminum hydride at −40°C afforded optically active *t*-butyl (+) 2-butyl-3,4-dihydroxypentanoate (+)**8a** (47.5%) and (−)2-benzyloxycarboxamido-3-*t*-butoxy-1-butanol **11**. De-*t*-butylation of (+)**8a** by the same manner as that of **8a** yielded crystalline (−)blastmycinolactol (−)**9a** with an optical rotation of $[\alpha]_D^{MeOH}$ −18°. Although the rotation of the synthetic specimen was considerably higher than the reported rotation of $[\alpha]_D^{MeOH}$ −5.21° for natural (−)blastmycinolactol[6] obtained from natural (+)blastmycinone, the IR spectrum of (−)**9a** in nujol was very similar to that of natural product.[6] *O*-Isovalerylation of (−)**9a** by the same manner as that of **9a** afforded (+)blastmycinone (+)**7a** with a rotation of $[\alpha]_D^{Chf}$ +10° similar to natural (+)blastmycinone.[6] The PMR spectrum of (+)**7a** was indistinguishable from that of (±)blastmycinone **7a**.

In the same procedure the lithium aluminum hydride reduction of (−)**10B** afforded the enantiomeric dihydroxyester (−)**8a**, from which the corresponding enantiomeric (+)blastmycinolactol (+)**9a** and (−)-blastmycinone (−)**7a** were derived successively.

Recently, we reported in a communication to the editor[10] the absolute configurations of natural (−)-blastmycinolactol and (+)blastmycinone as 2(*R*), 3(*R*), 4(*S*) on the basis of ORD, CD, PMR and through a stereospecific synthesis of the enantiomer (+)**9a** (Chart 2). From these results it was elucidated that (+)**10A** contained an enantiomer of **6a** which had the configuration 2(*R*), 3(*R*), 4(*S*) identical with that of naturally occurring blastmycinone, and that the related racemic diastereomers, **8a**, **6a**, **5a**, and **4a** had a 2,3-*threo*-3,4-*erythro* configuration.

De-*t*-butylation of (+)**10A** with trifluoroacetic acid afforded the desired hydroxyester-acid (type-I, R_3= benzyloxycarbonyl) which was immediately subjected to lactonization. A 0.04M benzene solution of the hydroxyester-acid was heated with about one molar equivalent trifluoroacetic anhydride at 65—70°C for 4 hr. To this mixture additional about one molar trifluoroacetic anhydride was added and was heated at the same temperature for 6 hr. The reaction mixture was immediately evaporated and the residue was chromatographed on a silica gel column to separate fractions containing dilactone compound **12A**. Purification of the crude product by column chromatography afforded **12A** as needles in a 0.8% yield based on (+)**10A**. The compound **12A** was confirmed to be a structurally homogeneous dilactone derivative by elemental analysis, molecular weight determination by mass spectrometry, IR and PMR spectra (Table 1). In this lactonization reaction no other kinds of HBr-ninhydrin positive lactonization product were detected and prolonged heating of the reaction mixture gave rise to a decomposition of **12A** accompanied by rapid formation of some HBr-ninhydrin negative by-products. Attempts to improve the yield of **12A** by use of other kinds of solvent or by changing the quantity of trifluoroacetic anhydride and the reaction temperature were unsuccessful.

On the other hand, the lactonization reaction of the diastereomeric hydroxyester-acid obtained from (−)-

a) Assignment verified by spin decoupling.
b) Splittings were verified by the spectrum of *ca.* 7% solution.

10B was carried out in the condition similar to that described above with exception of the prolonged reaction time (21 hr) to afford a dilactone compound **12B** as needles in a 3.1% yield. Elemental analysis, molecular weight determination, IR and PMR spectra showed **12B** to be a homogeneous diastereomer of **12A**. In this lactonization reaction, no HBr-ninhydrin positive lactones other than **12B** were also detected, however, the formation of two isomeric lactones, (−)**7a** and (−)**7b** as HBr-ninhydrin negative by-products, was found and they were isolated and characterized by tlc, PMR, and optical rotations.

The benzyloxycarbonyl group of **12A** was removed by catalytic hydrogenolysis and the resulting free amino dilactone **13A** was *N*-acylated with *O*-benzyl-3-nitrosalicylic acid *N*-hydroxysuccinimide ester.[1] The product **14A** (65% yield based on **12A**) was then hydrogenolyzed on palladium black and, finally, *N*-formylated with formic acid and DCCI. The final product was isolated by preparative layer chromatography (plc) and purified by recrystallization to afford antimycin A_3 (**1A**) as needles in a 27.3% yield based on **12A**.

The synthetic specimen showed mp 174.0—174.5°C and $[\alpha]_D^{Chf}$ +80°, which were identical with the reported values for the natural antimycin A_3.[15] The mass spectrum of **12A** showed a single molecular ion peak at *m/e* 520. The UV absorptions in methanol and IR absorptions in carbon tetrachloride assignable to lactone carbonyl, formamido and aromatic amido groups were also indistinguishable from those observed in the corresponding spectra of an authentic antimycin A complex.[16] The 100 MHz PMR spectrum of *ca.* 3% deuteriochloroform solution of the synthetic specimen measured in a micro cell was very similar to that of a 3% solution of the authentic sample in a standard cell as shown in Table 1.

Inspection of the 100 MHz PMR spectra in deuteriochloroform and deuteriobenzene of the authentic antimycin A complex revealed that all the antimycin components had the same stereochemistry in respect of their dilactone rings. In view of these points, we came to the conclusion that the synthetic antimycin A_3 had the same ring configuration and conformation as those of natural antimycin A. Through this synthesis of antimycin A_3, it has been confirmed that naturally occurring antimycin A_3 retained in its dilactone structure, the same configuration of (+)blastmycinone derived from the parent antibiotic.

De-*N*-benzyloxycarbonylation of (−)**12B** afforded the free amino dilactone **13B** accompanied by (−)-

15) K. Uzu, H. Kato, K. Kumabe, and H. Harada, *J. Antibiot., Ser. A*, **14**, 205 (1961).

16) The sample of antimycin A complex was generously supplied by the Kyowa Hakko Kogyo Co.: mp 139.0—139.5°C; $[\alpha]_D^{24}$ +80° (*c* 0.4, chloroform); molecular ions of the components at *m/e* (relaitve intensities), 562 (1), 548 (12), 534 (7), 520 (16), 506 (2), and 492 (2).

blastmycinone(−)**7a**, which was considered to be resulted by a spontaneous fragmentation (self-saponification) of **13B**. The reaction product was immediately *N*-acylated to give *N*-(*O*-benzyl-3-nitro) salicyloyl derivative **14B** (24%) and (−)**7a** (24%). The low yield of **14B** may be accounted for by the degradation of **13B** which proceeded parallel to the *N*-acylation reaction.

Preparation of **1B** from **14B** was smoothly carried out by the same procedure as that of **1A** from **14A** to afford the antimycin A_3 diastereomer **1B** with $[\alpha]_D^{Chf}$ −5° as a glassy solid in a 83% yield. The UV spectrum of **1B** was identical with that of **1A**, however, the IR spectrum of **1B** in carbon tetrachloride showed two lactone carbonyl bands at 1758 and 1735 cm^{-1}, instead of single band at 1756 cm^{-1} in that of **1A**. The PMR spectrum of *ca.* 5% deuteriochloroform solution of **1B** considerably differed from that of **1A**, especially, in the chemical shifts of ring protons (H-3, H-4), ring methyl protons (4-CH_3) and aromatic amide proton (3-NH) (Table 1).

The PMR spectra data tabulated in Table 1 indicated that such chracteristic differences between the spectra of **1A** and **1B** were also observed between those of other natural and unnatural types of dilactone derivatives, **12A**—**12B** and **14A**—**14B**. Therefore, this observation shows that the configurations and conformations of both types of dilactone compounds may be closely reflected on their PMR spectra.

We have already proposed the absolute configuration of antimycin A_3 as **1A**[10] based on the abovementioned configurational correlation between antimycin A_3 and natural (+)blastmycinone whose absolute configuration had independently been determined as (+)**7a**. In a similar manner the absolute configuration of the synthetic diastereomer of antimycin A_3 which was correlated to the enantiomeric (−)blastmycinone (−)**7a** should be determined as **1B**.

On paper chromatography with the solvent system water-ethanol-acetone (7:2:1)[17] which was generally used for detection of antimycin A components, both synthetic specimens of antimycin A_3 and its diastereomer showed, on the bioautogram (test organism, *Piricularia orizae*), the single spot corresponding to that of the natural antimycin A_3 in the antimycin complex.

Table 2. MIC(mcg/ml) of synthetic antimycin A_3(**1A**), natural antimycin A complex and synthetic diastereomer (**1B**)

Organisms	1 A	Natural antimycin A	1 B
Candida albicans 3147	12.5	12.5	>25
Candida krusei	50	50	>25
Trichophyton asteroides 429	50	50	>25
Trichophyton mentagrophytes 833	50	50	25
Piricularia oryzae	0.025	0.025	3.12
Pellicularia filamentosa (Sasaki)	25	25	25

Medium: 1% Glucose nutrient agar, 27°C.

Minimal inhibitory concentrations (MIC) of the synthetic specimens **1A** and **1B** and natural antimycin A complex were summarized in Table 2.

Experimental

Melting points were determined on a micro hot stage and are uncorrected unless otherwise noted. UV spectra were taken on a Hitachi Perkin-Elmer UV-VIS spectrometer 139 and IR spectra on a Hitachi IPI-2 spectrometer. PMR spectra were recorded on Varian A-60D and HA-100D spectrometers using TMS as an internal standard. Optical rotations were measured with a Zeiss Photoelectric Precision Polarimeter. Tlc was carried out on WAKOGEL B-5 (Wako Pure Chemical Industries, Ltd.) and silica gel column chromatography on WAKOGEL C-200 which was activated at 110°C for 1 hr. The following solvent systems were used: (A) petroleum ether–diisopropyl ether (IPE) (3:1), (B) hexane–butanone–acetone (20:1:1), (C) hexane–IPE (10:1), (D) benzene–acetone (20:1), (E) benzene–IPE (7:1), (F) petroleum ether–IPE (7:4), (G) benzene–ethyl actate (3:2), (H) petroleum ether–IPE (2:1), (I) benzene–acetone (10:1), (J) ibid. (15:1), (K) hexane–acetone (3:1), (L) hexane–ethyl acetate (3:1), and (M) ibid. (5:3). In general, all concentrations were carried out at reduced pressure below 40°C.

1) Methyl 2-Benzyloxypropanoate. 2-Benzyloxypropanoic acid[18] was treated with methanol and concd H_2SO_4 in a usual manner to obtain the ester in a 82% yield, bp 96—98°C/4.5 Torr, $n_D^{23.7}$ 1.4942.

Found: C, 68.36; H, 7.42%. Calcd for $C_{11}H_{14}O_3$: C, 68.03; H, 7.27%.

2) 2-Benzyloxypropanal (2). A solution of methyl 2-benzyloxypropanoate (7.0 g, 36.1 mmol) in hexane (131 ml) was cooled to −50°C and diisobutylaluminum hydride[19] (6.25 g, 44.0 mmol) was added under dry nitrogen. The solution was ketp at −50°C for 2.5 hr before saturated sodium bisulfite solution (200 ml) was added. The mixture was allowed to warm to room temperature and the layers were separated. The hexane layer was extracted several times with saturated sodium bisulfite solution (total 1.8 l). The combined aqueous layers were washed three times with 200 ml-portions of ether to remove a small amount of 2-benzyloxypropanol and then basified with 4N NaOH to pH 11 with cooling. The separated aldehyde was extracted with ether. The ether extract was washed with saturated NaCl sloution, dried over Na_2SO_4 and evaporated to give 5.21 g (88%) of **2** as a colorless oil; ν_{max}^{liq} 1735 cm^{-1} (CHO).

2,4-Dinitrophenylhydrazone of 2: Mp 112—113°C (methanol)

Found: C, 56.06; H, 4.92; N, 16.09%. Calcd for $C_{16}H_{14}O_5N_4$: C, 55.81; H, 4.68; N, 16.27%.

3) t-Butyl 2-Bromohexanoate (3). 2-Bromohexanoic acid was treated with isobutene and catalytic amount of concd H_2SO_4 in usual way to afford a fraction of **3** boiling at 63—67°C/2.5 Torr in a 77% yield. Analytical sample was obtained by silica gel column chromatography of the product with hexane: bp 73.0—74.5°C (bath temp.)/6 Torr; n_D^{25} 1.4452.

Found: C, 48.01; H, 7.69; Br, 31.86%. Calcd for $C_{10}H_{19}O_2Br$: C, 47.82; H, 7.63; Br, 31.82%.

4) t-Butyl 4-Benzyloxy-2-butyl-3-hydroxypentanoate (4).

(a) Modified Reformatsky Reaction of 2 and 3: Fresh magnesium shavings (1.35 g, 55.5 mmol) were covered with dry

17) W. C. Liu and F. M. Strong, *J. Amer. Chem. Soc.*, **81**, 4387 (1959).

18) L. Feldmann and H. O. L. Fischer, *Arch. Biochem.*, **14**, 117 (1947).

19) A 25% (W/V) solution of diisobutylaluminum hydride in hexane (Mitsuwa's Pure Chemicals) was used.

ether (22 ml) and they were activated by addition of few drops of methyl iodide. When the activation reaction had started, a solution of **2**[20] (5.7 g, 34.8 mmol) and **3** (9.3 g, 37.0 mmol) in dry ether (32 ml) was added under stirring at such a rate that the mixture refluxed gently. After stirring and refluxing for additional 2.5 hr in a water bath, the reaction mixture was cooled with ice-salt bath and decomposed with a mixture of cold 10% H_2SO_4 (54 ml) and crushed ice (15 g). The ether layer was washed with 5% $NaHCO_3$ and saturated NaCl solution and evaporated. The oily residue was dissolved in hexane (140 ml) and the solution was washed with saturated sodium bisulfite solution to remove unchanged **2**. The hexane layer was washed with saturated NaCl solution, dried and evaporated to afford a viscous oil (11.1 g) containing four diastereomers (**4a**, **4b**, **4c**, and **4d**) of title compound **4**.

(b) Preparative Separation of the Diastereomers of 4: The product (11.1 g) obtained in (a) was chromatographed on a silica gel column (2.20 kg, 8.0×79 cm) with the solvent system A to give four main fractions which were evaporated. The fraction 1 (R_f 0.40 A, 1.36 g) was purified by a silica gel column (270 g) with the solvent system B to afford a homogeneous diastereomer **4c** (1.23 g): bp 105—107°C (bath temp.)/0.001 Torr; R_f 0.40 A; $\nu_{max}^{CCl_4}$ (0.01M) 3500 (OH), 1725 and 1705 cm^{-1} (ester); δ ($CDCl_3$) 1.44 (s, Bu^t), 1.26 (d, 4-CH_3, J_{4,CH_3}=5.8 Hz).

Found: C, 71.35; H, 9.44%. Calcd for $C_{20}H_{32}O_4$: C, 71.39; H, 9.59%.

Additional sample of **4c** (0.23 g) was obtained by chromatographic separation of the fraction 2 (vide infra) and total yield of **4c** amounted to 1.46 g (12.4% based on **2**).

The fraction 2 (R_f 0.40 and 0.34 A, 1.14 g) was separated into two fractions by a silica gel column (230 g) with the solvent system A. The first fraction (R_f 0.40 A) gave **4c** (0.23 g) and the second one (R_f 0.34 A) afforded the product (0.77 g) which was shown to be a mixture of diastereomers **4a** and **4b** by inspection of its PMR spectrum, similar to the following fraction 3.

The fraction 3 (R_f 0.34 A) gave the product (4.33 g) which consisted of major diastereomer **4a** contaminated by minor diastereomer **4b**: δ ($CDCl_3$) 1.41 and 1.44 (s, Bu^t), 1.24 and 1.26 (d, 4-CH_3). Microanalysis of a micro distillated sample agreed with the molecular formula $C_{20}H_{32}O_4$ (Found: C, 71.44; H, 9.61%). The total yield of **4a** accompanied by **4b** thus amounted to 5.10 g (43% based on **2**). The content of **4a** in the combined products may be estimated to be *ca.* 83% on the basis of the result of Exp. 5(a).

The fraction 4 (R_f 0.23 A (main spot), 2.03 g) was purified by a silica gel column (400 g) with the solvent system B to give a homogeneous isomer **4d** (0.80 g, 6.8% based on **2**): bp 120—123°C (bath temp.)/0.005 Torr; R_f 0.23 A; $\nu_{max}^{CCl_4}$ (0.01M) 3570, 3470 (OH), 1735 and 1715 cm^{-1} (ester); δ ($CDCl_3$) 1.24 (d, 4-CH_3, J_{4,CH_3}=6.1 Hz) and 1.43 (s, Bu^t).

Found: C, 71.56; H, 9.48%. Calcd for $C_{20}H_{32}O_4$: C, 71.39; H, 9.59%.

(c) Isolation of the Major Diastereomer 4a: The Reformatsky reaction product (15.0 g) was subjected to silica gel column chromatography (1.5 kg, solvent system A) and the eluted fractions showing R_f 0.34 A were inspected by PMR and the fractions containing homogeneous **4a** were collected and evaporated: yield 1.55 g; bp 108—113°C (bath temp.)/0.001 Torr; R_f 0.34 A; $\nu_{max}^{CCl_4}$ (0.01M) 3590 (OH), 1725 and 1710 cm^{-1} (ester); δ($CDCl_3$) 1.24 (d, 4-CH_3, J_{4,CH_3}=6.0 Hz), 1.41 (s, Bu^t), 2.47 (m, H-2), 3.52 (dq, H-4, $J_{3,4}$=4.7 Hz), and 3.89 (dd, H-3, $J_{2,3}$=6.8 Hz).

Found: C, 71.46; H, 9.65%. Calcd for $C_{20}H_{32}O_4$: C, 71.39; H, 9.59%.

(d) Isolation of 4b: Repeated column chromatography (solvent system A) of several fractions which contained the products showing R_f 0.40 and 0.34 A (main spot) in the experiment 4(c) afforded a small amount of the fraction consisting almostly of the isomer **4b**. Although the PMR spectrum of this sample of **4b** revealed that it was still contaminated by a trace of **4a**, the main PMR signals corresponding to **4b** itself was observed therein as followed; δ ($CDCl_3$) 1.26 (d, 4-CH_3, J_{4,CH_3}=6.3 Hz), 1.43 (s, Bu^t), and 3.40—3.80 (m, overlapped 3-H and 4-H).

5) t-Butyl 4-Benzyloxy-2-butyl-3-isovaleryloxypentanoate (5a and 5b). *(a)*: A sample (1.86 g, 5.53 mmol) of the total mixture of **4a** and **4b** obtained in the experiment 4(b) was dissolved in dry pyridine (24 ml) and to this a solution of isovaleric anhydride (2.06 g, 11.0 mmol) in pyridine (12 ml) was added. After standing this mixture for 24 hr at room temperature, an additional isovaleric anhydride (1.03 g in 2 ml of pyridine) was added and kept for 48 hr in the same temperature. The reaction mixture was partitioned between water and ether and the aqueous layer was extracted with ether. The combined organic layers were washed with aqueous 10% citric acid, 5% $NaHCO_3$ and saturated NaCl solutions, successively. The dried ether solution was evaporated and the residue (2.33 g) was chromatographed on a silica gel column (240 g, 3.4×45 cm) with the solvent system C to afford three fractions which were inspected by tlc (system C). The first fraction (R_f 0.43C) gave the homogeneous isomer **5a** (1.42 g, 61.5%) corresponding to **4a**. Additional **5a** (0.31 g) was obtained by column chromatography (silica gel 60 g, solvent system C) of the second fraction (0.40 g) which consisted of **5a** contaminated by a trace of **5b**. Total yield of **5a** was 1.73 g (75%). This sample (190 mg) was again chromatographed on silica gel (19 g) with the solvent system D and the fraction of **5a** (125 mg) was subjected to micro distillation to afford an analytical sample of **5a**: bp 105—119°C (bath temp.)/0.002 Torr; R_f 0.43C; δ($CDCl_3$) 1.21 (d, 4-CH_3, J_{4,CH_3}=6.4 Hz), 1.38 (s, Bu^t), 2.55 (m, H-2), 3.58 (dq, H-4, $J_{3,4}$=4.0 Hz), and 5.44 (dd, H-3, $J_{2,3}$=8.2 Hz).

Found: C, 71.56; H, 9.69%. Calcd for $C_{25}H_{40}O_5$: C, 71.39; H, 9.59%.

The third fraction (R_f 0.37C) gave the diastereomer **5b** (0.39 g, 16.9%) corresponding to **4b** in a homogeneous state. Rechromatography of this sample using the solvent system C followed by micro distillation afforded an analytical sample of **5b**: bp 155—158°C (bath temp.)/0.04 Torr; R_f 0.37C; δ($CDCl_3$) 1.16 (d, 4-CH_3, J_{4,CH_3}=6.3 Hz), 1.42 (s, Bu^t), 3.73 (dq, H-4, $J_{3,4}$=3.2 Hz), and 5.27 (dd, H-3, $J_{2,3}$=9.1 Hz).

Found: C, 71.59; H, 9.70%. Calcd for $C_{25}H_{40}O_5$: C, 71.39; H, 9.59%.

(b): A sample (1.39 g) of **4a** isolated in the experiment 4(c) was *O*-isovalerylated by the same procedure as mentioned above to give a homogeneous sample of **5a** (1.45 g, 84%).

(c): A sample of **4b** in the experiment 4(d) was also *O*-isovalerylated and purified through a silica gel column to afford a homogeneous sample of **5b** in a 83% yield.

6) t-Butyl 4-Benzyloxy-2-butyl-3-isovaleryloxypentanoate (5c and 5d). *O*-Isovalerylations of **4c** and **4d** were performed by the same procedure as described in the experiment 5 to give the corresponding **5c** and **5d** in good yields, respectively. **5c**: bp 140—142°C (bath temp.)/0.01 Torr; δ($CDCl_3$) 1.18 (d, 4-CH_3, J_{4,CH_3}=6.2 Hz), 1.45 (s, Bu^t), 3.73 (dq,

20) The product **2** obtained in Exp. 2 was thoroughly dried under highly reduced pressure (0.001 Torr) at room temperature before use.

H-4, $J_{3,4}$=5.2 Hz), and 5.34 (dd, H-3, $J_{2,3}$=6.5 Hz).

Found: C, 71.57; H, 9.75%. Calcd for $C_{25}H_{40}O_5$: C, 71.39; H, 9.59%.

5d: bp 126—132°C (bath temp.)/0.002 Torr; $\delta(CDCl_3)$ 1.20 (d, 4-CH_3, $J_{4,CH3}$=6.5 Hz), 1.42 (s, Bu^t), 3.73 (dq, H-4, $J_{3,4}$=4.0 Hz), and 5.20 (dd, H-3, $J_{2,3}$=8.5 Hz).

Found: C, 71.10; H, 9.73%. Calcd for $C_{25}H_{40}O_5$: C, 71.39; H, 5.59%.

*7) t-Butyl 2-Butyl-4-hydroxy-3-isovaleryloxypentanoate (**6a**, **6b**, **6c**, and **6d**).* To a solution of **5a** (2.60 g) in methanol (65 ml) was added freshly prepared palladium black (*ca.* 800 mg) and the mixture was vibrated for 1 hr under bubbling with hydrogen. Completion of the hydrogenolysis was confirmed by tlc (solvent system E). The filtered solution was evaporated to give **6a** (1.98 g, 97%) as a colorless oil: ν_{max}^{liq} 3460 (OH) and 1730 cm^{-1} (ester); $\delta(CDCl_3)$ 1.18 (d, 4-CH_3, J_{4,CH_3}=6.5 Hz), 1.45 (s, Bu^t), 3.89 (dq, H-4, $J_{3,4}$=5.0 Hz), and 5.10 (dd, H-3, $J_{2,3}$=7.8 Hz).

By the same procedure, the diastereomers, **6b**, **6c**, and **6d** were also obtained from the corresponding diastereomers, **5b**, **5c**, and **5d** in a yield of 56,[21] 86,[21] and 96%, respectively. The products, **6a**, **6b**, **6c**, and **6d** were immediately used for the subsequent syntheses without further purifications, because their instability for silica gel chromatography or distillation.

*8) 2-Butyl-4-hydroxy-3-isovaleryloxypentanoic Acid-1, 4-Lactone [(±)Blastmycinone] (**7a**).* *(a)*: A sample (41.2 mg) of **6a** was dissolved in 0.08 ml of 5N HCl in dry dioxane and the solution was allowed to stand for 1 hr at room temperature. The reaction mixture was evaporated to afford **7a** (28.8 mg, 90%) as a colorless oil: bp 125—130°C (bath temp.)/8 Torr; R_f 0.66F; glc (polyester succinate on Shimalite 80—100 mesh, 190°C, He gas 125 ml/min) retention time (min) 7.8; $\nu_{max}^{CCl_4}$ 1782 (1,4-lactone) and 1754 cm^{-1} (ester); $\delta(CDCl_3)$ 1.45 (d, 4-CH_3, J_{4,CH_3}=6.5 Hz), 2.69 (m, H-2), 4.37 (dq, H-4, $J_{3,4}$=4.5 Hz), and 4.95 (dd, H-3, $J_{2,3}$=5.8Hz).

Found: C, 65.40; H, 9.16%. Calcd for $C_{14}H_{24}O_4$: C, 65.59; H, 9.44%.

(b): To a solution of (±)blastmycinolactol **9a** (9.7 mg) in dry pyridine (0.76 ml) was added isovaleric anhydride (0.04 ml). The mixture was kept at room temperature for 40 hr. The reaction mixture was partitioned between water and petroleum ether. The aqueous layer was extracted with petroleum ether and the combined organic layers were washed with aqueous 10% citric acid, 5% $NaHCO_3$ and saturated NaCl solution, successively. The dried solution was evaporated and the residue (14 mg) was purified through a silica gel column (2 g) with the solvent system F to give a sample of **7a** (7 mg, 50%), which was identified to the specimen of **7a** obtained in Exp. 8(a) by tlc, glc, and PMR criteria.

*9) Diastereomers, **7b**, **7c**, and **7d** of (±)Blastmycinone **7a**.* Samples of **6b**, **6c**, and **6d** were treated with 5N HCl in dioxane [Exp. 8(a)] to afford the corresponding diastereomeric lactones, **7b**, **7c**, and **7d**, in a yield of 91, 77, and 86%, respectively. The following data were obtained. **7b**: bp 125—130°C (bath temp.)/2.0 Torr; R_f 0.60F; $\nu_{max}^{CCl_4}$ 1798 (lactone) and 1745 cm^{-1} (ester); $\delta(CDCl_3)$ 1.36 (d, 4-CH_3, J_{4,CH_3}=6.5 Hz), 2.65 (m, H-2), 4.28 (dq, H-4, $J_{3,4}$=5.0 Hz), and 5.24 (dd, H-3, $J_{2,3}$=3.0 Hz).

Found: C, 65.76; H, 9.36%. Calcd for $C_{14}H_{24}O_4$: C, 65.59; H, 9.44%.

7c: bp 114—117°C (bath temp.)/2.0 Torr; R_f 0.48F; $\nu_{max}^{CCl_4}$ 1795 (lactone) and 1755 cm^{-1} (ester); $\delta(CDCl_3)$ 1.40 (d, 4-CH_3, J_{4,CH_3}=6.5 Hz), 2.72 (m, H-2), 4.51 (dq, H-4, $J_{3,4}$=0.7 Hz), and 5.20 (dd, H-3, $J_{2,3}$=6.0 Hz).

Found: C, 65.70; H, 9.41%. Calcd for $C_{14}H_{24}O_4$: C, 65.59; H, 9.44%.

7d: bp 135—139°C (bath temp.)/1.0 Torr; mp 38.5—39.0°C; R_f 0.33F; $\nu_{max}^{CCl_4}$ 1795 (lactone) and 1755 cm^{-1} (ester); $\delta(CDCl_3)$ 1.32 (d, 4-CH_3, $J_{4,CH3}$=6.5 Hz), 2.77 (m, H-2), 4.63 (dq, H-4, $J_{3,4}$=3.4 Hz), and 5.68 (dd, H-3, $J_{2,3}$=5.5 Hz).

Found: C, 65.80; H, 9.39%. Calcd for $C_{14}H_{24}O_4$: C, 65.59; H, 9.44%.

*10) 2-Butyl-3,4-dihydroxypentanoic Acid-1,4-Lactone, [(±)-Blastmycinolactol] (**9a**).* A solution of **4a** (23.5 mg) in methanol (3 ml) was stirred with palladium black for 40 min under bubbling with hydrogen. The reaction mixture was filtered and evaporated to give *t*-butyl 2-butyl-3,4-dihydroxypentanoate **8a** (22 mg) as a crystalline solid. The product **8a** was dissolved in trifluoroacetic acid (0.5 ml) and kept for 15 min at room temperature. The solution was evaporated and the syrupy residue was purified by a silica gel column (3 g) with the solvent system G to afford a crystalline product **9a** (12.7 mg, 89%). The product was recrystallized from ethyl acetate–petroleum ether to give a pure sample of **9a** (9.7 mg): mp 49.5—51.0°C; ν_{max}^{KBr} 3440 (OH) and 1735 cm^{-1} (lactone); $\delta(CDCl_3)$ 1.45 (d, 4-CH_3, J_{4,CH_3}=6.2 Hz), 2.58 (m, H-2), 3.84 (dd, H-3, $J_{2,3}$=8.5 Hz), and 4.25 (dq, H-4, $J_{3,4}$=7.0 Hz).

Found: C, 62.51; H, 9.42%. Calcd for $C_9H_{16}O_3$: C, 62.76; H, 9.36%.

*11) Optically Active Diastereomers [(+) **10A** and (−)**10B**] of t-Butyl 4-(N-Benzyloxycarbonyl-O-t-butyl-L-threonyloxy)-2-butyl-3-isovaleryloxypentanoate Derived from **6a**.* A solution of *N*-benzyloxycarbonyl-*O*-*t*-butyl-L-threonine[22] (1.82 g, 5.88 mmol) in dry ether (4.0 ml) was added dropwise during 20 min to a stirred solution of **6a** (1.94 g, 5.88 mmol), DCCI (1.34 g, 6.52 mmol) and dry pyridine (0.5 ml) in dry ether (6 ml) cooled at 0°C. Stirring at 0°C was continued for an additional hour. After standing at 0°C for 41 hr, to the reaction mixture a solution of DCCI (670 mg) in ether (1.8 ml) and dry pyridine (0.25 ml) was added and then a solution of the threonine derivative (910 mg) in ether (2 ml) was dropped under stirring at 0°C. After stirring at 0°C for 8 hr and standing at 0°C for 41 hr, further additions of DCCI (335 mg), dry pyridine (0.13 ml) and a solution of the threonine derivative (460 mg) in ether (2 ml) were undertaken in the same procedure as in the preceding additions and the reaction mixture was kept at 0°C for 24 hr. The precipitate of *N,N'*-dicyclohexylurea (1.67 g) was filtered off and the filtrate was treated with acetic acid (*ca.* 0.2 ml) under stirring at 0°C for 1 hr. An additional urea was removed and the filtrate was washed with 5% $NaHCO_3$, 10% citric acid and saturated NaCl solutions. The dried solution was evaporated to afford an yellow syrup (5.48 g).

The product (5.48 g) was chromatographed on a silica gel column (1.2 kg, 8×43 cm) with the solvent system H to collect three fractions which were concentrated. The first fraction gave a homogeneous sample of (+)**10A** (R_f 0.57H, 995 mg) and an additional sample of (+)**10A** (115 mg) was obtained by column chromatography of the second fraction (273 mg), whose tlc showed the two spots corresponding to (+)**10A** and (−)**10B**. The combined samples of (+)**10A** (1.11 g) was again chromatographed with the solvent system D to afford a pure sample of (+)**10A** (1.06 g, 29%) as a colorless syrup: $[\alpha]_D^{22}$ +10° (*c* 11.4, chloroform); $\delta(CDCl_3)$

21) In the case of the preparations of **6b** and **6c**, unchanged materials had to be removed through a short silica gel column (solvent system E).

22) E. Schröder, *Ann. Chem.*, **670**, 127 (1963).

1.15 (s, OBu^t), 1.19 (d, 4-CH$_3$, J_{4,CH_3}=6.2 Hz), 1.29 (d, 3'-CH$_3$, J=6.8 Hz), 1.48 (s, COOBu^t), 4.0—4.2 (m, H-2', H-3'), 5.05 (dq, H-4, $J_{3,4}$=3.0 Hz), 5.32 (dd, H-3, $J_{2,3}$=9.0 Hz), and 5.60 (d, 2'-NH, $J_{2',NH}$=9.0 Hz).

Found: C, 65.97; H, 9.10; N, 2.35%. Calcd for $C_{34}H_{55}O_9N$: C, 65.67; H, 8.92; N, 2.25%.

The third fraction afforded a sample of the diastereomer (−)**10B** (R_f 0.50H, 978 mg). To this was added an additional sample of (−)**10B** (102 mg) separated by column chromatography of the second fraction above-mentioned and the combined products (1.08 g) were purified by chromatography (solvent system D) to give a pure sample of (−)**10B** (1.01 g, 27.7%) as a colorless syrup: $[\alpha]_D^{22}$ −6° (*c* 10.1, chloroform); δ(CDCl$_3$) 1.13 (s, OBu^t), 1.19 (d, 4-CH$_3$, J_{4,CH_3}=6.5 Hz), 1.27 (d, 3'-CH$_3$, J_{3',CH_3}=6.8 Hz), 1.48 (s, COOBu^t), 4.1—4.3 (m, H-2', H-3'), 5.02 (dq, H-4, $J_{3,4}$=3.0 Hz), 5.30 (dd, H-3, $J_{2,3}$=8.6 Hz), and 5.53 (d, 2'-NH, $J_{2',NH}$=8.7 Hz).

Found: C, 65.90; H, 8.64; N, 2.29%. Calcd for $C_{34}H_{55}O_9N$: C, 65.67; H, 8.92; N, 2.25%.

*12) t-Butyl (+)(2*R*,3*R*,4*S*)-2-Butyl-3,4-dihydroxypentanoate [(+)8a] and Its Enantiomer [(−)8a].* A suspension of LiAlH$_4$ (255 mg, 6.73 mmol) in dry tetrahydrofuran (30 ml) was added in one portion to a stirred solution of (+)**10A** (1.05 g, 1.68 mmol) in dry tetrahydrofuran (30 ml) cooled to −45°C in a dry ice-methanol bath. After stirring at −45—−40°C for 1 hr, ethyl acetate (4 ml) was added to the reaction mixture. The mixture (pH 9) was gradually allowed to warm to 0°C and acidified to pH 2—3 with 2N HCl aqueous under cooling in an ice-bath. The resulting mixture was extracted with ether and ethereal extract was washed with 5% NaHCO$_3$ and saturated NaCl solution. The dried solution was evaporated to afford a colorless oil (1.09 g). This was chromatographed on a silica gel column (210 g, 4×45 cm) with the solvent system I to collect three fractions. From the first fraction the unchanged (+)**10A** (284 mg) was recovered. The second fraction gave (−)2-benzyloxycarboxamido-3-*t*-butyl-1-butanol (**11**) (302 mg): $[\alpha]_D^{20}$ −8° (*c* 2.19, chloroform).

Found: C, 65.04; H, 8.73; N, 4.70%. Calcd for $C_{16}H_{25}O_4N$: C, 65.06; H, 8.53; N, 4.74%.

The third fraction afforded the title compound (+)**8a** (197 mg, 47.5%): mp 48.0—48.5°C; $[\alpha]_D^{23}$ +16° (*c* 2.35, methanol).

Found: C, 63.56; H, 10.74%. Calcd for $C_{13}H_{26}O_4$: C, 63.38; H, 10.64%.

The another title compound (−)**8a** (116 mg, 44.6%) was obtained from (−)**10B** (655 mg) by the same procedure as described for the preparation of the enantiomer (+)**8a**: mp 48.1—48.7°C; $[\alpha]_D^{21}$ −16° (*c* 1.90, methanol).

Found: C, 63.17; H, 10.44%. Calcd for $C_{13}H_{26}O_4$: C, 63.38; H, 10.64%.

*13) (−)(2*R*,3*R*,4*S*)-2-Butyl-3,4-dihydroxypentanoic Acid-1,4-Lactone [(−)Blastmycinolactol][(−)9a] and Its Enantiomer [(+)9a].* By the procedure utilized to obtain **9a** from **8a**, the product (+)**8a** (190 mg) was de-*t*-butylated and lactonized. Purification by chromatography as in the preparation of **9a** followed by recrystallization from ether-petroleum ether afforded (−)**9a** (86.4 mg, 66.5%): mp 50.0—51.0°C; $[\alpha]_D^{22}$ −18° (*c* 1.61, methanol) [lit,[6] mp 49—50°C; $[\alpha]_D^{26}$ −5.27° (*c* 7.8, methanol)].

Found: C, 63.06; H, 9.51%. Calcd for $C_9H_{16}O_3$: C, 62.76; H, 9.36%.

In the same procedure as in the preparation of (−)**9a**, the enantiomer (+)**9a** (80 mg, 70%) was obtained from (−)**8a** (164 mg): mp 50.0—51.0°C; $[\alpha]_D^{23}$ +16° (*c* 1.60, methanol).

Found: C, 62.96; H, 9.56%. Calcd for $C_9H_{16}O_3$: C, 62.76; H, 9.36%.

The PMR spectra (in CDCl$_3$) of (−)**9a** and (+)**9a** were identical with that of (±)blastmycinolactol **9a** and the IR spectra (in nujol) of those were very similar to that[6] of natural product.

*14) (+)(2*R*,3*R*,4*S*)-2-Butyl-4-hydroxy-3-isovaleryloxypentanoic Acid-1,4-Lactone [(+)Blastmycinone][(+)7a] and Its Enantiomer [(−)7a].* The synthetic (−)blastmycinolactol (−)**9a** (23.9 mg) was treated with isovaleric anhydride-pyridin. Work up as described in Exp. 8(b) for the preparation of **7a** gave (+)blastmycinone (+)**7a** (15.3 mg, 42.5%) as a colorless oil: $[\alpha]_D^{23}$ +10° (*c* 1.5, chloroform) [lit,[6] $[\alpha]_D^{25}$ +11.5° (*c* 20.8, chloroform)]. This material was indistinguishable from (±)blastmycinone **7a** by PMR, tlc, and glc criteria.

(−)Blastmycinone (−)**7a** (22.6 mg, 46.5%) was obtained from (+)**9a** (32.4 mg) by the same procedure as described in the preparation of (+)**7a**: $[\alpha]_D^{25}$ −10° (*c* 2.26, chloroform). The PMR spectrum of (−)**7a** was identical with that of (+)**7a**.

*15) (+)(3*S*,4*R*,7*R*,8*R*,9*S*)-3-Benzyloxycarboxamido-7-butyl-4,9-dimethyl-1,5-dioxa-8-isovaleryloxycyclononane-2,6-dione [(+)-12A].* A mixture of (+)**10A** (2.24 g, 3.6 mmol) and trifluoroacetic acid (27 ml) was kept for 10 min at room temperature and then evaporated below 10°C. The residual syrup was coevaporated with ether repeatedly to remove trifluoroacetic acid. The final residue was dried over NaOH for 2 hr under reduced pressure to afford a syrupy de-*t*-butylated product, hydroxyester-acid. The porduct was immediately dissolved in dry benzene (97 ml) and to this was added trifluoroacetic anhydride (0.54 ml, 3.87 mmol). The mixture was heated at 65—70°C in an oil bath and the reaction course was monitored by tlc (solvent system J). After 2—3 hr a faint spot (R_f 0.77 J, HBr-ninhydrin positive) of (+)**12A** and two HBr-ninhydrin negative spots (R_f 0.60, 0.42J) of by-products appeared on tlc. After an additional hour a new HBr-ninhydrin negative spot (R_f 0.95J) appeared and to the reaction mixture was again added trifluoroacetic anhydride (0.54 ml). The heating was further continued for 6 hr, during which the spot of (+)**12A** became more definite, however, rapid formation of the two by-products (R_f 0.60 and 0.95J) was also observed. The reaction mixture was then immediately cooled and evaporated to dryness below 10°C to afford a syrup (2.20 g). As soon as possible the syrup was chromatographed on a silica gel column (300 g, 4.7×50 cm) with the solvent system J to collect fractions containing (+)**12A** (R_f 0.77J). The combined fractions were evaporated. The residual semicrystalline product (*ca.* 25 mg) was again chromatographed on silica gel (2.3 g) with the solvent system F to afford crystals of (+)**12A** (14.2 mg, 0.8%), whose tlc with solvent system K, J, and F showed a single spot. The crystals (14 mg) was recrystallized from ethyl acetate-petroleum ether to give an analytical sample of (+)**12A** (8.2 mg) as long needles: mp 109.0—109.5°C; $[\alpha]_D^{25}$ +70° (*c* 0.5, chloroform); $\nu_{max}^{CCl_4}$ (0.01M) 3440 (NH) and 1756, 1738 cm^{-1} (ester and amide); molecular ion at *m/e* 491.2473 (calcd, 491.2519).

Found: C, 63.65; H, 7.41; N, 2.61%. Calcd for $C_{26}H_{37}O_8N$: C, 63.52; H, 7.59; N, 2.85%.

*16) (−)(3*S*,4*R*,7*S*,8*S*,9*R*)-3-Benzyloxycarboxamido-7-butyl-4,9-dimethyl-1,5-dioxa-8-isovaleryloxycyclononane-2,6-dione [(−)-12B].* By the procedure of the preceding experiment 15, (−)**10B** (1.77 g, 2.84 mmol) was de-*t*-butylated. The product was immediately dissolved in dry benzene (74 ml) and to this was added trifluoroacetic anhydride (0.40 ml, 2.87 mmol). The mixture was heated at 65—70°C. After 30 min a faint spot (R_f 0.60 K, HBr-ninhydrin positive) of

(−)**12B** and a spot (R_f 0.79 K) of blastmycinone were detected on tlc. The heating was continued for 18 hr, during which the two spots became more definite and then trifluoroacetic anhydride (0.40 ml) was again added. After heating for additional 2 hr, the reaction mixture, whose tlc showed the formations of considerable amount of (−)**12B** (R_f 0.60 K) and blastmycinone (R_f 0.77 K) and of additional ninhydrin negative by-product (R_f 0.67 K), was evaporated below 20°C. The resulting syrup was chromatographed on a silica gel column (300 g, 4.5×40 cm) with the solvent system J to collect fractions containing (−)**12B** (R_f 0.77J) and blastmycinone (R_f 0.81J), which were evaporated. The residue (120 mg) was again chromatographed on a silica gel column (12 g, 1.2×25 cm) with the solvent system F to afford the following fractions:

Fraction 1. (−)blastmycinone (−)**7a**; 9.0 mg; $[\alpha]_D^{Chf}$ −9°
Fraction 2. (−)**7a**+(−)**7b** ; 15.2 mg
Fraction 3. (−)**7b** ; 22.3 mg; $[\alpha]_D^{Chf}$ −11°
Fraction 4. (−)**12B** (crystals) ; 43.5 mg (3.1% yield)

The oily products obtained from the fraction 1 and 3 were confirmed to be (−)**7a** and (−)**7b**, respectively, by PMR and optical rotations. The crystals obtained from the fraction 4 showed a single spot on each tlc with the solvent systems, K, J, and F. Recrystallization of the product (43 mg) from petroleum ether gave an analytical sample of (−)**12B** (25.7 mg): mp 87.0—87.5°C; $[\alpha]_D^{25}$ −18° (*c* 1.9, chloroform); $\nu_{max}^{CCl_4}$ (0.01M) 3428 (NH), 1758 and 1738 cm^{-1} (ester and amide); molecular ion at *m/e* 491.2451 (calcd, 491.2519).

Found: C, 63.75; H, 7.57; N, 3.12%. Calcd for $C_{26}H_{37}O_8N$: C, 63.52; H, 7.59; N, 2.85%.

17) Antimycin A_3 (1A). *(a) Amino Dilactone (13A)*: A solution of (+)**12A** (8.1 mg) in methanol (3 ml) was stirred with palladium black for 35 min under bubbling with hydrogen gas. The filtered reduction mixture was evaporated to yield the free amino dilactone **13A** (5.9 mg), whose tlc showed a single sopt detected by ninhydrin and 20% H_2SO_4 reagents.

(b): To a solution of **13A** (5.9 mg) in dry tetrahydrofuran (0.08 ml) was added *O*-benzyl-3-nitrosalicylic acid *N*-hydroxysuccinimide ester (6.2 mg). The mixture was kept for 3 hr at 36°C in an incubator. The reaction mixture (pH 4) was adjusted to pH 6 by addition of triethylamine and again incubated for 25 hr. The resulting solution was evaporated and the residue was chromatographed on silica gel column (0.85 g) with the solvent system L to afford *N*-(*O*-benzyl-3-nitro)salicyloyl derivative **14A** (6.4 mg, 65%) as a yellow glassy solid: $\nu_{max}^{CCl_4}$ (0.01M) 3390 (NH), 1749 (lactone) and 1675, 1603 cm^{-1} (amide).

(c): A solution of **14A** (6.2 mg) in methanol (3 ml) was stirred with palladium black under bubbling with hydrogen gas for 10 min. The filtered solution was evaporated to give a crystalline solid (5 mg). The product was dissolved in tetrahydrofuran (0.06 ml) and to this was added DCCI (4.5 mg) and 98% formic acid (0.8 μl) under ice-cooling. After standing for 4 hr in a refrigerator, the reaction mixture was evaporated and the residue was subjected to plc (one 20×20 cm silica gel plate) with the solvent system M. The strongest fluorescent band which showed the same R_f-value as that of authentic antimycin A complex, was collected and extracted with ether to afford pale orange crystals (4.2 mg). They were recrystallized twice from ether–petroleum ether to give an analytical sample of **1A** (2.3 mg, 27.3% based on (+)**12A**) as colorless needles: mp 174.0—174.5°C (corrected) [lit, 174.5—175°C,[15] 168—169°C,[6] 170.5—171.5°C[17]]; $[\alpha]_D^{24}$ +80° (*c* 0.2, chloroform) [lit, $[\alpha]_D^{26}$ +79.4° (*c* 1, chloroform),[15] $[\alpha]_D^{26}$ +64.3° (*c* 1.0, chloroform)[17]]; λ_{max}^{MeOH} nm (log ε), 225 (4.52) and 320 (3.86); $\nu_{max}^{CCl_4}$ (0.01M) 3420 (NH), 1756 (ester), 1715 (NHCHO), 1644 (ArCONH), 1610 (ArH) and 1531 cm^{-1} (ArCONH); molecular ion at *m/e* 520.2412 (calcd, 520.2421).

Found: C, 59.72; H, 7.15; N, 5.25%. Calcd for $C_{26}H_{36}O_9N_2$: C, 59.99; H, 6.97; N, 5.38%.

18) Diastereomer of 1A (1B). *(a)*: Amino Dilactone (**13B**). By the procedure of Exp. 17(a), (−)**12B** (29 mg) was hydrogenolyzed to afford a reduction product (19.7 mg) whose tlc (solvent L) showed a major ninhydrin positive spot of **13B** and two definite spots of blastmycinone and other ninhydrin positive product.

(b): The reduction product (19.7 mg) was treated with *O*-benzyl-3-nitrosalicylic acid *N*-hydroxysuccinimide ester (22 mg) by the same procedure for **13A**. The concentrated reaction mixture (50 mg) was chromatographed on a silica gel column (5 g) with the solvent system L to collect two fractions. The first fraction gave a colorless oil of (−)**7a** (3.3 mg, *ca.* 24%); $[\alpha]_D^{25}$ −9° (*c* 2.9, chloroform). The PMR spectrum of this ample was identical with that of the specimen of (−)**7a** obtained in Exp. 14. The second fraction afforded *N*-(*O*-benzyl-3-nitro)salicyloyl derivative of **13B** (**14B**) (9.1 mg, *ca.* 24% yield) as a yellow glassy solid: $\nu_{max}^{CCl_4}$ (0.01M) 3410 (NH), 2750 (ester), 1669 and 1602 cm^{-1} (amide).

(c): A sample of **14B** (23.2 mg) was hydrogenolyzed by the procedure of Exp. 17(c) to afford a reduction product whose tlc (solvent system L) showed a single spot by detection with ninhydrin, ethanolic $FeCl_3$ and 20% H_2SO_4 reagents. The product (18 mg) was *N*-formylated with 98% formic acid (2 μl) and DCCI (9.8 mg) in tetrahydrofuran at 0°C. Filtration of urea followed by concentration gave a yellow syrup (21 mg). The syrup was subjected to plc (two 20×20 cm silica gel plates) with the solvent system M to collect the strongest fluorescent bands. The ethereal extract of these bands was evaporated to afford **1B** (15.9 mg, 83% based on **14B**) as a pale yellow syrup. Further purification by plc gave an analytical sample as a colorless glass, whose tlc showed the same R_f-value as that of **1A**: $[\alpha]_D^{21}$ −5° (*c* 1.6, chloroform); λ_{max}^{MeOH} nm (log ε), 225 (4.55) and 320 (3.72); $\nu_{max}^{CCl_4}$ (0.01M) 3420 (NH), 1758 and 1735 (ester), 1714 (NHCHO), 1646 (ArCONH), 1612 (ArH), and 1531 cm^{-1} (ArCONH).

Found: C, 60.29; H, 7.21; N, 5.22%. Calcd for $C_{26}H_{36}O_9N_2$: C, 59.99; H, 6.97; N, 5.38%.

We wish to thank Prof. Hiroshi Yonehara for sample of antimycin lactone and PMR chart of blastmycinone, Prof. Hamao Umezawa for his helpful advice, Dr. Hiroshi Naganawa for the measurement of PMR spectra at 100 MHz, Dr. Masa Hamada for the microbiological tests and to Mr. Saburo Nakada for the elemental analyses.

The Oxidation of 2,3-Dihydro-4*H*-pyran-4-ones[1]

Kikumasa SATO, Seiichi INOUE, and Masao ŌHASHI*

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama

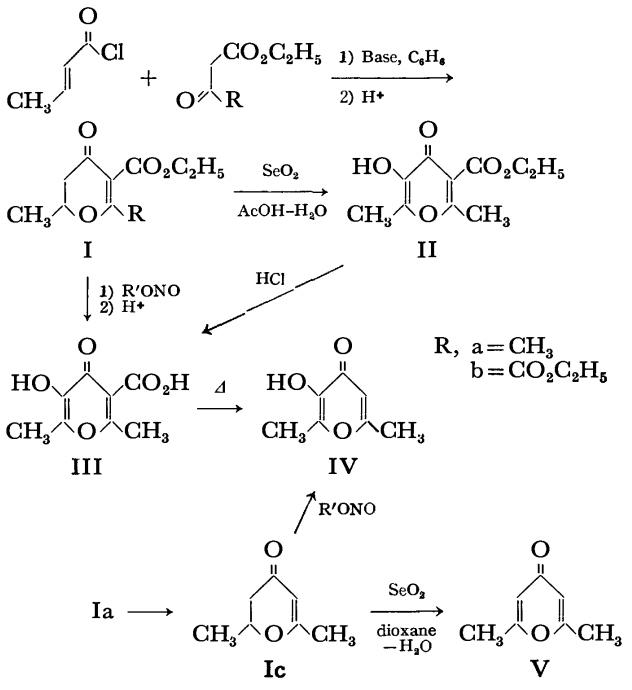
(Received June 29, 1972)

The synthesis and oxidation of substituted 2,3-dihydro-4*H*-pyran-4-ones are described. The reaction of crotonoyl chloride with β-ketoester gave dihydro-4*H*-pyran-4-ones (I). Dihydro-γ-pyrone (Ia) is oxidized, hydrolyzed, and subsequently decarboxylated to give 6-methyl maltol (IV).

3-Hydroxy-4*H*-pyran-4-ones, especially 3-hydroxy-2-methyl-4*H*-pyran-4-one, *i.e.*, maltol, have long been known and have been widely used as food flavors. Maltol has been synthesized from kojic acid or pyromeconic acid as the starting material.[2] Recently, these compounds have also been obtained[3] from inaccessible dihydro-γ-pyrones in low yields.

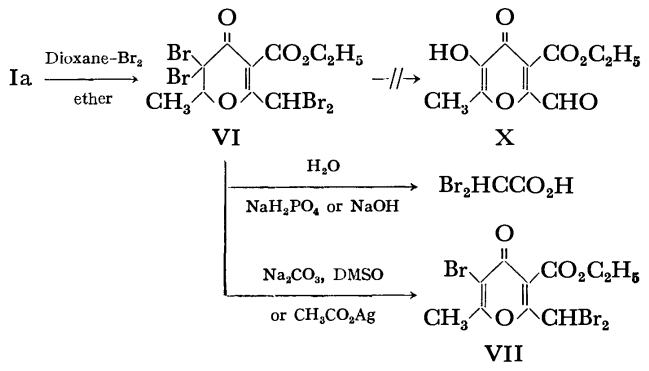
In this investigation, we aimed to get dihydro-γ-pyrones (I) and succeeded in preparing α-diketones by oxidation. We have previously reported on the oxidation of 2-carbethoxy-2-methylcyclopentanone to give 5-carbethoxy-2-hydroxy-5-methylcyclopent-2-en-1-one.[4] These studies have now been extended to dihydro-γ-pyrones (I). I was synthesized directly by the condensation of β-ketoesters with crotonoyl chloride.



5-Carbethoxy-2,3-dihydro-2,6-dimethyl-4*H*-pyran-4-one (Ia)[5] and 2,3-dihydro-2,6-dimethyl-4*H*-pyran-4-one (Ic)[6] has already been synthesized. 5,6-Dicarbethoxy-2,3-dihydro-2-methyl-4*H*-pyran-4-one (Ib) was obtained by the condensation of sodium ethyl oxalacetate[7] with crotonoyl chloride. The oxidation of Ia with selenium dioxide gave 5-carbethoxy-3-hydroxy-2,6-dimethyl-4*H*-pyran-4-one (II) in a low yield. The hydrolysis of II in hydrochloric acid afforded 5-hydroxy-2,6-dimethyl-4-oxo-4*H*-pyran-3-carboxylic acid (III) in a 75% yield, and subsequent decarboxylation of III in diphenyl ether at 250°C yielded 3-hydroxy-2,6-dimethyl-4*H*-pyran-4-one (IV) in a 30% yield. These compounds, II, III, and IV, had a characteristic odor like maltol and gave an intense violet color with ferric chloride.

However, α-diketone was not isolated from Ib. Dihydro-γ-pyrone (Ic) gave a dehydrogenated compound, 2,6-dimethyl-4*H*-pyran-4-one (V). Furthermore, the nitrosation of Ia followed by acid hydrolysis afforded III. However, Ib gave only a tarry material, and IV was obtained from Ic.

The bromination of Ia with an excess of dioxane dibromide in ether gave 3,3-dibromo-6-dibromomethyl-5-carbethoxy-2,3-dihydro-2-methyl-4*H*-pyran-4-one (VI) in a 72.4% yield. The structure of VI was assigned on the basis of its IR, and NMR spectra and the results of an elemental analysis.



The hydrolysis of VI with sodium biphosphate in dioxane–water at 85°C for 10 hr afforded dibromoacetic acid in an 80% yield. A similar compound was also prepared by the hydrolysis of a dilute sodium hydroxide solution at 0°C for 24 hr. The hydrolysis of 5-carbethoxy-2,3-dihydro-6-methyl-γ-pyrones has been shown to give

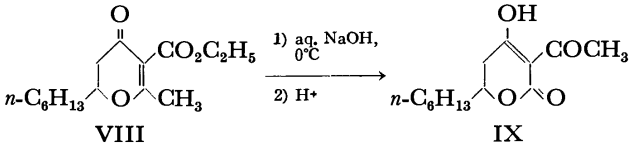
3-acetyl-5,6-dihydro-4-hydroxy-α-pyrones, together with δ-acetoxy-β-ketoesters.[5] Similarly, the treatment of aqueous sodium hydroxide with 5-carbethoxy-2-hexyl-2,3-dihydro-6-methyl-4*H*-pyran-4-one (VIII), which has been easily obtained by the condensation of ethyl acetoacetate with 2-nonenoyl chloride, afforded the corresponding α-pyrone (IX) in a 77.9% yield.



VIII IX

It may be supposed that compound VI is first hydrated to a double bond instead of to its two nucleophilic carbons, and that a subsequent ring cleavage produces dibromoacetic acid. On the other hand, the treatment of VI with equimolar amounts of sodium carbonate in DMSO provided 3-bromo-6-dibromomethyl-5-carbethoxy-2-methyl-4*H*-pyran-4-one (VII) in a 54.6% yield. When silver acetate and VI were refluxed in acetic acid, dehydrobromination also occurred to yield VII. Under various conditions, none of the expected hydrolysis product (X) could be isolated from the reaction mixture.

Accordingly, it may be supposed that the lack of success in introducing the α-carbonyl group into dihydro-γ-pyrones (I) is due to the low stability of the ring, as will be discussed above.

Experimental

All the melting points and boiling points are uncorrected. The infrared spectra were recorded with a Hitachi Model EPI-S2 spectrophotometer, and the ultraviolet spectra, with a Hitachi Model EPS-3T spectrophotometer. The NMR spectra were obtained on a JEOL Model C-60H spectrometer, with tetramethylsilane as the internal reference.

Materials. 5-Carbethoxy-2,3-dihydro-2,6-dimethyl-4*H*-pyran-4-one,[5] 2,3-dihydro-2,6-dimethyl-4*H*-pyran-4-one,[6] sodium ethyl oxalacetate,[7] *n*-butyl nitrite,[8] and crotonoyl chloride[9] were prepared by the method described in the literature. The other chemicals were commercially available and well purified by the usual procedures before use.

*5,6-Dicarbethoxy-2,3-dihydro-2-methyl-4*H*-pyran-4-one (Ib).* To a suspension of sodium ethyl oxalacetate (20 g) (0.095 mol) in 90 ml of dry benzene, 5.3 g (0.05 mol) of crotonoyl chloride diluted with 10 ml of benzene was added, drop by drop, at 15—20 °C for 30 min. The mixture was then refluxed at 70 °C for 1 hr with stirring. After cooling, 50 ml of cold water was added, and the mixture was made slightly acidic with 10% sulfuric acid. The organic layer was separated, and the aqueous layer was extracted with ether. The combined organic layer was washed with water and dried over magnesium sulfate. Fractional distillation under nitrogen gave ethyl oxalacetate and 6.2 g of an oil (bp 150—170 °C/0.7 mmHg). The redistillation of the latter oil gave 4.7 g (36.6%) of pure Ib; bp 142—147 °C/0.3 mmHg; n_D^{20} 1.4872; IR (neat) 1725, 1655 (C=O), 1568 (C=C), 1370, 1300—1030 cm^{-1} (C–O–C); NMR (CCl_4) 1.20 (3H, d, J=8.0), 1.29 (3H, t, J=7.0), 1.36 (3H, t, J=7.0), 2.3—3.1 (2H, m), 4.13 (2H, q, J=7.0), 4.20 (2H, q, J=7.0), 3.9—4.4 (1H, m). Found: C, 56.24; H, 6.66%. Calcd for $C_{12}H_{16}O_6$: C, 56.25; H, 6.29%. 2,4-Dinitrophenylhydrazone; mp 113—115 °C. Found: C, 49.05; H, 4.97%. Calcd for $C_{18}H_{20}N_4O_9$: C, 49.54; H, 4.62%.

*5-Carbethoxy-3-hydroxy-2,6-dimethyl-4*H*-pyran-4-one (II).* To a hot (80 °C) solution of 11.1 g (0.1 mol) of selenium dioxide in 100 ml of acetic acid and 4 ml of water, was added 10 g (0.05 mol) of Ia all at once. The mixture was refluxed with stirring for 24 hr, and then the precipitated selenium was filtered out. The filtrate was concentrated and distilled to give a yellow oil (bp 105—110 °C/0.2 mmHg); when this oil was allowed to stand overnight, it gave a crystalline material together with 4 g of recovered Ia. Filtration, followed by recrystallization from aqueous ethanol, afforded 410 mg (4.0%) of II as colorless needles; mp 155 °C; IR (KBr): 3260 (O–H), 1736, 1665 (C–O), 1605 (C=C), 1225, 1190, 1105 cm^{-1} (C–O–C); UV (EtOH) 222 mμ (ε 13560), 275 mμ (ε 7400); NMR ($CDCl_3$) 1.36 (3H, t, J=7.0), 2.30 (3H, s), 2.40 (3H, s), 4.43 (2H, q, J=7.0), 6.45 (1H, s); Found: C, 56.87; H, 5.94%. Calcd for $C_{10}H_{12}O_5$: C, 56.60; H, 5.70%.

*5-Hydroxy-2,6-dimethyl-4-oxo-4*H*-pyran-3-carboxylic Acid (III).* *a)*: A mixture of 170 mg of II and 3 ml of 6M hydrochloric acid was heated at 100 °C for 2 hr. The cooled mixture was extracted with chloroform and washed with water. The subsequent evaporation of the solvent gave a crude product; this was recrystallized from water to give pure III (112 mg, 75%) as colorless needles; mp 161 °C. IR (KBr): 3300, 3060—2640 (O–H), 1730, 1663 (C=O), 1620, 1570 (C=C) 1220, 1098 cm^{-1} (C–O–C); UV (EtOH), 223 mμ (ε 14000), 279 mμ (ε 6590); NMR ($CDCl_3$) 2.45 (3H, s), 2.86 (3H, s), 6.54 (1H, broad s). Found: C, 52.18; H, 4.72%. Calcd for $C_8H_8O_5$: C, 52.18; H, 4.38%.

b): Dry hydrogen chloride was introduced into a cold, stirred solution of 6.0 g (0.03 mol) of Ia in 40 ml of dry ether at 0 °C for 25 min. Then, 5.0 g (0.05 mol) of *n*-butyl nitrite in 5 ml of ether was added over a period of 30 min at 0—5 °C. The mixture was then heated at 35 °C for 4.5 hr. After cooling, the solvent was removed by distillation and the residue was hydrolyzed with 70 ml of 3M hydrochloric acid by refluxing for 5 hr. The removal of the hydrochloric acid, filtration, and subsequent recrystallization from water provided the product, III (1.0 g, 18.1%), as colorless needles; mp 160—161 °C. The infrared spectrum and the other chemical properties were identified with those of the III presented above.

*3-Hydroxy-2,6-dimethyl-4*H*-pyran-4-one (IV).* *a)*: A solution of 200 mg of III in 4.0 g of diphenyl ether was heated at 250—260 °C for 1 hr. After cooling, the reaction mixture was poured into 0.25M aqueous sodium hydroxide (8 ml) and the aqueous layer was separated. To remove the diphenyl ether, the aqueous layer was extracted with ether and acidified with hydrochloric acid. Extraction with ether, followed by evaporation, gave crude IV; this was recrystallized from water to provide IV (46 mg, 30%) as colorless needles; mp 159—160 °C (lit,[10] mp 162.5 °C). A mixed-melting-point determination with an authentic sample[10] indicated no depression. IR (KBr): 3230 (O–H), 1660 (C=O), 1617, 1580 (C=C), 1215 cm^{-1} (C–O–C); NMR ($CDCl_3$) 2.28 (3H, s), 2.34 (3H, s), 6.25 (1H, s), 7.32 (1H, s). Found: C, 59.97; H, 5.77%. Calcd for $C_7H_8O_3$: C, 60.00; H, 5.75%.

b): To a stirred solution of 1.26 g (0.01 mol) of Ic, 0.8 ml of hydrochloric acid, and 30 ml of ethanol, 3.2 g (0.031 mol)

of *n*-butyl nitrite diluted with 10 ml of ethanol was added at gentle refluxing for 5 min, and then the mixture was kept for 10 hr. The solvent was evaporated and the residue was recrystallized from water to yield 50 mg (3.6%) of IV; mp 159—160 °C.

2,6-Dimethyl-4H-pyran-4-one (V). A mixture of 1.26 g (0.01 mol) of Ic, 1.10 g (0.01 mol) of selenium dioxide, 25 ml of dioxane, and 2.5 ml of water was refluxed with stirring for 40 hr. After cooling the selenium was filtered out and the solvent was removed. The residue was extracted with chloroform, and the subsequent evaporation of the chloroform gave a black oil, which was then sublimed at 150 °C under reduced pressure (15—20 mmHg). The sublimed crystals were recrystallized from chloroform to give 154 mg (12.2%) of V as colorless needles; mp 129—130 °C (lit,[11] mp 132 °C); IR (KBr) 3040 (C–H), 1660 (C=O), 1610, 1590 (C=C), 1396, 1160 (C–O–C), 900 cm^{-1}. The infrared spectrum and the other chemical properties were identical with those of an authentic sample.[11]

3,3-Dibromo-6-dibromomethyl-5-carbethoxy-2,3-dihydro-2-methyl-4H-pyran-4-one (VI). Bromine (39.2 g, 0.248 mol) was stirred into 70 ml of dioxane with cooling over a period of 15 min. The mixture was then diluted with 35 ml of ether, and 7.0 g (0.035 mol) of Ia in 35 ml of ether was dropped in at room temperature over 15 min period. Then the mixture was refluxed for 7 hr and allowed to stand overnight at room temperature. The resulting mixture was poured into ice water. The organic layer was separated, and the aqueous layer was extracted with ether. The combined organic layer was washed with water and dried over magnesium sulfate. The evaporation of the solvent and recrystallization from ethanol afforded colorless plates (13.1 g, 72.4%); mp 88—89 °C IR (KBr): 1710, 1700 (C=O), 1600 cm^{-1} (C=C); NMR (CCl_4) 1.40 (3H, t, J=7.0), 1.95 (3H, d, J=6.0), 4.40 (2H, q, J=7.0), 4.67 (1H, m), 7.05 (1H, s). Found: C, 23.43; H, 2.11%. Calcd for $C_{10}H_{10}Br_4O_4$: C, 23.38; H, 1.96%.

Reaction of VI with Sodium Biphosphate. A mixture of 6.3 g (0.04 mol) of sodium biphosphate, 5.1 g (0.01 mol) of VI, 25 ml of water, and 25 ml of dioxane was stirred at 84—85 °C for 10 hr. After cooling, the organic layer was separated and the aqueous layer was extracted with ether. The combined organic layer was washed with water and dried over magnesium sulfate. After the removal of the ether, the distillation of the residual oil gave 1.8 g (80%) of dibromoacetic acid; bp 110—112 °C/5 mmHg (lit,[12] bp 195—197 °C/250 mmHg). IR (neat): 3020, 2630—2510 (O–H), 1720 (C=O), 910 cm^{-1}; NMR (CCl_4) 5.63 (1H, s), 10.05 (1H, s); mol. wt. 217 (alkali titration), $C_2H_2Br_2O_2$ require 218.

Reaction of VI with Sodium Hydroxide. A mixture of 5.0 g (0.01 mol) of VI, 4.0 g (0.1 mol) of sodium hydroxide, and 100 ml of water was stirred at 0 °C for 24 hr. The resulting mixture was acidified with hydrochloric acid and extracted with ether. After drying, the ether was evaporated and the residual oil was distilled to give 0.8 g (38%) of dibromoacetic acid; bp 90—98 °C/1.0 mmHg.

3-Bromo-6-dibromomethyl-5-carbethoxy-2-methyl-4H-pyran-4-one (VII). *a)*: A mixture of 20.4 g (0.04 mol) of VI and 4.3 g (0.04 mol) of sodium carbonate in 75 ml of DMSO was stirred at 20 °C for 3 hr. The resulting mixture was poured into ice water and extracted with chloroform. After drying, the solvent was evaporated and the residual solid was crystallized from aqueous ethanol to give 9.45 g (54.6%) of VII; mp 149—151 °C. IR (KBr): 1732, 1638 (C=O and C=C), 1395, 1010, 720 cm^{-1}; NMR ($CDCl_3$) 1.36 (3H, t, J=6.8), 2.56 (3H, s), 4.31 (2H, q, J=6.8), 6.59 (1H, s). Found: C, 27.95; H, 2.36%. Calcd for $C_{10}H_9Br_3O_4$: C, 27.74; H, 2.10%.

b): A mixture of 2.6 g (0.005 mol) of VI and 3.3 g (0.02 mol) of silver acetate in 40 ml of acetic acid was refluxed, with stirring, for 4 hr. To the mixture was then added 3 ml of water, after which the hot mixture was refluxed for an additional 2 hr. The subsequent filtration of the silver bromide and evaporation of the solvent gave a crude product. Recrystallization from aqueous ethanol afforded 0.8 g (38%) of VII as fine needles; mp 149—150 °C.

5-Carbethoxy-2-hexyl-2,3-dihydro-6-methyl-4H-pyran-4-one (VIII). A mixture of 5.0 g (0.21 mol) of magnesium turnings, 40 ml of absolute ethanol, 0.5 ml of carbon tetrachloride, and 50 ml of dry benzene was heated under reflux for 3 hr. The solvent was then distilled off, and 100 ml of benzene was added to the magnesium ethoxide. To this suspension, 26 g (0.2 mol) of ethyl acetoacetate was added below 30 °C, and then 36.6 g (0.21 mol) of 2-nonenoyl chloride[13] was slowly added over a period of 30 min at room temperature. The mixture was heated at 70 °C for 20 min with stirring. After cooling, the reaction mixture was acidified with 10% sulfuric acid. The organic layer was separated, and the aqueous layer was extracted with ether. The combined organic layer was washed with water, dried over sodium sulfate, and concentrated. The residue was distilled, thus giving VIII (15.3 g, 57%); bp 137—139 °C/0.3 mmHg, n_D^{20} 1.4825; IR (neat): 1710, 1680 (C=O), 1600 cm^{-1} (C=C); NMR (CCl_4) 0.88 (3H, t, J=7.0), 1.15 (3H, t, J=7.0), 1.30 (10H, broad s), 2.06 (3H, s), 2.28 (2H, d, J=8.2), 4.04 (2H, q, J=7.0), 4.18 (1H, m). Found: C, 66.80; H, 8.95%. Calcd for $C_{15}H_{24}O_4$: C, 67.14; H, 9.01%. 2,4-Dinitrophenylhydrazone; mp 110—113 °C.

3-Acetyl-6-hexyl-5,6-dihydro-4-hydroxy-2H-pyran-2-one (IX). A cold solution of 10.7 g (0.04 mol) of VIII and 3.2 g (0.08 mol) of sodium hydroxide in 160 ml of water was stirred at 0—2 °C for 24 hr. The resulting mixture was acidified with hydrochloric acid, and then the crystalline material was precipitated. Filtration and recrystallization from aqueous ethanol afforded IX (7.5 g, 77.9%) as colorless crystals; mp 69.5—70 °C; IR (KBr): 1690 (C=O), 1565 cm^{-1} (C=C); NMR ($CDCl_3$) 0.88 (3H, t, J=7.0), 1.30 (10H, broad s), 2.53 (3H, s) 2.62 (2H, d, J=1.8), 4.25 (1H, m), 17.4 (1H, s). Found: C, 64.77; H, 8.40%. Calcd for $C_{13}H_{20}O_4$: C, 64.98; H, 8.39%.

The authors wish to express their gratitude Mr. Mitsuo Sato for capable technical assistance in these experiments.

The Optical and Electrical Properties of Metal Photo-doped Chalcogenide Glasses

Isamu SHIMIZU, Hiraku SAKUMA, Hiroshi KOKADO, and Eiichi INOUE

Imaging Science and Engineering Laboratory, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo

(Received September 5, 1972)

The optical and electrical properties of the metal photo-doped chalcogenide glasses were studied. The optical absorption of the chalcogenide glasses (*e.g.*, the As–S, As–S–Te, and As–S–Se systems) was increased by the photo-doping of such metals as Ag and Cu in the region of their absorption edges. The electrical conductivity of the glasses also increased with the photo-doping of the metals. The effective band gap obtained from the results of the temperature dependency of the electrical conductivity decreased with the increase in the amount of metal which was photo-doped in the glasses. The results obtained in this study suggest that the metals photo-doped in the chalcogenide glasses behaved as structural modifiers of the glasses, and that the state of density in the gap was increased by the metal photo-doping.

When a binary layer of metal and chalcogenide glass is exposed to light, the metal diffuses into the glass layer. We gave the term "photo-doping"[1] to the phenomenon by analogy with the doping of foreign materials into a crystalline semiconductor. As a result of the metal photo-doping, some drastic changes take place in the optical, electrical, and chemical properties of the chalcogenide glasses. We have succeeded in using the metal-chalcogenide system as a recording process of the optical image.[2] For example, the difference in optical absorption between the metal-doped and undoped areas of the chalcogenide glass layer is sufficiently large to be recorded directly on the system by image-by-image exposure. We obtained a fine relief pattern from the image-by-image exposed layer by taking out the undoped metal with an acid and by etching the undoped chalcogenide glass area with an alkaline solution. This technique is useful in making an optical mask in microfabrication technology. It should be noted that the metal-chalcogenide glass system is suitable for holographic recording.

This paper will report the results on the optical absorption and electrical conductivity of various chalcogenide glasses in which metal is doped by illumination. Judging from the results of our studies undertaken from the standpoint of the band theory, the photo-doped metals in the glass act as structure modifiers of the chalcogenide glass.

Experimental

The materials were prepared by fusing a mixture of appropriate quantities of elements in an evacuated fused quartz tube at 650 °C for 8 hr with occasional agitation. Four compositions of the glasses, $(As_2S_3)_1I_x$, were prepared with $x=$ 0.55, 1.0, 1.5, and 2.0 by heating a mixture of As_2S_3 and iodine in an Ar gas atmosphere.

The binary layer of chalcogenide glass and metal was prepared on a substratum (slide glass) by the successive vacuum evaporation (1×10^{-5} Torr) of the chalcogenide glass and metal (Ag or Cu).

The absorption spectra of the films were measured with a spectrophotometer, Shimadzu MPS-50L. A multi-beam interferometer, Mizojiri Model II, was used to measure the thickness of the layers.

The electrical-conductivity measurements were taken with surface-type cells having Au electrodes 1 mm apart from each other and with a micro-ammeter Takeda Riken TRA-1 (DC apparatus).

Results and Dsicussion

The absorption spectrum of the binary layer represented the sum of the optical absorptions of the metal and chalcogenide glass layers. An area which had been illuminated showed an increase in transmittance in the visible and infra-red regions. This implies that the metal layer was doped into the chalcogenide glass by exposure to light. A typical example of the spectral change in the layer, showing the photo-induced reaction caused between metal and chalcogenide glass, is shown in Fig. 1. The photo-induced reaction took place at the interface of the layers when the incident photons had sufficient energy to excite the electrons of the chalcogenide glass. The tail of the absorption spectrum of the metal photo-doped glass was shifted to a longer wavelength than that of the undoped chalcogenide glass. The disappearance of the metal on the glass was confirmed by observing the decrease in the optical absorption of metal in the infrared region. To

show the change in the optical absorption of the chalcogenide glass layer caused by the photo-doping of the metal, the difference spectrum was made by plotting the difference in the optical absorption between doped and undoped glasses against the wavelength. Since chalcogenide glass layers (0.5 μm) thicker than the metal layer (200 Å) were used in these measurements, the change in the thickness of the chalcogenide glass layers resulting from the metal photo-doping was negligible. The difference spectral curves of As–S systems in which Ag 200 Å in thickness was photo-doped are shown in Fig. 2. The optical absorption

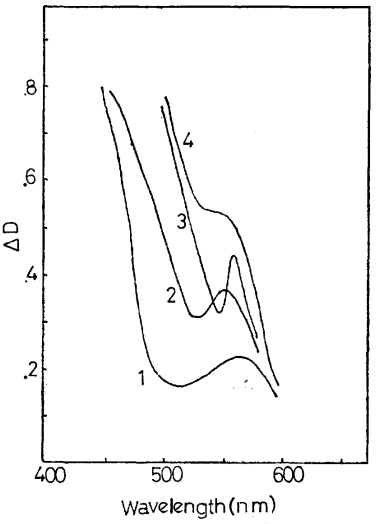

Fig. 4. Difference spectra of Ag (200 Å) photo-doped glasses (As–S–Se) system).
Curve 1: $As_{17.7}S_{70.8}Se_{11.5}$, 2: $As_{30}S_{50}Se_{20}$, 3: $As_{18}S_{40}Se_{42}$, 4: $As_{19}S_{27}Se_{54}$

was increased by metal photo-doping in each glass. Increases in the optical absorption were observed near the absorption tails of the glasses. Since no detectable change in the electron-beam diffraction pattern could be observed in the Ag photo-doped glass layer, it can be assumed that no devitrification was brought about by the Ag photo-doping. The increase in the optical absorption resulting from Ag photo-doping was also observed in other systems, such as As–S–Te and As–S–Se. The difference spectral curves are shown in Figs. 3 and 4. The increase in the optical absorption was in proportion to the amount of Ag which was photo-doped (see Curves 1 and 2 in Fig. 3). In the As–S–Se system, a discrete absorption band (maximum at 565 nm) was observed in the difference spectra, in addition to the increase in the optical absorption which was observed in the absorption tails of the host glasses.

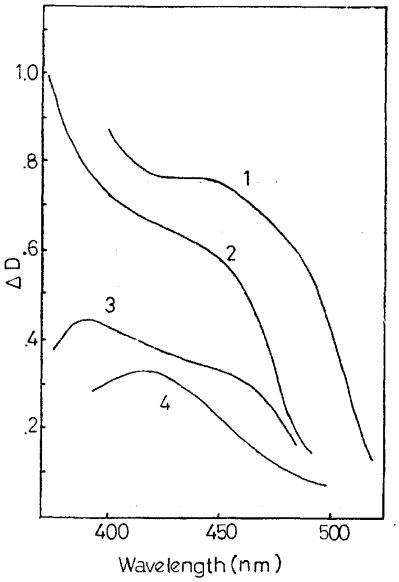

Fig. 5. Difference spectra of Ag (200 Å) photo-doped glasses ($(As_2S_3)_1I_x$).
Curve 1: $x=0$, 2: $x=0.51$, 3: $x=1.0$, 4: $x=1.98$.

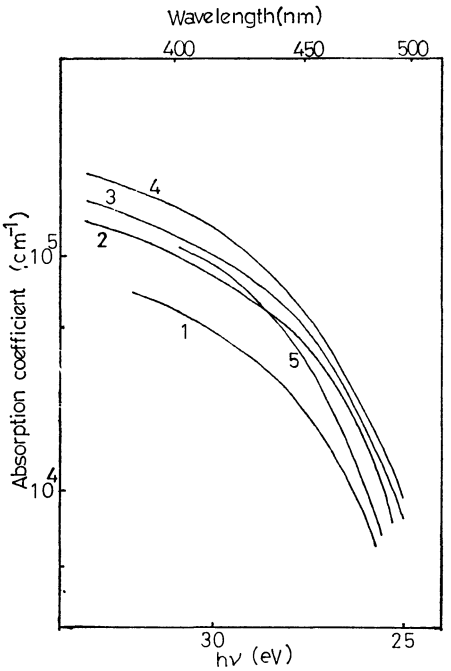

Fig. 6. Absorption spectra of the chalcogenide glasses ($(As_2S_3)_1I_x$).
Curve 1: $x=0$, 2: $x=0.51$, 3: $x=1.0$, 4: $x=1.98$.

The height of the band increased with an increase in the Se content in the glass. In this case, some localized level caused by the interaction between Ag and Se was assumed to be formed in the band gap by Ag photo-doping.

In the glass containing a halogen such as iodine, a charactristic effect on the optical absorption was observed when Ag was doped by illumination. Figure 5, for example, shows the difference spectral curves of the $(As_2S_3)_1I_x$ glass, in which Ag (200 Å in thickness) was photo-doped. A conspicuous increase in the optical absorption was found in the Ag-doped As_2S_3 ($x=0$). On the other hand, the increase in the optical iodine absorption was inhibited by the addition of to the glass. In this case, the tails of the optical absorption of the glasses ($(As_2S_3)_1I_x$) themselves extended to longer wavelengths than those of As_2S_3, as is shown in Fig. 6. From these results, it can be supposed that the photo-doped Ag in the glass is captured by iodine, forming a strong bond such as AgI.

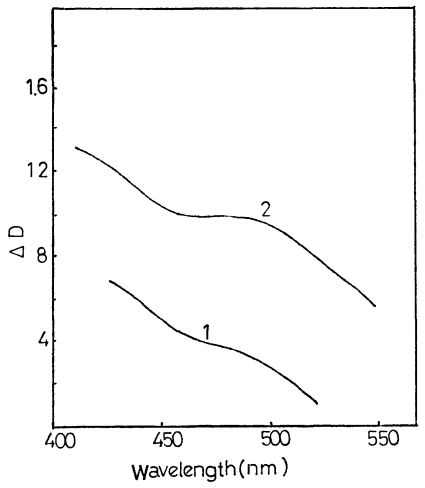

Fig. 7. Difference spectra of the Ag (200 Å) (curve 1) and the Cu (200 Å) (curve 2) photo-doped glass ($(As_2S_3)_1I_{1.98}$)

Figure 7 presents the difference spectral curves of $(As_2S_3)_1I_x$, in which the same amount of Cu as Ag was photo-doped. The increase in the optical absorption caused by the photo-doping of Cu was larger than that of Ag. In the case of Cu photo-doping, the range where the increase in the optical absorption was observed was extended to a longer wavelength than in the case of Ag.

The temperature dependence of the electrical conductivity of chalcogenide glass is generally written as:

$$\sigma = \sigma_0 \exp(\Delta E/kT) \quad (1)$$

where σ and σ_0 are the conductivities and whose ΔE, k, and T denote the activation energy, the Boltzmann factor, and the temperature in an absolute value (K) respectively. This relation tells us that there exists a gap between valence and conduction bands such as in the intrinsic crystalline semiconductors. Since thin film was used for photo-doping in our experiment, the electrical conductivity was measured by means of a surface type cell with Au electrodes 1 mm apart from each other. The current measured with the cell while applying DC voltage (IV) increased with an increase in the magnitude of Ag which had been photo-doped, as is shown in Fig. 8. Besides, the current while applying DC voltage (10 V) against the reciprocal of the absolute temperature was shown as a straight line in the chalcogenide glass ($As_{16}S_{80}Te_4$), in which a corresponding amount of Ag had been photo-doped (see Fig. 9). The ΔE values obtained from the slope of the lines are shown in Table 1. These results imply that the conductivity was increased by the Ag photo-doping, and that, at the same time, "the electrical band gap" ($2\Delta E$) was decreased. These results coincided qualitatively with those of studies of the effect of Ag as a foreign material on the electrical conductivity of chalcogenide glass.[3] In that experiment, the chal-

TABLE 1. "ELECTRICAL BAND GAP ($2\Delta E$)" OF THE Ag PHOTO-DOPED CHALCOGENIDE GLASSES

Composition	Photo-doped Ag (Å)	Band gap (eV)
$As_{16}S_{80}Te_4$	0	2.32
	300	0.98
	500	0.88
	2000	0.75
$As_{40}Se_{60}$	0	1.88
	500	0.72
	1000	0.68

cogenide glass containing Ag was prepared by fusing the chalcogenide glass and Ag.

Figure 10 shows the curve obtained by plotting the current against ($1/T$) for the $As_{16}S_{80}Te_4$ layer, in which Cu of a thickness of 500 Å had been photo-doped. The effective gap obtained from the slope was 0.48 eV.

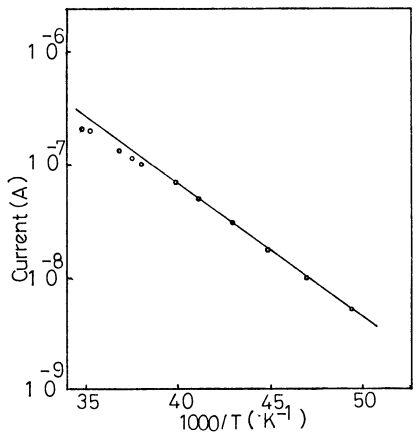

Fig. 10. Current *vs.* reciprocal temperature for the Cu (500 Å) photo-doped glass ($As_{16}S_{80}Te_4$).

This value was smaller than that of the same glass in which Ag of a thickness of 2000 Å had been photo-doped. This result coincided with the results of the effect of the photo-doped Cu on the optical absorption of the chalcogenide glass presented above. This means that Cu is a more effective modifier of the electrical structure of chalcogenide glass than is Ag.

From the theoretical ponit of view, the electrical structure of chalcogenide glass, with which the optical absorption and electrical conductivity mechanism can be elucidated sufficiently, is not clear. It is assumed by Mott[4] that the band structure of the semiconductor is retained, but with some alteration, especially since the curves of the density of the states from tails fall well inside the forbidden gap. Also Fritzsche, Cohen, and Ovshinsky[5] proposed the FCO band model modifying Mott's model to elucidate the optical and electrical properties of chalcogenide glasses.

From the standpoint of the band theory, the role of the metal which was doped into chalcogenide glass by illumination was considered to be a modifier in the band structure of the glass.

As was suggested by the band theory for the crystalline semiconductor, the absorption coefficient (α) in an indirect transition can be written as:

$$\alpha = \text{const}\frac{|M|^2}{h\nu}(h\nu - E_0)^2 \qquad (2)$$

where M is the matrix element of the electrical transition and whose $h\nu$ and E_0 denote the energy of the absorbed photon and the band gap respectively. If M is constant, plotting $(\alpha h\nu)^{1/2}$ against $h\nu$ should result in a straight line. Typical curves showing $(\alpha h\nu)^{1/2}$ versus $h\nu$ for the Ag photo-doped chalcogenide glasses are shown in Fig. 11. When the binary layer is used,

TABLE 2. "OPTICAL GAP (E_0)" OF THE Ag PHOTO-DOPED CHALCOGENIDE GLASSES

Composition	Photo-doped Ag (Å)	Optical gap (eV)
$As_{16}S_{80}Te_4$	0	2.30
	100	1.95
	300	1.65
	500	1.25
$As_{43.5}S_{56.5}$	0	2.14
	200	1.14
$As_{14.8}S_{85.2}$	0	2.24
	200	1.50
	400	1.25

the photo-induced doping is caused at its interface and the distribution of the photo-doped metal in the glass is not uniform. To improve the uniformity, therefore, the thin layer of the chalcogenide glass (600 Å) was used in this measurement. Except for their tails, the plots all show straight lines. The extrapolation of the linear portions of Fig. 11 intersect with the abscissa at the energy E_0; they are shown in Table 2. This value (E_0) is a convenient fiducial mark for locating the structureless absorption curve; one refers to it as the optical gap. The value for E_0 decreased with the increase in the amount of Ag which was photo-doped in the glass. This shows a tendency similar to the effect of photo-doped metal on the value for $2\Delta E$. However, the value for E_0 does not correspond quantitatively to that for $2\Delta E$ in each sample.

These results also support the idea that the photo-doped metals behave as structure modifiers in covalent noncrystalline semiconductors such as chalcogenide glasses. And resulting from the photo-doping of the metal, the state-density in the band gap increased. It may be supposed that the increases in the optical absorption and the electrical conductivity of the metal photo-doped chalcogenide glass are caused by the increase in the state-density in the gap.

Electron Transfer Between Tetracyanoethylene and Its Anion Radical

Raymond CHANG and Jeffery PIEHLER

Department of Chemistry, Williams College, Williamstown, Massachusetts, U.S.A.

(Received March 24, 1972)

The rate of homogeneous electron transfer reactions between an organic anion radical and its neutral molecule is usually close to the diffusion-controlled limit; however, such fast reactions can be conveniently studied by the electron spin resonance (ESR) technique.[1] It is now well known that many anion radicals can exist in thermodynamically distinct species called contact ion-pairs, solvent separated ion-pairs, and free ions.[2] For a given radical, the relative concentrations of these species depend on the nature of the metal cation, solvent, and temperature. In solvents of high dielectric constants such as dimethylformamide and hexamethylphosphoramide, these radicals are assumed to be in the free ion form[3] whereas in solvents of low dielectric constants such as 1,2-dimethoxyethane or tetrahydrofuran (THF) they are believed to be predominantly contact ion-pairs.[2] Although a detailed knowledge of the structure of such ion-pairs is often difficult to obtain, their reactivities can be readily compared from the rate measurements on the electron transfer reactions. For example, the second-order rate constants for the transfer reactions between naphthalene and its anion radical in THF with potassium and sodium as counter ions differ by at least a factor of three.[4,5] Presumably, as a result of the proximity of the metal cation in the ion-pair, a sandwich-type of collision complex is formed with the metal ion between two naphthalene molecules.[6] Thus we would expect that the size and charge distribution of the metal ion to have an important influence on the rate of transfer.

We report here the rate measurements on the electron transfer reactions between tetracyanoethylene (TCNE) and its anion radical ($TCNE^-$)

$$TCNE^- + TCNE \rightleftharpoons TCNE + TCNE^-$$

Table 1. SECOND-ORDER RATE CONSTANTS FOR ELECTRON TRANSFER IN THE TCNE–$TCNE^-$ SYSTEM IN THF AT 25 °C

Metal ion	$k \times 10^{-8}$ (M^{-1} sec^{-1})	Activation energy (kcal mol^{-1})
Li	1.8±0.2	2.8±0.2

in THF with alkali metals as the counter ion and present indirect evidence on the structure of ion-pair in solution. Table 1 summarizes the second-order rate constants together with the corresponding energies of activation. All the rates were measured in the so-called slow-limit.[1] The most surprising result from Table 1 is that all the rate constants are essentially the same. This implies that the reactivity of the TCNE anion radical is independent of the nature of its counter ion and hence the radical is probably in the free ion form. This is not in accordance with the low dielectric constant of THF (7.4)[7] and the fact that the cyanide functional groups are expected to tightly bind the metal ions. Furthermore, the rate constants here are about an order of magnitude smaller than those for aromatic hydrocarbon free ions. However, the results are at least consistent with the fact that no metal splittings are observed except perhaps in the case of cesium where the ESR lines are somewhat distorted at room temperature, suggesting that there might be a small, unresolved hyperfine interaction due to the cesium nucleus. Linear Arrhenius plots were obtained for all the systems from 20 °C to −60 °C. This suggests that over this temperature range there is only one type of radical anion present and its structure (with the metal ion) is insensitive to the change in dielectric constant of the solvent.

Calculation of the Nonradiative Transition Rate for the $^1B_{1u} \rightarrow {}^1B_{2u}$ Transition in Benzene

Noriyuki SHIMAKURA, Yuichi FUJIMURA, and Takeshi NAKAJIMA
Department of Chemistry, Faculty of Science, Tohoku University, Sendai
(Received December 24, 1971)

The nonradiative transition rate for the $^1B_{1u} \rightarrow {}^1B_{2u}$ transition in benzene was calculated taking into account the pseudo-Jahn-Teller distortion in the $^1B_{1u}$ state and using a crude adiabatic approximation. The calculated rate constant is compared with the experimental one reported by Katz *et al.*

In a previous paper,[1] we dealt with a theoretical estimate of the intramolecular nonradiative transition rates for various interstates of benzene as considered from a breakdown of the Born-Oppenheimer approximation. The calculations were carried out on many assumptions which were thought to be justified within statistical limit. Apart from the exact reproduction of experimental data for the nonadiabatic transition rate of $^1B_{1u} \rightarrow {}^1B_{2u}$ transition, there was a significant discrepancy between theory and experiment even in a qualitative sense.

Katz *et al.*[2] have experimentally determined the absorption widths of the $^1E_{1u}$, $^1B_{1u}$, and $^1B_{2u}$ excited states of benzene in solid rare-gas matrices to be about 300, 300, and 0 cm^{-1} respectively. In our calculation, the nonradiative transition rates for $^1E_{1u} \rightarrow {}^1B_{1u}$, $^1B_{2u}$ transitions were predicted to be appreciable, but it turned out that the rate for the $^1B_{1u} \rightarrow {}^1B_{2u}$ transition vanishes.

So far as the $^1B_{1u}$ state is assumed to be of D_{6h} symmetry and expressed by a wavefunction including only singly excited configurations, the transition density between the $^1B_{1u}$ and $^1B_{2u}$ states is exactly zero in π-electron approximation and consequently the nonradiative transition rate vanishes. When the excited states are given in terms of configurations including doubly excited states, the transition density does not vanish. However, the use of wavefunctions including doubly excited configurations as the electronic part of the zeroth-order Born-Oppenheimer vibronic state does not seem to have any significant influence on the nonradiative transition rate.

On the other hand, it is known[3-5] that the $^1B_{1u}$ excited state of benzene is subjected to the pseudo-Jahn-Teller interaction with the $^1E_{1u}$ excited state through vibrations of e_{2g} symmetry, and as a result takes D_{2h} conformations with a quinoidal form or an antiquinoidal. In order to refine the estimation of the nonradiative transition rate for the $^1B_{1u} \rightarrow {}^1B_{2u}$ transition, we should adopt the distorted conformations of D_{2h} symmetry as the zeroth-order Born-Oppenheimer state for the $^1B_{1u}$ state.

Using a simplified, virtual model Sharf and Silbey[6] estimated the line broadening due to interaction between the non-diagonal Born-Oppenheimer states in higher excited electronic states of polyatomic molecules. They used an approximate adiabatic wavefunction for the zeroth-order Born-Oppenheimer vibronic state, and showed that the estimated linewidth obtained with the use of the above wavefunction is of the order of 1 cm^{-1}, whereas experimentally observed linewidths are of several hundred cm^{-1}. Recently they discussed this discrepancy[7] and showed that the vibronic broadening can be properly described through the "crude adiabatic approximation,"[8] whereas the procedure based on the adiabatic wavefunction can be misleading if proper care is not taken. Since both the adiabatic and crude adiabatic Born-Oppenheimer approximations employ complete sets of states, an exact calculation of the nonradiative decay rate could start from either procedure and produce the same, correct result. Nevertheless, since we use the perturbation theory and consider only the lower-order contributions, it is no longer required for the values of the nonradiative transition rate calculated in the crude adiabatic and adiabatic Born-Oppenheimer schemes to be the same or for either scheme to agree with its exact values. It is therefore important to ascertain which scheme would give rise to the smallest higher-order corrections and lead to the fastest convergence. Choice of the zeroth-order wavefunction is related to the problem of which description is more convenient rather than more correct.

In this paper we calculate the nonradiative transition rate for $^1B_{1u} \rightarrow {}^1B_{2u}$, taking into account the pseudo-Jahn-Teller distortion in the $^1B_{1u}$ state and using the crude adiabatic approximation.

Method of Calculation

Let $|s>$ and $\{|l>\}$ denote the optically excited initial Born-Oppenheimer vibronic state and the manifold of isoenergetic Born-Oppenheimer vibronic levels belonging to a lower electronic state, respectively. These vibronic states are the eigenfunctions of a zeroth-order Hamiltonian, H_0, and nonradiative transition is induced by the perturbation term

$$V = H - H_0, \quad (1)$$

where

$$H = T(q) + V(q, Q) + T(Q), \quad (2)$$

$$H_0 = T(q) + V(q, Q_0) + T(Q). \quad (3)$$

$T(q)$ and $T(Q)$ denote the kinetic-energy operator for electronic motion and nuclear motion, respectively, and $V(q, Q)$ is the potential energy operator of the molecular Hamiltonian. Subscript 0 to Q indicates that the corresponding quantity should be evaluated at the ground-state equilibrium nuclear arrangement.

Using resolvent operator R,[9] the exact nonradiative transition rate can be expressed as

$$k_{nr} = \frac{2\pi}{\hbar}\sum_l |\langle s|R|l\rangle|^2 \delta(E_s^0 - E_l^0), \quad (4)$$

where

$$H_0|s\rangle = E_s^0|s\rangle,$$
$$H_0|l\rangle = E_l^0|l\rangle. \quad (5)$$

In the statistical limit, Eq. (4) may be rewritten as[9]

$$k_{nr} = \frac{2\pi}{\hbar}\sum_l |\langle s|V|l\rangle|^2 \delta(E_s^0 - E_l^0) \quad (6)$$

If the most probable path[10] (*vide infra*) can be found for the nonradiative transition, we can represent the nonradiative transition rate by the most dominant term corresponding to the most probable path in the summation in Eq. (6). The nonradiative transition rate from the initial vibronic state $\Psi(^1B_{1u})$ to the final vibronic state $\Psi(^1B_{2u})$, is then written as follows.

$$k_{nr} = \frac{2\pi}{\hbar}|v_{MPP}|^2, \quad (7)$$

where the coupling matrix element v_{MPP} is given by

$$v_{MPP} = \langle \Psi(B_{1u})|\{V(q, Q) - V(q, Q_0)\}|\Psi(B_{2u})\rangle. \quad (8)$$

Let us choose the equilibrium nuclear position for the ground electronic state as an origin and expand the potential energy operator in normal coordinates to the first order. Equation (8) is then rewritten as

$$v_{MPP} = \langle \Psi(B_{1u})|\sum_{i=1}^{3N-6}\{\partial V(q, Q)/\partial Q_i\}_0 Q_i|\Psi(B_{2u})\rangle. \quad (9)$$

Since energy difference between the $^1B_{1u}$ and $^1E_{1u}$ state of benzene is very small, the conventional perturbation scheme for the Herzberg-Teller intensity-borrowing mechanism is not a good approximation in describing the $^1B_{1u}$ state subjected to pseudo-Jahn-Teller interactions with the $^1E_{1u}$ level, and a more refined treatment should be applied. Such calculations for the $^1B_{1u}$ state coupled with the $^1E_{1u}$ state have been carried out by van der Waals *et al.*,[11] who maintained that a single e_{2g} vibration dominates the vibronic mixing. They expanded a proper variational vibronic wavefunction in terms of the crude adiabatic electronic wavefunction, $\Phi^0(=\Phi(q, Q_0))$, which is the electronic wavefunction at the equilibrium configuration in the ground state as in the following.

$$\Psi(B_{1u}) = \eta \prod_{j\neq e_{2g}^c}^{3N-8} \chi''(n, j), \quad (10)$$

$$\eta = \Phi^0(E_{1u}^-)\sum_n L_n\chi''(n, e_{2g}^c) + \Phi^0(B_{1u})\sum_n M_n\chi''(n, e_{2g}^c) + \Phi^0(E_{1u}^+)\sum_n N_n\chi''(n, e_{2g}^c), \quad (11)$$

where the double prime denotes vibrational wavefunctions belonging to the $^1B_{1u}$ state, superscript c to e_{2g} the C–C stretching vibrations, and $\chi''(n, j)$ refers to the harmonic nuclear vibrational function in the jth normal mode in its nth quantum state. L_n, M_n, and N_n are the expansion coefficients to be determined. The summation in Eq. (11) indicates that, to calculate η exactly, we should carry out summation infinitely, but for computational purposes it will have to be truncated. The following points can be inferred from Eqs. (10) and (11). (1) The total wavefunction for the $^1B_{1u}$ state is the product of the vibronic wavefunction which contains only the e_{2g} skeletal stretching mode and the vibrational wavefunction. (2) The vibrational wavefunction is the product of harmonic-oscillator wavefunctions. (3) Only the e_{2g}-type carbon skeleton stretching vibration (e_{2g}^c) is considered since it dominates the vibronic mixing between $^1B_{1u}$ and $^1E_{1u}$ states in benzene. (4) For the $^1B_{1u}$ state we construct a new trial vibronic wavefunction, which is expanded in terms of the crude adiabatic electronic

TABLE 3. CALCULATED ELECTRONIC PARTS

Electronic state		Accepting mode (k)	$\langle \Phi^0(f)\|\{\partial V(q, Q)/\partial Q_k\}_0\|\Phi^0(i)\rangle$(eV/Å)
Initial	Final		
$^1B_{1u}$	$^1B_{2u}$	a_{2g}	0
$^1E_{1u}^+ + {}^1E_{1u}^-$	$^1B_{2u}$	e_{2g}	0.3057

wavefunctions of the $^1E_{1u}^+$, $^1B_{1u}$, and $^1E_{1u}^-$ states. The expansion coefficients are further expanded in terms of the vibrational wavefunctions of e_{2g}-type, $\chi(n, e_{2g})$. Some calculated expansion coefficients, L_n, M_n, and N_n, for the vibrational wavefunctions corresponding to the lowest energy are summarized in Tables 1 and 2.

The wavefunction for the $^1B_{2u}$ state is written as follows,

$$\Psi(B_{2u}) = \Phi^0(B_{2u}) \prod_{j\neq 1}^{3N-6} \chi'(n, j) \tag{12}$$

where the prime denotes vibrational wavefunctions belonging to the $^1B_{2u}$ state. Thus we obtain for the coupling matrix element:

$$\begin{aligned} v = {} & \langle \Phi^0(B_{2u})|\{\partial V(q, Q)/\partial Q(e_{2g}^c)\}_0|\Phi^0(E_{1u}^-)\rangle \\ & \times \langle \chi(e_{2g}, n)|Q(e_{2g})|\sum_n L_n \chi(n, e_{2g}^c)\rangle \prod_{j\neq e_{2g}^c}^{3N-8} \langle \chi(n, j)|\chi(0, j)\rangle \\ & + \langle \Phi^0(B_{2u})|\{\partial V(q, Q)/\partial Q(a_{2g})\}_0|\Phi^0(B_{1u})\rangle \\ & \times \langle \chi(n, e_{2g}^c)|\sum_n M_n \chi(n, e_{2g}^c)\rangle \\ & \times \langle \chi(a_{2g}, 1)|Q(a_{2g})|\chi(a_{2g}, 0)\rangle \prod_{j\neq e_{2g}^c, a_{2g}}^{3N-9} \langle \chi(n, j)|\chi(0, j)\rangle \\ & + \langle \Phi^0(B_{2u})|\{\partial V(q, Q)/\partial Q(e_{2g}^c)\}_0|\Phi^0(E_{1u}^+)\rangle \\ & \times \langle \chi(e_{2g}, n)|Q(e_{2g})|\sum_n N_n \chi(n, e_{2g}^c)\rangle \prod_{j\neq e_{2g}^c}^{3N-8} \langle \chi(n, j)|\chi(0, j)\rangle. \end{aligned} \tag{13}$$

Here we have assumed that the vibrational wavefunctions for the $^1B_{1u}$ and $^1B_{2u}$ states are the same as those in the ground state.

We shall now treat the electronic and vibrational parts separately. The electronic parts can be calculated by the same method as that used previously.[1] The values of the calculated electronic parts are summarized in Table 3. Of the electronic parts

$$\langle \Phi^0(B_{2u})|\{\partial V(q, Q)/\partial Q(a_{2g})\}_0|\Phi^0(B_{1u})\rangle,$$

and

$$\langle \Phi^0(B_{2u})|\{\partial V(q, Q)/\partial Q(e_{2g})\}_0|\{\Phi^0(E_{1u}^+) + \Phi(E_{1u}^-)\}\rangle,$$

the former is zero, and the latter appreciable.

We must now decide the mode which accepts the excess energy. It is assumed that the e_{2g}-type C–C stretching vibration (1606 cm^{-1}) is the most probable path for accepting excess energy for the following reason. Equilibrium configuration differs for the ground and excited states of aromatic hydrocarbons only in the totally symmetric normal coordinate. Therefore, only the progression of totally symmetric vibration is observed in absorption and emission spectra of aromatic hydrocarbons. It is known that as the difference in equilibrium configuration and that in vibrational frequency between the initial and final electronic states become larger, the Franck-Condon factor becomes larger at the higher vibrational quantum number of the final states. We assume the vibrational frequencies of each excited electronic state to be the same as those of the ground state. To accept the same excess energy, the oscillator of the high vibrational frequency requires a small vibrational quantum number compared with that of the low vibrational frequency. Thus, the Franck-Condon factor also becomes larger for the higher vibrational frequency of the final state (see Ref. 12 for more details). The difference in the equilibrium configuration between the $^1B_{1u}$ and $^1B_{2u}$ states in benzene is large along the direction of the e_{2g} normal coordinate. In the present model, the nonradiative transition is considered to occur from the $^1B_{1u}$ state subjected to the pseudo-Jahn-Teller interaction with the $^1E_{1u}$ state. Only the e_{2g}-type carbon skeleton stretching vibration is effective in the above interaction and, is thus the most probable accepting mode.

Results and Discussion

The transition densities necessary for calculating the electronic parts of the coupling matrix element are shown in Fig. 1. The calculated nonradiative transition rate constant is given in Table 4 together with

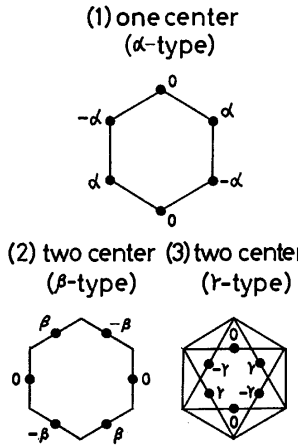

Fig. 1. The electronic energy surface of the lower singlet state of benzene as the function of a_{1g} and e_{2g} normal coordinate displacements.[a]

E_1[b]=4.9 eV E_2[b]=6.2 eV E_3[b]=7.0 eV

a) The same equilibrium points in the $^1E_{1u}$, $^1B_{1u}$, and $^1B_{2u}$ states along totally symmetric C–C stretching coordinate are assumed.

TABLE 4. NONRADIATIVE TRANSITION RATE CONSTANT

Transition	Calculated rate constant (Calculated half width)	Experimental rate constant (Experimental half width)
$^1B_{1u} \rightarrow {}^1B_{2u}$	3×10^{13} sec^{-1} (150 cm^{-1})	6×10^{13} sec^{-1} (300 cm^{-1})

12) W. Siebrand, *J. Chem. Phys.*, **46**, 440 (1967).

the experimental one, the former being in good agreement with the latter. There may be some cancellations among the various types of error arising from the approximations we employed.

We calculated the nonradiative transition rate from the $^1B_{1u}$ state, which undergoes the pseudo-Jahn-Teller interaction with $^1E_{1u}$ state, to the $^1B_{2u}$ state. We assume that the initial and final states can be expressed by the vibronic wavefunctions with a crude adiabatic wavefunction as an electronic factor. When we use the crude adiabatic wavefunction, the off-equilibrium electronic Hamiltonian is the dominant operator responsible for the line broadening or for the decay of the initial state.

The present calculation shows how the lowest order of the potential energy operator contributes to the nonradiative transition rate in the crude adiabatic approximation.

The procedure should be applied to other cases where the state to be dealt with is very near other states. In such cases, we must take into account the vibronic interaction (the pseudo-Jahn-Teller interaction) between these states, because the interaction between each state is very large.

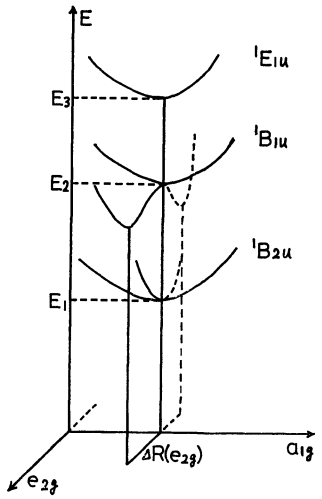

Fig. 2. Calculated transition density between the $^1B_{1u}$ and $(E^+_{1u}+E^-_{1u})$ states.
(1) $\alpha=0$ (2) $\beta=1/3$ (3) $\gamma=0$

The electronic energy surfaces of the $^1E_{1u}$, $^1B_{1u}$, and $^1B_{2u}$ states of benzene as the functions of the a_{1u} and e_{2g} normal coordinate displacements are shown in Fig. 2. The first strong vibrational component in the progressions of the absorption spectrum of the $^1B_{1u}$ state was assigned to $0\text{-}0+\nu_{18}(e_{2g})$.[2] Using these data and the assumed harmonic potential, we estimated the magnitude of difference in equilibrium configuration ΔR (e_{2g}) between the $^1B_{1u}$ and the $^1B_{2u}$ states, arising from the pseudo-Jahn-Teller interaction with the $^1E_{1u}$ state, to be about 0.1 Å.

Fisher and Schneider[13] analyzed the time dependent correlation function about the rate constant and calculated the rate for intersystem crossing from the $^3B_{1u}$ state to the ground state in benzene. They used the saddle point method[14,15] in order to find the most probable path for the intersystem crossing in benzene. They found that 66% (55%) of the energy goes into the C–H (C–D) breathing mode for benzene (deuterobenzene) and the other major energy sinks involve the totally symmetric skeletal breathing mode (990 cm^{-1}), the e_{2g} stretching mode (1584 cm^{-1}) and, to a smaller extent, the out-of-plane vibrations. It is apparent that a certain vibration accepts most of the excess energy. We took into consideration all the possible combinations of the vibrational overlap integrals under the constraint of conservation of the excess electronic energy of the final state.[1] The non-adiabatic Franck-Condon factor was taken as the average value of vibrational coupling matrix elements for computational purposes. We have employed the most probable path method and chosen the e_{2g} C–C stretching vibration as the most probable path. The difference in C–H bond length between the $^1B_{1u}$ and $^1B_{2u}$ states would be small and the C–H normal vibration could not serve as a good accepting mode.[16]

The SCF Screened Potential in π-Electron Systems

Toshitaka TERASAKA, Taizo IIJIMA,* Yuichi FUJIMURA, and Takeshi NAKAJIMA
Department of Chemistry, Faculty of Science, Tohoku University, Sendai
(Received May 24, 1972)

The screened potentials in π-electron systems have been calculated using the SCF orbitals and energies, and compared with Little's screened potentials calculated using the Hückel orbitals and energies. The characteristics of the screened potentials in benzenoid and nonbenzenoid aromatic hydrocarbons and in linear polyenes have been studied. It has been found that the use of the screened potential brings about considerable improvements in the triplet excitation energies in particular.

Recently, Gutfreund and Little[1,2] calculated the screened potential in the π-electron system of large conjugated molecules by means of the Random-Phase-Approximation (RPA) method,[3] which is familiar in the field of many-body physics. They have shown that, in the case of a π-electron system, the integral equation for the screened potential becomes a set of linear algebraic equations within the framework of the LCAO approximation. The results of a Hückel calculation are used in the algebraic equations to generate the screened potential, and with this potential an SCF calculation is performed. The excitation energies are calculated using the modified configuration-interaction (CI) method, in which a screened potential different from that used in the ground-state calculation is employed. The main results that they obtained are as follows: First, the qualitative behavior of the screened potential in the π-electron system is notably different from that in a metal or in an electron gas. In the metal and electron gas, the Coulomb potential of a test charge is effectively screened and behaves like $e^{-\lambda r}e^2/r$, where λ is of the order of several angstroms. On the other hand, in the π-electron system, the screened potential at sufficiently large distances exceeds the bare potential (that is, an antiscreening effect). Second, the screened potential shows a position dependence, although the bare potential does not. As a result, the Coulson-Rushbrooke theorem, which states that, in alternant hydrocarbons, the π-electron densities for all the carbon atoms are unity, does not generally hold for the SCF states calculated using the screened potential. Third, both singlet and triplet excitation energies calculated using the modified CI method assuming the screened potential agree more significantly well with the experimental values than do those calculated assuming the bare potential.

In the usual Pariser-Parr-Pople-type SCF calculation, the wavefunctions are determined by the Hartree-Fock potential, and *vice versa*, but the bare potential (consisting of one- and two-center repulsion integrals) is fixed through the SCF process. We wish to propose the following procedure for calculating the screened potential in π-electron systems using the SCF molecular-orbital wavefunctions and energies (this is the main purpose of this paper): at each step of an SCF calculation, let the screened potential be evaluated by the use of the wavefunctions and orbital energies obtained in that step, and then let us proceed to the next step using this screened potential. We call such a screened potential "the SCF screened potential", and the screened potential evaluated using the results of a Hückel calculation, "the Hückel screened potential".

We apply the above procedure to the SCF screened potential in combination with the variable bond-length SCF method,[4] which is known to reproduce well the equilibrium configurations of π-electron systems, to benzenoid and nonbenzenoid aromatic hydrocarbons, and to linear polyenes. We are concerned mainly with the following points: (1) the difference between the Hückel and SCF screened potentials; (2) the variation in the screened potential with respect to the sizes and forms of molecules, and (3) the position-dependence of the screened potential in the above molecules.

Theory

In the RPA method, the integral equation for the screened potential, V, has the following form:[1]

$$V(r_1, r_2, \omega) = V_0(|r_1-r_2|) + \iint dr dr' V_0(|r_1-r|)\pi_0(r, r', \omega)V(r', r_2, \omega), \quad (1)$$

where r_1, r_2, r, and r' are the coordinates of carbon atoms, where V_0 is the bare potential, where ω has the dimension of energy, and where the RPA polarization part, π_0, is given in terms of the single Green function, G_0, as:

$$\pi_0(r, r', \omega) = 2i\int \frac{d\omega'}{2\pi} G_0(r, r', \omega')G_0(r', r, \omega'-\omega). \quad (2)$$

In π-electron systems, the integral Eq. (1) becomes the following set of linear algebraic equations within the framework of the LCAO approximation:

$$V(r_1, r_2, \omega) = V_0(|r_1-r_2|) + \sum_m K(r_1, r_m, \omega)V(r_m, r_2, \omega), \quad (3)$$

where:

$$K(r_1, r_m, \omega) = \sum_n V_0(|r_1-r_n|)\pi_0(r_n, r_m, \omega) = \sum_n V_0(|r_1-r_n|)\sum_{ia} 4\varepsilon_{ia}u_{ia}(r_n)u_{ia}(r_m)/(\omega^2-\varepsilon_{ia})^2, \quad (4)$$

$$\varepsilon_{ia} = \varepsilon_i - \varepsilon_a, \qquad u_{ia}(r_n) = C_{in}C_{an},$$

where ε_i denotes the orbital energy, C_{in}, the atomic-orbital coefficient in a molecular orbital, and the Latin and Greek indices, the unoccupied and occupied orbitals respectively. The screened potential is given in the matrix notation:

$$V(\omega) = [I-K(\omega)]^{-1}V_0, \qquad (5)$$

where I is the unit matrix.

The screened potential in the ground state is calculated using Eq. (5), with $\omega=0$.

Method of Calculation

In this section, we shall briefly outline the following four procedures for use in calculating the screened potentials in the ground states of π-electron systems.

(1) Little's procedure[1] (the Hückel screened potential): The Hückel molecular-orbital wavefunctions and energies are used to evaluate the screened potential, and an SCF calculation is then carried out using this screened potential.

(2) A procedure that combines Procedure (1) with the variable bond-length SCF method:[4] at each step of an SCF calculation, the C–C bond lengths (r) are evaluated from the corresponding bond orders (p) by the use of the relation between r and p, r (Å)$=1.520-0.186p$. Next, the Hückel-type calculation is performed using the core resonance integral which is given by $\beta(r)=(1.397/r)^4\beta(1.397)$.[5] The screened potential is evaluated using the results of the Hückel-type calculation. Using this screened potential, we carry out the next step of the SCF calculation. The process is repeated until self-consistency with respect to the total energy of the ground state is reached.

(3) The screened potential is evaluated at each step of the SCF calculation (the SCF screened potential). Using the molecular orbitals and orbital energies obtained after an iteration of the SCF calculation, we evaluate the screened potential. This screened potential is taken as the potential for the next iterative SCF calculation. The iteration is continued until self-consistency is reached. Notice that, in Procedure (1), the SCF calculation is carried out using a constant Hückel screened potential, while, on the other hand, in Procedure (3), the SCF calculation is carried out using a variable SCF screened potential.

(4) A procedure that combines Procedure (3) with the variable bond-length method. As in the second procedure, at each step of the SCF calculation, the new bond lengths are obtained from the corresponding bond orders. The screened potential is evaluated by means of the bare potential obtained from the new bond lenghts. This screened potential is used in the calculation of the next step. The calculation is repeated until self-consistency is reached.

Results and Discussion

First, let us compare the two kinds of Hückel screened potentials obtained using two different types of bare potentials, the Pariser-Parr (PP) and Mataga-Nishimoto (MN) potentials. In Fig. 1, the two kinds of Hückel screened potentials in benzene are shown, together with both the PP and MN bare potentials. The two kinds of Hückel screened potentials show quite a similar tendency in that, at small distances, the screening is strong and at large distances the anti-screening is appreciable.[6] Although both types of bare one-center potentials have the same value, the two kinds of one-center screened potentials are different from each other, since the one-center screened potential includes the contribution from other positions through the two-center potentials. For the other compounds treated in this paper, we calculate the Hückel and SCF screened potentials using only the MN potential, because the

6) It is considered that the anti-screening appeared in π-electron systems at large distances has to do with the finite size of the system.[1]

screened potentials obtained assuming the PP and MN potentials will probably show a similar qualitative behavior.

Difference between the Hückel and SCF Screened Potentials. The Hückel and SCF screened potentials in naphthalene and the polyene ($C_{10}H_{12}$) are illustrated in Fig. 2. The SCF screened potential shows a tendency similar to the Hückel screened potential, but it is intermediate between the Hückel screened and the bare potentials. That is, the effects of the screening and anti-screening in the SCF screened potential are both weakened. It seems that, in the Hückel screened potential, the effect of the screening and anti-screening of π-electrons tends to be overestimated.

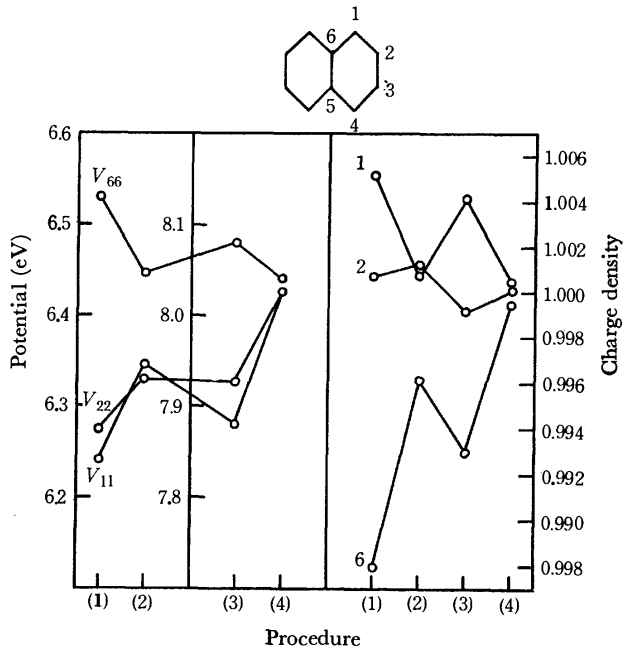

Fig. 3. The one-center screened potentials and charge densities in naphthalene calculated using the four procedures.

Figure 3 presents the one-center screened potentials and the charge densities in naphthalene calculated using the four procedures outlined above. It seems apparent that both the SCF procedure and the variable bond-length method have the effect of making the divergence among the calculated values small, and that this effect is stronger for the variable bond-length method than for the SCF procedure. As Procedure (4) involves both the SCF scheme and the variable bond-length method, the divergence becomes remarkably small. It may also be noted that such an effect appears for both the one-center screened potential and the charge density, and that the degree of breakdown of the Coulson-Rushbrooke theorem becomes appreciably small in the SCF state calculated using Procedure (4). In nonbenzenoid aromatic hydrocarbons and polyenes, there are no such definite effects.

Variation in the Hückel Screened Potential with Respect to the Sizes and Forms of the Molecules. The Hückel screened potentials in benzene, naphthalene, aceazulylene, and aceheptylene are presented in Fig. 4 and compared there with the bare potentials. In Fig. 5,

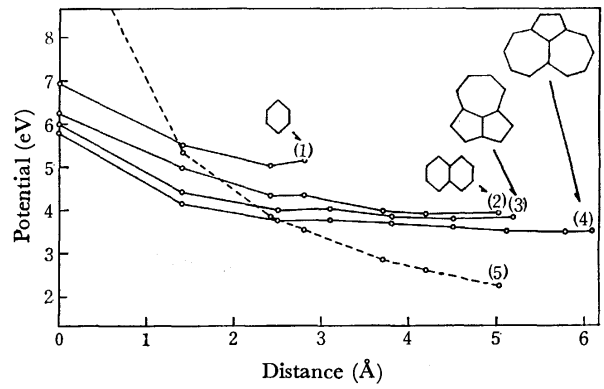

Fig. 4. The Hückel screened potentials; (1) benzene, (2) naphthalene, (3) aceazulylene, (4) aceheptylene, (5) the bare potential.

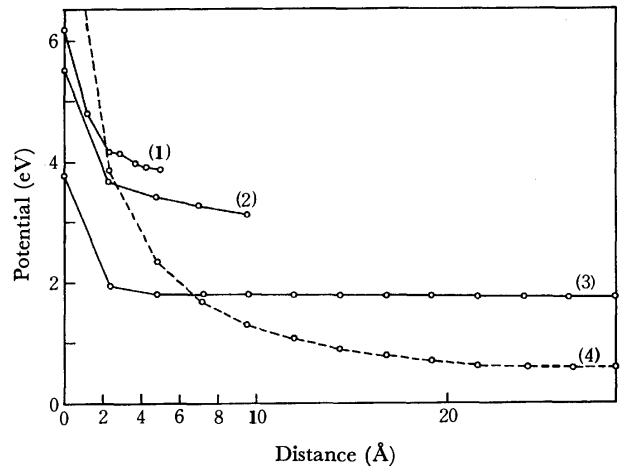

Fig. 5. The Hückel screened potentials in the polyenes ($n=10$ and 30); (1) naphthalene, (2) the polyene ($n=10$), (3) the polyene ($n=30$), (4) the bare potential.

the Hückel screened potentials in linear polyenes (the number of carbon atoms $n=10$ and 30) are shown and compared with the bare and the Hückel screened potentials in naphthalene ($n=10$). Since, in general, the effect of screening is different in various parts of molecules, there is a considerable divergence among the calculated screened potentials, in short ranges in particular; the average values are shown in these figures. From these figures, it will be seen that the screened potential in ring compounds decreases as the n increases, and that, when the n is the same, the screened potential is lower for the chain compound than for the ring compound. It may be stated generally that the larger or longer a molecule is, the stronger the screening in the short range and the weaker the anti-screening in the long range. In long linear polyenes, the Hückel screened potential tends to be constant even at small distances. In such a case, the atomic-orbital coefficients in molecular orbitals obtained from the SCF calculation using the Hückel screened potential tend to be the same as those of the Hückel orbitals.

Position Dependence of the Screened Potential in Polyenes and Benzenoid and Nonbenzenoid Aromatic Hydrocarbons. The carbon atoms in the polyene with $n=10$ are numbered as in Fig. 6. We divide the Hückel screened

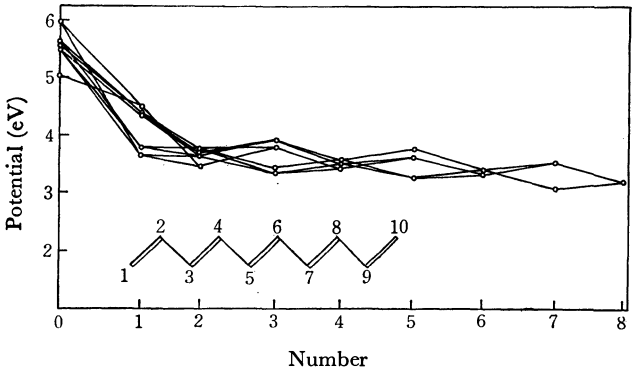

Fig. 6. The Hückel screened potentials in the polyene (n=10) plotted *versus* the number (for the meaning of the number, see the text).

potentials (Procedure (1)) into these groups: V_{11}, V_{12}, V_{13}, ···, $V_{1,10}$; V_{22}, V_{23}, ···, $V_{2,10}$; ···; V_{99}, $V_{9,10}$. In Fig. 6, the screened potentials in each group are plotted *versus* a number that indicates the kind of screened potential, that is, 0: one-center potentials V_{11}, V_{22}, V_{33}, ···; 1: the nearest two-center potentials V_{12}, V_{23}, V_{34}, ···; *etc.* Figure 6 shows that there are two kinds of numbers; that is, at an even number (including 0) one kind of screened potential exists, while at an odd number there exist two kinds of screened potentials in accordance with the strength of the screening.[7] The SCF screened potential (Procedure 3) in the polyene (n=10) presented in Fig. 7 shows a tendency similar to that in the Hückel screened potential.

and the 7-membered ring in aceheptylene, a tendency similar to that in the polyene appears, while in azulene, the 7-membered ring in aceazulylene, and the 5-membered ring in aceheptylene, at each of the numbers the various screened potentials have almost the same value.

We can understand the above characteristics of the screened potential as follows. In the polyene ($n=10$), the screened potentials can be divided into the following two groups according to the numbers:

one group: even numbers (including 0)

0: V_{11}, V_{22}, V_{33}, ⋯

2: V_{13}(), V_{24}(), ⋯

(The number of double bonds $N=1$)

4: V_{15}(), V_{26}(), ⋯ ($N=2$)

⋮

the other group: odd numbers

1: V_{12}(), V_{23}(), V_{34}(), ⋯

($N=1$) ($N=0$) ($N=1$)

3: V_{14}(), V_{25}(), V_{36}(), ⋯

($N=2$) ($N=1$) ($N=2$)

⋮

From the above classification of the screened potentials, it may be seen that there are two kinds of screening at the odd numbers in molecules such as polyene in which there exists a strong bond alternation, while there is only one kind of screening at the odd numbers in molecules which do not show a clear bond alternation—for example, benzene and azulene. In naphthalene, there is a fairly clear double-bond fixation, so that the characteristics of the screened potential in Fig. 8 are the same as those of the polyene.

Transition Energies of Benzene, Naphthalene, Aceazulylene, and Aceheptylene. Tables 1—4 show the transition energies calculated by using the modified CI method assuming the Hückel screened potential and the SCF screened potential, together with those calculated assuming the bare potential. In these tables, "variable" means that a calculation has been performed in combination with the variable bond-length SCF method. The results agree well with the experimental values. It may be noted that triplet excitation energies calculated using the screened potential are in better agreement with the experimental values than those calculated using the bare potential.

Studies on Fragment Ion Distribution and Reaction by the Use of a Charge Spectrometer. I. Mass Spectra of Methylamine after Charge Exchange with Fast Positive Ions and Their Recombination Energies

Toshio NAGATANI, Kenji YOSIHARA, and Takanobu SHIOKAWA
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received June 17, 1972)

Charge exchange reactions with fast positive ions were used to obtain the break down curve and internal energy distribution function of methylamine which differ in several points from those obtained by Sjögren with very slow ions. In the higher region, our results on the population in internal energy distribution function is greater than the previous ones. A valley of the internal energy distribution curve was found in the region 12.0—13.8 eV which is higher than that obtained by Sjögren. The values of RE were reestimated according to recent results.

From our interest in fragment ion distribution and reactivity in nuclear transformations we have studied ion-molecule reactions which might determine the chemical fate of the recoil atom. For direct detection of the reaction paths it was thought that mass spectroscopic methods would be suitable, and a specially designed mass spectrometer, was constructed.[1] This was found useful for studying basic ion-molecule reactions as well as initial charge distributions of decayed atoms.[2]

As regards ion-molecule reactions, typical studies of the ion-molecule reaction initiated by charge exchange have been successfully performed by the use of double mass spectrometers. Lindholm and his co-workers[3] extensively studied the break down curves and internal energy distribution functions of relatively simple gases by means of charge exchange. Valuable information has been obtained on the breaking up of the parent ions and the successive ion-molecule reactions in the reaction chamber. Energy of the incident beam in their work was limited to a low range (900 eV).

In the case of methylamine, Sjögren[4,5] studied the break down curve after the charge exchange reactions with slow ions, and elucidated the internal energy distribution function of the target molecule from the experimental results. It was found that a region with low probability for ionization exists between 11 and 12 eV, and above 15 eV the probability of ionization decreases again. The relation between the electronic structure of the molecule and the break down curve was discussed.

We have studied the dissociation of methylamine with fast ions and compared the results with those by Sjögren who studied it with slow ions. Using fast ions seems to be advantageous as dispersion of energy distribution is much narrow. Interesting findings were obtained on the internal energy distribution function of methylamine.

Experimental

Methylamine as a target molecule was prepared from methylamine hydrochloride (Tokyo Kasei Co.) of guaranteed grade. Methylamine hydrochloride was treated with a saturated solution of potassium hydroxide. Gas of methylamine evolved was dried and vacuum-distilled several times.

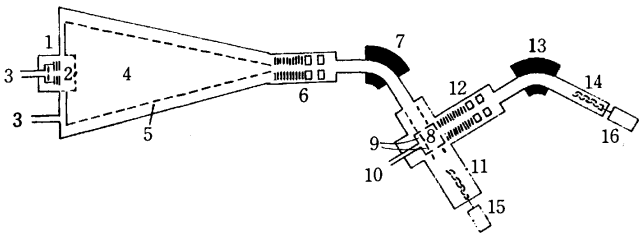

Fig. 1. Schematic diagram of the charge spectrometer.

The mass charge spectrometer is shown in Fig. 1. In place of the X-ray tube an external electron ion source T-2 (Hitachi Co.) may be used, as was the case in this work. Ions generated in an external ion source are introduced into 8 through 7, and impact the neutral atoms or molecules. The produced ions are led into the second analyzing system perpendicular to the incident ion, and detected by 14. Energy of the bombarding electrons in T-2 is 70.0 eV. Positive ions of various gases are produced and selected by the first analyzing system. Details of operation of this assembly have been described previously.[1]

Results and Discussion

The mass spectra of methylamine after charge exchange with 13 kinds of positive ions are shown in Table 1. Acceleration of the incident ions was set at 1850 V. All the values in the table are given when total ionization is normalized to 100. $C_6H_6^+$ was obtained from benzene, C^+ and CO_2^+ from carbon

(a) Results obtained by Sjögren.[4] (b) Present results.

dioxide, Cl^+ being a fragment ion of trichlorofluoromethane (m/e=35). All the other ions were produced from the corresponding rare gases.

The break down curve of methylamine has been constructed from Table 1 and is shown in Fig. 2. The relation between m/e and chemical formulas is as follows.

(31) $CH_3NH_2^+$	(30) $CH_2NH_2^+$
(29) $CHNH_2^+$	(28) $CHNH^+$
(27) CHN^+	(16) NH_2^+
(15) CH_3^+	(14) CH_2^+, N^+
(13) CH^+	(12) C^+

Figure 3 shows the internal energy distribution function determined by the measurement of a relative cross section to the charge exchange reactions. The shape of the break down curve in Fig. 2 agrees as a whole with that of Sjögren,[4] but our energy distribution function differs somewhat.

Appearance potentials of the major fragment ions from methylamine in Table 1 were determined by experiments in which the target gas was bombarded by ions He^+, Ar^+, and Xe^+ with kinetic energy of 4.0—40.0 eV. Values obtained for the mass peaks are: (31), 9.0; (30), 10.2; (28), 13.6; and (15), 14.4 eV. They are in line fairly good with the values reported.[4,6-10]

Recombination Energies of Bombarding Positive Ions. The recombination energies of positive ions and their abundances are corrected by evaluation of the data in Table 1. They differ somewhat from the published data.[4]

1. He^+ Recombination energy of He^+ was reported to be 24.58 eV. From the break down curve (Fig. 2), however, it seems that there may be a small contribution (5%) of the lower energy level which does not greatly exceed the lowest ionization potential of methylamine. This can be argued from the presence of mass peaks 31 and 30 (Table 1).

2. C^+ Electronic structures, recombination energies and their abundances are reported to be[4]

$2p^2P^0$: 11.26, 10.00, 8.58 eV	74%
$2p^2\,^4P$: 16.58, 12.40 eV	25%

However, the ratio $2p^2P^0$: $2p^2\,^4P$ is concluded to be

9) M. I. Al-Joboury and D. W. Turner, *ibid.*, **1964**, 4434.
10) K. Watanabe, *J. Chem. Phys.*, **26**, 542 (1957).

80: 20 from our results.

3. Ne^+ The recombination energies 21.56, 21.66 eV are adopted in this work.

4. Cl^+ The recombination energies of Cl^+ from CCl_3F are reported as follows.[4]

$3p^4\ ^3P$:	13.13, 13.01, 12.96 eV	80%
$3p^4\ ^1D$:	14.45, 14.34 eV	20%
$3p^4\ ^1S$:	16.47, 16.36 eV	0%
$3d^5D$:	15.66, 15.2 eV	0%

The intensity of (15) is extremely small as shown in Table 1. Thus, it is concluded that the level of $3p^4\ ^3P$ is predominant and the effect of the other levels can be neglected.

5. Ar^+ Recombination energies of the ion are 15.76 and 15.94 eV except those of higher levels. These values are adopted in this work.

6. Kr^+ 14.00 and 14.67 eV.

7. Xe^+ 12.13 and 13.44 eV.

8. Ne^{2+} Recombination energy of 10.5—12.0 eV was given when the process $^12s^22p^4 \rightarrow 2s^22p^43x$ occurred. However, the mass peak (28) should be present in almost equal probability with that of (27), and (14) is greater than (15). Therefore, the influence of the level having recombination energy higher than 25 eV is estimated to be about 10%. Probably this is casued by the process $2s^22p^4 \rightarrow 2s^22p^5$.

9. Ar^{2+} Recombination energy of about 9 eV is given for the process $3s^23p^4 \rightarrow 3s^23p^4nx$ which produces (31) by 21%. The remainder is based on the process $3s^23p^4 \rightarrow 3s^23p^5$ (recombination energy: about 24 eV).

10. Kr^{2+} The mass peak 31 of 6.9% is produced by the process $4s^24p^4 \rightarrow 4s^24p^4nx$ with recombination energy of about 9 eV. The remainder is based on the process $4s^24p^4 \rightarrow 4s^24p^5$ (recombination energy: about 21 eV).

11. Xe^{2+} Recombination energy is 18—20 eV (the process $5s^25p^4 \rightarrow 5s^25p^5$ occurs).

12. CO_2^+ In addition to recombination energy of 13.8 eV, the level very near the ionization potential of methylamine contributes about 5%. This increases (13).

13. $C_6H_6^+$ In addition to recombination energy of 9.2 eV, the levels of 10—12 eV are expected to be present. However, these effects are negligibly small and bring no noticeable influence. Absence of the species such as (15) and (14) confirms this argument.

Comparison of Results with Mass Spectra by Electron Impact. When mass spectra are obtained by electron impact, electron energy is usually less than 100 eV. These electrons produce many molecular ions in various excited states, and the average energy of the excited state is considered to be the order of 10 eV. These mass spectra may be computed by taking into consideration the break down curve (Fig. 2) and the internal energy distribution function as in Sjögren's case.[4] Table 2 gives the results calculated with our data, in comparison with the published ones.[4,11–13] Agreement with the observed spectra is satisfactory. However, discrepancy of the fragments produced in the higher energy region is present because population is approximately taken to be zero above 25 eV.

Electronic Structure and Dissociation of Methylamine. The electronic structure of methylamine is shown in Table 3. The data are taken mainly from those of Mulliken[14] and of Turner[15] revised by Sjögren.[5]

In comparison with the results by Sjögren[4] who studied similar phenomena in the low energy region of incident ions, the present results indicate that the [x] electrons are localized on the CH_3 group (IP 15.07 eV after Turner[15]), the [z] electrons on the NH_2 group (IP 16.57 eV after Turner[15]) having large efficiency for charge exchange (Fig. 3). Sjögren has shown only low probabilities for ionization of these groups.

15) M. I. Al-Joboury and D. W. Turner, *J. Chem. Soc.*, **1964**, 4434.

According to Mulliken, ionization of [y] electrons localized on the CN group is expected to occur at 13.5 eV. If this is the case, a steep rise of CH_3^+ or NH_2^+ will be seen at 13.5 eV in the break down graph. However, such an ionization seems to be suppressed by the weak interaction of the CH_3 and the NH_2 groups in the neighorhood of 13.5 eV (Fig. 2, Table 1). A similar discussion has been given by Sjögren,[4] but our experimental data seem to support this arguement more clearly.

The cause of the difference between our results and Sjögren's has not yet been completely explained. Dynamic treatment would be necessary to solve the problem.

The authors are indebted to Mr. M. Hiraga and Mr. Y. Takita for their kind cooperation throughout this work. They also thank Dr. T. Noda and his staff of Hitachi Co. for construction of the charge spectrometer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1309—1315 (1973)

Determination of the Intersystem Crossing Probabilities of Acridine in Various Alcohols[1]

Kunihiro TOKUMURA, Koichi KIKUCHI, and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki-Aoba, Sendai

(Received June 27, 1972)

Intersystem crossing probabilities ϕ_{ST} of acridine in methanol, ethanol, and 2-propanol were determined by two newly developed methods, relative (r) and absolute (a). The results are as follows. Methanol; 0.27 (r), 0.31 (a). Ethanol; 0.29 (r), 0.33 (a). 2-Propanol; 0.43 (r), 0.45 (a). The above ϕ_{ST} values added to the quantum yield values already obtained of photoreduction occurring at T(n-π^*), *viz.*, $2\phi_R{}^T$ (radical mechanism *via* T(n-π^*), disproportionation of semiquinone being taken into account by a factor of 2) + $\phi_M{}^T$ (molecular mechanism *via* T(n-π^*)), become about the same for the three alcohols. Thus the present data are consistent with our previous data on photoreduction if the intersystem crossing is assumed to occur mainly *via* S*(π-π^*)→T(n-π^*)→T(π-π^*) with the same total ϕ_{ST} for the three alcohols but with T(n-π^*) participating in the reaction in different extent according to the alcohol.

An interesting problem in the photoreduction of acridine is the participation of a higher T(n-π^*) state in the reaction. The possibility was porposed for the first time by Kellmann and Dubois in the photoreduction of acridine in methanol.[2] Vander Donckt and Porter found that only a singlet excited state is involved in the case of 2-propanol.[3] Wilkinson and Dubois also reported a similar result for ethanol.[4] Our results[5] were recently reexamined and corrected to some extent; they show that 53, 33, 31, and 0% of the entire reaction occur at T(n-π^*) in methanol, ethanol, *n*-propanol, and 2-propanol respectively,[6] in agreement with the results of Kellmann, Dubois[2] and Vander Donckt and Porter,[3] but not with those of Wilkinson and Dubois.[4]

The reason for this difference between the four kinds of alcohols is still unknown; determination of the intersystem crossing probabilities ϕ_{ST} in various alcohols might be enlightening. The lowest T(π-π^*) is most likely reached *via* T(n-π^*) since intersystem crossing occurs far more efficiently between n and π states than between π and π,[7] and the level of the former is nearer to the lowest singlet excited state. The ϕ_{ST}-values experimentally obtained are expected to be in the order 2-propanol>ethanol>methanol, if the yields of T(n-π^*) (sum of the yield of T(π-π^*) and the part of T(n-π^*) consumed in reaction) are the same for all the alcohols as is plausible.

Two methods have been newly developed for determining the ϕ_{ST} value. (a) A relative method in which a quantity of fluorescence emitted during a flash is taken as a measure of light absorption, and which is an application of the emission-absorption flash technique.[8] (b) An absolute method in which the quantity of light is measured by means of a K–Fe(III) oxalate actionometer. Knowledge of the yield of triplet state is necessary for both methods.

A necessary condition for the relative method is that the substance under investigation and the reference substance have a common wavelength region for both absorption and fluorescence. Anthracene which satisfies such a condition can be used as a reference for acridine,

but the fluorescence intensity of the latter is not strong and there is some difficulty in practice. The principle of the method is as follows. The triplet yield per one flash $[T]_0$ which is given by

$$[T]_0 = \frac{[D_T]_0(\lambda')}{\varepsilon_T(\lambda')d} \quad (1)$$

(where $[D_T]_0(\lambda')$, optical density immediately after a flash, $\varepsilon_T(\lambda')$, molar extinction coefficient at λ') is related to the quantity of light absorption by

$$[T]_0 = \phi_{ST}\int I_{ab}dt \quad (2)$$

in which the integral over the wavelength is omitted for the sake of simplicity. The time integrated fluorescence intensity is written as

$$\int I_F(\lambda)dt = \alpha(\lambda)\phi_F\int I_{ab}dt \quad (3)$$

where ϕ_F is the fluorescence quantum yield and $\alpha(\lambda)$ is a constant depending on the setup of the apparatus and experimental conditions. From Eqs. (1), (2), and (3) we have

$$\phi_{ST}\varepsilon_T(\lambda')d = \alpha(\lambda)\phi_F[D_T]_0(\lambda')\Big/\int I_F(\lambda)dt \quad (4)$$

Since this relation holds both for reference (A) and sample (B), it follows that

$$\frac{\phi_{ST}^B\cdot\varepsilon_T^B(\lambda')}{\phi_{ST}^A\cdot\varepsilon_T^A(\lambda')} = \frac{(\alpha(\lambda)\phi_F)^B}{(\alpha(\lambda)\phi_F)^A}\times\left\{\frac{[D_T]_0(\lambda')^B}{\int I_F^B(\lambda)dt}\Big/\frac{[D_T]_0(\lambda')^A}{\int I_F^A(\lambda)dt}\right\} \quad (5)$$

λ was chosen so that the fluorescence intensities of the two samples could be compared accurately. It is desirable that the fluorescence intensities of the two are nearly equal, that there is no reabsorption at λ and that $dI_F/d\lambda$ is small at λ for both compounds. If ϕ_{ST}^A is known, the experimental determinations of

$$\frac{\varepsilon_T^B(\lambda')}{\varepsilon_T^A(\lambda')}, \frac{(\alpha(\lambda)\phi_F)^B}{(\alpha(\lambda)\phi_F)^A} \text{ and } \left\{\frac{[D_T]_0(\lambda')^B}{\int I_F^B(\lambda)dt}\Big/\frac{[D_T]_0(\lambda')^A}{\int I_F^A(\lambda)dt}\right\}$$

are all that is required to evaluate ϕ_{ST}^B. These are obtained respectively from energy transfer experiments, comparison of fluorescence intensities and the plots of $[D_T]_0(\lambda')$ *vs.* $\int I_F(\lambda)\,dt$.

A direct method is suitable for a substance with weak or no fluorescence. Bowers and Porter developed a somewhat similar method to ours.[9] In order to determine the light absorbed by a sample I_{ab}, they used the relation

$$\frac{I_{ab}}{I_0} = \frac{\int T_f(\nu)[1-T_c(\nu)]d\nu}{\int T_f(\nu)d\nu}$$

where I_0 is the incident light and T_f and T_c are the transmission coefficients of a filter and a sample, respectively. I_{ab} was determined from I_0 and the magnitude of the right term obtained graphically from the transmission profiles of a filter and a sample.

Our method is more experimental in nature. As shown in Fig. 1 an argon lamp specially designed is

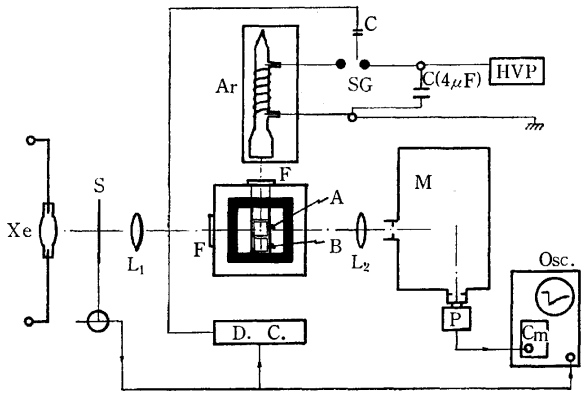

Fig. 1. Diagram of the flash apparatus.
Xe: xenon arc lamp, Ar: argon flash lamp (36 Torr). c: condenser, SG: spark gap, HVP: high voltage pulse, M: grating monochrometer, P: photomultiplier, Osc.: oscilloscope, Cm: comparator, D.C.: delay circuit, A: sample cell, B: actinometer cell, F: filter, L_1,L_2: lens, S: shutter.

placed about 7 cm from a sample cell. The lamp and cell are connected with a cylinder with inner wall painted black. Two cells for sample solution (A) and for actinometer solution (B) (K–Fe(III) oxalate) are placed close to each other. Three sets of measurements are necessary for determining the light quantity absorbed by a sample: a) n_A^0, the number of Fe(II) molecules produced by one flash in B-cell, is determined experimentally when the solvent is in A and the actinometer solution is in B. b) A similar quantity n_A^S is determined when the sample is charged in A and the actinometer solution in B. c) Putting the actinometer solution into A and B, similar quantities m_A in A and n_A^A in B are determined. Thus from (a) and (b), the light absorbed by a sample solution I_{ab}^S is given by

$$\frac{I_{ab}^S}{I_0^1} = \frac{n_A^0-n_A^S}{n_A^0} \quad (6)$$

where I_0^1 is the light intensity close to the inner front side of cell A. Similarly from (a) and (c) we have

$$\frac{I_{ab}^A}{I_0^1} = \frac{n_A^0-n_A^A}{n_A^0} \quad (7)$$

and

$$\frac{m_A}{\phi_{Fe(II)}} = I_{ab}^A\ (\phi_{Fe(II)}, \text{ quantum yield of actinometer}) \quad (8)$$

Hence

$$I_0^1 = \frac{n_A^0}{n_A^0-n_A^A}\times\frac{m_A}{\phi_{Fe(II)}} \quad (9)$$

From Eqs. (6) and (9) we obtain

$$I_{ab}^S = \frac{n_A^0-n_A^S}{n_A^0-n_A^A}\times\frac{m_A}{\phi_{Fe(II)}} \quad (10)$$

The method requires strict constancy in the energy output of the lamp.

Experimental

Substances. Specially purified anthracene was supplied by Prof. S. Kato, Tokyo University. Acridine was purified by the standard method. Proflavine sulfate ($C_{13}H_{11}N_3\cdot$

9) P. G. Bowers and G. Porter, *Proc. Roy. Soc. Ser A*, **296**, 435 (1967). G. Porter and P. G. Bowers, *ibid.*, *Ser .A*, **299**, 348 (1967).

$H_2SO_4 \cdot H_2O$, Tokyo Kasei) was treated with 10N NH_3 aqueous solution and was recrystallized three times from ethanol. Purity of a free base thus obtained was checked by elementary analysis and absorption spectrum. *o*-Phenanthroline (Wako Junyaku) was used without further purification. K-ferrioxalate ($K_3Fe(C_2O_4)_3 \cdot 3H_2O$) was prepared by mixing 300 ml aqueous solution of 1.5 M K-oxalate and 100 ml aqueous solution of 1.5 M $FeCl_3$. A crude sample was purified by recrystallization three times.

Apparatus. An ordinary flash apparatus was used. For the relative method, a xenon arc lamp was used for monitoring the absorption spectra of intermediates. A direct generator was used as a source in most experiments, but was replaced by a lead accumulator when the concentrations of intermediates were very low. The sample cell made of quartz and cylindrical in shape has a 10 cm light path. For the direct method, an argon (36 Torr) flash lamp (Fig. 1) was used. Its time characteristic is shown in Fig. 2 and transmissions of the filters in Fig. 3. All the measurements were made at room temperature.

Results

Relative Method. The test was carried out with 9-methyl and 9-phenylanthracene as a sample and anthracene as a reference. The ϕ_{ST} values obtained for ethanol solutions are listed in Table 1 together with the values given in literature. Though the results are found to be satisfactory, the experiments carried out with acridine whose fluorescence is very weak were difficult in contrast to those with great fluorescence intensity. A UVD-2 filter was used for the excitation of anthracene and acridine and VY-43 for the excitation of proflavine.

a) *Determination of the Quantity.*

$$\frac{[D_T]_0^B(\lambda_B') \Big/ \int I_F^B(\lambda)dt}{[D_T]_0^A(\lambda_A') \Big/ \int I_F^A(\lambda)dt}$$

The plots of $[D_T]_0$ *vs.* $\int I_F\, dt$ for anthracene and acridine in methanol, when both quantities were measured at various flash intensities, are shown in Fig. 4. The $[D_T]_0(\lambda')/\int I_F(\lambda)\, dt$ value was evaluated from the slope of the plot. λ was selected in such a way that the ratio of fluorescence intensities I_{An}/I_{Ac} is the smallest. This is also a necessary condition for the accurate determination of $\alpha(\lambda)\phi_F$.

Relative values of $\int I_F(\lambda)\, dt$ were obtained by taking a photograph of oscillogram, tracing it on section paper and measuring the area under the curve. A

2-Propanol	0.932	0.078 (λ=413 nm)	0.67_9	8.3_9	0.43

a) T-T absorption was measured at 421 nm.

correction was made for the scattered light in the case of acridine. The results are given in Table 2.

b) *Determination of* $(\alpha(\lambda)\phi_F)^B/(\alpha(\lambda)\phi_F)^A$. Solutions were degassed to eliminate the quenching action of oxygen. By adjusting the concentration, excitation was performed at a wavelength at which the absorbance is the same for anthracene and acridine. The fluorescence intensity ratio itself then affords the required quantity. Reabsorption was negligible at the wavelength employed. The results are given in Table 2.

c) *Determination of* $\varepsilon_T^B(\lambda')/\varepsilon_T^A(\lambda')$. An energy transfer method was used to determine the ratio of extinction coefficient. Proflavine was used as an energy donor. This substance has the lowest T-level at 17100 cm^{-1} which is far below the suspected T(n-π^*) level of acridine and significantly higher than the lowest T(π-π^*) of acridine (15840 cm^{-1}) and anthracene.[10] By using a VY-43 filter, proflavine alone can be excited. At moderate concentrations of acridine and anthracene, complete T-energy transfer occurs from donor to acceptor; $[D_T]_0$ of acceptor should then be proportional to $\int I_F\,dt$ of proflavine. The former was measured at 420 nm and the latter at 494 nm. 420 nm is a peak position of T-T absorption of anthracene. The peak of acridine T-T absorption is located at 440 nm but there is an appreciable absorption of proflavine at this wavelength. The plots for anthracene and acridine in methanol are given in Fig. 5. Equally satisfactory plots were obtained also for ethanol and 2-propanol. It was confirmed that the plot of $[D_T]_0$ *vs.* $\int I_F dt$ for the solution containing proflavine alone gives a satisfactory straight line. The results are summarized in Table 2. The ϕ_{ST} values were obtained from the three sets of data.

Absolute Method. The test was carried out with

anthracene in 2-propanol. The ϕ_{ST} value obtained was 0.7_6 which agrees fairly well with that in literature.

Determination of $[T]_0$: The optical density and molar extinction coefficient for T-T absorption are required for knowing the triplet concentration. Since $\varepsilon_T^{An}/\varepsilon_T^{Pr}$ and $\varepsilon_T^{Ac}/\varepsilon_T^{Pr}$ are known we need to determine the value of ε_T^{Pr}. Decay of T-T absorption and recovery of the ground state absorption were measured with very dilute solutions of proflavine (1×10^{-6} or 1.17×10^{-6} M). Proflavine has a tendency of dimerization which is especially large in 2-propanol. Hence higher concentrations are undesirable. As shown in Fig. 6, the log $[D_T^{Pr}]$ *vs.* t plot for the former and the log $(D_\infty-D)$ *vs.* t plot for the latter, both methanol solutions, give straight lines with the same slopes. (D_∞ is the optical density when the ground state is recovered completely.) Similar results were obtained for ethanol and 2-propanol solutions.

The $[D_T^{Pr}]$-values are plotted against the $(D_\infty-D)$ values of the corresponding time points in Fig. 7; both values were taken from the results in Fig. 6 and the similar ones. Figure 7 indicates that the ground state proflavine recovers in one to one correspondence as the triplet state decays. ε_T^{Pr} and then ε_T^{Ac} and ε_T^{An} were determined from the slopes and are listed in Table 3.

The yield of triplet state was obtained by extrapolating the decay curve of T-T absorption to the time point of 25 μsec after flashing. The time point was selected taking the time character of the flash lamp (Fig. 2) and the decay rate of the triplet acridine into consideration. n_T, the number of triplet molecules produced, was calculated from the equation

$$n_T = [T]_0 \times \frac{V_1 N}{1000} \qquad (11)$$

where V_1 is the irradiated volume and N is Avogadro's number.

Measurement of the Absorbed Light: Because of low power of the flash, flashing was repeated 30—60 times, for a K-Fe(III) oxalate actinometer to be applicable. The method of measurement was modified to some extent, particularly with respect to coloration. The pH was adjusted to 3.5. Reflection on the cell windows and light scattering were taken into consideration. A correction formula proposed for the case of parallel light was applied,[11] but the correction factors were almost within experimental error.

The quantity of light absorption can be determined by Eq. (10). It is desirable to keep the value of $(n_A^0-n_A^S)/n_A^0$ in the range 0.15—0.20 in order to secure uniform formation of the triplet state. This was not possible experimentally, but the results were satisfactory. It was confirmed that the absorption spectrum of the solution subjected to flashing 30—60 times changed little, indicating that scarcely any reaction occurred.

Optical density of Fe(II)-orthophenanthroline chelate complex at 510 nm D_{510} was measured after being

11) R. E. Hunt and J. L. Hill, *J. Chem. Phys.*, **15**, 111 (1947). M. J. Dignam and D. J. LeRoy, *ibid.*, **26**, 964 (1957). M. A. Davies and P. P. Manning, *J. Amer. Chem. Soc.*, **79**, 5148 (1957).

subjected to flashing 30—60 times. m_A was then evaluated by the following equations.

$$m_A = [Fe(II)]_1 \times \frac{V_2 N}{1000} \quad (12)$$

$$[Fe(II)]_1 = \frac{D_{510}}{\varepsilon_{510} \cdot d} \times \frac{1}{P}$$

where ε_{510} is the molar extinction coefficient of chelate complex, d the light path (1 cm), V_2 a volume of the solution of chelate complex and P the number of flashes.

From Eqs. (10), (11), and (12), ϕ_{ST} can be evaluated by

$$\phi_{ST} = \frac{n_T}{I_{ab}} = \frac{[T]_0}{[Fe(II)]_1} \times \frac{n_A^0 - n_A^A}{n_A^0 - n_A^S} \times \frac{V_1}{V_2}\phi_{Fe(II)} \quad (13)$$

The value of 1.15 was used as $\phi_{Fe(II)}$.[12]

The ϕ_{ST}-values of acridine are listed in Table 4 together with other related quantities. Constancy of the energy output was checked by observing the T-T absorption repeatedly in the course of experiment. This was confirmed by the constancy of m_A/n_A^0 for succeeding experiments. No systematic concentration dependence is observed. Experimental error can not be estimated accurately but might be less than $\pm 10\%$.

Discussion

The ϕ_{ST}-values of acridine obtained by the two methods are listed in Table 5 together with the quantum yields of photoreduction *via* various paths[6] and with other related data. We see that the values obtained by the relative method are systematically a little smaller than those by the absolute method. It is remarkable that the ϕ_{ST}-value in 2-propanol is significantly larger than that in methanol and in ethanol; this is common to the results by the two methods.

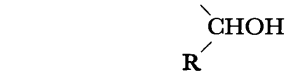
It seems reasonable to correlate the large value in 2-propanol with the fact that T(n-π^*) participates in the photoreduction to some extent in ethanol and methanol but not in 2-propanol. ϕ_M^S, ϕ_R^S, ϕ_M^T, and ϕ_R^T in the table are the quantum yields of photoreduction *via* four paths. Subscripts M and R stand for molecular and radical mechanisms, respectively, and superscripts S and T for singlet excited and T(n-π^*) states, respectively. The general scheme of the photoreduction of acridine in alcohols presented by us is as follows.[5,6]

$$A \xrightarrow{h\nu} {}^1A^*$$

$${}^1A^* \longrightarrow A \qquad {}^1A^* \longrightarrow A + h\nu'$$

$${}^1A^* + RCH_2OH \longrightarrow AH\cdot + RCHOH \quad \text{(radical mechanism)}$$

$${}^1A^* + RCH_2OH \longrightarrow AH_2 + RCHO \text{ or } \quad \text{(molecular mechanism)}$$



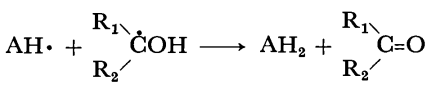
$${}^1A^* \longrightarrow {}^3A(n\text{-}\pi^*)$$

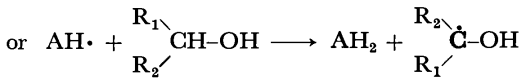
$${}^3A(n\text{-}\pi^*) \longrightarrow {}^3A(\pi\text{-}\pi^*)$$

$${}^3A(n\text{-}\pi^*) + RCH_2OH \longrightarrow AH\cdot + R\dot{C}HOH \quad \text{(radical mechanism)}$$

$${}^3A(n\text{-}\pi^*) + RCH_2OH \longrightarrow AH_2 + RCHO \text{ or } \quad \text{(molecular mechanism)}$$

$$AH\cdot + AH\cdot \longrightarrow AH_2 + A \text{ (disproportionation)} \quad \text{(in methanol and ethanol)}$$





(in 2-propanol)

It is to be noted that the half-reduced radical produced by radical mechanism undergoes disproportionation in methanol and ethanol while in 2-propanol, it is entirely transformed into acridan-type compound.[6,13] The entire quantum yields for the production of T(n-π^*) in methanol and ethanol are then given as the sum $\phi_{ST}+2\phi_R^T+\phi_M^T$. The values are the same for three alcohols within experimental error when one uses the ϕ_{ST} values by the absolute method. It is thus reasonable to consider that the entire quantum yield of the production of T(n-π^*) is about the same for the three alcohols. Thus one can say that the ϕ_{ST} values we obtained and the quantum yields of photoreduction already published are correlated with each other in a consistent way. ϕ_{total} is a fraction of singlet excited state which disappears by reaction, fluorescence and intersystem crossing; the calculation was made in a similar way to the above. Thus $1-\phi_{total}$ is a fraction of eventural

Table 5. Quantum yields of various processes occuring in the excited acridine

internal conversion.

Some remarks should be added on the nature of the reactive singlet excited state. Zanker and Prell[14] proposed that S*(n-π^*) instead of S*(π-π^*) is a reactive state for the photoreduction of 9-methylacridine in deaerated ethanol solution. According to their results, the quantum yields for the formation of T(π-π^*) (ϕ_{ST}) and for the photoreduction (ϕ(R)) have about the same temperature dependence with an activation energy of about 800 cal/mol. They concluded that S*(n-π^*) is located above S*(π-π^*) by this amount, both reaction and intersystem crossing occurring mainly at S*(n-π^*). Whitten and Lee also concluded[15] that S*(n-π^*) is a reactive state for the photoreduction of acridine by isopropyl alcohol, toluene, and *p*-methylanisole in some inert solvents. Assuming that reaction occurs only at singlet excited state, they investigated the dependence of ϕ(R) and of the fluorescence of acridine ϕ(F) on the concentration of reducing agents; they found that in most cases fluorescence intensity is scarcely affected by the occurrence of photochemical reaction. We feel, however, that some of their fluorescence intensity data are consistent with the occurrence of quenching on account of the reaction. They inferred that S*(n-π^*) is below S*(π-π^*) in all the cases irrespective of solvent polarity, and S*(π-π^*) attained immediately after the light absorption goes down more or less irreversibly to S*(n-π^*) where reaction and intersystem crossing occur in competition. Conclusions on the relative positions of π-π^* and n-π^* reached by the two groups differ and further studies are necessary to decide which is correct. If the intersystem crossing were to occur only *via* S*(n-π^*)→T(π-π^*), as they both concluded, reaction at T(n-π^*) state would never occur. Our present results, which are consistent with our previous data of the reaction quantum yields, strongly suggest that the intersystem crossing occurs to a significant extent *via* S*(π-π^*)→T(n-π^*)→T(π-π^*) in addition perhaps to the above path. But since the level difference between S*(n-π^*) and S*(π-π^*) is of the order of kT according to Zanker and Prell (although it appears that their values are not so reliable because of the composite nature of ϕ(R) and ϕ_{ST}), it seems more reasonable to consider that both S*(n-π^*) and S*(π-π^*) are mixed with each other to some extent by vibronic interaction. If this is the case, S*(π-π^*) may also participate in the reaction. The temperature dependence of ϕ_{ST} as well as of ϕ(R) would then become more complicated in nature and can not be treated simply by means of the Arrhenius plot. The relative positions would be inverted according to the polarity of solvent, contrary to Whitten and Lee's conclusion.

Although both the nature of the reactive singlet excited state and the process of intersystem crossing require further studies, there is scarcely any doubt that the intersystem crossing occurs for the most part *via* S*(π-π^*)→T(n-π^*)→T(π-π^*).

The Determination of the CMC of Surfactants in Some Organic Solvents

Shinya MUTO and Kenjiro MEGURO

Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received June 29, 1972)

Extra absorption spectra appeared when 7,7,8,8-tetracyanoquinodimethane (TCNQ) was solubilized into surfactant organic solvent solutions above the critical micelle concentration (CMC). It was found also that extra absorption spectra appeared when iodine was solubilized into surfactant organic solvent solutions above the CMC. In the former case, the extra absorption spectra are attributed to TCNQ anion radical salts formed between TCNQ and the surfactants. In the latter, the extra absorption spectra are due to charge-transfer interactions of iodine with the surfactants. The intensity of the absorption bands increased with the concentrations of the surfactant. The values of the CMC of the surfactants were determined from this spectral change. The CMC values obtained by the TCNQ solubilization method were larger than those obtained by the iodine solubilization technique. The difference in the CMC between the two methods was interpreted in terms of the difference in solubility and charge-transfer power to the organic solvent between iodine and TCNQ, and the difference in type of electron transition, that is, $n(D)\rightarrow\sigma(A)$ or $n(D)\rightarrow\pi(A)$.

The critical micelle concentrations (CMC's) of oil-soluble surfactants in organic solvents have frequently been determined in the past by three different methods, by the light-scattering method, by the vapour-pressure depression, and by the solubilization technique. As these methods are not easy, a more convenient and simple method is desirable.

In our previous paper,[1] we reported that when TCNQ, a well-known strong electron aceeptor, was solubilized into surfactant aqueous solutions above the CMC, a characteristic color appeared. This phenomenon was applied to the determination of the CMC of various surfactants in aqueous solutions.

Recently, we found that this solubilization is also useful for determining the CMC of oil-soluble surfactants in various organic solvents, for the TCNQ solubilized in surfactant organic solutions above the CMC has characteristic absorption spectra, probably because of the TCNQ anion radical formed by the charge transfer from the surfactant to the TCNQ.

The CMC's of surfactants have also been determined by an iodine-solubilization technique[2] in organic solvents.

In this paper, we will report on the characteristics of the charge-transfer solubilization of TCNQ into surfactant micelle in organic solvents and will compare our results with those of other methods.

Experimental

The surfactants used in this experiment were dodecyl pyridinium iodide and Aerosol OT.

Dodecyl pyridinium iodide (DPI) was synthesized by the usual method[3] in our laborotory; its purity was confirmed by the surface-tension and electroconductance methods.

Aerosol OT (sodium dioctyl sulfosuccinate) was supplied from the Nikko Chemical Co., and this sample was purified as follows. It was dissolved in methanol, and the undissolved material was excluded by means of a fine glass filter and subsequent drying.

TCNQ was synthesized according to a procedure described previously.[4] It was purified by five recrystallizations in acetonitrile. The crystals thus obtained had a rust-colored, flasky form; their purity was confirmed by elementary analysis and by studying the melting point.

Iodine of a G.R. garde was purified by sublimation.

Benzene, cyclohexane, *n*-heptane, and carbon tetrachloride were purified according to the procedure of Kitahara and Kon-no.[5] Chloroform, methyl alcohol, and acetonitrile were purified in the usual way.[6]

For ultraviolet, visible and near-infrared spectra studies, the TCNQ solutions were prepared as follows: a known quantity of the TCNQ was dissolved in a measured volume of various organic solvents (the TCNQ concentartion was about 10^{-4} mol/l), and then this solution was used as the stock solution of the TCNQ (A). The stock solution of the surfactant (B) contained a known concentration of the surfactant well above its CMC. By diluting the B solution with the A solution, a series of concentrations of the surfactant could be obtained, each with the same concentration of TCNQ. This series had to include concentrations above and below the CMC to be determined. All the solutions were prepared at room temperature.

Iodine-surfactant solutions were also prepared in the same manner as the TCNQ-surfactant solutions. In this case, the iodine concentration was kept at 5×10^{-4} mol/l for all the solutions.

The absorption spectra were measured by using a Hitachi Spectrophotometer (Model EPS-2).

Results and Discussion

Interaction between DPI and TCNQ. The absorption spectra of TCNQ solubilized in a chloroform solu-

TCNQ Concentration: 0.5 mmol/l

tion of DPI are shown in Fig. 1. As is shown in Fig. 1, the spectra at low surfactant concentrations have no appreciable absorption of the TCNQ anion radical (the underlined numbers show the concentration of the surfactant below the CMC). When the concentration reaches a certain value, the spectra change their form rapidly; new bands appear at 480, 680, 750, and 850 mμ, and the optical densities of these absorption bands increase with the concentration of the surfactant. The absorptions at 680, 750, and 850 mμ have already been confirmed as those of the TCNQ anion radical by many authors,[7] but the absorption at 480 mμ does not belong to the anion radical; this absorption band seems to be caused by charge-transfer interaction between the surfactant and the TCNQ. The rapid increase in optical densities at 680, 750, and 850 mμ above some surfactant concentration suggests a rapid increase in the amounts of TCNQ anion radicals in these systems. The reason for the rapid increase in the TCNQ anion radicals is considered to be as follows: it is known that the surfactants make inverted micelles at the CMC in organic solvents. Therefore, at concentrations above the CMC, the surfactant molecules concentrated in the micelle interact with the TCNQ and produce a kind of ionic charge-transfer complex; then the resulting TCNQ anion radicals which have ionic properties are solubilized in the hydrophilic inside of the inverted micelles. From this fact, it was recognized that the surfactant concentration at which the rapid increase in the absorption of the TCNQ anion radical occurred would correspond to the CMC value in organic solvents.

In Fig. 2, the optical density of the spectra of the TCNQ anion solubilized in DPI chloroform solutions is plotted against the surfactant concentrations. The CMC are given by an intercept of the resulting two lines. The CMC's of different surfactants in various organic solvents obtained by this method are summarized in Table 1.

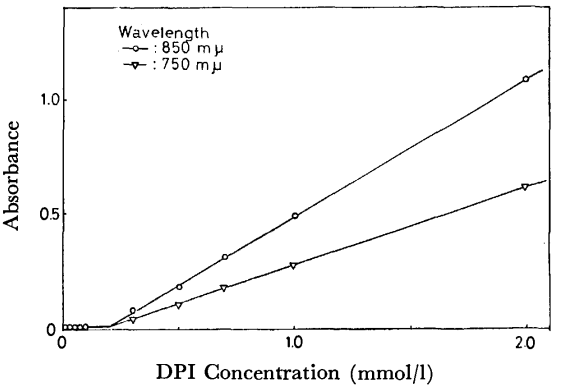

Fig. 2. Relationship between the absorbance and concentration of DPI chloroform solutions.

Table 1. CMC values of surfactants in various organic solvents (TCNQ method, at 20°C)

Surfactant	Solvent	CMC (mmol/l)	Wavelength (mμ)
DPI	Chloroform	0.2	850
	Benzene	0.07	850
	Methanol	—	
Aerosol OT	Chloroform	0.4	850
	Benzene	2.0	850
	Carbontetrachloride	0.6	277
	Methanol	—	

Ralston *et al.*[8] have found that dodecyl ammonium chloride in pure water makes a micelle and exhibits a clear break point in conductance-concentration curve at the CMC, but this break point does not become clear in suitable methyl-alcohol mixtures or in pure methyl alcohol. In these alcohol solutions, the dodecyl ammonium chloride behaves like a normal electrolyte over the entire range of concentration. They explain this fact by assuming a breakdown of the micelle.

This evidence was also confirmed by the spectra change between TCNQ and DPI in methyl alcohol solutions, in which the surfactant can not exist in the micelle form. Figure 3 shows the spectra of TCNQ in a methyl alcohol solution of DPI. The most characteristic feature of the spectra lies in the fact that the optical densities of the absorption peaks at 680, 750,

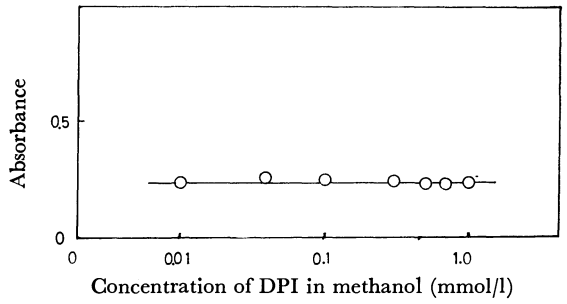

Fig. 4. Relationship between the absorption and concentration of DPI methanol solutions.

and 850 mμ, which are caused by the interaction between the TCNQ and the oxygen atom of methyl alcohol, are not influenced at all by the amounts of DPI. The optical density of TCNQ in DPI methyl alcohol solutions, plotted against the concentrations of DPI, are shown in Fig. 4, which shows more clearly that the optical densities do not change, but keep a constant value with the concentration of DPI. This can be explained by the breakdown of the micelle in the methyl alcohol solution.

Recently, Mukerjee *et al.*[9] found that a new band appeared at 290 mμ in a DPI micellar aqueous solution and a DPI chloroform solution. They reported that this band was due to the formation of a charge-transfer complex between the surfactant micelle and iodine, and also reported that this band could not be observed below the CMC.

We also confirmed that the appearance of the 290 mμ band can be used to as a means of recognizing the micelle formation of DPI in an organic solvent. When DPI was dissolved in chloroform, benzene, and water, a charge-transfer band was observed at 290 mμ. In the DPI methyl alcohol solution, however, the band was not found. This fact confirms that micelle formation does not occur in methyl alcohol solutions.

Interactions between Aerosol OT and TCNQ or Iodine. The absorption spectra of TCNQ solubilized in a chloroform solution of Aerosol OT are shown in Fig. 5. The shape of this absorption spectra is almost the same as that obtained in Fig. 1. This fact is particularly

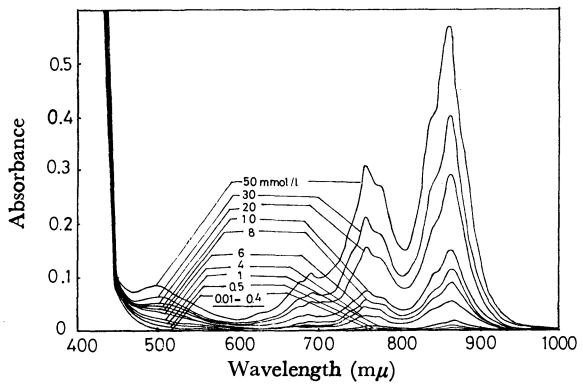

Fig. 5. Visible absorption spectra of TCNQ in Aerosol-OT chloroform solutions.
TCNQ concentration: 0.5 mmol/l

interesting. In this case, no remarkable absorption could be found in the spectra below the CMC, but new bands were observed at 480, 680, 750, and 850 mμ, above the CMC, and the intensities of these bands increased rapidly above the CMC of the surfactant. The surfactant concentration at which the rapid increase in optical densities of the TCNQ anion radical occurred would correspond to the CMC values in organic solvents. Indeed, the CMC value of Aerosol OT in benzene obtained by this method agrees with the data measured by Kon-no and Kitahara[10] (see Table 2). The CMC values of Aerosol OT in different organic solvents are summarized in Table 1.

TABLE 2. COMPARISON OF THE CMC OF AEROSOL OT BENZENE SOLUTION (mmol/l)

Method	Light scattering[a]	Depression of[a] vapour pressure	TCNQ method
CMC	2.8	2.3	2.0

a) K. Kon-no, and A. Kitahara, *Kogyo Kagaku Zasshi*, **68**, 2058(1965).

The data in Table 1 suggest that the micelle formation is influenced by the nature of the solvent; that is, the CMC values increase with the polarity of the solvent (see Table 3). The values in Table 3 agree with the results given by Kitahara and Kon-no.[10]

TABLE 3. THE RELATIONSHIP BETWEEN THE CMC OF SURFACTANTS AND DIELECTRIC CONSTANT OF ORGANIC SOLVENTS (Aerosol OT)

TCNQ method Solvent	Dielectric constant	CMC (mmol/l)
Benzene	2.27	2.0
Carbontetrachloride	2.24	0.6

Iodine method Solvent	Dielectric constant	CMC (mmol/l)
Benzene	2.27	0.9
Carbontetrachloride	2.24	0.3
Cyclohexane	2.01	0.2

Ross *et al.*[2] have described that iodine dissolved in benzene has a band at 490 mμ in its spectrum, but this band decreases upon the addition of a surfactant to this system and a new band appears at 360 mμ, the optical density of which increases with the concentration of the surfactant. They determined the CMC's of many surfactants in nonaqueous media by using the optical density of the iodine spectrum at 360 mμ.

When Aerosol OT was dissolved in various iodine solutions, such as benzene, cyclohexane, chloroform, and carbon tetrachloride, a new iodine band appeared; this band had a slight dependency on the character of the organic solvent. The ordinary band of iodine in an organic solvent, and the new band appearing after the addition of the surfactant, are listed in Table 4. A typical change in the spectrum of iodine in a cyclo-

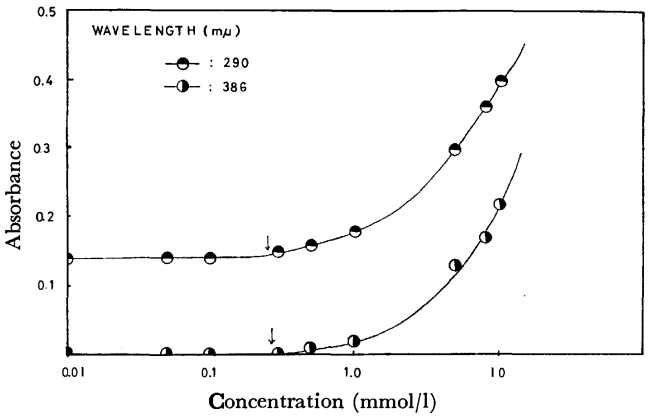

Fig. 7. Relationship between the absorbance and concentration of Aerosol OT cyclohexane solutions.

hexane solution upon the addition of a surfactant is shown in Fig. 6; the figure indicates that a new band appears at 386 mμ and increases in intensity with the concentration of the surfactant. In Fig. 7 the optical density of iodine in Aerosol OT cyclohexane solutions is plotted against the concentrations of Aerosol OT. In this figure, the value of the CMC is given by the change in the slope. The CMC's of several surfactants obtained by this iodine-solubilization technique are summarized in Table 4.

A comparison of the CMC values obtained by the TCNQ solubilization method with those obtained by the iodine method shows that the CMC values estimated by the iodine method are smaller than those obtained by the TCNQ method. At present, although we can not explain exactly why the difference occurs, it may be considered to be that the interaction between the TCNQ and the surfactant is a n(D)→π(A) transition, while the interaction between the iodine and the surfactant is a n(D)→σ(A) transition.

Strong *et al.*[11] have previously reported that the transition energy, ($h\nu_{ct}$), of the n(D)→σ(A) electron transition between a lower alcohol and iodine is about 5 eV.

The $h\nu_{ct}$ value found between Aerosol OT and iodine in cyclohexane and carbon tetrachloride is about 4.6 eV. This value agrees roughly with the value of 5 eV obtained by Strong *et al.* Accordingly, it may be concluded that the transition between Aerosol OT and iodine in cyclohexane and carbon tetrachloride is a n(D)→σ(A) transition.

On the other hand, the interaction between the TCNQ and the nitrogen atom or oxygen atom in the surfactant can be considered to be a n(D)→π(A) transition. From these results, the difference in the CMC between the two methods may originate from the difference in the type of transition between the TCNQ and iodine molecule, and from the difference in solubility to organic solvents.

The ionization potential of organic solvents can be

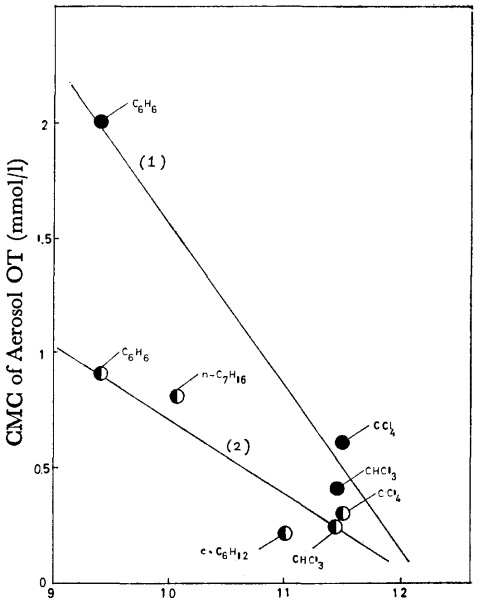

Fig. 8. Relationship between the CMC of Aerosol OT and ionization potential of organic solvents.
●: n–π type ◐: n–σ type

11) R. L. Strong, S. J. Rand, and J. A. Britt, *J. Amer. Chem. Soc.*, **82**, 5053 (1960).

considered to be a measure of the relative donor capacity of organic solvents. The plots of the CMC of Aerosol OT *vs.* the ionization potential of organic solvents are shown in Fig. 8, which suggests that the CMC values obtained by the $n(D)\rightarrow\pi(A)$ transition are larger than those obtained by the $n(D)\rightarrow\sigma(A)$ transition. In Fig. 8, Line (1) is the plot of CMC estimated by the TCNQ method against the ionization potential, while Line (2) is the plot of the CMC estimated by the iodine method against the ionization potential, as the TCNQ method depends on the $n(D)\rightarrow\pi(A)$ transition, and the idoine method, on the $n(D)\rightarrow\sigma(A)$ transition.

The authors wish to thank Dr. Ayao Kitahara for his advice, and the Nikko Chemical Co. for furnishing the samples.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1320—1324 (1973)

Adsorption and Inhibition Effect of Triton X at the Mercury/Solution Interface

Tetsuya OHSAKA, Hajime YAMAMOTO, and Tadashi YOSHIDA

Applied Electrochemical Laboratory, Graduate School of Science and Engineering, Waseda University, Nishi-okubo, Shinjuku-ku, Tokyo 160

(Received July 10, 1972)

The time dependence of differential capacity and that of polarographic current were observed to elucidate the adsorption behavior of Triton X. The adsorption showed a relatively ideal system of the diffusion-controlled type in which semi-infinite linear diffusion was assumed. The results from the two different observations agreed approximately. The Koryta equation was applied to obtain the maximum surface concentration Γ_m of Triton X in the adsorption of the monolayer. $\log \Gamma_m$ decreased linearly with increasing $\log \bar{M}$ (mean molecular weight), the slope being *ca.* -1. In the case of high bulk concentration, the adsorption showed unusual phenomena considered to be caused by the formation of a multi-layer which tended to become marked with the decrease of $\bar{M}$. The inhibition effect of Triton X on reduction current revealed approximately the same tendency regardless of cations Cd^{2+} and Cu^{2+}. Though the dependence of inhibitive action on $\bar{M}$ was relatively small, the degree of inhibition became somewhat small with increasing $\bar{M}$ in contrast to the cases of PVP and PEG. The shape of instantaneous *i vs. t* curve was approximately elucidated by Matsuda's treatment of the system where the limiting current was depressed by diffusion-controlled adsorption. The *i-t* curve revealed that the degree of inhibition scarcely increases until attainment of a certain high coverage when a sharp increase takes place.

The adsorption of water-soluble polymer at the mercury/solution interface is mainly controlled by diffusion. The behavior is approximately explained by means of the Koryta equation,[1] as shown in the cases of polyvinylpyrrolidone (PVP)[2] and polyethyleneglycol (PEG).[3] Triton X (alkylphenoxy polyethoxy ethanols)[4] is often used as a suppressor of the maximum wave in polarography. We examined its interfacial behavior by means of measurements of differential capacity and instantaneous current.

Schmid and Reilley[5] showed instantaneous current *vs.* time curves classified into three extreme cases. The current-time curve depressed by Triton X is a typical example of diffusion-controlled adsorption. Barradas and Kimmerle[6,7] examined the maximum surface concentration Γ_m of Triton X by means of two methods; measurement of suppression of the oxygen maximum wave[6] and that of the potential dependence of interfacial tension.[7] The disagreement between Γ_m's obtained by the two methods seems to result from the formation of a multi-layer. In the present investigation, the formation of a monolayer was considered primarily, the formation of a multi-layer being also taken into account.

Experimental

A DME (dropping mercury electrode) was used as a test electrode. Its drop time was about 12 s for the measurements of differential capacity and instantaneous current, and about 3—4 s for the polarographic measurements. The counter electrode was a cylindrical platinum net with a sufficiently large surface. All potentials were referred to the saturated calomel electrode (SCE).

