17) Serum LH levels 15 min after jugular vein injection of 0.5 and 2.5 ng LH-RH in six rats in each dose level were estimated. The dose response regression lines for natural and synthetic LH-RH prepared by two procedures were parallel. Using four point factorial assay,[18] the LH-RH activity of synthetic LH-RH was calculated as follows: synthetic LH-RH of A type elongation (amino acid content 76%), 121% of the potency of natural LH-RH (AVS 77-33 # 215-269, amino acid content 67.5%); synthetic LH-RH of B type elongation (amino acid content 78%), 125% of the potency of natural LH-RH. These values show that synthetic LH-RH prepared by the two types of chain elongation have full activity of natural LH-RH taking into consideration the ratio of amino acid content of synthetic products to that of natural one.

18) C. I. Bliss, "The Statistics of Bioassay," Academic Press, Inc., (1952).

XX was carried out by the same procedure as that for the first coupling except that the deprotection of *t*-butyl group was carried out with CF_3COOH/CH_2Cl_2 (1 : 1 v/v) containing 5% of 2-mercaptopyridine[13] to avoid decomposition of the acid-sensitive tryptophan residue. The amino acid ratios of the resulting resin–decapeptide amide after hydrolysis with 3 M *p*-toluenesulfonic acid[11] were as follows: Glu, 1.10; His, 1.01; Trp, 0.80; Ser, 0.95; Tyr, 1.03; Gly, 2.05; Leu, 1; Arg, 0.95;[19] Pro, 0.94; NH_3, 2.87. This shows that fragment condensation proceeds efficiently without protection of side chains of amino acids by this new method. The recovered amino components of fragments XVI and XX in the washing solvents, DMF and CH_2Cl_2, showed the same spots on tlc as with the starting fragments: the former was detected with ninhydrin, Pauly and Ehrlich reactions and the latter by ninhydrin and Cl-tolidine reactions. It was established that couplings of 1 g of new resin–glutamine with the recovered fragments XVI and XX gave a resin peptide with nearly the same amino acid ratios as those obtained in the above chain elongation.

The resin–decapeptide amide was treated with HF at room temperature for 30 min in the presence of anisole and 2-mercaptopyridine and the decapeptide amide was extracted with DMF. Cyclization of glutaminyl residue of the decapeptide amide to pyroglutamyl derivative (LH–RH) was achieved in acetic acid[20] at 80—100 °C for 30 min in the presence of aniosle and 2-mercaptopyridine. This decapeptide amide was purified on CM-Sephadex C-25[15c] as mentioned in A type elongation after separation of 2-mercaptopyridine by gel filtration on Sephadex G-25 in 1 M AcOH. The pure LH–RH (133 mg, 51% yield from the initial resin–glutamine) was obtained after desalting, lyophilization and precipitation from MeOH–Et_2O and drying at 40 °C *in vacuo* over P_2O_5. $[\alpha]_D^{20}$ −53.1° (*c* 1, 1% AcOH). The peptide was also characterized as diacetate and trihydrate after further drying at 80 °C for 5 hr *in vacuo* over P_2O_5. LH–RH activity of the purified decapeptide amide (amino acid content: 78%) which gave the same R_f values on various tlc as with the one prepared by A type elongation was compared at two dose levels with that of natural LH–RH (AVS 77-33 # 215-269), it exhibited full activity[17] of the natural LH–RH.

These new approaches demonstrate the advantages of preparing oligopeptides in good yields by a simple purification procedure since the contamination of similar peptides with small difference in sequence is eliminated. The introduction of tryptophan residue is more feasible than the usual solid phase synthesis since the number of acidolysis required for deblocking of protecting groups can be reduced.

Superiority of the oxidation-reduction process lies in the advantage it possesses of minimizing side reactions in carboxyl components. Thus, the side reaction, formation of acyl urea derivatives in dicyclohexylcarbodiimide method, and intensive restrictions on reaction solvent and temperature in azide method are eliminated.

Special practical merits of A and B types of elongation are as follows: type A, (1) it allows an attachment of the first amino acid in a rather homogeneous environment on the resin under milder conditions and in shorter reaction time than those carried out by ordinary methods and (2) the reaction conditions and operations are the same as for the subsequent chain-lengthening acylation and consequently incorporation of the esterification step in the automated process is possible. Type B, (1) chain elongation can be carried out in most cases with readily available Z-amino acids which can be used mostly without protection of side chains except carboxyl and amino groups, (2) excess amino components can be recovered unchanged and the formation of diacyl amide[21] can be avoided since the excess amino components are used in solution.

It is to be noted that solid phase peptide synthesis by oxidation-reduction condensation provides a versatile method which combines the advantages of the usual solid phase synthesis and the classical synthesis in solution.

Experimental

All melting points are uncorrected. Optical rotations were determined with a Perkin-Elmer Model 141 polarimeter. Amino acid analyses were performed on a Hitachi Amino Acid Analyzer, Model KLB-3B. Solid phase peptide synthesis was carried out by shaking with a manual apparatus. Thin layer chromatography was performed on precoated plates of silica gel G and cellulose F (E. Merck) at 5°.

Hydroxymethyl Resin (I) and Methylchloroformylated Resin (II). Chloromethylated copolystyrene-2% divinylbenzene (Schwarz-Mann, New York, Cl: 2.0 mmol/g, 50 g) was treated with potassium acetate, subsequently hydrolyzed and was converted into hydroxymethyl resin (I, Cl: 0%).[4] Similarly the hydroxymethyl resin (20 g) was allowed to react with phosgene and was further converted into methylchloroformylated resin (II). The resin of Cl content of 1.39 mmol/g was obtained.

I. A Type Elongation. Attachment of t*-Butyloxycarbonylglycine to the Hydroxymethyl Resin.* Hydroxymethyl resin (I) (4 g, OH: 8 mmol) was suspended in 40 ml of CH_2Cl_2 and shaken for 30 min in a vessel for solid phase synthesis and the resin was washed with CH_2Cl_2 (40 ml). After addition of 3 eq (24 mmol) each of *t*-butyloxycarbonyl glycine, 2,2′-dipyridyl disulfide in CH_2Cl_2 (20 ml) and shaking for a few min, 3 eq (24 mmol) of triphenylphosphine in CH_2Cl_2 (10 ml) was added at room temperature. The mixture was shaken for 24 hr at room temperature and washed successively with CH_2Cl_2 (30 ml × 3), EtOH (30 ml × 3) and DMF (30 ml × 3). The remaining free hydroxyl groups on the resin were covered by acetylation[10] with 10 eq (80 mmol) each of acetic anhydride and triethylamine in 30 ml of DMF for 2 hr and washed successively with DMF (30 ml × 3), EtOH (30 ml × 3) and CH_2Cl_2 (30 ml × 3). An aliquot of the resin (III) was hydrolyzed and glycine content was determined by amino acid analyzer to be 0.25 mmol/g of the resin.

Boc-Tyr(Bzl)-Gly-OEt (IV). To a stirred mixture of

19) The value was calculated from the amounts of Arg, Orn and $Arg(NO)_2$.

20) H. Matsuo, A. Arimura, R. M. G. Nair, and A. V. Schally, *Biochem. Biophys. Res. Commun.*, **45**, 822 (1971).

N-t-butyloxycarbonyl-*O*-benzyl-L-tyrosine (18.50 g, 50 mmol), ethyl glycinate (5.15 g, 50 mmol) and 2,2′-dipyridyl disulfide (11.00 g, 50 mmol) in 150 ml of dry CH_2Cl_2 was added triphenylphosphine (13.10 g, 50 mmol) in 50 ml of CH_2Cl_2 with ice-cooling. This was stirred for 6 hr at room temperature. After being left to stand overnight, the solvent was removed *in vacuo*, dissolved in 200 ml of ethyl acetate and washed successively with 10% citric-acid, water, 5% sodium bicarbonate and water. The solvent was evaporated after addition of silica gel (100 g) and the coated residue was applied to a dry column chromatography[22] on silica gel and the peptide was eluted with ether and crystallized from ethylacetate and petroleum ether; yield 20.0 g (87%); mp 123—126 °C; $[\alpha]_D^{20}$ 1.2° (*c* 2, MeOH).

Found: C, 65.91; H, 7.00; N, 6.25. Calcd for $C_{25}H_{32}O_6N_2$: C, 65.95; H, 7.02; N, 6.00.

Boc–Ser(Bzl)–Tyr(Bzl)–Gly–OEt (V). Compound IV (20 g, 40 mmol) was dissolved in 20 ml of CH_2Cl_2 and 50 ml of trifluoroacetic acid and stirred at room temperature for 1 hr. To the evaporated residue, 100 ml of ethyl acetate was added and washed first with saturated sodium bicarbonate, then water and dried over sodium sulfate. After evaporation of the solvent, the oily residue was used as ethyl *O*-benzyl-L-tyrosylglycinate. Dicyclohexylamine salt of *N-t*-butyloxycarbonyl-*O*-benzyl-L-serine (16.60 g, 43 mmol) was suspended in 10% citric acid (200 ml) and the mixture was extracted with ethyl acetate. The ethyl acetate layer was washed with water and dried over magnesium sulfate. The solvent was removed *in vacuo* and the residue was used as *N-t*-butyloxycarbonyl-*O*-benzyl-L-serine. To the stirred mixture of ethyl *O*-benzyl-L-tyrosylglycinate, *N-t*-butyloxycarbonyl-*O*-benzyl-L-serine and 2,2′-dipyridyl disulfide (11 g, 50 mmol) in 100 ml of CH_2Cl_2 was added triphenylphosphine (13.1 g, 50 mmol) in 50 ml of CH_2Cl_2 with ice-cooling and stirred at room temperature for 6 hr. After evaporation of solvent, the residue was dissolved in ethyl acetate and was washed successively with 10% citric acid, water, 5% sodium bicarbonate and water. Worked up as mentioned above, the tripeptide was obtained by dry column chromatography in ether and crystallization from ethyl acetate and petroleum ether; yield 19.00 g (71%); mp 63°C; $[\alpha]_D^{20}$ −9.0° (*c* 1, MeOH).

Found: C, 66.33; H, 6.87; N, 6.61. Calcd for $C_{35}H_{43}O_8N_3$: C, 66.33; H, 6.84; N, 6.63.

Boc–Ser(Bzl)–Tyr(Bzl)–Gly–OH (Fragment V). To a stirred mixture of 14.0 g (22 mmol) of IV in 100 ml of methanol was added 100 ml of water containing 1.0 g of sodium hydroxide. This was stirred at room temperature for 1 hr. The mixture was adjusted to pH 7 with acetic acid and evaporated *in vacuo*. The residue was dissolved in 100 ml of ethyl acetate and washed with 10% citric acid and water and dried over magnesium sulfate. The free acid peptide was obtained by crystallization from ethyl acetate–petroleum ether; yield 8.80 g (65%); mp 129—134°C; $[\alpha]_D^{20}$ −6.2° (*c* 1, MeOH).

Found: C, 65.51; H, 6.51; N, 7.10. Calcd for $C_{33}H_{39}O_8N_3$: C, 65.44; H, 6.49; N, 6.94. R_f 0.78 on silica gel G in *n*-BuOH: AcOH: H_2O (4: 1: 1) and R_f 0.72 on silica gel G in *n*-BuOH: AcOH: H_2O: Pyridine (30: 6: 24 :20). A portion of the peptide was deprotected with HF[12] for 2 hr at room temperature and hydrolysate in 6 M HCl gave the following amino acid ratios: Ser, 0.96; Tyr, 0.98; Gly, 1.

Boc–His(Tos)–Trp–OH (Fragment VI). Dicyclohexylamine salt of N^{α}-*t*-butyloxycarbonyl-N^{im}-tosyl-L-histidine(5.90 g, 10 mmol) and L-tryptophan ethyl ester hydrochloride (2.69 g, 10 mmol) were converted into free forms with citric acid and sodium bicarbonate respectively as in the preparation of IV. To a stirred mixture of N^{α}-*t*-butyloxycarbonyl-N^{im}-tosyl-L-histidine, L-tryptophan ethyl ester and 2,2′-dipyridyl disulfide (2.20 g, 10 mmol) in 30 ml of CH_2Cl_2 was added triphenylphosphine (2.62 g, 10 mmol) in 20 ml of CH_2Cl_2 with ice-cooling and the mixture was stirred at room temperature for 8 hr. The residue, after evaporation of solvent, was dissolved in ethyl acetate and washed successively with 10% citric acid, water, 5% sodium bicarbonate and water and dried over sodium sulfate. The solvent was evaporated and the residue was hydrolyzed with sodium hydroxide in methanol and water as in the preparation of V. After evaporation of methanol, the water layer was adjusted to pH 3 with acetic acid and extracted with *n*-buthanol saturated with water. The *n*-buthanol layer was washed with water saturated with *n*-buthanol and evaporated to dryness *in vacuo*. The dipeptide acid (4.05 g; 68%) was obtained from the residue by adding ether: mp 148—150 °C; $[\alpha]_D^{20}$ 15.2° (*c* 1, DMF).

Found: C, 58.54; H, 5.81; N, 11.80; S, 5.42%. Calcd for $C_{29}H_{33}O_7N_5S$: C, 58.47; H, 5.58; N, 11.75; S, 5.38%. R_f 0.80 on silica gel G in *n*-BuOH: AcOH: H_2O (4: 1: 1) and R_f 0.73 on silica gel G in *n*-BuOH: AcOH: H_2O: Pyridine (30: 6: 24: 20). Amino acid ratios (3M *p*-toluenesulfonic acid in the presence of 3-(2-aminoethyl)indole[11]): His, 1; Trp, 0.85.

〈Glu–OPcp (VII). To a stirred mixture of L-pyroglutamic acid (1.29 g, 10 mmol), pentachlorophenol 2.66 g (10 mmol) and 2,2′-dipyridyl disulfide (2.20 g, 10 mmol) in 40 ml of DMF was added triphenylphosphine (2.62 g, 10 mmol) in 20 ml of DMF with ice-cooling. The resulting mixture was stirred at room temperature for 5 hr and kept standing overnignt. After evaporation of solvent, the residue was crystallized from ethanol–ether and 2.32 g (62%) of the active ester was obtained: mp 196—198 °C, $[\alpha]_D^{28}$ +20.8° (*c* 2, DMF) lit,[14] mp 196—199 °C, $[\alpha]_D^{26}$ +21° (*c* 2, DMF).

Found: C, 35.26; H, 1.67; N, 3.96; Cl, 47.06%. Calcd for $C_{11}H_6Cl_5O_3N$: C, 35.00; H, 1.60; N, 3.71; Cl, 46.97%.

Boc–His(Tos)–Trp–Ser(Bzl)–Tyr(Bzl)–Gly–Leu–Arg(NO$_2$)–Pro–Gly–resin (VIII). Two grams of *t*-butyloxycarbonylglycine–resin (III, 0.25 mmol/g) were added to the vessel for solid phase peptide synthesis and the following steps were used to couple each new amino acid or peptide fragment: (1) washing with CH_2Cl_2 (15 ml×3); (2) prewash with trifluoroacetic acid/CH_2Cl_2 (1: 1 v/v); (3) removal of *t*-butyloxycarbonyl group with 15 ml of trifluoroacetic acid/CH_2Cl_2 (1: 1 v/v) for 30 min; (4) washing with CH_2Cl_2 (15 ml×3); (5) washing with $CHCl_3$ (15 ml×3); (6) neutralization with 15 ml of $Et_3N/CHCl_3$ (1: 10 v/v) for 10 min; (7) washing with $CHCl_3$ (15 ml×3); (8) addition of 3 fold excess (1.5 mmol) each of protected new amino acid or peptide fragment and 2,2′-dipyridyl disulfide in 10 ml of reaction solvent (CH_2Cl_2 or DMF); (9) addition of 3 eq (1.5 mmol) of triphenylphosphine in 5 ml of reaction solvent followed by a reaction period; (10) washing with reaction solvent (CH_2Cl_2 or DMF, 15 ml×3); (11) washing with ethanol (15 ml×3). The following *t*-butyloxycarbonyl amino acids were successively coupled at room temperature for 6 hr; Boc–Pro in CH_2Cl_2 Boc–Arg(NO$_2$)–OH in DMF[10] and Boc–Leu–OH·H_2O in CH_2Cl_2. In the case of Boc–Leu–OH·H_2O, 6 fold excess each of triphenylphosphine and 2,2′-dipyridyl disulfide was used. After the coupling of leucine, the peptide resin was treated with 10 fold excess (5 mmol) each of acetic anhydride and triethylamine in 15 ml of DMF for 2 hr[9] and was washed successively with DMF (15 ml×3) and ethanol (15 ml×3). The coupling of tetrapeptide–resin with Boc–Ser(Bzl)–Tyr(Bzl)–OH (fragment V) was carried out with a 1.5 fold excess of fragment V and 3 fold excess each of triphenylphosphine and 2,2′-dipyridyl disulfide in CH_2Cl_2 for 24 hr, followed by

22) B. Loev and K. M. Snader, *Chem. Ind.*, **1965**, 15. B. Loev and M. M. Goodman, *ibid.*, **1967**, 2026.

acetylation[9] with 10 fold excess each of acetic anhydride and triethylamine in DMF for 2 hr. The coupling of the resulting heptapeptide–resin with Boc-His(Tos)-Trp-OH (tragment VI) was achieved with 3 fold excess each of fragment VI, 2,2′-dipyridyl disulfide and triphenylphosphine in CH_2Cl_2 for 24 hr. A portion of this resin was treated with HF[12] at room temperature for 2 hr in the presence of 2-mercaptopyridine[13] and anisole and hydrolyzed in 3M *p*-toluenesulfonic acid[11] containing 0.2% of 3-(2-aminoethyl)indole for 24 hr and the hydrolysate gave the following amino acid ratios: His, 0.95; Trp, 0.84; Ser, 0.96; Tyr, 0.95; Gly, 2.12; Leu, 1; Arg, 0.93; Pro, 0.97.

Boc-His(Tos)-Trp-Ser(Bzl)-Tyr(Bzl)-Gly-Leu-Arg(NO_2)-Pro-Gly-NH_2 (IX). The nonapeptide–resin (VIII) was suspended in abs. ethanol and the stirred suspension was bubbled with a stream of ammonia from a refluxing solution of ammonia, which contained sodium as a drying agent, at −15—−30 °C for 8 hr with exclusion of moisture. The mixture was stirred overnight at −15—0 °C and subsequently at room temperature for 8 hr. After the evaporation of solvent, the residue was dried *in vacuo* over P_2O_5 and KOH. The cleaved material was extracted with DMF and methanol and the resin was removed by filtration. The combined filtrate was concentrated and applied to Sephadex LH-20 (2×130 cm) in DMF. The main peak was followed by two very small peaks detected by the absorption at 280 nm. The main peak was further purified with Avicel (Funakoshi Pharmaceutical Co., Tokyo) column (2.5×115 cm) in *n*-BuOH: AcOH: water (4: 1: 1) and followed by the filtration on Sephadex LH-20 in DMF. The fractions were condensed and the protected nonapeptide amide monohydrate was precipitated by adding ethyl acetate and ether. The precipitate was filtered, thoroughly washed with ethyl acetate and ether and dried *in vacuo* (P_2O_5 and KOH) to give an amorphous powder (373 mg, 48% based on Boc–glycine attached to the resin), mp 197—201 °C (decomp.), $[\alpha]_D^{25}$ −27.6° (*c* 1, DMF).

Found: C, 57.91; H, 6.35; N, 15.29; S, 1.81%. Calcd for $C_{76}H_{95}O_{17}N_{17}S \cdot H_2O$: C, 58.18; H, 6.23; N, 15.18; S, 2.04%. R_f 0.66 on silica gel G in *n*-BuOH: AcOH: H_2O (4: 1: 1) and R_f 0.75 on silica gel G in *n*-BuOH: AcOH: H_2O: Pyridine (30: 6: 24: 20). Amino acid analysis (3 M *p*-toluenesulfonic acid after HF treatment): His, 1.01; Trp, 0.82; Ser, 0.94; Tyr, 0.96; Gly, 2.04; Leu, 1; Arg, 0.88; Pro, 0.94; NH_3, 1.38. Amino acid analysis of an aminopeptidase M (Rohm and Hass Darmstadt) digest of the nonapeptide amide which was completely deprotected with HF in the presence of anisole and 2-mercaptopyridine gave: His, 1.06; Trp, 1.03; Ser, 1.02; Tyr, 1.02; Gly, 1.04; Leu, 1. No detection of Arg and Pro by the above amino acid analysis is due to the well-known resistance to enzymatic digestion of peptide bond involving proline.

⟨Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2 (LH-RH, X). In the coupling of completely deprotected nonapeptide with pentachlorophenyl L-pyroglutamate, 1.39 molar ratio of pyroglutamyl residue was found to be incorporated into nonapeptide when 1.5 eq of pentachlorophenyl pyroglutamate was used. The reaction conditions were so determined as not to use excess pentachlorophenyl glutamate. The protected nonapeptide (IX) 161 mg (0.123 mmol) was deprotected with 30 ml of dry HF for 1.5 hr at room temperature in the presence of 20 mg of 2-mercaptopyridine an i 1 ml of anisole. After the removal of HF and anisole *in vacuo*, the residue was washed with ether and dissolved in 100 ml of methanol and neutralized to pH 7 with Amberlite IRA-400 in methanol. The solvent was removed *in vacuo* and the residue was dissolved in 20 ml of DMF. To this mixture was added 0.85 eq of pentachlorophenyl L-pyroglutamate (VII) (35.5 mg, 0.942 mmol) and the mixture was stirred at room temperature for 2 hr and allowed to stand overnight. The solvent was evaporated and the peptide was precipitated by adding ethyl acetate and ether. The precipitate was dissolved in methanol and charged on the column of Amberlite IRP-64 (H^+) (1.5×8 cm) which was eluted first with methanol (200 ml) and then with 1% AcOH in methanol (700 ml). The elute of 1% AcOH in methanol was evaporated *in vacuo* and applied to Sephadex G-25 column (2.0×133 cm) in 1 M AcOH. After the evaporation of Ehlrich and Pauly positive fractions of the main peak, the decapeptide was precipitated from methanol–ethyl acetate–ether. The precipitate was dissolved in 150 ml of water and was further purified on CM-Sephadex C-25 (2.5×11 cm) as reported by N. Yanaihara *et al.*:[15] eluted successively with H_2O (150 ml), 0.1 M $AcONH_4$ (500 ml), 0.15 M $AcONH_4$ (500 ml) and 0.2 M $AcONH_4$ (500 ml). The main peak in 0.15 M $AcONH_4$ which was negative to ninhydrin was followed by a small peak in 0.2 M $AcONH_4$ positive to ninhydrin. The fractions containing a single component evaluated by Ehlrich, Pauly and Cl-tolidine reactions on tlc were pooled and evaporated *in vacuo* to 100 ml after acidification with AcOH. Desalting was achieved by lyophilization 3 times and further gel filtration on Sephadex G-25 in 1 M AcOH. The pure decapeptide amide was obtained by precipitation from methanol–ethyl acetate–ether after evaporation of solvent and dried *in vacuo* over P_2O_5 at 40°C for 12 hr: yield 46 mg (38% yield based on nonapeptide (IX)) $[\alpha]_D^{20}$ −54.2° (*c* 1, 1% AcOH) lit, $[\alpha]_D^{20}$ −50.5 ±2° (*c* 1, 1% AcOH)[15a], $[\alpha]_D^{20}$ −52.9° (*c* 1, 1% AcOH)[15b], $[\alpha]_D^{25}$ −48.2° (*c*0.5, H_2O)[15b]. Amino acid ratios (3 M *p*-toluenesulfonic acid[12]): Glu, 1.02; His, 0.98; Trp, 0.84; Ser, 1.01; Tyr, 0.99; Gly, 2.06; Leu, 1; Arg, 0.92; Pro, 0.96; NH_3, 1.35 and amino acid content was calculated to be 76% from the recovery value of leucine. The peptide was characterized as diacetate and trihydrate after further drying *in vacuo* at 80° over P_2O_5 for 5 hr.

Found: C, 52.32; H, 6.37; N, 17.56%. Calcd for $C_{55}H_{75}N_{17}O_{13} \cdot 2CH_3COOH \cdot 3H_2O$: C, 52.24; H, 6.61; N, 17.56%.

The product showed a single spot on various systems of tlc to Pauly, Ehlrich, Sakaguchi and Cl-tolidine reagents, the R_f values being identical with those reported in the literature[15a]: R_f 0.19 (lit, 0.16) on silica gel G and R_f 0.43 (lit, 0.44) on cellulose F in *n*-BuOH: AcOH: H_2O (4: 1: 5); R_f 0.51 (lit, 0.54) on silica gel G and R_f 0.61 (lit, 0.64) on cellulose F in $CHCl_3$: MeOH: 32%AcOH (12: 9: 4); R_f 0.44 (lit, 0.41) on silica gel G in *n*-BuOH: AcOH: Pyridine: H_2O (4: 1: 1: 2); R_f 0.79 (lit, 0.80) on cellulose F in $CHCl_3$: MeOH: 28%-NH_4OH (12: 9: 4).

II. B Type Elongation. Attachment of t-*Butyl* L-*Glutaminate to the Methylchloroformylated Resin.* The methylchloroformylated resin (II) 4 g (Cl: 1.39 mmol/g) was treated with 0.5 eq (2.78 mmol) each of *t*-butyl L-glutaminate and triethyl amine in 40 ml of $CHCl_3$ for 4 hr and successively with 10 eq (55.6 mmol) of diethylamine for 4 hr.[4] The content of glutamine of the resin (XI) was determined by amino acid analyzer to be 0.11 mmol/g.

Z-Tyr-Gly-OBu^t (XII). To a stirred mixture of 0.1 mol each of benzyloxycarbonyl-L-tyrosine (31.50 g), *t*-butyl glycinate (13.1 g) and 2,2′-dipyridyl disulfide (22 g) in 300 ml of DMF was added triphenylphosphine (26.2 g, 0.1 M) in 100 ml of CH_2Cl_2 and the mixture was stirred at room temperature for 9 hr. After working up as in the preparation of IV, crystallization from ethyl acetate–petroleum ether gave the dipeptide: 35.6 g (83%); mp 113—114°; $[\alpha]_D^{28}$ −22.4° (*c* 2, DMF).

Found: C, 64.25; H, 6.63; N, 6.70%. Calcd for $C_{23}H_{28}O_6N_2$: C, 64.47; H, 6.59; N, 6.54%.

Z-Ser(Bu^t)-Tyr-Gly-OBu^t (XIII). Compound XII 34.8 g (72 mmol) in 300 ml of methanol was hydrogenated over 10% Pd/C as a catalyst. The solvent was removed after filtration of the catalyst and dried *in vacuo* over P_2O_5. The residue, benzyloxycarbonyl-*O*-*t*-butyl-L-serine (17.7 g, 60 mmol) and 2,2'-dipyridyl disulfide 13.2 g (60 mmol), were dissolved in 200 ml of CH_2Cl_2. To this stirred mixture was added triphenylphosphine (15.70 g, 60 mmol) in 100 ml of CH_2Cl_2 with ice-cooling and the mixture was stirred at room temperature for 8 hr. After working up as in the preparation of IV, evaporation of solvent gave an amorphous powder: 27.5 g (80%); mp 105—115 °C; $[\alpha]_D^{20}$ −20.5° (*c* 1, MeOH).

Found: C, 60.92; H, 7.15; N, 7.30%. Calcd for $C_{30}H_{41}O_8N_3 \cdot H_2O$: C, 61.10; H, 7.35; N, 7.13%.

Z-Trp-Ser(Bu^t)-Tyr-Gly-OBu^t (XIV). Compound XIII (25.1 g, 44 mmol) was hydrogenated in methanol over 10% Pd/C as in the preparation of XIII. To a stirred mixture of the above *t*-butyl *O*-*t*-butyl-L-seryl-L-tyrosylglycinate, benzyloxycarbonyl-L-tryptophan (13.5 g, 40 mmol) and 2,2'-dipyridyl disulfide (8.80 g, 40 mmol) in 200 ml of DMF was added triphenylphosphine (10.5 g, 40 mmol) in 100 ml of CH_2Cl_2 with ice-cooling and the mixture was stirred at room temperature for 6 hr and kept standing overnight. The solvent was removed *in vacuo* and the residue was dissolved in 200 ml of ethyl acetate. The mixture was washed with 10% citric acid, water, 5% sodium bicarbonate and water and dried over sodium sulfate. The solvent was removed *in vacuo* after the addition of 100 g of silica gel. The coated residue was subjected to dry column chromatography and developed with ether. The coated layer was separated and the peptide was eluted with MeOH/$CHCl_3$ (1: 2 v/v). After the solvent was removed, the residue was dissolved in ethyl acetate, and washed with water. After being dried over sodium sulfate, the solution was condensed and the tetrapeptide was obtained by precipitation with the addition of petroleum ether: 23.5 g (78%); mp 138—140°; $[\alpha]_D^{20}$ −14.8° (*c* 1, DMF).

Found: C, 65.13; H, 6.89; N, 9.15%. Calcd for $C_{41}H_{51}O_9N_5$: C, 64.97; H, 6.78; N, 9.24%.

Z-His-Trp-Ser(Bu^t)-Tyr-Gly-OBu^t (XV). Compound XIV (16.65 g, 22 mmol) was hydrogenated over 10% Pd/C as in the preparation of XIII. To a stirred mixture of the above tetrapeptide, benzyloxycarbonyl-L-histidine (5.78 g, 20 mmol) and 2,2'-dipyridyl disulfide (4.40 g, 20 mmol) in 150 ml of DMF was added triphenylphosphine (5.24 g, 20 mmol) in 100 ml of CH_2Cl_2 with ice-cooling and the mixture stirred at room temperature for 8 hr. After being left to stand overnight, the solvent was evaporated *in vacuo* and the residue was dissolved in *n*-buthanol. The mixture was washed successively with 10% citric acid, water and 5% sodium bicarbonate and evaporated *in vacuo*. From the residue, pentapeptide was precipitated from methanol-ethyl acetate-ether and was further filtered with Sephadex LH-20 in DMF. It was crystallized from methanol-ethyl acetate-ether and dried *in vacuo* over P_2O_5: yield 13.90 g (78%); mp 172—175 °C; $[\alpha]_D^{20}$ −9.6° (*c* 1, DMF).

Found: C, 61.57; H, 6.58; N, 12.10%. Calcd for $C_{47}H_{58}O_{10}N_8 \cdot H_2O$: C, 61.83; H, 6.62; N, 12.27%. R_f 0.72 on silica gel G in *n*-BuOH: AcOH: H_2O (4: 1: 1) and R_f 0.74 on silica gel G in *n*-BuOH: AcOH: H_2O: Pyridine (30: 6: 24: 20). Amino acid ratios (3M *p*-toluenesulfonic acid hydrolysis): His, 1.01; Trp, 0.84; Ser, 0.98; Tyr, 0.97; Gly, 1.

H-His-Trp-Ser(Bu^t)-Tyr-Gly-OBu^t (Fragment XVI). Compound XV (679 ml, 0.66 mmol) was hydrogenated over Pd/C in methanol and the solvent was removed after filtration of the catalyst. The residue was dried *in vacuo* over P_2O_5 and was used as fragment XVI: R_f 0.47 on silica gel G in *n*-BuOH: AcOH: H_2O (4: 1: 1) and R_f 0.66 on silica gel G in *n*-BuOH: AcOH: H_2O: Pyridine (30: 6: 24: 20).

Z-Pro-Gly-NH$_2$ (XVII). To a stirred mixture of 50 mmol each of benzyloxycarbonyl-L-proline (12.50 g), ethyl glycinate 5.15 g and 2,2'-dipyridyl disulfide (11.00 g) in 150 ml of CH_2Cl_2 was added triphenylphosphine (13.10 g, 50 mmol) in 50 ml of CH_2Cl_2 with ice-cooling and the mixture was stirred at room temperature for 8 hr. After being left to stand overnight and worked up as in the preparation of XII, ethyl benzyloxycarbonyl-L-prolylglycinate was obtained as an oily substance. This product was dissolved in 1000 ml of abs. ethanol to which was added 500 ml of dry ammonia at −30 °C. After stirring was continued at room temperature for 58 hr, the solvent was removed and the dipeptide amide was obtained by crystallization from ethyl acetate: yield 13.80 g (89%); mp 120 °C; $[\alpha]_D^{20}$ −37.1° (*c* 1, MeOH).

Found: C, 58.88; H, 6.23; N, 13.92%. Calcd for $C_{15}H_{19}N_3O_4$: C, 59.02; H, 6.29; N, 13.77%.

Boc-Arg(NO$_2$)-Pro-Gly-NH$_2$ (XVIII). Compound XVII (10.10 g, 33 mmol) was hydrogenated as in the preparation of XIII. To a stirred mixture of L-prolylglycine amide, *t*-butyloxycarbonyl-N^G-nitro-L-arginine (9.60 g, 30 mmol) in 150 ml of DMF was added triphenylphosphine (7.86 g, 30 mmol) in 50 ml of DMF with ice-cooling and the mixture stirred at room temperature for 8 hr. After being left to stand overnight, the solvent was removed and dry column chromatography was developed with ethyl acetate. The coated layer was separated and the tripeptide was eluted with MeOH/$CHCl_3$ (1: 2). The solvent was removed and crystallization of the residue from ethyl acetate gave tripeptide: 11.00 g (78%); mp 157 °C; $[\alpha]_D^{20}$ −33.8° (*c* 1, MeOH).

Found: C, 45.62; H, 6.73; N, 23.45%. Calcd for $C_{18}H_{32}O_7N_8$: C, 45.66; H, 6.78; N, 23.68%.

Boc-Leu-Arg(NO$_2$)-Pro-Gly-NH$_2$ (XIX). Compound XVIII (10.40 g, 22 mmol) was dissolved in 30 ml each of trifluoroacetic acid and CH_2Cl_2 and stirred at room temperature for 1 hr. To the evaporated residue was added 500 ml of ether and the precipitate was filtered. it was dried over potassium hydroxide *in vacuo*. To a stirred mixture of the above trifluoroacetic acid salt of tripeptide, triethylamine (2.50 g, 25 mmol), 2,2'-dipyridyl disulfide (8.80 g, 40 mmol) and *t*-butyloxycarbonyl-L-leucine monohydrate (5.00 g, 20 mmol) in 100 ml of DMF was added triphenylphosphine (10.48 g, 40 mmol) in 50 ml of DMF. The mixture was stirred at room temperature for 6 hr and left to stand overnight. After evaporation of the solvent, the residue was dissolved in *n*-buthanol and washed successively with 10% citric acid, water, 5% sodium bicarbonate and water. The solvent was removed and the residue was subjected to dry column chromatography developed with ethyl acetate. From the coated layer the peptide was eluted with MeOH/$CHCl_3$ (1: 3) and crystallization from methanol-ethyl acetate-petroleum ether, after evaporation of the solvent, gave the tetrapeptide amide: 11.00 g (94%); mp 168—171 °C (decomp.); $[\alpha]_D^{20}$ −43.2° (*c* 2, DMF).

Found: C, 48.82; H, 7.42; N, 21.18%. Calcd for $C_{24}H_{43}O_8N_9$: C, 49.15; H, 7.34; N, 21.50%. R_f 0.56 on silica gel G in *n*-BuOH: AcOH: H_2O (4: 1: 1) and R_f 0.70 on silica gel G in *n*-BuOH: AcOH: H_2O: Pyridine (30: 6: 24: 20). Amino acid ratios: Leu, 1; Arg, 0.96[19]; Pro, 0.99; Gly, 1.03; NH_3, 1.39.

H-Leu-Arg(NO$_2$)-Pro-Gly-NH$_2$ (Fragment XX). Compound XIX (387 mg, 0.66 mmol) was dissolved in 20 ml of trifluoroacetic acid with ice-cooling and stirred at room temperature for 1 hr. Ether was added and the precipitate was collected by filtration. The precipitate was dissolved in methanol and neutralized with IRA-400 in methanol. The evaporated residue was dried over KOH *in vacuo* and used as

fragment XX: R_f 0.23 on silica gel G in *n*-BuOH: AcOH:H_2O (4: 1: 1) and R_f 0.61 on silica gel G in *n*-BuOH: AcOH: H_2O: Pyridine (30: 6: 24: 20).

Resin–Glu(NH_2)–His–Trp–Ser–Tyr–Gly–Leu–Arg(NO_2)–Pro–Gly–NH_2 (XXI). Two grams of resin–L-glutamine *t*-butyl ester (XI, 0.11 mmol/g) was added to the vessel for solid phase peptide synthesis and chain elongation was carried out according to the procedure for the preparation of VIII. The first coupling of the initial resin–glutamine with H–His–Trp–Ser(Bu^t)–Tyr–Gly–OBu^t (fragment XVI) was carried out by adding 3 eq (0.66 mmol) of triphenylphosphine in 5 ml of CH_2Cl_2 to a mixture of the resin and 3 eq (0.66 mmol) each of fragment XVI and 2,2′-dipyridyl disulfide in 10 ml of DMF. The mixture was shaken at room temperature for 10 hr followed by shaking for 24 hr after the further addition of 3 eq (0.66 mmol) each of triphenylphosphine and 2,2′-dipyridyl disulfide. A portion of the resulting resin was hydrolyzed in 3 M *p*-toluenesulfonic acid and the amino acid analysis gave the following ratios: Glu, 1.09; His, 0.98; Trp, 0.84; Ser, 0.96; Tyr, 0.95; Gly, 1; NH_3, 1.42. The recovered fragment XVI in the washing solvent of DMF and CH_2Cl_2 showed the same spot on tlc as the starting fragment XVI detected with ninhydrin, Pauly and Ehrlich reaction. Fragment XVI was isolated by gel filtration on Sephadex LH-20 in DMF: 160 mg (0.35 mmol). The second coupling of the resulting resin–hexapeptide with 3 eq (0.66 mmol) of H–Leu–Arg(NO_2)–Pro–Gly–NH_2 (fragment XX) was carried out by the same procedure as described in the first coupling except that the deprotection of *t*-butyl group (steps (2) and (3) in the preparation of VIII) was carried out with trifluoroacetic acid/CH_2Cl_2 (1: 1 v/v) containing 5% of 2-mercaptopyridine. The amino acid analysis (3 M *p*-toluenesulfonic acid) of an aliquot of the resin–decapeptide gave the following results: Glu, 1.10; His, 1.01; Trp, 0.80; Ser, 0.95; Tyr, 1.03; Gly, 2.05; Leu, 1; Arg, 0.95;[19] Pro, 0.94; NH_3, 2.87. The recovered fragment XX in the washing solvent was also identical on tlc with the starting material. It was established by the following experiment that the recovered fragments were used successfully in the next coupling. The coupling of 1g of a new resin–glutamine *t*-butyl ester (XI, 0.11 mmol/g) with the recovered fragment XVI (0.35 mmol) isolated as above and the recovered fragment XX in washing solvent after the evaporation of solvent gave similar results. The amino acid analysis gave: Glu, 1.07; His, 0.97; Trp, 0.80; Ser, 0.99; Tyr, 0.96; Gly, 2.06; Leu, 1; Arg, 0.94;[19] Pro, 0.98; NH_3, 2.93.

⟨Glu–His–Trp–Ser–Tyr–Gly–Leu–Arg–Pro–Gly–NH_2 (LH–RH, X). The resin–decapeptide (XXI) 2 g was treated with 30 ml of dry HF[13] for 30 ml at room temperature in the presence of 1 ml of anisole and 300 mg of 2-mercaptopyridine. After the removal of HF and anisole *in vacuo*, 150 ml of DMF was added and the resin was filtered off. The solution was condensed and the peptide was precipitated by adding ethyl acetate and ether. The glutaminyl residue of this decapeptide was cyclized[20] in 40 ml of acetic acid containing 200 mg of 2-mercaptopyridine and 20 ml of anisole at 80—100 °C for 30 min. After evaporation of solvent, the peptide was precipitated from methanol–ether. The peptide was dissolved in 200 ml of water and passed through a Dowex 1×2 (OAc) column to be converted into acetate form. The peptide was also purified on CM-Sephadex as in the preparation of X by A type elongation after the separation of 2-mercaptopyridine by gel filtration on Sephadex G-25; the main peak in 0.15 M $AcONH_4$ was proceeded by a small peak in 0.1 M $AcONH_4$. The fraction containing a single component was pooled and the pure decapeptide amide was obtained after desalting, precipitation and drying *in vacuo* over P_2O_5 at 40°: yield 133 mg (51% based on the glutamine attached to the resin); $[\alpha]_D^{20}$ −53.1° (*c* 1, 1% AcOH). Amino acid analysis (3 M *p*-toluenesulfonic acid hydrolysate: Glu, 1.02; His, 0.99; Trp, 0.81; Ser, 0.96; Tyr, 0.97; Gly, 2.02; Leu, 1; Arg, 0.96; Pro, 0.97; NH_3, 1.32 and amino acid content was calculated to be 78% from the recovery value of leucine. The peptide was homogeneous on various tlc described in the preparation of X by detection with Pauly, Ehrlich, Sakaguchi and Cl-tolidine reagents, the R_f values being identical with those of natural LH–RH and the synthetic LH–RH by A type elongation. The peptide was also characterized as diacetate and trihydrate after further drying *in vacuo* at 80°C over P_2O_5.

Found: C, 52.26; H, 6.64; N, 17.14%. Calcd for $C_{55}H_{75}N_{17}O_{13}\cdot 2CH_3COOH\cdot 3H_2O$: C, 52.24; H, 6.61; N, 17.56%.

Bioassay. LH–RH activities of the decapeptides were compared at 2 dose levels with that of natural LH–RH (AVS 77-33 #215-269, amino acid content 67.5%) in ovariectomized, estrogen-progesterone treated rats. Serum LH levels 15 min after the jugular vein injection of 0.5 and 2.5 ng LH–RH in six rats in each dose level were estimated by radioimmunoassay according to Niswender *et al.*[16] and expressed in terms of NIH-LH-S17. The dose response regression lines for natural and synthetic two decapeptides were parallel. Using four point factorial assay,[18] the LH–RH activities of synthetic LH–RH were calculated as follows: synthetic LH–RH of A type elongation (amino acid content 76%), 121% of the potency of natural LH–RH with 95% fiducial limits of 87—182%; synthetic LH–RH of B type elongation (amino acid content 78%), 125% of the potency of natural LH–RH with 95% fiducial limits of 91—173%. The values were in good agreement with the ratios of the amino acid contents of synthetic LH–RH to that of the natural one.

Appreciation is due to Drs. Y. Baba and K. Kitamura for participating in the biological assay and to Mr. T. Wada for statistical treatment. We would like to thank Drs. A. V. Schally and A. Arimura, Tulane University, for providing us with the natural LH–RH.

Studies of Reaction Mechanisms by All-valence Electron Semi-Empirical SCF MO Theories. VIII.[1] Electronic Structure and Valence Isomerization of *syn*- and *anti*-Tricyclo[4.2.0.0^{2,5}]octa-3,7-dienes

Hiizu IWAMURA, Hiroshi KIHARA, Kazuhiko MORIO, and Tosiyasu L. KUNII*

*Department of Chemistry, Faculty of Science, *Information Science Laboratory, Faculty of Science, and The Computer Centre, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received April 5, 1973)

The theoretical structures and heats of formation of *syn*- and *anti*-tricyclo[4.2.0.0^{2,5}]octa-3,7-dienes (**1** and **2**) have been investigated by the MINDO methods. An examination of their MO's reveals that there is an extensive mixing between the highlying σ-orbitals of the four-membered rings and the ethylenic π-orbitals, which makes the highest occupied MO's devoid of any ethylenic π-character. A degenerate valence isomerization (Eq. (7)) rather than the [2+2] cycloaddition is suggested as an excited-state reaction. An intermediately facile ($\Delta H^{\ddagger}$=23.1 kcal/mol) degenerate Cope rearrangement (Eq. (1)) is predicted for **1** under thermal conditions. The transition-state structure (**1′**) and the partitioned activation energy values obtained by the MINDO/2 methods are compared with those for the Cope rearrangement of semibullvalene (**3**) and 1,5-hexadiene. The deviation from planarity of the allyl groups in **1′** is the reason for the activation energy calculated for **1** being higher than that for **3**. The hypothetical paths from **1** to cubane in the electronic ground state are characteristic of the reaction with an anti-aromatic transition state.

Although the development of the chemistry of *syn*- and *anti*-tricyclo[4.2.0.0^{2,5}]octa-3,7-dienes (**1** and **2**) has been rather tardy since their first preparation as cyclobutadiene dimers by Nenitzescu and his co-workers in 1964,[2] their electronic structures are of great theoretical interest in that extensive through-space and/or through-bond interaction[3] between π- and high-lying σ-orbitals is expected. We will present here some possible chemical consequences of the orbital overlap as revealed by an examination of their molecular orbitals obtained by the MINDO approximations which are reputed to reproduce the ground-state properties of hydrocarbons reasonably well.[4] Two kinds of the valence isomerization of the *syn*-isomer **1**, one involving a degenerate Cope rearrangement and the other leading to cubane (Chart 1), are considered.

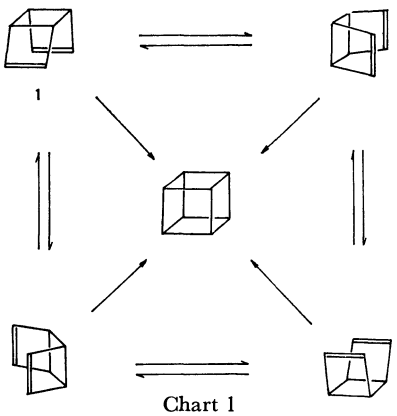

Chart 1

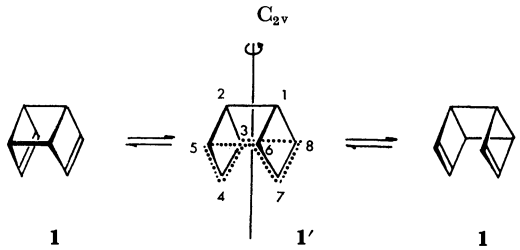
Method of Calculations

Since no structural data are available for **1** and **2**, their equilibrium geometries are sought by minimizing the total energies with respect to the changes in all the independent bond lengths and angles in the molecules. The geometry of the transition state **1′** for the Cope rearrangement was assumed *a priori* to have the C_{2v} symmetry, with the axis passing through the centers of the C_1–C_2 and C_4–C_7 bonds when the C_5–C_6 and C_3–C_8 bonds participate in the rearrangement (Eq. (1)); it was optimized much as in ground-state geometry.



(1)

In order to help verbalize the results of the molecular orbital studies, the partitioning of the total energy into one-center and two-center terms was carried out as presented by Gordon[5] and by Fischer and Kollmar[6] for the CNDO methods. In the framework of the MINDO/2 methods, both terms are defined by standard integrals as follows, with the second term consisting of the resonance (E_{AB}^{R}), exchange (E_{AB}^{X}), and electrostatic (E_{AB}^{S}) terms, respectively:

$$E_{\text{total}} = \sum_{A} E_A + \sum_{A<B}\sum E_{AB} \tag{2}$$

$$E_A = \sum_{\mu(A)} P_{\mu\mu}U_{\mu\mu} + \frac{1}{2}\sum_{\mu(A)} P_{\mu\mu}^2\langle\mu\mu|\nu\nu\rangle + \sum_{\mu\neq\nu}^{A}\sum^{A}\left\{P_{\mu\mu}P_{\nu\nu}\left[\langle\mu\mu|\nu\nu\rangle - \frac{1}{2}\langle\mu\nu|\mu\nu\rangle\right] + P_{\mu\nu}^2\left[\frac{3}{2}\langle\mu\nu|\mu\nu\rangle - \frac{1}{2}\langle\mu\mu|\nu\nu\rangle\right]\right\} \tag{3}$$

$$E_{AB} = E_{AB}^{R} + E_{AB}^{X} + E_{AB}^{S} \quad (4)$$
$$E_{AB}^{R} = 2\sum_{\mu(A)}\sum_{\nu(B)} P_{\mu\nu}\beta_{AB}(I_\mu + I_\nu)S_{\mu\nu}$$
$$E_{AB}^{X} = -\frac{1}{2}\gamma_{AB}\sum_{\mu(A)}\sum_{\nu(B)} P_{\mu\nu}^2$$
$$E_{AB}^{S} = P_A P_B \gamma_{AB} + (-P_A Z_B - P_B Z_A)\gamma_{AB} + Z_A Z_B[\gamma_{AB} + (1/R - \gamma_{AB}) \exp(-\alpha_{AB} R_{AB})]$$

In short, the total energy of molecules is considered to be determined by the nature of the constituent atoms and the chemical bonding energy, E_{AB} corresponding to the strength of the A–B bond. By taking a partial summation, the one-center energy is further divided into one due to hydrogen and another due to carbon atoms:

$$\sum_A E_A = \sum E_A^{H} + \sum E_A^{C} \quad (5)$$

The two-center terms are further subdivided to neighboring (E_{AB}^{N}) and non-neighboring (E_{AB}^{NN}) terms, where the A and B atoms in E_{AB}^{N} are, by definition, a pair connected by the chemical bond, while the pair of A and B in E_{AB}^{NN} are not directly bonded in a molecule.

The calculations were performed on a HITAC 5020E computer, with the use of a modified MINDO program originally written by Baird and distributed by the QCPE organization.[7]

Results and Discussion

(A) Results on Ground-state Geometry and Energy. The equilibrium geometries, neighboring two-center energies, and bond indices of Wiberg, as defined as Eq. (6),[8] are summarized for **1** and **2** in Table 1.

$$W_{AB} = \sum_{\mu}^{A}\sum_{\nu}^{B} P_{\mu\nu}^2 \quad (6)$$

The calculated bond lengths and angles are generally in good agreement with those observed for many cyclobutane and cyclobutene derivatives,[9] especially when the slight underestimation of the sp^2 to sp^3 single-bond length is taken as a natural consequence of one of the disadvantages of the MINDO/2 approximations.

The heats of formation and the ionization potentials obtained by the use of Koopmans' theorem are listed in Table 2. The MINDO/1 energy values are for the geometries of **1** and **2**, which are obtained by replacing the optimized bond lengths by the MINDO/2 with the standard bond lengths tabulated in Ref. 4(a). It is generally accepted that the strain energy of cyclobutane and cyclobutene rings is underestimated by the MINDO/2 by as much as 25 kcal/mol.[4] The values of the heat of formation calculated for **1** and **2** by this method are lower than those of the MINDO/1 by *ca.* 75 kcal/mol. The value when divided by three, the number of the four-membered rings present in **1** and **2**, gives 25 kcal/mol, in good agreement with the amount of the underestimation of the strain energy per four-membered ring. Thus, the MINDO/1 values are considered to represent more realistic theoretical values for the heat of formation. The value of 108 kcal/mol is obtained for **1** and **2** by Franklin's group-equivalent method for the heat of formation.[10]

The ionization potentials calculated by the MINDO/2 are in good agreement with the experimental ones.[11] The larger value found for **2** is well reproduced by the calculation; the origin of the difference in **1** and **2** will be discussed in Section (B).

We note that the **1** isomer is always predicted to be slightly less stable than the **2** isomer irrespective of the approximation of the MO methods employed. The **1**

isomer is calculated by the CNDO/2 method as well to be less stable by 2.4 kcal/mol. It is intuitively expected that the repulsive interaction between the 2pπ orbitals of the two facing ethylene groups in **1** might contribute to the destabilization, since the distance between the ethylene groups is only 2.93 Å. The energy partitioning study supports this expectation. The non-neighboring two-center energy value for C_3 and C_8 (=C_4 and C_7) is *ca.* 1.5 kcal/mol; the positive sign indicates destabilization, and the mechanism is found to be mostly electrostatic (see Table 3).[12] The slight widening of the angles between the cyclobutane and cyclobutene ring planes calculated for **1** compared to **2** could be due to this repulsive interaction. A further inspection of the dissected energy values reveals that, although the eclipsed hydrogen atoms, H_9 and H_{10}, in **1** also have non-neighboring repulsion, the effect is counterbalanced by the analogous interaction between pairs of eclipsed hydrogen and carbon atoms on the cyclobutane ring in **2**. The bonding interaction between the far-apart C_3 and C_8 (and C_4 and C_7 as well), together with the strengthening of the C_1–C_2 bond (and C_5–C_6) in **2**, as is shown in Table 2, suggest the role of a through-bond resonance interaction, *i.e.*, π-σ-π conjugation, between the two ethylenic moieties as another factor favoring **2** energetically.

(B) Molecular Orbital Construction. Turning now to the construction of the higher occupied molecular orbitals of **1** and **2**, we may note that the π-orbital approximations are a far from satisfactory description. The highest occcupied molecular orbitals are, first of all, not π-charactered, but are composed of σ-orbitals. The mixing of the ethylenic π-orbitals with σ-orbitals is extensive as a result of the presence of the high-lying σ-orbitals of cyclobutane and cyclobutene rings.[13] The unique topology of the carbon atoms in **1** and **2** also provides the necessary symmetry for the interaction. Ideally, three types of interaction, a, b, and c, are possible between the 2p-orbitals, as is shown in Chart 2. In connection with the relative stability of **1** and **2** discussed in the previous section, the a type interaction

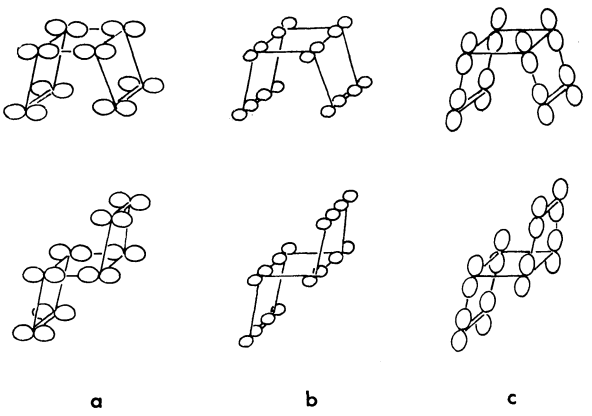

Chart 2

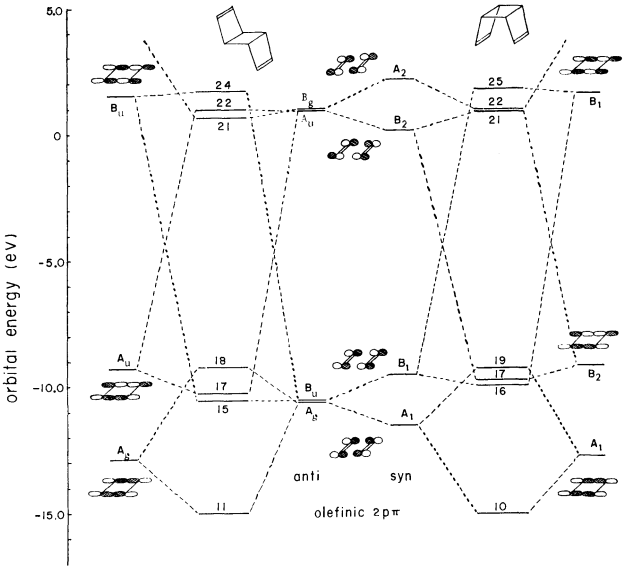

Fig. 1a. Type a interaction diagram for the mixing of two olefinic 2pπ orbitals and the σ orbitals of a cyclobutane ring. Symmetry classification uses the σ and i operations for **1** and **2**, respectively.

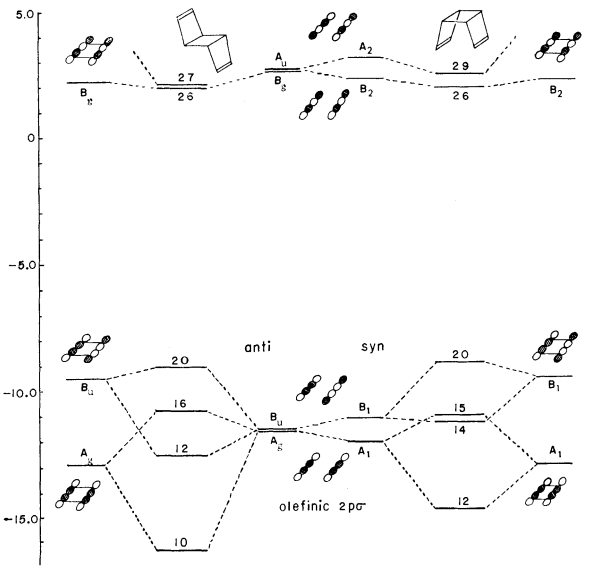

Fig. 1b. Type b interaction diagram for the mixing of two olefinic 2pπ orbitals and the σ orbitals of a cyclobutane ring. The directions of the atomic orbitals are idealized.

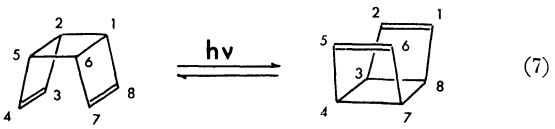
12) The sum of the Hückel molecular orbital energy values should not change theoretically by the interaction of the two facing ethylene groups, because the amount of the stabilization of the in-phase combination of the ethylenic π-orbitals and the destabilization of the out-of-phase combination cancel each other out. The terms other than electrostatic are, therefore, expected not to differ much between **1** and **2**.

13) L. Salem and J. S. Wright, *J. Amer. Chem. Soc.*, **91**, 5947 (1969); R. Hoffmann and R. B. Davidson, *ibid.*, **93**, 5699 (1971); J. S. Wright and L. Salem, *ibid.*, **94**, 322 (1972); P. Bischof, E. Haselbach, and E. Heilbronner, *Angew. Chem.*, **82**, 952 (1970).

is of prime importance in that many of the calculated higher occupied molecular orbitals are interpreted in terms of this type of interaction. The calculated coefficients of the atomic orbitals in the 10th, 16th, 17th, and 19th molecular orbitals of **1**, for example, are described by interaction diagram of Fig. 1a. To this is added the b type interaction, which results in the production of the highest occupied 20th molecular orbital of a σ-character. It is interesting to note that the lower ionization potential calculated for **1** compared to **2**, *i.e.*, the energy value of the highest occupied molecular orbital of **1** relative to **2** higher by 0.21 eV, is due to a larger splitting by this interaction in **1**, probably because of the through-space destabilization of the ethylenic σ-bonds. The failure to obtain cubane by the irradiation of **1** under direct and sensitized conditions[14] is possibly related to the fact that the highest occupied molecular orbital is not connected with the ethylenic π-orbitals. To make matters worse, the C_1–C_6 and C_2–C_5 bonds of the cyclobutane ring are now *anti*-bonding in the unoccupied molecular orbitals, *e.g.*, 21st and 26th, where the transannular π-orbital interaction between C_3 and C_8, and between C_4 and C_7, is effectively bonding. Thus, the cleavage of the ring would concomitantly result and a degenerate valence isomerization as depicted by Eq. (7) can be predicted as a possibility of an excited-state reaction.[1]



(7)

(C) Results on the Transition State for the Cope Rearrangement. Figure 2 shows the optimized geometry and (in parentheses) the Wiberg bond indices for the transition-state structure **1′**. The four-membered rings are folded so as to make a dihedral angle between the $C_2C_3C_5$ and $C_3C_4C_5$ planes of 25.8°. Notice also that each allyl group is not planar, but that the end carbon atoms, C_3, C_5, C_6, and C_8 are pyramidal, with the hydrogen atoms attached to them deviating outwards from the trigonal planes, *e.g.*, the $C_2C_3C_4$ plane, by 32.0°. The geometry is considered to be attained by an attempt to relieve the non-bonded interaction between the facing hydrogens on both sides of the allyl moieties on the one hand and to increase the overlap between the two allyl groups at their ends. In contrast, the hydrogen atoms attached to C_4 and C_7 are displaced by 14.5° from the $C_3C_4C_5$ and $C_6C_7C_8$ planes, respectively, in the direction of their approach. The deformation is favored by the smaller overlap between C_4 and C_7. When the overlap is appreciable, the intermediate will be somewhat like the geometry on the reaction coordinate leading to cubane and should be energetically unfavorable, as will be seen in Section (E). The distance between the two allyl groups in **1′** is 1.71 Å at the end carbons and 2.70 Å at the center. These values are quite similar to the corresponding values (1.75 and 2.81 Å respectively)[15] in the transition-state structure for the Cope rearrangement of semibullvalene **3**. In other words, the delocalization of electrons over the six carbon atoms (C_3 through C_8) in **1′** is expected to be as extensive as in the transition state of **3**. The heat of formation of **1′** obtained by the MINDO/2 method is 69.5 kcal/mol.

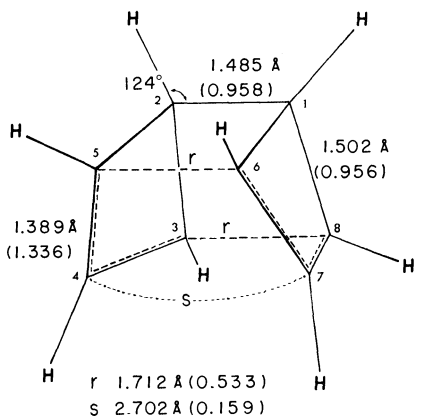


Fig. 2. The optimized bond lengths and the Wiberg's bond indices (in parentheses) for **1′**.

(D) On the Activation Energy for the Cope Rearrangement. The activation energy for the Cope rearrangement of **1** *via* **1′** is calculated as 23.1 kcal/mol on the basis of the difference between the MINDO/2 heats of formation for the ground state, **1**, and the transition state, **1′**.[16] Although the Cope rearrangement in **1** can be expected, from the similarity of the transition-state structure, to be as facile as in the case of **3** (see Section (C)), the value indicates that the reaction is not as easy as in bridged homotropilidenes, in which the activation energy is no more than 12 kcal/mol.[15] The reported thermal isomerizations of 1,3,4,6-tetrabromo-2,5,7,8-tetramethyltricyclo[4.2.0.$0^{2,5}$]octa-3,7-diene to the 1,4,5,8-tetrabromo-2,3,6,7-tetramethyl isomer (Eq. (8)) and of the hexachloro-derivative (Eq. (9)) support the result of the theoretical calculations.

15) A. Brown, M. J. S. Dewar, and W. W. Schoeller, *J. Amer. Chem. Soc.*, **92**, 5516 (1970); M. J. S. Dewar and D. H. Lo, *ibid.*, **93**, 7201 (1971); H. Iwamura, K. Morio, and T. L. Kunii, This Bulletin, **45**, 841 (1972).

16) A more reasonable energy value which includes the correct strain energy in **1′** may be obtained by the MINDO/1 calculation. There is, however, a fatal ambiguity in the latter method as regards the choice of the correct standard bond lengths for the allyl groups in **1′**. There are no *a priori* standard bond lengths tabulated for the bonds of an intermediate bond order or hybridization, and yet the calculated energy values are rather sensitive to these bond lengths. Although there is certainly strain energy in **1′** due to the presence of two four-membered rings, and although the release of the strain energy of one cyclobutane ring can be expected on going from **1** to **1′**, the effect is considered to be partly counterbalanced by the formation of two less strained cyclobutane-like rings approaching bicyclo[2.2.0]hexane in **1′**. Thus, as long as the difference in heats of formation is concerned, the MINDO/2 value is taken to represent a more reliable estimate of the activation energy for the degenerate Cope rearrangement of Eq. 1. Since the strain energy in **1** is still underestimated relative to that in **1′**, the activation energy obtained as heats of formation of the latter minus that of the former is likely to be overestimated. The value of 23.1 kcal/mol, may, therefore, be proposed as the upper limit of the activation energy.

Table 4. One-center and two-center terms in the activation energies for the Cope rearrangements of **1**, **3** and **4**

	ΔE_A(eV)		ΔE_{AB}(eV)		ΔE_{AB}(eV) and (in parentheses) bond length (Å) in the transition state for bonds

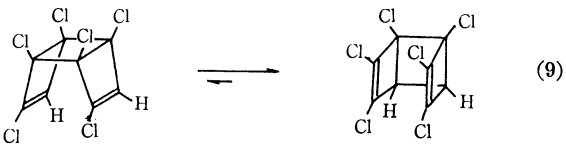
(8)[17]



(9)

Table 4 shows the total contributions to the activation energy of the one-center term (ΔE_A) for the carbon and hydrogen atoms, and of the two-center terms (ΔE_{AB}) for the neighboring (N) and non-neighboring (NN) pairs of the AB atom. These values are compared with those of the Cope rearrangements of 1,5-hexadiene **4** *via* the boat-type transition state and of semibullvalene **3**. These examples represent two extreme cases with respect to the facility of the reaction; the activation energies are *ca.* 40 kcal/mol[18] for the former and less than a few kcal/mol for the latter.[19]

The one-center terms, ΔE_A, for **1** to **1'** are characterized by an intermediately large negative value for carbon atoms. The effect is pronounced for the carbon atoms, $C_5(C_6)$ (−0.343 eV) and $C_4(C_7)$ (−0.354), in the allyl groups. The negative values of ΔE_A^C are parallel with the change (Δq_A) in the electron population of carbon atoms in passing from the reactant to the transition state; the Δq_A's are 0.008, 0.019, and −0.034 for $C_5(C_6)$, $C_4(C_7)$, and $C_3(C_8)$ respectively. The correlation can be understood quite easily by taking into account the change in the electronegativity of the carbon atoms which undergo rehybridization. On passing to the transition state, the s character of the orbitals directed from carbon atoms C_5 and C_6 to the adjoining atoms is increased, while it is decreased at C_3 and C_8. The decrease in the electronegativity of the latter carbons should tend to force the electrons on these atoms on to the neighboring C_4 and C_7. The increase in the electron population leads to the increase in the total one-center core attraction energy, ΔE_A^U. In the ground state of **3**, two allyl carbon atoms are members of a cyclopropane ring rich in p character. The change in the hybridization of these atoms on going from the ground to the transition state is, consequently, small. At the other end of the allyl moiety, the shortening of the distance, d, on passing to the transition state is smallest; the decrease in the s character of the hybridized orbitals on these carbon atoms is also small. These effects are found in the least change in ΔE_A^C value for the rearrangement of **3**. Thus, as far as the one-center terms are concerned, the ease of rearrangement is predicted to be in the order **4**>**1**>**3**, which is just the opposite of that determined by the total contributions to the activation energy.

It will, therefore, be seen that the greater facility of reaction in **3** compared with that of **1** and, more especially, with that of **4** is due to a large decrease in the ΔE_{AB}^N terms. There are three factors which are conceivable as the origin of the large negative ΔE_{AB}^N value in **3**: i) the strength of the interaction linking two allyl groups, ii) the strength of the bonds in each allyl moiety, and iii) the relief of the ring strain. The first factor is expressed by the ΔE_{AB}^N value due to the a+d interaction at the two ends of the allyl groups; it amounts to +0.914, −1.701, and −5.450 for the rearrangement of **3**, **1**, and **4**, respectively. The stabilizing order is in harmony with the decreasing atomic distances linking the two ends of the allyl moieties in the transition state, but is, again, opposite to the net order of the relative stability of the transition state. Secondly, the ΔE_{AB}^N between the atoms pertaining to the b and c bonds within the allyl group in **1'** and **1** (+1.258 eV) is much more than that in **3** (−1.763) and much less than that in **4** (+3.666). The destabilizing effect in the rearrangement of **4** can be interpreted in terms of the relatively long b (c) distance in the transition state. The corresponding b(c) distances in the transition state of **1** and **3** are, however, nearly the same at *ca.* 1.39 Å, which is the average C–C bond length of the order of 1.5; they are typified by those of benzene. A simple atomic distance *vs.* ΔE_{AB}^N argument does not hold in this case. As has been pointed out in Section (C), the allyl groups in **1'** are not planar any longer. A more careful examination of the **1'** structure reveals that

17) R. Criegee and R. Huber, *Chem. Ber.*, **103**, 1855 (1970).
18) W. von E. Doering and W. R. Roth, *Tetrahedron*, **18**, 67 (1962).
19) H. E. Zimmerman, R. W. Binkley, R. S. Givens, G. L. Grunewald, and M. A. Sherwin, *J. Amer. Chem. Soc.*, **91**, 3316 (1969).

the formally unpaired fourth valences of C_3 (C_5, C_6, and C_8 also) are not 2p orbitals but are $sp^{4.4}$ hybridized.[20] Moreover, they are directed to the opposite side of the $C_3C_4C_5$ ($C_6C_7C_8$) plane, inwards at the C_3 (C_5, C_6, and C_3) end and outwards at the C_4 and C_7 centers. The π-type overlap between the adjacent carbon atoms is necessarily inefficient, and the destabilization of **1'** relative to the transition state of **3** results in spite of a similar bond length b(c) (see Fig. 3).

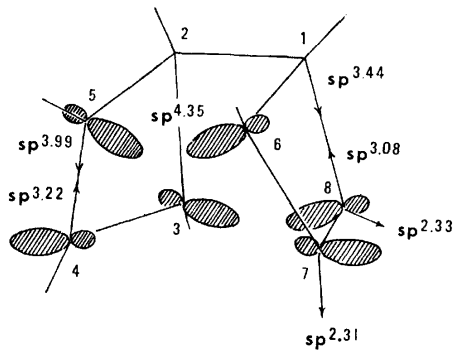


Fig. 3. Hybridization of the carbon atomic orbitals in **1'**.

Although it is not simple to define the strain energy by the E_{AB} of a specific bond, the E_{AB}^{N} (a, b, c) values in the ground state can be taken, in a sense, as a good measure of the intrinsic strain energy of these bonds, while ΔE_{AB}^{N} (f+g) may reflect the relief of the ring strain. We may note that the a bond in the cyclopropane ring of **3** is clearly weak when compared with those of **1** and **4**. The ΔE_{AB}^{N} due to bonds f and g is +0.099 and −0.050 for **1** and **3** respectively, and the stabilization of the transition state relative to the ground state is indicated. Thus, the relief of the ring strain seems to be another factor in the ease of rearrangement in **3**. The effect is not obvious in **1**.

(E) Intramolecular [2+2] Cycloaddition of 1 to Give Cubane. Several reaction paths from **1** leading to cubane were investigated in which the decrease in the cyclobutane/cyclobutene dihedral angle ($\Delta\theta$) from 119° to 90° was followed by changes in C–C bond lengths (Δr) and C–C–H bond angles ($\Delta\varphi$) according to a suitable function of $\Delta\theta$ (Eq. (10)). The general trend

$$\Delta r,\ \Delta\varphi \propto f(\Delta\theta) \qquad (10)$$

in the total energy *vs.* $\Delta\theta$ curve does not depend greatly on the type of $f(\Delta\theta)$ as long as the latter is reasonably chosen by model considerations. Figure 4 shows a typical example in which $f(\Delta\theta)=\Delta\theta$. Strictly speaking, however, the lengthening of the ethylenic double bonds and the displacement of the vinylic hydrogen atoms out of the trigonal planes appear to lag befind $\Delta\theta$ as the reaction proceeds in the energy minimum cross-section

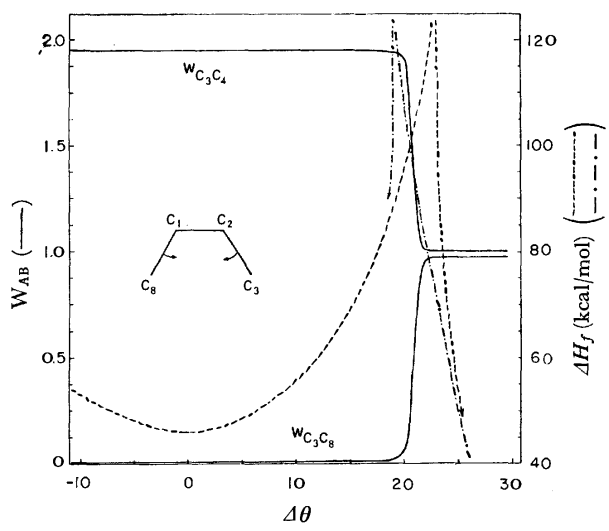

Fig. 4. The energy and the Wiberg's bond indices *vs.* $\Delta\theta$ plots for the ring closure of **1** ($\Delta\theta$=0) to give cubane ($\Delta\theta$=29.0°).

of the potential energy hypersurface interrelating **1** and cubane. The energy value rises steadily during the course of the reaction untill just before the end of change in the dihedral angle (at *ca.* 98°), when it starts to fall to the value corresponding to the heat of formation of cubane. At the same time the bond lengths r's, and the bond angles, φ's, change suddenly to values more or less close to those of cubane. The Wiberg's bond indices between atoms pertaining to bond formation and bond cleavage also change abruptly at this point of the reaction coordinate. We obtain a separate energy *vs.* $\Delta\theta$ plot when the reaction starts from cubane to **1**. All these trends indicate that the reactions refuse to occur when an attempt is made to force them, and provide a typical example of *anti*-aromatic reactions in the electronic ground state.[21-23]

The authors wish to acknowledge stimulating discussions with Professor M. Ōki. They are also indebted to the Ministry of Education for financial support of this work.

20) For the definition of the p character in individual hybrids in terms of the bond index of Wiberg, see C. Trindle and O. Sinanoglu, *ibid.*, **91**, 853 (1967).

21) M. J. S. Dewar and S. Kirschner, *ibid.*, **93**, 4291 (1971).

22) A rectangular disposition of the C_3, C_4, C_7, and C_8 and the C_{2v} symmetry as a whole, are assumed for the species throughout the reaction paths. The distortion from this geometry to a rhombic arrangement of the ethylenic carbon atoms with the total symmetry of C_2 results in the stabilization of the [2+2] interaction by means of the Jahn-Teller effect (see, *e.g.*, H. E. Zimmerman, *Accounts Chem. Res.*, **5**, 393 (1972)). However, the effect is expected to be counteracted by energy loss due to bond bending in the σ framework of the four-membered rings and, therefore, is not taken into present consideration.

23) Note added in proof. R. Gleiter, E. Heilbronner, M. Hekman, and H.-D. Martin, (*Chem. Ber.*, **106**, 28 (1973)) have reported the photoelectron spectral data and the molecular orbital analyses of **1** and **2**. Their results are in good agreement with ours.

The Reaction of Arylthallium(III) Compounds with Copper(II) and (I) Thiocyanates[1]

Sakae UEMURA, Satoru UCHIDA, Masaya OKANO, and Katsuhiko ICHIKAWA*

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

**Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606*

(Received May 10, 1973)

Arylthallium(III) acetate perchlorates reacted with copper(II) thiocyanate to afford aryl thiocyanates in various solvents. The Cu(I) salt was found to be less effective for the thiocyanation. The choice of solvent and the addition of potassium thiocyanate had a significant effect on the yield of aryl thiocyanates. The reaction with the mixture of copper(II) and potassium thiocyanates (1: 1) in dioxane showed the best result. Electron-releasing groups in the aromatic ring accelerated hydrodethallation, yielding aromatic hydrocarbons with a depression of the thiocyanate formation.

In previous papers we showed that the thallium in arylthallium(III) compounds can be replaced by the cyano group[2] or halogen[3] by a reaction with copper-(II) and (I) cyanides or with halides respectively. As another example of such replacement reactions, we will describe here how arylthallium(III) acetate perchlorate monohydrates (**1**), $ArTl(OAc)ClO_4 \cdot H_2O$, react with $Cu(SCN)_2$ in the presence of KSCN, mainly in a dioxane solvent, to afford aryl thiocyanates, sometimes along with aromatic hydrocarbons. In this connection, Taylor and McKillop have recently reported that the thiocyanation of arylthallium(III) bis(trifluoroacetates) with KSCN proceeds under UV irradiation.[4]

Results and Discussion

Phenylthallium(III) acetate perchlorate monohydrate (**1a**) and $Cu(SCN)_2$ were added to an appropriate solvent, such as water, alcohols, cyclic ethers, pyridine, or acetonitrile, and the stirred mixture was then heated under reflux to afford phenyl thiocyanate. Isomeric phenyl isothiocyanate could not be found in the products. The formation of $TlClO_4$ and a Cu (II) salt containing an acetoxy group, probably Cu(OAc)(SCN), was supposed on the basis of a study of the IR spectra. The reaction mixtures were generally heterogeneous, except in the cases of pyridine and acetonitrile solvents, because of the poor solubilities of $Cu(SCN)_2$ in water and the organic solvents used. Among the various solvents, dioxane was found to be the best solvent for preparing phenyl thiocyanate; with it the reaction proceeded even at 70 °C and was almost complete within 1 hr under reflux. However, most reactions including other solvents were carried out under reflux for 5 hr for convenience of comparison. Various results are shown in Table 1.

$$PhTl(OAc)ClO_4 \cdot H_2O + Cu(SCN)_2 \longrightarrow PhSCN + TlClO_4 + Cu(OAc)SCN + H_2O \quad (1)$$

In dioxane, the yield of phenyl thiocyanate was improved by the addition of KSCN; this addition probably caused an increased solubility of $Cu(SCN)_2$ in the solvent, even if to only a slight degree. When an equimolar mixture of $Cu(SCN)_2$ and KSCN was used in dioxane, the yield was more than 80%. A similar additive effect was observed in a homogeneous reaction using a pyridine or acetonitrile solvent, but unexpectedly, whether KSCN was present or absent, the yields of the thiocyanate were less than those in dioxane. On the contrary, when hydroxylic solvents (water, methanol, and ethanol) and tetrahydrofuran were used as solvents (in them KSCN is more soluble than in dioxane),[5] the addition of KSCN resulted in the formation of diphenylthallium(III) thiocyanate (**2**) and a depression in the yield of phenyl thiocyanate. In addition, separate experiments showed that, in hydroxylic solvents, **1a** readily reacted with KSCN at room temperature to give phenylthallium(III) dithiocyanate (**3**), which was then slowly converted into **2** on heating, while in dioxane no **3** was isolated at room temperature and considerable amounts of **2** were obtained on heating. Such a difference may arise from both the poor solubility of KSCN in dioxane and the high-boiling nature of the solvent, the latter of which is favorable for the transformation of **3** into **2**. A similar disproportionation has already been reported for phenylthallium(III) chloride and cyanide.[6] All the results are included in Table 1.

Here, let us consider the possibility of thiocyanate formation from **2** or **3**. When **2** was heated in dioxane, in either the presence or the absence of $Cu(SCN)_2$, no appreciable amounts of phenyl thiocyanate were formed. As to **3**, though its decomposition to give phenyl thiocyanate at above 120 °C had been reported,[6] such transformation was not observed, at least under reflux (65—101 °C) in the usual solvents. However, in the presence of $Cu(SCN)_2$, **3** afforded considerable amounts of phenyl thiocyanate, along with **2** (in dioxane). On the other hand, the reaction of **1a** with $Cu(SCN)_2$ under the same conditions gave only the thiocyanate in a higher yield. Thus, it may be deduced that, in

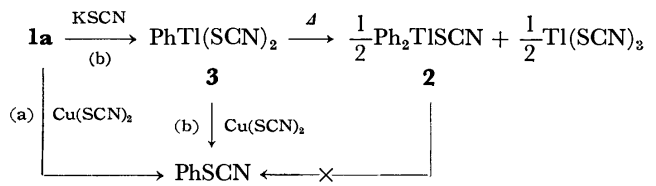
c) Solvent 25 ml.

dioxane, thiocyanation using a mixture of $Cu(SCN)_2$ and KSCN occurs directly by Path (a) mainly and *via* **3** by Path (b) partly, while in hydroxylic solvents it is accompanied by a significant formation of **3**, which may be responsible for the facile disproportionation. In connection with the reactivity of **3**, it is worthwhile



to note that phenylthallium(III) dichloride and bis(trifluoroacetate) were almost unreactive toward $Cu(SCN)_2$, even in the presence of KSCN in dioxane (see Table 1).

Although $Cu_2(CN)_2$ and CuCl could be used as reagents for cyano- and chlorodethallation respectively,[2,3] CuSCN was found to be not so effective for thiocyanodethallation. For example, the reaction of **1a** (10 mmol) with CuSCN (20 mmol) in dioxane gave a 12% yield of phenyl thiocyanate under reflux for 5 hr; the addition of KSCN (40 mmol) improved the yield to 22%. In the cases of tetrahydrofuran and pyridine solvents, only trace amounts of the thiocyanate were formed.

When certain arylthallium(III) acetate perchlorate monohydrates (**1b—e**) were treated with $Cu(SCN)_2$ in dioxane in the presence of KSCN, the corresponding arylthiocyanates and aromatic hydrocarbons were obtained, showing that both thiocyanation and protonation occurred at the position where the thallium was attached to the aromatic ring. As can be seen in Table 2, hydrodethallation is accelerated by the presence of electron-releasing groups as aromatic substituents and also with an increase in the water content in the reaction mixture. This is the same tendency as was previously observed in the reaction between **1** and $CuCl_2$.[3] Here, the proton clearly comes from water, and **1** may serve as a source of water when no external water was added to the reaction system. In thiocyanation, the reverse substituent effect was observed, indicating a nucleophilic character of the reaction; *e.g.*, the yields of aryl thiocyanates from **1d**

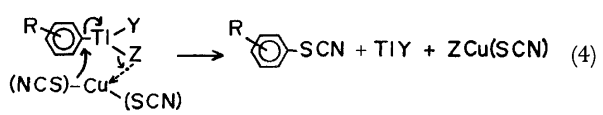
and **1e** were very low (below *ca.* 20%).

The following observations will also serve to make it possible to presume a probable reaction mechanism. In the reactions between equimolar amounts of **1a** and $Cu(SCN)_2$, the yields of phenyl thiocyanate sometimes exceeded 50%. Moreover, the pale green color of a dioxane solution of $Cu(SCN)_2$, though its solubility is very limited, did not change on 5 hrs' refluxing. These facts appear to exclude the possibility of thiocyanogen formation (by Eq. (3)) and its participation as reactive

$$Cu(SCN)_2 \longrightarrow CuSCN + \frac{1}{2}(SCN)_2 \qquad (3)$$

species, at least in dioxane, which has been the subject of several experiments.[7,8] A route *via* phenyl isothiocyanate was also eliminated by an experiment examining its isomerization. Further, the reaction between **1a** and a mixture of $Cu(OAc)_2$ and KSCN in dioxane afforded no phenyl thiocyanate, indicating that no ligand exchange to form $Cu(SCN)_2$ occurred. Thus, it is clear that the thiocyano group comes from $Cu(SCN)_2$ itself. Since no biphenyl was found in the reaction products from **1a**, the possibility *via* an organocopper compound can also be excluded. In addition, the reaction does not appear to involve a radical path, because when **1a** was treated with a mixture of $Cu(SCN)_2$ and KSCN in dioxane in the presence of acrylonitrile, neither an acrylonitrile polymer nor arylated acrylonitrile was formed and no effect on the yield of phenyl thiocyanate was observed.

After a consideration of all the above results, the most plausible mechanism involving a concerted nucleophilic substitution after coordination is proposed to be as follows:



(4)

In cases where KSCN is added to the reaction system, one might expect the participation of $Cu(SCN)_4^{2-}$ as the attacking species which would be a more powerful nucleophile than $Cu(SCN)_2$, since the formation of the complex anion from $Cu(SCN)_2$ and KSCN in acetonitrile has been established.[8] However, this seems to be very unlikely; the coordination number of Cu(II) is generally known to be 4, and hence the above anion is thought to be ineffective for such a reaction involving initial coordination.

Experimental

The IR spectra were taken with Hitachi EPI-2 and EPS-3T spectrometers. The NMR spectra were recorded by a Varian A-60 spectrometer in $CDCl_3$, using TMS as the internal standard. The glc analyses were carried out on a Shimadzu 5APTF apparatus, using PEG 6000(25%)-Chromosorb W (3 m) and Apiezon L (30%)-Celite (3 m) columns (He as the carrier gas).

Materials. All the organic materials except the arylthallium(III) compounds were purified immediately before use by distillation, while commercially-available CuSCN and KSCN were used without further purification. $Cu(SCN)_2$ was preqared by the reported method from $CuSO_4\cdot 5H_2O$ and KSCN.[8] The prepatation of various arylthallium(III) compounds, except for phenylthallium(III) dithiocyanate, and diphenylthallium(III) thiocyanate, was described in previous papers.[2,3]

Formation of Phenylthallium(III) Dithiocyanate (3) and Diphenylthallium(III) Thiocyanate (2). Reactions of Phenylthallium(III) Acetate Perchlorate Monohydrate (1a) with KSCN in Hydroxylic Solvents. By the addition of a solution of 1.9 g (20 mmol) of KSCN dissolved in water (25 ml) to an aqueous solution (25 ml) of 4.6 g (10 mmol) of **1a** at room temperature, **3** was readily obtained as a white amorphous precipitate in a 57% yield; mp 130—140 °C (d) [lit,[6] mp 100—120 °C (d)]. Found: C, 24.07; H, 1.22; N, 7.15%. Calcd for $C_8H_5N_2S_2Tl$: C, 24.16; H, 1.27; N, 7.05%. A similar reaction at the refluxing temperature in water for 5 hr gave a white precipitate, **2** (which is soluble in alcohols and insoluble in water), in a 36% yield; mp 285—287 °C. Found: C, 37.40; H, 2.39; N, 3.28%. Calcd for $C_{13}H_{10}NSTl$: C, 37.41; H, 2.59; N, 3.36%. The preparations of **3** and **2** could be carried out similarly in a methanol solvent. Further, when 2.0 g (5 mmol) of **3** was heated for 5 hr in refluxing methanol (25 ml) containing 0.5 g (5 mmol) of KSCN, 0.5 g (1.2 mmol) of **2** was formed.

Reactions of Arylthallium (III) Acetate Perchlorate Monohydrates (1) with Cu(SCN)$_2$ in Dioxane. The following example shows a typical experimental procedure. A mixture of 4.6 g (10 mmol) of **1a**, 1.8 g (10 mmol) of $Cu(SCN)_2$, and 1.9 g (20 mmol) of KSCN in 50 ml of dioxane was stirred at 101°C for 5 hr, during which period the color of the heterogeneous

7) H. P. Kaufmann and K. Küchler, *Ber.*, **67**, 944 (1934).

solution changed from pale black to deep yellow. After the filtration of the yellow precipitate (6.2 g), the yellow filtrate was diluted with aqueous NaCl (sometimes white **2** was precipitated) and extracted with benzene. The benzene extract contained 8.2 mmol (82% yield) of phenyl thiocyanate and no phenyl isothiocyanate (determined by glc; benzyl acetate was used as the internal standard). Phenyl thiocyanate was isolated in a pure form by distillation at 101—102 °C/18 mmHg. IR ν_{SCN} 2150 cm^{-1} (s). The washing of the yellow precipitate with hot water left a greyish-yellow solid (4.3 g), which was shown by IR spectroscopy to contain thiocyano and acetate and no perchlorate groups; it was probably a mixture of CuSCN, $Cu(SCN)_2$, and Cu(SCN)(OAc). The treatment of the water-washing containing perchlorate ion with dil. HCl gave a precipitate (1.5 g) of TlCl.

In similar reactions using other arylthallium(III) salts, the formation of the corresponding aryl thiocyanates and aromatic hydrocarbons was observed. The yields of both compounds were determined by glc (benzyl acetate and ethylbenzene were used respectively as the internal standards). Aromatic thiocyanates were isolated by distillation and identified by means of their IR and NMR spectra. *p*-Tolyl thiocyanate, bp 117—118 °C/20 mmHg; 3,4-dimethylphenyl thiocyanate, bp 140—141 °C/28 mmHg; *p*-Anisyl thiocyanate, bp 159—160 °C/27 mmHg.

Reactions of the Iodocarbenoid of Zinc. I. The Synthesis of Alkyl-substituted 7-Ethylcyclohepta-1,3,5-trienes *via* the Ring-expansion of Alkylbenzenes with Diethylzinc and Iodoform

Sotaro MIYANO and Harukichi HASHIMOTO

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980

(Received May 15, 1973)

By treatment with diethylzinc and iodoform, benzene gave 7-ethylcyclohepta-1,3,5-triene in a yield of 58%, along with a quantitative formation of ethyl iodide. Alkylbenzenes, including methyl-, ethyl-, isopropyl-, *tert*-butyl-, and *o*-dimethylbenzene, gave the corresponding alkyl-substituted 7-ethylcyclohepta-1,3,5-trienes in yields of 60, 45, 41, 35, and 52% respectively. The tropylium iodide resulting from the adduct of the iodocarbenoid of zinc to benzene (7-iodonorcaradiene) is suggested as an intermediate in the formation of the 7-ethylcycloheptatriene.

Recently Furukawa and Nishimura reported that the halocarbenoid of zinc obtained from diethylzinc and haloforms transfer the halomethylene groups to cyclohexene to give 7-halonorcaranes.[1] When iodoform was used as the halomethylene source, 7-iodonorcarane was obtained in only a trace amount.

In the course of our investigation of the zinc-carbenoid reaction, we found that alkyl-substituted 7-ethylcyclohepta-1,3,5-trienes are obtained by the treatment of diethylzinc and iodoform in alkylbenzenes.[2] In this report, we will describe the details of the reaction, and will present evidence for the tropylium iodide intermediate in the formation of 7-ethylcyclohepta-1,3,5-triene from benzene.

Results and Discussion

Reactions of Diethylzinc and Iodoform with Benzene. Table 1 shows the results of the reactions of diethylzinc and iodoform with benzene. To a stirred diethylzinc solution in benzene, iodoform was added over a 1 hr period under a nitrogen atmosphere, after which the reaction was continued for another 5 hr. Besides 7-ethylcyclohepta-1,3,5-triene and ethyl iodide, propylene and cyclohepta-1,3,5-triene were obtained as side reaction products in yields of 28 and 3% respectively (No. 4). The amount of ethyl iodide depended on the limiting component (iodoform or diethylzinc), and the total iodides recovered were almost equal to the iodoform consumed. These facts suggest the following stoichiometry for the formation of 7-ethylcycloheptatriene and propylene (Eqs. (1) and (2) respec-

tively):

$$C_6H_6 + CHI_3 + Et_2Zn \longrightarrow \text{(H, Et)} + EtI + ZnI_2 \quad (1)$$

$$CHI_3 + Et_2Zn \longrightarrow CH_3CH{=}CH_2 + EtI + ZnI_2 \quad (2)$$

Reactions of Alkylbenzenes. Table 2 shows that alkylbenzenes also gave the corresponding alkyl-substituted 7-ethylcyclohepta-1,3,5-trienes in fairly good yields on treatment with diethylzinc and iodoform. All the cycloheptatrienes were separated by distillation as mixtures of positional isomers and were confirmed by elemental analysis and by a study of their NMR and IR spectra. Though the ring-expansion of aromatic compounds by carbene or carbenoid reagents is well-known,[3] this iodocarbenoid reaction gives a convenient route for the synthesis of alkyl-substituted 7-ethylcycloheptatrienes from alkylbenzenes.

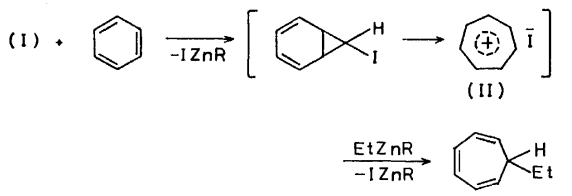
In a preliminary experiment, ethylzinc iodide[4] obtained from zinc-copper couple[5] and ethyl iodide also gave the 7-ethylcycloheptatriene when allowed to react with iodoform in benzene.

A competition study was carried out by allowing an equimolar mixture of benzene and isopropylbenzene to compete for a deficient amount of diethylzinc and iodoform. The latter gave 1.5 times more of the corresponding cycloheptatrienes than the former. This seems to show that the addition of the iodocarbenoid of zinc to the benzene nuclei is electrophilic in nature (*vide infra*).

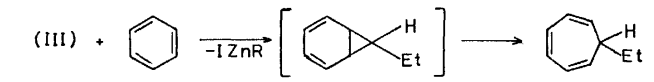
Anisole and chlorobenzene gave complex mixtures of unidentified products which contained cycloheptatriene derivatives, judging from the NMR spectra.

Addition of the Iodomethylene Group from the Iodocarbenoid of Zinc to the Benzene Ring, and the Tropylium Iodide Intermediate in the Formation of 7-Ethylcyclohepta-1,3,5-triene. The following two reaction paths are possible for the formation of 7-ethylcyclohepta-1,3,5-triene through the ring-expansion of benzene with diethylzinc and iodoform (Path (a) and Path (b))[6] (R=Et or I):

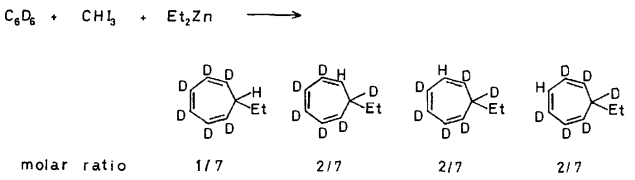
(a) $EtZnR + CHI_3 \longrightarrow EtI + CHI_2ZnR$ (I)



(b) $(I) + EtZnR \longrightarrow EtCHIZnR + IZnR$ (III)



Furukawa *et al.* reported the ring-expansion of aromatic compounds by means of the methylcarbenoid of zinc formed from diethylzinc and ethylidene iodide.[7] This might suggest the addition of propylidene from the ethylcarbenoid of zinc (III) to the benzene ring (Path (b)), but the following result shows that, in the present case, Path (a) is the reasonable one. After benzene-d_6 had been allowed to react with diethylzinc and iodoform, the 7-ethylcycloheptatriene-d_6 thus formed was analyzed by studying its NMR spectra. It was found that, in the 7-ethylcycloheptatriene-d_6, the hydrogen atom derived from iodoform was statistically distributed throughout the cycloheptatriene ring:



This fact can most reasonably be explained by the tropylium iodide intermediate (II) and the nucleophilic replacement of iodine by the ethyl group, thus forming 7-ethylcycloheptatriene.[8]

The isomer distribution of the cycloheptatrienes from toluene by this iodocarbenoid reaction is somewhat different from those obtained by the CH_3CHI_2–Et_2Zn[7a] and CH_2N_2-CuBr[10] systems, but it is consistent with that obtained by the chlorocarbenoid of lithium formed from methyllithium and methylene chloride.[11] For the latter reaction, tropylium chloride was detected as the intermediate in the formation of 7-methylcycloheptatriene from benzene.[12] There seems to be few reports dealing with the orientation of alkyltropylium

ions for the nucleophilic reaction,[13] and the preferential formation of 2-methyl-7-ethylcycloheptatriene from toluene is not yet explained.[14]

Propylene seems to be formed by the facile 1,2-hydride shift of the ethylcarbenoid of zinc (III).[12] Similar olefin-forming reactions have been reported for the reaction of Grignard reagents and bromoform.[16]

Experimental

Materials. Commercial diethylzinc was distilled under reduced pressure. The iodoform was recrystallized from ethanol-acetone. The alkylbenzenes and other materials were of commercial origin and were purified as usual. Distillation or recrystallization was carried out under a nitrogen atmosphere. Materials were stored under nitrogen.

The glc analysis was carried out on a Shimadzu GC 3AF apparatus equipped with hydrogen flame detectors; four different stainless steel columns (3 m×3 mm) were used, packed with Diasolid M coated with Silicone DC 550, Silicone DC 410, Apiezon Grease L, and PEG 2000 respectively.

Reaction of Benzene with Diethylzinc and Iodoform. The general procedure used for the reaction of diethylzinc, iodoform, and benzene was as follows. The reaction was carried out in a round-bottomed flask equipped with a magnetic stirrer, a thermometer, a reflux condenser topped with a nitrogen inlet, and a dropping funnel for a solid material[17] which had been charged with iodoform. The flask was flushed with prepurified nitrogen. In the flask we placed benzene and diethylzinc, and the stirred solution was heated to 40—45 °C. The iodoform was added, portion by portion, over a 1 hr period at 50 °C, and then the reaction was continued for another 5 hr. On the addition of the iodoform, an exothermic reaction was observed and the iodoform reacted smoothly. During the addition of the iodoform, white precipitates were formed in the reaction flask. At the end of the reaction, a small amount of water and then dilute nitric acid were added cautiously to the cooled mixture. The organic layer was washed successively with dilute nitric acid and water. The aqueous layer and combined aqueous washings were extracted with a small amount of benzene, and the content of the iodide ion was determined by Vorhard titration. The organic layer was washed with a dilute sodium carbonate solution and water, and then diluted with additional benzene to a 250 ml volume, from which a 10 ml portion was used for the quantitative determination of the ethyl iodide, cyclohepta-1,3,5-triene, and 7-ethylcyclohepta-1,3,5-triene formed. The remaining solution was dried over magnesium sulfate. After the removal of benzene and ethyl iodide by distillation, the residue was fractionated through a Vigreux column. Besides 7-ethylcyclohepta-1,3,5-triene, a high-boiling portion was obtained which was positive to the Beilstein test and which seemed to consist of the iodocyclopropanes derived from cyclo-

heptatrienes by the addition of the iodocarbenoid of zinc to the double bonds. Cyclohepta-1,3,5-triene was confirmed only by the retention time on glc because of its scarcity.

The isomer distributions of 7-ethylcycloheptatrienes from alkylbenzenes were determined by studying the glc[7a] and NMR[18] spectra (Table 2). The results of the separation of cycloheptatrienes are shown in Table 3.

Competition between Benzene and Isopropylbenzene. Benzene (0.30 mol) and isopropylbenzene (0.30 mol) competed for the iodocarbenoid reagent generated *in situ* from diethylzinc (0.050 mol) and iodoform (0.050 mol). Both gave the corresponding 7-ethylcycloheptatrienes, in yields of 0.00853 mol and 0.0126 mol respectively.

18) K. W. Egger and W. R. Moser, *J. Phys. Chem.*, **71**, 3699 (1967).

7-Ethylcyclohepta-1,3,5-triene-d_6. Under a nitrogen atmosphere, an 11 ml portion of commercial benzene-d_6 (Merck Co., deuterium content, 99%) was distilled over sodium into a reaction flask directly. The reaction was carried out as stated above using 1 ml (0.010 mol) of diethylzinc and 4.0 g (0.010 mol) of iodoform. A portion boiling at 70—72°C/45 mmHg, contaminated with a trace amount of ethyl iodide, was distilled into an NMR sample tube. The NMR analysis of the sample (*ca.* 5% solution in CCl_4, TMS) showed the statistical distribution of the hydrogen atom derived from iodoform throughout the cycloheptatriene ring within the limits of experimental error (Table 4).

The authors wish to acknowledge with pleasure their helpful discussions with Professor Mitsuhiko Hida.

The Preparation and Reactions of *N*-Substituted Hexafluoroisopropylideneimines

Nobuo ISHIKAWA and Tomoya KITAZUME

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 16, 1973)

N-Aryl- and *N*-alkylhexafluoroisopropylideneimines (**2**) were prepared from the hexafluorothioacetone dimer (**1**) by treatment with either aryl- or alkylamines. These imines reacted with alcohols and thiols to give three addition products, **7**, **8**, and **9**. Phenylhydrazone (**3**), semicarbazone (**4**), hydrazone (**5**), and azine (**6**) of hexafluoroacetone were also obtained directly from **1** and the corresponding carbonyl reagents.

Hexafluoroisopropylideneimine (**2**, R=H) and its-*N*-substituted derivatives appear to be useful intermediates for the syntheses of hexafluoroisopropyl compounds. Although Middleton *et al.*[1,2] have prepared the imine and its *N*-methyl derivative by the reaction of hexafluoroacetone with either ammonia or methylamine, followed by the dehydration of the resulting adducts, the present knowledge of the experimental conditions for the preferential elimination of water from adducts of hexafluoroacetone with other amines is far from satisfactory.

On the other hand, Zeifman *et al.*[3] prepared *N*-phenylhexafluoroisopropylideneimine (**2**, R=Ph) by a Wittig-like reaction, which involved the reaction of hexafluoroacetone with phenylisocyanate in the presence of triphenylphosphine oxide as the catalyst. Furthermore, they prepared the oxime and semicarbazone of hexafluoroacetone by the elimination of aniline from the corresponding adducts obtained from the condensation of *N*-phenylhexafluoroisopropylideneimine with hydroxylamine[4] and semicarbazide[5] respectively.

In the course of our investigation of the organic fluorine sulfur compounds, it was necessary to study the reactivity of fluoroalkylthiocarbonyl compounds. Hexafluorothioacetone is known as an unstable gas which dimerizes very readily into a stable liquid, 2,2,4,4-tetrakis(trifluoromethyl)-1,3-dithiethane (**1**).[6] Our studies of the nucleophilic reactions of this dimer have revealed that aryl- and alkylamines gave *N*-substituted hexafluoroisopropylideneimines easily, and that it is a convenient general method for the preparation of the imines of this type. Carbonyl reagents also gave the phenylhydrazone and semicarbazone of hexafluoroacetone directly.

We also carried out several nucleophilic addition reactions across the C=N– double bonds of these imines; we could thus obtain 2-alkoxy- and 2-alkylthio-2-arylaminohexafluoropropanes.

Results and Discussion

The Preparation of N-*Substituted Hexafluoroisopropylideneimines.* The dimer of hexafluorothioacetone (**1**) (bp 110 °C) can be prepared directly from hexafluoropropene and sulfur in sulfolan in the presence of potassium fluoride.[7] This compound is reported to be very

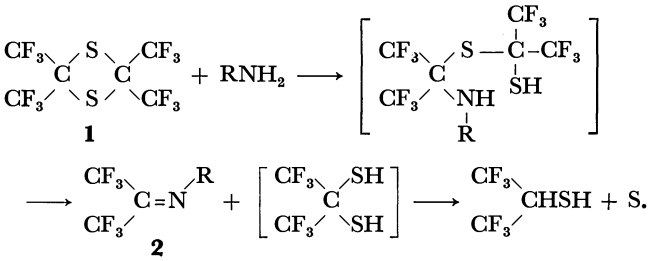
susceptible to bases and reacts with sodium methoxide in methanol rapidly to give a fluorine-free compound, dimethyl α-methylthio-α-methoxymalonate, in a poor yield.[6] However, no other nucleophilic reaction of this dimer has appeared in the literature. We carried out several reactions of the dimer with amines under more moderate conditions, and found that both aryl- and alkylamines reacted with the dimer at room temperature, with a liberation of sulfur.

For example, when the dimer was allowed to react with 2 mol of *p*-toluidine in dimethylformamide, an oily material was obtained. Among the various solvents examined, such as alcohol, acetonitrile, dioxane, and other polar solvents, dimethylformamide was the most effective in promoting the reaction.

The product was sulfur-free, but it still contained trifluoromethyl groups. The structure of this compound was elucidated by a study of the IR, ^1H and ^{19}F NMR, and mass spectra to be *N*-*p*-tolylhexafluoroisopropylideneimine (**2** R=$C_6H_4CH_3$). In the IR spectrum, the presence of the C=N group was shown by the band at 1660 cm^{-1}, and in the ^{19}F NMR spectrum, two singlet peaks, −8.4 and −16.1 ppm from ext. CF_3COOH in CCl_4, appeared, corresponding to *syn*- and *anti*-CF_3 respectively.[8-10] In the mass spectrum, the parent peak, M^+ 255, and other fragment peaks, such as *m/e* 186 ($C_9H_7NF_3$), 91 (C_7H_7), and 69 (CF_3), appeared appropriately.

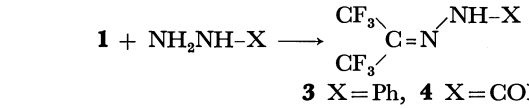
The other *N*-aryl hexafluoroisopropylideneimines were prepared similarly by using aniline and its substituted derivatives. Such alkylamines as *n*-propyl- and *n*-butylamine gave *N*-alkylimines, but in poorer yields. (Table 1).

Considering the yields of the products and the amount of sulfur liberated during the reaction, the reaction seemed to proceed according to the following scheme:



Many attempts to capture bis(trifluoromethyl)methanethiol in the reaction mixtures were unsuccessful, probably because of the extreme instability of this compound.

In addition to aryl- and alkylamines, phenylhydrazine and semicarbazide also attacked the dimer in dimethylformamide at room temperature; phenylhydrazone and semicarbazone of hexafluoroacetone were thus obtained.



3 X=Ph, **4** X=$CONH_2$

When unsubstituted hydrazine was used as nucleophile, the reaction in dimethylformamide was too vigorous and gave only a tarry material. In a milder solvent, such as acetonitrile, the reaction proceeded smoothly and hexafluoroacetone hydrazone (**5**) and

azine (**6**) were obtained in yields of 43 and 11% respectively.

$$\mathbf{1} + NH_2NH_2 \longrightarrow \underset{\mathbf{5}}{(CF_3)_2C{=}N{-}NH_2} + \underset{\mathbf{6}}{(CF_3)_2C{=}N{-}N{=}C(CF_3)_2}$$

Thus, the hydrazones of hexafluoroacetone were prepared directly from the hexafluorothioacetone dimer and the corresponding carbonyl agents; this seemed to be a convenient preparative route because several steps had previously been required for the preparation of these compounds.[5]

Hexafluoroisopropylideneimines are also susceptible to nucleophiles. Zeifman *et al.*[3,4] reported several reactions of the imines, especially reactions with amines, by which an exchange of imino groups occurred. We examined the addition of alcohols and thiols across the C=N– double bond of *N*-arylhexafluoroisopropylideneimines and prepared a number of 2-alkoxy- and 2-alkylthio-2-arylaminohexafluoropropanes, **7** and **8**, for pharmacological purposes.

Methyl and ethyl alcohols reacted with the imines by means of refluxing in the presence of a small amount of alkali, while ethanethiol reacted under a nitrogen atmosphere at room temperature. The structures of the products were evident from the IR and the ^1H and ^{19}F NMR spectra, as well as, from fluorine analysis. In each compound, only one singlet signal appeared in the ^{19}F NMR, and the presence of N–H was shown in the IR spectrum (Table 2).

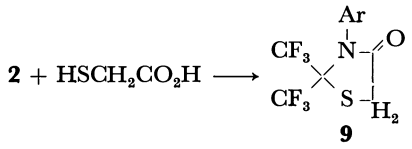
We have also prepared 3-aryl-4-thiazolidinones (**9**), which carry geminal trifluoromethyl groups at the 2-position, by the reaction of *N*-arylhexafluoroisopropylideneimines with thioglycolic acid (Table 3).



9

Experimental

Hexafluorothioacetone Dimer (1). This compound was prepared according to the method of Knunyants.[7] Bp 109—110 °C; yield, 74% (lit, bp 110—111 °C, yield, 72%).

N-*Arylhexafluoroisopropylideneimines (2).* These compounds were prepared in a similar manner; one example will be described below.

To a stirred mixture of *p*-toluidine (4.3 g, 0.04 mol) and dimethylformamide (40 ml), **1** (7.3 g, 0.02 mol) was added, drop by drop, at room temperature; stirring was then continued for 4 hr at that temperature. The liberated sulfur (0.43 g, 0.013 mol) was removed by filtration, and the filtrate was poured into water. The separated oily material was extracted with diethyl ether, and the extract was dried over magnesium sulfate. After removing the solvent, the residual oil was subjected to vacuum distillation. *N-p*-Tolylhexafluoroisopropylideneimine (**2**, R=*p*-$CH_3C_6H_4$) (3.5 g) (bp 85—86 °C/53 mmHg) was thus obtained in a yield of 35%. IR: 1660 (C=N), 1300, 1218 (C–F) cm^{-1}. NMR (in CCl_4): τ 7.69 (CH_3, s), 2.86—3.38 (arom-H).

Hexafluoroacetone Phenylhydrazone (3). Phenylhydrazine (2.5 g, 0.044 mol), **1** (8.0 g, 0.022 mol), and dimethylformamide (40 ml) were used as in the preceding reaction, and worked up similarly. A fraction with a bp of 91—92 °C/23 mmHg was collected to give **3** (3.7 g, 66%).

Hexafluoroacetone semicarbazone (**4**) was prepared in a similar manner.

Hexafluoroacetone Hydrazone (5) and Azine (6). Anhydrous hydrazine (9.6 g, 0.3 mol) was added, drop by drop, to a solution of **1** (36.4 g, 0.1 mol) in acetonitrile (80 ml), after which the mixture was stirred for 1.5 hr at room temperature. After removing the liberated sulfur by filtration, the filtrate was poured into water and worked up as usual. Two products were obtained by fractional distillation: azine, **6** (3.6 g, 11%) (bp 67—70 °C (lit,[1] bp 67—67.5 °C)) and hydrazone, **5** (15.4 g, 43%) (bp 93—96 °C (lit,[1] bp 95.5—96 °C)).

2-Alkoxy-2-arylaminohexafluoropropanes (7). An example will be given below.

A mixture of *N*-phenylhexafluoroisopropylideneimine (**2**, R=Ph) (3.7 g, 0.015 mol), methanol (6.4 g, 0.19 mol), and potassium hydroxide (1.0 g, 0.015 mol) was refluxed for 5 hr. The usual work-up process gave a product (**7**, R=Me, Ar=Ph), 1.4 g (34%) (bp 85 °C/25 mmHg). IR (KBr): 3306 (N=H), 1258, 1211, 1178 (C–F) cm^{-1}. NMR (in CCl_4): τ 5.50 (OMe), 2.55—3.27 (arom. and NH).

2-Ethylthio-2-arylaminohexafluoropropanes (8). Under a nitrogen atmosphere, a mixture of **2**, R=Ph (2.6 g, 0.011 mol), ethanthiol (0.8 g, 0.013 mol), and potassium hydroxide (0.8 g, 0.012 mol) was stirred for 5 hr at room temperature. The usual work-up process gave **8**, R=Et, Ar=Ph (0.9 g, 27%); bp 84 °C/31 mmHg. IR (KBr): 3286 (N–H), 1257, 1217 (C–F) cm^{-1}. NMR (in CCl_4): τ 7.30 (CH_2, q), 8.80 (CH_3, t), 2.12 (NH, broad), 2.79—3.32 (arom.).

2,2-Bis(trifluoromethyl)-3-aryl-4-thiazolidinones (9). A mixture of *N*-phenylhexafluoroisopropylideneimine (5.68 g), thioglycolic acid (6.0 g), triethylamine (0.5 g), and dried benzene (30 ml) was refluxed under a nitrogen atmosphere for 48 hr, and then the benzene was removed by distillation. The residue solidified on cooling; it was recrystallized from *n*-hexane to give **9**, Ar=Ph (6.3 g, 85%) (mp 97—99 °C). Other *N*-aryl compounds were prepared in a similar manner.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3263—3266 (1973)

The Effect of Acylamino Groups in Diazo-coupling Reactions

Yōji HASHIDA, Kazuo MITSUMURA, Shizen SEKIGUCHI, and Kohji MATSUI
Department of Chemistry, Faculty of Engineering, Gunma University, Tenjincho, Kiryu, Gunma 376

(Received May 23, 1973)

A kinetic study has been made of the coupling reactions of diazonium salts with *N,N*-dialkyl-*N'*-acyl-*m*-phenylenediamines, including *N'*-acetyl- (I, II), *N'*-benzoyl- (III), *N'*-carboethoxy- (IV), and *N'*-*p*-toluenesulfonyl derivatives (V, VI). It was found from the pH dependence of the apparent rate constant that the reactive species of a substrate varies with the pH of the medium, from an undissociated molecule to an anion formed by the ionization of an acylamino group. In the case of I, the activating effect of the dissociated acylamino group seems to be higher than that of the undissociated acylamino group by some 8 powers of ten.

Ordinary diazo-coupling reactions between diazonium ions and aromatic compounds activated by such an electron-releasing substituent as an amino- or phenoxide group are well-known electrophilic aromatic substitutions.[1] In a previous paper,[2] we have shown that a diazonium ion couples not only with the undissociated pyrrole, but also with the pyrrole anion, and that the coupling with the pyrrole anion takes place much more rapidly than that with the undissociated pyrrole, showing that the conjugate base of the pyrrole

1) H. Zollinger, "Azo and Diazo Chemistry," Interscience Publishers, New York, N.Y. (1961), p. 221.

2) K. Mitsumura, Y. Hashida, S. Sekiguchi, and K. Matsui, This Bulletin, **46**, 1770 (1973).

is a powerfully reactive species for this reaction. Although, in the pyrrole, the N–H group participates in ring formation, a similar activation of an aromatic molecule by the ionization of a substituent can be seen in the cases of phenols.[1] However, there has been no study of the acceleration of an aromatic electrophilic reaction by the ionization of a substituent in an aromatic molecule other than those of phenolic substances. From the same point of view, it may be expected that an aromatic compound bearing an acylamino group will provide a reactive substrate for the electrophilic substitution by means of the ionization of the acylamino N–H bond. This assumption has not, however, been proved.

This paper will report on the activation caused by the ionization of an acylamino group in the coupling reaction with *m*-acylamino anilines.

Experimental

Materials. Commercial *N,N*-bis(2-hydroxyethyl)-*N'*-acetyl-*m*-phenylenediamine (I) was recrystallized from methanol. The *N,N*-dimethyl-*N'*-acetyl-*m*-phenylenediamine (II) and *N,N*-dimethyl-*N'*-benzoyl-*m*-phenylenediamine (III) were prepared from *N,N*-dimethyl-*m*-phenylenediamine by acetylation and benzoylation respectively. The *N,N*-dimethyl *N'*-carboethoxy-*m*-phenylenediamine (IV) was prepared from *N,N*-dimethyl-*m*-phenylenediamine and ethyl chloroformate by the method of Schmidt.[3] Recrystallization from petroleum ether gave an analytical sample; mp 59—60 °C. Found: C, 63.73; H, 7.85; N, 13.14%. Calcd for $C_{11}H_{16}N_2O_2$: C, 63.44; H, 7.74; N, 13.44%. The *N,N*-dimethyl-*N'*-(*p*-toluenesulfonyl)-*m*-phenylenediamine (V) was prepared by the reaction of *N,N*-dimethyl-*m*-phenylenediamine with tosyl chloride. Recrystallization from aqueous methanol gave an analytical sample; mp 138—138.5 °C. Found: C, 62.43; H, 6.57; N, 8.17%. Calcd for $C_{15}H_{18}N_2O_2S$: C, 62.07; H, 6.21; N, 8.27%. The *N,N,N'*-trimethyl-*N'*-(*p*-toluenesulfonyl)-*m*-phenylenediamine (VI) was prepared by methylating V with dimethyl sulfate in water in the presence of sodium hydroxide. Recrystallization from methanol gave an analytical sample; mp 154—156 °C. Found: C, 63.30; H, 6.49; N, 9.17%. Calcd for $C_{16}H_{20}N_2O_2S$: C, 63.13; H, 6.62; N, 9.20%. The aromatic amines employed as diazo-components were purified by fractional distillation under reduced pressure before use.

pK_a *Measurements.* The pK_a values of the *N,N*-dimethylamino and *N,N*-(2-hydroxyethyl)amino derivatives (I—VI) were measured spectrophotometrically in the same solvent as that used in the kinetic experiment at 20 °C.

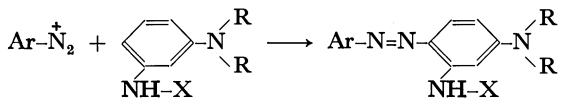
Kinetic Measurements. The rate of the coupling reaction was obtained by measuring the concentration of an azo-compound formed at an appropriate wavelength using a Hitachi 124 type spectrophotometer.[4,5] All the kinetic experiments were carried out in an approproate buffer solution at 20 °C under a constant ionic strength (μ; 0.04). The components of the buffer solution have been described elsewhere.[5] In the presence of a large excess of a substrate, the reaction followed a pseudo-first-order relationship (1):

$$k't = \ln \frac{E_\infty}{E_\infty - E_t} \quad (1)$$

where E_∞ and E_t denote the optical densities at an infinite time and at time t. In every case, the k' value thus obtained was reasonably constant up to at least 80—90% of the reaction. At the end of the kinetic measurements, the acidity of a reaction mixture was measured using a Toa HM-5A-type pH meter, thus confirming the constancy of the acidity of the medium during the reaction.

Results and Discussion

It is well known that *N,N*-dialkyl-*N'*-acyl-*m*-phenylenediamines couple with diazonium salts:[6,7]



R: H, CH_3, CH_2CH_3, CH_2CH_2OH, etc.
X: $COCH_3$, SO_2CH_3, $CONH_2$, etc.

In this investigation, *N,N*-bis(2-hydroxyethyl)-*N'*-acetyl-*m*-phenylenediamine (I), *N,N*-dimethyl-*N'*-acetyl-*m*-phenylenediamine (II), *N,N*-dimethyl-*N'*-benzoyl-*m*-phenylenediamine (III), *N,N*-dimethyl-*N'*-carboethoxy-*m*-phenylenediamine (IV), *N,N*-dimethyl-*N'*-(*p*-toluenesulfonyl)-*m*-phenylenediamine (V), and *N,N,N'*-trimethyl-*N'*-(*p*-toluenesulfonyl)-*m*-phenylenediamine (VI) were used as coupling components.

Although there was the possibility that more than one azo campound would be formed, thin-layer chromatograms of the reaction products obtained under the conditions employed in the kinetic measurements showed the presence of only one azo compound in every case.

The first-order dependence of the reaction rate on the concentration of a diazonium salt is apparent from the applicability of Eq. (1) to these reactions; the reaction rate (k') also showed a first-order dependence on the substrate concentration at a constant pH. Thus, at any given acidity, the reaction rate can be expressed by Eq. (2):

$$\text{Rate} = k(\text{Ar–}\overset{+}{\text{N}}_2)(\text{Substrate}) \quad (2)$$

To establish the kinetic form of the substrate, the dependence of the apparent rate constant (k') on the acidity of a medium was examined. The results are shown in Fig. 1 by plotting log k' against the pH values in the cases of Compounds I and II. From Fig. 1, it is obvious that there are three distinct regions in the pH-rate profile. For instance, in the case of Compound I, in the pH region below 5.0 log k' decreases with an increase in the acidity of a solution, while in the pH range between 5.0 and 7.0 k' is practically independent of the acidity of the solution. However, in the pH region above 7.0, log k' increases with a decrease in the acidity, and the slope of the line is close to unity in the pH range above 8.0. A similar pH-rate relation-

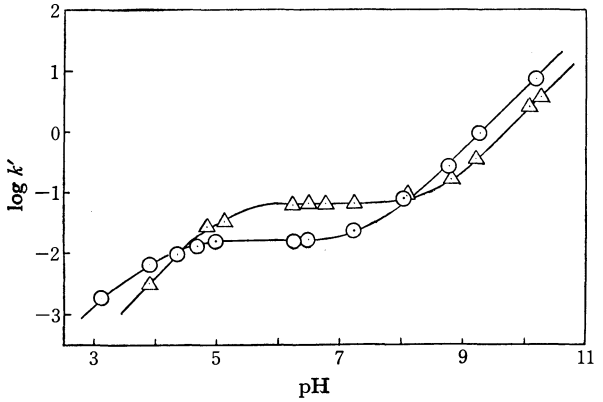

Fig. 1. pH-Rate profile for the reaction of *p*-methylbenzenediazonium salt with *N,N*-bis(2-hydroxyethyl)-*N'*-acetyl-*m*-phenylenediamine (I) (circles, ○), and with *N,N*-dimethyl-*N'*-acetyl-*m*-phenylenediamine (II) (triangles, △) in aqueous solution. (Initial concentration of substrate: 4×10^{-3} M. Initial concentration of diazonium salt: 4×10^{-5} M. k' in min^{-1})

Table 1. Ionization constants of *N,N*-bis(2-hydroxyethyl)amino- or *N,N*-dimethylamino groups of compounds (I—IV)

Compound	Solvent	pK_a
I	Water	3.55
II	Water	4.70
III	50% Methylcellosolve	3.80
IV	50% Methanol	4.36
V	50% Methylcellosolve	3.27
VI	50% Methylcellosolve	3.35

ship was also found to hold in the case of Compound II.

The pK_a value of I is 3.55, as is shown in Table 1. Therefore, the finding that the k' value decreased with an increase in the acidity of the medium in the pH region below 5 can be explained from the fact that the concentration of the free amine decreases with an increase in the acidity by means of the protonation at the *N,N*-bis(2-hydroxyethyl)amino group. The observed constancy of k' in the pH range between 5.0 and 7.0 may be due to the constancy of the concentration of the free amine in this region. Consequently, in the pH region below 7.0 the kinetic expression is given by Eq. (3), which is entirely consistent with that of the coupling reaction of ordinary aromatic amine:[1]

$$\text{Rate} = k_2(\text{Ar}\text{-}\overset{+}{\text{N}}_2)\left(\text{C}_6\text{H}_4(\text{NH-X})\text{-N}(\text{R})_2\right) \quad (3)$$

However, the finding in the pH region above 8.0 indicates the presence of a reactive species other than a free amine; the reactive species may be an anion formed by the ionization of the acylamino group, judging from the fact that the slope of the line in the pH-rate profile is close to unity, which may be understood by assuming that the concentration of the reactive anion increases by a factor of ten per pH unit in the given pH range. Accordingly, the kinetic equation in this pH region is expressed by Eq. (4):

$$\text{Rate} = k_2(\text{Ar}\text{-}\overset{+}{\text{N}}_2)\left(\text{C}_6\text{H}_4(\overset{\ominus}{\text{N}}\text{-X})\text{-N}(\text{R})_2\right) \quad (4)$$

It is well known that, in the coupling reaction of phenol, it is the phenoxide ion that reacts with a diazonium ion in a neutral or weak acidic solution. Although *N,N*-dialkyl-*N'*-acyl-*m*-phenylenediamine may be a weaker acidic substance than phenol, it is reasonable to assume that their conjugate bases also couple with a diazonium ion in a manner similar to that described above, even in a neutral solution.

The difference between the activating effects of an acetylamino and its conjugate base can be obtained by comparing their reactivities. The second-order rate constant (k_2) can be calculated according to Eq. (3) or Eq. (4) by dividing the first-order rate constant (k') by the stoichiometric concentration of the undissociated substrate or by the anion concentration respectively. However, the calculation of the anion concentration requires the pK_a value of an acetylamino compound. Unfortunately, in water, the measurements of the pK_a value of an acetylamino compound is impossible because of its high reactivity to hydrolytic cleavage in a strong alkaline solution. Therefore, the exact concentration of an anion under kinetic conditions can not be accurately determined. However, in isopropyl alcohol the acidity of acetanilide is known to be close to that of methanol.[8] On the other hand, the pK_a value of methanol was measured to be 15.5 in water.[9] Therefore, the pK_a value of acetanilide in water may also be close to this value. On the basis of the presence of an electron-releasing *N,N*-dialkylamino group in the *meta* position, I is assumed to be a weaker acid than acetanilide; therefore, we assume that the pK_a value of I is 16.0. By using this value, we obtained the rate constants (k_2) of 4.1 ($l\cdot mol^{-1}\cdot min^{-1}$) for the reaction of the undissociated molecule and 1.1×10^9 ($l\cdot mol^{-1}\cdot min^{-1}$) for the reaction of the anion; this implies that the activating effect of the conjugate base of an acetylamino group is higher than that of

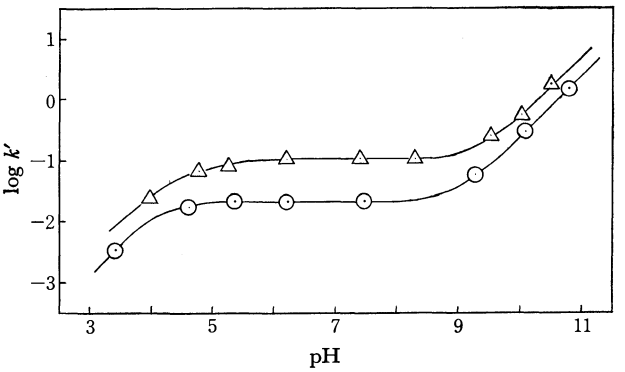

Fig. 2. pH-Rate profile for the reaction of *p*-methoxybenzenediazonium salt with *N,N*-dimethyl-*N'*-benzoyl-*m*-phenylenediamine (III) (circles, medium: 50 vol% methylcellosolve-water), and with *N,N*-dimethyl-*N'*-carboethoxy-*m*-phenylenediamine (IV) (triangles, medium: 50 vol% methanol-water). Concentration of reactants was identical to those described in Fig. 1. k' in min^{-1})

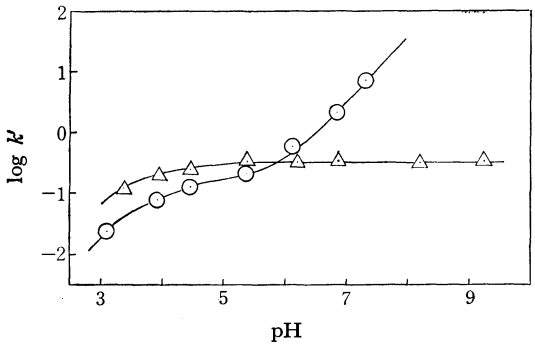

Fig. 3. pH-Rate profile for the reaction of *m*-methylbenzenediazonium salt with *N,N*-dimethyl-*N'*-(*p*-toluenesulfonyl)-*m*-phenylenediamine (V) (circles), and with *N,N,N'*-trimethyl-*N'*-(*p*-toluenesulfonyl)-*m*-pnenylenediamine (VI) (triangles) in 50 vol% methylcellosolve–water. (Concentration of reactions was identical to those described in Fig. 1. k' in min^{-1})

the parent group by some 8 powers of ten.

From a similar point of view, the coupling reactions with *N'*-benzoyl- (III), *N'*-carboethoxy- (IV), and *N'*-(*p*-toluenesulfonyl) (V) derivatives were also investigated. The pH dependences of the rate constant (k') in these cases are given in Figs. 2 and 4.

From these figures, it is obvious that the pattern of the pH-rate profile of these reactions is esesntially the same as that in the case of Compound I, although the pH region in which an anion enters the reaction varies considerably.

Additional evidence for the pariticpation of an anion was obtained from the reaction of *N,N,N'*-trimethyl-*N'*-(*p*-toluenesulfonyl)-*m*-phenylenediamine (VI), containing no acidic hydrogen atom in the acylamino group. In this case, the reaction rate was found to be independent of the pH value, even in an alkaline region, as can be seen in Fig. 3; this finding supports the validity of the view presented above.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3266—3269 (1973)

The Synthesis of 1,2-Diamino- and 1,2,3-Triaminoazulene Derivatives[1)]

Tetsuo Nozoe,* Toyonobu Asao,** and Masao Kobayashi***

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Aoba, Sendai 980

(Received May 28, 1973)

The diazo coupling reaction of 2-amino- (I), 2-acetamido-, and 2-amino-1-ethoxycarbonyl-azulene with *p*-toluene diazonium salt gave the corresponding 1-(*p*-tolylazo)azulene derivatives, II, V, and VIII respectively, in good yield; 2-amino-1,3-di(*p*-tolylazo)azulene (III) was also obtained by the reaction of I and two molar equivalents of *p*-toluene diazonium salt. The catalytic reduction of V and VIII afforded 2-acetamido-1-aminoazulene and ethyl 1,2-diaminoazulene-3-carboxylate as hydrochloride. The similar reduction of II and III yielded only a resinous product, and 1,2-diamino- or 1,2,3-triaminoazulene could not be isolated, not even as their salts. However, the reductive acetylation of II and III afforded the corresponding polyacetamidoazulenes. The ultraviolet and visible absorption spectra of these azulenes are indicated.

1-, 2-, 4-, and 6-aminoazulenes have been synthesized[2)] by several groups all as unstable compounds except for 2-aminoazulene,[2c)] and detailed investigation of 1-aminoazulene concerning to its basicity and spectroscopic properties have been reported.[2b)] Syntheses of polyaminoazulenes have also been attempted, but none of the polyaminoazulene have been reported except for their derivatives, 1,3-diacetamidozaulene[3)] and diethyl 2,5- and 2,6-diaminoazulene-1,3-dicarboxylate.[2e)]

In the present investigation, the syntheses of 1,2-diamino- and 1,2,3-triaminoazulene were attempted in order to compare their stabilities, basicities, and spectroscopic properties with those of aromatic amines and other aminoazulenes; our results will be reported herein.

Among the synthetic courses of these polyaminoazulenes, the reduction of 2-amino-1(or 1,3-di)-arylazoazulene derivatives was chosen.

The reaction of 2-aminoazulene (I)[2c)] and one molar equivalent of *p*-toluene diazonium salt in ethanol easily afforded 2-amino-1-(*p*-tolylazo)azulene (II) in a good yield, besides a small amount of 2-amino-1,3-di-(*p*-tolylazo)azulene (III). Compound (III) was also obtained by the reaction of I and two molar equivalents of the diazonium salt. The structure of the products

are assumed from the general reactivity of azulenes.[2a] By a similar method, 2-acetamidoazulene (IV)[2c] gave 2-acetamido-1-(*p*-tolylazo)azulene (V), and ethyl 2-aminoazulene-1-carboxylate (VI)[2c] and its 7-isopropyl derivative (VII)[4] afforded the corresponding 3-*p*-tolylazo derivatives (VIII and IX respectively). 2-Amino-5-isopropyl-1,3-di(*p*-tolylazo)azulene (X) was also obtained from 2-amino-5-isopropylazulene.[2c]

In contrast with the cases of Compounds IV, VI, and VII, the azo-coupling reactions of ethyl 2-acetamidoazulene-1-carboxylate[2c] and its 7-isopropyl derivative[4] were unsuccessful, and the starting materials were recovered.

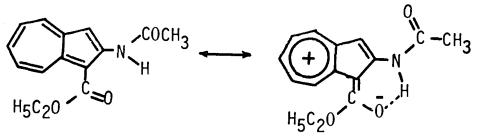
XII

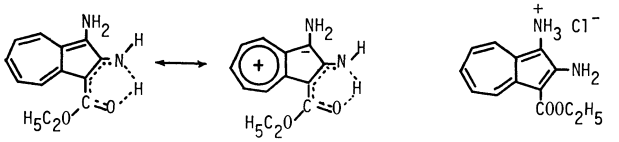
It is considered that such an unreactivity of the 2-acetamidoazulene derivatives for the electrophilic attack may be attributable to a contribution of the resonance form shown below caused by the electron-attractive effect of the ethoxycarbonyl group. This assumption is supported by the following spectroscopic data: ethyl 2-acetamidoazulene-1-carboxylate shows ν_{CO} at the low frequency of 1650 cm^{-1}, and NMR signals at a lower field (δ 7.3—7.6 (m, H_5—H_7), 8.06 (s, H_3), 8.27 (d, J=9 Hz, H_4), 9.03 (d, J=9 Hz, H_8), 11.45 (bs, NH), and 2.33 (NCH_3)) than the corresponding signals of 2-acetamidoazulene (δ 7.0—7.6 (m, H_1, H_3, H_5—H_7), 7.90 (NH), 8.15 (d, J=9 Hz, H_4, H_8) and 2.28 (NCH_3)).



In the reduction of II in ethyl acetate using 5% Pd-C as the catalyst, two molar equivalents of hydrogen were consumed, but the product was very unstable and was rapidly decomposed to a black resinous compound and could not be isolated even as hydrochloride or picrate. Therefore, the reductive acetylation of II was attempted in acetic anhydride; 1,2-diacetamidoazulene (XI) was thus obtained in a good yield as stable violet crystals. 1,2,3-Triaminoazulene also could not be isolated in the free state by the reduction of III; however, the reductive acetylation of III afforded 1,2,3-triacetamidoazulene (XII) as yellowish-green crystals. The 2-acetamido-1-aminoazulene (XIII) obtained by the reduction of V was also so unstable that it was isolated only as hydrochloride. Various attempts to isolate the free amino compound (XIII) from the hydrochloride failed. The acetylation of the hydrochloride or the reductive acetylation of V yielded the previously-obtained 1,2-diacetamidoazulene (XI).

From the reduction mixture of ethyl 2-amino-3-(*p*-tolylazo)azulene-1-carboxylate (VIII), ethyl 2,3-diaminoazulene-1-carboxylate (XIV) could not be isolated; however, monohydrochloride of XIV was obtained in a good yield as golden yellow crystals. In a similar manner, monohydrochloride of ethyl 1,2-diamino-5-isopropylazulene-3-carboxylate (XV) was obtained from the azo compound (IX). These hydrochlorides are considerably stable, but are gradually changed to black resin, and the attempted isolations of the free amines, XIV and XV, from the hydrochlorides resulted in resinification. The acetylation of these hydrochlorides or the reductive acetylations of VIII and IX afforded the corresponding diacetates (XVI[5] and XVII respectively).

In view of the facts that the 2-amino group may form a stable hydrogen bonding with the ethoxycarbonyl group and that the 1- and 3-positions of the azulene nucleus have the highest electron densities, the 1-amino group in XIV must have a higher basicity than the 2-amino group; therefore, it is considered that hydrogen chloride may form a salt with the 1-amino group, as is shown below.



The ultraviolet and visible absorption maxima of the aminoazulene and *p*-tolylazoazulene derivatives obtained above are shown in Table 1.

The visible absorption maxima shown in Table 1, together with that of 2-acetamidoazulene [λ_{max}^{MeOH} nm

5) 1,2-Diacetamidoazulene (XVI) has also been obtained by the reduction of ethyl 2-amino-3-nitrosoazulene-1-carboxylate; T. Nozoe, P.W. Yang, H. Ogawa, and T. Toda, This Bulletin, **41**, 2095 (1968).

Table 1. Ultraviolet and visible absorption maxima

(log ε); 540 (2.44) and 580^{sh} (2.38)] indicate that the acetamido groups at the 1- and 3-positions cause the absorption maxima to shift to longer wavelengths, according to the expanded Plattner rule.[3,6]

Experimental[7]

Coupling Reaction of 2-Aminoazulene with p-*Toluene Diazonium Chloride.* To a stirred solution of 2 g of 2-aminoazulene in a mixture of 30 ml of ethanol and 10 ml of dioxane, a solution of *p*-toluenediazonium chloride prepared from 1.79 g of *p*-toluidine was added at once under cooling with ice. After stirring for 2 hr, the solution was allowed to stand at room temperature overnight. A deep brown solid (3.4 g) was then filtered out; to the filtrate water (150 ml) was added, and it was extracted with chloroform. The extract was washed with water, dried over sodium sulfate and evaporated, leaving a deep reddish semi-solid. A benzene solution of the combined solids was chromatographed on an alumina column and eluted with benzene. The first effluent gave brown crystals (mp 180—195 °C), which were recrystallized from ethyl acetate to give 2-amino-1-3-di(*p*-tolylazo)azulene (III) (400 mg) as deep brown needles (mp 199—200 °C).

Found: C, 75.80; H, 5.66; N, 18.19%. Calcd for $C_{24}H_{21}N_5$: C, 75.96; H, 5.58; N, 18.46%.

The second effluent gave brown crystals (mp 150—160 °C), which were recrystallized from ethyl acetate to afford 2-amino-1-(*p*-tolylazo)azulene (II) (3.1 g) as brown crystals (mp 162—163 °C).

Found: C, 78.00; H, 5.78; N, 15.74%. Calcd for $C_{17}H_{15}N_3$: C, 78.13; H, 5.79; N, 16.08%.

*2-Acetamido-1-(*p-*tolylazo)azulene (V).* a) To a stirred solution of 185 mg of 2-acetamidoazulene in 4 ml of ethanol, a solution of *p*-toluene diazonium chloride prepared from 120 mg of *p*-toluidine was added at once under cooling with ice. After stirring for 2 hr, the solution was made slight alkaline by the addition of sodium hydrogen carbonate. Brown precipitate was then filtered out, dried, and dissolved in benzene, and the solution was chromatographed on an alumina column. The recrystallization of the crystals obtained from the effluent from ethanol gave 136 mg of V as reddish violet needles (mp 185—186 °C).

Found: C, 74.79; H, 6.01; N, 13.85%. Calcd for $C_{19}H_{17}ON_3$: C, 75.22; H, 5.65; N, 13.85%.

b) The acetylation of 50 mg of 2-amino-1-(*p*-tolylazo)-azulene with acetic anhydride gave 40 mg of V (mp 185—186 °C, undepressed on admixture with a sample prepared by Method a)).

Hydrochloride of 2-Acetamido-1-aminoazulene (XIII). A solution of 210 mg of V in 15 ml of ethyl acetate was submitted to catalytic hydrogenation in the presence of 50 mg of 5% Pd-C. After two molar equivalents of hydrogen had been uptaken, the catalyst was filtered off; the filtrate was shaken with 5 ml of concentrated hydrochloric acid, thus affording 110 mg of precipitate. Recrystallization from water gave 95 mg of black-violet needles (mp over 280 °C).

Found: C, 60.80; H, 5.22; N, 11.57%. Calcd for $C_{12}H_{12}ON_2 \cdot HCl$: C, 60.89; H, 5.11; N, 11.84%.

1,2-Diacetamidoazulene (XI). A solution of 1.22 g of 2-amino-1-(*p*-tolylazo)azulene in 190 ml of acetic anhydride was submitted to catalytic hydrogenation in the presence of 500 mg of 5% Pd-C. After two molar equivalents of hydrogen had been uptaken, the catalyst was filtered and the filtrate was evaporated, leaving a dark yellow residue, from which 55 mg of acetotoluidide were obtained. After the catalyst had been washed thoroughly with acetic acid, the washings were evaporated to give 540 mg of violet crystals. Recrystallization from acetic acid gave 1,2-diacetamidoazulene as violet crystals (mp 278 °C (decomp.)).

Found: C, 69.25; H, 5.61; N, 11.46%. Calcd for $C_{14}H_{14}O_2N_2$: C, 69.40; H, 5.83; N, 11.56%.

The same compound was also obtained in a good yield by the acetylation of the hydrochloride of 2-acetamido-1-aminoazulene with acetic anhydride.

1,2,3-Triacetamidoazulene (XII). A solution of 500 mg of 2-amino-1,3-di(*p*-tolylazo)azulene (III) in 100 ml of acetic anhydride was submitted to catalytic hydrogenation in the presence of 250 mg of 5% Pd-C. After four equivalents of hydrogen had been uptaken, the catalyst was filtered and washed with acetic acid. The combined filtrate and washing was concentrated to a small volume, thus affording yellowish-orange crystals; these crystals were recrystallized from ethanol to gave 276 mg of 1,2,3-triacetamidoazulene as yellowish-green crystals (mp 271—272 °C).

Found: C, 64.11; H, 5.63; N, 13.97%. Calcd for $C_{16}H_{17}O_3N_3$: C, 64.20; H, 5.72; N, 14.04%.

*Ethyl 2-Amino-3-(*p-*tolylazo)azulene-1-carboxylate (VIII).* To a solution of 215 mg of ethyl 2-aminoazulene-1-carboxylate in 4 ml of ethanol, a solution of *p*-toluenediazonium chloride prepared from 118 mg of *p*-toluidine was added under cooling with ice. After having been allowed to stand overnight, the solution was made slight alkaline; the precipitate was filtered and washed with water. A solution of the solid in benzene was chromatographed on an alumina column; subsequent recrystallization from ethanol gave 240 mg of ethyl 2-amino-3-(*p*-tolylazo)azulene-1-carboxylate as deep reddish crystals (mp 120—121 °C).

Found: C, 71.98; H, 5.34; N, 12.76%. Calcd for $C_{20}H_{19}O_2N_3$: C, 72.05; H, 5.74; N, 12.61%.

Hydrochloride of Ethyl 2,3-Diaminoazulene-1-carboxylate (XIV). A solution of 200 mg of ethyl 2-amino-3-(*p*-tolylazo)azulene-

7) All melting points are uncorrected.

1-carboxylate in 15 ml of ethyl acetate was submitted to catalytic hydrogenation in the presence of 50 mg of 5% Pd-C. After two molar equivalents of hydrogen had been uptaken, the catalyst was filtered and washed with ethyl acetate; the combined filtrate and washing was shaken with concentrated hydrochloric acid to give yellowish-orange crystals. Recrystallization from dilute hydrochloric acid gave 170 mg of XIV as golden yellow needles (mp over 260 °C).

Found: C, 58.33; H, 5.33; N, 10.91%. Calcd for $C_{13}H_{14}O_2N_2 \cdot HCl$: C, 58.45; H, 5.67; N, 10.51%.

Picrate of ethyl 2,3-diaminoazulene-1-carboxylate. Mp changed to black from around 215 °C.

Found: C, 49.67; H, 3.67; N, 15.28%. Calcd for $C_{19}H_{17}O_9N_5$: C, 49.67; H, 3.73; N, 15.25%.

Ethyl 2,3-Diacetamidoazulene-1-carboxylate (XVI). A solution of 150 mg of hydrochloride of XIV in acetic anhydride (1 ml) was heated on a water bath for 30 min. The excess acetic anhydride was then removed to leave a violet residue, which was dissolved in benzene; the solution was then chromatographed on an alumina column. Recrystallization from benzene gave 160 mg of XVI as light purple needles (mp 216—218 °C).

Found: C, 65.20; H, 5.57; N, 8.66%. Calcd for $C_{17}H_{18}O_4N_2$: C, 64.95; H, 5.77; N, 8.91%.

Ethyl 2-Amino-5-isopropyl-1-(p-tolylazo) azulene-3-carboxylate (IX). To a stirred solution of 210 mg of ethyl 2-amino-5-isopropylazulene-3-carboxylate in 3 ml of ethanol, a solution of *p*-toluene diazonium chloride prepared from 150 mg of *p*-toluidine was added under cooling with ice. After stirring for 2 hr, the solution was allowed to stand at room temperature overnight. The precipitate was filtered, and dissolved in benzene, and the solution was chromatographed on an alumina column. The effluent afforded reddish crystals, which were recrystallized from ethanol to give ethyl 2-amino-5-isopropyl-1-(*p*-tolylazo)azulene-3-carboxylate (220 mg) as reddish-brown crystals (mp 118—120 °C).

Found: C, 73.35; H, 6.51; N, 11.04%. Calcd for $C_{23}H_{25}O_2N_3$: C, 73.57; H, 6.71; N, 11.19%.

2-Amino-1,3-di(p-tolylazo)-5-isopropylazulene (X). To a stirred solution of 92 mg of 2-amino-5-isopropylazulene in 2 ml of ethanol, a solution of *p*-toluene diazonium chloride prepared from 120 mg of *p*-toluidine was added. After standing for a day, water was added and then extracted with benzene; the solution was subsequently chromatographed on an alumina column, 110 mg of 2-amino-1,3-di(*p*-tolylazo)-5-isopropylazulene as yellow-brown crystals (mp 170—171 °C (from ethyl acetate)) being thus obtained.

Found: C, 76.86; H, 6.15; N, 16.43%. Calcd for $C_{27}H_{27}N_5$: C, 76.93; H, 6.46; N, 16.62%.

Hydrochloride of Ethyl 1,2-Diamino-5-isopropylazulene-3-carboxylate (XV). A solution of 1 g of IX in 80 ml of ethyl acetate was submitted to catalytic hydrogenation in the presence of 300 mg of 5% Pd-C. After two molar equivalents of hydrogen had been uptaken, the catalyst was filtered; the filtrate was shaken with 10 ml of concentrated hydrochloric acid to give 380 mg of hydrochloride of XV as yellow crystals; the mp changed to black from around 250 °C, after washing with ethyl acetate.

Found: C, 62.03; H, 6.48; N, 8.71%. Calcd for $C_{16}H_{20}O_2N_2 \cdot HCl$: C, 62.23; H, 6.85; N, 9.07%.

Ethyl 1,2-Diacetamido-5-isopropylazulene-3-carboxylate (XVII). A solution of 50 mg of hydrochloride of XV in 0.3 ml of acetic anhydride was heated on a water bath for 30 min. The solvent was then removed; the residue was purified by chromatography (alumina, benzene) and then recrystallized from cyclohexane to give 30 mg of XVII as light purple needles (mp 162—164 °C).

Found: N, 7.62%. Calcd for $C_{20}H_{24}O_4N_2$: N, 7.86%.

Hydrolyses of *p*-Nitrophenyl(Oligodeoxyribonucleotide Succinate)s by Oligodeoxyribonucleotide *N*-Acetylhistidates on Polycytidylic Acid

Takeo SHIMIDZU* and Robert L. LETSINGER**

* *Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606*

** *Department of Chemistry, Northwestern University, Evanston, Illinois, U.S.A.*

(Received February 5, 1973)

The hydrolyses of *p*-nitrophenyl(oligonucleotide succinate)s, in which the oligonucleotides are *d*GpG, *d*GpT, *d*GpC, *d*GpA, and *d*GpGpG, by oligonucleotide *N*-acetylhistidates, in which the oligonucleotides are *d*GpG, *d*GpT, *d*GpC, *d*GpA, and *d*GpGpG, or by *d*GpG nicotinate were carried on polycytidylic acid (Poly C). While the hydrolysis did not occur at lower concentrations of them, it did take place at moderate concentrations, in the presence of Poly C. From the kinetics of the hydrolysis, it was concluded that the interaction between those oligonucleotide derivatives and Poly C was homogeneous at lower concentrations of them and heterogeneous at higher concentrations. The change in the viscosity of the reaction system was correlated with the kinetical results. The heterogeneity in the interaction can be explained as a contiguous stacking of the oligonucleotide derivatives on Poly C. The tendency of the contiguous stacking was great in *d*GpGpG *N*-acetylhistidate. The rate of the hydrolysis of Poly C was higher than that without Poly C. The order in magnitude of the interaction between the oligonucleotide derivatives and Poly C was *d*GpGpG-derivative>*d*GpGp-derivative>*d*GpC-derivative>*d*GpA-derivative>*d*GpT-derivative.

For the study of a chemical reaction on a macromolecule, it is very important to make clear the features of the interaction of a reactant onto the macromolecule. An interaction between polynucleotide and oligonucleotide will play an important role in the condensation of the oligonucleotide on the polynucleotide.

In continuation of an earlier study,[1] the present paper will report on the hydrolyses of *p*-nitrophenyl (oligodeoxyribonucleotide succinate)s, such as *p*-nitrophenyl (deoxyguanylyldeoxyguanosine succinate) (NPS-*d*GpG), -(deoxyguanylylthymidine succinate) (NPS-*d*GpT), -(deoxyguanylyldeoxycytidine succinate) (NPS-*d*GpC), -(deoxyguanylyldeoxyadenosine succinate) (NPS-*d*GpA), and -(deoxyguanylyldeoxyguanylyldeoxyguanosine succinate) (NPS-*d*GpGpG), by oligodeoxyribonucleotide *N*-acetylhistidates, such as deoxyguanylyldeoxyguanosine *N*-acetylhistidate (AH-*d*GpG), deoxyguanylylthymidine- (AH-*d*GpT), deoxyguanylyldeoxycytidine- (AH-*d*GpC), deoxyguanylyldeoxyadenosine- (AH-*d*GpA), and deoxyguanylyldeoxyguanylyldeoxyguanosine (AH-*d*GpGpG), and by deoxyguanylyldeoxyguanosine nicotinate (N-*d*GpG), on polycytidylic acid (Poly C). The hydrolysis of *p*-nitrophenyl(oligodeoxyribonucleotide succinate) proceeds by means of a nucleophilic reaction of an imidazolyl or nicotinyl group present in the latter derivatives. Though the substances used in the present work are not pure and homogeneous, they can still be used in substantially clarifying the features of the interaction of those reactants onto the macromolecule, Poly C.

The interaction between nucleotides is specific and selective, and its magnitude depends on the degree of polymerization of the nucleotides, the concentration of the nucleotides, the ionic strength of the solution, *etc.*[2] Even though guanosine is most liable to stack, no hypochromicity was, in general, observed in the cases of the guanosine dimer and Poly C at which concentrations were of the order of 10^{-4} M.[3] In the case of the enzymatic polymerization of oligonucleotide by DNA-dependent RNA polymerase, the effective degree of polymerization of the oligonucleotide was elucidated to be 6—7.[4] Nevertheless, a complex formation between Poly C and deoxyguanosine-5′-phosphate was suggested by the infrared spectrum under conditions of a higher concentration and a lower temperature.[5] Further, base-base interactions were observed in the dinucleotide model by means of studying the emission spectrum,[6] and in dinucleotide by means of studying the proton magnetic resonance spectrum.[7]

While the interaction between polynucleotide, Poly C, and the oligonucleotide derivatives used is complex, a characteristic mode of interaction is deduced in the present study of the hydrolysis.

Results and Discussion

From the mixing curves for Poly C and NPS-*d*GpG and for Poly C and AH-*d*GpG at the total nucleotide concentration of 7×10^{-4} M, the maximal hypochromicities which occurred at the minimal points were found to be about 1.0% and 2.5% respectively. The larger hypochromicity of the latter might be ascribed to the interaction between the histidyl moiety and the nucleotidic base.

Fig. 1 shows the hydrolysis of NPS-*d*GpG by AH-*d*GpG with Poly C and without Poly C. The rate[8] of the hydrolysis was negligible when the ratio of NPS-

*d*GpG and AH-*d*GpG to Poly C was less than 0.2, but it increased linearly when the ratio exceeded 0.3. When the ratio was over 1.3 the rate of increase of the hydrolysis with Poly C was parallel to that without Poly C. On the other hand, the hydrolysis rate without Poly C was proportional to the amount of the NPS-*d*GpG and AH-*d*GpG, and the line passed through the point of origin.

From the fact that the hydrolysis of the reactants in the presence of Poly C was not observed at lower concentrations, it can be concluded that the interaction between dinucleotide derivatives and Poly C is statistically homogeneous, so that the distance between the two dinucleotide derivatives is too long to cause the hydrolysis reaction. If the two reactants are stacked on Poly C so as to be contiguous with each other, the hydrolysis reaction takes place and the hydrolysis rate can be shown by the broken line[9] in Fig. 1. From the other fact that the hydrolysis rate increased linearly with the amount of the dinucleotide derivatives in the ratio range between 0.3 and 1.3, it can be concluded that, in this range, the derivative is stacked on Poly C contiguously to the derivatives which had previously been stacked on it. If the stacking is homogeneous in this range, the hydrolysis rate can be presented as by the dotted line[10] in Fig. 1. From the other fact that the hydrolysis rate at higher concentrations of the derivatives was almost parallel to that without Poly C, it can be concluded that the stacking of the derivatives on Poly C is saturated in this range and that an excess of them reacts freely with the Poly C.

The difference between the hydrolysis rates with and without Poly C, $R_{polyC}-R_0$, indicates the hydrolysis rate on Poly C. The hydrolysis rate on Poly C increased linearly with the concentration of the reactants, the dinucleotide derivatives, in the ratio of 0.3 to 1.3.

Fig. 2 shows the hydrolysis rate when the concentration of the catalyst, AH-*d*GpG, was a constant. The profile of the increase in the rate with respect to the concentration of the substrate, NPS-*d*GpG, is almost the same as that of Fig. 1 at lower concentrations. The saturation points are different with each concentration of AH-*d*GpG used. They increase with the concentration of AH-*d*GpG. This shows that the reaction on Poly C takes place where the substrate is stacked contiguously with the catalyst. The lowest concentration at which the reaction takes place decreases with the concentrations of the catalyst and the substrate.

The observations in Figs. 1 and 2 support the above-stated conclusions. It can be considered that Poly C does not take a helical configuration under these reaction conditions. Therefore, the following plausible explanation may be offered for this finding: The reactants which were stacked remotely on Poly C at their lower concentrations might not react, while the reactants which were stacked contiguously on Poly C at a moderate concentration could react. At a higher concentration, with a ratio exceeding 1.3, the additional reactants react freely from Poly C.

To estimate the hydrolysis rate on Poly C, let us define the rate as;

$$k_{eff} = (R_{polyC}-R_o)/(C-C_i)$$

where C is the concentration of the reactant, NPS-*d*GpG, and where C_i is the concentration which is the extrapolation of the linearly-increasing part of the rate *vs.* the concentration of NPS-*d*GpG in Fig. 1 to the intercept, or the lowest concentration of which the hydrolysis takes place. The rate constants of the hydrolyses, k_{eff}'s, on Poly C were substantially constants, which were estimated to be $(2.46\pm0.10)\times10^{-1}$ mol^{-1} sec^{-1} at the [NPS-*d*GpG]/[Poly C] ratios exceeding the threshold values respectively. The constancy of the

9) When two reactants are stacked on Poly C contiguously, the hydrolysis rate should be proportional to the concentration of NPS-*d*GpG. So that, the rate is presented as a straight line which passes the origin.

10) When two reactants are stacked on Poly C at random, the average probability of contiguous stacking of those reactants is presented as;

$\bar{P}_c \cong 2n/(n_0-n)$ $(n<n_0/3)$

where n_0 denotes the total contiguous stacking site on the Poly C and n does the number of stacked reactants. The concentration of the reactant (C) is almost proportional to n and the reaction rate is also proportional to $\bar{P}_c$, so the rate is expressed as;

the rate$\cong 2\alpha C/(n_0-\alpha C)$ $(\alpha C \leqq n_0/3)$

where α denotes the stacking factor of the reactant. When $\alpha C > n_0/3$, a proportionality between the rate and the concentration of the reactant will be given.

rate supports the above-mentioned explanation that the reactants stacked on Poly C react contiguously with each other in this range. In other words, the stacking of the reactants on Poly C takes place contiguously in the range of the [NPS-*d*GpG]/[Poly C] ratio exceeding the threshold value. From the hydrolysis rate without Poly C, which is shown in Fig. 1, the rate of the hydrolysis except on Poly C, k_0, is found to be $(0.54\pm0.1)\times10^{-1}\ l\ mol^{-1}\ sec.^{-1}$

Figure 3 shows the hydrolysis of dinucleotide derivatives with and without Poly C. In the case of the hydrolysis of NPS-*d*GpT by AH-*d*GpT, there was no evidence of the interaction with Poly C. In the cases of the hydrolyses of NPS-*d*GpC by AH-*d*GpC, of NPS-*d*GpA by AH-*d*GpA, and of NPS-*d*GpG by N-*d*GpG, similar phenomena were observed. The hydrolyses did not take place at lower concentrations of the oligonucleotide derivatives, and they were parallel to the rate without Poly C at higher concentrations. At moderate concentrations, the hydrolyses increased at a higher rate, similar to the case of the hydrolysis of NPS-*d*GpG by AH-*d*GpG.

To estimate the rate of the hydrolysis on Poly C, k_{eff}, and that without Poly C, k_0, the same calculations as have been described above have been made for each case. The results are tabulated in Table 1. Although the hydrolysis rate of NPS-*d*GpG by AH-*d*GpG on Poly C was 4 times faster than that without Poly C, the hydrolysis rate of NPS-*d*GpG by N-*d*GpG on Poly C was 2 times faster than that without Poly C. This difference might be due to different distances between the catalytic nucleophilic atoms and the stacking points of these nucleotidic materials. The fact that the concentrations at which the hydrolysis took place were substantially identical in both hydrolyses shows that the modes of the interactions of AH-*d*GpG and N-*d*GpG with Poly C are almost identical with that of AH-*d*GpG and NPS-*d*GpG with Poly C. Though it is not possible to quantify the interaction between dinucleotides and Poly C, it can be seen from the values of C_1's that its order is *d*GpG>*d*GpC>*d*GpA>*d*GpT.

Fig. 4 shows the hydrolyses of NPS-*d*GpGpG by AH-*d*GpGpG, of NPS-*d*GpG by AH-*d*GpGpG, and of NPS-

*d*GpGpG by AH-*d*GpG. Profiles of hydrolysis similar to Figs. 1 and 4 were observed.

The rates are tabulated in Table 2. From the hydrolyses of NPS-*d*GpG by AH-*d*GpG and of NPS-*d*GpGpG by AH-*d*GpGpG, it is very tempting to suppose that the distance between the substrates and the catalysts plays a role in the hydrolyses. Although the two relative rates of hydrolyses without Poly C were similar, the rates on Poly C were different. The longer distance was not preferable to the hydrolysis in spite of the tightly stacking on Poly C. The exhibition of very little increment in the hydrolysis of the latter might be due to the stacking of AH-*d*GpGpG and NPS-*d*GpGpG with each other. Furthermore, a directionality in the interaction might be considered with the difference between the rates of the hydrolyses of NPS-*d*GpG by AH-*d*GpGpG and that of NPS-*d*GpGpG by AH-*d*GpG. From the C_1's which are concentrations of the oligonucleotide derivatives when the hydrolysis took place, we learn that the mode of interaction of AH-*d*GpGpG with Poly C was rather favorable to the contiguous stacking.

The results of the reduced viscosity measurements of several reaction systems are tabulated in Table 3. While the reduced viscosity, η_{sp}/c, relating to Poly C did not change when relatively small amounts of NPS-*d*GpG and AH-*d*GpG were present in the system, the reduced viscosity decreased when amounts of NPS-*d*GpG and AH-*d*GpG of more than 0.50×10^{-3} M were present. The viscosity of the system of NPS-*d*GpG and AH-*d*GpG was negligible, of course. On the other hand, when an added Poly G existed in the Poly C solution, the reduced viscosity relating to Poly C obviously increased to 2.34(7). This increase in the viscosity was due to the added Poly G. To eliminate the effect of the viscosity of Poly G, we employed the total concentrations of those two polymeric materials, Poly C and Poly G, as the reference concentration, *c*; then, the reduced viscosity was estimated to be 1.10(5). This value was less than the arithmetic mean value of the reduced viscosities of Poly C and Poly G. This can be explained as the formation of a double strand of Poly C and Poly G by reference to the results of Fresco and Doty.[11] Using Poly A, they had obtained a lower viscosity under the condition of an interrupted helix and a higher viscosity under the condition of a random coil. Therefore, the decrease in the reduced viscosity of Poly C in the presence of a considerable amount of NPS-*d*GpG and AH-*d*GpG can be explained as a partial conformational change of Poly C at the interacting location where the stacking of those dinucleotide derivatives with Poly C took place.

Those results are compatible with the conclusions that the stacking of the dinucleotide derivatives with Poly C takes place statistically homogeneous at the initial stage and that afterwards the stacking occurs at the site contiguously to the pre-stacked one. Such a phenomenon may be caused by a conformational change in Poly C by the stacking of the oligonucleotide derivatives. This conclusion is an interesting concept compared with that of the homogeneous stacking previously believed.

Experimental

The hydrolyses reactions were carried out using a 1 : 100 ethanol-water solution containing 0.01 M of $MgCl_2$ and 0.0001 M of $Mg(OAc)_2$,[12] the pH of which was made up to 7.9 by tris-(hydroxymethyl)aminomethane.

The Poly C solution was made up to 0.7×10^{-3} M using the above buffer solution. Both solutions of dinucleotide and trinucleotide derivatives in a certain concentration were prepared fresh each time using the above buffer solution.

11) J. R. Fresco and P. Doty, *J. Amer. Chem. Soc.*, **79**, 3928 (1957).

12) Generally, existence of Mg^{2+} assists the complex formation of Poly C-Poly G, so that such magnesium salts were used in the present study. The existence of Mg^{2+} did not affect the absorbancy of Poly C in UV spectrum.

The experiments were carried out by mixing 2 ml of the Poly C solution, 1 ml of the substrate derivative of the *p*-nitrophenyl succinate solution, and 1 ml of the catalyst derivative of the *N*-acetylhistidate or nicotinates solution at 5 °C. The absolute amounts of the substrate and the catalyst were the same in all the experiments. The rates of the hydrolyses were measured by the increase in absorbance at 400 nm. In the case of the absence of Poly C, 2 ml of the above buffer solution instead a similar portion of the Poly C solution was used.

By analysing the reacted material in a paper chromatograph, it was proved that the hydrolyzed materials did not contain *p*-nitrophenylsuccinic acid. It can be said that the hydrolyses took place predominantly at the position between *p*-nitrophenyl and succinyl moieties.

The increase in absorbance can be treated as linear with the reaction time at lower conversions. The reaction followed the kinetics of the first-order with respect to the NPS-*d*GpG to the extent of 45% of the conversion. This shows that there might be no product inhibition in the reaction.

The viscosity was measured at 5±0.05 °C using a Ubbelohde-type viscometer.

Polycytidylic Acid (Poly C) and Polyguanylic Acid (Poly G). Poly C and Poly G were purchased from the Miles Chemical Co.; their sedimentation constants were 4.3 and 2.9 respectively.

p-*Nitrophenyl (deoxyguanylyldeoxyguanosine succinate) (NPS-*d*GpG).* In anhydrous pyridine, 40 mg of *N*-di-*p*-methoxytrityldeoxyguanylyl-*N*-di-*p*-methoxytrityldeoxyguanosine,[13] (DMTr)*d*G(DMTr)*d*G, and 20 mg of succinic anhydride was subjected to a reaction for 14 hr at room temperature; then we added 25 mg of *p*-nitrophenol and 40 mg of dicyclohexylcarbodiimide. After 14 hr, 10 ml of an aqueous solution of KH_2PO_4 was added. Then 90 ml of ethanol was added, and the resultant mixture was filtered. A filtrate was concentrated, and 40% acetic acid was added along with a small quantity of pyridine. After 5 hr, the solution was separated by centrifugation. The isolation of NPS-*d*GpG was achieved chromatographically in 70% ethanol using an anion-exchange resin, IR-45. The resulting NPS-*d*GpG contained 1.2 *p*-nitrophenyl groups per molecule, as indicated by the ultraviolet spectra before and after alkaline hydrolyses, which were achieved with 1 M NaOH. It is probable that the nitrophenylsuccinyl group is bonded predominantly to the 5′-O position of the nucleotide. The resulting NPS-*d*GpG did not obtain free carboxylic acid, since the present column separation showed that the resulting NPS-*d*GpG was found in one elution band, unlike the case of a free carboxylic acid.

p-*Nitrophenyl (deoxyguanylylthymidine succinate) (NPS-*d*GpT),* p-*Nitrophenyl (deoxyguanylyldeoxycytidine succinate) (NPS-*d*GpC),* p-*Nitrophenyl (deoxyguanylyldeoxyadenosine succinate) (NPS-*d*GpA),* and p-*Nitrophenyl (deoxyguanylyldeoxyguanylyldeoxyguanosine succinate) (NPS-*d*GpGpG).* The procedures to synthetize these materials were the same as that for NPS-*d*GpG, but using *N*-di-*p*-methoxytrityldeoxyguanylylthymidine, (DMTr)*d*GT, in lieu of (DMTr)*d*G(DMTr)*d*G, using *N*-di-*p*-methoxytrityldeoxyguanylyl-*N*-di-*p*-methoxytrityldeoxycytidine, (DMTr)*d*G(DMTr)*d*C, in lieu of (DMTr)*d*G(DMTr)*d*G, using *N*-di-*p*-methoxytrityldeoxyguanylyl-*N*-di-*p*-methoxytrityldeoxyadenosine, (DMTr)*d*G(DMTr)*d*A, in lieu of (DMTr)*d*G(DMTr)*d*G, and using *N*-di-*p*-methoxytrityldeoxyguanylyl-*N*-di-*p*-methoxytrityldeoxyguanylyl-*N*-di-*p*-methoxytrityldeoxyguanosine,[14] (DMTr)*d*G(DMTr)*d*G(DMTr)*d*G, in lieu of (DMTr)*d*G(DMTr)*d*G.

Deoxyguanylyldeoxygaunosine N-*acetylhistidate (AH-*d*GpG).* In anhydrous pyridine, 30 mg of *N*-di-*p*-methoxytrityldexoyguanylyl-*N*-di-*p*-methoxytrityldeoxyguanosine, (DMTr)*d*G(DMTr)*d*G, 30 mg of *N*-acetylhistidine, and 50 mg of dicyclohexylcarbodiimide were reacted for 4 days at room temperature. Then 30 ml of a KH_2PO_4 aqueous solution was added. An 50 ml of ethanol was added and filtered. Into the filtrate, the same amount of acetic acid was poured. After 5 hr the supernatant was separated by centrifugation. The isolation of AH-*d*GpG was achieved chromatographically in 70% ethanol using the anion-exchange resin. The resulting AH-*d*GpG contained 0.9 imidazolyl group per molecule, as indicated by the ultraviolet spectra in an acidic solution, in which the nucleotide had been removed by means of an ion-exchange column, before and after alkaline hydrolyses. In this case, it is probable that the histidyl group is bonded predominantly to the 5′-O position of the nucleotide.

Deoxyguanylylthymidine N-*acetylhistidate (AH-*d*GpT), Deoxyguanylyldeoxycytidine* N-*acetylhistidate (AH-*d*GpC), Deoxyguanylyldeoxyadenosine* N-*acetylhistidate (AH-*d*GpA), and Deoxyguanylyldeoxyguanylyldeoxyguanosine* N-*acetylhistidate (AH-*d*GpGpG).* The procedures to synthetize these materials were the same as that for AH-*d*GpG, but using (DMTr)*d*GT in lieu of (DMTr)*d*G(DMTr)*d*G, using (DMTr)*d*G(DMTr)*d*C in lieu of (DMTr)*d*G(DMTr)*d*G, using (DMTr)*d*G(DMTr)*d*A in lieu of (DMTr)*d*G(DMTr)*d*G, and using (DMTr)*d*G(DMTr)-*d*G(DMTr)*d*G in lieu of (DMTr)*d*G(DMTr)*d*G.

*Deoxyguanylyldeoxyguanosine nicotinate (*N-d*GpG).* Thirty mg of (DMTr)*d*G(DMTr)*d*G and 30 mg of nicotinyl chloride were reacted in anhydrous pyridine for 4 hr at room temperature. Two ml of methanol was added to esterify the excess of nicotinyl chloride; then the solution was condensed until it became cloudy, and 30 ml of acetic acid was added. After 4 hr, the isolation of N-*d*GpG was achieved chromatographically in a 50% ethanol aqueous solution, using the anion-exchange resin.

The nitrophenyl, imidazolyl, and nicotinyl contents in the above materials are tabulated in Table 4.

TABLE 4. CONTENTS OF NITRONPHENYL, IMIDAZOLYL, AND NICOTINYL GROUPS IN THE ESTERS

	Substrate	Catalyst
	p-Nitrophenyl-succinate	*N*-Acetyl-histidate
*d*GpG	1.2	0.9
*d*GpT	1.4	1.1
*d*GpC	1.2	0.9
*d*GpA	1.1	0.9
*d*GpGpG	1.0	0.9
		Nicotinate
*d*GpG		1.7

Studies on Pyrophosphates II. A New Method for the Synthesis of Nucleotide Coenzymes and Their Analogs

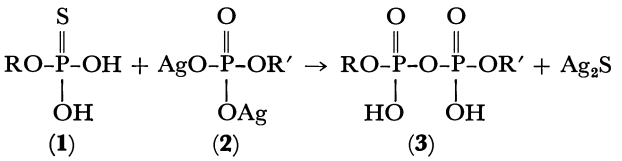
Iwao NAKAGAWA and Tsujiaki HATA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 2, 1973)

A new method for the synthesis of unsymmetrical pyrophosphates from the reaction of alkyl phosphorothioates and disilver salt of alkyl phosphates are described. Nucleotide coenzymes such as uridine diphosphate glucose, uridine diphosphate galactose, and flavin adenine dinucleotide was synthesized.

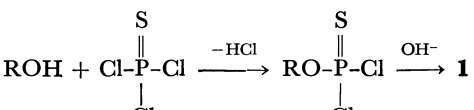
Information on the biological significance of a large number of nucleotide derivatives has increased rapidly and the domain of biochemistry of such compounds has been extended, one of them being nucleotide conenzymes which can be defined as unsymmetrical pyrophosphates having nucleoside residues. So far no biological function has been ascribed to symmetrical dinucleoside pyrophosphates, nor has any naturally occurring symmetrical pyrophosphate has been found. Consequently, development of the method for the selective synthesis of unsymmetrical pyrophosphates is of importance. The synthesis of nucleotide coenzymes were carried out by the use of reagents such as carbodiimide and related dehydrating reagents,[1] triesters of pyrophosphates,[2] α-pyridyl ester of phosphoric acid,[3] phosphoroamidates,[4] and *S*-ethyl phosphorothioates.[5] We have found a simple method for the selective synthesis of nucleotide coenzymes *via* nucleoside phosphorothioate intermediates[6] as shown in the following.



(1) (2) (3)

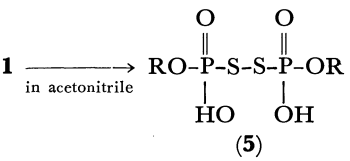
In this paper results of the experiments for the synthesis of nucleotide coenzymes and their analogs are described in detail.

Preparation of Phosphorothioates. The starting material, phosphorothioate derivatives (**1**), was prepared by hydrolysis of the corresponding thiophosphorodichloridate (**4**) obtained from the reactions of alcohol or nucleoside with thiophosphoryl chloride.



(4)

Alkyl thiophosphorodichloridates (**4**) are oily substances and purified by distillation (for their boiling points, see Experimental). Hydrolysis of **4** was performed in aqueous acetone at 0 °C in the presence of tertiary amines such as pyridine or triethylamine. Alkyl phosphorothioates (**1**) were extracted from the resulting mixture with ether and dried over sodium sulfate. After removal of ether at 5 °C, the phosphorothioates were dissolved in dry chloroform and stored in a refrigerator at 5 °C. They are stable under neutral and basic conditions at a temperature below 5 °C, but decompose in acidic medium even when kept at low temperature. Nucleoside phosphorothioates[7] were obtained by a similar procedure without isolating the intermediate **4**. Bis-triethylammonium salts of nucleoside phosphorothioates are stable solid substances. They are stable in dry pyridine at 5 °C, but unstable in acetonitrile or commercial pyridine, being converted into the corresponding P^1,P^2-bis-[nucleoside-5′-phosphoryl]disulfide (**5**).[8]



(5)

R = nucleoside residue

Preparation of Disilver Salt of Phosphates. Disilver salts (**2**) were prepared from the corresponding disodium salts and silver nitrate. In order to avoid the formation of silver oxide, a solution of the sodium salts was added slowly to a solution of excess silver nitrate with vigorous stirring. Disilver salts of *p*-nitrophenyl phosphate and adenosine 5′-phosphate precipitated from the reaction mixtures. In the cases of glucose-1-phosphate, galactose-1-phosphate, and riboflavin 5′-phosphate, the silver salts precipitated by addition of methanol.[9]

Synthesis of Unsymmetrical Pyrophosphates. Several unsymmetrical pyrophosphates (**3**) were obtained when 1 equiv. of bis-triethylammonium salt of phosphorothioate (**1**) was treated with 1.2 equiv. of disilver salt of phosphate (**2**) in dry pyridine at room temperature for five hours. The results are

summarized in Table 1. The pyrophosphates were characterized by ratio of nucleoside base to phosphate and by ultraviolet absorption.

No symmetrical pyrophosphate was detected when only 1.2 equiv. of **2** was used. Satisfactory yields are maintained even when insoluble disilver salts containing crystal water were used.

Experimental

Methods. Paper chromatography was performed by the descending technique using Toyo Roshi papers No. 51 and No. 51A. The solvent system used was isopropyl alcohol-conc. aqueous ammonia-water (7 : 1 : 2 v/v) (Solvent **A**). The R_f values of different compounds are listed in Table 1. Paper electrophoresis was carried out with an apparatus similar to that described by Markham and Smith.[10] The buffer solution used was 0.05 M phosphate (pH=8.0). Estimation of the yields of unsymmetrical pyrophosphates was most frequently carried out spectrophotometrically after elution of the spot from paper chromatograms run on Solvent A.

Thiophosphoryl chloride was prepared by the procedure of Knotz.[11] It was distilled (bp 125 °C) prior to use. *p*-Nitrophenyl phosphate was prepared as described previously.[12] Commercial disodium salt of glucose-1-phosphate, galactose-1-phosphate, adenosine 5′-phosphate, and riboflavin 5′-phosphate were used.

*Alkyl Thiophosphorodichloridate (**4**).* These compounds were prepared by procedures given in literature. Boiling points of ethyl,[13] *n*-propyl,[14] and *n*-butyl[15] derivatives were 71 °C (23 mmHg), 82—82 °C (22 mmHg) and 91—93 °C (19 mmHg), respectively. Isoamyl derivative 115—116 °C (23 mmHg), was prepared by a modification of the procedure of Martin *et al.*[15].

*Alkyl Phosphorothioates (**1**). General procedure.* To 150 ml of aqueous acetone (1 : 2 v/v) was added alkyl thiophosphorodichloridate (0.1 mmol) under cooling at 0 °C in the presence of triethylamine (0.4 mmol). The mixture was concentrated to dryness under reduced pressure. Evaporation was repeated three times until triethylammonium chloride precipitated from the pyridine solution. The precipitate was then filtered off and the filtrate was concentrated. Chromatogram of the residue developed by Solvent A gave a single spot of compound **1**. The residue was dissolved in dry pyridine and a standard solution of **1** was prepared. The content of **1** was determined by phosphate measurement. The standard solution can be kept in a refrigerator for several weeks.

Disilver Salt of Adenosine 5′-Phosphate. To an aqueous solution of silver nitrate (0.2 mmol) was added disodium salt of adenosine 5′-phosphate (0.1 mmol) with vigorous stirring. The precipitate which soon appeared was collected by centrifuging. It was washed with water and then with methanol and finally with ether. The silver salt was kept in a desiccator under protection from light.

Disilver Salt of p-*Nitrophenyl Phosphate.* This was prepared in a similar way to that for adenosine 5′-phosphate.

Disilver Salts of Glucose-1-Phosphate and Galactose-1-phosphate. Experiments were carried out as for adenosine 5′-phosphate. The silver salts precipitated by addition of methanol.

Disilver Salt of Riboflavin 5′-Phosphate. The reaction was carried out under the same conditions as in the case of adenosine 5′-phosphate. The reaction mixture was filtered and the filtrate was concentrated under reduced pressure until the precipitate appeared. After addition of methanol, red colored precipitate was collected and washed with methanol. The silver salt was dried over phosphorus pentoxide in a vacuum desiccator.

P^1-*Isoamyl* P^2-p-*Nitrophenyl Pyrophosphate.* To a suspension of disilver salt of *p*-nitrophenyl phosphate (508 mg, 1.2 mmol) in dry pyridine (20 ml) was added gradually a solution of bis-triethylammonium salt of isoamyl phosphorothioate (386 mg, 1.0 mmol) in dry pyridine (5 ml) with vigorous stirring. After 5 hr, the mixture was concentrated to dryness under reduced pressure at a temperature below 40 °C. The residue was shaken with four portions of a mixture of ethanol and concd. aqueous ammonia (2 : 1 v/v). The extracts were combined and concentrated. Water was then added and insoluble material was filtered off. The aqueous solution was neutralized by Dowex 50W-X8 (pyridinium form) and cyclohexylamine was added. The solution was concentrated to dryness. The residue was washed several times with chloroform and the extracts were combined and concentrated. Dicyclohexylammonium salt of P^1-isoamyl P^2-*p*-nitrophenyl pyrophosphate, separated by addition of dry ether and purified by reprecipitation, was obtained in an 83% yield based on isoamyl phosphorothioate. Mp 180—183 °C. Found: C, 48.06; H, 7.48; N, 7.95%. Calcd for $C_{23}H_{43}N_3P_2O_9$: C, 48.60; H, 7.57; N, 7.38%.

In a similar manner, P^1-ethyl P^2-*p*-nitrophenyl pyrophos-

phate, P^1-*n*-propyl P^2-*p*-nitrophenyl pyrophosphate and P^1-*n*-butyl P^2-*p*-nitrophenyl pyrophosphate were obtained. The data are given in Table 1.

Uridine Diphosphate Glucose. To a suspension of disilver salt of glucose-1-phosphate (monohydrate 59 mg, 0.12 mmol) in dry pyridine (0.5 ml) was added gradually a solution of bis-tri-*n*-butylammonium salt of 2′,3′-*O*-dibenzoyl uridine phosphorothioate (tetrahydrate 99 mg, 0.1 mmol) in dry pyridine (0.5 ml) with vigorous stirring. After 5 hr, the reaction mixture was filtered and the filtrate was passed through a column of Dowex 50W-X8 (pyridinium form). The eluate was treated with 0.2 M sodium hydroxide at room temperature for 30 min and then neutralized with Dowex 50W–X8 (pyridinium form). The solution was concentrated to a volume of 5 ml and applied to a column of Dowex 1–X8 (chloride form). Uridine 5′-phosphate was first eluted with 0.003 M hydrochloric acid in 0.01 M lithium chloride and then uridine diphosphate glucose with 0.003 M hydrochloric acid in 0.06 M lithium chloride. This was neutralized with lithium hydroxide and concentrated to a small volume. After addition of ethanol, dilithium salt of uridine diphosphate glucose was separated by addition of acetone. The precipitate was filtered and washed with acetone and then with dry ether. Uridine diphosphate glucose (dilithium salt) was obtained in 70% yield (43 mg). Found: C, 29.76; H, 4.93; N, 4.22%. Calcd for $C_{15}H_{22}N_2P_2Li_2O_{17}\cdot 2H_2O$: C, 29.31; H, 4.23; N, 4.57%. Determination of ratios of uridine, glucose, phosphorus gave 1.00 : 1.15 : 1.94; the calculated ratios 1 : 1 : 2.

Uridine Diphosphate Galactose. To a suspension of disilver salt of galactose-1-phosphate (monohydrate 59 mg, 0.12 mmol) in dry pyridine (0.5 ml) was added a solution of bis-triethylammonium salt of 2,′3,′-*O*-isopropylidene uridine 5′-phosphorothioate (48 mg, 0.10 mmol) in dry pyridine (0.5 ml) with vigorous stirring. After 5 hr, the reaction mixture was concentrated to dryness and the residue was treated with 10% sodium chloride (10 ml), hydrogen sulfide being passed into the solution. The precipitate was centrifuged and the supernatant liquid was concentrated to a small volume (*ca.* 5 ml). It was then treated with Dowex 50W-X8 (pyridinium form) and concentrated. The residue was dissolved in 80% acetic acid and heated at 100 °C for 10 min. After removal of acetic acid, the product showed the expected ultraviolet absorption characteristics ($\lambda_{max}^{H_2O}$ 262 mμ at pH=7), being homogeneous on paper electrophoresis (Mobility= 0.78 relative to uridine 5′-phosphate). The yield of uridine diphosphate galactose was 63% (630 $O.D._{262}$) based on 2′,3′-*O*-isopropylidene uridine 5′-phosphorothioate.

Flavin Adenine Dinucleotide. To a suspension of disilver salt of riboflavin 5′-phosphate (40 mg, 0.06 mmol) in dry pyridine (0.25 ml) was added slowly a solution of bis-triethylammonium salt of 2′,3′-*O*-isopropylidene adenosine phosphorothioate (tetrahydrate 25.2 mg, 0.05 mmol) in dry pyridine (0.25 ml) with vigorous stirring. After 27 hr, the mixture was concentrated under reduced pressure. The residue was treated with 10% sodium chloride (10 ml), hydrogen sulfide being then passed into the solution. The precipitate was centrifuged and the supernatant liquid was concentrated to a small volume (*ca.* 5 ml). This was treated with Dowex 50W-X8 (pyridinium form) and concentrated to dryness. The residue was dissolved in 80% acetic acid and heated at 100 °C for 10 min. This was concentrated and flavin adenine dinucleotide was obtained by electrophoretic separation. The yield was 51% based on 2′,3′-*O*-isopropylidene adenosine 5′-phosphorothioate.

$\lambda_{max}^{H_2O}$ 264, 375, 450 mμ. $\lambda_{260}/\lambda_{375}=4.00$; $\lambda_{375}/\lambda_{450}=0.95$; $\lambda_{260}/\lambda_{450}=3.80$ (at pH=7).

The authors heartily thank Professor Teruaki Mukaiyama for his encouragement and discussions throughout the investigation.

Reactions of *N*-Acylaminoacetamidine with 1,3-Bifunctional Compounds

Hiroaki UCHIDA, Hiroyuki IWASAWA, and Masaki OHTA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

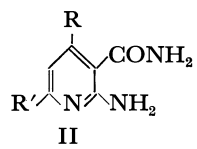
(Received May 4, 1973)

The reactions of *N*-benzoylaminoacetamidine(IIIa) and *N*-benzyloxycarbonylaminoacetamidine(IIIb) with various 1,3-bifunctional compounds were investigated. Both IIIa and IIIb were found to react with acetylacetone to produce 2-amino-3-benzoylamino-4,6-dimethylpyridine and 2-amino-3-benzyloxycarbonylamino-4,6-dimethylpyridine, respectively. On the other hand, IIIa reacted with ethyl acetoacetate or diketene to produce 2-(*N*-benzoylaminomethyl)-4-hydroxy-6-methylpyrimidine. Reaction of IIIb with malononitrile gave 1-amino-2-(*N*-benzyloxycarbonylaminoethylidene)malononitrile.

Amidines and 1,3-bifunctinal compounds react generally to form pyrimidines, and rarely to form another heterocyclic ring system. The reaction of malonamideamidine(I) with β-ethoxyacrolein diethylacetal or 1,3-dicarbonyl compounds has been reported[1,2] to produce 2-aminonicotinamide derivatives (II).

$H_2NCOCH_2C(=NH)NH_2$

I



II

Goldberg and Kelly[3] reported that the reaction product between *N*-benzoylaminoacetamidine(IIIa) and acetylacetone was 2-(*N*-benzoylaminomethyl)-4,6-dimethylpyrimidine(IVa) on the basis of elemental analysis only. We have followed their procedure to prepare IVa and obtained a product having an empirical formula $C_{14}H_{15}ON_3$ and the same melting point as described. However, the IR spectrum of the product

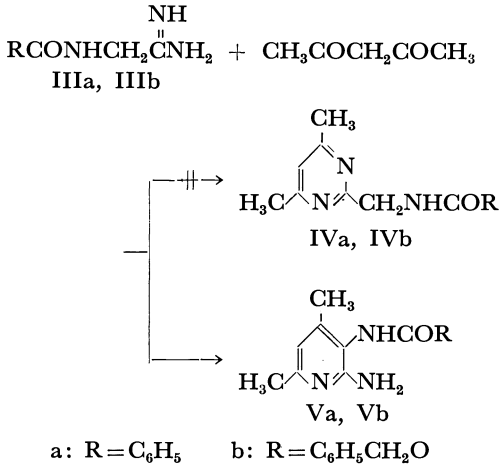
7	DMF	90	4	K_2CO_3	1 : 2	18

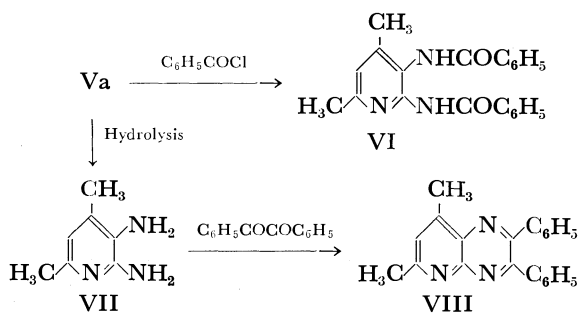
a) Used in the form of hydrochloride except in Reaction 5.
b) The same conditions as given in Ref. 3.
c) Ratio of free IIIa : alkali.

showed absorptions attributed to =NH, $-NH_2$, and an amide carbonyl group. Additional information was obtained from the NMR spectrum. There were singlet peaks at τ 0.50(1H) and τ 4.37(2H) which disappeared with the addition of deuterium oxide, and two at τ 7.73(3H) and τ 7.93(3H) due to unequivalent two methyl groups.

On the basis of spectral results it is reasonable to consider that the reaction proceeded, as in the case of formation of II from I, to form 2-amino-3-benzoylamino-4,6-dimethylpyridine(Va).



In order to collect chemical evidences on the assigned structure of Va, the following reactions were carried out. Treatment of Va with benzoyl chloride led to 2,3-dibenzoylamino-4,6-dimethylpyridine(VI). Hydrolysis of Va yielded 2,3-diamino-4,6-dimethylpyridine(VII) which condensed with benzil to produce 2,3-diphenyl-6,8-dimethylpyrido[2,3-*b*]-pyrazine(VIII). These properties can be explained satisfactorily only with Va and do not seem to occur with IVa.