The differential capacity at the mercury/solution interface was measured with a transformer impedance bridge of 1 kHz whose input was kept less than 10 mV_{P-P}. A series equivalent circuit with resistance and capacitance was used for the bridge measurement.

The instantaneous current *vs.* time curves were determined from the *iR* drop observed with a recorder or an oscilloscope in parallel with 2 kΩ resistance which was connected in series

with the DME and the polarization circuit.

Triton X-45, X-100, X-205, and X-405 (Rohm and Haas) were used without further purification, their degrees of polymerization for ethylene oxide groups being 5 ($\bar{M}$=430), 9—10 ($\bar{M}$=600—650), 20 ($\bar{M}$=1100), and 40 ($\bar{M}$=2000), respectively. Solutions were prepared from guaranteed reagent and triply-distilled water. All experiments were conducted in an atmosphere of purified nitrogen at 25°C in 1N sulfuric acid.

Results and Discussion

Dependence of Differential Capacity on Potential (C-E Curves). Figures 1-(a) and (b) show the *C-E* curves of Triton X-45 and X-405 at adsorption time of 5 s. The anodic peaks due to adsorption or desorption were observed at *ca.* 0—0.1 V. No cathodic peak was observed. The adsorption or desorption peaks become large with the increase in bulk concentration. The potential dependence of the peak is seen to some extent except for the case of Triton X-405. Since the differential capacity decreases with the increase of Triton X concentration in a more cathodic potential than an anodic peak, adsorption occurs in this range.

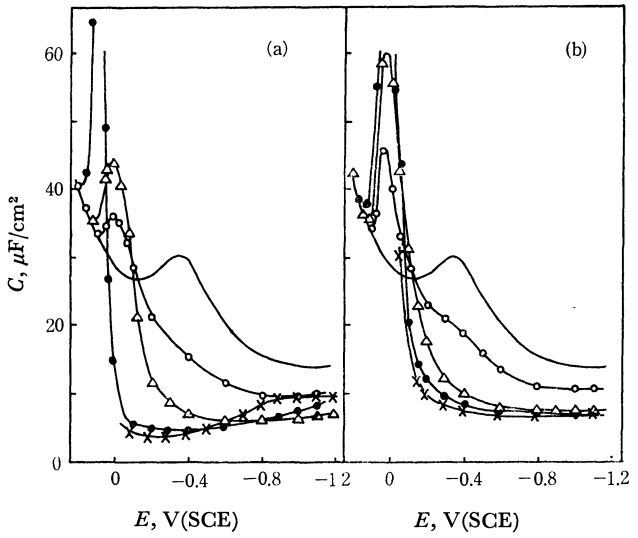

Fig. 1. The differential capacity *vs.* potential curves.
25 °C, adsorption time of 5 s, (a) 1N aqueous sulfuric acid +Triton X-45 (solid line: 0 mg/l, ○: 10 mg/l, △: 20 mg/l, ●: 60 mg/l, ×: 200 mg/l), (b) 1N aqueous sulfuric acid +Triton X-405 (solid line: 0 mg/l, ○: 10 mg/l, △: 20 mg/l, ●: 40 mg/l, ×: 100 mg/l).

In the case of high bulk concentration of Triton X-45, the differential capacity ascends gradually as the potential becomes more cathodic and finally becomes constant independent of potential. The ascent at the cathodic potential can hardly be ascribed to adsorption or desorption but rather to the formation of a multilayer of Triton X as stated by Barradas,[7] since the capacity after the ascent attains a constant value lower than that in the blank solution in a relatively wide range of potential. However, the ascent of differential capacity is scarcely seen in the case of Triton X-405. Since it becomes marked with decreasing $\bar{M}$ in the cathodic potential, it might be more easy for Triton X of low $\bar{M}$ to form the multi-layer.

Dependence of Differential Capacity on Adsorption Time. The differential capacity *vs.* time curve was measured at −0.6 V where the adsorption always attains equilibrium or saturation to form the monolayer. Figures 2-(a) and (b) show the C-$t^{1/2}$ relations of Triton X-45 and X-405, which indicate that the adsorption of Triton X is controlled by diffusion in a relatively low bulk concentration in the same way as in the cases of organic polymers.[2,3]

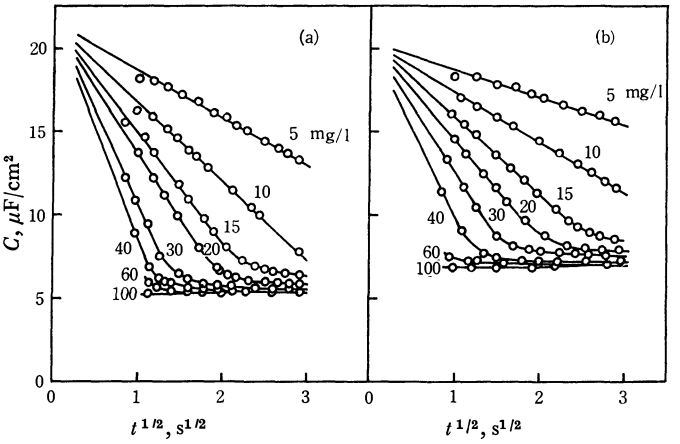

Fig. 2. The differential capacity *vs.* square root of time curves.

In the limiting case controlled by linear diffusion, the following relation (1)[8] can be derived from the Koryta equation[1] with the Frumkin parallel condenser model.[9]

$$C = C_0 - 0.736(C_0 - C_s)D^{1/2}\Gamma_m^{-1}at^{1/2} \text{ for } t<t_m \quad (1)$$

where C_0 and C_s are unit area capacities (μF/cm^2) for θ (coverage)=0 and θ=1, a the bulk concentration (mol/cm^3), D the diffusion coefficient (cm^2/sec), t the adsorption time (sec), t_m the time required to attain the saturated adsorption to form the monolayer and Γ_m the maximum surface concentration (mol/cm^2). Equation (1) holds for $t<t_m$. However, when $t\geq t_m$, the differential capacity becomes constant as follows.

$$C = C_s \quad (2)$$

It is seen from Eqs. (1) and (2) that C decreases linearly with $t^{1/2}$ or a when the adsorption is controlled by diffusion ($t<t_m$), while C becomes constant at the saturated adsorption ($t\geq t_m$).

The C-$t^{1/2}$ relation in Fig. 2 consists of two linear portion; one corresponding to that of diffusion-controlled adsorption (C decreases with $t^{1/2}$), and the other to that of saturated adsorption (C is constant). Thus, the results in Fig. 2 are explained by Eqs. (1) and (2). Extrapolation of the two linear portions gives the value of t_m. Though the differential capacity at the adsorption equilibrium somewhat depends on bulk concentration, the initial linear portion was extrapolated

to that of C_s for the sake of convenience. The observed C_s may be the value for the multi-layer, but the error due to the selection of C_s is considered to be small because of the small concentration dependence of C at the adsorption equilibrium. It is possible to calculate Γ_m by substituting t_m into the Koryta equation on the assumption of D. Directly obtainable values of $at_m^{1/2}$ ($=\Gamma_m/0.736D^{1/2}$) are also given in Table 1.

Polarograms. The adsorption behavior of surface-active compounds can also be investigated by the inhibition effect on current. Γ_m can be calculated by use of the Koryta equation from the instantaneous current *vs.* time relation (*i-t* curve) where the limiting current is inhibited by diffusion-controlled adsorption.

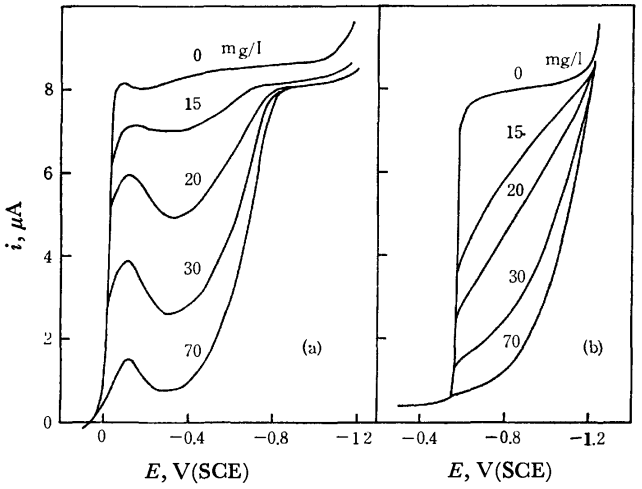

Fig. 3. Polarograms inhibited by Triton X-405.
1N sulfuric acid solution + Triton X-405, (a) depolarizer: 1 mM Cu^{2+}, (b): depolarizer: 1 mM Cd^{2+}.

Figures 3-(a) and (b) give typical examples of the inhibition effect of Triton X-405 on the reduction of Cu^{2+} and Cd^{2+} in 1N sulfuric acid. The reaction is depressed with increasing bulk concentration in both cases. The current peak at *ca.* −0.1 V for Cu^{2+} (Fig. 3-(a)) may be due to the desorption of Triton X-405 since the desorption peak is revealed at *ca.* −0.1 V in the *C-E* curves (*cf.* Fig. 1-(b)). The current begins to increase at *ca.* −0.7 V for Cu^{2+} and at *ca.* −1.0 V for Cd^{2+} (Fig. 3-(b)). The decrease of the inhibition effect can hardly be ascribed to the desorption of inhibitor but rather to the sufficient overpotential in view of the results in Fig. 1.

Instantaneous Current vs. *Time Curves.* The *i-t* relations for the reduction of Cu^{2+} and Cd^{2+} were examined at the potentials of −0.3 and −0.8 V, where the currents are most depressed. Since the *i-t* curves for the inhibition effect of Triton X on cadmium deposition showed a tendency similar to that on copper deposition, the latter is discussed herewith. Figures 4-(a) and (b) show the *i-t* curves of copper deposition inhibited by Triton X-100 and X-405. The initial portion of the *i-t* curve for the process inhibited by Triton X coincides with that for the process with no inhibitor, while the limiting current decreases rapidly at a certain time and finally the reaction is depressed almost completely after full coverage is attained. The time required to attain complete inhibition becomes

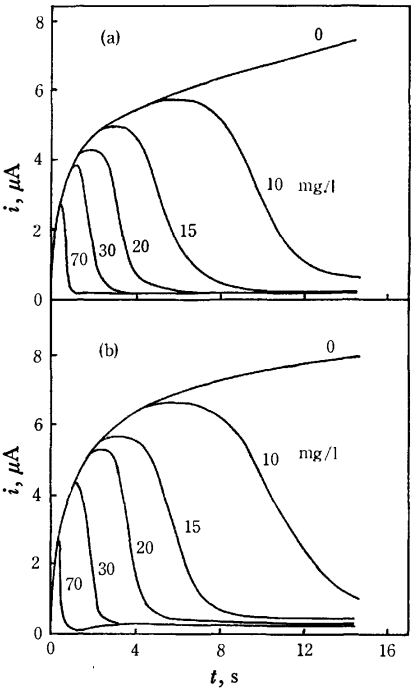

Fig. 4. Instantaneous current *vs.* time curves.
25 °C, −0.3 V, 1 mM Cu^{2+}, (a) 1N sulfuric acid solution + Triton X-100, (b) 1N sulfuric acid solution + Triton X-405.

shorter as the content of Triton X is increased.

The tendency of *i-t* curves for the process inhibited by PVP in 1N sulfuric acid is similar to that in the case of Triton X. However, the *i-t* curves for the process inhibited by PEG[3] show a different tendency, complete inhibition not being attained even at $\theta=1$. The tendency becomes more marked as $\bar{M}$ decreases, that is, the current after attainment of the full coverage depends distinctly on the bulk concentration especially in the case of a relatively low $\bar{M}$ of PEG. Such a tendency can be expected from the behavior of differential capacity which depends on the bulk concentration after attainment of adsorption equilibrium. As seen in Fig. 4, the current after t_m is almost completely inhibited by Triton X in spite of the concentration dependence of differential capacity after attainment of adsorption equilibrium (Fig. 2). Thus, the concentration dependence of C after $t \geq t_m$ may be caused by the formation of a multi-layer.

The time required to attain complete inhibition is given by extrapolating the portion of rapidly decreasing current in *i-t* curve to $i=0$. The t_m values obtained from the relations of $C\text{-}t^{1/2}$ and *i-t* are expressed by t_{mc} and t_{mi}, respectively.

Maximum Surface Concentration of Triton X. The values of $at_{mc}^{1/2}$ and $at_{mi}^{1/2}$ are given in Table 1, since the directly obtainable term in the Koryta equation is $at_m^{1/2}$ which corresponds to the ratio of Γ_m to $D^{1/2}$. The $at_{mc}^{1/2}$ (or $at_{mi}^{1/2}$) value somewhat depends on a, *viz.*, $at_{mc}^{1/2}$ (or $at_{ml}^{1/2}$) becomes somewhat large with a. Such a phenomenon was also observed in the case of PVP[2] and the variation of $at_{mc}^{1/2}$ with a was explained by means of the concentration dependence of diffusion coefficient or the effect of spherical diffusion.

Table 1. Comparison of $at_{mc}^{1/2}$ with $at_{mi}^{1/2}$.

Triton X	$at_{mc}^{1/2}$ a) (mg/l·s$^{1/2}$)	$at_{mi}^{1/2}$ b) (mg/l·s$^{1/2}$)	
		Cu^{2+}	Cd^{2+}
X- 45	35.2	34.8	35.1
X-100	35.4	39.7	42.1
X-205	30.7	37.5	40.6
X-405	43.5	42.5	47.3

a) The mean values of $at_{mc}^{1/2}$ at 5, 10, 15, and 20 mg/l.
b) The mean values of $at_{mi}^{1/2}$ [12] at 10, 20, and 30 mg/l.

The $at_{mc}^{1/2}$ values in Table 1 are the mean values of a at 5, 10, 15, and 20 mg/l, and the $at_{mi}^{1/2}$ values are those at 10, 20, and 30 mg/l. The Γ_m values of Triton X were calculated from the mean values of $at_{cm}^{1/2}$ (or $at_{mi}^{1/2}$) and D[10] assumed by Scholtan's relation[11] ($\bar{M}D^2=10^{-8}$).

Barradas and Kimmerle[6,7] give Γ_m values of Triton X-100 as follows: 22×10^{-10} mol/cm^2 by the interfacial tension measurement[7] and $1.3—1.4\times10^{-10}$ mol/cm^2 by the observation of suppression of polarographic oxygen wave.[6] They have ascribed the disagreement of the results to the formation of a multi-layer, namely, Γ_m by the electrocapillary data corresponds to that of the multi-layer adsorbed perpendicularly with the alkyl end in contact with mercury, while Γ_m by the suppression effect corresponds to that of nearly monolayer which is adsorbed on mercury with planar configuration. The Γ_m values given in Table 2 are considered to be those of the monolayer, since the dependence of differential capacity and that of inhibition upon the diffusion process of adsorbates may be caused mainly by the monolayer formation. From the linear relation of log Γ_m *vs.* log $\bar{M}$ with a slope of *ca.* -1, the configuration of monolayer of Triton X is expected to be flat, which is similar to the cases of PVP[2] and PEG ($\bar{M}\geq600$).[3]

The relation between C_s and thickness of adsorbed layer can be expressed by

$$C_s = \varepsilon/(4\pi\delta) \qquad (3)$$

where ε and δ are the dielectric constant and thickness of the adsorbed layer, respectively. The C_s of Triton X may correspond to that of the multi-layer, since it is relatively low and varies considerably with $\bar{M}$ as compared with the cases of PVP[2] and PEG.[3] The considerable dependence of C_s on $\bar{M}$ is inconsistent with the planar configuration of monolayer at the interface under the assumption of ε=constant. The fact that C_s becomes larger with the increase in $\bar{M}$ is also inconsistent with the configuration of monolayer adsorbed perpendicularly, because C_s should become small with increasing $\bar{M}$ in view of the inverse proportionality between δ and C_s (*cf.* Eq. (3)). Consequently, the configuration of multi-layer adsorbed perpendicularly, assumed by Barradas, is applicable to the results of C_s. It must be taken into account that Triton X of low $\bar{M}$ is apt to form the multi-layer as shown in Fig. 1.

Shape of Instantaneous Current vs. *Time Curve.* Some theoretical approaches to elucidate the polarographic current *vs.* time curve have been given.[1,12,13] The *i-t* curve for the system where the limiting current is inhibited by diffusion-controlled adsorption will be discussed, Weber *et al.*[12] and Kůta and Smoler[13] solved the problem of the inhibition effect on the rate constant of electrode reaction. Matsuda[14] has recently introduced the following theoretical equation for the *i-t*

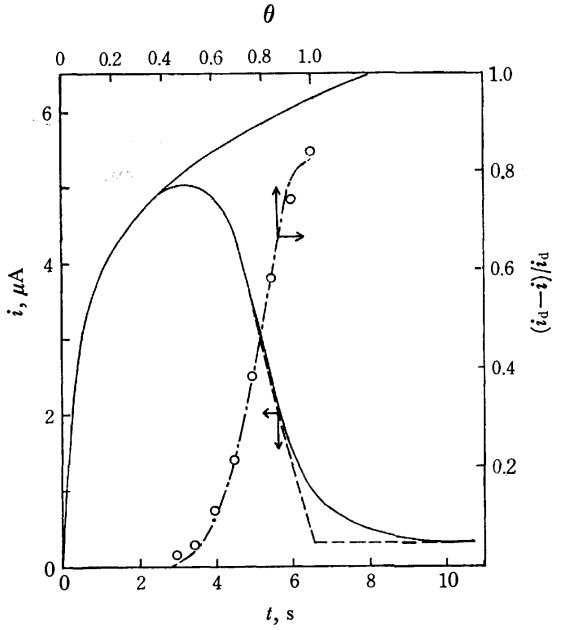

Fig. 5. The time-dependence of instantaneous current inhibited by Triton X, observed or calculated, and the coverage-dependence of inhibition by Triton X.

curve assuming that the adsorbed films are perfectly immobile.

$$i = i_d \frac{(1.35\lambda_\infty t^{1/2})^{1.091}}{1+(1.35\lambda_\infty t^{1/2})^{1.091}} \quad (4)$$

where i and i_d are the instantaneous currents with and without adsorbates, respectively, and λ_∞ is given by the following:

$$\lambda_\infty = [\lambda_2+(1-\theta)A/[(1-\theta)\{-\ln(1-\theta)\}]^{1/2}]\theta^{-1}$$

$$\lambda_2 = k_2/D_0^{1/2}, \qquad A = D_0/R_m = K'\theta^z$$

where k_2, D_0, and R_m are respectively the rate constant of forward reaction on the adsorbed surface, the diffusion coefficient of oxidized form of depolarizer and the mean radius of the congregated molecules adsorbed at the interface. K' and z are the arbitrary constants. A typical example in which the limiting current of copper deposition is inhibited by Triton X of 15 mg/l is given in Fig. 5 and shown by the solid line. The theoretical curve whose parameters ($\lambda_2=0.020$, $K'=0.347$, $z=-11.0$, and $t_{mi}=6.5$) are estimated from experimental data is given by the broken line. The shape of i-t curve is well explained by Matsuda's equation except for the region in the neighborhood of $t=t_{mi}$. Figure 5 shows also the inhibition effect by means of $(i_d-i)/i_d$ *vs.* θ relation. The coverage is given by the Koryta equation as $\theta=(t/t_{mi})^{1/2}$. Inhibition is hardly seen at a small coverage and then a sharp rise occurs at a certain coverage. Such a tendency is always revealed by the limiting current which is depressed by diffusion-controlled adsorption. The coverage at which the sharp rise of inhibition occurs may be dependent on the properties of the adsorbates and on the parameter, z, in Eq. (4). The shape of the i-t curve in a relatively ideal system can be explained with Eq. (4). However, further approaches must be made to explain the behavior somewhat deviating from the ideal one, *e.g.*, the i-t curve inhibited by PEG of a relatively low $\bar{M}$.[3]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1324—1329 (1973)

Adsorption of Organic Polymers on Platinum Electrode

Tetsuya OHSAKA, Yasuyuki ABE, and Tadashi YOSHIDA

Applied Electrochemical Laboratory, Graduate School of Science and Engineering, Waseda University, Nishi-okubo, Shinjuku-ku, Tokyo 160

(Received August 14, 1972)

The adsorption behavior of polyvinylpyrrolidone (PVP), polyethyleneglycol (PEG), and alkylphenoxy polyethoxy ethanols (Triton X) on a smooth platinum electrode was investigated by observation of the inhibition effect on the electrosorption of hydrogen and oxygen in the potential range between hydrogen and oxygen evolution. The adsorption of PVP, PEG, and Triton X on platinum always took place within the potential range from −0.20 to 1.25 V *vs.* SCE, the inhibition effect on the electrosorption of hydrogen and oxygen being distinctly shown. The order of inhibition of these adsorbates was Triton X>PVP>PEG. The inhibition effect became larger in most cases with decreasing mean molecular weight of adsorbate. In contrast to the case with a mercury, the adsorbates were oxidized or reduced on the platinum electrode in the adsorption range, the anodic peak due to oxidation being distinctly revealed in the case of PEG.

Many organic polymers are adsorbed so strongly on a DME that the adsorption process is mainly controlled by diffusion.[1-5] The adsorption behaviors of PVP (polyvinylpyrrolidone),[1,6] PEG (polyethyleneglycol),[2,7] and Triton X (alkylphenoxy polyethoxy ethanols)[5,8] investigated at the mercury/solution interface, are explained by means of the Koryta equation,[9] their saturated adsorption being established after diffusion process.

The adsorption of various organic substances on a solid electrode has been investigated by many authors from the viewpoint of corrosion inhibitors and organic additives in electrodeposition, but the adsorption of organic polymers on a solid electrode has been given little attention. We investigated the adsorption of water-soluble polymers on a smooth platinum electrode by observing the inhibition effect on the electrosorption of hydrogen and oxygen.

PVP has high adsorbability due to pyrrolidone radicals containing ketone radical and nitrogen atom. PEG is a polymer of ethylene oxide, extensible and highly crystalline. Triton X is a surface active agent

prepared by the reaction of *t*-octylphenol with ethylene oxide.

Experimental

The test electrodes were a platinum plate (1.870 cm^2), a platinum disk (0.071 cm^2) and platinum wire (0.160 cm^2). The counter electrode was a platinum plate having sufficiently large surface area, and the potentials were determined in reference to the saturated calomel electrode (SCE). Experiments were carried out in 1N sulfuric acid at 30°C in an atmosphere of purified nitrogen. Solutions were prepared with chemical grade reagents and triply-distilled water. PVP (BASF), PEG (Sanyo Chemical Industry), and Triton X (Rohm and Haas) were used without further purification: their mean molecular weight ($\bar{M}$) were 750000, 37000, and 10000 for PVP, 8400, 1000, and 600 for PEG and 2000 (X-405), 1100 (X-205), and 650 (X-100) for Triton X. Potentiostat (Nichia Keiki) and function generator (Nichia Keiki) were used for potential scanning. The test electrode, cleaned with concentrated nitric acid, was pretreated by cyclic scanning at a rate of 10 V/s in 1N sulfuric acid in order to obtain reproducible results. The cyclic scanning curve between −0.20 and 1.25 V was then recorded at a scanning rate of 0.1 V/s by means of a high response X-Y recorder (Toa Electronics). The differential capacity at 1 kHz was determined 5 min after setting the electrode potential by means of a universal bridge (Yokogawa).

Results and Discussion

During the anodic scanning (Fig. 1), adsorbed hydrogen is removed in the potential range −0.2—0.1 V, and an oxygen monolayer is formed in the range 0.55—1.25 V.[10-12] The potential range 0.1—0.55 is the so-called double layer charging region where platinum can be regarded as an ideally polarizable electrode. During the cathodic scanning, the peak at 0.5 V is caused by the reduction of adsorbed oxygen and two peaks between 0.1 and −0.2 V are caused by the electrosorption of hydrogen. The inhibition effect of polymer on the electrosorption can be examined from the decreasing amount of charge of adsorbed hydrogen or oxygen obtained by suitable integration. However, it will be discussed mainly by comparison of the current values at a certain potential, since the content of charge obtained by integrating the region extended over the wide potential range is too complicated due to the oxidation or reduction of adsorbates.

Adsorption of PVP. Figure 1 shows the potentiostatic *i-E* curves inhibited by PVP of $\bar{M}=10000$ whose inhibition effect is the most marked of the three kinds of PVP. During the course of anodic scanning, the two peaks due to the weakly and strongly adsorbed hydrogen become one peak having a constant current independent of the increase of PVP concentration. In the adsorbed oxygen region, the inhibition effect is revealed at the potentials 0.6—1.0, while the anodic current increases in the range 1.0—1.25 V with the addition of PVP. Such an increase may be ascribed

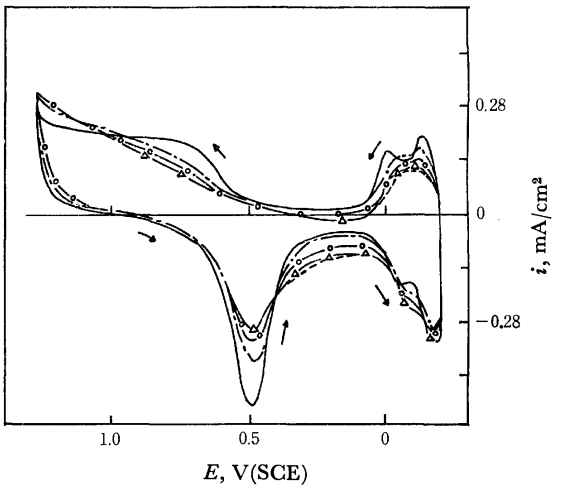

Fig. 1. Potentiostatic *i-E* curves on platinum electrode in the solution of 1N sulfuric acid + PVP, $\bar{M}=10000$.
30 °C, 0.1 V/s, concentration of PVP (—: 0 mg/l PVP, —·—: 10 mg/l, -○-: 50 mg/l, -△-: 150 mg/l, ---: 200 and 300 mg/l).

to either the growth of oxygen layer for the saturated electrosorption at a more positive potential depressed in the range 0.6—1.0 V, or to the oxidation of adsorbed PVP. Since the reduction peak of adsorbed oxygen decreases with increasing PVP concentration (*i.e.*, the amount of adsorbed oxygen decreases with the addition of PVP), the oxidation of PVP may cause the current increase in the anodic range 1.0—1.25 V. During the course of cathodic scanning, the current in the double layer region increases with the addition of PVP. This might result from the reduction of adsorbed PVP since the peak height of cathodic current increases with increasing content of PVP in the adsorbed hydrogen region in spite of the decrease of anodic peak current in this region.

If adsorption or desorption of PVP takes place within the scanning range, the diffusion of adsorbates may influence the adsorption behavior in a similar way to that on a mercury electrode.[1,2,4,5] The dependence of current value on the scanning rate shows a linear relation, which implies that the diffusion of adsorbates has no influence on the adsorption behavior and that PVP always establishes the adsorption equilibrium. Such a dependence of current value is also revealed in the cases of PEG and Triton X.

The anodic peak of the weakly adsorbed hydrogen (P_H) and the cathodic peak of the adsorbed oxygen (P_0) are markedly depressed by the addition of PVP. The dependence of inhibition effect on PVP content is examined in these two regions as shown in Fig. 2. The degree of inhibition is given by $(i_b-i)/i_b$ or $(Q_b-Q)/Q_b$, where i_b or Q_b is the current or charge in solution without adsorbates.

For the oxidation of weakly adsorbed hydrogen (P_H), the degree of inhibition increases sharply until 30 mg/l of PVP and then it increases slowly with increasing PVP concentration (Fig. 2-(a)). The shapes of curves obtained from the peak currents agree approximately with those obtained from the charges. The order of inhibition effect is $\bar{M}=10000>\bar{M}=750000>\bar{M}=37000$

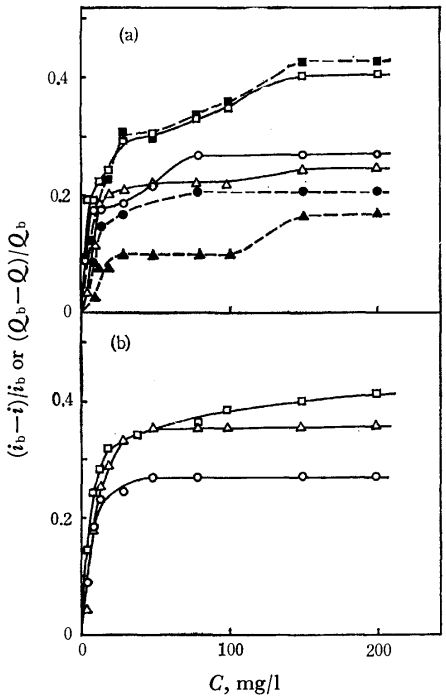

Fig. 2. Concentration dependence of the degree of inhibition on platinum electrode in the solution of 1N sulfuric acid +PVP.
30 °C, 0.1 V/s, solid lines: results from $(i_b-i)/i_b$, broken lines: results from $(Q_b-Q)/Q_b$, (a) the inhibition effect on the anodic peak due to electrosorption of hydrogen, □,■: $\bar{M}$=10000, △,▲: $\bar{M}$=37000, ○,●: M=750000, (b) the inhibition effect on the cathodic peak due to electrosorption of oxygen, □: $\bar{M}$=10000, △: $\bar{M}$=37000, ○: M=750000.

for the bulk concentration greater than 100 mg/l.

For the reduction of adsorbed oxygen (P_0), the degree of inhibition becomes also constant after the sharp increase, and the order of inhibition effect is $\bar{M}$=10000>$\bar{M}$=37000>$\bar{M}$=750000 (Fig. 2-(b)). Since the anodic peak in the adsorbed hydrogen region seems to be influenced by the reduction current of adsorbates, the degree of inhibition obtained from Fig. 2-(a) is somewhat doubtful. The order in Fig. 2-(b) is therefore more reliable than that in Fig. 2-(a). The inhibition effect seems to increase with the decrease in $\bar{M}$.

Adsorption of PEG. Figure 3 shows the adsorption behavior of PEG on a platinum electrode. The anodic peak P_H and the cathodic peak P_0 are depressed by the addition of PEG, while the anodic peak appears at *ca.* 0.7 V (P_{PEG}). The anodic current becomes larger than that in the solution without adsorbates in a range more positive than P_{PEG} and in the double layer charging region. The peak of P_{PEG} may result from the oxidation of adsorbed PEG in view of the depression of P_0 with increasing content of PEG. In a weakly adsorbed hydrogen region the cathodic peak height increases with increasing PEG concentration, which may be ascribed to the reduction of PEG. The degree of inhibition due to the adsorption of PEG can be hardly estimated from these results, as the reduction or oxidation of adsorbed PEG itself overlaps the inhibition effect.

For the purpose of examining the anodic peak at *ca.*

30 °C, 0.1 V/s, potential ranges (---: −0.2~1.25 V, -·-: −0.1~1.25, -○-: 0.0~1.25, -△-: 0.1~1.25, -×-: 0.2~1.25, ···: 0.3~1.25 V), solid line: *i-E* curve in the solution without adsorbates.

0.7 V (P_{PEG}), the cathodic limit of cyclic scanning was varied as shown in Fig. 4. The current growing at *ca.* 0.7 V begins to appear when the anodic scanning is started from 0.1 V, and a distinct peak is revealed at first by scanning from 0 V. Thus, adsorbates of the reduced type which cause the oxidaiton peak at 0.7 V seem to be produced at a more negative potential than 0.1 V, and the reduced type of adsorbates may increase as the potential becomes negative. It seems that the adsorbed amount of oxidized or reduced type of PEG depends on the electrode potential. However, the

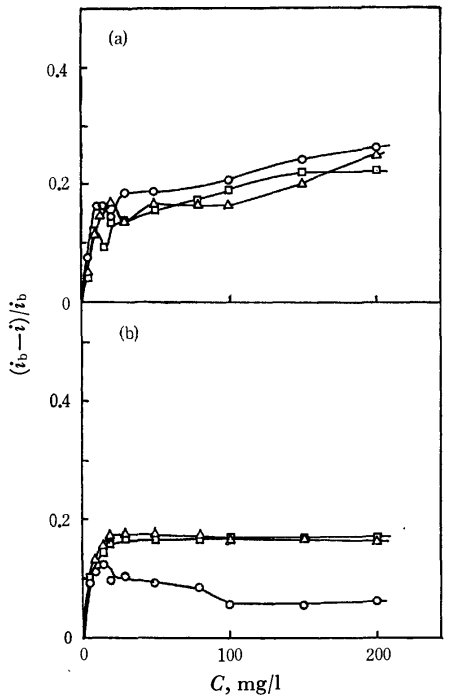

Fig. 5. Concentration dependence of the degree of inhibition on platinum electrode in the solution of 1N sulfuric acid + PEG.
30 °C, 0.1 V/s, (a) the inhibition effect on the anodic peak due to electrosorption of hydrogen, □: $\bar{M}$=600, △: $\bar{M}$=1000, ○: $\bar{M}$=8400, (b) the inhibition effect on the cathodic peak due to electrosorption of oxygen, □: $\bar{M}$=600, △: $\bar{M}$=1000, ○: $\bar{M}$=8400.

total amount of adsorbed PEG is expected to be independent of the potential from the results that the anodic peak at *ca.* 0.7 V (P_{PEG}) is not influenced by scanning after some interruption at −0.2 V and that the peak height increases linearly with the scanning rate.

The degrees of inhibition at P_H and P_0, estimated from the results in Fig. 3, are shown in Fig. 5. The degree of inhibition at P_H increases sharply until a bulk concentration of 10—20 mg/l, which may be influenced to some extent by the reduction of adsorbed PEG (Fig. 5-(a)). It decreases, however, to some extent with increasing PEG concentration just after the steep increase, after which it increases gradually. This may be ascribed to the increase of reduction current of PEG. Thus, the order of degree of inhibition (Fig. 5-(a)) is considered to be unreliable because of the overlapping of the reduction current of PEG and the oxidation current of adsorbed hydrogen.

The degree of inhibition becomes constant (Fig. 5-(b)) for the peak of P_0 at *ca.* 20 mg/l.[13] The order of inhibition is $\bar{M}$=600>$\bar{M}$=1000>$\bar{M}$=8400, namely, the degree of inhibition increases with the decrease of $\bar{M}$.

The peak of P_{PEG}, which may result from the oxidation of PEG, is examined from the concentration dependence of i/i_b at 0.7 V (Fig. 6). In a low concentration range, the value of i/i_b is less than unity and shows a minimum indicating inhibition of the electrosorption of oxygen, but it becomes larger than unity in the concentration range greater than 30—50 mg/l. In the case of PEG of $\bar{M}$=600 and 1000 which reveal P_{PEG}, i/i_b increases with the addition of PEG, while for PEG of $\bar{M}$=8400 which reveals no P_{PEG}, it remains constant in the concentration range greater than 100 mg/l. In the i/i_b plots at 1.0 V (not shown), PEG of $\bar{M}$=600 and 1000 reveal constant i/i_b (*ca.* 1.4) in the range greater than 100 mg/l, while PEG of $\bar{M}$=8400 shows nearly constant values somewhat larger than those of the above. Thus, PEG of high $\bar{M}$ may be more difficult to be oxidized as compared with that of low $\bar{M}$.

The differential capacity at the platinum/solution interface was determined 5 min after setting the electrode potential which was scanned from negative to

30 °C, capacity was determined at 5 min after setting the electrode potential, concentration of PEG, $\bar{M}$=1000 (●: 0 mg/l PEG, ○: 10 mg/l, △: 20 mg/l, □: 50 mg/l, ×: 100 mg/l, ▽: 200 mg/l).

13) In the case of $\bar{M}$=8400, it is peculiar that the degree of inhibition decreases gradually with PEG concentration after the appearance of a peak at *ca.* 20 mg/l. This remains to be explained.

positive (Fig. 7). In the potential range between hydrogen and oxygen evolution, there are three distinct regions for the platinum electrode. In solutions having no adsorbates, the pseudocapacity due to adsorbed hydrogen is revealed between −0.2 and 0.1 V. Hydrogen or oxygen is hardly adsorbed in the so-called double layer region 0.1—0.55 V, while the pseudocapacity due to adsorbed oxygen appears between 0.55 and 1.25 V.

The adsorbed hydrogen and oxygen regions shift to somewhat negative and positive sides, respectively, with the addition of PEG of $\bar{M}$=1000 (Fig. 7). It is certain from the capacity depression that the adsorption of PEG always occurs in these regions. In the adsorbed oxygen region, the capacity depression with increasing content of PEG is complicated. It is too difficult to discuss the capacity behavior in the adsorbed oxygen region from only the results shown in Figs. 3 and 7, though it is doubtless influenced by the oxidation of adsorbed PEG.

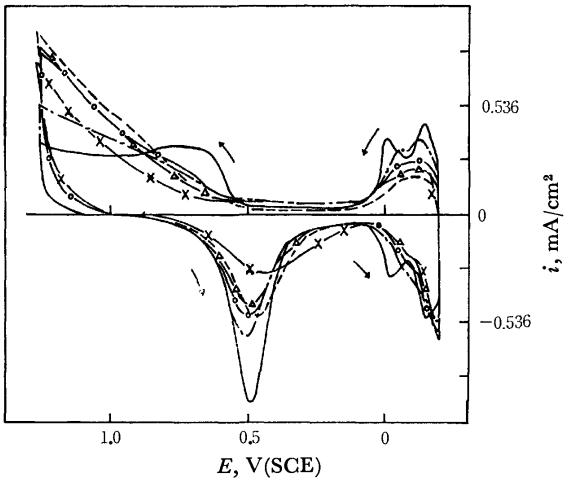

Fig. 8. Potentiostatic i—E curves on platinum electrode in the solution of 1N sulfuric acid + Triton X-205, $\bar{M}$=1100. 30 °C, 0.1 V/s, concentration of Triton X (——: 0 mg/l Triton X, – – –: 30 mg/l, -○-: 100 mg/l, -△-: 200 mg/l, -×-: 400 mg/l, – – –: 1000 mg/l).

Adsorption of Triton X. Figure 8 shows the i-E curves in 1N sulfuric acid containing Triton X of $\bar{M}$=1100. The degree of inhibition at P_H and P_0 and the increase of anodic current in the region $E \geq 0.9$ V are distinctly larger than those for PVP and PEG. The increase of anodic current in the region $E \geq 0.9$ V may be attributed to the oxidation of adsorbed Triton X because the peak of P_0 is depressed by the addition of Triton X. The reduction of oxidized Triton X may occur since the cathodic current increases at the potential of *ca.* 0.4——0.2 V in the cathodic scanning. In the case of Triton X, it is characteristic that the concentration dependence of current is complicated in the potential regions $E \geq 0.9$ V and P_0. Triton X can form micelles,[14] and the above behavior can be ascribed to the formation of multilayer.

Figure 9 shows the relation between the degree of inhibition and the bulk concentration in P_H and P_0

30 °C, 0.1 V/s, solid lines: results from $(i_b-i)/i_b$, broken lines: results from $(Q_b-Q)/Q_b$, (a) the inhibition effect on the anodic peak due to electrosorption of hydrogen, ◐,▲: X-100, $\bar{M}$=650, ●,▽: X-250, $\bar{M}$=1100, ○,△: X-405, $\bar{M}$=2000. (b) the inhibition effect on the cathodic peak due to the electrosorption of oxygen, ◐: X-100, $\bar{M}$=650, ●: X-205, $\bar{M}$=1100, ○: X-405, $\bar{M}$=2000.

regions. For P_H region, the degree of inhibition increases sharply until 100 mg/l and then becomes nearly constant (Fig. 9-(a)). The order of degree of inhibition is as follows: $\bar{M}$=650 (X-100)>$\bar{M}$=1100 (X-205)>$\bar{M}$=2000 (X-405). For P_0 region, the degree of inhibition *vs.* concentration curve reveals a maximum whose position seems to move to higher concentration range with increasing $\bar{M}$ (Fig. 9-(b)). In general,

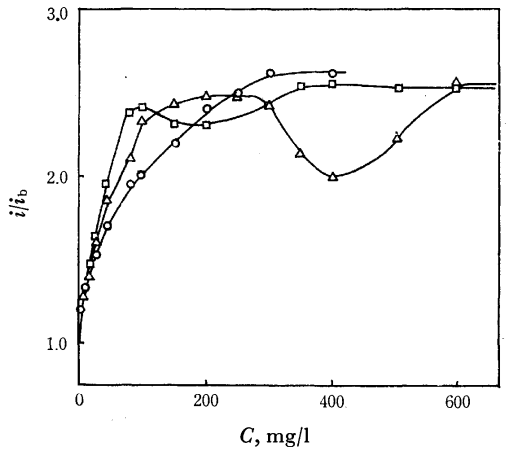

Fig. 10. Concentration dependence of anodic current at 1.2 V in the solution of 1N sulfuric acid + Triton X.
30 °C, 0.1 V/s, □: 1N sulfuric acid + Triton X-100, $\bar{M}$=650, △: 1N sulfuric acid + Triton X-205, $\bar{M}$=1100, ○: 1N sulfuric acid + Triton X-405, $\bar{M}$=2000.

critical micelle concentration (CMC)[15] of Triton X is *ca.* 10^{-2}% or 100 mg/l, and the adsorption of Triton X on mercury electrode shows unusual phenomenon owing to the formation of multilayer.[5,14] The maximum peak in Fig. 9-(b) seems to be related to the formation of multilayer.

Figure 10 shows the concentration dependence of i/i_b at 1.2 V, where the ratio of anodic current (i/i_b) is considered to be approximately proportional to the amount of oxidized Triton X on platinum. After the sharp increase, i/i_b at 1.2 V shows a minimum and then shows a nearly constant value of *ca.* 2.5. The minimum may be ascribed to the formation of a multilayer which prevents Triton X from being oxidized. However, it remains also unknown why the oxidation current increases again with the increase of Triton X content after the appearance of the minimum. It is interesting that the maximum positions in Fig. 9-(b) are nearly in agreement with the minimum positions in Fig. 10.

The inhibition effect of these polymers on the electrosorption of hydrogen or oxygen on platinum is small even in a relatively concentrated solution of adsorbate sufficient to form the monolayer. Such a small inhibition effect upon the process on a platinum electrode may be attributed to the roughness of a solid electrode, where the adsorbed layer of each polymer is considered to be irregular or porous.

Radacanu and Lorenz[16] have examined the process on a solid electrode, which is inhibited by β-naphthoquinoline or dibenzylsulfoxide. The inhibitors are oxidized or reduced by the addition or separation of proton, which may have some connection with hydrogen evolution. Such an analysis might be useful, though the reaction of polymer on platinum is too complicated (*e.g.*, local oxidation or reduction of polymer).

The authors are grateful to Mr. Yasuyuki Konoshima for his kind assistance.

Semiconducting Properties of Ln_2CuO_4 (Ln=Rare earths)

Tadao KENJO and Seishi YAJIMA

The Oarai Branch, The Research Institute for Iron, Steel and Other Metals, Tohoku University, Oarai, Ibaraki-ken

(Received July 19, 1972)

The temperature dependence of the resistivity and the thermoelectric power of Ln_2CuO_4 (Ln=rare earths) have been measured. The compounds of Gd, Sm, Nd, and Pr are semiconductive, while La_2CuO_4 shows metallic conductivity. The tetragonal lattice of La_2CuO_4 shrinks in the a axis and expands in the c axis compared to Pr_2CuO_4, in spite of the steady expansion of these lattice parameters for the compounds between Gd and Pr. The thermoelectric power of Ln_2CuO_4, but not La_2CuO_4, is negative, suggesting an electron-conducting or n-type semiconductor. The resistivity of the Ln_2CuO_4 at room temperature increases essentially with an increase in the atomic number of Ln. The plots of the thermoelectric power *vs.* the reciprocal temperature showed a steeper slope for the compounds of the heavier rare earths. The semiconductor-metal transition observed between La_2CuO_4 and Pr_2CuO_4 was explained in relation to the structural change (the shrinkage of the a axis and the expansion of the c axis) as being due to the change in the electron configurations of Cu^{2+}.

In the rare earth oxide–cupric oxide system, two different compounds were found: Ln_2CuO_4 (Ln=La, Pr, Nd, Sm, and Gd)[1] and $Ln_2Cu_2O_5$ (Ln=Tb, Dy, Er, Yb, and Y).[2] Tm, Ho, and Lu were expected to be of the same type as the latter one.[2] The Ln_2CuO_4 compounds are isostructural with tetragonal K_2NiF_4, whose space group is D_{4h}^{17} (I4/mmm).[3]

It should be noted that Ln_2CuO_4 is black.[1] The black color suggests that an appreciable number of electrons in the valence state are excited to a higher energy level by thermal energy as low as room temperature. Therefore, if the higher energy level to which electrons are excited is a conduction band, the conductivity of Ln_2CuO_4 will be in the region of the semiconductor. Further, the crystal structure of Ln_2CuO_4 seems to support the above expectation. In the crystal lattice of Ln_2CuO_4, Cu^{2+} is surrounded by six O^{2-} ions and forms a Cu–O–Cu chain toward the a axis without an interruption by Ln^{3+}. Since 3d-transition metals are thought to make an electron overlapping with O^{2-},[4-6] and since, in fact, the conductivity of

many oxides containing 3d-transition metals is in the region of the semiconductor,[4-6] it is very likely that the Cu–O–Cu chain in the Ln_2CuO_4 can be a path for electron transfer.

On the other hand, the role of Ln^{3+} in electrical conduction may not be as important as that of Cu^{2+}, because in the Ln–O bond such an electron overlapping as would contribute to electrical conduction cannot be expected. However, Ln^{3+} may affect the electrical properties and the structure of the compounds indirectly. The configuration of electrons of Cu^{2+}, particularly those of 3d-electrons, are influenced by the ligand field caused mainly by the effective negative charges on the six O^{2-} surrounding Cu^{2+} ions. Since the less electronegative rare earth, or larger rare earth cation, pushes electrons more strongly toward oxygen in the Ln–O bond, the effective negative charges on the O^{2-} of the compounds of less electronegative rare earth can be expected to be greater; in other words, the ligand field at the site of Cu^{2+} is made stronger by replacing Ln with less electronegative Ln. At this time it is difficult to make more detailed predictions of the effect of the ligand-field strength changed by various rare earth cations on the electrical properties of the compounds, but it would be interesting to see if the Ln_2CuO_4 compounds show semiconducting properties and if their electrical conductivity depends upon the size of the rare earth cations.

From the above reason, the compounds of La, Pr, Nd, Sm, and Gd were prepared, and their semiconducting properties investigated.

Experimental

Material and Reagents. Stock solutions of cupric nitrate were prepared by dissolving cupric nitrate of the Kanto Chemical Co., GR grade, into distilled water. Stock solutions of rare earth nitrates were prepared by dissolving each rare earth oxide (99.9% purity; Nippon Yttrium Co., Ltd.) into nitric acid. Both cupric nitrate and rare earth nitrate solutions were standardized against an EDTA standard solution, using XO as the indicator.

Procedure. The Ln_2CuO_4 samples were prepared from gel-like mixed hydroxides. This method is advantageous in giving well-mixed oxide mixtures and denser final specimens than the usual ceramic technique which consists of heating a mixture of the oxides of Cu and Ln. Aliquot portions of cupric nitrate and rare earth nitrate solutions were mixed together, and then a 1 M-NaOH solution was stirred in at 80 °C. The final pH of the solution was adjusted to 11. After the mixture had stood overnight, the mixed precipitates of the hydroxides were filtered and repeatedly washed with distilled water until no sodium ion was detected in the filtrate by the flame test. The gel-like mixtures thus obtained were dried at 120 °C and preheated at 750 °C for 4 hr in air. The samples thus obtained, partially converted to Ln_2CuO_4, were milled, pressed into 15-mmϕ pellets under a pressure of 2.5 t/cm^2, and heated again at 1000 °C for 15 hr in air. Then they were removed from the furnace and cooled in air to room temperature. The mole ratio of Cu to Ln of the samples thus obtained was determined by the following chelatometric titration method. Two aliquot portions were taken from sample solutions obtained by dissolving sample specimens into nitric acid. The total content of Cu^{2+} and Ln^{3+} in the first sample solution was determined using PAN as the indicator. The solution of sodium thiosulfate was added to the second one in order to mask the Cu^{2+}, and then the Ln^{3+} was titrated, using XO as the indicator. The Cu^{2+} content was calculated from the difference between the two titration data. The results of the chemical analysis showed $Ln_2O_3/CuO=1$ within $\pm 0.5\%$ for all the samples obtained. The bulk densities of the specimens obtained were 90—95% of the theoretical values calculated from the X-ray diffraction data. All the samples were found to be single-phase by means of an X-ray diffractometer.

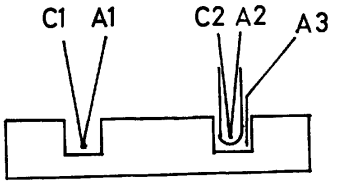

Fig. 1. A device for thermoelectric power measurements. C: chromel wire, A: alumel wire, C2-A2 thermocouple is coated with glass.

For the measurements of the resistivity and of the thermoelectric power, rods 12—13 mm long and 3—4 mm thick were used. The resistivity was measured by the 4-probe method, using Conductive Silver Coating Materials of Du Pont No. 6422 to connect the silver electrode with the oxide specimens. The thermoelectric power was measured using alumel-chromel thermocouples, as is shown in Fig. 1. Two couples of alumel-chromel thermocouples were inserted into two holes cut 8 mm apart in the specimen rods. One of them was coated with glass in order to avoid a short circuit through the rod (C2, A2),[7] and an additional alumel wire was attached to the hole in which the glass-coated thermocouple had been inserted (A3). All the contact between the specimens and the thermocouple wires was made using the Conductive Silver Coating Materials of Du Pont No. 6422. Since this contacting procedure involves heating at 700 °C for 4 hr and subsequent gradual cooling, the sample ends in being annealed. The sample temperature was measured by means of a C1–A1 thermocouple. The temperature difference was taken up from the A1–A2 couple while the C1 was connected with the C2. The potential difference due to the thermoelectric power was measured from the A1–A3 couple. The temperature difference between the two holes was adjusted to be less than 5 °C. All the voltage measurements for resistivity and thermoelectric power were performed by means of a Hitachi QPD_{74} potentiometric 2-pen recorder.

Results

The temperature dependences of the resistivity of various Ln_2CuO_4 are given in Fig. 2. Corrections for the bulk density were made by dividing the raw data by the ratio of the bulk to the theoretical density. These results indicate that the Ln_2CuO_4 (Ln=Gd~Pr) compounds are semiconductive and that La_2CuO_4 compound is metallic. The slopes in these plots are steeper in the higher temperature region than in the lower one except for metallic La_2CuO_4. These plots all seem to fall on identical curves in the high-temperature region.

7) The conductivity of the samples is so high, particularly at the high temperatures, that the temperature difference cannot be measured unless one of the thermocouples is glass-coated.

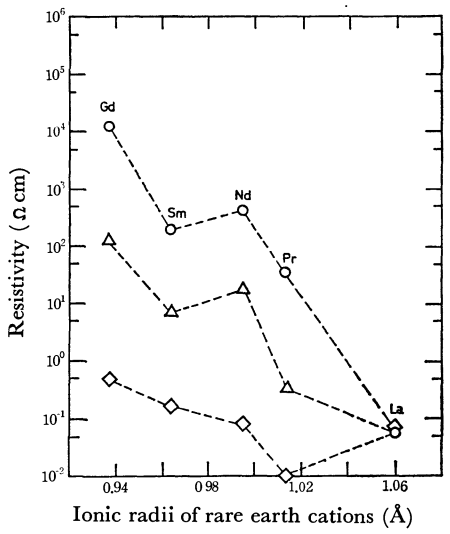

Fig. 5. Relation between resistivity and ionic radii of rare-earth cations of Ln_2CuO_4 compounds.
○: room temperature, △: 200 °C, ◇: 800 °C

The semiconductor-metal transition observed between Pr_2CuO_4 and La_2CuO_4 corresponds to the structural behavior of Ln_2CuO_4 shown in Fig. 3; the parameters of the tetragonal lattice, c and a, increase with an increase in the ionic radii of Ln^{3+} between Gd and Pr, but the c axis of La_2CuO_4 expands more greatly than would be expected from the manner between Pr and Gd and its a axis shrinks by 3.8% against that of Pr_2CuO_4.

As can be seen in Fig. 4, the thermoelectric power, α, in all the Ln_2CuO_4 compounds except for La_2CuO_4 is negative, suggesting an *n*-type semiconductor. The slopes in the α *vs.* $1/T$ plots decrease in this order, Gd<Sm≈Nd<Pr.

Figure 5 shows a dependence of the resistivity on the ionic radii[8] of the rare earth cations of Ln_2CuO_4. At room temperature, the resistivity decreases essentially with an increase in the ionic radii of rare earth cations and at high temperatures it is not so dependent on the ionic radii.

Discussion

The experimental results of this work can be summarized as follows: (1) All the Ln_2CuO_4 compounds except for La_2CuO_4 are semiconductive, while La_2CuO_4 is metallic. (2) The resitsivity, ρ, of Ln_2CuO_4 decreases essentially with an increase in the ionic radii of Ln^{3+}, most markedly at room temperature. The slopes of the log ρ—$1/T$ plots of all the Ln_2CuO_4 except for La_2CuO_4 are steeper at a higher temperature than at a lower, and seem to fall on identical curves at high temperatures. (3) The slope in the plot of the thermoelectric power, α, *vs.* $1/T$ decreases with an increase in the ionic radii of Ln^{3+}. The negative α values of all the Ln_2CuO_4 except for La_2CuO_4 suggest that they are electron conductors. (4) The crystal structure of Ln_2CuO_4 is tetragonal, and the lattice parameters, *c*

8) T. Moeller, "The Chemistry of the Lanthanides," Reinhold Publishing Corporation, New York, N.Y. (1963), p. 21.

and a, of Ln, but not La, increase with an increase in the ionic radii of Ln^{3+}. The axis, a, of La_2CuO_4, however, becomes smaller than that of Pr_2CuO_4 in spite of the fact that the ionic radius of La^{3+} is larger than that of Pr^{3+}, and its c axis expands more greatly than would be expected from the manner in the plots of c *vs.* the ionic radii of Ln^{3+} between Gd and Pr.

At this time it is hard to give a detailed explanation of the temperature dependence of resistivity shown in the summarized results (2), but we believe, as is generally thought for the same behavior of other semiconductors,[9] that the less steep slopes in the lower-temperature region are mainly due to an extrinsic excitation process and that the steeper ones in the higher-temperature region are ascribable to an intrinsic process.

Measurements of the thermoelectric power, as is well known, provide information on carriers.[10] The thermoelectric power, α, is related to the dependence of the number of carriers, n, on the temperature, T, by the following equation:

$$\alpha = d\Delta\phi/dT = (kT/e)(d \log n/dT)$$

where $\Delta\phi$ is the potential difference due to a temperature gradient given on a specimen rod, k is the Boltzmann constant, and e is the electronic charge. When the Maxwell distribution can be applied to $d \log n/dT$, or when:

$$n = N_0 \exp(-E/kT)$$

where E is the activation energy, and N_0, a constant, the following equation can be obtained:

$$\alpha = -E/Te.$$

This indicates that the slope in the plots of α *vs.* $1/T$ corresponds to the activation energy, E.[10]

The negative thermoelectric power (shown in Fig. 4) indicates that the carriers in Ln_2CuO_4 are electrons, supporting the extrinsic excitation procedure described in the previous paragraph, where it was not known whether the carriers were electrons or holes. The donor is most likely Cu^+ formed by a partial decomposition of Cu^{2+} to Cu^+, because Ln_2CuO_4 is decomposed to Cu_2O and Ln_2O_3 at 1000—1200 °C,[11] although no significant amount of Cu(I) was found from the chemical analysis in this study.[12]

A more detailed discussion of the electron configuration of Cu^{2+} is needed to explain the semiconductor-metal transition between Pr_2CuO_4 and La_2CuO_4 and the dependence of the activation energy on the ionic radii of Ln^{3+}. The valence electron configuration of Cu^{2+} is $3d^9$. As is shown in Fig. 6, Cu^{2+} is surrounded by six O^{2-} ions in the Ln_2CuO_4, so that the energy level of the 3d-electrons is split into several energy levels, depending upon the relative positions of the O^{2-} to Cu^{2+}. Now, the c axis is taken as z, and a is

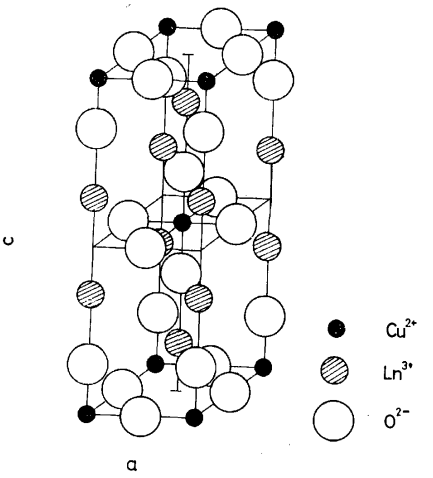

Fig. 6. Crystal structure of Ln_2CuO_4

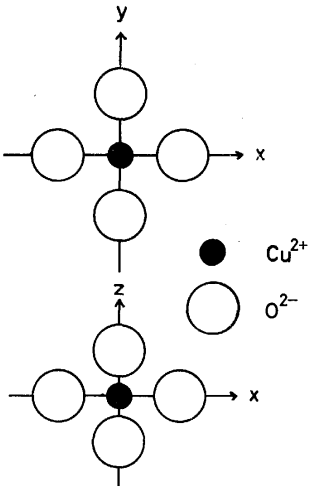

Fig. 7. Octahedron of CuO_6

taken as an x or y coordinate; the O^{2-} are situated on x or y, as is illustated in Fig. 7. The O^{2-} ion on x or y is not equivalent to that on z. It is not known yet which distance is longer, Cu–O on x (or y) or Cu–O on z, but the similar c/a value of K_2CuF_4 (3.066) to that of Gd_2CuO_4 (3.046) suggests that the ratio of $(Cu–O)_x$ to $(Cu–O)_z$ for Gd_2CuO_4 is essentially the same as that of $(Cu–F)_x$ to $(Cu–F)_z$ for K_2CuF_4, $(Cu–F)_x = 2.078$ Å and $(Cu–F)_z = 1.949$ Å.[3] Thus, we made an assumption, but one which is not essential in the following discussion, that $(Cu–O)_x$ is greater than $(Cu–O)_x$. Since the energy level of the 3d-electrons of Cu^{2+} is split in such a way as to minimize the electrostatic energy due to a repulsive force between the electrons on the Cu^{2+} and O^{2-} anions, the most stable 3d-electron configuration of Cu^{2+} probably consists of four levels, as is illustrated in Fig. 8. The energy gaps among these four levels are affected by the ligand-field strength, which depends mainly upon the effective negative charge on O^{2-}. This effective charge on O^{2-} might be influenced by the size of Ln^{3+} in the manner that a more negative charge is provided by the larger (or lighter) rare earth cations, because the larger cations, which come from less electronegative rare earths, may

12) The content of the oxygen was obtained from the data of chemical analysis of Cu and Ln, and from the weight of the samples dissolved for the chemical analysis.

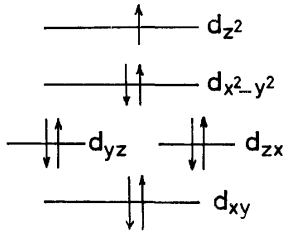

Fig. 8. 3d-electron configurations of Cu^{2+} in Ln_2CuO_4 (Ln=Gd, Sm, Nd, and Pr)

well push electrons more strongly toward oxygen in the Ln–O bond. The greater effective charge, or the greater ligand-field strength, enhances the split energy gap of the 3d-electrons, so that, in the course of replacing the smaller rare earth cation with the larger one, e_g levels rise faster than do the t_{2g} levels, and so that in a rare-earth cation, at last, the e_g levels might be higher than the 4s or 4p level, with a slight structural modification, if necessary.

The trend shown in Figs. 2 and 5, the greater resistivity of the smaller Ln^{3+} compounds, can be explained as being due to: (1) more donors (probably Cu^{+}) in the compounds of the larger rare earth cations and/or (2) the lower activation energy between the donor and the conduction level for the compounds of the larger rare earth cations. The temperature dependence of the resistivity alone (Fig. 2) does not clearly determine which factor predominates, because the slope in the log ρ—$1/T$ plots is not so markedly dependent upon the rare earth of the Ln_2CuO_4 and because the dependence of the mobility on the temperature may not be negligible, particularly for the sintered samples used in this study. The data of thermoelectric power shown in Fig. 4 suggest that the second case is more important; the slope in the plots of α—$1/T$ increases with a decrease in the size of the rare earth cations. The excess electron on the Cu^{+} probably occupies the $3d_{z^2}$, donor level, which rises as the ligand field becomes stronger, so that the energy gap between the donor and the conduction level may be reduced, thus leading to the lower activation energy of the compounds of the larger rare earth cations.

The compound of the largest rare earth cation is La_2CuO_4. The shrinkage of the a axis and the expansion of the c axis compared to Pr_2CuO_4 can be attributed to: (1) the depression of the electron density in the x and y directions instead of the enhancement of that in the z direction and/or (2) a new chemical interaction or bonding between Cu^{2+} and O^{2-} in the x and y directions. Since the metallic conduction of La_2CuO_4 surely suggests a new π-bond formation, because a σ-bond does not contribute to a metallic conduction, the second case described above must hold. The lowest energy level of electrons of Cu^{2+} which can make a π-bond with the 2p-electron of O^{2-} would be 4p, because: (1) the 3d levels except for e_g have already been filled, (2) electrons in the e_g levels are forbidden to make an overlapping with 2p in O^{2-} from the point of view of the symmetry, and (3) the 4s electron in Cu^{2+} can form only a σ-bond with 2p-electrons in O^{2-}. This new electron configuration is reasonable in view of the structural change observed between Pr_2CuO_4 and La_2CuO_4.

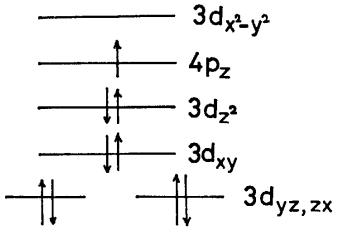

Fig. 9. Electron configuration of Cu^{2+} in La_2CuO_4

The shrinkage of the a axis and the expansion of c axis enhance the electrostatic repulsive force between the O^{2-} anion and the $3d_{x^2-y^2}$ electrons and reduce the same force between the O^{2-} anion and the $3d_{z^2}$ electrons respectively. If the shrinkage of the a axis is great enough, the $3d_{x^2-y^2}$ level would become higher than $4p_z$ as well as $3d_{z^2}$. La_2CuO_4 might be a case of this. If so, the above description leads to a similar electron configuration derived from the π-bond formation. Consequently, the most probable electron configuration is one electron in $4p_z$, two electrons in $3d_{z^2}$, and six electrons in t_{2g}, as is illustrated in Fig. 9. Thus, $4p_z$ electrons in Cu^{2+} form a π-bond with $2p_z$ electrons in O^{2-} over the Cu–O–Cu networks on the c planes, leading to a conduction band three quarters of which is filled with electrons. The conduction band described above also suggested by the magnetic properties of La_2CuO_4; Pauli paramagnetism was observed for La_2CuO_4, suggesting collective electrons rather than localized ones.[6]

Effective Ionic Charges of Several Uniaxial Crystals

Jiro HIRAISHI

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo

(Received August 1, 1972)

A simple equation was derived for obtaining the effective ionic charges of uniaxial crystals on the basis of a rigid ion model by using the optically active lattice vibration frequencies of the TO and LO modes. It was applied to several uniaxial crystals such as wurtzite type (ZnO, ZnS, CdS, and BeO) and rutile type (ZnF_2, TiO_2, SnO_2, and GeO_2) crystals. Lattice vibration frequencies of orthorhombic hydrogen chloride crystal were calculated by means of a point charge model to estimate the effect of the long range Coulomb interaction on the vibrational frequencies of molecular crystals.

It is well-known that large frequency splittings between transverse and longitudinal modes are observed for infrared active lattice vibrations of ionic crystals.[1] The TO–LO splitting arises from long range electrostatic interactions. Kellermann calculated the frequency dispersion curves of the NaCl crystal on the basis of a rigid ion model.[2] The transverse $\omega(\mathrm{T})$ and longitudinal frequencies $\omega(\mathrm{L})$ near the center of the Brillouin zone (wave vector $\boldsymbol{y}\sim 0$) for the crystals of the NaCl type can be calculated from the equations

$$\omega^2(\mathrm{T}) = (1/m_{\mathrm{Na}}+1/m_{\mathrm{Cl}})[\beta-(4\pi/3)(Ze)^2/v_{\mathrm{a}}] \quad (1)$$

$$\omega^2(\mathrm{T}) = (1/m_{\mathrm{Na}}+1/m_{\mathrm{Cl}})[\beta+(8\pi/3)(Ze)^2/v_{\mathrm{a}}] \quad (2)$$

where m_{Na}, m_{Cl}, and v_{a} represent the masses of the Na^+ and Cl^- ions and the volume of the unit cell, respectively, and β the force constant due to the short range interaction. The ionic charges on the Na^+ and Cl^- ions are given by $+Ze$ and $-Ze$, respectively. In the case of the NaCl crystal, the values of Z, β, and $(4\pi/3)(Ze)^2/v_{\mathrm{a}}$ are calculated to be 0.73, 0.34 md/Å, and 0.11 md/Å, respectively, by using the values of $\omega(\mathrm{T})$ (164 cm^{-1}) and $\omega(\mathrm{L})$ (262 cm^{-1}).[1] The result indicates that the long range electrostatic interaction greatly affects the frequency of the lattice vibration of ionic crystals, so that the long range electrostatic interaction should be taken into account in the frequency calculation of the ionic crystals.

Many investigators[3] have calculated the frequencies of the lattice vibrations of ionic crystals on the basis of various models, such as the rigid ion model with effective ionic charges,[4] shell model[5] and deformation dipole model.[6] The calculations for partially ionic crystals, such as SiC, ZnTe, and CdS have also been made.[4,7] In the present work, simple equations were derived to obtain the values of the effective ionic charges of several crystals of wurtzite and rutile types on the basis of the rigid ion model. Usually the effective ionic charges are taken as a parameter to fit the observed frequencies. However, the values of the effective ionic charges can be obtained from the TO–LO splittings, which do not depend on a model of the short range interaction.

For molecular crystals, the lattice vibration frequencies are usually calculated without the long range interaction. The frequencies of the hydrogen chloride crystal was also calculated on the assumption of a point charge on each atom to estimate the amount of TO–LO splittings and the effect of the long range interaction on the lattice vibration frequencies of such a molecular crystal.

Rigid Ion Model and Effective Ionic Charge

In the harmonic approximation, the equation of motion of particles in the crystal is given by

$$\boldsymbol{M}\omega^2\boldsymbol{u} = (\boldsymbol{R}+\boldsymbol{ZCZ})\boldsymbol{u} \quad (3)$$

by the rigid ion model, where the matrices $\boldsymbol{R}$ and $\boldsymbol{C}$ represent the short range and long range electrostatic interactions, respectively. The normal frequencies can be obtained by solving the secular equation

$$|\boldsymbol{M}\omega^2\boldsymbol{I}-\boldsymbol{R}-\boldsymbol{ZCZ}| = 0 \quad (4)$$

The $\boldsymbol{C}$ matrix can be calculated by using Ewald's transformation.[1,2,8] Using the notation of Born and Huang[1] Eq. (3) is written as

$$\begin{aligned}\omega^2\begin{pmatrix}\boldsymbol{y}\\ j\end{pmatrix}w_\alpha\left(k\middle|\begin{matrix}\boldsymbol{y}\\ j\end{matrix}\right) &= \sum_{k'\beta} C^{\mathrm{N}}_{\alpha\beta}\begin{pmatrix}\boldsymbol{y}\\ kk'\end{pmatrix}w_\beta\left(k'\middle|\begin{matrix}\boldsymbol{y}\\ j\end{matrix}\right) - e_k E_\alpha\sqrt{m_k}\\ &+ \sum_{k'\beta}(e_k e_{k'}/m_k)Q_{\alpha\beta}\begin{pmatrix}0\\ kk'\end{pmatrix}w_\beta\left(k\middle|\begin{matrix}\boldsymbol{y}\\ j\end{matrix}\right)\\ &- \sum_{k'\beta}(e_k e_{k'}/\sqrt{m_k m_{k'}})Q_{\alpha\beta}\begin{pmatrix}\boldsymbol{y}\\ kk'\end{pmatrix}w_\beta\left(k'\middle|\begin{matrix}\boldsymbol{y}\\ j\end{matrix}\right)\end{aligned} \quad (5)$$

where the α component of the displacement vector of the k-th particle in the l-th unit cell $u_\alpha(l/k)$ is given by

$$u_\alpha\begin{pmatrix}l\\ k\end{pmatrix} = (1/\sqrt{m_k})w_\alpha(k)\exp\left\{2\pi i\boldsymbol{y}\cdot\boldsymbol{x}\begin{pmatrix}l\\ k\end{pmatrix}-i\omega t\right\} \quad (6)$$

$\boldsymbol{x}(l/k)$ represents the Cartesian coordinate of the particle (l/k). The symlols e_k and m_k represent the ionic charge

and mass of particle k, respectively. $C^{N}_{\alpha\beta}(\boldsymbol{y}/_{kk'})$ is a mass-adjusted matrix of R and $Q_{\alpha\beta}(\boldsymbol{y}/_{kk'})$ is a complicated function of k, k' and wave vector $\boldsymbol{y}$, and can be calculated if the crystal structure is known.[9] The macroscopic field

$$E_\alpha = -(4\pi/v_a)(y_\alpha/|\boldsymbol{y}|)\sum_\beta (y_\beta/|\boldsymbol{y}|)\sum_{k'}(e_{k'}/\sqrt{m_{k'}})w_\beta\left(k'\left|\frac{\boldsymbol{y}}{j}\right.\right) \quad (7)$$

is not a regular function of $\boldsymbol{y}$ at $\boldsymbol{y}=0$. Its limiting value depends on the direction by which the point $\boldsymbol{y}=0$ is approached. It gives the TO-LO splittings of the frequencies of the infrared active vibrations.

When the matrices $\boldsymbol{R}$ and $\boldsymbol{C}$ are mass-adjusted, Eq. (4) is written as

$$|\omega^2\boldsymbol{I}-[\boldsymbol{R}+\boldsymbol{ZCZ}]| = 0 \quad (8)$$

where $\boldsymbol{I}$ represents an unit matrix. For a certain infrared active symmetry species at $\boldsymbol{y}\sim 0$, matrix $\boldsymbol{R}$ of the longitudinal mode is exactly the same as that of the transverse mode, while matrices $\boldsymbol{C}$(L) and $\boldsymbol{C}$(T), matrix $\boldsymbol{C}$ of the longitudinal and of the transverse modes, respectively, differ from each other, because of the existence of the macroscopic field. Equation (8) can then be given by

$$|\omega^2(\mathrm{L})\boldsymbol{I}-[\boldsymbol{R}+\boldsymbol{ZC}(\mathrm{L})\boldsymbol{Z}| = 0$$

and

$$|\omega^2(\mathrm{T})\boldsymbol{I}-[\boldsymbol{R}+\boldsymbol{ZC}(\mathrm{T})\boldsymbol{Z}| = 0 \quad (9)$$

We consider the crystals M_nX_m which contain only two different particles such as ZnO and TiO_2. The effective ionic charge on particle M can be written as Ze. The effective charge on particle X is then $-(n/m)Ze$, since the crystal should be electrically neutral. In Eq. (9), $\boldsymbol{Z}$ is a diagonal matrix, the elements of which are effective ionic charges of particles. When matrix $\boldsymbol{C}$ is taken to include the constants e and $-(n/m)e$, we can write matrix $\boldsymbol{ZCZ}$ as $Z^2\boldsymbol{C}$. Thus Eq. (9) becomes

$$\mathrm{Tr}\cdot[\boldsymbol{R}+Z^2\boldsymbol{C}(\mathrm{L})] = \sum_i \omega_i^2(\mathrm{L})$$

and

$$\mathrm{Tr}\cdot[\boldsymbol{R}+Z^2\boldsymbol{C}(\mathrm{T})] = \sum_i \omega_i^2(\mathrm{T}) \quad (10)$$

the value of Z being obtained from the equation

$$Z^2 = [\textstyle\sum_i \omega_i^2(\mathrm{L}) - \sum_i \omega_i^2(\mathrm{T})]/[\mathrm{Tr}\cdot\boldsymbol{C}(\mathrm{L}) - \mathrm{Tr}\cdot\boldsymbol{C}(\mathrm{T})] \quad (11)$$

where Tr. $\boldsymbol{C}$ represents the trace of the matrix $\boldsymbol{C}$.

Effective Ionic Charges of Several Wurtzite and Rutile Type Crystals

We apply Eq. (11) to crystals of wurtzite and rutile type, the transverse and longitudinal frequencies of which are all known.

Wurtzite Type Crystals. The space group of the wurtzite type ZnO crystal is C^4_{6v}-$P_{6_3}mc$ and the unit cell contains two formula units as shown in Fig. 1. At $\boldsymbol{y}\sim 0$, by factor group analysis the lattice vibrations can be classified into $2a_1+2b_1+2e_1+2e_2$. The vibrations of the symmetry species a_1 and e_1 are active in both infrared and Raman spectra, those of e_2 species

9) See the chapter V of Ref. 1.

a_1	$s_1=[z(Zn_1)+z(Zn_2)]/\sqrt{2}$
	$s_2=[z(O_1)+z(O_2)]/\sqrt{2}$
b_1	$s_1=[z(Zn_1)-z(Zn_2)]/\sqrt{2}$
	$s_2=[z(O_1)-z(O_2)]/\sqrt{2}$
e_1	$s_1=[x(Zn_1)+x(Zn_2)]/\sqrt{2}$
	$s_2=[x(O_1)+x(O_2)]/\sqrt{2}$
	$s_1'=[y(Zn_1)+y(Zn_2)]/\sqrt{2}$
	$s_2'=[y(O_1)+y(O_2)]/\sqrt{2}$
e_2	$s_1=[x(Zn_1)-x(Zn_2)]/\sqrt{2}$
	$s_2=[x(O_1)-x(O_2)]/\sqrt{2}$
	$s_1'=[y(Zn_1)-y(Zn_2)]/\sqrt{2}$
	$s_2'=[y(O_1)-y(O_2)]/\sqrt{2}$

are only Raman active, and those of b_1 species are optically inactive. The Cartesian symmetry coordinates are shown in Table 1. The acoustic modes belong to a_1 and e_1 species. When the point $\boldsymbol{y}=0$ is approached by 001 direction, $\boldsymbol{C}(\mathrm{L})a_1$ and $\boldsymbol{C}(\mathrm{T})e_1$ are obtained, where $\boldsymbol{C}(\mathrm{L})a_1$ represents matrix $\boldsymbol{C}$ of the longitudinal mode of a_1 species *etc.* On the other hand, when approached by 100 direction, we can get $\boldsymbol{C}(\mathrm{T})a_1$ and $\boldsymbol{C}(\mathrm{L})e_1$. The $\boldsymbol{C}$ matrices of b_1 and e_2 species are

independent of the direction of approach. For certain symmetry species $\mathrm{Tr}\cdot\boldsymbol{C}(\mathrm{L})-\mathrm{Tr}\cdot\boldsymbol{C}(\mathrm{T})$ in Eq. (11) can be calculated by use of the macroscopic field, Eq. (7) and the symmetry coordinates shown in Table 1. The results are

$$\mathrm{Tr}\cdot\boldsymbol{C}(\mathrm{L}) - \mathrm{Tr}\cdot\boldsymbol{C}(\mathrm{T}) = 8\pi(1/m_{\mathrm{Zn}}+1/m_{\mathrm{O}})e^2/v_a \qquad (12)$$

for both a_1 and e_1 species, where the effective ionic charges on Zn and O are $+Ze$ and $-Ze$, respectively. It is not necessary to calculate the complicated function $Q_{\alpha\beta}(\boldsymbol{y}|_{kk'})$. The values of Z obtained from Eqs. (11) and (12) for several wurtzite type crystals are summarized in Table 2.

factor group analysis into $a_{1g}+b_{1g}+a_{2g}+2a_{2u}+b_{2g}+2b_{2u}+e_g+4e_u$. The vibrations of the gerade symmetry species except for a_{2g} are Raman active, those of a_{2u} and e_u species infrared active, and those of b_{2u} and a_{2g} species optically inactive. The Cartesian symmetry coordinates are shown in Table 3. The acoustic modes are included in a_{2u} and e_u species. As in the case of wurtzite type crystals, $\mathrm{Tr}\cdot\boldsymbol{C}(\mathrm{L})-\mathrm{Tr}\cdot\boldsymbol{C}(\mathrm{T})$ can be obtained by using the macroscopic field and the symmetry coordinates. The result is given by

$$\mathrm{Tr}\cdot\boldsymbol{C}(\mathrm{L}) - \mathrm{Tr}\cdot\boldsymbol{C}(\mathrm{T}) = 16\pi(2/m_{\mathrm{R}}+1/m_{\mathrm{X}})e^2/v_{\mathrm{a}} \qquad (13)$$

for both a_{2u} and e_u species, where the effective ionic charges on R and X are $+2Ze$ and $-Ze$, respectively. The values of Z obtained from Eqs. (11) and (13) for several rutile type crystals are listed in Table 4. For the crystal GeO_2, two different sets of frequencies were reported.[16,17] Table 4 includes the vlaues of the effective charges on the basis of the two sets.

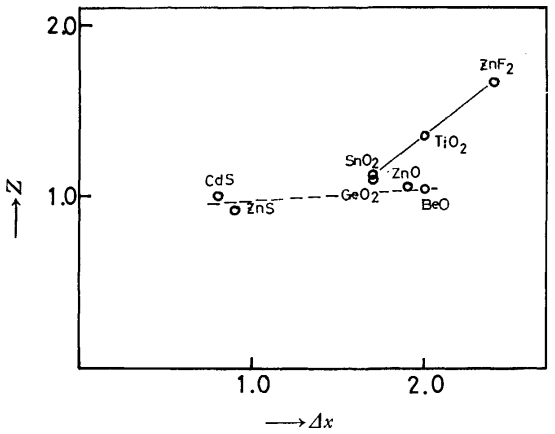

Fig. 3. The relation between the values of the effective ionic charges, Z, and the difference of the Pauling's electronegativity of the positive and negative ions, Δx.

The effective ionic charges on Zn for ZnO, ZnS, and ZnF_2 were found to be 1.05, 0.91, and 1.56 (2×0.78), respectively. The results indicate that the nature of the ionic bonds of oxide and sulfide is more covalent than that of fluoride. Table 4 also shows that the values of Z for the three rutile type oxides increases in the order of $GeO_2<SnO_2<TiO_2$. TiO_2 has a large ionic character, which gives rise to a large TO–LO splitting in the frequencies of a_{2u} species. Figure 3 shows the relation between the values of the effective ionic charges Z and the difference of Pauling's electronegativity[18] of the positive and negative ions $\Delta\chi$. For rutile type crystals a fairly good linear relation is found between Z and $\Delta\chi$. However, for the wurtzite type crystals the values of Z are almost constant.

The values of the effective ionic charges were obtained on the basis of the rigid ion model. However, the ions are not rigid, that is, polarizable. In order to estimate the effect of the polarizable ion, we consider the following two examples, for which the values of the ionic charges were obtained by a model which contained the polarization of ions. For CdS, Nusimovici and Balkanski[7] calculated the phonon frequencies to fit the observed phonon dispersion curves. On the basis of a model which includes valence-bond forces, rigid ion Coulomb forces and electronic and ionic polarization, they gave $1.02e$ as the value of the ionic charge which was very close to the value $1.00e$ in Table 2. Traylor *et al.*[3d] studied the phonon dispersion relation of rutile (TiO_2) and obtained the value $-1.26e$ as Z_0 on the basis of shell model. The value $1.26e$ is also close to the value $1.35e$ given in Table 4.

Orthorhombic Hydrogen Chloride Crystal

In ionic crystals long range interaction is of importance, but in molecular crystals it is usually omitted in the calculation of lattice vibration frequency. We tried to estimate its effect on the lattice vibration frequencies in molecular crystals, and chose orthorhombic hydrogen chloride crystal, since the system is simple and the frequency calculation at $y\sim 0$ was already made by Ito *et al.*[19] on the basis of the force field only due to short range interactions.

The space group of the crystal is C_{2v}^{12}—$Bb2_1m$ and the Bravais cell contains two HCl molecules.[20] Factor group analysis gives the result $4a_1+4b_1+2a_2+2b_2$. The a_1, b_1, and b_2 species contain one acoustic mode each, and can be expected to have different frequencies in transverse and longitudinal modes. The frequencies were calculated by Eq. (4). Matrix $\boldsymbol{R}$ was constructed by the same force field as that adopted by Ito *et al.*[19] Matrix $\boldsymbol{C}$ was set up according to the method of Kellermann[2] on the assumption that the hydrogen atom has an electric charge $+Ze$ and the chlorine atom $-Ze$. The value of Z was determined to be 0.18 from the distance between H and Cl atoms (1.27 Å) and the dipole moment (1.085 D) of the gaseous hydrogen chloride molecule. The distance between D and Cl atoms in the orthorhombic DCl crystal is 1.25 Å,[21] so that the value of Z in the crystal

can not differ much from the value obtained from gas. The values of the force constants due to the short range interaction were taken to be the same as those by Ito *et al.* The calculated results are shown in Table 5 in which 1 gives the frequencies without long range interaction and 2 those obtained with long range interaction.

As expected the effect of long range interaction in the case of the hydrogen chloride crystal is not so large as that in ionic crystals. The TO–LO splittings of the internal H–Cl stretching vibrations are 4 cm^{-1}. The largest TO–LO splitting of the lattice vibrations is 59 cm^{-1} which was obtained for the librational mode of b_2 species. The vibrational modes of the lowest frequencies of a_1, b_1, and a_2 species are approximately the translational modes of the HCl molecules. It is concluded that their frequencies do not depend on the long range interaction, since the frequencies of calculation 1 and TO and LO frequencies of calculation 2 are about the same. However, for the frequencies of the librational modes, which have the second lowest frequency of all symmetry species, the effect of long range interaction is much larger than that for translational modes.

Solubilization Behavior of Mixed Micelles of Anionic and Nonionic Surfactants in Relation to Their Micellar Structures

Fumikatsu Tokiwa and Kaoru Tsujii

Research Laboratories, Kao Soap Company, 2-1-3 Bunka, Sumida-ku, Tokyo 131

(Received August 4, 1972)

The solubilization behavior of mixed micelles of nonionic and anionic surfactants toward a water-insoluble dye, Yellow OB, has been studied. The surfactants examined were a nonionic surfactant, dodecyl polyoxyethylene ether (C_{12}POE), and anionic surfactants with the chemical structure of C_m-  -C_n-SO_3Na, where $m+n=8$ and where m or n is 0, 4, or 8 (and sodium decyl sulfonate for reference). The solubilization greatly depends on the position of the benzene ring in the hydrocarbon chain of the anionic surfactant mixed; in the mixture of C_{12}-POE and C_8-  -SO_3Na, the synergistic effect in solubilization is remarkable. The results have been discussed in relation to the structure or compactness of the polyoxyethylene shell of the mixed micelle, and in relation to the interaction of anionic and nonionic surfactants in their mixed micelle, which had previously been observed by NMR measurements.

In general, the solubilizing capacity of a nonionic surfactant of the polyoxyethylene type for water-insoluble matetials is much greater than that of an ionic surfactant with the same hydrocarbon chain length as that of the nonionic surfactant. For example, the solubilizing capacity of dodecyl polyoxyethylene ether (C_{12}POE) for a water-insoluble dye, Yellow OB, is approximately ten times greater than that of sodium dodecyl sulfate.[1] This fact suggests that the polyoxyethylene part in the molecule plays an important role in solubilization, and also that the solubilizing capacity depends greatly on the structure of the polyoxyethylene shell of the micelle.

In previous papers[2,3] studying mixed micelles of C_{12}POE and an anionic surfactant with a benzene ring in the molecule by nuclear magnetic resonance (NMR), it has been shown that, in the mixed micelle, an interaction occurs between the polyoxyethylene part of C_{12}POE and the benzene ring of the anionic surfactant. The extent of the interaction depends also on the position of the benzene ring in the hydrocarbon chain. Such an interaction might be related to the solubilization behavior of the mixed micelles of nonionic and anionic surfactants of these types.

In the present work, the solubilization behavior toward Yellow OB of the following mixed surfactant systems has been studied in order better to understand the interaction of two different surfactants in their mixed micelle and the effect of the structure of the polyoxyethylene shell of the mixed micelle on its solubilization behavior:

System I: C_8-  -SO_3Na and C_{12}POE

System II: C_4-  -C_4-SO_3Na and C_{12}POE

System III:  -C_8-SO_3Na and C_{12}POE

System IV: C_{10}-SO_3Na and C_{12}POE

The three anionic surfactants in Systems I, II, and III are different only in the position of the benzene ring in the hydrocarbon chain, and the C_{10}-SO_3Na surfactant in System IV has no benzene ring in the molecule.

Experimental

Materials. The sodium *p*-octylbenzene sulfonate (abbreviated to $C_8\phi S$), sodium δ-(4-butyl phenyl) butyl sulfonate (abbreviated to $C_4\phi C_4S$), and sodium ω-phenyloctyl sulfonate (abbreviated to ϕC_8S) were the same samples as those used in the previous experiments.[2,3] The sodium decyl sulfonate (abbreviated to $C_{10}S$) was prepared by the reaction: $C_8H_{17}CH{=}CH_2+NaHSO_3\rightarrow C_{10}H_{21}SO_3Na$, using *t*-butylperbenzoate as the catalyst. The product obtained, $C_{10}S$, was recrystallized three times from an ethanol-water mixture (95:5). The dodecyl polyoxyethylene ether with 9 oxyethylene units purified by the countercurrent solvent extraction method,[4] was the sample used in a previous work.[2] The polyethylene glycol (abbreviated to PEG), the average molecular weight of which was approximately 400, was of a reagent grade and was purified by ion exchange with Amberlite IR-120 and IRA-410. The Yellow OB (1-*o*-tolyl-azo-2-naphthylamine) was of a reagent grade; it was purified by a procedure previously described.[1]

Solubilization Measurements. The sample solutions were prepared by adding the desired amounts of the anionic surfactant to an aqueous solution of the nonionic surfactant, $C_{12}POE$, of 5×10^{-3} M. Solubilization runs were made in a water bath at 30 ± 0.1 °C for 65 hr to attain equilibrium, the procedure described elsewhere[1] being employed. The Yellow OB described above was used as a solubilizate. The amounts of the solubilized dye were determined by optical-density measurements at a wavelength of 445 mμ by means of a Shimadzu Model AQV-50 spectrophotometer.

The critical micelle concentration (CMC) and the solubilizing capacity of each surfactant were determined from the inflection and slope respectively of the solubilization *vs.* concentration curve.

A similar method was used to determine the solubility of Yellow OB in the mixed solvent of PEG and water at various mixing ratios.

Results and Discussion

Figure 1 shows the solubilization *vs.* concentration curves for Systems I, II, III, and IV, where the amount of Yellow OB, *S*, solubilized by mixed micelles is plotted against the molar concentration of each anionic surfactant, *C*, the concentration of the nonionic surfactant, $C_{12}POE$, being kept constant at 5×10^{-3} M. (On the ordinate, the value of *S* for $C_{12}POE$ alone is displaced to zero.) In System I, a remarkable, synergistic effect in the solubilization of the mixture of $C_8\phi S$ and $C_{12}POE$ is observed. In the other systems, however, their solubilizing capacities in the region of relatively low concentrations are smaller than that of $C_{12}POE$ alone; they depend on the type of anionic surfactant.

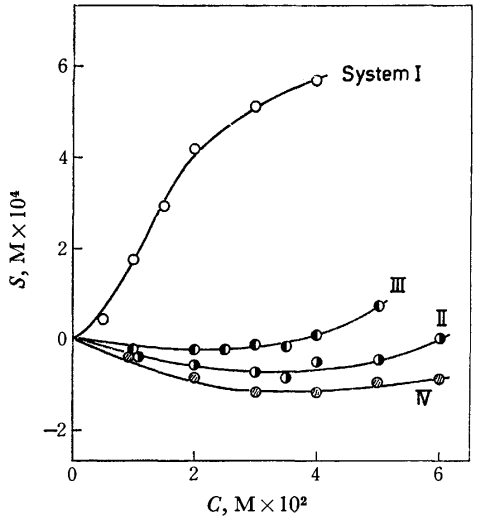

Fig. 1. The curves of the solubilization of Yellow OB *vs.* the concentration of anionic surfactant for Systems I, II, III, and IV at 30 °C, the concentration of $C_{12}POE$ being kept constant at 5×10^{-3} M.

It is known that when two different surfactants are mixed in an aqueous solution, mixed micelles are formed rather than the respective micelles of each surfactant. If we assume that the additivity rule can be applied to the solubilizing capacity, *s*, of these mixed micelles, then the value of *S* can be expressed as:

$$S = (C^t - C^\circ_{1,2})(s_1x_1 + s_2x_2) \quad (1)$$

where the subscripts 1 and 2 refer to anionic and nonionic surfactants respectively; *s*, the solubilizing capacity; *x*, the mole fraction in the micelle phase; $C^\circ_{1,2}$, the CMC of the mixture of the two surfactants, and C^t, the total concentration, *i.e.*, the sum of the concentrations of Surfactants 1 and 2. The $(C^t - C^\circ_{1,2})$ term in Eq. (1) expresses the concentration of surfactants forming mixed micelles. The values of s_1, s_2, and C^t are known, and the values of x_1, x_2, and $C^\circ_{1,2}$ may be estimated as will be shown below.

If we consider a two-component system consisting of both monomer and micelle phases, and assume the system to be ideal, we know that for each component the chemical potentials in the two phases are identical at equilibrium. Under such conditions, the equilibrium between monomers and micelles in a mixed solution of anionic and nonionic surfactants may be expressed[5,6] as:

$$y_1C^\circ_{1,2} = x_1C^\circ_1 \quad (2)$$

and:

$$y_2C^\circ_{1,2} = x_2C^\circ_2 \quad (3)$$

where *x* and *y* are the mole fractions of the surfactants in the micelle and monomer phases respectively, and where C° is the CMC. From Eqs. (2) and (3), the CMC of the mixed surfactants, $C^\circ_{1,2}$, may be written in the form:

$$C^\circ_{1,2} = (C^\circ_1 - C^\circ_2)x_1 + C^\circ_2 \quad (4)$$

as $x_1+x_2=1$ and $y_1+y_2=1$. By definition, on the other hand, the value of x_1 is expressed by:

$$x_1 = \frac{C_1^{\,M}}{C_1^{\,M}+C_2^{\,M}} = \frac{C_1^{\,t}-C_1^{\,m}}{C^t-C^\circ_{1,2}} = \frac{\alpha_1C^t-y_1C^\circ_{1,2}}{C^t-C^\circ_{1,2}} \quad (5)$$

where the superscripts m and M refer to the monomer and the micelle respectively, and where α_1 is the mole fraction of Surfactant 1 in the bulk solution. By combining Eq. (5) with Eqs. (2) and (4), we obtain:

4) K. Nagase and K. Sakaguchi, *Kogyo Kagaku Zasshi*, **64**, 635 (1961).

5) F. Daniels and R. A. Alberty, "Physical Chemistry," John Wiley, New York, N. Y. (1966), p. 145.

6) F. Tokiwa, K. Ohki, and I. Kokubo, This Bulletin, **41**, 2845 (1968).

$$x_1 = \frac{1}{2}\{(1+r)-[(1+r)^2-4r\alpha_1]^{1/2}\}$$

$$r = \frac{C^t}{C_1^\circ - C_2^\circ} \tag{6}$$

The value of $C_{1,2}^\circ$ can also be evaluated by substituting x_1 into Eq. (4). The values of C_1° and C_2° used for these calculations are given in Table 1, together with the values of s_1 and s_2 calculated from the slope of the S *vs.* C curve for each surfactant.

Table 1. Values of C_1° and C_2° (mol/l), and s_1 and s_2 (mol, yellow OB/mol, surfactant) for each system

	$C_1^\circ \times 10^2$	$C_2^\circ \times 10^4$	$s_1 \times 10^3$	$s_2 \times 10$
System I	1.17	1.30	13.0	1.13
System II	2.90	1.30	4.67	1.13
System III	3.45	1.30	8.20	1.13
System IV	4.50	1.30	5.50	1.13

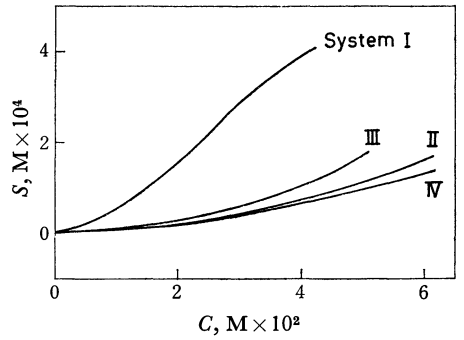

Fig. 2. The solubilization *vs.* concentration curves, calculated by Eq. (1), for Systems I, II, III, and IV.

Using the values of x_1 and x_2 (by definition, $x_2 = 1-x_1$) for Eq. (1), we can draw the S *vs.* C curves of Systems I, II, III, and IV shown in Fig. 1. When these calculated S *vs.* C curves are compared with the observed S *vs.* C curves shown in Fig. 1, we can see that Eq. (1) does not well explain the solubilization behavior of each system; that is, in System I the observed curve is higher than the calculated curve throughout the concentration region examined, and in Systems II, III, and IV the observed curves are lower than the calculated ones. As will be described later, the remarkable, synergistic effect in solubilization observed in System I can be explained in terms of a strong interaction between the benzene ring of $C_8\phi S$ and the polyoxyethylene chain of C_{12}POE in the mixed micelle.[2,3]

The solubilizing capacity of the C_{12}POE micelle toward Yellow OB is probably closely related to the compactness or structure of the polyoxyethylene shell of this micelle. According to previous works,[1,7] sodium dodecylpolyoxyethylene sulfate, which has an ionic head at the terminal of the polyoxyethylene chain, can solubilize the dye much less than C_{12}POE because of less compactness of the polyoxyethylene shell as a result of the electrical repulsion between the charged heads.

7) F. Tokiwa, *J. Phys. Chem.*, **72**, 4331 (1968).

In the present cases, by considerations similar to those indicated above, the polyoxyethylene shell of the C_{12}POE micelle will be made less compact or diluted by mixed micelle formation with an anionic surfactant. This will then result in less solubilization. The compactness of the polyoxyethylene shell consisting of n_2 molecules of C_{12}POE may be written in the form:

$$p = \frac{(M_{POE}/N)n_2}{v_{POE}} \tag{7}$$

where p is the compactness expressed by weight/volume; v_{POE}, the volume of the polyoxyethylene shell of the micelle; M_{POE}, the molecular weight of the polyoxyethylene chain of the C_{12}POE molecule, and N, the Avogadro number. When n_1 molecules of an anionic surfactant are incorporated into this micelle, the volume of the shell will be increased proportionally to n_1. Then, the value of p becomes:

$$p = \frac{(M_{POE}/N)n_2}{v_{POE}+\beta n_1} \tag{8}$$

where β is a constant, *i.e.*, the volume factor of the anionic surfactant molecule added.

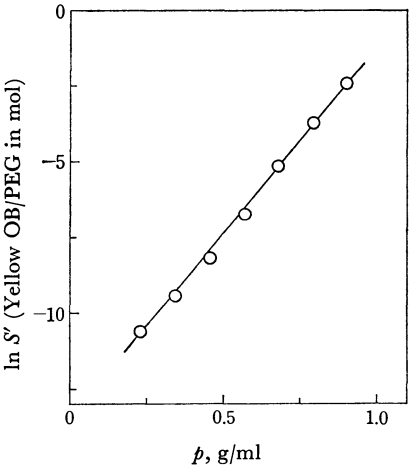

Fig. 3. The solubility of Yellow OB in aqueous PEG solution as a function of the concentration of PEG at 30 °C.

Let us now turn our attention to the solubility of Yellow OB in mixed solvents of PEG and water at different mixing ratios in order to relate p to the solubilizing capacity of mixed micelles. In Fig. 3, the logarithm of the solubility of Yellow OB, S', is plotted against the concentration of PEG, p, in aqueous solution [the value of p corresponds to p in Eq. (8)]. There is a linear relation between ln S' and p; it is given by the equation:

$$\ln S' = Ap + B \tag{9}$$

where A and B are constants. From the slope and intercept of the straight line, the A and B constants may be determined to be 12.2 ml/g and −13.5 respectively.

Here, we regard the polyoxyethylene shell of a mixed micelle as a "small" mixed solvent system consisting of PEG and water. The solubility, S', in Eq. (9), may then be put equal to the solubilizing capacity, S_{dil}^M, of a "diluted" polyoxyethylene shell of the mixed micelle, since the dilution of the polyoxyethylene shell

by an anionic surfactant and the dilution by water are considered to have a similar effect on the solubility of Yellow OB. Then, the compactness, p, of the shell given by Eq. (8) may be related to p in Eq. (9). By combining Eq. (8) with Eq. (9), we obtain:

$$\ln S^{M}_{dil} = A\frac{(M_{POE}/N)n_2}{v_{POE}+\beta n_1} + B$$

$$= A\frac{(M_{POE}/N)}{(v_{POE}/n_2)+\beta(n_1/n_2)} + B \qquad (10)$$

where (n_1/n_2) is the molar ratio of the anionic/nonionic surfactants in the micelle phase and has the relation:

$$n_1/n_2 = x_1/x_2 = x_1/(1-x_1) \qquad (11)$$

The value of (v_{POE}/n_2) is evaluated by inserting the value of S^{M}_{dil} at $x_1/x_2=0$, which may be estimated from the difference between the solubilizing capacities of C_{12}POE and sodium dodecyl sulfonate, into Eq. (10). By using Eq. (10), the S^{M}_{dil} *vs.* (x_1/x_2) curve, for example, at $\beta=15$ Å^3 is drawn in Fig. 4, where β is estimated as will be described later.

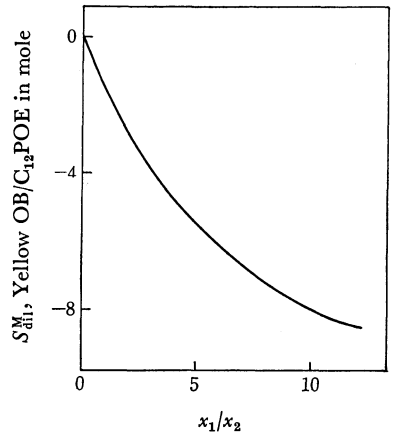

Fig. 4. The solubilizing capacity S^{M}_{dil} of a "diluted" polyoxythylene shell of mixed micelles as a function of x_1/x_2, according to Eq. (10).

From Eq. (6), the variable (x_1/x_2) in Eq. (11) can be given by two variables, C^t and α_1, which are determined in this case only by the concentration, C, of the anionic surfactant. Thus, S^{M}_{dil} can be converted into S_{dil}, which expresses the moles of Yellow OB solubilized per liter of the surfactant solution. In Fig. 5, the S_{dil} *vs.* C relationship at $\beta=15$ Å^3 for System IV is shown.

The constant β in Eq. (10) may be estimated as follows. In System IV, where the anionic surfactant, C_{10}S, has no benzene ring in the molecule, we assume that no interaction occurs between C_{10}S andC_{12}POE. On this assumption, the difference between the value observed (S_{obsd}) and the value calculated (S_{calcd}) by Eq. (1) may be ascribed to the dilution effect of C_{10}S on the polyoxyethylene shell of the C_{12}POE micelle, which can itself be evaluated from Eq. (10). Then, the constant β in Eq. (10) may be estimated by trial and error unitl the $(S_{obsd}-S_{calcd})$ *vs.* C curve overlaps with the S_{dil} *vs.* C curve. When the value of β is chosen as 15 Å^3, we obtain Fig. 5, where the broken line indicates the S_{dil} *vs.* C curve and where the solid line

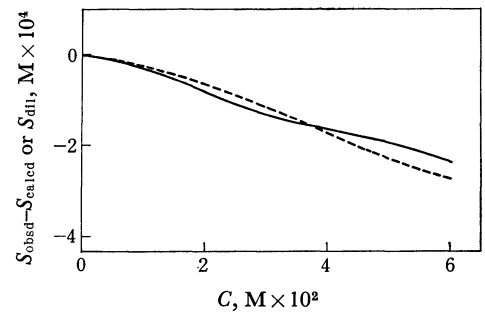

Fig. 5. The $(S_{obsd}-S_{calcd})$ *vs.* C_{calcd} curve (the solid line), and the S_{dil} *vs.* C curve (the broken line) for System IV.

indicates the $(S_{obsd}-S_{calcd})$ *vs.* C curve for System IV. These two curves are in relatively good agreement with each other, showing Eq. (10) to be reasonable although some deviation is seen at high concentrations.

The value of $\beta(=15$ Å$^3)$ seems somewhat smaller than the expected value. However, this can be explained by taking into consideration the facts that the hydrocarbon portion of the anionic surfactant molecule is located in the hydrocarbon core of the mixed micelle, and that only a part of the hydrophilic head can contribute to the dilution of the polyoxyethylene shell of the micelle. For the same reasons, it may be permissible to use the β value of C_{10}S for other anionic surfactants which have different structures of the hydrocarbon part.

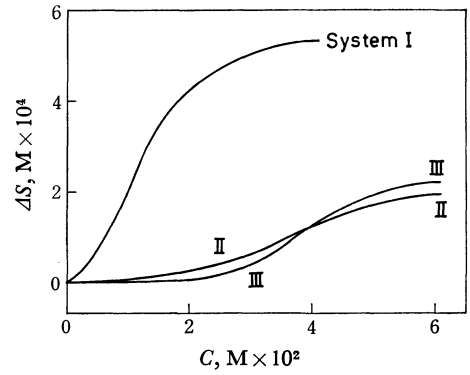

Fig. 6. The synergistic effect, ΔS, in solubilization as a function of C for Systems I, II, and III.

In System I, II, or III, where each anionic surfactant has a benzene ring in the molecule, the difference between the values of S_{obsd} and $(S_{calcd}+S_{dil})$ at a given concentration, C, of the anionic surfactant may be interpreted as a synergistic effect (ΔS) in the solubilization at this C. Figure 6 shows the ΔS *vs.* C curves for Systems I, II, and III; in the calculation of S_{dil}, β is also taken to be 15 Å^3, as has been described above. In System IV, of course, ΔS $(=S_{obsd}-(S_{calcd}+S_{dil})]$ is zero at any C, as has been assumed in the above discussion.

The NMR studies[2,3] of mixed micelles in Systems I, II, and III have shown that the polyoxyethylene chain of C_{12}POE interacts with the benzene ring of the respective anionic surfactant; the extent of the interaction is in order of System I>II>III. The remarkable high values of ΔS seen in System I may

be ascribed to this interaction. On the other hand, the ΔS values in Systems II and III are smaller than the value in System I at all concentrations, and no considerable difference is seen between these two systems. This may be explained by the weaker interaction between the polyoxyethylene chains and the benzene rings in mixed micelles, although the interaction in System II, observed by NMR measurement, is slightly stronger than that in System III.[3)]

The authors wish to express their thanks to Dr. H. Kita for his encouragement in this work, and Dr. Y. Inamoto and Mr. N. Takei for their help in preparing the samples.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1342—1346 (1973)

Interpretation of Photoelectron Spectra of Halomethanes

Shunji KATSUMATA and Katsumi KIMURA

Physical Chemistry Laboratory, Institute of Applied Electricity, Hokkaido University, Sapporo

(Received September 4, 1972)

Theoretical studies of the electronic structure of chloromethanes ($CH_{4-n}Cl_n$, where $n=1\sim4$) were carried out by the CNDO/2 method. The resulting Koopmans' theorem ionization energies were generally in good agreement with the experimental data available, and somewhat different assignments from those previously reported were obtained for the nonbonding orbitals. A "sum rule" was employed for interpreting the photoelectron bands of three series of di- and poly-halomethanes (chloro-, bromo-, and iodo-methanes) in terms of some localized molecular orbitals. Reasonable assignments were derived for the photoelectron spectra of all these halomethanes and the resulting assignments for the chloromethanes were in good accord with those obtained from the CNDO/2 calculation.

The high resolution photoelectron (PE) spectra of all the halomethanes $CH_{4-n}X_n$ ($n=1\sim4$; X=F, Cl, Br, and I) except CI_4 have been reported by Turner *et al.*,[1] Potts *et al.*,[2] and Ragle *et al.*,[3] and interpreted by them in terms of molecular orbital (MO) structures on experimental basis. A theoretical calculation of ionization energy (IE) for chloro- and bromomethanes has been carried out by Dixon *et al.*,[4] with a pseudo one-electron hamiltonian. The PE spectra and electronic structures[1-3] of methyl halides are simple and their outer orbital structures are well understood. For di- and poly-halomethanes, however, the PE spectra are more complicated and some partly conflicting results have been reported for spectral assignment by different workers.[1,2,4] Assignments of the experimental IE's of these compounds to their MO's still seem to remain unresolved, especially for outer electronic structures associated with the nonbonding orbitals of halogen atoms.

Theoretical studies on the electronic structures of fluoromethanes have been carried out with the semi-empirical CNDO/2 method by Davis[5] and Pullen *et al.*,[6] and with the GTO calculation by Brundle *et al.*[7] For other halomethanes, however, no CNDO calculations have been published yet.

We have undertaken a study of a series of chloromethanes using the CNDO/2 method. Furthermore, since Kimura *et al.*[8] recently proposed a sum rule with which the PE spectra of various alkyl monohalides from the methyl to the *n*-butyl can be interpreted in terms of several localized MO's, we employed this method to various polyhalomethanes.

CNDO/2 Calculations of Chloromethanes

The semi-empirical CNDO/2 method treating all the valence electrons in a molecule has been proposed by Pople *et al.*,[9] and extended by Santry and Segal.[10a] to various molecules containing the elements sodium through chlorine. We used this method in calculating IE's of the chloromethanes, taking 1s(H), 2s(C), 2p(C), 3s(Cl), and 3p(Cl) orbitals into account and assuming Koopmans' theorem.

We employed different sets of parameter values for C and H atoms as follows. (1) Values originally used by Pople *et al.*,[9] (2) values given by Del Bene and

9) a) J. A. Pople, D. P. Santry, and G. A. Segal, *J. Chem. Phys.*, **43**, S 129 (1965); b) J. A. Pople and G. A. Segal, *ibid.*, **43**, S 136 (1965); *ibid.*, **44**, 3289 (1966).

10) a) D. P. Santry and G. A. Segal, *ibid.*, **47**, 158 (1967); b) D. P. Santry, *J. Amer. Chem. Soc.*, **90**, 3309 (1968). When his parameter values were used, we employed $\gamma_{Cl}=15.01$ eV reported by H. G. Benson and A. Hudson, *Theoret. Chim. Acta*, **23**, 259 (1971).

Jaffé,[11] and (3) as for (2) except that $\beta_C = -14.0$ eV was used; For Cl atom: (a) values given by Santry and Segal,[10a] (b) values used by Santry,[10b] and (c) as for (a) except that $\beta_{Cl} = -20.0$ eV was used. A value of 14.28 eV was used for γ_{Cl}, evaluated by the approximate formula.[10a] Resonance integrals were approximated by $\beta_{AB} = {}^1/_2 K(\beta_A + \beta_B)$ where K was made to 0.75 when both A and B are Cl atom and 1.0 otherwise, since it has been pointed out by Santry and Segal[10a] that better results can be obtained by introducing such constants for K.

SCF conditions were that the energy of the lowest unoccupied MO and those of the highest and second highest occupied MO's converge within 5×10^{-4} eV. Bond lengths used for CH_3Cl,[12a] CH_2Cl_2,[12b] $CHCl_3$,[12c] and CCl_4[12d] were taken from literature. The calculation was carried out on an electronic computer FACOM 230-60 in Hokkaido University, using a program kindly offered by Dr. M. Tsuda.

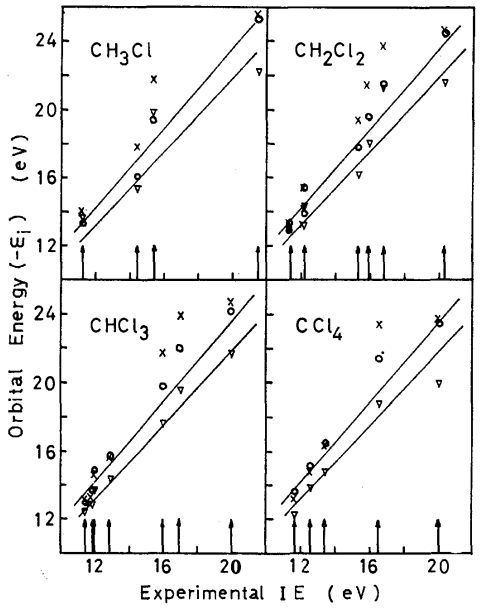

Fig. 1. Plots of the IE's calculated with different sets of parameter values against experimental values. The results obtained with parameter values (3) and (c) are indicated by ○, those of (1) and (a) by X, and those of (2) and (b) by ▽. The positions of experimental IE's are shown with an arrow. Two straight lines with $k=0.85$ (upper) and 0.92 (lower) are shown in each of the chloromethanes.

The IE's calculated with the different sets of parameter values are plotted in Fig. 1 against the corresponding experimental values. Two straight lines with $k=0.85$ and 0.92 are drawn to show a measure for adjusting the theoretical results. It is recognized from theoretical calculations available that the calculated IE's based on Koopmans' theorem are high compared with the experimental ones, so that much better agreement with experiment is obtained if Koopmans' theorem values are empirically reduced by a constant factor[13] or reduced by 4 eV.[14] This was done using a factor of $k=0.85$ or 0.92, as shown in Fig. 1.

a) Values of (3) and (c) and a factor of 0.85 for k were used.

The best sets of theoretical results obtained with the values of (3) and (c) are given in Table 1, corresponding to the data indicated by circles in Fig. 1.

Partial and Total sums of Orbital Energies of Halomethanes

In the region below about 17 eV, the PE bands of CH_3X, CH_2X_2, CHX_3, and CX_4 (X=Cl, Br, and I) are considered to be essentially due to ionization of electrons from the localized MO's such as n(X), σ(C–X), $\pi(CH_3)$, and $\pi(CH_2)$. This was supported by the present CNDO/2 calculation for a series of chloromethanes, and in this section we will deal with their IE's from a different standpoint.

If the MO's giving rise to the PE bands in the range 11—17 eV interact very little with inner orbitals such as 2s(C) and ns(X), the total sums of the orbital energies should be almost unchanged considering mutual interactions among the localized MO's. Therefore, we considered that on the basis of Koopmans' theorem the IE's should be interpreted in terms of interactions

c) Obtained from Eq. (1).
d) Assumed to be equal to the value for $\pi(CH_3)$.

among several localized MO's in unperturbed states.

Calculations of the theoretical partial sums are given in Table 2. They were carried out on the basis of the present CNDO/2 assignments by using the formulas given in brackets in which letters n, π, and σ denote parameter values. The parameter values are given in Table 3. Since electrons in the nonbonding orbital of HX and those in the σ(C–X) bonding orbitals of CH_3X are essentially in unperturbed states, the first photoelectron band of HX and the second band of CH_3X are considered to give good standards as unperturbed-state orbital energies. For $\pi(CH_3)$ the orbital energy in its unperturbed state can be estimated by simply considering that the first and third bands of CH_3X arise from the interaction of the $\pi(CH_3)$ and n(X) orbitals. Taking the centers of the Jahn-Teller splittings for the third IE's of CH_3X, we obtained an average value of -14.3 eV for the orbital energy of $n(CH_3)$ from the relation

$$\{-I_1(HX)\}_{av} + \varepsilon^0\{\pi(CH_3)\} = \{-I_1(CH_3X)\}_{av} + \{-I_3(CH_3X)\}_{av} \quad (1)$$

using available IE values. (I_1 values for HX were taken from Ref. 2, and I_1 and I_3 for CH_3X from Ref. 3 since the Jahn-Teller splittings are reported in Ref. 3).

The experimental partial sums (Table 2) were obtained by taking sums over the appropriate I_i's shown in parentheses also on the basis of the CNDO/2 assignments.

The partial sums are taken over the IE's in each symmetry species and the total sums are taken over all under consideration.

In calculating the partial and total sums for bromomethanes and iodomethanes, orbital orderings were assumed to be the same as those of chloromethanes.

Discussion

CNDO/2 Results. From the present calculation it was found that the resulting MO orders are almost independent of the different sets of parameter values with a few exceptions. The best set of calculated IE's is generally in good agreement with the corresponding experimental values (Table 1).

The PE spectrum of CH_3Cl has been reported by several workers,[1-3] the outer electronic structure being interpreted in terms of the orbital structure of $(e)^4(a_1)^2(e)^4$ which was earlier predicted by Mulliken.[15] Our result supports his assignment. Potts *et al.*[2] have observed a PE band at 21.5 eV and ascribed this to a_1(2s, C). However, we found the 21.5 eV band to be ascribed to a_1(3s, Cl) rather than a_1(2s, C). From the resulting wavefunctions it was found that 3pπ(Cl) orbital contributes to the highest occupied MO by 68% with mixing of the $\pi(CH_3)$ orbital, and that the contributions of 3pσ(Cl) and 2p(C) orbitals to the second inner MO are 43 and 46%, respectively. This indicates that the second MO of CH_3Cl is essentially due to σ(C–Cl) bonding.

For CH_2Cl_2, the electronic structure of $(a_2)^2(b_2)^2(a_1)^2(b_1)^2$ was derived for the chlorine nonbonding orbitals (Table 1). The PE spectrum of this compound in the 11—13 eV region consists of two sharp bands (11.40 and 12.22 eV) with nearly equal areas.[2] The spectral appearance indicates that these bands correspond to accidentally degenerate orbitals (in CH_2Br_2 and CH_2I_2 the nonbonding bands have been observed separately[1,2]). The a_2 orbital is strictly nonbonding, being located at the fourth. The order of the nonbonding orbitals obtained here partly differs from that assigned by Potts *et al.*[2] and Dixon *et al.*,[4] while in the inner orbitals the CNDO/2 assignments are in agreement with those proposed by Potts *et al.*[2] However, it is recognized that from a CNDO/2 calculation it is difficult to determine the order of two levels close to each other within about 0.5 eV. It is considered from a symmetry consideration of orbitals that the order of n(a_1) and n(b_2) in CH_2Cl_2 might be reverse and consequentely the assignment by Dixon *et al.*[4] is better.

The nonbonding orbital structure of $CHCl_3$ is expressed by $(e'')^4(a_2)^2(e')^4(a_1)^2$. This orbital assignment differs partly from that reported by other workers.[1,2,4] In CCl_4 the present calculation indicates $(e)^4(t_1)^6(t_2)^6$ for the nonbonding orbital structure, the order of the t_1 and t_2 orbitals being opposite to that reported,[2] and in disagreement with the prediction deduced from the consideration of spin-orbit splittings.[4]

When the parameter values of Santry[10b] are used for Cl, some minor changes occur in the orbital ordering; opposite orders are obtained between the b_1 and b_2 orbitals ascribed to the nonbonding orbitals of CH_2Cl_2 and also between the e′ and a_1 orbitals ascribed to the nonbonding orbitals of $CHCl_3$. It should be mentioned that the resulting MO orderings of the halomethanes depend on the selection of parameter values for Cl atom [(a) and (b)], but independent of those for C and H atoms [(1)—(3)]. The values of (3) and (c) are considerably close to those of (1) and (a) respectively, so that no different orderings occur. In the present work, (3) and (c) were used only for modifying the resulting IE values, giving the better results. From the shape of the spectrum of $CHCl_3$, it is reasonable to consider that the degenerate orbitals are ascribed to the second band rather than the first band. Thus we conclude that, as far as Cl parameter values are concerned, those proposed by Santry and Segal[10a] give better results than those used later by Santry.[10b]

Using the parameter values of (3) and (c), we also calculated total charge densities on the C, H, and Cl atoms of the chloromethanes, and obtained the following values: 4.08 (C), 0.95 (H), and 7.04 (Cl) for CH_3Cl; 3.70 (C), 1.04 (H), and 7.10 (Cl) for CH_2Cl_2; 3.45 (C), 1.11 (H), and 7.14 (Cl) for $CHCl_3$; 3.31 (C) and 7.17 (Cl) for CCl_4.

Partial and Total Orbital-Energy Sums. Good agreements were generally obtained for the total sums in all the halomethanes studied, indicating that the selection of the empirical orbital energies (Table 2) is appropriate. The total sum is independent of orbital assignment in the case of CH_2X_2, whereas in the molecules with the degenerate orbitals it depends on their orbital ordering. The partial sums of course depend always on orbital assignments. We tested various possible assignments and found that the CNDO/2 assignments given in Table 1 are also the best in terms of standard deviations calculated over all the partial sums for each series of CH_2X_2, CHX_3, and CX_4 (where X is Cl, Br, and I) except CI_4 whose PE data are not available.

In calculating the experimental partial sums with an appropriate combination of I_i, in addition to a numerical comparison of experimental and theoretical partial sums the magnitudes of interaction should be also taken into consideration. If there are two nondegenerate localized MO's interacting with each other, the interaction should shift the upper level upwards and the lower level downwards. In CH_2Cl_2, the n and σ levels belonging to a_1 interact with each other to give I_2 (11.40 eV) and I_6 (15.94 eV), causing shifts of 1.38 and 1.52 eV. The n and σ levels belonging to b_2 interact to give I_3 (12.22 eV) and I_6 (15.30 eV), causing shifts of 0.56 and 0.88 eV. Thus, it should be pointed out that the shifts as well as the parameter values we used for n and σ are appropriate. Rigorously speaking, n (or σ) levels in polyhalomethanes should split to some extent to give different orbital energies in different symmetry species because of mutual interactions among equivalent n (or σ). However, there are no remarkable discrepancies between calculated and experimental partial sums when no interactions are considered (Table 2).

If n (or σ) orbitals are split to a large extent by their linear combinations according to orbital symmetry, no good agreement can be obtained between the calculated and experimental partial sums. Taking partial sums over MO's, for instance, in a_1+b_2 and b_1+a_2 in CH_2X_2, better results should be obtained than those in a_1, a_2, b_1, and b_2 separately, where nonbonding

15) R. S. Mulliken, *Phys. Rev.*, **47**, 413 (1935).

orbitals belonging to a_1 and b_2 are symmetric and those belonging to b_1 and a_2 are antisymmetric with respect to the CCl_2 plane. Similar situations also occur in CHX_3 and CX_4. Taking a lower symmetry than the original molecular symmetry, such mutual interactions among n (or σ) can be cancelled in partial sums.

It is interesting to note that the a_2 orbital of CH_2X_2, the a_2 and e'' orbitals of CHX_3, and the t_1 and e orbitals of CX_4 are strictly nonbonding and that the corresponding IE's are in agreement with the n(X) parameter values within about 0.8 eV.

It seems reasonable that the a_2 orbital is completely nonbonding so that its IE is higher than those of other nonbonding orbitals interacting with the σ and π orbitals. The same situation occurs also in CHX_3 and CX_4, *viz.*, the a_2 and e'' orbitals in CHX_3 and the t_1 and e orbitals in CX_4 are lower than other nonbonding orbitals which interact with the σ and π orbitals. The present CNDO/2 calculation supports this view.

It should be mentioned that the sums of the experimental orbital energies can be interpreted in terms of simple model in which only a few localized MO's are taken into account for each of the halomethanes.

Potts *et al.*[2] have also reported PE data for BCl_3, BBr_3, BI_3 as well as their orbital assignments. Applying the sum rule to these compounds, we obtained values of about −125, −115, and −102 eV, respectively, for total sums, considerably close to the total sums obtained for $CHCl_3$, $CHBr_3$, and CHI_3 (−122, −112, and −100 eV, respectively). This indicates that the orbital energy of σ(B–X) is very close to that of σ(C–X) for each halogen.

Finally, let us consider total sums for fluoromethanes. Adopting the assignments proposed by Potts *et al.*,[2] the total experimental sums of CH_3F, CH_2F_2, CHF_3, and CF_4 are −60.72, −78.52, −93.60, and −128.40 eV, respectively,[16] while the corresponding calculated total sums are −60.20, −78.49, −96.46, and −138.10 eV, omitting the σ(C–F) orbital and using an empirical value of −16.05 eV for the nonbonding F orbital which is deduced from the first IE of HF[17] by use of Koopmans' theorem. Thus agreement between the experimental and calculated sums is surprisingly good except for CF_4, where a discrepancy of about 10 eV cannot easily be explained.

Although no unambiguous assignment can be concluded, the sum rule should be very helpful for spectral assignments, especially for analyzing an overlapping band.

16) We used the following values taken from the data of Potts *et al.* (see Ref. 2). CH_3F: 13.04(e), 17.06(e); CH_2F_2: 13.29, 15.25, 15.40, 15.58, 18.97; CHF_3: 14.80, 15.50, 16.16(e), 17.25(e); CF_4: 16.23(t), 17.47(t), 18.50(e).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1346—1353 (1973)

Chemical Approach to the Radiolysis of Polyphosphate Glass. I. Effects of Sb(III, V), Mo(V, VI) and U(IV, VI) Ions

Yoshimitsu KOBAYASHI and Niro MATSUURA

Department of Pure and Applied Sciences, College of General Education, University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received September 16, 1972)

The yields of radiation-induced electrons and holes trapped in the glass matrix are easily determined by introducing metal ions, such as Sb, Mo, and U ions, into water-soluble $NaPO_3$ polymer glass. Doping 1 mol % of these ions of a lower oxidation state wholly prevents the trapping of holes and results in oxidation to their higher oxidation states. A reaction in the reverse direction also occurs for the same ions of a higher oxidation state, which are converted into a lower one by reduction. This radiation-induced redox reaction has a minimum yield at a dopant composition corresponding to Sb_2O_4 for Sb(III)–Sb(V), Mo_6O_{17} for Mo(V)–Mo(VI), and U_3O_8 for U(IV)–U(VI) redox couples. The largest effective volume among these ions for capturing the holes is for Sb(III). In a high-dose region (10^{20} to 10^{21} eV/g), the yields of the redox products of these ions increase logarithmically with the γ-dose absorbed. This makes it difficult to determine the G-value of the redox products precisely. The approximate values are in an order of magnitude of 0.1 atom per 100 eV absorbed.

The radiation-induced rupture of a chemical bond in a solid polyphosphate glass causes paramagnetic or color centers. The results of a number of authors[1–8] are in agreement with a model which assigns the radia-

tion-induced visible colors to holes (electron-deficient centers), each trapped in a network forming a P–O tetrahedron with one or more non-bridging oxygen atoms present in a polyphosphate chain.[2] It is interesting to study from the chemical point of view the nature of these color centers by means of additives introduced into the glass as scavengers of the reactive species produced by radiation.[3–6] A systematic survey was undertaken to find the most adequate additive for estimating the quantitative yields of primary species, holes and electrons. Sodium polyphosphate is a water-soluble glass which is suitable for chemical treatment after exposure to γ-rays.

The change in the optical absorption in irradiated glass was compared with the products in aqueous solution of irradiated glass. Among the dozen additives so far investigated, this paper will treat the redox couples, Mo(V)–Mo(VI), Sb(III)–Sb(V), and U(IV)–U(VI), preferably employed as additives because their visible absorption spectra are separated from the optical absorptions due to holes.

Experimental

Preparation of the Glass. The base glass was prepared by the dehydration of $NaH_2PO_4 \cdot 2H_2O$ to which appropriate amounts of metal oxide, less than 1 mol %, had been admixed. The fusion was carried out in a platinum crucible, principally at 800 °C for 3 hr in air, in order to prepare the Sb(III), Mo(VI), and U(VI) doped glasses. For preparing the U(VI) doped glass, $UO_2(CH_3CO_2)_2 \cdot 2H_2O$ was employed in place of its oxide.[9] The U(IV) and Mo(V) enriched glasses should be melted in the presence of reducing agents under a reducing atmosphere or under vacuum of 10^{-6} Torr. The reducing atmosphere is effected by the use of a graphite crucible surrounded with a pile of graphite rods in an electric furnace or a quartz vessel placed in a vacuum line for vacuum melting.

Optical Measurements. The molten glass was poured into a brass mold with a rectangular form 8.3 mm thick, or it was chilled between two brass plates 2 mm apart. In order to eliminate the difference in the sample thickness and the scattering condition of the sample surface, a small correction was made by the normalization of background absorptions at about 700 nm. The spectra were taken and registered for optical absorption with an EPS-2 Model Hitachi Spectrophotometer, and for ESR spectra, with Japan Electron Optics Lab's JES-2BX model at a microwave frequency of 9400 Mc/s operating with 100 Kc/s field modulation. The molar extinction coefficient was determined by chemical analysis for Mo(V) as $\varepsilon = 17\ M^{-1}\ cm^{-1}$ and for U(IV) as $\varepsilon = 32.1\ M^{-1}\ cm^{-1}$.

Irradiation. The sample was irradiated with a Co^{60} γ-ray source of 3.8×10^{18} eV/g·hr 10 cm from the center in the Institute for Solid State Physics, the University of Tokyo. For the highdose irradiation a Co^{60} source of 1.8×10^{19} eV/g·hr was occasionally used. The irradiations and measurements were performed at room temperature, and the γ-dose calibration was carried out with a Fricke dosimeter, assuming that $G(Fe^{3+}) = 15.5$[10] and that the electron density per unit mass was identical between the glass and Fricke's solution.

Chemical Analysis. The chemical analysis of antimony was made by colorimetry with Folin's reagent for Sb(III) and with Rhodamine B as the reagent for Sb(V).[11] Antimony-doped samples were dissolved in dilute hydrochloric acid (2:1) to prevent the hydrolysis of $HSbCl_6$ to an irreversiblly-aquated form of $HSb(OH)_nCl_{6-n}$.[12,13] Reproducible resulsts were obtained when the dissolution of irradiated samples in hydrochloric acid was effected under the same conditions for a series of runs. The potentiometric titration of Mo(V) with 0.05N $K_2Cr_2O_7$[14] was made after dissolving the irradiated glass in 2N HCl over a water bath for 0.5 hr in order to ensure the decomposition of the polymer phosphate into the monomer. For U(IV), irradiated samples were dissolved in a 5% sulfuric acid solution by bubbling nitrogen gas through the solution to prevent the oxidation of U(IV) to U(VI) due to air oxygen[15] and by keeping the sample solution at about 80 °C during the dissolution in order to effect the complete hydrolysis of polyphosphate. The titration was effected by the addition of excess amounts of a $FeCl_3$ solution by the use of diphenylamine as an indicator. For the titration of the total uranium content, a 5% sulfuric acid solution of the sample glass was passed through a Jone's reductor, after which the resultant U(IV) solution was titrated in the same way.[16]

Results and Discussion

Sb Doped Glass, Effect of Antimony Ions. Upon the γ-irradiation of the polyphosphate glass, an optical absorption due to trapped holes appears with a maxi-

mum peak at 510 nm. Figure 1A shows that the increase in absorbance is proportional to the γ-dose absorbed. The glasses with a mean chain length of phosphate smaller than that of Graham salt have smaller absorptions, and the polyphosphate glass of a chain less than 10 is no more transparent.[17] For Graham salt, with an average chain length of 50 to 100, the optical absorption induced by irradiation is approximately the same, irrespective of the condition used in preparing the sample glass. When the exposure is prolonged beyond a certain limit, 10^{19} eV/g, the change in absorption is no longer linear with the dose, but increases much more slowly.

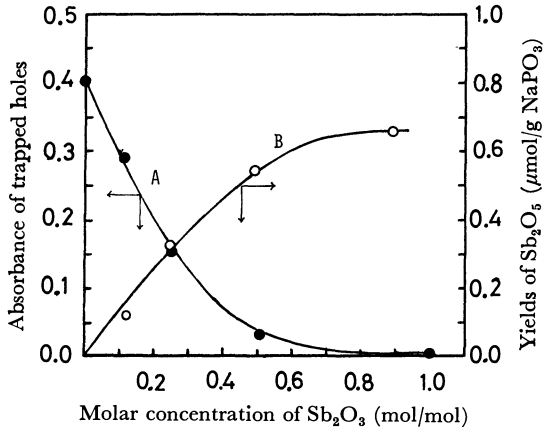

Fig. 2. A: Optical absorbancy at 510 nm due to trapped holes in $NaPO_3$ glass as function of doped Sb_2O_3 molar concentration (Sb_2O_3 mol/$NaPO_3$ mol)
B: Yields of Sb_2O_5 in μmol/g $NaPO_3$ from Sb_2O_3 doped in $NaPO_3$ glass after γ-irradiation of 3×10^{19} eV/g with variation of doped Sb_2O_3 concentration (Sb_2O_3 mol/$NaPO_3$ mol)

Antimony oxide, if one mole % is doped as Sb_2O_3 into polyphosphate glass, entirely suppresses the appearance of the red color due to holes. Pentavalent antimony oxide, Sb_2O_5, is ineffective unless a greater part of the antimony(V) is converted into antimony-(III) by thermal decomposition during the melting of a glass at a temperature higher than 650 °C. The optical absorption at 510 nm decreases exponentially with respect to the concentration of Sb(III). The exponential curve shown in Fig. 2 makes it possible to calculate the effective capture volume of Sb(III) as a hole-formation inhibitor using Stroud's Eq. (1).[5]

$$D_{h^+} = D^{\circ}_{h^+} \cdot \exp(-v \cdot C) \qquad (1)$$

In Eq. (1), D_{h^+} and $D^{\circ}_{h^+}$ are the optical absorbances of the hole in the presence and in the absence of the Sb(III) inhibitor, C, the concentration of Sb(III), and v, the effective volume of the inhibitor against hole formation by radiation. The concentration of Sb_2O_3, C for $D_{h^+}/D^{\circ}_{h^+}=1/e$, is found from Fig. 2 to be 0.125 mol % per one formula weight of $NaPO_3$. The effective capture volume, v, is calculated as 3.8×10^5 Å^3, which is a hundred times as large as the volume occupied by the Sb_2O_3 molecule in the form of Valentinite.[18]

Redox Yields of Sb in Glass. The initial G-values determined for 3×10^{18} eV/g or less are surprisingly large both with respect to the oxidation of Sb(III) to Sb(V) for Sb_2O_3 doped glass and with respect to the reduction of Sb(V) to Sb(III) for Sb_2O_5 doped glass. The curves represented in Figs. 1B and 2B demonstrate an extraordinary high yield of Sb(V), which attains, in the G-value, some ten molecules of Sb_2O_5 per 100 eV of γ-energy absorption. Such a G-value can not be expected from the mechanism of a radiation-induced redox reaction in a solid currently accepted in radiation chemistry.[19] However, in a higher dose region the G-values of Sb(V) formation in Sb(III) doped glass are greatly reduced to an ordinary value of around 0.1. The yields of Sb(III) from Sb(V) in irradiated glass are much more pronounced, attaining a G-value of several hundred in the low-dose region. The Sb(V) content of 1 mol% Sb_2O_5 doped glass prepared at 650 °C for 3 hr showed 90 μmol of Sb_2O_5 per gram of $NaPO_3$ glass before irradiation. This was decreased to 70 μmol/g after irradiation at a dose of 3×10^{18} eV/g. The data obtained are very few and not reliable enough for us to predict the mechanism of the radiation-induced reduction of Sb(V) to Sb(III), because the background content of Sb(III), increased upon thermal treatment before irradiation, surpasses the amount produced by radiation.

Since several oxides, such as Sb_6O_{13} and Sb_2O_4, are known[20] as stable phases in a pure antimony oxide system at a temperature between 650 and 900 °C, these species must be considered in addition to Sb(III) and Sb(V) oxides as major components in a molten glass. Accordingly, the chemical analysis of Sb(III) and Sb(V) was undertaken to see if there was a difference in the average oxidation state of antimony between pure oxide and the same oxide in glass. Figure 3 compares the Sb(III) content in Sb_2O_5 oxide with the same oxide doped into glass be thermal treatment at a temperature from 650 to 800 °C. About a half of the antimony is converted from Sb(V) to Sb(III) for pure oxide in this range of temperature, while the

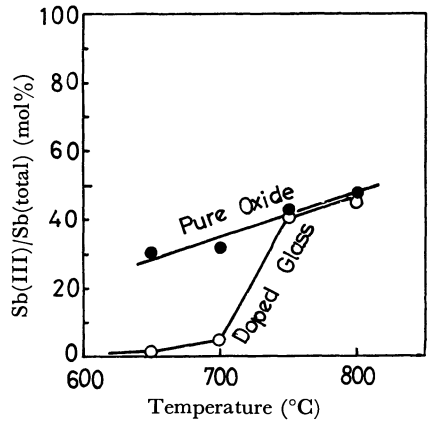

Fig. 3. Variation of Sb(III) content by thermal decomposition in the Sb_2O_5 as pure oxide and the Sb_2O_5 doped in $NaPO_3$ glass in a temperature range 650 to 800 °C.

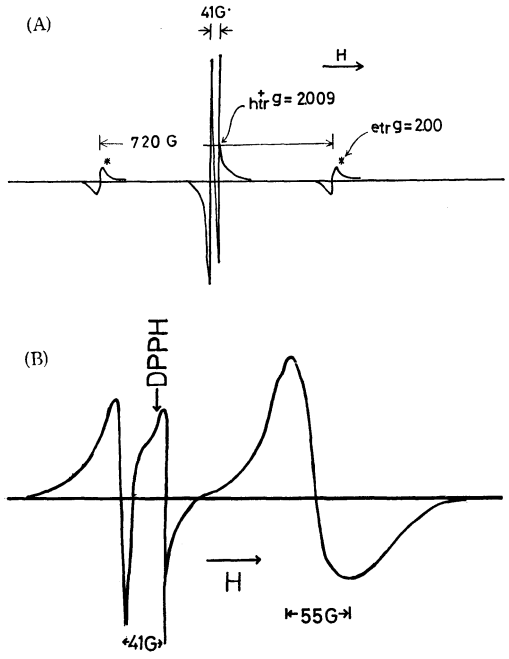

Fig. 6. ESR spectra of γ-irradiated polyphosphate glass. (A) non-doped glass with holes h_{tr} and electrons e^-_{tr}* (identified as PO_3^{2-})[7] (B) Mo(VI)O_3 doped glass with holes h^+_{tr} (right hand doublet) and Mo(V) signal (g=1.917)

the molecular extinction coefficient was determined, by using a sample 8 mm thick between two opposed flat surfaces, to be $\varepsilon=17\ M^{-1}\ cm^{-1}$. The latter spectrum is illustrated in Fig. 5. Figure 6 shows the ESR spectrum of the Mo(V)-containing glass; there is a broad singlet of g=1.917, with 55 Gauss peak-to-peak width which is attributable to the Mo(V) in the glass.[23-25]

Under γ-irradiation, the Mo(VI)-rich glass is red in color and the optical absorption at 510 nm increases with an increase in the absorbed γ-doses. On the contrary, Mo(V)-rich glass, colored bluish-green before irradiation, loses its original color by absorbing radiation energy, but shows no intensity change in the optical absorption at 510 nm due to trapped holes. In Mo(VI)-rich glass, ESR signals of the hole doublet and the Mo(V) singlet appear after irradiation, as is shown in Fig. 6; these two signal intensities grow as the absorbed radiation dose increases. The singlet due to Mo(V) continues to increase after the hole doublet attains saturation. In Mo(V)-enriched glass, no hole signal could be detected up to a sufficiently large γ-dose of 1.5×10^{22} eV/g. Accordingly, dopant molybdenum in the polyphosphate glass is effective for trapping both holes and electrons produced by γ-radiations through Processes (2) and (3):

$$\text{Mo(V)} + h_m = \text{Mo(VI)} \quad (2)$$

$$\text{Mo(VI)} + e_m = \text{Mo(V)} \quad (3)$$

In Eqs. (2) and (3), h_m and e_m are the mobile holes and electrons. Besides the processes postulated by (2) and (3), there must be several other reactions, involving trapping by the glass matrix and the recombination of holes and electrons through a certain recombination center. However, there is no means of detecting the recombination yields or of distinguishing the trapped holes and electrons in the glass matrix from those obtained in the presence of molybdenum.

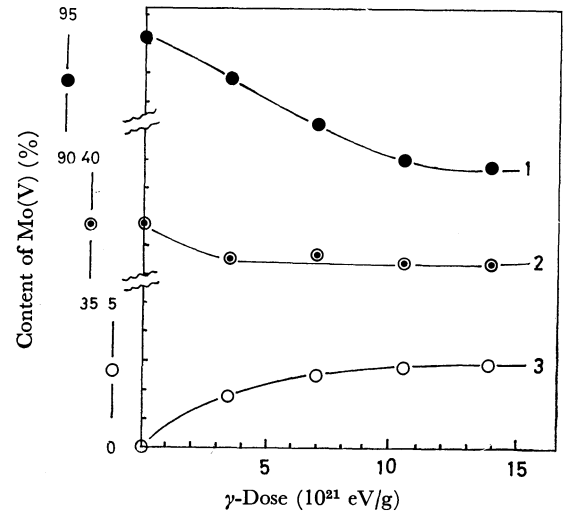

Fig. 7. Variation of Mo(V) content by radiation-effect in polyphosphate glass with total Mo 1 atom % per phosphorus. ●: Mo(V) rich glass (94% Mo^v), ⊙: glass with medium content of Mo(V) (37% Mo^v), ○: Mo(VI) rich glass (Mo^v trace)

Quantitative Estimation of the Dose Effect. The Mo(V) formation through Reaction (3) and the loss of Mo(V) through (2) in the irradiated glass were determined by studying the intensity changes in the optical absorption; the results are shown in Fig. 7. Curve 1 is for Mo(V)-rich glass; its optical density decreases in proportion to the absorbed γ-doses up to the dose of about 1.0×10^{22} eV/g. Beyond this limit, no further decrease of Mo(V) was observed. At the maximum dose of 1.5×10^{22} eV/g, four percent of doped Mo(V) was converted into Mo(VI); the G value calculated from the linear part of the curve is 0.11. Curve 3 is Mo(VI)-rich glass containing no detectable Mo(V), but exhibiting the green color of Mo(V) after irradiation. The radiation-induced formation of Mo-(V) from Mo(VI) is less than 0.03 mol% even at 1.5×10^{22} eV/g. Curve 2 is the intermediate case for the irradiated glass which contains comparative amounts of Mo(V) and Mo(VI). The curve shows little optical absorption change except for that in the very small dose region. Consequently, there must be a stationary condition of redox reaction between Mo(V) and Mo-(VI) at a Mo(V)/Mo(VI) ratio in the proximity of 1 to 2, if one mol % of Mo is present in the glass.

The trapping of holes and the conversion of Mo(VI) to Mo(V) through Reaction (3) are parallel reactions; the rates of the two processes can be followed by measuring the relative intensities of ESR signals for the hole doublet and the Mo(V) singlet. Figure 6B shows the use of these two ESR signals for estimating the relative concentration of trapped holes and Mo(V) in γ-irradiated glass. The observed ratio of trapped

Table 1. Trapped holes to Mo(V) concentration ratio, $[h_t^+]/[Mo(V)]$, measured by ESR absorption intensities in γ-irradiated Mo (1 atom %) doped glass

Mo(V) concentration [Mo(V)]/[Mo(total)] %	γ-Dose (10 eV/g) 3.6	7.2	10.8	14.5
Mo(V) enriched (94%)	0	0	0	0
Medium Mo(V) (35—40%)	0.64	1.27	1.11	1.45
Mo(V) poor (Mo(V) absent)	19.3	19.1	19.2	19.3

holes to produced Mo(V), $[h^+]/[Mo(V)]$, is represented in Table 1. For Mo(VI)-rich glass, this ratio is 19.3, independent of the absorbed dose, while the glass containing comparative amounts of Mo(V) and Mo-(VI), but slightly higher in Mo(VI), shows a $[h^+]/[Mo(V)]$ ratio 30 times lower. There is no trapped hole formation in Mo-doped glass if most of the Mo is present in the Mo(V) state. On the basis of these observations it is clear that the trapping of either holes or electrons, and also the transmutation of states from Mo(VI) to Mo(V) and in the reverse direction through Paths (3) and (2) respectively, depend on the Mo(VI)/Mo(V) ratio and on the total content of Mo in the irradiated glass.

Thermal Annealing. By the application of the usual temperature-elevating device of ESR attachment, an attempt was made to study the stability of holes and Mo(V) radicals.[26] There are two ESR signals attributable to the trapped holes and the Mo(V). Upon heating at 200 °C for 15 min the doublet signal due to holes disappears at once. By this thermal treatment the radiation-induced red color of the glass is lost, leaving a faint yellow color behind. Isothermal annealing were made at two fixed temperatures, 110 and 147 °C, by recording the changes in the peak height of the ESR signals every minute. As these isothermal curves are exponential, logarithmic plots of the signal intensity are illustrated in Fig. 8; these plots demonstrate the rapid decay of hole signals along with the invariant intensities of the Mo(V) singlet. Annealing at two temperatures allows us to estimate roughly the activation energy of hole decay. If thermal annealing can be explained only in terms of a recombination of holes with electrons, the decay of trapped holes obeys a bimolecular mechanism, but there is no experimental evidence to prove emission due to recombination during thermal treatment. By means of unimolecular mechanism the activation energy which reflects the average energy required for the escaping of trapped holes from a certain trap depth present in the irradiated polyphophate matrix can be estimated. From the curves in Fig. 8, the value is found to be 0.37 eV. As for the high stability of the Mo(V) produced by irradiation, it can be understood by taking account of the special stability of molybdenum blue oxide, Mo_nO_{3n-1}, as a polymer form which might be present in polyphosphate glass.

U-Doped Glass, Effect of Uranium. The absorption spectrum of U_3O_8-doped glass before γ-irradiation is shown in Fig. 9. By the chemical analysis of this glass, containing 1.0 atom percent of uranium per phosphorus, the content of U(IV) was found to be 32.4% of the total uranium, while the rest of uranium was U(VI). The UO_3-doped glass prepared by dehydrating a mixture of NaH_2PO_4 and $UO_2(CH_3CO_2)_2$ and by subsequent melting in open air is yellow in color and has no detectable U(IV). The broken curve in Fig. 9 shows a visible absorption due to U(VI) alone observed in the UO_3-doped glass, with a maximum located at 423 nm. By heating uranylacetate in a vacuum at from 800 to 900 °C for a hundred hours, a grey-black oxide was obtained; its U(IV) content was as large as 59% and it had the approximate composition of $UO_{2.4}$. The glass doped with 1 mol% of this oxide is green and has several visible absorption peaks, at 1120, 662, 545, 483, and 423 nm. The last one, 423 nm, may be ascribed to U(VI) and remains little affected by the variation in the U(IV) content in the glass. Table 2 compares the optical absorption at these peaks and the contents of U(IV) measured by chemical analysis[16] in three types of glass samples, with UO_3, U_3O_8, and UO_{2+x} as dopants. The molecular extinction was 32.1 M^{-1} cm^{-1} for U(IV), as determined by the maximum peak at 1120 nm.

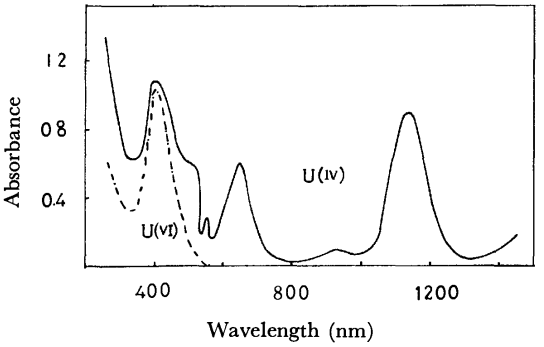

Fig. 9. Optical absorption spectra of U(IV) (full line) and U(VI) (broken line) in polyphosphate glass.

TABLE 2. OPTICAL ABSORPTION AT MAXIMUM PEAKS FOR URANIUM DOPED GLASSES (TOTAL URANIUM CONTENT 1 ATOM % TO P in $NaPO_3$ GLASS)

a) The values in parenthese show the optical densities calculated from U(VI) based on the value of 0.26

The Effect of γ-Radiation on Uranium. Exposure of U_3O_8-doped glass to γ-radiation produced a ESR singlet, with $g=2.6$ and a peak-to-peak width of 762 G, which was bleached by natural aging for one week. This type of ESR signal is shown in Fig. 10, along with the signals due to the holes and electrons trapped as usual found in the glass matrix. A similar type of ESR spectrum reported by Selbin[27] *et al.*, in thorium oxide and other halide compounds closely resembles ours in line shape and peak-to-peak width, but is very different in g-value ($g=1.52$). In $UO_{2.4}$-doped glass as well as in UO_3-doped polyphosphate glass, there were no other signals than holes and electrons trapped in the galss matrix when the glass was irradiated with γ-rays. Although no direct support of the formation of U(V) in the irradiated glass is available as a result of chemical analysis or optical-absorption measurements,[28] this center might be intimately related to the [U(IV)+h_m^+] center. Consequently, a metastable oxidation state of U(V) exists at room temperature only as a transient state from U(IV) to U(VI).

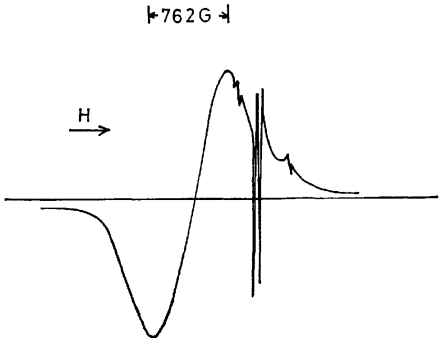

Fig. 10. ESR spectrum of γ-irradiated polyphosphate glass containing uranium(IV) ions, broad line at left with $g=2.6$ assigned to U(V).

Radiation-induced Redox Yields. Conversion between U(IV) and U(VI) and a reaction in the reverse direction in glass under the effect of γ-radiation are shown in Fig. 11. The optical absorption changed at 1120 nm, and the chemical analysis of U(IV)[16,28] was followed by irradiation as a function of the γ-dose. Curve a is

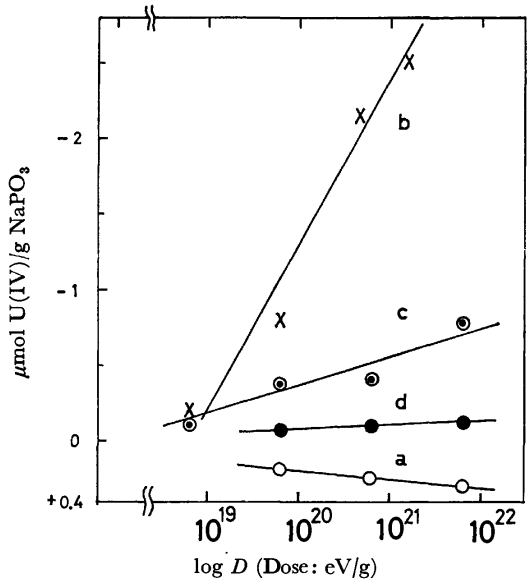

Fig. 11. Variation of U(IV) content as function of absorbed γ-energy in polyphosphate glass a: glass containing U^{VI} 1.00%, b: glass with U^{IV} 0.093%, c: glass with U^{IV} 0.32% 0.32% and U^{VI} 0.201%, and d: glass with U^{IV} 0.32% and U^{VI} 0.64%.

for 1 mol% UO_3 doped glass; it shows that the increase of U(IV) produced by irradiation is so slight as to be measured only by a logarithmic increase in the γ-dose. Curve d is for U_3O_8-doped glass with 0.32 atom % of U(IV) and 0.64 atom % of U(VI); it shows a continuous decrease in U(IV) with an increase in the γ-dose, but at a slower rate than in the case of curve C. At small doses, trapped holes are hard to detect by optical absorption, while ESR doublet signals due to holes begin to appear at a dose of 6×10^{18} eV/g. Curve c is for a glass sample containing 0.60 atom % of U(IV) and 0.20 atom % of U(VI), with an approximate dopant composition of $UO_{2.25}$. This sample glass shows an appreciable decrease in U(IV) content when it is exposed up to 6.4×10^{21} eV/g. These results Curves a, d and c, demonstrate that the exposure of uranium doped glass to γ-radiation causes the conversion of U(IV) to U(VI) or a reverse process, depending on the U(IV)/{U(IV)+U(VI)} ratio in the glass before irradiation. The yields of the converstion in the oxidation state of uranium have a minimum in the glass

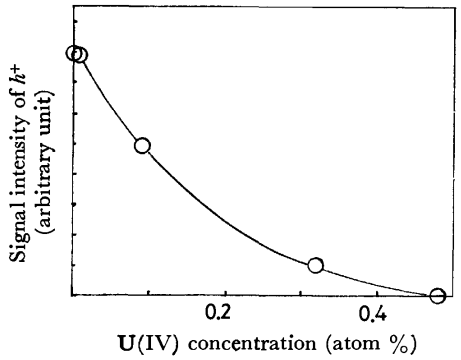

Fig. 12. ESR signal intensity of U(V) produced by γ-irradiation as metastable (U(IV)+h^+_{tr}) center as function of U(IV) concentration in polyphosphate.

27) J. Selbin and J. D. Ortego, *Chem. Rev.*, **69**, 6570m (1969).
28) D. A. Wenz, M. D. Adams, and R. K. Steuhenberg, *Inorg. Chem.*, **3**, 989 (1964).

with a U(IV)/{U(IV)+U(VI)} ratio at approximately 1:2, corresponding to the U_3O_8 composition.

As for the trapped holes thus produced, the intensities of the ESR doublet signals are greatly reduced by an increase in the doped U(IV) content, according to the exponential law shown in Fig. 12. Stroud's equation (1) provides an effective capture volume of U(IV) ions for dry or mobile holes that can be estimated to be 2.58×10^4 Å^3 from the curve in Fig. 12; this indicates a much smaller value than 3.8×10^5 Å^3 in the case of Sb_2O_3 as the dopant. The results in Fig. 12 also demonstrate that 40% of the dopant uranium must be present in the +4 oxidation state for the complete suppression of the trapped holes when 1.0 atom % uranium-doped glass is exposed to γ-radiation with a dose of 6×10^{19} eV/g. The maximum G values for the oxidation of U(IV) to U(VI) were obtained by doping 0.1 atom % of UO_2 oxide in a vacuum; they showed that 93% of uranium present in the +4 oxidation state. They are calculated to be 1.3 at 6×10^{19} eV/g and 0.833 at 6×10^{20} eV/g from the data shown by Curve b in Fig. 11.

Conclusion

For the three systems of redox couples that we have investigated, each has a minimum yields of radiation-induced redox at the concentration corresponding to these compositions; Sb_2O_4 for the Sb(III)–Sb(V) system, Mo_6O_{17} {Mo(V): Mo(VI)=1:2} for the Mo(V)–Mo(VI) system, and U_3O_8 for the U(IV) and U(VI) system, in polyphosphate galss.

The effective capture volumes are 3.8×10^5 Å^3 for U(IV) ions, with respect to the trapping holes. Mo(V) ions take an intermediate value between Sb(III) and U(IV) ions.

Abnormally high radiation yields are observed when antimony oxide is used as the dopant; this is, probably, a particular case of an antimony oxide system whose gas-cleaning action has been used in the glass industry, because of its high oxygen pressure of thermal decomposition.

The approximate G values are 0.9 for 0.57 mol% of Sb_2O_3 and 0.43 mol% of Sb_2O_5, 0.7 for 0.31 mol% of Sb_2O_3 and 0.69 mol% of Sb_2O_5, with respect to the formation of Sb_2O_3 at 1×10^{21} eV/g. The G values of the formation of Mo(V) from Mo(VI) are 0.54 for 0.5 atom % of Mo(VI)-doped glass and 0.18 for 1.0 atom % of U(IV) and a trace of U(VI). They are 1.3 at 6×10^{19} eV/g and 0.833 at 6×10^{20} eV/g. A more sensitive method of analysis of the product is required for a further discussion in detail of the G values, particularly of the initial G values, which are computed in a very-small-dose region.

A kinetic study of the rate of annealing indicates an unimolecular mechanism, providing an activation energy of 0.37 eV for bleaching trapped holes. In the case of Mo, the redox processes between the two oxidation states involve only one electron. In the cases of Sb and U, the difference in oxidation number is two. In these two cases, no conclusive identification of Sb(IV) and U(V) was obtained. However, strong evidence for the formation of an intermediate oxidation state has been presented, and it can be assumed that the redox reactions involved proceed through an one-electron step.

The authors wish to express their thanks to Dr. A. Barkatt, the University of Israel, for his valuable advice.

Dielectric Studies on Isobutyl Halides in the Liquid State

Arati DAS, Alpana GHATAK, and Abul HASAN
Optics Department, Indian Association for the Cultivation of Science, Calcutta-32, India
(Received July 25, 1972)

The activation energies of dielectric relaxation ΔH_τ in three isobutyl halides in the liquid state are found to be almost equal to the mean value of the electrostatic self energies of the *trans* and *gauche* isomers in the corresponding compounds. The energy difference between the two isomers in the liquid state obtained from the dipole moment measurements agree well with those obtained by the spectroscopic method.

From studies of dielectric relaxation of 1,2-dihaloethanes,[1] 1-chloro-2-bromoethane,[2] 1,2-ethane- and 1,2-propane dithiols and 1,2-dichloropropane,[3] it was observed that the activation energy of dielectric relaxation ΔH_τ was almost equal to the electrostatic self energies of polar *gauche* molecules in the liquid state. The electrostatic stabilization energy in all the above liquids was approximately equal to the amount of lowering of the energy difference between the *trans* and *gauche* isomers from the gaseous to the liquid state as pointed out by Wada.[4] These facts indicate that the activation energy ΔH_τ due to intermolecular interactions in these liquids is mainly electrostatic in nature. In order to examine this viewpoint further, the dielectric studies have been extended to the case of three isobutyl halides where the conformers have moderate dipole moments unlike the case of the molecules mentioned above. The results of these investigations are discussed in this paper.

Experimental

Pure samples of 1-chloro-2-methylpropane, 1-bromo-2-methylpropane and 1-iodo-2-methylpropane (Schuchardt, Germany) were distilled under reduced pressure before use. The dielectric permittivities ε' and dielectric losses ε'' of the liquids at different temperatures were measured by Surber's method at 1.62, 3.17 and 3.49 cm microwave regions. The static dielectric constant ε_0 was measured at 1 MHz and the refractive index n was obtained with an Abbe refractometer. The density d was measured with a picnometer and the viscosities η were determined with an Ostwald viscometer. The temperatures in all the experiments were controlled within ± 1°C by a thermostat.

Results

The values of ε_0, ε', ε'', and n^2 at different temperatures for all the liquids are given in Table 1. These data were fitted in Cole-Cole arc plots, some of which

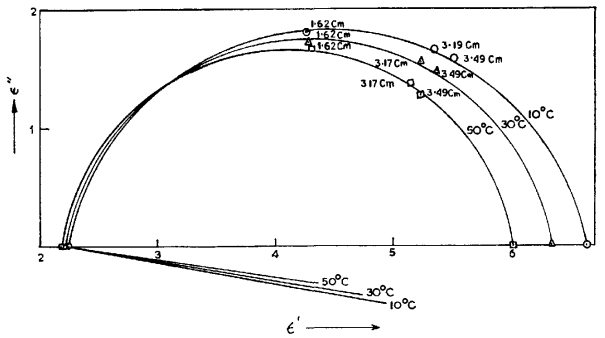

Fig. 1(c). Cole-Cole arc plots of isobutyl iodide at different temperature.

are shown in figures 1 (a, b, c). The most probable relaxation time τ and the distribution parameter α determined from the arc plots are given in Table 2. The activation energies for dielectric relaxation ΔH_τ and for viscous flow ΔH_η were obtained respectively from the straight line plots of log $T\tau$ *vs.* $1/T$ and log η *vs.* $1/T$ (Fig. 2). The values of ΔH_τ and ΔH_η are given in Table 2. The accuracies in the measurements of ε' and ε'' are 2 and 4% respectively.

Discussion

It can be seen from Table 2 that the most probable relaxation time τ of 6.55 psec at 10°C in isobutyl bromide is larger than 4.55 psec in isobutyl chloride but smaller than 9.37 psec in isobutyl iodide at the same temperature. This is consistent with the sizes of the molecules. The relaxation time τ and the distribution parameter α in all the liquids are seen

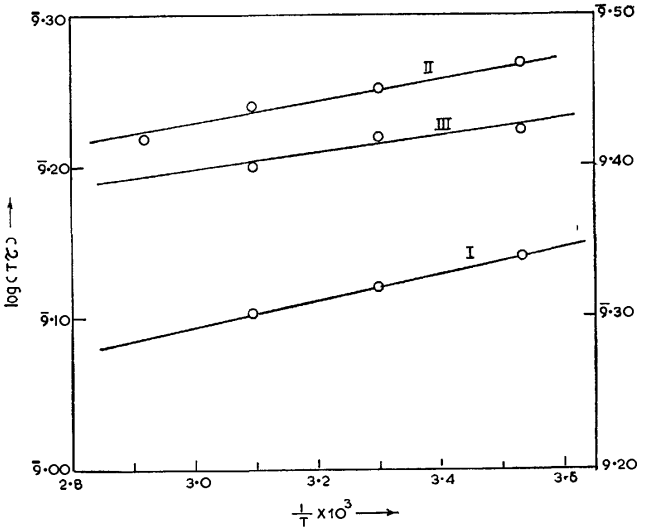

Fig. 2. Plots of log $T\tau$ *vs.* $1/T$.
Curve I: Isobutyl chloride (ordinate left),
Curve II: Isobutyl bromide (ordinate left),
Curve III: Isobutyl iodide (ordinate right).

to decrease with increase of temperature as is generally observed in polar liquids.

The activation energy of dielectric relaxation ΔH_τ is as usual less than the corresponding value for viscous flow ΔH_η in all the liquids. However, while the ΔH_τ-values decrease with increase in size of the molecules, the ΔH_η-values increase in the same order.

Activation Energy and Electrostatic Energy. In the case of some 1,2-disubstituted ethanes[1-3] the dipole activation energy was almost equal to the respective values of electrostatic energy of the polar *gauche* molecules in the liquid state. This is because in all these molecules the dipole moment of *trans* isomer is negligible compared to that of the *gauche* isomer. In the present case, however, in all the isobutyl halides both *trans* and *gauche* isomers have moderately large dipole moments, both contributing to the relaxation process, but as they are almost similar in size the τ-values would be almost the same. Thus it was not possible to analyse the dielectric data in terms of two relaxation processes one due to each, and the activation energy ΔH_τ for the isomers could not be obtained separately. The activation energy obtained experimentally has been taken as the average ΔH_τ of the *trans* and *gauche* isomers.

To correlate the average activation energy with the corresponding values of the electrostatic energy of the two isomers, the dipole moments of the *trans* and *gauche* forms for all the molecules were calculated from their geometrical structures using known bond moments and bond angle values: $\mu_{C-Cl} \approx 1.85$ D,[5] $\mu_{C-Br} \approx 1.7$ D,[5] $\mu_{CH_3} \approx 0.4$ D[6] the carbon valence angle $\approx 110°$ and the azimuthal angle of rotation $\approx 60°$. The value of μ_{C-I} was assumed to be ≈ 1.6 D, a little smaller than that of μ_{C-Br}. The calculated values of μ_g and μ_t are given in Table 3. The values of a^3 (≈ 40 Å^3—

Table 3. Values of d, m, μ_t, μ_g, and electrostatic energy E_g and E_t in kcal/mol

Temp °C	Density d	Mean moment (m) in D	Dipole moment		Electrostatic energy	
			trans μ_t	*gauche* μ_g	E_{trans}	E_{gauche}
	Isobutyl chloride					
10	0.881	1.92				
30	0.360	1.93	1.60	2.19	0.68	0.36
50	0.316	1.94				
	Isobutyl bromide					
10	1.296	1.91				
30	1.259	1.93				
50	1.230	1.94	1.50	2.01	0.51	0.28
70	1.210	1.95				
	Isobutyl iodide					
10	1.609	1.75				
30	1.580	1.78	1.38	1.90	0.40	0.20
50	1.546	1.81				

50 Å^3) were estimated from a comparison with the molecules of 1,2-dihaloethanes.[7] The electrostatic energies of the *trans* and *gauche* isomers of all the compounds calculated from the relation[7] $E=(\varepsilon-1)/(2\varepsilon+1)\cdot\mu^2/a^3$ are given in Table 3 and their mean values in Table 2. We see that the activation energy in each case is almost equal to the mean value of the electrostatic energies of the *gauche* and *trans* isomers of the respective compounds. This supports the conclusion drawn earlier.[1-3]

Energy Difference between the Isomers in the Liquid State. The energy difference between the isomers in all the liquids were obtained by the method given by Mizushima[7] with the values of the mean moments m of the molecules in the liquid state at different temperatures and the values of μ_g and μ_t calculated as above. The mean moments were calculated by using Onsager's equation[5] from the values of ε_0, d, and n. The energy differences between the two isomers in all the liquids thus obtained are found to agree fairly well with those obtained by spectroscopic studies[8] (Table 4).

Table 4. Energy difference ΔE in kcal/mol

Compound	Liquid (Present work)	Spectroscopic method[8]	
		Liquid	Vapour
Isobutyl chloride	0.39	0.37±0.15	0.23±0.09
Isobutyl bromide	0.20	0.26±0.12	0.3 ±0.03
Isobutyl iodide	0.24	—	—

It may be noted from Table 3 that the electrostatic energies of the *trans* isomer in all the molecules are larger than that of the *gauche* isomer. In the gaseous state also the *trans* isomer is of lower energy in all the compounds. Hence if the electrostatic energy in the liquids was mainly responsible for the intermolecular potential energy, the energy difference between the two isomers in the liquid state would be greater than that of the gaseous state. This is found to be true in the case of isobutyl chloride (Table 4).

On the MO Perturbation Theory of Molecular Rearrangements

Hiroshi FUJIMOTO, Morio MIYAGI, Shinichi YAMABE, and Kenichi FUKUI
Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto
(Received September 7, 1972)

The relationship between two simple Hückel MO perturbation treatments of electrocyclic reactions formerly proposed has been examined. The reason why the two different approaches give the same prediction with regard to the favorable paths of the reactions has been established numerically. A calculation of the thermal ring-closing of butadiene has been carried out, including both sigma and pi electrons.

In 1965, Woodward and Hoffmann suggested a selection rule for electrocyclic reaction of conjugated molecules.[1] Various intramolecular reactions as well as intermolecular reactions between two systems have been discussed on the basis of the symmetry properties of the molecular orbitals (MO) of the reactants and the product.[2-18] Since then, several theories for unimolecular reactions have been proposed.[19-24] Some MO and valence-bond (VB) calculations of the favorable course of electrocyclic reactions have also been carried out.[25-29] Among the theoretical approaches to the electrocyclic rearrangements of open conjugated chains, we can find two types of MO perturbation treatments on the level of the simple Hückel approximation.[5] One is to discuss the path of molecular rearrangements by examining the energy change caused by the introduction of a resonance integral between the two termini of a chain, representing the starting of ring-closing by the overlapping of the two terminal atomic orbitals (AO).[5a,b] The other is to apply a partitioning technique to the reaction; thereby, the ring-closing of a conjugated chain can be regarded as if it were an intersystem four-center interaction between the two fragments of a molecule.[5d] The basic idea of the partitioning technique originated from the perturbation theory for the intermolecular interaction of two independent systems has been developed successfully in numerous unimolecular reactions.[5d,f,30] In this paper, we intend first to examine the relationship between these perturbation approaches to molecular rearrangements and then to present some numerical results on the electrocyclic rearrangement of butadiene calculated by use of the extended Hückel MO wave function, in order to observe the behavior of sigma and pi electrons in the reaction.

Simple Hückel MO Perturbation Theory for Unimolecular Rearrangements

Let us first discuss the perturbation theory of the simple Hückel MO method.[31] When the resonance integral between the AO's r and s, represented by β_{rs}, varies by a small amount, $\Delta\beta_{rs}$, that between the

AO's t and u by an amount of $\Delta\beta_{tu}$, and so on, the change in the electronic energy is given by:

$$\Delta E \cong 4\sum_{i}^{\text{occ}}\sum_{(r,s)} c_r^{(i)}c_s^{(i)}\Delta\beta_{rs} + 2\sum_{i}^{\text{occ}}\sum_{j}^{\text{uno}} \frac{\{\sum_{(r,s)}(c_r^{(i)}c_s^{(j)}+c_r^{(j)}c_s^{(i)})\Delta\beta_{rs}\}^2}{\varepsilon_i-\varepsilon_j} \quad (1)$$

where c_r^i is the coefficient of the AO r in the MO i, where ε_i is its energy, and where $\sum^{\text{occ}}$ and $\sum^{\text{uno}}$ imply the summation over all the occupied and over all the unoccupied MO's respectively. Therefore, in the case of the ring-closing between the two termini r and s of a polyene, the energy change associated with this process is given approximately by:

$$\Delta E \cong 2P_{rs}\gamma\beta_{rs} \quad (2)$$

where P_{rs} is the mobile bond-order between the π AO's at the termini and where $\gamma\beta_{rs}$ is the resonance integral standing for the interaction. Since $\gamma\beta_{rs}$ and the overlap integral, s_{rs}, are opposite in sign, the positive $\gamma\beta_{rs}$ corresponds to the conrotatory, and the negative $\gamma\beta_{rs}$, to the disrotatory, ring-closing (Fig.1).

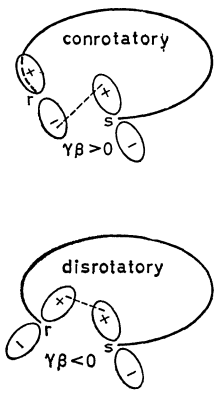

Fig. 1. A schematic representation of conrotatory and disrotatory ring-closing of a polyene.

In the ground-state of butadiene, P_{14} is negative, so the reaction should take place preferentially in such a way as to make $\gamma\beta_{14}$ positive. On the contrary, P_{14} is positive in the first excited-state in favor of the disrotatory ring-closing. The thermal and photochemical ring-closing of hexatriene should take place dominantly in a fashion opposite to that in the case of butadiene, because P_{16} is positive in the ground-state and negative in the first excited-state. In general, P_{rs} is negative in the ground-state and positive in the first excited-state for polyenes with $4n$-electrons, while it is positive in the ground-state and negative in the excited-state for polyenes with $4n+2$ electrons.[5a] The conclusion thus derived from the intramolecular first-order perturbation energy was found to be in excellent agreement with the experimental results and with the results of other theoretical approaches.

When we employ the partitioning technique, we can regard a ring-closing of a conjugated chain as a cyclic interaction between two fragments of a molecule (Fig. 2). The interaction energy between them can be given by (in the ground-state):

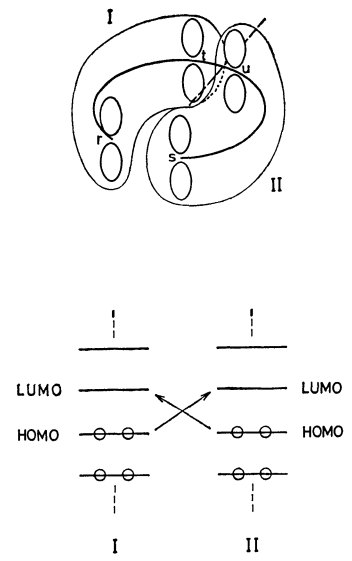

Fig. 2. A schematic representation of partitioning of a polyene into two fragments and the mode of orbital overlap interaction.

$$\Delta E' \cong 2\left(\sum_{i}^{\text{occ}}\sum_{j}^{\text{uno}} - \sum_{i}^{\text{uno}}\sum_{j}^{\text{occ}}\right)\frac{(c_r^{(i)}c_s^{(j)}\gamma\beta + c_t^{(i)}c_u^{(j)}\beta)^2}{\varepsilon_i-\varepsilon_j} \quad (3)$$

if we can assume that the interaction is sufficiently weak as to be called a "perturbation." Equation (3) tells us that the most favorable mode of interaction is determined by the orbital overlap interaction of the occupied MO's of one fragment and the unoccupied MO's of the other fragment. When the highest occupied (HO) MO of one part happens to be degenerate with the lowest unoccupied (LU) MO of the other, the interaction energy can be approximated by:

$$\Delta E' \cong -2|c_r^{(\text{HO})}c_s^{(\text{LU})}\gamma\beta + c_t^{(\text{HO})}c_u^{(\text{LU})}\beta| \quad (4)$$

Even not in such a condition, the interaction between the HOMO of one part and the LUMO of the other part, and the converse, play dominant roles in determining the favorable mode of interaction, in general, because the denominators of these terms in Eq. (3) are obviously smaller than those of the other terms.

When a polyene is partitioned into two odd electron fragments, the interaction energy is given by;

$$\Delta E' \cong -|c_r^{(\text{SO})}c_s^{(\text{SO}')}\gamma\beta + c_t^{(\text{SO})}c_u^{(\text{SO}')}\beta| \quad (5)$$

where SO and SO′ mean the singly-occupied nonbonding MO's of the two fragments.

Let us now consider the thermal ring-closing of butadiene (Fig. 3). When we divide butadiene into two ethylenic parts, the HOMO (S)–LUMO (A) interaction favors the *anti*-mode interaction. Here, S denotes the symmetric MO's with $c_r^{(i)}c_t^{(i)}>0$ and A indicates the antisymmetric MO's with $c_r^{(i)}c_t^{(i)}<0$; we may call the mode of interaction in which β and $\gamma\beta$ possess the same sign "*syn*-interaction," and that in which β and $\gamma\beta$ have different signs, "*anti*-interaction."[5c] The case of division into an allylic part and a single p AO also shows that the interaction should take place preferentially in the *anti*-mode. Accordingly, thermal ring-closing takes place dominantly in a conrotatory fashion.

The interaction between an ethylenic part and a

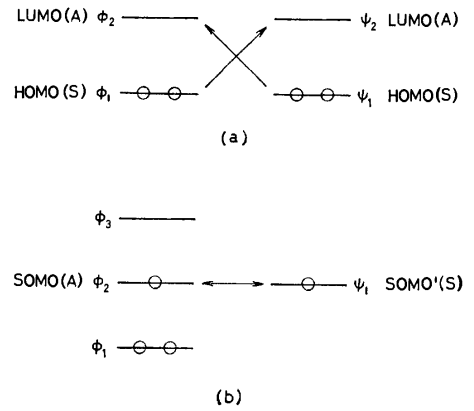

Fig. 3. Orbital overlap interaction in thermal ring-closing of butadiene.
(a) Division into two ethylenic parts
(b) Division into an allylic part and a single p AO

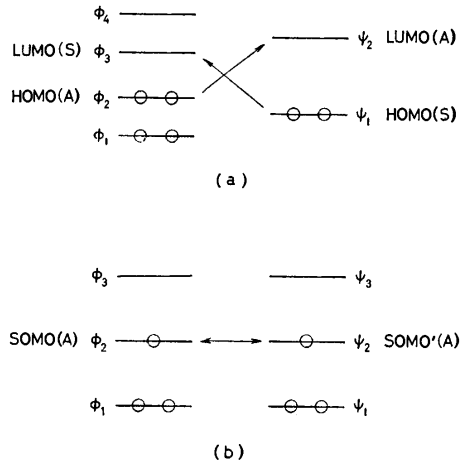

Fig. 4. Orbital overlap interaction in thermal ring-closing of hexatriene.
(a) Division into ethylenic and butadienic part
(b) Division into two allylic parts

butadienic part, and the interaction between two allylic parts, both prefer *syn*-interaction in the ground-state (Fig. 4). Therefore, the ring-closing of hexatriene is liable to occur in a disrotatory manner.

In order to discuss the favorable mode of photochemical reactions, we divide a conjugated chain into two parts, in which one has an excited-electron configuration. In this case, the interaction between SOMO and HOMO and the interaction between SOMO' and LUMO are predominant (Fig. 5).

$$\Delta E' \cong -|(c_r^{(SO)}c_s^{(HO)}\gamma\beta + c_t^{(SO)}c_u^{(HO)}\beta)^2 + (c_r^{(SO')}c_s^{(LU)}\gamma\beta + c_t^{(SO')}c_u^{(LU)}\beta)^2|^{1/2} \quad (6)$$

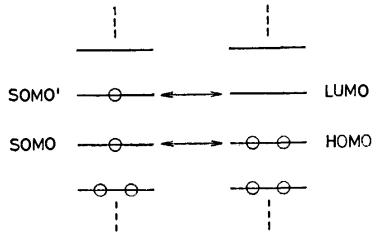

Fig. 5. Mode of orbital overlap interaction in photochemical ring-closing.

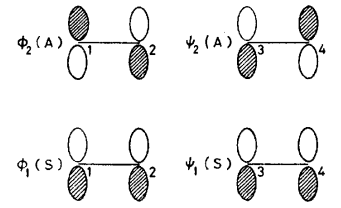
Equation (6) corresponds to the case in which SOMO degenerates with HOMO, and SOMO', with LUMO.[5b,32] In some cases, one of the two interaction terms is more important than the other. Consequently, the photochemical ring-closing of butadiene prefers the *syn*-interaction, and that of hexatriene, the *anti*-interaction. In general, the cyclic interaction between two fragments of a polyene with $4n$ electrons takes place preferentially in the *anti*-mode in the ground-state and in the *syn*-mode in the excited-state, while the interaction between two fragments of a polyene possessing $4n+2$ electrons favors the *syn*-mode in the ground-state and the *anti*-mode in the excited-state.[5d]

The Relation between Two Perturbation Approaches

As has been mentioned above, the rule derived from the partitioning analysis of orbital interactions in the thermal and photochemical ring-closing of conjugated chains can give the same prediction as the rule deduced from the intramolecular first-order perturbation. Now, let us discuss the relation between these two approaches to molecular rearrangements by means of some numerical calculations.

Table 1. Division of butadiene MO's into ethylene MO's

	MO's of butadiene[a]			
	φ_1	φ_2	φ_3	φ_4
ϕ_1	0.688	0.688	0.163	−0.163
ϕ_2	0.163	−0.163	−0.688	−0.688
ψ_1	0.688	−0.688	0.163	0.163
ψ_2	0.163	0.163	−0.688	0.688



$\phi_t = c_1^{(t)}\chi_1 + c_2^{(t)}\chi_2$ $\quad$ $\psi_j = c_3^{(j)}\chi_3 + c_4^{(j)}\chi_4$

a) MO's of butadiene are numbered in the order of increasing energy.

The four π MO's of butadiene can be expressed by linear combinations of the bonding and antibonding π MO's of two ethylenic fragments (Table 1). It should be noted that the signs of the coefficients depend on how the arbitrary factor, ± 1 is assigned the real MO's of two ethylenic parts. Here and in what follows, we always choose the signs of the MO's so as to make $c_t^{(i)}c_u^{(j)} > 0$, where t and u are the AO's between which the partition of a chain is made, and where i and j denote the MO's of the two fragments. By the use of the coefficients listed in Table 1, the first-order perturbation energy given by Eq. (2) for

32) C. Nagata, A. Imamura, Y. Tagashira, M. Kodama, and N. Fukuda, *J. Theor. Biol.*, **9**, 357 (1965).

the thermal ring-closing of butadiene can be rewritten as:

$$\Delta E = 0.8944\{(c_1^{(1)}c_4^{(2)} + c_1^{(2)}c_4^{(1)})\gamma\beta + (c_2^{(1)}c_3^{(2)} + c_2^{(2)}c_3^{(1)})\beta\} - 0.8944\beta$$

where 0.8944β is the conjugation stabilization of the 2,3-π bond and is common to both the conrotatory and disrotatory processes. The bonding and *anti*-bonding interactions between ϕ_1 and ψ_1 compensate for each other in the simple Hückel MO approximation. Consequently, the energy change associated with the thermal ring-closing can be represented by the interaction of occupied and unoccupied MO pairs, $\phi_1-\psi_2$ and $\psi_1-\phi_2$. Since ϕ_1 and ψ_1 are S MO's and ϕ_2 and ψ_2 are A MO's, the interaction should take place in the *anti*-mode. In the photochemical reaction, the energy change is expressed as:

$$\Delta E = 1.0000\{(c_1^{(1)}c_4^{(1)} + c_1^{(2)}c_4^{(2)})\gamma\beta + (c_2^{(1)}c_3^{(1)} + c_2^{(2)}c_3^{(2)})\beta\} + 0.4472\{(c_1^{(1)}c_4^{(2)} + c_1^{(2)}c_4^{(1)})\gamma\beta + (c_2^{(1)}c_3^{(2)} + c_2^{(2)}c_3^{(1)})\beta\} - 1.4472\beta$$

where 1.4472β is the conjugation energy of the 2,3-π bond in the first excited-state. It can be seen that the interaction between ϕ_1 and ψ_1 and the interaction between ϕ_2 and ψ_2 play dominant roles.

When we divide butadiene into an allylic part and a single p AO, the energy change is given by:

$$\Delta E = 2(0.2236c_1^{(1)} + 0.9487c_1^{(2)} + 0.2236c_1^{(3)})\gamma\beta + 2(0.2236c_3^{(1)} + 0.9487c_3^{(2)} + 0.2236c_3^{(3)})\beta - 1.7888\beta$$

where 1.7888β is the conjugation energy of the 3,4-π bond in the ground-state. We can see that the favorable mode of interaction is governed by the two SOMO's.

Next, let us consider the ring-closing of hexatriene. In case of the division of hexatriene into a butadienic part (ϕ_1, ϕ_2, ϕ_3, ϕ_4) and an ethylenic part (ψ_1, ψ_2), the interaction between ϕ_2 and ψ_2 and the interaction between ϕ_3 and ψ_1 predominate in the thermal ring-closing in favor of the *syn*-interaction, whereas the interaction between ϕ_2 and ψ_1 and the interaction between ϕ_3 and ψ_2 make major contributions to the energy change in the excited-state in favor of the *anti*-interaction (Table 2). The division of hexatriene into two allylic fragments shows the importance of the interaction between two SOMO's in the thermal ring-closing:

Table 2. Contributions of orbital interactions to the energy change in the ring-closing of hexatriene

	Thermal		Photochemical	
	ψ_1(S)	ψ_2(A)	ψ_1(S)	ψ_2(A)
ϕ_1 (S)	0.009	0.352	0.105	0.278
ϕ_2 (A)	−0.004	0.917	0.909	0.447
ϕ_3 (S)	0.917	−0.004	0.447	0.909

$$\Delta E = 0.0692\{(c_1^{(1)}c_6^{(1)} + c_1^{(3)}c_6^{(3)})\gamma\beta + (c_3^{(1)}c_4^{(1)} + c_3^{(3)}c_4^{(3)})\beta\} + 0.3418\{(c_1^{(1)}c_6^{(2)} + c_1^{(3)}c_6^{(2)} + c_1^{(2)}c_6^{(1)} + c_1^{(2)}c_6^{(3)})\gamma\beta + (c_3^{(1)}c_4^{(2)} + c_3^{(3)}c_4^{(2)} + c_3^{(2)}c_4^{(1)} + c_3^{(2)}c_4^{(3)})\beta\} + 0.2418\{(c_1^{(1)}c_6^{(3)} + c_1^{(3)}c_6^{(1)})\gamma\beta + (c_3^{(1)}c_4^{(3)} + c_3^{(3)}c_4^{(1)})\beta\} + 1.8616(c_1^{(2)}c_6^{(2)}\gamma\beta + c_3^{(2)}c_4^{(2)}\beta) - 1.5697\beta$$

The numerical results given above with respect to the thermal and photochemical ring-closing of butadiene and hexatriene have shown that the orbital overlap interaction between HOMO and LUMO (in the case of the partitioning of a polyene into two even electron systems) or between SOMO and SOMO′ (in the case of the partitioning of a polyene into two odd electron systems) plays a dominant role in controlling the stereochemical course of the thermal reaction, while the orbital overlap interaction between HOMO and SOMO and that between LUMO and SOMO′ are important in the photochemical ring-closing. This may be the reason why the partitioning analysis can give the same prediction as that of the first-order perturbation approach; at the same time it suggests that the two approaches to the molecular rearrangements can be equivalent in an approximate sense. The partitioning technique supplies us with the simplest way of discussing the molecular rearrangements in MO terms, regardless of whether any symmetry is retained throughout the reactions or not.

Inclusion of Sigma Electrons

Parr and his collaborators introduced the integral Hellmann-Feynman theorem to calculate the rotation barrier of ethane, obtaining a value of 2.4 kcal/mol; this is in good agreement with the experimental value of 2.9 kcal/mol.[33] Here we will present the results of calculation derived from the application of the theorem, though in a very approximate sense, to the ring-closing of butadiene. Let us consider a state, p, corresponding to a point on the reaction coordinate in the neighborhood of the initial state, i. Then, the energy change by going from i to p is given by;

$$\Delta E = E_p - E_i = \frac{\langle \Psi_i | \Delta H | \Psi_p \rangle}{\langle \Psi_i | \Psi_p \rangle} \qquad (7)$$

$$\Delta H = H_p - H_i$$

where H is the Hamiltonian operator of the system. If we can assume here that the wave function, Ψ_p, is expanded by the wave functions of the state, i:

$$\Psi_p = \Psi_i + \lambda\Psi_i^{(1)} + \lambda^2\Psi_i^{(2)} + \cdots \qquad (8)$$

the energy change can be represented by:

$$\Delta E = \langle \Psi_i | \Delta H | \Psi_i \rangle + \lambda\{\langle \Psi_i | \Delta H | \Psi_i^{(1)} \rangle - \langle \Psi_i | \Delta H | \Psi_i \rangle \langle \Psi_i | \Psi_i^{(1)} \rangle\} + \lambda^2\{\langle \Psi_i | \Delta H | \Psi_i^{(2)} \rangle + \cdots\} + \cdots \qquad (9)$$

The use of the matrix sum rule leads us to the same result as that obtained by Salem.[20] It should be noted that Eq. (7) holds only for the exact wave func-

33) a) H. J. Kim and R. G. Parr, *J. Chem. Phys.*, **41**, 2892 (1964). b) R. W. Wyatt and R. G. Parr, *ibid.*, **43**, s217 (1965).

tion. The concrete forms of $\Psi_i^{(1)}$, $\Psi_i^{(2)}$, $\cdots$, are not necessarily easily obtainable, in general. However, as long as we are concerned with the beginning stage of the reaction, λ is small and the energy change can be measured by taking only the first term, to the roughest approximation:

$$\langle\Psi_i|\Delta H|\Psi_i\rangle = \int\rho_{ii}(1)H'(1)d\tau_1 + \Delta V_{nn} \quad (10)$$

$$\rho_{ii}(1) = N\int\Psi_i^*(1, 2, \cdots, N)\Psi_i(1, 2, \cdots, N)d\tau_2\cdots d\tau_N$$

where ΔV_{nn} is the change in the nuclear repulsion energy and where N is the number of electrons in the system. The change in the Hamiltonian operator due to the change in the relative positions of the nuclei associated with ring-closing is given by:

$$H' = \sum_\mu\sum_k\left(\frac{1}{r_{\mu k}^p} - \frac{1}{r_{\mu k}^i}\right) \quad (11)$$

where μ and k denote the nucleus and the electron respectively, and where

$$r_{\mu k}^i = |\boldsymbol{r}_k - \boldsymbol{r}_\mu|$$
$$r_{\mu k}^p = |\boldsymbol{r}_k - \boldsymbol{r}_\mu'| = |\boldsymbol{r}_k - (\boldsymbol{r}_\mu + \Delta\boldsymbol{R})| = |r_{\mu k}^i - \Delta\boldsymbol{R}| \quad (12)$$

The deformation, $\Delta\boldsymbol{R}$, is given by:

$$\Delta\boldsymbol{R} = \Delta x\cdot\boldsymbol{i} + \Delta y\cdot\boldsymbol{j} + \Delta z\cdot\boldsymbol{k}$$

where $\boldsymbol{i}$, $\boldsymbol{j}$, and $\boldsymbol{k}$ are unit vectors in a three-dimensional space. Thus, we have;

$$\frac{1}{r_{\mu k}^p} - \frac{1}{r_{\mu k}^i} \cong \frac{x-A_x}{(r_{\mu k}^i)^3}\Delta x + \frac{y-A_y}{(r_{\mu k}^i)^3}\Delta y + \frac{z-A_z}{(r_{\mu k}^i)^3}\Delta z \quad (13)$$

where (A_x, A_y, A_z) is the Cartesian coordinate of the nucleus, μ. Consider the rotation of the methylene group about the carbon-carbon axis by an angle of ω (Fig. 6). By this rotation, hydrogen changes its position

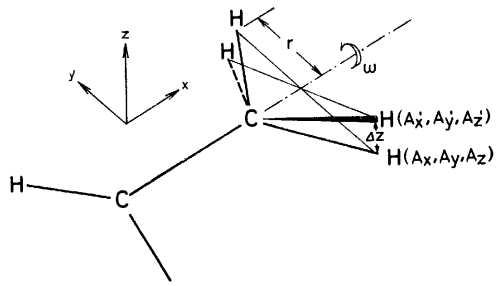

Fig. 6. A schematic representation of the rotation of methylene about carbon-carbon bond axis.

from (A_x, A_y, A_z) to (A_x', A_y', A_z'). Here, we have:

$$A_x' = A_x$$
$$A_y' = A_y + r(1-\cos\omega) \cong A_y + \frac{1}{2}r\omega^2 \quad (13)$$
$$A_z' = A_z + r\sin\omega \cong A_z + r\omega - \frac{1}{6}r\omega^3$$

Since we are concerned with the beginning stage of the reaction, we may disregard the second- and third-order terms with respect to ω. Therefore, we obtain:

$$\Delta x = \Delta y = 0,\ \Delta z = r\omega \quad (15)$$

By the use of the MO wave function for the ground-state, the diagonal element of the first-order density matrix is given by:

$$\rho_{ii}(1) = 2\sum_i^{occ}\phi_i(1)^2 \quad (16)$$

When the MO's ϕ_i are given, as usual, by the linear combinations of AO's, we obtain:

$$\Delta E \cong 2\sum_i^{occ}\sum_\mu\sum_r\sum_s c_r^{(i)}c_s^{(i)}\int\chi_r\frac{z-A_z}{r_{\mu k}^3}\chi_s d\tau\cdot\Delta z + \Delta V_{nn} \quad (17)$$

where χ_r and χ_s are the AO's. It can be seen that Eq. (17) has much the same form as Eq. (2), derived from the simple Hückel MO perturbation. A calculation was made with respect to the thermal ring-closing of butadiene by use of the extended Hückel MO's

Table 3. Energy gradient in the thermal ring-closing of butadiene at $|\omega| = 5°$

	Conrotatory	Disrotatory
ΔE_σ [a]	−4.036	−4.236
ΔE_π [a]	−1.265	−0.772

a) In eV/Bohr-radius unit.

(Table 3).[34] The integrals necessary for the calculation of the energy change were computed by the formula derived by Matsuoka, expanding the Slater AO's into the Gaussian basis set.[35] In the extended Hückel MO approximation, the sum of the energies of doubly-occupied MO's can be a measure of the total energy of the system in the ground-state.[36] Table 3 shows that π electrons favor a conrotatory ring-closing, while σ electrons prefer a disrotatory ring-closing. Furthermore, it is demonstrated that π electrons play a major role in determining the stereochemical course of the electrocyclic rearrangement of butadiene. The results given here are very approximate and can never be a quantitative measure for distinguishing the favorable reaction path. However, this calculation provides us with some information of the energetic aspects of two possible modes of the ring-closing of butadiene, including both the σ and π electrons.

In this paper, we have limited ourselves to the electrocyclic reaction of butadiene and hexatriene in order to accentuate the relation between different perturbation approaches. The methods presented here can be applied, in principle, to any kind of molecular rearrangement.

We are grateful to the Data Processing Center, Kyoto University, for its generous permission to use its FACOM 230-60 computer.

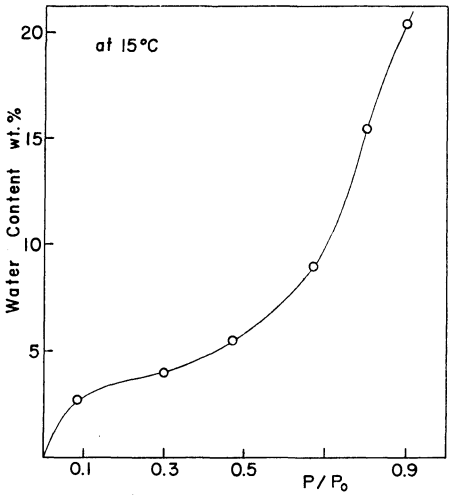

Fig. 2. The water adsorption isotherm of γ-alumina at 15 °C.

Dielectric Measurements. The complex dielectric constant and tan δ were measured using the transformer-bridge method, in the frequencies from 30 Hz to 3 MHz and using the transmission-line method, at 9.72 GHz. The design and the materials of the cell electrodes, the heating and cooling devices, and the measuring procedures employed in this experiment were the same as those in the previous papers.[10,11]

Results and Discussion

Three dielectric anomalies were found to exist in different frequency and temperature ranges on γ-alumina with and without adsorbed water; some of these results at 30 and 300 kHz are shown in Fig. 3. In the figure, three anomalies, I, II and III, are clearly seen at different temperatures. Anomaly II agrees approximately with that found by Ebert[2] and by Dransfeld.[4] These anomalies were dependent on the frequency, the temperature, and the water content.

Anomaly I. Figures 4 and 5 show the frequency effect of ε′ and tan δ at 55 °C, and the Cole-Cole arc

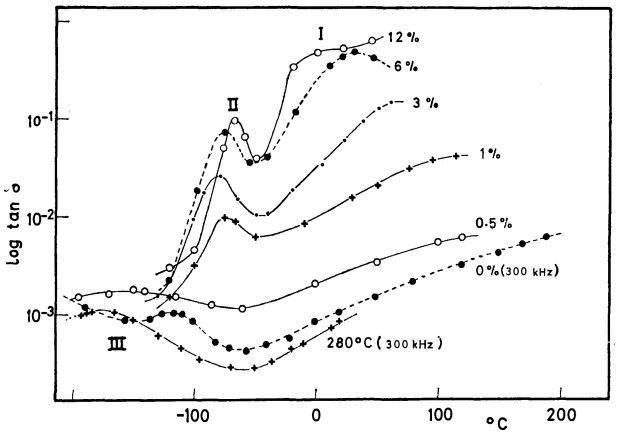

Fig. 3. The relations between temperature and tan δ at 30 kHz and 300 kHz of γ-alumina with various amount of adsorbed water and with heat-treatment, respectively.

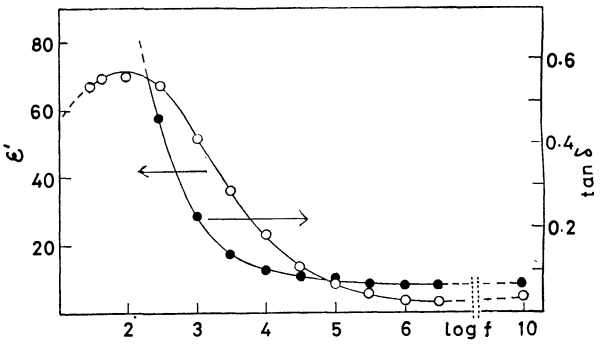

Fig. 4. The ε′ and tan δ *versus* frequency curves of γ-alumina in the range of the dielectric relaxation I containing 3% water at 55 °C.

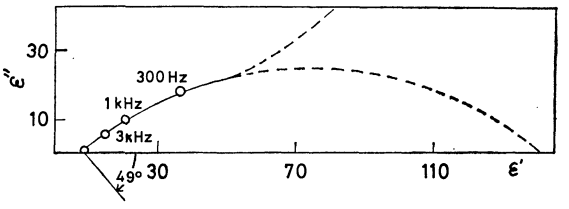

Fig. 5. The Cole-Cole arc of the Relaxation I of γ-alumina containing 3% water at 55 °C.

plot of Anomaly I at 3% water, respectively. These figures show that this anomaly is a dielectric relaxation (Relaxation I), although it seems difficult to tell whether Relaxation I is of the Debye-type or the Wagner-type. It seems clear that Relaxation I has some relation wit the proton in such forms as the ion, the hydroxyl group on the surface, and the adsorbed water, since the relaxation times shift markedly upon the deuterium exchange, as is shown in Fig. 6. The relation between

TABLE 1. THE ACTIVATION ENERGY, E, AND THE COEFFICIENT, τ_0, OF THE ARRHENIUS EQUATION OF THE RELAXATIONS I, II, AND III OF γ-alumina

Water content (%)	H_2O		D_2O	
	E (kcal/mol)	τ_0 (sec)	E (kcal/mol)	τ_0 (sec)
Relaxation I				
12	11.2±0.5	2×10^{-14}		
6	11.6±0.5	3×10^{-13}	12.2±0.5	1×10^{-14}
3	12.1±0.7	1×10^{-12}		
2	12.4±0.7	1×10^{-12}		
1	11.9±0.7	2×10^{-12}		
Relaxation II				
12	20.6±0.5	4×10^{-27}		
6	17.5±0.5	9×10^{-24}	18.8±0.5	2×10^{-26}
3	13.0±0.5	1×10^{-21}	14.4±0.5	2×10^{-21}
2	14.4±0.5	3×10^{-21}		
1	13.2±0.5	3×10^{-18}		
Relaxation III				
0.5	4.1±1.0	2×10^{-13}		
0.2	4.6±1.0	2×10^{-13}		
0	4.7±1.0	2×10^{-13}		

the relaxation times and the reciprocal temperatures, obtained from the Cole-Cole arc plot, is linear, as is shown in Fig. 6. The activation energy, E, and the coefficient, τ_0, in the Arrhenius expression are shown in Table 1. The values of E do not change with the water content, but those of τ_0 do change appreciably. The magnitude of Relaxation I ($\Delta \tan \delta_{max}$) was estimated from Fig. 7, by subtracting the value of the tan δ maximum from its base line; it is plotted against the water content in Fig. 8. The figure shows that Relaxation I disappears in the neighborhood of 0% water and increases proportionally to the water content up to about the second layer of the adsorbed water (about 6%).

Anomaly II. The relation between the complex dielectric constant and logarithm of frequency, and the Cole-Cole arc plot of Anomaly II at −79 °C, shown in Fig. 3, are given in Figs. 9 and 10 respectively. These curves suggest that this anomaly is a dielectric relaxation of the Maxwell-Wagner type (Relaxation II). The findings by Dransfeld[3] agree approximately

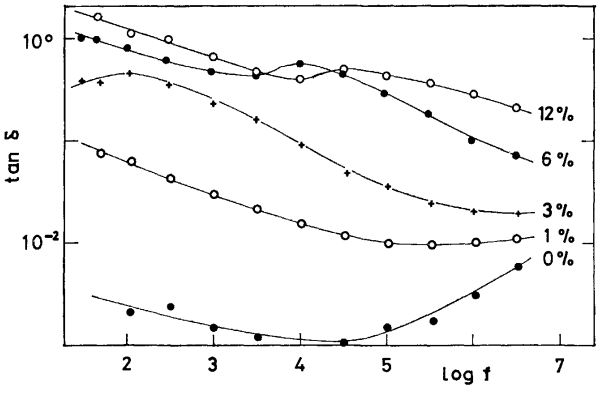

Fig. 7. The curves of frequency versus log tan δ of γ-alumina with various amount of water at 23 °C in the range of Relaxation I.

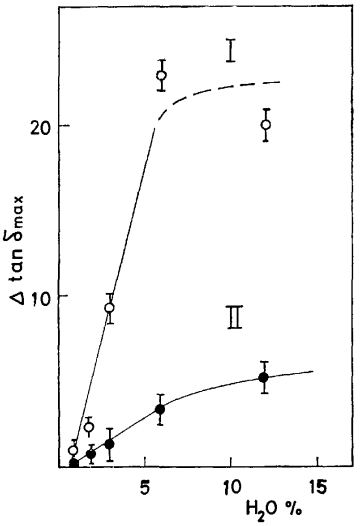

Fig. 8. The relations between the water content and Δ tan δ_{max} which was estimated as the difference of tan δ maxima of the Relaxations I (open circle) and II (full circle) and their baselines.

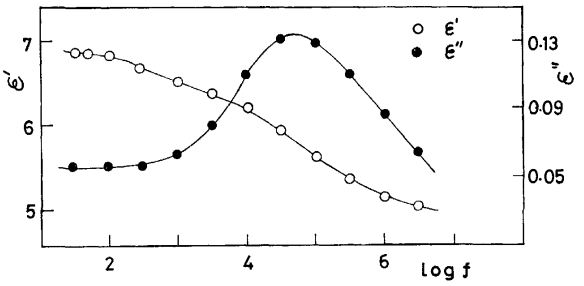

Fig. 9. The relations of ε' and ε'' to the frequency of the Relaxation II of γ-alumina having 3% adsorbed water at −79 °C.

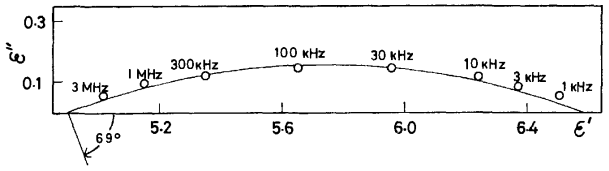

Fig. 10. The Cole-Cole arc of the Relaxation II of γ-alumina containing 3% adsorbed water at −79 °C.

with ours. Since Relaxation II showed a marked frequency shift upon the deuterium exchange, as is shown in Fig. 6, this relaxation seems to be related to either some form of adsorbed water or to some kind of hydroxyl group on the γ-alumina surface. The magnitude of Relaxation II ($\Delta \tan \delta_{max}$) is plotted in Fig. 8 with the same procedure as has been described in the case of Relaxation I. In this figure, Relaxation II behaves similarly to Relaxation I, and both of these relaxations disappear somewhere near 0% water. However, the point of disappearance is not yet known more exactly. The sample heat-treated in the range from 65 to 180 °C, after the saturation of the sample with water at room temperature, contains adsorbed water ranging from 2 to 0% respectively, when we take 180 °C as the desorption temperature. Therefore, it

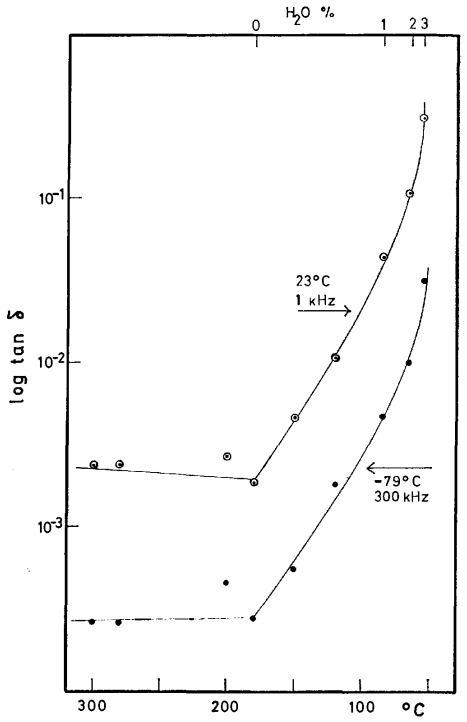

Fig. 11. The relations between tan δ and heat-treatment temperature of γ-alumina at 1 kHz and 300 kHz at 23 °C and −79 °C respectively.

might be possible to see the effect of water content on tan δ more clearly by replacing the horizontal and vertical coordinate axes of Fig. 8 with those of the heat-treatment temperature below and above 180 °C and of tan δ in the range of these dielectric relaxations respectively, as is seen in Fig. 11. The tan δ curves of 1 kHz at 23 °C and 300 kHz at −79 °C in this figure, being situated in the ranges of Relaxations I and II respectively, become constant above 180 °C. This suggests that Relaxations I and II both disappear at about 180 °C; the choice of this temperature as that of the desorption of adsorbed water, as has been mentioned in the previous section, therefore, seems reasonable. Ebert[2] and Dransfeld[3] vaguely attributed this relaxation to the dipole orientation and the proton migration of adsorbed water respectively. Although it may not be simply concluded that Relaxations I and II originate in the adsorbed water on the basis of the present result alone, it might be possible to draw inferences as follows: 1) The dielectric absorption intensity of Relaxation I is larger than that of Relaxation II; hence, Relaxation I might correspond to the larger weight-decrease, as is seen markedly below about 90 °C in Fig. 1. The effect of the adsorbed water for E and the τ_0 of Relaxation I is similar, to some extent, to that of the dielectric relaxation I of silica gel,[10] which was assigned to adsorbed water. Relaxation I might be related to the adsorbed water, being loosely bound to the surface. 2) Relaxation II is smaller than Relaxation I and might correspond to the smaller

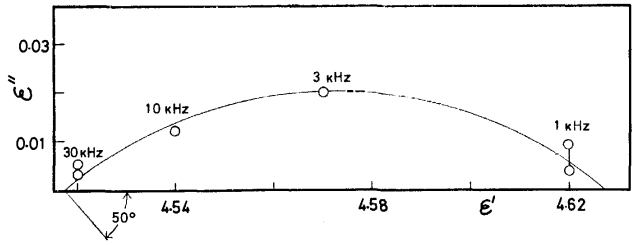

Fig. 12. The Cole-Cole arc of the Relaxation III of γ-alumina at −196 °C.

weight-decrease below about 190 °C in Fig. 1. The effect of adsorbed water for E and τ_0 of this relaxation is somewhat similar to the dielectric relaxation II of silica gel,[9] which was assigned to surface silanol. Relaxation II might thus be related to some kind of surface hydroxyl group which could be dehydrated very easily from the surface of γ-alumina.

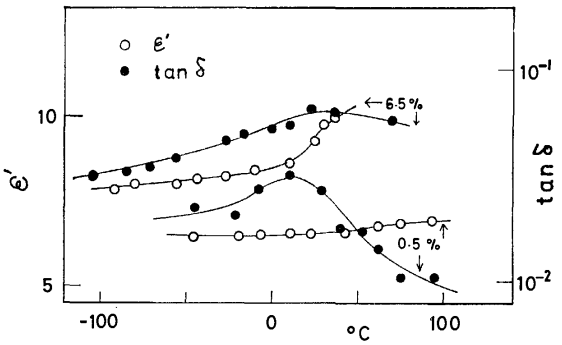

Fig. 13. The relations between tan δ and temperature of γ-alumina with 0.5 and 6.5% water at 9.72 GHz.

Anomaly III. The ε' and ε'' relations of Anomaly III, mentioned in Fig. 3, are plotted at −196 °C in Fig. 12. This relation constitutes the Cole-Cole arc and, therefore, means that Anomaly III is a dielectric relaxation (Relaxation III). The relation between the relaxation times of Relaxation III and the reciprocal temperature plotted in Fig. 6 is linear. Relaxation III becomes observable above the heat-treatment temperature of 120 °C or with a water content of less than 0.5% due to the decrease in the dielectric loss. Relaxation III might thus be related to some kind of hydroxyl group which has a weak interaction with the surroundings, considering the small value of E.

The Dielectric Anomaly at 9.72 GHz. A dielectric anomaly was observed at 9.72 GHz on γ-alumina with various amounts of adsorbed water, as is shown in Fig. 13. This anomaly seems to be a kind of dielectric relaxation according to the temperature effects of ε' and ε'', although the frequency effect could not be measured. We could not ascertain, from the Arrhenius plot in Fig. 6, whether this relaxation belongs to Relaxation II or to III. This relaxation seems, however, to belong to Relaxation II, in view of the similarity of the values of ε' and tan δ.

Ultraviolet Spectra of Hydrazide Solutions and Their Hydrolysis. I. Hydrolysis of Formhydrazide in Acid Solutions

Mitsuo MASHIMA and Fujiko IKEDA

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga

(Received August 19, 1972)

The protonation constant 1.99 of formhydrazide (pK_{BH^+}) has been obtained from measurements of its ultraviolet absorption in dilute sulfuric acid. From the absorption in concentrated sulphuric and perchloric acids, the apparent first-order rate constants of acid-catalyzed hydrolysis have been determined. The reaction mechanism of rate-determining steps has been proposed by means of the plots of Zucker-Hammett and Bunnett.

Ultraviolet absorption spectra and hydrolysis of amides have been of interest to a number of investigators. However, little is known about the ultraviolet spectra and hydrolysis of hydrazides. Edward, Hutchison and Meacock[1] determined the rate constants for the hydrolysis of acethydrazide in aqueous hydrochloric acid. They obtained the first-order rate constants which increase with the increase of acid concentration. For acethydrazide in 0.1N HCl, Lindegren and Niemann[2] determined the apparent ionization constant of $AcNHNH_3^+$ by potentiometric titration and obtained 3.24 for pK_{BH^+}. Recently, the present authors[3] have investigated ultraviolet spectra of some hydrazides in various solvents and have reported on the behavior of a band with maximum at about 190 mμ.

A series of works has been made for examining systematically the spectral change of hydrazides in aqueous solutions by adding electrolytes and non-electrolytes, and for determining the rate constant of the hydrolysis of hydrazides in acid- and alkali-media. The present communication deals with spectroscopical measurements of the protonation constant of formhydrazide and its rate constant of hydrolysis in sulphuric and perchloric acids.

Experimental

Materials and Apparatus. Formhydrazide was synthesized with methylformate and hydrazinehydrate and purified by recrystallization from ether–ethanol mixture: mp 54 °C. Formhydrazidehydrochloride was precipitated from a solution of formhydrazide dissolved in an aqueous hydrochloride by addition of ethanol and the precipitates were washed repeatedly with ethanol: mp 139 °C. Aqueous acid solutions were prepared by dilution of reagent-grade acids with water. They were standardized by titration with standard sodium hydroxide solution. Organic solvents, methanol and dioxane, were of spectrograde.

The ultraviolet solution spectra were measured with a Hitachi EPS-3T Recording Spectrophotometer equipped with a thermostated cell compartment. All the measurements were carried out at 25±0.01 °C.

Rate Measurements. Reactions were followed by recording the change in absorbance A with time. The apparent first-order rate constant k' was calculated graphically from plots of log $(A-A_\infty)$ *vs.* time (min) or by means of a computer program which gives, by adjustment of A_∞, the first-order rate constant which best fits the observed data. In view of the highly dilute reaction solutions, 10^{-3} M (mol/l), used for spectrophotometric examination, no attempt was made to isolate reaction products from the reaction solutions. It is expected that the products are formic acid and hydrazine (or hydrazinium ions). To check the A_∞, the absorption spectra of these materials dissolved in reaction media were examined and compared with those of reaction solutions.

Results and Discussion

Absorption Spectra. The ultraviolet solution spectra of formhydrazide and its hydrochloride are shown in Fig. 1. In water formhydrazide gives a broad absorption band asymmetrically broadened to the low energy side, having probably four component bands with maxima at about 188, 189, 192, and 193 mμ. Such an absorption is characteristic of the hydrazides in water.[3] For formhydrazide this band red-shifts to 203 mμ in methanol and to 212 mμ in dioxane (curves 2 and 3, Fig. 1). It has been tentatively assigned[3] to the $\pi\rightarrow\pi^*$ transition of the carbonyl π-electron system perturbed by the π-electron system of $NHNH_2$ group. If this is the case, the result is not in line with the view that the $\pi\rightarrow\pi^*$ transition band red-shifts by hydrogen bonding in hydroxylic solvents.[4]

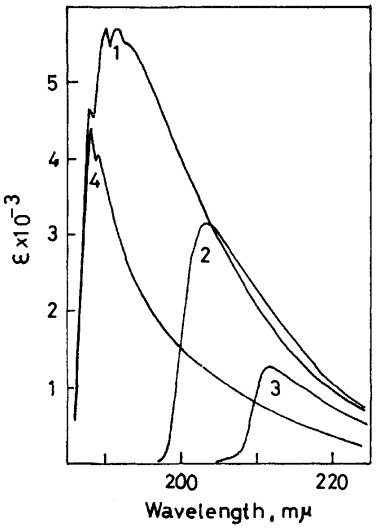

Fig. 1. Ultraviolet spectra of formhydrazide (1, in water; 2, in methanol; 3, in dioxane) and its hydrochloride (4, in water).

4) G. C. Pimental and A. L. McClellan, "The Hydrogen Bond," W. H. Freeman and Company, San Francisco (1960), Chap. 4.

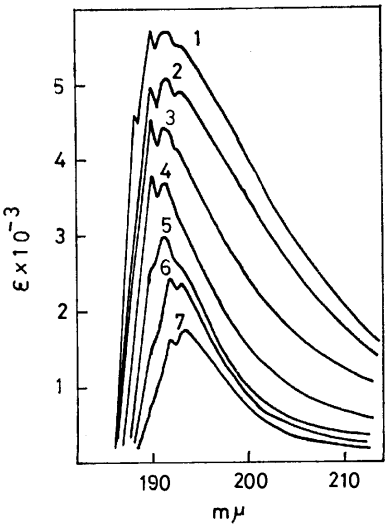

Fig. 2. Spectral changes of formhydrazide in dilute aqueous sulphuric acid.
The acid concentrations are (1) 0, (2) 0.5768×10^{-3}, (3) 0.2884×10^{-2}, (4) 0.1154×10^{-1}, (5) 0.5047×10^{-1}, (6) 0.5678×10^{-1}, (7) 0.1131N.

Formhydrazide hydrochloride in water shows two bands with maxima at 188 and 189 mμ. They are ascribable to electronic transition in formhydrazidinium ion, $HCONHNH_3^+$, which is expected to have two electronic transitions with nearly equal energies.

Spectral Changes in Highly Dilute Sulphuric Acid. Spectral changes in sulphuric acid more dilute than about 0.1N, are shown in Fig. 2. It is seen that the broad band absorbed by formhydrazide in water does not shift but the extinction coefficients are lowered successively with increasing acid concentrations. In such a dilute acid no change in absorbance was observed with time, but a delayed spectral change at about 0.1N (Fig. 3) and a marked change was observed at still higher concentration. The spectral changes with time indicate that the hydrolysis occurs in concentrated acid solutions.

The behavior of two bands absorbed by formhydrazide hydrochloride dissolved in sulphuric acid is shown in Fig. 4. When the concentration of acid is smaller than that of hydrochloride, no change of shape

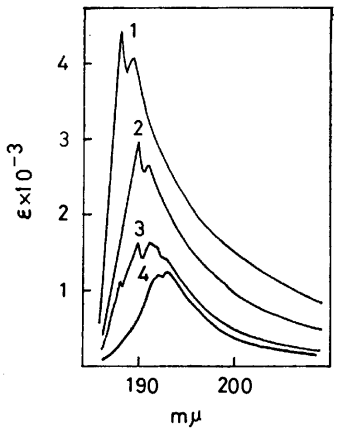

Fig. 4. Ultraviolet spectra $HCONHNH_2$–HCl in aq. H_2SO_4.
(1) 0; (2) 0.1442×10^{-2}; (3) 0.1048×10^{-1}; (4) 0.1442N.

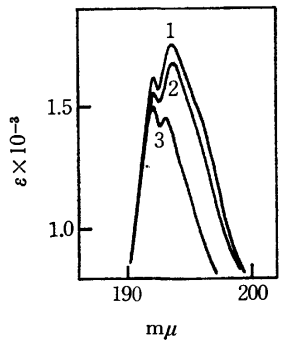

Fig. 3. Spectral change in 0.1132N H_2SO_4.
(1) 14 min (2) 2 hr (3) 17 hr after preparing the solution.

was observed but the two bands red-shift to 190 and 191 mμ, respectively. When the acid concentration exceeds that of hydrochloride, the absorption is similar, in both shape and positions of component peaks, to that of formhydrazide dissolved in water; it indicates that both formhydrazide in water and its hydrochloride in sulphuric acid of an appropriate concentration have the same absorbing species (compare curve 3, Fig. 4 with curve 1, Fig. 1). At still higher acid concentration, *e.g.* about 0.14N, the band is similar in both shape and positions of peaks to those of formhydrazide in about 0.11N of sulphuric acid (compare curve 4, Fig. 4 with curve 7, Fig. 2). Thus, both these solutions seem to have the same absorbing species differing from that contained in the aqueous solution of formhydrazide hydrochloride. The latter would be $HCONHNH_3^+$ or its hydrated species, and the former $HCONHNH_2$ or its hydrated species. From a comparison of 2, 3, and 4 in Fig. 4, it seems that at least two absorbing species are present in the solution giving curve 3. Consequently, in aqueous formhydrazide solution there will be an ionization equilibrium:

$$HCONHNH_3^+ + H_2O \rightleftarrows HCONHNH_2 + H_3O^+,$$

between hydrated molecular species and hydrated ionic species.

Calculation of Thermodynamic Protonation Constant. The ionized species shows the 190 mμ peak which is weakened with the increase of acid concentration (Fig. 2). Therefore, the extinction coefficients at 190 mμ seem to be suitable for calculating the equilibrium constant.

By measuring the extinction coefficient of a base, at any given wavelength, it is possible to calculate the value of pK_{BH^+} for the base from the following equation.[5]

$$pK_{BH^+} = \log\{(\varepsilon-\varepsilon_i)/(\varepsilon_m-\varepsilon)\} + \log(\gamma_i/\gamma_m) - \log a_{H^+}$$

where pK_{BH^+} is the negative logarithm of the thermodynamic dissociation constant for the equilibrium $BH^+ \rightleftarrows B + H^+$, γ_i and γ_m are the activity coefficients of the acid cation BH^+ and the base B, respectively, a_{H^+} is the activity of hydrogen ion; ε_i and ε_m are the extinction coefficients of BH^+ and B, respectively; ε is that due to absorbing species in an appropriate solutions. The values of $\log\gamma_i$ at 25 °C were calculated from the

5) L. A. Flexer, L. P. Hammett, and A. Dingwall, *J. Amer. Chem. Soc.*, **57**, 2103 (1935).

approximate Debye-Hückel equation $\log \gamma_i = -0.510 \times z^2 \times I/(1+1.32 \times I)$, where z is the valency of BH^+ (equal to unity in the present study) and I is the ionic strength of the medium. The values of I were calculated by assuming that in such a dilution as considered here sulphuric acid is almost completely ionized.[6] It was assumed that $\gamma_m = 1$. The values of a_{H^+} were assumed to be equal to those of the mean activity of sulphuric acid, $a_\pm (= m_\pm \gamma_\pm)$, whose values were calculated by using the mean activity coefficients obtained by interpolation from the values in literature.[7] The values of ε_i and ε_m were adjusted by means of a computer program to give the values of pK_{BH^+} which best fit the observed data of ε; the results of calculation are summarized in Table 1. In view of the value of pK_{BH^+} it would appear that formhydrazide is a weaker base than acethydrazide ($pK_{BH^+} = 3.24$).[2] This seems to be in line with the fact that formic acid is a stronger acid than acetic acid.

TABLE 1. VALUES OF pK_{BH^+} AT 25 °C

Hydrolysis in Sulphuric Acid. The change of absorbance with time was observed for the solutions of formhydrazide dissolved in sulphuric acid above about 0.1N. Typical one is shown in Fig. 5 for a reaction solution of formhydrazide (*ca.* 8×10^{-3} M) dissolved in sulphuric acid (*ca.* 8 M). The $\log (A - A_\infty)$ *vs.* t plots at the wavelengths where three peaks are shown primarily by the reaction solution are shown in Fig. 6. The plots give good straight lines having nearly the same slope except for some initial points. The slope therefore definitely gives the apparent first-order rate constant. The presence of points deviating

from the linear plot indicates that a reaction occurs prior to hydrolysis.

From a comparison of the primary absorption curves of reaction solutions, we see that both the shape of band and the potitions of component peaks change with increasing acid concentration. The initial abosrption curves are given in Fig. 7. In view of the change of the band with time, it is useless to compare the values of extinction coefficient with each other, but the positions of peaks are useful for examining the effects of acidity on the formhydrazide absorption. We give the following comments. (1) At relatively low acidity the absorption band has an intense peak with another rather weak peak (or a shoulder) on the high energy side. This band red-shifts with increasing acid concentration up to about 2 M, and further increasing acid concentration brings about a blue-shift. Moreover, the above main peak disappears prior to hydrolysis and the subpeak is weakened gradually with progress of hydrolysis (Fig. 8A). Thus, it would appear that in this region of acid concentrations the reaction solution contains initially two absorbing species affected by acid media. (2) Another case of typical changes of absorbance with time is shown in Fig. 8B which contains the absorption curves for reaction solutions made up of about 6 M sulphuric acid. The reaction solution shows initially the band with two peaks (the main peak on the high energy side and a subpeak on the low side). A similar band was observed in all the reaction solutions. Therefore, this band may be ascribed to the substrate hydrolyzed immediately. (3) Above about 7 M acid concentration, the reaction solution initially gives a broad absorption band with component peaks at the same positions as those of formhydrazide in water (compare curve 1, Fig. 5 with curve 1, Fig. 1) and increasing acid concentration does not affect the position of component peaks (see dashed cruves in Fig. 7). This indicates that the electronic states of formhydrazide are affected by structures or characters of water molecules in aqueous sulphuric acid. The band, composed of several component bands and observed in sulphuric acid above 7 M, is expected to arise from two absorbing species, one absorbing the band with two peaks at 188 and 189 mμ and the other at 190 and 191 mμ. With the progress of reaction two bands at higher wavelengths, 190 and 191 mμ, disappear first followed by the band at 188 mμ (Fig. 5).

Table 2. First-order rate constant (k') for hydrolysis of formhydrazide

a) Because of the velocity being too high, k' values in concentrations higher than those in the present study could not be determined.

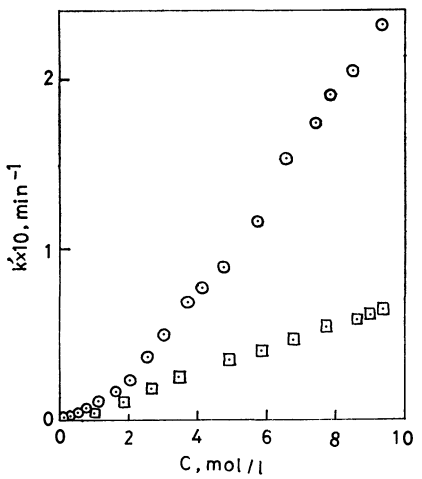

Fig. 9. Dependence of rate constants on acid concentration.
⊙: H_2SO_4, ⊡: $HClO_4$

Rate Constants of Hydrolysis in Sulphuric and Perchloric Acids. The apparent first-order rate constant k' was determined for formhydrazide in sulphuric and perchloric acids. The values of k' are given in Table 2 and the plot of k' *vs.* acid concentration (M) is shown in Fig. 9. The rate constant depends on the acid concentration but not in the same way for both acids. Thus the hydrolysis of formhydrazide seems to be acid catalyzed.

Zucker and Hammett[8] treated quantitavely rate-acidity dependence in acids for the first time. They grouped reactions into two categories, depending on whether the logarithm of the pseudo first-order rate constants were linear either $-H_0$ (negative Hammett's acidity function) or $\log C_{H^+}$ (molar concentration of hydrogen ion), with approximately unit slope. They assumed that reactions of the first type involved rate-determining unimolecular decomposition of protonated substrate (A1 mechanism) and those of the second type

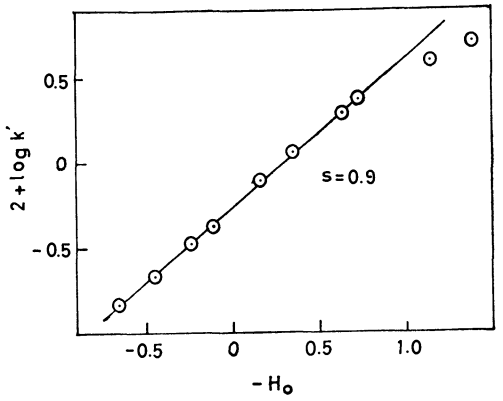

Fig. 10. Log k' *vs.* $-H_0$* plot for the hydrolysis of $HCONHNH_2$ in 0.1—3.0 M H_2SO_4.
* The H_0 values were obtained by interpolation from the values presented in Ref. 9a in the text.

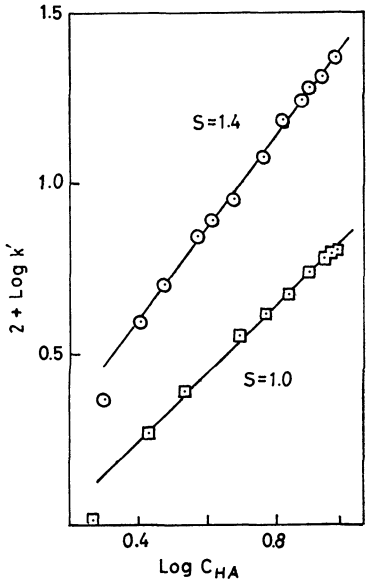

Fig. 11. Log k' *vs.* log M plot for the hydrolysis of $HCONHNH_2$ in moderately concentrated H_2SO_4 and $HClO_4$.

8) L. Zucker and L. P. Hammett, *J. Amer. Chem. Soc.*, **61**, 2791 (1939).

involved rate-determining attack on protonated substrate by a water molecule (A2 mechnism).[9]

In a limited range of acid concentrations (0.1—2.0 M), the k' *vs.* $-H_0$ plot (Fig. 10) is straight with a 0.9 slope; at high acid concentration above *ca.* 2 M, the log k' *vs.* log M plot (Fig. 11) is straight with a 1.0 slope (in perchloric acid) and a 1.4 slope (in sulphuric acid). According to the Zucker-Hammett hypothesis, the A1 mechanism seems to be suitable for the rate-determining stage of the hydrolysis of formhydrazide at low acid-concentrations; the A2 mechanism seems to be suitable at high acid-concentrations. However, objection to the Zucker-Hammett hypothesis was discussed theoretically and experimentally by Taft, Deno, and Shell[10] and by later workers.[11]

Bunnett[12] found empirically that, for a large number of reactions, plots of log $k'+H_0$ *vs.* the logarithm of the activity of water (log a_w) in the reaction medium are linear or very nearly linear. The slopes w of these plots vary over a wide range. From a comparison with reactions of known mechanism it was possible to classify reactions into three types according to the magnitude of w values and the role of water in the rate-determining step, as shown in Table 3.

Table 3. Mechanistic interpretation of w (after Bunnett[12])

Range of w value	Role of water in the rate-determining step
−2.5 to 0.0	not involved
+1.2 to +3.3	acts as a nucleophile
>+3.3	acts as a proton transfer agent

For the acid-catalyzed hydrolysis of formhydrazide in concentrated acid solutions, the Bunnett plot is given in Fig. 12 which contains the plot in sulphuric acid above 2.5 M and in perchloric acid above 1.8 M. It is of interest to see that the Zucker-Hammett plot (Fig. 11) gives only a straight line in the range of acid concentration examined in the present study, while the Bunnett plot gives straight lines composed of two parts. According to the Bunnett treatment the w values indicate the following reaction mechanisms of hydrolysis. In moderately strong acid solutions, 2.5—7 M sulphuric acid (w=5.0) and 1.5—6 M perchloric acid (w=5.5), the reaction mechanism contains proton transfer in rate-determining steps. Gillespie[13] has shown on the basis of results of Raman and NMR measurements that perchloric acid dissociates completely up to about 6 M.[14] He compared the H_0 values for these acids

at concentrations at which ionization is incomplete, and pointed out that the $HClO_4$ molecule and perhaps also the H_3O^+ ion have a greater proton donating ability in this medium than in H_2SO_4. This is consistent with our results: the rate-determining steps contain proton transfer in the range 1.5—6 M of perchloric acid concentration and the w value in perchloric acid is higher than that in sulphuric acid.

At a still higher acid-concentration than 7 M, water acts as a nucleophile in the slow step. The conclusion depends on the w value of 2.8 for sulphuric acid and of 3.1 for perchloric acid. In this region of acid concentration, both acids would be incompletely ionized. Wyatt[15] interpreted the incomplete ionization of sulphuric acid by postulating that the H_3O^+ ion tends to retain a molecule of hydration. The postulation seems to be consistent with the role of water.

Conclusion

Using a spectrophotometric method, we determined the protonation constant and the apparent first-order rate constant of the acid-catalyzed hydrolysis for formhydrazide.

The number 1.99 has been obtained for pK_{BH^+} of formhydrazide in highly dilute sulphuric acid. Hydrolysis occurs in relatively low dilution (0.1—2.0 M) and involves rate determining unimolecular decomposition of protonated substrate (A1 mechanism), using the Zucker-Hammett, log k' *vs.* $-H_0$ plot. However, in concentrated acid media the Bunnett, log $k'+H_0$ *vs.* log a_w plot is preferable for inspecting the reaction mechanism. Consequently, we have proposed the following mechanism: in the acid media 2—6 M the rate-determining steps contain proton transfer and above about 7 M water acts as a nucleophile.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1371—1374 (1973)

Ultraviolet Spectra of Hydrazide Solutions and Their Hydrolysis. II. Hydrolysis of Formhydrazide in Alkaline Solutions

Mitsuo MASHIMA and Fujiko IKEDA

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga

(Received October 7, 1972)

The aparent first-order rate constants of the base catalyzed hydrolysis of formhydrazide have been determined by ultraviolet absorption measurements. Three cases of hydrolysis applicable to three different ranges of NaOH concentrations were recognized. The activation entropies have been calculated from the change of rate constant with temperature. The effects of solvent basicity and temperature on the absorption spectra have also been studied.

Recently, the effects of amide structure, hydroxide ion concentration, temperature, and other variables on the kinetics of base-catalyzed hydrolysis of amides have been studied by a number of investigators.[1] Similar effects on the kinetics of alkaline hydrolysis of hydrazides have not been reported.

The hydrazides are expected to undergo hydrolysis catalyzed by both acid and base. The acidic hydrolysis of formhydrazide has been reported.[2] In the present work we have examined the effects of hydroxide ion concentration and temperature on the kinetics of base-catalyzed hydrolysis of formhydrazide.

Experimental

Materials and apparatus have been described.[2] The alkaline solvents were made by diluting the stock solution of NaOH (reagent grade) immediately before each set of measurements.

Results

Apparent First-Order Rate Constant (k_{obs}). The dependence of k_{obs} upon NaOH concentrations is shown in Table 1 and Fig. 1. The values of k_{obs} increase with increasing NaOH concentration up to a certain value, levelling off near *ca.* 0.5 mol/l, and then decrease gradually.

Table 1. Rate constants of the base-catalyzed hydrolysis of formhydrazide at 25°C

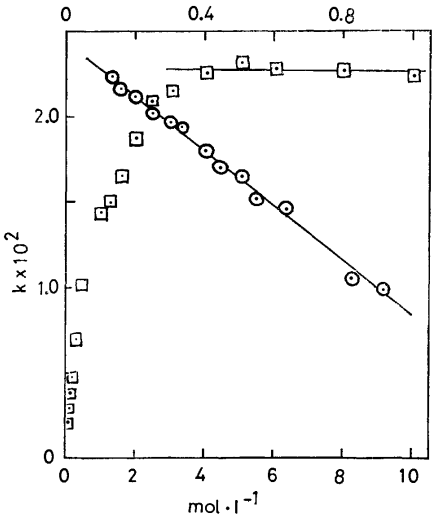

Fig. 1. The plot of k_{obs} *vs.* [NaOH]. ⊡: lower [NaOH] used the upper scale of abscissa, ⊙: higher [NaOH] used the down scale.

Kinetics in Dilute NaOH Solutions. In NaOH solutions (<*ca.* 0.5 mol/l) the reaction scheme is given by the following equations. NH_2NHCHO molecule and OH^- ion combine reversibly to form a complex (1) which decomposes slowly to form products (2).

$$NH_2NHCHO + OH^- \rightleftarrows NH_2NHC^-(OH)OH \quad \text{equil. const. } K \qquad (1)$$

$$NH_2NHC^-(OH)OH \longrightarrow HCOO^- + NH_2NH_2 \quad \text{rate const. } k \qquad (2)$$

Rate laws and K are given by

$$-d[F]/dt = k[A^-] \qquad (3)$$

$$-d[F]/dt = k_{obs}[F] \qquad (4)$$

$$K = \frac{[A^-]}{[A]}\frac{\gamma_{A^-}}{\gamma_A a_{OH^-}}, \qquad (5)$$

where A and A^- stand for NH_2NHCHO and $NH_2NHC^-(OH)OH$, respectively; F=total hydrazide (A+A^-); γ and a are activity coefficient and activity, respectively. The overall rate constant k_{obs} is readily combined with both k and K.

$$1/k_{obs} = 1/k + (1/kK)\times(\gamma_{A^-}/\gamma_A a_{OH^-}) \qquad (6)$$

A plot of $1/k_{obs}$ *vs.* $\gamma_{A^-}/(\gamma_A\times a_{OH^-})$ gives a straight line with a slope $1/kK$ and intercept $1/k$ (Fig. 2). The values of a_{OH^-} were assumed to be equal to those of mean activity ($a_\pm$) of NaOH, calculated by using mean activity coefficient obtained by interpolation from the values of Åkerlöf and Kegeles;[3] the values of γ_{A^-} were calculated from the approximate Debye-Hückel equation $\log\gamma_{A^-} = -0.510\times z^2\times(I)^{1/2}/(1+1.15\times(I)^{1/2})$, where z is the valency of A^- (equal to unity) and I is the ionic strength of aqueous NaOH solutions. A good extrapolation was obtained giving $k=3.03\times10^{-2}$ min^{-1}. With this value the slope gives $K=7.76$. Consequently, the linear plot indicates that in the region of NaOH concentration lower than *ca.* 0.5 mol/l the reaction scheme is given by equations 1 and 2, the rate-determining step being the unimolecular decomposition of the complex (Eq. 2). The true reaction mechanism will be complicated because of the change in hydration in passing from the reactants ($NH_2NHCHO+OH^-$) to the complex and to the resultants.

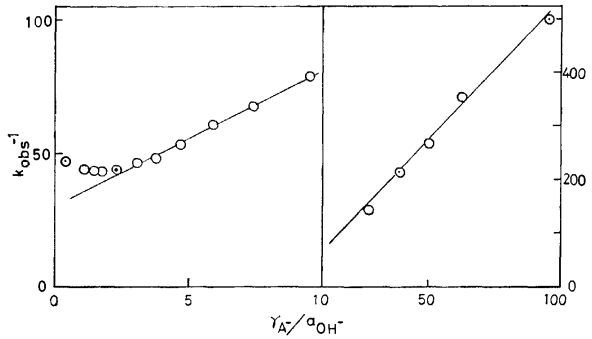

Fig. 2. The $1/k_{obs}$ *vs.* γ_{A^-}/a_{OH^-} plot.

Kinetics in Moderately Concentrated NaOH Solutions. A possible mechanism for the base catalysis is one in which the attacking species is hydroxide ion, the reaction scheme being given by

$$NH_2NHCHO + OH^- \overset{\text{slow}}{\rightleftarrows} HCOO^- + NH_2NH_2 \qquad (7)$$

In this case the overall rate constant k_{obs} can be combined with OH^- concentration by $k_{obs}=k[OH^-]$. As seen from Fig. 1, the plot of k_{obs} *vs.* [OH^-] (taken as equal to the stoichiometric concentration of NaOH) shows that k_{obs} is nearly constant in the narrow range of [NaOH], *ca.* 0.5—1 mol/l. Above *ca.* 1.5 mol/l k_{obs}

3) G. Åkerlöf and G. Kegeles, *J. Amer. Chem. Soc.*, **62**, 620 (1940).

decreases linearly with increasing [NaOH]. Thus, the base-catalyzed hydrolysis would proceed by Eq. (7) in these regions of [NaOH], the changes of hydration numbers being disregarded.

Dependence of Rate Constant on Temperature. Temperature effects were examined at 15, 20, 25, 30, and 35 °C for reaction solutions made with 0.250, 0.582, and 3.34 mol/l [NaOH] (substrate concentrations 1.5—0.6 × 10^{-3} mol/l). These concentrations lie in the three ranges where the hydrolysis proceeds in different ways. The Arrhenius plot, log k_{obs} *vs.* $1/T$ is shown in Fig. 3 and the values of k_{obs} in Table 2. The data give a straight line, the Arrhenius activation energy of 51.3 kcal/mol being obtained from its slope. The entropy of activation, 112 e.u., was calculated for 25 °C by means of the equation given by Bunnett.[4]

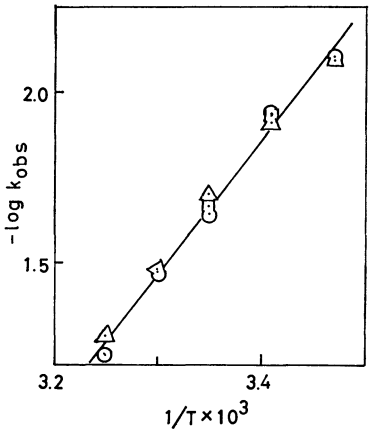

Fig. 3. Arrhenius plot, log k_{obs} *vs.* $1/T$.
⊡: 0.250, ⊙: 0.582, △: 3.34 mol/l.

Table 2. Temperature effects on k_{obs}

Temperature (°C)	$k_{obs} \times 10^2$, min^{-1} NaOH concentration, mol/l		
	3.34	0.582	0.250
15	0.799	0.788	—
20	1.23	1.15	1.16

Behavior of Absorption Maxima. The primal absorption maximum of reaction solutions shifts successively to longer wavelengths with increasing NaOH concentration and rising temperature. The temperature effects on λ_{max} is shown in Fig. 4 (the ordinate scale is not available for a comparison of absorption intensity). Figure 5 shows the plot of λ_{max} for a series of [NaOH] against the logarithm of mean activity $a_{\pm}$ of NaOH. At lower NaOH concentration the values of λ_{max} vary linearly with increase in log $a_{\pm}$, but at higher concentration a negative deviation from the line takes place. It is of interest that the change in the value of λ_{max} might be connected with this simple thermodynamic character of solvents.

Discussion

Mechanism of Hydrolysis. The products of alkaline hydrolysis of the hydrazides $RCONHNH_2$ would be carboxyl ions and hydrazine:

$$RCONHNH_2 + OH^- \longrightarrow RCO_2^- + NH_2NH_2. \quad (8)$$

We see that the reaction involves rate-determining unimolecular decomposition of the complex in dilute solutions,

$$S + OH^- \rightleftharpoons SOH^-$$

$$SOH^- \xrightarrow{slow} \neq \longrightarrow \text{products}$$

and the rate-determining nucleophilic attack of OH^- in moderately concentrated solutions,

$$S + OH^- \xrightarrow{slow} \neq \longrightarrow \text{products}.$$

Although the value of activation entropy is based on pseudo-first-order rate constants independent of solvent basicity, the observed medium independence of $\Delta S^{\neq}$ over the range of basicities 0.25—3.34 mol/l would not be expected to lead to such a constancy, provided a mechanism change is involved.

Correlation of k_{obs} with Acidity Function H_-. Yagil and others[5] summarized the formulation of rate expressions of eight types of base-catalyzed reactions, which can be divided into three groups. Our results (Eqs. 1, 2, and 7) belong to the group containing

5) M. Anbar, M. Bostelsky, D. Samuel, and G. Yagil, *J. Amer. Chem. Soc.*, **85**, 2380 (1963).

reactions expected to give a linear plot of $\log k_{obs}$ *vs.* $H_-+\log C_w$,[6] with about unit slope. The plot for our results is shown in Fig. 6 together with the Zucker-Hammett type plot, $\log k_{obs}$ *vs.* H_-. Both plots indicate that, in the range of NaOH concentration shown in Fig. 6, two linear parts can be obtained with slopes (<0.3) deviating greatly from unity, with a boundary point between them.

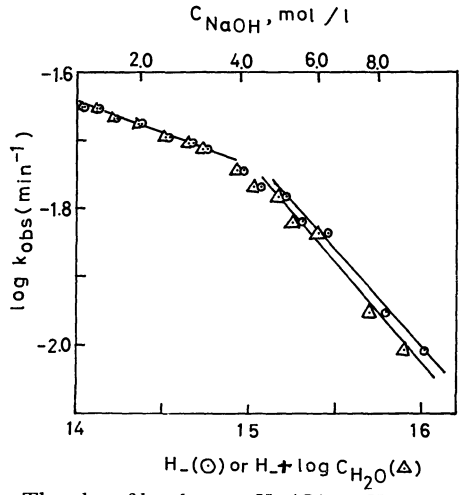

Fig. 6. The plot of $\log k_{obs}$ *vs.* H_- (⊙) or $H_-+\log Cw$ (△).

By analogy with the Bunnett treatment[7] of the acid-catalyzed reactions, $\log k_{obs}-H_-$ was plotted against the logarithm of water activity a_w (Fig. 7) for the hydrolysis in reaction solutions except for ones prepared with very dilute NaOH solutions. Three linear parts were obtained; in dilute NaOH solutions (<*ca.* 0.8 mol/l) with slope 40, in the range *ca.* 1—3 mol/l with 20 and >*ca.* 5 mol/l with 5.6. Assuming that these parts correspond to three types of hydrolysis, one is the rate-determining unimolecular decomposition of the complex $NH_2NHC^-(OH)OH$, and the other two due to the rate-determining nucleophilic attack of OH^- with different values of slope of the plot k_{obs} *vs.* [NaOH], the results being consistent with those given in the preceeding paragraph. As Rochester[8] has pointed out,

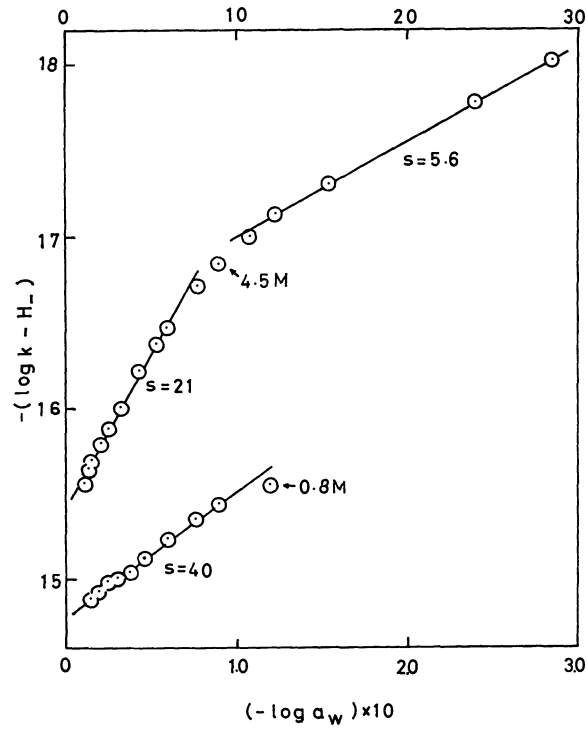

Fig. 7. The plot of $\log k_{obs}-H_-$ *vs.* $\log a_w$. The upper scale of abscissa is used for the upper plots and the lower scale for the lower ones.

the values of slopes of the linear plot, $\log k-H_-$ *vs.* $\log a_w$, would provide useful criteria for the mechanism of reactions in basic media.

Behavior of Absorption Maxima. Smith and Symons[9] ascribed the red-shifts of the first electronic absorption band of solvated iodide ions with temperature rise to an increase in the average radius of the solvent shell. As shown in Fig. 4, the maximum of primary absorption of reaction solutions shifts to longer wavelengths with temperature rise. The effect is ascribable to the change in energy levels of hydrated molecular or ionic species of formhydrazide and to the change of the water shell. It is of interest that there is a linear correlation between λ_{max} and $\log a_\pm$ of NaOH in the range <*ca.* 0.8 mol/l of basicities, where the rate constants have also been combined with $a_\pm$.

The Crystal and Molecular Structure of Piperazinium Terephthalate, $(H_2NC_4H_8NH_2)^{2+}(O_2C\cdot C_6H_4\cdot CO_2)^{2-}$

Setsuo KASHINO, Minoru SASAKI,* and Masao HAISA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received November 4, 1972)

Piperazinium terephthalate has been prepared and examined by X-ray analysis. The compound crystallizes in the monoclinic space group $P2_1/c$ with two formula units in a unit cell. The cell dimensions are: $a=9.45$, $b=8.30$, $c=8.33$ Å, and $\beta=117.3°$. The structure was determined by the Patterson method from the data collected with Cu$K\alpha$ radiation on Weissenberg photographs, and refined by the block-diagonal least-squares method with anisotropic temperature factors for non-hydrogen atoms and fixed isotropic ones for hydrogen atoms. The final R value is 0.108 for 941 non-zero reflections. Acid and base moieties occupy the positions of center of symmetry in the cell. Two N^+–H···O^- hydrogen bonds (2.612 and 2.737 Å) link a nitrogen atom of piperazine with two carboxyl oxygens of the acids related by c glide plane to form a three-dimensional hydrogen bond network, in which each oxygen atom accepts one hydrogen bond. The coordination around the nitrogen atom is nearly tetrahedral. The piperazine ring takes a chair form. The twisting angle between the carboxyl group and the benzene ring plane is 17.3°.

During the course of investigation of the structure of the addition compounds of piperidine with benzoic acids,[1] it was found desirable to extend studies to the addition compounds of bifunctional aromatic acids and bifunctional heterocyclic amines. The present paper reports the formation and the crystal and molecular structure of an addition compound of piperazine with terephthalic acid, showing that the compound is piperazinium terephthalate.

Experimental

Piperazinium terephthalate was prepared by dissolving equimolar quantities of terephthalic acid and piperazine in hot water. After the solution had been left to stand at room temperature, colorless prisms separated out. Mp 307 °C (decomp.); IR: antisymmetric $\nu(CO_2^-)$ 1565 cm^{-1}, symmetric $\nu(CO_2^-)$ 1385 cm^{-1}.

Found: C, 57.19; H, 6.56; N, 10.89%. Calcd for $C_{12}H_{16}N_2O_4$: C, 57.13; H, 6.39; N, 11.10%.

Crystals obtained by slow cooling from aqueous solution were monoclinic prisms elongated along the a axis. Cell constants were determined from Weissenberg and oscillation photographs using Cu$K\alpha$ radiation ($\lambda=1.5418$ Å), and calibrated with sodium chloride.

Crystal data: piperazinium terephthalate, $(H_2NC_4H_8NH_2)^{2+}(OOC\cdot C_6H_4\cdot COO)^{2-}$; formula weight=252.3; monoclinic, $a=9.45(2)$, $b=8.30(1)$, $c=8.33(2)$ Å, $\beta=117.3(2)°$, $V=580.4$ Å^3, $D_m=1.44_2$ (by flotation), $D_c=1.443$ g cm^{-3}, $Z=2$.

Linear absorption coefficient for Cu$K\alpha$; $\mu=9.2$ cm^{-1}, $F(000)=268$.

Absent spectra: $h0l$ when l is odd, $0k0$ when k is odd. Space group is $P2_1/c$.

Three different crystals with approximate dimensions $0.3\times0.3\times0.9$, $0.4\times0.3\times0.3$, and $0.3\times0.3\times0.3$ mm were used for a, b, and c axis photographs, respectively. Using Cu$K\alpha$ radiation, multiple-film equi-inclination Weissenberg photographs were taken for the layers from $0kl$ to $7kl$, from $h0l$ to $h5l$, and $hk0$. In all, 941 independent non-zero reflections were observed out of about 1350 possible reflections within the Cu$K\alpha$ sphere. Intensities were estimated by visual comparison with a calibrated intensity scale. After Lorentz, polarization, and spot-shape corrections were made, the intensities of various layers were put on the same relative scale by making use of all the common reflections. The relative values were put on an absolute scale by Wilson's method. No corrections for absorption and extinction effects were made.

Structure Analysis

Since only two molecular units of acid and base moieties were contained in a unit cell of the space

group $P2_1/c$, it was most plausible that each of the acid and base moieties should be centrosymmetric and occupy the center of symmetry of the cell. Thus, the center of gravity of the acid moiety was chosen to be (0, 0, 0) and that of the base moiety (1/2, 0, 0), a half of their molecular unit being taken as the asymmetric unit. Orientation of the acid moiety was sought using two-dimensional Patterson projections onto (1 0 0), (0 1 0), and (0 0 1), the (0 1 0) projection being especially suggestive. Approximate positional parameters of all non-hydrogen atoms were then determined by interpretation of the three-dimensional Patterson map. Position of the nitrogen atom was identified by short interatomic distances of about 2.6 Å from the two carboxyl oxygen atoms in the trial structure. The structure was refined by the block-diagonal least-squares method[2] with isotropic temperature factors to an R value of 0.165 and with anisotropic temperature factors to that of 0.125. A difference Fourier synthesis at this stage revealed all eight hydrogen atoms as shown in Fig. 1(b). Further refinement was made with anisotropic temperature factors for the non-hydrogen atoms and with fixed isotropic temperature factors ($B=1.7$ Å^2) for the hydrogen atoms using the following weighting scheme:

$$\sqrt{w} = 0.0, \quad \text{if } F_o < F_{min} \ (=1.0),$$
$$\sqrt{w} = 1.0, \quad \text{if } F_{min} \leq F_o \leq F_{max} \ (=17.0)$$

and

$$\sqrt{w} = F_{max}/F_o, \quad \text{if } F_o > F_{max}.$$

The final R value was 0.108 for 941 non-zero reflections. The final atomic parameters and their estimated standard deviations for non-hydrogen atoms are given in Table 1, and the final positional parameters for hydrogen atoms in Table 2. A composite drawing of the final electron-density map is shown in Fig. 1 along with the difference synthesis map. The observed and calculated structure factors are listed in Table 3.

The atomic scattering factors used were those of Hanson, Herman, Lea, and Skillman.[3] The numerical calculations were performed with the aid of a HITAC 5020E computer of the Computer Center, the University of Tokyo.

Results and Discussion

The projections of the crystal structure along the b and a axes are shown in Fig. 2. Two hydrogen bonds of nearly equal length link the nitrogen atom of piperazine with the carboxyl oxygen atoms to form a three-dimensional hydrogen bond network, in which each oxygen atom accepts one hydrogen bond; hydrogen bonds of length 2.737 Å link the acid and base moieties along [1 1 1] and other ones of length 2.616 Å link them along [1 0 2] infinitely. This hydrogen bond scheme explains the high melting point of this compound.

As shown in Fig. 3, the nitrogen atom is nearly tetrahedrally coordinated with the atoms C(6) and C(5') covalently and with the atoms O(1) and O(2') through hydrogen bonds. A difference map (Fig. 1(b)) shows that two hydrogen atoms belong to each nitrogen atom, the N–H bond lengths being determined to be 1.03 and 0.97 Å by the least-squares refinements. It can therefore be concluded that the present compound is composed of piperazinium cation and terephthalate anion, the hydrogen bonds between them being of the type N^+–H···O^-.

Bond angle C(1')–O(2')–N (111.9°) is approximately tetrahedral, but the angle C(1)–O(1)–N (147.0°) deviates considerably from regular tetrahedral angle. Corresponding to the difference, the hydrogen bond length between O(2') and N (2.612 Å) is significantly shorter than that between O(1) and N (2.737 Å). Similar geometries of the hydrogen bond system have been found in the 1: 1 addition compounds of piperidine with p-bromo- and p-chlorobenzoic acids.[1]

Bond lengths and angles of each ion are shown in Fig. 4. The two C–O bond lengths are almost equal to each other (1.251 and 1.255 Å) and shorter than

those found in terephthalic acid (1.262 and 1.272 Å),[4] supporting the fact that the acid is ionized. The angles C(2)–C(1)–O(1) and C(2)–C(1)–O(2) differ

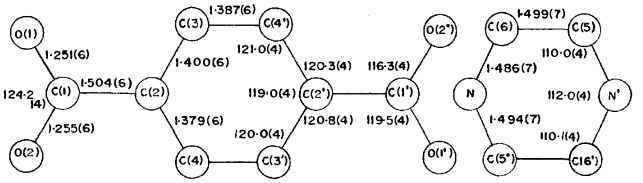

Fig. 4. Bond lengths (Å) and angles (°). The estimated standard deviations are shown in parentheses.

significantly; the former is 119.5° and the latter 116.3°. The mean C–C bond length in the benzene ring is 1.388 Å in agreement with that found in terephthalic acid (1.392 Å).[4] However, a quinonoid character in the benzene ring, which has been found in the terephthalic acid[4] and in terephthalate ion of calcium terephthalate trihydrate,[5] is not appreciable in this compound. The bond length between carboxyl carbon C(1) and aromatic carbon C(2) (1.504 Å) is significantly longer than the corresponding ones in the terephthalic acid (1.483 Å)[4] and in the terephthalate ion of calcium terephthalate trihydrate (1.487 and 1.495 Å).[5] In these two compounds the twisting angle of carboxyl group with respect to the plane of benzene ring are only 5.7—2.2°. In the present compound the angle amounts to 17.3°; distances of atoms C(1), O(1), and O(2) from the benzene ring plane are −0.009, −0.332, and 0.327 Å, respectively. A plausible explanation for the lengthening of the bond between aromatic C and carboxyl C is the diminution of the π-bond character resulting from a large twisting angle. A qualitatively similar relation between the bond length and twisting angle has been found in pyromellitic acid dihydrate.[6]

The molecular geometry of piperazinium ion is

identical within the limit of experimental errors with that found by Rérat[7] in piperazine dihydrochloride monohydrate. In the ion one nitrogen atom deviates upward from the plane through four carbon atoms by 0.65 Å and the other must deviate downward by the same distance. Thus the piperazine ring takes a normal chair form. The C–C bond length in the ring (1.499 Å) is in agreement with that found in piperazine hexahydrate (1.491 Å)[8] but significantly shorter than that found in piperazine by gas electron diffraction (1.540 Å).[9] The average C–N bond length is 1.490 Å, which is slightly longer than that observed in the hexahydrate (1.458 Å)[8] and in piperazine (1.467 Å).[9] The C–C–N angles are 110.1 and 111.0°, which are in agreement with those found in the hexahydrate (109.5 and 110.2°), but the C–N–C angle (112.0°) is slightly larger than that found in the hydrate (109.3°).

Intermolecular distances less than 3.5 Å are listed in Table 4. The structure is maintained by closely packed moieties to give a comparatively high density (1.44 g cm^{-3}).

ESR of Hot Ions: Ni(I) Complex Ions Produced in Rigid Solutions by γ-Irradiation

Chikara AMANO and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received November 17, 1972)

Electron spin resonance has been used to study Ni(I) complex ions produced at 77 K through reduction by γ-irradiation of Ni(II) complexes in glassy solvents. The Ni(I) complex ions give axially symmetrical spectra, suggesting that the Ni(I) ions favor tetragonally elongated octahedral form. From the *g*-values it can be shown that the Ni(I)-to-ligand bonding for different ligands increases in covalency in the order: H_2O<edta≪py∼en∼xanthate<phen<dipy≪CN^-. It can also be shown that the metal-to-ligand bonding of the Ni(I) complex ions is less covalent than that of the corresponding Cu(II) complexes. Measurement of the integrated intensity of the ESR spectrum of $[Ni(I)(H_2O)_6]^+$ with reference to a standard sample of $[Cu(II)(H_2O)_6]^{2+}$ shows that at a total dose of 1×10^6 R the yield of the Ni(I) species is $0.21\pm0.04\%$ of the host complex $[Ni(II)(H_2O)_6]^{2+}$. In addition to the anisotropic spectra of the Ni(I) complex ions, isotropic spectra have been observed in several cases, which are probably due to Ni(III) complex ions. Isotropic feature of these spectra may be explained in terms of dynamic Jahn-Teller effect involving the Ni(III) complex ions.

Metal ions of complexes in solids and in rigid solutions are often reduced by X- or γ-irradiation.[1-4] It has also been reported that oxidation of metal ions occurs in some cases.[5] With the gain or loss of an electron these complexes presumably change immediately in configuration of ligands to take structures with fairly long life-time, which give, in some cases, anomalous optical and ESR spectra.[6,7] For example, several Co(II) complex ions produced through reduction of Co(III) complexes by γ-irradiation have been shown to be in the low spin state ($S=1/2$), in contrast to the usual observation of high spin state ($S=3/2$) of Co(II) complexes.[7]

In a preceding paper, an attempt to produce Ni(I) ions in the host lattice by γ-irradiation of Ni(II) complexes has been reported, where it has been shown that only a few Ni(II) complexes give ESR spectra corresponding to Ni(I) state, and that the electronic structure of Ni(I) ions strongly depends on the host lattices.[8]

The present paper concerns with ESR of Ni(I) complex ions in rigid solutions carrying nitrogen and/or sulfur atoms as donating ones. The *g*-values will be used to discuss the nature of the Ni(I)-to-ligand bonding.

Experimental

Nickel(II) chloride hexahydrate was purified by an anion exchange method to remove a trace amount of cobaltous and cupric ions. Several samples with various molar ratios of nickel(II) ions to ligands were prepared. A mixture of ethylene glycol and water (2: 1 v/v) (EG–H_2O) was used as a glassy solvent. A mixture of *ortho*-, *meta*-, and *para*-xylene was also used as a glassy solvent. The systems studied are listed in Table 1. Degassed sample solutions were immersed

a) Rhombic ESR patterns

in liquid nitrogen and given at 77 K a γ-ray dosage of 1×10^6 R from ^{60}Co source with the dose rate of 5×10^4 R/h. ESR spectra were recorded at 77 K on a JEOL 3BSX spectrometer.

The yield of $[Ni(I)(H_2O)_6]^+$ was determined by comparing the integrated ESR intensity of Ni(I) complex ions with that of a standard sample which contained 6.02×10^{16} ions of $[Cu(II)(H_2O)_6]^{2+}$ in EG–H_2O.[9] The samples used in the present experiment contain 6.02×10^{18} ions of $[Ni(II)(H_2O)_6]^{2+}$ and the concentration of $[Ni(II)(H_2O)_6]^{2+}$ is 1.00×10^{-1} mol/l.

9) Since $[Cu(II)(H_2O)_6]^{2+}$ and $[Ni(I)(H_2O)_6]^+$ are almost the same with respect to the anisotropy of the *g*-tensor ($g_{//}=2.400$, $g_{\perp}=2.099$ for Cu(II) and $g_{//}=2.466$, $g_{\perp}=2.076$ for Ni(I)), the ESR transition probability, and hence, the integrated intensity is assumed equal to each other between these two complexes.

Results and Discussion

In all systems examined, the *g*-tensors are nearly axially symmetric. Since ^{61}Ni, only isotope with non-zero nuclear spin, has a very low natural abundance (1.25%), hyperfine structure due to nickel nuclei was not observed. Principal values of the *g*-tensor ($g_{//}$ and $g_{\perp}$) were obtained as usual, and the results are summarized in Table 2.

The yield of $[Ni(I)(H_2O)_6]^+$ was found to be 0.21 ± 0.04% of the amount of the host $[Ni(II)(H_2O)_6]^{2+}$ at a γ-ray dosage of 1×10^6 R.[10]

10) This corresponds to a *G*-value in radiation chemistry of 0.21 ± 0.04.

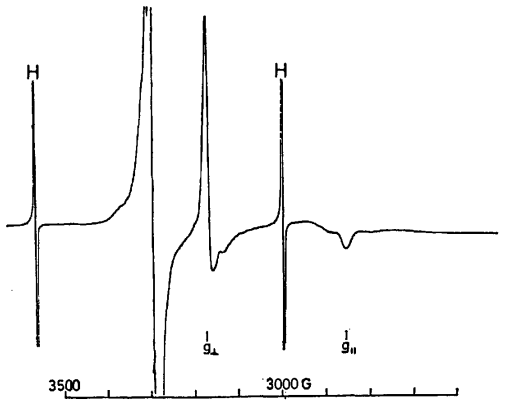

Fig. 2. ESR spectrum of $[Ni(I)\ (ethylxanthate)_2]^-$ produced by γ-irradiation in rigid xylene solution.

The Ni(I) complex ions produced by γ-irradiation are stable at 77 K for several days, but the ESR spectra disappear as soon as the samples are brought to room temperature. ESR spectra due to hydrogen atoms and radicals with unidentified structure are also observed at $g\sim2.0023$ from all samples. All the γ-irradiated samples other than those in rigid xylene solutions show a deep blue color, which is probably due to solvated electrons.

Assignment of ESR Spectra. Experimental results in Table 2 show that $g_{//}>g_{\perp}>g_e$ (=2.0023), and that the $g_{//}$-values are strongly dependent on the kind of ligands. It is also noted that g-shifts ($\Delta g=g_{obs}-2.0023$) are fairly large. The large g-shifts eliminate a possibility that these signals are due to radicals by the solvent and/or ligands. The relation of $g_{//}$, $g_{\perp}$, and g_e for various electron configurations and multiplets predicted by the ligand field theory is summarized in Table 3. High spin state ($S=3/2$) of d^7 electron configuration is eliminated from Table 3, since the observed spectra do not show the nature of high spin state. Complex ions with high spin state should have a spin-lattice relaxation time too short to permit the observation of ESR spectra at 77 K and, even if observed, should have large g-values of 4 or 6 by the contribution of orbital magnetic moment. The g-values in Table 3 have been calculated according to the framework of strong field approximation; cubic field, electron-electron repulsion and tetragonal field are successively applied as perturbations. Actually, we have built multiplet wavefunctions taking electron-electron repulsion into consideration to the first order, which are expressed as the linear combinations of seven electron wavefunctions of determinantal type. For instance, for the wavefunctions belonging to the ground state of ^2E_g we have

$$|^2E_g\ 1/2\ u\rangle = |d_{yz}\overline{d_{yz}}d_{zx}\overline{d_{zx}}d_{xy}\overline{d_{xy}}d_{3z^2-r^2}|$$
$$|^2E_g\ 1/2\ v\rangle = |d_{yz}\overline{d_{yz}}d_{zx}\overline{d_{zx}}d_{xy}\overline{d_{xy}}d_{x^2-y^2}|$$

All the multiplet wavefunctions are the eigenfunctions of spin-operators, S^2 and S_z, and are transformed in similar fashion with the bases of irreducible representations of O_h group. Tetragonal field is taken into account to the first order. Taking spin-orbit interaction ($H_{so}=\sum_{i=1}^{7}\xi(\vec{r}_i)\vec{l}_i\vec{s}_i$) and Zeeman interaction ($H_z=\sum_{i=1}^{7}\beta(\vec{l}_i+2\vec{s}_i)\vec{H}$) as perturbation, the second order energy is calculated within forty functions belonging to the ground and the one electron excited configurations. Although the results in Table 3 are obtained by using a simple crystal field theory, these relations should remain unchanged even if configuration interaction is taken into account in an LCAO MO formalism. As Table 3 shows, case A and case D are consistent with the experimental results. As far as we know, complex ions with the d^7 electron configuration have always been shown to be in the $^2A_{1g}$ state (case C), and a

d^7 electron configuration in the $^2B_{1g}$ state (case D) has not yet been proved to exist.[11–14] In view of these result, it may be concluded that the observed signals are due to Ni(I) complex ions having the $3d^9$ electron configuration in the $^2B_{1g}$ state (case A).

Structure of Ni(I) Complex Ions. The ESR spectrum shows that $[Ni(I)(H_2O)_6]^+$ has a tetragonally elongated octahedral form, while the host $[Ni(II)(H_2O)_6]^{2+}$ is known to have a regular octahedral form. The lowering of symmetry which is accompanied with the reduction of Ni(II) to Ni(I) is probably due to the Jahn-Teller effect; the ground state of $[Ni(I)(H_2O)_6]^+$ in O_h symmetry would be orbitally degenerate E_g, which is expected to suffer from Jahn-Teller distortion.

Ni(I) Ion-to-ligand Bonding. It has been shown that in a ligand field with D_{4h} symmetry, $g_{//}$ and $g_{\perp}$ for the d^9 electron configuration with $^2B_{1g}$ ground state are given by[15,16]

$$g_{//} = 2.0023 + 8\zeta_0\alpha\beta_1[\alpha\beta_1 - \alpha'\beta_1 S - \alpha'(1-\beta_1^2)^{1/2}T(n)/2]/\Delta E_{xy} \quad (1a)$$

$$g_{\perp} = 2.0023 + 2\zeta_0\alpha\beta[\alpha\beta - \alpha'\beta S - \alpha'(1-\beta^2)^{1/2}T(n)/2^{1/2}]/\Delta E_{xz} \quad (1b)$$

where α and α' are the coefficients for the B_{1g} antibonding orbital, β and $(1-\beta^2)^{1/2}$ are those for E_g, β_1 and $(1-\beta_1^2)^{1/2}$ are for B_{2g}; and ΔE_{xy} and ΔE_{xz} are energy separations between $^2B_{2g}$ and $^2B_{1g}$ and between ^2E_g and $^2B_{1g}$ respectively. Although the Ni(I) complex ions are most probably six-coordinated, Eqs. (1a) and (1b) will be used in the present study by making an assumption that overlap between orbitals of the fifth and sixth ligands and those of the Ni(I) ion is small. Following parameters k and k' represent the degree of delocalization of the 3d electrons of the nickel ion, and may be used as a measure of covalency in the Ni(I) complex ions.[16]

$$k = \alpha\beta_1[\alpha\beta_1 - \alpha'\beta_1 S - \alpha'(1-\beta_1^2)^{1/2}T(n)/2]/\Delta E_{xy} \quad (2a)$$

$$k' = \alpha\beta[\alpha\beta - \alpha'\beta S - \alpha'(1-\beta^2)^{1/2}T(n)/2^{1/2}]/\Delta E_{xz} \quad (2b)$$

It can be seen from Table 2 that the covalency increases in the order: H_2O (0.96) < edta (0.86) ≪ py (0.58) ~ en (0.58) ~ xanthate (0.58) < phen (0.56) < dipy (0.53) ≪ CN^- (0.27). The numbers in parentheses represent parameters k. This order is in agreement with that obtained for Cu(II) complexes (Table 4), well-known spectrochemical series.[17]

In the following the parameter k obtained for the Ni(I) complex ions are compared with those for the corresponding Cu(II) complexes:[18]

$[Ni(I)(H_2O)_6]^+$ (0.96) < $[Cu(II)(H_2O)_6]^{2+}$ (0.60)

$[Ni(I)(en)_2(H_2O)_2]^+$ (0.58) < $[Cu(en)_2(H_2O)_2]^{2+}$ (0.31)

$[Ni(I)(CN)_4]^{3-}$ (0.27) < $[Cu(II)(CN)_4]^{2-}$ (0.24)

In all these cases, the nature of the Ni(I) ion-to-ligand bonding appears to be less covalent than in the case of corresponding Cu(II) ions.

Isotropic Spectra. γ-Irradiated samples containing $[Ni(II)(H_2O)_6]^{2+}$ or $[Ni(II)(edta)(H_2O)]^{2-}$ give additional isotropic spectra. In the cases of $[Ni(II)(en)_3]^{2+}$, $[Ni(II)(phen)_3]^{2+}$ and $[Ni(II)(dipy)_3]^{2+}$ only the isotropic spectra were observed. As in the case of the Ni(I) ions discussed above, the g-shifts are fairly large and are sensitive to the kinds of ligands. These signals

observed at liquid nitrogen temperature disappear irreversibly when the samples are brought to room temperature.

If the isotropic feature of these spectra comes from dynamic Jahn-Teller effect of the Ni(I) complex ions, the g-values should be equal to $(g_{//}+2g_{\perp})/3$. This relation obviously does not hold for $[Ni(I)(H_2O)_6]^+$ and $[Ni(I)(edta)(H_2O)]^{3-}$. Anisotropic g-values, $g_{//}$ and $g_{\perp}$, estimated from this relation are too large for $[Ni(I)(en)_3]^+$, $[Ni(I)(phen)_3]^+$, and $[Ni(I)(dipy)_3]^+$ ($g_{//}\sim 2.4$, $g_{\perp}\sim 2.1$).

Another possibility is that the Ni(II) complexes are oxidized to produce Ni(III). Complex ions with d^7 configuration would have ^2E_g ground state in a strong ligand field with O_h symmetry. Since an orbitally degenerate E state has to be split by the Jahn-Teller effect, complexes with d^7 electron configuration would be lower in symmetry than O_h, and hence give anisotropic g-tensors. In the case of the dynamic Jahn-Teller effect, isotropic g-tensors would be observed. In some d^7 complexes, isotropic g-values have been reported, where the results were interpreted in terms of the dynamic Jahn-Teller effect.[13,14]

The high spin state ($S=3/2$) of d^7 complexes would have a spin-lattice relaxation time too short to permit observation of ESR spectra at 77 K and would not show the g-value of 2 which is observed in the present case.

In view of the above results it may be concluded that a Ni(III) species is produced along with Ni(I) species by γ-irradiation and that the dynamic Jahn-Teller effect is responsible for the isotropic feature of the ESR spectra.

We would like to thank Mr. Shingo Katsura of γ-ray irradiation center for experimental assistance and Dr. Tokuko Watanabe for valuable discussions. We would also like to thank Dr. Yoji Arata for helpful discussions and several remarks in the preparation of this paper.

ESR Studies on Radiation-Induced Polymerization of 1,3-Butadiene in Urea Canal Complexes[1)]

Toshio OHMORI,* Takahisa ICHIKAWA,** and Machio IWASAKI

Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya

(Received December 28, 1972)

The ESR spectrum of γ-irradiated 1,3-butadiene in urea canal complexes at 77 K consists of 7 lines with a hyperfine splitting of 15 G and is assigned to the monomer radical CH_3–CH=CH–$\dot{C}H_2$ which may be produced by hydrogen addition to the 1,3-butadiene. Upon warming to room temperature the spectrum changes into a 6×2-line spectrum ($a_1=14$ G and $a_2=4$ G), which is attributed to the propagating radical R–$C_\beta H_2$–C_αH=CH–$\dot{C}H_2$ occluded in the urea canals. On cooling back to 77 K, the 6×2-line spectrum is transformed into a 5-line spectrum ($a=14$ G); this spectral change is reversible with temperature and is interpreted in terms of oscillation of the propagating radical around the C_β–C_α bond. On further warming to 400 K, the propagating radical is converted to the "chain" allyl type radical R–CH_2–CH=CH–$\dot{C}$H–CH_2–R′, of which room-temperature spectrum consists of 7×2 lines ($a_1=14$ G and $a_2=4$ G). This radical conversion is explained by hydrogen atom transfer reaction within the propagating radical through the radical chain and/or between the propagating radical and a neighbouring polymer chain. Irradiated 1,3-butadiene-1,1,4,4-d_4 in urea canals is also examined and the results obtained confirm the above-mentioned identifications.

The polymerization of 1,3-butadiene in urea complexes was extensively investigated by White[2)] and the formation of *trans*-1,4-polybutadiene was obtained by irradiation with high energy electron at low temperatures. The initiation of polymer chain growth inside the crystalline lattice[3)] of canal complexes was reported to be quite difficult by other conventional means, *i.e.*, high pressure, heat, ultraviolet rays, and conventional initiators.[4)]

High energy radiation, however, can penetrate into the crystalline lattice of canal complexes. As a result, active species may be produced inside the crystalline lattice. ESR results of irradiated aliphatic monomers

* On leave from Research Laboratory, Japan Synthetic Rubber Co., Ltd.

1) Presented at the 21st Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1968.

2) D. M. White, *J. Amer. Chem. Soc.*, **82**, 5678 (1960).

3) The structure of a urea lattice in hydrocarbon-urea complexes was reported to be hexagonal (A. E. Smith, *Acta Crystallogr.*, **5**, 224 (1952)). There are six urea molecules in the unit cell with lattice parameters $a=8.23$ Å and $c=11.0$ Å. Along the c axis the urea molecules form the wall of a canal, of which diameter is 5—6 Å. 1,3-Butadiene molecules are packed in the canal.

4) J. F. Brown, Jr., and D. M. White, *J. Amer. Chem. Soc.*, **82**, 5671 (1960).

(ketones, ethers, and esters) in urea canals[5] have showed that monomer radicals are trapped inside the urea canals. This suggests the possibility that monomer radicals from irradiated 1,3-butadiene-urea complexes may be produced inside the crystalline lattice of the urea complexes. The monomer radicals produced would be expected to initiate the polymerization of 1,3-butadiene.

In our preliminary experiments the irradiation of pure solid 1,3-butadiene did not produce appreciable amounts of polymers, while a 25% conversion to polymer was reported in irradiated 1,3-butadiene-urea complexes.[2] The results indicate that packing of 1,3-butadiene in urea canals is very effective for the polymerization of 1,3-butadiene. One of reasons for this is supposed to be due to the fact that walls formed by the urea molecules can prevent bimolecular termination reactions between growing polymer chains unless two growing polymer chains are both present in an urea canal.

Although the reaction processes of polymerization have been investigated in detail for several solid monomers including 1,3-butadiene by means of ESR,[6] there seems to be no report regarding the nature of active species produced during polymerization in urea canals. In order to elucidate the mechanism of polymerization in urea canals, ESR studies of irradiated 1,3-butadiene-urea complexes have been made at temperatures in the range 77—400 K. The results obtained have indicated that the monomer radical is produced by hydrogen addition to the 1,3-butadiene at 77 K, followed by changing into the propagating radical at elevated temperature. Further warming leads to conversion to the "chain" allyl type radical by intra- and/or intermolecular hydrogen transfer.

Experimental

All the chemicals used for the preparation of the urea canal complexes, with the exception of 1,3-butadiene-1,1,4,4-d_4 (BD-*d*), were obtained from commercial source. The urea was recrystallized several times from water and was dried in a desiccator over anhydrous calcium chloride. The 1,3-butadiene without deuteration (BD-*h*) was distilled *in vacuo* from trap to trap. The BD-*d* was prepared by pyrolysis of the BD-*d*–SO_2 addition compound which was obtained by base-catalyzed deuterium exchange of the BD-*h*–SO_2 addition compound.[7]

The urea canal complexes of BD-*h* or BD-*d* were prepared by the method developed by White[2] with some modifications. A mixture of BD-*h* (60 wt%), urea (40 wt%), and methanol (traces) was sealed in a ESR sample tube and was kept in a low-temperature bath controlled at 218 K for 5 days. This temperature has been reported to be optimum for the formation of BD-*h*–urea complexes.[2]

Irradiation was carried out with a 3-KCi ^{60}Co source at 77 K. The dose rate was 1.5×10^5 R/hr and the total dose was 2×10^6 R. ESR spectra were obtained with a Japan Electron Optics Lab. Co. (JEOL) X-band spectrometer with 100 KHz field modulation at various temperatures. A liquid-nitrogen Dewar was used for measurements at 77 K and a variabletemperature accessory supplied by JEOL was employed form easurements at higher than 90 K.

Polymer products obtained after irradiation of BD-*h*–urea complexes were confirmed to be *trans*-1,4-polybutadiene by comparison of their infrared spectra and intrinsic viscosities with the data reported by White.[2]

Results and Discussion

Monomer Radical. Figure 1a shows the ESR spectrum of BD-*h*–urea complexes which were immediately measured at 77 K after irradiation at 77 K. The spectrum consists of 7 lines with a hyperfine splitting of 15 G. Any significant spectral change in the hyperfine structure did not take place after the sample was heated from 77 to 130 K and was cooled back to 77 K (Fig. 1b). The 7-line spectrum can be ascribed to the allyl type radical (radical I)

$$\overset{\beta}{C}H_3-\overset{\alpha3}{C}H=\overset{\alpha2}{C}H-\dot{\overset{\alpha1}{C}}H_2.$$

R_I

The formation of radical I may be accounted for by hydrogen addition to the conjugated double bond of BD-*h*.

Radical I has an unpaired spin coupling to four α and three β protons. The unpaired spin distribution of radical I is supposed to be approximately similar to that of the allyl radical $CH_2=CH-\dot{C}H_2$. The α-proton

coupling constants of radical I, therefore, are assumed to be $a_{\alpha 1}=a_{\alpha 3}=14$ G and $a_{\alpha 2}=4$ G from the values obtained for the allyl radical.[8]

The β-proton coupling constants of radical I can be estimated by the use of the relation[9]

$$a_\beta = 2Q_\beta \cdot \rho_\alpha \cdot \cos^2\theta. \quad (1)$$

In Eq. (1), Q_β is the constant, whose value is assumed to be 29.3 G from Ref. 8, ρ_α is the spin density on the α3-carbon atom, of which value is assumed to be 0.58 from Ref. 8, and θ is the angle between the H–C$_\beta$–C$_{\alpha 3}$ plane and the axis of p_z orbital on the α3-carbon atom. Assuming that the methyl protons of radical I are rapidly rotating, $\cos^2\theta$ in Eq. (1) is averaged out, *i.e.*, $\langle\cos^2\theta\rangle=1/2$. As a result, a_β for the rotating methyl protons is given by the expression

$$a_\beta(CH_3) = Q_\beta \cdot \rho_\alpha. \quad (2)$$

Substitution of the values ($Q_\beta=29.3$ G and $\rho_\alpha=0.58$) into Eq. (2) gives $a_\beta=16$ G. Using these coupling constants estimated and the component lines with Gaussian shape, one obtains the computed spectrum as shown in Fig. 1c. It shows good agreement with the observed spectrum (Fig. 1b).

Maas and Volman[10] have reported the ESR spectrum of radical I produced from 1-buten-3-ol by ultraviolet irradiation; $CH_3-CH(OH)-CH=CH_2 \rightarrow CH_3-CH=CH-\dot{C}H_2+OH$. Its spectrum (7 lines with $a=15$ G) is quite similar to Fig. 1b. An ESR spectrum similar to Fig. 1b has been observed also by Morgan and White[11] in the hydrogen bombardment of BD-*h*; $CH_2=CH-CH=CH_2+H \rightarrow CH_3-CH=CH-\dot{C}H_2$.

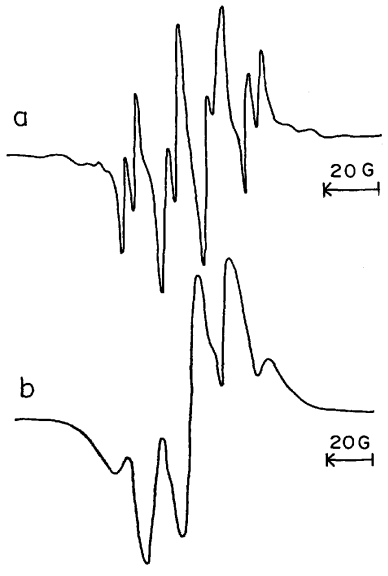

Fig. 2. ESR spectra of irradiated 1,3-butadiene–urea complexes after warming to room temperature. (a) Room-temperature spectrum. (b) 77 K spectrum.

Propagating Radical. Upon warming to room temperature, the 7-line spectrum (Fig. 1b) changed as shown in Fig. 2. The spectrum measured at room temperature (Fig. 2a) is a well resolved spectrum, consisting of 6 lines ($a_1=14$ G) which respectively further split into 2 lines ($a_2=4$ G). On cooling back to 77 K, the 6×2-line spectrum changed into a 5-line spectrum with a hyperfine splitting of 14 G (Fig. 2b). This result indicates the conversion of radical I to another radical species at elevated temperature. When the sample was warmed again to room temperature, the 5-line spectrum reverted to the 6×2-line spectrum. This reversible spectral change may be attributed to a reversible conformation change of the 5-line species with temperature as discussed later.

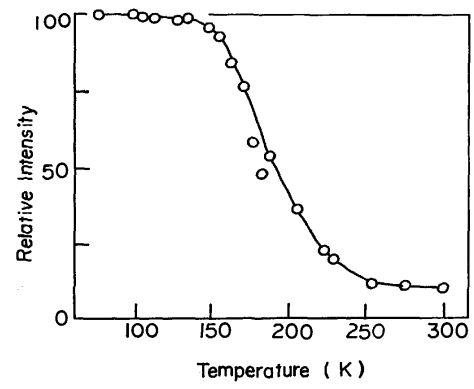

Fig. 3. Decay curve of radicals trapped in irradiated 1,3-butadiene–urea complexes.

Figure 3 shows the decay curve of radicals trapped in urea canals at 77 K. The relative intensity of the ESR signal was recorded after the sample had been annealed for 5 min at each elevated temperature. The radicals began to decay at 140—150 K and stopped decaying at 250—260 K. The radicals surviving after heat treatment up to 300 K were about 10% of the radicals initially trapped at 77 K and were stable at room temperature at least for several days.

Since White[2] has reported that the polymerization of irradiated BD-*h* in urea canals occurs at a low temperature of 195 K, the radical obtained after warming to room temperature is presumably attributable to the propagating radical (radical II) occluded in the urea canals:

$$R_I + n(CH_2=CH-CH=CH_2) \longrightarrow$$

$$R_I-(CH_2-CH=CH-CH_2)_{n-1}-\overset{\beta}{C}H_2-\overset{\alpha 3}{C}H=\overset{\alpha 2}{C}H-\overset{\alpha 1}{\dot{C}}H_2. \quad (3)$$

$$R_{II}$$

As this radical also belongs to the allyl type radical, the unpaired spin distribution is supposed to be similar to that of radical I. The α-proton coupling constants of radical II, therefor, are assumed to be the same as those of radical I, *i.e.*, $a_{\alpha 1}=a_{\alpha 3}=14$ G and $a_{\alpha 2}=4$ G. If both of the two β-coupling constants are 14 G, these five protons ($a_1=14$ G) and one proton ($a_2=4$ G) well account for the 6×2-line spectrum observed at room temperature. The computed spectrum (Fig. 4a) based upon these estimations is in good agreement with the observed spectrum (Fig. 2a).

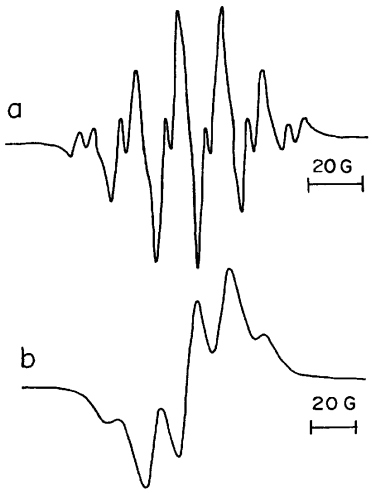

Fig. 4. Computed spectrum of the propagating radical. (a) Room-temperature spectrum. (b) 77 K spectrum.

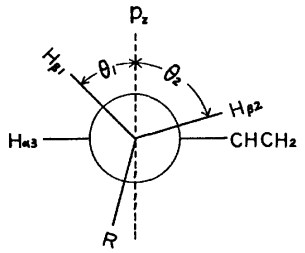

Fig. 5. Conformation of the propagating radical along the direction of the C_β–$C_{\alpha 3}$ bond.

It is well known that the coupling constants of β-methylene protons often exhibit temperature-dependent change[6c,d,12] due to hindered oscillation around the C_β–C_α bonds. At 77 K the motion of a β-methylene group in an aliphatic radical is usually considered to be almost frozen at a fixed conformation. The conformation of radical II at 77 K is depicted in Fig. 5 on the assumption of nonequivalent θ values for the two β protons ($\theta_1 \neq \theta_2$); this leads to nonequivalent β-coupling constants ($a_{\beta 1} \neq a_{\beta 2}$) from Eq. (1). Each of the a_β values can be determined by way of trial and error. When the a_β values were respectively taken to be 19 G ($\theta_1=42°$) and 5 G ($\theta_2=68°$), the appropriate computed spectrum was obtained as shown in Fig. 4b. It is to be noted that the equivalent coupling of 14 G observed at room temperature is nearly equal to the averaged value of 19 and 5 G. This strongly suggests that the two C_β–H bonds undergo rapid exchange or large amplitude oscillation about the two equilibrium positions ($\theta_1=42°$ and $\theta_2=68°$).

This equivalency of the two β-proton couplings may partly contribute to the better resolution of the room-temperature spectrum. However, partial average of α-proton anisotropic couplings due to overall rotation around the molecular chain axis of radical II would be the main cause of the sharper line width of the room-temperature spectrum; such a case has been often

reported for radicals trapped in urea canals.[13]

Radical Conversion at 400 K. When the sample was further warmed from 300 K to higher temperatures, radical II began to decay rapidly at 400 K and at the same time changed into another kind of radical. Its spectrum measured at room temperature consists of 7×2 lines ($a_1=14$ G and $a_2=4$ G) as shown in Fig. 6a, while the spectrum at 77 K consists of poorly resolved several lines (Fig. 6b). This spectral change was completly reversible with temperature in the range 77—300 K. The well resolved 7×2-line spectrum is obviously attributable to the interaction of an unpaired spin with six equivalent protons ($a_1=14$ G) and one proton ($a_2=4$ G). This indicates that the radical species is probably an allyl type radical with one more proton ($a=14$ G) than radical II.

At elevated temperature two types of reaction processes may be possible for the conversion of radical II. The one is migration of the unpaired spin site accompanied by intramolecular 1,3 and/or 1,5 hydrogen transfer through the polymer chain of radical II:

$$\sim CH_2\text{-}CH{=}CH\text{-}CH_2\text{-}CH_2\text{-}\dot{C}H\text{-}CH{=}CH_2 \longrightarrow \sim CH_2\text{-}CH{=}CH\text{-}\dot{C}H\text{-}CH_2\text{-}CH_2\text{-}CH{=}CH_2; \quad (4a)$$

$$\sim CH_2\text{-}CH{=}CH\text{-}CH_2\text{-}CH_2\text{-}CH{=}CH\text{-}\dot{C}H_2 \longrightarrow \sim CH_2\text{-}CH{=}CH\text{-}\dot{C}H\text{-}CH_2\text{-}CH{=}CH\text{-}CH_3. \quad (4b)$$

The other is hydrogen abstraction of radical II from a neighbouring polymer chain:[14]

$$R_{II} + \sim CH_2\text{-}CH{=}CH\text{-}CH_2\sim \longrightarrow \sim \overset{\beta 2}{C}H_2\text{-}\overset{\alpha 3}{C}H{=}\overset{\alpha 2}{C}H\text{-}\overset{\alpha 1}{C}H\text{-}\overset{\beta 1}{C}H_2\sim + R_{II}H. \quad (5)$$

R_{III}

All the reaction processes result in the formation of the

13) B. Birrell and O. H. Griffith, *J. Phys. Chem.*, **75**, 3489 (1971).

14) Probably, most of the walls of the urea canals are melted and destroyed by this heat treatment, because remarkable decrease of a cavity Q value which is due to loss of microwave power caused by melting urea molecules is observed for measurement at 400 K. Therefore, the reactions between polymer chains must be taken into consideration.

same "chain" allyl type radical (radical III).

At room temperature all the β-coupling constants of radical III are reasonably expected to become 14 G because of the motion of the β-methylene group as suggested in the case of radical II. The α-proton coupling constants of radical III are supposed to be similar to those of radical II; $a_{\alpha 1}=a_{\alpha 3}=14$ G and $a_{\alpha 2}=4$ G. Consequently, radical III at room temperature has these six equivalent protons ($a_1=14$ G) and one proton ($a_2=4$ G), giving the 7×2-line spectrum.

It is difficult to determine unequivocally the number of component lines from the broad spectrum measured at 77 K. The spectrum, however, agrees closely with the computed spectrum consisting of broad 7 lines ($a=15$ G) with the intensity ratios of 1:6:15:20:15:6:1, as shown in Fig. 6b by dotted lines. This indicates that radical III at 77 K has six equivalent protons with the coupling constants of about 15 G. The 15-G splitting should be due to the protons at the $\alpha 1$, $\alpha 3$, $\beta 1$, and $\beta 2$ positions and a small 4-G splitting expected from the coupling with the $\alpha 2$ proton should be smeared out by the broad line width ($\Delta H=15$ G).

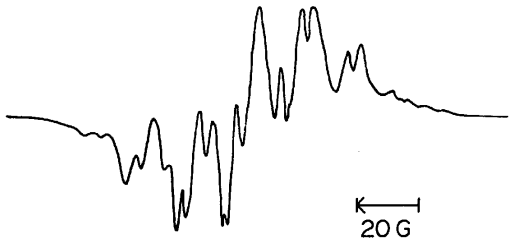

Fig. 7. ESR spectrum of irradiated trans-1,4-polybutadiene–urea complexes measured at room temperature.

It is interesting to note that a 7×2-line spectrum of Fig. 7 which is similar to Fig. 6a is obtained from irradiated *trans*-1,4-polybutadiene–urea complexes.[15] In this case, it seems probable that the radical species is formed by removal of a hydrogen atom from the polymer chain:

$$\sim\!\!\sim CH_2\text{–}CH{=}CH\text{–}CH_2\sim\!\!\sim \longrightarrow$$
$$\sim\!\!\sim CH_2\text{–}CH{=}CH\text{–}\dot{C}H\text{–}CH_2\sim\!\!\sim + H. \quad (6)$$

This results would seem to support the identification of the 7×2-line spectrum of Fig. 6a as radical III.

Recently, Shiga *et al.*[6e] found a 7×2-line spectrum similar to Fig. 6a in an irradiated single crystal of 1,3-butadiene after warming to 143 K and assigned the spectrum to the same species as radical III. The formation of radical III in the crystal was explained by a reaction mechanism similar to (4a) on the assumption of the presence of the propagating radical which was not able to be confirmed. In our case, the conclusive evidence has been obtained for the presence of the propagating radical which is stable even at room temperature. This difference with regard to radical stability might be due to the difference of crystal structure, *i.e.*, the propagating radical in the crystalline lattice of pure 1,3-butadiene might undergo rearrangement to radical III at lower temperature than that in the crystalline lattice of urea canal complexes does.

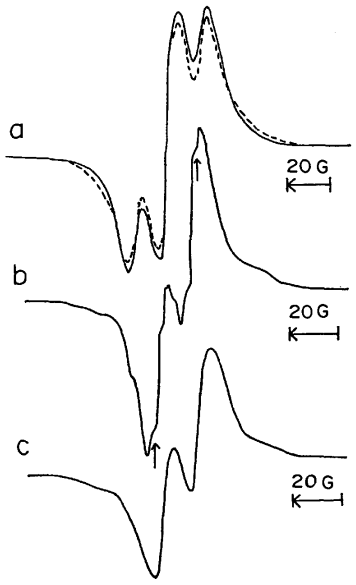

Fig. 8. ESR spectra of irradiated 1,3-butadiene-1,1,4,4-d_4–urea complexes. (a) 77 K spectrum measured immediately after irradiation. Dotted lines indicate the computed spectrum. (b) Room temperature spectrum. Arrows indicate the presence of small splittings. (c) 77 K spectrum after warming.

Radicals from 1,3-Butadiene-1,1,4,4-d_4. Using BD-*d*-urea complexes, a parallel experiment has been made in order to confirm the preceding identifications of the radicals formed in BD-*h*–urea complexes. The ESR spectrum of BD-*d* in urea canals irradiated and measured at 77 K consists of 3 lines with a hyperfine splitting of 15 G (Fig. 8a). There are two possible addition reactions for the formation of the monomer radical, *i.e.*, the hydrogen or deuterium addition to the conjugated double bond of BD-*d*. If the hydrogen addition is the case, the radical to be formed is

$$\overset{\beta}{C}HD_2\text{–}\overset{\alpha 3}{C}H{=}\overset{\alpha 2}{C}H\text{–}\dot{\overset{\alpha 1}{C}}D_2.$$
$$R_{IV}$$

The 3-line spectrum would be interpreted on the assumption; $a_{\alpha 1}{}^{H}=2.2$ G, $a_{\alpha 2}{}^{H}=4.0$ G, $a_{\alpha 3}{}^{H}=14$ G, $a_{\beta}{}^{H}=16.0$ G, and $a_{\beta}{}^{D}=2.5$ G, where the deuteron coupling constants are taken from the relation $a^{D}=0.153\ a^{H}$. The computed spectrum obtained by the use of these coupling constants is shown in Fig. 8a by dotted lines. It shows good agreement with the observed spectrum. Small splittings from the $\alpha 2$ proton and the deuterons are smeared out because of the broad line width ($\Delta H=7$ G).

On the other hand, the deuterium addition would be excluded, because the expected spectrum of the radical $CD_3\text{–}CH{=}CH\text{–}\dot{C}D_2$ consists of 2 lines from the splitting due to the $\alpha 3$ proton. These results suggest that the origin of the hydrogen added may be determined to be either urea or BD-*d* if radicals formed from BD-*d*–urea-d_4 complexes are identified as either $CD_3\text{–}CH{=}CH\text{–}\dot{C}D_2$ or $CD_2H\text{–}CH{=}CH\text{–}\dot{C}D_2$. An attempt to prepare the BD-*d*–urea-d_4 complexes, however, was not successful.

15) The complexes were prepared by storage of irradiated BD-*h*–urea complexes for several months at room temperature. Radicals trapped in the complexes almost disappeared during this storage.

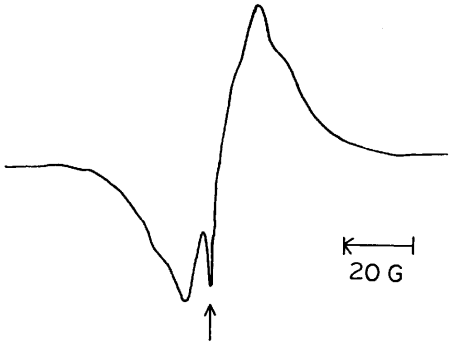

Fig. 9. ESR spectrum of polycrystalline 1,3-butadiene irradiated and measured at 77 K. A peak indicated by an arrow arises from color centers of the quartz sample tube.

It should be noted here that irradiated polycrystalline BD-*h* gives a poorly resolved spectrum at 77 K (Fig. 9) as compared with the spectrum obtained for BD-*h*–urea complexes (Fig. 1a). The formation of several types of radicals with different coupling constants may be the main cause of this poor resolution, as discussed by Shiga *et al.*[6e] Accordingly, the better resolution of Fig. 1a may be due to a selective formation of radical I in the presence of the urea molecules. The probable reaction mechanism explaining the selective radical formation would be proton transfer from the urea molecule to a butadiene anion radical which may be produced by attachment of an ejected electron:

$$(CH_2{=}CH{-}CH{=}CH_2)^- + CO(NH_2)_2 \longrightarrow CH_3{-}CH{=}CH{-}\dot{C}H_2 + CO(NH_2)(NH)^- . \quad (7)$$

Shida and Hamill[16] reported the formation of radical I in an irradiated 1,3-butadiene–methanol system and interpreted the radical formation in terms of a reaction mechanism similar to (7):

$$(CH_2{=}CH{-}CH{=}CH_2)^- + ROH \longrightarrow CH_3{-}CH{=}CH{-}\dot{C}H_2 + RO^- . \quad (8)$$

In an irradiated single crystal of fumaric acid-doped succinic acid, Iwasaki *et al.*[17] recently found the radical formed by the addition of an acidic proton of the host molecule to the fumaric acid-anion radical produced.

When the irradiated BD-*d*–urea complexes were warmed to room temperature and measured at room temperature, the 3-line spectrum at 77 K changed into a 2-line spectrum (a=14 G) with additional small splittings as shown in Fig. 8b. By this heat treatment, the formation of the propagating radical labeled by deuterium is expected from the results obtained for irradiated BD-*h*–urea complexes:

$$CHD_2{-}CH{=}CH{-}\dot{C}D_2 + (CD_2{=}CH{-}CH{=}CD_2)_n \longrightarrow CHD_2{-}CH{=}CH{-}CD_2{-}(CD_2{-}CH{=}CH{-}CD_2)_{n-1} {-}\overset{\beta}{C}D_2{-}\overset{\alpha 3}{C}H{=}\overset{\alpha 2}{C}H{-}\dot{\overset{\alpha 1}{C}}D_2 . \quad (9)$$

R_V

On cooling back to 77 K, the small splittings disappeared, while the 2-line components unchanged (Fig. 8c).

It is evident that the 14-G splitting between the 2-line components should be due to the α3 proton and the small splittings should be due to the α1 deuterons (a=2.2 G), the α2 proton (a=4.0 G), and the β deuterons (a=2.2 G). It is to be noted that the 2-line spectrum of radical V does not show noticiable temperature-dependent changes as compared with the 6×2-line spectrum of radical II. This supports the interpretation that the spectral change of radical II is caused by the temperature dependent β-proton coupligs.

An X-Ray Redetermination of the Crystal Structure of Tin(II) Chloride Dihydrate

Hideko KIRIYAMA, Katsuki KITAHAMA, Osamu NAKAMURA, and Ryôiti KIRIYAMA
The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka 565
(Received December 28, 1972)

The crystal structure of tin(II) chloride dihydrate, $SnCl_2 \cdot 2H_2O$ has been redetermined by a single crystal X-ray diffractometer technique. The crystal is monoclinic, space group $P2_1/c$ with $a=9.313$, $b=7.250$, $c=8.970$ Å, $\beta=114°55'$ and $Z=4$. The structure was solved by three-dimensional Patterson and electron density syntheses. An anisotropic least-squares refinement, based on 1695 independent reflections gave an R value of 0.04. The tin(II) atom forms a pyramidal complex with two chlorine atoms and one oxygen atom; the bond lengths in the pyramid are Sn–O, 2.33 and Sn–Cl, 2.50 and 2.56 Å and the bond angles are 86.9, 85.0, and 87.9°. These results support a view that the bonding in dichloroaquotin(II) complex is considerably ionic in character. This crystal consists of double layers of the aquocomplex, $SnCl_2 \cdot (OH_2)$, parallel to (100) with intervening layers of the second water molecules. Both kinds of the water molecules are linked together by hydrogen bonds of 2.74, 2.79, and 2.80 Å into two-dimensional networks. The structure reported previously was found to be in error, although its essential feature was quite similar to the present one.

The crystal structure of $SnCl_2 \cdot 2H_2O$ has been analysed by Kamenar and Grdenić (hereinafter abbreviated as K & G) in 1961.[1] According to their description, the crystal consists of dichloroaquotin(II) complexes and the second water molecules, both of which form alternate layers parallel to the (100) plane and are linked through hydrogen bonds alone. Such an arrangement of the water molecules, especially their hydrogen bonding scheme, strongly suggested the presence of dielectric anomaly similar to those found in copper(II) formate tetrahydrate[2] and also in potassium ferrocyanide trihydrate.[3] Recently, Kiriyama and Kiriyama have found a phase transition at −55 °C from dielectric measurements of this compound and have investigated its mechanism from many approaches such as electric conductivities, thermal analyses, X-ray diffractions, proton and deuteron magnetic resonances (PMR and DMR).[4]

On the basis of these results the phase transition could be ascribed to the ordering of hydrogen atoms within the layer of hydrogen bonded water molecules. However, it was noticed that our PMR and DMR data could not provide consistent locations of the hydrogen atom positions, so far as the crystal structure described by K & G was used. It was therefore thought profitable to redetermine the structure by use of a three-dimentional single crystal X-ray diffractometer, because the previous structure had been derived from incomplete data.

Experimental

Single crystals were prepared from about 18% hydrochloric acid saturated with tin(II) chloride, this being the best condition to obtain large transparent single crystals for NMR and dielectric measurements. The crystal used for the present X-ray work was a monoclinic prism of length 0.50 mm (the c-axis direction) and cross-section 0.08×0.10 mm^2. It was sealed in a Lindeman glass capillary to protect from atmospheric moisture. With the c-axis as the Φ-axis of the instrument, a set of intensity data was collected by use of a Rigaku automatic four-circle diffractometer with Mo$K\alpha$ radiation and the 2θ-ω scan technique. A total of 1695 independent reflections was measured up to a $\sin\theta/\lambda$ limit of 0.72 Å^{-1}. Their intensity data were corrected for polarization and Lorentz effects, but absorption correction was neglected becauce of the small μR value of 0.26.

Unit Cell and Space Group

The systematically absent reflections, $(0k0)$ with k odd and $(h0l)$ with l odd, confirmed the monoclinic space group of $P2_1/c$ originally derived by K & G. The cell dimensions were:

$a=9.313$, $b=7.250$, $c=8.970$Å, $\beta=114°55'$, $V=549.275$Å^3.

The calculated density of 2.707 g cm^{-3}, assuming a unit cell content of four formula units, agreed well with the value of 2.710 g cm^{-3} measured by K & G.

Structure Analysis and Refinement

Fourier syntheses of the three main projections were computed starting from the atomic coordinates given by K & G. The [010] and [001] projections were roughly consistent with their description of structure, while the [100] projection was in quite disagreement. Therefore, three-dimensional Patterson functions were calculated from 1695 reflection data and from this it became evident that all atoms, of course except hydrogens, were located incorrectly. This finding forced us to redetermine the crystal structure of this compound, instead of its refinement.

The tin and chlorine positions could be easily derived from the three-dimensioanl Patterson map, and the oxygen's were located from successive electron density calculations. New parameters thus obtained were used in a block-diagonal least-squares refinement. After four cycles of refinement in which were varied the coordinates, the individual isotropic temperature factors for all non-hydrogen atoms, a scale factor and an over-all temperature factor (a total of 22 parameters), the "discrepancy index" $R=\sum||F_o|-|F_c||/\sum|F_o|$ was

reduced to 0.063 for the observed reflections (0.068 including 47 unobserved reflections). At this stage of the refinement the structure obtained was checked by a three-dimensional (F_o-F_c) synthesis, which showed no ripple of more than $8e/Å^3$. Further refinements were computed with five cycles of least-squares calculations, which now included anisotropic temperature factors for tin, chlorine, and oxygen. The other parameters varied were the same as before; the total number was 47. During the last cycle, the shifts in coordinate or thermal parameter values were less than one tenth of the standard deviation for the parameter in question. The R value was now 0.040.

The atomic coordinates and the thermal parameters with their standard deviations obtained from the final anisotropic least squares refinement are listed in Tables 1 and 2. The observed and calculated structure factors are compared in Table 3. The atomic scattering factors used in the above calculations were those for neutral Sn, Cl, and O, respectively, given in International Tables Vol. III. All calculations were performed on the NEAC 2200/500 in the Computer Center Osaka University, using UNICS computer programs, HBLS-LV, RSSFR-5 and RSDA-4.

Description and Discussion of the Structure

The crystal structures projected along [100] and [010] are given in Figs. 1 and 2, respectively. It can be seen that tin(II) chloride dihydrate has a predominant layer-structure parallel to the (100) plane; it is built up from double layers of the dichloroaquotin (II) complex and intervening layers of the second water molecules. Apart from van der Waals forces, these layers are held together by hydrogen bonds. Such a description of the structure appears to be the same as the earlier one. However, the projection along the a axis given in Fig. 1 is largely different from that reported by K & G. It is conceivable that the lack of the [100] projection led the previous work to the erroneous conclusion. Both the structures are compared in Fig. 3, where only the aquocomplex double layers are shown for simplicity.

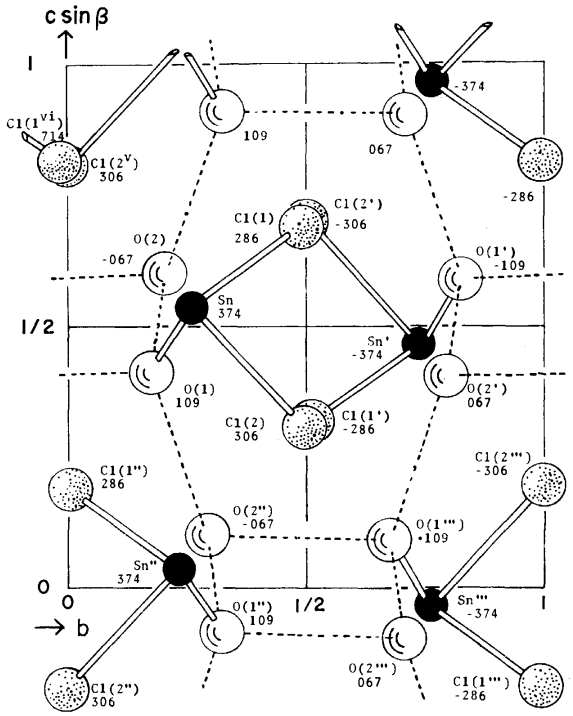

Fig. 1. The crystal structure viewed along the a axis. Hydrogen bonds are indicated by broken lines.

The main interatomic distances and bond angles with the corresponding estimated standard deviations are listed in Table 4, some of them are also shown in Figs. 4 and 5. These values are based on the parameters listed in Table 1. No correction for thermal motions was made.

Structure and Bonding of Dichloroaquotin(II) Complexes

A geometry of the tin(II) coordination is somewhat different from the previous one. The dimensions of the trigonal pyramid, $SnCl_2(OH_2)$ complex, are illus-

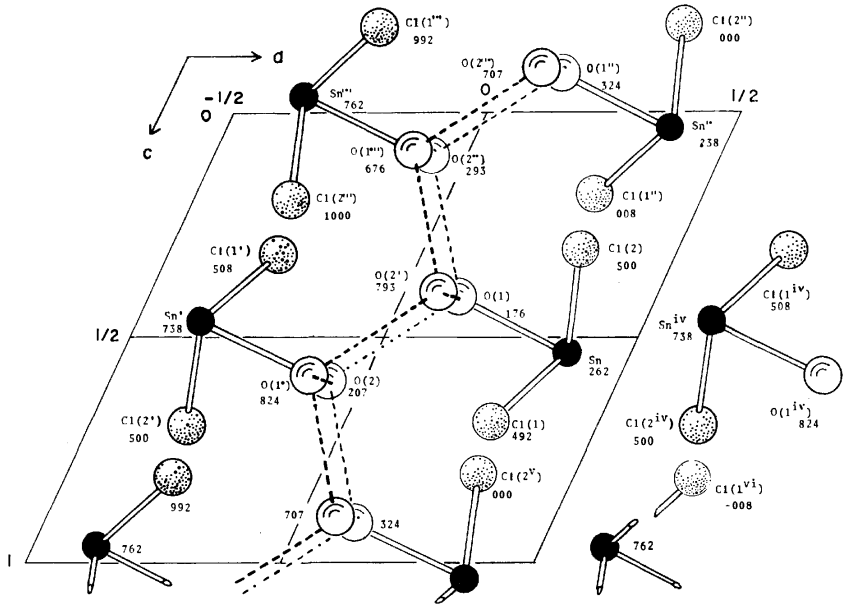

Fig. 2. The crystal structure viewed along the monoclinic *b* axis. Broken lines indicate hydrogen bonds.

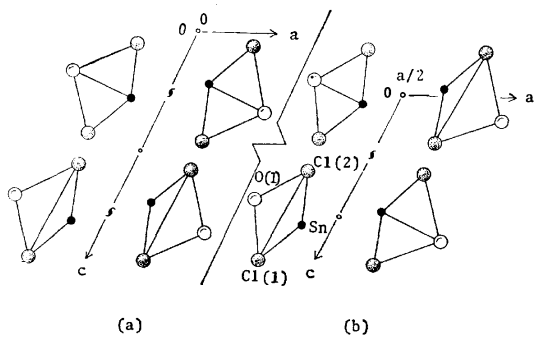

(a) (b)

Fig. 3. Comparison of the earlier structure (a) with the present one (b).

trated in Fig. 4. The tin atom is bonded to two chlorine atoms at distances of 2.50 and 2.56 Å and one oxygen atom at a distance of 2.33 Å; its pyramidal angles are 87.9, 86.9, and 85.0°. Four additional chlorine atoms at distances of 3.21, 3.34, 3.42, and 3.64 Å complete an environment of the tin atom (Table 4(b)). The difference between the two Sn–Cl bond lengths in each pyramid, 0.06 Å, is significantly large, this being thirty times the standard deviation. This might be reasonable if the effects of the lone-pair electrons of a tin atom in the adjacent complex and possibly of the hydrogen bonds are different for two chlorine atoms. The average Sn–Cl distance of 2.53 Å

Table 4. Distances (Å) and angles (°) in $SnCl_2 \cdot 2H_2O$ (Standard deviations in parentheses)

(a)	In the aquocomplex $SnCl_2(OH)_2$			
	Sn–Cl (1)	2.500 (2)	Cl (1)–Sn–Cl (2)	87.85 (8)
	Sn–Cl (2)	2.562 (2)	Cl (1)–Sn–O (1)	84.96 (14)
	Sn–O (1)	2.325 (5)	Cl (2)–Sn–O (1)	86.86 (13)
(b)	On other side of the Sn atom			
	Sn–Cl (1″)	3.416 (3)	Sn–Cl (1^{VI})	3.654 (2)
	Sn–Cl (2^{IV})	3.209 (2)		
	Sn–Cl (2^{V})	3.336 (2)		
(c)	Around the water oxygen atoms			
	O (1)–O (2)	2.800 (9)	O (2′)–O (1‴)–O (2‴)	109.80 (23)

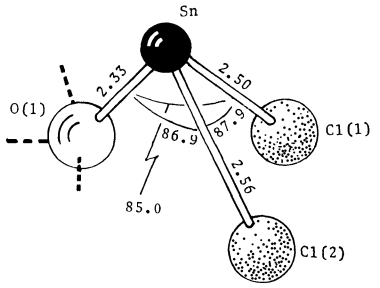

Fig. 4. The geometry of trigonal pyramid, $SnCl_2(OH)_2$ in $SnCl_2 \cdot 2H_2O$.

is close to those of 2.54, 2.54, and 2.63 Å for $K_2SnCl_4 \cdot H_2O$ and also of 2.50, 2.52, and 2.55 Å for $CsSnCl_3$, both of which contain pyramidal trichlorotin(II) complex ions.[5,6]

Molecules of anhydrous tin(II) chloride, $SnCl_2$, in the vapor phase are bent with a bond angle of 95° and with lengths of 2.42 Å.[7] In contrast with these, the tin atom in the crystalline state forms a pyramid with three chlorine atoms at 2.67, 2.78, and 2.78 Å and with Cl–Sn–Cl bond angles 78.0, 79.6, and 79.6°. It is noted here that three additional chlorine atoms at 3.06, 3.18, and 3.28 Å from the tin atom complete the distorted octahedron.[8] The increase in the Sn–Cl bond length of the molecular form must imply an increase in ionic character of this bond. A comparison of these coordinations of the tin atoms with that of $SnCl_2 \cdot 2H_2O$ indicates that an ionicity of the Sn–Cl bond in dichloroaquotin(II) complex molecules is less than that in the anhydrous crystal. This view is supported by ^{119}Sn Mössbauer studies, which have shown that the isomer shifts for the tin(II) atoms in $SnCl_2 \cdot 2H_2O$ and $SnCl_2$ are +(1.30—1.70) and +(2.40—2.50) mm/sec respectively (relative to α-Sn), as compared with a calculated value of +5.6 mm/sec for the hypothetical Sn^{2+} ion.[9]

On the other hand, the Sn–O bond length in the dichloroaquotin(II) complex was found to be 2.32 Å which was larger than the previous value (2.16 Å) given by K & G and also longer than that (2.21 Å) in tin(II) oxide.[10] A recent X-ray work on $KSn(HCOO)_3$ has shown that $Sn(HCOO)_3^-$ ions have again pyramidal configurations with Sn–O distances of 2.14, 2.17, and 2.18 Å and with bond angles of 78.4, 82.9, 83.2°.[11] A comparison of these values suggests that the Sn–O bond in the $SnCl_2(OH_2)$ complex is not essentially covalent, or at least less covalent than those in $KSn(HCOO)_3$ and SnO. However, it must be pointed out that the tin(II) atom in $SnSO_4$ has also a definite pyramidal three coordination with Sn–O bond distances of 2.27, 2.27, 2.25 Å and O–Sn–O angles of 79.0, 77.1, 77.1.[12]

The pyramidal bond angles of 85.0, 86.9, and 87.9° for $SnCl_2 \cdot 2H_2O$ are considerably less than the tetrahedral value required by the sp^3 hybrid configuration, as observed in many tin(II) compounds. Such the pyramidal three coordination of the tin atom can be explained in terms of strong repulsion between lone pair and bond pair from the covalent viewpoint or in terms of an unsymmetrical crystal field distorsion from the electrostatic viewpoint. The experimental values of the bond lengths precisely determined as well as the Mössbauer isomer shift support the idea that the bonding in the dichloroaquotin(II) complex is considerably ionic in character.

Arrangement of the Hydrogen Bonds

Figure 5 shows interatomic distances and bond angles concerning two kinds of the water molecules, one of which, $H_2O(1)$, is coordinated with the tin atom and the other $H_2O(2)$ is not so. Both water oxygen atoms have approximately tetrahedral configurations. These coordinations suggest that one of the lone pairs of oxygen O(1) is specifically directed toward the tin atom and the other is toward a hydrogen bond donor oxygen, namely $H_2O(1)$ is of type H according to the classification by Chidambaram *et al.*[13] Whereas, the water molecule $H_2O(2)$ is probably of type E with the two lone pairs directed toward two hydrogen bond donor oxygens.

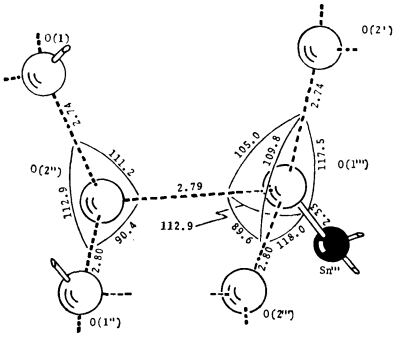

Fig. 5. The coordination of two kinds of water molecules.

The most striking feature of the structure is the arrangement of these water molecules, in particular their hydrogen bonding scheme. Different types of the water molecules are alternately connected by hydrogen bonds and the resulting sheets run parallel to (100) planes throughout the structure (Fig. 2). As mentioned earlier, this compound undergoes the phase transition with sharp peaks of the dielectric constant and the DC conductivity at −55 °C.[4] The remarkable dielectric dispersion observed in the high temperature phase, only when the electric field is applied in the (100) plane, can easily be understood on the basis of the

present structure. Thus, in combination of the NMR results the phase transition can be interpreted in terms of the order-disorder model of the hydrogen atoms within the two-dimentional network of O–H—O hydrogen bonds.

It is interesting to note that there are only three O–H···O hydrogen bonds with distances of 2.736, 2.794, and 2.800 Å and with O··O··O angles near the tetrahedral angle against four available protons of two non-equivalent water molecules. Direct location of these hydrogen atoms was studied by proton and deuteron magnetic resonance and also neutron diffraction experiments.[14,15] These results confirmed our expectation that the hydrogen atom free from the O–H···O bonds should be directed toward one or two chlorine atoms. The further details will be published soon.

As given in Table 2, thermal parameters for all atoms are noticeably large, indicating large thermal motion. Actually this crystal dissolves in its own water of crystallization at about 40 °C.

In passing through the transition and also on deuterium substitution, no significant change in the non-hydrogen atom positions could be detected from the X-ray and the subsequent neutron diffraction works. At the transition point, however, the layer spacing, $a\sin\beta$, of $SnCl_2 \cdot 2H_2O$ did reduce suddenly by an amount of 0.02 Å and the line profiles of all (h00) reflections in the low temperature phase became broader, their half widths being twice the corresponding ones in the high temperature phase.

(Received January 20, 1973)

The molecular structure of nortricyclene (tricyclo[2.2.1.$0^{2,6}$]heptane) has been studied by gas phase electron diffraction. The average values of the bond distances and their limits of error are: r_g(C–C)$=1.532\pm0.003$ Å and r_g(C–H)$=1.11_4\pm0.01_1$ Å. It is further shown that $r_g(C_3–C_4)=1.55_4\pm0.01_3$ Å, $r_g(C_1–C_2)+r_g(C_2–C_3)=3.04_2\pm0.01_0$ Å, and $\angle C_1–C_7–C_4=96.9\pm0.5°$.

As a part of the structure studies of polycyclic molecules,[1] we have recently determined the structures of norbornane (bicyclo[2.2.1]heptane)[2] and quadricyclene (tetracyclo[2.2.1.$0^{2,6}$.$0^{3,5}$]heptane)[3] by gas electron diffraction. These two compounds have considerably different $C_1–C_7–C_4$ angles, $93.1\pm1.7°$ and $98.5\pm2°$, respectively. Nortricyclene (tricyclo[2.2.1.$0^{2,6}$]heptane), placed between the above molecules, forms a sequence of increasingly strained compounds (Fig. 1); the strain energies are estimated to be about 18, 45, and 100 kcal/mol for norbornane, nortricyclene, and quadricyclene, respectively.[4,5] The solvolytic reactivity of 3-bromonortricyclene is about equal to that of *endo*-3-substituted norbornane and very much less than that of *exo*-3-substituted norbornane.[6]

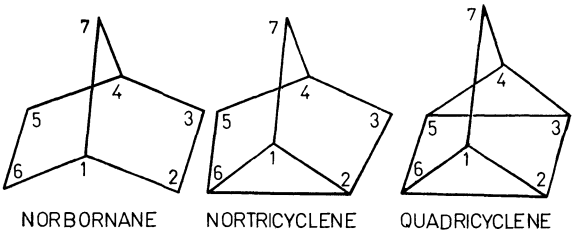

Fig. 1. a) Norbornane, b) Nortricyclene, c) Quadricyclene.

The molecular geometry of nortricyclene was first studied by the visual electron diffraction method by Heilbronner and Schomaker.[7] They determined the average C–C bond distance to be 1.527 Å and showed that the $C_2–C_3$ and $C_3–C_4$ distances have normal values (about 1.54 Å) if the $C_1–C_2$ distance is close to that in cyclopropane (about 1.50 Å). They also estimated the $C_1–C_7–C_4$ angle to be 96.5° with a limit of error of about 2°. One of its derivatives, 4-chloro-

nortricyclene, has recently been investigated by electron diffraction[8] and by microwave spectroscopy.[9] The present study aims to supply further information on the structure of nortricyclene.

Experimental

A sample of nortricyclene (bp 108—110 °C) with less than 3% impurity, most of which was norbornene, was kindly supplied by Professor I. Tabushi of Kyoto University.[10] Diffraction experiments were carried out at 20 °C with a sample pressure of 30 Torr. Three diffraction photographs taken with 40 kV electrons at a camera length of 107.73± 0.01 mm were analyzed.[11] Diffraction photographs of CO_2 were used for calibration. The molecular intensity curves and the radial distribution curves (Figs. 2, 3) were obtained by standard procedures[12] in the q range from 25 to 120 Å^{-1}.

12) Numerical experimental data of the leveled total intensity have been deposited with the Chemical Society of Japan (Document No. 7311).

Analysis

The data were analyzed under the following assumptions:

1) The molecule has C_{3v} symmetry.
2) All C–H bond lengths are equal.
3) Angle H–C–H equals 110°, the angle in norbornane.[2]
4) The H–C_i–H and C–C_i–C angle bisectors (i= 3, 5, 7) are colinear.
5) The methine C–H bonds make equal angles with the adjacent C–C bonds.
6) Vibrational mean square amplitudes and shrinkage corrections (r_a-r_α)[2,13] were calculated from a reasonable set of Urey-Bradley force field parameters (Table 1) and held constant. The calculated values are listed in Table 2.

Table 1. Urey-Bradley force field parameters assumed for nortricyclene[a]

K_{CC}	2.2	H_{CCC}	0.3	$F_{C\cdots C}$	0.2
K_{CH}	4.0	H_{CCH}	0.2	$F_{C\cdots H}$	0.5
		H_{HCH}	0.43	$F_{H\cdots H}$	0.05

a) The units of K and F are md/Å and of H are md. The estimated force constants are taken from Table 1 of Ref. 2 and modified slightly.

Table 2. Calculated mean amplitudes (l_{ij}) and shrinkage corrections (d_{ij}) for nortricyclene[a] (10^{-4}Å)

$C_1\cdots C_4$	586	−1	$C_1\cdots H_4$	947	20
$C_3\cdots C_5$	721	−5	$C_5\cdots H_{7a}$	1016	34
$C_1\cdots C_3$	665	−4	$C_5\cdots H_{7b}$	1537	−23
$H_{7a}\cdots H_{7b}$	1302	120	$C_6\cdots H_{7a}$	1019	30
$C_1\cdots H_2$	1025	56	$C_6\cdots H_{7b}$	1441	−11
$C_3\cdots H_2$	988	60	$C_4\cdots H_2$	929	37

a) The amplitudes and shrinkage corrections[2] (r_a-r_α) calculated for 20 °C.

7) The asymmetry parameter κ for the C–H bond was assumed to be 1.0×10^{-5} Å^3, and the rest of the κ parameters were ignored.[14]

Under the above assumptions the structure is defined by five parameters: the C_1–C_2 (r_1), C_2–C_3 (r_2), C_3–C_4 (r_3) and C–H (average) distances (r_g) and angle C_1–C_7–C_4 (θ defined in the r_a structure[13]). The constraint that all the C–C bond distances were equal was added initially and the average bond distances were determined by a least squares analysis.[15] The best estimates and limits of error were: $r_g(C\text{–}C)_{av}=1.531_8\pm0.002$ Å and $r_g(C\text{–}H)_{av}=1.114\pm0.011$ Å, and the effective C–C

C–H_{av}			34	−14	22
$\angle C_1$–C_7–C_4				23	−32
k					124

a) Defined in Ref. 16. Units of distances, angle and index of resolution (k) are 10^{-4} Å, 10^{-4} rad. and 10^{-4}, respectively.

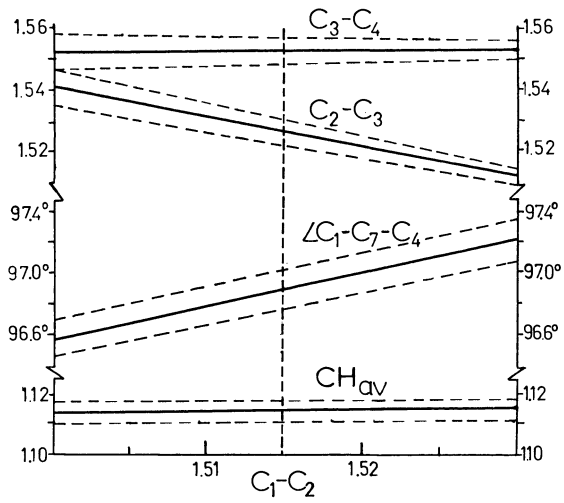

Fig. 4. Correlation of refined parameters with C_1–C_2 in nortricyclene. The vertical dashed line indicates the most probable structure. See text.

mean amplitude was 0.0549±0.003 Å.

Then the constraint of equal C–C distances was released. A series of least squares analyses showed that our experimental data contained information to determine four structural parameters. Thus the r_1 parameter was fixed to several different values, and the rest of the parameters were refined. A typical error matrix[16] is given in Table 3. The most probable estimates of the varied parameters do not depend on the choice of their initial values, but they are not necessarily independent of the choice of r_1. The dependence of the refined parameters on r_1 is shown in Fig. 4 where the value of each parameter bracketed by one standard deviation is plotted against r_1. The r_3 and the C–H_{av} distances are nearly independent of r_1, but the r_2 distance and θ vary linearly with r_1, so that the following equations are found to exist:

$$r_1 + r_2 = 3.04_2 \pm 0.01_0 \text{ Å} \quad (1)$$

$$\theta = 96.8_6 \pm 0.4 + 20(r_1 - 1.515)° \quad (2)$$

The above relations were also confirmed by examination of the weighted sum of squared residuals, $\boldsymbol{V'PV}$, determined for each model. The sum forms a deep valley in the parameter hyperspace along the path defined by Eq. (1). $\boldsymbol{V'PV}$ varies very slowly along that path and forms a shallow minimum at $r_1 \sim 1.51_5$ Å. The parameter values corresponding to this r_1 value are listed in Table 4. The observed intensity and

a) The distances are r_g and the angles are derived from the thermal average (r_a) structure.
b) The errors are 2.5 times a standard deviation derived from a combination of constraint, least squares and scaling errors (See text and Table 5). The values proportional to a indicate the correlation of each parameter with the value of C_1–C_2. The estimated upper limit of a is 0.015 Å.
c) r_a structure. Ref. 7.
d) Dependent parameter values calculated from the structure determined in the present study.

radial distribution curves and those calculated from the best model agree with each other within experimental error (Figs. 2 and 3).

The error limits given in Table 4 contain contributions from several sources: (a) Most of the errors due to constraints 2) through 7) listed above are small compared to the least squares standard errors, as listed in Table 5. They are assumed to be the changes in the refined parameter values caused separately by: (1) allowing the methine C–H distance to be 0.01 Å less than the methylene distance, (2) changing angle H–C–H by 3°, (3) displacing the H–C_i–H angle bisectors by 2° from their respective C–C_i–C angle bisectors toward C_4, (4) bending the methine C–H bond 3° away from the three-fold axis, (5) increasing each vibrational amplitude uniformly by 5%, (6)

f) Ref. 9. The distances and angles are derived from Kraitchman's equation.

diminishing each shrinkage correction by 10% and (7) changing the C–H asymmetry parameter by 30%. (b) The reproducibility of each of the refined parameters among the three plates was less than or equal to the least squares standard deviation. (c) As for the effects of the above assumptions on the separate analysis of the r_2 and r_3 distances, the mean amplitudes of the C–C bonds (5) are the only important source of error. When the three C–C amplitudes were increased uniformly by 5%, the least squares values for the r_2 and r_3 distances were changed by 0.006 Å and −0.007 Å, respectively. (d) An estimated standard error[17] of 0.04% in the scale factor was counted. (e) The square root of the sums of squares of the above errors was multiplied by 2.5 to give the error limit listed after each parameter in Table 4.

With reference to the r_a(C–C) distances in cyclopropane,[18] 1.510±0.002 Å and in 4-chloronortricyclene,[8] 1.510±0.016 Å, r_1 is assumed to be 1.515± a Å, where the upper limit of a is estimated to be 0.015. The second error limit proportional to a, listed separately in Table 4, accounts for the uncertainty in r_1 and the effects of the correlation among the parameters shown in Fig. 4. Thus the final estimates of the r_2 and θ parameters are 1.53±0.02 Å and 96.9± 0.5°, respectively.

It should be mentioned that the above assignment of the radial distribution peak at 2.4 Å is not unique. This peak is mainly composed of the three nonbonded C–C distances: C_1-C_3, C_1-C_4, and C_3-C_5, and an alternative assignment corresponding to θ equal to 105.3°, instead of 96.9°, is also consistent with the electron diffraction data, as Heilbronner and Schomaker pointed out.[7] They noted, however, that the force field consistent with such an equilibrium structure does not compare reasonably with force fields of related molecules. Further evidence that this assingment is hardly acceptable is given by a comparison of this angle with the corresponding angle in 4-chloronortricyclene (Table 6). In the chloro compound the microwave rotational constants[9] allow no ambiguity of this sort, and the C–C assignment in the electron diffraction study[8] is also less ambiguous than in nortricyclene.

Discussion

The nortricyclene structure reported by Heilbronner and Schomaker[7] has been confirmed to be accurate to within their reported limits of error (Table 4). The present study has considerably increased the accuracy of the molecular intensity and of the structural parameters. The average C–C bond length, 1.532±0.003 Å, is nearly equal to the corresponding average value for 4-chloronortricyclene, 1.527±0.003 Å (r_a)[8] or 1.530 Å (r_0).[9] It is considerably shorter than the average bond length in norbornane,[2] 1.549±0.003 Å, but not significantly different from the value in quadricyclene,[3] 1.529±0.003 Å. This reflects the effect of formation of a cyclopropane ring, with its relatively short bonds, in the transformation from norbornane to nortricyclene. In the transformation from nortricyclene to quadricyclene, however, there seem to be balancing effects of formation of a cyclobutane ring, with its relatively long bonds, and that of another cyclopropane ring. The C_3-C_4 bond, 1.55_4 Å, is longer than C_2-C_3, 1.52_7 Å, and appears to be only slightly longer than the value in cyclopentane, 1.546±0.001 Å.[19] The C_2-C_3 bond seems to be similar to the r_s value, 1.522 Å, found in methylcyclopropane.[20] Bond angles determined in the present study agree reasonably well with the corresponding angles in the chloro compound. Angle $C_1-C_7-C_4$ increases regularly among norbornane, nortricyclene and quadricyclene. A more precise deter-

(Received October 17, 1972)

Deuterated methyl ethyl sulfides, $CD_3SCH_2CH_3$ and $CH_3SCD_2CD_3$, were prepared, and their infrared spectra were recorded in the gaseous, liquid, and solid states. The normal coordinates of methyl ethyl sulfide, its deuterated analogues, and diethyl sulfide have been treated by the use of a modified Urey-Bradley potential field. The conformational analyses of these sulfides were made by the aid of the calculations. In the gaseous and liquid states, two forms (T and G) have been confirmed to exist for $CH_3SCH_2CH_3$, and three forms (TT, TG, and GG), for $CH_3CH_2SCH_2CH_3$. In the solid state, $CH_3SCH_2CH_3$ or $CH_3CH_2SCH_2CH_3$ exists in one form: T or TT. The observed infrared frequencies were compared with the calculated frequencies and were fully assigned.

In our previous papers, we reported the infrared spectra of methyl ethyl sulfide[1] and diethyl sulfide;[2] we postulated two and three conformations for methyl ethyl and diethyl sulfides respectively. However, we could not assign all of the infrared bands observed in the CH_3 rocking, CH_2 deformation, and C–S stretching regions. The purpose of this paper is to make the full assignments of the infrared bands of these sulfides, and to determine the skeletal conformations of methyl ethyl and diethyl sulfides. In order to confirm the vibrational assignments, the normal coordinates have been treated for these molecules. The vibrational analysis has also been extended to deuterated methyl ethyl sulfides: $CD_3SCH_2CH_3$ and $CH_3SCD_2CD_3$.

Vibrational Assignment

Deuterated methyl ethyl sulfides were prepared from CD_3I and CH_3CH_2SH, and from CD_3CD_2Br and CH_3SNa. The method of infrared recording and the instrument used have been described previously.[1] Both samples are contaminated with a very small amount of the normal species. The obtained infrared data are summarized in Tables 1 and 2. The spectra of $CD_3SCH_2CH_3$ are more complicated than those of the normal species. The spectra of $CH_3SCD_2CD_3$ are the most complicated of the three. The observed bands of annealed films are well resolved in both deuterated species. The assignments of the observed bands were made on the basis of the band intensities, band envelopes, and normal coordinates.

Methyl Ethyl Sulfide-d_3. The bands of the methyl group which is bonded to the sulfur atom are shifted directly upon deuteration. The two CD_3 degenerate deformation bands are expected around 1050 cm^{-1}. In this frequency region, we observed fairly complex band peaks. The bands at 1045 and 1040 cm^{-1} in the liquid state are assigned to the CH_3 rocking and the CD_3 degenerate deformation vibrations with reference to the band intensities. The CD_3 symmetrical deformation band is expected around 950 cm^{-1}, while the two CD_3 rocking vibrations are expected around 750 cm^{-1}. We observed some bands in the expected regions and assigned these bands as is shown in Table 1, although the assignments are not straightforward. Below 1400 cm^{-1}, in particular below 800 cm^{-1}, over half of the bands disappear in the solid state. Most of the disappearing bands may be related to the rotational isomerism.

Methyl Ethyl Sulfide-d_5. The ethyl-group vibrations are shifted to a lower frequency region upon deuteration. The other bands except for the C–C stretching band are not so much affected upon deuteration. For this species, the bands observed below 1100 cm^{-1} are very complex. According to the result of the normal-coordinate calculation, each of the normal coordinates can be said to be fairly well coupled with one another—in particular in the CD_3 and CD_2 deforma-

tion regions. However, the bands arising from CH_3 and CD_2CD_3 groups are fairly well separated.

Normal Coordinate Treatment

We made the normal coordinate treatment for four species: $CH_3SCH_2CH_3$, $CD_3SCH_2CH_3$, $CH_3SCD_2CD_3$, and $CH_3CH_2SCH_2CH_3$. The molecular parameters used in the computations were: r(C–H) or r(C–D)=1.09 Å, r(C–S)=1.81 Å, r(C–C)=1.54 Å, and ϕ(CSC)=99°; the other bond angles were assumed to be tetrahedral. The force field used was the Urey-Bradley type potential modified by some interactions. The correction terms were: p, p', p'', n, n', t, g, t', g', t'', g'', and l. The corrections of p, p', n, t, and g have been explained in the first paper of this series.[3] The additional corrections were the bond-interaction constant, p'', between the C–S and C–C bonds; the angle interaction constant, n', between the CCH (or CCD) and HCH (or DCD) angles in the methyl group bonded to the carbon atom; the *trans* and *gauche* coupling constants, t' and g', between the CCH (or CCD) and SCC angles in the methyl group bonded to the carbon atom; the *trans* and *gauche* coupling constants, t'' and g'', between the methylene HCC (or DCC) and methyl CCH (or CCD) angles in the ethyl group, and the angle-interaction constant, l, between the SCH and HCC (or DCC) angles or the CCH (or

* See text. a) c, solution-bands. b) A_2 species in parentheses.
The other notations are the same to Table 4.

The constants of p', p'', n', t', g', t'', g'', and l were assumed to be reasonable in value. It has been supposed that the potential constants are common for all species. The obtained set of the force constants is listed in Table 3. The calculated frequencies of methyl ethyl and diethyl sulfides are summarized in Tables 4—7, together with the observed frequencies.

Molecular Forms. We may suppose two forms, T (C_s) and G (C_1), on methyl ethyl sulfide and three forms, TT (C_{2v}), TG (C_1), and GG (C_2), on diethyl sulfide. Since the GG′ form of diethyl sulfide may have a higher energy than the other forms, we excluded this form from the conformational analysis of diethyl sulfide. The analysis of the molecular forms is made mainly on the bands observed in the CH_2 (or CD_2) rocking, C–S stretching, and skeletal deformation regions. Considering the numbers of the bands which remain in the crystalline films, we may conclude that methyl ethyl and diethyl sulfides exist in one form in the solid state. For methyl ethyl sulfide and the deuterated analogues, the frequencies calculated for the T form correspond well to their solid bands. For

diethyl sulfide, the frequencies calculated for the TT form agreed well with their solid bands. We may, therefore, conclude that the stable forms in the solid state for methyl ethyl and diethyl sulfides are the T and TT forms respectively. The results are in accord with the previous results.[6-9]

In the liquid-state or gaseous-state spectra, we observed more bands than would be expected for one conformation. The bands which disappear in the solid state of methyl ethyl sulfide and its deuterated species correspond well with the frequencies calculated for the G form. For diethyl sulfide, the bands at 1425, 1272, 1066, 971, 782, 762, 696, 638, 384, 306, and at 260 cm^{-1}, which disappear in the solid state, agreed well with the frequencies calculated for the TG form. We still have several bands remaining unassigned in the liquid or gaseous spectra of diethyl sulfide: one band in the CH_3 rocking region, one to three bands in the C–C stretching region, two bands in the CH_2 rocking region, and two to four bands in the skeletal deformation regions. It is unlikely that all of these bands are due to overtones or sum-combinations. Most of these bands correspond well with the frequencies calculated for the GG form. We, therefore, assigned most of these bands to the vibrations of the GG form.

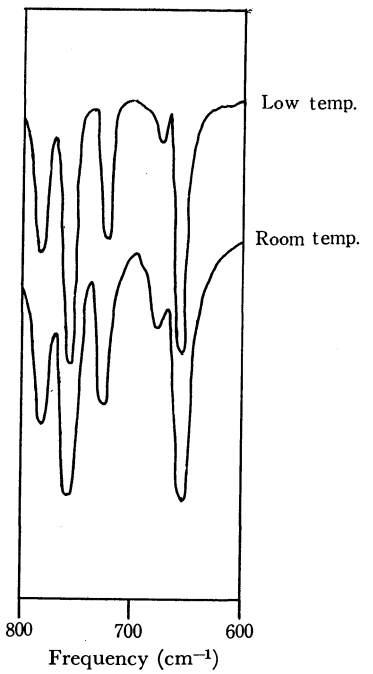

Fig. 1. Infrared spectra of methyl ethyl sulfide in the 800—600 cm^{-1} region observed in the liquid state.

Discussion

Perchard[10] made the vibrational analyses of eight isotopic species of methyl ethyl ether. He concluded that two forms, T and G, exist at room temperature, the former being more stable, and the T form in the solid state, and that the energy difference between the two forms in the liquid state is *ca.* 1.35 kcal/mol. For methyl ethyl sulfide, the intensities of the bands at 783 and 676 cm^{-1} decrease upon cooling, as is shown in Fig. 1. The low-temperature spectrum was recorded at a temperature slightly above its melting point. These bands correspond well to the frequencies calculated for the G form. Thus, the G form is the less stable conformation in the liquid state. The conformations of sulfides correspond well with those of ethers. For methyl isopropyl sulfide,[11] we previously obtained the energy difference of *ca.* 1—1.5 kcal/mol. We suppose that the energy difference for methyl ethyl sulfide is *ca.* 1 kcal/mol.

Recently, Scott and El-Sabban[12] made the normal coordinate treatment for diethyl sulfide, and concluded that the GG form has too much energy to exist as the stable form. Moreover, Snyder and Zerbi[13] and Wieser *et al.*[14] have treated the vibrational spectra and normal coordinates for diethyl ether, and have denied that diethyl ether exists in the GG form with stability. Wieser *et al.* assumed that diethyl ether exists in the TT and TG conformations at room temperature; the TT form is more stable than the TG form by *ca.* 1.1 kcal/mol. They also suggested that the C–H···O intramolecular hydrogen bond stabilizes the TT form. On the other hand, Snyder[15] reported a few of the bands due to the GG conformation for *n*-pentane. He also suggested that the TG form is more stable than the GG form, although there is not so much energy difference between the TG and GG, and TT and TG conformations; the stability is in the order of TT>TG>GG. With reference to the cases of diethyl ether and *n*-pentane, one of the less stable forms of diethyl sulfide may be the TG conformations. As we discussed in the last section, we observed very weak bands which fit the frequencies calculated for the GG form well. Therefore, the existence of the GG form has also been confirmed. The result for *n*-pentane also supports this result. We may now conclude for diethyl sulfide that three conformations of the TT, TG, and GG coexist in the liquid and gaseous states, while only one, namely, the TT form, exists in the solid state.

Figure 2 shows the relations in the observed and calculated frequencies and the frequency shift upon deuteration for the three isotopic methyl ethyl sulfides. The calculated frequencies in general correspond well

with the observed ones. The frequency shifts upon deuteration can also be well explained by the calculations. In Table 8 the observed and calculated frequencies for the C–C stretching, C–S stretching, and SCC bending bands for the T form are listed. The observed C–C stretching bands are shifted to a higher frequency region through the $CH_3SCH_2CH_3$, $CD_3SCH_2CH_3$, and $CH_3SCD_2CD_3$ species. The calculated frequencies also show this tendency. On the other hand, the C–S stretching and SCC bending bands are shifted to a lower-frequency region through the above-mentioned species. The calculated frequencies fairly well support the observed tendency. For the G form, the observed frequency shifts upon deuteration are also explained by the normal coordinate treatment. The higher-frequency shift of the C–C stretching band can be understood if we consider that the band is pushed up to a higher frequency region by the CD_3 and CD_2 deformation vibrations.

A_2 Modes of Diethyl Sulfide. For the TT form of diethyl sulfide, the two C–H stretching bands and one each of the CH_3 degenerate deformation, CH_2 twisting, CH_3 rocking, CH_2 rocking, C–C torsion, and the C–S torsional bands belong to the A_2 species. We previously made the assignments of the A_2 modes of dimethyl sulfide[16] by examining the annealed spectra. In the diethyl sulfide, we can expect the distortion of the molecular structure upon crystallization. If the site symmetry of C_{2v} for diethyl sulfides does not remain in the solid state, the former seven bands may appear in the region we recorded.

One of the doublet bands around 2940 cm^{-1} can be assigned to the A_2 mode. The analyses of the annealed bands at 1449, 1442, and 1436 cm^{-1} are very difficult. We may, however, assign one of these bands to the A_2 species. The liquid bands at 1248 and 1028 cm^{-1} persist in the solid state with intensities much weaker than in the liquid state. We can assign these bands to the A_2 twisting and rocking vibrational modes. The frequencies of the observed bands fit the calculated A_2 frequencies well. Among the A_2 modes, the CH_2 rocking, and C–C torsional bands were not observed in the annealed spectra. We now consider that the CH_2 rocking and C–C torsional bands are essentially too weak to appear in the spectrum. Thus, we were able to identify most of the bands belonging to the A_2 species of diethyl sulfide.

a) Solid-state bands.

Snyder and Zerbi[13] assigned the bands at 1148 (vw) and 811 cm^{-1} (vw) of diethyl ether to the A_2 species. Also, the bands which may be due to the A_2 modes appear in the C–H stretching and CH_3 degenerate deformation regions in the solid-state spectra. On the other hand, for the species of dimethyl ether, Snyder and Zerbi[13] observed bands which may be due to the A_2 species in the annealed spectra —at 2907 (w) or 2877 (m), 1445 (w), and 1152 cm^{-1} (w)—, although they did not identify them as the A_2 modes. Therefore, it is likely that dimethyl and diethyl ether do not maintain the C_{2v} site symmetry in the solid state either.

CH_3 and CH_2 Deformation Regions. The CH_3 and CH_2 deformation bands of the sulfides in the [T] form are summarized in Table 9. The observed data of dimethyl sulfides are taken from Reference 16. The CH_3 degenerate deformation vibrations appear in the 1480—1420 cm^{-1} region. There are two sorts of symmetrical deformation vibrations, namely, the vibrations of the methyl groups bonded to the sulfur atom (I) and those bonded to the carbon atom (II). The CH_3 symmetrical deformation bands of Case I appear around 1320 cm^{-1}, and the corresponding bands of Case II, around 1380 cm^{-1}. The CH_3 rocking vibrations in the ethyl group are strongly coupled together with the C–C stretching and/or the CH_2 deformation vibrations. In a previous note on methyl ethyl sulfide,[1] we assigned the five bands in the 990—940 cm^{-1} region to the CH_3 rocking vibrations, but we noticed that the bands in the higher-frequency region were not assigned to the sole vibrational mode. It is more reasonable to consider now that the bands at 968 and 962 cm^{-1} in the annealed state of methyl ethyl sulfide are the results of crystal-field splitting. The band at 960 cm^{-1} in the liquid spectrum is assigned to the vibration of the G form. The CH_2 bending vibrations appear in the 1440—1420 cm^{-1} region. The bands assignable to the CH_2 wagging and twisting vibrations appear very close together.

C–S Stretching Region. The C–S stretching bands are shifted to a lower frequency region from dimethyl to diethyl sulfides. This is easily recognized by considering the masses of the groups bonded to the sulfur atom. In a previous note on diethyl sulfide,[2] the band at 738 cm^{-1} in the liquid state was identified as the C–S stretching fundamental. However, this band is too high to assign to the C–S stretching fundamental and too low to assign to the CH_2 rocking fundamental in view of the results on the normal coordinates. At the present time, we cannot reasonably explain this liquid band.

Ionic Mobility of Some Inorganic Ions in Mixed Solvents from Electromigration on Paper

M. M. LAHIRI, B. K. SEAL,* and S. K. MUKHERJEE
Department of Agriculture, University of Calcutta, Calcutta, India
(Received August 24, 1972)

Measurements of ionic mobilities of a number of cations and anions in nonaqueous and mixed solvents were made from electromigration on filter paper, and the apparent advantages of the ionophoretic method over other modern techniques have been explained. The values so obtained have been corrected for (a) electroosmotic and (b) tortuosity (*i.e.*, 'added migration path length') effects, in order to compare them with those in free solution. Considering the combined effect of dielectric constant and viscosity the ionic mobilities obtained by the electrophoretic method are considered to be of correct order of magnitude. The ionic mobilities at constant dielectric constant when plotted against reciprocal of viscosity show a slight deviation from linearity.

A number of direct and indirect methods are available for the determination of ionic mobilities in liquid media under an applied electric field. Of the earlier ones, the methods of Lodge,[1] Whetham,[2] and Hittorf[3] should be mentioned. The most precise one is the moving boundary method, developed by MacInnes,[4] Longsworth,[5] Shedlovsky,[6] and Tiselius.[7]

Whatever the method, the less accurate one of Hittorf or the more precise moving boundary method, they are all time-consuming and require accurate chemical analysis and elaborate techniques. By comparison, the ionophoretic technique lends itself to less complicated equipments which are easy to manipulate. It has also become apparent that it provides fairly accurate values of ionic mobility within a comparatively short time. The promise of paper ionography as an elegant and simple means of measuring ionic mobilities has come to the fore recently. However, a sufficient amount of data is not yet available for the purpose of establishing the potentialities of the technique. Although simple, its degree of reproducibility under varying working conditions has to be accurately ascertained.

Data on ionic mobilities in nonaqueous and mixed media are conspicuous for their paucity. In spite of some inherent difficulties of nonaqueous solutions, ionic mobilities of several alkali metal ions and of a few halide ions have been measured by Gordon and his collaborators[8] in anhydrous methanol and ethanol at 25°C from a combined study of transference number and the equivalent conductivity. Measurement of individual ionic mobilities in formamide ($D=109$) has also been reported.[9] The ionophoretic technique allows more convenient measurements in nonaqueous and/or mixed media, and hence this possibility has been explored to a large extent. Mixed solvents have been preferred because they permit a continuous variation of macroscopic parameters, namely the dielectric constant and the viscosity.

Principle

The factors governing the ionic migration in solution in an electric field can be classified as:

(a) Characteristics related to the particular ion under investigation, namely its charge (sign and magnitude), size, shape, tendency to dissociate, and tendency for complex formation and amphoteric behaviour, if any.

(b) Environmental factors such as electrolyte concentration, ionic strength, dielectric properties, pH, temperature, viscosity, etc.

(c) The uniformity and intensity of the applied field.

In addition, two other important factors often called "barrier effects", influencing the speed of ions are: (i) electroosmotic effect caused by the movement of charged medium, and (ii) tortuosity factor of 'added migration path length' owing to the winding nature of the path created by the fibrous structure of the filter paper. These two factors and consequent corrections according to McDonald and Bermes[10] have been discussed in an earlier communication.[11] McDonald and Bermes have shown that acceptable values of mobility of small as well as macro ions may be obtained after making these two corrections.

As mentioned earlier,[11] four measurements are required for each set of experimental conditions. These include measurement of ionographic mobility,

and R_D, a modified R_f as in classical chromatography of the migrant and of the electroosmotic indicator.

The general expression:

$$U = \frac{U_E}{R_D^M} \pm \frac{U_{el}}{R_D^{el}}$$

(where U_E denotes the ionographic mobility of the migrant and U_{el} that of the indicator and R_D^M and R_D^{el} denote the R_D values of the migrant and the indicator, respectively) has been utilised for the determination of free solution mobilities of some inorganic ions in mixed solvents. The negative sign is used if the migrant is positively charged, the positive sign if it is charged negatively.

Experimental

In the present communication are included the results for Cu^{2+}, Ni^{2+}, SCN^-, HSO_4^-, $[Fe(CN)_6]^{3-}$ and $[H_2Fe(CN)_6]^{2-}$ ions. HSO_4^- and $[H_2Fe(CN)_6]^{2-}$ actually resulting from the conversion of SO_4^{2-} and $[Fe(CN)_6]^{4-}$ respectively, in the back ground electrolyte having 0.05M acidity. The concentrations used were of the order 10^{-2}M prepared from reagent grade chemicals.

The reagents employed for detecting the ionic species on paper were as follows. Copper and nickel were detected by first spraying the paper with a saturated solution of rubeanic acid in ethanol and then holding the strip over ammonia vapour. Copper gave a dirty green colour and nickel a blue colour. Ferrocyanide and thiocyanate ions on paper were detected by spraying with a dilute solution of ferric chloride. The former gave a deep blue and the latter, a deep red colour. Ferricyanide was detected by spraying the strip with a dilute solution of ferrous sulphate when a blue colour was obtained. Sulphate was detected first by spraying the neutral paper with a 0.05 per cent solution of sodium rhodizonate in water, drying it, and then with a 0.02 per cent aqueous solution of $BaCl_2$, when a colourless spot on a reddish background was obtained. The electroosmotic indicator, glucose (concentration 0.005 g/ml), was detected on paper by spraying the neutral paper strip with an alcoholic solution of aniline oxalate and then heating it to 120°C when a brown spot appeared.

Micropipettes (1 ml capacity, graduated up to 10^{-3} ml) were used to spot a small volume of the substance under investigation on chromatographic paper. The Precision Ionograph (designed by Research Specialties Co., Richmond, California) which utilises the horizontal paper strip in the electrolyte-saturated condition was used with Whatman chromatographic paper No. 1 and the appropriate electrolyte solutions.

The media consisted of solvent mixtures having different dielectric constants. For this purpose, pure and distilled methanol, ethanol, 2-propanol, acetone, dioxane, and ethylene glycol were mixed with water and hydrochloric acid in definite proportions by weight so as to obtain mixtures of known dielectric constants at a particular temperature and of known acidity (0.05M). The "barrier effects" for the above-mentioned ions were evaluated by measureing the R_D values of the migrants and of the electroosmotic indicator in solvent mixtures of different dielectric constants with the help of a locally fabricated Ionograph similar to that proposed by McDonald and Bermes[10] under conditions identical with those above.

To start with an ionographic experiment, two strips (3.8× 57 cm) were simultaneously moistened with the electrolyte from both ends taking care to avoid excess electrolyte and then pressed gently between two dry filter paper sheets in order to make them, as far as possible, uniformly wet. The strips were then placed in position inside the chamber so that they were pulled horizontally taut by pressing gently the graphite electrodes on each end inside the electrolyte vessels. In order that each strip might offer the same resistance towards current flow, which could be observed from the equal length of each strip exposed above the solvent level, the strips were so placed that the mid-point line of each strip just touched the pointed end of a narrow plastic stick on which it rested. Electrolyte was then poured to the same level in each electrode vessel in order to avoid hydrodynamic flow of fluid in the paper, which was independent of electrical potential. A direct current at 200 V was applied for five minutes in order to drain out any excess solvent. The flow of current was then stopped, and to the marked mid-point of each strip, 0.002 ml of a mixture of the solutions of salt and glucose was carefully spotted. The chamber was then made gas-tight virtually by placing a cover and then closing the points of junction of the cover and the top of the base by means of cellophane adhesive tape. The temperature of the chamber was maintained constant at 25°C, thus reducing evaporation of the solvent from the strip to a minimum. A direct current at 200 V was applied for 30 min. The strips were then dried and sprayed with the reagent specific for the particular ion and again dried. The distance of migration of the ion together with the R_D values were utilised for calculation of free solution mobilities.

For ionographic experiments carried out in pure organic media such as formamide, special care was taken to use completely dehydrated copper and nickel salts for preparing solutions in formamide. Anhydrous sulphates of copper and nickel were obtained in the following processes.

(a) Reagent quality $CuSO_4 \cdot 5H_2O$ was heated in an air-oven first at 100°C to obtain the compound of stoichiometric composition $CuSO_4 \cdot H_2O$. This was further heated to 250°C when almost colourless and dehydrated $CuSO_4$ was obtained. The latter sample was finally heated to 360°C to result in anhydrous $CuSO_4$.

(b) Reagent quality $NiSO_4 \cdot 7H_2O$ was heated in an air-oven first at 120°C to obtain a compound having the stoichiometric composition $NiSO_4 \cdot 2H_2O$ which was further heated to 290°C when yellow and anhydrous $NiSO_4$ was obtained.

Anhydrous sulphates of copper and nickel thus obtained were dissolved separately in anhydrous formamide containing HCl upto the acidity of 0.05M and the respective solutions were used in the electromigration experiments in formamide.

Attempts were also made to use, as far as possible, moisture-free formamide which was obtained by lime-distillation under reduced pressure.[12] The boiling point of the moisture-free formamide prepared was 137.5°C under a reduced pressure of 40 mmHg.

Dry hydrogen chloride gas obtained by the action of reagent quality sulphuric acid on analytically pure sodium chloride (previously dried at 120°C overnight) was bubbled into the distilled formamide upto the acidity of 0.05M. Precautions were taken to avoid moisture-contamination as far as possible by keeping the solvent in an all-glass air-tight vessel and reducing the time between the initial preparations and final electromigration experiments.

The purity (particularly with regard to water content) of the sample of formamide was confirmed spectroscopically using IR and NMR techniques. Further information regarding the purity of the sample was obtained from a study

12) L. R. Dawson, T. M. Newell, and W. J. McCreary, *J. Amer. Chem. Soc.*, **76**, 6024 (1954).

of vapour phase chromatography.

IR spectra of (a) formamide, (b) formamide containing HCl upto the acidity of 0.05M (vide experiments) and (c) formamide previously kept under moist atmosphere were studied separately. The spectra of (a) and (b) showed no free water band and intermolecular hydrogen bonded water, and hydrogen bonded-NH group could not be distinguished from the spectra because both absorb practically in the same region. IR spectra of sample (c) suggests that formamide is not highly susceptible to moisture absorption. Moreover, a high resolution NMR spectrum of the sample of formamide taken by a Varian spectrometer (operating frequency 56.445 MHz) showed no line for the water proton even at considerably high gain of the amplifier. A vpc study of the formamide sample further confirmed the absence of water.

Results and Discussion

Details of composition by weight of the different solvent mixtures and the values of their dielectric

a) Since the electrophoretic movement of glucose (used as the electroosmotic indicator) in each of the above-mentioned mixed solvents (Table 2) was zero, determination of R_D value (used as the correction for tortuosity effect of a migrant through the paper) was not done. The electroosmotic effect has been found to be negligible in different nonaqueous solvents[13)]

constants are given in Table 1(A), the R_D values of ions studied in various solvent mixtures in Table 1(B) and the calculated mobilities in Table 2. The ionic mobility varies linearly with the dielectric constant of the medium as shown in Fig. 1. We see that with decreasing dielectric constant of the mixed solvents the ionic mobility gradually decreases. Except for the mixtures containing ethylene glycol, the variations of ionic mobility in the others are more or less similar. The graphs in Fig. 1 when extrapolated to the dielectric constants of the pure organic components give values of the ionic mobilities at a finite concentration (10^{-2}M) and at a particular acidity (0.05M HCl) in these different media. However, verification of these values by direct measurement has not been possible owing to the high resistance in the nonaqueous solvents which as a result evaporate quickly. The ethylene glycol graphs, to be noted, extrapolate to an absurdly negative value.

In each of the mixed media, glucose used as an electroosmotic indicator was found to be practically immobile. This does not mean necessarily that electroosmosis is absent, but under such conditions the ionic

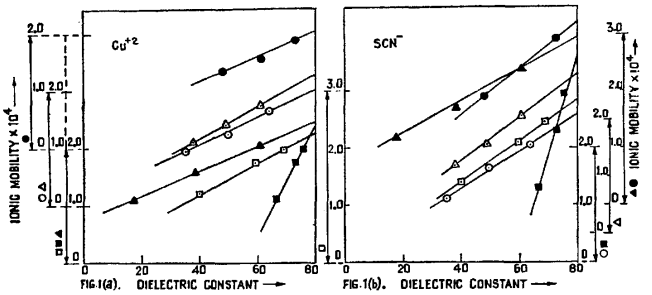

Fig. 1. Ionic mobilily *vs.* dielectric constants.
Solvent mixtures:
1) 2-Propanol: Water: HCl (○)
2) Ethanol: Water: HCl (△)

6) Ethylene glycol: Water: HCl (■)

mobilities have to remain uncorrected for this effect. Glucose is therefore unsuitable as an indicator in mixed media, where the magnitude of electroosmotic effect may in reality be very small. Actually Strickler and Mathews[13] found the electroosmotic effect to be negligible in different nonaqueous solvents.

Table 3.

(Experimental conditions: electrolyte medium: formamide-hydrogen chloride mixture (0.05M); (dielectric constant=109.5 and viscosity=0.033 Poise at 25°C); temperature=25°C; potential gradient=3.508 V/cm; time=30 min.)

Migrant	Distance of migration (mm)	R_D value[a]	Computed mobility $\times 10^4$, (cm²/Vsec)	Computed mobility $\times 10^4$ (cm²/Vsec)	
				0.1M HCl	0.1M $HClO_4$
Glucose	0.0	—	—	—	—
Cu^{2+}	2.0	1.0	0.32(0.89)	2.35	—
Ni^{2+}	3.0	1.0	0.48(1.11)	2.61	—
Br^-	8.0	1.0	1.27(1.36)	—	3.61
I^-	8.5	1.0	1.35(1.36)	—	3.61
SCN^-	7.5	1.0	1.19(1.09)	—	2.89
$Cr_2O_7^{2-}$	8.0	0.95	1.33(1.19)	—	3.14
$[Fe(CN)_6]^{3-}$	8.5	1.0	1.35(1.33)	—	3.51

a) Since the electrophoretic movement of glucose (used as the electroosmotic indicator) in the above-mentioned medium was zero, determination of its R_D value was not done. The values in parentheses in the fourth column are the theoretical mobilities.

Of pure organic media, measurements in formamide (D=109) could be successfully made for Cu^{2+}, Ni^{2+}, Br^-, I^-, SCN^-, $Cr_2O_7^{2-}$, $[Fe(CN)_6]^{3-}$ ions in hydrochloric acid. The results are shown in Table 3. Comparing these with the values of ionic mobilities in aqueous media containing HCl and $HClO_4$, it is noted that the ionic mobilities are considerably lower in formamide, particularly for Cu^{2+} and Ni^{2+} ions. The expected increase in ionic mobility in formamide due to its high dielectric constant has apparently not been made due to other factors. One such factor is the viscosity of formamide solutions but it alone cannot explain the decrease observed for Cu^{2+} and Ni^{2+} ions. Even in aqueous mixtures of organic solvents where viscosities are of this order (2-propanol: water–HCl, 40: 60), the ionic mobilities are not so low. One plausible explanation may be as follows: In the aqueous mixtures of organic solvents, the cations remain preferentially hydrated in view of the high polarity and dielectric constant of water and hence the observed mobilities in these mixtures are essentially those of hydrated Cu^{2+} and Ni^{2+} ions. In formamide, the anions remain perhaps unsolvated as in other solvent mixtures and are not therefore much affected, in so far as their mobilities are concerned. This expectation receives support from theoretically computed mobilities[14] which agree fairly well with those observed for these anions in formamide medium. But Cu^{2+} and Ni^{2+} ions are perhaps solvated as usual, and because of the bulkier formamide molecule being attached to these cations thus forming complex basic salts[16] the mobilities are considerably reduced. The solvation of Cu^{2+} and Ni^{2+} ions by formamide is supported by the fact that formamide and its mono- and di-alkyl derivatives and the corresponding compounds derived from acetic acid are known to form complexes with the first group transition elements. Drago *et al.* have actually prepared hexacoordinated complexes of Ni^{2+} and Cr^{3+} ions with the above-mentioned ligands and have studied their spectra and other properties.[17] It is to be noted that care was taken to use completely dehydrated copper and nickel salts for preparing solutions in formamide (vide experiments).

From the graphs in Fig. 1, the mobilities of ions corresponding to any particular value of dielectric constant of the media can be read off. The mobilities corresponding to one such value of D=60 are recorded in Table 4, showing that they are different even though measured, so to say, at the same dielectric constant. Considering the combined effect of viscosity and dielectric constant the ionic mobilities recorded in Tables 2 and 4 are considered to be of correct order of magnitude except in ethylene glycol–water–HCl mixture of dielectric constant 60, where ionic mobilities are absurdly low even a negative value is shown for $[H_2Fe$-

13) A. Strickler and J. H. Mathews, *J. Amer. Chem. Soc.*, **44**, 1647 (1922).

14) The mobilities have been calculated from the quation $U_1 = \eta_{H_2O}/\eta_1 \cdot \varepsilon_1/\varepsilon_{H_2O} U_{H_2O}$ where U_1 is the ionic mobility in mixed medium, η_1 and ε_1 are respectively the viscosity and the dielectric constant of the medium. This expression has been obtained from Walden equation $U = Ze/6\pi\eta r$, assuming that the Stokes ionic radii remain unaltered on changing the medium and the mobility is linearly proportional to the dielectric constant (*cf.* Fig. 1). In calculating the mobilities we have assumed that the mobilities of anions in 0.05M HCl will be close to those in 0.1M $HClO_4$ at the same anion concentration. The mobilities observed of Cu^{2+} and Ni^{2+} ions in 0.05M HCl are 2.37 and 2.93.[15]

$(CN)_6]^{2-}$. Consequently the nature of the solvent medium and the ionic size in this medium are both going to influence the measured mobilities.

Viscosity is another factor influencing ionic mobility. The latter has been plotted in Fig. 2 against the viscosity of each of the solvent mixtures, from which it is seen that the curves are more or less smooth. Two and sometimes three or more curves intersect; these points being iso-viscous the corresponding mobilities may be termed iso-viscous mobilities. It is probable that irrespective of the nature of the ion, the curvature of the graphs is characteristic of the particular solvent system. The effect of viscosity under iso-dielectric condition (D=60) is shown by the data given in Table 4. If, however, the ionic mobilities at D=60 are plotted against the fluidity of the media assuming that Stokes ionic radii remain unaltered on changing the medium we have the graphs shown in Fig. 3 which are more linear than those in Fig. 2. The dielectric constants of two ethylene glycol: water: 0.05M HCl sys-

tems are close to that of water. Consequently any effect on ionic mobility in these media will be purely a viscosity effect. Accordingly we calculated the mobilities of ions in these media knowing those in water, on the assumption that the Stokes ionic radii remain unaltered. The agreement between the observed and calculated mobilities is, in view of the assumptions made, considered satisfactory. The results are shown in Table 4(b).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1414—1417 (1973)

Kinetics and Mechanism of the Transformation of Vaterite to Calcite

M. Subba Rao

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore-12, India

(Received June, 1, 1972)

The transformation of vaterite to calcite was investigated systematically. The transition temperature and the energetics of the transformation were determined from differential thermal curves. The variations of lattice constants and crystallite size, accompanying the transformation were studied by X-ray diffractometry. The kinetics of transformation were investigated in the temperature range 460—490°C. The kinetic data were analysed with the help of three separate solid-state models.

Anhydrous calcium carbonate is known to exist in three crystalline modifications—calcite, aragonite, and vaterite. All the three modifications could be prepared synthetically. Calcite is the stable form of calcium carbonate at ordinary pressure and temperature. Aragonite and vaterite are metastable modifications which transform to calcite on heating. Although the transformation of aragonite to calcite has been studied by several investigators, the only kinetic study on the transformation of anhydrous vaterite to calcite appeared to be the dilatometric investigation of Pruna *et al.*[1] However, there were quite a few investigations of the transformation of vaterite in contact with mother liquor. Here again there was considerable controversy regarding the transformation product. Lucas[2] reported that in the presence of mother liquor, vaterite was transformed to calcite and no aragonite was formed. On the other hand according to Faivre and Wallaeys,[3] both aragonite and calcite were formed by the transformation of nascent vaterite in contact with mother liquor. More recently Bischoff[4] has studied the transformation of vaterite to aragonite in aqueous medium in the presence of magnesium ions.

Owing to the incomplete and often conflicting information existing in the literature regarding the transformation of vaterite, a systematic investigation of the transformation of anhydrous vaterite was carried out. Apart from the kinetics of transformation, the effect of thermal treatment on the cell constants and crystallite sizes was followed from the stage of preparation to well beyond the transformation temperature. The kinetic data were analysed with the help of standard solid state models and the most appropriate model was indicated.

Experimental

Preparation of Vaterite.[5] A solution of 50 g potassium carbonate in 700 ml distilled water and containing 300 ppm sodium hexametaphosphate was heated to 60°C and the solution stirred briskly with a magnetic stirrer. 0.1M calcium chloride solution was added at an average rate of 0.5 ml min^{-1} till 200 ml of the solution were mixed. The crystals of vaterite were filtered off on a sintered glass crucible, washed thoroughly with distilled water and dried by washing with alcohol and ether. The anhydrous vaterite was preserved in a tightly stoppered bottle in a desciccator.

DTA of Vaterite. Differential thermal curves of known weights of vaterite and quartz were obtained on the Shimadzu-Recording DTA apparatus type DT-2A. Ignited alumina was the reference material. The sample and the reference material were uniformly packed into platinum containers which rest on Pt-Pt 10% Rh thermocouples. A heating rate of 12.5°C min^{-1} was employed.

High Temperature Thermostat. The thermostatic unit consisted of a nichrome-wound electrical tubular furnace, placed vertically. Kinetic studies were performed by dropping 20—25 mg of the vaterite sample into 6 mm *i.d.* fused silica tubes situated in the thermostat. The silica tubes rested

in an alloy steel cylindrical block situated midway in the furnace and insulated from the ends of the furnace by means of fire-clay plugs. Temperature was measured by means of a chromel-alumel thermocouple inserted in a fused silica sheath and inserted in a hole at the centre of the alloy steel block. The thermocouple was previously calibrated against melting and fusion points of standard solids. Furnace temperature was monitored by a Tinsley Vernier Potentiometer and controlled by means of a Sunvic energy regulator and variac autotransformer. Recorded temperatures are believed to be accurate to ± 2°C. Experimental runs were terminated by quickly removing the silica tube from the steel block at predetermined time intervals followed by immediate quenching in cold water. The quenched samples were analysed to determine the fractions of calcite and vaterite present in them.