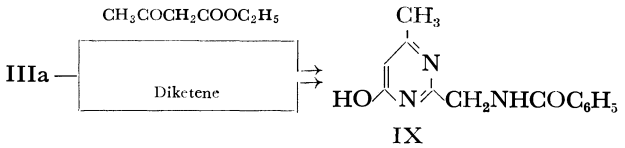
In order to learn whether the pyrimidine derivative (IVa) could be formed by the present reaction and for the purpose of improving the yield of Va, the reaction was carried out under various conditions (Table 1). All efforts to improve the yield of Va were unsuccessful. This can be attributed to the facile hydrolysis of free amidine(IIIa) in alkaline medium which competes with the formation of Va. In fact, a considerable amount of *N*-benzoylaminoacetamide was obtained as a by-product in each experiment. The reaction at room temperature, in benzene, or in acetic acid in the presence of sodium acetate gave no Va.

The reaction of *N*-benzyloxycarbonylaminoacetamidine(IIIb) with acetylacetone in ethanol in the presence of sodium ethoxide proceeded in a similar way affording 2-amino-3-benzyloxycarbonylamino-4,6-dimethylpyridine(Vb) in a poor yield. The assignment of structure Vb was based on its composition, IR and NMR spectra.

The reactivity of the methylene groups in IIIa and IIIb is considered to be much lower than that of the methylene group in I. It is notable that the methylene group in III participated in the ring formation.

Next, the reaction of IIIa with ethyl acetoacetate in the presence of sodium hydroxide was studied. The product, having an empirical formula $C_{13}H_{13}O_2N_3$, is soluble in aqueous sodium hydroxide and devoid of primary amino absorption in the IR spectrum. The doublet centered at τ 5.65 (2H, J=2.8 Hz) in the NMR spectrum assigned to methylene protons changed to a singlet, the triplet at τ 1.10(1H, J=2.8 Hz) disappearing with the addition of deuterium oxide. This indicates that the methylene protons are coupled with the =NH of the neighboring amide group. Elemental and spectrometric analyses identified the product as 2-(*N*-benzoylaminomethyl)-4-hydroxy-6-methylpyrimidine (IX).

As an alternative synthesis of IX, diketene was made to react with IIIa in ethanol at 0 °C. The product was identical with that previously prepared.



The reaction of IIIa with other 1,3-bifunctional compounds was also studied. The following reagents were used as 1,3-bifunctional compounds, *i.e.*, benzoylacetone, dibenzoylmethane, ethyl dimethylmalonate, methyl acrylate, and acetylacetaldehyde dimethylacetal. The reactions were carried out in ethanol at 45 °C for 2 days or under reflux for 4 hours in the presence of potassium carbonate or sodium ethoxide. All trials to isolate the expected product were unsuccessful.

Amidine IIIa is known to react with malononitrile and ethyl cyanoacetate to yield 1-amino-2-(*N*-benzoylaminoethylidene)malononitrile and ethyl 1-amino-2-(*N*-benzoylaminoethylidene)cyanoacetate, respectively.[3] A similar condensation of ethyl cyanoacetate with formamidine or benzamidine in the absence of alkali was reported.[4] We have now found that the reaction of IIIb with malononitrile proceeds analogously, 1-amino-2-(*N*-benzyloxycarbonylaminoethylidene)malononitrile(X) being obtained.

$$\text{IIIb} + CH_2(CN)_2 \rightarrow C_6H_5CH_2OCONHCH_2C{=}C(CN)_2 \quad (\text{X: } NH_2)$$

Experimental

All melting points were uncorrected. The NMR spectra were recorded at 60 MHz using tetramethylsilane as an internal standard.

2-Amino-3-benzoylamino-4,6-dimethylpyridine(Va). To a solution of 9 g (90 mmol) of acetylacetone in 75 ml of ethanol was added 15 g (70 mmol) of IIIa hydrochloride[3] and 10 g (72 mmol) of potassium carbonate, and refluxed for 4 hr with stirring. The reaction mixture was concentrated and the residue was dissolved in 70 ml of 10% hydrochloric acid. Insoluble *N*-benzoylaminoacetamide [mp 183 °C (lit,[3] 186 °C), 5 g (40%)] was removed by filtration, the filtrate being made alkaline with 10% aqueous sodium hydroxide. Precipitates were collected and recrystallized from methanol to give colorless needles of Va, mp 197—198 °C, 3.9 g (23%).

Found: C, 69.57; H, 6.51; N, 17.71%. Calcd for $C_{14}H_{15}ON_3$: C, 69.69; H, 6.27; N, 17.42%. IR(KBr) cm^{-1}: 3425, 3300, 3180, 1635, 1530. NMR ($CDCl_3$)τ: 0.50 (s, 1H), 1.80—2.67 (m, 5H), 3.55 (s, 1H), 4.37 (s, 2H), 7.73 (s, 3H), 7.93 (s, 3H).

2,3-Dibenzoylamino-4,6-dimethylpyridine(VI). To a solution of 1.2 g (5 mmol) of Va in 20 ml of 10% hydrochloric acid was added 0.7 g (5 mmol) of benzoyl chloride under ice cooling. Aqueous sodium hydroxide (10%) was added dropwise until the solution became alkaline. The precipitates were collected and recrystallized from dimethylformamide to give white powder of VI, mp 223—225 °C, 1.1 g (64%).

Found: C, 73.01; H, 5.61; N, 12.27%. Calcd for $C_{21}H_{19}O_2N_3$: C, 73.03; H, 5.54; N, 12.17%. IR(KBr) cm^{-1}: 3215, 1653, 1532. NMR (DMSO-d_6)τ: 1.77—2.63 (m, 10H), 2.90 (s, 1H), 5.87 (s, 2H) 7.54 (s, 3H), 7.71 (s, 3H).

2,3-Diamino-4,6-dimethylpyridine(VII). A solution of 2 g (8.3 mmol) of Va in 30 ml of 10% hydrochloric acid was heated under reflux for 6 hr. On cooling, benzoic acid which separated out was removed by filtration. The filtrate was treated with charcoal, concentrated to *ca.* 10 ml, and then made strongly alkaline with 10% aqueous sodium hydroxide to give crystalline substance. Recrystallization from water afforded colorless needles of VII, mp 156—158 °C, 0.9 g (79%).

Found: C, 61.59; H, 7.99; N, 30.32%. Calcd for $C_7H_{11}N_3$: C, 61.29; H, 8.08; N, 30.63%. IR(KBr) cm^{-1}: 3380, 3320. NMR (DMSO-d_6)τ: 3.81 (s, 1H), 4.74 (s, 2H), 5.86 (s, 2H), 7.88 (s, 3H), 8.00 (s, 3H).

2,3-Diphenyl-6,8-dimethylpyrido[2,3-b]pyrazine(VIII). A mixture of 0.69 g (5 mmol) of VII and 1.05 g (5 mmol) of benzil was heated for 30 min, the temperature being maintained at 120 °C. The reactants melted first and solidified again. Recrystallization from a mixture of ethanol and benzene gave colorless prisms of VIII, mp 189—190 °C, 1.4 g (89%). Found: C, 81.19; H, 5.56; N, 13.27%. Calcd for $C_{21}H_{17}N_3$: C, 81.00; H, 5.50; N, 13.50%. IR (KBr) cm^{-1}: 3030, 1590, 770, 700. NMR($CDCl_3$)τ: 2.23—2.87 (m, 10H and 1H of CH), 7.20 (s, 6H).

2-(N-Benzoylaminomethyl)-4-hydroxy-6-methylpyrimidine(IX). An ethanol solution of sodium ethoxide prepared from 0.7 g (30 mmol) of sodium and 30 ml of ethanol was added to a solution of 6.4 g (30 mmol) of IIIa hydrochloride in 20 ml of ethanol under ice cooling and the precipitated sodium chloride was removed by filtration. To the filtrate was added 3.9 g (30 mmol) of ethyl acetoacetate. This was transferred to an evaporating dish and evaporated to dryness in a desiccator over sulfuric acid. The residue was added to a mixture of 10 ml of 20% aqueous sodium hydroxide and 30 ml of ethanol, and stirring was continued at room temperature for 2 days. The reaction mixture was concentrated *in vacuo* and 20 ml of water was added. The water-insoluble substance was removed by filtration, and filtrate was neutralized with 5% hydrochloric acid to afford the precipitate. Recrystallization from dimethylformamide gave colorless needles of IX, mp 241—242 °C, 2.1 g (29%).

Found: C, 63.89; H, 5.26; N, 17.08%. Calcd for $C_{13}H_{13}O_2N_3$: C, 64.19; H, 5.38; N, 17.29%. IR(KBr) cm^{-1}: 3300, 1633. NMR (DMSO-d_6)τ: 1.10 (t, 1H), 2.1—2.5 (m, 5H), 3.93 (s, 1H), 5.65 (d, 2H), 6.67 (s, 1H), 7.87 (s, 3H).

Reaction of IIIa with diketene. A solution of IIIa (30 mmol) in ethanol was prepared by the same procedure as in the preceding experiment. To this was added dropwise 2.6 g (30 mmol) of diketene at 0 °C. Crystals began to separate out after 30 min. The reaction mixture was stirred at room temperature for 1 day. Precipitates were collected and recrystallized from dimethylformamide to give 2.2 g (32%) of IX, mp 241—242 °C. Found: C, 63.96; H, 5.30; N, 17.44%. Spectral data were identical with those obtained in the preceding experiment.

N-Benzyloxycarbonylaminoacetamidine(IIIb) hydrochloride. To a solution of ammonia in ethanol (50 ml, 15% by wt) was added 10 g (37 mmol) of ethyl imino(*N*-benzyloxycarbonylamino)acetate hydrochloride[5] and stirred for 1 hr. The resulting solution, after being allowed to stand at room temperature for 2 days, was concentrated in a desiccator over sulfuric acid. Recrystallization of the residue from acetonitrile gave colorless plates of IIIb hydrochloride, mp 112—113 °C (lit,[5] 78 °C), 5.5 g (62%). Found: C, 48.93; H, 5.52; N, 17.48%. Calcd for $C_{10}H_{14}O_2N_3Cl$: C, 49.39; H. 5.79; N, 17.24%. IR(KBr) cm^{-1}: 3500—2700, 1690, 1525. NMR(DMSO-d_6)τ: 0.87 (b.s, 4H), 2.17 (b.s, 1H), 2.63 (s, 5H), 4.90 (s, 2H), 5.92 (d, 2H).

Reaction of IIIb with acetylacetone. To an ethanol solution of sodium ethoxide prepared from 0.76 g (33 mmol) of

sodium and 30 ml of ethanol was added a solution of 6.8 g (28 mmol) of IIIb hydrochloride in 30 ml of ethanol under ice cooling. After removing sodium chloride 3.6 g (36 mmol) of acetylacetone was added and refluxed for 4 hr and then concentrated. To the residue was added 50 ml of chloroform. The crystal, insoluble in chloroform, was collected and recrystallized from ethanol to give colorless needles of *N*-benzyloxycarbonylaminoacetamide, mp 133—134 °C, 2.4 g (41%).

Found: C, 57.40; H, 6.05; N, 13.70%. Calcd for $C_{10}H_{12}O_3N_2$: C, 57.68; H, 5.81; N, 13.45%. IR(KBr) cm^{-1}: 3380, 3315, 3180, 1690, 1655, 1535.

The chloroform solution was concentrated and the residue was subjected to column chromatography on alumina and eluted with ethyl acetate to afford Vb. Recrystallization from a mixture of benzene and ligroin gave colorless needles, mp 162—163 °C, 1.0 g (13%). Found: C, 66.51; H, 6.19; N, 15.41%. Calcd for $C_{15}H_{17}O_2N_3$: C, 66.40; H, 6.31; N, 15.49%. IR(KBr) cm^{-1}: 3450, 3300, 3180, 1700, 1617, 1602. NMR($CDCl_3$)τ: 2.71 (s, 5H), 3.13 (b.s, 1H; exchanged with D_2O), 3.67 (s, 1H), 4.87 (s, 2H), 5.27 (s, 2H; exchanged with D_2O), 7.79 (s, 3H), 7.99 (s, 3H).

*1-Amino-2-(*N*-benzyloxycarbonylaminoethylidene)malononitrile(X).* A solution of IIIb (10 mmol) in 20 ml of ethanol containing sodium ethoxide (2 mmol) was prepared by a similar procedure to that in the preceding experiment. To this solution was added 0.66 g (10 mmol) of malononitrile and refluxed for 30 min. After cooling to room temperature, crystals which separated out were recrystallized from ethanol to give colorless needles of X, mp 169—170 °C, 1.5 g (62%). Found: C, 60.68; H, 4.46; N, 22.13%. Calcd for $C_{13}H_{12}O_2N_4$: C, 60.93; H, 4.72; N, 21.86%. IR(KBr) cm^{-1}: 3400, 3350, 2220, 2190, 1715, 1650, 1548. NMR (DMSO-d_6)τ: 1.33 (b.s, 1H), 1.57 (b.s, 1H), 2.61 (b.s, 1H), 2.63 (s, 5H), 4.93 (s, 2H), 5.98 (d, 2H).

(Received May 14, 1973)

N^{i}-Formyltryptophan has proved to be more resistant than tryptophan against oxidation mediated by hydrogen chloride in acetic acid. N^{α}-*t*-Butyloxycarbonyl-N^{i}-formyltryptophan has been synthesized *via* nonaqueous *acylation* reaction and used for the solid-phase synthesis of tryptophan-containing peptides, in combination with hydrogen chloride in formic acid as the reagent for cleavage of the *t*-butyloxycarbonyl group. The validity of the method has been demonstrated, on the basis of several criteria, in the synthesis of the tryptophan-containing octapeptide, Lys-Gly-Val-Leu-Ala-Gly-Trp-Leu.

In solid-phase synthesis of tryptophan-containing peptide, repeated deprotection of the Boc[2] group with hydrogen chloride in acetic acid brings about more or less oxidative destruction of tryptophan even in the presence of 2-mercaptoethanol as a scavenger.[3] Because of such well-known acid lability of tryptophan, it has been of special value to develop a new reagent for cleavage of the Boc group which would not produce the undesirable oxidation and to find out an acid-stable tryptophan derivative suitable for peptide synthesis. Hydrogen chloride in formic acid has recently been introduced as a reagent for cleavage of the Boc group in the solid-phase synthesis of the tryptophan-containing heptapeptide. Its effectiveness has been demonstrated on the basis of relevant chemical and physical properties of the resulting heptapeptide and its derivatives.[3] The merit of the reagent is ascribed to its greater ability to prevent oxidation of tryptophan owing to the reductive nature of formic acid.

Tryptophan undergoes formylation at its indole nitrogen in hydrogen chloride–formic acid as described by Previero *et al.*[4] and in our previous reports.[3] This formyl group is removed easily in a weakly alkaline medium or by dissolving formylated derivatives in dimethylformamide containing hydrazine hydrate without any serious influence on other amino acids.[3] It seemed of interest to examine whether N^{i}-formyltryptophan is more resistant than tryptophan against oxidation mediated by acids, since it would satisfy the prerequisite that the group introduced for stabilization of indole nucleus should be removed under mild conditions without affecting other residues. Thus, the acid-stability of N^{i}-formyltryptophan was tested using 1 M hydrogen chloride in acetic acid and compared with tryptophan as a reference.

Changes of N^{i}-formyltryptophan[3] and tryptophan in 1 M hydrogen chloride in acetic acid were followed

1) A part of this paper was presented at the 10th Symposium on Peptide Chemistry, Sapporo, September 26 and 27, 1972.

2) All amino acids in this report are of the L-configuration. Abbreviations used are: Boc, *t*-butyloxycarbonyl; Z, benzyloxycarbonyl; Trp, trytophan; Trp(CHO), N^{i}-formyltryptophan; NCPS–Cl, 2-nitro-4-carboxyphenylsulfenyl chloride; Trp(NCPS), 2-thio-(2-nitro-4-carboxyphenyl)-tryptophan; βME, 2-mercaptoethanol; HCl, hydrogen chloride; AcOH, acetic acid; Et_3N, triethylamine; DMF, dimethylformamide; EtOH, ethanol; HF, anhydrous hydrofluoric acid.

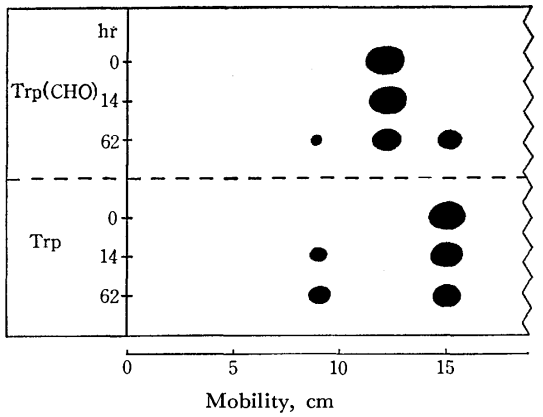

Fig. 1. Electrophoreograms of the solutions of N^{i}-formyltryptophan and tryptophan in 1 M hydrogen chloride in aceuc acid after 14 and 62 hr of standing. Fresh solutions of these amino acids in 0.1 M hydrochloric acid were used as references. The spots were developed with ninhydrin. The substance at 9 cm from the original line was Ehrlich-negative and is noted as "unidentified substance" in the text.

by paper electrophoresis and UV absorption spectra at appropriate time intervals. In Fig. 1 are shown electrophoreograms for the two solutions after 14 and 62 hr of standing. After 14 hr, an Ehrlich-negative, less mobile unidentified substance was detected for the test solution of tryptophan in an appreciable amount. On the other hand, N^{i}-formyltryptophan remained unchanged. After 62 hr of standing, however, about one-half of N^{i}-formyltryptophan had been deformylated to produce tryptophan and the unidentified substance was also present although in a very small quantity. At that time the amount of the unidentified substance in the test solution of tryptophan had increased markedly. These phenomena indicate that N^{i}-formyltryptophan in 1 M hydrogen chloride in acetic acid is first deformylated and tryptophan thus formed is successively oxidized to produce the unidentified substance. It should be noted that there was a long time lag for the conversion of N^{i}-formyltryptophan into tryptophan. It is concluded that N^{i}-formyltryptophan is more resistant than tryptophan against oxidation mediated by the acid at least within a limited period. Thus, use of N^{i}-formyltryptophan has been undertaken for the solid-phase synthesis of tryptophan peptide.

t-Butyloxycarbonylation of α-amino group of N^{i}-formyltryptophan with Boc-chloride[5] or Boc-azide[6] in an aqueous alkaline medium (pH 9.0) was unsuccessfull because of alkali lability and insolubility at a near-neutral pH of N^{i}-formyltryptophan. *Acylation,* therefore, was carried out in nonaqueous, triethylamine-buffered dimethylformamide. The method gave an yield as high as 89% for N^{α}-Boc-N^{i}-formyltryptophan. This type of nonaqueous *t*-butyloxycarbonylation might be widely applicable for hydrophobic amino acid with suitable solubility in dimethylformamide.

This paper describes the use of N^{α}-Boc-N^{i}-formyltryptophan and hydrogen chloride in formic acid for the Merrifield type solid-phase synthesis of tryptophan peptide. The method has been compared with two other methods: one making use of Boc-tryptophan and hydrogen chloride in formic acid, and the other Boc-tryptophan and hydrogen chloride in acetic acid containing βME. The latter method is usually applied to the solid-phase synthesis of tryptophan peptide.[7] Arbitrarily sequenced octapeptide consisting of amino acids which do not absorb near-ultraviolet light except for tryptophan, Lys–Gly–Val–Leu–Ala–Gly–Trp–Leu, was selected as a model peptide to test the methods.

The three octapeptides were built up as usual, in parallel, starting from Boc-leucyl resin and using either a 6—7 fold molar excess of hydrogen chloride (0.4 M) in formic acid or a 15-fold molar excess of hydrogen chloride (1 M) in acetic acid containing 2% βME. ε-Amino group of lysine was protected with the Z group. At every neutralization step, chlorides were determined on the combined dimethylformamide washings. As seen in Fig. 2, levels of chloride titrated for hydrogen chloride–formic acid systems were 83—84% of that for hydrogen chloride–acetic acid system. Such phenomena have always been observed in all other comparable experiments although the reason has not yet been clarified.

The larger halves of the three protected octapeptide resins [**1a** (*via* Boc–Trp(CHO)—HCl–HCOOH), **1b** (*via* Boc–Trp—HCl–HCOOH), and **1c** (*via* Boc–Trp—HCl–AcOH–βME)] were cleaved by hydrazine hydrate in dimethylformamide.[3,8] In order to remove non-peptide substances derived from the resin, the three products for Boc–Lys(Z)–Gly–Val–Leu–Ala–Gly–Trp*–Leu–$NHNH_2$[9] [**2a** (*via* Boc–Trp(CHO)—HCl–HC-

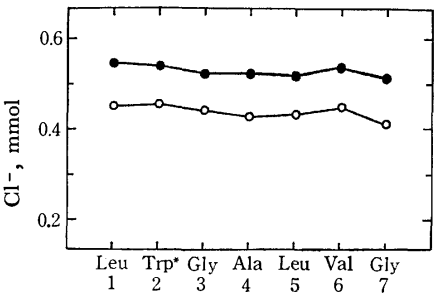

Fig. 2. Millimoles of chlorides determined at neutralization steps in the solid-phase syntheses using HCl–HCOOH (-○-) and HCl–AcOH (-●-). Values presented are those for 1.00 g each of Boc-leucyl resin used. Two runs using HCl–HCOOH gave the same titration values. Details are described in the ' Experimental" section.

9) Asterisk signifies that Trp may or may not denote pure tryptophan. In some cases the denotation is extended to derivatives.

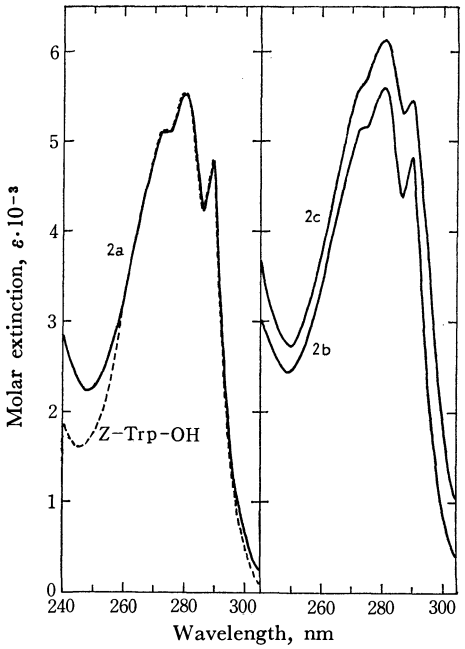

Fig. 3. Ultraviolet absorption spectra of the protected octapeptide hydrazides, **2a**, **2b**, and **2c**, and Z–Trp in methanol.

OOH), **2b** (*via* Boc–Trp—HCl–HCOOH), and **2c** (*via* Boc–Trp—HCl–AcOH–βME)] were reprecipitated (see Experimental). Yields were in parallel with levels of chloride titrated in the neutralization steps. The UV absorption spectra of **2a** and **2b** were virtually identical with that of Z-tryptophan except that a trough in the 240—250 nm region showed somewhat greater absorption and was shifted to the red by 2—3 nm (Fig. 3). Such phenomena suggest that **2a** and **2b** are contaminated to only a minor extent by oxidized species, but it seems likely that an increase of absorption in the 240—250 nm region owes to some extent to the additional peptide absorption as discussed by Beaven and Holiday.[10] On the other hand, extinction of **2c** at 280 nm, for example, was about 20% greater than those of **2a** and **2b**, reflecting oxidative destruction of indole chromophore to a considerable extent.

Small portions of **1a**, **1b**, and **1c** were cleaved with anhydrous hydrofluoric acid in the presence of anisole,[11] to produce **3a**, **3b**, and **4c**, respectively. The formyl group is still attached more or less to tryptophan residues of **3a** and **3b** since it is resistant to anhydrous hydrofluoric acid as well as anhydrous triethylamine in dimethylformamide in the neutralization step. Hydrogen chloride–acetic acid never acetylates tryptophan. **3a** and **3b** were chromatographed on a Sephadex G–25 column (Fig. 4): the peptides recovered from the major peaks are denoted by **3a**† and **3b**†, respectively. **3a**† gave a spectrum typical of N^i-formyltryptophan,[12] indicating that a N^i-formyltryptophan residue is kept intact. The spectrum of **3b**† showed that about one-half of tryptophan involved is formylated. **3a** and **3b** were then treated with 0.1 M aqueous triethylamine for removing the formyl group to produce completely deprotected peptides, **4a** and **4b**.

Figure 5 shows gel-chromatographic patterns of **4a**, **4b**, and **4c** on a Sephadex G–25 column: the peptides from the major peaks for **4a** and **4b** are denoted by **4a**† and **4b**†, respectively. In contrast to **4a** and **4b**, **4c** gave a complex profile owing to its heterogeneity. The peptide from peak II (denoted by **4c**-II) exhibited

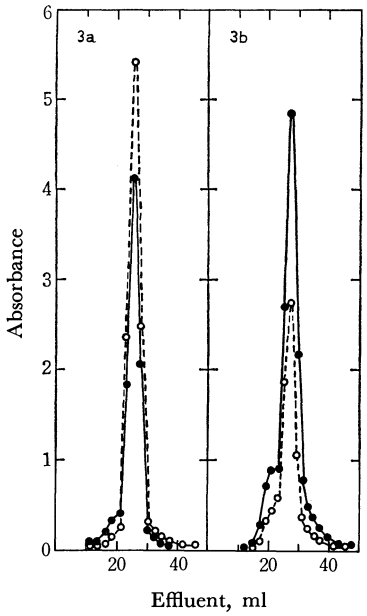

Fig. 4. Chromatographies on a Sephadex G–25 column (0.9×61 cm) of the octapeptides, **3a** and **3b** (7 mg each), which were obtained by cleavages of the peptide resins, **1a** and **1b**, with HF. Elutions were conducted with 5% AcOH and monitored by absorptions at 280 (-●-) and 300 (···○···) nm.

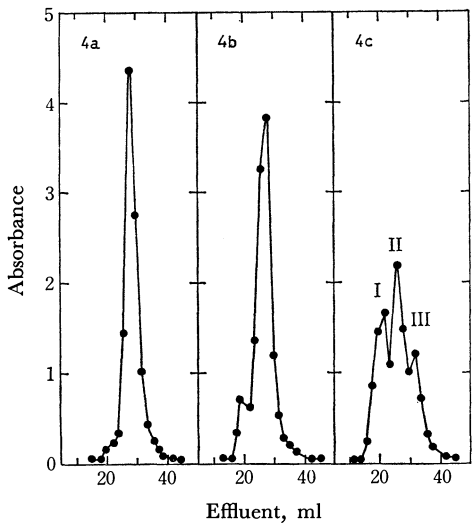

Fig. 5. Chromatographies on a Sephadex G–25 column (0.9×61 cm) of the completely deblocked peptides, **4a**, **4b**, and **4c** (5 mg each). Elutions were conducted with 5% AcOH and monitored by absorption at 280 nm.

11) S. Sakakibara, Y. Shimonishi, Y. Kishida, M. Okuda, and H. Sugihara, This Bulletin, **40**, 2164 (1967); J. Lenard and A. B. Robinson, *J. Amer. Chem. Soc.*, **89**, 181 (1967).

12) Spectra of N^i-formyltryptophans have been presented in a previous paper.[3]

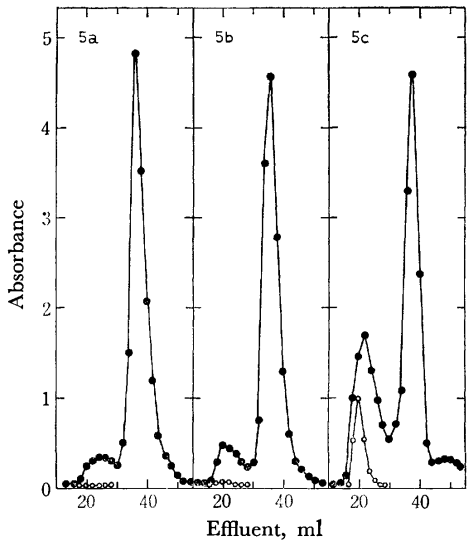

Fig. 6. Chromatographies on a Sephadex G-25 column (0.9×61 cm) of the peptides, **5a**, **5b**, and **5c**, which were obtained by reactions of **4a**, **4b**, and **4c** (7 mg each) with NCPS-Cl. Elutions were conducted with 5% AcOH and monitored by absorptions at 280 (-●-) and 585 (-○-) nm.

a similar spectrum to that given by **4a**† and **4b**† but was contaminated by a minor component of less mobility on paper electrophoresis. **4c**-I and **4c**-III consisted of peptides involving oxidized tryptophan. For further inspection of purity, **4a**, **4b**, and **4c** were treated with NCPS-Cl[13,14] as described[3] and the modified peptides (denoted by **5a**, **5b**, and **5c**, respectively) were examined chromatographically and spectrally. During the modification, the reaction mixture for **4c** became dark blue, giving an absorption maximum at 585 nm. The mixture for **4b** was yellow slightly tinged with blue but that for **4a** was yellow. If only intact tryptophan is involved, the reaction mixture should be yellow. It is extremely likely that oxidized tryptophans form blue substances upon reaction with NCPS-Cl. Chromatography of the modified peptides was carried out on the same column as for the unmodified ones, elutions being monitored by absorptions at 280 and 585 nm (Fig. 6). The peptides from the major peaks for **5a** and **5b**, denoted by **5a**† and **5b**†, were pure yellow and showed an increased adsorptivity on the gel compared with **4a**† and **4b**† (Figs. 5 and 6).[15] Such shifts suggest that **4a**† and **4b**† involve only pure tryptophan peptide. This was confirmed by the fact that **5a**† and **5b**† exhibited the same spectra as 2-thio-(2-nitro-4-carboxyphenyl)-tryptophan[14] (Table 1) and gave a single band by paper chromatography. Although **5c** gave a major peak at almost the same elution volume as for **5a**† and **5b**†, the peptide from the major peak for **5c**, denoted by **5c**†, was brownish yellow and

a) (s), shoulder.

contaminated by two additional minor impurities. The spectrum of **5c**† was rather different from that of 2-thio-(2-nitro-4-carboxyphenyl)-tryptophan.

Octapeptide samples were hydrolyzed in the presence of 3% thioglycolic acid[16] and the contents of tryptophan were analyzed on amino acid analyzer. Yields of tryptophan from the protected peptide hydrazides **2a**, **2b**, and **2c** were distinctly lower than those of the corresponding unprotected peptides, *e.g.*, **3a**, **3b**, and **4c**. The peptides **2c** and **4c** synthesized by use of HCl-AcOH-βME gave about 20—30% lower yields of tryptophan compared with the peptides prepared by use of HCl-HCOOH. Yield of tryptophan for **3b** was lower to some degree than that for **3a**, indicating that **3b** involves somewhat more oxidized peptide. As seen in the elution diagrams for **3a** and **3b** as well as **4a** and **4b** (Figs. 4 and 5), the oxidized peptides were eluted in part of shoulder prior to the major peak and shoulders for **3a** and **4a** were smaller than those for **3b** and **4b**, respectively. Considering these observations together with differences in physical properties between **2a** and **2b**, the peptides *via* Boc-Trp(CHO)—HCl-HCOOH are superior in quality to those *via* Boc-Trp—HCl-HCOOH. However, when both the crude unprotected peptides were purified on a Sephadex G-25 column, the resulting purified ones showed the same behaviors in terms of electrophoresis, chromatography, and chemical modification by NCPS-Cl and gave the same yields for tryptophan on amino acid analysis. The results demonstrate usefulness of hydrogen chloride in formic acid for the solid-phase synthesis of tryptophan peptide, and show pre-introduction of the formyl group to indole nucleus to be so effective as regards the protection of tryptophan from oxidation under solid-phase synthesis conditions. N^{α}-Boc-N^{i}-Formyltryptophan will be a useful derivative for synthesis of longer, complex tryptophan-containing peptides which may resist purification.

Experimental

General experimental and analytical procedures used were those described in the previous paper.[3] Thin-layer chromatography was performed using methanol-ethyl acetate (3 : 1 v/v) (solvent 1) and paper chromatography *n*-butanol-acetic acid-water (4 : 1 : 5 v/v, upper layer) (solvent 2). Paper electrophoresis was carried out under the following conditions: paper, Whatman 3 MM (57 cm length); solvent, 0.24 M formic acid (pH 2.08); voltage gradient, 48 V/cm; period, 90 min. All peptides in the present experiments moved towards the cathode. Amino acids and peptides were detected by a spray of ninhydrin (0.2% solution in 80%

16) H. Matsubara and R. H. Sasaki, *Biochem. Biophys. Res. Commun.*, **35**, 175 (1969).

ethanol). Modified Ehrlich reagent (0.5% solution of *p*-dimethylaminocinnamaldehyde in 0.5 M hydrochloric acid) was also used for the detection of tryptophan and its peptides. For amino acid analysis, peptides were hydrolyzed with constant boiling hydrochloric acid containing 3% thioglycolic acid in an evacuated, sealed tube at 110 °C for 24 hr. Formic acid (analytical grade, 98—100%, Merck) was used without purification. Acetic acid was refluxed over potassium permanganate, dehydrated with boron triacetate and distilled.[17] Concentration of hydrogen chloride in formic acid or acetic acid was determined by the modified Volhard method.[18]

Stability Test of N^{i}*-Formyltryptophan and Tryptophan in 1 M Hydrogen Chloride in Acetic Acid.* Trp(CHO)·HCl[3] and tryptophan (40 mg each) were respectively dissolved in 5 ml of 1 M HCl in AcOH and the solutions were allowed to stand at room temperature. After 14 and 62 hr of standing, aliquots of the solutions were subjected to paper electrophoresis, and 0.5 ml portions were taken and dried by lyophilization. The residues were dissolved in water and UV spectra were taken. After 14 hr no spectral change was observed for the test solution of tryptophan, when compared with untreated tryptophan, except for somewhat greater absorption in the 240—250 nm region, but an Ehrlich-negative, less mobile unidentified substance was detected in an appreciable amount on paper electrophoresis. On the other hand, Trp(CHO) was unchanged on paper electrophoresis although the test solution became tinged with yellow and the fine structure of the spectrum in the 280—290 nm region was only slightly disturbed. After 62 hr of standing, however, about one-half of Trp (CHO) had been deformylated to produce tryptophan and the unidentified substance was also present although in a minute quantity. Amount of the unidentified substance in the test solution for tryptophan had increased markedly but the spectrum was virtually the same as before.

N^{α}*-Boc-*N^{i}*-Formyltryptophan.* To a solution of 2.68 g (10 mmol) of Trp(CHO)·HCl in 60 ml of DMF was added 4.2 ml (30 mmol) of Et_3N followed by 3.0 ml of Boc-azide. The mixture was stirred at room temperature for 2 days. Gelatinous stuff appeared at the beginning but gradually dissolved with the progress of reaction except for Et_3N·HCl. The mixture was poured into 300 ml of 0.5 M citric acid and an oil deposited was extracted with 150 ml of ethyl acetate. The ethyl acetate layer was washed four times with water, dried over anhydrous sodium sulfate and evaporated below 40 °C nearly to dryness. The syrup was crystallized by adding petroleum ether and by scratching. Crystals were filtered and washed with petroleum ether, 2.98 g (89%); mp 102—104 °C; $[\alpha]_D^{21}$ +22.3° (*c* 1.61, EtOH); λ_{max} (EtOH) 242 (log ε 4.23), 293 (log ε 3.67), 301 nm (log ε 3.67).

Found: C, 61.24; H, 6.26; N, 8.35. Calcd for $C_{17}H_{20}O_5N_2$: C, 61.43; H, 6.07; N, 8.43%.

Boc-Leucyl Resin. Chloromethylated copolystylene-divinylbenzene (2%) resin (1.3 mmol Cl/g) obtained from the Protein Research Foundation, Osaka, was esterified with Boc-Leu.[3] Amino acid analysis indicated the leucine content to be 0.56 mmol/g.

Boc-Lys(Z)-Gly-Val-Leu-Ala-Gly-Trp-Leu-resins (**1a**, **1b**, and **1c**).* Boc-Leucyl resin (1.00 g each) was placed in three reaction vessels of the type described by Merrifield for repeated deblocking, rinsing and coupling procedures. The procedures used for the stepwise addition of the appropriate Boc-amino acids were almost the same as described[3] except that either a 6—7 fold molar excess of HCl (0.4 M) in HCOOH (8 ml) or a 15-fold molar excess of HCl (1 M) in AcOH (8 ml) was used for the cleavage of the Boc group. About 8—9 ml portions of the appropriate solvents were used for rinsing and coupling procedures. βME (2% by volume) was added to HCl-AcOH and also to the AcOH washes after deprotection. The Boc group on valine amino group was not completely cleaved by 30 min shaking in 0.4 M HCl in formic acid. The acid treatment was repeated twice for all runs. Yields: **1a**, 1.42; **1b**, 1.44; and **1c**, 1.48 g.

At every neutralization step, Et_3N-DMF for neutralization and DMF washings were pooled, chlorides being determined by the modified Volhard method (Fig. 2).

Boc-Lys(Z)-Gly-Val-Leu-Ala-Gly-Trp-Leu-*$NHNH_2$ *(**2a**, **2b**, and **2c**).* To suspensions of **1a**, **1b**, and **1c** (0.80 g each) in 3 ml of DMF was added 1.0 ml each of 100% hydrazine hydrate and the mixtures were shaken for 3 days at room temperature. The DMF solutions were separated by filtration and the resins were rinsed several times with DMF. The combined filtrates were evaporated *in vacuo* nearly to dryness. The hydrazides quickly solidified upon addition of water and were filtered and washed with water. The crystalline products were dissolved in hot methanol and insoluble materials were filtered off. The filtrates were evaporated *in vacuo* nearly to dryness and the residues were dissolved in a small volume of DMF. To these solutions were added larger volumes of water and the crystalline precipitates were filtered: **2a**, 159 mg (76% of **2c**), mp 235—236 °C, $[\alpha]_D^{21}$ −28.7° (*c* 0.223, DMF), R_f(1) 0.90; **2b**, 169 mg (81% of **2c**), mp 233—234 °C, $[\alpha]_D^{21}$ −27.7° (*c* 0.235, DMF), R_f(1) 0.89; and **2c**, 209 mg, mp 217—219 °C, $[\alpha]_D^{21}$ −25.7° (*c* 0.296. DMF), R_f(1) 0.89.[19] UV Spectra were taken in the methanolic solutions (Fig. 3), A_{281}/A_{248}[20] for **2a**, 2.42; A_{281}/A_{249} for **2b**, 2.24; and A_{282}/A_{250} for **2c**, 2.09. Amino acid analysis data are presented as 1.00 for lysine. **2a**: Lys 1.00, Trp 0.75, Gly 1.92, Ala 0.95, Val 0.97, Leu 1.92. **2b**: Lys 1.00, Trp 0.72, Gly 1.99, Ala 0.98, Val 0.94, Leu 1.91. **2c**: Lys 1.00, Trp 0.45, Gly 2.12, Ala 1.05, Val 1.08, Leu 1.95.

Found **2a**: C, 58.39; H, 7.65; N, 15.13. **2b**: C, 58.63; H, 7.76; N, 15.15. **2c**: C, 58.12; H, 7.63; N, 14.96. Calcd for $C_{54}H_{82}N_{12}O_{12}\cdot H_2O$: C, 58.46; H, 7.63; N, 15.15%.

Lys-Gly-Val-Leu-Ala-Gly-Trp(CHO)-Leu (**3a** and **3b**) and Lys-Gly-Val-Leu-Ala-Gly-Trp*-Leu (**4a**, **4b**, and **4c**).* **1a**, **1b**, and **1c** (0.140 g each) were respectively treated with 3—4 ml of HF for 1 hr at 0 °C in the presence of anisole (0.2 ml). After removal of HF *in vacuo*, the peptides released were extracted with four 3 ml portions of 20% AcOH. The aqueous solutions were shaken with ethyl ether and lyophilized. Yields: **3a**, 30 mg; **3b**, 32 mg; and **4c**, 39 mg. Amino acid analyses of the samples gave the following ratios. **3a**: Lys 1.00, Trp 0.91,[21] Gly 2.05, Ala 1.03, Val 1.00, Leu 1.95. **3b**: Lys 1.00, Trp 0.80, Gly 2.07, Ala 1.04, Val 0.97, Leu 1.97. **4c**: Lys 1.00, Trp 0.58, Gly 2.01, Ala 1.12, Val 1.07, Leu 2.12. **3a** and **3b** (7 mg each) were chromatographed on a Sephadex G-25 column (0.9×61 cm) using 5% AcOH (Fig. 4). Fractions of the major peaks were lyophilized to give **3a**† and **3b**†. Their spectra were taken in 5% AcOH and compared with those of Trp(CHO) and the mixtures of

19) When 47% hydrobromic acid was sprayed to cleave the Boc group, a spot turned purple.

20) *A* signifies absorbance at the indicated wave lengths. Such ratios are presented as a sort of measure for the extent of oxidation for tryptophan.

21) The formyl group of Trp(CHO) was spontaneously removed by heating in constant boiling hydrochloric acid at 110 °C with concomitant formation of tryptophan. Thioglycolic acid produced no side reaction.

Trp(CHO) and tryptophan in varying ratios. Amino acid analyses gave the following ratios. **3a**†: Lys 1.00, Trp 0.87. **3b**†: Lys 1.00, Trp 0.86. **3a** and **3b** (15 mg each) were dissolved in 1.5 ml of 0.1 M aqueous Et_3N and the solutions were allowed to stand at 0 °C for 10 min. Lyophilization of the solutions gave **4a** and **4b** as white fluffy powders.

*Chromatographies of the Octapeptides (**4a**, **4b**, and **4c**) on a Sephadex G-25 Column.* **4a**, and **4b**, and **4c** (5 mg each) were chromatographed on a Sephadex G-25 column (0.9× 61 cm) using 5% AcOH. The elutions were monitored by absorption at 280 nm (Fig. 5). Fractions of the major peaks for **4a** and **4b** were lyophilized to give **4a**† and **4b**†. Fractions of three peaks for **4c** were lyophilized. The resulting peptides were subjected to paper electrophoresis and their spectra were taken in 5% AcOH. Mobilities on paper electrophoresis (cm): **4a**†, 13.2; **4b**†, 13.2; **4c**-I, 14.5 (broad); **4c**-II, 13.2 (major) and 24.2 (minor); and **4c**-III, 11.7 (broad). Absorbance ratios: A_{280}/A_{247} for **4a**†, 2.17; and A_{280}/A_{247} for **4b**†, 2.20; A_{282}/A_{254} for **4c**-I, 1.45; A_{280}/A_{249} for **4c**-II, 2.05; and A_{280}/A_{251} for **4c**-III, 1.98. R_f's (2): **4a**†, 0.69; **4b**†, 0.69; **4c**-I, 0.53; **4c**-II, 0.69 (major) and 0.13 (minor); and **4c**-III, 0.75. Amino acid analyses gave the following ratios. **4a**†: Lys 1.00, Trp 0.88. **4b**†: Lys 1.00, Trp 0.86.

*Reactions of the Octapeptides (**4a**, **4b**, and **4c**) with NCPS-Cl and Chromatographies of the Modified Peptides (**5a**, **5b**, and **5c**) on a Sephadex G-25 Column.* To solutions of **4a**, **4b**, and and **4c** (7.0 mg each) in 1.2 ml of 80% HCOOH were added 19.5 mg each of NCPS-Cl and the solutions were stirred for 5 hr at room temperature and lyophilized. Color changes observed during the course of reactions have been described in the text. The dried residues were scratched with five 2 ml portions of acetone containing 2% concentrated hydrochloric acid in order to remove the excess reagent. The peptides were separated by centrifugation from the acetone solutions and finally dissolved in water, and the solutions were lyophilized. The dried peptides were dissolved in 0.6 ml of 5% AcOH and chromatographed on a Sephadex G-25 column (0.9×61 cm). The elutions were monitored by absorptions at 280 and 585 nm (Fig. 6). Fractions of the major peaks for **5a**, **5b**, and **5c** were lyophilized to give **5a**†, **5b**†, and **5c**†, respectively. Their spectra were taken in 5% AcOH and compared with that of Trp(NCPS) (Table 1). **5a**† and **5b**† (both pure yellow) gave a single band on paper chromatography, R_f (2) 0.80. On paper electrophoresis they did not move from the original line owing to extreme adhesiveness to the paper. **5c**† (brownish yellow) was shown on paper electrophoresis to contain two impure peptides in addition to the yellow peptide identical with **5a**† and **5b**†. Major and minor impurities moved 0.5 and 7.7 cm, respectively.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3285—3288 (1973)

The Reactions of the Hexafluorothioacetone Dimer with Nucleophiles in the Presence of the Fluoride Ion

Tomoya KITAZUME and Nobuo ISHIKAWA

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received June 11, 1973)

In the KF-DMF system, the hexafluorothioacetone dimer (**1**) reacted with alcohols, alkanethiols, and thiophenols under mild conditions. The products, **2**, **3**, **10**, and **12**, were assumed to have resulted from the hexafluorothioacetone monomer (**4**) and the nucleophiles. Cycloadducts of **4** and anthracene or styrene were also obtained readily from the dimer (**1**) and the dienes.

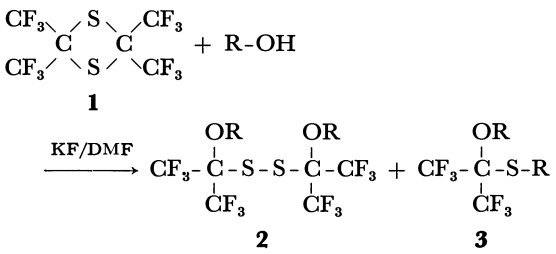
2,2,4,4-Tetrakis(trifluoromethyl)-1,3-dithiethane (**1**), a dimer of hexafluorothioacetone, is a stable compound derived from hexafluoropropene and sulfur.[1] In an earlier communication,[2] we reported on the reactions between the dimer and amines or carbonyl reagents, which gave *N*-substituted hexafluoroisopropylideneimines. However, attempts to have other nucleophiles, such as alcohols and thiols, react with the dimer were unsuccessful.

In our continued studies of the nucleophilic reactions of the dimer, we have found that, in the presence of potassium fluoride, **1** in dimethylformamide reacted with alcohols and thiols, thus giving the reaction products of these nucleophiles with hexafluorothioacetone itself.

Results and Discussion

Reaction of Hexafluorothioacetone Dimer with Alcohols. Although the dimer, **1**, reacted with aryl or alkyl amines in dimethylformamide at room temperature,[2] no reaction was observed with alcohols even at a higher temperature. The presence of a small amount of potassium fluoride, however, promoted the reaction very much, and it proceeded smoothly at room temperature. The products of this reaction were bis-[1-alkoxy-1-(trifluoromethyl)-2,2,2-trifluoroethyl] disulfide (**2**) and 1-alkoxy-1-(trifluoromethyl)-2,2,2-trifluoroethyl alkyl sulfide (**3**).

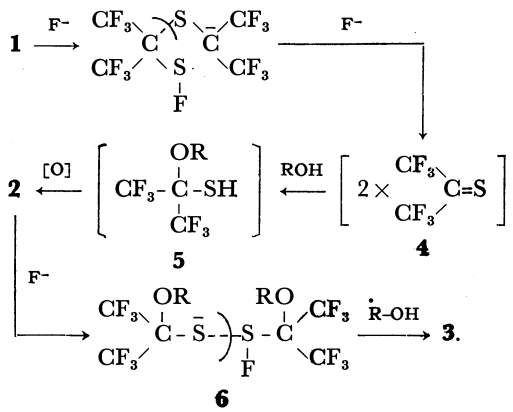
1) I. L. Knunyants, *Dokl. Akad. Nauk SSSR*, **183**, 598 (1968).
2) N. Ishikawa and T. Kitazume, This Bulletin, submitted for publication.



The structures of these compounds were elucidated by a study of the ^1H and ^{19}F NMR and the mass spectra. The ^{19}F NMR spectra of both **2** and **3** showed only one singlet signal each, *i.e.*, −9.2 ppm for **2** (R=Me) and −7.20 ppm for **3** (R=Me), from ext. CF_3CO_2H in CCl_4. The patterns of the ^1H NMR spectra were also simple. Only one singlet signal at τ 6.28 (OMe) for **2** (R=Me) and two singlet signals at τ 6.40 (OMe) and 7.80 (SMe) for **3** (R=Me) appeared. In the mass spectrum of **2** (R=Me), the base peak, *m/e* 181 ($C_4H_3F_6O$), and other fragment peaks, such as *m/e* 213 ($C_4H_3F_6OS$), 69 (CF_3), 64 (S_2), and 31 (OMe), appeared appropriately. The parent peak, M^+ 426, was not observed, but this is not strange because, in di-*tert*-alkyl disulfides, it is known that the parent peak appears very weakly.[3]

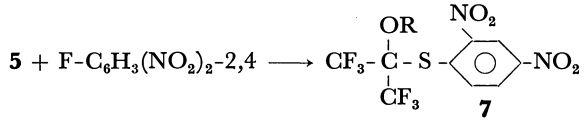
Among the various catalysts examined in connection with the above reaction, only alkali metal fluorides such as potassium and sodium flouride, were effective; alkalies, such as potassium and sodium hydroxide or potassium carbonate, had no catalytic activity. Further, in protonic solvents such as alcohols, no reaction occurred even in the presence of potassium fluoride. These results made it evident that the fluoride ion, especially the unsolvated active ion, catalyzed the reaction.

We presumed that the reaction proceeded according to the following scheme:



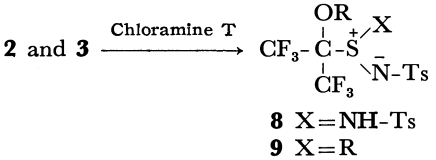
It was initiated by the active fluoride ion in the polar aprotic solvent, which attacked the sulfur atom of the dimer, **1**; it thus accelerated the formation of the reactive hexafluorothioacetone monomer, **4**. Alcohol as a nucleophile reacted with **4**, thus giving 1-alkoxy-1-(trifluoromethyl)-2,2,2-trifluoroethanethiol (**5**), which was subsequently oxidized to disulfide, **2**. The attack of the fluoride ion on sulfur occurred again, and the resulting anionic sulfur (**6**) probably reacted with alcohol to give **3**.

In order to obtain evidence for this scheme, we carried out the following reactions. To capture the intermediate thiol, **5**, the **1** and methanol in the KF–DMF system were reacted in the presence of 2,4-dinitrofluorobenzene; the 2,4-dinitrophenyl sulfide (**7**) (R=Me) was thus obtained in a good yield.

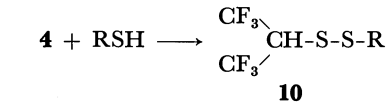


Further, the disulfide **2** (R=Me) reacted with methanol in the KF–DMF system to give **3** (R=Me), proving **2** and **3** were formed successively.

It is well known that sulfides[4] and disulfides[5] give *N*-sulfonylsulfilimines and sulfonimidosulfinsulfonylimine derivatives with Chloramine T. From disulfides, **2**, and sulfides, **3**, these derivatives were obtained as two crystalline compounds, (**8**) and (**9**) (Table 1).



Reaction of the Dimer with Thiols. Middleton *et al.* reported that, in the reaction of the hexafluorothioacetone monomer with alkanethiols, the thiocarbonyl group behaves as would be expected if sulfur were positive; the following addition reaction was observed:



Since hexafluorothioacetone was assumed to be formed during the reaction of the dimer **1** in the KF–DMF system, we carried out the reaction using alkanethiols as the nucelophile. For example, *n*-butanethiol and **1**, together with potassium fluoride, were allowed to react in dimethylformamide at room temperature; the disulfide **10** (R=*n*-Bu) was thus obtained as the main product. Ethanethiol also gave a similar product, **10** (R=Et).

When thiophenol and thiocresol were used in the above reaction, the main products were 3:1 (C_3F_6S:ArSH) and 4:1 adducts, **12** (*n*=**2** and **3**) respectively. Adducts of this kind were also reported by Middleton *et al.*, although they did not make clear on which side the disulfide bonding was.[6]

We elucidated the structure of **12** by studying the NMR and mass spectra. For example, the ^{19}F NMR of **12** (Ar=Ph, *n*=2) revealed three signals, one doublet and two singlets of the same intensity, and the ^1H NMR contained one multiplet signal at τ 6.24 in addition to the aromatic-proton signal. The mass spectrum gave the molecular ion and other fragment ions, as is

a) Erom ext. CF_3CO_2H in CCl_4.

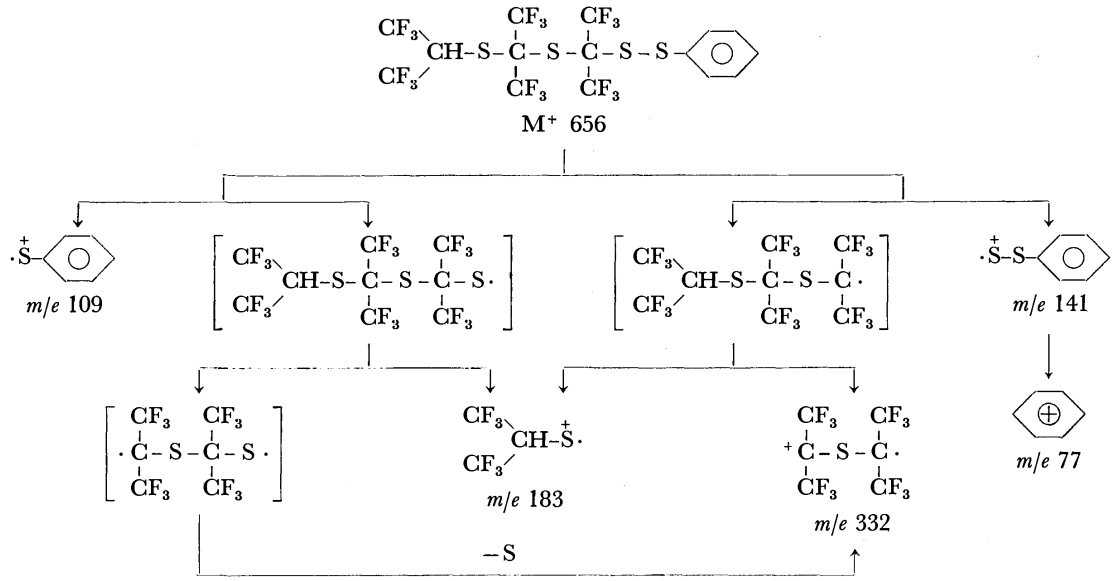

Fig. 1. Mass fragmentation of 12 (Ar = Ph).

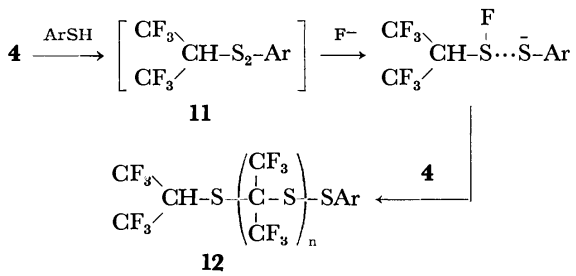
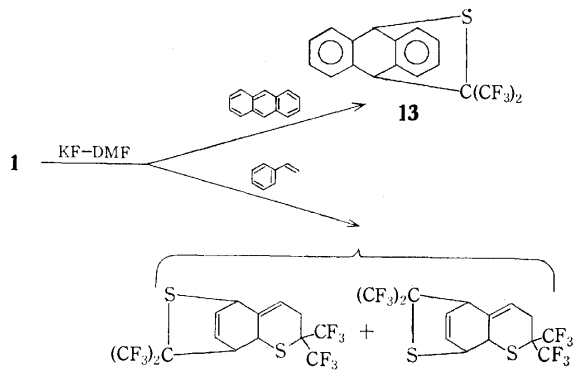
shown in Fig. 1. On the other hand, the fragment peaks, $C_6H_5S_2^+$ and $C_3HF_6S_2^+$, which are characteristic of the disulfide bond,[3,7,8] appeared in considerable strength and no fragment corresponding to $C_3HF_6S_2^+$ was observed. This means that there is C–S_2–Ar group, but no C–S_2–CH$(CF_3)_2$ group, in the molecule.

From these results, the reaction scheme and the structures of the products were estimated to be as is shown below:





Preparation of Cycloadducts from the Hexafluorothioacetone Dimer. Further confirmation of hexafluorothioacetone as an intermediate was made by the formation of the cycloadducts with dienes.

7) S. Kozuka, H. Takahashi, and S. Oae, This Bulletin, **43**, 129 (1970).

8) I. L. Knunyants and L. S. German, *Dokl. Akad. Nauk SSSR*, **201**, 603 (1971).

Since Middleton reported that hexafluorothioacetone gives cycloadducts with dienes very easily,[9] we carried out the reaction of the dimer **1** with anthracene and with styrene in the KF–DMF system. As expected, the **13** and **14** cycloadducts were obtained respectively; they were similar to those prepared by Middleton.

Experimental

*Reaction of **1** with Methyl Alcohol.* Into a mixture of potassium fluoride (4.6 g, 0.08 mol), **1** (14.6 g, 0.04 mol), and dimethylformamide (30 ml), methyl alcohol (3.8 g, 0.12 mol) was added, drop by drop; the whole was then stirred for 24 hr at room temperature. The reaction mixture was poured into water, and the separated oily matter was extracted with ethyl ether. The extract was dried over magnesium sulfate, and the solvent was removed. The vacuum distillation of the residue gave **3** (R=Me) (bp 101—102 °C/120 mmHg (3.8 g, 23%)) and **2** (R=Me) (bp 113—115 °C/24 mmHg (5.8 g, 68%)).

The reactions with other alcohols were run similarly; two products, **2** and **3**, were obtained in each case (Table 1).

*1-Alkoxy-1-(trifluoromethyl)-2,2,2-trifluoroethyl 2',4'-dinitrophenyl Sulfide (**7**).* A mixture of **1** (7.3 g, 0.02 mol), potassium fluoride (2.4 g, 0.041 mol), methanol (1.4 g, 0.04 mol), 2,4-dinitrofluorobenzene (3.7 g, 0.02 mol), and dimethylformamide (30 ml) was stirred for 48 hr at room temperature, and then the reaction mixture was poured into water. The resulting precipitate was collected and recrystallized from cyclohexane, thus giving crystals of **7** (R=Me) (mp 76—77 °C) in a yield of 73%. Found: F, 29.5%. Calcd: F, 30.0%. IR: 1526, 1352 (NO_2) cm^{-1}. NMR: ^1H, τ 1.62 (Ph), 6.16 (OMe); ^{19}F, −8.80 ppm from ext. CF_3CO_2H in CCl_4.

The sulfide, **7** (R=Et) (mp 82—83 °C), was also prepared in a similar way. Found: F, 28.6%. Calcd: F, 28.9%.

S-[*1-Ethoxy-1-(trifluoromethyl)-2,2,2-trifluoroethyl*]-S-p-*toluenesulfonamide*-N-p-*toluenesulfonylsulfilimine (**8**).* Into a solution of **2** disulfides (R=Et, 1.0 g, 2 mmol) in ethanol (30 ml), we added Chloramine T (3.0 g, 10 mmol) at room temperature, and then the whole was stirred for 48 hr. The reaction mixture was then poured into a cold dilute sodium hydroxide solution. The precipitate was filtered and recrystallized from benzene to give **8** (R=Et, 1.6 g, 64%) (mp 125—126 °C).

9) W. J. Middleton, *J. Org. Chem.*, **30**, 1390 (1965).

S-[*1-Ethoxy-1-(trifluoromethyl)-2,2,2-trifluoroethyl*]-S-*ethyl*-N-p-*toluenesulfonylsulfilimine (**9**).* To a mixture of the **3** sulfide (R=Et, 2.05 g, 8 mmol), Chloramine T (3.0 g, 10 mmol), and methanol (30 ml), we added, drop by drop, a mixture of acetic acid (1.0 ml) and methanol (5 ml) at room temperature. The whole was then stirred for 48 hr and poured into a cold dilute sodium hydroxide solution. The precipitate was collected and washed with water. Recrystallization from benzene gave **9** (R=Et, 2.24 g, 66%) (mp 129—130 °C).

Other Chloramine T derivatives were obtained by a similar procedure (Table 1).

*Reaction of **1** with Butanethiol.* A mixture of **1** (7.3 g, 0.02 mol), butanethiol (3.6 g, 0.04 mol), potassium fluoride (2.4 g, 0.04 mol), and dimethylformamide (20 ml) was stirred for 24 hr at room temperature, and then the whole was poured into water. An oily matter was subsequently extracted with ethyl ether, and the solvent was removed. The vacuum distillation of the residue gave **10** (R=*n*-Bu) (bp 85—86 °C/21 mmHg (2.0 g, 55% on the basis of the consumed BuSH.)) and di-*n*-butyl disulfide (2.4 g, bp 118—119 °C/21 mmHg). **10** (R=*n*-Bu): Found: F, 41.4%, Calcd for $C_7H_{10}F_6S_2$: F, 41.9%. NMR: ^1H, τ 6.2 (m, $(CF_3)_2$-CH); ^{19}F, δ −12 ppm (d) (from ext. CF_3CO_2H in CCl_4).

When ethanthiol was used in the above reaction, a similar disulfide, **10** (R=Et) (bp 74—76 °C/58 mmHg), was obtained in a 47% yield. Found: F, 46.3%. Calcd: F, 46.7%. NMR: ^1H, τ 6.31 (m); ^{19}F, δ −11.6 ppm (d).

*Reaction of **1** with Thiophenol.* A mixture of thiophenol (2.2 g), **1** (3.6 g), potassium fluoride (1.2 g), and dimethylformamide (20 ml) was allowed to react as has been described above. A subsequent work-up gave an oil, **12** (Ar=Ph, *n*=2) (2.2 g, 51%, bp 94—95 °C/70 mmHg, Found: F, 51.6%, Calcd for $C_{15}H_6F_{18}S_4$: F, 52.1%).

p-Thiocresol gave a similar product, **12** (Ar=*p*-MeC_6H_4, *n*=3) (bp 87—89 °C/19 mmHg, 40%; Found: F, 53.3%. Calcd: F, 53.5%).

*Hexafluorothioacetone-anthracene Adduct (**13**).* A mixture of **1** dimer (7.3 g, 0.02 mol), anthracene (7.2 g, 0.04 mol), potassium fluoride (2.4 g), and dimethylformamide (30 ml) was stirred at room temperature for 48 hr, and then the mixture was poured into water. The precipitate was collected and recrystallized from *n*-hexane, thus, giving **13** (mp 121—122 °C (lit,[9] mp 123—124 °C)) in a yield of 82%.

Styrene reacted in a similar way, thus giving a mixture of isomers (**14**) (bp 125—127 °C/3 mmHg (lit,[9] bp 103—104 °C/1.2 mmHg)) in a 24% yield.

**The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received November 30, 1972)

Since Lewis *et al.*[1] found absorption bands due to transitions between the lowest and higher triplet states, many studies have been made in this field.[2] In addition to strong triplet-triplet transition bands measured at the initial stage of the study, weak low-energy bands were observed by Kellogg[3] and by other authors.[4] Polarization of these bands were investigated by El-Sayed and Pavlopoulos[5] and by others.[6] Thus, a considerable amount of T-T absorption data are now available for theoretical consideration.[7-10]

Theoretical studies of T-T transitions have been made by the composite method,[11] by the Pariser-Parr-Pople method,[12-14] and also by the open-shell SCF MO CI procedure.[15] The transition energies and oscillator strengths calculated so far agree less satisfactorily for the T-T transitions than for the singlet-singlet transitions. Furthermore, most of these theoretical studies are concerned with only a few strong absorption bands for each molecule.

In this paper, the SCF MO CI calculations based on the Pariser-Parr-Pople procedure[16] were applied to the T-T transitions of aromatic hydrocarbons by taking the stable geometrical structure of the lowest triplet state for each molecule and by considering weak T-T transition bands in addition to strong bands.

Method of Calculation

We employed the Pariser-Parr-Pople SCF MO CI procedure,[16] taking all the singly excited configurations for benzene and naphthalene and taking the lower 40 singly excited configurations for each symmetry for anthracene, pyrene, chrysene, and coronene. The penetration integrals were disregarded. The core resonance integral (β) was taken to be proportional to the overlap integral, the value at the equilibrium C-C bond distance of benzene, $\beta_0 = -2.39$ eV, being taken as the standard. Two-center Coulomb repulsion integrals were estimated by the Nishimoto-Mataga approximation.[17] One-center Coulomb integrals and orbital exponents were determined by using the method described by Iwata and Shida.[18]

The results of X-ray crystal analysis experiments[19] of naphthalene, anthracene, pyrene, chrysene, and coronene were used at the first stage of the calculation, and thereafter the geometrical configurations of the lowest triplet states were estimated by using the standdar bond order-bond length relation.[20] The bond lengths used for the final calculation are shown in Fig. 1.[2] The calculations were performed with a FACOM 270-30 computer. Weaker bands ($\varepsilon_{max} \sim 10^2$) in the longer wavelength region can be assigned to symmetry forbidden or parity forbidden transitions. The calculated transitions forbidden from both symmetry and parity are disregarded.

All the calculated transition energies were found to be larger by $\sim 2000\ cm^{-1}$ than the corresponding observed values. Therefore, we reduced all the calculated T-T transition energies by $2000\ cm^{-1}$. A similar correction was made by Orloff.[12]

Results and Discussion

The $^3E_{2g}^- \leftarrow {}^3B_{1u}^+$ transition energy, 41000 cm^{-1}, calculated for benzene agrees well with the observed band position, 40800 cm^{-1}.[9] The T-T transition energies of naphthalene were calculated to be 20600, 25200, 31100, 39100, and 47000 cm^{-1} for the transitions from the lowest triplet ($^3B_{2u}^+$) state to the $^3A_g^-$, $^3B_{1g}^-$, $^3A_g^-$, $^3B_{1g}^-$, and $^3B_{1g}^-$ states, respectively, the oscillator strengths and the directions of transition moments (in parentheses) being 0.063 (y), 0.48 (x), 0.39 (y), 0.007 (x), and 0.92 (x), respectively. Four bands were observed for naphthalene at ~20000 cm^{-1}, ~25000 cm^{-1}, 29300 cm^{-1}, and 38500 cm^{-1}.[2,4] The calculated values agree well with the observed transition energies for the four longer wavelength bands. Furthermore, the oscillator strength and the direction of the transition moment calculated for the second longest wavelength band agree well with the observed results (f=0.32, x-polarized).[5]

The four T-T absorption bands were observed for anthracene at~12000 (f=0.0017), ~20000 (f=0.038), ~24000 (f=0.68, x-polarized[5]), and 35700 cm^{-1}.[2,4] The calculated transition energies are 11900, 21000, 23600, and 35700 cm^{-1} for the transitions from the lowest triplet ($^3B_{2u}^+$) state to the $^3A_g^+$, $^3A_g^-$, $^3B_{1g}^-$, and $^3A_g^-$ states, respectively, the oscillator strengths and the directions of transition moments (in parentheses) being calculated to be 0.00, 0.061 (y), 0.80 (x), and 0.37 (y), respectively. The calculated results agree well with the observed ones obtained so far.

The transition energies and oscillator strengths observed and calculated for pyrene are shown in Table 1, together with the band assignment.

The T-T absorption bands were observed for chrysene at ~12000 (f=0.003), 17200 (f=0.40), 24900 (f=0.016), 35200 (f=0.32), and 39500 (f=0.65) cm^{-1}.[4,9] The calculated transition energies are 11900, 17400, 25600, 35400, and 37900 cm^{-1} with the calculated oscillator strengths of 0.007, 0.76, 0.021, 0.26, and 0.37, respectively. The second longest wavelength band was found experimentally to be polarized almost parallel with the L_a band,[6] in good agreement with the theoretical prediction. The five observed bands can be assigned to the $^3A_g^- \leftarrow {}^3B_u^+$ transitions.

Table 1. The observed and calculated transition energies, ΔE's (in the units of 10^3 cm^{-1}), oscillator strengths, f's, directions of polarization, and the assignments of the T-T absorption spectrum of pyrene

Observed			Calculated			
ΔE	f	Polarization[6]	ΔE	f	Polarization	Assignments
11[4]	0.0005		12.5	0		$^3B_{3u}^- \leftarrow {}^3B_{2u}^+$
13.2[4]	0.002		14.0	0		$^3B_{3u}^- \leftarrow {}^3B_{2u}^+$
16.7[4]	0.008		18.3	0		$^3B_{1g}^+ \leftarrow {}^3B_{2u}^+$
~20[4]	0.022	x	21.6	0.051	x	$^3B_{1g}^- \leftarrow {}^3B_{2u}^+$
22.2[6]			23.1	0		$^3A_g^+ \leftarrow {}^3B_{2u}^+$
			24.6	0		$^3B_{3u}^- \leftarrow {}^3B_{2u}^+$
~25[4]	0.48	y	26.7	0.84	y	$^3A_g^- \leftarrow {}^3B_{2u}^+$
27.8[8]	0.03		28.6	0		$^3B_{1g}^+ \leftarrow {}^3B_{2u}^+$
~31[8]	0.08		33.1	0.044	x	$^3B_{1g}^- \leftarrow {}^3B_{2u}^+$
34.4[8]	0.16		35.9	0.24	y	$^3A_g^- \leftarrow {}^3B_{2u}^+$
38.6[8]	0.13		40.1	0.30	x	$^3B_{1g}^- \leftarrow {}^3B_{2u}^+$

Four bands were observed for coronene at ~10000, ~16000, 20800, and ~25000 cm^{-1} with the oscillator strengths of 0.0005, 0.08, 0.16, and 0.12, respectively.[7,21] The longest wavelength band is assigned to the parity forbidden transition (ΔE=7900 cm^{-1}, $^3E_{2g}^+ \leftarrow {}^3B_{1u}^+$). The higher transition energies were calculated to be 12600, 20800, and 25900 cm^{-1} with the oscillator strengths of 0.06, 0.41, and 0.22, respectively. These three bands can be assigned to the $^3E_{2g}^- \leftarrow {}^3B_{1u}^+$ transitions.

One of the characteristics of our calculation is to adopt the stable geometrical configuration of the lowest triplet state in which the bonds are generally elongated compared with those of the structure in the ground state. This reduces the $|\beta|$ values to some extent and brings about a narrowing of the energy separation between the higher and lower transition energies for each of the aromatic hydrocarbon molecules.[22] This is a reason why the present calculation can explain quantitatively the observed peak positions over wide wavelength region. Our assignments are different from those by Orloff[12] in some points; for example, we assigned the 38500 cm^{-1} band of naphthalene to the $^3B_{1g}^- \leftarrow {}^3B_{2u}^+$ transition and the 35700 cm^{-1} band of anthracene to the $^3A_g^- \leftarrow {}^3B_{2u}^+$ transition, while Orloff assigned both bands to the $^3B_{3g}^+ \leftarrow {}^3B_{2u}^+$ transition. Our assignmens give better agreements between the observed and theoretical results concerning both transition energies and absorption intensities. Furthermore, in view of the fact that we are concerned with greater number of observed bands (including weak ones) for each molecule, our assignments are more reasonable than those by Orloff.[12]

21) Unpublished results by Windsor and Novak; private communication to one of the authors (S.N.) from Dr. Windsor, to whom the authors' thanks are due.

22) For example, the transition energies calculated for naphthalene by the use of the ground state geometry are 19400, 26200, 31900, 40700, and 50100 cm^{-1}; the corresponding value obtained by the use of the excited state geometry being 20600, 25200, 31100, 39100, and 47000 cm^{-1}.

Energetic Consideration of $C_5H_5^+$ Ions Produced from Various Precursors by Electron Impact

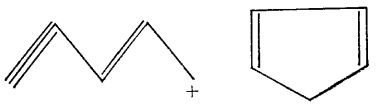
Susumu TAJIMA and Toshikazu TSUCHIYA

National Chemical Laboratory for Industry, 1-1-5, Honmachi, Shibuya-ku, Tokyo 151

(Received March 31, 1973)

It is well known[1] that the $C_7H_7^+$ ions produced from various precursors (C_7H_7Z) decompose into the $C_5H_5^+$ ions by losing C_2H_2. The structure of the $C_7H_7^+$ ions has been investigated by various methods.[1-3] To the authors' knowledge, however, the structure of the $C_5H_5^+$ ions produced by the $C_7H_7Z^+ \rightarrow C_7H_7^+ + Z \rightarrow C_5H_5^+ + C_2H_2$ reaction has not yet been examined.

Occolowitz and White have concluded[4] that the structure of the $C_5H_5^+$ ions derived from some compounds can be identified as the (a) structure rather than the (b) structure shown in Fig. 1 by measuring the heat of formation.[5] Natalis and Franklin have also reported[6] similar conclusions reached by the same method.



(a) ΔH_f: 277 kcal/mol (Ref. 4) (b) ΔH_f: 240 kcal/mol (Ref. 5)

Fig. 1. Schematic diagram of the structure of the $C_5H_5^+$ ion from 3-penten-1-yne (a) and cyclopentadienyl radical (b).

In order to examine the structure of the $C_5H_5^+$ ions produced from the derivatives of toluene and benzene, we have now measured the heat of formation of the $C_5H_5^+$ ions from these compounds and compared them with that of 3-penten-1-yne and the cyclopentadienyl radical.[4,5]

The apparent heat of formation of the $C_5H_5^+$ ions, $\Delta H_f(C_5H_5^+)$, is calculated from the following equation:

$$\Delta H_f(C_5H_5^+) = \Delta H_f(M) + A.P(C_5H_5^+) - \sum \Delta H_f(N) - E \quad (1)$$

where $\Delta H_f(M)$ is the heat of formation of the neutral molecule; $A.P(C_5H_5^+)$ is the appearance potential of the $C_5H_5^+$ ion, $\sum \Delta H_f(N)$ is the algebraic sum of the heat of formation of the neutral fragments, and E is the excess energy of the fragments at the threshold.

The values of $A.P(C_5H_5^+)$ from the compounds obtained in the present experiment using a CEC 21-103C mass spectrometer are given in the second column in Table 1. These A.P values were obtained by the E.D.D technique;[7] the details of the experiment have already been described.[8] Each value is the average of at least three measurements. The experimental error is within ± 0.2 eV.

The values for the heat of formation of the $C_5H_5^+$ ions calculated from Eq. (1) using the A.P values in Table 1 and the literature values[9] for $\Delta H_f(M)$ and $\Delta H_f(N)$ are given in the fourth column in Table 1. The value of E is usually determined from the width of the observed metastable peak.[4,10] The value seldom exceeds 10 kcal/mol, with a few exceptions, such as is the case of NO loss. In this experiment, we estimated

the heat of formation by neglecting E. Therefore, the data will show a tendency to have a little higher value. Taking the experimental error into consideration, the overall error is considered to be less than 20 kcal/mol. It is evident from the data of the heat of formation (Table 1) that all these values coincide with the heat of formation of 3-penten-1-yne (277 kcal/mol)[4] within the limits of experimental error, except for the values from *o*-nitrotoluene (the value of *m*-nitrotoluene is slightly higher than the limit of the experimental error, but it probably belongs to the former group). The values for the former group are considerably higher than the heat of formation of the $C_5H_5^+$ ion from the cyclopentadienyl radical (240 kcal/mol).[5] According to the results of Occolowitz and White,[4] we can also regard the $C_5H_5^+$ ions from the compounds studied here as having the (a) structure in Fig. 1.

Beynon *et al.* have reported[11] that the $C_5H_5^+$ ions are produced from *o*-nitrotoluene molecular ions by the following two reactions:

$$C_7H_7NO_2^+ \xrightarrow{-OH} C_7H_6NO^+ \xrightarrow{-CO} C_6H_6N^+ \xrightarrow{-HCN} C_5H_5^+ \quad (2)$$

$$C_7H_7NO_2^+ \xrightarrow{-NO_2} C_7H_7^+ \xrightarrow{-C_2H_2} C_5H_5^+ \quad (3)$$

Therefore, the heat of formation of the $C_5H_5^+$ ion for *o*-nitrotoluene, calculated from both Eq. (2) and Eq. (3), is given in Table 1. The structure of the $C_5H_5^+$ ion produced from Reaction (2) cannot be assigned on the basis of the present experiment alone. The value calculated from Reaction (3) is considerably lower than that of *m*- and *p*-nitrotoluene. The value (259.2 kcal/mol) shown in Table 1 as having been obtained from Reaction (3) was calculated by using A.P.= 13.5 eV. However, taking the mechanism of the production of the $C_5H_5^+$ ion given in Eq. (3) into account, the structure of the $C_5H_5^+$ ion of *o*-nitrotoluene produced by Reaction (3) seems to be identical with that of the *m*- and *p*-compounds. If this assumption is valid, the $\Delta H_f(C_5H_5^+)$ obtained from Eq. (3) for *o*-nitrotoluene should be close to that obtained for *m*- and *p*-compounds. In that case, assuming the $\Delta H_f(C_5H_5^+)$ is about 290 kcal/mol, the A.P value of the $C_5H_5^+$ ions for *o*-nitrotoluene obtained from Eq. (3) must be close to 14.8 eV. Therefore, a break in the ionization efficiency curve of the $C_5H_5^+$ ion for *o*-nitrotoluene is expected to occur at about 14.8 eV. As may be seen in Fig. 2, there is a break at about 14.8 eV. Consequently, it may be inferred that, while the onset of the $C_5H_5^+$ ion from Reaction (2) is at 13.5 eV (shown by the a arrow in Fig. 2), that of the $C_5H_5^+$ ion from Reaction (3) is at about 14.8 eV (shown by the b arrow).

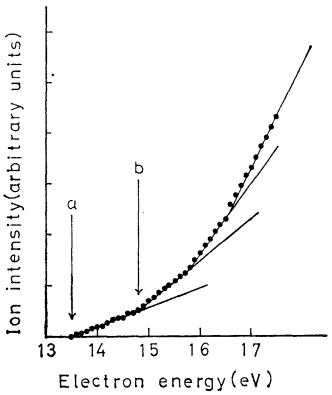

Fig. 2. Ionization efficiency curve for the $C_5H_5^+$ ion from *o*-nitrotoluene.

If the appearance potentials of the metastable ions corresponding to the $C_6H_6N^+ \rightarrow C_5H_5^+ + HCN$ and $C_7H_7^+ \rightarrow C_5H_5^+ + C_2H_2$ reactions can be measured, then the above assumption will be confirmed.

The authors wish to thank Mr. Nobuhide Wasada of this Laboratory for his valuable discussions.

Visual Autoclaving Studies of Hydrothermal Changes in Sugar Solutions

Tominosuke KATSURAI and Yoshihiro MAKIDE

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received March 24, 1973)

Visual autoclaving studies of hydrothermal changes have so far been restricted to inorganic compounds.[1] Lately it occurred to us that an extension of the studies to organic compounds might add to our information on hydrothermal changes. Sugars were chosen because they resemble inorganic compounds as regards their behavior towards solvents; that is, they are easily soluble in water but not in organic solvents. By such a choice, we were able to find a new mode of the concentration dependence of hydrothermal changes.

Sugars. Commercial saccharose, dextrose, and levulose of the best grade were used. Solutions of various concentrations were put into 5 tubes of Pyrex glass (dia. 10 mm). They were evacuated with a water-jet pump, sealed, and subjected to visual autoclaving. Solutions with concentrations of 0.4M, 0.1M, 0.04M, 0.01M and 0.004M were autoclaved up to 230°C in 1.5 hr, and the resulting changes were observed. Coloration took place in each solution at a certain temperature, which rose with a decrease in the concentration. Reproducibility of the values of the coloration temperature was within ± 3 °C. Levulose underwent the change most easily. Above the coloration temperature, a deepening in color took place with a rise in the temperature, followed by a coagulation of the particles which separated from the solution. All the 0.4M solutions turned into two phases, a dark precipitate and a brown liquid. The sugar appeared to be charred in water.[2] The changes became less marked with a decrease in concentration, all the 0.004M solutions turning brown with hardly any precipitate. The onset of coloration of each 0.4M solution took place at a temperature slightly higher (2—8 °C) than that of the corresponding solid sugar observed when heated in an open glass tube.

The results are shown in Fig. 1. The concentration range of the solutions being great, it was necessary to reduce the scale for representation. For this, the average inter-solute distance was used instead of the logarithm of the concentration. This was found to be effective also for giving an intuitive picture of a non-dissociated solution. If we put r=inter-solute distance and c=molar concentration, their relation is given by[3]

$$r = 12/\sqrt[3]{c} \qquad (1)$$

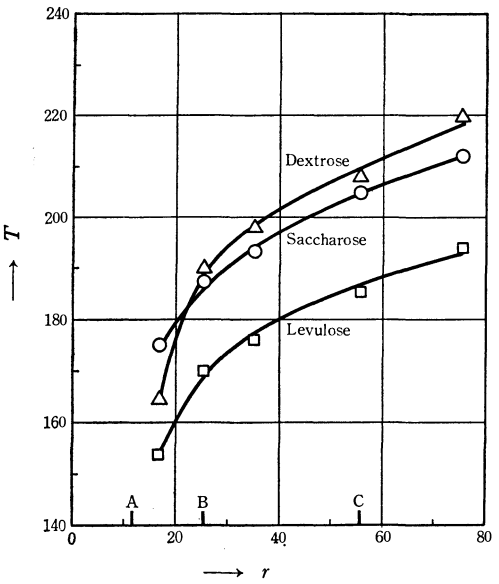

Fig. 1. Concentration dependence of coloration temperature
T=coloration temperature in °C.
r=average inter-solute distance in Å
Points A, B, and C correspond to 1M, 0.1M, and 0.01M, respectively.

The concentration dependence of the coloration temperature T is given in terms of the curve T *vs.* r. The area above the curve represents the zone in which the solution undergoes changes, while that under the curve is the zone in which the solution remains stable. The concentration dependence here is in contrast to the case of electrolytes (hydrolysis), where a high concentration makes the solution stable.

Equation (1) can be obtained as follows. We assume that solute particles are of equal size and are not dissociated. Let us take the case in which 6.02×10^{23} (Avogadro's number) particles are distributed uniformly in a space of 1 liter volume. The inter-solute distance, say l, can be taken as a unit distance corresponding to one molar solution. For its evaluation we replace the problem with one of packing. Suppose that a volume of 1 liter is closely packed with 6.02×10^{23} spheres of equal size; then the distance between the centers of the nearest neighbors, or the diameter of the

1) For the principal achievements attained by visual autoclaving, see T. Katsurai and K. Sone, This Bulletin, **41**, 519 (1968).

2) The precipitate obtained from 0.4 M levulose was subjected to electron-diffraction study. The diffraction pattern indicated that the precipitate consists of dielectric and polymerized matter differing from electro-conductive carbon. The precipitate seems to be formed by the hydrothermal polymerization of levulose. We owe this information to Dr. Shigeto Yamaguchi, National Institute for Research in Inorganic Materials.

3) This formula was found to be useful also for obtaining the empirical formula for the optimum concentration in hydrothermal precipitation; T. Katsurai, This Bulletin, **44**, 3207 (1971). The applicability of Formula (2) can be extended to a case where we have a solvent only. If we put l=10.3 Å (tetrahedral packing) and c=55.3 (number of moles of water in 1 liter), we obtain r=2.70 Å, which agrees with the distance between water molecules experimentally obtained; T. T. Wall and D. F. Hornig, *J. Chem. Phys.*, **43**, 2084 (1965).

sphere, gives the required value. It is not unique, but differs according to the mode of packing.

Mode of packing	l in Å
Closest	13.3
Cubic	11.8
Tetrahedral	10.3

Since the concentration (number of solute particles in unit volume) is inversely proportional to the third power of the inter-solute distance, we obtain the following relation for the conversion of concentration into inter-solute distance:

$$r = l/\sqrt[3]{c} \qquad (2)$$

For our present purpose, the value 12 is taken as an approximation of the average (11.8Å) of the three values of l. We thus obtain Eq. (1). This can be taken for granted when we consider the fluctuation of the positions of the solute particles.

Some modifications in the experimental procedure should be added:[4] (a) for the simultaneous observation of the changes taking place in the 5 tubes, it is advantageous to keep the circular disk supporting the sealed tubes rotating and the ring burner below the disk fixed; (b) the appropriate r.p.m. of the disk is 3, and (c) the tubes are tilted 30° from the direction of gravity. This makes the circulation of the stream in the solution caused by heating smoother, and the shock given to the test tube caused by contingent bumping smaller.

On Liquefaction Caused by the Trituration of Pairs of Solid Compounds. II

Tominosuke KATSURAI and Koko MAEDA

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351
Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Tokyo 112

(Received May 25, 1973)

In a previous paper a report was given on pairs of solid compounds which give rise to liquefaction on trituration.[1] Urea was found to cause liquefaction with most of the inorganic compounds examined. Tests, not rigorous but practical, were prescribed to find pairs for liquefaction. We have since extended our search for new pairs utilizing the tests and have been able to find some. We are still far from grasping the principle for the selection of the pairs, but a systematic representation of the data will suffice for the present (Table 1).

The experimental procedure and the mode of representation are the same as before. A pair consists of (a) an inorganic compound with water of crystallization and (b) an organic compound. The former is considered to liberate water for liquefaction as a result of interaction with the latter. For (a), sulfates were chosen because of their small hygroscopicity, while for (b) we chose salts of organic acids and bases with a fairly large solubility in water. Some inorganic and organic compounds were also chosen for the sake of

+++ denotes rapid, ++ moderately fast, + slow, and − no liquefaction

comparison.

We see that many of the pairs found consist of combinations of reagents with which weare familiar. They would have been found much earlier if liquefaction had attracted attention. It is expected that more pairs will be found by future attempts.

A few remarks should be added. Of (a), $Na_2SO_4\cdot 10H_2O$ and $Al_2(SO_4)_3\cdot Na_2SO_4\cdot 10H_2O$ undergo liquefaction to a great extent. Among the sodium phosphates, $Na_2HPO_4\cdot 12H_2O$ undergoes liquefaction most easily. Besides urea, several organic compounds as well as alkali thiocyanates were found to cause liquefaction with inorganic compounds.

The following combinations are suitable for the demonstration of liquefaction:

$Na_3PO_4\cdot 12H_2O + NH_2NHCONH_2\cdot HCl$

$Na_2HPO_4\cdot 12H_2O + CH_3COONH_4$

$ZnSO_4\cdot 7H_2O + C_2H_5NH_2\cdot HCl$

$ZnSO_4\cdot 7H_2O + NH=C(NH_2)_2\cdot HCl$

Thermal Decomposition Studies of the Ammonium Forms of the Crystalline Zirconium Phosphate Ion Exchanger

Yoshitsugu HASEGAWA

Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Nakamachi, Koganei, Tokyo 184

(Received January 16, 1973)

Ammonium-ion exchange on a crystalline zirconium phosphate (c-ZrP) had been studied, and the formation of two phases, $Zr(NH_4PO_4)_{1.33}(HPO_4)_{0.67}\cdot H_2O$ (Phase I) and $Zr(NH_4PO_4)_2\cdot H_2O$ (Phase II), has been found.[1] It is known that c-ZrP has two phosphate protons and that they exist in the ratio of 1 to 1.[2] However, the results obtained earlier for the ammonium-ion exchange showed that the phosphate protons seemed to exist in the ratio of 2 to 1. This result differs from that expected from the known properties of c-ZrP. In the present study, the thermal decomposition of the ammonium forms of c-ZrP was examined by means of thermogravimetry, and the enthalpy changes in the decomposition processes were measured by differential scanning calorimetry. Moreover, the changes in the phases of the samples during heating were analysed by means of X-ray powder diffraction. On the basis of these results, the state of the ammonium ions and the waters in the exchanger were discussed.

Experimental

Preparation of the Samples. c-ZrP and Phases I and II were prepared as has been described in the previous papers.[1,3]

Apparatus and Procedure. Thermogravimetry (TG) and Differential Scanning Calorimetry (DSC). The TG curves were obtained with a Rigaku TJG-DTA 8020 apparatus in static air, using a platinum crucible. The DSC curves were obtained with a Rigaku DSC 8000 apparatus in a dynamic nitrogen stream and at a flow rate of 300 ml/min. The measurement was made using samples of about 5—10 mg with a mesh size of 100—200 in an aluminum pan. In both thermal measurements, the heating rate was fixed at 5 °C/min. The standard substances used were KNO_3, $KClO_4$, and Zn.

X-Ray Study. The X-ray powder patterns were obtained with Ni filtered copper X-rays, using a Rigaku Geigerflex (Rigaku Denki Co., Ltd.).

Results and Discussion

Thermal Studies. The thermogravimetric data obtained are shown in Table 1. For each decomposition step, we attempted to detect ammonia by means of evolved gas analysis. Ammonia was found in the first and second steps. As is shown in the DSC curves (Fig. 1), the first decomposition reaction was complex. Thus, the detection of ammonia was carried out at the beginning and at the end of the reaction. Ammonia was not detected at the beginning. Hence, Phases I and II released one mole of water and almost simultaneously 0.33 or one mole of ammonia in the first step. One mole of ammonia was released in the second step. The last step corresponded to the polymerization of *ortho*-phosphate groups.

Table 1. Weight loss on heating phases I and II

Temperautre range (°C)	Total weight loss (%)		
	TG	DSC[a]	Theoretical
Phase I			
70—270	7.4	7.4	7.3
270—400	11.6	12.1	12.5
540—640	16.0	—	18.1
Phase II			
50—270	11.0	10.8	10.4
270—400	16.0	16.0	15.5
540—640	20.0	—	20.9

a) The samples analysed by the differential scanning calorimeter were weighed batchwise after heating.

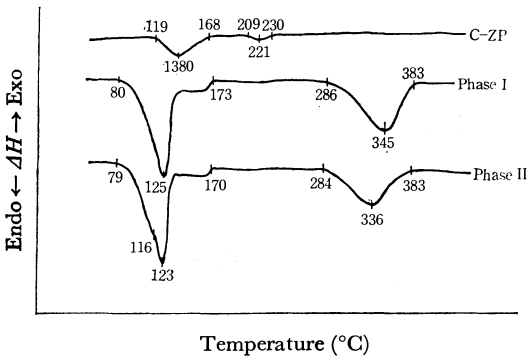

Fig. 1. The DSC curves of c-ZrP, Phases I and II.

In the DSC study, the heating rate, the gas-flow rate, and the packing manner of the samples were varied in order to isolate each reaction in the first step, but the attempt was unsuccessful. The DSC curves obtained are shown in Fig. 1. The DSC curves of Phase I agreed with that of Phase II except for the details in the first step. The DSC curves in Fig. 1 showed that the enthalpy changes in the reactions were endothermic.

When the decomposition reactions of Phases I and II were compared with those of the ammonium phosphates of some metals reported by Erdey and Gal,[4] the effect of zirconium on the release of ammonia seemed to be small and the interaction between the ammonium ions and phosphate groups appeared to be dominant. The temperature range corresponding to the first decomposition is similar to that of diammonium

monohydrogen phosphate (max., about 170 °C). The second decomposition-temperature range is similar to the decomposition temperature of ammonium chloride (max., 345 °C) or ammonium sulfate (max., 330 °C).[5] According to Erdey *et al*,[4,5] the decomposition temperature of ammonium salts is inversely proportional to the basicity of the anion bases in the salts. Hence, the ammonia released in the first and second steps will originate from the ammonium ions exchanged with the proton on c-ZrP at higher pH values, and at lower pH values, respectively (see Fig. 1 in Ref. 1). The decomposition temperature observed in the second step is higher than that expected from the basicity of the monohydrogen phosphate group. This is mainly due to the structural change in the solid phase (*cf.* X-ray study).

From the DSC curves in Fig. 1, the characteristics of the water in the ammonium-form exchanger can be deduced to be as follows. The dehydration of c-ZrP in the first step took place at a relatively higher temperature and the enthalpy change was small. This reflects the zeolitic nature of the water in c-ZrP.[6,7] In contrast to c-ZrP, the dehydration of Phases I and II shifted to a lower temperature and the DSC curves resembled that of a hydrated water. This change in the water in the exchanger is more apparent if we compare the enthalpy change, ΔH, for c-ZrP with those for Phases I and II. The ΔH's of c-ZrP and Phases I and II for the first step were equal to 5, 15, and 25 and those for the second step, to 0.6, 13, and 14 kcal/mol, respectively. It is not apparent why the second peak for c-ZrP is present. The ΔH for the dehydration of c-ZrP is about equal to that of the hydrogen bond. The ΔH's in the second step for Phases I and II showed a good agreement. In view of the structural changes in Phases I and II by heating (see X-ray study), it is assumed that the differences in the ΔH's between Phases I and II are due to the presence of 0.67 moles of ammonium in both the forms. Therefore, the enthalpy changes can be calculated to be 10 kcal/H_2O and 15 kcal/NH_3 respectively.

As the standard heat of the formation of Phases I and II and their specific heats are not known, the heat of the reaction in each step can not be calculated. However, it is interesting to compare the ΔH's obtained in this study with the heat of reaction of the ammonium phosphates. The standard heats of the formation of mono-, di-, triammonium phosphate (crystal), and ammonia (gas) are −347, −376, −402, and −11 kcal/mol respectively.[8] The specific heat of ammonia at a constant pressure as a function of the temperature has also been established.[9] Assuming that the difference in the specific heats of solid phases is negligibly small, as is assumed in the case of aquopentaammine chromium (III) complexes,[10] the heats of the reactions of di- to mono- and of tri- to diammonium phosphate can be calculated. The resulting values are 18 kcal/mol at 500 K and 15 kcal/mol at 700 K. These values are almost equal to the ΔH's obtained for Phases I and II at the second decomposition step and to the calculated value. It may be deduced that the ammonium ions and the phosphate group in the exchanger and in the salts interact to the same extent. The deduction stated is coincident with the observation on the decomposition temperatures of Phases I and II.

a) The values from Ref. 8.

X-Ray Study. The interplanar distances of the samples (*d* values) after heating to 220 and 420 °C in a differential scanning calorimeter are shown in Table 2. It is apparent that Phases I and II were converted to an identical phase (Phase III) by the first decomposition. After the second decomposition, both phases showed the same diffraction patterns as that of the c-ZrP heated to 420 °C. Further, the heated samples were equilibrated with vapor of ammonia and water, and then examined again. Their X-ray diffraction patterns were then identical with that of the original ones. This fact suggests that the thermal decomposition reactions are reversible. The *d* value of anhydrous zirconium bis(monohydrogen *ortho*-phosphate) obtained above did not agree with that reported by Clearfield *et al.*[11]

It is already known that c-ZrP has a layer structure and contains a cavity with a radius of about 1.3Å and that the first reflection in the X-ray diffraction patterns represents its interlayer distance.[12] The interlayer distances accompanying the thermal decomposition differ from those with the ion exchange.[1] That is, in the ion-exchange process the interlayer distance of 9.5Å changed to 8.2Å, while in the thermal decomposition it changed to 7.5Å. These facts suggest that one water molecule contributes to the structural change in the exchanger. Moreover, the shrinkage of the interlayer distance in the thermal decomposition will cause an increase in the apparent acidity of the phosphate group and the decomposition temperature in the second step will be raised.

The Near-ultraviolet Absorption of Aqueous Solution of Copper(II) Ammine Complex with an Excess of Ammonia

Masatomi SAKAMOTO* and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka 812

(Received June 12, 1973)

In 1941 Kubota[1] observed absorption spectra of copper(II) ammine complex in aqueous solutions with various concentration of ammonia, and found that an absorption appears in the near-ultraviolet region (~31 kK) at the presence of some excess ammonia. Kubota attributed the origin of this absorption to the formation of *trans*-$[Cu(NH_3)_4(OH)_2]$. However, his conclusion appears to be based on an old-fashioned theory, and therefore, it was attempted in this study to clarify the origin of the band in the light of the modern ligand field theory.

Recently, Kida *et al.*[2,3] studied some binuclear copper(II) complexes bridged with two alkoxo or hydroxo groups, and concluded that a band at the near-ultraviolet region (28—31 kK) is attributable to the charge transfer transition from nonbonding π-orbitals of bridged oxygen atoms to copper ions. Thus, it is expected that the origin of the near-ultraviolet band observed for copper(II)-ammonia solution should reasonably be explained by a similar basis to that of the above cases.[2,3]

Results and Discussion

Figure 1 shows the near-ultraviolet absorption spectra of copper sulfate with various concentration of ammonia. The result qualitatively agrees with that reported by Kubota. As seen in Fig. 1 the solution of Cu/NH_3= 1/10 showed the maximum absorption at 31.5 kK.

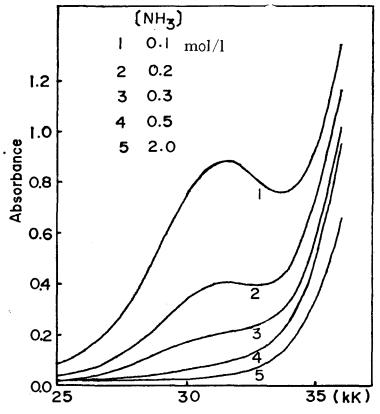

Fig. 1. UV spectra of 0.01 M $CuSO_4$ in aqueous ammonia solutions.

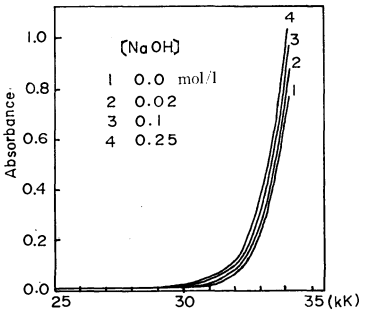

Fig. 2. UV spectra of aqueous solutions containing 0.01 M $CuSO_4$ and 0.1 M ethylenediamine at various OH^- concentrations.

However, in the copper(II)-ethylenediamine solution, as indicated in Fig. 2, no specific band was observed in the ultraviolet region (28—31 kK) even at the addition of sodium hydroxide. If the near-ultraviolet absorption were due to the formation of $[Cu(NH_3)_4(OH)_2]$ as Kubota concluded,[1] a similar absorption should have been observed for the solutions of Fig. 2 where $[Cu\ en_2(OH)_2]$ should exist in some extent. Therefore, it is obvious that the band is not due to the *trans*-coordination of two hydroxide ions.

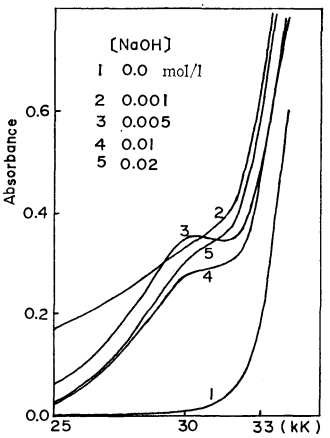

Fig. 3. UV spectra of aqueous solutions containing 0.01 M $CuSO_4$ and 0.018 M ethylenediamine at various OH^- concentrations.

As shown in Fig. 3, however, in the copper(II)-ethylenediamine solution with the mole ratio of 1: 1.8, a remarkable absorption was observed at 30.8 kK when sodium hydroxide was added. From this fact and the results of our previous studies,[2,3] we assume that the band is due to partially formed di-μ-hydroxo-bis-(ethylenediamine)dicopper(II) ion. Considering from

the stepwise stability constants[4] an appreciable amount of $[Cu\ en\ aq]^{2+}$ is present in the solution of Cu/en=1/1.8 (where aq denotes "aquated"). Accordingly, addition of sodium hydroxide to this solution will lead to formation of the dihydroxo-bridged binuclear complex. Further addition of sodium hydroxide may cause destruction of the binuclear structure, accompanying the decrease of the near-ultraviolet band, as observed in Fig. 3. Recently, the formation of the dihydroxo-bridged

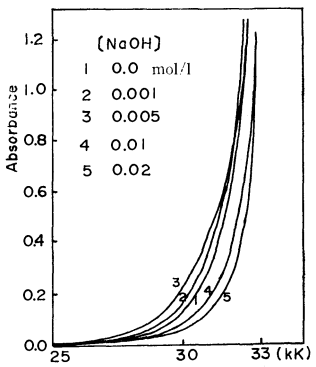

Fig. 4. UV spectra of aqueous solution containing 0.01 M $CuSO_4$ and 0.01 M diethylenetriamine at various OH^- concentrations.

binuclear complex under a similar condition was proved by the potentiometric study of Barbucci *et al.*[5]

In a solution of copper(II)-diethylenetriamine solution with the 1:1 ratio the dihydroxo-bridged binuclear complex is not liable to be formed even at a high pH region, but only mononuclear complexes, such as $[Cu\ dien\ aq]^{2+}$ and $[Cu\ OH\ dien\ aq]^{+}$, are formed. In fact, as shown in Fig. 4, no appreciable near-ultraviolet band was observed in the spectra of the copper(II)-diethylenetriamine solutions of various OH^- concentrations. This is supporting our view for the origin of the near-ultraviolet band, and eliminating the possibility that a mononuclear complex with hydroxide ion at an in-plane coordinating position, such as $[Cu(OH)_2\ en\ aq]$, $[Cu\ OH\ en\ aq]^{+}$ or $[Cu\ OH\ dien\ aq]^{+}$, is the origin of the near-ultraviolet band.

From the above discussion we may conclude that the absorption band at the near-ultraviolet region observed for the aqueous copper(II)-ammonia solution is attributable to the partially formed binuclear complex $[(NH_3)_2Cu(OH)_2Cu(NH_3)_2]^{2+}$. The decrease of intensity of the absorption at the very high concentration of ammonia can be well elucidated in terms of the conversion of the binuclear species into the mononuclear tetraammine complex.

Polarographic and ESR Studies on the Electrode Reactions of Tris(2,2′-bipyridine)iron(II) in Acetonitrile

Nobuyuki TANAKA, Tateaki OGATA, and Shigeya NIIZUMA

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received June 13, 1973)

In a previous paper[1] it was reported that in acetonitrile tris(2,2′-bipyridine)iron(II) was reduced to iron(I), iron(0) and iron(−I) complexes at the dropping mercury electrode. In that study, however, those complexes which were considered to be formed at the electrode were not isolated and their oxidation states were not confirmed by other techniques.

In this study the reduction products of tris(2,2′-bipyridine)iron(II) ($[Fe(bipy)_3]^{2+}$) were obtained by controlled potential electrolysis in acetonitrile and their ESR spectra were measured to clarify the oxidation states of those reduction products.

Experimental

Tris(2,2′-bipyridine)iron(II) perchlorate, $[Fe(bipy)_3](ClO_4)_2$, was synthesized according to the literature.[2] Acetonitrile was purified by the method presented by Coetzee.[3]

The polarographic measurement was carried out using an H-type cell and an aqueous saturated calomel electrode (SCE) at 25 °C. ESR spectra of reduction products which were obtained by controlled potential electrolysis were measured by the method of Geske and Maki[4] with an X-band JEOL P-10 ESR spectrometer and Mn^{2+} in MgO as standard.

Results and Discussion

A direct current (d.c.) polarogram of $[Fe(bipy)_3]^{2+}$ in acetonitrile with 0.05M $(C_2H_5)_4NClO_4$ as supporting electrolyte gave six reduction waves, although the sixth wave was not well-defined, as shown in Fig. 1 (Curve a). The limiting current of each of the first three waves was found to correspond to the value of one-electron reduction, while those of the fourth and fifth wave

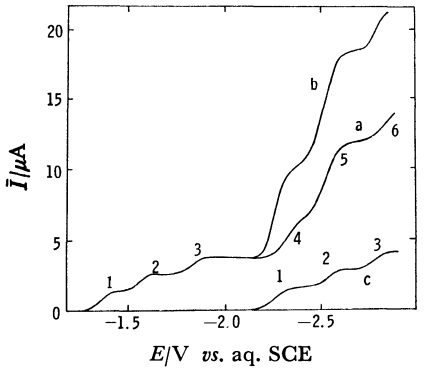

Fig. 1. D.c. polarograms of $[Fe(bipy)_3](ClO_4)_2$ and 2,2′-bipyridine in acetonitrile with 0.05 M $(C_2H_5)_4NClO_4$. (a) 0.5 mM $[Fe(bipy)_3](ClO_4)_2$, (b) a+0.6 mM 2,2′-bipyridine and (c) 0.3 mM 2,2′-bipyridine. Residual current and IR drop are corrected.

were those of two- and six-electron reduction, respectively. On the addition of free 2,2′-bipyridine the wave heights of the last three waves increased, as seen from Curve b in Fig. 1. The ligand itself undergoes reduction in acetonitrile at −2.24, −2.53, and −2.77 V *vs.* aq. SCE with the limiting current ratio of 1 : 1 : 1 (see Curve c in Fig. 1). Half-wave potentials of the reduction waves of $[Fe(bipy)_3]^{2+}$ and those of 2,2′-bipyridine in acetonitrile are given in Table 1. These

Electrolytic solution[a)]	Half-wave potential/V *vs.* aq. SCE				
	1st	2nd	3rd	4th	5th
I	−1.35	−1.55	−1.82	−2.32	−2.52
II				−2.26	−2.51
III	−2.24	−2.53	−2.77		

a) I: 0.5 mM $[Fe(bipy)_3](ClO_4)_2$+0.05 M $(C_2H_5)_4NClO_4$.
II: I+0.6 mM 2,2′-bipyridine.
III: 0.3 mM 2,2′-bipyridine+0.05 M $(C_2H_5)_4NClO_4$.

experimental results suggested that the last three waves must be attributed to the reduction of ligand coordinated in and/or dissociated from the complex. Although the first three waves are considered to be due to the reduction of tris(2,2′-bipyridine)iron complex,[1)] their electron transfer mechanisms are still in question; it has not been decided whether electrons enter to the ligand orbitals or to the metal ones.

In order to obtain the definitive information of the nature of the reduction products, ESR spectra of the reduction products which were obtained by controlled potential electrolysis at various potentials were measured at room temperature.

The parent complex $[Fe(bipy)_3]^{2+}$, which has been reported to be diamagnetic[2)], gave no ESR signal. A solution of reduction product obtained by electrolysis at −1.45 V, where a univalent complex $[Fe(bipy)_3]^+$ was considered to be formed, was purple and gave an ESR signal shown in Fig. 2. The g-value and the peak to peak width (ΔH_{msl}) were calculated to be 1.995_4 and 97 gauss, respectively. From the polarographic results and from the evidence that the intensity of this

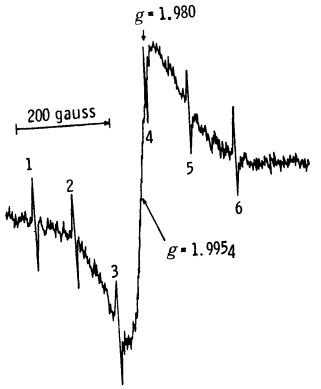

Fig. 2. ESR spectrum of the reduction product of $[Fe(bipy)_3](ClO_4)_2$ obtained by electrolysis at −1.45 V *vs.* aq. SCE. Signals of 1 to 6 are the hyperfine structures of Mn^{2+}.

signal did not change by the addition of excess free 2,2′-bipyridine, the signal of $g=1.995_4$ was considered to be due to $[Fe(bipy)_3]^+$.

It is known that most of the d^7 metal ions give g-values much greater than 2[5)]. Goodman and Raynor[6)], however, suggested that six-coordinated nominally d^7 spin-paired ion would give a low g-value if suitable π-bonded ligands were present with low-lying π^* orbitals available.

In the case of $[Fe(bipy)_3]^+$ which has a low g-value, therefore, it seems reasonable to consider that the iron exists as Fe^{2+} (d^6, spin-paired) and an unpaired electron is localized mainly on the ligand orbitals, because 2,2′-bipyridine possibly has low-lying vacant π^* orbitals.

On electrolysis at −1.70 V, where the formation of $[Fe(bipy)_3]$ was expected, black crystals grew up at the surface of the mercury electrode and the solution which was in contact with the crystals was purple. In this case, two ESR signals were observed; one had a g-value of 1.995_4 and the other, a g-value of 2.08 and ΔH_{msl} of about 800 gauss. The former signal was the same as that of $[Fe(bipy)_3]^+$, while the latter was found to coincide with that of $[Fe(bipy)_3]$ reported by Hall and Reynolds[7)]. These results seem to support that $[Fe(bipy)_3]$ was formed at the potential of the second wave and that $[Fe(bipy)_3]$ reacts with $[Fe(bipy)_3]^{2+}$ to form $[Fe(bipy)_3]^+$ in solution. The ESR signal of g-value of 2.08 suggested that $[Fe(bipy)_3]$ has the iron of d^8 configuration, although the optical spectrum of $[Fe(bipy)_3]$ obtained in 1,2-dimethoxyethane indicated that the unpaired electrons exist also in the ligand orbital.[7,8)]

The brown solution of reduction product generated by electrolysis at −2.10 V gave ESR spectrum with g-value of 1.995_4 and ΔH_{msl} of 14 gauss both in the absence and in the presence of free 2,2′-bipyridine as shown in Fig. 3.

The g-value found for this product did not coincide with the reported value of 2.0031 for the solid of $Na[Fe(bipy)_3]$,[8)] in spite of the expectation of the formation of $[Fe(bipy)_3]^-$ complex at this potential. The dif-

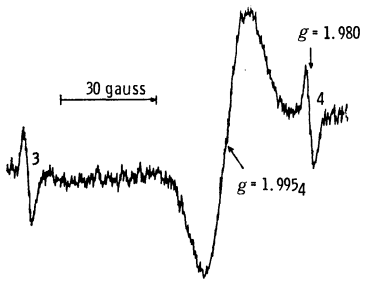

Fig. 3. ESR spectrum of the reduction product of $[Fe(bipy)_3](ClO_4)_2$ obtained by electrolysis at −2.10 V *vs.* aq. SCE. Signals of 3 and 4 are the hyperfine structures of Mn^{2+}.

ference between the observed *g*-value and the reported one is now under consideration.

The fact that, at the beginning of electrolysis at −2.10 V, ESR spectra with *g*-values of 1.995_4 and 2.08, which corresponded to those of $[Fe(bipy)_3]^+$ and $[Fe(bipy)_3]$ respectively, were also obtained seems to support proportionation reactions between the products and the parent complex taking place.

At −2.40 V, the formation of two kinds of reduction products was observed. One was the same as the product obtained by electrolysis at −2.10 V and the other was considered to be bipyridine anion radical from its *g*-value. Only the latter signal increased its intensity by continued electrolysis. This supports that bipyridine and/or its anion radical were formed by the dissociation of the reduction product such as $[Fe(bipy)_3]^{2-}$ either at the electrode surface or in the solution. Bipyridine anion radical was obtained in acetonitrile by electrolysis of 2,2′-bipyridine at −2.40 V and gave ESR spectrum with *g*-value of 2.003_6 and ΔH_{msl} of 7.5 gauss.

In conclusion, it should be emphasized that the observations mentioned above are in a sharp contrast with those in aqueous solutions, because in aqueous solutions the complexes of low oxidation states such as $[Fe(bipy)_3]^+$ and $[Fe(bipy)_3]^-$ are considered not to be formed electrochemically either at the electrode surface or in the solution.

(Received March 14, 1973)

The synthesis[1,3] of the sugar analogs, in which the ring oxygen is replaced by phosphorus, is intriguing, not only from the point of view of the chemistry, but also from that of biochemistry. In the present paper we will report on the syntheses of 5-deoxy-5-(ethylphosphonyl)-3-*O*-methyl-D-xylopyranose (IVa) and 5-(butylphosphonyl)-5-deoxy-3-*O*-methyl-D-xylopyranose (IVb).

Result and Discussion

As a starting material, we used 5-bromo-5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose (I).[4] Ethyl ethyl-(5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose-5)-phosphinate (IIa) and ethyl butyl-(5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose-5)-phosphinate (IIb) were obtained almost quantitatively by the Michaelis-Arbuzov reaction of I with diethyl ethylphosphonite and diethyl butylphosphonite respectively. The reduction of IIa and IIb with sodium bis(methoxyethoxy) aluminum hydride (Red Al) in tetrahydrofuran (THF) gave a syrup of ethyl-(5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose-5)-phosphine oxide (IIIa, 97%) and butyl-(5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose-5)-phosphine oxide (IIIb, 77%) respectively. The PMR spectrum of IIIa (IIIb) in chloroform-*d* showed a characteristic J_{P-H} value[5] of 458 Hz at τ 3.08 (459 Hz at τ 3.07); it disappeared on deuteration. The IR spectrum of IIIa (IIIb) showed the absorption of a P–H group at 2320 cm^{-1} (2310 cm^{-1})[6] and that of a P=O group at 1240 cm^{-1} (1240 cm^{-1}).[7]

The hydroysis of IIIa (IIIb) with diluted hydrochloric acid (3 N) in water at 80—100 °C for 6 hr afforded a syrup of IVa (IVb) in a 61% (65%) yield. The studies of PMR (D_2O and DMSO-d_6) and the IR spectra of IVa (IVb) showed that IVa (IVb) had three OH groups and no P–H group. Moreover, the acetyla-

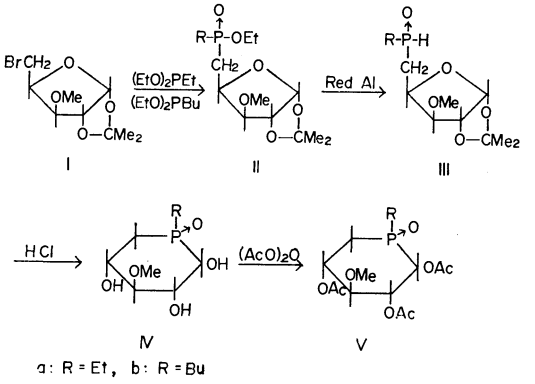
tion of IVa (IVb) with acetic anhydride in pyridine gave, in good yields, crystals of the tri-*O*-acetylated compound, Va (Vb), the PMR data and elemental analysis of which showed that Va (Vb) was 1,2,4-tri-*O*-acetyl-5-deoxy-(ethylphosphonyl)-3-*O*-methyl-D-xylopyranose [1,2,4-tri-*O*-acetyl-5-(butylphosphonyl)-5-deoxy-3-*O*-methyl-D-xylopyranose]. Therefore, IVa and IVb must be 5-deoxy-5-(ethylphosphonyl)-D-xylopyranose and 5-(butylphosphonyl)-5-deoxy-D-xylopyranose respectively.



Experimental

The melting points were determinted by means of a Yanagimoto micro melting point apparatus. The infrared spectra were mesured on a Hitachi EPI-G-2 grating spectrophotometer. The nuclear magnetic resonance spectra were taken at 60 MHz on a Hitachi R-2 spectrometer, using tetramethylsilane as the internal or external standard. Thin-layer chromatography (tlc) was carried out on microscope slides coated with silica gel,[8] using ethyl acetate–petroleum ether ((1:1 v/v) (A); (3:7 v/v (B)) and methanol–chloroform ((1:7 v/v) (C)), and the spots were visualized with a sulfuric acid–ethanol solution (10%).

Ethyl Ethyl-(5-deoxy-1,2-O-isopropylidene-3-O-methyl-α-D-xylofuranose-5)-phosphinate (IIa). A mixture of 5-bromo-5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose (6 g) and diethyl ethylphosphonite (15 ml) was refluxed under nitrogen for 6 hr at 130—145 °C. During the reaction, diethyl ethylphosphonite (2 ml) was added several time. The excess of the phosphonite was then distilled *in vacuo* to give colorless needles of IIa (6.9 g, an almost quantitative yield), which was sufficiently pure for the subsequent conversion; mp 67.5—70.0 °C (from ethyl acetate–*n*-hexane (1:4 v/v); R_f (Solvent B) 0.2; $[\alpha]_D^{12}$ −50° (*c* 6.2, chloroform); IR (KBr): 1240 cm^{-1} (P=O); PMR ($CDCl_3$): τ 4.20 (1H, d, $J_{1,2}$= 4 Hz, H-1), 4.45 (1H, d, overlapping with H-4, H-2), 5.97 (2H, q, $POCH_2$–), 6.35 (1H, t, H-3), 6.63 (3H, s, OCH_3).

Found: C, 50.04; H, 8.51%. Calcd for $C_{13}H_{25}O_6P$: C, 50.64; H, 8.17%.

Ethyl Butyl-(5-deoxy-1,2-O-isopropylidene-3-O-methyl-α-D-xylofuranose-5)-phosphinite (IIb). Compound I (5.5 g) was treated with diethyl butylphosphonite as has been described above to give crystals pf IIb in an almost quantitative yield: mp 45.0—46.0 °C (from ethyl acetate–*n*-hexane (1:5 v/v)); $[\alpha]_D^{19}$ −39° (*c* 1.1, chloroform); IR (KBr): 1240 cm^{-1} (P=O); PMR ($CDCl_3$): τ 4.2 (1H, d, $J_{1,2}$=4 Hz, H-1), 5.45 (1H, d, overlapping with H-4, H-2), 5.95 (2H, q, P–OCH_2–), 6.34 (1H, t, H-3), 6.60 (3H, s, OCH_3).

Found: C, 52.39; H, 9.08%. Calcd for $C_{15}H_{29}O_6P$: C, 53.56; H, 8.68%.

Ethyl-(5-deoxy-1,2-O-isopropylidene-3-O-methyl-α-D-xylofuranose-5)-phosphine Oxide (IIIa). To IIa (2.2 g) in THF (150 ml) Red Al (70% benzene solution) (2.8 g) in THF (100 ml) was added under a nitrogen atmosphere in an iced-salt bath for 30 min. After 1 hr's stirring at room temperature, the reaction mixture was neutralized with hydrochloric acid in THF and a few drops of water were added. The filtration and evaporation of the filtrate gave a syrup of IIIa (1.8 g, 97%) which was sufficiently pure for the subsequent conversion. An analytical sample was obtained by tlc separation; R_f 0.05 (Solvent A): $[\alpha]_D^{19}$ −44°[9] (*c* 2.9, chloroform); IR (KBr); 2320 cm^{-1} (P–H), 1240 cm^{-1} (P=O); PMR ($CDCl_3$): τ 3.08 (1H, *m*, disappearing on deuteration, J_{P-H}=458 Hz, P–H), 4.18 (1H, d, $J_{1,2}$=4 Hz, H-1), 5.41 (1H, d, overlapping with H-4, H-2), 6.32 (1H, t, H-3), 6.60 (3H, s, OCH_3).

Butyl-(5-deoxy-1,2-O-isopropylidene-3-O-methyl-α-D-xylofuranose-5)-phosphine Oxide (IIIb). Compound IIb (3.0 g) was treated as has been described above, and the reaction product was separated by silica gel-column chromatography (Solvent C) to give a syrup of IIIb (2.0 g, 77%): R_f 0.05 (Solvent C); $[\alpha]_D^{19}$ −43°[9] (*c* 4.3, chloroform); IR (KBr): 2310 cm^{-1} (P–H), 1240 cm^{-1} (P–O): PMR ($CDCl_3$): τ 3.07 (1H, *m*, disappearing on deuteration, J_{P-H}=459 Hz, P–H), 4.12 (1H, d, $J_{1,2}$= 4 Hz, H-1), 5.51 (1H, d, overlapping with H-4, H-2), 6.34 (1H, t, H-3), 6.65 (3H, s, OCH_3).

5-Deoxy-5-(ethylphosphonyl)-3-O-methyl-D-xylopyranose (IVa). A solution of IIIa (0.5 g) and concentrated hydrochloric acid (1.0 ml) in water (25 ml) containing small amounts of THF was heated at 80—100 °C under a nitrogen atmosphere. The THF was evaporated during the reaction. The hot solution was neutralized with silver carbonate; subsequent filtration and evaporation gave a colorless syrup of IVa (0.3 g, 71%); hydroscopic solid; R_f 0.20 (Solvent C): $[\alpha]_D^{14}$ 0.0° [9] (*c* 2.6, water); IR (KBr): 1240 cm^{-1} (P=O); PMR (D_2O): τ 6.40 (3H, s, OCH_3), 7.3—9.5 (7H, m, H-5,5′, P–C_2H_5); (DMSO-d_6): τ 6.0—7.0 (8H, m, three of them disappearing on deuteration).

5-(Butylphosphonyl)-5-deoxy-3-O-methyl-D-xylopyranose (IVb). Compound IIIb (1.0 g) was treated as has been described above to give a hydroscopic solid of IVb (0.5 g, 65%); R_f 0.20 (Solvent C); $[\alpha]_D^{17}$ 0.0° [9] (*c* 3.4, water); IR (KBr): 1240 cm^{-1} (P=O); PMR (DMSO-d_6): τ about 6.4 (4H, three of them disappearing on deuteration), 6.72 (3H, s, OCH_3), 7.8—9.8 (11H, m, H-5,5′, P–C_4H_9).

1,2,4-Tri-O-acetyl-5-deoxy-5-(ethylphosphonyl)-3-O-methyl-D-xylopyranose (Va). The treatment of IVa (0.30 g) with acetic anhydride in pyridine in the usual way gave a colorless solid (0.44 g, 94%); R_f 0.95 (Solvent C); mp 227—229 °C (from ethanol); $[\alpha]_D^{17}$ 0.0 ° (*c* 0.87, chloroform); IR (KBr): 1240 cm^{-1} (P=O); PMR ($CDCl_3$); τ 4.5—5.1 (3H, m), 6.57 (3H, s, overlapping with one proton, OCH_3(, 7.90, 7.94, 7.95 (9H, s, 1,2,4-$OCOCH_3$).

Found: C, 47.95; H, 6.85%. Calcd for $C_{14}H_{28}O_8P$: C, 48.00; H, 6.62%.

1,2,4-Tri-O-acetyl-5-(butylphosphonyl)-5-deoxy-3-O-methyl-D-xylopyranose (Vb). Compound IVb (0.50 g) was treated as has been described above to give crystals of Vb (0.70 g, 93%); R_f 0.95 (Solvent C); mp 218.5—220 °C; $[\alpha]_D^{17}$ −8.1° (*c* 4.2, chloroform); IR (KBr): 1240 cm^{-1} (P=O); PMR ($CDCl_3$): τ 4.1—5.1 (3H, m), 6.50 (3H, s, overlapping with one protone, OCH_3), 7.86, 7.92, 7.95 (9H, s, 1,2,4-$OCOCH_3$).

Found: C, 50.47; H, 7.43%. Calcd for $C_{16}H_{27}O_8P$: C, 50.79; H, 7.19%.

8) Silica-Layer G-10, Nakarai Chemicals, Ltd.

9) This sample seemed to be fairly pure from the observation of its PMR spectrum and tlc, but it was not enough pure for an elemental analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3303—3304 (1973)

The Formation of Carbon-Carbon and Carbon-Oxygen Bonds in the Oxidation of Enolizable Ketones with Iron(III) Chloride

Hiroo INOUE, Yoshikazu KIMURA, and Eiji IMOTO

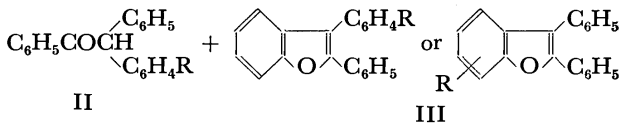
Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received April 11, 1973)

We have recently reported that the oxidation of enolizable alkyl aryl ketones with iron(III) chloride brings about carbon-carbon coupling and/or the chlorination of the α-methylene group.[1] Here we undertook the study of the heterogeneous oxidation of benzyl phenyl ketone (I) with iron(III) chloride in benzene and chlorobenzene. As a result, we found that the reaction differs from those of alkyl aryl ketones and results in the direct arylation of the α-methylene group by a two-electron oxidation. Furthermore, it was found that ring closure by carbon-oxygen coupling occurs in the oxidation of the arylation product (II) with two phenyl groups at the α-position of the carbonyl group.

$$C_6H_5COCH_2C_6H_5 + C_6H_5R \xrightarrow{FeCl_3}$$

I a: R=H b: R=Cl



II III

When a solution of I in benzene containing dispersed iron(III) chloride was refluxed for several hours, the I was converted to 2,2-diphenylacetophenone (IIa) and 2,3-diphenylbenzofuran (IIIa) was formed. Iron(III) chloride was reduced to iron(II) chloride. The nuclear chlorination did not occur at all. The irradiation of a solution of I in benzene in the presence of iron(III) chloride also gave IIa, along with a small amount of IIIa, although I undergoes photolysis to 1,2-diphenylethane, benzaldehyde, and 1,2,3,4-tetraphenyl-1,4-butanedione in the absence of iron(III) chloride.[2] The results are shown in Table 1. The addition of a small amount of water to the reaction system did not have any significant effect on the reaction pathway.

TABLE 1. THE OXIDATION OF I WITH IRON(III) CHLORIDE IN BENZENE OR CHLOROBENZENE[a]

Solvent	Therm. or *hv*	Reaction time hr	Yield of product, % II	Yield of product, % III	Recovery %
C_6H_6	Reflux	7	83	7	7
C_6H_6[b]	Reflux	7	72	8	11
C_6H_6	*hv*	2.5	33	0.2	53
C_6H_5Cl	Reflux	7	60[c]	—	19

a) The amount of $FeCl_3$: 1.02 mmol in 5 ml of the solvent. The concentration of I: 10^{-1} mol/l. The amounts of the products were determined by glc.

b) Water was added into the reaction system (the molar ratio of $H_2O/FeCl_3$: 1.3).

c) This is the yield of the *p*-isomer.

When chlorobenzene was used as the solvent, the *p*-isomer of IIb was isolated by a treatment similar to that used in the case of benzene (Table 1). However, the *o*- and *m*-isomers and IIIb could not be isolated because their yields were considerably lower than that of the *p*-isomer. The reaction of 2-chloro-2-phenylacetophenone (IV) with chlorobenzene in the presence of aluminum chloride at room temperature also gave the *p*-isomer of IIb in a 63% yield. Furthermore, the *p*-isomer has been prepared by the Friedel-Crafts reaction of benzoin with chlorobenzene in the presence of sulfuric acid.[3] These facts suggest strongly that the reaction proceeds *via* an intermediate (V) which is formed by a two-electron oxidation, followed by the reaction with the solvent, since, in the reaction of the α-keto radical formed by a one-electron oxidation, it is predicted that the yields of the *o*- and *m*-isomers will become higher. Such a process has been considered

$$I \xrightarrow{FeCl_3} \underset{V}{C_6H_5\overset{+}{C}OCHC_6H_5} \xrightarrow{C_6H_5R} II$$

in the oxidative dimerization of phenols with a variety of oxidants.[4] In the oxidation of alkyl aryl ketones with iron (III) chloride, we have reported that the homogeneous reaction results in the coupling of the α-keto radical, while, in the heterogeneous system, α-chlorination occurs by means of a two-electron oxidation.[1] Therefore, the fact that the arylation proceeds by a two-electron oxidation may be explained as resulting from the heterogeneous oxidation by iron(III) chloride. The phenyl group at the α-position of I must be required for the reaction of V with benzene, since the oxidation of propiophenone with iron(III) chloride in benzene resulted in only chlorination, without any arylation. This result agreed with the fact that 1-bromo-1-phenyl-2-propanone undergoes Friedel-Crafts reaction, 2-bromoacetophenone showing no reaction with benzene in the presence of aluminum chloride.[5]

$$C_6H_5COCH_2CH_3 \xrightarrow[C_6H_6]{FeCl_3} C_6H_5COCHCH_3 \quad (Cl)$$

On the other hand, IIIa was produced consecutively

from IIa by the oxidative ring closure with iron(III) chloride; when a solution of IIa in benzene containing iron(III) chloride was refluxed for 2 hr, IIIa was obtained in a 10% yield, with an 85% recovery of IIa, although IIIa was converted to a polymeric material in a longer reaction time. The arylation and chlorination at the α-position of the carbonyl group did not occur. The formation of IIIa indicates that the stereochemical conditions of IIa strongly favor the ring closure by carbon-oxygen coupling, as is shown in the syntheses of xanthones, which can be effected by oxidizing 2,3′-dihydroxybenzophenones with alkaline ferricyanide.[6]

Experimental

Materials. The I was prepared by the method described in the literature.[7] The anhydrous iron(III) chloride was prepared by the sublimation of commercial iron(III) chloride under a reduced pressure of 1 mmHg at 300 °C.

Oxidation of I with Iron(III) Chloride. A solution of 5 mmol of Ia in 30 ml of benzene or chlorobenzene containing 10.1 mmol of the dispersed anhydrous iron(III) chloride was refluxed for 7 hr, or was irradiated under stirring with a Pyrex-covered 100-W high-pressure mercury lamp at the distance of 6 cm under a nitrogen atmosphere at room temperature for 2.5 hr. Hydrogen chloride was generated during the reaction. After the reaction period, the precipitate, which contained mainly iron(II) chloride, was filtered off. The iron(II) chloride was confirmed spectrophotometrically by the *o*-phenanthroline method.[8] The filtrate was submitted to chromatography on alumina (elution with dry benzene), leading to the separation of IIa and IIIa. After removing the benzene, the residue (IIa or IIIa) was recrystallized from ethanol. The isolation of *p*-IIb was carried out according to the method used in the case of IIa, IIa (mp 134—136 °C (lit,[9] 136 °C)) exhibited NMR (CCl_4) signals at δ 5.87 (s, 1H, CH), and 7.16—7.98 (m, 15H, aromatic protons) and an IR (KBr plate) peak at 1675 cm^{-1} (CO). Mass *m/e*, 272 (parent peak). IIIa (mp 121—122 (lit,[10] 123 °C)) exhibited NMR (CCl_4) signals of aromatic protons at δ 7.04—7.60. Mass *m/e*, 270 (parent peak). *p*-IIb (mp 102—104 °C (lit,[3] 104 °C)) exhibited NMR (CCl_4) signals at δ 5.85 (s, 1H, CH) and 7.10—7.94 (m, 14H, aromatic protons) and an IR (KBr plate) peak at 1670 cm^{-1} (CO). Mass *m/e*, 305 and 306 (parent peaks).

Reaction of IV with Chlorobenzene in the Presence of Aluminum Chloride. A solution of 1.2 mmol of IV in 3 ml of chlorobenzene containing 1.4 mmol of the dispersed aluminum chloride was refluxed for 50 min. After the solution had then cooled to room temperature, *p*-IIb was isolated by a method similar to that used in the case of IIa; the amount was determined by glc.

Oxidation of Propiophenone with Iron(III) Chloride. A solution of 1.1 mmol of propiophenone in 3 ml of benzene containing 2 mmol of the dispersed anhydrous iron(III) chloride was refluxed for 22 hr. 2-Chloropropiophenone[1] was obtained in a 40% yield, along with the recovery of propiophenone. No other products were detected by glc at all.

Oxidation of IIa with Iron(III) Chloride. A solution of 0.3 mmol of IIa in 3 ml of benzene containing 0.6 mmol of the dispersed anhydrous iron(III) chloride was refluxed for 2 hr. The reaction mixture was submitted to glc analysis. IIIa was thus obtained in a 10% yield.

Analyses. The amounts of the products in the reaction mixture were determined by means of glc using a 3 mm × 1 m column of 30% high-vacuum silicon grease on Celite 545 (80—100 mesh).

Reaction of 4-Acetylsydnones

Hsien-Ju TIEN, Kazusato KANDA, Akiko CHINONE, and Masaki OHTA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received June 4, 1973)

Due to their unique mesoionic character, sydnones have been the subject of continued study since their discovery in 1935.[1] Although sydnones have been extensively investigated, little is known concerning the synthesis and reaction of 4-substituted sydnones. We reported the synthesis of 4-acetylsydnones by the reaction of sydnones with acid anhydrides in the presence of perchloric acid.[2] In this paper, we describe the reaction of 4-acetylsydnones whose structures are analogous to that of acetophenone.

Reaction of 4-acetyl-3-phenylsydnone (I) with benzaldehyde in the presence of alkali afforded 4-cinnamoyl-3-phenylsydnone (III), and 4-acetyl-3-benzylsydnone (II) reacted with benzaldehyde to give α-(4-cinnamoylsydnon-3-yl)stilbene (IV). 4-(Bromoacetyl)-3-phenylsydnone (V) and 3-benzyl-4-(bromoacetyl)sydnone (VI) were obtained by the reaction of I and II with bromine, respectively, in chloroform under irradiation of visible light. Corresponding dibromoacetyl derivatives, VII and VIII, were obtained when the above reaction was carried out in the presence of two equivalents mole of bromine. However, tribromoacetyl derivatives were not obtained even in the presence of three equivalents

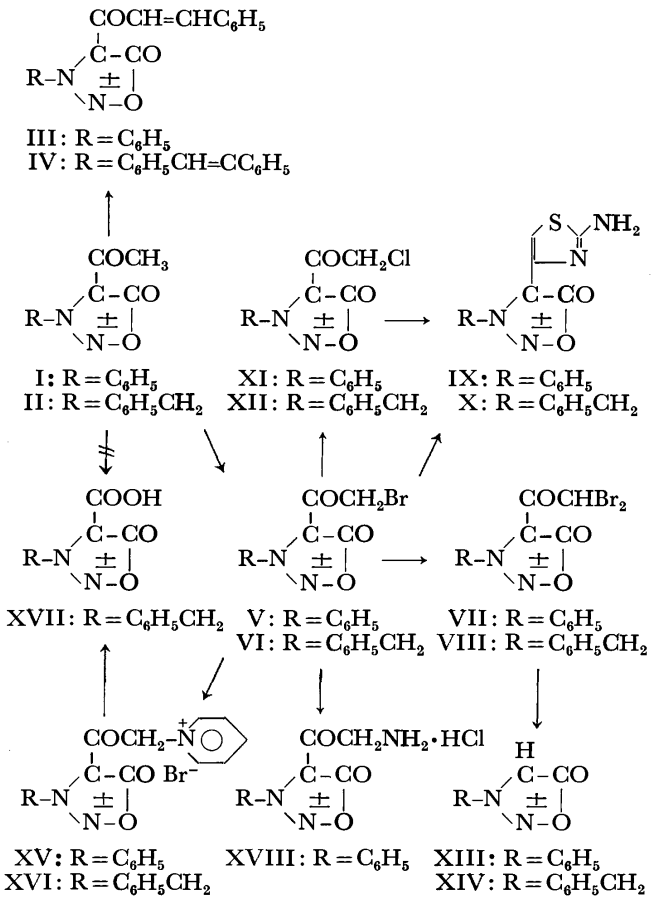
mole of bromine. Compound V reacted with thioures to give sydnone-substituted thiazole derivative IX, and VI afforded X. Treatment of V and VI with calcium chloride in DMSO afforded chloroacetyl derivatives, XI and XII, which reacted with thiourea to give IX and X, respectively. Haloform reaction of neither I nor II proceeded, and resulted in a recovery of the starting material. Treatment of V with sodium hydroxide and bromine yielded 3-phenylsydnone (XIII). Brief heating of an aqueous sodium hydroxide solution of VII afforded XIII, and VIII yielded 3-benzylsydnone (XIV) by the same treatment. These results show that mono- and dibromoacetylsydnones are unstable to alkali. Pyridinium salts, XV and XVI, were obtained by treatment of V and VI with pyridine, respectively. Compound XVI afforded 3-benzylsydnone-4-carboxylic acid (XVII) by treatment with alkali, while XV did not afford corresponding carboxylic acid but 3-phenylsydnone was obtained. 4-(Aminoacetyl)-3-phenylsydnone hydrochloride (XVIII) was obtained by the reaction of V with hexamethylenetetramine followed by treatment with hydrochloric acid. 3-Benzyl-4-morpholinoacetylsydnone was obtained by treating VI with morpholine. The behavior of bromo derivatives and pyridinium salts toward alkali described above suggests that the substituents at position 3 and ω-position of side chain affect, to some extent, the mode of cleavage at bond a or b of  grouping.



Experimental

4-Cinnamoyl-3-phenylsydnone (III). Compound I (2.0 g) was suspended in an alkaline solution (sodium hydroxide 0.5 g, water 5 ml, ethanol 3 ml) and 1.0 g of benzaldehyde was added and the reaction mixture was stirred for 10 min at room temperature. The precipitates were collected and washed well with water and then with cold ethanol. Recrystallization from ethanol afforded yellow needles with a mp of 145—147 °C (yield 52%).

Found: C, 69.86; H, 4.11; N, 9.59%. Calcd for $C_{17}H_{12}O_3N_2$: C, 70.71; H, 4.20; N, 9.78%. IR: 1785, 1655, 1590, 1420, 1040 cm^{-1}.

α-(4-Cinnamoylsydnon-3-yl)stilbene (IV). Compound IV was prepared form II and benzaldehyde by the same method as mentioned above. Recrystallization from isopropyl alcohol afforded colorless prisms with a mp of 105—106 °C (yield 30%).

Found: C, 75.73; H, 5.14; N, 7.20%. Calcd for $C_{25}H_{18}O_3N_2$: C, 76.13; H, 4.60; N, 7.10%. IR: 1780, 1650, 1470, 1050, 1038 cm^{-1}.

4-Bromoacetylsydnones, V and VI. To a solution of I (2.0 g) in 30 ml of chloroform, 1.6 g of bromine was added under irradiation of visible light. After 15 min, the color of bromine bleached. The solvent was removed *in vacuo* and the residue was recrystallized from ethanol to give pale yellow crystals with a mp of 110—111 °C (yield 70%).

Found: C, 42.69; H, 2.76; N, 10.00%. Calcd for $C_{10}H_7O_3N_2Br$: C, 42.40; H, 2.47; N, 9.89%. IR: 3050, 2975, 2925, 1790, 1680, 1420, 1010, 770, 680 cm^{-1}.

By the same method, VI was obtained from 8.8 g of II and 6.4 g of bromine in 100 ml of chloroform. Recrystallization from ethanol gave colorless needles with a mp of 64.5—65.5 °C (yield 70%).

Found: C, 44.48; H, 3.06; N, 9.63%. Calcd for $C_{11}H_9O_3N_2Br$: C, 44.44; H, 3.06; N, 9.43%. IR: 3000, 1780, 1760, 1660, 1465, 1035, 735, 705 cm^{-1}.

4-(Dibromoacetyl)sydnones, VII and VIII. To a solution of I (5.0 g) in 100 ml of chloroform, a little portion of chloroform solution of bromine (9.0 g/60 ml) was added under irradiation of visible light. After the initiation of the reaction, residual bromine solution was added dropwise and the solution was refluxed by heating with the tungsten lamp for 1 hr. During the irradiation, evolved hydrogen bromide was repelled by the stream of N_2. The solvent was removed *in vacuo* to give oily residue, to which a small amount of petroleum ether was added to crystallize. Reprecipitation of VII from a benzene solution with *n*-hexane afforded pale yellow prisms with a mp of 86—87 °C (yield 67%).

Found: C, 33.47; H, 1.86; N, 7.52%. Calcd for $C_{10}H_6O_3N_2Br_2$: C, 33.17; H, 1.66; N, 7.74%. IR: 1785, 1690, 1420, 1005, 770 cm^{-1}.

By the same method, VIII was prepared from 2.2 g of II and 3.2 g of bromine. Reprecipitation from a benzene solution with *n*-hexane afforded colorless needles with a mp of 80.5—81.5 °C (yield 80%).

Found: C, 35.11; H, 2.13; N, 7.45%. Calcd for $C_{11}H_8O_3N_2Br_2$: C, 35.25; H, 2.19; N, 7.57%. IR: 3000, 1760, 1682, 1470, 1000, 705 cm^{-1}.

Reaction of V with Thiourea. A solution of 1.4 g of V and 0.4 g of thiourea in 20 ml of ethanol was refluxed for 10 min. The precipitates were collected by filtration and dissolved in dilute ethanol (1: 1) and the solution was neutralized with sodium hydrogen carbonate. The precipitates were recrystallized from ethanol to give IX as yellow needles with a mp of 181—182 °C (yield 70%).

Found: C, 50.68; H, 3.13; N, 21.79; S, 12.10%. Calcd for $C_{11}H_8O_2N_4S$: C, 50.77; H, 3.08; N, 21.54; S, 12.31%.

IR: 3425, 3280, 3150, 1750, 1630, 1215 cm^{-1}.

Reaction of VI with Thiourea. Compound VI was treated with thiourea as mentioned above to give X. Recrystallization from ethanol gave X as yellow needles with a mp of 125—127 °C (yield 66%).

Found: C, 52.39; H, 3.73; N, 20.42; S, 11.98%. Calcd for $C_{12}H_{10}O_2N_4S$: C, 52.55; H, 3.65; N, 20.44; S, 11.68%. IR: 3375, 3295, 3200, 3120, 1745, 1730, 1620, 1520, 1325, 1180 cm^{-1}.

4-(Chloroacetyl)sydnones, XI and XII. Compound V (2.8 g) was dissolved in 20 ml of DMSO which was saturated with calcium chloride, and the solution was allowed to stand at room temperature for 48 hr. The reaction mixture was poured into ice-water and the precipitates were collected. Recrystallization from ethanol afforded colorless plates with a mp of 127—129 °C.

Found: C, 50.18; H, 2.94; N, 11.76%. Calcd for $C_{10}H_7O_3N_2Cl$: C, 50.31; H, 2.94; N, 11.74%. IR: 3060, 2990, 2945, 1790, 1775, 1693, 1280 cm^{-1}. NMR τ ($CDCl_3$) 2.15—2.60 (m, 5H), 5.33 (s, 2H).

By the same method, XII was prepared from VI and calcium chloride. Recrystallization from ethanol afforded colorless needles with a mp of 67—70 °C (yield 24%).

Found: C, 52.21; H, 3.59; N, 11.18%. Calce for $C_{11}H_9O_3N_2Cl$: C, 52.27; H, 3.56; N, 11.09%. IR: 1798, 1765, 1690, 1680, 1448, 1385, 1268, 1010 cm^{-1}.

Pyridinium Salt of VI (XVI) and 3-Benzylsydnone-4-carboxylic Acid (XVII). Compound VI was dissolved in 17 ml of pyridine and precipitates separated in a few minutes. Ether (30 ml) was added to the reaction mixture and precipitates were collected and recrystallized from ethanol, mp above 300 °C (yield 27%).

Found: C, 51.24; H, 3.87; N, 11.10%. Calcd for $C_{16}H_{14}O_3N_3Br$: C, 51.06; H, 3.72; N, 11.17%. IR 1780, 1675, 1635, 1480, 1005 cm^{-1}.

Pyridinium salt (0.75 g) thus obtained was added to a sodium hydroxide solution (sodium hydroxide 0.4 g, water 15 ml), and the solution was heated at 50 °C for 10 min. After filtering off the precipitates, filtrate was made acidic to Congo red with concentrated hydrochloric acid and kept to stand overnight at room temperature. Separated oily product was dissolved in methanol and treated with activated charcoal. Solvent was removed *in vacuo* to give XVII as colorless crystals. Recrystallization from hot water afforded colorless needles with a mp of 154—156 °C (yield 11%, calcd from pyridinium salt).

Found: C, 54.16; H, 3.81; N, 12.85%. Calcd for $C_{10}H_8O_4N_2$: C, 54.55; H, 3.64; N, 12.73%. IR: 3100—2500 (br), 1825 (sh), 1785, 1680, 1500, 1493, 1220, 1100 cm^{-1}.

Pyridinium Salt of V (XV) and its Treatment with Alkali. Compound XV was prepared from V and pyridine as mentioned above. Recrystallization from 90% ethanol afforded XV as pale yellow crystals with a mp of 226—228 °C (dec.).

Found: C, 49.49; H, 3.31; N, 11.45%. Calcd for $C_{15}H_{12}O_3N_3Br$: C, 49.72; H, 3.31; N, 11.60%. IR: 3025, 3010, 1780, 1685, 1640, 1492, 1470, 1435, 1015, 755, 685 cm^{-1}.

Pyridinium salt (1.8 g) thus obtained was heated at 50—60 °C in an alkaline solution (sodium hydroxide 1 g, water 30 ml) for 10 min. Precipitates were collected and washed with water. Recrystallization from ethanol gave 0.3 g of 3-phenylsydnone.

4-(Aminoacetyl)-3-phenylsydnone hydrochloride (XVIII). To a chloroform solution of V (5.6 g/30 ml), a chloroform solution of hexamethylenetetramine (2.8 g/30 ml) was added and the reaction mixture was stirred for 24 hr at room temperature. Precipitates were collected and washed with chloroform. The precipitates were added to ethanol–concentrated hydrochloric acid (20—8.5 ml) and the solution was stirred for 3 days at room temperature. In the course of stirring, precipitates were dissolved completely and then the reaction product separated out. Precipitates were collected and stirred for 10 min in 10 ml of water. Recrystallization from methanol gave XVIII, mp 180 °C (yield 78%).

Found: C, 46.68; H, 4.11; N, 16.11%. Calcd for $C_{10}H_{10}O_3N_3Cl$: C, 46.86; H, 3.91; N, 16.41%. IR: 3000—2850 (br), 1790, 1690 cm^{-1}.

3-Benzyl-4-morpholinoacetylsydnone. To a chloroform solution of VI (3.0 g/20 ml), a chloroform solution of morpholine (1.75 g/20 ml) was added under cooling with ice-water and the reaction mixture was kept at low temperature for 2 hr. Precipitates were filtered off and filtrate was concentrated *in vacuo*. Resulted oily product was dissolved in benzene and precipitates were filtered off. The benzene solution was concentrated and a small amount of petroleum ether was added to crystallize. Reprecipitation from acetone solution with ether afforded orange prisms with a mp of 121—123 °C (yield 97%).

Found: C, 59.62; H, 5.68; N, 13.71%. Calcd for $C_{15}H_{17}O_4N_3$: C, 59.39; H, 5.65; N, 13.86%. IR: 2955, 2875, 1840, 1770, 1755, 1673, 1432, 1110, 985, 710 cm^{-1}.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3307—3308 (1973)

The Diels-Alder Reaction of 1,3,5-Cycloheptatriene with Thiobenzophenone

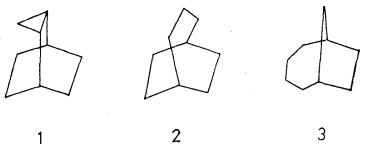
Yutaka OHNISHI, Yutaka AKASAKI, and Atsuyoshi OHNO

Sagami Chemical Research Center, 4-4-1 Nishiohnuma, Sagamihara-shi, Kanagawa 229

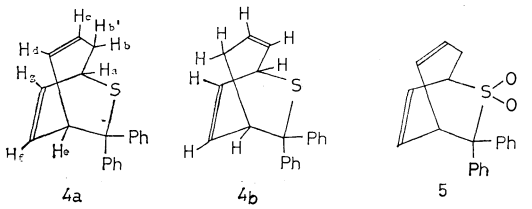
(Received June 11, 1973)

1,3,5-Cycloheptatriene (CHT) is known to undergo the Diels-Alder reaction with various dienophiles. In most cases, the structure of the adduct thus formed has tricyclo[3.2.2.$0^{2,4}$]nonane skeleton, **1**, instead of simple (2+4) cycloadduct, **2**.[1-4] There are two exceptions, one of which is the cycloadduct of CHT with nitrosobenzene and the other is that of CHT with acrolein. The structure of the former cycloadduct was initially thought to have **2**-type skeleton, but recently it was re-examined and found to have **3**-type skeleton, or a (2+6) cycloadduct.[5] The latter adduct, which was formed in minor (~10%) yield along with major (~30%) tricyclic **1**-type adduct, is believed to have a skeleton of **2**-type, but, unfortunately, the position of the formyl group in this adduct was not determined because its formation was confirmed after hydrogenation.[6]

We have found that the Diels-Alder reaction of CHT with thiobenzophenone affords **2**-type cycloadduct with regiospecificity.[7] Regiospecific formation of a bicyclic Diels-Alder adduct from unsubstituted CHT has never been reported in earlier papers.



1 2 3



4a 4b 5

Results and Discussion

Thiobenzophenone does not react with CHT at room temperature without light.[8] However, from the reaction mixture at 90—100 °C, the Diels-Alder adduct, **4a**, was isolated in 40% yield along with some unidentified materials. The structure of **4a** was confirmed by the 100 MHz NMR spectrum (Fig. 1) with the decoupling technique and by the oxidation to the corresponding sulfone, **5**.

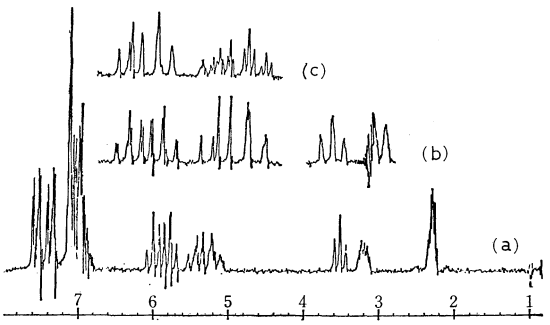


Fig. 1. The NMR spectra of (a) 6,6′-diphenyl-7-thiabicyclo-[3.2.2]nona-3,8-diene, **4a**, in benzene-d_6; (b) that with irradiation at H_b; and (c) that with irradiation at H_a. Spectra (b) and (c) are recorded with doubled scale.

The spectrum is consistent with the structure **4**, but inconsistent with any those of other cycloadducts. Although structures **4a** and **4b** are possible for the adduct, the former structure is prefered over the latter by the following reason; in **4b**, the phenyl ring at the *exo*-position should cause larger difference than that observed here in the chemical shift of signals due to H_b and H_b'. Namely, the signal at δ 2.30 in benzene-d_6 appears as an AA′XY-type multiplet. The double irradiation at the resonance positions of H_a and H_c simplifies this signal to an AA′-type quartet. Contrary the spectrum of **5** shows the large difference in chemical shifts of H_b (δ 3.13 in $CDCl_3$) and H_b' (δ 2.38 in $CDCl_3$). In addition, the signal from H_a (δ 3.94 in $CDCl_3$) in the sulfone appears at more down-field than that from H_a (δ 3.65 in $CDCl_3$) in the sulfide and the reverse is true for H_e protones in the sulfide and sulfone.

It is known that thiobenzophenone is a good dienophile.[9] The formation of the tricyclic Diels-Alder adducts from CHT is accounted for by two ways: the one proposes lower reactivity of CHT than that of norcaradiene, which is in equilibrium with the triene.[10,11] The other, based on kinetics, prefers to propose C_2–C_7 bond formation at the transition state of the cycloaddition from CHT itself.[12] Although we cannot discuss the mechanism of the cycloaddition in

detail,[13] the present result suggests that the existence of reactive norcaradiene, if any, does not necessarily mean the formation of tricyclic Diels-Alder cycloadducts.

Experimental

Reaction of Thiobenzophenone with CHT. A mixture of thiobenzophenone (1.0 g) and CHT (15 ml) in an ampoule was degassed and sealed. The sample was heated at the temperature of boiling water until complete decolorization of thiobenzophenone took place (2.5 days). After excess CHT had been evaporated, the residue was chromatographed on a column of silica gel with elution by a mixture of *n*-hexane and benzene (4: 1 v/v). The first elution gave 0.26 g of unidentified material. From the second elution 0.67 g of crystals were obtained. Recrystallizations of crystals from a mixture of benzene and *n*-hexane gave **4a** in 40% yield; mp 170—172 °C.

The structure of **4a** was confirmed by the following data: NMR (δ from TMS, benzene-d_6)[14] 3.23 (H_a), 2.36 (H_b or H_b'), 2.23 (H_b' or H_b), 5.20 (H_c), 5.46 (H_d), 3.55 (H_e), 6.04 (H_f), 5.81 (H_g), and 6.8—7.7 (H_{ar}). Coupling constants (J_{xy}, Hz) 2.0 (ab), 3.2 (bc), 11.6 (cd), 8.0 (de), 7.0 (ef), 9.0 (fg), 6.0 (ag), 1.0 (eg), 1.0 (af), 18.0 (bb'). Irradiation at the resonance position of $H_b(H_b')$ made signals from H_a, H_c, and H_d to be broad doublet, doublet, and doublet of doublet, respectively, with no change for signals from H_e, H_f, and H_g. On irradiation at H_a, H_c appeared as double triplets, H_g as doublet, and H_f as doublet of doublet, but the signal from H_d did not change. Mass spectrum (*m/e*) 290 (M^+), 200, 199, 198 (Ph_2CS^+, base), 197, 121, 92, 91, and 77.

Found: C, 82.50; H, 6.34; S, 10.91%. Calcd for $C_{20}H_{18}S$: C, 82.50; H, 6.25; S, 11.40%.

Oxidation of 4a. A solution composed of **4a**, (100 mg) and two equivalents of *m*-chloroperbenzoic acid in 10 ml of dichloromethane was stirred for a day at room temperature. After working-up and recrystallizations from *n*-hexane–benzene, **5** was obtained in quantitative yield: mp 260 °C. IR: 1135 and 1305 cm^{-1}.

Found: C, 74.54; H, 5.66; S, 10.14%. Calcd for $C_{20}H_{18}O_2S$: C, 74.53; H, 5.63; S, 9.93%.

13) Note that thiobenzophenone has a heteropolar double bond and two-step mechanism is possible to this compound.

14) The spectrum in chloroform-*d* did not show well-resolved signals.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3308—3310 (1973)

Nuclear Magnetic Resonance Study of the Stereoisomeric 2-Oxazolidone and 2-Phenyl-2-oxazoline Derivatives of α-Amino-β-hydroxy Acids[1)]

Shuji FUTAGAWA,* Toshishige INUI,** and Tetsuo SHIBA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received June 19, 1973)

NMR studies on β-substituted α-amino acids have revealed that the coupling constant ($J_{\alpha\beta}$) between C_α–H and C_β–H is larger in *erythro* form than in *threo* form in case of β-methylleucine[2)] or isoleucine derivatives.[3)] However, it is well known that the value of the coupling constant in such >CH–CH< system is considerably effected by the environmental linkage. In fact, in our experiment for comparison of $J_{\alpha\beta}$ value of free α-amino-β-hydroxy acids, the relationship was found to be reversed, that is, *threo* form always showed the relatively larger value than *erythro* form as shown in Table 1.

Furthermore, the small differences in $J_{\alpha\beta}$ values observed in a group of α-amino-β-hydroxy acids may not allow its use for assignment of relative configurations, even if a pair of pure diastereoisomeric compounds is obtained.

Table 1. Chemical shifts and coupling constants of free α-amino-β-hydroxy acids in D_2O

$$\mathrm{R\text{-}CH(OH)\text{-}CH(NH_2)\text{-}CO_2H}$$

R	*threo*		*erythro*	
	H_α (ppm)	$J_{\alpha\beta}$ (Hz)	H_α (ppm)	$J_{\alpha\beta}$ (Hz)
CH_3	3.62	5.0	3.81	4.2
C_6H_5	3.88	4.5	4.83	4.2
CH_2CO_2H	3.70	4.1	3.92	3.8
$(CH_3)_2CH$–	a)		3.91	3.2
	4.05	5.0	4.10	4.6

a) Measurements of these values were impossible, since chemical shifts of H_α and H_β were overlapped.

Since the coupling constants in the aliphatic compounds as mentioned above are revealed as an average value contributed from relatively stable rotational isomers of each diastereomer, it is expected that a difference between J_{erythro} and J_{threo} could be enlarged if amino and hydroxy groups are fixed in an appropriate ring which prevents a free rotation of α-β carbon-carbon bond.

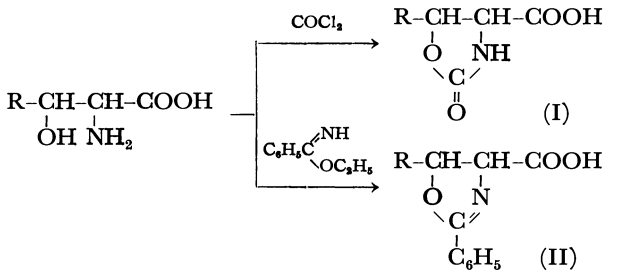
α-Amino-β-hydroxy acids were known to be cyclized either with phosgene or with iminoether to the corresponding 2-oxazolidone (I) or 2-phenyl-2-oxazoline (II) derivatives respectively without any configurational changes.[4] We prepared 2-oxazolidone derivative of six diastereoisomeric pairs of α-amino-β-hydroxy acids, *i.e.*, DL-threonine, β-phenyl-DL-serine, β-hydroxy-DL-glutamic acid, β-hydroxy-DL-aspartic acid, β-hydroxy-DL-leucine and β-furyl-DL-serine, the configurations of which are known definitely. We also synthesized the diastereoisomeric pairs of 2-phenyl-2-oxazoline derivative of DL-threonine, β-phenyl-DL-serine and β-hydroxy-DL-leucine.



The coupling constants $J_{\alpha\beta}$ measured for those derivatives are summarized in Tables 2 and 3. The

erthro form corresponds to *cis* H_α–H_β relationship concerning with the ring plane and *threo* form to *trans* one. The $J_{\alpha\beta}$ values for both isomers of 2-oxazolidone derivatives converged within narrow range as far as tested, that is, *cis* isomers are centered to 9.6±0.6 Hz and *trans* one to 5.0±1.0 Hz. Similar separation of $J_{\alpha\beta}$ values for *cis* and *trans* compounds are observed in cases of 2-phenyl-2-oxazoline derivatives.

Although the couplings in such heterocyclic systems cannot be satisfactorily explained,[5] the observed values in this experiment indicated that the configurational relationship of *threo* and *erythro* isomers of α-amino-β-hydroxy acids can be assigned undoubtedly by the analysis of NMR spectra of their 2-oxazolidone or 2-phenyl-2-oxazoline derivatives. Furthermore, formation and purification of 2-oxazolidone derivative from a small amount of the sample of α-amino-β-hydroxy acid can be carried out very easily. Therefore, this procedure will present a convenient and practical method for determination of configurational isomerism of α-amino-β-hydroxy acid.

A criterion on an advantage of this method was tested in the case where only one form of two diastereoisomeric isomers of α-amino-β-hydroxy acid was obtained. In our another synthetic study of the new amino acid, *i.e.* β-hydroxyornithine, first we obtained only one unknown form of its derivative.[6] Thus 5-(2-benzyloxycarbonylaminoethyl)-2-oxazolidone-4-carboxylic acid prepared from synthetic DL-β-hydroxyornithine showed the coupling constant $J_{\alpha\beta}$ of 9.0 Hz. From this single value, we assigned this isomer to ***cis***, namely, *erythro* form, and this conclusion was successfully applied to further synthetic study.[6] Later we could obtain the other form of DL-β-hydroxyornithine and its 2-oxazolidone derivative gave the expected value of $J_{\alpha\beta}$ of 5.2 Hz as *trans* type, namely, *threo* isomer.[6]

Experimental

The NMR spectrum was obtained at room temperature

with a Varian T-60 spectrometer at 60 MHz. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate was used as an internal reference in deuterium oxide solution and tetramethylsilane was used for tetradeuteromethanol and deuterochloroform solutions. The chemical shifts are expressed as ppm from the reference peak.

Preparation of 2-Oxazolidone Carboxylic Acid Derivatives of α-Amino-β-hydroxy Acid. α-Amino-β-hydroxy acid (30 mg) was dissolved in 1M potassium hydroxide solution (10 ml) and was cooled to 5 °C. Then, a solution of phosgene (1.5 g) in toluene (10 ml) was added all at once. After stirring for an additional hour, the aqueous layer separated from the toluene layer was acidified with concentrated hydrochloric acid and extracted three times with 10 ml portion of ethyl acetate. The combined extract was dried and evaporated to dryness. The residue was dissolved in CD_3OD and the solution was directly analyzed by NMR.

Preparation of 2-Phenyl-2-oxazoline Ester Derivatives of α-Amino-β-hydroxy Acid. α-Amino-β-hydroxy acid methyl ester hydrochloride (50 mg) was dissolved in ethanol (10 ml) in a 30 ml flask and mixed with a solution of benziminoethyl ether (1.0 g) in ethyl ether (5 ml). The mixture was stirred vigorously at 20 °C for 1 hr. After addition of water (10 ml), the reaction mixture was extracted three times with each 10 ml portion of ethyl ether, and then evaporated to dryness. The residue was dissolved in $CDCl_3$ and the solution was directly analyzed by NMR.

Synthesis of Dinucleoside Analog of Uracil-Uracil

Toru SEITA, Masayoshi KINOSHITA, and Minoru IMOTO*

Department of Applied Chemistry, Osaka City University, Sumiyoshi, Osaka 558

**Department of Applied Chemistry, Kansai University, Senriyama, Suita 564*

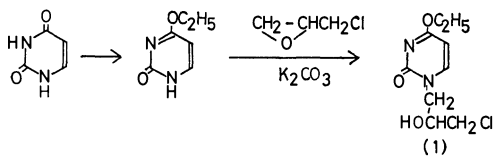
(Received June 21, 1973)

We have been attempted to prepare nucleic acid analogs in which the ribose or deoxyribose ring is replaced with an aliphatic moiety.[1-4] In order to study base-base interaction Browne, Eisinger, and Leonard[5] have studied the synthesis of dinucleotide analogs. On the other hand, Fecher *et al.*[6] synthesized the dinucleoside such as 5'-(9-adenyl)-5'-deoxy derivatives of thymidine.

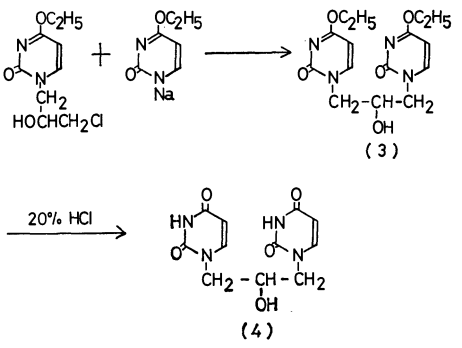
To extend this study, we have synthesized a new type dinucleoside analog of uracil-uracil.

1-(2'-Hydroxy-3'-chloropropyl)-4-ethoxy-2-pyrimidinol (**1**) was synthesized by the reaction of 4-ethoxy-2-pyrimidinol[7] with epichlorohydrin in dimethylformamide (DMF) containing potassium carbonate. The separation of product was accomplished by chromatography on silica gel using benzene–ethanol as solvent. The compound **1** was treated with 20% hydrochloric acid to give 1-(2'-hydroxy-3'-chloropropyl)uracil (**2**). Condensation of compound **1** with sodium salt of 4-ethoxy-2-pyrimidinol was carried out in DMF to give 1',3'-bis(1-4-ethoxy-2-pyrimidinol)-2'-propanol (**3**).

When compound (**3**) was treated with 20% hydrochloric acid at 85—90 °C 1',3'-bis(1-uracil)2'-propanol (**4**) was afforded in good yield.



Scheme 1.



Scheme 2.

The observed extinction coefficient of **4** was approximately the same value as that of 1',3'-bis(1-uracil)-trimethylene, $Ur(CH_2)_3Ur$, shown by Browne, Eisinger, and Leonard. The compound **4** showed a small blue shift of UV when compared with the compound **2**. The compound **4** will give many derivatives through the reaction of its 2'-hydroxy group. UV data were listed in Table 1.

Experimental

The melting points are uncorrected. The IR and UV spectra were measured by a JASCO Model IR-G Spectrometer and Hitachi Recording Spectrometer Model ESP-3T, respectively.

1-(2'-Hydroxy-3'-chloropropyl)-4-ethoxy-2-pyrimidinol (1). A mixture of 4-ethoxy-2-pyrimidinol (5.0 g, 36 mmol), epichlorohydrin (3.3 g, 36 mmol), and a trace of anhydrous potassium carbonate in DMF (80 ml) was stirred at 70—80 °C for 10 hr. After allowing to cool to room temperature the reaction mixture was filtered off and the filtrate was evaporated under the reduced pressure. 10 ml of ethanol was poured into the residue and kept in refrigerator overnight. The resulting white precipitate was filtered off and washed with excess ethanol. The filtrate and washing were combined, then evaporated and the oil residue was chromatographed on silica gel (Mallinckrodt). Elution with benzene–ethanol (4: 1) gave the product. The product was recrystallized from benzene to give the compound (**1**) (5.1 g (62%)) as colorless needles.

Mp 121—122 °C, UV; $\lambda_{max}^{H_2O}$ 275 mμ, IR (Potassium bromide) 3200 (OH), 1620 (4-ethoxy-2-pyrimidinol ring); Found: C, 46.22; H, 5.19; N, 11.65%. Calcd for $C_9H_{13}N_2O_3Cl$: C, 46.44; H, 5.63; N, 12.05%.

1-(2'-Hydroxy-3'-chloropropyl)uracil (2). Compound (**1**) (0.46 g, 2 mmol) was treated in 20% hydrochloric acid, evaporated and the residue was recrystallized from benzene–ethanol (4: 1) to give compound (**2**) (0.32 g (80%)) as colorless needles.

Mp 153—156 °C; IR (Potassium bromide): 3350 (OH), 1660 (Uracil ring); Found: C, 41.28; H, 4.88; N, 13.88%. Calcd for $C_7H_9N_2O_3Cl$: C, 41.07; H, 4.44; N, 13.70%.

1',3'-Bis(1-4-ethoxy-2-pyrimidinol)-2'-propanol (3). Mixture of compound (**1**) (3.36 g, 20 mmol) and sodium salt of 4-ethoxy-2-pyrimidinol (4.24 g, 20 mmol) was stirred in DMF at 70 °C for 2 days. The reaction mixture was filtered off and the filtrate was evaporated under reduced pressure. The resulting white precipitate was recrystallized from ethanol to give compound (**3**) (3.9 g (58%)) as colorless pales.

Mp 229—231 °C, IR (Potassium bromide); 3250 (OH), 1630 (4-ethoxy-2-pyrimidinol ring); Found: C, 53.05; H, 6.28; N, 16.37%. Calcd for $C_{15}H_{20}N_4O_5$: C, 53.55; H, 6.00; N, 16.66%.

1',3'-Bis(1-uracil)-2'-propanol (4). Compound (**3**) (3.36 g, 10 mmol) was stirred in 20% hydrochloric acid at 90 °C for one hour, evaporating to dryness. The white precipitate was recrystallized from water to give compound (**4**) (2.68 g, (92%)) as colorless needles.

Mp 139—142 °C, IR (Potassium bromide): 3250 (OH), 1660 (Uracil ring); Found: C, 46.68; H, 4.58; N, 19.67%. Calcd for $C_{11}H_{12}N_4O_5$: C, 47.13; H, 4.32; N, 20.00%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3311—3312 (1973)

A Facile Synthesis of Mellein

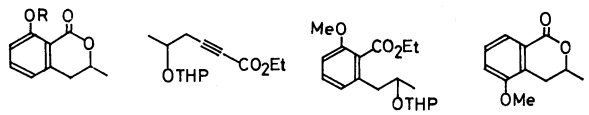
Yoshitsugu ARAI, Tadao KAMIKAWA, and Takashi KUBOTA*

Faculty of Science, Osaka City University, Sugimotocho, Sumiyoshi-ku, Osaka 558

(Received June 26, 1973)

The application of the Diels-Alder reaction to the preparation of 2,3-disubstituted phenols[1] from 1-methoxycyclohexa-1,4-diene and suitable dienophiles has now been extended to the synthesis of mellein (**1a**),[2] which had been isolated from the culture broth of *Aspergillus mellus*. In this paper we report a four-step synthesis of **1a**.

4-(2-Tetrahydropyranyloxy)pent-1-yne[3] was treated with *n*-butyllithium and ethyl chloroformate to give an ethyl ester (**2**). Heating the mixture of **2** and 1-methoxycyclohexa-1,4-diene in a sealed tube at 180 °C for 22 hr gave an aromatic ester (**3**; 73%), which, on base hydrolysis and acid treatment, gave (±)-mellein methyl ether (**1b**), [mp 67—68 °C], in 87% yield. Treatment of **1b** with boron tribromide gave (±)-mellein **1a**, [mp 38—38.5 °C], in 85% yield, which was identical in all respects (IR and NMR) with the authentic sample.[2]



(1a) R=H (1b) R=Me (2) (3) (4)

The minor product of the Diels-Alder reaction, after hydrolysis and acid treatment, was proved to be **4** from physical data.

Birch and Dastur found that dichloromaleic anhydride catalyzes the conversion of 1-methoxycyclohexa-1,4-diene into 1-methoxycyclohexa-1,3-diene.[4]

* Present address: Kinki University, Kowakae, Higashiosaka-shi, Osaka 577.

4) A. J. Birch and K. P. Dastur, *Tetrahedron Lett.*, **1972**, 4195.

Hoping the improvement of the yield, we have applied this reagent to the Diels-Alder reaction. Heating the mixture of 1-methoxycyclohexa-1,4-diene, **2** and dichloromaleic anhydride gave **1b** in one step in 48% yield.

Experimental

Ethyl 5-(2-Tetrahydropyranyloxy)-2-hexynoate (2). To a solution of 4-(2-tetrahydropyranyloxy)pent-1-yne (16.8 g) in 50 ml of abs. ether was added an ethereal solution of *n*-butyllithium (prepared from 17.13 g of *n*-butyl bromide and 2.15 g of lithium in 100 ml of abs. ether) at −70 °C in 15 min under argon atmosphere and the mixture was stirred for 15 min at this temperature. The mixture was gradually allowed to warm to −10 °C during 5 hr, then poured into ice-water and extracted with ether. The solvent was removed and the residue was distilled under reduced pressure to give **2** (14.5 g, 60%), bp. 112—112.5 °C/0.15 mmHg. ν_{max} (liquid film) 2240, 1715, and 1250 cm^{-1}.

The Ester (3). (a) A mixture of 2.4 g of 1-methoxycyclohexadienes (1,3- and 1,4- 1: 3), 2.4 g of **2** and 30 mg of *N*-phenyl-2-naphthylamine was heated at 180 °C for 22 hr in a sealed tube. The crude product was distilled under reduced pressure to give 0.54 g of the recovered ester (**2**) and 2.26 g (73%) of the ester (**3**), bp 125—127 °C/0.07 mmHg. ν_{max} (liquid film) 1730, 1600, 1585, and 1470 cm^{-1}. (b) A mixture of 10 g of 1-methoxycyclohexadienes, 13.8 g of **2**, 10 mg of dichloromaleic anhydride, and 100 mg of *N*-phenyl-2-naphthylamine was heated at 180 °C for 20 hr in a sealed ube. Fractional distillation under reduced pressure gave (±)-mellein methyl ether (**1b**) bp 112—113 °C/0.03 mmHg (5.2 g, 48%), which was recrystallized from ether–light petroleum to give colorless prisms, mp 67—68 °C (lit,[2] mp 66—67 °C).

(±)-Mellein Methyl Ether (1b). The ester (**3**; 3.27 g) was dissolved in 10 ml of 0.5 M methanolic sodium hydroxide solution and the solution was allowed to stand at room temperature for 48 hr. The mixture was acidified with 40 ml of 2 M hydrochloric acid and refluxed for 30 min. After removal of the organic solvent, the aqueous phase was extracted with chloroform. Evaporation of the extract gave an oil (2.64 g) which was chromatographed on silica gel. Elution with benzene–AcOEt (9: 1) gave **4** as colorless prisms, mp 85—86 °C (from $CHCl_3$–ether), (0.27 g, 13%). ν_{max} ($CHCl_3$) 1715, 1600, and 1590 cm^{-1}, δ ($CDCl_3$) 1.50 (d, 3H, *J* 5 Hz), 2.62 (dd, 1H, *J* 11, 17 Hz), 3.14 (dd, 1H, *J* 4, 17 Hz), 3.84 (s, 3H), 5.40 (m, 1H), 7.05 (dd, 1H, *J* 2, 8 Hz), 7.32 (t, 1H, *J* 8 Hz), and 7.70 (dd, 1H, *J* 1.5, 8 Hz). Found: C, 68.69; H, 6.31%. Calcd for $C_{11}H_{12}O_3$: C, 68.73; H, 6.29%.

Further elution with the same solvent mixture gave (±)-mellein methyl ether (**1b**), mp 67—68 °C, colorless prisms (from ether–light petroleum), (1.69 g; 87%).

(±)-Mellein (1a). To a cooled soln of BBr_3 (0.4 ml) in 10 ml of dry CH_2Cl_2 was added a soln of **1b** (192 mg) in 8 ml of dry CH_2Cl_2 (−70°) under atmosphere of argon. The mixture was gradually allowed to warm up to room temperature and kept overnight. The mixture was poured into ice-water and extracted with $CHCl_3$. Removal of the solvent gave (±)-mellein (**1a**) as crystals (151 mg, 85%), which was recrystallized from *n*-hexane to give colorless prisms, mp 38—38.5 °C (lit,[2] mp 37—38 °C). The IR and NMR spectra are identical with that of the published data.[2]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3312—3313 (1973)

Isolation and Characterization of a Yellow Pteridine from *Drosophila melanogaster* Mutant *sepia*

Katsura SUGIURA, Shinichiro TAKIKAWA,* Motoo TSUSUE,* and Miki GOTO

Department of Chemistry, Gakushuin University, Toshima-ku, Tokyo 171

**Biological Laboratory, Kitasato University, Sagamihara, Kanagawa 228*

(Received June 30, 1973)

It is well known that the wild type flies of *Drosophila melanogaster* have red and yellow eye-pigments and the mutant *sepia* has only yellow pigments, *i.e.* sepiapterin and isosepiapterin.[1-4] This paper describes the isolation and characterization of an additional pteridine compound from *D. melanogaster sepia*. On the basis of mass spectrum, UV spectra, NMR spectrum and chemical reactions, the structure of the third pteridine compound from the *sepia* flies was proved to be 6-acetyl-2-amino-4-hydroxy-7,8-dihydropteridine.

Experimental

Isolation of the Compound (sepiapterin C).[5-7] *D. melanogaster sepia* was reared in bottles at 25 °C with sterile yeast medium (1000 ml water, 50 g cane sugar, 9 g agar powder, 80 g dry yeast, and 5 ml propionic acid). Flies were harvested on the 1st, 5th, and 9th days after eclosion and stored at −20 °C until extraction.

The flies (50 g) were homogenized in a waring blender with 500 ml of 50% aqueous ethanol for 4 min. The homo-

5) The pteridines from the *sepia* flies are named as sepiapterin A, B, and C systematically, *i.e.*, sepiapterin: sepiapterin A; isosepiapterin: sepiapterin B; actually isosepiapterin is no isomer of sepiapterin.

genate was heated on a boiling water bath for 20 min. It was then centrifuged at 2000 g for 10 min. The extraction procedure was repeated two more times with 50% ethanol (each 400 ml). The supernatants were combined and concentrated to a small bulk at 30 °C. The solution was put on the top of a pH 7 ECTEOLA cellulose column (5 × 30 cm), and the column washed with distilled water. A yellow, a blue and a purple fluorescent bands were eluted, successively. The eluate of the first band (main band) was evaporated to a small bulk *in vacuo*. The solution was put on the top of a P-cellulose column (4 × 30 cm), which was then eluted with distilled water. The yellow fraction was separated into three bands; each band was eluted and the eluate evaporated to dryness *in vacuo*. The yellow compounds of the first and the second bands were identified as riboflavin and sepiapterin A, respectively, by means of paper chromatography and UV absorption spectra. The eluate of the third band contained two yellow compounds, which were separated by chromatography on a cellulose column (3 × 25 cm) using the solvent, 1-butanol, ethanol, water (2 : 1 : 1), The substance of the first band was sepiapterin B and that of the second sepiapterin C. The latter fraction was concentrated to dryness and further purified on a Sephadex column (3 × 28 cm, G-25, fine) (elution: 0.005% ammonia). The eluate was concentrated to dryness and the residue was crystallized from water to give yellow needles, yield, 0.3 mg. The sepiapterin contents (mg/50 g) in sepia flies were calculated from UV absorptions (values on the 1st, 5th, and 9th days after eclosion): sepiapterin A, 19.8, 34.4, 34.4; sepiapterin B, 0.36, 1.33, 1.87; sepiapterin C, 0.27, 0.36, 0.37.

Structure of Sepiapterin C. The mass spectrum was determined with a Nihondenshi JEOL-01SG mass spectrometer (a direct inlet system). The ionizing energy was 75 eV and the temperature of the ion source 120—200 °C. The UV spectra were determined using a Hitachi ESP-3 spectrometer and the NMR spectrum using a JEOL-C60 HL spectrometer.

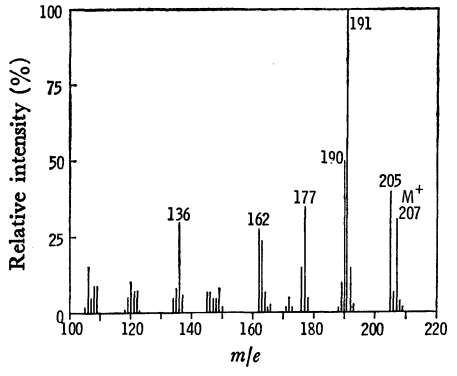

Fig. 1. Mass spectrum of sepiapterin C.

The molecular formula of sepiapterin C was determined to be $C_8H_9N_5O_2$ by mass spectrometry (M^+: 207.0774; Calcd for $C_8H_9N_5O_2$, 207.0754) (for mass spectrum, see Fig. 1). Sepiapterin C was proved to be a 6-substituted pterin, as its alkaline permanganate oxidation gives 6-carboxypterin. The formation of 2,4-dinitrophenylhydrazone showed the presence of a carbonyl group at the side chain. The UV-spectra of sepiapterin C are essentially identical with those of sepiapterin A and sepiapterin B (Fig. 2). From these evidences, the structure of 6-acetyl-2-amino-4-hydroxy-7,8-dihydropteridine was postulated for sepiapterin C.

This formulation was well supported by NMR spectrum and the fragmentation pattern of the mass spectrum (the fragmentations are summarized in Fig. 3; the fragment ion, *m/e* 191 remained to be clarified).[8] NMR (DMSO-d_6, 40 °C, TMS): 2.27 ppm (3H, singlet, $-CO-CH_3$), 4.05 (2H, singlet, $-CH_2-$), 6.62 (2H, singlet, $-NH_2$), 7.27 (1H, singlet, $-NH-$) and 9.96 (1H, singlet, $-NH-$); the signals of 6.62, 7.27, and 9.96 ppm disappeared with addition of D_2O. Finally, 6-acetyl-2-amino-4-hydroxy-7,8-dihydropteridine was prepared by the reaction of 7,8-dihydropterin and pyruvic acid.[9] The identity of the product with sepiapterin C was confirmed by means of paper chromatography, UV and mass spectral determinations. R_f-values of pteridines are summarized in Table 1.

A Note on the Kinetic Parameter Determination at the DME by Koutecký's Method

J. N. GAUR and S. K. BHARGAVA
Chemical Laboratories, University of Rajasthan, Jaipur, India

(Received May 24, 1973)

In Koutecký's[1,2] method the fundamental equation is

$$\frac{i_l}{i_d} = F(x) - \xi H_c(x) = F'(x) \tag{1}$$

where

$$x = K_f\left(\frac{12t}{7D}\right)^{1/2} \tag{2}$$

and

$$\xi = 50.4D^{1/2}m^{-1/3}t^{1/6} \tag{3}$$

i_l is the maximum instantaneous current of the single drop at the potential E, i_d is the maximum instantaneous current of the single drop in the limiting current region, $F(x)$ is a function related with the current at potential E to the current at infinity and $H_c(x)$ is a correction factor introduced because of the curvature of the drop. Koutecký has given a table of numerical values of $F(x)$ and $H_c(x)$ at particular value of x.

Meites and Israel[3] have extended this into a more mathematical form by using Koutecký's table. They found that $\log x$ varies linearly with $\log F(x)/\{1-F(x)\}$ as

$$\log\lambda = -0.1300 + 0.9163\log\frac{F(x)}{1-F(x)} \tag{4}$$

where for simplicity they have taken $\lambda=(7/12)^{1/2}x$ and they assume that diffusion at the electrode surface is linear. Then in Eq. (1) i_l/i_d is virtually equal to $F(x)$ so Eq. (4) can be written as

$$\log\lambda = -0.1300 + 0.9163\log\frac{i}{i_d-i} \tag{5}$$

Heterogeneous rate constant can be described by

$$K_{fh} = K^\circ_{fh}\exp\left(-\frac{\alpha nFE}{RT}\right) \tag{6}$$

on combining Eqs. (2), (5), and (6) yields

$$E_{d.e.} = \frac{0.05915}{\alpha n}\log\frac{1.349K^\circ_{fh}t^{1/2}}{D^{1/2}} - \frac{0.0542}{\alpha n}\log\frac{i}{i_d-i} \tag{7}$$

which may be written

$$E_{d.e.} = E_{1/2} - \frac{0.0542}{\alpha n}\log\frac{i}{i_d-i} \tag{8}$$

With

$$E_{1/2} = \frac{0.05915}{\alpha n}\log\frac{1.349K^\circ_{fh}t^{1/2}}{D^{1/2}} \tag{9}$$

In these equations both $E_{d.e.}$ and $E_{1/2}$ are referred to N.H.E.

Instead of Eq. (5) we find

$$\log\lambda = 0.0523 + 0.9619\log\frac{i}{i_d-i} \tag{10}$$

On combining Eqs. (2), (6), and (10) we obtain

$$E_{d.e.} = \frac{0.05915}{\alpha n}\log\frac{K^\circ_{fh}t^{1/2}}{1.128\times D^{1/2}} - \frac{0.05690}{\alpha n}\log\frac{i}{i_d-i} \tag{11}$$

which may be written

$$E_{d.e.} = E_{1/2} - \frac{0.05690}{\alpha n}\log\frac{i}{i_d-i} \tag{12}$$

with

$$E_{1/2} = \frac{0.05915}{\alpha n}\log\frac{K^\circ_{fh}t^{1/2}}{1.128\times D^{1/2}} \tag{13}$$

In deriving Eqs. (5) and (10) we have considered that diffusion to the electrode surface is linear, but if we consider spherical diffusion then we have to consider the second factor of Eq. (1) *i.e.* $\xi H_c(x)$. Values of $H_c(x)$ are given in the Koutecký's table and the value of ξ changes with capillary to capillary and also depends on the metal ion, solvent *etc.* In our laboratory[4,5] it has been found that the value of ξ lies between 0.05 to 0.25. Keeping this in view we have taken different values of ξ from 0.0 to 0.3 and calculated the value of $F'(x)$ for different values of ξ. We find that $\log x$ again varies linearly with $\log F'x/\{1-F'(x)\}$

TABLE 1. VALUES OF ξ, C, AND m

ξ	C	m
0.000	0.0523	0.9619
0.025	0.0606	0.9650
0.050	0.0679	0.9646
0.060	0.0711	0.9660
0.070	0.0745	0.9662
0.080	0.0778	0.9664
0.090	0.0815	0.9667

3) L. Meites and Y. Israel, *J. Amer. Chem. Soc.*, **83**, 4903 (1961).
4) D. S. Jain, Ph. D. Thesis, University of Rajasthan, Jaipur, India (1965).
5) N. K. Goswami, Ph. D. Thesis, University of Rajasthan, Jaipur, India (1967).

(For all values of ξ)

$$\log \lambda = C + m \log \frac{F'(x)}{1-F'(x)} \tag{14}$$

Different values of C and m at particular value of ξ are given in the Table 1. It is also found that the value of C increases as the value of ξ increases and a linear relation exists between ξ and C which can be represented as

$$C = 0.0523 + 0.3335\xi \tag{15}$$

Value of m also increases with the value of ξ, at lower values of ξ untill 0.1 then onwards becomes constant.