X-Ray Diffraction Technique. X-Ray diffraction photographs of the heat-treated samples were taken using Rich Seifert X-ray unit with filtered copper radiation. 114.6 mm dia. Philips Debye-Scherrer Camera and a cylindrical specimen 0.3 to 0.5 mm dia. were employed. Bragg angles in the range 30—60°θ for the different reflections of vaterite and calcite were measured. The data were subjected to Cohen's[6] least-squares refinement and cell constants were calculated. By measuring the line broadening of the (104) reflection of calcite and (112) reflection of vaterite, the crystalline sizes were calculated using Scherrer[7] equation.

X-Ray powder diffraction photographs of the kinetic samples were taken in a 57.3 mm dia. Philips Debye-Scherrer Camera. Densitometer records of the (104) reflection of calcite and (110), (112), and (114) reflections of vaterite were obtained, employing photovolt transmission density unit and the multiplier photometer model 520-M. In this model full-scale deflection in the most sensitive range corresponds to 0.01 microlumen. The relation[8] between the intensity and fraction of calcite in the mixture was found to be

$$f_c = \frac{I_{104(c)}}{I_{110(v)} + I_{112(v)} + I_{104(c)} + I_{114(v)}} \quad (1)$$

Employing Eq. (1), the fraction of calcite in the kinetic samples was calculated.

Results and Discussion

The differential thermal curve for the sample of vaterite is shown in Fig. 1. The small exothermic peak with the peak temperature of 567°C is attributed to the transformation of vaterite to calcite. The heat of transformation ΔH was calculated by comparison with the peak of $\alpha \rightleftharpoons \beta$ transition in quartz. ΔH was found to be 145 cal mol^{-1}. E_a for the transformation using the method of Borchardt and Daniels[9] was found to be 120 kcal mol^{-1}.

The variation of unit cell volume of calcite and vaterite with temperature is shown in Fig. 3. There is a small contraction in the lattice prior to transformation. The variation of crystallite size with temperatures is represented in Fig. 2. There is a considerable decrease in the crystallite size of vaterite around the transformation temperature.

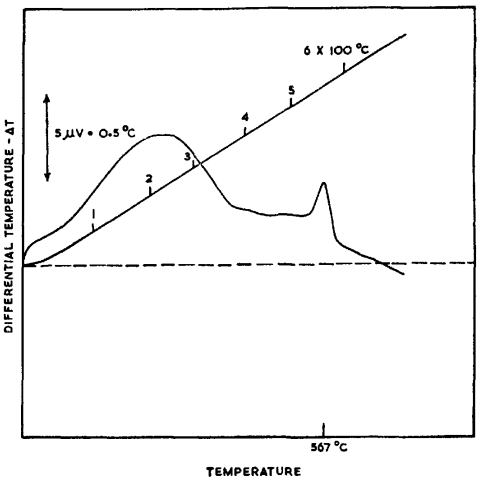

Fig. 1. Differential thermal curve of vaterite.

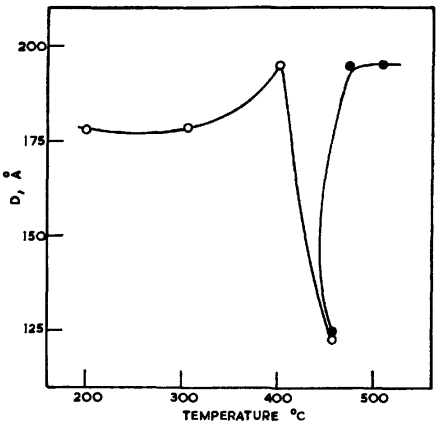

Fig. 2. Variation of the crystallite size of varite-calcite with temperature.

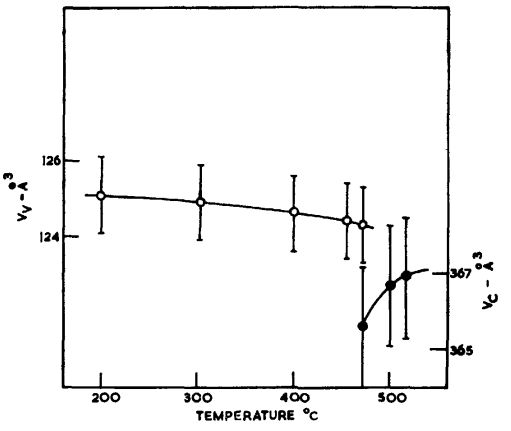

Fig. 3. Variation of lattice constants of vaterite-calcite with temperature.

The experimental results on the transformation rate studies over the temperature range 460—490°C are shown in Figs. 4 and 5. The extent of transformation of vaterite to calcite as a function of time under isothermal conditions is shown in Fig. 4, while in Fig. 5 the conversion of vaterite to calcite as a function of temperature at different times is shown. All the curves in Fig. 5 intersect the temperature axis at 450°C. This can be taken as the point where the rate of trans-

formation is immeasureably slow, *i.e.*, it takes infinite time.

The transformation curves in Fig. 4, exhibit short acceleratory periods. The kinetic data have been analysed with the help of three models (1) Avrami's[10] equation, (2) Honig's[11] order-disorder theory as applied to diffusionless transitions in solids and (3) Mampel's[12] equation. The relation derived by Avrami[10] includes the interaction between grains of the new phase during transformation. The approximate form of the Avrami rate equation is

$$1 - \alpha = \exp(-kt^n) \qquad (2)$$

where α is the fraction of vaterite transformed to calcite in time 't'. A plot of $\log_{10}\ln(1/1-\alpha)$ against $\log_{10}t$ should give a straight line with 'n' as the slope. Figure 6 shows that the kinetic data on the transformation of vaterite to calcite comply reasonably well with equation (2). The slopes of the lines vary from 1.38 to 1.46 with an average value of 1.42. This value is midway between 4/3 and 3/2. The value of 4/3 gives

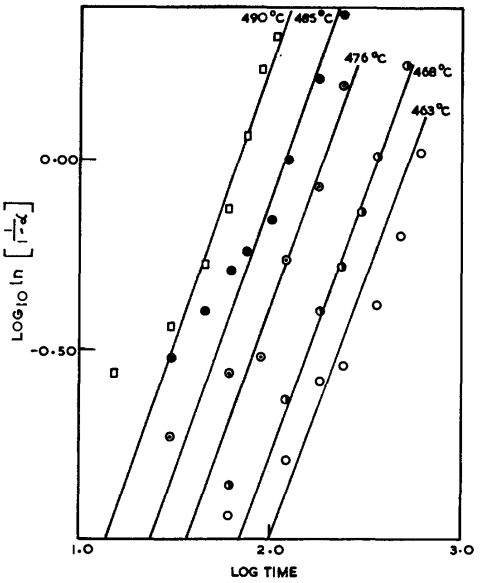

Fig. 6. Avrami plots of the vaterite-calcite transformation data.

a better fit and n is found to be 4/3 in the transformation of aragonite to calcite (communicated to the Indian Journal of Chemistry) which is analogous to the transformation of vaterite to calcite. Hence, the slope is approximated to 4/3 here too. From the slopes of the plots of $-\ln(1-\alpha)^{3/4}$ *vs.* t, a value for the activation energy is extracted and it is found to be 85 kcal mol^{-1}.

In the theory proposed by Honig,[11] a solid undergoing a transformation is represented by the change in the lattice units which transform from an initial state to a final state by two different ways, *i.e.*, a nucleation process and a propagation process. Through application of the methodology of order-disorder theory, Honig[11] has derived the following generalised rate equation.

$$-\frac{1}{k_n}\cdot\frac{d\alpha_0}{dt} = \alpha_0 + \frac{Zk_p}{k_n}\left\{\frac{-1+[1+4(C-1)\alpha_0(1-\alpha_0)]^{1/2}}{2(C-1)}\right\} \qquad (3)$$

In the present transformation α_0 is the fraction of vaterite remaining at time 't', C is a parameter indicating the tendency towards phase aggregation, k_p and k_n are the rate constants for the propagation and nucleation mechanisms respectively. For large values of C the generalised rate equation may be integrated to obtain

$$Zk_p(t-t_0)/(C-1)^{1/2} = \cos^{-1}(2\alpha_0-1) \qquad (3a)$$

Honig has evaluated C as $(1+k_p/k_n)^2$, and thus Eq. (3a) takes on the approximate form

$$Zk_n(t-t_0) = \cos^{-1}(2\alpha_0-1) \qquad (4)$$

where Z is the coordination number of a site in the lattice under consideration and t_0 is an arbitary constant evaluated by curve fitting.

Figure 7 shows that the vaterite→calcite transformation data fit Eq. (4) fairly well. The slope of the lines gives the value of Zk_n. The variation of Zk_n with temperature is shown in Fig. 8.

The value of the exponent in the Avrami's equation (*i.e.*, n=4/3) suggests that the kinetics of the trans-

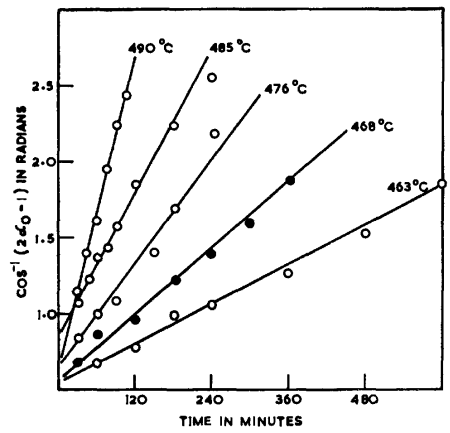

Fig. 7. Order-disorder plots of vaterite-calcite transformation data.

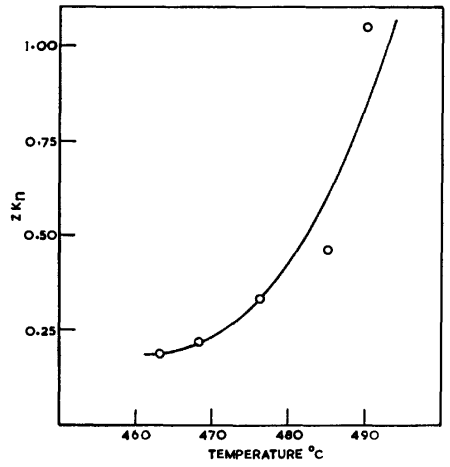

Fig. 8. Variation of Zk_n with temperature.

formation might depend on the interfacial area between the two solids. If the rate of a reaction depends on the area of the interface between the two solids, it can be represented by a 2/3 power law.

The 2/3 power law, *i.e.*, $dx/dt=kx^{2/3}$ can be reduced to the more familiar form

$$1-(1-\alpha)^{1/3} = kt \qquad (5)$$

where α is the fraction transformed in time 't'.

Equation (5) is the familiar contracting volume model, which has been employed to explain the kinetics of thermal decomposition of solids.

Figure 9 shows a few representative plots of the vaterite→calcite transformation data using Eq. (5). Two different linear portions can be recognised on each of the plots. From the slopes of these plots activation energies have been calculated. The values of E_a are 85 kcal mol^{-1} and 95 kcal mol^{-1} respectively for each of the two regions.

Equation (5) is equivalent to one of the limiting forms of Mampels[12] equation. In the Mampel[12] model $k=v/r$ where v is the rate of advance of the interface and r is the radius of the particle.

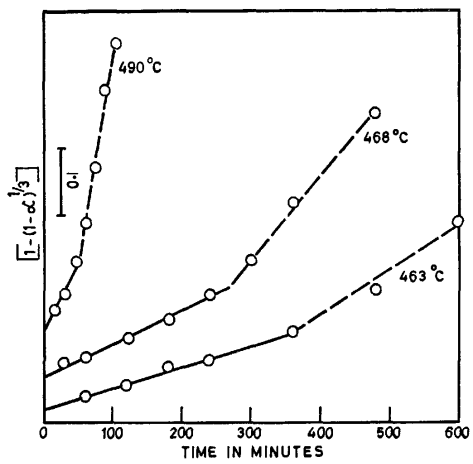

Fig. 9. Plots of $[1-(1-\alpha)^{1/3}]$ *vs.* time for the transformation of vaterite to calcite.

Considering the powder as composed of a large number of isotropic spheres of uniform radius, Mampel derived a general expression for the fraction decomposed, from probability considerations, taking into account the possibility of the overlapping of the zones of decomposition spreading out from neighbouring nuclei. The general expression reduces to simpler forms for three special cases: (i) for small values of t, α is proportional to t^4, (ii) for intermediate periods Eq. (5) gives a close approximation, and (iii) for the final period the reaction tends towards unimolecular law. Mampel has shown that the limits of the three periods are largely determined by the ratio r/v. For very fine powders practically the whole of the reaction follows the unimolecular law. For particles of intermediate size the reaction is represented reasonably well by Eq. (5).

In the present transformation Eq. (5) has been used to explain both the acceleratory and deceleratory kinetics. The slopes of the plots are different for the two regions. There is a break up of particles during the transformation. The particles are probably not reduced to fine powders. It is perhaps this change in the particle size which is responsible for the change in the slope.

Hence, Eq. (5) based on nucleation on the surface and progress of the reaction by interfacial growth is found to explain the complete course of the reaction. Further, in none of the kinetic samples, aragonite phase was detected. In the transformation of anhydrous vaterite to calcite, aragonite is not an intermediate phase.

The author expresses his grateful thanks to Professor A. R. Vasudeva Murthy for suggesting this problem and the advice rendered at different stages of the investigation.

Transmission of Substituent Effects through Oxygen and Sulfur Atoms. I. ^{1}H Chemical Shifts of Ring-substituted Phenyl Vinyl Ethers and Sulfides

Takayuki FUENO, Okitsugu KAJIMOTO, Kunisuke IZAWA, and Mitsuru MASAGO*

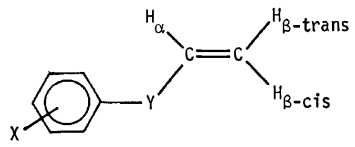
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka
**Yoshitomi Pharmaceutical Company, Yoshitomi-cho, Chikujo-gun, Fukuoka*

(Received October 7, 1972)

The proton chemical shifts of the vinyl group in ring-substituted phenyl vinyl ethers (PVE) and sulfides (PVS) were measured and related to the Hammett σ constants. It was found that the ρ value for the *β-trans* proton of PVS, $-0.448\ \tau/\sigma$, is greater in magnitude than that of PVE, $-0.378\ \tau/\sigma$, in contrast to the tendency reported for the methyl hydrogens in anisole and thioanisole. The results can best be explained in terms of the concept of the through-conjugative ($p\pi$-$d\pi$-$p\pi$) behavior of the sulfur atom interposed between two unsaturated groups.

The transmission of substituent effects has been a subject of continuous interest to organic chemists ever since Hammett's proposal of the ρσ relationship.[1] One of the recent problems in this field concerns the role of d-orbitals in transmitting the electronic effects of substituents. Marcus *et al.*[2] summarized numerous reports on the Hammett dependence of ^{1}H chemical shifts in compounds of the XC_6H_4T–H type, in which X is the substituent, and C_6H_4T, the transmitting group. Particular attention was paid to oxygen and sulfur when they form part of T. Thus, by comparing the ρ-values for phenol (T=O) and anisole ($T=OCH_2$) with those for the corresponding sulfur analogs, *i.e.*, thiophenol (T=S) and thioanisole ($T=SCH_2$), they found that the efficiency of oxygen in transmitting the substituent effects is generally greater than that of sulfur. They also discussed the transmission efficiencies of these atoms by citing several experimental results other than ^{1}H chemical shifts and commented that the sulfur atom must show greater efficiency when it acts as an electron acceptor in conjugated systems ("conjugative-acceptor case"). At that time, however, no appropriate and decisive example was available.

The present series of investigations was undertaken in order to look into the mode of the transmission of substituent effects through the sulfur atom both experimentally and theoretically, and thereby to elucidate the mechanism of transmission in relation to the nature of sulfur bondings. In this paper, we will compare the substituent effects on the ^{1}H chemical shifts of vinyl hydrogens in ring-substituted phenyl vinyl ethers (I; Y=O) and sulfides (I; Y=S). These compounds are characterized by the intervention of an oxygen or divalent sulfur atom between two unsaturated moieties,



(Y = O,S) I

thus fulfilling Marcus' condition for the "conjugative-acceptor case." For the sake of comparison, the ^{1}H chemical shifts of ring-substituted allylbenzenes and styrenes were also measured.

Experimental

Materials. Ring-substituted phenyl vinyl ethers,[3] phenyl vinyl sulfides,[4] and styrenes[5] were synthesized according to the methods given in the literature. Ring-substituted allylbenzenes were prepared from allyl bromide and the corresponding bromobenzenes through Grignard coupling; the boiling points (°C/mmHg) of the products were: *p*-CH_3O 83/9.5, *p*-CH_3 75/23.5, *m*-CH_3 60/10, H 156—157/760, *p*-Cl 82/15.5 and *m*-Cl 83/25.

NMR Measurements. The NMR spectra were recorded on a JNM 4H-100 spectrometer (JEOL) operating at a frequency of 100 MHz. All the compounds were examined at room temperature as 10% (by volume) solutions in CCl_4. The chemical shifts did not vary significantly with concentration, and they were accurate to within ±0.05 Hz. TMS was used as the internal standard.

Assignment of Signals. The NMR signals for the ethylenic α, *β-cis*, and *β-trans* protons of phenyl vinyl ethers and sulfides appear as three quartets. They were assigned to the relevant protons on the basis of the well-known differences in the coupling constants, J_{gem}, J_{trans}, and J_{cis}. The chemical shifts were determined as the mean value of each set of quartet peaks. The ABX system analysis was also carried out by computer calculations; this confirmed the results. In the case of allylbenzenes, the singals of the ethylenic protons were split into three sets of twelve peaks. The complicated signals were analyzed by computer calculations for a 5-spin system.

Results

Table 1 summarizes the H–H coupling, J (Fig. 1), for phenyl vinyl sulfide (PVS), phenyl vinyl ether (PVE), allylbenzene (ABz), and styrene (St). The values of J are not sensitive to ring-substitution within the limits of experimental error.

The chemical shifts, τ, observed for the vinyl protons are listed in Table 2. It can be seen that the τ-values

tend to decrease with the increase in the electron-accepting ability of the substituents.

In Fig. 2, the chemical shifts of the *β-trans*, *β-cis*, and α protons of PVE derivatives are plotted against the Hammett σ constans of the substituents. Least-squares fits of the plots to the linear relationships, $\tau_X-\tau_H=\rho\sigma$, resulted in the sensitivity constants, ρ, of −0.378, −0.324, and −0.121 τ/σ for the *β-trans*, *β-cis*, and α protons, respectively. The plots of the *β-trans* protons were found to be better correlated with σ than those of the remaining two types of protons.

The proton chemical shifts of the PVS, ABz, and St derivatives were examined likewise. The results are given in Table 2, where the correlation coefficients, *r*, and standard deviations, *s*, are listed together with the ρ-values. The α protons of ABz and St derivatives were hardly correlated with σ. The ρ-values for both the *β-trans* and *β-cis* protons were found to decrease in magnitude in the order: PVS>PVE>St>ABz. In Fig. 3, the Hammett plots of the *β-trans* protons for the four types of compounds are shown.

Recently, Yamada, Tsuno, and Yukawa[6] succeeded in improving the Hammett-type correlation for the chemical shifts of *m*-substituted aromatic side-chain protons by introducing correction terms for the ring-current diminution by substitution and for the substituent magnetic anisotropy. These corrections do not appear to be important in our *β-trans* protons, probably because they are situated relatively distant from the substituents. Thus, the ρ-values for the *β-trans* protons may be used as a basis for discussing the relative effi-

ciencies of oxygen, sulfur, and carbon atoms in transmitting the effects of ring substituents to the side chains.

Discussion

(A) Electronic Behavior of Oxygen and Sulfur. The proton chemical shifts and coupling constants of several alkyl vinyl sulfides have recently been reported by Ceccarilli and Chiellini.[7] Comparing their results with those for oxygen analogs,[8] they suggested that the decreased shielding of the terminal vinyl protons in the sulfides is due to the electron-accepting conjugation of the sulfur atom. The lower-field shifts of the *β-trans* protons of phenyl vinyl sulfides relative to the ethers (Table 2) can be interpreted in a similar manner.

The chemical shift of a proton bonded to a carbon atom is thought to depend largely on the total electron density at that carbon atom. This view has recently been supported theoretically.[9] With these points in mind, we may discuss the electronic behavior of the intervening atom or group, Y, in $C_6H_5YCH{=}CH_2$ and $C_6H_5YCH_3$.

The chemical shifts of the side-chain protons in the two types of compounds, where Y is O, S, and CH_2, are compared in Table 3. We see that the τ-values of the β-hydrogens in $C_6H_5YCH{=}CH_2$ decrease in the order: PVE>ABz>PVS, *i.e.* O>CH_2>S. The order changes into CH_2>S>O for the methyl hydrogens in $C_6H_5YCH_3$. Since the electron density of the β-carbon in the vinyl compounds is controlled mainly by the electron-donating or -accepting character of Y through the π-bond, the O>CH_2>S order should be taken to reflect the order of the π-electron-donating ability of these atoms or group. In the same manner, it should be the effect of Y through the σ-bond that determines the electron density of the methyl carbon in $C_6H_5YCH_3$. The observed order of chemical shifts, CH_2>S>O, suggests that the electron-accepting character of Y through the σ-bond increases in the CH_2>S>O order. Therefore, it can be said that oxygen behaves as a π-doner-σ-acceptor, while divalent sulfur acts as a π,σ-acceptor, provided allylbenzene is taken as the standard.

Table 3. Comparisons of the proton chemical shifts

Compound	Proton	Chemical shifts (τ) –O–	–S–	$-CH_3-$
$C_6H_5YCH_3$	methyl	6.34[2]	7.58[2]	8.80[10]
$C_6H_5YCH{=}CH_2$	α	3.45	3.56	4.09
	β-cis	5.33	4.77	5.00
	β-trans	5.67	4.75	5.00

(B) Transmission Efficiency. The ρ-values for the methyl proton in $XC_6H_4YCH_3$ and the *β-trans* protons in $XC_6H_4YCH{=}CH_2$ are summarized in Table 4. Toluene, in which no atom is interposed between the phenyl ring and the methyl group, has a ρ value of -0.214 τ/σ. When a CH_2 group intervenes, ρ decreases in magnitude to -0.113,[10] about one half the value for toluene. When the CH_2 group is replaced by an oxygen atom, the efficiency of transmission increases to -0.270,[11] which exceeds in magnitude the corresponding value for toluene. That is to say, the electronic effect is transmitted with amplification under the influence of the oxygen atom. On the contrary, the sulfur atom has no such effect. The ρ value of thioanisole is only -0.115,[2] nearly equal to that of ethylbenzene. This indicates that, in $XC_6H_4YCH_3$, sulfur is a less efficient transmitter of substituent effects than oxygen.

In $XC_6H_4YCH{=}CH_2$, the transmission efficiency attenuates on going from styrene (-0.335) to allylbenzene (-0.126) and is amplified by the insertion of oxygen

Table 4. ρ-Values for the chemical shifts of terminal protons

Compound	Proton	ρ (τ/σ) –O–	–S–	$-CH_2-$	–None–
$X-C_6H_4Y-CH_3$	methyl	-0.270[11]	-0.115[2]	-0.113[10]	-0.214[2]
$X-C_6H_4Y-CH{=}CH_2$	*β-trans*	-0.378	-0.448	-0.126	-0.335

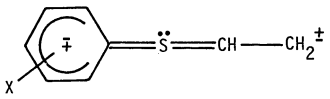
(−0.378), in just the same manner as in $XC_6H_4YCH_3$. One surprising exception is the enhancement of the transmission efficiency of sulfur; the ρ value (−0.448) of PVS is not only greater than that of styrene but exceeds the value for PVE. This finding can be deemed as the first clear example of a case which supports Marcus' conjecture regarding an enhanced transmission efficiency of sulfur relative to oxygen.[2)]

Comparing the transmission efficiencies of sulfur and oxygen, Marcus *et al.*[2)] only mentioned that sulfur must be favored over oxygen in situations where the d-orbitals of sulfur can participate in conjugation. In our opinion, however, this reasoning is still rather ambiguous.

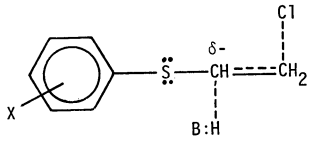
According to Price and Oae,[12)] the sulfur atom shows three unique conjugative contributions in addition to the usual electron-donating conjugation common to oxygen and sulfur. Of the three contributions, the electron-accepting and electron-sharing pπ-dπ conjugations play important roles in stabilizing the anionic and radical intermediates. The remaining one is expected to be important when the sulfur atom is placed between two unsaturated groups. This contribution is often referred to as the "through-conjugative" contribution.

As the system examined here has two unsaturated groups directly bonded to the sulfur atom, it seems reasonable to attribute the cause of the enhanced transmission to the through-conjugative contribution of the sulfur atom. That is, the transmission of substituent effects is considered to be enhanced by the contribution of the following canonical structure involving a pπ-dπ-pπ conjugation:



II

In connection with the above argument, recent experimental results by Oae and Yano[13)] are of particular interest. They examined the E2-type elimination reaction of β-arylthioethyl chloride kinetically and found that the ρ value for this reaction, 1.98, was greater than that of the oxygen analog, 1.33. As the intermediate suggested for this reaction (III) has a structure similar to that of PVS, it is probable that the "through-conjugative" contribution of the sulfur atom shows up in the transition state. In addition, the reported ratio of reaction constants between sulfur and oxygen derivatives ($\rho_s/\rho_o=1.49$) is a little greater than that observed



III

in our PMR measurements ($\rho_s/\rho_o=1.19$). This suggests that the ρ_s/ρ_o ratio increases with an increase in the anionic character of the system considered.

In conclusion, the sulfur atom behaves as a strong transmitter of substituent effects when interposed between two unsaturated groups. This can be interpreted in terms of the "through-conjugation" of the sulfur atom.

The authors are grateful to Mr. Y. Terawaki of this Faculty for his measurements of the proton magnetic resonance spectra and to Professor T. Otsu of Osaka City University for supplying the *p*-nitrophenyl vinyl sulfide.

Transmission of Substituent Effects through Oxygen and Sulfur Atoms. II. ^{13}C Chemical Shifts of Ring-Substituted Phenyl Vinyl Ethers and Sulfides

Okitsugu KAJIMOTO, Masaru KOBAYASHI, and Takayuki FUENO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received October 7, 1972)

The ^{13}C chemical shifts of ring-substituted phenyl vinyl ethers and sulfides were measured and discussed in relation to the change in electron distribution caused by the ring-substitution. The Hammett plots of the shifts for the terminal carbon confirm the greater transmission efficiency of sulfur atom. An "inverse" substituent effect was found for the α-carbon of both compounds. This suggests that the bond-polarization plays an important role in the transmission of electronic effect.

In the preceding paper,[1] transmission of substituent effects through oxygen and divalent sulfur has been investigated for proton-magnetic-resonance (PMR) chemical shifts. The usual Hammett ρσ treatment revealed that divalent sulfur atom, when interposed between two conjugated systems, behaves as a more efficient transmitter of the electronic effect than oxygen atom. It was then suggested that the d-orbital of sulfur may play an important role in the transmission of substituent effect by an additional resonance contribution termed "through-conjugation."

Critically speaking, however, some uncertainty attaches to the investigation of substituent effect based on PMR substituent chemical shifts. Proton chemical shifts do not reflect a unique physical quantity of molecules. They are affected by several factors such as the diamagnetic as well as paramagnetic shielding by electrons of the hydrogen atom in question and the adjacent atom.[2] On the other hand, ^{13}C chemical shifts can be definitely related to the electron density of the carbon atom of interest. Therefore, measurements of the ^{13}C substituent chemical shifts enable us to estimate directly the electronic effects of substituents on the electron densities of various carbon atom in molecules.

In this paper, we compare the ^{13}C chemical shifts of substituted phenyl vinyl ethers and sulfides. The substituent effects on the terminal carbon were found to be in line with the results of PMR studies.[1] Further, the substituent dependence of the chemical shifts of other carbon atoms offered an interesting information on the mechanism of the transmission of electronic effects.

Experimental

The ^{13}C NMR spectra (neat) were taken at 26°C on a JEOL C-60HL spectrometer equipped with a 15.09 MHz RF unit. The signal-to-noise ratio of the spectra was enhanced by the ^{13}C–H noise decoupling. The chemical shift measurements were carried out by a nuclear resonance single side-band technique; they were accurate to within ±0.2 ppm. CS_2 was used as an external standard; higher-field shifts were represented by positive δ values.

Results

Assignments were based on the additivity rule[3] and on the splitting of peaks on partial decoupling. There are some uncertainties in the assignment of the peaks spaced within 1 ppm. All the peaks assigned are listed in Tables 1 and 2.

The ^{13}C chemical shifts δ of the α and β carbons were found to be linearly correlated with Hammett σ values, as shown in Figs. 2 and 3, respectively. The ρ values, defined by $\delta_X-\delta_H=\rho\sigma$, are listed in Table 3, together with correlation coefficients r and standard deviations s. It is noteworthy (1) that, with both the α- and β-carbons, PVS has the ρ values greater in

magnitude than those of PVE and (2) that, for both PVE and PVS, the ρ values for β-carbons are positive while those for α-carbons, negative.

Discussion

Electron Distributions in PVE and PVS. There have been several treatments of the relation between ^{13}C chemical shift and the electron density of the carbon atom. Spiesecke and Schneider[4] measured the ^{13}C chemical shifts δ for $C_5H_5^-$, C_6H_6, $C_7H_7^+$, and $C_8H_8^{++}$ and proposed the empirical relation

$$\delta = 160(q_\pi - 1) \text{ ppm} \quad (1)$$

where q_π is the π-electron density of the carbon atom in question. Karplus and Pople[5] justified the above equation on the basis of π-molecular orbital calculations.

Recently, Tokuhiro and Fraenkel[6] calculated the ^{13}C chemical shifts of nitrogen heterocycles using the Karplus-Pople equation coupled with all-valence-shell-electron SCF-MO's. They found that, even though the observed shifts are roughly linear with the π-charge, the linearity is considerably improved when δ is plotted against the total electronic charge. Using the CNDO wave functions of Bene and Jaffé,[7] they obtained the equation;

$$\delta = 155(q_{\pi+\sigma} - 4) \text{ ppm} \quad (2)$$

where $q_{\pi+\sigma}$ is the total electron density on the carbon atom of interest. Bloor and Breen[8] also obtained linearity between δ and *total charge* using CNDO/2 MO's.

In reality, however, many approximations are invoked for the derivation of Pople's equation from the

formal expression of Ramsey. Therefore, one should be careful in applying the above linear relationship to carbon nuclei of much different environment. In such cases, chemical shifts may be largely affected by factors other than electron density. For the compounds treated in this paper, however, all the carbon nuclei are situated in so similar a condition that it would be reasonable to assume a roughly linear relationship. In what follows, therefore, we will consider the ^{13}C chemical shift as a measure of the electron density on carbon atom.

Table 4. Side chain ^{13}C chemical shifts (ppm from CS_2)

Compound	Carbon	Chemical shifts		
		-O-	-S-	$-CH_2-$

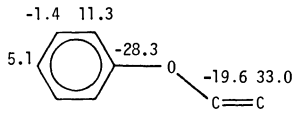
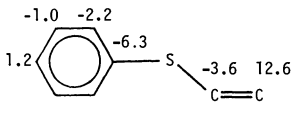
b) G. B. Savitsky and K. Namikawa, *J. Chem. Phys.*, **67**, 2430 (1963).

Table 4 summarizes the side-chain ^{13}C chemical shifts of anisole, PVE and their sulfur analogs. The methyl carbon of anisole shows a shift considerably lower than that of thioanisole. This implies that oxygen attracts electron through σ-bond more strongly than does sulfur. On the other hand, the ethylenic β-carbon of PVE is observed at δ about 20 ppm higher than that of PVS. This reflects a strong π-donating character of oxygen. These results confirm the validity of our conclusion which was previously drawn on the basis of ^1H chemical shifts of the same compounds.

Illustrated below are the ^{13}C chemical shifts of the various carbons of PVE and PVS with respect to benzene. Because of the parallelism between δ and electron density, these shifts may be regarded as representing the electron distribution over the molecules. Positive values correspond to excess electron.

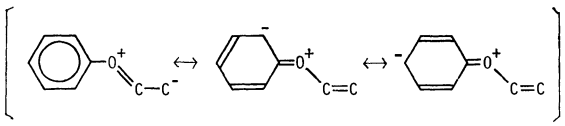


I



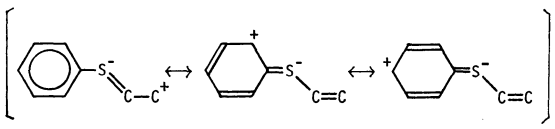
II

It is seen that the presence of oxygen atom increases the electron densities of the β carbon of the vinyl moiety as well as the *ortho* and *para* carbons of the benzene ring. The tendency is in accord with the prediction which can be made on the basis of classical canonical structures.



III

On the other hand, the charge distribution is rather uniform in PVS. This can also be rationalized by considering the canonical forms in which the sulfur atom acts as a π-electron accepter.

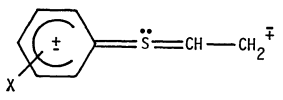


IV

Participation of such structures in resonance should neutralize the charge alternation caused by III, resulting in a flat distribution of electrons.

Substituent Effects on the Chemical Shifts of α and β Carbons. The Hammett-type substituent effects on ^{13}C chemical shifts were first reported by Spiesecke and Schneider[9] for monosubstituted benzenes. Later on, Dhami and Stothers[10] measured the ^{13}C chemical shifts of ring-substituted styrenes, anisoles, acetophenones, and methyl benzoates. Side-chain ^{13}C chemical shifts of these compounds, however, did not show clear dependence on Hammett's σ except for the β-carbon of styrenes. Our present work provides additional examples of fairly good Hammett dependence of ^{13}C chemical shifts. Moreover, it gives us interesting informations concerning the transmission of electronic effects.

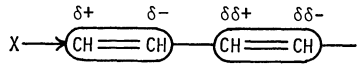
First, we compare the magnitudes of ρ between PVE and PVS. Thus, the ρ values for PVS are about 1.5 times greater than thoes of PVE with both the α and β carbons, indicating an enhanced transmission of substituent effects through sulfur atom. As has been described previously, this is considered to have been caused mainly by the through-conjugative participation of sulfur d-orbitals in π-conjuagtion. The presence of $p\pi$-orbitals in both sides of sulfur atom is the essential condition for it. The concept can best be represented pictorially by the structure



V

Next, the signs of ρ enable us to deduce the mechanism of transmission. For the β-carbons of both PVE and PVS, the observed peaks tend to show lower-field shifts with the increase in the σ-value of substituent groups. This means that the electron density on carbon atom decreases as the electron-withdrawing ability of substituents increases. For the α-carbon, however, the chemical shift shows an "inverse" dependence on substituents; an electron-withdrawing substituent increases the electron density on the α-carbon.

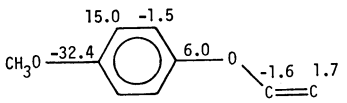
One explanation for these facts may be given in terms of bond polarization. It is not unreasonable to consider that the substituent effects are transmitted by successive polarization of –CH=CH– units.



In the *p*-CH_3O derivatives for instance, the increments in the ^{13}C chemical shifts caused by the ring substitu-

9) H. Spiesecke and W. G. Schneider, *J. Chem. Phys.*, **35**, 731 (1961).
10) K. S. Dhami and J. B. Stothers, *Can. J. Chem.*, **43**, 479 (1965); *ibid.*, **43**, 510 (1965); *ibid.*, **44**, 2855 (1966); *ibid.*, **45**, 233 (1967).

tion are as follows:



Successive bond polarization can clearly be seen.

Thus, the direction of substituent effect on the α-carbon should be the reverse of that on the β-carbon. Validity of this concept has already been proved for the case of *trans*-1-substituted-1,3-butadienes by comparing the observed ^{13}C chemical shifts with the electron distribution calculated by the CNDO/2 method.[11] Similar theoretical treatments of PVE and PVS will be given in a subsequent paper.

In conclusion, sulfur atom transmits the electronic effect of substituents more efficiently than oxygen atom, primarily through its pπ-dπ-pπ conjugation. Substituent effects on the ^{13}C chemical shifts of the α and β carbons of a vinyl group are opposite in direction, indicating polarization of the vinyl π-bond.

The authors are indebted to Mr. H. Okuda, this Faculty, for the ^{13}C NMR measurements.

Transmission of Substituent Effects through Oxygen and Sulfur Atoms. III. The Ionization Equilibrium Constants of Ring-substituted *cis*-β-Phenoxyacrylic Acids

Okitsugu KAJIMOTO, Masaru KOBAYASHI, and Takayuki FUENO

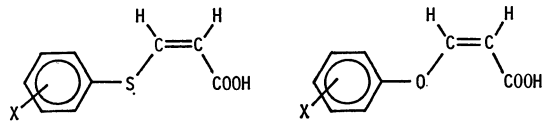
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received October 7, 1972)

cis-β-Phenoxyacrylic acid and several of its ring-substituted derivatives were prepared, and their ionization constants were determined in 50% ethanol–water at 25 °C. The Hammett ρ value for the ionization of these acids, 0.439, is smaller than that reported for *cis*-β-phenylthioacrylic acids, 0.531. The greater efficiency of the sulfur atom in transmitting the substituent effects is explainable in terms of the "through-conjugation" of the sulfur atom in the thioacrylate anions formed.

In the preceding two papers,[1,2] we treated the effects of substituents on the ^1H and ^{13}C chemical shifts of phenyl vinyl ether and sulfide. It was found that the sulfur atom behaves as a more efficient transmitter of substituent effects than does oxygen when it is interposed between two unsaturated groups. This finding offered strong evidence for the presence of a "through-conjugation" in sulfur bondings.[3] In this paper we will examine the ρ values for acid ionization, since ionization equilibria are fundamental to Hammett's ρσ relationship.

Hogeveen[4] reported the ionization constants of *cis*-β-phenylthioacrylic acids (I, abbreviated as *cis*-β-PSA hereafter).[5] For the purpose of comparison, we prepared *cis*-β-phenoxyacrylic acid (II, abbreviated as *cis*-β-POA) and its *p*-CH_3O, *m*-CH_3O, *p*-CH_3, *m*-CH_3, *p*-Cl, and *m*-Cl derivatives, and measured their ionization constants, K_a. The ρ-value for *cis*-β-PSA was found to be greater than that for *cis*-β-POA.



I II

Experimental

Synthesis of cis-β-*Phenoxyacrylic Acids.* The *cis*-β-phenoxyacrylic acids were prepared by the direct *trans* addition of a substituted phenol to propiolic acid in aqueous potassium hydroxide.

$$XC_6H_4OH + HC{\equiv}CCOOH \xrightarrow{OH^-} II$$

The procedure for preparation was analogous to that used for the base-catalyzed addition of thiophenol to propiolic acid.[6] A substituted phenol (0.1 mol) was dissolved in 60 ml of 4N potassium hydroxide, and then the solution was heated to 60—70°C under stirring. After 0.1 mol of propiolic acid had been added, the mixture was stirred for 2—3 hr at 70—80 °C and then cooled. On acidifying the solution with hydrochloric acid, a sol layer was separated out. The liquid layer, together with the sol layer, was subjected to extraction with ether. A 5% aqueous potassium hydroxide was added to the extract, and the aqueous layer was carefully neutralized, and then separated from the ethereal layer. The subsequent acidification of the aqueous layer with hydrochloric acid gave a solid product. It was isolated by filtration and recrystallized from ligroin. The products were identified by elemental analysis and by NMR spectral measurements (Table 1).

In preparing *cis*-β-POA, we at first followed Gottesman's method:[7]

1) T. Fueno, O. Kajimoto, K. Izawa, and M. Masago, This Bulletin, **46**, 1418 (1973).

2) O. Kajimoto, M. Kobayashi, and T. Fueno, *ibid.*, **46**, 1422 (1973).

3) C. C. Price and S. Oae, "Sulfur Bonding," Ronald Press, New York, N. Y. (1962).

4) H. Hogeveen, *Rec. Trav. Chim.*, **83**, 813 (1964); H. Hogeveen, G. Maccagnani, and F. Taddei, *ibid.*, **83**, 937 (1964).

5) In this paper we refer to the ethylenic carbon atoms at the positions α and β with respect to the –COOH group as the α and β carbons, respectively. Therefore, care must be taken when one compares the properties of these carbon atoms with those of the α and β carbons in phenyl vinyl ether or thioether.

a) The figures in parentheses are for *trans*-β-phnoxyacrylic acid.

$$C_6H_5ONa + HC{\equiv}CCOOEt \xrightarrow[H_2O]{OH^-} \text{II}$$

He reported that the product had a mp of 129 °C and concluded it to be a *cis*-acid. Our NMR measurement, however, revealed that it was a *trans* isomer. For the *p*-Cl derivative, also, a mixture of *cis* and *trans* isomers was formed. No doubt, his identification was erroneous.

Determination of the Ionization Constants. The pK_a values were determined potentiometrically with a Hitachi-Horiba Model F-5 pH meter at 25±0.5 °C by the ordinary method.[8] A 25 ml portion of 0.01N acid in aqueous ethanol (50% by volume) was titrated with a 0.1N potassium hydroxide solution under a nitrogen flow. The pK_a values were then calculated by the following equation:

$$pK_a = pH + \log \frac{[HA]-[H^+]}{[A^-]+[H^+]}$$

where [HA] is the concentration of acid, $[A^-]$ is the stoichiometric concentration of ionized acid, which can be regarded as equal to the concentration of KOH added, and $[H^+]$ is the hydrogen-ion concentration as determined from the measured pH, which can be neglected when the pH is above 5.

In practice, the pK_a of each acid was determined as an average value of eight data measured in the pH range of 4.7—6.3. The scatters of the measured data from the average value did not exceed ±0.02.

NMR Measurements. The details were described in a previous paper.[1] Samples, 10% in $CDCl_3$, were examined at room temperature. The experimental errors were no greater than ±0.5 Hz.

IR Measurements. The IR spectra of β-POA's were recorded on a Hitachi Perkin-Elmer 225 spectrometer as 5×10^{-3} mol/l CCl_4 solutions in a 1 cm quartz cell. On the dilution of the solution, the associated OH stretching peak of *cis*-β-POA did not change in its intensity relative to the free OH peak. Evidently this peak originates from intramolecular hydrogen bonding.

Results

The apparent ionization constants of substituted *cis*-β-POA measured by the above method are given in Table 2, together with those of *cis*-β-PSA reported by Hogeveen.[4] The Hammett relationship was found to hold, as is shown in Fig. 1. The least-squares fit gave ρ=0.439, with the correlation coefficient of 0.974. The ρ value is smaller than that of 0.531 which was reported by Hogeveen for *cis*-β-PSA.

The chemical shifts of the α-proton of *cis*-β-POA are plotted against the Hammett σ-values in Fig. 2; this

TABLE 2. IONIZATION CONSTANTS (pK_a) OF *cis*-β-PHENOXYACRYLIC AND *cis*-β-PHENYLTHIOACRYLIC ACIDS

plot gives the ρ value of $-0.154\ \tau/\sigma$. The corresponding value for *cis*-β-PSA[4] was found to be −0.230.

Discussion

(A) Transmission of Substituent Effects. We will compare the relative efficiencies of oxygen and sulfur atoms in transmitting the electronic effects of substituents on the ionization constants of $XC_6H_4YCH_2COOH$ and $XC_6H_4YCH{=}CHCOOH$.

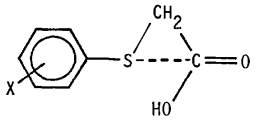
Behaghel and Rollmann[9] measured the ionization constants of $C_6H_5OCH_2COOH$, $C_6H_5SCH_2COOH$, $C_6H_5SeCH_2COOH$, and some of their derivatives. However, recent measurements of pK_a by Pasto *et al.*[10] for substituted phenylthioacetic acids have revealed that the data obtained by those workers are not reliable. Hence, we have evaluated the ρ value on the basis of the pK_a data reported by the latter workers. Fortunately, the ionization constants of phenoxyacetic acids have also been extensively examined in aqueous solution by Hayes and Branch.[11] For the sake of fair comparisons, we selected the CH_3O, CH_3, H, Cl, and NO_2 derivatives and evaluated the ρ-values with respect to only these substituents. The results are summarized in Table 3.

Phenoxyacetic acids show a slightly larger ρ value (0.312) than phenylthioacetic acids (0.296)—*i.e.*, O>S. Conversely, with the acrylic type of acids, the result is O<S, as has already been described. Thus, there is an enhanced transmission by the sulfur atom interposed between two unsaturated groups. This fact reinforces the validity of the concept of the "through-conjugative" behavior of the sulfur atom.[1,2] The conjugation is considered to be involved more favorably in the anions formed than in the undissociated acids.

Table 3. ρ-Values and the related quantities for the ionization equilibria

	$X-C_6H_4-Y-CH_2COOH$		$X-C_6H_4-Y-CH=CHCOOH$(*cis*)	
	O[11]	S[10]	O	S[4]
ρ	0.312	0.296	0.439	0.531
r	0.985	0.980	0.974	0.991
s	0.021	0.021	0.046	0.035
n[a]	9	8	7	6
pK_a(X=H)	3.17	3.53	6.02	5.93

a) The number of substituents.



III

A comparison of the ρ values of the acetic acid derivative gives us additional information of interest. For ^1H chemical shifts, the ρ value varied by a factor of 2 on going from aniosles (−0.270) to thioanisoles (−0.115).[1] In acid dissociation, the diminution in the ρ value is very small. This distinction can be understood by considering the nonbonding interaction[12] between the sulfur atom and the carbonyl group in phenylthioacetic acids III. That is, the acids are provided with two routes for the transmission of the substituent effects, one through σ-bonds and the other through direct nonbonding interaction. The dependence of pK_a on the substituents can thus become greater than would be expected simply from the inefficient transmission through the σ-bonds alone.

The ^1H chemical shifts observed for *cis*-β-POA deserve special attention. The shifts of the α-proton in the *cis*-acids were found to conform to the Hammett relationship, with ρ=−0.154. The ρ value obtained is smaller in magnitude than that for the sulfur analogs, −0.230. These results are in line with our previous observations with phenyl vinyl ethers and sulfides.[1,5]

(B) Relative Acid Strengths of Unsubstituted Acids. The pK_a values of the unsubstituted acids of interest are listed at the bottom of Table 3. Phenoxyacetic acid is more acidic than phenylthioacetic acid, whereas *cis*-phenoxyacrylic acid is a weaker acid than its sulfur

11) N. V. Hayes and G. E. K. Branch, *J. Amer. Chem. Soc.*, **65**, 1555 (1943).

12) Such an interaction has also been proposed by Oae and Yano.[13] They investigated the effect of ring-substituents on the E2 elimination of 3-phenylthio-propyl chlorides and their oxygen analogs. Rate of elimination for the phenylthio derivatives showed Hammett type dependence with the reaction constant of 0.37, while, for oxygen analogs, no noticeable substituent dependence could be found. From this fact, they suggested that the nonbonding interaction may be operative between sulfur atom and terminal two carbons at the transition state.

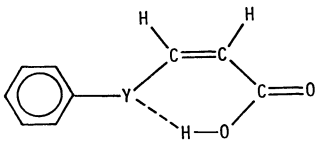
IV



V

analog. This contrast may be explained by considering the anionic form of these acids. With β-phenylthioacrylic acid, the anion, IV, is much stabilized by the electron-accepting conjugation of the sulfur atom. As the acid dissociation equilibria are controlled by the stability of the resulting anion, the thioacrylic acid may well show a greater acidity than its oxygen analog. By contrast, in the case of saturated acids, no such conjugation can occur, resulting in the greater acidity of the oxygen-containing acid because of the greater electronegativity of the oxygen atom.

In addition, the acidity of *trans*-β-POA is greater than that of its *cis* isomer, contrary to the case of cinnamic acids.[14] Such a trend has already been pointed out for β-PSA by Hogeveen, but he gave no explanation.[4] It might be explained in terms of hydrogen-bonded six-membered ring in the *cis*-acids. The hydrogen bonding in V should prevent the ionization, thus decreasing its acidity. This is not the case for *trans*-acid.

The IR measurements of *cis*- and *trans*-β-POA confirm the above interpretation. *cis*-β-POA shows two peaks, at 3543 and 3483 cm^{-1}; the former corresponds to free OH stretching, while the latter corresponds to the intramolecular associated OH stretching.[15,16] By contrast, the *trans* isomer gives only one peak of free OH, at 3546 cm^{-1}. For β-PSA, we have no data, but the situation is probably the same as in β-POA. In fact, a report is available which shows that the electron-donating ability of ethereal sulfur is nearly the same as, or a little greater than, that of oxygen in the hydrogen bonding.[17]

Bond Orbital Calculations on the Methane and Silane Molecules

Susumu KOHDA and Shigeyoshi KATAGIRI

Department of Chemistry, Faculty of Science, Hirosaki University, Hirosaki 036

(Received September 14, 1972)

The non-empirical calculations of CH_4 and SiH_4 are carried out by the bond orbital (BO) and McWeeny and Ohno (MBO) methods. The lowest total energies obtained in these calculations are −40.1621 and −290.1809 a.u. for CH_4 and SiH_4 respectively. The ordinary SC–LCAO–MO calculations are also made for the sake of comparison using the same parameters. The results are compared with the similar calculations of H_2O and NH_3, we can thus see that the BO and MBO calculations show almost the same features as in H_2O and NH_3.

With various approximations and different basis sets, many theoretical calculations have been done for a number of polyatomic molecules. The more complicated the molecular wave functions become, the less lucid the chemical intuition or pictorial image for the chemical bonds, lone pairs, and inner shells becomes. Hurley, Lennard-Jones, and Pople,[1] and Parr and Parks[2] gave satisfactory discussions of the separated-electron-pair method in which electrons in a molecule are classified into groups for the chemical bonds, lone pairs, and inner shells, and in which the total wave function is written as an anti-symmetrized product of the localized two-electron functions, one for each group. McWeeny and Ohno[3] have carried out the non-empirical calculations of the water molecule using such a concept. They proposed a method of constructing the electron-pair functions from orbitals with pair nonorthogonality which were not given by the former authors explicitly. They obtained a fairly good total energy as compared with the ordinary SC–LCAO–MO results. Tsuchida and Ohno[4] made a similar calculation of NH_3, and concluded that the general features were almost the same for H_2O and for NH_3.

In this investigation, we carried out the non-empirical calculations of CH_4 and SiH_4 using the SC–LCAO–MO, BO, and McWeeny and Ohno methods (They utilized

1) A. C. Hurley, J. E. Lennard-Jones, and J. A. Pople, *Proc. Roy. Soc. Ser. A.*, **220**, 446 (1953).

2) J. M. Parks and R. G. Parr, *J. Chem. Phys.*, **28**, 335 (1958).

3) R. McWeeny and K. Ohno, *Proc. Roy. Soc. Ser. A*, **255**, 367 (1960).

4) A. Tsuchida and K. Ohno, *J. Chem. Phys.*, **39**, 600 (1963).

the term "modified electron-pair method." Here we will call it the "modified bond orbital method," MBO). The MBO approximation is an extension of BO. We will describe these methods briefly in the following sections.

The CH_4 and SiH_4 molecules differ from H_2O and NH_3 in the point that the former molecules have no lone pair. In SiH_4, furthermore, the valence orbital quantum number is higher than in the others by one. Therefore, it seemed that it would be interesting to see, in the BO and MBO methods, whether or not the frozen-core approximation is as adequate in the CH_4 and SiH_4 molecules as in H_2O and NH_3.[3,4]

The basis sets used throughout this paper are the minimal Slater-type AO's. The orbital exponents have the following values, which were obtained from Slater's rules except for the hydrogen 1s AO's:

$$\delta_{1s}(C)=5.7,\ \delta_{2s}(C)=\delta_{2p}(C)=1.625 \text{ and } \delta_{1s}(H)=1.2$$

for CH_4, and:

$$\delta_{1s}(Si)=13.7,\ \delta_{2s}(Si)=\delta_{2p}(Si)=4.925,$$
$$\delta_{3s}(Si)=\delta_{3p}(Si)=1.383 \text{ and } \delta_{1s}(H)=1.2$$

for SiH_4. The molecular geometry is assumed to be tetrahedral for both molecules. The bond distances are fixed to be 2.05 a.u.[14] and 2.796 a.u.[5] for the C–H and Si–H bonds respectively.

SC-LCAO-MO Calculation

The CH_4 molecule has been studied by many authors using semi-empirical and non-empirical methods.[6–15] For the SiH_4 molecule, however, there have not been many studies.[16–18] Among others, Boers and Lipscomb[19] recently reported SC–LCAO–MO calculations with and without Si 3d AO's. The sets of orbital exponents and bond distances in our calculations are different from theirs. We made ordinary SC–LCAO–MO calculations[20] in order to compare them with the BO and MBO calculations.

Table 1. CH_4

1) Orbital energy and MO

$$\boldsymbol{b} = (1s, b_1, h_1, b_2, h_2, b_3, h_3, b_4, h_4) \quad (4)$$

by the procedure of McWeeny and Ohno.[3] That is, all the valence orbitals were Schmidt-orthogonalized to the carbon inner shell (1s), the carbon 2s′ and 2p orbitals were tetrahedrally hybridized, and finally all the obtained orbitals were orthonormalized according to Lowdin's method. The result is expressed by the matrix form as:

$$\boldsymbol{b} = \boldsymbol{a}\boldsymbol{V} \quad (5)$$

where $\boldsymbol{V}$ is the (9×9) transformation matrix. The orthonormalized orbitals, b_i and h_i, were used to construct the bond orbitals (BO's). As the b_i points to the ith H atom, the ith BO is defined by:

$$B_i = \sqrt{1-\lambda^2}\, b_i + \lambda h_i \quad (6)$$

where λ is a variational parameter. We constructed the ground-state wave function from these BO's as follows:

$$\Psi = \det|1s\bar{1}sB_1\bar{B}_1B_2\bar{B}_2B_3\bar{B}_3B_4\bar{B}_4|, \quad (7)$$

the orbitals without and with a bar in the Slater determinant accomodate electrons with α and β spins respectively.

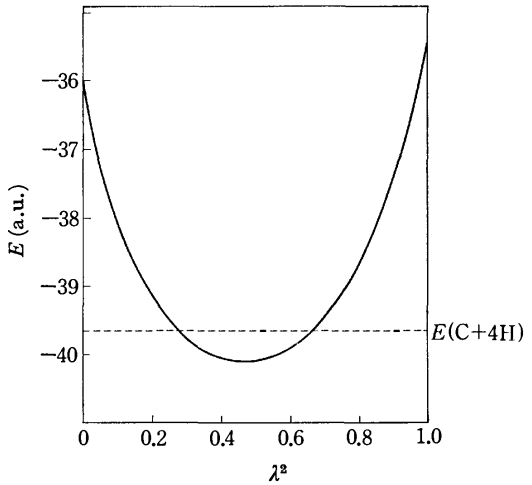

Fig. 1. The total energy of CH_4 as a function of λ^2. The dotted line is the energy of four atoms (E. Clementi, *J. Chem. Phys.*, **40**, 1944 (1964)).

The total energy is expressed as a function of the parameter, λ^2, the calculated results are shown in Fig. 1. The variational parameter which makes the total energy minimum is found to be $\lambda^2=0.46$. This value is very close to those for H_2O ($\lambda^2=0.43$) and NH_3 ($\lambda^2=0.42$). The minimum value, −40.1074 a.u., of the total energy is only slightly higher than the SC–LCAO–MO result, −40.1130 a.u., presented in the previous section.

Silane. The valence orbitals of the Si atom are the 3s and 3p AO's, and we assume that the 2s and 2p AO's also form the inner shells. The basis set, $\boldsymbol{a}$, is transformed into the orthonormalized basis set, $\boldsymbol{b}$, in the same manner as in CH_4:

$$\boldsymbol{a} = (1s, 2s, 3s, 2p_x, 2p_y, 2p_z, 3p_x, 3p_y, 3p_z, H_1, H_2, H_3, H_4) \quad (8)$$

$$\boldsymbol{b} = (1s, 2s, 2p_x, 2p_y, 2p_z, b_1, h_1, b_2, h_2, b_3, h_3, b_4, h_4) \quad (9)$$

$$= \boldsymbol{a}\boldsymbol{V} \quad (10)$$

where $\boldsymbol{V}$ is the (13×13) transformation matrix. The ground-state wave function is expressed as:

$$\Psi = \det|(K^2)(L^8)B_1\bar{B}_1B_2\bar{B}_2B_3\bar{B}_3B_4\bar{B}_4| \quad (11)$$

where (K^2) and (L^8) indicate $(1s\bar{1}s)$ and $(2s\bar{2}s2p_x\bar{2}p_x2p_y\bar{2}p_y2p_z\bar{2}p_z)$ respectively, and where B_i are the BO's defined in Eq. (6).

In Fig. 2 the total energy is given as a function of λ^2. We find the minimal energy to be −290.1267 a.u. when λ^2 is 0.48; this value is not very different from that of CH_4. The total energy is, however, considerably higher than that of the SC–LCAO–MO result, −290.1690 a.u.

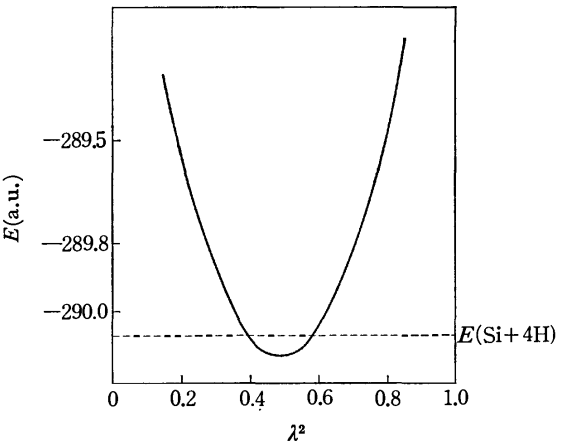

Fig. 2. The total energy of SiH_4 as a function of λ^2. The dotted line is the energy of four atoms (E. Clementi, *J. Chem. Phys.*, **40**, 1944 (1964)).

MBO Calculation

By using the orthonormalized orbitals, b_i and h_i, obtained in the previous section, two BO's, B_i and $\tilde{B}_i$, are defined as follows:

$$B_i = \sqrt{1-\lambda^2}\, b_i + \lambda h_i \quad (12)$$

$$\tilde{B}_i = \sqrt{1-\mu^2}\, b_i + \mu h_i, \quad (13)$$

from which we construct the electron-pair function of the ith bond as Eq. (14):

$$(B_i\tilde{B}_i) = N[\det|B_i\bar{\tilde{B}}_i| + \det|\tilde{B}_i\bar{B}_i|] \quad (14)$$

where N is a normalization constant. The total wave functions of the ground state are given by Eqs. (15) and (16) for CH_4 and SiH_4 respectively:

$$\Psi_m = \det|(K^2)(B_1\tilde{B}_1)(B_2\tilde{B}_2)(B_3\tilde{B}_3)(B_4\tilde{B}_4)| \quad (15)$$

$$\Psi_s = \det|(K^2)(L^8)(B_1\tilde{B}_1)(B_2\tilde{B}_2)(B_3\tilde{B}_3)(B_4\tilde{B}_4)|. \quad (16)$$

Equation (14) reflects the concept of the "different orbitals for different spins"; and the total energy expressions for CH_4 and SiH_4 become a little more complicated because of the overlap between B_i and $\tilde{B}_i$, which is given as $\sqrt{(1-\lambda^2)(1-\mu^2)}+\lambda\mu$.

The dependence of the total energy on the parameters, λ^2 and μ^2, is shown in Figs. 3 and 4 for each molecule. The best pairs of the parameters, λ^2 and μ^2, are 0.74 and 0.19, and 0.78 and 0.20, which give the total energies of −40.1621 and −290.1809 a.u. for CH_4 and SiH_4 respectively. The lowering of the

total energy from the SC-LCAO-MO result is bigger in CH_4 than in SiH_4. However, the lowering from the BO calculation is about the same for both molecules.

In Table 3 the results are summarized, along with the results of other calculations for the sake of comparison.

Discussion

Tsuchida and Ohno[4] discussed the degree of localization for the two basic AO's of NH_3, which correspond to the basic AO's given in Eqs. (3) and (4) for CH_4 in our calculations. They calculated the self-Coulomb integral $(\chi\chi|\chi\chi)$[23] as the measure of the localization for the atomic orbital, χ. In our orthonormalized and original AO's, the self-Coulomb integrals are:

$$(hh|hh) = 0.8432 \text{ a.u.}$$
$$(HH|HH) = 0.7500 \text{ a.u.}$$

for CH_4, and:

$$(hh|hh) = 0.8722 \text{ a.u.}$$
$$(HH|HH) = 0.7500 \text{ a.u.}$$

for SiH_4. We can see that the orthonormalized AO's are more localized than the original AO's in both molecules.

In the MO theory, as is well known, a wave function given by a single Slater determinant is invariant with respect to the unitary transformation among the doubly-filled MO's. Moreover, we can construct, from the MO's in Tables 1 and 2, the equivalent orbitals,[24-27] ψ_i, which may be considered as localized orbitals along the ith C–H or Si–H bond. For example, ψ_2 of SiH_4 may be expressed as follows:

$$\psi_2 = \frac{1}{2}(3a_1+2t_{2,x}+2t_{2,y}+2t_{2,z}),$$

where other MO's are assumed to form purely the inner shells of the Si atom, not entering into the chemical bond, and are neglected. Rewritten in terms of original AO's, the equivalent orbital is:

$$\psi_2 = 0.027(1s) - 0.096(2s) + 0.324(3s) - 0.073(2p) + 0.268(3p) + 0.864(H_2) - 0.163(H_1+H_3+H_4).$$

Comparing the above equivalent orbital with the corresponding bond orbital, B_2, at the optimum parameter:

$$B_2 = 0.021(1s) - 0.079(2s) + 0.301(3s) - 0.055(2p) + 0.287(3p) + 0.521(H_2) - 0.034(H_1+H_3+H_4),$$

we can see that the two orbitals, ψ_2 and B_2, are very similar; this is the same in the case of the CH_4 molecule. It is notable that we can get such similar orbital by entirely different approaches. Such a similarity of the two orbitals has already been shown in NH_3.[4]

The BO calculation gives a higher total energy than does the SC-LCAO-MO calculation, but the MBO calculation gives a lower one in both molecules if the same basis set is used. In SiH_4, as is shown in Eq. (9), the 2s and 2p AO's are fixed as inner shells and are not allowed to take part in the binding. The gross atomic populations of the 2s and 2p AO's resulting from the SC-LCAO-MO calculation are smaller than

2. This seems to be the reason why the energy lowering from the SC–LCAO–MO results by the MBO method is smaller in SiH_4. In the MBO calculation we take into account the electron correlation between the different spins, α and β, to some extent. However, no such consideration is taken into account in the BO calculation. The optimum values of λ^2 and μ^2 are considerably different from that of λ^2 in the BO for both the molecules. This is also clearly reflected in the B_i and $\tilde{B}_i$ orbitals, given in Eqs. (12) and (13). These orbitals for SiH_4 are as follows:

$$B_2 = 0.014(1s) - 0.064(2s) + 0.035(3s) - 0.031(2p) + 0.087(3p) + 0.901(H_2) - 0.022(H_1+H_3+H_4),$$

$$\tilde{B}_2 = 0.025(1s) + 0.087(2s) + 0.527(3s) - 0.073(2p) + 0.452(3p) + 0.110(H_2) - 0.052(H_1+H_3+H_4).$$

The energy lowering from the BO approximation should be regarded as resulting from this intrabond correlation.

To summarize briefly, we can obtain, without self-consistent iterative calculations, total energies comparable to or slightly better than the SC–LCAO–MO results. And the optimum polarization parameters, in the BO method, take about the same value in CH_4, SiH_4, NH_3, and H_2O. It may be considered that the above obtained values are useful as the optimum polarization parameters for the covalent X–H bond of other molecules.

We are now preparing the application of the BO method to the excited states of CH_4.[28]

The authors wish to express their hearty thanks to Professor K. Ohno for his valuable discussions.

The molecular integrals were calculated on the HITAC 5020E Computer at the University of Tokyo Computer Centre, using the library program written by Professor H. Taketa. The authors are very grateful to him for his helpful communications about the use of the program (Y4/TC/AD05; Molecular Integral over CGTO).

The rest of the calculations were carried out on the NEAC 2200 Model 700 Computer at the Tohoku University Computer Center and on the HIPAC 103 Computer at Hirosaki University.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1432—1437 (1973)

A Method of Correction of the Angular Resolution for Determination of Absolute Total Cross Sections Using Molecular Beams

Isao KUSUNOKI*

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received May 25, 1972)

A general method is given for the correction of angular resolution for the case in which primary beams have a monochromatic velocity and the target gases in the scattering chamber have Maxwellian distribution. In the center-of-mass system the differential cross section for small angles are expressed by three analytical formulas. An apparent differential cross section in the laboratory system is given by averaging contributing differential cross sections in the center-of-mass system. For correction of the angular resolution, the detection probability R is defined for rectangular beams and detector. Using the apparent differential cross section with R-function and beam profile, we can determine the correction factor $\Delta Q_{\mathrm{eff}}(v_{\mathrm{i}})/Q_{\mathrm{eff}}(v_{\mathrm{i}})$. The expression of angular resolution has been applied to previous experimental data.

In a previous study for the determination of absolute total cross sections using molecular beams,[1] sources of error were pointed out and corrected. However, Busch's correction[2] used for the angular resolution of the beam apparatus is not complete, because the formula is only applicable to the case $v_{\mathrm{i}} \gg v_{\mathrm{kw}}$ (*i.e.*, the velocity of the primary beam is much greater than the most probable velocity of the target gases). This is not always the case for experiments in thermal energy range. A general method applicable for slow primary beams is discussed in this paper. For the sake of simplicity, it is assumed that the primary beams have a monochromatic velocity and the target gases in the scattering chamber have Maxwellian distribution.

1. Differential Cross Section in the Center-of-mass System

In the thermal energy range, the total scattering cross section and the differential cross section for small angles are mainly determined by the van der Waals force. The van der Waals potential is given by

$$V(r) = -C/r^{s}. \tag{1}$$

The van der Waals constant C is related to the absolute total cross section Q by the Schiff-Landau-Lifshitz approximation as follows.

$$Q = p(s)\left[\frac{C}{\hbar g}\right]^{2/(s-1)}, \tag{2}$$

* Present address: Reseach Institute for Scientific Measurements, Tohoku University, Sanjo, Sendai 980.

1) I. Kusunoki, This Bulletin, **44**, 2067 (1971).

2) F. Busch, *Z. Phys.*, **193**, 412 (1966).

where

$$p(s) = \frac{\pi^2[2f(s)]^{2/(s-1)}}{\sin\left(\frac{\pi}{2}-1\right)\Gamma\left(\frac{2}{s}-1\right)}.$$

In this case the differential cross section in the classical theory is given by[3]

$$\sigma_c(\theta) = \frac{(s-1)^{2/s}}{s}\left(\frac{2f(s)C}{\mu g^2}\right)^{2/s}\theta^{-2(s+1)/s}, \quad (3)$$

where

$$f(s) = \frac{\sqrt{\pi}\,\Gamma\left(\frac{s-1}{2}\right)}{2\Gamma\left(\frac{s}{2}\right)},$$

μ is the reduced mass, and g the relative velocity. According to Mason *et al.*,[4] this formula is only applicable above the critical angle,

$$\theta_c \approx \left[\frac{\pi^2\hbar^2}{2\mu}\right]^{s/2s-2}[(s-1)f(s)C]^{-1/(s-1)}E^{-(s-2)/(2s-2)}, \quad (5)$$

where

$$E = \frac{1}{2}\mu g^2. \quad (6)$$

For $s=6$ the angle corresponds to

$$\theta_c \simeq 4.445\theta^*. \quad (6)$$

where

$$\theta^* = \frac{1}{k}\sqrt{\frac{\pi}{Q}} \quad (7)$$

and $k=\mu g/\hbar$.

The differential cross section for very small angle can be approximated by a semi-classical theory; Mason *et al.* put it into the following compact exponential form.

$$\sigma_s(\theta) = \left[\frac{kQ}{4\pi}\right]^2\left[1+\tan^2\left(\frac{\pi}{s-1}\right)\right]\exp\left[-\frac{g(s)k^2Q\theta^2}{8\pi}\right], \quad (8)$$

where

$$g(s) = \left[\Gamma\left(\frac{2}{s-1}\right)\right]^2\left[2\pi\Gamma\left(\frac{4}{s-1}\right)\right]^{-1}\tan\left(\frac{2\pi}{s-1}\right), \; s>5 \quad (9)$$

However, Eq. (8) is only applicable for angles such as

$$\theta < [\pi^2 g(s)/2]^{-1/2}\theta_c. \quad (10)$$

For $s=6$ this is reduced to $\theta<0.31\theta_c(=1.38\theta^*)$.

From the above discussion the differential cross sections for the angular range $\theta_c>\theta>0.31\theta_c$ cannot be obtained. But in Busch's paper both Eqs. (3) and (8) are used to express the differential cross section over the whole small angular range, connecting the two equations at the larger one ($2.817\theta^*$) of the angles where they intersect. It seems that the differential cross section is overestimated in the angular range $2.817\theta^*>\theta>1.38\theta^*$. (See Fig. 1). We have used a modified classical cross section given by Mason *et al.* in the angles smaller than θ_c:

$$\sigma_m(\theta) = \sigma_c(\theta)[1+(2kb\theta)^{-2}+\cdots]$$
$$\simeq \sigma_c(\theta)\left[1+\frac{\pi}{2k^2\theta^2Q}\right]. \quad (11)$$

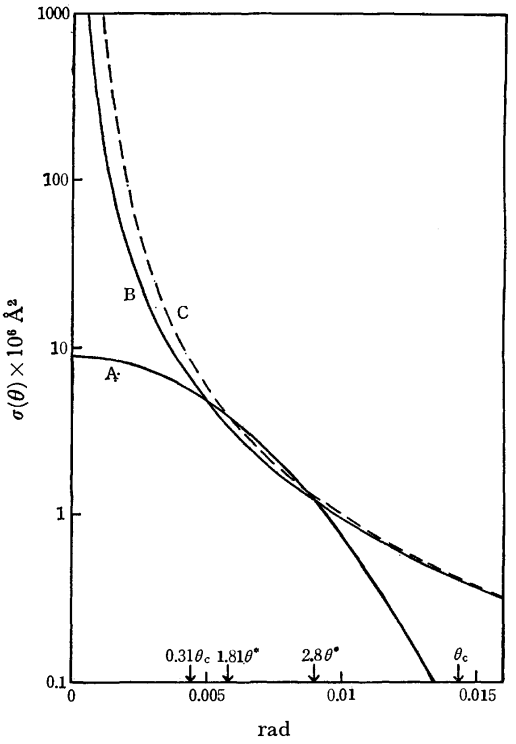

Fig. 1. Differential cross section for K–Ar at g=800 m/s. Curve A is the small-angle quantum result according to Eq. (8), Curve B is the classical result according to Eq. (5), and Curve C (dashed curve) the almost classical result according to Eq. (11).

To connect Eqs. (11) and (8) smoothly, the angles of the cross points of the two equations were estimated by a computer under the experimental conditions given previously.[1] The inner angle of the cross points was always obtained near $\theta=1.81\theta^*$. The differential cross sections for small-angle scattering are then expressed by the following three formulas.

$$\begin{aligned} &\theta > 4.445\theta^* && \sigma(\theta) = \sigma_c(\theta) \\ &4.445\theta^* > \theta > 1.81\theta^* && \sigma(\theta) = \sigma_m(\theta) \\ &1.81\theta^* > \theta && \sigma(\theta) = \sigma_s(\theta). \end{aligned} \quad (12)$$

By the use of these differential cross sections, the curve of $\sigma(\theta)$ turns out to be smoothen as shown in Fig. 1.

2. Differential Cross Section in the Laboratory System

For the correction of the angular resolution in the laboratory (LAB) system, it is necessary to convert the differential cross sections from the center-of-mass (c.m.) system into the LAB system. Figure 2 shows the geometrical relationship for the transformation. The notations in Fig. 2 are as follows.

$\boldsymbol{v}_i$, the velocity vector of the beam particle before the collision in the LAB system.

$\boldsymbol{v}_k$, the velocity vector of the target particle before the collision in the LAB system.

$\boldsymbol{u}_i$, the velocity vector of the beam particle before the collision in the c.m. system.

(Primed quantities such as $\boldsymbol{v}_i'$, $\boldsymbol{v}_k'$, and $\boldsymbol{u}_i'$ designate "after the collision".)

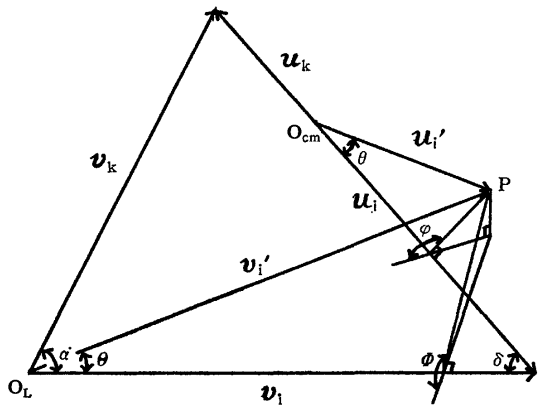

Fig. 2. The definition of quantities for the transformation from the center-of-mass system to the laboratory system.

g, the relative velocity vector before the collision.
α, the angle between v_i and v_k.
δ, the angle between g and v_i.
θ, the deflection angle of the beam particle in the c.m. system.
Θ, the deflection angle of the beam particle in the LAB system.
φ, the azimuthal angle of the vector of u_i' in the c.m. system.
Φ, the azimuthal angle of the vector of v_i' in the LAB system.

The magnitude of the relative velocity is then given by

$$g = \sqrt{v_l^2+v_k^2-2v_lv_k\cos\alpha}, \tag{13}$$

and the angle δ by

$$\delta = \sin^{-1}\frac{v_k\sin\alpha}{\sqrt{v_l^2+v_k^2-2v_lv_k\cos\alpha}}. \tag{14}$$

Therefore, both values of g and δ are determined by a set of (v_i, v_k, α).

For elastic collisions it is evident that a small angle in the c.m. system is transformed into a small angle in the LAB system. According to Helbing,[5] the transformation formulas between the c.m. system and the LAB system can be approximated for small deflection angles as follows.

$$\Theta = \theta\left(\frac{\mu g}{m_iv_i}\right)(1-\sin^2\delta\cos^2\varphi)^{1/2}, \tag{15}$$

$$\tan\Phi = \tan|\varphi|/\cos\delta, \quad \varphi \gtrless 0 \rightleftarrows \Phi \gtrless 0 \tag{16}$$

$$\frac{d\omega}{d\Omega} = \left(\frac{m_iv_l}{\mu g}\right)^2|\cos\delta|^{-1}. \tag{17}$$

The differential cross section in the LAB system can then be given by

$$\sigma(\Theta, \Phi) = \sigma(\theta, \varphi)\frac{d\omega}{d\Omega}, \tag{18}$$

where θ is determined by a set of $(v_i, m_i, v_k, m_k, \alpha, \varphi, \Theta)$. The total cross section $Q(g)$ in Eqs. (8) and (11) is related to $Q(v_i)$ by Eq. (2):

$$Q(g) = Q(v_i)\left(\frac{v_l}{g}\right)^{2/s-1}. \tag{19}$$

If the target gas follows the Maxwellian distribution $f(v_k)$ and isotropic spatial distribution, the particles scattered into a laboratory angle Θ are originated from those scattered at various angles in the c.m. system. In such a case, the apparent differential cross section for small-angle scattering in the LAB system is given by

$$\sigma_{ap}(v_i, \Theta) = \frac{1}{4\pi}\int_0^\pi\int_0^\infty\int_0^{2\pi}\sigma(\theta)\frac{d\omega}{d\Omega}f(v_k)\sin\alpha d\varphi dv_k d\alpha. \tag{20}$$

If the apparent differential cross section multiplied by $2\pi\sin\Theta$ is integrated from 0 to π, the effective total cross section averaged by the thermal motion of the target gas will be obtained:

$$Q_{eff}(v_l) = 2\pi\int_0^\pi\sigma_{ap}(v_l, \Theta)\sin\Theta d\Theta \tag{21}$$

3. Correction of the Angular Resolution

Beam apparatus always have finite angular resolution for detection of scattering events. If the cross section of the beam is a very small circle and that of the detector a circle of finite radius, the apparatus will have a constant resolving power γ at a distance from a scattering point to the detector. In this case, the correction value of the total cross section for the beam deflected into small angles is given by

$$\Delta Q_{eff}(v_l) = 2\pi\int_0^\gamma\sigma_{ap}(v_i, \Theta)\sin\Theta d\Theta. \tag{22}$$

In general, however, cross sections of the beam and the detector are narrow rectangles.[1] In such a case, the angular resolving power is not constant, but depends on the position in the plane of the detector and the scattering point in the scattering region. Let us consider the dependence of resolution on the position of a beam particle in a scattering plane and on the position of detection of the particle. (See Fig. 3.)

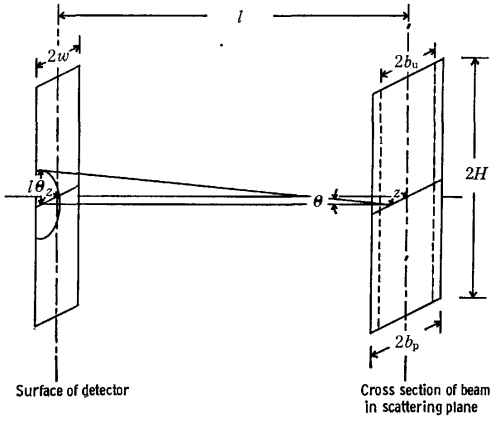

Fig. 3. Geometrical parameters for the correction of angular resolution.

It is assumed herewith that the width of the beam is much smaller than its height, the intensity distribution in the beam is uniform along its height and the detector has infinite length. The intensity distribution along its width is determined by the geometrical relationship of the beam apparatus. The widths of the umbra and penumbra in the trapezoidal profile are given by

$$2b_u = \left\{w_c-(w_s-w_c)\frac{l_{cd}}{l_{sc}}\right\}, \tag{23}$$

5) R. Helbing, *J. Chem. Phys.*, **48**, 472 (1968).

and

$$2b_p = \left\{w_c + (w_s + w_c)\frac{l_{cd}}{l_{sc}}\right\}, \tag{24}$$

respectively, where w_c and w_s are the widths of the collimating slit and source slit, respectively, l_{cd} is the distance from the collimating slit to the detector, and l_{sc} is the distance from the source slit to the collimating slit. If the central line of the beam along its height coincides with that of the detector, the intensity of the unscattered primary beam depends on the horizontal distance z from the vertical central line, and is given by

$$\begin{aligned} &z < b_u && i_0(z) = i_m, \\ &b_u < z < b_p && i_0(z) = \frac{b_p - z}{b_p - b_u} i_m, \\ &b_p < z && i_0(z) = 0, \end{aligned} \tag{25}$$

where i_m is the intensity per unit width in the umbra. The intensity of the unscattered beam measured by the detector is then given by

$$I_0 = \int_{-w}^{w} i_0(z)\mathrm{d}z, \tag{26}$$

where $2w$ is the width of the detector.

Consider a particle scattered from a point at a distance l from the plane of the detector and at a distance z from the vertical central line of the beam (Fig. 3). If the trajectories of the incident particles at the scattering plane are sufficiently parallel to each other, a part of the beam scattered through an angle Θ and falling on the detector is given by

$$2\pi n i(z) R(z, l, \Theta)\sigma_{ap}(\Theta) \sin\Theta \mathrm{d}\Theta, \tag{27}$$

where n is the density of the scattering gas, $i(z)$ is the beam intensity at the scattering point, and $R(z,l,\Theta)$ is the portion of the circumference of the circular cone of the scattered beam intercepted by the detector. When the radius of the base of the circular cone at the detector is r, we have $\Theta \equiv \tan^{-1} r/l \simeq r/l$ for small angle scattering. Thus the R-function is given by the following expressions.

for $z \geq w$

$$\begin{aligned} &z - w \geq l\Theta && R(z, l, \Theta) = 0, \\ &z + w \geq l\Theta \geq z - w && R(z, l, \Theta) = \frac{1}{\pi}\cos^{-1}\left(\frac{z-w}{l\Theta}\right), \\ &l\Theta \geq z + w && \\ & && R(z, l, \Theta) = \frac{1}{\pi}\left\{\cos^{-1}\left(\frac{z-w}{l\Theta}\right) - \cos^{-1}\left(\frac{z+w}{l\Theta}\right)\right\}, \\ &l\Theta \gg z + w && R(z, l, \Theta) \longrightarrow \frac{2w}{\pi l\Theta}, \end{aligned} \tag{28}$$

for $z < w$

$$\begin{aligned} &l\Theta \leq w - z && R(z, l, \Theta) = 1, \\ &z + w \geq l\Theta > w - z && \\ & && R(z, l, \Theta) = 1 - \frac{1}{\pi}\cos^{-1}\left(\frac{w-z}{l\Theta}\right), \\ &l\Theta > w + z && \\ & && R(z, l, \Theta) = 1 - \frac{1}{\pi}\cos^{-1}\left(\frac{w-z}{l\Theta}\right) \\ & && \quad - \frac{1}{\pi}\cos^{-1}\left(\frac{w+z}{l\Theta}\right), \\ &l\Theta \gg w + z && R(z, l, \Theta) \longrightarrow \frac{2w}{\pi l\Theta}. \end{aligned} \tag{29}$$

for special case of $z = 0$

$$\begin{aligned} &l\Theta \leq w && R(l, \Theta) = 1, \\ &l\Theta > w && R(l, \Theta) = 1 - \frac{2}{\pi}\cos^{-1}\left(\frac{w}{l\Theta}\right), \\ &l\Theta \gg w && R(l, \Theta) \longrightarrow \frac{2w}{\pi l\Theta}. \end{aligned} \tag{30}$$

The parameter z takes values smaller than b_p. Thus when Θ is much larger than b_p/l and w/l, the R-function can be approximated by $2w/\pi l\Theta$ which is independent of z.

If the width of the beam is much smaller than that of the detector, the correction of the effective total cross section is given by

$$\begin{aligned} \Delta Q_{eff}(v_i) &= 2\pi\int_0^{\pi} R(\Theta)\sigma_{ap}(v_i, \Theta)\sin\Theta \mathrm{d}\Theta \\ &\simeq 2\pi\int_0^{\Theta'} \sigma_{ap}(v_i, \Theta)\Theta \mathrm{d}\Theta \\ &\quad + 2\pi\int_{\Theta'}^{3\Theta'} \sigma_{ap}(v_i, \Theta)\Theta \sin^{-1}\frac{w}{l\Theta}\mathrm{d}\Theta \\ &\quad + 4w/l\int_{3\Theta'}^{\pi} \sigma_{ap}(v_i, \Theta)\mathrm{d}\Theta, \end{aligned} \tag{31}$$

where $\Theta' = w/l$. However, it is not appropriate to give an absolute value for the correction of the total cross section. It is better to use the ratio $\Delta Q_{eff}(v_i)/Q_{eff}(v_i)$. Thus, the correction factor for the above case is given by

$$\frac{\Delta Q_{eff}(v_i)}{Q_{eff}(v_i)} = \frac{\int_0^{\pi} R(\Theta)\sigma_{ap}(v_i, \Theta)\sin\Theta \mathrm{d}\Theta}{\int_0^{\pi}\sigma_{ap}(v_i, \Theta)\sin\Theta \mathrm{d}\Theta}. \tag{32}$$

If the width of the beam is larger than that of the detector, a part of the beam does not contribute to I_0 but some atoms in that part are scattered into the detector. In this case, the correction factor at constant l is given by

$$\frac{\Delta Q_{eff}(v_i)}{Q_{eff}(v_i)} = \frac{\int_0^{b_p}\int_0^{\pi} i(z)R(z, \Theta)\sigma_{ap}(v_i, \Theta)\sin\Theta \mathrm{d}\Theta \mathrm{d}z}{\int_0^{w}\int_0^{\pi} i(z)\sigma_{ap}(v_i, \Theta)\sin\Theta \mathrm{d}\Theta \mathrm{d}z}. \tag{33}$$

If the values of b_p/l and w/l are smaller than the critical angle Θ^* which corresponds to θ^*, the R-functions which contribute mostly to the correction value are independent of z. Thus, Eq. (33) is approximated by

$$\frac{\Delta Q_{eff}(v_i)}{Q_{eff}(v_i)} \simeq F \times \frac{\int_0^{\pi}\bar{R}(\Theta)\sigma_{ap}(\Theta)\sin\Theta \mathrm{d}\Theta}{\int_0^{\pi}\sigma_{ap}(\Theta)\sin\Theta \mathrm{d}\Theta}, \tag{34}$$

where

$$F = \frac{\int_0^{b_p} i_0(z)\mathrm{d}z}{\int_0^{w} i_0(z)\mathrm{d}z}, \tag{35}$$

and

$$\bar{R}(\Theta) = \frac{\int_0^{b_p} i_0(z)R(z, \Theta)\mathrm{d}z}{\int_0^{b_p} i_0(z)\mathrm{d}z}. \tag{36}$$

The value of F is obtained from the geometrical relation between the beam profile and the detector width, and

the value of the $\bar{R}$-function can be easily calculated by a computer.

The more complete correction formula for the angular resolution is

$$\frac{\Delta Q_{\mathrm{eff}}(v_1)}{Q_{\mathrm{eff}}(v_1)} = \frac{\int_{l_{cd}-L}^{l_{cd}}\int_{-b_p}^{b_p}\int_0^{\pi} i_0(z)e^{-nQ(l_{cd}-l)}R(z,l,\Theta)\sigma_{ap}(v_1,\Theta)\sin\Theta d\Theta dz dl}{\int_{l_{cd}-L}^{l_{cd}}\int_{-\mathrm{Min}(b_p,w)}^{\mathrm{Min}(b_p,w)}\int_0^{\pi} i_0(z)e^{-nQ(l_{cd}-l)}\sigma_{ap}(v_1,\Theta)\sin\Theta d\Theta dz dl}, \quad (37)$$

where L is the effective length of the scattering chamber. However, if l_{cd} is much greater than L, Eq. (33) can be used as a satisfactory correction for angular resolution.

4. Application

Equation (34) has been applied to the previous experimental data.[1] The $\bar{R}$-function expressed by Eq. (36) was calculated by a computer for $b_p=0.049$ mm, $b_u=0.02$ mm, $w=0.0175$ mm, and $l=85$ mm. The $\bar{R}$-function has an asymptote at $\Theta \gg 2w/l$ as shown in Fig. 4. In order to obtain the apparent differential cross sections, Eq. (20) was also calculated by a computer by means of the Monte Carlo method. In this calculation the van der Waals constants obtained in the previous paper were used.[1] In Fig. 5 the apparent differential cross sections multiplied by $2\pi \sin\Theta$ are shown for the several different beam velocities in K–Ar system. Shaded areas show the correction parts of the total cross sections given by

$$2\pi\int_0^{\pi}\bar{R}(\Theta)\sigma_{ap}(\Theta)\sin\Theta d\Theta \quad (38)$$

In Eq. (34), F is the ratio of the beam profile to that covered by the detector, and the denominator is equal to the effective total cross sections obtained by the experiment. Values of Eq. (34) were estimated for the various primary beam velocities and are shown in Fig. 6 together with the values calculated by Busch's formulas,[6] the latter being a little larger. It should be noted that our correction factors do not vary as $v_1^{4/5}$ as is predicted by Busch, and for K–Ar system the

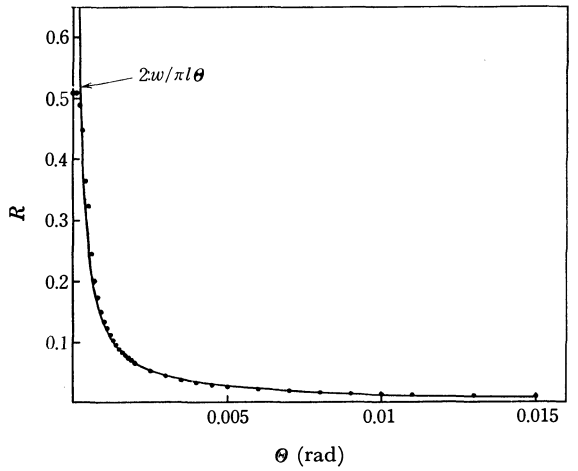

Fig. 4. Plot of $R(\Theta)$ calculated for the previous experimental parameters.

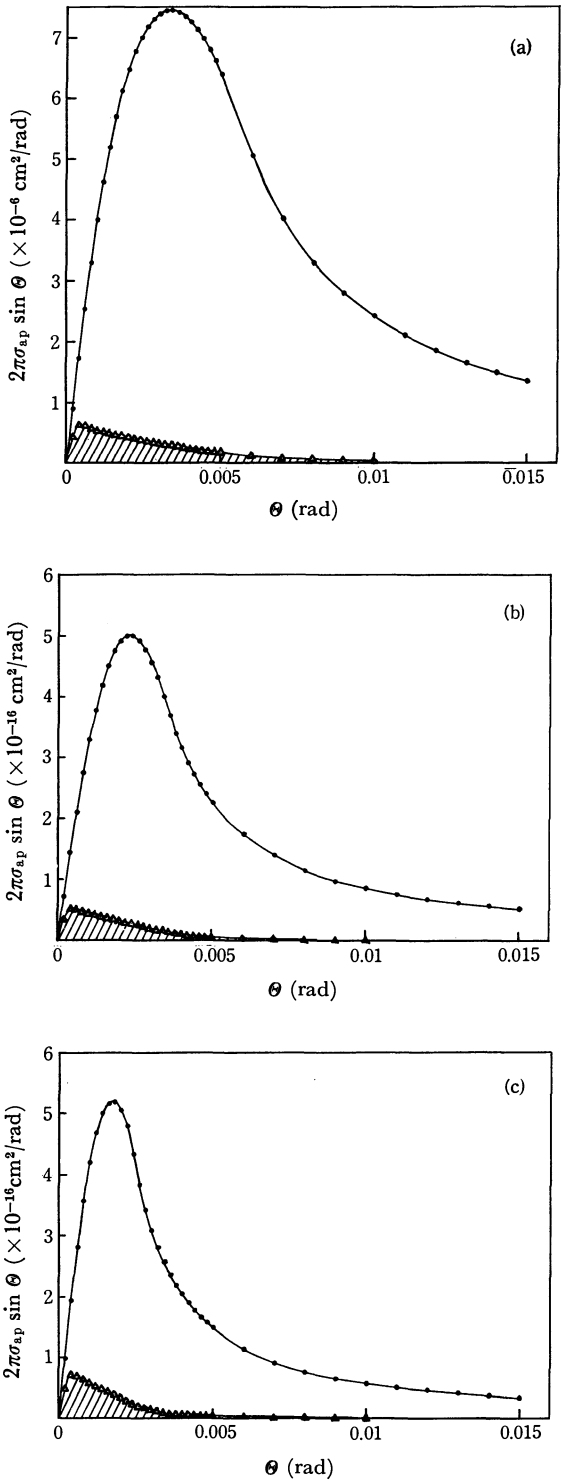

Fig. 5. Differential cross sections at small angles in the laboratory system.
K–Ar system. (a) $v_1=400$ m/s, (b) $v_1=720$ m/s, (c) $v_1=1100$ m/s.
Shaded areas show the parts deflected into the detector.

values become larger in low velocity range. It shows that Busch's approximation can not be applied to a

6) Busch gave different formulas for the correction of the angular resolution in Ref. 2 and in *Z. Phys.*, **199**, 518 (1967). The values calculated by the formula in Ref. 2 are smaller than in the other paper.

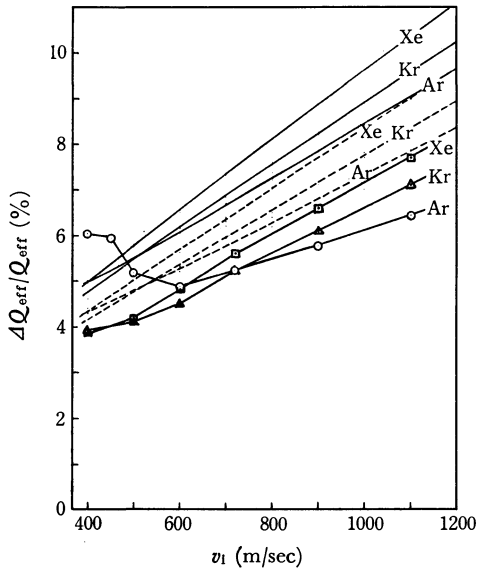

Fig. 6. Plots of $\Delta Q_{eff}(v_i)/Q_{eff}(v_i)$ for K–Ar, K–Kr, and K–Xe systems. Curves were obtained from Busch's formulas;

$$\frac{\Delta Q}{Q} = 0.0765\sqrt{Qk_i^2}\gamma\left(1+\frac{0.368}{x^2}\right) \text{ for the solid curve,}$$

$$\frac{\Delta Q}{Q} = 0.0665\sqrt{Qk_i^2}\gamma\left(1+\frac{0.376}{x^2}\right) \text{ for the dashed curve.}$$

case under usual experimental conditions in the thermal energy range.

In the above calculation to estimate correction ratio the van der Waals constants given in the previous paper were used. The correction applied there was not as good as here. However, the correction ratio varies only slightly with the change of constant value. For example, ten percent change of the value of C in K–Ar system results in five percent change of $\Delta Q_{eff}/Q_{eff}$ at $v_i = 720$ m/sec. Therefore, the values of the absolute effective total cross section estimated by the present method were hardly affected by the applied values of C. Therefore, if we start with a reasonable value of C, the estimated C will be almost similar to the initial one.

To reestimate the previous experimental data, the effective total cross sections have been corrected for the angular resolution using the values in Fig. 6 at first. Following the procedure, the effective total cross sections have been corrected by the thermal motion of the target gases, and the absolute total cross sections Q_w were obtained. The van der Waals constants reestimated from these Q_w are

$$C_{K-Ar} = 231\times10^{-60}\ \text{erg}\cdot\text{cm}^6$$

$$C_{K-Kr} = 337\times10^{-60}\ \text{erg}\cdot\text{cm}^6$$

$$C_{K-Xe} = 515\times10^{-60}\ \text{erg}\cdot\text{cm}^6$$

These values are a little smaller than the previous values. However, the conclusions in the previous paper have not been affected by the present procedure.

The author would like to thank Professor Kumasaburo Kodera for his valuable advice. The FACOM 230-60 computer system of Kyoto University was used for the calculation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1437—1441 (1973)

A Study on Restricted Rotation in 1-Acylpyrroles[1)]

Taku MATSUO, Hideto SHOSENJI,* and Reiji MIYAMOTO**

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka 812

(Received July 4, 1972)

Restricted rotation of the *N*-acyl group in 1-acylpyrroles was studied by means of NMR spectroscopy. The free energy of activation ($\Delta F_c^{\ddagger}$) for 1-formylpyrrole is 14.1 kcal/mol, which is less than that for DMF by 6.8 kcal/mol. The value of $\Delta F_c^{\ddagger}$ decreases in the order 1-formyl-, 1-acetyl-, and 1-benzoyl-pyrrole in exactly the same manner as is found in the series of *N,N*-dimethylamides with the corresponding acyl group: the difference in $\Delta F_c^{\ddagger}$ between a pair of compounds with the same acyl group in the two series remains constant (*ca.* 6 kcal/mol). The $\Delta F_c^{\ddagger}$-value for 3,4-dimethyl-1-acetylpyrrole is larger than that for 1-acetylpyrrole by 1 kcal/mol. In this particular case, the entropy of activation was found to be responsible for the difference in barrier height.

Restricted rotation about the C–N bond in 1-acylpyrroles was studied by two groups.[2)] The origin of restricted rotation has been suggested to be the partial double bond character of the C–N bond between the pyrryl and carbonyl groups as in the case of dimethylformamide and its analogues. Since the ionization potential of pyrrole (8.97 eV) is close to that of dimethylamine (8.93 eV),[3)] the significance of the ionic structure (I) may be as great as that in the case of dimethylformamide.

(I) (II)

A study of the electronic spectra of 1-acylpyrroles has also revealed that the π electron system of the carbonyl group strongly interacts with that of the pyrryl group.[4] Hence, the suggested origin of the barrier to the internal rotation is a very reasonable explanation. In order to study the nature of the barrier further in detail, the temperature dependence of the NMR spectra of a series of 1-acylpyrroles was investigated.

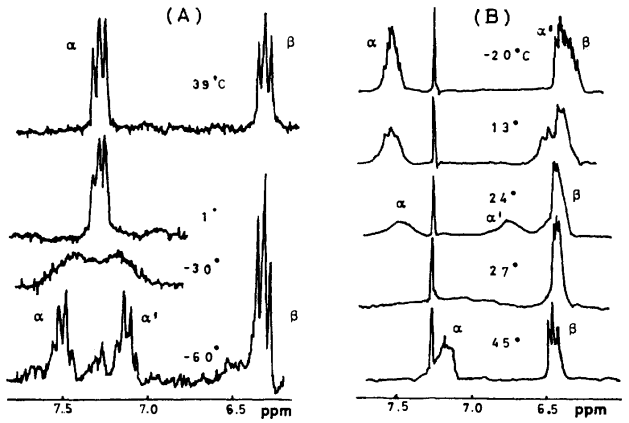

Fig. 1. The temperature dependence of the ring proton signals of 1-acetylpyrrole (A) and 1-pentachlorobenzoylpyrrole (B).

Results and Discussion

NMR spectra of most 1-acylpyrroles are temperature dependent. Two examples are shown in Fig. 1. At low temperature, the signals due to the protons at the 2- and 5-positions split into two peaks which indicate that the two methine protons are under nonequivalent electromagnetic environments. The nonequivalence is ascribed to the fact that the rotation of the carbonyl group about the C–N bond is restricted. Since the spin systems of most of the 1-acylpyrroles under investigation are rather complex, an accurate value for the rate of rotation at various temperatures can be obtained only through a complete line-shape analysis including the effects of spin-spin couplings. It is known, however, that the free energy of activation ($\Delta F_c^{\ddagger}$) at the coalescence temperature (T_c) can be obtained with reasonable accuracy by the use of an approximate method based on Gutowsky and Holm's equation and absolute rate theory:

$$\Delta F_c^{\ddagger} = R \cdot T_c \ln (k \cdot T_c \cdot \tau_c / h) \quad (1)$$

where

$$\tau_c = \sqrt{2}/(\pi \delta \nu_0) \quad (2)$$

The values of $\Delta F_c^{\ddagger}$ thus obtained are practically good enough to be used for comparing the barrier heights between various amides.[5] The results are summarized in Table 1. The barrier to the internal rotation decreases in the order 1-formyl-, 1-acetyl-, and 1-benzoylpyrrole. The same trend is also observed with *N,N*-dimethylamides, when the acyl group is changed in the order formyl, acetyl, and benzoyl group.[5] In order to examine the relationship between these two series of compounds, the barriers to the restricted rotation in *N,N*-dimethylamides are compared with those for 1-acylpyrroles with the corresponding acyl group (Table 2).[6] The difference in $\Delta F_c^{\ddagger}$ between a pair of compounds with the same acyl group in the two series is defined as $\delta\Delta$. We should notice that the $\delta\Delta$-values are nearly the same among the investigated three acyl groups.

Table 1. Spectral data for the restricted rotations of 1-acylpyrroles

Compound	$\delta\nu_0$ [a]	T_c [b]	$\Delta F_c^{\ddagger}$ [c]
1-Formylpyrrole	21.0	5	14.1
1-Acetylpyrrole	22.9	−28	12.5
3,4-Dimethyl-1-acetylpyrrole	24.7	−5	13.5
1-Benzoylpyrrole		<-70	
3,4-Dimethyl-1-benzoylpyrrole	38[d]	−56	11[e]
1-(2′,4′,6′-trimethylbenzoyl)pyrrole	73	65	16.5
1-Pentachlorobenzoylpyrrole	67	27	14.6

a) Peak separation (Hz) at the temperature where the rate of rotation is slow enough in NMR time scale. The errors are within 0.5 Hz unless specified.
b) Coalescence temperature in °C.
c) Free energy of activation in kcal/mol for the restricted rotation. Accuracies are estimated to be 0.1 kcal/mol.
d) The error is less than 2 Hz.
e) The error is less than 0.2 kcal/mol.

Table 2. Difference in barrier heights between *N,N*-dimethylamides and 1-acylpyrroles

Barrier	*N,N*-Dimethylformamide	*N,N*-Dimethylacetamide	*N,N*-Dimethylbenzamide
$\Delta F_c^{\ddagger}$ [a]	20.9	18.1	16.0
$\delta\Delta$ [b]	6.8	5.6	6[c]

a) The free energy of activation (kcal/mol) for *N,N*-dimethylamides as summarized by Stewart and Siddall[5].
b) The difference in $\Delta F_c^{\ddagger}$ between *N,N*-dimethylamides and 1-acylpyrroles with the corresponding acyl group.
c) The barrier in 1-benzoylpyrrole is estimated to be 10 kcal/mol as described in Footnote 6.

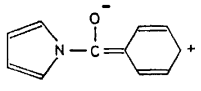
6) The barrier for 1-benzoylpyrrole itself could not be obtained, since the coalescence temperature was below −70°C which was the lowest limit accessible in the present experiment. The approximate barrier height, however, may be estimated as follows. Assuming that the $\delta\nu_0$ value for 1-benzoylpyrrole is equal to that for 3,4-dimethyl-1-benzoylpyrrole, and that T_c is −75 °C, the barrier height is calculated to be 10 kcal/mol, which may be taken to be an approximate value for the upper limit of $\Delta F_c^{\ddagger}$ for 1-benzoylpyrrole. On the basis of the $\Delta F_c^{\ddagger}$ value for 3,4-dimethyl-1-benzoylpyrrole (11 kcal/mol), we can also estimate $\Delta F_c^{\ddagger}$ for 1-benzoylpyrrole to be approximately 10 kcal/mol, provided that the effect of the methyl groups on the 3- and 4-positions is assumed to lower the barrier by 1 kcal/mol as in the case of 1-acetylpyrrole and 3,4-dimethyl-1-acetylpyrrole.

The barrier to the internal rotation is mainly determined by two factors: the electronic state of the molecule as represented by its double bond character, and the steric hindrance during the rotation. The relative importance of these two factors is expected to vary considerably depending on the nature of the substituent on the amide group. Let us first consider the case of 1-formylpyrrole and *N,N*-dimethylformamide. By the use of molecular models, it is easily understood that no steric strain is expected during the internal rotation around the C–N bond. The barrier height in this case should therefore be determined by purely electronic factors alone. The difference in $\Delta F_c^{\neq}$, 6.8 kcal/mol, is thus taken to represent the fact that the double bond character of the C–N bond in 1-formylpyrrole is less than that in *N,N*-dimethylformamide.

In the case of 1-acetylpyrrole, a completely planar configuration can not be assumed because the presence of steric strain is indicated by the molecular model. The plane of the acetyl group should be twisted with respect to that of the pyrryl group in the ground state. In other words, the valley of the potential energy curve for 1-acetylpyrrole should be shallower than that for 1-formylpyrrole. Thus, the decrease in the rotational barrier in 1-acetylpyrrole is ascribed to the decrease in the double bond character due to the presence of steric strain in the ground state as in the case of *N,N*-dimethylacetamide.[5] In addition, it is also understood that the effect of the pyrryl group is very close to that of the *N,N*-dimethylamino group, since the decrease in $\Delta F_c^{\neq}$ on going from 1-formylpyrrole to 1-acetylpyrrole is almost the same as the difference in the rotational barrier between *N,N*-dimethylformamide and *N,N*-dimethylacetamide.

The case of 1-benzoylpyrrole is an example where both electronic and steric factors are equally important. In analogy to the case of *N,N*-dimethylbenzamide,[5] the contribution of cross conjugation between the phenyl and carbonyl groups as represented by III is expected to be effective in reducing the barrier height in 1-benzoylpyrrole. In addition, we can not disregard the



(III)

fact that 1-benzoylpyrrole is not expected to take a completely planar configuration because of the large steric hindrance between the phenyl and the pyrryl groups. As a consequence, the C–N bond is expected to be slightly twisted already in the ground state so that its double bond character is reduced. This might be another reason for the barrier height in 1-benzoylpyrrole being so much lower than that in 1-formylpyrrole.

The steric factors become extremely important in the case of 1-(2′,4′,6′-trimethylbenzoyl)pyrrole and 1-pentachlorobenzoylpyrrole. The steric hindrance due to the substituents at the *ortho* positions forces the carbonyl group to take an almost perpendicular position with respect to the plane of the phenyl group. The pyrryl group, on the other hand, seems to remain coplanar

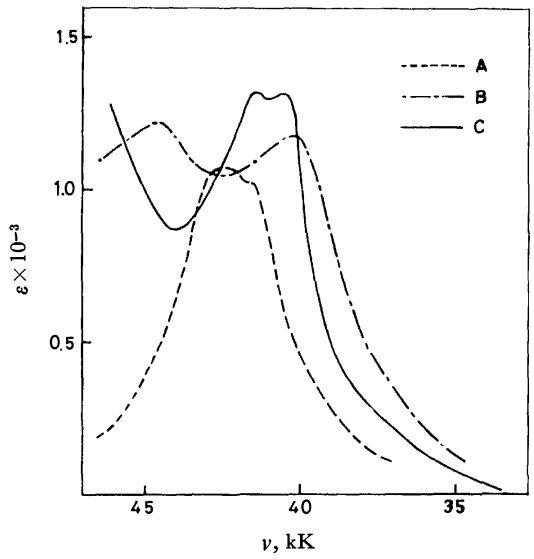


Fig. 2. Electronic absorption spectra of 1-acetylpyrrole (A), 1-benzoylpyrrole (B), and 1-(2′,4′,6′-trimethylbenzoyl)-pyrrole (C) in *n*-hexane.

with the carbonyl group. This is strongly supported by the fact that the electronic spectra of 1-(2′,4′,6′-trimethylbenzoyl)pyrrole is found to be close to that of 1-acetylpyrrole than that of 1-benzoylpyrrole (Fig. 2). In correspondence with this, the barrier heights in 1-(2′,4′,6′-trimethylbenzoyl)pyrrole and 1-pentachlorobenzoylpyrrole are surprisingly large as compared with that in 1-benzoylpyrrole (Table 1). Due to the above steric factors, the contribution of cross conjugation as represented by III is considered to be negligible in the electronic structures of 1-(2′,4′,6′-trimethylbenzoyl)pyrrole and 1-pentachlorobenzoylpyrrole. As a consequence, the double bond character of the C–N bond in 1-benzoylpyrrole is expected to increase on the introduction of substituents at both *ortho* positions. In other words, the valley of the potential energy curve for the restricted rotation becomes deeper than in the case without substituents. The present results are in agreement with this expectation. However, we should further notice that the barrier in 1-(2′,4′,6′-trimethylbenzoyl)pyrrole exceeds that in 1-formylpyrrole by more than 2 kcal/mol. This is unlikely to be explained by the change in the electronic factor alone. On the other hand, it is easily understood from the molecular model that the internal rotation of the pyrryl group with respect to the carbonyl group is strongly hindered in the transition state by the presence of substituents at the *ortho* positions. In other words, the top of the potential energy curve for the restricted rotation of the C–N bond in 1-(2′,4′,6′-trimethylbenzoyl)pyrrole is considered to be appreciably raised by the steric hindrance due to the two methyl groups. This steric hindrance may be mainly responsible for the extraordinary large $\Delta F_c^{\neq}$-value for 1-(2′,4′,6′-trimethylbenzoyl)pyrrole. The data for 1-pentachlorobenzoylpyrrole may be analogously explained as due to the combined influence of the two different effects of the substituents at the *ortho* position: the increase in the double bond character of the C–N bond in its

ground state and the presence of large steric hindrance to the internal rotation in the transition state. The slightly lower barrier height in 1-pentachlorobenzoylpyrrole, in comparison with that in 1-(2′,4′,6′-trimethylbenzoyl)pyrrole, can be correlated with the fact that the van der Waals radius of chlorine atom (1.8 Å) is less than that for the methyl group (2.0 Å). Exactly the same type of *ortho*-substituent effects as described above have also been known in the study of internal rotation of *N,N*-dimethylbenzamide.[7] The difference in $\Delta F_c^{\ddagger}$ between 1-(2′,4′,6′-trimethylbenzoyl)pyrrole and *N,N*-dimethyl-2,4,6-trimethylbenzamide (6.0 kcal/mol) is not far from the corresponding difference between 1-formylpyrrole and *N,N*-dimethylformamide (6.8 kcal/mol). On the basis of this result together with the data in Table 2, it is concluded that the double bond character of the C–N bond in 1-acylpyrrole is invariably less than that in the corresponding *N,N*-dimethylamide by an almost constant amount irrespective of the nature of the acyl group.

If an electron-donating group is substituted on the pyrryl group, the significance of the ionic structure (I) increases and the barrier height will be raised as long as the steric factors are not affected by the substitution. In expectation of these effects, the restricted rotation of 3,4-dimethyl-1-acylpyrroles was further investigated in detail. On the introduction of methyl groups at the 3- and 4-positions of 1-acylpyrrole, $\Delta F_c^{\ddagger}$ is found to increase by 1 kcal/mol in comparison with the case without the methyl groups (Table 1). Analogously, the barrier to the internal rotation in 1-benzoylpyrrole is clearly raised by the introduction of methyl groups at the 3- and 4-positions of the pyrryl group.[6] These effects of the methyl groups on the 3- and 4-positions of the pyrryl group are surprisingly large, if we recall the fact that the difference in $\Delta F_c^{\ddagger}$ between 1-acylpyrroles and *N,N*-dimethylamide is no more than 6 kcal/mol. In order to clarify the methyl substitution effect on the barrier height in detail, the temperature dependence of the proton signals of 3,4-dimethyl-1-acetylpyrrole was studied by the use of total line-shape analysis. The ring proton signals of this compound should be analyzed as a part of a ABX_3Y_3 system in principle. No one has analyzed the NMR spectra of such a complex system under chemical exchange. On the other hand, the method of analysis for AB spin system with chemical exchange between A and B has been well established.[8] Thus the present data were analyzed by the use of the line shape comparison method for the AB spin system with a slight modification. The signals for the ring protons at the 2- and 5-positions were calculated at first by the use of Heidbergs' line shape equation for the AB spin system.[8] The contribution of the methyl protons at the 3- and 4-positions was then taken into consideration by assuming that each ring proton signal was split into a quartet

The Crystal and Molecular Structure of 4,10b-Methano-8*H*-benzo[*ab*]cyclodecen-8-one

Ryosuke YAHASHI,* Hirotaka SHIMANOUCHI, and Yoshio SASADA

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received August 24, 1972)

4,10b-Methano-8*H*-benzo[*ab*]cyclodecen-8-one ($C_{14}H_{10}O$), a stable derivative of so-called 1,6-methano[10]-annulene, forms reddish orange crystals of the space group Pbca, with eight molecules in a unit cell with dimensions of $a=16.567$, $b=14.090$, and $c=8.418$ Å. The structure was solved by the symbolic addition method and refined by the block-diagonal least-squares method. The final R factor was 0.080 for the 1386 independent observed reflections. The lengths of the peripheral bonds of the [10]annulene nucleus do not exhibit any apparent alternation. The peripheral eight atoms are approximately coplanar. The C–O distance (1.236 Å) is longer than those in quinones and tropones, and it is consistent with the large dipole moment and high basicity of the present molecule.

Contrary to the prediction by Hückel's(4n+2)rule, so-called [10]annulene does not show aromaticity. This is because [10]annulene is not likely to take a stable planar conformation.[1] The bridged analogs (I) of the [10]annulene,[2-4] however, are aromatic, and the X-ray analyses of several derivatives have indicated that the [10]annulene nucleus has the structural characteristics of the aromatic compound. Recently, 4,10b-methano-8*H*-benzo[*ab*]cyclodecen-8-one (II),[5b] a derivative of 1,6-methano[10]annulene (Ia), has been synthesized by Murata *et al.*[5a] Although it was anticipated that the condensed six-membered ring would result in a strain in the molecule, the aromatic character is retained in the ten-membered ring of II; for instance, a diamagnetic ring current has been observed.[5]

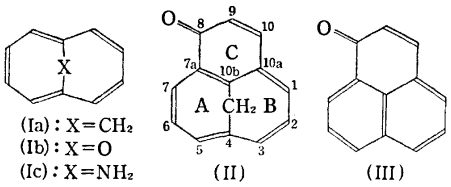
5) a) I. Murata, T. Nakazawa, and T. Tatsuoka, *ibid.*, **1971**, 1789. b) In reference 5a this compound was called 1*H*-cyclohexa[4,5,6-*de*]methano[10]annulen-1-one.

II can also be regarded as a bridged analog of phenalenone (III), which is a highly polarized ketone.[6] It is interesting that II is more polar than III.[5a]

The present work has been undertaken in order to examine the effect of the condensed ring on the aromaticity of the [10]annulene system and to ascertain the structural basis of the highly-polarized nature of II.



Experimental

Crystals of **II**, kindly supplied by Professor **I.** Murata, were recrystallized from the ether–petroleum ether mixture. They were reddish-orange mass crystals. The unit-cell dimensions were determined from zero-layer Weissenberg photographs about the *b* and *c* axes. Spacings of about 40 reflections, calibrated with superimposed aluminum powder lines, were subjected to the least-squares treatment. The density of the crystals was measured by the flotation method. Since the systematic absences of reflections are *hk*0 for *h* odd, *h*0*l* for *l* odd, and 0*kl* for *k* odd, the space group was determined to be Pbca. The crystal data of II are summarized in Table 1.

TABLE 1. CRYSTAL DATA

Crystal system	Orthorhombic
Space group	Pbca
a	16.567±0.004 Å
b	14.090±0.003 Å
c	8.418±0.002 Å
Volume of a unit cell	1965.0 Å^3
Density calculated	1.312 g·cm^{-3}
Density measured	1.316 g·cm^{-3}
F(000)	816
μ(Cu*K*α)	6.51 cm^{-1}
Number of molecules per unit cell	8

The reflections were recorded, using Cu*K*α radiation, on equi-inclination multiple-film Weissenberg photographs for 0—10 layers around the *b* axis and 0—6 layers around *c*. The dimensions of the crystals used were 0.35×0.2×0.7 mm and 0.6×0.2×1.3 mm for the *b* and *c* axis rotations respectively.

The intensities were first estimated by visual comparison with a standard scale prepared with the same crystal. Since then a TV-densitometer has become available, and it has been proved that the TV-densitometer method is more accurate and time-saving than the visual method.[7] Therefore, the intensities were remeasured by means of the TV-densitometer.

The intensity data of 2019 independent reflections (90.0% within the Cu*K*α sphere) were collected; 632 of them were

TABLE 2. FINAL ATOMIC COORDINATES AND TEMPERATURE FACTORS AND THEIR STANDARD DEVIATIONS
All quantities are multiplied by 10^4 except temperature factors of hydrogen atoms. E.s.d.'s are in parentheses. The anisotropic temperature factors are expressed in the form of exp $\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)\}$.

found to have zero intensity. Lorentz and polarization corrections were made as usual, but the absorption correction was omitted. The intensities of elongated reflections on upper-layer photographs were corrected for spot size by a method proposed by Takenaka.[8]

Structure Determination and Refinement

In the earlier stage of the structure determination, visual data were used. The symbolic addition procedure was used for sign-determination. As a starting set, the signs of the following strong reflections were chosen;

h	k	l	$\|E\|$	sign
8	1	6	3.26	+
9	5	5	2.78	+
15	4	2	2.77	+
13	7	6	2.65	A
4	11	4	2.55	B

where A and B were symbols.

Using the triple-product sign relationships, the signs of 160 reflections out of 275 with $|E| \geq 1.5$ were determined in terms of A and B. From a further investigation of the list of the triple-product sign relations, it seemed most probable that A is — and B is +. The *E*-map computed with these signs clearly showed all fifteen non-hydrogen atoms.

The structure factors were calculated using these fifteen atoms, the *R* factor being 0.425 for the observed reflections. A Fourier refinement and the block-diagonal least-squares refinement were carried out successively. Four cycles of calculations using isotropic temperature factors reduced the *R* factor to 0.231. Anisotropic temperature factors were then introduced, and the *R* factor dropped to 0.155. At this stage, the coordinates of the hydrogen atoms were given by assuming a suitable geometry. The strongest reflection, 022, was excluded because it seemed to suffer from secondary extinction. The *R* factor decreased to 0.135 after four cycles; the isotropic hydrogen atoms were also shifted. Since the intensity data measured by means of the TV-densitometer became available at this stage, they were used for further refinement. After six cycles, the *R* factor was reduced to 0.080 for the observed reflections, excluding the 022 reflection. When this was included, $R=0.081$.

The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[9] The final coordinates and temperature factors are given in Table 2. The observed and calculated structure factors are listed in Table 3.

The thermal ellipsoids of atoms are shown in Fig. 1. It seems that the entire molecule undergoes a rigid-body libration around the center of gravity. Then, the thermal motion of the molecule was analysed, assuming that all atoms form a rigid body.[10]

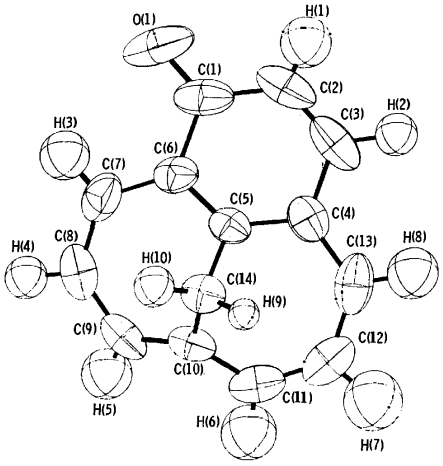

Fig. 1. Thermal ellipsoid of the molecule at the 50% probability level, viewed along the normal to its mean plane.

Table 4. Rigid-body thermal motion

(a) Principal axes of the molecule relative to the crystal axes (a, b, c)

Moment of inertia (Atomic weight·Å²)		Direction cosines of eigen vectors l	m	n
1	434.0	0.922	0.114	0.370
2	665.5	0.215	−0.945	−0.246
3	1024.7	−0.322	−0.307	0.896

(b) Rigid-body vibration tensors

$$\mathbf{T} = \begin{pmatrix} 0.0047 & -0.0068 & 0.0035 \\ & 0.0450 & -0.0010 \\ & & 0.0341 \end{pmatrix}$$

$$\sigma(\mathbf{T}) = \begin{pmatrix} 0.0029 & 0.0026 & 0.0031 \\ & 0.0033 & 0.0034 \\ & & 0.0054 \end{pmatrix} \text{ in Å}^2$$

$$\boldsymbol{\omega} = \begin{pmatrix} 17.74 & 0.50 & 2.66 \\ & 14.43 & 4.24 \\ & & 34.92 \end{pmatrix}$$

$$\sigma(\boldsymbol{\omega}) = \begin{pmatrix} 4.24 & 2.15 & 2.62 \\ & 2.78 & 2.11 \\ & & 1.91 \end{pmatrix} \text{ in deg}^2$$

(c) Principal axes of the **T** and $\boldsymbol{\omega}$ tensors relative to the crystal axes

	R.m.s. amplitude	Direction cosines of eigen vectors l	m	n
T	0.181 Å	−0.644	−0.215	0.735
	0.197	−0.623	0.705	−0.339
	0.229	0.445	0.676	0.558
$\boldsymbol{\omega}$	3.7 deg	0.281	−0.866	−0.414
	4.2	−0.950	−0.189	−0.249
	6.0	−0.137	−0.463	0.876

The anisotropic temperature factors, B_{ij}, were transformed to U tensors referred to the three principal axes of the moment of inertia of the molecule, the origin of the coordinate system being at the center of gravity (Table 4(a)). The translation and libration tensors, **T** and $\boldsymbol{\omega}$, of the rigid molecule were derived from U's. Since the agreement between the U's observed and those calculated from **T** and $\boldsymbol{\omega}$ was good (Table 5), the rigid-body model was justified.

The positions of the electron-density peaks are shifted

by the molecular libration. Therefore, the bond lengths and angles were corrected for this effect using the eigen values and vectors of ω (Table 4(b) and 4(c)).

The computations were done on a HITAC 5020E computer at the University of Tokyo and on a HITAC 8500 computer at Tokyo Institute of Technology. The programs in the Universal Crystallographic Computation Program System[11] were used with some modifications. Three programs, TLSU for the determination of the cell dimensions, TDRW for the data reduction, and DEAM for plotting the thermal ellipsoid, all written by Takenaka, were used.

Results and Discussion

Molecular Geometry. The bond lengths and angles are illustrated in Fig. 2. The lengths corrected for thermal motion are listed in Table 6. Since these corrections are fairly small, the following discussion is based on the uncorrected values. The corrected bond

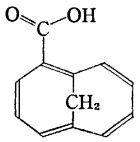
angles are not listed; the maximum correction is 0.2°.

The lengths of the peripheral bonds of the [10]-annulene nucleus do not exhibit any apparent alternation, and all the C–C bond lengths except for C(11)–C(12) and C(12)–C(13) are quite close to that in benzene (1.392±0.004 Å).[12]

The eight atoms, C(4), C(6), C(7), C(8), C(9), C(11), C(12), and C(13), are approximately coplanar; the displacements of these atoms from their mean plane are given in Table 7. Similar characteristics are found in 1,6-methano-cyclodecapentaene-2-carboxylic acid (IV);[13] the root-mean-square deviations of the



(IV)

eight atoms are 0.025 Å for the present compound and 0.034 Å for IV.[13] It seems that the planarity of the nucleus and, therefore, the aromaticity are not affected by the condensation of the six-membered ring(C). The torsion angles of the bonds, C(4)–C(5), C(5)–C(6), C(9)–C(10), and C(10)–C(11), which inevitably have large values in the [10]annulene nucleus, as is shown in Fig. 3(a), are also nearly equal to the corresponding angles in IV.[13]

In the methylene bridge, the C(10)–C(14) bond

Dihedral angles between the planes

1 ∧ 2	26.3°	3 ∧ 4	175.7°	5 ∧ 6	136.7°	7 ∧ 8	91.2°
3 ∧ 5	20.7°	4 ∧ 6	18.4°	5 ∧ 9	67.3°	6 ∧ 9	69.3°

length (1.509 Å) is in good agreement with the typical value for the C(sp^3)–C(sp^2) bond (1.505±0.005 Å),[12] while the C(5)–C(14) length (1.477 Å) is significantly shorter. The C(4)–C(5)–C(6) angle is smaller than C(9)–C(10)–C(11). This is consistent with the C–C-length difference in the bridge. These changes may reasonably be interpreted as a result of the strain by the ring (C). The same explanation may also apply to the significant decrease in the internal angles at C(7) and C(13) in comparison with those in IV.[13]

The C(5)–C(14)–C(10) angle (94.8°) is significantly smaller than the corresponding angles in 1,6-methanocyclodecapentaene-2-carboxylic acid (IV) (99.6°)[13] and 11,11-difluoro-1,6-methano-[10]annulene (101°),[14] and is larger than that in tricarbonyl-1,6-methanocyclodecapentaenechromium (92.4°).[15]

The spatial approaches of the bridged methylene protons to the [10]annulene nucleus are shown in Fig. 4.

The C(1)–O(1) bond distance (1.236 Å) is significantly longer than the C=O double-bond lengths in quinones (1.222 Å in *p*-benzoquinone,[16] 1.223 Å in 2,5-dimethyl-*p*-benzoquinone,[17] 1.224 Å in 2,2-di(1,4-naphthoquinone)[18]) and in tropones (1.228 Å in 4,5-benzotropone,[19] 1.227 Å in 2,7-dimethyl-4,5-benzotropone,[20] 1.225 Å in 5,7-dibromo-2,3-benzotropone,[21] 1.227 Å in 5-chloro-2,3-benzotropone[21]). (c) The molecule viewed along the normal to the plane 9 in Table 7. 0.25 Å, 0.08 Å, 0.39 Å, and 0.40 Å are the deviations of C(5), O(1), C(7), and C(13), respectively from the plane 2 in Table 7.

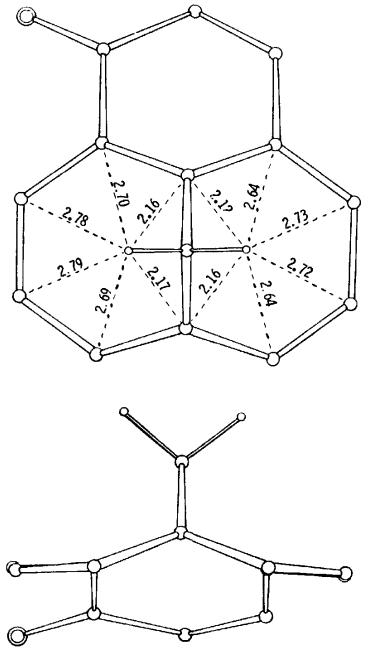

Fig. 4. The spatial approaches (Å) of the bridged methylene protons to the [10]annulene nucleus.

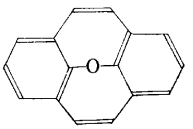
tion of the C=O bond is consistent with the low carbonyl stretching frequency (1605 cm^{-1}).[5] This observation suggests the highly polarized nature of the C=O bond in the present compound, which explains the large dipole moment (4.36 D)[5] and the high basicity (pK_b= −2.6).[5]

The C(1)–C(6) bond (1.491 Å) is slightly longer than the typical C(sp^2)–C(sp^2) single bond,[22] suggesting that its double-bond nature is negligibly small. On the other hand, the C(1)–C(2) and C(3)–C(4) bond lengths are almost equal to one another and are significantly shorter than C(1)–C(6). This may indicate the resonance interaction of the carbonyl group with the [10]annulene nucleus through C(1)–C(2)–C(3)–C(4), not through the C(1)–C(6) bond. This interaction may perturb the π-electron system of the [10]annulene nucleus so as to result in the longer C(12)–C(13) and shorter C(11)–C(12) bonds. It is interesting that the effect of the carbonyl group emerges in the most distant portion of the molecule. This explains well the large dipole moment of the present molecule.

The C(2)–C(3) length (1.331 Å) seems not to favor the above hypothesis, since it is as short as the C=C distance in ethylene.[23] Cruickshank suggests, however, that the ethylene distance might not be used as the standard value for double bonds in a different environment.[24] A possible explanation for the shortening is that the polarization of the C=O group may lead to an increase in the p character in the C(1)–C(2) bond and to a concomitant increase in the s component in the C(2)–C(3), which reduces the length.[25] This reasoning is supported by the values of the C(6)–C(1)–C(2) angle (115.9°) and C(1)–C(2)–C(3) (123.5°). It should be added that, although a contraction of the internal angles at the carbonyl carbons has been observed, the present angle is the smallest among the various quinones.[16–18]

In the six-membered ring (C), five atoms, C(1), C(2), C(3), C(4), and C(6), are coplanar within the limits of error (Plane 2 in Table 7), while only the C(5) atom deviates (by 0.25 Å) (Fig. 3(c)). The mutual displacements of C(5) and C(7) from Plane 2 result in the twist of the C(1)–C(6) bond. If this bond were of double-bond character, it should cause a displacement of C(2) from the reference plane to form a slight boat conformation, as has been reported for the case of the benzene ring in 8,16-oxido-*cis*[2,2]metacyclophane-1,9-diene (V).[26] This is not the case; the C(2)



(V)

atom does not deviate significantly; this is consistent with the view of the bond nature of C(1)–C(6) presented above.

The three-dimensional feature of the molecule is shown in Fig. 3. The dihedral angle between Plane 7 and Plane 8 is 91.2°, and the non-bonded distance between C(5) and C(10) is 2.199 Å. The overlap integral, *S*, between the 2p-orbitals of C(5) and C(10) is estimated using the tables by Mulliken, Rieke,

22) M. J. S. Dewar and H. N. Schmeising. *Tetrahedron*, **11**, 96 (1960).

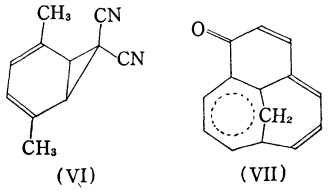
Orloff, and Orloff,[27] where the 2p-orbitals are assumed to be normal to the above planes. The calculated value of 0.142 for $S_{5,10}$ is twice as large as the $S_{1,6}$ of 0.072 reported for the cycloheptatriene ring of thujic acid.[28] In connection with this, the conformation of the seven-membered ring(A) has been examined. As may be seen in Fig. 3(b), the ring is in a boat conformation, with angles of 67.3 and 20.7° between Plane 5 and Plane 9, and between Plane 5 and Plane 3, respectively. These values lie between the corresponding values in the norcaradiene structure (VI) (71.9 and



(VI) (VII)

4.2°)[29] and those in the cycloheptatriene structure in thujic acid (47.9 and 24.4°).[28] This suggests some contribution from the (VII) structure to the ground-state structure of the molecule.

Crystal Structure. The packing diagram of the crystal viewed along the *c* axis is shown in Fig. 5. The shortest C···C, O···H, and H···H contacts are 3.468, 2.47, and 2.32 Å respectively. The packing appears to be fairly efficient, but there are no abnormally short intermolecular contacts. Therefore, the distortions of the molecule, which do exist, may be ascribed to intramolecular rather than to intermolecular effects. The molecules are so arranged that the large dipole moments cancel each other out by means of the center of symmetry.

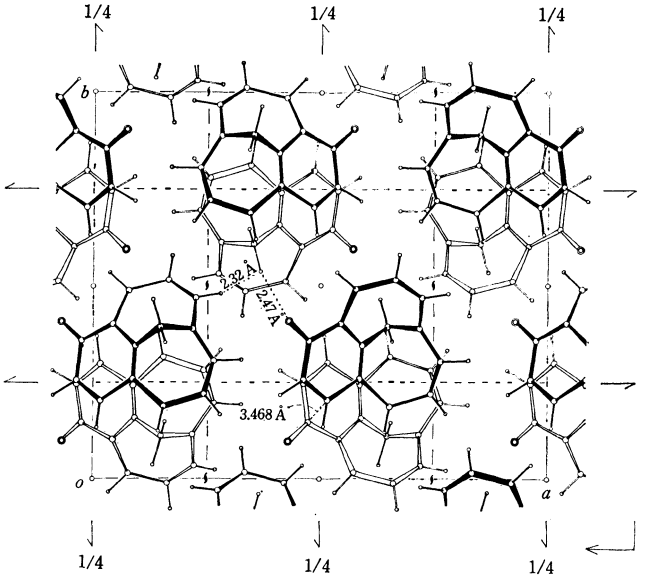


Fig. 5. The crystal structure projected along the *c* axis with some short intermolecular contacts (Å).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1450—1454 (1973)

Studies on the Fragment Ion Distribution and Their Reactions by the Use of a Charge Spectrometer. II. The Charge Exchange Reactions in Methanol with Fast Positive Ions

Toshio NAGATANI, Kenji YOSHIHARA, and Takanobu SHIOKAWA

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai

(Received August 28, 1972)

Distribution of fragment ions after bombardment of a methanol molecule with various positive ions has been studied by the use of a double mass spectrometer. It was found that the internal energy distribution function has fine structures. The appearance potentials of the fragment ions were re-estimated. From the results the mass spectra of methanol by electron impact were interpreted fairly accurately. The successive ion-molecule reactions after the charge exchange were studied by increasing pressure in the reaction chamber. The behaviors of the metastable ions were also investigated.

Friedman *et al.*[1] studied electron impact of methanol with a mass spectrometer, and observed unimolecular decomposition of the molecular ions of the excited states. They tried to interpret their results by the theory of the rate processes.[2] Their results showed a discrepancy from the theoretical values, which seems to result from the inaccuracy of the internal energy distribution function they used.

1) L. Friedman, F. A. Long, and M. Wolfsberg, *J. Chem. Phys.*, **27**, 613 (1957).

2) H. M. Rosenstock, M. B. Wahlenstein, A. L. Wahrhaftig, and H. Eyring, *Proc. Nat. Acad. Sci. U. S.*, **38**, 667 (1952).

Wilmenius and Lindholm[3] also studied dissociation of methanol by impact of slow positive ions and tried to interpret the results by means of an internal energy distribution function. Their results showed no essential change from those of Friedman *et al.* in which a flat distribution 10.9(ionization potential)—18.1 eV was assumed. It is not appropriate to assume such a simple distribution if a more precise consideration is adopted.

The authors studied the break down curve and the internal energy distribution function of methanol by impact of fast positive ions by means of a double mass spectrometer. This study is an extention of the previous work on methylamine[4,5] which is of an isoelectric structure with methanol. A more accurate interpretation of mass spectra by electron impact has been made by improvement of the internal energy distribution function.

Successive ion-molecule reactions in the reaction chamber have been studied by increasing pressure of the neutral molecules. The behaviors of metastable ions were traced.

Experimental

Details of the apparatus[6a] have been described.[6b] Methanol of a reagent grade was purified by repeated distillation. The gases used for the positive ion sources were almost the same as in the previous work.[6b]

The mass spectra of methanol after charge exchange with fast positive ions (1850 eV) are shown in Table 1. The recombination energies are not always considered to be the same as those for the experiment of methylamine. Evaluation of the recombination energy is as follows.

(1) He^+. 24.58 eV.

(2) Ne^+. 21.56 and 21.66 eV.

(3) Cl^+. This ion is of *m/e* ratio 35, produced by electron bombardment of CCl_3F. As the contribution from $3p^4\ ^1S$ and $3d\ ^5D$ is very small, ions with *m/e* ratios (32) and (31) are produced predominantly. The ion with the ratio (15) is obtained through the contribution of $3p^4\ ^1D$ by 5.4%.

(4) Ar^+. 15.76 and 15.94 eV.
The minor peak which is present near peak (27) comes from the metastable transition $CH_2OH^+ \rightarrow CHO^+$. This is not a collision induced dissociation reaction but a unimolecular decomposition.

(5) Kr^+. 14.00 and 14.67 eV.
Contribution from the high energy levels is negligibly small.

(6) Xe^+. Mainly 12.13 and 13.44 eV.
About 5% contibution is derived from the higher energy levels.

(7) Ne^{2+}. Besides the recombination energies of 10.5—12.0 eV, recombination of $2s^22p^4 \rightarrow 2s2p^5$ can contribute to the charge exchange. The latter is about 10% in methylamine,[4] while it is as large as about 30% in methanol. The absolute value of this energy is higher than 25 eV which is the upper limit of the energy we considered, since the relation (13)>(14)>(15) holds among the abundances of the ions (Table 1, Fig. 1). Contribution of this recombination energy in the higher region will give a small error in estimation of the cross section of charge exchange.

(8) Ar^{2+}. A mass peak (32) of 5.6% is given by the process $3s^23p^4\ ^3P$ or ^1D to $3s3p^6$ which has a recombination energy of 11.5—12.5 or 13—14 eV. Peak (31) is produced by 8.0% due to the same process. Contribution from the

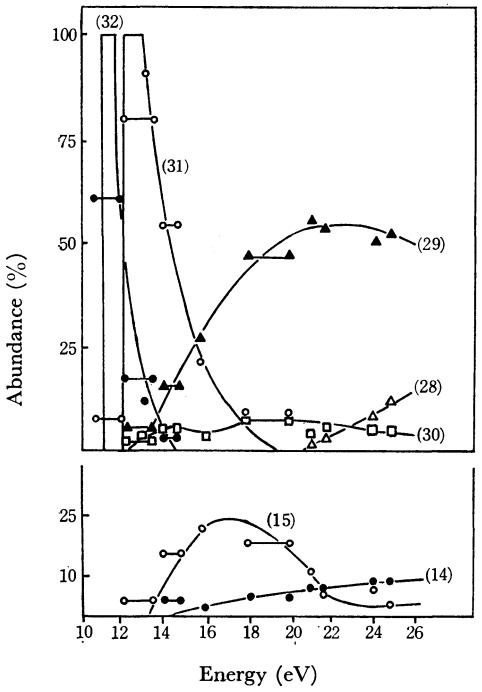

Fig. 1. Breakdown curve of methanol.

6) a) This can be used also for the study of the ion-molecule reaction as a tandem mass spectrometer. b) T. Shiokawa, K. Yoshihara, M. Yagi, T. Omori, H. Kaji, M. Hiraga, T. Nagatani, and Y. Takita, *Mass Spectrosc.*, **18**, 1230 (1970).

process $3s^23p^4 \rightarrow 3s^23p^4$ nx can be neglected. When the breakdown curve is drawn, the fragment ions such as (29), (28), and (14) produced by the charge exchange of recombination energy 24.0 eV should be corrected by about 15%.

(9) Kr^{2+}. 21.0 eV.

(10) Xe^{2+}. 18—20 eV.

Breakdown Curve and Energy Distribution Function. The breakdown curve determined from the fragment distribution (Table 1) and the recombination energies of the ions is shown in Fig. 1. The internal energy distribution function of methanol obtained from the measured values of the cross section for the charge exchange reactions is shown in Fig. 2.

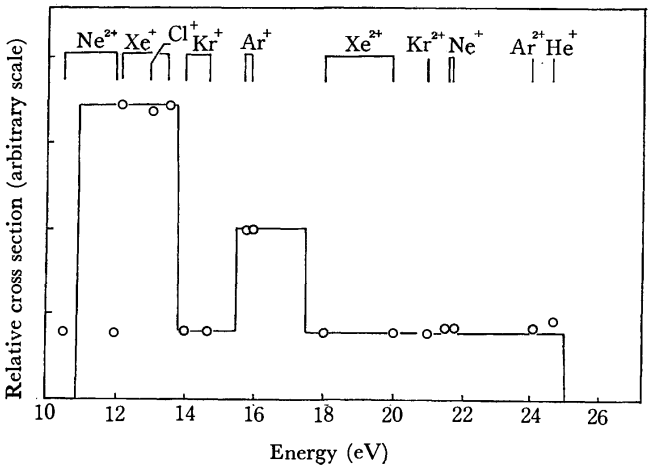

Fig. 2. Internal energy distribution function of methanol.

The behaviors of the seven dominant fragment ions (Fig. 1) are in line with the results of Wilmenius and Lindholm[3] but the appearance potentials are not always the same as those of Friedman *et al.* Potentials will be considered as follows.

(32) CH_3OH^+: 10.9 eV.

(31) CH_2OH^+: 12.0 eV.

These values are slightly lower than those of Friedman *et al.*,[1] but in good accrodance with those of Wilmenius and Lindholm.[3]

(30) $CHOH^+$: Formation of this ion starts from 12.3 eV, and it increases and then decreases, showing the second increase at about 16 eV. This indicates that there are two processes in the formation of the ion of *m/e* (30). The precursor ions corresponding to these processes are the ion of *m/e* (32) and (31).

(29) CHO^+: 13.1 eV.

Wilmenius and Lindholm[3] adopted the value of 14.2 eV. However, we have good evidence that the energy is lying at 13.1 eV from the experiment using the source volume as a cascade type double mass spectrometer.[7]

(28) CO^+. It was difficult to decide the appearance potential accurately. As shown in Table 1, a small quantity of the ion with *m/e* already appeared in the lower energy region (this might be due to contamination of N_2^+), but it is obvious that the value of the appearance potential is beyond 20.0 eV (Fig. 1). In this work we adopted 20.0 eV. The value supports the view that the formation of species (28) is due to the dissociation (32)→(28)+4H.[1]

(15) CH_3^+: 13.3 eV.

This is slightly lower than the value 14.0 eV previously reported.[1,2,8] In the experiment using a charge spectrometer as a cascade-type double mass spectrometer[7] it was determined to be 13.3 eV. This value is best responsible to the trend of the break down curve in the present study.

(14) CH_2^+: 14.2 eV.

The internal energy distribution function has a valley as in the case of methylamine[4] in the range 14.0—15.5 eV (Fig. 2). The ionization potential of (y) electron localized in CO has been reported to be 13.1 eV[3] or 14.64 eV.[9] Thus, the valley shows the presence of interaction which suppresses the formation of CH_3^+ and/or OH^+ by breaking of the C–O bond after the ionization of the (y) electrons. Up to now, the energy distribution function of methanol was assumed to be rectangular while that for methylamine[4,10] and for acetylene[11] were reported to possess valleys. The fact that a valley can be seen also in methanol suggests the presence of the interaction between the CH_3 and OH groups, although it is weaker than in the case of methylamine and acetylene.

Discussion

Comparison of the Present Data with Those of Mass Spectra by Electron Impact. The integrated value taken from the breakdown curve is expected to agree with the mass spectra by electron impact regardless of the contribution of high energy excitation of the molecules. Usually mass spectra obtained by electron bombardment is considered to satisfy these conditions, because the bombarding electrons used for ionization have kinetic energy less than 100 eV. The mass spectra are shown in Table 2. Results for ions of energy higher than 20 eV tend to disagree (Table 2, see (28)). This is because the contribution of ions with energies beyond 25 eV has been neglected in the energy distribution curve (Fig. 2). Except for this the agreement is quite satisfactory.

Reactions of Excited Ions. As in the case of methylamine the reactions of excited ions produced by charge exchange were investigated as a function of increasing gas pressure. The results for Cl^+ as a source material of the charge exchange are shown in Fig. 3. The experiments using He^+, Ne^+, Ar^+, Kr^+, Xe^+, Ne^{2+},

Table 2. Comparison of mass spectra by electron impact with those calculated from the results of charge exchange (in %)

m/e	Electron impact		Calculated from charge exchange
	Friedman[1]	Cummings[12]	
14	1.5	2.1	2.9
15	8.5	12.4	10.5
28	5.5	2.1	1.2
29	19.5	26.2	27.3
30	2.6	3.1	4.2
31	37.2	34.5	33.6
32	25.2	19.7	20.6

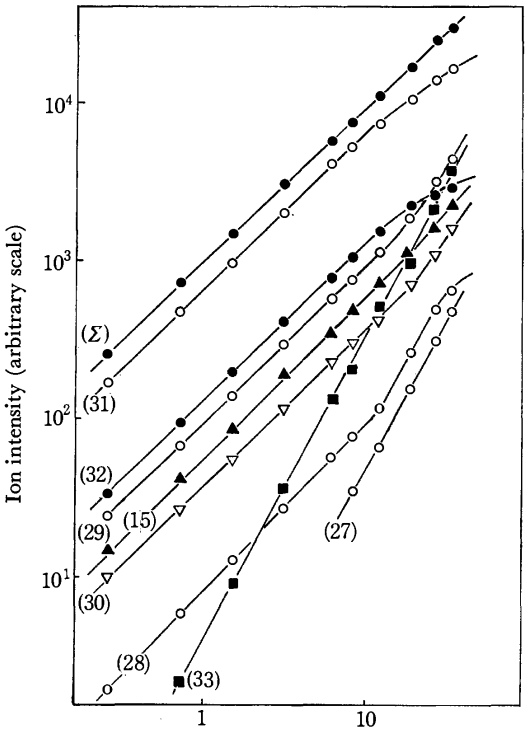

Fig. 3. Pressure dependence of the fragment ion intensity in methanol bombarded by Cl^+.

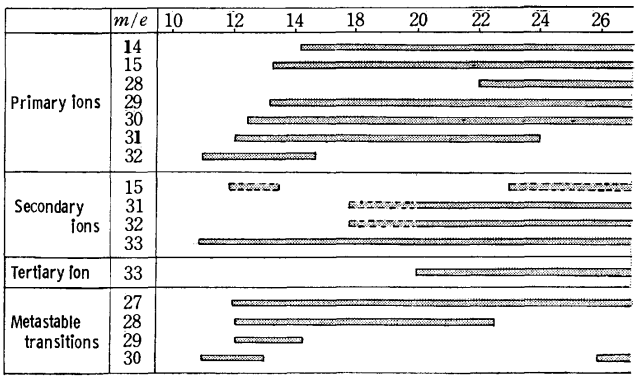

Fig. 4. Occurrence of various ions and its relation to the energy range.

Ar^{2+}, Kr^{2+}, and Xe^{2+} have also been carried out in the same way.[13] From the results we can analyze the relation between the appearance of ions and their energy range as shown in Fig. 4. Some interesting aspects in four energy regions are discussed.

(i) 10.9—12.0 eV: The parent ion is predominantly produced for the primary process. A secondary ion (33) is produced by proton transfer or hydrogen atom transfer between the parent ion and the methanol molecule. Metastable transition can be explained by elimination of a hydrogen atom from the parent ion (32) at the moment of collision with the methanol molecules.

13) T. Nagatani, Thesis Tohoku Univ., (1970).

(ii) 12.0—15.0 eV: (31) is the principal fragment ion for the primary process although (32) contributes to some extent. Its regeneration can be observed as a secondary process for methylamine. In the case of methanol, however, such a process cannot be observed. It was revealed[7] that the charge transfer cross section for methanol is very small in this region compared to the total ionization cross section. This supports the view that there is no secondary process producing (31) except for the formation of (33).

Metastable transition is caused by elimination of a hydrogen atom or molecule from (31) or (30). A possibility of the presence of the isomers $CH_2{=}O^+H$ and $C^+H_2{-}OH$ could be detected in this case.

(iii) 15.0—18.0 eV: Main primary ions are (31), (29), and (15). (33) is again produced in this region as a secondary product, but the mechanism of its formation is not clear.

(iv) 18.0—25.0 eV: (29) is predominant, various secondary and tertiary ions being also observed. Proton transfer, charge transfer and hydride ion transfer between (29) and methanol produce the ions (33), (32), and (31), respectively.

With regard to metastable transition, the metastable peak (27) is observed according to the process

$$(29) + CH_3OH \longrightarrow (28) + H + CH_3OH$$

This causes an apprarent peak at (27). We also see the presence of the metastable peak (30) above 24 eV. This species may be produced by the dissociation of the ion (32) through its regeneration reaction on collision between ions (29) or (28) and methanol molecules. It was revealed that (32) easily dissociated above 24 eV.[7]

Table 3. Ion-molecule reactions in methanol

Energy	Process	Mass peak
10.9—12.0 eV	H^+ transfer:	
	$CH_3OH^+ + CH_3OH \longrightarrow CH_3OH_2^+$	(33)
	H transfer:	
	$CH_3OH^+ + CH_3OH \longrightarrow CH_3OH_2^+$	(33)
	Metastable transition:	
	$CH_3OH^+ \xrightarrow{-H} CH_2OH^+$	(30)
12.1—15.0 eV	H^+ transfer:	
	$CH_2OH^+ + CH_3OH \longrightarrow CH_3OH_2^+$	(33)
	Metastable transition:	
	$CH_2OH^+ \xrightarrow{-H} CHOH^+$	(29)
	$CH_2OH \xrightarrow{-2H} CHO^+$	(27)
	$CHOH \xrightarrow{-H} CHO^+$	(28)
18.0—25.0 eV	H^+ transfer:	
	$CHO^+ + CH_3OH \longrightarrow CH_3OH_2^+$	(33)
	Electron transfer:	
	$CHO^+ + CH_3OH \longrightarrow CH_3OH^+$	(32)
	H^- transfer:	
	$CHO^+ + CH_3OH \longrightarrow CH_2OH^+$	(31)
	Metastable transition:	
	$CHO^+ \xrightarrow{-H} CO^+$	(27)

The C–O bond rupture leads to the formation of ions (15) *etc.* There is only a weak interaction between the CH_3 group and the OH group, which makes breaking of the bond easy.

The ion-molecule reactions in methanol are summarized in Table 3.

Kotoyori *et al.*[14] studied the reactions of methanol with accelerated rare gas ions and discussed the formation of the final chemical species. They concluded that charge exchange reactions are not important in determination of the final chemical products.

The authors thank Mr. M. Hiraga for his kind cooperation throughout this work.

Derivatographic Studies on Transition Metal Complexes. X.[1] Thermal Octahedral-to-Square Planar Transformation of Ni(*NN*-deen)$_2$X$_2$·*n*H$_2$O in Solid Phase[2]

Ryokichi TSUCHIYA, Seiji JOBA, Akira UEHARA, and Eishin KYUNO
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received June 22, 1972)

Thermal reactions of the complexes [Ni(H$_2$O)$_2$(*NN*-deen)$_2$]X$_2$·*n*H$_2$O (*NN*-deen is *N,N*-diethylethylenediamine and X is Cl or Br) were investigated. It was found by derivatography and spectral and magnetic measurements that the bromide undergoes transformation from octahedral to square planar structure by "deaquation" upon heating, whereas the chloride turned to the dichloro complex by thermal "deaquation-anation" losing the coordinated water and drawing chloride ion into the coordination sphere with retention of octahedral structure around the central metal. No such transformation could be found in the corresponding iodide and nitrate, since only diamagnetic complexes, [Ni(*NN*-deen)$_2$]X$_2$ (X is I or NO$_3$), and no paramagentic complexes were obtained.

When a nickel(II) atom is surrounded by the same six ligands forming a regular octahedral configuration, it forms a blue type complex with magnetic moment 3.1—3.2 B.M. due to two unpaired electrons in 3d orbital with a small orbital contribution.[3] The red, brown and yellow nickel(II) complexes show a diamagnetic behavior due to the lower energy of the triplet ground state relative to the singlet state,[4,5] taking a planar structure in a strong field with coordination number 4. Some green and blue nickel(II) complexes are known,[3] which take a tetrahedral structure with coordination number 4 having two unpaired 3d electrons.

Since the three types of nickel(II) complexes give characteristic electronic spectra as regards symmetry,[6,7] the structure of the complexes and their thermal reaction products can be assigned by observing the spectra and other physical properties.

It is of interest to investigate the structural transformation of nickel(II) complexes upon heating. Structural transformations after complete dehydration of nickel(II) complexes containing *C,C'*-substituted ethylenediamine are known.[8,9] Nickel(II) complexes containing ethylenediamine itself[3] or its *N*-alkyl-substituted products[6] as diamine such as Ni(diamine)$_2$X$_2$·*n*H$_2$O or Ni(diamine)$_2$X$_2$, are known. However, no detailed studies on the structural change upon heating have been made.

Studies on the thermal structural transformation of some metal complexes have been carried out recently by means of derivatography.[1,10-12] The present work was undertaken to find whether or not the nickel(II) complexes with *N,N*-diethylethylenediamine undergo structural transformation from octahedral to square planar in the solid phase depending upon the kind of counter anions.

Experimental

Preparation of Complexes. *N,N*-Diethylethylenediamine was of commercial reagent grade and used without purification. Complexes Ni(*NN*-deen)$_2$Cl$_2$·2H$_2$O, Ni(*NN*-deen)$_2$Br$_2$·3H$_2$O, Ni(*NN*-deen)$_2$I$_2$ and Ni(*NN*-deen)$_2$(NO$_3$)$_2$ were prepared by the known method,[6] their chemical formulas being identified by elemental analysis and spectral measurement.

Derivatographic Measurements. The derivatograms were obtained with a MOM Derivatograph Typ-OD-102.[13] 0.5 g of finely powdered sample (100—200 mesh inch^{-1}) was used in each run. Measurements were carried out under a constant flow of nitrogen stream with a heating rate of 1 °C min^{-1} unless otherwise stated.

Spectral Measurements. Visible and UV spectra in the solid state were measured by the diffuse reflectance method with a Hitachi EPU-2A spectrophotometer equipped with a standard Hitachi reflection attachment. IR spectra were obtained with JASCO-IR-E and IR-F infrared spectrophotometers.

Magnetic Measurements. The effective magnetic moments were evaluated from the magnetic susceptibilities measured by the Gouy method at room temperature. Hg[Co(NCS)$_4$] was used as reference material. Susceptibilities of the complexes were corrected by applying Pascal's constants of the elements involved.

Results and Discussion

Derivatography. The derivatograms of Ni(*NN*-deen)$_2$Cl$_2$·2H$_2$O and Ni(*NN*-deen)$_2$Br$_2$·3H$_2$O are shown in Fig. 1. The former shows a loss of two moles of water upon heating at 80—110 °C in the TG curve, an endothermic peak appearing in the DTA curve. It seems that the anhydrous complex Ni(*NN*-deen)$_2$Cl$_2$ is produced.

The bromide complex loses one mole of water at 30—65 °C and two moles at 70—110 °C, giving two endothermic peaks in the corresponding dehydration temperature ranges in the DTA. The anhydrous complex Ni(*NN*-deen)$_2$Br$_2$ seems to be formed.

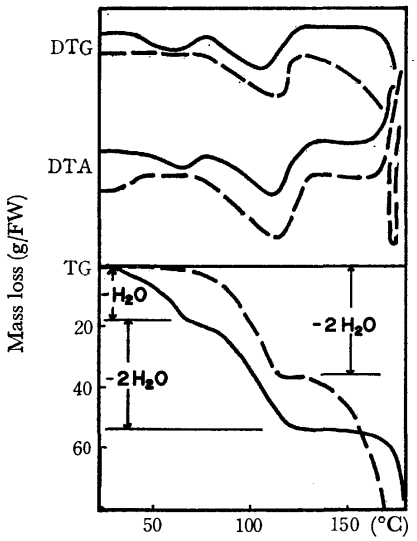

Fig. 1. Derivatograms of Ni(*NN*-deen)$_2$Cl$_2$·2H$_2$O(----) and Ni(*NN*-deen)$_2$Br$_2$·3H$_2$O (——).

Absorption Spectra. The visible absorption spectra of the complexes Ni(*NN*-deen)$_2$X$_2$·nH$_2$O measured in solid state by the diffuse reflectance method are shown in Fig. 2, together with those of the anhydrous complexes Ni(*NN*-deen)$_2$X$_2$ (X is Cl or Br), obtained by heating the corresponding hydrated complexes at 110 °C.

13) F. Paulik, J. Paulik, and L. Erdey, *Talanta*, **13**, 1405 (1966).

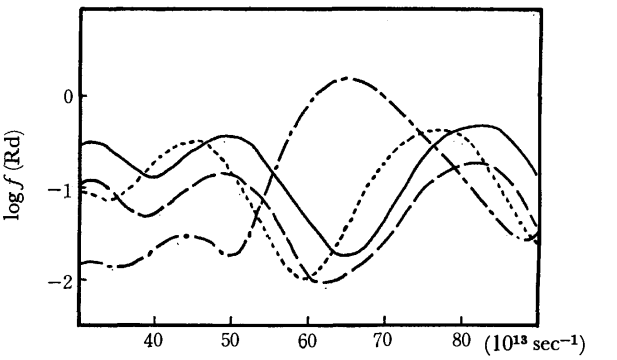

Fig. 2. Electronic spectra of Ni(*NN*-deen)$_2$Cl$_2$·2H$_2$O (——), Ni(*NN*-deen)$_2$Br$_2$·3H$_2$O (——) and those after heating them at 110 °C (----) and at 110 °C (————).

We see from Fig. 2 that the hydrated complexes Ni(*NN*-deen)$_2$X$_2$·nH$_2$O both give three absorption bands at 30, 49, and 80×10^{13} sec^{-1}, which can be assigned to the electron transitions taking place in the Oh symmetry complexes of d^8 metal,[6,7] $^3A_{2g}\rightarrow{}^3T_{2g}$, $^3A_{2g}\rightarrow{}^3T_{1g}$ (F) and $^3A_{2g}\rightarrow{}^3T_{1g}$ (P), respectively, irrespective of the kind of counter ions such as Cl$^-$ or Br$^-$.

The absorption spectra of the anhydrous complexes Ni(*NN*-deen)$_2$X$_2$, where X is I or NO$_3$, are given in Fig. 3. They show that the anhydrous complexes Ni(*NN*-deen)$_2$X$_2$ both give a relatively strong absorption band at 64—65$\times10^{13}$ sec^{-1}, characteristic of the square planar structure in nickel(II) complexes and probably assignable to the transition $^1A_{1g}\rightarrow{}^1A_{2g}$.

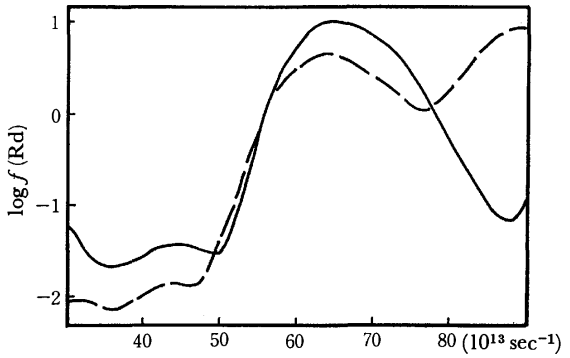

Fig. 3. Electronic spectra of Ni(*NN*-deen)$_2$I$_2$ (——) and Ni(*NN*-deen)$_2$(NO$_3$)$_2$ (——).

We see that the spectrum of the anhydrous chloride obtained upon heating is analogous to that of the mother hydrated chloride except for a slight shift of maximum peak to the longer wavelength region (Fig. 2), whereas the spectrum of the anhydrous bromide is analogous to that of the anhydrous iodide and nitrate (Fig. 3). The results suggest that the hydrated chloride turns to the dichloro complex through deaquation-anation upon heating with retention of the octahedral coordination, while the bromide is converted into the square planar coordination as the result of dehydration alone. Thus, the hydrated chloride and bromide are both diaquo octahedral complexes and their thermal reactions can be assumed to proceed as follows.

$$[Ni(H_2O)_2(NN\text{-deen})_2]Cl_2 \longrightarrow [NiCl_2(NN\text{-deen})_2] + 2H_2O$$

$$[Ni(H_2O)_2(NN\text{-deen})_2]Br_2\cdot H_2O \longrightarrow [Ni(NN\text{-deen})_2]Br_2 + 3H_2O$$

From the similarity of spectra of the anhydrous complex bromide (Fig. 2) and of the iodide and nitrate (Fig. 3), the complex iodide and nitrate can be represented by $[Ni(NN\text{-deen})_2]I_2$ and $[Ni(NN\text{-deen})_2](NO_3)_2$, respectively.

IR Spectra. Infrared and far-infrared absorption spectra were measured in order to see whether the anions in the complexes are coordinated and to obtain configurational information. The IR spectra of the diaquo complexes exhibit an absorption peak assigned to the stretching vibration, ν_{OH}, at *ca.* 3200 cm^{-1} and that for the bending vibration, δ_{OH}, at *ca.* 1600 cm^{-1}, the patterns of the chloride and bromide being the same. This supports the results given by electronic absorption measurement and derivatography where the diaquo complex chloride and bromide are represented by $[Ni(H_2O)_2(NN\text{-deen})_2]Cl_2$ and $[Ni(H_2O)_2(NN\text{-deen})_2]Br_2\cdot H_2O$ respectively.

The IR spectra of the anhydrous complex chloride and bromide obtained by heating the corresponding diaquo complexes are shown in Fig. 4, together with those of the iodide and nitrate. The absorption peaks of the OH group in the former two complexes are quenched as a result of dehydration, and the patterns of the bromide, iodide, and nitrate are approximately analogous to each other but differ from that of the chloride. These results confirm the chemical formulas $[Ni(NN\text{-deen})_2]Br_2$, $[Ni(NN\text{-deen})_2]I_2$, $[Ni(NN\text{-deen})_2](NO_3)_2$, and $[NiCl_2(NN\text{-deen})_2]$ for the bromide, iodide, nitrate, and chloride, respectively, in which the former three have a square planar structure and the last one has an octahedral structure with chloride ions in coordination.

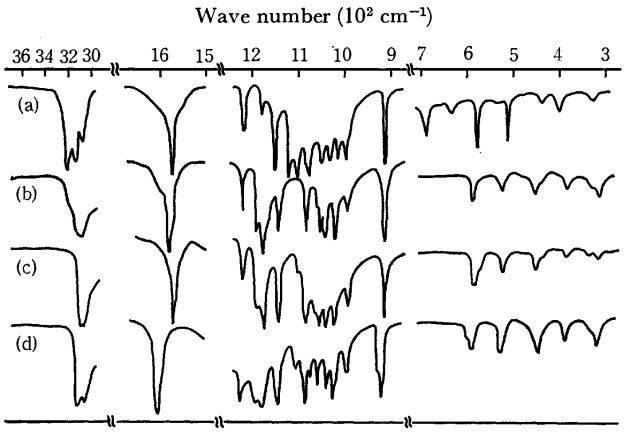

Fig. 4. IR and Far-IR spectra of (a) $Ni(NN\text{-deen})_2Cl_2$, (b) $Ni(NN\text{-deen})_2Br_2$, (c) $Ni(NN\text{-deen})_2I_2$, and (d) $Ni(NN\text{-deen})_2(NO_3)_2$.

Magnetic Susceptibility Measurement. The values of the effective magnetic moments of the complexes are summarized in Table 1 together with their colors. The fact that the diaquobis(diamine) complex chloride and bromide, including the dichloro complex formed by heating the former, show paramagnetism and the anhydrous iodide and nitrate diamagnetism confirms the respective structures predicted by spectral measurements. It was found that the hydrated diaquo complex bromide lost paramagnetism remarkably upon heating (Table 1).

Table 1. Magnetic moments and colors of the complexes

Complex	Color	Magnetic moment μ_{eff} (B.M.)
$[Ni(H_2O)_2(NN\text{-deen})_2]Cl_2$	blue	3.21 (28 °C)
$[Ni(H_2O)_2(NN\text{-deen})_2]Br_2\cdot H_2O$	blue	3.30 (20 °C)
$[Ni(NN\text{-deen})_2]I_2$	orange	diamag.
$[Ni(NN\text{-deen})_2](NO_3)_2$	orange	diamag.
$[NiCl_2(NN\text{-deen})_2]$	green	3.19 (20 °C)
$[Ni(NN\text{-deen})_2]Br_2$	orange yellow	0.9 (20 °C)

It is concluded that the diaquo complex bromide undergoes structural transformation from octahedral to square planar configuration by way of thermal deaquation in a solid phase, whereas the diaquo complex chloride undergoes no structural transformation but a thermal deaquation-anation reaction, forming the dichloro complex simultaneously (Fig. 5).

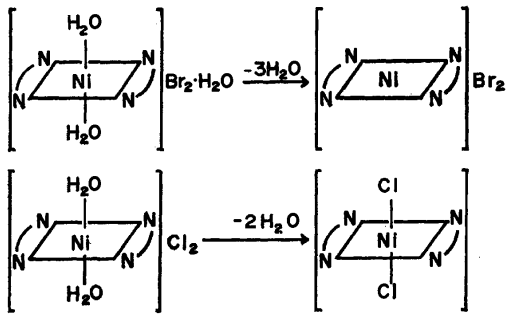

Fig. 5. Thermal reaction schemes of $[Ni(H_2O)_2(NN\text{-deen})_2]Br_2\cdot H_2O$ and $[Ni(H_2O)_2(NN\text{-deen})_2]Cl_2$.

Alkoxy and Phenoxy Bridged Dimeric Copper(II) Complexes with Salicylaldimine Ligands

J. O. MINERS and E. SINN*

Chemistry Department, Victoria University of Wellington, P.O. Box 196, Wellington, New Zealand

(Received December 13, 1971)

The tridentate Schiff base *N*-3-hydroxy-*n*-propylsalicylaldimine can be coordinated with copper(II) to form three kinds of dimeric oxy-bridged antiferromagnetic complexes (metal: ligand ratio—1: 1), as well as the normal monomeric complex. In one of the dimeric complexes pairs of copper atoms are bridged by pairs of the deprotonated alcoholic oxygens of the ligands. The others have an extra ligand X (X=–Cl, $-ONO_2$) per copper atom, the metals are bridged by phenolic oxygens, the alcoholic hydroxyls are not deprotonated, but are either coordinated (if X=Cl) to five-coordinated copper atoms in discrete dimer molecules, or participate in intermolecular hydrogen bonding linking individual dimeric molecules in which the copper atoms are four-coordinated. In the presence of pyridine, ammonia, or mild inorganic base, a rearrangement reaction can be induced, resulting in conversion of the phenolic-bridged (five-coordinated copper) dimer into the related alcoholic-bridged (four-coordinated copper) dimer. This behaviour is not followed by *N*-hydroxyethylsalicylaldimine which appears to form only one kind of copper complex [Cu(Lig)X] (X=–Cl, $-ONO_2$); in which the metal atoms are essentially planar and do not take part in strong antiferromagnetic interactions.

Yamada *et al.*[1a] and Kato *et al.*[1b] found that 3-hydroxy-*n*-propylsalicylaldimine can be used to form dimeric copper(II) complexes. Two possible structures were recognised for these complexes, I and II, of which I was preferred by the latter authors.[1b]

Contemporary and subsequent work on salicylaldimines without alcoholic side-chains showed that binuclear and trinuclear complexes can be formed very readily using the ability of phenolic oxygens to become three-coordinated.[2] Bidentate salicylaldimines were used to form dimers, III(a),[3] III(b),[4] and tetradentate salicylaldimines to form bi- and tri-nuclear metal complexes IV[5] and V.[6] The structures were assigned on the basis of synthetic, magnetic, ultraviolet-visible and infrared data. In particular a shift of about 20 cm^{-1} in the infrared absorption near 1540 cm^{-1} tentatively assigned to the phenolic C–O stretch,[3,4] was found to be characteristic of the formation of complexes III—V from monomeric complexes. This infrared shift can be taken as characteristic of bridging *via* the phenolic oxygens of salicylaldimines, and if bridging occurs without involving the phenolic oxygens, as in structure I, no such shift is expected.

Single crystal X-ray studies have since confirmed these structures for two binuclear copper(II) complexes of type III,[7] and three of type IV,[7,8] and two mixed metal complexes of type V, one with metal atoms (Cu–Na–Cu) in a flattened isosceles triangular array[9] and one with the metals (Cu–Mn–Cu) in a straight line.[10] A complex of type III, but with the substituent R-groups 3-hydroxy-*n*-propyl, has also been subjected to X-ray study, and found to have phenolic oxygen bridged structure, with the alcoholic hydroxyl groups coordinated to the copper atoms VI.[11]

These results appear to indicate a preference for bridging *via* phenolic oxygens in polynuclear salicylaldimines, even if alocholic oxygens are available in the ligand. However, the nonexistence of alcoholic oxygen bridges does not necessarily follow. It is now of interest to determine whether such bridging occurs, and, if it does, under what conditions. We report here an investigation of dimeric complexes with -R-OH substituted salicylaldimines, where R=$-CH_2-CH_2-$ and $-CH_2-CH_2-CH_2-$.

Regardless of whether alocholic or phenolic oxygen bridging is preferred in complex I (or II), this complex is closely related to complex VI. Complex VI, $[CuC_{10}H_{11}NO_2 \cdot HCl]_2$ may be regarded as a hydrochloride addition compound of complex I (or II) $[CuC_{10}H_{11}NO_2]_2$, and it should therefore be possible to find conditions for the conversion of the less stable of the two complexes to the more stable, and perhaps also for the reverse reaction. This aspect is also investigated.

Experimental

The parent monomeric complexes were prepared in the standard way[12] by warming the copper(II) complex of the salicylaldehyde or 5-chlorosalicylaldehyde with the appro-

priate amine, and recrystallising from chloroform–ethanol. Cu(PrOH·Sal)$_2$ formed as an oil, and a solid was obtained only after standing.

The copper chloride or nitrate adducts were prepared by the standard method for complexes of type III,[3,4] *viz.* by the reaction of the appropriate copper(II) salicylaldimine complex with copper(II) chloride or copper(II) nitrate in methanol.

For brevity, we denote 3-hydroxy-*n*-propylsalicylaldimine and 2-hydroxyethyl-5-chlorosalicylaldimine as 3-PrOH·Sal and EtOH·ClSal respectively. Deprotonation of the alcoholic hydroxyl group is indicated by omission of "H" from the abbreviation.

Analytical data are listed in Table 1.

Infrared Spectra. IR spectra were determined on nujol and hexachlorobutadiene mulls of the compounds. Both a Unicam SP200 and a Perkin-Elmer 221 spectrophotometer were used to obtain the spectra. The spectrum of a polystyrene film was recorded on the same chart as a reference to allow accurate measurements of the bands.

Electronic Spectra. Electronic spectra were determined on the solid compounds using a Unicam SP200 spectrophotometer.

Electron Spin Resonance Measurements. ESR measurements were made on a Varian V4502-15 ESR spectrometer at the Physics and Engineering Laboratory of the D.S.I.R., Wellington. We are grateful to Mr. M. Collins for access to this apparatus.

Magnetic Susceptibility Measurements.[14] Magnetic susceptibility measurements were made as previously described,[3,5] in the range 100—400°K on a cryostat-controlled Gouy balance apparatus. The agreement of the observed magnetic susceptibility values, per gram atom of copper, χ_M (corrected for diamagnetism using Pascal's constants[13] with the Bleaney-Bowers Eq. (1) was tested where appropriate, and the value of the singlet-triplet separation, $-2J$, and of the Landé splitting factor, g, obtained from the best fit.[2-5,14]

$$\chi_M = \frac{Ng^2\beta^2}{3kT}\left(1+\frac{1}{3}e^{-2J/kT}\right)^{-1} + N\alpha \qquad (1)$$

Here the symbols have their usual meanings. $N\alpha$ was assumed to have the value 6×10^{-5} c.g.s.e.m.u.[2-5,14,15] Where Eq. (1) was not satisfied, the data was compared with Eq. (2) for trinuclear complexes,[16] as well as models for infinite lattice interactions

$$\chi_M = \frac{Ng^2\beta^2}{12kT}\cdot(e^{-A+B}+e^{-A-B}+10e^{A})/$$
$$(e^{-A+B}+e^{-A-B}+2e^{A}) + N\alpha \qquad (2)$$

where $A=(J_{12}+J_{23}+J_{13})/kT$, $B=(J_{12}^2+J_{23}^2+J_{13}^2-J_{12}J_{23}-J_{12}J_{13}-J_{23}J_{13})^{1/2}/kT$ and the J_{ij} are the exchange integrals between the three pairs of copper atoms.

Magnetic moments (in Bohr Magnetons) were calculated using the relation

$$\mu_{eff} = \sqrt{8.0(\chi_M - N\alpha)T}$$

In the absence of magnetic exchange interactions, g may be estimated from the relation $\mu_{eff}=g\sqrt{S(S+1)}$.

X-Ray Powder Diffraction Patterns. X-Ray diffraction paterns were recorded using a powder diffractometer with a Phillips Wide Range Goniometer PW1050/25.

Density Measurements. Densities were measured at 20°C by suspending crystals in solutions of equal density. The suspending solutions comprised acetone–carbon tetrachloride–bromoform mixtures and their densities were measured with a set of hydrometers calibrated to 0.0005 g cm^{-3}. The observed crystal densities are considered accurate and reproducible to $\pm$0.005 g cm^{-3}.

Results and Discussion

Magnetic Properties. Kato *et al.*[1] prepared complexes I (or II) [Cu(3-PrO·Sal)]$_2$ with four different ring substituents X, but found the properties to be so similar within the series that the complex with X=H can be taken as a representative compound when making comparisons with compounds belonging to different groups. In fact, variation of the ring substituent X in [Cu(3-PrO·Sal)]$_2$ has rather less effect on the properties than similar variation of X in complexes of type III[2,5-7] or IV.[2-6,17] This suggests that [Cu(3-PrO·Sal)]$_2$ may belong to a different category than III and IV, in agreement with the postulate for structure I for the complex.[1b]

Table 2 lists the magnetic properties of the various complexes with 3-PrOH·Sal, EtOH·Sal, and EtOH·ClSal. The complexes with 3-PrOH·Sal behave as binuclear antiferromagnets and Fig. 1 compares the experimental data with those calculated from Eq. (1). The values of J and g required to fit the data are listed in Table 3. The data indicate a much stronger interaction in [Cu(3-PrO·Sal)]$_2$ than in any of the others, again suggesting that complexes of the types [Cu·

[Cu(EtOH·Sal)Cl]	$<$10	2.06			
[Cu(3-PrOH·Sal)NO_3]$_2$	320	2.08	2.29	2.037	2.12$\pm$0.01
[Cu(3-PrOH·Sal)Cl]$_2$	470	2.09	2.31	2.048	2.14$\pm$0.01
[Cu(3-PrO·Sal)]$_2$	1020[c]	2.10	—	—	2.05$\pm$0.03[d]

a) Accuracy of J is expected to be better than 3%; accuracy of g should be about 4% when estimated from Eq. (1).
b) Not evaluated (see text).
c) Accuracy is expected to be low due to very low paramagnetism.
d) Accuracy low owing to very small population of the triplet state, which results in very poor signal to noise ratio.

LigH]$_2$ and [Cu·Lig·X]$_2$ fall into two separate categories where LigH=3-PrOH·Sal.

The relative accuracy of experimental points on the χ *vs.* T curves is much greater than their absolute accuracy, and therefore the accuracy of J values obtained by comparison with Eq. (1) is expected to be high while the accuracy of the g values is expected to be low. ESR measurements were made at room temperature and at 77 K to obtain accurate g values. The values of g were estimated from the ESR spectra in the normal way.[18] (Table 3).

The magnetic properties of the complexes [Cu(EtOH·ClSal)X] differ markedly from their 3-PrOH·Sal analogues. When X=Cl, the complex shows no significant interactions and when X=ONO_2, antiferromagnetic interactions are observed, but the magnetic properties are more consistent with Eq. (2) than Eq. (1). However, we do not consider the data to be sufficiently characteristic to make a positive assignment of structure, at this stage. Measurements down to liquid helium temperatures are desirable, and X-ray

crystallographic studies will be undertaken to clarify the situation.

Spectra. The electronic spectra of the complexes, listed in Table 3, indicate a four-coordinated environment[5,19] about copper, for all the complexes except $[Cu(3\text{-}PrOH \cdot Sal)Cl]_2$, VI, which is known to be five-coordinated, with a trigonal bipyramid configuration. The spectrum of complex VI is similar to those[20] of known[21] distorted bipyramidal complexes such as [Cu(tren)NCS]SCN and $[Cu(bipy)_2I]I$. The most noteworthy feature of the spectra is the difference between the complexes $[Cu(3\text{-}PrOH \cdot Sal)X]_2$ (X=Cl, NO_3). It appears that when X is changed from Cl to NO_3, the structure changes from VI to a four-coordinate arrangement. This behaviour is not paralleled by the analogous complexes with EtOH·ClSal.

The spectra of the four-coordinated complexes suggest a copper environment that is closer to planar than tetrahedral. The shift of 500 cm^{-1} from $[Cu(EtOH \cdot ClSal)NO_3]$ to $[Cu(3\text{-}PrOH \cdot Sal)NO_3]_2$ suggests a slightly greater distortion from planarity in the latter complex,[6,19] since the ligand field strengths of EtOH·ClSal and 3-PrOH·Sal should be fairly close in magnitude. The other differences between the absorption maxima of the four-coordinate complexes are expected to arise from differences in ligand field strengths (X= Cl, NO_3, or no ligand) as well as the differences in the relative distortions from planarity.

Infrared Spectra. The formation of a phenolic oxygen bridge between two metal atoms is considered to result in a shift (~20 cm^{-1}) to higher energies of the salicylaldimine phenolic C–O stretching frequency near 1540 cm^{-1}. This is therefore a most important band for structural assignments and is listed for each complex in Table 4. The expected shift is observed in all the complexes with 3-PrOH·Sal except $[Cu(3\text{-}PrO \cdot Sal)]_2$, indicating absence of phenolic oxygen bridging, and hence structure I for this complex, but structures of types III and VI for the other complexes. Of the complexes with EtOH·Sal and EtOH·ClSal, only $[Cu(EtOH \cdot ClSal)NO_3]$ exhibits a small shift in this region, indicating weak phenolic oxygen bridges for this complex and no significant phenolic bridging for the other complexes.

The infrared absorptions due to the nitrato group in $[Cu(EtOH \cdot ClSal)NO_3]_2$ and $[Cu(3\text{-}PrOH \cdot Sal)NO_3]_2$ confirm that the nitrate is coordinated rather than ionic, but add no new information, since infrared spectra cannot distinguish between mono- and bidentate nitrate coordination.[22] It is therefore necessary to invoke the structural assignment from visible spectra

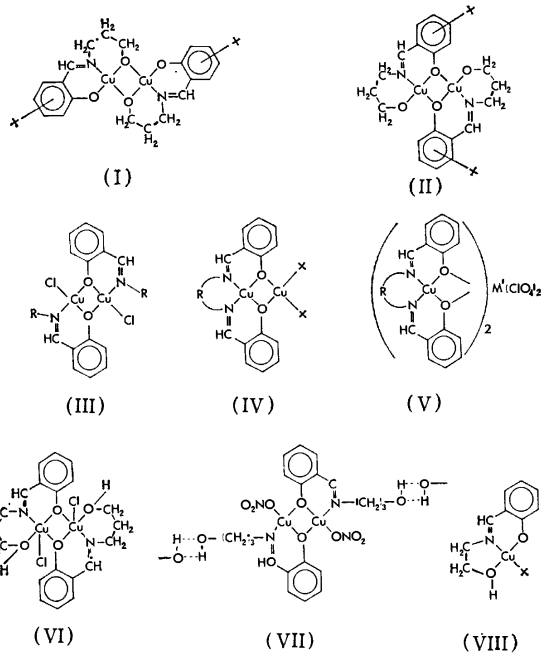
22) K. Nakamoto "Infrared Spectra of Inorganic and Coordination Compounds," Wiley, N. Y. (1963).

to determine monodentate nitrato coordination. Such coordination appears to be necessary in order to make up the required coordination number in each case. (In the special case where the alcoholic oxygens are involved in hydrogen bonding they are unlikely to be available for coordination to copper). These nitrato complexes are similar to the nitrato complexes of type III with Cl replaced by monodentate ONO_2.[4] In all these complexes, infrared absorptions at 790—813, 1005—1022, 1280—1286, 1488—1495 cm^{-1}, typical of coordinated nitrate,[22,23] were observed only in the nitrato complexes, but not in the analogous chloro derivatives (III or VI), nor in the parent monomeric Schiff base complexes.[4]



The O–H stretching region, 2800—3500 cm^{-1}, was examined to determine the bonding of the OH group (Table 4). As expected, $[Cu(3\text{-}PrO\cdot Sal)]_2$ has no bands in this region. Complex VI, which has the OH group coordinated to the metal, has a high energy band in this region. Similar bands occur in all but one of the remaining complexes, suggesting similar coordination of the OH groups. The significant exception is $[Cu(3\text{-}PrOH\cdot Sal)NO_3]_2$ which has a lower energy band, in keeping with a structure involving hydrogen bonding to the hydroxyalkyl group. This postulate is supported by the observation of extensive intermolecular hydrogen bonding in the X-ray study of $[Cu(EtOH\cdot Sal)_2]$[24] while the analogous complex $[Cu(EtOH\cdot ClSal)]_2$ has its OH band at 3100 cm^{-1}. Thus the most likely structure for the complex $[Cu(3\text{-}PrOH\cdot Sal)NO_3]_2$ is VII. The infrared evidence is not conclusive for the complexes involving EtOH·Sal and EtOH·ClSal since some of the bands are weak and broad, but when the other evidence is taken into account, the most likely structure for these complexes is VIII. Cross-linking *via* intermolecular Cu–O or hydrogen bonds, or both, between individual molecules of type VIII seems probable, especially in the complex $[Cu(EtOH\cdot ClSal)NO_3]$ and to a lesser extent $[Cu(EtOH\cdot Sal)NO_3]$. The former complex should perhaps be formulated as $[Cu(EtOH\cdot ClSal)NO_3]_n$ but, as discussed above, n may not be reliably evaluated at this stage. Fortunately, these complexes readily form large (green) crystals, so that single crystal X-ray studies should be accessible.

Rearrangement Reactions. To test the possibility of the interconversion reaction (3),

$$[Cu(3\text{-}PrO\cdot Sal)]_2 + HX \rightleftharpoons [Cu(3\text{-}PrOH\cdot Sal)X]_2 \quad (3)$$

complex I, $[Cu(3\text{-}PrO\cdot Sal)]_2$ was treated with HCl in methanol, and deep brown crystals which separated from the mixture were shown to be identical with complex VI $[Cu(3\text{-}PrOH\cdot Sal)Cl]_2$, having identical infrared spectra and X-ray diffraction patterns, and the same melting points, densities and optical spectra. The reverse conversion was effected by boiling VI in the base pyridine. Dark red crystals which separated on cooling were shown by the same techniques to be identical with I. In each case the reaction appeared to be complete in a few minutes. The procedure was repeated with the nitrato analogue, VII, and a period of days was required for a smaller yield of the product. This slower reaction is not surprising in view of the different structures VI and VII proposed for the chloro and nitrato complexes: the former could undergo internal rearrangement more readily than the latter. The mechanism of these reactions is under further investigation.

It has not been found possible to prepare the complex analagous to I using EtO·Sal in place of 3-PrO·Sal.[1,25] It appears that dimeric analogues to VI using EtOH·Sal in place of 3-PrOH·Sal are not readily formed either.

Conclusion

The main structures I, VI, and VII, occur in copper(II) complexes with *N*-3-hydroxy-*n*-propylsalicylaldimine, and direct chemical interconversion between them is possible. When the hydroxypropyl group is shortened to hydroxyethyl, only one structure, VIII, seems likely, with some degree of molecular aggregation.

$$CuL_2 + CuX_2 \longrightarrow 2[CuLX]$$

In the 3-PrOH·Sal complexes, if the alcoholic oxygen is not deprotonated, bridging occurs easily *via* the phenolic oxygens to form binuclear complexes. The alcoholic oxygen may be coordinated as in VI, but need not be, and may participate in intermolecular hydrogen bonding (VII) instead. When the alcoholic oxygen is deprotonated and coordinated, bridging *via* this oxygen (I) is preferred.

Binuclear Metal Complexes. VI.[1] Syntheses and Properties of Binuclear Copper(II) Complexes of 2,6-Bis[*N*-(β-dialkylaminoethyl)iminomethyl]-4-methylphenol[2]

Hisashi Okawa, Tadashi Tokii,* Yasuomi Nonaka, Yoneichiro Muto,* and Sigeo Kida

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka 812

**Department of Chemistry, Saga University, Saga*

(Received September 18, 1972)

A new series of binuclear copper(II) complexes, $[Fsal(=NenNR_2)_2Cu_2X]^{2+}$ (R=Me and Et, X=Cl, Br, and OH), were synthesized, where $Fsal(=NenNR_2)_2$ indicates the Schiff base prepared from 2,6-diformyl-4-methylphenol and *N,N*-dialkylethylenediamine (alkyl=methyl(Me) and ethyl(Et)). Two copper(II) ions are connected with the phenolic oxygen and X. The complexes obtained were characterized by elemental analyses, infrared and visible spectra, molar conductivities in methanol, ESR spectra and magnetic susceptibilities. It was found that the stability of the complexes decreases in the order X=OH≫Br>Cl. It was concluded from cryomagnetic measurements that the effect of the bridging group X on spin-coupling decreases in the order OH≫Br>Cl.

It is known that 2,6-diformyl-4-methylphenol and its Schiff base derivatives[3-7] form a novel class of binuclear copper(II) complexes, in which two copper(II) ions are bridged with two different groups. We suggested that there is a relationship between the simply coordinating and bridging groups concerning the stability of the binuclear copper(II) complexes.[5] In order to find the relationship it is necessary to synthesize many binuclear copper(II) complexes with a variety of coordinating and bridging groups. We attempted the preparation of some binuclear copper(II) complexes of the Schiff bases 2,6-bis[*N*-(β-dialkylaminoethyl)iminomethyl]-4-methylphenol made from 2,6-diformyl-4-methylphenol and *N,N*-dialkylethylenediamine (alkyl=methyl and ethyl).

We synthesized six binuclear copper(II) complexes of the type $[Fsal(=NenNR_2)_2Cu_2X]^{2+}$, where $Fsal(=NenNR_2)_2$ denotes the Schiff bases and X the second bridging group (phenolic oxygen will be called the first bridging group). The structures and properties of the complexes were studied by elemental analyses, IR and visible spectra, molar conductivities in methanol, ESR spectra and magnetic susceptibilities, magnetic exchange interaction also being examined. Since only the second bridging group in the complexes is variable, we can estimate its effect on the spin-coupling between the two copper(II) ions.

Experimental

Syntheses. The synthetic method for 2,6-diformyl-4-methylphenol was described elsewhere.[4]

[Fsal(=NenNMe$_2$)$_2$Cu$_2$Cl]Cl$_2$: 2,6-Diformyl-4-methylphenol (330 mg) and anhydrous copper(II) chloride (538 mg) were dissolved in absolute methanol (30 ml). To the solution was added a solution of *N,N*-dimethylethylenediamine (352 mg) in absolute methanol (5 ml). The reaction mixture was warmed and concentrated to 15 ml to give green needles. They were recrystallized from anhydrous methanol–benzene.

Found: C, 38.08; H, 5.22; N, 10.59; Cl, 19.64%. Calcd for $C_{17}H_{27}N_4OCl_3Cu_2$: C, 38.03; H, 5.07; N, 10.44; Cl, 19.81%.

[Fsal(=NenNMe$_2$)$_2$Cu$_2$Br]Br$_2$: To a solution of 2,6-diformyl-4-methylphenol (330 mg) and anhydrous copper(II) bromide (894 mg) in methanol (30 ml) was added a methanolic solution (5 ml) of *N,N*-dimethylethylenediamine (352 mg). After the reaction mixture was boiled and concentrated to 20 ml, dark green needles were obtained. They were filtered and washed with a small amount of cold absolute methanol.

Found: C, 30.52; H, 4.22; N, 8.36; Br, 35.37%. Calcd for $C_{17}H_{27}N_4OBr_3Cu_2$: C, 30.47; H, 4.06; N, 8.36; Br, 35.77%.

[Fsal(=NenNMe$_2$)$_2$Cu$_2$OH](ClO$_4$)$_2$: 2,6-Diformyl-4-methylphenol (330 mg), *N,N*-dimethylethylenediamine (352 mg) and copper(II) perchlorate hexahydrate (1482 mg) were mixed in methanol (30 ml). The reaction mixture was concentrated to 15 ml and diluted with water (15 ml) to give greenish blue prisms. They were recrystallized from water to give blue prisms.

Found: C, 31.74; H, 4.58; N, 8.69; Cu, 19.51%. Calcd for $C_{17}H_{28}N_4O_{10}Cl_2Cu_2$: C, 31.59; H, 4.37; N, 8.67; Cu, 19.66%.

[Fsal(=NenNEt$_2$)$_2$Cu$_2$Cl]Cl$_2$: This compound was prepared by a method similar to that for $[Fsal(=NenNMe_2)_2Cu_2Cl]Cl_2$. Recrystallization was carried out from anhydrous methanol–ethanol.

Found: C, 42.51; H, 6.01; N, 9.13; Cl, 18.12%. Calcd for $C_{21}H_{35}N_4OCl_3Cu_2$: C, 42.54; H, 5.95; N, 9.45; Cl, 17.94%.

[Fsal(=NenNEt$_2$)$_2$Cu$_2$Br]Br$_2$: This complex was synthesized by treating 2,6-diformyl-4-methylphenol (330 mg), anhydrous copper(II) bromide (894 mg) and *N,N*-diethylethylenediamine (464 mg) in ethanol. Violet prisms separated were collected and washed with a small amount of ethanol.

Found: C, 32.92; H, 4.83; N, 7.19; Br, 31.62%. Calcd for $C_{21}H_{35}N_4OBr_3Cu_2 \cdot 2H_2O$: C, 33.09; H, 5.1[illegible]; N [illegible].35; Br, 31.44%.

An anhydrous complex was obtained when the dihydrate was recrystallized from absolute methanol three times and then heated at 110 °C under reduced pressure.

[Fsal(=NenNEt$_2$)$_2$Cu$_2$OH](ClO$_4$)$_2$: The synthetic method for this complex is nearly the same as that for $[Fsal(=NenNMe_2)_2Cu_2OH](ClO_4)_2$. The violet needles separated were collected and recrystallized three times from water.

Measurements. Infrared spectra were measured with a Hitachi EPI-S2 spectrophotometer in the region 4000—650 cm^{-1} on a KBr disk. Electronic spectra on solids and in solutions (methanol, water and pyridine) were determined with a Hitachi EPS-3T recording spectrophotometer. ESR spectra (X-band) were measured on powder and in solutions with a JES-ME-3 spectrometer at various temperatures. Magnetic susceptibilities were determined by the Gouy method in the range from liquid nitrogen to room temperature. The apparatus for the measurements was described elsewhere.[5] Effective magnetic moments μ_{eff} were calculated by the equation

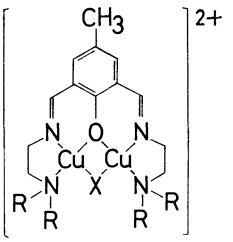
$$\mu_{eff} = 2.83\sqrt{(\chi_A - N\alpha)T},$$

where χ_A is the atomic susceptibility corrected by use of Pascal's constants[8,9] for diamagnetism and $N\alpha$ the temperature independent paramagnetism of copper(II) ion. Molar conductivities of the complexes were determined in an absolute methanol solution (*ca.* 10^{-3} mol) at 25 °C.

Results and Discussion

Some IR absorption bands of the complexes are given in Table 1. Very sharp peaks at 3510 cm^{-1} in $[Fsal(=NenNMe_2)_2Cu_2OH](ClO_4)_2$ and $[Fsal(=NenNEt_2)_2Cu_2OH](ClO_4)_2$ are assigned to the O–H stretching vibration. Two peaks in the region 1650—1635 cm^{-1} may be assigned to the C=N stretching vibrations. The skeletal vibration[10] observed at 1555—1560 cm^{-1} supports the binuclear structure bridged with a phenolic oxygen.[11] Two strong bands near 1320 and 1080 cm^{-1} are tentatively assigned to the C–O and =C–N stretching vibrations, respectively.[10] Two OH-bridged complexes show a broad, strong band due to perchlorate ion[12] in the region 1120—1060 cm^{-1}.

Molar conductivities of the complexes in absolute methanol are given in Table 1. All complexes were found to be 1:2 electrolytes. The mass spectrum of $[Fsal(=NenNEt_2)_2Cu_2Cl]Cl_2$ exhibits two peaks at m/e= 521 and 523, attributable to the $[Fsal(=NenNEt_2)_2Cu_2Cl]^+$ ion. Thus two peaks at m/e=458 and 460 and two peaks at m/e=359 and 360 may be assigned to the $Fsal(=NenNEt_2)_2CuCl^+$ and $Fsal(=NenNEt_2)_2^+$ ions respectively. We concluded that the complexes possess the binuclear structure shown in Fig. 1.



R=CH_3 and C_2H_5 X=Cl, Br, and OH

Fig. 1. Structure of $[Fsal(=NenNR_2)_2Cu_2X]^{2+}$.

The d-d bands of the complexes are given in Table 2. As was expected from spectrochemical series, the reflection spectra of the OH-bridged complexes have a d-d band at higher energy than those of the corresponding halogen-bridged complexes. However, the energy difference in d-d band (2.1—5.5 kK) between the OH-bridged and the halogen-bridged complexes is markedly larger than that in the case of the glycine-Schiff base complexes (0.9—1.0 kK).[5] This indicates

that the OH- and the halogen-bridged complexes possess a molecular structure differing from each other in solid states, depending on the counter ions. Since no appreciable coordination is expected for perchlorate ion, the coordination around the copper(II) ion in the OH-bridged complexes may be practically planar. In this case a larger steric requirement of the ethyl group compared with the methyl group will exclude the fifth coordination in the apical position. The coordination bonds in tetragonal plane in $[Fsal(=NenNEt_2)_2Cu_2OH](ClO_4)_2$ are therefore much strengthened and its solid spectrum has a band at higher energy than $[Fsal(=NenNMe_2)_2Cu_2OH](ClO_4)_2$. On the other hand the halogeno ion in $[Fsal(=NenNR_2)_2Cu_2X]X_2$ (X=Cl and Br) will coordinate to the copper(II) ion to form a five-coordination. Such a tetragonal-pyramidal structure was found for similar binuclear copper(II) complexes.[13] In the five-coordinate complexes the ethyl group will make a larger internal strain compared with the methyl group. In fact, $[Fsal(=NenNEt_2)_2Cu_2X]X_2$ has a d-d band at lower energy than the corresponding $[Fsal(=NenNMe_2)_2Cu_2X]X_2$ (X=Cl and Br).

All the above complexes appear to take a five- or six-coordinate structure in methanol with the solvent molecule in an apical position. However, the six-coordination seems impossible judging from the steric hindrance between the R and methanol molecules. The OH-bridged complexes have a d-d band at a lower energy in methanol than in a solid state. This suggests that the coordination around copper(II) is tetragonal-pyramidal in methanol. The halogeno-bridged complexes possess a d-d band at higher energy in methanol than in a solid state. This implies that a halogeno atom in the fifth coordination position was replaced by a solvent molecule in methanol.

Both the OH-bridged complexes may keep the same structure in water, in methanol and in pyridine. The halogeno-bridged complexes are only stable in absolute methanol and easily decomposed in water and in pyridine. The Br-bridged complexes seem to be more stable than the corresponding Cl-bridged complexes, since $[Fsal(=NenNR_2)_2Cu_2Cl]Cl_2$ was partly decomposed after long exposure to air. Thus the relative stability of the complexes increases in the order X=OH$\gg$Br$>$Cl. This is the reverse of that found for the series of binuclear copper(II) complexes derived from 2,6-diformyl-4-methylphenol and glycine.[5]

The powder ESR spectra of the $[Fsal(=NenNMe_2)_2Cu_2X]^{2+}$ complexes (X=Cl, Br, and OH) are given in Fig. 2. Each spectrum is very similar to the corresponding spectrum of the $[Fsal(=NenNEt_2)_2Cu_2X]^{2+}$ complexes. The Cl-bridged complex showed a broad band (*ca.* 6000 gauss width) centered around 3500 gauss. Similar broad spectra was observed for dichloro-μ-chloro-μ-(2,6-diformyl-4-methylphenolato)dicopper(II)[3] and for the binuclear copper(II) complexes of the Schiff bases derived from 2,6-diformyl-4-methylphenol and α-amino acids.[5] The spectrum of the Br-bridged complex was also broad. The signal observed at 1700 gauss may be assigned to the $\Delta M_s=2$ transition. A signal at 3200 gauss may be due to the presence of a trace of impurity of mononuclear species. The spectrum of the OH-bridged complex showed two signals at 6000 and 1600 gauss, tentatively assigned to the $\Delta M_s=1$ and the $\Delta M_s=2$ transitions respectively. The ESR spectra of the complexes in methanol and of the OH-bridged complexes in water and in pyridine showed no signal except for a weak band at 3200 gauss due to paramagnetic impurity.

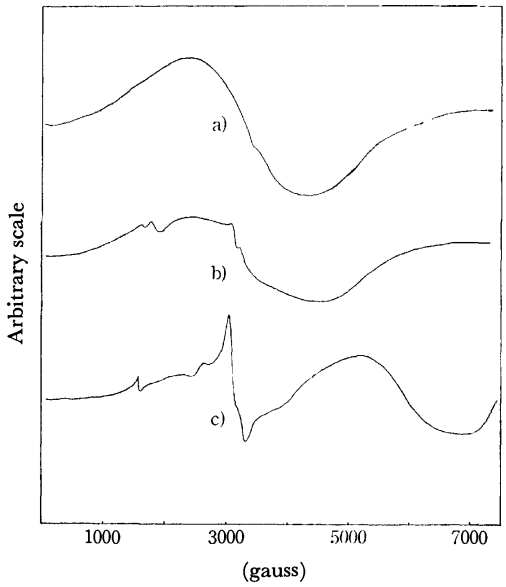

Fig. 2. ESR spectra of $[Fsal(=NenNMe_2)_2Cu_2X]Y_2$.
a) X=Cl, Y=Cl; b) X=Br, Y=Br;
c) X=OH, Y=ClO_4.

The ESR spectrum of $[Fsal(=NenNEt_2)_2Cu_2OH](ClO_4)_2$ was measured at various temperatures. The results are given in Fig. 3. Intensities of the signals at 5500 and 1600 gauss decrease with the lowering of temperature; the signal at 5500 gauss practically disappeared at 133 K. It is clear that an antiferro-

magnetic exchange interaction occurs between the two copper(II) ions.

All the complexes showed demagnetisation by spin-pairing in line with the results of the ESR data. Magnetic susceptibilities were measured over a temperature range 70—300 K. Experimental data can be explained on the basis of the Bleaney-Bowers equation[14]

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp(-2J/kT)\right]^{-1} + N\alpha,$$

where the symbols have their usual meanings. The $-2J$, g, and $N\alpha$ values were determined by the best fit of the χ_A value to the Bleaney-Bowers equation (Fig. 4). The values are given in Table 3. The $-2J$ value, which is the energy separation between the singlet and triplet states, indicates the degree of the spin-exchange interaction between the copper(II) ions.

14) B. Bleaney and K. D. Bowers, *Proc. Roy. Soc., Ser. A*, **214**, 451 (1952).

The spin-exchange interaction may be caused by a super exchange mechanism rather than direct overlapping of 3d-orbitals, since the distance between two metal ions is about 2.9 Å for the complex of a structure similar to the present complexes.[7] The halogen-bridged complexes were found to have nearly the same molecular structure, their powder X-ray diffraction spectra being practically the same. If we suppose as a first approximation that the degree of the spin-exchange through the first bridging group is the same throughout the series of complexes, then the $-2J$ value reflects the effect of the second bridging group on spin-pairing between the copper(II) ions. The results given in Table 3 indicate that the bromide bridge is more effective in spin-coupling than the chloride bridge in both series of complexes. This is in line with the results obtained for the copper(II) halides[15] and the cobalt(II) complexes.[16] On the other hand, the two OH-bridged complexes have much larger $-2J$ values than the others. It is well-known[15] that oxygen-bridges are generally more effective than halogeno-bridges in spin-coupling. It may be said that the effect of the second bridging group on the antiferromagnetic exchange interaction increases in the order X=OH$\gg$Br$>$Cl.

It is interesting to consider the correlation between the d-d band and the $-2J$ value of the complexes. It is clear that $[Fsal(=NenNEt_2)_2Cu_2OH](ClO_4)_2$ has a d-d band at higher energy and a larger $-2J$ value than $[Fsal(=NenNMe_2)_2Cu_2OH](ClO_4)_2$. In the halogeno-bridged complexes, $[Fsal(=NenNMe_2)_2Cu_2X]X_2$ (X=Cl and Br) always shows a d-d band at higher energy and a larger $-2J$ value than the corresponding $[Fsal(=NenNEt_2)_2Cu_2X]X_2$. This implies that the more planar the configuration around the copper(II) ion the larger the magnetic exchange between the copper(II) ions. This trend in the d-d band and $-2J$ value has been found by Muto *et al.*[17] and Kato *et al.*[18] for the binuclear copper(II) complexes of pyridine-*N*-oxides and *N*-aryl-salicylaldimines. The binuclear copper(II) complex prepared from pyridine-*N*-oxide and copper(II) bromide has a magnetic moment 0.29 B.M., which is smaller than 0.63 B.M. for the complex made from copper(II) chloride. It was recently demonstrated by X-ray analysis[19] that these magnetic moments are explained in terms of the planarities of the complexes.

Transference of Water to the Nitrobenzene Phase for the Extraction of Tris(1,10-phenanthroline)iron (II) and Tris(2,2′-bipyridine)iron(II) Chelate Salts

Yuroku YAMAMOTO, Tsunehiko TARUMOTO, and Takao TARUI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received October 2, 1972)

The amount of water transferred to the nitrobenzene phase was determined for the extraction of ion pairs of tris(1,10-phenanthroline)iron(II) and tris(2,2′-bipyridine) iron(II) with halide and pseudohalide anions. For both chelate systems the smaller the anion, the greater the amount of water transported, very similar results being obtained for a common anion. The results were discussed in relation to water of crystallization, extractability and temperature effect.

During the course of studies on the solvent extraction mechanism of tris(1,10-phenanthroline)iron(II) and tris(2,2′-bipyridine)iron(II) chelate ion pairs, our attention was drawn to the problem of how ion pairs are hydrated. We showed[1] that a small amount of water in nitrobenzene greatly affects the heats of solution of the chelate salts.

In order to investigate the role of water in solvent extraction, the amount of water transported by the ion pairs was determined. Similar studies were carried out by varying chelate cations.[2] However, no effects of anions were observed. We observed a very clear trend depending on the counter anions. Similar results were obtained between both chelate salts with a common counter anion. A part of the work has been reported.[3]

Experimental

Materials. Crystals of $Fe(phen)_3(ClO_4)_2$, $Fe(phen)_3(SCN)_2$, $Fe(phen)_3I_2$, $Fe(phen)_3Br_2$, $Fe(bipy)_3(ClO_4)_2$, $Fe(bipy)_3(SCN)_2$, $Fe(bipy)_3I_2$, and $Fe(bipy)_3Br_2$ were prepared as follows. In 400 ml of water, 0.01 mol of Mohr's salt and 0.03 mol of 1,10-phenanthroline or 2,2′-bipyridine were dissolved. To the resulting dark red solution was added 30 ml of saturated solution of sodium salt of a corresponding anion and the solution was condensed to an appropriate volume on a water bath at about 80 °C. The solution was cooled to room temperature and the crystalline precipitate was separated by filtration. Crystals thus obtained were recrystallized twice from water and air-dried. The purity was confirmed by analysis at the Center for Chemical Analysis of Kyoto University. The analytical results are shown in Table 1.

Nitrobenzene of analytical reagent grade was successively washed with sulfuric acid, sodium hydroxide and distilled water, and was then distilled under reduced pressure.

Apparatus. A Karl Fischer automatic titrator, MK-SS of Kyoto Electronics Co., Ltd. was used for determination of the water content. The concentration of the chelate salts was determined with a spectrophotometer, Hitachi 139.

Procedure. In a glass bottle, 100 ml of nitrobenzene was mixed with 50 ml of water for 4 days under stirring with a magnetic stirrer at 25±0.1 °C and the water content in nitrobenzene was occasionally checked by Karl Fischer titration. It was found that stirring for 24 hr was sufficient for the water content in nitrobenzene to become constant. A certain amount of a chelate salt was then added to this mixed solvent and the solution was stirred for 3 hr. Distribution of the chelate salt between water and nitrobenzene was found to be complete after 10 min stirring from measurement of the absorbance of both phases (510 nm for aqueous phase and 516 nm for organic phase). For an aliquot of the nitrobenzene extract, the water content was determined by titration. The concentration of the chelate salt was determined from the absorbance at 516 nm with the aid of a calibration curve prepared beforehand.

Results and Discussion

The water content at 25 °C was plotted against the concentration of $Fe(phen)_3I_2$ as in Fig. 1. The lines

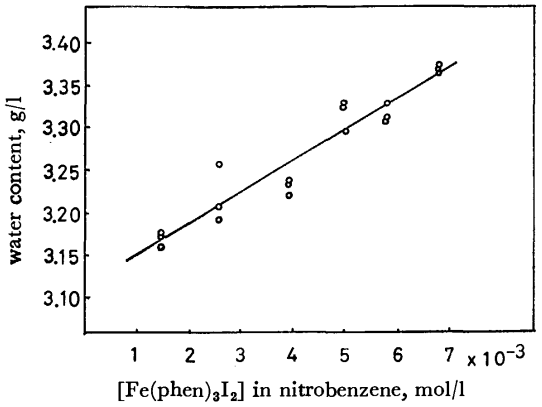

Fig. 1. Water content *vs.* the concentration of the chelate salt in nitrobenzene, 25 °C.

were drawn by means of the least-squares method. The water content increases linearly as the chelate salt concentration increases. This holds for all the other chelate salts. The concentration ranges tested were: (1) phenanthroline series, for perchlorate $1.8—5.2\times10^{-2}$, for thiocyanate $0.89—7.4\times10^{-3}$, for iodide $1.5—6.8\times10^{-3}$ and for bromide $1.4—2.4\times10^{-4}$ mol/l, (2) bipyridine series for perchlorate $3.6\times10^{-3}—3.8\times10^{-2}$, for thiocyanate $7.2\times10^{-4}—6.0\times10^{-3}$ for iodide $1.4—6.8\times10^{-3}$ and for bromide $7.2\times10^{-5}—4.8\times10^{-4}$ mol/l in the nitrobenzene phase.

The water content in nitrobenzene in the absence of chelate salts was 2.57 g/kg and the cross sections of the plots, water content *vs.* chelate salt concentration agreed with this within experimental error. Thus the number of water molecules transported by the chelate salts was calculated from the slope of the plots. The results are shown in Table 2 where they are also compared with the number of water of crystallization obtained from TGA measurements and elemental analyses.

Very similar results were obtained for the two series. Bipyridine-bromide salt shows a somewhat lower value than that of the corresponding phenanthroline salt because the concentration of $Fe(bipy)_3Br_2$ in the aqueous phase is much higher than that of $Fe(phen)_3Br_2$. For the phenanthroline series, there is a consistency between the number of transported water and that of water of crystallization. Also for the bipyridine series similar results were obtained between the transferred water and the water of crystallization except for iodide. The consistency for the former series might be fortuitous,

	Br	25	3.6 ±1.9	5	5
		20	—		

there being no reason why the crystalline state should be similar to the ions in solution. However, it can be concluded that water is transported exclusively by the anions and the chelate cations take no part in the transference. The chlorides did not offer any useful information because of their extremely low extractability.

Temperature effect was also studied by carrying out the same procedure at 20 °C. Lower values were obtained as shown in Table 2. The solubility of water in nitrobenzene was also found to decrease as the temperature is lowered (2.57 g/kg at 25 °C and 2.16 g/kg at 20 °C). This suggests that the water transported by the chelate salts is in equilibrium with the dissolved water in nitrobenzene.

The ability of the anions to carry water into the nitrobenzene phase seems to be related to the tendency of their hydration; the smaller the anions, the greater the amount of water transported. This may cause the lower extractability of the ion pairs with smaller counter anions.[4] However, it is difficult to conclude from our results whether the transferred water in nitrobenzene exists hydrated to the anions or it is dispersed in the organic phase.

Cadmium and Silver Sulfide-impregnated Silicone Rubber Membranes as Selective Electrodes for Cadmium Ions

Hiroshi HIRATA and Kenji DATE

Wireless Research Laboratory, Matsushita Electric Industrial Co., Ltd., Kadoma, Osaka 571

(Received September 12, 1972)

Silicone rubber membranes impregnated with mixtures of cadmium sulfide and silver sulfide were developed as selective electrodes for cadmium ions in a solution. Both co-precipitated and sintered mixtures could be used as the active materials for the electrode membrane, but here the membrane which contained a mixture in which cadmium sulfide had been added to silver sulfide after they had been precipitated individually did not show the satisfactory response characteristics. The Nernstian slope was obtained in the activity range from 10^{-1} to 10^{-5} M Cd^{2+}, while the analytical range was from 10^{-1} to 10^{-6} M. These potentials did not change at pH values from 2.5 to 7.5. Among common ions, silver, copper(II), mercury(II), iron(III), sulfide, and iodide ions interfered seriously. About 10—100 times as many lead and bromide ions and more than 1000 times as many alkali metals, alkaline earth metals, zinc, aluminum, nickel, manganese(II), cobalt, nitrate, and perchlorate ions were tolerated in coexistence with cadmium ions.

Many attempts have recently been made to obtain the precipitate-impregnated membranes as selective electrodes.[1] Pungor[2] developed silver salt-impregnated silicone rubber membrane electrodes for chloride, bromide, iodide, sulfide, and silver ions.

As for ion-selective electrodes for cations other than silver ions, various kinds of precipitate-impregnated membranes were made. These membrane electrodes, however, proved unsatisfactory for potentiometric measurements, either because they did not give the desired response or because they had no selectivity toward particular ions in a solution.

Copper(I) sulfide-impregnated silicone rubber membrane electrodes have been developed for copper(II) ions in our laboratory.[3] The internal electrode and internal solution have been eliminated by attaching the membrane to the surface of a metal directly. Lead sulfide-impregnated silicone rubber membrane electrodes for lead ions have also been described in a previous paper,[4] in which an investigation of the soaking effect of the membrane before the measurement has been presented.

On the other hand, a cadmium ion-selective compressed membrane electrode, the membrane of which comprised an intimate mixture of silver sulfide and cadmium sulfide, has been developed by Frant and Ross.[1] Subsequently, a cadmium ion-selective ceramic membrane electrode has been prepared by applying a hot-pressing method; this membrane contains cadmium sulfide, silver sulfide, and copper(I) sulfide.[5]

The present paper will describe the development of selective electrodes for cadmium ions using cadmium and silver sulfide-impregnated silicone rubber membranes, which have the same construction as has been described in the previous papers. It will also discuss the incorporation effect of silver sulfide.

Experimental

Apparatus and Reagents. An Orion Model 801 digital pH/mV meter was used to make the potentiometric measurements. A Horiba Seisakusho 2530-05T saturated calomel electrode was used as the reference electrode. The silicone rubber was obtained from the Shin-Etsu Chemical Co., and all the reagents were Nakarai Chemical reagent-grade materials and were used without further purification.

Preparation of Cadmium and Silver Sulfide-impregnated Silicone Rubber Membrane Electrodes. The preparation of the active materials can be divided roughly into the following two methods; the co-precipitation method, which consists of bubbling hydrogen sulfide through an aqueous solution containing cadmium and silver nitrates in order to precipitate a mixture of silver and cadmium sulfides at room temperature, and the sintering method, which consists of the sintering of the mixture of cadmium and silver sulfides at 300—500 °C for 3 hr in a stream of hydrogen sulfide at 50—100 ml min^{-1}. The silver sulfide for the sintered mixture was prepared by the direct reaction of silver metal powder and sulfur in a nitrogen gas stream, as has previously been described.[6] The cadmium sulfide was made by bubbling hydrogen sulfide through an aqueous solution of cadmium nitrate at room temperature.

The sulfide-mixture thus sintered was ground to a particle size of less than 10 μm. The powdered mixture of cadmium and silver sulfides was then mixed with 25 w/w% of silicone rubber. A platinum plate (1 mm thick) or wire (1 mm in diameter) which was directly connected with a leading wire was coated with the mixture to a thickness of about 0.5 mm. After being polymerized, the membrane was held in a plastic holder filled with epoxy resin.

The membrane electrode was then soaked in a 10^{-2} M aqueous solution of cadmium nitrate at 25 °C for a week.

Measurement of Potentials The potentials developed by the membrane electrode in the test solution were measured with a saturated calomel electrode as the reference electrode at 25±0.1 °C. The slope of the straight line of E *vs.* log $a_{Cd^{2+}}$ and the concentration range for the obedience to Nernst's law were investigated in order to evaluate the validity of the electrode membrane.

Magnetic stirring was employed at a constant rate to insure good reproducibility. Between measurements, the

electrode pair was rinsed several times with distilled water. The outer chamber of the double-junction reference electrode was drained and filled daily prior to the measurements of the potentials with 0.1 M of potassium nitrate solution.

No potential changes were observed on filling. Standard solutions containing 10^{-4} M or less of Cd^{+2} should be prepared whenever their potentials are measured. Otherwise, deviations from the Nernst law may arise through the adsorption of the solution on the wall of a beaker and the contamination of the solution.

Results and Discussion

The copper(II) sulfide-impregnated silicone rubber membrane selectively responded to cupric ions,[3] although copper(II) sulfide was a crystal with a high-electron conductivity.[7] However, the copper(II) sulfide-compressed membrane did not respond to cupric ions unless silver sulfide was added. Lead sulfide is also a semiconducting polar crystal with a high-electron conductivity at room temperature.[8] Nevertheless, the lead sulfide-impregnated silicone rubber membrane electrode responded to lead ions and showed a good selectivity, as has been described in a previous paper.[4] However, a pure lead sulfide sintered or compressed membrane, in which no trace of silver could be detected by emission spectroscopy, proved inert to lead ions in a solution. On the basis of the above results, the differentiation in the behavior of heterogeneous and homogeneous membrane electrodes seems to involve not only mechanical but also electrochemical problems.

The pure cadmium sulfide used was an insulator at room temperature, so that the cadmium sulfide-impregnated silicone rubber membrane electrode provided no meaningful response as an ion-selective electrode for cadmium ions. When the pure cadmium sulfide was sintered in a nitrogen gas stream including a slight amount of oxygen, pulverized, and impregnated in silicone rubber, the membrane thus obtained could act as a semiconductor. Its conductivity is supposed to be induced by the presence of a slight excess of cadmium produced by oxidation of cadmium sulfide. The potentials produced by the electrode membrane were unsteady and sensitive to the presence of static charges and visible light. This electrode membrane could not provide the Nernstian slope at all.

In the case of cadmium sulfide mixed with a metal sulfide other than silver sulfide, such as a cadmium sulfide-cuprous sulfide system, the sintered mixture-impregnated silicone rubber membrane electrode did not exhibit any effective response toward cadmium ions, although the membrane had semiconductive characteristics because of the conductivity of cuprous sulfide.

When cadmium sulfide was incorporated with silver sulfide in the silicone rubber membrane, the electrode fabricated from the membrane showed sensitive and stable potentials toward cadmium ions. Figure 1 shows the relationship between the potentials and the activities

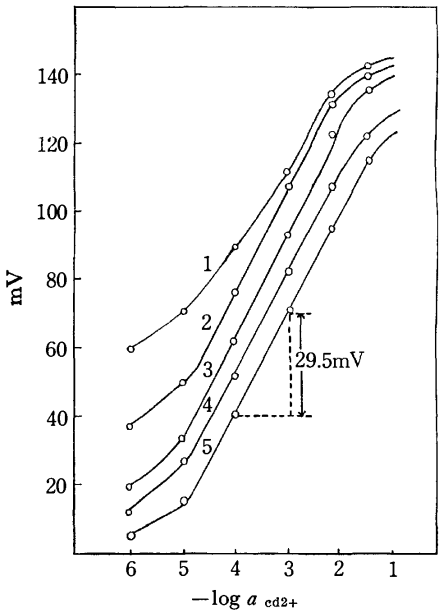

Fig. 1. Relationship between electrode potential and activity of cadmium ion. Weight ratio of CdS to Ag_2S. 1. 80 to 20, 2. 60 to 40, 3. 20 to 80, 4. 10 to 90, 5. 5 to 95.

of cadmium ions by the silicone rubber membrane electrodes containing a mixture of cadmium sulfide and silver sulfide prepared by the precipitation method.

Only the membranes containing an intimate and uniform mixture of silver sulfide and cadmium sulfide obtained by the co-precipitation method showed very satisfactory potential changes in relation to the concentration of cadmium ions. However, sufficient potential changes were not observed with the membrane containing a mixture of cadmium and silver sulfides which had been separately precipitated. The differentiation of the structure of the two mixtures has, however, not yet been clarified enough.

The co-precipitate-impregnated membrane electrode yielded a linear response toward cadmium ions over a concentration range of 10^{-1}—10^{-5} M cadmium nitrate, with an observed slope of 29.5 mV per log Cd^{2+} unit at 25 °C; this is in good agreement with the Nernst law. The analytical concentration range by this electrode was 10^{-1}—10^{-6} M. However, the best membrane of the impregnated silicone rubber electrode is less sensitive than the compressed or sintered membrane electrodes.[5] In general, the response characteristics, such as the sensitivity and response rate, of a precipitate-impregnated silicone rubber membrane electrode seems to be inferior to those of a precipitate-compressed or a precipitate-sintered membrane electrode.

As for the composition of the active materials, more than 60 w/w % of cadmium sulfide and less than 40 w/w % of silver sulfide could not provide sufficient potential changes or high response rates to the changes in the cadmium ion concentration.

When the mixture of cadmium sulfide and silver sulfide obtained by the sintering method was used as an active material, the silicone rubber membrane showed almost the same response characteristics as the co-precipitate-impregnated one. However, the sufficient

8) R. L. Petritz and W. W. Scanlon, *Phys. Rev.*, **97**, 1620 (1955).

potential changes were not observed with the membrane containing the mixture of cadmium and silver sulfides which had been separately prepared by the reaction of the corresponding metal and sulfur.

The response time of the measuring cell was a few sec for 10^{-2} M Cd^{+2} and about ten min for a 10^{-6} M solution. The membrane had to be soaked in a 10^{-2} M cadmium nitrate solution for more than 5 days after its preparation. However, once the membrane was soaked, the potentials were stable and steady even if the membrane was exposed to air for more than two weeks.

When the fraction of the silicone rubber in the membrane was more than 50% by weight, the potentials were unsteady and unstable, so that it could not be measured. When it was decreased to less than 50%, the time required for soaking in the solution of cadmium nitrate decreased and the potentials became more stable; potential properties similar to those shown in Fig. 1 were thus obtained. However, the lower the fraction of silicone rubber in the membrane, the lower the adhesive force.

Effect of Temperature. The co-precipitate- or the sintered mixture-impregnated silicone rubber membrane electrodes are affected by changes in the temperature. The single potential of a reference electrode changes slowly with the temperature because of changes in the solubility equilibrium on which the electrode potential depends. The potential of the silicone rubber membrane electrode for cadmium ions also varies with the temperature, as is indicated by the Nernst factor, 2.303 $RT/2F$, within the limits of experimental error. The electrodes could be safely used at temperatures between 0 and 60 °C.

Influence of pH. The desirable pH of a solution was adjusted with newly-prepared buffer solutions. Figure 2 shows the influence of pH on the potentials of cadmium ion-selective silicone rubber membrane electrodes in 10^{-2} and 10^{-4} M Cd^{+2} solutions.

The potentials did not change between pH 2.5 to 7.5. They decreased sharply, however, when the pH increased above 7.5, for the precipitation of $Cd(OH)_2$ occurred. Of course, the pH at which the precipitation begins depends on the concentration of cadmium ions. The resulting curves in Fig. 2 also show that the measurable pH-range is independent of the presence of silicone rubber. The cadmium sulfide content in the membrane did not affect the range of pH, either.

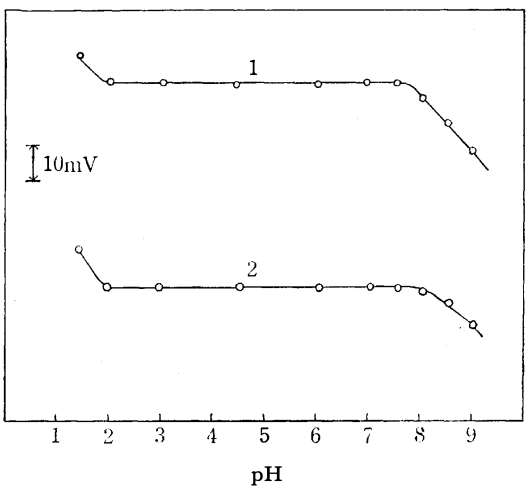

Fig. 2. Influence of pH. 1. 10^{-2} M Cd^{2+}, 2. 10^{-4} M Cd^{2+}

Dynamic Response Rate. When an ion-selective membrane electrode is used for the concentration control of a reaction process or as an indicator electrode in the potentiometric titration, the dynamic response characteristics are very important factors. The cadmium ion-selective precipitate-impregnated silicone rubber membrane electrode was evaluated by exposing the electrode to a rapid change in cadmium-ion concentration (exactly twofold) and recording the e.m.f. *vs.* time function. Some typical response curves are represented in Fig. 3. In the observed concentration range, the co-precipitate-impregnated electrode was found to establish the equilibrium reading rather rapidly after the applied concentration was changed. The sintered mixture-impregnated membrane electrode could equilibrate more quickly than the co-precipitate-impregnated one.

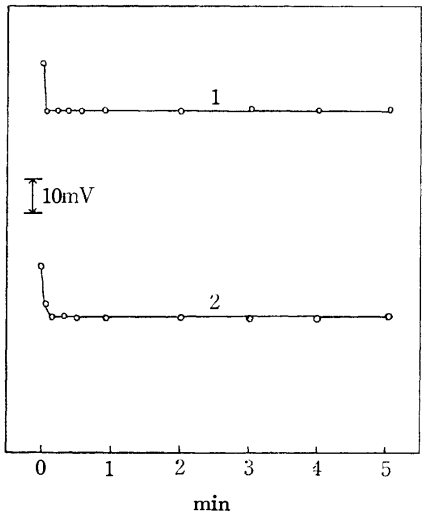

Fig. 3. Dynamic response rate.
1. 10^{-2} M—5×10^{-3} M, 2. 10^{-4} M—5×10^{-5} M

All of the curves thus obtained were smooth and of an identical shape; the e.m.f. values expected on the basis of the calibration curves were attained in all cases. The response rate of the electrode used depends on the stirring method, the efficiency of the solution mixing, and the cleanliness of the membrane surface, but is independent of the initial ion concentration over the entire range studied.

However, when the impregnated silicone rubber membrane contained a mixture in which cadmium sulfide had been added to silver sulfide after they had been precipitated individually, the electrode fabricated from this membrane did not show a fast dynamic response rate.

Selectivity. No electrode is entirely selective toward a particular ion in a solution, and the presence of the other ions may seriously impair electrode performance. It is, therefore, important to be aware of such interferences. An approximate selectivity con-

stant can be derived experimentally from the ratio of ionic concentrations where the interfering ions cause a deviation from the expected theoretical slope, 2.303 $RT/2F$. Tests of the effects of several ions on the membrane electrodes were made in solutions containing 10^{-4} M of cadmium ions. The concentration ratios of common ions to cadmium ions were varied from 1 to 1000. Among common ions, silver, copper(II), mercury(II), iron(III), sulfide, and iodide ions interfered seriously. About 10—100 times as many lead and bromide ions and more than 1000 times as many alkali metals, alkaline earth metals, zinc, aluminum, nickel, manganese(II), cobalt, nitrate, and perchlorate ions were tolerated in coexistence with cadmium ions.

The numerical selectivity ratios of the electrode for cadmium ions with respect to these common ions were not evaluated, but in view of these findings it is clear that this electrode is well suited for the selective analytical measurement of cadmium ion activity in a wide variety of practical systems.

The authors wish to thank Dr. S. Kisaka, Dr. K. Sugihara, and Dr. S. Mori for their encouragement during this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1471—1479 (1973)

Electronic Spectra of High-Spin Iron(III) Tetraphenylporphins

Hiroshi KOBAYASHI, Yasuo YANAGAWA, Hisajiro OSADA,
Shuji MINAMI, and Masayuki SHIMIZU

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received September 16, 1972)

Characterization of the electronic absorption spectra of high-spin iron(III) porphyrins was carried out on the basis of observation and theoretical calculation for tetraphenylporphinatoiron(III) and -manganese(III) complexes.

Electronic absorption spectra of the iron(III) porphyrins have not been wholly understood, although experimental correlations between the electronic structure and spectra have been studied mainly for analysis of their behaviors in the biological processes. Many physico-chemical studies have been carried out on the ferri-hemoproteins occurring in nature such as methemoglobin, catalase, peroxidase, and cytochromes.[1] We present in this paper a characterization of the electronic absorption spectra of high-spin iron(III) porphyrins on the basis of observation and theoretical calculation for tetraphenylporphinatoiron(III) and -manganese(III) complexes.

Experimental

Synthesis of the Metal-free Base of Tetraphenylporphin. $\alpha,\beta,\gamma,\delta$-Tetraphenylporphin (TPP) was synthesized from pyrrole and benzaldehyde by the method of Adler *et al.*[2] Methods developed by Rothermund and by others[3] were also used in preliminary experiments. TPP was precipitated from chloroform elute of the product by adding excess methanol. The crystals thus obtained were recrystallized from chloroform-methanol mixture. Chromatographic purification was repeated on activated alumina columns using chloroform as solvent and also eluent. After the eluate was concentrated, excess methanol was added. Purple needle crystals thus obtained were identified by elemental analysis.

Found: C, 86.02; H, 5.18; N, 8.94%. Calcd for $C_{44}H_{30}N_4$: C, 85.97; H, 4.92; N, 9.11%.

The electronic absorption spectrum of the product dissolved in benzene was in excellent agreement with reported spectra.[4-6]

Syntheses of Tetraphenylporphinatoiron(III) Complexes. The methods of Rothermund and Menotti[7] and Dorough *et al.*[8] were employed with some modification. About 500 mg of the metal-free base and 300 mg sodium chloride were dissolved in 50 ml chloroform. A saturated solution of ferrous acetate in acetic acid, prepared just before use by dissolving iron powder in 150 ml glacial acetic acid while still warm, was added to a chloroform solution of TPP. The mixture was refluxed for 3 hr and then most of the chloroform and acetic acid was distilled off. When the solution was concentrated up to 50 ml, TPPFe(III)Cl was precipitated by adding methanol. The crystals thus obtained were repeatedly recrystallized from the mixed solvent chloroform-methanol. The recrystallized blue violet needle crystals were identified

by elemental analysis.

Found: C, 74.81; H, 4.11; N, 7.76; Fe, 7.82%. Calcd for $C_{44}H_{28}N_4FeCl$: C, 75.07; H, 4.01; N, 7.96; Fe, 7.93%. Iron was determined by colorimetry using phenanthroline.

TPPFe(III)Br, TPPFe(III)I, TPPFe(III)SCN, and TPPFe(III)$OCOCH_3$ were synthesized and purified by similar methods to those for TPPFe(III)Cl. The products were identified by elemental analyses (Table 1).

Synthesis of Tetraphenylporphinatomanganese(III) Chloride. TPPMn(III)$Cl\cdot H_2O$ was prepared by the method of Rothermund and Menotti.[7] The metal-free base and manganese(II) acetate were refluxed in a mixed solvent chloroform-acetic acid. Recrystallization from mixed solvent dry chloroform-ligroin gave green crystals. The absorption spectrum of the complex dissolved in pyridine was in good agreement with that in the literature.[9]

Found: C, 74.85; H, 4.30; N, 8.18; Mn, 7.67%. Calcd for $C_{44}H_{28}N_4MnCl\cdot H_2O$: C, 73.28; H, 4.19; N, 7.77; Mn, 7.62%.

Manganese was determined by colorimetry after it had been oxidized to permanganate.

Measurements of Absorption Spectra and Magnetic Circular Dichroism. Electronic absorption spectra were recorded on a Shimadzu recording spectrophotometer Model MPS-50 and a Beckman DU spectrophotometer using quartz cells of 0.1 and 1.0 cm light path. Solvents were benzene, methanol and pyridine purified by fractional distillations using a 1.5 m wire packed column and dried by the usual procedures.[10]

The absorption spectra of powder samples were measured by the opal glass method.[11] Instead of an opal glass plate, we placed a sheet of tracing paper smeared with the solid sample in front of the window of an end-on type photomultiplier in the Shimadzu spectrophotometer. The absorption spectra thus obtained were better than those observed by the original opal glass method.

Circular dichroism under an external magnetic field (MCD) was measured by a JASCO automatic recording spectropolarimeter Model ORD/UV-5 with CD attachment and an electromagnet.[12] The magnetic field was set at 10000 Gauss.

Magnetic Susceptibility. Magnetic susceptibilities of the complexes were measured at room temperature by means of the Gouy method. After calibrating for the diamagnetic term by the usual method,[13] the magnetic moment of complexes was evaluated. The magnetic moment in solution was also determined by the same method.

TABLE 2. MAGNETIC MOMENTS OF IRON(III)- AND MANGANESE (III) TETRAPHENYLPORPHINS

Complex	Magnetic moment (Bohr magneton)	Number of unpaired electrons	Spin state
TPPFe(III)Cl	5.88	5	$S=5/2$
TPPFe(III)Br	6.08	5	$S=5/2$
TPPFe(III)I	5.71	5	$S=5/2$
TPPFe(III)SCN	5.75	5	$S=5/2$
TPPFe(III)$OCOCH_3$	6.03	5	$S=5/2$
TPPFe(III)Cl in chloroform	5.6	5	$S=5/2$
TPPMn(III)$Cl\cdot H_2O$	4.98	4	$S=2$

Results and Discussion

Iron(III) porphins with an ionic axial ligand such as Cl^-, Br^-, I^-, SCN^-, CH_3COO^- are in the high-spin state $S=5/2$. The spin state of TPPFe(III)X was identified by magnetic susceptibility measurements. The results are summarized in Table 2. These high-spin TPPFe(III)X complexes with different axial ligands actually gave the same absorption spectrum in shape and position. A typical absorption spectrum of TPPFe(III)X ($S=5/2$) in benzene is shown in Fig. 1. The spectrum has a more complicated profile as compared with the typical absorption spectra obtained for the lowest (π, π^*) transitions of the square planar metal porphins. Figure 1 also shows characteristic

absorption spectra of the metal-free porphin (D_{2h}) and square planar metal porphins (D_{4h}).

The general feature of the absorption spectrum of TPPFe(III)X is in good agreement with that of a characteristic absorption spectrum of the high-spin species of ferri-hemoproteins. George, Beetlestone and Griffith separated high- and low-spin spectral types for the ferri-hemoproteins by combining spectroscopic and magnetic data,[14] and showed that in the case of ferri-hemoproteins, the iron(III) porphyrin is in an equilibrium between two spin states $S=5/2$ and $S=1/2$. They were able to get limiting spectra from the mixture spectra of two spin states. Although the existence of negative absorption regions shows some deficiency in their assumptions, the overall results seem to be sound.

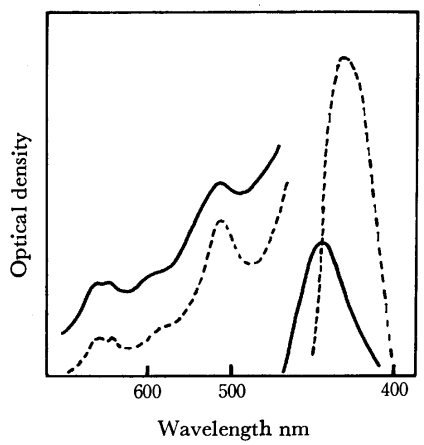

Fig. 2. Absorption spectrum of TPPFe(III)Cl in the solid state.
——: powder ---: benzene solution

The magnetic susceptibility measurement of TPPFe(III)Cl in chloroform solution indicates that the spin state found in the solid state is well preserved in chloroform solution. Chloroform was used instead of benzene because of the higher solubility of porphin. The absorption spectrum of TPPFe(III)Cl in chloroform was coincident with that of the benzene solution. In contrast, the solid state absorption spectrum of TPPFe(III)Cl obtained by the modified opal glass method was in good agreement with that of the benzene solution except for a red shift of the Soret band in the solid state which might be due to an exciton coupling between the strong Soret oscillators packed in a molecular crystal (Fig. 2). The spin state of the complex TPPFe(III)Cl does not change upon dissolution. Thus such a complicated spectrum as shown in Fig. 1 should be assigned to the absorption spectrum characteristic of high-spin iron(III) porphin.

The lowest excitations in a typical D_{4h} metal porphin are assigned to the lowest (π, π^*) transitions approximately described by a 50-50 admixture of the transitions $(3a_2)\rightarrow(4e)$ and $(1a_1)\rightarrow(4e)$, where $(3a_2)$ and $(1a_1)$ are the highest occupied orbitals and (4e) the degenerate lowest vacant orbitals. A configuration interaction between these two excited configurations

gives rise to the lowest transition of forbidden character and the second lowest transition of allowed character, the former being Q transition and the latter B transition (or Soret transition). This is a four-orbital description of the lowest (π, π^*) transition in porphin.[15] The lowest electronic excitations of TPPZn(II), in which only a very small π interaction between metal and porphin is present, are well described by the four-orbital model.[16,17] However, the model can not ex-

plain the lowest excitations of high-spin TPPFe(III)X complexes. A similarity in the visible absorption spectra of high-spin iron(III) porphin and the metal-free base has been pointed out.[18] However, these two porphins show quite different MCD spectra as shown in Figs. 3 and 4. The visible and near-ultraviolet absorption spectra of the metal-free base are described as the lowest (π, π^*) transitions. Thus the splitting of the visible Q band was, in principle, well reproduced by a Pariser-Parr-Pople molecular orbital calculation.[17]

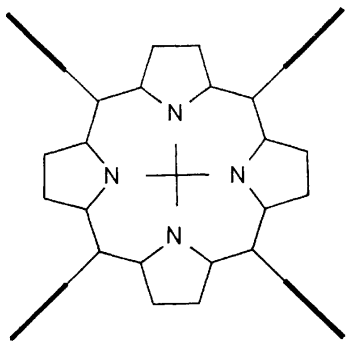

Fig. 5. Molecular geometry of metal tetraphenylporphin. Phenyl groups are actually perpendicular to the molecular plane of porphin.

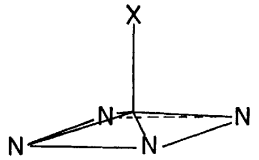

Fig. 6, The coordination sphere of iron(III) ion in TPPFe(III)X. Iron ion is slightly out of the porphin plane.

Tetraphenylporphin has a planar structure as shown in Fig. 5. The central iron is displaced out-of-plane from the nitrogen atoms by 0.4 Å as found by X-ray crystallographical studies on various metal porphyrins including metal tetraphenylporphins.[19,19a] The structure of the coordination sphere of iron(III) ion in TPPFe(III)X is schematically shown in Fig. 6. A simple argument in terms of the angular-overlap model predicts the ordering of d orbitals in a planar ligand field of porphin:[20]

$$\varepsilon(x^2-y^2) = \Delta,\ \varepsilon(z^2) = \Delta/3,\ \varepsilon(xy) = \varepsilon(yz) = \varepsilon(zx) = 0,$$

where Δ is the ligand field splitting parameter. Since a mixing between z^2 and s orbitals is crucial in a planar environment, $\varepsilon(z^2)$ is much lower than that predicted from the angular-overlap model and is, in fact, close to zero. The energy difference $\varepsilon(x^2-y^2)-\varepsilon(z^2)$ varies with the axial ligand field and can be parametrized as $x\Delta$. The energy of the possible ground configurations of TPPFe(III)X is approximately given as follows:

$$\begin{aligned}
&{}^6A_1\ [(xy)(yz)(zx)(z^2)(x^2-y^2)] && (2-x)\Delta - 35B,\\
&{}^4A_2\ [(xy)^2(yz)(zx)(z^2)] && (1-x)\Delta - B,\\
&{}^2E\ \ [(xy)^2(zx)^2(yz)] && \\
&\quad\ [(xy)^2(yz)^2(zx)] && 20B,
\end{aligned}$$

where B is Racah's electrostatic interaction parameter (assumed $C=4B$). The energy diagram of the ground configuration is given in Fig. 7. The value of Δ in porphin has been evaluated 25—31B by an extended Hückel molecular orbital calculation.[21] The value was consistent with the observations on tetraphenylporphinatoiron(II) complexes.[20] As Fig. 7 shows, the

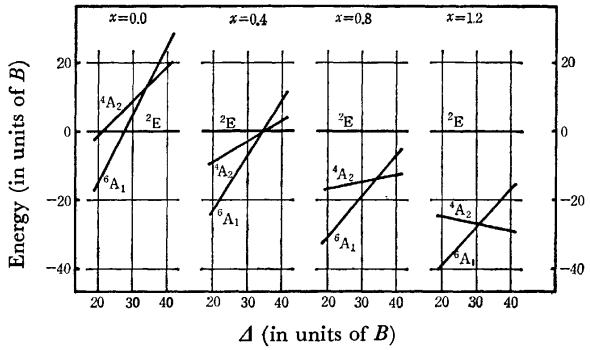

Fig. 7. Energy diagrams of the ground state of iron(III) ion in TPPFe(III)X. Δ is the ligand field splitting parameter in units of B and $x\Delta(\varepsilon(x^2-y^2)-\varepsilon(z^2))$, the axial ligand field parameter.

most stable ground configuration for Δ=25—31B is ^{6}A if the axial ligand field is not so strong. Since the axial ligand field of the complexes studied is as weak as x=0.4—1.0, the ground configuration is ^{6}A and all the five d orbitals are singly occupied. Thus the spin-allowed excited states should be sextet. The charge-transfer excitations of an electron in the highest filled porphin π orbitals to the half-filled d_{zx} and d_{yz} orbitals (dπ orbitals) give rise to degenerate excited states of E symmetry. Since iron dπ orbitals and the lowest vacant orbitals 4e of porphin are of the same centrosymmetry, an electronic delocalization between these orbitals appreciably occurs when they are energetically close. Thus the lowest excited sextets of E symmetry should be described by a superposition of the antisymmetric product wavefunctions ^{6}E[^{3}E($1a_1\rightarrow 4e$)·^{6}A], ^{6}E[^{3}E($3a_2\rightarrow 4e$)·^{6}A], ^{6}E[^{1}E($1a_1\rightarrow 4e$)·^{6}A], ^{6}E[^{1}E($3a_2\rightarrow 4e$)·^{6}A], ^{6}E[^{2}A$_1$($1a_1$)·^{5}E(dπ)], and ^{6}E[^{2}A$_2$($3a_2$)·^{5}E(dπ)],

where $^3E(1a_1\rightarrow 4e)$, $^3E(3a_2\rightarrow 4e)$, $^1E(1a_1\rightarrow 4e)$, and $^1E(3a_2\rightarrow 4e)$ denote the wavefunctions of the lowest porphin-localized triplet and singlet excited states, respectively, ^6A denotes the ground iron(III) sextet state, and $^6E[^2A_1(1a_1)\cdot{}^5E(d\pi)]$ and $^6E[^2A_2(3a_2)\cdot{}^5E(d\pi)]$ the excited state arising from the "porphin to iron(III) ion" charge-transfers $1a_1\rightarrow d\pi$ and $3a_2\rightarrow d\pi$, respectively. Delocalization between the orbitals $d\pi$ and 4e connects two states that differ by a single orbital, as in $^6E[^{1,3}E(1a_1\rightarrow 4e)\cdot{}^6A]$ and $^6E[^2A_1(1a_1)\cdot{}^5E(d\pi)]$, $^6E[^{1,3}E(3a_2\rightarrow 4e)\cdot{}^6A]$ and $^6E[^2A_2(3a_2)\cdot{}^5E(d\pi)]$.

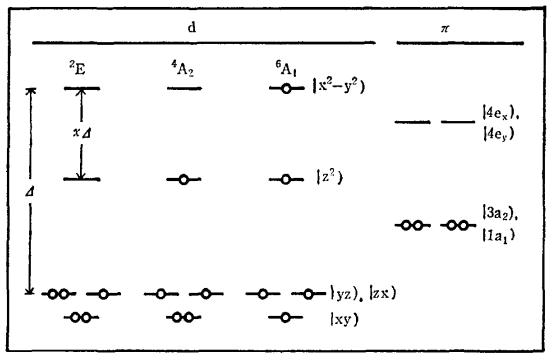

Fig. 8. Energy levels of the top filled and the lowest vacant orbitals (schematic).

The energies of the charge-transfers from $1a_1$, $3a_2$ to $d\pi$ are not as low as expected from the orbital energy diagrams shown in Fig. 8, since the charge-transfer needs an extra work done for a change of the electrostatic potential term. When an electron makes a transfer from the conjugation circuit of porphin with radius R to the central iron(III) ion, the extra work done against a change in the electrostatic potential is approximately given e^2/R assuming a neutral charge distribution in the ground state. The radius R of the main conjugation circuit of porphin is estimated to be 3.3 Å from the X-ray data. Thus e^2/R is evaluated to be 4.4 eV.[19]

The energies of the lowest excitations localized in porphin are given as follows. For the transition $1a_1\rightarrow 4e$,

$$\varepsilon(4e)-\varepsilon(1a_1)-(a_1a_1|ee)+\binom{2}{0}(a_1e|a_1e)$$

and for the transition $3a_2\rightarrow 4e$,

$$\varepsilon(4e)-\varepsilon(3a_2)-(a_2a_2|ee)+\binom{2}{0}(a_2e|a_2e)$$

where ε denotes molecular orbital energy, $(a_1a_1|ee)$ and $(a_1a_1|ee)$ denote the Coulomb integrals over the molecular orbitals, $1a_1$, $3a_2$, and 4e, $(a_1e|a_1e)$ and $(a_2e|a_2e)$, the exchange integrals, and the upper integer of $\binom{2}{0}$ denotes the coefficient for the singlet and the lower one for the triplet. Gouterman has pointed out an accidental degeneracy of the top filled orbitals on the basis of the observed substituent effects of the singlet-singlet absorption spectra of porphins.[15] Strictly speaking, it is an accidental degeneracy of the lowest excited singlet configurations rather than one of the top filled orbitals:

$$\begin{aligned}&\varepsilon(4e)-\varepsilon(1a_1)-(a_1a_1|ee)+2(a_1e|a_1e)\\&\fallingdotseq\varepsilon(4e)-\varepsilon(3a_2)-(a_2a_2|ee)+2(a_2e|a_2e).\end{aligned}$$

Experimental evidences show that the excited singlet configuration $(1a_1)(4e)$ is slightly lower than the excited singlet configuration $(3a_2)(4e)$. The energies of these configurations are given by $(E+2K)\pm(E'+2K')$, where $E\equiv\varepsilon(4e)-\{\varepsilon(3a_2)+\varepsilon(1a_1)\}/2-\{(a_2a_2|ee)+(a_1a_1|ee)\}/2$, $E'\equiv\{\varepsilon(1a_1)-\varepsilon(3a_2)\}/2+\{(a_1a_1|ee)-(a_2a_2|ee)\}/2$, $K\equiv\{(a_2e|a_2e)+(a_1e|a_1e)\}/2$, and $K'\equiv\{(a_2e|a_2e)-(a_1e|a_1e)\}/2$. The energies of the lowest excited singlets are given by $(E+2K)\pm\sqrt{(E'+2K')^2+(2K'')^2}$, where $2K''$ denotes configuration interaction matrix $2(a_1e|a_2e)$. Gouterman's finding that $E'+2K'\fallingdotseq 0$ does not necessarily imply an accidental degeneracy of the lowest triplets. The energies of the lowest triplets are given by $E\pm E'\fallingdotseq E\mp 2K'$. As experimental evidences show, $E'+2K'\equiv\varepsilon$ is small but positive. Thus the triplet $(3a_2)(4e)$ is lower than the triplet $(1a_1)(4e)$ when $2K'>\varepsilon$, but higher when $2K'<\varepsilon$. A Pariser-Parr-Pople SCMO calculation has revealed that $\varepsilon\fallingdotseq 0$, $2K'>\varepsilon$ and $\varepsilon(1a_1)\fallingdotseq\varepsilon(3a_2)$. Thus the lowest triplet is much likely to be $(3a_2)(4e)$, although it was recently assigned to the triplet $(1a_1)(4e)$ because of no nitrogen hyperfine structure being observed in the ESR spectrum of the lowest triplet of zinc(II) porphin.[22] The orbital $(1a_1)$, in fact, lacks populations on the central nitrogens, whereas the orbital (4e) has populations on the nitrogens as well as $(3a_2)$. No further evidences to support the lowest triplet $(1a_1)(4e)$ have been presented.

A circular box is described by a radial coordinate r and angular coordinate θ. Orbitals are written $|\pm k)=f(r)\exp(\pm ik\theta)$, where k denotes orbital angular momentum. The orbital pair $(3a_2\pm i1a_1)/\sqrt{2}$ can be identified with the degenerate pair of circular box orbitals $|\pm 4)=f(r)\exp(\pm 4i\theta)$, and the lowest empty 4e orbitals $|\pm 5)=f(r)\exp(\pm 5i\theta)$.[23] In the ground state, a pair of orbitals which has z components of angular momentum $\lambda_z=\pm 4$ and angular momentum $\lambda=4$ is filled with four electrons; the ground configuration is denoted $(4)^4$ and has zero angular momentum $\Lambda_z=0$. The first excited configurations arise by exciting a $\lambda=4$ electron to an orbital with $\lambda=5$, and are denoted $(4)^35$. The configurations give rise to degenerate pairs of excited states with $\Lambda_z=\pm 1$ and $\Lambda_z=\pm 9$.

A degenerate $d\pi$ orbital pair, zx and yz, causes a charge-transfer interaction with the porphin π molecular orbitals of E symmetry. The orbital pair can be rewritten $|\pm 1)=(zx\pm iyz)/\sqrt{2}$, where ± 1 denotes the z components of angular momentum $\lambda=1$. A one-electron term connecting the orbitals $|\pm 1)$ and $|\pm 5)$, $(\pm 1|h^{\mathrm{eff}}|\pm 5)\equiv\beta$, gives rise to a delocalization of the porphin π electrons toward the half-filled iron(III) $d\pi$ orbitals.

The electrons in the orbitals with $\lambda=1$, $\lambda=4$, and $\lambda=5$ are assumed to move in a one-electron effective core field set up by the nuclei and the remaining electrons and to interact with one another by the two-

electron term e^2/r_{ij}. Wavefunctions are taken as Slater determinants which are eigenfunctions of total spin sextet. In Table 3 are given the sextet states arising from the configurations $\varepsilon\theta\zeta(1)^2(4)^4$, $\varepsilon\theta\zeta(1)^3(4)^3$, and $\varepsilon\theta\zeta(1)^2(4)^3(5)$, ε denoting iron x^2-y^2 orbital, θ, z^2 orbital and ζ, xy orbital, respectively. Slater determinants are then taken as follows:

$$|+5\rangle \equiv |\varepsilon\theta\zeta+1-1+4+\bar{4}-4+\bar{1}|$$

$$|-3\rangle \equiv |\varepsilon\theta\zeta+1-1+4+\bar{1}-4-\bar{4}|$$

$$\begin{aligned}|+9a\rangle \equiv [&5\{|\varepsilon\theta\zeta+1-1+4+\bar{4}-4+\bar{5}|\\ &+|\varepsilon\theta\zeta+1-1+4+\bar{4}-\bar{4}+5|\}\\ &-2\{|\varepsilon\theta\zeta+1-\bar{1}+4+\bar{4}-4+5|\\ &+|\varepsilon\theta\bar{\zeta}+1-1+4+\bar{4}-4+5|\\ &+|\varepsilon\bar{\theta}\zeta+1-1+4+\bar{4}-4+5|\\ &+|\bar{\varepsilon}\theta\zeta+1-1+4+\bar{4}-4+5|\}]/\sqrt{70}\end{aligned}$$

$$\begin{aligned}|+1a\rangle \equiv [&5\{|\varepsilon\theta\zeta+1-1+4+\bar{5}-4-\bar{4}|\\ &+|\varepsilon\theta\zeta+1-1+\bar{4}+5-4-\bar{4}|\}\\ &-2\{|\varepsilon\theta\zeta+1-\bar{1}+4+5-4-\bar{4}|\\ &+|\varepsilon\theta\zeta+\bar{1}-1+4+5-4-\bar{4}|\\ &+|\varepsilon\theta\bar{\zeta}+1-1+4+5-4-\bar{4}|\\ &+|\varepsilon\bar{\theta}\zeta+1-1+4+5-4-\bar{4}|\\ &+|\bar{\varepsilon}\theta\zeta+1-1+4+5-4-\bar{4}|\}]/\sqrt{70}\end{aligned}$$

$$\begin{aligned}|+9b\rangle \equiv \{&|\varepsilon\theta\zeta+1-1+4+\bar{4}-4+\bar{5}|\\ &-|\varepsilon\theta\zeta+1-1+4+\bar{4}-\bar{4}+5|\}/\sqrt{2}\end{aligned}$$

$$\begin{aligned}|+1b\rangle \equiv \{&|\varepsilon\theta\zeta+1-1+4+\bar{5}-4-\bar{4}|\\ &-|\varepsilon\theta\zeta+1-1+\bar{4}+5-4-\bar{4}|\}/\sqrt{2},\end{aligned}$$

where no bar implies spin α, a bar implies spin β and the molecular orbitals are denoted by their λ_z values.

The energies of the excited sextets including porphin triplets (^6E_T, $|\pm 9a\rangle$ and ^6E_T, $|\pm 1a\rangle$), porphin Q and B singlets (^6E_Q, $|\pm 9b\rangle$ and ^6E_B, $|\pm 1b\rangle$), and "porphin to high-spin iron(III)" charge-transfer states ($^6E_{CT}$, $|\pm 5\rangle$ and $^6E_{CT}$, $|\mp 3\rangle$) are given in Table 3 in terms of energy parameters E, E_{CT}, K_1, and K_9, where $K_1 \equiv K+K''$ and $K_9 \equiv K-K''$. The mixing terms are also given in Table 3 in terms of delocalization parameter β and off-diagonal corrections for the circular box model. As stated before, we have $\varepsilon \equiv E'+2K'$ and $\varepsilon' \equiv E'$. An off-diagonal term between the charge-transfer states

$$\varepsilon'' \equiv \{\varepsilon(1a_1)-\varepsilon(3a_2)\}/2 + \{(a_1a_1|d\pi d\pi)-(a_2a_2|d\pi d\pi)\}/2$$

is introduced. Coulomb repulsions $(a_1a_1|d\pi d\pi)$ and $(a_2a_2|d\pi d\pi)$, however, are less sensitive to the angular nodal character of the wave functions involved and do not differ much from other. Thus ε'' should be rather small.

To reproduce the transition energies and the intensity ratio of Q and B bands of TPPCo(II), it has been assumed that

$$E = 14810\ \text{cm}^{-1},\ K_1 = 4600\ \text{cm}^{-1},\ K_9 = 2530\ \text{cm}^{-1}$$

and $\varepsilon = \varepsilon' = \pm 1480\ \text{cm}^{-1}$.[24] Since a change in E was expected for tervalent central metal ion, the parameters were readjusted to give a better description of the spectrum of TPPCo(III)Cl complex:

$$E = 13070\ \text{cm}^{-1},\ K_1 = 4600\ \text{cm}^{-1},\ K_9 = 2730\ \text{cm}^{-1}$$

and $\varepsilon = \varepsilon' = \pm 1340\ \text{cm}^{-1}$. From the coefficients on nitrogens of the molecular orbital 4e[17] and a value of resonance integral assumed by Hanazaki and Nagakura for a calculation of tris(bipyridine)iron(II) complex,[25] β was obtained as $-3000\ \text{cm}^{-1}$. The lowest excited sextets were calculated for a variety of E_{CT} and ε's. They are shown as a function of E_{CT} in Fig. 9. The lowest excitations of high-spin TPPFe(III)X complex (Fig. 10) are well reproduced $E_{CT} = 12500\ \text{cm}^{-1}$. Contributions of the composite excited states to each of the lowest excited states are given in Table 4, together with the effective numbers of the transferred charge in the excited states. The MCD spectrum of TPPFe(III)-Cl in benzene (Fig. 3) shows a normal A-term dispersion in each absorption band. This reveals that each of the lowest excited states is degenerate and has a characteristic orbital angular momentum. The value

24) H. Kobayashi, T. Hara, and Y. Kaizu, This Bulletin, **45**, 2148 (1972).

of the orbital angular momentum in porphin excited state calculated by the circular box model (Table 4) is just an index of the orbital angular momentum but can predict a correct sign of A-term dispersion.[24] However, the molecular orbital calculations in a rather sophisticated form have given a wrong sign of A-term dispersion in the B band.[26]

Contributions of the "porphin to metal" charge-transfer excited states depend upon dπ electron affinity of the π electron-accepting metal ion. The electron affinity is estimated by application of the method of Griffith[27] using atomic spectroscopic data.[28] Differences between the dπ electron affinities of high-spin manganese(III), high-spin iron(III) and low-spin iron(III) are evaluated as shown in Table 5. The order of the electron affinity is low-spin Fe(III)>high-spin Fe(III)>high-spin Mn(III). Since σ-donation of the porphin nitrogens neutralizes the positive charge of the central metal ion, the electron affinity should be corrected for the electroneutralization effect.[29] The correction must be sizable, however, the ordering obtained above is still applicable to the metal ion in complex. A higher tendency of reduction is expected for a molecular environment to stabilize the low-spin iron(III) porphin, but the "porphin to iron" charge-

transfer excited states are too low to cause an appreciable interaction with the porphin (π, π^*) excited states. In fact, a spectrum assigned to the low-spin iron(III) porphyrin by George *et al.*[14] does not differ much from the (π, π^*) spectrum of typical metal porphyrin.

The charge-transfer states in high-spin manganese(III) porphin must be as high as the porphin B state. In fact, a remarkable splitting of the B band is observed (Fig. 11). The charge-transfer excited states slightly higher than B state push down the B state and grant an intensity to the porphin singlet-triplet excitations by similar configuration interactions as in the case of high-spin iron(III) porphin. The energy matrices are given in Table 3. The absorption spectrum of TPPMn(III)Cl·H_2O was well reproduced (Fig. 11) by a calculation assuming $E_{CT}=25000$ cm^{-1}, $\beta=-4000$ cm^{-1}. The MCD spectrum of TPPMn(III)Cl·H_2O in benzene is shown in Fig. 12. A normal A-term MCD dispersion with $A/D=1$ was observed in the 21000 cm^{-1} band. Boucher also obtained a similar MCD spectrum of protoporphin IX dimethylester manganese(III) chloride in chloroform.[9] Such spectrum has been observed in the B band of typical metal porphins. Mixing of the "porphin to manganese(III)" charge-transfer excitations gives rise to a remarkable spectral shift and a redistribution of spectral intensity, but the 21000 cm^{-1} transition is still predominantly made of B excitation (Table 6). The value of β in high-spin manganese(III) was assumed to be slightly higher than that of high-spin iron(III) so as to reproduce the observation. The iron(III) in TPPFe(III)Cl is pentacoordinate and is out-of-plane from the coordinating nitrogens according to X-ray studies, whereas the manganese(III) in TPPMn(III)Cl·H_2O is

The assumed parameter values are $E=13070\ cm^{-1}$, $E=25000\ cm^{-1}$, $K_1=4600\ cm^{-1}$, $K_\theta=2730\ cm^{-1}$, $\beta=-4000\ cm^{-1}$, $\varepsilon=1340\ cm^{-1}$, $\varepsilon'=-1340\ cm^{-1}$, and $\varepsilon''=0\ cm^{-1}$.

hexacoordinate and must be in the nitrogen plane. Thus the conjugation between the central ion and porphin is increased in TPPMn(III)Cl·H_2O.

Since metal dπ and the lowest vacant π orbitals 4e are of the same symmetry, an electron delocalization between them occurs appreciably when they are energetically close to each other. The delocalization effect grants the charge-transfer excitation an intensity of the allowed B excitation, although the pure charge-transfer excitation, in principle, is forbidden. In the case of open-shell configurations such as in high-spin iron(III) and high-spin manganese(III), the charge-transfer state causes a connection not only with singlet but also with triplet (π, π^*) states, making the singlet-triplet (π, π^*) excitations partially allowed. Thus the complex spectra of high-spin iron(III)- and manganese(III) porphyrins are assigned to the excited states arising from the configuration interactions of porphyrin excited triplet and singlet (π, π^*) states and "porphyrin to metal" charge-transfer excited states.

Our sincere thanks are due to Dr. Kiyoko Yamamoto for her advice concerning the preparation of tetraphenylporphin, and also to Dr. Kazuo Shibata for his suggestion on the opal glass method. One of the authors (H. K.) wishes to thank Profs. M. Kotani, W. S. Caughey, and M. P. Gouterman for their helpful discussions.

Identification of Normal Paraffins and Olefins from Thermal Decomposition Products of Polyethylene

Takeaki A. IIDA, Kenichi HONDA, and Hiroshi NOZAKI
Institute of Industrial Science, University of Tokyo, Roppongi, Minato-ku, Tokyo 106
(Received August 25, 1972)

Straight-chain components of the high boiling fractions of thermal decomposition products of low-density polyethylene were obtained through urea adduct formation, and analyzed by chromatographic separation methods. They were found to be a mixture of approximately 60 wt% of paraffins (C_{10} to C_{30}), 35 wt% of terminal olefins (C_{10} to C_{26}), and 5 wt% of nonterminal olefins (C_{10} to C_{26}) with predominantly 2-alkenes. A silica gel–silver nitrate mixture was found to be useful for chromatographic separation of hydrocarbon components.

Thermal decomposition products of polyethylene are a complex mixture of saturated and unsaturated hydrocarbons. It is important to know the types of these compounds as well as to determine the structures of individual hydrocarbons, not only for elucidation of the mechanism of thermal decomposition of polyethylene, but also for regeneration of polyethylene as an industrial raw materials.

Thermal decomposition products of polyethylene have been determined by many investigators. Kambe and Shibasaki[1] analyzed the thermal decomposition products of polyethylene by gas chromatography and identified several paraffins and olefins with carbon numbers from C_5 to C_9. Tsuchiya and Sumi[2] made a comprehensive analysis of the volatile thermal decomposition products by gas chromatography. They discussed the mechanism of the decomposition by assuming intramolecular transfer of free radicals. The result was valuable for identification of the thermal decomposition products consisting of low boiling fractions of hydrocarbons from C_1 to C_6. Madorsky[3] determined thermal decomposition products of polyethylene by mass spectrometry. Moiseev[4] used gas chromatography for the separation of decomposition products of low boiling fractions, and explained the formation of volatile thermal decomposition products by assuming intramolecular transfer of radicals or isomerization. However, high boiling fractions which constitute a major portion of decomposition products have not been so extensively investigated. The present work deals with the identification of straight-chain hydrocarbons of thermal decomposition products of low-density polyethylene obtained through urea adduct formation. Emphasis was placed on the separation and identification of an olefin mixture.

Experimental

Materials used. Commercial low-density polyethylene was used; its properties are given in Table 1.

Thermal Decomposition. The apparatus is illustrated in Fig. 1. A universal-joint Pyrex Claisen-flask containing 10 g of sample was prepared. Nitrogen gas was introduced into the flask in order to prevent the oxidation of polyethylene and decomposition products. The sample was decomposed for 120 min at 420°C. The high boiling fractions, which constitute 75 wt% of thermal decomposition products, were collected in a flask (5, Fig. 1), heated with a water bath at 80 °C. The mixture of saturated and olefinic hydrocarbons was used as a starting material.

TABLE 1. PROPERTIES OF LOW-DENSITY POLYETHYLENE

Appearance: white, translucent, solid

Analysis. *(1) Reagents*: Silica gel impregnated with silver nitrate for elution column chromatography was prepared by thoroughly mixing 40 grams of silica gel (Wakogel, C-100) and 8 g of 50% aqueous silver nitrate, followed by drying in the dark at 120 °C for 4 hr.[5] Thin-layer plates of silica gel–silver nitrate were prepared by spraying the usual 250-micron layer of silica gel (Wakogel, B-10) with 20% aqueous silver nitrate, followed by reactivation at 110°C for 10—15 min. A *n*-hexane–benzene mixture (20 to 1) was used as a developing solvent system. Spots were detected by spraying 60% sulfuric acid and heating at 100 to 150°C.

(2) Apparatus: For gas-liquid chromatography (glc) on a preparative scale, a Beckman Megachrom instrument with 2 m columns in parallel was used. The column packing was 7% methyl silicone polymer (SE-30) coated on 40- to 60-mesh Microsorb F. The temperature range was 193—203 °C. For analytical glc, a Shimadzu Model GC-4APE1 instrument was used in conjunction with a hydrogen flame detector. Dual column, 4 mm in diameter and 2 m in length packed with

1.5% OV-17 on silanized Shimalite W, were generally used with a temperature program of 4 °C per minute. Nitrogen was used as carrier gas. Infrared spectra were obtained by Hitach-Perkin Elmer Model 210 Spectrophotometers.

(3) Procedure: The thermal decomposition product of the high boiling fraction was resolved into straight-chain and branched-chain hydrocarbons through a urea complex formation technique. The infrared spectra of these straight-chain hydrocarbons were first obtained. Analytical glc of this sample was obtained with the use of OV-17 column. Tlc as well as elution column chromatography (silica gel–silver nitrate) were carried out to separate paraffin, terminal olefin and nonterminal olefins. The amounts of paraffin, terminal olefin and nonterminal olefin were determined by direct weighing of the concentrates. Each peak separated by the analytical glc and consisting of hydrocarbon of the same carbon number was fractionated by preparative scale glc with the use of SE-30 column. The double bond distribution in nonterminal olefin was estimated by ozonolysis of the fractioned hydrocarbon followed by glc analysis of the derived carboxylic acid methyl esters.

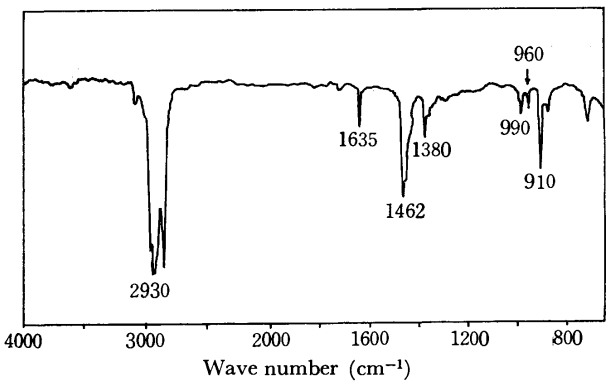

Fig. 2. Infrared spectrum of straight-chain paraffin and olefin from the thermal decomposition products of polyethylene.

Results and Discussion

The yield of urea adduct formation of straight-chain paraffin and olefin mixture was about 25 wt% of the high boiling fractions. Infrared spectra of the straight-chain hydrocarbons are shown in Fig. 2. The spectra at 2930 and 1462 cm^{-1} correspond to stretching band and deformation band of C–H bond, respectively. Methyls are observed at 1380 cm^{-1}, terminal olefins at 910 and 990 cm^{-1} (deformation bands) and 1635 cm^{-1} (stretching band) and nonterminal olefin (*trans*) at 960 cm^{-1} (deformation band). Thus, it can be said that the hydrocarbon mixture consists of paraffins, terminal olefins and nonterminal olefins. Analytical glc of the straight-chain paraffin and olefin mixture added with authentic specimens of *n*-paraffins of $C_{16}H_{34}$, $C_{20}H_{42}$, $C_{26}H_{54}$ is shown in Fig. 3. We see that carbon numbers are distributed from C_{10} to C_{30} through a maximum at around C_{16}. It is also noted that each peak from C_{11} to C_{26} shows two resolved peaks. Since there is the possibility of separation of olefin and paraffin of the same carbon numbers on the glc of OV-17 column, the two peaks probably represent olefin and paraffin of the same carbon numbers.

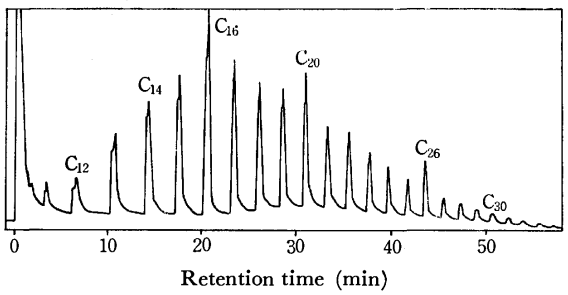

Fig. 3. Gas chromatogram of straight-chain hydrocarbons from the decomposition products of polyethylene.

Paraffin, terminal olefin and nonterminal olefins were completely separated from each other on tlc as well as by elution column chromatography. Among olefins, the terminal one was most strongly adsorbed; the more the double bond goes toward the center of the chain, the less it is adsorbed. Tlc (silica gel–silver nitrate) showed three spots, assigned by infrared spectra to be paraffin, nonterminal olefin, and terminal olefin in this order. The amounts of paraffin, terminal olefin and nonterminal olefin separated by elution column chromatography using silica gel–silver nitrate are given in Table 2.

Table 2. Amounts of paraffin, nonterminal olefin, and terminal olefin separated by elution column chromatography

Sample No.	Paraffin (wt%)	Nonterminal olefin (wt%)	Terminal olefin (wt%)	Tar (wt%)
1	62.7	5.7	30.6	1.0
2	65.1	5.5	28.2	1.1
3	52.6	5.6	40.9	1.0
4	56.7	5.2	37.2	0.9

Figure 4 shows the analytical glc of the normal paraffin concentrate separated by elution column chromatography (silica gel–silver nitrate) with *n*-$C_{16}H_{34}$ added as an authentic specimen. In this case the peak on C_{16} is not resolved. On the other hand, as shown in Fig. 5, the analytical glc of the terminal olefin concentrate with *n*-$C_{16}H_{34}$ added shows two resolved peaks on the C_{16} peak. It was found by the retention time of *n*-$C_{16}H_{34}$ that peak A corresponds to terminal olefin and peak B to paraffin of *n*-$C_{16}H_{34}$. It was also confirmed that nonterminal olefin and terminal olefin were not separated from each other

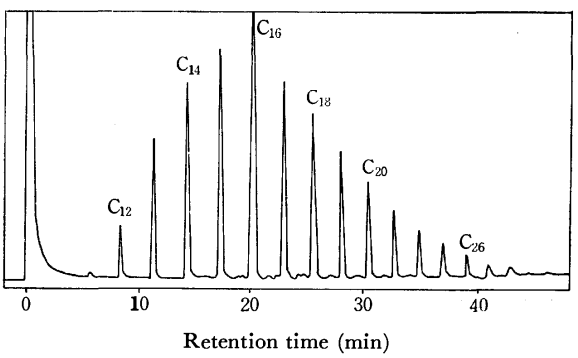

Fig. 4. Gas chromatogram of straight-chain paraffins from the thermal decomposition products of polyethylene.

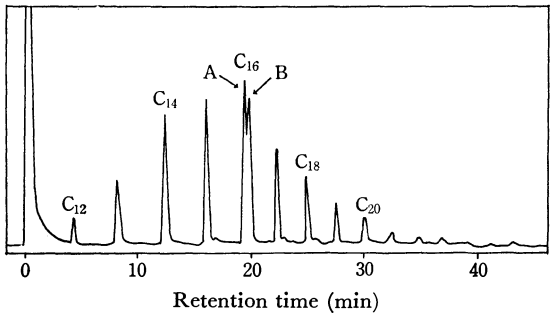

Fig. 5. Gas chromatogram of straight-chain terminal olefins from the thermal decomposition products of polyethylene.

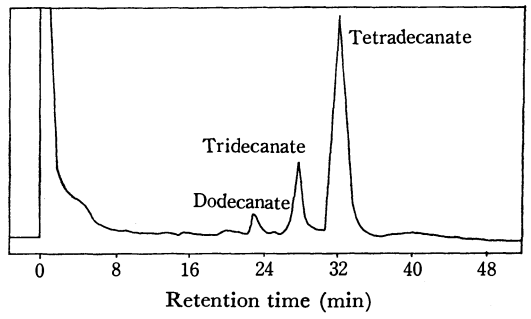

Fig. 6. Gas chromatogram of carboxylic acid methyl esters obtained from straight-chain C_{16} nonterminal olefins.

on the glc of OV-17 column. It is therefore considered that two resolved peaks correspond to olefin and paraffin of the same carbon numbers, respectively.

In order to determine the double bond distribution in nonterminal olefins, the ozonolysis of C_{16} nonterminal olefin concentrate fractionated by preparative scale glc was carried out and glc analysis of the derived carboxylic acid methyl esters was followed. The result is shown in Fig. 6. A noticeable fact about the straight-chain olefinic components is that double bond distribution is strongly favored toward the end of the chain. This supports the mechanism of the decomposition reaction on the assumption of intramolecular transfer of free radicals from the end of the chain to the center as proposed by Tsuchiya and Sumi.[2]

Many usages of this decomposition product are considered, a prospective one being the production of biodegradable detergents from terminal olefins.[6]

The authors wish to express their appreciation to Professor S. Makishima for valuable discussions and Dr. A. Tahara and Dr. T. Iida for suggestions and the measurements of glc. They also thank Mr. T. Kiuchi for help in the experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1482—1488 (1973)

Asymmetric Hydrogenation of C=O Double Bond with Modified Raney Nickel. XXVII. Asymmetric Hydrogenation of Acetylacetone*

Tadashi TANABE**

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Osaka

(Received April 14, 1972)

The asymmetric (enantioselective) hydrogenation process of acetylacetone (AA), which is a highly enolized compound, was studied by the use of catalysts modified with D-tartaric acid, and L-glutamic acid. AA corroded the Raney nickel catalyst during the hydrogenation. The modification protected the catalyst from corrosion, and the protective effects by the amino acids were greater than that by the hydroxy acid. The modification with tartaric acid increased the hydrogenation velocity of AA, but the amino acid hardly affected the hydrogenation velocity. The glutamic acid on the catalyst surface reacted with AA to form a Schiff base during the hydrogenation. The hydrogenation proceeded mainly by means of a two-step process *via* 2-pentanol-4-on. The modifying pH and temperature affected the asymmetric activity of the catalyst. In the first step of the hydrogenation, the catalyst modified with D-tartaric acid showed a high asymmetric activity, but the one modified with L-glutamic acid exhibited a low asymmetric activity as a result of the Schiff base formation. In the second step, the modification with D-tartaric acid promoted the formation of racemic 2,4-pentanediol (II), and the L-glutamic acid increased the production of *meso* II.

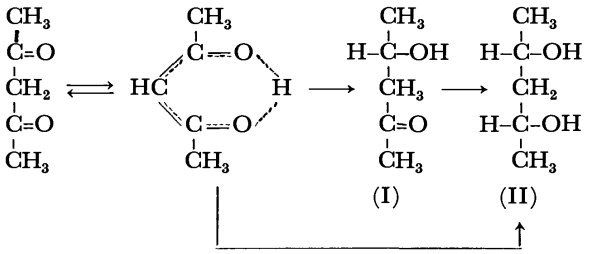
The asymmetric (enantioselective) hydrogenations of methyl acetoacetate with asymmetrically-modified Raney nickel catalysts have been extensively studied in our laboratory.[1] The relation between the asymmetric activity in the hydrogenation of methyl acetoacetate (MAA) and the structure of the modifying reagent has been clarified, and the interaction of MAA and the modifying reagents has been discussed.

* A part of this study was presented at the 24th Annual Meeting of the Chemistry Society of Japan, Osaka, 1971.

** Present address: Department of Medical Chemistry, Faculty of Medicine, Kyoto University, Sakyo-ku, Kyoto.

1) Y. Izumi, *Angew. Chem. Int. Ed. Engl.*, **10**, 871 (1971).

In the course of the investigation, β-diketone and β-keto ester were found to be favorable substrates for the asymmetric hydrogenation.[2] As the β-diketone or the β-keto ester is a highly enolized compound, the favorable character of these compounds might be related to their enolization. β-Diketone and β-keto ester have also been characterized as strong chelating reagents. Accordingly, their characters should be studied from the viewpoint of their chelation during the hydrogenation process. In the present work, the hydrogenation mechanism of acetylacetone (AA), which is a strong chelating reagent, and the contribution of the chelation of the substrate on the catalyst surface have been investigated.



Scheme 1.

If two carbonyl groups are adsorbed planarly and are hydrogenated in a single step on the catalyst surface, the hydrogenation product thus formed 2,4-pentanediol (II), may be expected to be the *meso* isomer, as is shown in Scheme 1. However, if the reaction proceeds by a successive two-step process, 2-pentanol-4-on (I) should be produced as the intermediate and the final hydrogenation product might be a mixture of racemic and *meso* 2,4-pentanediol. The asymmetric hydrogenation of AA could occur only by means of the latter mechanism. As it seemed that the modification might change the hydrogenation mechanism, the asymmetric hydrogenation of AA was studied using catalysts modified with L-glutamic acid and D-tartaric acid, and unmodified ones.

Experimental

Preparation of the Modified Raney Nickel Catalyst.[3] One gram of Raney nickel alloy (Ni: Al=4: 6) was developed with 14 ml of a 20% sodium hydroxide solution, and the mixture was kept for 1 hr at 100 °C. After the removal of the sodium hydroxide solution by decantation, the catalyst was washed with 300 ml of water. One hundred and fifty milliliters of a 1—2% modifying solution, which had been adjusted to the specified pH and temperature, was then added to the catalyst, and the mixture was allowed to stand at the specified temperature for 1.5 hr. After the modifying solution had then been removed by decantation, the catalyst was washed once with water and twice with methanol.

Asymmetric Hydrogenation of the Substrate and Hydrogenation Velocity. Ten millimiters of the substrate was hydrogenated with a modified Raney nickel catalyst prepared from 1.0 g of the alloy in a glass vessel placed in a 0.1 *l* shaking autoclave. The hydrogenation temperature and the initial pressure were 65±3 °C and 100 kg/cm² respectively. When the calculated amount of hydrogen was consumed, the hydrogenation was stopped and the product was distilled. The hydrogenation rate was calculated from the readings of the gauge at intervals of fifteen or twenty minutes.

a) 2-Pentanol-4-on. The fraction with 70—90 °C/20 mmHg was collected and treated with basic cupric carbonate at 60 °C for 3 hr. After the removal of the cupric carbonate and the precipitated cupric acetylacetonate by filtration, the liquid was distilled under reduced pressure and fractionated into two main fractions, 73—77 and 107—109 °C/22 mmHg. The fraction with a bp of 73—77 °C/21 mmHg was collected and redistilled through a McMahon column (10 cm) packed with stainless wire-netting (3 mm, 100 mesh) (bp 75—76 °C/21 mmHg), while the fraction with a bp of 107—109 °C/22 mmHg was left for 2,4-pentanediol.

b) 2,4-Pentanediol. The fraction with a bp of 107—109 °C/22 mmHg was collected.

Measurement of the Corroded Nickel from the Catalyst. Ten milliliters of acetylacetone was hydrogenated with 0.4 g of the modified catalyst, and the reaction was stopped at the point when the one mole of hydrogen has been consumed. The catalyst was removed by filtration, and the catalyst was washed with methanol. The filtrate and the washings were combined, and the solution was concentrated to dryness under reduced pressure. Twenty-five milliliters of nitric acid (d=1.48) and 25 ml of water were then added to the residue, and the mixture was kept 24 hr at 90 °C. The resulting solution was concentrated to dryness under reduced pressure. After the addition of 25 ml of water, the solution was concentrated to dryness; a 25 ml portion of a 14% aqueous ammonium solution was added to the residue, and the insoluble material was removed by filtration. Dimethylglyoxime saturated in conc. aqueous ammonia was added to the filtrate until no further nickel dimethylglyoxime was precipitated. The reaction mixture was allowed to stand for 1 hr at room temperature, and then the nickel dimethylglyoxime was collected using a glass filter, washed with 50 ml of conc. aqueous ammonia, dried at 60 °C for 4 hr in a vacuum desiccator, and weighed.[4]

Preparation of Schiff Base of Acetylacetone and Disodium Glutamate.[5] Six grams of L-glutamic acid was dissolved in a mixture of 4 g of sodium hydroxide, 15 ml of acetylacetone, 10 ml of water, and 100 ml of methanol. The solution was then concentrated to dryness, and the residue was recrystallized from methanol. Yield, 8 g. Found: C, 43.96; H, 4.93; N, 4.94%. Calcd for $C_{10}H_{13}O_5N \cdot Na_2$: C, 43.96; H, 4.80; N, 5.13%. $[\alpha]_D^{20}$ +70.4° (*c* 4, water).

Measurement of the Optical Rotation of the Product. The optical rotations of 2,4-pentanediol and 2-pentanol-4-on were measured in a 1 dm tube without dilution. The absolute configurations of (−)-2,4-pentanediol and (−)-2-pentanol-4-on were identified as R, and their specific rotations were calculated to be −47 and −18°.[6]

Measurement of the Components in a Reaction Mixture. Ten milliliters of acetylacetone (0.1 mol) was hydrogenated with 0.4 g of a modified Raney nickel catalyst; at the point when the calculated atoms of hydrogen had been taken up, the reaction was stopped. The contents of acetylacetone, 2,4-pentanediol, and 2-pentanol-4-on were estimated by gas-liquid chromatography. Conditions: column, 1.5% NPGS

on Chromosorb W, 3-m glass column, temp. 95 °C.

Ratios of Racemic and meso *2,4-Pentanediols in the Reaction Mixture.* The ratios of racemic and *meso* 2,4-pentanediols were estimated from the gas-liquid chromatograms of the benzylidene derivatives.[6] Since the deviations of the ratios of the racemic and *meso* diols after and before distillation were within a few percent, the error by distillation can be disregarded.

Results and Discussion

The Protective Effect of the Modification Against the Corrosion of Nickel by Acetylacetone (AA). Acetylacetone is known as a strong corrosive reagent of metals, and the corrosion of the nickel catalyst with AA was found in the course of the study of the asymmetric hydrogenation with the modified Raney nickel catalyst.

a) 400 mg of catalyst and 10 ml of acetylacetone were used.
b) Two moles of hydrogen was adsorbed.
c) Shaked for the same hours as in No. 1 under no hydrogen at 65 °C.

In order to study the interaction between the substrate and the nickel of the catalyst, the amount of the corroded nickel half-way through the hydrogenation of AA was determined according to the method of Brunk.[4] The results are shown in Table 1. Also in Table 1 are listed the amounts of the corroded nickel from the unmodified catalyst the half-way through and after the completion of the hydrogenation.

As may be seen in Table 1, the unmodified catalyst was more strongly corroded than the modified catalysts and as much as 30% of the nickel was dissolved. The modified catalysts, however, were corroded increasingly in the order of those modified with histidine, glutamic acid, and tartaric acid. The order was the reverse of that of the stabilities of the nickel chelates of these modifying reagents.

The results suggest that the modifying reagents inhibit the formation of the nickel chelate of AA and protect the catalyst surface from corrosion by AA. The nickel chelate was not detected in the reaction mixture at the completion of the hydrogenation. This fact shows that the nickel chelate once formed in the reaction system is hydrogenated to 2,4-pentanediol and nickel metal. The same observation has also been made previously in the hydrogenations of the nickel chelate of β-ketocarbonyl compounds with a modified Raney nickel catalyst.[7]

The results presented above suggest that AA is hydrogenated with an unmodified catalyst in a way very similar to that of the nickel chelate. In the hydrogenation with a modified catalyst, however, AA is hydrogenated without forming a complete chelate by the action of the modifying reagent.

10 ml of acetylacetone or methyl acetoacetate was hydrogenated with 400 mg of catalyst. a: acetylacetone; b: methyl acetoacetate.
-□- unmodified; -○- modified with D-tartaric acid at pH 5.0, 0 °C; -△- modified with L-glutamic acid at pH 5.0, 0 °C.

The Effect of the Modification on the Hydrogenation Velocity. The changes in the hydrogen uptake during the initial 5 hr in the hydrogenations of AA and MAA with the catalyst modified with D-tartaric acid, and with L-glutamic acid are shown in Fig. 1. in comparison with those hydrogenated with an unmodified catalyst.

In the cases of both AA and MAA, the catalyst modified with tartaric acid had about twice the hydrogenation activity of the catalyst modified with glutamic acid and the unmodified catalyst. The hydrogenation activity of the catalyst modified with glutamic acid was slightly weaker than that of the unmodified catalyst in the hydrogenation of AA. Moreover, in the hydrogenation of MAA, the two catalysts had similar activities.

These facts seem to show that the modification does not inhibit the absorption of the substrate and that tartaric acid and glutamic acid on the catalyst surface

7) T. Tanabe, T. Ninomiya, and Y. Izumi, This Bulletin, **43**, 2276 (1970).

may contribute to the enantiotopic selection *via* different mechanisms.

The Change in the Reaction Component Attended by the Progress of Hydrogenation. The hydrogenation of AA into 2,4-pentanediol (II) can be considered to take place *via* two processes: a one-step process by which II is produced directly from AA, and a two-step process by which II is produced *via* 2-pentanol-4-on (I). In order to clarify the effect of the modification on the hydrogenation process of AA, the changes in the components in the hydrogenation systems were studied during the progress of hydrogenation. The amounts of AA, I, and II were determined by gas-liquid chromatography; the results are shown in Fig. 2.

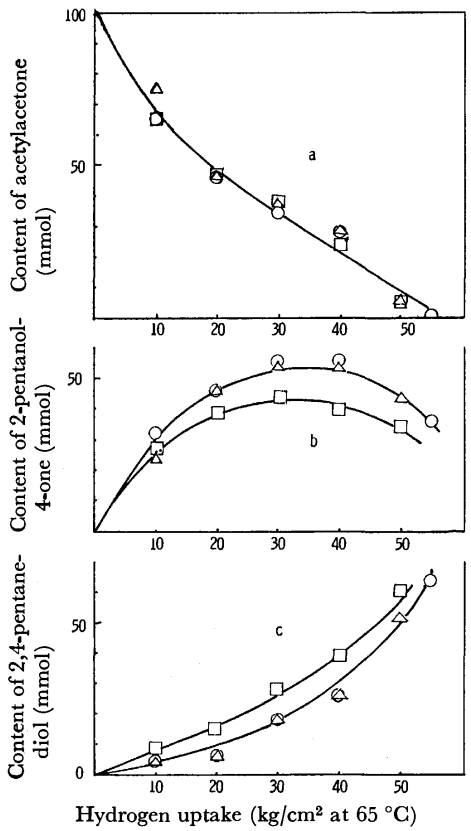

Fig. 2. Effects of modification on contents of acetylacetone, 2-pentanol-4-on and 2,4-pentanediol.
a: acetylacetone; b: 2-pentanol-4-on; c: 2,4-pentanediol.
-□- unmodified; -○- modified with D-tartaric acid; -△- modified with L-glutamic acid. The catalyst was modified at pH 5.0, 0 °C.

As may be seen in Fig. 2, the initial consumptions of AA ($-dAA/d\not{p}$) by both modified and unmodified catalysts are 87 mmol/kg·cm^{-2}·g-cat. and no effects of the modifications are observed. The initial formation of I by the unmodified and modified catalysts were about 70 and 80 mmol/kg·cm^{-2}·g-cat. respectively. Accordingly, more than eighty percent of AA was converted to II by the two-step process with the unmodified catalyst, and the modification improves the two-step process of hydrogenation. These facts show that the hydrogenation of AA with a Raney nickel catalyst mainly proceeds by the two-step process.

The Effect of the Modifying pH *on the Asymmetric Activity of the Catalyst.* In the hydrogenation of AA, the effect of the modifying pH on the asymmetric activities of the catalysts modified with D-tartaric acid and L-glutamic acid were investigated; the results are shown in Figs. 3 and 4. The asymmetric activities of the catalysts are represented by the optical rotation of 2,4-pentanediol. Also, the components of racemic 2,4-pentanediol in the hydrogenation products are shown in the figures. Upon modification with D-tartaric acid, the maximum asymmetric activity was observed at pH 10. The ratio of the DL-compound to the *meso*-compound was not affected by the modifying pH of the catalyst.

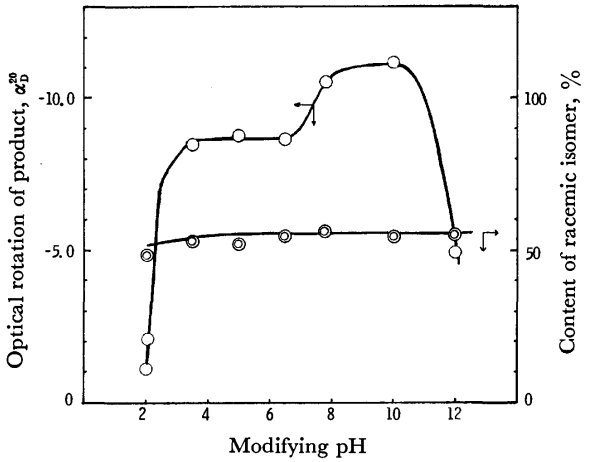

Fig. 3. Effect of modifying pH on asymmetric hydrogenation of acetylacetone on modification with D-tartaric acid at 0 °C and content of racemic 2,4-pentanediol.

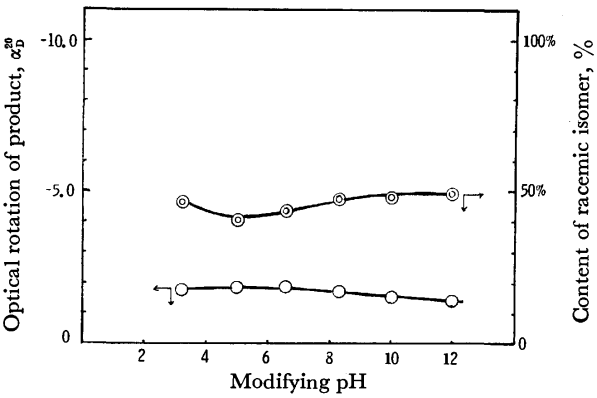

Fig. 4. Effect of modifying pH on asymmetric hydrogenation of acetylacetone using Raney nickel catalyst modified with L-glutamic acid at 0 °C and component of racemic 2,4-pentanediol.

The effect of the modifying pH was found to be closely related to the result obtained in the study of the adsorption of AA on the evaporated nickel film by Ninomiya of our research group.[8] That is, AA adsorbs in different states on the evaporated nickel films pretreated with tartaric acid at pH 2, 5, and 9. The optimum modifying pH for the asymmetric activity of the catalyst at pH 8—10 and a shoulder at pH 3—6 seem to correspond to the two different adsorption

8) T. Ninomiya, *ibid.*, **45**, 2551 (1972).

spectra of AA at pH 5 and 9.

Upon modification with L-glutamic acid, the asymmetric activity of the catalyst and the content of the racemic isomer were not influenced by the modifying pH. The asymmetric activity of the catalyst was found to be much less than that of the one modified with tartaric acid. The results show that the asymmetric hydrogenation of AA with the catalyst modified with glutamic acid proceeds under a different mode of interaction between the modifying reagent and the substrate from that of the catalyst modified with tartaric acid.

The Effect of the Modifying Temperature on the Asymmetric Activity of the Catalyst. The effect of the modifying temperature on the asymmetric activity of the catalyst was studied; the results are shown in Table 2.

TABLE 2. EFFECT OF MODIFYING TEMPERATURE

Modifying reagent	Modifying condition		Optical rotation of 2,4-pentanediol, α_D^{20}
	Temp. (°C)	pH	
D-Tartaric acid	0	5.0	−8.78
D-Tartaric aicd	100	5.0	−17.39
D-Tartaric acid	0	10.0	−12.15
D-Tartaric acid	100	10.0	−12.96
L-Glutamic acid	0	5.0	−1.88
L-Glutamic acid	100	5.0	−1.26

Upon modification with D-tartaric acid, the asymmetric activity of the catalyst modified at pH 5.0 was increased by the increase in the modifying temperature, while the catalyst modified at pH 10 was not affected by the modifying temperature. The asymmetric activity of the catalyst modified with L-glutamic acid at pH 5.0 decreased with the increase in the modifying temperature. These results show that the two acids on the catalyst surface affect the asymmetric hydrogenation in different manners.

The Asymmetric Activity of the Recovered Catalyst Modified with Glutamic Acid. As AA can react with an amino acid and produce the Schiff base,[5] there is a possibility that the glutamic acid on the catalyst surface changes into the Schiff base during the hydrogenation of AA.

In order to make clear this possibility, the recovered catalyst once used in the hydrogenation of AA was subjected again to the hydrogenation of MAA; the results are compared with the asymmetric activities of the catalysts modified with the Schiff base of L-glutamic acid and acetylacetone in Table 3. In the hydrogenation of MAA, the catalyst once used for the hydrogenation of AA did not show the original asymmetric activity of the catalyst modified with L-glutamic acid.

These facts show that the amino group of glutamic acid on the catalyst surface reacts with AA and forms the Schiff base during the hydrogenation, as is shown in Scheme 2:

$$\mathrm{R\text{-}NH_2 + AA \longrightarrow R\text{-}N{=}C(CH_3)\text{-}CH_2\text{-}COCH_3 \longrightarrow R\text{-}N\text{-}C(CH_3){=}CH\text{-}CO\text{-}CH_3}\ (\mathrm{H})$$

Scheme 2.

The Effect of the Corrosion of Nickel on the Asymmetric Activity of the Catalyst. As has already been described, a part of the catalyst turned out to be the nickel-AA chelate and the chelate is hydrogenated to 2,4-pentanediol and nickel at the completion of the hydrogenation. Therefore, the asymmetric activities of the catalysts may be expected to vary with the change in the surface structure. In order to study the alterations of the asymmetric activities of the catalysts during the hydrogenation of AA, the optical rotations of 2,4-pentanediol produced at the middle and completed stages of hydrogenation were measured; the results are shown in Table 4.

The asymmetric activity of catalyst modified with tartaric acid at 0 °C slightly decreased, while that of the one modified at 100 °C did not change, during the hydrogenation. The asymmetric activities of the catalysts modified with glutamic acid rather increased with the progress of the hydrogenation.

The Asymmetric Hydrogenation of AA to I with the Modified Raney Nickel Catalyst. As the hydrogenation of AA was found to proceed by the successive hydrogenation mechanism, it was obvious that AA undergoes the

Table 5. Asymmetric hydrogenation of AA to I with modified catalyst

Modifying conditions	Optical rotation of 2-pentanol-4-on, α_D^{20} (P%)
D-Tartaric acid pH 5.0, 0 °C	−6.02 (33)
D-Tartaric acid pH 5.0, 100 °C	−10.44 (57)
L-Glutamic acid pH 5.0, 0 °C	−0.44 (2.4)
L-Glutamic acid pH 5.0, 100 °C	−0.20 (1.1)

stereospecific hydrogenation in, two steps, AA to I and I to II. In order to determine the asymmetric yields of the products in the step of AA to I, I was isolated from the reaction mixture at the point of an hydrogen uptake of one mole; the optical rotations and asymmetric yields of the products obtained are shown in Table 5.

Table 6. Effect of asymmetric center of I on hydrogenation of I to II with unmodified catalyst

Optical purity of substrate, 2-pentanol-4-on	Optical yield of product, 2,4-pentanediol	Content of racemic diol
57%	28%	50%
2.4%	1.2%	50%

As may be seen in the table, the asymmetric yields (P%) of the hydrogenation with the catalysts modified with D-tartaric acid at 0 and 100 °C were 33 and 56% respectively. These asymmetric yields are quite similar to those in the hydrogenation of MAA, the keto-enol equilibrium of which shifts more to the keto form than does that of AA. Low asymmetric yields (2.4 and 1.1%) were observed with the catalyst modified with L-glutamic acid. The results with D-tartaric acid suggest that the keto-enol equilibrium does not affect the asymmetric yield of the product. The results obtained in the hydrogenation of AA with the catalyst modified with glutamic acid can not be compared with the asymmetric yields in the hydrogenation of MAA because of the Schiff base formation of glutamic acid with AA.

The Diastereoselectivity[1] *of the Unmodified Catalyst in the Hydrogenations of I to II.* Because of the possibility of the diastereoselective hydrogenation of I under the influence of the asymmetric center of I, partially optically-active I was hydrogenated with the unmodified catalyst; the optical purities of the products are shown in Table 6.

As the optical purities of II are half of those of I, and as the racemic isomers of II are 50%, it is obvious that the second asymmetric center at the 4-position is produced without any influence of the already existing asymmetric center at the 2-position. In other words, the unmodified catalyst showed no diastereoselectivity to I.

The Enantioselectivity and the Diastereoselectivity of the Modified Catalyst in the Hydrogenation of I to II. In order to determine the enantioselectivities and the diastereoselectivities of the catalysts modified with L-glutamic acid and D-tartaric acid, pratially optically-active I was hydrogenated with catalysts modified under the same conditions as those used for the preparation of partially optically-active I. The proportions of racemic and *meso* isomers were determined by the gas-liquid chromatography of their optical purities of the products.

Also in Table 7, the conversion rates of 2*R*-I (or 2*S*-I) to 2*R*, 4*R*- and 2*R*, 4*S*-II (or 2*S*, 4*R*- and 2*S*, 4*S*-II), K_{RR} and K_{RS} (or K_{SR} and K_{SS}) are shown; the ratios of the conversion rate, K_{RR}/K_{RS} (or K_{SR}/K_{SS}) are calculated from these results.

The K_{RR}/K_{RS} and K_{SR}/K_{SS} ratios of the catalyst modified with D-tartaric acid at 0 °C (100 °C) were 1.3 (1.8) and 1.0 (1.2) respectively. These facts show that the carbonyl groups of both *R*-I and *S*-I were hydrogenated to the alcohol with a 4*R*-configuration independently of the asymmetric center of I. That is, the hydrogenation was enantioselective rather than diastereoselective.

On the other hand, in the hydrogenation with the catalyst modified with L-glutamic acid at 0 °C (100 °C), the K_{RR}/K_{RS} and K_{SR}/K_{SS} ratios were 0.75 (0.67) and 1.7 (1.8) respectively. The results indicate that the carbonyl group at the 4-position of I with the 2*R*- or 2*S*-configuration is reduced to the alcohol with the 4*S*- or 4*R*-configuration respectively rather than with a 4*R*- or 4*S*-configuration. That is, new asymmetric centers which have absolute configurations, the reverse of those of I are produced by the catalyst modified

TABLE 7. STEREOSPECIFIC HYDROGENATION OF I TO II WITH MODIFIED RANEY NICKEL CATALYST

Modifying reagent (Temp. °C)	Content of Opt. isomer of I (%)	Ratio	Content of Opt. isomer of II (%)	Obs. Opt. yield (*RR-SS*)	Content of racemic diol (*RR*+*SS*)	Content of *meso* diol (*RS*+*SR*)

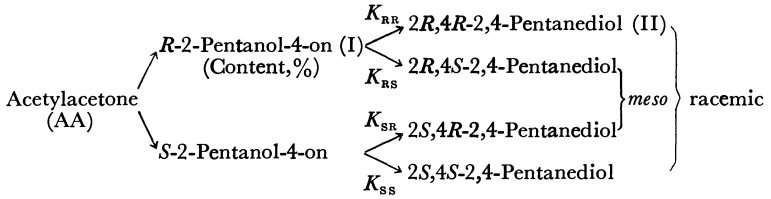
	S-(50)	$K_{SR}/K_{SS}=1.8$	*SR*(32) *SS*(18)			



with glutamic acid. That is the catalyst modified with glutamic acid has a stronger diastereoselectivity than enantioselectivity.

Furthermore, both the catalysts modified with tartaric acid and glutamic acid increased in enantioselectivity and in diastereoselectivity respectively with the increase in the modifying temperature. These facts seem to suggest that the changes in the asymmetric activities of the catalyst with the modifying temperature are not caused by the change in the intrinsic adsorption mode of the modifying reagent. It can also be concluded that asymmetric hydrogenations with the catalysts modified with tartaric acid and with glutamic acid proceed *via* different mechanisms.

Conclusion

When AA was hydrogenated with the catalyst modified with tartaric acid, the effective asymmetric hydrogenations were performed at the step of AA to I in a very similar asymmetric yield, as in MAA, which has a keto-enol equilibrium constant different from that of AA. This fact indicates that the apparent keto-enol equilibrium of the substrate is not an important factor in the enantioselection of the substrate. At the step of I to II, the catalysts modified with tartaric acid and with glutamic acid showed enantioselectivity and diastereoselectivity respectively. The unmodified catalyst has neither enantioselectivity nor diastereoselectivity.

AA usually strongly corrodes the Raney nickel catalyst during the hydrogenation, but the modification protected the catalyst from the corrosion by AA. The hydrogenation velocity, however, was not decreased by the modification. Evidence which suggests a difference in the hydrogenation mechanisms in the catalysts modified with tartaric acid and glutamic acid were found in the hydrogenation velocities of AA, in asymmetric activities of AA to I and I to II, and in the modifying pH and temperature dependencies of the asymmetric activities of the catalysts. The glutamic acid on the catalyst surface reacted with AA and became the Schiff base derivative during the hydrogenation.

The auther wishes to express his thanks to Professor Yoshiharu Izumi for his continuous guidance and help, and also to Miss Kiku Koike and Mrs. Nobuko Okuhara for making the elemental analyses.

Peptide Synthesis *via* *N*-Acylated Aziridinone.[1] II. The Reaction of *N*-Acylated Aziridinone and Its Use in Peptide Synthesis

Muneji MIYOSHI

Department of Synthetic Chemistry, Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., Kashima-cho, Higashiyodogawa-ku, Osaka 532

(Received July 21, 1972)

Optically active *N*-acylated aziridinone, which was synthesized by the dehydration of the corresponding L-acylamino acid, was treated with various nucleophiles, such as alcohol, amine, and water. The ring fission of the aziridinone took place exclusively at the carbonyl-nitrogen bond to give L-acylamino acid derivatives. The reaction was used successfully in the peptide synthesis, using an amino acid ester as a nucleophile. A retention of the optical activity was observed throughout the reaction.

Interest in aziridinone chemistry has increased since Baumgarten[2] first proved the existence of *N*-*t*-butyl-3-phenylaziridinone by spectral studies in 1961. Recently, a number of data on the physical and chemical properties of the aziridinone have been accumulated, and work on it is still in progress.

The aziridinone chemistry reported[3-8] thus far may be summarized as follows.

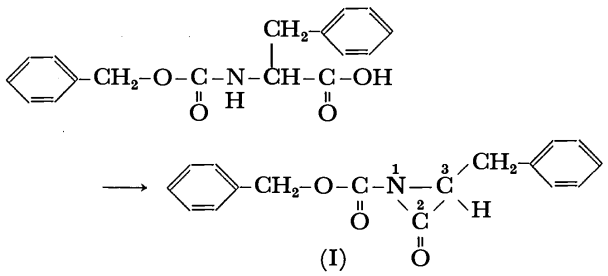
All of the aziridinones synthesized to date have the *N*-substituent, which is an electron-donating and a sterically bulky alkyl group. Among them, *N*-*t*-butyl and *N*-adamantyl-aziridinones were isolated in the pure form.

Among the substituents at *C*-3, the bulky alkyl group generally increases the stability of the ring, while the aryl group decreases the stability of the aziridinone under otherwise identical conditions. *C*-3 disubstituted aziridinones are more stable than *C*-3 monosubstituted ones under the same conditions. In general, the *N*-*t*-alkyl-aziridinones isolated and investigated are very reactive with nucleophiles to give the corresponding adducts by the fission of the three-membered ring. Depending on the nucleophiles, a high selectivity is observed in the type of ring opening. For example, reactions with proton-containing nucleophiles, such as water, alcohols, amines, and ethyl glycinate, lead exclusively to amides because of the fission at the alkyl-nitrogen bond. On the other hand, reactions with aprotic nucleophiles, such as sodium methoxide and potassium *t*-butoxide, give amino acid derivatives as the only product, corresponding to a ring-opening at the carbonyl-nitrogen bond.

In the previous paper,[9] the author reported a new method of synthesizing the optically-active *N*-acylated aziridinones, which have a hydrogen atom on the asymmetric carbon at *C*-3, from the corresponding L-acylamino acids. The present paper will describe the reactivity of the new *N*-acylated aziridinones and an approach to the peptide synthesis by the use of these compounds.

Results and Discussion

Reactions of 3-Benzyl-1-benzyloxycarbonylaziridin-2-one (I) with Various Nucleophiles. The 3-benzyl-1-benzyloxycarbonylaziridine-2-one (I) was synthesized by the dehydration of benzyloxycarbonyl-L-phenylalanine (Z-Phe), as had been described in detail previously.[9]



(I)

The crystals of I were dissolved in anhydrous tetrahydrofuran (THF), and all of the reactions with nucleophiles were carried out at −10——0 °C over a period of one hour under stirring. The nucleophiles used in this study were water, *t*-butyl alcohol, potassium *t*-butoxide, aniline, and benzylamine. The results are summarized

5	H_2O	$(Z\text{–Phe})_2O$	47.2	144—146	+14.6(Dioxane)
6	H_2/Pd		78.5	96—98	−110.4(THF)

in Table 1.

It is interesting to note that all of the products obtained are amino acid derivatives, corresponding to the fission of the carbonyl-nitrogen bond on the ring. The exclusive selectivity of this ring fission is observed even when *t*-butyl alcohol is used as a proton-containing nucleophile. The same product of benzyloxycarbonyl-L-phenylalanine *t*-butyl ester (Z–Phe–OBu^t) is also obtained by the use of potassium *t*-butoxide, which is an aprotic nucleophile.

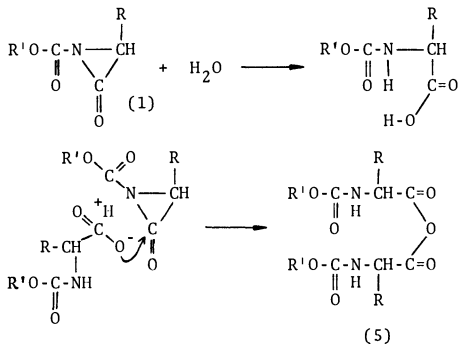
The fact that the ring fission always takes place at the carbonyl-nitrogen bond, no matter what the species of the attacking nucleophiles, may be attributed to the lower electron density on the ring of I compared with that of *N*-*t*-alkyl-aziridinone.

As an urethan carbonyl group affects lone-pair electrons of the nitrogen atom so as to decrease the electron density, the protonation ability of the nitrogen atom on the ring as a Lewis-base would be diminished. Therefore, a nucleophile would selectively attack the carbonyl carbon, even if a proton donor were present in the reaction media. Further, the effect of the *N*,*N*-diacyl group should also be taken into consideration. The possibility of the selective ring fission at the carbonyl-nitrogen bond would be greatly increased because of the sensitive reactivity of the *N*-substituted diacyl group. The results of an MO calculation also support the above explanation of the observed ring fission; these data will be summarized later.

It is also interesting to note that the reaction of I with water leads to the formation of an intermolecular anhydride of Z–Phe (5), while catalytic hydrogenation over palladium-black in ether gives the corresponding intramolecular anhydride (6); the so-called "*N*-carboxy-α-amino acid anhydride" (NCA).

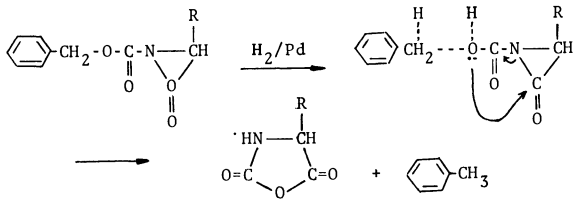
Wieland and Bernhard[10] reported that Z-amino acid reacted with phosgene ($COCl_2$) at 0 °C in the presence of tertiary amine to form the same intermolecular anhydride (5). In this study, I was directly treated with water to form Z–Phe in the first step; the formation of the anhydride (5) would occur *via* an intermolecular attack by the ionized carboxyl anion of the Z–Phe on the carbonyl carbon of the other molecule of the aziridinone.

On the contrary, hydrogenolysis takes place at the benzyl-oxygen bond to form toluene and a carbamic



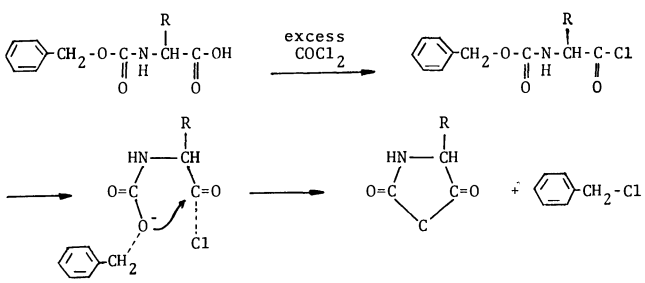
(5)

acid residue, when catalytic hydrogenation is carried out in anhydrous ether. Therefore, the fast intramolecular attack by the carboxyl group on the adjacent carbonyl carbon in the same molecule must then take place before the decarboxylation of the carbamic acid occurs.



(6)

The proposed mechanism is partially similar to that of the NCA formation reaction commonly employed. In this case, the intramolecular attack by the carboxyl group of the carbamic acid on the activated carbonyl group in the same molecule takes place under anhydrous conditions at 40—60 °C.



It should also be noted that the retention of the full optical activity is observed in every reaction. This observation suggests two significant facts. The first is that I has a full optical activity and that racemization does not occur during the ring-formation reaction. The

second is that the ring-opening reaction of I with various nucleophiles also proceeds without racemization.

Reaction of N-*Acylated Aziridinone with Nucleophiles.* From the subsequent study, it was found that the isolation of I synthesized is not always necessary for the sake of the successive reaction with nucleophiles; the reaction was performed directly by the use of the I without isolation before use. Thus, the reaction procedure may not only be simplified but may also be applied to other *N*-acylated aziridinones which are not isolated in the crystalline form. The results are summarized in Table 2.

Reaction of N-*Acylated Aziridinones with Amino Acid Derivatives.* The crystal of I was dissolved in chloroform, and into this solution was added a solution

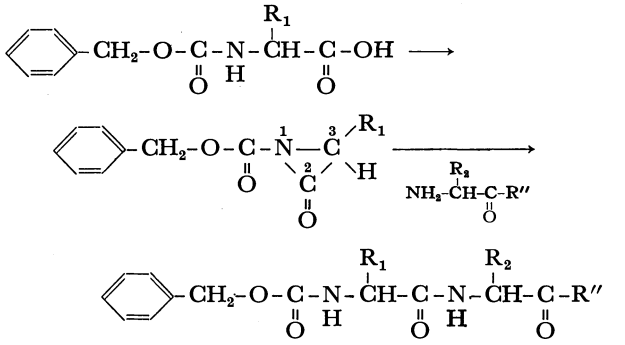
of ethyl glycinate at −10——20 °C under stirring for one hr. The reaction proceeded selectively to form an optically-active peptide by the fission of the carbonyl-nitrogen bond, as had been expected.

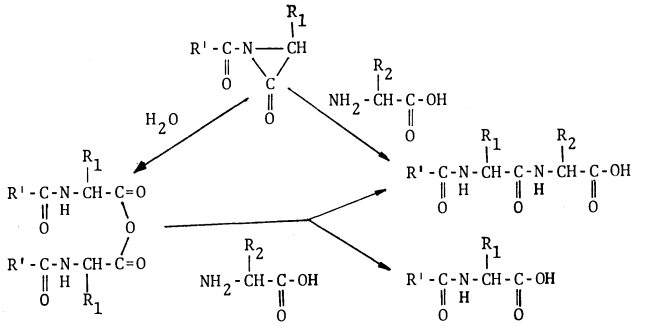
An amino acid ester hydrochloride dissolved in chloroform ($CHCl_3$) was neutralized with an equivalent triethylamine (TEA) and used for further experiments without removal of triethylamine hydrochloride (TEA–HCl) formed in the solution.

Various 3-substituted-1-benzyloxycarbonyl-aziridin-2-ones were prepared from the corresponding benzyloxycarbonyl-L-amino acid (Z–AA) in the same manner as had been described earlier.[9] Into the reaction mixture of the aziridinone was directly added a solution of amino acid ester at −10——20 °C under stirring; the reaction was then allowed to continue for one hr.

Prior to the reaction, a functional group in the side chain of Z–AA was protected by a protecting group commonly used in peptide chemistry. It was found that the reaction also proceeded selectively by the fission of the carbonyl-nitrogen bond to form an optically-active peptide. The results are summarized in Table 3.



When free amino acid was used as a nucleophile, it was dissolved in 2 N sodium hydroxide and the coupling reaction was carried out in an aqueous solvent system. In this case, free amino acid would react with either of the aziridinone and the anhydride resulting from the decomposition of the aziridinone by the excess water, as is shown in the next scheme.

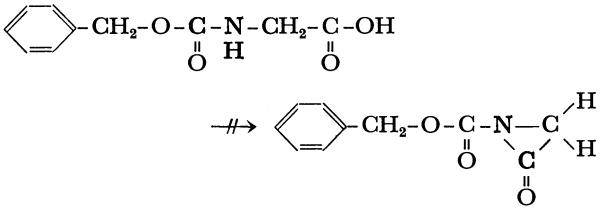


The substituent at *C*-3 in the 3-substituted-1-benzyloxycarbonyl-aziridin-2-one corresponds to the side chain (R_1) of amino acid. As is shown in Table 3, no distinct difference in the yields of the peptides was observed among the reaction of ethyl glycinate with the aziridinones derived from alanine, valine, leucine, and isoleucine. In fact, each of the reactions seems to proceed with little difference in the tlc. The variety of the yields observed in the reactions seems rather to be caused by the experimental conditions.

In most conventional peptide coupling methods, however, it is well known that the yield of a desired peptide is still unsatisfactory with an amino acid containing a bulky alkyl side chain. It should be noted that, in this coupling method, the bulkiness of the side chain (R_1) of amino acid does not have any substantial effect on the yields of the peptides.

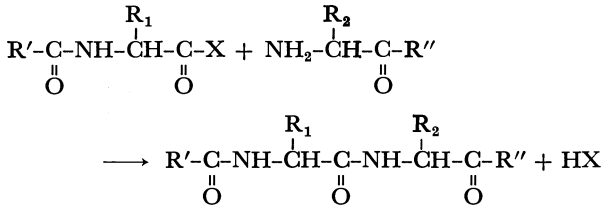
As has been mentioned earlier, a bulky alkyl group at *C*-3 in the *N*-*t*-alkyl-aziridinone generally increases the stability of the ring under otherwise identical conditions. In the formation of the aziridinone, the bulkiness of R_1 would bring about a good result by diminishing the decomposition of the extremely reactive ring. Such a contribution of the bulky R_1 to the formation of the ring would offset its lower reactivity in the subsequent ring opening reaction with an amino acid ester due to the steric effect of R_1.

The corresponding aziridinone derived from benzyloxycarbonyl-glycine (Z–Gly, R_1=H) was, however, too unstable to be isolated. The product resulting from the subsequent reaction with ethyl glycinate could not be identified, though Wieland and Heinke[11] reported that *N*,*N*′-dibenzyloxycarbonyl-glycylglycine was obtained from the reaction of Z–Gly with ethyl glycinate by the use of their "phosphorus oxychloride method."



In the case of an imino acid such as proline, the *N*-substituted-aziridinone cannot be formed and the coupling method in the present study can not be used.

A Characteristic of the New Peptide Coupling Method. A peptide coupling is generally carried out by two consecutive procedures; first introducing an electron-withdrawing group to the carboxyl group of acyl amino acid in order to activate the carbonyl carbon, and then, reacting it with the amino group of the other amino acid and peptide, as is shown in the next scheme:



An activating group (X) should be eliminated before the nucleophilic substitution by an amino group to the carbonyl carbon is accomplished. The HX formed subsequently in the reaction media must be removed in order for the reaction to proceed completely. The reactivity is influenced by the ease of the elimination of the activating group (X), and the reaction proceeds *via* either an elimination reaction mechanism or a substitution reaction mechanism, depending on the

reaction conditions.

On the contrary, the *N*-acylated aziridinone does not involve any leaving group in the molecule. The acylated nitrogen atom, which is a member of the skeleton of amino acid itself, plays an effective role as a kind of electron-withdrawing group. Thus, the activation of the carbonyl-carbon depends largely upon the lower electron density on the ring as well as upon the extremely strained structure of the hetero three-membered ring, and the peptide coupling proceeds *via* a ring-opening addition reaction mechanism.

The retention of the full optical activity observed in the resulting peptides is caused by the following factors:

1) The reaction proceeds *via* a ring-opening addition reaction mechanism and no leaving group is eliminated during the reaction.

2) The addition reaction takes place rapidly at −10——20 °C within an hour because of the reactivity of the aziridinone.

3) No bases other than the amino acid ester itself are present in the reaction media, and no base-catalyzed abstraction of a proton on the asymmetric carbon takes place during the coupling reaction.

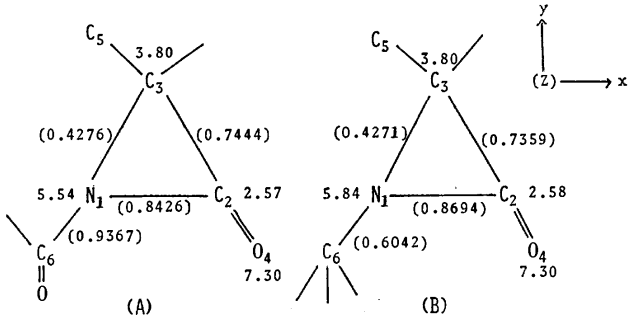
Thus, the new coupling method *via* *N*-acylated aziridinone will serve as a useful technique for peptide synthesis.

MO Calculation. An MO calculation of two types of aziridinone was carried out by the extended Hückel method[12–14] in order to find a clue to the explanation of the experimental results in the nucleophilic ring-opening reaction of *N*-acylated aziridinone.

1-Benzyloxycarbonyl-3-methyl-aziridinone (**A**) and 1-*t*-butyl-3-methyl-aziridinone (**B**) were chosen as the models of the *N*-acylated- and *N*-*t*-alkyl-aziridinones respectively.

For the input data of the bond length and the bond angles of the aziridinone ring, the X-ray analysis data of 1,3-diadamantyl-aziridinone reported by Wang *et al.*[8] were used; that is, the configuration at the nitrogen is pyramidal (the nitrogen atom lying 0.534 Å from the plane defined by its three substituents), and the adamantyl groups are *trans* to each other.

The calculated bond populations and atomic populations are shown in Scheme 1.



Scheme 1. Bond populations and atomic populations of the Aziridinone (A) and (B).
(A): 1-carbobenzoxy-3-methyl-aziridinone
(B): 1-*t*-butyl-3-methyl-aziridinone

A remarkable difference between (**A**) and (**B**) was observed, especially in the populations of N_1. The bond population of N_1–C_2 in (**A**) was smaller than that in (**B**) (0.8426; 0.8694) because of the increased interaction of N_1–C_6 (0.9367; 0.6042). A less atomic population of N_1 (5.54; 5.84) was also obtained, showing that the total electron density on the ring of (**A**) was much reduced compared to that of (**B**).

The AO populations of N_1 show that the decrease in the total charge of N_1 in (**A**) is mainly governed by the charge on the *Px*-orbital, corresponding to the reduced contribution of the N_1–C_2 bond.

AO Populations of N_1

Orbital	*S*	*Px*	*Py*	*Pz*	Total
(**A**)	1.4161	1.1460	1.3623	1.6252	5.5496
(**B**)	1.4975	1.3185	1.3979	1.6294	5.8433

In the nucleophilic ring opening reaction of the aziridinone, the position of the ring fission depends largely upon the nature of the attacking nucleophile as well as on the electronic structure of the ring, in which both HOMO and LUMO play a significant role.

The calculated electron densities at HOMO are shown in Table 4.

In the case of (**A**), the lone pairs scarcely exist on either N_1 or O_4. Under such circumstances, protonation does not occur even when a proton donor is present in the reaction system.

On the contrary, both N_1 and O_4 in (**B**) have enough lone pairs at HOMO to protonate if a proton donor is

12) R. Hoffmann, *J. Chem. Phys.*, **39**, 1397 (1963); R. S. Mulliken, *ibid.*, **23**, 1833 (1955); R. S. Mulliken, *ibid.*, **23**, 1841 (1955).

13) T. Yonezawa, K. Shimizu, *Yuki Gosei Kagaku Kyokai Shi*, **26**, 719 (1968).

14) The resonance integrals (H_{rs}) were evaluated by the Mulliken approximation, where S_{rs} represents the overlap integral between AOs

$$H_{rs} = \frac{1.75}{2}(H_{rr}+H_{ss})\cdot S_{rs}$$

MO: molecular orbital AO: atomic orbital HOMO: highest occupied MO LUMO: lowest unoccupied MO.

present. It is noted that, in the electron density of N_1 in (**B**), the contribution of the *Px*-orbital is the largest, showing that the lone pair of N_1 at HOMO would partially delocalize with the carbonyl oxygen (O_4).

The electron densities at LUMO in Table 4 clearly show that the interaction of an attacking nucleophile with C_2 is the largest and that the addition of a nucleophile takes place selectively at the C_2 position if a proton donor is absent. In spite of the decisive difference on the total electron density between C_2 and C_3 in (**B**), the AO electron densities of both *Px*- and *Py*-orbitals of C_3 at LUMO are greater than those of C_2. The possibility of the nucleophilic attack on C_3 in (**B**) seems, accordingly, to be greater than that in (**A**) if an attacking nucleophile comes from near the direction of the *x* or *y*-axis.

On the other hand, in a proton-containing reaction system, the protonation of (**B**) will occur, prior to the attack of the nucleophile, at the position of either N_1 or O_4, since both of them have a reactive lone pair at HOMO.

In this case, the reaction may proceed in a different way, as has been reported previously.[3-7]

Although more quantitative claculations will be required to discuss further in detail, the calculated data presented above may reasonably explain the experimental results observed in the present study.

Experimental

The melting points are uncorrected. Thin layer chromatography (tlc) was performed with silica gel G (Merck), and the spots were detected by ninhydrin on heating at 100 °C after developing in the buffer solution ($CHCl_3$: AcOEt: AcOH, 85: 15: 3). The IR spectra were obtained using a Shimadzu IR-27G apparatus. The NMR spectra were recorded at 60 MHz in $CDCl_3$ with TMS as the internal standard using a Hitachi R-20A apparatus. The optical rotations were measured with a Yanagimoto OR-100 apparatus. THF, ether, and petroleum ether used throughout this experiment were dried over sodium metal wire after distillation. The $COCl_2$ gas was absorbed on dry ether to prepare the $COCl_2$–ether solution and was stored in a refrigerator. The TEA was purified by distillation before use.

Benzyloxycarbonyl-L-phenylalanine t-*Butyl Ester (1) and (2).* (a) Crystals of 3-benzyl-1-benzyloxycarbonylaziridin-2-one (1) (2.81 g, 0.01 mol) were dissolved in 30 ml of THF. Into this solution 15 ml of *t*-butanol was added with stirring at −10 °C. Subsequently, a 3 ml portion of pyridine was added to the reaction mixture. A ninhydrin positive spot at R_f 0.9 on tlc decreased, and at R_f 0.8 a new spot appeared; the latter detected by HBr/ninhydrin (hydrobromic acid must be sprayed over the plate prior to the detection by ninhydrin). After 1 hr, ethyl acetate (100 ml) was added to the reaction mixture, which was then washed with 5% sodium bicarbonate, 1M hydrochloric acid, and water successively, and dried over magnesium sulfate. The organic layer was evaporated under reduced pressure, and the residue was crystallized with ethyl acetate and petroleum ether. Recrystallization from the same solvents afforded 2.96 g (83.3%). Mp 81—82 °C, $[\alpha]_D^{20}$ −6.0° (*c* 1, EtOH). IR: $\nu_{C=O}$ 1745, 1695 cm^{-1}; ν_{NH} 3380 cm^{-1}. Found: C, 71.29; H, 6.80; N. 3.77%. Calcd for $C_{21}H_{25}NO_4$: C, 70.90; H, 7.09; N, 3.94%. Lit,[15] $[\alpha]_D^{20}$ −4.4° (*c* 2, EtOH).

(b) Freshly-prepared potassium *t*-butoxide (15 g, containing excess *t*-butanol) suspended in 50 ml of THF was stirred into a solution of I (2.81 g, 0.01 mol) in 30 ml of THF at −10 °C, and the reaction was allowed to continue for 1 hr at −10—0 °C. Then, ethyl acetate (150 ml) was added to the reaction mixture, and it was worked up in the same manner as had been described above. The crystals, 2.02 g (56.8%), were identified with those afforded in (a).

Benzyloxycarbonyl-L-phenylalanine Anilide (3). Into a solution of I (2.81 g, 0.01 mol) in THF (30 ml), 10 ml of aniline was added with stirring at −10 °C. After 1 hr, ethyl acetate (100 ml) was added; the reaction mixture was then washed with 1M hydrochloric acid, 5% sodium bicarbonate and water successively, and dried over magnesium sulfate. Evaporation *in vacuo* gave the product, which was subsequently recrystallized from ethyl acetate and petroleum ether. Yield, 3.16 g (84.6%), mp 164—166 °C, $[\alpha]_D^{20}$ +30.0° (*c* 1, THF). IR: $\nu_{C=O}$ 1690, 1655, 1540 cm^{-1}; ν_{NH} 3300 cm^{-1}. Found: C, 73.65; H, 5.92; N, 7.53%. Calcd for $C_{23}H_{22}N_2O_3$: C, 73.78; H, 5.92; N, 7.48%.

Benzyloxycarbonyl-L-phenylalanine Benzylamide (4). Into a solution of I (2.81 g, 0.01 mol) in THF (30 ml), 10 ml of benzylamine was added with stirring at −10 °C; stirring was then continued for 1 hr at −10—0 °C. After ethyl acetate (100 ml) had then been added, the reaction mixture was worked up in the way described in (3). Recrystallization from ethyl acetate gave 3.31 g (85.3%). Mp 157—158 °C, $[\alpha]_D^{20}$ −12.0° (*c* 1, DMF). IR: $\nu_{C=O}$ 1685, 1645, 1540 cm^{-1}; ν_{NH} 3300 cm^{-1}. Found: C, 74.40; H, 6.21; N, 7.34%. Calcd for $C_{24}H_{24}N_2O_3$: C, 74.20; H, 6.23; N, 7.21%.

Benzyloxycarbonyl-L-phenylalanine Anhydride (5). I (2.81 g, 0.01 mol) was dissolved in a mixture of THF (20 ml) and ethyl acetate (50 ml) at −10 °C; then 10 ml of water was stirred and the reaction temperature was allowed to rise to −5—0 °C over a 30 min period. The tlc showed two spots of R_f 0.7 and R_f 0.5 (Z–Phe) which were detected by HBr/ninhydrin respectively. The reaction mixture was washed twice with ice-cold 2% sodium bicarbonate and dried over magnesium sulfate. Evaporation *in vacuo* gave the product, which was subsequently recrystallized from ethyl acetate. 1.37 g (47.2%), mp 144—146 °C, $[\alpha]_D^{20}$ +14.6° (*c* 1, dioxane). IR: $\nu_{C=O}$ 1830, 1755, 1695 cm^{-1}; ν_{NH} 3300 cm^{-1}. Found: C, 70.15; H, 5.66; N, 4.76%. Calcd for $C_{34}H_{32}N_2O_7$: C, 70.33; H, 5.56; N, 4.83%. Lit,[16] mp 139—140 °C, $[\alpha]_D^{20}$ +19.7° (*c* 1, CH_2Cl_2).

4-Benzyl-2,5-oxazolidinedione (6). I (2.81 g, 0.01 mol) was dissolved in 100 ml of ether at 0 °C. After adding 1 g of 5% palladium-charcoal to the solution, catalytic hydrogenation was carried out under bubbling hydrogen gas at room temperature over a period of 30 min. Tlc showed a new spot at R_f 0.8, which was detected by ninhydrin. After the filtration of the catalyst, the ether was evaporated under reduced pressure on an ice bath. To the residue ether and petroleum ether were added; the solution was then stored in a refrigerator. Recrystallization from the same solvents yielded 1.50 g (78.5%); mp 96—98 °C (decomp.). $[\alpha]_D^{20}$ −110.4° (*c* 1, THF). IR: $\nu_{C=O}$ 1855, 1760 cm^{-1}; ν_{HN} 3250 cm^{-1}. NMR ($CDCl_3$, δ): 7.25 (m, 5H), 6.37 (bs, 1H), 4.54 (q, 1H), 3.10 (dd, 2H). Found: C, 63.51; H, 4.80; N, 7.20%. Calcd for $C_{10}H_9NO_3$: C, 62.82; H, 4.75; N, 7.33%.

Benzyloxycarbonyl-L-valine Methyl Ester (7). To a solution of benzyloxycarbonyl-L-valine (25.1 g, 0.1 mol) in 200 ml of THF, $COCl_2$–ether solution (50 ml, containing 0.1 mol of

15) G. W. Anderson and F. M. Callahan, *J. Amer. Chem. Soc.*, **82**, 3359 (1960).

16) E. Wünsch and G. Wendlberger, *Chem. Ber.*, **100**, 160 (1967).

$COCl_2$) was added at −20 °C. TEA (14 ml, 0.1 mol) in 30 ml of ether was then stirred drop by drop to the solution over a period of 30 min at −20 °C. After 30 min, TEA (14 ml, 0.1 mol) in 30 ml of ether was added, drop by drop, to the reaction mixture again. After an additional 30 min of stirring at −20 °C, 100 ml of methanol was added to the reaction mixture; the reaction temperature was then allowed to rise to −5——10 °C with stirring for 1 hr. Ethyl acetate (500 ml) was added to the reaction mixture, it was washed with 5% sodium bicarbonate, 1 N hydrochloric acid, and water successively, and the organic layer was dried over magnesium sulfate. The evaporation to the solvent under reduced pressure afforded the product, which was subsequently recrystallized from ethyl acetate and petroleum ether. 21.7 g (81.9%). Mp 54—56 °C, $[\alpha]_D^{20}$ −18.9° (*c* 1, MeOH). IR: $\nu_{C=O}$ 1745, 1690 cm^{-1}; ν_{NH} 3350 cm^{-1}. Found: C, 63.59; H, 7.46; N, 5.47%. Calcd for $C_{14}H_{19}NO_4$: C, 63.38; H, 7.22; N, 5.28%. Lit,[17] mp 56—57 °C, $[\alpha]_D$ −16.0° (*c* 3.1, EtOH).

General Procedure for the Anhydrides (8—11). Benzyloxycarbonyl-L-amino acid or *p*-halogeno-benzyloxycarbonyl-L-amino acid (0.1 mol) was dissolved in 200—300 ml of THF. To the solution, $COCl_2$–ether (50 ml, containing 0.1 mol of $COCl_2$) was added at −20——30 °C. TEA (14 ml, 0.1 mol) in 30 ml of ether was stirred, drop by drop, into the solution during 30 min at the same temperature. After 30 min, TEA (14 ml, 0.1 mol) in 30 ml of ether was added again in the same way as above. After an additional 30 mins' stirring, 600 ml of ethyl acetate was added; the reaction mixture was then washed with 100 ml of ice-cold water. The washing of the organic layer with ice-cold water was repeated several times. Then the organic layer was washed twice more with ice-cold 2% sodium bicarbonate, and it was dried over magnesium sulfate. The evaporation of the solvent *in vacuo* gave the product, which was recrystallized from ethyl acetate and petroleum ether. IR: $\nu_{C=O}$ 1830—1810; 1760—1750, 1700—1685 cm^{-1}; ν_{NH} 3350—3300 cm^{-1}.

Benzyloxycarbonyl-L-alanine Anhydride (8). Mp 120—122 °C, $[\alpha]_D^{20}$ −11.0° (*c* 1, THF). Found: C, 60.41; H, 5.71; N, 6.29%. Calcd for $C_{22}H_{24}N_2O_7$: C, 61.67; H, 5.65; N, 6.54%.

Benzyloxycarbonyl-L-valine Anhydride (9). Mp 96—98 °C, $[\alpha]_D^{20}$ +10.7° (*c* 1, THF). Found: C, 64.53; H, 6.64; N, 5.78%. Calcd for $C_{26}H_{32}N_2O_7$: C, 64.45; H, 6.66; N, 5.78%.

p-*Bromo-benzyloxycarbonyl-L-phenylalanine Anhydride (10).* Mp 147—148.5 °C, $[\alpha]_D^{20}$ +2.0° (*c* 1, THF). Found: C, 55.30; H, 4.09; N, 3.79; Br, 21.64%. Calcd for $C_{34}H_{30}N_2O_7Br_2$: C, 54.57; H, 4.08; N, 3.68; Br, 20.29%.

p-*Chloro-benzyloxycarbonyl-L-phenylalanine Anhydride (11).* Mp 149—150 °C, $[\alpha]_D^{20}$ −3.0° (*c* 1, THF). Found: C, 62.67; H, 4.95; N, 4.30; Cl, 10.73%. Calcd for $C_{34}H_{30}N_2O_7Cl_2$: C, 62.72; H, 4.60; N, 4.33; Cl, 10.25%.

p-*Toluenesulfonyl-L-phenylalanine Methyl Ester (12).* To a solution of *p*-toluenesulfonyl-L-phenylalanine (31.9 g, 0.1 mol) in 300 ml of THF, $COCl_2$–ether solution (50 ml, containing 0.1 mol of $COCl_2$) was added at −20 °C. TEA (14 ml, 0.1 mol) in 30 ml of ether was then added, drop by drop, to the solution at −20——30 °C. After 30 min, TEA (14 ml, 0.1 mol) in 30 ml of ether was added, drop by drop, to the reaction mixture again, and it was worked up in the same manner as had been described in (7). 17.5 g (52.5%). Mp 91—93 °C, $[\alpha]_D^{20}$ +3.1° (*c* 1, MeOH). IR: $\nu_{C=O}$ 1730 cm^{-1}; ν_{NH} 3270 cm^{-1}. Found: C, 60.89; H, 5.79; N, 4.36%. Calcd for $C_{17}H_{19}NO_4S$: C, 61.25; H, 5.75; N, 4.20%.

Benzyloxycarbonyl-L-phenylalanyl-glycine Ethyl Ester (13). To a solution of ethyl glycinate hydrochloride (1.4 g, 0.01 mol) in 30 ml of $CHCl_3$, TEA (1.4 ml, 0.01 mol) was added for neutralization. Crystals of I (2.81 g, 0.01 mol) were dissolved in 20 ml of THF at −10 °C. Into this solution of I, the $CHCl_3$ solution of ethyl glycinate was added at −10——20 °C; the reaction was then allowed to continue for 1 hr with stirring at the same temperature. After adding 40 ml of $CHCl_3$ to the reaction mixture, it was washed with 5% sodium bicarbonate, 1 N hydrochloric acid and water successively, and dried over magnesium sulfate. The evaporation of the solvent under reduced pressure afforded the product, which was recrystallized from ethyl acetate and petroleum ether. Yield, 3.22 g (83.8%), mp 109—111 °C, $[\alpha]_D^{20}$ −16.8° (*c* 1, EtOH). IR: $\nu_{C=O}$ 1760, 1695, 1655, 1540 cm^{-1}; ν_{NH} 3300 cm^{-1}.

General Procedure of the Reaction of 3-Substituted-1-benzyloxycarbonylaziridin-2-one with Amino Acid Ester. L-Amino acid ester hydrochloride (0.05 mol) was dissolved in 150—200 ml of $CHCl_3$, which was then neutralized with TEA (7 ml, 0.05 mol) at 0 °C. To a solution of benzyloxycarbonyl-L-amino acid (0.05 mol) in 100—200 ml of THF, a $COCl_2$–ether solution (25 ml, containing 0.05 mol of $COCl_2$) was added at −20——30 °C. TEA (7 ml, 0.05 mol) in 15 ml of ether was stirred, drop by drop, into the solution over a period of 30 min at −20——30 °C. After 30 min, TEA (7 ml, 0.05 mol) in 15 ml of ether was added again to the reaction mixture in the same way. After an additional 30 min, into the reaction mixture, a $CHCl_3$ solution of the L-amino acid ester was then added at −20 °C; the reaction proceeded for 1 hr at −10——20 °C. A 400 ml portion of $CHCl_3$ was then added to the reaction mixture; it was washd with 5% sodium bicaronate, 1 N hydrochloric acid, and water successively, and dried over magnesium sulfate. The organic layer was evaporated under reduced pressure, then the crude product was crystallized with an appropriate solvent system.

Among the compounds listed in Table 3, there are some exceptions. In the case of Z–Phe–Val(Me)–OMe (21), considerable amounts of the *N*-methyl valine methyl ester still remained in the reaction mixture after 1 hr; they were detected by ninhydrin on tlc. The reaction was continued ovrenight with stirring at 0——10 °C. In the case of Z–Phe–Ile–Gly–OMe (24), the dipeptide ester was reacted with the aziridinone; the reaction proceeded in the same manner as had been described in the other cases of amino acid esters.

General Procedure of the Reaction of 3-Substituted-1-benzyloxycarbonylaziridin-2-one with Free Amino Acid. To a solution of benzyloxycarbonyl-L-amino acid (0.05 mol) in THF (200 ml), $COCl_2$–ether (25 ml, containing 0.05 mol of $COCl_2$) was added at −20——30 °C. TEA (7 ml, 0.05 mol) in ether (15 ml) was then stirred, drop by drop, into the solution over a 30 min period at the same temperature. After 30 min, TEA (7 ml, 0.05 mol) in ether (15 ml) was again added to the reaction mixture in the same manner as above. After 30 min, to the reaction mixture, a solution of L-amino acid (0.05 mol) in 2M sodium hydroxide was added at −10 °C; the reaction was then continued overnight with stirring at 0——5 °C. After adding ethyl acetate (600 ml), the reaction mixture was washed with 1 N hydrochloric acid and water, and then dried over magnesium sulfate. Evaporation *in vacuo* gave a mixture of Z-dipeptide and Z-amino acid. Crystallization was repeated with an appropriate solvent system.

p-*Toluenesulfonyl*-L-*phenylalanyl-glycine Ethyl Ester (29)*. To a solution of *p*-toluenesulfonyl-L-phenylalanine (31.9 g, 0.1 mol) in THF (200 ml), a $COCl_2$–ether solution (50 ml, containing 0.1 mol of $COCl_2$) was added at −20 °C. TEA (14 ml, 0.1 mol) in ether (30 ml) was added, drop by drop, to the solution at −20——30 °C. After 30 min, TEA (14 ml, 0.1 mol) in ether (30 ml) was again added to the reaction mixture in the same way as above. Ethyl glycinate hydrochloride (14 g, 0.1 mol) dissolved in $CHCl_3$ (300 ml) was neutralized with TEA (14 ml, 0.1 mol); then the $CHCl_3$ solution was stirred into the reaction mixture at −20 °C. The reaction was allowed to continue overnight at 0—10 °C. 600 ml of $CHCl_3$ was added to the reaction mixture, which was then worked up in the same manner as had been described as the General Procedure. Recrystallization from ethyl acetate afforded 19.9 g (49.4%).

A Kinetic Study on the Decomposition of Benzyl *N*-(Hydroxymethyl)carbamate in Alkaline Solution[1]

Shigeya TAKEUCHI

Department of Chemistry, Faculty of Education, Toyama University, Gofuku, Toyama

(Received August 11, 1972)

The decomposition of benzyl *N*-hydroxymethylcarbamate (*N*-BHMC) by potassium hydroxide was carried out in a mixed solvent dioxane–water. The following rate equation was obtained. $R_0=k[N\text{-BHMC}]_0[\text{KOH}]_0$, where $[N\text{-BHMC}]_0$ and $[\text{KOH}]_0$ denote the initial concentrations of *N*-BHMC and potassium hydroxide, respectively. The equation is analogous to that of Ugelstadt[2] obtained for the hydrolytic decomposition of *N*-hydroxymethylbenzamide. Thus the reaction was assumed to proceed *via* the three steps:

1) $C_6H_5CH_2OCONHCH_2OH + OH^- \rightleftharpoons C_6H_5CH_2OCONHCH_2O^- + H_2O$
2) $C_6H_5CH_2OCONHCH_2O^- \rightleftharpoons C_6H_5CH_2OCONH^- + CH_2O$
3) $C_6H_5CH_2OCONH^- + H_2O \rightleftharpoons C_6H_5CH_2OCONH_2 + OH^-$

We studied the reaction of benzyl carbamate (BC) with formaldehyde (F) in an aqueous dioxane solution using potassium hydroxide as a catalyst.[3] It was found that the rate equation is given by

$$R_0' = k'[\text{BC}]_0[\text{KOH}]_0[\text{F}]_0^{1 \text{ or } 0}$$

and the reaction order of formaldehyde changes from 1 to 0 with its concentration.

The following rate equation was obtained for the rate of decomposition of benzyl *N*-hydroxymethylcarbamate (*N*-BHMC) by potassium hydroxide.

$$R_0 = k[N\text{-BHMC}]_0[\text{KOH}]_0$$

where $[N\text{-BHMC}]_0$ and $[\text{KOH}]_0$ denote the initial concentrations of *N*-BHMC and potassium hydroxide, respectively.

The mechanism for decomposition of *N*-BHMC might be the same as Ugelstadt's in the reaction of the hydrolytic decomposition of *N*-hydroxymethylbenzamide.

Experimental

Materials. Benzyl carbamate was prepared by the method of Kraft[4] and recrystallized from toluene. Commercial toluene was used without further purification. Commercial dioxane was distilled at 101 °C.

Preparation of N-BHMC. To 15.1 g (0.1 mol) of benzyl carbamate in a 300 ml three-necked flask equipped with a stirrer, thermometer and condenser were added 12.2 g (0.15 mol) of 37% formaldehyde and 100 ml of water. The reaction mixture was stirred for 30 min at 60 °C at pH 8.6. Subsequently, the mixture was dissolved in 30 ml of methanol and cooled in a refrigerator. The solid separated was recrystallized from toluene to give *N*-BHMC as white needles; 10.2 g (5.6%), mp 86.5—87.5 °C. A test with a Tollens reagent was positive. IR (cm^{-1}); 3330 (ν(NH), ν(OH)), 1690 (ν(C=O)), 1520 (ν(CN)+δ(NH)). NMR (ppm); 7.94 (1H, –NH–), 7.39 (5H, $-C_6H_5$), 5.5—5.7 (1H, –OH), 5.1 (2H, $-CH_2-$), 4.4—4.64 (2H, $-N-CH_2O-$).

Found: C, 59.22; H, 6.38; N, 7.81%. Calcd for $C_8H_9NO_2$: C, 59.35; H, 6.59; N, 7.69%.

Measurement of the Rate of Decomposition. The rate was derived by measurement of the quantity of formaldehyde formed from the hydrolytic decomposition of *N*-BHMC.

A mixture of fixed amount of *N*-BHMC and 35 ml of dioxane was placed in a 50 ml volumetric flask and kept at constant temperature. After 20—30 min, a fixed amount of an aqueous solution of potassium hydroxide and then water were added up to the marked line, the time when the potassium hydroxide was added being taken as the starting time. 5 ml of the reaction mixture was then taken out at intervals. The concentration of the formaldehyde caused by the decomposition of *N*-BHMC was estimated by the KCN–

$Hg(NO_3)_2$ method.[5]

Results and Discussion

Reaction Order of N-*BHMC in the Hydrolytic Decomposition.* With the concentration of potassium hydroxide kept at 8.55×10^{-4} mol/l, the concentration of *N*-BHMC varied from 0.01 to 0.08 mol/l. A linear relationship was obtained between $\log a/(a-x)\times10^{-3}$ and t, where the initial concentrations of *N*-BHMC and formaldehyde resulting from the reaction were given as a and x. Figure 1 shows the relationship between $\log a/(a-x)\times10^{-3}$ and t.

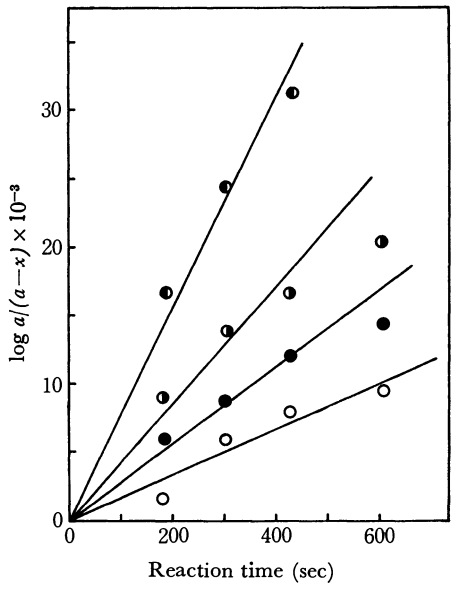

Fig. 1. The relationship between $\log a/(a-x)$ and t.
a=initial concentrations of *N*-BHMC.
x=consumption of *N*-BHMC.
N-BHMC in mol/l: -○- 0.01; -●- 0.02; -◑- 0.04; -◐- 0.08.

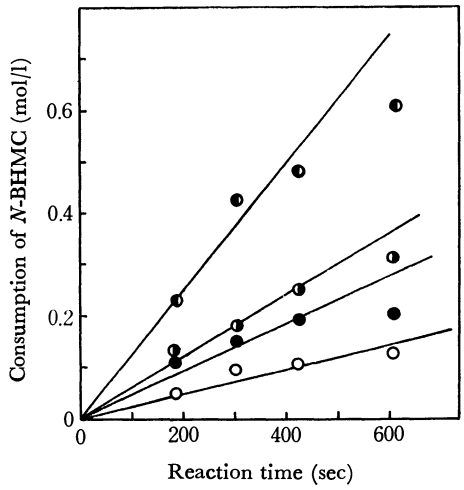

Fig. 2. The consumption of *N*-BHMC *vs.* reaction time at 35 °C.
The reaction conditions were as follows:
N-BHMC 0.04 mol/l. KOH 2.57—12.82×10^{-4} mol/l.

4) W. M. Kraft, *J. Amer. Chem. Soc.*, **70**, 3569 (1948).
5) J. I. de Jonge and J. de Jonge, *Rec. Trav. Chim. Pays-Bas*, **72**, 356 (1953).

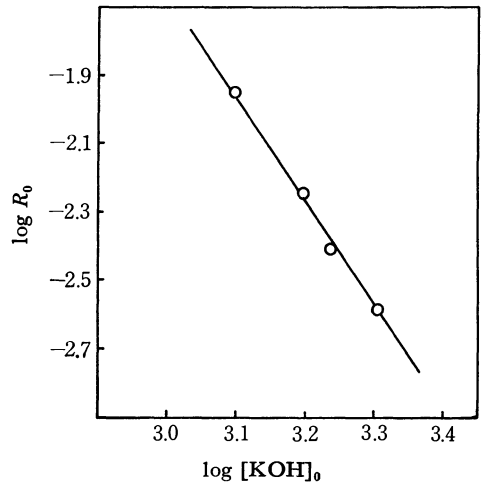

Fig. 3. The relationship between the rate and the concentration of KOH.

The reaction order of *N*-BHMC on the formation of formaldehyde is concluded to be 1.

Reaction Order of Potassium Hydroxide. With the concentration of *N*-BHMC kept at 0.04 mol/l, the concentration of potassium hydroxide varied from 2.57 to 12.82×10^{-4} mol/l. The rate of formation of formaldehyde increased linearly with progress of the reaction (Fig. 2), and the reaction order in potassium hydroxide was determined to be 1 from the slope of the straight line (Fig. 3).

From these results, the rate equation can be represented as follows.

$$R_0 = k[N\text{-BHMC}]_0[\text{KOH}]_0$$

Activation Energy of the Reaction. The activation energy of reaction of decomposition of *N*-BHMC in the presence of potassium hydroxide was calculated to be 14.4 kcal/mol at 30, 35, 40, 45, and 50 °C (Fig. 4). The value was higher than that of the reaction of formation of *N*-BHMC from benzyl carbamate and formaldehyde (13.8 kcal/mol). The activation entropy was calculated to be −22.24 e.u.

The Reaction Mechanism. Benzyl carbamate and

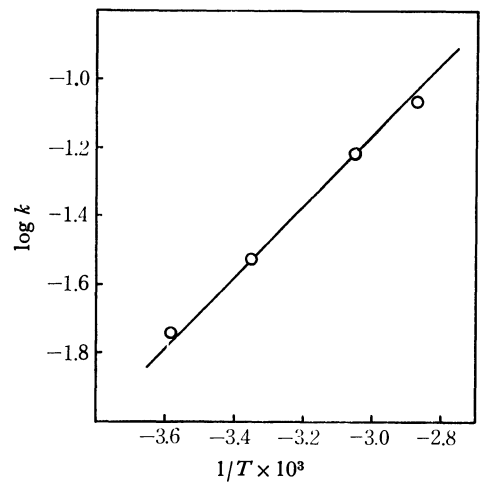

Fig. 4. The relationship between $\log k$ and T.

formaldehyde were proved to be obtained from the reaction of decomposition of *N*-BHMC.

$$C_6H_5CH_2OCONHCH_2OH \xrightarrow{OH^-} C_6H_5CH_2OCONH_2 + CH_2O$$

The reaction might proceed *via* the three steps which Ugelstadt showed in the reaction of decomposition of *N*-hydroxymethylbenzamide.

(1) $C_6H_5CH_2OCONHCH_2OH + OH^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} C_6H_5CH_2OCONHCH_2O^- + H_2O$

(2) $C_6H_5CH_2OCONHCH_2O^- \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} C_6H_5CH_2OCONH^- + CH_2O$

(3) $C_6H_5CH_2OCONH^- + H_2O \rightleftharpoons C_6H_5CH_2OCONH_2 + OH^-$

Reactions (1) and (3) are supposed to reach equilibria rapidly. The rate of decomposition is given by

$$R_0 = k_2[C_6H_5CH_2OCONHCH_2O^-] \quad \text{(a)}$$

From the steady state method we obtain

$$\frac{d[N\text{-BHMC}^-]}{dt} = k_1[N\text{-BHMC}][OH^-] - k_{-1}[N\text{-BHMC}^-] - k_2[N\text{-BHMC}^-] = 0$$

Thus

$$[N\text{-BHMC}^-] = \frac{k_1[N\text{-BHMC}][OH^-]}{k_{-1}+k_2} \quad \text{(b)}$$

From Eqs. (a) and (b) we get

$$R_0 = \frac{d[F]}{dt} = k_2[N\text{-BHMC}^-] = \frac{k_2k_1[N\text{-BHMC}][OH^-]}{k_{-1}+k_2} = \frac{k_2k_1}{k_{-1}+k_2}[N\text{-BHMC}][OH^-] = k[N\text{-BHMC}][OH^-]$$

The author wishes to express his thanks to Prof. Minoru Imoto, Kansai University, for his guidance,to Prof. Masayoshi Kinoshita, Osaka City University, for suggestions and encouragement, and to Dr. Eisaku Ninagawa, for valuable discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1498—1501 (1973)

The Reactions of 2-Hydroxybenzophenones with Lead Tetraacetate and Manganic Acetate

Kazu KUROSAWA, Yasuko SASAKI,* and Mikio IKEDA**

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-2-39-1, Kumamoto

(Received August 11, 1972)

2-Hydroxy-4-methoxy- and 2-hydroxy-4,4′-dimethoxybenzophenones were oxidized to dimeric compounds with lead tetraacetate and with manganic acetate. 2-Hydroxy-2′,4,4′-trimethoxy- and 2-hydroxy-3′,4,4′-trimethoxybenzophenones were oxidized to substituted xanthones. The structures of the products were determined by NMR and mass spectra, and were confirmed by syntheses.

In the reaction of phenolic compounds with lead tetraacetate, it was demonstrated that oxidative cyclization took place in 2′-hydroxychalcones[1,2] and in the Schiff base from *o*-aminophenols,[3] giving rise to aurones and benzoxazols respectively. We investigated the reactions of 2-hydroxybenzophenones with lead tetraacetate and with manganic acetate in the hope that they could be oxidized to xanthones; it was found that trisubstituted 2-hydroxybenzophenones did give xanthones and that mono- and di-substituted 2-hydroxybenzophenones give dimeric products.

When 2-hydroxy-4-methoxybenzophenone (Ia) and 2-hydroxy-4,4′-dimethoxybenzophenone (Ib) were treated with lead tetraacetate and with manganic acetate respectively, several products (II, III, IV, and VI) were isolated after separation by column chromatography and preparative tlc. They are listed in Table 1.

Product (IIb) has a higher melting point (232—234 °C), and its mass spectrum showed the molecular ion at *m/e* 514, corresponding to a molecular formula of $C_{30}H_{28}O_8$. This indicates that IIb is a dimeric compound. The IR and UV spectra of IIb were very similar to those of Ia and Ib (Table 2). The NMR spectra (60 MHz) of IIa, IIb, their acetates (Ac-IIa and Ac-IIb), and a methyl ether (Me-IIb) showed two singlets in the aromatic region, indicating the presence of *para*-related protons. This reveals that the newly-formed bond is located at the C_5-position in IIb. The chemical shifts of the protons and other protons on phenyl and *p*-methoxyphenyl groups were well correlated in these compounds (Table 3). These spectral data showed that IIb is 5,5′-bis(*p*-methoxybenzoyl)-4,4′-dihydroxy-2,2′-dimethoxybiphenyl. The structure of IIa was also determined to be 5,5′-dibenzoyl-4,4′-dihydroxy-2,2′-dimethoxybiphenyl.

The IIIb product, $C_{15}H_{14}O_5$ (mp 164—165 °C), was obtained only when lead tetraacetate was used in the

reaction; it was isolated from the mother liquor of IIb. The IR spectrum of IIIb was quite similar to those of IIa and IIb except that an absorption due to a hydroxyl group appeared at 3565 cm^{-1}. Its NMR spectrum showed two singlets in the aromatic region, again indicating the presence of *para*-related protons: the rest of the spectrum was very close to that of IIb. Thus, the structure of IIIb was determined to be 2-(*p*-methoxy) benzoyl-5-methoxyhydroquinone; this was finally confirmed by synthesis. The reaction of 2-methoxyhydroquinone[9] and anisic acid, with boron-trifluoride as a catalyst, gave IIIb. IIIa was also prepared in a similar way.

The IVb product, $C_{30}H_{24}O_9$ (analysis and mass spectrum) (mp 207—208 °C), showed complicated carbonyl absorptions (1620—1680 cm^{-1}) in the IR spectrum, indicating the presence of quinone carbonyls. The NMR spectrum of IVb (60 MHz) exhibited four methoxy groups (at δ 3.76, 3.85, 3.88, and 3.91), three protons (at δ 6.02 (s), 6.40 (s), and 7.38 (s)), two *para*-substituted phenyl groups (at δ 6.83 (d, 2H), 7.78 (d, 2H), 7.00 (d, 2H), and 7.52 (d, 2H)), and a proton at a lower field corresponding to a hydroxyl proton. These spectral data showed that a bond formation took place at the phenyl group having the hydroxyl group. This leads to two possible structures; *p*-quinone (IVb) and *o*-quinone (IVb'). Considering that the singlet appeared at δ 6.02, the *p*-quinone structure (IVb) is favored; IVb' must be oxidized further to a symmetrical biquinone which was not found in the reaction mixture. The IVb was determined to be 3-(4'-hydroxy-2'-methoxy-5'-*p*-methoxybenzoyl) phenyl-2-methoxy-5-(*p*-methoxy)benzoylbenzoquinone. Similarly, the structure of IVa was also determined to be 5-benzoyl-3-

(5'-benzoyl-4'-hydroxy-2'-methoxy)phenyl-2-methoxybenzoquinone. Benzoic acid (VIa) and anisic acid (VIb) were obtained from the reaction mixtures of Ia and Ib respectively, and were identified with authentic samples by studying their IR spectra.

When 2-hydroxy-2',4,4'-trimethoxybenzophenone (Ic) and 2-hydroxy-3',4,4'-trimethoxybenzophenone (Id) were oxidized with lead tetraacetate or with manganic acetate, Vc and Vd respectively were obtained as the products. The mass spectrum of Vc showed the molecular ion at *m/e* 256, corresponding to a molecular formula of $C_{15}H_{12}O_4$; this indicated that an intramolecular coupling between the hydroxyl group and the C_2'-position in Ic took place and that the methanol was removed from Ic. Vc was found to be 3,6-dimethoxyxanthone; it was identical with that prepared from Ie.[6] The structure of Vd was similarly determined to be 2,3,6-trimethoxyxanthone. This was also identified by independent synthesis from If.

2,4-Dimethoxybenzoic acid (VIc) and 3,4-dimethoxybenzoic acid (VId) were isolated from reaction mixtures of Ic and Id respectively. They were identified with authentic samples by a comparison by their IR spectra and also by the vpc of their methyl esters. Thus, the reaction takes place as expected in the cases of Ic and Id, but the reaction with Ia and Ib are not so simple.

The formation of the dimeric products (IIa, IIb, IVa, and IVb) may suggest a free radical mechanism,[10-12] but an ionic mechanism cannot be ruled out, for a phenoxylium cation has been known to convert to a dimeric product with phenol:[13]

$$ArOH + ArO^+ \longrightarrow \text{dimeric product} + H^+$$

Both paths are equally probable, and no conclusive evidence to differentiate these two paths in the present situation is available at this time.

Although only four of the benzophenones were examined so far, this reaction was shown to be an useful method in synthesizing xanthones from 2-hydroxybenzophenones.

Experimental

NMR spectra were recorded for deuteriochloroform solutions with a Hitachi NMR spectrometer model R-20B with

tetramethylsilane as an internal standard; IR spectra were recorded for chloroform solutions with a JASCO DS 403G grating spectrometer; UV spectra were obtained for methanol solutions with a Hitachi EPS-3T spectrophotometer; mass spectra were recorded with a Hitachi mass spectrometer, RMU-6L; vpc were recorded with a Shimadzu GC-1C using polyethyleneglycol-succinate at 200 °C. Preparative and analytical tlc were carried out with Wakogel B10. Melting points were determined with a Yanagimoto micro-melting-point apparatus and uncorrected.

Materials. Lead tetraacetate and manganic acetate were prepared according to the references.[14,15]

2-Hydroxybenzophenones. 2-Hydroxybenzophenones (Ib, Ic, and Id) were prepared from 3-methoxyphenol and corresponding benzoic acids with boron trifluoride as catalyst and purified by recrystallization from ethanol. Ia was obtained from partial methylation of 2,4-dihydroxybenzophenone[4] which was prepared by the reaction of resorcinol and benzoic acid. If was prepared by the reaction of 3,4-dimethoxyphenol[16] (500 mg) and 2-hydroxy-4-methoxybenzoic acid[17] (450 mg) with phosphorus oxychloride (3.5 ml) and fused zinc chloride (1.5 g) heating at 65—70 °C for 1 hr and separated on silica gel (20 g) eluting with benzene, followed by recrystallization from ethanol. IIIa and IIIb were prepared by the reaction of 2-methoxyhydroquinone[9] (10 mmol), and benzoic acid (10 mmol) and anisic acid (10 mmol), respectively, with boron trifluoride etherate (20 ml), heating at 100 °C for 30—45 min. This gave IIa (5%) and IIIb (26%), respectively.

Reaction of Lead Tetraacetate with 2-Hydroxybenzophenones (Ia—d). 2-Hydroxybenzophenone (10 mmol) and lead tetraacetate (20 mmol) were dissolved in acetic acid (100 ml) and heated at 100 °C for 5 hr. After removal of the acetic acid, the resulting viscous liquid was treated with 2N sulfuric acid and then extracted with chloroform (100 ml). The chloroform layer was washed with aqueous sodium bicarbonate and saturated sodium chloride solution. The chloroform solution was evaporated and the residue was separated on silica gel (100 g). The column was eluted with benzene and then chloroform. From benzene fraction, II, III, and V were obtained after recrystallization from benzene or ethanol. The chloroform fraction was concentrated and again separated on tlc effected with chloroform, but this failed to give any crystalline compound. After acidification of the sodium bicarbonate solution, VI was obtained.

Reaction of Manganic Acetate with 2-Hydroxybenzophenones (Ia—d). 2-Hydroxybenzophenone (10 mmol) and manganic acetate (40 mmol) was dissolved into acetic acid (100 ml) containing acetic anhydride (1.0 ml). The mixture was heated at 100 °C until the colour of the manganic acetate disappeared. It usually took 5 hr. After removal of the acetic acid and acetic anhydride, the remaining viscous liquid was treated with 2N sulfuric acid (100 ml) and then extracted with chloroform. Working up in the same way as in the above, products II, IV, V, and VI were obtained.

Acetylation of II. IIa (100 mg) and IIb (100 mg), respectively, were treated with acetic anhydride (0.5 ml) in pyridine (1 ml) at room temperature overnight. The reaction mixture was poured into iced water and the precipitates were collected. After recrystallization from ethanol Ac-IIa (89 mg, 75%) and Ac-IIb (106 mg, 91%) were obtained.

Methylation of IIb. IIb (50 mg) was treated with dimethylsulfate (128 mg) in acetone (10 ml) containing anhydrous potassium carbonate (283 mg) under reflux for 4 hr. After removal of the acetone, the residue was triturated with water and the precipitates were collected. The crude product was recrystallized from ethanol to give a methyl ether (Me-IIb) (42 mg, 80%).

2,3,6-Trimethoxyxanthone (Vd). 2,2′-Dihydroxy-4,4′,5-trimethoxybenzophenone (If) (100 mg) was heated in water in a sieled tube at 230—240 °C for an hr. The crude product was collected and recrystallized from a mixture of chloroform and ethanol. This gave Vd (64 mg, 68%).

Authors wish to thank Dr. Shinzaburo Hishida and the staff of Hitachi Co., Ltd. at Katsuta for measuring NMR and mass spectra.

Chemistry of Mixed Transition-metal Complexes. V.[1] The Preparation of Several Mixed Transition-metal Complexes with Two μ-Diphenylphosphido Groups

Katsutoshi YASUFUKU and Hiroshi YAMAZAKI
The Institute of Physical and Chemical Research, Wako-shi, Saitama

(Received August 21, 1972)

Several mixed transition-metal complexes with two μ-diphenylphosphido groups as bridging ligands were prepared from bis(diphenylphosphine)metal complexes and diiodometal complexes by means of the action of amine or a Grignard reagent.

Homometallic dinuclear complexes with two μ-phosphido groups have been studied extensively,[2] but few of the heterometallic dinuclear complexes are known. Only one patent claim of $(CO)_nM\text{-}(\mu\text{-}PR_2)_2\text{-}M'(CO)_m$ [M=Cr, Mo, W (n=4), M'=Fe (m=3), R=Ph; M=Cr, M'=Mo (n= m=4), R=CH_3,] has been reported.[3] In the previous papers[4,5] of this series, we reported the preparation of mixed transition-metal complexes with one μ-diphenylphosphido group from the diphenylphosphinemetal complexes and the halogenometal complexes by dehydrohalogenation with amines. Now, we wish to report the preparation of several mixed transition-metal complexes with two μ-diphenylphosphido groups from bis(diphenylphosphine)metal complexes and diiodometal complexes; this is as an extension of the previous work.

Results and Discussion

The treatment of an equimolar mixture of carbonyl-π-cyclopentadienyldiiodocobalt (I) and tricarbonyl-bis-(diphenylphosphine)iron (II) with excess diethylamine in methylene chloride at room temperature gave π-cyclopentadienylcobalt-bis(μ-diphenylphosphido)tricarbonyliron (III) as brown crystals. The mass spectrum shows the molecular ion at m/e 634 and ions corresponding to the successive losses of three carbonyls. The IR spectrum (in benzene) shows $\nu_{C\equiv O}$ at 2000s and 1945s cm^{-1} and indicates that the carbonyls are all of the terminal type.

$$\underset{\text{I}}{\pi\text{-}C_5H_5Co(CO)I_2} + \underset{\text{II}}{(HPh_2P)_2Fe(CO)_3} \xrightarrow{Et_2NH} \underset{\text{III}}{\pi\text{-}C_5H_5Co(\mu\text{-}PPh_2)_2Fe(CO)_3}$$

A similar treatment of a mixture of I or tetracarbonyl-diiodoiron (IV) with tetracarbonyl-bis(diphenylphosphine)molybdenum[6] failed to give the desired mixed-metal complexes, although the tetracarbonyl-molybdenum-bis(μ-diphenylphosphido)tricarbonyliron had been prepared by the reaction of tetracarbonyl-diphenylphosphineiron with pentacarbonyl-chlorodiphenylphosphinemolybdenum.[3]

It is known that bis(triphenylphosphine)-π-cyclopentadienyl-cobalt and -rhodium, π-$C_5H_5M(PPh_3)_2$ (M=Co, Rh), can readily be prepared by the treatment of triphenylphosphine-π-cyclopentadienyl-diiodo-cobalt and -rhodium with isorpopylmagnesium bromide in the presence of triphenylphosphine.[7] We also attempted to prepare new bis(diphenylphosphine)metal complexes of the π-$C_5H_5M(PPh_2H)_2$ type according to this procedure. The treatment of I, π-cyclopentadienyl-diiodo-rhodium (V), or -iridium (VI) with an equimolar amount of diphenylphosphine afforded monodiphenylphosphine complexes of the π-$C_5H_5M(PPh_2H)I_2$ type (VII, M=Co; VIII, M=Rh; IX, M=Ir). The treatment of I or V with two molar equivalents of diphenylphosphine, or the treatment of VII or VIII with one molar equivalent of diphenylphosphine, gave bis-diphenylphosphine complexes of the π-$C_5H_5M(PPh_2H)_2I_2$ type (X, M=Co; XI, M=Rh). No corresponding iridium complex was obtained. The compounds thus obtained are summarized in Table 1. All the compounds are very stable in air. The solubility of the bis-diphenylphosphine complexes is lower than that of the corresponding mono-diphenylphosphine complexes, probably because of the influence of the partial ionic character.

Though attempts to isolate the π-$C_5H_5M(PPh_2H)_2$ complexes were not successful, several new mixed transition-metal complexes with two μ-diphenylphosphido groups were obtained by the reaction of the bis-diphenylphosphine complexes, X and XI, with isopropylmagnesium bromide in the presence of some diiodometal complexes. Thus, the treatment of X with excess isopropylmagnesium bromide in the presence of an equimolar amount of IV gave III in a yield comparable with that of the amine method described above. The use of isopropylmagnesium bromide instead of the amine in the reaction of I with II also afforded III. This suggests that the Grignard reagent may act not only as a reducing agent, but also as a base, though no

a) Measured in $CDCl_3$. Protons of PPh_2 appeared in 2.0—3.3 τ as multiplet.
b) No elemental analysis was carried out because of the failure to obtained enough amount.

exact mechanism is clear from these observations only. Tricarbonyliron-bis(μ-diphenylphosphido)-π-cyclopentadienylrhodium (XII) was prepared from XI and IV by a similar treatment. The mass spectrum of XII showed a pattern similar to that of III.