By combining Eqs. (2), (6), and (14) we obtained:

$$E_{\text{d.e.}} = \frac{0.05915}{\alpha n} \log \frac{K_{\text{fh}}^{\circ} t^{1/2}}{(\text{antilog } C) D^{1/2}} - \frac{0.05915m}{\alpha n} \log \frac{i}{i_{\text{d}}-i} \tag{16}$$

which may be written

$$E_{\text{d.e.}} = E_{1/2} - \frac{0.05915m}{\alpha n} \log \frac{i}{i_{\text{d}}-i} \tag{17}$$

With

$$E_{1/2} = \frac{0.05915}{\alpha n} \log \frac{K_{\text{fh}}^{\circ} t^{1/2}}{(\text{antilog } C) D^{1/2}} \tag{18}$$

In Eqs. (9), (13), and (18) the potentials are referred to normal hydrogen electrode. If the potentials are referred to the standard potential of that couple then the equations will correspond to the standard rate constant.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3315—3316 (1973)

Synthesis of Bridged Bicycloferrocene: Participation of Anhydrous Aluminum Chloride in the Condensation Reaction

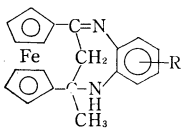
Yoshimori OMOTE, Ryuichiro KOBAYASHI, Yoshio NAKADA, and Noboru SUGIYAMA

Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, Otsuka, Tokyo 112

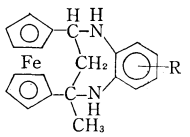
(Received July 3, 1973)

Only a few papers[1] are known on the synthesis of bridged bicycloferrocenes. We now wish to report a new method for one-step synthesis of bridged bicycloferrocenes from 1,1′-diacetylferrocene-aluminum chloride complex (I).[2] Anhydrous aluminum chloride is known to catalyze the condensation reaction of *o*-benzoylbenzophenone with *o*-phenylenediamine.[3] Two acetyl groups of the complex (I) are expected to be accessible to two amino groups in the reaction of (I) with aromatic diamines such as *o*-phenylenediamine, because of their orientation in the same direction by aluminum chloride participation.

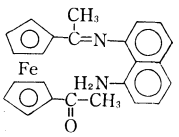
A mixture of (I) and *o*-phenylenediamine was heated in a molten state to give (IIa), whose structure was determined on the basis of the following evidences. The elemental analysis was in accord with (IIa). The mass spectrum of (IIa) indicated a peak at *m/e* 342 (M^+). The infrared spectrum showed a N–H absorption at 3340 cm^{-1} and a C=N absorption at 1610 cm^{-1}. The NMR spectrum is also consistent with (IIa), especially showing AB quartets at τ 6.96 (d, 1H, J= 11.4 Hz) and 7.51 (d, 1H, J=11.4 Hz) (methylene protons). In order to confirm the structure of (IIa), it was reduced with sodium borohydride in methanol to give (IIIa). In a similar manner, reaction of (I) with 4-methyl-1,2-diaminobenzene gave a product (IIb), which on reduction with sodium borohydride gave (IIIb). A nonbridged compound was obtained in the reaction of (I) and 1,8-diaminonaphthalene, which was determined to have structure (IV). The reason why no bridged ferrocene could be obtained in the reaction of (I) and 1,8-diaminonaphthalene can be considered to be that the distance between two amino groups of this diamine is too short to form a bridge with the complex (I). The formation of (II) can be explained by the condensation of carbonyl groups and aromatic amino groups, followed by intramolecular aldol type condensation.



(IIa): R=H
(IIb): R=CH_3



(IIIa): R=H
(IIIb): R=CH_3



(IV)

Experimental

Bridged Bicycloferrocene (IIa). 1,1′-Diacetylferrocene-aluminum chloride complex (I) was prepared according to the literature.[2] The complex (1.44 g) was mixed with *o*-phenylenediamine (1.94 g) in a stoppered flask and the mixture was heated in a molten state at 90—100 °C in an oil bath for 5 min. The reaction mixture was extracted three times with 10 ml of benzene each. The extract was evaporated *in vacuo* and chromatographed on a silica gel column in benzene–ethyl acetate (10: 1) to give the product (6%), which was recrystallized from benzene–*n*-hexane as orange needles, mp 274—280 °C (dec.).

Found: C, 70.44; H, 5.32; N, 7.98%. Calcd for $C_{20}H_{18}FeN_2$: C, 70.19; H, 5.30; N, 8.18%. IR (KBr) cm^{-1}: 3340, 1610. UV: λ_{max}^{EtOH} nm (ε) 237 (26000), 296 (4170), 344 (5040), 443 (658). NMR ($CDCl_3$): τ 2.66—3.16 (m, 4H), 5.21 (m, 4H), 5.57 (m, 3H), 5.90 (m, 2H), 6.96 (d, 1H, J=11.4 Hz), 7.52 (d, 1H, J=11.4 Hz), 8.50 (s, 3H). Mass *m/e* 342.

Bridged Bicycloferrocene (IIb). The complex (1.44 g) was mixed with 4-methyl-1,2-diaminobenzene (2.18 g) and the mixture was heated in a molten state at 100 °C for 3 min. The reaction mixture was worked up as described above to give the product (11%), which was recrystallized from benzene–*n*-hexane as yellowish organge needles, mp 280.5—282.0 °C.

Found: C, 70.86; H, 5.70; N, 8.03%. Calcd for $C_{21}H_{20}FeN_2$: C, 70.60; H, 5.64; N, 7.86%. IR (KBr) cm^{-1}: 3345, 1615. UV: λ_{max}^{EtOH} nm (ε) 237 (26000), 266 (8700), 306 (4100), 346 (4870), 438 (673). NMR ($CDCl_3$): τ 2.78—3.41 (m, 3H), 5.21 (m, 4H), 5.57 (m, 3H), 5.91 (m, 2H), 6.97 (d, 1H, J=11.4 Hz), 7.52 (d, 1H, J=11.4 Hz), 7.68 (s, 3H), 8.50 (s, 3H).

Reduction of Bridged Bicycloferrocene (IIa). Sodium borohydride (100 mg) was added to bridged bicycloferrocene (IIa) (60 mg) in 50 ml of methanol in portions and the mixture was stirred for 30 min at room temperature. After addition of 10 ml of water, the reaction mixture was extracted with 100 ml of ethyl ether and the organic layer was washed with water, dried over anhydrous sodium sulfate, evaporated *in vacuo*, and recrystallized from benzene–*n*-hexane as yellow rods (IIIa) (78%), mp 225—227.5 °C.

Found: C, 69.71; H, 5.88; N, 7.91%. Calcd. for $C_{20}H_{20}FeN_2$: C, 69.80; H, 5.85; N, 8.15%. IR (KBr) cm^{-1}: 3360. UV λ_{max}^{EtOH} nm (ε) 222 (28400), 308 (2880), 441 (180). NMR ($CDCl_3$): τ 3.22 (s, 4H), 5.67 (m, 2H), 5.77—6.18 (m, 7H), 6.72 (bs, 2H), 7.46—8.10 (m, 2H), 8.46 (s, 3H).

Reduction of Bridged Bicycloferrocene (IIb). Sodium borohydride (140 mg) was added to bridged bicycloferrocene (IIb) (40 mg) in 60 ml of methanol in portions and the mixture was stirred for 30 min at room temperature. The reaction mixture was worked up as described above to give the product (85%), which was recrystallized from benzene–*n*-hexane as yellow prisms (IIIb), mp 195—197 °C.

Found: C, 70.38; H, 6.32; N, 7.88%. Calcd. for $C_{21}H_{22}FeN_2$: C, 70.40; H, 6.18; N, 7.81%. IR (KBr) cm^{-1}: 3365. UV: λ_{max}^{EtOH} nm (ε) 222 (30600), 312 (2960), 444 (193). NMR ($CDCl_3$): τ 3.35 (s, 3H), 5.62 (m, 2H), 5.77—6.16 (m, 7H), 6.98 (bs, 2H), 7.45—7.75 (b, 2H), 7.75 (s, 3H), 8.47 (s, 3H).

The Compound (IV). The complex (2.09 g) was mixed with 1,8-diaminonaphthalene (4.10 g) and the mixture was heated in a molten state at 90—95 °C for 1.5 hr. The reaction mixture was worked up as described above to give the product (12%), which was recrystallized from benzene–*n*-hexane as orange plates, mp 218.5—220.5 °C.

Found: C, 70.26; H, 5.38; N, 6.99%. Calcd. for $C_{24}H_{22}FeN_2O$: C, 70.26; H, 5.40; N, 6.83%. IR (KBr) cm^{-1}: 3380, 3350, 1642, 1601. UV: λ_{max}^{EtOH} nm (ε) 235 (48600), 269 (7000), 350 (13000), 463 (475). NMR ($CDCl_3$): τ 2.53—2.90 (m, 5H), 3.37—3.53 (m, 1H), 5.24 (t, 2H), 5.48 (t, 2H), 5.80 (m, 4H), 5.95 (m, 2H), 7.62 (s, 3H), 8.17 (s, 3H).

Photochemical Reactions of Aromatic Compounds. XVII.[1] The Photocyclization of *N*-(*o*-Chlorobenzyl)aniline

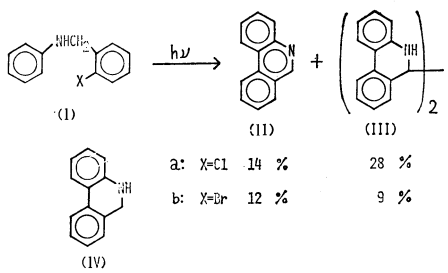
Kazuhiko MIZUNO, Chyongjin PAC, and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Suita-shi, Osaka 565

(Received July 3, 1973)

The dehydrohalogenative photocyclization has been shown to be of potential use for the synthesis of some alkaloids.[2] However, the starting halides are limited to iodides and bromides, and difficulties have been generally encountered in the case of chlorides. In the previous papers,[3] we have reported the photoinduced reduction of halobenzenes with *N,N*-dimethylaniline, which affords the dehalogenative adducts in the maximum yield in the case of chlorobenzene. Therefore, *N*-(*o*-chlorobenzyl)aniline (Ia) can be expected to undergo an intramolecular dehydrohalogenative photocyclization and we did obtain the cyclized products (II) and (III) in moderate yields.

Irradiation was carried out for an acetonitrile–water (9: 1) solution of *N*-(*o*-halobenzyl)anilines (Ia—b) in the presence of sodium hydroxide through a Pyrex glass by a high pressure mercury arc. Phenanthridine (II)[4] and 5,5′,6,6′-tetrahydro-6,6′-biphenanthridyl (III)[4] were isolated from the reaction mixture by column chromatography on silica gel.



In the present photoreactions, the primary product can be expected to be 9,10-dihydrophenanthridine (IV), but it could not be isolated. However, when the photoreactions were monitored by the UV spectra, the

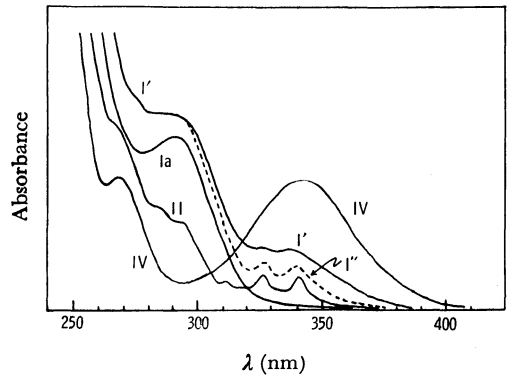

Fig. 1. The UV spectra in acetonitrile solutions: Ia (1.1×10^{-3} M of Ia); I′ (after irradiation of Ia at 313 nm in a degassed solution); I″ (after irradiation of I′ at 366 nm after I′ was air-saturated; II (phenanthridine); IV (9,10-dihydrophenanthridine). The absorption intensities are in arbitrary unit.

characteristic broad absorption maximum of IV at 342 nm appeared by the irradiation of Ia at 313 nm (Fig. 1). Further irradiation of the solution resulted in the decrease of the broad absorbtion band with the appearance of the bands similar to II at 326 and 342 nm. In fact, IV was found to be quantitatively oxidized into II by the treatment of column chromatography on silica gel and easily photolyzed into II and an unknown dimeric material (V), though III was not detected. The structure of V has not been determined, since it is insoluble in usual organic solvents. Therefore, it is suggested that the primary product IV might be oxidized into II during the work-up procedures and also photolyzed into II and the other products during the irradiation. On the other hand, the formation of III cannot be rigorously interpreted at present.

Although Ogata and Takagi have reported the photorearrangement of *N*-(*p*-chlorobenzyl)-*p*-toluidine,[5] the rearranged products, *o*-amino-*o*-chlorodiphenylmethane and *p*-amino-*o*-chlorodiphenylmethane, could not be obtained in appreciable amounts.

5) Y. Ogata and K. Takagi, This Bulletin, **44**, 2186 (1971).

Experimental

All the melting points and boiling points are uncorrected. Spectroscopic analyses of the organic products were carried out as follows; the IR spectra using a high Hitachi EPI-S2 spectrophotometer, the UV spectra using a Hitachi RMU-6E spectrometer. The acetonitrile was purified as uasul. The aniline, *o*-chlorobenzyl chloride and *o*-bromotoluene were distilled under nitrogen stream *in vacuo* before use.

The Preparation of The Starting Halides, Ia and Ib. Ia was obtained from aniline and *o*-chlorobenzylchloride according to the method described for the preparation of *N*-benzylaniline[6]: bp 160—163 °C/4 mmHg; ν_{max}^{KBr} 3380 cm^{-1} (N–H);. $\lambda_{max}^{C_2H_5OH}$ (ε) 296 (1090) and 246 nm (21010); Found: C, 71.36; H, 5.01; N, 6.37; Cl, 16.45%. Calcd for $C_{13}H_{12}NCl$: C, 71.26; H, 5.56; N, 6.43; Cl, 16.28%.

In a similar way, Ib was obtained from aniline and *o*-bromobenzyl bromide prepared by the bromination of *o*-bromotoluene with *N*-bromosuccinimide: bp 184—189 °C/7 mmHg; ν_{max}^{KBr} 3393 cm^{-1} (N–H); $\lambda_{max}^{CH_3CN}$ (ε) 293 (2470) and 244 nm (12820). Found: C, 59.63; H, 4.72; N, 5.12; Br, 30.78%. Calcd for $C_{13}H_{12}NBr$: C, 59.54; H, 4.58; N, 5.34; Br, 30.53%.

Irradiation of Ia and Ib. A solution of (Ia) (1 g) and sodium hydroxide (0.2 g) in 200 ml of acetonitrile–water (9: 1) was irradiated through a Pyrex glass under a nitrogen atmosphere at room temperature by a high-pressure mercury arc for 30 hr. After removal of the solvent *in vacuo*, the residue was dissolved in 200 ml of ether, washed by water and dried over magnesium sulfate. After removal of the ether, the residue was subjected to column chromatography on silica gel. Benzene eluted III (0.23 g) which was recrystallized from benzene–hexane: mp (dec.) 183—184 °C (lit,[4] 175—185 °C), ν_{max}^{KBr} (KBr disk) 3240 cm^{-1} (N–H); *m/e* 360 (M^+) and 180. Found: C, 87.02; H, 5.51; N, 7.69%. Calcd for $C_{26}H_{20}N_2$: C, 86.63; H, 5.59; N, 7.77%.

Benzene containing 10% of ether eluted 0.04 g of II, which was recrystallized from hexane: mp 105.5—106.5 °C (lit,[4] 105—106 °C). Found: C, 87.41; H, 4.83; N, 7.74%. Calcd. for $C_{13}H_9N$: C, 87.12; H, 5.06; N, 7.82%.

Further elution gave brownish tarry materials, the sublimation of which afforded 0.075 g of II.

In a similar way, irradiation of Ib afforded II (0.08 g) and III (0.06 g).

Chemical Effects of Osmium Neutron Capture Recoils. III. Cation Effect in Crystalline Mixtures of $K_4Os(CN)_6$-$K_4Fe(CN)_6$-$Cs_4Fe(CN)_6$

El-Hussieny M. DIEFALLAH and Jack G. KAY*

Department of Chemistry, Assiut University, Assiut, Egypt

**Department of Chemistry, Drexel University, Philadelphia, U.S.A.*

(Received July 11, 1972)

Changes in retention between crystals with different cations and the same Szilard-Chalmers component have been attributed to a cation effect. The effect is closely associated in many cases with that of changing crystal structure and thermal effects. The latter refers to the thermal response of the lattice and its effect on product distribution and is thought to differ for each crystalline modification. Studies of the effects of changing crystalline environment or cations have made us to realize the importance of certain factors involved.[1-5]

Observations with a wide variety of crystalline compounds[1] have shown that compounds with a similar crystal structure but different cations or Szilard-Chalmers elements show large variations in initial parent retention, so that cation effects may be more important than crystal structure effects. The role played by the cation in the retention reaction is not completely understood. Although the effect has been interpreted in certain cases as one of electron affinity of the cation,[5] and in others as being attributable to the state of hydration of the crystal,[2] the results do not agree. Explanations were given based on the differences due to radiation dose effects and to radiation chemical processes resulting from cation activation,[6] or to cage effects arising from differences in the masses of surrounding atoms or ions.[4]

We have studied osmium recoil effects in crystalline mixtures of the type $K_4Os(CN)_6$-$K_4Fe(CN)_6$-$Cs_4Fe(CN)_6$ in order to investigate the role of the cation in diluted systems. Crystals of the pure components were either available commercially or prepared as previously described.[7] Crystalline mixtures of $K_4Os(CN)_6$-$K_4Fe(CN)_6$-$Cs_4Fe(CN)_6$ containing a fixed Os- to Fe- mole ratio (1 : 1) and cesium to potassium mole ratios ranging from 0 : 1 to 1 : 1 were precipitated from a hot saturated solution of pure components by adding absolute alcohol. Each mixture was then filtered, washed several times with alcohol, and vacuum dried at about 100 °C. Chemical analysis of each mixture agrees well with the composition of the solution of pure components. X-Ray powder diffraction spectroscopy of the pure components and their mixtures show that the X-ray pattern for $Cs_4Fe(CN)_6$ differs from that for $K_4Fe(CN)_6$ and $K_4Os(CN)_6$; the mixture gives diffraction lines which is not properly related to the pure components.[8] This indicates that the cesium and potassium salts are not isomorphous and hence their crystalline mixtures are not true mixed crystals.

Neutron irradiations were carried out at a thermal neutron flux of 1.8×10^{12} n/cm^2/s, fast neutron flux of 1.8×10^{12} n/cm^2/s and gamma ray dose rate of about 1.4×10^7 rad/hr. The potassium-cesium salt mixtures were each irradiated for 6.0 hr and then analyzed by paper electrophoresis.[7] The duration of the electrophoretic separation was three hours and the counting of paper strips started several hours after the completion of irradiation in order to minimize the effect of any radiocesium contamination. The osmium activity appeared mainly in two peaks,[7,8] one due to OsO_2 remaining at the starting point and the other due to the parent peak migrating towards the anode. Since only the parent species should be stable in aqueous solution, it is believed that all partially reconstituted species hydrolyze or react immediately in solution to give OsO_2 and that most of the activity found in the parent peak actually comes from a cyanoosmate precursor present as such in the irradiated crystal.[7,8]

The results of cyanoosmate(II) parent retention determined as a function of $Cs_4Fe(CN)_6$ mole fraction in the cesium–potassium crystalline mixtures are given in Table 1. We see that replacement of cesium for potassium causes a large decrease in parent retention.

TABLE 1. CYANOOSMATE(II) RETENTIONS IN $K_4Os(CN)_6$-$K_4Fe(CN)_6$-$Cs_4Fe(CN)_6$ CRYSTALLINE MIXTURES WITH A FIXED 1:1 Os- to Fe- mol RATIO

$Cs_4Fe(CN)_6$ mole fraction	Cesium-to-potassium mole ratio	Percent retention
0.0	0.0	51±3
0.166	0.20	25±3
0.286	0.40	32±3
0.375	0.60	25±4
0.445	0.80	20±3
0.500	1.00	20±4

The observed decrease in cyanoosmate(II) retention due to the replacement of potassium by cesium cannot be explained on the basis of cage effects, as this would predict an increase in retention because of better caging around the recoil atom being provided by the massive Cs^+ ions. Potassium cation has a higher affinity for

electrons than cesium, and this could provide an explanation.[5] However, the increase in absorbed radiation dose and neutron activation with increasing cesium mole fraction in the crystalline mixtures causes excessive damage which may also account for the lowering in parent retention.

In general, the probability of parent reformation is not only determined by the density of lattice defects and radiation damage in the crystal, but also by the energy of activation for release from traps. It is believed that an increase in parent retention would correspond to an increased probability for an electron capture reaction by the parent precursor fragment taking place in the solid.[7] Changes in initial parent retention could be discussed on the basis of an electron acceptor-donor mechanism involving electron-hole traps and electron recombination centers. The energy of activation for defect release depends on the details of electronic structure of the solid which is determined by the crystal structure and types of cations, anions and ligands or the nature of the chemical bonds.[9] Thus it is expected that the more ionic cesium salt with a larger band gap would increase the trap depth and activation energy for reactions giving rise to initial retention. This interpretation is more reasonable than that based only on differences in density of lattice defects.

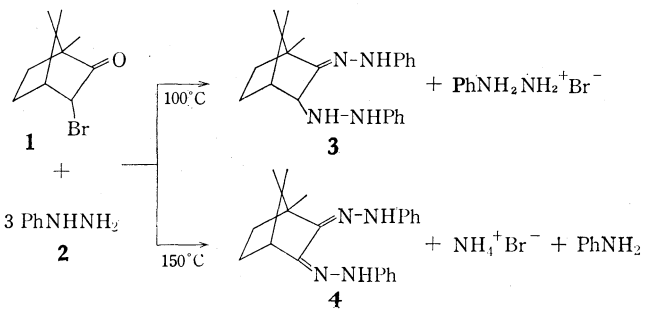
Reactions of 3-Bromocamphor with Phenylhydrazine[1)]

Angelo G. GIUMANINI,[2)] Luciano CAGLIOTI, and Walter NARDINI
Instituto di Chimica Organicae Industriale, University of Bologna, 40136 Bologna, Italy

(Received September 25, 1972)

The interaction of 3-bromocamphor (**1**) with phenylhydrazine (**2**) at 100 °C yielded camphor phenylhydrazinophenylhydrazone,[3)] perhaps in the tautomeric formula **3**, a colorless crystalline compound, mp 136—137 °C, moderately stable in air, surprisingly[4)] stable to prolonged heating at 100 °C *in vacuo* and treatment with **2** at 150 °C. Compound **3** was identified on the basis of its molecular weight (M^+ *m/e* 348), elemental analysis and unequivocal spectral evidences.

When the reaction was carried out at 150 °C, after a few minutes a vigorous exotherm set in with the evolution of ammonia and the formation of aniline to give an excellent yield of camphor osazone **4**, a yellow crystalline compound, mp 149—152 °C, whose structure was supported by spectral characteristics. That the camphor framework was intact was ascertained by the PMR spectrum, which exibited three singlets in 1 : 1 : 1 ratio at δ 0.74, 0.87, and 1.03 ppm, an A_2B_2 quartet centered at 1.48 ppm and a deformed doublet at 2.80 ppm in addition to a complex aromatic pattern. The infrared spectrum of **4** showed two absorption bands for the γ_{NH} at *ca.* 3300 cm^{-1} due to the free and associated secondary amine[5)] and the presence of monosubstituted phenyl groups with three bands between 650 and 800 cm^{-1}. The parent peak (M^+ *m/e* 346) was also the most prominent in the mass spectrum at 70 eV. The ultraviolet spectrum was closely similar in band location and relative intensities to that of cyclohexane osazone.[6)]



Reciprocal support for structures **3** and **4** was given by the facile conversion of the former into the latter by reflux with **2** in acetic acid.

In an experiment under the conditions and the workup procedure described by Balbiano[3)] we isolated only a compound **5** melting at 191—192 °C in a trace

1) This work was supported by Grants nos. 69.00367.115.621 (to L. C.) and 70.00143/03 (to A.G.G.) from the Italian Research Council (CNR).

2) To whom inquiries should be addressed: Center for Mass Spectrometry, University of Bologna, Via S. Giacomo, 5, 40126 Bologna.

3) A supposed camphor phenylhydrazinophenylhydrazone was described by Balbiano, *Gazz. Chim. Ital.*, **15**, 246 (1886) and **17**, 95 (1887), as a red compound, mp 55 °C.

4) Phenylhydrazinophenylhydrazones are a very rare type of compounds, only two of them having been described: L. Caglioti, G. Rosini and F. Rossi, *J. Amer. Chem. Soc.*, **88**, 3865 (1965); H. Simon, G. Heubach, and H. Wacker, *Chem. Ber.*, **100**, 3106 (1967). These compounds are believed to be the key intermediates on the way to osazones in Weygand's mechanism of osazone formation: for a recent review see: S. Kitaoka, *Kagaku-no-Ryoiki*, **18**, 475 (1964).

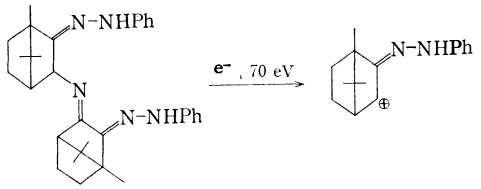
amount. Its analytical data fitted the composition $C_{32}H_{41}N_5$, confirmed by the mass spectrum (M^+ *m/e* 495). Strong insolubility in common NMR solvents prevented recording of the PMR spectrum. Infrared analysis of this bright yellow product showed weak absorptions at 3320 and 3160 cm^{-1}, which can be tentatively ascribed to the ν_{NH} of hydrazone functions, strong bands between 650 and 750 cm^{-1} indicating the presence of monosubstituted phenyl groups. The characteristic bornane doublet was found at 1380 cm^{-1}, as well as intense ν_{CH} absorptions in the expected range. Mass spectral data (M^+ *m/e* 495, "aliphatic" peaks at *m/e* 15, 27, 41, 55 and the peak *m/e* 241, which can be hypothetically pictured as **6** together with the other evidences indicated a structure containing intact camphor moieties and phenyl rings, perhaps **5**.



5 **6**

Our results support the theory according to which a phenylhydrazinophenylhydrazone is an intermediate in the formation of osazones under acid catalysis (HBr or AcOH), though it was not confirmed in which elementary step subsequent to **3** the acid intervened.

Experimental

Mp and bp are uncorrected. UV spectra were recorded with a spectrometer Unicam sp. 800. IR spectra were recorded with a Beckman IR 5, calibrated with polystyrene film. Spectra of solids were recorded by the KBr technique.

PMR spectra were recorded with a Varian DP 60, using TMS as internal standard and a frequency meter Hewlett Packard 241 A to establish peak locations (δ values, ppm). Mass spectra were obtained with a double focusing Perkin Elmer 270, with an ion source temperature of *ca.* 200 °C.

Camphor Phenylhydrazinophenylhydrazone (3). **1** (17 mmol) and **2** (54 mmol) were kept at 100 °C under N_2 for 1 hr. About 10 min after immersion into a warm oil bath, a homogeneous, almost colorless solution was formed from which a white precipitate appeared at once. At the end the whole mixture appeared as a red orange solid mass, from which phenylhydrazinium bromide was obtained by repeated washings with dry ether. The ether solution was extracted with chilled 15% HCl, dried over Na_2SO_4 and evaporated to yield a red oil having the smell of camphor. No osazone **4** was present (tlc). Careful sublimation gave some unreacted **1** (8%), whereas the residue solidified upon cooling, mp 55 °C. Addition of a small amount of methanol to this residue separated a compound, mp 191—192 °C after two crystallizations from methanol, in trace amount, mass spectrum (solid inlet 150 °C): M^+ 495, ten highest peaks 92 (100%), 93 (98), 77 (96), 241 (91), 91 (85), 242 (53), 94 (38), 107 (37), 108 (32) and 255 (32); Found: C, 77.00; H, 8.33; N, 14.05%; Calcd for $C_{32}H_{41}N_5$: C, 77.53; H, 8.34; N, 14.13%; IR bands at 1600, 1500, 1450, 1380, 1310, 1260, 1195, 1150, 1130, 1095, 1070, 1020, 995, 880, 775, 745, 705 and 685 cm^{-1}. This was compound **5**: the mother liquor after its precipitation gave a 47% yield of product **3**, mp 136—137 °C, after crystallization from hexane–ether, UV (95% EtOH): λ_{max} (ε): 346 (2427), 280 (32680), and 242 (24100) nm; IR: 3250, 3200, 3160, 3100, 2925, 1600, 1550, 1540, 1500, 1495, 1450, 1390, 1337, 1310, 1270, 1240, 1170, 1150, 1140, 1128, 990, 972, 917, 878, 858, 818, 798, 750, and 695 cm^{-1}; Mass spectrum (solid inlet 75 °C, 10 highest peaks): 93 (100%), 92 (99.5), 94 (25), 77 (87), 107 (37), 108 (36), 105 (29), 255 (80), 241 (20), and 159 (15) with M^+ 348; PMR ($CDCl_3$): 7.05 (m, 10H), 3.62 (s, 3H), 2.60 (s, 1H), 1.86 (s, 1H), 1.54 (d, 4H), 1.085 (s, 3H), and 0.965 (s, 3H) ppm; Found: C, 76.12; H, 8.20; N, 16.18%; Calcd for $C_{22}H_{28}N_4$: C, 75.82; H, 8.10; N, 16.08%. This compound was separated from other runs by absorption chromatography on silica gel using hexane–ether as an eluant. A quantitative transformation of **1** was achieved at 100 °C for 4 hr. Compound **3** was recovered unchanged by heating it alone at 100 °C *in vacuo*, refluxing it in methanol and heating it with phenylhydrazine at 150 °C.

Camphor Osazone (4). *A*) A mixture of 115 mmol of **1** was immersed into an oil bath at 150 °C: dissolution of **1** was promptly followed by a vigorous exothermic reaction. When the reaction subsided, the mixture was kept for 5 min at 150 °C, then cooled to 75 °C and taken up with warm water, cooled to room temperature and extracted with concentrated HCl and ether. The dried ether solution (Na_2SO_4) was evaporated to give 7.38 g of a yellow resinous mixture, which turned green at once upon exposure to air. Absorption chromatography (silica gel/ether–hexane) gave 88.5% crude **4**, mp 149.5—152 °C, after crystallization from methanol, pure yield 86%, UV (95% EtOH): λ_{max} (ε): 375 (16940), 304 (13250), and 254 (16640); IR: 3300, 2900, 1600, 1575, 1500, 1380, 1260, 1210, 1160, 1115, 1075, 1020, 995, 915, 880, 840, 785, 750, 715, and 685 cm^{-1}; PMR ($CDCl_3$): 7.21 (m, 10H), 2.80 (d, 1H, J=7 Hz), 1.48 (deformed q, 4H, J=7 and 25±2 Hz), 1.03 (s, 3H), 0.875 (s, 3H), and 0.74 (s, 3H) ppm; Mass spectrum (solid inlet 100 °C, 10 highest peaks): 346 (M^+), 254, 212, 210, 93, 92, 91, 77, 238, and 347; Found: C, 76.31; H, 7.77; N, 15.92%; Calcd for $C_{22}H_{26}N_4$: C, 76.26; H, 7.56; N, 16.17%.

B) The osazone **4** was obtained in practically quantitative yield by treating **3** with an excess of **2** and a few drops of AcOH at reflux temperature during 30 min. Direct interaction of **1** with **2** in acetic acid did not give good results.

Impurity Effect on Domain Formation in a Nematic Liquid Crystal

Jun NAKAUCHI,* Masaaki YOKOYAMA, Hiroshi SAWA,* Ken-ichi OKAMOTO,**
Hiroshi MIKAWA, and Shigekazu KUSABAYASHI**

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received February 19, 1973)

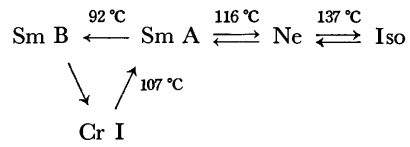
The effect of impurity on domain formation in an ethyl anisal-*p*-aminocinnamate nematic liquid crystal was investigated. With the decrease of the content of ionic impurities, the threshold voltage of the domain formation increases and the size of the domain patterns becomes larger. With blocking electrodes, the domain patterns could not be seen, although molecular orientation was still observed. When a negative electrode is coated partly with Nesa and partly with gold, the domain patterns appear first in the Nesa (*n*-type) part. When an electric field is cut and applied within one second intervals, the domains reappear at the same places. The mechanism of domain formation is discussed.

It is well-known that the optical properties of nematic liquid crystals are remarkably altered when electric fields are applied. Anomalous alignment called "domain" occurs at a low field strength. This phenomenon was first found by Williams in the nematic state of a *p*-azoxyanisole liquid crystal,[1] and has since been studied by many investigators.[2-6] Helfrich[7] proposed a quantitative theory describing the behavior of nematic liquid crystals with DC electric field near the critical field strength of domain formation. With DC electric field, ionic impurities influence the electro-optical properties of a liquid crystal.[7,8] However, there are few reports on the effect of impurities. We thought it of interest to elucidate the effect of impurities in a liquid crystal on the process of domain formation.

The present report deals with the effect of impurities on domain formation in a nematic liquid crystal. Our results for ethyl anisal-*p*-aminocinnamate (EAPAC) show that the current, probably due to ionic impurities, considerably contributes to the size and shape of the domain patterns.

Experimental

EAPAC was synthesized according to the literature.[9-11] EAPAC was purified by recrystallizations from absolute ethanol, and was dried sufficiently under reduced pressure. Three EAPAC samples (I, II, and III) each having different electrical conductivity, were obtained by recrystallization once, twice, and three times, respectively. Phase transition temperatures were determined with a differential scanning calorimeter (Rigaku Model 8001). Heating and cooling rates were controlled to within 5 °C/min.



There is no conspicuous difference in phase transition temperature between samples I, II and III. Although Vorländer reported the presence of another crystal phase II with transition at 83 °C from Sm B,[11] no such phase could be observed. Other phase transition temperatures showed good agreement with those reported by Vorländer.

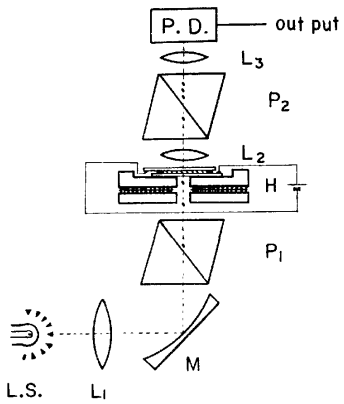


Fig. 1. Experimental alignment for observing the optical behavior of EAPAC in the nematic state. L.S: light source, M: mirror, L_1: condensing lens, L_2,L_3: objective and ocular lenses, P_1,P_2: polarizer and analyzer, P.D.: photodiode, H: heater plate.

All measurements were made in a nematic region. The domain patterns were observed under a Leitz polarizing microscope in the transmission mode with crossed nicols. The experimental alignment for observing the optical behavior is shown in Fig. 1. An EAPAC sample held between two Nesa-coated glass electrodes with a Teflon spacer (50 μ thickness), was set on a heater plate, which was then placed on the stage of a microscope. The optical response when the electric field was applied, was detected with a photodiode (NEC PD32) equipped at the top of a microscope and displayed on an oscilloscope (National VP517A). The DC current-voltage characteristics were measured by using a sandwich type cell with temperature control within 0.5 °C.

Results and Discussion

The threshold voltage of domain formation was determined from the change of the transmitted light intensity as a function of the applied voltage by a similar method to that reported by Williams.[1] The threshold field strengths of the domain formation in I, II, and III were about 560, 600, and 700 V/cm, respectively. These critical points correspond to the applied voltage for the appearance of extinction crosses which are observed by a polarizing microscope.

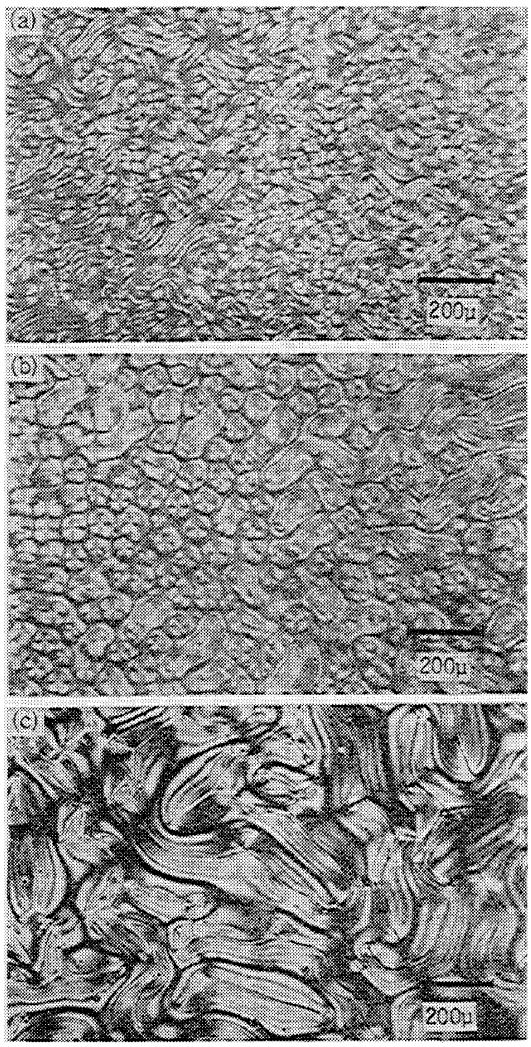

Fig. 3. The typical domain patterns of EAPAC (a) Sample I (applied voltage 4V, 50 μ thickness, 128 °C), (b) Sample II (4 V, 50 μ, 128 °C), and (c) Sample III (4.5 V, 50 μ, 128 °C).

Figure 2 shows the DC current-voltage characteristics for I, II, and III. Their conductivities are of the order 10^{-7}, 10^{-8}, and $10^{-9}\,\Omega^{-1}\,cm^{-1}$, respectively. These rather high values of conductivity at DC electric field indicate that ionic conduction is predominant. A difference in DC electrical conductivity was, however, clearly observed with the number of recrystallization times. Taking this difference in conductivity into consideration, the difference in the threshold voltage of domain formation for the samples is considered to be due to the different degree of contribution of ionic impurities. Thus, ionic impurities to some extent

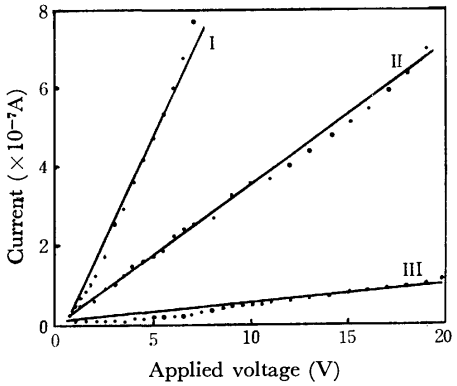

Fig. 2. Current-voltage characteristics of the EAPAC samples I, II, and III measured at 128 °C. The separation of electrodes is 50 μ.

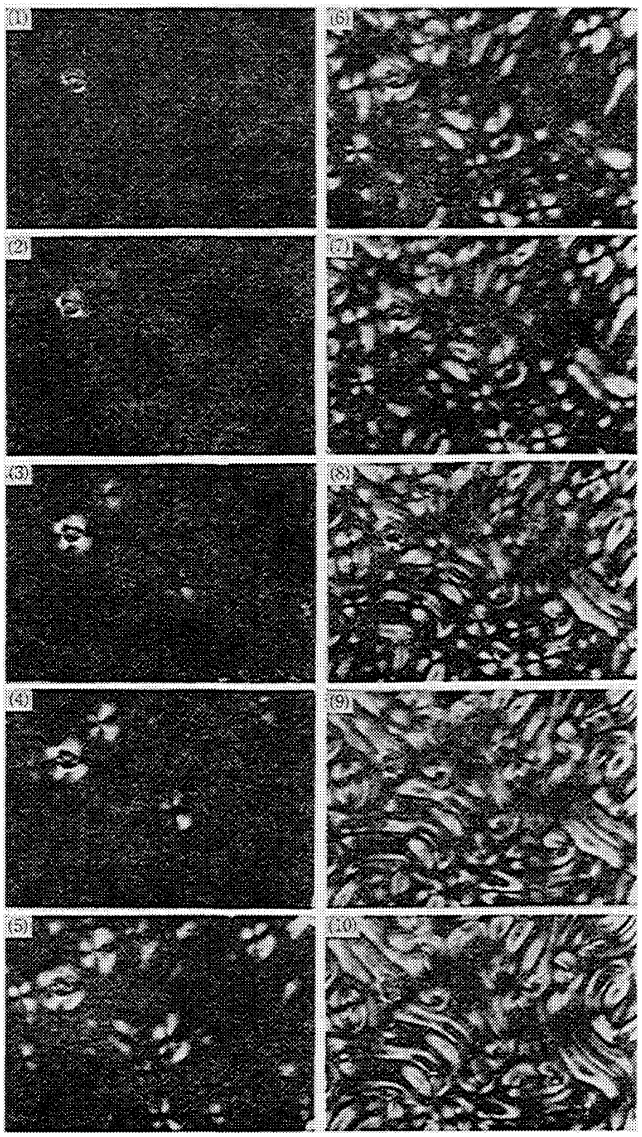

Fig. 4. The process of the domain formation of EAPAC Sample III (5 V, 50 μ, 130 °C) observed by a 16 mm moving camera. The 10 frames shown here are selected in the order of the process with appropriate intervals, 0.3 s for 1)—7) and 1 s for 7)—10).

influence the domain formation. Typical domain patterns of I, II, and III are shown in Fig. 3. The process of domain formation for III observed by a 16 mm moving camera with a crank speed of 64 frames per second is shown in Fig. 4. At the threshold voltage, Maltese cross-like extinction crosses of spherulites appear and then increase in number. As the voltage increases further, some of the crosses link with each other and gradually grow independently into long stripes everywhere, and finally form the characteristic cellular domain patterns of EAPAC. The size of the cellular domain becomes larger with the number of recrystallization times, *viz.*, with the decrease of impurities (Fig. 3). The domain patterns of III appear at slightly higher applied voltage (4.5 V) than those of the other two samples (4 V). The outer domain wall, shown in the figure as a dark obscure part with the pattern of a slightly stretched circle occurs in the neighborhood of the negative electrode. On the other hand, the inner wall which had been produced by the linking of the extinction crosses can be observed near the positive electrode by focusing a microscope in sharp focus. Penz[12] reported that even at the domain formation voltage the hydrodynamic flow of a *p*-azoxyanisole liquid crystal occurred. In the case of EAPAC it was also found that a dust particle in a domain moves in a circular motion between the two electrodes through these inner and outer domain walls. When observed carefully, a dust particle moves from the negative electrode to the positive electrode through the inner domain wall and inversely through the outer domain wall. This phenomenon may imply that the hydrodynamic flow of a liquid crystal is necessary to produce the domain pattern.

In order to examine the effect of the contact of an electrode and a liquid crystal, experiments were made with blocking electrodes, Nesa electrodes being covered with thin mica sheets (10 μ thickness). In the case of both positive and negative blocking electrodes, the domain pattern could not be observed even in the voltage region of the dynamic scattering mode. However, a transient increase of transmission was still observed under the crossed polarizers at the instant of applying an electric field, the transmission decreasing gradually to a final steady state value (Fig. 5). The transient increase of transmission may be caused by the orientation of the dipoles of EAPAC molecules to the direction of an electric field, and then the back field due to these ordered dipoles may decrease the effect of the external field, and a final arrangement of dipoles in a steady state may be attained with decreasing transmission. Thus, only the molecular orientation is observable and the domain pattern does not appear in the case of blocking electrodes. This suggests that not only the orientation of molecules but also the stationary current is necessary for the domain formation with DC electric field. Since an electron injection or electron transfer to EAPAC molecules, if any, is possible only in the case of direct contact to the electrodes and not in blocking electrodes, the electron transfer to EAPAC molecules from the negative electrode may play an important role in the domain formation.

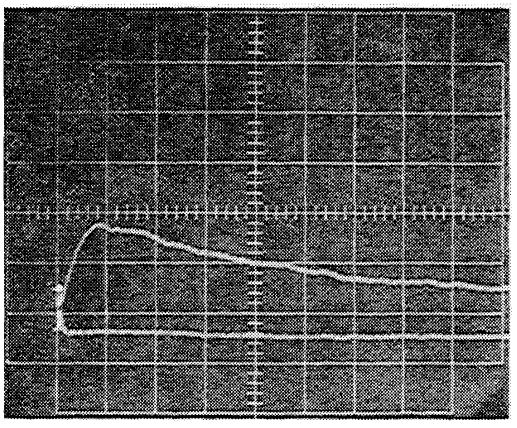

Fig. 5. Transient transmission change with blocking electrodes observed under the crossed polarizers. The upper and lower curves indicate the changes at the instant of switching on and off electric field (4×10^4 V/cm), respectively. Vertical axis: arbitrary transmittance, sweep: 100 ms/division.

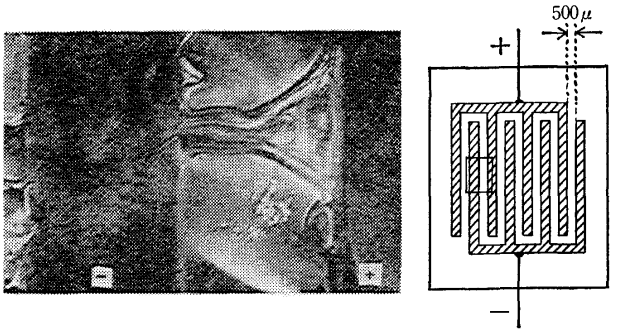

Fig. 6. The domain patterns of EAPAC observed with a gold surface cell on glass plate (10^3 V/cm, 127 °C). The place corresponding to the photograph is indicated by square in the schematic figure of the electrode.

Furthermore, in the case of the negative electrode plate coated half with Nesa and half with gold, the domain patterns appear first in the Nesa-coated part and subsequently in the gold part as the field strength increases. Provided that electron injection is required for the domain formation, this phenomenon is easily understood because an electron injection occurs more easily from the *n*-type Nesa part than from gold. The result of the optical measurement under a surface cell with the separation of 500 μ between two electrodes is shown in Fig. 6. The measurement with surface type electrodes corresponds to the case of viewing transversely the domain pattern between two sandwich type electrodes. In this case, the striped structure due to hydrodynamic flow of EAPAC molecules was observed, and the source point of the hydrodynamic flow was considered to coincide with the site of electron injection at the negative electrode.

Another experimental result suggests that the ionic impurities in a liquid crystal have an influence on the initial process of the domain formation. The extinction crosses or domain patterns reappear in the same

12) P. A. Penz, *Mol. Cryst. Liquid Cryst.*, **15**, 141 (1971).

position for the quick switching (about 1 s intervals) of the applied field, while the position as well as the shape of the domain patterns change when an electric field is applied again after an interval long enough for the ionic impurities stuck to the electrodes to diffuse. The domain patterns in the nematic state are still memorized even if the temperature once rises to the isotropic region or once falls to the crystal region keeping the applied field.

Taking all the measurements into account collectively, the process of EAPAC domain formation may be considered as follows. When an electric field is applied, ionic impurities in a liquid crystal are attracted and migrate to the negative electrode. Here, ionic impurities sticking to the electrode lower the electrode potential, and the electron transfer from the electrode to EAPAC molecules as an electron acceptor, *i.e.*, electron injection, may easily occur as Heilmeier has suggested.[8] This injection site corresponds to the place where the extinction crosses can be observed with a polarizing microscope at the threshold voltage of the domain formation. The injected electrons are captured by EAPAC molecules and cause the hydrodynamic flow of a liquid crystal and finally produce the characteristic domain pattern. Thus, (1) the domain inner wall gushes out from the negative electrode as the injection site, and (2) with a smaller amount of ionic impurities, the number of injecting sites becomes smaller and hence the size of the domain becomes larger.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3324—3330 (1973)

The Self-diffusion of Chloride Ions in Divalent Metal Chloride Crystallites with $CdCl_2$-type Structure

Yoshihiro SENSUI

Institute for Atomic Energy, Rikkyo University, Yokosuka 240-01

(Received April 18, 1973)

The self-diffusion of chloride ions in $MgCl_2$- and $CoCl_2$-crystallites with the $CdCl_2$-type structure was studied, the results being compared with previous data on $MnCl_2$ and $NiCl_2$. The diffusion rate was measured through gas/solid-isotopic exchange reactions in a carefully cleaned vacuum system. The results were analyzed by the use of a model of semi-infinite crystal. The Arrhenius plots of apparent diffusion coefficient consist of two segments of line, from whose slopes the activation heat of migration E and the apparent heat of formation of vacancies H_v/n_v are determined. [H_v denotes the total heat of formation of two anion vacancies and one catoin vacancy with n_v= 2 or 3.] The values for E and H_v/n_v were 0.55 and 1.1 eV in $MgCl_2$ and 1.3 and 2.0 eV in $CoCl_2$, respectively. A linear relationship holds between the logarithms of pre-exponential factor of the diffusion coefficient and E or $(E+H_v/n_v)$; *viz.*, the theta-rule holds in this case. In the initial stage of the exchange reaction, ions or atoms in the surface region of crystals were observed to easily migrate. Sodium ions doped deliberately as impurity enhance the diffusion of chloride ions. It is concluded that the diffusion takes place through the vacancy mechanism.

Chemical processes in solids are closely related to migration of atoms or ions in crystals, which is controlled by imperfections in the crystal. The isotopic exchange reaction between crystals and gaseous molecules is one of the simplest surface reactions, and can be used as a useful means of measuring the self-diffusion of ions in crystals. Although diffusion is studied through measurements of electric conductance, it is desirable to confirm the validity of diffusion law by the tracer method.

Most studies on the self-diffusion of anions in solids have dealt with alkali halides, and a few with polyvalent metal halides.[1-3] Dearth of data on the latter crystals may be ascribed to the following. Most of such crystals are easily hydrated and volatile when dehydrated, making the manipulation of samples difficult. Chemical bonds in these crystals are partly ionic and partly covalent,[4] and theoretical interpretations of experimental data may not be as straightforward as in pure ionic crystals. As for theoretical studies, only rough ideas were applied to polyvalent metal fluoride.[5]

In the present paper, the results of studies of the self-diffusion of Cl^- ions in $MgCl_2$- and $CoCl_2$-crystallites with the $CdCl_2$-type structure are compared with the results on $MnCl_2$[2] and $NiCl_2$.[3] Some of these crystals are used as solid catalysts for chlorination of hydrocarbons in gaseous phase.[6]

Experimental

Apparatus and General Procedure. The apparatus used was made of Hario-glass, except for the two Teflon stoppers in the circulation pump (Fig. 1). The system consists of a reaction vessel, a thin-wall-type G.M. counter, a circulation pump, a Bourdon-type pressure gauge and a supplier of chlorine gas.

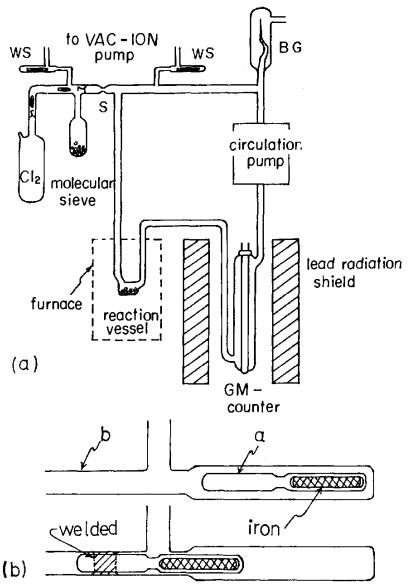

Fig. 1(a). Apparatus for the gas/solid-isotopic exchange reaction. WS, welding seal; BG, Bourdon type vaccuum gauge; S, common type seal.
(b) Detail of welding seal with a high conductance.

The samples were dehydrated by baking at 60—80 °C for 5—10 hr in a vacuum. The temperature was then gradually raised to 200 °C over 3—5 hr and kept at that temperature for 3—7 hr. After pre-baking in a vacuum, the system was sealed off from a diffusion pumping line, thus being made grease free. Further baking-out was carried out with a Vac-Ion pump. The system was isolated when the residual pressure became lower than 5×10^{-7} Torr during the course of baking of the sample at about 350 °C. The sample thus obtained was free from any external contamination of grease and water vapor, and its surface was adequately clean for the present purpose,[7] even though ultra high vacuum (below 10^{-9} Torr) could not be reached. A welding-seal was improved to be less-resistive as shown in Fig. 1 (b). To seal the system, a glass rod *a* is inserted into the outer tube *b* with the aid of magnet, the rod being welded to the outer tube.

First the temperature of the sample was raised to the reaction temperature. Purified chlorine gas was then carefully introduced into the system through a breakable seal and circulated by a circulation pump during the course of reaction. The reaction was followed by counting 0.714 MeV β-ray from ^{36}Cl in the gaseous phase, diffused from the crystallites, with the thin-wall-type GM counter. The temperature of the sample was controlled within 0.2 °C of a preset temperature by the aid of a PID-controller.

Materials Chlorine gas with a nominal purity of 99.8% (contained in a glass cylinder, Takachiho Chemical Co., Ltd.) was distilled and dehydrated with a Linde-3A molecular sieve in a vacuum system. Dehydration of chlorine gas is indispensable.[7]

Radioactive dichlorides were obtained by the isotopic dilution method. Their precipitates were prepared by a modified Marshall's method;[8] *i.e.*, by adding about 100 parts of distilled ethyl ether to one part of a nearly saturated alcoholic solution of the chlorides. Ethyl alcohol used had been dehydrated with a Linde-3A molecular sieve and distilled prior to use. After replacing the supernatant phase with ethyl ether, the precipitates were transferred into the vacuum system together with ethyl ether evaporated in situ. Conditions for preparation and properties of specimens are as follows.

$MgCl_2\cdot6H_2O$ (Merck G.R. reagent, item No. 5833) contains univalent impurities (Na^+ and K^+) nominally amounting to 20 ppm, the specific activity of the resulting radioactive dichloride being about 65 μCi/g. Special care was taken in the treatment of $MgCl_2$ specimens, since the substance is easily splashed by sudden heating in a vacuum and easily turns to magnesium hydroxychloride at 118 °C in air. The crystallites of $MgCl_2$ baked-out in a vacuum had a BET area of about 24 m^2/g.

Cobalt dichloride was prepared by the reaction between cobalt sponge (L. Light Co., Ltd., assay 99.99%) and distilled hydrochloric acid. It contained 20 ppm of sodium as determined by radio-activation analysis, the specific activity being about 5.3 μCi/g. The crystallites of $CoCl_2$ had a BET area of about 6 m^2/g.

Results and Analysis

The diffusion equation by Fick can be solved under the following boundary conditions: 1) the system is homogeneous and isotropic, 2) the initial concentration of radio-tracer is uniform over the crystals, and 3) the ratio of the amount of tracer diffused out (n) to that in the bulk is so small that the model of semi-infinite media can be used. Then n is given as a function of time t:[9]

$$n = (2AN_0)(Dt/\pi)^{1/2}, \tag{1}$$

where A denotes the surface area of specimen, N_0 the initial concentration of the tracer in the crystal, and D the diffusion coefficient. If we denote the counting rate by C, we obtain the following equation as a solution of the diffusion equation.[2,3]

$$C = C_0 + (2AN_0/\alpha\sqrt{\pi})(D_1t_1+D_2t_2+\cdots)^{1/2} \tag{2}$$

or

$$(C-C_0)^2 = (4A^2N_0^2/\alpha^2\pi)(D_1t_1+D_2t_2+\cdots) \tag{3}$$

where C_0 denotes the counting rate resulting from ^{36}C, diffused out of the surface region of the crystals, and α the conversion factor between C and n. Suffix i specifies the number of runs carried out successively for a given sample. In real crystals the properties of the surface region differ from those in the bulk, even though the bulk is homogeneous with respect to diffusion.[3,7,10] The diffusion coefficients in the surface region, in general, are much larger than those in the bulk. In the initial stage of the exchange reaction, diffusion from the surface region is observed, and then

bulk diffusion takes place.[3,7] Such a surface effect is taken into consideration as a correction term C_0 in Eqs. (2) and (3).

If the single path mechanism is applicable, the plots of $(C-C_0)^2$ against time may well be fitted by a straight line, and the Arrhenius plots of D_i may become a linear line.

Magnesium Dichloride. Diffusion experiments were carried out in the temperature range 180—350 °C. The exchange reaction referred to the surface of the crystallites proceeded even at −21 °C as shown in Fig. 2, while the self-diffusion of chloride ions in the bulk did not occur appreciably at temperatures below 180 °C. This indicates that chloride ions much more easily migrate in the surface region of the crystallites than in the bulk and Eqs. (2) or (3) is applicable to the present system. Three samples of magnesium dichloride crystallites were used to check the reproducibility of the data. The total counting rate in the gaseous phase are plotted against the square root of reaction time in Fig. 3(a), which represents an initial stage of the diffusion reaction at 180 °C. Except for the initial portion, the experimental points lie on a straight line, where the bulk diffusion may control the reaction; namely, the results can be well described by Eq. (2). However, there are some ambiguities as to the start of the reaction on the time scale. Measured time t should be replaced by an effective time interval $(t+\delta)$, where the value for δ is determined by the method given previously.[2,3] The abscissa in Fig. 3 is the effective time thus corrected. On the other hand, the intersection of the asymptote with the ordinate

gives a value for C_0. By using C_0-values thus determined, $(C-C_0)^2$ are plotted against time in Fig. 4, in which the points obtained lie on straight lines within experimental error. It is considered that the scattering of the data is mainly attributable to an incomplete mixing of ^{36}Cl in gaseous phase and partly to some drifts in the back-ground-counting rate. From the linear relationship the validity of the homogeneous crystal model may be envisaged. Values for $(4A^2N_0^2/\pi\alpha^2)D$ can be obtained from the slopes of the lines. Arrhenius plots of these values are shown in Fig. 6, in which all the curves consist of two segments of lines with breaks at about 270 °C ($1/T=1.85\times10^{-3}$ K^{-1}) and two kinds of slope are found.

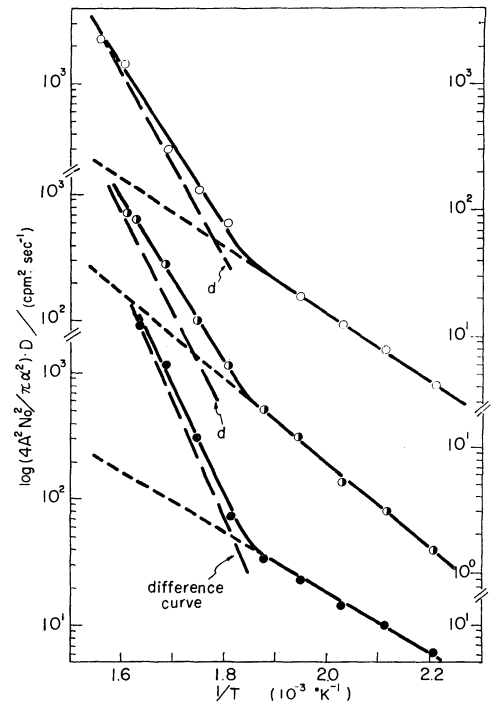

Fig. 6. Arrhenius plots of the apparent diffusion rates in $MgCl_2$.
○, Sample No. I; ◑, No. II; ●, No. III.

In the vacancy diffusion mechanism, the diffusion coefficient D may be expressed as[11]

$$D = D_0(1)\exp[-E/kT] + D_0(2)\exp[-(E+H_v/n_v)/kT] \quad (4)$$

where both $D_0(1)$ and $D_0(2)$ denote terms containing activation entropy and frequency, E is activation energy for the migration of vacancy, and H_v/n_v the apparent heat of the formation per one vacancy. The value for n_v depends on the mechanism of its formation, and we must make a choice between conceivable mechanisms.

If the vacancy mechanism of diffusion can be applied, the slopes in the lower temperature regions give the activation energy for migration of vacancy or Cl^- ions, E. When we plot the difference between the observed curve in the lower one, straight lines are obtained. The value for $(E+H_v/n_v)$ can be determined from the slope of the difference curve as given in Table 1.

Cobalt Dichloride. The temperature range studied was 180—360 °C. It may safely be assumed that chloride ions migrate more easily in the surface region than in the bulk. The total counting rate in the gaseous phase is plotted against the square root of effective time, $(t+\delta)^{1/2}$, in Fig. 3(b). In this case also experimental points lie on a straight line, except for the initial portion; namely, Eq. (2) can be applied to the $CoCl_2/Cl_2$ system. By the use of the values for C_0 obtained in Fig. 3(b), $(C-C_0)^2$ are plotted against reaction time in Fig. 5. The experimental points lie on straight lines within experimental error, the homogeneous crystal model thus being also valid in the

present case. Values for $(4A^2N_0^2/\pi\alpha^2)D$ determined from the slopes of lines are plotted against $1/T$ in Fig. 7. These curves have a similar form to those in Fig. 6, having breaks at about 320 °C ($1/T=1.7\times10^{-3}$ K^{-1}). The temperature of the break point is slightly higher than that on $MgCl_2$. The values for E and $(E+H_v/n_v)$ obtained are also given in Table 1.

If monovalent metal ions are doped in crystals of divalent metal dichloride, anion vacancies may be produced to satisfy electrical neutrality conditinon in the crystal. This effect was examined for $CoCl_2$ crystallites doped with sodium, whose concentration was 250 ppm as determined by radioactivation analysis. The same diffusion law was also valid in the doped crystallites. Arrhenius plots of the apparent diffusion coefficient are shown in Fig. 7. We see that the doped crystal has no break in the line in the temperature range studied, while the undoped crystallites containing 20 ppm of sodium have a break. From the slope of the line referring to the doped crystallites, the activation heat was evaluated to be 1.2 eV which is in harmony with E of the undoped crystallites (*cf.* Table 1); namely, the activation heat observed in doped crystallites should be referred to the activation energy for migration of vacancy or Cl^- ion. Thus, the experimental results support the theoretical prediction that the position of break point depends on the content of impurity, and the assumption that the vacancy migration is a dominant mechanism.

Discussion

In crystals with the $CdCl_2$-type structure, chlorine atoms are arranged in the cubic closest-packing structure and a metal atom occupies an octahedral hole made of six chlorine atoms, forming a sandwich structure with a layer arrangement ……(Cl–M–Cl)(Cl–M–Cl)……. Since the primary valence of the metal and chlorine atoms are satisfied within each sandwich, the van der Waals force operates between adjacent sandwiches.[13] However, the situation is not so simple; namely, there are two types of layer arrangements in the closest-packing structure, *i.e.*, the cubic type, ……ABC·ABC……, and the hexagonal one, ……AB-ABA……. Choice between the two structures is determined by the magnitude of the interaction between the metal layer and the chlorine layer in the adjacent sandwiches. If the interaction is very weak, the diffusion of Cl^- ions may be highly anisotropic, while, if strong, it approaches an isotropic diffusion. At the present stage of our knowledge on crystal structures, nothing can be predicted as to the magnitude of such interactions. We can only say that the experimental data are well described by a model of isotropic diffusion.

The values for $D_0(1)$ and $D_0(2)$ in Eq. (6) obtained with this model are given in Table 2. Plots of log $D_0(j)$ against the activation heat lie on a straight line as shown in Fig. 8; namely, the theta-rule[12] holds. This means that the method of analysis used is supported.

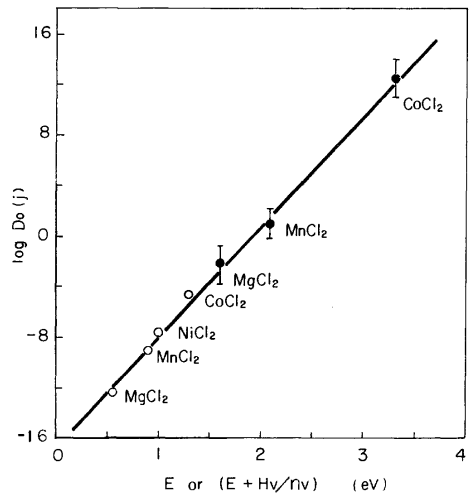

Fig. 8. Linear relationship between log $D_0(j)$ and E or $(E+H_V/n_V)$.
$D_0(j)$ is the pre-exponential factor of diffusion coefficient and given in the unit of $cm^2 \cdot s^{-1}$.
○ and ● refers to E and $(E+H_V/n_V)$, respectively.

According to Benson and his co-workers,[10] the surface of ionic crystal is deformed; namely, anions and cations in the surface region are displaced towards outer and inner directions from ideal lattice points, respectively. Such a distortion may increase the surface reactivity of the crystal. This prediction was proved quantitatively in the case of alkali chloride by Takaishi and Sensui.[7,14] Benson's theory may not be applied to divalent metal chloride crystals without further refinements, since these crystals have partly covalent nature. However, we can expect qualitatively that the surface region has different properties from the bulk, and ions in the surface region can migrate more easily than in the bulk. This prediction was semi-quantitatively proved in $NiCl_2$ crystallites.[3] Let us analyze the data on $MgCl_2$ to verify the prediction.

It may be safely assumed that there are two domains in the first layer of the crystal surface and that the distortion in the first layer influences the configuration of the second layer. The reverse reaction from the gaseous phase to the solid is ignored due to the boundary condition mentioned above, the kinetic equation being given by[3]

$$\begin{aligned}
&dn_g(i)/dt = k_1(i)n_1(i)\\
&dn_1(i)/dt = -k_1(i)n_1(i) - k_2(i)n_1(i) + k_2(i)n_2(i)\\
&dn_2(i)/dt = -k_2(i)n_2(i) + k_2(i)n_1(i) - k_3n_2(i) + k_3n_3(i)\\
&n(i) + n_1(i) + n_2(i) + n_3(i) = 3a(i), \qquad (5)
\end{aligned}$$

and

$$n_g = \sum_{i=1}^{2} n_g(i),\quad n_1 = \sum_{i=1}^{2} n_1(i),\quad n_2 = \sum_{i=1}^{2} n_2(i),\quad n_3 = \sum_{i=1}^{2} n_3(i),$$

$$a = \sum_{i=1}^{2} a(i),$$

where n_i denotes the number of ^{36}Cl in the i-th layer at time t; a, the number of ^{36}Cl contained in each layer at $t=0$; k_i, the apparent rate constant of the exchange reaction between the $(j-1)$th and the j-th layers; subscript g, the gaseous phase; and (i), the i-th kind of domain. In Eq. (5) it is assumed that $k_3(1)$ and $k_3(2)$ have the same value, k_3. If ^{36}Cl in gaseous phase amounting to a results in a counting rate C_s, it can be expressed as $C_s=\alpha \cdot a$ and $C/C_s = n_g/a$. Then, the solution of Eq. (1) is expressed[3] as

$$\begin{aligned}
\frac{C(i)}{C_s(i)} = \frac{n_g(i)}{a(i)} = {}& \frac{k_1(i)}{\rho_+(i)\rho_-(i)}\left\{\frac{k_2(i)k_3}{\lambda} - \rho_+(i) - \rho_-(i) - k_1(i)\right\}\\
&- \frac{k_1(i)k_2(i)k_3}{\lambda[\lambda+\rho_+(i)][\lambda+\rho_-(i)]}\exp(-\lambda t)\\
&- \frac{k_1(i)}{\rho_+(i)[\rho_+(i)-\rho_-(i)]}\left\{\rho_-(i) + k_1(i) - \frac{k_2(i)k_3}{\lambda+\rho_+(i)}\right\}\exp[\rho_+(i)t]\\
&- \frac{k_1(i)}{\rho_-(i)[\rho_-(i)-\rho_+(i)]}\left\{\rho_+(i) + k_1(i) - \frac{k_2(i)k_3}{\lambda+\rho_+(i)}\right\}\exp[\rho_-(i)t]
\end{aligned}$$

with

$$\begin{aligned}
2\rho_\pm = {}& -[k_1(i) + 2k_2(i) + k_3]\\
&\mp[k_1(i)^2 + 4k_2(i)^2 + k_3^2 - 2k_1(i)k_3]^{1/2} \qquad (6)
\end{aligned}$$

where λ denotes an effective rate constant for the decrease in n_3. By a comparison of Eq. (5) with the experimental curves, the best-fitting values for k_1(i), k_2(i) and k_3 are determined with the aid of an electronic computer. The results are well described by the theory, as shown in Fig. 2. The Arrhenius plots of $k_1(i)$ and $k_2(i)$ are given in Fig. 9; the activation energies for the exchange reaction are obtained to be: 3.4 kcal/mol (=0.15 eV) for the active part of the first layer, 7 kcal/mol (=0.3 eV) for the less-active one, 10 kcal/

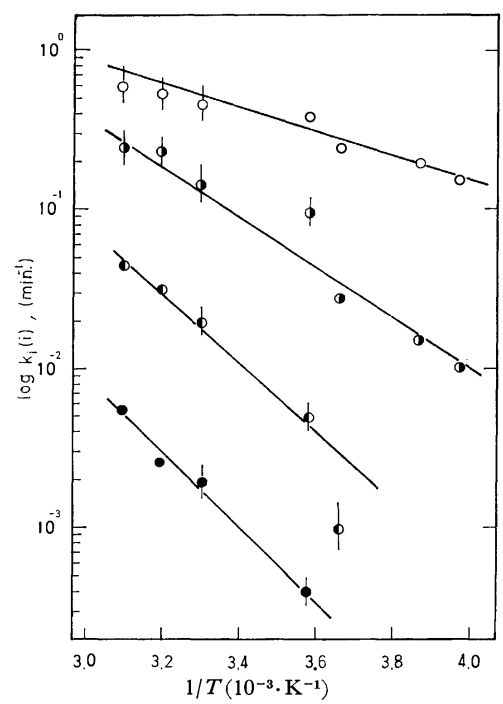

Fig. 9. Arrhenius plots of the rate constants for the exchange reaction in the surface region of $MgCl_2$ crystallites.
○, active domain in the first layer; ◑, less-active domain in the first layer; ◐, active domain in the second layer; ●, less-active domain in the second layer.

14) T. Takaishi and Y. Sensui, *Trans. Faraday Soc.*, **65**, 131 (1969).

mol (=0.43 eV) for the active part of the second layer, and 11 kcal/mol (=0.48 eV) for the less-active one. The activation energies of the exchange reaction converge to that of the self-diffusion more rapidly in $MgCl_2$ than in $NiCl_2$. This conclusion is semi-quantitative, since the present data on $MgCl_2$ are less quantitative. In $MnCl_2$ and $CoCl_2$, such a surface effect was observed only qualitatively but distinctly. Thus, we can say that high reactivity of the surface is a fairly common phenomenon which may be of value for further studies in connection with catalytic properties.

The value for n_v in Eq. (4) could not be determined. However, Simkovich[15] studied the mechanism of electrical properties and arrived at the conclusion that the associated vacancy is dominantly formed as

$$0 \rightarrow (V_{Pb}V_{Cl})' + V_{Cl}' + H_v$$

where V_x' denotes the vacancy of x atom (or ion). It may generally be considered that vacancies with effective charge, 2e, are rather unstable electrostatically and apt to form associated vacancies. If so, we may apply the above mechanism to other MeX_2 crystals; namely, $n_v=2$ may be presumed.

The author would like to express his gratitude to Prof. Tetsuo Takaishi, Rikkyo University, for valuable suggestions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3330—3335 (1973)

The Reflection Spectra of Simple Salts of the Tetracyanoquinodimethane Anion Radical

Yukako Oohashi and Tadayoshi Sakata*

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo 106

(Received April 20, 1973)

The reflection measurements were carried out for fourteen simple salts of the tetracyanoquinodimethane (TCNQ) anion radical over the range from 5000 to 42000 cm^{-1} by Avery's method. The solid-state spectra show three bands (CT, YI, and YII) and exhibit distinct differences depending on the cation species. According to the differences in the transition energy (σ_i) and the oscillator strength (f_i), the fourteen salts were classified into three groups (A, B, and C). The solid-state spectra of Group A resemble that of the dimer in an aqueous solution. Group B is characterized by the red shift of the CT band and the intensity increase in the YII band. The spectra of Group C exhibit a vibrational structure in the YI band which is similar to the monomer spectrum in an aqueous solution. Moreover, the large dispersion of the refractive index and the intensity increase in the bands of local excitation were observed for Group C. The electronic structures of these groups were studied by the use of the composite-system method. By taking account of the crystal structure of RbTCNQ-I, belonging to Group A, the stabilization energy (J^*) of the ground state was calculated from σ_{CT} and f_{CT}. The J^* values for ten salts in Group A correspond well to the singlet-triplet separation in the ground state observed by ESR measurements.

The electrical,[1-4] magnetic,[5-9] and optical properties,[10,11] and the crystal structures[12-20] have been extensively investigated with the anion radical salts of 7,7,8,8-tetracyanoquinodimethane (TCNQ). These results indicate that, in the crystalline state, the mode of the packing of TCNQ radicals exerts an important effect on the physical paoperties. X-ray crystal analysis studies clarified that TCNQ radicals form a one-dimensional column in a crystal and that the interplanar spacing is 3.16—3.6 Å.[12-20] The rather short interplanar spacing causes the strong charge-transfer (CT) interaction between TCNQ radicals in a column which is essential to an understanding of the electronic

properties. The absolute absorption intensity of the solid state gives quantitative knowledge about that interaction. The crystals of these radical salts, however, exhibit strong absorptions over the visible and ultraviolet regions, so that the transmission measurement is very difficult. On the other hand, the reflection measurement is useful for the determination of a strong absorption intensity, as has been described in the previous paper.[21]

In the present study, we measured the reflection intensities of the pressed pellets of fourteen simple salts of TCNQ anion radical and obtained the oscillator strength (f) for each transition. On the basis of these results and the reported crystal structures, we classify the fourteen simple salts into three groups and discuss the characteristics of each group.

Experimental

Materials. The samples used in this experiment were prepared by the method described in the literature[1] except for the Rb salts. RbTCNQ-I was prepared by the diffusion method described by Hoekstra,[18] and RbTCNQ-II was obtained by the rapid mixing of two hot acetonitrile solutions of RbI and TCNQ. The fourteen simple salts of TCNQ used are LiTCNQ, NaTCNQ, KTCNQ, RbTCNQ-I, RbTCNQ-II, CsTCNQ, NH_4TCNQ, (Ph_3PCH_3)TCNQ, MorpholiniumTCNQ (MorTCNQ), $BaTCNQ_2$, $FeTCNQ_2 \cdot 3H_2O$, $CoTCNQ_2 \cdot 3H_2O$, $NiTCNQ_2 \cdot 3H_2O$, and $MnTCNQ_2 \cdot 3H_2O$.

Measurements. The samples were ground with an agate mortar and were pressed by a KBr disc presser at about 10 kbar. The reflection intensity of the pressed pellet was measured by means of an apparatus constructed by our laboratory. The experimental details are the same as those described in the previous paper.[21] By the analysis of these reflection data, the refractive index (n) and the extinction coefficient (k) were determined, and the oscillator strength (f) for each transition was calculated by means of the equation:

$$f = \frac{m}{e^2 n_0} \int 4n(\nu)k(\nu)\nu d\nu.$$

Here, n_0 is the number of molecules in a unit volume and ν is the frequency of light. The f values were calculated in this study per TCNQ radical. In the figures of the present paper, the $4\pi n(\nu)k(\nu)/2.303\lambda C$ value (ε') will be plotted to show the wave number dependence of the absorption intensity of the solid-state spectrum (C: molar concentration of TCNQ radical, λ: wavelength).

Results and Discussion

Figure 1 shows the absorption spectra of LiTCNQ in an aqueous solution and a solid-state spectrum obtained from the reflection measurements. The TCNQ anion radical exhibits a reversible dimerization in the aqueous solution when the temperature is varied.[22] The monomer and the dimer spectra in the aqueous solution are shown in Fig. 1. From an open-shell SCF–LCAO–MO–CI calculation, t e electronic transitions at 11800 and 24800 cm^{-1} of the monomer spectrum were assigned to the locally-excited (LE) transitions in a TCNQ radical, polarized parallel to the long axis (y) of the anion radical. The present calculatoin shows that, in the region up to 50000 cm^{-1}, another band with a strong intensity (f=0.8) appears at 43000 cm^{-1}, polarized parallel to the short axis (x) of the anion radical. In the dimer state, the low-energy CT configuration exists and interacts with the LE configurations. The bands at 15800 and 36200 cm^{-1} of the dimer are shifted from the monomer positions by the interaction with the CT configuration, and the band at 11000 cm^{-1} has the CT character.

The observed solid-state spectra exhibit distinct differences depending on the species of the cation. On the basis of the transition energies (σ_i) and the oscillator strengths (f_i) of the solid-state spectra, the fourteen

21) Y. Oohashi and T. Sakata, This Bulletin, **46**, 765 (1973).

22) R. H. Boyd and W. D. Phillips, *J. Chem. Phys.*, **43**, 2927 (1965).

simple salts of the TCNQ radical were summarized into three groups (A, B, and C), as may be seen in Table 1. Here, the absorption peaks are denoted as CT, YI, and YII. The common feature of Group A is that the f_{YI}/f_{YII} ratio (0.5) and the $\sigma_{YI}-\sigma_{CT}$ (5000—6000 cm^{-1}) and $\sigma_{YII}-\sigma_{YI}$ splittings (11000 cm^{-1}) are all almost equal to those of the dimer in the solution. However, the oscillator strengths of the YI band of Group A, with respect to that of the dimer in the solution, are equal for the TCNQ salts of the Li, K, Rb-I, NH_4, and Ni cations, 1.5 times for the salts of the Mn, Co, and Fe cations, and 2.0 times for those of the Na and (Ph_3PCH_3) cations. Therefore, Group A is further divided into three subgroups, A1, A2, and A3 (Fig. 2).

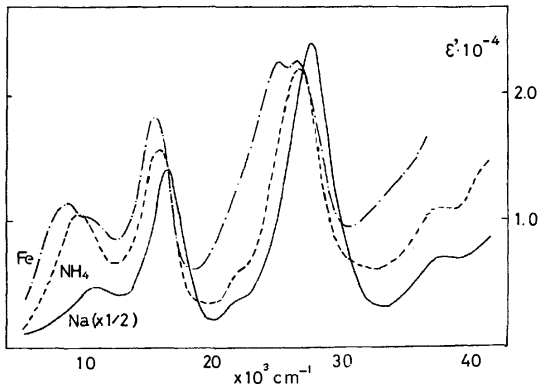

Fig. 2. The solid-state spectra of Al(NH_4TCNQ), A2(Fe-TCNQ$_2$·3H_2O) and A3(NaTCNQ). ε' in this work is the value per one TCNQ radical.

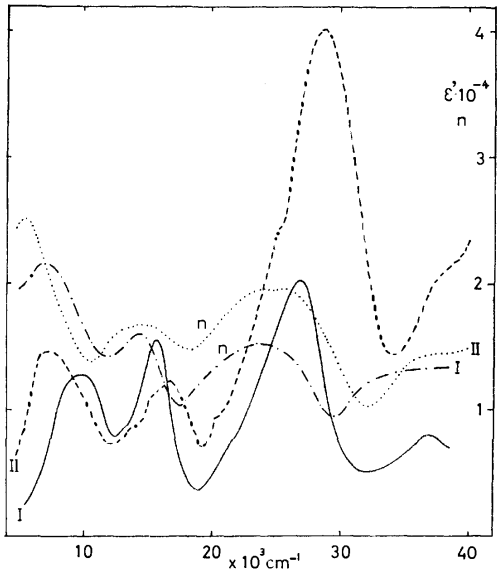

Fig. 3. The solid-state spectra and the refractive indexes of RbTCNQ-I(I) and RbTCNQ-II(II).

Figure 3 shows the solid-state spectra of RbTCNQ-I and RbTCNQ-II, together with the wave number dependence of the refractive indexes (n). The CT bands of RbTCNQ-II and CsTCNQ have an asymmetric shape and appear at 7400 and 7200 cm^{-1} respectively. These show a distinct red shift compared with the CT bands of Group A, and as a result, the

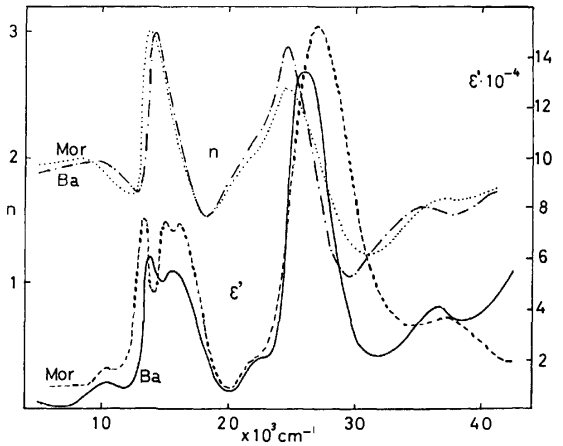

Fig. 4. The solid-state spectra and the refractive indexes of MorpholiniumTCNQ(Mor) and BaTCNQ$_2$(Ba).

$\sigma_{YI}-\sigma_{CT}$ splitting (9000 cm^{-1}) becomes large. The YII band increases remarkably in intensity. These two salts belong to Group B.

As may be seen in Fig. 4, the YI bands of the solid-state spectra of BaTCNQ$_2$ and MorTCNQ exhibit some structure, and the oscillator strengths of the YI and YII bands are larger than those of Groups A and B, especially for MorTCNQ, while the f_{YI}/f_{YII} ratios are about 0.5. The intensity of the CT band is very weak and is almost equal to that of the dimer in the solution. From the above-mentioned features, these two salts are denoted as Group C. The observed transition energies and oscillator strengths of the fourteen simple salts are tabulated in Table 2.

Group A. The solid-state spectra of Group A are shown in Figs. 1—3 and Figs. 5 and 6. Among these ten simple salts, the crystal structure has been

reported for RbTCNQ-I,[18] and for KTCNQ[20] as the preliminary data. In the crystal of RbTCNQ-I, the dimer of TCNQ radicals (the radical spacing is 3.159 Å) form a one-dimensional column (the interval between the dimers is 3.484 Å). In the dimer unit, the radicals overlap each other, with a shift (0.84 Å) along the x axis. In the case of KTCNQ, the axis of the radical column almost coincides with the axis normal to the molecular plane.

The TCNQ radical has one odd electron in the ninth molecular orbital (φ_9). By our calculation of the open-shell SCF–CI, the lowest LE state was assigned to the $\varphi_8 \rightarrow \varphi_9$ transition, and the second lowest LE state, mainly to the $\varphi_9 \rightarrow \varphi_{10}$ transition; the higher LE state is found at 43000 cm^{-1} in the region up to 50000 cm^{-1}. Therefore, in this study of the electronic structure of the solid state, it is sufficient to take account of the interaction between the ground (G), LEI, LEII, and CT configurations. The CT configuration under consideration corresponds to the $\varphi_9 \rightarrow \varphi_{9'}$ transition (φ_9 and $\varphi_{9'}$ denote the MO's of the two radicals forming a dimer unit).

$$G = 1/\sqrt{2}\,(|8\bar{8}98'\bar{8}'\bar{9}'| - |8\bar{8}\bar{9}8'\bar{8}'9'|)$$

$$\mathrm{LEI}^{\pm} = 1/2[(|8\bar{9}98'\bar{8}'\bar{9}'| - |9\bar{8}\bar{9}8'\bar{8}'9'|) \pm (|8\bar{8}99'\bar{8}'\bar{9}'| - |8\bar{8}\bar{9}8'\bar{9}'9'|)]$$

$$\mathrm{LEII}^{\pm} = 1/2[(|8\bar{8}108'\bar{8}'\bar{9}'| - |8\bar{8}\bar{1}08'\bar{8}'9'|) \pm (|8\bar{8}98'\bar{8}'\bar{1}\bar{0}'| - |8\bar{8}\bar{9}8'\bar{8}'10'|)]$$

$$\mathrm{CT}^{\pm} = 1/\sqrt{2}\,(|8\bar{8}9'8'\bar{8}'\bar{9}'| \pm |8\bar{8}98'\bar{8}'\bar{9}|)$$

The doubly occupied MO's φ_1—φ_7 are neglected. Here, the + and — signs denote the symmetric and the antisymmetric properties with respect to the symmetric center. Since the TCNQ molecule has the symmetry of D_{2h}, LEI and LEII do not interact with CT for the above-mentioned two modes of radical packing. Therefore, the configuration interaction occurs only between G and CT^+. The oscillator strength (f_{CT}) and the transition energy (σ_{CT}) of the CT band are calculated as follows:

$$f_{CT} = 1.085 \times 10^{-5} \frac{\beta^2 \sigma_{CT} R_{CT}^2}{\sigma_{CT}^2 + \beta^2}$$

and:

$$\sigma_{CT} = 1/2(E_{CT} + \sqrt{E_{CT}^2 + 4\beta^2}) \quad (\sigma_{CT}: \text{ in } cm^{-1}).$$

Here, E_{CT} is the configuration energy of CT^+, and β is the interaction parameter between G and CT^+. R_{CT} is the distance between the radical centers in Å units. Then, from the observed values of σ_{CT}, f_{CT}, and R_{CT}, the β value can be calculated as follows:

$$|\beta| = \sigma_{CT}\left(1.085 \times 10^{-5} \frac{\sigma_{CT} R_{CT}^2}{f_{CT}} - 1\right)^{-1/2}$$

Moreover, the stabilization energy (J^*) of the ground state is obtained as β^2/σ_{CT}. Table 3 shows the values of $|\beta|$ and J^* calculated from the reflection data. The value of R_{CT} was known only for KTCNQ (3.5 Å) and RbTCNQ-I (3.42 Å); therefore, for the other eight salts, R_{CT} was assumed to be 3.42 Å. For the R_{CT} value of 3.8 Å, the change in the $|\beta|$ value is less than 10%.

On the basis of the crystal data for RbTCNQ-I, the overlap integral ($S_{99'}$) between φ_9 and $\varphi_{9'}$ was calculated by the use of the Slater-type AO's[23] as 0.037. On the other hand, β is related to $\beta_{99'}$ by this equation; $\beta = 2\beta_{99'}$. Here, $\beta_{99'} = \int \varphi_9(1)\, H^C(1)\, \varphi_{9'}(1)\, d\tau_1$ and $H^C(1)$ is the one-electron Hamiltonian of the crystal. $|\beta_{99'}|$ was found from the reflection data to be 0.35 (Table 3). The ratio of $|\beta_{99'}|$ to

23) F. Clementi and D. L. Raimondi, *J. Chem. Phys.*, **38**, 2686 (1963).

$S_{99'}$ thus obtained is 9.5; this is reasonable. Table 3 shows the signlet-triplet splitting (J_{ESR}) of the ground state as determined by the ESR studies.[4,24] The ground configuration for the dimer system splits into the singlet (^{S}G) and the triplet (^{T}G) terms due to the exchange interaction (K) between the two unpaired electrons. By means of Mulliken's approximation, K and β are expressed as follows:

$$K = -A/2(S_{99'})^2$$

and:

$$\beta = -AS_{99'}$$

$$A = -\int\varphi_9(1)\varphi_9(2)\mathscr{H}\varphi_9(1)\varphi_9(2)d\tau_{12} - \int\varphi_9(1)\varphi_{9'}(2)\mathscr{H}\varphi_9(1)\varphi_{9'}(2)d\tau_{12}$$

where $\mathscr{H}$ is the Hamiltonian for the dimer system. Then, J_{ESR} is related to K and J^* by this equation:

$$J_{ESR} = -2K + J^* = AS_{99'}(1+A/\sigma_{CT}).$$

For the case of RbTCNQ-I, the A/σ_{CT} value is evaluated to be 13 from the observed values of J_{ESR} (0.29 eV), σ_{CT} (1.2 eV), and the calculated $S_{99'}$ (0.037). Therefore, the effect of the exchange interaction is almost negligible. The correspondence of J^* and J_{ESR} is good, taking account of the experimental error and the assumptions used for the calculation. The small value of J^* (0.07 eV) for the dimer in the solution is also reasonable.

If there is interaction between the CT^- and LE^- configurations, the f_{YI}/f_{YII} ratio differs from that of the dimer in the solution, as is the case with a very weak interaction. However, the f_{YI}/f_{YII} ratio and the $\sigma_{YI}-\sigma_{CT}$ and $\sigma_{YII}-\sigma_{YI}$ splittings observed for Group A show only slight change, and they are almost equal to the corresponding values of the dimer in the solution. Therefore, it seems that the salts belonging to Group A take the same packing form of the radical pair as RbTCNQ-I. The absolute intensities of the LE bands increase from A1 to A2 and A3, while the f_{YI}/f_{YII} ratio stays constant. The reason for this increase is not clear.

Table 4. Results of open-shell SCF–CI calculation

	RbTCNQ-I		RbTCNQ-II	
	cm^{-1}	f	cm^{-1}	f
LEI	9770	0.33	11300	0.28
LEII	21900	0.68	22200	0.74
LEIII	43300	0.77	43900	0.76

Group B. The crystal structure of RbTCNQ-II was reported by Shirotani *et al.*[19] TCNQ radicals form one-dimensional columns, in which the radicals are piled with equal spacing, with a shift of 1.86 Å along the y axis.

The transition energy and the oscillator strength of the radical monomer were calculated by the use of the molecular structures of RbTCNQ-I and RbTCNQ-II (Table 4). The slight difference in the bond lengths has a considerable effect on these transitions. Although the quantitative coincidence with the experimental values is not sufficient, it may be said that the f_{LEI}/f_{LEII} ratio is smaller for RbTCNQ-II than for RbTCNQ-I. First, we will consider the dimer model in discussing the electronic states of RbTCNQ-II solid. For the type of the radical packing of RbTCNQ-II, the $CT^{\pm}$ configurations interact with all the configurations under consideration. The matrices for the configuration interaction are:

Symmetric	G	0			
	LEI^+	0	E_I^+		
	$LEII^+$	0	0	E_{II}^+	
	CT^+	$2\beta_{99'}$	$-\sqrt{2}\beta_{89'}$	$\sqrt{2}\beta_{910'}$	E_{CT}^+
Asymmetric	LEI^-	E_I^-			
	$LEII^-$	0	E_{II}^-		
	CT^-	$\sqrt{2}\beta_{89'}$	$\sqrt{2}\beta_{910'}$	E_{CT}^-	

Here, $E_{CT}^+=E_{CT}^-(=E_{CT})$ was assumed. The configuration energies were estimated in the following way. The configuration energies of the locally-excited states, E^+ and E^-, show splitting by the interradical interaction, V, of the transition dipoles. The transition moments obtained from the open-shell calculation are almost equal for LEI and LEII. Therefore, the V values calculated on the basis of the crystal structures are −0.56 and −0.23 eV for RbTCNQ-I and RbTCNQ-II respectively. By the use of the reflection results and V, $E_I=1/2\ (E_I^+ + E_I^-)=1.00$ eV and $E_{II}=1/2\ (E_{II}^+ + E_{II}^-)=2.42$ eV were obtained for RbTCNQ-I. As may be seen in Table 4, the calculated E_I and E_{II} are higher for RbTCNQ-II than for RbTCNQ-I by 1500 and 300 cm^{-1} respectively. These differences were added to the E_I and E_{II} values obtained above for the RbTCNQ-I crystal. Thus, for the RbTCNQ-II crystal, E_I and E_{II} were determined to be 1.19 and 2.46 eV, and E_I^+, E_{II}^+, E_I^-, and E_{II}^- were calculated to be 0.96, 2.23, 1.42, and 2.69 eV respectively. E_{CT} was treated as a parameter (0.50—1.50 eV), and the values of β_{ij} were varied over the range of $k=-10$——-50 ($\beta_{ij}=kS_{ij}$). The S_{ij} used was calculated by the use of the Slater-type AO's.[23] The oscillator strengths were calculated on the basis of the transition moments obtained by the open-shell calculation for LEI and LEII. By comparison with the experimental results of RbTCNQ-II, a good fit was obtained by the set of $k=-20$ and $E_{CT}=0.75$ eV (Table 5). When the radicals are piled in an infinite column, f_{CT} becomes twice as large as f_{CT} for the dimer unit. Since the

YI	13800 15400	0.5	13500 15100 16100	0.9	11800 13400 14700	0.27	15800	0.22
YII	26200	1.1	27000	2.1	24800	0.47	26300	0.46

calculated CT band shows the 93% CT character, 0.20 corresponds to $0.39\times1/2$. Since this calculation does not take account of the effect of the infinite column and makes use of several assumptions, no quantitative discussion is available. The magnitudes of $k=-20$ and $E_{CT}=0.75$ eV are reasonable. In this treatment, the observed large intensity increase in the YII band could not be explained. This shows the importance of the long-range interaction. The calculations were carried out on the basis of Rhodes' [25] theory for intensity borrowing. The $\sum_{m}^{*n} G_{am\beta n}e_{am}e_{\beta n}$ factor for the YI and YII bands was four times as large for RbTCNQ-II as for RbTCNQ-I. Although a detailed discussion is impossible without the knowledge of the higher energy LE bands, it is clear that RbTCNQ-II is more sensitive to the intensity borrowing than is RbTCNQ-I.

Group C. Table 6 shows the transition energy and the oscillator strength of Group C, together with the data of the monomer and the dimer in the aqueous solution. The YI band of the monomer spectrum has a very sharp vibrational structure, the main vibrations of which are 1600 and 2900 cm^{-1} (Fig. 1). The vibrations of the YI bands, about 1600 cm^{-1} for $BaTCNQ_2$, and 1600 and 2700 cm^{-1} for MorTCNQ, are assigned to the above vibrations. The CT bands of both salts have an intensity almost equal to that of the dimer in the solution. On the other hand, the intensities of the LE bands show a remarkable increase, especially for MorTCNQ. The intense dispersion of the refractive index near the peaks of the LE bands is characteristic of Group C. This dispersion is one of the reasons for the large oscillator strength of the LE bands. Recently, it was reported that the MorTCNQ crystal contains the dimer unit of the TCNQ radicals, overlapping each other with a little shift along the x axis, and that its spacing is 3.28 Å.[26] For this mode of the radical packing, the interaction does not occur between the CT^- and the LEI^- configurations. The vibrational structure of the YI band may, therefore, be retained. Our observation of the weak CT band and the presence of the vibrational structure suggests a small contribution of the CT interaction in the solid state. However, the intensity increase in the LE bands and the outstanding dispersion of the refractive index cannot be discussed in detail at present.

The Relation of the Optical Spectrum to the Other Physical Properties. The magnitudes of the electrical resistivities of the salts of Group A are all in the order of 10^3—10^5 ohm cm, except for the case of the (Ph_3PCH_3) TCNQ (4×10^{10} ohm cm).[1,27] The salts of Group B have resistivities of 10^2 (RbTCNQ-II)[28] and 3×10^3 ohm cm (CsTCNQ).[27] By an analysis of the solid-state spectra, the CT components of the ground states are found to be a little larger for Group A (25%) than for Group B (20%). These results show that the resistivity is not sensitive to the CT character of the ground states. The TCNQ anion radical salts of Group A show the dimer formation in the solid state. On the other hand, in the salts of Group B, the radicals are piled up by equal spacings. Therefore, it may be suggested that the presence of the alternation of the radical spacing makes the resistivity large. The recent work on the MorTCNQ crystal structure also supports the above suggestion. This crystal exhibits a large alternation of the planar spacing between TCNQ anion radicals (3.28 and 3.61 Å) and shows a large electrical resistivity (10^9 ohm cm).[27]

The phase transitions of the TCNQ simple salts were observed by measurements of the absolute paramagnetic susceptbility and the electrical conductivity.[29,30] The transition temperatures are in the range of 338—391 K[29] or 348—395 K[30] for NaTCNQ, KTCNQ, and RbTCNQ-I. For RbTCNQ-II and CsTCNQ, they are 231 and 254 K[29] (210 K)[30] respectively. From our conclusion that the optically-classified groups take a different radical packing in the solid state, it is very reasonable that Group A and B behave differently in the phase transitions.

The authors would like to express their deep gratitude to Professor Saburo Nagakura of this Institute for giving them the chance to do this work and for his helpful discussions and critical reading of the manuscript. Our thanks are also due to Dr. Suehiro Iwata of the Institute of Physical and Chemical Research for his kindness in putting his computer program at our disposal.

A Note on the Intermolecular Orthogonalized Orbital

Hiroshi KATO and Shingo ISHIMARU*

(Received May 7, 1973)

The procedure for treating the molecular interaction is simplified by using the intermolecular orthogonalized orbital given by the method of Löwdin, and the accuracy of the approximation is examined, giving examples of the proton spin density of the solvated electron and the delocalization energy between chemically-interacting molecules. The following is then concluded: the intermolecular orthogonalized orbital is a kind of perturbed wavefunction of the molecule interacting with the other system and can most reasonably be applied when the Mulliken-type approximation for the intermolecular integrals can well be used. Its utility with regard to the three-system problem is also briefly discussed.

There have been many investigations[1-3] pointing out the important role of orbital overlapping between chemically-interacting molecules. However, the treatment considering the overlap effect is troublesome, particularly in the perturbation calculation. Consequently, in the present paper, we will try to calculate the electronic state of the composite system of molecules by the use of the intermolecular orthogonalized orbital given by the method of Löwdin[4] and will examine the accuracy of the approximation. An analogous calculation has frequently been performed in obtaining the spin density of a solvated electron on solvent molecules.[5-7] However, the wavefunction of the electron, ϕ^0, is orthogonalized only to the occupied orbitals of solvent molecules, ϕ_i, as follows:

$$\phi^0 = (\phi_e - \sum_i^{occ} S_{ei}\phi_i)/(1-\sum_i^{occ} S_{ei}^2)^{1/2}, \quad (1)$$

where ϕ_e is the non-orthogonalized orbital of the excess electron and where $S_{ei}=\langle\phi_e|\phi_i\rangle$. However, this type of orbital constructs a wavefunction which describes only the electron transfer from the occupied orbitals of solvent molecules to the excess electron orbital; in this sense, it is desirable that ϕ^0 be orthogonal also to the vacant orbitals of solvent molecules. Hence, we employ here a wavefunction satisfying this additional restriction.

Procedure

The basic notations used in this paper are summarized below:

	System A	System B
Fock operator	F_A	F_B
Occupied orbital	i, j	k, l
Vacant orbital	m, n	p, q
All orbital	a	b
Eigenvalue	ε_a	ε_b
Total energy in the ground state	W_A	W_B

Let us assume that the SCF MO's of the closed-shell systems, A and B, have already been obtained as:

$$F_A|a\rangle = \varepsilon_a|a\rangle, \quad F_B|b\rangle = \varepsilon_b|b\rangle. \quad (2)$$

The occupied orbitals orthogonalized to all of the orbitals of the other system and normalized to the second order of overlap integrals are given by:

$$\left.\begin{aligned} |i^0\rangle &= |i\rangle - \frac{1}{2}\sum_b S_{ib}|b\rangle + \frac{3}{8}\sum_b\sum_a S_{ib}S_{ba}|a\rangle \\ |k^0\rangle &= |k\rangle - \frac{1}{2}\sum_a S_{ka}|a\rangle + \frac{3}{8}\sum_a\sum_b S_{ka}S_{ab}|b\rangle \end{aligned}\right\} \quad (3)$$

which lead to $\langle i^0|j^0\rangle=O(S^3)$ and $\langle i^0|k^0\rangle=O(S^4)$, where S implies an intersystem overlap integral. We tentatively construct an antisymmetrized wavefunction using these orbitals in the following manner:

$$\Phi^0 = ||\cdots i^0\bar{i}^0\cdots j^0\bar{j}^0\cdots k^0\bar{k}^0\cdots l^0\bar{l}^0\cdots|| \quad (4)$$

where $i^0\bar{i}^0=i^0(\mu)\alpha(\mu)\ i^0(\nu)\beta(\nu)$ (μ, ν: the numbers of electrons, and α, β: spin functions). At this point of the discussion, we proceed without making definite what this wavefunction stands for. The "energy" corresponding to this wavefunction is given by:

$$W_T^0 = \langle\Phi^0|H|\Phi^0\rangle, \quad (5)$$

in which H is the hamiltonian operator of the composite system. Equation (5) is approximately written as follows:

$$\begin{aligned} W_T^0 \approx\ & W_A + W_B + Q_{AB} \\ & -2\sum_i\sum_k S_{ik}[Q_{A,ik}+Q_{B,ik}-S_{ik}(Q_{A,kk}+Q_{B,ii})] \\ & -\sum_i\sum_p S_{ip}[Q_{A,ip}+Q_{B,ip}-\frac{1}{2}S_{ip}(3Q_{B,ii}+Q_{A,pp}) \\ & +\frac{1}{2}S_{ip}(\varepsilon_p-\varepsilon_i)] \\ & -\sum_k\sum_m S_{km}[Q_{A,km}+Q_{B,km}-\frac{1}{2}S_{km}(3Q_{A,kk}+Q_{B,mm}) \\ & +\frac{1}{2}S_{km}(\varepsilon_m-\varepsilon_k)], \end{aligned} \quad (6)$$

where

$$Q_{AB} = 2\sum_i\langle i|V_B|i\rangle + 2\sum_k\langle k|V_A|k\rangle + 2\sum_i\sum_k\langle k|2J_i-K_i|k\rangle + (\text{repulsions between cores of A and B}), \quad (7)$$

$$Q_{A,ik} = \langle i|V_A+\sum_j(2J_j-K_j)|k\rangle \quad etc., \quad (8)$$

in which V is the core field and in which J and K are the Coulomb and exchange operators. In Eq. (6), the

6) D. E. O'Reilly, *ibid.*, **41**, 3736 (1964).
7) K. Fueki, *ibid.*, **45**, 183 (1966).

terms which are of the first and of the second order with regard to the overlap integrals are of the same order of magnitude. If the molecules considered to be non-polar, we may be permitted to put:

$$Q_{AB} \approx 0,\ Q_{A,ik} \approx Q_{B,ik} \approx \cdots \approx 0. \tag{9}$$

Hence, Eq. (6) is simplified as:

$$W_I^o \approx W_A + W_B - \frac{1}{2}\sum_i\sum_p S_{ip}^2(\varepsilon_p - \varepsilon_i) - \frac{1}{2}\sum_k\sum_m S_{km}^2(\varepsilon_m - \varepsilon_k). \tag{10}$$

On the right-hand side of this equation, the latter two terms express the stabilization brought about by the delocalization of the electronic charge between two molecules.

Other quantities are also easily obtained as follows. By the interaction with System B, the i-th orbital of A varies to:

$$\begin{aligned}\varepsilon_i^o \approx{}& \varepsilon_i + Q_{B,ii} \\ &- \frac{1}{2}\sum_b S_{ib}[Q_{A,ib} + Q_{B,ib} - \frac{1}{2}S_{ib}(\varepsilon_i - \varepsilon_b) \\ &- \frac{1}{2}S_{ib}(3Q_{B,ii} + Q_{A,bb})] \\ &- 2\sum_i\sum_j\sum_b S_{jb}\langle jb|ii\rangle - 2\sum_i\sum_a\sum_l S_{al}\langle al|ii\rangle \\ &+ \frac{1}{2}\sum_i\sum_j\sum_b S_{jb}^2(3J_{ij} + J_{ib}) + \frac{1}{2}\sum_i\sum_a\sum_l S_{al}^2(3J_{il} + J_{ia}) \\ &+ \frac{1}{2}\sum_i\sum_l\sum_b S_{ib}^2(3J_{il} + J_{lb})\end{aligned} \tag{11}$$

and the matrix elements concerning the charge transfer and the electronic excitation, which should vanish when intermolecular SCF MO's are used, are, respectively:

$$\begin{aligned}\langle\Phi_{i\to p}^o|H|\Phi^o\rangle \approx{}& \frac{1}{2}[Q_{A,ip} + Q_{B,ip} - S_{ip}(Q_{A,pp} + Q_{B,ii})] \\ &- \frac{1}{2}[\sum_{a\neq i} S_{ap}Q_{B,ia} + \sum_{b\neq p} S_{ib}Q_{A,pb}] \\ \langle\Phi_{i\to m}^o|H|\Phi^o\rangle \approx{}& Q_{B,im} - \frac{1}{2}\sum_b S_{ib}(Q_{A,mb} + Q_{B,mb}) \\ &- \frac{1}{2}\sum_b S_{bm}(Q_{A,ib} + Q_{B,ib}) \\ &+ \sum_b S_{ib}S_{mb}\Big[\frac{1}{8}(\varepsilon_i + \varepsilon_m) - \frac{1}{4}\varepsilon_b \\ &+ \frac{3}{8}(Q_{B,ii} + Q_{B,mm}) + \frac{1}{4}Q_{A,bb}\Big].\end{aligned} \tag{13}$$

Furthermore, it may be noted that the intermolecular orthogonalized orbital is convenient for treating the three-system (A, B, and C) problem; then:

$$|i^o\rangle = |i\rangle - \frac{1}{2}\sum_r S_{ir}|r\rangle + \frac{3}{8}\sum_r\sum_s S_{ir}S_{rs}|s\rangle, \tag{14}$$

where r indicates all the molecular orbitals of the two systems except A, and where s indicates all those of the two systems except the system to which r belongs. Here, $\langle i^o|i^o\rangle = 1 + O(S^3)$. The accuracy is inferior to that in the case of two systems. With the use of Eq. (14), the core integral is written as:

$$\begin{aligned}\langle i^o|H^c|i^o\rangle = {}& \langle i|H^c|i\rangle - \sum_r S_{ir}\langle i|H^c|r\rangle \\ &+ \frac{1}{4}\sum_r\sum_{r'} S_{ir}S_{ir'}\langle r|H^c|r'\rangle \\ &+ \frac{3}{4}\sum_r\sum_s S_{ir}S_{rs}\langle i|H^c|s\rangle,\end{aligned} \tag{15}$$

where $H^C = T + V_A + V_B + V_C$ (T: the one-electron kinetic operator) and where r and r' belong to the same group of molecules. It is clear in Eq. (15) that the three-center integrals emerge from the second and last terms. Thus, according to the orthogonalization procedure, the three-system problem becomes tractable.

Now, let us compare the above treatment with that of Devaquet,[9] in which the following intermolecular SCF MO for two closed-shell molecules is used:

$$|i^{int}\rangle = |i\rangle(1 - \gamma_i) - \sum_b c_{ib}|b\rangle + \cdots, \tag{16}$$

where:

$$\begin{aligned}\gamma_t &= \frac{1}{2}\sum_b c_{tb}(c_{tb} - 2S_{ib}) \\ c_{ib} &= \frac{F_{ib} - S_{ib}F_{ii}}{F_{bb} - F_{ii}} \\ &\approx \frac{\frac{1}{2}S_{ib}(\varepsilon_b - \varepsilon_t) + \left[\frac{1}{2}(Q_{A,ib} + Q_{B,ib}) - S_{ib}Q_{B,ii}\right]}{\varepsilon_b - \varepsilon_i + Q_{A,bb} - Q_{B,ii}}\end{aligned} \tag{17}$$

(F: Fock operator for the composite system of two molecules). If we set:

$$\frac{1}{2}(Q_{A,ib} + Q_{B,ib}) - S_{ib}Q_{B,ii} = 0,\ Q_{A,bb} - Q_{B,ii} = 0, \tag{18}$$

i.e.,

$$Q_{A,ib} + Q_{B,ib} = S_{ib}(Q_{A,bb} + Q_{B,ii}), \tag{19}$$

c_{ib} and γ_i become:

$$c_{ib} \approx \frac{1}{2}S_{ib} \text{ and } \gamma_i \approx -\frac{3}{8}\sum_b S_{ib}^2 \tag{20}$$

respectively. Equation (16) agrees with Eq. (3) if we take only the i term in the summation with respect to a in Eq. (3). Equation (19) is regarded as a "Mulliken-type approximation" for intermolecular integrals in the case of non-polar molecules.

The interaction energies given by Eqs. (3) and (16) are similar except for the term:

$$\left.\begin{aligned}&-2\sum_i\sum_p \frac{I_{ip}^2}{\varepsilon_p - \varepsilon_i} - 2\sum_k\sum_m \frac{I_{km}^2}{\varepsilon_m - \varepsilon_k} \\ &I_{ip} = \frac{1}{2}(Q_{A,ip} + Q_{B,ip}) \quad etc.\end{aligned}\right\} \tag{21}$$

which appears only in the expression of Devaquet. That is, the intermolecular orthogonalized orbital is a kind of approximate perturbed wavefunction of the molecule interacting with the other system, and the validity depends on the adequacy of the approximation represented by Eq. (19). Under the condition that Eq. (19) is well satisfied, the total wavefunction of the single Slater determinant composed of orthogonalized orbitals (Eq. (4)), which includes the resulting charge-transfer and polarization effects, is considered to describe the electronic state of the composite system appropriately.

a) The model is formed by four solvent molecules with one OH or NH bond oriented toward the cavity center. The orbital exponent of the 1s AO for the solvated electron is 0.3 a.u.$^{-1}$.
b) Ref. 10.

Examples

Table 1 shows the calculated spin densities of the solvated electron on the proton of solvent molecules. The values of I are larger than those of II; this is because in the former the delocalization, from the 1s AO of the excess electron to the vacant orbitals of solvent molecules, and from the occupied orbitals to the 1s AO, are both included, while in the latter only the delocalization from the occupied orbitals to the 1s AO is included. The discrepancy of this I from that of our previous work[10] is mainly caused by the approximation corresponding to omitting the term of (21). The result of II for the ammoniated electron differs very much from O'Reilly's.[6] This may be brought about by the differences between the wavefunctions applied and the approximation in estimating the molecular integrals. For the hydrated electron, the spin density of II is almost identical with Fueki's,[7] *ca.* 0.01, which is given in the same manner as II by the orbital exponent of the 1s AO for an excess electron, 0.312 a.u.$^{-1}$. At any rate, the spin polarization mechanism contributes dominantly in the case of a solvated electron in polar solvents; therefore, the values obtained by the orthogonalized orbital, which gives only an approximate spin delocalization term through the second order of the overlap integral, are unsatisfactory.

In Table 2, the results concerning the delocalization energies between a hydrogen molecule and carbene, between borane and borane, and between carbene and ethylene are compared with those of Fukui *et al.* For models (1) and (2), the present values are overestimated by a factor of several times.[11] For Model (3), the error is as small as *ca.* 16% and when the intermolecular distance R becomes smaller (Model (4)), the error increases. In Model (3), the perturbation expansion with the overlap is suitable because of the large intermolecular distance; besides, Eq. (19) can be expected to be satisfied successfully.

Conclusion

The intermolecular orthogonalized orbital is a kind of perturbed wavefunction of the molecule interacting with the other system, and, with the use of the orbital, the approximate expression of the interaction energy can easily be derived. It should be noticed, however, that the wavefunction can most reasonably be applied when the Mulliken-type approximation for the intermolecular integrals can be used. This means that, for the case in which the Gaussian-type orbitals are favorably used,[13] it is appropriate to use the intermolecular orthogonalized orbital. Moreover, according to the present procedure, the three-system problem becomes tractable.

The authors wish to thank Professor Kenichi Fukui for his valuable discussions. They also wish to thank Mr. Morio Miyagi and Mr. Shigeyuki Kato for thier generous permission to cite unpublished data.

Arrangement of Acridine Orange in the Poly-α, L-glutamic Acid–Acridine Orange Complex

Yukio SATO and Masahiro HATANO

The Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai 980

(Received May 8, 1973)

The temperature dependencies of the absorption and circular dichroism spectra of the poly-α,L-glutamic acid-acridine orange complex were observed at the temperatures in the range of 23—95 °C. The circular dichroism spectra were resolved into several Gaussian components by means of a computer online system. Thus, the circular dichroism spectrum can be resolved to five components. The shorter-wavelength bands, consisting of one positive and one negative element, were assigned to the transitions polarized parallel to and perpendicular to the axis of the α-helix of polypeptide respectively. On the other hand, the longer-wavelength bands, having equal magnitudes but signs opposite to each other, were assigned to the transition of the acridine orange dimer bound to polymer. The fifth band, at the shortest wavelength was uncertain. On the basis of these results, the arrangement of acridine orange molecules bound to poly-α,L-glutamic acid was discussed. Thus, two kinds of arrangements of acridine orange molecules were postulated. One is a left-handed super-helix around the right-handed α-helix of the polypeptide in the acidic pH region, and the other is a right-handed super-helix around the core of the α-helix in the alkaline pH region when the molar ratio of glutamyl residues to the dye is kept around unity. In these two complexes, there are dimeric acridine orange molecules bound to the polymer; in the latter complex, the super-helix consists of dimeric acridine orange molecules. Two types of arrangements of acridine orange molecules around the polypeptide were offered for the elucidation of the circular dichroism spectra of the complex of acridine orange with poly-α,L-glutamic acid in an aqueous solution.

Stryer and Blout studied the optical rotatory properties of dyes bound to polypeptides.[1] They made the interesting observation that an extrinsic Cotton effect in the wavelength region corresponding to the absorption bands of bound dye was obtained only when the dye combined with the helical form of poly-α,L-glutamic acid (PLGA). They also explained their results in a manner consistent with the dye-aggregation concept. Thus, they postulated three types of models for the elucidation of the Cotton effects observed in the complex of acridine orange (AO) with PLGA. According to their concept, the acquired optical rotatory power of the bound dye molecule can be only one of two types, configurational or conformational. A configurationally-induced Cotton effect could arise from the interaction of the symmetric dye chromophore with the local asymmetric environment of the α-carbon atom of the polypeptide. On the other hand, a conformationally-induced Cotton effect might result from the interaction among several symmetric dye chromophores which have been oriented to one another in the axial chirality sense by binding to the asymmetric polypeptides.

A conformationally-induced Cotton effect could arise from the aggregates of the dye molecules, which superimpose on the α-helix of polypeptide to form a superhelix in a single-screw sense or which form a tangential helix to the α-helix of polypeptide. Their data favor the conformational type of induced Cotton effect.

On the other hand, Yamaoka and Resnik[2] assumed that the induced Cotton effect in the PLGA–AO complex was caused by a vicinal dissymmetry around the asymmetric carbons in PLGA, since the induced Cotton effect was observed even at very high values of the ratio of the glutamyl residue to the dye (R/D). This assumption of Yamaoka's agrees with the configurationally-induced Cotton effect proposed by Stryer and his collaborator.[1]

In a previous paper,[3] we reported that the induced Cotton effect in the PLGA–AO complex arose from an interaction between the dimerically-bound AO molecules and that the induced Cotton effect arose from a helical arrangement of the dye along the main chain of the polypeptide.

The structure of this complex has not yet been established, although the structure was discussed in another report.[4] In this paper, we wish to report on our study of the arrangement of AO molecules on PLGA by means of some analyses of the effect of the temperature on their circular dichroism and on the absorption spectra. We will consider the origin of the induced Cotton effects on the basis of curve resolution for the observed circular dichroism bands. Furthermore, we will show the possible models of the PLGA–AO complex both in the case of pH=4.5 at small R/D (the ratio of the glutamyl residues to the dye molecules) values and in the case of the alkaline pH region at a R/D value of around unity. The induced circular dichroism bands can be explained by these models.

Experimental

The materials and the procedure are the same as those described previously.[5] The temperature in the optical cell was measured by means of a Takara Thermistor, Type SPD-1D, and allowed to equilibrate for 5 min before each

reading. The computer used for the curve fitting was a JEC-6 Spectrum Computer of the Japan Electron Optics Lab. Co., Ltd.

All the data presented below are reduced to the molar basis of the total AO concentration and are expressed by the molar extinction coefficient, ε, and the molar ellipticity, $[\theta]$. The molar ellipticity of the band at 222 nm is obtained on the basis of the molar quantity of the glutamyl residue.

Results

Effect of Temperature on the PLGA–AO Complex. Although Eyring and his collaborators[6] observed the effect of the temperature on the optical rotation of the PLGA–AO complex, they did not analyze this phenomenon. Therefore, we analyzed the temperature effect on the absorption and circular dichroism spectra of the PLGA–AO system with the variation in the value of the R/D ratio and in that of the pH of the system.

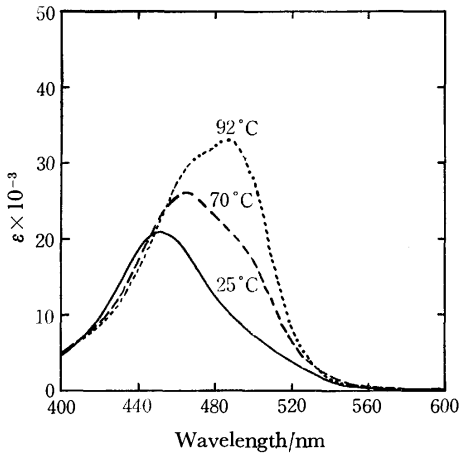

Fig. 1. Temperature dependence of absorption spectrum of PLGA–AO system. R/D=10, pH=4.5, [AO]=2×10^{-5}M.

When the PLGA–AO solution was gradually heated, the absorption spectrum changed, as is shown in Fig. 1. This variation may be due to a dissociation of AO molecules from the PLGA–AO complex or to a deaggregation of the AO molecules in the complex. This phenomenon was quite the reverse of the that anticipated. The course of the variation in the absorption spectrum was followed by measurements of the changes in the absorbance of the bands at 450 and 492 nm. The former band can be assigned to a band due to the aggregated AO, and the latter band, to the monomeric AO.[7] The temperature-dependent variations of the absorption bands at 450 and 492 nm in the R/D ratios of 10 and 1 are shown in Figs. 2 and 3 respectively. From these figures it can be seen that there are two types of shapes in these curves; this may be due to a difference between the arrangements of AO molecules bound to PLGA in the R/D ratios of 10 and 1. In order to discriminate the types of the arrangements of AO, the course of the decrease in

the molar ellipticities at the wavelengths of 435, 465, and 520 nm were observed; the variations in the ellipticities are summarised in Fig. 4. The circular dichroism (CD) bands at 435 and 465 nm may be ascribed to the aggregated AO in a helical fashion, and that at 520 nm, to the dimerically-bound AO.[3,4] The shapes of the temperature-dependent variation curves at 435 and 465 nm are similar to each other, but the shape at 520 nm is different. This indicates that the dimeric AO molecules are not in a helical arrangement. Furthermore, the variations in the residue molar ellipticities of PLGA samples with various degrees of polymerization were measured in the presence or in the absence of AO molecules; the results are shown in Figs. 5 and 6 respectively. From Fig. 5, it may safely be said that a complete helix-coil transition of PLGA does not occur in this temperature range. This may be because the glutamyl residues acquire a somewhat negative heat of ionization with

an increase in the temperature.[8] On the other hand, Fig. 6 shows the occurrence of the helix-coil transition for the PLGA–AO system in the observed temperature range. This may reflect the dissociation of AO molecules from the complex, or it may suggest that a raising of the temperature disturbs the formation of an array of AO molecules on PLGA anions. In other words, it is suggested that the aggregation of AO molecules on PLGA favors keeping the α-helix structure of PLGA itself.

Effect of the Degree of Polymerization of PLGA on the Dye Aggregation in the PLGA–AO Complex. As has previously been reported,[3,5] the pH, the R/D ratio, and a neutral salt addition can all affect the extent of the dye aggregation on PLGA. Figure 7 shows the

relation between f_H (helix fraction of PLGA in the PLGA–AO system) and the molar ellipticities of CD bands at 435, 465, and 520 nm. The values of f_H can be estimated from the residue molar ellipticities at 222 nm. The molar ellipticities at 435 and 465 nm increase with an increase in the f_H value, whereas that at 520 nm increases gradually with an increase in the f_H value up to 0.5 and then is almost constant in the case f_H values higher than 0.5. Figure 7 indicates that a higher f_H value than 0.2 is necessary to induce a Cotton effect in the visible region. The magnitudes of the molar ellipticities at 435 and 520 nm are dependent mainly on the helical aggregated and dimeric AO fractions respectively.[3,4] Figure 8 gives the relation between the degree of the polymerization of PLGA and the ratio of the molar ellipticity of the CD band at 520 nm to that at 435 nm. This indicates that none of all the AO molecules bound to PLGA

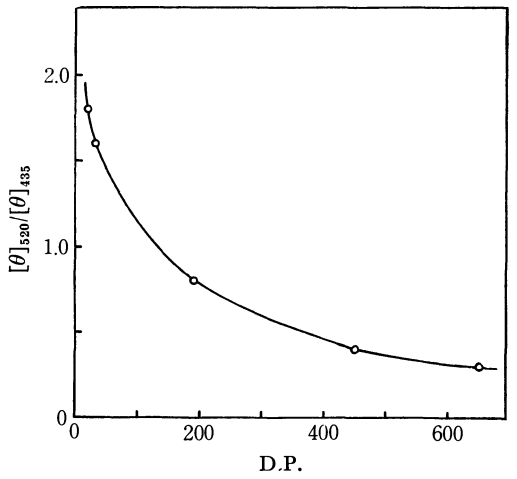

Fig. 8. Plots of ratio of magnitude of molar ellipticities at 520 nm to magnitude at 435 nm *vs.* degree of polymerization of PLGA (D.P.) in PLGA–AO system.
R/D=10, pH=4.5, [AO]=2×10^{-5} M.

are dimeric, since the relation shown in Fig. 8 is not linear. This consideration is supported by the findings on neutral salt effects on the PLGA–AO system.[3]

Curve Fitting. In order to assign the CD bands observed in the PLGA–AO system, we resolved the CD bands by a conventional Gaussian fitting method. Figure 9 shows the most favorable curve fitting for the case of R/D=10 and pH=4.5, and Fig. 10, for the case of R/D=1 and pH=9.1. In both figures, the solid lines indicate the observed curves, whereas the dotted lines indicate Gaussian curves obtained by the use of a computer.

Discussion

Aggregation of AO Molecules on PLGA. Ballard *et al.*[4] reported that the aggregation of AO molecules in the PLGA–AO complex has the form of a left-handed super-helix around the core of the right-handed α-helix of PLGA in a acidic pH region. On the other hand, we found that AO molecules are arranged to form a right-handed super-helix in the alkaline pH region at a R/D of around unity.[5] In a previous paper,[3] the CD band at 520 nm was assigned to the band due to the AO dimer bound to the helical PLGA in an acidic aqueous solution. Furthermore, the magnitude of the CD band at 520 nm is nearly constant at various R/D values, from 4 to 500, (as is shown in Table 1); therefore, it may safely be said that the PLGA–AO complex consists of both dimeric AO and helical AO molecules. The dimeric AO molecules contribute almost nothing to the rotational strength at 435 and 465 nm, since the increase in dimeric AO molecules is not accompanied by an increase in the magnitude at 435 and 465 nm.[3]

Arrangement of AO Molecules Bound to PLGA in the Acidic pH *Region.* In the acidic pH region, it was found, by using a variation method, that one AO molecule interacts with three glutamyl residues in PLGA.[9] Since AO molecules have a strong stacking tendency, the molecules are not randomly distributed among the available sites on a helical PLGA, but occupy sites adjacent to one another on the PLGA

9) B. C. Myhr and J. G. Foss, *Biopolymers*, **10**, 425 (1971).

and stack with each other.[10] The angle, v, between the direction of the long-axis electronic-transition moment of the AO molecule and the helix axis of PLGA may have values in the range from 5° to 40°.[4] If the thickness of the AO molecule is assumed to be 3.2 Å, and if the distance between the 3-dimethyl amino group and the 6-dimethyl amino group along the long axis of the AO molecule itself is 9.6 Å, the schematic model of the PLGA–AO complex shown in Fig. 11 can be used. In this case, the geometry of the binding sites of PLGA is that of α-helix, *i.e.*, 3.6 residues/turn, a vertical distance of 1.5 Å from each other, and a radius 5.4 Å.[11]

On the basis of the geometry of AO molecules in the PLGA–AO complex, the v angle can be determined to be near 15°; this seems plausible in view of Ballard's results[4] and the geometrical positions of the binding sites on PLGA. The short axis of the AO plane may be slightly tangentially-oriented with respect to the axis of the α-helix of PLGA, since this complex gives a positive CD band near 295 nm, where a transition polarized along the short axis of AO appears.[5]

A frequency interval, $\Delta\nu$, between the two transition energies which interact each other is given by:[12]

$$\Delta\nu = 2\mu^2 G/hcd^3 \qquad (1)$$

where G is the geometric factor for the dipole-dipole interaction with the limitting values of $+2$ and -1, h is Planck's constant, c is the velocity of light, and d is the distance between the two transition moments. The dipole strength, μ^2, of the visible absorption band of monomeric AO is 47×10^{-36} c.g.s.[12]

A Gaussian analysis, as is shown in Fig. 9, for the CD curve of the PLGA–AO complex in the acidic pH region suggests the presence of one positive CD band at 520 nm and one negative CD band at 490 nm. The magnitudes of the two bands at 520 and 490 nm are nearly equal to each other, but the signs are opposite. In the pair of bands, the frequency interval is 1100 cm^{-1}. The geometric factor, G, is assumed to be $+1$ because of the antiparallel sandwich type of AO dimer, and the distance from the center of one AO molecule to that of the nearest neighbor AO molecule in the PLGA-AO complex can be estimated to be 7.6 Å, which is a reasonable value.

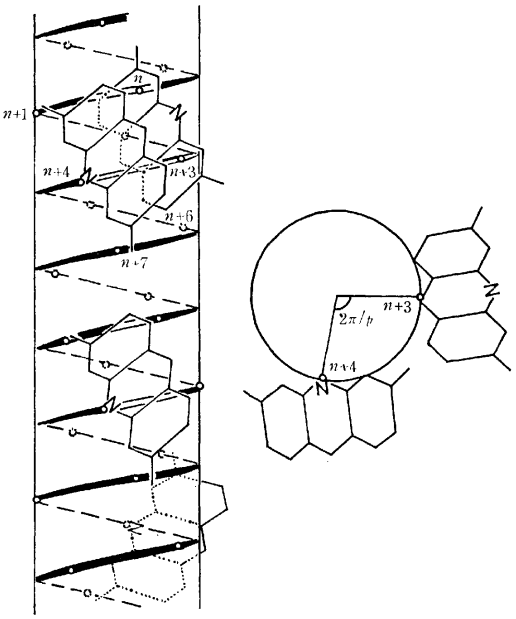

Fig. 11. Schematic model of PLGA–AO complex and the correlation between the positions of dimeric AO molecules in acidic pH.

In the PLGA–AO complex, two types of interaction between the transition dipoles of the AO molecules in the helical array bound to the helical PLGA can be expected. One is dependent on the radius of the helix, whie the other is dependent on the pitch. The radius-dependent rotational strength, R, is given by the following equation:[12]

$$R_{//} = -R_{\perp} = 2\pi a\mu_v\mu_t \sin^2(\pi/P) \qquad (2)$$

where a is the radial distance of each transition dipole from the helical axis and where $(2\pi/P)$ is the angle in radian about the axis between the two adjacent dipoles, which refer to Fig. 11. The rotational strengths, $R_{//}$ and $R_{\perp}$, arise from the resultant electronic transitions, which are polarized parallel and perpendicular to the helix axis respectively. The moments, μ_v, μ_t, and μ_r are, respectively, the vertical, tangential, and radial components of the dipole vector, μ, in the cylindrical coordinate frame of the helix. If the AO molecular planes lie at an angle of 15° to the axis of the helix, the pitch-dependent rotational strength can be neglected. Hence, the radial components of the interactions between the two excitation dipoles could be considered; the rotational strength was estimated to be 25×10^{-40} c.g.s., assuming the angle to be 15°. This value was obtained on the approximation that the dimeric AO molecules were attached to the glutamyl residues numbered (n, $n+3$, $n+6$) and ($n+1$, $n+4$, $n+7$) in the sequence along the polypeptide backbone of the α-helix of PLGA. This approximation was based on the finding that the distance between the dimeric AO molecules was nearly equal to that between the binding residues numbered $n+3$ and $n+4$. On the other hand, the experimental value of the rotational strength obtained from the CD magnitude of the bands at 520 and 490 nm was 23×10^{-40} c.g.s.; it was obtained using the following equation:

$$R = 0.696\times10^{-42}\sqrt{\pi}\,[\theta_k]\frac{\Delta_k}{\lambda_k} \qquad (3)$$

where $[\theta_k]$, Δ_k, and λ_k are the molar ellipticity, the half-band width, and the wavelength of the k-th CD band respectively. This experimental value agrees with the calculated one. Accordingly, the postulated scheme for the arrangement of AO molecules bound to PLGA may be plausible. As is shown in Fig. 11, two AO molecules attached to the glutamyl residues numbered (n, $n+3$, $n+6$) and ($n+1$, $n+4$, $n+7$) form the dimeric AO. Besides, the aggregated AO molecules have the form of a left-handed super-helix around the core of the α-helix of PLGA. These aggregated AO mole-

10) D. F. Bradley and M. K. Wolf, *Proc. Natl. Acad. Sci., U.S.*, **45**, 944 (1959).

12) B. J. Gardner and S. F. Mason, *Biopolymers*, **5**, 79 (1967).

cules have two CD bands, a negative CD band at 465 nm and a positive CD band at 435 nm, arising, respectively, from the transitions polarised parallel to and perpendicular to the axis of the α-helix of PLGA.[4] As is shown in Fig. 9, there are a negative component at about 460 nm and a positive component at about 450 nm in the CD curve of the PLGA–AO complex. These components can be assigned to the transitions polarized parallel and perpendicular to the axis of the α-helix of PLGA.

Arrangement of AO Molecules Bound to PLGA in the Neutral and Alkaline pH *Regions.* In the neutral and alkaline pH regions, PLGA is substantially ionized and randomly coiled in an aqueous solution. However, we have found that the PLGA–AO complex has a helical structure even in the neutral and alkaline pH regions at a R/D of unity.[5] In this case, the ring nitrogen cations of AO molecules bind to the carboxylate anions of PLGA side chains; these AO cations may be neutralized enough by the ion coupling to stack together. From the sign of the CD band near 450 nm (Fig. 10), it was considered that the arrangement of AO molecules bound to PLGA at R/D=1 and pH=9 may be such that their long axes form a right-handed super-helix around the PLGA chain. Thus, the formation of stacked dimeric AO molecules on PLGA is most plausible.

Over the same geometry of the α-helix of PLGA with that in an acidic aqueous medium, an array of aggregated AO, at R/D=1 and pH=9, may be arranged in such way as is shown in Fig. 12. In this case, one positive CD band and one negative CD band can be observed at 540 nm and at 500 nm respectively. In view of the steric hindrance between the dimethylamino groups of the AO molecules, the transition dipoles of the AO molecules may lie at an angle of about 51° to the axis of α-helix of PLGA. In this complex, AO molecules attached to the glutamyl residues numbered n, $n+3$, and $n+6$ may form two pairs of dimers. On the basis of these presumptions, the rotational strength arising from the interaction between dimeric AO molecules can be estimated to be 101×10^{-40} c.g.s. Therefore, the total rotational strength originating from dimeric AO molecules is 202×10^{-40} c.g.s. This value is very small compared with the experimental value. The rotational strength obtained from resolved CD curves using Eq. (3) amounts to 480×10^{-40} c.g.s. This extraordinarily large rotational

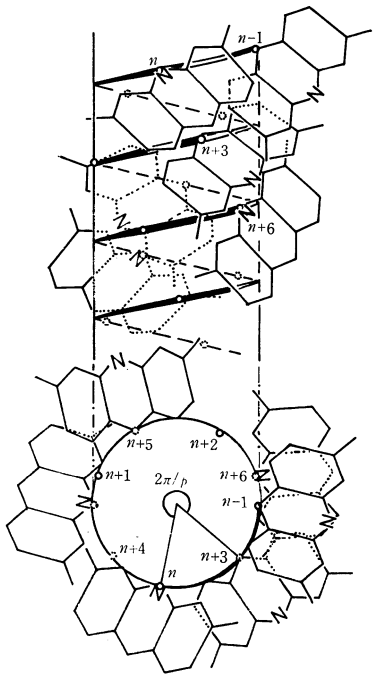

Fig. 12. Schematic model of PLGA–AO complex and the correlation between the positions of dimeric AO molecules at R/D=1, pH=9.

strength may arise from an interaction between the neighboring AO molecules on PLGA numbered $n-1$, $n+1$, $n+2$, *etc.* In the case of an R/D of unity in the alkaline pH region, the dimeric AO molecules should form an aggregate more tightly and should interact with each other. Therefore, the interaction between the dimeric AO units must be considered to be stronger in this case than in the case of a large value of R/D in the acidic pH region.

These closely-spaced AO molecules around the core of the α-helix of PLGA may also give an extraordinarily large rotational strength at 222 nm,[5] one which results from the coupling of the spin-forbidden n-π^* transition of polypeptide with some other allowed π-π^* transition of the AO molecule.

The polarization directions of the AO molecules and dimeric AO could be assigned by means of a polarization technique using a liquid crystal, one which is oriented by the application of an electric field. This experimental technique and our results will be described elsewhere in the near future.

Charge-transfer and Proton-transfer in the Formation of Molecular Complexes. VII.[1] Complex Isomerism in Several Anilinium Alkyl-substituted Picrates

Nobuaki INOUE and Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 11, 1973)

o-Chloroanilinium and *o*-bromoanilinium methylpicrates are obtainable not only as yellow-colored salts, but also as unstable, monotropic reddish-orange forms. Spectroscopic studies have revealed that the latter are charge-transfer complexes composed of the aniline molecule acting as an electron-donor and the acid molecule acting as an acceptor. Similar monotropic forms have been found in combinations of dimethylpicric acid with *o*-iodoaniline, *o*-bromoaniline, and *N,N*-dimethylamino-*p*-benzaldehyde.

About half a century ago, Hertel found that yellow-colored *o*-bromoanilinium picrate turns reddish-orange upon heating above 95 °C.[2] On the basis of the similarity in color and melting point with the corresponding *s*-trinitrobenzene complex, he concluded that the deeply-colored high-temperature form is a molecular compound composed of the aniline and the acid. As was confirmed by our spectroscopic examinations,[3] this is a charge-transfer complex in present-day terminology. The yellow picrate and the reddish-orange picric acid complex are enantiotropically related to each other. Hertel named this phenomenon "complex isomerism". Several more combinations including *o*-iodoanilinium picrate have been reported by Hertel to behave similarly.

With the hope of finding new organic compounds which exhibit solid-state transformations accompanied by a color change, we have examined series of anilinium methylpicrates and dimethylpicrates. These alkyl-substituted picric acids have been reported by Mariella *et al.* to form salts with aniline and its *N,N*-dimethyl derivative.[4] All of them have been noted to decompose at their melting points.

Experimental

Materials. The methylpicric acid and dimethylpicric acid were prepared by the nitration of *m*-cresol and 3,5-dimethylphenol respectively.[5] All the aromatic amines used in this work were commercially obtained. The anilinium alkyl-substituted picrates were precipitated by mixing the component compounds separately dissolved in chloroform or benzene.

Measurements. The vibrational and electronic spectra were measured as has been reported in the first paper of this series.[6] The X-ray measurements were made with a Toshiba recording diffractometer, Model ADG-301, using filtered copper radiation.

Results and Discussion

The combinations of methylpicric acid with *N,N*-diethyl-*m*-toluidine (pK_a=7.12), *N,N*-dimethyl-*o*-toluidine (6.11), *N,N*-dimethyl-*m*-toluidine (5.34), *N,N*-dimethylaniline (5.15), and *N*-methylaniline (4.85) give yellow compounds in both the solid and molten states. The presence of broad vibrational bands in the region from 2250 to 2750 cm^{-1} indicates that they are true phenolates formed by means of proton-transfer from the acid to the anilines. The solid products with the following seventeen anilines (arranged in the order of decreasing pK_a values) were also found to be salts: *p*-anisidine, *p*-phenetidine, *p*-toluidine, 2,4-dimethylaniline, *m*-toluidine, aniline, *o*-anisidine, *o*-phenetidine, *o*-toluidine, *m*-anisidine, *p*-chloroaniline, *m*-chloroaniline, 3-nitro-4-methylaniline (2.96), *o*-chloroaniline (2.71), *o*-iodoaniline (2.60), *o*-bromoaniline (2.55), and *m*-nitroaniline (2.46). The first twelve salts rapidly decompose below or at the melting points; therefore, the color of the melts could not be observed at all. On the other hand, the yellow salts derived from the last five turn red or reddish-orange upon melting. As will be described in the following paragraph, this color change can be attributed to the appearance of an additional electronic absorption near 500 nm. Moreover, the melting is accompanied by the replacement of the vibrational bands assignable to the NH_3^+ group by those characteristic of the NH_2 group. Therefore, we may conclude that these phenolates isomerize into complexes of the charge-transfer type at their melting points. Such an isomerization by melting has already been observed by us in some anilinium picrates and also in 2,4-dinitrophenolates.[6,7]

The lower limit of the pK_a range of aniline, in which the phenomenon of complex isomerization by melting is observable, has been shown to be close to the pK_a value of the acid component in the cases of the 2,4-dinitrophenolates.[7] On the other hand, the limit could not be determined in the cases of the picrates because of the lack of anilines in the desired pK_a range. Nonetheless, *p*-nitroaniline, the pK_a value of which is located a little above the value of picric acid, was found to form a charge-transfer complex. In the present case, the pK_a value of the acid component has not

been well established. Although Moore and Peck have reported that the acidity of methylpicric acid is considerably lowered ($pK_a=2.8$) as compared to that of picric acid itself,[5] this value may be in the range from 1 to 2, according to Mariella *et al.*[4]

When the reddish-orange melts of *o*-chloroanilinium and *o*-bromoanilinium methylpicrates are solidified, the color does not return to yellow. After storage at room temperature for several days; however, a gradual change to yellow became noticeable. Contrary to the case with most of the complex isomers studied by Hertel, these reddish-orange forms are monotropically related to the yellow forms. The melting point of the yellow form of the *o*-chloroanilinium methylpicrate was found to be higher than that of the reddish-orange form (101—102 *vs.* 72—73 °C), in accordance with Hertel's observation for the only complex isomers monotropically related to each other (4-bromo-1-naphthylamine-2,6-dinitrophenol; 91—92 *vs.* 85 °C).[8] For the *o*-bromoanilinium salt, the corresponding values are 102—103 °C and 74—75 °C. As is shown in Fig. 1, the reflectance spectrum of the yellow form of the *o*-chloroaniline complex has a strong absorption below 450 nm which is assignable to the methylpicrate ion. Upon melting, a broad absorption band covering the range from 450 to 570 nm appears. The unstable form shows a strong absorption in the same region as the melt does. The similarity between the spectrum of the reddish-orange form and that of the *s*-trinitrobenzene complex (shown by Curve d) indicates that this broad absorption band arises from the charge-transfer interaction between the amine and the acid. The weakness of the charge-transfer absorption in the melt may be explained by a partial dissociation of the complex to the component molecules at high experimental temperatures.

The examination of the vibrational spectra in the region from 2000 to 4000 cm^{-1} was more rewarding, and bands characteristic of the aniline and anilinium ion were well verified. In Fig. 2, the spectrum of the yellow form is compared with that of the melt and also with that of the reddish-orange form. The broad bands located at 2550 and 2820 cm^{-1} in the yellow form constitute the pattern characteristic of the anilinium ion. The sharp bands in the unstable form appearing 3250 and 3500 cm^{-1} may be assigned to the aniline, more particularly to a NH_2 stretching vibration. The spectrum of the melt consists of rather broad bands but is undoubtedly similar to that of the reddish-orange form, in accordance with the conclusion drawn on the basis of the electronic spectra. The behavior of the *o*-bromoanilinium methylpicrate resembles that of the above-mentioned *o*-chloroanilinium salt. On the other hand, the molten charge-transfer complexes of 3-nitro-4-methylaniline, *o*-iodoaniline, and *m*-nitroaniline reversibly isomerize into yellow salts upon solidification.

N,*N*-Dimethylamino-*p*-benzaldehyde, 2,5-dichloroaniline, and *p*- and *o*-nitroanilines, the pK_a values of which are the lowest among those of the anilines examined, ranging from −0.26 to 1.62, were found to form charge-transfer complexes in both solids and melts. These observations seem to be in accordance with the view that the pK_a value of methylpicric acid is in the range from 1 to 2.

Dimethylpicric acid forms yellow salts, which rapidly decompose below or at the melting points, with the following anilines: *p*-anisidine, *p*-phenetidine, 2,4-dimethylaniline, *N*-methylaniline, *m*-toluidine, aniline, *o*-anisidine, *o*-phenetidine, *o*-toluidine, *m*-anisidine, *p*-

8) E. Hertel and J. van Cleef, *Ber.*, **61**, 1545 (1928).

chloroaniline, *m*-chloroaniline, and 3-nitro-4-methylaniline. Their pK_a values are 2.96 or higher. The dimethylpicrates derived from *o*-chloroaniline, *o*-iodoaniline, *o*-bromoaniline, *m*-nitroaniline, and *N,N*-dimethylamino-*p*-benzaldehyde turn red or reddish-orange upon melting. Their melting points are consistently higher than those of the corresponding methylpicrates, 133—134 *vs.* 101—102, 96—97 *vs.* 89—90, 124—125 *vs.* 102—103, 123—124 *vs.* 110, and 99—100 *vs.* 82 °C respectively. The isomerization to complexes of the charge-transfer type was proved by spectroscopic examinations, as has been described for the cases of the methylpicrates. Among the five, the complexes of *o*-iodoaniline, *o*-bromoaniline, and *N,N*-dimethylamino-*p*-benzaldehyde were found to solidify without any color change. However, none of them was stable enough to be heated to the melting point. Even the physical measurements at room temperature could be carried out only for the last-mentioned complex. Thus, these complex isomers are also monotropically related to the yellow salts. The acidity of dimethylpicric acid has been estimated to be lower by 0.5 pK_a unit than that of methylpicric acid.[5] Nevertheless, we found that *N,N*-dimethylamino-*p*-benzaldehyde forms a charge-transfer complex with methylpicric acid, but a true phenolate with dimethylpicric acid. Charge-transfer complexes of dimethylpicric acid were obtained with 2,5-dichloroaniline and *p*-nitroaniline.

Hertel and Schneider have found that the complex isomers of 4-bromo-1-naphthylamine-2,6-dinitrophenol have crystal structures distinctly different from each other;[9] this is also the case with ours. The X-ray diffraction patterns are schematically presented in Fig. 3 for all the pairs examined. The longest spacings in the unstable forms of the methylpicrates are shorter than those in the stable yellow forms; *e.g.*, 7.2 Å *vs.* 9.2 Å in the isomers of the *o*-chloroaniline complex.

9) E. Hertel and K. Schneider, *Z. Phys. Chem.*, **B13**, 387 (1931).

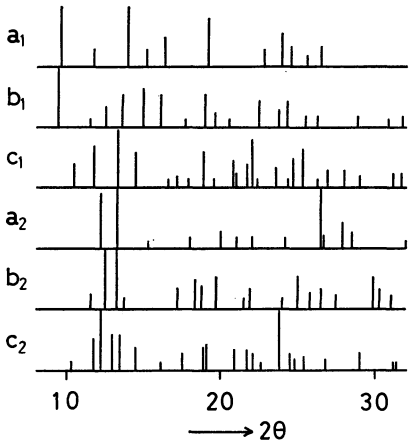

Fig. 3. X-Ray diffraction patterns, a) the *o*-chloroaniline-methylpicric acid, b) the *o*-bromoaniline-methylpicric acid, and c) the *N,N*-dimethylamino-*p*-benzaldehyde-dimethylpicric acid. The subscript 1 denotes the stable form and 2 the unstable form.

All the aromatic amines in the eight pairs of the complex isomers found by Hertel are halogenated derivatives.[2] The observations made by Hertel and also by us strongly suggest that the chance of finding complex isomers is high in the salts derived from halogenated amines, especially *o*-haloanilines. However, the amines in our five pairs of complex isomers include one free from halogen; that is, *N,N*-dimethylamino-*p*-benzaldehyde. In addition, a pair of complex isomers has been prepared by us with another amine bearing no halogen. When *o*-dianisidine is combined with tetranitrobiphenyl-4,4'-diol in a mole ratio of 1 : 1, a yellow salt and a black complex of the charge-transfer type are obtained.[1]

The authors wish to express their thanks to Professor Thosio Yokokawa for letting them use the X-ray diffractometer.

Small-angle Electron Scattering by Gases. CS_2 and CCl_4

Makoto NAGASHIMA, Shigehiro KONAKA, Takao IIJIMA, and Masao KIMURA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 14, 1973)

The small-angle scattering intensity of 40 keV electrons by CS_2 and CCl_4 molecules has been measured by the use of a counting unit. The experimental intensities have been compared with the theoretical values for the independent-atom-model, and an analysis of the comparison has shown the consistency of the present results with Tavard's energy relation. The difference intensity, $\Delta\sigma(s)$, of CCl_4 has shown oscillatory behavior resulting from the distortion of charge distribution due to chemical-bond formation.

The study of the charge distribution of atoms and molecules by means of a small-angle scattering experiment of high-energy (~40 keV) electrons has been shown to be feasible and promising by several recent works.[1-6] In most of them, molecules consisting of light atoms were investigated and the results interpreted in terms of the effect of the chemical binding and electron correlation on the charge distribution. Since the theoretical scattering intensity calculated from the exact molecular wave function is not available except for a few very simple cases, a direct comparison of the experimental results with the theoretical intensity is generally impossible at present. The theoretical relationship between the scattering intensity and the electronic energy of the molecular system given by Tavard and co-worker[7] has been useful for a semi-quantitative discussion of the experimental results. The difficulty in intensity measurements in the small-angle region was largely decreased by the use of a new diffraction unit with the scintillation-counting system in place of the photographic plate.[4,6]

The following atom and molecules have so far been successfully investigated by the counting technique; Ne,[2] CH_4,[3] CO_2,[4,8] N_2O,[4] and N_2[5] by Bonham and co-workers, and H_2O[6] by Konaka. All of them consist of atoms in the first row of the periodic table. The present study is an extension of these previous works along the same line of interest to molecules which contain atoms in the second row of the periodic table. For these atoms, the correlation energy is fairly large. To see how far the observed scattering intensity is consistent with the correlation energy estimated by Clementi[10] was the main purpose of the present study. However, the quantitative discussion of the result has been obscured by the uncertainty in our knowledge of the relativistic effect, which can not be ignored for the second-row atoms.

Experimental

The diffraction experiment was carried out on a counting unit which was reported elsewhere.[6] The experimental conditions were as follows: accelerating voltage, 41 kV, stabilized within 0.01%; camera length, 107 cm; pressure in the diffraction chamber, 2.0×10^{-6} Torr without sample gas injection and 3.5×10^{-6} Torr during measurement. A liquid nitrogen cold trap was placed close to the nozzle. The accumulated count was in the range of 2000—600000, and the time of measurement for a single data-point was 20 s. The data covered the range of $s=0.6-9$ Å^{-1} at intervals of 0.5 Å^{-1}.

The residual gas correction was carried out by the method of Fink and Bonham.[4] However, the second nozzle for the background measurement was not placed close to the main nozzle; rather, it was in between the nozzle and the detector, about 30 cm from the main nozzle and close to the wall of the diffraction chamber. This modification was made simply because of the difficulty in doing additional machine work for the small specimen-chamber. The amount of gas-injection through the second nozzle was adjusted so that the reading of the vacuum gauge was the same as that of the first run of the scattering measurements for a gas sample from the main nozzle. The present method is effective enough to make the residual gas correction for the background scattering from the almost uniformly-distributed gas in the scattering chamber, which is the major portion of the residual gas in the present unit for condensable samples.

The measured electron counts were first corrected for the counting loss due to the finite resolving time of the scaler. Then the normalized relative intensity, I_{exp}, was obtained by;

$$I_{exp} = C\left(N_G^D\frac{N_G^{M_0}}{N_G^M} - N_B^D\frac{N_B^{M_0}}{N_B^M}\right) \quad (1)$$

where $N_{G,B}^{D,M,M_0}$ are the corrected counts of the scanning detector (D) and monitor (M) for the sample gas (G) and background (B). The superscript M_0 indicates the reference value of the monitor count, and C is the normalization constant. This equation is valid on the assumption that the variation in the scattering intensity from the sample gas is proportional to the variation due to background scattering. The incident beam current was not monitored during measurements in the unit of the present study. However, an independent observation of the scattering count from a solid specimen indicated that the stability of the beam current was within

8) In Ref. 4, difficulty in the normalization of CO_2 and N_2O data to the theoretical intensity was reported. However, it was found recently that there were errors in the calculated values of the theoretical curve and the experimental data showed sufficient consistency with the Tavard's relation. Similar result for CO_2 was obtained also by the present authors.[9]

a) Normalized to I_{IAM} at s=6.5—8

b) The symbol σ denotes the estimated standard error of I_{exp}, which include the error resulting from the uncertainty in s. The relative errors σ/I_{exp} are shown in percentage unit.

5%. Therefore, a systematic error of 5% may be included in the second term of Eq. (1); this error is, fortunately, smaller than the random error of $N_G{}^D$.

The scale factor, $L\lambda$, was calibrated by Debye-Scherrer rings of gold-foil.[11]

Results and Discussion

The experimental intensity, I_{exp}, was normalized to the theoretical intensity for the independent-atom-model,[1] I_{IAM}, in the s-range of 6.5—8. The final values of I_{exp} were obtained as the average of six sets of data from three independent measurements. Two sets of data were obtained for each measurement by scanning both sides of the main beam. The values of I_{exp} and I_{IAM} are shown in Table 1, together with the estimated uncertainties evaluated in much the same way as in Ref. 6.

The theoretical I_{IAM} value was calculated by the use of the elastic and inelastic scattering factors[12] based on the Hartree-Fock wave functions and by the use of the structure parameters[13] taken from the literature. The elastic scattering factor is the partial wave amplitude, even though Tavard's equation is valid only for the Born amplitude. The necessity and meaning of this treatment were discussed by Kohl and Bonham.[1]

The s^2I_{exp} and s^2I_{IAM} curves are compared in Figs. 1 and 2 for CS_2 and CCl_4 respectively. The difference intensities, $\Delta\sigma(s)=s^4[I_{exp}-I_{IAM}]$, are shown in Figs. 3 and 4.

Analysis of the Results by Means of Tavard's Energy Relation. In the present scheme of analysis, where I_{IAM} is calculated on the basis of the Hartree-Fock wave functions of the atoms, the energy relation given by Tavard and co-worker[7] can be reduced to the following expression;[1]

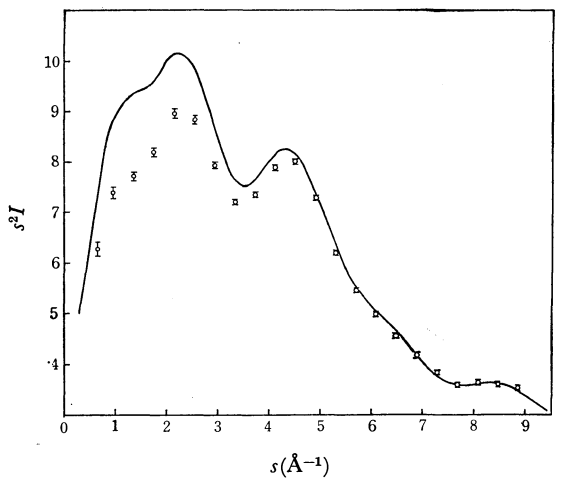

Fig. 1. Comparison between the experimental and theoretical (IAM) s^2I intensities for CS_2. ——: Theoretical intensity curve calculated using partial wave amplitude. ○: Experimental intensity. The vertical bar of experimental intensity shows the experimental standard error.

11) The lattice constant 4.078Å was used.

$$E_b = \Delta E + E_1 - E_{corr} - E_{rel}, \quad (2)$$

where;

$$\Delta E = \frac{1}{2\pi}\int_0^\infty \sigma(s)ds.$$

In this equation, E_b is the binding energy of the molecule, E_1 is one-half of the lowering of the potential energy of the IAM molecule from that of the separated atoms, and E_{corr} and E_{rel} are the sum of the correlation energies for all the atoms and that of the relativistic energies respectively. All the terms in this expression have negative values.[14] The contribution to the first integral from the s-region beyond the normalization point was assumed to be zero.

According to the theoretical estimations,[10c,15] the relativistic energy, E_{rel}, is comparable to E_{corr} for the present molecules. Since the relativistic Hamiltonian contains terms other than the Coulomb interaction between charged particles, Tavard's equation in the form of Eq. (2) becomes invalid. According to Bonham and Cox,[16] a modified version of Tavard's equation can be obtained by putting a factor of 1.5—2.0 to E_{rel} for the K-shell electrons of He-like ions,[17] where the relativistic effect appears as the charge contraction due to an increase in the effective mass of electrons. However, the decrease in scattering intensity corresponding to the relativistic effect confined in the charge distribution of the inner core should show up in a wide s-range extending to large scattering angles. The integral of $\Delta\sigma(s)$, which is obtained from a rather limited s-range, could not contain the contribution from the E_{rel} term of at least K-shell electrons. By a similar argument, the K-shell correlation energy is most probably excluded from the integration of $\Delta\sigma(s)$. Although the charge contraction by the mass-effect in outer cores may be very small, the contribution of the relativistic energy of outer cores to Tavard's equation can not necessarily be assumed to be negligible. In the present stage of knowledge, it seems to be most reasonable to regard the relativistic energy of the outer cores as a theoretical uncertainty in Tavard's relation. Equation (2) was modified by this conjecture to:

$$\Delta E + E_1 = E_b + E^*_{corr} \quad \text{with} \pm E^*_{rel}, \quad (3)$$

where E^* means that the contribution from the K-shell is not included; this equation was tested by the experimental data. The results were satisfactory, as is shown in Table 2. By considering that the radius of the L-shell of S and Cl is smaller than those of the first-row atoms, it is worth comparing the experimental values with the theoretical energies, where both the K- and L-shell energy are excluded for S and Cl. This is also shown in Table 2, where the energies without the contribution of the K- and L-shells are denoted by E^{**}. The agreement is poor. The exclusion of the whole L-shell seems, therefore, to be too extreme.

14) Note that in Eq. (11) of Ref. 1 the correlation energy E_{corr} is taken as a positive quantity and the relativistic energy is neglected.

Further correction for the vibrational effect,[18] which is of the order of the zero-point energy (a few hundredth of an a.u.), was neglected in the present analysis.

Comparison of I_{exp} and I_{IAM} in the Large s-Region by Means of Photographic Data. Since the s-range covered by the present counting experiment is rather limited, it is often uncertain whether or not the normalization at $s=6.5$—8 might have introduced a systematic error, thus leading to an underestimation of the absolute value of ΔE. In order to be sure that there is no such systematic error, the scattering intensity of CS_2 was carefully examined in the larger s-region by the use of the best photographic plate which has so far been obtained by the diffraction unit for the precise determination of the molecular structure.[19]

The s^4I_{exp} values up to $s=12$ are compared with s^4I_{IAM} in Fig. 5, where the counting data are also shown. The agreement of the counting data with the photographic intensity in the overlapping region, especially in the $7<s<9$ region is satisfactory. The agreement of the photographic data with the IAM intensity in the larger s-region up to $s=19$ is almost perfect, although the data beyound $s=12$ are not shown in the figure. The slight discrepancy between the counting and photographic data in $4.5<s<7$ seems to show an experimental imperfection still existing in the photographic data, because the increase in the intensity in this region has been experienced to be most sensitive to a slight misalignment of the slit system and/or the nozzle assembly. The photographic data in the $s<5$ region are not reliable enough because of the uncertainty in the effective sector correction and possible extraneous scattering from the main-beam stopper.

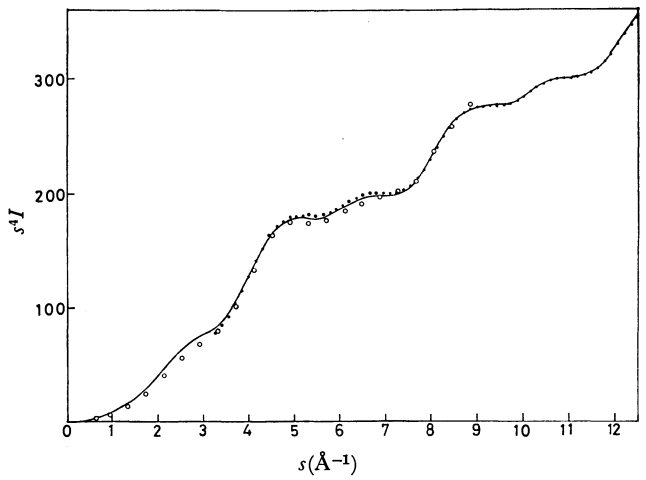

Fig. 5. Comparison of the photographic experimental, counting experimental and theoretical (IAM) s^4I intensities for CS_2. ——: Theoretical (IAM) curve calculated using partial wave amplitude.
• : The photographic experimental intensity.
o : The counting experimental intensity.

The comparison leads to the conclusion that there can be no better alternative for the normalization of the counting data in the present study, unless the precision of the intensity measurement is greatly improved.

Effect of Multiple Scattering. It has been pointed by several recent studies[20–23] that the effect of intramolecular multiple scattering appears in two ways: the double scattering, which reduces the atomic background intensity in the small s-region, and the triple scattering, which leads to a correction term containing a geometric factor. The first effect may be important in the interpretation of the experimental scattering intensity in terms of the binding and correlation energies, as in the present paper. The second one is related to the structure determination and also to the oscillatory behavior of the $\Delta\sigma(s)$ curve, as will be discussed in the next section.

The double-scattering contribution was, therefore, calculated for CCl_4 by means of Eq. (11) of Ref. 22. Also, one of the present authors (S.K) calculated the multiple effect for CCl_4 by means of the formalism of the eikonal approximation.[24] Both of these results indicated that the amount of the multiple effect for s^4I_T is less than 2 in the scale of Fig. 4, which is well within the limits of experimental uncertainty. Furthermore, the multiple effect for the atomic back-

ground of s^4I_T is found to be a monotonously increasing function within the s-range of 0—9; therefore, if one is to normalize the experimental intensity at s=6.5—8 to the IAM intensity which is corrected for the multiple effect, the ΔE value becomes almost equivalent to that obtained without the multiple correction, the difference being less than 0.1 a.u. Thus, the effect of multiple scattering seems to be safely ignorable in the present scheme of analysis.

Oscillatory Behavior of $\Delta\sigma(s)$. As is shown in Fig. 4, the $\Delta\sigma(s)$ curve of CCl_4 shows oscillatory behavior which is very similar to the interference pattern of diffraction pictures. In fact, the difference in s-values for the first and second maxima corresponds to that of the interference pattern for the Cl···Cl atom-pair in the CCl_4 molecule. This result can be reasonably understood in the light of the theoretical study of molecular Hartree-Fock cross sections for diatomic molecules performed by Kohl and Bartell.[25]

The oscillatory part of $\Delta\sigma(s)$ is primarily attributable to the interference of scattered electrons where the scatterers are a nucleus and the distorted part of the electron cloud around other nuclei produced by the chemical-bond formation, and it is denoted by $\Delta\sigma_{ne}$. Although the distortion of the charge density is generally not simple, it may be more or less described by an expansion around each nucleus in the Legendre polynomials, with radial function as coefficients. Then, the Fourier transform gives $\Delta\sigma_{ne}$, which consists of terms of the spherical Bessel functions, $j_n(sr_{AB})$, where r_{AB} is a nucleus-nucleus separation in the molecule. The $j_n(sr_{AB})$ can show up in a limited range of s as an oscillatory function with the characteristic distance of r_{AB}, irrespective of the order n. In general, $\Delta\sigma_{ne}$ is only a small portion of the total $\Delta\sigma$. However, the multiplicity of Cl···Cl separation due to the high symmetry of this molecule and the large scattering power of the Cl atom seem to have made the $\Delta\sigma_{ne}$ detectable, while the $\Delta\sigma_{ne}$ of CS_2 is perhaps of the order of the uncertainty of the total $\Delta\sigma$.

A similar oscillatory contribution can also be expected from the intramolecular multiple scattering. According to a preliminary calculation on the basis of the eikonal approximation,[24c] the peak-to-peak difference in the oscillatory multiple effect for CCl_4 is 1.2 or less in the scale of Fig. 4, which is only a small fraction of the observed oscillatory part of the $\Delta\sigma(s)$ curve.

The $\Delta\sigma_{ne}$ forms a part of the elastically-scattered intensity and is a one-electron property. Thus, the molecular Hartree-Fock wave function can be a satisfactorily good description for the calculation of $\Delta\sigma_{ne}$, and, conversely, the oscillatory part of the observed $\Delta\sigma$ curve can be an observable for testing a computed charge distribution of molecules. The usefulness of Tavard's equation is limited to a great extent by the uncertainties in the intensity measurement, which are amplified by the multiplication of s^4 for large s-values. A comparison of I_{exp} itself with the theoretical descriptions over all the observed region seems to be more fruitful for the future program of the small-angle scattering study, as the computation of molecular cross-sections becomes more familiar to experimentalists as well as to theoreticians.

Added Discussion. Relativistic-Hartree-Fock (RHF) calculations of atoms have been performed by several authors. The most extensive ones were obtained by Coulthard[27] and more recently by Malý and Hussonnois.[28] The first Born scattering factors were calculated by Doyle and Turner[29] on the basis of Coulthard's RHF atomic potentials; they are available for atoms from He through U. In these calculations, the Hamiltonian is expressed as:

$$\mathscr{H} = \mathscr{D} + \mathscr{B},$$

where $\mathscr{D}$ is the sum of the one-electron Dirac Hamiltonians for all the electrons plus the Coulomb interaction terms of the $1/r_{12}$ type and $\mathscr{B}$ is the sum of the relativistic two-electron terms, *viz.*, the Gaunt term and the retardation term. The wave function is made self-consistent with respect to $\mathscr{D}$, and the $\mathscr{B}$ term is neglected. The charge distribution used in the calculation of the scattering factors then corresponds to the $\mathscr{D}$ term.

By integrating $\Delta=(Z-f_x)^2_{RHF}-(Z-f_x)^2_{HF}$ for Ne up to s=60 Å^{-1}, where the integrand almost coverges to zero, it was found that the integrated value was nearly 15% larger than E_D-E_{HF}, where E_D means the eigen value of the $\mathscr{D}$ term, in absolute value. The difference, Δ, for Cl extends to more than s=60 Å^{-1}, with a small but appreciable magnitude. However, if $(Z-f_x)^2_{RHF}$ is normalized to $(Z-f_x)^2_{HF}$ at s=8 Å^{-1}, as in the present scheme of analysis, the energy obtained by integrating the differences in the $s<8$ Å^{-1} range amounts to −0.026 a.u., that is, −0.10 a.u. for four Cl atoms.

Theoretical uncertainty still remains concerning the effect of the $\mathscr{B}$ term on the charge distribution. Since the energy correction due to the $\mathscr{B}$ term is only 10% of E_D-E_{HF} for atoms heavier than Ne,[30] the uncertainty, $\pm E_{rel}$, mentioned in the text might be too pessimistic. Another uncertainty arises from the neglect of the inelastic scattering intensity in the discussion mentioned above. The inelastic part is probably important in the small-angle region investigated in the present study. The calculation of the inelastic scattering factors on the RHF basis is very much awaited.

The Electronic Spectrum of *p*-Benzosemiquinone Anion in Aqueous Solution

Shun-ichi FUKUZUMI, Yoshio ONO, and Tominaga KEII

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 19, 1973)

The electronic spectrum of *p*-benzosemiquinone anion in aqueous solution formed through the oxidation of hydroquinone with manganese dioxide was measured at room temperature. The absorption maxima were found at 430, 404, and 316 mμ with shoulders at 371 and 310 mμ. It was confirmed that these absorption maxima are due to the same species *p*-benzosemiquinone anion, on the ground that their kinetic behaviors are the same. The molar extinction coefficients of the absorption maxima and the oscillator strengths of the absorption bands were estimated.

Semiquinones are known to be intermediates in the quinone–hydroquinone redox systems. ESR studies gave unambiguous evidence for the presence of these important radicals.[1] While the electronic spectra of the substituted *p*-benzosemiquinones such as durosemiquinone or 2,5-di-*t*-butyl-*p*-benzosemiquinone have been established,[2-5] the spectrum of non-substituted *p*-benzosemiquinone has hardly been studied at all.

Two methods of producing *p*-benzosemiquinone anions have been employed so far; the chemical oxidation of hydroquinone in alkaline solutions[4,6] and the photolysis of hydroquinone in rigid media at 77 K.[7-9]

Using a rapid flow method for the air oxidation of hydroquinone in an alkaline solution, Diebler *et al.*[6] found the absorption maxima at 430 and 404 mμ. Harada and Matsunaga[4] succeeded in the observation of fairly good electronic spectra of several substituted *p*-benzosemiquinone anions, stabilized sterically by bulky substituents, in highly viscous solutions at room temperature, but could not record a good spectrum of the simplest *p*-benzosemiquinone anion though they found the absorption maxima at 432 and 408 mμ in the visible region. A drawback in this method of preparation is that *p*-benzosemiquinone anions are too unstable in an alkaline solution.

By the ultraviolet irradiation of hydroquinone in an alkaline ethanol solution at 77 K, Kimura *et al.*[9] obtained a spectrum with three bands, each with several absorption maxima and ascribed the spectrum to *p*-benzosemiquinone anion [$\cdot OC_6H_4O^-$], on the ground that it was similar to that of 2,5-di-*t*-butyl-*p*-benzosemiquinone anion mentioned above. However, interference by the presence of other species cannot be completely eliminated with this method. It seemed of prime importance therefore to prepare semiquinone anions in a stable condition. We have found that *p*-benzosemiquinone anion is easily formed when a neutral aqueous solution of hydroquinone is passed through a column of manganese dioxide, and that the anion thus formed is quite stable at room temperature even in the atmosphere. The rate of radical decay follows the first order kinetics with the rate constant 5.7×10^{-3} (min^{-1}).

By applying this technique to the preparation of the radical we could distinctly observe the electronic spectra of *p*-benzosemiquinone anion and the molar extinction coefficients were determined.

Experimental

p-Benzosemiquinone anion was prepared by passing an aqueous solution of hydroquinone through tubing (I.D. 6 mm) packed with 0.7 g of manganese dioxide (20—30 mesh). The initial concentrations of hydroquinone were 10—30 mM. The outlet of the MnO_2 column was directly connected to the optical cell. A flat type ESR cell for aqueous solutions, supplied by Japan Electron Optics Laboratory (JEOL), was also used for the measurements of electronic spectra, enabling us to measure both electronic and ESR spectra under the same conditions. The path length of the cell is 0.38 mm.

The electronic spectra were registered with a Shimadzu spectrophotometer, Model MPS-5000. The ESR measurements were carried out with a JEOL-X band spectrometer (JES-3BS-X). The concentration of *p*-benzosemiquinone anion was determined by comparison of the area under the absorption curve of the anion and that of 1,1-diphenyl-2-picrylhydrazyl (DPPH) in benzene.

Results and Discussion

The electronic spectra were measured with various feed rates of the hydroquinone solution. Besides the bands due to hydroquinone and *p*-benzoquinone, bands appeared in the near ultraviolet and visible regions, as shown in Figs. 1 and 2, respectively. Figure 1 was obtained by subtracting the absorption of hydroquinone of the initial concentration from the observed spectra. In the visible region, there is no appreciable overlapping of the bands due to hydroquinone or *p*-benzoquinone.

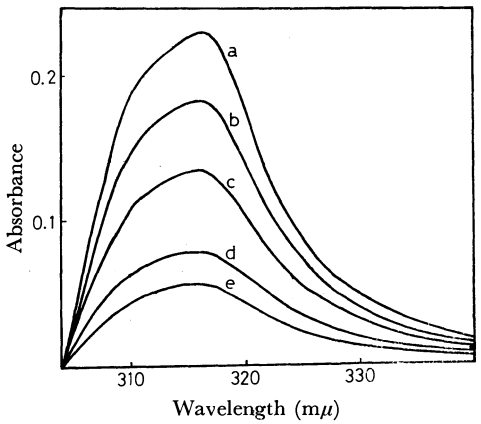

Fig. 1. Electronic spectra of *p*-benzosemiquinone anion in the ultraviolet region. The 20 mM hydroquinone solution was fed with the rates of (a) 0.15, (b) 0.38, (c) 0.81, (d) 3.9, and (e) 7.0 ml/min. (path length 0.38 mm)

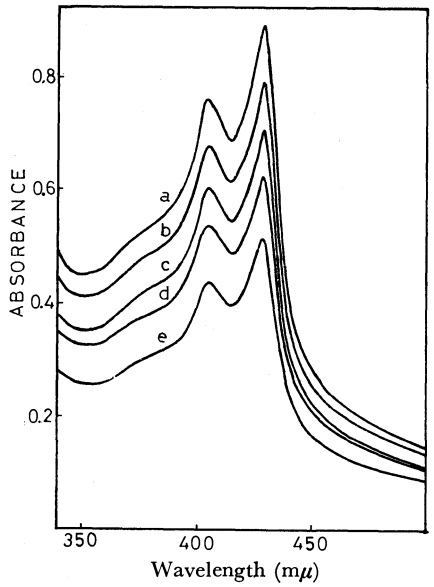

Fig. 2. Electronic spectra of *p*-benzosemiquinone anion in the visible region. The 30 mM hydroquinone solution was fed with the rates of (a): 0.68, (b): 1.0, (c): 1.3, (d): 2.2, and (e): 4.7 ml/min. (path length 1.0 cm)

The absorption maxima were observed at 430, 404, ~371, and ~310 mμ.

The kinetic behavior of the bands was studied in order to ascertain whether all the absorption maxima are due to *p*-benzosemiquinone anion. Previous ESR work showed that the concentration of the semiquinone anion was expressed as a function of the feed rate of the solution in the following way:

$$\ln \frac{[S]_\infty - [S]}{[S]_\infty} = -k\frac{V}{F} \qquad (1)$$

where [S] is the concentration of semiquinone anion at the exit of the MnO_2 column of volume V, when the feed rate of the solution is F, $[S]_\infty$ is the concentration at the infinitesimal feed rate and k the rate constant. Thus, if the absorption at the wavelength λ is caused solely by the semiquinone anion, the following relationship should hold.

$$\ln \frac{[A]^\lambda_\infty - [A]^\lambda}{[A]^\lambda_\infty} = -k\frac{V}{F} \qquad (2)$$

where $[A]^\lambda$ and $[A]^\lambda_\infty$ are the absorbance at wavelength λ when the feed rates are F and infinitesimal, respectively.

$\log([A^\lambda_\infty - [A]^\lambda)$ is plotted against $1/F$ at the wave-

* designates a shoulder

lengths of the absorption maxima in Fig. 3. It is evident that the changes of absorbance with feed rates are well expressed by Eq. (2) and the slope of each line gives the same value of k. In the case of other initial concentrations of hydroquinone, 20 and 30 mM, the same results were obtained. Since all the absorption maxima show the same kinetic behavior, it is concluded that all absorption maxima in Figs. 1 and 2 are due to the same species, *viz.*, *p*-benzosemiquinone anion. The ESR work confirmed that *p*-benzosemiquinone anion was the only paramagnetic species in the solution, and the neutral semiquinone ($\cdot OC_6H_4$-OH) or hydroquinone cation did not exist.

The positions of absorption maxima observed in this work are compared with those observed by other workers in Table 1. The values of the two maxima at the longer wavelengths agree with those obtained by Diebler *et al.*[6] The absorption maxima at the shorter wavelengths have not been reported for non-substituted *p*-benzosemiquinone anion at room temperature, but the corresponding maxima have been obtained for 2,5-di-*t*-butyl-*p*-benzosemiquinone anion.[4] Comparing the maxima for 2,5-di-*t*-butyl-*p*-benzosemiquinone anion with those of the non-substituted, all the bands of the former slightly red-shift. This can be understood as the effect of the electron-donating substituents [$-C(CH_3)_3$] on the benzene ring.

The molar extinction coefficients (ε_{max}) of the absorption maxima were calculated. The absolute concentration of the *p*-benzosemiquinone anion was determined from ESR intensity. The results are given in Table 1. The magnitude of the extinction coefficients suggests that all the absorption bands are caused by π-π^* transitions. The absorption maxima of 430 and 404 mμ are considered to be caused by the same π-π^* transition and their splitting is due to the C–O stretching vibration in the exited state.[4]

Table 2. Comparison between the observed and the calculated values of transition energy and the oscillator strength (f)

Observed		Calculated (11)		
Transition energy (eV)	f[a]	Transition energy (eV)	f	Symmetry type
2.88	0.06	2.960	0.03	$^2B_{3g}$–$^2B_{1u}$
3.34	0.03	3.479	0.11	$^2B_{3g}$–^2A_u
3.93	0.35	4.458	0.69	$^2B_{3g}$–$^2B_{1u}$

a) The oscillator strength f is evaluated from the well-known formula, $f=4.23\times10^{-9}\int\varepsilon(\nu)d\nu$.

Harada[11] carried out the molecular orbital calculation with the Pariser-Parr method on *p*-benzosemiquinone anion and estimated the transition energies and the oscillator strengths. The experimental values obtained in this study are compared with those calculated by Harada in Table 2. The agreement between the observed and the calculated values is fairly good for this type of calculation on molecules with hetero atoms.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3355—3358 (1973)

Hydrogen Formation in the Gas-Phase Radiolysis of C_2H_4-D_2O Mixtures

Ken-ichi KUWABARA and Yoshihiko HATANO

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received May 24, 1973)

The total hydrogen yields and their isotopic compositions have been measured in the gas-phase radiolysis of C_2H_4–D_2O mixtures at room temperature. A mixture of D_2O ($<$10 mol %) with a large amount of C_2H_4 was used to avoid the effect of the wall on the decomposition of D_2O. The contribution of thermal hydrogen atoms to the hydrogen formation may reasonably be excluded in this system. The kinetic treatment of D_2 and HD formation suggests the decomposition mechanism of D_2O. No important contribution of hot hydrogen atoms was observed. The yield of hydrogen from the D_2O formed by the unimolecular process, $G_{1D}=0.4$, was nearly equal to the molecular hydrogen yield reported previously.

In the radiolysis of pure water vapor, the hydrogen yield is very small.[1,2] The radiolysis in the presence of various organic additives, however, has shown a fairly large yield of hydrogen atoms.[3–9] The importance of excited hydrogen atoms in the physicochemical stage of the radiation effect on water vapor has been predicted by Platzman.[10] He suggested that such atoms might be electronically excited and pro-

duced *via* excitation from superexcitation. Actually, the measurement of the Lyman and Balmer radiation has been made in the collisions of fast electrons on water vapor, in which the possible role of superexcited water molecules as important precursors of electronically-excited hydrogen atoms has been discussed.[11] The yield of superexcited water molecules has been theoretically estimated by Santer and Bednar.[12] In the radiation chemistry of water vapor, however, few experiments have been made to examine this hydrogen atom.[13]

Recently, in the radiolysis of various hydrocarbons, evidence has been presented of the important role of hydrogen atoms with excess energy, called "hot hydrogen atoms".[14] That is, bimolecular hydrogen formation in the radiolysis of olefins or paraffins with a radical and an electron scavenger has been interpreted in terms of the hydrogen atom abstraction by hot hydrogen atoms formed by direct excitation, which must at least partially involve superexcitation.

The present investigation has been made in order to examine the nature of hydrogen atoms produced in the radiolysis of water vapor.

Experimental

Research-grade ethylene supplied by the Takachiho Shoji Co. was condensed at 77 K and degassed several times before use. Gas-chromatographic analysis using a silica gel column showed a purity of more than 99.95%, most of the impurities consisted of ethane. Deuterium oxide (>99.8 D%) stored in a nitrogen atmosphere was used without further purification except for the usual degassing at 77 K.

Cylindrical glass vessels about 300 ml in volume and fitted with break-off seals were baked in air at about 400 °C and then evacuated at less than about 10^{-5} mmHg for several hours. After this treatment, the required amounts of deuterium oxide and ethylene were introduced into the vessel. The total pressure for each sample was about 300 mmHg.

The samples were irradiated by ^{60}Co γ-rays at room temperature. The dose rate was 5.2×10^{19} eV/g·hr, and the total dose was 5.2×10^{20} eV/g of ethylene. The dose rate was based on the yield of hydrogen from ethylene, using $G(H_2)=1.31$.[15]

After irradiation the samples were attached to a vacuum line and the seals were broken. The product gases noncondensable at 77 K were collected by means of a Toepler pump. The total hydrogen yield was determined by gas chromatography using a molecular sieve-5A column. The isotopic composition of hydrogen was determined by means of a Hitachi RMU-5 mass spectrometer.

Results and Discussion

In the radiolysis of water vapor the wall has a large effect on the hydrogen formation.[2] The hydrogen yield depends considerably on the cleanliness of the vessel surface. In our case, however, the partial pressure of water vapor is less than 10% of the total, which is about 300 mmHg and which is formed mainly by ethylene. The effect of the wall mentioned above may be of lesser importance for the hydrogen formation in this experiment.

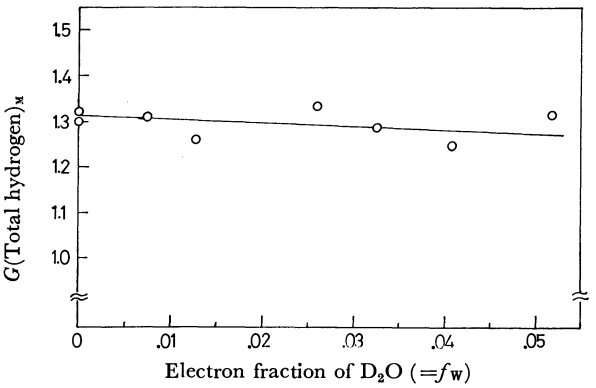

Fig. 1. Yields of hydrogen in the radiolysis of C_2H_4–D_2O mixtures.

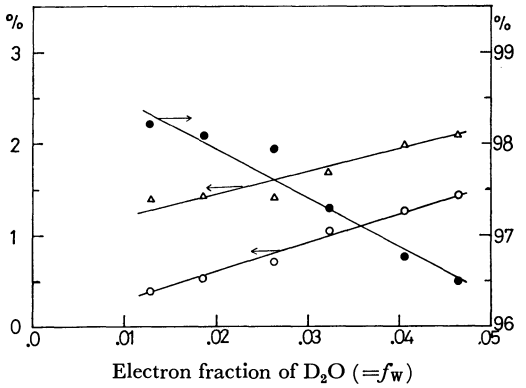

Fig. 2. The isotopic composition of hydrogen produced in the radiolysis of C_2H_4–D_2O mixtures.
●: H_2, △: HD, ○: D_2.

In Fig. 1, G(total hydrogen)$_M$, the number of hydrogen molecules formed per 100 eV of the energy absorbed by the C_2H_4–D_2O mixtures, is plotted against the electron fraction of D_2O ($=f_W$). G(total hydrogen)$_M$ decreases only a little with an increase in the D_2O concentration. Figure 2 shows the isotopic composition of the total hydrogen as a function of f_W. Both the D_2 and HD contents increase linearly with an increase in the f_W. By the extrapolation to zero concentration of D_2O, the D_2 content becomes zero, whereas the HD content has an intercept.

Now, let us consider the hydrogen formation from the C_2H_4–D_2O mixtures. In the first place, the contribution of thermal hydrogen atoms will be considered. Ethylene has a high reactivity for them[16] and the addition reaction (1) may be dominant compared with the abstraction reactions, (2) and (3):

13) R. S. Dixson, *Radiation Res. Rev.*, **2**, 237 (1970).
14) Y. Hatano and S. Shida, *J. Chem. Phys.*, **46**, 4784 (1967); Y. Hatano, S. Shida, and M. Inokuti, *ibid.*, **48**, 940 (1968); Y. Hatano, S. Shida, and S. Sato, This Bulletin, **41**, 1120 (1968); Y. Hatano, *ibid.*, **41**, 1126 (1968).
15) G. G. Meisels, *J. Chem. Phys.*, **41**, 51 (1964).
16) K. R. Jennings and R. J. Cvetanovic, *ibid.*, **35**, 1233 (1961).

$$H(\text{or } D) + C_2H_4 \longrightarrow C_2H_5(\text{or } C_2H_4D) \quad (1)$$

$$H(\text{or } D) + C_2H_4 \longrightarrow H_2(\text{or } HD) + C_2H_3 \quad (2)$$

$$H(\text{or } D) + D_2O \longrightarrow HD\ (\text{or } D_2) + OD \quad (3)$$

Thus, the contribution of the abstraction reaction of thermal hydrogen atoms to hydrogen formation must be excluded. The ethyl radicals in Reaction (1) are vibrationally excited at first and possibly dissociate again. Under these experimental conditions, however, such as a total pressure of about 300 mmHg at room temperature, these excited radicals are changed predominantly to thermal ethyl radicals by collisional deactivation and are not responsible for the hydrogen formation. Thus, thermal hydrogen atoms may be unimportant for the hydrogen formation in this system.

Secondly, the possibility of hydrogen formation through various ion-molecule reactions may also be eliminated on the basis f the following discussion.[17]

Positive-charge or proton transfer from $C_2H_4^+$ to D_2O and hydrogen-atom transfer from D_2O to $C_2H_4^+$ seems to be energetically impossible.

$$C_2H_4^+ + D_2O \longrightarrow C_2H_4 + D_2O^+; \quad \Delta H = 47 \text{ kcal/mol} \quad (4)$$

$$C_2H_4^+ + D_2O \longrightarrow C_2H_3 + HD_2O^+; \quad \Delta H = 11\pm4 \text{ kcal/mol} \quad (5)$$

$$C_2H_4^+ + D_2O \longrightarrow C_2H_4D^+ + OD; \quad \Delta H = 32\pm4 \text{ kcal/mol} \quad (6)$$

However, secondary ions which are known to exist in the high-pressure mass spectrometry of ethylene[19] can possibly undergo proton transfer to D_2O to produce D_2HO^+.

The formation of D_2O^+ *via* the direct effect of ionizing radiation on D_2O will invoke the following ion-molecule reactions:

$$D_2O^+ + C_2H_4 \longrightarrow D_2O + C_2H_4^+; \quad \Delta H = -47 \text{ kcal/mol} \quad (7)$$

$$D_2O^+ + C_2H_4 \longrightarrow OD + C_2H_4D^+; \quad \Delta H = -15\pm4 \text{ kcal/mol} \quad (8)$$

$$D_2O^+ + C_2H_4 \longrightarrow D_2HO^+ + C_2H_3; \quad \Delta H = -37\pm4 \text{ kcal/mol} \quad (9)$$

$$D_2O^+ + D_2O \longrightarrow D_3O^+ + OD; \quad \Delta H = -22\pm4 \text{ kcal/mol} \quad (10)$$

Even if D_3O^+ was present in this system, it seems that, on energetic grounds, we can exclude the possibility of the hydrogen formation through ion-molecule reactions (11) and (12) between D_3O^+ and C_2H_4.

$$D_3O^+ + C_2H_4 \longrightarrow D + D_2O + C_2H_4^+; \quad \Delta H = 94\pm4 \text{ kcal/mol} \quad (11)$$

$$D_3O^+ + C_2H_4 \longrightarrow HD + D_2O + C_2H_3^+; \quad \Delta H = 68\pm6 \text{ kcal/mol} \quad (12)$$

The possibility of the hydrogen formation through ion-molecule reactions between D_2HO^+ and C_2H_4 may similarly be excluded.

The HD formation *via* the neutralization of $C_2H_4D^+$ in Reaction (8) might be considered, but such a possibility may be excluded because of the experimental finding in the radiolysis of ethylene that hydrogen formation is not affected by the addition of electron scavengers. Such a neutralization would produce thermal hydrogen atoms to be scavenged by ethylene itself.

The hydrogen observed in this experiment might be formed by the molecular detachment from C_2H_4 and D_2O, or by the hydrogen-atom-abstraction reaction of the hot hydrogen atoms, H′ and D′, produced from C_2H_4 and D_2O respectively *via* direct excitation. Hot hydrogen atoms might also be produced *via* the neutralization of D_3O^+ or D_2HO^+ with an electron.[20] In the next scheme, however, this possibility is excluded; it will be discussed later.

$$C_2H_4 \rightsquigarrow H_2(+\cdots) \quad G_{1H} \quad (13)$$

$$\searrow H'(+\cdots) \quad G_{2H} \quad (14)$$

$$D_2O \rightsquigarrow D_2(+\cdots) \quad G_{1D} \quad (15)$$

$$\searrow D'(+\cdots) \quad G_{2D} \quad (16)$$

$$H' + C_2H_4 \longrightarrow H_2 + C_2H_3 \quad k_1 \quad (17)$$

$$H' + D_2O \longrightarrow HD + OD \quad k_2 \quad (18)$$

$$D' + C_2H_4 \longrightarrow HD + C_2H_3 \quad k_3 \quad (19)$$

$$D' + D_2O \longrightarrow D_2 + OD \quad k_4 \quad (20)$$

Assuming the energy absorbed by each component in a mixture of C_2H_4 and D_2O to be proportional to the electron fraction of C_2H_4 and D_2O, one can estimate the yield of HD on the basis of the amount of energy absorbed in the mixture:

$$G(HD)_M = G_{2H}(1-f_w)\frac{1.6f_wk_2}{(1-f_w)k_1+1.6f_wk_2} + G_{2D}f_w\frac{(1-f_w)k_3}{(1-f_w)k_3+1.6f_wk_4} \quad (I)$$

Similarly, the yields of D_2 and H_2 are given, respectively, by:

$$G(D_2)_M = G_{1D}f_w + G_{2D}f_w\frac{1.6f_wk_4}{(1-f_w)k_3+1.6f_wk_4} \quad (II)$$

$$G(H_2)_M = G_{1H}(1-f_w) + G_{2H}(1-f_w)\frac{(1-f_w)k_1}{(1-f_w)k_1+1.6f_wk_2} \quad (III)$$

Now, assuming that $k_2/k_1=k_4/k_3$ $(=\alpha)$, we obtain the following equations:

17) The exothermic direction of the processes is examined assuming the following heats of formation;[18]
$\Delta H_f(C_2H_4)=12.5$ kcal/mol, $\Delta H_f(H_2O)=-57.8$ kcal,
$\Delta H_f(C_2H_4^+)=255$ kcal/mol, $\Delta H_f(H_2O^+)=232$ kcal/mol,
$\Delta H_f(C_2H_5^+)=220\pm4$ kcal/mol, $\Delta H_f(H_3O^+)=143\pm4$ kcal/mol,
$\Delta H_f(C_2H_3^+)=281\pm2$ kcal/mol,
$\Delta H_f(H)=52.1$ kcal/mol, $\Delta H_f(OH)=9.3$ kcal/mol,
$\Delta H_f(H_2)=0$, and $\Delta H_f(C_2H_3)=65$ kcal/mol.
It is also assumed that no isotope effect exists.

18) J. L. Beauchamp and S. E. Buttrell Jr., *J. Chem. Phys.* **48**, 1783 (1968).

19) P. Kebarle, R. M. Haynes, and S. Searles, "Ion-Molecule Reactions in the Gas Phase," Advances in Chemistry Series 58, American Chemical Society, Washington, D. C. (1966), p. 210.

20) It has already been suggested that D_2 or HD may not be formed directly *via* neutralization of D_3O^+ or D_2HO^+ with an electron.[7]

$$\frac{(1-f_w)f_w}{G(HD)_M} = \frac{1}{1.6G_{2H}\alpha+G_{2D}} + \frac{1.6\alpha-1}{1.6G_{2H}\alpha+G_{2D}} \times f_w \quad (I')$$

$$\frac{G(D_2)_M}{f_w} = G_{1D} + 1.6G_{2D}\alpha f_w \quad (II')$$

$$\frac{G(H_2)_M}{1-f_w} = (G_{1H}+G_{2H}) - 1.6G_{2H}\alpha f_w \quad (III')$$

whe e Eqs. (II)′ and (III)′ apply to the case of $f_W \ll 1$. The (II)/(I) ratio gives;

$$\frac{G(D_2)_M(1-f_w)}{G(HD)_M} = \frac{G_{1D}}{1.6G_{2H}\alpha+G_{2D}} + \frac{1.6\alpha(G_{1D}+G_{2D})-G_{1D}}{1.6G_{2H}\alpha+G_{2D}} \times f_w \quad (IV)$$

Plots of the left-hand side of these equations, (I)′, (II)′, (III)′, and (IV), against f_W should give straight lines. The intercepts and the slopes of these lines will give G_{1H}, G_{2H}, G_{1D}, G_{2D}, and α. They are shown in Figs. 3 and 4.

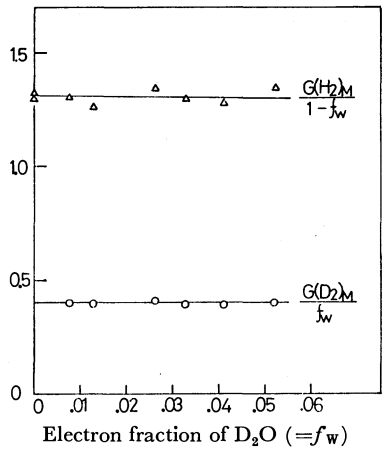

Fig. 3. $G(H_2)_M/(1-f_W)$ and $G(D_2)_M/f_W$ as a function of f_W.

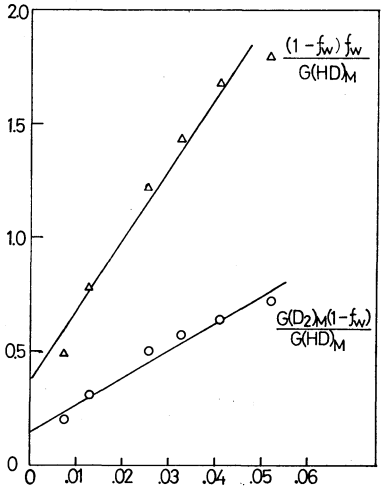

Fig. 4. $(1-f_W)f_W/G(HD)_M$ and $G(D_2)_M(1-f_W)/G(HD)_M$ as a function of f_W.

The yield of unimolecular hydrogen from C_2H_4, $G_{1H}=1.28$. The yield of the hct hydrogen atom from C_2H_4, $G_{2H}=0.03\pm0.01$. The yield of unimolecular hydrogen from D_2O, $G_{1D}=0.4$. The yield of the hot hydrogen atom from D_2O, $G_{2D}=0.0\pm0.1$. The value of α is nearly equal to 50.

These results apparently do not show that hot hydrogen atoms have an important role in this system. The conclusion does not necessarily follow, however, that they are not formed in the radiolysis of pure water vapor, where a fairly large amount of hydrogen atoms, $G(H)\cong 8$, has already been detected and divided into the following two kinds in a ratio of 3 to 5; hydrogen atoms formed *via* the neutralization process and those formed *via* direct excitation.[5,7,8] The above experimental results show that at least the latter kind of hydrogen atoms may not be hot. To describe the former, the possibility of the formation of H′ or D′ *via* the neutralization of D_3O^+ or D_2HO^+ mentioned above must be discussed here. By including this possibility in the above schemes (13)—(20) one may not easily establish the kinetic equations as (I)—(III). The yields of hot hydrogen atoms may not easily be estimated on the basis of the amount of the energy absorbed in each component. Similar experiments have been undertaken in the presence of 0.5 mol % SF_6, where the possibility of the above neutralization processes may reasonably be excluded. The same kinetic treatment as Eqs. (I)—(III) leads to exactly the same results for G_{1H}, G_{2H}, G_{1D}, G_{2D} as those obtained in the absence of SF_6.[21] On the basis of this fact, it seems that, the possibility of the formation of D′ or H′ *via* neutralization is not large. The hydrogen atoms formed *via* neutralization, however, can not be completely described; further investigations will be required.

A hot hydrogen atom here corresponds to the precursor of the bimolecular formation of hydrogen, which is non-scavengeable by ethylene. If a hot hydrogen atom reacts with ethylene such as:

$$D' + C_2H_4 \longrightarrow C_2H_3D + H$$

to form a thermal hydrogen atom which is scavenged by ethylene itself, the yield of hot hydrogen atoms estimated here will indicate the lower limit.

The value of $G_{1D}=0.4$ is nearly equal to the "molecular" hydrogen yield, which is unaffected by an electron scavenger.[2,4-6,8,22] The most reasonable process for the formation of "molecular" hydrogen is the molecular detachment of hydrogen from the excited state formed *via* direct excitation.

The authors wish to thank Professor Shoji Shida and Dr. Satoshi Takao for their valuable suggestions.

21) The value of α is nearly half of that in the absence of SF_6. The value of α itself and the decrease of α by the addition of SF_6 may not reasonably be explained here.

Dielectric Relaxation and Molecular Structure. VII. Structure of the Molecules of Diphenylene Dioxide Type

Yoshinori KOGA, Hiroaki TAKAHASHI, and Keniti HIGASI

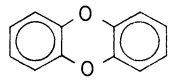
School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160

(Received May 29, 1973)

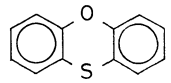
The dielectric constants and losses of diphenylene dioxide, phenoxathiin, thianthrene, xanthene and phenothiazine have been measured in dilute solution of benzene at the millimeter-wave frequency of 100 GHz at 20 °C. Diphenylene dioxide is found to have a very small dielectric relaxation time which is associated with the change in dipole orientation by the intramolecular change (butterfly motion). The dipole moment of this molecule is small but not considered to be zero. Similar to thianthrene, which has a folded structure about the S–S axis, diphenylene dioxide is also folded about the O–O axis or can easily have a folded structure. Phenoxathiin and the other two molecules have a folded structure and the dielectric relaxation times (at 100 GHz) reveal the effect of the butterfly-flapping motion associated with the barrier height for this internal motion.

Both planar and non-planar configurations of diphenylene dioxide have been concluded from measurements of the dipole moments. According to Bennett, Earp and Glasstone[1] it has a planar structure since their measurements indicated a zero moment, while Higasi[2] inferred that it would have a folded structure since its dipoe moment amounts to 0.64 D. The observed difference between ${}_{\infty}P_2$ and R_D may possibly be due to a rather large atomic polarization arising from the vibration of the molecule about the O–O axis. For this reason Smith[3] considered that diphenylene dioxide is planar.

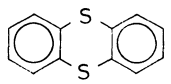
From a recent X-ray crystal analysis[4] it was revealed that the molecule of diphenylene dioxide is not fixed at the coplanar configuration in solid. In addition Davies and Swain[5] discovered a dielectric absorption due to the butterfly-flapping motion for diphenylene dioxide in polystyrene matrix.



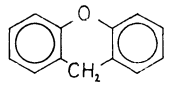
I: Diphenylene dioxide



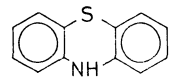
II: Phenoxathiin



III: Thianthrene



IV: Xanthene



V: Phenothiazine

Diphenylene dioxide (I) and related molecules (II), (III), (IV), and (V) were studied in order to obtain further information on the molecular configuration and intramolecular configurational changes.

Experimental

The frequencies of the dielectric measurements are 96.382 GHz (*ca.* 100 GHz) and 1 MHz (for the static value). Pure samples of diphenylene dioxide (mp 119 °C) and phenoxathiin (mp 56.5 °C) were kindly provided by Professor S. Uyeo, Kyoto University. Other compounds were obtained from commercial sources, and were purified by recrystallization. Benzene employed as the solvent was prepared in the usual way. The apparatus and experimental technique for dielectric measurements were the same as those used previously.[6]

TABLE 1. REFRACTIVE INDICES, ABSORPTIONS, DIELECTRIC CONSTANTS AND LOSSES OF DIPHENYLENE DIOXIDE IN BENZENE SOLUTION AT 96.382 GHz (20 °C)

Weight fraction	n	k	ε'	ε''
0.00000	1.5110	0.0022	2.2831	0.0068
0.02126	1.5156	0.0023	2.2970	0.0069
0.05325	1.5200	0.0029	2.3104	0.0087
0.08243	1.5247	0.0030	2.3248	0.0093
0.09217	1.5258	0.0032	2.3281	0.0098

The complex refractive indices $n^*=n-ik$, n and k being the real and imaginary parts, respectively, have been measured for three or four different dilute solutions of the same sample at 20 °C. The dielectric constants ε' and the losses ε'' were obtained from n and k by $\varepsilon'=n^2-k^2$ and $\varepsilon''=2nk$ (Table 1). The slopes of a' and a'' were obtained on the assumption that the linear relationship of ε' and ε'' with the concentration (weight fraction) w_2 exists.

$$\varepsilon' = \varepsilon_1' + a'w_2$$
$$\varepsilon'' = \varepsilon_1'' + a''w_2 \quad (1)$$

In addition, a_0, a_D and b are the slopes for the static dielectric constant ε_0, the square of refractive index n_D (for the sodium D-line) and the specific volume v against the weight fraction, respectively (Table 2).

TABLE 2. SLOPES a_0, a', a'', a_G, a_D, AND b IN BENZENE SOLUTION (20 °C)

Substance	a_0	a'	a''	a_G	a_D	b
Diphenylene dioxide	0.496	0.447	0.038	0.418	0.254	−0.320
Phenoxathiin	1.035	0.521	0.135	0.486	0.380	−0.352
Thianthrene	1.470	0.511	0.111	0.498	0.434	−0.372
Xanthene	1.140	0.367	0.097	0.355	0.266	−0.281
Phenothiazine	3.227	0.676	0.311	0.638	0.480	−0.367

$$\varepsilon_0 = \varepsilon_{10} + a_0 w_2, \quad n_D^2 = n_{1D}^2 + a_D w_2$$
$$v = v_1 + b w_2, \quad \varepsilon_\infty = \varepsilon_{1\infty} + a_\infty w_2 \qquad (2)$$

The total molar polarization of the solute at infinite dilution ($w_2 \to 0$) is approximately given by Halverstadt and Kumler[7] in the following form:

$${}_\infty P_2 \simeq M_2\left\{\frac{3a_0 v_1}{(\varepsilon_{10}+2)^2} + (v_1+b)\frac{\varepsilon_{10}-1}{\varepsilon_{10}+2}\right\} \qquad (3)$$

where M_2 is the molecular weight of the solute. If a_∞ and $\varepsilon_{1\infty}$ are used instead of a_0 and ε_{10}, respectively, the distortion polarization P_A+P_E instead of ${}_\infty P_2$ will be obtained by

$$P_A + P_E \simeq M_2\left\{\frac{3a_\infty v_1}{(\varepsilon_{1\infty}+2)^2} + (v_1+b)\frac{\varepsilon_{1\infty}-1}{\varepsilon_{1\infty}+2}\right\} \qquad (4)$$

Similarly, the molecular refraction for the D-line R_D will be given by

$$R_D \simeq M_2\left\{\frac{3a_D v_1}{(n_{1D}^2+2)^2} + (v_1+b)\frac{n_{1D}^2-1}{n_{1D}^2+2}\right\} \qquad (5)$$

The atomic polarization P_A will be estimated roughly by $(P_A+P_E)-R_D$ if $R_D \approx P_E$ and $\varepsilon_{10} \approx \varepsilon_{1\infty} \approx {n_{1D}}^2$ (see Appendix 1). Thus we have an estimate for P_A by

$$P_A \simeq M_2\left\{\frac{3(a_\infty - a_D)v_1}{(\varepsilon_{10}+2)^2}\right\} \qquad (6)$$

The relaxation time of the solute τ is calculated by use of two equations:[8]

$$\tau = \frac{1}{\omega}\frac{a''}{a'-a_\infty} \equiv \tau(1) \qquad (7)$$

$$\tau = \frac{1}{\omega}\frac{a_0-a'}{a''} \equiv \tau(2) \qquad (8)$$

If one assumes a_∞ to be equal to a_D, the values τ (1) will become much smaller than τ (2); and if a_∞ is given by a_G defined in Eq. (9), τ (1) will become identical with τ (2).

$$a_\infty \simeq a_G \equiv a' - \frac{(a'')^2}{a_0-a'} \qquad (9)$$

Perhaps a_G evaluated from a' and a'' at a very high frequency (100 GHz) would be a good estimate for a_∞ and is often close to a_∞ obtained from Cole-Cole plots. Thus Eq. (4) can be rewritten by using a_G instead of a_∞:

$$P_A + P_E \simeq M_2\left\{\frac{3a_G v_1}{(\varepsilon_1'+2)^2} + (v_1+b)\frac{\varepsilon_1'-1}{\varepsilon_1'+2}\right\} \qquad (10)$$

where $\varepsilon_{1\infty}$ is also replaced with ε_1'.

The dipole moment μ is estimated by

$$\mu = \left\{\frac{9kTM_2}{4N\pi}({}_\infty P_2 - (P_A+P_E))\right\}^{1/2} \qquad (11)$$

On the assumption that $\varepsilon_{10} \approx \varepsilon_1'$ for non-polar solvents we can obtain approximately

$${}_\infty P_2 - (P_A+P_E) \simeq M_2\left\{\frac{3(a_0-a_\infty)v_1}{(\varepsilon_1'+2)^2}\right\} \qquad (12)$$

Therefore

$$\mu^2 \simeq \frac{27kTM_2 v_1}{4N\pi}\frac{a_0-a_\infty}{(\varepsilon_1'+2)^2} = B^2(a_0-a_\infty) \qquad (13)$$

where

$$B = \left\{\frac{27kTM_2}{4N\pi d_1}\right\}^{1/2}\frac{1}{(\varepsilon_1'+2)} \qquad (14)$$

and d_1 is the density of the solvent. Equations (13) and (14) are equivalent to the corresponding formulae of the previous work[8,9] (see Appendix 2). The relaxation times and polarization data are given in Tables 3 and 4, respectively.

TABLE 3. TWO RELAXATION TIMES $\tau(1)$, $\tau(2)$ AND DIPOLE MOMENTS BASED ON Eqs. (3), (10) AND (11) TOGETHER WITH LITERATURE VALUES. $\tau(1)$ IS OBTAINED ON THE ASSUMPTION OF $a_\infty = a_D$ (20 °C)

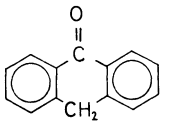
Discussion

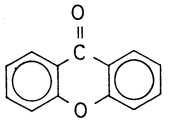
The dielectric relaxation time of diphenylene dioxide (I) in benzene solution is 2.1 ps (calculated as $\tau(2)$). If $a_\infty \simeq a_D = 0.254$ is assumed, $\tau(1)$ will be only 0.3 ps. In contrast to this, anthrone (VI) and xanthone

7) I. F. Halverstadt and W. D. Kumler, *J. Amer. Chem. Soc.*, **64**, 2988 (1942).
8) K. Higasi, This Bulletin, **39**, 2157 (1966).
9) K. Higasi and O. Kiyohara, *Bull. Inst. Appl. Elect.*, **18**, 24 (1966).

(VII) have much larger relaxation times 21.2 and 21.0 ps, respectively, in benzene solution.



VI: Anthrone



VII: Xanthone

The small values observed for τ of diphenylene dioxide are certainly not due to the change of dipole orientation by rotation of the whole molecule.

When there exist two independent paths from the same initial state to the same final state with opposite directions of the molecular dipole, a single relaxation time τ will be observed which is related to the relaxation times τ_m and τ_b for the two individual processes by

$$\frac{1}{\tau} = \frac{1}{\tau_m} + \frac{1}{\tau_b} \qquad (15)$$

Suppose that Eq. (15) is valid in this case and some internal process such as the butterfly motion (with a small τ_b value) is considered. If we assume $\tau_m=21$ ps for molecular rotation and $\tau_b=2.5$ ps for butterfly motion, we shall obtain from Eq. (15) $\tau=2.2$ ps which compares well with $\tau(2)=2.1$ ps. This would be an evidence for a slightly folded structure in the equilibrium state.

The dipole moment of diphenylene dioxide is calculated to be 0.36 D from Eqs. (3), (10), and (11). Or, we may calculate it to be 0.38 D from Eq. (A-4) on the basis of the relaxation time $\tau(2)=2.1$ ps. Both values are smaller than 0.64 D obtained from the previous measurement of the static dielectric constant.[2] However, they are not zero so that one may conclude that very likely the molecule of diphenylene dioxide would have a non-planar configuration. At the same time one may notice that the atomic polarization of this molecule is 6.2 cm^3, *i.e.*, about 12% of R_D; diphenylene dioxide has a rather large atomic polarization as Smith[3] pointed out.

The dielectric relaxation time of phenoxathiin is calculated by Eq. (8) to be $\tau(2)=6.3$ ps which compares favorably with 7.0 ps (Hufnagel *et al.*[10]), but is somewhat less than 10 ps given by Anderson and Smyth.[11] These small values of τ for phenoxathiin are related to the butterfly motion. The dipole moments of phenoxathiin in benzene at room temperature from static measurement are 1.09 D (Higasi[2]), 0.97 D (Hufnagel, Klages, and Knobloch[10]) and 1.00 D (Leonard and Sutton[12]). The present work gives the total dipole moment 0.99 D on the basis of Eqs. (3), (10) and (11).

The folded structure of thianthrene has been well established by means of both X-ray crystal analysis[13,14] and dielectric measurements in solution.[3] Anderson and Smyth[11] found the dielectric relaxation time to be 31, 24, and 19 ps at 20, 40, and 60 °C, respectively. In the present experiment, however, it is only 14.3 ps at 20 °C. This seems to indicate the imporatnce of the butterfly motion. Suppose $\tau_m=21$ ps and $\tau_b=50$ ps, τ will be given as 14.8 ps from Eq. (15). It is reasonable to assume a larger τ_b for thianthrene than τ_b of diphenylene dioxide, since thianthrene has a high barrier of inversion by the butterfly motion. The atomic polarization of thianthrene is about 5% of P_E.

From their Kerr effect studies, Aroney, Hoskins, and Le Fevre[15] concluded that the preferred solution-state conformation of xanthene is a slightly folded structure defined by a dihedral angle of 160° (±6°). The dielectric relaxation time of xanthene is somewhat smaller than that of anthrone and of xanthone. Phenothiazine obtained from thianthrene by replacing S by N–H group has also a smaller relaxation time 13.6 ps. In both cases the internal motion process seems to help decrease the relaxation time observed at 100 GHz.

The activation process of butterfly inversion of a folded molecule $C_6H_4\langle{}^{X}_{Y}\rangle C_6H_4$ may be described as a change of the valence angles of the central atoms X and Y, that is, from the valence angles, ϕ_X and ϕ_Y, of the folded configuration at an equilibrium state to the valence angles, ϕ_X and ϕ_Y,[16] at the coplanar configuration. The energy U needed to change the two valence angles from ϕ_X and ϕ_Y to ϕ_X and ϕ_Y will be approximated by

Table 5. Dihedral angles θ, valence angles ϕ, bond lengths r and angle bending force constants H

TABLE 6. ACTIVATION ENERGY (U) FOR INVESRION ESTIMATED FROM Eq. (16)

Atoms X	Atoms Y	$\Delta\phi_X$ (°)	$\Delta\phi_Y$ (°)	U kcal/mol	U (literature) kcal/mol
O	O	0.43		0.005	0.29,[2] 0[5]
O	S	15	10	3.9	1.20,[2] 2.63[5]
S	S	17		6.2	5.50,[2] 5.00[5]
O	C	3	2.5	0.2	
S	N	14	6	2.4	2.87[5]

$$U = (1/2)H_{CXC}r_X^2\Delta\phi_X^2 + (1/2)H_{CYC}r_Y^2\Delta\phi_Y^2 \qquad (16)$$
$$\Delta\phi_X = \phi_X - \phi_X, \quad \Delta\phi_Y = \phi_Y - \phi_Y$$

where H_{CXC} and H_{CYC} are the angle bending force constants and r_X and r_Y the bond lengths of X and Y atoms, respectively. The literature values of θ, ϕ, r, and H are given in Table 5 and the values U thus estimated in Table 6. For diphenylene dioxide, $\Delta\phi_o = 0.43°$, r(C–O)=1.43 Å[2] and H_{COC}=0.30 mdyn/Å[17] Eq. (16) gives U=0.005 kcal/mol. This is in accordance with the small value 2.5 ps assumed for τ_b. For the inversion barrier of thianthrene we can obtain 6.2 kcal/mol by using the values of $\Delta\phi_S = 17°$, r(C–S)= 1.773 Å[14] and H_{CSC}=0.157 mdyn/Å.[17] The conjugation energy at the coplanar position should decrease these barrier heights, while the viscosity of the solvent would hinder the inversion.

The observed relaxation time for phenoxathiin, 6.3 ps, is close to an average of 2.1 ps (diphenylene dioxide) and 14.3 ps (thianthrene). The inversion barrier of phenoxathiin 3.9 kcal/mol lies between those for the two molecules.

The molecular dipole of phenoxathiin has two components, $\mu_{//}$ directed along the O–S axis for the overall rotation and $\mu_\perp$ perpendicular to the same axis for the butterfly motion. Hence, two dipolar relaxations should be observed; however, the absorption due to the butterfly motion predominates overall rotation since $(\mu_\perp/\mu_{//})^2$ is estimated to be very large, *i.e.*, 12: 1.[5] One can say with certainty that the observed relaxation time at 100 GHz corresponds to that of butterfly motion.

The relaxation time of xanthene is 13.2 ps, which is smaller than that of xanthone and of anthrone by 30—40%. From the analysis of its dipole moment one would expect two dipolar relaxations, the ratio of their intensities $(\mu_\perp/\mu_{//})^2$ being about 1: 20. The observed lowering of the relaxation time might be explained in the following way. The inversion barrier of xanthene is less than 1 kcal/mol and hence the relaxation time associated with the butterfly motion would be similar to τ_b for diphenylene dioxide. If one assumes the relaxation time for the overall rotation to be 20 ps and that for the butterfly motion 2.5 ps, one can estimate $\tau(2)$ obtainable for any frequency for any value of $(\mu_\perp/\mu)^2 = C_2$ by using the method given in the preceding paper.[18] The result of calculations for 100 GHz is shown by curve A and that for 10 GHz by curve B in Fig. 1. At the frequency of this experiment, $\tau(2)$ is equal to 13.2 ps for C_2=0.1 (*cf.*, 19.4 ps for C_2=0.1 at 10 GHz). Consequently, the lowering in relaxation time might be due to the butterfly inversion, although the dipole component associated with this internal process is not significant enough.

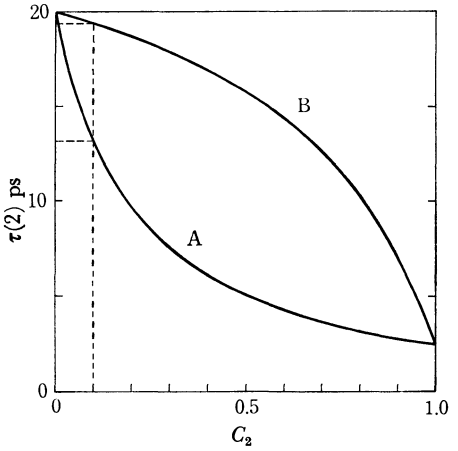

Fig. 1. Dependence of the relaxation time $\tau(2)$ upon the weight of internal process C_2.
A: 100 GHz, B: 10 GHz.

For phenothiazine we find a similar lowering in the relaxation time. Phenothiazine is assumed to have a quasi-equatorial form from X-ray evidence.[19] There are two independent relaxation processes, overall and internal. The dipole component associated with the internal motion is larger than that for xanthene, while the barrier height (see Table 6) for the inversion is found to be much larger. Increase in the above two quantities causes cancellation of the effects so that very likely the relaxation time is lowered to a similar extent to that for xanthene.

Concluding Remarks

1. Atomic polarization as well as the dipole moment of the solute can be obtained from the dilute solution method by use of extended Halverstadt-Kumler equations.

2. Atomic polarization is found to be large for diphenylene dioxide and phenothiazine.

3. Discussion is given for a small but non-zero polarity of diphenylene dioxide. As indicated by X-ray evidence[4] this molecule perhaps is folded about the O–O axis having two shallow potential minima. Or possibly it has one minimum with a very flat potential curve.

4. Thianthrene, phenoxathiin and phenothiazine are folded molecules with two potential minima. Xanthene also has a folded structure either with one potential minimum or two minima.

5. The molecules of $C_6H_4\langle\overset{X}{X}\rangle C_6H_4$ type have the single relaxation time τ which is related to the relaxation time τ_m and τ_b by Eq. (15).

6. The molecules of $C_6H_4\langle\overset{X}{Y}\rangle C_6H_4$ type have two

dipolar relaxations. The average relaxation time $\tau(2)$ is a function of $(\mu_{//}/\mu)^2=C_2$ and the frequency of the measurement.[18]

Appendix

I. P_A is obtained by subtracting Eq. (5) from Eq. (4) and neglecting Δ^2.

$$P_A \simeq M_2\left\{\frac{3a_\infty v_1}{(\varepsilon_{1\infty}+2)^2}-\frac{3a_D v_1}{(n_{1D}^2+2)^2}+(v_1+b)\times\left[\frac{(\varepsilon_{1\infty}-1)}{(\varepsilon_{1\infty}+2)}-\frac{(n_{1D}^2-1)}{(n_{1D}^2+2)}\right]\right\}$$
$$\simeq M_2\left\{\frac{3[(a_\infty-a_D)(\bar{\varepsilon}_1+2)-2\Delta(a_\infty+a_D)]v_1}{(\bar{\varepsilon}_1+2)^3}+\frac{6\Delta(v_1+b)}{(\bar{\varepsilon}_1+2)^2}\right\} \quad \text{(A-1)}$$

where

$$\bar{\varepsilon}_1=\frac{1}{2}(\varepsilon_{1\infty}+n_{1D}^2) \quad \text{(A-2)}$$

and

$$\Delta=\frac{1}{2}(\varepsilon_{1\infty}-n_{1D}^2) \quad \text{(A-3)}$$

For $n_{1D}^2=\varepsilon_{1\infty}$, Eq. (6) follows immediately from (A-1).

II. For dilute solution of a polar molecule in a non-polar solvent, there is a familiar equation between the dipole moment μ and the relaxation time τ.[20]

$$\mu^2=\frac{6750kT}{NC\pi}\frac{\varepsilon''}{(\varepsilon'+2)^2}\frac{1+(\omega\tau)^2}{\omega\tau} \quad \text{(A-4)}$$

where C is the concentration in mol liter^{-1}. Introducing Eq. (8) for τ in Eq. (A-4) and assuming $\varepsilon'\approx\varepsilon_1'$, we have

$$\mu^2=\frac{6750kT}{N\pi}\frac{1}{(\varepsilon_1'+2)^2}\frac{(a_0-a')^2+(a'')^2}{a_0-a'} \quad \text{(A-5)}$$

Therefore

$$\mu^2=\frac{27000kT}{4N\pi}\frac{1}{(\varepsilon_1'+2)^2}(a_0-a_\infty)=B^2(a_0-a_\infty) \quad \text{(A-6)}$$

where

$$B=\left\{\frac{27000kT}{4N\pi}\right\}^{1/2}\frac{1}{(\varepsilon_1'+2)} \quad \text{(A-7)}$$

The value of B in (A-7) differs from that in Eq. (14) since the concentration of the solute is expressed in units of molar concentration in (A-7) and in units of weight fraction in Eq. (14).[8,9] If $a_D=a_\infty$, then

$$\mu=B(a_0-a_D)^{1/2} \quad \text{(A-8)}$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3363—3366 (1973)

The Primary Photochemical Process of 4-Nitropyridine *N*-Oxide. III. Its Photochemical Behavior in an Aqueous Solution

Norisuke HATA, Isao ONO, and Kenji OSAKA

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

(Received June 19, 1973)

4-Nitropyridine *N*-oxide does not undergo photochemical changes in an aqueous solution. When small amounts of 2-propanol or tetrahydrofuran were added to a deaerated solution, however, the 4-nitropyridine *N*-oxide was found to be reduced photochemically to afford 4-hydroxylaminopyridine *N*-oxide. From the measurements of the quantum yields and from flash-spectroscopic experiments under various conditions, such a photoinduced reduction of 4-nitropyridine *N*-oxide in deaerated water was revealed to be initiated by a hydrogen-atom abstraction from a 2-propanol or tetrahydrofuran by the triplet species. The situation was quite different from the case of an alcoholic solution, in which some intermediate species originating from the excited singlet state was responsible for the photoreduction.

As has been described in a previous paper,[1] the photochemical reaction of 4-nitropyridine *N*-oxide in alcohol (methanol, ethanol, 2-propanol, or glycerol) involves some intermediate species, A, A′, or B, originating from the excited singlet state; Process I (the photochemical formation of 4-hydroxypyridine *N*-oxide nitrate) proceeds *via* a transient complex between the intermediate A′ and the unexcited molecule, while Process II (the photochemical formation of 4-hydroxylaminopyridine *N*-oxide) is initiated by a hydrogen-atom abstraction from a solvent molecule by the intermediate B, which is produced from another intermediate, A.

However, the 4-nitropyridine *N*-oxide in water is quite stable to light.[2] Considering the fact that even Process I does not proceed in an aqueous solution, the primary process may be inferred to be quite different from that in alcohol. In order to make this point

clear, therefore, the present authors have carried out investigations by means of both steady-light irradiation and flash spectroscopy for the 4-nitropyridine *N*-oxide in deaerated water.

Experimental

The 4-nitropyridine *N*-oxide used in this experiment was synthesized and purified according to the method given in the literature.[3] Reagent-grade tetrahydrofuran and 2-propanol (Wako Pure Chemical Industries) were used without further purification.

The apparatus and procedures for both the steady-light and flash experiments were the same as those reported previously.[1,4]

Results and Discussion

Photochemical changes were not induced for the 4-nitropyridine *N*-oxide when it was irradiated with 313 nm light in deaerated water. The introduction of small amounts of 2-propanol or tetrahydrofuran (THF) into the solution, however, was found to result in the photochemical reduction of 4-nitropyridine *N*-oxide to the 4-hydroxylaminopyridine *N*-oxide, while no such production occurred when *tert*-butyl alcohol was added instead of 2-propanol or THF. Such a photoinduced reaction of 4-nitropyridine *N*-oxide in an aqueous solution was completely prevented by the dissolved oxygen. As an example, Fig. 1 shows the progressive spectral change of 4-nitropyridine *N*-oxide (7.0×10^{-5} M) in deaerated water containing 1.2×10^{-1} M THF on 313 nm irradiation. As can be seen from the figure, as the irradiation time increased the absorption spectrum of 4-nitropyridine *N*-oxide decreased progressively in intensity and a new absorption band with its maximum at 283 nm appeared, which coincided with that of 4-hydroxylaminopyridine *N*-oxide.

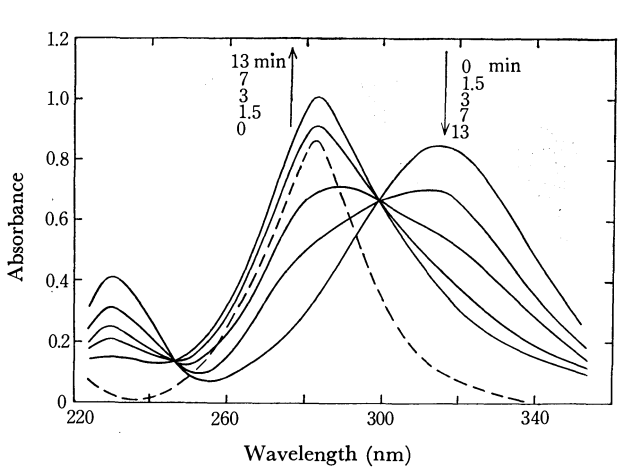

Fig. 1. The progressive spectral change of 4-nitropyridine *N*-oxide in deaerated water (7.0×10^{-5} M) containing a 1.2×10^{-1} M THF on 313 nm irradiation. Numbers refer to the irradiation time. The broken curve represents the absorption spectrum of 4-hydroxylaminopyridine *N*-oxide in water (4.7×10^{-5} M).

4) N. Hata, E. Okutsu, and I. Tanaka, This Bulletin, **41**, 1769 (1968).

The quantum yields (Φ) of the disappearance of 4-nitropyridine *N*-oxide were determined as a function of the concentration of 2-propanol or THF added as the reducing agent, or of the concentration of the hydrogen-donor (RH) in an aqueous solution (7.0×10^{-5} M) at room temperature. Figure 2 shows the results thus obtained; a linear relationship may be seen to exist between the reciprocals of Φ and [RH].

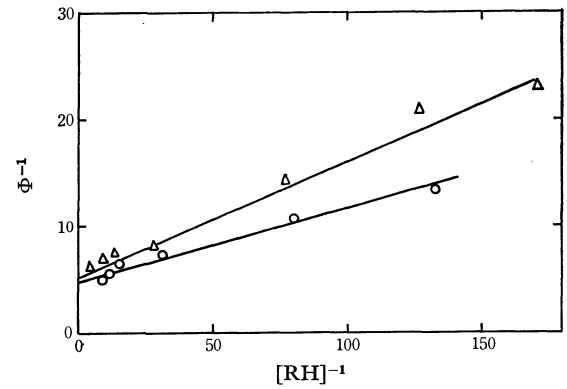

Fig. 2. Quantum yield (Φ) *vs.* concentration of hydrogen-donor (-○-: THF, -△-: 2-propanol) in deaerated aqueous solution (7.0×10^{-5} M) at room temperature, on 313 nm irradiation.

Next, in order to clarify whether or not the photochemical process of 4-nitropyridine *N*-oxide in water involves the same intermediates as in the case of an alcoholic solution, flash-spectroscopic examinations were undertaken in a deaerated aqueous solution at room temperature. Figure 3 shows the absorption spectra of the transient species produced by a flash illumination, where the spectrum was plotted after the flash and also at a specified time interval following the flash. Thus, the transient absorptions were observed around 380 and 550 nm, but they completely disappeared in the presence of oxygen. The decay analyses for these transient absorptions were carried out by applying the first-order rate law at various wavelengths; two examples, at 380 nm and at 540 nm, are presented in Fig. 4. It is clear from the figure that the decay curve for the 540 or 380 nm absorption can be resolved into

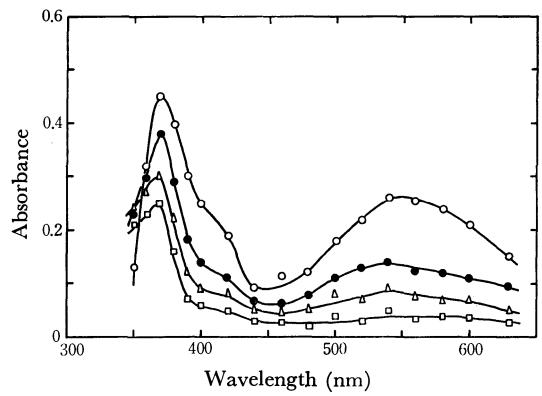

Fig. 3. Transient spectra of 4-nitropyridine *N*-oxide in deaerated water (7.0×10^{-5} M) at room temperature. (1) -○-, (2) -●-, (3) -△-, and (4) -□- indicate the spectrum taken at 20 μsec, 60 μsec, 100 μsec, and 200 μsec, respectively, after the flash.

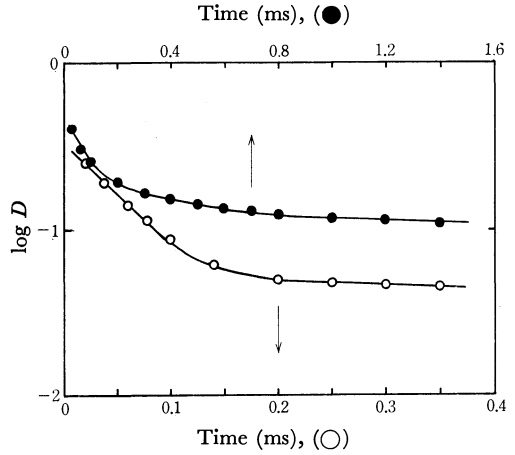

Fig. 4. Decay analysis for the transient absorption at 380 nm (●) and 540 nm (○).

a two- or three-component decay. Consequently, the transient absorptions were revealed to be due to three intermediate species, X, Y, and Z; their individual spectra are shown in Fig. 5. The intermediate X, with its absorptions around 380 and 550 nm, decayed with a rate constant (k_X) of $3.3\times10^4\ s^{-1}$, whereas the intermediates Y and Z (about 370 nm) decayed with rate constants (k_Y and k_Z) of $3.8\times10^3\ s^{-1}$ and $7.0\times10^2\ s^{-1}$ respectively.

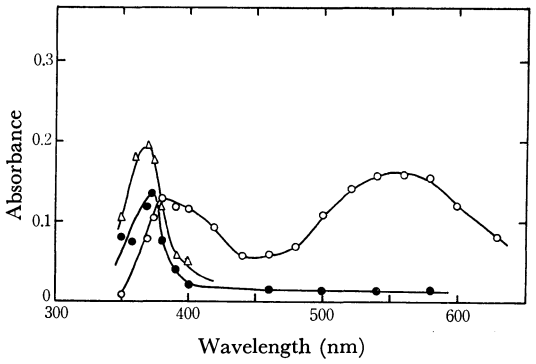

Fig. 5. Absorption spectra of the intermediate species X (-○-), Y (-●-) and Z (-△-) resolved by the decay analyses at different wavelengths.

Then, the effect of a hydrogen-donor on the decay rate was investigated in order to elucidate which intermediate is responsible for the photochemical reduction of 4-nitropyridine *N*-oxide. The decay rate (k_x) of the intermediate X, as is shown in Fig. 6, increased linearly with an increase in the concentration of THF, while that (k_Y or k_Z) of the intermediate Y or Z was independent of the concentration of THF. Quite similar results were also obtained when the 2-propanol was added as a hydrogen-donor instead of THF.[5] These results lead to the conclusion that the intermediate X is responsible for the hydrogen-atom abstraction from a THF or 2-propanol.

Although the transient spectrum in water (Fig. 3) is closely similar in appearance to that in alcohol (Figs. 1 and 2 in Ref. 1), the nature of the intermediate species involved seems to be different in each case, for a reason to be presented below. In the case of an alcoholic solution,[1] the decay of the transient absorption (~550 nm) appeared immediately after the flash had been clearly observed to be followed by the appearance of the 380 nm absorption. Moreover, these absorption spectra have been obtained even in an oxygen-saturated solution, indicating that all the intermediate involved originated from the excited singlet state of 4-nitropyridine *N*-oxide. In the case of an aqueous solution, however, apparently the two absorption systems (Fig. 3) appeared simultaneously within the time of the flash (10 μs), although they were located in the same spectral region as in the case of an alcoholic solution. In addition, they were completely quenched by the dissolved oxygen, suggesting that the intermediates involved is due to a triplet and related species. It is remarkable that, whereas the decay rate (k_Y) of the intermediate Y was independent of [RH], the absorption intensity was observed to decrease with an increase in [RH]. As an example, Fig. 7 shows the decrease in the absorption intensity of the intermediate Y with an increased concentration of 2-propanol. This can possibly be interpreted by assuming the following pathways, (i) and (ii), for the decay of the intermediate X:

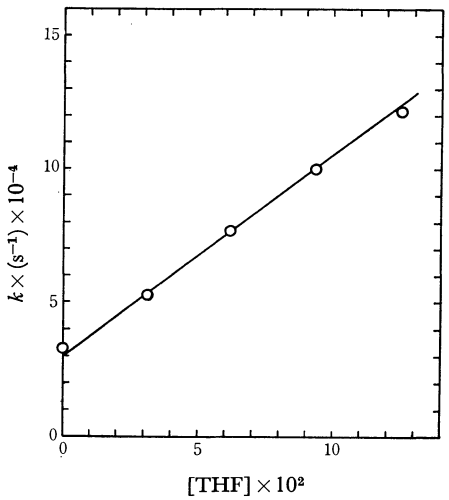

Fig. 6. The effect of THF on the decay rate of the intermediate X in deaerated water at room temperature (concentration of 4-nitropyridine *N*-oxide: 7.0×10^{-5} M).

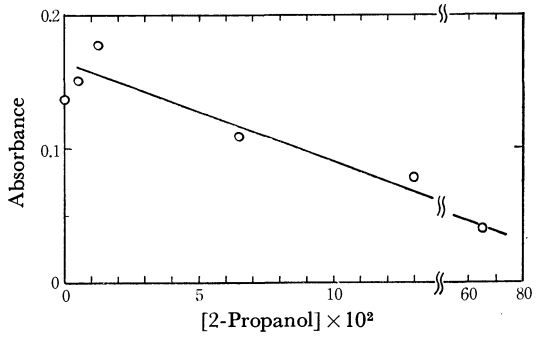

Fig. 7. The effect of the concentration of 2-propanol on the absorption intensity of the intermediate Y in deaerated water at room temperature (concentration of 4-nitropyridine *N*-oxide: 7.0×10^{-5} M).

5) In this case, the decay rate (k_Z) of the intermediate Z was observed to decrease initially with an increased concentration of 2-propanol, although the reason was quite ambiguous at present.

$$\text{Intermediate X} \xrightarrow{+RH} \begin{cases} \longrightarrow \text{Hydrogen-atom abstraction} & \text{(i)} \\ \longrightarrow \text{Intermediate Y} & \text{(ii)} \end{cases}$$

That is, as the concentration of the hydrogen-donor increases, the hydrogen-atom abstraction (i) would become much more important than the formation of the intermediate Y (ii), leading to a decrease in the absorption intensity of the intermediate Y. The fact that the absorption intensity at 350 nm was observed to increase slightly with the lapse of time (Fig. 5) seems to support the idea that the intermediate Y[6] could be produced from the intermediate X. Judging from these facts, it appears reasonable to assign the intermediate X to the lowest triplet state (T_1) of 4-nitropyridine *N*-oxide.[7] Accordingly, the following reaction scheme can be obtained.

	Rate
$S_0 + h\nu \longrightarrow S_1$	I_a
$S_1 \longrightarrow S_0$	$k_1[S_1]$
$S_1 \longrightarrow T_1$	$k_2[S_1]$
$T_1 + RH \longrightarrow$ Hydrogen-atom abstraction	$k_3[T_1][RH]$
$T_1 \longrightarrow Y$	$k_4[T_1]$
$T_1 \longrightarrow S_0$	$k_5[T_1]$

where the intermediate Z is not involved because of the ambiguous nature.

Assuming the photostationary state conditions, the quantum yield of the 4-nitropyridine *N*-oxide disappearance is given by the following equation:

$$1/\Phi = 1/\Phi_{isc} + (k_4+k_5)/\Phi_{isc}k_3[RH] \quad (1)$$

where Φ_{isc} represents the efficiency of the S_1–T_1 intersystem crossing as follows:

$$\Phi_{isc} = k_2/(k_1+k_2) \quad (2)$$

Thus, if Processes I and II, both of which proceed from the S_1 state,[1] can be neglected in an aqueous solution, a linear relationship should be expected to exist between the reciprocals of Φ and [RH]. The experimental results shown in Fig. 2 gave a straight line, in accordance with Eq. (1), and thus supporting the proposed reaction scheme. The values of Φ_{isc} and $(k_4+k_5)/\Phi_{isc}k_3$ were estimated from the slope and intercept of the straight-line respectively. Meanwhile, according to the reaction scheme presented above, the decay rate (k_X) of the intermediate X, or the triplet species, may be given by the following equation:

$$k_X = k_4 + k_5 + k_3[RH] \quad (3)$$

As has been described before, it was seen that the decay rate (k_X) of the intermediate X was directly proportional to the concentration of 2-propanol or THF; this was consistent with Eq. (3). Therefore, k_3 was evaluated from the slope of the straight line, while k_4+k_5 was estimated by extrapolating [RH] to zero. The value of Φ_{isc}, k_3 and k_4+k_5 thus obtained are listed in Table 1. The values of $(k_4+k_5)/k_3$ determined from both the steady-light and flash spectroscopic experiments are also given in Table 1; these values agree approximately with each other. This also supports the proposed reaction scheme.

TABLE 1. OBSERVED VALUES OF Φ_{isc}, k_3 AND k_4+k_5 IN AN AQUEOUS SOLUTION CONTAINING A HYDROGEN-DONOR AT ROOM TEMPERATURE

Hydrogen-donor	Φ_{isc}[a]	k_3[b] (l mol^{-1} s^{-1})	k_4+k_5[b] (s^{-1})	$(k_4+k_5)/k_3$
THF	0.20	7.5×10^5	3.0×10^4	0.016[a], 0.040[b]
2-Propanol	0.19	7.1×10^5	3.0×10^4	0.021[a], 0.042[b]

a) Represents the value determined from the steady-light experiment (Fig. 2).
b) Represents the value determined from the flash spectroscopic experiment (Figs. 6 and 7).

The following conclusions can be drawn from the experimental results described above. The photochemical reduction of 4-nitropyridine *N*-oxide in deaerated water proceeds through the lowest triplet state (probably, π,π^*),[8] whereas in an alcoholic solution the intermediate species resulting from the S_1 state is responsible for the photoreduction. Also, in an aqueous solution, approximately 20% of the 4-nitropyridine *N*-oxide in the S_1 state undergoes an intersystem crossing into the T_1 state responsible for the hydrogen-atom abstraction, but the intermediate A (and therefore B as well) and A′ are scarcely formed at all; thus, Process I does not occur. In the case of an alcoholic solution, on the other hand, the formation of the intermediate species A (and therefore, of B) and A′ from the S_1 state is considered to become much more predominant than the S_1–T_1 intersystem crossing; thus, both Processes I and II proceed. These conclusions are of particular interest in relation to the effect of the solvent on a dynamic behavior of the excited singlet state of 4-nitropyridine *N*-oxide. Further studies of these points are now in progress.

In conclusion, the authors wish to thank Professor Shiro Matsumoto for his permission to use the flash-photolysis apparatus.

6) The intermediate Y does not undergo chemical changes but it seems to be converted to the 4-nitropyridine *N*-oxide (S_0), although the structure is not clear at present.

7) Exactly, a comparison of the decay time of the transient absorption with that of the phosphorescence of 4-nitropyridine *N*-oxide in a deaerated water at 77 K must be made to identify the intermediate X to the lowest triplet state of *N*-oxide, but it was experimentally too difficult under such conditions.

Molar Volume of Ions

Fumio HIRATA and Kiyoshi ARAKAWA
Research Institute of Applied Electricity, Hokkaido University, Sapporo 060
(Received June 20, 1973)

A formula based on the scaled particle theory of fluids has been derived for the intrinsic volume of ions. Validity ranges of earlier semiempirical formulas are discussed in the light of the formula. Using the theoretical values of the intrinsic volumes of ions, values of volume contraction caused by ion-water interactions are estimated.

The partial molar volume of ions at infinite dilution, $\bar{V}_{\text{ion}}$, has turned out to be one of the most important quantities for elucidating the structure and properties of aqueous solutions of electrolytes. $\bar{V}_{\text{ion}}$ is given by

$$\bar{V}_{\text{ion}} = \bar{V}_{\text{int}} + \Delta\bar{V}, \tag{1}$$

where $\bar{V}_{\text{int}}$ is the inrinsic volume of ions, and $\Delta\bar{V}$ is the volume contraction caused by ion-solvent interactions. Intrinsic volume is defined as *the volume of spherical cavities in which ions are contained,*[1] *or non-hydrated partial molar volume of ions.*[2]

Studies have been carried out to estimate the magnitude of $\bar{V}_{\text{ion}}$, $\bar{V}_{\text{int}}$ and $\Delta\bar{V}$.[1-10] Hepler gave the following equation.[1]

$$\bar{V}_{\text{ion}} = Ar_{\text{X}}^3 - B/r_{\text{X}}, \tag{2}$$

where Ar_{X}^3 and $-B/r_{\text{X}}$ correspond to $\bar{V}_{\text{int}}$ and $\Delta\bar{V}$, respectively, and r_{X} is the crystal radius of an ion. From Eq. (2) and observed values of the partial molar volume, A and B were determined empirically. The values of Ar_{X}^3 given by Hepler were about twice as much as $4\pi r_{\text{X}}^3 N_{\text{A}}/3 (=2.52\, r_{\text{X}}^3)$, where N_{A} is Avogadro's number, r_{X} being given in Å.

Since the studies on $\bar{V}_{\text{ion}}$ by Stokes and Robinson[3] and by Hepler,[1] a number of studies have been carried out but with only partial success. For theoretical estimation of $\bar{V}_{\text{ion}}$, it is important to calculate the values of $\bar{V}_{\text{int}}$. Attempts were carried out to find expressions for $\bar{V}_{\text{int}}$. They are summarized as follows.[2]

$$\bar{V}_{\text{int}} = Ar_{\text{X}}^3 \tag{3}$$

$$= 2.52r_{\text{X}}^3 + A'r_{\text{X}}^2 \tag{4}$$

$$= 2.52(r_{\text{X}}+a)^3. \tag{5}$$

In Eq. (3) A is positive and larger than 2.52.[1,3-7] In Eq. (4) the contribution from a surface effect of ions in addition to the crystal volume, $2.52\, r_{\text{X}}^3$ is taken into consideration.[7,8,10] In Eq. (5), $\bar{V}_{\text{int}}$ is expressed with the assumption that the ionic radius is larger than that in crystals by an amount a. Assuming that "the dead space" in packing of hard spheres "corresponds to a hollow sphere of constant thickness", Glueckauf estimated the magnitude of an additive term to the crystal radius, a.[9] Since Eqs. (3), (4), and (5) are based on semiempirical and intuitive considerations, there remains an arbitrariness for estimating the values of $\bar{V}_{\text{int}}$. The expressions are found to be inconsistent with each other, their applicability being restricted. Thus, it is necessary to remove the uncertainty in the estimation of $\bar{V}_{\text{int}}$.

It is the purpose of this report to give a theoretical expression for the intrinsic volume of ions on the basis of the scaled particl theory of liquids[11] in order to make clear the physical meanings of the semiempirical expressions, and to investigate ion-water interactions through a discussion on $\Delta\bar{V}$.

Application of the Scaled Particle Theory

The Scaled Particle Theory.[11-13] The theory is based on the consideration of the properties of a new distribution function $G(r)$, where "$\rho G(r)$ is defined as the local concentration of molecular centers adjacent to a spherical cavity of radius r from which all molecular centers are excluded".[11] ρ is the number density of the fluid. The *key relation* of the theory is

$$G(d) = g(d), \tag{6}$$

where $g(r)$ is the radial distribution function at a separation r and d is a rigid sphere diameter. Noting that Eq. (6) is an exact relation for hard sphere fluids, Reiss *et al.* arrived at an approximate analytical expression for $G(r)$ by combining the packing of hard spheres with the thermodynamical consideration for the formation of spherical cavities. They derived an equation of state for hard sphere fluids, which is identical with the equation derived by Wertheim[14] as an analytical solution of Percus-Yevick equation for hard sphere fluids. It was proved that the equation is useful for various real fluids.[15,16] The theory is not only rigorous to the same extent as the Percus-Yevick equation, but also intuitive like a model theory.

The Partial Molar Volume of Solute. Pierotti made use of the theory to obtain the expression for solubility

of non-polar gases in water.[17] The partial molar volume of solute at infinite dilution $\bar{V}_2$ is obtained as a partial derivative of chemical potential of the solute in a very dilute solution. The resulting equation is

$$\bar{V}_2 = (\partial\bar{G}_c/\partial p)_{N,T} + (\partial\bar{G}_i/\partial p)_{N,T} + RT\beta_T \quad (7)$$
$$= \bar{V}_c + \bar{V}_i + RT\beta_T \quad (8)$$

where β_T is the isothermal compressibility of the solvent. $\bar{V}_c$ and $\bar{V}_i$ appear since the process of introduction of a solute molecule into the solvent is considered to take place in two steps. The first step is "the creation of a cavity in the solvent of a suitable size to accomodate the solute molecule".[17] The reversible work required for the process is $\bar{G}_c$, which is given by the scaled particle theory as follows.

$$\bar{G}_c = K_0 + K_1 d_{12} + K_2 d_{12}^2 + K_3 d_{12}^3, \quad (9)$$

where d_{12} is $(d_1+d_2)/2$, and d_1 and d_2 are diameters for solvent and solute molecules, respectively. The second step is "the introduction into the cavity of a solute molecule which interacts with the solvent according to some potential law".[17] The reversible work required is $\bar{G}_c$. The K values in Eq. (9) were evaluated from the scaled particle theory[13] to be

$$K_0 = RT\{-\ln(1-y) + (9/2)[y/(1-y)]^2\} - (\pi p d_1^3)/6$$
$$K_1 = -(RT/d_1)\{[6y/(1-y)] + 18[y/(1-y)]^2\} + \pi p d_1^2$$
$$K_2 = (RT/d_1^2)\{[12y/(1-y)] + 18[y/(1-y)]^2\} - 2\pi p d_1$$
$$K_3 = (4/3)\pi p, \quad (10)$$

where $y=(\pi d_1^3\rho)/6$, ρ is the number density of solvent molecules, p pressure, R gas constant and T absolute temperature. The last term on the right-hand side of Eq. (9) is the work expended in creating a cavity of volume, $4\pi d_{12}^3/3$. The third and second terms are surface work and additive terms accounting for the curvature dependence of surface tension, respectively. The first term is a function of density and temperature.

Equations (7)—(10) are now applied to ionic solutions. By neglecting the term $RT\beta_T$, Eq. (8) is reduced to Eq. (1). $\bar{V}_{ion}$, $\bar{V}_{int}$, and $\Delta\bar{V}$ in Eq. (1) correspond to $\bar{V}_2$, $\bar{V}_c$, and $\bar{V}_i$ in Eq. (8), respectively. Thus, using the ionic radius r_X, $\bar{V}_c$ ($\equiv\bar{V}_{int}$) is expressed as follows, after sine calculations.

$$\bar{V}_c \equiv \bar{V}_{int} = 2.52r_X^3 + A'r_X^2 + A''r_X + A''' \quad (11)$$

A', A'', and A''' are expressed as

$$A' = RT\beta_T\{12y/(1-y)^2 + 36y^2/(1-y)^3\}/d_1^2$$
$$A'' = RT\beta_T\{6y/(1-y)^2\}/d_1$$
$$A''' = RT\beta_T\{y/(1-y)\}. \quad (12)$$

Validity and Interpretation of Various Semiempirical Equations

The physical meaning and validity of semiempirical Eqs. (3), (4), and (5) are interpreted on the basis of Eqs. (11) and (12). Equation (3) by Hepler, and Stokes and Robinson includes only the cubic term, the value of A being determined empirically and intuitively. Formally, Eq. (3) is seen to drop out the second, third and fourth terms in Eq. (11). Equation (4) by Conway *et al.* and other workers includes cubic and square terms, A' being determined empirically. Equation (4) is seen formally to drop out the third and fourth terms in Eq. (11). Equation (5) has a cubic polynomial form similar to Eq. (11). Concerning Eq. (5), the value a was determined by Glueckauf as follows.

$$a = (3\phi_w/4\pi N)^{1/3} - r_w = (18.02/2.52)^{1/3} - 1.38$$
$$= 0.55,$$

where ϕ_W is the molar volume of water, r_W the radius of water molecule.[18] This intuitive consideration by Glueckauf is explained theoretically by means of Eqs. (11) and (12).

The values of coefficients A', A'', and A''' calculated by means of Eq. (12) are given in Table 1. The values of a', a'', and a''' are determined by comparing Eq. (5) with Eqs. (11) and (12). Equation (5) is expanded as follows.

TABLE 1. VALUES A', A'', A''' CALCULATED BY Eq. (12) AND VALUES a', a'', a''' BY COMPARING Eq. (5′) WITH Eq. (11)[a]

Temperature (°C)	A'	A''	A'''	a'	a''	a'''
0	4.527	2.291	0.662	0.60	0.55	0.64
25	4.310	2.187	0.639	0.57	0.54	0.64
50	4.434	2.270	0.666	0.59	0.55	0.64
75	4.735	2.454	0.727	0.63	0.57	0.66

a) In calculating A and a, r_X in Eqs. (11), (12), and (5) is represented in Å.

$$\bar{V}_{int} = 2.52r_X^3 + 7.56ar_X^2 + 7.56a^2r_X + 2.52a^3. \quad (5')$$

The coefficients of the second, third and fourth term in Eq. (5′) correspond to A', A'', and A''' in Eq. (11), respectively. The values of a obtained using the values of A', A'', and A''' in Table 1 are denoted by a', a'', and a'''. From the fact that the values of a' and a'' remain nearly constant and equal to Glueckauf's value 0.55, and from the formal agreement of the formula with Eq. (11), Glueckauf's equation is found to be the most reasonable of Eqs. (3)—(5). On the other hand, disagreement of a''' indicates that a representation such as Eq. (5) is an over-simplification.

For the sake of comparison, the values of A' and a obtained by various methods are shown in Table 2,

TABLE 2. VALUES OF A' AND a OBTAINED BY VARIOUS METHODS

	A' (from Eq. (4))	a (from Eq. (5))
B. E. Conway *et al.*[8]	3.15	
R. Noyes[7]	4.09	0.45
M. Panckhurst[10]	4.03	0.436
E. Glueckauf[9]		0.55
F. J. Millero[19]	4.0	0.45

17) R. A. Pierotti, *J. Phys. Chem.*, **67**, 1840 (1963), *ibid.*, **69**, 281 (1965).

18) $\phi_w=(4/3)\pi N(r+a)^3$. The value of a was used as a constant increment over the crystal radius of ions in solutions.

19) F. J. Millero, *J. Phys. Chem.*, **73**, 2417 (1969).

A' from Eq. (4) and a from Eq. (5). It turns out that values of A' and a determined by semiempirical and intuitive methods are all underestimated when compared with those in Table 1.

Estimation of $\Delta\bar{V}$

The values of the volume contraction caused by ion-water interactions are calculated by means of Eqs. (1), (11), (12) and the experimental values of $\bar{V}_{ion}$. The assignment of $\bar{V}_{ion}$ to each ion from the observed values of $\bar{V}$ for electrolytes has attracted the interest of workers in this field, many conventional methods having been presented.[2] For the partial molar volume of H^+, the value $\bar{V}_{H^+}=0$ has been used conventionally. We adopt here the value $-5.0\,cm^3$ for $\bar{V}_{H^+}$ as the most adequate.[2] $\bar{V}_{ion}$ of other ions are obtained from the conventional values of partial molar volume of ions $\bar{V}_{conv}$ which have been estimated assuming that $\bar{V}_{H^+}=0$. The values of $\bar{V}_{conv}$ were tabulated by Millero.[2] The values $\Delta\bar{V}$ calculated from the values of $\bar{V}_{int}$ determined with the use of Eqs. (11) and (12) and those of $\bar{V}_{ion}$, are shown in Table 3 for various univalent ions. Pauling's crystal radii are used as ionic radii r_X in the calculation.

In alkali and halogen ions, the magnitudes of $|\Delta\bar{V}|$ are seen to decrease with the increase of ionic radii, except for Li^+ ion. The behavior is interpreted as an electrostatic aspect in ion-water interactions. However, it should be remarked that the obtained results depend on the choice of the value of $\bar{V}_{H^+}$ used here.[1,4]

The magnitude of $|\Delta\bar{V}|$ of the tetraalkylammonium ions increases with increasing ionic size. This behavior cannot be interpreted only in the light of electrostatic interactions between ions and water molecules but by the iceberg formation around the ions. We have shown recently by an ultrasonic study that icebergs formed around tetraalkylammonium ions have a dense and hard structure, and the trend of iceberg formation increases with the ionic size.[20] The behavior of $\Delta\bar{V}$ in tetraalkylammonium ions given in Table 3 is consistent with the conclusion of the ultrasonic study. It is interesting to compare the difference between the values of $\Delta\bar{V}$ of two subsequent ions, such as Me_4N^+ and Et_4N^+. The values of $(\Delta\bar{V}_{Et_4N^+}-\Delta\bar{V}_{Me_4N^+})$, $(\Delta\bar{V}_{Pr_4N^+}-\Delta\bar{V}_{Et_4N^+})$ and $(\Delta\bar{V}_{Bu_4N^+}-\Delta\bar{V}_{Pr_4N^+})$ at 25 °C are −14.7, −26.3, and −27.9 cm³/mol, respectively. This supports our conclusion that the trend of iceberg formation seems to be appreciable at Pr_4N^+.[20]

Table 3. The values of $\Delta\bar{V}$ $(=\bar{V}_{ion}{}^{a)}-\bar{V}_{int}{}^{b)})$ (cm³/mol)

Ion	r_X(Å)	0 °C	25 °C	50 °C	75 °C
H^+		−5.0	−5.0	−5.0	−5.0
Li^+	0.60	−9.7	−9.9	−10.4	−11.3
Na^+	0.95	−17.6	−15.0	−14.3	−13.7
K^+	1.33	−15.5	−13.1	−12.9	−13.0
Rb^+	1.48	−14.8	−12.4	−12.2	
Cs^+	1.69	−15.0	−12.5	−12.1	−12.4
F^-	1.36	−15.7	−14.1	−15.6	−17.3
Cl^-	1.81	−13.1	−10.8	−11.2	−13.2
Br^-	1.95	−13.0	−10.3	−10.2	−12.1
I^-	2.16	−13.6	−9.7	−9.1	−11.3
Me_4N^+	3.47	−84.8	−80.8	−81.0	−80.7
Et_4N^+	4.00	−101.1	−95.5	−95.4	−93.3
Pr_4N^+	4.52	−128.7	−121.8	−119.7	−118.8
Bu_4N^+	4.94	−160.1	−149.8	−143.9	−133.1
Am_4N^+	5.29		−171.7		

a) The values are obtained from the conventional values of partial molar volume of ions $\bar{V}_{conv}$ which have been estimated assuming that $\bar{V}_{H^+}=0$. That is, $\bar{V}_{ion}=\bar{V}_{conv}\pm5.0\,cm^3/mol$ (+for anions, −for cations). The values of $\bar{V}_{conv}$ are those compiled by Millero.[2]
b) The values are calculated by Eqs. (11) and (12).

Radiotracer Studies on Adsorption of Surface Active Substance at Aqueous Surface. V. Effects of Additives on the Adsorption of Tritiated Nonionic Surfactant

Kazuo TAJIMA and Makio IWAHASHI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received July 7, 1973)

The effects of additives on the adsorption of tritiated hexaoxyethylene dodecyl monoether ($TD(EO)_6$) at the air-solution interfaces have been determined at 30 °C. The salting-out effect has been found to follow the Hofmeister series for the sodium salts of various anions, whereas a constant amount has been found for the adsorption increase due to the addition of various chlorides varying with the type of cation. The salting-in effect is observed for denaturants such as urea, urea nitrate and guanidine nitrate, but not for di- and tri-ethylene glycols.

It was reported[1] that the adsorbed amount of tritiated hexaoxyethylene dodecyl monoether ($TD(EO)_6$) at the air-solution interface is in good agreement with the surface excess based on the Gibbs adsorption isotherm for concentration dependence of the surface tension of its solution. The molecular area at the saturated adsorption has been found to be 60.8 Å^2, the value being slightly larger than that for sodium dodecyl sulfate.[2,3]

Several papers have dealt with the effects of additives in nonionic surfactant solutions upon their surface-chemical characters such as cloud point,[4] critical micelle concentration,[5] thinning of film,[6] and surface tension lowering.[7] All these phenomena were studied basically by means of adsorption, which, however, has never been determined directly. Another problem is how to make use of the Gibbs adsorption isotherm for calculation of the adsorbed amount in a mixed solution of a nonionic surfactant and a strong electrolyte. We have made an attempt to determine the adsorbed amounts of $TD(EO)_6$ at the interfaces between humidified nitrogen and its solutions containing strong electrolytes or denaturants frequently used for studying the mechanism of salting-in and salting-out of surfactants.

Experimental

Materials. The tritiated nonionic surfactant was the same as that used in the previous experiment.[1,3] All the additives were purified by appropriate procedures; distillation for di- and triethylene glycols and recrystallization for strong electrolytes, urea, urea and guanidine nitrates. All the crystalline additives were finally degreased by Soxhlet extraction.

Procedures. The surfactant solution was prepared by dissolving $TD(EO)_6$ in an aqueous solution of an additive. The adsorbed amount was determined by the same procedures as described previously.[1-3] The radioactivity was measured by sheet scintillation counting in an atmosphere of 98%-humidified nitrogen at 30±0.1 °C. The surface tension was measured by the Wilhelmy plate method under the same conditions as in the adsorption experiments. The concentration of the nonionic surfactant solution, throughout all experiments, was kept constant at 4.00×10^{-5} mol/l, at which the adsorption reached the saturated values, 2.73×10^{-10} mol/cm^2 for the salt-free solution.

Results and Discussion

Salt Effects. Ionic specificity does not appear to influence the adsorption of $TD(EO)_6$ at its solution/nitrogen interfaces for any of Li, Na, K, and Cs chlorides (Fig. 1). The peculiar behavior of Rb^+ probably comes from some impurity contained in the sample of RbCl. On the other hand, an order of $Cl^->NO_3^->I^->SCN^-$ has been found for enhancement of the surfactant adsorption due to the addition of their sodium salt (Fig. 2). The order is in accord with the lyotropic series for hydration of various ions.[8] The same tendency has been found for the salt effects on the time required for formation of black film of polyoxyethylene nonylphenyl ether solution.[6] Malik and Jhamb[9] ob-

served similar effects with electrolytic additives on the lowering of cmc for Tween 20, 40, and 80 in their solutions. All these phenomena are explicable by almost the same co-ordination number, *i.e.*, 3.8 for Li^+, 3.7 for Na^+, 3.8 for K^+, and 3.5 for Cs^+, for relatively small cations surrounded by common anions (chloride) of larger size.[10] On the other hand, the result (Fig. 2) probably reflects the different charge density due to the variation of ionic radius.

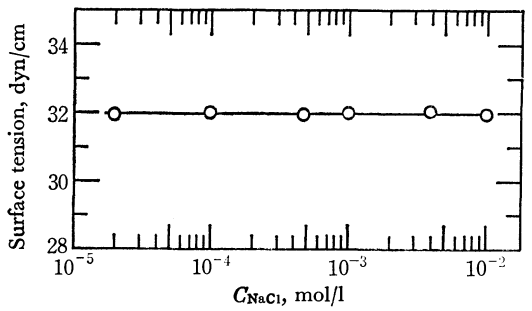

Fig. 3. Surface tension as a function of concentration of NaCl added to the solution of $TD(EO)_6$ ($C_D=4.0\times10^{-5}$ mol/l) at 30 °C.

The surface tension given as a function of NaCl added to $TD(EO)_6$ in solution is shown in Fig. 3. For such a system, the surface tension γ is expressed as

$$-d\gamma = RT\Gamma_D d\ln a_D + RT\Gamma_{Na^+} d\ln a_{Na^+} + RT\Gamma_{Cl^-} d\ln a_{Cl^-} \quad (1)$$

in terms of surface excess Γ, activity a of individual components in the solution, gas constant R, and absolute temperature T. Subscripts D, Na^+, and Cl^- denote surfactant, sodium and chloride ions, respectively. From the constancy of surfactant concentration and the electrical neutrality in surface and bulk phases, it follows that $dC_D=0$, $\Gamma_{Na^+}=\Gamma_{Cl^-}=\Gamma_{NaCl}$, and $C_{Na^+}=C_{Cl^-}=C_{NaCl}$. Thus Eq. (1) can be rewritten as follows,

$$-\frac{d\gamma}{RT\,d\ln C_{NaCl}} = \Gamma_D\frac{d\ln f_D}{d\ln C_{NaCl}} + 2\Gamma_{NaCl}\left(1+\frac{d\ln f_{\pm}^{NaCl}}{d\ln C_{NaCl}}\right) \quad (2)$$

where $f_{\pm}^{NaCl}$ is the mean activity coefficient of NaCl in the solution. Because of the small value of C_D ($=4.0\times10^{-5}$ mol/l) in comparison with C_{NaCl} ($=10^{-2}\sim10^{-5}$ mol/l), the Debye-Hückel limiting law can be applied. Thus

$$-\frac{d\ln f_{\pm}^{NaCl}}{d\ln C_{NaCl}} = \frac{A}{2}C_{NaCl}^{1/2} \quad (3)$$

where A is a constant. From the empirical relationship, $-[d\gamma/(RT\ d\ln C_{NaCl})]_D=0$ (see Fig. 3), Eq. (2) becomes

$$\Gamma_D = \frac{A\Gamma_{NaCl}}{\Delta_{NaCl}}C_{NaCl}^{1/2} - \frac{2\Gamma_{NaCl}}{\Delta_{NaCl}} \quad (4)$$

where $\Delta_{NaCl}=d\ln f_D/d\ln C_{NaCl}$. In the $\Gamma_D\sim C_{NaCl}^{1/2}$ relationship (Fig. 4), a value of 1×10^{-10} mol/cm^2/(mol/l)$^{1/2}$ is obtained for $A\Gamma_{NaCl}/\Delta_{NaCl}$ from the linear portion at $C_{NaCl}>1\times10^{-4}$ mol/l. If we assume the empirical relationship,[11]

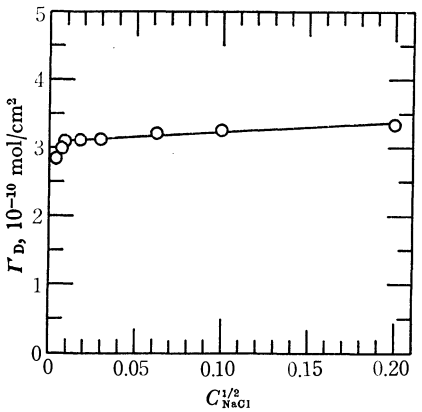

Fig. 4. Γ_D *vs.* $C_{NaCl}^{1/2}$

$$\gamma_{NaCl} = 1.92C_{NaCl} + \gamma_{H_2O} \quad (5)$$

for explaining a surface tension increase from γ_{H_2O} to γ_{NaCl} due to the addition of NaCl to water, the result $-0.762\ C_{NaCl}\times10^{-10}$ mol/cm^2 is obtained for the adsorbed amount of NaCl at its solution surface. If we furt er assume that the Γ_{NaCl} value remains unchanged by addition of $TD(EO)_6$ and A is 1.14 (l/mol)$^{1/2}$ at 30 °C, we obtain

$$-\ln f_D = 0.869C_{NaCl} \quad (6)$$

The relationship is essentially the same as the equation proposed by McDevit and Long[12] for a solution of benzene in aqueous salt solution. Mukerjee[13] derived a similar relationship for the activity coefficient for nonionic amphiphiles dissolved in aqueous salt solutions of various concentrations. It is natural to find a negative value of Δ_{NaCl} so as to give a smaller f_D value corresponding to a larger C_{NaCl} value.

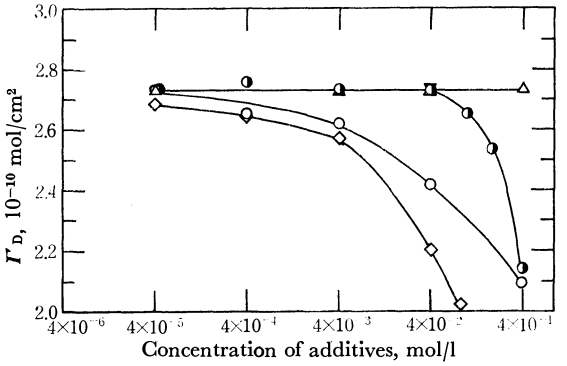

Fig. 5. Effects of various denaturants on the adsorbed amount of $TD(EO)_6$ at 30 °C.
The bulk concentration of $TD(EO)_6$ is 4.0×10^{-5} mol/l.
○: urea, ◑: urea nitrate, ▼: diethylene glycol,
△: triethylene glycol, ◇: guanidine nitrate.

Denaturant Effects. Figure 5 shows the effects of urea, urea nitrate, guanidine nitrate, di- and triethylene glycols on the adsorbed amounts of the surfactant. Addition of the denaturants causes a decrease in the adsorbed amount in the order guanidine nitrate> urea>urea nitrate>glycols, the tendency being in parallel with the effect of similar additives on the cmc elevation of Triton X-100 in its solutions[14] and on the denaturation of proteins.[15] A marked lowering of Γ_D at a concentration of urea nitrate higher than 4.0×10^{-2} mol/l might indicate a decrease in activity of ionic species. In fact, the conductivity~concentration relationship for urea nitrate (Fig. 6) gives a distinct deviation from a linear portion in log-log scale. The rather weak effect of glycols on the adsorption of $TD(EO)_6$ is understandable when we consider their weak action as denaturants.

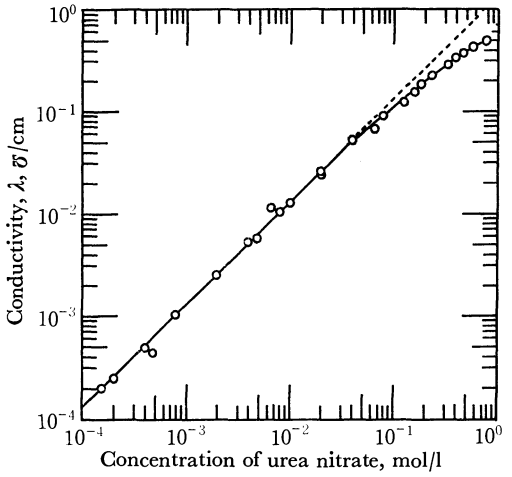

Fig. 6. Conductivity of aqueous solution of urea nitrate at 30 °C.

The surface tensions of urea solution with and without the nonionic surfactant are shown in Fig. 7. As in the derivation of Eq. (2), we obtain

$$-\left[\frac{d\gamma}{RTd\ln C_U}\right]_D = \Gamma_D\frac{d\ln f_D}{d\ln C_U} + \Gamma_U\left(1+\frac{d\ln f_U}{d\ln C_U}\right) \quad (7)$$

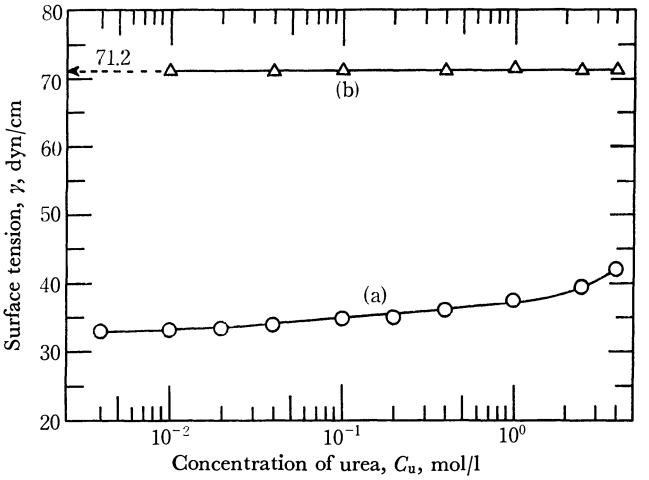

Fig. 7. Surface tension of urea solution with (a) and without (b) $TD(EO)_6$ ($C_D=4.0\times10^{-5}$ mol/l) at 30 °C.

for surface tension γ as a function of the concentration C_U and the activity coefficient f_U of urea in the solution. The left side term in Eq. (7) is given empirically by

$$\left[\frac{d\gamma}{RTd\ln C_U}\right]_D = 4.5\times10^{-11}C_U^{0.15} \quad (8)$$

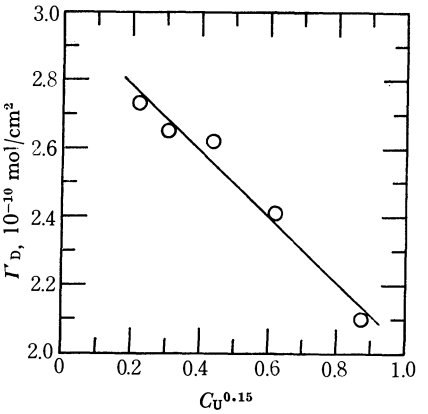

Fig. 8. Test of Eq. (9).

in the region below 0.4 mol/l of urea solution. Assuming $\Gamma_U=0$ from the inclination of curve (b) in Fig. 7, we can rewrite Eq. (7) as follows.

$$\Gamma_D = -\frac{4.5\times10^{-11}}{\Delta_U}C_U^{0.15} \quad (9)$$

where $\Delta_D=d\ln f_U/d\ln C_U$, which is obtainable as the inclination of the linear portion of $\Gamma_U\sim C^{0.15}$ relationship. It is obvious that $\Delta_U>0$ shows a salting-in effect of urea on surfactant. Sears[16] reported a marked expansion of the monolayer of stearic acid when it is spread on an aqueous urea solution, unless the surface pressure is too high. It is likely that the urea molecules are anchored on the ethoxyl groups of the surfactant.

The authors wish to express their hearty thanks to Professor M. Muramatsu for valuable discussions and for help in the preparation of the paper. Financial support from the Matsunaga Science Foundation is gratefully acknowledged.

Radical Formation Initiated by the Biphotonic Excitation of Acridone

Yoshikatsu MIYASHITA, Shigeya NIIZUMA, Hiroshi KOKUBUN, and Masao KOIZUMI
Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980
(Received March 20, 1973)

The photochemical formation of alcohol radical has been found to occur in the rigid solvent of ethanol (77 K) and in the polyvinyl alcohol (PVA) film (77 K and at room temperature), when acridone is dissolved as a sensitizer. It has been established that by absorbing two photons stepwise acridone gives rise to radicals which abstract hydrogen atoms from alcohol molecules, this being called the radical reaction mechanism and abbreviated as R-R mechanism. The energies necessary for the radical formation were estimated by determining energy levels of acridone and examining the wavelength dependence of the reaction. They differed for ethanol (77 K), PVA (77 K) and PVA (room temp.), perhaps due to the cage effect. The feature of the R-R mechanism has been compared with that of the energy transfer type (E-T mechanism) in which the energy is transferred from the higher triplet of solute to solvent molecules. When methyl iodide with a lower dissociation energy is added to an ethanol solution of acridone (77 K) and is then irradiated by an exciting light ineffective for R-R mechanism, methyl radical is formed by E-T mechanism. When the two types of reaction were energetically possible, E-T mechanism occurred more easily than R-R mechanism.

Photochemical reactions initiated by the absorption of two photons *via* the lowest triplet state are fully established.[1-7] Studies on the biphotonic sensitized solvent decomposition so far reported have led to the conclusion that the mechanism is the energy transfer from higher triplet states of solute to solvent molecule.[2-5] Siegel *et al.*[2,3] chose the ethanol solution of naphthalene and extensively studied the formation of solvent radicals from the excited solvent molecules produced by the energy transfer from the higher excited triplet states of naphthalene. In these cases the electronic states of the solvent molecules susceptible to dissociation should be located somewhat lower than the higher triplet states of solute molecules. It was found that only the T-levels above the fourth T-level of naphthalene lying 60 kK above the ground state are effective for the solvent radical formation. In the case of ethanol the direct radical formation also occurs upon irradiating the solvent alone with a light of about 50 kK.[8] This state is possibly responsible for the sensitized reaction.

It is expected that the formation of solvent radicals occurs also *via* the biphotonic formation of solute radicals which subsequently abstract hydrogen atoms from solvent molecules. This radical reaction mechanism (R-R mechanism) is thought to be common in view of the fact that alcohols act as a H-donor to many reducible substances; for instance, the ethanol radical is formed by one photon reduction of acridine in ethanol at room temperature and also by one photon decomposition of acridan in ethanol at liquid nitrogen temperature.[9]

However, no such example has been found in literature, although the unimolecular biphotonic solute radical formation was reported for *p*-xylene.[7] We have found the occurrence of such a biphotonic solvent radical formation *via* R-R mechanism when acridone dissolved in rigid organic solvents is irradiated with the light of a lower energy than in the case of energy transfer mechanism (E-T mechanism). We have also found that radical formation by E-T mechanism also occurs when the substance with a lower dissociation energy such as CH_3I is added to the ethanol solution of acridone at 77 K.

Experimental

The decomposition of solute and solvent was examined by measuring the ESR signals and the electronic absorption spectra. A JEOL P-10 type ESR spectrometer was used. Light from a superhigh pressure mercury arc (Ushio USH-500D) was used with or without filters (Toshiba UV-39, UV-35, Hoya-crystal U-2). The intensity distribution of the radiation output from the mercury arc and transmittances of

filters are shown in Fig. 1.

Materials. Polyvinyl alcohol (PVA) (Koso-Kagaku) and ethanol (Wako-Junyaku, G.R.) were used without further purification. Methyl iodide (Wako-Junyaku, E.P.) was purified by the standard method. Acridone (Tokyo-Kasei, G.R.) was recrystallized from ethanol. The concentration of acridone was usually $10^{-3}\sim10^{-4}$ M. PVA films were about 200 μ in thickness.

Results

Triplet State of Acridone. For the present investigation it is desirable to know the triplet levels of acridone. A stepwise biphotonic process *via* the lowest triplet states requires that the triplet state concentration is appreciable and this in turn requires a long lifetime of the triplet state. These data were therefore determined.

Phosphorescence was observed near 20 kK in glassy ethanol and PVA at 77 K. The triplet lifetimes evaluated from the decay of phosphorescence are as follows.

Solvent	Temp.	τ(s)
EtOH	77 K	2.0
PVA	77 K	2.0
	R.T.	1.2

Acridone in PVA at room temperature showed phosphorescence, the lifetime of which was not much shorter than that at 77 K. T-T absorption of acridone in PVA was observed by flash technique at room temperature. The triplet lifetime was approximately the same as that of phosphorescence. T-T absorption spectrum in ethanol at room temperature is shown in Fig. 2.[10] There are two absorption bands, one near 17.5 kK and the other above *ca.* 28 kK. The energy diagram of acridone obtained from these data is given in Fig. 3.

The steady state concentration of the lowest triplet state, $\phi_{ST}I_{ab}\tau$ (ϕ_{ST}, S*-T transition probability; τ, the lifetime of the lowest triplet state) was estimated to be of the order 10^{-5} M under the present experimental conditions. It is expected that a considerable amount of the lowest triplet molecules is excited to higher triplet states. A $\Delta m=\pm2$ signal from acridone in the lowest triplet state was observed. The value of the zero-field splitting parameter D* was 0.065 cm^{-1}, which is comparable with that of acridine, 0.0688 cm^{-1}.[11]

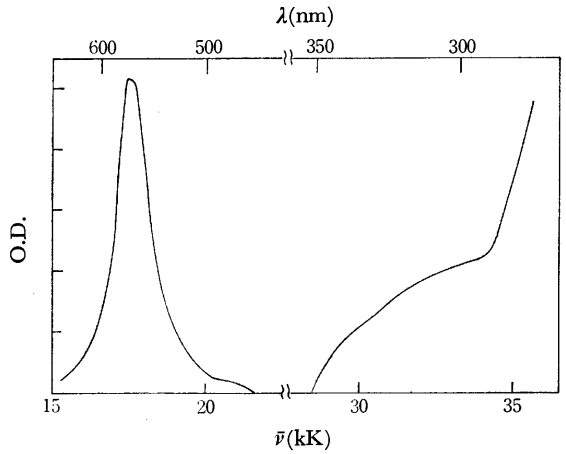

Fig. 2. T-T absorption spectrum of acridone in ethanol at room temperature.

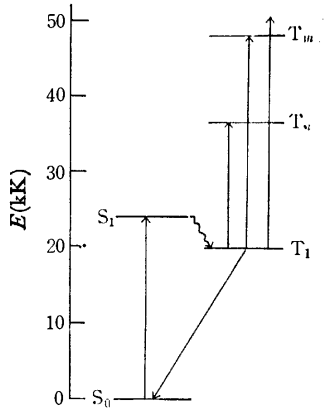

Fig. 3. Energy diagram of acridone.

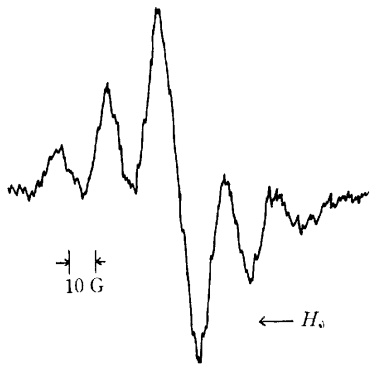

Fig. 4. ESR spectrum of photoproducts in deaerated ethanol solution irradiated with a UV-35 filter at 77 K.

Reaction in Ethanol Solution at 77 K. Deaerated ethanol solutions of acridone were irradiated with a UV-35 filter. The ESR spectrum of radicals is shown in Fig. 4. Broadly speaking, the spectrum consists of five lines, which can be safely attributed to ethanol radical ($CH_3\dot{C}HOH$), but a very high central line suggests the contamination of some other species. Irradiation with a UV-39 filter, on the other hand, did not give any signals.

The effect of light intensity on the rate of radical formation was examined by assuming the following relation between the two quantities,

$$d[R]/dt = kI_0^n \quad (1)$$

where [R] is radical concentration, I_0 light intensity, and n and k are constants characteristic for the reaction.

The value of n was found to be 1.7. Thus the rate of radical formation is nearly proportional to the square of light intensity.

Radical formation was accompanied by a purple coloration, which disappeared upon warming the ir-

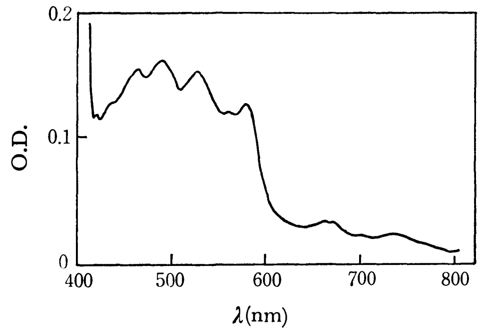

Fig. 5. Absorption spectrum of intermediates in ethanol upon irradiation with a UV-35 filter at 77 K.

radiated sample to room temperature. The absorption spectrum of the irradiated sample at 77 K is shown in Fig. 5. Since the ethanol radical does not absorb the visible light,[12] it is ovbious that some other intermediates are produced from acridone. Hence an abnormally high central line in the ESR spectrum is safely attributed to the intermediates originating from acridone.

The irradiated sample, when warmed to room temperature, showed a prominent decrease of the main absorption bands of acridone. The decrease was very slight in the case of irradiation with a UV-39 filter, the irradiated sample not being colored.

We can conclude that in ethanol at 77 K, formation of the ethanol radical is accompanied with the decomposition of acridone, as shown in Table 1.

Abs., Acridone decomposed

The effect of the dissolved oxygen on the reaction was examined. Irradiation with a UV-35 filter of the aerated solutions gave the ESR signal of an ethanol radical. But the signal was unsymmetric from the initial stage of irradiation and gradually truned into a peroxide-like signal (Fig. 6). It can be said that oxygen participates in the reaction mainly after a biphotonic process has been completed.

Reaction in Polyvinylalcohol Films. Polyvinylalcohol is a solvent which is glassy at room temperature. When PVA films containing 10^{-3} M acridone were irradiated

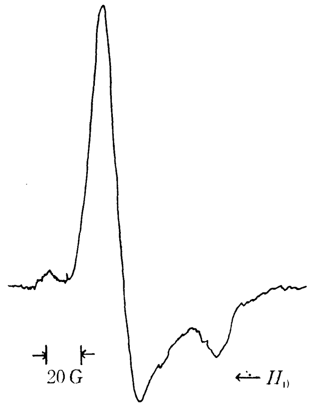

Fig. 6. ESR spectrum of photoproducts in aerated ethanol solution, 15 min. after irradiation with a UV-35 filter at 77 K.

at 77 K with a UV-35 filter and a U-2 filter whose limit of transmission is 10 nm shorter than for UV-35, they did not give any ESR signal. Irradiation with a total output from the mercury arc at 77 K gave a three line ESR spectrum (Fig. 7), no signal being detected in the case of PVA alone.

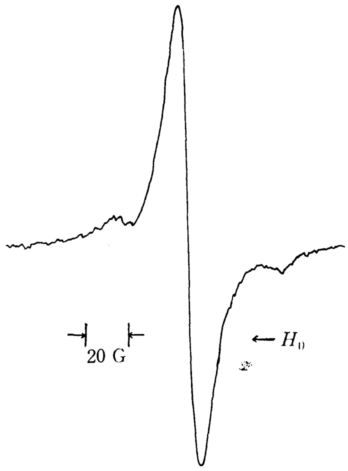

Fig. 7. ESR spectrum of photoproducts in PVA irradiated with a total output from mercury arc at 77 K.

These radical species were stable at 77 K. When irradiated samples were warmed up to room temperature, the ESR signals were still observed although the intensities were somewhat decreased and decayed slowly. When an irradiated sample was warmed to the glass transition temperature (70—80 °C), the signal disappeared completely.

Since a coupling constant of the radical is about 35 Gauss[13] there is no doubt that a polyvinylalcohol

$$(\sim CH_2\text{-}\dot{C}(OH)\text{-}CH_2\sim)$$

radical is formed. The polyvinylalcohol radical formed by γ-ray irradiation was investigated by Ogawa.[13] He reported that a crystalline region gives an ESR signal of three lines and an amorphous region, a broad line, the resulting spectrum consisting of the two com-

13) S. Ogwa, *J. Phys. Soc. Japan*, **16**, 1488 (1960).

ponents. The present result reconfirms this conclusion. The radical species not being attacked by oxygen was found to be stable in the presence of oxygen at 77 K.

The effect of light intensity on the rate of radical formation was examined by means of Eq. (1). The value of n was found to be 1.8, supporting a biphotonic nature of the main reaction. As in the ethanol solution at 77 K, irradiation with a U-2 filter which gave no ESR signal did not cause any change in the main absorption bands of acridone. Irradiation by a total output from the mercury arc caused a decrease in the main absorption bands of acridone with the appearance of a new absorption in the visible region at *ca.* 100 K.

It is remarkable that the irradiation of samples at room temperature with a U-2 fillter which caused no reaction at 77 K gave the ESR signal accompanied with a change of absorption spectrum in the visible and ultraviolet regions. The results obtained are listed in Table 1, which leads to the conclusion that the formation of a solvent radical is always accompanied by the decomposition of acridone.

Reaction in Ethanol Containing Methyl Iodide at 77 K. Since the irradiation with UV-39 (total energy $\leq$46 kK) does not decompose acridone in ethanol at 77 K, a possible mechanism for biphotonic radical formation in the wavelength region below 46 kK is only energy transfer. According to Terenin *et al.*[5] the minimum energy required for the direct photodissociation of methyl iodide is 5.0 eV (40 kK). It is therefore expected that the irradiation of acridone in ethanol containing methyl iodide gives rise to methyl radical by the biphotonic E-T mechanism.

The deaerated ethanol solutions of acridone containing methyl iodide (20%) which were glassy at 77 K were irradiated with the use of UV-39. ESR spectra due to a methyl radical (1 : 3 : 3 : 1 intensity ratio and a 24 Gauss hyperfine splitting) and an ethanol radical were detected. The height of the central line could be interpreted as originating only from the ethanol radical. The effect of light intensity on the rate of radical formation was examined by Eq. (1) and a value of 1.8 was obtained for n supporting a biphotonic process. Irradiation with UV-35 also produced the two kinds of radical. In both cases the ESR spectra in the initial stage mainly consisted of methyl radicals. The methyl radical disappeared with the life-time of 13 min, which agrees with the value in literature,[8] only the ethanol radical remaining in the later stage. Figure 8 gives an example of the variation of ESR spectra with time after irradiation. When the irradiated sample was kept in the dark, the ethanol radical increased with a decrease of the methyl radical. This implies that the methyl radical abstracts a hydrogen atom from ethanol according to $\dot{C}H_3 + C_2H_5OH \longrightarrow CH_4 + CH_3\dot{C}HOH$.

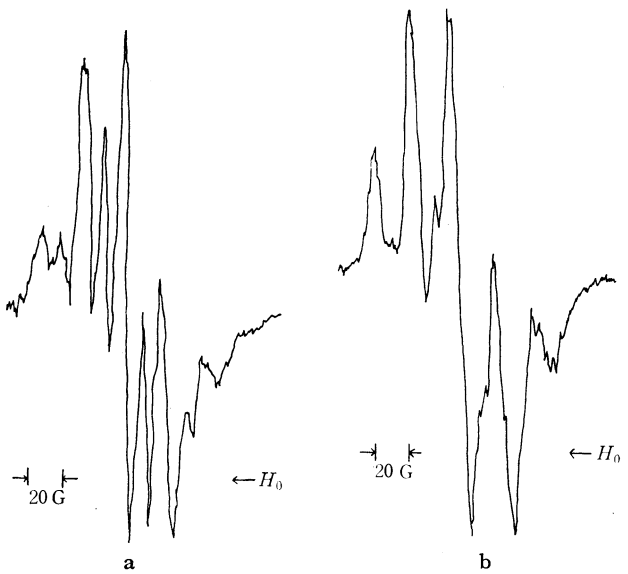

Fig. 8. ESR spectrum of photoproducts in deaerated ethanol solution containing 20% methyl iodide, a) 2 min, b) 20 min after irradiation with a UV-35 filter at 77 K.

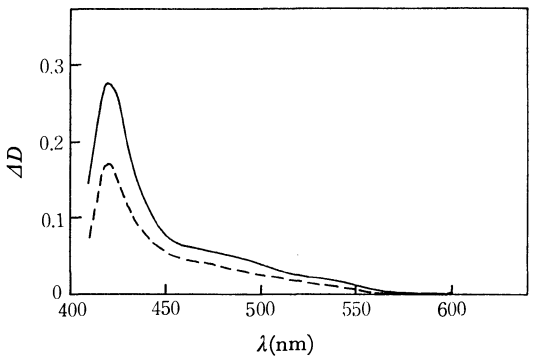

Fig. 9. The difference spectra between the irradiated (with a UV-35 filter) and non-irradiated deaerated ethanol solution containing 20% methyl iodide at 77 K.
----: 10 min irradiation, ——: 40 min irradiation.

The irradiation imparted an yellow color to the solution. The difference spectrum between the irradiated (with UV-35) and non-irradiated solution is shown in Fig. 9. The band located at 420 nm is safely assigned to iodine, the spectrum with no band near 500 nm supports an E-T mechanism, acridone not being decomposed. Irradiation with UV-35 is certainly energetically capable of bringing about R-R mechanism in addition to E-T mechanism. However, it is judged from the above results that E-T mechanism predominates, giving a larger quantity of methyl radicals in the initial stage.

It was established experimentally that the excitation in the T-T absorption band corresponding to 17.5 kK (the total excess energy, 37.5 kK) is not effective. Therefore the total energy required in the present case is 46 kK. This is consistent with the statement of Terenin *et al.*[5]

Discussion

The energy of the second photon required for the decomposition of acridone is obtained from Figs. 1 and 3. In both ethanol and PVA, irradiation with a UV-39 filter which excites the T-T absorption around 17.5 kK did not induce reaction. Thus 37.5 kK (17.5 kK plus the energy of the lowest triplet state) is not effective for the formation of an ethanol radical *via*

Table 2. Total energies required for radical formation

Sensitizer	Solvent	Temp.	Energy (kK)	Radicals
Acridone	EtOH	77 K	E≥50	$CH_3\dot{C}HOH$
	PVA	77 K	E≥53	$\sim CH_2-\dot{C}(OH)-CH_2\sim$
		R.T.	E≥46	
	EtOH (20% CH_3I)			
		77 K	E≥46	$\dot{C}H_3$, $CH_3\dot{C}HOH$
Naphthalene	EtOH	77 K	E≥60	$CH_3\dot{C}H_2$, $CH_3\dot{C}HOH$

R-R mechanism. The total energies required for the radical formation in the present systems are listed in Table 2. The results of Siegel *et al.*[2,3] on the naphthalene–ethanol system are given for the sake of comparison. Naphthalene as a sensitizer is not decomposed in ethanol at 77 K; the mechanism of radical formation is E-T. On the other hand the present mechanism is R-R.

It is interesting to compare the general features of the two mechanisms. First, the energy required for E-T mechanism is remarkably higher than that for R-R. This is natural, because ethanol does not absorb the light below *ca.* 50 kK. Sullivan and Koski,[8] using the light in this region, investigated the radicals produced by the direct photochemical decomposition of ethanol. Several radicals were detected but the main one was $C_2H_5\cdot$. The total energy of 60 kK required for radical formation which Siegel *et al.*[2,3] obtained is consistent with the result of direct photodecomposition. The energies of the four lowest triplet levels of naphthalene being about 45.6, 47, 48, and 60 kK, the lowest three are deficient in energy for exciting ethanol. On the other hand, the energy required for R-R mechanism naturally depends upon the solute employed. Once a solute radical is produced, the formation of an ethanol radical usually occurs very easily, *e.g.*, it is produced by one photon decomposition of acridan in ethanol at 77 K.[9]

Secondly, various types of radicals are produced by E-T mechanism while only the ethanol radical is produced by R-R mechanism. This is also reasonable since various types of radicals are expected to be formed with a high excitation energy followed by the secondary photochemical and thermal reactions between them and their mother substances. However, Judeikis and Siegel[14] proposed the sequence

$$^3S^* + CH_3CH_2OH \longrightarrow S + CH_3CH_2OH^* \quad (0)$$

$$CH_3CH_2OH^* \longrightarrow CH_3\dot{C}HOH + H\cdot \quad (1)$$

$$CH_3\dot{C}HOH + h\nu \longrightarrow CH_3\dot{C}HOH^* \quad (2)$$

$$CH_3\dot{C}HOH^* + CH_3CH_2OH \longrightarrow CH_3CHO + CH_3\dot{C}H_2 + H_2O \quad (3)$$

where $^3S^*$ is a highly excited triplet state solute molecule. Their finding that the $CH_3\dot{C}HOH$ radical is the only species observed during the early part of photolysis in ethanol strongly suggests that reaction (1) is the first step of dissociation. It is likely[12] that the ethanol radical has an absorption increasing from 300 to 200 nm which gives the ethyl radical according to (2) and (3).

In the case of R-R mechanism, the exciting light is so low in energy that (2) and (3) do not occur. In fact we could establish the occurrence of (2) and (3) when the deaerated solutions of acridone in ethanol were irradiated with a total output from the mercury arc. Thus the initial spectrum consisted mainly of ethanol radicals while at a later stage of continuous irradiation, the quantity of ethyl radicals gradually increased. It is not yet certain whether the decomposition of acridone is unimolecular, but this is most likely the case in view of the fact that acridone is not easily reduced by ethanol.

The cage effect is important for the formation of separate radicals. Rigidity of the medium, relative orientation of solute and solvent molecules as well as the microscopic structure around the solute molecules are important factors in addition to the excitation energy. The difference in the required energy for ethanol and PVA at 77 K may be due to the cage effect. In PVA, a rather hard medium as compared with ethanol, the diffusion of two radicals apart from each other may require a little higher energy than for ethanol. This is supported by the fact that at room temperature the required energy for PVA decreases to a smaller value than for ethanol. Another evidence is the occurrence of P-type delayed fluorescence at room temperature but not at 77 K.

It is intersting that acridone acts as a sensitizer for the biphotonic decomposition of methyl iodide. It has been established by Terenin *et al.*[5] that this compound dissociates when the energy 5.1—5.6 eV is supplied from various sensitizers raised *via* biphotonic process to higher triplet levels. Further, it is known that the absorption of light around 40 kK causes the direct dissociation of this compound. The continuous band located in this region is a n-σ* transition.[15] Therefore there is no doubt that the triplet acridone with the excess energy of ≥46 kK gives rise to dissociation of methyl iodide by E-T mechanism. The ethanol radical is formed by the secondary radical reaction which is quite reasonable in view of similar reactions already reported. It is thus strange that Terenin *et al.*, without observing the formation of ethanol radical, proposed the combination of two methyl radicals into ethane.

It is very suggestive that E-T mechanism overwhelms R-R mechanism when they are both energetically possible. Perhaps this indicates that energy transfer occurs far more quickly than the dissociation of a molecule for which rearrangement of atoms is usually required. It is not yet clear what kinds of intermediate are produced from acridone.

Kinetics of the Hydrolysis of Diethyl Acetal Catalyzed by Iron(III) in Aqueous Solution

Goro WADA and Machiko SAKAMOTO

Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630

(Received May 4, 1973)

The catalytic activity of iron(III) on the hydrolysis of diethyl acetal was investigated in aqueous solutions. The reaction rate was followed dilatometrically. The reaction is of the first order with respect to acetal concentration, the rate constant being expressed by

$$k_{app}=k_0+k_H[H^+]+k_{Fe}[Fe].$$

The respective rate constants are $k_0=1.30\times10^{-4}$ s^{-1}, $k_H=1.28$ M^{-1} s^{-1}, and $k_{Fe}=1.86$ M^{-1} s^{-1} at an ionic strength $\mu=0.2$ M and 25 °C. A tentative reaction scheme for iron(III) catalysis was proposed.

Diethyl acetal is known to be easily hydrolyzed on producing acetaldehyde and ethanol under the acid catalysis *via* an A-1 mechanism.

$$CH_3CH(OC_2H_5)_2 + H_2O \xrightarrow{H^+} CH_3CHO + 2C_2H_5OH \quad (1)$$

Although investigations on the solvent and substituent effects on the reaction mechanisms were carried out in detail,[1-12] the catalytic activities of various metal ions have not so far been studied. We have measured the rates of the hydrolysis of diethyl acetal in the presence of iron(III) and determined the rate constants of the individual reaction steps.

Experimental

Materials. Diethyl acetal (Schuchardt München, Germany) was used without further purification. Its density at 25 °C was 0.827 g/cm^3 which agreed with that in literature. Iron(III) perchlorate was prepared by dissolving pure iron wire in perchloric acid and oxidizing it with hydrogen peroxide. Pure water obtained by distillation of city water which had been treated with ion-exchange resin was used.

Procedure of Rate Measurement. As the hydrolysis of diethyl acetal proceeds, its aqueous solution increases in volume at constant temperature. Since the hydrolysis proceeds almost irreversibly and the increase in volume of the solution is proportional to the degree of reaction, the reaction rate can be followed by means of dilatometry. The dilatometer consists of a glass tube about 1 cm in diameter, connected with a vertical capillary of 0.03 cm in diameter and of 30 cm in height at one end of the tube. The other end is attached to a glass stop-cock, through which the reaction solution is quickly introduced from the reservoir where two reactant solutions are mixed at the initiation of hydrolysis. The content of the dilatometer is about 70 cm^3. The dilatometer and the other vessels containing the reactant solutions were set in a thermostat at 25 °C in advance. The ionic strength was always kept at $\mu=0.2$ M with sodium perchlorate.

Photometry. A Hitachi UV-VIS spectrophotometer Model 139 and a Hitachi recording spectrophotometer EPS-3T were used for the concentration determination of iron(III) and for the observation of the spectral variation during the course of reaction.

Results and Discussion

If we denote the heights of the reaction solution surface in the capillary of the dilatometer at time t and at the time of completion of the reaction by h and h_∞ respectively, the plots of $\log(h_\infty-h)$ against t always exhibit straight lines, indicating that the reaction is of the first order with respect to acetal concentration [A]. The slopes give apparent rate constants, k_{app}.

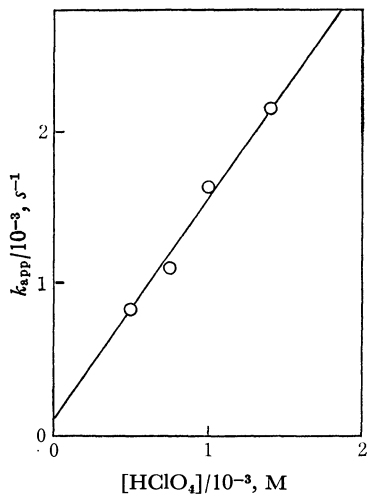

Fig. 2. Relationships between k_{app} and $[HClO_4]$ at [Fe]=0 (extrapolated) and $[A]=5.55\times10^{-2}$M.

The relationships between k_{app} and total iron concentration, [Fe], at various acid concentrations, $[HClO_4]$, are shown in Fig. 1. It is seen that k_{app} is linear with respect to [Fe] with a common slope irrespective of $[HClO_4]$. The intercepts of the straight lines also show a linear relationship with $[HClO_4]$ as is depicted in Fig. 2. The apparent rate constant can therefore be expressed by the sum of three terms, *viz.*

$$k_{app} = k_0 + k_H[H^+] + k_{Fe}[Fe] \quad (2)$$

The individual rate constants are determined from Figs. 1 and 2 as $k_0=1.30\times10^{-4}\ s^{-1}$, $k_H=1.28\ M^{-1}\ s^{-1}$, and $k_{Fe}=1.86\ M^{-1}\ s^{-1}$ at $\mu=0.2$ M and 25 °C. The value of k_H agrees fairly well with that in the literature.[4]

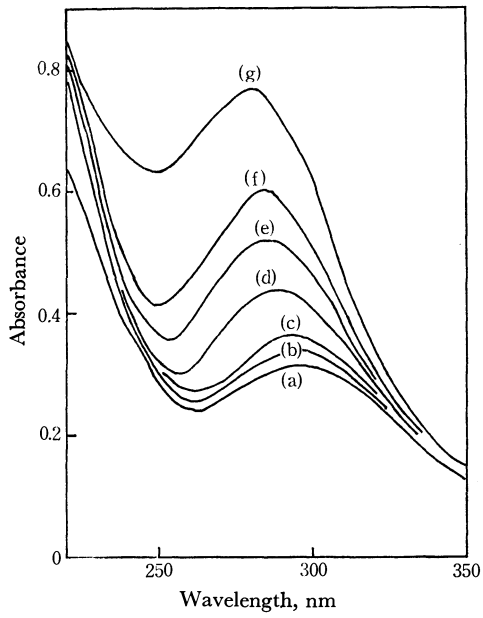

Fig. 3. Spectral changes with time of diethyl acetal hydrolysis at $[A]=5.55\times10^{-2}$M, $[Fe]=1.5\times10^{-4}$M, and $[HClO_4]=6.14\times10^{-5}$M.
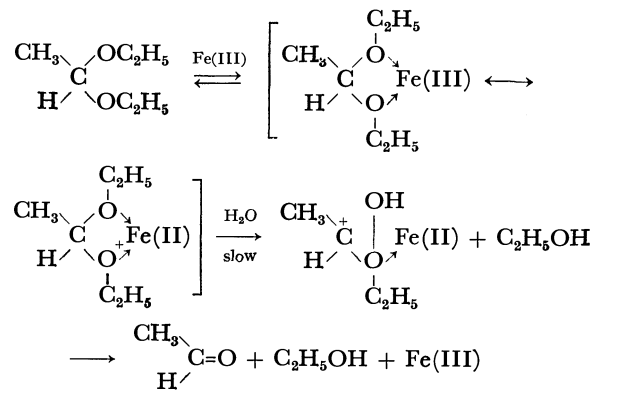
(a): t=0, (b): 3 min, (c): 15 min, (d): 30 min, (e): 60 min, (f): 90 min, (g): 240 min.

The three terms in the right-hand side of Eq. (2) might correspond to the respective three reaction paths; (i) a spontaneous one without catalyst, (ii) an acid catalysis, and (iii) an iron(III) catalysis. Since k_{Fe} is independent of the acid concentration, the iron catalysis is not wholly attributed to the apparent increment of hydrogen ion concentration due to the hydrolysis of Fe^{3+}_{aq} at the given acid concentration. The expected increment of hydrogen ion concentration under the present conditions is too small to be compared with the observed catalytic effect resulting from iron(III). The chemical forms of iron(III) in the reaction system are predominantly Fe^{3+}_{aq} and $FeOH^{2+}$, and their concentration ratio should change according to the variation in the acid concentration. However, the catalytic activity of iron(III) was not seriously affected by its chemical form. A presumable reaction scheme in analogy with acid catalysis[13,14] might be as follows;



in which Fe(III) behaves as a Lewis-type acid-base catalyst.

Spectral changes during the reaction are shown in Fig. 3, where the absorption in the wavelength range 200—400 nm increases with time and finally reaches a spectrum with a peak at 280 nm. The final absorption spectrum subtracted by the initial one agrees with that in the absence of iron(III) catalyst at infinite reaction time. Thus, the reaction products are found to be the same irrespective of whether the reaction is catalyzed by acid or iron(III), although the absorption spectrum in this wavelength range is mainly due to acetaldehyde and not to acetal or ethanol. The hypothetical intermediate of a complex between iron(III) and acetal was not recognized, probably because of the fact that the formation of the complex was very minute or no distinct absorption band appeared in the wavelength range studied.

Catalytic activities of metal ions other than iron(III) were also qualitatively determined. Silver(I), copper(II), cobalt(II), and zinc(II) were found to be less catalytic than iron(III).

Emission Spectra of Benzonitrile, Aniline, and Nitrobenezene by Controlled Electron Impact

Masaharu Tsuji, Teiichiro Ogawa, and Nobuhiko Ishibashi
Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka 812
(Received April 24, 1973)

The emission spectra of benzonitrile, aniline, *N,N*-dimethylaniline, and nitrobenzene under controlled electron-impact excitation (60—300 eV) were investigated at a very low pressure. Bands of the parent molecules were observed in the 260—410 nm region on benzonitrile and anilines, and were assigned to the S_1–S_0 transitions. However, no emission of the parent molecule was observed on nitrobenzene and this was attributed to the spin-orbit coupling effect of the nitro group and the predissociation of the excited parent molecule. Bands of the following fragment species were observed for all four compounds: H(Balmer series), CH($A^2\Delta$–$X^2\Pi$), and CN($B^2\Sigma$–$X^2\Sigma$). In addition, NH($A^3\Pi$–$X^3\Pi$) band on aniline and NO($A^2\Sigma$–$X^2\Pi$, $B^2\Pi$–$X^2\Pi$), CO($b^3\Sigma$–$a^3\Pi$), and CO^+ ($A^2\Pi$–$X^2\Sigma$, $B^2\Sigma$–$X^2\Sigma$) bands on nitrobenzene were observed. The linear relationships between the electron beam current and the emission intensities of the parent molecules and the fragment species indicated that most of the excited species were produced by primary electron-molecule collision processes (CN of anilines, CO, and CO^+ were found to be exceptional). The mechanism of the excitation and the fragmentation of the parent molecules and the comparison of the present spectra with those by discharge and by optical excitation were discussed. It was concluded that some excited species were produced through superexcited states.

As sources for exciting the electronic levels of molecules, ultraviolet radiation, such as Hg and Xe emission (5—21 eV), and X-ray radiation (1000 eV and above) have been widely used. However, few studies have been conducted in the energy region between these two methods. The excitation by electron impact is one of the most effective methods for this region. As early as 1946 the emission spectra of various benzene derivatives under electron impact in a hollow cathode discharge were investigated by Woeldike and Schüler[1] and the effects of the substituents were discussed. However, in an electric discharge, since many secondary processes occur in many cases, it is difficult to distinguish which processes are the primary ones. In this respect, the crossed electron and molecular-beam method is of great advantage as a method for exciting molecules, for the electron beam can be controlled easily and the pressure of the collision chamber can be so low that intermolecular collisional perturbation can be almost neglected during the lifetime of the excited species.

In recent years, the emission spectra of such molecules as N_2, CO, and NO and of some simple organic molecules have been extensively investigated by this method. Among the molecules which have a nitrogen atom, nitrogen,[2] ammonia,[3,4] hydrazine,[4] and methylamine[5] have been investigated, and much interesting information has been acquired regarding the excitation, the ionization, and the fragmentation processes not only of the ionized species, which can be detected by mass spectrometry, but also of neutral unstable ones. The emission spectra of benzene have been studied by this method by Vroom[6] and Smith.[7] The former has determined absolute emission cross sections for Lyman and Balmer radiation from hydrogen atoms formed in the dissociative excitation of benzene by electron impact (0.05—6 keV). The latter has measured the lifetimes of the vibrational levels of the $^1B_{2u}$ state using an electron beam phase shift method. However, few studies have been carried out on the photoemission of other aromatic molecules.

In the previous papers, the emission spectra of aromatic hydrocarbons[8] and of aromatic halides[9] by controlled electron impact (60—300 eV) have been reported. Characteristic bands of the parent molecules have been obtained from benzene, toluene, xylenes, fluorobenzene, and anisole[10] and assigned to the S_1–S_0 electronic transitions. However, chloro- and bromobenzenes failed to show such a band; instead, they showed pronounced progression bands of HCl^+ or HBr^+ and weak lines of Cl^+ or Br^+. It has been reported that benzonitrile and aniline show a strong photoemission of the parent molecules, both by discharge[1] and by optical excitation, while nitrobenzene does not. This has been ascribed to a rapid dissipation of the electronic transition energy through the nitro group and to the dissociation of the carbon-nitrogen bond.[11] In the present study, the emission spectra of these simple benzene derivatives by controlled electron impact will be reported and compared with those obtained by discharge and by optical excitation. Moreover, the mechanism of the electron-molecule collision which gives rise to the excitation, the ionization, and the fragmentation of the parent molecules will be discussed in connection with the results of the relationships between the emission intensities and the electron beam current.

Experimental

The electron-impact apparatus is essentially identical to that described in the previous papers.[8,12] The electrons emitted from the hot tungsten filament were accelerated by three electrodes and were led to the collision chamber through a slit. The accelerating voltage was variable from 60 to 300 V, with an energy spread of at least 6—10 eV; the electron beam current used was 10—1000 μA. The sample gas was injected through a nozzle 0.3—1.0 mm in diameter and collided with the electron beam perpendicularly. The gas pressure was estimated to be 10^{-3}—10^{-2} mmHg in the region of collisions.

The photoemission from the excited species was observed by the use of a Jarrell-Ash JE25 monochromator, which had a reciprocal dispersion of 33 Å/mm. The slitwidth of the monochromator used was 100 μm and 300 μm.

The aniline and nitrobenzene were obtained from the Kishida Chemical Co., and the benzonitrile and *N,N*-dimethylaniline, from Wako Pure Chemical Ind. All the reagents used were of a JIS guaranteed grade. They were distilled and degassed *in vacuo* a few times just before use. The mass spectrum was taken with a Hitachi RML-6E mass spectrometer. The accelerating voltage was 100 V.

Results and Discussion

Benzonitrile. A typical emission spectrum of benzonitrile under electron-impact excitation in the 250—450 nm region is shown in Fig. 1. The impact voltage was 200 V, and the electron beam current was 700 μA in this measurement. A characteristic band of the parent molecule was observed in the 260—330 nm region. This band was assigned to the electronic transition of benzonitrile from the lowest excited singlet state to the ground state, which is related to the $^1B_{2u}$—$^1A_{1g}$ transition of benzene. Woeldike[1] observed a discrete emission spectrum in the 270—310 nm region in a hollow cathode discharge. Fluorescence spectra excited by Mn and Fe sparks at the vapor pressure of about 20 mmHg were photographed, and the vibronic bands were assigned, by Bass.[13] In the present spectrum, several discrete vibronic bands appear above the broad background (the continuous part of the band) and the vibrational structure closely resembles those of toluene[8] and fluorobenzene,[9] which are identical to benzonitrile in symmetry. The discrete band at the shortest wavelength (274 nm) was assigned to the (0,0) band of benzonitrile. Similar bands have been observed at 267 nm on toluene and at 264 nm on fluorobenzene. Other discrete bands on the longer-wavelength side of 274 nm may be interpreted as the vibrational structure with the fundamental frequencies given by Bass. On its shorter-wavelength side, weak unresolved features were observed; they were assigned to the transitions from the higher vibrational levels of the upper state to some vibrational levels of the ground state. These bands were also observed in the spectra of toluene and fluorobenzene. Since the pressure of the collision chamber was so low ($\leq 10^{-2}$ mmHg) that the intermolecular collisional perturbation was small in the lifetime of the excited state, the emission from the higher vibrational levels of the upper state was observed even from the molecule with less symmetry than benzene.

Other bands in the 355—430 nm region were assigned to the bands of fragment species. The lines at 434, 410, and 397 nm, decreasing in intensities as the wavelength becomes shorter, belong to the Balmer series of the hydrogen atom, which are denoted by H_γ, H_δ, and H_ε respectively. The band at 431 nm belongs to the (0,0) band of CH($A^2\Delta$–$X^2\Pi$). These band systems have always been observed in various benzene derivatives.[8-10] The most intense band systems in the 358—359 nm, 385—388 nm, and 415—422 nm regions were assigned to the main sequences with $\Delta v = 1, 0, -1$ of CN($B^2\Sigma$–$X^2\Sigma$), and several weak bands in the 363—403 nm region, to the tail bands of this violet system.

The relationships between the emission intensities and the electron beam current are shown in Fig. 2. The emission intensities of the parent molecule and of the fragment species of H, CH, and CN are proportional to the electron beam current. This finding indicates that the excitation and the fragmentation of benzonitrile take place through primary electron-molecule collisions, just as in the cases of other benzene derivatives.[8,9] The excitation of a π electron of benzonitrile is concluded to be a one-electron process. The mechanism of the excitations and fragmentations can, then, be described as below:

$$\mathrm{PhCN} \xrightarrow{e} \mathrm{PhCN}^* \xrightarrow{h\nu} \text{ground state} \qquad (1)$$

$$\mathrm{PhCN} \xrightarrow{e} \mathrm{PhCN}^{**} \begin{cases} \xrightarrow{\text{fast}} \mathrm{PhCN}^* \\ \xrightarrow{\text{fast}} \mathrm{H}^*, \mathrm{CH}^*, \mathrm{CN}^* \end{cases} \xrightarrow{h\nu} \text{ground state} \qquad (2)$$

where superscript * signifies excited states from which the molecules radiate and where ** indicates a superexcited state, as was pointed out by Platzman,[14] which lasts for a length of time shorter than or equal to one period of vibration of the molecule. Since the excitation energy of the hydrogen Balmer series is larger than the first ionization potential of benzonitrile, it can be concluded that hydrogen atoms are produced through superexcited states. It seems that PhCN* is produced through two processes, (1) and (2), although their relative importance cannot be determined in the present study.

Aniline and N,N-*Dimethylaniline.* Typical emission spectra of aniline and *N,N*-dimethylaniline under electron-impact excitation in the 250—450 nm region are shown in Figs. 3 and 4 respectively. The electron beam of 300 eV at 1 mA was used for the measurement of the former, while that of 200 eV at 700 μA was used for the latter. Bands of the parent molecules were observed in the 280—375 nm region on aniline and in the 295—410 nm region on *N,N*-dimethylaniline. These bands are shifted to longer wavelengths by about 10 nm and about 25 nm from the (0, 0) band of toluene (267 nm) respectively, and they agree well with the fluorescence bands in solution.[15] The former band was assigned to the A^1B_2–X^1A_1 electronic transition for aniline.[16] The vibrational structure of aniline is more complicated than that of benzonitrile, and the fraction of the background is larger. The emission spectrum of *N,N*-dimethylaniline is very broad, and the fine structure is no longer observed, probably because the symmetry of the aniline molecule is destroyed, as has been shown in the case of the absorption spectrum.[17] Woeldike[1] observed a continuous emission spectrum of aniline in the region from 285 to 330 nm. Blondeau, Quack, and Stockburger[18,19] investigated the resonance fluorescence spectra of various benzene derivatives, such as benzene, toluene, xylenes, and aniline, at low pressures ($\leq$0.1 mmHg) by irradiation with light of narrow bandwidth; they concluded that aromatic molecules exhibit resonance fluorescence. It was shown that the difference in the initially-irradiated levels resulted in different progression bands, and the most striking feature was the loss of structure and an increase in the fraction of the background when the molecules were excited to higher vibronic levels. It is known that, in the spectrum of aniline, pronounced progression bands due to the strongly anharmonic inversion vibration of NH_2 group exist in addition to those due to the symmetric vibration,[16,18,19] and that these progression bands complicate the vibrational structure. In addition, since the exciting energy of the present study is higher than the optical excitation, molecules are expected to be excited to the closely-spaced higher vibrational levels of the upper state, from which the fast intramolecular vibrational rearrangement occurs. Since aniline has more vibrational states which can strongly interact with the initially-excited state than do benzene, toluene, and fluorobenzene, the initial vibrational modes will be converted to other modes more easily. Thus, the complex vibrational structure and the large fraction of the background in the present spectrum are partly due to the appearance of the complicated progression bands, and partly due to the further overlapping of these progression bands because

of the wider energy distribution of the incident electrons used and because of the higher excitation energy used in the present study.

A doublet band at 336—337 nm was assigned to the (0,0) and (1,1) bands of NH($A^3\Pi$–$X^3\Pi$). All the other bands on anilines were assigned to the H, CH, and CN bands, which appeared also on benzonitrile.

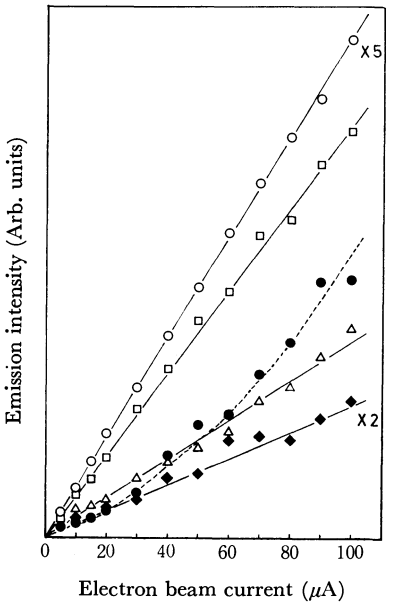

Fig. 5. Dependence of photoemission intensities of aniline on the electron beam current. Impact voltage 200 V.
○: $C_6H_5NH_2$ (314 nm), ●: CN (388 nm), □: Hγ, △: CH (431 nm), ◆: NH (336 nm).

The emission intensities of the parent molecules and the fragment species, such as H, CH, and NH of aniline and *N,N*-dimethylaniline, are found to be proportional to the electron beam current, as is shown in the case of aniline in Fig. 5. Similar results have been obtained from various benzene derivatives[8,9] and other organic molecules, such as methane,[20] methanol,[21] and amines.[5] Consequently, the excitations of the parent molecules and the fragmentations of H, CH, and NH by electron impact under the present crossed-beam method are concluded to take place generally through one-electron processes.

The emission intensities of the CN bands of aniline and *N,N*-dimethylaniline are found to be proportional to about 1.4 and about 1.2 powers of the electron beam current respectively, as is shown in Fig. 5. These results indicate that the photoemission processes of CN produced from anilines are different from those of other fragment species, such as H, CH, and NH, and that of CN produced from benzonitrile. It seems that a certain secondary process is involved in the production of the excited CN species. It is noteworthy that a similar result was obtained for the CN produced from pyridine,[22] whose emission intensity was found to be proportional to 1.5 powers of the electron beam current. Since the radiation lifetime of the CN $B^2\Sigma(v'=0)$ state was measured[23] as 39—85 ns, collisions between the excited species and the neutral molecule can be neglected at such a low pressure as 10^{-3}—10^{-2} mmHg. Furthermore, in the present experimental situation, the possibility of the second collision of one neutral species with another electron is also expected to be small. A collision process between an electron and a positive-ion may be involved in the production of CN. It should be noticed that the production of CN from benzonitrile, whose emission intensity is proportional to the electron beam current, proceeds with one C–CN bond scission, whereas the production of CN from anilines and pyridine, whose emission intensities are not linear, needs the scissions of at least two skeletal bonds. Particularly, in the case of aniline and pyridine, the cleavage of the stable ring must take place.

Nitrobenzene. A typical emission spectrum of nitrobenzene under electron-impact excitation in the 200—600 nm region is shown in Fig. 6. The impact voltage was 200 V, and the electron beam current was 1 mA in this measurement. There are pronounced bands of CO and CO^+; they were assigned as in the cases of anisole[10] and phenol,[24] as will be shown below. The emission bands at 283—331 nm were assigned to the progression, $v'=0$, of the third positive system ($b^3\Sigma$–$a^3\Pi$) of CO; those at 219—247 nm, to the progressions, $v'=0$, 1, 2, of the first negative system ($B^2\Sigma$–

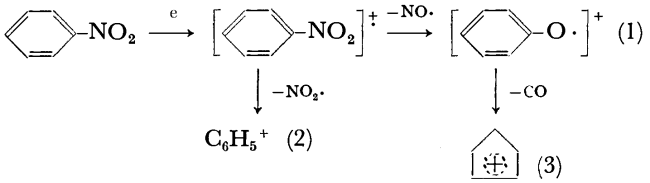
$X^2\Sigma$) of CO^+, and the characteristic doublet bands at 335—590 nm, to the progressions, $v''=0$, 1, 2, of the comet-tail system ($A^2\Pi$–$X^2\Sigma$) of CO^+. The relative emission intensities of the main progression of this comet-tail system of nitrobenzene agree with those of CO by 200 eV impact.[25] The bands at 255—276 nm were assigned to the sequences with $\Delta v=-3$, -4 of the NO γ system ($A^2\Sigma$–$X^2\Pi$), and those at 289 and 359 nm, to the (0,6) and the (0,10) bands of the NO β system ($B^2\Pi$-$X^2\Pi$). Other bands were assigned to the H, CH, and CN bands observed on benzonitrile and anilines.

It is concluded from the linear relationships between the emission intensities and the electron beam current that H, CH, and NO species are produced by one-electron processes. Meanwhile, the emission intensities of CO and CO^+ species are found to be proportional to about 1.2 powers of the electron beam current. Thus, the production of these species is not a simple one-electron process, and it seems that positive ions of some kind are involved, as in the case of the CN produced from anilines. Since the energy of the $b^3\Sigma$ state of CO is larger than the first ionization potential of nitrobenzene, it seems that the CO species are produced through some superexcited states.

It should be noticed that there is no direct carbon-oxygen bond in the nitrobenzene molecule. The pressure of the collision chamber is so low that no recombination between carbon and oxygen atoms may occur. Meanwhile, from the analysis of the mass spectrum,[26] it was suggested that the decomposition of nitrobenzene proceeded as is shown below;



The mass spectrum was measured in order to compare the relative intensities of these peaks. The intensities of the fragment peaks, (1), (2), and (3), relative to the parent peak were found to be 0.32, 2.55, and 0.37 respectively. The fragment species of CO and CO^+ may be produced through the positive ions, as has been described above.

Nitrobenzene exhibited no emission of the parent molecule in the present study, as was found in the case of the excitations by photons and by discharge.[1] This is partly due to the fast intersystem crossing processes, since the lowest excited level is the *n* nonbonding orbital. Another reason for this is the dissociation of the carbon-nitrogen bond, as was pointed out by Lewis and Calvin.[11] The relative intensity of the phenyl cation peak to the parent one was measured as 2.55 for nitrobenzene, while those for benzonitrile[27] and chlorobenzene[9] were reported to be 0.056 and 0.68 respectively. This indicates that the cleavage of the carbon-nitrogen bond can easily take place. Thus, it is concluded that the spin-orbit interaction and the predissociation of the parent molecule prevent the appearance of the band of the parent molecule under electron-impact excitation.

Concluding Remarks. Benzonitrile, aniline, and *N,N*-dimethylaniline were found to show the emission bands of the transitions from the lowest excited singlet state to the ground state of the parent molecules. The appearances and the positions of these bands do not change appreciably when the impact energy changes between 60—300 eV. It may be concluded that the molecules receive enough excess energy even though the exciting energy is 60 eV.

A pronounced feature of the electron-impact excitation is that the optically-forbidden singlet-triplet transition may be allowed. However, such a transition could not be observed under 60—300 eV electron-beam excitation in the present study, and the observed spectra are similar to those of optical excitation because the parent molecules are excited only to the singlet states. Meanwhile, in the energy loss spectrum of benzene, optical selection rules hold for 200—300 eV electrons,[28] while three singlet-triplet transitions were observed in addition to three singlet-singlet transitions under low energy electron impact[29] (13.6 and 20.0 eV). Thus, it is expected that a singlet-triplet transition will be observed when the impact energy is lowered to the near threshold value in the present method, although several experimental difficulties have to be overcome.

The first ionization potentials of benzene, benzonitrile, aniline, *N,N*-dimethylaniline, and nitrobenzene have been reported to be 9.56,[30] 10.09,[30] 8.32,[30] 7.51,[31] and 10.18[30] or 10.26[31] eV respectively. All these values are smaller than the excitation energy of the hydrogen atom (13.32 eV for the Balmer line H_ε); the first ionization potential of nitrobenzene is also smaller than the excitation energy of the CO $b^3\Sigma(v'=0)$ state (10.38 eV).[32] It is concluded that hydrogen atoms are produced in the dissociative excitations of benzonitrile, aniline, and nitrobenzene, as has been shown before, and that these dissociative processes probably proceed through superexcited states. It seems that the superexcited states also play an important role in the production of the CO from nitrobenzene and other fragment species.

The emission intensities of the line of H_γ relative to the (0,0) band of CH and the ratios of the H atom to the CH group in these molecules are shown in Table 1. This comparison is valid because the emission intensities of H and CH are proportional to the electron beam current and also to the gas pressure of the collision

chamber as has been shown in the cases of benzene[8] and fluorobenzene.[9] It should be noticed that the numbers of the second column and those of the third column correspond very well within the limits of experimental error. Therefore, the probabilities of the production of the excited H and CH species, whose fragmentation processes are competitive ones, are found to be almost equal in these simple benzene derivatives. In the case of aniline, it seems that the production of excited hydrogen atoms from the hydrogens in the NH_2 group and in the benzene ring is almost equally probable. These results may imply that similar super-excited states are involved in the collision with electrons with energy of 200 eV for the fragmentations of H and CH, whatever the substituents of the benzene ring are.

The authors wish to express their thanks to Professor Tetsuro Seiyama and Miss Shizue Saeki for the measurement of the mass spectrum, and to Mr. Minoru Toyoda and Mr. Totaro Imasaka for their discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3385—3391 (1973)

Dielectric Constant Measurement on Organic Crystalline Powder

Kikujiro Ishii,[1] Minoru Kinoshita,[1] and Haruo Kuroda
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received June 4, 1973)

The microwave cavity perturbation method was applied for the measurement of the dielectric constants for polycrystalline samples of ten aromatic compounds (naphthalene, anthracene, phenanthrene, pyrene, chrysene, perylene, durene, acenaphthene, biphenyl, and *p*-terphenyl.) The method is shown to give a reasonable result, if the effect of the second order perturbation term is properly included and if Böttcher's equation is carefully applied in transforming an apparent dielectric constant obtained on a powder sample into the mean dielectric constant of a crystal. The nature of the ordinarily used cavity perturbation equation and of Böttcher's transformation equation is discussed in this respect. The obtained mean dielectric constants are; naphthalene 2.87, anthracene 3.12, phenanthrene 2.96, pyrene 3.14, chrysene 3.09, perylene 3.34, durene 2.55, acenaphthene 2.94, biphenyl 2.88, and *p*-terphenyl 2.98. The molecular polarization calculated from these values agreed quite well with the values estimated from the bond polarization given by Le Fèvre *et al.*

Only few measurements have been reported on the dielectric constants of aromatic molecular crystals, although the dielectric properties are of essential significance in understanding their electric behaviors. The reason for this may be attributable to the difficulties most frequently found in the shape and the amount of a sample when the usual method of dielectric constant measurement is applied. In the usual method, we must fill up the whole space between the electrodes with a fairly good amount of sample.[2] However, it is difficult to obtain a single crystal of sufficient size and shape in the case of molecular crystal of interest. When a compressed powder specimen is used, there are a problem in fitting itself to electrode surfaces and other apprehensions[3] that the crystallites may be oriented in some direction on compression.

It is, therefore, desirable to establish a simple method to measure the dielectric constant on a small amount of crystalline material. For this purpose, we adopted the cavity perturbation method in the X-band microwave region. This method is found to be useful for polycrystalline samples if applied with proper care. In this paper we will describe the experimental procedures, and the dielectric constants of ten polycrystalline aromatic compounds determined with this method. We will discuss also some fundamental problems related to the cavity perturbation method.

Method of Measurement

Cavity Perturbation Method. In the cavity perturbation method, the change in the resonant frequency of the microwave cavity is related to the dielectric constant of the sample inserted into the cavity.

If a small sample, of which the dielectric constant and the magnetic permeability are given respectively

1) Present address: The Institute for Solid State Physics, the University of Tokyo, Roppongi, Minato-ku, Tokyo.

2) See, for example, C. P. Smyth, "Dielectric Behavior and Structure," McGraw-Hill, New York, (1955), Chapter VI.

3) C. C. Meredith and G. F. Wright, *Can. J. Chem.*, **38**, 1177, (1960).

by ε_1 and μ_1, is inserted into a resonant cavity, the change in the resonant frequency, f_1-f_0, is given[4] by,

$$-\frac{f_1-f_0}{f_1}=\frac{\int_{V_1}(\varepsilon_1-\varepsilon_0)\boldsymbol{E}_1\cdot\boldsymbol{E}_0^*\mathrm{d}v+\int_{V_1}(\mu_1-\mu_0)\boldsymbol{H}_1\cdot\boldsymbol{H}_0^*\mathrm{d}v}{\varepsilon_0\int_V\boldsymbol{E}_0\cdot\boldsymbol{E}_0^*\mathrm{d}v+\mu_0\int_V\boldsymbol{H}_0\cdot\boldsymbol{H}_0^*\mathrm{d}v} \tag{1}$$

where f_0 and f_1 are the resonant frequencies of the cavity, in the absence and presence of the sample, respectively, ε_0 and μ_0 denote the dielectric constant and magnetic permeability of vacuum, $\boldsymbol{E}_0$ and $\boldsymbol{H}_0$ the undisturbed electric and magnetic field vectors and $\boldsymbol{E}_1$ and $\boldsymbol{H}_1$ the resulting field vectors when the sample is loaded. V_1 and V indicate that the integration should be carried out within the volume of the sample and whole volume of the cavity, respectively.

The frequency, the dielectric constant and the magnetic permeability should, in general, be considered as complex quantities. However, in the case of low-dielectric-loss and diamagnetic material, we assume that all the quantities are real, and also that μ_1 is equal to μ_0. Then using the relation,

$$\varepsilon_0\int_V\boldsymbol{E}_0\cdot\boldsymbol{E}_0^*\mathrm{d}v=\mu_0\int_V\boldsymbol{H}_0\cdot\boldsymbol{H}_0^*\mathrm{d}v, \tag{2}$$

one gets Eq. (3) which concerns only the electrical field and the dielectric constant.

$$-(f_1-f_0)/f_1=(\varepsilon_s-1)\left(\int_{V_1}\boldsymbol{E}_1\cdot\boldsymbol{E}_0^*\mathrm{d}v\right)\Big/2\left(\int_V\boldsymbol{E}_0\cdot\boldsymbol{E}_0^*\mathrm{d}v\right), \tag{3}$$

where $\varepsilon_s=\varepsilon_1/\varepsilon_0$.

In the usual measurement of the dielectric constant, the equation in the first order approximation has been used[5,6] by assuming that the dielectric constant of a sample is small, and/or that its volume is also small compared with that of the cavity. In this case, putting $\boldsymbol{E}_1$ equal to $\boldsymbol{E}_0$, the dielectric constant of the sample is calculated by an equation which includes only the known electric field $\boldsymbol{E}_0$. For a rectangular cavity of the reasonance mode of TE_{k0m}, assuming that $\boldsymbol{E}_0$ is constant in the sample, this equation is written as[5]

$$-(f_1-f_0)/f_1=2(\varepsilon_s-1)\cdot V_1/V. \tag{4}$$

For a sample of relatively large volume and large dielectric constant, on the other hand, the first order equation is not promised to hold. Kaminow and Harding[7] and Hatta[8] gave equations of higher approximation which contain the quadratic term of ε_s. However, since the physical meanings of these equations are not given plainly, and since these equations lead to quite different results,[9] we tried to use another equation which was derived according to the general perturbation theory.[10]

Considering a wave equation in a cavity, and regarding the sample inserted into the cavity as a perturbation, one may derive an equation in which the square of the resulting resonant frequency is given by an expansion in ε_s-1. If one takes the first three terms of Eq. (I, 3) in Appendix I, he obtains a quadratic equation of ε_s (see Appendix I),

$$\frac{f_1^2-f_0^2}{f_1^2}=-(\varepsilon_s-1)\frac{\int_{V_1}\boldsymbol{E}_0\cdot\boldsymbol{E}_0^*\mathrm{d}v}{\int_V\boldsymbol{E}_0\cdot\boldsymbol{E}_0^*\mathrm{d}v}+(\varepsilon_s-1)^2\cdot\mathrm{A}, \tag{5}$$

where A is the factor which represents the second order perturbation effects.

Calculation of the factor A (see Appendix II) indicated that the second order term is not negligible under the experimental condition in this work. This term has a large value when ε_s is large and sometimes well exceeds five percent of the first order term in spite of our intention to get ε_s-1 with an accuracy within several percent. Therefore we explicitly took account of this term and calculated ε_s by solving the quadratic equation.

Calculation of Mean Dielectric Constant of Crystal. Many formulae have been proposed for the calculation of the dielectric constant of a crystal (which we denote by ε) from the apparent dielectric constant measured on a powder sample. We employed Böttcher's equation for the calculation of the dielectric constant of a molecular crystal, since it gives a relatively good result[11] among those equations.

Assuming that the environment of a spherical powder particle is continuous dielectric, Böttcher derived the following equation;[12]

$$\varepsilon=\frac{3\delta\varepsilon_a+2\varepsilon_a(\varepsilon_a-1)}{3\delta\varepsilon_a-(\varepsilon_a-1)}, \tag{6}$$

where ε_a is the apparent dielectric constant of the sample and δ is the ratio of the volume actually occupied by the microcrystals to the apparent volume of the powder filled in the sample cell. Polder and van Santen[13] showed that this equation also hold for non-spherical particles when the dielectric constant of the crystal is not large. Therefore we adopted it for our powder samples without correction.

We should note that ε is the mean dielectric constant of a crystal when it has anisotropic dielectric constant.

Experimental

Apparatus. The block diagram of the apparatus is shown in Fig. 1. The microwave generated by the klystron was introduced into the test cavity, of which the resonance mode is TE_{105}. The klystron was frequency-swept at a 50 Hz rate around the resonant frequency of the cavity, and the resonance was detected with a crystal detector and displayed on an oscilloscope. The output of the klystron was partly introduced into a cavity wavemeter, Hitachi M240B, through a directional coupler. Representing the resonance of it

simultaneously on the oscilloscope, the resonant frequency of the test cavity was measured.

The test cavity was made with copper waveguide and copper plates. Its volume is 25.7 cm^3. The resonant frequency and the Q-factor are about 9.36 GHz and 4500, respectively, when it contains the empty sample cell.

The sample holder and the cell are shown in Fig. 2. The sample cell made with fused quartz was bound on the brass holder with a small amount of binding agent of cyanoacrylate, and was inserted into the cavity at the point of the maximum electric field. The outer diameter of the cell is 4.0 mm, and the volume is measured to be 89.9 mm^3 by weighing cyclohexane, *n*-heptane and benzene filled in the cell.

All the measurements were carried out in atmosphere and at room temperature.

Samples. Organic liquids were used after distillation over calcium chloride. In the case of *p*-xylene, in addition to this procedure, fractional crystallization was repeated for several times. The solid samples were used after purification by sublimation *in vacuo* or recrystallization followed by drying under a reduced pressure.

The powder sample was prepared by grinding crystals in an agate mortar just before the measurement, and stuffed into the cell without pressure. The volume fraction δ was determined using the total volume of the microcrystals which was calculated from the weight and the crystal density. By changing the amount of powder and stuffing procedure, we were able to vary δ in the range around 0.4—0.5.

Table 1. Dielectric constants of organic liquids[a)]

Substance	1st Order	Corrected 1ts Order	2nd Order	Literature[b)]
n-Heptane	1.94	1.97	1.94	1.924
Cyclohexane	2.04	2.07	2.03	2.023
p-Xylene	2.30	2.34	2.28	2.270
Benzene	2.31	2.35	2.29	2.284

Results

Dielectric Constants of Organic Liquids. For the first we measured the dielectric constants of organic liquids to ascertain the adequacy of the cavity perturbation method. In Table 1 the results for four organic liquids calculated by three different methods are shown. The results in the second column (1st Order) are obtained using Eq. (4). The results shown in the next column (Corrected 1st Order) are obtained by introducing a factor of 0.971 in the right-hand side of Eq. (4) as a correction for the ununiform electric field in the specimen. The fourth column (2nd Order) shows the results obtained by solving Eq. (5). The numeric factor, A, in the second order term was calculated for the test cavity and the sample cell used, using the computer, HITAC 5020E, of the Computer Center of the Tokyo University, and found to be $0.035 \times 4V_s/V_c$ (see Appendix II). In the last column, the dielectric constants reported for these liquids are given for comparison. One can see that the second order perturbation method gives better results.

Dielectric Constants of Aromatic Molecular Crystals. Since, as stated before, crystalline powder was used as the sample in this work, we calculated first the apparent dielectric constant of the specimen (including the empty space between the microcrystals) by the method of the second order perturbation, and then the mean dielectric constant of the crystal was calculated by Böttcher's equation.

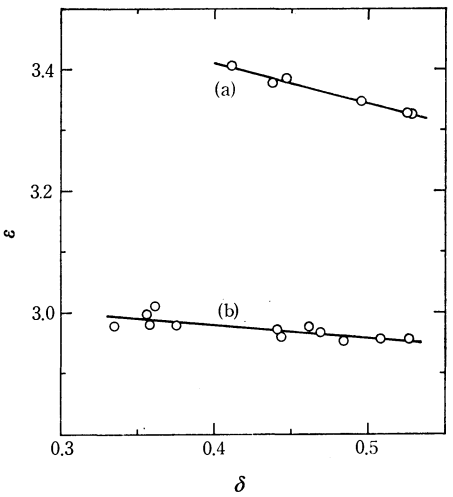

Fig. 3. The variations of ε with δ for (a) perylene and (b) phenanthrene.

In Fig. 3, the results for perylene and phenanthrene are shown as the examples. If Böttcher's equation was quite adequate to this calculation, ε should be independent of δ. However, as shown in this figure, ε calculated by the equation varies with δ. Similar variation was seen for all the substances studied.

After examining the experimental results, the following properties of the calculated ε and its relation to δ became clear;

(1) The δ-dependence of ε can be approximated by a linear line when δ is in the region from 0.4 to 0.55.

(2) When the mean dielectric constant of the crystal is considered to be small (about three or smaller), in most of the cases, the line shows small negative slope. For the substances of which the dielectric constant are reported, ε's calculated by this method almosts agree with those values.

(3) When the dielectric constant is large, the inclination of the line has a large negative value, and ε is small compared with the reported value. In Fig. 4, the results for NaCl is shown as an example of this case.[14]

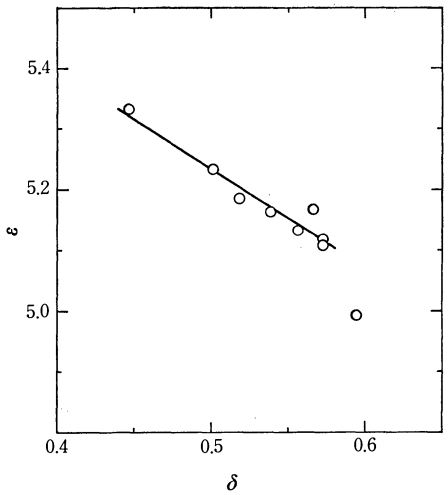

Fig. 4. The variation of ε with δ for NaCl, for which the dielectric constant is reported to be 5.90 (Ref. 15).

For the substances of which ε does not exceed four, we tentatively adopt the value of ε, as the mean dielectric constant of the crystal, which is obtained by interpolating or extrapolating the linear line to the point of δ equal to 0.5. The reason for this estimation will be discussed later. The results obtained for ten aromatic molecular crystals are shown in Table 2. In this table, are also given the value of the crystal density, which was used to calculate δ, and the inclination of the δ-dependence of ε. In addition, the reported dielectric constants are given for some substances.

When the dielectric constant of a crystal is larger than four, it seems a little difficult to get a reliable value of the mean dielectric constant by this simple method.

14) Almost the same results were obtained by N. L. Conger and and S. E. Tung, *Rev. Sci. Instr.*, **38**, 384 (1967). For NaCl, they obtained 5.28 as ε for $\delta=0.54$ by the usual first order method. The results for KCl given in Table 2 in their paper are not consistent together. The value, 4.76 in the sixth column is considered to be incorrect.

Table 2. Mean dielectric constants of aromatic molecular crystals

Substance	Mean dielectric constant	Density	Inclination[a]	Literature[b]
Naphthalene	2.87	1.169	0.02	2.85[c] 2.8[d]
Anthracene	3.12	1.250	−0.21	
Phenanthrene	2.96	1.209	−0.21	
Pyrene	3.14	1.271	−0.55

Discussion

Contribution of Second Order Term in Cavity Perturbation Method. Although the cavity perturbation method has been applied to the dielectric and/or magnetic measurement by several investigators, very few attempts have been made to experimentally examine whether this method gives a proper value of dielectric constant or magnetic permeability. In most of the studies using this method, the absolute value of dielectric constant obtained was discussed only qualitatively.

In this work, we attempted to settle the procedure for obtaining a reliable value of dielectric constant on solid materials, especially organic molecular crystals.

The treatment using the second order perturbation theory reduced the ambiguity inherent to the ordinary first-order perturbation method.

The results for the organic liquids given in Table 1 show the characteristics of the three different calculation methods. In the cases shown there, we can compare the dielectric constant at microwave frequency with the values reported for the lower frequency, because all these liquids are non-polar. In this work, the ordinary first order method gives a good result when the dielectric constant of the sample is around two. However, for the sample of which the dielectric constant is larger, it has a tendency to give a little larger value than the reported value. Furthermore, if we consider a correction for the smallness of the electric field at the off-center part in the specimen, the values become still larger as they are shown in the third column in Table 1.

By starting from the general perturbation theory, the higher order perturbation terms are introduced without any special consideration. The second order term has a value of 0.035 (ε_s-1) time of the absolute value of the field-uncoreected first order term for the sample cell used here, and contributes to ε_s as a deducting term. One can now understand the reason why the ordinary first order equation gives a reasonable

result in this work when ε_s is around two. In that case, the field correction and the higher order terms are cancelling each other.

The results obtained by including the second order term are shown in the fourth column of the table. These values are quite reasonable, although they are also larger than the reported values by about 0.01. We consider that this small deviation comes from the error in the estimated volumes of the cavity and the sample cell. It is also possible that the differences are due to small amounts of water and/or organic impurity in the sample.

Böttcher's Equation. As already described Böttcher's equation does not give constant results when δ is changed. It ought to be ascertained, therfore, whether the δ-dependence of ε is the intrinsic character of this equation or this dependence appears only when this equation is applied to the result of the cavity perturbation method.

van Vessem and Bijvoet[11] extensively studied on the correction equations for dielectric constants measured on powder sample. They measured dielectric constants on powder samples of some ionic crystals, and concluded that Böttcher's equation gives a relatively good result when the grain-size is sufficiently small compared to the dimension of the electrodes. Their conclusion is based on the fact that the apparent dielectric constant of the powder sample calculated from the known dielectric constant of the crystal agreed well with the observed apparent dielectric constant for a wide range of δ. However, inversely calculating ε from their experimental values of the apparent dielectric constant, we found that their results did not give constant ε either. Two examples are shown in Fig. 5. The inclination has obviously a large negative value for the sample of which the dielectric constant of the crystal is very large compared with that of the surrounding medium. Seemingly, the δ-dependence is the intrinsic nature of this equation although it is small when the dielectric constant of the crystal is not very large compared with that of the surroundnig medium. By examing their data, we found that Böttcher's equation gives reasonable value of ε when δ is around 0.5, and that it gives improperly small ε for very large δ (say, larger than 0.6).

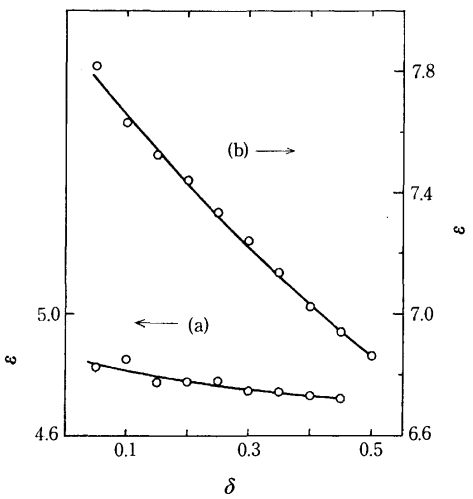

Fig. 5. The variations of ε with δ for (a) KCl and (b) NH_4Cl, where the values of ε are calculated from the apparent dielectric constants measured in the suspenders, CCl_4–CBr_4 and CCl_4–C_6H_6 mixtures, by van Vessem and Bijvoet (Ref. 11). The dielectric constants they used in their calculation are 4.70 for KCl, 2.372 for CCl_4–CBr_4 mixture, 6.85 for NH_4Cl and 2.234 for CCl_4–C_6H_6 mixture.

Although the cause of this δ-dependence of ε is not clear yet, we consider that it results from the basic assumption made by Böttcher. He assumed that the environment of a spherical particle in the powder sample can be considered as a continuous dielectric with the dielectric constant equal to the apparent dielectric constant of the sample. Starting from it and homogeneously distributing the polarization in the particles into the whole space in the specimen, he obtained the field which is identical with the field where a single spherical particle is placed. However, the actual "local" external field, in which a powder particle is placed, is the superposition of the external field and the field which results from the polarization of the surrounding particles. The latter field is a superposition of the fields which are the functions of the distances between the particle considered and the charges and/or the dipoles on other particles. Therefore, when δ is small, the particle is more polarized than expected by Böttcher's equation. Consequently, this equation gives large ε for small δ. The deviation may be pronounced in the case of a material of large dielectric constant.

As to the effect of the size of the particle, it was found[11] that the apparent dielectric constant appears smaller for the larger grain-size powder when δ's are equal. Therefore, although Böttcher's equation is derived without imposing any assumption on the size of the particle, it may be inadequate to apply this equation for the sample of large grain-size.

The shape of the powder particle seems to affect the δ-dependence of ε. The positive inclinations given in Table 2 for some substances are considered to manifest the effect of it. However, since the inclinations are not large, we need not make much of this effect in this work.

The experimental error in our result of ε is large when δ is small, because the errors accompanied in the measured weight and the frequency change become serious in this case. On the other hand, the result for very large δ (say, larger than 0.55) is not reliable. It may be due to the inhomogeneous stacking of the sample in the cell.

Taking account of our experimental results and above considerations, we arrived at the following conclusions.

(1) Böttcher's equation gives reasonable results for a material of small dielectric constant when δ is in the region around 0.5 and the grain-size of the powder is sufficiently small.

(2) When the difference between the dielectric constant of a crystal and that of the surrounding medium is large, the δ-dependence of ε is serious and it is rather difficult to estimate the proper value of the dielectric constant of the crystal. In this case, the effects of the shape and the size of the particle may be also important.

Mean Dielectric Constants and Molecular Polarizations of Aromatic Molecular Crystals. The mean dielectric constants were estimated for the aromatic molecular crystals given in Table 2. Unfortunately, so far as we know, very few reliable data have been reported for the dielectric constants of organic molecular crystals. The data given in the table are the ones quoted from the book edited by von Hippel.[15] The mean dielectric constants estimated from our simple measurement agree well with these data. For anthracene, anisotropic dielectric constants of a single crystal at low frequency were recently reported.[16] The mean dielectric constant estimated in the present work qualitatively agrees with these single crystal data.

Using the mean dielectric constant obtained, we calculated molecular polarization, P, defined by,

$$P = M(\varepsilon-1)/d(\varepsilon+2),$$

where M is the molecular weight and d is the crystal density, and ε is the isotropic dielectric constant of the crystal, for which we used the mean dielectric constant. The molecular polarization is estimated in good approximation as the sum of the values characteristic to atoms or bonds.[17]

Table 3. Molecular polarization[a]

Substance	Experiment	Calculated[b]	Difference
Naphthalene	42.1	41.2	0.9
Anthracene	59.0	57.2	1.8
Phenanthrene	58.3	57.2	1.1
Pyrene	66.3	64.8	1.5
Chrysene	73.6	73.2	0.4
Perylene	81.9	80.8	1.1
Durene	44.4	43.3	1.1
Acenaphthene	49.8	48.2	1.6
Biphenyl	50.3	49.5	0.8
p-Terphenyl	74.4	73.9	0.5

a) Unit; cm^3/mol.
b) See text.

In Table 3, the molecular polarization calculated from the mean dielectric constants are given in the second column. The values given in the third column are calculated using the "electronic" bond polarizations estimated by Lè Fevre and Steel.[17,18] They estimated those quantities by assuming a dispersion equation and extrapolating the bond refractions to the limit of the infinite wavelength. Therefore the polarization calculated using their values is considered to give the "electronic" molecular polarization at the infinite wavelength. As shown in the last column, the difference between the experimental value and the estimated one is, in general, small positive value. Although these small differences cannot be discussed quantitatively, it is not impossible to attribute the differences to the contribution from the "atomic" polarization.[19] The good agreement for many substances seems to imply that the additivity of the bond polarization is valid in these aromatic molecules.

The authors wish to thank Professor Hideo Akamatu for his kind encouragement throughout this work. They are also indebted to Dr. Toshiaki Ohta for making the computer program for the calculation of the second order perturbation term.

Appendix I

The electric field, $\boldsymbol{E}$, in a resonant cavity containing a low-loss dielectric specimen satisfies the wave equation,

$$\nabla^2\boldsymbol{E} + \omega^2\varepsilon_r\varepsilon_0\mu_0\boldsymbol{E} = 0, \qquad \text{(I, 1)}$$

where ε_r is equal to ε_s, the dielectric constant of the specimen relative to the vacuum, inside the specimen and unity outside of it. Substituting $\omega^2\varepsilon_0\mu_0$ by $-\chi$ and adding the factor $\chi\boldsymbol{E}$ to the both sides of this equation, one gets

$$\{\nabla^2-(\varepsilon_r-1)\chi\}\boldsymbol{E} = \chi\boldsymbol{E}. \qquad \text{(I, 2)}$$

If one regards the second term in the left-hand-side of this equation as a perturbation, according to the usual treatment of the perturbation theory, one gets the n-th eigen-value of $\boldsymbol{E}$, χ_n, as

$$\chi_n = \chi_{n,0} + \langle\boldsymbol{E}_{n,0}|-(\varepsilon_r-1)\chi_n|\boldsymbol{E}_{n,0}\rangle + \sum_{k\neq n}\frac{1}{\chi_{n,0}-\chi_{k,0}}|\langle\boldsymbol{E}_{n,0}|-(\varepsilon_r-1)\chi_n|\boldsymbol{E}_{k,0}\rangle|^2 + \cdots, \qquad \text{(I, 3)}$$

where $\boldsymbol{E}_{n,0}$ and $\boldsymbol{E}_{k,0}$ are the n-th and k-th eigen-states of the electric field in the non-perturbed cavity, and $\chi_{n,0}$ and $\chi_{k,0}$ are the corresponding eigen-values of them. This equation is considered to give a more general expression to the relation between the dielectric constant of a specimen and the change of the resonant frequency, since it was obtained without imposing any restriction on the dielectric constant and the volume of the specimen.

If one takes account of the first three terms in the right-hand-side of Eq. (I, 3), rearranging χ_n and $\chi_{n,0}'$ one gets

$$\frac{\chi_n-\chi_{n,0}}{\chi_n} = \langle\boldsymbol{E}_{n,0}|-(\varepsilon_r-1)|\boldsymbol{E}_{n,0}\rangle + \sum_{k\neq n}\frac{\chi_n}{\chi_{n,0}-\chi_{k,0}}|\langle\boldsymbol{E}_{n,0}|-(\varepsilon_r-1)|\boldsymbol{E}_{k,0}\rangle|^2. \qquad \text{(I, 4)}$$

Since ε_r-1 has the finite value only in the volume of the specimen, rewriting χ in the form of frequency, $f=\omega/2\pi$, one gets the same equation as Eq. (5), in which $f_{n,0}$, f_n, $\boldsymbol{E}_{n,0}$ and ε_r in the specimen are written as f_0, f_1, $\boldsymbol{E}_0$ and ε_s, respectively. The factor **A** is

$$\sum_k{}'\frac{f_1^2}{f_0^2-f_{k,0}^2}\left(\int_{V_1}\boldsymbol{E}_0\cdot\boldsymbol{E}_{k,0}^*\mathrm{d}v\right)^2, \qquad \text{(I, 5)}$$

where the summation should be carried out for all the normal modes of the unperturbed cavity except the n-th mode.

When the perturbation is considered to be very small, and if one takes the first two terms in the right-hand-side of Eq. (I, 3) one gets the same result as Eq. (3) by rewriting the equation as before and assuming $f_1+f_0=2f_1$.

19) Since most of the molecules dealt with in this work are non-polar, the molecular polarization can be explained with the electronic and atomic polarizations. The latter may be in a magnitude of only several percent of the former for these substances (see, for instance, Chapter XIV of Ref. 1).

Appendix II

For a rectangular cavity of the resonance mode $TE_{k,0,m}$, the electric field is given by,

$$E_y = B \sin \frac{k\pi x}{a} \sin \frac{m\pi z}{c}, \qquad \text{(II, 1)}$$

where a and c are the width and the length of the cavity, and B is a function of time which gives the amplitude of the standing wave. The electric fields of other directions, E_x and E_z, do not exist for this resonance mode.

If a cylindrical specimen, of which the height is identical with that of the cavity, b, is placed at the point of the maximum electric field of TE_{105} mode, it is easily shown that the normal modes, which have finite values of overlap integrals with the TE_{105} mode in the volume of the specimen, are only $TE_{k',0,m'}$ modes with odd k' and $(k', 0, m') \neq (1, 0, 5)$.

Substituting the electrical fields of these normal modes into Eq. (I, 5), one obtains

$$\frac{16}{(abc)^2} \sum_{k',m'} \frac{f_1^2}{f_0^2 - f_{k'0,m'0}^2} \times \left(\int_{V_1} \sin \frac{\pi x}{a} \sin \frac{5\pi z}{c} \sin \frac{k'\pi x}{a} \sin \frac{m'\pi z}{c} dv \right)^2 \qquad \text{(II, 2)}$$

as the factor A, where $16/(abc)^2$ is the normalization constant.

The sum was calculated by the numerical integration and found to converge sufficiently when we took account of the modes of the resonant frequency up to about 200 GHz. Since the resulting frequency f_1 is not varied so much with the specimens, we can assume the formula (II, 2) as a constant. It was found to be $0.035 \times 4\ V_s/V_c$ for the geometry of the cavity and the sample cell used.

Photoelectron Spectra and Sum Rule Consideration. Higher Alkyl Amines and Alcohols[1)]

Shunji KATSUMATA, Toshio IWAI, and Katsumi KIMURA

Physical Chemistry Laboratory, Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received June 5, 1973)

Photoelectron spectra of higher alkyl amines and alcohols (Me, Et, *n*- and *i*-Pr, and *n*-Bu) have been measured with the 584 Å line of helium. Seven photoelectron bands corresponding to p-type MO's were identified for ethylamine and ethanol. Nine bands were observed for *n*- and *i*-propylamine and *n*- and *i*-propanol, and eleven for *n*-butylamine and *n*-butanol, in addition to the first C_{2s} bands appearing at about 19 eV. The sum rule previously proposed by Kimura *et al.* has further been applied to the compounds studied here. Total sums of vertical ionization energies in the region below 18 eV have been found to be well reproduced by the sums of appropriate energies estimated for the p-type localized MO's, using Koopmans' theorem. Information on orbital character has also been obtained from the sum rule in each symmetry species.

Recent advances in vacuum-ultraviolet photoelectron spectroscopy have made it possible to determine ionization energies of molecular valence orbitals with high precision and possible to obtain quantitative information on valence orbital energies on the basis of Koopmans' theorem.

Recent photoelectron works by Kimura *et al.*[2-5)] have suggested that "sum rule" holds for vertical ionization energies to a considerably wide extent. Briefly speaking, for each alkyl halide, a total sum of experimental vertical ionization energies below about 17 eV was well reproduced by a simple summation of empirical energy values assumed for p-type localized MO's, using Koopmans' theorem. It should be mentioned that the empirical values used in those works were estimated on the basis of accurate photoelectron data of simple related molecules. In the present work, we have considered it very interesting to investigate how far such a sum rule holds for other kinds of compounds, and have undertaken to study series of alkyl amines and alcohols, by placing major emphasis on the sum rule.

The alkyl amines and alcohols studied here have partly been studied with a retarding grid-type technique for the first time by Al-Joboury and Turner[6,7)] and later by Dewar and Worley.[8)] Methanol has also been studied by ESCA by Siegbahn *et al.*[9)] Recently, high-resolution photoelectron spectra of several alkyl alcohols have been reported by Baker *et al.*[10)] and by

Robin and Kuebler,[11] and those of methylamine and its related compounds by Cornford *et al.*[12] For higher alkyl amines, however, no high-resolution spectra have been published so far.

Price *et al.*[13] have recently reported He II photoelectron spectra of many organic compounds including methylamine and methanol, and have shown that the photoelectron bands due to 2s electrons of C, N, and O atoms appear in the region from 20 to 40 eV.

On a theoretical side, orbital calculations of methylamine[12,14] and methanol[8,9,11,15] have been carried out by Fink and Allen (*ab initio*),[14,15] Dewar and Worley (MINDO),[8] Siegbahn *et al.* (CNDO),[9] Cornford *et al.* (INDO),[12] and Robin and Kuebler (GTO).[11] According to these theoretical treatments, the valence orbital structures of methylamine and methanol have well been established to be (1a″)(5a′)(6a′)(2a″)(7a′) and (5a′)(1a″)(6a′)(7a′)(2a″), respectively. For the higher alkyl compounds, no such orbital structures have been reported.

Experimental

Commercial samples of the alkyl amines and alcohols were used after purification. Measurements of photoelectron spectra were carried out several times for each compound with a JASCO PE-1 high-resolution photoelectron spectrometer described before,[2] using He 584 Å resonance line. Calibration of an ionization energy scale was carried out using known ionization energies of Xe as a standard substance.

Results

Photoelectron spectra obtained for the amines and alcohols in the region below about 20 eV are shown in Fig. 1 (where only those of *n*-butylamine and *n*-butanol are not shown), no distinct vibrational structure being observed. As seen from Fig. 1, methylamine shows five bands which are clearly separated from one another and well correspond to those reported by Cornford *et al.*[12] For ethylamine, a total of seven bands including a slight shoulder at 13.8 eV were distinguished. This shoulder was carefully checked to be correct in the present measurement, because it is missing in literature. Ten and twelve bands were identified for propylamines and *n*-butylamine, respectively.

The spectrum of methanol consists of five bands, while that of ethanol shows six maxima and one slight shoulder at about 14.5 eV, which we consider as one of the ionization bands. In addition to seven bands reported previously for *n*-propanol by Baker *et al.*,[10] we observed two more bands appearing as slight shoulders at about 13.4 and 15.3 eV, and a maximum at 19.51 eV, so that a total of ten bands were identified in the region studied here. Similarly, for *i*-propanol, a slight shoulder at about 14 eV and a maximum at 19.52 eV were observed in addition to the bands already reported.[10] Twelve bands were found for *n*-butanol, including five new bands not reported previously.

Vertical ionization-energy (IE) values thus obtained from the maxima and shoulders of the photoelectron spectra are summarized in Tables 1 and 2. The IE values estimated from the shoulders are somewhat uncertain, which are shown in parentheses.

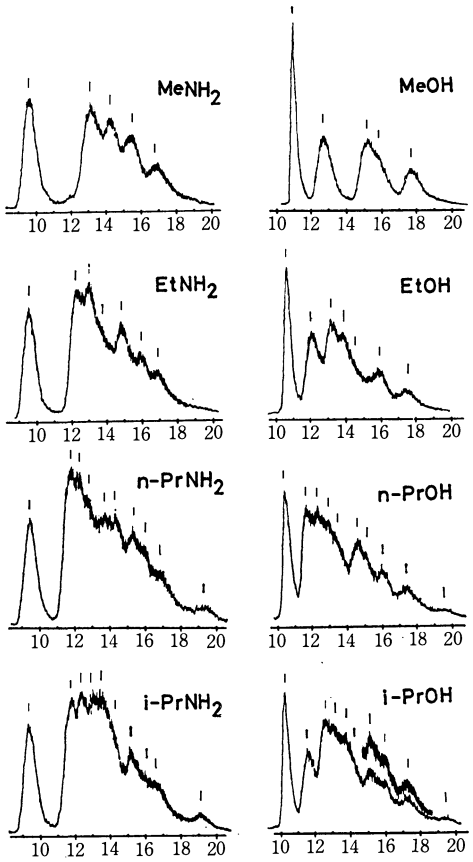

Fig. 1. Photoelectron spectra of alkyl amines and alcohols (methyl, ethyl and *n*- and *i*-propyl). Abscissas are in eV units. Vertical lines indicate the locations of the vertical ionization energies given in Tables 1 and 2.

a) Only high-resolution data are shown. Robin and Kuebler[11] also report I_1 values for ethanol (10.62 eV), n-propanol (10.50 eV) and i-propanol (10.42 eV). Values in parentheses are shoulders and those in square brackets show the C_{2s}-orbital bands.

Discussion

Photoelectron Bands and Ionization Energy Data. Most of the amines and alcohols studied here have previously been studied with a retarding-potential technique.[6-8] Agreements between the high-resolution and the retarding-potential IE's are not always good and some values are lacked in the latter. The high-resolution data already reported for the alkyl amines and alcohols[10,12] are compared in Tables 1 and 2. As far as comparison is possible in Tables 1 and 2, the present experimental IE's are generally in good agreement with the literature values, although some IE values are missing in the previous works.[10]

It should be pointed out that in each compound the number of the photoelectron bands observed here in the region below 18 eV is in accord with the number of p-type localized MO's. In fact, there should exist five, seven, nine, and eleven p-type localized MO's in the methyl, ethyl, n- and i-propyl and n-butyl compounds, respectively. The highest ionization-energy bands appearing at about 19 eV for the propyl and butyl compounds should be attributed to the first C_{2s} bands, since these bands correspond to the C_{2s} bands of propane and butane observed at about 19 eV by Potts *et al.*[13] using a He II source. According to these authors,[13] the first C_{2s} band of ethane appears at about 20.3 eV, and the O_{2s} band of methanol as well as the N_{2s} band of methylamine appear in the region higher than 20 eV.

In our previous works of higher alkyl halides,[2,5] we have identified all the p-type bands appearing in the He I region, which are the halogen nonbonding orbitals, the C–C and C–halogen bonding orbitals, and the methyl- and methylene-group pseudo-π orbitals. A similar situation can be expected to occur in the alkyl amines and alcohols. Namely, the photoelectron bands are expected to correspond to the O and N nonbonding (n) orbitals, the C–C, C–O, C–N, and O–H σ orbitals, and the pseudo-π orbitals of the CH_3–, $-CH_2$–, and NH_2–groups.

Experimental Total Energies for p-Type Orbitals. Assuming Koopmans' theorem, a total sum of MO energies are given by

$$T = -\sum_i I_i \qquad (1)$$

where I_i denotes the ith ionization energy. The 2s-type ionization energies (I_{10} for propylamines and propanols, I_{12} for n-butylamine and n-butanol) are removed in the calculations of the total sums. The results of such total sums for all the compounds studied here are summarized in Table 3, indicating that differences in T between two successive alkyl anologues approximately equal one another with an average value of $\Delta T = -26.04 \pm 0.25$ eV. This value should correspond to the orbital-energy change due to the substitution by the $-CH_2-$ group in alkyl compounds.

Table 3. The total orbital energies (T, in eV) of the p-type MO's for the alkyl amines and alcohols, obtained on the assumption of Koopmans' theorem

Alkyl amines	T	ΔT	Alkyl alcohols	T	ΔT
$MeNH_2$	−69.58		MeOH	−71.97	
		−26.36			−25.67
$EtNH_2$	−95.94		EtOH	−97.64	
		−25.78			−26.12
n-$PrNH_2$	−121.72		n-PrOH	−123.76	
(i-$PrNH_2$)	(−121.97)	−26.29	(i-PrOH)	(−123.62)	−26.02
n-$BuNH_2$	−148.01		n-BuOH	−149.78	

ΔT (average) = -26.04 ± 0.25

Using vertical IE's obtained for twelve alkyl halides (RX: R=Me to *n*-Bu; X=Cl, Br, I),[2] an average value of $\Delta T = -26.07 \pm 0.47$ eV was obtained, in excellent agreement with the above value (−26.04 eV). Furthermore, using IE values reported for methane, ethane, propane, isobutane, and neopentane,[16] an average value of −26.0 eV was obtained for ΔT, again very close to the above. Therefore, the ΔT value −26.04 eV obtained here may undoubtedly be allotted to the p-type localized orbitals consisting of the CC σ and CH_2 pseudo-π orbitals. In fact, it is interesting to see that the ΔT value is almost equal to the sum of −11.75 and −14.30 eV which have previously been proposed for σ_{CC} and π_{CH_2} by the present authors.[2] The comparison of T's in Table 3 also suggests that the present PE measurements were correctly carried out without missing any right bands or taking any wrong bands into account.

It should be pointed out that according to a theoretical study by Hoffmann,[17] $(2n+1)$ p-type MO's of alkanes (C_nH_{2n+2}) are located higher than about −17 eV whereas 2s-type MO's are below about −20 eV. Dewar and Worley[8] have also indicated from their MINDO method that in several alkyl alcohols the number of MO's with ionization energies higher than 20 eV is in agreement with that expected for 2s-type MO's and all the p-type MO's show ionization energies smaller than about 15 eV. These theoretical treatments seem to suggest that 2s- and 2p-type MO's in an alkyl compound may reasonably be distinguished.

TABLE 4. LOCALIZED ORBITAL ENERGIES (in eV) USED FOR PARTIAL AND TOTAL SUMS

$\varepsilon^0(n_N) = -10.80$	$\varepsilon^0(\sigma_{CN}) = -14.42$	$\varepsilon^0(\pi_{NH_2}) = -15.77$
$\varepsilon^0(n_O) = -12.61$	$\varepsilon^0(\sigma_{CO}) = -15.19$	$\varepsilon^0(\sigma_{OH}) = -15.57$
$\varepsilon^0(\sigma_{CC}) = -11.75$	$\varepsilon^0(\pi_{CH_2}) = \varepsilon^0(\pi_{CH_3}) = -14.30$	

p-Type Localized MO's. Generally speaking, in a secular equation, the total value of all eigenvalues is equal to the sum over all diagonal elements, independent of off-diagonal elements. Therefore, such a sum rule may approximately be applied to our problem of orbital energies. When a molecule has a certain symmetry, the sum rule holds for orbital energies in each symmetry species, so that such a partial sum is helpful for assigning the observed IE's to MO's. We used empirical values given in Table 4 as localized MO energies which were selected in such that (1) the values for n_N and n_O were taken from the first IE's of ammonia and water, respectively, (2) the values for σ_{CN} and σ_{CO} were from the third IE's of methylamine and methanol, respectively, (3) the values for π_{NH_2} and σ_{OH} were taken so as to reproduce the total experimental orbital energies of methylamine and methanol, respectively, (4) the values for σ_{CC}, π_{CH_3}, and π_{CH_2} were the same as those previously used.[2]

Evaluation of Total Energy Sum for p-Type Orbitals. The total energies of p-type orbitals in alkyl amines ($C_nH_{2n+1}NH_2$) and alkyl alcohols ($C_nH_{2n+1}OH$) may be expressed by

$$T = \varepsilon^0(n_N \text{ or } n_O) + \varepsilon^0(\pi_{NH_2} \text{ or } \sigma_{OH}) + \varepsilon^0(\sigma_{CN} \text{ or } \sigma_{CO}) + (n-1)\varepsilon^0(\sigma_{CC}) + (n-1-2m)\varepsilon^0(\pi_{CH_2}) + (2+2m)\varepsilon^0(\pi_{CH_3}) \quad (2)$$

where $m=1$ for *i*-propylamine and *i*-propanol and otherwise $m=0$.

TABLE 5. COMPARISON OF THE EXPERIMENTAL PARTIAL AND TOTAL SUMS (in eV) BETWEEN THE CALCULATED ONES

	Exptl	Calcd
Methylamine (C_S)	$T = -69.58$	−69.59

gauche-type interaction (C_1)		
$(I_1, I_4, I_6) \rightarrow (n_N, \pi_{CH_2}, \pi_{CH_3})$	$P = -39.10$	−39.40
$(I_2, I_3, I_5, I_7) \rightarrow (\sigma_{CC}, \pi_{CH_3}, \sigma_{CN}, \pi_{NH_2})$	$P = -56.84$	−56.24
trans-type interaction (C_S)		
$(I_1, I_3, I_4, I_5) \rightarrow a'(n_N, \sigma_{CC}, \pi_{CH_3}, \sigma_N)$	$P = -51.11$	−51.27
$(I_2, I_6, I_7) \rightarrow a''(\pi_{CH_2}, \pi'_{CH_3}, \pi_{NH_2})$	$P = -44.83$	−44.37
Ethanol	$T = -97.64$	−98.02
gauche-type interaction (C_1)		
$(I_1, I_3, I_4, I_6) \rightarrow (n_O, \sigma_{CC}, \pi_{CH_3}, \sigma_{CO})$	$P = -53.56$	−53.85
$(I_2, I_5, I_7) \rightarrow (\pi_{CH_2}, \pi_{CH_3}, \sigma_{OH})$	$P = -44.08$	−44.17
trans-type interaction (C_S)		
$(I_2, I_3, I_4, I_7) \rightarrow a'(\sigma_{CC}, \pi_{CH_3}, \sigma_{CO}, \sigma_{OH})$	$P = -56.60$	−56.81
$(I_1, I_5, I_6) \rightarrow a''(n_O, \pi_{CH_2}, \pi'_{CH_3})$	$P = -41.04$	−41.21
n-Propylamine	$T = -121.72$	−121.69
i-Propylamine	$T = -121.97$	−121.69
n-Propanol	$T = -123.76$	−124.07
i-Propanol	$T = -123.62$	−124.07
n-Butylamine	$T = -148.01$	−147.74
n-Butanol	$T = -149.78$	−150.12

The T's calculated from Eq. (2) using the values of Table 4 are shown in Table 5, compared with the corresponding experimental T's. The calculated T's for the higher alkyl amines and alcohols (Table 5) are generally in good agreement with experiment.

Evaluation of Partial Orbital-Energy Sums. Methylamine and methanol are of symmetry C_{2s}, so that their MO's are divided into two groups; one (a') symmetric to the molecular plane and the other (a'') antisymmetric. Interactions in a' in methylamine are considered to occur among the n_N, π_{CH_3}, and σ_{CN}, while the π'_{CH_3} and π_{NH_2} in a'' are expected to mix considerably with each other. As seen from Table 5, the partial sums in a' and a'' for this molecule are in excellent agreement with $-(I_1+I_3+I_4)$ and $-(I_2+I_5)$, respectively, the agreement not only suggesting a validity of the selection of the orbital energy parameters but also providing an information about orbital character. Such orbital interactions are also shown in an energy diagram of Fig. 2, in which the experimental levels are correlated with the initial localized MO's. From the sum rule consideration, the orbital

16) J. N. Murrell and W. Schmidt, *J. Chem. Soc., Faraday Trans.*, II, **68**, 1709 (1972).
17) R. Hoffmann, *J. Chem. Phys.*, **40**, 2047 (1963).

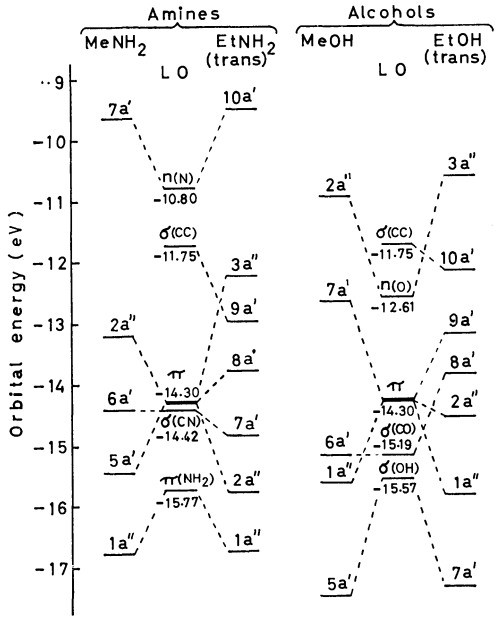

Fig. 2. Energy level diagrams of methylamine, ethylamine, methanol and ethanol. The experimental energy levels are correlated with the initial localized MO levels (I.O).

structure of methylamine may be concluded to be [1a", 5a', 6a', 2a", 7a'] in decreasing order of ionization energy. It should be mentioned that this orbital ordering is in completely agreement with the theoretical result reported by Fink and Allen.[14]

For methanol, a valence orbital structure of [5a', 1a", 6a', 7a', 2a"] has already been established from the theoretical treatments.[9,11,15] It is interesting to see that the same orbital ordering can be obtained from the present calculation of partial sums (Table 5). $I_1(2a'')$ and $I_4(1a'')$ in this molecule result mainly from the conjugative interaction between the n_O and π'_{CH_3} orbitals belonging to a", while $I_2(7a')$, $I_3(6a')$, and $I_5(5a')$ are due to the interaction of the π_{CH_3}, σ_{CO}, and σ_{OH} orbitals. The orbital correlation are also shown in Fig. 2.

Ethylamine and ethanol in gaseous phase are known to exist in *trans* and *gauche* forms from a microwave spectroscopy,[18] although unknown about which form is predominant. In the present work, therefore, orbital assignments for these ethyl compounds were considered in the two types of conformations as shown in Table 5. (The diagram in Fig. 2 for these compounds shows the levels obtained on the basis of the *trans* conformations.) Even in the *gauche* form with no symmetry, orbital interactions seem to divide into two groups; one consisting of the MO's which are approximately in plane with regard to the N–C–C (or O–C–C) plane and the other being approximately out of plane. No partial sums are shown in Table 5 for the propyl and butyl compounds since there are no conformational informations available. Finally, it should be pointed out that, in the case of *trans* ethanol, the 10a' level may be correlated with the σ_{CC} level probably because of the inductive effect of the OH group (Fig. 2).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3395—3399 (1973)

Electroluminescence in Pentacene Doped Anthracene Crystals

Nobuko I. WAKAYAMA,* Nobuyuki WAKAYAMA,** and D. F. WILLIAMS

National Research Council of Canada, Ottawa, Ontario K1A OR6, Canada

(Received June 8, 1973)

The recombination radiation spectrum and its transient behavior were measured on a pentacene doped anthracene crystal. The recombination radiation spectrum was more sensitive to chemical or physical impurities than optically sensitized fluorescence spectrum. The intensity of both anthracene and pentacene emission was approximately proportional to the current. Anthracene or pentacene emission was found to consist of three components differing by their decay times; component 1 (decay time $<10^{-5}$ s), components 2,3 (decay times in the millisecond region, $\tau_2<\tau_3$). The component 1 was due to singlet excitons generated directly by carrier recombination. The component 2, the decay time of which was 2—3 ms, was due to triplet exciton annihilation, for its decay time was not affected by a reverse bias voltage and was equal to one half of the observed phosphorescence lifetime. The component 3, which was removed by a reverse bias voltage, was due to detrapped-trapped carrier recombination. Pentacene chemical impurity works as carrier traps or tirplet exciton traps. Anthracene lattice defects work as carrier traps. The SCLC measurement showed the existence of an electron discrete trap introduced by pentacene and electron and hole exponential traps. The present experimental results showed het importance of traps in the recombination process in a mixed crystal.

For several years electrochemical electrodes have been used to produce electroluminescence in anthracene crystals from the recombination of the injected electrons and holes.[1,2] For pure crystals the electroluminescence

spectra and fluorescence spectra are the same if it is recognized that reabsorption may be more prominent in electroluminescence, since this is produced in the bulk of the crystal. However, electroluminescence can easily be modified in intensity and energy distribution by doping the crystal with any materials which will act as a carrier trap.[3,4] It has been seen that the bulk properties of a molecular crystal are easily perturbed by included molecules. The traps caused by the guest are more evident in the spectral distribution of electroluminescence than in that of optically sensitized fluorescence. As electron-hole recombination events finally produce singlet and triplet excitons, it is expected that electroluminescence will show a time behavior relating to the lifetime of these excitons, 10^{-8} and 10^{-3} s respectively.[2] It should be, however, born in mind that the transient behavior of the singlet exciton is not usually detected because of the slower rate-determining steps (carrier recombination) involved. The traps will change the temporal dependence of electroluminescence, particularly that due to the long lived triplet exciton. We have studied the electroluminescence of a pentacene doped anthracene crystal to see the influence of the traps on the recombination radiation of a mixed crystal. We measured the temperature dependence of Space-Charge-Limited-Currents (SCLC) to get insight into the distribution of the traps in the crystal and steady state electroluminescence. The temporal dependence of anthracene and pentacene emission was measured to study the growth reaction of electroluminescence.