π-$C_5H_5M(PPh_2H)_2I_2$ + $I_2Fe(CO)_4$
X (M=Co), XI (M=Rh) IV

$\xrightarrow{i\text{-PrMgBr}}$ π-C_5H_5M(–P(Ph)–)$_2$–$Fe(CO)_3$

III (M=Co)
XII (M=Rh)

The similar treatment of XI with I afforded π-cyclopentadienylcobalt-bis(μ-diphenylphosphido)-π-cyclopentadienylrhodium (XIII).

π-$C_5H_5Rh(PPh_2H)_2I_2$ + π-$C_5H_5Co(CO)I_2$
XI I

$\xrightarrow{i\text{-PrMgBr}}$ π-C_5H_5Rh(–P(Ph)–)$_2$–Co-π-C_5H_5

III

The homometallic bis-μ-diphenylphosphido complexes of cobalt (XIV) and of rhodium (XV) were obtained by the treatment of the mono-diphenylphosphine complexes, VII and VIII respectively, with isopropylmagnesium bromide. The iridium analogue (XVI) was also obtained from IX, though the yield was very low. The cobalt complex (XIV) is already known,[8] but the other two complexes are new ones. All the compounds are stable in air, and in their mass spectra the parent ion peak is the strongest in every case.

π-$C_5H_5M(PPh_2H)I_2$ $\xrightarrow{i\text{-PrMgBr}}$ π-C_5H_5M(–P(Ph)–)$_2$–M-π-C_5H_5

VII (M=Co), VIII (M=Rh), XI (M=Ir)

XIV (M=Co)
XV (M=Rh)
XVI (M=Ir)

The reaction of an equimolar mixture of the monodiphenylphosphine complexes of cobalt (VII) and rhodium (VIII) with isopropylmagnesium bromide afforded a mixture of XIII, XIV, and XV as the product. A similar treatment of a mixture of the

8) R. G. Hayter, *Inorg. Chem.*, **2**, 103 (1963).

mono-diphenylphosphine complexes of rhodium (VIII) and iridium (IX) gave only a mixture of XV and XVI. The failure to detect a mixed metal complex of rhodium and iridium is probably the result of differences in the reactivities of the mono-diphenylphosphine complexes and/or the stabilities of the reaction intermediates.

The data for the bis(μ-diphenylphosphido)metal complexes prepared are collected in Table 2.

Experimental

The preparations were carried out under an atmosphere of nitrogen. The diphenylphosphine was prepared as has been described in a previous paper,[5] while the tricarbonyl-bis-(diphenylphosphine)iron was prepared by the method of Thompson.[6] The carbonyl-π-cyclopentadienyl-diiodo-cobalt (I),[9] π-cyclopentadienyl-diiodo-rhodium (V),[10] and -iridium (VI)[11] were prepared according to the known procedures. The melting points were determined using a Yanaco micro-melting-point apparatus. The spectra were measured with a Perkin-Elmer grating infrared spectrophotometer, Type 521, a JEOL nuclear magnetic resonance spectrometer, Type C-60, and a JEOL mass spectrometer, Type 1S, at 75 eV.

Preparation of Diphenylphosphine Complexes. To a solution of I (2.0 g, 4.9 mmol) in CH_2Cl_2 (50 ml) was added diphenylphosphine (1.0 g, 5.4 mmol) under magnetic stirring. After the evolution of gas had ceased, the solution was concentrated. The subsequent addition of hexane gave black crystals of VII (2.3 g). For analytical purposes, the compound was purified by chromatography on a silica-gel column (Wakogel C-200).

In the case of the preparation of the rhodium and iridium analogues (VIII and IX), the reactions were continued until all of the almost-insoluble V and VI disappeared.

For the preparation of the bis-diphenylphosphine complexes (X and XI), two molar equivalents of diphenylphosphine to V or VI were employed.

The results are summarized in Table 1.

Preparation of π-$C_5H_5M(\mu$-$PPh_2)_2Fe(CO)_3$ (III, M=Co; XII, M=Rh). *Method (a)*: I (0.10 g, 0.25 mmol) and II (0.12 g, 0.23 mmol) were stirred in THF (12 ml) with diethylamine (0.3 ml) at room temperature for two days. The reaction mixture was then evaporated under reduced pressure, and the residue dissolved in benzene was chromatographed on a silica-gel column. From the brown fraction eluted with a hexane–benzene mixture (1/1), dark brown crystals of III (0.024 g) were obtained.

Method (b): To a solution of X (0.23 g, 0.31 mmol) and IV (0.15 g, 0.35 mmol) in THF (20 ml) and benzene (10 ml) was added isopropylmagnesium bromide (5 ml) in ether (5 ml). The reaction mixture was hydrolyzed with aqueous ammonium chloride, and the organic layer was dried with sodium sulfate. After concentration, the residue was chromatographed on a silica-gel column and eluted by a benzene–hexane mixture (1/1). From the brown eluate, dark brown crystals of III (0.033 g) were obtained.

By the same procedure, the rhodium-iron complex, XII (0.039 g), was obtained from XI (0.24 g, 0.30 mmol) and IV (0.13 g, 0.31 mmol).

Mcthod (c): I (0.10 g, 0.25 mmol) and II (0.12 g, 0.23 mmol) were treated in THF (10 ml) and benzene (5 ml) with isopropylmagnesium bromide (2 mmol) in ether (2 ml) at 0 °C for 5 hr. A procedure similar to that used in the (b) method gave III (0.018 g).

Preparation of π-$C_5H_5Co(\mu$-$PPh_2)_2Rh$ π-C_5H_5 (XIII). To a solution of XI (0.26 g, 0.33 mmol) and I (0.41 g, 0.10 mmol) in THF (15 ml) and benzene (30 ml) was added lsopropylmagnesium bromide (6 mmol) in ether (6 ml) at 0 °C. After several minutes, the reaction mixture was hydrolyzed with aqueous ammonium chloride and the organic layer was dried with sodium sulfate. After concentration, the residue was chromatographed on an alumina column and eluted by a benzene–hexane mixture (1/1). From the brown eluate, black crystals of XIII (0.054 g) were obtained.

Preparation of π-$C_5H_5M(\mu$-$PPh_2)_2M$ π-C_5H_5, (XIV, M=Co; XV, M=Rh; XVI, M=Ir). A solution of VII (0.56 g, 1.0 mmol) in benzene (20 ml) was treated, drop by drop with isopropylmagnesium bromide (5 mmol) in ether (5 ml) at 0 °C. By a procedure similar to that presented above, black crystals of XIV (0.14 g) were obtained. Similarly, XV and XVI were prepared. All of the bis-μ-phosphido complexes thus prepared are summarized in Table 2.

Arylation of Olefin with Iodobenzene Catalyzed by Palladium

Kunio MORI, Tsutomu MIZOROKI, and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received October 4, 1972)

Arylation of propylene, ethylene, styrene, and methyl acrylate with iodobenzene was found to be catalyzed by metallic palladium in methanol to give methylstyrene, styrene, *t*-stilbene, and methyl cinnamate, respectively. Their yields and selectivities increased significantly by the addition of excess potassium acetate as an acceptor of hydriodic acid formed. The course of catalytic reaction is discussed in terms of the oxidative addition of iodobenzene to a palladium complex of low oxidation state.

Oxidative addition of organic halides to metal complexes of low oxidation state is well-known a method of σ-organometallic complexes. Before such an addition is made to a catalytic reaction, it should be considered whether the metal complex of low oxidation state specified as a catalyst is regenerated during the course of reaction. In the carbonylation of phenyl halide catalyzed by bis(triphenylphosphine)carbonylchlororhodium(I) in benzene,[1] benzoyl and halogen ligands are reductively eliminated from $C_6H_5CORh(PPh_3)_2(CO)(Cl)(X)$ to give benzoyl halide and $Rh(PPh_3)_2(CO)Cl$, with the result that the rhodium(I) complex works well as the catalyst. Nickel tetracarbonyl is also labile for oxidative addition of organic halides such as phenyl and allyl halides to give acyl nickel carbonyls.[2,3] In this case, however, these nickel complexes decompose into nickel(II) halide to give α-diketones or esters, their formation depending on the solvent used. Accordingly, nickel carbonyl seems to have no catalytic activity for the carbonylation of organic halide except under enforced reaction conditions. It was shown[4] that the carbonylation rate of phenyl halide with nickel carbonyl in methanol increased significantly by the addition of potassium acetate as an acceptor of hydrohalogenic acid formed. It was considered that the acid strongly inhibited the coordination of carbon monoxide to regenerate a nickel carbonyl of low oxidation state. The same effect of potassium acetate is also observed in the palladium black-catalyzed carbonylation of phenyl halide[5] in spite of the fact that metallic palladium has a higher oxidation potential than nickel. These results led us to investigate the effect of potassium acetate on other kinds of catalytic reactions to see whether the inhibition by proton is observed only in carbonylation. It was found that palladium black is highly active and selective for the catalytic arylation of olefin with iodobenzene in the presence of potassium acetate.[6] The present paper deals with the palladium catalyzed arylation of propylene, ethylene, styrene, and methyl cinnamate with phenyl halide to give the corresponding styrene derivatives.

Experimental

A given amount of palladium catalyst ($PdCl_2$ or Pd-black) and a methanol solution (30—35 ml) of phenyl halides and potassium acetate were placed in a titanium-alloy autoclave (100 ml) equipped with a magnetic stirrer (when liquid olefin was used, it was also dissolved in the methanol solution). The autoclave was purged thoroughly with nitrogen and gaseous olefin was then introduced. In the case of liquid olefin, nitrogen gas was charged up to 10 kg/cm^2. The autoclave was heated up to the desired temperature by an electric furnace within 20 min. and the temperature was kept constant for 2—3 hr. It was then cooled rapidly to room temperature with water and gaseous materials were discharged. The products were taken out from the autoclave by using a sufficient amount of methanol or acetone, and they were separated from palladium black before their amounts were quantitatively determined by gas chromatography, using a suitable substance as an internal standard. A DC-550 columun was used for the determination of styrene, α-, β-methylstyrene, methyl cinnamate, and phenyl halides, and a SE-30 columun for 1,1-diphenylethylene and *t*-stilbene with hydrogen as a carrier gas. All materials were commerical products, their purity being checked by gas chromatography before use.

Results

The effect of potassium acetate (pK_a of CH_3COOH= 4.7) on the arylation of ethylene with iodobenzene catalyzed by palladium dichloride in methanol was examined. The results are shown in Table 1. The yield of styrene increased with increase in the amount of potassium acetate, no residual iodobenzene being detected when the amount (mole) of potassium acetate added exceeded that of iodobenzene used. Most of the palladium dichloride was reduced to metallic palladium after the reaction. Pyridine (pK_a of $C_5H_5NH^+$=5.4) and sodium benzoate (pK_a of C_6H_5COOH=4.2) showed a similar effect on the arylation of ethylene. No catalytic arylation, however, was observed with potassium trichloroacetate (pK_a of CCl_3COOH=0.7). Palladium black also catalyzed the arylation with high activity as shown in Table 1. There is hardly any difference between palladium dichloride and palladium black in catalytic activity. The effect of acetic acid as a solvent was examined, since hydriodic acid formed by arylation gives potassium iodide and acetic acid during the reaction when potassium acetate is present in the reaction

medium. The addition of acetic acid as the solvent considerably decreased the yield of styrene (Table 2).

The effects of the amount of palladium black and palladium dichloride on the conversion of iodobenzene were examined at 75 °C, 100 °C, and 125 °C. The degrees of conversion of iodobenzene are plotted against the amount of palladium catalyst in Fig. 1. The conversion at 100 °C becomes nearly constant when the amount of palladium black and palladium dichloride exceeds 0.5 and 2.5 mmol, respectively. Palladium black seems to be more active than palladium dichloride. It is to be noted that a large amount of palladium dichloride gives nearly the same conversion as that obtained from palladium black. The selectivity of styrene formation is 60—90% (Table 1). Even under a higher pressure of ethylene, the selectivity is less than 90%, *t*-stilbene and 1,1-diphenylethylene being always detected. It was found that styrene is also arylated with iodobenzene to give quantitatively *t*-stilbene and 1,1-diphenylethylene (Table 3). This is why the selectivity of styrene from ethylene and iodobenzene is always less than 90%. The results of arylation of propylene, ethylene, styrene, and methyl acrylate are summarized in Table 4. These olefins give almost quantitatively methylstyrene, styrene, *t*-stilbene, and methyl cinnamate, respectively. Propylene gives a considerable amount of α-methylstyrene as well as β-methylstyrene, while methyl acrylate gives exclusively methyl cinnamate. Reactivity of phenyl halide decreases in the order $C_6H_5I > C_6H_5Br \gg C_6H_5Cl$, whereas the arylation of ethylene or propylene with a bromobenzene derivative (Table 5) shows that the reactivity of bromobenzene derivatives decreases in the order *p*-chlorobromobenzene > bromobenzene ≥ *p*-bromotoluene > *p*-bromoanisole. On the other hand, the yields of arylation product with bro-

mobenzene indicate that the reactivity of olefins decreases approximately in the order propylene>ethylene>styrene>methyl acrylate, where no arylation of methyl acrylate with bromobenzene is observed. Addition of triphenylphosphine slightly increased the yield of methylstyrene from propylene and bromobenzene. However, no effect was observed in the isomer distribution of methylstyrene. Triphenylphosphine reacted with iodobenzene to give tetraphenylphosphonium iodide almost quantitatively under the same reaction condition (calcd for $(C_6H_5)_4PI$: H, 4.17%; C, 60.37%; I, 27.23%. Found: H, 4.3%; C, 61.8 %; I, 27.2%).

Discussion

It was reported that ethylene or styrene is arylated with benzene in the presence of palladium(II) diacetate ($C_6H_6+C_6H_5CH=CH_2+Pd(AcO)_2 \rightarrow$ t-$C_6H_5CH=CH$-$C_6H_5+Pd+2AcOH$).[7] The arylation, however, consumes a stoichiometric amount of palladium(II) diacetate, which is reduced to metallic palladium. The arylation is not catalytic with respect to palladium with no simultaneous reoxidation of metallic palladium. Heck found that σ-phenylpalladium(II) acetate prepared from phenylmercuric acetate and palladium diacetate reacts with olefin under mild condition to give styrene derivatives:[8]

$$C_6H_5Hg(AcO) + Pd(AcO)_2 \rightarrow (C_6H_5)Pd(AcO) + Hg(AcO)_2$$

$$C_6H_5Pd(AcO) + CH_2=CH_2 \rightarrow C_6H_5CH=CH_2 + Pd + AcOH$$

In this case, the palladium(II) compound is also reduced into metallic palladium, arylation taking place stoichiometrically. However, arylation of olefin with iodobenzene is effectively catalyzed by metallic palladium, its catalytic efficiency being significantly large.

Palladium(II) dichloride is easily reduced to metallic palladium in a boiling methanol solution. Thus, most of the palladium(II) dichloride we used should be present as metallic palladium during the course of arylation. This may be why practically no difference is observed between palladium dichloride and metallic palladium in their catalytic activities (Table 1). The reaction rate must be determined by some interaction of phenyl halides with palladium catalyst, since their reactivity decreases in the order $C_6H_5I>C_6H_5Br\gg C_6H_5Cl$, which is parallel with the strength of bond energy between carbon and halogen atom. The question is whether the arylation is catalyzed by palladium black suspended in the methanol solution, or by palladium complex dissolved in it. If the suspended palladium black catalyzes the arylation of ethylene, the yield of styrene should increase with the amount of palladium catalyst, since the surface area of palladium black contacting iodobenzene must increase with the amount of palladium black. The yield of styrene, however, does not increase (Fig. 1). This suggests that an active species of the catalyst is some palladium complex dissolved in the methanol solution. Accordingly, the highest rate of arylation of olefin would be obtained with a saturated solution of the palladium complex. Palladium complexes are slightly soluble

in methanol, with the result that the conversion of iodobenzene does not increase with the increase in the amount of palladium catalyst (Fig. 1).

Another point to be considered is what kind of palladium complex is supplied from the palladium black suspended during the course of reaction. If the complex were present in the form of palladium(II) compound, arylation with benzene would be expected. This was examined by the arylation of styrene with benzene in the presence of iodobenzene, using a relatively large amount of palladium black. The total amount of arylation product (*t*-stilbene and 1,1-diphenylethylene) is almost equal to that of iodobenzene consumed (Table 6). This supports the view that palladium black supplies no palladium(II) compound which is active for the arylation of styrene with benzene. It can thus be postulated that the oxidation state of the active palladium complex is low, probably zero, in the solution.

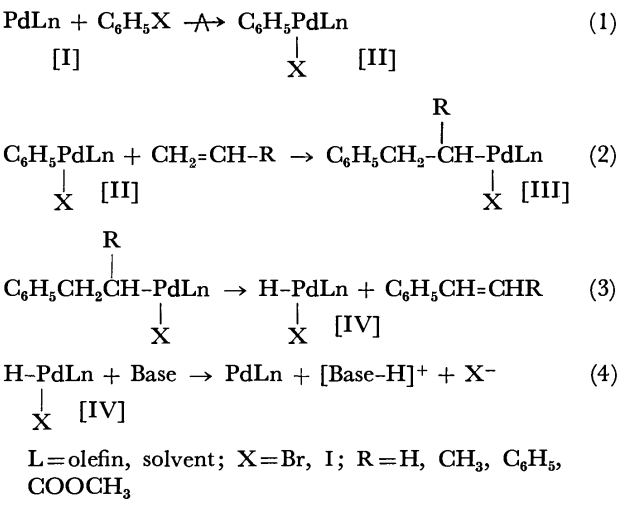
a) Based on the amount of C_6H_5I consumed

Taking into account the well-known oxidative addition of phenyl halide to low valent palladium complexes to give σ-aryl palladium(II) halide,[9] the following reaction scheme can be proposed;



Phenyl halide is oxidatively added to low valent palladium complex [I] to give σ-phenyl palladium complex[II], to which the olefin is inserted, followed by elimination of β-hydrogen to give [IV] and arylation product. Paths (2) and (3) have been investigated in detail.[8] Arylation with iodobenzene is significantly enhanced in a basic medium. This is in line with the fact that the yield of styrene considerably decreased in acetic acid solvent (Table 2). Such a basic medium should be favorable for paths (3) and (4) to regenerate the low valent palladium complex[10] and also for preventing the decomposition of σ-complex[II]. A stoichiometric reaction of styrene with bis(triphenylphosphine)σ-phenyl(iodo)palladium(II) was examined in methanol at its reflux temperature for the effect of potassium acetate on the reaction paths analogous to (2) and (3). No arylation of styrene was observed even in the presence of a large amount of potassium acetate, probably because triphenylphosphine inhibited the coordination of styrene to the palladium complex. The role of potassium acetate remains unclarified.

Syntheses of Some Cyanine Dyes of Bunte Salt Type

Masashi YAMAMOTO, Shigeo NAKAMURA, Kunio YOSHIMURA,
Masuo YUGE, Shiro MOROSAWA, and Akira YOKOO

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received October 18, 1972)

In order to investigate the photosensitivity of compounds such as photosensitizing dyes of Bunte salt type which have not been synthesized yet, the following compounds were prepared: 1,1′-di-(2-potassiumsulfothioethyl)-4,4′-tricarbocyanine acetate (VI), 1,1′-di-(2-potassiumsulfothioethyl)-2,2′-tricarbocyanine acetate (VII), 6,6′-dimethyl-3,3′-di-(2-potassiumsulfothioethyl)dithiacarbocyanine acetate (VIII), and 3-(2-bromoethyl)-3′-(sulfothioethyl)-5,6,5′,6′-tetramethoxydithiacarbocyanine (XII).

Three kinds of substituted 1-(2-bromoethyl)quinolinium bromide(II) (4-methyl (a), 2-methyl- (b), and 6-ethoxy-2-methyl- (c)) were subjected to reaction with sodium thiosulfate to yield the corresponding thiosulfates (IIIa, b, and c), respectively. Similarly, four kinds of substituted 4-(2-bromoethyl)benzothiazolium bromides (IV) (2-methyl- (a), 2,6-dimethyl-, (b), 6-methoxy-2-methyl- (c), and 2,5-dimethyl- (d)) gave the corresponding thiosulfates (Va, b, c, and d).

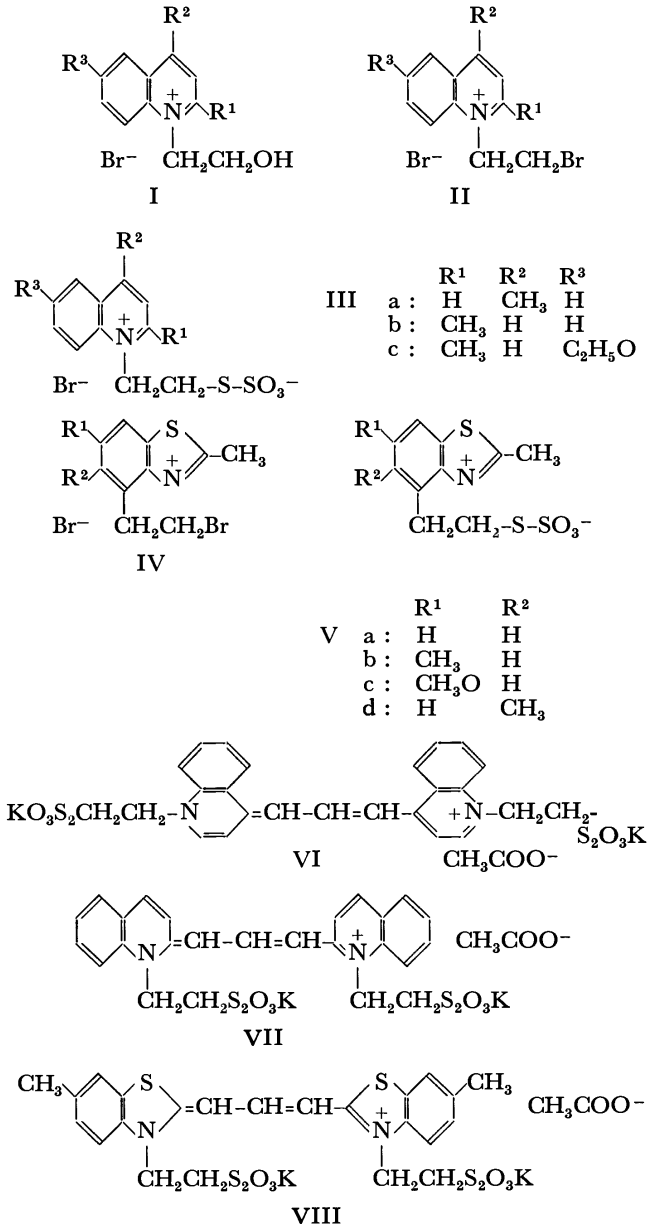

Fig. 1.

IIIa, IIIb and Vb yielded the corresponding cyanine dyes (VI, VII and VIII) in low yields on being heated[1] with aniline and ethyl orthoformate, followed by heating with acetic anhydride and potassium acetate. IIIa, IIIb, and Va gave their thiosulfates (IX, X and XI) by heating with aniline and ethyl orthoformate. In order to introduce a thiosulfate group into the carbocyanine dye, 3,3′-di-(2-bromoethyl)-5,6,5′,6′-tetramethoxydithiacarbocyanine bromide (XIV) was derived from the corresponding hydroxyethyl compound (XIII). However, it was found that only one bromoethyl group in XIV was converted into the sulfothioethyl group with sodium thiosulfate.

An attempt to obtain 1,1′-di-(2-potassiumsulfothioethyl)-2,4′-tricarbocyanine acetate by heating a mixture of IX and IIIb in the presence of acetic anhydride and potassium acetate gave a powder, which had an absorption maximum in the visible region, λ(MeOH)[2]

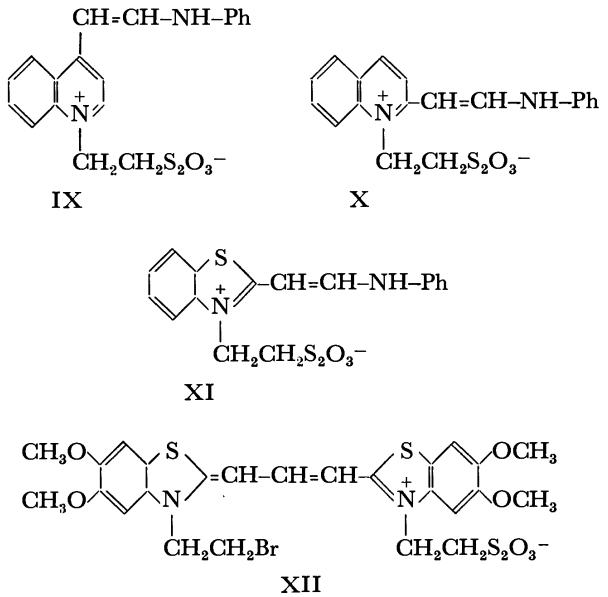

Fig. 2.

673—674 (ν(KBr)[3] 1209 and 1025). Reaction of IIIa with 1-(2-hydroxyethyl)-4-(phenylaminoethenyl)quinolinium bromide, expected to form 1-(2-hydroxyethyl)-1'-(2-potassiumsulfothioethyl)-4,4'-tricarbocyanine acetate, gave a powder possessing an absorption maximum in the visible region, λ(MeOH) 728 (ν(KBr) 1232, 1195, and 1021). An attempt to prepare 3,3'-di-(2-potassiumsulfothioethyl)dithiacarbocyanine acetate as in the formation of VIII yielded a crystal which showed an absorption maximum in the visible region, λ(EtOH) 556—557 (ν (KBr) 1221—1208 and 1024).

Experimental[4]

1-(2-Bromoethyl)-4-methylquinolinium Bromide (IIa). A mixture of 10.0 g of 1-(2-hydroxyethyl)-4-methylquinolinium bromide (I) and 8.0 g of phosphorus tribromide was heated at 110 °C for 10 min. The reaction mixture was triturated repeatedly with ether, and the solid was recrystallized from ethanol to give 11.4 g of colorless crystals, mp 205 °C (decomp.).

S-[2-(4-Methylquinolinium-1-yl)ethyl]thiosulfate (IIIa). A mixture of 10.0 g of IIa and 8.0 g of sodium thiosulfate in 120 ml of water was heated on a water bath for 2.5 hr and then kept in a refrigerator. The crystals fromed were collected, washed with 30 ml of ethanol and finally recrystallized from water to yield 8.4 g of colorless crystals, mp 216—218 °C (decomp.), ν(KBr) 1230, 1215, and 1027.

Found: C, 50.73; H, 4.48; N, 4.81%. Calcd for $C_{12}H_{13}NO_3S_2$: C, 50.87; H, 4.59; N, 4.95%.

S-[2-(2-Methylquinolinium-1-yl)ethyl]thiosulfate (IIIb). A mixture of 10.6 g of IIb and 8.1 g of sodium thiosulfate in 130 ml of water was heated on a water bath for 1 hr. After being left to stand at room temperature, the crystals deposited were recrystallized from water to give 7.9 g of colorless crystals, mp 227—228 °C (decomp.). ν(KBr) 1247, 1233, 1224, 1208, and 1022.

Found: C, 50.97; H, 4.47; N, 4.76%. Calcd for $C_{12}H_{13}NO_3S_2$: C, 50.87; H, 4.59; N, 4.95%.

S-[2-(6-Ethoxy-2-methylquinolinium-1-yl)ethyl]thiosulfate (IIIc). A mixture of 5.0 g of IIc and 3.4 g of sodium thiosulfate in 30 ml of water was heated on a water bath for 1 hr, and then kept in a refrigerator. The resulting crystals were recrystallized from water to give 1.5 g of colorless crystals, mp 223 °C (decomp.). ν(KBr) 1234—1217 and 1022.

Found: C, 51.51; H, 5.59; N, 3.90%. Calcd for $C_{14}H_{17}NO_4S_2$: C, 51.34; H, 5.20; N, 4.28%.

S-[2-(2-Methylbenzothiazolium-3-yl)ethyl]thiosulfate (Va). A mixture of 5.6 g of IVa and 4.1 g of sodium thiosulfate in 20 ml of water was heated at 80—90 °C for 10 min. The crystals formed on standing were collected and recrystallized from water to give 2.9 g of colorless crystals, mp 191—193 °C (decomp.). ν(KBr) 1240, 1228, 1221, 1208, 1193, and 1023.

Found: C, 41.28; H, 3.37; N, 4.61%. Calcd for $C_{10}H_{11}NO_3S_3$: C, 41.50; H, 3.80; N, 4.84%.

S-[2-(2,6-Dimethylbenzothiazolium-3-yl)ethyl]thiosulfate (Vb). A mixture of 7.0 g of IVb and 5.0 g of sodium thiosulfate in 10 ml of water was treated as for Va. Yield, 3.9 g of colorless crystals, mp 203—204°C (decomp.), ν(KBr) 1246, 1230, 1209, 1021, and 1011.

Found: C, 43.12; H, 4.22; N, 4.37%. Calcd for $C_{11}H_{13}NO_3S_3$: C, 43.54; H, 4.29; N, 4.62%.

S-[2-(6-Methoxy-2-methylbenzothiazolium-3-yl)ethyl]thiosulfate (Vc). A mixture of 7.3 g of IVc and 5.0 g of sodium thiosulfate in 10 ml of water was treated as for Va. Yield, 4.6 g of colorless crystals, mp 206—207 °C (decomp.). ν(KBr) 1245, 1220, 1204, and 1016.

Found (dried at 130°C, 3 hr): C, 40.84; H, 4.08; N, 4.44%. Calcd for $C_{11}H_{13}NO_4S_3$: C, 41.35; H, 4.07; N, 4.39%.

S-[2-(2,5-Dimethylbenzothiazolium-3-yl)ethyl]thiosulfate (Vd). A mixture of 7.0 g of IVd and 5.0 g of sodium thiosulfate in 10 ml of water was treated as for Va. Yield, 4.0 g of colorless crystals, mp 192—194 °C (decomp.). ν(KBr) 1237, 1220 (shoulder), 1213, and 1020.

Found (dried at 120°C, 3 hr): C, 42.63; H, 4.04; N, 4.41%. Calcd for $C_{11}H_{13}NO_3S_3$: C, 43.54; H, 4.29; N, 4.62%.

1,1'-Di-(2-potassiumsulfothioethyl)-4,4'-tricarbocyanine Acetate (VI). A mixture of 1.3 g of finely-powdered IIIa, 0.80 g of aniline and 0.35 g of ethyl orthoformate was heated at 88 °C under stirring for 20 min. 3.0 g of acetic anhydride and 1.5 g of potassium acetate were added to the mixture, which was then heated at 110—120 °C for 10 min. The reaction mixture was triturated three times with ether, methanol, and water successively, and then finally with 50 ml of hot water. The residue was then extracted three times by refluxing with a 500 ml-portion of methanol each time. The combined methanolic solution was concentrated to 300 ml, passed through a column (cellulose powder) maintained at 50—55 °C, and then eluted with 2 l of hot methanol. A blue-colored fraction of the eluate was concentrated to 50 ml and set aside to yield 30 mg of crystals, mp 241—242 °C (decomp.). Soluble with difficulty in water and most organic solvents. λ (MeOH) 728 (ε 2.05×10^5). ν (KBr) 1234, 1200, and 1028—1019.

Found: C, 45.36; H, 4.39; N, 3.75%. Calcd for $C_{27}H_{26}K_2N_2O_8S_4$: C, 45.46; H, 3.68; N, 3.93%.

1,1'-Di-(2-potassiumsulfothioethyl)-2,2'-tricarbocyanine Acetate (VII). A mixture of 0.50 g of finely-powdered IIIb, 0.40 g of aniline and 0.25 g of ethyl orthoformate was heated at 120 °C for 9 min under stirring. To this were added 0.80 g of acetic anhydride and 0.80 g of potassium acetate, and the mixture was heated at 140 °C for 9 min. The reaction mixture was successively triturated and decanted with ether, ethanol, and water. The residue was refluxed twice with a 500 ml-portion of methanol, transferred to a Soxhlet apparatus and further extracted with methanol to give 140 mg of crystals, mp 236—237 °C (decomp.). Soluble with difficulty in water and most organic solvents. λ (MeOH) 625 (ε 1.51×10^5). ν (KBr) 1236, 1214, and 1027.

Found: C, 45.08; H, 3.42; N, 3.96%. Calcd for $C_{27}H_{26}K_2N_2O_8S_4$: C, 45.46; H, 3.68; N, 3.93%.

6,6'-Dimethyl-3,3'-di-(2-potassiumsulfothioethyl)dithiacarbocyanine Acetate (VIII). A mixture of 0.60 g of Vb, 0.20 g of aniline and 0.30 g of ethyl orthoformate was heated at 100°C for 5—10 min. To this were added 0.20 g of acetic anhydride and 0.27 g of potassium acetate, and heating was continued for 5—10 min at 160 °C. The reaction mixture was successively triturated with hot ethanol and hot water, and the residue was extracted three times with a 100 ml-portion of hot methanol each time. The combined methanolic solution was passed through a column (cellulose powder) maintained hot, and eluted with hot methanol. A red-colored fraction of the eluate was again passed through

3) Indicated in cm^{-1}.

4) IR peaks appearing only in the regions 1200—1230 (strong) and 1020 (strong) and considered to be characteristic of the thiosulfate group of Bunte salt are given.

the column. The red fraction of the eluate gave 45 mg of crystals on concentration, mp 223—225 °C (decomp.). Soluble with difficulty in water and most organic solvents. λ (MeOH–H_2O (19 : 1)) 570 (ε 2.6×10^4). ν (KBr) 1240—1203, and 1027.

Found: C, 39.78; H, 3.68; N, 3.89%. Calcd for $C_{25}H_{26}K_2N_2O_8S_6$: C, 39.86; H, 3.46; N, 3.72%.

S-[*2-(4-Phenylaminoethenylquinolinium-1-yl)ethyl*]*thiosulfate (IX).* A mixture of 1.15 g of IIIa, 0.60 g of aniline and 0.70 g of ethyl orthoformate was heated at 123 °C for 10 min under stirring. The reaction mixture was triturated successively with ether, ethanol, and hot water. The residue was recrystallized from DMF–DMSO (1 : 1) to give 1.25 g of crystals, mp 252—253 °C (decomp.). λ (MeOH) 492. ν (KBr) 1227, 1220, and 1014.

Found (dried at 120 °C, 3 hr): C, 58.40; H, 5.03; N, 7.27%. Calcd for $C_{19}H_{18}N_2O_3S_2$: C, 59.05; H, 4.67; N, 7.25%.

S-[*2-(2-Phenylaminoethenylquinolinium-1-yl)ethyl*]*thiosulfate (X).* A mixture of 0.28 g of IIIb, 0.30 g of aniline and 0.40 g of ethyl orthoformate was heated at 120 °C for 15 min under stirring. The reaction mixture was triturated successively with ether, ethanol, and hot water. The residue was dissolved in methanol, and the solution was passed through a column (cellulose powder). Concentration of a yellow-colored fraction of the eluate yielded crystals, which were recrystallized from methanol. Yield, 80 mg, mp 240—241 °C (decomp.). λ (MeOH) 451. ν (KBr) 1245, 1235, 1227, 1024 (shoulder), and 1019.

Found: C, 57.10; H, 5.12; N, 6.49%. Calcd for $C_{19}H_{18}N_2O_3S_2\cdot CH_3OH$: C, 57.39; H, 5.30; N, 6.69%.

S-[*2-(2-Phenylaminoethenylbenzothiazolium-3-yl)ethyl*]*thiosulfate (XI).* A mixture of 3.7 g of Va, 1.0 g of aniline and 0.80 g of ethyl orthoformate was heated at 100 °C for 10 min under stirring. The reaction mixture was triturated with ethanol and decanted. The residue was dissolved in methanol and passed through a column (cellulose powder). Concentration of a yellow-colored fraction of the eluate gave crystals, which were then recrystallized from methanol. Yield, 1.4 g, mp 250—252 °C. λ (MeOH) 420. ν (KBr) 1244, 1232, 1203, and 1022.

3,3'-Di-(2-hydroxyethyl)-5,6,5',6'-tetramethoxydithiacarbocyanine Bromide (XIII). A mixture of 2.0 g of 3-(2-hydroxyethyl)-5,6-dimethoxy-2-methylbenzothiazolium bromide, 0.60 g of anilline, and 0.90 g of ethyl orthoformate was heated at 115 °C for 7 min under stirring. To this were added 1.8 g potassium acetate and 0.70 g of acetic acid, and heating was continued at 160 °C for 7 min. The reaction mixture was triturated successively with ether, ethanol, and water. Recryatallization of the residue from methanol–ether gave crude crystals, which were dissolved in methanol. The methanolic solution was passed through a column (cellulose powder), and eluted with methanol. The crystals from the eluate on concentration were similarly treated twice. Yield, 1.6 g, mp 259—260 °C. λ (MeOH) 605.

Found: C, 50.65; H, 4.99; N, 4.69%. Calcd for $C_{25}H_{29}BrN_2O_6S_2$: C, 50.25; H, 4.86; N, 4.69%.

3,3'-Di-(2-bromoethyl)-5,6,5',6'-tetramethoxydithiacarbocyanine Bromide (XIV). A mixture of 0.50 g of XIII and 3.8 g phosphorus tribromide was kept at room temperature for 5 hr. The reaction mixture was triturated with benzene, and the residue was recrystallized from methanol–ether (1 : 1). The crystals formed were dissolved in methanol, treated chromatographically as for XIII, and finally recrystallized from methanol. Yield, 0.43 g, mp 226—228 °C. λ (MeOH) 605.

Found: C, 41.12; H, 3.69; N, 3.75%. Calcd for $C_{25}H_{27}Br_3N_2O_4S_2$: C, 41.50; H, 3.74; N, 3.87%.

3-(2-Bromoethyl)-3'-sulfothioethyl-5,6,5',6'-tetramethoxydithiacarbocyanine (XII). A mixture of 1.0 g of XIV and 0.90 g of sodium thiosulfate in 300 ml of methanol was heated under reflux for 20 hr. The reaction mixture was carefully concentrated by distilling methanol until XII began to crystallize (otherwise, excess sodium thiosulfate deposited.) The crystals, after recrystallization once from methanol–ether, were dissolved in methanol, passed through a column (cellulose powder), and eluted with DMF. The crystals obtained from the eluate were finally recrystallized from methanol. Yield, 0.70 g, mp 213—215 °C, λ (MeOH) 610 ε 6.24×10^4). ν (KBr) 1270—1223 and 1025.

Found: C, 41.25; H, 4.41; N, 4.07; S, 16.55%. Calcd for $C_{25}H_{27}BrN_2O_7S_4\cdot3H_2O$: C, 41.14; H, 4.53; N, 3.84; S, 17.59%. Found (dried at 145 °C, 7 hr): C, 44.17; H, 4.57; N, 4.06%. Calcd for $C_{25}H_{27}BrN_2O_7S_4$: C, 44.43; H, 4.00; N, 4.15%.

Formation of Sulfur Ylids by Catalytic Action of Dialkoxy Disulfides[1]

Haruo MATSUYAMA, Hiroshi MINATO, and Michio KOBAYASHI
Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo

(Received November 30, 1972)

In the presence of a catalytic amount of a dialkoxy disulfide, dimethyl diazomalonate spontaneously reacted with a dialkyl sulfide in the absence of light at room temperature, and the corresponding sulfonium ylid was formed. The kinetics and products of this reaction were investigated, and its mechanism was discussed.

Very little has been published on the chemistry of dialkoxy disulfides, which can be prepared from sulfur monochloride and alcohols. In our laboratories various reactions of these interesting compounds have been studied, and the mechanisms of their reactions with Lewis acids have been described in a recent publication.[2]

In an attempt to study the reaction between diisopropoxy disulfide and bis(methoxycarbonyl)carbene, the disulfide was mixed with dimethyl diazomalonate in dimethyl sulfide at room temperature. Surprisingly, an ylid was formed in the absence of light at room temperature.

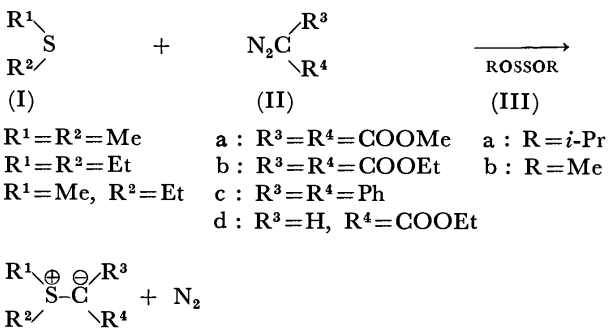
The formation of an ylid from dimethyl diazomalonate and dimethyl sulfide was reported by Ando *et al.*[3] They stated that the diazomalonate decomposed and yielded the corresponding carbene only when the diazo compound was irradiated with a UV light or heated near 110 °C in the presence of a copper catalyst.

$$N_2C(CO_2CH_3)_2 + CH_3SCH_3 \xrightarrow[10\text{—}15\,^\circ\text{C},\ 30\ \text{hr}]{i\text{-PrOSSOPr-}i} CH_3\overset{\oplus}{S}(\overset{\ominus}{C}(CO_2CH_3)_2)CH_3 + N_2$$

The formation of sulfur ylids by catalytic action of dialkoxy disulfides was studied, and the results are described in this paper.

Results and Discussion

When dimethyl diazomalonate (IIa) was dissolved in a dialkyl sulfide (I) in the presence of a catalytic amount of diisopropoxy disulfide (IIIa) at room temperature, nitrogen gas was evolved and the corresponding ylid was formed in a good yield. Table 1 summarized the results of the reactions with several sulfides.



(I) (II) (III)

a : $R^1=R^2=Me$ a : $R^3=R^4=COOMe$ a : R = *i*-Pr
b : $R^1=R^2=Et$ b : $R^3=R^4=COOEt$ b : R = Me

$R^1=R^2=Me$	(hν)[c]	88	
	($CuSO_4$, 110 °C)[c]	75	

a) A mixture consists of a sulfide 30 mmol, $N_2C(CO_2Me)_2$ 5 mmol, and *i*-PrOSSOPr-*i* 1 mmol.
b) Dark reaction (covered with aluminum foil).
c) Reference 3); in the absence of diisopropoxy disulfide.

In the absence of III, no reaction was observed between I and II. No reaction was observed between II and III either. Reaction took place only when the three components are present. III is simply a catalyst and remains unchanged. The diazo compounds decompose smoothly at room temperature without irradiation of UV light. Visible light cannot be the cause for the reaction, since the decomposition proceeded equally well when the reaction flask was completely covered and shielded from light.

When the rates of evolution of nitrogen from a mixture of I, IIa and IIIa were determined, they were of first order in IIa at least until about 50% decomposition. The half life of IIa at 20 °C was about 4 hr, and the first order rate constant k_1 was 3.84×10^{-5} sec.$^{-1}$

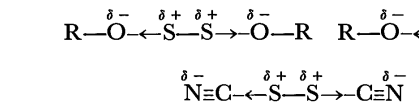
Table 2. Comparison of the sulfides possessing catalytic activity on the reaction between dimethyl diazomalonate and dimethyl sulfide[a]

Catalytic sulfides[b]	Temp. (°C)	10^5k_1 (sec^{-1})	$\tau_{1/2}$ (hr)	Ylid (%)	N_2 (%)
MeOSSOMe	20	4.5	4.7	71	81
EtOSSOEt	20	8.1	2.6	68	96
i-PrOSSOPr-*i*	20	5.1	4.0	75	90
EtOSOEt	20	6.4	5.0	66	93
NC–SS–CN	25		*ca.* 3 days	50	

a) A mixture consists of Me_2S 30 mmol, $N_2C(CO_2Me)_2$ 5 mmol, and a catalytic sulfide, 1 mmol.
b) Found to be inactive: MeSSMe, $Et_2NSSNEt_2$, BzSSBz, ClSSCl.

In an attempt to determine what is responsible for the catalytic activity of III, other compounds possessing similar catalytic activity were sought for. As Table 2 shows, dialkyl sulfoxylates, ROSOR, and thiocyanogen, NC–SS–CN, were found to be effective, whereas dimethyl disulfide, diethylamino disulfide, benzoyl disulfide and sulfur monochloride were inactive.

Since the electronegativity of sulfur is 2.5 and that of oxygen is 3.5,[4] the electron density on the sulfur atoms of III must be smaller due to the presence of the electron-withdrawing oxygen atoms. The electron density on the sulfur atoms of dialkyl sulfoxylates and thiocyanogen must be small due to the presence of the electron-withdrawing alkoxy and cyano groups.



Therefore, the divalent sulfur atom containing a small positive charge due to electron-withdrawing substituents is probably responsible for the catalytic formation of ylids from I and II.

Various diazo compounds were examined as to their reactivity, and the results are summarized in Table 3. In mixtures with Ib and IIIa, dimethyl and diethyl diazomalonates decomposed smoothly at room temperature, yielding an ylid and nitrogen. Ethyl diazoacetate, diphenyldiazomethane and ethyl azidoformate decomposed very slowly (about 10% decomposition in 4 days). Three diazo compounds containing an acetyl group did not decompose at all.

Table 3. Comparison of the reactivities of diazo compounds with diethyl sulfide in the presence of diisopropoxy disulfide at 20 °C[a]

Diazo compounds[b]	10^5k_1 (sec^{-1})	$\tau_{1/2}$ (hr)	Ylid (%)	N_2 (%)
$N_2C(COOMe)_2$	3.8	4.3	67	84
$N_2C(COOEt)_2$	0.7	27.5	45	57

a) A mixture consists of Et_2S 30 mmol, R_2CN_2 5 mmol, and *i*-PrOSSOPr-*i* 1 mmol.
b) No Reaction: $N_2C(COMe)_2$, $N_2C(COMe)(COOMe)$, $N_2C(COMe)(COOEt)$. Very slow decomposition (ca 10%/4 day): $N_2CHCOOEt$, N_2CPh_2, N_3CO_2Et.

Table 4. Comparison of the reactivities of sulfides with dimethyl diazomalonate in the presence of diisopropoxy disulfide[a]

Sulfides[b]	Temp. (°C)	10^5k_1 (sec^{-1})	Rel. React.	$\tau_{1/2}$ (hr)
MeSMe	17	4.0	5	5.2
EtSEt	17	3.2	4	5.9
	17	0.80	1	24
MeSEt	20	0.66	0.8	29

a) A mixture consists of a sulfide 30 mmol, $N_2C(COOMe)_2$ 5 mmol, and *i*-PrOSSOPr-*i*, 1 mmol.
b) No reaction: PhSMe, PhSEt, Dimethyl sulfoxide. Slow reaction: *n*-BuSMe (ylid 66% in 10 days at 20 °C).

Then, various dialkyl sulfides were examined as to their reactivity, and the results are summarized in Table 4. In mixtures with IIa and IIIa, methyl phenyl sulfide, ethyl phenyl sulfide and dimethyl sulfoxide did not react at all, and *n*-butyl methyl sulfide reacted very slowly (the yield of ylid was 66% after 10 days at 20°C). These findings suggest that an electron-rich sulfide is reactive, and the reaction is slow with a bulky alkyl group.

The pseudo first order rate constants determined from the rates of nitrogen evolution show that dimethyl sulfide and diethyl sulfide react with IIa quite rapidly, whereas ethyl methyl sulfide and tetrahydrothiophene react slowly. Thus, the electronic and steric effects in this reaction are rather complex, and not straightfoward.

When Ia, IIa and IIIb were mixed in an NMR tube, and the changes of the concentrations of the reactants were observed, it was found that the decrease of IIa corresponded to the formation of the ylid, whereas IIIb remained unchanged. The results are shown in Fig. 1. It is clear that III is not a reactant, but a catalyst. However, the increase in the concentration of III resulted in the increase in the rate of nitrogen evolution. An induction period of about 10 min was observed, during which nitrogen was not evolved.

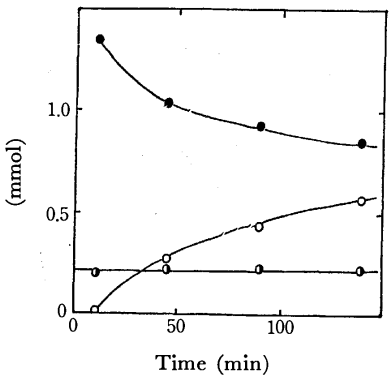


Fig. 1. Changes of amounts of the reactants and products in an NMR Tube at 35 °C.
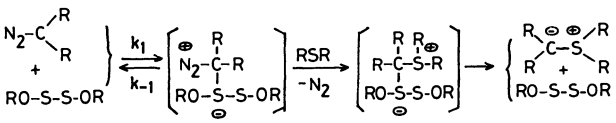
(The initial mixture consists of Ia 2.42, IIa 1.35, IIIb 0.20, and CH_3NO_2 1.85 mmol)
●: $N_2C(CO_2Me)_2$, ○: $Me_2\overset{\oplus}{S}-\overset{\ominus}{C}(CO_2Me)_2$, ◑: MeOSSOMe

The experiments described so far used excess I as the solvent. When the mixture was diluted with such polar solvents as nitromethane and acetonitrile, the decomposition of IIa became slower. When *n*-hexane was used as the solvent, IIa did not decompose.

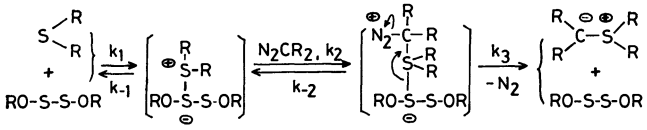
The rates of the decomposition of IIa in a mixture with Ib and IIIa were determined at various temperatures, and it was found that the rates were in the order of $k_{20°}>k_{17°}>k_{30°}$. It is clear that above a certain temperature this reaction becomes slower.

As for the mechanism of this reaction, the following two pathways seem possible. Scheme 1 involves the formation of a complex between II and III, and the complex is supposed to react with I.

3) W. Ando, T. Yagihara, S. Tozune, S. Nakaido, and T. Migita, *Tetrahedron Lett.*, **1969**, 1979.
4) L. Pauling, "Nature of the Chemical Bond," Cornell Univ. Press, Ithaca (1960), p. 88.



Scheme 1.

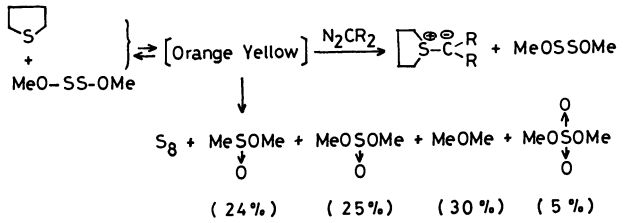


Scheme 2.

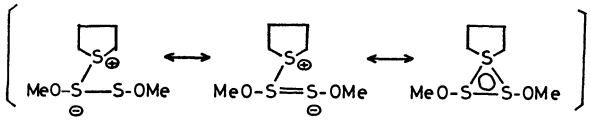
Scheme 2 involves the formation of a complex between I and III, and the complex is supposed to react with II.

Attempts were made in order to detect the presence of complexes in the mixtures of I, II, and III. The UV spectrum of a mixture of IIa and III did not show any sign of interaction between them. The UV spectra of the mixtures of Ia and III, or Ib and III showed no sign either.

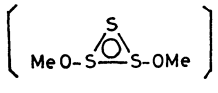
However, when tetrahydrothiophene was mixed with IIIb, the mixture turned orange yellow. If IIa was added to this colored mixture, the corresponding ylid was formed and IIIb was recovered unchanged. If IIa was not added and the mixture was allowed to stand at room temperature for more than ten minutes, sulfur precipitated, and the products of decomposition of IIIb were found.



The five products shown above are the compounds found as the products of the decomposition of IIIb when the latter was mixed with triethyloxonium tetrafluoroborate.[2] As the species present in the orange yellow mixture, the following structure seems probable.



In our previous paper dealing with the reaction between IIIb and $Et_3O^+BF_4^-$, evidence was presented indicating the presence of the following intermediate.



Scheme 2 is favored on the basis of the findings that IIIb and tetrahydrothiophene form the orange yellow complex which readily react with IIa, forming the ylid and nitrogen. Thus, the data described in this paper suggest that the reactions among I, II and III are represented by Scheme 2.

Experimental

Materials. Dimethyl sulfide, tetrahydrothiophene, dimethyl disulfide and dimethyl sulfoxide were of reagent grade and used without further purification. Other sulfides were prepared from the corresponding sodium mercaptides and alkyl halides.[5] Dimethoxy disulfide, diethoxy disulfide and diisopropoxy disulfide were synthesized by the method of Thompson.[6] Diethyl sulfoxylate was prepared from the reaction between diethoxy disulfide and sodium ethoxide by the method of Meusen.[7] Thiocyanogen[8] and benzoyl disulfide[9] were prepared by the methods described in the literature. Sulfur monochloride was freshly distilled, and used immediately. Diethylamino disulfide was synthesized by adding sulfur monochloride (0.1 mol) to a dichloromethane solution of diethylamine (0.4 mol) at 0 °C; bp 115 °C/6 mmHg. Dimethyl diazomalonate, diethyl diazomalonate, acetyldiazoacetone, methyl acetodiazoacetate and ethyl acetodiazoacetate were prepared by transdiazotization of corresponding carbonyl compounds with tosyl azide.[10] Ethyl diazoacetate,[11] diphenyldiazomethane (mp 31—32 °C; lit,[12] 29—33 °C) and ethyl azidoformate[13] were prepared according to the methods described in the literature.

Kinetics and Products. A 50 ml flask containing a mixture of 30 mmol of I, 5 mmol of II and 1 mmol of III was placed in a constant-temperature bath, and the amount of nitrogen evolved was determined by use of a gas buret. After the evolution of nitrogen ceased, a small amount of *n*-hexane was added to the mixture, and the ylid crystals formed were filtered and weighed. The melting points, IR and NMR spectra of the ylids obtained were identical with those reported in the literature.[14]

Reaction in an NMR Tube. A mixture of Ia (2.42 mmol), IIa (1.35 mmol) and IIIb (0.20 mmol) containing nitromethane (1.85 mmol) as the internal standard was placed in an NMR tube at 35 °C, and decreases of $(C\underline{H}_3)_2S$ (δ, 2.01 ppm) and $N_2C(CO_2C\underline{H}_3)_2$ (3.75 ppm) absorptions and increases of $(C\underline{H}_3)_2\overset{\oplus}{S}-\overset{\ominus}{C}(CO_2CH_3)_2$ (2.82 ppm) absorption were determined on the basis of the absorption of CH_3NO_2 (4.33 ppm).

(Received November 30, 1972)

Stereoselectivities in diazomethane and nitromethane reaction of methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-α-D-ribo-hexopyranosid-3-ulose were examined. Reduction of the epoxidation product (**2**) gave an epimeric 3-*C*-methyl derivative in contrast with that obtained by the Grignard reaction. Comparison of NMR spectra of the corresponding di-*O*-acetate of the both epimers proved that **2** has the gluco-configuration. Ring-opening of the epoxide with alkali, methanolic ammonia, and acid gave the corresponding 3-*C*-hydroxymethyl, 3-*C*-aminomethyl (**17**), and de-*O*-benzylidenated product, respectively. Hydrogenation of the 3-*C*-nitromethyl derivative (**21**) obtained by nitromethane condensation, in the presence of Raney nickel, accompanied with benzoyl-migration to give 3-*C*-benzamidomethyl derivative (**22**). De-benzoylation of **22** with methanolic potassium hydroxide gave 3-*C*-aminomethyl derivative (**26**) and an orthoester-type compound. Comparison of **26** with **17** and their derivatives indicated that **21** has the allo-configuration. The both configurations were also supported by the optical rotation of 3-*C*-benzamidomethyl derivatives in cuprammonium solution.

In the previous paper,[1] we reported that the nitromethane and the Reformatsky reaction of 1,2 : 5,6-di-*O*-isopropylidene-α-D-ribo-hexofuranos-3-ulose gave D-allo-type branched-chain sugars, while the diazomethane reaction afforded D-gluco-type product, indicating that the reagent attacked the carbonyl group from the more hindered site. The stereoselectivity of the latter stimulated us to examine with a pyranosid-3-ulose, and nitromethane and diazomethane reaction of methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-α-D-ribo-hexopyranosid-3-ulose (**1**)[2] were examined in this report.

Results

Diazomethane Condensation. Diazomethane condensation of **1** in benzene–ethanol gave a sirupy spiro-epoxide (**2**) in 77% yield. In order to determine the configuration, **2** was hydrogenated with lithium aluminium hydride to the 3-*C*-methyl derivative (**3**), which was successively converted into the corresponding 2-*O*-acetate (**4**) and 2,3-di-*O*-acetate (**5**) by base- and acid-catalyzed acetylation, respectively. On the other hand, a 3-*C*-methyl derivative (**6**) obtained by the Grignard reaction, of which the configuration was assigned to be of allo-type,[2,3] was also converted into 2-*O*-acetate (**7**) and 2,3-di-*O*-acetate (**8**). Comparison of **3** with **6** and their derivatives showed that they are 3-epimers to each other, and the chemical shifts of *tert*-acetoxy protons in **5** (δ 1.95) and **8** (δ 2.05) indicated an equatorial and axial one, respectively.[4] Thus, the configuration of **2** was confirmed to be of D-gluco-type.

The epoxide-ring of **2** resisted, to some extent, to alkaline opening than the corresponding furanose derivative,[1] and alkali treatment of **2** at room temperature gave de-*O*-benzoylated epoxide (**9**), which was further converted to the 2-*O*-acetate (**10**). Treatment of **9** with refluxing aqueous potassium hydroxide for 10 hr gave a water-soluble 3-*C*-hydroxymethyl derivative (**11**), which was then acetylated to 2,3-di-*O*-acetate (**12**). Acetonation of **11** gave 3,3′-*O*-isopropylidene derivative (**13**), of which the position of the isopropylidene group was determined from the fact that **13** gave the mono-*O*-acetate (**14**) by base-catalyzed acetylation. The epoxide-ring opening was also performed by refluxing **2** with 80% acetic acid, accompanying with hydrolysis of the benzylidene group, to give methyl 2-*O*-benzoyl-3-*C*-hydroxymethyl-α-D-glucopyranoside (**15**), which was confirmed by conversion into the corresponding tetra-*O*-acetate (**16**). Moreover, treatment of **9** with ethanolic ammonia in a sealed tube at 90 °C for 3 hr gave 3-*C*-aminomethyl derivative (**17**), which was then converted into the corresponding *N*-benzoyl derivative (**18**), its di-*O*-acetate (**19**), and *N*,*O*-triacetate (**20**), respectively.

Nitromethane Condensation. Reaction of **1** with nitromethane in tetrahydrofuran in the presence of sodium methoxide gave a 3-*C*-nitromethyl derivative (**21**) in 80% yield. Hydrogenation of **21** in the presence of Raney nickel accompanied with the migration of 2-*O*-benzoyl group to give 3-*C*-benzamidomethyl derivative (**22**). Base- and acid-catalyzed acetylation of **22** gave the corresponding 2-*O*-acetate (**23**) and 2,3-di-*O*-acetate (**24**), respectively. Debenzoylation of **22** with methanolic potassium hydroxide gave 3-*C*-aminomethyl derivative (**26**), an orthoester-type product (**25**), and **22**. Comparison of **22** with **18**, **24** with **19**, and **26** with **17** indicated them to be 3-epimers to each other. Furthermore, the positive rotational change ($[M]_{436}^{\text{Cupra A}}$ +1670°) of **22** in cuprammonium solution[5] and negative change ($[M]_{436}^{\text{Cupra A}}$ −635°) of **18** indicated D-allo and D-gluco-configuration, respectively. Thus, the configuration of **21** was proved to be of D-allo-type.

Compound **25**, having still two phenyl groups in the NMR and analytical data, showed no absorptions of amino and oxazolidine groups in IR spectrum, and changes to **22** by standing in a moist state. Attempted acetylation of **25** in dry pyridine gave quantitatively 3-*C*-acetamidomethyl-2-*O*-acetyl derivative (**27**) which was also obtained by acetylation of **26**. From these facts, **25** was deduced to be methyl 3-*C*-aminomethyl-4,6-*O*-benzylidene-2,3,*N*-benzylidine-α-D-allopyranoside. Formation of **25** will be explained by the nucleophillic attack of hydroxyl anions at C_2- and C_3-positions on the sterically favorable carbonyl function of benzamido group to give the thermodynamically controlled product. Conversion of **25** into **27** might occur through hydrolysis of acyloxonium ion formed by cleavage of the orthoamide bond by *N*-acetylation.[6]

On the other hand, partial hydrogenation of **21** in the presence of palladium-charcoal or hydrolysis with 0.1 N-sulfuric acid gave methyl 2-*O*-benzoyl-3-*C*-nitromethyl-α-D-allo-pyranoside (**28**), which was then converted into the tri-*O*-acetate (**29**) by acid-catalyzed acetylation. Acetonation of **28** gave an isopropylidene derivative (**30**), which was converted to mono-*O*-acetate (**31**). The structure of **30** was deduced to be 3,4-*O*-isopropylidene derivative from the chemical shift of C–CH_3 protons (δ 1.47 and 1.49).[7]

Discussion

On the stereoselectivities in nucleophilic addition to methyl 4,6-*O*-benzylidene-α-D-ribo-hexopyranosid-3-uloses, following facts are known. Reduction[8] of 2-*O*-tosyl derivative; reduction,[8] the Grignard[9] and dimethyloxosulfonium methylide[10] reaction of the corresponding 2-acetamido-2-deoxy derivative; and the Grignard[11] and the oxosulfonium ylide[12] reaction of 2-deoxy derivative gave D-allo-type products, while the reaction of acetonitrile with the 2-deoxy derivative in liquid ammonia gave D-gluco-type product.[13] These results indicate that nucleophiles in the former reactions attacked the carbonyl group from the less hindered site, and in the latter from the hindered site (Fig. 1). Thus, nitromethane condensation mentioned here is classified into the former type, though it generally gives various mixture of diastereomers,

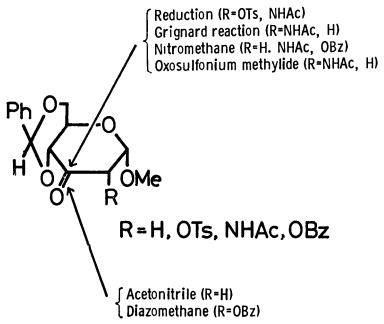

Fig. 1.

depending on the condition used.[14]

On the other hand, stereoselectivity of diazomethane addition is usually complicated by the formation of ring-expanded product depending on the solvent used. For an example, Flaherty *et al.*[15] obtained 30% of the ring-expanded product and a small amount of normal epoxide of D-gluco-type by the reaction with methyl 4,6-*O*-benzylidene-2-deoxy-α-D-erythro-hexopyranosid-3-ulose in methanol. However, 1,2-*O*-isopropylidene-α-D-furanos-3-uloses gave the normal spiro-epoxides which are resulted by attacking the reagent from the inside of the V-shaped *cis*-fused five-membered ring.[1,16] Reaction of methyl α-D-pyranosid-2-uloses in ether–alcohol, having two oxygens at the both vicinal carbon, gave a mixture of diastereomers,[17] however, one which has the epoxide carbon in the site of C_1-methoxy group was predominant. Inch *et al.*[18] examined the steric influence of *C*-alkyl group vicinal to the carbonyl group by the reaction with 4,6-*O*-benzylidene-3-deoxy-3-*C*-ethyl-α-D-arabino- and -ribo-hexo-pyranosid-2-ulose, and showed that *C*-ethyl group in reverse side to C_1-methoxy group enhanced the formation of the predominant product mentioned above, and that in the same side hindered it to afford another epimer predominantly. They discussed on the conformation of zwitterionic intermediates for explanation of the configuration of ring-expanded products.

However, accumulated data mentioned here indicate that the stereoselectivity might be controlled at first by attractive interactions between vicinal or neighboring hydroxyl oxygens and diazomethylene cation of zwitterionic intermediates, and therefore, the polarity of solvents play an important role. The complemental stereoselectivities of the Grignard and diazomethane reaction mentioned by us and by Horwitz *et al.*[16] support this deduction. Thus, the steric position of C_1-methoxy oxygen for the carbonyl group might control the configuration of the product in this experiment.

Experimental

All melting points are uncorrected. The solutions were evaporated under diminished pressure at a bath temperature not exceeding 45 °C. Specific rotations were measured in a 0.5-dm tube, with a Carl Zeiss LEP-Al Polarimeter. The IR spectra were recorded with a Hitachi Model EPI-G2 grating IR spectrophotometer. The NMR spectra were taken in deuteriochloroform, with a JNM-4H-100 MHz Spectrometer using tetramethylsilane as an internal standard. Chemical shifts and coupling constants were recorded in δ and Hz units, and frequencies in cm^{-1}.

*Methyl 3,3′-Anhydro-2-O-benzoyl-4,6-O-benzylidene-3-C-(hydroxymethyl)-α-D-glucopyranoside (**2**).* To a suspended solution of **1** (4 g, 10.4 mmol) in benzene (150 ml)–ethanol (50 ml) was added dropwise a solution of diazomethane (20 mmol) in ether (50 ml) at 0 °C. With proceeding the reaction, the mixture turned to homogeneous. After standing at 0 °C for 3 hr and at room temperature for 28 hr, the solution was evaporated, and the resulted sirup was fractionated through Kiesel-gel (70—325 mesh, Merck Co.), by eluating with benzene–methanol (15 : 1). From the first fraction, the spiro-epoxide was obtain as a sirup in 77.3% (3.2 g) yield. $[\alpha]_D^{23}$ +113° (*c* 1.06, $CHCl_3$); IR: 1720 (ester), 1590 and 710 (Ph); NMR: *ca.* 7.30 and 7.95 (2× Ph, m), 5.51 (PhCH=), 5.41 (H_1; d, $J_{1,2}$=3.7), 5.10 (H_2; d), 4.35 (H_5; sex, $J_{4,5}$=13.5), 3.97 (H_{6e}; t, $J_{6a,6e}$ =10, $J_{5,6e}$= 10), *ca.* 3.91 (H_4; d), *ca.* 3.90 (H_{6a}; t, $J_{5,6a}$=10), 3.40 (OMe), 3.20 (epoxy-CH_2; s).

Found: C, 65.77; H, 6.10%. Calcd for $C_{22}H_{22}O_7$; C, 66.32; H, 5.57%.

*Methyl 4,6-O-Benzylidene-3-C-methyl-α-D-glucopyranoside (**3**).* To a solution of **9** (800 mg, 2.64 mmol) in ether (30 ml) was added lithium aluminium hydride (0.2 g, 53 mmol), and the mixture was refluxed for 7 hr. The excess $LiAlH_4$ was carefully decomposed with water, and the water layer was extracted with ether. The combined ether extract was washed with water, dried with anhydrous magnesium sulfate, and evaporated to give a colorless sirup. The sirup was crystallized and recrystallized from chloroform–*n*-hexane. Yield, 86% (690 mg). A similar treatment of **2** gave the same compound in 79% yield. Mp 80—82 °C; $[\alpha]_D^{23}$ +91.0° (*c* 1.25, $CHCl_3$); IR: 3523 and 3250 (OH); NMR; 1.40 (C–CH_3; s).

Found: C, 60.84; H, 7.16%. Calcd for $C_{15}H_{20}O_6$: C, 60.80; H, 6.80%.

2-*O*-Acetyl and 2,3-di-*O*-acetyl derivatives of **3** was prepared as follows.

*a) 2-O-Acetate (**4**):* Acetylation of **3** with acetic anhydride in pyridine gave sirupy acetate in a quantitative yield. $[\alpha]_D^{23}$ +72.5° (*c* 1.44, $CHCl_3$); IR: 3450 (OH), 1740 (ester); NMR: 2.50 (OH; s), 2.10 (OAc), 1.45 (C–CH_3).

Found: C, 59.94; H, 6.60%. Calcd for $C_{17}H_{22}O_7$: C, 60.34; H, 6.55%.

*b) 2,3-Di-O-acetate (**5**):* A solution of **3** (100 mg) and *p*-toluenesulfonic acid (20 mg) in acetic anhydride (3 ml) was stirred at room temperature for 1.5 hr, poured into ice-water, and the resulted solution was extracted with chloroform. The extracts were washed with sodium bicarbonate

and then water, dried, and evaporated to give a crystals which was recrystallized from ethanol–*n*-hexane. Yield, 91% (105 mg); mp 156—157°C; $[\alpha]_D^{23}$ +15.4° (*c* 0.95; $CHCl_3$); IR: 1740 (ester); NMR: *ca.* 7.37 (Ph; m), 5.89 (H_2; d, $J_{1,2}$= 4.2), 5.55 (PhCH=), 4.87 (H_1; d), 4.85 (H_4; d, $J_{4,5}$=7.5), 4.30 (H_5; sex, $J_{5,6a}=J_{5,6e}$=7.5), 3.97—3.65 (H_{6a} and H_{6e}; m), 3.40 (OMe), 2.14 (*sec*-OAc), 1.95 (*tert*-OAc), 1.62 (C–CH_3).

Found: C, 60.18; H, 6.45%. Calcd for $C_{19}H_{24}O_8$: C, 59.99; H, 6.36%.

*2-O-Acetyl and 2,3-Di-O-acetyl Derivatives of Methyl 4,6-O-benzylidene-3-C-methyl-α-D-allopyranoside (**6**).* *a) 2-O-Acetate (**7**)*: This compound was obtained from **6**[2,3] by the usual method in a quantitative yield. Mp 95—96 °C; $[\alpha]_D^{23}$ +69.8° (*c* 1.2, $CHCl_3$). IR: 3475 (OH), 1730 (OAc); NMR: 2.16 (OAc), 1.28 (C–CH_3).

Found: C, 60.66; H, 6.72%. Calcd for $C_{17}H_{22}O_7$: C, 60.34; H, 6.55%.

*b) 2,3-Di-O-acetate (**8**)*: Acid-catalyzed acetylation of **6** gave **8** in a quantitative yield, which was recrystallized from ether–*n*-hexane. Mp 97—98°C; $[\alpha]_D^{23}$ +53.5° (*c* 1.03, $CHCl_3$); IR: 1740 (OAc); NMR: *ca.* 7.35 (Ph; m), 5.51 (PhCH=), 4.90 (H_1; d, $J_{1,2}$=4.2), 4.71 (H_2; d), 4.40—3.55 (H_4, H_5, H_{6a} and H_{6e}; m), 3.40 (OMe), 2.16 (*sec*-OAc), 2.05 (*tert*-OAc), 1.78 (C–CH_3).

Found: C, 60.41; H, 6.52%. Calcd for $C_{19}H_{24}O_8$: C, 59.99; H, 6.36%.

*Methyl 3,3′-Anhydro-4,6-O-benzylidene-3-C-(hydroxymethyl)-α-D-glucopyranoside (**9**).* A solution of **2** (1.0 g, 2.51 mmol) and potassium hydroxide (0.5 g) in acetone (20 ml)–water (10 ml) was stirred for 1.5 hr, until **2** has disappeared on tlc. Evaporation of acetone caused deposition of needles, which was gathered after further addition of water (15 ml). These crystals (0.67 g) contain crystalline water detectable in IR (3200, 3450, 3530 cm^{-1}) and NMR spectra. Recrystallization from ethanol–acetone gave needles in 81.5% (0.62 g) yield. Mp 179—180 °C; $[\alpha]_D^{23}$ +111 ° (*c* 1.06, $CHCl_3$); IR: 3320 (OH).

Found: C, 60.01; H, 5.83%. Calcd for $C_{15}H_{18}O_6 \cdot 1/3H_2O$: C, 59.98; H, 5.60%.

Usual acetylation of **9** gave the sirupy *2-O-acetate* (**10**) in a quantitative yield. $[\alpha]_D^{23}$ +96.0° (*c* 1.04, $CHCl_3$); IR; 1750 (OAc); NMR: 7.26 (Ph; m), 5.45 (PhCH=), 5.15 (H_1; d, $J_{1,2}$=3.7), 4.92 (H_2; d), 4.40—3.65 (H_4, H_5, H_{6a} and H_{6e}; m), 3.35 (OMe), 3.07 and 2.98 (epoxy-CH_2; ABq, $J_{a,b}$=5), 2.05 (OAc).

Found: C, 60.75; H, 6.09%. Calcd for $C_{17}H_{20}O_7$: C, 60.71; H, 5.99%.

*Methyl 3-Acetoxymethyl-2-O-acetyl-4,6-O-benzylidene-α-D-glucopyranoside (**12**).* A suspended solution of **9** (2.0 g) and potassium hydroxide (1.5 g) in water (75 ml) was refluxed for 10 hr to make the solution homogeneous, and then extracted with *n*-butanol, after neutralization of the cooled solution with 2N-hydrochloric acid. The extracts was washed with a small amount of water, evaporated to give a sirup (**11**) (1.7 g, 80%); $[\alpha]_D^{23}$ +77.8° (*c* 1.44, $CHCl_3$).

Found: C, 57.67; H, 6.81%. Calcd for $C_{15}H_{20}O_7$: C, 57.68; H, 6.46%.

Acetylation of **11** by the usual method give the sirupy *di-O-acetate* (**12**) in a quantitative yield. $[\alpha]_D^{23}$ +53.6° (*c* 1.14, $CHCl_3$); IR: 3450 (OH), 1735 (OAc); NMR: 7.32 (Ph; m), 5.41 (PhCH=), 5.10 and 4.27 ($C_3'H_2$; ABq, J= 12.5), 4.96 (H_1; d, $J_{1,2}$=3.7), 4.83 (H_2; d), 4.27 (H_5; m), 4.05—3.55 (H_4, H_{6a} and H_{6e}; m), 3.37 (OMe), 2.12 (*sec*-OAc), 1.78 (OAc).

Found: C, 57.46; H, 6.35%. Calcd for $C_{19}H_{24}O_9$: C, 57.57; H, 6.10%.

*Methyl 4,6-O-Benzylidene-3,3′-O-isopropylidene-α-D-glucopyranoside (**13**).* A suspended solution of **11** (200 mg, 0.64 mmol), anhydrous cupric sulfate (0.5 g) in acetone (20 ml) containing one drop of conc. sulfuric acid was stirred for 24 hr at room temperature, neutralized with barium carbonate, filtered through active carbon, and the filtrate was evaporated to give a sirup (210 mg). Crystallization of the sirup from ethanol–water gave needles in 53% (120 mg) mg) yield. Mp 133—134 °C; $[\alpha]_D^{23}$ +55.0° (*c* 1.18, $CHCl_3$); IR: 3500 (OH).

Found: C, 61.35; H, 7.00%. Calcd for $C_{18}H_{24}O_7$: C, 61.35; H, 6.86%.

Acetylation of **13** by the usual method gave the sirupy 2-O-*acetate* (**14**) in a good yield. $[\alpha]_D^{23}$+49.8° (*c* 1.31, $CHCl_3$); IR: 1750 (OAc), 1370 and 1380 (C–CH_3); NMR: *ca.* 7.40 (Ph; m), 5.60 (PhCH=), 5.03 (H_1; d, $J_{1,2}$=3.7), 4.89 (H_2; d), 4.40 and 4.25 ($C_3'H_2$; ABq, J=9.7), 4.45—4.20 (H_5; m), 3.90—3.60 (H_4, H_{6a} and H_{6e}; m), 3.38 (OMe), 2.16 (OAc), 1.49 and 1.36 (2×C–CH_3).

Found: C, 60.85; H, 7.09%. Calcd for $C_{20}H_{26}O_8$: C, 60.90; H, 6.64%.

*Methyl 3-C-Acetoxymethyl-3,4,6-tri-O-acetyl-2-O-benzoyl-α-D-glucopyranoside (**16**).* A solution of **2** (300 mg, 0.753 mmol) in acetic acid (80%, 60 ml) was refluxed for 18 hr, and evaporated to give a sirup. *n*-Butanol solution (150 ml) of the sirup was washed with saturated sodium bicarbonate and then a small amount of water, decolorized, and evaporated to give a sirup (**15**) in 73% (180 mg) yield. $[\alpha]_D^{23}$ +112° (c 1.10, $CHCl_3$).

Found: C, 54.34; H, 6.11%. Calcd for $C_{15}H_{20}O_8$: C, 54.87; H, 6.14%.

Acid-catalyzed acetylation of **15** (120 mg) gave **16** in a quantitative yield, which was recrystallized from ether–*n*-hexane. Mp 84—86°C; $[\alpha]_D^{23}$ +109° (*c* 1.01, $CHCl_3$); NMR: *ca.* 8.13 and 7.55 (Ph; m), 6.24 (H_1; d, $J_{1,2}$=3.75), 5.92 (H_4; d, $J_{4,5}$=10.0), 5.03 (H_2; d), 5.02 and 4.85 ($C_3'H_2$: ABq, J=10.5), 4.48—4.02 (H_5, H_{6a} and H_{6e}; m), 3.42 (OMe), 2.10, 2.08, 2.00, and 1.92 (4×OAc).

Found: C, 55.63; H, 5.72%. Calcd for $C_{23}H_{28}O_{12}$: C, 55.62; H, 5.69%.

*Methyl 4,6-O-Benzylidene-3-C-aminomethyl-α-D-glucopyranoside (**17**).* A solution of **9** (1.0 g, 3.3 mmol) in saturated ethanolic ammonia (25 ml) was heated for 3 hr in a sealed tube at 80—90°C, and evaporated to give needles, which was recrystallized from ethanol. Yield, 78% (0.8 g); mp 158—159 °C; $[\alpha]_D^{23}$ +92.0° (*c* 1.07, $CHCl_3$). IR: 3390 and 3350 (OH), 3300 (NH_2).

Found: C, 57.87; H, 6.87; N, 4.45%. Calcd for $C_{15}H_{21}NO_6$: C, 57.86; H, 6.80; N, 4.50%.

Acyl derivatives (**18**, **19**, and **20**) of **17** was obtained as follows.

*a) N-Benzoyl Derivatives (**18**)*: To a solution of **17** (300 mg, 0.965 mmol) in methanol (20 ml) was added benzoic anhydride (225 mg, 1.0 mmol) and the resulted solution was refluxed for 5 hr, evaporated to give a sirup which was crystallized from ether. Yield, 67.5% (260 mg); mp 154—155°C; $[\alpha]_D^{23}$+12.0° (*c* 1.05, $CHCl_3$). IR: *ca.* 3400 (NH and OH), 1640 (amide).

Found: C, 63.60; H, 6.20; N, 3.67%. Calcd for $C_{22}H_{25} \cdot NO_7$: C, 63.60; H, 6.07; N, 3.37%.

*b) 2,3-Di-O-acetyl-N-benzoyl Derivative (**19**)*: Acid-catalyzed acetylation of **18** gave the corresponding sirupy di-*O*-acetate in a quantitative yield. $[\alpha]_D^{23}$ −40.8° (*c* 1.48, $CHCl_3$).

Found: C, 62.44; H, 5.96; N, 2.77%. Calcd for C_{26}-

$H_{29}NO_9$: C, 62.51; H, 5.85; N, 2.80%.

*c) N,O-Triacetate (**20**)*: Acid-catalyzed acetylation of **17** (100 mg, 0.329 mmol) gave the *N,O*-triacetate in 97% (136 mg) yield. Mp 180—181°C; $[\alpha]_D^{23}$ −19.6° (*c* 1.36, $CHCl_3$). IR: 3300 (NH), 1750 and 1730 (OAc), 1640 and 1555 (amide); NMR: 7.42 (Ph; s), 6.45 (NH), 5.94 (H_1; d, $J_{1,2}$=4.7), 5.50 (PhCH=), 5.10 (H_4; d, $J_{4,5}$=10.0), 4.84 (H_2; d), 4.42—3.80 (H_5, $H_6{}^a$ and H_6 ; m), 3.87 and 3.68 ($C_3{}'H_2$; ABq, J=9.5), 3.39 (OMe), 2.13 (*sec*-OAc), 1.97 (NAc), 1.77 (*tert*-OAc).

Found: C, 57.62; H, 6.24; N, 3.30%. Calcd for $C_{21}H_{27}NO_9$: C, 57.66; H, 6.22; N, 3.20%.

*Methyl 2-O-Benzoyl-4,6-O-benzylidene-3-C-nitromethyl-α-D-allopyranoside (**21**)*. To a solution of nitromethane (30 ml) in tetrahydrofuran (30 ml) were added successively sodium methoxide (Na; 0.4 g, 174 mmol) and **1** (6 g, 156 mmol) with stirring, the resulted solution was stirred for 3 hr at room temperature, neutralized with acetic acid (60%), extracted with chloroform. The extract was washed with water, and evaporated to give needles which was recrystallized from acetone–ethanol. Yield, 80.5% (5.6 g); mp 169—170°C; $[\alpha]_D^{23}$ +73.8° (*c* 1.0, acetone). IR: 3440 (OH), 1720 (OBz), 1543 (NO_2); NMR: *ca.* 8.08 and 7.46 (Ph; m), 5.58 (PhCH=), 5.22 (H_1; d, $J_{1,2}$=4.3), 5.20 (H_2; d), 4.75 and 4.70 ($C_3{}'H_2$; ABq, J=12.0), 4.41 (H_{6e}; q), 4.25 (OH), 4.22 (H_5; sex, $J_{5,6a}$=9.0, $J_{5,6e}$=4.5), 3.81 (H_{6a}; t, $J_{6a,6e}$=9.0), 3.74 (H_4; d, $J_{4,5}$=9.5), 3.43 (OMe).

Found: C, 59.60; H, 5.40; N, 2.91%. Calcd for $C_{22}H_{23}NO_9$: C, 59.32; H, 5.21; N, 3.14%.

*Methyl 4,6-O-Benzylidene-3-C-benzamidomethyl-α-D-allo-pyranoside (**22**)*. A solution of **21** (4 g, 9 mmol) in methanol (100 ml) was hydrogenated in an autoclave in the presence of Raney nickel at 30 atm, 70 °C for 6 hr, filtered in hot state, and evaporated to give prisms which were recrystallized from ethanol. Yield, 2.4 g (65%); mp 234—235°C; $[\alpha]_D^{23}$ −19.3° (*c* 1.0, acetone).

Found: C, 64.04; H, 5.84; N, 3.40%. Calcd for $C_{22}H_{25}NO_7$: C, 63.60; H, 6.07; N, 3.37%.

Acetyl derivatives of **22** was synthesized as follows;

*a) 2-O-Acetate (**23**)*: Acetylation of **22** by the usual method and recrystallization of the product from ethanol–*n*-hexane gave 23 in 77% yield. Mp 214—215°C; $[\alpha]_D^{23}$ +44.4° (*c* 0.96, $CHCl_3$). IR: 3490 (OH), 3430 (NH), 1720 (OAc), 1642 and 1515 (amide); NMR: 7.70—7.30 (2×Ph; m), 7.00 (NH), 4.90 (H_1; d, $J_{1,2}$=4.0), 4.86 (H_2; d), 4.35 (H_{6e}; q, $J_{5,6e}$=9.5), 4.10 and 3.35 (C_3H_2; ABq. J=13.5), *ca.* 4.02 (H_5; m), 3.58 (H_4; d, $J_{4,5}$=9.5), 3.24 (H_{6a}; q, $J_{6a,6e}$=9.3), 2.13 (OAc).

Found: C, 62.96; H, 5.87; N, 3.09%. Calcd for $C_{24}H_{27}NO_8$: C, 63.01; H, 5.95; N, 3.06%.

*b) 2,3-Di-O-acetate (**24**)*: Acid-catalyzed acetylation of **22**, and recrystallization of the product from ethanol–*n*-hexane gave **25** in 83% yield. Mp 175—176°C; $[\alpha]_D^{23}$+23.1° (*c* 1.05, $CHCl_3$).

Found: C, 62.43; H, 5.84; N, 2.83%. Calcd for $C_{26}H_{29}NO_9$: C, 62.51; H, 5.85; N, 2.80%.

*De-N-benzoylation of **22***. A suspended solution of **22** (3.0 g) in methanolic potassium hydroxide (6 g in 15 ml) was refluxed for 5 hr, the precipitate (sodium benzoate) was filtered off, and the filtrate was poured into water. The resulted solution was extracted with chloroform, and the extract was washed with water, and evaporated to give crystals which were recrystallized from acetone. Yield, 0.9 g (36%). The structure of this crystal was determined to be methyl 4,6-*O*-benzylidene-2,3,*N*-benzylidine-3-*C*-(hydroxymethyl)-α-D-allopyranoside (**25**). Mp 194—197°C (dec.); $[\alpha]_D^{23}$ +64.2° (*c* 1.0, EtOH); IR: 1600 (Ph), 1525 (C–N), and 1380.

Found: C, 61.03; H, 6.35; N, 3.20%. Calcd for $C_{22}H_{23}NO_6\cdot 2H_2O$: C, 60.96; H, 6.28; N, 3.23%.

On the other hand, the water layer was extracted with *n*-butanol, after neutralization with 4N hydrochloric acid. Evaporation of *n*-butanol extracts gave de-*O*-benzoylated free amine **26** (24.0%, 0.6 g) and **22** (23.3%, 0.7 g) by fractional crystallization from methanol. Mp 205—210°C (dec.); $[\alpha]_D^{23}$ +79.4° (*c* 1.0, H_2O); IR: 3350 (OH), 3120 and 3050 (NH_2).

Found: C, 51.85; H, 6.27; N, 3.80%. Calcd for $C_{15}H_{21}NO_6\cdot 2H_2O$: C, 51.86; H, 7.25; N, 4.03%.

Base-catalyzed acetylation of **25** and **26** gave the corresponding 3-C-*acetamidomethyl*-2-O-*acetyl derivative* (**27**) in a quantitative yield. Mp 168°C; $[\alpha]_D^{23}$+39.7° (*c* 0.92, $CHCl_3$); IR: 3430 (OH), 3360 (NH), 1720 (ester), 1650 and 1530 (amide).

Found: C, 57.65; H, 6.11; N, 3.43%. Calcd for $C_{19}H_{25}NO_8$: C, 57.71; H, 6.37; N, 3.54%.

*Methyl 2-O-Benzoyl-3-C-nitromethyl-α-D-allopyranoside (**28**)*. To a solution of **21** (3.0 g) in acetone (20 ml) was added portionwise 0.2 N sulfuric acid (15 ml) at 40 °C, maintained at the temperature for 3 hr, neutralized with sodium bicarbonate, and concentrated. The residue was extracted with ethanol, and the ethanol solution was evaporated to give a sirup which was recrystallized from methanol–water. Yield, 87% (2.1 g); mp 152—154°C; $[\alpha]_D^{23}$ +92.5° (*c* 1.0, ethanol). IR: 3410 and 3510 (OH), 1720 (OBz), 1540 (NO_2).

Found: C, 50.83; H, 5.03; N, 4.04%. Calcd for $C_{15}H_{19}NO_9$: C, 50.42; H, 5.36; N, 3.92%.

This compound was also prepared by partial hydrogenation of **22** in the presence of palladium-charcoal in 53% yield, and it was converted into sirupy tri-*O*-acetate (**29**) by acid-catalyzed acetylation in 90% yield. $[\alpha]_D^{23}$ +91.5° (*c* 1.25, $CHCl_3$); IR: 1720 and 1760 (ester), 1550 (NO_2).

Found: C, 52.97; H, 5.55; N, 2.87%. Calcd for $C_{21}H_{25}NO_{12}$: C, 52.17; H, 5.21; N, 2.90%.

*Methyl 2-O-Benzoyl-3,4-O-isopropylidene-3-C-nitromethyl-α-D-allopyranoside (**30**)*. A suspended solution of **28** (1 g), and anhydrous cupric sulfate (2 g) in acetone (50 ml) containing one drop of sulfuric acid was stirred for 3 days at room temperature, neutralized with barium carbonate, filtered, and the filtrate was evaporated to give a sirupy product. The sirup was fractionated through a Kiesel gel 60 (Merck) column with benzene–methanol effluent (15 : 1) to give **28** (0.25 g) and **30** (0.67 g, 58%) which was crystallized from ethanol–*n*-hexane. Mp 138—139°C.

Found: C, 54.18; G, 5.57; N, 3.83%. Calcd for $C_{18}H_{23}NO_9$: C, 54.40; H, 5.83; N, 3.53%.

Acid-catalyzed acetylation of **30** gave *6*-O-*acetate* (**31**) in a quantitative yield, which was recrystallized from ethanol–*n*-hexane. Mp 143—143.5°C; IR: 1720 (ester), 1560 (NO_2), 1370 (CCH_3); NMR: 8.07—4.51 (Ph; m), 5.87 (H_1; d, $J_{1.2}$=5.1), 4.99 (H_2; d), 4.64 (C_3H_2; s), 4.58—5.10 (H_4, H_5, and $H_{6a,b}$; m), 3.40 (OMe), 2.10 (OAc), 1.40 and 1.29 (2×CCH_3).

Found: C, 54.44; H, 5.77; N, 3.11%. Calcd for $C_{20}H_{25}NO_{10}$: C, 54.66; H, 5.74; N, 3.19%.

The authors are grateful to Mr. Hitoshi Matsumoto for NMR measurements, and members of the Laboratory of Organic Analysis for elemental analysis.

Optically Active Triptycenes. VI.[1] Optical Resolution of 2,5-Dihydroxy-8-methoxycarbonyltriptycene and Absolute Configuration of 2,5-Dimethoxy-8-methoxycarbonyltriptycene

Yasumi SHIMIZU, Taketoshi NAITO, Fumio OGURA, and Masazumi NAKAGAWA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received December 1, 1972)

After several unsuccessful attempts, optical resolution of 2,5-dihydroxy-8-methoxycarbonyltriptycene could be attained by means of bis-camphanate derivative. The absolute configuration of (+)-2,5-dimethoxy-8-methoxycarbonyltriptycene derived from (+)-2,5-dihydroxy-8-methoxycarbonyltriptycene was determined as 1*R*,6*S* by chemical correlation with (+)-2,5-dimethoxy-7-dimethylaminotriptycene hydrobromide whose absolute configuration had been proved to be 1*R*,6*S* by the X-ray structure analysis using the Bijvoet method.

Optically active triptycene derivatives can be regarded as ideally suited model compounds for the study of rotatory properties in view of their rigid and definite molecular structure. As reported in previous papers, 2,5,7- and 2,5,8-trisubstituted triptycene derivatives have been synthesized and one of the former compounds has been resolved into enantiomers[2] which could be transformed in a number of optically active 2,5,7-trisubstituted triptycenes bearing various kinds of substituent groups.[3] We have also reported the synthesis and absolute configuration of optically active 2,7-disubstituted triptycenes[4] and the analysis of their CD spectra.[5]

The direction of long-axis polarized transition moment in 7-substituted benzene ring in 2,5,7-trisubstituted triptycenes is parallel to the three-fold symmetry axis of triptycene skeleton, whereas the direction of the transition moment in 8-substituted nucleus in 2,5,8-trisubstituted derivatives should deviate from the parallel direction.[6] Therefore, it seemed to be of considerable interest to compare the optical rotatory properties of 2,5,8-trisubstituted triptycenes with those of 2,5,7-trisubstituted analogues. The present paper deals with the optical resolution of 2,5-dihydroxy-8-methoxycarbonyltriptycene and determination of the absolute configuration of its dimethyl ether derivative by chemical means.

Optical Resolution. The optical resolution of 2,5-disubstituted-8-carboxytriptycenes using the carboxyl group (R_2) as a handle was encountered by serious difficulty. Since the difficulty seemed to be ascribable to the remote position of R_2 from the asymmetric center, 2,5-dihydroxy-8-carboxytriptycene was converted into 2,5-diacyloxy-8-carboxytriptycenes (IIIa–d) bearing various acyl groups with increasing steric requirement to increase the interaction with resolving agent attached to carboxyl group at 8-position. All

attempts to resolve IIIa–b with optically active amines and alkaloids gave fruitless results. Partial resolution was observed in the case of IIId. However, complete resolution could not be achieved owing to a gradual decomposition of IIId during the course of fractional recrystallization. Considering the presence of carboxyl groups in acyloxy substituents in IIId, the introduction of acid phthalate groups into 2- and 5-positions was attempted. But bis-acid phthalate derivative could not be obtained in pure form. The attempts of resolution *via* menthoxyacetate (IIIe) or urethane (IIIf) gave unsatisfactory results. The alkaloid salts of IIIj and cholesteryl derivatives (IIIk and IIIl) could be obtained in good crystalline states. However, no optical resolution could be attained with these derivatives.

Considering these fruitless results, we decided to use camphanic acid as resolving agent[7] which has a reacting site at a proximity of its own asymmetric center. The synthesis of 2,5-dihydroxy-8-methoxycarbonyltriptycene (IIIh) was performed by the reported method[2] with modification. The Diels-Alder reaction of *p*-benzoquinone with 2-methoxycarbonylanthracene was carried out in dioxane in place of benzene resulting in a much higher yield of the adduct (II, 65%). The adduct (II) could be separated in a high melting and low melting stereoisomers by recrystal-

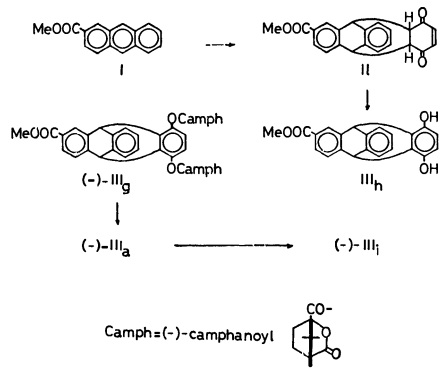
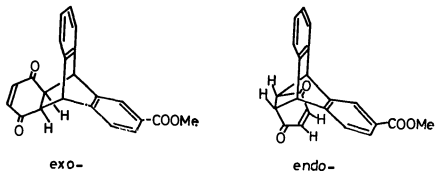


Scheme 1. Optical resolution of 2,5-dihydroxy-8-methoxycarbonyltriptycene (IIIh).



lization from methanol which could be assigned to *exo*- and *endo*-isomers, respectively, on the basis of NMR spectral evidence. As illustrated in Fig. 1, *endo*-isomer exhibits poorly resolved signal of olefinic protons at τ 3.62, whereas the olefinic protons of *exo*-isomer gave a sharp singlet at τ 3.63. The splitting of signal of *endo*-isomer can be reasonably attributed to the anisotropy of methoxycarbonyl group situated in a relatively proximate position. Treatment of a mixture of *endo*- and *exo*-isomers (II) in benzene with hydrogen chloride yielded 2,5-dihydroxy-8-methoxycarbonyltriptycene (IIIh).

(−)-Camphanic acid chloride was prepared from (+)-camphor *via* (+)-camphoric acid, (−)-camphoric anhydride and (−)-monobromocamphoric anhydride.[8]

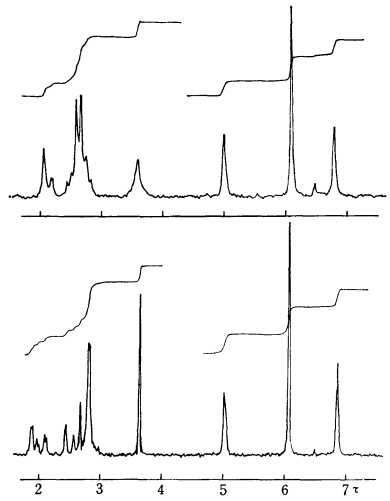


Fig. 1. NMR spectra of *endo*- (top) and *exo*-adducts (bottom) (II).

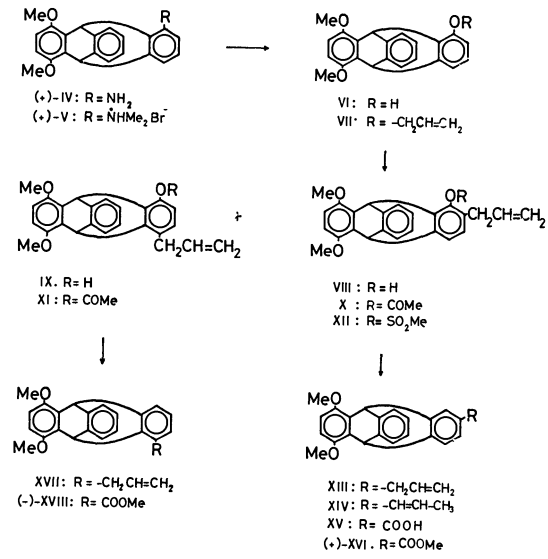
8) O. Aschan, *Acta Soc. Sci. fenn.*, **21**, 1 (1895); *Chem. Zentr.*, **1895II**, 967.

The reaction of acid chloride with IIIh in pyridine afforded bis-camphanate (IIIg) in a high yield (82—97%). Bis-camphanate (IIIg) was repeatedly recrystallized from methanol (4—7 times) to give crystals with a constant specific rotation. The resolved bis-camphanate (IIIg) was dissolved in methanol saturated with hydrogen chloride and the mixture was refluxed to convert IIIg into (−)-IIIh and methyl camphanate. Chromatography of the reaction product on silica gel afforded (−)-IIIh in a quantitative yield. (−)-2,5-Dimethoxy-8-methoxycarbonyltriptycene (IIIi) was obtained from (−)-IIIh on treatment with dimethyl sulfate.

Absolute Configuration. The reaction of allyl chloride with crude phenol (VI) obtained by hydrolysis of the diazonium salt of (+)-2,5-dimethoxy-7-aminotriptycene (IV)[3b] afforded (+)-allyl ether (VII).



Scheme 2. Chemical correlation of 2,5,7-trisubstituted triptycene with 2,5,8-trisubstituted triptycene.

The Claisen rearrangement of (+)-VII in boiling diethylaniline gave rearranged products (VIII and IX) in an almost quantitative yield. Separation of VIII and IX could be attained by chromatography on silica gel. Although the purification of the allylic phenols (VIII and IX) were found to be difficult, the IR spectrum of IX in Nujol exhibits a sharp absorption at 3400 cm^{-1} due to stretching vibration of OH group, on the other hand, the spectrum of VIII shows a broad absorption at 3300—3350 cm^{-1}. Broadening of the band to higher wave number can be presumably attributed to an increased crowding by the presence of vicinal allyl group. Acetylation of VIII and IX yielded pure X and XI, respectively. The NMR spectra of X and XI provide further support for the assigned structures. The bridgehead protons of XI exhibit signals at τ 4.10 and 3.88. On the other hand, those of X give signals at τ 4.20 and 4.15. The signal at τ 3.88 in XI can be assigned to bridgehead proton at C-6 which suffers the deshielding effect of acetoxyl group at C-7. The fact that the bridgehead protons of X resonate at nearly the same field (τ 4.20

and 4.15) indicates a decrease of deshielding effect of acetoxyl group due to a twisting by a steric interference with the vicinal allyl substituent.

Crude methanesulfonate (XII) obtained from VIII and methanesulfonyl chloride was treated with sodium in liquid ammonia[9] to give XIII. Allylic rearrangement of XIII with potassium hydroxide in diethylene glycol yielded propenyl derivative (XIV). 2,5-Dimethoxy-8-carboxytriptycene (XV) obtained by permanganate oxidation of XIV was converted into (+)-methyl ester (XVI). The NMR spectrum of XVI was found to be identical with that of (−)-IIIi obtained by the optical resolution of (±)-IIIh. The melting points [(+)-XVI: mp 255.8—256.1 °C; (−)-IIIi: mp 256.1—256.8 °C] and optical rotations [(+)-XVI: $[\alpha]_D^{16}$+11.3°, $[\alpha]_{500}^{16}$+19.7° (*c* 0.531, dioxane); (−)-IIIi: $[\alpha]_D^{20}$−10.3°, $[\alpha]_{500}^{16}$−20.5° (*c* 0.291, dioxane)] indicate clearly that (+)-XVI is the antipode of (−)-IIIi. Because the absolute configuration of (+)-V derived from (+)-IV has been determined as 1*R*, 6*S* by the Bijvoet method of X-ray structure analysis,[10] the chemical correlation of (+)-XVI with (+)-IV clearly demonstrates 1*R*,6*S* absolute configuration of (+)-XVI, *i.e.*, 1*R*,6*S* absolute configuration of (−)-IIIi.

A mixture of VIII and IX obtained by the Claisen rearrangement of (+)-VII was converted into a mixture of propenyl derivatives (XIV and XVII) according to the method used for VIII. Permanganate oxidation of the mixture XIV and XVII followed by esterification afforded (+)-XVI and (−)-XVIII. The NMR spectrum of (−)-XVIII is identical with that of (+)-2,5-dimethoxy-7-methoxycarbonyltriptycene (XIX).[3b]. The specific rotations of (−)-XVIII and (+)-XIX indicate that the former is the enantiomer of the latter [(−)-XVIII: $[\alpha]_D^{20}$−23.2°; (+)-XIX: $[\alpha]_D^{25}$+25.5° (*c* 0.7475, dioxane)]. Because it is evident that (−)-XVIII is derived from *para*-Claisen rearrangement product (IX), and (+)-IV, the parent compound of (+)-XVI and (−)-XVIII, has been prepared from (+)-XVIII,[3b] the formation of (−)-XVIII from (+)-IV provides an interesting instance of conversion of absolute configuration of triptycene derivative by the transfer of a substituent group from 7- to 10-position.

Experimental

The melting points were measured on Mettler FP2 apparatus and Shimadzu Kohfler micro hot stage, and uncorrected. Purified and anhydrous solvents were used, unless otherwise stated. The IR spectra were obtained on Hitachi EPI-2 or JACSO DS-301 spectrometer. The electronic spectra were measured with Hitachi EPS-3T spectrophotometer. The NMR spectra in deuteriochloroform were taken with Varian A-60 spectrometer using TMS as an internal standard and given in τ-values. The rotations and CD spectra were obtained on Yanagimoto ORD-185 and JASCO J-20 spectropolarimeters, respectively. The shoulder and inflection are denoted with an asterisk. Only the main peaks of IR and NMR spectra were recorded.

Preparation of Adduct (II). To a hot solution of 2-methoxycarbonylanthracene (I, 10.0 g, 0.042 mol) in dioxane (120 ml) was added in one portion a solution of *p*-benzoquinone (10.0 g, 0.093 mol) in the same solvent (50 ml). After being stirred for 7 hr, the mixture was concentrated under reduced pressure and the quinone remained was removed by steam distillation. The residue was extracted with benzene and crystalline solid (13.7 g) obtained by working up the benzene extract was recrystallized twice from methanol to give a mixture of *endo*- and *exo*-II as yellow crystals (9.5 g, 65%). Repeated recrystallization of the mixture from methanol afforded *exo*-II (less soluble) and *endo*-II (more soluble).

exo-II, mp 188—189 °C (sintered at 170 °C), IR (KBr disk): $\nu_{C=O}$ 1717, 1677 cm^{-1}, NMR: 6.87 (s, 2H, bridge), 6.07 (s, 3H, $-CO_2CH_3$), 5.02 (s, 2H, bridgehead), 3.63 (s, 2H, olefinic), 1.88—2.81 (m, 7H, aromatic), UV: $\lambda_{max}^{dioxane}$ (ε) 240* (15,600), 247* (13,600), 251* (12,300), 257* (9,010), 262* (6,490), 269* (3,110), 275* (2,180), 284* (1,390), 360* (71.5), 378 (76.3), 400* (55.7), 420* (22.5) nm.

Found: C, 76.30; H, 4.73%. Calcd for $C_{22}H_{16}O_4$: C, 76.73; H, 4.68%.

endo-II, mp 149—157 °C (sintered at 148 °C), IR (KBr disk): $\nu_{C=O}$ 1725, 1675 cm^{-1}, NMR: 6.81 (s, 2H, bridge), 6.11 (s, 3H, $-CO_2CH_3$), 5.01 (s, 2H, bridgehead), 3.62 (broad s, 2H, olefinic), 2.07—2.83 (m, 7H, aromatic), UV: $\lambda_{max}^{dioxane}$ (ε) 238.5 (16,200), 243.5 (15,500), 249 (16,000), 255 (15,100), 261 (9.170), 271* (2,710), 284* (1,380), 360* (69.1), 377 (78.8), 395* (63.8), 410* (18.0) nm.

Found: C, 76.18; H, 4.76%. Calcd for $C_{22}H_{16}O_4$: C, 76.73; H, 4.68%.

2,5-Dihydroxy-8-methoxycarbonyltriptycene (IIIh). Hydrogen chloride was introduced to a solution of a mixture of *endo*- and *exo*-II (20.0 g, 0.058 mol) in benzene (400 ml). After the mixture was allowed to stand for 4 hr at room temperature, the reaction mixture containing colorless fine crystals was concentrated under reduced pressure. The residue was recrystallized from benzene to yield IIIh, colorless crystals, mp 159—162 °C, 17.1 g (85%), IR (Nujol mull): ν_{OH} 3270, $\nu_{C=O}$ 1690 cm^{-1}.

Found: C, 76.56; H, 5.06%. Calcd for $C_{22}H_{16}O_4$: C, 76.73; H, 4.68%.

IIIh was also obtained in a 60.8% yield by refluxing a mixture of 2,5-dihydroxy-8-carboxytriptycene[2] (14.5 g), methanol (73 ml) and sulfuric acid (4.4 ml) for 8 hr.

2,5-Bis(camphanoyl)-8-methoxycarbonyltriptycene (IIIg). A solution of IIIh (15.0 g, 0.0436 mol), camphanoyl chloride[8] (20.8 g, 0.0960 mol) in pyridine (330 ml) was allowed to stand overnight at room temperature. The mixture was poured onto ice-water (2 l) and extracted with benzene. The extract was washed successively with 1 M hydrochloric acid, water, 1% aqueous sodium hydrogen carbonate and water, and dried. Concentration of the extract afforded colorless crystals, mp 141—188°C, 21.1 g (81.8%), IR (Nujol mull): 1795, 1730 cm^{-1}.

The crystals decomposed on an attempted chromatography on silica gel.

A portion of the bis-camphanate (2.7 g) was repeatedly recrystallized from methanol (4—7 times) to obtain bis-camphanate with constant specific rotation, mp 195.9—198.2 °C (the mp gradually increased to 240 °C and again decreased to the constant value during the course of recrystallization), IR (Nujol mull) 1800, 1730 cm^{-1}, $[\alpha]_{390}^{15}$

9) H. W. Thompson, *J. Org. Chem.*, **33**, 621 (1968).

10) N. Sakabe, K. Sakabe, K. Ozeki-Minakata, and J. Tanaka, presented at the 9th International Congress of Crystallography (1972); *Acta Crystallogr.*, **B28**, 3441 (1972).

$-20.4°$ (c 0.588, dioxane).

Found: C, 71.25; H, 5.73%. Calcd for $C_{42}H_{40}O_{10}$: C, 71.58; H, 5.72%.

Optically pure bis-camphanate was also obtained when a solution of the crude bis-camphanate (2.7 g) in dichloromethane (10 ml) was mixed with hot methanol (500 ml) and the mixture was concentrated to one-half of its original volume.

(−)-2,5-Dihydroxy-8-methoxycarbonyltriptycene (IIIh). To a mixture of optically pure bis-camphanate (IIIg, 2.05 g) in methanol (140 ml) was introduced hydrogen chloride for 40 min under ice-cooling, and the mixture was refluxed for 5 hr to give a colorless homogeneous solution. After one-half of the methanol had been removed under reduced pressure at room temperature, the reaction mixture was poured into a saturated sodium chloride solution (300 ml) and extracted with ether. The extract, after being washed with a saturated aqueous sodium chloride, was concentrated under reduced pressure. Crude crystals (1.96 g) thus obtained were chromatographed on silica gel (Merck, 250 g). Elution with benzene–ether (9 : 1) afforded methyl camphanate (1.04 g). Crude (−)-IIIh (1.13 g) obtained by elution with benzene–ether (7.5 : 2.5) was recrystallized from a small amount of benzene to give pure (−)-IIIh, colorless crystals, 0.90 g (90%), $[\alpha]_{589}^{20}$ −9.71° (c 0.258, ethanol).

(−)-2,5-Dimethoxy-8-methoxycarbonyltriptycene (IIIi). A solution of (−)-IIIh (37.0 mg, 0.107 mmol) in acetone (30 ml) was refluxed for 6 hr under stirring with dimethyl sulfate (112 mg) in the presence of anhydrous potassium carbonate (200 mg). The reaction mixture was worked up by the usual way to give crude (−)-IIIi which was dissolved in benzene and passed through a short column of alumina. Crystals obtained from the filtrate were recrystallized from methanol to give pure (−)-IIIi, mp 256.1—256.8 °C (racemate, mp 248—249 °C), $[\alpha]_D^{20}$ −10.3° (c 0.291, dioxane), UV: λ_{max}^{EtOH} (ε) 303* (4.030), 292 (6,480), 285* (5,830), 267 (7,870), 226 (35,700), 203.5 (52,800) nm, CD: λ_{max}^{EtOH} ($\Delta\varepsilon$) 320 (+0.3), 299.2 (−3.11), 289.8 (+1.80), 280.5 (−0.29), 268.0 (+9.41), 261.5 (+4.99), 243.5 (+20.9), 229.0 (−44.9), 218.6 (+31.9), 208.4 (−35.5) nm.

Found: C, 77.35; H, 5.49%. Calcd for $C_{24}H_{20}O_4$: C, 77.40; H, 5.41%.

2,5-Dimethoxy-7-allyloxytriptycene (VII). (+)-2,5-dimethoxy-7-aminotriptycene[3b] (IV, 6.95 g, 21.1 mmol) was dissolved in hot acetic acid (307 ml) and a solution of sodium nitrite (0.49 g, 21.3 mmol) in water (42 ml) and acetic acid (100 ml) were added at 12—14 °C over a period of 1 hr. After the mixture being stirred for 30 min at the same temperature, the solution of diazonium salt was added dropwise over a 40-min period to boiling 3 M sulfuric acid under vigorous stirring, and stirring was continued for further 30 min under reflux. Precipitate obtained on cooling the reaction mixture was washed with water to give crude (+)-VI, 6.44 g (92%). A mixture of the crude (+)-VI (6.34 g, 19.2 mmol), acetone (340 ml), potassium carbonate (8.4 g), allyl chloride (4.0 g) and a small amount of sodium iodide was refluxed for 19 hr under stirring. Further amount of allyl chloride (2.0 g) was added during the period of reflux. Insoluble material was removed by filtration and the filtrate was concentrated under reduced pressure. The residue was extracted with benzene. The extract, after washing and drying, was evaporated under reduced pressure to give crude (+)-VII (7.3 g). The crude (+)-VII was chromatographed on alumina. Crystals obtained from benzene-eluate were recrystallized from the same solvent to yield pure (+)-VII, mp 255.0—256.0 °C, 4.57 g (59.3% based on (+)-IV), (racemate, mp 229.5—231.0 °C).

Found: C, 80.94, H, 6.07%. Calcd for $C_{25}H_{22}O_3$: C, 81.05; H, 5.99%.

(+)-2,5-Dimethoxy-7-hydroxy-8-allyltriptycene (VIII) and (−)-2,5-Dimethoxy-7-hydroxy-10-allyltriptycene (IX). A solution of (+)-VII (4.25 g, 11.5 mmol) in diethylaniline (450 ml) was refluxed for 6 hr under nitrogen atmosphere. The reaction mixture was acidified with 8 M hydrochloric acid under ice-cooling and then mixed with water (2.5 l), and extracted with benzene. The extract, after being washed and dried, was evaporated to give an amorphous solid (4.27 g). The solid dissolved in benzene was chromatographed on silica gel (Merck). Elution with benzene afforded (+)-VIII 3.37 g (79.3%), IR (Nujol mull): 3300—3550 (broad), 715 cm^{-1}, and (−)-IX, 0.82 g (19.3%), IR (Nujol mull): 3400 (sharp), 735, 725 cm^{-1} was obtained from benzene–ether eluate (8 : 2).

(+)-2,5-Dimethoxy-7-acetoxy-8-allyltriptycene (X). The product obtained by the acetylation of (+)-VIII (223 mg, 0.602 mmol) with acetic anhydride (7 ml) and sodium acetate (0.1 g) by the usual way was dissolved in benzene and chromatographed on silica gel. The crystals obtained from benzene-eluate were recrystallized twice from ethanol, mp 166.8—169.0 °C, 137.0 mg (55%) (racemate, mp 167.0—168.0°C), IR (Nujol mull): $\nu_{C=O}$, 1770, 1760*, $\nu_{C=C(allyl)}$, 1645 cm^{-1}, $[\alpha]_D^{20}$ +13.0° (c 0.276, dioxane), NMR: 7.57 (s, CH_3CO–), 6.25 (s, CH_3O–), 4.20, 4.15 (bridgehead), 3.57 (aromatic H(3), H(4)).

Found: C, 78.18; H, 5.95%. Calcd for $C_{27}H_{24}O_4$: C, 78.62; H, 5.86%.

(−)-2,5-Dimethoxy-7-acetoxy-10-allyltriptycene (XI). According to the procedure for (+)-X, (−)-IX was converted into (−)-XI, mp 223.0—223.7 °C (from ethanol), 0.58 g (61%), IR (Nujol mull): $\nu_{C=O}$, 1770, $\nu_{C=C(allyl)}$, 1645 cm^{-1}, $[\alpha]_D^{20}$ −5.6° (c 0.252, dioxane),, NMR: 7.60 (CH_3CO–), 6.25 (CH_3O–), 4.10, 3.88 (bridgehead), 3.55 (aromatic, H(3), H(4)), 3.28 (aromatic, H(8), H(9), AB-quartet, J_{AB}= 8 Hz).

Found: C, 78.25; H, 5.77%. Calcd for $C_{27}H_{24}O_4$: C, 78.62; H, 5.86%.

(+)-2,5-Dimethoxy-8-allyltriptycene (XIII). Methanesulfonyl chloride (2.0 g) was added to a solution of (+)-VIII (3.37 g, 9.09 mmol) in pyridine (30 ml). After being kept at room temperature overnight, the reaction mixture was poured onto ice-water, acidified with 3 M hydrochloric acid and extracted with benzene. After being washed and dried, the solvent was removed under reduced pressure, yielding crude (+)-XII, 3.95 g (97%) as an amorphous solid, IR (Nujol mull): 1360 cm^{-1} (racemate, 1350 cm^{-1}). A solution of crude (+)-XII, 3.89 g (8.67 mmol) in tetrahydrofuran (150 ml) was added to liquid ammonia. Sodium, 0.51 g (22.3 mg-atom) was added to the stirred solution. After being stirred for 10 min, ammonium chloride (5 g) was added to the reaction mixture, and allowed to stand overnight at room temperature. Volatile material was removed under reduced pressure and the residue was extracted with benzene. The extract, after washing and drying, was concentrated to give crude amorphous (+)-XIII, 3.17 g which was chromatographed on silica gel (Merck). Elution with carbon tetrachloride–benzene (3 : 7) afforded crude (+)-XIII, 1.40 g (48%). Recovered (+)-VIII, 1.40 g (42%) was obtained from ether–benzene (1 : 9) eluate which was converted into (+)-XII and reduced with sodium in liquid ammonia. This procedure was repeated twice to give (+)-XIII (total 2.66 g, 83.9%) and recovered (+)-VIII (0.18 g, 5.4%).

(+)-2,5-Dimethoxy-8-propenyltriptycene (XIV). A mixture of (+)-XIII (2.68 g, 7.57 mmol), diethylene glycol (27 ml) and finely powdered potassium hydroxide (3.0 g) was heated to 190—220 °C for 1.5 hr. Crystals deposited were washed successively with a small amount of diethylene glycol and water to yield (+)-XIV, colorless needles, 2.45 g (91.5%). Second crop of crystals obtained from the mother liquor were recrystallized from ethanol, yielding pure (+)-XIV, 0.16 g (total yield 2.61 g, 97.6%), mp 226.2—231.0 °C, NMR: 8.21 (d, J=5 Hz, CH_3 of propenyl), 4.17 (s, bridgehead).

Found: C, 84.63; H, 6.25%. Calcd for $C_{25}H_{22}O_2$: C, 84.71; H, 6.26%.

(+)-2,5-Dimethoxy-8-methoxycarbonyltriptycene (XVI). Potassium permanganate (5.24 g) was added to a solution of (+)-XIV (2.20 g, 6.21 mmol) in acetone (920 ml) and the mixture was stirred at room temperature overnight. Excess permanganate was reduced by sodium hydrogen sulfite and manganese dioxide was removed by filtration. The residue obtained by evaporation of the solvent was mixed with 3M hydrochloric acid and extracted with benzene. The extract, after being washed and dried, was concentrated to yield crude (+)-XV (2.44 g). A mixture of the crude (+)-XV, (2.41 g), methanol (150 ml) and concentrated sulfuric acid (5 ml) was refluxed for 8 hr and the reaction mixture was worked up by the usual way to yield crude amorphous (+)-XVI (2.66 g) which was chromatographed on alumina. Crystals obtained from benzene-eluate were recrystallized from methanol, yielding pure (+)-XVI, mp 255.8—256.1 °C, 0.803 g (34.8% based on XIV), $[\alpha]_D^{16}$ +11.7° (c 0.531, dioxane). (racemate, mp 248—249 °C, sintered at 237 °C).

The NMR spectrum of (+)-XVI was found to be identical with that of (−)-2,5-dimethoxy-8-methoxycarbonyltriptycene (IIIi).

Found: C, 77.39; H, 5.37%. Calcd for $C_{24}H_{20}O_4$: C, 77.40; H, 5.41%.

(−)-2,5-Dimethoxy-7-methoxycarbonyltriptycene (XVIII). A mixture of VIII and IX, product of the Claisen rearrangement of (+)-VII, was converted into a mixture of propenyl derivatives (XIV and XVII) according to the procedure used in the transformation of (+)-VIII into (+)-XIV. Permanganate oxidation followed by esterification of the mixture of XIV and XVII afforded a mixture of (+)-XVI and (−)-XVIII which was repeatedly chromatographed on alumina using carbon tetrachloride–benzene (1 : 4) as an eluant. Crystals obtained from initial eluate were recrystallized from methanol to give (−)-XVIII, mp 267.4—268.0 °C $[\alpha]_D^{20}$ −23.2° (c 0.198, dioxane). (−)-XVIII gave an identical NMR spectrum with that of (+)-2,5-dimethoxy-7-methoxycarbonyltriptycene prepared by a different route.[3b]

Found: C, 76.80; H, 5.33%. Calcd for $C_{24}H_{20}O_4$: C, 77.40; H, 5.41%.

Preparation of 2,5-Diacyloxy-8-carboxytriptycenes (IIIa—d). Crude 2,5-dihydroxy-8-carboxytriptycene[2] was heated with a large excess of corresponding acid anhydride or acid chloride in the absence or presence of solvent. The reaction mixture was treated with water and the acid formed from excess of reagent was removed. Crude materials were purified by recrystallization. The structures were confirmed by elemental analyses, IR and NMR spectroscopy. Reaction conditions, melting points, solvent of recrystallization and yields are summarized in Table 1.

2,5-Bis(1-menthoxyacetoxy)-8-methoxycarbonyltriptycene (IIIe). To an ice-cooled solution of IIIh (2.10 g, 6.10 mmol) in pyridine (10 ml) was added *l*-menthoxyacetyl chloride (3.12 g, 13.4 mmol) over a 10-min period under nitrogen atmosphere. The mixture was stirred for 80 min under ice-cooling and then for 17 hr at 33 °C. The neutral portion of the reaction product dissolved in benzene was passed through a column of silica gel (30 g) and eluted successively with benzene–ligroin and benzene. Crude IIIe (2.25 g, 50.6%) obtained from the eluates was recrystallized 3 times from methanol–methyl acetate to give pure IIIe, mp 177.5—181 °C, $[\alpha]_D^{25}$ −53.1° (methanol). IIIe gave unsatisfactory result of hydrogen analysis.

Found: C, 74.96; H, 6.87%. Calcd for $C_{46}H_{56}O_8$: C, 74.97; H, 7.66%.

2,5-Dimethoxy-8-carboxytriptycene (IIIj). A mixture of IIIi (0.67 g), acetic acid (44 ml) and 3M sulfuric acid (11 ml) was refluxed for 12 hr. Colorless crystals (0.575 g, 88.7%) deposited on cooling the reaction mixture, after being washed with water and dried, were recrystallized from methanol and then sublimed *in vacuo* to give pure IIIj. IIIj showed double melting points, mp 140—150 °C, mp 280.2—283.5 °C.

Found: C, 76.86; H. 5.03%. Calcd for $C_{23}H_{18}O_7$: C, 77.08; H, 5.06%.

Preparation of 8-Cholesteryloxycarbonyltriptycene Derivatives (IIIk and IIIl). IIIa and IIIb in tetrahydrofuran were converted into corresponding acid chloride by the reaction with thionyl chloride according to the usual way. A mixture of the acid chloride, cholesterol and pyridine was heated. The reaction product dissolved in benzene was chromatographed on alumina. IIIk and IIIl were obtained from benzene eluate. Their IR and NMR spectra were found to be consistent with the assigned structures. They gave satisfactory data of elemental analyses. Reaction conditions and physical properties are summarized in Table 2.

TABLE 1. 2,5-DIACYLOXY-8-CARBOXYTRIPTYCENE (IIIa—d)

Product	Dihydroxy compound (g)	Acylating agent (g)	Solvent (ml)	Reaction time (hr)	Reaction temp. (°C)	Yield (g)	Yield (%)	Mp (°C)	Solvent of recryst.
IIIa[2]	2.1	acetic anhydride (40 ml) + sodium acetate 16.3	none	4	100	1.9	49.5	235—237	acetic acid
IIIb	0.92	isobutyric anhydride 9	none	1.5	100	0.95	72.2	137—145	benzene
IIIc	3.49	trimethylacetyl chloride 7.2	pyridine 6	3.0	reflux	1.26	23.7	253—255	methanol
IIId	4.0	succinic anhydride	pyridine 100	7.5	75	5.25	81.5	167—172.5	ethyl acetate

Table 2. 8-Cholesteryloxycarbonyltriptycene derivatives (IIIk and IIIl)

Product	Triptycene (g)	Cholesterol (g)	Solvent (ml)	Reaction temp. (°C)	Reaction time (hr)	Mp (°C)	$[\alpha]_D$ in dioxane	Solvent of recryst.
IIIk	1.00	1.10	20	85	3.5	212—216	+6.18° (*c* 0.648)	ethanol
IIIl	1.10	0.92	5	75	5.0	196—201	+11.2° (*c* 0.807)	methanol–methyl acetate

(+)-2,5-Bis(1-α-naphthylethylcarbamoyl)-8-methoxycarbonyltriptycene (IIIf). To a boiling solution of IIIh (1.00 g, 2.91 mmol) in toluene (80 ml) was added a solution (−)-1-α-naphthylethyl isocyanate (1.20 g, 6.11 mmol) in the same solvent (20 ml). After several drops of triethylamine had been added, the mixture was refluxed for 5 hr under stirring. Crude IIIf (2.13 g, IR: ν_{NH} 3300, $\nu_{C=O}$ 1720 cm^{-1}) obtained by evaporating the solvent under reduced pressure was recrystallized 6 times from carbon tetrachloride to give pure IIIf, 39.7 mg, mp 140—144 °C, $[\alpha]_D^{24}$ +12.9° (*c* 1.07, benzene). IIIf (25 mg) thus obtained was dissolved in a mixture of acetic acid (10 ml) and concentrated hydrochloric acid (10 ml) and the mixture was refluxed for 4 hr. 2,5-Dihydroxy-8-carboxytriptycene formed showed no optical activity.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1525—1528 (1973)

Aminosugars. XXI. Conformation of Cyclic Imido Groups Attached to the Glucopyranose-ring[1]

Masaharu IWAKAWA and Juji YOSHIMURA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 18, 1972)

Conformation of cyclic imido groups at different positions on *O*-acetylated-D-glucopyranose-ring was examined from the anisotropic effect of the carbonyls on vicinal ring-protons. The imide-plane at β-C_1, C_3 were deduced to be slightly inclined counter-clockwise, from the right angle to the mean plane of the pyranose ring, and that at α-C_2 and C_4 clockwise. 3-Deoxy-1,2 ; 5,6-di-*O*-isopropylidene-3-phthalimido-α-D-gluco- and -allofuranose were also examined.

Conformations of lactol-rings of monosaccharides[2] and their derivatives[3] in solution have been widely analyzed by NMR, however, those of substituents have been scarcely studied. In the course of synthetic studies of this series, we have noticed in NMR spectra of some phthalimido and succinimido derivatives that some vicinal ring protons showed a remarkable shift to lower fields, reflecting the steric direction of the magnetic anisotropy of the imide-carbonyl groups. This paper deals with the conformation of the cyclic imide-ring attached to various positions of the D-glucopyranose-ring in terms of comparison of the chemical shift of ring protons with that of the corresponding acetamido derivative.

Results and Discussion

Acetylated 2-deoxy-2-phthalimido-α- (**1**)[4,5] and -β-D-glucopyranose (**2**)[6], and 2-deoxy-2-succinimido-α- (**3**)[7] and -β-D-glucopyranose (**4**)[7,8] have been generally synthesized by the imidation method of tetra-*O*-acetyl-2-amino-2-deoxy-α- and -β-D-glucose[4,6,7,8] or by simulutaneous acetylation and imidation of mono-*N*-acylated derivative.[5] Benzyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-α-D-glucopyranoside (**5**) and ethyl 3-*O*-acetyl-4,6-*O*-benzylidene-2-deoxy-2-phthalimido-α-D-glucopyranoside (**6**), 1-*N*-phthalyl 2,3-di-*O*-acetyl-4,6-*O*-benzylidene-β-D-glucopyranosylamine (**7**), methyl 2-*O*-acetyl-4,6-*O*-benzylidene-3-deoxy-3-phthalimido-α-D-glucopyranose (**8**), and methyl 2,3,6-tri-*O*-acetyl-4-deoxy-4-phthalimido-β-D-glucopyranoside (**9**) were newly prepared by the latter method from suitable starting materials. 3-Deoxy-1,2;5,6-di-*O*-isopropylidene-3-phthalimido-α-D-allofuranose (**10**) and -α-D-glucofuranose (**11**) were synthesized by the former method from the corresponding aminosugars.

All NMR spectra of new compounds and other cyclic imide derivatives, except that of **1**[5], were measured at 100 MHz, and analyzed with double resonance techniques. To estimate the deshielding effect of imide-carbonyl groups, NMR spectra of the corres-

ponding acetamido derivatives were taken in the same conditions, except that of **1**—**4**[9] and **8**.[10] The corresponding acetamido derivatives of **6**, **7**, and **9** were newly prepared. The chemical shift differences ($\Delta\delta$ values) of vicinal ring protons between cyclic imido and acetamido derivatives were summarized in Table 1, together with that of 1,3,4,6-tetra-*O*-acetyl-2-(*N*-acetylacetamido)-2-deoxy-α- (**12**) and -β-D-glucopyranose (**13**) reported by Inch *et al.*[9]

Comparison of $\Delta\delta$ values of **12** (α-anomer) and **13** (β-anomer) showed that only H_3 proton was shifted remarkably (0.91 ppm) in the case of **12**, while both H_1 and H_3 protons were substantially deshielded (0.83 and 0.72 ppm) in the case of **13**. The similar tendency was also observed in the case of phthalimido (**1**, **2**) and succinimido (**3**, **4**) derivatives, however, deshielding of H_3 proton in α-anomers (**1**, **3**) was further enhanced from 0.33 to 0.45 ppm compared with **12**. The steric direction of magnetic anisotropy of acetylacetamide-carbonyl groups in **12** and **13** might be, to some extent, controlled by the steric compression, and that in **1**—**4** are to be fixed by chemical bonding. Inch et al explained the difference in $\Delta\delta_{H_3}$ of **12** and **13** by the additional deshielding effect of axial C_1-acetoxy group, however, this enhancement must be attributed to the difference of the steric direction of magnetic anisotropy between non-fixed and fixed imide-carbonyl groups, in which the cyclic imide plane is inclined toward H_3 proton by the repulsion of axial C_1-acetoxy group, as was shown in Fig. 1. These deductions were supported by the fact that the deshielding effect on H_3-proton in **5** (1.42 ppm) and **6** (1.35 ppm) are still

large. Difference in these values may indicate that the benzyloxy group is bulkier than the ethoxy group.

It is interesting that the sum of $\Delta\delta$ value of H_1 and H_3 protons is almost constant in 2-phthalimido derivatives (**1**, **2**, **5**, **6**), regardless of the configuration of anomeric carbon, the smaller sum in succinimido and acetylacetamido derivatives might be attributed to the absence of the anisotropy of benzene ring, and the randomness of the conformation of carbonyl groups, respectively.

On the other hand, Booth[11] showed that the plane of phthalimide in *trans*-4-(*t*-butyl)-1-phthalimidocyclohexane ring is at right angle to the mean plane of the cyclohexane ring in the preferred conformation and that the vicinal axial protons resonate at about 0.7 ppm lower magnetic field than the vicinal equatorial protons by the deshielding effect of the magnetic anisotropy of the phthalimide-carbonyl group. The difference of $\Delta\delta$ value of H_1-proton in α- and β-anomers are consistent with that of cyclohexane derivative. X-ray analysis of phthalimido-cyclohexane[12] and phthalimide itself[13] showed the co-planerity of three bonds of nitrogen and the conformation offered by Booth.[11] An attempted estimation of deshielding effect of an imide-carbonyl group on the vicinal protons from theoretically calculated values of long-range shielding[14] indicated that the values in the α-anomers and the general tendency in β-anomers consisted with that of measured. Consequently, the phthalimide-plane in **1** is inclined clockwise about 30—35°.

The $\Delta\delta$ value of H_2-proton in **7** is a little bit larger than that of H_3 in **2**, indicating an electrostatic repulsion between the carbonyl group and lone paired electrons of the lactol-oxygen (Fig. 2). In contrary, a smaller $\Delta\delta$ value of H_2 in **8** than that of H_1 and H_3 in **2** indicates a little counterclockwise inclination of the phthalimide ring, though $\Delta\delta$ value of H_4 could not be estimated. In the case of 4-phthalimido derivative (**9**), larger $\Delta\delta$ value of H_5 than that of H_3 indicates that C_5-acetoxymethyl is bulkier than C_3-acetoxy group.

In case of 3-deoxy-1,2-*O*-isopropylidene-3-phthalimido-α-D-furanoses in which C_2 and C_3 atoms are displaced in opposite side from the plane of the other ring atoms, the remarkable shift of H_5 in **10** indicates that the phthalimide ring is inclined clockwise about 30°, in order to decrease the steric hindrance with endomethyl of 1,2-*O*-isopropylidene group and the repulsion with C_2-oxygen, while the phthalimido group in **11** seems to be free from such hindrances.

Thus, the steric direction of anisotropy of cyclic imido group is diagnostic for the steric compression and electrostatic effect of environment.

Experimental

Melting points were determined with Yanaco micro melting point apparatus and not corrected. Optical rotations were measured with a Carl Zeiss LEP-Al Polarimeter, in a 0.5-dm tube. NMR spectra were taken with JEOL 4H-100 NMR spectrometer in 10% deuteriochloroform solution containing tetramethylsilane as an internal reference. Chemical shifts and coupling constants were given in δ and Hz units, respectively.

General Synthesis of Cyclic Imido Derivatives: a) Free aminosugars were treated with phthalic anhydride or succinic anhydride in appropriate quantity of methanol, and after standing overnight the corresponding monoacylated compounds were obtained as precipitates or as a sirup by evaporation of the solution. The products were dried over phosphorous pentoxide and then treated with acetic anhydride (2 equimolar amounts) in pyridine solution. After standing 1 day at room temperature the mixture was poured into ice-water, and precipitates appeared (**6**) were filtrated and recrystallized from suitable solvents. When a sirup deposited, it was extracted with chloroform, and the sirup obtained from the extracts were purified chromatographically, using a column or preparative thin layer of silicagel (**5**, **7**, **8**, **9**).

b) A solution of aminosugar (1 mmol) and phthalic anhydride (1.1 mmol) in pyridine (1 ml) was kept overnight at room temperature, and then acetic anhydride (2 mmol) was added. After 24 hr, the mixture was poured into ice-water, the sirup deposited was extracted with chloroform and treated in the usual manner. The product was chromatographed on silica gel column (**10**, **11**).

*Benzyl 3,4,6-tri-O-acetyl-2-deoxy-2-phthalimido-α-D-glucopyranoside (**5**)* was prepared from benzyl 2-amino-2-deoxy-α-D-glucopyranoside hydrochloride.[15] A sirup was obtained in 24% yield. $[\alpha]_D^{23}=+173°$ (*c* 1.69, $CHCl_3$); NMR: 1.85, 2.03, and 2.10 (3×Ac), 3.80—4.35 (H_5, H_6, and $H_{6'}$; m), 4.45 and 4.72 ($-CH_2-$; ABq, $J_{AB}=11.75$), 4.52 (H_2; q, $J_{1,2}=3.75$, $J_{2,3}=11.25$), 5.00 (H_1; d), 5.08 (H_4; t, $J_{3,4}=J_{4,5}=10.0$), 6.70 (H_3; q), 7.10 (Ph; s), 7.80 (Ph; m).

Found: C, 61.20; H, 5.19; N, 2.80%. Calcd for $C_{27}H_{27}NO_{10}$: C, 61.71; H, 5.18; N, 2.67%.

*Ethyl 3-O-acetyl-4,6-O-benzylidene-2-deoxy-2-phthalimido-α-D-glucopyranoside (**6**)* was obtained in 26% yield from ethyl 2-acetamido-2-deoxy-α-D-glucopyranoside[16] by benzylidenation, de-*N*-acetylation, and phthalimidation. $[\alpha]_D^{23}=+125°$ (*c* 0.88, $CHCl_3$); NMR: 1.10 (CH_3; t, $J=7.0$), 1.90 (OAc), 3.2—4.4 ($-CH_2-$; H_4, H_5, H_6 and $H_{6'}$), 4.55 (H_2; q, $J_{1,2}=3.75$, $J_{2,3}=11.25$), 4.93 (H_1; d), 5.52 (-CH=; s), 6.70 (H_3; q, $J_{3,4}=10.0$), 7.3—7.9 (2×Ph; m).

Found: C, 64.23; H, 5.39; N, 3.00%. Calcd for $C_{25}H_{25}NO_8$: C, 64.39; H, 5.49; N, 2.92%.

The corresponding acetamide derivative was prepared by the treatment with acetic anhydride in pyridine in 54% yield. Mp. 181.5—182°C (EtOH); $[\alpha]_D^{20}=+44.6°$ (*c* 1.09, $CHCl_3$); NMR: 1.25 (CH_3; t, $J=7.0$), 1.98 (OAc), 2.08 (NAc), 3.4—4.1 (H_4, H_5, H_6, $H_{6'}$, and $-CH_2-$), 4.33 (H_2: sextet, $J_{1,2}=3.75$, $J_{2,3}=J_{H_3,NH}=10.0$), 4.85 (H_1; d), 5.35 (H_3; t, $J_{3,4}=10.0$), 5.55 (-CH=; s), 5.90 (NH; d), 7.40 (Ph; m).

Found: C, 60.03; H, 6.62; N, 3.65%. Calcd for $C_{19}H_{25}NO_7$: C, 60.14; H, 6.64; N, 3.69%.

*1-N-Phthalimido-2,3-di-O-acetyl-4,6-O-benzylidene-β-D-glucopyranosylamine (**7**)* was prepared from 4,6-*O*-benzylidene-β-D-glucopyranosylamine[17] in 93% yield, and recrystallized from ethyl acetate. Mp. 238.5—240°C; $[\alpha]_D^{23}=-37.0°$

Photochemical Reaction of 1,2-Naphthoquinone and Its Derivatives with Xanthene[1]

Kazuhiro MARUYAMA and Akio TAKUWA*

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

**Department of Chemistry, Faculty of Literature and Science, Shimane University, Matsue*

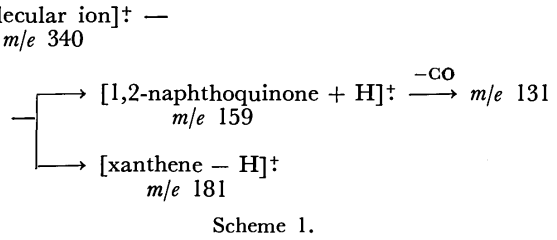
(Received December 27, 1972)

In contrast to other *o*-quinones, photochemical reaction of 1,2-naphthoquinone with xanthene gave a 1 : 1 adduct in which xanthene moiety is attached to position C_4, *i.e.*, 1,4-dihydro-2-hydroxy-4-xanthyl-1-ketonaphthalene (**2a**). The analogous photo-adducts, **2b**, **2c**, and **2d**, were obtained by the photochemical reaction of 3-chloro-1,2-naphthoquinone, 3-bromo-1,2-naphthoquinone, and 6-bromo-1,2-naphthoquinone with xanthene, respectively. The dynamic aspect of these reactions was also examined using the CIDNP technique and the reaction mechanism was discussed.

When *o*-quinones are irradiated in solution in the presence of hydrogen donors, "1,2-adduct" or "1,4-adduct"[2] is generally obtained corresponding to nature of the solvent used.[3] For example, Rubin[4] has shown that phenanthraquinone was irradiated in alkyl benzenes to give "1,2-adduct" and in ethers to give "1,4-adduct," respectively. Thus, the photochemical reactions of *o*-quinones, especially of phenanthraquinone, with hydrogen donors have been extensively investigated. However, the photochemical reaction of 1,2-naphthoquinone has not yet been described presumably from the view of its instability. However, it has been reported that the photochemical reactions of 1,2-naphthoquinone derivatives with aromatic aldehyde and stilbene[5] gave "1,4-adduct" and dioxin, respectively. Photochemical reaction of 1,2-naphthoquinone, 3-chloro-1,2-naphthoquinone, 3-bromo-1,2-naphthoquinone, and 6-bromo-1,2-naphthoquinone with xanthene as hydrogen donor were investigated in this work.

Results and Discussion

Reaction Products and Structure Determination. Equimolar 1,2-naphthoquinone and xanthene dissolved in benzene was irradiated in the usual glass tube for five hours. Photo-adduct precipitated is unstable in polar solvent or to a prolonged irradiation, it decomposes gradually to 1,2-naphthoquinone, its quinhydrone, 9,9′-bixanthyl, and some tarry matters. The structure of the photo-adduct was confirmed by the followings: the mild oxidation of the adduct, **2a**, with potassium permanganate gave phthalic acid and xanthone. The IR spectrum of **2a** exhibited the presence of both of intramoleculary hydrogen bonded hydroxyl group (3375 cm^{-1}) and chelated carbonyl (1640 cm^{-1}) group. The peaks at *m/e* 340, 181, 159, and 131 found in the mass spectrum of **2a** were interpreted in the term of scheme 1.



Scheme 1.

Elemental analysis and these results described above indicate that **2a** is a 1 : 1 adduct of 1,2-naphthoquinone and xanthene. The NMR spectrum of **2a** is shown in Fig. 1 and Table 1. The assignment of corresponding protons in Table 1 were confirmed by the followings. The signal at δ : 1.55 disappeared on addition of deutrium oxide in the sample, therefore it is due to hydroxyl proton (H_α). When the signal at δ : 3.93 (quartet) was irradiated by the spin decoupling technique, the doublet signals at δ : 4.54 and 5.76 changed to singlet, respectively. The signal at δ : 4.54 could not be observed with the photo-adduct which was obtained by the photochemical reaction of 1,2-naphthoquinone with xanthene-9-d_2, and at the same time the signal at δ : 3.93 changed to doublet. These results indicate that H_γ coupled with H_β and H_δ, respectively and thus H_δ is assigned to methine proton of xanthene moiety in the photo-adduct. Analogous photo-adducts having similar structure (**2b**, **2c**, and **2d**) were obtained by the photochemical reaction of 3-chloro-1,2-naphthoquinone, 3-bromo-1,2-naphthoquinone, and

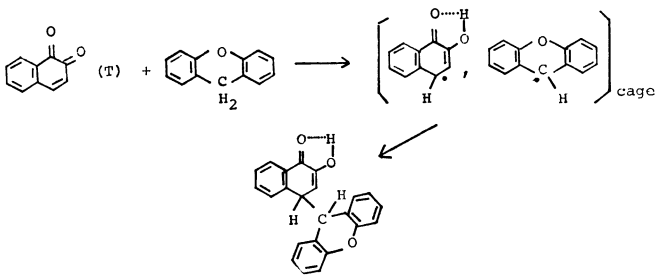
6-bromo-1,2-naphthoquinone with xanthene. The NMR spectra of these photo-adducts are summarized in Table 1.

Reaction Mechanism and CIDNP. 1,2-Naphthoquinones have a maximum absorption band owing to n–π^* transition at 520—527 nm (ε, 66—162) in chloroform.[6] 1,2-Naphthoquinone and its halogeno derivatives in benzene are excited *via* n–π^* to their photochemically active triplet states. The excited species abstract hydrogen from xanthene and simultaneously radical pair may be formed in solvent cage. The resulting radical pair is to be coupled to produce the photo-adduct. When the radical pair couples to give such a photo-adduct, the proton at the nearest-neighbor to the coupling center may give rise to the polarized PMR signals.[7] In the examination of the photochemical reaction of 1,2-naphthoquinone with xanthene in benzene by CIDNP technique, we could



Scheme 2.

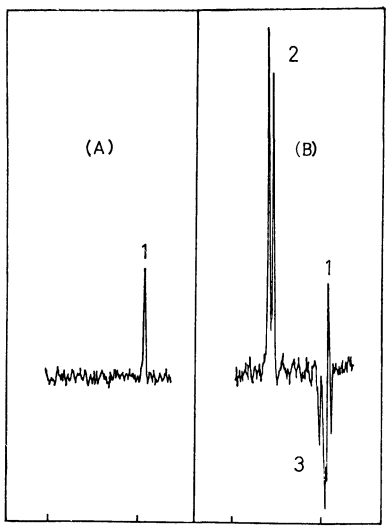


Fig. 2. Polarized PMR spectrum observed in the reaction of 1,2-naphthoquinone with xanthene in benzene solution.
A) Before irradiation. Signal 1: methylene protons of xanthene.
B) During the cource of irradiation. Signal 1: methylene protons of xanthene. Signal 2: absorption polarized signals, which correspond to the methine proton (H_δ) of xanthene rest in photo-adduct, **2a**. Signal 3: emission polarized signals, which correspond to the 4-position proton (H_γ) of quinone rest in photo-adduct, **2a**.

recognize the strongly polarized PMR signals only at δ : 4.34 (doublet, enhanced absorption), and δ : 3.93 (quartet, enhanced emission) signals. (Fig. 2). The CIDNP signals of photochemical reaction of 3-chloro-1,2-naphthoquinone with xanthene are shown in Fig. 3. Photochemical reaction of 6-bromo-1,2-naphthoquinone and 3-bromo-1,2-naphthoquinone with xanthene revealed the analogous polarized PMR signals in Figs. 2 and 3, respectively. The chemical shifts of these polarized PMR signals coincided with the δ-values of H_γ and H_δ in photo-adducts (**2a**–**2d**) as shown in Table 1. These phenomena indicate that the C_4-position of semiquinone radical coupled with xanthyl radical to give adduct. "1,2-Adduct" or "1,4-adduct" was not produced even in the course of reaction. If it was produced, a singlet polarized PMR signal (due to methine proton of xanthene moiety) should be observed as an instance of photochemical reaction of phenanthraquinone with xanthene.[8] The CIDNP

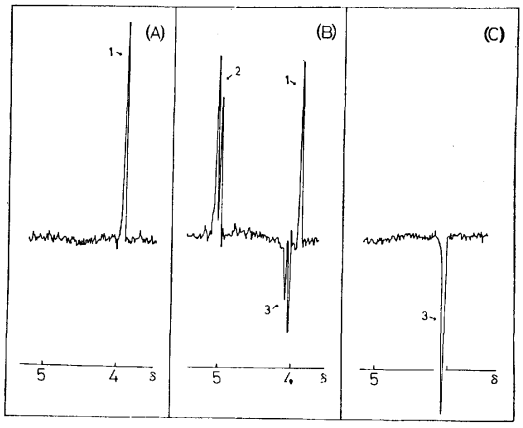

Fig. 3. Polarized PMR spectrum observed in the reaction of 3-chloro-1,2-naphthoquinone with xanthene in benzene solution.
A) Before irradiation. Signal 1: methylene protons of xanthene.
B) During the course of irradiation. Signal 1: methylene protons of xanthene. Signal 2: absorption polarized signals, which correspond to the methine proton (H_δ) of xanthene rest in photo-adduct, **2b**. Signal 3: emission polarized signals, which correspond to the 4-position proton (H_γ) of quinone rest in photo-adduct, **2b**.
C) Enhanced emission signal observed during irradiation in the reaction of 3-chloro-1,2-naphthoquinone with xanthene-9-d_2. Signal 3 due to the 4-position proton of the quinone rest in photo-adduct.

signal of the photochemical reaction of 3-chloro-1,2-naphthoquinone with xanthene-9-d_2 is shown in Fig. 3-C. The doublet enhanced absorption signals (due to the methine proton of xanthene moiety) in Fig. 3-B could not be observed and singlet enhanced emission signal was only observed corresponding to the doublet enhanced emission signal in Fig. 3-B. Therefore, the doublet enhanced absorption signals and enhanced emission signal in Fig. 3-B correspond to the proton of quinone moiety and the methine proton of xanthene moiety, respectively.

Experimental

Materials. 1,2-Naphthoquinone (mp 121—122 °C) was prepared by the oxidation of 1-amino-2-naphthol hydrochloride with ferric chloride.[9] 6-Bromo-1,2-naphthoquinone (mp 156 °C) was prepared by the oxidation of 6-bromo-2-naphthol with Fremy's salt.[6] 3-Chloro-1,2-naphthoquinone (mp 171 °C)[10] and 3-bromo-1,2-naphthoquinone (mp 164 °C)[11] were prepared by the chlorination and bromination of 1,2-naphthoquinone, respectively. Xanthene-9-d_2 was prepared by the reduction of xanthone with lithium aluminium deuteride.[12] Xanthene commercially available was further purified by recrystallization.

Spectra. Infrared spectra were taken with Jasco IR-G and Hitachi 215 infrared spectrometers with KBr disc. NMR spectra were observed with a JEOL C-60 HL spectrometer in $CDCl_3$(saturated) as a solvent and TMS as an internal indicater.

Photochemical Reaction. A typical photochemical reaction was accomplished as the following: 1,2-Naphthoquinones (0.5 mmol) and xanthene (0.5 mmol) dissolved or suspended in benzene was irradiated in ordinary glass tube by 300 W high-pressure mercury arc lamp through 5—10 cm thick water layer at 0—5 °C. Yield was nearly 50—60% in all cases.

Analyses of Photochemical Products. 1,4-Dihydro-2-hydroxy-4-xanthyl-1-ketonaphthalene (**2a**): A suspension of 1,2-naphthoquinone and xanthene in benzene was irradiated for 5 hr. A white needles deposited was collected and recrystallized from benzene–petroleum at ordinary temperature; White needles, mp 121—123 °C (dec.); IR, ν_{OH}: 3375, $\nu_{C=O}$: 1640 cm^{-1}). Elemental analysis, Found, C: 81.31, H: 4.81%. Calcd for $C_{23}H_{16}O_3$, C: 81.16, H: 4.74%. Oxidation of **2a** with potassium permanganate in acetone–water solution gave phthalic acid, mp 190—190.5 °C and xanthone, mp 173 °C, undepressed on admixture with an authentic specimen.

*1,4-Dihydro-2-hydroxy-3-chloro-4-xanthyl-1-ketonaphthalene (**2b**).* Irradiation of the benzene solution of 3-chloro-1,2-naphthoquinone and xanthene was for 4 hr. The characteristic orange-red color of the quinone faded to pale yellow. Removal of the benzene under reduced pressure left a yellowish brown solid mass. It was washed with petroleum ether and then small amount of benzene, and recrystallized from benzene–petroleum ether, pale yellow leaves, mp 157—158 °C (dec.); ν_{OH}: 3375 cm^{-1}, $\nu_{C=O}$: 1665 (w), 1640(vs) cm^{-1}, Found; C: 73,63, H: 3.86%, Calcd for $C_{23}H_{15}ClO_3$, C: 73.70, H: 4.03%.

*1,4-Dihydro-2-hydroxy-3-bromo-4-xanthyl-1-ketonaphthalene (**2c**)* Separation and purification were the analogous work-up described above, pale yellow prism, mp 143—144 °C (dec.); ν_{OH}: 3375 cm^{-1}, $\nu_{C=O}$: 1665 (w), 1640 (vs) cm^{-1}; Found, C: 65.85, H: 3.54%, Calcd for, $C_{23}H_{15}BrO_3$, C: 65.81, H: 3.61%.

*1,2-Dihydro-2-hydroxy-4-xanthyl-6-bromo-1-ketonaphthalene (**2d**).* Irradiation of the benzene solution of 6-bromo-1,2-naphthoquinone and xanthene was for 2 hr. The characteristic reddish brown color of the quinone faded to almost colorless. Benzene was removed under reduced pressure, and the resulting brown solid was washed with petroleum ether and then with benzene containing 50% petroleum ether, and recrystallized from benzene–petroleum ether; white needles, mp 130—131 °C (dec.); ν_{OH}: 3375 cm^{-1}, $\nu_{C=O}$: 1640 cm^{-1}; Found, C: 65.71, H: 3.54%, Calcd for $C_{23}H_{15}BrO_3$, C: 65.89, H: 3.61%.

CIDNP Examination. Investigation of these photochemical reactions by CIDNP technique was performed using JEOL C-60 HL spectrometer, equipped with the modified NMR probe for the photo-irradiation. The detailed method used was described in this Bulletin by K. Maruyama *et al.*[7]

Studies on Nitro Sugars. III.[1] The Synthesis of 3-Nitrohexofuranose Derivatives

Tetsuyoshi TAKAMOTO, Yoh-ichi YOKOTA, Rokuro SUDOH, and Toshio NAKAGAWA*

Department of Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

**Department of Chemistry, Yokohama City University, Mutsuura-cho, Kanazawa-ku, Yokohama 236*

(Received July 31, 1972)

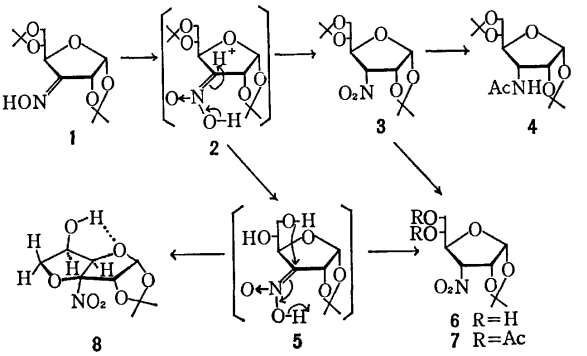
The oxidation of 1,2;5,6-di-*O*-isopropylidene-3-oximino-α-D-*ribo*-hexofuranose (**1**) with trifluoroperacetic acid at a low temperature afforded, in a 75% yield, the corresponding 3-nitro-allofuranose (**3**), but at a high temperature it gave at least three nitro compounds, *i.e.*, **3**, 3-deoxy-1,2-*O*-isopropylidene-3-nitro-α-D-allofuranose (**6**) and 3,6-anhydro-3-nitro-α-D-glucofuranose (**8**). **6** was converted to 5,6-di-*O*-acetate (**7**) and confirmed by comparison with the 3-epimer (**11**), which was prepared by the acetonation of 3-deoxy-3-nitro-D-glucose, partial hydrolysis and acetylation. The structure of **8** was instrumentally determined and supported by the fragmentation pathways in its mass spectrometry. The formation of **8** was assumed to proceed through nitronic acid (**5**) as an intermediate.

In our studies of nitro sugars for synthesizing some kinds of carbohydrate derivatives,[2,3] *e. g.*, branched sugars,[4] epoxides,[4] polyamino sugars,[5] and 2′-nucleosides,[6] a new method of synthesizing nitro sugars, particularly 2- and 3-nitro sugars, in an entirely different way had been required as a matter of course. Recently, we have presented[7] a novel route to nitro sugars with the following reaction sequence: >CH–OH⟶>C=O⟶>C=NOH⟶>CH–NO_2; in this route we used trifluoroperacetic acid oxidation[8] for the final step, and thus synthesized some 3-deoxy-3-nitro-α-D-pento- and hexo-furanose in excellent yields. Thie new method seems to promise a wide application, being capable of introducing a nitro group into a desired position of a furanose ring as well as of a pyranose one.[9]

In connection with the examination of this method, we now describe the oxidation of 3-oximino-hexofuranose derivative, the isolation of two by-products and the determination of their structures.

Results and Discussion

When 1,2;5,6-di-*O*-isopropylidene-3-oximino-α-D-*ribo*-hexofuranose (**1**)[10] was treated below 5 °C with trifluoroperacetic acid in the presence of dibasic sodium phosphate in acetonitrile, the corresponding 3-deoxy-3-nitroallo-furanose (**3**), $\nu_{as\ NO_2}$ 1560 cm^{-1}, was easily prepared in a 75% yield.[7] The *allo*-configuration of **3** was assigned on the basis of the coupling constant, $J_{2.3}$ (4.5 Hz)[11] and a chemical identification; the catalytic reduction of **3**, followed by *N*-acetylation, gave, in an 86% yield, 3-acetamido-3-deoxy-1,2; 5,6-di-*O*-isopropylidene-α-D-allofuranose (**4**), which was characterized by comparison with an authentic sample.[12]



Scheme 1.

On the tlc of the reaction mixture, at least two by-products were detected. Under refluxing conditions, in contrast to the case with a low temperature, compound **3** was not detected, but the amounts of the by-products increased. The two by-products, 3-deoxy-1,2-*O*-isopropylidene-3-nitro-α-D-allofuranose (**6**) and 3,6-anhydro-1,2-*O*-isopropylidene-3-nitro-α-D-glucofuranose (**8**), were isolated by column chromatography, with benzene–acetone (20 : 1) as the eluent.

The structural and configurational assignments of these products rest on chemical as well as on spectroscopic evidence. The former was converted to the corresponding 5,6-di-*O*-acetate (**7**), which showed that $J_{2.3}$=3.5 Hz[11] can be assigned to the *allo*-configuration, when compared with the *gluco*-isomer (**11**), which has not coupling constant between H-2 and H-3 (see Fig. 2). The latter, $C_9H_{13}NO_7$, was unchanged by periodate oxidation and recovered. In the IR spectra, $\nu_{as\ NO_2}$ band at 1550 cm^{-1} (KBr disc) and a weak intramolecular hydrogen bond between the hydroxyl group and the ring-oxygen atom at 3555 cm^{-1} in the 0.15—0.004 mol/l concentration range in chloroform

are observed. In the NMR spectrum, as is shown in Table 1, two methyl protons of the *O*-isopropylidene group, one hydroxyl proton, and six ring-proton signals of the sugar skeleton are observed. The NMR data suggest the absence of the ring proton at the C-3 position. Furthermore, the mass spectrum provides two significant pieces of information regarding the structure; the M–CH_3 ion peak at *m/e* 232, which is characteristic[13] of *O*-isopropylidene derivatives, and the M–NO_2 peak at *m/e* 201, which means a specific structure since no split of $-NO_2$ at the first step was observed[14] in the mass spectra of ten new nitro sugars which have a secondary nitro group besides nitroolefin and **8**. Consequently, the 3,6-anhydro structure of **8** was found to agree with all these data; it was also supported by the fragmentation pathways, as is shown in Fig. 1.

As is shown in Table 2, the formation of **3**, **6**, and **8** was obviously dependent on the temperature and on the ratio of trifluoroperacetic acid and dibasic sodium phosphate used as a buffer. In this reaction, as is shown in Scheme 1, the intermediary nitronic acid (**2**) may be normally converted to **3** through prototropy from the upper side of the furanose ring under mild conditions. In the presence of a smaller amount of the buffer and/or under an elevated temperature, however, **3** should be hydrolyzed to afford **6**. On the other hand, the 3,6-anhydro derivative **8** may be formed through the intermediate (**5**) which is derived from **2** by partial hydrolysis with trifluoroacetic acid under

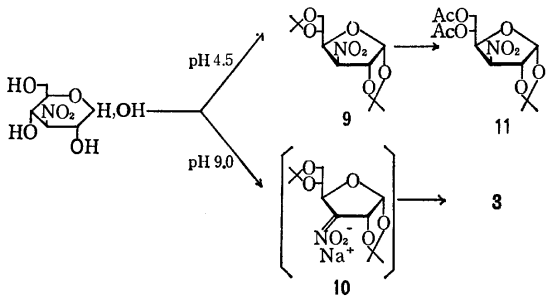
severe conditions; that is, an oxygen atom at the C–6 position of **5** attacks the cationic C–3 carbon atom to form oxidatively the 3,6-anhydro structure because of the presence of the peracid. However, the conversion of **5** to **6** through prototropy may also be possible. Under acidic conditions, nitronic acids are generally accessible to protonation, followed by a nucleophilic attack such as that of a hydroxide and bromide ion to afford nitroso compounds.[15] However, the formation of **8**, with a nitro group, can not be interpreted by a similar mechanism. Therefore, the removal of a hydride ion from the nitronic acid with the assistance of the peracid may enhance the cationic character of the C–3 carbon atom, thus making the hydroxyl oxygen atom at C–6 attack it nucleophilically.



Scheme 2.

In order to discuss NMR-spectrometrically a 3-nitrohexofuranose series, the synthesis of the *gluco*-isomer by the usual acetonation[16] was examined. However, it failed in the case of the usual neutralization, which is performed in an alkaline medium. The acetonation[17] of 3-deoxy-3-nitro-D-glucose in acetone using zinc chloride and phosphoric acid, followed by neutralization at pH 9, afforded **3** in a 15% yield, whereas at pH 4.5 3-deoxy-1,2; 5,6-di-*O*-isopropylidene-3-nitro-α-D-glucofuranose (**9**) was obtained in an 18% yield. Through the intermediary of aci-salt (**10**), **3** might be formed. The partial hydrolysis of **9**, followed by acetylation with acetic anhydride and boron trifluoride, afforded, in a 34% yield, 5,6-di-*O*-acetyl-3-deoxy-1,2-*O*-isopropylidene-3-nitro-α-D-glucofuranose (**11**), which was confirmed by the coupling constant, $J_{2,3}=0$, in the NMR spectrum (Fig. 2).

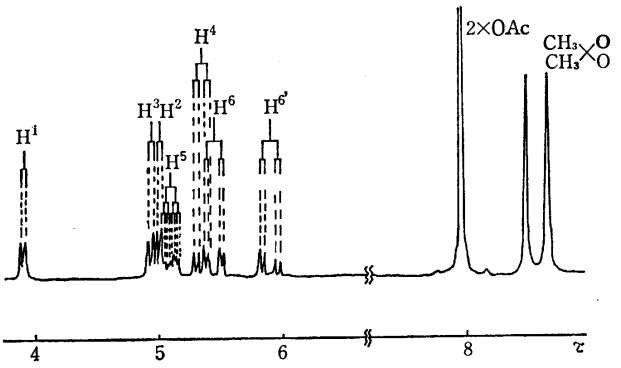


Fig. 2. 100 MHz NMR spectrum of 5,6-di-*O*-acetyl-3-deoxy-1,2-*O*-isopropylidene-3-nitro-α-D-glucofuranose (**11**).

Experimental

General. All the melting points were determined in capillaries and are uncorrected. The specific rotations were measured with a Carl Zeiss photoelectric polarimeter. The NMR spectra were recorded at 100 MHz with a JNM-4H-100 (JEOL) spectrometer in chloroform-*d*, using tetramethylsilane as the internal standard. The column chromatography was carried out on silica gel (100 mesh, Mallinckrodt, St. Louis). The tlc's were performed on silica gel (Wakogel B-5, Japan), with a solvent system of (A) benzene–acetone (30 : 1) or (B) benzene–methanol (19 : 1). All the evaporation were performed *in vacuo*.

*3-Dexoy-1,2;5,6-di-O-isopropylidene-3-nitro-α-D-allofuranose (**3**).* Into a solution of trifluoroperacetic acid in acetonitrile, prepared by mixing successively 90% hydrogen peroxide (289 mg, 7.64 mmol), trifluoroacetic anhydride (1.93 g, 9.2 mmol), acetonitrile (8 ml), dibasic sodium phosphate (7.3 g, 51.4 mmol), and urea (0.05 g), 1,2;5,6-di-*O*-isopropylidene-3-oximino-α-D-*ribo*-hexofuranose (**1**)[10] (1 g, 3.66 mmol) was slowly stirred below 5 °C. After 2 hr, the mixture was evaporated below 40 °C and extracted with chloroform (4× 20 ml); the extract was washed with water three times and evaporated. The resulting crystals were recrystallized from chloroform/petroleum ether to give 0.8 g (75%), showing a mp of 112—113 °C, $[\alpha]_D^{20}$ +106° (*c* 1, $CHCl_3$), IR(KBr): 1560 cm^{-1} (ν_{NO_2}) and tlc (solvent A): R_f 0.37.

Found: C, 50.01; H, 6.61; N, 4.81%. Calcd for $C_{12}H_{19}NO_7$: C, 49.82; H, 6.62; N, 4.84%.

*3-Acetamido-3-deoxy-1,2;5,6-di-O-isopropylidene-α-D-allofuranose (**4**).* Into a suspension of prehydrogenated 10% Pd–C (0.5 g) in methanol containing 1 M acetic acid (1.6 ml), **3** (0.45 g) was stirred in an atmosphere of hydrogen at 1 atm. After 24 hr, the reaction mixture, absorbing 138 ml of hydrogen (theoretical: 110 ml), was filtered and evaporated; then the residue was dissolved in methanol (10 ml) and acetylated with acetic anhydride (0.3 ml) at room temperature. After 1 hr, the mixture was evaporated until it became odorless. The remaining crystals were recrystallized from ethanol/petroleum ether to give 0.4 g (86%); mp 126—127 °C; $[\alpha]_D^{20}$ +73° (*c* 1, $CHCl_3$). The other data agreed completely with the authentic sample.

*5,6-Di-O-acetyl-3-deoxy-1,2-O-isopropylidene-3-nitro-α-D-allofuranose (**7**).* Into a mixture of 90% hydrogen peroxide (79.4 mg, 2.1 mmol), trifluoroacetic anhydride (525 mg, 2.5 mmol), acetonitrile (3 ml), dibasic sodium phophate (355 mg, 2.5 mmol) and urea (10 mg), **1** (273 mg, 1 mmol) was stirred at room temperature. The reaction mixture was evaporated below 40 °C and chromatographed on a silica-gel column (10×2.7 cm) with chloroform. The eluate was collected in 50-ml portions. Fractions No. 5—8 were combined and evaporated. The remaining sirup was treated with acetic anhydride (160 mg) in pyridine (4 ml) at room temperature. After the reaction mixture had stood for 1.5 hr, its evaporation gave crude crystals which were subsequently recrystallized from ether–petroleum ether. Yield, 75 mg (23%); mp 106—107 °C; $[\alpha]_D^{20}$ +110° (*c* 0.9, $CHCl_3$);

*3,6-Anhydro-1,2-O-isopropylidene-3-nitro-α-D-glucofuranose (**8**).* Into a mixture of 90% hydrogen peroxide (289 mg, 7.64 mmol), trifluoroacetic anhydride (1.93 g, 9.2 mmol), acetonitrile (2 ml), dibasic sodium phosphate (2.93 g, 20.6 mmol), and urea (73 mg), **1** (1 g, 3.66 mmol) was stirred. The mixture was heated at 55 °C for 1 hr and then evaporated. The mixture was put on a silica-gel column (7.2×3.0 cm) with benzene. After the elution of 150 ml of benzene, **8** was eluted with benzene–acetone (19 : 1) and recrystallized from chloroform–petroleum ether. Yield, 146 mg (16%); mp 140—141 °C; $[\alpha]_D^{20}$ +58° (*c* 1, $CHCl_3$); IR(KBr): 1550 cm^{-1} (ν_{NO_2}); tlc (solvent B): R_f 0.52.

Found: C, 43.78; H, 5.10; N, 5.43%. Calcd for $C_9H_{13}NO_7$: C, 43.73; H, 5.30; N, 5.67%.

Acetonation of 3-Deoxy-3-notro-D-glucose. A mixture of 3-deoxy-3-nitro-D-glucose (200 mg), acetone (8 ml), zinc chloride (290 mg), and 85% phosphoric acid (250 mg) was stirred at room temperature for 24 hr. The reaction mixture was then slowly stirred into a diluted sodium carbonate solution, with the pH kept at 9.0 or 4.5. Chromatography on a silica-gel column with benzene, followed by recrystallization, afforded **3** (40 mg, 15%) or **9** (49 mg, 18%). **9**: mp 61—62 °C; $[\alpha]_D^{20}$ +7.3° (*c* 1, $CHCl_3$); IR(KBr): 1550 cm^{-1} (NO_2); tlc (solvent A): R_f 0.37.

Found: C, 49.96; H, 6.50; N, 4.83%. Calcd for $C_{12}H_{19}NO_7$: C, 49.82; H, 6.62; N, 4.84%.

*5,6-Di-O-acetyl-3-deoxy-1,2-O-isopropylidene-3-nitro-α-D-glucofuranose (**11**).* Into a solution of **9** (200 mg) in acetone (15 ml), 0.8% sulfuric acid (15 ml) was stirred. After 21 hr, the solution was completely neutralized with barium carbonate and filtered. The filtrate was evaporated and acetylated with acetic anhydride (0.5 ml) and boron trifluoride etherate (2 drops). Then the reaction mixture was evaporated and chromatographed with benzene. The fraction containing **11** was easily detected by tlc. The recrystallization of the residue from ether–petroleum ether afforded crystalline **11** (69 mg, 34%); mp 79—80 °C; $[\alpha]_D^{20}$ +17° (*c* 1.1, $CHCl_3$); IR(KBr): 1740 (C=O), 1550 cm^{-1} (NO_2); tlc (solvent A): R_f 0.18.

Found: C, 46.59; H, 5.76; N, 4.04%. Calcd for $C_{13}H_{19}NO_9$: C, 46.85; H, 5.75; N, 4.20%.

The authors wish to thank Mitsubishi Gas Chemical Co., Inc., for the gift of 90% hydrogen peroxide and Mr. Hitoshi Matsumoto for recording the NMR spectra.

The Acid-catalyzed Isomerization of α-Ylangene and α-Ylangene Epoxide

Yoshimoto OHTA and Yoshio HIROSE

The Institute of Food Chemistry, Dojimanaka, Kita-ku, Osaka 530

(Received August 17, 1972)

Upon treatment with dilute mineral acid, α-ylangene afforded two alcohols with amorphane carbon skeletons, 10β-hydroxyamorpha-4-ene (**16**) and 10α-hydroxyamorpha-4-ene (**17**). The carbonic acid-induced isomerization of α-ylangene epoxide yielded 3α-hydroxy-α-amorphene (**19**), 3α-hydroxy-δ-amorphene (**20**), and 3α,10α-dihydroxyamorpha-4-ene (**21**). The structures of these compounds were strictly determined, and the revised structure **16** of δ-cadinol proposed by Lin was shown to conflict with the results of the isomerization of α-ylangene and with the previously-reported conversion of α-copaene into δ-cadinol (**10**) and T-muurolol (**11**) under similar conditions.

As has been reported in a previous communication, some tricyclic sesquiterpene hydrocarbons containing a cyclopropane or a cyclobutane ring adjacent to a double bond in their molecule, such as α-cubebene (**1**), α-copaene (**2**), and α-ylangene (**3**), were easily isomerized by dilute mineral acid to give hydrocarbons and alcohols of the cadalene type.[1] Cadina-4,6(1)-diene (**4**), δ-cadinene (**5**), cadina-1,4-diene (**6**), cubenol (**7**), and epi-cubenol (**8**) were obtained from α-cubebene, and α-muurolene (**9**), δ-cadinene, δ-cadinol (**10**), and T-muurolol (**11**) from α-copaene. α-Ylangene afforded α-amorphene (**12**) and δ-amorphene (**13**), together with a small amount of oxygenated compounds of an unestablished structure.

Recently, Ohloff and his co-workers[2] performed the proton-induced isomerization of α-copaene epoxide in aqueous carbonic acid and reported the formation of three products, including (−)-3β-hydroxy-T-muurolol, which had previously been isolated from *Taiwania Cryptomerioides* by Lin.[3] These acid-catalyzed reactions are helpful in correlating these closely-resembling sesquiterpenoids of the cadalene type. In this paper, we wish to report the structure determination of compounds obtained from α-ylangene and α-ylangene epoxide by dilute-acid treatments.

Isomerization of α-Ylangene. α-Ylangene **3** was allowed to react with 0.1 N-sulfuric acid in aqueous acetone under reflux for three hours. Two sesquiterpene hydrocarbons, α-amorphene **12** and δ-amorphene **13**, were then isolated as the major components of the product (90%) in a ratio of 2 : 1, together with three oxygen-containing compounds (**15**—**17**) in a total amount less than 10% of the product. None of these

3) Y. H. Kuo, Y. S. Cheng, and Y. T. Lin, *Tetrahedron Lett.*, **1969**, 2375.

polar compounds isolated were identical with any material previously reported.

Compound (**15**) is an oil exhibiting the molecular ion at *m/e* 222 ($C_{15}H_{26}O$) and the base peak at *m/e* 161 in its mass spectrum. In its IR spectrum, no absorption maxima due to a hydroxyl or a carbonyl group or a double bond are observed, while the four strong bands in the region between 1145—1050 cm^{-1} suggest the presence of oxide linkage. Signals assignable to an isopropyl group at 0.86 and 0.88 (each 3H, doublets) and two methyl groups on the carbon-bearing ether-oxygen atom at 0.99 and 1.08 ppm were observed in its NMR spectrum. These spectral data led us to conclude that the structure of this oxide as **15**.

Compound (**16**) showed a molecular ion at *m/e* 222 ($C_{15}H_{26}O$) and an absorption maximum due to a hydroxyl group at 3650 cm^{-1}. Its NMR spectrum exhibited the signals attributable to an isopropyl group (0.88 and 0.96, two doublets), a methyl group on a carbon-bearing hydroxyl group (1.19), and an olefinic methyl group and a proton (1.68 and 5.47 ppm). On dehydration with thionyl chloride in pyridine, it afforded two hydrocarbons in a ratio of 1 : 1.5, which were confirmed to be α-amorphene **12** and δ-amorphene **13** respectively by comparing their IR spectra and retention times in glc with those of the authentic samples. These chemical and spectral proofs support the idea that this compound is an amorphene-type alcohol carrying the hydroxyl group at C-10 and the trisubstituted double bond at C-4, as is shown by its structure **16**.

Compound (**17**) also showed a molecular ion at *m/e* 222 ($C_{15}H_{26}O$) and a hydroxyl absorption band at 3300 cm^{-1}. Its NMR spectrum closely resembled that of **16**; 0.90 and 0.96 (an isopropyl group), 1.22 (a methyl group on a carbon-carrying hydroxyl group), 1.64 (3H) and 5.34 ppm (1H) (a trisubstituted double bond). The dehydration of this alcohol with thionyl chloride in pyridine furnished one major and two minor hydrocarbons; the main product (above 90%) was identified as α-amorphene, while the others were identified as γ-(**14**) and δ-amorphene. Thus, Compound **17** is probably an epimeric isomer of **16** in view of the configuration of the hydroxyl group at C-10. The configurations of the hydroxyl groups of these alcohols, **16** and **17**, may be supposed to be β-axial and α-equatorial respectively on the basis of the results of their dehydration reactions. It is generally accepted that the *trans*-antiparallel elimination of the water molecule from an alcohol occurs by means of the action of thionyl chloride in pyridine, and, in our case, one of the epimeric isomers carrying the α-equatorial hydroxyl group at C-10 can be expected to give α-amorphene as the main dehydration product, since only the β-hydrogen atom at C-9 is *trans*-antiparallel toward the hydroxyl group in the amorpha-4-ene skeleton. Thus, the **17** alcohol is determined to be 10α-hydroxy-amorpha-4-ene. In contrast, the configuration of the hydroxyl group of the **16** alcohol, which afforded α- and δ-amorphene in a comparable ratio, was reasonably decided to be β-axial, since the α-hydrogen atoms on both C-1 and C-9 satisfied this condition.

Isomerization of α-Ylangene Epoxide. The reaction of α-ylangene with monoperphthalic acid in the presence of anhydrous sodium carbonate afforded α-ylangene epoxide (**18**) in a good yield. On treatment with aqueous carbonic acid in the same way as has been reported by Ohloff,[2] the epoxide yielded two monoalcohols (**19**, **20**) and a diol (**21**). The diol was crystallized from the reaction-product mixture, while the others were purified by chromatography on a silica-gel column.

Compound **19** showed a molecular ion at *m/e* 220 ($C_{15}H_{24}O$) and its absorption maximum at 3350 cm^{-1}. In its NMR spectrum, the signals assignable to the following groupings are observed: an isopropyl group (0.92 and 0.95), two olefinic methyls (1.72) and protons (5.3 and 5.45), and a secondary hydroxyl proton (4.00 ppm, multiplet, $W_{1/2h}$ 21 Hz). The oxidation of **19** with manganese dioxide furnished an unsaturated ketone (**22**), $\nu_{C=O}$ 1670 cm^{-1}, which was chromatographically and spectroscopically identical with the authentic material obtained from α-amorphene by *tert*-butyl chromate oxidation.[4] Therefore, the secondary hydroxyl group was located at C-3 of the α-amorphene skeleton, and the structure of this alcohol was concluded to be 3-hydroxy-α-amorphene **19**.

Another mono-ol **20**, $C_{15}H_{24}O$ (M^+ 220), ν_{OH} 3350 cm^{-1}, exhibited the following NMR signals: 0.92 (6H, doublet, an isopropyl group), 1.62 and 1.70 (two olefinic methyls), 5.46 (an olefinic proton), and 4.10 ppm (1H, multiplet, $W_{1/2h}$ 20 Hz, a secondary hydroxyl proton). On the basis of these spectral data and the mechanism of this epoxide-cleavage reaction,[2] the structure of this alcohol was established as **20** except for the stereochemistry of the hydroxyl group at C-3.

The last compound obtained from the epoxide, needle crystals (mp 136 °C), showed a molecular ion at *m/e* 238 ($C_{15}H_{26}O_2$) in its mass spectrum. The spectral data showed the signals for an isopropyl group (0.92, 6H, doublet, 1380 and 1385 cm^{-1}), a trisubstituted double bond (3H at 1.71 and 1H at 5.36, 1660 and 840 cm^{-1}), a tertiary methyl group on a carbon-bearing hydroxyl group (singlet at 1.13), and a secondary hydroxyl group (1H multiplet at 4.18 ppm, $W_{1/2h}$ 19 Hz, 3400 cm^{-1}). On acetylation with acetic anhydride in pyridine at room temperature, it afforded a hydroxy acetate in an excellent yield (ν_{max} 3350, 1740 cm^{-1}). The secondary hydroxyl group was placed at the allylic position C-3, since it gave, on oxidation with manganese dioxide, an α,β-unsaturated hydroxy ketone (**23**), ν_{max} 3500, 1640 cm^{-1}; downfield-shifted olefinic methyl (1.77 ppm) and proton (6.55 ppm). Furthermore, the reduction of the monoacetate of **21** with calcium in liquid ammonia[5] yielded a sole product which was identical in all respects with the **17** obtained from α-ylangene directly.

All of the allylic hydroxyl groups of **19**, **20**, and **21** can be expected to have the same configuration and

4) Y. Ohta and Y. Hirose, *Tetrahedron Lett.*, **1969**, 1601.
5) K. Takeda, K. Sakurai and H. Ishii, *Tetrahedron*, **27**, 6049 (1971).

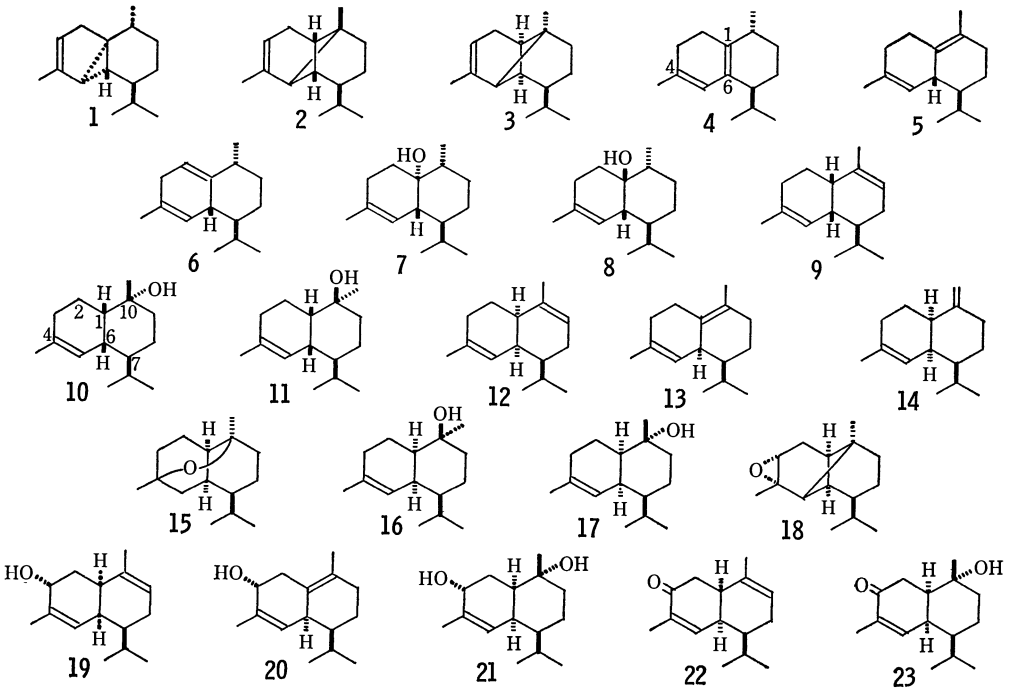

Fig.

can be decided as α-equatorial, since the observed $W_{1/2h}$ values of the secondary hydroxyl protons of these compounds are 21, 20, and 19 Hz respectively; the corresponding protons in the two tetrahydro derivatives obtained from **19** by catalytic hydrogenation also exhibited signals with $W_{1/2h}$ values of 21 and 25 Hz respectively in their NMR spectra. The stereochemistry of the tertiary hydroxyl group at C-10 of the diol **21** was reasonably decided to be α-equatorial on the basis of the reaction mechanism[2] and the successful conversion of **21** into **17**.

No compounds of the amorphane carbon skeleton with an oxygen functional group have yet been isolated from natural sources, but it is highly probable that some of them will be found in nature considering the stability and the biogenetical accessibility of such compounds.

Recently, Lin and his co-workers proposed a revised structure **16** for δ-cadinol that has an amorphane carbon skeleton.[6] However, this revised structure conflicts with the results that the acid-catalyzed isomerization of α-copaene afforded δ-cadinol and T-muurolol,[1] and that the dehydration of δ-cadinol yielded α- and γ-muurolene and δ-cadinene[6,7] 10β-Hydroxyamorpha-4-ene **16**, obtained from α-ylangene in our experiment, has a structure corresponding to their revised δ-cadinol, but it shows no identity with δ-cadinol in any other respect. Accordingly, we wish to propose again the previous structure **10** for δ-cadinol.

6) Y. T. Lin, Y. S. Cheng, and Y. H. Kuo, *ibid.*, **27**, 5337 (1971).

7) The dehydration of δ-cadinol with thionyl chloride in pyridine was carried out in our laboratory, too; α-muurolene (80%), γ-muurolene (15%), and δ-cadinene (5%) were identified as the dehydration products.

Experimental

The melting points are uncorrected. The NMR spectra were taken on a Hitachi model R-20B NMR spectrometer (60 MHz), using TMS as the internal standard, and the chemical shifts are given in δ-values. The mass spectra were measured on a Hitachi RMU-6 mass spectrometer at 80 eV. The optical rotations were measured on a Perkin-Elmer model 141 polarimeter. The IR spectra were recorded on a Hitachi model EPI-G2 spectrophotometer. A Hitachi F6-D gas chromatograph fitted with a HB-2000 capillary column (0.25 mm × 45 m) was used for the analytical glc, and a Varian model 90-P gas chromatograph, for preparative purposes.