Experimental

The crystal ingot was melt grown in a Bridgeman type furnace[5] under helium gas from highly purified anthracene containing 10^{-4} M pentacene (Princeton Organics). Single crystals, 1 mm thick, were cleaved parallel to ab plane from the bottom portion of the ingot where pentacene concentration was thought to be 10^{-6} M considering the segregation coefficient. Neither the sensitized fluorescence nor the absorption of pentacene was observed in the conventional way with the crystal used in the work. Electron and holes were injected along the c'-direction, *i.e.*, perpendicular to the cleavage plane. The electrode contact area was 0.44 cm^2. Solution of anthracene ions were used as injecting contacts.[1,2] (*i.e.*, Na-anthracene ion salt in tetrahydrofuran as an electron injecting electrode and anthracene-$AlCl_3$ in CH_2Cl_2 as a hole injecting electrode). The crystal temperature was varied by blowing cold nitrogen gas over the crystal held in a quartz Dewar system. Steady state measurements of the current-voltage (J-V) dependence, electroluminescence intensity-current (I-J) dependence and electroluminescence spectral distribution-current dependence were made over the temperature range from 200 to 300 K. Using a pulsed voltage supply the transient behavior of anthracene and pentacene electroluminescence was observed. The experimental apparatus for the pulsed voltage measurement is shown in Fig. 1. Each wavelength region was selected by combining appropriate band pass filters Optics Technology 550R, 600R and Corning glass 2-63, for pentacene and O-T 500B plus Corning glass 5-57, 5-64 and 5-61 for anthracene. The pulsed voltage supply used was capable of producing a square voltage pulse of 4000 V for up to 120 ms duration with rise and decay times of $<10^{-5}$ s/kV. A cooled EMI 9558 photomultiplier used as a detector was coupled with a time averaging computer to increase signal/noise ratio when required. As the number of the traps depends on the concentration of pentacene, experimental data were produced all at the same crystal platelet.

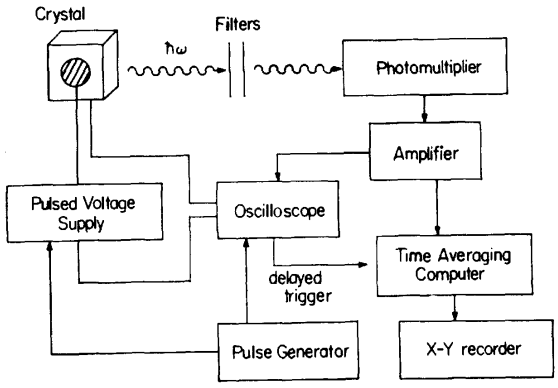

Fig. 1. Experimental apparatus for pulsed voltage measurement.

Results and Discussion

(a) The Temperature Dependence of Space Charge Limited Current (SCLC). As expected, steady state space charge limited hole and electron current-voltage-temperature curves all showed the presence of considerable trapping. At room temperature currents were 10^4—10^6 times smaller than predicted trap free currents.[6] The

results for injected electron currents are shown in Fig. 2. In the low voltage region the electron currents were proportional to the square of the voltage, while at higher voltage they increased with fourth power of the voltage. These results indicate the presence of an exponential energy distribution of electron traps plus a discrete trap. From the temperature dependence of the currents in the low voltage quadratic region, we obtained the depth of an electron discrete trap, 0.44 eV. Here the temperature dependence of the carrier mobility was neglected since it has only minor effects. This depth agrees with the electron trap depth estimated from the difference in electron affinities of anthracene and pentacene, 1.341−0.653=0.7 eV.[7] Similarly an estimation of a hole trap at 0.6 eV[8] can be made from the respective ionization energies, however the experimental results of hole currents-voltage-temperature dependence only showed the presence of exponential traps. The electron and hole exponential traps are considered to be due to structural defects caused by the inclusion of pentacene molecules.[9]

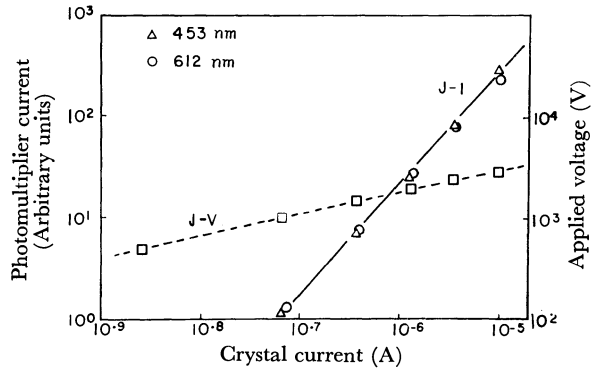

Fig. 3. Crystal currents, J, dependence on applied voltage $V(J-V)$ □, and dependence of anthracene △ (453 nm) and pentacene ○ (612 nm) electroluminescence intensity, I, with crystal current, $J(I-J)$.

(b) Double Injected Current-Voltage-Temperature (J-V-T) Dependence. The relation between the currents and applied voltage (J-V) at room temperature is shown in Fig. 3. $J \propto V^{4.4}$ was found in the crystal. The double injected current was always greater than that observed for single carrier injection, but was still in the order of 10^2—10^4 times smaller than predicted by Child's law (trap free). The current decreased exponentially with respect to T^{-1} over the temperature range 200—300 K, as observed in pure anthracene crystal.[10]

(c) Crystal Current-Electroluminescence Intensity and Spectral Distribution Dependence. The electroluminescence spectra at various temperatures are shown in Fig. 4. The optically excited (anthracene singlet) fluorescence spectrum of the same crystal comes from anthracene only. The 0-0, 0-1 bands of anthracene fluorescence

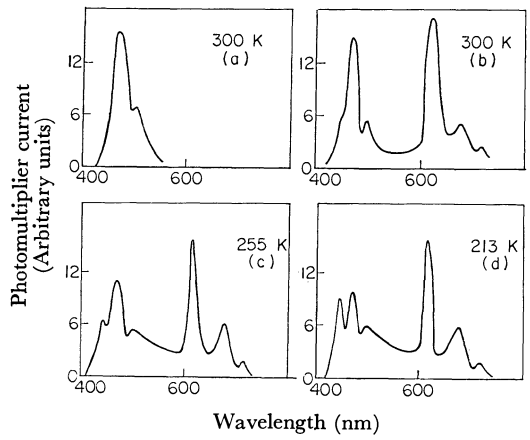

Fig. 4. Comparison of optically sensitized fluorescence spectrum at room temperature (a) and electroluminescence spectra at 300, 255, 213 K (b), (c), (d). The current density was 2.5×10^{-7} A·cm^{-2}.

were reabsorbed in both the electroluminescence and the fluorescence spectra. In the electroluminescence spectra, components due to anthracene 453 and 480 nm and those due to pentacene, 612 and 668 nm are easily recognized. The emission peak at 612 nm is the 0-0 level of the first excited singlet state of pentacene, in agreement with an analysis obtained from high resolution fluorescence spectra of pentacene.[11,12] As the crystal currents decreased or the temperature was lowered to 213 K, little change in relative intensity of the pentacene peaks occurred, and no additional peaks appeared in the pentacene fluorescence regions. As the temperature was lowered, the 0-1 band of anthracene singlet emission became visible, together with a broad background emission, maximum 480 nm. The appearance of the background emission indicates that the anthracene lattice has been considerably perturbed, as observed in SCLC measurement and structural defects work as carrier traps at low temperature. If this background emission is substracted, the ratio of anthracene emission: pentacene one decreased as the temperature was lowered. This suggests that pentacene trap becomes prominent at lower tem perature. The fact that chemical impurity, pentacene is more evident in electroluminescence than in the optically sensitized fluoresceyce shows that pentacene electroluminescence is not due to the energy transfer from anthracene singlet. At room temperature both anthracene (453 nm) and pentacene (612 nm) electroluminescence intensity increased approximately linearly with the crystal current as shown in Fig. 3. These results are different from anthracene-tetracene system.[3,4]

(d) Transient Behavior of Electroluminescence. The transient behavior of both the crystal current and pentacene emission under 2000 V pulsed voltage is shown in Fig. 5. General behavior of the transient current was similar to that obtained for pure anthracene crystals.[2] The anthracene emission behaves similarly

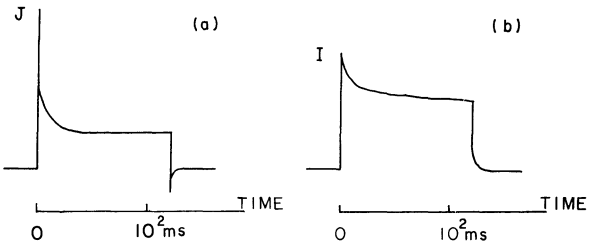

Fig. 5. Transient behavior of crystal current (a) and pentacene electroluminescence (b) under 2000 V.

to that of pentacene. The pulsed voltage was varied from 1000 to 3000 V. Though the voltage pulse decay was less than 10^{-5} s/kV, a considerable tail was observed in both anthracene and pentacene electroluminescence, with a decay time in the millisecond region. Both the anthracene and pentacene emission consist of the prompt decay component (component 1, the decay time $<10^{-5}$ s) and the delayed ones (component 2 and 3, their decay times in the millisecond region). The prompt electroluminescence emanating from both the guest and host is thought due to the singlet exciton produced by the carrier recombination like the pure anthracene crystals.[1,2] The prompt pentacene emission is thought due to the recombination in a pentacene trap, considering the SCLC experimental result. The ratio of the delayed: prompt electroluminescence intensity increased as the voltage was lowered and the current decreased, as shown in Table 1. The transient

TABLE 1. THE RESULTS COMPARING THE RELATIVE INTENSITY OF THE DELAYED ANTHRACENE AND PENTACENE ELECTROLUMINESCENCE COMPARED TO THE TOTAL ANTHRACENE AND PENTACENE ELECTROLUMINESCENCE

Applied voltage	Crystal currents	Totalel electroluminescence intensity (relative units)	Ratio Intensity delayed / Intensity total
Anthracene emission			
3000 V	1×10^{-5} A	294	0.062
2000	1.3×10^{-6}	26	0.17
1000	7×10^{-8}	1.1	0.28
Pentacene emission			
3000 V	1×10^{-5} A	240	0.12
2000	1.3×10^{-6}	28	0.18
1000	7×10^{-8}	1.4	0.37

behavior of the delayed pentacene eimssion is shown in Fig. 6. Two components with different decay times (component 2; 2—3 ms, component 3; 10 ms) are found. Anthracene delayed electroluminescence shows the similar behavior (component 2; 2—3 ms, component 3; 5—6 ms). The component 3 of both anthracene and pentacene emission was removed by applying a reverse bias voltage (500—1500 V), and was considered due to detrapped-trapped carrier recombination. The contribution from component 3 to

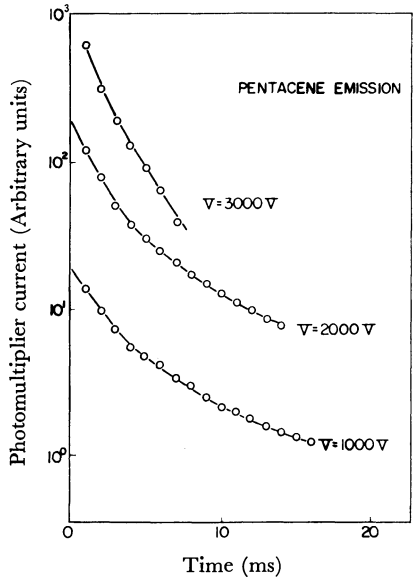

Fig. 6. Transient behavior of the delayed pentacene electroluminescence after the decay of the pulsed voltage 1000, 2000, 3000 V.

the total delayed emission increased as the voltage was lowered. Under 3000 V, the component 3 was not observed. The existence of component 3 in anthracene emission indicates that anthracene structural defects work as carrier traps, as observed in SCLC measurement and electroluminescence spectra. The decay time of component 2 was obtained by substracting component 3 or applying a reverse bias voltage. The component 2 is thought to be produced by triplet-triplet annihilation because it was not affected by a reverse bias voltage. The lifetime of anthracene triplet excitons was measured to check the above conclusion. Optical excitation of anthracene triplet by a He–Ne laser (50 mW, 6328 Å) gave red delayed luminescence, the decay time of which was 5.2 ms. In the above measurement a photomultiplier was coupled with a time averaging computer because the emission intensity was very weak. No blue delayed emission was observed in the crystal in a similar experimental condition. The red delayed emission is either phosphorescence of anthracene or delayed fluorescence of pentacene. As the emission intensity was linear with the excitation light intensity, we can regard it as anthracene phosphorescence. The measured anthracene triplet lifetime, 5.2 ms, is comparable with that obtained from the delayed fluorescence excited by a giant ruby laser in an anthracene crystal which contains 2 ppm pentacene.[13] Calculated decay time of anthracene triplet-triplet annihilation, which is a half of anthracene triplet lifetime, agrees with the observed decay time 2—3 ms of the component 2 in anthracene electroluminescence. If we consider the energy levels in a pentacene doped anthracene crystal, the component 2 of pentacene emission is thought due to pentacene triplet-anthracene triplet heterofusions. Impurity delayed fluorescence which comes from trapped triplet-

13) H. Baessler, G. Vaubel, and H. Kallmann, *J. Chem. Phys.*, **53**, 370 (1970).

free triplet exciton annihilation was reported.[14,15] The ratio of the delayed: the total anthracene emission intensity, 0.06 under 3000 V, when the component 3 did not exist is less than the value, 0.39, obtained in a pure anthracene crystal.[2] This is because anthracene triplet exciton is consumed by both annihilation with an anthracene triplet and a pentacene triplet, or the triplet energy is localized or trapped in a mixed crystal.[16]

The electroluminescence of a pentacene doped anthracene crystal is influenced by traps, either pentacene impurity traps or anthracene structural defect traps. Pentacene emission is more evident in the electroluminescence spectra than the optically sensitized fluorescence. Both anthracene and pentacene emission was found to consist of a prompt and two kinds of delayed emission. Pentacene impurity is concluded to work as carrier or triplet exciton traps in the growth reaction of every component of pentacene electroluminescence. The existence of the component 3 and the background defect electroluminescence in anthracene emission indicates that anthracene structural defects work as traps, too.

We wish to thank Prof. M. Kotani for many discussions. We wish also to thank Mr. Yves Lupien who grew the crystal.

Vibration-Rotation Spectrum of Methyl Fluoride. I. Analysis of $2\nu_3$ Band

Jun NAKAGAWA, Isao SUZUKI,* Takehiko SHIMANOUCHI, and Tsunetake FUJIYAMA**

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

***Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158*

(Received July 6, 1973)

The $2\nu_3$ band of methyl fluoride has been measured with a high-resolution infrared spectrometer. The following molecular constants are obtained: $\nu_0=2081.382$, $B''=0.85172$, $B'=0.82955$, $(A''-A')=0.01953$, $D_J''=1.95\times10^{-6}$, $D_J'=1.78\times10^{-6}$, $D_{JK}''=1.47\times10^{-5}$ (assumed), $D_{JK}'=1.93\times10^{-5}$, and $(D_K''-D_K')=5.9\times10^{-6}$ cm^{-1}. In addition, the hot band ($3\nu_3\leftarrow\nu_3$) and the isotope $^{13}CH_3F$ band have been observed and analyzed. The cubic force constant k_{333} was also obtained from the vibration-rotation constants.

The vibration-rotation spectra of methyl fluoride have been studied by many investigators. Pickworth and Thompson[1] measured $2\nu_3$, ν_4, and some other bands above 2000 cm^{-1}. Smith and Mills[2] studied the ν_3 and ν_6 fundamental bands with special attention to the x,y-type Coriolis interaction between the two fundamentals.[2,3] Jones, Popplewell, and Thompson[4] reported the analysis of the ν_2, ν_5, $\nu_3+\nu_4$, and $2\nu_4$ bands together with those of CD_3F. Blass and Edwards[5] and Anttila and Huhanantti[6] obtained molecular constants from some combination bands with high-resolution spectrometers. The microwave studies of this molecule were reported by Gordy and his coworkers.[7-11]

The $2\nu_3$ band of methyl fluoride has been measured under high resolution ($\Delta\nu\simeq0.04$ cm^{-1}) and its rotational structures have been analyzed. With this resolving power, the J-structures in the Q-branch are completely resolved. In addition, the structures due to different values of K are observed. Since this band is free from overlapping, the highly accurate molecular constants have been determined from the simultaneous analysis of P-, Q-, and R-branches. The present paper reports the result of this study. The $2\nu_3$ band is expected to have the x,y-type Coriolis interaction with the $\nu_3+\nu_6$ band similar to that observed between the ν_3 and ν_6 fundamentals. As pointed out by Smith and Mills,[2] the effect of this interaction is much more profound in the weaker $\nu_3+\nu_6$ band and may not be seen on the $2\nu_3$ band. However, the precise determination of the vibration-rotation levels in the $2\nu_3$ band is highly desirable for the analysis of the $\nu_3+\nu_6$ band.

Experimental

The sample was purchased from PCR Inc. of USA with the stated purity of 99% and used without further purification.

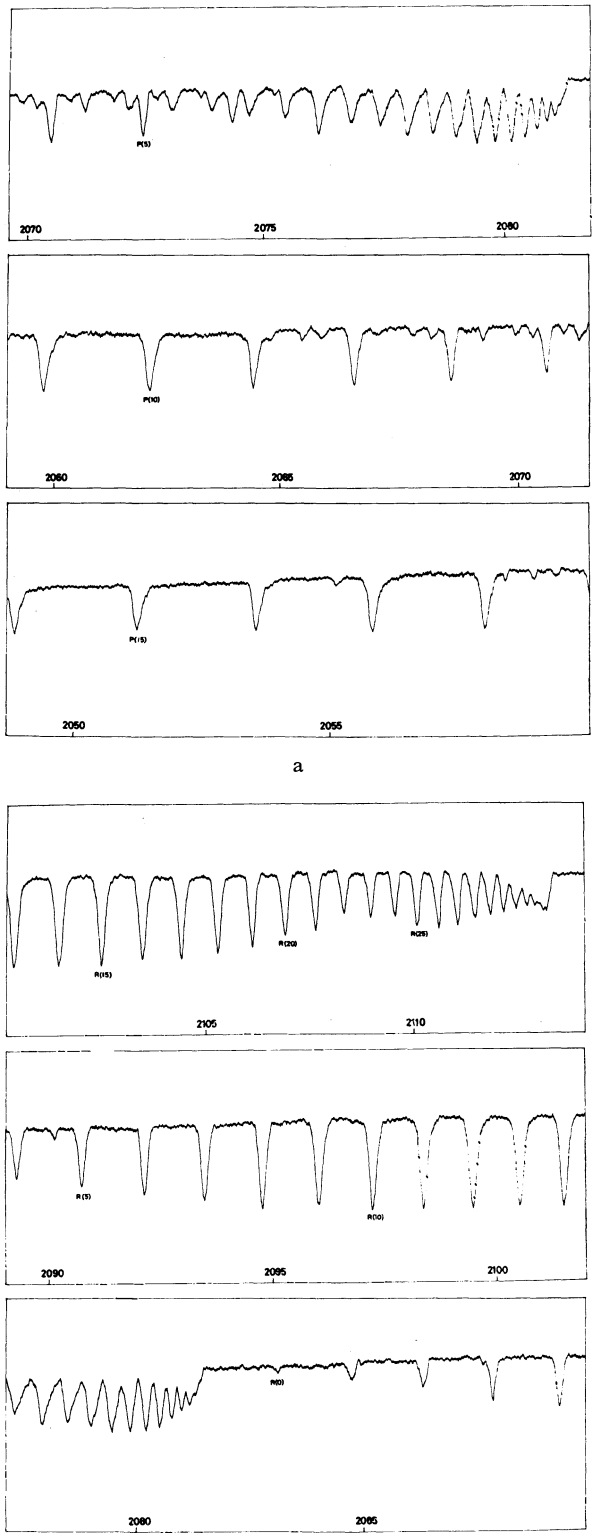

Fig. 1. The rapid scan spectrum of the $2\nu_3$ band of CH_3F. Path length=6 m. Pressure=3 mmHg. Resolution=0.10 cm^{-1}.
1a. P-branch. 1b. R-branch.

A high-resolution vacuum spectrometer which was designed and constructed in our laboratory[12] has been used; this spectrometer was equipped with a plane replica grating of Bausch and Lomb Co., Ltd. (echelle type, 206×102 mm^2 ruled area, 31.6 lines per mm, and blazed at 176.6 cm^{-1} in the first order), the grating is double passed and the 11-th and 12-th orders were used in this work. The collimating mirror was 30 cm diameter and 250 cm focal length with the f-number approximately 25. A CaF_2 prism spectrometer of Wadsworth type mount was used to seperate the grating orders. An InSb detector was used at liquid-nitrogen temperature. The spectrometer was operated under the resolution of about 0.04 cm^{-1} throughout this work. A White type long-path cell was used and its path length was kept at 6 m. The sample pressures used were 3 and 5 mmHg.

The frequencies of the observed lines were calibrated using the standard lines of carbon monoxide.[13] The standard deviation of the fitted lines was 0.006 cm^{-1} and the accuracy of the observed lines was believed to be better than ±0.01 cm^{-1}.

Observed Spectra

The rapid scan spectrum ($\Delta\nu\simeq0.1$ cm^{-1}) is illustrated in Fig. 1 with the assignment of several lines. The spacings of the P- and R-branches are large and their assignment can be done without ambiguity. In addition, the following spectral features are found.

(1) As shown in Fig. 2, the Q-branch is completely

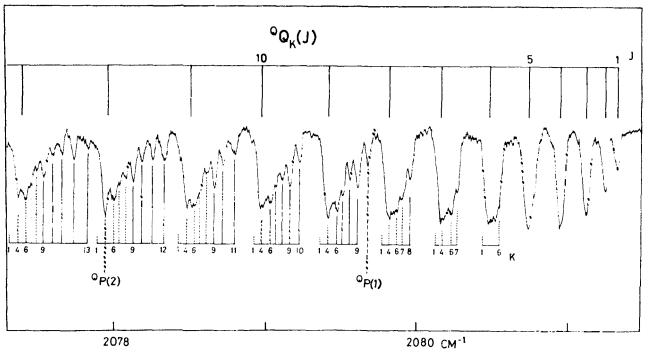

Fig. 2. The J-, and K-structures of the Q-branch of $2\nu_3$ band. Path length=6 m. Pressure=5 mmHg. Resolution=0.04 cm^{-1}.

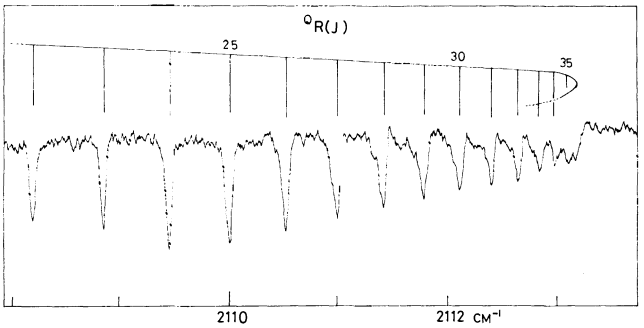

Fig. 3. The R-branch head of the $2\nu_3$ band. Path length=6 m. Pressure=3 mmHg. Resolution=0.04 cm^{-1}.

13) K. N. Rao, C. J. Humphreys, and D. H. Rank, "Wavelength Standards in the Infrared." Academic Press, New York, London (1966).

resolved into its J-components. Additional structures due to different K-values are observed.

(2) A band head is formed at high-frequency side of R-branch. The spacing of the R-branch decreases with increasing J-values; it finally reaches the edge at $J=36$ (see Fig. 3).

(3) An anomaly of relative intensity is observed in the P- and R-branches, particularly in the R-branch. The lines at $J=20$—25 are weak in comparison with the other lines.

(4) A number of lines due to the hot band ($3\nu_3 \leftarrow \nu_3$) and the isotope $^{13}CH_3F$ band are identified.

Analysis of Vibration-Rotation Structures

When none of the degenerate vibrations is excited, the energy levels of the v-th vibrational state are given by the formula,

$$T_v(J,K) = G(v) + B_vJ(J+1) + (A_v-B_v)K^2 - D_J^vJ^2(J+1)^2 - D_{JK}^vJ(J+1)K^2 - D_K^vK^4, \quad (1)$$

where $G(v)$ is the vibrational energy, A_v and B_v are the rotational constants, and D_J^v, D_{JK}^v, and D_K^v are the centrifugal distortion constants.

From the selection rule for a parallel band ($\Delta K=0$, $\Delta J=0, \pm1$), the transition frequencies can be calculated as the differences between the energy levels of the upper and the lower states.

Main Band ($2\nu_3 \leftarrow 0$). In the present analysis, the following assumption is made: the value of D_{JK} in the ground state is fixed to 1.47×10^{-5} cm^{-1} which has been obtained from microwave study.[10] The transition frequencies may be written as

$$\begin{aligned}\nu(J'',K'';J',K') &= T(J',K') - T(J'',K'') \\ &= \nu_0 + B'J'(J'+1) - D_J'J'^2(J'+1)^2 \\ &\quad + [(A'-A'')-(B'-B'')]K''^2 - B''J''(J''+1) \\ &\quad + D_J''J''^2(J''+1)^2 - [D_{JK}'J'(J'+1) \\ &\quad - D_{JK}''J''(J''+1)]K''^2 - (D_K'-D_K'')K''^4, \end{aligned} \quad (2)$$

where $''$ and $'$ refer to the lower and upper states respectively.

Since the J-components in the Q-branch as well as the P- and R-branches are completely resolved, the assignment of the J-value can be done without difficulty. As mentioned earlier, the complex structures due to the K-values are found in the Q-barnch. Since the statistical weights of the $K=3p$ levels are twice those of the $K=3p\pm1$ levels in methyl fluoride, the assignment of these K-values can be done in consideration of the statistical weight and the relation $K \leqq J$.

In the P- and R-branches, no structures due to the K-values are observed. In these two branches, the values of K at the intensity maxima are determined with the aid of the simulated spectra. For $^QR(8)$ branch, for example, the intensity maximum is found near $K=3$, and for $^QR(5)$ it is found near $K=2$.

In order to obtain the molecular constants, we have applied the least-squares method to Eq. (2), using the K-values together with J. Since we cannot determine A'' and A', and D_K'' and D_K' seperately, eight independent parameters may be obtained from the observed data. The molecular constants obtained from the present study are listed in Table 1 with the corresponding constants previously determined. In Table 2, the observed and calculated frequencies are listed with their assignments. The lines which are not fully resolved are given zero or smaller weights. The standard deviation of the data is 0.007 cm^{-1}.

Hot Band ($3\nu_3 \leftarrow \nu_3$) and Isotope Band. Two additoinal series of the P- and R-branches are observed between the lines of the main band, which can be assigned as the hot band ($3\nu_3 \leftarrow \nu_3$) and the isotope ($^{13}CH_3F$) band (see Fig. 4). The intensity ratio is expected to be 1.1: 1.3: 100 for the isotope band, the hot band, and the main band respectively. We may assign the stronger series as hot band and the weaker series as isotope band. As the Q-branch heads of these two series are found near 2049.7 and 2039.6 cm^{-1}, the J-values in these series can be assigned. Recently the $2\nu_3$ band of $^{13}CH_3F$ was measured by Duncan *et al.*[14] with 60% enriched sample, and their results confirm the present assignment. Since the

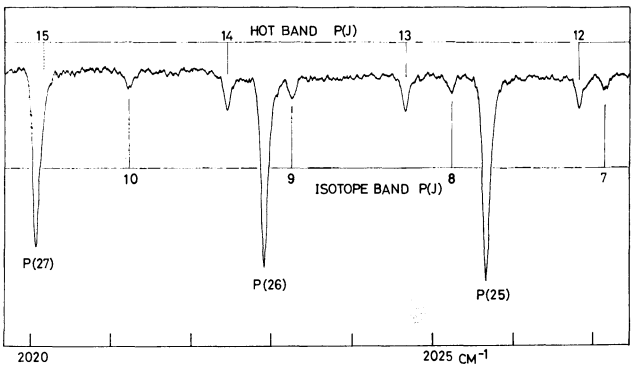

Fig. 4. The hot band and the isotope band of CH_3F. Path length=6 m. Pressure=5 mmHg. Resolution= 0.08 cm^{-1}.

Q-branch lines in the hot band and the isotope band are too weak to be analyzed and none of the structures due to different values of K are resolved, the following equation is used for the transition frequencies,

$$\nu_m^{P,R} = \nu_0 + (B'+B'')m + (B'-B''-D_J'+D_J'')m^2 - 2(D_J'+D_J'')m^3 - (D_J'-D_J'')m^4, \quad (3)$$

where m equals to $J+1$ for R-branch and $-J$ for P-branch.

The least-squares method was applied to Eq. (3), and the following equations were obtained.

Table 3. The molecular constants obtained from $(3\nu_3 \leftarrow \nu_3)$ band of CH_3F (in cm^{-1})

	This work		Smith *et al.*[2]
$\nu_0+\{(A'-A'')-(B'-B'')\}K^2-(D_K'-D_K'')K^4$	2049.835	(5)[a]	
ν_0	2049.811		
$B''-D_{JK}''K^2$	0.84035	(16)	0.8401
B''	0.84048		
$B'-D_{JK}'K^2$	0.81896	(16)	
B'	0.81913		
$(B''-B')$	0.02135	(4)	
D_J''	1.93×10^{-6}	(21)	1.86
D_J'	1.82×10^{-6}	(21)	
$(D_J''-D_J')$	0.11×10^{-6}	(6)	

a) The numbers in parentheses represent twice of the standard errors to be attached to the last significant figures.

a) (observed frequency—calculated frequency) × 1000 cm^{-1}

$$\nu_m^{P,R} = 2049.835 + 1.65932m - 0.021392m^2 - 7.51 \times 10^{-6}m^3 + 1.13 \times 10^{-7}m^4, \quad \text{(for hot band)}$$

$$\nu_m^{P,R} = 2039.680 + 1.63687m - 0.020983m^2 - 7.17 \times 10^{-6}m^3 - 0.21 \times 10^{-7}m^4. \quad \text{(for isotope band)} \quad (4)$$

These constants include the contributions from the K^2 and K^4 terms, because the K-values at the intensity maxima are not equal to zero. If we assume $K=3$ at the intensity maxima and the values $[(A'-A'')-(B'-B'')]$, D_{JK}'', D_{JK}', and $(D_K'-D_K'')$ to be the same as those of main band, we can estimate the 'true' molecular constants. In Tables 3 and 4, the molecular constants which were corrected for the K-dependent terms are tabulated together with the corresponding constants obtained by Smith and Mills,[2] by Duncan *et al.*,[14] and by Gilliam and Gordy.[7] In Table 5, the observed and calculated frequencies are listed. The standard deviations of these data are 0.008 cm^{-1} for the hot band and 0.012 cm^{-1} for the isotope band.

Discussion

The molecular constants given in Table 1 have been obtained from the simultaneous analysis of 135 transitions in the P-, Q-, and R-branches. Their values, particularly those for ν_0, $(B'-B'')$, and $(D'-D'')$, are determined very accurately. This is also the first case, as far as we know, in which the $(A'-A'')$ value is obtained for the parallel band of methyl fluoride. From the analysis of the ν_3 fundamental band, Smith and Mills[2] estimate $|(A'-A'')-(B'-B'')|=|\alpha_3^A-\alpha_3^B|=0.0002$ cm^{-1}. Our present result (0.0013 cm^{-1}) is one order of magnitude larger than their estimation, but quite close to the value recently obtained from laser spectroscopy (0.0011 cm^{-1}).[15]

For the hot band and isotope band, the number of observed lines is not enough to determine the centrifugal distortion constants with high accuracy. The standard errors of these constants are comparatively larger than the other ones.

In the $2\nu_3$ band the $(B''-B')$ value is fairly large in comparison with $(B''+B')$, which makes the R-branch to have a distinct band head. If the centrifugal distortion terms and the K-dependent terms in Eq. (2) are neglected, the following expression quadratic to J is obtained for R-branch.

$$\nu(J;J+1) = \nu_0 + (B''+B')(J+1) - (B''-B')(J+1)^2, \quad (5)$$

which has a maximum at $J=[(B''+B')/2(B''-B')]-1=37$.

15) T. Y. Chang and J. D. McGee, *Appl. Phys. Lett.*, **19**, 103 (1971).

The rotational constants of v-th vibrational state can be expressed as,

$$B_v = B_e - \sum_s \alpha_s^B (v_s + d_s/2) + \sum_s \sum_{s'} \gamma_{ss'}^B (v_s + d_s/2)(v_{s'} + d_{s'}/2) + \cdots \quad (6)$$

where B_e is the equilibrium rotational constant, α_s^B and $\gamma_{ss'}^B$ are the vibration-rotation constants, and d_s is the degree of the degeneracy. From the analysis of ν_3 fundamental band,[2] the value of $\alpha_3^B = (B'' - B')$ was given as 0.01134 (± 3) cm^{-1}. The present results yield 0.01180 cm^{-1} for α_3^B and 0.00023 cm^{-1} for γ_{33}^B.

The vibration-rotation constants, α_3^B and α_3^A can be written as the sum of the harmonic and anharmonic parts.[16,17]

$$\alpha_3^B = \alpha_3^B(\text{harm}) + \alpha_3^B(\text{anharm}),$$
$$\alpha_3^B(\text{harm}) = -(2B_e^2/\omega_3)[3A_{33}^{xx} + 4\{(\zeta_{34}^x \omega_4)^2/(\omega_3^2 - \omega_4^2) + (\zeta_{35}^x \omega_5)^2/(\omega_3^2 - \omega_5^2) + (\zeta_{36}^x \omega_6)^2/(\omega_3^2 - \omega_6^2)\}],$$
$$\alpha_3^B(\text{anharm}) = -4\pi B_e^2 (c/h)^{1/2}\{3a_3^{xx} k_{333}/\omega_3^{3/2} + a_1^{xx} k_{133}/\omega_1^{3/2} + a_2^{xx} k_{233}/\omega_2^{3/2}\}, \quad (7)$$
$$\alpha_3^A = \alpha_3^A(\text{harm}) + \alpha_3^A(\text{anharm}),$$
$$\alpha_3^A(\text{harm}) = -6A_e^2 A_{33}^{zz}/\omega_3$$
$$\alpha_3^A(\text{anharm}) = -4\pi A_e^2 (c/h)^{1/2}\{3a_3^{zz} k_{333}/\omega_3^{3/2} + a_1^{zz} k_{133}/\omega_1^{3/2} + a_2^{zz} k_{233}/\omega_2^{3/2}\}, \quad (8)$$

in which $a_s^{\alpha\alpha}$ and $A_{ss}^{\alpha\alpha}$ are related, respectively, to the first and the second derivatives of moment of inertia $I_{\alpha\alpha}$, expanded in normal coordinate Q_s. $\zeta_{ss'}^{\alpha}$ is the Coriolis coupling constant.

If the harmonic force field is known, the constants which appear in Eqs. (7) and (8) may be calculated. From the force field which was obtained in our laboratory[18] the following relations are derived;

$$\alpha_3^B(\text{obsd}) = 0.01180,$$
$$\alpha_3^B(\text{harm}) = -0.00031,$$
$$\alpha_3^B(\text{anharm}) = -0.000180\, k_{333} - 0.000004\, k_{133} + 0.000005\, k_{233}, \quad (9)$$

and

$$\alpha_3^A(\text{obsd}) = 0.00977,$$
$$\alpha_3^A(\text{harm}) = -0.0009,$$
$$\alpha_3^A(\text{anharm}) = +0.000070\, k_{333} - 0.000189\, k_{133} + 0.000242\, k_{233}. \quad (10)$$

Since both α_3^B(harm) and α_3^A(harm) are found relatively small and have opposite signs to the α_3^B(obsd) and α_3^A(obsd), the anharmonic parts α_3(anharm) seem to have a predominant role. Although three cubic force constants are involved in the expression, the coefficient of k_{333} is about 40 times larger than the other two in Eq. (9). Therefore, if we consider the cubic diagonal force constant k_{333} only, we could have -67 cm^{-1} for k_{333}. The three coefficients in Eq. (10) are of the same order and we cannot determine the other two cubic force constants.

Table 6. Comparison between the ν_3 of CH_3F and diatomic C–F molecule (in cm^{-1})

CH_3F		C–F[19]	
ν_3	1048.60[2]	ν	1286.26
$2\nu_3$	2081.38	2ν	2550.99
$3\nu_3$	3098.42	3ν	3794.92
ω_3°	1064.37	ω_e	1308.1
x_{33}	8.01	$\omega_e x_e$	11.10
y_{333}	+0.02	$\omega_e y_e$	0.093
α_3^B	0.01180	α_e	0.01840
γ_{33}^B	0.00023	γ_e	0.00011
k_{333}	-67	k_3	-91

A rough estimation of k_{333} may be done from the spectroscopic data of diatomic CF,[19] since the normal coordinate Q_3 is chiefly associated with the C–F stretching coordinate. The data which are obtained from the analysis of CF molecule are listed in Table 6 in comparison with those of the C–F stretching vibration of methyl fluoride. When we assume the Morse function for the potential of C–F stretching vibration, the following relation can be obtained,

$$k_3(\text{CF})/\omega_e(\text{CF}) = k_{333}(\text{CH}_3\text{F})/\omega_3(\text{CH}_3\text{F}). \quad (11)$$

With the aid of Eq. (11) and Table 6, the k_{333} is estimated to be -75 cm^{-1}, which has certainly correct order of magnitude.

As mentioned earlier, the x,y-type Coriolis interaction would likely occur between the $2\nu_3$ band and the $\nu_3+\nu_6$ band. The selection rule for this type of interaction is $\Delta J=0$, $\Delta k=+1$, and $\Delta l=+1$ or $\Delta J=0$, $\Delta k=-1$, and $\Delta l=-1$,[3] where $K=|k|$. We have observed the combination $\nu_3+\nu_6$ band and made a preliminary analysis. From the molecular constants so far available, we can predict that the interaction would be strong at relatively high K levels ($K\sim 25$).

The intensity anomaly due to the Coriolis interaction will be seen more clearly in the weaker $\nu_3+\nu_6$ band. The more precise analysis of the $\nu_3+\nu_6$ combination band is being attempted, the result will be published in the near future.

This research has been supported by the grant from the Ministry of Education. Helpful discussions from Dr. Koichi Yamada are deeply appreciated.

Vibrational Spectra and Molecular Conformations of Dialkyl Disulfides

Hiromu SUGETA, Akikatsu GO, and Tatsuo MIYAZAWA
Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565
(Received July 9, 1973)

The infrared and Raman spectra of several dialkyl disulfides were measured and their conformations were discussed in relation with the characteristic S–S and C–S stretching vibrations. The infrared spectra in the solid state and the temperature dependence of Raman spectra were measured for ethyl methyl disulfide and diethyl disulfide. For ethyl methyl disulfide, the *gauche-gauche* isomer was more stable than the *trans-gauche* isomer by about 0.9 kcal/mol while for diethyl disulfide the *gauche-gauche-gauche* isomer was more stable than the *trans-gauche-gauche* isomer by about 0.6 kcal/mol in the liquid state. Only the *gauche-gauche* form for ethyl methyl disulfide and only the *gauche-gauche-gauche* form for diethyl disulfide were observed in the solid state.

For vibrational analyses of Raman spectra of proteins, it is necessary to establish correlations between vibrational spectra and conformations of side-chain groups and related model molecules. The correlations between the S–S and C–S stretching frequencies and conformations of the disulfide group >C–S–S–C< were proposed in our previous communication.[1]

The stable conformation about the S–S bond of disulfide groups was established to be *gauche*, with the internal-rotation angle of nearly 90°. Accordingly, the molecular conformation of dialkyl disulfides was concerned with the internal rotation about the C–S and C–C bonds of the –C–C–S–S–C–C– group.

The infrared spectra of several dialkyl disulfides were studied early by Thompson and Trotter[2] and by Sheppard.[3] The vibrational assignments of dimethyl disulfide,[4] diethyl disulfide[5] and di-*n*-propyl disulfide[6] were made by Scott *et al.*, together with the collection of early data of infrared and Raman frequencies for their thermodynamic studies. Detailed investigations on dimethyl disulfide were made later by Hayashi[7] and by Frankiss.[8] The infrared and Raman spectra of di-*tert*-butyl disulfide were also measured by Scott *et al.*[9] in detail. The infrared and Raman spectra of a series of disulfides and diselenides were measured by Allum *et al.*[10] The normal vibrations of dimethyl disulfide, ethyl methyl disulfide and di-*tert*-butyl disulfide were treated by Scott and El-Sabban.[11]

In the present paper, the infrared and Raman spectra of several dialkyl disulfides are reported in some detail and molecular conformations of disulfides will be discussed, especially for ethyl methyl disulfide and diethyl disulfide.

Experimental

The dialkyl disulfides treated in the present study include dimethyl disulfide [CH_3SSCH_3], ethyl methyl disulfide [$CH_3CH_2SSCH_3$], diethyl disulfide [$CH_3CH_2SSCH_2CH_3$], diisobutyl disulfide [$(CH_3)_2CHCH_2SSCH_2CH(CH_3)_2$], diisopropyl disulfide [$(CH_3)_2CHSSCH(CH_3)_2$], di-*sec*-butyl disulfide [$CH_3CH_2CH(CH_3)SSCH(CH_3)CH_2CH_3$], methyl *tert*-butyl disulfide [$CH_3SSC(CH_3)_3$], di-*tert*-butyl disulfide [$(CH_3)_3CSSC(CH_3)_3$], and di-*tert*-amyl disulfide [$CH_3CH_2C(CH_3)_2SSC(CH_3)_2CH_2CH_3$].

Ethyl methyl disulfide was prepared from Bunte salt and ethyl mercaptan according to the method reported by Milligan and Swan.[12] Methyl *tert*-butyl disulfide was also prepared from Bunte salt and *tert*-butyl mercaptan, analogous to the method of Milligan and Swan[12] [bp 51 °C/20 Torr]. For other disulfides, commercial samples were used after distillation.

Infrared spectra in the liquid and solid states were measured with Hitachi EPI-G3 and EPI-L infrared spectrophotometers. Raman spectra in the liquid state were measured with a JEOL Raman spectrometer (Model JRS-02AS) with an argon-ion laser (488.0 or 514.5 nm).

Results and Discussion

S–S and C–S Stretching Vibrations. The Raman spectra in the region of the S–S and C–S stretching vibrations (750—500 cm^{-1}) of dialkyl disulfides are shown in Fig. 1. The characteristic S–S stretching frequencies of dialkyl disulfides are summarized in Table 1. S–S stretching vibrations of dialkyl disulfides give rise to strong Raman lines and weak infrared-absorption bands while C–S stretching vibrations give rise to strong Raman lines and fairly strong infrared-absorption bands. Accordingly, observations of Raman spectra as well as infrared spectra are important for identifications of S–S stretching vibrations.

As reported previously,[1] the S–S stretching frequencies of disulfide groups depend upon the molecular conformations about the C–S bonds. The frequencies of S–S stretching vibrations of the X–C–S–S–C–Y group are specified with the atoms X and Y which occupy the two *trans* sites with respect to the sulfur atoms; the S–S stretching vibrations lie at about 510 cm^{-1} for the conformation with two hydrogen atoms

a) Unexpected vibrations are marked with the — sign.

at both *trans* sites [ν(H,H)], at about 525 cm^{-1} for the conformation with a hydrogen atom at one *trans* site and a carbon atom at the other *trans* site [ν(H,C)], and at about 540 cm^{-1} for the conformation with two carbon atoms at both *trans* sites [ν(C,C)].

For dimethyl disulfide, methyl *tert*-butyl disulfide, and di-*tert*-butyl disulfide, no rotational isomers are expected other than the molecular conformation with the *gauche* S–S bond. In fact, for each of the three molecules, only one S–S stretching vibration was observed. On the other hand, for other disulfides with the possibility of rotational isomerism about the C–S bonds, two S–S stretching vibrations were in fact observed in the Raman scattering and infrared absorption. For di-*primary*-alkyl disulfides of the present study, two S–S stretching vibrations, ν(H,H) and ν(H,C), were observed in the liquid state (Table 1). This observation indicates that the *gauche-gauche-gauche* (GGG) and *trans-gauche-gauche* (TGG) isomers coexist for the $-C-CH_2-S-S-CH_2-C-$ group. For di-*n*-propyl disulfide and diisobutyl disulfide, two types (P_H and P_C) of C–S stretching vibrations were observed (see Ref. 1), indicating the coexistence of rotational isomers about the $>C-CH_2-$ bonds.

For di-*secondary*-alkyl disulfides [isopropyl or *sec*-butyl], two S–S stretching vibrations, ν(H,C) and ν(C,C), were observed (see Fig. 1 and Ref. 1), indicating the presence of rotational isomers about C–S bonds. For di-*sec*-butyl disulfide, two types of C–S stretching vibrations, S_{HH} and S_{CH}, were observed (see Ref. 1), indicating the coexistence of rotational isomers about the C–C bonds too.

For di-*tert*-amyl disulfide, rotational isomers about the C–S bonds are expected. However, for any isomer about the C–S bonds, the two *trans* sites are occupied by carbon atoms either of methyl groups or of methylene groups, and in fact only one S–S stretching vibration, ν(C,C), was observed in the Raman scattering. On the other hand, two types of C–S stretching vibrations, T_{HHH} and T_{CHH}, were observed for di-*tert*-amyl disulfide (see Ref. 1 and Fig. 1), indicating the coexistence of rotational isomers about the $-CH_2-C\lessdot$ bond.

Methyl tert-*Butyl Disulfide.* For methyl *tert*-butyl disulfide, no rotational isomers are expected other than the molecular conformation with the *gauche* S–S bond. Accordingly, the vibrational spectra of methyl *tert*-butyl disulfide were measured to confirm the characteristic vibrations of disulfide groups. The Raman spectrum of methyl *tert*-butyl disulfide in the liquid state is shown in Fig. 2. The infrared and Raman frequencies in the liquid state are given in Table 2, together with the vibrational assignments.

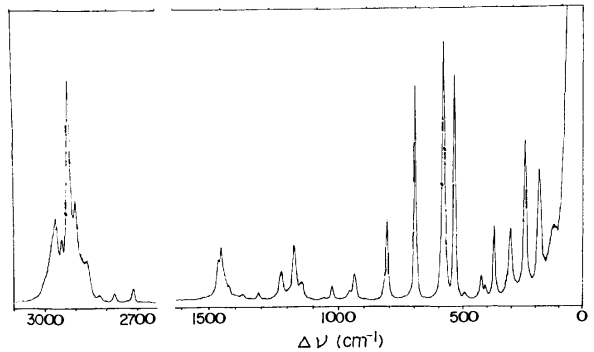

Fig. 2. The Raman spectrum of methyl *tert*-butyl disulfide in the liquid state at room temperature. Excited with an argon-ion laser (488.0 nm).

a) vs: very strong, s: strong, m: medium, w: weak, vw: very weak, sh: shoulder, br: broad.

The vibrational assignments were readily made with reference to the vibrational spectra of dimethyl disulfide[7,8] and di-*tert*-butyl disulfide,[9] since the vibrational spectra of methyl *tert*-butyl disulfide were found to be practically the composite of those of dimethyl disulfide and di-*tert*-butyl disulfide. Three very strong Raman lines at 528, 575, and 691 cm^{-1} were assigned to the characteristic S–S stretching [ν(H,C)], CH_3–S stretching, and $C(CH_3)_3$–S stretching vibrations [T_{HHH}]. The vibrational frequencies higher than 800 cm^{-1} were assigned, as given in Table 2, to the vibrations of the CH_3–S and $(CH_3)_3C$–S groups. In the region lower than 450 cm^{-1}, skeletal deformation and torsional vibrations are expected. The vibrational frequencies in the region 420—300 cm^{-1} are assigned to the skeletal deformation vibrations of *tert*-butyl group as given in Table 2. The Raman lines at 236 and 176 cm^{-1} are assigned to the C–S–S bending vibrations of the CH_3–C–S–S and $(CH_3)_3C$–C–S–S group, respectively.

Ethyl Methyl Disulfide. Ethyl methyl disulfide is the simplest one of the dialkyl disulfides for which rotational isomers about C–S bonds are expected to coexist. The infrared spectra of ethyl methyl disulfide in the region 3500—500 cm^{-1} were previously reported by Allum *et al.*[10]

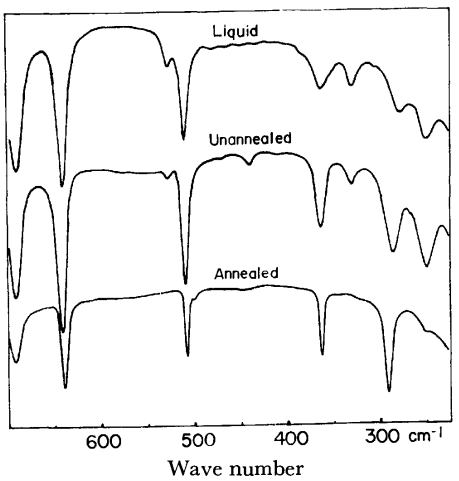

Fig. 3. The infrared spectra of the liquid (room temperature), unannealed solid (77 K), and annealed solid (77 K) of ethyl methyl disulfide.

TABLE 3. OBSERVED FREQUENCIES (cm^{-1}), RELATIVE INTENSITIES,[a] AND VIBRATIONAL ASSIGNMENTS OF ETHYL METHYL DISULFIDE

a) See the footnote a of Table 2.
b) The – sign indicates infrared bands which disappear on crystallization.

In the present study, the Raman spectra as well as infrared spectra were measured in the liquid state. The infrared spectra in the solid state (condensed from the vapor and then annealed) and the temperature dependence of the Raman intensities in the liquid state were also measured for detailed analyses of rotational isomerism. In Fig. 3, the infrared spectra in the region 700—200 cm^{-1} are shown for the liquid, unannealed solid and annealed solid. In Table 3, the observed vibrational frequencies in the region 800—200 cm^{-1} are given, together with the vibrational assignments. The infrared frequencies observed in the region higher than 500 cm^{-1} agree closely with the data reported previously by Allum *et al.*[10]

The infrared observation of two CH_2 rocking vibrations at 781 and 761 cm^{-1}, two C–S stretching vibrations at 667 and 642 cm^{-1}, two S–S stretching vibrations at 526 and 510 cm^{-1}, and five skeletal deformation vibrations below 400 cm^{-1} indicates the coexistence of the rotational isomers about the C–S bond in the liquid state. For the annealed solid, however, the infrared bands at 761, 642, and 510 cm^{-1} are still observed but the bands at 781, 667, and 526 cm^{-1} disappeared. Also the skeletal deformation vibrations at 328 and 248 cm^{-1} disappear on annealing.

For the molecule of ethyl methyl disulfide CH_3–CH_2–S–S–CH_3, there are two rotational isomers, *gauche-gauche* (GG or G'G') and *trans-gauche* (TG or TG'). For the GG form, hydrogen atoms occupy the two *trans* sites with respect to the S–S bond and accordingly the S–S stretching vibration is expected to lie at about 510 cm^{-1} [ν(H,H)] whereas for the TG form, the two *trans* sites are occupied by one hydrogen atom and one carbon atom and the S–S stretching vibration is expected to lie at about 525 cm^{-1} [ν(H,C)]. Since on annealing the infrared band at 510 cm^{-1} remains but the band at 525 cm^{-1} disappears, it may be concluded that the TG and GG forms coexist in the liquid state but only the GG form persists in the solid state.

The energy difference between the TG and GG forms was studied by the measurement of the temperature dependence of the Raman spectra in the liquid state. Thus, over the temperature range +20——65 °C, the relative intensities of Raman lines were measured for the pairs (TG and GG) at 669 and 641 cm^{-1}, 524 and 509 cm^{-1}, and 327 and 362 cm^{-1}. The GG isomer was found to be more stable than the TG isomer by 0.9±0.2 kcal/mol.

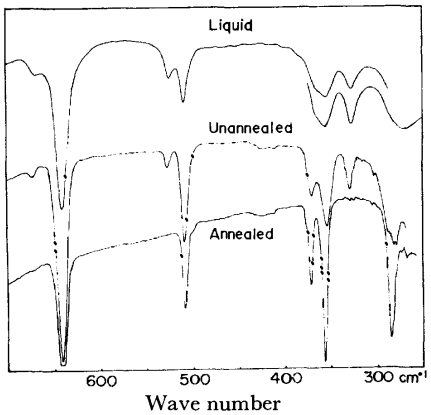

Fig. 4. The infrared spectra of the liquid (room temperature), unannealed solid (77 K), and annealed solid (77 K) of diethyl disulfide.

a) See the footnote a) of Table 2.
b) See the footnote b) of Table 3.
c) The underlined notations T and G indicate that the vibrational mode is largely localized on the side of the *trans* and *gauche* C–S bond, respectively.

Diethyl Disulfide. For the molecule of diethyl disulfide CH_3–CH_2–S–S–CH_2–CH_3, there are two C–S bonds about which rotational isomerism is expected. Possible rotational isomers are *gauche-gauche-gauche* (GGG or G'G'G'), *trans-gauche-gauche* (TGG or TG'G'), and *trans-gauche-trans* (TGT or TG'T).

Previous data of the infrared (>500 cm^{-1}) and Raman spectra were summarized by Scott *et al.*[5] In the present study, the infrared spectra (>200 cm^{-1}) were measured for the liquid, unannealed solid and annealed solid, and the Raman spectra of the liquid were measured at various temperatures. The infrared spectra (700—200 cm^{-1}) of the liquid, unannealed solid and annealed solid are shown in Fig. 4. In Table 4, the frequencies observed in the region 800—200 cm^{-1} are given, together with vibrational assignments. The vibrational frequencies in the region higher than 800 cm^{-1} agreed closely with previous data,[5] and accordingly are not included in Table 4.

On crystallization of the sample, the infrared band due to the S–S stretching vibration at 510 cm^{-1} [ν(H,H)] persists but the band at 525 cm^{-1} [ν(H,C)] disappears, similar to the case of ethyl methyl disulfide. Accordingly, it may be concluded that at least the GGG and TGG isomers coexist in the liquid state but only the GGG form persists in the crystalline state.

The infrared bands at 781 (CH_2 rock.), 667 (C–S stretch.), and 329 cm^{-1} (C–C–S deform.) disappear on crystallization and are assigned to the TGG form. These vibrations of the TGG form of diethyl disulfide closely correspond to those of the TG form of ethyl

methyl disulfide, indicating that the vibrational modes are largely localized on the side of the *trans* C–S bond. For similar reasons, the infrared bands due to the CH_2 rocking, C–S stretching and C–C–S deformation vibrations largely localized on the side of the *gauche* C–S bond of the TGG form are possibly overlapped with the corresponding bands of the GGG form (762, 640, and 365 or 358 cm^{-1}) in the liquid state.

The energy difference between the TGG and GGG forms of diethyl disulfide was studied by the measurement of the temperature dependence of the Raman spectra in the liquid state. Over the temperature range +20——68 °C, the relative intensity of the Raman lines at 523 (TGG) and 508 cm^{-1} (GGG) were measured. The GGG isomer was found to be more stable than the TGG isomer by 0.6 ± 0.2 kcal/mol.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3411—3415 (1973)

Isocyanide-phosphine Complexes of Cobalt(I)

Sei OTSUKA and Michele ROSSI*

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received February 8, 1973)

Diamagnetic penta-coordinate Co(I) complexes of formula, $[Co(p\text{-}CH_3C_6H_4NC)_4(PPh_3)]X$ (**1**) and $[Co(p\text{-}CH_3C_6H_4NC)_3(PPh_3)_2]X$ (**2**) ($X=Cl^-, Br^-, I^-, ClO_4^-, BPh_4^-$) were obtained from $CoX(PPh_3)_3$ or $CoX_2(PPh_3)_2$. Their ^1H NMR spectra served to deduce the trigonal bipyramidal structure. The aromatic ring proton NMR spectra and the IR CN stretching absorptions of radial modes were discussed in terms of the $d\pi$-$p\pi$ back bonding.

Recently isocyanide transition metal complexes have resumed considerable attention. Much of the impetus for the current research may stem from the unique property of isocyanide ligands which are capable of stabilizing a wider range of metal valency states than the isoelectronic molecule, carbon monoxide. Both the CN functional group and the substituent provide spectroscopic information valuable for structural assignments and for discussions on the nature of the metal-ligand bonding. Another interesting property is the reducing ability. Thus Co(I) complexes $[Co(RNC)_5]X$ are accessible from Co(II) halides by treating with an excess of RNC (R=alkyl or aryl). We were interested in comparing the structural chemistry in a series of $[Co(RNC)_{5-n}L_n]^+$. When our study was commenced no mixed complexes of this series were known except for $[Co(p\text{-}CH_3C_6H_4NC)_3(PPh_3)_2]^+$ which was reported without detail.[2] After completion of the work,[3] a paper describing $[Co(t\text{-}BuNC)_4AsPh_3]^+$, $[Co(t\text{-}BuNC)_3(PPh_3)_2]^+$ and others appeared,[4] but failed to report the preparation of $[Co(RNC)_4PPh_3]^+$. We were able to synthesize two types $[Co(RNC)_3(PPh_3)_2]^+$ and $[Co(RNC)_4PPh_3]^+$ ($R=p\text{-}CH_3C_6H_4$–) in addition to the known pentakis complex. Their stabilities and well-defined IR and NMR spectra enabled us to deduce their molecular structure to be isostructural (trigonal bipyramid). The series $[Co(RNC)_{5-n}L_n]^+$ ($n=0, 1, 2$) consitutes a system relevant for the study of the nature of isocyanide coordination to a low-valent metal. In view of the unusual ^1H NMR spectrum of the aromatic ring protons of free $p\text{-}CH_3C_6H_4NC$, which is due to the magnetic anisotropy of the C≡N– group, ^1H NMR spectra of the coordinated isocyanide deserve scrutiny.

Experimental

Materials. Commercial chemicals were used without further purification. *para*-Tolylisocyanide was prepared by the formamide–potassium *t*-butoxide method.[5] Compounds $[CoCl_2(PPh_3)_2]$[6] and $[CoCl(PPh_3)_3]$[7] were prepared by the procedures given in literature.

Instruments. The infrared spectra were measured with a Hitachi-Perkin Elmer Model 225 as Nujol mulls between CsI discs and in acetone solution in 0.1 mm NaCl cells. Proton nuclear magnetic resonance spectra were measured with a 100 MHz. Model JNM 4H-100 of JEOL using TMS as internal standard.

Syntheses of Compounds. *Tetrakis*-p-*tolylisocyanide-triphenylphosphinecobalt* (*I*) *chloride*: $CoCl(PPh_3)_3$ (1.2 g, 1.434 mmol) and *p*-tolylisocyanide (0.75 g, 6.4 mmol) were mixed in 100 ml of benzene at 5—10 °C under nitrogen atmosphere to give a yellow solution containing dark residue. The filtered solution was concentrated and treated with hexane affording a yellow powder. The powder was washed with hexane and dried under vacuum. Yield 0.6 g, 50% (calculated from the cobalt). Mp 80 °C (decomposition). Found: C, 71.27; H, 5.57; N, 6.59; Cl, 4.18%. Calcd for $C_{50}H_{43}ClN_4PCo$: C, 72.77; H, 5.25; N, 6.79; Cl, 4.30%.

Tetrakis-p-*tolylisocyanide-triphenylphosphinecobalt* (*I*) *Perchlorate*: A solution of $[Co(p\text{-}CH_3C_6H_4NC)_4PPh_3]Cl$ in cold ethanol

and a solution of $[Co(p\text{-}CH_3C_6H_4NC)_4PPh_3]_2[CoCl_4]$ in cold methanol were treated separately with an excess of $NaClO_4$ affording the same compound. The product was washed with water and cold methanol, and dried under vacuum. Yellow crystals, mp 144—146 °C (decomposition). Λ_M=24.9 mho cm^2 mol^{-1} (10^{-3} M nitrobenzene solution at 21 °C). Found: C, 67.61; H, 5.19; N, 6.47; Cl, 4.02%. Calcd for $C_{50}H_{43}ClN_4O_4PCo$: C, 67.53; H, 4.87; N, 6.30; Cl, 3.99%.

*Tetrakis-*p*-tolylisocyanide-triphenylphosphinecobalt(I) Tetraphenylborate*: A solution of $[Co(p\text{-}CH_3C_6H_4NC)_4PPh_3]Cl$ in ethanol was treated at 10 °C with an excess of $NaBPh_4$ affording yellow crystals. The product was washed with cold ethanol and dried under vacuum. Mp 90—92 °C (decomposition). Λ_M=16.2 mho cm^2 mol^{-1} (10^{-3} M nitrobenzene solution at 21 °C). Found: C, 79.16; H, 5.62; N, 4.94%. Calcd for $C_{74}H_{63}BN_4PCo$: C, 80.14; H, 5.73; N, 5.05%.

*Tetrakis-*p*-tolylisocyanide-triphenylphosphinecobalt(I) Tetrachlorocobaltate* (II): A suspension of 3.5 g of $CoCl_2(PPh_3)_2$ (5.36 mmol) in 30 ml of acetone was treated with 4 g of *p*-tolylisocyanide (33.2 mmol) at room temperature. The mixture was stirred for a few minutes affording a yellow-green solution; green crystals were formed by addition of a small portion of hexane. The product was washed with acetone and dried under vacuum. Yield 1.7 g, 53.5% (based on the cobalt). Mp 106—108 °C (decomposition). Found: C, 67.59; H, 5.38; N, 6.06; Cl, 8.11%. Calcd for $C_{100}H_{86}Cl_4N_8P_2Co_3$: C, 67.47; H, 4.87; N, 6.29; Cl; 7.96%.

*Tris-*p*-tolylisocyanide-bis-triphenylphosphinecobalt(I) chloride*: Method (a): The above yellow solution obtained after the filtration of $[Co(p\text{-}CH_3C_6H_4NC)_4PPh_3]_2[CoCl_4]$ was treated with another portion of hexane affording yellow crystals. The product was washed with hexane and dried under vacuum. Yield 0.45 g, 8.7%. Method (b): A mixture of 0.5 g of $[Co(p\text{-}CH_3C_6H_4NC)_4PPh_3]Cl$ (0.61 mmol) and 0.2 g of PPh_3 (0.76 mmol) was dissolved in hot benzene; the filtered solution afforded yellow crystals on cooling. The product was washed with benzene and dried under vacuum. Mp 175 °C. Λ_M=25.8 mho cm^2 mol^{-1} (10^{-3} M nitrobenzene solution at 21 °C). Found: C, 73.87; H, 5.81; N, 4.31; Cl, 3.75%. Calcd for $C_{60}H_{51}ClN_3P_2Co$: C, 74.26; H, 5.30; N, 4.33; Cl, 3.65%.

*Tris-*p*-tolylisocyanide-bis-triphenylphosphinecobalt(I) bromide*: A mixture of 1.5 g of $CoBr_2(PPh_3)_2$ (2.09 mmol) and 1.5 g of *p*-tolylisocyanide (12.8 mmol) in 15 ml of acetone was stirred at room temperature to give a yellow solution and a small amount of green residue. The filtered solution was treated with hexane to afford yellow crystals. Yield 0.4 g, 18.8%. Mp 192—194 °C. Λ_M=24.7 mho cm^2 mol^{-1}. (10^{-3} M nitrobenzene solution at 21 °C). Found: C, 70.60; H, 5.32; N, 4.18; Br, 8.30%. Calcd for $C_{60}H_{51}BrN_3P_2Co$: C, 71.01; H, 5.07; N, 4.14; Br, 7.87%.

*Tris-*p*-tolylisocyanide-bis-triphenylphosphinecobalt(I) iodide*: A mixture of 1.5 g of $CoI_2(PPh_3)_2$ (1.8 mmol) and 1.1 g of $p\text{-}CH_3C_6H_4NC$ (9.4 mmol) in 20 ml of acetone was stirred at room temperature to give a brown solution. On being left to stand, brown crystals of the known Co(II) complex, $Co(p\text{-}CH_3C_6H_4NC)_4I_2$, were formed (1.0 g, 71% of the cobalt). The filtered solution was treated with hexane to afford orange crystals of the product. Yield 0.35 g, 18.3%. Mp 195 °C. Λ_M=21.9 mho cm^2 mol^{-1} (10^{-3} M nitrobenzene solution at 21 °C). Found: C, 66.31; H, 5.16; N, 3.87%. Calcd for $C_{60}H_{51}IN_3P_2Co$: C, 67.87; H, 4.84; N, 3.96%. The compound $Co(p\text{-}CH_3C_6H_4)_4I_2$ was identified by its elemental analysis and mp.

*Tris-*p*-tolylisocyanide-bis-triphenylphosphinecobalt(I) perchlorate*: Method (a): A solution of $[Co(p\text{-}CH_3C_6H_4NC)_3(PPh_3)_2]Cl$ in ethanol was treated at room temperature with an excess of $NaClO_4$, affording yellow-orange crystals. Method (b): A solution of $[Co(p\text{-}CH_3C_6H_4NC)_4PPh_3]_2[CoCl_4]$ in methanol was heated to boliling point and treated with an excess of $NaClO_4$; on cooling orange crystals of the product were formed. The product was washed with water and cold ethanol and dried under vacuum. Mp 205 °C. Λ_M= 24.7 mho cm^2 mol^{-1} (10^{-3} M nitrobenzene solution at 21 °C). Found: C, 69.12; H, 5.33; N, 4.09; Cl, 3.68%. Calcd for $C_{60}H_{51}ClN_3O_4P_2Co$: C, 69.67; H, 4.97; N, 4.06; Cl, 3.43%.

*Tris-*p*-tolylisocyanide-bis-triphenylphosphinecobalt(I) tetraphenylborate*: A solution of $[Co(p\text{-}CH_3C_6H_4NC)_3(PPh_3)_2]Cl$ in ethanol was treated at room temperature with an excess of $NaBPh_4$ to afford yellow crystals. The product was washed with ethanol and dried under vacuum. Mp 183 °C. Λ_M=15.7 mho cm^2 mol^{-1} (10^{-3} M nitrobenzene solution at 21 °C). Found: C, 81.03; H, 6.07; N, 3.36%. Calcd for $C_{84}H_{71}BN_3P_2Co$: C, 80.44; H, 5.71; N, 3.35%.

Results and Discussion

Preparation. Penta-coordinated Co(I) complexes of formula $[Co(RNC)_4P]X$ and $[Co(RNC)_3P_2]X$ (RNC=$p\text{-}CH_3C_6H_4NC$, P=PPh_3) were prepared from phosphine-halide complexes of Co(I) or Co(II). The complex $[Co(RNC)_4P]Cl$ is readily obtainable by treating the tetrahedral, green Co(I) complex, $CoCl(PPh_3)_3$,[7] with a slight excess of *p*-tolylisocyanide (RNC/Co=4.5) in benzene at 5—10 °C; it was isolated in about 50% yield in the form of yellow powder, air-stable, moderately soluble in benzene and very soluble in polar solvents. The cation $[Co(RNC)_4P]^+$ was also produced by treating the tetrahedral Co(II) complex $CoCl_2(PPh_3)_2$[6] with an excess of the isocyanide (RNC/Co=6.2) in acetone at room temperature, and isolated as the tetrachlorocobaltate salt. The complex salts $[Co(RNC)_4P]Y$ (Y=ClO_4^-, X^-, and BPh_4^-) were obtained by metathetic exchange of the chloride anion in an alcoholic solution. The IR and NMR spectra indicate that the tetrakis-isocyanide-mono-phosphine complex salts obtained by both methods are always contaminated with a small amount (10—25%) of impurities which are a mixture of $[Co(RNC)_3P]X$ and $[Co(RNC)_5]X$ in an approximately equimolar amount. All these compounds form yellow, air-stable crystals and behave in solution as uni-univalent electrolytes (Λ_M=16—25 mho cm^2 mol^{-1} in nitrobenzene at 21 °C). They melt with decomposition at relatively low temperature (80—146 °C) indicating thermal instability of the cation $[Co(RNC)_4P]^+$ in comparison with $[Co(RNC)_3P_2]^+$. Consistent with the formal oxidation state Co(I), they are diamagnetic, normal chemical shift values being observed for the proton NMR spectra.

The reaction of $CoCl_2(PPh_3)_2$ with $p\text{-}CH_3C_6H_4NC$ produced, besides $[Co(RNC)_4P]_2CoCl_4$, the tris-isocyanide-bis-phosphine complex $[Co(RNC)_3P_2]Cl$ in a low yield. The corresponding bromide complex $[Co(RNC)_3P_2]Br$ was similarly obtained by starting from $CoBr_2(PPh_3)_2$ and the isocyanide in a molar ratio of 1 : 6.1; in this case we were unable to detect the formation of the $[Co(RNC)_4P]^+$ cation.

The reaction of $CoI_2(PPh_3)_2$ with $p\text{-}CH_3C_6H_4NC$ in acetone proceeds differently producing only a small

amount (18%) of the expected compound $[Co(RNC)_3P_2]I$, the predominant reaction product being the known Co(II) complex $Co(RNC)_4I_2$.[8] This result is in contrast to the successful reduction of $CoI_2(PR_3)_2$ with carbon monoxide leading to $CoI(CO)_2(PR_3)_2$.[9]

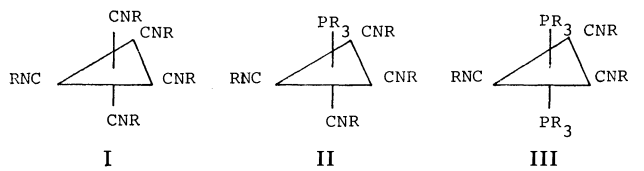
The cation $[Co(RNC)_4P]^+$ is readily transformed into a very stable cation $[Co(RNC)_3P_2]^+$ by reaction with an excess of phosphine. Thus $[Co(RNC)_3P_2]Cl$ was obtained by treating $[Co(RNC)_4P]Cl$ with PPh_3 in benzene as an insoluble product. The tris-isocyanide-bis-triphenylphosphine complexes were isolated in a form of orange yellow crystals, which are also diamagnetic and uni-univalent electrolytes in solution. They show high melting points (175—205 °C) and unusual stability against oxygen and reducing agents.

Failure of isolation of pure $[Co(RNC)_4P]X$ suggests the presence of equilibrium (1) in solution. Thus an acetone solution containing equimolar amounts of $[Co(RNC)_3P_2]ClO_4$ and $[Co(RNC)_5]ClO_4$ was prepared (at 22 °C) to follow reaction (1) with ^1H NMR.

$$2[Co(RNC)_4P]^+ \rightleftarrows [Co(RNC)_3P_2]^+ + [Co(RNC)_5]^+ \quad (1)$$

The spectrum indicates that $[Co(RNC)_4P]ClO_4$ is formed in about 70% yield within 5 min after the mixing and that the concentration of $[Co(RNC)_4P]ClO_4$ remains practically constant after 2 days. The equilibrium is apparently favorable for the formation of $[Co(RNC)_4P]^+$. However, an accurate measurement of this equilibrium would be hampered as the following observation implies. When $NaClO_4$ was added to an ethanol solution of $[Co(RNC)_4P]_2CoCl_4$ the least soluble complex $[Co(RNC)_3P_2]ClO_4$ (100% purity) was slowly precipitated out, whereas the addition of $NaClO_4$ to the cold (below 10 °C) methanol solution caused rapid precipitation of $[Co(RNC)_4P]ClO_4$ (about 90% purity).

Structure. The ^1H NMR spectrum of complex $[Co(CH_3C_6H_4NC)_5]ClO_4$[10] shows a singlet absorption at τ 7.58 (15 H) assignable to the methyl protons and a slightly broad singlet at τ 2.68 (20 H) due to the ring protons (Fig. 1). An infrared study on $[Co(C_6H_5NC)_5]ClO_4$[11] suggested the molecular structure to be trigonal bipyramid. Later the stereochemistry for $[Co(CH_3NC)_5]ClO_4$ was established by a single-crystal X-ray analysis.[12] By analogy the same stereochemistry may be assumed for $[Co(p\text{-}CH_3C_6H_4NC)_5]ClO_4$. Unexpectedly the ^1H NMR spectrum shows



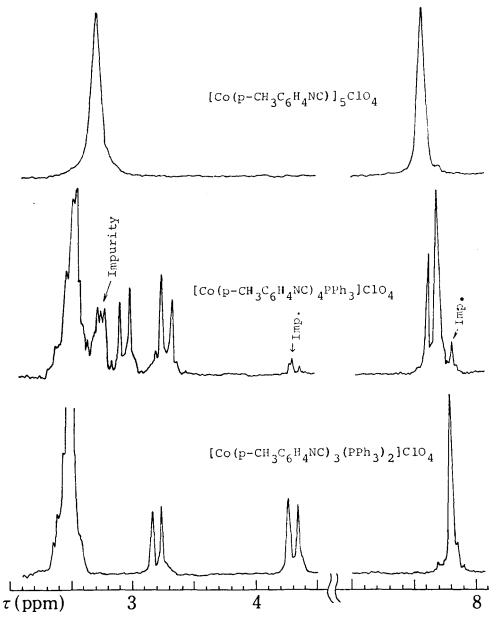


Fig. 1. NMR spectra of *p*-tolylisocyanide Co(I) complexes.

only one sharp singlet resonance for the methyl protons implying the stereochemical non-rigidity in solution[4] or the rapid ligand exchange.[4a]

The NMR spectrum of $[Co(RNC)_3P_2]ClO_4$ shows a singlet at τ 7.80 (~9 H), and two doublet resonances with coupling constant 8 Hz due to ring protons at τ 4.28 (~6 H) and τ 3.17 (~6 H). In addition to resonances a complex peak (~30 H) appeared at τ 2.46, which is assignable to the ring protons of the triphenylphosphines (Fig. 1). The observation of one sharp singlet for the methyl protons suggests equivalence with respect to the isocyanide ligation. Consistent with this is the AB type resonance for the isocyanide ring protons. Thus the complex is deduced to have a trigonal bipyramidal structure with the two phosphine ligands at axial positions (III).

The NMR spectrum of the $[Co(RNC)_4P]^+$ cation was somewhat complicated owing to the contamination of $[Co(RNC)_5]^+$ and $[Co(RNC)_3P_2]^+$. Subtraction of the absorptions due to the latter two leaves a spectrum showing two singlets for the methyl protons at τ 7.68 (~9 H) and 7.62 (~3 H), and three doublet resonances for ring protons at τ 3.25 (J 8 Hz, 6 H), 2.90 (J 8 Hz, 6 H), and 2.70 (J 5 Hz, 4 H). Based on the coupling schemes and the intensity data, the ring proton resonances at τ 3.25 and τ 2.90 (12 H), a typical AB type spectrum for *para*-disubstituted aromatic ring protons, are assigned to those of three equivalent *p*-tolylisocyanide ligands and the one at τ 2.70 (~4 H) with J=5 Hz to the ring protons of the axial isocyanide ligand. The assignment is supported by the intensity ratio (3/1) for the methyl protons. Thus a trigonal bipyramidal structure (II) is also confirmed.

It may be of interest to examine the infrared spectra. Table 1 summarized the CN stretching absorptions measured in Nujol mull and in acetone solution. The CN stretching frequencies of $[Co(PhNC)_5]^+$ have been reported by Cotton and Parish,[11] who observed with a rock-salt prism two CN stretching bands corresponding

to the E′ and A_2'' modes. Our solution spectrum (Fig. 2) for $[Co(RNC)_5]^+$ measured with a grating spectrometer also shows two strong CN bands as expected for the trigonal bipyramidal configuration. If $[Co(RNC)_4P]^+$ has C_{3v} symmetry, it will require three CN stretching bands ($2A_1$ and E). Two medium and one strong absorptions are observable; the intensity data suggest that the band at 2088 cm^{-1} corresponds to E mode vibration and the other two bands of medium intensity to A_1 mode. For the isostructural (C_{3v}) penta-coordinate carbonyl complexes of a formula $ML(CO)_4$, where M is Fe or Co and L is PR_3, SiR_3, SnR_3, GeR_3, *etc*, the carbonyl stretching band of the lowest frequency was assigned to E mode and the two higher bands to A_1 mode.[13] The cation $[Co(RNC)_3P_2]^+$ of D_{3h} symmetry should show only one CN stretching (E′). The strong band at 2067 cm^{-1} is presumably assignable to E′ mode vibration. In addition to the fundamental vibration a medium intensity band appears at 2035 cm^{-1}. Very weak additional bands also occur for $[Co(RNC)_4P]^+$ and $[Co(RNC)_5]^+$. Observation of more bands than required by the group theory is not uncommon for complexes ligated by CO, C≡N⁻, or RNC.[14] A rationale could be a combination or overtone band whose intensity is gained by Fermi resonance with the fundamental, a deviation from the idealized symmetry[11] which renders the totally symmetric mode slightly infrared active, or a ^{13}C isotopic band. We have no proof at the moment for discernment of these effects. However, we regard the weak absorptions to be non-fundamental. Despite complications, an important feature is observable from Fig. 2. The most intense bands corresponding to either E or E′ mode are the radial modes, decrease in wave numbers along the series: $[Co(RNC)_5]^+ > [Co(RNC)_4P]^+ > [Co(RNC)_3P_2]^+$. The decrease in CN stretching frequencies is explicable in terms of the increase in back donation to the equatorial isocyanide ligands due to the increase in number of the more electron-donating PPh_3 molecule.[15a] This view receives further support from the NMR spectroscopic study below.

NMR Spectra. Free *p*-tolylisocyanide in $CDCl_3$ shows a sharp signal at τ 7.66 which is due to the methyl protons and a somewhat broader signal at τ 2.8 whose top splits slightly into doublet (J 2 Hz). In *para*-disubstituted benzenes additivity of the substituents effect on the chemical shift of the ring protons are generally recognized and interpreted in terms of pi-electron densities.[15,16] However, no report along this line has been made on the aromatic isocyanides. Further we are unable to locate the isocyanide group in the Hammett scale. As the electron-attracting property is apparent,[17] it is unlikely that CH_3– and C≡N– groups are comparable with respect to the overall electronic effect (mesomeric plus inductive effect). The proximity between the chemical shifts for H_o and H_m appears to be a fortuitous result derived from the substituent electronic effect plus the neighbor

magnetic anisotropy. Thus the known empirical equation (1)[15] for the substituent electronic effects, should be modified into Eq. (2) to accommodate the latter effect,[18-21] where σ_o is the chemical shift for H_o, σ_M the magnetic screening constant, and α determines the contribution.

$$\sigma_E = d_o(R_1) + \gamma(R_1)d_m(R_4) \quad (1)$$

$$\sigma_o = \sigma_E + \alpha\sigma_M \quad (2)$$

The chemical shift for H_m may be expressed by an equation analogous to Eq. (1), since the neighbor anisotropy decreases with the cube of distance.[22] An interesting fact is a nearly linear correlation between the NC stretching frequencies (E or E′ mode) and the chemical shifts of ring protons. The H_m or H_o proton shows a regular up-field shift in the series $[Co(RNC)_{5-n}P_n]^+$ (n=0, 1, 2). The $\Delta\nu$ (difference with respect to ν_{NC} of free *p*-$CH_3C_6H_4NC$) and $\Delta\tau$ (difference with respect to τ values of free *p*-$CH_3C_6H_4NC$) values for n=0, 1, 2 are respectively 26, 43, 64 (cm^{-1}) and −0.12, 0.45, 1.48 (ppm) for H_m; $\Delta\tau$ values for H_o are −0.12, 0.10, and 0.37 (*vide infra* for the assingment). These values reasonably satisfy relation $\Delta\tau=k\Delta\nu$. Since vibronic characteristics of a bond are not influenced by the magnetic property, the linear correlation implies either a negligible contribution of term $\alpha\sigma_M$ or a linear dependency of the magnetic term upon the electronic term σ_E. Although it is difficult to assess the absolute value of term $\alpha\sigma_M$ (and the two factors may be inseparable), a qualitative discussion can be given as follows. The magnetic field due to electric currents at an acetylenic or an isocyanide group[19,23] is expected to decrease with increase in electron drainage into the anti-bonding π orbital. This is understandable if we consider an effective overlap of pπ orbitals of a CN group with those of the aromatic ring, which occurs only with one of the two orthogonal pπ double bonds of the CN group. The overlap leads to a delocalized system M—C≡N—Aryl, thus relating to the effectiveness of the metal-ligand π-back bonding. The axial symmetry of a triple bond responsible for the magnetic anisotropy will readily be destroyed with inequal participation of the pπ bonds in the delocalized system M—C≡N—Aryl. Interaction of moiety M–C≡N– with the aromatic ring attached was demonstrated explicitly by unpaired spin density in some paramagnetic metal complexes.[24] Coefficient α decreases linearly with increase in dπ-pπ back bonding, and the abnormal ^1H NMR spectrum of *p*-$CH_3C_6H_4NC$ relaxes dramatically to that of $[Co(RNC)_4P]^+$ or $[Co(RNC)_3P_2]^+$ typical for *para*-disubstituted benzenes.

It is evident that the contribution of σ_M in free *p*-$CH_3C_6H_4NC$ renders the chemical shift for H_o higher than that for the coordinated isocyanide molecule bringing up the chemical shift of H_o near to that of H_m. If this is the case, the two ring proton resonances in $[Co(RNC)_4P]^+$ and $[Co(RNC)_3P_2]^+$ can be assigned; *i.e.*, the higher field resonance to H_m and the lower one to H_o. A slight downfield shift (−0.12 ppm relative to free(*p*-$CH_3C_6H_4NC$) observed for the ring protons in $[Co(p\text{-}CH_3C_6H_4NC)_5]^+$ is also explicable in terms of a σ-type donation from the isocyanide ligand to the Co(I) ion.

The Dissolution of $CaMg(SiO_3)_2$ in Acid Solutions[1]

Isao SANEMASA* and Takashi KATSURA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 15, 1973)

The dissolution phenomena of synthesized diopside, $CaMg(SiO_3)_2$, and a glassy material of the same composition in an acid solution were studied. The results observed in the dissolution of the glass were as follows; the molar concentrations of Ca dissolved in the solution are equal to those of Mg throughout the dissolution of the glass. The rate at which the cations go into solutions are proportional to the surface area up to about a 60% dissolution. The dissolution behavior of silica is similar to that of cations. A residual layer rich in silica is formed, one which is no longer dissolved after the removal of the cations. The results observed in the dissolution of the crystalline diopside were as follows; there is an initial rapid dissolution of the components, followed by another process. The molar ratios of the Ca ions to the Mg ions, and of each cation to silica in the solutions, are larger than those in the solid during the course of the reaction; they are especially large in the initial dissolution stage. An essential feature of diopside dissolution is that the Ca ions are more readily removed from the crystal than are the Mg ions. This fact is also confirmed in the natural diopside crystal. While the rates of the dissolution of the cations are not affected by the concentrations of HCl and $HClO_4$, the concentration of H_2SO_4 does have an influence. Diopside cannot be dealt with as a single species participating in the heterogeneous reaction because its various components show selective dissolution. The mechanism of the dissolution of diopside will be discussed in connection with its structure.

Dissolution studies of minerals in various solutions have been made mainly from the practical point of view.[2,3] Only a few studies have been reported on the silicate structure and its reactivity in solution. Luce *et al.*,[4] however, who studied the dissolution of serpentine, forsterite, and enstatite, reported on the relationship between the silicate structure and the diffusion coefficients of silicon and magnesium.

In a previous paper,[5] the dissolution phenomena of olivine in various acid solutions were reported.

Pyroxenes can be divided, according to the crystal systems, into orthorhombic and monoclinic pyroxenes. The essential feature of all pyroxenes, however, is the linkage of SiO_4 tetrahedra by sharing two out of four corners, thus forming continuous chains with the composition of $(SiO_3)_n$,[6] in contrast to the olivine structure with fundamental isolated SiO_4 tetrahedra. Diopside, which has the monoclinic form, was studied crystallographically by Warren and Bragg,[7] and its unit cell was found to be $4[CaMg(SiO_3)_2]$.

In this experiment, the dissolution phenomenon of diopside in acid solutions was studied in comparison with that of a glassy material of the same composition in order to obtain some information concerning the reactivity and the solid structure.

Experimental

Materials. In the present study, diopside was synthesized, because natural diopside always contains some iron. The synthetic method was as follows. Firstly, appropriate amounts of CaO, MgO, and SiO_2 corresponding to the composition of $CaMg(SiO_3)_2$ were thoroughly mixed with ethyl alcohol. Then the mixture was heated at 1450 °C and quenched in cold water to obtain a glassy material. The glass was crushed in an agate mortar and mixed well. The operations of mixing, melting, and rapid cooling were repeated three times. The glass was heated overnight at 1100 °C to obtain a completely crystallized phase. The powder X-ray diffraction pattern is in complete agreement with the NBS natural diopside data.[8] Electron microprobe analysis[9] showed homogeneous particles (about 5 μ). The synthesized diopside and the glass were ground in an agate mortar and then fractionated by suspension in methyl alcohol. Two kinds of particle sizes of the glass were obtained: one was 20—40 μ, and the other was 40—80 μ. The particle size of the synthesized diopside was 20—40 μ, but strict uniformity of size could not be obtained because of the brittle property of the particles.

In this study, a finely powdered sample of a natural diopside was used; it had been obtained from Gongen-yama, Ehime Prefecture. This diopside had the following chemical composition[10]: SiO_2, 51.86; TiO_2, 0.20; Al_2O_3, 1.02; Fe_2O_3, 0.99; FeO, 1.73; MnO, 0.02; MgO, 17.09; CaO, 25.24; Na_2O, 0.08; K_2O, 0.06; $H_2O(-)$, 0.25; $H_2O(+)$, 1.88%. The atomic percentages of Mg, Fe, and Ca were 46.6, 4.0, and 49.4 respectively.

Reagents, Equipment, and Measurements. All the chemicals used were of an analytical-reagent grade. The apparatus used in the present study was the same as that described in the previous paper[5] except for the volume of the reaction vessel, which was 200 ml in the present study. The powdered sample (100—200 mg) was dispersed, with small amounts of water, in 100 ml of an acid solution, after which the mixture was stirred at 600 rpm. The rate of the dissolution of the sample was not affected by stirring in the range from 150 to 1200 rpm. Aliquots of the solution were

pipetted out at various reaction times and immediately filtered through a membrane-filter (0.45 μ in pore size), and the filtrates were submitted to chemical analysis. The silica was determined spectrophotometrically using the silicomolybdate yellow method. The calcium and magnesium were determined by atomic absorption measurements after the addition of a lanthanum buffer[11] to avoid interference due to the presence of silica.

Results and Discussion

Dissolution of $CaMg(SiO_3)_2$ Glass. Figure 1 shows the relationship between the concentrations of Ca dissolved in HCl solutions and the reaction times under various conditions. The molar concentrations of Mg which are leached into the solutions were found to be nearly equal to those of Ca at any time under varying experimental conditions. Figure 2 shows the relationship between the concentrations of the dissolved silica and the reaction times under different conditions. From Figs. 1 and 2, it may be noted that the dissolution behavior of the cations and silica is virtually the same. The concentrations of silica, however, are much lower than those of the cations when their relative contents in the glass are taken into account. After the summation of Ca and Mg, the molar ratios to SiO_2 in the solution are almost constant; the ratio is approximately 6 throughout the reaction. Most of the cations in the sample were depleted by the reaction after reaching a constant value of about 4.25 mM. The broken lines in Fig. 1 show the results of experiments in which twice the amount of the sample was used as that represented by the solid lines. The constant value of 8.5 mM of the dotted lines in Fig. 1 is just twice as high as that of the solid lines, regardless of the sample size, the acid concentration, and the temperature. On the other hand, only 15% of the entire silica of the sample was dissolved when the concentration of dissolved silica approached a value of 1.4 mM, as represented by the solid lines in Fig. 2. No colloidal silica was found under the present experimental conditions. When taking 200 mg of a 40—80 μ size sample, the concentrations of silica in the 0.1 and 1 N HCl solutions are 2.3 and 2.6 mM respectively after reaching a constant value. These values are significantly lower than the value of 2.8 mM calculated from the 100 mg sample. This suggests that the dissolution of a silica-rich layer formed by the reaction depends on the acid concentration as well as on the specific surface area of the sample.

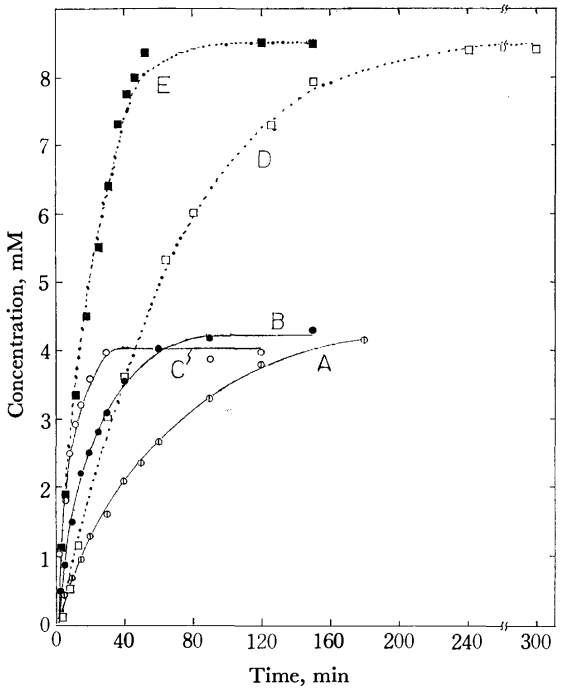

Fig. 1. Dissolution of calcium from the glass when taken 100 mg of 20—40 μ sample in 0.1 N HCl at 5 (A), 15 (B), and 25 °C(C) and when taken 200 mg of 40—80 μ sample in 0.1 N (D) and 1 N (E) HCl at 10 °C.

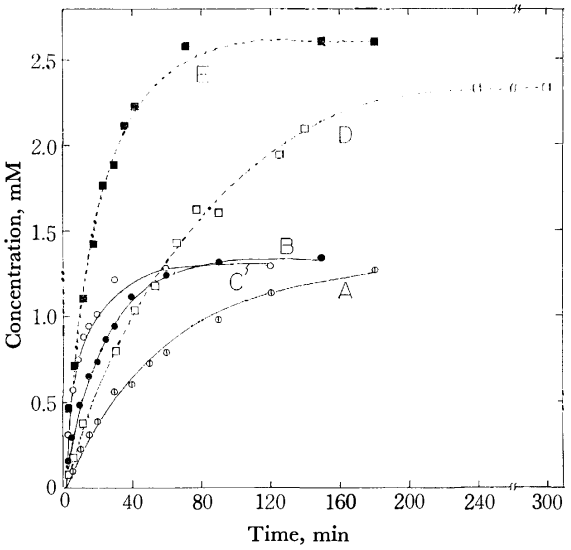

Fig. 2. Dissolution of silica from the glass. Each mark corresponds to that in Fig. 1.

Since the silica of the glass does not affect the dissolution process of the cation, regardless of the particle size and other experimental conditions, the cations in the glass may be considered to be independent parts of the solid. Consequently, the rate of the dissolution of the cation can be treated in the same way as in the case of olivine,[5] in which

$$-\mathrm{d}w/\mathrm{d}t = k_0 sC \qquad (1)$$

where w and s indicate the weight and the surface area of the "particle" which remains at the reaction time, t, respectively; where k_0 is the rate constant per unit area, and where C is the concentration of the reactant. Equation (2) may be derived from Eq. (1) as has been described in a previous paper;[5]

$$1-(1-\alpha)^{1/3} = 1/3\, kW_0^{-1/3}t \qquad (2)$$

where k is a constant and where α has the following definition;

$$\alpha = (W_0 - W)/W_0 = (\Delta W)_{t,\mathrm{sol}}/W_0$$

where W_0 is the weight of the sample taken at time zero and where $(\Delta W)_{t,\mathrm{sol}}$ is the weight loss of the cation in the sample at time t, as can be determined by

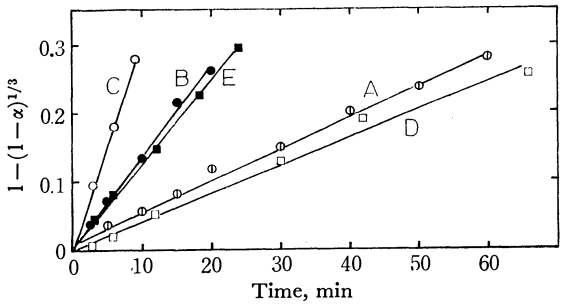

Fig. 3. Plots of dissolution rate of calcium from the glass according to Eq. (2). Each mark corresponds to that in Fig. 1.

the concentrations of the cations in the solution. The plot of $1-(1-\alpha)^{1/3}$ *vs.* t is shown in Fig. 3. As a matter of convenience, the plots are limited only to the case of the dissolution of Ca, but there is no distinction between Ca and Mg. Figure 3 gives straight lines up to about a 60% dissolution of the cations of the glass. This suggests that the rates of the dissolution of cations are directly proportional to the surface area of the solid sample. The relationship between the slopes of the straight lines in Fig. 3 and the reaction temperature is illustrated by the Arrhenius plot shown in Fig. 4. The apparent activation energy is found to be 16 kcal/mol.

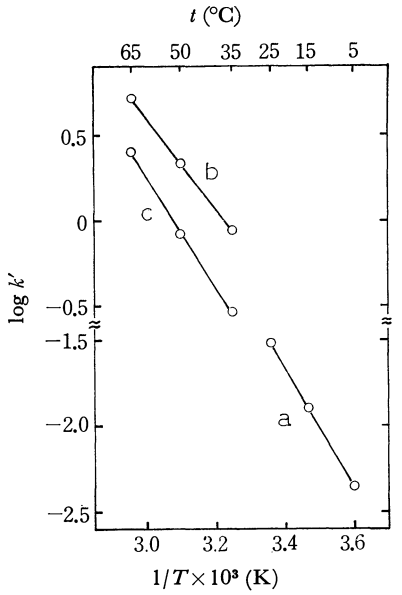

Fig. 4. Arrhenius plots for the dissolution of cation from the glass and diopside.
a: Ca from the glass, b: Ca from diopside, C: Mg from diopside.
In the case of the glass, k' corresponds to $1/3\ kW_0^{-1/3}$ in Eq. (2), while in the case of diopside, k' is estimated from the slopes in the plots of square concentration of each cation against time in Fig. 6 and is then expressed in mM^2/hr.

In order to give a more detailed explanation of the mechanism of the dissolution process of the cations of the glass, experiments were performed in which the cations were added at time zero. The results of these investigation are shown in Fig. 5. The concentrations of Ca and Mg added alternatively to a 0.1 N HCl solution at time zero were 3.5 and 1.99 mM respectively. From Fig. 5 it is evident that the added cation of Ca or Mg does not affect the dissolution of the Ca and Mg of the glass.

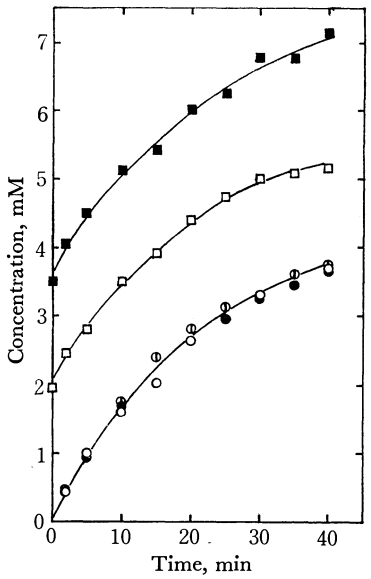

Fig. 5. Effect of added calcium, 3.50 mM (■) and magnesium, 1.99 mM (□) on the rate of dissolution of cation from the glass by using 0.1 N HCl at 15 °C.
○: none added, ⓘ: Ca when Mg added, ●: Mg when Ca added.

Some of the results obtained in the present study are suitable to illustrate the mechanism of the dissolution of the glass in an acid solution. When cations on the surface of the glass pass into the solution by means of a reaction at the interface, hydrated protons diffuse into the solid and are adsorbed on negatively-charged oxygen ions. Then, cations of the glass, in which they are distributed at random and are undistinguishable from each other, are transported to the solution, thus leaving cavities. This is followed by a transportation to the bulk solution, involving diffusion through the residual layer of the silica. A part of the hydrated protons contained in the cavities can be used to break up the silica chain to be dissolved. The broken chains thus formed can be recombined by hydrogen bonds in various directions to form a three-dimensional framework such as silica gel. An X-ray examination of the sample after the reaction shows a broad peak corresponding to silica gel (22—23° as 2θ in CuK_α). Therefore, the dissolution of the silica of the glass appears to be accompanied by that of the cations.

According to Bircumshaw,[12] a reaction between a solid and a solution generally comprises the following steps:

(a) the transportation of solute molecules to the interface,
(b) adsorption on the surface,
(c) reaction on the surface,
(d) the desorption of reaction products, and
(e) the recession of the products from the interface.

In addition to these steps, (f) the diffusion process

12) L. L. Bircumshaw and A. C. Riddiford, *Quart. Rev.*, **6**, 157 (1952).

through the residual layer formed by the reaction, must be considered in the present case. The rate of dissolution of the cations of the glass up to about 60% is considered to be controlled by step (c) in view of the following experimental results: the stirring speed has no influence on the rate, the activation energy is quite high (16 kcal/mol), the rate obeys Eq. (2) and not the so-called parabolic law, and additional cations have no influence on the rate. However, the rate of the dissolution of the cations over 60% is gradually lowered below the value anticipated from Eq. (2). This may be attributable to the influence of the diffusion process of the cations through the residual layer of silica, the thickness of which is increasing.

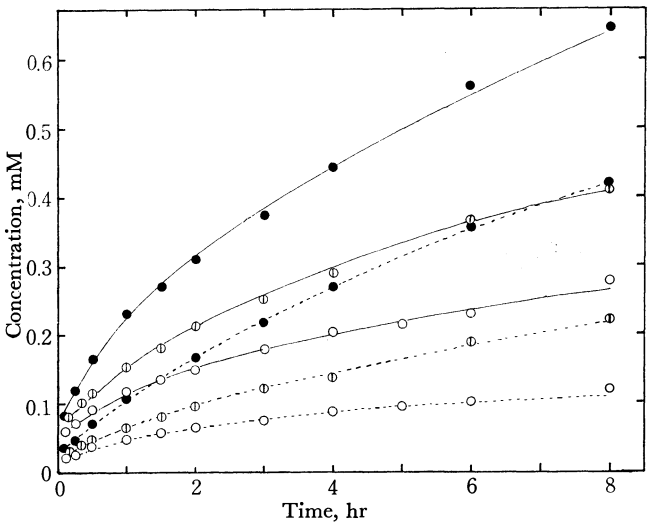

Fig. 6. Dissolution of calcium (solid) and magnesium (broken) from diopside in 0.1 N HCl at 65 (●), 50 (◐) and 35 °C (○).

The Dissolution of Diopside. Figure 6 shows the concentrations of Ca and Mg which are leached from 200 mg of the synthetic diopside with 0.1 N HCl solutions at 35, 50, and 65 °C. The molar ratios of Ca/Mg in the solutions are greater than unity, and are especially high in the earlier part of the reaction, in which the ratios are in the range from about 2 to 3. In order to ascertain the effect of the temperature on the rate of the dissolution of cations, the square concentrations of Ca and Mg in the solution are plotted against the time for the sake of convenience. Straight lines are thus obtained for Ca, while in the case of Mg linear plots can be drawn after 2 or 3 hr. The relationship between the slope of the straight line for each cation and the reaction temperature is illustrated in Fig. 4. According to the Arrhenius plot, the apparent activation energies for Ca and Mg can be estimated from Fig. 4 to be 12 and 15 kcal/mol respectively. This suggests that the rate of the dissolution of Mg is affected by the temperature change more intensively than that of Ca.

In order to investigate the effect of the acid concentration on the dissolution of diopside, experiments were carried out at 65 °C by using HCl solutions of concentrations ranging from 0.1 to 1 M. From the results, it can be seen that the concentration of HCl solutions

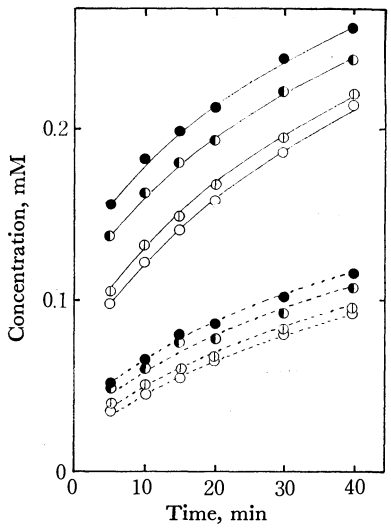

Fig. 7. Effect of HCl concentration on the dissolution of calcium (solid) and magnesium (broken) from diopside at 65 °C.
●, 1; ◐, 0.5; ◑, 0.2; ○, 0.1 N.

in this range has no influence on the rate of the dissolution of either Ca or Mg during the course of the reaction (8 hr), but is reflected only by the initially-dissolved amount of the cations. This effect was investigated in more detail by varying the concentrations of HCl solutions, with emphasis on the earlier part of the reaction (Fig. 7). It can be seen from Fig. 7 that variations in the acid concentration affect the initially-dissolved amount of Ca more intensively than that of Mg. There is an initial rapid increase in the concentration of each cation, an increase which cannot be followed by lowering both the reaction temperature and the acid concentration. The results in the $HClO_4$ solutions ranging from 0.1 to 2 N are almost the same as those obtained

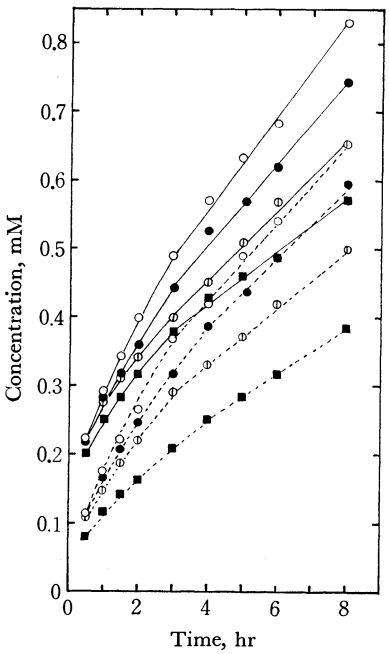

Fig. 8. Effect of H_2SO_4 concentration on the dissolution of calcium (solid) and magnesium (broken) from diopside at 65 °C.
○, 2; ●, 1; ◑, 0.5; ■, 0.1 N.

in HCl. On the other hand, the results in H_2SO_4 solutions (see Fig. 8) are different from those in HCl and $HClO_4$ solutions. From Fig. 8, it is evident that the rates of the dissolution of cations increase with an increase in the concentrations of acid, and that the concentrations of cations increase linearly with the time in the later steps of the reaction. There is also a difference in the reactivities of the cations; that is, the amount of Ca initially dissolved is about three times larger than that of Mg. Responsible for the specific action of H_2SO_4 appear to be the HSO_4^- species in the solution, as has also been observed in the dissolution of olivine[5] and gibbsite.[13]

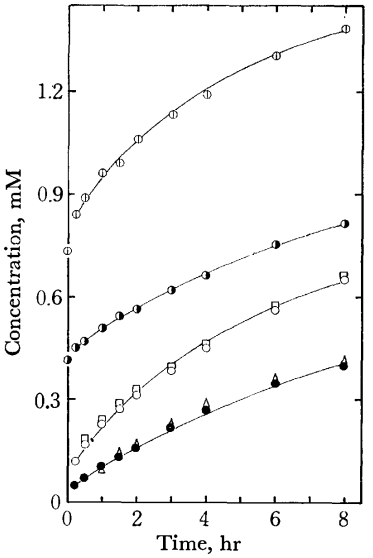

Fig. 9. Effect of added calcium, 0.73 mM (◐) and magnesium, 0.411 mM (◑) on the rate of dissolution of cation from diopside in 0.1 N HCl solutions at 65 °C.
○, Ca when none added; □, Ca when 0.411 mM of Mg added;
●, Mg when none added; △, Mg when 0.73 mM of Ca added.

In order to obtain information about the leaching of cations from diopside, experiments were carried out in which known amounts of Ca or Mg ions were added at the start of the reaction by using 0.1 N HCl solutions at 65 °C. From the results of these investigations (shown in Fig. 9), it can be seen that, on the addition of 0.73 mM of Ca or 0.41 mM of Mg, the concentration of each cation observed at any time is equivalent to the sum of the concentrations of the added and the dissolved cations. In the presence of a twofold concentration of each cation, this sum is lowered to about 10% in each case. However, this value is not precise because of an uncertainty in the determination of such a high concentration of added cation.

As the next step, the dissolution of silica from diopside was investigated. Figure 10 shows the results of a series of experiments which were carried out at 65 °C by using HCl and H_2SO_4 solutions of varying concentrations. Colloidal silica was not detectable under these experimental conditions. It can be seen from Fig. 10 that the rate of the dissolution of silica increases with an increase in the acid concentration.

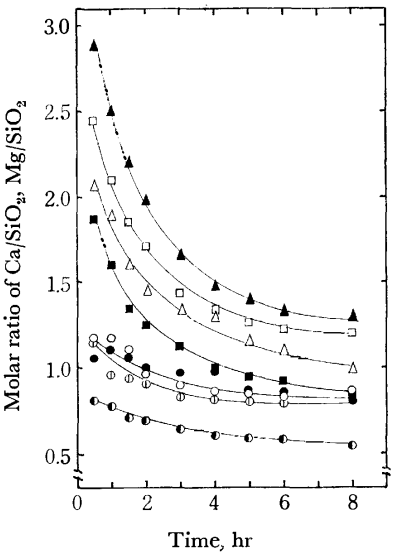

Fig. 11. Molar ratio of Ca/SiO_2 and Mg/SiO_2 in solution dissolved from diopside at 65 °C.
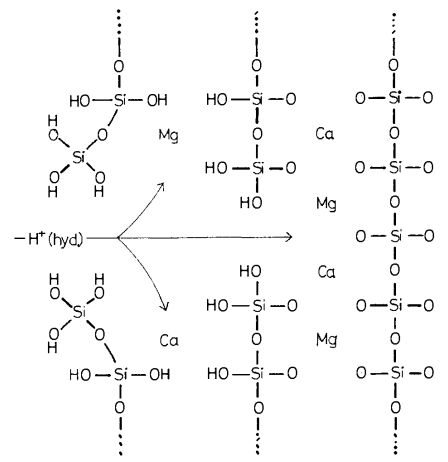
Ca/SiO_2: ■, 1 N HCl; □, 0.1 N HCl; △, 1 N H_2SO_4; ▲, 0.1 N H_2SO_4.
Mg/SiO_2: ◐, 1 N HCl; ◑, 0.1 N HCl; ●, 1 N H_2SO_4; ○, 0.1 N H_2SO_4.

The dependence on the time of the molar ratios of Ca or Mg to SiO_2 in the solutions under the same experimental conditions is shown in Fig. 11. From the figure it can be seen that the dissolution is selective not only with respect to Ca and Mg, but also between cations and silica, since the ratio of each cation to silica in the solid is 0.5. At higher concentrations of HCl, however, the molar ratio of Mg/SiO_2 in solution approaches that in the solid because the dissolution of silica is enhanced by an increase in the acid concentration, while that of the cation is not.

Discussion on the Dissolution of Diopside. The dissolution of diopside can be divided into two processes: one is the initial rapid dissolution, which cannot be followed even if the reaction temperature and the acid concentration are both lowered, while the other is the successive dissolution after the initial dissolution. Cations to be dissolved in the solution must be liberated from the negatively-charged oxgen ions surrounding them. On the solid surface, the distances of Ca–O and Mg–O will be slightly different from those in the "perfect" diopside lattice, as was pointed out by Pryor *et al.*[14] in their dissolution study of ferric oxide. In the diopside crystal, moreover, there are good cleavages parallel to the direction of the silica-chain arrangement. Consequently, the dissolution takes place most readily at the surface, where the energy required for dislodging the cations is smaller than in the interior. At the same time, silica is dissolved, but its amount is considerably smaller than that of the cation (see Fig. 11). This selective dissolution of silica might be due to its chain structure, which consists of SiO_4 tetrahedra. Consequently, after the removal of the cations, the silica-chain, parts of which are broken, remains, forming a residual layer containing Si–OH groups which probably shows almost the same directional arrangement as the crystal. Judging from the selective dissolution between Ca and Mg, a part of the Mg may be contained in this residual layer. The problem is, however, to find out from which direction of the silica-chain, *i.e.*, parallel or at right angles, the reactants (hydrated protons) enter into the solid and in which direction the soluble products go out. If the existence of cleavages in the diopside parallel to the direction of the chain is assumed, the reaction may proceed predominantly at right angles to the chains, and a dissolution process of the kind shown in Scheme 1 may be suggested. In the diopside, silica-chains are combined to one another by an equal number of Ca and Mg ions. After the rapid removal of cations and the severance of the silica-chain, which may be caused by the adsorption of hydrated protons on the negatively-charged oxygen ions of the solid surface, the hydrated protons enter the solid through the open parts of the chain;



Scheme 1.

a part of them permeate parallel to the chains, and the remainder, at right angles. As cations are removed from the chains, these are set free just as if opening a "fastener" and undergo successive hydrolysis to be dissolved. The hydrated protons participating in the reaction may mainly be consumed in the hydrolysis reaction, because the rates of the dissolution of cations are not affected by the concentration of acid, while that of silica is dependent on the acidity. Consequently, the dissolutions of the cations and the silica appear to be independent of each other. In this respect, there is a substantial difference between diopside and its glass (see Figs. 1, 2, and 11). This difference may be attributed to residual silica layers in diopside which are not in a suitable arrangement to be recombined in the three-dimensional networks as they are in the glass.

It is problematical whether or not the rates of dissolution of cations are controlled by their diffusion process through the channels in the residual silica layers, as is shown in Scheme 1. It is, however, somewhat difficult in our present study to clarify the rate-determining step for two reasons. One reason is the uncertainty of the sample size. A part of the synthesized diopside probably consists of agglomerates of particles of a smaller size; therefore, the particle size is not uniform. The other is that the amounts of cations dissolved into the solution are only 8% or less of the solid under the selected experimental conditions. Regardless of these disadvantages, though, the results summarized below can be used in examining the problem of diffusion:

(1) The concentrations of the cations increase almost linearly with $t^{1/2}$ except for the initial rapid stages in HCl and $HClO_4$ (Fig. 6).
(2) While in H_2SO_4 they increase almost linearly with t in the later stages of the reaction (Fig. 8).
(3) The apparent activation energies of Ca and Mg are different from each other (Fig. 4).
(4) The addition of cations has no influence on the rates of dissolution (Fig. 9).
(5) Although the molar ratio of Mg/SiO_2 in the 1 N HCl solution approaches that in the solid as the reaction proceeds (Fig. 11), the dissolution mode of Mg is not changed.

Of these results, (1) seems to indicate that the rate of the dissolution of cations is controlled by the diffusion of the reactants and/or the reaction products. On the other hand, (2), (4), and (5) do not seem to show that the rate of dissolution of cation is controlled by the diffusion of the reaction products. Furthermore, (2) and (3) seem to give little evidence that the rate of dissolution of cations is controlled by the diffusion of the reactants. Consequently, the present experimental results do not necessarily support the assumption that the rate of the dissolution of cations is controlled by the diffusion process only. A better picture or a more detailed mechanism of acid-reactivity of diopside in connection with the silica-chain structure could be obtained by employing a single crystal.

In the dissolution of cations, there is an important and substantial difference between diopside and its

14) M. J. Pryor and U. R. Evans, *J. Chem. Soc.*, 3330 (1947).

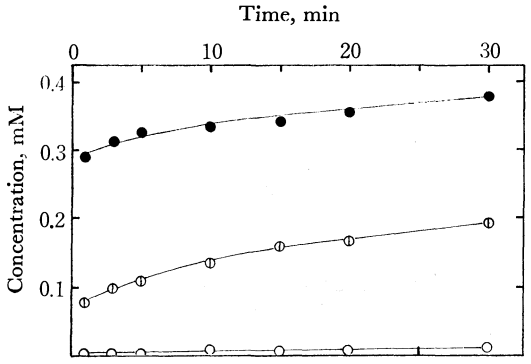


Fig. 12. Dissolution of calcium (●), magnesium (◐), and iron (○) from natural diopside in 0.1 N HCl at 65 °C.

glass. That is, in the glass the dissolution behavior of Ca and that of Mg are undistinguishable from each other, while in diopside Ca is more readily dissolved than Mg, especially in the preliminary stage of the reaction. This phenomenon appears to be essential for diopside; it was also observed in the dissolution of natural diopside (see Fig. 12). It can be seen from Fig. 12 that the concentration of Ca which is initially dissolved is more than three times larger than that of Mg, and that the initial rapid dissolution of the cations is promoted because of the large specific surface area of the pulverized sample, with its abundant cleavages. The reason why Ca in diopside passes more readily into a solution than does Mg might be attributable, when this case is compared with that of glass, to the difference in the states of the cations. That is to say, in the glass a fused structure is "frozen in" in which Ca and Mg are randomly distributed and in which the cations are kept as far apart as possible by vigorous thermal movement and by mutual repulsion. On the other hand, in diopside Ca is surrounded by eight, and Mg by six oxygen atoms. However, we cannot offer a more detailed explanation of the situation.

We wish to express our deep gratitude to Dr. Takejiro Ozawa and to Dr. Minoru Yoshida of the Tokyo Institute of Technology for their guidance and encouragement throughout this work. We are also indebted to Dr. Shigeo Aramaki of The Earthquake Reserch Institute of The University of Tokyo, who examined the synthetic diopside by means of electron-micro-probe analysis. We wish to express our thanks to Dr. Mitsuo Muramatsu of Tokyo Metropolitan University for his helpful discussion. Thanks are also due to Mr. Hiroshi Haramura, who kindly supplied us with an analyzed sample of natural diopside.

Polarographic Studies of the Rates of the Dissociation Reactions of Cobalt(II)-Iminodiacetate, -Aspartate, and -2,2′-Ethylenedioxydi(ethylamine)-*N*,*N*,*N*′,*N*′-tetraacetate Complexes

Mutsuo KODAMA

Department of Chemistry, College of General Education, Hirosaki University, Bunkyo, Hirosaki 036

(Received March 22, 1973)

The cobalt(II)-IDA, -Asp, and -GEDTA complexes produce kinetic wave due to their dissociation preceding the electron-transfer step at the electrode surface. From an experimental examination of the nature of these kinetic waves, the dissociation mechanisms were determined to be:

i) IDA and Asp systems,

$CoX_2^{2-} \rightleftarrows CoX^0 + X^{2-}$ rate-determining step

$CoX^0 + 2e^- + Hg \rightleftarrows Co(Hg) + X^{2-}$

ii) GEDTA system,

$CoY_2^{6-} \rightleftarrows CoY^{2-} + Y^{4-}$ in a rapid equilibrium

$CoY^{2-} \rightleftarrows CoY^{2-}{}^*$ rate-determining step

$CoY^{2-}{}^* + 2e^- + Hg \rightleftarrows Co(Hg) + Y^{4-}$

where $CoY^{2-}{}^*$ is the electroactive cobalt(II)–GEDTA complex produced upon the partial dissociation of the normal cobalt(II)–GEDTA complex with a 1:1 composition. From the relative rate constants for these complexes, the detailed structures of the reaction intermediates in their dissociation were also obtained.

In earlier papers,[1,2] we reported systematic studies of the polarographic behavior of the nickel(II)–iminodiacetate (IDA), –aspartate (Asp), and –glutamate (Glut) complexes and those of the nickel(II), zinc(II), and cadmium(II)–2,2′-ethylenedioxydi(ethylamine)-*N*,*N*,*N*′,*N*′-tetraacetate (GEDTA) complexes. All these complexes produce kinetic waves as a result of their dissociation at the electrode surface. From an experimental examination of the nature of these kinetic waves, we concluded that (1) the kinetic waves observed in the polarography of the nickel(II)–IDA,

1) M. Kodama, H. Nunokawa, and N. Oyama, This Bulletin, **44**, 2387 (1971).

2) M. Kodama and N. Oyama, *ibid.*, **45**, 2169 (1972).

-Asp, -Glut, and -GEDTA complexes and of the zinc(II)-GEDTA complex can be ascribed to the reduction of the metal(II) aquo ions formed upon the dissociation of the metal(II)-aminopolycarboxylate complexes, whereas (2) the kinetic wave in the cadmium(II)-GEDTA system may be ascribed to the reduction of the cadmium(II)-GEDTA complex formed by the partial dissociation of the original complex. The cobalt(II)-IDA, -Asp, and -GEDTA complexes also produce kinetic waves as a result of their dissociation. In this paper, we will report a systematic study of the nature of the above-mentioned kinetic waves and will determine the dissociation mechanism and rates. Furthermore, from a comparison of the dissociation rate constants with those estimated on the basis of the proposed reaction intermediates, the structure of the reaction intermediates will be described in detail.

Experimental

Reagents. The procedure used to prepare the standard cobalt(II) nitrate solution was described previously.[1] L-Aspartic acid (Asp), iminodiacetic acid (IDA), and 2,2′-ethylenedioxydi(ethylamine)-*N*,*N*,*N*′,*N*′-tetraacetic acid (GEDTA) were recrystallized from their aqueous solutions by adding pure ethanol and hydrochloric acid. The standard solutions of Asp, IDA, and GEDTA were prepared by dissolving known amounts of recrystallized Asp, IDA, and GEDTA in redistilled water. All the other chemicals used were of analytical-reagent grade and were used without further purification.

Apparatus and Experimental Procedures. All the DC current-voltage curves were measured by using a manual polarograph similar to that of Kolthoff and Lingane[3] or a Yanagimoto pen-recording polarograph, PA-102. The characteristic feature of the dropping mercury electrode used in this study was described previously.[4] All the other apparatus and the experimental procedures employed were also described in the above-mentioned paper.[4] The ionic strength of the solution was adjusted to 0.30 by adding an appropriate amount of pure sodium perchlorate. In this study, no buffer mixture was used, because the sample solutions always contained a large excess of uncomplexed Asp, IDA, or GEDTA and, hence, may be considered to have a sufficient buffer capacity over the entire pH range covered ($8.10<pH<9.70$ in the IDA system, $8.45<pH<10.40$ in the Asp system, and $7.80<pH<8.50$ in the GEDTA system).

Results and Discussion

Polarographic Behavior of the Cobalt(II)-GEDTA Complex. In an acetate buffer solution containing a large excess of GEDTA, the cobalt(II)-GEDTA complex gives a single well-defined reduction wave, one which is diffusion-controlled in nature. Its half-wave potential is located at far more negative potentials than that of the cobalt(II) aquo ion. Therefore, the polarographic step observed in the acetate buffer solution can be ascribed to the direct reduction of the cobalt(II)-GEDTA complex. As is shown by the polarograms in Fig. 1, the wave-height decreases appreciably with increases in the solution pH and in the concentration of uncomplexed GEDTA; finally, the polarographic wave shows a kinetic-controlled nature. By examining the nature of the above kinetic wave with the aid of the well-known relation employed by Koryta in the polarographic study of the cadmium(II)-nitrilotriacetate complex,[5] the reaction mechanism was studied. As is clear from the Koryta equation, if the cobalt(II) ion forms only a 1 : 1 ratio complex with GEDTA and if its dissociation at the electrode surface is rate-determining, the following relation can be derived for the kinetic wave:

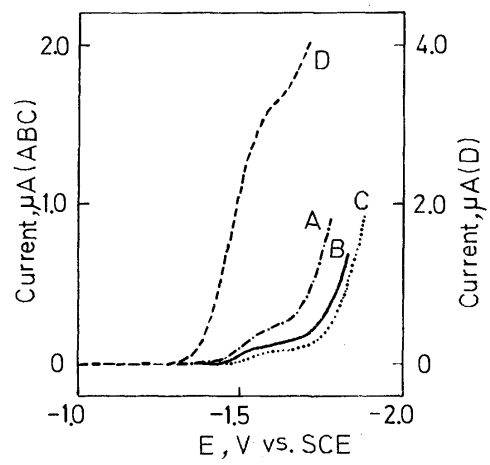

Fig. 1. Polarograms of the cobalt(II)-GEDTAcomplex, 25.0 °C, $\mu=0.30$.
A) Concentration of cobalt(II) ion = 1.0 mM
Concentration of GEDTA = 11.8 mM
pH = 7.85
B) Concentration of cobalt(II) ion = 1.0 mM
Concentration of GEDTA = 39.4 mM
pH = 7.86
C) Concentration of cobalt(II) ion = 1.0 mM
Concentration of GEDTA = 11.8 mM, pH = 8.35
D) Concentration of cobalt(II) ion = 0.53_2 mM
Concentration of GEDTA = 20.0 mM
Concentration of acetate ion = 0.06 M, pH = 5.45

$$CoY^{2-} \underset{}{\overset{k_d}{\rightleftharpoons}} Co^{2+} + Y^{4-} \quad \text{rate-determining step} \qquad (1)$$

$$\frac{i_k}{i_d - i_k} = 0.886 \sqrt{\frac{k_d \cdot (\alpha_H)_Y \cdot t}{K_{CoY} \cdot [Y]_f}} \qquad (2)$$

where K_{CoY}, $[Y]_f$, and $(\alpha_H)_Y$ are the formation constant of a 1 : 1 composition cobalt(II)-GEDTA complex, the concentration of uncomplexed GEDTA, and the (α_H) value of GEDTA respectively. Here, i_d in Eq. (2) is the hypothetical diffusion current. Previously,[6,7] we mentioned finding in our polarographic study that the nickel(II), copper(II), and cadmium(II) ions can form 1 : 1 and 1 : 2 ratio complexes with GEDTA under normal experimental conditions. If the cobalt(II) ions also form a 1 : 2 ratio complex with GEDTA, and if the dissociation of the 1 : 1 ratio complex is rate-determining, we can hypothesize the following mechanism(I):

3) I. M. Kolthoff and J. J. Lingane, "Polarography," Vol. I, Interscience Publishers, New York (1952), p. 297.
4) M. Kodama, Y. Fujii, and T. Ueda, This Bulletin, **43**, 2085 (1970).
5) J. Koryta, *Collect. Czech. Chem. Commun.*, **24**, 3057 (1959).
6) M. Kodama and T. Ueda, *Nippon Kagaku Zasshi*, **91**, 138 (1970).
7) M. Kodama and Y. Tominaga, This Bulletin, **42**, 394 (1964).

(I)
$$CoY_2^{6-} \overset{K_2}{\rightleftharpoons} CoY^{2-} + Y^{4-} \quad (3)$$
$$CoY^{2-} \overset{k_d}{\rightleftharpoons} Co^{2+} + Y^{4-} \quad \text{rate-determining step} \quad (4)$$

For the above reaction mechanism, one can derive Eq. (5) for the kinetic wave:

$$\frac{i_k}{i_d - i_k} = 0.886 \sqrt{\frac{k_d \cdot (\alpha_H)_Y \cdot t}{K_{CoY} \cdot [Y]_f}} \cdot \frac{1}{1 + K_2' \cdot [Y]_f} \quad (5)$$

where K_2' is the conditional second successive formation constant of the cobalt(II)–GEDTA complex.

On the other hand, if the partial dissociation of the 1 : 1 ratio cobalt(II)-GEDTA complex, which is in a rapid equilibrium with the 1 : 2 ratio complex, is rate-determining, and if the resulting complex, CoY^{2-*}, is reducible at the electrode (Mechanism II), the following relation can be derived:

$$\frac{i_k}{i_d - i_k} = 0.886 \sqrt{\frac{k_d \cdot t}{K}} \cdot \frac{1}{1 + K_2' \cdot [Y]_f} \quad (6)$$

where K is the equilibrium constant for (7).

(II)
$$CoY_2^{6-} \rightleftharpoons CoY^{2-} + Y^{4-} \quad \text{in a rapid equilibrium} \quad (3)$$
$$CoY^{2-} \overset{k_d}{\rightleftharpoons} CoY^{2-*} \quad \text{rate-determining step} \quad (7)$$

Furthermore, if the cobalt(II) ion forms only a 1 : 1 ratio complex with GEDTA, and if its partial dissociation (7) is slow-step, the $i_k/(i_d - i_k)$ value should be independent of the concentration of uncomplexed GEDTA, $[Y]_f$, and the solution pH. As has been stated above, the i_k value, however, decreases with increases in the $[Y]_f$ value and in the solution pH. Therefore, the above reaction mechanism can be eliminated. As is shown in Fig. 2, only the plot of

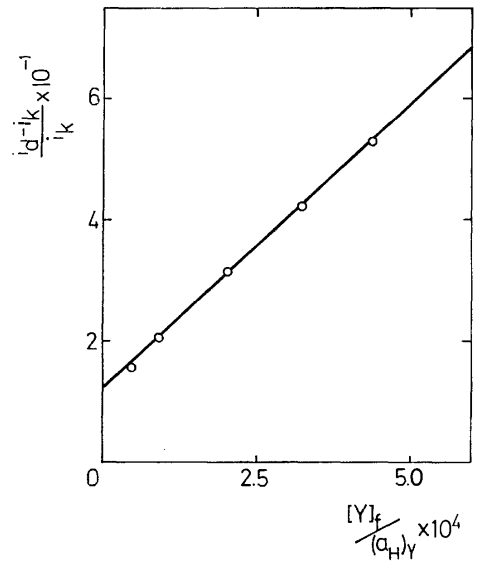

Fig. 2. Plot of $(i_d - i_k)/i_k$ against $[Y]_f/(\alpha_H)_Y$, GEDTA system, 25.0 °C, $\mu = 0.30$.
Concentration of cobalt(II) ion = 1.0 mM
Concentration of GEDTA = 10.8 mM

$(i_d - i_k)/i_k$ against the $[Y]_f/(\alpha_H)_Y$ yielded a linear relation for the cobalt(II)–GEDTA system. As is clear from the foregoing discussion, this indicates that the cobalt(II) ion forms 1 : 1 and 1 : 2 ratio complexes with GEDTA and that the reaction mechanism can be represented by (II). With the aid of Eq. (6), the

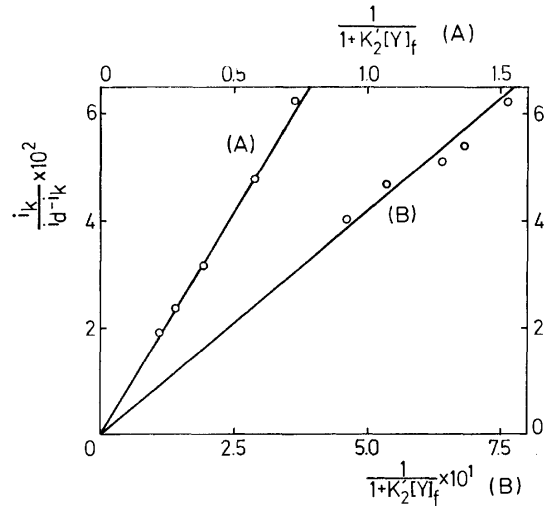

Fig. 3. Plot of $i_k/(i_d - i_k)$ against $1/(1 + K_2' \cdot [Y]_f)$, GEDTA system, 25.0 °C, $\mu = 0.30$.
Concentration of cobalt(II) ion = 1.0 mM
A) Concentration of GEDTA = 10.8 mM
pH ranged from 7.80 to 8.50
B) GEDTA concentration ranged from 10.0 mM to 40.0 mM. pH = 7.82.

second successive formation constant, K_2, was determined to be $7.8_4 \times 10^3$ from the ratio of the slope to the intercept of the straight line in Fig. 2. By using the K_2 value thus estimated, the effects of the concentration of uncomplexed GEDTA and the solution pH on the $i_k/(i_d - i_k)$ value were examined. The plot of $i_k/(i_d - i_k)$ against $1/(1 + K_2' \cdot [Y]_f)$ yielded a linear relation passing through the point of origin (Fig. 3). The k_d value obtained from the slope of the straight line (A) agreed well with that obtained from the slope of the straight line (B). This agreement also lends strong support to the reaction mechanism proposed by the present author for the cobalt(II)–GEDTA system.

Polarographic Behavior of Cobalt(II)–IDA and –Asp Complexes. Both cobalt(II)–IDA and –Asp com-

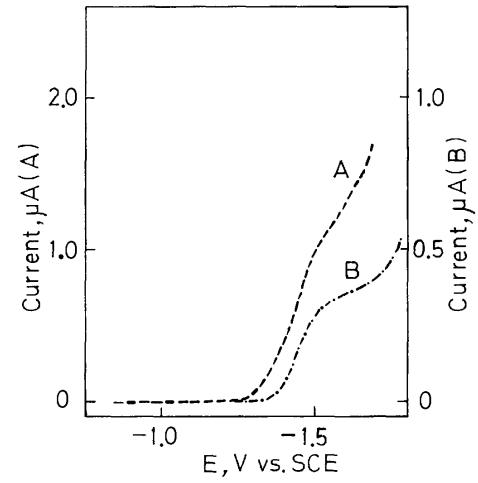

Fig. 4. Polarograms of the cobalt(II)–Asp and–IDA complexes, 25.0 °C, $\mu = 0.30$.

A) Aspartate concentration = 38.0 mM, pH = 9.23
B) Iminodiacetate concentration = 18.0 mM, pH = 8.58

plexes also produced kinetic waves in alkaline solutions containing excess IDA or Asp. Typical polarograms are given in Fig. 4. In both cases, the plot of the $i_k/(i_d-i_k)$ value against $(\alpha_H)_X^{1/2}$ (at constant uncomplexed IDA or Asp, $[X]_f$) or $(\alpha_H)_X^{1/2}\cdot[X]_f^{1/2}$ yielded a linear relation passing through the point of origin (Figs. 5 and 6). Here, $(\alpha_H)_X$ is the (α_H) value of IDA or Asp. In considering that the cobalt(II) ion can form 1 : 1 and 1 : 2 ratio complexes with IDA and Asp under the present experimental conditions, the above fact evidently implies that the reaction mechanism for the kinetic currents of cobalt(II)–IDA and –Asp complexes can be expressed as:

$$\text{(III)}\quad \begin{cases} CoX_2^{2-} \rightleftarrows CoX^0 + X^{2-} & \text{rate-determining step} \\ CoX^0 + 2e^- + Hg \rightleftarrows Co(Hg) + X^{2-} \end{cases}$$

corresponding to the following relation:

$$\frac{i_k}{i_d-i_k} = 0.886\sqrt{\frac{k_d\cdot(\alpha_H)_X\cdot t}{K_2[X]_f}} \qquad (8)$$

The dissociation rate constant, k_d, was determined from the slope of the linear relation between the $i_k/(i_d-i_k)$ value and $(\alpha_H)_X^{1/2}$ or $(\alpha_H)_X^{1/2}\cdot[X]_f^{-1/2}$. In both systems, the k_d value determined from the slope of the linear relation between the $i_k/(i_d-i_k)$ and $(\alpha_H)_X^{1/2}$ agreed well with that determined from the slope of the linear relation between the $i_k/(i_d-i_k)$ and $(\alpha_H)_X^{1/2}\times[X]_f^{-1/2}$. All the k_d values determined in this study are listed in Table 1, together with other numerical values.[8]

a) Determined in this study.
b) In the case of GEDTA system, this corresponds to k_d in Eq. (7).

As was discussed in connection with the dissociation reactions of nickel(II)–IDA and –Asp complexes,[1] it is reasonable to believe that (1) less than three bond breakages are involved in the rate-determining step, (2) the cobalt(II)–oxygen (carboxylate) bond breakage is much faster than the cobalt–nitrogen (amine) bond breakage, and (3) the five-membered chelate ring is less substitution-labile than the six-membered chelate ring in the dissociation of the cobalt(II)–aminopolycarboxylate complex. Therefore, one can assume the reaction intermediates I and II in Fig. 7 for the dis-

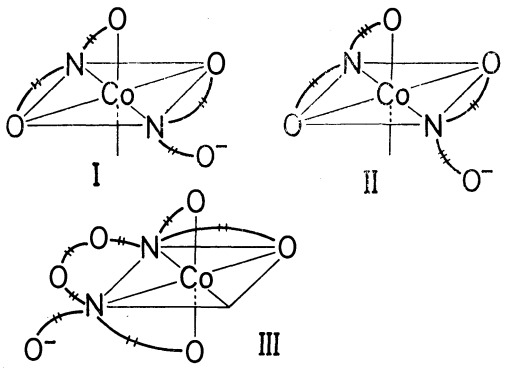

Fig. 7. Reaction intermediates.

8) L. G. Sillen and A. E. Martell, "Stability Constants of Metal-Ion Complexes," 2nd ed., The Chemical Society, London (1964).

sociation of cobalt(II)–IDA and –Asp complexes respectively. In general, the observed rate constant can be related to the rate constant for breaking X^{2-} away from the reaction intermediate, k_{rds}, the stability constant of the reaction intermediate, K_{inter}, and the K_{MX} value in the following manner:[1]

$$k_d = k_{rds} \cdot \frac{K_{inter}}{K_{MX}} \cdot K_{st} \cdot K_{elec} \quad (9)$$

Since, in the above reaction intermediates, both IDA and Asp anions are bonded to the cobalt(II) ion through a glycinate chelate ring, K_{inter} can be approximated by the formation constant of the cobalt(II)–glycinate complex, $K_{Co\text{-}gly}$. K_{MX} in Eq. (9) should be the second successive formation constant of the cobalt(II)–IDA or –Asp complex, K_2. The above relation suggests that, provided that the k_{rds} value for the IDA system is equal to that for the Asp system, the observed rate constant should be inversely proportional to the second successive formation constant corrected for the statistical factor.[9] The observed rate constant ratio was successfully compared with the ratio calculated by means of Eq. (9) (Table 1). In this study, we discovered that the cobalt(II) ion can also form a 1:2 ratio complex with the GEDTA anion. In sharp contrast with the EDTA anion, where two iminodiacetate groups are separated by two carbon atoms, the two nitrogen atoms of the GEDTA anion, where two iminodiacetate groups are separated by six carbon atoms and two oxygen atoms, have nearly identical protonation constants.[10] All these facts may mean that, under most conditions, the two iminodiacetate groups act as if they were unrelated entities in the complex formation with metal(II) ions. Therefore, it is not unreasonable to believe that the GEDTA anion in the electroactive cobalt(II)–GEDTA complex, CoY^{2-*}, is coordinated to the cobalt(II) ion through one iminodiacetate group, and that, hence, the dissociation of the first IDA group of the GEDTA anion is the rate-determining step. When the two IDA groups act as if they were functionally independent, the K value in Eq. (6) must be equal to $K_{CoY}/(K_{CoY})_{IDA} \times 2$. Here, 2 is the statistical factor. With the aid of the above relation, K was calculated to be $10^{3.74}$. This value agrees well with the K_2 value determined in this study, showing the validity of the estimation of the K value. In the above calculation, the cobalt(II)–*N*-(2-hydroxyethyl)iminodiacetate complex was employed as a model. The fact that the overall formation constant for the cobalt(II)–IDA complex, CoX_2^{2-}, is nearly identical with that of the 1:2 cobalt(II)–GEDTA complex also gives strong support to the above explanation. By using the K value thus estimated, the k_d value was calculated to be 2.07×10^1. This is about ten times smaller than that predicted from the reciprocal of the K value on the basis of the reaction intermediate III (see Table 1). However, the discrepancy between the rate constant ratio observed and that calculated can be explained in terms of the rotational barrier of the dissociating iminodiacetate group around the C–C or C–O bond.[9] The formation rate constants, k_f's, were also calculated from the $K_2 = k_f/k_d$ relation by using the k_d values determined in this study. The estimated k_f values for the IDA, Asp, and GEDTA systems are nearly identical with the characteristic water exchange rate constant of the cobalt(II) ion, $k_{Co}^{-H_2O}$ (Table 1).[11] Because the complexation reaction which involves the formation of an equilibriated outer-sphere complex, preceding the loss of a coordinated water molecule as the rate-determining step, the rate constant, k_f, can be written as the product of the outer-sphere association constant, K_{os}, and $k_{Co}^{-H_2O}$. As predicted by the Fuoss equation,[12] the K_{os} value for the outer-sphere association process, in which one of the reacting species is uncharged, is smaller than unity. Therefore, in considering that the coordinated ligand tends to increase the exchange rate of the remaining coordinated water,[13,14] the rate constant for the formation of the higher complex from the uncharged lower complex, which proceeds through the common water-loss mechanism, must be nearly identical with the characteristic water exchange rate. Thus, the above fact that the k_f values for the IDA and Asp systems are nearly identical with the $k_{Co}^{-H_2O}$ value can be explained by assuming a reaction mechanism where an outer-sphere complex formation between CoX^0 and X^{2-} precedes the loss of a coordinated water molecule from the CoX^0 as the rate-determining step. In the case of the GEDTA system, the fact that the k_f value is nearly identical with the $k_{Co}^{-H_2O}$ value can also be accounted for by assuming a reaction mechanism which involves the dissociation of water from the CoY^{2-*} as the rate-determining step following the initial weak association (outer-sphere association in nature) between the free IDA group of the GEDTA anion in CoY^{2-*} and the formally-uncharged cobalt(II) coordinated by the IDA group.

Spectra of Nickel(II)-Azide Complexes in Organic Solvents

R. ABU-EITTAH and S. ELMAKABATY
Department of Chemistry, Faculty of Science, Cairo University, Giza, Egypt
(Received September 12, 1972)

The complexing properties of nickel(II) ion with azide ion, in a number of organic solvents, are investigated by spectroscopic methods. The electronic absorption spectra of Ni(II)-N_3^- solutions were studied in the visible-ultraviolet regions using dimethylformamide, absolute methanol and absolute ethanol as solvents. The composition of the possibly obtained complexes was investigated using the continuous variation and the slope ratio methods. The composition of the predominant complex was dependent on the solvent used. Formation as well as dissociation constants of the obtained complexes were computed.

The structure of nickel(II) complexes has been the aim of extensive studies.[1-4] Octahedral, square planar and tetrahedral geometries are known for nickel(II) complexes.[5-7] Piper and Koertge studied the spectra of $[Ni(H_2O)_6]^{2+}$ at low temperature.[8] Conductometric, potentiometric and spectrophotometric studies have shown that the 1 : 1 nickel azide complex predominates in aqueous medium.[9-11] Complexation between azide ion and many transition metals, other than nickel, has been investigated.[12,13]

The complexing power of azide ions with regard to several metal ions in aqueous solutions have been studied using polarographic as well as potentiometric methods.[14]

Experimental

Preparation of standard solutions of nickel perchlorate and of sodium azide was done as explained before.[13] Solvents used were: absolute methanol, absolute ethanol (Apolda grade reagent) and dimethylformamide (Prolabo grade reagent) that were purified by conventional methods found in the literature.[15] Spectra were scanned using a Beckman DK spectrophotometer and a 1.0 cm silica cells.

Results and Discussion

Complexes of Ni(II) and N_3^- in Absolute Methanol. Structure of the Complexes: In water as a solvent, the complex in $[Ni(H_2O)_6]^{2+}$, possessing a simple octahedral geometry, shows two absorption bands at 14, 286 and 25, 641 cm^{-1}. These bands are assigned to the $^3A_{2g} \rightarrow {}^3T_{1g(F)}$ and $^3A_{2g} \rightarrow {}^3T_{1g(P)}$ transitions respectively. In addition to these bands, the ion shows an absorption band in the UV region (~250 nm) which i rather weak. In methanol as a solvent the ion show

(Fig. 1) the same absorption bands that were slightly red-shifted. On adding azide ion to the Ni(II) solution, the formed azidoaquo nickel(II) complex is also assumed to possess octahedral structure. Mixing of ligands will cause but a slight distortion from the simple cubic symmetry. Displacement of water molecules by azide ions can be represented as:

$$[Ni(H_2O)_6]^{2+} + XN_3^- \rightleftharpoons [Ni(H_2O)_{6-X}(N_3)_X]^{+2-X} + XH_2O$$

The number of azide ions ligated to the Ni(II) ion will be dependent on the solvent used. In water, as a solvent, it has been proved that only one azide ion is ligated to the Ni(II) ion.[10,16] If we use an organic solvent, miscible with water, we expect that the number of N_3^- ions ligated to Ni(II) ion will increase.

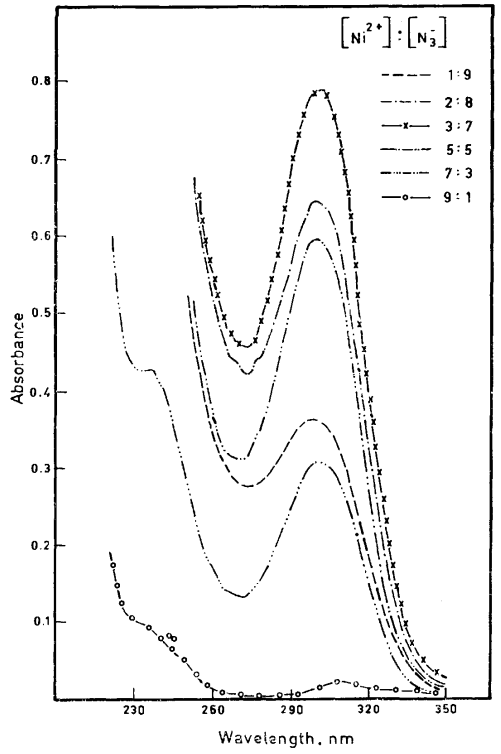

Fig. 2. Absorption spectra of nickel azide solutions in methanol.

Figure 2 shows the absorption spectra of solutions, in absolute methanol, made by mixing nickel perchlorate and sodium azide with total concentration of 2×10^{-3} M. The formed nickel azide complex has an absorption band of its own with λ_{max} at 300 nm. Absorbance of free Ni(II) or azide ions is negligible at this wavelength. It is interesting to remember that the monoazidoaquonickel(II) complex[16] has an absorption band of its own at ~290 nm. This suggests that the nature of the Ni(II)-N_3^- complex, when water is the solvent, differs from its nature when absolute methanol is the solvent. Job's[17] method of continuous variation was applied to results of Fig. 2. In Fig. 3 one plots the absorbance *versus* the mole

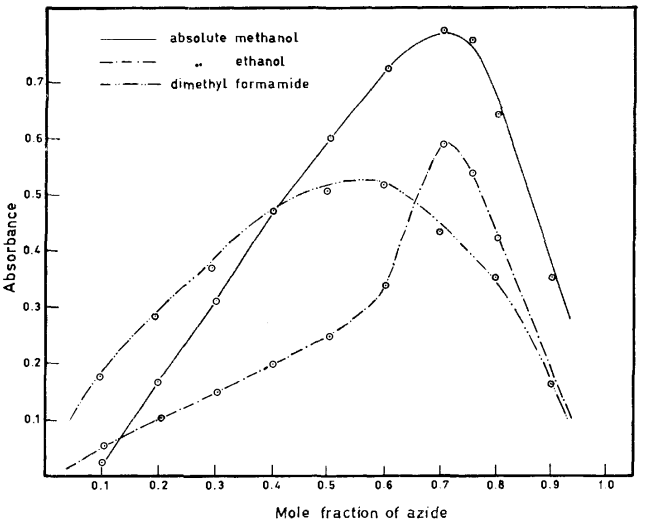

Fig. 3. Structure of nickel azide complexes, in different solvents, using the continuous variation method.

fraction of azide ion. A well-defined maximum appears at 0.7 mol fraction of azide ion which suggests that the predominant nickel azide complex may be the 1:2 or the 1:3 complex. Data needed to plot Fig. 3 are given in Table 1.

TABLE 1. VARIATION OF ABSORBANCE OF NICKEL-AZIDE SOLUTIONS WITH AZIDE ION CONCENTRATION, IN DIFFERENT SOLVENTS (ABSOLUTE ALCOHOLS AND DIMETHYLFORMAMIDE)

$[Ni^{2+}]:[N_3^-]$	Absorbance		
	Methanol (300 nm)	Ethanol (302 nm)	Dimethyl-formamide (305 nm)
1:9	0.36	0.165	0.165
2:8	0.645	0.425	0.35
2.5:7.5	—	0.540	—
3:7	0.795	0.590	0.43
4:6	0.725	0.34	0.52
5:5	0.600	0.25	0.51
6:4	0.470	0.20	0.475
7:3	0.310	0.15	0.37
8:2	0.165	0.10	0.285
9:1	0.02	0.055	0.18

To confirm the above results, the slope ratio method was applied.[18] Spectra of solutions made by mixing constant excess $[Ni^{2+}]$, 4×10^{-3} M with variable $[N_3^-]$, from 0.6×10^{-3}—1.0×10^{-3} M, were scanned. Also, spectra of solutions made by mixing constant excess $[N_3^-]$, 1.6×10^{-3} M with variable $[Ni^{2+}]$ from 0.1×10^{-3} to 0.5×10^{-3} M were scanned. In Fig. 4 we plot the absorbance (at 300 nm) *versus* the concentration of the variable components. Straight lines are obtained, ratio between their slopes gives the ratio of the two components of the complex. Results of Fig. 4 give a ratio of 1:2.79 of the $[Ni^{2+}]$: $[N_3^-]$ in the obtained nickel azide complex. This suggests that in methanol, the

Table 2. Absorbances of nickel(II)-azide solutions containing constant excess $[Ni^{2+}]$, with variable $[N_3^-]$ and others containing constant excess $[N_3^-]$ with variable $[Ni^{2+}]$ in absolute methanol at 300 nm

Constant $[Ni^2]^+$: 4×10^{-3}		Constant $[N_3^-]$: 1.6×10^{-3}	
$[N_3^-]$	Absorbance	$[Ni^{2+}]$	Absorbance
0.6×10^{-3}	0.1	0.1×10^{-3}	0.145
0.7×10^{-3}	0.155	0.2×10^{-3}	0.32
0.8×10^{-3}	0.245	0.3×10^{-3}	0.5
0.9×10^{-3}	0.28	0.4×10^{-3}	0.66
1×10^{-3}	0.35	0.5×10^{-3}	0.74

1:3 nickel azide complex is obtained. Data needed to plot Fig. 4 are given in Table 2.

Stability Constants: The predominant complexes were found to be the 1:2 and the 1:3 complexes. Dissociation constant K' was computed following the Harvey-Manning method.[18] Dissociation of the nickel azide complex can be represented by:

$$[Ni(N_3)_n]^{+2-n} \rightleftharpoons Ni^{2+} + nN_3^-$$

C	0	0	initial concentration
$C(1-\alpha)$	αC	$n\alpha C$	equilibrium concentration

The dissociation constant K' is given by.

$$K' = (\alpha C)(n\alpha C)^n/C(1-\alpha)$$

where, "α" represent the degree of dissociation and is given by $(A_m-A_S)/A_m$. The value of (A_m) represents the absorbance when all the nickel present is complexed, that of (A_S) is the absorbance at the stoichiometric molar ratio of N_3^- to Ni^{2+} in the complex. The value of "n" will be the number of azide ions per ion of nickel and "C" will be taken as the concentration of nickel used.

The spectra of a series of nickel-azide solutions, with the ratio $[Ni^{2+}]$: $[N_3^-]$ varying from 1:1 to 1:20 were scanned. The absorbance at 300 nm is plotted against the number of moles azide per mole nickel in Fig. 5. The values of (α) were found to be 0.584 and 0.471, from Fig. 5, at "n" equals to 2 and 3. Data needed to plot Fig. 5 is given in Table 3.

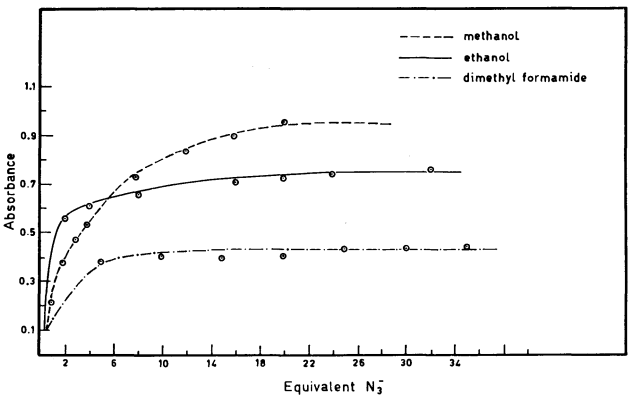

Fig. 5. Variation of absorbance of nickel azide solution with azide concentration.

Table 3. Absorbance of nickel-azide solutions in different solvents

$[Ni^{2+}]$:$[N_3^-]$	Absorbance		
	Methanol (300 nm)	Ethanol (302 nm)	Dimethyl-formamide (305 nm)
1:1	—	0.205	—
1:2	0.37	0.555	—
1:3	0.47	—	—
1:4	0.53	0.600	—
1:5	—	—	0.365
1:8	0.71	0.64	—
1:10	—	—	0.39
1:12	0.83	—	—
1:15	—	—	0.385
1:16	0.89	0.695	—
1:20	0.95	0.71	0.4
1:24	—	0.73	—
1:25	—	—	0.435
1:30	—	—	0.435
1:32	—	0.75	—
1:35	—	—	0.450

Substituting by these values in the equation for K' one gets 0.208×10^{-6} and 0.9×10^{-10} for the dissociation constants of the 1:2 and 1:3 nickel azide complexes. Formation constants of these complexes are 4.8×10^6 and 1.99×10^{10} respectively. These values reflect the quite stability of the obtained nickel azide complex.

Nickel(II)-azide Complexes in Absolute Ethanol. To see the effect of solvent on the composition of Ni(II)-azide complexes, the spectra of mixtures of nickel perchlorate and sodium azide were studied using absolute ethanol as a solvent. Mixtures were prepared so as the total concentration was 1.0×10^{-3} M. Job's method of continuous variation was applied to the results of the spectra (Fig. 3). In absolute ethanol, as a solvent, formation of more than one complex was evident. Figure 3 shows a break at azide mole fraction of 0.6, peak at azide mole fraction of 0.72 and a

break at azide mole fraction of 0.8. This means that the complexes: $[Ni(N_3)_2(H_2O)_4]^0$; $[Ni(N_3)_3(H_2O)_3]^-$ and $[Ni(N_3)_4(H_2O)_2]^{2-}$ are obtained on mixing nickel perchlorate and sodium azide solutions in absolute ethanol as a solvent. Formation of more than one complex, at the same time, is expected not to give a well-defined spectrum. This can be seen from Fig. 6 where the spectra of Ni(II)–N_3^- solutions, in the

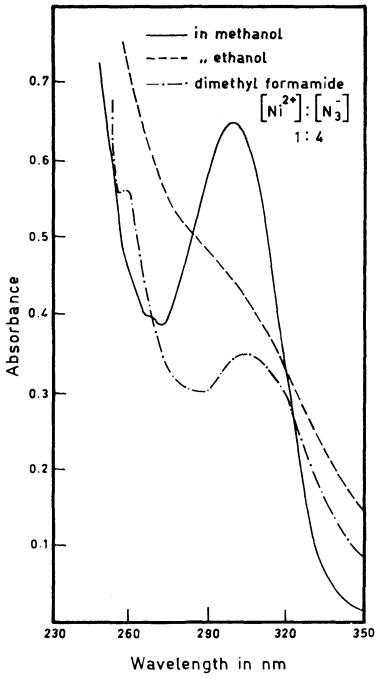

Fig. 6. Absorption spectra of nickel(II)-azide solutions in different solvents.

studied solvents, are given. In absolute ethanol, bands were not well defined as they were in other solvents which indicates the formation of more than one complex.

The slope ratio method was used to confirm the composition of nickel azide complex when absolute ethanol is the solvent. In Fig. 4 the relation between absorbance (at 302 nm) and concentration of the variable component is plotted. Data needed to plot this curve is given in Table 4.

Table 4. Absorbances of nickel-azide solutions with excess constant $[Ni^{2+}]$ and with excess constant $[N_3^-]$ in absolute ethanol as a solvent

$[Ni^{2+}]=4\times10^{-3}$		$[N_3^-]=0.8\times10^{-3}$	
$[N_3^-]$	Absorbance (302 nm)	$[Ni^{2+}]$	Absorbance (302 nm)
0.6×10^{-3}	0.215	0.05×10^{-3}	0.075
0.7×10^{-3}	0.27	0.1×10^{-3}	0.155
0.8×10^{-3}	0.315	0.15×10^{-3}	0.26
0.9×10^{-3}	0.37	0.2×10^{-3}	0.38
1×10^{-3}	0.445	0.25×10^{-3}	0.5

The slope ratio method indicated that with the used concentrations of Ni^{2+} and N_3^- a 1:4 nickel azide complex is probably obtained.

The instability constant of the 1:4 nickel azide complex was computed as before. In Fig. 5 we plot the absorbance (at 302 nm) *versus* the moles of azide per mole of nickel. From that figure values of (α), (A_m), and (A_S) were computed. The value of "*n*" was used as 4 and *K'* was computed to be 26.214×10^{-16}. Hence the formation constant of the 1:4 nickel azide complex is found to be 3.81×10^{14}.

Complexes of Ni(II) and N_3^- Ions in Dimethylformamide. The extent of displacement of the water molecules, in the inner coordination sphere of Ni(II), by azide ions was investigated when dimethylformamide was the solvent. The absorption spectra of mixtures of sodium azide and nickel perchlorate, using dimethylformamide as a solvent, were investigated. To begin with spectra of solutions of constant total concentration (1.0×10^{-3} M) were scanned. In Fig. 6 the spectrum of one of these mixtures is given. The nickel azide complex, obtained when dimethylformamide is the solvent, has a well-defined and discrete absorption band of its own at 305 nm. In Fig. 3, absorbance is plotted *versus* the mole fraction of azide, a well-defined and discrete maximum appears at an azide mole fraction of 0.6 which suggests that the 1:2 nickel azide complex predominates. Data needed to draw Fig. 3 are given in Table 1.

The slope ratio method was used to confirm the composition of nickel azide complex when dimethylformamide is the solvent. A series of solutions was prepared containing constant excess sodium azide 0.2×10^{-2} M and variable concentrations of nickel perchlorate 0.7×10^{-3} to 0.3×10^{-3} M. Another series of solutions was prepared containing constant excess nickel perchlorate 0.2×10^{-2} M and variable concentration of sodium azide 0.7×10^{-3} to 0.3×10^{-3} M. Absorbance was plotted *versus* the concentration of variable in Fig. 4. Data needed to plot Fig. 4 are given in Table 5. Results of Fig. 4 confirmed that a 1:2 nickel azide complex is obtained when dimethylformamide is the solvent.

Table 5. Absorbances of nickel azide solutions containing excess $[Ni^{2+}]$ and others containing excess $[N_3^-]$ in dimethylformamide

$[Ni^{2+}]=0.2\times10^{-2}$		$[N_3^-]=0.2\times10^{-2}$	
$[N_3^-]\times10^3$	Absorbance	$[Ni^{2+}]\times10^3$	Absorbance
0.70	0.690	0.70	1.20
0.60	0.590	0.60	1.03
0.50	0.493	0.50	0.84
0.40	0.415	0.40	0.680
0.30	0.305	0.30	0.490

The stability constant of the 1:2 nickel azide complex, in dimethylformamide, was obtained using the procedure adopted before. Absorption spectra of Ni(II)–N_3^- solutions with $[Ni^{2+}]$: $[N_3^-]$ ratio varying from 1:5 to 1:35 were scanned. In Fig. 4 absorbance is plotted *versus* the number of moles azide per mole nickel. Data need to plot Fig. 5 is given in Table 3 proceeding as before and using "*n*" equal to "2" the dissociation constant *K'* of the 1:2 nickel azide complex, in dimethylformamide, is found to be 0.21×10^{-6} or the formation constant is of the order of 5×10^6.

In Fig. 6, we present the spectra of Ni(II)–N_3^- solutions of the same concentration but in different solvents. The figure shows that λ_{max} for the obtained nickel azide complex is dependent on the solvent used. This indicates that the structure of the nickel azide complex is dependent on the solvent used. In absolute ethanol the spectrum is not well defined which indicates that more than one complex are obtained at the same time. In Table 6 we present the stability constants of the nickel azide complexes possibly obtained in different solvents.

Table 6. Stability constants (K) of the nickel azide complexes in different solvents

Solvent	Complex $[Ni^{2+}]:[N_3^-]$	K
Absolute methanol	1:2	4.8×10^6
	1:3	1.99×10^{16}
Absolute ethanol	1:4	3.81×10^{14}
Dimethylformamide	1:2	5×10^6

Conclusion: When $Ni(ClO_4)_2 \cdot 6H_2O$ is dissolved in water, the nickel ion exists in the simple octahedral geometry with the structure $[Ni(H_2O)_6]^{2+}$. When the solute is dissolved in organic solvents as absolute methanol, ethanol, or dimethylformamide, the octahedral geometry of the Ni(II) complex ion persists though the six ligands may not be entirely water molecules. When the hydrated salt is dissolved in some non-aqueous solvent, depending on the coordination power of the solvent the water molecules are fully or partially substituted by the solvent molecules. This is indicated from Fig. 1, where λ_{max}, intensity of the band and even splitting of some bands is solvent dependent. On adding azide ion to the solution, it has been found that the extent of H_2O (or other solvent molecules) displacement by N_3^- is dependent on the solvent used. When water is the solvent only one H_2O molecule is displaced. With organic solvents, two, three and four molecules were displaced by two, three and four azide ions. The specific complex has it own spectrum.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3431—3434 (1973)

Kinetics of the Formation of MoO_{3-x} at Elevated Temperatures from a Mixture of MoO_3 and α-Al_2O_3

Yoshihide KOTERA and Akifumi UENO

National Chemical Laboratory for Industry, Mita, Meguro-ku, Tokyo 153

(Received March 28, 1973)

The kinetics of the formation of MoO_{3-x} from a mixture of MoO_3 and α-Al_2O_3 was studied by means of high temperature X-ray diffraction. The species of MoO_{3-x} formed in the temperature range 600—700 °C were identified as $MoO_{2.88}(Mo_8O_{23})$, $MoO_{2.76}(Mo_{17}O_{47})$, and $MoO_{2.75}(Mo_4O_{11})$. The activation energies of their formation were estimated to be 18.4 kcal/mol for Mo_8O_{23}, 23.0 kcal/mol for $Mo_{17}O_{47}$ and 29.2 kcal/mol for Mo_4O_{11}. Other types of species of MoO_{3-x} observed above 800 °C were $MoO_{2.89}(Mo_9O_{26})$ and MoO_2. Little effect of water vapor, oxygen or nitrogen on the formation of the species was observed. No MoO_{3-x} was observed in the mixture of MoO_3 with SiO_2 or α-Fe_2O_3.

Detailed X-ray studies on the existence of the oxide intermediates between molybdenum dioxide and molybdenum trioxide have been made by Magneli *et al.*[1] by heating the mixture of molybdenum trioxide and molybdenum metal powder *in vacuo* in a glass tube at temperatures up to 700 °C. The following phases were identified by means of X-ray powder photography.

α-phase	MoO_3	orthorhombic
β-phase	Mo_9O_{26}	monoclinic
β'-phase	Mo_8O_{23}	monoclinic
γ-phase	Mo_4O_{11}	monoclinic
δ-phase	MoO_2	monoclinic

In later works other species such as $Mo_{17}O_{47}$, $Mo_{18}O_{52}$, and Mo_5O_{14} were shown to exist, their crystal structures being determined exactly.[2,3] The formation of these oxide intermediates was found, however, only in the case where a mixture of molybdenum trioxide and molybdenum metal powder or that of molybdenum trioxide and molybdenum dioxide was heated.

Recently a hydrodesulfurizing catalyst consisting of molybdenum trioxide, cobalt oxide and alumina was developed[4] and its active species studied extensively. Crystallographic[5] and spectroscopic[6] investigations on the mixture of molybdenum trioxide or alumina with cobalt oxide have been made to some extent. The reaction product between alumina and cobalt oxide was elucidated by structural and magnetic studies.[7] Formation of $CoAl_2O_4$ was observed when a mixture

of cobalt compound and alumina was heated above 850 °C, while at lower temperature only the oxidation or reduction of cobalt oxide would occur.[8] However, studies on the mixture of alumina and molybdenum trioxide have not been carried out thoroughly. A new compound containing molybdenum trioxide, alumina and silica was prepared and studied by the X-ray diffraction method.[9] The aim of the present work is to clarify the crystallographic changes of molybdenum trioxide mixed with α-alumina during the course of heating and to study the kinetics of the formation of MoO_{3-x} in the mixture.

Experimental

Molybdenum trioxide (Climax Molybdenum Co.) containing less than 0.05% of metallic impurities was employed. α-Alumina and α-ferric oxide were of guaranteed grade, while silica containing less than 0.01% of metallic impurities was converted into α-cristobalite by heating at 1100 °C before use.

Molybdenum trioxide and α-alumina were mixed well and the mixture was set in a platinum sample holder for the measurement of high temperature X-ray diffraction during the course of reaction. Temperature fluctuation did not exceed ±2 °C during the measurement. The X-ray instrument was operated at 35 KV with a filament current of 15 mA, a nickel filter being employed for CuKα radiation to provide an incident wave length of 1.5405 Å. Reflection peaks at 2θ angles were recorded on the strip chart, and the "d" values corresponding to these angles were calculated from the Bragg diffraction law. Oxygen or nitrogen was obtained from cylinders. It was wetted by passing through water at 20 °C (water vapor pressure 17.5 mmHg), or dried by passing above calcium chloride. The flow rate was held constant by means of a Venturi type manometer.

Relative amounts of the species were estimated from the measurements of the peak heights recorded on the strip chart. In order to determine the relative amount of the formed MoO_{3-x} species during the course of reaction, the characteristic peaks of X-ray diffraction pattern were selected as follows, $2\theta = 12.7°$ for MoO_3, 14.4° for Mo_8O_{23}, 15.8° for $Mo_{17}O_{47}$ and 23.7° for Mo_4O_{11}. Reproducibility of the peak height was within ±5% error.

Results

A typical X-ray diffraction pattern is shown in Fig. 1, where the mixture of the oxide with a MoO_3/α-Al_2O_3 weight ratio of 2: 1 was heated at 650 °C for 2 hr in a stream of dry nitrogen gas. New species such as Mo_4O_{11}, Mo_8O_{23}, and $Mo_{17}O_{23}$ were identified by a comparison of their 'd' values with those in calibration graphs[10] (Fig. 1).

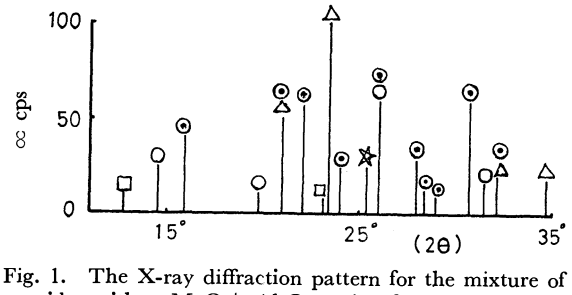

Fig. 1. The X-ray diffraction pattern for the mixture of the oxides with a $MoO_3/\alpha\text{-}Al_2O_3$ ratio of 2: 1 after heated at 650 °C for 2 hr (□: MoO_3, △: Mo_4O_{11}, ○: Mo_8O_{23}, ⊙: $Mo_{17}O_{47}$, ☆: α-Al_2O_3).

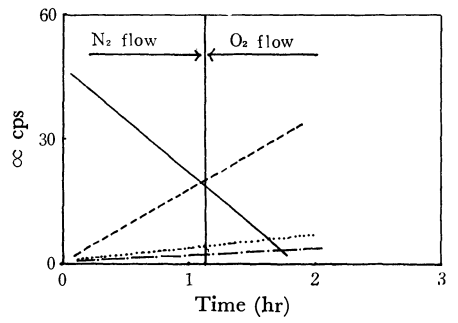

Fig. 2. The behaviors of MoO_{3-x} observed at 650 °C and the effect of the surrounding atmosphere on the reaction. ——: MoO_3, ----: Mo_4O_{11}, -·-·-: Mo_8O_{23}, ·····: $Mo_{17}O_{47}$.

The changes of peak height for the respective MoO_{3-x} observed during the course of heating are shown in Fig. 2. We see that the effect of surrounding atmosphere on the reduction is not noticeable. Reduction of MoO_3 to MoO_{3-x} at 600, 650, or 700 °C was analyzed, the formation of Mo_8O_{23}, $Mo_{17}O_{47}$, and Mo_4O_{11} as well as the decrease of molybdenum trioxide being plotted in Figs. 3, 4, 5 and 6, respectively.

The rate of formation of respective MoO_{3-x} and that of the decomposition of MoO_3 were of zeroth order with respect to the molybdenum oxide concentrations (Fig. 2). The rate constant for the formation of MoO_{3-x} and that for the decomposition of molybdenum trioxide were calculated from the initial slopes of the

curves in Figs. 3—6. The activation energies for the formation of MoO_{3-x} and the decomposition of molybdenum trioxide were estimated from the Arrhenius plot in Fig. 7. The deviation of each plot from the straight line is within ±5%. Values of the activation energies thus obtained were 18.4, 23.0, and 29.2 kcal/mol for the formation of Mo_8O_{23}, $Mo_{17}O_{47}$ and Mo_4O_{11} and 27.8 kcal/mol for the decomposition of MoO_3, respectively.

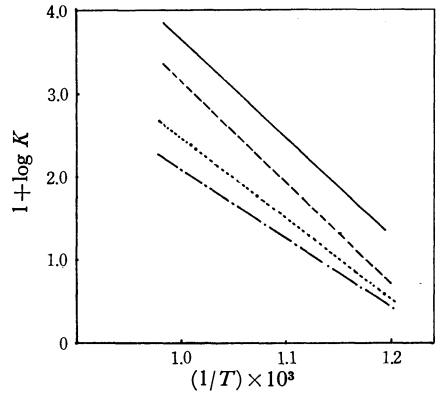

Fig. 7. The standard Arrhenius plot for the formation of MoO_{3-x} and the decomposition of MoO_3. ——: MoO_3, ----: Mo_4O_{11}, -·-·-: Mo_8O_{23}, ·····: $Mo_{17}O_{47}$.

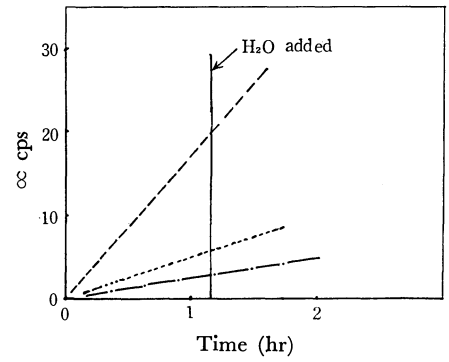

Fig. 8. The effect of the additional water vapor on the formation of MoO_{3-x} at 650 °C. ----: Mo_4O_{11}, -·-·-: Mo_8O_{23}, ·····: $Mo_{17}O_{47}$.

Figure 8 shows that no change of reaction rate was observed when the wet nitrogen was introduced into the mixture with a MoO_3/α-Al_2O_3 weight ratio of 2: 1 after being heated at 650 °C for 70 min in a stream of dry nitrogen. This indicates that no effect of the ambient water vapor is observed upon the rate of formation of MoO_{3-x}.

Dsicussion

A catalyst consisting of molybdenum and cobalt compounds and alumina was developed to hydrodesulfurize light or heavy oil[4] and was studied on its active species. A crystallographic investigation[5] on molybdenum and cobalt compounds showed that the formation of $CoMoO_4$ was observed by heating the mixture of cobalt oxide and molybdenum trioxide above 700 °C, and at lower temperature the other types of molybdenum cobalt oxides formed, while it was assumed from the spectroscopic investigation[6] that the octahedron of $[CoO_6]$ might be the active species of the catalyst consisting of molybdenum and cobalt compounds and alumina. However it is very difficult to clarify the active species. It seems important to assure the reaction between two oxides under the conditions for the preparation of the catalyst.

The behavior of the mixture of cobalt compound and alumina was studied during the calcination at temperatures where catalysts are prepared.[8] The formation of cobalt aluminate spinel above 850 °C was observed by means of high-temperature X-ray diffraction and chemical analysis. At lower temperature cobalt oxide behaves in the mixture with alumina in almost the same way as alone.

The behavior of the mixture of molybdenum compounds and alumina has not been so extensively studied. It was proposed[11] that three new compounds might be formed during the heating of the mixture of molybdenum trioxide and γ-alumina. The formation was assumed by the appearance of new X-ray lines. We reported[9] that the new compound is formed by heating the mixture of molybdenum trioxide and alumina when either oxide contains silica. The above postulate would be the case where molybdenum trioxide or γ-alumina is contaminated by silica. In the present study with the use of alumina or molybdenum trioxide free from silica, new X-ray lines were found, which are representative for MoO_{3-x}[1,2] as shown in Fig. 1.

The formation of the respective MoO_{3-x} species was spontaneously observed as shown in Figs. 2—5.

From the results it is assumed that the reduction of MoO_3 to MoO_{3-x} does not proceed in a successive reduction of molybdenum trioxide to dioxide through Mo_8O_{23}, $Mo_{17}O_{47}$, and Mo_4O_{11}, but by a parallel reduction from MoO_3 to respective MoO_{3-x}. The

activation energies estimated above are assumed to represent those for each step of the parallel reduction.

The decrease of molybdenum trioxide was observed as shown in Figs. 2 and 6. The activation energy estimated above would be the weighted mean of three parallel reactions. The amount of sublimation of molybdenum oxide is negligibly small since the measurement of high-temperature X-ray diffraction was carried out between 600 and 700 °C and molybdenum trioxide sublimes above 800 °C.[12]

In order to know whether molybdenum oxides form compounds with α-alumina or not, an aqueous solution of ammonia was poured into a mixture of MoO_3 and α-alumina which had been ignited at 650 °C for 2 hr. X-Ray analysis of the residue was carried out, the X-ray pattern being found to be that of only α-alumina. While molybdenum oxides are known to be soluble in aqueous ammonia,[13] it is deduced that molybdenum oxides did not form any compounds with α-alumina by heating under the conditions cited above.

The effect of alumina or silica upon the electron spin resonance spectrum of molybdenum was recently studied.[14] It was observed that the ESR spectrum due to molybdenum supported on alumina differed from that on silica but no reason was given. When silica was heated with molybdenum trioxide instead of α-alumina, no reduction of molybdenum trioxide was observed up to 800 °C.

R. Schenck *et al.*[15] observed the evolution of oxygen by heating the mixture of alumina and cupric oxide. This was explained by assuming that alumina promotes the reduction of cupric oxide by the formation of a spinel phase of $CuO \cdot Al_2O_3$. They also reported the reduction of cupric oxide by ferric oxide in a similar way to that by alumina. For molybdenum trioxide α-alumina similarly reduced MoO_3 to MoO_{3-x}, but no reduction of MoO_3 occurred by heating with α-ferric oxide up to 800 °C. The spinel formula $MoAl_2O_4$ does not seem to be a reaction intermediate during calcination of the mixture of molybdenum trioxide and alumina.

The authors express their thanks to Dr. S. Shin, Miss M. Yonemura and Mr. T. Sekine for their useful discussion and encouragement.

The Fluorination of Carbonyl Sulfide[1]

Shunji NAGASE, Hajime BABA, Kazuo KODAIRA, and Takashi ABE
Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya 462
(Received May 9, 1973)

The electrochemical fluorination of carbonyl sulfide has been carried out. Carbonyl fluoride and sulfur hexafluoride were obtained as the principal products. The influence of the operating conditions on the reaction has been examined. In addition, a method has been developed for the production of sulfur hexafluoride. This involves the passage of carbon monoxide and sulfur over a catalyst; the resultant gas formed is subsequently introduced into a current-carrying anhydrous hydrogen fluoride in an electrolytic cell. Sulfur hexafluoride was thus obtained in a good yield.

Carbonyl sulfide has been subjected to fluorination by elementary fluorine,[2] oxygen difluoride,[3] and cobalt trifluoride,[4] and has been shown to yield fluorinated cleaved products. The present paper will describe the results of a study of the electrochemical fluorination of carbonyl sulfide. This work was initiated with the hope that the electrochemical process for the fluorination of carbonyl sulfide may produce a fully-fluorinated compound retaining the original sulfur-carbon-oxygen skeleton. However, it was found that, upon electrochemical fluorination, the carbon-sulfur bond in carbonyl sulfide was cleaved, yielding carbonyl fluoride and sulfur hexafluoride as the principal products.

This paper will also deal with a method developed for the production of sulfur hexafluoride, an important commercial sulfur-fluorine compound, by the application of the electrochemical process for the fluorination of gaseous compounds.[5] The method involves the passage of a mixture of carbon monoxide and sulfur over a catalyst to convert them into carbonyl sulfide, and then blowing it into a current-carrying anhydrous hydrogen fluoride in an electrolytic cell. This gave sulfur hexafluoride of a relatively high purity in a good yield.

Experimental

Fluorination of Carbonyl Sulfide. Carbonyl sulfide (97.5% min) obtained from the Matheson Co., carbon monoxide (99.5%), ethylene (99.5%), and propylene (99.1%) obtained from the Takachiho Chemical Industrial Co., were used. The other reagents were commercial-grade chemicals. The apparatus used was similar to one described earlier.[6] The effective surface area of the anodes and cathodes in an electrolytic cell was 7.7 dm^2. A 450 ml portion of anhydrous hydrogen fluoride was used.

The fluorination was conducted by procedures similar to those used before.[5] As an example, the procedures for Run 2 shown in Table 1 will be described. Carbonyl sulfide (25 ml/min) in a cylinder was blown with helium (90 ml/min) through a bubbler into the anhydrous hydrogen fluoride in the cell, while a current was being passed through it at an average anodic current density of 3.0 A/dm^2 at 5.5—6.5 V and at 5—6 °C. It was preferable to use a conductivity additive, sodium fluoride (4 g), for this electrolysis.

The gases generated from the cell were passed through a reflux condenser, a sodium fluoride tube, and were then bubbled into an aqueous solution of sodium sulfite in gas-washing bottles,[6] where the carbonyl fluoride in the product was hydrolyzed and converted into carbon dioxide and hydrogen fluoride, and a small amount of oxygen difluoride was removed. The gases were then guided to cold traps kept in ice and in liquid nitrogen.

The collected product, containing subliming compounds (carbon dioxide and sulfur hexafluoride), was first roughly distilled by the use of a low-temperature rectification unit. Each fraction was then analyzed by GC [(Shimadzu GC-1C), column; 0.3 cm *i.d.* × 1.8 m long stainless steel tube packed with 60/80 mesh silica gel, temperature; 80 °C, carrier; helium] as usual. IR measurements [(Hitachi EPI-S2), a gas cell equipped with NaCl windows] were also carried out.

For 3 hrs' operation, a total of 15.7 g (0.262 mol) of carbonyl sulfide was supplied; the following compounds were thus obtained; carbon tetrafluoride (0.4 g, 0.005 mol), sulfur hexafluoride (18.2 g, 0.125 mol), carbon dioxide (4.8 g, 0.109 mol), carbonyl sulfide (7.2 g, 0.120 mol), and trifluoromethyl peroxide (0.6 g, 0.004 mol).

In order to ascertain the composition of the exit gas before contact with water, a sample gas was occasionally withdrawn directly from the sampling valve fixed next to the sodium fluoride tube, and analyzed by GC [(Shimadzu GC-2C), column; for example, 0.3 cm i.d. × 10 m long polytetrafluoroethylene tube packed with Daifl oil # 3 (Daikin Industries Co.) on 20/80 mesh Shimalite F (Shimadzu Seisakusho Co.), temperature; 0 °C, carrier; helium] and by IR. Special care has been exercised to detect the formation of compounds sensitive to moisture, such as pentafluorosulfur carbonyl fluoride.[7]

Preparation of Sulfur Hexafluoride. The apparatus consisted of a molten-sulfur tube, an electrolytic cell, a sodium fluoride tube, gas-washing bottles, and cold traps. Most of these were the same as those used for the fluorination of carbonyl sulfide. They were connected in series. The molten-sulfur tube was made of glass; it was a long-neck (3 cm *i.d.* × 20 cm long), round-bottomed, 50 ml flask fitted with two glass tubings at the top for the inlet and the outlet of gases. The lower end of the inlet tubing was under the surface of the molten sulfur in the flask. About 25 g of sulfur was placed in the bottom, while activated charcoal was packed in the neck of the flask. The gas-washing bottles contained 20% of a sodium hydroxide solution saturated

a) {(Mol of each product)/(mol of COS fed)} × 100.

b) {(Mol of CF_3OOCF_3 × 2)/(mol of COS fed)} × 100.

with sodium sulfite. A small amount of potassium iodide was also added.

In operation, carbon monoxide (19 ml/min) was fed as a blowing gas into the molten-sulfur tube kept at 330 °C in an electric furnace. A mixture of carbon monoxide and sulfur vaporized was passed through an activated charcoal zone, where both elements were converted into carbonyl sulfide, which was subsequently introduced into the current-carrying anhydrous hydrogen fluoride in the cell. (Electrolysis conditions; anhydrous hydrogen fluoride used, 450 ml; sodium fluoride added, 4 g; anodic current density, 3.2 A/dm²; cell voltage, 6.3—6.5 V; cell temperature, 5—6 °C).

The fluorinated products were passed through the reflux condenser, the sodium fluoride tube, and the gas-washing bottles, and then were led to cold traps immersed in ice and in liquid nitrogen. The sulfur hexafluoride thus obtained, containing small amounts of by-products, was purified as follows. By the use of the low-temperature rectification unit, carbon tetrafluoride was distilled at −128——126 °C at atmospheric pressure (fraction 1); then the top of the column was kept at −65— −60 °C, and sulfur hexafluoride was taken out at 700—750 mmHg (fraction 2). Bistrifluoromethyl peroxide and sulfuryl fluoride remained in the column. It was possible to remove completely a trace of sulfuryl fluoride in the sulfur hexafluoride by passing fraction 2 through a glass tube (3 cm *i.d.* × 40 cm long) containing 5/7 mesh silica gel.

After 4 hrs' operation, 6.1 g (0.190 g.atom) of sulfur was vaporized from the sulfur-molten tube, and 25.8 g (0.177 mol) of sulfur hexafluoride (purity, 99.9%) was thus obtained (yield 93.2%), together with small amounts of carbon tetrafluoride, bistrifluoromethyl peroxide, and sulfuryl fluoride. Ethylene, propylene, and carbonyl chloride were also examined as blowing gases. The experiments for the preparation of sulfur hexafluoride from these starting materials were conducted much as in the case of carbon monoxide.

Results and Discussion

The fluorination of carbonyl sulfide resulted in the cleavage of the carbon-sulfur bond:

$$COS \xrightarrow{[F]} CF_4,\ COF_2,\ SF_6,\ CF_3OOCF_3$$

The reaction conditions and results obtained are shown in Table 1. If the carbon-sulfur bond was not cleaved completely, such a compound as pentafluorosulfur carbonyl fluoride[7] would be obtained. In this work, even under the preferred conditions for milder fluorination[8] of gaseous compounds (the higher feed rate used in Run 3), the cleavage of the carbon-sulfur bond occurred. A low-temperature fluorination also yielded fragmented products; feed rate, 35 ml/min; cell temperature, −25 °C; product composition (mol %), carbon tetrafluoride (0.9), carbonyl fluoride (58.8), sulfur hexafluoride (18.8), carbonyl sulfide (21.1), and bistrifluoromethyl peroxide (0.3).

Under severe fluorination conditions (Run 1), a considerable amount of bistrifluoromethyl peroxide was obtained. The formation of this may be explained in terms of the coupling of two trifluoromethoxy radicals, most likely produced by the attachment of a fluorine radical to the carbonyl fluoride formed in the course of the fluorination.

In contrast to the carbon-sulfur bond, the carbon-oxygen bond was rather stable to the electrochemical fluorination,[5] as is shown by the kinds and amounts of fluorinated products formed. The bonding energy for the carbon-oxygen bond in carbonyl sulfide is much greater than that for the carbon-sulfur bond.[9] This may be the primary cause for the present results. Salinovich *et al.*[2] examined the reaction of carbonyl sulfide with elementary fluorine under a variety of operating conditions and observed a very rapid reaction, which gave carbonyl fluoride and sulfur hexafluoride. Earlier Silvey and Cady[4] obtained similar results in the fluorination of carbonyl sulfide with cobalt trifluoride. From these observations,[2,4] together with the present results described above, it may be stated that it is difficult to fluorinate carbonyl sulfide and still totally retain the sulfur-carbon-oxygen skeleton by direct methods of fluorination.

The process described herein for the preparation of sulfur hexafluoride can be expressed as follows:

$$CO \xrightarrow{S} COS \xrightarrow{[F]} COF_2,\ SF_6 \xrightarrow{\text{Alkali}} SF_6$$

Because it is of commercial importance, sulfur hexafluoride has been prepared by a number of methods. An electrochemical process was often employed.[10] In the present method, the starting material is elemental

sulfur, and the fluorination proceeds smoothly. Although the process involves the loss of carbonyl fluoride, it affords sulfur hexafluoride of high purity in a good yield (93.2%).

The action of carbon monoxide upon sulfur is known to produce carbonyl sulfide.[11] The method described in the Experimental Section was also efficient in converting carbon monoxide into carbonyl sulfide. For example, when the feed rate of carbon monoxide was 19 ml/min, the conversions were as follows: 72% at 250 °C, 88% at 280 °C, and 97% at 300 °C. The conditions for 100% conversion (at 330 °C) were applied for the run illustrated in the Experimental Section.

When ethylene or propylene was used as the blowing gas instead of carbon monoxide, they were converted into carbon disulfide and hydrogen sulfide.[12] The amount of the olefin introduced with helium into the molten-sulfur tube was so adjusted that it reacted almost completely with the sulfur. The activated charcoal was again used as the catalyst for this reaction. The whole process can be represented by the following formulae:

$$CH_2{=}CH_2 \xrightarrow[320°C]{S} CS_2,\ H_2S$$

$$\xrightarrow{[F]} SF_6(CF_4,\ C_2F_6,\ CF_3SF_5,\ C_2F_5SF_5,\ SO_2F_2,\ CS_2)$$

$$CH_3CH{=}CH_2 \xrightarrow[350°C]{S} CS_2,\ H_2S$$

$$\xrightarrow{[F]} SF_6(CF_4,\ C_2F_6,\ CF_3SF_5,\ C_3F_8,\ SO_2F_2)$$

In the case of ethylene,[13] some representative results obtained were as follows: composition of the product (mol %): carbon tetrafluoride (13.5), hexafluoroethane (1.0), sulfur hexafluoride (68.9), trifluoromethylsulfur pentafluoride (13.3), pentafluoroethylsulfur pentafluoride (0.5), sulfuryl fluoride (0.8), and carbon disulfide unchanged (2.0); the yield[14] of sulfur hexafluoride (20.0 g, 0.137 mol) was 39.2%. A small amount of sulfur was found in the electrolytic cell.

In the case of propylene,[15] the products were carbon tetrafluoride (6.9), hexafluoroethane (1.0), sulfur hexafluoride (82.1), trifluoromethylsulfur pentafluoride (4.5), octafluoropropane (4.3), and sulfuryl fluoride (1.1), and the yield[14] of sulfur hexafluoride (23.0 g, 0.158 mol) was 63.2%.

Carbonyl chloride was also useful as a blowing gas. The whole process may be described as follows:

$$COCl_2 \xrightarrow[360\,°C]{S} COS,\quad S_2Cl_2 \xrightarrow{[F]} SF_6(COF_2,\ COS)$$

The products[16] were carbonyl fluoride (41.1), sulfur hexafluoride (45.0), and carbonyl sulfide (13.9), and the yield[14] of sulfur hexafluoride (26.3 g, 0.180 mol) was 73.2%. As far as the preparation of sulfur hexafluoride is concerned, the process using carbon monoxide is superior to all others among those studied in the present work.

The Magnetic Properties of Iron(II) Complexes with 2-(2′-Pyridyl)imidazole and Its Derivatives

Yoshihiro SASAKI and Tsunenobu SHIGEMATSU

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received May 14, 1973)

The magnetic susceptibilities and Mössbauer spectra of iron(II) complexes of 2-(2′-pyridyl)imidazole (PI), 2-(6′-methyl-2′-pyridyl)imidazole (6-MPI), and 2-(2′-pyridyl)benzimidazole (PBI) have been measured in the 4.2—298 K temperature range. The results show that $Fe(II)(PI)_3(ClO_4)_2H_2O$ and $Fe(II)(PBI)_3(ClO_4)_2H_2O$ have a spin equilibrium between $^1A_1$ and $^5T_2$, while $Fe(II)(6\text{-}MPI)_3(ClO_4)_2H_2O$ does not have such an equilibrium. The temperature dependence and magnitude of the magnetic data for $Fe(II)(PBI)_3(ClO_4)_2H_2O$ and $Fe(II)(6\text{-}MPI)_3(ClO_4)_2H_2O$ have been calculated by using a parametric ligand-field approximation. The results indicate that the orbital splittings of the $^5T_2$ ground state due to trigonal distortion are -2000 and -800 cm^{-1} for $Fe(II)(6\text{-}MPI)_3(ClO_4)_2H_2O$ and $Fe(II)(PBI)_3(ClO_4)_2H_2O$ respectively.

Transition-metal octahedral complexes with the electronic configuration d^6 may exist in either one of two different electronic ground states, $^5T_2$ (high-spin $t_2^4e^2$) and $^1A_1$ (low-spin t_2^6). Under special circumstances, the energy difference between these two states at a certain temperature may become comparable to the thermal energy, kT. If, at a field strength, Δ, close to the mean spin-pairing energy, π, the separation of the two states attains a value within the thermally-accessible range, an equilibrium between the $^1A_1$ and $^5T_2$ states can be expected to occur. Orgel has suggested that the diamagnetism of tris(1,10-phenanthroline)iron(II) complexes can not be expected from simple ligand-field calculations in which $\Delta<\pi$ (Fe^{2+}; 17600 cm^{-1}).[1] The complex formation must, therefore, produce a marked decrease in π from the estimated free ion value. Thus, iron(II) complexes with α-diimine chelate rings appear to be close to a $^5T_2$–$^1A_1$ crossover system. Certain iron(II) complexes of 2-(2′-pyridyl)imidazole, 2-(2′-pyridyl)imidazoline and 2-methyl-1,10-phenanthroline, exhibit anomalous magnetic behavior indicative of the $^5T_2$–$^1A_1$ crossover.[2-6]

We have prepared iron(II) octahedral complexes with 2-(6′-methyl-2′-pyridyl)imidazole (I, R=CH_3; 6-MPI) and 2-(2′-pyridyl)benzimidazole (II; PBI); the variations in their magnetic susceptibilities and Mössbauer spectra with the temperature will be reported in this paper. Moreover, we have re-examined an iron complex with 2-(2′-pyridyl)imidazole (I, R=H; PI) and will report the results here.

Experimental

Preparation of the Reagents. (*a*) *2-(2′-Pyridyl)imidazole.* A procedure similar to that described by Chiswell *et al.* was used[7] except that, after extracting 2-(2′-pyridyl)imidazole many times with ether, the solvent was removed from the combined, dried ether extracts and the residual oil was sublimated *in vacuo* twice. Pale yellow crystals were collected and recrystallized from ethyl acetate as white crystals; mp 134.5—135 °C.

(*b*) *2-(6′-Methyl-2′-pyridyl)imidazole.* This reagent was prepared similarly from 6-methylpyridine-2-aldehyde; white crystals, mp 169 °C.

(*c*) *2-(2′-Pyridyl)benzimidazole.* A procedure similar to that described by Walter and Freiser was used.[8] α-Picolinic acid and *o*-phenylenediamine were allowed to react with each other at 170—180 °C for 3 hr. The product was crystallized from ethanol-water solution as red-violet crystals and was then sublimed. The recrystallization of the sublimate from ethyl acetate, followed by sublimation, yielded white crystals of 2-(2′-pyridyl)benzimidazole; mp 220 °C.

Preparation of Complexes. All preparations were carried out in a nitrogen atmosphere using air-free water and ethanol. All the complexes were dried *in vacuo* over silica gel at room temperature.

(*a*) *Tris-[2-(2′-pyridyl)imidazole] Iron(II) Perchlorate Monohydrate.* Solutions of 2-(2′-pyridyl)imidazole (2.2 g) in ethanol (10 ml) and ferrous perchlorate hexahydrate (1.8 g) in water (10 ml) were mixed. The dark red solution thus formed was concentrated to half-volume under reduced pressure; the complex was then precipitated on cooling. When it was recrystallized from 1:1 ethanol-water, dark red crystals were obtained. Found: C, 40.50; H, 3.29; N, 17.33; Fe, 7.90%. Calcd for $FeC_{24}H_{23}N_9O_9Cl_2$: C, 40.69; H, 3.27; N, 17.80; Fe, 7.88%.

(*b*) *Tris-[2-(6′-methyl-2′-pyridyl)imidazole] Iron(II) Perchlorate Monohydrate.* This complex was prepared similarly from 2-(6′-methyl-2′-pyridyl)imidazole; yellow crystals. Found: C, 42.67; H, 3.76; N, 16.80; Fe, 7.34%. Calcd for $FeC_{27}H_{29}N_9O_9Cl_2$: C, 43.22; H, 3.90; N, 16.80; Fe, 7.44%.

(*c*) *Tris-[2-(2′-pyridyl)benzimidazole] Iron(II) Perchlorate Monohydrate.* Solutions of 2-(2′-pyridyl)benzimidazole (2.9 g) and ferrous chloride tetrahydrate (1.0 g) in minimum quantities of ethanol were mixed. Perchloric acid (2.2 ml

of 70% aqueous solution) and water were then added, and reddish-brown crystals were precipitated. Found: C, 50.02; H, 3.31; N, 14.41; Fe, 6.65%. Calcd for $FeC_{36}H_{29}N_9O_9Cl_2$: C, 50.37; H, 3.41; N, 14.69; Fe, 6.51%.

Magnetic Measurements. Magnetic susceptibilities were measured using a torsion balance magnetometer. The molar susceptibilities were corrected for diamagnetism, using the following corrections: Fe^{2+}, −13; H_2O, −13; ClO_4^-, −32; 2-(2′-pyridyl)imidazole, −82; 2-(2′-pyridyl)benzimidazole, −118; 2-(6′-methyl-2′-pyridyl)imidazole, −97 (in units of 10^{-6} cgs/mol). The effective magnetic moment, μ_{eff}, was obtained from the relation: $\mu_{eff}=2.828\sqrt{\chi'_M T}$, χ_M' being the fully corrected molar susceptibility, and T, the temperature in K.

Mössbauer Effect Measurements. The Mössbauer spectra were obtained with a scanning velocity spectrometer in the time mode. The radiation source was ^{57}Co diffused into a copper foil and kept at room temperature during all measurements. The velocity scale was calibrated with metallic iron, and the velocity was determined to an accuracy of ±0.04 mm/s.

Electronic Spectra. The electronic spectra of these complexes were measured with a Hitachi 323 automatic recording spectrophotometer.

Results and Discussion

Magnetic Data. The results of magnetic susceptibility measurements of polycrystalline samples between 77 and 298 K are listed in Table 1, while the variation in μ_{eff} with the temperature is shown in Fig. 1. The magnetic-moment values for $Fe(II)(6\text{-}MPI)_3(ClO_4)_2H_2O$ are characteristic of an iron(II) ion in a $^5T_2$ ground state. Within the 77—298 K temperature range, the susceptibility follows the Curie-Weiss law: $\chi'_M=C/(T-\Theta)$; the resulting value of the Weiss constant, Θ, is −3°.

The magnetic-moment values for the other complexes indicate that these compounds possess anomalous magnetic properties. The values of susceptibility for $Fe(II)(PI)_3(ClO_4)_2H_2O$ are in agreement with those reported by Goodgame and Machado.[2] The temperature dependence of the Curie-Weiss plot for $Fe(II)(PBI)_3(ClO_4)_2H_2O$ is shown in Fig. 2. This plot exhibits that, within the 220.5—298 K temperature range, the susceptibility follows the Curie-Weiss law and that the value of the Weiss constant, Θ, is −2°.

The increase in χ'_M with a rise in the temperature

seems to be caused by either an antiferromagnetic interaction between iron(II) ions or by a thermal equilibrium involving terms of different spin multiplicities. Since all the complexes contain three ligand molecules around a central ion and since the Weiss constants of the complexes are small, it seems unlikely that an iron-iron antiferromagnetic interaction occurs in these compounds. Therefore, the most plausible explanation is that there is an equilibrium between two different spin states. Octahedral iron(II) complexes may exist in either the $^5T_2$ or the $^1A_1$ ground state, and the energy separation between these two states may become comparable to the thermal energy, kT, under special circumstances.[9] Thus, we suggest that the observed results can be explained in terms of a spin equilibrium involving $^5T_2$ and $^1A_1$ electronic states.

Table 2. Mössbauer parameters δ^{IS} and ΔE_Q (in mm/s)

Compound	Temp. (K)	δ^{IS} (S=0)	ΔE_Q (S=0)	δ^{IS} (S=2)	ΔE_Q (S=2)	Ratio of peak intensity a_h/a_l
$Fe(II)(PI)_3(ClO_4)_2H_2O$	298	0.40	0.40	—	—

	100	—	—	1.13	2.43	
	77.2	—	—	1.13	2.43	

error = ±0.04 mm/s.

Mössbauer Spectra. The Mössbauer effect can be readily distinguished between the low- and high-spin forms of iron(II).[10] Characteristically S=0 Fe^{II} ions have an isomer shift, δ^{IS}, in the −0.1—+0.4 mm/s range with respect to iron, and have a quadrupole splitting, ΔE_Q, which is strongly dependent on coordination, 0.0—1.0 mm/s. For S=2 Fe^{2+} ions, δ^{IS} is in the 0.9—1.6 mm/s range and ΔE_Q, in the 1.2—3.5 mm/s range. The values of the Mössbauer parameters for the present complexes are listed in Table 2. These parameters were computed by fitting the data to the Lorentzian by means of a least-squares computer program. The Mössbauer spectra of $Fe(II)(PBI)_3(ClO_4)_2H_2O$ at 298, 77.2, and 4.2 K are shown in Fig. 3.

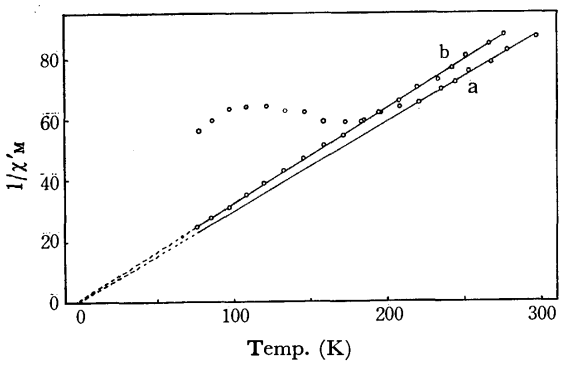

Fig. 2. Plots of resiprocal molar susceptibilities against absolute temperature.
a: $Fe(II)(PBI)_3(ClO_4)_2H_2O$, b: $Fe(II)(6\text{-}MPI)_3(ClO_4)_2H_2O$.

The spectra of $Fe(II)(6\text{-}MPI)_3(ClO_4)_2H_2O$ at 298, *ca.* 100, and 77.2 K consist of a doublet expected for the S=2 Fe^{2+} ion, which has a distortion, leaving an orbital singlet as the ground state. The spectrum of $Fe(II)(PI)_3(ClO_4)_2H_2O$ at 298 K, on the other hand, consists of a doublet due to the low-spin isomer, and the resonance lines due to the high-spin isomer cannot be observed because of the lower relative concentration of the high-spin form. The spectrum of $Fe(II)(PBI)_3(ClO_4)_2H_2O$ at 298 K consists of a doublet centered at 0.96 mm/s, with a quadrupole splitting of 1.99 mm/s, and the spectra at 77.2 and 4.2 K change into two doublets. We attribute the outer peaks to Fe^{2+} in the S=2 state, and inner pair, to Fe^{II} in the S=0 state.

Table 3. Absorption maxima in the electronic spectra

Compound	d-d Band (log ε) (cm^{-1})	CT band (log ε) (cm^{-1})
$Fe(II)(PI)_3(ClO_4)_2H_2O$	—	25100
		20500
$Fe(II)(PBI)_3(ClO_4)_2H_2O$	—	20400
$Fe(II)(6\text{-}MPI)_3(ClO_4)_2H_2O$	11900 (0.91)	26200 (2.78)
	8600 (0.83)	

Electronic Spectra. The band maxima in the electronic spectra measured in ethanol are listed in Table 3. The molar extinction coefficients of $Fe(II)(PI)_3(ClO_4)_2H_2O$ and $Fe(II)(PBI)_3(ClO_4)_2H_2O$ vary with their concentrations. The electronic spectrum of $Fe(II)(6\text{-}MPI)_3(ClO_4)_2H_2O$ is characteristic of a high-spin complex whose d-d band splits into two components. The average of the band energies may be taken as a rough estimate of the ligand-field splitting, Δ. In this way, we obtained $\Delta \simeq 10300\ cm^{-1}$ for $Fe(II)(6\text{-}MPI)_3(ClO_4)_2H_2O$.

Calculation of the Ligand-field Parameters. We carried out a ligand-field calculation for d^6 quintet states, including the spin-orbit coupling and the trigonal component in the ligand field. Since we worked within a ^5D state, this calculation does not include the singlet state in the spin equilibrium.

The predominant cubic field splits the atomic ^5D term into $^5T_2$ and appriximately 10000 cm^{-1}-higher-lying ^5E. The ligand-field splitting parameter, Δ, for $Fe(II)(6\text{-}MPI)_3(ClO_4)_2H_2O$ is 10300 cm^{-1}. The trigonal distortion splits the $^5T_2$ ground term into ^5E and $^5A_1$, and the separation between these terms is called δ. Whenever the orbital doublet, ^5E, is the lowest, the sign of δ can be chosen as positive, and *vice versa*. If the z axis is taken along the (1,1,1) direction of the octahedron, the trigonal potential, V_t, has the form:

$$Ar^2C_0^{(2)}(\theta,\varphi) + Br^4[C_0^{(4)}(\theta,\varphi) - 1/2\sqrt{7/10}(C_3^{(4)}(\theta,\varphi) - C_{-3}^{(4)}(\theta,\varphi))] \quad (1)$$

9) Y. Tanabe and S. Sugano, *J. Phys. Soc. Japan*, **9**, 776 (1954).
10) J. F. Duncan and R. M. Golding, *Quart. Rev.*, **19**, 36 (1965).

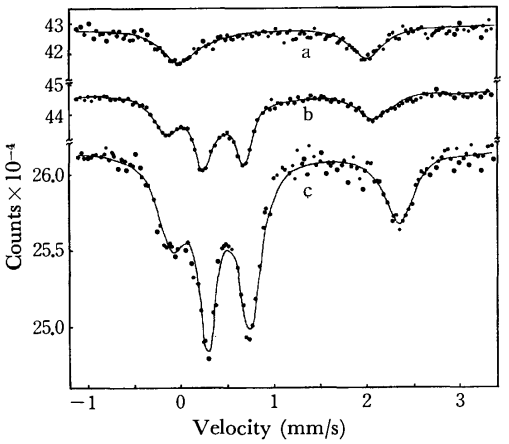

Fig. 3. Mössbauer spectra of $Fe(II)(PBI)_3(ClO_4)_2H_2O$.
a: 298 K, b: 77.2 K, c: 4.2 K.

where $C_m^{(k)}(\theta,\varphi)=(4\pi/(2k+1))^{1/2}Y_{km}(\theta,\varphi)$. δ is calculated by using the parameters, v and v', of Pryce and Runciman.[11] Their parameters are related to the parameters in Eq. (1) in the following way:

$$\overline{Ar^2} = v - 2\sqrt{2}v'$$
$$\overline{Br^4} = \frac{4}{3}v + 2\sqrt{2}v'. \quad (2)$$

Since $\delta \ll \Delta$ in general, δ depends almost entirely on the value of v and is not sensitive to v'. Thus, v' is assumed to be zero throughout the discussion.

The matrix elements of the Hamiltonian:

$$H = V_t - \lambda L \cdot S \quad (3)$$

were evaluated within the 15 states $|M_L M_S>$ of a $^5T_2$ term classified according to their M_J values. The eigenvalues and eigenfunctions generated in this calculation may be used to evaluate the magnitude and temperature dependence of the effective magnetic moment of a high-spin ferrous system.

The usual Van Vleck formulation is used for the magnetic susceptibility. It has to be calculated separately in both the direction parallel to and that perpendicular to the principal axis. The average magnetic susceptibility, $\bar{\chi}$, may be obtained from the principal magnetic susceptibilities, $\chi_{//}$ and $\chi_\perp$ according to:

$$\bar{\chi} = \frac{1}{3}(\chi_{//}+2\chi_\perp). \quad (4)$$

Then, the average magnetic moment, $\bar{\mu}$, was determined by $\bar{\chi}$ as a function of parameters, v and λ, and the orbital reduction factor κ.

The curves of the average magnetic moment against the temperature for various values of v are shown in Figs. 4 and 5. It can be seen that the temperature dependence of the magnetic moment for a positive v value is qualitatively different from that for a large negative v value. For a positive v value, there is a maximum in the curve, while for a large negative v value, the curve is essentially flat down to ~15 K. Taking account of the covalency effects, we fixed $\lambda=-80$ cm^{-1} and $\kappa=0.8$. Thus, the value of δ can

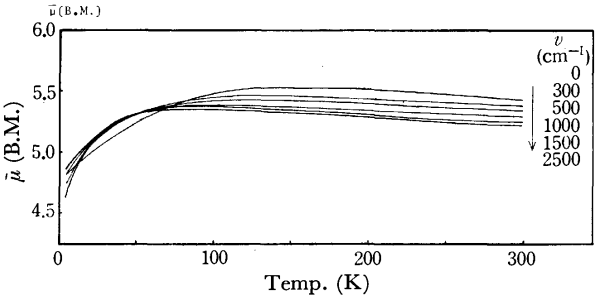

Fig. 4. Temperature dependence of the average magnetic moment of a high-spin ferrous complex as a function of trigonal distortion for positive values of v.
$\lambda=-80$ cm^{-1}, $\kappa=0.8$.

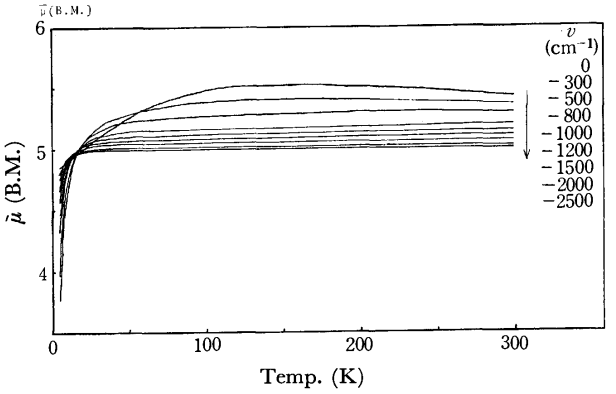

Fig. 5. Temperature dependence of the average magnetic moment of a high-spin ferrous complex as a function of trigonal distortion for negative values of v.
$\lambda=-80$ cm^{-1}, $\kappa=0.8$.

be easily determined by the curve-fitting method. The solid lines for $Fe(II)(6\text{-}MPI)_3(ClO_4)_2H_2O$ and $Fe(II)(PBI)_3(ClO_4)_2H_2O$ in Fig. 1 were calculated for $v=-2000$ and -800 cm^{-1} respectively. It is immdeiately clear from Fig. 1 that v is negative, giving an orbital singlet as the ground state, and that $\delta\simeq-2000$ and -800 cm^{-1} for $Fe(II)(6\text{-}MPI)_3(ClO_4)_2H_2O$ and $Fe(II)(PBI)_3(ClO_4)_2H_2O$. The quadrupole splitting in the Mössbauer spectra of $Fe(II)(PI)_3(ClO_4)_2H_2O$ and $Fe(II)(PBI)_3(ClO_4)_2H_2O$ in S=0 arises from this trigonal distortion. It has been reported that $Fe(II)(bipy)_3(ClO_4)_2$, which is in a low-spin form, exhibits a similar quadrupole splitting.[12] Therefore, this complex probably has a large trigonal distortion.

Two approaches have been previously employed to interpret the crossover system qualitatively. The first is the calculation of the temperature dependence of the susceptibility in terms of the Boltzmann distribution between $^5T_2$ and $^1A_1$ states separated from each other by a fixed energy, ΔE.[13] However, this method is not successful in the present case. The second approach is an empirical one in which one calculates an equilibrium constant in terms of the relative concentrations of the high- and low-spin forms.[1,14] We define the equilibrium constant as $K=[HS]/[LS]$, which is cal-

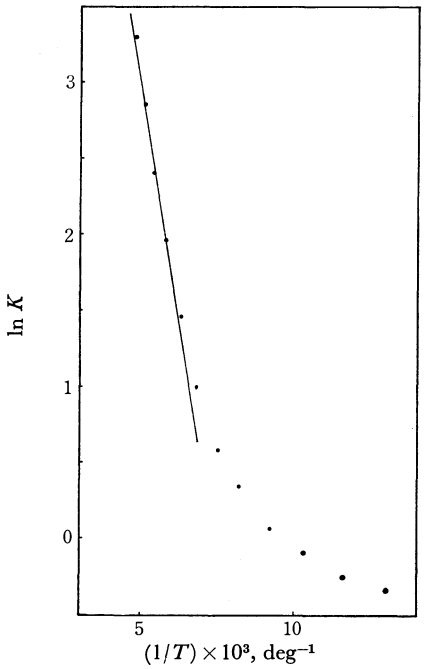

Fig. 6. Plot of $\ln K$ for $Fe(II)(PBI)_3(ClO_4)_2H_2O$ against $1/T$.

culated easily from the observed results. In order to calculate K, it is assumed that the susceptibility of the $^5T_2$ state follows the Curie-Weiss law within the temperature range of 77—298 K and that the temperature-independent paramagnetism for the $^1A_1$ state is 50×10^{-6} cgs/mol.[13] According to this assumption, the K value of $Fe(II)(PBI)_3(ClO_4)_2H_2O$ at 77.2 K is 0.71. Figure 6 shows the temperature dependence of $\ln K$ as calculated from the experimental susceptibility of $Fe(II)(PBI)_3(ClO_4)_2H_2O$. The curvature of the $\ln K$ against $1/T$ plot reveals that this method is inadequate over the full temperature range. However, ΔH is essentially constant over the 159.4—207.8 K range and is listed in Table 4, along with the ΔS calculated there. Assuming that the Weiss constant is $-2°$ and that $\chi'_M=11000\times10^{-6}$ cgs/mol at 298 K (these represent typical experimental values for such species), one can plot $\ln K$ against $1/T$ and calculate ΔH and ΔS for $Fe(II)(PI)_3(ClO_4)_2H_2O$ (Table 4).

TABLE 4. THERMODYNAMIC PARAMETERS FOR SPIN EQUILIBRIUM

Compound	Temperature range (K)	ΔH (kcal/mol)	ΔS (e.u.)
$Fe(II)(PBI)_3(ClO_4)_2H_2O$	159.4—207.8	2.49	18.43
$Fe(II)(PI)_3(ClO_4)_2H_2O$	210.3—281.8	2.96	6.89

The entropy change for a simple spin equilibrium between singlet and quintet states may be only 3.2 eu. Since the ΔS values in the $^5T_2$–$^1A_1$ equilibria of these complexes are larger than 3.2 eu, it appears that additional factors, such as changes in the bond length and/or lattice spacing, play an important role in deciding the details of the temperature variation in the magnetic susceptibilities.

We can also obtain the relative concentrations of the low- and high-spin forms in $Fe(II)(PBI)_3(ClO_4)_2H_2O$ from the Mössbauer spectra if the recoilless fractions are same for the two states (it is not likely that they are very different). Then, the equilibrium constant, K, is 0.63 at 77.2 K and 0.61 at 4.2 K. The results indicate that *ca.* 40% of the molecules are permanently in a $^5T_2$ state. According to the model for a spin equilibrium between $^5T_2$ and $^1A_1$ suggested by Bari and Sivardière, all the molecules should exist in a $^1A_1$ state at a considerably low temperature.[15] Therefore, we suggest that two chemical species may co-exist, one exhibiting a spin equilibrium and the other existing in a $^5T_2$ state. The asymmetry of 2-(2′-pyridyl)-benzimidazole as a chelating ligand allows, in theory, the formation of *vicinal* and *meridional* geometric isomers. Then, such geometric isomerism may result in the formation of two isomers possessing some different magnetic properties.

Recently a report about the magnetic behavior of some iron(II) complexes containing 2-(2′-pyridyl)benzimidazole was published.[16] The results indicate the existence of a $^5T_2$–$^1A_1$ spin equilibrium, but the details are not consistent with our investigation because these samples are different from the present complex.

Conclusion

The temperature dependence of the magnetic moments of $Fe(II)(PI)_3(ClO_4)_2H_2O$ and $Fe(II)(PBI)_3(ClO_4)_2H_2O$ indicate the presence of a spin equilibrium between the $^5T_2$ and $^1A_1$ states. The results of the Mössbauer spectra of $Fe(II)(PBI)_3(ClO_4)_2H_2O$ are consistent with the existence of such a spin equilibrium. This behavior is in marked contrast to that of $Fe(II)(6\text{-MPI})_3(ClO_4)_2H_2O$, which is a high-spin complex within the temperature range of 77—298 K. The difference in the magnetism of these complexes arises from the steric hindrance introduced by the 6′-methyl group.

The temperature dependence and magnitude of the magnetic moments of $Fe(II)(PBI)_3(ClO_4)_2H_2O$ and $Fe(II)(6\text{-MPI})_3(ClO_4)_2H_2O$ existing in a $^5T_2$ state can be reproduced well using the parametric ligand-field theory. The results indicate that the orbital splittings of the $^5T_2$ state due to trigonal distortion are -2000 and -800 cm^{-1} for $Fe(II)(6\text{-MPI})_3(ClO_4)_2H_2O$ and $Fe(II)(PBI)_3(ClO_4)_2H_2O$ respectively.

The authors wish to thank Dr. T. Shinjo and Mr. T. Matsuzawa for permitting us to use equipments for Mössbauer and magnetic measurements, respectively and for their helpful discussions.

The Preparation and Absorption Spectra of the Mixed *cis*-Dicyano Complexes of Cobalt(III) with Carbonato or Related Ligands

Shuhei FUJINAMI and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received May 23, 1973)

By the reaction of the $[Co(CO_3)_3]^{3-}$ complex and KCN, the complex anion, $[Co(CN)_2(CO_3)_2]^{3-}$, has been isolated as the tris(ethylenediamine)cobalt(III) salt. From this dicarbonato-complex anion, related dicyano complexes, $[Co(CN)_2(CO_3)(C_2O_4)]^{3-}$ and $[Co(CN)_2(C_2O_4)_2]^{3-}$ have then been obtained as $\Lambda(+)_{589}$-$[Co(en)_3]^{3+}$ salts, with resolutions into the active forms. Other related complexes, $[Co(CN)_2(dtc)_2]^-$ and $[Co(CN)_2(xan)_2]^-$ (dtc=dimethyldithiocarbamate anion, xan=methylxanthate anion), have also been prepared as potassium salts from the dicarbonato complex. The absorption spectra of all of the dicyano complexes have been measured, as have the CD spectra of the resolved dicyano complexes. Based on these spectral data, the geometrical structures of all the dicyano complexes have been identified as of the *cis* form. The $[Co(CN)(malo)_2OH_2]^{2-}$ complex has been isolated as potassium salt. From the PMR spectrum, the structure has been determined as the *trans* form. The polarized spectra of a crystal of this complex have also been measured.

It is generally said that the synthesis of a complex containing two different ligands which are considerably separated in the spectrochemical series[1] is difficult because a disproportionation reaction takes place easily. In fact, several complexes containing the cyanide ion, which occupies the highest position of the series, and ammonia, which is ranked in a middle position, have been prepared by methods which guard against the disproportionation reaction.[2-10] In a previous work,[4] we ourselves used potassium tricarbonatocobaltate(III) as the starting material for the synthesis of cyano-ammine-series complexes. At that time, we observed the formation of some species containing both cyano and carbonato ligands in the midst of the preparation reaction. Recently, we succeeded in isolating a species, the dicyanodicarbonatocobaltate(III) complex, from a reaction mixture of tricarbonatocobaltate(III) and cyanide.[11] Afterward, we attempted to prepare related complexes, such as bis(oxalato) and bis(malonato) complexes, from the dicarbonato complex. Furthermore, other similar dicyano complexes containing the dimethyldithiocarbamato ligand (abbreviated as dtc) or the methylxanthato(xan) were also prepared from the dicarbonato complex. In the present paper the preparation of these dicyano complexes and their electronic absorption spectra will be reported in detail. The spectra of other dicyano complexes containing H_2O ligands will also be reported. The cyanobis(malonato)-aquocobaltate(III) complex is also isolated in this work.

Experimental

Materials. The dimethylammonium dimethyldithiocarbamate, $(CH_3)_2NH_2(CH_3)_2NCS_2$, and potassium methylxanthate, KCH_3OCS_2, were freshly prepared according to the literature methods.[12] The other reagents were of reagent-grade quality.

Preparation. 1) *$\Lambda(+)_{589}$-Tris(ethylenediamine)cobalt(III) cis-dicyanodicarbonatocobaltate(III) Dihydrate, $\Lambda(+)_{589}$-[Co(en)$_3$]·cis-[Co(CN)$_2$(CO$_3$)$_2$]·2H$_2$O.* The preparative method has been described in an earlier paper,[11] but the description will be given here again because this method is the basis for the syntheses of the other complexes. To a cold, green solution of tricarbonatocobaltate(III)[13] ($CoCl_2 \cdot 6H_2O$ 10 g (0.048 mol) scale) we added potassium cyanide (7.5 g, 0.12 mol) in portions. The mixture was then stirred vigorously at room temperature for an hour, whereby a deep red solution was obtained. (This solution was used not only in this preparation but also in other preparations to be discussed later.) The solution was carefully neutralized with aqueous perchloric acid and then filtered. The filtrate was charged on an ion-exchange column containing 100—200 mesh Dowex 1-X8 resin in the Cl form (diameter, 5 cm; resin height, 15 cm). By elution with an aqueous solution of KCl (1 M), a red band came out of the column, after a green band. This red effluent was concentrated at about 30 °C. A small amount of ethanol was added to the concentrate, and then the whole was kept in a refrigerator in order to precipitate some salts, such as KCl. After the removal of the precipitates, an aqueous solution of $\Lambda(+)_{589}$-$[Co(en)_3]Br_3 \cdot 2H_2O$[14] was added to the filtrate. When the whole was then kept in a refrigerator, needle-like crystals of the desired complex, colored brown-violet, were deposited. These were washed with cold water, ethanol, and ether in turn, and finally dried *in vacuo*. The yield was about 1.5 g. Found: C, 23.93; H, 5.68; N, 22.10%. Calcd for $[Co(C_2H_8N_2)_3] \cdot [Co(CN)_2(CO_3)_2] \cdot 2H_2O$: C, 23.73; H, 5.58; N, 22.13%.

This compound showed the same CD spectrum as the $\Lambda(+)_{589}$-$[Co(en)_3]^{3+}$ complex itself. Attempts to obtain an usual compound such as potassium (or calcium) salt ended in failure because of the great solubility of such salt and because of the instability of the species in an aqueous solution.

2) *$\Lambda(+)_{589}$-Tris(ethylenediamine)cobalt(III)* cis-*dicyanocar-*

bonatooxalatocobaltate(III) Monohydrate, $\Lambda(+)_{589}$-[*Co(en)*$_3$]·cis-[*Co(CN)*$_2$*CO*$_3$(*C*$_2$*O*$_4$)]·*H*$_2$*O*. To a deep red solution obtained by the procedure described in 1), we added ground powder of oxalic acid (12 g, 0.1 mol) little by little. Then the solution was stirred vigorously at room temperature for 4—5 hours. After that, a chromatographic separation similar to that described in 1) was carried out using an aqueous solution of KCl (2 M). The effluent was quickly dried at about 30 °C, and the residue was extracted with methanol several times. The extracted solution was dried up again, and the remaining material was dissolved in a minimum amount of water. After a saturated aqueous solution of the $\Lambda(+)_{589}$-[Co(en)$_3$]Br$_3$ complex and a little ethanol had been added to the solution, it was kept in a refrigerator until brown-red crystals deposited. This crude complex was then recrystallized from water. The compound exhibited a different CD spectrum from that of $\Lambda(+)_{589}$-[Co(en)$_3$]$^{3+}$ itself, indicating the successful resolution of this dicyano complexes. Yield, about 0.03 g. Found: C, 25.11; H, 5.05; N, 20.94%. Calcd for [Co(C$_2$H$_8$N$_2$)$_3$]·[Co(CN)$_2$CO$_3$(C$_2$O$_4$)]·H$_2$O: C, 24.82; H, 4.92; N, 21.05%.

3) $\Lambda(+)_{589}$-*Tris(ethylenediamine)cobalt(III)* cis-*Dicyanobis(oxalato)cobaltate(III) Hexahydrate*, $\Lambda(+)_{589}$-[*Co(en)*$_3$]·cis-[*Co(CN)*$_2$(*C*$_2$*O*$_4$)$_2$]·6*H*$_2$*O*. A deep red solution obtained by the procedure described in 1) was acidified with ground powder of oxalic acid until the resulting solution showed pH 5; the solution was then stirred at room temperature for 5 hours. After that, the reacted solution was treated in the same way as has been described in 2). When the final solution was kept in a refrigerator, a foliate red crystal was deposited. The compound showed a CD spectrum different from that of the precipitant, indicating a successful resolution. Yield, about 0.03 g. Found: C, 22.38; H, 5.13; N, 17.53%. Calcd for [Co(C$_2$H$_8$N$_2$)$_3$][Co(CN)$_2$(C$_2$O$_4$)$_2$]·6H$_2$O: C, 22.72; H, 5.32; N, 17.66%.

4) *Potassium* cis-*Dicyanobis(dimethyldithiocarbamato)cobaltate (III) Monohydrate*, cis-*K*[*Co(CN)*$_2$*(dtc)*$_2$]·*H*$_2$*O*. To a cold, deep red reaction mixture, we added an aqueous solution of the dimethyldithiocarbamate (16 g, 0.1 mol) in portions. The mixture was stirred at room temperature for half an hour and then filtered. The filtrate was quickly dried up at ca. 25 °C, and the residue was extracted with methanol several times. After the concentration of the extracted solution to a small volume, the solution was poured into a column of alumina for chromatography (5×25 cm). By elution with methanol, a red band of the desired complex, next to a green band, came out. The eluted solution was then concentrated, and ether was added. When the solution was then kept in a refrigerator, dark red crystals were deposited. They were collected and washed with cold methanol and ether in turn. Yield, about 3 g. Found: C, 23.45; H, 3.51; N, 13.40; S, 31.82%. Calcd for K[Co(CN)$_2$(C$_3$H$_6$NS$_2$)$_2$]·H$_2$O: C, 23.52; H, 3.46; N, 13.71; S, 31.39%.

5) *Potassium* cis-*Dicyanobis(methylxanthato)cobaltate(III) Monohydrate*, cis-*K*[*Co(CN)*$_2$*(xan)*$_2$]·*H*$_2$*O*. The method was quite similar to that in 4); the xanthate ligand (14 g, 0.1 mol) was, however, used instead of the dtc ligand. Yield, 1 g. This complex is very unstable, even in the solid state. Found: C, 19.28; H, 2.55; N, 7.65; S, 33.78%. Calcd for K[Co(CN)$_2$(C$_2$H$_3$OS$_2$)$_2$]·H$_2$O: C, 18.84; H, 2.11; N, 7.33; S, 33.53%.

6) *Potassium* trans-*Cyanobis(malonato)aquocobaltate(III) Monohydrate*, trans-*K*$_2$[*CoCN*(malo)$_2$*OH*$_2$]·*H*$_2$*O*. To the cold, deep red solution mentioned in 1), we added finely ground malonic acid until the resulting solution showed pH 5. The mixture was stirred at room temperature for 3 hours, and then the solution was chromatographed in the same manner as has been described in 1). A blue-violet band came out upon elution with a KCl solution (1 M). This effluent was evaporated to dryness at 30 °C, and the residue was extracted with methanol several times. The extract was then again dried up, and the residue was dissolved in a minimum amount of water. After acetone was added, the solution was kept in a refrigerator until needle-like crystals had been deposited. They were collected and washed with methanol, acetone, and ether in turn. Yield, 1 g. Found: C, 20.68; H, 2.10; N, 3.81%. Calcd for K$_2$[CoCN(C$_3$H$_2$O$_4$)$_2$-OH$_2$]·H$_2$O: C, 20.84; H, 2.00; N, 3.47%.

Measurements. The infrared absorption spectra (IR) were measured by means of a JASCO IRA-2 grating infrared-spectrophotometer. The KBr disk method was used in the range of 400—4000 cm^{-1}. For the measurement of the electronic absorption spectra in solution, a Hitachi EPU-2A spectrophotometer was used. The circular dichroism spectra (CD) were recorded on a JASCO Model ORD/UV-5 spectrophotometer with a CD attachment, with samples converted to sodium salts in solution. The proton magnetic resonance spectra (PMR) were recorded on a JEOL C-60H spectrometer (60 Mc/sec) using sodium 3-(trimethylsilyl)propanesulfonate as the internal reference at room temperature. The electronic absorption spectra of single crystals were measured through the good offices of Professor Yukio Kondo of Rikkyo University, Tokyo.

Results and Discussion

Characterization. The IR spectra of the present [Co(CN)$_2$(O–O)$_2$]$^{3-}$-type complexes are very complicated because of the existence of the [Co(en)$_3$]$^{3+}$ complex as their counter ions, but it was possible to confirm the chelation of CO_3^{2-} or $C_2O_4^{2-}$ ions according to the methods of the literature.[15,16] The ν(CN) band was observed at 2155, 2140, and 2150 cm^{-1} for the dicarbonato, the carbonatooxalato, and bis(oxalato) complexes respectively. The IR spectra of the [Co(CN)$_2$(S–S)$_2$]$^-$-type complexes resembled those of the corresponding tris(dtc) and tris(xan) complexes in the spectra due to ligand absorption. The ν(CN) band was observed at 2110 and 2115 cm^{-1} for the xan and dtc complexes respectively. It is worthy of notice that the ν(CN) bands of these (S–S) chelated complexes appear in a region lower by *ca.* 30 cm^{-1} compared with those of the (O–O) chelated complexes. This fact may be related to the nephelauxetic effects[17] of the dtc and xan ligands. Evidence for the chelated malonate ion and the coordinated water molecule in the [CoCN-(malo)$_2$OH$_2$]$^{2-}$ complex was obtained from its IR spectrum. The ν(CN) band was observed at 2145 cm^{-1}.

Since the [Co(CN)$_2$CO$_3$(C$_2$O$_4$)]$^{3-}$ and [Co(CN)$_2$-(C$_2$O$_4$)$_2$]$^{3-}$ complexes could be resolved with the $\Lambda(+)_{589}$-[Co(en)$_3$]$^{3+}$ ion, the geometrical structures of these complexes were identified as of the *cis*-form. With the [Co(CN)$_2$(CO$_3$)$_2$]$^{3-}$ complex, the resolution

was unsuccessful, but its structure was regarded as *cis*-form from the fact that the electronic absorption spectrum of this complex was very similar to those of the resolved complexes.

In the PMR spectrum of the $[CoCN(malo)_2OH_2]^{2-}$ complex, resonance signals due to the methylene groups in the chelated malonate rings were observed at 2.98, 3.29, 3.66, and 3.97 ppm; these are classified as an AB pattern with a coupling constant of J=18.6 Hz. This pattern suggests a structure *trans* with respect to CN^- and H_2O; two sets of AB patterns may be expected for *cis* structure of the complex. In fact, the $[Cogly(malo)_2]^{2-}$ complex[18] exhibits very complicated methylene signals because of the malonato ligand.

The Absorption and CD Spectra for the Dicyano Complexes. The absorption spectra of the $[Co(CN)_2(O\text{-}O)_2]^{3-}$-type complexes were measured in aqueous solutions of the tris(ethylenediamine) salts and in solutions of the sodium salts obtained by means of ion exchange. A spectrum obtained by subtracting the spectrum of the $[Co(en)_3]^{3+}$ complex itself from the observed spectrum for the tris(ethylenediamine) salt coincided with the spectrum for the sodium salt. Therefore, only the spectra of the sodium salts are shown in Fig. 1, while the numerical data are summarized in Table 1. The spectra show three well-separated maxima at *ca.* 18, 23, and 28 kK. No such marked splitting has ever been reported with the *cis*-form complexes. Hereafter, these three maxima (or bands) will be represented by Ia, Ib, and II from the lower energy. After the $[Co(CN)_2(CO_3)_2]^{3-}$ and the $[Co(CN)_2CO_3(C_2O_4)]^{3-}$ had been dissolved in aqueous perchloric acid, the resulting solutions were submitted to spectrum measurements. (The results are shown in Fig. 2 and Table 1.) It was ascertained that the complex species thus formed were chromatographically pure, and that the observed spectra were completely reformed into the spectra of the parent complexes, when excess Na_2CO_3 was added to the $HClO_4$ solution. From these facts, the spectra in Fig. 2 may be considered to be those for the tetra-

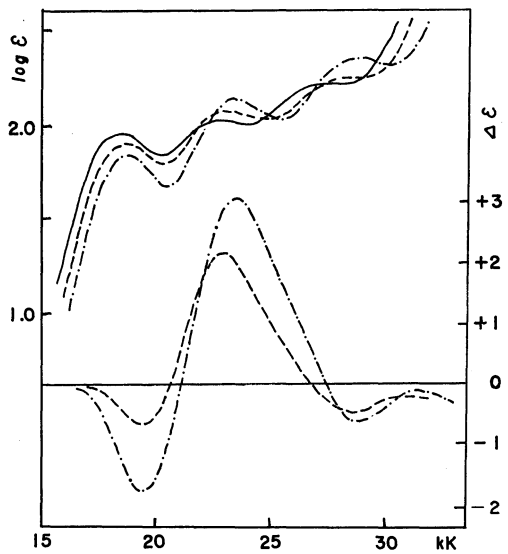

Fig. 1. Absorption and CD spectra of dicyano complexes. ——: $[Co(CN)_2(CO_3)_2]^{3-}$, – – –: $[Co(CN)_2CO_3(C_2O_4)]^{3-}$, –·–·–: $[Co(CN)_2(C_2O_4)_2]^{3-}$, (Na salts).

aquo and diaquo complexes, *cis*-$[Co(CN)_2(OH_2)_4]^{+}$ and $[Co(CN)_2(C_2O_4)(OH_2)_2]^{-}$. A characteristic difference of these spectra from those of the present complexes is the decreased intensity of the II band. The dicyanobis(malonato) complex species, the attempt at the isolation of which was unsuccessful, exhibits a spectrum rather more similar to that of the tetraaquo complex species (Fig. 5) than to that of the dicarbonato (or bis(oxalato)) complex. This fact suggests that the intensity of the II band is related to the rigidity of

18) K. Yamasaki, J. Hidaka, and Y. Shimura, This Bulletin, **42**, 119 (1969).

the O–O ligand. Krishnamurthy and his co-workers[19] have reported the absorption spectrum of the *cis*-$[Cr(CN)_2(OH_2)_4]^+$ complex, which is very similar to the spectrum of our cobalt(III) complex. They said that one component of the second absorption band might be hidden under the middle maximum (corresponding to the Ib band), which is a component of the first absorption band; they based their suggestion on the meagerness of the third maximum (II Band). However, we consider that the Ib bands in our dicyano complexes are due to a split component of the first absorption band, judging from the fact that the Ib maxima for the $[Co(CN)_2(C_2O_4)_2]^{3-}$ and $[Co(CN)_2CO_3(C_2O_4)]^{3-}$ complexes coincide with their CD maxima (Fig. 1). However, it is interesting that the intensities of the Ib maxima are greater than those of the Ia bands.

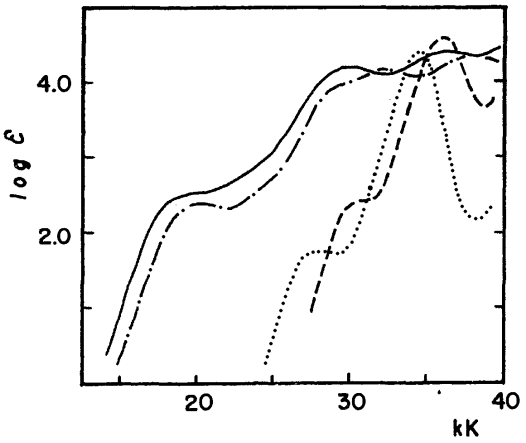

Fig. 3. Absorption spectra of sulfur-contained complexes.
——: $K[Co(CN)_2(dtc)_2]$, -·-·-: $K[Co(CN)_2(xan)_2]$,
·····: KCH_3OCS_2, ——: $(CH_3)_2NH_2(CH_3)_2NCS_2$.

The spectra of the $[Co(xan)_3]$ and $[Co(dtc)_3]$ complexes have been reported by Kida *et al.*,[20] but there has been no report on mixed complexes with the xan (or dtc) ligand and another ligand. In a complex containing such a (S-S) ligand, the d-d transition bands are covered, at a higher energy, by the allowed transition bands of the ligand. In fact, each absorption spectrum of the $[Co(CN)_2(dtc)_2]^-$ and $[Co(CN)_2(xan)_2]^-$ complexes (Fig. 3, Table 1) shows a well-defined maximum at a lower energy and a shoulder at a higher energy. However, by a comparison of these spectra with those of the carbonato (or oxalato) complex, the present dtc and xan complexes may be regarded as *cis* complexes. If the complexes are *trans*, entirely different spectra from those of the *cis*-$[Co(CN)_2(O-O)_2]$-type complexes may be expected.

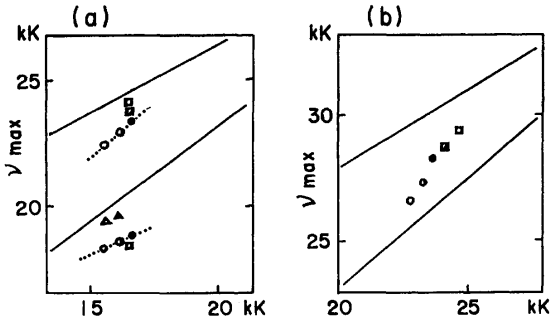

Fig. 4. The relationships between the absorption maxima of the dicyano complexes (ν_{max}) and the predicted values.

●: $[Co(CN)_2(C_2O_4)_2]^{3-}$, ◪: $[Co(CN)_2C_2O_4(OH_2)_2]^-$,
□: $[Co(CN)_2(OH_2)_4]^+$, △: $[Co(CN)_2(dtc)_2]^-$,
▲: $[Co(CN)_2(xan)_2]^-$.

In order to discuss further the d-d bands of the present dicyano complexes, we divided each absorption curve into three symmetrical Gaussian[21,22] within a 3% error. The results of the analysis are summarized in Table 2. These analysed values are taken on a vertical axis in Fig. 4, while the absorption maxima for the $[Co(O)_6]$- and $[Co(S)_6]$-type complexes are placed on a horizontal line; (a) concerns the Ia and Ib bands, and (b), the II band. The solid lines in Fig. 4 represent the predicted values according to Yamatera's treatment.[23] However, the δ_π parameter was ignored and only the δ_σ parameter was taken into consideration for the second absorption band. Thus, the separation from a solid line on the vertical axis is a measure of the deviation from the theoretical treatment. That is, it indicates the distortion from octahedral symmetry or the degree of covalency between metal and ligand bonding. It is commonly considered that, in this figure, the distortion is removed upon the change in ligands from CO_3^{2-} to $C_2O_4^{2-}$.

Concerning the Ia bands, the analysed values for the complexes containing carbonate and oxalate ions make a line with a considerable separation, one which becomes larger from the CO_3^{2-} ligand to the $C_2O_4^{2-}$ ligand. The analysed values for the aquo complexes will be found below. On the other hand, the analyzed values for the dtc and xan complexes could be found in a place close to the corresponding solid line. From these relations, it may be said that a complex containing a ligand ranking in a higher position in the nephelauxetic series exhibits much less deviation of the Ia-band maximum than would be predicted.

Concerning the Ib bands, a line connecting the analysed values for the complexes with the carbonato and oxalato ligands is also not parallel to the solid line, and it has a narrower separation upon the change in ligands from CO_3^{2-} to $C_2O_4^{2-}$. The separation between the Ia and the Ib, consequently, becomes larger in that order.

The analysed values of the II band are found between the two solid lines, and the rule of average environment[17,24] does not hold.

Figure 1 shows the CD spectra of the resolved dicyano complexes, as measured with aqueous solutions of sodium salts prepared by means of ion-exchange chromatography. Each spectrum reveals three peaks, with the signs (−), (+), (−) corresponding to the Ia, Ib, and II bands. It is noteworthy that the second peak dominates the first in each spectrum, and that the dominant peaks coincide perfectly with the Ib maxima. The $\Lambda(+)_{589}$-$[Co(C_2O_4)_2(NH_3)_2]^-$ complex[13] exhibits two peaks, with (+) and (−) signs, in the first absorption band region. The CD spectrum of the $\Lambda(+)_{589}$-$[Co(CN)_2(en)_2]^+$ complex[25] shows two positive peaks in the region, and suggests cancellation with a considerably large band with a minus Cotton sign. By comparing these spectra with those of our dicyano complexes, the dominant peak can be assigned to the B_1 component in C_{2v} symmetry, while the lower energy peak can be assigned to the (A_2+B_2) component. Thus, from the sign in the transition (*i.e.*, minus), the Λ configuration can be assigned to the complexes concerned.

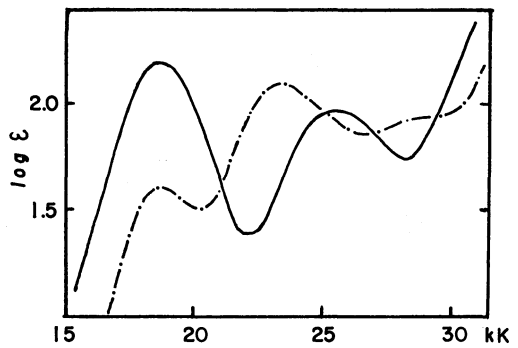

Fig. 5. Absorption spectrum of *trans*-cyanoaquobis(malonato)-cobaltate(III) complex.
——: $K_2[CoCN(malo)_2OH_2]$, -·-·-: $[Co(CN)_2(malo)_2]^{3-}$, (Na salt).

Absorption Spectra of the $[CoCN(malo)_2OH_2]^{2-}$ *Complex.* Figure 5 shows the absorption spectrum in solution. The spectrum exhibits no apparent splitting of the d-d bands, and the second absorption band has a rather weaker intensity and a broadened shape compared with the first absorption band. The maximum of the first band (Table 1) is at middle position between the A_2 and E component (C_{4v} symmetry), as predicted by Yamatera's treatment. On the other hand, this maximum coincides well with the Ia maximum for the $[Co(CN)_2(malo)_2]^{3-}$ complex, as may be seen in Fig. 5. This fact suggests that the first band of this cyano-aquo complex comes dominantly from the E component if this chromophore is treated as being tetragonal.

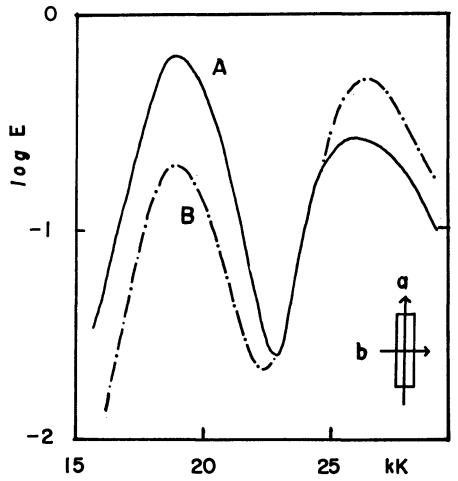

Fig. 6. Polarized single crystal spectra of *trans*-$K_2[CoCN(malo)_2OH_2]\cdot H_2O$ complex at *ca.* 90 K.
(A): along a axis ——; (B): along b axis (b⊥a)-·-·-.
log *E* represents observed absorbancy.

The polarized spectra of a crystal of this complex are shown in Fig. 6. The dichroism of the complex can be clearly observed. It can also be seen from the spectra that the relations between the intensities of the first and second bands are reversed according to the axes of polarization. Furthermore, the spectrum measured along the axis of the crystal (a) shows a red shift and a broadened shape, compared with the spectrum along the (b) axis in the region of the second absorption band. These crystal spectra are not understood precisely, because no X-ray analysis was done. However, in order to explain the observed spectra, let us now suppose that all the molecular axes of this complex are parallel to each other in the crystal. Under the C_{4v} symmetry, the A_2 and B_2 components become forbidden transitions, while the E component becomes an allowed transition; this can not, however, explain the reversed intensities and the broadened unsymmetrical second band. On the other hand, when the C_{2v}[26] molecular symmetry is adopted for this complex, only the A_2 component of the first band (corresponding to A_2 in C_{4v}) becomes a forbidden transition, while the B_1 and B_2 components (corresponding to E in C_{4v}) become allowed. From this, the first band in the

spectrum (A) may be attributed to the (B_1, B_2) components. From the group-theoretical consideration, the inflation at the second band in the same spectrum (A) can also be attributed to the (B_1, B_2) components. Consequently, the second band in the spectrum (B) must be mainly due to the A_1 transition (B_2 in C_{4v}). Judging from the coincidence of the second absorption band maxima between the solution and the crystal spectra, the intensity of the II band in the solution spectrum should come dominantly from the B_2 component (in C_{4v}). With the $[Co(L)(NH_3)_5]$- and *trans*-$[Co(L)_2(NH_3)_4]$-type complexes, Piper *et al.*[27] have reported that, if L represents CN^-, the effect of δ_π should serve to increase the splitting of the second absorption band. Accordingly, it would seem to be reasonable to observe the splitting of the second absorption band in the present $[Co(C)(O)_5]$-type complex.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3448—3452 (1973)

The Isomerism of Metal Complexes Containing Multidentate Ligands. IV. The Cobalt(III) Complex of Linear Pentaethylenehexamine[1]

Yuzo Yoshikawa and Kazuo Yamasaki

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received June 7, 1973)

The cobalt(III) complex incorporating sexidentate linear pentaethylenehexamine(1,14-diamino-3,6,9,12-tetraazatetradecane) as the ligand was prepared by the reaction of the ligand with $[CoBr(NH_3)_5]Br_2$ at room temperature in the presence of active charcoal. The resulting solution was subjected to column chromatography on *SP*-Sephadex, geometrical and optical isomers with four different configurations were then separated and characterized by their electronic and infrared absorption, circular dichroism, and PMR spectra. They have the chemical composition of $[Co(C_{10}H_{28}N_6)]Cl_3 \cdot nH_2O$, n being 1.5—3.

Linear pentaethylenehexamine(abbreviated as linpen) is able to function as a sexidentate ligand of stereochemical importance, but so far no study has been published of its cobalt(III) complex. A few copper(II), lead(II), and cadmium(II) complexes have been studied polarographically,[2] and one preliminary report[3] on the isolation of the copper(II), nickel(II), zinc(II), and mercury(II) complexes has been published. We have now prepared the cobalt(III) complex of linpen and isolated all the geometrical and optical isomers by means of column chromatography on ion-exchange Sephadex.

Experimental

Ligands. The ligand, linpen, a product of the Tokyo Kasei Co., was first purified by fractional distillation, the fraction distilling at 165—170 °C(0.05 mmHg)being collected. The distillate was then converted to the hydrochloride and re-precipitated by adding hydrochloric acid to its concentrated aqueous solution. This precipitation procedure was repeated several times until a constant infrared spectrum of the hydrochloride was obtained. Found: C, 26.28; H, 7.63; N, 18.71; Cl, 46.69%. Calcd for $C_{10}H_{28}N_6 \cdot 6HCl$: C, 26.62; H, 7.60; N, 18.63; Cl, 47.15%.

Preparation of the Complex, $[Co(linpen)]Cl_3 \cdot nH_2O$. An aqueous solution of linpen hydrochloride(2.6 g) was neutralized with sodium hydroxide to pH 9.2. To this solution 2.0 g of $[CoBr(NH_3)_5]Br_2$ and 0.5 g of active charcoal were added, and then the mixture was stirred at 25 °C for 24 hr. After the charcoal had been removed, the filtrate was subjected to column chromatography to separate the isomers.

Separation of the Isomers. In the following chromatographic separation, a column of the size, $\phi 2.7 \times 140$ cm, of *SP*-Sephadex was always used; the absorbance of the eluate at 470 nm was plotted against V/V_0, the ratio of the eluate volume *versus* the void volume of the column.[4] The symbols used in the present report, (+) and (−), denote the optical

rotation at 589 nm. The water of crystallization is different for each isomer, the numbers of which are listed in Table 1.

The I Isomer: The prepared complex was adsorbed on *SP*-Sephadex and eluted by means of a 0.18 M sodium (+)-tartrate solution; the elution curve was thus obtained (Fig. 1-a). The first four peaks were found to correspond to the two pairs of enantiomers; they were named (+)-I, (−)-I, (+)-II, and (−)-II respectively.

The fractions (V/V_0=3.3—4.0) corresponding to the (+)-I and (−)-I isomers were again adsorbed on *SP*-Sephadex after dilution and then eluted with a 1 M sodium chloride solution. By adding potassium hexacyanocobaltate(III) to this eluate, the hexacyanocobaltates of (+)-I and (−)-I were precipitated; they were then converted to the chlorides by stirring with an anion-exchange resin(Dowex 1-X8, 200—400 mesh) in the chloride form. On the evaporation of each filtrate, yellow crystals of the (+)-I and (−)-I, $[Co(linpen)]Cl_3 \cdot 2H_2O$, were obtained. Found: C, 27.80; H, 7.39; N, 19.23% for the (+)-I and C, 27.67; H, 7.40; N, 19.58% for the racemic I. Calcd. for $CoC_{10}H_{28}N_6Cl_3 \cdot 2H_2O$: C, 27.70; H, 7.44; N, 19.38%.

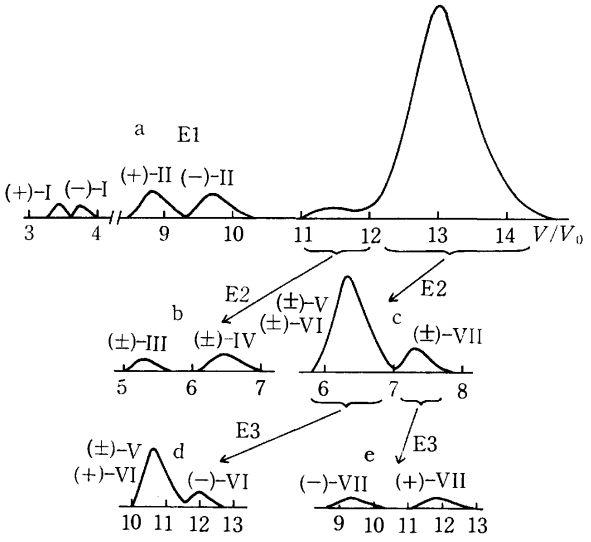

Fig. 1. Elution curves of the isomers of $[Co(linpen)]^{3+}$. The eluents E1, E2, and E3 are 0.18 M sodium (+)-tartrate, a mixture of 0.18 M sodium sulfate and 0.01 N hydrochloric acid, and 0.3 M sodium (+)-tartratoantimonate, respectively.

The II Isomer: The fractions V/V_0=8.4—10.3 (Fig. 1-a), when treated in the same way as above, yielded the (+)- and (−)-enantiomers of the II isomer. The (+)-enantiomer was further separated into two isomers by chromatography with a 0.18 M sodium sulfate solution containing 0.01 N HCl as the eluting agent, but these separated isomers were labile and isomerized into a mixture during separation on the column, so they could not be obtained in pure states. The (−)-II isomer behaved in the same way. Therefore, it may be concluded that the II isomer consists of a mixture of two conformational isomers which isomerize very quickly to each other.

The III and IV Isomers: The fractions V/V_0=11.0−12.0 (Fig. 1-a) were again adsorbed on *SP*-Sephadex and eluted with a 0.18 M sodium sulfate solution containing 0.01 N HCl. As is shown in Fig. 1-b two peaks of optically inactive isomers were obtained. The yellow, fast-moving isomer was named III, and the yellowish-brown, slow-moving one, IV. Since the complete resolution of these isomers, III and IV, into their enantiomers by chromatography was difficult, the optically-pure enantiomers of III and IV were obtained by the isomerization of the (+)-II and (−)-II isomers respectively. The (+)-II gave a mixture of the (−)-III and (−)-IV isomers which were then separated by elution with a 0.18 M sodium sulfate solution containing 0.01 N HCl. The (−)-II similarly gave a mixture of the (+)-III and (+)-IV isomers.

The V, VI, and VII Isomers: A large peak corresponding to the fractions V/V_0=12.6−14.5(Fig. 1-a) was further separated into two peaks by elution with a 0.18 M sodium sulfate solution containing 0.01 N HCl(Fig. 1-c). The large first peak at V/V_0=6−7 was further separated into two by elution with a 0.3 M sodium (+)-tartratoantimonate(III) solution (Fig. 1-d). From the first peak, the (±)-V isomer was precipitated as the hexacyanocobaltate, leaving the (+)-VI isomer in the mother liquor, from which it could not be isolated in a pure state. The fractions corresponding to the small second peak contained the pure (−)-VI(Fig. 1-d). This isomer, (−)-VI, readily isomerized in a neutral or alkaline solution into a mixture of the (−)-V, the (−)-VI, and a small amount of the (−)-VII isomers. By applying to this mixture the separation procedure shown in Figs. 1-c and d, pure (−)-V and (−)-VI were obtained.

The fractions corresponding to a small second peak in Fig. 1-c can be resolved into the (−)-VII and (+)-VII isomers by elution with a 0.3 M sodium (+)-tartratoantimonate(III) solution(Fig. 1-e). The VII isomer is labile and isomerizes readily in a neutral solution into a mixture of the V, VI, and VII isomers. Therefore, it should always be handled in an acid solution.

Measurements. The electronic absorption(AB), infrared, and circular dichroism(CD) spectra were measured at 25 °C with a Hitachi recording spectrophotometer 323, a JASCO-402G infrared spectrophotometer, and a JASCO J-20 spectrophotometer respectively. The NaCl disk was used for the infrared spectrum measurement. The PMR spectra in 0.1 N DCl(D_2O) were measured by means of a JEOL model JNM-MH-100 spectrometer, with DSS as the internal standard. When the signals due to the amino-hydrogen atoms overlapped with those due to the hydrogen of HOD, an additional amount of concentrated DCl was used to shift the latter signals.

Results and Discussion

Isomerization Reaction. In a neutral solution without active charcoal the I and II isomers do not isomerize, while the III and IV isomers isomerize under the same conditions, to give their mixture; V, VI, and VII also give their mixture. In an alkaline solution of pH 12 without active charcoal, the (−)-II isomerizes partly into a mixture of (+)-III and (+)-IV; this specific isomerization reaction was used to prepare the optically pure III and IV as has been described above. In a borate buffer solution of pH 9.0 and in the presence of active charcoal, each of the I—VII isomers isomerizes to give a mixture of all the isomers at 60 °C after 2—8 hr.

The formation ratio found experimentally in the preparative work was I: II: III: IV: V: VI: VII= 9: 15: 1: 2: 47: 23: 3; it varies to some extent with the experimental conditions.

Number of Possible Isomers. When linpen is coordinated to cobalt(III) as a sexidentate ligand, four different configurational isomers, A, B, C, and D, can

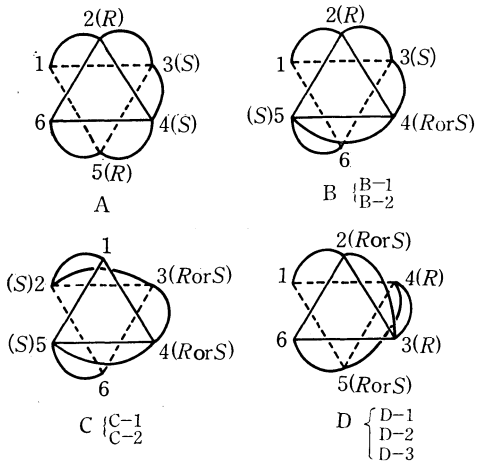

Fig. 2. Four geometric isomers of $[Co(linpen)]^{3+}$.

be expected (Fig. 2). If the absolute configurations around the secondary amine-N atoms are taken into account, the number of isomers increases. For the A structure, the absolute configurations of the nitrogen atoms are fixed; *R* for the N2 and N5, and *S* for the N3 and N4. Thus, only one isomer is possible. For the B structure, the absolute configuration of the N2 is fixed to *R*, and those of the N3 and N5, to *S*, whereas the N4 can take either the *R* or *S* configuration. Thus, two isomers are possible for the B structure. For the C structure, both the N2 and N5 are fixed to *S*. As the N2, N3, N4, and N5 are adjacent to each other on the same plane, their absolute configurations are not independent; both the N3 and N4 atoms should take the same configuration, that is, *RR* or *SS*. Therefore, two isomers are possible. For the D structure, the absolute configurations of the N3 and N4 are fixed to R, but the configuration of the N2 is independent of that of the N5. Consequently, three isomers are possible, isomers which have the *RR*, *RS*, and *SS* configurations for the N2 and N5 atoms. Thus, when the absolute configurations around the secondary amine-N atoms are taken into consideration, the symmetry of the A and C structures and two of the D structures is C_2, while that of the B structure is C_1; that of the third one of the D structures is also C_1. Consequently, the number of isomers is 1 for the A, 2 each for the B and C, and 3 for the D structure, making a total of 8. This number agrees with the number of isomers actually found.

If the conformation (δ or λ) of each chelate ring is further taken into account, the number of possible isomers increases much more. These conformational isomers, however, can not be separated under the present experimental conditions because of the rapid inversion of their conformations.

The AB and CD Spectra. The AB and CD spectra were measured in a 0.01N HCl solution except for the (+)-I and (+)-II isomers; the results are shown in Fig. 3 and Table 2. The absorption maxima are at 21600—20800 cm^{-1} (462—480 nm) for the first band, at 29500—29100 cm^{-1} (339—344 nm) for the second band, and at 44800—43100 cm^{-1} (223—232 nm) for the charge transfer band, indicating a 6N-type cobalt-

			21.3	(−4.38)							44.4	(+28.7)

region.[5] The (+)-II isomer has only one positive CD peak in the first absorption region (Fig. 3-b); from its sign it is identified as having the "Λ" configuration also (*cf.* Table 3).

The (+)-III and (+)-IV isomers were obtained by the isomerization of the (−)-II isomer in an alkaline solution of pH 12 without any active charcoal. Since these two isomers have a main CD component with the plus sign in the first absorption region (Fig. 3-b), their absolute configurations were identified as "Λ". As the starting substance, (−)-II, has the "Δ" configuration, a complicated isomerization mechanism with a configuration inversion is suspected. Under the same experimental conditions the formation of the (+)-II isomer from the (−)-II isomer is less than 0.4% in amount.

All the CD spectra of the (−)-V, (−)-VI, and (−)-VII isomers (Fig. 3-b) have the main peak with the minus sign in the first absorption region; from the sign of the CD peak, these isomers were all determined to have the "Δ" configuration.

Summarizing the results shown in Figs. 3-a and 3-b, the (+)-I has a main plus peak on the longer wavelength side of the first absorption region, and a small minus peak on the shorter wavelength side. The (+)-II and (+)-III isomers both have only a plus peak, in the same region. The (+)-IV isomer shows a small plus peak and a large minus peak, whereas the (−)-V, (−)-VI, and (−)-VII isomers all have a small plus peak and a large minus peak, in the same region. In the present section, the relationship between the sign of the main CD peak and the absolute configuration of each isomer has been discussed.

There is a very weak CD peak for the (−)-V isomer at 17000 cm^{-1} (589 nm) ($\Delta\varepsilon=-0.02$) and for the (−)-VI isomer at 16200 cm^{-1} (616 nm) ($\Delta\varepsilon=-0.01$). The origin of this weak peak is not yet clear. One possibility is the spin-forbidden band which is similar to the $^3T_{2g}\leftarrow{}^1A_{1g}$ transition of $[Co(en)_3]^{3+}$.[6] Another possibility is a band remaining after the cancellation of two bands with opposite signs which are situated close to each other. The positions of these weak peaks are too low in frequency to be attributed to the first absorption band split by a low symmetry, like C_1 or C_2.

It is often assumed that the CD spectrum in the visible region is the sum of the hypothetical CD components attributed to the configuration around the metal, the conformation of the chelate rings, and asymmetric nitrogen atoms; the actual situation in the present case is not so simple, however, because no additivity rule holds for the CD spectra of the III and IV isomers, or for those of the V, VI, and VII isomers, each pair of which has the same configuration around the metal. Concerning the CD spectrum in the charge transfer region, the peak intensity seems to be proportional to the net sum of the absolute configurations of the skew chelate pairs, as is shown in Table 3.

The Infrared Spectra. The infrared spectra of the I—VII isomers in the region 2000—4000 cm^{-1} are shown in Fig. 4. It may be noted that the III—VII isomers show a strong band at about 2880 cm^{-1} which

TABLE 3. THE RELATIONSHIP BETWEEN THE NET SUM OF THE ABSOLUTE CONFIGURATIONS OF THE SKEW CHELATE PAIRS AND THE PEAK INTENSITY OF THE CD SPECTRUM IN THE CHARGE TRANSFER REGION

is similar to the band at 2879[7] cm^{-1} of *mer*-$[Co(dien)_2]Br_3 \cdot 2H_2O$,[8] dien being diethylenetriamine. The band of the dien complex has been identified as the >NH stretching vibration, which is characteristic of the *mer* structure. Therefore, the band at about 2880 cm^{-1} of the III—VII isomers can be assigned to the same vibration. The I and II isomers also have a weak-medium band at about 2880 cm^{-1}, but this band does not seem to be assignable to the same >NH stretching vibration, for it does not shift on deuteration. As the I isomer has no >NH group of the *mer* structure, the absence of the above >NH vibration is understandable. The II isomer is identified as having the B structure with a *mer* structure (*vide infra*). Nevertheless, it does not show a band similar to those of the III—VII isomers shown above. The reason for this is not yet clear, though it may be due to some structural differences between them.

The PMR Spectra and the Assignment of the Structures. The PMR spectra of the I—VII isomers were studied in 0.1N $DCl(D_2O)$ in order to obtain information on their configurations. The spectra are shown in Fig. 5. The signals due to HOD are omitted in Fig. 5 for the sake of simplicity. Since the signals due to the methylene protons are very complicated, they were not taken into consideration, either; only the protons attached to nitrogen were considered. The most complicated spectrum, which the II isomer shows, may be assigned to the isomer with the least symmetric structure, that is, to the B structure with the C_1 symmetry. The I isomer exists as a single isomer, and neither is separated further nor isomerizes into other isomers in a neutral solution. Therefore, the I isomer is identified as having the A structure. The PMR spectrum of I is symmetrical in shape, in accordance with the C_2 symmetry.

Since the V, VI, and VII isomers isomerize to their mixtures in a neutral solution, these isomers may be identified as having the D structure, which has three isomers. On the basis of the PMR spectral pattern, the VI isomer may presumably be assigned to the unsymmetrical *RS* configuration connected with the N2 and N5 atoms. Further, based on a very simple conformational analysis and the fact that the V isomer is formed more abundantly than VII, the V isomer is identified as having the *SS* configuration, and the VII isomer, the *RR* configuration connected with the N2 and N5 atoms. Finally, the remaining III and IV isomers are identified as having the C structure. As the amount of III and IV formed are not appreciably different, it is not possible to decide which isomer of the C structure is to be assigned to III or IV.

The structures assigned on the basis of the facts presented above are summarized in Table 1.

The X-ray determination of the structures of several isomers is now under way in the laboratory of Professor Y. Saito, The University of Tokyo.

7) The frequency of this band was erroneously printed in the previous report (Ref. 4) as 2848 cm^{-1}.

Trimethylenediamine Complexes. III.[1] *cis-trans* Isomeric Pairs of Diazido- and Dicyano-bis(trimethylenediamine)cobalt(III) Complexes

Hiroshi KAWAGUCHI* and Shinichi KAWAGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received June 20, 1973)

trans-Diazido- and dicyano-bis(trimethylenediamine)cobalt(III) complexes have been prepared by the ligand substitution reactions of *trans*-dichlorobis(trimethylenediamine)cobalt(III) complexes in methanol. The corresponding *cis* isomers were obtained by similar reactions in aqueous solutions. The structural assignment of these isomeric pairs was made on the basis of electronic, infrared and nuclear magnetic resonance spectra.

As an extension of our synthetic studies on the diacidobis(trimethylenediamine)cobalt(III) complexes,[1] we have prepared the *cis-trans* isomeric pairs of diazido- and dicyano-complexes. The corresponding *cis*- and *trans*-diazidobis(ethylenediamine)cobalt(III) complexes were reported by Staples and Tobe.[2] The *cis*-dicyanobis(ethylenediamine)cobalt(III) salt was synthesized by Rây and Sharma as early as 1951,[3] but the *trans* isomer has long been unknown. Muto, Baba, and Yoneda[4] succeeded in preparing *trans*-$[Co(CN)_2en_2]Cl$ by the reaction of *trans*-$[CoCl_2en_2]NO_3$ or *cis*-$[CoCl_2en_2]Cl$ with potassium cyanide in dimethyl sulfoxide. Konya, Nishikawa, and Shibata[5] also obtained both *cis*- and *trans*-$[Co(CN)_2en_2]Cl$ by the reaction of $[Coen_3]Cl_3$ with potassium cyanide in a cold aqueous solution containing activated charcoal.

Various diacidobis(trimethylenediamine)cobalt(III) complexes were derived from *trans*-$[CoCl_2tn_2]Cl$ by the ligand substitution reactions in methanol and all of them were shown to have the *trans* configuration.[6] The method has been successfully extended to the preparation of *trans*-$[Co(N_3)_2tn_2]NO_3$ and *trans*-$[Co(CN)_2tn_2]Cl$ in the present study. The corresponding *cis* isomers were afforded by similar reactions in aqueous solutions.

Experimental

trans-*Diazidobis(trimethylenediamine)cobalt(III) Nitrate.* *trans*-$[CoCl_2tn_2]NO_3$ (1.7 g) was dissolved in a minimum quantity of hot methanol. To this was added a methanol solution of twice as many moles of sodium azide (0.75 g), and the mixture was heated to 40 °C or above for an hour, and left to stand overnight. Very dark green crystals were filtered, washed with a small quantity of methanol, and dried in air.

Found: C, 20.63; H, 5.87; N, 43.43%. Calcd for $C_6H_{20}N_{11}O_3Co=[Co(N_3)_2tn_2]NO_3$: C, 20.40; H, 5.71; N, 43.62%.

cis-*Diazidobis(trimethylenediamine)cobalt(III) Nitrate.* Two grams of *trans*-$[Co(NO_3)_2tn_2]NO_3$ were dissolved in 10—13 ml of water. To this was added at 0 °C an aqueous solution (5 ml) of sodium azide (0.6 g) and the mixture was kept standing in ice for 2 hr. A small quantity of the precipitated *trans* isomer was filtered, and a few ml of cold water was added to the filtrate, which was stored overnight in a refrigerator. Very dark violet crystals were filtered, washed with methanol and dried (ca. 0.5 g). The finely powdered compound was dissolved again in a minimum quantity of water, and the insoluble portion was filtered off. The solution was saturated with ammonium nitrate and kept standing overnight in ice. The recrystallized pure compound was filtered, washed successively with cold water and methanol and air-dried.

Found: C, 20.42; H, 5.78; N, 43.39%.

trans-*Dicyanobis(trimethylenediamine)cobalt(III) Chloride Monohydrate.* One gram of *trans*-$[CoCl_2tn_2]Cl$ and 3g of silver oxide were suspended in methanol (40 ml) and stirred at room temperature for about 2 hr. The initial green color finally turned to violet. Precipitates of silver chloride and remaining silver oxide were filtered off. Three times as many moles of potassium cyanide were added and dissolved with stirring for about 1 hr. The solution, warmed on a hot water bath for a while, turned brownish, and a small amount of precipitate was separated out. The mixture was concentrated to half its volume by evaporation under reduced pressure. The crude product (3 g) was purified with a cation-exchange resin (Dowex 50 W-X8, 110—200 mesh) in the lithium form. A 0.2 M solution of lithium chloride was used as an eluent, and the effluent was evaporated under reduced pressure until crystals began to appear. Ethyl alcohol was added to the concentrate to precipitate more crystals, which were filtered, washed with ethanol and dried over calcium chloride. The final yield was 1.8 g.

Found: C, 30.81; H, 6.99; N, 26.26%. Calcd for $C_8H_{22}N_6OClCo=[Co(CN)_2tn_2]Cl\cdot H_2O$: C, 30.73; H, 7.09; N, 26.88%. When a concentrated solution of this compound was gradually cooled, crystals of $[Co(CN)_2tn_2]Cl\cdot 3H_2O$ were separated out. These crystals were subjected to X-ray analysis.

cis-*Dicyanobis(trimethylenediamine)cobalt(III) Chloride.* *cis*-$[Co(CN)_2tn_2]_2S_2O_3$ was prepared by the method of Ohkawa *et al.*,[7] and was transformed into the chloride by means of anion exchange chromatography.

Found: C, 31.61; H, 6.88; N, 28.33%. Calcd for $C_8H_{20}N_6ClCo=[Co(CN)_2tn_2]Cl$: C, 32.61; H, 6.84; N, 28.54%.

Measurements. Electronic absorption spectra were measured with Hitachi EPS-2 and Shimadzu QV-50 spectrophotometers. Infrared absorption spectra in the 4000—650

cm^{-1} region were measured with a Hitachi infrared spectrophotometer EPI-2, and those in the 700—200 cm^{-1} region with a Hitachi grating infrared spectrophotometer EPI-L. The NMR spectra were recorded at 60 MHz with TMS as the external reference on a JEOL C-60 HL spectrometer.

Results and Discussion

Diazidobis(trimethylenediamine)cobalt(III) Complexes. From the analytical data the identical empirical formula $[Co(N_3)_2tn_2]NO_3$ was found to be valid for both the very dark green crystals prepared by the reaction of *trans*-$[CoCl_2tn_2]NO_3$ with sodium azide in methanol, and the very dark violet crystals derived from *trans*-$[Co(NO_3)_2tn_2]NO_3$ in aqueous solutions. Thus, the two compounds are isomeric with each other, and two possibilities can be considered: ionization isomerism or geometrical isomerism. If the nitrate group is coordinated to the cobalt atom, the mode of linkage must be clarified.

The structural aspects of coordinated nitrate groups have been studied extensively,[8] and the vibrational spectra are useful for distinguishing between ionic and coordinated nitrate groups.[9] Both *trans*-$[CoCl(NO_3)tn_2]NO_3$[6] and *trans*-$[Co(NO_3)_2tn_2]NO_3$[10] exhibit very strong absorptions in the IR around 1500, 1260, and 990 cm^{-1} which are assignable to the coordinated nitrate group. Neither of the present complexes, however, shows such absorptions, indicating non-ligation of the nitrate group. They can thus be considered to be a pair of *cis-trans* isomers.

In previous papers,[1,6] Baldwin's criterion[11] of using the CH_2-rocking vibration for distinguishing geometrical isomers was shown to be helpful in many cases. However, it is not applicalbe to the present diazido complexes, since both show a single peak at 890 or 895 cm^{-1}. The IR spectra in the lower frequency region are shown in Fig. 1. The spectrum (1) of the dark-violet isomer prepared in aqueous solutions is more complicated than that (2) of the dark-green isomer obtained in methanol. The former exhibits three peaks while the latter only one in the diagnostic ν(Co–N(tn)) region[12] (490—540 cm^{-1}). The absorption band around 590 cm^{-1} which is assignable to the δ(NNN) is also different. The dark-violet isomer can thus be concluded to have a *cis* configuration.

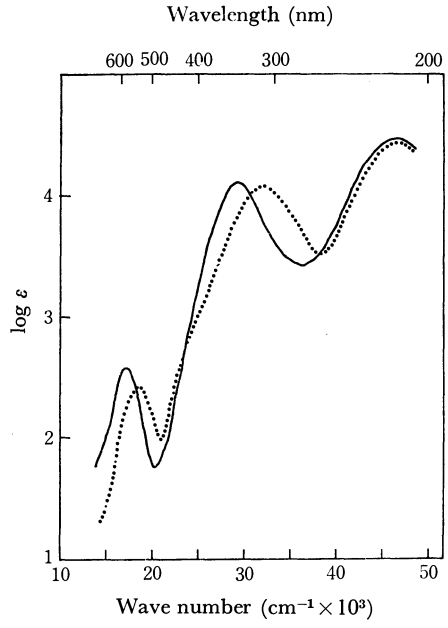

Fig. 2. Absorption spectra of *trans*(——)- and *cis*(……)-$[Co(N_3)_2tn_2]NO_3$ in aqueous solutions.

The electronic spectra of $[Co(N_3)_2tn_2]NO_3$ in aqueous solutions are shown in Fig. 2. Both *cis* and *trans* isomers are not entirely inert, but gradually undergo the aquation reaction. However, addition of sodium azide to the complex solutions in concentration of 3 M or 6 M did not alter the spectra at all, revealing that the solutions are not contaminated with aquated species during the course of spectral measurements. In the case of $[Co(N_3)_2en_2]ClO_4$, the intensity of the first absorption band is nearly equal for *cis* and *trans* isomers.[2] In contrast, *cis*-$[Co(N_3)_2tn_2]NO_3$ exhibits a weaker peak at the shorter wavelength region than the *trans* isomer. A similar feature was also observed for *cis*- and *trans*-$[Co(NCS)_2tn_2]SCN$.[1]

cis-$[Co(N_3)_2tn_2]NO_3$ is quite stable in the solid state at room temperature, but if its aqueous solution is evaporated upon heating, crystals of the *trans* isomer are separated out. This is the reason why cold aqueous solutions were employed for preparation of the *cis* isomers.

Dicyanobis(trimethylenediamine)cobalt(III) Complexes. The *cis*-$[Co(CN)_2tn_2]^+$ complex was first prepared by Ohkawa, Fujita, and Shimura, the *cis*-assignment being

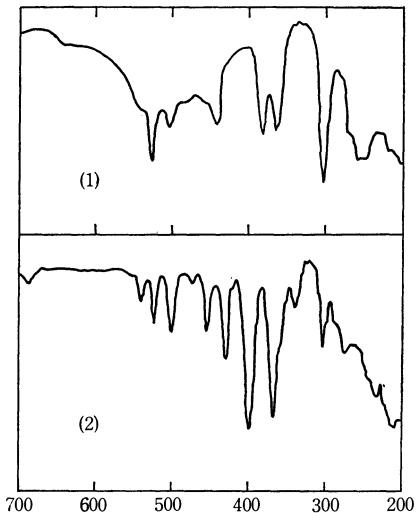

Fig. 3. Infrared spectra of *trans*-$[Co(CN)_2tn_2]Cl \cdot H_2O$(1) and *cis*-$[Co(CN)_2tn_2]Cl$(2) in the 700—200 cm^{-1} region (Nujol mull).

made on the splitting of the C≡N stretching band.[7] No corresponding *trans* isomer could be prepared by the direct reaction of *trans*-$[CoCl_2tn_2]Cl$ with potassium cyanide in methanol, but it could be obtained by a similar reaction after the action of silver oxide. A yellow plate of *trans*-$[Co(CN)_2tn_2]Cl \cdot 3H_2O$ was subjected to X-ray crystal analysis.[13] Crystal data: monoclinic, $a=17.906(5)$, $b=10.753(6)$, $c=8.575(5)$ Å, $\beta=95.74(5)°$, $Z=4$, $D_c=1.33$, $D_m=1.31$ g·cm^{-3}, $\mu(Ni-K_\alpha)=38.5$ cm^{-1}; space group C_c. The *trans* configuration was ascertained, and the linear orientation of Co–C–N and the chair conformation of the six-membered chelate rings were clarified (R=0.121).

13) H. Hasegawa, K. Matsumoto, H. Kuroya, H. Kawaguchi, and S. Kawaguchi, Presented at the 20th Symposium on the Coordination Compounds of the Chemical Society of Japan, 18A18, Tokyo, November, 1970.

The IR spectra of the two isomers in the low-frequency region are shown in Fig. 3. The curve for the *cis* isomer is a little more complicated than that for the *trans* isomer. In the CH_2-rocking region the *cis* isomer exhibits a distinct shoulder at the lower frequency side of a rather sharp peak at 898 cm^{-1}, while the *trans* compound shows a broad symmetric band at 892 cm^{-1}. Their electronic spectra are shown in Fig. 4. Just as in the case of the corresponding ethylenediamine complexes,[4,5] the *trans* isomer has a remarkable shoulder in the longer wavelength side of the first band.

The present synthetic method for the *trans*-$Co(CN)_2tn_2^+$ complex was also applied to the preparation of *trans*-$Co(CN)_2en_2^+$ and a satisfactory yield was attained; 1 g of *trans*-$[Co(CN)_2en_2]Cl$ was obtained from 4 g of *trans*-$[CoCl_2en_2]Cl$.

NMR Studies. The proton NMR spectra of diamagnetic tris(diamine)metal complexes have been studied extensively in recent years. The ethylenediamine chelate rings in these complexes have *gauche* conformations[14] with either δ or λ chirality. It has been established theoretically[15] and experimentally[16] that the Men_3 complexes undergo rapid ring inversion at room temperature. Appleton, Hall, and Hawkins[17] pointed out, however, that the methylene protons of the ethylenediamine ligand can not be equivalent even if the rapid conformational equilibration is attained, since the environment of an axial proton in a δ conformer is not identical with that of an axial proton in a λ conformer due to the presence of the other two chelate rings.

Although there is no environmental difference among NH_2 and CH_2 protons respectively in *trans*-MX_2en_2 complexes, there exists some additional complexity in the case of *cis*-MX_2en_2 in comparison with Men_3. The NH_2 protons situated in the *cis* position to both the X groups are inherently nonequivalent to the other NH_2 protons which are *cis* to one X and *trans* to the other X. A similar discrimination should be extended to the adjacent α-CH_2 groups. The different patterns of NH_2 proton signals in *cis*- and *trans*-CoX_2en_2 complexes have frequently been exemplified since the original work of Clifton and Pratt.[18] Distinct splitting of CH_2 bands is also observed for *cis*-$[Co(H_2O)_2en_2](ClO_4)_3$ in 1.8 M D_2SO_4.[19]

A six-membered chelate ring, on the other hand, is capable of existing in several conformational types such as "chair," "boat," and "skew boat" or "twist" conformations. An optically active trimethylenediamine complex $(-)_D$-$[Cotn_3]Br_3 \cdot H_2O$ was shown to have the tris-chair conformation.[20] However, the tris-chair con-

formation seems to be only slightly more stable than the tris-skew-boat conformation.[21] The CD spectra of $Cotn_3^{3+}$ ions in solutions were interpreted to indicate the equilibrium between these two conformers.[22] The conformational inversion is quite rapid as evidenced by the observation that the NMR spectra of $Pdtn_2^{2+}$ and $Pttn_2^{2+}$ complexes are no more complicated than the spectrum of $tn(HCl)_2$.[23]

The six-membered chelate rings in several diacidobis(trimethylenediamine)cobalt(III) complexes have also been revealed to have the chair form in crystals,[10,24] but seem to undergo rapid conformational interconversion in solutions. Figure 5-(1) shows the NMR spectra of *trans*-$[Co(CN)_2tn_2]Cl$ in D_2O containing *ca.* 1 M DCl. Three peaks are observed at 6.15, 7.25, and 8.25 τ with the relative integral intensities 2: 2: 1. The broad lowest-field band disappears in solutions without acid as is illustrated in Fig. 6-(1), and can thus be attributed to the amine protons. The remaining two peaks which are not influenced by pH of the solution may be assigned to the methylene protons. The observed area ratio unequivocally indicates that the lower-field signal is due to the α-CH_2 and the higher-field one to the β-CH_2 protons. Here the methylene protons are designated as: NH_2–$CH_2(\alpha)$–$CH_2(\beta)$–$CH_2(\alpha)$–NH_2. The α-CH_2 signal in Fig. 5-(1) reveals the characteristic five-line pattern, but that in Fig. 6-(1) is essentially a triplet because of the quenching of coupling with NH_2 protons by deuteration. These features indicate the magnetic equivalence of methylene protons in trimethylenediamine ligands by virtue of the rapid conformational interchange as discussed above.

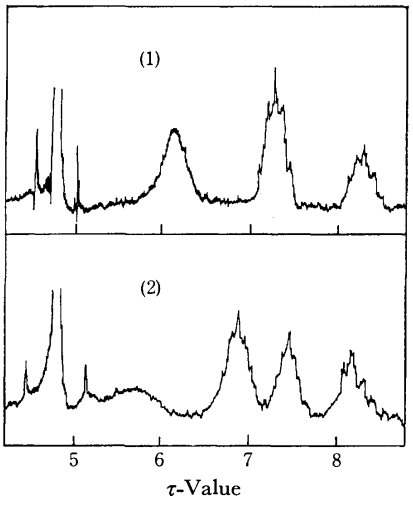

Fig. 5. Proton NMR spectra of *trans*(1)- and *cis*(2)-$[Co(CN)_2tn_2]Cl$ in acidic D_2O solutions.

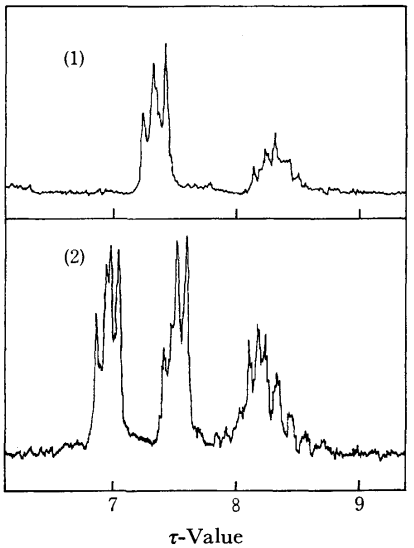

Fig. 6. Proton NMR spectra of *trans*(1)- and *cis*(2)-$[Co(CN)_2tn_2]Cl$ in neutral D_2O solutions.

On the other hand, the spectra of *cis*-$[Co(CN)_2tn_2]Cl$ give three methylene signals at 6.87, 7.44, and 8.14 τ both in acidic and neutral D_2O solutions, and their area ratios are about 1.9: 1: 1 (Fig. 5-(2)) and 1: 1: 1 (Fig. 6-(2)), respectively. These features indicate that there exist two kinds of nonequivalent protons in the α-CH_2 groups, which are distinctly differentiated under the strong influence of cyanide ligands.

The very broad signal of NH_2 protons around 5.7 τ has about one half of the expected area (Fig. 5-(2)). It seems improbable on the basis of the following that 50% of the NH_2 protons was exchanged with D_2O immediately after dissolution. (1) The rate data of base-catalyzed hydrogen exchange of ammine and ethylenediamine cobalt(III) complexes in D_2O[25] suggest that the exchange reaction of the trimethylenediamine complex in the present solution containing 1 M DCl can not be so rapid. (2) The observed NMR spectrum shows no change at all even after one-day standing. Thus it seems appropriate to consider that the NH_2

proton signal is split into two bands in the case of *cis*-$Co(CN)_2tn_2^+$, one appearing around 5.7 τ and the other overlapping with the lowest-field methylene peak. The observed larger integral intensity of the latter peak supports this interpretation.

The spectra of *trans*- and *cis*-$[Co(NCS)_2tn_2]SCN$ in dimethyl sulfoxide-d_6 are shown in Fig. 7. The configurational assignments of these complexes have already been reported.[1,24] The spectrum of the *trans* isomer gives three signals at 5.00, 7.60, and 8.20 τ, which are assigned to NH_2, α-CH_2, and β-CH_2 protons, respectively. A sharp peak at 6.70 τ and an overlapping peak at 7.50 τ are attributed to impurities in the solvent. The α-CH_2 absorption in *cis*-$[Co(NCS)_2tn_2]SCN$ is partially split into two bands at 7.65 and 7.85 τ, although the separation is not so complete as in the case of *cis*-$Co(CN)_2tn_2^+$. This might suggest that the thiocyanate anion does not exert so strong an influence as the cyanide anion. A similar degree of splitting of the α-CH_2 absorption was also noticed in the spectrum of $CoCO_3tn_2^+$ in neutral D_2O.[26] The NH_2 absorption in *cis*-$[Co(NCS)_2tn_2]SCN$ shows a very complicated pattern and can not be interpreted, especially in reference to the rather simple pattern exhibited by NH_2 protons of *cis*-$[Co(N_3)_2tn_2]NO_3$.

The spectra of *trans*- and *cis*-$[Co(N_3)_2tn_2]NO_3$ in DMSO-d_6 are shown in Fig. 8. The α-CH_2 signal is not split in this *cis* isomer. The azide group may exert a weaker effect on the α-CH_2 protons than the thiocyanate ligand. Buckingham, Durham, and Sargeson[19] also observed no splitting of the CH_2 signals in the CoX_2en_2 complexes where both of the coordinating atoms of X are nitrogen, *i.e.* X=NH_3, N_3^-, NO_2^-, or 1/2en. However, the NH_2 signal of *cis*-$Co(N_3)_2tn_2^+$ is split into two bands quite remarkably, permitting the differentiation from the *trans* isomer. The minor NH_2 band observed at 6.05 τ in the spectrum of *trans*-$[Co(N_3)_2tn_2]NO_3$ (Fig. 8-(1)) is not explicable at present. It might be due to the partial solvolysis.

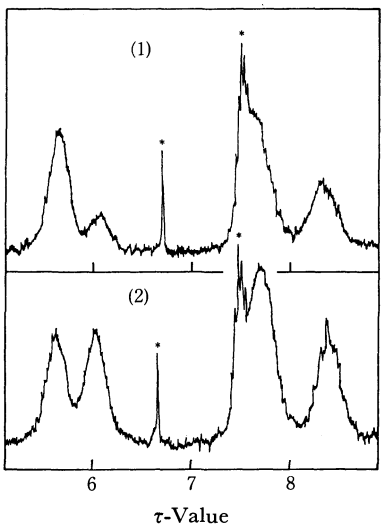

Fig. 8. Proton NMR spectra of *trans*(1)- and *cis*(2)-$[Co(N_3)_2tn_2]NO_3$ in dimethyl sulfoxide-d_6 solutions, asterisks denoting impurity bands.

Mixed Ligand Complex Formation between Monodentate Ligands and Various Tridentate Ligand-Copper(II) Complexes

Osamu YAMAUCHI, Hiroshi BENNO, and Akitsugu NAKAHARA

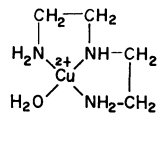
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received June 29, 1973)

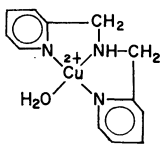
Formation of mixed ligand complexes between monodentate ligands (L) and copper(II) complexes of tridentate ligands (A) has been investigated by potentiometric titration and thermal analysis. Thus, the constants, log K_m, for the formation of the complexes of type CuA·L from CuA and L have been calculated from the titration curves by the method of non-linear least-squares. A refers to diethylenetriamine, dipicolylamine, 2,2′,2″-terpyridine, ethylenediamine-*N*-monoacetic acid, iminodiacetic acid, or pyridine-2,6-dicarboxylic acid and L to pyridine, *p*-phenolsulfonic acid, *n*-butylamine, or hydroxy group. The stability series in each system with L fixed has been interpreted in terms of the strength of A as a Lewis base, expressed by the sum of pK_a ($\sum pK_a$), as well as back-donation. In the absence of significant steric hindrance, favorable combination of donor atoms around copper(II) has been found to be between aromatic nitrogens and negative oxygens. Thermal stability of the isolated complexes of type CuA·PY, where PY is pyridine, was also in line with the stability sequence in solution.

Recent interest in the mechanisms of the biological reactions involving metal ions as central atoms has prompted a variety of basic studies on mixed ligand metal complexes. Sigel *et al.*[1-3] investigated systematically the complex formation between copper(II)-2,2′-bipyridine and oxygen- and/or nitrogen-containing bidentate ligands, and gave explanations to the affinity and the driving force leading to mixed ligand complexes.

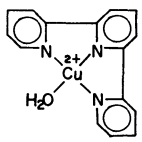
It seems reasonable to assume that, in the course of a biological reaction, the central metal ion is surrounded by a multidentate ligand, leaving only one coordination site available for the second ligand. In this connection, Angelici and Allison[4] reported the mixed complex formation between substituted diethylenetriamine complexes of copper(II) and several amino acids which coordinate as bidentate ligands, and Hauer *et al.*[5] reported the reactions of polyamines with copper(II)-triglycine. However, it is of further interest to study the coordination of purely monodentate ligands to copper(II) complexes of tridentate ligands of different types.



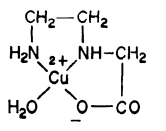
Cu(dien)



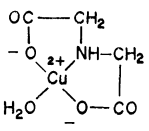
Cu(dpa)



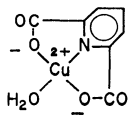
Cu(terpy)



Cu(edma)



Cu(ida)



Cu(pdca)

In order to find out the effects of combination of two ligands around copper(II) on the stability of the resulting mixed ligand complex, we investigated the complex formation of pyridine (PY), *p*-phenolsulfonic acid (PPS), and *n*-butylamine (BA) with the copper(II) complexes of diethylenetriamine (Cu(dien)), dipicolylamine (Cu(dpa)), 2,2′,2″-terpyridine (Cu(terpy)), ethylenediamine-*N*-monoacetic acid (Cu(edma)), iminodiacetic acid (Cu(ida)), and pyridine-2,6-dicarboxylic acid (Cu(pdca))[6] by potentiometric titration and thermal analysis.

Experimental

Materials. *Copper(II) Complexes*: The binary complexes (CuA) used are $Cu(dien)(NO_3)_2$, $Cu(dpa)Cl_2$, $Cu(terpy)(ClO_4)_2 \cdot H_2O$, Cu(edma)Cl, $Cu(ida) \cdot 2H_2O$, and $Cu(pdca) \cdot 2H_2O$, all of which were prepared from equal amounts of a ligand and an appropriate salt of copper(II) in water or aqueous ethanol.

Mixed ligand complexes of type CuA·PY, where A is dien, terpy, ida, or pdca, were obtained by recrystallizing the binary complexes from aqueous pyridine. The relevant elemental analysis data are summarized in Table 1.

Ligands: Pyridine and *n*-butylamine were converted to the perchlorates, which were purified by recrystallization from water. Sodium *p*-phenolsulfonate was purchased from Nakarai Chemicals Co., and recrystallized from water.

All the other chemicals used were of reagent grade, distilled and deionized water being used.

pH Titrations. *(a) Reagents*: 0.1 M KOH was prepared according to Albert,[7] and stored under a nitrogen atmosphere. 0.01 M $Cu(NO_3)_2$ was prepared by dissolving copper(II) nitrate trihydrate in water and standardized against standard zinc by chelatometric titration.[8]

6) These binary complexes will be abbreviated as CuA in the text hereinafter. Mixed complexes of CuA with the second ligand L will generally be described as CuA·L, where L is pyridine (PY), *p*-phenolsulfonate (PPS), *n*-butylamine (BA), or hydroxy group (OH). Thus, the complex of Cu(dien) with pyridine is expressed as Cu(dien)·PY. All the charges are omitted for simplicity.

[Cu(ida)PY]	39.47	39.77	3.69	3.34	10.23	10.36
[Cu(pdca)PY]	46.82	47.25	2.62	2.50	9.11	9.26

a) The complexes are tentatively expressed by assuming that copper(II) is four-coordinate.

(b) Apparatus: A Radiometer PHM 4d pH meter with a G202B glass electrode and a K401 calomel electrode was used after standardization with a Horiba standard buffer solution (pH 4.01).

(c) Procedure: Titrations were carried out at concentrations of 4×10^{-3}—8×10^{-3} M in water (μ=0.1(KNO_3)) at 25 °C under a nitrogen atmosphere. Details of the procedure were essentially the same as before,[9] and conversion of pH to -log [H^+], where [H^+] denotes the hydrogen ion concentration, was done in the manner described.[9]

Measurement of Absorption Spectra. The absorption spectra of various mixtures of Cu(dien) and pyridine (10^{-2}—10^{-3} M) were measured in water at pH 7.0 with a Shimadzu MPS 50L recording spectrophotometer.

Measurement of Thermal Stability. The thermal stabilities of the mixed ligand complexes were measured with a Rigaku Denki Thermoflex No. 8001, the rate of temperature elevation being 5 °C per minute.

Results and Discussion

Typical titration curves of the complexes CuA in the presence of the equimolar amounts of pyridine, *p*-phenolsulfonate, and *n*-butylamine are shown in Figs.

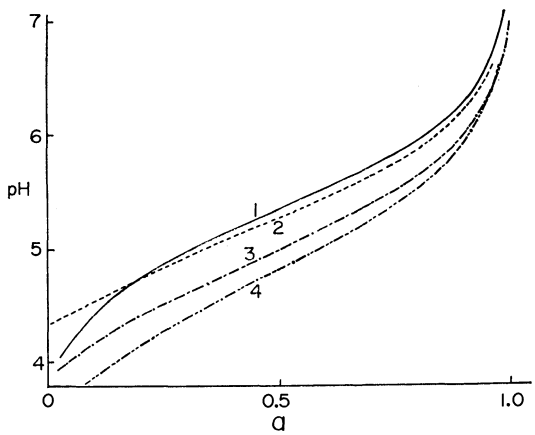

Fig. 1. Titration curves of pyridine in the presence and the absence of CuA. *a* is moles of KOH added per mole of ligand.
1, PY alone; 2, Cu(dien): PY=1: 1; 3, Cu(ida): PY=1: 1; 4, Cu(pdca): PY=1: 1.

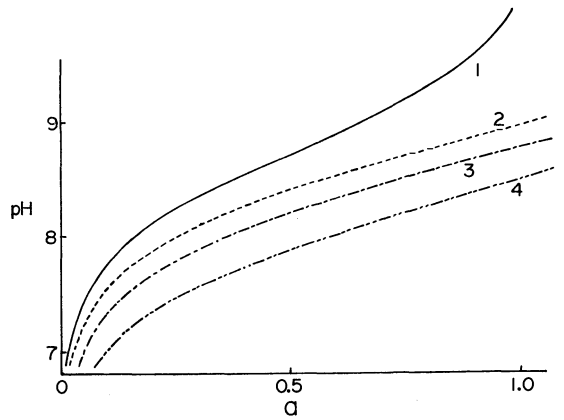

Fig. 2. Titration curves of *p*-phenolsulfonate in the presence and the absence of CuA.
1, PPS alone; 2, Cu(dien): PPS=1: 1; 3, Cu(dpa): PPS=1: 1; 4, Cu(terpy): PPS=1: 1.

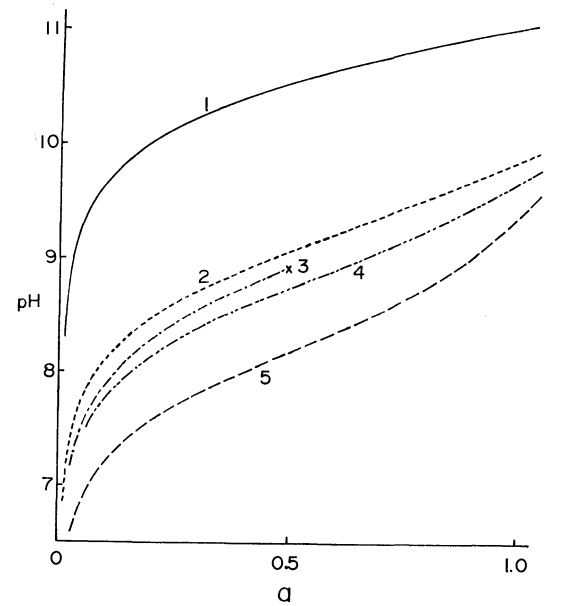

Fig. 3. Titration curves of *n*-butylamine in the presence and the absence of CuA.
1, BA alone; 2, Cu(dien): BA=1: 1; 3, Cu(edma): BA=1: 1; 4, Cu(dpa): BA=1: 1; 5, Cu(terpy): BA=1: 1.

9) O. Yamauchi, H. Miyata, and A. Nakahara, This Bulletin, **44**, 2716 (1971).

1, 2, and 3, respectively. The pH decrease due to the presence of CuA indicates mixed ligand complex formation in these systems. There seems to be protonation of A in the CuA·PY series at pH below 5, whereas formation of the hydroxy complexes should be taken into account for CuA·PPS and CuA·BA systems which lack the pH jump at $a=1.0$. Cu(ida)·L and Cu(pdca)·L systems, where L=*p*-phenolsulfonate or *n*-butylamine, did not afford reliable titration curves owing to precipitation.

The absorption spectra of Cu(dien)·PY system at various Cu(dien): pyridine ratios in water at pH 7.0 showed the isosbestic point at 635 nm, which indicates the following reaction is the only one around this pH (charges are omitted for simplicity):

$$\mathrm{Cu(dien)} + \mathrm{PY} \rightleftharpoons \mathrm{Cu(dien)\cdot PY}$$

This is also confirmed by the compositions of the mixed ligand complexes isolated as crystals.

From these observations, we assumed the following equilibria for the mixed ligand systems with the constants defined:

$$\mathrm{HL} \overset{K_a}{\rightleftharpoons} \mathrm{H} + \mathrm{L} \qquad (1)$$

$$K_a = \frac{[\mathrm{H}][\mathrm{L}]}{[\mathrm{HL}]}$$

$$\mathrm{CuA} + \mathrm{L} \overset{K_m}{\rightleftharpoons} \mathrm{CuA\cdot L} \qquad (2)$$

$$K_m = \frac{[\mathrm{CuA\cdot L}]}{[\mathrm{CuA}][\mathrm{L}]}$$

where HL refers to protonated monodentate ligand, and K_a and K_m are the acid dissociation constant and the stability constant, respectively. Dissociation of CuA to Cu and A (free tridentate ligand) may safely be neglected in the pH range investigated. The equilibria (3) and (4) were also considered at low and high pH, respectively:

$$\mathrm{CuA\cdot H} \overset{K_H}{\rightleftharpoons} \mathrm{CuA} + \mathrm{H} \qquad (3)$$

$$K_H = \frac{[\mathrm{CuA}][\mathrm{H}]}{[\mathrm{CuA\cdot H}]}$$

$$\mathrm{CuA} + \mathrm{OH} \overset{K_{OH}}{\rightleftharpoons} \mathrm{CuA\cdot OH} \qquad (4)$$

$$K_{OH} = \frac{[\mathrm{CuA\cdot OH}]}{[\mathrm{CuA}][\mathrm{OH}]}$$

where CuA·H and CuA·OH refer respectively to protonated and hydroxy complex.

The equilibrium constants K_H, K_{OH}, and K_m were calculated on the basis of the mole balances for total CuA and total L, and the electroneutrality of solution. Computation of the constants was made by the method of non-linear least-squares with the use of a NEAC 2200/500 computer, the program and the conditions for convergence being essentially the same as those reported.[9,10] Table 2 shows the calculated equilibrium constants along with the pK_a values of ligands A taken from the literature. The pK_H ($-\log K_H$) values for Cu(dpa), Cu(terpy), and Cu(pdca) are as low as 1.2—1.6 with large variances (>1) and not reliable. The constants K_{OH} were calculated from the data for *n*-butylamine and *p*-phenolsulfonate, for which hydrolysis was evident from the titration curves, and the values from the two systems agreed with each other to within 0.3 log unit. The $\log K_{OH}$ value of 4.75 for Cu(dien)·OH is in good agreement with the reported values of 4.58[11] and 5.17.[12]

The theoretical titration curves calculated by these constants coincided very well with the experimental ones, and the differences expressed in titer were less than 0.01 ml over the entire ranges (usually 0.2—1.0 ml).

The mixed complexes of pyridine with Cu(dien), Cu(dpa), and Cu(terpy), containing donor nitrogens only, have lower stability than the complexes with Cu(edma), Cu(ida), and Cu(pdca), suggesting that negative oxygens at the coordination sites increase the stability of the resulting complexes. According to Tanaka, the $\log K_m$ values can be calculated by a general equation derived from mechanistic considerations, and the experimental values for Cu(dien), Cu(dpa), Cu(edma), and Cu(ida) could be reproduced satisfactorily by the equation.[13]

TABLE 2. EQUILIBRIUM CONSTANTS OF CuA·L SYSTEMS (25±0.05 °C; μ=0.1 (KNO_3))[a]

CuA	$\sum pK_a$[b]	pK_H	$\log K_m$ L[c]			$\log K_{OH}$[g]
			PY	PPS	BA	
Cu(dien)	23.41[d]	3.24±0.12	1.77±0.09	1.72±0.27	3.49±0.15	4.75±0.12
Cu(dpa)	11.02[e]	<2	1.76±0.09	2.37±0.09	3.76±0.27	5.11±0.06
Cu(terpy)	6.97[d]	<2	1.81±0.06	2.71±0.12	4.71±0.09	5.67±0.06
Cu(edma)	18.95[f]	3.19±0.06	2.09±0.01	1.75±0.27	4.09±0.15	4.77±0.09
Cu(ida)	12.03[d]	2.67±0.15	2.65±0.02			
Cu(pdca)	6.78[d]	<2	2.97±0.02			

a) Variances are three times the estimated standard deviations.
b) The $\sum pK_a$ value is the sum of three constants of each ligand except terpy, ida, and pdca where the first dissociation constants are negligibly small.
c) The pK_a values determined in the present study are: PY, 5.26±0.03; PPS, 8.66±0.03; BA, 10.62±0.09. The value of 13.88 was used for the apparent ion product of water (pK_w').

As to the *p*-phenolsulfonate series, Cu(dpa) and Cu(terpy), both with aromatic nitrogens, form more stable mixed complexes than Cu(dien) does. The stabilities of the CuA·OH systems as seen from the log K_{OH} values exhibit the same trend as observed in the *p*-phenolsulfonate series.

The complexes with *n*-butylamine, CuA·BA, are more stable than CuA·PY and CuA·PPS, probably because of the high pK_a of *n*-butylamine. Their stabilities increase with added aromatic nitrogens and carboxylate oxygens.

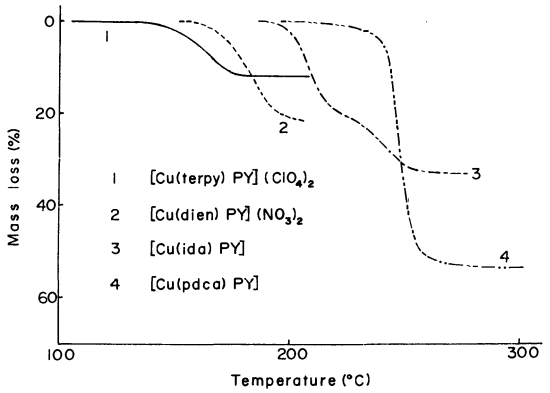

Fig. 4. Thermal analysis of CuA·PY.
Mass loss due to evaporation of pyridine:

Curve	Found (%)	Calcd (%)
1	12	14
2	21	21
3	31	29

Figure 4 shows the thermal decomposition curves of four pyridine-containing mixed complexes. Curves 1—3 correspond well to loss of pyridine from the complexes, and curve 4 may be explained in terms of decarboxylation of pyridine-2,6-dicarboxylic acid as well as evaporation of pyridine. The thermal stability is in the order Cu(terpy)·PY≤Cu(dien)·PY<Cu(ida)·PY<Cu(pdca)·PY, which is in line with the stability series in solution.

It is interesting to compare the stability of the copper(II)–pyridine bonding in CuA·PY with that in the binary complex according to the difference defined by the equation:

$$\Delta \log K_m = \log K_m - \log K_1$$

where $\log K_1$=2.52 (Ref. c) in Table 2) and refers to the stability constant of the 1:1 copper(II)–pyridine complex. The $\Delta \log K_m$ values are calculated to be negative for Cu(dien) (−0.75), Cu(dpa) (−0.76), Cu(terpy) (−0.71), and Cu(edma) (−0.43), and positive for Cu(ida) (0.13) and Cu(pdca) (0.45), which indicates that the bonding is destabilized in the first four complexes as compared with the binary complex.[14]

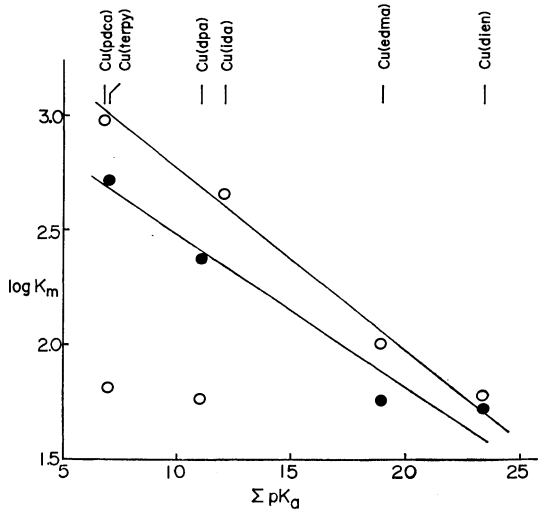

Fig. 5. Relationships between log K_m and $\sum$ pK_a in the CuA–PY and CuA·PPS series.
CuA·PY: ○, CuA·PPS: ●.

The affinity of the binary complex CuA for the second ligand L is considered to be dependent on the electronegativity of the central metal ion or, inversely, the basicity of the first ligand A. If A is a strong base, copper(II) in CuA will be less electrophilic and its binding with L will be weaker. Thus, we may expect a certain relationship between the stability constant log K_m and the sum of pK_a of the corresponding A, $\sum$pK_a, which is taken as indicative of the strength of the ligand as a Lewis base. From the plots of log K_m against $\sum$pK_a as shown in Fig. 5 for CuA·PY and CuA·PPS, we see a general trend in the four series that the stabilities of the ternary complexes usually decrease with the increase of the basicity of A with some anomalies. The exceptionally low stabilities of Cu(terpy)·PY and Cu(dpa)·PY are explained to be due to the steric interactions, as visualized by the molecular models, of 2,2′,2″-terpyridine or dipicolylamine with incoming pyridine, because the corresponding complexes with *p*-phenolsulfonate and hydroxy group are satisfactorily in the expected order. As pointed out by Sone *et al.*,[15] steric requirements for the second ligand can be a decisive factor leading to the stabilization in the mixed complex, and the above instances may be regarded as the results of the steric effects exerted on the part of the second ligand in a negative way.

On the other hand, a somewhat different view is also possible regarding the stability of mixed complexes. Griesser and Sigel[1] stressed the importance of back-donation in the formation of the ternary complexes which have π-acceptors such as 2,2′-bipyridine and pyrocatechol. They observed the favored formation of Cu(2,2′-bipyridine)·pyrocatechol, compared with Cu(2,2′-bipyridine)·ethylenediamine, and ascribed it to the cooperative interactions of the two π-acceptors.

14) However, on purely statistical ground, we should take into account the factors due to preoccupation of the coordination sites in CuA. If we simply assume copper(II) to be four-coordinate, we may correct the K_1 value according to the equation

$$\frac{K_{n+1}}{K_n} = \frac{n(N-n)}{(n+1)(N-n+1)}$$

where N and n refer to the coordination number of copper(II) and the sites occupied by ligand as in $[Cu(H_2O)_{N-n}L_n]$, respectively. Since PY in CuA·PY is the fourth ligand to get into the site, we may take K_4/K_1 as the correction factor:

$$\frac{K_4}{K_1} = \frac{K_2}{K_1} \times \frac{K_3}{K_2} \times \frac{K_4}{K_3} = \frac{1}{16}.$$

This gives us the statistical value of 1.32 in place of 2.52 and makes all the Δ log K_m values positive.

15) K. Sone, S. Utsuno, and T. Ogura, *J. Inorg. Nucl. Chem.*, **31**, 117 (1969).

In accordance with their finding, Cu(dpa)·PPS and Cu(terpy)·PPS are more stable than Cu(dien)·PPS and Cu(edma)·PPS.

An alternative explanation is based on Pearson's rule of hard and soft acids and bases,[1,16,17] according to which back-donation in CuA makes Cu(II) a harder acid which favors the bonding with hard bases like *p*-phenolsulfonate and hydroxy group. The stability sequences observed in the CuA·PPS and CuA·OH series serve as the evidence for this view. All these observations suggest that combination around copper(II) of aromatic nitrogens with negative oxygens is more favorable than that between nitrogen atoms only.

Considering that the stability of binary complexes is proportionally related to the pK_a of ligands, the mentioned effects of $\sum pK_a$ suggest that the second ligand L has greater affinity for CuA having lower stability, provided that steric factors are negligible. This may point to the favorable combination, or the selectivity, of ligands around metal ions in general.

The authors are grateful to Mr. Yasuaki Uno of this college for measurement of thermal stability and to the members of the Osaka University Computation Center for computation. This investigation was supported in part by a grant from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3462—3466 (1973)

The Nucleophilic Ring-opening Reactions of α,α'-Dinitrocycloalkanones

Yoshinari KOBAYASHI

Nagoya Research Laboratory, Chemicals Research and Development Laboratories, Toray Industries, Inc., Ohe-cho, Minato-ku, Nagoya 455–91

(Received October 23, 1972)

The keto and enolic characters of 2,6-dinitrocyclohexanone (**1**), 2,6-dinitro-4-methylcyclohexanone (**2**), and 2,7-dinitrocycloheptanone (**3**) were spectroscopically investigated and discussed. It was found that the reactions of **1** and **2** with nucleophiles can take either of two courses, depending upon the nucleophiles used: (a) the addition to the enol carbon or carbonyl carbon of the keto form, followed by ring-opening giving 2,6-dinitro- and 2,6-dinitro-4-methyl-hexanoates respectively; (b) the abstraction of the 2- and 6-protons, followed by the formation of the corresponding di-*aci*-nitronates. Primary alkoxide ions belong to the (a) group, whereas secondary and tertiary alkoxide ions, NH^-_2, RHN^-, and AcO^-, belong to the (b) group. The IR and UV spectra of the resultant α,ω-dinitrocarboxylic acid esters were also discussed.

The basic cleavage of α-nitroketones has attracted considerable synthetic interest.[1–7] The application of this cleavage to 2,6-dinitrocyclohexanone (**1**) was supposed to realize a novel simple three-step DL-lysine synthesis starting from cyclohexanone,[8] *e.g.*, the dinitration of cyclohexanone and ring-opening to 2,6-dinitrohexanoic acid, followed by its hydrogenation. During the present investigation, the same process was independently patented.[10] However, it was found that the ring-opening reactivities of **1** and 2,6-dinitro-4-methylcyclohexanone (**2**) were largely dependent on the nucleophiles especially on the bukiness of the alkoxides, and that the corresponding di-*aci*-nitronates were formed by the attack of secondary and tertiary alkoxides instead of by cleavage. The present paper will report on the chemical behaviors of **1**, **2** and 2,7-dinitrocycloheptanone (**3**) in response to the attack of alkoxides.

Results and Discussion

The structures of α,α'-Dinitrocycloalkanones. In general, α-nitroketones can be represented by three possible tautomeric structures-nitroketone, nitroenol, and *aci*-nitroketone forms.[11] The IR spectrum of **1** in the solid state (in a KBr disk) reveals a sharp carbonyl absorption at 1740 cm^{-1}, indicating the presence of a

Table 1. C=O absorptions of cyclohexanone and its nitoro derivatives

Compound	ν C=O (cm^{-1})	Shift (cm^{-1})	Ref.
Cyclohexanone	1712	—	
2-Nitrocyclohexanone	1739	27	27)
2,6-Dinitrocyclohexanone	1740 (1748)[a)]	1 (7)	5)

a) Ref. 5.

keto form.[12)] As is shown in Table 1, the introduction of a nitro group to the 2-position of cyclohexanone brings a marked shift in C=O absorption, but the further introduction of a nitro group to the 6-position of 2-nitrocyclohexanone causes almost no change. This suggests that one of the nitro groups may be co-planar with C=O, while the other is not.[13)] It has been pointed out[14)] that, as a result of the trigonal geometry of the carbonyl carbon, an equatorial substituent in the 2-position of cyclohexanone is nearly eclipsed by the carbonyl oxygen, whereas an axial substituent in this position is staggered with respect to this oxygen atom. Therefore, the first nitro group is an equatorial substituent, and the second is axial. Thus, 2,6-dinitro-substituents exist in a *trans*-configuration in which electrostatic repulsions and Johnson's $A^{(1,2)}$ strain[15)] are minimal. However, in an acetone solution, **1** was shown to exist nearly completely in the enol form by a study of the UV (λ_{max}: 310 nm) and NMR spectra (–C=CH–: τ 4.20, 1H, quartet); this is in accordance with Feuer's results[16)] reporting that the enol form is favored in aprotic solvents. However, even in methanol **1** showed an enol band at 310 nm (ε 4.67×10^2), suggesting that **1** has a tendency to enolize gradually even in protic solvents.[17)] The crystalline solid of **2** was determined to exist in the enol form by a study of the IR spectrum (1640 (C=C) and 3450 cm^{-1} (OH); no C=O absorption). Compound **3** in the solid state was shown to exist nearly entirely in the keto form by a study of the IR spectrum (1750 cm^{-1} (C=O)). However, in an alcoholic solution of **3** the enol absorption at 339 nm (ε 3.54×10^2) appears together with keto absorption at 280 nm (ε 2.00×10^2), indicating an equilibrium between keto and enol forms.

The Ring-opening Reactions. The treatment of **1** with an aqueous solution of sodium carbonate gave 1,5-dinitropentane. This reaction is similar to that of potassium 1-nitro-2-keto-3-cyclohexanenitronate[18)] and may be supposed to involve ring-opening, followed by the decarboxylation of the resultant 2,6-dinitrohexanoic acid. The ring-opening reactions of **1** and **2** in primary alcohol to 2,6-dinitrohexanoic and 2,6-dinitro-4-methylhexanoic acid esters respectively proceeded even in the presence of catalytic quantities of the corresponding alkoxide ions. The reactions proceeded similarly in alcoholic solutions of alkali hydroxides. In striking contrast, in the presence of stoichiometric amounts of secondary and tertiary alkoxide ions, **1** and **2** afforded 2-keto-1,3-cyclohexanedinitronate and 2-keto-4-methyl-1,3-cyclohexanedinitronate instead of the ring-opening products. The reactions of **1** and **2** with NH_2^-, NHR^-, or AcO^- also yielded the corresponding di-*aci*-nitro compounds, from which the starting materials were recovered by neutralization. Accordingly, it appears that the nucleophiles can be divided into two classes on the basis of their reactivity towards **1** and **2**: (a) one class which induces the ring-opening of **1** and **2** and (b) another which affords di-*aci*-nitro compounds. This discrimination was made possible by the observation of the UV spectra of **1** and **2** in alcoholic solutions in the presence of alkoxide ions. As is shown in Tables 2 and 3, the UV spectra of **1** in the presence of Class (a) nucleophiles are characterized by a maximum absorption at 233—235 nm, accompanied by a shoulder in the range between 310 and 325 nm; this shoulder remained even if the solutions were allowed to stand for a long time. However, the UV absorptions of **1** in the presence of the Class (b) nucleophiles are lacking in shoulder absorptions. The absorption bands of the nitronate anions are broad and intense ($\varepsilon\cong10000$),

Table 2. Time dependency of UV spectra of 2,6-dinitrocyclohexanone in basic methanol solution at 28°C

Time (hr)	1/10M-NaOH		1/10M-NaOMe	
	λ_{max} (nm)	ε (x10^3)	λ_{max} (nm)	ε (x10^3)

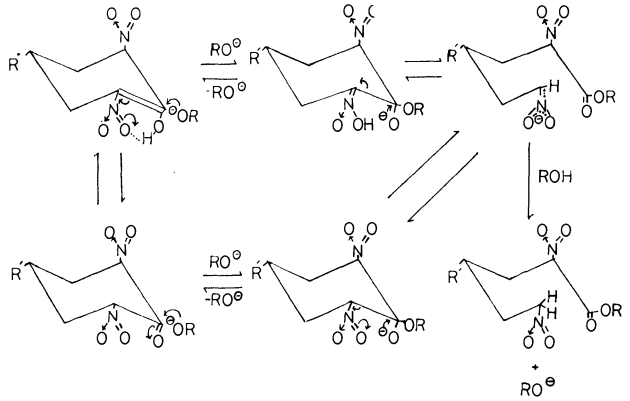
16) H. Feuer, in Abstracts 152nd American Chemical Society Meeting, New York, N.Y., Sep. 1966 (Paper No. S–157).

17) Feuer reported that **1** exists in ethanol solely as keto form (Ref. 16).

18) H. Feuer and R. S. Anderson, *J. Amer. Chem. Soc.*, **83**, 2960 (1961).

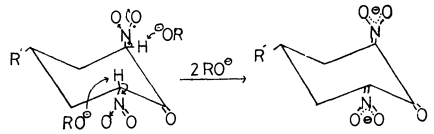
with maxima 230—240 nm[19,20] due to the π-π^* transition. The absorption in the 310—325 nm range may be due to the enol form of **1** and may be supposed to be a p-π^* transition in α-nitro-olefines.[21] The results indicate that **1** and **2** undergo the ring cleavage in nucleophilic solvents where **1** and **2** are in the enol form. The mechanism of the ring opening of **1** and **2** by the attack of the Class (a) nucleophiles may be interpreted according to Scheme I. The addition of alkoxide ions to the enol carbons or the attack of the ketonic form result in ring cleavage, thus leading to the formation of alkyl 2,6-dinitrohexanoates with nitroalkyl moieties which, in a basic solution, give the UV absorption at 233—235 nm and a shoulder absorption at 310—325 nm resulting from the small contribution of the equilibrated enol form. The ring-opening reactions proceed catalytically as the alkoxide ions are regenerated.



1:R′=H, **2**:R′=Me, **R**=primary alkyl groups

Scheme I

The Class (b) nucleophiles abstract the 2- and 6-protons to form the corresponding di-*aci*-nitro compounds, as is shown in Scheme II.



1:R′=H, **2**:R′=Me, R=secondary, tertiary alkyl groups

Scheme II

The difference in the reactivities between Class (a) and Class (b) nucleophiles may be ascribed to the steric factors and to the basicity of the alkoxide ions.

In connection with the ring-opening reactivities, **1** seemed to be more readily ruptured than 2-nitrocyclohexanone. For example, in the aqueous solution of potassium iodide, **1** afforded 1,5-dinitropentane even at room temperature, but 2-nitrocyclohexanone remained unchanged under the same conditions.

UV and IR Spectra of α,ω-Dinitro-carboxylic Acid Esters. The ring-cleavage products of α,α'-dinitrocycloalkanones are typical compounds containing two different kinds of nitro groups in one molecule. Some spectral information about these different kinds of nitro groups was obtained.

(a) UV Spectra: It has been reported that aliphatic nitro compounds and α-nitro-carboxylic acid esters are characterized by broad π-π^* transition bands of a low intensity (ε 20—40) in the 270—284 nm[22,23] region. As is shown in Table 4, the α,ω-dinitrocarboxylic acid esters were generally found to exhibit these transitions at 255—270 nm, showing a red shift with a stronger absorption. Such trends may be interpreted in terms of the repulsions between two different nitro groups in a molecule. The introduction of methyl groups as a side chain resulted in a blue shift. The maxima absorptions were not affected by the change in carboalkoxy groups. In free nitro-forms, the difference between α- and ω-nitro groups in α,ω-dinitrocarboxylic acid esters is small. However, in *aci*-nitro forms, the

conjugated α-nitronate groups (O=C-C=N$\langle$O, O$^-$) exhibit the π-π^* transition at 305—307 nm (ε 5×10^3—1.2×10^4), while the *aci*-nitro groups isolated from carboalkoxy groups showed the absorption in a shorter-wavelength range (233—235 nm).

(b) IR Spectra: On the effect of an electron-attracting α-substituent on the IR spectra of aliphatic nitro compounds, Haszeldine[23] and Brown[24] reported that asymmetrical stretching bands shifted to higher frequencies, whereas the symmetrical stretching bands moved to lower frequencies and there was no significant change in the C–N stretching vibrations. As is shown in Table 5, the present results on α,ω-dinitro-carboxylic acid esters are in exact accordance with the previously reported data. It was shown that both the asymmetrical and symmetrical stretching bands were doublets, whereas the C–N stretching vibrations were singlets. The shifts upon the introduction of carboalkoxy groups were greater in the asymmetrical stretching of nitro groups than in the symmetrical stretching. The shifts seemed to be increased in the order of the electron-attractive properties of carboalkoxy groups.

Experimental

The UV spectra were determined by means of a Hitachi double-beam spectrophotometer, Model 124. The IR spectra were recorded on a Hitachi infrared spectrophotometer, EPI-G_2. The NMR spectra were kindly determined by Drs. Kenkichi Nukada and Hajime Saito of the Basic Research Laboratories, Toray Industries, Inc., using a Varian HA-100 apparatus with TMS as the internal standard. The mp's were measured on a Yanagimoto micro-melting points apparatus with a heat block and are uncorrected.

Disodium 2-Keto-1,3-cyclohexanedinitronate (4). The dinitration procedure was similar to that described for the dipotassium salt,[26] except that sodium amide was used instead of potassium amide. The salt was purified by the use of aqueous methanol. Yield, 92.0%. Mp 240—245 °C (dec). IR (KBr): 1620 (C–O), 1410 and 1230 cm^{-1}(C–NO_2^-). UV (MeOH): 205 (ε 9.65×10^2), 280 (sh, 4.21×10^2), and 308 nm (9.65×10^2). NMR (D_2O): τ 7.80 (2H, t, J=6 Hz, 5-CH_2), and 6.83 (4H, t, J=6 Hz, 4- and 6-CH_2). Found: C, 30.94; H, 2.87; Na, 18.85%. Calcd for $C_6H_6N_2O_5Na_2$: C, 31.05; H, 2.61; Na, 19.81%.

2,6-Dinitrocyclohexanone (1). The compound was obtained from 4[5]. Colorless needles. Mp 110 °C (lit,[25] 110.5 °C). IR (KBr): 3600 (OH, w), 1740 (C=O, vs), 1560 (ν_{as} NO_2), and 1380 cm^{-1} (ν_s NO_2). UV (MeOH): 310 nm (ε 4.67×10^2). NMR (acetone-d_6): τ 4.20 (1H, q, J_{aa}=12 Hz, J_{ae}=6 Hz, 2- and 6-CH), and 7.1—8.2 (7H, m.).

Disodium 2-Keto-5-methyl-1,3-cyclohexanedinitronate. The salt was prepared by the dinitration of 4-methylcyclohexanone.[26] Scaly yellow crystals (from water-acetone). Yield, 75%; mp 222—223 °C. IR (KBr): 1648 (C=N), 1600 (C=O), 1430, 1380 (CH_3), 1280 (ν_{as} NO_2^-), and 1170 cm^{-1} (ν_s NO_2^-). Found: C, 34.39; H, 3.38; N, 11.03%. Calcd for $C_7H_8N_2O_5Na_2$: C, 34.16; H, 3.28; N, 11.38%.

2,6-Dinitro-4-methylcyclohexanone (2). The compound was prepared by the neutralization of the above disodium salt. Yield, 100%. Colorless granular crystals from methanol; mp 76—77.5 °C. IR (KBr): 3450 (OH), 1740 (C=O, vw), 1640 (C=C), 1555 (ν_{as} NO_2), 1460, 1380 (CH_3), and 1360 cm^{-1} (ν_s NO_2). The compound exists in the enol form. However, after having been allowed to stand overnight, the solid was transformed into an oily state in the keto form. IR (neat) 3450 (OH, vw), 1740 cm^{-1} (C=O, vs).

Disodium 2-Keto-1,3-cycloheptanedinitronate. This compound was prepared by the dinitration of cycloheptanone in the presence of sodium amide. Yellowish-red crystals (from water-methanol). Yield 71%; mp 215—216.5 °C(dec). IR (KBr): 1600 (C=O), 1240 (ν_{as} NO_2), and 1140 cm^{-1} (ν_s NO_2).

2,7-Dinitrocycloheptanone (3). The compound was obtained by the neutralization of the above disodium salt. Yield, 79%. Colorless needles (from methanol), mp 84.5—86.0 °C. IR (KBr): 3450 (OH, vw); 1720 (C=O), 1540 (ν_{as} NO_2), and 1340 cm^{-1} (ν_s NO_2). UV (EtOH): 339 (ε 3.52×10^2), and 280 nm (sh. 2.00×10^2). Found: C, 41.86; H, 5.43; N, 13.60%. Calcd for $C_7H_{10}N_2O_5$; C, 41.58; H, 4.99; N, 13.86%.

The Ring-opening Reactions of 2,6-Dinitrocyclohexanone (1)

(a) In an Aqueous Sodium Carbonate Solution: 1,5-Dinitropentane: To an aqueous sodium carbonate solution (62 mg; 0.7 mmol in 10 ml), we added **1** (1.0 g, 5.3 mmol). The mixture was then stirred at room temperature for 1 hr, followed by acidification with concd HCl. Then, the acidic solution was extracted with ether and the ethereal extract was dried over anhydrous sodium sulfate. After the removal of the solvent, the residue was distilled *in vacuo*. Yield, 0.81 g (94%);

25) H. Wieland, P. Garbsch, and J. J. Chavan, *Ann.*, **461**, 295 (1928).
26) H. Feuer, A. M. Hall, S. Golden, and R. I. Ritz, *J. Org. Chem.*, **33**, 3622 (1968).
27) H. Feuer snd P. M. Pivawer, *ibid.*, **31**, 3152 (1966).

bp 135 °C/1.5 mmHg. IR (neat): 1550 (ν_{as} NO_2), which is superimposable upon that of an authentic sample[18].

(b) By Sodium Methoxide: *Methyl* 2,6-*dinitrohexanoate*: *(i) Stoichiometric reaction*: To **1** (3.0 g, 15.9 mmol) in methanol (50 ml), we added, drop by drop, sodium methoxide (18.3 mmol) in methanol (25 ml) at 47—50 °C. After stirring for 2 hr, the solution was acidified with HCl gas. After the removal of the solvent, dry ether was added to the residue, followed by filtration. The filtrate was dried over anhydrous sodium sulfate. After the removal of the ether, the residue was distilled *in vacuo*. Bp 141—144 °C/0.5 mmHg. Yield, 2.9 g (83%). The IR, NMR, and UV spectra were identical with those reported by Feuer *et al.*[5]

(ii) Catalytic Reaction: To **1** (11.3 g, 0.06 mol) in methanol (200 ml), we added, drop by drop, sodium methoxide (0.55 g, 0.01 mol) in methanol (50 ml) at 50 °C. The whole solution was then worked up by the procedure described above. Yield, 11.4 g (86%).

(c) By Sodium Ethoxide. Ethyl 2,6-*Dinitrohexanoate*: The procedure was similar to that described for (b), but using sodium ethoxide in ethanol. Bp 132 °C/0.5 mmHg. Yield, 75%. n_D^{25} 1.4612. IR (neat): 1750 (C=O), 1562, 1553 (ν_{as} NO_2), 1376, 1374 (ν_s NO_2), 1200 (C-O), and 860 cm^{-1} (C-N). UV (MeOH): 261 nm (ε 3.55×10^2). NMR (acetone-d_6), τ 4.56 (1H, t, J=7.0 Hz, 2-CH), 5.44 (2H, t, J=7.0 Hz, 6-CH_2), 5.77 (2H, q, J=7.0 Hz, -COOC$H_2$$CH_3$) 7.6 8.6 (4H, m, 4-, 5-$CH_2$), and 8.42 (2H, q, J=8.0 Hz, 3-CH_2). Found: C, 41.39; H, 5.91; N, 12.30%, mol wt (in acetone), 228. Calcd for $C_8H_{14}N_2O_6$: C, 41.02; H, 6.03; N, 11.96%; mole wt, 234.2.

(d) By Sodium n-*Propoxide.* n-*Propyl* 2,6-*Dinitrohexanoate*: The procedure was similar to that described for (b). Bp 152—162 °C/0.5 mmHg. Yield, 81%; n_D^{25}: 1.4627. IR (neat): 1750 (C=O), 1562, 1554 (ν_{as} NO_2), 1380, 1378 (ν_s NO_2), and 1200 cm^{-1} (C-O). UV (MeOH): 263 nm (ε 3.94×10^2). NMR (acetone-d_6): τ 4.52 (1H, t, J=7.0 Hz, 2-CH), 5.46 (2H, t, J=8.0 Hz, 6-CH_2), 5.83 (2H, t, J=7.0 Hz, -COOCH_2 CH_2CH_3), 7.35—8.05 (4H, m, 4-, 5-CH_2), 8.40 (2H, sex, J=7.0 Hz, -OCH_2C$H_2$$CH_3$) and 8.42 (2 H, q, J=7.0 Hz, 3-CH_2). Found: C, 40.36; H, 6.55; N, 11.06%; mol wt (in acetone), 221. Calcd for $C_6H_{16}N_2O_6$: C, 40.67; H, 6.83; N, 11.86%; mol wt 236.2.

*(e) Di-*aci*-nitration by Sodium Isopropoxide.* To **1** (3 0 g, 15.9 mmol) in isopropoxide, we added, drop by drop, sodium isopropoxide (16.0 mmol) in 2-propanol at 65—70 °C. After continuing stirring for 5.5 hr at 70 °C, the solution was cooled to room temperature and then acidified with HCl gas. After the subsequent evaporation of the solvent *in vacuo*, acetone was added to the residue. The whole solution was then filtered, and the solvent was distilled off. The residue was found to be the recovered starting material (2.5 g). In secondary and tertiary alcoholic solutions containing the corresponding sodium alkoxide, such as isopropoxide and *iso-*, *sec-*, and *tert-*butoxides, **1** and **2** gave the di-*aci*-nitro derivatives from which the corresponding starting materials were recovered by acidification.

(f) By Sodium n-*Butoxide*: n-*Butyl* 2,6-*Dinitrohexanoate*: In a manner similar to that described for (b), **1** (3.0 g, 15.9 mmol) was transformed into *n*-butyl 2,6-dinitrohexanoate. Yield, 3.1 g (74.5%). Bp 142 °C/0.5 mmHg. n_D^{25}, 1.4603. IR (neat): 1740 (C=O), 1562, 1555 (ν_{as} NO_2), and 1376 cm^{-1} (ν_s NO_2). UV (MeOH): 264 nm (ε 300). NMR (acetone-d_6); τ 4.54 (1H, t, J=7.0 Hz, 2-CH), 5.47 (2H, t, J=8.0 Hz, 6-CH_2), and 5.78 (2H, t, J=7.0 Hz, -COOCH_2-CH_2-). Found: C, 46.14; H, 7.03; N, 11.05%; mol wt (in acetone), 224. Calcd for $C_{10}H_{18}N_2O_6$: C, 45.79; H, 6.92; N, 10.68; mol wt 262.3.

(g) By Potassium Hydroxide in n-*Amyl Alcohol*: n-*Amyl* 2,6-*Dinitrohexanoate*: To **1** (3.0 g, 15.9 mmol) in *n*-amyl alcohol (100 ml) at 60 °C, we added, drop by drop, *n*-amyl alcohol (50 ml) containing potassium hydroxide (0.1 g). After stirring for 4.5 hr at 60 °C, the whole solution was worked up in the usual manner. Bp 137 °C/0.5 mmHg. Yield, 2.98 g (68%). IR (neat): 1750 (C=O), 1570, 1556 (ν_{as} NO_2), and 1380 cm^{-1} (ν_s NO_2). UV (MeOH): 265 nm (ε 292). NMR (acetone-d_6): τ 4.55 (1H, t, J=7.0 Hz, 2-CH), 5.45 (2H, t, J=7.0 Hz, 6-CH_2), and 5.80 (2H, t, J=7.0 Hz, -$COOCH_2$), Found: C, 48.69; H, 7.50; N, 10.27%; mol wt (in acetone) 250. Calcd for $C_{11}H_{20}N_2O_6$: C, 47.82; H, 7.30; N, 10.14%; mol wt 276.3.

The Ring-Opening Reactions of 4-*Methyl* 2,6-*Dinitrocyclohexanone (2)*: *(a) By Potassium Hydroxide in Methanol. Methyl* 2,6-*Dinitro*-4-*methylhexanoate*: To **2** (4.0 g, 19.8 mmol) in methanol (100 ml), we added, drop by drop, methanol (50 ml) containing potassium hydroxide (0.3 g) at 50—55 °C. After stirring for 1 hr at this temperature, the solution was worked up in the usual manner. Yield, 4.0 g (86.3%); bp 132—138 °C/2.0 mmHg. IR (neat): 1740 (C=O), 1563, 1552 (ν_{as} NO_2), and 1381 cm^{-1} (ν_s NO_2). UV (MeOH): 225 nm (ε 270). NMR (CCl_4): τ 4.8 (1H, t, J=8.0 Hz, 2-CH), 5.6 (2H, t, J=8.0 Hz, 6-CH_2), and 6.2 (3H, s, -$COOCH_3$). Found: C, 41.65; H, 6.33; N, 11.57%. Calcd for $C_8H_{14}N_2O_6$: C, 41.02; H, 6.03; N, 11.98%.

(b) By Potassium Hydroxide in Ethanol: *Ethyl* 2,6-*Dinitro*-4-*methylhexanoate*: The procedure was similar to that described above. Yield, 85%; bp 120—126 °C/1.5 mmHg. IR (neat): 1740 (C=O), 1566, 1552 (ν_{as} NO_2), and 1380 cm^{-1} (ν_s NO_2). UV (MeOH): 255 cm (ε 266). Found: C, 44.06; H, 6.88; N, 11.73%. Calcd for $C_6H_{16}N_2O_6$: C, 43.58; H, 6.50; N, 11.29%.

The Ring-opening Reactions of 2,7-*Dinitrocycloheptanone (3)*. *(a) By Potassium Hydroxide in Methanol*: *Methyl* 2,7-*Dinitroheptanoate*: To **3** (3.0 g) in methanol, we added, drop by drop, methanol (50 ml) containing potassium hydroxide (0.5 g) at 65 °C. After stirring for 1.5 hr, the whole solution was worked up in the usual manner. Yield, 72%. Bp 164 °C/0.01 mmHg. IR (neat): 1750 (C=O), 1563, 1552 (ν_{as} NO_2), 1376, and 1374 cm^{-1} (ν_s NO_2). UV (MeOH): 265 nm (ε 183). Found: C, 41.77; H, 6.45; N, 11.64%. Calcd for $C_8H_{14}N_2O_6$: C, 41.02; H, 6.03; N, 11.96%.

(b) By Potassium Hydroxide in Ethanol. Ethyl 2,7-*Dinitroheptanoate.* By the usual method, ethyl 2,7-dinitroheptanoate was obtained in an 81% yield. Bp 105 °C/2×10^{-3} mmHg. IR (neat): 1750 (C=O), 1563, 1552 (ν_{as} NO_2), 1376, and 1374 cm^{-1} (ν_s NO_2). UV (MeOH): 265 nm (ε 297). Found: C, 44.19; H, 7.08; N, 11.01%. Calcd for $C_9H_{16}N_2O_6$: C, 43.54; H, 6.50; N, 11.29%.

(c) By Potassium Hydroxide in n-*Butanol.* n-*Butyl* 2,7-*Dinitroheptanoate.* The method was similar to those described in (a). Yield, 80%. Bp 146 °C/5×10^{-3} mmHg. IR (neat): 1750 (C=O), 1563, 1553 (ν_{as} NO_2), 1380, and 1378 cm^{-1} (ν_s NO_2). UV (MeOH): 255 nm (ε 357). Found: C, 48.35; H, 7.87; N, 9.49%. Calcd for $C_{11}H_{20}N_2O_4$: C, 47.82; H, 7.30; N, 10.14%.

The Photolysis of 3,3-Pentamethyleneoxaziridine

Yoshinari KOBAYASHI

Nagoya Research Laboratory, Chemicals and Development Laboratories, Toray Industries, Inc., Ohe-chyo, Minato-ku, Nagoya 455–91

(Received March 13, 1973)

The ultraviolet irradiation of 3,3-pentamethyleneoxaziridine (**1**) gave two classes of photo-products: (a) cyclohexanol and *n*-capronamide, the formation of which proceeds preferentially through the excited triplet state of **1**, and (b) ε-caprolactam, dicyclohexylideneazine, and cyclohexanone, which are mainly furnished *via* the singlet state of **1**. The correlation of the selectivity of (a)-class products with the triplet-state energy of the quenchers used made it possible to estimate that the lowest triplet energy of **1** was approximately 60 kcal/mol. The sensitized photolysis of **1** using sensitizers, the triplet-state energy of which was more than nearly 60 kcal/mol, gave *n*-capronamide predominantly. The photolytic decomposition rate of **1** was compared with those of 2-methyl-3,3-tetramethyleneoxaziridine (**2**), 2-methyl-3,3-pentamethyleneoxaziridine (**3**), and cyclohexanone oxime. The mechanism of the photolysis of **1**, including homolytic N–O bond rupture, was also discussed.

The photo-Beckmann rearrangement, the photochemical conversion of oximes into the corresponding amides, has been the subject of considerable study in the last decade.[1] The reaction scheme through the intermediacy of oxaziridines for the photo-induced Beckmann rearrangements has been confirmed in indirect ways.[1e,1f,1l] Nevertheless, there has been relatively little direct evidence to substantiate the photochemical transformation of oxaziridines into the corresponding amides.[2] Recently, two short communications on the photolyses of *N*-phenyl-oxaziridines[4] and 3,3-pentamethyleneoxaziridine (**1**)[1m] into the amides have been reported. The present author has independently[5] investigated the photolyses of cycloalkanespiroöxaziridines including **1** in relation to the photo-Beckmann rearrangement of cyclohexanone oxime.

Results and Discussion

Reaction Products. The ultraviolet irradiation of a solution of **1** in ether[6] (about 10—11 wt%) with a low-pressure mercury arc lamp at a temperature between −2 and 0 °C in a quartz apparatus led to six kinds of photo-products: cyclohexanol (5—6%), cyclohexanone (29—37%), dicyclohexylideneazine (2—3%), *n*-capronamide (9—11%), ε-caprolactam (36—50%), and a trace of dodecanediamide. In the thermolysis of **1**, the dimeric product was reported to be 1,1′-dihydroxyazocyclohexane[8] instead of dicyclohexylideneazine. In the photolysis of cyclohexanone oxime in ether a small amount of the azine and a trace of dodecanediamide were also detected.[9] The formation of the azine and dodecanediamide implies a homolytic N–O bond cleavage in **1**, followed by coupling. The photo-products of the relatively stable 2-methyl-3,3-tetramethyleneoxaziridine (**2**) and 2-methyl-3,3-pentamethyleneoxaziridine (**3**) were predominantly the corresponding *N*-substituted cyclic lactam (60—80%) and cycloalkanone (20—40%). Small amounts of the corresponding cycloalkanol and ring-opened amide were also detected.

Decomposition Rate. The photochemical decomposition rates of **1**, **2**, **3**, and cyclohexanone oxime were shown to be of the first order, and the relative rates based upon **1** (in ether) were 1.0, 0.38, 2.9, and 0.17 respectively. The results show that *N*-methyl substituted spiroöxaziridines decomposed faster than the corresponding *N*-unsubstituted spiroöxaziridines with the same ring size. A comparision of the photolytic decomposition of **2** with that of **3** showed that the decomposition rate of the oxaziridine with a spiro-five-membered ring (**2**) was approximately one third that of the oxaziridine with a spiro-six ring size (**3**). The photolytic decomposition rate of cyclohexanone oxime in ether was comparatively small in comparision with

b) In all cases the selectivity of dodecanediamide was trace.

that of **1**. The decomposition rates of the spiro-öxaziridines were dependent upon the polarity of the solvents used; *e.g.*, the relative decomposition rates of **3** in cyclohexane, ether, and 2-propanol were found to be 1.3, 2.0, and 2.6 respectively. The results showed a tendency for greater rates in more polar solvents.

Triplet-state Quenching. The photolyses of **1** in ether in the presence of a number of triplet-state quenchers with triplet-state energy (E_T)[10] were investigated. In these experiments lights longer than 2537 Å of a low-pressure mercury arc were elaborated so as to be cut by liquid filters to avoid the direct absorption of light by the quenchers added. The results are summarized in Table 1. The experiments using piperylene were also repeated by changing the concentration of the quenchers (less than 85 mmol/l). From the results thus obtained the following conclusions may be drawn:

(a) The selectivity of *n*-capronamide decreased with an increase in the amount of piperylene added. From the view point of the correlation of the selectivities of products with E_T, the selectivity of *n*-capronamide was discontinuous. It was approximately 17% in the presence of quenchers with E_T values of more than 60 kcal/mol, but abruptly fell to about 5% or less when quenchers whose E_T were less than 60 kcal/mol were used. From these results, it can be estimated that the formation of *n*-capronamide proceeds preferentially *via* the excited triplet state of **1**, the energy of which is approximately 60 kcal/mol. This estimation was also supported by the sensitized photolysis of **1**, as will be described later.

(b) The selectivity of cyclohexanol also decreased linearly in the presence of quenchers with E_T values of less than approximately 60 kcal/mol. Moreover, when more than 5 mol% (based on **1**) of piperylene was added, no substantial amount of cyclohexanol could be detected. Consequently, cyclohexanol was also formed mainly *via* the triplet state of **1**, whose energy was estimated to be approximately 60 kcal/mol.

(c) There was no connection between the ε-caprolactam selectivity and the amounts of piperylene added. However, when the formations of both *n*-capronamide and cyclohexanol were suppressed by quenchers with E_T values of less then approximately 60 kcal/mol, the ε-caprolactam selectivity apparently increased.

(d) The formation of both dicyclohexylideneazine and cyclohexanone were independent of the amount of piperylene added, and there was no special correlation of these selectivities with E_T.

Hence, although the photo-products cannot be clearly classified, it can be roughly deduced that the formations of ε-caprolactam, dicyclohexylideneazine, and cyclohexanone proceed *via* the excited singlet state of **1**, whereas *n*-capronamide and cyclohexanol are formed *via* the triplet state, whose E_T energy is approximately 60 kcal/mol. The effect of a quencher with an E_T value of less than 60 kcal/mol can be explained by the internal conversion from the triplet state of **1** to that of the quencher.

Sensitized Photolysis. The sensitized photolysis of **1** was investigated with a high-pressure mercury arc. In these experiments, the ultraviolet range of light (less than 2537 Å) was absorbed by a Pyrex glass vessel and liquid filters so as to interrupt the direct absorption of light by **1**. The results are given in Table 2. The 1-acetonaphthone (E_T=56.4 kcal/mol) sensitized photolysis of **1** yielded no cyclohexanol, but only a very small amount of *n*-capronamide. In sharp contrast, the photolysis of **1** in the presence of such sensitizers as benzene (E_T=84 kcal/mol) and benzophenone (E_T=68.5 kcal/mol) yielded both *n*-capronamide and cyclohexanol in comparatively high yields. As has been mentioned above, both *n*-capronamide and cyclohexanol were preferentially produced *via* the triplet state of **1**, whose energy was estimated to be approximately 60 kcal/mol. In the sensitized reaction of **1** using sensitizers with E_T of more than nearly 60 kcal/mol, the triplet state of **1** was supposed to be efficiently formed by the internal conversion, resulting in comparatively high yields of *n*-capronamide and cyclohexanol. On the contrary, the formation of such products as ε-caprolactam and dicyclohexylideneazine, which proceeded *via* the singlet state of **1**, was almost suppressed. In the sensitized reactions using sensitizers with a triplet-state energy of less than approximately 60 kcal/mol, the main sensitized reaction was suppressed and **1** gave cyclohexanone predominantly, as in the

Table 2. Sensitized photolysis of **1** in ether with a 270-W high pressure mercury arc

Sensitizer[a]	Benzene	Benzophenone	Piperylene	1-Acetonaphthone
E_T (kcal/mol)	84	68.5	58.8	56.4

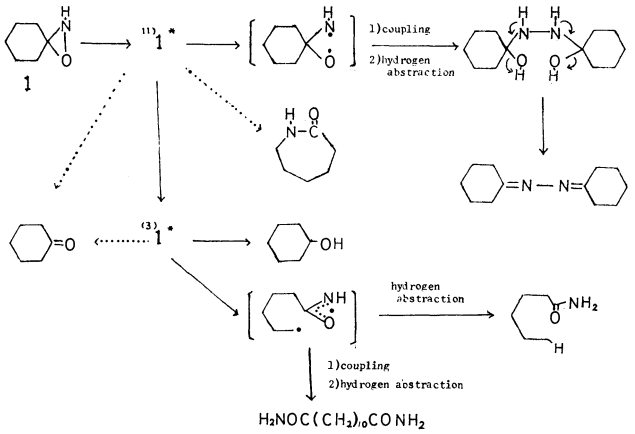
a) Addition amounts of sensitizers were 5 mol% based on **1** (17.5 mmol/l).
b) Investigated at the temperature of −2 °C.
c) Gas chromatographical separation was unsuccessful due to the presence of benzophenone.

1-acetonaphthone-sensitized photolysis. The photolysis of **1** sensitized by piperylene (E_T=58.8 kcal/mol) was a borderline case and gave considerable amounts of *n*-capronamide and cyclohexanol.

Reaction Mechanism. The oxaziridines, **2** and **3**, in methanol have absorption maxima at 200 nm (ε 172) and 207 nm (ε 112.8) respectively. No other maxima can be observed at longer wavelengths. The primary photo-excitation is, therefore, assumed to be either a forbidden n-σ* or σ-σ* transition. The main photolytic route of **1** may be summarized as is shown in Scheme 1.



Scheme 1.

Because of the relatively short lifetime of the excited singlet state of **1**, the intramolecular rearrangement leading to ε-caprolactam was supposed to be predominant, and it was supposed that only a part of it undergoes coupling to give dicyclohexylideneazine. The formation of dodecanediamide was supposed to involve the same intermediate as that of *n*-capronamide.

Experimental

Apparatus. The IR spectra were recorded on a Hitachi infrared spectrophotometer, type EPI-G_2. The UV spectra were obtained on a Hitachi spectrophotometer type, 124, using a 10 mm quartz cell. The NMR spectra were measured on a Varian A 100 (100 MHz) spectrometer, using TMS as the internal standard.

Light Sources. Both an Ushio UL-5UQ 50-W low-pressure mercury arc and a Hanovia 2-W-U low-pressure mercury arc lamp were used. In the sensitized photolyses, a Wako Electric 270-W high-pressure mercury lamp was used.

Materials. The ether solution of **1** (the concentration was approximately 10—11 wt%) was prepared in the manner described by Schmitz and Murawski.[7] In a similar manner,[11] **2** and **3** were also prepared and isolated by distillation *in vacuo*. Authentic *N*-methyl-ε-caprolactam was prepared by the reaction of ε-caprolactam with dimethylsulphate.[12] Dicyclohexylideneazine was prepared by the condensation of cyclohexanone and hydrazinehydrate in benzene under reflux. *n*-Capronamide was prepared by the chlorination of *n*-caproic acid with thionyl chloride, followed by amidation. All the quenchers were commercially available and were of an analytical grade.

General Procedure for the Photolysis of 1. Irradiations were carried out in a quartz vessel immersed in a brine bath at temperature between −2 and 0 °C. The concentration of the ether solution of **1** used was usually 10—11 wt%. The solution was photolized until the **1** had been completely decomposed. The unreacted oxaziridine was periodically determined iodometrically.[13] The yields of all the photo-product were determined by means of gas chromatography. The free cyclohexanone containing the ether solution of **1** was determined by means of gas chromatography by subtracting the content of **1** from the total cyclohexanone content in the solution, as determined by the alkaline hydrolysis of **1** and by the subsequent determination of the resultant cyclohexanone. The identification of photo-products was as follows: (a) ε-caprolactam: The irradiated solution was condensed and then distilled *in vacuo*; bp 100—124 °C/5 mm. The fraction obtained was recrystallized from cyclohexane; mp 68 °C. The IR spectrum (KBr disk) was superimposable upon that of an authentic sample. (b) *n*-capronamide: from the condensed photolytic solution, it was isolated by preparative gas chromatography. The IR spectrum (KBr disk) was superimposable upon that of an authentic sample. (c)

10) Triplet-state energies of quenchers were cited from, a) W. C. Herkstroeter, A. A. Lamola, and G. S. Hammond, *J. Amer. Chem. Soc.*, **86**, 4537 (1964). b) L. M. Stephenson and G. S. Hammond, *Angew. Chem. Internat. Edit.*, **8**, 261 (1969).

11) E. Schmitz, R. Ohme, and D. Murawski, *Chem. Ber.*, **98**, 2516 (1965).

12) R. E. Benson and T. L. Cairins, *J. Amer. Chem. Soc.*, **70**, 2114 (1948).

13) In these determinations, the titre is equal to the sum of **1**, chloramine, and *N*-chlorocyclohexylideneimine. Therefore, the contents of **1** were obtained by subtraction the chlorine titre determined by Volhard method from the total iodometric titre.

dicyclohexylideneazine: It was isolated using elution-column chromatography on silica gel, using chloroform as the solvent; bp 99—102 °C/1 mmHg; mp 29.2—30.8 °C. UV: λ_{max}^{MeOH} 210 nm (2.55×10^4), 231 nm (6.57×10^3). Mass: (M^+ 192). IR (KBr): 1630 cm^{-1} (C=N). NMR ($CDCl_3$): δ 2.53 (q, 8H, $J_{a,a}=12$ Hz, $J_{a,e}=6$ Hz, α-CH_2), δ 1.4—2.0 (m, 12H, β, γ-CH_2). (Found: C, 74.47; H, 10.31; N, 14.88%). (d) cyclohexanol: it was separated by gas chromatography and was identified by means of the IR spectrum of an authentic sample. (e) dodecanediamide: It was identified by gas chromatography and the IR and mass spectra.

The Photolysis of ***2***. Twenty grams of **2** in methanol (150 ml) were irradiated with a low-pressure mercury arc at a temperature between −2 and 0 °C. After the complete decomposition of **2** (checked by iodometry), the photoproducts were directly determined by gas chromatography. The main product (*N*-methyl-α-piperidone) was obtained by the evaporation of the solvent and by subsequent distillation *in vacuo*. Yield, 71%. Bp 85—86.5 °C/5 mmHg. IR (liquid): superimposable upon that of an authentic sample. NMR ($CDCl_3$): δ 3.2—3.4 (m, 2H, δ-CH_2), δ 2.40 (s, 3H, N-CH_3), δ 2.25—2.45 (m, 2H, α-CH_2), δ 1.75—2.00 (m, 4H, β, γ-CH_2). (Found: C, 62.99; H, 9.54; N, 12.49%).

The Photolysis of ***3***. The various solutions of **3** (concentration: 2.3—2.5 mol/l) were irradiated with a low-pressure mercury arc as has been described above. The main product was obtained by the evaporation of the solvent, followed by reduced distillation (bp 71 °C/0.75 mmHg); it was identifed as *N*-methyl-ε-caprolactam. IR (liquid): 1630 cm^{-1} (C=O). NMR ($CDCl_3$): δ 3.25—3.45 (m, 2H, ε-CH_2), 2.93 (s, 3H, N-CH_3), 2.40—2.60 (m, 2H, α-CH_2), 1.4—1.9 (m, 6H, β, γ, δ-CH_2). (Found: C, 65.56; H, 10.17; N, 11.05%).

Quenching Reactions of ***1***. To about 205 g of the ether solution of **1**, the concentration of which was approximately 0.35 mol/l, we added a quencher so as to adjust the concentration to 17.5 mmol/l. The mixture was then transferred to a quartz vessel and was irradiated at a temperature between 12 and 0 °C using a 50-W low-pressure mercury arc. The lights, whose wavelength was longer than 2537 Å, were cut by liquid filters composed of copper and cobalt salts. Irradiation was continued until the conversion of **1** reached more than 90%. The products were then analyzed by means of gas chromatography.

Sensitized Photolysis of ***1***. To about 115 g of an ether solution of **1** (concentration, 0.35 mol/l) we added a sensitizer to adjust the concentration to 17.5 mmol/l. The mixture was then transferred to a Pyrex glass vessel and was irradiated at −2 °C using a 270-W high-pressure mercury arc. The irradiated solution was then worked up in the usual manner.

The author is grateful to Mr. Nobumasa Anjiki for his technical assistance and to Dr. Hajime Saito of Toray Industries, Inc., for the measurements of the NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3470—3474 (1973)

Carboxylation of Phenol Derivatives. XXI. The Formation Reaction of the Complex from Alkali Phenoxide and Carbon Dioxide[1]

Ichiro HIRAO and Taketoshi KITO

Laboratory of Industrial Chemistry, Department of Chemical Engineering, Kyushu Institute of Technology, Tobata-ku, Kitakyushu-shi 804

(Received December 8, 1972)

The yield of the complex was examined using eleven potassium phenoxide or substituted phenoxides. The phenoxide with an electron-donating group gave a complex in a better yield than did that with an electron-attracting group. The infrared spectra of the four complexes were measured. From these results, it was concluded that, in the complex, the carbon atom of carbon dioxide binds to the oxygen atom or the π-electron of alkali phenoxide. The thermal analyses of the complex were also conducted by DTA and TGA in an atmosphere of carbon dioxide; a strong endothermic peak and a rapid weight loss were observed at the temperatures from 120 to 140 °C.

Hydroxybenzoic acids are mainly synthesized by the Kolbe-Schmidt reaction, and many methods have appeared for this reaction since Kolbe discovered it in 1860.[2] Some methods of preparing hydroxybenzoic acids are as follows:[2-4] (a) the reaction of alkali phenoxide with carbon dioxide in the absence of a solvent or in a nonpolar solvent; (b) the reaction of alkali phenoxide with carbon dioxide in an aprotic polar solvent such as dimethylformamide; (c) the reaction of phenol with carbon dioxide in the presence of an excess amount of potassium carbonate; (d) the reaction of alkali phenoxide with alkali alkyl carbonate, *etc.* Of these, a typical reaction is the (a) method, and the reaction mechanism has been investigated exclusively in reference to this method. The general procedure is divided into two steps. The first step is the absorption of carbon dioxide by alkali phenoxide at a low temperature (about 100 °C). The second step is the heating of the mixture obtained in the first step, the temperature being held at 150—160 °C for several hours.[2] In the first step, it is known that a certain product is formed when phenoxide comes into contact with carbon dioxide. Some investigations of

this product have been done, but they have almost all been done in connection with the mechanism of the Kolbe-Schmidt reaction or in connection with the preparation of hydroxybenzoic acid.[5,6] However, in this paper the yields and analytical results of this product and its related compounds will be described.

Experimental

Complex Formation Reaction. In a 300 ml glass autoclave, we placed 100 ml of a light oil (as a medium of heat) and 0.02 mol of potassium phenoxide. After the air had been replaced by nitrogen, the autoclave was heated, vigorously stirred, and then kept at the prescribed temperature. The pressure was released and then a carbon dioxide pressure was exerted. The pressure was kept at a constant value during the reaction. Some adduct, which we will represent as "complex" or [I] for the sake of convenience, was formed from potassium phenoxide and carbon dioxide according to Eq. (1):

(1)

At the prescribed time, the carbon dioxide was replaced by nitrogen and the autoclave was allowed to cool to room temperature.

Determination of the Complex. It is difficult to separate the complex from unreacted potassium phenoxide because the complex is hardly soluble in either ordinary organic solvents or alkali phenoxides (we found that the adduct was also formed from DMF and alkali phenoxide when the latter was dissolved in DMF[7] and that alkali alkyl carbonate was formed when the complex was dissolved in alcohol;[8] therefore, they can not be used as solvents) and is thermally unstable.[5] For the above reasons, the determination of the complex was carried out according to the following procedure.

The lid of the autoclave was taken off, and the light oil was sucked out through a glass-filter by applying a vacuum. In this procedure, one must take care that the reaction mixture does not come in contact with the moisture or the carbon dioxide in the air.

A test tube, in which 50 ml of aqueous KOH solution (about 1 M) had been placed, was inserted into the autoclave, and then the lid was put on tightly. Then, making the aqueous KOH solution run over from the test tube by inclining the autoclave, the complex was caused to decompose into potassium phenoxide and carbon dioxide, the latter being absorbed by the aqueous KOH solution to change into potassium carbonate or potassium bicarbonate. The number of complex molecules formed should be equal to the total number of the molecules of potassium carbonate and potassium bicarbonate if the reaction proceeds according to Eqs. (1) and (2):

[I] + excess KOH ⟶

(2)

The reaction mixture was diluted with water to 500 ml; from this solution a 5 ml portion was pipetted and titrated with 0.1 M HCl. In most cases there are two clear inflexion points, that is, P_1 and P_2, which generally appear at the pH values of 7.9 and 4.6 respectively. At P_1, the potassium carbonate is completely converted to potassium bicarbonate. In the range from P_1 to P_2 only potassium bicarbonate, whose amount should be equal to the amount of the complex, is present. Therefore, the number of complex molecule formed in this reaction is obtained by multiplying the difference between P_1 and P_2 by 100.

When the solution contains some hydroxy acid which is formed in the carboxylation of potassium phenoxide by carbon dioxide, P_2 is generally indistinct. In such a case, the following procedure could be used. To 5 ml of the aqueous solution, hydrochloric acid was added until P_1 was attained. At this point, the aqueous solution contains only potassium bicarbonate and mono potassium salt of hydroxy acid as potassium salts in amounts represented here as A mol and B mol respectively. When a sufficient amount of M mol of hydrochloric acid is further added, $M-(A+B)$ mol of hydrochloric acid and B mol of hydroxy acid remain as acid components. This solution was again titrated with 0.1 M aqueous sodium bicarbonate. There is also a clear inflexion point, P_3, which generally appears at the pH of 4.5. When N mol of sodium bicarbonate is added until P_3 (at P_3 both hydrochloric acid and hydroxy acid are neutralized by sodium bicarbonate) is attained, the following equation must be valid:

$$M - (A+B) + B = N \qquad \therefore \quad A = M - N$$

The yield of the complex can be calculated according to Eq. (3), where: L represents the number of molecules of potassium phenoxide used as the starting material.

$$\text{Complex yield (\%)} = \frac{M-N}{L} \times \frac{500}{5} \times 100 \qquad (3)$$

Infrared Absorption Spectra of the Complex. The spectra were measured with a Japan Spectroscopic spectrometer (IRA-2).

The complex was prepared at room temperature by the method described above, but light oil was replaced by *n*-hexane because the latter has no absorption in the carbonyl absorption region. The complex containing *n*-hexane was placed on filter paper, which blots *n*-hexane, and was then suspended in Nujol on a mortar.

Differential Thermal Analysis (DTA) and Thermogravimetric Analysis (TGA). The complex was prepared as follows. Potassium phenoxide was set in the apparatus and heated at 150 °C in a vacuum. After 1 hr, it was allowed to cool to room temperature, applying a vacuum, and then the atmosphere was replaced by carbon dioxide.

After 30 min, the temperature was again raised at a rate of about 3 °C/min in an atmosphere of carbon dioxide. Apparatus: Cho Keiryoki, $TRDA_1$-L.

Results and Discussion

Effect of the Reaction Temperature and the Reaction Time. The yields of the complex and of the hydroxybenzoic acids were examined under various conditions. Potassium phenoxide was heated under a carbon dioxide pressure of 5 kg/cm² for 30 min at various temperatures. The results are shown in Table 1.

The complex was formed in a 76—80% yield at temperatures lower than 70 °C and then decreased above that temperature. On the contrary, such

hydroxybenzoic acids as salicylic acid and *p*-hydroxybenzoic acid were formed at 100 °C in only a 4.1% yield. The effect of the reaction time on the yields of complex and hydroxybenzoic acids was examined at 150 °C (see Table 1). On the basis of these results, it can be said that the complex yield decreases at temperatures higher than 70 °C not because it changes into hydroxybenzoic acids, but because it is thermally unstable.

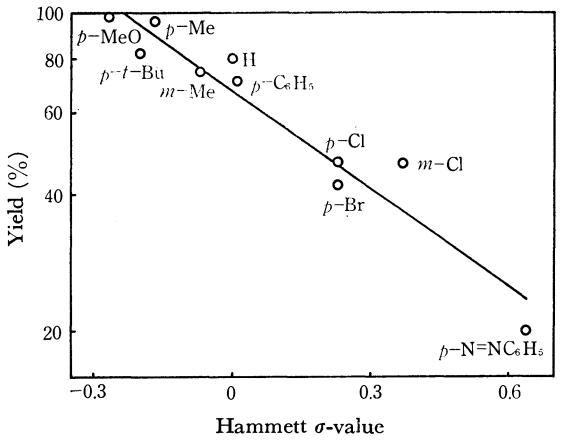

Fig. 1. Effect of the substituent on the yield of complex.
CO_2: 5 kg/cm², temp: 70 °C, time: 30 min

Reaction:  (complex)

Ordinate: a logarithmic graduation
p-SO_3K: $\sigma = +0.64$, Yield 5.8%. This point is omitted in this figure because it deviates largly from the straight line.

Effect of the Substituent. Potassium salts of phenols were heated at 70 °C under a carbon dioxide pressure of 5 kg/cm² for 30 min. In Fig. 1 the complex yields are plotted against the Hammett σ-values. We observed a linear relationship between the yield and the σ-value, and it was concluded that a phenoxide with an electron-donating group, that is, a lower σ-value, gave the complex in a better yield than that with an electron-attracting group.

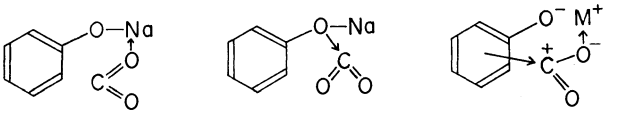
Some discussions have been made of the alkali phenoxide–carbon dioxide complex because the complex has been regarded by some investigators to an important intermediate in the carboxylation of alkali phenoxide, the Kolbe-Schmidt reaction. For example, Schmidt[2)] considered that the intermediate, which we will here describe as the complex, is an alkali phenyl carbonate. He proposed the following reaction processes, Eqs. (4) and (5). The second step, Eq. (5),

$$C_6H_5ONa + CO_2 \longrightarrow C_6H_5OCOONa \quad (4)$$

$$C_6H_5OCOONa \longrightarrow HOC_6H_4COONa \quad (5)$$

is a rearrangement of sodium phenyl carbonate to salicylic acid.

By infrared study Hales and his co-workers[5)] determined the structure of the adduct obtained from sodium phenoxide and carbon dioxide as II. (Many authors have described the molecule of carbon dioxide in the complex as a bending form, as is shown in the figure, without explanation, although carbon dioxide is usually considered to have a straight-lined form; however, Kwan and his co-workers[9)] presumed the structure of carbon dioxide in the complex to be a bending form on the basis of the infrared study.) They proposed the structure of II on the basis of the fact that it has an IR absorption due to the carbonyl band at 1684 cm^{-1}. They considered that if the product is a sodium phenyl carbonate, it must have a carbonyl absorption at about 1630 cm^{-1} because sodium methyl carbonate has an absorption due to carbonyl at 1630 cm^{-1}. In addition, dimethyl carbonate and methyl phenyl carbonate possess carbonyl absorptions at 1748 and 1754 cm^{-1} respectively, indicating that the phenyl group has little effect on the position of the carbonyl absorption. However, we consider that although they rejected the sodium phenyl carbonate structure on the basis of a reasonable method, no clear structure can be given because whether carbon dioxide binds to sodium metal or to the residue can not be determined by only their IR investigations. Shilov and his co-workers[10)] proposed that the structure of the complex can be denoted as III, not II, because II must be very weak; however, this assumption was not based on experimental data.



[II] [III] M=K, Na [IV]

The results presented in Fig. 1 also give some interesting information. If the oxygen atom of carbon dioxide binds to the alkali atom, as is shown in II, the poorer the electron density on the alkali atom, the stronger the binding force between the alkali atom and carbon dioxide. Therefore, the yield of a complex must increase as the substituent on the phenyl nucleus attracts an electron from the nucleus or the oxygen

atom. However, this idea is contrary to the results shown in Fig. 1. The results in Fig. 1 suggest that the (III) structure is more reasonable than the (II) structure because it is expected that the yield increases as the electron density on the oxygen atom of phenoxide increases. On the other hand, another structure, a π-complex structure shown as IV, which we have described here ionically, is possible; a similar structure has been proposed by Hales and his co-workers[5] as one state in the carboxylation of sodium phenoxide. In IV, of course, carbon dioxide should bind to the alkali atom more loosely than to the π-electron on the phenyl nucleus. However, we have no reliable data for a discussion as to which structure, (III) or (IV), is more reasonable.

Infrared Absorption Spectra. The IR absorptions due to the carbonyl groups of four complexes were measured; the results are listed in Table 2.

Table 2. Infrared spectra of the complex

Complex	$\nu_{C=O}(cm^{-1})$
	1645
	1650 1628
	1685
	1668

a) Lit,[5] 1684 cm^{-1}.

First, the validity of the (II) structure is considered in the following. The O^-K^+ bond in potassium phenoxide is more polarized than the O^-Na^+ bond in sodium phenoxide. Therefore, the K atom in potassium phenoxide is more positive than the Na atom in sodium phenoxide, but the electron density on the former may be higher than that on the latter because the ionic radius of K^+ is greater than that of Na^+. Yamamoto explained,[11] on this basis, a greater tendency toward the solubility of Na salts compared with K salts and other differences between sodium and potassium compounds. If this assumption is true, $C_6H_5OK \leftarrow O_2C$[12] can be expected to give a carbonyl absorption at a higher frequency than does $C_6H_5ONa \leftarrow O_2C$ since the oxygen atom of carbon dioxide binds to the K atom more loosely than to the Na atom.

On the other hand, it is obvious that the electron density on the Na atom in sodium *p*-cresoxide is higher than that on the Na atom in sodium phenoxide. Therefore, $p\text{-}CH_3C_6H_4ONa \leftarrow O_2C$ is also expected to give a carbonyl absorption at a higher frequency than does $C_6H_5ONa \leftarrow O_2C$. However, the results listed in Table 2 were not in accord with this expectation.

On the contrary, the following expectations can be drawn from the (III) structure. The electron densities on the oxygen atoms in potassium phenoxide and sodium *p*-cresoxide may be higher than that on the oxygen atom in sodium phenoxide. Therefore, both $C_6H_5O(K) \rightarrow CO_2$ and $p\text{-}CH_3C_6H_4O(Na) \rightarrow CO_2$[13] can be expected to give carbonyl absorptions at lower frequencies than does $C_6H_5O(Na) \rightarrow CO_2$ because the carbon atom of carbon dioxide may be neutralized by the oxygen atom in potassium phenoxide or sodium *p*-cresoxide to a greater extent than by that in sodium phenoxide. A similar reasoning can be also drawn from the (IV) structure. The results listed in Table 2 are in good agreement with the above expectations.

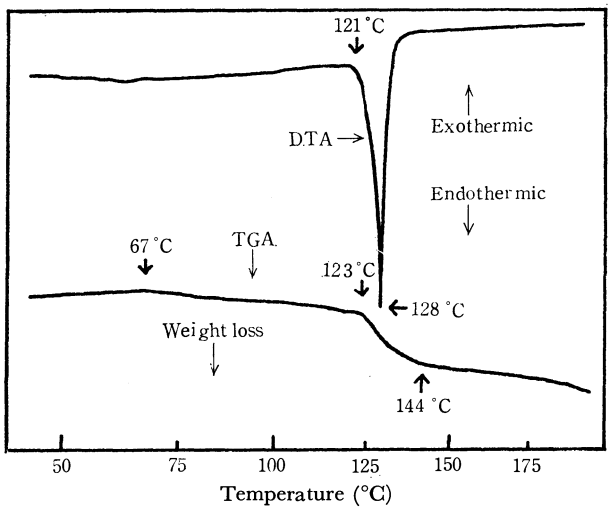

Fig. 2. DTA and TGA curves of the complex.

DTA and TGA. The complex obtained from potassium phenoxide and carbon dioxide was analyzed by DTA and TGA in an atmosphere of carbon dioxide. The results are shown in Fig. 2. In this experiment, the following reactions may occur: (a) the decomposition of the complex, (b) the formation of monopotassium salicylate and monopotassium *p*-hydroxybenzoate by the carboxylation of potassium phenoxide, (c) the conversion of the monopotassium salts into the dipotassium salts, and (d) the rearrangement of dipotassium salicylate to dipotassium salt of *p*-hydroxybenzoic acid. The weight loss in the range of the temperatures from 67 to 123 °C in Fig. 2 may correspond to the (a) process; this is in good agreement with the results listed in Table 1.

On the other hand, the weight loss did not occur below 200 °C when monopotassium salicylate or monopotassium *p*-hydroxybenzoate was heated in an atmosphere of carbon dioxide, while it began at 165 °C when a mixture of monopotassium *p*-hydroxybenzoate, monopotassium salicylate, and potassium phenoxide (weight ratio of 1 : 2 : 7) was heated in an atmosphere of nitrogen. In the latter case, the weight loss must be caused by the evaporation of the phenol formed in Eq. (6). In

13) The $C_6H_5O(M) \rightarrow CO_2$ formula represents a complex with the structure of III.

addition, we often observed the following phenomenon. A complex was prepared from potassium phenoxide and carbon dioxide in light oil at room temperature, and then the temperature was gradually raised (about 2 °C/min). When the temperature reached about 130 °C, the solid coagulated in a mass, but it was soon dispersed into the light oil.

On the basis of these data, the strong endothermic peak and the rapid weight loss in the range of temperatures from 120 to 140 °C in Fig. 2 can be explained as follows: the monopotassium salt of hydroxybenzoic acid converts into the dipotassium salt by taking a potassium atom from the complex. At that time, the complex decomposes and liberates carbon dioxide, which results in a strong endothermic peak and a great decrease in weight. The coagulation observed must be one step in this process.

Thanks are due to Mr. Hiroshi Yamaguchi and Mr. Kazumi Hirakawa for their assistance in the experimental work.

Syntheses and the Beckmann Fission of Cyclic α-Hydroxyimino Ketones

Mutsuo KATAOKA and Masaji OHNO

Basic Research Laboratories, Toray Industries, Inc., Tebiro, Kamakura 248

(Received April 2, 1973)

A convenient method for the preparation of α-hydroxyimino cycloalkanones has been established by the reaction of cycloalkanones and nitrosyl chloride. ω-Cyanocarboxylic acids or their derivatives were obtained in good yield by the Beckmann rearrangement of these α-hydroxyimino ketones.

Nitrosyl chloride addition to cycloolefins followed by displacement reactions with nucleophilic reagents such as alcohols, thioalcohols, and alkylamines provides a method of preparing various α-substituted oximes[1] which are attractive intermediates for the Beckmann fission.[2] The overall sequence is equivalent to a cleavage of the double bond in the cycloolefins, affording ω-cyanoaldehydes.[3]

No attempt has been made to prepare ω-cyanocarboxylic acids expected from the cleavage of cyclic α-hydroxyimino ketones,[4,5] from cycloalkanones such as cyclohexanone, cyclooctanone, and cyclododecanone.

In the present paper, we wish to report a convenient method for preparing α-hydroxyimino ketones of medium rings from ketones and the Beckmamm fission of such α-hydroxyimino ketones into ω-cyanocarboxylic acids. The results are compared with those of six-membered ring system.

Results and Discussion

Preparation of Cyclic α-Hydroxyimino Ketones. Although the preparation of acyclic α-hydroxyimino ketones from acyclic ketones or β-keto acids is well-known,[6] there is little information on the synthetic application of cyclic α-hydroxyimino ketones. We became interested in the study of α-hydroxyimino ketones of medium ring system, since these cyclic parent compounds are now easily available.[7]

Cyclododecanone and cyclooctanone were treated with an equivalent amount of nitrosyl chloride in the presence of a catalytic amount of hydrogen chloride, affording 2-hydroxyiminocyclododecanone (I) and 2-hydroxyiminocyclooctanone (II) in quantitative and in 87% yields, respectively. It was found that the presence of hydrogen chloride was essential at the beginning of the reaction, no reaction taking place or a long induction peiord being observed in its absence. The action of hydrogen chloride must be the enolization of the ketones as seen in typical cases of nitrosating agents such as alkyl nitrite–alkoxide and alkyl nitrite–hydrogen chloride.[6] I was obtained in the state of hydrochloride, being deposited during nitrosation from the reaction medium such as ether or petroleum benzine at low temperatures (0—5 °C), and the hydrochloride was easily transformed into the free oxime simply by being warmed up to room temperature. However, it was necessary to neutralize the hydrochloride of II with sodium bicarbonate to transform it into the free form. Neither dinitrosation nor nitrosochlorination was observed in the reactions of cyclododecanone and cyclooctanone.

Nitrosation of cyclohexanone was studied in detail by several groups, and it was found that dinitrosation occurs very easily. Ferris prepared 2,6-dihydroxyiminocyclohexanone by the reaction of cyclohexanone and methyl nitrite as a key intermediate for the synthesis of lysine,[5] and Taira obtained it by treatment of

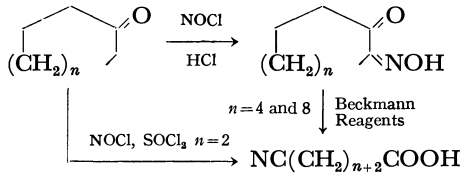
cyclohexanone with nitrosyl chloride at temperatures above −20 °C.[8] Mononitrosation of cyclohexanone requires careful reaction conditions. Thus, 2-hydroxyiminocyclohexanone (III) was obtained by treatment with 2-ethyl-*n*-hexyl nitrite[9] or by nitrosation of 2-carbethoxycyclohexanone.[10] We found that the degree of nitrosation of cyclohexanone with nitrosyl chloride is controlled by the reaction temperature. Mononitrosation of cyclohexanone occurs below −50 °C in the presence of hydrogen chloride, and dinitrosation at temperatures above −20 °C. A mixture of mono- and dihydroxyimino compounds was obtained at temperatures −50——20 °C. III was obtained in the state of unstable hydrochloride and free oxime was obtained in 62% yield after neutralization with aqueous sodium hydroxide.