Isomerization of α-Ylangene. α-Ylangene was obtained from essential oil of the fruit of *Schisandra chinensis* as the main component of the oil. The oil was fractionally distilled under reduced pressure, and the fraction (bp 93—94 °C/9 mmHg) was chromatographed over neutral alumina (Merck, Grade II-III), using *n*-hexane as the solvent, to remove the oxygenated compounds. The hydrocarbon fraction thus obtained was further chromatographed over silica gel impregnated with 15% of silver nitrate, using *n*-hexane as the solvent, to give pure α-ylangene, which was identified by an IR spectrum comparison[8], $[\alpha]_D$ +55.6° (in chloroform). A solution of α-ylangene(3.5 g) in 2 l of 70% aqueous acetone containing 0.1 N sulfuric acid was heated under reflux for 3 hr. After cooling, the reaction mixture was neutralized with a 10% sodium bicarbonate solution, the solvent was then evaporated off to about a half volume under reduced pressure. The residue was extracted with ether, and the organic layer was washed with water and dried over anhydrous sodium sulfate. The product (3.0 g) was subjected to chromatographic separation on neutral alumina, and a hydrocarbon fraction (2.7 g) eluted with *n*-hexane and a fraction of oxygenated compounds (0.24 g) eluted with a 10% ether-*n*-hexane mixture were obtained. The hydrocarbon fraction was shown to consist of three compounds in

a ratio of 10 : 60 : 30 by analytical glc; the mixture was subjected to glc separation (Carbowax 20 M, 3/8″×20 ft column at 180 °C) to give α-ylangene, α-amorphene ($[\alpha]_D$ −127.6°, in chloroform) and, δ-amorphene ($[\alpha]_D$ +16.1° in chloroform) in order. The fraction of the polar compounds was shown to contain three compounds, (**15**), (**16**), and (**17**), in a ratio of 2 : 2.5 : 3, when purified by preparative glc (SE-30, 3/8″×10 ft column at 190 °C), they showed the following physical data. *Oxide (**15**)*; liquid, MS: *m/e* 222 (M^+, $C_{15}H_{26}O$, 72%) and 161 (base peak); IR: 1370, 1360, 1240, 1140, 1080, 1060, 1050, 1010, 1000, 985, and 970 cm^{-1}; NMR (CCl_4): 0.86 and 0.88 (each 3H, two doublets, J=6.0 Hz, $-CH(C\underline{H}_3)_2$), 0.99 and 1.08 (each 3H, singlet, $-O-\overset{|}{C}-C\underline{H}_3$). *10α-Hydroxyamorpha-4-ene (**16**)*; Oil, $[\alpha]_D$ −3.4°(*c*, 0.3 in chloroform), MS: *m/e* 222 (M^+, $C_{15}H_{26}O$), 189, 161(100%), 121, 120, 119, and 105; IR: 3650, 1660, 1390, 1080, 920, 865 and 780 cm^{-1}; NMR ($CDCl_3$): 0.88 and 0.96 (each 3H, two doublets, J=6.0 Hz, $-CH(C\underline{H}_3)_2$), 1.19 (3H, singlet, $HO-\overset{|}{C}-C\underline{H}_3$), 1.68 (3H, broad singlet, $-\overset{|}{C}=\overset{|}{C}-C\underline{H}_3$) and 5.47 (1H, broad singlet, $-\overset{|}{C}=\overset{|}{C}-\underline{H}$). *10β-Hydroxyamorpha-4-ene (**17**)*; mp 42 °C (recrystallized from petroleum ether), $[\alpha]_D$ −8.7° (*c* 0.5, chloroform), MS: *m/e* 222 (M^+, $C_{15}H_{26}O$), 204, 189, 164, 161, 121, and 95 (100%); IR: 3300, 1670, 1385, 1380, 1370, 1120, 1000, 940, 860, and 825 cm^{-1}; NMR ($CDCl_3$); 0.90 and 0.96 (each 3H, two doublets, J=6.0 Hz, $-CH(C\underline{H}_3)_2$), 1.22(3H, singlet, $HO-\overset{|}{C}-C\underline{H}_3$), 1.64 (3H, broad singlet, $-\overset{|}{C}=\overset{|}{C}-C\underline{H}_3$) and 5.34 (1H, broad singlet, $-\overset{|}{C}=\overset{|}{C}-\underline{H}$).

*Dehydration of 10β-Hydroxyamorpha-4-ene (**17**).* The alcohol **17** (7 mg) was dissolved in pyridine (1 ml) and treated with 30 mg of thionyl chloride at 0 °C for 15 min. The reaction mixture was poured into 30 ml of an ice-cold 10% sodium bicarbonate aqueous solution and extracted with 50% ether–*n*-hexane. The organic layer was washed with water and dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent gave 5 mg of an oily product which was subjected to glc separation; the α-amorphene (60%) and δ-amorphene (40%) thus obtained were identified by comparing their IR spectra with those of authentic samples.

*Dehydration of 10α-Hydroxyamorpha-4-ene (**16**).* A solution of 15 mg of **16** in 1 ml of pyridine was treated with thionyl chloride (75 mg) at 0 °C for 20 min. The subsequent usual work-up of the reaction mixture afforded 10 mg of a hydrocarbon mixture; after glc separation, α-amorphene (above 90%), γ-amorphene, and δ-amorphene were identified by comparing their IR spectra and R_t in glc with those of authentic samples.

Epoxidation of α-Ylangene. Into a solution of α-ylangene (5.0 g) in dichloromethane (100 ml) suspended in anhydrous sodium carbonate (3.9 g), and 8.4% ether solution of monoperphthalic acid (4.9 g) was stirred, drop by drop, at 0° C over a 15 min period. The reaction mixture was stirred at 4 °C for 18 hr. The precipitate was then filtered off using a glass filter, and the filtrate was washed with water and dried over anhydrous potassium carbonate. The oily product thus obtained (4.8 g) was subjected to column chromatographic purification over neutral alumina, using dichloromethane as the solvent, to give 4.5 g of α-ylangene epoxide **18**, which showed the following spectral data: prominent peaks at *m/e* 220 (M^+, $C_{15}H_{24}O$), 177 and 107 (100%) in its mass spectrum; absorption bands at 1380, 1375, 1370, 1095, 1060, 1020, 900, 840, 830, 820, and 720 cm^{-1} in its IR spectrum; NMR signals (CCl_4) at 0.86 (6H, doublet, J=5.4 Hz, $-CH(C\underline{H}_3)_2$), 0.88 (3H, singlet, $-\overset{|}{C}-C\underline{H}_3$), 1.29 (3H, singlet, $-\overset{|}{C}(\overset{O}{\diagdown\diagup})\overset{|}{C}-C\underline{H}_3$), 2.10 (1H, singlet, $\underline{H}C-\overset{|}{C}(\overset{O}{\diagdown\diagup})\overset{|}{C}-$), and 2.86 (1H, broad peak, $-\overset{|}{C}(\overset{O}{\diagdown\diagup})\overset{|}{C}-\underline{H}$).

Isomerization of α-Ylangene Epoxide. α-Ylangene epoxide (2.0 g) was added to a solution of dry ice (4 g) dissolved in 80 ml of freshly-distilled water. The mixture was shaken vigorously using a mechanical shaker for 20 hr at room temperature. The subsequent extraction of the reaction mixture with 300 ml of ether, drying over anhydrous sodium sulfate, and evaporation of the solvent afforded 1.8 g of a viscous oil which was stored, after the addition of 10 ml of an ether–*n*-hexane mixture (1 : 2), in a refrigerator overnight to deposit needle crystals of the diol **20**. The crystals (310 mg) were then filtered off and recrystallized from 50% ether in *n*-hexane; mp 136.0—136.5 °C, $[\alpha]_D$ +32.6° (*c* 0.3, chloroform), IR: 3400, 1660, 1415, 1385, 1380, 1120, 1040, 1025, 950, 905, and 840 cm^{-1}; MS; *m/e* 238 (M^+, $C_{15}H_{26}O_2$), 220, 202, 177 and 159 (100%); NMR ($CDCl_3$): 0.87 and 0.93 (each 3H, two doublets, J=6.0 Hz, $-CH(C\underline{H}_3)_2$, 1.13 (3H, singlet, $HO-\overset{|}{C}-C\underline{H}_3$), 1.71 (3H, broad singlet, $-\overset{|}{C}=\overset{|}{C}-C\underline{H}_3$), 4.18 (1H, broad peak, $W_{1/2h}$ 19 Hz, $HO-\overset{|}{C}-\underline{H}$) and 5.36 (1H, broad singlet, $-\overset{|}{C}=\overset{|}{C}-\underline{H}$). Found: C, 75.84; H, 10.88%. Calcd for $C_{15}H_{26}O_2$: C, 75.58; H, 11.00%.

The mother liquor was subjected to column chromatography over silica gel; 3α-hydroxy-δ-amorphene **20** (400 mg) and 3α-hydroxy-α-amorphene **19** (1.0 g) were then obtained by elution with 20% ether in *n*-hexane. *3α-Hydroxy δ-amorphene (**20**)*, oil, $[\alpha]_D$ +61.7° (*c*, 0.5 in chloroform), showed the following spectral data: IR: 3350, 1660, 1385, 1370, 1040 and 840 cm^{-1}; NMR ($CDCl_3$): 0.92 (6H, doublet, J=6.0 Hz, $-CH(C\underline{H}_3)_2$), 1.62 (3H, broad singlet, $-\overset{|}{C}=\overset{|}{C}-C\underline{H}_3$), 1.70 (3H, doublet, J=2.5 Hz, $-\overset{|}{C}=\overset{|}{C}-C\underline{H}_3$), 4.10 (1H, multiplet, $W_{1/2h}$ 20 Hz, $HO-\overset{|}{C}-\underline{H}$), and 5.46 (1H, broad singlet, $-\overset{|}{C}=\overset{|}{C}-\underline{H}$). *3α-Hydroxy-α-amorphene (**19**)*, oil $[\alpha]_D$ −69.9° (*c*, 1.4 in chloroform), showed the following spectral data: IR: 3350, 1660, 1385, 1370, 1050, 1015, 850, 830, and 785 cm^{-1}; NMR ($CDCl_3$): 0.92 and 0.95 (each 3H, two doublets, J=6.0 Hz, $-CH(C\underline{H}_3)_2$), 1.72 (6H, finely-split multiplet, two olefinic methyl groups), 4.00 (1H, broad peak, $W_{1/2h}$ 21 Hz, $HO-\overset{|}{C}-\underline{H}$), 5.3 (1H, broad singlet, $-\overset{|}{C}=\overset{|}{C}-\underline{H}$), and 5.4 (1H, broad peak, $-\overset{|}{C}=\overset{|}{C}-\underline{H}$).

*Oxidation of 3α-Hydroxy-α-amorphene (**19**).* To a solution of **19** (300 mg) in 50 ml of dichloromethane, manganese dioxide (3 g) was added; the mixture was then sitrred for 3.5 hr at room temperature. The subsequent filtration of the reagent and evaporation of the solvent gave 250 mg of an oily product. A pure sample obtained by glc separation (Carbowax 20 M, 3/8″×5 ft column at 180 °C) showed IR bands at 1670, 1380, 1370, 1110, 1095, 940, 900, and 825 cm^{-1}. This α,β-unsaturated ketone was identified with the authentic α-amorphene-3-one **22** obtained from α-amorphene by *tert*-butyl chromate oxidation by comparing their IR spectra, R_f on tlc and R_t in glc.

*Oxidation of the Diol (**21**).* Manganese dioxide (350 mg) was added to a solution of the diol **21** (50 mg) in dichloromethane (10 ml), the mixture was then stirred for 3 hr at room temperature. The usual work-up of the reaction mixture afforded crystals of α,β-unsaturated hydroxy ketone

23 (45 mg), which were then recrystallized from *n*-hexane; mp 129.5—130.5 °C; IR: 3500, 1640, 1408, 1375, 1365, 1110, 940, and 900 cm^{-1}; NMR ($CDCl_3$): 0.95 and 1.03 (each 3H, two doublets, J=6.0 Hz, $-CH(C\underline{H}_3)_2$), 1.00 (3H, singlet, $HO-\overset{|}{C}-C\underline{H}_3$), 1.77(3H, broad singlet, $-CO-\overset{|}{C}=\overset{|}{C}-C\underline{H}_3$), and 6.55 (1H, broad singlet, $\underline{H}C=\overset{|}{C}-\overset{|}{C}=O$).

*Acetylation of the Diol (**21**).* The diol **21** (145 mg) was treated with dry pyridine (5 ml) and acetic anhydride (1 ml) at room temperature for 5.5 hr. The reaction mixture was poured into a dilute sodium bicarbonate solution and extracted with ether. The organic layer was washed with water, dried over anhydrous sodium sulfate, and evaporated to give crude mono acetate (140 mg), which was then recrystallized from *n*-hexane; mp 117—118 °C, IR: 3275, 1740, 1250, 1125 and 1015 cm^{-1}; NMR ($CDCl_3$): 0.95 and 0.90 (each 3H, two doublets), $-CH(C\underline{H}_3)_2$), 1.19 (3H, singlet, $HO-\overset{|}{C}-C\underline{H}_3$), 1.62 (3H, broad peak, $-\overset{|}{C}=\overset{|}{C}-C\underline{H}_3$), 2.05 (3H, singlet, $C\underline{H}_3COO-$), 5.45 (1H, multiplet, $AcO-\overset{|}{C}-\underline{H}$), and 5.60 (1H, broad singlet, $-\overset{|}{C}=\overset{|}{C}-\underline{H}$). Found: C, 72.75; H, 10.02%. Calcd for $C_{17}H_{28}O_3$: C, 72.82; H, 10.06%.

Reduction of the Diol Monoacetate. A solution of the monoacetate (85 mg) in toluene (3 ml) was stirred, drop by drop over a 15 min period, into a solution of calcium (0.8 g) in liquid ammonia (40 ml) at −70 °C. After the subsequent addition of ammonium chloride (3 g) to the mixture, the ammonia was evaporated. Water (150 ml) was added to the residue, and the residue was extracted with ether; the extract was washed with water dried over anhydrous sodium sulfate. The crude product was shown by tlc to contain almost a sole component, which was purified by glc separation (SE-30, 3/8″×10 ft column at 190 °C). The IR and NMR spectra, R_t in glc and R_f on tlc, of this reduction product were shown to be identical with those of 10α-hydroxyamorpha-4-ene **17**.

Intramolecular Participation of Sulfide Linkage in the Reactivity of Carbene and Diazoalkanes. I. Alkylcarbenes and Diazoalkanes Bearing Alkylthio, Arylthio, and Allylthio Groups on α-Carbon

Iwao Ojima and Kiyosi Kondo

Sagami Chemical Research Center, Nishi-Onuma, Sagamihara 229

(Received October 4, 1972)

α-Alkyl- and α-arylthioalkylcarbenes were thermally or photochemically generated from the corresponding ketones according to a modification of the Bamford-Stevens method. The carbenes thus generated were found to form labile episulfonium ylides, which then rearranged to vinyl sulfides. The episulfonium ylides were trapped with diethyl maleate and dimethyl fumarate. An α-allylthioalkylcarbene was generated by the photolysis of α-allylthioacetophenone tosylhydrazone in the presence of sodium methoxide at −70 °C; this afforded α-allylthiostyrene exclusively. A smooth thio-Claisen rearrangement of the resulting α-allylthiostyrene was also observed. 3-Thiabicyclo[3.1.0]hexane was obtained when α-allylthioacetophenone tosylhydrazone was decomposed thermally at 150 °C, or photochemically at 10 °C in the presence of bases. The mechanisms of these new reactions are also discussed.

The formation of ylides by an intermolecular electrophilic addition of carbenes to the lone pair of hetero atoms is a well-known reaction.[1] This behavior of carbenes led us to postulate that a carbene carbon is transformed into an ylide carbon by the intramolecular participation of the sulfur atom when a sulfide linkage is present in the same molecule. Although an ordinary carbene is electrophilic and can be added to electron-deficient olefins only with great difficulty,[2] the carbene of this type would act as a nucleophilic reagent, similar to the Wanzlick's carbenes[3] and cycloheptatrienylidene.[4] In addition, the above-mentioned intramolecular reaction of carbenes may afford small, hitherto unknown ring ylides, which are difficult to prepare by the usual salt methods.[5] In this respect, we have already reported, in preliminary form, evidence for the intervention of the thietanonium ylide generated from the carbene bearing sulfide linkage on the γ-position.[6,7] We have now investigated the reactions of alkyl carbenes bearing alkylthio, arylthio, and allythio groups on α-carbon. This paper will present a full account of our research into this subject.

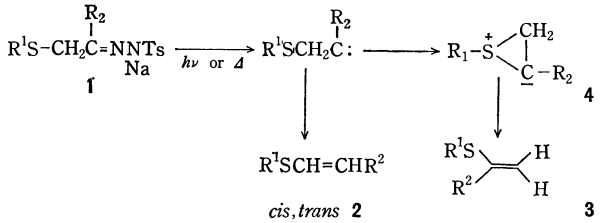
Results and Discussion

Reactions of α-Alkylthio- and α-Arylthio-alkylcarbenes. In 1967, Kirmse and Buschhoff reported the effects of ether linkage on the β-position,[8] and Robson and Shechter reported those of oxygen, nitrogen, and sulfur on the β-position,[9] in view of the neighboring effects of hetero atoms on carbenes. The effects of hetero atoms on the β-position may be summarized as follows: i) An alkoxy group on the β-position promoted markedly a rearrangement of a methyl on the α-carbon to the carbene carbon. The rate of the rearrangement of the alkoxy group is faster than that of hydrogen in the case of bis(α-alkoxy)alkylcarbene. ii) The rearrangement of an arylthio group on the α-carbon of the carbene is quite effective as compared with those of an alkoxy and alkylamino groups. In the latter communication, they observed an exclusive 1,2-shift of arylthio group to the electron-deficient center and interpreted the reaction as a concerted process through an ylide-like transition state. However, a possibility of the existence of an intermediate ylide still remains. Therefore, the reaction was reinvestigated in detail in the hope of obtaining evidence for the intervention of episulfonium ylide.

Carbenes were generated by the thermal or photochemical decomposition of sodium salts of the tosylhydrazones(**1a—d**), in accordance with the Bamford-Stevens method.[10] The results of the thermal decomposition in diglyme at 150 °C and of photolysis using a high-pressure Hg lamp in monoglyme at 10 °C are listed in Table 1, while the supposed reaction paths are described in Scheme 1.

As for the configuration of the olefin **2** produced by the 1,2-hydride shift, it is noteworthy that the ratios of the thermodynamically-unstable *cis*-isomer were



Scheme 1.

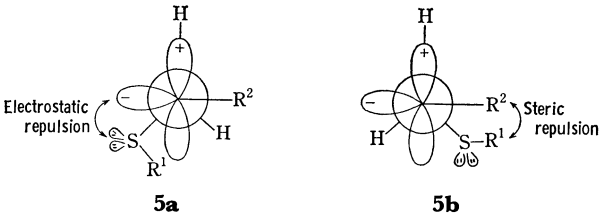

Scheme 2.

predominant in all cases examined: $R^1=R^2=$Ph, *cis*/*trans*=98/2; $R^1=$Et, $R^2=$Ph, *cis*/*trans*=66/34 and $R^1=t$-Bu, $R^2=$Ph, *cis*/*trans*=69/31. The results can reasonably be explained by considering the conformations of the singlet carbenes. It has generally been accepted that the hydrogen migration occurs in the singlet state.[11] Scheme 2 depicts the Newman projection of the singlet carbene.

The *trans*-olefin will be produced from the **5a** conformation and the *cis*-olefin, from **5b**. From the steric point of view, **5a** is expected to be more stable than **5b**. However, from the electronic point of view **5a** is less stable, because of the electrostatic repulsion between the lone pair of the sp^2-hybridized carbene and those of the sulfur atom. The preferential formation of the *cis*-isomers means that the electrostatic repulsion is the dominant factor in determining the conformations of these carbenes. Similar results were observed by Kirmse and Buschhoff in the case of α-alkoxyalkylcarbenes,[8] and by Yamamoto and Moritani in the case of α-carbethoxyalkylcarbenes.[12] As for the olefin, **3**, produced by the rearrangement of the alkylthio or arythio group, the probability of the rearrangement is considerably affected both by the substituent on the carbene carbon and that on the sulfur atom. That is, the ratio of the migration *vs.* the hydride shift seems to be determined by the stability of the hypothetical episulfonium ylide. In general, a phenyl group on ylide carbon delocalizes the negative charge by means of a resonance effect. On the contrary, a methyl group on the same carbon destabilizes the ylide by its inductive effect. In the case of thermolysis, the ratio of the olefin **3** to the olefin **2** was reduced remarkably from 10/90 to 40/60, as the substituent on the ylide carbon was changed from phenyl to methyl; this behavior might reflect the thermal stability of the intermediate episulfonium ylide. In sharp contrast with this, the phenyl substituent on sulfur plays a key role in determining the ratio of the olefin **3** to the olefin **2** when the carbene is produced by photolysis. Though we have no persuasive explanation for the phenomena, the result is probably due to the inherent difference between the two types of carbenes, *i. e.*, thermally- and photochemically-generated carbenes.

All attempts to trap these carbenes by cyclohexene were in vain. Furthermore, no reaction could be observed with such electron-rich olefins as morpholinocyclohexene and dihydropyran. However, these

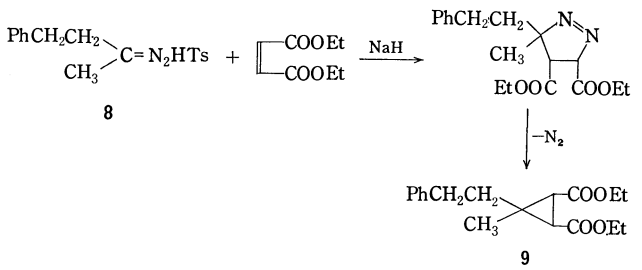
Scheme 3.

carbenes were found to react with electron-deficient olefins, *e. g.*, α, β-unsaturated carboxylic esters, to produce cyclopropanes in good yields.

The configuration of the obtained cyclopropanes was found to be *trans* about the substituent, **X**, irrespective of the configurations of the starting olefins. The configuration was determined on the basis of its NMR spectrum, in which the methylene protons adjacent to the sulfur atom displayed an AB quartet caused by asymmetric vicinal carbon. The results are summarized in Table 2. Consequently, as is shown in Scheme 3, the reaction should proceed in a two-step mechanism *via* betain, **7**. It might be said that the expected transformation of carbene to ylide was successfully realized by its nucleophilic addition to electron-deficient olefins. However, much as in the case of cycloheptatrienylidene[4] the possibility of the formation of cyclopropane *via* pyrazoline can not be rigorously excluded, because the diazoalkane is knwon to be the precursor of the carbene in the decomposition of tosylhydrazones by the Bamford-Stevens procedure.[10,13,23] To clarify this possibility, the tosylhydrazone **8** which has a structure quite analogous with **1d** except for the absence of sulfide linkage in the same molecule, was reacted under the same conditions in the presence of diethyl maleate.

The cyclopropane **9**, which is considered to be formed through the 1,3-cycloaddition of the diazoalkane



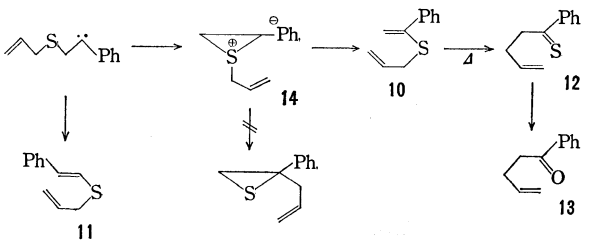
8 **9**

Scheme 4.

to the olefin, was obtained in only a 15% yield. This result indicates that a part of the cyclopropane **6** might be produced by the 1,3-cycloaddition route. However, the major path should be the ylide process. These results suggest that the reaction might become a useful synthetic device for the formation of cyclopropanes which can not be obtained by the usual carbene process.

Intramolecular Reactions of α-Allylthioalkylcarbene. The reaction of the α-allylthioalkylcarbene obtained from the sodium salt of α-allylthioacetophenone tosylhydrazone (**1e**) was investigated. In sharp contrast with that observed at 10 °C (*vide infra*), the photochemically-produced carbene showed a characteristic behavior.

At least three types of reactions leading to the final products are possible for this carbene, as is shown in Scheme 5: The 1,2-hydride shift to the olefin **11**, the 1,2-migration of the allylthio group through the intermediate ylide, **14**, and the [2,3]sigmatropic rearrangement[6] of the ylide **14**. A careful examination of the photolysate by NMR indicated that the carbene was transformed into a mixture of allyl 1-phenylvinyl sulfide, **10** (89%), and allyl 2-phenylvinyl sulfide, **11** (11%), in an almost quantitative yield. The ratio of *cis*-**11** to *trans*-**11** was found to be 79 : 21, which is again in good agreement with the results observed in the cases of alkylthio- and arylthio-alkylcarbenes. The allyl vinyl sulfide, **10**, obtained was thermally unstable. Thus, the structure was determined by measuring the NMR spectrum of the photolysate at −23 °C. The spectrum clearly demonstrated that the predominant component in the photolysate was the olefin **10**. In this case, the episulfonium ylide, **14**, can also be assumed to be an intermediate in the reaction.



14 **10** **12** **11** **13**

Scheme 5.

When the photolysate was kept in the dark at room temperature for a few hours, an intensive violet color spread over the solution and its NMR spectrum became completely different from that of **10**. This compound was stable under a nitrogen atmosphere, and its electronic spectrum displayed an absorption maximum at 560 nm which was almost the same as that of thioaceto-

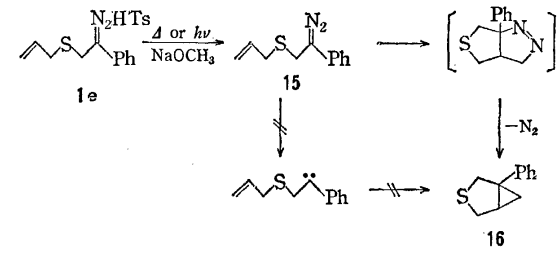
phenone and which could be assigned to the n–π^* transition of the thio-carbonyl function. On the basis of these spectra, this compound was assigned to thioketone, **12**. Chemical evidence for the thioketone, **12**, was also obtained; the violet color of the thioketone, **12**, gradually disappeared under atmospheric conditions. The products were separated and purified by column chromatography on silica, and the ketone, **13**, and sulfide, **11**, were finally isolated. The structure of the ketone, **13**, was determined by studying its NMR, IR, and mass spectra. Although the thio-Claisen rearrangements were observed in many systems,[15] that of a simple allyl vinyl sulfide system has not yet been reported. A recent report by Corey and Shulman[16] described how their attempted thermal thio-Claisen rearrangement of R_2C=$CHSCH_2CH$=CH_2 at 160—180 °C was unsuccessful, and how mercuric oxide was found to be an effective catalyst to promote the rearrangement and produce aldehyde directly. In our system, however, the thio-Claisen rearrangement occurs quite smoothly at room temperature without the aid of any catalyst. The substituent on the vinyl group seems to have a decisive effect on the ease of this rearrangement. That is, though two allyl vinyl sulfides were obtained in our system, only one, *i. e.*, the sulfide **10**, underwent thio-Claisen rearrangement, while the other, *i. e.*, the sulfide **11**, was recovered unchanged. The ease must be due partly to the stability of the product.

Intramolecular 1,3-Cycloaddition of α-Allylthioalkyldiazoalkane. α-Allylthioacetophenone tosylhydrazone (**1e**) was thermally decomposed in diglyme in the presence of sodium methoxide at 150 °C. The distillation of the reaction mixture under reduced pressure or the purification of the product by column chromatography afforded 1-phenyl-3-thiabicyclo[3.1.0]-hexane (**16**) as the sole isolable product in a 68.5% yield; no olefins caused by the carbenic process could be detected in the product. The photodecomposition of the sodium salts of tosylhydrazone, **1e**, in monoglyme at 10 °C also afforded 3-thiabicyclo[3.1.0]-hexane **16** in an 87.5% yield. The carbenic process of this α-allylthio system was observed only when the photolysis was carried out at −70 °C. Thus, the cycloaddition must involve a thermal process at some stage of the consecutive reactions. The formation of 3-thiabicyclo[3.1.0]hexane, **16**, can be explained by assuming an intramolecular cycloaddition of the diazoalkane to the double bond of the allylthio group to afford the bicyclic pyrazoline and the subsequent elimination of a molecular nitrogen, as is shown in Scheme 6.



Scheme 6.

A similar behavior was also observed when a β-allylthioalkyldiazoalkane was generated by the thermal decomposition of the corresponding tosylhydrazone. In the latter case, we could actually isolate the bicyclic pyrazoline.[17] The first step of the thermolysis is known to be the formation of the diazo compounds.[23] As far as we know, there has been no report on the formation of the diazo compounds from the corresponding sodium salts of tosylhydrazones under photolytic conditions. We could, however, actually observe a characteristic red color of the compounds during the initial stage of the photolyses of **1a**∼**1e**. Thus, the intramolecular 1,3-cycloaddition of the transient diazo function to the allyl moiety seems to be a quite effective process, even at 10 °C. The reason for the ease of this cycloaddition might be its intramolecular nature. The high performance of the reaction may open a novel synthetic route to thiabicyclic systems.

Experimental

Measurements. The melting points and boiling points were uncorrected. The infrared spectra were recorded on a Hitachi-Perkin-Elmer Model 337 Infracord or a Hitachi EPI-G3 spectrophotometer, using samples as neat liquid, KBr disks, or Nujol mulls. The nuclear magnetic resonance spectra were obtained by the use of a Varian HA-100 or Hitachi R20-B spectrometer, using TMS as the internal standard. The mass spectra were measured with the use of a Hitachi RMU-6E spectrometer at 70 eV. Analytical gas chromatography (vpc) was carried out on a Hitachi K-53 equipped with a flame-ionization detecter using a 1 m×3 mm column packed with 20% SE-30 or 10% QF-1 on chromosorb W. Photolyses were carried out with the use of a 450-W high-pressure mercury lamp (Ushio Electric Inc.).

*Materials. α-Phenylthioacetophenone Tosylhydrazone (**1a**):* Benzenethiol (13.8 g, 0.125 mol) was added to a solution of

15) For example, D. J. W. Schuijl, and L. Brandsma, *Rec. Trav. Chim. Pays-Bas*, **87**, 957 (1968); H. Kwart and T. J. George, *Chem. Commun.*, **1970**, 433.

16) E. J. Corey and J. I. Schulman, *J. Amer. Chem. Soc.*, **92**, 5522 (1970).

17) K. Kondo and I. Ojima, *Chem. Commun.*, **1972**, 63.

200 ml of absolute ethanol and 2.88 g of sodium (0.125 g-atom). To this solution, 25 g of α-bromoacetophenone (0.125 mol) in 100 ml of ethanol was added slowly, and then the mixture was gradually heated to reflux for 2 hr. After the reaction mixture had been cooled to room temperature, the precipitated sodium bromide was filtered off and the filtrate was concentrated. The residue was dissolved in chloroform, washed with water, and dried over anhydrous magnesium sulfate. After the solvent had been removed, the oily product was cooled with dry ice to afford yellow crystals. The product was recrystallized from ethanol; 15.7 g (55%) of pure α-phenylthioacetophenone were thus obtained. Mp 52 °C (lit,[18] 53—54 °C).

A mixture of 12 g (0.65 mol) of tosylhydrazide and 11.4 g (0.05 mol) of α-phenylthioacetophenone in 100 ml of ethanol was heated for half an hour under reflux. Then, the solution was cooled with dry ice; white needles of the tosylhydrazone, **1a**, were thus precipitated (16.8 g, 85%). Mp 105—106 °C. Found: C, 63.72; H, 4.93; N, 6.98; S, 16.13%. Calcd for $C_{21}H_{20}N_2O_2S_2$: C, 63.51; H, 5.08; N, 7.06; S, 16.17%.

In a similar manner, α-ethylthioacetophenone tosylhydrazone (**1b**) and α-*t*-butylthioacetophenone tosylhydrazone (**1c**) were prepared. α-Ethylthioacetophenone: bp 120 °C/1.5 mmHg (lit,[19], 106 °C/0.3 mmHg). Tosylhydrazone **1b**: Colorless needles, mp 126—127 °C. Found: C, 58.43; H, 5.69; N, 8.05; S, 18.41%. Calcd for $C_{17}H_{20}N_2O_2S_2$: C, 58.59; H, 5.78; N, 8.04; S, 18.40%. α-*t*-Butylthioacetophenone: bp 124 °C/2.5 mmHg. Tosylhydrazone **1c**: Colorless needles, mp 175—176 °C. Found: C, 60.44; H, 6.27; N, 7.27; S, 17.10%. Calcd for $C_{19}H_{24}N_2O_2S_2$: C, 60.61; H, 6.42; N, 7.44; S, 17.03%.

*α-Phenylthioacetone Tosylhydrazone (**1d**)*: α-Phenylthioacetone was prepared from 20 g (0.182 mol) of benzenethiol, 4.2 g (0.182 g-atom) of sodium, and 25 g (0.183 mol) of bromoacetone in 150 ml of absolute ethanol in a manner similar to that used in the case of α-phenylthioacetophenone; 17.5 g (57%) of the ketone were thus obtained. Bp 100—102 °C/1.0 mmHg (lit,[20] 160—165 °C/22 mmHg). The tosylhydrazone of α-phenylthioacetone was prepared from 16.7 g (0.1 mol) of the ketone and 20 g (0.107 mol) of tosylhydrazide in the presence of a few drops of concentrated sulfuric acid in 150 ml of ethanol at room temperature (29.1 g, 87%). mp 148—149 °C. Found: C, 57.36; H, 5.15; N, 8.29; S, 19.17%. Calcd for $C_{16}H_{18}N_2O_2S_2$: C, 57.46; H, 5.42; N, 8.38; S, 19.17%.

*Thermal Decomposition of the Tosylhydrazones, **1a-d***: A typical procedure will be described for the thermal decomposition of α-phenylthioacetophenone tosylhydrazone (**1a**).

The tosylhydrazone **1a** (396 mg, 1.0 mmol) was dissolved in 50 ml of diglyme, and then a 60-mg portion (*ca.* 1.2 mmol) of sodium hydride (50% suspension in mineral oil) was stirred in. After the evolution of hydrogen had ceased, the reaction flask was immersed into an oil bath which was maintained at 180 °C. The reaction mixture was heated under reflux for a few minutes; during this time the evolution of nitrogen was observed. After the precipitated sodium *p*-toluenesulfinate had been filtered off, the reaction mixture was concentrated under reduced pressure, dissolved in chloroform, washed with water, and then dried over anhydrous magnesium sulfate. The products were determined by studying the NMR spectrum, which was measured after the crude products had been distilled under reduced pressure. The yields and products ratios were calculated by comparing the vpc peak area of the crude products with that of pure samples, which had been prepared from benzenethiol and phenylacetylene,[21] and by analysing the integration of the NMR spectrum of the crude products. The total yield (**2a**+**3a**) was 44.5%.

In a similar manner, other tosylhydrazones (**1b—d**) were decomposed; olefins (**2** and **3**) were thus obtained in similar yields and were detected by means of the vpc and/or NMR spectra. Authentic samples were prepared from ethanethiol and phenylacetylene,[21] 2-methyl-2-propanethiol and phenylacetylene, and benzenethiol and allen.[22] The NMR spectral data for the olefinic protons of these vinyl sulfides are listed in Table 3.

*Photolyses of the Tosylhydrazones, **1a—d***: A typical procedure will be described for the photolysis of α-phenylthioacetophenone tosylhydrazone (**1a**).

The tosylhydrazone, **1a** (396 mg, 1.0 mmol), was dissolved in 20 ml of monoglyme, and then 60 mg (*ca.* 0.12 mmol) of sodium hydride in mineral oil was added to a pyrex cell. After the initial evolution of hydrogen had ceased, the reaction mixture was bubbled with dry nitrogen gas and then irradiated externally with a 450-W high-pressure Hg lamp for several hours. After the irradiation, the reaction mixture was concentrated, dissolved in chloroform, washed with water, and dried over anhydrous magnesium sulfate. The products were detected by NMR and vpc, as has been described above. The total yield (**2a**+**3a**) was 82%.

Similarly, other tosylhydrazones were photolysed; olefins (**2** and **3**) were thus obtained in similar yields.

*Thermal Decompositions of the Tosylhydrazones (**1a**, **1d**, and **8**) in the Presence of Electron-deficient Olefins.* A typical procedure will be described for the thermolysis of α-phenylthioacetone tosylhydrazone (**1d**) in the presence of diethyl maleate.

α-Phenylthioacetone tosylhydrazone (**1d**) (1.00 g, 3.0 mmol) was dissolved in 50 ml of diglyme, and then a 180-mg portion (ca. 3.6 mmol) of sodium hydride in mineral oil was added. After the evolution of hydrogen had been completed, a 2.6-g portion (15.1 mmol) of diethyl maleate was added. Then, the reaction flask was immersed into an oil bath, the temperature of which was maintained at 180°C with stirring. After the evolution of nitrogen had ceased, the reaction mixture was refluxed for an hour. The sodium *p*-toluenesulfinate thus precipitated was filtered off using a glass filter, and the filtrate was distilled to remove the solvent and unreacted diethyl maleate. The residue was dissolved in chloroform, washed with water, and dried over anhydrous magnesium sulfate. The solution was concentrated and chromatographed on silica (WAKO C-200). The cyclopropane **6b** (664 mg, 67%) was eluted by benzene.

In a similar manner, the cyclopropanes **6a**, **6c**, and **9** were obtained in 72, 61, and 15% yields, respectively. The yields of the cyclopropanes, as calculated from the vpc peak areas, were about ten percent higher than those obtained from chromatographic separations. 1-Phenyl-1-phenylthiomethyl-2,3-dicarboethoxycyclopropane (**6a**): NMR (CCl_4, TMS): τ 9.05 (H^a: t, J_{ac}=7Hz, 3H), 8.70 (H^b: t, J_{bd}= 7 Hz, 3H), 7.32 (H^f, H^g; AB_q, J_{fg}=6 Hz, 2H), 6.54 (H^e:

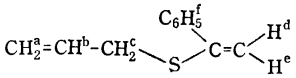
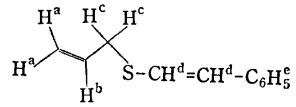
*α-Allylthioacetophenone Tosylhydrazone (**1e**).* To 150 ml of absolute ethanol, a 1.55-g portion (0.068 g-atom) of sodium was added. After the evolution of hydrogen had ceased, a 5.0-g portion (0.068 mol) of allylmercaptan was added to the solution, and the mixture was stirred for an hour. Into the solution we then stirred a solution of 13.5 g (0.068 mol) of bromoacetophenone in 100 ml of absolute ethanol; then, the reaction mixture was gradually heated to reflux over a 1-hr period. The sodium bromide thus precipitated was filtered off, and the filtrate was concentrated. The residue was dissolved in chloroform, washed with water, dried over anhydrous magnesium sulfate, and distilled. Yield, 61%. $PhCOCH_2SCH_2CH_2{=}CH_2$: bp 102—104 °C/0.2 mmHg, IR (neat): 1690 ($\nu_{C=O}$) 985 and 920 cm^{-1} $\left(\delta\ \begin{matrix}H\\H\end{matrix}\!\!>C=C<\!\!H\right)$.

The tosylhydrazone, **1e**, was prepared from 3.78 g (0.0207 mol) of α-allylthioacetophenone and 3.66 g (0.0207 mol) of tosylhydrazide in 95% ethanol in the presence of a drop of concentrated sulfuric acid. Tosylhydrazone **1e**: Colorless prisms, mp 106—107 °C, Found: C, 59.55; H, 5.79; N, 7.67; S, 17.84%. Calcd for $C_{18}H_{20}N_2O_2S_2$: C, 59.97; H, 5.59; N, 7.77; S, 17.79%.

*Photolysis of α-Allylthioacetophenone Tosylhydrazone (**1e**) in the Presence of Sodium Methoxide at Low Temperatures.* The tosylhydrazone **1e** (360 mg, 1.0 mmol) was dissolved in 30 ml of monoglyme in the photolysis vessel, and a 60-mg portion (1.1 mmol) of sodium methoxide was added. The solution was bubbled with nitrogen, and then stirred with a magnetic stirrer for an hour and irradiated. The temperature of the dry ice-ethanol solution was kept constant at −70 °C during the irradiation. The solution was irradiated for about 2.5 hr until the pink-color of the diazo compound had disappeared; then, the precipitated sodium *p*-toluenesulfinate was filtered off rapidly. The cool filtrate was concentrated under a vacuum; the residue was dissolved in cold ether and was washed with ice water as quickly as possible and the organic layer was dried over anhydrous magnesium sulfate in a dry ice box. The solution was then again concentrated by the use of a vacuum pump; the residue was dissolved in deuterochloroform including tetramethylsilane and poured into a NMR sample tube under a stream of nitrogen, after which the tube was closed. The NMR sample was stored in a dry ice–ethanol solution, and the NMR spectrum was measured at −23 °C. The predominant product was found to be 1-phenylvinyl allyl sulfide (**10**). **10**: NMR ($CDCl_3$, TMS, −23°C): τ 6.71 (H^c: d, $J_{bc}=7$ Hz, 2H), 5.10—4.85 (H^a: m, 2H), 4.80 (H^e: s, 1H), 4.54 (H^d; s, 1H), 4.40—3.90 (H^b: m, 1H), and 2.80—2.30 (H^f: m, 5H).



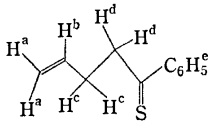
The structures of the minor products, *cis*- and *trans*-2-phenylvinyl allyl sulfides, were determined by studying their nmr and mass spectra. The pure sample was obtained by chromatography on silica, employing *n*-hexane as the eluent. **11**: NMR (CCl_4, TMS, *cis*, *trans* mixture): τ 6.69 (H^c: d, $J=7$ Hz, 2H), 5.00—4.70 (H^a: ,m 2H), 4.40—3.90 (H^b: m, 1H),



3.80 (*cis*-H^d; AB_q, $J=11$ Hz) (2H)
3.51 (*trans*-H_d: AB_q, $J=15$ Hz)
and 2.90—2.50 (H^e: m, 5H) mass: $m/e=176$ M^+, 135 M^+-41, base peak, 91 $C_7H_7^+$, and 77 Ph^+. When the sample which had been subjected to the NMR measurement was left at room temperature for half an hour, a violet color spread over the solution. The NMR spectrum was again measured at room temperature. The spectrum showed the disappearance of the olefin **10** and the production of new species which showed a benzoyl-type spectrum. The electronic spectrum of the sample showed an absorption maximum at 560 nm in the visible region; such an absorption maximum is characteristic of thiophenones. On the basis of these spectra, the new

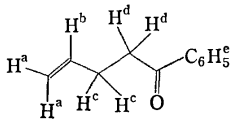
species which was produced thermally was assigned to buten-3-yl phenyl thioketone (**12**). When the sample was left under atmospheric conditions at room temperature overnight, the violet color completely faded. The precipitated, white solid, which was probably sulfur, was filtered off, and the filtrate was chromatographed on silica. Buten-3-yl phenyl ketone (**13**) was eluted with benzene. The NMR spectrum of the ketone, **13**, closely resembled that of the thioketone, **10**.

10: NMR ($CDCl_3$, TMS): τ 7.44 (H^c: quartet, $J=7$ Hz, 2H), 6.70—6.50 (H^d: m, 2H), 5.20—4.70 (H^a: m, 2H), 4.35—3.85 (H^b: m, 1H), 2.85—2.35 and 2.10—1.90 (H^e: m, 5H).



Although the absorption assigned to $CH_2{}^d$ was considered to be a triplet, it appeared as a multiplet. Therefore, a decoupling technique was employed to ascertain the assignments of $CH_2{}^c$ and $CH_2{}^d$. No unusual coupling could, however, be observed. That is, the absorption peak assigned to $CH_2{}^c$ appeared as a doublet ($J=6$ Hz) when $CH_2{}^d$ was irradiated, and the peak assigned to $CH_2{}^d$ appeared as a singlet when $CH_2{}^c$ was irradiated. Consequently, it is unclear why the peak assigned to $CH_2{}^d$ did not appear as a triplet.

13: NMR (CCl_4, TMS): τ 7.58 (H_c: quartet, $J=7$ Hz, 2H), 7.04 (H^d: t, $J=7$ Hz, 2H), 5.20—4.85 (H^a: m, 2H), 4.40—3.90 (H^b: m, 1H), and 2.90—2,50, 2.20—2.00 (H^e: m, 5H).



IR (neat): 1680 ($\nu_{C=O}$), 1635 (ν_{C-O}) and 970, 910 cm^{-1} $\left(\delta \begin{matrix} H \\ \end{matrix}\!\!>\!\!=\!\!<\!\!\begin{matrix} H \\ H \end{matrix}\right)$.

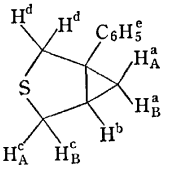
Mass: 160 M^+, 105 $PhCO^+$, base peak, and 77 Ph^+.

*The Thermal Decomposition and Photolysis of α-Allylthioacetophenone Tosylhydrazone (**1e**).* The tosylhydrazone, **1e** (360 mg, 1.0 mmol), and 60 mg (1.1 mmol) of sodium methoxide were dissolved in 40 ml of monoglyme in the photolysis vessel and stirred. The solution was bubbled with a dry nitrogen stream, and the vessel was closed. Photolysis was carried out using a 450-W high-pressure Hg lamp for 3 hr, after which the vessel was cooled by a water stream during irradiation. The sodium *p*-toluenesulfinate thus precipitated was filtered off, and the residue was concentrated and chromatographed on silica. 1-Phenyl-3-thiabicyclo[3.1.0]hexane (**16**) (87.5%) was eluted, with benzene as the sole product.

The thermal decomposition of the tosylhydrazone **1e** was carried out in a manner similar to that used in the case of the decomposition of the **1a-d** tosylhydrazones, though sodium methoxide was used instead of sodium hydride. The vacuum distillation of the reaction mixture afforded 3-thiabicyclo [3.1.0]hexane(**16**) in a 68.5% yield.

The yields were calculated by comparing the vpc peak area of the crude product with that of pure samples.

16: NMR (CCl_4, TMS): τ 9.17 ($H_A{}^a$: quartet, $J_{ab}=8$ Hz, 1H), 8.49 ($H_B{}^a$: t, $J_{ab}=4$ Hz, $J_{aa}=1$ H, 6 Hz), 8.23 (H^b: quintet, $J_{ab}=8$ Hz, 4 Hz, $J_{bc}=4$ Hz, 0 Hz, 1H), 7.14 ($H_A{}^c$: d, $J_{cc}=11$ Hz, $J_{bc}=0$ Hz, 1H), 6.90 (H^d: AB_q, $J_{dd}=11$ Hz, 2H), 6.79 ($H_B{}^c$: quartet, $J_{bc}=4$ Hz, $J_{cc}=11$ Hz, 1H), and 3.00—2.70 (H : m, 5H).



Mass: 176 M^+ base peak, 143 M^+–SH, 135 M^+-41  , 128 M^+-48,  , 91 C_7H_7, and 77 Ph^+. Found: C, 74.98; H, 6.74; S, 18.23%. Calcd for $C_{11}H_{12}S$: C, 74.95; H, 6.86; S, 18.19%.

Circular Dichroism Studies of Ring-conformational and rotational Equilibria in 2-Isopropenylcyclohexanones[1]

(Received September 16, 1972)

The temperature-dependent circular dichroism of optically active β,γ-unsaturated ketones, (2*S*, 5*R*)-(−)-2-isopropenyl-2,5-dimethylcyclohexanone (**2**) and (2*S*, 5*R*)-(−)-2-isopropenyl-5-methylcyclohexanone (**3**), and of the corresponding saturated ketones, (2*S*, 5*R*)-(−)-2-isopropyl-2,5-dimethylcyclohexanone (**1**), has been measured at the n→π^* transition in order to determine the relative disposition between the carbonyl group and the ethylenic bond of the isopropenyl group of the β,γ-unsaturated ketones. The compound (**2**) exhibited the sign of a Cotton effect opposite to that of the corresponding saturated compound (**1**), and the circular dichroism of the compound (**3**) behaved quite differently from menthone (**4**). The result has been discussed mainly in terms of the geometry of the carbonyl group and the ethylenic bond of the isopropenyl group. Thus, it has been concluded that the preferred conformations of the compounds (**1**), (**2**), and (**3**), are **1A**, **2A-III**, and **3A-I** respectively.

Circular dichroism (CD) measurements at various temperatures have been found to be very useful in studying the conformational analysis of a flexible α,β-unsaturated carbonyl compound, because of the peculiar sensitivity of this method to subtle conformational alteration.[3-5] The long-wavelength β,γ-unsaturated carbonyl transition has been previously pointed out[6,7] to take on some of the aspects usually characteristic of the transitions of dissymmetric chromophores; the amplitude of Cotton effect curves in β,γ-unsaturated ketones is known[6,7] to be critically dependent on the relative disposition between the carbonyl group and the ethylenic bond. This concept has now been applied to the conformational analysis of β,γ-unsaturated carbonyl compounds in a situation where the free rotation may occur. This paper will deal with the relative disposition between the carbonyl chromophore and the ethylenic bond of β,γ-unsaturated ketones, (2*S*, 5*R*)-(−)-2-isopropenyl-2,5-dimethylcyclohexanone (**2**) and (2*S*, 5*R*)-(−)-2-isopropenyl-5-methylcyclohexanone (**3**), as studied by means of the temperature-dependent circular dichroism at the n→π^* transition and in comparison with the circular dichroism of the corresponding saturated ketones, (2*S*, 5*R*)-(−)-2-isopropyl-2,5-dimethylcyclohexanone (**1**) and (2*S*, 5*R*)-(−)-2-isopropyl-5-methylcyclohexanone (**4**).[8]

Results and Discussion

The CD curves of (2*S*, 5*R*)-(−)-2-isopropyl-2,5-dimethylcyclohexanone (**1**) in selected solvents showed only a positive Cotton effect. However, a decrease in the rotational strength was observed upon changing the solvent from a nonpolar to a polar one. The methylmenthone (**1**) may exist in two interconvertible chair conformations, **1A**⇌**1B**. According to the octant rule, the conformer **1A** should exhibit a positive Cotton effect, and the conformer **1B**, a negative one. Therefore, the positively-rotating conformer **1A** with an equatorial isopropyl group is preferential in the nonpolar solvents. The temperature-dependent CD curves of the compound (**1**) in the MI (Fig. 1) and the EPA solvents both exhibited only a positive Cotton effect with the increase in the rotational strength upon a lowering of the temperature from 25 to −186 °C. The increase in the positive sign is attributable mainly

to the contribution of the ring conformation, and also partly to the rotational preferred conformation of the isopropyl group.[9] In that case, the isopropyl group contributes to the rotational strength only when the compound (**1**) takes the conformer **1A**. Therefore, this positive increase implies that the positively-rotating conformer, **1A**, is more stable than the conformer **1B** in respect to the energetic and steric requirements. Thus, the compound (**1**) exclusively exists in the conformer **1A**, frozen out, at −186 °C.

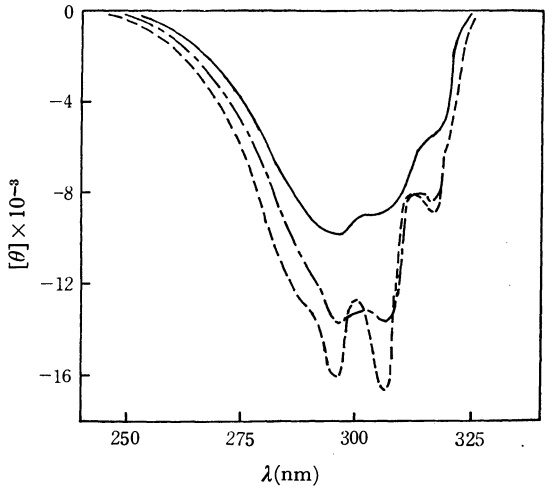

Fig. 2. CD curves of (2*S*, 5*R*)-(−)-2-isopropenyl-2,5-dimethylcyclohexanone (**2**) in the MI solvent: —— at +25 °C, — — — at −74 °C, and --- at −186 °C.

The CD curves of (2*S*, 5*R*)-(−)-2-isopropenyl-2,5-dimethylcyclohexanone (**2**) in various solvents exhibited only a negative Cotton effect with an increase in the rotational strength upon changing the solvent from a polar to a nonpolar one, in contrast with the case of the corresponding saturated compound (**1**). The CD curves in the MI solvent are illustrated in Fig. 2. The methylisopulegone (**2**) may exist in two interconvertible chair conformations, **2A**⇌**2B**, as well as the corresponding saturated compound (**1**). The conformer **2B** should exhibit a negative Cotton effect. If the free rotation of the isopropenyl group of the conformer **2A** is assumed not to contribute to the sign of a Cotton effect, the conformer **2A** may exhibit a positive Cotton effect. Therefore, the negative sign of a Cotton effect observed may be caused by the conformer **2B**. As has been mentioned above, however, the most preferred conformation of the methylmenthone (**1**) is the conformer **1A** with the equatorial isopropyl group at lower temperatures. The replacement of the isopropyl group with the slightly less bulky isopropenyl one is considered not to induce the inversion of the alkylated cyclohexane skeleton. Accordingly, the most preferred conformation for the compound (**2**) should be the conformer **2A** with the equatorial isopropenyl group at lower temperatures. The negative Cotton effect observed for the compound (**2**) should, consequently, be attributable to the relative disposition between the carbonyl group and the ethylenic bond of the isopropenyl group in the conformer **2A**, as has been pointed out previously.[6,7] The sign and the rotational strength of the Cotton effect of β,γ-unsaturated ketones are critically dependent on the array of double bonds.

The possible preferred conformations of the isopropenyl group in the conformer **2A** by the Newman projection with the corresponding octant projection, as viewed from C-8 to C-2, may be represented as is shown in Chart 1, judging from the conformation of 1-butene[10] and the energy barrier of *n*-butane.[11] The maximum interaction between the 9-methyl group and the 3-methylene or the 11-methyl group may be approximated by a butane function with a maximum value of 6.0 kcal/mol. The signs of a Cotton effect shown were predicted by an examination of the model[12] for each conformation in Chart 1. The conformers **2A-I** and **2A-II** should exhibit a positive Cotton effect and the conformer, **2A-III**, a negative one. The strong negative sign of the compound (**2**) at −186 °C was thus attributed to the conformer **2A-III**. Therefore, the conformer **2A-III** in the chair form is preferential at lower temperatures and in nonpolar solvents.

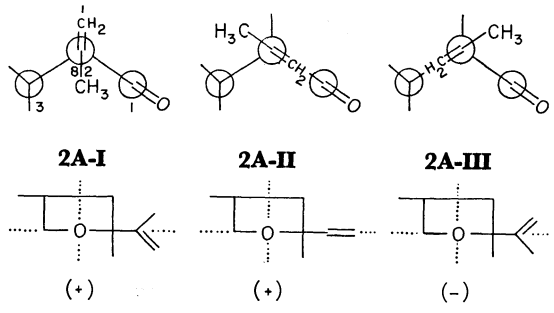

Chart 1. Possible preferred conformations, octant projections of the ethylenic bond in the conformation **2A** as viewed from C-8 to C-2, and the predicted signs of a Cotton effect.

The CD curves of both compound (**2**) and compound (**1**) in decalin showed a decrease in the rotational strength with the change of the temperature from −74 to +150 °C, although the signs are opposite. This implies that the positively-rotating conformer, **1A**, decreased with an increasing population of the unstable conformer, **1B**, when the temperature was raised. The negatively-rotating conformer, **2B**, like the compound (**1**), will increase at higher temperatures, exhibiting an augmentation of the negative CD curves. However, the opposite situations observed in the CD cruves of the compound (**2**) and the compound (**1**) seem to indicate that the contribution of a Cotton effect caused by the free rotation of the isopropenyl group in the conformer **2A** overcomes the contribution of a Cotton effect of the increasing conformer, **2B**.

The CD curves of isopulegone, (2*S*, 5*R*)-(−)-2-isopropenyl-5-methylcyclohexanone (**3**), showed only a

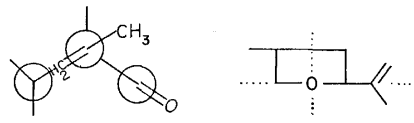
3A 3B

negative Cotton effect with an increase in the rotational strength in a nonpolar solvent, such as carbon tetrachloride, over that in a polar one. The ketone (**3**) may exist in two interconvertible chair conformations, **3A** and **3B**. The negative Cotton effect should be attributed to the conformer **3B** and/or to the conformer **3A-I** shown in Chart 2, in the same way as has been discussed in connection with the compound (**2**). The observation of a strong negative Cotton effect for the compound (**3**) in nonpolar solvents obviously indicates that the compound is composed of the conformer **3A-I** and the conformer **3B** in a conformational equilibrium, **3A**⇌**3B**, since, even if the isopropyl group of (−)-menthone (**4**) is replaced by the slightly less bulky isopropenyl group, the populations of the unstable diaxial conformer with a strong negative Cotton effect will probably comprise at least 3%, in a manner similar to that in the case of the parent compound, (−)-menthone (**4**).[8]



3A-1 (−)

Chart 2. The preferred conformation, the octant projection of the ethylenic bond in the conformation **3A** as viewed from C-8 to C-2, and the predicted sign of a Cotton effect.

This interpretation is further supported by the variable temperature circular dichroism. Upon the lowering of the temperature from +25 to −186 °C, the CD curves of the compound (**3**) exhibited a negative Cotton effect with the increase in the rotational strength in the EPA solvent (Fig. 3), but with the decrease in the MI solvent (Fig. 4). The decrease in the rotational strength of a neagtive Cotton effect in the nonpolar solvent was interpreted as an indication of the increase in the energetically more stable, diequatorial conformer, **3A**, at the sacrifice of the diaxial conformer, **3B**, with the stronger rotational strength, upon the lowering of the temperature. This result is further supported by high-temperature CD curves in decalin. At higher temperatures, the CD curves exhibited an increase in the negative sign, implying the augmentaion of the unstable diaxial conformer, **3B**, with the strong rotational strength, analogously to the case of (−)-menthone (**4**).[8] On the other hand, the increase in the rotational strength of the negative sign in the EPA solvent at lower temperatures implies the preference of the conformer **3A** at room temperature and the increase in the population of the conformer **3A-I** upon the lowering of the temperature. Thus, it seems likely that the most preferred conformation of the compound (**3**) is **3A-I**.

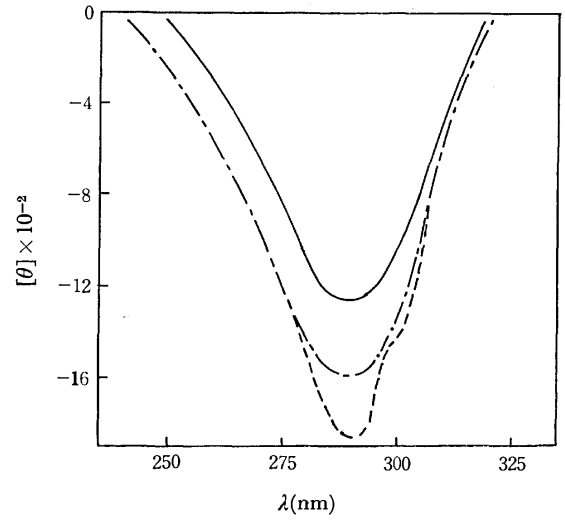


Fig. 3. CD cruves of (2*S*, 5*R*)-(−)-2-isopropenyl-5-methylcyclohexanone (**3**) in the EPA solvent: —— at +25 °C, ——— at −74 °C, and ---- at −186 °C.

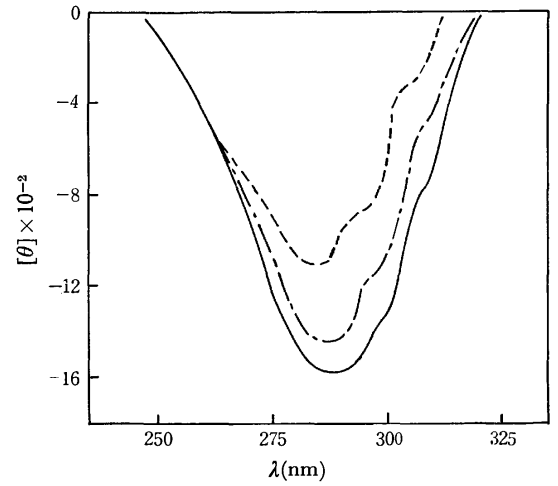

Fig. 4. CD curves of (2*S*, 5*R*)-(−)-2-isopropenyl-5-methylcyclohexanone (**3**) in the MI solvent: —— at +25 °C, ——— at −74 °C, and ---- at −186 °C.

The absolute value of the rotational strength of the β,γ-unsaturated ketones was four to five times that of the corresponding saturated compounds. It is likely that the array between the carbonyl group and the ethylenic bond in the conformer **2A-III** and **3A-I** contributes to the increase in their molecular ellipticity by several times, as compared with the corresponding saturated compounds.

Experimental

Measurements. The CD curves were obtained by means of a Japan Spectroscopic Co., Ltd., automatically-recording spectropolarimeter, Model ORD/UV-5, equipped with a circular dichroism attachment, using a variable-temperature CD cell. The EPA solvent was composed of ether–isopentane–ethanol in the ratio of 5:5:2 by volume. The MI solvent was composed of methylcyclohexane–isopentane of the ratio of 1:3 by volume. The NMR, IR, and UV spectra, although not shown below completly, exactly supported the structure

of the compounds on which the CD curves were measured. Gas-chromatographic analyses were made at 100—150 °C, using a Hitachi Perkin-Elmer F6-D gas chromatograph with a flame ionization-type detector and a 3 mm×1 m column packed with 10%-polyethylene glycol-6000 on Celite.

(2S, 5R)-(−)-2-Isopropyl-2,5-dimethylcyclohexanone (1). The catalytic hydrogenation of methylisopulegone (**2**) (200 mg) (described later) in methanol on 10% palladium-charcoal gave the compound (**1**) (150 mg) with the following properties: bp 176 °C, n_D^{25} 1.4543, $[\alpha]_D^{25}$ −7.3° (MeOH, *c* 0.1636); 99.7% pure by analytical glc; NMR (CCl_4) 0.72—1.00 ppm (m, 12H, $-CH_3$); ν_{max}^{liq} 1700 (C=O), 1378, and 1392 cm^{-1} (isopropyl group); λ_{max}^{MeOH} 291 nm (ε 38.0); CD (max) in MeOH (*c* 0.164): $[\theta]_{308}^{+25°}$ +932, in dioxane (*c* 0.189): $[\theta]_{308}^{+25°}$ +1467, in isooctane (*c* 0.192): $[\theta]_{311}^{+25°}$ +1530, in CCl_4 (*c* 0.163): $[\theta]_{311}^{+25°}$ +1973, in decalin (*c* 0.184): $[\theta]_{300}^{-74°}$ +1452, and $[\theta]_{310}^{-74°}$ +1531, $[\theta]_{300}^{+25°}$ +1333, $[\theta]_{305}^{+74°}$ +935, $[\theta]_{305}^{+150°}$ +606, in EPA (*c* 0.131): $[\theta]_{300}^{+25°}$ +1379 and $[\theta]_{310}^{+25°}$ +1352, $[\theta]_{300}^{-74°}$ +2023 and $[\theta]_{310}^{-74°}$ +2071, $[\theta]_{299}^{-190°}$ +3698 and $[\theta]_{308}^{-190°}$ +3742.

(2S, 5R)-(−)-2-Isopropenyl-2,5-dimethylcyclohexanone (2). This compound was synthesized by the methylation of (+)-pulegone (bp 81—82 °C/5 mmHg, n_D^{25} 1.4843, d_4^{25} 0.9303, $[\alpha]_D^{25}$ +23.0° (neat)) following the method in the literature.[13] It was found to be 99.5% pure by analytical glc and showed the following physical properties: bp 69—70 °C/8 mmHg, n_D^{25} 1.4682, d_4^{25} 0.9231, $[\alpha]_D^{25}$ −139.2° (neat); the semicarbazone derivative, mp 201—202 °C; NMR (CCl_4) 0.96 ppm (d, *J*=6.0 Hz, 3H, $CH-CH_3$), 1.10 (s, 3H, $-CH_3$), 1.68 (s, 3H, $=C-CH_3$), 4.76 and 4.88 (m, 2H, $=CH_2$); ν_{max}^{liq} 3075, 1640, 890 ($C=CH_2$), 1706 cm^{-1} (C=O); λ_{max}^{MeOH} 294 nm (ε 51.6); CD (max) in MeOH (*c* 0.135): $[\theta]_{296}^{+25°}$ −6411, in dioxane (*c* 0.175): $[\theta]_{295}^{+25°}$ −6642, in isooctane (*c* 0.042): $[\theta]_{298}^{+25°}$ −9782, in CCl_4 (*c* 0.095): $[\theta]_{300}^{+25°}$ −10841, in decalin (*c* 0.062): $[\theta]_{307}^{-74°}$ −14300, $[\theta]_{297}^{+25°}$ −12016, $[\theta]_{298}^{+74°}$ −10598, $[\theta]_{300}^{+150°}$ −8487, in EPA (*c* 0.063): $[\theta]_{298}^{+25°}$ −8765, $[\theta]_{301}^{-74°}$ −9794 and $[\theta]_{308}^{-74°}$ −10406, $[\theta]_{297}^{-190°}$ −13416 and $[\theta]_{305}^{-190°}$ −14522.

(2S, 5R)-(−)-2-Isopropenyl-5-methylcyclohexanone (3). The oxidation of (−)-isopulegol (bp 93.0 °C/10 mmHg, n_D^{25} 1.4676, d_4^{25} 0.9052, $[\alpha]_D^{25}$ −22.3° (neat)) with a chromium trioxide-pyridine complex afforded the compound (**3**): bp 86 °C/10 mmHg, n_D^{25} 1.4670, d_4^{25} 0.9252, $[\alpha]_D^{25}$ +7.9° (neat); 94% pure by analytical glc; NMR (CCl_4) 1.40 ppm (d, *J*=4.0 Hz, 3H, $CH-C\underline{H}_3$), 1.70 (s, 3H, $=C-CH_3$), 4.63 and 4.79 (m, 2H, $=CH_2$); ν_{max}^{liq} 3050, 1649, 890 ($C=CH_2$), 1712 cm^{-1} (C=O); λ_{max}^{MeOH} 297 nm (ε 29.7); CD (max) in MeOH (*c* 0.166): $[\theta]_{288}^{+25°}$ −1104, in dioxane (*c* 0.185): $[\theta]_{294}^{+25°}$ −1598, in isooctane (*c* 0.166): $[\theta]_{294}^{+25°}$ −1510, in CCl_4 (*c* 0.125): $[\theta]_{295}^{+25°}$ −1685, in decalin (*c* 0.185): $[\theta]_{293}^{-74°}$ −1510, $[\theta]_{294}^{+25°}$ −1518, $[\theta]_{294}^{+74°}$ −1598, $[\theta]_{296}^{+150°}$ −1635.

Asymmetric Hydrogenation of C=O Double Bond with Modified Raney Nickel. XXVI. Asymmetric Hydrogenation of β-Keto Esters

Tadashi TANABE* and Yoshiharu IZUMI

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Suita, Osaka 565

(Received March 9, 1972)

It was found that the Raney nickel catalyst modified with the α-amino or α-hydroxy acid catalyzed the hydrogenations of β-keto esters to the corresponding β-hydroxyesters in good asymmetric yields, and that the alkoxy moiety of the ester of acetoacetic acid influenced the asymmetric yields.[1] For the elucidation of the enantiotopic selection[2] mechanism of the modified Raney nickel catalyst, the effect of the bulk of the acyl group on the asymmetric yield of the product has been studied with various methyl acylacetates.

Experimental

Preparation of the Substrate. The methyl acylacetates were prepared by the ester-interchange of the ethyl acylacetates with sodium methoxide in methanol. The ethyl acylacetates were synthesized by the decomposition of the acylated malonic esters, which had been prepared from magnesium malonate and acyl chloride by the method of Riegel *et al.*[3] Ethyl oxalacetate was prepared by the condensation of ethyl acetate and ethyl oxalate with sodium.[4]

Optical Resolution of DL-*3-Hydroxy*-n-*valeric Acid.* One hundred grams of ethyl propionylacetate[2] was reduced with 2.4 g of a Raney nickel catalyst[1]; the product was hydrolyzed with a slightly excess 50% sodium hydroxide solution and acidified with concd hydrochloric acid equivalent to the alkali used. After concentration *in vacuo*, the acid was extracted with acetone and the acetone was removed by distillation under reduced pressure. Seventy grams of the acid was thus obtained.

Quinine monohydrate (152 g) in 1 l of water was neutralized with 50 g of DL-3-hydroxy-*n*-valeric acid at 100°C. Then the solution was cooled to room temperature. The quinine salts were collected by filtration and recrystallized once from water. Yield, 90 g; mp 112°C.

Found: C, 65.33; H, 8.19; N, 5.91%. Calcd for $C_{25}H_{36}O_6N_2$: C, 65.19; H, 7.88; N, 6.08%.

$[\alpha]_D^{20}$ −119° (*c* 1, ethanol).

Ninety grams of the quinine salt was suspended in 1.5 l of water and decomposed with 90 ml of a 10% sodium hydroxide solution. The mixture was then let stand overnight, after which the quinine was removed by filtration. The solution was washed with 150 ml of chloroform five times, neutralized with N hydrochloric acid, and concentrated to dryness. The sodium salt was extracted with ethanol, and the ethanol solution was cooled to room temperature. The sodium salts were filtered off and dried in a vacuum desiccator at 60°C. Yield, 26 g; mp 116 °C. $[\alpha]_D^{20}$ +8.48° (*c* 4, water).

Found: C, 41.65; H, 6.95%. Calcd for $C_5H_9O_3Na \cdot 1/4H_2O$: C, 41.52; H, 6.62%.

Preparation of Methyl L$_8$[5]-*(+)-3-Hydroxy*-n-*valerate.* Five grams of the sodium salt was dissolved in 50 ml of water; the solution was then acidified with 3.2 ml of concd hydrochloric acid and concentrated to dryness under reduced pressure. The acid was extracted with 100 ml of ether and esterified with diazomethane.[6] After the removal of the ether, the ester was distilled under reduced pressure. Yield, 3.6 g; bp 81°C/17 mmHg.

Found: C, 53.80; H, 9.33%. Calcd for $C_6H_{12}O_3$: C, 54.53; H, 9.15%.

α_D^{20} +18.60 (without dilution).

Preparation of the Modified Raney Nickel Catalyst and Measurement of the Asymmetric Activity of the Catalyst. The procedures for the preparation of the modified Raney nickel catalyst and the measurement of the asymmetric activity were the same as have been described in a previous paper.[7]

Results and Discussion

In order to elucidate the effect of the bulk of the acyl group of the β-keto ester on the asymmetric activity of the catalyst, various methyl acylacetates and diethyl oxalacetate were hydrogenated with catalysts modified with L-glutamic acid and D-tartaric acid. The acyl groups used were propionyl, *n*-butyryl, isobutyryl, and octanoyl groups. The results are compared in Table 1 with those of the hydrogenation of methyl acetoacetate.

With the catalysts modified by D-tartaric acid, and by L-glutamic acid, the methyl acylacetates were hydrogenated to the products of the levorotatory optical rotation.[8]

Upon modification with tartaric acid, the asymmetric yield was higher in methyl propionylacetate than in methyl acetoacetate and a product with a large op-

8) The optical rotations of the methyl esters of optically-active 3-hydroxycaproic acid, 3-hydroxy-4-methyl-*n*-valeric acid, and 3-hydroxycapric acid have not been obtained successfully. However, the optical rotations of optically-pure methyl 3-hydroxybutyrate and methyl 3-hydroxy-*n*-valerate were 23.8 and 18.6° respectively and the elongation of the carbon chain in the 3-hydroxy-*n*-aliphatic acid seems to be accompanied by a decrease in the optical rotation.

tical rotation was obtained in the hydrogenation of methyl isobutyrylacetate. These facts suggest that the bulk of the acyl group contributed to the enantiotopic selection of the substrate by D-tartaric acid on the catalyst surface. Upon modification at 100°C, a higher asymmetric yield (66%) was obtained in the hydrogenation of methyl propionylacetate.

The catalyst modified with L-glutamic acid was found to have a different asymmetric activity than the one modified with D-tartaric acid. Though the asymmetric directions of the products were levorotatory, it seemed that the asymmetric yields of the products were not much affected by the bulk of the acyl group. Accordingly, a high asymmetric yield would not be obtained by the modification of the acyl group of the methyl acylacetate.

Diethyl oxalacetate was not asymmetrically hydrogenated with the catalyst modified with tartaric acid, as may be seen in Table 1. This result suggests that the smaller defference in the groups around the carbonyl group to be reduced may result in the difficulty of the enantiotopic selection by the modifying reagent.

The results presented above show that the sorts of the substituents and the steric requirement around the carbonyl group of the substrate are very important for the enantiotopic selection by the modifying reagent, especially in the asymmetric hydrogenation by the catalyst modified with tartaric acid.

The authors wish to express their thanks to Miss Kiku Koike and Mrs. Nobuko Okuhara for their elemental analyses and to the Kawaken Fine Chemicals Co., Ltd., Tokyo for the supply of Raney nickel.

Viscosity *B* Coefficients for Some Alkyl Sulfates in Aqueous Solutions

Kunio TAMAKI, Yōko ŌHARA, and Yoshio ISOMURA

Department of Chemistry, Yokohama City University, Kanazawa-ku, Yokohama 236

(Received May 29, 1972)

In the previous paper,[1] the change in the partial molal heat capacity of a homologous series of sodium alkyl sulfates has been discussed in terms of the change in water structure for the dissolution of the solutes into water. This paper will drscribe our experimental findings on the viscosity of sodium alkyl sulfates in aqueous solutions.

Experimental

The viscosities were measured in Ubbelohde-type viscosimeters with flow times for water at 25 °C of about 800 s in a constant-temperature bath controlled to ±0.01 °C of the specified temperature. It was found that the kinetic energy correction was negligible in this work. The densities were measured in Ostwald pycnometers. The relative viscosities were calculated in the usual manner, using the data on the flow time and the density. The sodium alkyl sulfates used were the same samples as those described in the previous paper.[1]

Results and Discussion

The viscosity of an aqueous solution of electrolytes, η, can be represented by the Jones-Dole equation:[2]

$$\eta/\eta_0 = 1 + AC^{1/2} + BC \quad (1)$$

where η_0 is the viscosity of water, C is the concentration (molality), A is the constant related to the ion-ion interaction, and B is the viscosity B coefficient. Equation (1) is thus converted to:

$$(\eta/\eta_0 - 1)/C^{1/2} = A + BC^{1/2} \quad (2)$$

When the left-hand side of Eq. (2) is plotted against $C^{1/2}$, the viscosity B coefficient is obtained as the slope of a linear line. For example, Fig. 1 shows the results of the plotting of Eq. (2) at 25 °C. The values of the viscosity B coefficient thus obtained are summarized in Table 1. The estimated error in the B values is ±0.005. The constant, A, was theoretically interpreted by Falkenhagen and can be calculat-

Pentyl	—	0.504	0.457	—	—
Hexyl	—	0.582	—	—	—

ed using the data of the limiting equivalent conductivity of the salt, cation, and anion.[3] In this work, the electrical conductivities were measured with a Yokogawa BVZ-13A audio-frequency bridge using a frequency of 1000 Hz. In general, the calculated values of *A* were found to be in good agreement with those obtained from the semi-empirical Eq. (2).

The *B* values for the homologous sodium alkyl sulfates increase linearly with the number of carbon atoms in the alkyl chains at 25 °C. The average increment per methylene group is 0.079. Similar relations have been observed for homologous alkylammonium bromides[4] and for homologous amino acids, $NH_3^+(CH_2)_xCOO^-$.[5] The increments per methylene group were 0.080 at 25 °C for the alkylammonium bromides[4] and 0.084 at 25 °C for the amino acids.[5] The contribution permethylene group to the viscosity *B* coefficient is considered to be about 0.080 at 25 °C.

As far as we are aware, there has been no report of a negative *B* coefficient for organic electrolytes in water.[4-8] This suggests the water-structure-making effect for all organic electrolytes, if we adopt the view of Gurney,[9] the *B* coefficient being interpreted in terms of a specific ion-solvent interaction. However, the viscosity *B* coefficient consists of the contribution from the ion-solvent interaction plus the contribution from the size of the ion (Einstein effect).[10] Large molecular ions such as organic ions may be expected to have a large viscosity increment arising from the Einstein effect.[10] With regard to the temperature dependence of the *B* values, this Einstein effect will remain fairly constant and better criteria for structure influences will be obtained.[10] Kay *et al.*[6] reported an increase in the viscosity *B* coefficient with the temperature for a structure-breaking ion such as tetramethylammonium salt and a decrease for a structure-making salt, such as tetrapropyl- and tetrabutylammonium salts. A similar relation has been reported for the homologous amino acids.[5] It may be seen in Table 1 that the methyl salt, a structure-breaking solute,[1] shows a slight increase in *B* value with the increase in the temperature between 25 and 50 °C, and that the ethyl salt, a borderline solute,[1] is rather insensitive to the temperature between 10 and 50 °C. On the other hand, for propyl salt, which is classified as a structure-making solute,[1] the *B* value decreases slightly with the temperature between 25 and 45 °C. A more remarkable decrease was found in the range of 25—35 °C for pentyl salt, which is an excellent structure-making solute.[1] On comparing these facts with those given in the previous paper,[1] it may be concluded for the homologous sodium alkyl sulfates that there is a close relationship between the temperature dependence of the viscosity *B* coefficient and the change in the partial molal heat capacity.[1]

The *B* values listed in Table 1 are naturally made up of the sum of the contributions from both sodium and alkyl sulfate ions. Fortunately, the B values of the sodium ion is practically constant between 15 and 42.5 °C.[10] Therefore, the temperature dependence of the viscosity *B* coefficient of the sodium salts discussed above conveniently reflects the nature of the alkyl sulfate anions.

Synthesis of Bis(2,4,5-trimethylphenyl)-, Bis(2,4,6-trimethylphenyl)-, and Bis(3,4,5-trimethylphenyl)tetramethyloctadecanonaene

Toshio HAMASAKI*, Kiyoshi CHIN**, Nobuhisa OKUKADO, and Masaru YAMAGUCHI

Department of Chemistry, Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812

(Received September 12, 1972)

Three isomeric aromatic carotenoid hydrocarbons (I, II, and III) were synthesized, in order to compare them with unidentified minor carotenoid hydrocarbons present in a sea sponge "*Reniera japonica*", known to produce three aromatic carotenoids (IV, V, and VI) as the major constituents of its coloring matter.[1] None of these synthetic products have so far been proved to be identical with those from a natural source.

I R=R'=2,4,5-$(CH_3)_3C_6H_2$-
II R=R'=2,4,6-$(CH_3)_3C_6H_2$-
III R=R'=3,4,5-$(CH_3)_3C_6H_2$-
IV (isorenieratene) R=R'=2,3,6-$(CH_3)_3C_6H_2$-
V (renieratene) R=2,3,6-$(CH_3)_3C_6H_2$-, R'=2,3,4-$(CH_3)_3C_6H_2$-
VI (renierapurpurin) R=R'=2,3,4-$(CH_3)_3C_6H_2$-

Synthesis was carried out according to the conventional $C_{10}+C_{20}+C_{10}$ route,[2] where crocetin dialdehyde was condensed with an appropriate trimethylbenzilidenetriphenylphosphorane.

The highest λ_{max} of the synthetic and natural aromatic pigments are listed in Table 1 in the order of decreasing wavelength. Variations of λ_{max} can be satisfactorily explained in terms of non-planarity between benzene ring and polyene chain, caused by 2- and 6-standing methyl groups and the buttressing effect of 3-standing methyl groups on benzene rings.

TABLE 1. THE HIGHEST λ_{max} OF AROMATIC CAROTENOIDS

Compound	III	I	VI	V	II	IV
λ_{max} (benzene, mμ)	491	490	486	477	471	466

The pigments were adsorbed on alumina (Merck, neutral; Grade II: from benzene solution) in the following sequence of decreasing adsorbability: III, VI, I, V, II, IV.

Experimental

Materials. 2,4,5-, 2,4,6-, and 3,4,5-Trimethylbenzyl alcohol were prepared by lithium aluminium hydride reduction of the corresponding methyl trimethylbenzoates. The recrystallized alcohols melted at 83—83.5°C (lit, 83—83.5°C[3]), 86.5—87°C (lit, 87—88°C[4]) and 74—75°C (lit, 78°C[5]), respectively.

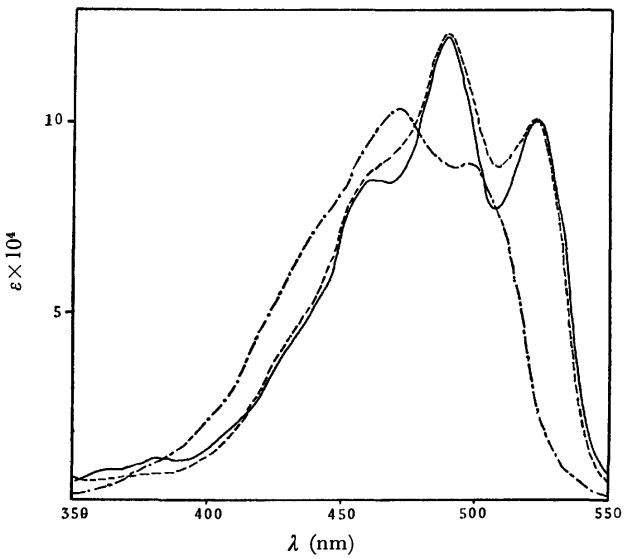

Fig. 1. Absorption curves of I (----), II (—·—·), and III (——) (benzene).

(Trimethylbenzyl)triphenylphosphonium Bromides. These were prepared from the corresponding alcohols in a similar way to that described by Cooper *et al.* on analogous phosphonium bromides.[6] (2,4,5-Trimethylbenzyl)triphenylphosphonium bromide: colorless prisms, mp 204—205°C (Found: C, 70.79; H, 6.32. Calcd for $C_{28}H_{28}BrP$: C, 70.74; H, 5.94%). 2,4,6-Trimethylbenzyl analogue: colorless needles, mp 243—245 °C (Found: C, 69.70; H, 6.15%). 3,4,5-Trimethylbenzyl analogue: colorless plates, mp 250—252 °C (Found: C, 70.20; H, 6.29%).

1,18-Bis(2,4,5-trimethylphenyl)-3,7,12,16-tetramethyloctadecanonaene (I). An ethereal solution of phenyllithium (0.8 M, 0.4 ml) was added to a stirred suspension of (2,4,5-trimethylbenzyl)triphenylphosphonium bromide (121 mg) in ether (4 ml). After stirring for one hour, two drops of methylene chloride were added to destroy excess base. A solution of crocetindial[7] (25 mg) in methylene chloride (1 ml) was then added, and the mixture was stirred under reflux for four hours. The mixture was diluted with methanol (50 ml), and kept at 0 °C overnight. The precipitate was washed with boiling methanol several times and recrystal-

Interaction Parameters of Poly(*o*-chlorostyrene)-Solvent Systems

Kunihiko GEKKO and Kimiyoshi MATSUMURA*

Department of Food Science and Technology, Faculty of Agriculture, Nagoya University, Nagoya 464

** Department of Chemistry, Aichi Kyoiku University, Kariya 448*

(Received August 14, 1972)

The thermodynamic properties of a polymer-solvent mixture have generally been analysed using the equation introduced by Flory and Huggins:[1,2]

$$\ln a_1 = \ln (1-v_2) + v_2 + \chi v_2^2 \quad (1)$$

where a_1, v_2, and χ represent the activity of the solvent, the volume fraction of the polymer, and the interaction parameter between the polymer and the solvent respectively. It has been indicated, on the basis of both experimental and theoretical studies,[3-7] that the χ value depends on the polymer concentration. However, we do not have enough systematic investigations[8-10] to be able to understand the characteristic behavior of χ in relation to such physical quantities of the polymer and the solvent as the dipole moment. In this paper, we will discuss the effects of the concentration and the dipole moment on the interaction parameters of poly(*o*-chlorostyrene)-solvent systems by means of isopiestic vapor-pressure measurements.

Experimental

Materials. Atactic poly(*o*-chlorostyrene)(PoCS) was prepared and fractionated following the method reported in the previous paper.[11] The average molecular weight of the polymer used in this experiment was determined to be 60.7×10^4 by measuring the intrinsic viscosity of toluene solutions at 25°C.[12] The density of this material was 1.268 and 1.255 g/ml at 25 and 40°C respectively. To clarify the dipole-moment effect of the solvent on χ, we used benzene and methyl ethyl ketone (MEK) as solvents; they have almost identical molar volumes and cohesive energy densities. These solvents were purified by the conventional purification method.

Methods. The apparatus and procedures for measuring the equilibrium vapor sorption were similar to those used in a previous paper.[6] The volume fraction of the polymer at equilibrium was calculated from the experimentally-determined weight fraction by assuming that the solvent volume and the polymer volume are additive on mixing. The activity, a_1, of the solvent was obtained from $a_1 = P_1/P_1^0$, where P_1^0 and P_1 are the vapor pressure of the pure solvent and of the solvent on the polymer solution respectively at a given temperature.

Results and Discussion

The sorption isotherms of benzene and MEK for PoCS are shown in Fig. 1, in which the data for polystyrene(PS)–benzene[13] and PS–MEK[14] systems are also shown as references. It is clear that benzene more easily comes into contact with both polymers, PoCS and PS, than MEK does. This is consistent with the fact that MEK becomes a theta solvent for PoCS at 25 °C, though benzene is a good solvent.[12] From the values of v_2 and P_1/P_1^0, we calculated the Flory-Huggins interaction parameter, χ, using Eq. (1). The values thus obtained are listed in Table 1 and are plotted against v_2 in Fig. 2. In general, the concentration dependence of χ has been expressed by a series of v_2 by Huggins:[7]

$$\chi = A + Bv_2 + Cv_2^2 + \cdots\cdots \quad (2)$$

where A, B, C, *etc.* are constant values independent

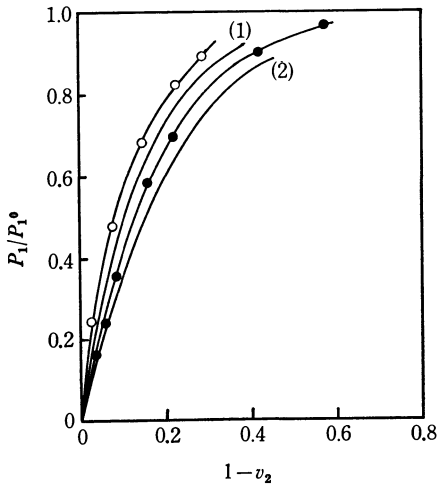

Fig. 1. The sorption isotherms of benzene (-●-) and MEK (-○-) for PoCS at 25 °C. The line (1) and (2) represent the data for PS–MEK system at 25 °C[14] and PS–benzene system at 20 °C[13], respectively.

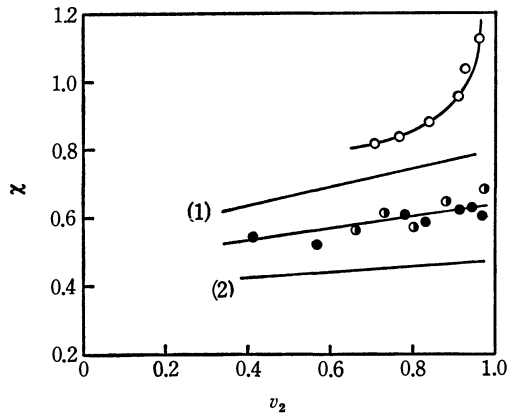

Fig. 2. The concentration dependence of χ for PoCS–benzene (-●-, 25 °C; -◑-, 40 °C) and PoCS–MEK (-○-, 25 °C) systems. The lines (1) and (2) represent the data for PS–MEK system at 25 °C[14] and for PS–benzene system at 20 °C[13], respectively.

of the concentration. In the system of PoCS–benzene, there exists a linear relation with a small positive slope between v_2 and χ, similar to the case in the PS–benzene solution. The effect of the temperature on χ for this system could not be ascertained in this experiment, which may suggest that there is almost no heat of mixing. On the other hand, in the PoCS–MEK system there is remarkable concentration dependence of χ, requiring the third and the higher terms on the right-hand side of Eq. (2), and the χ values are considerably larger than those of the PoCS–benzene system.

Now, it is considered that χ depends on the enthalpy factors, such as the cohesive energy and the interaction energy due to the dipole moment or the hydrogen bonding between the solvent and polymer molecules, and also on the entropy factors, such as the size and shape of the polymer and solvent molecules. The molar volume of MEK is 89.6 ml/mol, which is close to that of benzene, 89.3 ml/mol at 25°C. Further the solubility parameters of benzene and MEK are 9.15 and 9.22 $(cal/ml)^{1/2}$ respectively. Judging from these data, there seems to be almost no difference in the solvent power between the two solvents. Accordingly, the characteristic difference in χ between the systems of PoCS–benzene and PoCS–MEK is probably due to such factors as the molecular shapes, the hydrogen-bonding abilities, and the dipole moments of the solvents; the dipole moment of benzene is zero, and that of MEK is 2.75 Debye (D). We may consider that the effect of the hydrogen bond is not so predominant for this characteristic behavior of PoCS–MEK system, by analogy with the results for the vapor-pressure behavior of the polypropylene–MEK and natural rubber–MEK systems.[5]

According to Yamakawa *et al.*,[8] the thermodynamic interaction parameter, χ, is the sum of the χ^* which arises from the non-polar interaction and the χ_p which arises from the polar interaction; that is, $\chi=\chi^*+\chi_p$. For the concentration dependence of χ_p, the following conclusion was also obtained by them:

(a) χ_p increases with an increase in the concentration when the dipole moment of the solvent (μ_1) is greater than that of the polymer segment(μ_2)

(b) $\chi_p=0$ when $\mu_1=\mu_2$

(c) χ_p decreases with an increase in the concentration when $\mu_1<\mu_2$. It was also found that the polarizabilities of the solvent and the polymer segment affect χ_p to a smaller extent than the dipole moments do.[8] Furthermore, χ^* may usually be considered as a slowly decreasing function of the concentration from both the theoretical and experimental points of view.[8,15,16] In analyzing the results we obtained on the basis of the above theoretical conclusion, we take

15) M. Fixman, *J. Chem. Phys.*, **35**, 889 (1961).

16) P. J. Flory, "Principles of Polymer Chemistry," Cornell University Press, Ithaca, New York (1953), p. 515.

0.36D for the μ_2 of PS[17] and assume that the μ_2 of PoCS is the same as the dipole moment of *o*-chlorotoluene, 1.43D, since no value has been reported for the μ_2 of PoCS.

The remarkable increase in χ with the polymer concentration for the PoCS–MEK system where $\mu_1 > \mu_2$ suggests that, for this system, the contribution of χ_p to the total χ is significant in comparison with that of χ^*, as much as in the PS–MEK system. That is, the continuum model of concentrated solutions by Yamakawa *et al.*[8] is considered to be valid for the PoCS–MEK system also. On the other hand, the χ values for the systems of PoCS–benzene and PS–benzene increased slowly with the concentration, as is shown in Fig. 2, though they should decrease with the concentration judging from the fact that $\mu_1 < \mu_2$, if the continuum model is valid for these systems. This discrepancy of the continuum model for the PoCS–benzene system may be due to the orientation of the benzene rings of the polymer and the solvent, since such an orientation has been found in the case of the PS-benzene system.[18]

Laser-induced Chemical Reactions. VI. On the Formation Processes of Acetylene

Ko Taki

Faculty of Industrial Hygiene, Kitasato University, Sagamihara-shi, Kanagawa 228

Pil Hyon Kim and Susumu Namba

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received August 18, 1972)

The reactions of the carbon vapor produced by various methods[1-9] with hydrocarbons have been extensively studied. In previous papers,[10,11] the present authors have described the reactions of carbon vapor produced by the irradiation of a focused laser beam with hydrogen and low-molecular-weight hydrocarbons.

It has been assumed that, in the reaction of the carbon vapor produced by the laser irradiation with hydrocarbons, C_2 species play the main role in the product-forming step. Acetylene is the main product. The formation of acetylene has been considered to consist of hydrogen abstraction by C_2 species. However, there have been some doubts as to the product-forming processes, because acetylene may also be formed by the thermal decomposition of the reactant on the heated target surface or by the decomposition caused by the collision of the vaporized species with the reactant (collisional decomposition). The evidence for this is that when the laser beam was irradiated on a nickel metal target in ethane,[12,13] some decomposed fragmented hydrocarbons (mainly acetylene) were produced. In this case, the fraction of the thermal decomposition is considered to be small as compared with the collisional decomposition, because when the power density of the irradiated beam was lowered so as not to vaporize the target material, the acetylene yield decreased remarkably.

In this paper, by using a ^{14}C-enriched carbon target and a hydrocarbon reactant, or by using a graphite target and ^{14}C-labeled ethane as the reactant, the details of the formation processes of acetylene were investigated.

Experimental

Preparation of the ^{14}C-enriched Carbon Target. The ^{14}C-enriched carbon target was prepared by the thermal decomposition of ^{14}C-labeled acetylene at 1000°C in a quartz tube, as is shown in Fig. 1. The carbon film deposited on the quartz plate was used as the target. In a preliminary experiment, the target did not give gas chromatographically any other gaseous products except carbon monoxide[14] upon laser irradiation in a vacuum.

Preparation of the ^{14}C-labeled Ethane. The ^{14}C-labeled ethane was prepared by the reduction of ^{14}C-labeled acetylene by using PtO_2 and H_2 in a closed system, and it was purified gas chromatographically using a silica gel column.

Laser Irradiation. The laser-irradiation apparatus and experimental procedures were described previously.[10,11] The carbon target in a 7-ml cell filled with ethane or ethylene was irradiated by a focused laser beam. The output energy

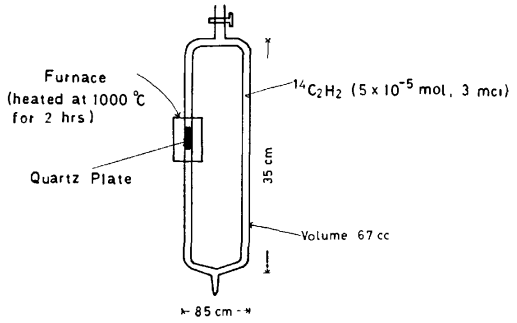

Fig. 1. Preparation of ^{14}C-enriched carbon target.

and pulse duration of the ruby laser were about 3 J and 0.5 ms respectively.

Analysis and Measurement of Radioactivity. The analysis of the products and the measurement of the radioactivity were performed on a radio-gaschromatograph. In the reaction of the ^{14}C-labeled ethane with carbon vapor from the graphite target, the specific activity was calculated from both the radioactivity and the product yield. In the reaction of ethane or ethylene with radioactive carbon vapor from the ^{14}C-enriched carbon target, the radioactivity was enough to be detected by one-pulse laser irradiation, but the product yield was too small to be determined[16] by radio-gaschromatography. In this case, the total activity was measured by adding a carrier.

Results and Discussion

When the laser beam was irradiated on nonradioactive graphite in ^{14}C-labeled ethane, the main product was acetylene, as has been described previously; the radioactivity was also found in acetylene, as is shown in Table 1. The radioactivity of acetylene indicates that the formation process of acetylene is due not only to the abstraction by C_2, but also to the decomposition of ethane.

On the other hand, when the laser beam was irradiated on the ^{14}C-enriched carbon film in ethane, radioactivity was found in the acetylene produced, but not in the ethylene produced. The above results indicate that ethylene is produced by the decomposition of ethane.

Table 1. Specific activity in the reaction of carbon vapor with ^{14}C-labeled ethane

Specific activity (μCi/mol)		Specific activity ratio of ethane to acetylene (α/β)	K_1/K_2 ($\alpha/\beta-1$)
Ethane (Substrate)	Acetylene (Product)		
1.95	0.92	1.6—2.1	0.6—1.1
0.94	0.60		

Ethane pressure: 400—700 Torr.

When the laser beam was irradiated on the ^{14}C-enriched carbon film in ethylene, the radioactivity of the acetylene produced was about twice that of the C_4-compounds produced, but the yield of acetylene was about six times that of the C_4-compounds, as is shown in Table 2. The data show that the formation of acetylene is due to the decomposition of ethylene, also.

When radioactive ethane is used as the reactant, by assuming the C_2 species to be the reaction species, the main formation processes of acetylene may be estimated as follows:

$$C_2H_6^* + C_2 \xrightarrow{K_1} C_2H_2 + \text{other hydrocarbons} \quad \text{abstraction.} \tag{1}$$

$$C_2H_6^* + C_2 \xrightarrow{K_2} C_2H_2^* + \text{other hydrocarbons} \quad \text{decomposition.} \tag{2}$$

$$C_2H_6 + C_2 \xrightarrow{K_3} C_2H_2 + \text{other hydrocarbons} \quad \text{abstraction.} \tag{3}$$

$$C_2H_6 + C_2 \xrightarrow{K_4} C_2H_2 + \text{other hydrocarbons} \quad \text{decomposition.} \tag{4}$$

$C_2H_6^*$ and $C_2H_2^*$ indicate radioactive ethane and acetylene. Reactions (2) and (4) show the collisional decomposition of ethane. The ratio of the amount of the active material to that of the nonactive one is derived from the specific activity, and the value of $C_2H_6^*/C_2H_6=\alpha$ and $C_2H_2^*/C_2H_2=\beta$ are extremely small. The ratio of the product yield can be derived as follows:

$$\frac{C_2H_2}{C_2H_2^*} = \frac{K_1[C_2][C_2H_6^*]+K_3[C_2][C_2H_6]+K_4[C_2][C_2H_6]}{K_2[C_2][C_2H_6^*]} = \frac{1}{\beta} \tag{5}$$

Since the two rates of abstraction reactions, (1) and (3), and also the two rates of decomposition reactions, (2), and (4), are equal,

$$K_1 = K_3 \text{ and } K_2 = K_4 \tag{6}$$

Then,

Table 2. Activity in the reaction of ^{14}C-enriched carbon vapor with ethylene

Total activity of products (cps)			Activity ratio of C_4-compounds to acetylene (γ)	Yield ratio of acetylene to C_4-compounds (δ)	K_9/K_{10} ($1/(\gamma\delta-2)$)
C_4-compounds		Acetylene			
Diacetylene	Vinylacetylene				
4500	680	8550	0.46—0.61	—6	0.6—1.3
3130	420	7730			

Ethylene pressure: 600—700 Torr.

16) The product yield was determined by the flame ionization detector.

$$\frac{K_1}{K_2} = \left(\frac{\alpha}{\beta} - 1\right)\frac{1}{\alpha+1} \approx \frac{\alpha}{\beta} - 1 \quad (7)$$

The ratio of the rate constant of the abstraction to that of the decomposition was calculated from the experimental data; the value thus obtained was from 0.6 to 1.1 under those experimental conditions.

Similar results are also obtained in the reaction of the carbon vapor from the ^{14}C-enriched carbon target with ethylene. In this case, the following schemes are assumed:

$$C_2H_4 + C_2^* \xrightarrow{K_8} C_4^*\text{-compounds} \quad (8)$$
addition.[17]

$$C_2H_4 + C_2^* \xrightarrow{K_9} C_2H_2^* + C_2H_2 \quad (9)$$
abstraction.

$$C_2H_4 + C_2^* \xrightarrow{K_{10}} C_2H_2 + \text{other hydrocarbons} \quad (10)$$
decomposition.

17) If the nonradioactive C_4-compounds are produced partly by the thermal decomposition of two molecules of ethylene, the value K_9/K_{10} becomes smaller than $1/(\gamma\delta-2)$ by the similar calculation. The result may not be conflicted with the conclusion of this paper.

Reactions (8), (9), and (10) are also applicable to nonactive C_2 species. The ratio of the total activity of C_4-compounds to that of acetylene shows the ratio of the rate constant of K_8 to K_9 ($K_8/K_9=\gamma$). The ratio of the acetylene yield to the C_4-compound yield can be derived as follows:

$$\frac{\text{Acetylene}}{C_4\text{-compounds}} = \frac{2K_9 + K_{10}}{K_8} = \delta \quad (11)$$

Therefore,

$$\frac{K_9}{K_{10}} = \frac{1}{\gamma\delta - 2} \quad (12)$$

The ratio of the rate constant of the abstraction to that of the decomposition was calculated to be from 0.6 to 1.3 under those experimental conditions. This is in agreement with the result obtained in the reaction of carbon vapor with ^{14}C-labeled ethane.

From the above results, it may be concluded that the formation processes of acetylene are due to the collisional decomposition of the reactant with the vapor produced by the laser irradiation, as well as to the abstraction by C_2 species.

The authors wish to acknowledge the help of Dr. M. Matsui in the measurement of radioactivity using radio-gaschromatography.

Photoelectron Spectra of Tetrahydropyran, 1,3-Dioxane, and 1,4-Dioxane

Tsunetoshi KOBAYASHI and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo 106

(Received September 12, 1972)

Photoelectron spectroscopy is useful for the study of electronic structures of molecules, in particular of occupied orbital energies of molecules. In this paper, we study the photoelectron spectra of such cyclic ethers as tetrahydropyran, 1,3-dioxane, and 1,4-dioxane, special attention being paid upon the interaction between oxygen lone pair orbitals in dioxanes which contain two oxygen atoms.

Experimental

Materials. Tetrahydropyran, 1,3-dioxane, and 1,4-dioxane were purified in usual ways and their purities were checked with gas chromatograms and NMR spectra.

Measurements. Photoelectron spectra (PES) were measured with a JASCO Model PE-1 photoelectron spectrometer by using the 584 Å helium resonance line as a light source.

Theoretical

The CNDO/2[1] calculation was carried out for the cyclic ethers under consideration by a FACOM 270—30 computer at the Institute of Physical and Chemical Research. The geometrical structure of 1,4-dioxane necessary for the calculation was taken from Ref. 2, and those of tetrahydropyran and 1,3-dioxane were properly assumed on the basis of the appropriate data given in Ref. 2. These compounds take a chair form at room temperature.[2-4]

Results and Discussion

PES of these cyclic ethers are shown in Fig. 1, and the vertical ionization potentials (Ip_v's) obtained from PES are summarized in Table 1. The observed orbital energies, ε_{obs}, estimated by Koopmans' theorem,[5] $\varepsilon_{obs}=-Ip_v$, are shown in Fig. 2a. In Fig. 2b, the orbital energies calculated by the CNDO/2 method, ε_{calc}'s, are shown for the purpose of comparison.

TABLE 1. OBSERVED VERTICAL IONIZATION POTENTIALS (Ip_v's) OF TETRAHYDROPYRAN, 1,3-DIOXANE, AND 1,4-DIOXANE IN eV

PES band	Tetrahydropyran	1,3-Dioxane	1,4-Dioxane
1	9.48 a'	10.12 a''	9.41 a_g
2	10.90 a'	10.38 a'	10.60 a_g
3	11.57 a''	11.66 a'	11.27 b_g
4	12.19	12.07	12.86
5	12.53	12.80	13.26
6	13.30 (broad)	14.00	13.60
7	14.28	14.17	14.06
8	15.23 (broad)	15.21 (broad)	15.40 (broad)

Concerning the first Ip's of these compounds, the relative height of the calculated molecular orbitals reproduces quite well the observed tendency as clearly seen in Fig. 2. Therefore, we may assign the first Ip's of these compounds to the highest occupied orbitals given by the CNDO/2 calculations. That is to say, the first Ip's of tetrahydropyran, 1,3-dioxane,

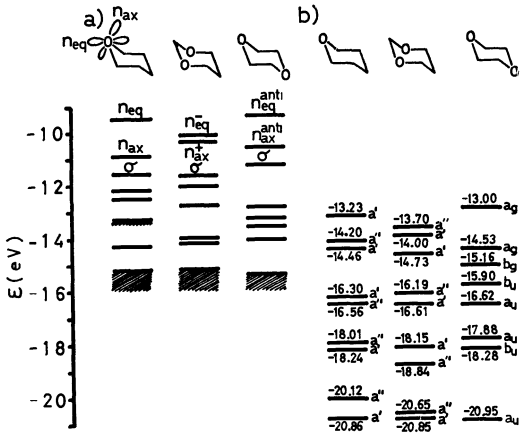

Fig. 2. Orbital energy diagrams.
a) The observed orbital energy diagram obtained on the assumption, $\varepsilon = -Ip_v$ (Koopmans' theorem).
b) The orbital energy diagram obtained by the CNDO/2 calculation.

and 1,4-dioxane may be ascribed to the equatorial type lone pair (n_{eq}) orbital of the oxygen atom, to the antibonding combination of the two n_{eq} orbitals of the two oxygen atoms (n_{eq}^-), and the antiparallel type combination of the two n_{eq} orbitals of the two oxygen atoms (n_{eq}^{anti}), respectively.

Cradock and Whiteford[6] assigned the first (10.04 eV), second (11.91 eV), and third (13.43 eV) bands of methyl ether to $b_1(n)$, $a_1(n)$, and $b_2(\sigma)$ from the analogy with the assignment on the water molecule.[7] The splitting between the two n orbitals is 1.87 eV for methyl ether. The corresponding three bands appear at 9.61, 11.08 (adiabatic) and 11.92 eV (adiabatic) for ethyl ether,[8] the splitting between the two n orbitals being 1.47 eV (adiabatic). These three bands correspond well in their positions to the lower energy three bands of tetrahydropyran at 9.48, 10.90, and 11.57 eV. This seems to mean that the second band of tetrahydropyran may be related with the non-bonding orbital.[9] According to this assignment, the splitting between the n_{eq} and n_{ax} orbitals is 1.42 eV.

The CNDO/2 calculation shows that the orbitals of 1,3-dioxane are ordered from the top as follows: n_{eq}^-, n_{ax}^+, σ, n_{ax}^-, σ, n_{eq}^+. The second highest occupied MO, n_{ax}^+, is represented by the bonding type combination of the two n_{ax} orbitals of the two oxygen atoms. The calculated energy difference between the n_{eq}^- and n_{ax}^+ orbitals (0.30 eV) corresponds well to the observed difference between the first and second bands (0.26 eV). This may support the assignment of the

8) M. I. Al-Joboury and D. W. Turner, *J. Chem. Soc.*, **1964**, 4434.
9) This assignment is reverse to the prediction from the CNDO/2 calculation. Since the observed splitting between the second and third orbitals is rather small for tetrahydropyran (0.67 eV), their orders may be difficult to be determined by the CNDO/2 calculation.

second band. According to the above-mentioned order of the orbitals, the observed fourth and sixth bands of 1,3-dioxane may tentatively be assigned to the n_{ax}^- and n_{eq}^+ orbitals, respectively, and the splittings between the n_{ax}^+, and n_{ax}^- orbitals and between the n_{eq}^- and n_{eq}^+ orbitals amount to 1.69 and 3.88 eV, respectively. The two n_{eq} orbitals of 1,3-dioxane may interact through space rather than through bond[10] because the overlap integral between them is not small, while the two n_{ax} orbitals may interact through bond rather than through space.

According to the CNDO/2 calculation shown in Fig. 2, the occupied MO's of 1,4-dioxane decrease their energies in the following order: $n_{eq}^{anti} > n_{ax}^{anti} > \sigma > n_{ax}^{para} > \sigma > \sigma > n_{eq}^{para}$. Here n_{ax}^{para} and n_{eq}^{para} mean the parallel type combinations of the two n_{ax} orbitals and of the two n_{eq} orbitals, respectively. According to this tentative assignment, the splittings between the n_{ax}^{anti} and n_{ax}^{para} orbitals and between the n_{eq}^{anti} and n_{eq}^{para} orbitals may become 2.26 eV and 4.65 eV, respectively. In 1,4-dioxane the interactions between the two n_{ax} orbitals as well as between the two n_{eq} orbitals may occur through bond rather than through space.

Recently Sweigart and Turner[11] reported the PES of these compounds and discussed the interaction between nonbonding orbitals belonging to two different oxygen atoms of each molecule. In their study, however, they did not make any theoretical calculation and did not consider the presence of the two types (equatorial and axial) of nonbonding orbitals on each oxygen atom of these compounds.

Microwave Spectrum and Centrifugal Distortion Effects of Thionyl Fluoride

Ichiro YAMAGUCHI, Osamu OHASHI, Hirotaka TAKAHASHI, Takeshi SAKAIZUMI, and Masao ONDA

Department of Chemistry, Faculty of Science and Technology, Sophia University, Tokyo 102

(Received September 14, 1972)

Ferguson analysed the microwave spectrum of thionyl fluoride and obtained the structure and dipole moment of the molecule.[1] Assignment of the spectral lines was so made that the low J R-branch lines fit the frequencies calculated from the rigid molecular model. The reported frequencies, however, do not coincide with the calculated values in a high J range. The larger the J value, the greater the deviation; *e. g.*, for the line $12_{93} \leftarrow 12_{94}$ the deviation is as large as 11.44 MHz. The centrifugal distortion effect is expected to account for the deviation. In this paper we report on several series of Q-branches newly observed for the normal species $^{32}S^{16}O^{19}F_2$, and the analyses of the spectrum taking into account the centrifugal distortion effect.

Thionyl fluoride was synthesized by the reaction of thionyl chloride with antimony(III) fluoride.[2] Conventional microwave spectrometers were used with 100 kHz Stark modulation. The sample pressure was 0.01—0.015 mmHg and the spectrum was observed at dry ice and room temperatures. The frequency range observed was 8.0—36.0 GHz.

The observed transition frequencies are given in Table 1. Spectral analysis was made on the basis of Watson's formula for the centrifugal distortion effect.[3] Thionyl fluoride molecule has C_s symmetry. It may therefore be inappropriate to account for the observed deviations by considering the first order perturbation terms only. However, it can be seen from the table that the deviation of observed frequencies from the calculated ones obtained by the least squares fit with Watson's formula is very small throughout, and the higher order terms were therefore neglected.

The transition frequencies calculated from the rigid rotor model with the rotational constants given by Ferguson were the first reference to the assignment of the observed lines. However, deviations of the observed frequencies were apparent from the rigid rotor model frequencies. It was worthwhile to divide the lines into several series, each having a specific set of K_{-1} and K_{+1} (Table 1). The observed frequencies in a series, when appropriately assigned, showed a regular variation of the deviation with changing J value, which greatly helped in obtaining the final assignment. The assigned lines were used for the least squares fit of transition frequency. This process was continued until most of the observed frequencies coincide with the calculated ones, the centrifugal corrections also being shown in Table 1.

The effective rotational constants and centrifugal distortion coefficients thus obtained are shown in Table 2, together with the rotational constants given by Ferguson.

In our assignments of many spectral lines, taking into account the centrifugal distortion effect, we found some misassignments made by Ferguson. Examples are given in Fig. 1, where the spectra (a) observed, (b) calculated for a model with centrifugal distortion

effect, (c) calculated for rigid model, and (d) observed by Ferguson are arranged in order for the region 24.6—24.7 GHz. In this region, two series of spectral lines with different sets of K_{-1} and K_{+1} overlap each other.

It is shown that, even for transitions with relatively small J values, analysis without considering the cen-

trifugal distortion effect leads to making misassignments for molecules such as thionyl halides.[4] Clear and unequivocal assignments are given in Fig. 1.

The authors are greatly indebted to Dr. C. Matsumura, the Government Chemical Research Institute, for use of the spectrometer and computer.

4) Cf. e. g., J. Burie, J. -L. Destombes, A. Dubrulle, and G. Journel, *C. R. Acad. Sci. Paris Ser. B*, **267**, 48 (1968); G. Journel, A. Dubrulle, J. -L, Destombes, and C. Marliere, *ibid.*, **271** 331 (1970).

Note added in proof. A paper by Lucas and Smith (*J. Mol. Spectrosc.*, **43**, 327 (1972)) appeared after this article had been accepted. They analysed the microwave spectrum of thionyl fluoride and obtained centrifugal distortion constants up to sextic ones. Their quartic constants, when transformed into Watson's type constants, differ from ours. It has been confirmed, however, that the constants converge to our values, if the transformed quartic constants are inserted into the least squares fit procedure we adopted (up to the quartic terms) as the initial data for iterations.

Studies on the Interaction between Long Chain Alcohols and Alkyl Sulfates. III. Magnetic Properties of Intermolecular Complexes

Yoshikiyo MOROI, Kinshi MOTOMURA, and Ryohei MATUURA
Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812

(Received October 19, 1972)

In previous papers, reports were given on the formation of intermolecular complexes between long chain alcohols and metal alkyl sulfates.[1,2] Magnetic properties were examined for the complexes, formed between dodecyl alcohol and dodecyl sulfate, $M(DS)_2$, of divalent metal cations such as Mn^{2+}, Co^{2+}, Ni^{2+}, and Cu^{2+} by measuring the electron spin resonance (ESR) and magnetic susceptibility. It is expected that the difference in magnetic property between complex L and complex H, formed above and below the melting point of dodecyl alcohol (25 °C), respectively,[2] can be found by these methods.

Experimental

The apparatus for ESR measurement was a JEOL JES-ME-3X spectrometer of variable-temperature type. Molar ratio of alcohol to sulfate was 6.

Magnetic susceptibilities were measured by Gouy's method. Because of stickiness of the complex it was mixed with NaCl powder (90% wt.) and used as the sample. The specific susceptibility was calculated by Wiedemann's additivity law[3] from the value of the mixed sample:

$$\chi = \chi_1 P_1 + \chi_2 P_2 \cdots\cdots \chi_n P_n \qquad (1)$$

where χ is susceptibility of the mixture; χ_n and P_n are susceptibility and weight fraction for the components, respectively. The value of χ_{NaCl} used was -0.515×10^{-6} e.m.u.[4] In order to examine applicability of this dilution method the magnetic susceptibilities of $CuSO_4\cdot5H_2O$ and $M(DS)_2\cdot nH_2O$ were also measured using not only sodium chloride but also naphthalene as a dispersion medium. Since color of the mixture of $CuSO_4\cdot5H_2O$ with NaCl changes with time, the susceptibility was measured just after mixing. Reproducibility was checked by repeating measurement twice for each mixed sample. The result was satisfactory.

Results and Discussion

It is difficult to discuss the electronic state of metals except copper with the results of ESR measurement, since they are in a state of high spin. Thus, only the

complex of copper was examined by ESR at various temperatures. The results are shown in Fig. 1. The ESR spectra show hardly any difference between complexes L, H, and $Cu(DS)_2 \cdot 4H_2O$ (a, b, d in Fig. 1). It is evident that the four ligands around the copper atom form a typical square-planar structure. The isotropic pattern at a higher temperature (c in Fig. 1) indicates the dissolution of the complex into DOH.

Table 1. Magnetic susceptibilities and magnetic moments

Sample	Temp. (°C)	$\chi \times 10^6$ (emu)	μ_{eff} (B.M.)
$CuSO_4 \cdot 5H_2O$	25	6.2	1.9
$CuSO_4 \cdot 5H_2O$	25	6.2	1.9
$CuSO_4 \cdot 5H_2O$ (*)	25	5.8	1.9
$Mn(DS)_2 \cdot 6H_2O$	25	19	5.6
$Mn(DS)_2 \cdot 6H_2O$	25	18	5.5
$Mn(DS)_2 \cdot 4DOH$ (L)	20	9.8	5.7
$Mn(DS)_2 \cdot 6DOH$ (H)	35	6.7	5.3
$Co(DS)_2 \cdot 6H_2O$	25	12	4.5
$Co(DS)_2 \cdot 4DOH$ (L)	20	3.0	5.7
$Co(DS)_2 \cdot 6DOH$ (H)	35	4.0	4.2
$Ni(DS)_2 \cdot 6H_2O$	25	5.5	3.0
$Ni(DS)_2 \cdot 4DOH$ (L)	20	6.3	4.6
$Ni(DS)_2 \cdot 6DOH$ (H)	35	1.9	2.6
$Cu(DS)_2 \cdot 4H_2O$	25	1.7	1.6
$Cu(DS)_2 \cdot 4H_2O$ (*)	25	2.3	1.9
$Cu(DS)_2 \cdot 4DOH$ (L)	20	2.0	(2.5)
$Cu(DS)_2 \cdot 6DOH$ (H)	35	1.3	2.1

(*): the dispersing agent is naphthalene.

It is concluded that the alcohol molecules enter the region of metal dodecyl sulfate and form the intermolecular complex with it, the chemical structure around the metal being scarcely changed.

The results of specific susceptibility and magnetic moment are given in Table 1. Since the main object is to detect the difference in chemical state between the complex H and complex L, effective magnetic moment μ_{eff} was calculated by the following equation neglecting diamagnetic term.

$$\mu_{eff} = \sqrt{\frac{3k\chi T}{N\beta^2}} \quad \text{(B.M.)} \qquad (2)$$

where k is Boltzmann's constant, T absolute temperature, N Avogadro's number and β the Bohr magneton. From the fairly good reproducibility of the results of $CuSO_4 \cdot 5H_2O$ and $Mn(DS)_2 \cdot 6H_2O$, it is evident that a difference exists between the values of μ_{eff} of complexes H and L, which means that they are in different chemical states. Metals except manganese in complex H are more similar in chemical state to those in $M(DS)_2 \cdot nH_2O$ than those in complex L. For manganese, there was little difference in the chemical state between $Mn(DS)_2 \cdot 6H_2O$, $Mn(DS)_2 \cdot 4DOH$ and $Mn(DS)_2 \cdot 6DOH$.

We might conclude that a long chain alcohol infiltrates into the crystal of a metal alkyl sulfate to form a intermolecular complex with the hydroxyl group of the alcohol intermediating. The intermolecular energy was found to be similar in order to that of hydrogen bonding, namely 7—8 kcal/mol-alcohol.[1,2]

The authors wish to express their thanks to Dr. T. Isobe for his kind help and discussion.

Synthesis of a Nucleotide Analog Preparation of 7-(2′-Acetoxypropyl)theophylline 3′-Phosphate

Toru SEITA, Kiyoshi YAMAUCHI, Masayoshi KINOSHITA, and Minoru IMOTO*

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

** Department of Applied Chemistry, Kansai University, Suita, Osaka 565*

(Received August 11, 1972)

Phosphorylation of the nucleoside analog 9-(2′,3′-dihydroxypropyl)adenine and its polycondensation using *N,N′*-dicyclohexylcarbodiimide as a dehydrating agent gave an oligomer of the nucleotide analog, oligo-3-(9-adenyl)-2-hydroxypropyl phosphate.[1] The polynucleotide analog containing adenine showed a significant hypochromic effect mixed with denaturated RNA or DNA.[2] This shows that the polynucleotide analog retains its polynucleotide-like behaviors such as hypochromicity after the substitution of ribose with 2′,3′-propanediol.

The position of phosphorylation, primary or secondary, is of interest as regards the preparation of such nucleotide analogs.

We have studied the preparation of a nucleotide analog, 7-(2′-acetoxypropyl)theophylline 3′-phosphate.

Tritylation[3] of 7-(2′,3′-dihydroxypropyl)theophylline (I) was carried out with trityl chloride in refluxing dry pyridine. 7-(3′-Trityloxy-2′-hydroxypropyl)-theophylline (II) was obtained in 42% yield and showed a new infrared absorption at 870 cm^{-1} corresponding to the trityl group. Compound (II) gave

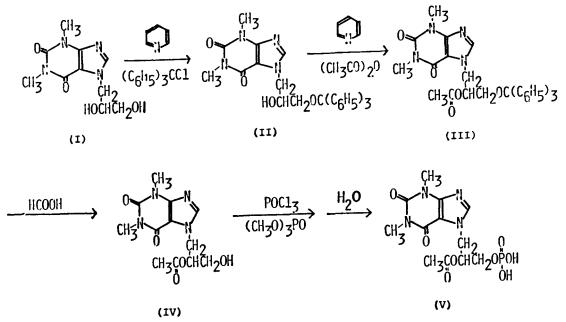
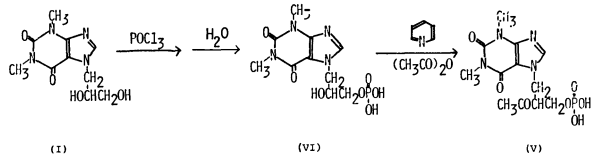


Scheme 1.

7-(2′-acetoxy-3′-trityloxypropyl)theophylline (III) by the reaction with acetic anhydride in pyridine. The infrared spectrum showed a strong absorption at 1730 cm^{-1} corresponding to the carbonyl group. The trityl group was then removed by treatment with 98% formic acid at room temperature, to give 7-(2′-acetoxy-3′-hydroxypropyl)theophylline (IV). Phosphorylation of IV with phosphorus oxychloride in trimethyl phosphate yielded 7-(2′-acetoxypropyl)theophylline 3′-phosphate (V).

When the reaction of free 7-(2′,3′-dihydroxypropyl)-theophylline (I) with phosphorus oxychloride was carried out in trimethyl phosphate,[4] compound (VI) was obtained in 41% yield. This was further treated with Ac_2O to afford VII.



Scheme 2.

The infrared and ultraviolet spectra, melting point, R_f value and elementary analytical values of compound (VII) agree well with those of V. This suggests that VI is 7-(2′-hydroxypropyl)theophylline 3′-phosphate, propanediol derivatives containing nucleoside bases such as I being phosphorylated selectively at the primary hydroxyl group, by means of phosphorus oxychloride.

Experimental

Infrared absorption spectra were taken on a Jasco Model IR-G Spectrometer, and ultraviolet absorption spectra on a Hitachi Spectrometer Model EPS-3T. Paper chromatography was carried out by ascending technique using Whatman No. 3 paper. All melting points are uncorrected.

7-(2′-Hydroxy-3′-trityloxypropyl)theophylline (II). To a refluxing solution of 7-(2′-,3′-dihydroxypropyl)theophylline (I) (20 g; 79 mmol) in dry pyridine (300 ml) was added dropwise a solution of trityl chloride (23 g; 83 mmole) in dry pyridine (150 ml). The addition was completed in 7 hr and then the mixture was allowed to stand at room temperature. The mixture was poured into 2 l of ice-water with continuous stirring. Solid material was collected by filtration and recrystallized from ethanol to give colorless needles; mp 175—176 °C. Yield, 16.2 g (42%). Found: C, 69.87; H, 5.41; N, 11.01%. Calcd for $C_{29}H_{28}N_4O_4$: C, 70.14; H, 5.64; N, 11.29%.

7-(2′-Acetoxy-3′-trityloxypropyl)theophylline (III). Compound (II) (14.85 g; 30 mmol) was added to a mixture of acetic anhydride (70 ml) and dry pyridine (100 ml) and stirred for 20 hr at room temperature. The reaction mixture was poured into 0.5 l of ice-water with rapid stirring. Solid material was collected by filtration and recrystallized from ethanol to give III as colorless needles; mp 137—138 °C. Yield, 8.72 g (55%). Found: C, 69.49; H, 5.59; N, 9.72%. Calcd for $C_{31}H_{30}N_4O_5$: C, 69.13; H, 5.61; N, 10.40%.

7-(2′-Acetoxy-3′-hydroxypropyl)theophylline (IV). Compound (III) (8.7 g; 16.7 mmol) was dissolved in 98% formic acid (70 ml). The solution was kept at room temperature for 40 hr. The precipitate was filtered off and the filtrate was concentrated under reduced pressure. The residue was recrystallized from ethanol to give colorless needles; mp 129—131 °C. Yield, 0.72 g (15%). Found: C, 48.98; H, 5.42; N, 18.48%. Calcd for $C_{12}H_{16}N_4O_5$: C, 48.68; H, 5.44; N, 18.91%.

7-(2′-Acetoxypropyl)theophylline 3′-Phosphate (V). To a solution of compound (IV) (0.7 g; 2.37 mmol) in trimethyl phosphate (8 ml) was added phosphorus oxychloride (0.4 g; 2.6 mmol) at 0 °C followed by stirring for 8 hr. Water was then added and stirring was continued for 40 min. After evaporation of water at a temperature below 50 °C, a mixture of ethanol and ether (3 : 7) was added. White precipitate was chromatographed on silica gel (Mallinckrodt). Elution with *n*-propanol–concd NH_4OH–water (6 : 2 : 2) gave 0.22 g of (V). Recrystallization from ethanol gave 0.2 g (22%) of (V) as colorless needles; mp 137—138 °C. Found: C, 38.79; H, 4.56; N, 14.37%. Calcd for $C_{12}H_{17}N_4O_8P$: C, 38.30; H, 4.56; N, 14.89%.

$\lambda_{max}^{H_2O}$ 274 mμ (ε=8000); 264 mμ (ε=8600), 255 mμ (ε=7800). R_f=0.45 (solvent; *n*-propanol–concd NH_4OH–H_2O 6 : 2 : 2).

Acetylation of Compound (VI). Compound (VI) (1.0 g; 3 mmol) was allowed to react with acetic anhydride (15 ml) in dry pyridine (20 ml) and the mixture was stirred for 20 hr. at room temperature. The solid product was collected by filtration and recrystallized from acetic anhydride–pyridine (4 : 6). The product was compound (V). Yield, 0.42 g (37%).

The Isolation of *trans*-Chrysanthenyl Acetate and Chrysanthenone from the Essential Oil of *Chrysanthemum shiwogiku*

Akihiko MATSUO, Yasuto UCHIO, Mitsuru NAKAYAMA, and Shûichi HAYASHI

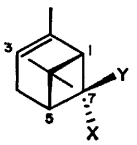
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda, Hiroshima 730

(Received September 12, 1972)

In the course of our chemosystematic investigation of *Crysanthemum* species native in Japan, the essential oil of *Chrysanthemum shiwogiku* Kitam. (Japanese name, Shiogiku; chromosomes, 2n=72) was examined, (+)-*trans*-chrysanthenyl acetate being isolated as the major component (23.2%). Furthermore, seven monoterpenoids containing (+)-chrysanthenone (2.1%) were isolated, and the occurrence of a trace of *trans*-chrysanthenol was confirmed gas chromatographically. Although (+)-chrysanthenone[1] and (−)-*cis*-chrysanthenyl acetate[2] have been previously isolated from other plants of the same *Chrysanthemum*, and (−)-*trans*-chrysanthenol has been synthesized from (−)-α-pinene by Joulain and Rouessac[3] immediately after the present investigation was carried out, (+)-*trans*-chrysanthenyl acetate has not yet been synthesized, nor has it been isolated in nature.

Experimental

The essential oil ($[\alpha]_D$ −11.7°, n_D 1.4830, d_4 0.9395) was obtained by the steam-distillation of stalks and leaves of the plants collected beside the sea at Maruyama in Muroto City in a 0.06% yield of the fresh plants. It was subjected to fractional distillation at reduced pressure and then to silica gel elution chromatography with a mixed solvent of hexane and ethyl acetate (4 : 1) in order to isolate each component.



(I) X=OAc, Y=H

(II) X=OH, Y=H

(III) X,Y=O

Chart

Results and Discussion

(+)-trans-*Chrysanthenyl Acetate (I).* The main component ($[\alpha]_D$ +32.0°, 1.75% in $CHCl_3$; n_D 1.4666) has $C_{12}H_{18}O_2$ (M^+ 194). The IR and NMR spectra exhibited a geminal dimethyl (ν_{max}^{liq} 1375 and 1360 cm^{-1}; $\delta_{ppm}^{CCl_4}$ 0.88 and 1.25, each 3H, s), a trisubstituted double bond containing a methyl group (ν 795 cm^{-1}; δ 1.57, 3H, q, J=2.0 Hz and 5.30, 1H, m), and a methine proton (δ 4.87, 1H, t, J=6.0 Hz) bearing an acetoxy residue (ν 1740, 1248, and 1035 cm^{-1}; δ 1.88, 3H, s). Since the NMR spectrum closely resembled that of α-pinene[4] except for the singlet at δ 1.88 and the triplet at δ 4.87, the compound could be characterized as the acetate of a hydroxyl derivative of α-pinene. When this acetate was treated with lithium aluminium hydride in dry ether, it underwent reduction and was converted into a secondary alcohol (II) ($C_{10}H_{16}O$; $[\alpha]_D$ −55.0°, 1.04% in $CHCl_3$; 3.5-DNB, mp 112—113°C; ν_{max}^{liq} 3450, 1085 and 795 cm^{-1}), whose NMR spectrum ($\delta_{ppm}^{CCl_4}$ 0.87 and 1.22, each 3H, s; 1.68, 3H, q, J=2.0 Hz; 4.20, 1H, t, J=6.0 Hz; 5.51, 1H, m) was in a good agreement with that of the (−)-*trans*-chrysanthenol (II) synthesized lately from (−)-α-pinene.[3] Especially, the coupling constant (t, J=6.0 Hz) of the C_7-methine proton signal showed the alcohol to be of the *trans*-form. The secondary alcohol (II) was further oxidized with a Conforth reagent in pyridine to give a unique four-membered ring ketone (III), ($[\alpha]_D$ +63.8°, 0.26% in $CHCl_3$; ν_{max}^{liq} 1780, 1380, 1370, 790, and 740 cm^{-1}; $\delta_{ppm}^{CCl_4}$ 1.20 and 1.23, each 3H, s; 1.73, 3H, q, J=2.0 Hz; 5.31, 1H, m), whose IR and NMR spectra coincided with those of (+)-chrysanthenone.[5] Therefore, it was concluded that the original compound was the (+)-*trans*-chrysanthenyl acetate.

(+)-Chrysanthenone (III) and trans-*Chrysanthenol (II).* A ketone ($[\alpha]_D$ +30.0°, 0.30% in isooctane) was isolated through silica gel elution chromatography: its IR and NMR spectra coincided with those of the chrysanthenone obtained from the chrysanthenyl acetate as described above. In the gas chromatography of the essential oil, a small peak corresponding to *trans*-chrysanthenol was detected by the use of SE-30 and PEG-6000 columns, but further identification was not attempted.

Other Constituents. From the essential oil, α-pinene (0.8%), camphene (2.3%), sabinene (1.0%), *p*-cymene (12.7%), camphor (10.9%), borneol (5.5%), bornyl acetate (2.8%), α-copaene (0.3%), β-elemene (1.4%), β-caryophyllene (2.9%), ε-cadinene (5.7%), and caryophyllene oxide (1.3%), in addition to the above α-pinene derivatives, (+)-*trans*-chrysanthenyl acetate (23.3%), *trans*-chrysanthenol (trace) and (+)-chrysanthenone (2.1%), were isolated and identified by IR, NMR, and mass spectrometries.

The authors are indebted to Professor Ryûso Tanaka, Department of Botany, Hiroshima University, for collecting and identifying the plant material.

The Selective Hydrogenation of the Knoevenagel Condensates of Acetylacetone with Aldehydes Catalyzed by Raney Nickel as a Route to 3-Substituted 2,4-Pentanediones[1]

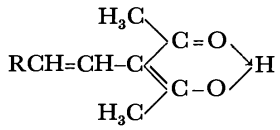
Kaku UEHARA, Mitsuo ITO, and Makoto TANAKA

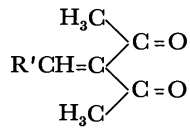
Department of Applied Chemistry, Faculty of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka 591

(Received October 30, 1972)

In an earlier communication,[2] it has been reported briefly that the Knoevenagel condensate of acetylacetone with butyraldehyde or propionaldehyde was hydrogenated with Raney nickel to give 3-butyl- or 3-propyl-2,4-pentanedione. In this paper, the hydrogenation of some other Knoevenagel condensates of acetylacetone with aldehydes will be described in more detail as a new general route to 3-substituted 2,4-pentanediones.

In the presence of piperidine, acetylacetone reacted with butyraldehyde, propionaldehyde, crotonaldehyde, acetaldehyde, benzaldehyde, and furfural to give the Knoevenagel condensates **1**, **2**, **3**, **4**, **5**, and **6** respectively.





1: R=CH_3CH_2–, **2**: R=CH_3–, **3**: R′=CH_3CH=CH–

4: R′=CH_3–, **5**: R′=  , **6**: R′= 
1 and **2** exist predominantly in the enol form and give green crystalline copper(II) chelates. On the other hand, **3** to **6** have no labile hydrogen to form the enol, and therefore give no crystalline copper(II) chelate.

These condensates, **1** to **6**, were hydrogenated with Raney nickel to give 3-butyl-2,4-pentanedione (**7**), 3-propyl-2,4-pentanedione (**8**), 3-ethyl-2,4-pentanedione (**9**), 3-benzyl-2,4-pentanedione (**10**), 3-furfuryl-2,4-pentanedione (**11**), and 3-tetrahydrofurfuryl-2,4-pentanedione (**12**). These diketones are effective chelating agents and give gray crystalline copper(II) chelates. The data o the hydrogenation of **1** to **6** are shown in Table 1.

Table 1. The hydrogenation of Knoevenagel condensates

Knoevenagel condensate		Raney nickel (g)	Temp. (°C)	Time (min)	Product		Yield (%)
No.	(g)				No.	(g)	
1	20	1	70	60	**7**	17.1	86
2	20	2	70	60	**8**	16.8	83
3	15	1.5	70	455	**7**	13.2	88
4	5.5	0.3	70	150	**9**	4.0	72
5	16	1	70	150	**10**	14.1	88
6	12	1	50	30	**11**	8.6	72
6	12	1	70	70	**12**	9.0	84

In the hydrogenation of **6** at 50 °C, it was possible to interrupt the reaction to obtain **11**. The present method seems to be a general route to 3-substituted 2,4-pentanedions.

At the temperature of 100 or 120°C, a low-boiling fraction, such as 2-heptanone, benzylacetone, or tetrahydrofurfurylacetone, was produced as a by-product by the deacylation of the corresponding diketones. These monoketones remained without further hydrogenation to alcohols even at the temperature of 120 °C. This fact suggests that β-diketone modifies the hydrogenation activity of the Raney nickel in the manner described by Izumi *et al.*[3]

By the addition of **7**, the rate of the hydrogenation of 2-heptanone was decreased, resulting in a decrease in the yield of 2-heptanol. In the hydrogenation of 4-hepten-2-one, it was found that the hydrogen uptake occurred in two stages, and that the rate of the first stage was little affected by the addition of **7**. When the reaction was interrupted after the absorption of one mole equivalent of hydrogen, only 2-heptanone was formed. The additive, **7**, was recovered unchanged after the hydrogenation.

These results suggest that the activity of Raney nickel is decreased only for the carbonyl group and that, therefore, the selectivity for the C=C double bond is increased in the presence of 3-substituted 2,4-pentanedione. The modifying action of the β-diketone probably had a favorable effect on the selective hydrogenation of the Knoevenagel condensates of acetylacetone with aldehydes to 3-substituted 2,4-pentanedione.

Experimental

All the boiling points are uncorrected. The acetylacetone, aldehydes, and piperidine were of a reagent grade and were obtained from commercial sources. The Raney nickel used in this work was of the W-1 type, prepared by the ordinary method.[4] A stirring-type autoclave with a void of 100 ml was used as the reaction vessel.

Knoevenagel Condensates of Acetylacetone with Aldehydes. An equimolar mixture of acetylacetone and an aldehyde was placed in a 200-ml flask equipped with a stopper. After cooling, 0.4 mol%[5] of piperidine was added, drop by drop,

5) The large exess of piperidine resulted in an appreciable decrease in the yield of Knoevenagel condensates.

and the mixture was kept at 0 °C for 7 hr. The reaction mixture was then subjected to fractional distillation. 3-(1-Butenyl)-2,4-pentanedione (**1**); bp 92—95 °C/16 mmHg (lit,[6] bp 83—85.5 °C/9 mmHg), n_D^{19} 1.4839, yield, 60%. 3-(1-Propenyl)-2,4-pentanedione (**2**); bp 81—84 °C/14 mmHg, n_D^{25} 1.4845, yield, 56.8%. Found: C, 68.74; H, 8.90%, Calcd for $C_8H_{12}O_2$: C, 68.54; H, 8.90%. 3-(2-Butenylidene)-2,4-pentanedione (**3**); bp 117—120 °C/20 mmHg, n_D^{25} 1.5175, d_4^{25} 1.0120, yield, 54%. 3-Ethylidene-2,4-pentanedione (**4**); bp 90—95 °C/20 mmHg, n_D^{25} 1.4652 (lit,[7] bp 44—45°C/0.04 mmHg, n_D^{25} 1.4608), yield, 7.6%. 3-Benzylidene-2,4-pentanedione (**5**); bp 142—143 °C/4 mmHg, n_D^{25} 1.5180, yield, 44%. 3-Furfurylidene-2,4-pentanedione (**6**); bp 120—124 °C/2 mmHg (lit,[8] bp 128—129 °C/4 mmHg), n_D^{30} 1.5872.

Hydrogenation of the Knoevenagel Condensates. Each condensate, from **1** to **6**, was dissolved in 5 ml of ethanol and then hydrogenated in an atmosphere of hydrogen under an initial pressure of 100 kg/cm² at 50 to 120 °C with Raney nickel. After the theoretical amount of hydrogen had been taken up, the reaction mixture was subjected to fractional distillation. The following products were thus obtained: 3-Butyl-2,4-pentanedione (**7**); bp 99—103 °C/14 mmHg, n_D^{29} 1.4428 (lit,[9] bp 98—102 °C/16—17 mmHg, n_D^{25} 1.4442). 3-Propyl-2,4-pentanedione (**8**); bp 93—96 °C/21 mmHg (lit,[10] bp 75—77 °C/12 mmHg), n_D^{25} 1.4420. 3-Ethyl-2,4-pentanedione (**9**); bp 80—83 °C/25 mmHg, n_D^{17} 1.4399 (lit,[11] bp 80—81 °C/21 mmHg). 3-Benzyl-2,4-pentanedione (**10**); bp 90—94 °C/1 mmHg, n_D^{25} 1.5265(lit, [12] bp 115—118 °C/4 mmHg, n_D^{25} 1.5236). 3-Furfuryl-2,4-pentanedione (**11**); bp 107—108 °C/4 mmHg, n_D^{16} 1.4963; IR spectrum: 1720 (C=O), 1680 (C=C), 1600 (enol), 1070 cm⁻¹ (C–O–C). Mass spectrum: *m/e* 180 (parent peak), *m/e* 137 $(P\text{–}COCH_3)^+$, *m/e* 81 . 3-Tetrahydrofurfuryl-2,4-pentanedione (**12**); bp 109—112 °C/2 mmHg, n_D^{17} 1.4676, IR spectrum: 1720 (C=O), 1600 (enol), 1070 cm⁻¹ (C–O–C). Mass spectrum: *m/e* 184 (Parent peak), *m/e* 141 $(P\text{–}COCH_3)^+$, *m/e* 85 , *m/e* 71 .

The IR spectra of the hydrogenated products from **7** to **10** were identical with those of the authentic samples which had been prepared by the reaction of sodium acetylacetonate with alkyl halides.[13,14]

*Copper(II) Chelate from **7** to **12**.* The copper(II) chelates from **7** to **12** were prepared by mixing an aqueous solution of cupric acetate and an ethanol solution of the hydrogenated products from **7** to **12**. They were then recrystallized from benzene–ligroin. The microanalyses were as follows: **7**, Found: C, 57.51; H, 8.24%. Calcd for $C_{18}H_{30}O_4Cu$: C, 57.80; H, 8.03%. **8**, Found: C, 55.05; H, 7.77%, Calcd for $C_{16}H_{26}O_4Cu$: C, 55.55; H, 7.58%. **9**, Found: C, 52.84; H, 7.10%, Calcd for $C_{14}H_{22}O_4Cu$: C, 52.90; H, 6.98%. **10**, Found: C, 65.04; H, 5.93%, Calcd for $C_{24}H_{26}O_4Cu$: C, 65.21; H, 5.93%. **11**, Found: C, 56.72; H, 5.25%, Calcd for $C_{20}H_{22}O_6Cu$: C, 56.92; H, 5.25%. **12**, Found: C, 55.29; H, 6.90%, Calcd for $C_{20}H_{30}O_6Cu$: C, 55.86; H, 7.03%.

Hydrogenation of 2-Heptanone or 4-Hepten-2-one. 2-Heptanone was a commercial G.R.-grade sample. 4-Hepten-2-one was prepared by the deacylation of **1** in the presence of its copper(II) chelate in methanol.[15] They were hydrogenated with 100 kg/cm² hydrogen with Raney nickel in the presence of **7** at 70 °C. In the course of the reaction, the hydrogen-uptake was followed manometrically. The fractional distillation of the reaction mixture gave 2-heptanol (bp 74—75 °C/23 mmHg) and/or 2-heptanone (bp 54—55 °C/17 mmHg).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1568—1569 (1973)

The Ring-Opening Reactivities of Three-Membered Cyclic Compounds. I. The Ring-Opening Reactions of Three-Membered Cyclic Compounds by Hydrogen Chloride

Hiroshi KAKIUCHI and Takao IIJIMA

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Ooka, Minami-ku, Yokohama 233

(Received March 14, 1972)

There have been many reports about the relative reactivities of cyclic ethers in cationic copolymerizations,[1-3] and these reactivities have been evaluated as linear combinations of the basicity of the ring and the ring strain[2] or the radical dissociation energy of the broken bond.[3]

There have, however, been few reports discussing how the changes in the heteroatoms of the rings influence the reactivities of heterocyclic compounds.[4,5] In this paper, the ring-opening reactions of three-membered cyclic compounds by hydrogen chloride will be studied in toluene in order to discuss their relative reactivities. As three-membered rings, methyl cyclopropane (MCP), propylene oxide (PO), propylenimine (PI), and propylene sulfide (PS) will be used.

Results and Discussion

Ring-opening reactions of MCP were carried out at 40 °C and 60 °C. In these reactions, isobutyl chloride, **1a**, could not be observed; only *sec*-butyl chloride, **1b**, could be detected by gas chromatography. The ring-opening reaction rate was so slow that the kinetic study was difficult.

TABLE 1. RATE CONSTANTS FOR THE RING-OPENING REACTIONS BY HCl

Reaction temp. (°C)[a]	PO 10^2k_2 (l/mol s)	PI 10^2k_2 (l/mol s)	PS 10^4k_2 (l/mol s)

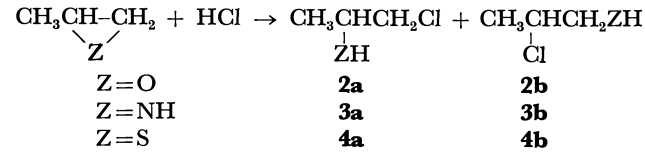
0	1.46 1.48 1.34	1.52 1.70	

a) ±0.1°C

The ring-opening reactions of three-membered heterocyclic compound by HCl obey second-order kinetics, depending on the first order both in the heterocyclic compound concentration and in the HCl concentration. The kinetic results are shown in Table 1. According to the Eyring equations, the activation parameters were calculated; they are shown in Table 2. In these reaction systems, two kinds of reaction products were produced:



The ring-opening reaction products of PO were separated into their components, **2a** and **2b**, by gas chromatography, and each of them was analyzed by NMR spectroscopy. In the gas chromatogram, two peaks of the reaction products were observed with retention times 8.7 and 11.4 min, respectively. The chemical shift of the methyl protons of the former is 8.70 τ, and that of those of the latter, 8.50 τ. Considering the difference between the shielding effect due to a substituent in the β-position to methyl protons, the former is **2a**, and the latter, **2b**.[6]

Two kinds of aminopropanols in the PI–HCl reaction system were analyzed by NMR(D_2O) spectroscopy. The methyl-proton spectra of two kinds of reaction products were separated into 1.35 and 1.55 ppm, respectively; the lower-field absorption in the signals was assigned to the abnormal product, **3b**.

In the ring-opening reaction of PS, two kinds of chloropropanethiols were analyzed by both gas chromatography and NMR(C_6H_6) spectroscopy according to the modified method of Schwarz.[7]

The results of product analyses (Table 2) show that the ring-opening reactions of three-membered heterocyclic compounds proceed *via* an S_N2-type mechanism and that the normal products, **2a**, **3a**, and **4a**, are produced in larger amounts.[5,8] The reaction rate decreases in the following order: PO, PI, PS, and MCP. The order of the reactivity corresponds to neither that of the basicity[9] nor that of the ring strain[10]

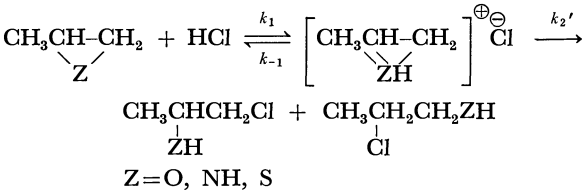
Ring strain[c] (kcal/mol)	27.43	27.28	26.87	19.78
Association const[d] with phenol K (l/mol)	?	5.95	139	1.081

a) At 30 °C, b) At room temp., c) Ref. 10, d) At 20 °C. See ref. 9. That of PI was calculated from the average value of ethylene imine and 2,2-dimethylethylene imine.

(Table 2). In the protonic acid system, the ring-opening reaction is that of the conjugate acid by the anion, as follows:



Z=O, NH, S

The apparent rate constant, k_2, can, then, be expressed as the product of the equilibrium constant, $K(=k_1/k_{-1})$, and the rate constant of the elementary reaction, k_2'. The former is related to the basicity of the ring, while the latter is influenced by the ring strain of the conjugate acid. However, it is difficult to find the dependence of the ring-opening reactivity on either the ring strain or the basicity of the ring, because the relation between the ring strain of the three-membered ring and that of its conjugate acid is unknown and the equilibrium constant can not be determined.

The details of the reactions of MCP in other protonic acid systems will be reported in the near future.

Experimental

Reagents. Methyl cyclopropane was prepared by the method of Demjanoff[11] and was dried over phosphorus pentoxide. Propylene oxide was a commercial product; it was dried over calcium hydride and then distilled; bp 35.0 °C. Propyleneimine was prepared by the method of Wenker,[12] dried over sodium metal, and distilled; bp 64.0—66.0 °C. Propylene sulfide was prepared by the method of Bordwell *et al*,[13] dried over anhydrous sodium carbonate, and distilled; bp 72.0—75.0 °C. All three-membered cyclic compounds were distilled just before use. Toluene was purified by the usual method, and the anhydrous HCl solution in toluene was prepared by the method of Manson.[14]

Kinetic Measurements. The reaction was carried out in toluene under dry nitrogen in a 200 ml four-necked flask equipped with a thermometer, a stirrer, and a cooler. The gas chromatographic conditions in the MCP–HCl reaction were: internal standard, carbon tetrachloride; column materials, 25 wt% tricresyl phosphate 75 cm×3 mm; column temp., 40 °C; carrier gas, He 50 ml/min. The rate constants for the reaction of PO with HCl were measured in the following manner. At desired time intervals, a constant volume of the reaction mixture was withdrawn and poured into a constant volume of a potassium hydroxide methanol solution (M/10). The conversion of PO was calculated from the amount of the remaining potassium hydroxide, which was determined with a benzoic acid methanol solution (M/25), using phenolphthalein as the indicator. The reaction rate of PO was too fast to determine the conversion of PO by gas chromatography. Kinetic measurements of the reaction of PI with HCl were carried out in the same manner as those of the PO–HCl reaction system except that initial mole ratio, HCl/PI, was controlled at 2. The true residual values of HCl were calculated as twice the apparent values of HCl, because two kinds of aminopropanols act as bases in the back titration. The influence of PI should be negligible, for PI is a weak and it consumes only HCl 1×10^{-5} mol/PI 0.01 mol. The rate constants for the reaction of PS with HCl were measured by determining the residual PS under the following gas chromatographic conditions: internal standard, chlorobenzene; column material, 25 wt% tricresyl phosphate 75 cm×3 mm; column temp., 120 °C; carrier gas, He 50 ml/min. In this reaction, the residual HCl could not be determined because the reaction products, chloropropanethiols, act as acids.

Product Analyses. *sec*-Butyl chloride was prepared as an authentic sample from *sec*-butyl alcohol. The gas chromatographic conditions in the PO–HCl reaction system were: column material, carbowax 1500 300 cm×3 mm; column temp., 80 °C; carrier gas, He 50 ml/min. 2-Chloro-*n*-propylamine hydrochloride was prepared as an authentic sample from 1-amino-2-propanol hydrochloride; mp 186.0—187.0 °C(lit,[15] 187—190 °C). 2-Chloropropane-1-thiol, **4b**, was prepared by the method of Davis *et al.*;[16] it contained about 10% of the isomer, **4a**.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1570—1571 (1973)

4-(1,2-Diacetoxyethyl)pyridine and Its Chemical Properties

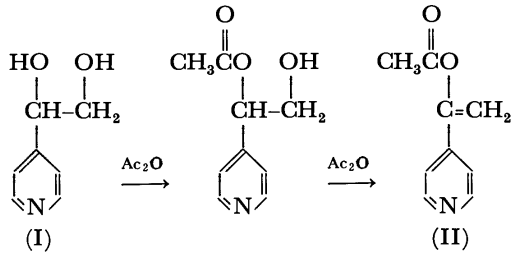
Toshiyuki FURUYAMA, Koichi MORI, Ichiro NAGOYA, Kazuo TAMURA, and Masatsugu YOSHINO

Technical Research Laboratory, Asahi Chemical Industry Co., Ltd., Nakadai, Itabashi-ku, Tokyo 174

(Received November 28, 1972)

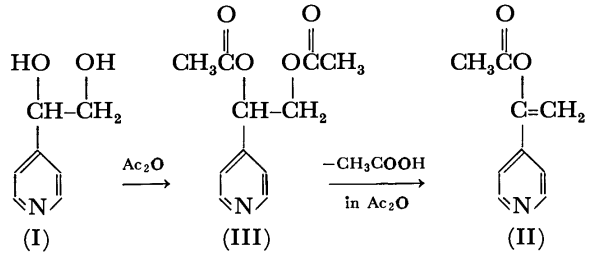
A new compound 4-(1,2-diacetoxyethyl)pyridine was synthesized from reaction of (4-pyridyl)-1,2-ethanediol (I) with acetic anhydride. It was converted into α-acetoxy-4-vinylpyridine (II) (yield, 85%) on being heated in acetic anhydride. The compound shows a characteristic NMR spectrum with respect to its methylene splitting, indicating that the two protons on methylene are not chemically equivalent.

Haas *et al.*[1] treated (I) with acetic anhydride and obtained α-acetoxy-4-vinylpyridine. They stated that the formation of 4-(1,2-diacetoxyethyl)pyridine (III) was unlikely since the deacetylation of the analogous compound, 2-(1,2-diacetoxyethyl)pyridine, seldom affords α-acetoxy-2-vinylpyridine. Their proposed mechanism which involves an intermediate compound of a half acylated diol is shown.



Scheme (1)

Having succeeded in synthesizing α-acetoxy-4-vinylpyridine (II) from 4-(1,2-diacetoxyethyl)pyridine in an 85% yield, we propose a mechanism which involves the formation of (III) as follows.



Scheme (2)

Results and Discussion

The formation of III from I is fast and the yield is quantitative. 4-(1,2-Diacetoxyethyl)pyridine, bp. 112 °C/0.28 mmHg, mp. 46.5 °C (DSC method) and $n_D^{25.5}$ 1.4908, can be distilled from the reaction solution by the removal of the acetic acid formed and excess acetic anhydride just after I is dissolved into acetic anhydride. In this case the molar ratio of I to acetic anhydride is 1 : 7.5. The reaction (exothermic) was carried out at inner temperature of *ca.* 40 °C for 30 min under occasional water cooling.

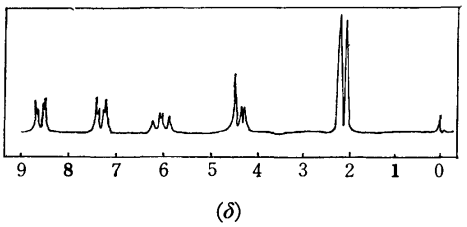


Fig. 1. 60 MHz NMR spectrum 4-(1,2-diacetoxyethyl)pyridine in $CDCl_3$.

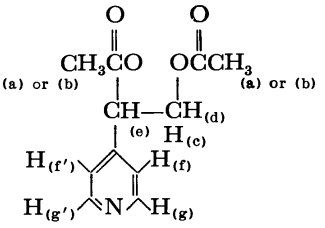
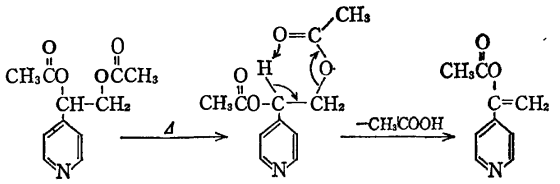
The NMR spectrum of III at 60 MHz in deuterochloroform at room temperature is shown in Fig. 1. The methylene peaks ($H_{(c)}$, 4.33 δ; $H_{(d)}$, 4.37 δ) appear as three peaks ($|J_{(c)(e)}|$, 7 cps; $|J_{(d)(e)}|$, 4.5 cps; $|J_{gem}|$, 12 cps), and the methine peaks ($H_{(e)}$, 6.03 δ) were four peaks.



This indicates that the methylene protons are not chemically equivalent. A similar example of aspartic acid in D_2O, was reported by Silverstein and Bassler,[2] where methylene protons adjacent to the asymmetric carbon appear as a triplet. However, the possibility that 4-(1,2-diacetoxyethyl)-pyridine takes a specific conformation cannot be ruled out, since the deacetylation of 4-(1,2-diacetoxyethyl)pyridine *via* a six membered transition state easily takes place to form α-acetoxy-4-vinylpyridine (scheme (3)).



Scheme 3.

A kinetic study for the deacetylation reaction of III was carried out in acetic anhydride at 130 °C (Fig. 2). The deacetylation obeys a first order reaction.

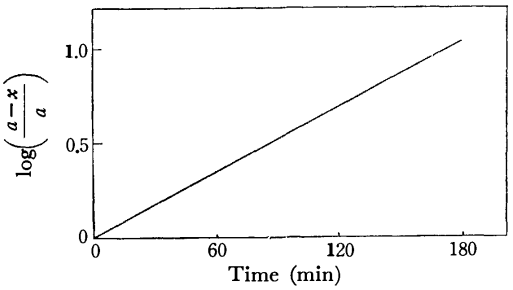

Fig. 2. The deacetylation reaction of 4-(1,2-diacetoxyethyl)-pyridine at 130°C.
a: initial 4-(1,2-diacetoxyethyl)pyridine (mol)
x: product formed (mol)

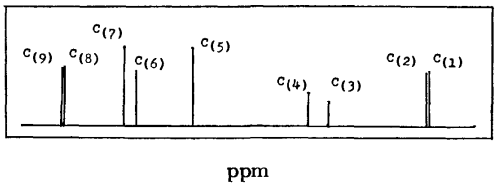

Fig. 3. Carbon-13 NMR spectrum of 4-(1,2-diacetoxyethyl)-pyridine in D_2O.

The yield of deacetylation is as high as 50%, according to the Haas method[1] or the improved Haas method,[3] in contrast to the present method (85% yield) which involves III as an intermediate compound.

A carbon-13 NMR spectrum of III proves the formation of 4-(1,2-diacetoxyethyl)pyridine (Fig. 3).

α-Acetoxy-4-vinylpyridine which was synthesized by the present method can be crystallized with mp of 12.6 °C, and be polymerized with both γ-rays and radical initiators.[4]

Experimental

4-(1,2-Diacetoxyethyl)pyridine. To 10 g (0.07 mol) of pyridyl)-1,2-ethanediol was added 55 g (0.54 mol) acetic anhydride. The reaction started exothermally, pasty (4-pyridyl)-1,2-ethanediol being gradually dissolved. The system was maintained at approximately 40 °C for 30 min by occasional water cooling. Acetic acid and the excess acetic anhydride were removed under reduced pressure. The subsequent vacuum distillation gave 4-(1,2-diacetoxyethyl)pyridine in a quantitative yield: bp. 112°C/0.28 mmHg. mp. 45.6°C (DSC method). $n_D^{25.5}$ 1.4908. Found: C, 59.2; H, 5.9; N, 6.3%. Calcd for $C_{11}H_{13}O_4N$: C, 59.2; H, 5.9; N, 6.3%.

Deacetylation. A mixture of 10 g (0.045 mol) of 4-(1,2-diacetoxyethyl)pyridine and 35 g (0.343 mol) of acetic anhydride was maintained at 130°C for 6 hr in thermobath. The subsequent fractional distillation under reduced pressure gave α-acetoxy-4-vinylpyridine, yield 85%, mp 12.6°C. The results for bp and elemental analysis for C, H, and N are the same as described previously.[3] Kinetic study was carried out by taking small portion of the reaction mixture and measuring the decreasing methylene protons with a 60 MHz NMR instrument.

Carbon-13 NMR Spectrum. This was measured with JEOL 100 MHz spectrometer (JNM-PET-100) in heavy water at room temperature by the pulse Fourier transform NMR method.[5]

Carbon-13 NMR: $C_{(1)}$ or $C_{(2)}$, ppm 20.9 or 21.1; $C_{(3)}$ 66.2; $C_{(4)}$, 73.3; $C_{(5)}$, 122.6; $C_{(6)}$, 147.2; $C_{(7)}$, 149.9; $C_{(8)}$ or $C_{(9)}$ 173.3 or 173.9 (TMS reference).

Synthesis of Some Substituted Nucleoside Analogs

Toru SEITA, Masayoshi KINOSHITA, and Minoru IMOTO*

Depatment of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka 558

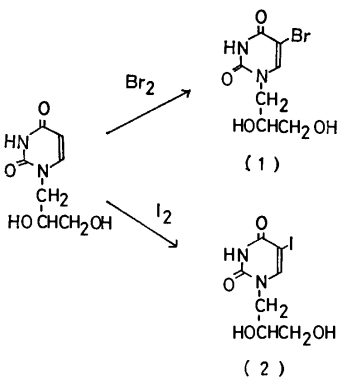
**Department of Applied Chemitry, Kansai University, Suita, Osaka 565*

(Received December, 1972)

Polymers which contain nucleic acid bases in their main chain or in side groups present many interesting problems with respect to their physicochemical properties. But the water-insolubility of polymers was often encountered and was unsuitable for the study of physicochemical properties. This problem was solved by the introduction of phosphoric ester group into the main chain of polymer.[1-2] The authors have synthesized, further, water-soluble polymers particularly paying attention to the new structural analogs of nucleic acid.[3] Takemoto *et al.* reported on the derivatives of nucleic acid bases.[4]

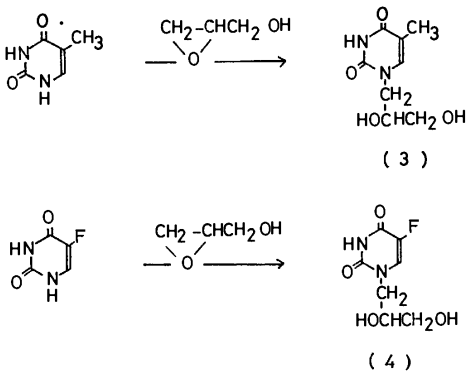
In this paper we describe the synthesis of 5-substituted uracil. The oligomers and polymers obtained from compounds of these types may provide a mean of studying chemotherapeutic applications. One of the most interesting utilization may be the incorporation of 5-halouracils into polymer, especially of the most important anti-cancer material, 5-fluorouracil.

Bromination of 1-(2′,3′-dihydroxypropyl)-uracil was carried out using bromine in mixture of 0.5 M nitric acid and *p*-dioxane to give 1-(2′,3′-dihydroxypropyl)-5-bromouracil (**1**). When 1-(2′,3′-dihydroxypropyl)-uracil was refluxed with iodine under similar condition described above, the 1-(2′,3′-dihydroxypropyl)-5-iodouracil (**2**) was formed in good yield. The position of substitution of bromine or iodine atom was confirmed by ultraviolet absorption. The ultraviolet absorption spectra of **1** and **2** are shifted toward longer wavelength than that of 1-(2′,3′-dihydroxypropyl)-uracil. The position of halogen atom was also checked by the absence of absorption peak at τ 4.2 corresponding to H-5 of uracil ring.



Scheme 1.

Thymine was treated with glycidol in DMF containing a trace of anhydrous potassium carbonate at 60—70 °C. Chromatography of reaction mixture on silica gel using benzene–ethanol as solvent gave the 1-(2′,3′-dihydroxypropyl)-5-methyluracil (**3**). Also the reaction of 5-fluorouracil with equimolar glycidol was carried out under similar condition to give 1-(2′,3′-dihydroxypropyl)-5-fluorouracil (**4**).



Scheme 2.

Experimental

The IR spectra were run on a JASCO Model IR-G Spectrometer. The UV spectra were measured by a Hitachi Recording Spectrometer Model ESP-3T. The NMR spectra were recorded with a Hitachi-Perkin-Elmer apparatus, Model R-20.

1-(2′,3′-Dihydroxypropyl)-5-bromouracil (1). A solution of 1-(2′,3′-dihydroxypropyl)-uracil (1.86 g, 10 mmol) dissolved in a mixture of 0.5 M nitric acid (20 ml) and *p*-dioxane (80 ml) was added to a solution of bromine (2.4 g, 15 mmol) in 20 ml of carbon tetrachloride, and the solution was stirred at room temperature for 3 hr. The reaction mixture was evaporated under reduced pressure to dryness. The oil residue is dissolved in ethanol, and the solution was evaporated to dryness. The obtained precipitate was recrystallized from ethanol to give **1** (2.5 g, (85%)) as colorless needles.

Mp 202—204°C, UV: $\lambda_{max}^{H_2O}$ 211 mμ (ε=9800), 283 mμ (ε=9100), IR: 3300 (OH), 1700, 1650 (bromouracil ring) and 1090, 1030 (primary and secondary alcohol C–O); NMR (DMSO-d_6) τ −1.15 (br s, 1, N_3–H), 2.0 (s, 1, C_6–H), 5.5 (br s, 2, $C_{2',3'}$-OH), 5.8—6.5 (m, 3, $C_{2',3'}$–H), 6.65 (br s, 2, C_1, –H); Found: C, 31.69; H, 3.48; N, 10.49%. Calcd for $C_7H_9N_2O_4Br$: C, 31.71; H, 3.42; N, 10.56%.

1-(2′,3′-Dihydroxypropyl)-5-iodouracil (2). Into a solu-

tion of 1-(2′,3′-dihydroxypropyl)-uracil (0.86 g, 10 mmol) in a mixture of 0.5 M nitric acid (20 ml) and *p*-dioxane (80 ml), iodine (5.1 g, 20 mmol) was added and the solution was refluxed for 3 hr. After allowing to cool to room temperature, the solvent was evaporated under reduced pressure. The residue was recrystallized from ethanol to give **2** (2.18 g, (80%)) as colorless needles.

Mp. 196—198°C, UV: $\lambda_{max}^{H_2O}$ 219 mμ (ε=12000), 292 mμ (ε=9800), IR; 3350 (OH), 1690, 1660 (iodouracil ring) and 1090, 1020 (primary and secondary alcohol C–O); NMR (DMSO-d_6) τ −1.15 (br s, 1, N_3–H), 1.9 (s, 1, C_6–H), 5.6 (br s, 2, $C_{2',3'}$–OH), 5.9—6.4 (m, 3, $C_{2',3'}$–H), 6.5 (br s, 2, $C_{1'}$–H); Found: C, 26.86; H, 2.90; N, 8.62%. Calcd for $C_7H_9N_2O_4I$: C, 26.93; H, 2.90; N, 8.97%.

*1-(2′,3′-Dihydroxypropyl)-5-methyluracil (**3**).* Thymine (1.25 g, 10 mmol) and glycidol (0.74 g, 10 mmole) in DMF (50 ml) containing a trace amount of anhydrous potassium carbonate was stirred at 60—65°C for 8 hr. The solvent was evaporated to dryness under reduced pressure. The residue was chromatographed over silica gel using a mixture of benzene and ethanol (4 : 1) as solvent. The obtained product was recrystallized from benzene–ethanol (7 : 1) to give the compound **3** (0.8 g, (40%)) as colorless needles.

Mp. 145—146°C, UV: $\lambda_{max}^{H_2O}$ 210 mμ (ε=13500), 273 mμ (ε=12000), IR: 3500 (OH), 1660 (thymine ring) and 1090, 1040 (primary and secondary alcohol C–O); NMR (DMSO-d_6) τ −1.15 (br s, 1, N_3–H), 8.2 (s, 3, N_5–CH_3), 2.8 (s, 1, C_6–H), 5.6 (br s, 2, $C_{2',3'}$–OH), 5.9—6.5 (m, 3, $C_{2',3'}$–H), 6.6 (br s, 2, $C_{1'}$–H); Found: C, 47.81; H, 5.89; N, 13.87%. Calcd for $C_8H_{12}N_2O_4$: C, 48.02; H, 6.04; N, 13.99%.

*1-(2′,3′-Dihydroxypropyl)-5-fluorouracil (**4**).* 5-Fluorouracil (1.29 g, 10 mmol) and glycidol (0.74 g, 10 mmol) was reacted in the way described in the case of **3**. The obtained product was recrystallized from a mixture of benzene–ethanol (9 : 1) to give the compound **4** (0.76 g, (38%)) as colorless needles.

Mp. 147—149°C; UV $\lambda_{max}^{H_2O}$ 210 mμ (ε=9800), 275 mμ (ε=9000), IR: 3350 (OH), 1720, 1650 (fluorouracil ring) and 1070, 1020 (primary and secondary alcohol C–O); NMR (DMSO-d_6) τ −1.18 (br s, 1, N_3–H), 2.2 (d, 1, C_6–H), 5.2 (br s, 2, $C_{2',3'}$–OH), 6.0—6.6 (m, 3, $C_{2',3'}$–H), 6.7 (br s, 2, $C_{1'}$–H); Found: C, 41.42; H, 4.51; N, 13.76%. Calcd for $C_7H_9N_2O_4F$: C, 41.18; H, 4.44; N, 13.72%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1573—1575 (1973)

Bildung von 1,4-Bis(2,2′-biphenylylen)-1,3-butadien[1)]

Masahiro MINABE und Kazuo SUZUKI

Abteilung für Chemische Industrie der Universität Utsunomiya, Ishii-cho, Utsunomiya 321-31

(Eingegangen am 27. Juni 1972)

Bekanntlich wird bei der Michaelschen Reaktion von 9,9′-Bifluorenyliden (**5**) mit Fluoren (**1a**) in Äthanol in Gegenwart von Natrium-äthylat als Katalysator neben 9,9′:9′,9″-Terfluorenyl, Schmp 293° (zers) (**8b**) auch 1,4-Bis(2,2′-biphenylylen)-1,3-butadien (**6a**)[2)] in kleiner Menge gebildet.[3)] 1,4-Bis(4,4′-dibrom-2,2′-biphenylylen)-1,3-butadien sowie 1-(4,4′-Dibrom-2,2′-biphenylylen)-4-(2,2′-biphenylylen)-1,3-butadien sind bereits als Nebenprodukte der Reaktion von 2,7,2′,7′-Tetrabrom-9,9′-bifluorenyliden mit **1a** erhalten worden.[4)] Ferner ist bekannt, dass durch Erhitzung unter Rückfluss von Fluorens in Gegenwart einer Base in Äthanol unter Durchleitung von Sauerstoff entsprechende 1,3-Butadiene gebildet werden.[5)]

Nachdem die Michaelsche Reaktion von **5** mit **1a** wiederholt worden war und die Produkte überprüft worden waren, wurde festgestellt, dass 9,9′:9′,9″-Terfluorenyl, Schmp 257° (zers) (**8a**), **8b**, **6a**, 9-Äthylidenfluoren (**3**),[6)] Fluorenon (**2a**), und 1,6-Bis(2,2′-biphenylylen)-1,3,5-hexatrien (**7**)[7)] isoliert wurden.

Falls auf einem ähnlichen Weg wie Stahrfoss[5a)] in Gegenwart von Kaliumhydroxyd **1a** in Äthanol aufgelöst und bei Durchleitung von Sauerstoff unter Rückfluss erhitzt wurde, wurden **6a**, **7**, **2a**, **3**, und **1a** erzeugt, während jedoch nur **1a** zurückgeblieben war, wenn dieselbe Reaction in Stickstoff-Atmosphäre ausgeführt oder Äthanol statt Methanol eingesetzt wurde.

In einem anderen Fall wurde durch die Reaktion von **1a** mit Acetaldehyd in Stickstoff-Atmosphäre in Gegenwart einer Base in Methanol **3** in kleiner Menge isoliert.[8)] Da jedoch **6a** nicht durch die Einwirkung von Lösungsmitteln ausser Äthanol (z. B. Methanol und Pyridin) gebildet wird, ist anzunehmen, dass das Reaktionsprodukt **3** von **1a** mit Äthanol ein Zwischenprodukt bei der Bildung von **6a** sein dürfte. Also sollte ein Teil des Äthanols als Lösungsmittel infolge der Gegenwart von Sauerstoff[9)] und Base zu Acetaldehyd oxydiert und weiter durch die Kondensation

Schema 1.

mit **1a** zu **3** geführt werden.

Durch Erhitzung unter Rückfluss von **3** und 2-Chlorfluorenon (**2b**) in Methanol–Kali–Lösung in Stickstoff-Atmosphäre wird 1-(4-Chlor-2,2′-biphenylylen)-4-(2,2′-biphenylylen)-1,3-butadien (**6b**) in einer Ausbeute von 17% erhalten, während dieselbe jedoch nicht durch die Reaktion mit 2-Chlorfluoren (**1b**) beobachtet worden ist.

Dieses Experiment ergab, dass als ein Bildungsweg von **6a** die Kondensation von **2a** mit **3** in Betracht gezogen wird. Es ist jedoch anzunehmen, dass infolge der Existenz von Sauerstoff in dem Reaktionssystem unter den Bedingungen der Michaelschen Reaktion **3** oxydiert wurde und so sich dessen Oxydationsprodukt an der Bildung von **6a** beteiligt hatte. In der Tat wurde zwar durch die Erhitzung unter Rückfluss von der Lösung **3** in Methanol in Gegenwart von Kaliumhydroxyd in Stickstoff-Atmosphäre nur **3** wiedergewonnen, jedoch entstand **7** in kleiner Menge durch die Reaktion mit **3** bei Durchleitung von Sauerstoff.

Durch die Reaktion von β-(9-Fluorenyliden)acetaldehyd (**4**),[10] welches aus **3** über β-(9-Fluorenyliden)-äthanol[11] in 2-stufiger Oxydation synthetisiert ist, wurde neben **1b** **6b** in einer Ausbeute von 77% erhalten; und durch Reaktion von **3** mit **4** wurde entsprechendes Kondensationsprodukt **7** isoliert.

Aus den obigen Ergebnissen lässt sich schliessen, dass die Bildung von 1,3-Butadienen nach dem dargestellten Schema abläuft. Ein Teil des Äthanols wurde zu Acetaldehyd oxydiert und dann durch Kondensation mit Fluorens zu 9-Äthylidenfluorens übergeführt. Durch die Reaktion von diesem 9-Äthylidenfluorens mit Fluorens wurden entsprechende 1,3-Butadiene gebildet, und durch die Oxydation von diesen 9-Äthylidenfluorens wurde entsprechendes Aldehyd gebildet, welches durch die Kondensation mit Fluorenons schliesslich 1,3-Butadiene gebildet hatte. Es ist jedoch nicht klar, welche von beiden Reaktionen unter den experimentallen Bedingungen der Michaelschen Reaktion zuerst abläuft.

Beschreibung der Versuche

Die Schmelzpunkte sind unkorrigiert. Sämtliche IR Spektren wurden nach der KBr-Methode gemessen. Zur Messung der NMR-Spektren war JEOL-60HL (Japan Electron Optics Lab. Co., Ltd.) (TMS als innerer Standard) in CCl_4 massgebend.

Michaelsche Additionsreaktion von ***5*** *mit* ***1a***: Eine Mischung von **5** (3.28 g, 10 mMol), **1a** (1.99 g, 12 mMol), Natriumäthylat (5.0 g), und absolutem Äthanol (50 ml) wurde in einem Bombenrohr bei 97—100 °C 11 Std erhitzt. Die nach Abkühlung auf Raumtemperatur abgeschiedenen Kristalle wurden filtriert und aus Pyridin, Benzol, und Essigsäureäthylester umkristallisiert und **8a** (2.1 g, 43%), Schmp 254—256 °C (zers), **8b** (0.30 g, 6%), Schmp 292—293 °C (zers), **6a** (0.08 g, 2%) in rotgelblichen Nadelkristallen, Schmp 365 °C (zers) (Lit.[2] Schmp 381 °C), und **7** in geringer Menge, in rötlichen Nadelkristallen, Schmp 330 °C (zers) (Lit.[12] Schmp 331.5—333°C), erhalten.

Der nach dem Zusatz von Wasser in die Äthanol-Mutterlauge abgeschiedene Niederschlag wurde der nach Trocknung über Benzol-Aluminiumoxyd chromatographiert, wobei aus den Fraktionen **3** (0.02 g, 1%), Schmp 102—104 °C (Pikrät, Schmp 155—156 °C), und **1a** (0.09 g, 5%), Schmp 112—114 °C, erhalten wurden. Aus dem gelblichen Adsorptionsband wurde mit Äthanol **2a** (0.1 g, 2%), Schmp 83—85°C, eluiert.

Reaktion von ***1a***. *1) Einwirkung von Sauerstoff in Äthanol*: Die Lösung von **1a** (8.3 g, 50 mMol) und Kaliumhydroxyd (5.0 g) in Äthanol (100 ml) wurde unter Durchlei-

9) Im allgemeinen wird die Michaelsche Additionsreaktion dieser Art bei Vorhandensein von Luft vorgenommen.

10) E. D. Bergmann, H. W.-Feilchenfeld, und N. Mandel, *Vietnamica Chim. Acta*, **1966**, 129; *Chem. Abstr.*, **72**, 3278 (1970).

11) R. Kuhn und U. Breyer, *Ann. Chem.*, **661**, 173 (1963).

12) E. F. Magoon und L. Zechmeister, *J. Amer. Chem. Soc.*, **77**, 5642 (1955).

tung von Säuerstoff 10 Std unter Rückfluss erhitzt, wobei die abgeschiedenen Rot-Kristalle aus Pyridin umkristallisiert wurden, so dass **6a** (0.21 g, 2.4%) und **7** (0.01 g, 0.1%) erhalten wurden. Bei der Behandlung der Äthanol-Mutterlauge in der gleichen Weise wie oben konnten **2a** (0.17 g, 1.8%), **3** (1.19 g, 12.4%), und **1a** (6.68 g, 80.5%) isoliert werden.

2) Reaktion mit Acetaldehyd: In die Mischung von Kaliumhydroxyd (5.0 g) und **1a** (8.3 g) in Methanol (130 ml) wurde Methanol-Lösung (10 ml) mit Acetaldehyd (2.5 g) unter säuerstoff-frei getrocknetem Stickstoff 20 Min lang getropft. Weiter wurde ein langer Rückflusskühler mit Eiswasser zugefügt und 40 Min unter mildem Rückfluss erwärmt, wonach durch Sublimation und Umkristallisation **3** (0.016 g, 0.2%) und **1a** (6.96 g, 84%) isoliert wurden.

*Reaktion von **3**.* *1)* Die Lösung von **3** (3.84 g, 20 mMol) in Methanol (150 ml) mit Kaliumhydroxyd (5.0 g) wurde unter Durchleitung von Sauerstoff 10 Std unter Rückfluss erhitzt, woraus ein abgeschiedenes rotes Produkt nach der Umkristallisation aus Pyridin **7** (0.17 g, 5%) lieferte. Aus der Methanol-Mutterlauge liessen sich nach der üblichen Aufbereitung **2a** (0.10 g, 3%) und **3** (2.58 g, 67%) gewinnen.

*2) Reaktion mit **2b***: Die Lösung von Methanol (150 ml) mit Kaliumhydroxyd (5.0 g) wurde nach dem Zusatz von **3** (1.92 g, 10 mMol) und **2b** (2.15 g, 10 mMol) in Stickstoff-Atmosphäre 10 Std unter Rückfluss erhitzt. Der abgeschiedene Niederschlag wurde abgesaugt und aus Pyridin umkristallisiert, wobei **6b** (0.63 g, 17%), Schmp 370—372 °C (zers), erhalten wurde. Gef: C, 86.43; H, 4.18%. Ber für $C_{28}H_{17}Cl$: C, 86.48; H, 4.41%.

Aus der Methanol-Mutterlauge wurden **3** (1.57 g, 82%) und **2b** (1.72 g, 80%) gewonnen.

*Oxydation von **3** mit Selendioxyd*: **3** (10.0 g) und Selendioxyd (3.2 g) wurden in verfeinerter Essigsäure (160 ml) 1 Std unter Rückfluss erhitzt. Dann wurde das von Selen befreite Filtrat mit Wasser verdünnt und mit Benzol extrahiert, dann wurde die Benzolschicht über Aluminium-oxyd chromatographiert, wobei aus dem rötlichen Aluminiumoxyd-Adsorptionsband β-(9-Fluorenyliden)äthanol (1.3 g, 12%), Schmp 146—147 °C in einem farblosen Nadelkristall, erhalten wurde. Mass: m/e 208 (M^+). IR: 3205 cm^{-1} (–OH).

Das weitere Acetyl-Derivat wurde durch Einwirkung von Essigsäureanhydrid in wasserfreiem Benzol erhalten. Nach der Umkristallisation aus Äthanol wurden farblose Nadelkristalle, Schmp 97—98 °C, gebildet. Gef: C, 81.58; H, 5.64%. Ber für $C_{17}H_{14}O_2$: C, 81.72; H, 5.79%. Mass: m/e 250 (M^+). IR: 1735 cm^{-1} (>C=O). NMR: δ 2.05 (s, 3H), 5.16 (d, 2H), 6.53 (t, 1H), und 7.03—7.68 ppm (m, 8H).

Oxydation von β-(9-Fluorenyliden)äthanol mit Mangandioxyd: Eine Probe von 0.9 g wurde in Benzol (250 ml) gelöst und durch eine Säule (etwa 4 cm) mit Mangandioxyd (15 g) (E. Merck, zur Synthesis) laufen lassen. Nach Trennung und Reinigung durch Chromatography über Aluminiumoxyd und Umkristallisation wurden **4** (0.33 g, 37%), Schmp 116.5—117.5 °C, in einem gelblichen Nadelkristall und **2a** (0.1 g, 10%) isoliert. IR von **4**: 1656 cm^{-1} (–CHO).

2,4-Dinitrophenylhydrazon von **4**, rötliche Nadeln vom Schmp 324—326 °C (zers). Gef: C, 65.12; H, 3.53; N, 14.60%. Ber für $C_{21}H_{14}N_4O_4$: C, 65.28; H, 3.65; N, 14.50%.

*Reaktion von **4** mit **1b***: Die Lösung von **4** (206 mg, 1 mMol) und **1b** (200.5 mg, 1 mMol) in Methanol (15 ml) mit Kaliumhydroxyd (500 mg) wurde in Stickstoff-Atmosphäre 40 Min unter Rückfluss erhitzt, wobei nach der Umkristallisation von abgeschiedenen Kristallen aus Pyridin **6b** (300.9 mg, 77%) erhalten wurde. Ferner wurde aus der Methanol-Mutterlauge **4** (3.0 mg, 1%) zurückgewonnen.