Table 1. IR spectra of I, II, and III (in CCl_4)

α-Hydroxyimino Ketone	mp °C	ν_{OH} (Free) cm^{-1}	ν_{OH} (Bonded) cm^{-1}	$\Delta\nu$ cm^{-1}	Configuration
III	60—64	3560	3240	320	*syn*
II(*syn*)	101—103	3580	3260	320	*syn*
II(*anti*)	oil	3580	—	—	*anti*
I	69—70	3560	—	—	*anti*

It should be mentioned that the configuration of the cyclic α-hydroxyimino ketones obtained depends upon the ring size. The configurations of I, II, and III were determined spectroscopically[11] and the results are shown in Table 1. The configuration of III, which so far has not been discussed, was found to be exclusively *syn*, and 8-membered α-hydroxyimino ketone (II) was shown to be a mixture of *syn* and *anti* forms in equal amount, but the configuration of I was found to be exlcusively *anti*.



Beckmann Fission of Cyclic α-Hydroxyimino Ketones. The cyclic α-hydroxyimino ketones thus obtained were subjected to the Beckmann rearrangement under various conditions. The results are summarized in Table 2. 2-Hydroxyiminocyclododecanone (I) afforded 11-cyanoundecanoic acid or its derivatives as expected from the *anti* configuration of I. However, when I was treated with phosgene, oily and crystalline substances were obtained. The former was found to be the cyanoacid chloride (VI, 39% yield) and the latter dodecanedioic imide (VIII, 6% yield). This result shows that the usual Beckmann rearrangement occurs to some extent under specific conditions. Direct treatment of cyclododecanone with nitrosyl chloride and acetic anhydride in the presence of sulfuric acid, using ether as a solvent, followed by hydrolysis, gave IV in 87% yield. This one-step Beckmann fission from the cyclic ketone seems to be specific to acetic anhydride, since the reaction did not occur when other anhydrides were used. 2-Acetoxyiminocyclododecanone (XII) prepared quantitatively by treatment of I with acetic anhydride or direct treatment of cyclododecanone with nitrosyl chloride and acetic anhydride in the presence of hydrogen chloride, underwent Beckmann fission under basic conditions using aqueous sodium hydroxide to afford IV in a quantitative yield. The results show that the choice of reagent and/or catalyst not only decides the terminal functions in various ways but also influences the mechanism of fission.

In the case of Beckmann fission of II, both forms of *syn* and *anti* configurations gave 7-cyanoheptanoic acid (XIII) in excellent yields, showing that the pattern of Beckmann rearrangement does not always depend upon the stereochemistry of the α-hydroxyimino ketone.

Treatment of 2-hydroxyiminocyclohexanone (III) which exists only in *syn* form with sulfuric acid, 97% phosphoric acid or thionyl chloride recovered most of the starting material along with some intractable tarry products, showing that the *syn* α-hydroxyimino ketone resists the Beckmann fission as expected.[12] Preparation

of 5-cyanovaleric acid by direct treatment of cyclohexanone with nitrosyl chloride and thionyl chloride was attempted as in the case of 12-membered ketone. Nitrosyl chloride was added to a solution of cyclohexanone and thionyl chloride in ether at −50 °C, but the fission did not occur 2-hydroxyiminocyclohexanone hydrochloride was obtained. However, when the reaction was carried out in the presence of sulfuric acid and dimethylformamide[13] as catalysts, 5-cyanovaleric acid (XIV) was successfully obtained in 60% yield. Direct methanolysis of the reaction mixture gave methyl 5-cyanovalerate (XV) in 46% yield. Thus it might be reasonable to assume that the reaction proceeds through the direct cleavage of 2-nitrosocyclohexanone or *anti* form of 2-hydroxyiminocyclohexanone before the dinitrosation of cyclohexanone or the transformation to *syn* form occurs.

Experimental

All melting points are uncorrected. The IR spectra were measured with a Hitachi EPI S-2 spectrophotometer. Hydroxyl absorption bands in the 3600 cm^{-1} region were examined in carbon tetrachloride with a Perkin-Elmer Model 125 grating spectrophotometer using 1.5 cm sodium chloride cell. The NMR spectra were measured with a Varian A 60 spectrophotometer. Molecular weights were determined with a Hitachi Perkin-Elmer Model 115 molecular weight apparatus.

2-*Hydroxyiminocyclodecanone (I).* Hydrogen chloride was passed through a solution of cyclododecanone (20 g) in petroleum benzine (200 ml) for 5 min with stirring at 0 °C. A solution of nitrosyl chloride (8.5 g) in the same solvent (30 ml) was then added over a period of 30 min. The mixture was stirred for 1 hr at 2 °C and the solvent was evaporated under reduced pressure. The pale yellow solid obtained was chromatographed over silica gel. The solid (21.3 g, 97%) obtained was recrystallized from petroleum ether, mp 69—70 °C.

Found: C, 68.41; H, 10.05; N, 6.70%. Calcd for $C_{12}H_{21}O_2N$: C, 68.21; H, 10.02; N, 6.63%.

When ether was employed as a solvent in the same reaction, fine crystals were deposited during the reaction. The substance was proved to be 2-nitrosocyclododecanone dimer (1%), mp 133—134 °C.

Found: C, 68.01; H, 10.00; N, 6.42%; mol wt, 431. Calcd for $C_{24}H_{40}O_4N_2$: C, 68.21; H, 10.02; N, 6.63% mol wt, 423.

2-*Hydroxyiminocyclooctanone (II).* Hydrogen chloride was passed through a solution of cyclooctanone (10 g) in ether (100 ml) for 3 min with stirring at −25 °C, and a solution of nitrosyl chloride (6.3 g) in the same solvent (20 ml) was added over a period of 20 min. The mixture was stirred for 10 min at −25 °C, and aqueous sodium bicarbonate was added. The organic layer was separated, washed with water and dried. The oily product obtained by evaporation of the solvent was chromatographed over silica gel. The fractions eluted first afforded the *anti* form of II as an oily substance (5.16 g, 42%); the fractions eluted next afforded the *syn* form of II as a solid product (5.54 g, 45%). The latter was recrystallized from ether, mp 101—103 °C. IR (see Table 1). Found: C, 61.97; H, 8.42; N, 8.93%. Calcd for $C_8H_{13}O_2N$: C, 61.91; H, 8.44; N, 9.03%.

13) H. H. Bosshard, R. Mory, M. Schmid, and H. Zollinger, *Helv. Chim. Acta*, **42**, 1653 (1959).

The oily material was further purified by silica gel chromatography; one spot on tlc. IR (see Table 1).

Found: C, 61.69; H, 8.48; N, 8.70%. Calcd for $C_8H_{13}O_2N$: C, 61.91; H, 8.44; N, 9.03%.

2-*Hydroxyiminocyclohexanone (III).* Hydrogen chloride was saturated in a solution of cyclohexanone (10.5 g) in ether (100 ml) with stirring at −10 °C. A solution of nitrosyl chloride (4.5 g) in the same solvent (20 ml) was added over a period of 20 min at −50 °C. The mixture was stirred for 10 min at −50 °C, nitrogen was bubbled at −10 °C to remove the hydrogen chloride. Aqueous sodium hydroxide (30%) was added to the reaction mixture at −10 °C, and the pH was adjusted to 7. The ethereal layer was separated and the aqueous layer was extracted four times with chloroform. The combined organic layers were dried and the solvent was removed. The brown oil thus obtained was chromatographed over silica gel, giving III (5.52 g, 62%) as a white solid showing mp 60—64 °C. NMR (CCl_4): δ 9.2 (s, 1H), 2.79 (t, 2H), 2.47 (t, 2H), and 1.82 ppm (m, 4H).

Treatment of III with 2,4-dinitrophenylhydrazine gave the osazone, mp 216—217 °C.

Found: C, 45.96; H, 3.56; N, 23.41%; mol wt, 474. Calcd for $C_{18}H_{16}O_8N_8$: C, 45.76; H, 3.41; N, 23.72%; mol wt, 472.

11-*Cyanoundecanoic Acid (IV).* To a mixture of 97% phosphoric acid (10 ml) and sulfuric acid (1 ml) was added finely powdered II (1.0 g) at room temperature with stirring. The mixture was stirred for 3 hr at room temperature and poured into ice water (50 g). The mixture was extracted with ether and the extract was washed with water and dried. 11-Cyanoundecanoic acid (0.98 g, 98%) obtained after evaporation of the solvent was recrystallized from benzene–petroleum benzine, mp 54—55 °C.

Found: C, 68.34; H, 9.91; N, 6.66%. Calcd for $C_{12}H_{21}O_2N$: C, 68.21; H, 10.02; N, 6.63%.

11-*Carbamoylundecanoic Acid (V).* Finely powdered I (1.0 g) was added with stirring to sulfuric acid (10 ml) cooled with ice. The reaction mixture was allowed to stand at room temperature for 1.3 hr and poured into ice water (50 g). A white solid product was obtained by filtration, washed with water and dried in a vacuum desiccator. 11-Carbamoylundecanoic acid (1.04 g, 96%) obtained as white powder was recrystallized from acetone, mp 130—131 °C.

Found: C, 62.61; H, 10.14; N, 6.13%. Calcd for $C_{13}H_{23}O_3N$: C, 62.85; H, 10.11; N, 6.11%.

11-*Cyanoundecanoyl Chloride (VI).* A solution of thionyl chloride (6.66 g) in ether (15 ml) was added with stirring over a period of 30 min at room temperature to a solution of I (9.17 g) and dimethylformamide (1 ml) in ether (90 ml). The mixture was stirred for 30 min at room temperature and the solvent was removed under reduced pressure. The residual liquid was distilled under reduced pressure (bp 146—147 °C/2.0 Torr), affording 11-cyanoundecanoyl chloride (6.21 g, 62%) as colorless liquid.

Found: C, 62.87; H, 8.69; N, 5.92; Cl, 15.55%. Calcd for $C_{12}H_{20}ONCl$: C, 62.73; H, 8.77; N, 6.11; Cl, 15.43%.

Hydrolysis of the reaction mixture gave 11-cyanoundecanoic acid (IV) in 93% yield.

Ammonolysis of the reaction mixture gave 11-cyanoundecanoyl amide (VII) in 96% yield. It was recrystallized from benzene, mp 86—87 °C.

Found: C, 68.14; H, 10.68; N, 13.05%. Calcd for $C_{12}H_{22}ON_2$: C, 68.53; H, 10.54; N, 13.32%.

Treatment of I with Phosgene. A solution of phosgene (12 g) in dichloromethane (76 ml) was added with stirring to a solution of I (20.0 g) in the same solvent (100 ml) at room temperature. The mixture was stirred for 1.5 hr at

room temperature and divided into three fractions.

(1) Water (20 ml) was added to the reaction mixture (50 ml) and the mixture was stirred for 1 hr at room temperature. The organic layer was separated and the aqueous layer was extracted with ether. Combined organic layers were washed with water and dried. Evaporation of the solvent gave a mixture of liquid and crystals. Ether (10 ml) was added to the mixture and the crystals were separated by filtration. Dodecanedioic imide (VIII, 345 mg, 6%) was obtained, recrystallized from a mixed solvent of acetone–benzene, mp 137—138 °C.

Found: C, 68.49; H, 10.05; N, 6.44%; mol wt, 214. Calcd for $C_{12}H_{21}O_2N$: C, 68.21; H, 10.02; N, 6.63%; mol wt, 211.

11-Cyanoundecanoic acid (4.08 g, 71%) and 11-carbamoylundecanoic acid (0.20 g, 3%) were separated from the liquid after being subjected to silica gel chromatography.

(2) After evaporation of the solvent of the reaction mixture (74 ml), a crystalline solid was separated by filtration. The solid was proved to be VIII. Distillation of the filtrate gave 11-cyanoundecanoyl chloride (VI, bp 134—135 °C/0.4 Torr, 3.57 g, 39%).

(3) Methanol (30 ml) was added to the reaction mixture (50 ml) and the mixture was stirred for 2 hr at room temperature. Methyl 11-cyanoundecanoate (4.6 g, 75%) and methyl 11-carbamoylundecanoate (1.0 g, 15%) were obtained after being subjected to silica gel chromatography. The former (IX) was purified by distillation, bp 133—137 °C/0.4 Torr.

Found: C, 69.19; H, 10.43; N, 6.29%. Calcd for $C_{13}H_{23}O_2N$: C, 69.29; H, 10.29; N, 6.22%.

The latter (X) was recrystallized from a mixed solvent of benzene–petroleum benzine, mp 97—98 °C.

Found: C, 64.25; H, 10.41; N, 5.75%. Calcd for $C_{13}H_{25}O_3N$: C, 64.16; H, 10.36; N, 5.76%.

Treatment of I with Acetic Anhydride and Sulfuric Acid. Three drops of sulfuric acid were added to a stirred solution of I (3.21 g) and acetic anhydride (2.0 g) in ether (35 ml), and the solution was stirred for 2 hr at room temperature. Ice water (50 g) was added to the reaction mixture and stirred for 30 min. Aqueous layer was extracted with ether and the combined organic layers were dried and the solvent was removed under reduced pressure. A mixed anhydride (XI, 3.66 g, 95%) of IV and acetic acid was obtained. IR (NaCl): 1820 and 1750 cm^{-1}. 11-Cyanoundcanoic acid (2.97 g, 93%) was obtained after being subjected to chromatography over silica gel. Ammonolysis of XI gave IV (65%) and VII (16%).

2-Acetoxyiminocyclododecanone (XII). 2-Hydroxyiminocyclododecanone (I, 2.52 g) was dissolved in acetic anhydride (10 ml) and the solution was heated at 50 °C for 1 hr. After treatment of the reaction mixture in the usual manner, acetate (XII, 2.91 g, 96%) was obtained and recrystallized from petroleum benzine, mp 60—61 °C.

Found: C, 66.46; H, 9.41; N, 5.59%. Calcd for $C_{14}H_{23}O_3N$: C, 66.37; H, 9.15; N, 5.53%.

Treatment of 2-Acetoxyiminocyclododecanone (XII) with Aqueous Sodium Hydroxide. Aqueous sodium hydroxide (5%, 20 ml) was added to a stirred solution of XII (1.5 g) in ether (2 ml), and the solution was stirred for 2 hr at room temperature. The reaction mixture was acidified with dilute hydrochloric acid and extracted with ether. 11-Cyanoundecanoic acid (1.19 g, 95%) was obtained by the usual method.

7-Cyanoheptanoic Acid (XIII). 2-Hydroxyiminocyclooctanone of *syn* form (II, *syn*) was treated with 97% phosphoric acid under the same reaction conditions as in the case of I. 7-Cyanoheptanoic acid (XIII) was obtained in 80% yield and recrystallized from petroleum ether, mp 34—35 °C. The *anti* form afforded XIII in 78% yield by the same treatment.

Found: C, 62.19; H, 8.42; N, 9.10%. Calcd for $C_8H_{13}O_2N$: C, 61.91; H, 8.44; N, 9.03%.

5-Cyanovaleric Acid (XIV) To a solution of cyclohexanone (10 g), sulfuric acid (1 ml), and dimethylformamide (5 ml) in ether (100 ml) was added a solution of nitrosyl chloride (7 g) in ether (20 ml) with stirring at −20 °C over a period of 20 min. The mixture was stirred for 10 min at −10 °C, and cooled to −30 °C. Aqueous sodium hydroxide (30%, 100 ml) was added and the mixture was stirred for 1 hr at room temperature. After separation of the ethereal layer, the aqueous layer was acidified with hydrochloric acid and extracted with dichloromethane. Evaporation of the solvent gave crude 5-cyanovaleric acid (XIV, 8.0 g) as pale brown liquid. Pure 5-cyanovaleric acid (6.8 g, 52%) was obtained by distillation under reduced pressure, bp 114—115 °C/0.2 Torr.

Found: C, 56.75; H, 7.01; N, 11.02%. Calcd for $C_6H_9O_2N$: C, 56.68; H, 7.14; N, 11.02%.

Methyl 5-cyanovalerate (XV) was obtained in 46% yield by methanolysis of the reaction mixture, bp 80—82 °C/1.0 Torr.

Found: C, 59.79; H, 7.90; N, 9.60%. Calcd for $C_7H_{11}O_2N$: C, 59.55; H, 7.85; N, 9.92%.

The Activation of Bivalent Sulfur Compounds with Cupric Chloride and Zinc Chloride. The Benzylation and Acylation of Aromatic Compounds with Sulfides and Thiol Esters

Kazuo MAEKAWA, Koichi NARASAKA, and Teruaki MUKAIYAMA

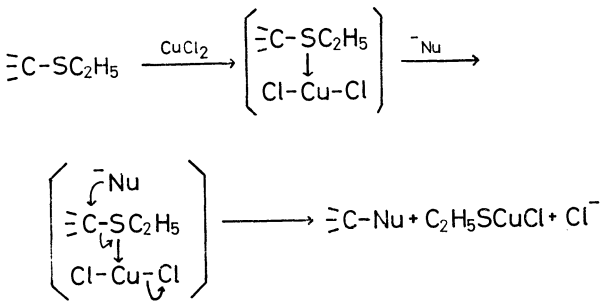
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 4, 1973)

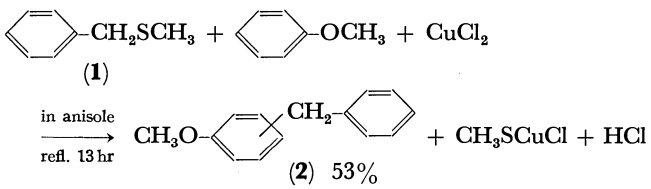
Benzylation of aromatic compounds, such as anisole, *m*-xylene, toluene, and benzene, with various benzyl sulfides in the presence of equimolar amounts of cupric chloride and zinc chloride was investigated. For example, in the case of benzylation of anisole with 4-benzylthiopyridine, *o*- and *p*-benzylanisoles were obtained in 79% yield in the presence of cupric chloride and zinc chloride. On the other hand, when the reaction was carried out in the presence of cupric chloride alone, the yield of benzylanisoles was low. The similar activation with cupric chloride and zinc chloride was successfully applied to the reaction of aromatic compounds with benzaldehyde diethylthioacetal and to the acylation of aromatic compounds with 1,2-bis(acylthio)ethanes.

The benzylation of aromatic compounds such as anisole, *m*-xylene, toluene, and benzene with benzyl sulfides in the presence of cupric chloride and zinc chloride were reported briefly in the previous paper.[1] In this report, these reactions are explained in detail with additional new results.

During the investigation on carbon–carbon bond forming reactions using benzaldehyde diethylthioacetal, benzophenone diethylthioacetal, and ethyl orthotrithioformate, it was found that these compounds react readily with active methylene compounds or anisole in the presence of cupric chloride to give the condensation or substitution products.[2] The reaction would be reasonably explained by considering an initial formation of a reactive intermediate, a coordinated compound of the bivalent sulfur compound with cupric chloride, which in turn is attacked by nucleophiles to give condensation or substitution products.



Based on the result, the reaction of sulfides with aromatic compounds was further investigated with the expectation that the sulfides would also be activated by the coordination with cupric chloride. When an anisole solution of equimolar amounts of benzyl methyl sulfide (**1**) and cupric chloride was heated to reflux, the generation of hydrogen chloride was observed immediately. After being stirred for 13 hr under reflux, the resulting precipitates were filtered off and the filtrate was concentrated under reduced pressure. Through the purification by silica gel column chromatography and distillation, *o*- and *p*-benzylanisoles (**2**, bp 115—116 °C/1.5 mmHg) were obtained in 53% yield.



In order to increase the yield of benzylated products, a variety of benzyl sulfides (**3**), in which RS group would be stabilized by the resonance effect as an anion, was used in place of **1** in the above reaction. However, the yields of **2** were poor by the treatment of **3** in refluxing anisole in the presence of an equimolar amount of cupric chloride for 5 hr as shown in Table 1.

This result suggests that, only by the examination into the structure of leaving group (RS–), benzyl sulfides (**3**) are not sufficiently activated for generation of benzyl cation. Then, the coupled use of cupric chloride and zinc chloride was examined according to the assumption that the electron density of benzylic carbon would be decreased by coordination of zinc chloride to ring nitrogen atom. In fact, when the anisole solution of 4-benzylthiopyridine (**3e**) and equimolar amounts of cupric chloride and zinc chloride was heated to reflux for 5 hr, the yield of **2** was increased up to 79%. Similarly, in the reaction of other sulfides, yields of **2** were remarkably increased by the combined use of cupric chloride and zinc chloride. The results are shown in Table 1.

The yields of **2** were hardly improved and **2** were obtained in less than 10% yield when the some typical Lewis acids such as aluminum chloride, stannic chloride, ferric chloride, and boron trifluoride diethyletherate were used together with cupric chloride in place of zinc chloride. Among various Lewis acids examined, it was apparently shown that zinc chloride is most effective when it was used together with cupric chloride, but **2** could not be detected when zinc chloride was used alone. Then in order to examine the possibility that the increase of the yield may result from a coordination of zinc chloride to ring nitrogen atom of sulfides, the reaction of benzyl methyl sulfide (**1**) having no nitrogen atom in a molecule was investigated in the presence of equimolar amounts of cupric chloride

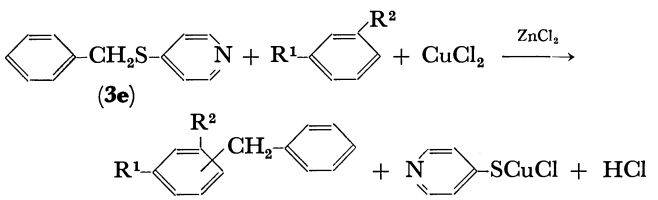
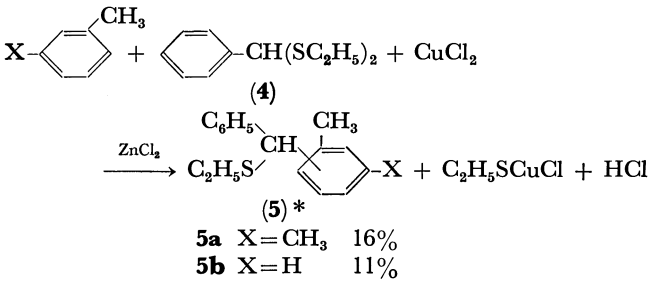
and zinc chloride. When anisole solution of **1**, cupric chloride and zinc chloride was heated to reflux for 5 hr, the yield of **2** was increased up to 76% as compared with the previous reaction using cupric chloride alone. The result indicates that zinc chloride would activate cupric chloride or the complex of cupric chloride with sulfide rather form a coordinated compound with sulfide.

In a similar way, the benzylation of other aromatic compounds such as *m*-xylene, toluene, and benzene with 4-(benzylthio)pyridine (**3e**) was carried out by the combined use of cupric chloride and zinc chloride, and the corresponding benzylated products, benzylxylenes, *o*- and *p*-benzyltoluenes, and diphenylmethane were obtained in 54, 34, and 15% yields respectively.



R^1	R^2	Yield (%)
CH_3	CH_3	54
CH_3	H	34
H	H	15

Previously, it was shown that benzaldehyde diethylthioacetal (**4**) reacts with anisole in the presence of cupric chloride to give the substituted product in good yield. On the other hand, it was shown that **4** did not react with other aromatic compounds such as *m*-xylene and toluene. The present method for the activation of sulfides with cupric chloride and zinc chloride was successfully applied to the reaction of **4** with *m*-xylene or toluene. When **4** was treated with *m*-xylene or toluene in the presence of equimolar amounts of cupric chloride and zinc chloride for 5 hr at room temperature, phenylxylylmethyl ethyl sulfides (**5a**) or phenyltolylmethyl ethyl sulfides (**5b**) were obtained in 16 or 11% yield.



5a X=CH_3 16%
5b X=H 11%

* These structures are supported by elemental analysis and mass spectrum, but the study of structural isomerism remains not to be examined.

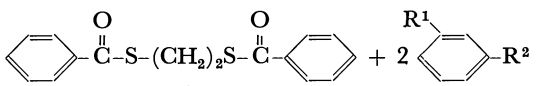
α,ω-Bis(benzylthio)alkanes (**6**) were also used effectively for the benzylation of aromatic compounds in place of the sulfides (**1** and **3**). It is expected that these sulfides (**6**) would form the chelate complexes by the intramolecular coordination of cupric chloride to the two sulfur atoms of the sulfide and benzyl cation would be easily generated. When **6** were treated in the presence of cupric chloride alone or cupric chloride and zinc chloride in refluxing anisole for 5 hr, benzylanisoles (**2**) were obtained as shown in Table 2.

TABLE 2.

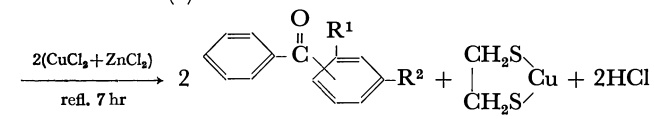
	n	Yield of 2 (%) $CuCl_2$	$CuCl_2+ZnCl_2$	$2(CuCl_2+ZnCl_2)$
6a	2	14	47	49
6b	3	11	56	58
6c	4	26	62	53

Bromobenzene was also benzylated by the reaction with 1,2-bis(benzylthio)ethane (**6a**) in the presence of equimolar amounts of cupric chloride and zinc chloride, and *o*- and *p*-bromophenylphenylmethanes were obtained in 14% yield.

Next, in order to examine the possibility of the cleavage of carbon–sulfur bond of thiolester by the use of cupric chloride and zinc chloride, the reaction of bis(acylthio)ethane with aromatic compounds was investigated. When anisole or *m*-xylene solution of 1,2-bis(benzoylthio)ethane (**7**) was heated to reflux in the presence of 2 equiv. of cupric chloride and zinc chloride for 7 hr, methoxybenzophenone (**8**) or phenylxylylketones (**9**) were obtained in 16 or 35% yield respectively together with about 15% of the recovered starting material (**7**).

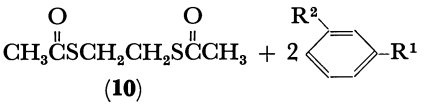


(7)

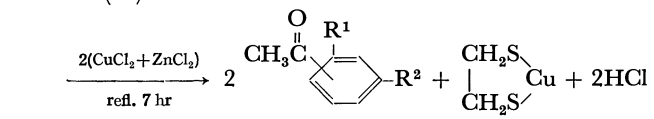


(8) $R^1=CH_3O$-, $R^2=H$ 16%
(9) $R^1=CH_3$, $R^2=CH_3$ 35%

In a similar manner, 1,2-bis(acetylthio)ethane (**10**) reacted with anisole, *m*-xylene, and toluene to give acetylation products (**11**, **12**, **13**) together with unidentified products.



(10)



(11) $R^1=CH_3O$, $R^2=H$ 11%
(12) $R^1=R^2=CH_3$ 15%
(13) $R^1=CH_3$, $R^2=H$ 7%

In conclusion, it is noted that sulfides are sufficiently activated by the combined use of cupric chloride and zinc chloride and are attacked by aromatic compounds such as anisole, *m*-xylene, and toluene along with the cleavage of carbon–sulfur bond to form substitution products. This method for activation of sulfides by cupric chloride was successfully applied to our works of hydrolysis of 1,3-dithianes and reductive desulfurization of sulfides.[3]

Experimental

Materials. Commercially available cupric chloride and zinc chloride were used. They were dried over phosphorus pentoxide *in vacuo* at about 130 °C before use.

Benzyl methyl sulfide (**1**) and benzaldehyde diethylthioacetal (**4**) were prepared according to the procedures in literatures and purified by distillation: **1**, bp 97—101 °C/27 mmHg;[5] **4**, 135—136 °C/8 mmHg.[6]

Benzyl sulfides (**3a—f**) and α,ω-bis(benzylthio)alkanes (**6a—c**) were prepared by the treatment of the corresponding thiols with benzyl chloride in 95% ethanol in the presence of sodium hydroxide: **3a**, bp 120 °C/2 mmHg (lit, bp 134—135 °C/4 mmHg);[7] **3b**, bp 145—147 °C/1 mmHg (lit, bp 159—163 °C/3 mmHg);[8] **3c**, mp 184—185 °C (lit, mp 182—183 °C);[9] **3d**, mp 39—40 °C (lit, mp 40—41 °C);[10] **3e**, mp 64—65 °C (lit, mp 61—62 °C);[11] **3f**, bp 145—146 °C/2 mmHg (lit, bp 92—94 °C/0.1 mmHg);[11] **6a**, mp 34—35 °C (lit, mp 38 °C);[12] **6b**, bp 158 °C/0.07 mmHg (lit, bp 218—221 °C/8—9 mmHg);[13] **6c**, bp 167 °C/0.08 mmHg (Found: C, 71.38; H, 7.11; S, 21.30%. Calcd for $C_{18}H_{22}S_2$: C, 71.50; H, 7.11; S, 21.17%).

Thiolesters (**7**) and (**10**) were prepared by treatment of the petroleum ether solution of 1,2-ethanedithiol and pyridine with the corresponding acyl chlorides at 0 °C: **7**, mp 95 °C (lit, mp 96 °C);[14] **10**, mp 68—69 °C (lit, mp 68—73 °C).[15]

Reaction of Benzyl Methyl Sulfide (1) with Anisole in the Presence of an Equimolar Amount of Cupric Chloride. A mixture of **1** (1.38 g, 0.01 mol), cupric chloride (1.35 g, 0.01 mol) and dry anisole (30 ml) was heated to reflux for 13 hr. The color of the solution turned black and white precipitates formed. The precipitates were filtered off and the filtrate was concentrated under reduced pressure. The residue was then purified by silica gel column chromatography. The eluate with petroleum ether was concentrated and distilled, giving 1.05 g (53%) of benzylanisoles (**2**) (bp 115—116 °C/1.5 mmHg). The isomer ratio (*para* to *ortho*) of benzylanisoles was determined to be about 2 by two sets of singlets at τ 6.50 and 6.47 (ratio 2: 1, total area 3H) due to the methyl group. Found: C, 84.63; H, 7.07%. Calcd for $C_{14}H_{14}O$: C, 84.81; H, 7.12%. IR: 2830(OCH_3), 1030(C–O) cm^{-1}. Mass: M^+ 198, *m/e* 183[M^+–CH_3], *m/e* 167[M^+–OCH_3], *m/e* 121[M^+–C_6H_5], *m/e* 91[$C_6H_5CH_2^+$]. NMR: (in CCl_4) τ 6.50 (s, 2H, *p*-OCH_3), 6.47 (s, 1H, *o*-OCH_3), 6.25 (s, 1.3H, *p*-$C_6H_5CH_2$), 6.12 (s, 0.7H, *o*-$C_6H_5CH_2$–), 2.40—3.45 (m, 9H, aromatic protons).

Benzyl sulfides (**3a—f**) were treated in refluxing anisole with an equimolar amount of cupric chloride for 5 hr, and **2** was obtained according to the same procedure. The yields of **2** were listed in Table 1.

Reaction of 4-(Benzylthio)pyridine (3e) with Anisole in the Presence of Equimolar Amounts of Cupric Chloride and Zinc Chloride. A mixture of **3e** (2.01 g, 0.01 mol), cupric chloride (1.35 g, 0.01 mol), zinc chloride (1.36 g, 0.01 mol), and dry anisole (50 ml) was heated to reflux for 5 hr. According to the same procedure, benzylanisoles (**2**) were obtained (1.57 g, 79%).

Similarly, **3a—d** and **3f** were treated with equimolar amounts of cupric chloride and zinc chloride in refluxing anisole for 5 hr, and the yields of **2** were listed in Table 1.

Reaction of 4-(Benzylthio)pyridine (3e) with m-*Xylene in the Presence of Equimolar Amounts of Cupric Chloride and Zinc Chloride.* A mixture of **3e** (2.01 g, 0.01 mol), cupric chloride (1.35 g, 0.01 mol), zinc chloride (1.36 g, 0.01 mol) and dry *m*-xylene (50 ml) was heated to reflux for 7 hr. The reaction mixture was purified according to the same procedure as mentioned in the reaction of **1** with anisole, and phenylxylylmethanes (bp 115 °C/3 mmHg, 2 or 5- and 4-isomers in a ratio of 2: 13) were obtained in 54% (1.06 g) yield. Found: C, 92.03; H, 8.08%. Calcd for $C_{15}H_{16}$: C, 91.78; H, 8.22%. NMR: (in CCl_4) τ 7.92 and 7.80 (s, 5.2H, 4-isomer-CH_3), 7.85 (s, 0.8H, 2 or 5-isomer-CH_3), 6.20 (s, 1.7H, 4-isomer-$CH_2C_6H_5$), 6.08 (s, 0.3H, 2 or 5-isomer-$CH_2C_6H_5$).

Phenyltolylmethanes and diphenylmethane were also obtained by treating **3e** with toluene and benzene. Their

physical properties and analytical data are as follows. Phenyltolylmethanes (*ortho* and *para* isomers in a ratio of 5: 4): bp 109—109.5 °C/3.5 mmHg. Found: C, 92.43; H, 7.90%. Calcd for $C_{14}H_{14}$: C, 92.26; H, 7.74%. NMR: (in CCl_4) τ 7.85 (s, 1.3H, *p*-CH_3), 7.76 (s, 1.7H, *o*-CH_3), 6.18 (s, 1.1H, *o*-$CH_2C_6H_5$), 6.13 (s, 0.9H, *p*-$CH_2C_6H_5$). Diphenylmethane: bp 83 °C/4 mmHg. Found: C, 92.07; H, 7.30%. Calcd for $C_{13}H_{12}$: C, 92.81; H, 7.19%. Mass: M^+ 168, *m/e* 91 [$C_6H_5CH_2^+$].

Reaction of Benzaldehyde Diethylthioacetal (4) with m-*Xylene in the Presence of Equimolar Amounts of Cupric Chloride and Zinc Chloride.* A mixture of **4** (4.24 g, 0.02 mol), cupric chloride (2.69 g, 0.02 mol), zinc chloride (2.73 g, 0.02 mol), and dry *m*-xylene (50 ml) was stirred for 8 hr at room temperature and kept standing overnight. The precipitates were filtered off and the filtrate was concentrated under reduced pressure. The resulting oil was chromatographed on alumina gel. In order to hydrolyze the recovered **4**, the petroleum ether eluate was concentrated and treated in refluxing 95% ethanol in the presence of potassium hydroxide for half an hour. After removal of the solvent, the residue was extracted with ether and washed with water. The ether layer was concentrated and chromatographed on silica gel. The petroleum ether eluate was distilled and 0.98 g (16%) of phenylxylylmethyl ethyl sulfides (**5a**, bp 165 °C/4 mmHg) were obtained. Found: C, 79.40; H, 7.87; S, 12.57%. Calcd for $C_{17}H_{20}S$: C, 79.65; H, 7.86; S, 12.48%. Mass: *m/e* 195 [M^+–C_2H_5S], *m/e* 179 [M^+–C_6H_5], *m/e* 151 [M^+–$C_6H_3(CH_3)_2$]. Similarly, phenyltolylmethyl ethyl sulfides (**5b**, bp 150—151 °C/4 mmHg) were produced from **4** and toluene. Found: C, 79.52; H, 7.60; S, 12.78%. Calcd for $C_{16}H_{18}S$: C, 79.31; H, 7.49; S, 13.21%. Mass: *m/e* 181 [M^+–C_2H_5S], *m/e* 165 [M^+–C_6H_5], *m/e* 151 [M^+–C_6H_4-CH_3].

Reaction of 1,3-Bis(benzylthio)propane (6b) with Anisole in the Presence of Two Equimolar Amounts of Cupric Chloride and Zinc Chloride. A mixture of **6b** (2.88 g, 0.01 mol), cupric chloride (2.69 g, 0.02 mol), zinc chloride (2.73 g, 0.02 mol), and dry anisole (50 ml) was heated to reflux for 5 hr. The reaction mixture was treated according to the same procedure as in the case of the reaction of benzyl methyl sulfide (**1**) and anisole, and 2.22 g (56%) of benzylanisoles (bp 119—123 °C/3 mmHg) were obtained.

Reaction of 1,2-Bis(benzylthio)ethane (6a) with Bromobenzene in the Presence of Equimolar Amounts of Cupric Chloride and Zinc Chloride. A mixture of **6a** (2.74 g, 0.01 mol), cupric chloride (1.35 g, 0.01 mol), zinc chloride (1.36 g, 0.01 mol), and dry bromobenzene (50 ml) was heated to reflux for 6 hr. After filtration of a tarry substance, the filtrate was purified by silica gel column chromatography and distillation. Bromophenylphenylmethanes (*ortho* and *para* isomers in a ratio of 9: 11) were obtained, 0.69 g (14%) (bp 122 °C/1 mmHg). Found: C, 63.31; H, 4.60%. Calcd for $C_{13}H_{11}Br$: C, 63.18; H, 4.49%. NMR: (in CCl_4) τ 6.34 (s, 1.1H, *p*-$C_6H_5CH_2$), 6.49 (s, 0.9H, *o*-$C_6H_5CH_2$), 2.40—3.30 (m, 9H). Mass: *m/e* 248 (M^++2) and 246 (M^+) (*ca.* 1: 1 ratio).

Reaction of 1,2-Bis(benzoylthio)ethane (7) with Anisole in the Presence of Equimolar Amounts of Cupric Chloride and Zinc Chloride. A mixture of **7** (6.04 g, 0.02 mol), cupric chloride (2.69 g, 0.02 mol), zinc chloride (2.73 g, 0.02 mol), and dry anisole (50 ml) was heated to reflux for 7 hr. The tarry substance sticked to the vessel was filtered off and the filtrate was chromatographed on silica gel. The petroleum ether eluate gave a viscous oil, which was fractionated by distillation to give 0.92 g of phenyl benzoate (bp 119—121 °C/4 mmHg, mp 70 °C) and 1.73 g of the starting material (**7**) (mp 93 °C). The benzene eluate was condensed and distilled to give 0.70 g (8%) of methoxybenzophenone (**8**, bp 156 °C/2.5 mmHg, mp 59—61 °C): Found: C, 79.03; H, 5.69%. Calcd for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%. IR: 2840 (OCH_3), 1638 (C=O), and 1020 (C–O) cm^{-1}. NMR: (in $CDCl_3$) τ 6.07 (s, 3H, OCH_3), 2.0—3.07 (m, 9H). The ether eluate gave 0.74 g of benzoic acid (mp 120—121 °C). The reaction of 1,2-bis(benzoylthio)ethane (**7**) with *m*-xylene was carried out according to the same procedure, and phenylxylylketones (**9**) were isolated in 35% yield, (bp 130 °C/1 mmHg, 2 or 5- and 4-isomers in a ratio of 1: 9). Found: C, 85.52; H, 6.71%. Calcd for $C_{15}H_{14}O$: C, 85.68; H, 6.71%. IR: 1665 (C=O) cm^{-1}. NMR: (in $CDCl_3$) τ 7.87 (s, 0.7H, 2 or 5-isomer-CH_3), 7.66 and 7.61 (s, 5.3H, 4-isomer-CH_3), 2.10—3.05 (m, 8H).

Reaction of 1,2-Bis(acetylthio)ethane (10) with Anisole in the Presence of Two Equimolar Amounts of Cupric Chloride and Zinc Chloride. A mixture of **10** (1.78 g, 0.02 mol), cupric chloride (2.69 g, 0.02 mol), zinc chloride (2.73 g, 0.02 mol), and dry anisole (50 ml) was heated to reflux for 7 hr. According to the same procedure as in the above experiment, 0.54 g of unidentified products and 0.32 g (11%) of methoxyacetophenone (**11**, bp 88 °C/1 mmHg) were obtained. Found: C, 71.42; H, 6.65%. Calcd for $C_9H_{10}O_2$: C, 71.98; H, 6.71%. NMR: (in $CDCl_3$) τ 7.48 (s, 3H, CH_3-CO), 6.16 (s, 3H, OCH_3), 2.0—3.15 (m, 4H). Mass: M^+ 150, *m/e* 135 [M^+–CH_3], *m/e* 107 [M^+–$COCH_3$].

Similarly, the reaction of **10** with *m*-xylene or toluene was carried out, and the physical properties and analytical data of the products (**12** or **13**) were as follwos. **12**: bp 103—104 °C/13 mmHg. Found: C, 80.43; H, 8.39%. Calcd for $C_{10}H_{12}O$: C, 81.04; H, 8.16%. NMR: (in CCl_4) τ 7.67 (s, 3H, CH_3), 7.52 (s, 6H, CH_3+$COCH_3$), 2.38—3.03 (m, 3H). Mass: M^+ 148, *m/e* 133 [M^+–CH_3], *m/e* 105 [M^+–$COCH_3$]. **13**: bp 84 °C/10 mmHg. NMR: (in CCl_4) τ 7.63 (s, 3H, $COCH_3$ or CH_3), 7.56 (s, 3H, CH_3 or $COCH_3$), 2.15—2.91 (m, 4H). Mass: M^+ 134, *m/e* 119 [M^+–CH_3], *m/e* 91 [M^+–$COCH_3$].

Kinetic Study of the Pyrolysis of 1- and 2-Phenylethyl Phenyl *N*-Tosylsulfilimines[1]

Shigeru OAE, Katsumasa HARADA, Kenji TSUJIHARA, and Naomichi FURUKAWA

(Received April 26, 1973)

The pyrolysis of 1-phenylethyl phenyl *N*-tosylsulfilimine was found to proceed more than 10^3 times faster than that of ethyl phenyl derivative. The large rate enhancement suggests that the mechanism changes from an ideal *cis*-elimination to nearly E1 type. However, substituent effect, kinetic isotope effect with 1-phenylethyl-2,2,2-d_3 phenyl *N*-tosylsulfilimine and solvent effect clearly reveal that the reaction proceeds *via* an intramolecular concerted process.

In a previous paper we reported that the pyrolysis of alkyl *N*-tosylsulfilimine having β-hydrogen gives olefin in a high yield,[2] and the reaction was suggested to proceed through a concerted *cis*-elimination process based on both kinetic and stereochemical results.[3]

When the sulfilimine having both α and β phenyl groups was subjected to pyrolysis, the rate of the reaction was found to be accelerated by a factor of 10^3 times higher than the unsubstituted sulfilimine. This enormously large rate enhancement by the phenyl groups gives rise to a consideration of the nature of the concerted process for the pyrolysis namely, whether or not the reaction proceeds *via* an internal concerted *cis*-elimination route[4] or through a different mechanism such as E1 type mechanism[5] or radical pair mechanism[6] involving the rate-determining C–S bond cleavage or through some alternative pathway which involves the rate-determining C–H bond fission at the transition state[7] (nearly carbanion type mechanism). All the possible mechanistic pathways are schematically shown in Fig. 1.

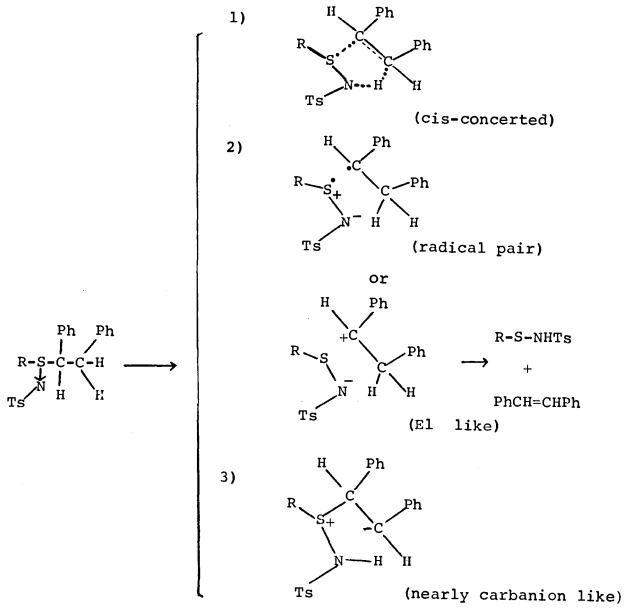

Fig. 1. Possible mechanistic scheme for the E1 reaction.

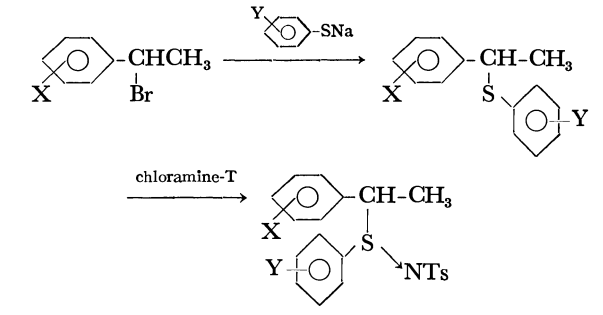
In order to understand the nature of the pyrolysis and thus be able to make a choice of mechanism, 1- and 2-phenylethyl phenyl *N*-tosylsulfilimines were prepared and subjected to pyrolysis. This paper gives a detailed account of the kinetic study of the pyrolysis and implication of the data for understanding of the mechanism.

Results and Discussion

Preparation of Sulfilimine. The sulfilimines used for the pyrolysis were 1-(substituted)phenylethyl phenyl- (I), 1-phenylethyl(substituted)phenyl (II) and 2-phenylethyl phenyl *N*-tosylsulfilimines (III) prepared by treating the corresponding sulfides with chloramine-T in methanol solution, as shown below. The mp, elemental analyses, and IR spectra are listed in Table 1.



I : X=*p*-CH_3, H, Cl, *m*-NO_2, Y=H
II: X=H, Y=*p*-CH_3O, *p*-CH_3, H, *p*-Cl

a) The compound is unstable at room temperature and decomposes gradually during the course of purification.

Kinetics and Product Analysis. The pyrolysis was carried out by heating a solution of the desired sulfilimine in benzene. Products were not isolated after reaction except in the case of 2-phenylethyl phenyl *N*-tosylsulfilimine, from which styrene was isolated in more than 60% yield. However, the products derived from (I) and (II) were found to be both substituted styrene and arenesulfenyl *p*-toluenesulfonamide, since the NMR spectrum of the reaction mixture in $CDCl_3$, which had been left to stand for some days until the signals of methine and methyl protons of the sulfilimine disappeared, showed a complete 1 : 1 mixture of substituted styrene and arenesulfenyl *p*-toluenesulfonamide as shown in Fig. 2. We can thus conclude that the yield of olefin is nearly quantitative. The kinetic measurements were carried out by following the IR absorption band of the product, *i.e.* the –NH– band of arenesulfenyl *p*-toluenesulfonamide appeared at 3280 cm^{-1}. The rates of the pyrolysis were correlated with the first-order rate equation. The kinetic data obtained from the above reaction are summarized in Tables 2 and 3.

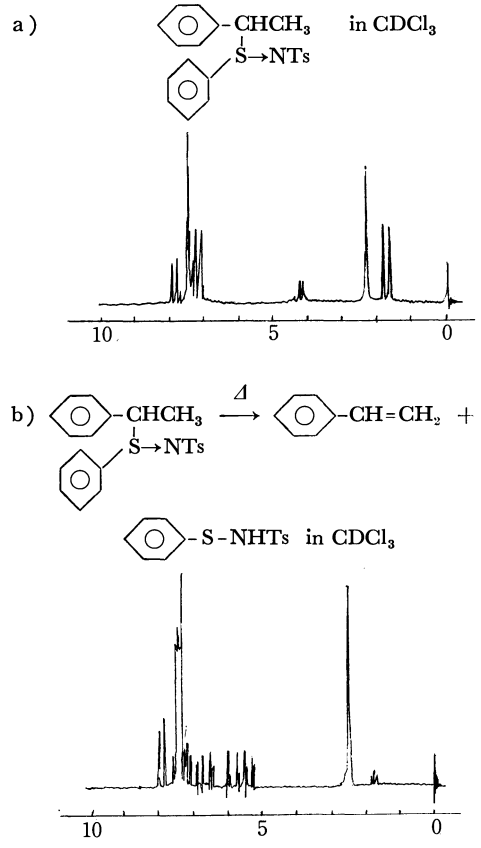

Fig. 2. NMR Spectra of 1-phenylethyl phenyl sulfilimine (a) and the products after the Reaction (b).

Solvent Effect. The pyrolysis was carried out in various solvents, the rate constants obtained being summarized in Table 4. We see that the pyrolysis is not much affected by solvent. Even the change in polarity of the solvent from benzene (ε=2.27) to nitrobenzene (ε=34.6) or acetonitrile (ε=37.5) changes the rate not more than five fold. This seems to indicate that the transition state of the reaction is neither ionic nor radical. In ethanol, the reaction proceeded slowly and the yield of olefin was low. Apparently the initial C–S bond cleavage took place concurrently with the elimination giving rise to some substitution products such as 1-phenyl ethyl ethyl ether. The rate is also low in chloroform suggesting that the hydrogen bond formation between imino nitrogen and acidic hydrogen of chloroform prevents an attack of the terminal nitrogen to β-proton. This is also the case with ethanol. Acetonitrile also retards the reaction slightly. As in a similar retardation of pyrolysis in DMSO, the dipolar

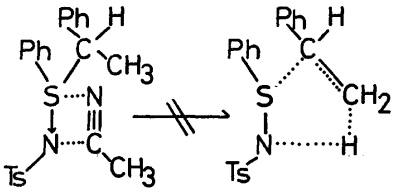
interaction between acetonitrile and the sulfilimine shown schematically below would be responsible for the small retardation.



Hammett Equation and Isotope Effect. The substituent effects (Table 2) seem to be correlated nicely with Hammett σ values. Substituents Y gave a good straight line with $\rho_Y = +0.90$, while the effect of X is very small and gave hardly any correlation with either σ or σ^+ values. Apparently the electron-donating substituent such as *p*-CH_3 accelerated the reaction while the electron-withdrawing substituent retarded it. The ρ values though small, indicate a negative trend and is roughly estimated to be $\rho = -0.2$. The Hammett relation is shown in Fig. 3. The kinetic isotope effect was measured from the rate constants of 1-phenylethyl 2,2,2-d_3 phenyl *N*-tosylsulfilimine and the corresponding undeuterated compound, and found to be $k_H/k_D = 2.90$. The data in Table 3 indicate that the rate promotion in the pyrolysis is found to be mainly due to α-phenyl group which accelerates the reaction around 10^3 times as compared to one without it, while the β-phenyl group accelerates the reaction only 1.5 times or at most 2.5 times, though correcting the number of available β hydrogen atoms. The following conclusions can be obtained. (1) The rather small rate-enhancing effect of the β-phenyl group rules out the nearly carbanion like mechanism, since either E1 or E2 reaction which is presumed to proceed *via* nearly carbanion-like mechanism[7] should show an enormous large rate enhancement by β-phenyl group. For example, ethyl methyl phenethyl amine oxide undergoes E1 reaction more than 10^2 times faster than the phenyl unsubstituted derivative, while dimethyl ethyl phenethyl quarternary ammonium hydroxide decomposes 2.7×10^4 times faster than the compound having no β-phenyl group. (2) Although a large rate enhancement by the α-phenyl group could suggest an E1 route, this is

ruled out since both N–H bond forming and C–S bond breaking are apparently involved in the transition state in view of the relatively large β-hydrogen kinetic isotope effect. Recently an E1-like mechanism was proposed by Burgess, Penton, and Taylor for the solvolyitic internal elimination reaction of 1,2-diphenylethyl-*N*-carbomethoxysulfamate triethylammonium salt. In this case the kinetics suggests that although stereospecificity is maintained, only a small β-hydrogen kinetic isotope effect (1.05~1.08) is obtained.[8] The small negative ρ_x value might suggest the involvement of a radical pair mechanism proposed by Cram[6] for the pyrolysis of the four diastereomeric 1,2-diphenyl-1-propyl phenyl sulfoxides. However, this is also ruled out since the free radical mechanism involving the prior C–S bond cleavage is not in accord with the relatively large kinetic isotope effect. The ESR taken with the reaction conditions did not show any signals and there was no particular effect by oxygen or radical scavenger. Styrene placed in the reaction vessel did not polymerize under the reaction conditions. Thus, the radical type mechnism can be ruled out. (3) Recently we found that optically active benzyl *p*-tolyl *N*-tosylsulfilimine undergoes very facile thermal racemization apparently *via* pyramidal inversion[9] without involving C–S bond fission. This result together with the solvent effect on the pyrolysis indicates that either the initial radical or the ionic C–S bond fission mechanism (2) can be neglected. Thus, the present data are consistent with the *cis*-concerted mechanism which we predicted.[2,3] Although the relative rate of α-phenyl substituted sulfilimine is 10^3 times larger than that of the unsubstituted one, both ρ_y and isotope effects are nearly identical in both series. *i.e.*, $\rho_y=+0.90$ (α-phenyl), +0.90 (α-H); $k_H/k_D=2.90$ (α-phenyl), 3.03 (α-H) respectively. Therefore, the pyrolysis of these sulfilimines appears to proceed *via* an ideal five-membered transition state during the course of reaction regardless of the structural change. The large rate enhancement by the α-phenyl group is undoubtedly associated with the stabilization of the transition state by the effective conjugation with the developing double bond at the transition state.[10] The small negative trend of ρ_x value appears somewhat strange, but it may be due to the change of transition state with the change of substituent on the phenyl ring, namely the timing of C–S bond fission and C–H bond fission differs with substituent, compensating the substituent effect. This phenomenon is also observed in the case of E2 reaction of α-substituted phenethyl bromide.[11] These results suggest that the pyrolysis of sulfilimine proceeds *via* an internal concerted *cis* elimination involving a five membered transition state though the reaction is accelerated 10^3 times by the α-phenyl group.

Experimental

Preparation of Sulfilimine. 1- And 2-arylethyl bromides were prepared according to the known method.[12] They were treated with sodium thiophenoxide in ethanol solution to afford the corresponding sulfide in a 70% yield. The sulfilimines were prepared by treating the sulfides with chloramine-T.[13] A typical example is as follows. 1-Phenylethyl phenyl sulfide (2 g) was dissolved in 25 ml of methanol containing a drop of acetic acid. To this was added 2.9 g of chloramine-T in methanol at 0 °C. After being stirred for 1 hr, methanol was removed at room temperature. The residue was added to ice–water containing a dilute sodium hydroxide solution. The precipitates were separated and dried. The crude crystals were recrystallized from methanol. The yield was 50%. The IR spectral data are summarized in Table 1.

Product Analysis. The products were not actually isolated. The identification of substituted styrenes and arenesulfenyl *p*-toluenesulfonamide was carried out by means of NMR and IR spectra. Sulfilimine was dissolved in $CDCl_3$ in an NMR tube. The tube was kept standing at room temperature or heated at 50 °C until the methyl doublet or methine quartet of phenylethyl protons completely disappeared. The spectra obtained were all of 1:1 mixture of styrene and the sulfenamide. In benzene solution, the products were the same as those in $CDCl_3$.

Preparation of 1-Phenylethyl-2,2,2-d_3 *Phenyl* N-*Tosylsulfilimine.* *Acetophenone-*d_3: Acetophenone (5.0 g) was dissolved in 15 ml of dioxane containing 5.0 g of deuterium oxide, and 0.5 g of triethylamine. The mixture was heated at 100 °C for 10 hr. Water was removed as a dioxane azeotrope and dioxane was removed by distillation. A new mixture of dioxane, deuterium oxide, and triethylamine was added to the residue. The procedure was repeated four times. The NMR spectra showed no protons in the methyl group (2.5 ppm) bp 87 °C/2 mmHg.

*1-Phenylethyl Alcohol-*2,2,2-d_3: The deuterated acetophenone (5.0 g) was reduced with lithium alminum hydride by the usual method. Bp 90 °C/10 mmHg, yield 55%.

*1-Phenylethyl Bromide-*2,2,2-d_3: The deuterated alcohol was

1-Phenylethyl-2,2,2-d_3 *Phenyl* N-*Tosylsulfilimine*: The sulfilimine was prepared from the sulfide and chloramine- T. Mp 102.0—103 °C, yield 73%.

Kinetics. A pre-cooled solution of 0.5～1% sulfilimine in anhydrous solvents was prepared and sealed into 2 ml ampoules, which were immersed in a constant temperature bath. At an appropriate time, the ampoules were taken out one by one and frozen in a dry-ice–acetone bath to stop the reaction. The reaction rate was then calculated by following the increase of the IR intense –NH– stretching absorption band at 3280 cm^{-1} due to sulfenamide produced. The reaction was found to follow a good first-order kinetic equation. A typical example of the kinetics is shown in Table 5.

(Received May 17, 1973)

The ^{13}C spectrum taken during the reaction of 4-picoline *N*-oxide with acetic anhydride at 110 °C in the NMR cavity (23.5 kG) shows a pair of emission lines at 15.8 and 154.4 ppm and enhanced absorption at 29.6 and 125.0 ppm (TMS-based). The signals are found to be due to 4-ethylpyridine formed as a minor product of the reaction and are interpreted in terms of the memory effect of the polarization induced in the precursor 4-picolyl–acetoxy radical pair.

The chemically induced dynamic nuclear polarization (CIDNP) of ^{13}C nuclei is expected to give valuable information on the spin distribution among the carbon atoms in radical species and on the rates of formation and decomposition of radical pair intermediates. Simplified spectra due only to net polarization can be obtained since the multiplet effect derived from the ^{1}H–^{13}C coupling is excluded when the wide-band proton decoupling technique is employed, as is usually the case in ^{13}C NMR spectroscopy. The wide variety of spin-lattice relaxation time of ^{13}C compared to that of ^{1}H may also be of help in interpreting the observed polarization in terms of the kinetics and mechanisms of free radical reactions. However, experimental studies have so far been hampered by the technical difficulty caused by short sampling time of the polarization signals over the wide ^{13}C chemical shift region in question in the course of fast free radical reactions.[2)] In contrast with conventional continuous wave NMR, a recently introduced Fourier transform pulsed NMR spectroscopy adequately meets the above requirement for the CIDNP study. We wish to report on the ^{13}C CIDNP spectra obtained during the reaction of 4-picoline *N*-oxide with acetic anhydride.

Results and Discussion

^{13}C CIDNP Spectra. A 3 M solution of 4-picoline *N*-oxide in acetic anhydride was heated at 110 °C in the magnetic cavity of a ^{13}C NMR spectrometer (25.15 MHz). The Fourier transform pulsed NMR spectra were obtained from the time domain signals accumulated nine times during a given 10 s span in the course of the reaction (see Experimental for details). At the beginning of the reaction, the absorption signals at 127.0 and 138.7 ppm (TMS based) due to the ring $C_{(3)}$ and $C_{(2)}$ atoms, respectively, of 4-picoline *N*-oxide were seen in addition to those at 21.0 (for CH_3)[3)] and 167.2 ppm (for C=O) of the solvent (see Fig. 1a). As the reaction proceeded, the singals of the starting materials diminished gradually and disappeared in 140 s after the start of the reaction. At 100 s we observed growth of a pair of emission lines at 15.8 and 154.4 ppm and absorption signals at 29.6 and 125.0 ppm. The intensity of these peaks increased until about 140 s (Fig. 1b), when it started to decrease and was null in 300 s. Time development of the polarization during the reaction is summarized in Fig. 2. At the end of the reaction, only two absorption peaks of the products were barely detected under the signal to noise ratios of the experimental conditions. We found on a chart of 100 scan accumulation signals due mainly to 4-picolyl acetate; 19.8 (CH_3), 64.5 (CH_2), 122.5 ($C_{(3)}$), 146.1 ($C_{(4)}$), 148.8 ($C_{(2)}$), and 174.4 ppm (C=O).[4)] No signal could be seen at the chemical shifts where the polarized signals appeared (Fig. 3*a*).

3) Also for the CH_3 signal of 4-picoline *N*-oxide.

4) The carbonyl chemical shift of acetic acid coincided.

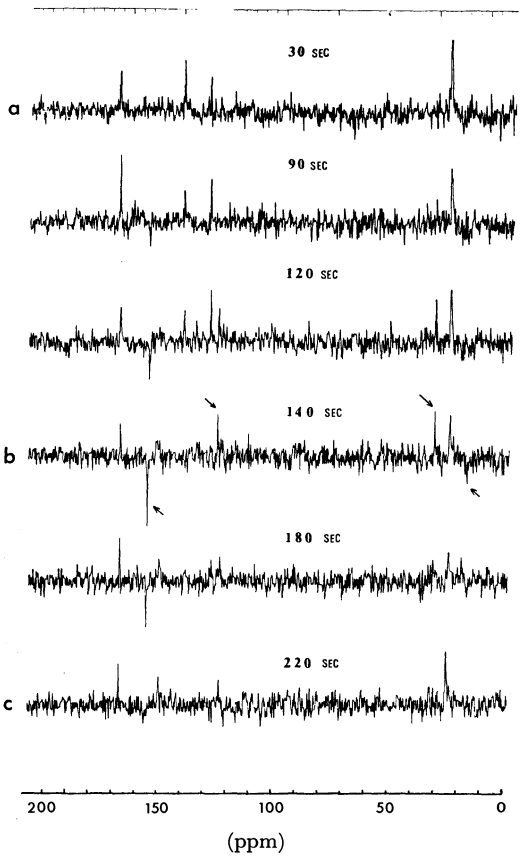

Fig. 1. 25.15 MHz ^{13}C spectra obtained during the course of the reaction of 4-picoline *N*-oxide with acetic anhydride at 110 °C.

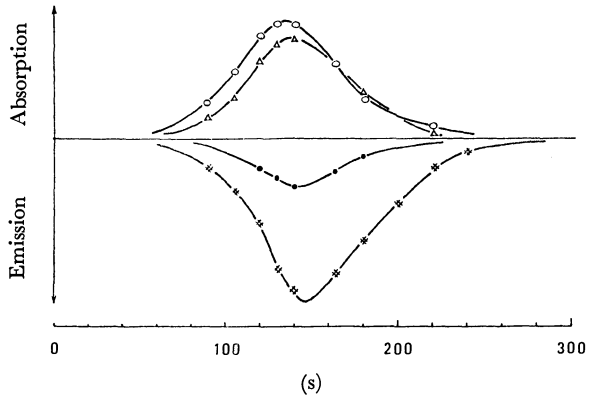

Fig. 2. Time development of the polarization signals due to 4-ethylpyridine during the reaction of 4-picoline *N*-oxide in acetic anhydride at 110 °C. The signal intensities are in arbitrary unit.

By comparison with the ^{13}C spectrum of the authentic sample (Fig. 3b), the emission signals observed during the reaction were assigned to the methyl carbon and ring $C_{(4)}$ while the enhanced absorption peaks corresponded to the methylene carbon and ring $C_{(3)}$ of 4-ethylpyridine formed as a minor product according to Scheme 1. It is reasoned that the chemical yield of 4-ethylpyridine was so low that its NMR absorption could not be observed in the final reaction mixture (Fig. 3a). At the maximum intensity of polarization, we could not detect the signals due to 4-picolyl acetate which should have been formed approximately fifty

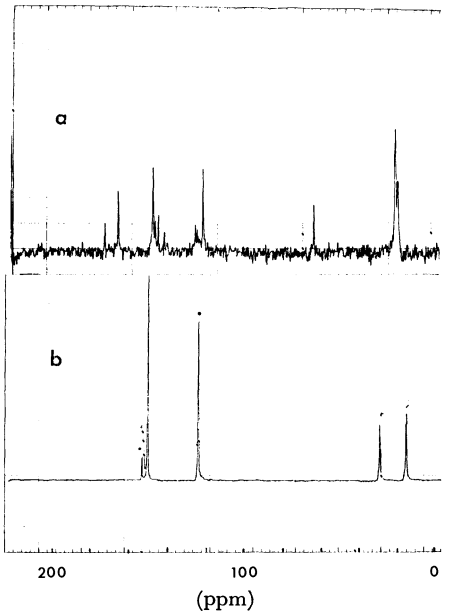

Fig. 3. ^{13}C spectra obtained after the end of the reaction of 4-picoline *N*-oxide in acetic anhydride at 110 °C (a), and of authentic 4-ethylpyridine (b). See text for the assignment of the signals.

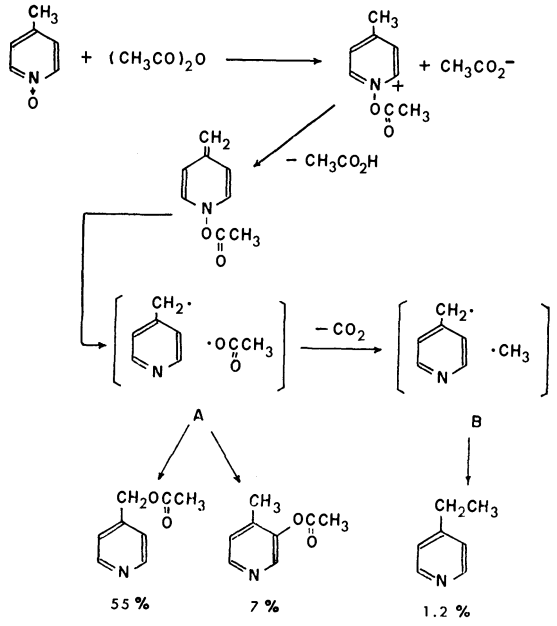

Scheme 1. (Yields of the products were determined by vpc.)[5]

times as much as 4-ethylpyridine. Since the signal to noise ratio of the strongest emission line was five (Fig. 1b), the apparent enhancement factor of polarization is roughly estimated to be 250.

Origin of the 4-Ethylpyridine Polarization. Examination of the polarization pattern in terms of the current radical pair theory of CIDNP[6] enables us to confirm

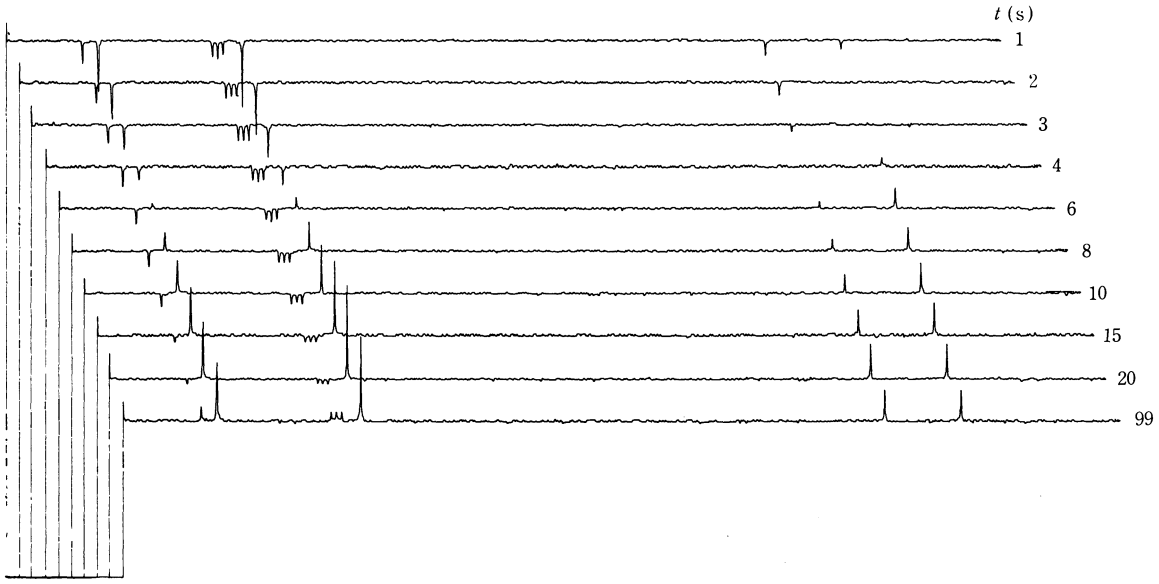

Fig. 4. Carbon-13 partially relaxed Fourier transform spectra of 4-ethylpyridine (containing 30% benzene-d_6 as an internal lock). A waiting period t in a 180 °–t–90 ° pulse sequence is indicated. See text and Fig. 3b for the signal assignment.

equilibrated conditions as the result of lack of signal enhancement due to operation of a ^{13}C–H Overhauser effect (Fig. 3b), it shows the strongest amplitude in polarization spectrum (Fig. 1b, 2). The hyperfine coupling constant is not necessarily the largest for the carbon atom. The effect is considered to originate from the slower spin-lattice relaxation rate of the quaternary carbon atom which usually has relaxation times an order of magnitude greater than those of carbon atoms carrying a proton. The intensities of CIDNP spectra are approximately proportional to the nuclear spin relaxation times.[15] In order to verify the above reasoning for the effect, T_1 measurements were performed by means of 180°–t–90° pulse sequence method. The results are summarized in Table 2.

Table 2. ^{13}C spin-lattice relaxation times (T_1) for 4-ethylpyridine

^{13}C	T_1 (s)
CH_3	3.8
CH_2	6.7
$C_{(2)}$	7.8
$C_{(3)}$	7.8
$C_{(4)}$	96.8

As expected, ring $C_{(4)}$ of 4-ethylpyridine which lacks the dipole-dipole relaxation mechanism with the attached proton has a T_1 value almost ten times as great as that of the other carbons. As another manifestation of the relaxation effect on CIDNP spectra, we note in Fig. 2 that the relative intensity of the $C_{(4)}$ signal is prominent at a later stage (150—300 s) of the reaction wkere intensities are more susceptible to relaxation mechanism in the product.

Experimental

The Fourier transform pulsed NMR spectra were taken on a JNM-PFT-100 FT NMR System. An internal D lock at 15.359 MHz was made on DMSO-d_6 sealed in a capillary and placed concentrically in a sample tube of 8 mm o.d. The sample temperature was controlled by preheated nitrogen and was measured by a calibrated thermocouple in an effluent gas stream. A short radiofrequency 40° pulse of 8 μsec width was applied with a repetition time of 1.1 s over the ^{13}C spectrum width of 6.25 kHz. Nine scans on 2048 data points were accumulated in a magnetic dram of 16 kW which allowed us to obtain four separate spectra in the course of a single run of the reaction. After completion of the sampling, each accumulated time domain signal was Fourier transformed. The signals of individual ^{13}C were obtained as a single line with the use of wide-band proton decoupling with 100.00 MHz radiofrequency of 35—40 W. All the spectra were of *v*-mode which was phase corrected by computer calculation. Five runs of the reaction on a 3 M batch solution were carried out in order to construct Fig. 2.

For T_1 measurements, 180°–t–90° pulse sequences were used, and the values of T_1 were obtained from least-squares fits of the logarithm of the heights of the 90° pulse responses as a function of t. The original data are shown in Fig. 4. A sample of 4-ethylpyridine was neat liquid with approximately 30% benzene-d_6 as an internal lock and was not degassed to simulate the reaction conditions.

The authors gratefully acknowledge support of this work by the Ito Science Foundation. They also wish to thank Dr. T. Fukumi for the T_1 measurements.

Effect of Pressure on the Rate of Solvolysis. Hydrolysis of 1-Aryl-1-methylethyl Chlorides[1]

Akira SERA, Toshifumi MIYAZAWA, Tadashi MATSUDA, Yoichi TOGAWA, and Kazuhiro MARUYAMA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received June 5, 1973)

The effect of pressure on the hydrolysis rates of 1-aryl-1-methylethyl chlorides were investigated, and the activation volumes, ΔV_0^*, were calculated. Electron-donating substituents in an aryl group gave less negative ΔV_0^* values and electron-withdrawing substituents gave more negative ΔV_0^* values. The observed values of ΔV_0^* were found to correlate with σ^+. These observations are interpreted in terms of the dependence of the degree of solvation at the transition state of the reaction. The temperature dependence of ΔV_0^* is also discussed.

In recent years, the effect of pressure on the rates of organic reactions in solution has been extensively studied.[2] Rate measurements of reactions under high pressure allow us to estimate activation volumes, ΔV^*, by means of the following expression;

$$\Delta V^* = -RT(\delta \ln k/\delta P)_T \quad (1)$$

where ΔV^* is the partial molal volume change when a reactant(s) is converted into a transition-state species. An examination of the pressure effect on the kinetic rates can give a great deal of information about the transition states of the reactions. The general usefulness of the activation volume as a diagnostic probe of reaction mechanisms is well recognized.[3] The reaction constant, ρ, in the Hammett equation depends upon the reaction conditions; hence, a variation in the external pressure might influence the value of ρ. Equation 2[4] implies a linear correlation of ΔV^* with respect to σ;[5]

$$-\delta\Delta V^* = 2.303RT\sigma(\delta\rho/\delta P)_T \quad (2)$$

where $\delta\Delta V^* = \Delta V_X^* - \Delta V_H^*$ and where ΔV_H^* and ΔV_X^* are activation volumes for unsubstituted and substituted substrates, respectively (the subscript x denotes a substituent). However, there have been only a few investigations of the substituent dependence of the activation volumes.[2d,6-10]

We undertook the present investigation in order to obtain fundamental data necessary for the estimation of the substituent dependence of the activation volume, for this is essential for getting detailed information about the transition states of organic reactions. The hydrolysis of 1-aryl-1-methylethyl chlorides in 90% aqueous acetone at 25.0 °C seems to be a suitable model reaction for the present purpose, because; a) this is a reaction in which a neutral molecule in an initial state leads to a highly dipolar transition state, b) the reaction mechanism is rather unambiguous, and c) the rate of reaction is known to give an excellent linear correlation with σ^+ and the value of ρ is considerably large.

Results and Discussion

The hydrolysis of 1-aryl-1-methylethyl chlorides in "90% aqueous acetone" (see Experimental section) at 25.0 °C were followed by a conductometric method under pressure. The first-order rate constants were calculated by the Guggenheim method[11] or by the usual first-order rate expression.[12] The results are summarized in Table 1. Logarithmic plots of the rate constants shown in Table 1 against Brown-Okamoto's σ^+ values exhibit an excellent linear relationship under pressure. Clearly $|\rho|$ decreases as the applied pressure increases.[13] Figure 1 shows a typical plot of $\log k$ (1-phenyl-1-methylethyl chloride) against pressure; this proves the linear relationship between $\log k$ and pressure in this case. With some electron-withdrawing substituents, the plots inclined to show slight convex curvature. In the present investigation, however, all the values of ΔV_0^*, the activation volume at atmospheric pressure, were calculated by means of Eq. (1) and the following equation using the method of least-squares:

$$\ln k = a + bP \quad (3)$$

Substituent Dependence of ΔV_0^*. As has been

Hydrolysis of 1-phenyl-1-methylethyl chloride in 90% aqueous acetone at 25.0 °C.

pointed out by Evans and Polanyi,[14] $\Delta V^{\ddagger}$ may conveniently be regarded as being constituted of two terms: $\Delta_1 V^{\ddagger}$, which represents a change in the volume of a reacting molecule(s) during an activation process, and $\Delta_2 V^{\ddagger}$, which is a corresponding change in the volume of the surrounding solvent molecules caused by their rearrangement. In a unimolecular ionization process, $\Delta_2 V^{\ddagger}$ is actually the dominating term.[3]

14) M. G. Evans and M. Polanyi, *Trans. Faraday. Soc.*, **31**, 875 (1935).

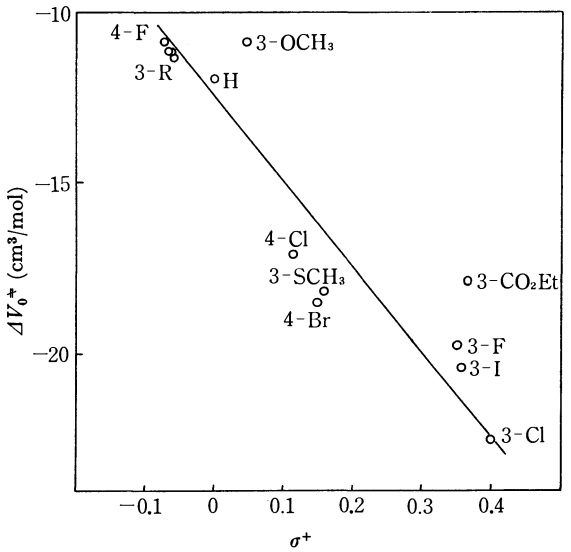

Fig. 2. Plot of $\Delta V_0^{\ddagger}$ against σ^+.

The values of $\Delta V_0^{\ddagger}$ in Table 3 are all negative and are found in the range from −10 to −25 cm³/mol. The contribution of carbonium-ion-like species at the transition state of the present reaction is well established, and the stability of the transition state is governed by the degree of electronic charge delocalization by a given substituent. Negative values of $\Delta V_0^{\ddagger}$ for solvolytic reactions are usually referred to as "electrostriction". That is, a partially-charged transition-state species exerts an electrostatic attractive force on nearby polar solvent molecules; as a result, volume contraction occurs. Thus, the degree of charge delocalization should correspond to this electrostatic volume contraction in the transition state. Figure 2 shows such correlation, with a negative slope, between $\Delta V_0^{\ddagger}$ and σ^+ as anticipated by Eq. (2). The trend shown is qualitatively in good accordance with the above prediction; that is, the more the charge delocalization in

the transition state, the less negative the value of ΔV_0^* becomes.[15]

Temperature Dependence of ΔV_0^*. A few data on the temperature dependence of the activation volume, $\delta\Delta V^*/\delta T$, have been previously reported,[16] and this parameter has been disucssed in terms of the difference in the degree of charge development. In general, $\delta\Delta V^*/\delta T$ is represented as the difference in the temperature dependence of the partial molal volumes between the transition state and the initial state;

$$\delta\Delta V^*/\delta T = \delta\bar{V}_t/\delta T - \delta\bar{V}_g/\delta T \qquad (4)$$

where $\bar{V}_t$ and $\bar{V}_g$ are the partial molal volumes of the transition state and the initial state, respectively.

In Table 4 the dependence of the rate of hydrolysis for 1-phenyl-1-methylethyl chloride on pressure at various temperatures is presented. The activation volumes thus obtained are also shown. As is shown, $\delta\Delta V_0^*/\delta T$ has a negative sign in the present reaction.[17] This implies, according to Eq. (4), that the electrostriction in the activation process results in a tight transition-state solvation shell whose volume is less responsive to temperature change (less expansive) than that of the initial state. Table 4 also shows that sign of $\delta\Delta S^*/\delta P$ seems to be positive, although the estimation of a numerical value of this parameter is, unfortunately, restricted. It seems that the pseudo-thermodynamic relationship;

$$-(\delta\Delta S^*/\delta P)_T = (\delta\Delta V^*/\delta T)_P \qquad (5)$$

is fulfilled.

Activation Volume—Activation Entropy Relationship. Electrostriction is a phenomenon where a strong electrostatic interaction exerts between an ion or a highly polar species and the surrounding solvent molecules. Therefore, the degree of freedom of the solvent molecules is restricted, resulting in a decrease in the entropy of the system. In fact, reactions which have large negative ΔV_0^* values are known to be characterized by large negative ΔS^* values. Accordingly, one can anticipate the presence of a rough proportionality between ΔV_0^* and ΔS^*. Figure 3 shows a fairly good correlation between these two parameters. That the correlation holds in the present reaction strongly supports the validity of the application of the electrostriction theory in the present mechanistic representation of the reaction.

TABLE 3. SUBSTITUENT EFFECT ON ΔV_0^* FOR HYDROLYSIS OF 1-ARYL-1-METHYLETHYL CHLORIDES

c) At 25.0 °C.

15) The position of the transition states along reaction coordinates might change a little with substituents. However, we ignore this small change and hence assume that the observed $\delta\Delta V_0^*$ reflects a difference in the solvation term, $\delta\Delta_2 V_0^*$.[14]

16) M. J. Mackinnon and J. B. Hyne, *Can. J. Chem.*, **49**, 3840 (1971).

17) The value of $\delta\Delta V_0^*/\delta T$ is roughly estimated as −0.1 cm³ mol^{-1} degree^{-1}. The value indicates the intervention of a highly polar transition state.[16]

Experimental

Materials. The materials employed in the present experiment were prepared by the methods reported in the references quoted by Brown and his co-workers.[18] The purity of each material was found to be satisfactory by checking mp, n_D, NMR and IR spectra, and by elemental and glc analyses in the stage of the corresponding alcohol and/or olefin. These alcohols and olefins were converted into the corresponding tertiary chlorides by the method of Brown and Rei.[19] The products were directly used for the rate measurements without further purification.[20]

Solvent. Acetone was dried over anhydrous potassium carbonate and was then distilled at least twice. Commercially available conductivity water was employed and was stored out of contact with air. Brown and his co-workers[18] prepared the reaction solvent mixture by volume. However, in the present investigation, we employed "88.5% aqueous acetone (wt/wt)". This solvent was found to be kinetically equivalent to Brown's "90% aqueous acetone (v/v)"; that is, 1-phenyl-1-methylethyl chloride and 1-(4-fluorophenyl)-1-methylethyl chloride gave an identical solvolysis rate, respectively, in these two solvents.

High-Pressure Apparatus. The high-pressure apparatus is shown in Fig. 4. The pressure vessel is equipped with an electric head which is replaceable, if necessary, by a sampling assembly. The pressure-transmitting fluid was a silicon oil, KF-96 (200 cs, Shin-etsu Chem. Ind.), and pressure was applied by means of a hand-pump. The Bourdon gauge was reliable to ± 10 kg/cm^2 at 1000 kg/cm^2. The thermostat was controlled to 25.0 ± 0.015 °C or 35.0 and 40.0 ± 0.02 °C.

Kinetic Measurements. The conductivity cell employed throughout the experiment is shown in Fig. 4. A kinetic solution was prepared by mixing a weighed substrate with 90% aqueous acetone at ambient temperature ($[RX]_0 = 0.01$—0.04 mol/l). The cell was rinsed well with this solution, filled, and placed in the high-pressure vessel. The electric conductivity of the solution was then measured by means of Radiometer model CDM-3 and Yanagimoto model MY-8 conductivity outfits. The first readings were taken after the establishment of the thermal equilibria in the cell. A preliminary experiment using a thermocouple directly inserted into the cell showed that thermal equilibria in the cell were established after 12 min in the case of an applied pressure of 400 kg/cm^2 and a vessel temperature of 0 °C (pre-chilled vessel medium, *n*-hexane); 17 min, 700 kg/cm^2, 0 °C; 18 min, 700 kg/cm^2, 15 °C; 37 min, 700 kg/cm^2, 25 °C (in all cases, the bath temperature was kept at 25.0 °C).

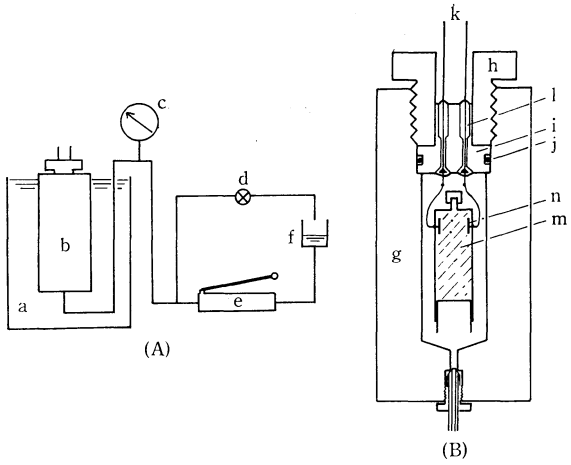

Fig. 4. High-pressure apparatus.

B) Diagram of pressure vessel. g: stainless steel vessel, h: gland nut, i: electric head, j: O-ring, k: electric leads, l: epoxy-resin, m: glass conductivity cell, n: platinum electrodes.

First-order rate constants were calculated by the Guggenheim method[11] or by the usual first-order rate expression[12] using the method of least-squares. In the former case, 10 pairs of readings were made for each run ($\Delta t \fallingdotseq$ two half lives). In the latter case, calibration plots of the conductance of the standard hydrogen chloride solution at several pressures against the concentrations (determined by titration) of hydrogen chloride in the solution were made. To obtain the "infinite titer", aliquots of the kinetic solution were added to an appropriate amount of 50% aqueous acetone; the solutions were then allowed to stand at ambient temperature for at least ten half lives, after which they were titrated with a standard alkaline solution, using methyl red as an indicator.

Optical Resolution and Stereochemistry of γ-Hydroxyglutamic Acid[1]

Yong Kyun LEE* and Takeo KANEKO**

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received June 11, 1973)

Four optical isomers of γ-hydroxyglutamic acid were prepared in pure states by optical resolution of two racemic diastereoisomers through brucine salt of *N*-benzyloxycarbonyl amino acid or strychnine salt of *N*-benzoyl derivative. Configurations of α- and γ-asymmetric carbon atoms of these isomers were estimated from contribution to molecular rotation and character of taste exhibition. These determinations were confirmed by chemical degradations to aspartic acid and malic diamide of the definite configurations. Cyclization of each racemic diastereomer to either lactone or lactam was also investigated.

γ-Hydroxyglutamic acid has been found in plants, *e.g.*, *Phlox decussata*,[2] *Hemerocallis* species,[3] and *Linaria vulgaris*.[4] Occurrence of this amino acid was also reported as an intermediate in hydroxyproline metabolism,[5] and in bovine gallbladder bile as *N*-terminal residue in heptapeptide.[6] In the previous paper,[7] the authors devised a new method to synthesize this amino acid and reported a separation procedure of the resulting mixture of two diastereoisomers. Greenstein and Benoiton demonstrated an enzymic resolution of two diastereoisomers of this amino acid and estimated steric configurations of these isomers indirectly based on the stereochemistry of hydroxy acid derived from the amino acid.[8] In this paper, we present an optical resolution of both racemic diastereoisomers of γ-hydroxyglutamic acid by chemical method *via* salt formation with brucine or strychnine and an unambiguous determination of stereochemistry for each optical isomer through direct degradation to the compounds of established configurations. In addition, we now report some other properties of this amino acid, for instance, one example of the relationship of a stereostructure of amino acid with its taste, and also a trend of cyclization for each diastereomeric isomer to lactone or lactam.

For the optical resolution of one diastereoisomer A of γ-hydroxyglutamic acid with the higher melting point of 172—173 °C (decomp.),[7] it was converted to several *N*-acyl derivatives and its salt formation with various resolution reagents was tested. The best result was obtained in the case of brucine salt with *N*-benzyloxycarbonyl amino acid. Thus, one optical isomer (−)-A was obtained by acid hydrolysis of a sparingly soluble salt and the other isomer (+)-A from more soluble salt, both in optically pure states.

The resolution of another diastereoisomer B with the lower melting point of 166 °C (decomp.)[7] was carried out by fractional crystallization of strychnine salt with *N*-benzoyl amino acid. Optical isomers (−)-B and (+)-B were secured from a sparingly soluble salt and a non-crystalline soluble salt respectively.

TABLE 1. PROPERTIES OF OPTICAL ISOMERS OF γ-HYDROXYGLUTAMIC ACID

	Mp (°C) (decomp.)	$[\alpha]_D$ (°)	Concentration (%)	Solvent	Taste
L(−)-A	172—173	−12.5	2.0	H_2O	Strongly tasty
		+3.0	5.0	20% HCl	
D(+)-A	172—173	+12.7	3.0	H_2O	Tasteless
		−3.2	5.0	20% HCl	
D(−)-B	166	−19.5	2.0	H_2O	Tasteless
		−37.3	1.5	20% HCl	
L(+)-B	166	+20.0	2.0	H_2O	Weakly tasty
		+38.0	1.5	20% HCl	

Physical and physiological properties of the four optical isomers of γ-hydroxyglutamic acid thus obtained were summarized in Table 1. The taste of one isomer (−)-A is resembled to that of L-glutamic acid but with milder nuance and weaker strength. If this amino acid is obeyed to the empirical rule concerning with the relationship of stereochemistry of amino acid with taste exhibition which had been originally found by one of the authors,[9] configuration of α-asymmetric carbon atom of both isomers (−)-A and (+)-B exhibiting the meaty taste, should belong to L-amino acid series and that of the other tasteless isomers (+)-A and (−)-B to D-series. It is also observed that the presence of γ-hydroxy group in this amino acid effects the strength of taste as in the case of β-hydroxyglutamic acid.[10]

The molecular rotations of the four isomers both in 20% hydrochloric acid and aqueous solution are listed

Table 2. Molecular rotation and calculated contribution of α-carbon atom of four stereoisomers of γ-hydroxyglutamic acid

Isomer	$[M]_D$		$[M]_{HCl}-[M]_{H_2O}$	α[a]		$\alpha_{HCl}-\alpha_{H_2O}$
	20% HCl	H_2O		20% HCl	H_2O	
(−)-A	+4.9	−20.4	+25.3	+33.5	+6.1	+27.4
(+)-A	−5.2	+20.7	−25.9	−33.1	−5.6	−27.5
(−)-B	−60.9	−31.8	−29.1	−33.1	−5.6	−27.5
(+)-B	+62.0	+32.6	+29.4	+33.5	+6.1	+27.4

a) $\alpha=1/2([M]_{\mp A}+[M]_{\pm B})$

in Table 2. It was noticed that, in the isomers (−)-A and (+)-B, a difference of two values in hydrochloric acid and aqueous solution was positive and that in (+)-A and (−)-B was negative. Furthermore, the same tendencies were recognized at the calculated values of contribution of α-carbon atoms to molecular rotation for each isomer. These facts may indicate that, according to Lutz and Jirgensons' rule,[11] the configuration of α-carbon atoms of (−)-A and (+)-B shlould be L-form and (+)-A and (−)-B must have D-configuration at α-carbon atoms.

In order to confirm the above estimation, one optical isomer of γ-hydroxyglutamic acid was degradated to aspartic acid by the following chemical procedure. Thus, *N*-benzyloxycarbonyl-(−)-A was oxidized with potassium permanganate followed by hydrolysis with 20% hydrochloric acid to yield aspartic acid which was identified with L-isomer from observed optical rotation value $[\alpha]_D^{15}$ +25.9° in hydrochloric acid. From this result, L-configuration of α-carbon atom of (−)-A was established in accordance with the deduction from the molecular rotation values and taste exhibition. Similarly, *N*-benzoyl-(−)-B was oxidized to give D-aspartic acid, indicating that its α-carbon atom possesses D-configuration.

For determination of the configuration of γ-carbon atom of this amino acid, one isomer (+)-A was oxidized with chloramine T to β-formyllactic acid which was then further oxidized to malic acid with bromine in a similar way to the degradation of β-hydroxyglutamic acid[12] as shown in Fig. 1. A specific rotation of diamide prepared from malic acid thus obtained was measured to be $[\alpha]_D^{18}$ +59.0° in methanol. This value corresponds to (R)-malic diamide of $[\alpha]_D^{18}$ +60.8°. Similarly, the same compound derived from (+)-B showed a specific rotation of $[\alpha]_D^{17}$ +60.0° in methanol. Therefore, it is concluded that γ-carbon atoms of (+)-A and (+)-B possess R-configuration and those of (−)-A and (−)-B belong to S-series.

Steric configurations of four optical isomers of γ-hydroxyglutamic acid deduced from the results obtained above are summarized and represented by Fischer's projection formula in Fig. 2. This conclusion coincides with the conclusion by Greenstein and Benoiton.[8]

If γ-hydroxyglutamic acid is cyclized either to lactone or to lactam, steric relationships of *cis-trans* isomerism

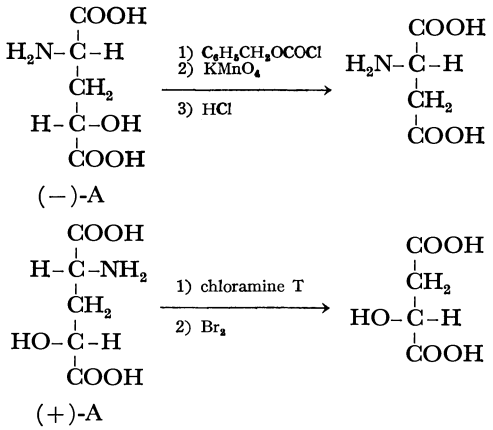

Fig. 1. Oxydative degradations of stereoisomers of γ-hydroxyglutamic acid.

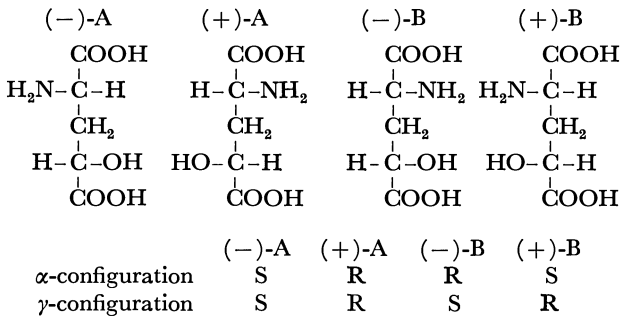

Fig. 2. Steric configurations of four optical isomers of γ-hydroxyglutamic acid.

concerning the ring planes will be resulted as shown in Fig. 3, each isomer corresponding to the four optical isomer mentioned in Fig. 2 respectively. In the lactone I and the lactam III, both derived from the isomer A, two substituents on the ring planes located each other at *cis* positions, while those in lactone II and lactam IV derived from the isomer B are at *trans* positions. It has been known that *allo*-γ-hydroxyproline, in which hydroxy and carboxy group are positioned at *cis* direction on pyrrolidine ring, can form bicyclic compound by lactonization. Since the lactams III and IV of γ-hydroxyglutamic acid can be considered as δ-oxo-γ-hydroxyproline, a relationship of stereochemistry of γ-hydroxyglutamic acid with cyclization seemed to be worthy of further investigation.

In fact, the racemic isomer A gave the lactone I hydrochloride which was easily crystallized.[7] When this hydrochloride was treated with pyridine, or the compound A was attempted to be esterified, a free lactone I was readily obtained.[7] On the contrary a

12) C. R. Harington and S. S. Randall, *Biochem. J.*, **25**, 1917 (1931).

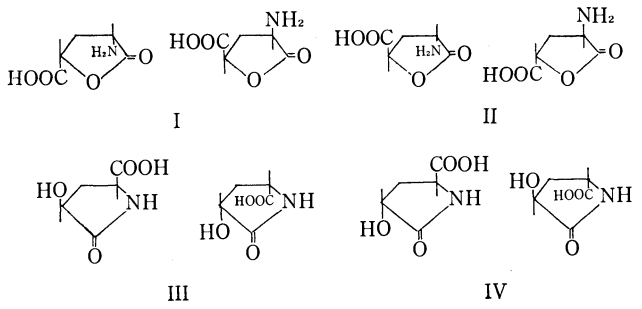

Fig. 3. Steric configurations of lactones and lactams derived from four optical isomers of γ-hydroxyglutamic acid.

free lactone II could not be obtained by the similar procedure from another racemic isomer B. In this case, esterification of the compound B gave mono- and diester hydrochloride, the latter of which could be converted to γ-hydroxyglutamic acid lactam ester with sodium hydrogencarbonate. The fact that isomer A can be easily lactonized compared with isomer B as demonstrated above, may be related to the resulting structure in the former lactone where amino and γ-carboxy groups in *cis* position could be interacted each other to stabilize the ring structure.

We next attempted to form the bicyclic compound of γ-hydroxyglutamic acid as shown in Fig. 4. The racemic isomer A was first converted to *N*-benzyloxycarbonyl derivative V which was readily cyclized to the lactone carboxylic acid VI with hydrochloric acid.[7] Methyl esterification of VI gave monomethyl ester VII and dimethyl ester VIII. When the lactone monoester VII was hydrogenated in dioxane using palladium black, a diketopiperazine IX was obtained unexpectedly. A similar diketopiperazine was also obtained from *N*-benzyloxycarbonyl-γ-hydroxy-DL-glutamic acid B lactone monomethyl ester. Hydrogenolysis of the diester VIII in aqueous methanol afforded directly a lactam ester X which was then saponified to yield a lactam carboxylic acid XI. Any trials for further lactonization of the lactam XI to make the bicyclic compound has not been succeeded.

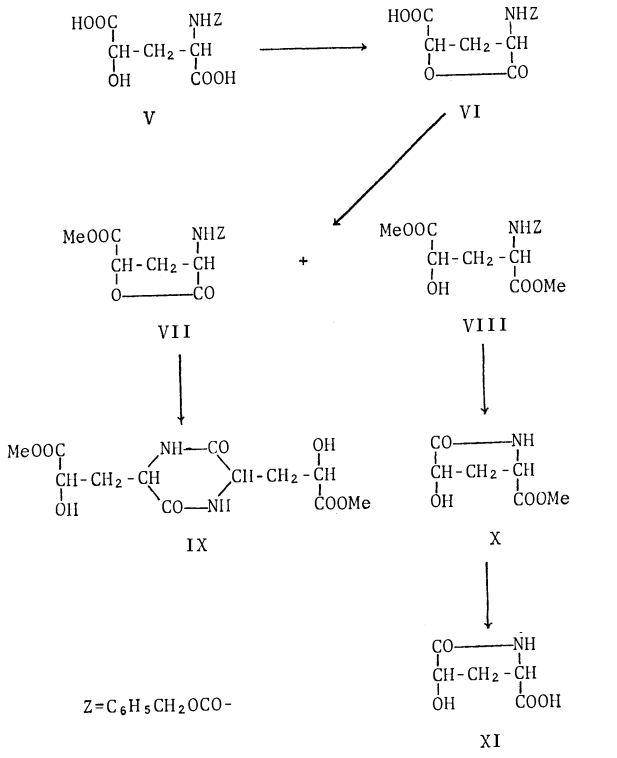

Fig. 4. Scheme for attempt at formation of bicyclic compound of γ-hydroxyglutamic acid.

Experimental

All melting points are uncorrected. Elemental analyses were carried out by Mr. Masakazu Okumiya and Miss Kiku Koike in our Department. For paper chromatography on Toyo paper No. 51, a developing solvent of *n*-butanol–acetic acid–water (4: 1: 2 v/v) was used.

Resolution of N-*Benzyloxycarbonyl Derivative of One Diastereoisomer A of γ-Hydroxy-*DL-*glutamic Acid.* To a solution of *N*-benzyloxycarbonyl derivative (25 g) of a racemic diastereoisomer A hydrate of γ-hydroxyglutamic acid with mp 172—173 °C (decomp.)[7] in 95% ethanol (350 ml), brucine (67 g) was added. The mixture was heated for 10 min to obtain the complete dissolution and then evaporated *in vacuo*. Water (30 ml) was added to the residue and evaporation was repeated twice to remove ethanol completely. Residual syrup was dissolved in water (600 ml) and kept in a refrigerator overnight to give crude crystals (45 g). The crystals were filtered and recrystallized three times from water (200 ml each) to give pure brucine salt (38 g). The salt was dissolved in water (600 ml) and decomposed by addition of 1 M sodium hydroxide to phenolphthalein alkaline on cooling. Crystals of brucine deposited were removed by filtration. The filtrate was neutralized with 6 M hydrochloric acid and concentrated under reduced pressure to 200 ml.

The solution was acidified to Congo red with 6 M hydrochloric acid and extracted with ethyl acetate repeatedly. The combined extract was dried over anhydrous sodium sulfate and concentrated to afford crystals of *N*-benzyloxycarbonyl-γ-hydroxy-L(−)-glutamic acid. This was recrystallized from ethyl acetate, yield, 8 g (66%), mp 124—125 °C (decomp.), $[\alpha]_D^{20}$ −18.0° (*c* 3.3, 99% ethanol).

Found: C, 52.62; H, 5.36; N, 4.65%. Calcd for $C_{13}H_{15}O_7N$: C, 52.52; H, 5.09; N, 4.71%.

The mother liquor from crystals of the crude brucine salt mentioned above was concentrated to about 50 ml. Crystals deposited were removed by filtration. The filtrate was further concentrated and kept at room temperature for a few days. After removal of a small amount of crystals by filtration, the mother liquor was decomposed with aqueous sodium hydroxide as mentioned above to give *N*-benzyloxylcarbonyl-γ-hydroxy-D(+)-glutamic acid, yield, 6 g (50%), mp 124—125 °C (decomp.), $[\alpha]_D^{15}$ +18.0° (*c* 3.0, 99% ethanol).

Found: C, 52.61; H, 5.21; N, 4.68%.

*γ-Hydroxy-*L*(−)-glutamic acid.* *N*-Benzyloxycarbonyl-γ-hydroxy-L(−)-glutamic acid (2.5 g) obtained above was refluxed with 20% hydrochloric acid (25 ml) for 4 hr. The solution was evaporated *in vacuo*. Water was added to the residue and evaporation was repeated. Finally, the residue was dissolved in water and treated with silver carbonate to remove hydrochloric acid. The filtrate was again evaporated and the residue was crystallized from water and ethanol. Recrystallization from water gave pure γ-hydroxy-L(−)-glutamic acid, yield, 1 g, mp 172—173 °C (decomp.), $[\alpha]_D^{10}$ −12.5° (*c* 2.0, water), $[\alpha]_D^{10}$ +3.0° (*c* 5.0, 20% hydrochloric acid).

Found: C, 36.96; H, 5.52; N, 8.53%. Calcd for $C_5H_9O_5N$: C, 36.81; H, 5.56; N, 8.59%.

*γ-Hydroxy-*D(+)*-glutamic Acid.* In a similar manner to the above experiment, γ-hydroxy-D(+)-glutamic acid was obtained from its *N*-benzyloxycarbonyl derivative, mp 172—173 °C (decomp.), $[\alpha]_D^{10}$ +12.7° (*c* 3.0, water), $[\alpha]_D^{10}$ −3.2° (*c* 5.0, 20% hydrochloric acid).

Found: C, 36.96; H, 5.58; N, 8.56%.

Resolution of N*-Benzoyl Derivative of One Diastereoisomer B of γ-Hydroxy-*DL*-glutamic Acid.* To an aqueous solution (300 ml) of *N*-benzoyl derivative (18 g) of one racemic diastereoisomer B of γ-hydroxyglutamic acid with mp 166 °C (decomp.),[7] strychnine (47 g) was added on warming. Insoluble material was filtered off while hot and the filtrate was evaporated *in vacuo*. To the residue, ethanol (30 ml) was added, and evaporation was repeated twice. To the residual syrup, 95% ethanol (200 ml) was added and the mixture was kept in a refrigerator overnight to yield crystals of crude salt (29 g). This was recrystallized from 95% ethanol (100 ml) three times to give pure salt (22 g). The strychnine salt was dissolved in water (600 ml) and then decomposed with 1 M sodium hydroxide. Strychnine deposited was filtered off and the filtrate was acidified with 20% hydrochloric acid to Congo red. It was evaporated *in vacuo* to give *N*-benzoyl-γ-hydroxy-D(+)-glutamic acid lactone, yield, 6 g (66%), mp 224—225 °C, $[\alpha]^{15}$ +70.8° (*c* 1.3, 99% ethanol).

Found: C, 57.95; H, 4.61; N, 5.55%. Calcd for $C_{12}H_{11}O_5N$: C, 57.83; H, 4.45; N, 5.62%.

The mother liquor from the above crystalline strychnine salt was evaporated to remove the salt of D(+)-lactone deposited. The residual syrup was treated as above to give crude crystals of *N*-benzoyl-L(−)-lactone. They were recrystallized from 1 M hydrochloric acid, mp 224—225 °C, $[\alpha]_D^{10}$ −71.3° (*c* 1.5, 99% ethanol).

Found: C, 57.79; H, 4.38; N, 5.54%.

*γ-Hydroxy-*D(−)*-glutamic Acid.* *N*-Benzoyl-D(+)-lactone (2.3 g) obtained above was dissolved in 20% hydrochloric acid (25 ml) and refluxed for 4 hr. The solution was evaporated *in vacuo*. Evaporation after addition of water was repeated. The residue thus obtained was dissolved in a little water and treated with pyridine and ethanol to give crude crystals of γ-hydroxy-D(−)-glutamic acid. Recrystallization from water afforded pure crystals, yield, 1 g, mp 166 °C (decomp.), $[\alpha]_D^{15}$ −19.5° (*c* 2.0, water), $[\alpha]_D^{15}$ −37.3° (*c* 1.5, 20% hydrochloric acid).

Found: C, 36.70; H, 5.60; N, 8.58%. Calcd for $C_5H_9O_5N$: C, 36.81; H, 5.56; N, 8.59%.

*γ-Hydroxy-*L(+)*-glutamic Acid.* In a similar procedure to that of D(−)-amino acid, γ-hydroxy-L(+)-glutamic acid was obtained from *N*-benzoyl-L(−)-lactone, mp 166 °C (decomp.), $[\alpha]_D^{15}$ +20.0° (*c* 2.0, water), $[\alpha]_D^{15}$ +38.0° (*c* 1.5, 20% hydrochloric acid).

Found: C, 36.59; H, 5.70; N, 8.66%.

Determination of Configuration at α-Carbon Atom of γ-Hydroxyglutamic Acid. (i) Oxidation of N*-Benzyloxycarbonyl-γ-hydroxy-*L(−)*-glutamic Acid.* A derivative of one optical isomer (−)-A, *i.e.*, *N*-benzyloxycarbonyl-γ-hydroxy-L(−)-glutamic acid (1 g) was dissolved in water (50 ml). The solution was added dropwise into an aqueous solution (30 ml) of potassium permanganate (0.8 g) at 25—30 °C with stirring. The stirring was continued for additional 10 min, and then filtered. The filtrate was acidified with 6 M hydrochloric acid (3 ml) and then evaporated. The residue was dissolved in 6 M hydrochloric acid (15 ml) and refluxed for 3 hr. After cooling, the solution was washed with ether, and an aqueous layer was evaporated *in vacuo*. The residue was treated with ethanol to remove potassium chloride by filtration. The filtrate was evaporated again and the residue thus obtained was crystallized from pyridine and ethanol. Recrystallization from water gave crystals of L-aspartic acid. This sample was identified with authentic L-aspartic acid on paperchromatogram, yield, 200 mg, $[\alpha]_D^{15}$ +25.9° (*c* 1.7, 10% hydrochloric acid). Lit.,[13] $[\alpha]_D^{20}$ +25.8° (*c* 2, 6 M hydrochloric acid).

Found: C, 36.42; H, 5.41; N, 10.65%. Calcd for $C_4H_7O_4N$: C, 36.09; H, 5.30; N, 10.52%.

(ii) Oxidation of N*-Benzoyl-γ-hydroxy-*D(+)*-glutamic Acid Lactone.* Permanganate oxidation of *N*-benzoyl derivative of the isomer (−)-B gave D-aspartic acid in a similar procedure to that in (i). On paperchromatogram, the product was identified with the authentic aspartic acid. $[\alpha]_D^{15}$ −25.0° (*c* 1.0, 10% hydrochloric acid).

*Determination of Configuration at γ-Carbon Atom of γ-Hydroxyglutamic Acid. (i) Oxidation of γ-Hydroxy-*D(+)*-glutamic Acid.* One optical active isomer (+)-A, *i.e.*, γ-hydroxy-D(+)-glutamic acid (2.2 g) was dissolved in 1 M hydrochloric acid (15 ml). The solution was made slightly alkaline by addition of 5% aqueous sodium hydroxide on cooling, and aqueous solution (15 ml) of chloramin T (4.2 g) was added. The reaction mixture was warmed at 60 °C for 2 hr. *p*-Tosylamide deposited on cooling was filtered off. Combined filtrate and washings were extracted with ethyl ether and the aqueous layer was acidified with hydrochloric acid. Bromine water prepared from 5 g of bromine and 100 ml of water was added to the solution and the mixture was kept at room temperature for 48 hr until the bromine color almost disappeared. Excess bromine was decomposed by addition of aqueous sodium thiosulfate. The solution was concentrated *in vacuo* to 30 ml, and extracted with ethyl ether. After removal of ether from the extract, the residue was dissolved in methanol and esterified with diazomethane in the usual manner. The product was purified by distillation and a fraction of bp 100—110 °C/6 mmHg was collected (0.7 g). A solution of this dimethyl ester in methanol (30 ml) was saturated with ammonia, and kept at room temperature in a sealed tube for 4 days. The solvent was evaporated to yield crude R(+)-malic diamide (0.3 g, 17%). It was recrystallized from methanol, mp 157—158 °C, $[\alpha]_D^{15}$ +59.0° (*c* 1.0, methanol).

Found: C, 36.60; H, 6.28; N, 21.20%. Calcd for $C_4H_8O_3N_2$: C, 36.36; H, 6.10; N, 21.20%.

*(ii) Oxidation of γ-Hydroxy-*L(+)*-glutamic Acid.* From one optical isomer (+)-B, *i.e.*, γ-hydroxy-L(+)-glutamic acid, R(+)-malic diamide was obtained by the similar procedure to that in (i), mp 157—158 °C, $[\alpha]_D^{17}$ +60.0° (*c* 1.0, methanol).

Found: C, 36.43; H, 6.14; N, 21.37%.

*γ-Hydroxy-*DL*-glutamic Acid B Lactone Hydrochloride.* The racemic isomer B was dissolved in a small amount of concentrated hydrochloric acid and then kept over phosphorus pentoxide in a vacuum desiccator to yield needles of the hydrochloride, mp 187—189 °C (decomp.).

Found: C, 30.04; H, 5.05; N, 6.83; Cl, 17.27%. Calcd for $C_5H_{10}O_5NCl$: C, 30.08; H, 5.05; N, 7.02; Cl, 17.48%.

*γ-Hydroxy-*DL*-glutamic Acid B Mono- and Diethyl Ester Hydrochloride.* To a suspension of the racemic isomer B (2 g) in anhydrous ethanol (50 ml), dry hydrogen chloride was saturated. The mixture was kept at room temperature overnight and then concentrated. To the residue, a small amount of acetone was added to yield crystals. Recrystallization from ethanol and acetone gave pure monoester, yield, 1.6 g (57%), mp 168 °C (decomp.).

13) T. Kaneko and H. Katsura, "Chemistry of Proteins," Vol. 1, Kyoritsu-Shuppan, Tokyo (1969), p. 113.

Found: C, 37.06; H, 6.20; N, 6.36; Cl, 16.14%. Calcd for $C_7H_{14}O_5NCl$: C, 36.93; H, 6.20; N, 6.15; Cl, 15.58%.

The mother liquor from crystals of the monoester was evaporated. The residue was crystallized to afford diester, yield, 0.8 g (26%), mp 90—95 °C (decomp.).

Found: C, 41.13; H, 6.99; N, 5.46; Cl, 14.59%. Calcd for $C_9H_{18}O_5NCl$: C, 42.28; H, 7.10; N, 5.48; Cl, 13.87%.

*γ-Hydroxy-*DL*-glutamic Acid B Lactam Ethyl Ester.* The diethyl ester (1.5 g) obtained above was dissolved in water (15 ml), and sodium hydrogencarbonate (0.6 g) was added. The mixture was extracted with ethyl acetate five times. The combined extract was dried with sodium sulfate and then concentrated to a syrup. It was crystallized from ethyl acetate and petroleum ether and then recrystallized from the same solvents, yield, 0.4 g (40%), mp 70—73 °C.

Found: C, 48.30; H, 6.52; N, 7.82%. Calcd for $C_7H_{11}O_4N$: C, 48.35; H, 6.40; N, 8.09%.

N-*Benzyloxycarbonyl-γ-hydroxy-*DL*-glutamic Acid A Lactone Methyl Ester (VII).* To a solution of *N*-benzyloxycarbonyl-γ-hydroxy-DL-glutamic acid A lactone (VI)[7] (2 g) in methanol (5 ml), ethyl ether solution of diazomethane was added at 0 °C until yellow color remained. The solvent was removed under reduced pressure to deposite crystals. They were recrystallized from 70% aqueous methanol, yield, 1.4 g (70%), mp 106.5—108 °C.

Found: C, 57.82; H, 5.23; N, 4.71%. Calcd for $C_{14}H_{15}O_6N$: C, 57.33; H, 5.16; N, 4.78%.

*γ-Hydroxy-*DL*-glutamic Acid A Lactam Methyl Ester (X).* When the esterification of VI (15 g) in methanol (35 g) was carried out using excess diazomethane in the above experiment, a syrup of the expected *N*-benzyloxycarbonyl-γ-hydroxy-DL-glutamic acid A dimethyl ester (VIII) was obtained. Through a solution of the syrup thus obtained in a mixture of methanol (100 ml) and water (50 ml), hydrogen was passed at 45 °C in the presence of palladium black (500 mg). The catalyst was removed by filtration and the solvent was removed to give crystals. Recrystallization from water gave crystals with 1 mol of crystallization water, yield, 4 g (47%), mp 70.5—71.5 °C. After drying at the refluxing temperature of acetone for 15 hr, the melting point rised up to 109—110 °C.

Found: C, 45.26; H, 5.69; N, 8.68%. Calcd for $C_6H_9O_4N$: C, 45.28; H, 5.70; N, 8.80%.

*γ-Hydroxy-*DL*-glutamic Acid A Lactam (XI).* The lactam methyl ester X (2.5 g) was dissolved in 5% aqueous sodium hydroxide (1.5 ml) and allowed to stand at room temperature overnight. The solution was passed through Dowex-50 (H^+ form) column, and the acidic eluate was concentrated *in vacuo* to deposit crystals, yield, 1.4 g (61%), mp 182 °C (decomp.).

Found: C, 41.25; H, 4.94; N, 9.46%. Calcd for $C_5H_7O_4N$: C, 41.38; H, 4.86; N, 9.65%.

*Diketopiperazine (IX) of γ-Hydroxy-*DL*-glutamic Acid A Methyl Ester.* Into a solution of VII (1 g) in anhydrous dioxane (40 ml), hydrogen was passed in the presence of palladium black (300 mg). After the hydrogenation had been finished, the catalyst was removed by filtration. The filtrate was concentrated *in vacuo* to give crystals. They were recrystallized twice from dioxane and then from water, yield, 0.8 g (73%), mp 192 °C (decomp.); ν_{max} 3400, 1675 cm^{-1}. A diketopiperazine structure was deduced for this product from its IR spectrum and elemental analyses in addition to the observation of negative ninhydrin test.

Found: C, 45.32; H, 5.89; N, 8.89%. Calcd for $C_{12}H_{18}O_8N_2$: C, 45.28; H, 5.70; N, 8.80%.

N-*Benzyloxycarbonyl-γ-hydroxy-*DL*-glutamic Acid B Lactone Methyl Ester.* *N*-Benzyloxycarbonyl-γ-hydroxy-DL-glutamic acid B lactone[7] (2.8 g) was esterified with diazomethane in the usual manner. The product was recrystallized from 70% aqueous methanol, yield, 1.9 g (65%), mp 109—110 °C.

Found: C, 57.37; H, 5.20; N, 4.88%. Calcd for $C_{14}H_{15}O_6N$: C, 57.33; H, 5.16; N, 4.78%.

*Diketopiperazine (IX) of γ-Hydroxy-*DL*-glutamic Acid B γ-Methyl Ester.* Hydrogenolysis of the lactone methyl ester (1 g) obtained above in anhydrous dioxane using palladium black in the usual manner afforded the diketopiperazine which was recrystallized from 99% aqueous ethanol, yield, 0.7 g (64%), mp 204 °C (decomp.).

Found: C, 45.33; H, 5.73; N, 7.91%. Calcd for $C_{12}H_{18}O_8N_2$: C, 45.28; H, 5.70; N, 7.91%.

The *N*→*O* and *N*→*S* Migrations of the *s*-Triazinyl Groups of *N,N*-Di-*s*-triazinyl Derivatives of *o*-Aminophenol and *o*-Aminothiophenol

Shigeo TSUNODA, Takeo SHIOJIMA, Yōji HASHIDA, Shizen SEKIGUCHI, and Kohji MATSUI

(Received June 16, 1973)

N,N-Bis(dichloro-*s*-triazinyl)-2-aminophenol reacted with an excess of dimethylamine or methylamine to give *N,O*-bis(*s*-triazinyl)-2-aminophenol and *N*-*s*-triazinyl-2-aminophenol upon the aminodechlorination, *N*→*O* migration, and cleavage of the *s*-triazinyl group. However, *N*-(dimethoxy-*s*-triazinyl)-*N*-(dichloro-*s*-triazinyl)-2-aminothiophenol reacted with an excess of dimethylamine to give merely a disulfide of *N*-*s*-triazinyl-2-aminothiophenol upon the aminodechlorination and cleavage of the dimethoxy-*s*-triazine nucleus. On the other hand, *N,N*-bis(*s*-triazinyl)-arylamines containing no *ortho*-OH or -SH group were stable to the attack by amines, while phenoxy-dimethoxy-*s*-triazine or phenylthio-dimethoxy-*s*-triazine reacted readily with dimethylamine to give dimethylamino-dimethoxy-*s*-triazine upon the fission of phenol or thiophenol. From these resutls, the reactions of the *N,N*-bis(*s*-triazinyl) derivatives of both *o*-aminophenol and *o*-aminothiophenol with amines to give the corresponding *N*-*s*-triazinyl derivatives are considered to proceed by means of an intramolecular nucleophilic attack by the phenoxide or thiophenoxide anion on the *s*-triazine ring carbon to give the *N,O*- or *N,S*-bis(*s*-triazinyl) derivative upon the *N*→*O* or *N*→*S* migration of the *s*-triazinyl group, followed by the cleavage of the *O*- or *S*-*s*-triazinyl group to give the final product. However, when the intermediary derivative is stable to amine, the intermediate is obtained as the major final product.

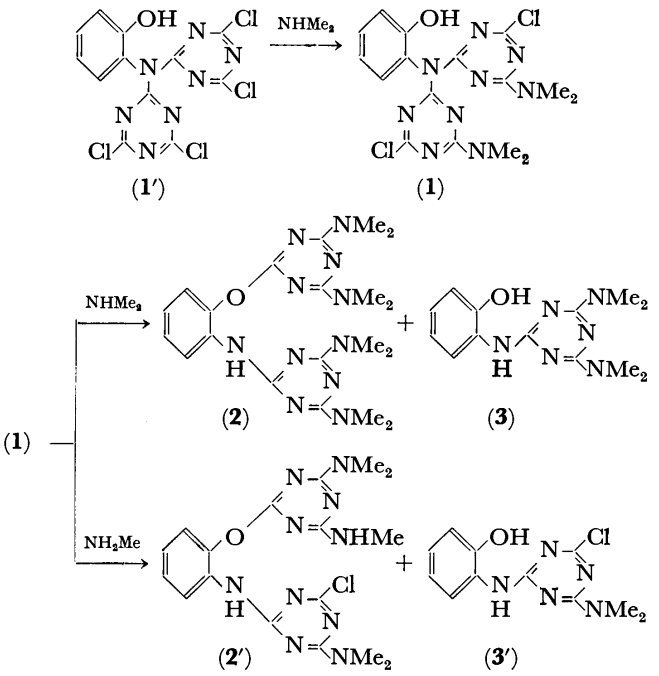
In previous papers we reported that *O*-*s*-triazinyl-2-aminophenols and *S*-*s*-triazinyl-2-aminothiophenols rearrange to give the corresponding *N*-*s*-triazinyl derivatives in protic solvents, especially readily in the presence of acid[1] or photochemically,[2] and that *O*-(dimethoxy-*s*-triazinyl)-2-aminophenol and *S*-(dimethoxy-*s*-triazinyl)-2-aminothiophenol give *N*-(acyl)-*N*-(*s*-triazinyl)- or *N,N*-bis(*s*-triazinyl) derivatives upon the *O*→*N* or *S*→*N* migration of the *s*-triazinyl group on acylation or *s*-triazinylation.[3] In addition, the *O*-*s*-triazinyl groups of *N*-(dichloro-*s*-triazinyl)-*O*-(*s*-triazinyl)-2-aminophenols migrate to give *N,N*-bis(*s*-triazinyl)-2-aminophenols on the methoxydechlorination[3] of the active chlorine atoms in the *N*-*s*-triazine nucleus.

In these ways, in the ordinary Smiles rearrangements of *s*-triazinyl derivatives of *o*-aminophenol and *o*-aminothiophenol, the *s*-triazinyl group migrates from the oxygen or sulfur atom to the amino nitrogen atom, as in the rearrangements of nitrophenyl derivatives of *o*-aminophenol.[4] However, on the contrary, we have found that some *N,N*-bis(*s*-triazinyl) derivatives of *o*-aminophenol and *o*-aminothiophenol rearrange to give *N,O*-bis(*s*-triazinyl)- or *N,S*-bis(*s*-triazinyl) derivatives or/and their cleaved products upon treatment with amines.

This paper will report on reverse Smiles rearrangements involving the *N*→*O* and *N*→*S* migrations of aromatic systems with *N,N*-bis(*s*-triazinyl) derivatives of *o*-aminophenol and *o*-aminothiophenol, in which rearrangements the *s*-triazinyl group migrates as an aromatic system.

Results and Discussion

N→O *Migration of the* s-*Triazinyl Group of* N,N-*Bis(s-triazinyl)-2-aminophenols in the Reaction with Amines.* In the reaction of *N,N*-bis(dichloro-*s*-triazinyl)-2-aminophenol (**1′**)[5] with dimethylamine in a molar ratio of 1 : 4, two chlorine atoms were replaced to give *N,N*-bis(4-chloro-6-dimethylamino-*s*-triazin-2-yl)-2-aminophenol (**1**). However, when (**1′**) was treated with



(**1′**) (**1**) (**2**) (**3**) (**2′**) (**3′**)

an excess of dimethylamine at room temperature in acetone, *N,O*-bis[4,6-bis(dimethylamino)-*s*-triazin-2-yl]-2-aminophenol (**2**) was obtained as the main product, along with a small amount of *N*-[4,6-bis(dimethylamino)-*s*-triazin-2-yl]-2-aminophenol (**3**).

Apparently, the formation of **2** results from the *N*→*O* migration of the *s*-triazinyl group and the replacement of the chlorine atoms by dimethylamino groups. However, it is uncertain whether **3** results from a cleavage of the *s*-triazinyl group from **1** or from *N,O*-bis(*s*-triazinyl)-2-aminophenol (**2**). A similar rearrangement was observed when **1** was treated with methylamine; in this case, however, *N*-(4-chloro-6-dimethylamino-*s*-triazin-2-yl)-2-aminophenol (**3'**) and *N,O*-bis(*s*-triazinyl)-2-aminophenol containing one residual chlorine atom were obtained. The latter is considered to be *N*-(4-chloro-6-dimethylamino-*s*-triazin-2-yl)-*O*-(4-dimethylamino-6-methylamino-*s*-triazin-2-yl)-2-aminophenol (**2'**) from the facts that **3'** was obtained in this reaction and that an active chlorine atom in the *O*-*s*-triazinyl nucleus is more reactive towards nucleophiles than that in the *N*-*s*-triazinyl nucleus. The results suggest that the *N*→*O* migration of the *s*-triazinyl group took place prior to the replacement of the chlorine atom by the methylamino group. When pyridine was used as a base, only unchanged **1** was recovered under similar reaction conditions. On the other hand, in the reaction of **1** with an excess of sodium methoxide only *N*-(4-dimethylamino-6-methoxy-*s*-triazin-2-yl)-2-aminophenol was obtained upon the fission of one of the *s*-triazinyl groups.

N→S *Migration of the* s-*Triazinyl Group in the Reaction of* N,N-*Bis(*s-*triazinyl)-2-aminothiophenols with Dimethylamine.* When *N*-(dichloro-*s*-triazinyl)-*N*-(dimethoxy-*s*-triazinyl)-2-aminothiophenol (**4**)[3] was treated with dimethylamine in a molar ratio of 1 : 2, a replaced product of one chlorine atom (**5**) was obtained. However, with an excess of dimethylamine (**4**) gave a disulfide of *N*-[bis(dimethylamino)-*s*-triazinyl]-2-aminothiophenol (**6**) and 2-dimethylamino-4,6-dimethoxy-*s*-triazine[5] upon the cleavage of the dimethoxy-*s*-triazinyl group; *N,S*-bis(*s*-triazinyl)-2-aminothiophenol was not obtained in this case. A similar result was also obtained when *N*-(4-chloro-6-methoxy-*s*-triazin-2-yl)-*N*-(4,6-dimethoxy-*s*-triazin-2-yl)-2-aminothiophenol (**7**) was treated with an excess of dimethylamine.

Generally, *N*-(acyl)-*N*-(*s*-triazinyl)- or *N,N*-bis(*s*-triazinyl)-arylamines are readily decomposed to give *N*-acyl- or *N*-*s*-triazinylarylamines upon the cleavage of the acyl or one of the *s*-triazinyl groups by sodium hydroxide or sodium methoxide, even in the absence of an *ortho*-OH or -SH group. Therefore, in the reaction of **1** with sodium methoxide to give *N*-*s*-triazinyl-2-aminophenol, a process involving the intermediary formation of *N,O*-bis(*s*-triazinyl)-2-aminophenol is unlikely. However, *N,N*-bis(*s*-triazinyl)-arylamines are fairly stable to amines when an *ortho*-OH or -SH group is absent; therefore, *N,N*-bis(*s*-triazinyl)-arylamine containing active chlorine atoms undergo merely a replacement of the chlorine atoms upon treatment with amines.

Thus, *N*-(4,6-dichloro-*s*-triazin-2-yl)-*N*-(4,6-dimethoxy-*s*-triazin-2-yl)-4-chloroaniline (**9**), whose triazinyl groups are expected to be somewhat more reactive towards nucleuphiles than those of **5** and **7** because of the presence of the *p*-chloro substituent, reacted with an excess of dimethylamine to give merely a replaced product (**10**), without any cleavage of the *s*-triazinyl group, under similar reaction conditions. On the other hand, 2,4-dimethoxy-6-phenoxy-*s*-triazine and 2,4-dimethoxy-6-phenylthio-*s*-triazine gave 2-dimethylamino-4,6-dimethoxy-*s*-triazine[6] upon treatment with an excess of dimethylamine. Similarly, **2** gave **3** and tris(dimethylamino)-*s*-triazine when treated with dimethylamine, although the reaction took place very slowly. In addition, **10** did not react with phenol or thiophenol in the presence of dimethylamine to give a derivative of phenoxy-*s*-triazine or phenylthio-*s*-triazine under similar reaction conditions.

From these results, it may be considered that the reaction of **5** or **7** with dimethylamine to give **6** or **8**, and the formation of **3** in the reaction of **1** with di-

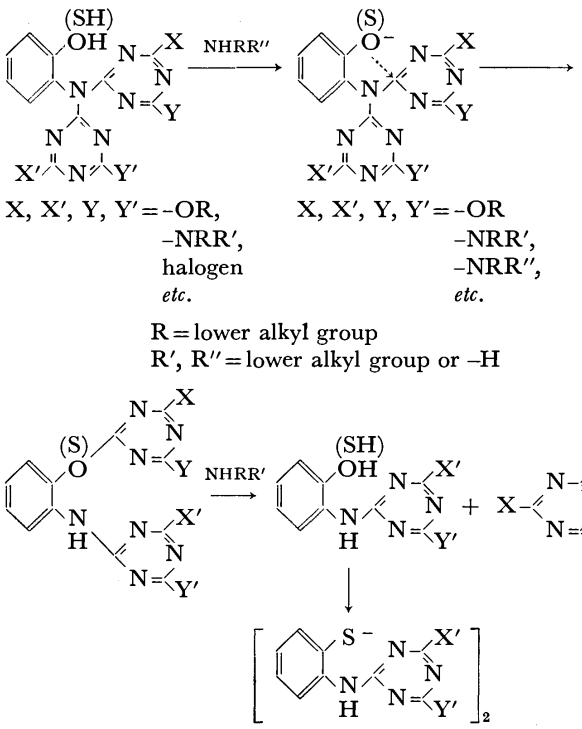
methylamine, does not proceed by means of a direct attack by dimethylamine on the *s*-triazine ring carbon of the *N,N*-bis(*s*-triazinyl) derivatives; the presence of the *ortho*-OH or -SH group is assumed to play an important role in the cleavage of the *s*-triazinyl group in these reactions.

The participation of the neighboring –OH or –SH group may be explained reasonably by means of an intramolecular nucleophilic attack on the *s*-triazine nucleus by the phenoxide or thiophenoxide anion formed in the presence of amine; this assumption may be supported by the fact that, for instance, the peak of the hydroxy proton of **1** (δ 8.40) almost disappears on the addition of amine in acetone. When two *s*-triazinyl groups of different kinds are present, the nucleophilic attack may be anticipated to take place preferentially upon the more electron-deficient ring carbon, as in Reactions (**5**) and (**7**). The fact that, in the reaction of **1** with methylamine, the $N\rightarrow O$ migration of the *s*-triazinyl group took place prior to the replacement may be explained by a similar reason; the reactivity of the *s*-triazine nucleus of **1** towards the intramolecular nucleophilic attack by the phenoxide anion is assumed to be greater than that of the replaced product. Thus, in the reaction of *N,N*-bis(*s*-triazinyl)-2-aminophenol or 2-aminothiophenol containing an active chlorine atom with amines, the replacement and rearrangement are considered to take place competitively. When the chlorine atom is reactive enough, the replacement may occur preferentially; however, when the chlorine is not so reactive, the rearrangement may take place prior to the replacement. The intermediary *N,O*- or *N,S*-bis(*s*-triazinyl) derivative thus formed may react with amine to give the *N*-*s*-triazinyl derivative upon the cleavage of the *O*- or *S*-*s*-triazinyl group. When the *O*-*s*-triazinyl group is reactive enough towards amines, only the *N*-*s*-triazinyl derivative may be obtained as the final product, as in the cases of **5** and **7**. However, when the intermediary compound is not so reactive towards amines, the *N,O*- or *N,S*-bis(*s*-triazinyl) derivative can be expected to be obtained as the final product, as in the case of **1**.

From these results, it can be said that, in the reactions of *N,N*-bis(*s*-triazinyl) derivatives of *o*-aminophenol or *o*-aminothiophenol with bases, the processes of the reactions and reaction products vary depending upon the basicities and nucleophilic reactivities of the bases employed. In a reaction with a base of a high nucleophilic reactivity such as sodium methoxide, the reaction proceeds by means of a direct nucleophilic attack at the *N*-*s*-triazine nucleus to give the *N*-*s*-triazinyl derivative. However, in a reaction with amines, the nucleophilic attack at the *s*-triazine nucleus takes place indirectly by means of the phenoxide or thiophenoxide anion upon the $N\rightarrow O$ or $N\rightarrow S$ migration of the *s*-triazinyl group. However, when the amine is a weak base, as in the case of pyridine, the rearrangement does not take place.

Therefore, the reactions of **1**, **5**, and **7** with amines to give not only the *N,O*-bis(*s*-triazinyl) derivatives, but also the corresponding *N*-*s*-triazinyl derivatives, are considered to involve the $N\rightarrow O$ and $N\rightarrow S$ migrations of *s*-triazinyl groups; these migrations can be regarded as examples of the reverse Smiles rearrangement.



Experimental

All the melting points are uncorrected. The NMR spectra were taken on a Varian A-60D spectrometer, using tetramethylsilane as the internal standard. The elemental analyses were performed in the Micro-analytical Center of Gunma University. The reaction products were identified by means of a study of their NMR spectra, by elemental analyses, by studying their solubility in an alakline solution, and by mixed-melting-point tests with authentic samples.

Materials. The *N,N*-bis(dichloro-*s*-triazinyl)-2-aminophenol (**1'**),[5] *N*-(dichloro-*s*-triazinyl)-*N*-(dimethoxy-*s*-triazinyl)-2-aimnothiophenol (**4**),[3] and *N*-(dichloro-*s*-triazinyl)-*N*-(dimethoxy-*s*-triazinyl)-*p*-chloroaniline (**9**)[7] were prepared by the methods already described.

2,4-Dimethoxy-6-phenoxy-s-triazine To a solution of 53 g (0.30 mol) of 2-chloro-4,6-dimethoxy-*s*-triazine in 200 ml of chloroform, we added an aqueous solution of 31 g (0.33 mol) of phenol and 13.5 g (0.34 mol) of sodium hydroxide in 200 ml of water. After 6 hrs' stirring at 60 °C, the solvent was evaporated. The recrystallization of the residue from ligroin yielded 2,4-dimethoxy-6-phenoxy-*s*-triazine in an almost quantitative yield. (Mp 102—102.5 °C. Found: C, 56.55; H, 5.01%. Calcd for $C_{11}H_{11}N_3O_3$: C, 56.65; H, 4.75%.)

A similar method was adopted for the preparation of 2,4-dimethoxy-6-phenylthio-*s*-triazine. (Mp 69—69.5 °C, recrystallized from ligroin. Found: C, 54.44; H, 4.45%. Calcd for $C_{11}H_{11}N_3O_2S$: C, 54.00; H, 4.45%.)

(i) Reaction of N,N-*bis(dichloro-s-triazinyl)-2-aminophenol (**1'**) with dimethylamine in a molar ratio of 1: 4.* To a stirred solution of 3.4 g (0.0084 mol) of **1'** in 100 ml of acetone, 4.0 g (0.034 mol) of a 40% dimethylamine solution was added, drop by

7) N. Nohara, S. Sekiguchi, and K. Matsui, *J. Heterocycl. Chem.*, **7**, 519 (1970).

drop, at 0 °C. After 3 hrs' stirring, the mixture was poured into 300 ml of ice–water. The precipitate thus formed was filtered, dried, and recrystallized from ethylbenzene to afford *N,N*-bis(4-chloro-6-dimethylamino-*s*-triazin-2-yl)-2-aminophenol (1) in an almost quantitative yield. (Mp 187—188 °C. Found: C, 45.79; H, 4.16%. Calcd for $C_{16}H_{17}Cl_2N_9O$: C, 45.49; H, 4.06%. NMR (CD_3Cl) δ 8.40 (broad, 1H), 7.26 (m, 4H), 3.17 (s, 9H), 3.01 (s, 3H.)

(ii) Reaction of **1′** *with an Excess of Dimethylamine.* To a stirred solution of 1.04 g (0.0025 mol) of **1′** in 150 ml of acetone, 13 g (0.012 mol) of a 4% dimethylamine solution was added, drop by drop, at 20 °C, after which the mixture left overnight at room temperature. The subsequent evaporation of the acetone gave a residue which, on recrystallization from acetone, yielded *N,O*-bis[bis(dimethylamino)-*s*-triazinyl]-*o*-aminophenol (**2**) (mp 184.5—185.5 °C)[3] in an almost quantitative yield. The thin-layer chromatogram (developed on a silica gel layer; developing solvent, acetone: benzene= 1: 10 by volume) of the reaction mixture showed the presence of *N*-[4,6-bis(dimethylamino)-*s*-triazin-2-yl]-2-aminophenol (**3**).[1b]

(iii) Reaction of **1** *with methylamine.* Into a stirred solution of 1.03 g (0.0024 mol) of **1** in 150 ml of acetone, we stirred 8.9 g (0.01 mol) of a 4% methylamine solution, drop by drop. After 48 hrs' stirring at 50 °C, the solvent was evaporated. The residue was purified by column chromatography on silica gel, using a mixture of benzene and acetone (10: 1 by volume) as the developing solvent; this yielded 0.27 g (26.7%) of *N*-(4-chloro-6-dimethylamino-*s*-triazin-2-yl)-*o*-(4-dimethylamino-6-methylamino-*s*-triazin-2-yl)-2-aminophenol (**2′**) and 0.015 g (2.25%) of **3′**. **2′**; [mp 209—210 °C, recrystallized from benzene. Found: C, 48.54; H, 4.97%. Calcd for $C_{17}H_{21}ClN_{10}O$; C, 48.98; H, 5.07%. NMR (DMSO-d_6) δ 8.90 (broad, 1H), 7.76 (broad, 1H), 7.25 (m, 4H), 3.03 (s, 12H), 2.73 (s, 3H).] The structure of Compound **3′** was confirmed by a mixed-melting-point test with an authentic sample prepared by a method to be described below. Into a stirred solution of 15.5 g (0.06 mol) of *N*-(dichloro-*s*-triazinyl)-2-aminophenol[5] in 200 ml of acetone, 14.4 g (0.12 mol) of a 40% dimethylamine solution was added, drop by drop, at 0 °C. After standing for 5 hr at room temperature, the reaction mixture was poured into 500 ml of ice–water. The precipitate thus formed was filtered, dried, and recrystallized from benzene to give *N*-(4-chloro-6-dimethylamino-*s*-triazin-2-yl)-2-aminophenol (**3′**) in a 91% yield. [Mp 222—223 °C. Found: C, 49.98, H, 4.60%. Calcd for $C_{11}H_{12}ClN_5O$; C, 49.69; H, 4.55%. NMR (DMSO-d_6) δ 8.51 (broad, 1H), 7.76 (broad, 1H), 6.81 (m, 4H), 3.08 (s, 6H).]

(iv) Reaction of N-*(dichloro-s-triazinyl)*-N-*(dimethoxy-s-triazinyl)*-2-*aminothiophenol (4) with dimethylamine.* Into a solution of 4.2 g (0.01 mol) of **4** in 100 ml of acetone, we stirred, drop by drop, 2.3 g (0.02 mol) of a 40% solution of dimethylamine at 5 °C. After 1 hr's stirring at 10 °C, the mixture was poured into 300 ml of ice–water; the precipitate thus formed was filtered and dried. Recrystallization from benzene–ligroin gave an analytical sample of *N*-(4,6-dimethoxy-*s*-triazin-2-yl)-*N*-(4-chloro-6-dimethylamino-*s*-triazin-2-yl)-2-aminothiophenol (**5**) in an almost quantitative yield. Mp 168.5 °C. Found: N, 26.76%. Calcd for $C_{16}H_{17}ClN_8O_2S$; N, 26.62%.

(v) Reaction of **5** *with an excess of dimethylamine.* A procedure similar to that described above was employed using 5.0 g of a 40% solution of dimethylamine. After 10 hrs' stirring at room temperature, the mixture was poured into 300 ml of ice–water, and the precipitate thus formed was filtered and dried. Recrystallization from benzene–ligroin yielded a disulfide of *N*-[bis(dimethylamino)-*s*-triazinyl]-2-aminothiophenol (**6**). [Mp 184—185 °C, in an 85% yield. Found: C, 54.14; H, 6.08%. Calcd for $C_{26}H_{34}N_{12}S_2$: C, 53.96; H, 5.92%. NMR (DMSO-d_6), δ 8.60 (s, 1H), 7.65 (m, 4H), 3.00 (s, 12H).] The thin-layer chromatogram of the reaction mixture proved the presence of 2-dimethylamino-4,6-dimethoxy-*s*-triazine.[5]

(vi) Reaction of **4** *with Sodium Methoxide.* Into a solution of 4.2 g (0.01 mol) of Compound **4** in 100 ml of dioxane, we stirred, drop by drop, an equimolar methanolic solution of sodium methoxide at 0 °C. After 1 hr's stirring at 0 °C, the mixture was poured into 300 ml of ice–water; the precipitate thus formed was then filtered and dried. Recrystallization from benzene–ligroin yielded *N*-(4-chloro-6-methoxy-*s*-triazin-2-yl)-*N*-(4,6-dimethoxy-*s*-triazin-2-yl)-2-aminothiophenol (**7**) in an 80% yield. (Mp 146.5—147 °C. Found: C, 44.45; H, 3.68; N, 24.12%. Calcd for $C_{15}H_{14}ClN_7O_3S$: C, 44.18; H, 3.46; N, 24.04%.)

(vii) Reaction of **7** *with an Excess of Dimethylamine.* Compound **7** was treated with an excess of dimethylamine by a method similar to that described in (v). The crude product was purified by recrystallization from benzene–ligroin to give a disulfide of *N*-(4-dimethylamino-6-methoxy-*s*-triazinyl)-2-aminothiophenol (**8**) in a 70% yield. Mp 190—191 °C. Found: C, 52.30; H, 5.27%. Calcd for $C_{24}H_{28}N_{10}O_2S_2$: C, 52.16; H, 5.11%. NMR (DMSO-d_6) δ 8.98 (s, 1H), 7.0 (m, 4H), 3.80 (s, 3H), 3.03 (s, 6H). A thin-layer chromatogram of the reaction mixture showed the presence of 2-dimethylamino-4,6-dimethoxy-*s*-triazine.

(viii) Reaction of N-*(dichloro-s-triazinyl)*-N-*(dimethoxy-s-triazinyl)*-p-*chloroaniline (9) with dimethylamine.* To a stirred solution of 4.1 g (0.01 mol) of **9** in 100 ml of acetone, 4.0 g (0.1 mol) of a 40% dimethylamine solution was added, drop by drop, at room temperature. After 5 hrs' stirring, the mixture was poured into 300 ml of ice–water; the precipitate was filtered and dried. Recrystallization from acetone yielded *N*-[4,6-bis(dimethylamino)-*s*-triazin-2-yl]-*N*-(4,6-dimethoxy-*s*-triazin-2-yl)-*p*-chloroaniline (**10**) in an almost quantitative yield: mp 172—173 °C. Found: N, 29.26%. Calcd for $C_{18}H_{22}ClN_9O_2$: N, 29.18%. In a thin-layer chromatogram of the reaction mixture, no spots of *N*-[4,6-bis-(dimethylamino)-*s*-triazin-2-yl]-4-chloroaniline and 2-dimethylamino-4,6-dimethoxy-*s*-triazine were observed.

(ix) Reaction of **2**, *2,4-dimethoxy-6-phenoxy-s-triazine and 2,4-dimethoxy-6-phenylthio-s-triazine with dimethylamine.* A typical run is shown in the case of 2,4-dimethoxy-6-phenoxy-*s*-triazine. 5 g of a 4% solution of dimethylamine was stirred, drop by drop, into a solution of 0.2 g of 2,4-dimethoxy-6-phenoxy-*s*-triazine in 30 ml of acetone. Stirring was continued for 10 hr at 25 °C, and then the mixture was poured into 100 ml of ice–water. The precipitate was filtered and dried. The product was purified by column chromatography to give 0.035 g of 2,4-dimethoxy-dimethylamino-*s*-triazine. A thin–layer chromatogram of the reaction mixture showed the presence of phenol.

Reaction between Methyl-*p*-tolylmethoxysulfonium Salt and Nucleophiles[1]

Kuniaki TSUMORI, Hiroshi MINATO, and Michio KOBAYASHI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

(Received June 26, 1973)

The reactions of methyl-*p*-tolylmethoxysulfonium ion with such nucleophiles as tertiary amines, triphenylphosphine, thiophenolate anion and *p*-toluenesulfinate anion were investigated. The points of attack vary with nucleophile; the sulfonium ion receives nucleophilic attacks at its methoxy oxygen, methoxy carbon, sulfonium sulfur, S–CH_3 hydrogen or O–CH_3 hydrogen atoms. Optically active methyl-*p*-tolylmethoxysulfonium ion was also synthesized, and its reactions with benzylethylphenylamine, benzylmethylphenylphosphine and benzyl ethyl sulfide were studied. In the cases of the amine and the sulfide, the methylated products had optical activity. Thus, the methoxysulfonium ion can act as an optically active methylating agent.

Several alkoxysulfonium ions, $R_1R_2\overset{\oplus}{S}OR_3$, were prepared by alkylating the corresponding sulfoxides with trialkyloxonium ions.[2] Although alkoxysulfonium ions are expected to undergo interesting reactions with various nucleophiles, only a few papers have been published on these reactions. Johnson and Phillips reported that removal of the proton on the α-carbon of the alkoxy group of an alkoxysulfonium ion yields an aldehyde and a sulfide, and removal of the proton on the carbon atom adjacent to the sulfonium sulfur results in a Stevens-type rearrangement, an α-alkoxysulfide being formed.[2a,3] Johnson and McCants studied the reaction between an optically active alkoxysulfonium salt and hydroxide anion and found that the sulfoxide obtained possessed inverted configuration.[2b] Reaction with arylmagnesium halides gave triarylsulfonium salt with inverted configuration.[4]

Studies on the reactions of alkoxysulfonium ions with amines, phosphines, and sulfides seemed to be of great interest, and such investigations have been carried out in our laboratories. The results are described in this paper.

Results and Discussion

Reactions between methyl-*p*-tolylmethoxysulfonium tetrafluoroborate (I) and several nucleophiles in dichloromethane were studied at room temperature by means of NMR spectroscopy.

Reactions between I and Amines. Reaction of I with triethylamine or pyridine was rapid and completed soon after mixing, but that with *N,N*-dimethylaniline took 4 days and that with benzylethylphenyl amine took 7 days for completion. The results are shown in Table 1.

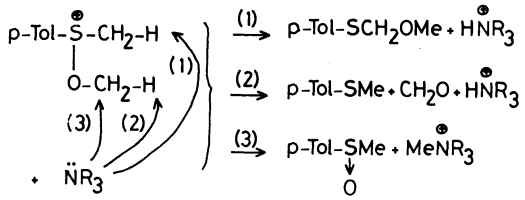
The reactions between I and amines can be summarized in the following scheme.

Table 1. Products of reactions between I and amines

Product (mol/100 mol I)	Amines				Path[c]
	Et_3N	Me_2NPh	C_5H_5N	PhEtNCH$_2$Ph	
p-Tol-S-Me	45	9.1	4.8	10	H_o
p-Tol-$\overset{\oplus}{S}Me_2$	0	0	0	13	H_o
(CH_2O)[a]	(45)	(9.1)	(4.8)	(25)	H_o
p-Tol-S-CH_2OMe	55	27	48	43	H_s
$H\overset{\oplus}{N}R_3$	97	32	(52.8)[b]	(66)[b]	H_s+H_o
p-Tol-S-Me ↓ O	0	63	47	33	OMe
$Me\overset{\oplus}{N}R_3$	0	61	32	17	OMe

a) Estimated from the amounts of *p*-Tol-S-Me and *p*-Tol-$\overset{\oplus}{S}Me_2$.

b) Estimated from the amounts of *p*-Tol-S-Me, *p*-Tol-$\overset{\oplus}{S}Me_2$ and *p*-Tol-S-CH_2OMe c) See text and schemes.



Three paths are possible for these amines; 1) deprotonation at $\overset{\oplus}{S}$–CH_2–H (path H_S), 2) deprotonation at O–CH_2–H (path H_o) and 3) demethylation at O–Me (path OMe). Deprotonation at S–CH_2–H will form a methoxysulfonium ylid, which is converted into methoxymethyl *p*-tolyl sulfide by a rearrangement similar to the Stevens or Pummerer rearrangement.

The deprotonation at $\overset{\oplus}{S}$–CH_2–H followed by rearrangement of the methoxy group appears to be the most plausible path for the formation of methoxymethyl *p*-tolyl sulfide.

a) Yield of methyl *p*-tolyl sulfoxide. b) Yield of methyl *p*-tolyl sulfide and dimethyl-*p*-tolylsulfonium ion. c) Yield of methoxymethyl *p*-tolyl sulfide. d) (Yield of methyl *p*-tolyl sulfoxide) − (yield of dimethyl-*p*-tolylsulfonium ion). e) pK_a of $\overset{\oplus}{H}NR_3$: Ref. 5. f) Pearson's nucleophilicity constant, $N_{MeI} = \log(k/k_{MeOH})$; Ref. 6.

Dimethyl-*p*-tolylsulfonium salt was found only when benzylethylphenylamine was used. The reaction of I with this amine was very slow, and the methyl *p*-tolyl sulfide formed by the path H_o must have been further methylated by the methoxysulfonium ion still remaining unreacted in the medium.

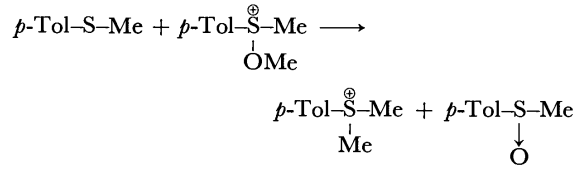

Table 2 summarizes the points of attack of the amines on I. The variations in the attacking points can be explained as follows. Since triethylamine is the strongest base among the four amines, its reaction is 100% H-attack and no C-attack was observed. *N,N*-Dimethylaniline is a much weaker base than triethylamine by a factor of 320000, but its nucleophilicity is smaller only by a factor of 10. Therefore, its main reaction was C-attack. Pyridine is a base of about equal strength but a slightly weaker nucleophile than *N,N*-dimethylaniline, and its H-attack percentage is greater than that of *N,N*-dimethylaniline. Though the basicity of benzyl ethyl phenyl amine is not available in the literature, it is expected to be comparable to or slightly greater than that of *N,N*-dimethylaniline. The much greater percentage of its H-attack is ascribable mainly to a steric factor; the crowded tertiary amine can attack the O–Me group only slowly and H-attack predominates.

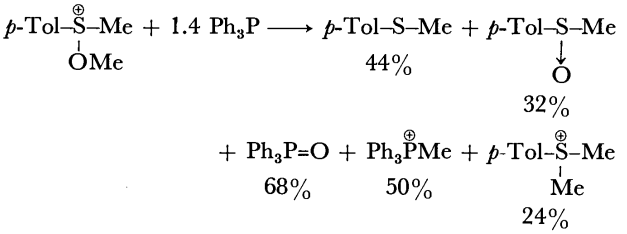
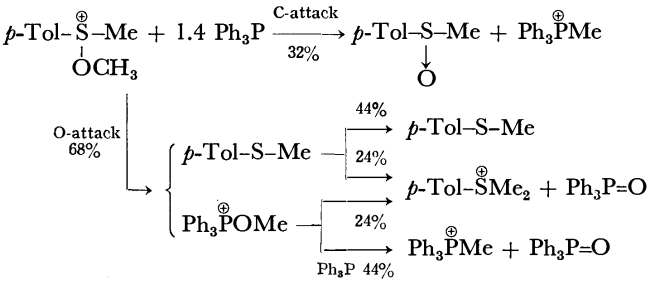
Reaction between I and Triphenylphosphine. The products of the reaction between I and triphenylphosphine are summarized as follows.



These products can be explained by assuming that triphenylphosphine attacks I at both the O–Me and O–Me positions. A reaction scheme consistent with the experimental results is shown below.

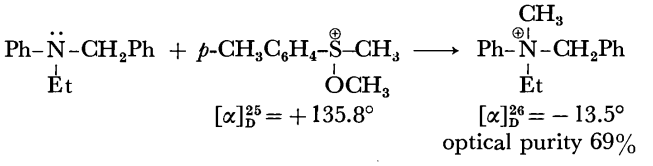


Since triphenylphosphine is a very weak base, it does not give the products of deprotonation. Although the nucleophilic attack of amines takes place only at the methoxy carbon atom, that of triphenylphosphine is mainly at the methoxy oxygen atom and the methoxy carbon attack is a minor reaction.

When triphenylphosphine attacks the methoxy oxygen atom of I, methoxytriphenylphosphonium ion is produced, which is expected to react further with triphenylphosphine. The experimental results show that this was what took place. When equal moles of I and triphenylphosphine were mixed, about 30% of I remained unreacted. The amounts of products formed were determined after a sufficient amount of triphenylphosphine was added and all of I present was consumed. Methoxyphosphonium ion has been postulated as an intermediate in the reaction of a phosphine with peroxides,[7a] or Arbuzov reactions.[7b,c]

Reactions between Optically Active I and Nucleophiles. When optically active I is let to react with nucleophiles, it is expected that the products have some optical activity. In order to check this possibility, the reactions with benzylethylphenylamine, benzylmethylphenylphosphine and benzyl ethyl sulfide were studied.

When R-(+)-I was let to react with benzyl ethyl phenyl amine, a salt-like product obtained was found to be a 77:23 mixture of $(Ph)(PhCH_2)\overset{\oplus}{N}(Me)(Et)$ and $p\text{-}CH_3C_6H_4\overset{\oplus}{S}(CH_3)_2$(by NMR). The optical purity of the methylated amine was 33%.



When R-(+)-I was let to react with benzylethylphenylphosphine, the phosphine oxide produced was found to have no optical activity.

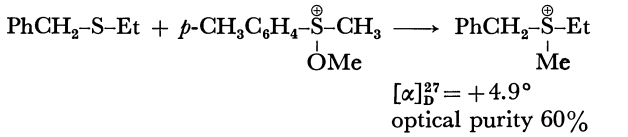
6) R. G. Pearson, H. Sobel, and J. Songstad, *J. Amer. Chem. Soc.*, **90**, 319 (1968).

7) a) M. A. Greenbaum, D. B. Denney, and A. K. Hoffman, *ibid.*, **78**, 2563 (1956); b) A. Macgaekus and R. Kaehne, *Ber.*, **31**, 1048 (1898); c) E. A. Arbuzov, *Zh. Russ. Fiz. Khim. Obshch.*, **38**, 687 (1906).

If the reactions taking place were simply the nucleophilic attack of the phosphine on the oxygen atom adjacent to the asymmetric sulfur atom, some optical activity is expected. The fact that no optical activity was found indicates that what took place was more complex than a simple S_N2 reaction of the phosphine on the methoxy oxygen atom.

When R-(+)-I was let to react with benzyl ethyl sulfide, the benzylethylmethoxysulfonium tetrafluoroborate produced was found to have some optical activity.

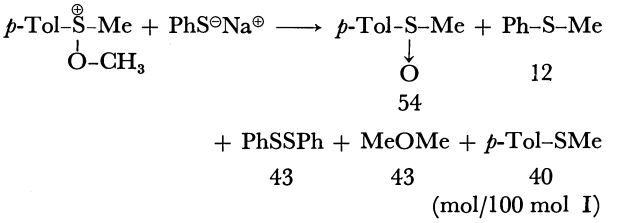


$[\alpha]_D^{27} = +4.9°$
optical purity 60%

Since this salt was not crystalline, it was subjected to anion-exchange on an $NaClO_4$ column. However, the crystalline sulfonium perchlorate obtained showed no optical activity. It is possible that racemization took place during the anion-exchange procedure.

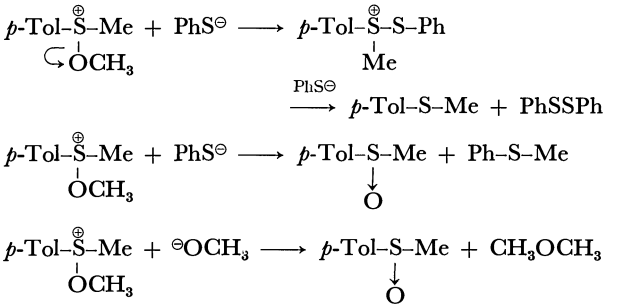
Thus, it has been established that optically active I can be used as stereoselective methylating agent for amines and sulfides.

Reaction between I and Sodium Thiophenolate. The products of the reaction between I and sodium thiophenolate are summarized as follows.

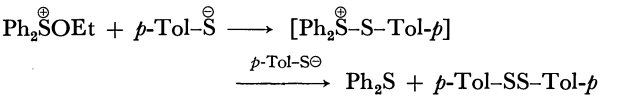


(mol/100 mol I)

These results indicate that the following reactions probably took place.

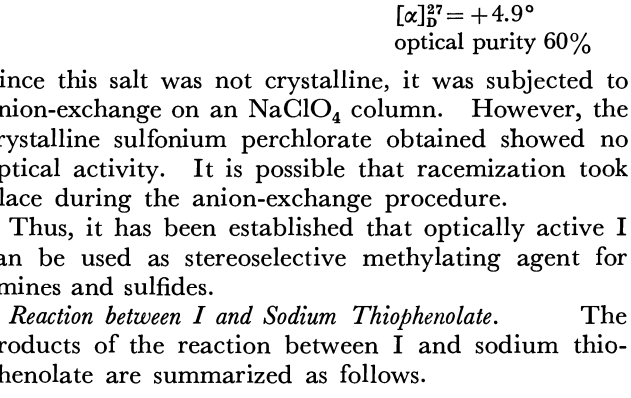


Thus thiophenolate anion attacks at both the sulfonium sulfur and methoxy carbon atoms. Oae and Khim reported that *p*-toluenethiolate anion attacks exclusively at the sulfonium sulfur atom of ethoxydiphenylsulfonium ion, and diphenyl sulfide and di-*p*-tolyl disulfide are the products.[8]



Recently Smallcombe and Caserio[9] reported that the rate constant k_2 for the reaction, $Me_2\overset{\oplus}{S}SMe + MeS\text{-}SMe \rightarrow Me_2S + Me\overset{\oplus}{S}(SMe)_2$, is extremely large ($1.04 \times 10^4\ M^{-1}\ s^{-1}$ at 40 °C). This suggests that the reaction between *p*-Tol(Me)$\overset{\oplus}{S}$SPh and $\overset{\ominus}{S}$Ph must be very fast, and as soon as *p*-Tol(Me)$\overset{\oplus}{S}$SPh is formed by the S-attack of thiophenolate anion on I, it is quickly converted into methyl *p*-tolyl sulfide and diphenyl disulfide.

Reaction between I and Sodium p-*Toluenesulfinate.* The products of the reaction between I and sodium *p*-toluenesulfinate are summarized as follows.



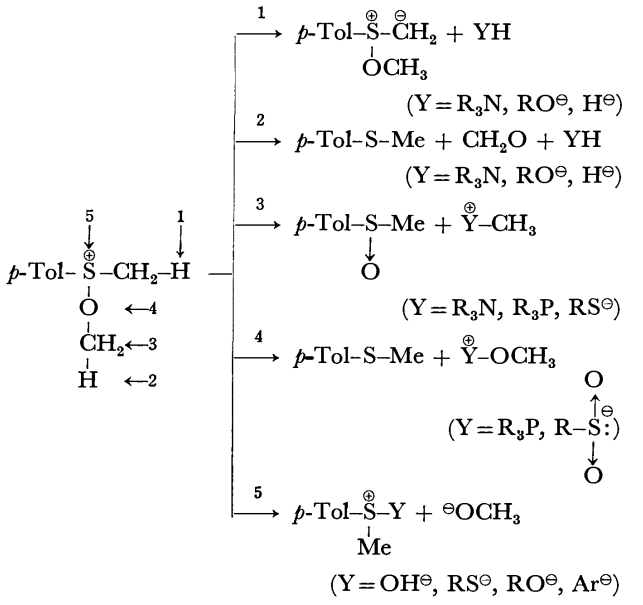
(mol/100 mol I)

These results suggest that the following reactions took place.

The formation of di-*p*-tolyl α-disulfone can be explained by the reaction steps involving the attack of the sulfinate on the S atom of I.

On the basis of these findings and other data reported in the literature, the reactions of methyl-*p*-tolylmethoxysulfonium ion with nucleophiles can be summarized as follows.

8) S. Oae and Y. H. Khim, This Bulletin, **42**, 3528 (1969).
9) S. H. Smallcombe and M. C. Caserio, *J. Amer. Chem. Soc.*, **93**, 5826 (1971).



Thus, methyl-*p*-tolylmethoxysulfonium ions can receive nucleophilic attack at five positions, and in this respect methylarylmethoxysulfonium ions are unique and interesting.

Experimental

Materials. Methyl-*p*-tolylmethoxysulfonium tetrafluoroborate (I) was synthesized by methylation of methyl *p*-tolyl sulfoxide with trimethyloxonium tetrafluoroborate in dichloromethane, and recrystallized from dichloromethane–ether;[2b] mp 65—68 °C; NMR, δ, 2.51 (s, $ArCH_3$), 3.57 (s, S-CH_3), 4.00 (s, S-OCH_3) ppm.

Methoxymethyl *p*-tolyl sulfide was prepared by condensation of chloromethyl *p*-tolyl sulfide with methanol in the presence of pyridine;[10] bp, 80—84 °C/4 mmHg; NMR, δ, 2.26 ppm ($ArCH_3$), 3.35 (s, OCH_3), 4.85 (s, SCH_2), 7.16 (q, ArH).

Dimethyl-*p*-tolylsulfonium tetrafluoroborate was synthesized by methylation of methyl *p*-tolyl sulfide with trimethyloxonium tetrafluoroborate, and recrystallized from dichloromethane–ether; NMR, δ, 2.50 ppm (s, $ArCH_3$), 3.27 (s, S-CH_3), 7.65 (q, ArH). Dimethylphenylsulfonium tetrafluoroborate was prepared in a similar manner; NMR, δ, 3.26 (s, S-CH_3), 7.87 (s, ArH).

Methyltriphenylphosphonium tetrafluoroborate was synthesized by methylation of triphenylphosphine with trimethyloxonium tetrafluoroborate; NMR, δ, 2.81 (d, CH_3), 7.77 (m, ArH).

General Procedure for the Reactions between I and Nucleophiles. An equimolar mixture of I and a nucleophile was let to react in dichloromethane, and the progress of the reaction was followed by means of NMR spectroscopy. The amounts of the products were determined from the integrated values on NMR spectra by using 1,1,2,2-tetrachloroethane as the internal standard. Each product was isolated by extraction, recrystallization or elution chromatography, and identified by comparing its melting point, glc retention time, IR or NMR spectrum with those of an authentic sample prepared separately.

Reaction between I and Pyridine. Pyridine (0.90 g, 11.4 mmol) was added to a dichloromethane solution (30 ml) of I (2.9 g, 11.4 mmol) in a 50 ml flask. Exothermic reaction took place, and pyridinium salts precipitated. After the white solids were filtered, the filtrate was concentrated, and the oily residue was extracted with hexane several times. Most of methyl *p*-tolyl sulfoxide remained unextracted. Evaporation and vacuum-distillation of the hexane extracts yielded methyl *p*-tolyl sulfoxide (bp, 110 °C/29 mmHg) and methoxymethyl *p*-tolyl sulfide (bp, 86—90 °C/3 mmHg). The pyridinium salts were recrystallized from dichloromethane–ether several times, and *N*-methylpyridinium chloride was isolated as crystals.

Reaction between I and Triphenylphosphine. Triphenylphosphine (3.1 g, 11.8 mmol) was added to a dichloromethane solution (15 ml) of I (3.0 g, 11.8 mmol). After 3 hr, the NMR spectrum of the solution indicated that 30% of I remained unreacted. When 1 g of phosphine was added, I disappeared completely. The solution was evaporated, and the residual oil was extracted with ether. Ether-isoluble residue was recrystallized from dichloromethane–ether, and methyltriphenylphosphonium salt and dimethyl-*p*-tolylsulfonium salt were isolated. The mother liquor of the recrystallization was evaporated, and elution chromatography of the residue yielded triphenylphosphine oxide. The ethereal extracts were evaporated, and the residue was subjected to elution chromatography on an alumina column; methyl *p*-tolyl sulfide and methyl *p*-tolyl sulfoxide were isolated.

Synthesis of Optically Active R-(+)-*Methyl* p-*Tolyl Sulfoxide.*[11] An anhydrous ether solution (100 ml) of methylmagnesium iodide (103 mmol) was added drop by drop to a stirred ether solution (500 ml) of (−)-menthyl *p*-toluenesulfinate (51.7 mmol) in 1 hr at 0 °C. The solution was stirred at room temperature for 3 hr, and then refluxed overnight. A saturated NH_4Cl solution (200 ml) was added for hydrolysis, and the ethereal layer was separated. The aqueous layer was extracted with ether three times, the combined ethereal extracts were dried over anhydrous magnesium sulfate, and the ether was evaporated. Elution chromatography (alumina, 300 mesh) of the residue gave *R*-(+)-methyl *p*-tolyl sulfoxide; $[\alpha]_D^{26}$ +136.5° (*c* 3.8, acetone).

Synthesis of Optically Active R-(+)-*Methyl*-p-*tolylmethoxysulfonium Tetrafluoroborate* (I_R). To a dichloromethane solution (20 ml) of *R*-(+)-methyl *p*-tolyl sulfoxide (2.0 g, 13.0 mmol) was added trimethyloxonium tetrafluoroborate (1.94 g, 13.0 mmol), and the mixture was stirred for 1.5 hr. After filtration, addition of ether to the cooled filtrate yielded white crystals, which were recrystallized from dichloromethane-ether; 2.4 g (9.4 mmol), 72%; $[\alpha]_D^{25}$ +135.8° (*c* 6.07, CH_2Cl_2).

Reaction between I_R and Benzylethylphenylamine. A mixture of I_R (3.0 g, 11.8 mmol) and benzylethylphenylamine (4.0 g, 19.0 mmol) in dichloromethane (30 ml) was let to react at room temperature for 8 days. After the solvent was evaporated, the residue was washed with ether and the ether-insoluble fraction was stirred with 30% NH_3–H_2O (30 ml) and dichloromethane (20 ml) for 1 day. The solvents were evaporated, and the residue was extracted with dichloromethane. The extracts were dried over anhydrous $MgSO_4$ and evaporated. The NMR spectrum of the residue showed it to be a 77: 23 mixture of (Ph) ($PhCH_2$)$\overset{\oplus}{N}$(Me)(Et) and *p*-$CH_3C_6H_4\overset{\oplus}{S}Me_2$. The optical activity of the salt was determined; $[\alpha]_D^{26}$ −13.5° (*c* 3.7, CH_2Cl_2), optical purity, 69% (optically pure (Ph) ($PhCH_2$)$\overset{\oplus}{N}$EtMe, $[\alpha]_D^{25}$ −19.6°).[12]

Reaction between I_R and Benzylmethylphenylphosphine.

10) L. A. Walter, L. H. Goodson, and R. J. Foshinder, *J. Amer. Chem. Soc.*, **67**, 655 (1945).

11) K. K. Andersen, *Tetrahedron Lett.*, **1962**, 93.

12) H. O. Jones, *J. Chem. Soc.*, **85**, 227 (1904).

Dibenzylphenylphosphonium iodide was prepared by the reaction between dibenzylphenylphosphine and methyl iodide;[13] yield, 19.4%; mp, 206—209 °C (lit,[13] 207-208 °C). Lithium aluminium hydride (0.7 g, 18.4 mmol) was added to a stirred suspension of dibenzylmethylphenylphosphonium iodide (5.0 g, 11.6 mmol) in tetrahydrofuran (60 ml) under a nitrogen atmosphere. After the mixture was refluxed for 42 hr, dichloromethane (100 ml) was added. After 3 hr the jelly substance formed was filtered under a nitrogen atmosphere. To this filtrate containing benzylmethylphenylphosphine was added I_R (3.3 g, 12.9 mmol). After the mixture was allowed to stand at room temperature overnight, the solvent was evaporated, and the residue was extracted with ether. Repeated recrystallization of the ether-insoluble residue from CH_2Cl_2–Et_2O yielded $PhCH_2\overset{\oplus}{P}PhMe_2\overset{\ominus}{B}F_4$, mp 120—122 °C. The mother liquor of the recrystallization was evaporated, and the residue was chromatographed on an alumina column; with CH_2Cl_2–Et_2O as the eluant MePhPh-CH_2P=O was obtained; mp 146—147 °C; $[\alpha]_D^{28}$ *ca.* 0 (*c* 6.7, CH_2Cl_2).

Reaction between I_R and Benzyl Ethyl Sulfide. A mixture of I_R (2.7 g, 10.6 mmol) and benzyl ethyl sulfide (2.0 g, 14.5 mmol) in dichloromethane (20 ml) was allowed to stand at room temperature for 3 days. Its NMR spectrum showed that I_R had disappeared completely. Ether (30 ml) was added, and the ether-insoluble fraction was dissolved in dichloromethane (20 ml), and again ether (30 ml) was added. This procedure was repeated for 6 times. Evaporation of the ether-insoluble fraction yielded solids; $[\alpha]_D^{27}$ +4.9° (*c* 6.08, CH_2Cl_2), optical purity, 60% (optically pure $MeEt\overset{\oplus}{S}CH_2Ph\overset{\ominus}{Cl}O_4$, $[\alpha]_D^{25}=+8.20°$).[14]

The benzylethylmethylsulfonium tetrafluoroborate obtained was subjected to anion exchange by its aqueous acetone solution to an Amberlite IRA-400 column (ClO_4^-). Evaporation of the solvents and recrystallization of the residue from CH_2Cl_2–Et_2O gave crystals of $MeEt\overset{\oplus}{S}CH_2Ph\overset{\ominus}{Cl}O_4$; $[\alpha]_D^{25}$ *ca.* 0 (*c* 6.0, CH_2Cl_2).

Reaction between I and Sodium Thiophenolate. Sodium thiophenolate (1.3 g, 5.3 mmol) was added to a dichloromethane solution (10 ml) of I (0.70 g, 5.3 mmol). Reaction was soon completed. Diphenyl disulfide, methyl *p*-tolyl sulfoxide, methyl ether, methyl phenyl sulfide and methyl *p*-tolyl sulfide were obtained as the products. The amounts of methyl phenyl sulfide and methyl *p*-tolyl sulfide were determined by NMR spectroscopy.

Reaction between I and Sodium p-*Toluenesulfinate.* Anhydrous sodium *p*-toluenesulfinate (4.5 g, 25.3 mmol) was slowly added with stirring to a dichloromethane solution (30 ml) of I (3.9 g, 15.3 mmol). Exothermic reaction occurred. After one day, the solution was separated from the solids. Evaporation of the solution yielded crystals and oil. Crystals were found to be di-*p*-tolyl α-disulfone. Vacuum distillation of the oil yielded methyl *p*-tolyl sulfide (40 °C/0.02 mmHg) and a mixture of methyl *p*-toluenesulfinate and methyl *p*-toluenesulfonate (50—70 °C/0.02 mmHg).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3507—3510 (1973)

Studies on Aminosugars. XXXV. Syntheses of 3′,4′-Dideoxyneamine and 3′- and 4′-*O*-Methylneamines[1]

Tetsuo JIKIHARA,* Tsutomu TSUCHIYA,* Sumio UMEZAWA,* and Hamao UMEZAWA**

**Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223*

***Institute of Microbial Chemistry, Kamiosaki, Shinagawa-ku, Tokyo 141*

(Received July 9, 1973)

3′,4′-Dideoxyneamine and 3′- and 4′-*O*-methylneamines have been prepared from neamine *via* 5,6-*O*-cyclohexylidene-tetra-*N*-methoxycarbonylneamine (**2**).

As described in previous papers, 3′-deoxykanamycin[2] and 3′,4′-dideoxykanamycin B[3] exhibited strong antibiotic activity against resistant bacteria carrying R factor and resistant *Pseudomonas aeruginosa*, whereas 3′-*O*-methylkanamycin[2,4] was inactive, suggesting the steric hindrance of binding of the antibiotic with ribosomes by 3′-*O*-methyl group. The present investigation was undertaken to prepare an active neamine derivative against resistant bacteris, and to confirm the occurrence of the same steric hindrance in neamine which is an essential moiety of kanamycin B.

In order to protect the four amino groups, neamine was treated with methyl chloroformate in aqueous acetone to give tetra-*N*-methoxycarbonylneamine (**1**). The methyl chloroformate was here selected instead of ethyl or benzyl chloroformate because *N*-methoxycarbonyl group was expected to be stable in acidic

1) A part of this paper was read by S. Umezawa at Symposium of New Natural Products Syntheses, XXIIIrd International Congress of Pure and Applied Chemistry at Boston, U.S.A., July 28, 1971; XXIIIrd ICPAC, Vol. 2, 173, Butterworth, London. methanol used in a later reaction. The compound **1** was allowed to react with 1,1-dimethoxycyclohexane in dimethylformamide (DMF) in the presence of catalytic amount of *p*-toluenesulfonic acid at 50 °C under reduced pressure.[5] In the initial stage of this reaction, three derivatives, 3′,4′- and 5,6-*O*-monocyclohexylidene derivatives (**2′** and **2**, respectively) and 3′,4′;5,6-di-*O*-cyclohexylidene derivative (**2″**, minor) were formed but after standing overnight, the derivative **2′** disappeared and a mixture of **2** and **2″** was obtained. Addition of methanol converted **2″** to **2** and the conversion to the starting material (**1**) was very slight. Chromatographic separation gave **2** in a yield of 78%.

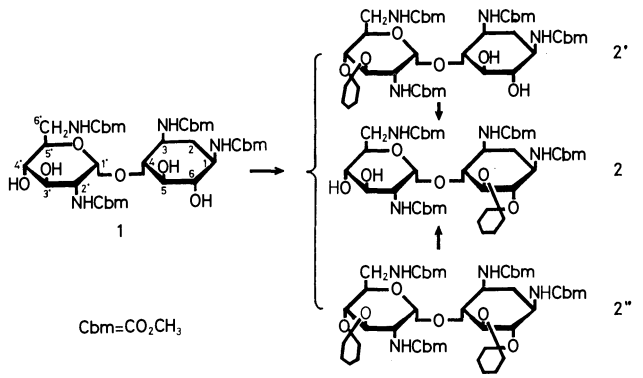

Chart 1.

Mesylation of **2** gave 3′,4′-di-*O*-mesyl derivative (**3**), and treatment of **3** with sodium iodide and zinc dust in DMF, similarly as described in a previous paper,[3] gave 3′-eno derivative (**4**) in a yield of 80%. Catalytic hydrogenation gave 3′,4′-dideoxy derivative (**5**), and removal of the protecting groups in a usual way gave 3′,4′-dideoxyneamine (**6**). Similar deblocking of the 3′-eno derivative (**4**) gave 3′,4′-dideoxy-3′-enoneamine (**7**).

To prepare 3′- and 4′-*O*-methylneamines, compound **2** was subjected to methylation. In preliminary experiments, methylation with methyl iodide–silver oxide and methyl iodide-barium oxide was tried, however, *O*-methylation with these reagents was accompanied by *N*-methylation, rendering the isolation of products difficult. Haworth methylation with dimethyl sulfate–aqueous sodium hydroxide was suitable in this case. Since attempts to separate 3′- and 4′-*O*-methyl derivatives (**8a**, **8b**) was unsuccessful, the mixture was acetylated and then chromatographed over silica gel to give 4′-*O*-acetyl-3′-*O*-methyl- and 3′-*O*-acetyl-4′-*O*-methyl derivatives (**9a**, **9b**) which were thereafter deblocked by the usual method to give 3′-*O*-methylneamine (**10**) and 4′-*O*-methylneamine (**11**), respectively.

The structures of **10** and **11** were confirmed by tetramine copper(II) sulfate (TACu)[6] method. The reagent forms a copper complex exclusively with vicinal amino and hydroxyl groups, which exhibits $\Delta[M]_{436\,(TACu)}$ $\pm 900°$ if the groups have —60° dihedral angle. The compound **10** showed $\Delta[M]_{TACu}$ +730°. The high positive increment indicated that a complex is formed at 1-NH_2 and 6-OH groups. In **11**, TACu forms complexes both at 1-NH_2 and 6-OH, and at 2′-NH_2 and 3′-OH, resulting in a small increment by the intramolecular compensation of the contributions of the two complexes opposite in sign and approximately equal in magnitude.

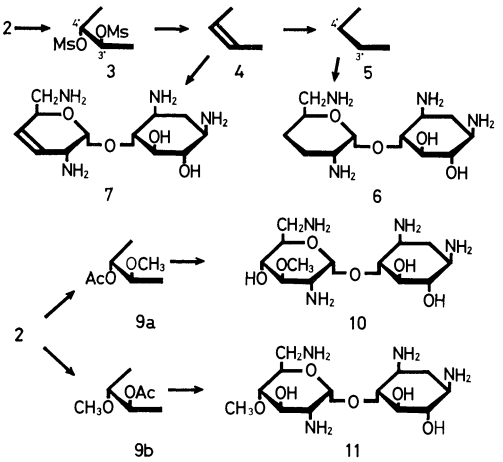

Chart 2.

The synthetic 3′,4′-dideoxyneamine showed[1] antibacterial activity against resistant *E. coli* and *Pseudomonas aeruginosa*, whereas 3′- and 4′-*O*-methylneamines showed markedly decreased activity, suggesting that, though the hydroxyl groups do not play important role in the mechanism of antibacterial action, there is a strong steric factor associated with the hydroxyl groups.

Experimental

Thin layer chromatography (tlc) was carried out on silica gel and the spots were visualized with sulfuric acid.

Tetra-N-*methoxycarbonylneamine (1)*[7]. Crude product of **1** obtained by the procedure reported[8] was desalted by dissolving it in hot dioxane and the dioxane-soluble product was reprecipitated from methanol, $[\alpha]_D^{20}$ +67° (*c* 0.5, water).

Found: C, 42.50; H, 6.40; N, 9.53%. Calcd for $C_{20}H_{34}N_4O_{14}\cdot 1/2\,H_2O$: C, 42.63; H, 6.26; N, 9.94%.

NMR (dimethyl sulfoxide-d_6): τ 6.80, 6.60, 6.50, 6.43 (3H, s, each, $-COOCH_3$).

5,6-O-Cyclohexylidene-tetra-N-*methoxycarbonylneamine (2)*. To the suspension of **1** (5.43 g) in dry DMF (57 ml), 1,1-dimethoxycyclohexane (5.76 ml) and fuse-dried *p*-toluenesulfonic acid (170 mg) were added and the mixture was heated at 55 °C under stirring and reduced pressure (20 Torr). After 20 min, the starting material (R_f 0 on tlc with chloroform–ethanol (8:1)) disappeared and after 1.5 hr the mixture became composed from three products (R_f 0.9 (**2″**), 0.45 (**2**) and 0.40 (**2′**)). The solution was allowed to stand overnight at 25 °C, whereupon *2′* almost disappeared. Methanol (3 ml) was added and the solution was allowed to stand at 45 °C for 1.5 hr. By this treatment, **2** became major constituent

and **2″**, minor one. Saturated sodium hydrogen carbonate solution was added and the mixture was evaporated. The residue was extracted with chloroform and the solution was evaporated to give a pale brown solid (5.8 g). This was chromatographed on a column of silica gel (300 g) with chloroform–ethanol (12:1) containing 1% triethylamine. The portions containing **2** and **2″** were evaporated to give solids, 4.85 g (78%) and 0.9 g, respectively. **2**: $[\alpha]_D^{25}$ +37° (*c* 1, methanol).

Found: C, 49.44; H, 6.82; N, 8.93%. Calcd for $C_{26}H_{42}N_4O_{14}$: C, 49.20; H, 6.67; N, 8.83%.

NMR spectra of the compounds **2′** and **2″** showed the presence of mono- and di-cyclohexylidene group, respectively.

5,6-O-Cyclohexylidene-3′,4′-di-O-mesyl-tetra-N-methoxycarbonylneamine (3). To a solution of **2** (1.89 g) in dry pyridine (37 ml), mesyl chloride (1.0 g) was added and the solution was allowed to stand at 30 °C overnight and then at 50 °C for 2 hr. After addition of 0.3 ml of water, the solution was concentrated to approximately one-tenth of the original volume and the concentrate was poured into saturated sodium hydrogen carbonate solution. The precipitate was extracted with chloroform and the extract was washed with water, dried over sodium sulfate and evaporated. The residue was chromatographed on a short column of silica gel (30 g) with chloroform–ethanol (15:1) containing 1% triethylamine. The portion containing **3** was evaporated to give a solid, 2.24 g (95%), $[\alpha]_D^{25}$ +50.4° (*c* 1, methanol).

Found: C, 42.77; H, 5.85; N, 6.97; S, 7.89%. Calcd for $C_{28}H_{46}N_4O_{18}S_2$: C, 42.53; H, 5.86; N, 7.09; S, 8.11%.

NMR ($CDCl_3$): τ 6.90 and 6.73 (each 3H, s, SO_2CH_3).

5,6-O-Cyclohexylidene-3′,4′-dideoxy-3′-eno-tetra-N-methoxycarbonylneamine (4). To a solution of **3** (1.28 g) in dry DMF (30 ml), anhydrous sodium iodide (15 g) and zinc dust (7 g) were added and the mixture was heated in an oil bath (98 °C) for 2 hr under stirring. Chloroform (70 ml) was added and the resulting precipitate was removed by centrifugation and the precipitate was washed with chloroform. Mother solution and the washings combined were mixed with sodium hydrogen carbonate solution and, after filtration, the filtrate was evaporated to give a syrup, which was dissolved in chloroform. The solution was washed with sodium thiosulfate solution and with water, dried over sodium sulfate and evaporated to give amorphous powder, 0.78 g (80%), $[\alpha]_D^{25}$ −39° (*c* 1, methanol).

Found: C, 52.08; H, 6.78; N, 9.10%. Calcd for $C_{26}H_{40}N_4O_{12}$: C, 52.00; H, 6.71; N, 9.33%.

NMR ($CDCl_3$): τ 4.28 (2H, slightly broadened s, H-3′,4′).

5,6-O-Cyclohexylidene-3′,4′-dideoxy-tetra-N-methoxycarbonylneamine (5). A solution of **4** (368 mg) in methanol (7 ml) containing water (0.2 ml) was hydrogenated with platinum oxide and hydrogen (50 psi) at room temperature for 3 hr. The reaction mixture was filtered and evaporated to give amorphous powder, 339 mg (92%), $[\alpha]_D^{23}$ +34° (*c* 0.6, methanol).

Found: C, 51.58; H, 6.95; N, 9.20%. Calcd for $C_{26}H_{42}N_4O_{12}$: C, 51.82; H, 7.03; N, 9.30%.

NMR ($CDCl_3$): τ 4.92 (1H d, J=3.5 Hz, H-1′), 6.30, 6.32 and 6.34 (6H, 3H, 3H, s, respectively, $NHCO_2C\underline{H}_3$), 8.1—8.8 (~15H broadened signal, cyclohexylidene protons, H-3′,3′,4′,4′ and H-2_{ax}).

3′,4′-Dideoxyneamine (6). To a solution of **5** (299 mg) in methanol (5.3 ml), 0.5 M barium hydroxide solution (17 ml) was added and the mixture was heated at 105 °C for 11 hr. Carbon dioxide was introduced at 100 °C and the precipitate was removed by centrifuging and the precipitate was washed with hot water. Mother solution and the washings combined were evaporated to give a residue, which was again dissolved in water, filtered, and evaporated. The solid residue was dissolved in 1 M hydrochloric acid (5 ml) and the solution was refluxed for 1 hr. After concentration with occasional addition of water, the concentrate was neutralized with Amberlite IRA-400 (OH form) to pH 4 and, after filtration, the solution was charged on a column of Amberlite CG 50 (NH_4^+ form) and developed with 0—0.3 M ammonia with gradual increase in concentration. 2-Deoxystreptamine and by-products were eluted in an early stage (at about 0.2 M ammonia) and **6** followed (at about 0.3 M ammonia). The portion containing **6** was evaporated to give a solid, 115 mg (74%), $[\alpha]_D^{20}$ +102° (*c* 1, water).

Found: C, 48.56; H, 9.12; N, 18.42%. Calcd for $C_{12}H_{26}N_4O_4\cdot 1/2H_2O$: C, 48.14; H, 9.09; N, 18.72%.

NMR (D_2O): τ 9.1—7.8 (6H m, H-2,3′,4′), 4.82 (1H d, J=3.5 Hz, H-1′). The pattern at τ 9.1—7.8 was quite similar with that of 3′,4′-dideoxykanamycin B base[3].

3′,4′-Dideoxy-3′-enoneamine (7). Compound **4** (1.9 g) was treated similarly as described for the preparation of **6** from **5** and the product obtained by treatment of Amberlite CG 50 column chromatography was neutralized with sulfuric acid solution. Addition of methanol gave a solid, which was further purified by passing a short column of active carbon, 802 mg (80%), $[\alpha]_D^{20}$ −19.4° (*c* 1, water).

Found: C, 27.85; H, 6.40; N, 10.28; S, 12.28%. Calcd for $C_{12}H_{24}N_4O_4\cdot 2H_2SO_4\cdot 2H_2O$: C, 27.69; H, 6.20; N, 10.76; S, 12.32%.

NMR (D_2O): τ 8.3—7.2 (2H m, H-2), 4.30 (1H d, J=3 Hz, H-1′), 4.1—3.5 (2H m, H-3′,4′). The pattern at τ 4.1—3.5 was similar with that of methyl 2,6-diamino-2,3,4,6-tetradeoxy-α-D-*erythro*-hex-3-enopyranoside sulfate.[8]

A Mixture of 5,6-O-Cyclohexylidene-tetra-N-methoxycarbonyl-3′-O-methylneamine (8a) and 5,6-O-Cyclohexylidene-tetra-N-methoxycarbonyl-4′-O-methylneamine (8b). To a solution of **2** (2.90 g) in acetone (58 ml), 30% sodium hydroxide solution (4 ml) and dimethyl sulfate (1 ml) were added and the mixture was stirred at room temperature for 1 hr. On tlc with chloroform–2-propanol (15:1) the solution showed three spots of R_f 0.26 (**8a**+**8b**), 0.35 (mono-*O*-methyl-mono-*N*-methyl derivatives) and 0.5 (di-*O*-methyl derivative). Ammonia solution was added and, after stirring for a while, the solution was evaporated to give a residue, which was dissolved in chloroform and the solution was washed with sodium hydrogen carbonate solution and with water, dried over sodium sulfate and evaporated. A pale yellow residue (2.8 g) was chromatographed on a column of silica gel (120 g) with chloroform–2-propanol (25:1). The portion containing **8a** and **8b** was evaporated to give a solid, 1.40 g (47%).