*Reaktion von **4** mit **3***: Bei der Reaktion von **4** mit **3** (192 mg, 1 mMol) anstelle von **1b** bei der obigen Reaktion wurden **7** (189.9 mg, 50%), **3** (69.6 mg, 36%), und **4** (3.1 mg, 1%) isoliert.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1575—1576 (1973)

The NQR Spectrum and Structure of Hexachloropentafulvene[1)]

Israel AGRANAT,[2a)] Michael HAYEK,[2b)] and David GILL[2b,c)]

The Hebrew University of Jerusalem, Jerusalem, Israel

(Received July 10, 1972)

Pure nuclear quadrupole resonance (NQR) studies on molecular crystals have been applied to the determination of distribution of molecular electrons.[3-6)] Recently, West and his co-workers have successfully applied NQR spectroscopy to the study of the perchlorocarbon series.[7-9)] The validity of this method depends on correct assignments of the wealth of resonance (obtained experimentally) to the different chlorine atoms present in the molecule under study. We wish to report the ^{35}Cl NQR spectra of hexachloropentafulvene (I)[10,11)] and 3,4-bis(dichloromethylene)-1,2-dichlorocyclobutene (II)[12)] and their analyses in

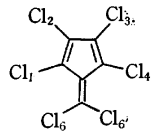
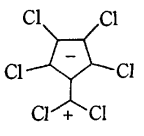
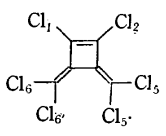
terms of the dipolar and spatial structures of these nonbenzenoid cyclic conjugated chlorocarbons.[13,14]



I



Ia



II

The spectrum of I consists of the following six frequencies: 36.783, 37.163, 37.805, 38.086, 38.179, and 38.303 MHz. They fall into two groups, A and B, centered at 37.0 MHz (2 lines) and 38.1 MHz (4 lines), respectively. The large frequency separation between the two groups of lines (>1 MHz) indicates the presence of at least two types of chlorine atoms. The splitting within each group may still be attributed to solid-state intermolecular forces.[5,6,15] In order to draw any conclusions from the NQR spectrum pertaining to the dipolar character or to the spatial structure of I, a correct assignment of the resonances of the NQR spectrum is necessary. Out of the various possible alternatives, one point emerges clearly: the frequencies of Cl_2 and Cl_3 are represented by group A and not by Group B. This assignment is based on the analysis of the NQR spectra of a series of 1,2,3,4-tetrachlorofulvenes and related substances, which indicate that the ^{35}Cl resonance of Cl_2 and Cl_3 appears consistently in the 36.5 MHz region, and is not affected by the substituents at the exocyclic (6,6′) positions.[16] Thus group B should be assigned to Cl_1, Cl_4, Cl_6, and Cl_6'. The alternative assignment suggested by Hashimoto and Mano[17] which attributed group A to Cl_6 and Cl_6' and group B to Cl_1, Cl_2, Cl_3, and Cl_4 does not seem to be justified. They claimed that their assignment was supported by the contribution of the dipolar, "aromatic" structure Ia to the ground state of I. The experimental dipole moment of I in (cyclohexane) solution (1.00D),[18] *does not* indicate any substantial contribution of Ia in the ground state. In any event, the extent of such a contribution cannot account for a decrease in the resonance frequencies of Cl_6 and Cl_6'. Moreover, such a contribution should cause not only a decrease in the electron density of the p_π orbitals of Cl_6 and Cl_6', but also an increase in the respective electron densities of Cl_1, Cl_2, Cl_3, and Cl_4. As shown above, there is no evidence of a shift to higher frequencies of Cl_2 and Cl_3 which should have accompanied such an increase. We conclude that the NQR spectrum of I does not reveal the presence of a contribution of Ia.

The most striking feature in the NQR spectrum of I is the shift to higher frequencies (38.1 MHz region) of the two chlorine atoms "*ortho*" to the "fulvenic" double bond, Cl_1 and Cl_4. The shift is even greater than the one observed in the ^{35}Cl NQR spectrum of octachloropentafulvalene (37.7 MHz region) and interpreted as due to noncovalent intramolecular interactions of the bucking C–Cl groups.[19] This shift (in I) could be explained in terms of the strong perturbations of the electrons of Cl_1 and in the C_1–Cl_1 bond produced by the C_6–Cl_6 dipole.[20] The spatial relationship between Cl_1 and Cl_6 resembles somewhat the *peri*-relationship of the chlorine atoms in positions 1 and 8 in the naphthalene nucleus. Accordingly, an analogy may be drawn from the ^{35}Cl NQR spectrum of 1,2,3,6,7,8-hexachloronaphthalene, in which the resonance representing Cl_1 and Cl_8 appears at *ca.* 38.2 MHz (77 K).[21]

In contrast to I, the ^{35}Cl NQR spectrum of its pseudoalternant isomer II (3 lines at 36.358, 37.835, and 37.971 MHz) was not irregular. For II, Hashimoto and Mano reported six lines falling into two groups centered at *ca.* 36.4 MHz (two lines) and 38.0 MHz (four lines).[17] In particular, the 36.4 MHz resonance due to the chlorine atoms attached directly to the cyclobutene ring (Cl_1 and Cl_2) appears in the normal region for such chlorine atoms. The absorption is thus not shifted to higher frequencies by the electrostatic field of the C_6–Cl_6 and C_5–Cl_5 dipoles. The absence of such an effect (relative to the respective effect observed in I) may be explained by the different geometry of the molecule imposed by the cyclobutene ring. Consequently, the distances between the C_6–Cl_6 dipole and Cl_1 (and the C_1–Cl_1 bond) are larger and their relative orientation is different from that in I.

On the basis of the NQR spectrum of I we predict a small distance between Cl_1 and Cl_6.

We are greatly indebted to Dr. K. Mano of the Research Institute for Atomic Energy, Osaka City University, Sumiyoshiku, Osaka, Japan, for conveying to us his results prior to publication.

13) The measurements were taken using a regenerative detector at 80 K, and were observed on the oscilloscope screen with a signal-to-noise ratio of 10: 1, the error being ~0.001 MHz.

Electronic Properties of the Neutral Radicals from Phenothiazines

Mamoru KAMIYA, Takehiro MITSUI, and Yukio AKAHORI
Shizuoka College of Pharmacy, Oshika, Shizuoka 420

(Received June 15, 1972)

In the course of numerous studies of phenothiazine radicals, it has been found by the ESR method that a neutral phenothiazinyl radical is produced from phenothiazine by photochemical and chemical oxidations.[1-4] However, little attention has been paid to the substituted radicals or to the electronic spectrum of the non-substituted radical itself. In this note we shall discuss the assignment of the electronic spectra of the phenothiazinyl radicals, with reference to the ESR spectra and the effect of air-contact upon the radical decay, and with the aid of a theoretical calculation of the electronic spectra.

Experimental and Calculation

1-Methylphenothiazine and 1-methoxyphenothiazine were prepared by the thionation of the corresponding diarylamines.[5] The compounds used were purified by repeated sublimations under a high vacuum. Two different methods, that is, the chemical method of Tsujino[4] and the photochemical method of Shine and Mach,[1] were used for the radical formation because such by-products as the phenothiazine nitroxide radical and phenothiazine dimers, which would be less destroyed by air-contact than the phenothiazinyl radical, are likely to be produced by these methods. The solvent used in the chemical oxidation was prepared by mixing equimolar amounts of spectro-grade dimethyl sulfoxide and acetic anhydride. The radical solutions were prepared by dissolving materials in degassed solvents. The solutions were filtered by means of a glass filter and directly led to a UV cell or an ESR tube. All of these procedures were performed in a vacuum line. The electronic absorption spectra were recorded with a Hitachi EPS-2 spectrophotometer using a 10 mm cell. The ESR spectra were obtained with a Nippon-Denshi JES-3BS-X spectrometer with 100 KHz modulation.

The calculations of the electronic spectra of phenothiazinyl radicals were performed by means of the open-shell SCF method[6] with limited CI. The two-center Coulomb integrals were evaluated by means of the Nishimoto-Mataga formula, and the core-resonance integrals by means of the variable β-core method. The CI calculations were done including 24 singly-excited configurations composed of $(i\rightarrow k)_\alpha$, $(i\rightarrow k)_\beta$, $(i\rightarrow m)$, and $(m\rightarrow k)$, where φ_m=half-occupied orbital; $i=m$-3, m-2, m-1, and $k=m+1$, $m+2$, $m+3$; the notations of $(i\rightarrow k)_\alpha$ and $(i\rightarrow k)_\beta$ were taken from Ref. 7.

Results and Discussion

As is shown in Fig. 1, new absorption maxima appear at 462 and 615 nm upon the chemical oxidation of phenothiazine. The longer-wavelength band has a shoulder near 645 nm. The λ_{nm}^{max} values for 1-methylphenothiazine were 464 and 610 nm. The absorption curve changes in the wavelength region shorter than 400 nm had to be excluded on account of the largely overshadowing absorption of the parent molecules. These solutions exhibited the strong ESR spectra due to the corresponding neutral radicals. The ESR spectrum of the 1-methylsubstituted radical shown in Fig. 2 is reported for the first time here. Though not completely resolved, the spectrum could be analyzed with $a^N=7.0$—7.2, $a_{3,7}^H=3.5$, $a_9^H=2.2$—2.5, and $a_{2,8}^H=0.7$—0.9 gauss. These values are not very different from the values for the non-substituted radicals.[2,4] On the other hand, only a weak absorption with λ_{nm}^{max} ~470 nm appeared upon the chemical oxidation of 1-methoxyphenothiazine, and a weak ESR signal was observed only after the temperature had been lowered to −30°C.

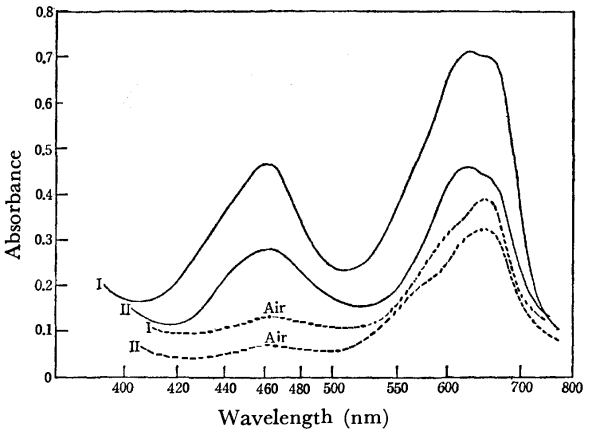

Fig. 1. The electronic spectra observed at the formation of phenothiazinyl radicals in a degassed DMSO+Ac_2O solution. (I) non-substituted and (II) 1-methyl-substituted phenothiazines.

After the exposure of the solutions to air, the absorbance of the longer-wavelength peak showed considerable values even when no ESR spectrum of the radicals could be detected clearly. At this stage, the location of the λ_{nm}^{max} of the longer-wavelength band shifted to 640—645 nm, just in the region where a shoulder had been observed in the initial spectrum. The solutions which were exposed to air until the ESR spectrum could not be detected were submitted to thin-layer chromatography using petroleum ether–ether (2 : 1) as the developing solvent. The 1,10′- and 3,10′-dimers of phenothiazine were detected by

$\beta_{C-C}=-0.51\,P_{C-C}-1.84$, $\beta_{C-N}=-0.53\,P_{C-N}-2.02$, $\beta_{C-S}=-0.33\,P_{C-S}-1.80$, $\beta_{C-H_3}=-4.111$.

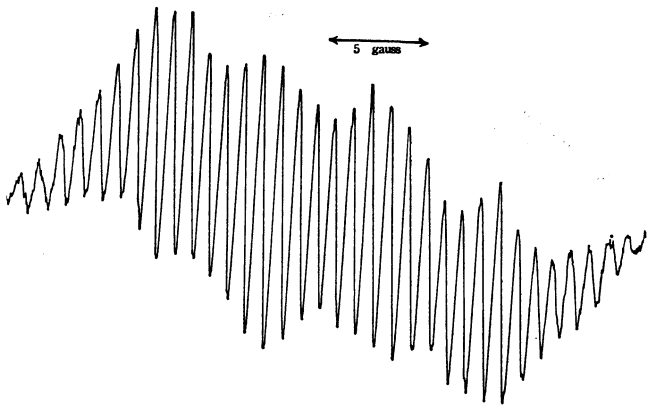

Fig. 2. The ESR spectrum of 1-methylphenothiazinyl radical produced in DMSO+AC_2O at room temperature.

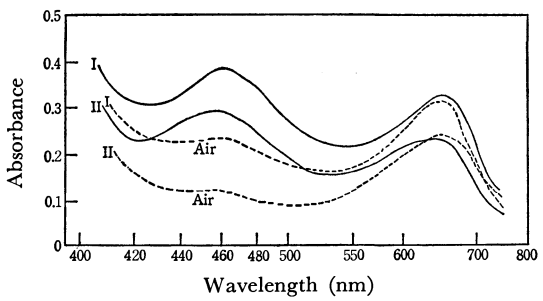

Fig. 3. The electronic spectra observed at the formation of phenothiazinyl radicals in a photoirradiated ethanol solution. (I) non-substituted and (II) 1-methyl-substituted phenothiazines.

means of the spots with R_f=0.8—0.9 and 0.4—0.5 respectively, in accordance with the findings of Tsujino.[8] The 3,10'-dimer of 1-methylphenothiazine was also detected with the spot, R_f=0.3—0.4. The spots, R_f=0.0—0.2, which are probably related to the polymerized by-products, were also found in the two systems. These results serve to correlate the 640—645 nm absorption with the radical-decay products.

In the photochemical oxidations, the λ_{nm}^{max} values of the new absorption maxima are 459 and 650 nm for the phenothiazine solution, and 462 and 653 nm for the 1-methylphenothiazine solution. When these solutions were exposed to air until the ESR signal could not be detected, the longer-wavelength bands alone retained considerable values of absorbance. According to the results of the adopted method of irradiation using an Ushio XS-501A xenon lamp, the changes in the absorption spectrum of the 1-methoxyphenothiazine solution took place very slowly, to the extent that a weak absorption maximum around 650 nm was found after 15 hr's irradiation.

The calculated data of the electronic spectra indicate the existence of weak transitions below 2 eV which might be masked by the strong absorptions of the radical-decay products. This trend appears to be promoted remarkably by the CI calculation. The calculated data both with and without CI suggest that moderately intense transitions of the neutral radicals exist in the region of the shorter-wavelength bands which are observed upon the radical formations.

The authors wish to thank Mr. Takeshi Akiyama for his co-operation in making the spectroscopic measurements. Thanks are also due to Dr. Michiya Itoh of the University of Tokyo and Dr. Fumihiko Hirota of Shizuoka University for useful guidance and discussion.

2,2-Dimethyl[7](2,6)pyridinophane and the Flipping of Its Heptamethylene Chain

Shinsaku FUJITA, Kazuo IMAMURA, and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Sakyo-ku, Kyoto 606

(Received October 20, 1972)

The NMR spectra of heterophanes give useful information on the stereochemistry of the polymethylene chains incorporated.[1-8] The present report will deal with two 2,2-dimethyl derivatives of [7](2,6)pyridinophane (I).

The methylation of [7](2,6)pyridinophan-1-one (II) with potassium *t*-butoxide and methyl iodide gave 2,2-dimethyl[7](2,6)pyridinophan-1-one (III), the Huang Minlon reduction of which then afforded 2,2-dimethyl-[7](2,6)pyridinophane (IV).

At room temperature, the NMR spectrum of IV (Fig. 1) showed the singlet signal of 1-methylene at δ 2.58 and the singlet signal of *gem*-dimethyl at δ 0.84. The two-proton multiplet centered at δ 0.01 was assigned to the C-4 protons by analogy with [7]-(2,6)pyridinophane (I) itself.[5] In the most reasonable crown-type conformation (V) for IV, one proton (H_x) on C-4 was forced into the π-cloud and should be subject to anisotropic shielding due to the pyridine ring. At low temperatures (−87.5 °C and −111 °C), the two methyl groups, finding themselves in different environments, showed two broad singlets, at δ 1.04 and δ 0.56 respectively (Fig. 1). The AB spin system of 1-methylene showed an average singlet peak at room temperature, but a typical AB quartet at low temperatures. The C-4 protons were also found to exhibit a one-proton signal at δ −1.44.

These facts indicated that the conformation of IV was frozen to the extreme conformer (V) at low temperatures. The estimated energy barriers ($\Delta G_c^{\ddagger}$) for the conformational change (V⇄V′) are shown in Table 1, as well as the coalescence temperature (T_c). The NMR spectra of the ketone (III) was also temperature-dependent. The signal of the methyl groups appeared as a singlet (δ 1.21) at room temperature, broadened at the coalescence temperature (−61.0 °C) and then reappeared as two broad singlets (δ 1.26 and δ 1.06) at −94.0 °C). The estimated $\Delta G^{\ddagger}_c$ value is shown in Table 1.

Experimental

2,2-Dimethyl[7](2,6)pyridinophan-1-one (III). A solution of [7](2,6)pyridinophan-1-one (II) (567 mg, 3.0 mmol)[5] in *t*-butyl alcohol (5 ml) was added to a solution (10 ml) of potassium *t*-butoxide (from 4.0 g of potassium). The mixture was heated under reflux for 1 hr. After cooling, methyl iodide (10 ml) was added in one portion, and then the mixture was heated at reflux for 19 hr. The reaction mixture was poured into water and extracted with ether. The combined ethereal extracts were dried over sodium sulfate and concentrated *in vacuo*. The concentrate was methylated once more with potassium *t*-butoxide (from 3.0 g of potassium) and methyl iodide (10 ml). The crude product was distilled, giving III as a colorless oil (441 mg, 68%); bp 77 °C/0.07 mmHg. IR (neat): 3075, 2960, 2927, 2875, 1679, 1590, 1574, 1474, 1458, 1440, 1379, 1354, 1322, 1298, 1245, 1208, 1147, 1070, 1020, 999, 911, 863, 819, 775, 752, 739, 664 cm^{-1}. a) The dynamic NMR spectra were determined on a JEOL C-60-H spectrometer at 60 MHz, using $CFCl_3$ as the solvent and tetramethylsilane as the internal standard. See Fig. 1. b) $\Delta G^{\neq}{}_c = 2.303RT_c(10.319 - \log k_c + \log T_c)$ (Ref. 9).
c) Determined at −111 °C. d) $k_c = \pi\Delta\nu/\sqrt{2}$ (Ref. 9). e) $k_c = \pi\sqrt{\Delta\nu^2 + 6J_{AB}{}^2}/\sqrt{2}$ (Ref. 9).
f) As the signal of the low-field counterpart of the C-4 protons was concealed behind those of other methylenes, the $\Delta\nu$ value was estimated on the basis of the average chemical shift at room temperature and of the high-field shift at a low temperature.
g) Reported in Ref. 5. h) Determined at −111 °C. i) Determined at −94.0 °C.

Found: C, 77.5; H, 8.7; N, 6.2%. Calcd for $C_{14}H_{19}NO$: C, 77.4; H, 8.8; N, 6.5%.

2,2-Dimethyl[7](2,6)pyridinophane (IV). To a solution of potassium hydroxide (127 mg, 2.3 mmol) in triethylene glycol (5 ml), were added the ketone (III) (160 mg, 0.74 mmol) and hydrazine hydrate (80%, 0.5 ml). The mixture was heated under nitrogen at a reflux temperature for 2 hr. An additional portion of hydrazine hydrate (0.1 ml) was added during this period. The bath temperature was raised to 230 °C, and the excess hydrazine and water were distilled off over a 3-hr period. After the solution had been cooled, water was added to the mixture and the product was extracted with *n*-hexane. The combined extracts were dried over sodium sulfate. Concentration and distillation afforded the 2,2-dimethyl derivative (IV) (50 mg, 33%); bp 49°C/0.2 mmHg. IR (neat): 3070, 2955, 2930, 2870, 1590, 1579, 1459, 1383, 1362, 1325, 1239, 1138, 1086, 994, 862, 810, 798, 755, 747, 729, 710 cm^{-1}. MS *m/e* (relative abundance): 203 (38), 202 (17), 188 (34), 161 (13), 160 (18), 149 (15), 147 (44), 146 (18), 134 (11), 121 (23), 120 (80), 108 (10), 107 (100), 106 (19), 77 (14), 41 (18). UV $\lambda_{max}^{n\text{-hexane}}$ 214 (3.94), 269.5 (3.34).

Found: C, 82.6; H, 10.5; N, 6.8%. Calcd for $C_{14}H_{21}N$: C, 82.7; H, 10.4; N, 6.9%.

A Temperature-jump Study of the Kinetics of the Complex Formation of Iron(III) with *m*-Nitrophenol

Kiyoshi TAMURA

Department of Chemistry, Defense Academy, Yokosuka 239

(Received December 7, 1972)

By a new method here proposed, an expression of the relaxation time has been obtained for the formation of the monocomplex of iron(III) with a univalent anionic ligand. The method enables us to express the rate equation in a manner analogous to the second-order reaction, and to calculate the relaxation time with less mathematical labor. The validity of the treatment has been confirmed by applying it to the analysis of the complex formation reaction of iron(III) with *m*-nitrophenol. The kinetic measurement was performed with the temperature-jump method in an acidic aqueous solution at 25 °C and at an ionic strength of 0.10. Over the acidity range studied ($0.005 \leqq [H^+] \leqq 0.026$ M), the complex formation occurs significantly *via* one path: $FeOH^{2+} + m\text{-}NO_2C_6H_4OH \rightleftharpoons m\text{-}NO_2C_6H_4OFe^{2+} + H_2O$. The forward and backward rate constants obtained are $5.9 \times 10^2\ M^{-1}\ s^{-1}$ and $1.8 \times 10^2\ s^{-1}$ respectively. These results have been confirmed by examining the earlier kinetic data on similar reactions.

The reactions of iron(III) complexes in aqueous solutions have been the object of much recent interest[1-3] because of the apparent dependence of the formation rates of the complexes on the basicity of the entering ligand; no such dependence is shown by the bivalent transition or by most alkaline earth metal ions, where the rate-determining step is considered to be the removal of a water molecule from the inner coordination sphere of the cation. The apparent ligand specificity has been almost entirely removed by the general reaction mechanism proposed by Seewald and Sutin[4] and later developed by Cavasino and his co-workers.[5] Also, kinetic studies[4-10] have shown that the reaction mechanism interprets well the rates of the formation of iron(III) complexes with anionic ligands of a wide range of basicity.

Recently, Osugi, *et al.*[11] studied the complex formation of iron(III) with *p*-nitrophenol, which is an anionic ligand of a very high basicity. Soon after, Cavasino and Dio[12] also investigated similar reactions with some monosubstituted phenols. However, there was some inconformity concerning the reaction paths reported by these authors, and little kinetic information has been given elsewhere on complex formation with such ligands of a very high basicity.

The reactions of iron(III) with high-basicity ligands may be important as an extreme example of the reaction mechanism, and so more detailed investigations are required. In the present investigation, the complex formation of iron(III) was studied, with *m*-nitrophenol as the ligand. The kinetic measurement was carried out by the temperature-jump relaxation method. The present author has also proposed a new method of analysis for calculating the relaxation time with less mathematical labor; this method was elucidated in the course of this investigation.

Experimental

Materials. All of the chemicals used were of a reagent grade. Each sample solution was prepared by mixing appropriate ammounts of solutions of 0.05 M $Fe(NO_3)_3$, 0.1 M $m\text{-}NO_2C_6H_4OH$, and 0.1 M $HClO_4$, by then adjusting the ionic strength to 0.10 by the addition of KNO_3, and finally by diluting to a definite volume. The content of iron(III) in the ferric nitrate solution was determined by complexometric titration with disodium EDTA,[13] and the concentration of the acid solution was standardized with sodium hydroxide.

Temperature-jump Apparatus. The temperature-jump apparatus was a modification of those described by Hammes and Fasella[14] and by Kresheck *et al.*[15] It was operated by a single-beam optical system. A schematic diagram and the construction of the observation cell are shown in Figs. 1 and 2 respectively. The cell is constructed from an acrylresin disk 2 cm thick, through the center of which a hole 1 cm square has been bored. The solution chamber consists of the hole and the gold-coated walls of the brass electrodes, and accommodates 2 cm^3 of the solution. Two quartz windows enable optical observation through the solution, with a path of 1 cm. The temperature of the solution is controlled within ± 0.2 °C by circulating thermostated ethanol through the hollow electrodes.

A 0.4 μF condenser bank charged to 16 kV was discharged through the cell by means of an air gap. The temperature jump of the solution was 5 ± 0.5 °C, as determined by the change in the absorbance (at 550 mμ) of a phenolphthalein

solution. The indicator solution used contained 6×10^{-8} M phenolphthalein and 0.02 M glycine; the pH and the ionic strength were 9.5 and 0.10 (with KNO_3) respectively. The relaxation time of the heating period was 40 μs at this ionic strength.

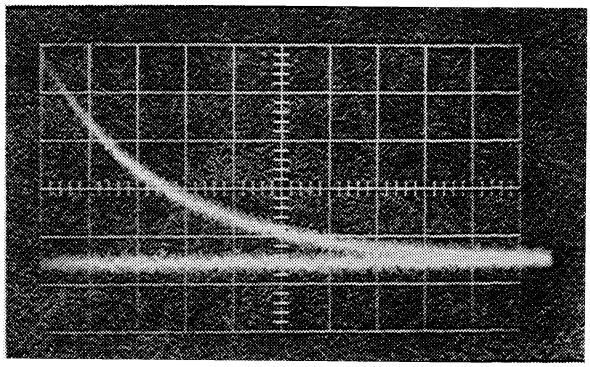

Fig. 3. An oscillograph of the temperature-jump relaxation experiment for iron(III) with *m*-nitrophenol. The data for this system are given in the last raw of Table 1. The sweep rate is 2 ms per division. The upper curve shows the relaxation effect corresponding to an increase in absorbance. The lower straight-line is the following trace of this curve after the intermittent time of 20 ms, showing an attainment of the transient equilibrium.

Results

The temperature-jump measurement was carried out at the wavelength of 508 mμ, where the *m*-NO_2-$C_6H_4OFe^{2+}$ ion exhibits the maximum absorbance.[16] All the solutions cited in Table 1 showed a single relaxation effect in the time range of 2×10^{-4}—0.05 s; this effect may be associated with the complex formation reaction. A second, smaller effect was also observed in the time range longer than this; the relaxation time was very roughly estimated not to be smaller than 0.4 s. The second relaxation effect did not interfere with the evaluation of the relaxation time related to the complexation. Blank solutions containing only ferric nitrate or *m*-nitrophenol at the same conditions of concentration, ionic strength, and pH had not shown any evidence of relaxation effect in the same time ranges. Moreover, there was no discernible kinetic difference between the sample solutions after several hours had elapsed and a few months had, after preparation. A representative relaxation effect of the complex formation is shown in Fig. 3.

16) Z. L. Ernst and F. G. Herring, *Trans. Faraday Soc.*, **61**, 454 (1965).

The reciprocal relaxation time (τ^{-1}) was evaluated by the plot of the logarithm of the oscilloscope amplitude *vs.* the time. Here, the least-squares method was employed to obtain the most probable value. All the relaxation times quoted in Table 1 are means of at least five runs; the maximum error is about ±10%.

The pH of each solution was measured at 25±0.5 °C with a Hitachi-Horiba pH meter, Model F-7SS, calibrated with standard buffer solutions. The equilibrium hydrogen-ion concentrations were calculated from the measured pH values by using the activity coefficient (0.825)[17]; they are also shown in Table 1. The hydrogen-ion concentration thus obtained agreed within ±3% with that which was evaluated from the stoichiometric concentration of perchloric acid by taking into account the reaction equilibria, (3), (4), and (5).

Discussion

Potentiometric[18] and spectrophotometric[19–23] studies have shown that the following equilibria exist in an aqueous acid solution containing ferric ions with m-nitrophenol:

$$HA \rightleftharpoons A^- + H^+ \qquad K_H \qquad (1)$$

$$Fe^{3+} + A^- \rightleftharpoons FeA^{2+} \qquad K_c \qquad (2)$$

$$Fe^{3+} + HA \rightleftharpoons FeA^{2+} + H^+ \qquad K_b \qquad (3)$$

$$Fe^{3+} + H_2O \rightleftharpoons FeOH^{2+} + H^+ \qquad K_{OH} \qquad (4)$$

$$2\,FeOH^{2+} \rightleftharpoons Fe_2(OH)_2^{4+} \qquad K_d \qquad (5)$$

where HA indicates m-$NO_2C_6H_4OH$ and where K_H, K_c, K_b ($=K_HK_c$), K_{OH}, and K_d are the equilibrium constants for the corresponding reactions. Here, the presence of $Fe(OH)_2^+$ may be ignored.[24,25] Reaction (5) occurs so slowly that it may contribute little to the complex formation kinetics; for the present conditions, the reported rate constants[26,27] give $\tau \geqq 0.4$ s, which corresponds with the second relaxation time observed.

With these hypotheses, the overall mechanism for the formation of the FeA^{2+} complex may be expressed in a general form:[5,6,9]

$$\begin{array}{ccc} Fe^{3+} + A^- + H^+ & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & \\ \Big\downarrow\uparrow K_H & & \\ Fe^{3+} + HA & \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} & FeA^{2+} + H^+ \\ \Big\downarrow\uparrow K_{OH} & & \Big\downarrow\uparrow K_x \\ FeOH^{2+} + HA + H^+ & \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} & Fe(OH)A^+ + 2\,H^+ \\ \Big\downarrow\uparrow K_H & & \\ FeOH^{2+} + A^- + 2\,H^+ & \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} & \end{array} \qquad (6)$$

where the water molecule was omitted from the reactions for the sake of simplicity. The protolytic reactions (vertical steps) occur rapidly relative to the complex formation reactions, and are considered to be in equilibria throughout the course of the complex formation. Hence, only one relaxation time, associated with slower metal-complex formation reactions, can be obtained from the reaction scheme; the solution has already been given by Cavasino and his co-workers.[5,6,9] However, the present author will present here a different method of analysis, one which simplifies the rate equation and which makes it possible to calculate the relaxation time with less mathematical labor.

We notice the rapid protolytic reactions and express the overall free metal ions, free ligands, and metal-complexes by M, L, and ML, respectively, defining their concentrations as follows:

$$[M] \equiv [Fe^{3+}] + [FeOH^{2+}] \qquad (7)$$

$$[L] \equiv [A^-] + [HA] \qquad (8)$$

$$[ML] \equiv [FeA^{2+}] + [Fe(OH)A^+] \qquad (9)$$

with these conditions and definitions:

$$\alpha \equiv \frac{[Fe^{3+}]}{[M]} = \frac{[H^+]}{K_{OH}+[H^+]} \qquad (10)$$

$$\beta \equiv \frac{[A^-]}{[L]} = \frac{K_H}{K_H+[H^+]} \qquad (11)$$

$$\gamma \equiv \frac{[FeA^{2+}]}{[ML]} = \frac{[H^+]}{K_x+[H^+]} \qquad (12)$$

where K_x is the equilibrium constant of the hydrolysis of FeA^{2+}. Then, the rate equation is given by:

$$\frac{d[ML]}{dt} = k_f[M][L] - k_b[ML] = k_f\left([M][L] - \frac{[ML]}{K}\right) \qquad (13)$$

where:

$$k_f = k_1\alpha\beta + k_2\alpha(1-\beta) + k_3(1-\alpha)(1-\beta) + k_4(1-\alpha)\beta \qquad (14)$$

$$k_b = k_{-1}\gamma + k_{-2}\gamma[H^+] + k_{-3}(1-\gamma)[H^+] + k_{-4}(1-\gamma) \qquad (15)$$

$$K = \frac{k_f}{k_b} = K_c\left(\frac{\alpha\beta}{\gamma}\right) \qquad (16)$$

Here, k_f and k_b may be called the (apparent) overall forward and backward rate constants respectively.

By expanding Eq. (13) in the vicinity of the equilibrium concentrations and by using conservation relations:

$$\Delta[M] = \Delta[L] = -\Delta[ML] \qquad (17)$$

we obtain:

$$\frac{d\Delta[ML]}{dt} = -k_f\left([M]+[L]+\frac{1}{K}-\frac{[ML]}{K^2}\frac{\Delta K}{\Delta[ML]}\right)\Delta[ML] \qquad (18)$$

where the symbol Δ indicates the deviation from the equilibrium value. From Eq. (18), the relaxation time, τ, is given by:

$$\frac{1}{\tau} = k_f B \tag{19}$$

where:

$$B = [M] + [L] + \frac{1}{K} + \phi \tag{20}$$

and:

$$\phi \equiv -\frac{[ML]}{K^2}\frac{\Delta K}{\Delta[ML]} = \frac{(\alpha-\beta-\gamma+1)^2[M][L]}{[H^+]+\alpha(1-\alpha)[M]+\beta(1-\beta)[L]+\gamma(1-\gamma)[ML]} \tag{21}$$

The term ϕ results from the fact that K is a function of $[H^+]$, which varies rapidly following the slower complex formation reactions. The last form of Eq. (21) can readily be obtained from Eqs. (16), (10), (11), and (12) by using the condition of electroneutrality together with Eq. (17); here, the contribution of $[OH^-]$ has been ignored in the calculations. All the quantities in Eqs. (19), (20), and (21) are expressed by the equilibrium values, and the K defined in Eq. (16) reduces to the apparent equilibrium constant, or to what is called the "apparent stability constant": $K=[ML]/[M][L]$.

The evaluation of B from Eqs. (20) and (21) requires the values of [M], [L], [ML], α, β, and γ. In the present case, the hydrolysis constant, K_x, could, unfortunately, not be found in the literature. However, that of $FeSCN^{2+}$ has been reported to be $K_x=6.5\times10^{-5}$ at $\mu=1.2$ and 25 °C.[28] Moreover, the second hydrolysis constant of the ferric ion[24,25] may be regarded as the hydrolysis constant of the $FeOH^{2+}$ complex: $K_x=(0.8\text{—}2)\times10^{-5}$ at $\mu\approx0$ and 25 °C. As these complexes give similar K_x values in spite of the large difference between the basicities of the thiocyanate and hydroxide ions (*i.e.*, $pK_H=1$ and 16), the same order of magnitude may be assigned to the K_x value for the monocomplex of iron(III) with the univalent anionic ligand. Therefore, in the acidity range ($[H^+]=0.005\text{—}0.026$ M) of the present work, the condition of $K_x \ll [H^+]$, which is equivalent to that of $[Fe(OH)A^+] \ll [FeA^{2+}]$, may be satisfied, and we obtain $\gamma=1$ and $[ML]=[FeA^{2+}]$ by means of Eq. (12). This corresponds to the steady-state assumption for the concentration of $Fe(OH)A^+$ usually adopted.[5-12] Under the present acidity conditions, the concentration of the free phenolate ion, A^-, is much lower than that of the acid ligand, HA, as $pK_H=8$ for *m*-nitrophenol; $\beta\approx[A^-]/[HA]$ is in the range $10^{-6}\text{—}10^{-7}$. Therefore, we need only the $[Fe^{3+}]$, $[FeOH^{2+}]$, [HA], and $[FeA^{2+}]$ concentrations to evaluate B. These equilibrium concentrations were obtained from the total stoichiometric concentrations of iron(III) and *m*-nitrophenol, from the equilibrium hydrogen-ion concentration, in Table 1, and from the equilibrium constant, K_b, K_{OH}, and K_d.

Milburn and his co-workers[18-21] reported several values of K_b in the course of their potentiometric[18] and spectrophotometric[19-21] studies. Desai and Milburn[21] obtained, most recently, by their careful spectrophotometric measurements: $K_b=0.94\times10^{-2}$ at $\mu=0.10$ and 25 °C. As the somewhat larger values reported earlier[18-20] left moderately large uncertainties in the absolute values,[21] this value was adopted as the most reliable value available at present. The values of K_{OH} and K_d at $\mu=0.10$ and 25 °C were obtained from Milburn and Vosburgh's measurements[22]: $K_{OH}=2.89\times10^{-3}$ and $K_d=1.7\times10^2$.

The overall forward rate constant, k_f, was calculated by means of Eq. (19), using the $1/\tau$ value in Table 1 and the value of B. The results are also shown in Table 1. As could be expected from Eq. (14), the k_f value depends only on the hydrogen-ion concentration; it decreases with an increase in the hydrogen-ion concentration. From the present condition, $\beta\approx10^{-6}\text{—}10^{-7}$, together with the k_f value in Table 1, it seems that we may safely ignore the first and fourth terms in Eq. (14); if these terms contribute significantly to k_f, the k_1 and k_4 values should be greater than $10^6\ M^{-1}\ s^{-1}$, values such as have not been observed for other univalent anionic ligands.[4,5,8,9] Ignoring β with respect to 1 in the second and third terms in Eq. (14) and dividing by $(1-\alpha)$, we obtain:

$$\frac{k_f}{1-\alpha} = \frac{k_2[H^+]}{K_{OH}} + k_3 \tag{22}$$

As is shown in the last column of Table 1, the value of $k_f/(1-\alpha)$ is practically independent of the hydrogen-ion concentration; the deviations from the mean value are almost within the limits of the experimental errors in τ (*ca.* $\pm10\%$). Therefore, the first term of Eq. (22) may be ignored, and the k_3 value is determined to be $(5.9\pm0.6)\times10^2\ M^{-1}\ s^{-1}$.

By inserting the approximate relations $k_f=k_3(1-\alpha)$, $\gamma=1$, and $\beta=K_H/[H^+]$ into Eq. (16), and by using the equilibrium relations of $K_HK_c=K_b$ and $k_3/k_{-3}=K_xK_b/K_{OH}$, we obtain:

$$k_b = \frac{k_3 K_{OH}}{K_b} = k_{-3} K_x \tag{23}$$

The last form of Eq. (23) corresponds to the third term of Eq. (15). From the second form of Eq. (23), the k_b value was obtained as $(1.8\pm0.2)\times10^2\ s^{-1}$.

From the above results, the following reaction path may be said to contribute mainly to the rate of the complex formation:

$$FeOH^{2+} + HA \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} Fe(OH)A^+ + H^+ \underset{K_x}{\rightleftharpoons} FeA^{2+} + H_2O \tag{24}$$

where the forward and backward rate constants correspond to k_3 and k_b respectively.

For the monocomplex formation of iron(III) with substituted phenols, earlier kinetic studies have been made by Osugi *et al.*[11] and by Cavasino and Dio[12] with temperature-jump measurements at $\mu=0.10$ and at 25 °C. With *p*-nitrophenol as the ligand, the former

28) M. W. Lister and D. E. Rivington, *Can. J. Chem.*, **33**, 1572 (1955).

authors[11] obtained the same reaction path as (24), showing a considerable contribution of the reaction path involving the rate constant, k_2. On the other hand, the latter authors[12] found the sole effective reaction path to be (24), with some monosubstituted phenols. The above authors[11,12] reported k_3 values over the range of $(1.1—3.2)\times10^3$ M^{-1} s^{-1}; these values are two times or more larger than the present value. However, the k_3 values of the above authors[11,12] may require some corrections, for they used in their calculations Milburn[20] or Ernst and Herring[12] K_b values, which are, except for the case of (unsubstituted) phenol, somewhat larger than those of Desai and Milburn,[21] whose value was adopted in this study as the most recent and reliable value. According to Cavasino and Dio's approximation,[12] the k_3 value is almost proportionally affected by the K_b value used: $k_3 \approx K_b/(K_{OH}\tau)$.

The kinetic data of the above authors[11,12] were then re-examined by using Desai and Milburn's K_b values and by using the present method of calculation. All the data examined, including that of Osugi *et al.*, did not show any significant contribution of the rate constant, k_2, to the complex formation rates. The value, $k_2=32$ M^{-1} s^{-1}, reported by Osugi *et al.*[11] may result mainly from their method of estimation, which overweighes the data in the low-acidity region. The above results confirm again the present conclusion of the sole reaction path (24). The k_3 values in Table 2 are those

Table 2. Kinetic data for the formation of iron(III) monocomplexes with substituted phenols at $\mu=0.10$ and 25 °C

estimated by the present author, except that for m-cresol, which is the original value.[12] The K_b values used for the calculation and the pK_H values for the ligand are also shown in the same table. As has been expected, the k_3 values re-estimated are all smaller than the original ones, except for the case of phenol, which gives the same value as the original one.[12] These values conform well with the present author's value.

We notice further that the k_3 values in Table 2 lie in a comparatively narrow range, $(3.5—16)\times10^2$ M^{-1} s^{-1}, in spite of the different nature and position of the substituent groups in the aromatic ring and the different basicity of the entering ligand ($pK_H=7—10$). As has been pointed out by Cavasino and Dio,[12] this suggests that the first step of reaction path (24) may proceed through the S_N1 mechanism, which involves the loss of a water molecule in the rate-determining step. However, the k_3 values in Table 2 are somewhat smaller than those reported in the earlier kinetic studies[4,5,9,10] for the corresponding reactions with HN_3,[4,5] HF,[4,5] CH_3CO_2H,[9] $ClCH_2CO_2H$,[9] $C_2H_5CO_2H$,[9] and $C_6H_5CH(OH)CO_2H$[10]: $k_3=(2.56—7.4)\times10^3$ M^{-1} s^{-1} at 20—25 °C and at $\mu=0.1—1.0$. A full explanation must await further investigations.

As is shown in Eqs. (7)—(21), the present method of analysis is mathematically simpler and more suggestive than the treatments of the previous investigators.[3,5,6,8,9,11,12] However, except for the different definitions of k_f and B, the present expression of the relaxation time, Eq. (19), is essentially equivalent to that of Cavasino and his co-workers[5,6,9] (with $\gamma=1$), and also to that of Osugi *et al.*[11] (with $\gamma=1$ and $\beta=0$). The apparent forward rate constant (usually designated as k_f or k_{obs}) differs from author to author, simply because they select different reactions as representative in the reaction scheme. Cavasino and his co-workers[5,9] took the reaction involving Fe^{3+} with A^- as representative; the k_{obs} used by them corresponds to the $k_f/\alpha\beta$ in the present expression, which exhibits a much higher order of magnitude with such ligands of a very high basicity as phenols.[12] Osugi *et al.*[11] selected the reaction of Fe^{3+} with HA as representative; the k_f used by them is equivalent to the k_f/α (with $\beta=0$) in the present study.

The k_f defined by Eq. (14) has a more general form, without taking any definite reaction as representative, and may give the value of the moderate magnitude with a ligand of a wide range of basicity. From the reasons above, the present author considered it appropriate as an (apparent) overall forward rate constant of complexation. A similar treatment has been given by Hammes and Schimmel,[29,30] but they ignored the term corresponding to ϕ in Eq. (20) and so their expression may be applicable only to strongly buffered reaction systems.[30] The present treatment may be easily extended to the analysis of more complicated reactions, such as protonated complex formation reactions.

Through this investigation, the present author considered that the validity of the present method of analysis may be well confirmed, and also that the functioning of the newly built temperature-jump apparatus was satisfactory.

The Adiabatic Compressibility of Nonelectrolyte Aqueous Solutions in Relation to the Structures of Water and Solutions. II.

Harumi ENDO

Department of Applied Physics, Defense Academy, Yokosuka 239

(Received September 16, 1972)

From the temperature dependency of the adiabatic compressibility in aqueous systems of nonelectrolytes, established by ultrasonic measurements, it is concluded that structural units to be termed "liquid clathrate hydrates" do exist for various systems, the concentration of the zero temperature coefficient of adiabatic compressibility representing the composition-mole-ratio, r_c^β(water/solute), for these hydrates. Hydrates with r_c^β= 7.2/3 (for methanol, formamide, and urea) and 17 (for acetone and ethanol) correspond to the solid clathrate hydrates of Structures I and II respectively, while those with r_c^β=24, 28, 32, *etc*, can be explained on the basis of appropriate assumptions.

In the previous paper,[1] the sound velocity (V) and density (ρ) in aqueous solutions of urea (U), dimethylurea (DMU), thiourea (TU), acetamide (AA), acetone (A), and dimethylformamide (DMF) were measured, and the adiabatic compressibility (β) of solutions was calculated at various concentrations (μ: mole fraction) by means of the relation: $\beta = 1/(\rho \cdot V^2)$. In that paper, it was found that, for each system, the V–μ curves and β–μ curves for various temperatures have a common intersection at the fixed concentrations of μ_c^V and μ_c^β respectively, the sound velocity (V_c) and adiabatic compressibility (β_c) of a solution at these concentrations being independent of the temperature over a certain range (ΔT_c^V and ΔT_c^β respectively). In the cases of aqueous solutions of A and ethanol (Et), the mole ratio r_c^V=(water/solute) at μ_c^β was equal to the number of water molecules in the framework of the solid clathrate hydrate (Structure II type). Therefore, we assumed that the structure of this type also exists in solutions, and named this structure "liquid clathrate hydrate". From these results, it may be expected that, for solutions other than A and Et, the value of r_c^β also corresponds to the number of water molecules of a liquid clathrate hydrate of another type characteristic of the respective solutes.

In the present study, the adiabatic compressibility of aqueous solutions of diethylurea (DEU), formamide (F), dimethylacetamide (DMAA), and diethylacetamide (DEAA) will be determined over the temperature range from 20 to 50 °C, and over that of hexamethylenetetramine (HMT) from 22 to 50 °C, by measuring the densities and the sound velocities of the solutions.

As in the previous paper,[1] the parameters, V_c, β_c, ΔT_c^V, ΔT_c^β, μ_c^V, and μ_c^β, are determined for these systems in order to examine their relation with the liquid structure. Two other parameters, v_c^V (volume fraction for 20 °C at μ_c^V) and v_c^β (volume fraction for 20 °C at μ_c^β), are introduced. On the basis of a model of the liquid clathrate hydrate, the properties and the dissolved states of a solute in water are discussed by means of the β_c—r_c^β relationships for various systems.

Experimental

Materials. The DEU and HMT were purified by the recrystallization of reagent-grade products from absolute alcohol. To purify F, DMAA, and DEAA, the reagent-grade products are distilled twice under reduced pressure before use.

Apparatus. A crystal-controlled ultrasonic interferometer operating at a frequency of 5 MHz is used to measure the standing waves. The measuring cell containing a solution is immersed in an oil bath, the temperature of which is kept constant within ±0.1 °C.

Results

In Figs. 1—5, the sound velocity is plotted against the mole fraction for aqueous solutions of DEU, F, DMAA, and DEAA respectively over the temperature range of ΔT=20—50 °C and HMT over the range of ΔT=22—50 °C. All of the V–μ curves (Figs. 1—5) within a certain temperature range (ΔT_c^V) have a common intersection at a fixed concentration (μ_c^V). Although this temperature range (ΔT_c^V) is usually narrow (*ca.* 15—20 °C), this intersection is clearly discernible. The values of V_c, ΔT_c^V, and μ_c^V for the various aqueous systems here investigated are summarized in Table 1, together with the previous results[1] and a few data found in the literature.[2-6]

Figures 6—10 show the β–μ curves for aqueous solutions of DEU, F, DMAA, and DEAA respectively over the observed temperature range from 20 to 50 °C and HMT over the range of ΔT=22—50 °C. The β–μ curves for a certain temperature range also intersect at a common point. The numerical values of μ_c^β are slightly different from those of μ_c^V, while the temperature range, ΔT_c^β, is nearly the same as ΔT_c^V. The β_c, ΔT_c^β, and μ_c^β values at the converging point in the β–μ curves are summarized in Table 2. Table 2 also contains the data of the previous study[1] and those taken from other authors.[2-6]

In Fig. 11, V_c is plotted against the mole ratio r_c^V=(water/solute) at μ_c^V for various solutes. This plot shows that r_c^V shifts to a higher value with an increase in the molecular weight of solutes, but no clear

relationship is found between V_c and r_c^V, even among the items of the homolog series.

In Fig. 12, V_c is plotted against the volume fraction (v_c^V) at 20°C at μ_c^V. According to this plot, however, the points for AA, A, Me (methanol), and F markedly deviate from the plotted curve, the latter three having nearly the same sound velocity. Each of them, other than A, is the lowest-molecular-weight substance in the homolog.

It is possible that the smooth curve can be subdivided into two straight lines meeting at (1630 m/s, 21.0 vol %). One group consists of the U-homolog series, HMT, and G, for which:

$$V_c = 403\, v_c^V + 1547 \text{ (m/s)} \quad (v_c^V \text{ in volume fraction})$$

while the other consists of the F-, AA-, and alcohol-homolog series, except for the lowest-molecular-weight substances in each homolog, for which:

$$V_c = 1143\, v_c^V + 1390 \text{ (m/s)}$$

In Fig. 13, β_c is plotted against r_c^β for various solutes. According to this plot, the homolog series may be classified into two groups. The first group is that of the AA-homolog series, for which an approximately linear relationship between β_c and r_c^β holds:

$$\beta_c = (0.0225\, r_c^\beta + 38.7) \times 10^{-12} \text{ (cm²/dyn)}$$

The second group is that of another homolog series, for which the β_c—r_c^β curves are not linear.

In Fig. 14, β_c is plotted against v_c^β, the volume fraction at 20 °C at μ_c^β, instead of at r_c^β. According to this plot, in a manner similar to that in the case of V_c—v_c^V plot, the solutes studied fall on a smooth curve independent of the sort of solute. Here also, as in the case of the V_c—v_c^V plot, the points for AA, A, Me and F deviate from a smooth curve, these solutes,

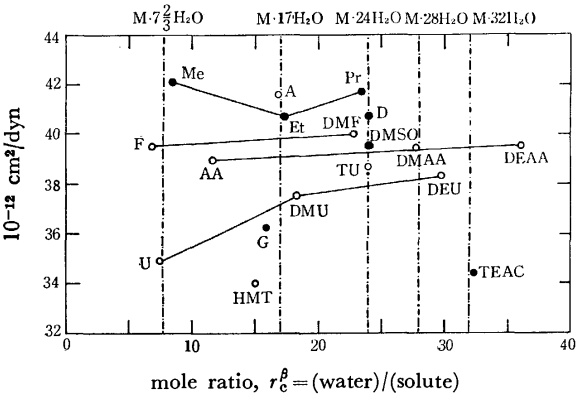

Fig. 13. β_c *vs.* r_c^β for various solutes.
○: present study, ●: others, ——: homolog series.

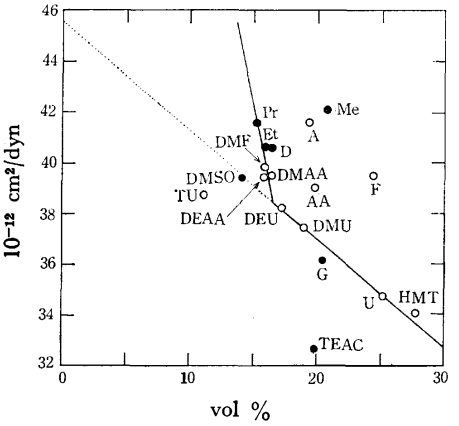

Fig. 14. β_c *vs.* v_c^β (vol % at 20°C) for various solutes.
○: present study, ●: otheres.

other than A, being the lowest-molecular-weight substances in each homolog. The plots in Fig. 14 may be divided into three groups. The first group is the U-homolog series, HMT, dimethyl sulfoxide (DMSO), glycerin (G), *etc.* The second group is the F-, AA-, and alcohol-homolog series, except the lowest-molecular-weight substances in each homolog, and dioxane (D). The third group is the remaining substances (the lowest-molecular-weight substance in each homolog and A).

In the first group, a plot of β_c against v_c^β gives a straight line:

$$\beta_c = (45.6 - 42.7\, v_c^\beta) \times 10^{-12} \text{ (cm²/dyn)} \quad (1)$$

where 45.6×10^{-12} cm²/dyn is the compressibility of water at 20 °C. The second group corresponds to the following equation:

$$\beta_c = (77.5 - 236.7\, v_c^\beta) \times 10^{-12} \text{ (cm²/dyn)} \quad (2)$$

Here, the range of v_c^β is given by $(0.135 \leqq v_c^\beta \leqq 0.165)$. The two straight lines (1) and (2) meet at a point of (38.5×10^{-12} cm²/dyn, 16.5 vol%). In the third group, however, no such relationship exists between β_c and v_c^β.

Discussion and Considerations

The X-ray diffraction studies of liquid water suggest that the water has long-range ordered structure.

The framework of the structure in liquid water consists of a hexagonal ice-I structure with numerous cavities, which can accommodate another species of water, the non-hydrogen-bonded water.

The compressibility (β) of liquid water consists of two parts:

$$\beta = \beta_\infty + \beta_{st} \tag{3}$$

where β_∞ is the instantaneous compressibility due to the compression of the molecules and the intermolecular distance, and where β_{st} is the structural compressibility due to the breakdown of intermolecular bonds accompanying the destruction of the open structure. Therefore, the temperature derivatives of β in aqueous solution are given by:

$$\frac{d\beta}{dT} = \frac{d\beta_\infty}{dT} + \frac{d\beta_{st}}{dT} \tag{4}$$

It may be assumed that Eq. (3) is also applicable to nonelectrolyte aqueous solutions. Also, it may be assumed that the number of clusters of water molecules does not change appreciably up to μ_c^β, the solute molecules being all accommodated in water-clusters. The instantaneous compressibility, β_∞, consists of two parts, one due to the instantaneous compression of clusters and the other due to the compression of the intercluster distance. The former does not change appreciably because the elasticity of the cluster is mainly caused by the framework, the cavity-site water molecules, and the solute molecules adopted in water-clusters not contributing to the elasticity. Also, the latter does not change up to μ_c^β, because the number of clusters does not change up to μ_c^β: there are no free solute molecules, either. Therefore, it may be concluded that β_∞ is quite constant and that $d\beta_\infty/dT = 0$ up to μ_c^β. This solution model, accommodating all the solute molecules in water-clusters up to a certain concentration, is presumably consistent also with the partial molal volume data. It has been reported that the value of the partial molal volume of water in ethanol solution[7] is independent of the concentration up to about 10-mol% Et, nearly corresponding to our, μ_c^β, while the partial molal volume of Et diminishes up to this concentration, and then increases again. For higher concentrations, $\mu > \mu_c^\beta$, it may be assumed that the increase in the number of solute molecules accompanies the increase in the number of clusters, this decreasing β_{st} and increasing β_∞. On the basis of this model we obtain Table 3 showing the temperature derivatives of β_∞ and β_{st} for various concentration ranges. In the aqueous solutions at μ_c^β within ΔT_c^β, it can be seen from Figs. 6—10 that $d\beta/dT = 0$. As it is assumed that $d\beta_\infty/dT = 0$ for $\mu \leqq \mu_c^\beta$, it follows that $d\beta_{st}/dT = 0$ at $\mu = \mu_c^\beta$. It follows that $d\beta_{st}/dT = 0$ for $\mu > \mu_c^\beta$ also, because $\beta_{st} \fallingdotseq 0$ for this concentration range, according to our model. Therefore, it may be concluded that the structure of a solution at the crossing concentration for the β–μ curves consists of repeat-units with a mole ratio of r_c^β, which may be termed "liquid clathrate hydrate". The repeat-unit, presumably being a caga-like structure, may be similar to the solid clathrate hydrate known for a few solutes.

TABLE 3. THE CONCENTRATION DEPENDENCE OF TEMPERATURE DERIVATIVES OF ADIABATIC COMPRESSIBILITY IN AQUEOUS SOLUTIONS

Concentration	Model		Experimental
	$\frac{d\beta_\infty}{dT}$	$\frac{d\beta_{st}}{dT}$	$\frac{d\beta}{dT} = \frac{d\beta_\infty}{dT} + \frac{d\beta_{st}}{dT}$
$\mu < \mu_c^\beta$	0	<0	<0
$\mu = \mu_c^\beta$	0	0	0
$\mu > \mu_c^\beta$	>0	0	>0

In Fig. 13, β_c is plotted against r_c^β for all the substances listed in Table 2. As can be seen in Fig. 13, most of the solutes fall nearly on parallel (dotted) straight lines $r_c^\beta = \text{const.}$ Some of these mole ratios correspond to those known in solid clathrate hydrates: we can assume the existence of liquid clathrate hydrates with the same structure, while other can be be explained on the basis of some simplified assumptions.

There are two sorts of hydrates which are known as Structures I and II respectively. Structure I includes hydrates of small molecules, such as Cl_2, SO_2, and ethylene oxide. Structure II for hydrates has been found in larger hydrating molecules, such as A, Et, and tetrahydrofuran. The unit cell of Structure I, containing 46 water molecules, consists of a close packing of two dodecahedra, consists of 20 water molecules and with a radius of 5.2 Å, and six tetradecahedra, consisting of 24 water molecules and with a radius of 5.9 Å.

If the guest molecules, M, occupy only the larger cavity, the ideal stoichiometrical composition will be $6M \cdot 46H_2O$, *i. e.*, $r_c^\beta = 7.2/3$. When the tetradecahedra containing a solute are freely floating in the liquid water in the isolated state, without composing a solid clathrate hydrate of the Structure-I type, the composition of this polyhedra is $M \cdot 24H_2O$, *i. e.*, $r_c^\beta = 24$. In the Structure II solid clathrate hydrate, the unit cell containing 136 water molecules consists of 16 dodecahedra with a radius of 4.8 Å, and 8 hexadecahedra with a radius of 6.9 Å. Here, the hexadecahedra consist of 28 water molecules. If only the larger cavity is occupied by a guest molecule, the ideal stoichiometrical composition in Type II will be $8M \cdot 136H_2O$, *i. e.*, $r_c^\beta = 17$. When the hexadecahedra containing a solute are freely floating in solution, the composition of this polyhedra is $M \cdot 28H_2O$, *i. e.*, $r_c^\beta = 28$. As can be seen in Fig. 13, $r_c^\beta = 20$ is absent in $\beta_c^\beta - r_c^\beta$ curves for various solutes. From these results, it can be concluded that the dodecahedra with a radius of 4.8—5.2 Å are too small to accommodate a solute in their cavity.

It should be noted that among the many quaternary ammonium salts, only tetrabutyl- and tetraamylammonium salts form solid clathrate hydrates, while no solid clathrate hydrate is known for tetraethylammonium chloride (TEAC). As may be seen from Ref.

7) A. G. Mitchell and W. F. Wynne-Jones, *Disscus. Faraday Soc.*, **15**, 161 (1953).

4, TEAC has a converging point in the β–μ curves. Here, the value of r_c^β is found to be 32.6. This r_c^β, 32, presumably corresponding to that of the octadecahedra. Therefore, it may be concluded that TEAC also forms a liquid clathrate hydrate in liquid water in a manner similar to that in the cases of other nonelectrolyte solutes.

It may be noticed in Fig. 13 that a larger solute molecule exhibits a lower compressibility, β_c, for the same r_c^β, *i. e.*, for the same liquid clathrate structure. This is to be expected, because cavities accommodating larger solute molecules are more "rigid" when the polyhedra are crushed by acoustic pressure; this may correspond to the so-called "rigidity" of icebergs around a solute molecule (*e. g.*, tetraalkylammonium salts[8]).

It is known that, in some cases,[9,10] the framework-structure of water in solid clathrate hydrates may be replaced by solute molecules. Therefore, it seems reasonable to assume that the framework-structure of water in aqueous solutions may also be replaced by a solute molecule in some cases. It may be seen in Eqs. (1) and (2) that the coefficient of v_c^β in the latter is remarkably larger than that in the former. This presumably indicates that the latter group of molecules (such as the F-, AA, and alcohol-homolog series, except for the lowest-molecular-weight substances in each homolog) fill up the cavity only, while the former group (such as the U-homolog series, DMSO, and TU) also collaborates as constitutive parts in forming the framework.

The author wishes to thank Prof. T. Sasaki of the Tokyo Metropolitan University for his helpful discussions and generous support of this research and also Prof. O. Nomoto of the Defense Academy for valuable suggestions and discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1591—1596 (1973)

Mössbauer Study of the Thermal Decomposition Products of $SrFeO_4$

Toshio ICHIDA*

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received December 11, 1972)

The thermal decomposition products of $SrFeO_4$ were studied by ^{57}Fe-Mössbauer-effect and X-ray-diffraction measurements. Below 300 °C in air, an amorphous Fe^{3+} product was formed. The Fe^{4+} or Fe^{5+} state was not observed in the process. A single-phase product with a perovskite structure was obtained in air at temperatures above 400 °C. The products obtained between 400 and 650 °C showed cubic symmetry, but above 700 °C they showed tetragonal distortion. Two kinds of Fe^{3+}-ion sites were detected in the tetragonal $SrFeO_x$ compounds. All the products obtained under the oxygen pressures from 50 to 500 atm and at temperatures from 300 to 900 °C showed cubic symmetry. The Fe^{3+}/Fe^{4+} ratio in those products was determined from the relative intensities of the Mössbauer absorptions.

Regarding the abnormal valence states of iron, several works have been reported. As examples of hexavalent iron compounds, K_2FeO_4, $SrFeO_4$, and $BaFeO_4$ are known[1-3] and their magnetic properties have been investigated.[4-6] It is well known that tetravalent iron, Fe^{4+}, is formed easily in alkaline-earth orthoferrate, $RFeO_x$ (R=Ca, Sr, Ba; $2.5<x\leqq3.0$).[7-17]

The present author and his associates have prepared pure samples of the three hexavalent iron compounds and investigated their magnetic properties.[5,6] The decomposition products of K_2FeO_4 and $BaFeO_4$ have also been investigated. In the case of K_2FeO_4, no intermediate valence state was observed between the hexavalent and trivalent states.[18] By the decomposition of

$BaFeO_4$ in the low temperature range, two new phases were found with the composition of $BaFeO_x$ ($2.5<x<3.0$).[19] As for the decomposition of $SrFeO_4$, there has been no detailed report except for a brief paper by Scholder *et al.*, which reported that a perovskite, $SrFeO_3$, was formed by heating $SrFeO_4$ in an oxygen atmosphere at about 700 °C.[20] As will be reported in this paper, perovskite-type $SrFeO_x$ compounds with various oxygen deficiencies were obtained by heating $SrFeO_4$ under different conditions.

There have been several reports concerning the perovskite-type $SrFeO_x$ system. All of the $SrFeO_x$ samples used in the previous works were prepared by the ordinary ceramic method; α-Fe_2O_3 and strontium carbonate or strontium formate were treated under various oxygen pressures and temperatures. Watanabe[7] measured the magnetic susceptibility and electrical conductivity of $SrFeO_x$ compounds containing Fe^{4+} ions, and suggested the combined effect of the double exchange and the usual exchange interactions in these compounds. The Mössbauer-effect of the $SrFeO_x$ ($2.5<x<3.0$) compounds was measured by Shirane *et al.*[8] They found that the isomer shift of the tetravalent-state iron in $SrFeO_{2.86}$ was about 0.0 mm/s relative to that of pure iron. MacChesney *et al.*[9,10] prepared $SrFeO_x$ ($2.5<x\leqq3.0$) compounds by equilibrating $SrFeO_{2.50}$ at oxygen pressures ranging from 0.2 to 855 atm. They also studied the crystallographic and magnetic properties of $SrFeO_x$ ($2.5\leqq x\leqq3.0$) compounds by means of X-ray-diffraction, Mössbauer-effect, susceptibility, and resistivity measurements.

The present work was undertaken in order to investigate equilibrium phases in a lower temperature range for the $SrFeO_x$ system. As a starting material, the hexavalent iron compound, $SrFeO_4$, has a definite merit; the equilibrium state is attained more rapidly in fine particles of the decomposition products than in those of the other starting materials thus far used. X-ray-diffraction and Mössbauer-effect measurements were carried out in order to examine each of the products. The ratios of Fe^{3+} ans Fe^{4+} ions in the perovskite-type products were estimated by the curve resolutions of the Mössbauer spectra.

Experimental

Using a pure sample of K_2FeO_4 obtained by a previously-reported procedure,[18] $SrFeO_4$ was prepared according to the method of Scholder *et al.*[3]

To a mixed solution of strontium hydroxide and strontium acetate, a 0.5% potassium hydroxide solution containing K_2FeO_4 was added. The filtered precipitate of $SrFeO_4$ was stored in a desiccator after having been washed with chilled alcohol and acetone successively. In the preparation of $SrFeO_4$, the distilled water, from which the carbon dioxide had been expelled, was used in order to prevent the formation of strontium carbonate. All of the reactions were carried out at about 0 °C in order to avoid the reduction of Fe^{6+} ions. By the X-ray-diffraction technique, the sample was confirmed to be a single phase of $SrFeO_4$. The particle shape of $SrFeO_4$, observed by means of an electron microscope, was granular, with a diameter of 2—4 μ. The measurements of the magnetization and the Mössbauer-effect were carried out at 80 K in order to be sure of the absence of any ferromagnetic impurity and any iron ion other than the Fe^{6+} ions.[6]

This pure sample of $SrFeO_4$ was then heated under the oxygen pressures from 0.2 to 500 atm. For the heating in air or in an oxygen atmosphere, the sample was spread thinly on a boat made of porcelain or platinum; it was heated then below 1200 °C for 50 hr and cooled rapidly to room temperature. For some of the samples, the heating period was prolonged to 1500 hr, but no difference was observed in the experimental results of the X-ray-diffraction and Mössbauer-effect measurements. For the heating under high oxygen pressures, the sample was placed in a test tube of silica or gold; this test tube was put in a cone-seal hydrothermal reaction vessel made of Stellite. These samples were quenched to cold water with the reactor after being kept at temperatures below 900 °C for 50 hr under oxygen pressures of less than 500 atm.

The phase identification of the products obtained was accomplished by X-ray-diffraction techniques. In the measurements of the lattice parameters of cubic or tetragonal $SrFeO_x$ compounds, the (200) reflections were used. The Mössbauer-effect measurements were carried out using an apparatus consisting of an Elron driving unit, AME-20, and a Northern Scientific Co. 1024-channel pulse-height analyzer, NS-600. The temperature of the absorber was varied between 4.2 and 293 K. The gamma-ray source, ^{57}Co embedded in Cu metal, was always kept at room temperature. The calibration of the velocity scale was made by using pure Fe and α-Fe_2O_3 as standard absorbers. The isomer shift is expressed relative to pure Fe metal. The ratios of the Fe^{3+} and Fe^{4+} ions, and the isomer shifts and quadrupole splittings of the products were estimated from the ^{57}Fe Mössbauer spectra by using a Curve Resolver-310 (Du Pont Co.).

Results and Discussion

X-Ray-diffraction Measurements. Strontium fer-

rate, $SrFeO_4$, began to decompose abruptly at about 70 °C in air. The products formed below 300 °C in air showed no X-ray-diffraction peak. The products obtained by heating $SrFeO_4$ in air or in an oxygen atmosphere at temperatures from 400 to 650 °C consisted of a single phase of a cubic perovskite structure, while those formed above 700 °C were a single phase of a tetragonal perovskite structure. The products obtained under the oxygen pressures from 50 to 500 atm and at temperatures from 300 to 900 °C were a single phase of a cubic perovskite structure.

The lattice constants were measured using the (200) reflections; the results are depicted in Fig. 1. It has been known in the $SrFeO_x$ ($2.5<x\leqq3.0$) system with the perovskite structure that the lattice constants decreased with an increase in the Fe^{4+}-ion concentration, for the Fe^{4+} ion has a smaller ionic radius than the Fe^{3+} ion. According to Clevenger,[13] the ionic radii of the Fe^{3+} and Fe^{4+} ions are 0.67 Å and 0.59 Å respectively.

Mössbauer-effect Measurements. The Mössbauer spectrum, measured at room temperature, of the decomposition products obtained by heating $SrFeO_4$ for 4 hr at 160 °C in air consisted of a narrow single-line absorption at −0.86 mm/s and a broad symmetric doublet. The narrow single-line absorption is characteristic of the Fe^{6+} state. This absorption disappeared when the amorphous product was heated at 160 °C for more than 10 days. The Mössbauer spectra of the amorphous decomposition product measured at room temperature and at 4.2 K are shown in Fig. 2. At room temperature, a broad symmetric doublet was observed. The isomer shift and quadrupole splitting of the doublet were +0.35±0.02 mm/s and 0.57±0.02 mm/s respectively. A set of six broad absorptions with the internal magnetic field of 480±5 kOe appeared at 4.2 K. These Mössbauer parameters are characteristic of the Fe^{3+} state. All of the iron ions in the amorphous product were trivalent. No intermediate valence state, the Fe^{5+} or Fe^{4+} ion, was detected in any decomposition product in this work. Judging from the Mössbauer spectra and from the fact that no X-ray diffraction peak was observed, it seems that the product consists of ultrafine particles which show superparamagnetism at room temperature. The broad line-width is caused by the inhomogeneity of the crystallographic circumstances of the iron ions. These results observed in the thermal decomposition process of $SrFeO_4$ are very similar with those found in the case of K_2FeO_4.[18]

The Mössbauer absorption spectra of the products with a cubic perovskite structure obtained by heating $SrFeO_4$ below 600 °C in air are shown in Fig. 3 (spectra measured at room temperature) and in Fig. 4 (at 4.2 K). The results show that most of the iron ions in the cubic perovskite phase obtained at lower temperatures were in trivalent state and that the Fe^{4+}-ion concentration increased gradually with the increase in the heating temperature up to 600 °C. Besides, it was found that, in these products with a cubic perovskite structure, there was only one kind of species for each of the Fe^{3+} and Fe^{4+} ions. In Fig. 3, the results of the curve resolutions obtained by fitting the paramagnetic Mössbauer spectra with Lorentzian curves using a Curve Resolver-310 (Du Pont Co.) are represented by broken lines. The paramagnetic spectrum of the Fe^{3+} ions was composed of a symmetric doublet with an isomer shift of +0.22±0.02 mm/s, and with a quadrupole splitting of 0.63± 0.02 mm/s, while that of the Fe^{4+} ions was composed of a singlet with an isomer shift of +0.07±0.02 mm/s.

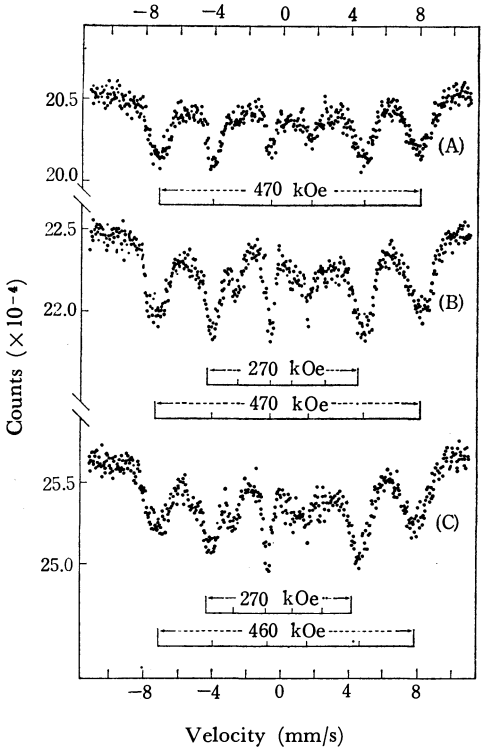

Fig. 4. ^{57}Fe Mössbauer absorption spectra at 4.2 K of cubic perovskite $SrFeO_x$ compounds obtained by heating $SrFeO_4$ in air at 400 °C(A), 500 °C(B), and 600 °C(C).

The Mössbauer spectra of the products with a tetragonally distorted perovskite structure, obtained by heating at 800 °C and 1200 °C in air, are shown in Fig. 5 (spectra measured at room temperature) and in Fig. 6 (at 4.2 K). In contrast to the cubic samples (Fig. 3), two extra absorptions appeared at about +1.0 mm/s and −0.3 mm/s in the spectrum of a tetragonal sample obtained by heating at 800 °C in air. The relative intensities of these two outer-most absorptions increased with the increase in the heating temperature. This spectrum should be interpreted as having two kinds of Fe^{3+} sites in the tetragonal phase. This interpretation is supported by the results in a magnetically-ordered state. In Fig. 5, the results of the curve resolutions are represented by broken lines. The paramagnetic Mössbauer spectra of tetragonal $SrFeO_x$ samples were composed of three kinds of absorptions: (1) a singlet of Fe^{4+} with an isomer shift of +0.07±0.02 mm/s, (2) an Fe^{3+}-I doublet of Fe^{3+} with an isomer shift and a quadrupole splitting of +0.19±0.02 mm/s and 0.63±0.02 mm/s respectively, and (3) an Fe^{3+}-II doublet of Fe^{3+} with an isomer shift and a quadrupole splitting of +0.38±0.02 mm/s and 1.25±0.02 mm/s respectively. Fe^{3+}-I is similar to those in the cubic perovskite phase (Fig. 3).

The Mössbauer spectra of tetragonally-distorted samples measured at 4.2 K (Fig. 6) were very complex. In the spectrum of the tetragonal perovskite sample obtained at 800 °C in air (Fig. 6), two kinds of magnetically-split Fe^{3+} absorptions were observed; one had an internal magnetic field of 500 kOe and a negligibly small quadrupole interaction, and the other,

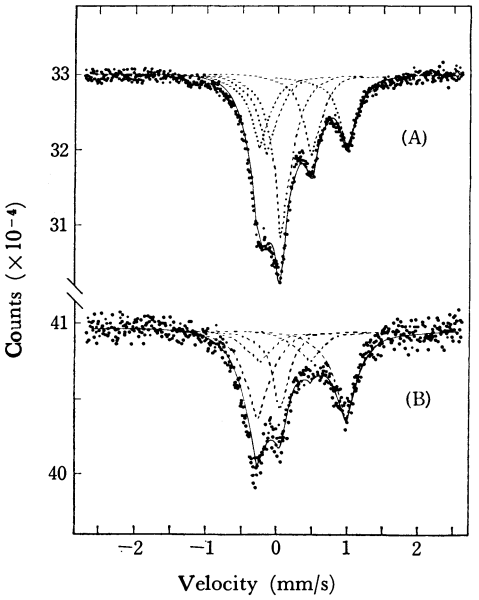

Fig. 5. ^{57}Fe Mössbauer absorption spectra at 293 K of tetragonal perovskite $SrFeO_x$ compounds obtained by heating $SrFeO_4$ in air at 800 °C(A) and 1200 °C(B).

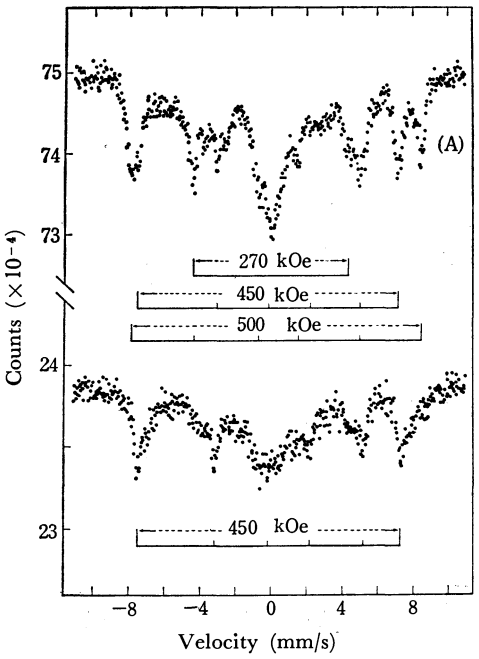

Fig. 6. ^{57}Fe Mössbauer absorption spectra at 4.2 K of tetragonal perovskite $SrFeO_x$ compounds obtained by heating $SrFeO_4$ in air at 800 °C(A) and 1200 °C(B).

an internal magnetic field of 450 kOe and a large quadrupole interaction (S_1—S_2; −2.30±0.05 mm/s). The absorption due to Fe^{4+} ions showed an internal magnetic field of 270 kOe, which was consistent with the data on Fe^{4+} ions in the cubic perovskite phase with a large oxygen deficiency (Fig. 4). The spectra of the tetragonally-distorted $SrFeO_x$ samples showed that a considerable part of both the Fe^{3+} and Fe^{4+} ions was in a paramagnetic state even at 4.2 K (see Fig. 6). It was obvious that the relative intensity of the Fe^{3+}-II increased with the increase in the heating temperature from 800 to 1200 °C. The Mössbauer

spectrum measured at 4.2 K on the tetragonal $SrFeO_x$ sample obtained at 1200 °C in air consisted mainly of magnetically-ordered Fe^{3+}-II absorptions and a paramagnetic absorption. The relative intensities of the Fe^{4+} absorptions and Fe^{3+}-I was small.

The X-ray results show that a sample has a cubic structure if the heating temperature is lower than 700 °C. In the Mössbauer results, however, the Fe^{3+}-II doublet appeared in a sample heated at 650 °C as a result of local distortion.

As is shown in Fig. 1, the perovskite-type products obtained by heating $SrFeO_4$ below 900 °C and at oxygen pressures from 50 to 500 atm showed no tetragonal distortion. The lattice constants of the products obtained under the oxygen pressures of 500 atm were near 3.850 Å, which had previously been reported as the value for the non-defective cubic perovskite, $SrFeO_3$.[10] The product obtained at 700 °C and at oxygen pressures of 500 atm showed the smallest lattice constant, therefore; it was supposed that it had the largest Fe^{4+} concentration among the samples obtained in this work. The Mössbauer spectra of the sample are shown in Fig. 7. The results of the curve resolutions on the paramagnetic spectrum are represented there by broken lines.

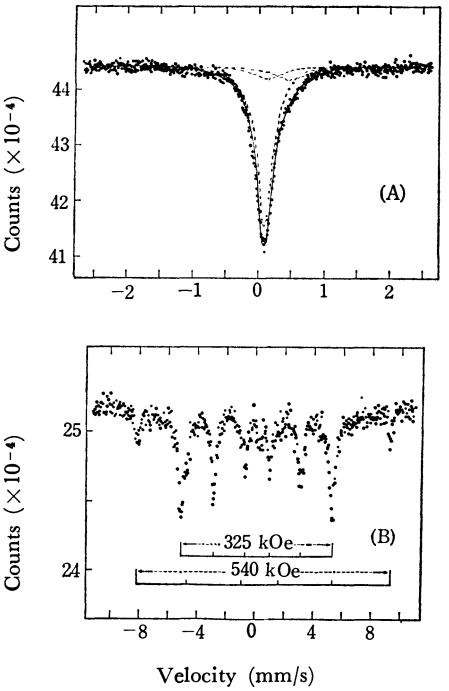

Fig. 7. ^{57}Fe Mössbauer absorption spectra at 293 K(A) and 4.2 K(B) of a cubic perovskite $SrFeO_x$ compound obtained by heating $SrFeO_4$ at 700 °C and the oxygen pressures of 500 atm.

The relative intensity of Fe^{3+}/Fe^{4+} was estimated by measuring the areas of the Mössbauer absorption spectra. Consequently, it was confirmed that the relative intensity does not change with the temperature. The oxygen contents in the $SrFeO_x$ products formed under various conditions were determined by using the ratio of the Fe^{3+} and Fe^{4+} ions thus obtained. The results are shown in Fig. 8. Isobaric curves for

Comparison with Previously-reported Results. It has been reported, for the $SrFeO_x$ ($2.5<x\leqq3.0$) system, that the cubic perovskite structure was no longer stable when the concentration of Fe^{3+} ion exceeded 30%.[10] Then a tetragonal distortion occurred. When the concentration of Fe^{3+} was more than 70%, the other phase, $SrFeO_{2.50}$, with a dicalcium ferrite structure, became more stable than the perovskite. On the other hand, in the present work, a cubic perovskite $SrFeO_x$ product with a Fe^{3+}-ion concentration of about 90% was obtained when $SrFeO_4$ was heated in air below 650 °C. The tetragonal perovskites obtained above 700 °C in air included Fe^{3+} ions in a concentration of 60—80%. Such a disagreement with the previous data may be due to the difference in the starting material.

In the case of $BaTiO_3$, which has the same perovskite structure, it has been reported that the crystal system of the compound is affected by the particle size.[21,22] Barium titanate, $BaTiO_3$, is transformed from a cubic to a tetragonal system below the Néel temperature (393 K). Ern[21] reported that fine particles (200 Å) of barium titanate obtained by a wet method show a cubic perovskite structure with $a_0=4.035$ Å even at room temperature. Nishimoto *et al.*[22] also prepared fine particles (≧500 Å) of barium titanate by the thermal decomposition of barium titanyl oxalate tetrahydrate, $BaTiO(C_2O_4)_2\cdot4H_2O$, at temperatures from 600 to 1100 °C; they found that the tetragonality decreased with a decrease in the particle size. In the present case of $SrFeO_x$ compounds obtained by heating $SrFeO_4$ at low temperatures, the cubic structure with a high oxygen deficiency

seems to be stabilized when the particle size is small.

Another characteristic of the Mössbauer spectra observed on the tetragonal $SrFeO_x$ (Fig. 6) was the existence of a paramagnetic component even at 4.2 K. Gallagher *et al.*[9] have also observed very similar spectra on oxygen-deficient $SrFeO_x$. Since the linewidth of their X-ray peaks was very narrow, it is not possible that these samples consist of ultra-fine particles which show superparamagnetism even at 4.2 K. At the present stage, no likely interpretation can be proposed, but the oxygen vacancies with high concentrations should play an important role in determining the magnetic properties. There remain some unsolved problems with regard to the complicated magnetic structure of $SrFeO_x$ ($2.5<x<3.0$) compounds.

The author would like to express his hearty thanks to Professor Toshio Takada for his guidance during the course of this work. The author also wishes to thank Professor Yoshichika Bando, Dr. Teruya Shinjo, Dr. Masao Kiyama and Dr. Koji Kosuge for their continuous guidance and helpful discussions. Thanks are also due to Dr. Mitsuo Imai and Dr. Koji Sanbongi of the Research Laboratories, Kawasaki Steel Corporation for their warm encouragement. He also wishes to thank the Kawasaki Steel Corporation for giving him an opportunity to study at Kyoto University.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1596—1602 (1973)

Apparent Molal Volumes of Some Organic Electrolytes in a Dilute Aqueous Solution at 5, 25, and 45 °C

Masao SAKURAI

Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 11, 1972)

The apparent molal volumes, ϕ_v, of five series of homologous organic salts of the $H(CH_2)_nCOONa$ (n=0—6), $(CH_2)_n(COONa)_2$ (n=0,2,3,4,6,8), $H(CH_2)_nNH_3Cl$ (n=0,2,6), $(CH_2)_n(NH_3Cl)_2$ (n=2,3,6), and $H(CH_2)_nSO_3Na$ (n=1,2) types in a dilute aqueous solution have been measured by means of a float method as a function of the concentration and the temperature. The coefficients of the deviation of ϕ_v from the Debye-Hückel limiting law, b_v, are negative for most organic electrolytes. The large positive b_v values observed for the sodium oxalate and sodium succinate solutions at 5 °C have been attributed to ion-pair formation. The partial molal expansibility of organic ions has been evaluated and interpreted on the basis of the multilayer hydration model proposed by Frank and Wen. The estimation of volume increments per CH_2 group suggests that the influences of ammonium ions on the hydrophobic hydration around CH_2 groups differ significantly from those of carboxylate ions. The volume change accompanying the substitution of a terminal hydrogen atom with an ionic group has been calculated, and discussed in connection with the overlapping effect of electrostriction in bolaform electrolytes.

Our previous short communication[1] has pointed out that the volumetric behavior of polyelectrolytes in an aqueous solution appears to be complicated by the fact that the interactions between ionic groups or hydrophobic groups on a polymer chain do not disappear even at an infinite dilution. In order to elucidate the complicated behavior of the polyelectrolytes, reliable volumetric information on various organic salts must be established.

It is well known that the concentration and temperature dependence of the apparent molal volumes, ϕ_v, of tetraalkylammonium halides (n-R_4NX) in water are abnormal compared to the case of simple electrolytes.[2-7] For example, the concentration dependence of the ϕ_v of n-Bu_4NBr exhibits both a maximum and a minimum, and the limiting partial molal volumes of the R_4NX do not go through a maximum when plotted against the temperature. This anomalous volumetric behavior of the R_4NX has been interpreted in terms of the enhancement or stabilization of the hydrogen-bonded structure of water in the vicinity of the nonpolar hydrocarbon portion of the R_4N^+ ions (hydrophobic hydration).

In the studies of the R_4NX solutions, the electrostriction of water molecules by the R_4N^+ ions has been considered to be almost negligible, since the central charges are completely masked by the large hydrocarbon groups. For more common organic electrolytes, there have been some careful examinations of the concentration dependence of ϕ_v at 25 °C in the cases of mono-, di-, and trisubstituted aliphatic ammonium salts,[8-10] cyclic ammonium

salts,[11] sodium carboxylates,[12] and sodium alkylsulfates.[13,14]

This report will describe the results of precision-density measurements of the dilute aqueous solutions of several organic salts of the 1-1 and 2-1 (bolaform) types at 5, 25, and 45° C. The apparent molal volumes and the partial molal expansibilities have been calculated from these density data.

Experimental

Materials. The *n*-alkylamine hydrochlorides and sodium salts of formic, acetic, and propionic acids were reagent grade materials and were recrystallized from ethanol, acetone, or water. The dihydrochlorides of ethylenediamine, trimethylenediamine, and hexamethylenediamine were precipitated from ethanol solutions of the amines by the addition of an equivalent amount of hydrochloric acid, and were then washed with ethanol and acetone. All the other salts were prepared by the neutralization of the corresponding carboxylic acids or alkylsulfonic acids with sodium hydroxide, and were purified by crystallization from water-ethanol or water-acetone mixtures. Each salt was dried under a vacuum for at least 3 days before use. Deionized water was distilled using an quartz still.

Procedure. The solution densities were evaluated to six decimal places by means of a float method similar to that described by Desnoyers and Arel.[8] The float, with a volume of about 200 ml, was suspended to the pan of a Mettler balance (Model H20T) by a thin nylon thread (0.11 mm dia.). The volume of the float was calculated by weighing it in air and in pure water at a constant temperature. The temperature inside the cell was controlled to ±0.001 °C by circulating water from a well-insulated bath. The densities of pure water were taken as 0.999992, 0.997075, and 0.990244 g/ml at 5, 25, and 45 °C respectively.[15] The water was degassed to prevent the formation of bubbles on the float during the experiment. The effect of the surface tension at the nylon-solution interface was neglected. The reproducibility of the density measurements was found to be better than 2×10^{-6} g/ml.

The solutions were prepared by adding weighed amounts of the concentrated stock solutions into a cell containing a known amount of pure water. Only for sodium oxalate was dry solid salt added because of its low solubility in water.

The apparent molal volumes were calculated from the density measurements using this equation:

$$\phi_v = \frac{1000(d_0-d)}{mdd_0} + \frac{M}{d} \qquad (1)$$

where d_0 is the density of water; d, that of the solution; M, the molecular weight of the salt, and m, its molality.

Results

The concentration dependence of the apparent molal volumes of the electrolytes can be fitted to the equation of Redlich and Meyer:[16]

$$\phi_v = \phi_v^\circ + S_v\sqrt{c} + b_v c \qquad (2)$$

where ϕ_v° is the limiting apparent molal volume; S_v, the theoretical limiting slope; b_v, an empirical constant determined from the experimental results, and c, the molar concentration converted from the known density. The limiting slope can be derived from the Debye-Hückel limiting law; hence, it depends on the temperature, the physical properties of the solvent, and the valence factor of the electrolytes. The values of S_v for 1-1 and 2-1 electrolytes at 5, 25, and 45 °C were calculated from the table in Ref. 16.

A few typical examples of the plots of $\phi_v - S_v\sqrt{c}$ *vs.* c are shown in Figs. 1 and 2. From these figures, the values of the ϕ_v° (equal to the limiting partial molal volume, $\bar{V}^\circ$) and the b_v slope were calculated for all the electrolytes studied. The results are given in Table 1. The $\bar{V}^\circ$ values of sodium formate, sodium acetate, and sodium butyrate at 25°C are in good agreement with the data reported by King.[12]

Discussion

Deviations from the Limiting Law. As is shown in Table 1, most of the b_v values are more or less negative, like those of simple electrolytes, except at lower temperatures. The negative deviation from the limiting law is expected if the equation for the concentration dependence of ϕ_v is derived from the extended Debye-Hückel law, including the ion-size parameter, a (Owen-Brinkley equation).[7] The extremely large negative b_v values observed for bolaform electrolytes may be accounted for qualitatively by this equation. Since the increase in the chain length is equivalent to the increase in a, very nega-

tive b_V values should be observed for larger bolaform electrolytes.

However, the Owen-Brinkley equation cannot give a reasonable interpretation of the positive b_V values observed for some electrolytes at 5°C, or of the change in b_V values with the increase in the chain length in the case of the 1-1 type homologous series, in which the a values are all the same.[8,17] From these points of view, the study of the b_V as a function of the size, the charge, and the temperature is assumed to provide useful information about ion-ion interactions.

The b_V values observed for 1-1 electrolytes become more negative with the increase in the number of CH_2 groups; this is analogous to the results obtained for n-alkylamine hydrobromides by Desnoyers and Arel.[8]

In aqueous solutions, as is well recognized, hydrophobic solutes enhance or stabilize the hydrogen-bonded structure of water in the vicinity of the nonpolar groups. Such a nonpolar group-water interaction is sometimes called "hydrophobic hydration" to distinguish it from normal hydration. Experimental evidence has confirmed a net contraction in volume when hydrophobic hydration takes place, although there has been no general agreement on the exact nature of the structure of water in this hydration layer.[18] At present it seems most reasonable to interpret the volumetric behavior of nonpolar solutes

17) J. E. Desnoyers, M. Arel, and P. A. Leduc, *Can. J. Chem.* **47**, 547 (1969).
18) E. Wicke, *Angew. Chem., Int. Ed.*, **5**, 106 (1966).

in water in terms of the formation of "quasi-clathrate cages."[2,4]

As the concentration increases, the overlap of these cage systems results in a more efficient contraction in volume as a result of the co-operative stabilization of the hydrogen-bonded structure. Consequently, larger negative b_v values should be observed for the 1–1 organic salts with larger hydrocarbon portions.

Millero has pointed out that an examination of the temperature dependence of b_v can reveal the nature of the ion-ion interactions.[19,20] Table 1 shows that the effects of the temperature on the b_v are similar to the cases of more common electrolytes such as NaCl, in that $\partial b_v/\partial T$ is negative for all the organic salts except for the *n*-hexylamine hydrochloride solution, in which $\partial b_v/\partial T$ is positive as in *n*-Bu_4NBr. The latter behavior may be interpreted on the basis of the assumption that the volume contraction caused by the overlap of the hydrophobic hydration with the increase in concentration is more pronounced at lower temperatures, since the hydrogen-bonded structure of water is stabilized at low temperatures.

For the bolaform electrolytes, the $\partial b_v/\partial T$ values are much more negative. In contrast with the effect of hydrophobic hydration, the negative contribution of the electrostriction to the ϕ_v is more pronounced at higher temperatures, according to the Drude-Nernst equation.[7] Therefore, the negative $\partial b_v/\partial T$ value can be interpreted in terms of the overlap of the highly-electrostricted regions caused by charges in the like sign of the divalent bolaform ions.

It is noteworthy that the b_v values for sodium oxalate and sodium succinate are large and positive at 5°C. The positive b_v value has been interpreted in terms of the cation-anion interactions[21] or the ion-pair formation.[19] The ion-pair formation may be regarded as the limiting case of the cation-anion attraction. Thus, one can predict an ion-pairing in aqueous solutions of the bolaform electrolytes such as sodium oxalate at very low temperatures.

Partial Molal Volumes and Expansibilities of Ions. The study of the limiting partial molal volume, $\overline{V}^\circ$, and the limiting partial molal expansibility, $\overline{E}^\circ = \partial\overline{V}^\circ/\partial T$, may be a useful tool for elucidating ion-water interactions. It has been well established that the $\overline{V}^\circ$ of an electrolyte is equal to the sum of its ionic components: $\overline{V}^\circ = \overline{V}^\circ(\text{cation}) + \overline{V}^\circ(\text{anion})$.[21] Many workers have attempted to determine the individual ionic volume by means of various methods, and many different values of the partial molal volume of a proton, $\overline{V}^\circ(H^+)$, have been reported.[7]

In the present analysis, we have utilized the equation for the temperature dependence of the $\overline{V}^\circ(H^+)$ proposed by Millero:[7]

$$\overline{V}^\circ(H^+) = -5.1 - 0.008\,T - 1.7 \times 10^{-4}T^2 \qquad (3)$$

Table 2. Values of $\overline{V}^\circ$ (ion) at 5, 25, and 45 °C, and $\overline{E}^\circ$ (ion) at 15 and 35 °C

n	$\overline{V}^\circ$(ion) (ml/mol)			$\overline{E}^\circ$(ion) (ml/mol deg)

			$H(CH_2)_nSO_3^-$		
2	76.3	78.2	79.7	0.095	0.075

By using this equation and the additivity principle, one can calculate the values of $\overline{V}^\circ(Cl^-)$ and $\overline{V}^\circ(Na^+)$ from the $\overline{V}^\circ$ data for HCl[22] and NaCl,[19] and hence those of the $\overline{V}^\circ$(ion) for the organic ions from our $\overline{V}^\circ$ data. The results are given in Table 2, together with the $\overline{E}^\circ$(ion) values at 15 and 35 °C.

The $\overline{V}^\circ$(ion) and $\overline{E}^\circ$(ion) can be divided into four major components on the basis of the multilayer hydration model proposed by Frank and Wen:[23]

$$\overline{V}^\circ(\text{ion}) = \overline{V}^\circ(\text{cryst}) + \overline{V}^\circ(\text{elect}) + \overline{V}^\circ(\text{disord}) + \overline{V}^\circ(\text{str}) \qquad (4)$$

$$\overline{E}^\circ(\text{iron}) = \overline{E}^\circ(\text{cryst}) + \overline{E}^\circ(\text{elect}) + \overline{E}^\circ(\text{disord}) + \overline{E}^\circ(\text{str}) \qquad (5)$$

where (cryst) means the crystal partial molal component; (elect), the contribution of the electrostrictional effect; (disord), that of the disordered or void space-packing effect, and (str), that of hydrophobic hydration. A detailed discussion of the natures of these components has been given by Millero.[7]

Table 2 shows that the $\overline{E}^\circ$(ion) values for the alkylammonium ions are much smaller than those for the carboxylate ions with the same hydrocarbon chains. As has been mentioned above, the volume decrease due to the electrostriction is, as a first approximation, more pronounced at higher temperature. Therefore, this finding may be attributed to the larger contribution of the $\overline{E}^\circ$(elect) for the NH_3^+ group than for the COO^- group, because of a low charge density on the

COO^- group due to electron delocalization.[12] This also appears to fit well the findings on the volume changes for ionization reactions reported by Kauzmann *et al*; the volume decrease accompanying the ionization of carboxylic acids is only one half that of alkylamines.[24] It should, however, be noted that there remains some uncertainty as to the above conclusion because of an ambiguity in the determination of the absolute $\overline{V}^\circ(H^+)$ values.

It is of interest to examine the temperature dependence of the $\overline{E}^\circ$(ion) in connection with the hydrocarbon-chain length. Table 2 apparently shows that the $\partial\overline{E}^\circ(\text{ion})/\partial T$ value is negative for the $n=0$ compounds, nearly zero for $n=2$, and positive for $n=6$ in the series of both *n*-alkylammonium ions and carboxylate ions. The positive temperature dependence of the $\overline{E}^\circ$, which has been found for R_4NX or hydrophobic nonelectrolytes, implies that the $\overline{V}^\circ$-temperature plot does not go through a maximum; in this it is unlike the simple inorganic ions. This behavior can be ascribed to the effect of the hydrophobic hydration around the long hydrocarbon chains, since the hydrogen-bonded structure of water is sensitive to the temperature and, hence, the negative contribution of $\overline{V}^\circ$(str) to the $\overline{V}^\circ$(ion) should become less important as the temperature is increased. A similar discussion has been made by Hepler in relation to the pressure dependence of the partial molal heat capacity.[25]

The finding that the hydrophobic hydration predominantly contributes to the ion-water interactions for the ions with $n>2$ is consistent with the findings on the heat of transfer from H_2O to D_2O for sodium carboxylates reported by Snell and Greyson[26] and on that for *n*-alkylamine hydrobromides reported by Desnoyers *et al.*[27]

Particular attention should be given to the fact that the $\overline{E}^\circ$(ion) values of the ammonium ion and the ethylammonium ion are negative, while $\overline{E}^\circ(Na^+)$ is positive. At least the tendency that $\overline{E}^\circ(Na^+)>\overline{E}^\circ(NH_4^+)$ or $\overline{E}^\circ(EtNH_3^+)$ is not affected by any choice of the $\overline{V}^\circ(H^+)$ values. Millero *et al.*[5] have accounted for the low $\overline{E}^\circ$ of the NH_4Cl in terms of the ability of NH_4^+ to form an "icelike" structure. Their proposal, however, could not interpret the negative $\partial\overline{E}^\circ(NH_4^+)/\partial T$ value. Although we have no clear explanation of this finding at present, it might be correlated with the unknown nature of the $\overline{V}^\circ$(disord) or $\overline{E}^\circ$(disord) terms for organic ions. Furthermore, it should be kept in mind that the last three components in Eqs. (4) and (5) are inseparable from each other as a result of their overlapping or competing effects, as will be described in the following section.

Partial Molal Volume of a CH_2 Group. The difference in the $\overline{V}^\circ$ for the successive homologous salts is taken as the contribution of a methylene group, $\overline{V}^\circ(CH_2)$, to the limiting partial molal volume of the organic ion in water. This quantity may be affected by the changes in the overlapping or competing effects between $\overline{V}^\circ$(elect), $\overline{V}^\circ$(disord), and $\overline{V}^\circ$(str). The $\overline{V}^\circ(CH_2)$ values are shown in Fig. 3 as a function of the chain length, and are compared with similar data obtained for other homologous organic salts.[3,8,11]

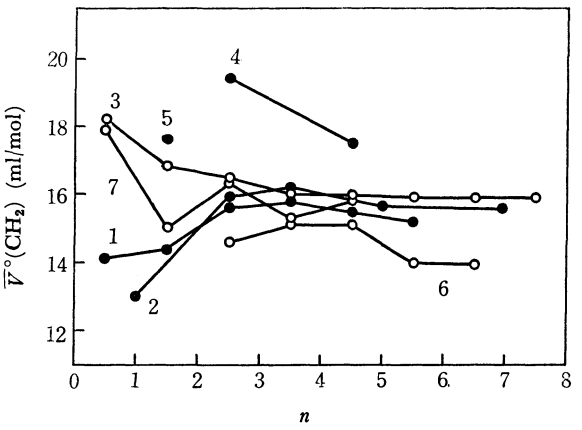

Fig. 3. The values of $\overline{V}^\circ(CH_2)$ as a function of chain length, calculated from the $\overline{V}^\circ$ data of homologous salts. 1: $H(CH_2)_nCOONa$, 2: $(CH_2)_n(COONa)_2$, 3: $H(CH_2)_nNH_3Br$,[8] 4: $(CH_2)_n(NH_3Cl)_2$, 5: $H(CH_2)_nSO_3Na$, 6: $(CH_2)_nNH_2Cl$,[11] 7: $[H(CH_2)_n]_4NBr$.[3,8]

It appears that the values of $\overline{V}^\circ(CH_2)$ approach about 16 ml/mol at 25 °C as the chain length increases. This value is quite similar to those obtained for sodium alkyl sulfates[14] and alcohols.[28] The methylene groups far apart from ionic groups may promote the structure of water in their vicinity without any disturbance by the ionic groups. Therefore, it can be stated that the partial molal volume of a CH_2 group in water is about 16 ml/mol at 25 °C when such a "normal" hydrophobic hydration takes place.

On the other hand, the deviations of the $\overline{V}^\circ(CH_2)$ values from the value of 16 ml/mol can be predicted for the electrolytes with shorter hydrocarbon chains as a result of the influences of the ionic groups. As Fig. 3 clearly shows, in fact, positive deviations are found for ammonium salts and sulfonates, and negative deviations for carboxylates. These results suggest that the influence of the COO^- group on the hydrophobic hydration surrounding CH_2 groups is significantly different from that of the NH_3^+ or SO_3^- groups.

For cyclic ammonium salts,[11] the $\overline{V}^\circ(CH_2)$ values deviate from the 16 ml/mol value even for longer-chain salts; this may indicate that the partial molal volume of a CH_2 group in a cyclic structure differs from that in an open chain.

It should be noted that the $\overline{V}^\circ$ values of the R_4NBr series increase in a peculiar manner with the increase in the alkyl-chain length. This implies that one cannot obtain a linear relation between the $\overline{V}^\circ$ and

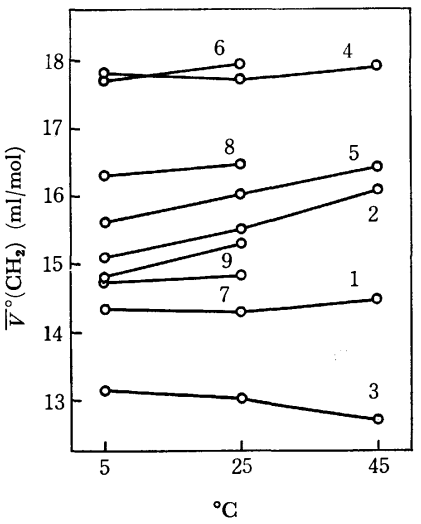

Fig. 4. Temperature dependence of the $\overline{V}°(CH_2)$ evaluated from the difference in the $\overline{V}°$ values of the salts with $n=$ 0, 2 and 6; 1: $H(CH_2)_nCOONa$; (2−0), 2: $H(CH_2)_n$-$COONa$; (6−2), 3: $(CH_2)_n(COONa)_2$; (2−0), 4: $H(CH_2)_nNH_3Cl$; (2−0), 5: $H(CH_2)_nNH_3Cl$; (6−2), 6: $[H(CH_2)_n]_4NBr$; (1−0),[4,8] 7: $[H(CH_2)_n]_4NBr$; (2−1),[4] 8: $[H(CH_2)_n]_4NBr$; (3−2),[4] 9: $[H(CH_2)_n]_4NBr$; (4−3).[4]

the molecular weights of cations, though such a relationship was assumed by Conway *et al.*[3] in order to determine the ionic partial molal volume of the Br^- ion.

The effect of the temperature on the $\overline{V}°(CH_2)$ value is shown in Fig. 4, together with the data for R_4NBr series.[4] The mean values of $\overline{V}°(CH_2)$, evaluated from the difference in the $\overline{V}°$ values of ethylamine and *n*-hexylamine hydrochloride, $\Delta\overline{V}°(n=6-2)$, are in excellent agreement with the values calculated for alcohols[28] at all the temperatures studied. Therefore, these values may reflect the effect of "normal" hydrophobic hydration at all temperatures. The partial molal volume of a CH_2 group far apart from the ionic group for the sodium carboxylates is apparently smaller than that for the *n*-alkylamine hydrochlorides at all temperatures. In both series, however, the temperature dependence of the $\overline{V}°(CH_2)$ is almost linear or slightly concave upward.

The mean values of $\overline{V}°(CH_2)$ evaluated from $\Delta\overline{V}°$ $(n=2-0)$ for both series exhibit less temperature dependence, while their absolute values differ greatly. Furthermore, the temperature dependence of the $\overline{V}°(CH_2)$ calculated from the $\overline{V}°$ values of sodium oxalate and succinate is obviously negative. Such a negative temperature dependence may be attributed to the strong influences of electrostriction on the $\overline{V}°$, as was discussed in the preceding section.

It should be noticed that we were unable to find any distinct difference in the temperature dependences of the $\overline{V}°(CH_2)$ values between carboxylate ions and *n*-alkylammonium ions. On the other hand, the $\overline{V}°$ (CH_2) values are considerably different in their dependences on the chain length. A similar situation is found in the results for the R_4NBr solutions (Fig. 4). If the marked difference in the $\overline{V}°(CH_2)$ behavior were caused by any structural change of water, it would also cause a difference in the temperature dependence of the $\overline{V}°(CH_2)$ value between carboxylate ions and *n*-alkylammonium ions. The experimental results, however, do not coincide with this prediction. Therefore, it may be concluded that the volume change caused by the overlapping or competing effects between $\overline{V}°$(elect), $\overline{V}°$(disord), and $\overline{V}°$(str) is insensitive to the temperature. An alternative explanation is that the $\overline{V}°$(ion) in Eq. (4) involves another additional component, whose nature is less temperature-sensitive. In this connection we wish to call attention to a calculation for the volume change on the mixing of hard spheres of different sizes.[29]

Volume Change for the Substitution with an Ionic Group. It is of interest to evaluate the volume change for the substitution of a terminal hydrogen atom on a hydrocarbon chain with an ionic group as follows:

$$H(CH_2)_nH \xrightarrow{\Delta\overline{V}_1°} H(CH_2)_nCOO^-$$

$$H(CH_2)_nCOO^- \xrightarrow{\Delta\overline{V}_2°} {}^-OOC(CH_2)_nCOO^-$$

Table 3. $\overline{V}°$ of hydrocarbons, $H(CH_2)_nH$, in water at 25 °C

n	1	2	3	4	5	6
$\overline{V}°$ (ml/mol)	37.3[a]	51.2[a]	66.8[a]	82.7[b]	98.6[b]	114.5[b]

a) Ref. 30.
b) These values were evaluated by the addition of $\overline{V}°(CH_2)=15.9$ ml/mol[8,28] to the $\overline{V}°$ value of propane.

Table 4. The volume changes for the substitution of H atom with ionic groups at 25 °C

n	$\Delta\overline{V}_1°$(ml/mol)	$\Delta\overline{V}_2°$(ml/mol)
	$H(CH_2)_nH \rightarrow H(CH_2)_nCOO^- \rightarrow {}^-OOC(CH_2)_nCOO^-$	
1	18.6	—
2	9.1	7.0
3	9.1	7.3
4	9.0	7.7
5	8.6	—
6	7.9	8.4
	$H(CH_2)_nH \rightarrow H(CH_2)_nNH_3^+ \rightarrow {}^+H_3N(CH_2)_nNH_3^+$	
1	−6.6[a]	—
2	−3.2	−14.3
3	−2.7[a]	−10.9
4	−2.6[a]	—
5	−2.5[a]	—
6	−2.4	−6.5

a) These values were calculated from the $\overline{V}°$ data of Desnoyers and Arel[8] for *n*-alkylamine hydrobromides assuming that $\overline{V}°(Br^-)-\overline{V}°(Cl^-)=6.9$ ml/mol[21] at 25 °C.

29) P. Assarsson and F. R. Eirich, *J. Phys. Chem.*, **72**, 2710 (1968).

$$H(CH_2)_nH \xrightarrow{\Delta\bar{V}_1^\circ} H(CH_2)_nNH_3^+$$
$$\xrightarrow{\Delta\bar{V}_2^\circ} {}^+H_3N(CH_2)_nNH_3^+$$

The partial molal volumes of methane, ethane and propane in water were taken from the data by Masterton;[30] they are listed in Table 3.

The results are given in Table 4. As the number of methylene groups is increased, the $\Delta\bar{V}_1^\circ$ values decrease for the carboxylate ions, whereas the opposite order was observed for the alkylammonium ions. This finding might be correlated with the difference in the $\bar{V}^\circ(CH_2)$ observed for these two homologous series.

30) W. L. Masterton, *J. Chem. Phys.*, **22**, 1830 (1954).

It is noteworthy that the $\Delta\bar{V}_2^\circ$ values are much more negative than the $\Delta\bar{V}_1^\circ$ values in the case of substitution with the NH_3^+ group. This behavior may be interpreted in terms of the "reinforcing effect on the electrostriction,,[24] as a result of the overlap of the electrostricted regions around the two NH_3^+ groups on the bolaform ion. It seems that the reinforcing effects caused by the diammonium ions are more remarkable than in the case of the dicarboxylate ions.

The author wishes to thank Professor Tsurutaro Nakagawa, Professor Tsuyoshi Komatsu, and Mr. Toshio Nakajima for their helpful advice. The present work has been supported in part by a Grant for Scientific Research from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1602—1609 (1973)

Excited States and Intermediates in the Photochemistry of Chromium(III) Complexes Studied by Flash Method

Takeshi OHNO and Shunji KATO

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received September 19, 1972)

Photoreactions of $K_3[Cr^{III}(NCS)_6]$ and $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$ were investigated by means of a flash technique. At low temperature (−87 °C), the lowest excited doublet states (^2E_g) of the complexes were easily observed on d–d excitation in acetone, the yields decreasing rapidly with rising temperature. In methanol–ethyleneglycol–water, ^2E_g states of both complexes were easily observed at dry-ice temperature, but not at −46 °C. Thus, the lowest excited quartet state ($^4T_{2g}$), the precursor of ^2E_g state, should rapidly undergo photolysis at room temperature before being converted into the ^2E_g state. The rate of thermal degradation of $^4T_{2g}$ state including chemical reactions was calculated to be *ca.* 10^{10} s^{-1} at room temperature. The decay rate of ^2E_g state was estimated to be *ca.* 10^5 s^{-1} at room temperature. In the presence of organic compounds having carbonyl group, a strong and sharp absorption band near the UV region was observed at room temperature. Irradiation of UV light produced $(NCS)_2^-$ radical for both complexes.

It is well-known that ligands in some chromium(III) complexes in solution are replaced by solvent molecules on photo-excitation.[1] In such a reaction, it is important to make certain which excited state of the complex ion is reactive. It is possible to estimate the reactivities of the excited states from their electronic configurations. Chromium-ligand bonds might be elongated in the excited quartet states with an electronic configuration of $(t_2)^2(e)$ in view of a strong field approximation. However, the bond length in the excited doublet state with the configuration $(t_2)^2(\bar{t}_2)$, may be similar to that in the ground state. In principle, the broad absorption band and the large separation between the 0–0 bands of the absorption and emission spectra show a deformation of structure in the excited state. Thus, it is inferred that the excited quartet states differ to a great extent from the ground state in conformation, but not the excited doublet state. It is reasonable that the larger the deformation of the excited state, the easier for a solvent molecule to make a new bond with the central metal ion of the complex. On the other hand, ^2E_g with a long natural lifetime (10^{-1}∼10^{-3} s) will be more favorable for reaction than the short living $^4T_{2g}$ (10^{-9}∼10^{-10} s).[2,3]

Many reports have appeared dealing with reaction states. Some of them support the view that the doublet state takes part in the reaction. The quantum yields of the photochemical reactions of chromium (III) complexes such as $[Cr^{III}(NH_3)_6]^{3+}$, $[Cr^{III}(NCS)_4(NH_3)_2]^-$, $[Cr^{III}(urea)_6]^{3+}$, and $[Cr^{III}(NCS)_6]^{3-}$ are known to be independent of the excitation wavelength.[4-6] This suggests that the lowest excited states are the reacting species.

6) E. E. Weger and A. W. Adamson, *J. Amer. Chem. Soc.*, **88**, 394 (1966).

Plane[5] and Schläfer[7] supposed that the reacting species was the lowest excited doublet state (^2E_g). This inference seemed to be supported by the fact that the yield of the phosphorescence (0.23) at low temperature[2] was close to that of the aquation reaction (0.28) at room temperature for $K_3[Cr^{III}(NCS)_6]$.

Some others support the view that the quartet states are also reactive. In the case of *cis*-$[Cr^{III}(en)_2(OH)_2]^+$, the quantum yield ratio of *cis-trans* isomerization to aquation was dependent on the excitation wavelength (the ratio was 1.5 on excitation to the first excited quartet state $^4T_{2g}$, and 2.8 to the second excited quartet state $^4T_{1g}$, and 9.6 to ^2E_g at 25 °C[8]). In the case of $[Cr^{III}(NCS)(NH_3)_5]^{2+}$, the quantum yield on direct excitation to ^2E_g is not larger than that to $^4T_{2g}$ and $^4T_{1g}$ states.[9] Chen and Porter[10] and Longford *et al.*[11] proposed the participation of $^4T_{2g}$ state as well as ^2E_g state in the photoreactions of Chromium(III) complexes. They stated that photolysis was less effectively quenched by iodide, hydroxyl and $[Cr^{III}(CN)_6]^{3-}$ than phosphorescence was.

The reacting states in the photolysis of chromium complexes remains still unclarified. We tried to solve the problem by means of the technique of flash photolysis. Phosphorescent states (^2E_g) of some chromium complexes such as $K_3[Cr^{III}(NCS)_6]$ and $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$ were observed by the flash method in a rigid solvent (EPA) at −196 °C.[12] Transient intermediates such ^2E_g state were investigated in a wide temperature range for the purpose of clarifying the mechanism of the photochemical reactions.

Experimental

Apparatus and Procedure. Flash experiments at low temperature were carried out with a flash apparatus.[12] A quartz cell was placed in a Dewar filled with methanol which was cooled with dry ice or liquid nitrogen. Temperature was measured with a copper-constantan thermojunction inserted in the sample solution.

For flash experiments at room temperature, the following flash apparatus was used. Two lamps were placed 5 cm apart in parallel. The sample cell was made of a glass tube, 100 mm long and 10 mm in inner diameter with silica windows at the end. It was located between the two lamps.

Some glass filters (Toshiba) and solution filters were set between the sample cell and the flash lamps. Their transmittances are shown in Fig. 1.

The outputs of a photomultiplier, 1P-28 (Hamamatsu TV.) were recorded with a Hitachi synchroscope V-116. Transient absorption spectra were composed from the oscillographic data of the absorption change observed at various wave numbers. The absorption change in near IR rigion was photographed on Sakura infra-red film. Number of photons absorbed by a chromium complex was measured with a Reineck salt actinometer.[6]

Materials. $K_3[Cr^{III}(NCS)_6]4H_2O$, $NH_4[Cr^{III}(NCS)_4(NH_3)_2]3/2H_2O$, and $[Co^{III}(NCS)(NH_3)_5]SO_4\cdot 2H_2O$, were prepared by the methods reported by Dakin,[13] Roesler,[14] and Werner,[15] respectively.

Potassium iodide was recrystallized three times from water. Ferric nitrate of G. R. grade was used without further purification. Acrylamide of high purity was supplied by Prof. H. Takemura of Nara Women's University. Ethanol was refluxed with silver nitrate, dried over calcium oxide and distilled. Other solvents (G. R. grade) such as methanol, ethyleneglycol, ethylacetate, dimethylformamide, acetophenone, and acetonitril were used without further purification.

Results

General Aspects. The absorption spectrum of $K_3[Cr^{III}(NCS)_6]$ in acetone at room temperature is shown in Fig. 1. Two weak absorption bands in visible region have been assigned to d-d transitions ($^4A_{2g}\rightarrow{}^4T_{2g}$: 17.8 kK, $^4A_{2g}\rightarrow{}^4T_{1g}$: 24.2 kK) and a strong absorption in near UV region to ligand excitation.[16]

When a 2.0×10^{-3} M acetone solution of $K_3[Cr^{III}(NCS)_6]$ was flashed with visible light (filter-24) below −30 °C, the transient spectrum observed agreed with that in EPA solution at −196 °C (Fig. 2). Hence, it is safe to regard it as the ^2E_g state of $K_3[Cr^{III}(NCS)_6]$. With temperature rise, the production of ^2E_g became smaller and could not be detected at 0 °C. A sharp band appeared near the UV region (28.2 kK) above −30 °C. At room temperature, only this band was prominent. The intermediate showing it is denoted by "X".

·····: 10^{-3} M of the complex in polymethylmethacrylate at -196 °C 100J flash with filter-24.

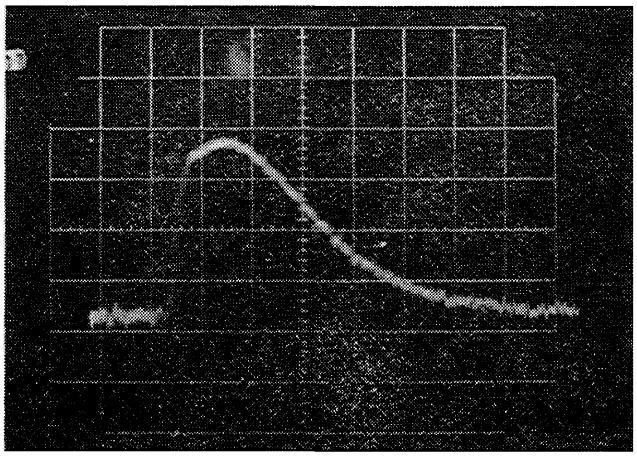

Fig. 5. A typical oscilogram of a transient absorption, observed at 26.3 kK, when a 10^{-3} M acetone solution of $K_3[Cr^{III}(NCS)_6]$ was flashed with filter-24 at -78°C. One large division is 10 μs.

produced transiently a broad band in addition to the sharp band of X at room temperature (Fig. 3). The broad absorption spectrum in visible region is due to a third intermediate denoted by "R". R vanished several milliseconds after flashing, while X survived a few seconds after the disappearance of R.

A single flash with filter-24 on $K_3[Cr^{III}(NCS)_6]$ at room temperature produced 4×10^{-5} M of free thiocyanate ion which was analyzed as ferric thiocyanate.

As in the case of $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$, three intermediates were detected depending on experimental conditions. As shown in Fig. 4, a transient absorption observed at -61 ± 5 °C can be assigned to ^2E_g state referring to the absorption spectrum of ^2E_g state at -196 °C in polymethylmethacrylate. With rise in temperature the yield of ^2E_g state decreased, R and X becoming observable. The absorption maximum and the decay rate of X for $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$ were similar to those of X for $K_3[Cr^{III}(NCS)_6]$.

In the case of other solvents, the behaviors of three

intermediates were very similar to those in acetone except that X was not observed in methanol, ethanol, and water.

Observed intermediates under various experimental conditions are listed in Table 1. The excitation in d-d band (to $^4T_{2g}$ and $^4T_{1g}$) produces ^2E_g state below −10 °C and X above −30 °C, the excitation in the ligand band (UV) produces R in acetone.

^2E_g State. When a 10^{-3}M acetone solution of $K_3[Cr^{III}(NCS)_6]$ was flashed at −78 °C, absorbance of the ^2E_g state reached maximum at 10 μs and then decreased rapidly (Fig. 5).

The decay was of first order and the rate constant did not vary in the range from −87 °C to −10 °C. Hence the initial absorbances due to ^2E_g produced by flashing were obtained in high accuracy by analysis of the decay curves. The absorbance was 3.0 at 27 kK for a 1.0×10^{-3} M acetone solution of $K_3[Cr^{III}(NCS)_6]$ at −78 °C, and decreased to 0.66 at −46 °C. In order to avoid experimental errors due to smaller absorbance at higher temperature, more concentrated acetone solution (4.0×10^{-3} M) of $K_3[Cr^{III}(NCS)_6]$ was examined above −54 °C. The values 2.0 at −46 °C and 0.23 at −9 °C were obtained as the initial absorbances of ^2E_g. At 0 °C, production of the ^2E_g state could not be detected even during the course of flash illumination with more concentrated solutions. The effect of temperature upon production is shown in Fig. 6.

The ordinate gives the quantum yield calculated on the conventional assumption that yield is unity −87 °C. Thus, the calculated yields are the largest possible values.

In the case of $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$ in acetone, similar behaviors were observed. The lifetime was constant from −87 °C to −18 °C, making the measurement of the relative yield accurate. The quantum yields are calculated also on the assumption that yield is unity at −87 °C. The temperature dependence of the quantum yield is shown in Fig. 7.

In the cases of ethanol and ethanol–ethyleneglycol (1 : 1) solutions of $K_3[Cr^{III}(NCS)_6]$, temperature dependence of the yield of the ^2E_g state was similar to that in acetone solution. Absorbance could still be detected at −30°C for 5.0×10^{-3} M ethanol–ethyl-

a) The "mixed" indicates a mixture of methanol, ethyleneglycol, and water (2 : 2 : 3).

eneglycol (1 : 1) solution of $K_3[Cr^{III}(NCS)_6]$.

For methanol-ethyleneglycol-water solutions (2 : 2 : 3) of $K_3[Cr^{III}(NCS)_6]$ and $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$, transient absorption was easily observed at −100 °C. However, it weakened rapidly with temperature rise, and could not be observed at all above −45 °C. Changes of yields with temperature are shown in Figs. 6 and 7. The accuracy is less satisfactory than in the case of the acetone solution, as the lifetime of the ^2E_g state greatly changes in the range from −100 °C to −50 °C. The absorbances in various conditions are shown in Table 2.

The quantum yield Φ_E is formulated as follows.

$$\Phi_E = \frac{k_i}{k_i + k_d} \tag{1}$$

where k_i and k_d are rate constants of intersystem crossing and thermal deactivation of $^4T_{2g}$ state (precursor of ^2E_g state), respectively. Eq. (1) is rewritten as follows.

$$\ln\left(\frac{1}{\Phi_E} - 1\right) = \ln\frac{k_d}{k_i} \tag{2}$$

$$= \ln\frac{A_d}{A_i} - \frac{E_d - E_i}{RT} \tag{3}$$

where suffixes d and i denote the thermal deactivation process and the intersystem crossing process, respectively, A and E the frequency factor and the activation energy, respectively. When the temperature dependence of quantum yield (Fig. 6) is analyzed by means of Eq. (3), a linear relation with a break at −62 °C is obtained for both complexes in methanol-ethyleneglycol-water (Fig. 8).

The decay processes are of first order with respect to the concentration of the ^2E_g state, and the rate constants are the same for all complexes examined, 5.0×10^{-4} s^{-1} in acetone, independent of temperature and concentration (Fig. 9). On the other hand, in methanol-ethyleneglycol-water solvent, the decay rates are dependent on temperature as shown in Table 2 and Fig. 10. The apparent activation energy of the deactivation process of the ^2E_g state was obtained to be 11 kcal/mol in a temperature region higher than −70 °C for both complexes.

Intermediate X. Intermediate X observed in acetone solutions of $K_3[Cr^{III}(NCS)_6]$ and $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$ on d-d excitation at room temperature, has a sharp absorption band near the UV region. Similar spectra were observed in ethylacetate, dimethylformamide, acetophenone and polymethylmethacrylate, but not in ethanol, methanol, aceto-

nitril, and water on d-d excitation. It is worth noticing that all solvents in which the intermediate appeared have a carbonyl group, and that the wave number of the absorption maxima does not depend upon the species of the complex but upon the solvent as shown in Table 3 and Fig. 11.

Decay of the intermediate, regarded as of first order process, also depends on the solvent (Table 3). It is very slow except the case of dimethylformamide. Characteristics such as yields, absorption maxima and decay constants differ with solvent. Thus, X is assumed to be a reaction product between solvent and photoproduct of the complex. For the sake of confirmation the behavior of X was studied in mixed solvents of acetone and ethanol (Table 4). Its production and lifetime gradually decrease with increasing fraction of ethanol, but is observable even in 90% ethanol solution.

Intermediate R. When 1.0×10^{-3} M acetone solution of $K_3[Cr^{III}(NCS)_6]$ was irradiated with UV light, a transient species intermediate R with absorption maximum at 21.5 kK was observed. This was also produced from both complexes in other solvents such as ethanol, methanol, and water. A single flash irradiation through UV filter made an absorbance of 0.15 at absorption maximum, and finally gave 180 μM of free thiocyanate ion. The absorption spectrum due to R was also observed in aqueous solution of $[Co^{III}(NCS)(NH_3)_5]SO_4$ on irradiation of full light. Cobalt(III) was reduced to cobalt(II) during the course of photodecomposition of the complex. It is reasonable that NCS^- coordinating to cobalt is oxidized to thiocyanate radical, accompanied by the reduction of cobalt(III), since thiocyanate ion has the highest reducing potential in the system.

To clarify the character of R, potassium iodide or acrylamide was added as a radical scavenger. Decay of R in all the cases examined was of first order process with respect to R. Addition of the scavenger to an aqueous solution of $K_3[Cr^{III}(NCS)_6]$, reduced the lifetime under aerobic conditions. The decay constant observed (k_{obs}) is given by

$$k_{obs} = k_o + k_S[S] \quad (4)$$

where k_o denotes the decay constant in the absence of scavenger and k_S the second order rate constant of the reaction between R and a scavenger, and [S] the concentration of the scavenger. From the dependence of decay constants on the concentration of scavenger (Fig. 12), the value of k_S are evaluated as shown in Table 5.

$K_3[Cr^{III}(NCS)_6]$	2.8×10^3	KI	5.0×10^8
$[Co^{III}(NCS)(NH_3)_5]SO_4$	2.3×10^3	Acrylamide	1.6×10^6

Discussion

Changes of the quantum yields and the lifetimes of ^2E_g states from -100 °C to -10 °C give information on the behaviors of both $^4T_{2g}$ and ^2E_g states. The values of the quantum yields of the ^2E_g state (Table 6) were calculated on the assumption that the quantum yields were unity at -87 °C in acetone and -100 °C in the methanol-etyleneglycol-water. They fall less than 0.1 at -25 °C. The quantum yield at room temperature was extrapolated to be the order of 10^{-3}. However, the quantum yields of decomposition of the complexes are 0.12—0.34 at room temperature. It is worth noticing that they are much higher than the extrapolated yields at room temperature. The quantum yield of decomposition increased but the yields of ^2E_g state decreased with rising temperature (Fig. 7). Thus, it is concluded that the decomposition of the complexes in the $^4T_{2g}$ state competes with the intersystem crossing to the ^2E_g state and that $^4T_{2g}$ decomposes rapidly before being converted into ^2E_g state at room temperature.

The low quantum yield (<0.1) at -25 °C, means that the rate constant of the thermal deactivation (k_d) of $^4T_{2g}$ is at least ten times as large as that of the intersystem crossing (k_i) according to Eq. (1). Because of the fall of Φ_E with temperature, k_d may be much larger at room temperature. The rate constant of the fluorescence process (k_f, the reciprocal of the natural lifetime) is calculated to be about 10^5 s^{-1} using Einstein's equation of spontaneous transition probability.[17] For all complexes examined, no fluorescence has been detected even at -196 °C. Therefore, k_i may be 10^4 times as large as k_f on the ground that fluorometers can detect fluorescence with a quantum yield of 10^{-4}. Accordingly, k_d is estimated to be larger than 10^{10} s^{-1} at room temperature.

On the other hand, the rate constant of phosphorescence process (the reciprocal of natural lifetime) is obtained to be $10\sim10^3$ s^{-1} by Einstein's equation. The observed lifetime of ^2E_g state indicated that the rate constant of thermal deactivation for both complexes was 5.0×10^4 s^{-1} at -9 °C——-87 °C in acetone and at about -50 °C in the mixed solvent. It is surprising that the change of lifetime with temperature was largely dependent on the solvents and not on the complexes. It is inferred that a strong interaction of the fluid solvent with ^2E_g probably causes its degradation to the ground state or $^4A_{2g}$.

Comparing the rate constants (10^{10} s^{-1}) of the thermal deactivation of the $^4T_{2g}$ and ^2E_g states (10^5 s^{-1}, it is concluded that the former is influenced by solvent molecules more strongly. It should be pointed out that the temperature dependence of Φ_E does not change with the species of the complexes but with solvent. This shows that the deactivation processes of the $^4T_{2g}$ state consist in the interaction of the solvent molecules, which lead to chemical change in part. It is plausible that long metal-ligand bonds in the $^4T_{2g}$ state induce the interaction of the central metal with solvent which results in bimolecular reaction. A bimolecular reaction is also suggested by the fact that $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$ was almost non-reactive at -70 °C (Fig. 7). If a hexa-coordinated complex is dissociated in its excited state and decomposes monomolecularly on irradiation, the yield of photochemical reaction will be independent of temperature. $Cr^0(CO)_6$ is such a case, decomposing photochemically to five coordinated complex with high efficiency even at -196 °C.[18]

TABLE 6. QUANTUM YIELDS OF THE DECOMPOSITION OF COMPLEXES AND ^2E_g STATE FORMATION

Complex	Solvent	Decomposition	^2E_g formation
$K_3[Cr^{III}(NCS)_6]$	acetone	0.12 (23°C)	0.03 (−9°C)
	mixed		0.07 (−45°C)
	water	0.26 (23°C) [a]	
$NH_4[Cr^{III}(NCS)_4(NH_3)_2]$	acetone	0.13 (41°C)	0.10 (−18°C)
	mixed	0.25 (23°C) [b]	0.10 (−46°C)
	water	0.34 (40°C) [a]	

a) E. E. Wegner and A. W. Adamson, *J. Amer. Chem. Soc.*, **88**, 394 (1966).
b) A. W. Adamson, *J. Phys. Chem.*, **71**, 798 (1967).

It is difficult to say whether the second excited state, $^4T_{1g}$, reacts in its lifetime or not. It is generally believed that the second excited states of aromatic molecules have too short a lifetime (10^{-12} s) to react or fluoresce with a few exception.[19] The situation is assumed to be the same for the $^4T_{1g}$ state of chromium complexes, though, if predissociative, it will decompose in one vibration. From this point of view, one can not deny the view that the chemical reaction would take place during the course of lifetime.

The complexes decomposed at higher temperature. Intermediate X appeared in solvents having carbonyl group such as acetone, but not in ethanol, methanol, acetonitrile, and water. If X were produced in the monomolecular decomposition of the complexes also in ethanol and water but not detected because of the rapid quenching of the solvents, a small amount of ethanol would effectively shorten the lifetime of X. Actually, however, X has a long lifetime of 0.12 s even in 90% ethanol solution. It is not reasonable to consider that X decays too rapidly to be detected in pure ethanol when it has a long lifetime of 0.12 s in 90% ethanol solution. When acetone was added to ethanol by 10%, appreciable amount of X was produced.

17) J. G. Calvert and J. M. Pitts, Jr., "Photochemistry," John Wiley and Sons, Inc., New York (1967), p. 173.
18) W. Strohmeier and K. Gerlach, *Chem. Ber.*, **94**, 398 (1961).
19) M. Beerand and H. C. Longuet-Higgins, *J. Chem. Phys.*, **23**, 1390 (1955).

It is thus concluded that acetone is required as a reactant to produce X. Data were not sufficient to identify X, but we might guess that the species produced by a reaction between acetone and the complexes on irradiation, is probably either $[Cr^{III}(NCS)_5(CH_3)_2CO]^{2-}$ or $(NCS)^- \cdot (CH_3)_2CO$. The latter, a molecular complex between thiocyanate ion and acetone, is more probable from the fact that ketones form molecular complexes with sodium iodide, lithium iodide, or sodium hydrogensulfide which are similar to thiocyanate salts in chemical aspect. $[Cr^{III}(NCS)_5(CH_3)_2CO]^{2-}$ cannot be considered to have such a short lifetime as observed.

The absorption spectrum of R agrees with that of the transient species found by Adams *et al.*[20] Baxendale and Scott found[21] the same spectrum in the radiolysis of pottassium thiocyanate aqueous solution and attributed it to $(NCS)_2^-$ on the basis of its kinetical dependence on potassium thiocyanate concentration, but no evidence was given to show it to be a radical. It is concluded that R is a radical because it reacts very fast with radical scavengers such as potassium iodide and acrylamide. Formation of acrylamide radical in a reaction between R and acrylamide was confirmed by the fact that the polymerization of acrylamide solution containing $[Co^{III}(NCS)(NH_3)_5](NCS)_2$ is initiated by illumination.[22]

Chromium(II) could not be detected in the photoreactions of $K_3[Cr^{III}(NCS)_6]$ and $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$ in deaerated solution. Another transient species with very short lifetime (a few μs) was observed in deaerated ethanol solution of the complex, which has a broad absorption spectrum with maximum at 13.6 kK. Since the maximum and lifetime of the transient absorption are similar to those of solvated electron,[23] the following reaction seems to take place,

$$[Cr^{III}(NCS)_6]^{3-} + h\nu \rightarrow [Cr^{III}(NCS)_4]^- + (NCS)_2^- + e_{solv} \quad (5)$$

Summary

Excitation to the d–d excited state $^4T_{2g}$ of $K_3[Cr^{III}(NCS)_6]$ and $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$, is followed by both nonradiative transition to the ^2E_g and the release of one of the ligands (thiocyanate ion). With temperature rise, the release of thiocyanate ion becomes faster and the freshly released thiocyanate ion forms an adduct with carbonyl compound such as acetone and ethylacetate, which decomposes slowly. Irradiation of UV light to the complexes produces a thiocyanate ion radical $(NCS)_2^-$.

Charge-transfer and Proton-transfer in the Formation of Molecular Complexes. VI.[1] 3,3′,5,5′-Tetranitrobiphenyl-4,4′-diol Complexes with Aromatic Amines

Gunzi SAITO and Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received October 20, 1972)

The 3,3′,5,5′-tetranitrobiphenyl-4,4′-diol complexes with twenty-eight aromatic monoamines were prepared and characterized on the basis of their compositions and vibrational and electronic spectra. Many amines were found to form yellow-colored complexes with a 1 : 1 composition and orange- or red-colored complexes with a mole ratio of 2 : 1 or higher. The former complexes appeared to be salts formed by means of the proton-transfer from the diol to the amine molecule, while the latter appeared to be complexes of a new type where charge-transfer and proton-transfer interactions simultaneously operate. The deep coloration of the latter complexes was interpreted in terms of a charge-transfer interaction between the anion derived from the diol and the second monoamine molecule. Furthermore, the complexes with ten aromatic diamines were examined. The 1 : 1 *o*-dianisidine complex was of particular interest in that it is either of the charge-transfer type or of the proton-transfer type, depending upon the preparative conditions.

Recently, we showed that, as is established on the basis of the vibrational and electronic spectra, the orange-colored α-naphthylamine-picric acid (2 : 1) complex previously prepared by Kofler consists of the picrate ion, the protonated amine, and the α-naphthylamine molecule.[2,3] The deep coloration of this complex was attributed to the charge-transfer interaction between the picrate ion and the naphthylamine molecule. For brevity, such a complex will be denoted as

1) Part V: Y. Matsunaga, This Bulletin, **46**, 998 (1973).

2) A. Kofler, *Z. Elektrochem.*, **50**, 200 (1944).

3) Y. Matsunaga and G. Saito, This Bulletin, **45**, 963 (1972).

a complex of the CPT type because of the simultaneous operation of charge-transfer (CT) and proton-transfer (PT) interactions between the component molecules.

With the hope of extending the scope of complexes of the CPT type, we then examined the picric acid complexes with benzidine and its five derivatives.[4] We suggested three possible cases of complexes of the CPT type in these combinations and found examples for two of them. In the 1 : 1 complexes with *o*-tolidine, *o*-dianisidine, and *N,N,N′,N′*-tetramethylbenzidine, a part of the diamine molecule was found to act as a proton-acceptor, while the other part acted as an electron donor. This case may be schematically shown as follows:

$$H_2N\text{-}\phi\text{-}\phi\text{-}NH_3^+\cdots\cdots{}^-O\text{-}Pi$$
$$\vdots$$
$$H_2N\text{-}\phi\text{-}\phi\text{-}NH_3^+ \qquad \text{(I)}.$$

Secondly, the black-colored complex with benzidine of a 2 : 1 composition was also found to be of the CPT type. The mode of interaction in this case may be analogous to that in the above-mentioned naphthylamine complex and may be shown by:

$$H_2N\text{-}\phi\text{-}\phi\text{-}NH_3^+\cdots\cdots{}^-O\text{-}Pi$$
$$\vdots$$
$$H_2N\text{-}\phi\text{-}\phi\text{-}NH_2 \qquad \text{(II)}.$$

The last case is expected to be found among complexes of a 1 : 2 composition, where one of the picric acids is a proton donor and where the other is an electron acceptor. The constitution may be described by the following formula:

$$H_2N\text{-}\phi\text{-}\phi\text{-}NH_3^+\cdots\cdots{}^-O\text{-}Pi$$
$$\vdots$$
$$PiOH \qquad \text{(III)}.$$

Unfortunately, no example of the complex represented by this formula could be found among the picric acid complexes. As has been demonstrated with the picric acid and 2,4-dinitrophenol complexes with aromatic monoamines,[5,6] a delicate balance between the pK_a value of picric acid and the first and second pK_a values of the diamine must be achieved to produce such a complex.

Many aromatic monoamines are available and can cover a wider range of pK_a values than can benzidine and its derivatives; therefore, the chance of finding complexes of the CPT type represented by:

$$HO\text{-}\phi\text{-}\phi\text{-}O^-\cdots\cdots H_3N^+\text{-}Ar$$
$$\vdots$$
$$H_2N\text{-}Ar \qquad \text{(IV)}$$

may be much better than that of finding complexes represented by (III). 3,3′,5,5′-Tetranitrobiphenyl-4,4′-diol, hereafter abbreviated as TNBP, seemed to be the best choice for this purpose. The pK_a value in methanol has been determined by Hart and Detroit to be 4.90±0.06.[7] As Schwarzenbach and Rudin have shown that the pK_a values of *o*- and *p*-nitrophenols measured in 49% ethanol, are smaller by as much as 2 than those measured in 95% ethanol,[8] we may predict that TNBP is a weaker acid than picric acid (pK_a= 0.42 in water), but is a stronger acid than 2,6-dinitrophenol (pK_a=3.71 in water).[9,10] As for the electron-acceptor strength, TNBP is as strong as picric acid and *s*-trinitrobenzene, as will be described in the following section.

Experimental

Materials. The TNBP was prepared, starting from benzidine, by the procedure of Kunze[11] or that of Borsche and Scholten.[12] Recrystallization from glacial acetic acid gave fine, yellow-colored needles. In the former procedure, biphenyl-4,4′-diol was isolated as an intermediate by the method given by Hirsch.[13] The complexes were precipitated by mixing various amounts of the component compounds separately dissolved in hot benzene. Their compositions were determined by elementary analysis.

Measurements. The vibrational spectra of the solid samples were recorded as hexachloro-1,3-butadiene mulls on a JASCO IR-G infrared spectrophotometer, and the electronic spectra, on a Beckman DK-2A spectroreflectometer.

Results and Discussion

Electron-acceptor Strength of TNBP. In order to estimate the electron-acceptor strength of TNBP, the energies of the CT absorption maxima in the TNBP complexes with a series of electron donors were compared with those in the corresponding complexes of picric acid, *s*-trinitrobenzene, and *p*-chloranil. The absorptions were mostly measured in solids, but some were also measured in chloroform. The values obtained are listed in Table 1. Here, the electron donors are arranged in terms of the energy of the CT absorption maximum observed with the *p*-chloranil complex in chloroform. The energy values in the complexes of three nitro compounds with a given electron donor are close to each other; therefore, the electron-acceptor strength of TNBP appears to be comparable with those of picric acid and *s*-trinitrobenzene. The plot of the energies of the CT absorption maxima in the complexes of TNBP (Y) against those in the corresponding *p*-chloranil complexes (X) is covered by this equation:

$$Y = X + (4.1\pm1.0) \qquad (1)$$

The solid TNBP complexes with pyrene, anthracene, perylene, phenothiazine, and benzo[*c*]- and dibenzo-[*c,h*]-phenothiazines were found by elementary analysis to be of a 1 : 1 composition. The compositions of the amine complexes in Table 1 will be discussed in the following sections.

Spectra of TNBP and Its Salts. The diffuse reflectance spectrum of TNBP shows an absorption maxi-

mum at 26.3 kK. In chloroform, the maximum is shifted to 27.6 kK. This value is a little lower than that of 28.2 kK observed in methanol by Hart and Detroit.[7] These authors located the absorption maximum of the monovalent anion at 22.4 kK when examining the spectral change upon the addition of sodium methoxide. The disodium salt was isolated as a bright red powder. The absorption maximum is located at 21.6 kK in the solid salt and at 22.0 kK when dissolved in acetone. In the vibrational spectra of the solid TNBP and the disodium salt, a band at about 3100 cm^{-1} assignable to the CH stretching is the only sharp one observed in the region from 2000 to 4000 cm^{-1}.

The Monoamine Complexes. The solid complexes were isolated; the twenty-eight aromatic monoamines are arranged in the order of decreasing pK_a value in Table 2.[17] An interesting result of the present study is the observation that the nine primary amines out of sixteen with pK_a values higher than 2.71 form yellow complexes of a 1 : 1 composition and also orange or red complexes of a 2 : 1 composition. Regardless of the composition, all of them show a vibrational pattern characteristic of phenolates of primary amines.

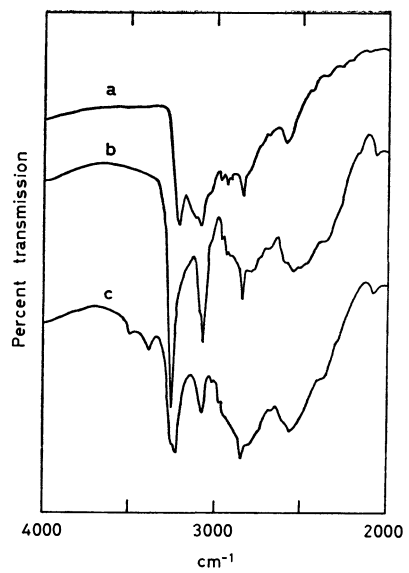

Fig. 1. Vibrational spectra; (a) *p*-anisidine-picric acid, (b) *p*-anisidine-TNBP (1:1), (c) *p*-anisidine-TNBP (2:1).

In other words, the spectra in the region from 2000 to 4000 cm^{-1} more or less resemble those of the corresponding picric acid complexes, which are known to be of the PT type. For example, the vibrational spectra of the 1 : 1 *p*-anisidine complex is compared with that of the picric acid complex in Fig. 1. Moreover, the similarity between the spectrum of the 1 : 1 complex and that of the 2 : 1 complex must be noted. Thus,

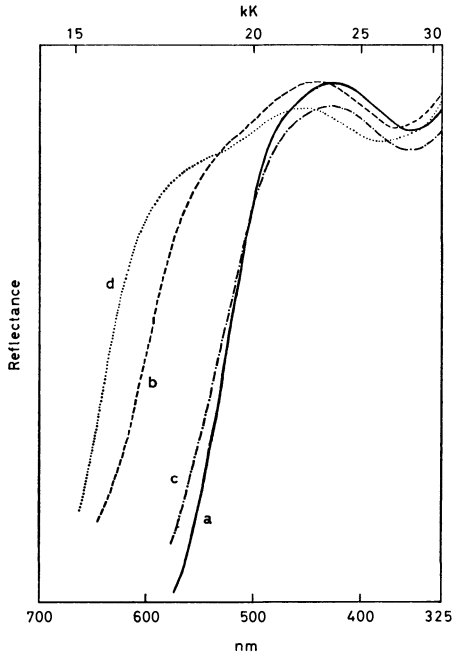

Fig. 2. Reflectance spectra; (a) *p*-anisidine-TNBP (1:1), (b) *p*-anisidine-TNBP (2:1), (c) aniline-TNBP (1:1), (d) aniline-TNBP (2:1).

the presence of PT from TNBP to the amine molecule in both the 1 : 1 and 2 : 1 complexes seems to be certain. In addition, the presence of two weak bands at 3380 and 3480 cm^{-1} in the spectrum of the 2 : 1 complex clearly indicates that the second amine is not protonated.

In general, the 1 : 1 complex exhibits a broad absorption band with a maximum at about 23.1—24.6 kK, which may be attributed to the TNBP monovalent anion. On the other hand, an additional absorption appears in most of the 2 : 1 complexes as a shoulder located on the lower-energy side of the main band. Obviously the deep coloration of the 2 : 1 complex is due to the appearance of this low-energy band. Fig. 2 presents the reflectance spectra of the 1 : 1 and 2 : 1 *p*-anisidine complexes. The absorption maximum appearing at 23.5 kK (425 nm) in the 1 : 1 complex is shifted a little towards the lower-energy side by combination with the second amine molecule. Furthermore, a new absorption can be seen in the region from 500 to 650 nm. The shoulder is located around 19 kK (525 nm). By analogy with the case of picric acid,[3,18] we may assume that the electron-acceptor strength of TNBP is not much affected by the dissociation. The location of the above-mentioned shoulder is fairly close to the energy value given by Eq. (1) with $X=16.2$. This result is strikingly different from the observation made for complexes represented by (I) and also from what would be expected for the complexes represented by (III). We established in a previous paper that the electron-donor strength of the monoprotonated diamine cation is essentially determined by that of the unprotonated half. The present result leads to the conclusion that the 2 : 1 *p*-anisidine complex is of the CPT type represented by Formula (IV). Although the vibrational bands to be assigned to the neutral amines are hardly detectable in the other eight 2 : 1 complexes, the fact that these amines are weaker bases than *p*-anisidine leaves little doubt as to the absence of PT in the second amine molecules. These complexes are probably of the same nature, judging from the deep coloration or the appearance of a new absorption on the lower-energy side of the main band; see the other example presented in Fig. 2. The deeply colored 2 : 1 complexes of *o*-phenetidine, *o*-chloroaniline, and α-naphthylamine with the characteristic vibrational pattern of phenolates of primary amines may also be of the same CPT type. On the other hand, the 2 : 3 complex of *p*-anisidine and the 3 : 2 complex of *o*-phenetidine are both yellow. Their vibrational spectra indicate the presence of PT. No additional electronic absorption band to be assigned to the CT interaction can be detected in them.

Upon heating, the 2 : 1 complex easily loses one molecule of the amine. However, further heating results in decomposition. These processes can be well demonstrated by the vibrational spectra. For example, the spectrum of the 2 : 1 *p*-toluidine complex turns into that of the 1 : 1 complex when it is heated to about 160 °C. This change is accompanied, of course, by the loss of the low-energy absorption band characteristic of the 2 : 1 compoex. After heating to 220 °C, the vibrational pattern differs substantially from that of TNBP. Thus, the amine participating in the CT interaction with the TNBP anion is much more easily removable than the one acting as a proton acceptor.

o-Anisidine was found to form complexes of 5 : 2 and 5 : 1 compositions in addition to that of a 1 : 1 composition. The coexistence of NH_2 and NH_3^+ groups is proved by their vibrational spectra (see Fig. 3). The intensities of the bands due to the NH_2 group are rather weak; therefore, we may explain the earlier observation that the corresponding bands are hardly observable in most of the 2 : 1 complexes of the CPT type. The shift of the strong absorption band at 23.8

kK in the 1 : 1 complex by about 1 kK towards the lower-energy side in the 5 : 2 complex and the appearance of a low-energy absorption in the latter complex may be seen in Fig. 4. In view of the magnitude of the pK_a value of the amine, and also the location of the band arising from the proton-donor component, TNBP may be supposed to be in the form of the monovalent anion; however, it is not clear how many anisidine molecules are involved in the CT interaction. The spectroscopic examination of the 5 : 1 *p*-chloroaniline complex showed that this complex can be classified into the same group as the above-mentioned *o*-anisidine complexes.

Of the amines with pK_a values below 2.60, some complexes are of the CT type and some are of the CPT type. No PT interaction was detected in the complexes of the following four bases: *o*-iodoaniline, *N,N*-dimethylamino-*p*-benzaldehyde, diphenylamine, and phenyl-α-naphthylamine. The pK_a value of the last mentioned is not known. As we may see in Table 2, naphthylamines are weaker bases than aniline; therefore, this amine is undoubtedly weaker than diphenylamine, and so the weakest among the amines employed. By contrast, the vibrational spectra of complexes of *o*-bromoaniline and *m*-nitroaniline, which have pK_a values slightly lower than that of *o*-iodoaniline, indicate the occurrence of PT in the complex formation. This irregularity reflects the fact that *o*-iodoaniline is the strongest electron donor among these three; $X=18.6$ for *o*-iodoaniline, compared with the values of 20.0 and 22.7 for *o*-bromoaniline and *m*-nitroaniline respectively. In accordance with the assumption made earlier, these observations suggest that the first pK_a value of TNBP in water is close to the pK_a values of these amines: 2.46—2.60. Although both diphenylamine and phenyl-α-naphthylamine have been known to form 1 : 2 complexes with *s*-trinitrobenzene,[19] the compositions of the TNBP complexes differ from each other, reflecting the size of the component molecules.

Now let us turn our attention to the complexes of *N*-substituted anilines, which are the strongest proton acceptors among the amines examined. They form deeply colored 1 : 1 complexes with TNBP, despite the occurrence of PT, as is indicated by their vibrational spectra. For example, the russet 1 : 1 *N,N*-dimethylaniline complex exhibits the vibrational pattern characteristic of phenolates of tertiary amines, with bands located in the region from 2250 to 2750 cm^{-1}.[20] A strong absorption located at 22.0 kK is observed in the electronic spectrum. The deep coloration must be wholly attributed to the breadth of this band. Besides the 1 : 1 complex, these amines give 5 : 3, 5 : 2, 2 : 1, and/or 3 : 1 complexes. Their color is deeper than that of the 1 : 1 complexes. In the case of the complexes of *N,N*-diethyl-*m*-toluidine, the strongest proton acceptor studied here, red powders with 2 : 1 and 3 : 1 compositions were obtained. Their electronic spectra are similar to each other and show a strong absorption at 21.3 kK (see Fig. 4). If the complexes are of the CPT type, the CT band can be predicted to appear at about 17 kK, according to Eq. (1). Nonetheless, we cannot see any indication of the presence of such a band. As the location of a strong absorption band is a little lower than that in complexes of the CPT type, and as the amine has a high pK_a value, the TNBP in this complex may be in the form of a divalent anion. If so, the second pK_a value of TNBP must be as high as the range covered by these amines. Thus, the difference between the first and second pK_a of the biphenyldiol is appreciably larger than that found for benzidine. This may be the reason why we can easily find complexes of the CPT type represented by (IV), but not those of the type represented by (III). *N*-Methylaniline, the only *N*-monosubstituted aniline used in this work, gives samples containing more amine than 1 : 2. Such preparations easily lose the amine even at room temperature; therefore, we could isolate no other stoichiometric complex.

The Diamine Complexes. The complexes prepared are listed in Table 3. They may be classified into two groups, those of the PT type and those of the CT type. *o*-Dianisidine can form complexes of both the PT and CT types.

The 1 : 1 complexes with *o*-tolidine, *p*-phenylenediamine, 1,5-diaminonaphthalene, and 1,6-diaminopyrene clearly exhibit the vibrational bands characteristic of the NH_3^+ group, but not those characteristic of the NH_2 group. On the other hand, the appearance of the electronic absorption band in the range from 22.5 to 23.6 kK may be accounted for by proposing that the 1 : 1 complex is composed of the TNBP monovalent anion and the monoprotonated diamine cation. The reason why the vibrational bands due to NH_2 group are not detectable remains unknown; however, we have

encountered the same problem in the 2 : 1 monoamine complexes. The yellowish-orange form of the *o*-dianisidine complex is another member of this group. As is shown in Fig. 5, the protonation of the diamine is firmly established by the broad vibrational bands appearing below 3000 cm^{-1}. The electronic absorption band arising from the proton-donor component is located at 23.5 kK; see Curve a, plotted using the Kubelka-Munk function, in Fig. 6. On the basis of a comparison between the pK_a values of benzidine, 4.95 and 3.85, and that of aniline, 4.59, the second pK_a value of *o*-dianisidine is expected to be below 4. Consequently, the possibility that two protons are transferred from the TNBP to the *o*-dianisidine molecule may be eliminated. If this complex is of the CPT type, the electronic spectrum may be similar to that of the 5 : 2 *o*-anisidine complex, shown in Fig. 4, as the electron-donor strength of the monoprotonated *o*-dianisidine may be anticipated to be close to that of *o*-anisidine. No absorption ascribable to the CT interaction between the TNBP monovalent anion and the monoprotonated diamine cation was observed in the *o*-dianisidine complex. This conclusion also applies to the 1 : 1 diamine complexes discussed above.

The coexistence of NH_2 and NH_3^+ groups in the 3 : 2 complexes with benzidine and diaminodurene is evidenced by the vibrational spectra, which are in accordance with a high ratio of the NH_2 group to NH_3^+ group. Nevertheless, no CT absorption band can be found in them. Tetramethylbenzidine combines with TNBP in a mole ratio of 1 : 2. As this diamine is a strong base, the constitution may be expressed by $[(CH_3)_2NH\text{-}\phi\text{-}\phi\text{-}NH(CH_3)_2]^{2+}(HO\text{-}\phi\text{-}\phi\text{-}O^-)_2$. The location of a strong electronic absorption at 22.8 kK seems not to be inconsistent with this expression.

A further result of importance in this study is that *o*-dianisidine can form not only a PT complex, but also a CT complex, with TNBP. On the mixing of benzene solutions containing equimolar amounts of the component compounds, a yellow complex was precipitated, while a small amount of fine, black needles appeared together with the yellow precipitate when the solutions were diluted and when a large excess of the diamine was employed. The black needles were separated from the mixture with tweezers. Surprisingly, the mole ratio of the diamine to TNBP was found to be identical in these two specimens. The black form exhibits vibrational bands assignable to the NH_2 group at 3395 and 3490 cm^{-1} and an electronic absorption assignable

to the CT interaction at 16.6 kK (see Figs. 5 and 6). The shoulder appearing at about 23 kK suggests that our black specimen is slightly contaminated with the yellow form. The band maximum located at 28.5 kK may be attributed to the TNBP molecule. The transitions from the black form to the yellow one, and *vice versa*, have so far not been observed. 3,3′-Dihalo-*o*-tolidines are the weakest bases among the diamines employed. The 1 : 1 complexes with TNBP are of the CT type. The energies of the CT absorption bands in these complexes are given in Table 1.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1616—1619 (1973)

Infrared Study of Carbon Dioxide Adsorbed on Magnesium and Calcium Oxides

Yasuo FUKUDA and Kozo TANABE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received August 14, 1972)

The infrared absorption spectra of CO_2 adsorbed on MgO and CaO were measured in the wide region 700—4000 cm^{-1} at various amounts of adsorbed CO_2 and temperatures of adsorption and desorption. It has been found that both uni- and bidentate carbonates are formed on MgO when a small amount of CO_2 is adsorbed and that unidentate carbonates predominate as the amount of adsorbed CO_2 is increased. On the other hand, only unidentate species were formed on CaO at room temperature independently of the amount of adsorbed CO_2, but bidentate species were also formed on CaO when the temperature of adsorption was high. The unidentate carbonates formed on both MgO and CaO at room temperature partially changed to bidentate carbonates upon evacuation at higher temperatures. The correlation between $\Delta\nu=|\nu_1-\nu_5|$ and the partial charge on oxygen atoms of various oxides, which corresponds to basic strength on the surface, was examined.

Calcium and magnesium oxides were reported recently to catalyze the esterification of benzaldehyde,[1] the dehydrochlorination of chlorinated ethanes,[2] the decomposition of diacetone alcohol[3] and the isomerization of olefins such as 1-butene,[4] limonene *etc.*[5] It has been pointed out that their catalytic activities are entirely due to the surface basic properties[1-5] and depended largely on the amount of adsorbed carbon dioxide.[3,4] Therefore, it is desirable to study the adsorption of acidic carbon dioxide on the basic oxides in order to characterize the basic properties.

Infrared studies of adsorbed CO_2 have been made for various oxides such as NiO,[6] TiO_2,[7] ZnO,[8] BeO[9] and MgO[10,11] but not for CaO. As for MgO, the formation of bidentate carbonate and carbonate ion was reported by Gregg and Ramsay[10] and that of bi- and unidentate carbonates by Evans and Whateley.[11] However, since the former authors did not observe the spectra in the low frequency region below 1200 cm^{-1}, while the latter ones did not study the spectral change with the amount of adsorbed CO_2, we attempted to observe the spectra in the region of 4000—700 cm^{-1} by varying greatly the amounts of adsorbed CO_2 and by changing the temperature of desorption to make clearer the behavior of adsorbed species. The spectra of CO_2 adsorbed on CaO were observed similarly to those for MgO. It is the purpose of the present work to distinguish the difference in adsorbed species of CO_2 between MgO and CaO and to study the correlation of basic properties of the oxides with the observed spectral data.

Experimental

Thin discs of calcium hydroxide (guaranteed reagent of Kanto Chemical Co.) and basic magnesium carbonate (guaranteed reagent of E. Merck Co.) prepared by pressing at 120 kg/cm^2 were mounted on a Nichrome wire holder placed in the heating zone of an infrared cell and decomposed to their oxides by evacuating at 700 °C for 3 hr. The calcined discs were moved into the optical path with a magnet and evacuated to about 4×10^{-6} mmHg at room temperature. The cell (66.8 ml of a dead space) was constructed of quartz and had cemented sodium chloride windows.

The amounts of CO_2 (99.99% purity) dosed into the cell were determined volumetrically. The spectra of adsorbed CO_2 were observed 30 min after CO_2 was introduced. Since no absorption band for free CO_2 (2350 cm^{-1}) was observed in any experiment, all the CO_2 dosed were regarded as adsorbed on the oxides. Desorption of CO_2 was carried out by evacuating samples at temperatures of 25—700 °C for 30 min.

All the measurements of infrared spectra were carried out at room temperature with a Hitachi model 215 infrared spectrophotometer.

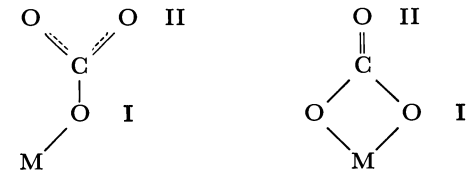
The weights of the samples determined after a series of IR spectral measurements were 10.0 and 20.8 mg for MgO in Fig. 1 and CaO in Fig. 3, respectively. The surface areas measured by nitrogen adsorption were 52 and 158 m^2/g, respectively, for CaO and MgO evacuated at 700 °C for 3 hr.

Results and Discussion

Both calcium and magnesium oxides heat-treated at 700 °C *in vacuo* for 3 hr showed infrared absorption bands at 840—1100 cm^{-1} (a broad band at 1000 cm^{-1} and a weak one at 840 cm^{-1} on MgO; a weak band at 1100 cm^{-1} and a broad one at 1060 cm^{-1} on CaO) which are due to the oxides themselves but no bands for OH and CO_2 which are possible impurities in the oxides. Both samples on which CO_2 was adsorbed showed no bands above 1700 cm^{-1}.

Adsorption of CO_2 on MgO at Room Temperature. Figure 1 shows the spectral changes caused by varying the amounts of CO_2 adsorbed on MgO. The stronger bands at 1670, 1315, 1000 and 850 cm^{-1} and the broad or weak bands at 1550, 1410 and 1050 cm^{-1} were observed in spectrum (2) of Fig. 1, where 0.23×10^{-3} mmol of CO_2 was adsorbed. In spectrum (3) of Fig. 1 where the adsorbed amount of CO_2 was increased, new bands appeared at 1630, 1280, 950 and 830 cm^{-1} and all the bands increased in intensity in spectrum (4). In spectra (5) and (6), the intensity of the bands at 1550, 1410, 1050 and 860 cm^{-1} increased, while the intensity of the other bands decreased.

On the basis of the analysis by Fujita *et al.*,[12] Evans and Whateley[11] considered that the splitting of the carbonate ion asymmetric stretching band (ν_3) is about 100 and 300 cm^{-1} for unidentate and bidentate carbonate, respectively, as shown below.[13] And they reported that the bands at 1665, 1325, 1005 and 850 cm^{-1} observed for CO_2 adsorbed on MgO could be assigned



unidentate complex bidentate complex

to the bidentate carbonate complex and those at 1510, 1390, 1035 and 865 cm^{-1} to the unidentate carbonate complex. They attributed the strong bands at 1625 and 1275 cm^{-1} to bidentate carbonate or bridging carbonate because of the large splitting of the two bands. However, if bridging carbonate is of the type $\begin{matrix}-O\\-O\end{matrix}\!\!>\!C{=}O$, the band should appear at 1750 cm^{-1}.[14] Therefore, the bands at 1625 and 1275 cm^{-1} are believed due to bidentate carbonate. From these results, the bands at 1670, 1315, 1000 and 850 cm^{-1} and those at 1630, 1280, 950 and 830 cm^{-1} are assigned to bidentate carbonate. The bands at 1550, 1410, 1050 and 860 cm^{-1} can be assigned to the unidentate carbonate complex.

It is concluded from these observations that both uni- and bidentate carbonates are formed on MgO when a small amount of CO_2 is adsorbed and that unidentate carbonate is predominantly formed when there is a large amount of adsorbed CO_2.

Desorption of CO_2 from MgO. The changes in the spectra of a sample, which had CO_2 adsorbed at room temperature, produced by evacuation at 25—700 °C for 30 min are shown in Fig. 2. In spectra (1)

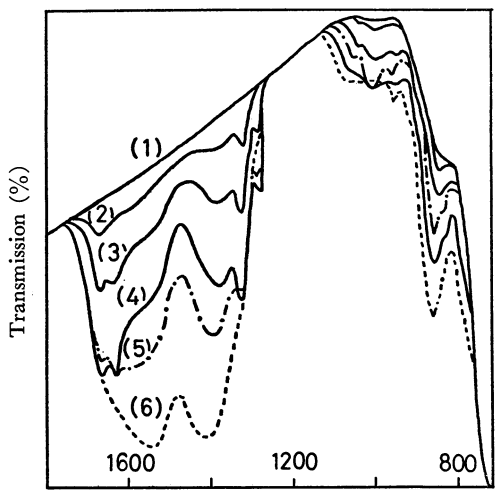


Fig. 1. Spectral changes for CO_2 adsorbed on MgO at room temperature for various adsorbed amounts; (1); 0 mmol (background), (2); 0.23×10^{-3} mmol ($\theta=0.02$), (3); 0.69×10^{-3} mmol ($\theta=0.06$), (4); 2.2×10^{-3} mmol ($\theta=0.16$), (5); 2.9×10^{-3} mmol ($\theta=0.25$), (6); 5.2×10^{-3} mmol ($\theta=0.38$).

13) Evans and Whateley[11] assumed that $\Delta\nu=|\nu_1-\nu_5|$ is a splitting of the carbonate ion asymmetric stretching band (ν_3), where ν_1 represents $\nu(C-O_{II})+\nu(C-O_I)$, $\nu(C-O_{II})$ and ν_5 does $\nu(C-O_{II})$, $\nu(C-O_I)+\delta(O_ICO_{II})$ for uni- and bidentate carbonate complexes, respectively.[12] However, Fujita *et al.*[12] say that it is impossible to determine which of three C–O stretching vibrations is due to the splitting of ν_3. Therefore, $\Delta\nu$ was used instead of the splitting of ν_3 in the present work.

14) L. H. Little, "Infra-Red Spectra of Adsorbed Species," Academic Press, London and New York (1965).

where the sample was evacuated at room temperature, broad bands appeared at 1550, 1410 and 1050—1000 cm^{-1} with weak bands at 1670, 1330 (shoulder) and 845 cm^{-1}. These bands were not changed by evacuation at 100 °C. By elevating evacuation temperature to 240 °C (spectra (2)), the spectra were changed greatly. The bands at 1550 and 1410 cm^{-1} decreased in intensity, while those at 1670 and 1330 cm^{-1} increased. The bands at 1050—1000 cm^{-1} became sharp at 1030 cm^{-1} and the band at 845 cm^{-1} shifted to 855 cm^{-1}. All bands decreased greatly in intensity on evacuation at 400 °C and the bands at 1800—1100 cm^{-1} disappeared at 700 °C.

The spectral changes caused by CO_2 desorption indicate that some unidentate carbonate is converted to bidentate carbonate by evacuation at 240 °C and both carbonates disappear at 700 °C.

Adsorption of CO_2 on CaO at Room Temperature. The absorption spectra of CO_2 adsorbed on CaO are shown in Fig. 3. Five bands were observed at 1520, 1490, 1415, 1060 and 860 cm^{-1} when 2.8×10^{-4} mmol of CO_2 was adsorbed. With an increase in the amount of adsorbed CO_2, the intensities of these bands increased and those at 1520 and 1490 cm^{-1} became a broad band at 1510 cm^{-1}. When the amount of adsorbed CO_2 was increased to more than 8.2×10^{-3} mmol, a band appeared at 2350 cm^{-1} and it disappeared upon evacuation at room temperature. Since the band at 2350 cm^{-1} is assigned to gaseous CO_2 and 8.2×10^{-3} mmol of dosed CO_2 corresponds to $\theta=0.96$ (calculated by assuming that the cross-section area of CO_2 is 19.5 Å^2), the five bands are attributed to the surface species. Because the value of $\Delta\nu$ is about 100 cm^{-1}, these bands may be assigned to a unidentate carbonate complex and the bands at 1520—1490, 1415, 1060 and 860 cm^{-1} to $\nu(C\text{-}O_{II})$, $\nu(C\text{-}O_{II})+\nu(C\text{-}O_{I})$, $\nu(C\text{-}O_{I})+\nu(C\text{-}O_{II})$ and π vibrations, respectively. Thus, the adsorbed species of CO_2 on CaO is different from that on MgO and only unidentate carbonate independent of the amount of adsorbed CO_2 is formed.

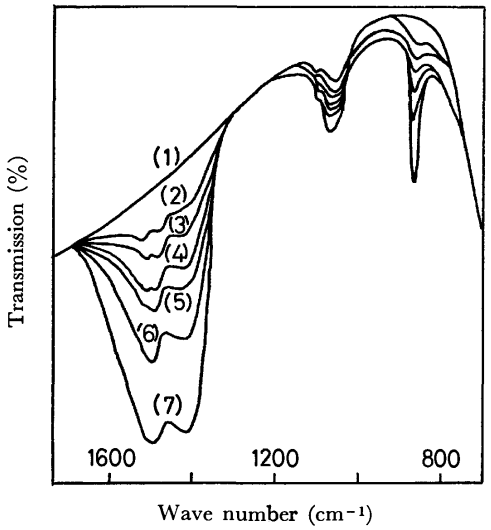

Fig. 3. Spectral changes for CO_2 adsorbed on CaO at room temperature at various adsorbed amounts; (1); 0 mmol (background) (2); 2.8×10^{-4} mmol ($\theta=0.03$), (3); 5.6×10^{-4} mmol ($\theta=0.06$), (4); 9.3×10^{-4} mmol ($\theta=0.10$), (5); 1.2×10^{-3} mmol ($\theta=0.13$), (6); 2.4×10^{-3} mmol ($\theta=0.26$), (7); 5.0×10^{-3} mmol ($\theta=0.55$).

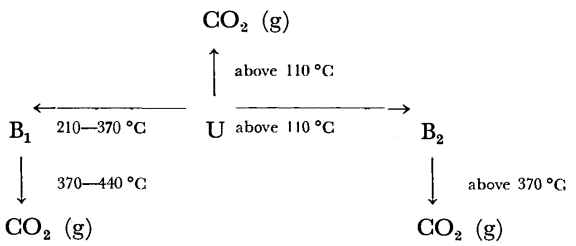
Desorption of CO_2 from CaO. The spectral changes produced by CO_2 adsorbed on CaO at room temperature and evacuated at 310—700 °C are shown in Table 1. Many bands were observed when the sample was evacuated at 210—370 °C and new bands appeared upon evacuation at 110 and 210 °C.

On the basis of the observed characteristic features of the spectral changes upon CO_2 desorption, the bands other than unidentate species bands are classified into the following two groups; one (B_1) include bands at 1635, 1290—1302 and 980 cm^{-1} and the other (B_2) include bands at 1550—1570, 1308—1315, 1050 and 850 cm^{-1}. Since the value of $\Delta\nu$ is about 300 cm^{-1} in both the groups, they are assigned as bidentate carbonate complexes.

The behavior of CO_2 adsorbed on CaO is shown below,



where U is the unidentate carbonate complex.

Table 1. Changes of the bands upon evacuation at various temperatures

Evac. temp. °C	25	110	210	310	370	460
		B_2 1570(A), 1308(A)	B_2 1570(I), 1308(I)	B_2 1550(I), 1315	B_2 1550(D), 1315(D)	B_2 1550, 1315, 1050, 850
			B_1 1635(A), 1290(A), 970(A)	B_1 1635(I), 1302, 980	B_1 1635(D), 1302(D), 980(D)	
	U 1500, 1420, 1060, 860	U 1500(D), 1420(D), 1060, 860	U 1500(D), 1420(D), 1060, 860	U 1500(D), 1420(D), 1050, 850	U 1500(D), 1420(D), 1050(D), 850(D)	

U: Unidentate carbonate, B_1, B_2; Bidentate carbonate, (I); Increase in intensity of the band, (D); Decrease in intensity of the band, (A); New band appeared by evacuation.

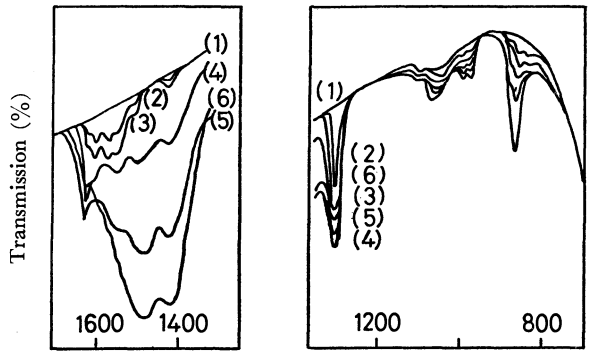


Fig. 4. Spectral changes for CO_2 adsorbed on CaO at 350 °C for various adsorbed amount; (1); 0 mmol (background), (2); 0.23×10^{-3} mmol, (3); 0.46×10^{-3} mmol, (4); 0.69×10^{-3} mmol, (5); 2.2×10^{-3} mmol, (6); 2.5×10^{-3} mmol.

Adsorption of CO_2 on CaO at 350 °C. Figure 4 shows the spectral changes produced by varying the amount of CO_2 which was adsorbed on CaO at 350 °C.

In the case of a small amount of adsorbed CO_2, the bands at 1635—1550 and 1308—1302 cm^{-1} were stronger than those around 1500 and 1430 cm^{-1} and the latter increased with increasing amount of adsorbed CO_2. Judging from the value of $\Delta\nu$, the former bands can be assigned to a bidentate carbonate complex and the latter to a unidentate carbonate complex, though it is difficult to assign all bands observed.

Correlation of $\Delta\nu=|\nu_1-\nu_5|$ with the Partial Charge δ_0 on Oxygen of Metal Oxides. It was reported that the active sites of MgO and CaO for decomposition of diacetone alcohol are basic sites (O^{2-} ions) and the activity is related to the partial charge on oxygen or the basic strength of the oxides.[15] Since CO_2 is bonded to surface oxygen to form uni- or bidentate carbonates, $\Delta\nu$ is also expected to be related to δ_0. In the case of bidentate carbonate, the values of $\Delta\nu$ are known to be 420 cm^{-1} for BeO[9] and were found to be 350 and 240 cm^{-1} for MgO and CaO, respectively. The values of δ_0 for BeO, MgO and CaO are known to be −0.35, −0.50 and −0.57 respectively.[16] Therefore, a correlation between $\Delta\nu$ and δ_0 seems to exist in the case of alkaline earth metal oxides. However, the correlation does not hold in the cases of TiO_2[7] and ThO_2.[17] This seems to indicate that the magnitude of $\Delta\nu$ does not depend only on δ_0, since CO_2 needs to bond not only to surface oxygen, but also to surface metal for the formation of bidentate carbonate.

In the case of unidentate carbonate, the values of $\Delta\nu$ are known to be 150—190 cm^{-1} for ZnO[8], TiO_2[7] and ThO_2[17] and were found to be 140 and 70 cm^{-1} for MgO and CaO respectively. Since δ_0 values for these oxides are −0.27∼−0.29, −0.50 and −0.57 respectively, there exists a fairly good correlation. However, more data for $\Delta\nu$ with oxides will be needed for a full discussion of this correlation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1619—1623 (1973)

Initiation Step of Methane Pyrolysis. Further Studies on Initiation Step of Methane Pyrolysis

Takayuki YANO

Institute of Space and Aeronautical Science, University of Tokyo, Meguro-ku, Tokyo 153

(Received October 7, 1971)

The pyrolysis of diluted mixture of equimolar CH_4 and CD_4 were performed in a shock tube between ~1500 K and ~1600 K, and pyrolysis products were quantitatively determined. A small amount of oxygen contaminating the sample gases had no influence on the results. The isotope exchange reactions in the equimolar lean mixture of H_2 and D_2 were also performed under the same conditions of methane pyrolysis. The results explained that the isotope exchange reaction between H_2 and D_2 had no influence on the hydrogen isotopic distribution produced by the CH_4–CD_4 pyrolysis. From the hydrogen isotopic distribution of the products of CH_4–CD_4 pyrolysis, methyl radical mechanism was confirmed as the initiation step of methane pyrolysis.

In the previous paper,[1] it was concluded that the initiation step of the methane pyrolysis was

$$CH_4 \longrightarrow CH_3 + H \qquad (1)$$

but not be

$$CH_4 \longrightarrow CH_2 + H_2. \qquad (2)$$

This conclusion was derived from the predominant yield of HD molecule produced by the pyrolysis of an equimolar mixture of CH_4 and CD_4. If there is any side-reaction, however, and if it affects the isotopic distribution among hydrogen, the above-mentioned conclusion would become uncertain. It is desirable, therefore, to study the effects of the side-reactions on the hydrogen isotopic distribution. The following three exchange reactions, that is, (i) the reaction between reactant molecules, CH_4 and CD_4; (ii) the reaction between reactant methane and product hydrogen; and (iii) the reaction between product hydrogen

1) T. Yano and K. Kuratani, This Bulletin, **41**, 799 (1968).

molecules are examined. The effect of the small amounts of oxygen should be also taken into account, since Meyerson and Watt[2] have proved that the small amounts of oxygen accelerate the decomposition rate of hydrogen molecules significantly. If the considerable amounts of hydrogen atoms were formed by this reaction, the predominant yield of species HD would be obtained.

The exchange reaction between CH_4 and CD_4 behind a reflected shock wave was studied by Burcat and Lifshitz[3] in the temperature range from 1340 to 1745 K. When their rate equation is applied to the typical experimental runs reported in the previous paper, the extent of the exchange between CH_4 and CD_4 is calculated to be $(CD_3H)/(CD_4)=0.1$, *i.e.*, only 10% each of CH_4 and CD_4 may be converted to CH_3D and CD_3H, respectively. Then, if CH_3D and CD_3H are initially formed and then pyrolysis occurs, hydrogen molecules would be formed as follows by the methylene mechanism,

$$0.90\ CH_4 \rightarrow CH_2 + H_2$$

$$0.10\ CH_3D \rightarrow CH_2 + HD \text{ or } CHD + H_2 \text{ in equal amount}$$

$$0.10\ CD_3H \rightarrow CD_2 + HD \text{ or } CHD + D_2 \text{ in equal amount}$$

$$0.90\ CD_4 \rightarrow CD_2 + D_2 \qquad (3)$$

and the ratio of $(H_2) : (HD) : (D_2)$ would be 0.95 : 0.10 : 0.95. This clearly shows that the amount of HD produced by this scheme is much less than that obtained by the CH_4–CD_4 pyrolysis experiment. The effect of this side-reaction, (i), may be ignored.

The effect of the second reaction (ii) can be estimated by the results of Watt *et al.*[4] and the isotopic distribution ratio by the methylene mechanism proves

$$(H_2) : (HD) : (D_2) = 1.0 : 0.28 : 1.0. \qquad (4)$$

Therefore, the effect of the second side-reaction may also be neglected.

As to the third side-reaction, (iii), circumstances are rather complicated. According to the rate law of Bauer,[5] an appreciable amount of HD is formed by the H_2–D_2 exchange reaction and it will be quite difficult to decide whether the initiation step of the methane pyrolysis will be eq. (1) or eq. (2). Later, however, Lifshitz[6] corrected the Bauer's result and when Lifshitz's result is adopted for the calculation the amount of HD is smaller than the value calculated from the Bauer's rate expression. The amount of HD calculated would be further small, if the H_2–D_2 exchange reaction occurs through the bimolecular process and the phenomenological expression given by Bauer can be used. Only a little influence on our previous conclusion is expected. These discrepancies are mainly due to the difference of the reaction order with respect to hydrogen. Accordingly, to know the effect of the third side-reaction to the methane pyrolysis, it is desirable to reinvestigate the exchange reaction of hydrogen molecules itself in the same low concentration as actually observed in the methane pyrolysis.

Experimental

High quality hydrogen (99.9999%), deuterium (99.5%) obtained from Takachiho Co. and high quality argon (99.999 %) supplied by Tomoe Co. were used without further purification.

For the study of the isotopic exchange between hydrogens, 1% of H_2 and 1% of D_2 were mixed with 98% of argon and after being kept over night, this mixture was further diluted tenfold by argon gas. The latter mixture was shock heated.

For the study of the effect of the trace amounts of oxygen on the methane pyrolysis, 99.5% perdeuteromethane (CD_4) from Matheson Co., pure methane (99.5%) and high quality argon were used.

Oxygen contents in CH_4 and CD_4 were analyzed by gas chromatography and were found to be 0.5% and 50 ppm, respectively. The gas chromatographic system was built into a vacuum line to avoid air contamination. For the removal of a small amount of oxygen from methanes, impure methane was passed through a freshly reduced copper column at 160 °C. By this process, the oxygen content in the original CD_4 and CH_4 was reduced from 5000 to 50 and from 50 to 7 ppm, respectively. The oxygen content in the high quality argon gas, was also analyzed in a similar manner after being passed through the copper column at 160 °C, and it was confirmed to be less than 1 ppm. Then, two gas mixtures of 6% each of CH_4 and CD_4 in high quality argon gas were prepared. In the mixture A, purified CH_4 and CD_4 were diluted in argon and in the mixture B, unpurified CH_4 and CD_4 were used. Consequently the oxygen levels of mixture A and B were about 3 and 300 ppm, respectively.

In addition to the careful preparation of sample gases, the contamination during the storage and the gas handling was also examined. Gas mixtures were kept for at least 15 hours in a gas holder to accomplish complete mixing. Then, a part of the sample gas was analyzed by gas chromatography before shock heating and it was confirmed that the oxygen contamination during the storage was negligible. The gas leak of the driven section of the shock tube, however, was about 6×10^{-5}Torr/min and the air contamination from this was to be estimated. High quality argon was introduced into the driven section to the level of 65 Torr and was kept for two days. After that, the gas was analyzed by gas chromatography. Oxygen contamination was about 300 ppm after 48 hr at the total pressure of 65 Torr. That is, about 0.5 ppm of oxygen was mixed into the sample gas since it took 5 min to handle the sample gas in the driven section before shock firing.

The shock tube used in this study was the same that Tsuda and Kuratani[7] used, but the volume of a damp tank of driver gas was changed from 20 l to 80 l to decrease the amount of driver gas mixing into the sample gas after reaction. As soon as the shock was fired and the reaction was over, the reaction mixture behind the reflected shock wave was withdrawn into an evacuated vessel and its composition was determined by the gas chromatograph Shimadzu GC-1C. Isotopic hydrogen molecules were separated by an alumina column coated with $MnCl_2$ of 2 m length at 77 K. After the separation of H_2, HD and D_2, the gas flow, using He

as a carrier gas, was introduced into the heated column of CuO to oxidize these components to water vapors and was detected by a cathetometer. The analysis of the hydrocarbons were also made by the gas chromaotgraphy with a charcoal column of 1 m length and a hydrogen flame ionization detector.

Results

H_2–D_2 Exchange Reaction. Reaction times behind the reflected shock wave were assumed to be the same as the residence time observed by a pressure transducer at an end plate and were nearly 1 ms. The temperature range was 1135~1940 K. Reaction rates observed, $\Delta(\mathrm{HD})/\Delta t$, are compared with those calculated by Bauer's rate law in Table 1. It is obvious that the isotope exchange rate is about one hundredth of the rate calculated from the equation obtained by Bauer at high concentration of hydrogen molecules and that the reaction orders with respect to H_2 and D_2, given by Bauer, is not accurate at least at the low concentration ranges of hydrogen. For the accurate estimation of the partial reaction order with respect to H_2 and D_2, it is necessary to study in the concentration range as wide as possible. Bauer carried out the study in a relatively high concentration, while the present work was studied in a relatively low concentration, and when two experiments are combined, the sum of the partial orders can be estimated more accurately.

Since the argon concentration in above two experiments is alike, the difference of the reaction rate due to the argon concentration may be ignored. Therefore, the empirical power-rate expression was deduced to

$$\Delta(\mathrm{HD})/\Delta t = k(\mathrm{H_2})^y(\mathrm{D_2})^x \qquad (5)$$

in which k includes the contribution of argon. When the mixtures were restricted to the equimolar ones, the sum of the partial reaction orders, or $n=x+y$, and the activation energy, E, could be determined by the least-squares method (Fig. 1). From the figure, the values of E and n were determined to be 41.2 kcal/mol and 1.80 respectively.

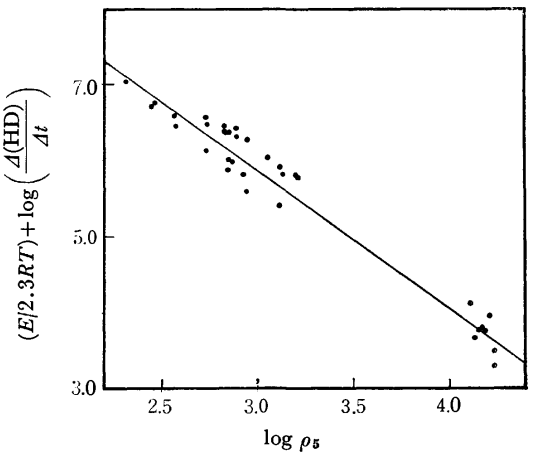

Fig. 1. The determination of reaction order n by the relation derived from Eq. (5) with E=41.2 kcal/mol at the least standard deviation. (n=1.80 from the slope)

CH_4–CD_4 Pyrolysis. *Mixture A*: Reaction times behind the reflected shock wave were about 1 ms and the temperature range was 1501~1678 K. For all of the experimental runs, (H_2) : (HD) : (D_2) ratios were examined and for some, hydrocarbons were also analyzed as shown in Table 2. The average ratios $(HD)/(H_2)$ and $(D_2)/(H_2)$ were 1.56±0.05 and 0.50±0.05, respectively. These values are slightly different from those in the previous paper[1] (1.7 and 0.6 respectively). Because of the improved separation between gas chromatographic peaks, the ratios obtained in the present work are more accurate than those in the previous paper.

Mixture B: Temperature range was 1470~1608 K. The average ratios $(HD)/(H_2)$ and $(D_2)/(H_2)$ were