Found: C, 50.21; H, 6.95; N 8.32%. Calcd for $C_{27}H_{44}N_4O_{14}$: C, 49.99; H, 6.84; N, 8.64%.

4′-O-Acetyl-5,6-O-cyclohexylidene-tetra-N-methoxycarbonyl-3′-O-methylneamine (9a) and 3′-O-Acetyl-5,6-O-cyclohexylidene-tetra-N-methoxycarbonyl-4′-O-methylneamine (9b). The mixture of **8a** and **8b** described above was treated with acetic anhydride and pyridine in a usual manner to give a mixture of monoacetyl derivatives quantitatively. On tlc with chloroform–2-propanol, the mixture showed a spot of R_f 0.5, while on tlc with benzene–ethyl acetate (1:4), it showed two spots of R_f 0.26 (**9a**) and 0.39 (**9b**), although **8a** and **8b** could not be separated by column chromatography with this system. The mixture (1.4 g) was chromatographed on a column of silica gel (95 g) with benzene–ethyl acetate (2:5) and the portions containing **9a** (640—1200 ml portion) and **9b** (300—570 ml portion) were evaporated to give solids, 0.58 g (42%) and 0.72 g (52%), respectively. **9a**: mp 129—131 °C, $[\alpha]_D^{20}$ +46° (*c* 1, methanol).

Found: C, 50.28; H, 6.54; N, 8.04%. Calcd for $C_{29}H_{46}N_4O_{15}$: C, 50.43; H, 6.71; N, 8.11%.

NMR ($CDCl_3$): τ 8.8—8.2 (11H, cyclohexyl and H-2_{ax}), 7.88 (3H s, OAc), 6.55 (3H s, OCH_3), 6.31 (12H s, $NHCO_2CH_3$), 5.12 (1H t, J=9.5 Hz, H-4′), 4.81 (1H d, J=3.5 Hz, H-1′). **9b**: mp 123—127 °C, $[\alpha]_D^{20}$ +44° (*c* 1, methanol).

Found: C, 50.56; H, 6.85; N, 8.00%. Calcd for $C_{29}H_{46}N_4O_{15}$: C, 50.43; H, 6.71; N, 8.11%.

NMR ($CDCl_3$): τ 8.8—8.2 (11H), 7.92 (3H s, OAc), 6.53 (3H s, OCH_3), 6.53 (3H), 6.32 (6H) and 6.28 (3H) (each s, $NHCO_2CH_3$), 4.83 (1H t, J=10 Hz, H-3′), 4.80 (1H d, J=3.5 Hz, H-1′).

3′-O-Methylneamine (10). A sample of **9a** was treated likewise as described in the preparation of **6** from **5**, yield 74%, $[\alpha]^{20}$ +122° (*c* 1, water), $\Delta[M]^{20}_{436\,(TACu)}$ +730°.

Found: C, 43.86; H, 8.59; N, 16.06%. Calcd for $C_{13}H_{28}N_4O_6\cdot H_2O$: C, 44.05; H, 8.53; N, 15.81%.

NMR (D_2O): τ 8.80 (1H q, J=12 Hz, H-2_{ax}), 8.02 (1H double t, J=4, 4 and 13 Hz, H-2_{eq}), 6.40 (3H s, OCH_3), 4.71 (1H d, J=3.5 Hz, H-1′).

4′-O-Methylneamine (11). A sample of **9b** was treated as above, yield 78%, $[\alpha]_D^{20}$ +126° (*c* 1, water), $\Delta[M]^{20}_{436\,(TACu)}$ −200°.

Found: C, 43.93; H, 8.56; N, 16.00%. Calcd for $C_{13}H_{28}N_4O_6\cdot H_2O$: C, 44.05; H, 8.53; N, 15.81%.

NMR (D_2O): τ 8.80 (1H q, J=12 Hz, H-2_{ax}), 8.02 (1H double q, J=4, 4 and 13 Hz, H-2_{eq}), 6.44 (3H s, OCH_3), 4.72 (1H d, J=3.5 Hz, H-1′).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3510—3513 (1973)

(1,3-Dithiolan-2-yl)trimethylammonium Iodide. An Electrophilic Dithiolanylating Reagent[1)]

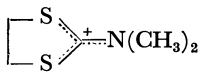
Kazuhisa HIRATANI, Takeshi NAKAI, and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

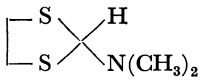
(Received July 13, 1973)

The reactions of (1,3-dithiolan-2-yl)trimethylammonium iodide (**5**), readily obtained by methylation of 2-dimethylamino-1,3-dithiolane (**2**), with aromatic amines were studied. It was found that **5** served as an electrophilic 1,3-dithiolanylating reagent; the reactions with aniline, *N*-methylaniline, and benzylamine gave *N*-dithiolanylated products while those with *N*,*N*-dimethylaniline and indole yielded exclusively *C*-dithiolanylated products *via* aromatic substitutions. Furthermore, *C*-dithiolanylated compounds were hydrolyzed to aldehydes using HgO–$BF_3 \cdot OEt_2$. The present aldehyde synthesis has been compared with an alternative electrophilic formylation method, the Vilsmeier reaction.

In a previous paper[2)] we reported that the hydride reduction of various dithiocarbamidium ions including 2-dimethylamino-1,3-dithiolan-2-ylium ion (**1**) gave the corresponding formamide thioacetals in moderate yields. In the present work the synthetic utility of 2-dimethylamino-1,3-dithiolane (**2**) obtained from **1** has been studied.

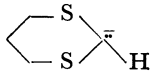


1

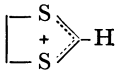


2

The utility of thioacetals, especially 1,3-dithianes, for the synthesis of aldehydes and ketones has been well established.[3)] In most cases, however, the introduction of the dithianyl group was nucleophilically carried out by using dithianyl anion (**3**) and electrophiles such as alkyl halides. On the other hand, little information has been available on the electrophilic introduction of dithianyl or dithiolanyl group mainly because dithiolanyl cation (**4**) has not been characterized.[4)] Recently the formation of **4** has been only observed in the mass spectrum of 1,3-dithiolane[5)] and in the process of oxidation of 1,3-dithiolane derivatives by 2,3-dichloro-5,6-dicyano-1,4-quinone.[6)]



3



4

In this work, in order to obtain a new electrophilic dithiolanylating reagent derived from **2**, the quarternary ammonium salts (**5**) were prepared by methylation of **2** with methyl iodide, and the reactions of **5** with various nucleophiles (NuH), mostly electron-rich aromatic compounds, have been investigated. Furthermore, the

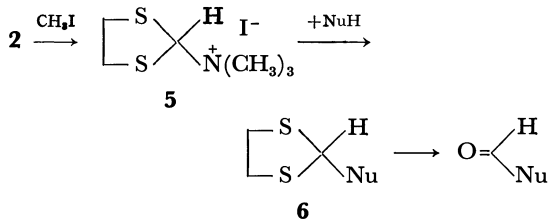
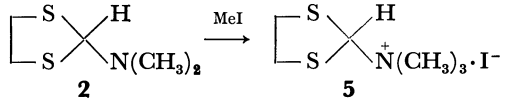
hydrolysis of some resultant 1,3-dithiolanes (**6**) to aldehydes has been studied.



The scope and limitation of the use of reagent **5** for dithiolanylating nucleophiles also described and compared with those of Vilsmeier's reagent, one of the most well-known of electrophilic formylating reagents.

Results and Discussion

Preparation of (1,3-Dithiolan-2-yl)trimethylammonium Iodide (5). Dithiolane **2** was prepared by the hydride reduction of dithiolanylium perchlorate (**1**) using sodium dihydrobis(2-methoxyethoxy)aluminate (RDB).[2] **2** was also obtained by the following more convenient method. Treatment of dimethylformamide (DMF) in tetrahydrofuran (THF) with 1,2-ethanedithiol in the presence of an equimolar amount of benzoyl chloride gave **2** in 76% yield. This was quarternarized with methyl iodide in aprotic solvents giving (1,3-dithiolan-2-yl)trimethylammonium iodide (**5**) in 83% yield. The NMR spectrum of **5** in dimethyl sulfoxide-d_6 showed three singlet signals at δ 3.16 (N–CH_3), 3.60 (S–CH_2), and 6.83 (=C–H).



The NMR spectrum confirmed that the methylation occurred on the nitrogen, not on the sulfur atom of **2**. It should be noted that the methine proton of **5** has an absorption at a much lower field (δ 6.85) than that of **2** (δ 6.01) due to quarternarization of the dimethylamino group of **2**.

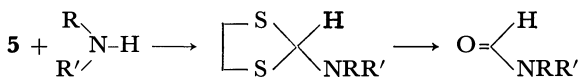
Reactions of the Ammonium Salt 5 with Various Aromatic Amines. Ammonium iodide **5** is expected to be capable of dithiolanylating nucleophiles analogously to cation **4**, accompanied by the elimination of trimethylamine. In this work, the reactions of **5** with the following aromatic amines were studied: aniline, *N*-methylaniline, *N,N*-dimethylaniline, indole, benzylamine, diphenylamine, and phenothiazine. The reactions were carried out in DMF at 40 °C for 1 hr giving products (**6**) having 1,3-dithiolanyl group along with trimethylammonium iodide except for the cases of diphenylamine and phenothiazine in which the reactants were recovered unchanged. The structures of **6** were elucidated by elemental analysis and spectroscopic methods. In particular the position of the dithiolanylation was determined by NMR and IR spectroscopic methods, and, in some cases, confirmed through identification of aldehydes obtained from the hydrolysis of the dithiolanylated products described below. The yields and physical properties of (**6**) are summarized in Table 1. We see that the position of

Table 1. 1,3-Dithiolanylation of Aromatic Compounds

Aromatics	Product	Yield %	Mp, °C (bp, °C/mmHg)
Aniline	**6a**	72	liq.[a]
N-Methylaniline	**6b**	51	liq.[a] (125—129/1.0)[b]
N,N-Dimethylaniline	**6c** 	54	103—104
Indole	**6d** 	78	116—119
Benzylamine	**6e** 	57	liq.[a]
Diphenylamine, Phenothiazine	No Reactions		

a) Purified by column chromatography. b) Prepared by the hydride reduction of carbonium ion, see Experimental.

the introduced 1,3-dithiolanyl group varies with the structure of the aromatic amine employed. In the cases of aniline, *N*-methylaniline, and benzylamine, only *N*-dithiolanylated products were obtained. On the other hand, the reactions of **5** with *N,N*-dimethylaniline and indole gave exclusively *C*-dithiolanylated products *via* aromatic displacement reactions. The former *N*-dithiolanylating reaction might provide a versatile method for synthesizing a variety of formamide thioacetals, eventually formamides from primary and secondary amines. The *N*-dithiolanyl group can be converted into the *N*-carbonyl groups by the hydrolysis: for example, treatment of *N*-(1,3-dithiolanyl)-*N*-methylaniline (**6b**) with HgO–$BF_3 \cdot Et_2O$ gave *N*-phenyl-*N*-methylformamide in 78% yield.



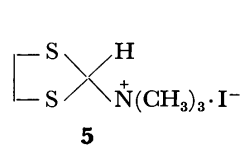
The observed orientation of the aromatic *C*-dithiolanylation, on the other hand, is in agreement with the orientation observed with other electrophilic aromatic substitutions of these aromatic amines, *e.g.* the Vilsmeier reaction.[7]

Hydrolysis of the Dithiolanylated Products to Aldehydes. The hydrolysis of the *N*-dithiolanylated product (**6b**) and the *C*-dithiolanylated products (**6c** and **6d**) was studied. Hydrolysis was accomplished by using red mercury oxide–boron trifluoride etherate[8] in aqueous THF yielding the corresponding aldehydes in good yields. The aldehydes thus obtained were identified by IR spectra and comparisons of their physical properties with those of authentic samples. In short,

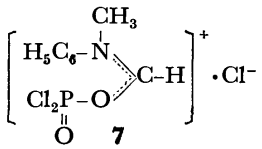
7) The *para* position in *N,N*-dimethylaniline and the 3-position in indole are the most reactive sites for electrophilic substitution: For a review of the Vilsmeier reaction, see M.-R. Maheas, *Bull. Chim. Soc. Fr.*, **1962**, 1982.

8) E. Vedejs and P. L. Fuchs, *J. Org. Chem.*, **36**, 366 (1971).

ammonium salt **5** can be used as an electrophilic formylating reagent just as Vilsmeier's reagent, *e.g.*, *N*-formyl-*N*-methylaniline–phosphorus oxychloride complex (**7**).[9]

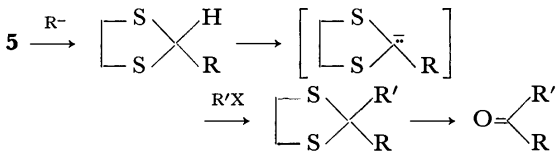


5



7

Let us compare the present aldehyde synthesis with the Vilsmeier reaction. First, it should be emphasized that a synthetic advantage of the present method over the Vilsmeier method is that aldehyde precursors, 1,3-dithiolanylated compounds, can be readily isolated, hence, a subsequent desirable reaction can be carried out under the protection of the aldehyde group by the 1,3-dithiolane ring. Isolation of the 1,3-dithiolanylated products might provide a unique method for ketone synthesis *via* the following sequences.



Secondly, it is concluded that the range of application of the present aldehyde synthesis covers more limited aromatics and heterocyclics, compared with Vilsmeier's reagent. Ammonium salt **5** did not react with diphenylamine, phenothiazine or anisole, while Vilsmeier's reagent is capable of undergoing aromatic substitution with these aromatics giving aldehydes. It can be said that the electrophilic reactivity of **5** is smaller and more selective than that of Vilsmeier's reagent (**7**).

Experimental

General. All melting and boiling points are uncorrected. IR and UV spectra were recorded with Hitachi EPI-S2 and EPS-3T spectrophotometers, respectively. NMR spectra were obtained with Japan Electron Optics JNN PS-100 and MH-60 spectrometers. Chemical shifts are reported in ppm from tetramethylsilane as an internal standard.

2-Dimethylamino-1,3-dithiolane (2). Dithiolane **2** was prepared by the hydride reduction of the dithiolanylium salt **1** following previous procedures.[2] In a large scale experiment the following alternative method is recommended which is a modification of the procedures of R. Ohme[10] employed for the synthesis of trialkyl orthoformates.

In a 200-ml three-necked flask, equipped with a mechanical stirrer, dropping funnel and thermometer, was placed a solution of 7.3 g (0.10 mol) of DMF and 9.4 g (0.10 mol) of 1,2-ethanedithiol in 100 ml of THF, which was then cooled below 0 °C. To the stirred solution was added dropwise 14.1 g (0.10 mol) of benzoyl chloride over a period of 1 hr. The reaction temperature was then raised up to 40 °C and the mixture was stirred for 6 hr. The reaction flask was cooled to room temperature giving white precipitates which were filtered and washed three times with 50-ml portions of ether. The precipitates were then dissolved in cooled water and to the aqueous solution was added dropwise an aqueous sodium carbonate solution until the solution became weakly basic. The solution was extracted three times with100-ml portions of ether. The combined ether solutions were dried over anhydrous sodium sulfate. After removal of the drying agent followed by distillation of the ether, distillation of the liquid residue gave 11.4 g (76.5%) of **2**. bp 78—79 °C/2.0 mmHg (lit[2] 57—58 °C/1.5 mmHg). The physical properties and spectra data of this distillate were in agreement with those of an authentic sample.[2]

Preparation of (1,3-Dithiolan-2-yl)trimethylammonium Iodide (5). To a solution of 8.0 g (54 mmol) of **2** in 100 ml of THF was added excess methyl iodide. The mixture was stirred at room temperature for 3 hr giving white precipitates which were filtered and washed several times with THF. Recrystallization of the precipitates from anhydrous acetonitrile gave 13 g (83%) of white crystals, mp (dec.) 152 °C. Found: C, 24.91; H, 4.71; N, 4.95%. Calcd for $C_6H_{14}NS_2I$: C, 24.75; H, 4.85; N, 4.81%.

Reaction of 5 with Aniline. In a 50-ml three-necked flask equipped with a mechanical stirrer, condenser and thermometer was placed a solution of 1.50 g (5.1 mmol) of **5** in 20 ml of DMF. To the stirred solution was added 0.50 g (5.3 mmol) of aniline. The mixture was stirred at 40 °C for 1 hr, and then poured into water. The aqueous solution was extracted three times with 50-ml portions of ether. The combined ethereal solutions were washed four times with water and dried over anhydrous magnesium sulfate. Removal of the ether gave 1.0 g of a pale brown oil. The oil was subjected to chromatography on silica gel with chloroform giving 0.70 g (72%) of **6a**; IR (neat): 3340 cm^{-1} (N-H); NMR (CCl_4): δ 3.24 (m, 4H, S-CH_2), 4.1—4.5 (broad, 1H, N-H), 6.33 (d 1H C-H), and 6.5—7.4 (m, 5H, aromatic-H) UV (EtOH, nm): 248.5.

Reaction of 5 with N-Methylaniline. In a similar manner, the reaction of **5** (1.50 g, 5.1 mmol) with *N*-methylaniline (0.60 g, 5.6 mmol) in 20 ml of DMF at 40 °C for 1 hr gave an oil (0.90 g). The oil was subjected to chromatography on silica gel with chloroform. The first eluent gave 0.54 g (51%) of **6b**; n_D (25 °C) 1.640. The second eluent contained 0.24 g of the starting material, *N*-methylaniline. The IR and UV spectra of **6b** were in complete agreement with those of an authentic sample prepared by the reaction of 2-(*N*-methyl-*N*-phenylamino)-1,3-dithiolan-2-ylium perchlorate with sodium dihydrobis(2-methoxyethoxy)aluminate (yield, 66%), bp 125—129 °C/1.0 mmHg; n_D (25 °C) 1.639. **6b**; NMR (CCl_4): δ 2.92 (s, 3H, N-CH_3), 3.17 (m, 4H, S-CH_2), 6.98 (m, 1H, C-H), and 6.7—7.7 (m, 5H, aromatic-H); UV (EtOH, nm): 253. Found: C, 56.05; H, 6.10; N, 6.10%. Calcd for $C_{10}H_{13}NS_2$: C, 56.83; H, 6.20; N, 6.63%.

Reaction of 5 with N,N-Dimethylaniline. In a similar manner, the reaction of **5** (1.50 g, 5.1 mmol) with *N,N*-dimethylaniline (0.62 g, 5.1 mmol) in 20 ml of DMF at 30—40 °C for 2 hr gave 0.61 g (54%) of **6c** which was recrystallized from ethanol giving colorless plates, mp 103—104 °C; NMR ($CDCl_3$): δ 2.94 (s, 6H, N-CH_3), 3.44 (m, 4H, S-CH_2), 5.77 (s, 1H, C-H), 6.74 (d, 2H, aromatic-H), and 7.49 (d, 2H, aromatic-H); UV (EtOH, nm): 270. Found: C, 59.00; H, 6.72; N, 6.06%. Calcd for $C_{11}H_{15}NS_2$: C, 58.62; H, 6.71; N, 6.21%.

Reaction of 5 with Indole. In a similar manner, the reaction of **5** (1.50 g, 5.1 mmol) with indole (0.59 g, 5.0 mmol) in 20 ml of DMF at 40 °C for 2 hr gave 0.90 g (78%) of **6d** which was recrystallized from ethanol giving colorless plates, mp 116—119 °C; IR (KBr): 3400 cm^{-1} (N-H); NMR ($CDCl_3$): δ 3.50 (m, 4H, S-CH_2), 6.23 (s, 1H, C-H), 7.47 (m, 4H, aromatic-H), and 7.95—8.30 (broad, 2H, N-H

and 2-C–H) ppm; UV (EtOH, nm): 221.5, 274, 280, and 290.5. Found: C, 59.36; H, 5.00; N, 6.27%. Calcd for $C_{11}H_{11}NS_2$: C, 59.69; H, 5.01; N, 6.33%.

Reaction of **5** *with Benzylamine.* In a similar manner, the reaction of **5** (1.50 g, 5.1 mmol) with benzylamine (0.50 g, 4.7 mmol) in 20 ml of acetonitrile at 60 °C for 3 hr gave 0.60 g (57%) of **6e** which was purified by means of column chromatography (silica gel) giving a colorless liquid; n_D (20 °C) 1.623; IR: 3330 cm^{-1} (N–H); NMR ($CDCl_3$): δ 1.94 (s, 1H, N–H), 3.23 (s, 4H, SCH_2), 3.93 (s, 2H, N–CH_2), 5.91 (s, 1H, C–H), and 7.38 (s, 5H, aromatic–H). Found: C, 56.83; H, 6.08; N, 6.43%. Calcd for $C_{10}H_{10}NS_2$: C, 56.83; H, 6.20; N, 6.63%.

Hydrolyses of 1,3-Dithiolanyl Compounds with Mercury Oxide (Red) Boron Trifluoride Etherate. a) p-*(1,3-Dithiolan-2-yl)*-N,N-*dimethylaniline (6c)*: In a 50-ml three-necked flask, equipped with a mechanical stirrer, dropping funnel, gas inlet, condenser and thermometer, was placed a suspension of 0.59 g (2.7 mmol) of red mercury oxide and 0.38 g (2.7 mmol) of boron trifluoride etherate in 1: 9 THF–water (10 ml). The mixture was stirred at room temperature under nitrogen atmosphere and then 0.30 g (1.3 mmol) of **6c** in 20 ml of THF was added dropwise to the mixture over a period of 0.5 hr. After the reaction mixture was stirred at room temperature for 1 hr, precipitates formed were filtered and the filtrate was poured into water. The aqueous solution was extracted three times with 50-ml portions of ether, and the combined ether solutions were washed three times with water and dried over anhydrous magnesium sulfate. After removal of the drying agent followed by distillation of the ether, 0.80 g of a yellow oil was obtained. The oil was subjected to chromatography on silica gel with benzene giving 0.17 g (85%) of *p-N,N*-dimethylaminobenzaldehyde; mp 71—73 °C (lit[11] 73 °C).

b) 3-(1,3-Dithiolan-2-yl)indole (6d): In a similar manner, the reaction of **6d** (0.30 g, 1.3 mmol) with red mercury oxide (0.59 g, 2.7 mmol) and boron trifluoride etherate (0.38 g, 2.7 mmol) gave 0.16 g (80%) of 3-formylindole; mp 189—191 °C (lit[12] 193—195 °C).

c) N-*(1,3-Dithiolan-2-yl)*-N-*methylaniline (6b)*: In a similar manner, the reaction of **6b** (1.05 g, 5.0 mmol) with red mercury oxide (2.0 g, 10 mmol) and boron trifluoride etherate (1.4 g, 10 mmol) gave 0.52 g (78%) of *N*-methylanilide. The IR spectrum of this product was in complete agreement with that of an authentic sample.

(Received July 19, 1973)

7-Bromo-7-fluoronorcarane, 1-bromo-1-fluoro-2-phenylcyclopropane, and 7-bromo-7-fluoro-2-oxanorcarane were reduced with tri-*n*-butylsilane or di-*n*-butylsilane at 100—145 °C in the presence of a small amount of radical initiator, to afford the corresponding monofluorocyclopropanes. It has been found, by examining the stereochemistry of the reduction, that the extent of stereospecificity is dependent on the reaction temperature as well as on the kind of the silicon hydride used. Comparison of these results with those of the tri-*n*-butyltin hydride reduction shows that the reactivity of metal hydrides as a reducing agent of *gem*-dihalocyclopropanes is in the order $Bu_3SnH > Bu_2SiH_2 > Bu_3SiH$. These observations are well explained by postulating that the α-fluorocyclopropyl radical has a pyramidal configuration and that the extent of stereospecificity is determined by the relative rates of its inversion of configuration and its hydrogen abstraction from the tin or silicon hydride. The reduction of 7,7-dibromonoracrane with tri-*n*-butylsilane or di-*n*-butylsilane gave a mixture of the two geometrical isomers of 7-bromonoracrane, whose composition (*endo*-Br/*exo*-Br≒3.0) was nearly identical irrespective of the reaction temperature and of the reactivity of silicon hydride.

It has been known that organosilicon hydrides are capable of reducing organic halides.[1] Thus, the reduction of chloro- or bromoalkanes has been effected with triethylsilane in the presence of aluminum chloride,[2,3] and with trichlorosilane under irradiation of light.[4] Palladium-catalyzed reactions of tri-substituted organosilanes with halocarbons including aromatic halides are also known to result in halogen-hydrogen exchange, to afford a good yield of organosilicon halides.[5] It has been suggested that the reduction of aliphatic halides with organosilicon hydrides proceeds by an ionic mechanism in the presence of aluminum chloride,[2] and by a free-radical chain mechanism under irradiation of light.[4]

Nagai and his collaborators[6] have found that the reduction with organosilicon hydrides in the liquid phase can be effected by use of radical initiator such as benzoyl peroxide, and proposed the following mechanism:

$$\text{Initiator} \longrightarrow \text{In}\cdot$$
$$\text{In}\cdot + R_3SiH \longrightarrow InH + R_3Si\cdot$$
$$R_3Si\cdot + R'X \longrightarrow R_3SiX + R'\cdot$$
$$R'\cdot + R_3SiH \longrightarrow R'H + R_3Si\cdot$$

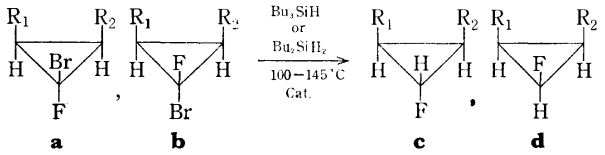
The mechanism shown above is very similar to the one proposed for the reduction of organic halides with organotin hydrides,[7] which have been found to reduce *gem*-halofluorocyclopropanes in an essentially stereospecific manner to yield the corresponding monofluorocyclopropanes.[8]

This paper describes the results of the reduction of some *gem*-bromofluorocyclopropanes with tri-*n*-butyl- and di-*n*-butylsilane, with emphasis directed upon the stereochemistry of the reaction as compared with that of the organotin hydride reduction.

Results

The *gem*-bromofluorocyclopropanes employed for the present study were 7-bromo-7-fluoronorcarane (**1**), 1-bromo-1-fluoro-2-phenylcyclopropane (**2**), and 7-bromo-7-fluoro-2-oxanorcrane (**3**). They were prepared, as a mixture of two geometrical isomers (**a** and **b**), by the reaction of bromofluorocarbene with cyclohexene, styrene, and 2,3-dihydro-4*H*-pyran, respectively.[9,10]

The reduction of these *gem*-bromofluorocyclopropanes was effected by use of 1.4—3 equivalents of tri-*n*-butyl- or di-*n*-butylsilane at 100—145 °C in the presence of a small amount of azobisisobutyronitrile (AIBN) or di-*t*-butyl peroxide (DTBP), to afford the corresponding monofluorocyclopropanes (**c** and **d**).



a **b** **c** **d**

1 : R_1, R_2=-$(CH_2)_4$-
2 : R_1=Ph, R_2=H
3 : R_1, R_2=-O-$(CH_2)_3$-

The monofluorocyclopropanes thus formed were identified by comparison of their glpc retention times and infrared absorption spectra with those of authentic samples obtained by the reduction with tri-*n*-butyltin hydride.[8]

Table 1 summarizes the results of the reduction of 7-bromo-7-fluoronorcarane (**1**). As is shown in the table (run 1), the reduction of a mixture of the *exo*-F (**1a**) and the *endo*-F isomer (**1b**) with tri-*n*-butylsila neat 140—145 °C gave a mixture of 7-*exo*-fluoro- (**1c**) and 7-*endo*-fluoronorcarane (**1d**). Analysis by glpc showed the isomer ratio of the product (*exo*-F/*endo*-F=1.22) was not identical with the one of the starting material (*exo*-F/*endo*-F=1.67). This result is in sharp contrast with that of the organotin hydride reduction, where complete stereospecificity has been observed.[8] In order to obtain more detailed information about the stereochemistry of the reaction, the two isomers (**1a** and **1b**) were separated from each other by preparative glpc, and were reduced separately (runs 2—9).

When tri-*n*-butylsilane was used at 100 °C, a mixture of **1c** and **1d** was obtained either from **1a** or from **1b** (runs 2 and 6); the isomer ratio of the product was

21	Bu_2SiH_2	DTBP	140	1	75/25

78/22 or 15/85, respectively, indicating 22 or 15% inversion had occurred during the reaction. The increase of the reaction temperature to 140 °C increased the relative amount of the inversion product to 39 or 32%, respectively (runs 3 and 7).

The use of di-*n*-butyl-, in place of tri-*n*-butylsilane at 100 °C gave only one isomer of 7-fluoronorcarane with complete retention of configuration (runs 4 and 8), but at 140 °C a small amount (4—5%) of the inversion product was formed (runs 5 and 9).

Similar stereochemical results were obtained in the reduction of the *anti*-F (**2a**) and the *syn*-F isomer (**2b**) of 1-bromo-1-fluoro-2-phenylcyclopropane (**2**) at 100 °C; the reduction with di-*n*-butylsilane occurred in a more stereospecific manner than with tri-*n*-butylsilane. The experimental data are shown in Table 2.

In the reduction of the pure *endo*-F isomer (**3b**) of 7-bromo-7-fluoro-2-oxanorcarane (**3**) with di-*n*-butylsilane, a mixture of the *exo*-F (**3c**) and the *endo*-F isomer (**3d**) of 7-fluoro-2-oxanorcarane was formed even at 100 °C. Here again, it was observed that the use of tri-*n*-butylsilane or the increase of the reaction temperature caused the increase of the relative amount of the inversion product (**3c**). The data are given in Table 3.

In Table 4 are shown the results of the reduction of 7,7-dibromonorcarane (**4**). It proceeded much more readily than that of its bromofluoro analogue (**1**), and gave a mixture of 7-*exo*-bromo- (**5c**) and 7-*endo*-bromonorcarane (**5d**). The isomer ratio of the product (*endo*-Br/*exo*-Br=3.0), which was not affected appreciably either by the reaction temperature or by the kind of silicon hydride, was not very different from the one observed in the reduction with tri-*n*-butyltin hydride.[12]

Discussion

Tri-*n*-butyltin hydride has been shown to reduce *gem*-chlorofluorocyclopropanes at 80 °C in the presence of an appropriate radical initiator such as AIBN, and *gem*-bromofluorocyclopropanes at room temperature in the absence of catalyst, to afford the corresponding monofluorocyclopropanes.[8,9] Since neither tri-*n*-butyl- nor di-*n*-butylsilane could reduce *gem*-chlorofluorocyclopropanes even at 140 °C in the presence of radical initiator, and since the reduction of *gem*-bromofluorocyclopropanes with di-*n*-butylsilane occurred under milder conditions than with tri-*n*-butylsilane, it may be concluded that the reactivity of these hydrides increases in the order $Bu_3SiH < Bu_2SiH_2 < Bu_3SnH$. This order of reactivity is in good agreement with the recent work of Kaplan,[13] who compared the hydrogen-transfer ability of some group IV hydrides and found the order $Ph_3SiH < Ph_2SiH_2 < Ph_3GeH < Ph_3SnH$.

The fact that the reduction with organosilicon hydrides could not be effected in the absence of radical initiator strongly suggests that the reaction follows a free-radical chain mechanism similar to the one already proposed for the reduction of aliphatic halides.[4,6] Very probably it involves the intermediate formation of the α-fluorocyclopropyl radical as one of the chain-

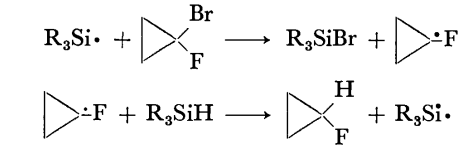
propagating steps, and may be formulated as follows:

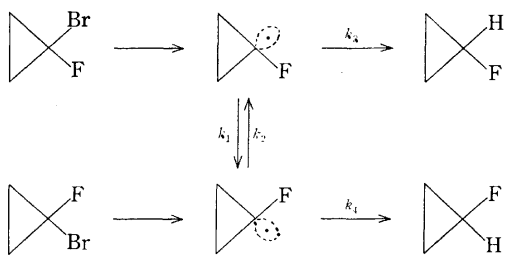
Initiator ⟶ In·

$In\cdot + R_3SiH \longrightarrow InH + R_3Si\cdot$



As was described in the preceding section, the reduction of *gem*-bromofluorocyclopropanes with organosilicon hydrides is essentially less stereospecific than that with organotin hydrides under similar conditions. Moreover, the isomer ratio of the product, *i.e.*, the extent of stereospecificity, is dependent on the reaction temperature as well as on the kind of silicon hydride used.

These observations are well explained by postulating that the α-fluorocyclopropyl radical has a pyramidal structure and that the extent of stereospecificity is determined by the relative rates of its hydrogen abstraction from the silicon or tin hydride (k_3 or k_4), and of its inversion of configuration (k_1 or k_2).



If the reduction is effected with organotin hydrides, which possess an extremely high reactivity toward radicals,[14] the hydrogen transfer from the hydride to the α-fluorocyclopropyl radical should occur at a much faster rate than the inversion of configuration. If the reduction is effected with the less reactive organosilicon hydrides, however, the rate of hydrogen transfer should become slower, and the extent of stereospecificity should be decreased. The experimental results are in good agreement with these expectations. The higher stereospecificity associated with di-*n*-butyl- than tri-*n*-butylsilane may be attributed to the higher reactivity of di-*n*-butyl- than tri-*n*-butylsilane toward radicals.

The low stereospecificity in the reduction of 7-bromo-7-fluoro-2-oxanorcarane (**3**), relative to 7-bromo-7-fluoronorcarane (**1**), is another problem of interest. As analogous effect of ring oxygen has been noted in the reduction of 7-chloro-7-fluoro-2-oxanorcarane with tri-*n*-butyltin hydride,[8] although the origin of the effect is not yet clear at present.

Experimental

Materials. *gem*-Bromofluorocyclopropanes **1**, **2**, and **3** were prepared by the addition reaction of bromofluorocarbene, generated from dibromofluoromethane and potassium *t*-butoxide, to the corresponding olefin.[9] The separation of isomers **1a** and **1b**, and of **2a** and **2b**, was performed by preparative glpc (7.5% TCP on 60/80 Celite 545 at 100 °C and at 80 °C, respectively). The isolation of pure **3b** was accomplished by treating the reaction mixture, containing both **3a** and **3b**, with quinoline at 140 °C for 2 hr, followed by vacuum distillation. Tri-*n*-butylsilane, bp 102—104°/21 mmHg (lit,[15] 215—220 °C), was prepared by the reaction of trichlorosilane with an excess of *n*-butylmagnesium bromide in ether; yield 77%. Di-*n*-butylsilane, bp 63 °C/28 mmHg (lit,[16] 160 °C/773 mmHg), was prepared by the reduction of di-*n*-butylchlorosilane, obtained from trichlorosilane and two equivalents of *n*-butylmagnesium bromide, with lithium aluminum hydride; yield 62%.

7,7-Dibromonorcarane (**4**) was prepared by the addition reaction of dibromocarbene to cyclohexene.

General Procedure for Reduction of gem-*Bromofluorocyclopropane* (**1**, **2**, and **3b**). In a 30 ml, three-necked flask fitted with a thermometer, a magnetic stirrer, an inlet tube for nitrogen, and a reflux condenser was placed a mixture of a *gem*-bromofluorocyclopropane (1.3—3.2 g), 1.4—3 equivalents of tri- or di-*n*-butylsilane, and a small amount of radical initiator (AIBN or DTBP). It was stirred under nitrogen under the condition shown in Table I, II, or III. The isomer ratio of the products was determined by glpc (5% Apiezon Grease L on 60/80 Celite 545 at 80—100 °C) before distillation. In general, the *exo*- or *anti*-F isomer (**1c**, **2c**, or **3c**) had a shorter retention time than the *endo*- or *syn*-F isomer (**1d**, **2d** or **3d**). The yields were calculated by glpc analysis with mesitylene or *n*-dodecane as internal reference. The identification of the products was made by comparing their glpc retention times and infrared absorption spectra with those of authentic specimens.[8] In the reduction of **2** and **3b**, some unidentified by-products were formed.

Reduction of 7,7-Dibromonorcarane (4). The procedure was essentially the same as the one described above. The reaction conditions listed in Table IV were sufficient for 100% conversion. In glpc the *exo*-Br isomer (**5c**) had a shorter retention time than the *endo*-Br isomer (**5b**). The products were identified by comparison with authentic specimens.[12]

Cycloaddition Reaction of Cycloheptatriene and Nitrosobenzene Derivatives

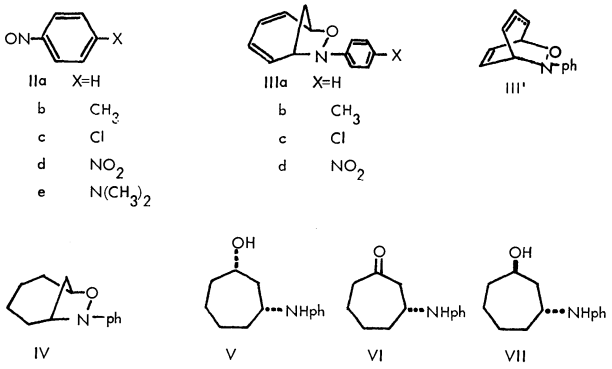
Shô Itô, Sen-ichi Narita,* and Katsuya Endo
Department of Chemistry, Tohoku University, Sendai 980
(Received July 23, 1973)

Structures of the cycloaddition products obtained from cycloheptatriene and *para*-substituted nitrosobenzene have rigorously been established by NMDR experiments and by degradation of the representative member, the cycloheptatriene-nitrosobenzene adduct, to 3-anilinocycloheptanone. All the adducts were found to be of [6+2] type. The ionic mechanism has been proposed for the cycloaddition in order to account for the substitution effect on the benzene ring.

The reaction of cycloheptatriene and nitrosobenzene is known to yield a 1 : 1 cycloaddition product.[1] Structure of this compound was once assigned to be III' in analogy with the similar reactions of the latter and various conjugated polyenes.[2] This structure was later revised to IIIa on the basis of spectroscopic and a few chemical informations.[3] However, discrimination between two structures seemed insufficient on the spectroscopic data presented and an attempted direct chemical confirmation failed.[3] This paper presents conclusive chemical as well as spectroscopic evidences, which unambiguously establish the structure IIIa for the adduct, and also deals with the discussion on the nature of the reaction.

Reaction of cycloheptatriene (I) and nitrosobenzene (IIa) at room temperature for three days yielded a colorless crystalline product IIIa in 17% yield. The melting point and all the spectroscopic properties are in agreement with the values previously reported.[1,3] Proton magnetic resonance signals (100 MHz) of IIIa appear at δ 2.01—2.60 (m, 2H, $-CH_2-$), 4.22 (m, 1H, HCN–), 4.81 (m, 1H, HCO–), 6.03 (br.s, 4H, olefinic H) and 6.9—7.4 ppm (m, 5H, phenyl). NMDR experiment, irradiating at the methylene signals simplified both signals at 4.22 and 4.81 ppm, but caused no effect on the rest, while irradiation of both methine signals (NMTR) altered the methylene resonance to a clean AB pattern with J=12 Hz. These observations unambiguously establish the location of the methylene group next to both methines, and hence, combined with the informations reported before,[1,3] eliminate all possible structures but IIIa.

This conclusion was further confirmed by the chemical correlation. The adduct IIIa was catalytically reduced to the tetrahydro derivative IV.[1] The N–O linkage was then cleaved by zinc in acetic acid to afford an anilinocycloheptanol V, which was then oxidized with manganese dioxide to give the corresponding ketone VI. This ketone was identical (mixed mp, IR and NMR) with 3-anilinocycloheptanone prepared from 2-cycloheptenone and aniline in absolute ethanol. Sodium borohydride reduction of the ketone VI afforded another 3-anilinocycloheptanol VII in a quantitative yield. Consideration of the reaction sequence allowed assignment of *cis* and *trans* configuration for V and VII, respectively.



Several *p*-substituted nitrosobenzene derivatives (IIb—d) also yielded the similar type of products (IIIb—d), but the rate of the reaction, therefore the yield of the product, depends very much on the *para* substituents on the benzene ring. Thus electron—withdrawing substituents such as chlorine or nitro group markedly enhanced the reactivity as well as the product yields, while strong electron donating substituents such as dimethylamino group completely inhibited the reaction, and IIe was recovered unchanged after 30 days under the reaction condition (*cf.* Table 1). These accelerating effects are in the sequence of $NO_2>Cl>H>CH_3>N(CH_3)_2$ which is parallel to Hammett's σ value.

In all the cases when the reaction was observed, the [6+2] type of structures were secured by NMR data

Table 1. The cycloaddition of cycloheptatriene and para-substituted nitrosobenzene derivatives

Substituent	Reaction condition[a]	Product (yield %)
$N(CH_3)_2$	30 days at room temp.	No reaction
CH_3	6 days at room temp.	IIIb (5.9%)
H	3 days at room temp.	IIIa (11.6%)
Cl	3 days at toom temp.	IIIc (17.3%)
NO_2	5 hrs at 0 °C[b]	IIId (6.3%)

a) The reaction was carried out in $CHCl_3$ at dark under N_2 atmosphere.
b) Rapid decomposition of IId takes place at room temperature even at 0 °C. No IId was detected after 5 hr.

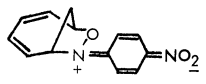
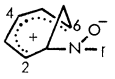
for the products. The UV spectra of these adducts having maxima at 240 and 265 nm, are also very similar to each other, except for the *p*-nitronitrosobenzene adduct, IIId, which exhibits maxima at 237 and 352 nm. Contribution of the resonance structure IIId′ may be responsible for this anomaly.



IIId′



[A]

A small amount of azoxybenzenes correspond to the nitrosobenzenes employed were always formed during the reaction. Although the formation of these compounds suggests the occurrence of a hydride transfer between cycloheptatriene and nitrosobenzene derivatives resulting in the possible formation of tropylium ion, the latter is not involved in the cycloaddition reaction, since tropylium perchlorate and *p*-chloronitrosobenzene (IIc) resulted in the exclusive formation of tropone and *p,p′*-dichloroazoxybenzene (VIIIc) when reacted in aqueous dioxane (1 : 2) at room temperature.

These results indicate that the reaction is the type between an electron rich triene and an electron deficient nitrosobenzene derivative, remniscent of electronic requirement in normal Diels-Alder reactions.[4]

Since the concerted thermal [6s+2s] cycloaddition is forbidden,[5] the present reaction must proceed through either concerted [6s+2a] or an ionic or a free radical mechanism. Although the experiments described above do not fully discriminate these three possibilities, the observation that the 1 : 1 adduct is the only product isolated even in the presence of excess of nitrosobenzenes, which is a good radical scavenger, suggests the radical mechanism unlikely. On the other hand, the substitution effect observed would favor the ionic mechanism. Thus the electron deficient nitrogen of the nitroso group attacks the π-electron system of cycloheptatriene resulting in the dipolar intermediate [A]. This may then cyclize at either one of the cationic centers at 2, 4, and 6. Consideration of angle strain as well as the conjugation of double bond in the product leaves the 1,6-bonding most probable.

Experimental

All the melting points are uncorrected. The IR spectra were recorded on a Hitachi EPI-2 spectrophotometer, and UV spectra on a Hitachi ESP-3 spectrometer. The NMR spectra were observed with Varian HA-100 and/or A-60 spectrometer, using $CDCl_3$ as a solvent, unless otherwise stated. The chemical shifts are given in ppm relative to the internal TMS. The coupling constants are shown in Hz (s: singlet; d: doublet; t: triplet; q: quartet; m: multiplet). The mass spectra were obtained on a Hitachi RMU-6D and RMU-7 mass spectrometer operating an ionization energy of 70 eV.

9-Phenyl-8-oxa-9-azabicyclo[4,2,1]nona-2,4-diene (IIIa). A solution of nitrosobenzene (IIa, 987 mg) and cycloheptatriene (I, 5 g) in chloroform (30 ml) was allowed to stand for 3 day under nitrogen. The solution was then concentrated under a reduced pressure, and the residue chromatographed on a silica gel column. Petroleum ether–benzene eluted a colorless compound, which was identified as azoxybenzene (VIIIa) by its IR spectra. Further chromatography with benzene–chloroform eluted a colorless compound (IIIa, 285 mg, 11.6%), mp 108—109°C (from cyclohexane); *m/e* 156, 107, 92, 91; λ_{max}^{MeOH} 238 nm (ε 12300), 264 nm (ε 6300); δ 2.01—2.60 (m, 2H), 4.22 (m, 1H), 4.81 (m, 1H), 6.03 (br. s, 4H), 6.9—7.4 (m, 5H). These spectroscopic data agreed well with those reported for IIIa.[1,3]

A similar reaction in benzene at 0—5 °C for 16 day resulted in somewhat better yield (17.5%).

Reaction of Cycloheptatriene and para*-Substituted Nitrosobenzene Derivatives.* The reaction and work up followed the procedure described above. The reaction conditions were listed in Table 1. Dimethylaminonitrosobenzene (IIe) was recovered unchanged after 30 days under the reaction condition. IIIb: mp 99—100 °C (from petroleum ether); Found: C, 79.74; H, 7.16%. Calcd for $C_{14}H_{15}NO$: C, 78.84; H, 7.09%. *m/e* 213 (M^+); λ_{max}^{MeOH} 238 nm (ε 13300), 265 nm (ε 8300); δ 2.18 (s, 3H), 2.30 (m, 2H), 4.21 (m, 1H), 4.84 (m, 1H), 6.09 (m, 4H), 7.01 and 7.07 (q, AB type, J=9.0, 4H); ν_{max}^{KBr} 1615, 1505, 1301, 1167. *p,p′*-Dimethylazoxybenzene (VIIIb) mp 69—71 °C. IIIc: mp 101—102 °C (from cyclohexane); Found: C, 66.11; H, 5.23%. Calcd for $C_{13}H_{12}NOCl$: C, 66.81; H, 5.18%. *m/e* 235 and 233 (M^+); λ_{max}^{MeOH} 246 nm broad (ε 17600); δ 2.33 (m, 2H), 4.20 (m, 1H), 4.81 (m, 1H), 6.05 (m, 4H), 7.20 and 7.35 (q, AB type J= 9.0, 4H); ν_{max}^{KBr} 1590, 1448, 1291, 1169, 1086. *p,p′*-Dichloroazoxybenzene (VIIIc) mp 156—157 °C. IIId: mp 107—108° (from benzene-cyclohexane); Found: C, 63.98; H, 4.99%. Calcd for $C_{13}H_{12}N_2O_3$: C, 63.92; H, 5.39%. *m/e* 244 (M^+); λ_{max}^{MeOH} 237 nm (ε 9600), 352 nm (ε 11000); δ 2.51 (m, 2H), 4.45 (m, 1H), 4.90 (m, 1H), 6.14 (m, 4H), 7.06 and 8.22 (q, AB type, J=9.5, 4H); ν_{max}^{KBr} 1592, 1505, 1338, 1242, 1175, 1112, 1089.

Catalytic Hydrogenation of IIIa. A solution of IIIa (140 mg) in methanol was hydrogenated for 4 hr in the presence of PtO_2 (15 mg). Concentrate of the mixture, after the removal of the catalyst, was chromatographed on a silica gel column. Elution with chloroform yielded pale yellow oil (IV, 80 mg), which crystallized on standing. Mp 27—28 °C, *m/e* 203 (M^+); λ_{max}^{MeOH} 239 nm (ε 9400); $\nu_{max}^{liq.}$ 2920, 1600, 1490, 1198, 1008, 762, 696; δ 1.20—2.06 (m, 6H), 4.03 (m, 1H), 4.86 (m, 1H), 7.33 (m, 5H).

cis-*3*-N-*Phenylaminocycloheptanol (V).* The hydrogenation product IV (70 mg) and HCl-activated zinc powder (200 mg) was stirred in acetic acid (10 ml) under nitrogen for 30 min. The mixture was partly neutralized (pH—5) with 2M aqueous sodium hydroxide and then made alkaline with sodium carbonate. The chloroform extract of the resulting solution was worked up as usual to afford a pale yellow oil (V, 62 mg) which was purified further by chromatography. $\nu_{max}^{liq.}$ 3350, 1605, 1506, 1302, 1028, 750, 698; δ ~1.8 (m, 10H), 3.43 (m, 1H), 3.93 (m, 1H), 6.47—7.32 (m, 5H). V crystallizes with a mole of ether of crystallization, mp 48—51 °C.[1]

3-N-*Phenylaminocycloheptanone (VI).* A chloroform solution (5 ml) of V (110 mg) was added to a suspension of active manganese dioxide (600 mg) in the same solvent (15 ml) and the mixture was stirred at room temperature for 18 hr under nitrogen. The reaction mixture was filtered and the filtrate chromatographed on silica gel. Elution

with chloroform afforded a crystalline product (IV, 21 mg), mp 63—64 °C (from *n*-hexane); Found: C, 76.78; H, 8.73; N, 6.14%. Calcd for $C_{13}H_{17}NO$: C, 76.81; H, 8.43; N, 6.86%. *m/e* 203 (M^+); λ_{max}^{MeOH} 249 nm (ε 14600), 296 nm (ε 2500); ν_{max}^{KBr} 3350, 1692, 1602, 1506, 1315, 1280, 991, 745, 694; δ 1.80 (m, 8H), 2.65 (m, 2H), 3.61 (br. 2H), 6.90—7.40 (5H).

Michael Addition of Aniline to 2-Cycloheptenone. 2-Cycloheptenone (301 mg), prepared from 2-bromocycloheptanone and quinoline, was allowed to react with aniline (5 ml) in absolute ethanol (5 ml) at room temperature for 20 hr. The reaction mixture was worked up normally to yield a colorless crystalline compound, mp 62—63 °C (from *n*-hexane); mixed mp with VI 62—63 °C. All the spectroscopic properties were identical with those of VI.

$NaBH_4$ Reduction of VI. The reduction of VI (55 mg) with $NaBH_4$ (50 mg) in methanol (7 ml) at room temperature for 1 hr followed by usual work up yielded an isomeric alcohol VII, mp 86—87 °C (from cyclohexane); *m/e* 205 (M^+); ν_{max}^{KBr} 3350, 1601, 1494, 1035, 760, 700.

Reaction of p-*Chloronitrosobenzene with Tropylium Perchlorate.* Tropylium perchlorate (764 mg) and *p*-chloronitrosobenzene (IIc) (471 mg) was stirred in dioxane-water (2:1, 40 ml) for 2 hr under nitrogen. Along the reaction proceeded, the green solution turned to yellow and crystalline particles precipitated. The crystals were collected and recrystallized to give 334 mg (78%) of *p,p'*-dichloroazoxybenzene (VIIIc), mp 156—157 °C. The filtrate was worked up normally, followed by silica gel chromatography to yield 22 mg of tropone, which was identified by its IR spectra.

The authors are grateful to Dr. T. Nishida and Mr. I. Miura at NEVA, Ltd., for the NMDR and NMTR measurements.

Layered Compounds. XV.[1] Synthesis and Properties of Multilayered Cyclophanes

Tetsuo Otsubo, Shigeyoshi Mizogami, Ikuko Otsubo, Zenzaburo Tozuka, Akiko Sakagami, Yoshiteru Sakata, and Soichi Misumi

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

(Received August 10, 1973)

A series of multilayered cyclophanes up to sixfold were synthesized by 1,6-Hofmann elimination method. Odd layered and some dissymmetric ones were derived by means of cross-breeding pyrolysis of mixed quaternary ammonium hydroxides. The electronic spectra, absorption, emission, and CT absorption of charge-transfer complexes, of these cyclophanes exhibited remarkable transannular π-electronic interaction among chromophores closely stacked by methylene bridges. The interaction is increased eminently when the layer is varied from single to quadruple, but becomes less effective from quadruple to fivefold and no longer appreciable for more than fivefold one.

Aromatic compounds in which two or more chromophores are closely bound by methylene bridges, *i.e.*, layered compounds, are known as quite suitable models for the study of the transannular π-electronic interaction. [2.2]Paracyclophane,[2] one of the typical layered compounds, has been extensively studied by Cram and his co-workers from the viewpoints of the transannular interaction which results from the face-to-face proximity of two benzene rings to one another and many unusual chemical and physical behaviors have been reported to appear.[3] Such a face-to-face compression of the benzene rings brings about extreme molecular deformation or strain to the molecule, *i.e.*, extraordinarily short ring-to-ring distances, elongated benzyl–benzyl σ-bonds, and boat-shaped benzene rings.[4] These striking characteristics have attracted many organic and physical chemists' attentions and thereafter led to a great development of the chemistry of "cyclophane,"[5] *e.g.*, paracyclophanes,[3] metacyclophanes,[6] layered condensed aromatic cyclophanes,[7] and heterophanes.[8]

In these studies the emphasis has been on the exploration of the double layered aromatic compounds, and there have been reported only two of more than two layered cyclophanes so far. A triple-layered cyclophane was synthesized by Hubert[9] and a quadruple-

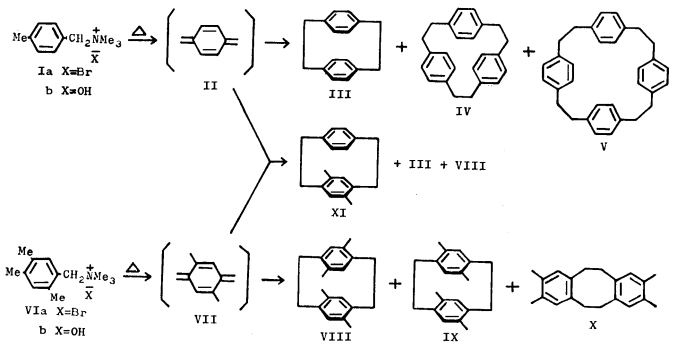


Scheme 1.

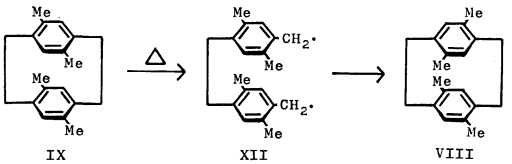
layered one by Longone,[10] but both ones were considered as mixture of configurational isomers and no report for separation was described.

In order to study the transannular interaction in more detail, we have designed syntheses of a series of multiple-layered cyclophanes. The synthesis of [2.2]-paracyclophane has been achieved by pyrolysis of *p*-xylene,[2,11] intramolecular Wurtz reaction,[12] 1,6-Hofmann elimination reaction,[8] and recently by photolysis of sulfide.[13] Of those procedures we took up the 1,6-Hofmann elimination method for synthesis of all multilayered paracyclophanes since the intermediate products were relatively accessible.

Results and Discussion

Synthesis of Double-Layered Cyclophanes (Scheme 1). On a pyrolysis of *p*-methylbenzyltrimethylammonium hydroxide (Ib), [2.2]paracyclophane(III) was obtained in 10—17% yield.[8] It is considered to proceed through *p*-xylylene intermediate II.[14] After examining a number of pyrolytic conditions we observed that when a small amount of xylene was used in the place of toluene as a solvent, its yield was raised to 29% and [2.2.2]-paracyclophane (IV)[15] and [2.2.2.2]paracyclophane (V)[16] were concomitantly obtained in 8.4 and 2.2% yields, respectively.

Longone and Chow obtained 4,7,12,15-tetramethyl-[2.2]paracyclophane (VIII) in a 20% yield along with 2,3,8,9-tetramethyl-*sym*-dibenzocyclooctadiene (X) by pyrolysis of duryltrimethylammonium hydroxide (VIb).[10] On dimerization of the intermediate VII, the dimer structure VIII where methyl groups on both rings are positioned in staggered form and the other one IX where all methyl groups are eclipsed are properly considered as the producible isomers. They reported that the product was assigned to dissymmetric form VIII on the basis of optical resolution by the Newman resolving agent and that the symmetric form IX couldn't be afforded owing to mutual overcrowding of four methyl groups.[17] By treatment with a small amount of *n*-pentane, however, we could separate a very slight amount (0.1% yield) of the sparingly soluble, eclipsed form IX (C_{2h} symmetry) from the readily soluble, staggered form VIII (D_2 symmetry).



The mass spectra of both forms show entirely identical pattern, supporting an isomeric relationship with each other. Fairly higher melting point of IX than that of VIII suggests that the former is more symmetric. Moreover, a definitive evidence for this isomeric relationship could be provided by the conversion of IX to VIII in the thermochemical process. Thus, when a solution of IX in *n*-tridecane or hexachlorobutadiene was heated at *ca.* 195 °C for 3 hr, VIII was afforded almost quantitatively, probably through a biradical intermediate (XII).[18] In addition, the structural assignment of two isomers was made on the basis of the nuclear Overhauser effect and the steric compression effect as described in the next paper.[20]

Cross-breeding pyrolysis of an equimolar mixture of Ib and VIb gave [2.2]paracyclophane (III) and its methyl derivatives VIII and XI. 4,7-Dimethyl[2.2]-paracyclophane (XI) was isolated by fractional crystallization.

Synthesis of Triple-Layered Cyclophanes (Scheme 2). Quaternary ammonium salts XIIIa and XIVa were prepared from the corresponding methyl derivatives of [2.2]paracyclophanes, XI and VIII, by successive treatments with *N*-bromosuccinimide and trimethylamine according to Longone's procedure.[10] Cross-breeding pyrolysis of a quaternary ammonium hydroxide XIIIb, derived by ion exchange from XIIIa, with Ib gave non-substituted triple-layered cyclophane (XV) together with double-layered one III and quadruple-layered ones, XIX and XX. Column chromatography on silica gel gave a 1.3% yield of XV in a pure state.

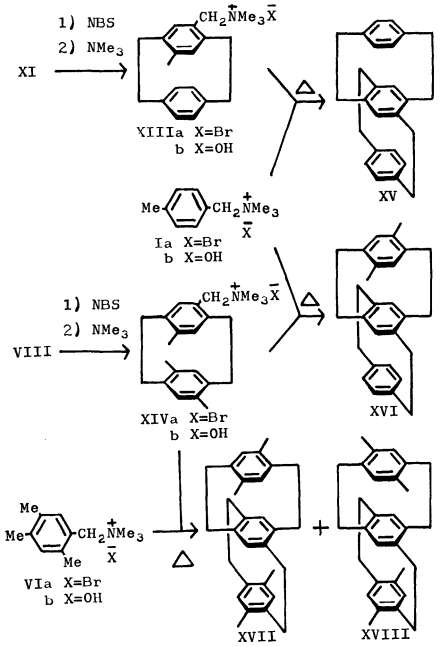
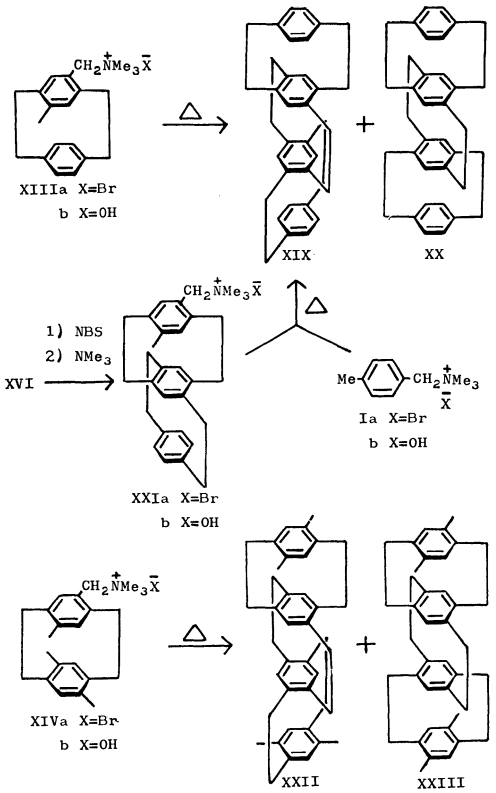


Scheme 2.

Dimethyl triple-layered cyclophane XVI was similarly prepared from XIVb and Ib in a 1.8% yield.

Tetramethyl triple-layered ones were obtained by cross-breeding pyrolysis of XIVb with VIb. Careful and elaborate column chromatography on silica gel gave a 1.1% yield of XVII and a 1.1% yield of XVIII. The structure of these isomers was determined on the basis of the chemical shifts of aromatic protons on NMR spectra. Thus, in the former isomer two signals of aromatic protons appear in a 1:2 ratio of integral strength which corresponds to the ratio of inner-to-outer aromatic protons, whereas in the latter isomer three signals appear in a 1:1:1 ratio which indicates the existence of two types of outer protons different in magnetic environment. One can easily see from the structures, XVII and XVIII, that the differences in magnetic shielding and steric crowding give rise to those aromatic proton ratios. In contrast to large difference in yields of tetramethyl double-layered compounds, VIII and IX, the formation of XVII and XVIII in a same yield may be best accounted for assuming that the steric crowding between methyl and benzylmethylene groups mutually eclipsed in XVIII might be less than that crowding between two methyl groups in IX because the methylene groups in problem would be bent toward the remaining benzene ring.

Synthesis of Quadruple-Layered Cyclophanes (Scheme 3). Pyrolysis of XIIIb in boiling xylene afforded a mixture of non-substituted quadruple-layered compounds, XIX (D_2 symmetry) and XX (C_{2h} symmetry). By treatment of the mixture with carbon tetrachloride–acetone (1:3), the readily soluble compound (1.1% yield) was separated from the sparingly soluble one (0.75% yield). The both compounds show similar NMR, IR, UV spectra, identical mass spectrum and empirical formula. It indicates obviously an isomeric relationship of both compounds. Although the structure of both isomers seemed to be difficult to determine, the easily soluble isomer could be assigned to the structure



Scheme 3.

XIX by direct comparison with an independently synthesized sample as described below. Thus, cross-breeding pyrolysis of an ammonium hydroxide XXIb, derived from dimethyl triple-layered cyclophane XVI in the usual manner, with Ib afforded only the dissymmetric isomer XIX which was proved to be identical in all respects with the readily soluble isomer obtained by pyrolysis of XIIIb. Consequently the other, sparingly soluble isomer should be assigned to more symmetric structure XX.

Longone reported the formation of a mixture of isomeric tetramethyl quadruple-layered cyclophanes,

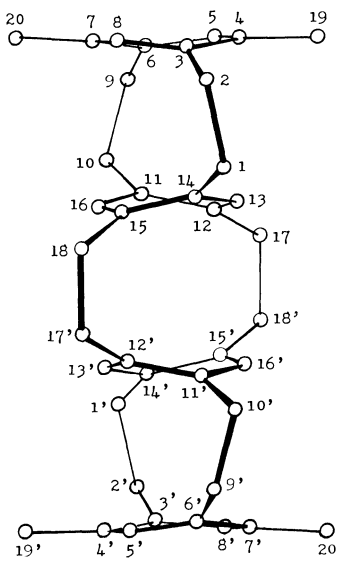


Fig. 1. Profile of quadruple-layered cyclophane XXIII viewed down the b axis.

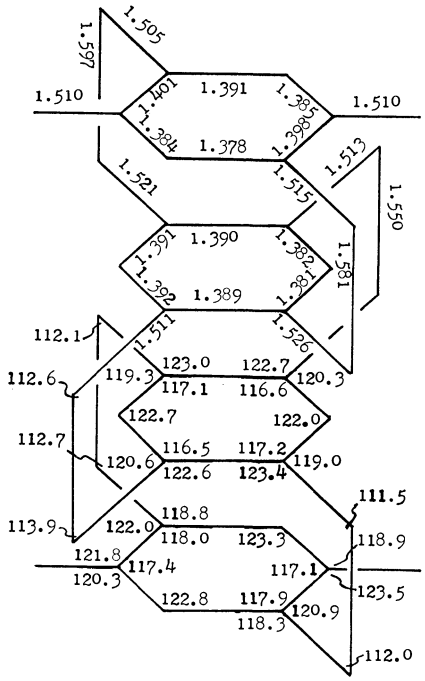

Fig. 2. Bond lengths and angles. The standard deviations are 0.010 Å in bond lengths and 0.6 ° in bond angles.

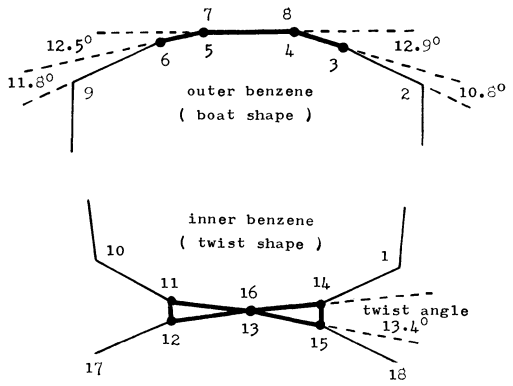

Fig. 3. Distortion of outer and inner benzene rings.

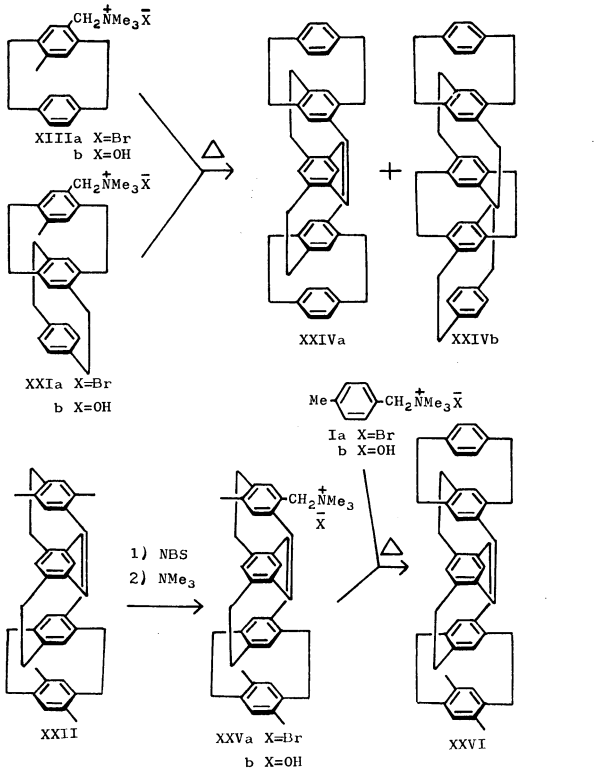
XXII (D_2 symmetry) and XXIII (C_{2h} symmetry), by pyrolysis of a quaternary base XIVb, but failed in separating them.[10] By treatment of a mixture of the isomers with the same solvent as in the case of non-substituted system, the readily soluble isomer (3.2% yield) was separated from the sparingly soluble one (1.6% yield). For the structures of two isomers we tentatively assigned the more soluble isomer to XXII (D_2 symmetry) and the less soluble one to XXIII (C_{2h} symmetry) by comparison of isomers ratio, solubility, and electronic spectra with non-substituted system. Recently the exact molecular structure of the less soluble isomer was determined by X-ray crystallographic analysis as shown in Figs. 1—3.[19] The figures show that the less soluble isomer has a C_{2h} symmetric structure and four benzene rings are closely stacked in a manner to be well superposed. Also the figures demonstrate significant strain of the molecule in such a manner that outer benzene rings are bent into boat shape as in the case of [2.2]paracyclophane (III),[4] whereas the inner rings are forced to be distorted remarkably by both π-electron repulsion between benzene rings and tension with two pairs of methylene bridges above (C_1–C_2 and C_9–C_{10} in Fig. 1) and below (C_{17}–C_{18}' and C_{18}–C_{17}') the benzene moiety and consequently deformed into a twist form as shown in Figs. 1 and 3. The four benzene layers are stacked with about equal ring-to-ring distances, that is, two outer-to-inner and one inner-to-inner. The mean value of those distances is 3.03 Å which is comparable to that of [2.2]paracyclophane and about independent of the increase of layers. Accordingly such a structural situation must be applied to all of other multilayered cyclophanes.



Scheme 4.

Synthesis of Fivefold-Layered Cyclophanes (Scheme 4). Pyrolysis of an equimolar mixture of quaternary bases XIIIb and XXIb afforded non-substituted fivefold-layered cyclophane XXIV along with quadruple-layered ones (XIX and XX) and polymers. Separation by liquid chromatography gave a 5% yield of pure XXIV which is probably a mixture of two isomers, XXIVa (D_2 symmetry) and XXIVb (C_2 symmetry).

Dimethyl derivative XXVI was obtained in a 1.1% yield by cross-breeding pyrolysis of Ib and XXVb which was prepared from tetramethyl quadruple-layered cyclophane XXII having D_2 symmetric configuration.

Synthesis of Sixfold-Layered Cyclophanes (Scheme 5). Sixfold-layered cyclophanes were obtained by pyrolysis of a quaternary base XXIb in boiling toluene. After column chromatography, a readily soluble product was

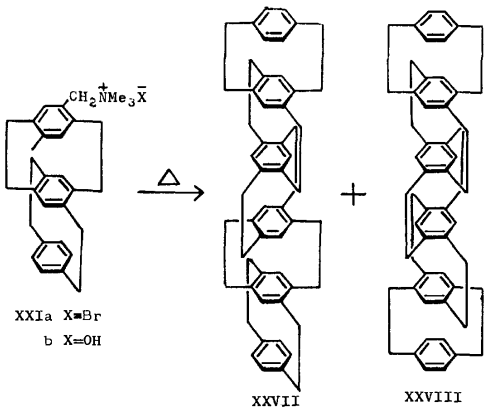

Scheme 5.

separated from a less soluble one in a 2:1 product ratio by treatment with benzene. The NMR, IR, and UV spectra of both isomers are fairly similar. On analogy with quadruple-layered cyclophanes, it is presumed that the structure of the readily soluble, major isomer is XXVII (D_2 symmetry), whereas the sparingly soluble, minor one is XXVIII (C_{2h} symmetry).

Properties. All of the multilayered cyclophanes are stable under ordinary conditions in spite of considerably strained structure. However, when the compounds are allowed to stand for a long time in halogenated hydrocarbon solvents, they decompose gradually. The isomer bearing higher symmetry generally displays higher melting point compared with the other isomer. All of more than three layered [2.2]paracyclophanes decompose with color change to brown and without melting at temperature above 240 °C.

The NMR, IR, and mass spectral data are consistent with the structures of above multilayered cyclophanes. The NMR spectra reveal a striking feature that all the aromatic protons appear at considerably higher field due to diamagnetic shielding effect.[20]

Infrared Spectra. The IR spectra of [2.2]paracyclophane system are known to reveal obvious features as follows. One is the increase of the intensity of a band in 1580—1600 cm^{-1} region, which relates to the increased double bond character due to the distortion of the benzene rings.[21] The other is the appearance of a strong new maximum at 720 cm^{-1} for [2.2]paracyclophane III and at 709 cm^{-1} for 4,7,12,15-tetramethyl[2.2]paracyclophane VIII as shown in Table 1. Longone stated that these bands might be associated with the distorted benzene rings.[22] In practice, other layered cyclophanes also exhibit the characteristic band around 700 cm^{-1}, whereas [2.2.2]paracyclophane IV bearing less strained benzene rings shows a weak band at 721 cm^{-1}, and [2.2.2.2]paracyclophane V and *p,p'*-dimethylbibenzyl bearing strain-free rings no band in this region.

More detailed examination of more than two layered, non-substituted cyclophanes shows that two bands

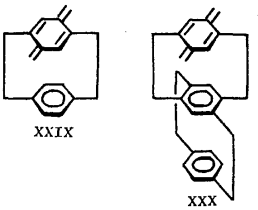
a) KBr disc.

appear near 710 cm^{-1} comparable to characteristic, lower wavenumber band of double-layered cyclophanes and near 680 cm^{-1} and that the more the number of benzene layers increases, the stronger the relative intensity of the lower wave number band to the higher one becomes. It is reasonable to assume that the higher band is associated with the boat-shaped outer benzene rings and the lower band with twist-shaped inner benzene rings.

The spectra of dimethyl compounds XVI and XXVI show a strong new peak near 695 cm^{-1} together with above two bands of which the band at 680 cm^{-1} becomes broad. On the other hand, tetramethyl derivatives XVII, XVIII, XXII, and XXIII show two absorption bands near 695 and 665 cm^{-1}. By comparing the spectra of the three groups of cyclophanes, *i.e.*, non-substituted, dimethyl, and tetramethyl compounds, the band near 695 cm^{-1} of dimethyl and tetramethyl compounds probably originates from outer benzene rings more distorted by methyl groups, whereas the band near 665 cm^{-1} of tetramethyl compounds from the twist-shaped inner benzene rings. It is also observed that the two peaks of those methylated compounds appear in slightly lower wave number than the corresponding ones of non-substituted compounds owing to methyl substituents.

Mass Spectra. [2.2]Paracyclophane exhibits a characteristic mass spectrum where molecular ion peak and a fragment one corresponding to *p*-xylylene appear as predominant signals. In the spectra of multilayered cyclophanes, it is observed in general that the molecular ion is a base peak and the more layered



20) The discussions of NMR spectra of multilayered cyclophanes will be described in detail in Part XVI: This Bulletin, **46**, No. 12 (1973) in press.

p-xylylene fragment ions such as XXIX and XXX become greater. This appears to be caused by the stabilization due to transannular charge delocalization.

Electronic Absorption Spectra. Figure 4 shows the electronic absorption spectra of non-substituted multilayered cyclophanes. The absorption curves are hardly affected by methyl substitution and show no difference in configurational isomers. The figure demonstrates strong bathochromic and hyperchromic effects as the number of layers increases successively. In particular those effects are prominent as the layer is varied from single to double. Thus a band at 270 nm associated with $^1B_{2u}$ transition of *p,p'*-dimethylbibenzyl disappears in the spectrum of [2.2]paracyclophane (III), and new peaks are observed to appear at 244, 286, and 302 nm instead. These spectral features have been explained by two predominant effects, that is, distortion of benzene ring and transannular π-electronic interaction between two rings.[23] In order to study the former effect, a series of [m]paracyclophanes were synthesized and examined.[24] The absorption bands of [m]paracyclophanes are somewhat shifted to longer wavelength with the decrease of methylene number, but the extent of deformation in absorption curves is not so large for [8]paracyclophane[25] which is considered as strain molecule comparable to [2.2]paracyclophane and even for extremely strained [7]paracyclophane.[26] Such a minor effect of the ring torsion on electronic spectra is also observed in the spectra of isomeric tetramethyl[2.2]-paracyclophanes, VIII and IX (Fig. 5). In spite of severe ring strain due to steric repulsion of mutually eclipsed methyl groups, the latter isomer shows a spectrum comparable to that of the former. As the layer is altered from double to triple, the absorption curve becomes further structureless with large bathochromic shift, increased intensity of the band near 290 nm, and appearance of a new peak at 347 nm. In this case the ring distortion effect is hardly considered to be responsible for such marked bathochromic shift because the extent of ring torsion is not so different between the double-layered and triple-layered compounds. Accordingly, the spectral change must be explained mainly by the transannular π-electronic interaction or delocalization. In theory, the configurational interactions of charge-transfer and neutral excitation states were applied with success for interpretation of the spectra of the layered paracyclophanes.[27]

With increasing layer number from the tripled to the fivefold, the absorption curves become broader successively, but the intensity per unit chromophore increases gradually. However, the spectrum of the sixfold one shows that the curve shape and the intensity per unit chromophore are nearly equal to that of the fivefold one, supporting no further increase of the transannular π-electronic interaction.

was carried out to obtain further information concerning the transannular interaction. The spectra are shown in Table 2. Both fluorescence and phosphorescence spectra exhibit large bathochromic shifts with successive increase of layer number as well as the absorption spectra just described above (Fig. 6). Such a shift is particularly remarkable as the layer is altered up to the tripled. In contrast to ambiguous positions of the longest wavelength bands in the absorption spectra, the emission maxima are clearly distinguishable for the tripled and the quadrupled cyclophanes. These spectra also indicate no further increase of transannular π-electronic interaction for more than five fold-layered cyclophanes.

Lifetime of Phosphorescence. The effect of the transannular π-electronic interaction on the various spectra of multilayered compounds can also be discussed from the lifetime of phosphorescence. As shown in Table 2, the lifetime tends to become progressively shorter and to converge in the same manner as band shifts on absorption and fluorescence spectra. It is well explainable by the postulate that the transannular π-electronic interaction lowers the energy gap between the ground and the triplet states and thereby increases the probability of radiationless deactivation.

Charge-Transfer Complexes. It is well known that in a series of π-complexes consisted of methylated benzenes and tetracyanoethylene (TCNE), there is a correlation between the position of the long-wavelength band and the association constant, K, of the complexes.[28] Increased transannular electronic interaction was also reported to be reflected in π-basicity of multilayered cyclophanes.[10,29] The transannular electron release to the complexed face ring from the remaining benzene rings is expected to take place. Table 3 and Fig. 7, indeed, show that with increasing number of layers in this series of cyclophanes, the long-wavelength maxima of TCNE complexes shift to longer wavelength and hence the donor character of the cyclophanes increases progressively. It is noteworthy that even in the case of fivefold one, such electron release is still effective for stabilization of the complex XXXI. Unfortunately, the spectrum of the sixfold compound

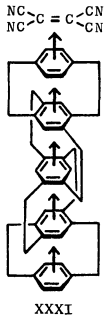
failed to be measured owing to very low solubility of its dark blue TCNE complex.



XXXI

The use of 1,3,5-trinitrobenzene (TNB) as an acceptor makes possible to measure the complex spectrum of sixfold-layered compound and also shows a tendency analogous to TCNE complexes as summarized in Table 4. Thus, the long-wavelength bands of charge-transfer complexes display marked bathochromic shift and the equilibrium constants, K_x, increase significantly as the layers increase. It is noteworthy that the complexes of fivefold and sixfold compounds exhibit quite identical spectra. In other words, there is no difference in transannular electron-releasing between them.

Experimental

Melting points are uncorrected. All solvents are of reagent grade unless otherwise specified. Chromatography was done with neutral alumina (Woelm, activity I) or silica gel (Merck, activity II—III) of about 20 to 100 times of mixture to separate. The use of a long column often results in the decomposition of multilayered cyclophanes. General procedure for Hofmann pyrolysis was described in detail in the experiment for [2.2]paracyclophane (III).

NMR measurements were made with a Hitachi Perkin-Elmer R-20 spectrometer (60 MHz) on dilute solutions in carbon tetrachloride or deuteriochloroform using tetramethylsilane as an internal standard. Infrared spectra were taken on a Jasco DS-402 spectrophotometer. Mass spectra were determined on a Hitachi RMU-7 spectrometer at 70 eV using direct insertion technique. UV spectra were recorded on a Hitachi EPS-3T spectrophotometer. Emission spectra at liquid nitrogen temperature were taken on a Hitachi MPF-2A spectrophotometer attached with a HTV R-446F photomultiplier in EPA (ethyl ether–isopentane–ethanol of 5:5:2 volume ratio) or tetrahydrofuran–ethanol (1:1 volume ratio). All solvents were of spectroscopic grade (Merck or Tokyo Kasei Kogyo) and used without further purification. A solution of about 1×10^{-3} M was prepared and degassed by freeze-pump-thaw method. Emission spectra were uncorrected. Lifetimes of phosphorescences were calculated from the exponential decay curves which were recorded on a synchroscope screen and photographed. The experimental errors are within $\pm5\%$.

[2.2]Paracyclophane (III), [2.2.2]Paracyclophane (IV), and [2.2.2.2]Paracyclophane (V). A solution of *p*-methylbenzyltrimethyl ammonium bromide (Ia, 10 g, 41 mmol) in 200 ml of distilled water was passed through a column containing strongly basic anion exchange resin, Amberite IRA-400[30] which is converted to its hydroxide form with large excess of 2 M sodium hydroxide solution. A mixture of the resulting aqueous solution (500 ml) of quaternary base (Ib), distilled xylene (50 ml), and phenothiazine (1 g) was placed in a three-necked, pear-shaped flask fitted with a mechanical stirrer and a water separator of Dean-Stark type attached

30) Instead of Amberite IRA-400, Dowex 1-X8, 50—100 mesh is currently available for ion exchange.

to a reflux condenser. The mixture was heated with stirring and water was removed as xylene azeotrope over a period of 4 hr. When the removal of water had been approximately completed, trimethylamine began to evolve and some polymers precipitated. After additional heating with stirring for 6 hr, the reaction mixture was allowed to cool and insoluble solid was separated by filtration. The solid was washed eight times with each 30 ml of hot benzene. The combined benzene washing was evaporated to dryness to give 0.83 g of crude [2.2]paracyclophane (III). The filtrate was chromatographed on neutral alumina (Woelm, activity I). Elution with benzene–hexane (1: 9) gave first 0.39 g of [2.2]paracyclophane (III), then 0.36 g (8.4%) of [2.2.2]paracyclophane (IV), and finally 0.095 g (2.2%) of [2.2.2.2]-paracyclophane (V).

The combined [2.2]paracyclophane, 1.22 g (29%), was recrystallized from chloroform, colorless prisms, mp 285 °C in a sealed tube (lit, [8]285—287 °C in a sealed tube). NMR (CCl_4) τ 3.65 (s, 8H, ArH), 6.99 (s, 8H, CH_2); mass *m/e* 208 (M^+, 56), 104 (100); IR (KBr disc, cm^{-1}) 3030 (w), 3005 (w), 2947 (w), 2920 (m), 2893 (w), 2847 (w), 1589 (m), 1497 (m), 1412 (m), 1087 (m), 936 (m), 893 (m), 806 (s), 720 (s), 622 (s), 508 (s).

[2.2.2]Paracyclophane was recrystallized from acetone, colorless plates, mp 162—163 °C (lit,[15] 166—167 °C). NMR (CCl_4) τ 3.43 (s, 12H, ArH), 7.12 (s, 12H, CH_2); mass *m/e* 312 (M^+); IR (KBr disc, cm^{-1}) 2995 (m), 2890 (s), 2830 (m), 1512 (s), 1438 (s), 1094 (m), 916 (m), 803 (m), 787 (s), 721 (w), 583 (s), 468 (s).

[2.2.2.2]Paracyclophane was recrystallized from acetone, colorless plates, mp 179—181 °C (lit,[16] 179—182 °C). NMR (CCl_4) τ 3.39 (s, 16H, ArH), 7.19 (s, 16H, CH_2); mass *m/e* 416 (M^+); IR (KBr disc, cm^{-1}) 2995 (m), 2910 (s), 2835 (m), 1510 (s), 1435 (s), 1198 (m), 1094 (m), 928 (m), 812 (s), 583 (s), 566 (m).

Staggered and Eclipsed 4,7,12,15-Tetramethyl[2.2]paracyclophanes (VIII and IX). The ammonium hydroxide aqueous solution (*ca.* 1 l) derived from 20.0 g (73.5 mmol) of duryltrimethylammonium bromide (VIa) in the usual way was mixed with 500 ml of distilled xylene and three spatulas of phenothiazine, and heated with stirring. After water was removed by azeotropic distillation, further reflux was continued for 12 hr and the mixture was cooled. The insoluble polymers (4.53 g) were removed by filtration and the filtrate was dried over anhydrous magnesium sulfate. After the solvent was evaporated, the residue was subjected to column chromatography on silica gel (Merck, activity II—III) using petroleum ether as eluent. From the first eluate was isolated a mixture of two isomeric 4,7,12,15-tetramethyl[2.2]paracyclophanes, VIII and IX. The minor isomer IX was separated from the readily soluble, staggered form VIII by treatment with a small amount of pentane. From the next eluate was isolated 2,3,8,9-tetramethyl-*sym*-dibenzocyclooctadiene (X) in a 0.4% yield.

The staggered form VIII was recrystallized from petroleum ether (yield 20%), colorless prisms, mp 106—107 °C (lit,[10] 105—107 °C). NMR (CCl_4) τ 3.75 (s, 4H, ArH), 6.8—7.6 (A_2B_2, 8H, CH_2), 8.04 (s, 12H, CH_3); mass *m/e* 264 (M^+, 66), 132 (100); IR (KBr disc, cm^{-1}) 2994 (m), 2937 (s), 2855 (m), 1604 (m), 1495 (s), 1444 (s), 1394 (m), 1367 (m), 1247 (m), 1030 (m), 902 (s), 850 (m), 819 (m), 709 (s), 512 (m), 466 (m), 440 (m).

The eclipsed form IX was recrystallized from 1: 3 carbon tetrachloride–acetone, 0.1% yield, colorless plates, mp 230—232 °C in a sealed tube. NMR (CCl_4) τ 3.93 (s, 4H, ArH), 6.5—7.7 (A_2B_2, 8H, CH_2), 7.85 (s, 12H, CH_3); mass *m/e* 264 (M^+, 66), 132 (100); IR (KBr disc, cm^{-1}) 2908 (s), 2853 (m), 1598 (m), 1497 (s), 1454 (m), 1392 (s), 1370 (m), 1030 (m), 895 (s), 708 (s), 510 (m), 434 (m). Found: C, 90.55; H, 9.14%. Calcd for $C_{20}H_{24}$: C, 90.85; H, 9.15%.

The compound X was recrystallized from ethyl acetate, colorless prisms, mp 239—240 °C after sintering at *ca.* 210 °C in a sealed tube (lit,[10] crystallized from chloroform, mp 209—211 °C in a sealed tube). Mass *m/e* 264 (M^+); NMR ($CDCl_3$) τ 3.18 (s, 4H, ArH), 7.04 (s, 8H, CH_2), 7.83 (s, 12H, CH_3); IR (KBr disc, cm^{-1}) 3000 (m), 2965 (w), 2937 (m), 2920 (m), 2855 (w), 1496 (m), 1448(s), 1328 (m), 1024 (m), 997 (m), 933 (m), 892 (s), 554 (s).

4,7-Dimethyl[2.2]paracyclophane (XI). The aqueous solution (*ca.* 600 ml) of quaternary bases, Ib and VIb, derived from a mixture of 10.0 g (40.1 mmol) of Ia and 11.1 g (40.8 mmol) of VIa in the usual way, was mixed with 100 ml of distilled xylene and 0.6 g of phenothiazine, and water was removed by azeotropic distillation with stirring. Evolution of trimethylamine began and further reflux was continued for 15 hr. The reaction mixture was cooled, insoluble polymers were filtered off, and then the filtrate was dried over anhydrous magnesium sulfate. After concentration the residue was treated with a small amount of petroleum ether, and insoluble [2.2]paracyclophane (III) was filtered off. The filtrate was chromatographed on silica gel (Merck, activity II—III) using petroleum ether for elution to give a mixture of 4,7-dimethyl[2.2]paracyclophane (XI) and 4,7,12,-15-tetramethyl[2.2]paracyclophane (VIII). The dimethyl derivative XI was purified by fractional crystallization from petroleum ether and carbon tetrachloride–acetone (1: 3), successively (yield 5.6%), colorless plates, mp 154—155 °C. NMR (CCl_4) τ 3.32 (dd, J=8 Hz, J'=2 Hz, 2H, ArH), 3.74 (dd, J=8 Hz, J'=2 Hz, 2H, ArH), 4.12 (s, 2H, ArH), 6.5—7.7 (m, 8H, CH_2), 7.95 (s, 6H, CH_3); mass *m/e* 236 (M^+, 68), 132 (100), 104 (45); IR (KBr disc, cm^{-1}) 2920 (s), 2850 (m), 1594 (m), 1496 (m), 1435 (m), 941 (m), 907 (s), 873 (m), 797 (s), 715 (s), 587 (m), 533 (m). Found: C, 91.32; H, 8.49%. Calcd for $C_{18}H_{20}$: C, 91.47; H, 8.53%.

Quaternary Ammonium Bromides, XIIIa, XIVa, XXIa, and XXVa. All the quaternary ammonium bromides, XIIIa, XIVa, XXIa, and XXVa, were prepared from the corresponding methyl derivatives according to the general procedure described below.

A given methyl cyclophane was brominated with a less amount than the equivalent of *N*-bromosuccinimide in carbon tetrachloride under reflux. After removal of insoluble succinimide, the solution was washed with water, dried over anhydrous magnesium sulfate, and then treated with an excess amount of trimethylamine in ether. The resulting white precipitate of quaternary ammonium bromide was filtered off and washed repeatedly with carbon tetrachloride. The ammonium salt thus obtained in good yield was used to the following reaction without purification.

These quaternary ammonium bromides were recrystallized from distilled water to give hydrated white crystals. XIIIa: mp 167—170 °C; NMR ($CDCl_3$) τ 3.23 (AB doublet, J=8 Hz, 1H, ArH), 3.41 (s, 1H, ArH), 3.46 (s, 2H, ArH), 3.61 (AB doublet, J=8 Hz, 1H, ArH), 3.80 (s, 1H, ArH), 5.17 (AB quartet, 2H, NCH_2), 6.69 (s, 9H, NCH_3), 6.5—7.5 (m, 8H, CH_2), 7.47 (s, H_2O), 7.89 (s, 3H, CH_3); IR (Nujol mull, cm^{-1}) 3400 (s, H_2O), 1595 (m), 975 (m), 925 (m), 875 (s), 795 (m), 717 (s), 595 (m). XIVa: dec>210 °C with melting; NMR ($CDCl_3$) τ 3.10 (s, 1H, ArH), 3.46 (s, 1H, ArH), 3.64 (s, 1H, ArH), 3.94 (s, 1H, ArH), 5.28 (AB quartet, 2H, NCH_2), 6.65 (s, 9H, NCH_3), 6.5—7.5 (m, 8H, CH_2), 7.84 (s, 3H, CH_3), 7.94 (s, 6H, CH_3), 8.11 (s, H_2O); IR (Nujol mull, cm^{-1}) 3400 (s, H_2O), 1595 (m), 975 (m), 930 (m), 885 (s), 720 (s). XXIa: dec>240 °C; NMR ($CDCl_3$) τ 3.78 (s, 5H,

ArH), 4.02 (s, 1H, ArH), 4.20 (s, 1H, ArH), 4.50 (s, 1H, ArH), 5.49 (AB quartet, 2H, NCH_2), 6.79 (s, 9H, NCH_3), 6.6—7.6 (m, 16H, CH_2), 8.08 (s, 3H, CH_3), 8.25 (s, H_2O); IR (Nujol mull, cm^{-1}) 3380 (s, H_2O), 980 (s), 880 (s), 795 (m), 710 (s), 685 (m), 515 (m).

Triple-layered [2.2]Paracyclophane (XV). A mixture of 3.5 g (9.4 mmol) of the quaternary ammonium bromide XIIIa and 2.3 g (9.4 mmol) of *p*-methylbenzyltrimethylammonium bromide (Ia) dissolved in distilled water was converted to the hydroxides, XIIIb and Ib, in the usual way using ion exchange resin. The resulting solution (*ca.* 800 ml) was mixed with 200 ml of distilled xylene and a spatula of phenothiazine, and dehydrated by azeotropic distillation under nitrogen atmosphere. After water was removed, the reaction mixture was refluxed for an additional 17 hr and allowed to cool. The insoluble polymers were removed by filtration and the filtrate was dried over anhydrous magnesium sulfate. The solvent was evaporated and the residue was chromatographed on silica gel (Merck, activity II—III). Elution with petroleum ether gave first double-layered cyclophane (III), then triple-layered one (XV), and finally quadruple-layered ones (XIX and XX).

Triple-layered compound (XV) was recrystallized from carbon tetrachloride-acetone (1:3) (yield 1.3%), colorless plates, mp 230 °C dec. in a sealed tube. NMR (CCl_4) τ 3.92 (s, 8H, ArH), 4.65 (s, 2H, ArH), 6.8—7.7 (m, 16H, CH_2); mass *m/e* 338 (M^+, 100), 234 (66), 104 (14); IR (KBr disc, cm^{-1}) 2980 (m), 2910 (s), 2840 (m), 1584 (m), 1495 (m), 1427 (s), 1405 (m), 1198 (m), 1177 (m), 968 (m), 937 (m), 901 (s), 863 (s), 794 (s), 708 (s), 680 (s), 605 (m), 517 (s). Found: C, 92.31; H, 7.72%. Calcd for $C_{26}H_{26}$: C, 92.26; H, 7.74%.

Dimethyl Triple-layered [2.2]Paracyclophane (XVI). In the same manner as non-substituted triple-layered compound XV, dimethyl triple-layered compound XVI was synthesized from quaternary ammonium bromides, XIVa and Ia. Dimethyl derivative XVI was purified by column chromatography on silica gel (Merck, activity II—III) and recrystallization from petroleum ether (yield 1.8%), colorless plates, mp 146—148 °C. NMR (CCl_4) τ 3.88 (s, 4H, ArH), 4.30 (s, 2H, ArH), 4.36 (s, 2H, ArH), 6.8—8.1 (m, 16H, CH_2), 8.17 (s, 6H, CH_3); mass *m/e* 366 (M^+, 100), 262 (10), 234 (34), 132 (12), 104 (7); IR (KBr disc, cm^{-1}) 2840 (s), 1577 (m), 1426 (s), 1165 (m), 895 (s), 870 (s), 792 (m), 710 (w), 695 (s), 673 (m), 593 (m), 520 (s). Found: C, 91.55; H, 8.29%. Calcd for $C_{28}H_{30}$: C, 91.75; H, 8.25%.

Tetramethyl Triple-layered [2.2]Paracyclophanes (XVII and XVIII). The hydroxide solution (*ca.* 1.8 l), derived from a mixture of quaternary ammonium bromides XIVa (15.6 g, 38.8 mmol) and VIa (10.7 g, 39.3 mmol) in the usual way, was mixed with 300 ml of distilled xylene and 2.0 g of phenothiazine, and then pyrolyzed as described for non-substituted compound XV. After polymers were removed, the reaction mixture was chromatographed on silica gel (Merck, activity II—III). Elution with petroleum ether gave first double-layered cyclophane (VIII), second a mixture of isomeric triple-layered ones, XVII and XVIII, and finally quadruple-layered ones, XXII and XXIII. The isomer XVII was separated from XVIII by careful chromatography, where the former was eluted first. Tetramethyl derivative XVII was recrystallized from acetone-ethanol (1:1) (yield 1.1%), colorless plates, mp 245—246 °C in a sealed tube. NMR (CCl_4) τ 3.94 (s, 2H, ArH), 4.33 (s, 4H, ArH), 6.7—7.7 (m, 16H, CH_2), 8.11 (s, 12H, CH_3); mass *m/e* 394 (M^+, 100), 262 (58), 132 (35); IR (KBr disc, cm^{-1}) 2920 (s), 2850 (s), 1590 (m), 1490 (s), 1432 (s), 1164 (m), 895 (s), 693 (s), 660 (m), 537 (m), 508 (m), 452 (m). Found: C, 91.27; H, 8.83%. Calcd for $C_{30}H_{34}$: C, 91.31; H, 8.69%.

The other isomeric tetramethyl derivative XVIII was recrystallized from acetone-ethanol (1:1) (yield 1.1%), colorless plates, mp 204—205 °C. NMR ($CDCl_3$) τ 4.17 (s, 2H, ArH), 4.21 (s, 2H, ArH), 4.28 (s, 2H, ArH), 6.7—7.8 (m, 16H, CH_2), 8.10 (s, 12H, CH_3); mass *m/e* 394 (M^+, 100), 262 (72), 132 (35); IR (KBr disc, cm^{-1}) 2900 (s), 2850 (s), 1585 (m), 1490 (s), 1440 (s), 1391 (m), 1367 (m), 1250 (m), 1025 (m), 889 (s), 688 (s), 660 (m), 537 (m), 507 (m), 451 (m). Found: C, 91.38; H, 8.84%. Calcd for $C_{30}H_{34}$: C, 91.31; H, 8.69%.

Quadruple-layered [2.2]Paracyclophanes (XIX and XX). a) From Quaternary Salt XIIIa: The aqueous solution (*ca.* 400 ml) containing the quaternary ammonium hydroxide XIIIb, which was derived from 1.4 g (3.7 mmol) of the bromide XIIIa, was heated in the presence of 50 ml of distilled xylene and a spatula of phenothiazine under nitrogen atmosphere for azeotropic distillation. Insoluble polymers were removed from the reaction mixture and the filtrate was dried over anhydrous magnesium sulfate. After evaporation the residue was chromatographed on neutral alumina (Woelm, activity I). Elution with benzene-petroleum ether (2:8) gave a mixture of isomeric quadruple-layered compounds, XIX and XX. The readily soluble isomer XIX was separated from the sparingly soluble isomer XX by treatment with carbon tetrachloride-acetone (1:3).

The quadruple-layered cyclophane XIX was recrystallized from carbon tetrachloride-acetone (1:3) (yield 1.1%), colorless plates, dec>240 °C. NMR (CCl_4) τ 4.02 (s, 8H, ArH), 4.88 (s, 4H, ArH), 6.7—7.9 (m, 24H, CH_2); mass *m/e* 468 (M^+, 100), 364 (41), 234 (69), 104 (33); IR (KBr disc, cm^{-1}) 2915 (s), 2840 (m), 1582 (m), 1424 (s), 1180 (m), 980 (m), 933 (m), 897 (m), 868 (s), 795 (s), 713 (s), 674 (s), 603 (m), 521 (s). Found: C, 92.12; H, 7.80%. Calcd for $C_{36}H_{36}$: C, 92.26; H, 7.74%.

The other isomeric quadrupled one XX was recrystallized from toluene (yield 0.75%), colorless prisms, dec>250 °C. NMR (CCl_4) τ 4.02 (s, 8H, ArH), 4.90 (s, 4H, ArH), 6.7—7.9 (m, 24H, CH_2); mass *m/e* 468 (M^+, 100), 364 (34), 234 (42), 104 (24); IR (KBr disc, cm^{-1}) 2915 (s), 2840 (m), 1582 (s), 1428 (s), 1178 (m), 934 (m), 895 (s), 865 (s), 794 (s), 710 (s), 687 (s), 598 (m), 516 (s). Found: C, 91.99; H, 7.69%. Calcd for $C_{36}H_{36}$: C, 92.26; H, 7.74%.

b) Alternative Synthesis of XIX from Quaternary Salts, Ia and XXIa. A mixture of 0.60 g (2.5 mmol) of *p*-methylbenzyltrimethylammonium bromide (Ia) and 0.80 g (1.6 mmol) of quaternary ammonium bromide (XXIa) dissolved in distilled water was converted to the hydroxide form in the usual way. The resulting hydroxide solution (*ca.* 450 ml) was mixed with 20 ml of distilled toluene and 20 mg of phenothiazine, and heated with stirring under nitrogen. After water was removed by azeotropic distillation, further reflux continued for 6 hr. The reaction mixture was allowed to cool and the insoluble polymers (0.15 g) were filtered off. After drying over anhydrous magnesium sulfate, the filtrate was subjected to column chromatography on neutral alumina (Woelm, activity I). Elution with benzene-hexane (1:1) gave first 30 mg of [2.2]paracyclophane (III) and then 24 mg (3.2%) of quadruple-layered compound XIX. The properties of this product were quite identical with those of the readily soluble isomer obtained by pyrolysis of XIIIb.

Tetramethyl Quadruple-layered [2.2]Paracyclophanes (XXII and XXIII). The cyclophanes, XXII and XXIII, were synthesized from quaternary ammonium bromide XIVa in the same method as non-substituted quadruple-layered compounds, XIX and XX. The isomers, XXII and XXIII, were also separated by the treatment with the same solvent

as for non-substituted ones. The readily soluble isomer XXII was recrystallized from chloroform-ether-petroleum ether (1:1:1) and toluene, successively (yield 3.2%), colorless prisms, dec>240 °C. NMR (CCl_4) τ 4.43 (s, 4H, ArH), 4.53 (s, 4H, ArH), 6.8—8.1 (m, 24H, CH_2), 8.19 (s, 12H, CH_3); mass *m/e* 524 (M^+, 100), 392 (39), 262 (23), 132 (14); IR (KBr disc, cm^{-1}) 2900 (s), 2850 (s), 1585 (m), 1485 (m), 1428 (s), 1248 (m), 1185 (m), 1035 (m), 975 (m), 891 (s), 692 (s), 665 (m), 527 (m), 508 (m), 438 (m). Found: C, 91.35; H, 8.56%. Calcd for $C_{40}H_{44}$: C, 91.55; H, 8.45%.

The sparingly soluble isomer XXIII was recrystallized from toluene (yield 1.6%), colorless prisms, dec>240 °C. NMR (CCl_4) τ 4.45 (s, 4H, ArH), 4.52 (s, 4H, ArH), 6.8—8.1 (m, 24H, CH_2), 8.20 (s, 12H, CH_3); mass *m/e* 524 (M^+, 100), 392 (39), 262 (36), 132 (14); IR (KBr disc, cm^{-1}) 2900 (s), 2840 (s), 1583 (m), 1483 (m), 1445 (s), 1250 (m), 1165 (m), 1028 (m), 964 (m), 887 (s), 696 (s), 669 (m), 525 (m), 508 (m), 453 (m). Found: C, 91.77; H, 8.64%. Calcd for $C_{40}H_{44}$: C, 91.55; H, 8.45%.

Fivefold-layered [2.2]Paracyclophane (XXIV). The aqueous quaternary base solution (*ca.* 800 ml) derived from 1.2 g (3.2 mmol) of XIIIa and 1.5 g (2.9 mmol) of XXIa was added into 30 ml of distilled xylene and 50 mg of phenothiazine, and refluxed with stirring under nitrogen. After removal of water, heating was continued for an additional 6 hr. After cooling the insoluble polymers were filtered off and the filtrate was chromatographed on neutral alumina (Woelm, activity I) using benzene-hexane (2:8) as eluent to give a mixture of quadruple-layered compounds, XIX and XX, and fivefold-layered one XXIV. The separation of this mixture was performed by liquid chromatography using chloroform as eluent. This gave first XXIV and then a mixture of XIX and XX. The compound XXIV was recrystallized from carbon tetrachloride-acetone (1:3) (yield 5%), colorless microcrystals, dec>240 °C. NMR (CCl_4) τ 4.04 (s, 8H, ArH), 4.97 (s, 4H, ArH), 5.12 (b.s, 2H, ArH), 6.8—8.0 (m, 32H, CH_2); mass *m/e* 598 (M^+, 100), 494 (33), 364 (63), 234 (21), 104 (41); IR (KBr disc, cm^{-1}) 2910 (s), 2830 (m), 1585 (s), 1483 (m), 1425 (m), 1181 (m), 935 (m), 895 (m), 870 (s), 795 (s), 714 (m), 671 (s), 603 (m), 517 (s). Found: C, 91.67; H, 7.56%. Calcd for $C_{46}H_{46}$: C, 92.26; H, 7.74%.

Dimethyl Fivefold-layered [2.2]Paracyclophane (XXVI). Tetramethyl quadruple-layered [2.2]paracyclophane XXII (1.00 g, 1.91 mmol) was brominated with 0.27 g (1.52 mmol) of *N*-bromosuccinimide under reflux in 12 ml of carbon tetrachloride. After removal of succinimide, the solution was washed, dried over anhydrous magnesium sulfate, and then mixed with an excess amount of trimethylamine in ether under ice-cooling. The mixture was brought to room temperature slowly and the resulting white precipitate was collected and thoroughly washed with carbon tetrachloride. The quaternary ammonium bromide XXVa thus obtained was mixed with 0.5 g (2.1 mmol) of *p*-methylbenzyltrimethylammonium bromide (Ia) in 300 ml of distilled water and subjected to the ion exchange process. The resulting hydroxide solution (*ca.* 500 ml) was added into 15 ml of distilled xylene and 100 mg of phenothiazine, and heated with stirring under nitrogen. After removal of water, heating was continued for 6 hr. The insoluble polymers were filtered off and the filtrate was chromatographed on neutral alumina (Woelm, activity I). Elution with benzene-hexane (1:9) gave [2.2]paracyclophane (III) and [2.2.2]paracyclophane (IV). Further elution with 2:8 benzene-hexane gave dimethyl fivefold-layered [2.2]paracyclophane XXVI in a 1.1% yield based on NBS, colorless plates from 1:3 carbon tetrachloride-acetone, dec>250 °C. NMR (CCl_4) τ 4.04 (s, 4H, ArH), 4.47 (s, 2H, ArH), 4.64 (s, 2H, ArH), 4.96 (s, 2H, ArH), 5.08 (s, 2H, ArH), 6.9—8.1 (m, 32H, CH_2), 8.24 (s, 6H, CH_3); mass *m/e* 626 (M^+, 100), 522 (14), 494 (27), 392 (32), 364 (24), 262 (10), 234 (17), 132 (22), 104 (35); IR (KBr disc, cm^{-1}) 2910 (s), 2835 (m), 1584 (s), 1482 (m), 1425 (s), 1250 (m), 1178 (m), 892 (s), 790 (m), 712 (w), 693 (m), 672 (s), 665 (s), 600 (m), 518 (s). Found: C, 92.19; H, 7.93%. Calcd for $C_{48}H_{50}$: C, 91.96; H, 8.04%.

Sixfold-layered [2.2]Paracyclophanes (XXVII and XXVIII). The aqueous quaternary ammonium hydroxide solution (*ca.* 600 ml), prepared from 1.6 g (3.1 mmol) of the bromide XXIa in the usual way, was added into 30 ml of toluene and 20 mg of phenothiazine. The mixture was refluxed with stirring under nitrogen. After the removal of water was completed by azeotropic distillation, heating was continued for an additional 6 hr. After cooling to room temperature, the insoluble polymers (0.55 g) were separated. The filtrate was chromatographed on neutral alumina (Woelm, activity I) and elution with benzene-hexane (1:1) gave a mixture of isomeric sixfold-layered [2.2]paracyclophanes, XXVII and XXVIII. The readily soluble isomer XXVII was separated from the sparingly soluble one XXVIII by treatment of a minimum amount of benzene. The isomer XXVII was recrystallized from toluene (yield 4.7%), colorless plates, dec>250 °C. NMR (CCl_4) τ 4.06 (s, 8H, ArH), 5.00 (s, 4H, ArH), 5.20 (s, 4H, ArH), 7.1—8.3 (m, 40H, CH_2); IR (KBr disc, cm^{-1}) 2920 (s), 2840 (m), 1584 (s), 1472 (s), 1424 (s), 1183 (m), 974 (m), 935 (m), 894 (m), 875 (s), 794 (s), 713 (m), 673 (s), 602 (m), 518 (s). Found: C, 92.01; H, 7.64%; mol wt 734 (vapor pressure osmometry). Calcd for $C_{56}H_{56}$: C, 92.26; H, 7.74%; mol wt 729.

The other isomer XXVIII was recrystallized from xylene (yield 2.4%), colorless microcrystals, dec>250 °C. NMR ($CDCl_3$) τ 3.95 (s, 8H, ArH), 4.95 (s, 4H, ArH), 5.19 (s, 4H, ArH), 6.9—8.2 (m, 40H, CH_2); IR (KBr disc, cm^{-1}) 2920 (s), 2840 (m), 1584 (s), 1482 (s), 1425 (s), 1181 (m), 975 (m), 933 (m), 894 (m), 874 (s), 796 (m), 715 (m), 677 (s), 603 (m), 517 (s). Found: C, 92.07; H, 7.74%. Calcd for $C_{56}H_{56}$: C, 92.26; H, 7.74%.

Thermal Isomerization from Eclipsed Form (IX) to Staggered Form (VIII) of Tetramethyl[2.2]paracyclophane. Thermal isomerization from IX to VIII could be easily observed in NMR spectra. Thus, when IX in hexachlorobutadiene was heated at 190 °C, signals of VIII gradually appear with disappearance of signals of IX, and after 2 hr IX was completely transformed to VIII accompanying with insoluble black decomposition product. For preparative purpose, 10 mg of IX was dissolved in 0.5 ml of *n*-tridecane and degassed by freeze-pump-thaw method. The resulting solution in a sealed tube was heated at 195 °C for 3 hr. After cooling the product was chromatographed on silica gel (Merck, activity II—III). After *n*-tridecane, VIII was eluted with *n*-hexane in nearly quantitative yield.

Layered Cyclophane-TCNE and -TNB Complexes. Commercial tetracyanoethylene (TCNE) was recrystallized from chlorobenzene and then sublimed twice under reduced pressure. Commercial 1,3,5-trinitrobenzene (TNB) was recrystallized three times from ethanol and then three times from carbon tetrachloride. Dichloromethane and chloroform are of spectroscopic grade (Merck) and used without further purification. The charge-transfer spectra of layered cyclophane-TCNE and -TNB complexes were recorded on a Hitachi EPS-3T spectrophotometer. Most of the multilayered cyclophane complexes exhibit unchanged absorption maxima though the relative concentrations of two components are varied. Equilibrium constants and molar extinction coefficients for the TNB complexes were determined in the

manner described by Benesi and Hildebrand.[31] Measurements were carried out at four points in the presence of excess acceptor; the mole concentrations of the donor were varied from 0.003 to 0.005 M, while the TNB concentrations from 0.03 to 0.15 M. In the case of tetramethyl[2.2]paracyclophane (VIII), on the other hand, the donor concentration was varied from 0.025 to 0.15 M, while the acceptor concentration was kept constant at 0.002 M. Every complex of multilayered cyclophane here presented gave a good linear plots, supporting that the complex consists conclusively of 1 : 1 ratio one.

Application of the Mannich Reaction to 1-Azaazulan-2-one. Syntheses of Seven-Membered Analogues of Tryptophan and Related Compounds[1]

Akira SATO,* Shigeo NOZOE,** Takashi TODA, Shuichi SETO***, and Tetsuo NOZOE****

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received August 23, 1973)

Application of the Mannich reaction to 1-azaazulan-2-one (I) gave 3-dimethylamino-1-azaazulan-2-one (III) in a good yield. Tryptophan analogue and related compounds having this structure (I) were synthesized by the reactions of the quaternary base (VI) of III with potassium cyanide and diethyl acetylaminomalonate. Also, some other reactions of III and VI are reported.

Since 1954, the syntheses and reactions of 1-azaazulan-2-ones (2*H*-cyclohepta[*b*]pyrrol-2-ones) have been investigated,[2,3] and also synthetic studies of some physiologically interesting derivatives of them have been carried out.[4] However, the syntheses of physiologically more interesting 1-azaazulan-2-one derivatives whose structures are analogous to indolacetic acid and/or tryptophan have only been quoted by one of the authors (T.N.) in the monograph.[5] In this paper, we wish to describe the experimental details about the syntheses of seven-membered analogues of tryptophan and related compounds having 1-azaazulan-2-one (I) structure by the application of Mannich reaction.

(I) (Ia)

It is known that I is a tautomer of 2-hydroxy-1-azaazulane (Ia), though the keto-form (I) is predominant,[5] and the electron density is high at the 3-position[6] as in the case of azulene. In fact the electrophilic substitution reactions take place at its 3-position.[2a,d] Therefore, the Mannich reaction to I was expected to give good results. When the reaction was applied to I, 3-morpholinomethyl-1-azaazulan-2-one (II) and 3-dimethylamino-1-azaazulan-2-one (III) were obtained in good yields, respectively. However, fairly large amounts of bis[1-azaazulan-2-on-3-yl]methane (IV)[4a] were formed as a by-product when diluted acetic acid was employed as a solvent. The formation of the same type of bis-methylene compounds was observed in the cases of hydroxymethylation of I[4a] and the Mannich reactions of several azulene compounds.[7] Not as in the case of the Mannich reaction of pyrroles,[8] the order of the addition of the

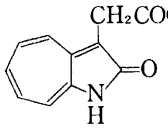
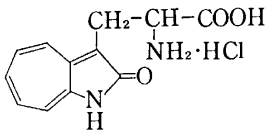
reagents did not cause any effect to the yields of II and III.

A catalytic hydrogenolysis of III afforded 3-methyl-1-azaazulan-2-one (V) and a treatment of III with methyl iodide gave its quaternary base (VI) respectively, in good yields. (1-Azaazulan-2-on-3-yl)acetonitrile (VII) and ethyl α-ethoxycarbonyl-β-(1-azaazulan-2-on-3-yl)propionate (VIII) were obtained by the reactions of VI with potassium cyanide and diethyl malonate, respectively. (1-Azaazulan-2-on-3-yl)acetic acid (IX), an indolacetic acid analogue, was obtained by the hydrolysis of VII. The hydrolysis of VIII and the following thermal decomposition of the free dicarboxylic acid (X) gave β-(1-azaazulan-2-on-3-yl)-propionic acid (XI).



(IX)

As we have reported[4a] an attempted synthesis of α-aminopropionic acid derivatives of I from the condensation products of 3-formyl-1-azaazulan-2-one with hippuric acid or nitromethane was unsuccussful. Under the modified conditions as in the case of gramine quaternary base,[9] the treatment of VI with acetoamido- and formamido-malonic acid diethyl esters afforded ethyl α-acetylamino-α-ethoxycarbonyl-β-[1-azaazulan-2-on-3-yl]propionate (XII) and ethyl α-ethoxycarbonyl-α-formylamino-β-[1-azaazulan-2-on-3-yl]propionate (XIII). α-Amino-β-[1-azaazulan-2-on-3-yl]propionic acid (XIV), a seven-membered analogue of tryptophan, was successfully obtained by the hydrolyses of XII and XIII. Application of the Schmidt reaction to ethyl α-acetyl-β-[1-azaazulan-2-on-3-yl]propionate (XV), which was synthesized from VI and acetoacetic ester, and hydrolysis of the obtained *N*-acetyl derivative (XVI) also gave XIV. The amino acid (XIV) shows red-violet colorations by the ninhydrin test.



(XIV)

The reactions of quaternary base (VI) with other nucleophilic reagents, such as ethylmercaptan, diethyl nitromalonate, and methyl nitroacetate afforded [1-azaazulan-2-on-3-yl]methyl ethyl sulfide (XVII), ethyl α-ethoxycarbonyl-α-nitro-β-[1-azaazulan-2-on-3-yl]propionate (XVIII), and methyl α-nitro-β-[1-azaazulan-2-on-3-yl]propionate (XIX), respectively.

All the compounds obtained are listed in the table.

Experimental[10]

3-Morpholinomethyl-1-azaazulan-2-one (II). A mixture of 120 mg of I, 75 mg of morpholine, and 120 mg of 27% formalin was heated for 2 hr at 60 °C with stirring. After cooling, the reaction mixture was extracted with ethyl acetate and the combined organic layers were washed with water, dried over sodium sulfate and chromatographed on alumina. Alcohol elutes afforded 120 mg of orange yellow needles of II, mp 206—207 °C, from alcohol.

Found: C, 68.67; H, 6.25; N, 11.96%. Calcd for $C_{14}H_{16}O_2N_2$: C, 68.83; H, 6.60; N, 11.47%.

3-Dimethylaminomethyl-1-azaazulan-2-one (III). To a solution of 17 ml of acetic acid and 2.20 g of 40% dimethylamine, 200 mg of paraformaldehyde and 1.0 g of I were added. After it was heated for 12 hr at 40 °C, 30 ml of water was added to the solution and then brown precipitates (*ca.* 5%) formed was collected by filtration. The precipitates were recrystallized from ethyl acetate to give brown micro needles, mp>300 °C, which were identical with the authentic sample of IV[4a] by comparison of their IR spectra. The pH of the mother layer was adjusted *ca.* 10 with sodium carbonate, extracted with ethyl acetate, and the combined organic layers were washed with water. After dried over sodium sulfate, the extracts were chromatographed on alumina and alcohol elutes afforded orange red prisms of III; mp 149—150 °C, from ethyl acetate; yield 1.12 g.

Found: C, 71.26; H, 6.98; N, 13.85%. Calcd for $C_{12}H_{14}ON_2$: C, 71.35; H, 6.67; N, 13.85%.

When the reaction was carried out in the 60% aqueous acetic acid, *ca.* 30% of IV was obtained and the yield of III

was reduced.

3-Methyl-1-azaazulan-2-one (V). To a solution of 100 mg of III in 15 ml of methanol, 20 mg of 10% Pd-charcoal catalyst was added and then the reduction was carried out. After 13 ml of hydrogen was taken up, the catalyst was separated by filtration, and the methanol was removed by distillation. The residues were recrystallized from ethyl acetate to give orange yellow needles of V, mp 218—220 °C: yield, 95%.

Found: N, 8.85%. Calcd for $C_{10}H_9ON$: N, 8.80%.

3-Dimethylaminomethyl-1-azaazulan-2-one Methiodide (VI). Two hundred mg of III and 140 mg of methyl iodide in 2 ml of absolute alcohol were stirred for 2 hr at room temperature. The quaternary base of III was obtained as orange brown precipitates, mp 187—188 °C (dec.); yield, 300 mg.

Found: N, 8.54%. Calcd for $C_{13}H_{17}ON_2I$: N, 8.14%.

(1-Azaazulan-2-on-3-yl)acetonitrile (VII). A solution of 100 mg of potassium cyanide and 200 mg of VI in 60% alcohol was heated for 1 hr at 50 °C with stirring and then allowed to stand overnight at room temperature. After the alcohol was removed under reduced pressure, the obtained residue was washed well with water, dried in a desiccator, and recrystallized from ethyl acetate to give 80 mg of orange brown prisms of VII, mp 224—225 °C.

Found: C, 71.46; H, 4.10; N, 14.87%. Calcd for $C_{11}H_8ON_2$: C, 71.72; H, 4.38; N, 15.21%.

(1-Azaazulan-2-on-3-yl)acetic Acid (IX). One hundred mg of VII was refluxed for 4 hr in 2 ml of 20% potassium hydroxide solution, and then the solution was acidified with 6 M hydrochloric acid. The formed precipitates were collected by filtration, washed with water, dried in a desiccator and then recrystallized from alcohol to give 100 mg of IX, mp 236—237 °C (dec.).

Found: C, 65.42; H, 4.74; N, 6.68%. Calcd for $C_{11}H_9O_3N$: C, 65.02; H, 4.46; N, 6.89%.

Ethyl α-Ethoxycarbonyl-β-(1-azaazulan-2-on-3-yl)propionate (VIII). A solution of 113 mg of VI and 53 mg of diethyl malonate in 5 ml of absolute alcohol was added drop by drop into the sodium ethoxide solution which was prepared from 15 mg of sodium and 1 ml of absolute alcohol with stirring and heated for 2 hr at 60 °C. After it was allowed to stand overnight at room temperature, the alcohol was removed under reduced pressure. The residue was acidified with 1M sulfuric acid, extracted with ethyl acetate and then the combined organic layers were washed with water and dried over sodium sulfate. The solution was chromatographed on alumina and ethyl acetate eluates gave 70 mg of orange scales of VIII, mp 119—120 °C, from ethyl acetate.

Found: N, 4.52%. Calcd for $C_{17}H_{19}O_5N$: N, 4.41%.

β-(1-Azaazulan-2-on-3-yl)propionic Acid (XI). Thirty mg of VIII was heated in 5 ml of 30% potassium hydroxide for 5 hr at 100 °C, and after cooling the resulted solution was acidified with 6M hydrochloric acid to form yellow micro needles of X, mp 188—189 °C (dec.) from alcohol; yield, 20 mg. The dibasic acid (X) was heated at 190 °C to decompose with carbon dioxide evolution. After recrystallization of the residues from alcohol, 18 mg of yellow needles of XI, mp 214—216 °C (dec.), was obtained.

Found: N, 6.15%. Calcd for $C_{12}H_{11}O_3N$: N, 6.45%.

Ethyl α-Acetamido-α-ethoxycarbonyl-β-(1-azaazulan-2-on-3-yl)-propionate (XII). A solution of 200 mg of diethyl acetamidomalonate[11] and 350 mg of VI in 20 ml of absolute alcohol was added to sodium ethoxide solution prepared from 2 ml of absolute alcohol and 20 mg of sodium and heated for 4 hr at 60 °C. After it was allowed to stand overnight at room temperature, the alcohol was removed under reduced pressure. The residues were washed with water and dried in a desiccator to give 200 mg of orange prisms of XII, mp 173—174 °C from ethyl acetate.

Found: C, 60.42; H, 5.97; N, 7.35%. Calcd for $C_{19}H_{22}O_6N_2$: C, 60.95; H, 5.92; N, 7.48%.

Ethyl α-Ethoxycarbonyl-α-formamido-β-(1-azaazulan-2-on-3-yl)-propionate (XIII). A solution of 350 mg of VI and 220 mg of diethyl formamidomalonate[11] in 20 ml of absolute alcohol was added to sodium ethoxide solution prepared from 25 mg of sodium and 2 ml of adsolute alcohol. The reaction mixture was treated as the case of XII to give 280 mg of orange prisms of XIII, mp 181—182 °C from ethyl acetate.

Found: C, 60.30; H, 5.41; N, 7.83%. Calcd for $C_{18}H_{20}O_6N_2$: C, 59.99; H, 5.85; N, 7.77%.

α-Amino-β-(1-azaazulan-2-on-3-yl)propionic Acid Hydrochloride (XIV). Three hundred mg of XII in 3 ml of conc. hydrochloric acid was heated for 4 hr at 100 °C, and then concentrated under reduced pressure to give yellow residues. Recrystallization of the residues from alcohol gave 200 mg of yellow needles of XIV, mp 260—261 °C (dec.). This compound showed red-violet color by ninhydrin reagent.

Found: C, 53.88; H, 4.80; N, 10.13%. Calcd for $C_{12}H_{12}O_3N_2HCl$: C, 53.64; H, 4.87; N, 10.43%.

XIV was also obtained by the same acid hydrolysis of XIII and XVI in quantitative yields.

Ethyl α-Acetyl-β-(1-azaazulan-2-on-3-yl)propionate (XV). To a solution of 350 mg of VI and 130 mg of ethyl acetoacetate in 5 ml of absolute alcohol, a sodium ethoxide solution prepared from 20 mg of sodium and 2 ml of absolute alcohol was added and heated at 60 °C for 5 hr. After it was allowed to stand overnight at room temperature, 180 mg of orange prisms of XV, mp 147—148 °C from ethyl acetate, was obtained by the same treatment as the case of the preparation of XII.

Found: C, 67.16; H, 5.77; N, 4.96%. Calcd for $C_{16}H_{17}O_4N$: C, 66.88; H, 5.96; N, 4.88%.

Ethyl α-Acetylamino-β-(1-azaazulan-2-on-3-yl)propionate (XVI). A solution of 300 mg of XV in 10 ml of chroloform and conc. sulfuric acid was heated at 40 °C, and to this solution 80 mg of sodium azide was added with stirring. The reaction mixtures were stirred for one and half hr and then poured into crushed ice. The chloroform layer was washed with water, dried over sodium sulfate and removed under reduced pressure to give 150 mg of yellow micro needles of XVI, mp 179—180 °C from ethyl acetate-alcohol.

Found: C, 63.74; H, 5.83; N, 9.09%. Calcd for $C_{16}H_{18}O_4N_2$: C, 63.56; H, 6.00; N, 9.27%.

S-(1-Azaazulan-2-on-3-yl)methyl Ethyl Sulfide (XVII). A solution of 200 mg of VI and 50 mg of ethylmercaptan in 3 ml of dioxane and 0.5 ml of 2 M sodium hydroxide was heated at 60 °C for 1 hr and allowed to stand overnight at room temperature. After the solvent was removed under reduced pressure, the formed residues were acidified with 6 M hydrochloric acid, washed with water, and dried in a desiccator to give 80 mg of orange scales of XVII, mp 172—173 °C from ethyl acetate.

Found: C, 66.03; H, 5.78; N, 6.18%. Calcd for $C_{12}H_{13}ONS$: C, 65.72; H, 5.98; N, 6.38%.

Ethyl α-Ethoxycarbonyl-α-nitro-β-(1-azaazulan-2-on-3-yl)-propionate (XVIII). A solution of 200 mg of VI and 120 mg of diethyl nitromalonate in 5 ml of absolute alcohol was added to a sodium ethoxide solution prepared from 15 mg of sodium and 1 ml of absolute alcohol, and then heated at 60 °C for 4 hr. After it was allowed to stand overnight at

11) Prepared by the method of following paper: S. Tatsuoka, T. Kinoshita, and R. Nakamori, *Yakugaku Zasshi*, **71**, 702 (1951).

room temperature, the alcohol was removed and the obtained residues were washed with water. Recrystallization of the residues from ethyl acetate gave 100 mg of yellow needles of XVIII, mp 158—159 °C.

Found: C, 56.83; H, 4.81; N, 7.67%. Calcd for $C_{17}H_{18}O_7N_2$: C, 56.35; H, 5.01; N, 7.73%.

Methyl α-Nitro-β-(1-azaazulan-2-on-3-yl)propionate (XIX). A solution of 350 mg of VI and 12 mg of methyl nitroacetate in 5 ml of absolute methanol was added to a sodium methoxide solution prepared from 100 mg of sodium methoxide and 1 ml of absolute methanol. After the reaction mixture was treated as above, 180 mg of yellow needles of XIX, mp 186—187 °C from methanol, was obtained.

Found: C, 57.05; H, 4.37; N, 9.70%. Calcd for $C_{13}H_{12}O_5N_2$: C, 56.52; H, 4.38; N, 10.14%.

The Synthesis of 3-Methyl-5-(2-aminoalkyl)isoxazoles

Choji KASHIMA and Yoshihiko TSUDA
Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo 112

(Received February 1, 1973)

The reaction of 3,5-dimethylisoxazole with Schiff bases gave 3-methyl-5-(2-aminoalkyl)isoxazole derivatives in the presence of sodium amide in liquid ammonia. The *N*-alkylation on the anilino group of 3-methyl-5-(2-anilino-2-phenylethyl)isoxazole resulted in deamination, thus giving 3-methyl-5-styrylisoxazole. The reaction of 3,5-dimethylisoxazole with benzonitrile gave 3-methyl-5-(2-aminostyryl)isoxazole, which was then reduced to 3-methyl-5-(2-amino-2-phenylethyl)isoxazole.

It has been previously reported[1] that the 5-methyl group of 3,5-dimethylisoxazole (**1**) is metallated by the reaction of sodium amide in liquid ammonia, and that the sodium salt of **1** is alkylated by alkyl halides. Also, **1** reacts with some electrophilic reagents in the presence of butyllithium in anhydrous ether.[2] This paper will describe the reaction of **1** with Schiff bases or benzonitrile in the presence of sodium amide in liquid ammonia; we thus synthesized 3-methyl-5-(2-aminoalkyl)-isoxazole derivatives or 3-methyl-5-(2-aminostyryl)-isoxazole (**10**), which was subsequently reduced to 3-methyl-5-(2-amino-2-phenylethyl)isoxazole (**12**). It is very interesting to synthesize such aminoalkyl-isoxazole derivatives because of their antipyretic, analgetic, antiinflammatory, and antitussive activities.[3]

Results and Discussion

3,5-Dimethylisoxazole (**1**) was treated with an equimolar amount of *N*-benzylideneaniline, one of the Schiff bases, in the presence of an equimolar amount of sodium amide in liquid ammonia to give two products, A (mp 113 °C) and B(mp 236 °C). A was a 1:1 adduct of isoxazole and the Schiff base. From the IR and NMR spectra, the structure of A was deduced to be 3-methyl-5-(2-anilino-2-phenylethyl)isoxazole (**2**). For the confirmation of the structure, **2** was hydrogenated on platinum oxide in ethanol to give 1,2-diphenyl-6-methyl-2,3-dihydro-4-pyridone (**3**), which was identical with an authentic sample.[4] The product B was a 1:2 adduct of isoxazole and the Schiff base. From the IR and NMR spectra, the structure of B was found to be 3-methyl-5-[2-(1,3-dianilino-1,3-diphenyl)propyl]isoxazole (**4**). The yields of **2** and **4** based on the Schiff base, were 31 and 49% respectively. In the presence of butyllithium in dry THF, **1** and *N*-benzylideneaniline also gave **2** and **4** in yields of 15 and 9% respectively.

Similarly, **1** was treated with *N*-benzylidene-*p*-toluidine in the presence of sodium amide in liquid ammonia to give a 1:1 adduct (**5**) and a 1:2 adduct (**6**). However, the reaction of **1** with *N,N'*-bis(*p*-tolyl)-ethylenediimine[5] gave as the sole product a 2:1 adduct, 2,3-di(*p*-toluidino)-1,4-bis(3-methyl-5-isoxazolyl)butane (**7**). In the case of *N*-benzylidenebutylamine, **1** did not react under the condition of either butyllithium in THF or sodium amide in liquid ammonia.

In a previous paper,[1] it was described that 3-methyl-5-*sec*-butylisoxazole was synthesized by the reaction of **1** with an equimolar amount of methyl iodide, followed by a reaction with an equimolar amount of ethyl bromide in the presence of 2 molar amounts of sodium amide. In this reaction, it is suggested that 3-methyl-5-ethylisoxazole anion is formed by the excess sodium amide after the addition of methyl iodide. Therefore, the reaction of **1** with an equimolar amount of benzyl bromide, followed by a reaction with an equimolar amount of *N*-benzylideneaniline, was carried out in the presence of 2 molar amounts of sodium amide. Scheme 1

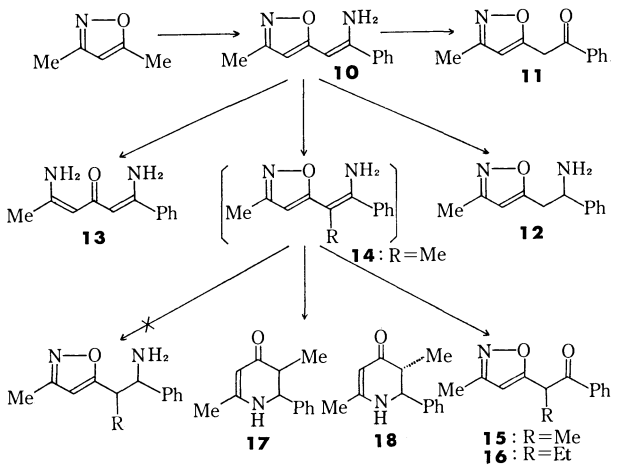
this reaction, 3-methyl-5-[2-(1-anilino-1,3-diphenyl)-isoxazole (**8**) was obtained in a 25% yield. However the reaction of **1** with an equimolar amount of ethyl bromide, followed by a reaction with an equimolar amount of *N*-benzylideneaniline, gave only 3-methyl-5-*n*-propylisoxazole and no amino derivatives. When 3-methyl-5-*n*-propylisoxazole was treated with *N*-benzylideneaniline in the presence of an equimolar amount of sodium amide, the reaction did not occur and the starting materials were recovered. When **1** was treated with an equimolar amount of *N*-benzylideneaniline, followed by a reaction with an equimolar amount of benzyl bromide in the presence of 2 molar amounts of sodium amide, the expected product (**8**) was not obtained. From the NMR and IR spectra and the elemental analysis, the products were found to be **4**, *N*-benzylaniline, *N*,*N*-dibenzylaniline, and 3-methyl-5-styrylisoxazole (**9**). Similarly, the reaction products from **1**, *N*-benzylideneaniline and ethyl bromide were found to be **4**, *N*-ethylaniline, *N*,*N*-diethylaniline, and **9**. These results suggested that the alkylation of **2** occurred on the N atom to give trisubstituted amines and tetrasubstituted ammonium compounds. However, these alkylated compounds were unstable in a basic solution and easily eliminated the amines to produce **9**.

Since the reaction of **1** with benzonitrile catalyzed by butyllithium in ether has been reported to produce 3-methyl-5-benzoylmethylisoxazole (**11**) (mp 72 °C),[2] the reaction of **1** with benzonitrile was reexamined in the presence of sodium amide in liquid ammonia. The resulting residue was directly recrystallized from the *n*-hexane–benzene mixture. From the spectral data and the elemental analysis, the structure of the product



Scheme 2

was deduced to be 3-methyl-5-(2-aminostyryl)isoxazole (**10**). By passing through the silica gel column, **10** was easily hydrolyzed to give **11**, which was identified by a mixed-melting-point determination with an authentic sample and the spectral data. When **10** was reduced with sodium borohydride in methanol, the enamino group of **10** was selectively reduced to give 3-methyl-5-(2-amino-2-phenylethyl)isoxazole (**12**). By the hydrogenation on platinum oxide in ethanol, the isoxazole ring was cleaved, but the enamino group was not reduced. The product was deduced to be 1-phenyl-1,5-diaminohexa-1,4-dien-3-one (**13**), on the basis of the spectral data and the elemental analysis.

Furthermore, **10** was expected to alkylate on either the N atom or the C atom of the enamino group. For determining the alkylation site, **1** was treated with an equimolar amount of benzonitrile, followed by a reaction with an equimolar amount of methyl iodide in the presence of 2 molar amounts of sodium amide. Since the purification of the product (**14**) failed, the mixture was hydrolyzed by passing through a silica gel column. Thereby, 3-methyl-5-(1-benzoylethyl)-isoxazole (**15**), the C-alkylated product, was obtained. Similarly, 3-methyl-5-(1-benzoylpropyl)isoxazole (**16**) was obtained from **1**, benzonitrile, and ethyl bromide. However, it was impossible to detect the *N*-alkylated product by this method. Thus, the hydrogenation of **14** with palladium on charcoal was carried out to give two products. By a study of the IR and NMR spectra and the elemental analysis, the structures of these products were determined to be *cis*- (**17**) and *trans*-2-phenyl-3,6-dimethyl-2,3-dihydro-4(1*H*)pyridone (**18**): no *N*-alkylated products could be detected. These results showed that the *N*-alkylation of enamine (**10**) did not occur, and also that **14** was hydrogenated at the enamino group and then at the isoxazole ring.

In conclusion, the synthesis of 3-methyl-5-(2-amino-alkyl)isoxazoles was accomplished by the reaction of **1** with Schiff bases in the presence of sodium amide, or by the reaction of **1** with benzonitrile, followed with a hydride reduction.

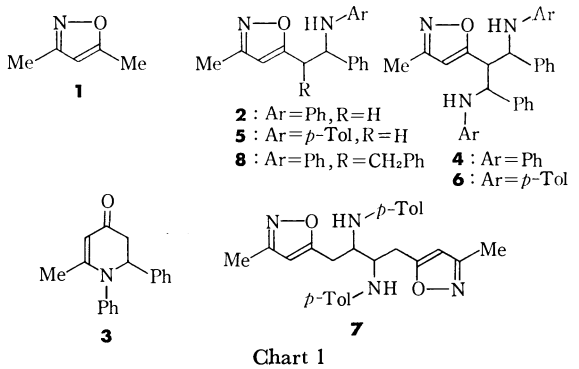


Chart 1

Experimental

The General Procedure. *a) By the Use of Sodium Amide in Liquid Ammonia*: To a sodium amide suspension, which has been prepared from sodium (0.01 mol) and liquid ammonia (*ca.* 50 ml) in the presence of ferric chloride, **1** (0.01 mol) in anhydrous ether (15 ml) was added. After stirring for 1 hr under a nitrogen stream at −50 °C, the Schiff base (0.01 mol)

was added; stirring was then continued for another 2 hr at −50 °C. The mixture was subsequently neutralized with ammonium chloride, and the ammonia was removed at room temperature. To the residual ether solution, dichloromethane was added. The dichloromethane solution was washed with aqueous sodium chloride and dried over anhydrous sodium sulfate. After the removal of the solvent, the residue was purified by recrystallization and/or silica gel column chromatography.

b) By the Use of Butyllithium: To a solution of **1** (0.01 mol) in dry THF (30 ml), an *n*-hexane solution (20%) of butyllithium (0.01 mol) was added at −40 °C. The mixture was stirred for 1 hr under nitrogen. After the addition of the Schiff base (0.01 mol), the stirring was continued for another 4 hr at −40 °C. The solution was then warmed to room temperature and washed with water. The aqueous layer was extracted with dichloromethane. The combined organic layer was dried over anhydrous sodium sulfate and concentrated. The residue was then purified as above.

3-Methyl-5-[2-(1,3-dianilino-1,3-diphenyl)propyl]isoxazole (4): Purified by recrystallization from chloroform; mp 236 °C; yield, 49%. IR (KBr): 3400, 1605, 1500, 745, 695, and 685 cm^{-1}. UV: λ_{max}^{EtOH} 246 (ε 25200) and 295 nm (3600). NMR δ_{CDCl_3} 2.14 (s, 3H), 3.3 (m, 1H), 4.55 (broad s, 2H), 5.07 (m, 2H), 5.63 (s, 1H) and 7.3—6.35 ppm (m, 10H). Found: C, 81.28; H, 6.35; N, 8.69%. Calcd for $C_{31}H_{29}N_3O$: C, 81.08; H, 6.36; N, 9.14%.

3-Methyl-5-(2-anilino-2-phenylethyl)isoxazole (2): The mother solution in the crystallization of **4** was concentrated and recrystallized from *n*-hexane; mp 113 °C; yield, 31%. IR (KBr): 3320, 1600, 1525, 1495, 745, 700, and 690 cm^{-1}. UV: λ_{max}^{EtOH} 247 (ε 14100) and 297 nm (2390). NMR: δ_{CDCl_3} 2.20 (s, 3H), 3.17 (d, J=7 Hz, 2H), 3.95 (broad s, 1H), 4.70 (t, J=7 Hz, 1H), 5.70 (s, 1H), 7.3—6.36 (m, 5H) and 7.27 ppm (s, 5H). Found: C, 77.46; H, 6.52; N, 10.10%. Calcd for $C_{18}H_{18}N_2O$: C, 77.67; H, 6.52; N, 10.07%.

3-Methyl-5-(2-p-toluidino-2-phenylethyl)isoxazole (5): This was purified by silica gel column chromatography with a benzene ethyl acetate mixture, and the eluate was recrystallized from an *n*-hexane benzene mixture; mp 117 °C; yield, 13%. IR (KBr): 3300, 1615, 1600, 1525, 815 and 805 cm^{-1}. UV: λ_{max}^{EtOH} 249 (ε 14000) and 306 nm (2300). NMR: δ_{CDCl_3} 2.18 (s, 3H), 2.21 (s, 3H), 3.17 (d, J=7 Hz, 2H), 3.4 (broad s, 1H), 4.68 (t, J=7 Hz, 1H), 5.70 (s, 1H), 7.0—6.3 (AB-q, J=9 Hz, 4H) and 7.27 ppm (s, 5H). Found: C, 78.21; H, 7.13; N, 9.58%. Calcd for $C_{19}H_{20}N_2O$: C, 78.05; H, 6.90; N, 9.58%.

3-Methyl-5-[2-(1,3-di-p-toluidino-1,3-diphenyl)propyl]isoxazole (6): This was purified by silica gel column chromatography with a benzene–ethyl acetate mixture, and the eluate was recrystallized from an ethyl acetate–ethanol mixture; mp 167 °C; yield, 56%. IR (KBr): 3350, 1610, 1510, 805, and 700 cm^{-1}. UV: λ_{max}^{EtOH} 249 (ε 27200) and 304 nm (3600). NMR: δ_{CDCl_3} 2.15 (s, 9H), 3.7 (m, 1H), 4.1 (broad s, 2H), 5.0 (m, 2H), 5.68 (s, 1H) and 7.3—6.3 ppm (m, 18H). Found: C, 81.05; H, 6.94; N, 8.45%. Calcd for $C_{33}H_{33}N_3O$: C, 81.28; H, 6.82; N, 8.62%.

2,3-Di(p-toluidino)-1,4-bis(3-methyl-5-isoxazolyl)butane (7): This was purified by silica gel column chromatography with a benzene–ethyl acetate mixture, and the eluate was recrystallized from benzene; mp 153 °C; yield, 66%. IR (KBr): 3400, 1610, 1515, 810, and 790 cm^{-1}. UV: λ_{max}^{EtOH} 253 (ε 31700) and 304 nm (4170). NMR: δ_{CDCl_3} 2.22 (s, 6H), 2.25 (s, 6H), 3.1 (m, 6H), 3.85 (broad s, 2H), 5.80 (s, 2H) and 7.1—6.4 ppm (AB-q, J=9 Hz, 8H). Found: C, 72.51; H, 7.13; N, 12.81%. Calcd for $C_{26}H_{30}N_4O_2$: C, 72.53; H, 7.02; N, 13.01%.

The Reaction of 1 with Alkyl Halide, Followed by the Reaction with N-Benzylideneaniline. To a sodium amide (0.02 mol) suspension in liquid ammonia (50 ml) an ether (15 ml) solution of **1** (0.01 mol) was added. After stirring for 1 hr at −50 °C, alkyl halide (0.01 mol) in ether (10 ml) was added. The mixture was then stirred for another 2.5 hr. *N*-Benzylideneaniline (0.01 mol) was then added to the mixture, and it was stirred for another 2.5 hr. After neutralization with ammonium chloride, the reaction mixture was treated by the general method.

3-Methyl-5-[2-(1-anilino-1,3-diphenyl)propyl]isoxazole (8): The eluate of silica gel chromatography was concentrated and recrystallized from *n*-hexane; mp 133 °C; yield, 25%. IR (KBr): 3400, 1605, 1505, 1490, 790 and 695 cm^{-1}. UV: λ_{max}^{EtOH} 248 (ε 14700) and 296 nm (2300). NMR: δ_{CDCl_3} 2.10 (s, 3H), 3.13 (d, J=6 Hz, 2H), 3.44 (t, J=6 Hz, 1H), 4.3 (broad s, 1H), 4.68 (d, J=6 Hz, 1H), 5.41 (s, 1H) and 7.3—6.35 ppm (m, 15H). Found: C, 81.73; H, 6.80; N, 7.54%. Calcd for $C_{25}H_{24}N_2O$: C, 81.49; H, 6.57; N, 7.60%.

The Reaction of 1 with N-Benzylideneaniline, Followed by Alkylation. To a sodium amide (0.02 mol) suspension in liquid ammonia (50 ml) an ether solution of **1** (0.01 mol) was added. After the mixture had been stirred for 1 hr at −50 °C, *N*-benzylideneaniline (0.01 mol) was added to the mixture, after which it was stirred for another 2.5 hr. To the mixture alkyl halide (0.01 mol) in ether (10 ml) was then added. The stirring was continued for another 2.5 hr. After a usual work-up, the products were compared with authentic samples.

3-Methyl-5-styrylisoxazole (9): Mp 91.5 °C; yield 23%. IR (KBr): 1645, 1580, 1565, 1410, 965, 795, 760, and 695 cm^{-1}. UV: λ_{max}^{EtOH} 222 (ε 8900), 227 (9900), 234 (7600) and 301 nm (30100). NMR: δ_{CCl_4} 2.25 (s, 3H), 5.96 (s, 1H), 7.35—6.6 (AB-q, J=16 Hz, 2H) and 7.5—7.1 ppm (m, 5H). Found: C, 77.75; H, 6.18; N, 7.36%. Calcd for $C_{12}H_{11}NO$: C, 77.81; H, 5.99; N, 7.56%.

The Hydrogenation of 2. An ethanol (30 ml) solution of **2** was hydrogenated with platinum oxide (6.0 mg) for 15 hr. After the subsequent removal of the catalyst and the solvent, the residue was chromatographed on silica gel with a benzene–ethyl acetate mixture. The products were identified by comparison with authentic samples.

3-Methyl-5-(2-aminostyryl)isoxazole (10). To a sodium amide (0.01 mol) suspension in liquid ammonia (*ca.* 50 ml) **1** (0.01 mol) in dry ether (15 ml) was added. After stirring for 1 hr at −60 °C, the ether solution (10 ml) of benzonitrile (0.01 mol) was added. The stirring was then continued for another 2 hr. After a usual work-up, the residue was recrystallized from an *n*-hexane–benzene mixture; mp 85 °C; yield, 49%. IR (KBr): 3500, 3400, 1630, 1610, 1580, 975, 810, 770, 745 and 695 cm^{-1}. UV: λ_{max}^{EtOH} 230 (ε 9600) and 331 nm (18800). NMR: δ_{CDCl_3} 2.25 (s, 3H), 5.15 (broad s, 2H), 5.34 (s, 1H), 5.79 (s, 1H) and 7.7—7.2 ppm (m, 5H). Found: C, 72.07; H, 6.23; N, 14.19%. Calcd for $C_{12}H_{12}N_2O$: C, 71.98; H, 6.04; N, 13.99%.

3-Methyl-5-benzoylmethylisoxazole (11). **10** was passed through a silica gel column with a benzene–ethyl acetate mixture; the eluate was then concentrated, and the residue was recrystallized from an *n*-hexane–benzene mixture; yield, 95%. The product was identified by comparison with an authentic sample.

3-Methyl-5-(2-amino-2-phenylethyl)isoxazole (12). To **10** (500 mg) in methanol (20 ml) was added sodium borohydride (136 mg) at room temperature. The mixture was then stirred for 20 hr. The resulting residue was distilled; bp 174—180 °C/6 mmHg; yield, 27%. IR (liquid film): 3350, 3300, 1605, 800, and 700 cm^{-1}. NMR: δ_{CCl_4} 1.6 (broad s, 2H),

2.17 (s, 3H), 2.90 (d, J=7 Hz, 2H), 4.22 (t, J=7 Hz, 1H), 5.65 (s, 1H) and 7.20 ppm (s, 5H). Found: C, 70.63; H, 7.27; N, 13.49%. Calcd for $C_{12}H_{14}N_2O$: C, 71.26; H, 6.98; H, 13.85%.

*1-Phenyl-1,5-diaminohexa-1,4-dien-3-one (**13**).* The ethanol (10 ml) solution of **10** (237 mg) was hydrogenated on platinum oxide (4.6 mg). After the removal of the catalyst and the solvent, the residue was recrystallized from an *n*-hexane–benzene mixture; mp 129 °C; yield, 56%. IR (KBr): 3400, 1630, 1535, 1305, 1150, 960, 800, 770 and 685 cm^{-1}. UV: λ_{max}^{EtOH} 240 (ε 10300), 265 (6200) and 375 nm (19700). NMR: δ_{CDCl_3} 1.89 (s, 3H), 4.90 (s, 1H), 5.18 (s, 1H), 8.0—6.0 (broad s, 4H, disappeared by D_2O exchange) and 7.6—7.1 ppm (m, 5H). Found: C, 71.30; H, 7.06; N, 13.82%. Calcd for $C_{12}H_{14}N_2O$: C, 71.26; H, 6.98; N, 13.85%.

*The Reaction of **1** with Benzonitrile, Followed by Alkylation.* To a sodium amide (0.015 mol) suspension in liquid ammonia (*ca.* 50 ml) **1** (0.01 mol) in dry ether (15 ml) added. After the mixture had been stirred for 1 hr at −60 °C, an ether solution (15 ml) of benzonitrile (0.01 mol) was added; the stirring was then continued for 1 more hr. After the addition of alkyl halide (0.01 mol) in ether (15 ml), the stirring was continued for another 2 hr at −60 °C. After a usual work-up, the resulting residue was passed through a silica gel column with benzene–ethyl acetate and the product was recrystallized from an *n*-hexane–benzene mixture.

*3-Methyl-5-(1-benzoylethyl)isoxazole (**15**)*: Yield, 7%; mp 48 °C. IR (liquid film): 1685, 1605, 980, 800, and 690 cm^{-1}. NMR: δ_{CCl_4} 1.49 (d, J=7 Hz, 3H), 2.11 (s, 3H), 4.84 (q, J=7 Hz, 1H), 5.81 (s, 1H) and 8.0—7.2 ppm (m, 5H). Found: C, 72.77; H, 6.14; N, 6.57%. Calcd for $C_{13}H_{13}NO_2$: C, 72.54; H, 6.09; N, 6.51%.

*3-Methyl-5-(1-benzoylpropyl)isoxazole (**16**)*: Yield, 24%; mp 59 °C. IR (KBr): 1685, 1600, 1000, 810, 730, and 690 cm^{-1}. NMR: δ_{CCl_4} 0.96 (t, J=7 Hz, 3H), 2.4—1.7 (m, 2H), 2.20 (s, 3H), 4.65 (t, J=8 Hz, 1H), 5.83 (s, 1H) and 8.1—7.2 ppm (m, 5H). Found: C, 73.40; H, 6.70; N, 6.05%. Calcd for $C_{14}H_{15}NO_2$: C, 73.34; H, 6.59; N, 6.11%.

*The Hydrogenation of **14**.* The crude **14** (529 mg) was hydrogenated with palladium on charcoal (5%, 77 mg) in ethanol (25 ml) at room temperature for 15 hr. After the removal of the catalyst and the solvent, the residue was chromatographed on a silica gel column with a benzene–ethyl acetate mixture. The products were recrystallized from benzene.

cis-*2-Phenyl-3,6-dimethyl-2,3-dihydro-4(1H)pyridone (**17**)*: Mp 168 °C; yield, 14%. IR (KBr): 3220, 1600, 1580, 1525, 1250, 810, 760 and 700 cm^{-1}. NMR: δ_{CDCl_3} 0.85 (d, J=7 Hz, 3H), 2.05 (s, 3H), 2.8—2.0 (m, 1H), 4.80 (d, J=4 Hz, 1H), 4.97 (s, 1H), 5.2 (broad s, 1H) and 7.29 ppm (s, 5H). Found: C, 77.73; H, 7.54; N, 6.91%. Calcd for $C_{13}H_{15}NO$: C, 77.58; H, 7.51; N, 6.96%.

trans-*2-Phenyl-3,6-dimethyl-2,3-dihydro-4(1H)pyridone (**18**)*: Mp 166 °C; yield, 19%. IR (KBr): 3220, 1600, 1580, 1525, 1230, 805, 785, 750, and 690 cm^{-1}. NMR: δ_{CDCl_3} 0.89 (d, J=7 Hz, 3H), 2.00 (s, 3H), 2.52 (m, 1H), 4.21 (d, J=13 Hz, 1H), 4.96 (s, 1H), 5.3 (broad s, 1H) and 7.34 ppm (s, 5H). Found: C, 77.50; H, 7.56; N, 6.89%. Calcd for $C_{13}H_{15}NO$: C, 77.58; H, 7.51; N, 6.96%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3536—3544 (1973)

Stereochemistry of the C and D Rings of *C*-Nor-*D*-homosteroids. I. The Birch Reduction of "Jervine-11β-ol" and Related Compounds

Akio MURAI, Keiko ARITA, and Tadashi MASAMUNE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 1, 1973)

The Birch reduction of "jervine-11β-ol" (**4**) was reinvestigated in detail. Two unknown (**6** and **7**) and two known compounds (**8** and **9**) with established configurations were newly isolated besides the previously obtained products (**2** and **5**). The main product (**2**), the C_{17} configuration of which has been left undefined, was degraded into a methyl ketone (**18**) *via* a known saturated compound (**14**) (Chart 2) or correlated with an α,β-unsaturated ketone (**23**) (Chart 3). These transformations confirmed the configuration of **2** (C_{17}–H) to be β, since the steric structures of compounds **18** and **23** have been determined in an unambiguous manner. On the other hand, the structures and configurations of **6** and **7** were elucidated as shown by the formulas on the respective spectral data as well as by hydrogenation of **6** to **14** (Chart 4) and by hydrolysis of an 11β-alcohol (**24**=**7a**), obtained by reduction of the ketone **23**, to **7** (Chart 4). These results together with those of the Birch reductions of 11-deoxojervine (**1**) and product **7** are summarized as follows: Products **2**, **6**, **7**, and **9** with the saturated 17-carbon all take the β-hydrogen configuration at C_{17}, products **3** and **5** with the C_{13}–C_{17} double bond the α-hydrogen configuration at C_{12}, and products **8** and **9** with the saturated carbons at C_{13} and C_{17} the β-hydrogen configuration at C_{12}.

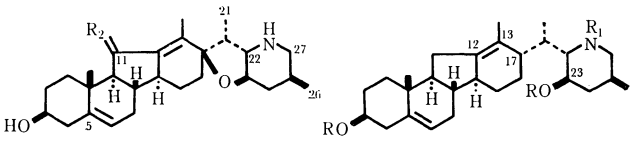
The C and D rings of *C*-nor-*D*-homosteroids show a steric behavior differing in many respects from that of normal steroids. The stereochemistry of both rings of the Birch redution products of "jervine-11β-ol" and related compounds involve several unresolved problems. We reported[1] that 11-deoxojervine (**1**) produced two diols (**2**) and (**3**) in 42 and 16% yields, respectively, and "jervine-11β-ol" (**4**) gave one (**2**) of

* Part XX of *C*-Nor-*D*-homosteroids and Related Alkaloids; Part XIX, T. Masamune and T. Orito, This Bulletin, **45**, 1888 (1972).

1) a) T. Masamune, M. Takasugi, and Y. Mori, *Tetrahedron Lett.*, **1965**, 489; b) T. Masamune, K. Kobayashi, M. Takasugi, Y. Mori, and A. Murai, *Tetrahedron*, **24**, 3461 (1968).

the diols and a triol (**5**) in 50 and 5% yields, respectively, by treatment with lithium in ethylamine. However, the C_{17} configuration of the main product **2** remained undefined. Compound **2** is not only an important intermediate in a series of reactions to correlate jervine and veratramine and hence to establish the C_9 configuration of jervine, but also could be a useful intermediate for skeletal transformation of the present *C*-nor-*D*-homosteroids into normal steroids.[2] Thus it became necessary to determine the configuration of **2** and improve its yield. The hydrogenation products of **2**, key substances (**14** and **15**) in the correlation in question, remained undetermined at the configurations at C_{12}, C_{13}, and C_{17}. This led us to reexamine the relevant Birch reduction of **4** and related compounds. We have isolated several compounds including **2** and **5** and elucidated their structures and configurations. The results are described in this paper.

The reduction was carried out under two different conditions; lithium and ethylamine (as in the previous work[1]) and lithium and a 5: 2: 2 mixture of ammonia, dioxane, and tetrahydrofuran. Three new compounds (**6**, **7**, and **8**) were isolated besides **2** and **5** under the former conditions, and two compounds (**6** and **9**) along with **2** and **5** under the latter (see Table). Compounds **5**,[1] mp 217—218 °C, **8**,[3] mp 239.5—241.5 °C, and **9**,[4] mp 234—236 °C, proved to be the known substances with established configurations. The structures and configurations of the other compounds **2**, **6**, and **7** are given in the following sections.



1 $R_2=H_2$
4 $R_2=$–OH,···H
Jervine $R_2=O$

2 $R=R_1=H$
2a $R=R_1=Ac$

a) Yields of isolated crystalline products.
b) New compounds.
c) Reported yield (Ref. 1b), 50% as **2**.
d) Reported yield (Ref. 1b), 5%.

Configuration at C_{17} of Compound 2. Compound **2**, mp 194.5—195.5 °C, was isolated *via* the 3-*O*,23-*O*,*N*-triacetyl derivative (**2a**), mp 195—197 °C, since it showed the same R_f value as **6**. **2** was subjected to degradation in the same way as Johnson's fragmentation;[5] namely, **2** was converted with *N*-chlorosuccinimide (NCS) into the *N*-chloro derivative, which on treatment with sodium methoxide and then with acid gave an aldehyde (**10**), ν_{max} 2710 and 1720 cm^{-1}, and τ 0.25 (1H, broad singlet, CHO) and 9.10 (3H, doublet with J=7 Hz, 21-Me). The aldehyde, extremely unstable in the air, was further degraded, with *n*-butyl nitrite and sodium methoxide, to an oxime (**11**), mp 161—164 °C, in 61% yield from **2**, whose NMR spectrum displayed a broad signal with W_H= *ca.* 20 Hz at τ 7.04 due to the C_{17} proton. The oxime, when treated with sodium bisulfite in refluxing ethanol[6] and then with hydrochloric acid afforded a multicomponent mixture,[7] from which two products (**12**), mp 141—142.5 °C, and (**13**), mp 167.5—169 °C, were isolated in 10 and 36% yields. The former, which gave the monoacetate (**12a**), mp 119.5—120 °C, was assigned structure **12** on the basis of the mass (*m/e* 272, M^+), IR (no C=O absorption) and NMR spectra (no sharp peaks except two singlets at τ 9.04 and 8.44 due to 19- and 18-Me in the higher field, and only one C_6 olefinic proton signal at τ 4.65 in the lower field). Formation of **12** would be tentatively rationalized by assuming partial isomerization of the C_{12}–C_{13} double bond of **13** or **11** to the C_{13}–C_{17} position, hydration, retro-Claisen reaction and remigration of the resulting C_{13}–C_{17} double bond. On the other hand, the major product **13** was identified as the expected compound formed by simple hydrolysis of the oxime **11**. In accordance with the assigned structure, the mass spectrum (*m/e* 314, M^+) indicated a molecular formula $C_{21}H_{30}O_2$, and the IR and NMR spectra exhibited the presence of a C_{17} acetyl substituent (ν_{max} 1695 cm^{-1} and τ 7.91, singlet) and a 18-methyl group attached to the C_{12}–C_{13} double bond (τ 8.48, singlet). The NMR spectrum (τ 6.90, a broad signal with W_H= *ca.* 23 Hz)[4] and the ORD curve (a large positive

Cotton effect, $a=+279°$)[8] indicated the C_{17} hydrogen to possess the β-configuration. Furthermore, on treatment of **13** with alkali in refluxing methanol, most of the starting material remained unchanged with no configurational change at C_{17}, supporting the 17β-hydrogen, while isomerization of the C_{12}–C_{13} double bond occurred only partially (less than 20%). This would be caused by serious steric interaction between 18- and 21-methyl groups with the resulting α,β-unsaturated 20-ketone.[9] However, in view of the low yield of **13** as well as of the difficult derivation of **13** to a known compound,[10] it became desirable to determine the relevant configuration more clearly. The low yield in the hydrolysis of oxime **11** was expected to be improved by saturation of the C_{12}–C_{13} double bond.

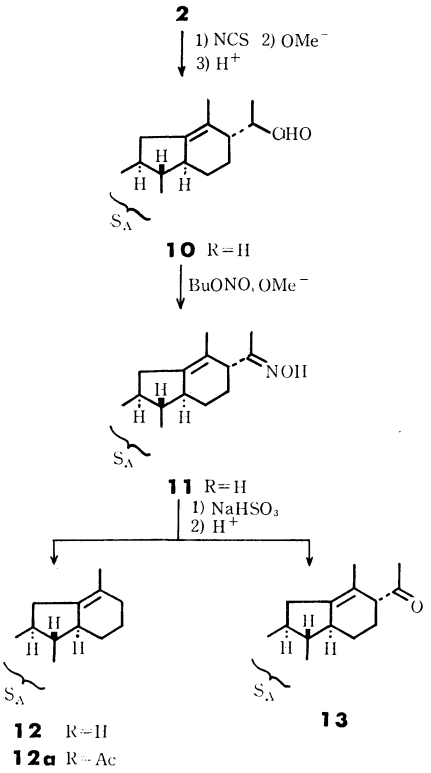

Chart 1

Hydrogenation of **2** over prereduced rhodium-platinum oxide (3: 1) catalyst[11] in acetic acid proceeded smoothly, two moles of hydrogen being consumed within 1 hr, and produced a single product (**14**),[12] mp 185.5—186 °C, in 76% yield. It would be very improbable that migration of the C_{12}–C_{13} double bond occurred during the facile hydrogenation, because the same hydrogenation over only platinum required a long time (21—90 hr) for absorption of 2 mol of hydrogen and afforded a 36% yield of the isomeric compound (**15**),[13] mp 183—185 °C, along with **14**. Isomer **15** would probably be formed by migration of the C_{12}–C_{13} double bond to C_{13}–C_{17} followed by hydrogenation. While these products had already been prepared,[1] their configurations have been left undetermined. Thus, compound **14** was degraded in the same manner as **2** and converted into an oxime (**17**), mp 174—176 °C, *via* an aldehyde (**16**), amorphous, ν_{max} 2710 and 1723 cm^{-1}, and τ 0.35 (1H, singlet). Mild hydrolysis[6] of **17** afforded the corresponding methyl ketone, mp 135—137 °C, ν_{max} 1699 cm^{-1} and τ 7.89 (3H, singlet), in high yield from **14**, which proved to be identical with a known compound (**18**) with established configurations (17β-H).[14] Likewise, compound **15** was converted into the corresponding methyl ketone (**21**), mp 70—72 °C and ν_{max} 1704 cm^{-1}, in good yield, *via* an aldehyde (**19**) and an oxime (**20**). This ketone **21** displayed a broad peak with W_H=22 Hz at τ 6.40 due to the C_3 proton in the NMR spectrum, indicative of the A/B *trans*-fused linkage. It was stable against alkali (no epimerization at C_{17}) but differed from a well-defined compound (**22**)[15] prepared from jervine. On the basis of the *cis*-addition of hydrogen to double bonds[16] and the chemical shifts of 19-Me protons

(τ 9.26, probably *trans* C/D linkage),[17] compound **15** would possibly be formulated as structure **15**. Thus, these findings confirmed the conclusion (17β-H) in the preceding section.

Further confirmation could be obtained by correlating **2** with a compound (**23**)[18] with unambiguous configurations,[4] prepared readily from jervine by a three-step process. Reduction of **23** with sodium borohydride in refluxing dioxane followed by acetylation of the product afforded a multi-component mixture, from which three compounds were isolated by preparative tlc. One, mp 213—215 °C, isolated in 14% yield, could be assigned to formula **24** on the spectral data, ν_{max} 3570 cm^{-1} and τ 8.74 (singlet, 19-Me)[17] and 8.23 (singlet, 18-Me). Compound **24** was converted by oxidation with chromic anhydride in pyridine into the original ketone **23a**, indicative of retention of the C_{17} configuration during the course of sodium borohydride reduction. Treatment of **24** with lithium in ethylamine and subsequent acetylation resulted in formation of **2a** in 74% yield, establishing the configuration in question to be β. Incidentally, the other two compounds resisted crystallization, but mild hydrolysis effected formation of two crystalline *N*-acetyl compounds, mp 248—251 °C and 241—242 °C. These could be inferred to possess structures **25** and **26**, but were not further examined.

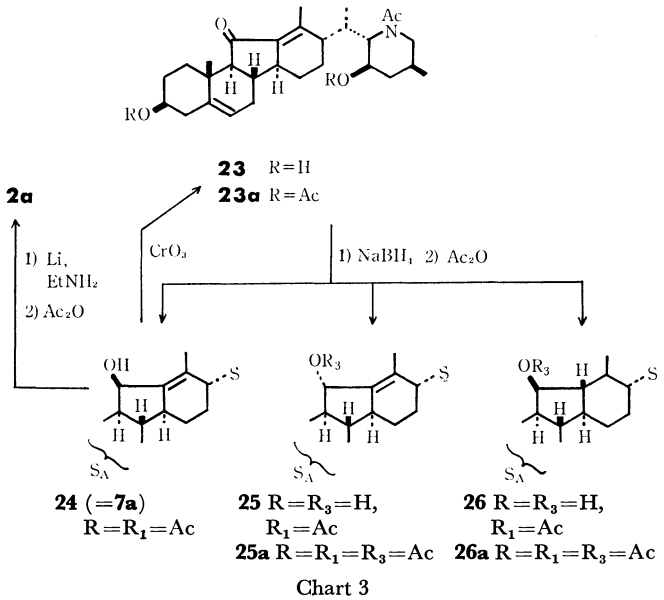

Chart 3

Structure and Configuration of Compound 6. This compound could be isolated as the 3-*O*,23-*O*,*N*-triacetyl derivative (**6a**), mp 173—174 °C, which on hydrolysis gave **6**, mp 229—231.5 °C. Compound **6a**, $C_{33}H_{49}O_5N$, exhibited a parent peak at *m/e* 539 and a broad singlet with W_H=9 Hz at τ 4.62 due to two olefinic protons in the mass and NMR spectra. These indicated the compound to be an isomer of **2a** and to be formulated most favorably as structure **6a**. In fact, **6a** was produced by a modification of the Huang-Minlon procedure[19] for the Wolff-Kishner reduction of **23** followed by acetylation in 45% yield along with **2a** (30%), and also obtained by treatment of **24** with lithium in a 5:2:2 mixture of ammonia–dioxane–tetrahydrofuran and subsequent acetylation in 12% yield. The reduction of **24** with lithium in ethylamine gave no detectable amount of **6**. These transformations confirmed not only a planar structure of **6** but also the β-configuration at C_{17}. On the other hand, hydrogenation of **6a** over rhodium-platinum[11] in acetic acid for 2 hr led to saturation of the compound and, after hydrolysis, formation of the *N*-acetyl compound, mp 180—182 °C and ν_{max} 1641 cm^{-1}, which was identical with a compound (**14a**), mp 180.5—182.5 °C, obtained by triacetylation of **14** followed by partial hydrolysis. These results indicate that the hydrogen at C_{13} possesses α-configuration, since migration of the C_{11}–C_{12} double bond would be very improbable during the course of hydrogenation. On the basis of these configurational assignments, the Wolff-Kishner reduction would be rationalized by assuming that it proceeds by path B[20] (Chart 4) and is completed by axial approach of the proton source to the C_{13}, as elaborated by Zimmerman[21] in many examples of reketonization of enols.

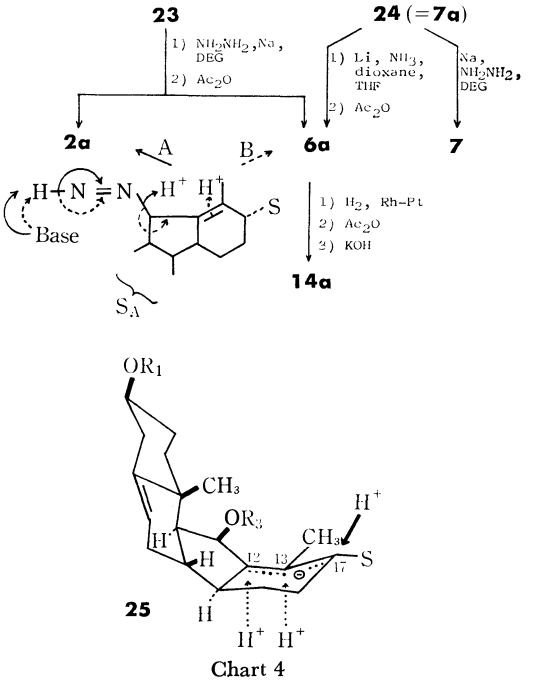

Chart 4

Structure and Configuration of Compound 7. The compound was analyzed for $C_{27}H_{43}O_3N$ and showed peaks at *m/e* 429, 141, and 114 in the mass spectrum. The spectrum not only supported the molecular formula but also indicated cleavage of the C_{17}–O ether bond,

suggesting formula **7**. Thus **24** was hydrolyzed for 17 hr under the conditions of a modified Huang-Minlon procedure.[19] The product was identical with **7**, confirming the structure and configuration of compound **7**.

Summary of Results. The results of the Birch reduction of **4** and **7a** (=**24**), together with those of **1**,[1] are summarized as follows. Apart from compound **8**, all C_{17}-saturated compounds **2**, **6**, **7**, and **9** take the β-hydrogen configuration at C_{17}, while compounds **3** and **5** with the C_{13}–C_{17} double bond possess the α-hydrogen at C_{12}. As shown with simpler model compounds,[22] these results would probably be caused by the continued maximum overlap[21,23] between the π-orbitals at C_{12}, C_{13}, and C_{17} of reduction carbanion intermediates such as **25**, on approach of the proton sources.[22] It is to be noted that saturated compounds **8** and **9** were formed, resulting from reduction of isolated double bonds under the Birch conditions. Moreover, the fact that **8** and **9** adopt the β-hydrogen configuration at C_{12} can be well interpreted, considering the results of the Birch reduction[4] of **23** as well as *trans*-hydrogenation[16] of jervine over platinum in acetic acid leading to the corresponding 12β,13α-dihydro compounds, since protonation at C_{12} of the respective reaction intermediates, C_{12}–C_{13} anion radical or dianion formed from **4** *via* the relevant double bond and 11-en-11-ol or 11-en-11-olate from **23** and jervine, wound proceed in the same manner as reketonization of enols.[21]

Experimental

All the mps were measured in sealed capillaries and uncorrected. The homogenity of each compound was always checked by tlc on silica gel (Wakogel B-5) using various solvent systems, and the spots were developed with ceric sulfate in dil. sulfuric acid and/or iodine. The optical rotations, ORD curves, and IR spectra were measured in chloroform, methanol, and Nujol, respectively, unless otherwise stated. The NMR spectra were obtained in deuterochloroform at 60 and/or 100 MHz, and the chemical shifts were given in τ-values, TMS being used as an internal reference. Abbreviations "s, d, t, m, br, and sh" in the NMR and IR spectra denote "singlet, doublet, triplet, multiplet, broad and shoulder," respectively.

Birch Reduction of "Jervine-11β-ol" (4) with Lithium in Ethylamine (cf. Ref 1b). To **4** (800 mg) dissolved in refluxing anhydrous ethylamine (31 ml) was added finely divided lithium metal (647 mg), and the mixture was refluxed under vigorous stirring for 2.5 hr. After addition of ammonium chloride, the mixture was warmed to remove the solvent, and the residue mixed with water (50 ml) and extracted with chloroform repeatedly. The chloroform solution was washed with water, dried with anhydrous sodium sulfate and evaporated to leave amorphous residue (974 mg), which showed 5 spots on tlc and was separated by preparative tlc, using a 10: 1 mixture of ether and methanol and 46 plates; each was made of silica gel (Wakogel B-5, 10 g) with an area of 20 cm by 20 cm.

Each fraction was extracted with methanol, and the solution evaporated below 50 °C. The residue was again dissolved in chloroform, washed with a 5% sodium bicarbonate solution and water, treated with active charcoal, dried and evaporated. The most mobile fraction (90 mg), amorphous, showed a parent peak at *m/e* 413 in the mass spectrum but was not further examined. The second fraction (502 mg) was treated with acetic anhydride (11 ml) and pyridine (11 ml) at room temperature for 17 hr. After removal of the solvents, the residue was treated with water and chloroform, and the chloroform solution was washed with 1M hydrochloric acid, a 5% sodium bicarbonate solution and water, dried and evaporated to leave amorphous substance (733 mg), which partially crystallized on trituration with aqueous methanol. The crystalline material was collected by filtration and recrystallized from the same solvent to give 3-*O*,23-*O*,*N*-triacetyl-22,27-imino-17β-jerva-5,12-diene-3β,23β-diol (**2a**, 400 mg), mp 195—197 °C (lit,[1b] 188—190 °C); $[\alpha]_D$ −48.0° (lit,[1b] −12.3° in 95% EtOH); mass, *m/e* 539 (M^+); IR, ν_{max} 1738, 1625, 1239 and 1025 cm^{-1}; NMR τ 9.23 and 8.84 (each 3H, d, J=6.5 and 7 Hz, 21- and 26-Me or *vice versa*), 9.05 (3H, s, 19-Me), 8.50 (3H, s, 18-Me), 7.99 (6H, s, $OCOCH_3$), and 7.89 (3H, s, $NCOCH_3$) (*cf.*, Ref 1b). On the other hand, the filtrate was evaporated and then separated into two parts by preparative tlc(ether–benzene 1: 2, and 18 plates). Each acetone eluate was worked up as mentioned above, and the more mobile fraction (41 mg) crystallized on trituration with isopropyl ether and was recrystallized to yield 3-*O*,23-*O*,*N*-triacetyl-22,27-imino-17β-jerva-5,11-diene-3β,23β-diol (**6a**, 12 mg), mp 173—174 °C; $[\alpha]_D$ −28.5°; mass, *m/e* 539 (M^+); IR, ν_{max} 1740, 1637, 1240, 1040, and 1025 cm^{-1}; NMR, τ 9.04 (3H, s, 19-Me), and 4.63 (2H, br s W_H=9 Hz, H at C_6 and C_{11}).

Found: C, 73.22; H, 9.34; N, 2.26%. Calcd for $C_{33}H_{49}O_5N$: C, 73.43; H, 9.15; N, 2.60%.

The less mobile fraction (135 mg) crystallized from aqueous methanol, (77 mg), mp 191—194 °C, and was identical with **2a**.

The third, middle fraction (104 mg) was crystallized and recrystallized from methanol–acetone to give 22,27-iminojerva-5,13(17)-diene-3β,11β,23β-triol (**5**, 49 mg), mp 217—218 °C, which was identical with an authentic sample.[1b]

The fourth fraction (62 mg) crystallized on trituration from methanol–acetone, mp 221—225 °C, and was recrystallized from the same solvent to yield 22,27-imino-17β-jerva-5,12-diene-3β,11β,23β-triol (**7**, 13 mg), mp 228—231 °C, which was identical with a compound prepared by hydrolysis of **24** (=**7a**), described later; IR, ν_{max} 3420 and 1046 cm^{-1}.

The least mobile fraction (31 mg) crystallized on trituration with methanol–acetone, mp 235—236 °C, and was recrystallized from the same solvent to afford 22,27-imino-17β,23β-oxidojerv-5-ene-3β,11β-diol (**8**, 17.5 mg), mp 239.5—241.5 °C, which was identical with an authentic specimen.[3]

Birch Reduction of 4 with Lithium and a Mixture of Ammonia, Dioxane, and Tetrahydrofuran (THF). To a suspended mixture of **4** (800 mg) in liquid ammonia (200 ml), dry dioxane (80 ml) and dry THF (80 ml) was added lithium (565 mg), and the mixture was stirred vigorously under reflux for 1 hr. To the refluxing mixture was added dropwise dry ethanol (7.2 ml) for 4 min, when the blue color disappeared. After addition of lithium (315 mg), the mixture was again refluxed under stirring for 15 min and, on addition of dry ethanol (4 ml) for 2 min, became colorless again. After removal of the ammonia, the solvents were evaporated below 50 °C, and the residue was mixed with water (50 ml) and extracted with chloroform repeatedly. The chloroform solution was worked up as mentioned above to give crystalline residue (812 mg), showing 5 spots on tlc. Fractional recrystallizations from

22) T. Masamune, H. Matsue, and M. Fujii, This Bulletin, **45**, 1812 (1972).

23) G. Stork and S. D. Darling, *J. Amer. Chem. Soc.*, **86**, 1761 (1964).

methanol–acetone afforded crystalline material (489 mg), which showed a single spot corresponding to the second fraction in the preceding reduction (run a). All mother liquors were combined and separated into 5 parts by preparative tlc, using a 10: 1 mixture of ether and methanol and 31 plates. The most mobile fraction (14 mg), amorphous, was identical with the corresponding one in run a.

The second fraction (255 mg) was combined with the afore-mentioned crystalline material and acetylated with acetic anhydride (13 ml) and pyridine (13 ml) at room temperature overnight. The product (1018 mg), showing two spots, crystallized on trituration with aqueous methanol and, on recrystallization from the solvent, afforded **2a** (666 mg), mp 192—194 °C. The filtrates were combined and separated by preparative tlc (ether–benzene 1: 2, and 19 plates) and worked up as in run a. The more mobile fraction (109 mg) afforded **6a** (76 mg), mp 168—170 °C (from isopropyl ether), and the less mobile (113 mg) **2a** (62 mg), mp 193—195 °C (from aqueous methanol).

The middle fraction (7 mg) crystallized on trituration with methanol–acetone and was recrystallized from the same solvent to give **5** (0.5 mg), mp 214—215 °C, which was identical with sample **5** in run a in the mass spectrum and R_f value on tlc.

The fourth fraction (41 mg) crystallized on trituration with methanol–acetone (19 mg), mp 234—236 °C.

Recrystallization from the same solvent afforded 22,27-imino-17β-jerv-5-ene-3β,11β,23β-triol (**9**), which was identical with an authentic sample.[4]

The last fraction (19 mg) crystallized on trituration with methanol–acetone, (11 mg) mp 179—180 °C, but was not further examined.

Compound **2a** was hydrolyzed as follows. To diethylene glycol (DEG) (100 ml) with dissolving sodium (3 g) was added anhydrous hydrazine (20 ml), and the solution was refluxed for 30 min. After addition of **2a** (2.06 g), the whole solution was refluxed for 21 hr and then cooled, when the condenser was replaced by a distillation apparatus. The solution was again heated for 30 min, evaporating off the hydrazine, cooled and poured into ice-water (one l), when precipitates separated and were collected by filtration, washed with water repeatedly and dissolved in methanol. The methanol solution was evaporated to leave amorphous substance, which crystallized on trituration with acetone (1.45 g), mp 194—194.5 °C. This was recrystallized for analysis to give **2**, mp 194.5—195.5 °C (lit,[1b] 193—195 °C); $[\alpha]_D$ −70.6° (MeOH) (lit,[1b] −61° in 95% EtOH); mass, *m/e* 413 (M^+); IR, ν_{max} 3385, 3105, 1063, 1039, 888, and 812 cm^{-1}.

Found: C, 78.15; H, 10.51; N, 3.33%. Calcd for $C_{27}H_{43}O_2N$: C, 78.40; H, 10.48; N, 3.39%.

Compound **6a** (101 mg) was hydrolyzed in the same manner as **2a**, using DEG (5 ml), sodium (200 mg), and hydrazine (1 ml). The product crystallized on trituration with acetone, (66 mg), mp 228—229 °C. This was recrystallized for analysis to give **6**, mp 229—231.5 °C; $[\alpha]_D$ −85.0° (MeOH); mass, *m/e* 413 (M^+); IR, ν_{max} 3390, 3130, 1079, 1068, 1039, 890, and 812 cm^{-1}.

Found: C, 77.97; H, 10.46; N, 3.41%. Calcd for $C_{27}H_{43}O_2N$: C, 78.40; H, 10.48; N, 3.39%.

*17α-Acetyletiojerva-5,12-dien-3β-ol 20-oxime (**11**).* To a solution of **2** (5.0 g) in dry THF (250 ml) was added *N*-chlorosuccinimide (NCS) (2.0 g), and the mixture was stirred at room temperature for 2 hr. After removal of the solvent below 28 °C, the residue was mixed with methanol (150 ml). To the suspended mixture was added 2M sodium methoxide in methanol (150 ml) under cooling with an ice-bath in a stream of nitrogen. The mixture was stirred at room temperature for 4.5 hr, when the mixture became homogeneous, and then evaporated below 45 °C. The residue was mixed with water and then with 6M hydrochloric acid (100 ml) under cooling, stirred vigorously at room temperature overnight and filtered. The precipitates were dissolved in chloroform, and the chloroform solution washed with 1M hydrochloric acid, a 5% sodium bicarbonate solution and water, dried and evaporated below 27 °C to leave amorphous 20-aldehyde (**10**, 4.0 g), which showed a single spot; mass, *m/e* 328 (M^+) and 270 (M^+–side chain, CH_3CHCHO); IR, ν_{max} 3600, 3450, 2710, 1720, and 1047 cm^{-1}; NMR, τ 9.10 (3H, d J=7 Hz, 21-Me), 9.01 (3H, s, 19-Me), 8.42 (3H, s, 18-Me), 6.45 (1H, m W_H=26 Hz, H at C_3), 4.65 (1H, br a W_H=9 Hz, H at C_6), and 0.25 (1H, s, CHO).

To a cooled solution of **10** (1.06 g) in methanol (50 ml) were added *n*-butyl nitrite (6 ml) and 1.7M sodium methoxide in methanol (50 ml) under nitrogen, and the solution was allowed to stand in a refrigerator (6 °C) for 14 hr. After removal of the solvents below 39 °C, the residue was mixed with water (30 ml) and acidified to pH 3 by dropwise addition of 6M hydrochloric acid (15 ml) under cooling and stirring, and then extracted with chloroform. The chloroform solution was washed with a 5% sodium bicarbonate solution, dried and evaporated below 30 °C to leave oil, which was purified by preparative tlc (ether–benzene 1: 1, and 35 plates). The main fraction, acetone eluate, was evaporated and redissolved in chloroform, and the solution gave amorphous substance (650 mg), which crystallized on trituration with methanol–isopropyl ether, mp 148—151 °C. Recrystallization from the same solvent afforded an analytical sample of 20-oxime (**11**), mp 161—164 °C; $[\alpha]_D$ +37.3°; IR, ν_{max} 3435, 3255, 1660, and 1054 cm^{-1}; NMR, τ 9.03 (3H, s, 19-Me), 8.53 (3H, s, 18-Me), 8.29 (3H, s, 21-Me), 7.04 (1H, br W_H=20 Hz, H at C_{17}), 6.50 (1H, br W_H=28 Hz, H at C_3), and 4.62 (1H br s, W_H=9 Hz, H at C_6).

Found: C, 76.77; H, 9.85; N, 3.76%. Calcd for $C_{21}H_{31}O_2N$: C, 76.55; H, 9.48; N, 4.25%.

*Etiojerva-5,12-dien-3β-ol (**12**) and 17α-Acetyletiojerva-5,12-dien-3β-ol (**13**).* A solution of **11** (650 mg) in ethanol (35 ml) and water (24.5 ml) containing sodium bisulfite (1.36 g) was refluxed under stirring for 13 hr.[6] After removal of the solvents, the residue was stirred vigorously with 1M hydrochloric acid (70 ml) and chloroform (70 ml) at room temperature for 2 hr. After separation of the chloroform layer, the aqueous solution was extracted with chloroform repeatedly. All the chloroform solutions were combined, washed with 1M hydrochloric acid, a 5% sodium bicarbonate solution and water, dried and evaporated to give amorphous residue (390 mg), showing 6 spots, which was separated by preparative tlc (ether–benzene 1: 2, and 21 plates).

The first, most mobile fraction (66 mg) crystallized on trituration with acetone–isopropyl ether (53 mg), mp 138—139 °C. Recrystallization from isopropyl ether afforded an analytical sample of **12**, mp 141—142.5 °C; $[\alpha]_D$ −68.3°; mass, *m/e* 272 (M^+); IR, ν_{max} 3250 and 1058 cm^{-1} (no C–O absorption); NMR, τ 9.04 (3H, s, 19-Me), 8.44 (3H, s, 18-Me), 8.39 (1H, s, OH, checked by addition of D_2O), 6.47 (1H, br W_H=24 Hz, H at C_3), and 4.65 (1H, br s W_H=10 Hz, H at C_6).

Found: C, 84.02; H, 9.99%. Calcd for $C_{19}H_{28}O$: C, 83.77; H, 10.36%.

Compound **12** (47 mg) was acetylated with acetic anhydride (1 ml) and pyridine (1 ml) at room temperature overnight. After being worked up as usual, the mixture gave crystalline substance (47 mg), which was recrystallized from aqueous acetone to give the monoacetate (**12a**, 27 mg), mp 114—117.5 °C. This was recrystallized from the same solvent for analysis;

mp 119.5—120 °C; $[\alpha]_D$ −83.9°; mass, *m/e* 254 (M^+–AcOH); IR, ν_{max} 1727, 1241 and 1030 (no OH absorption); NMR, τ 9.03 (3H, s, 19-Me); 8.44 (3H, s, 18-Me), 7.96 (3H, s, OCOCH$_3$), 5.39 (1H, septet J=4 Hz, H at C_3), and 4.61 (1H, br.s W_H=12 Hz, H at C_6).

Found: C, 80.05; H, 9.48%. Calcd for $C_{21}H_{30}O_2$; C, 80.21; H, 9.62%.

The second, main fraction (223 mg), crystalline, was recrystallized from acetone–isopropyl ether to yield **13** (198 mg), mp 167.5—168 °C. This was recrystallized from the same solvent for analysis; mp 167.5—169 °C; $[\alpha]_D$ +68.2°; ORD, $[\phi]_{311}^{peak}$ +120°, $[\phi]_{287}$ 0°, $[\phi]_{259}^{trough}$ −159°, a=+279°; mass, *m/e* 314 (M^+); IR, ν_{max} 3456, 1695, and 1065 cm^{-1}; NMR, τ 9.03 (3H, s, 19-Me), 8.48 (3H, s, 18-Me), 8.17 (1H, s, OH, checked by addition of D_2O), 7.91 (3H, s, 21-Me), 6.90 (1H, br W_H=23 Hz, H at C_{17}), 6.48 (1H, br W_H=23 Hz, H at C_3), and 4.64 (1H, br s W_H=9 Hz, H at C_6).
Found: C, 80.46; H, 9.43%. Calcd for $C_{21}H_{30}O_2$: C, 80.21; H, 9.62%.

The third fraction (40 mg), oil, was a mixture of two products having almost the same R_f values; IR ($CHCl_3$), ν_{max} 1644 and 1047 cm^{-1}. Each of the fourth (13 mg) and last (13 mg) fractions showed a single spot on tlc and no C=O absorption maxima. None of these fractions were further examined.

Compound **13** (47 mg) was treated with 5% potassium hydroxide in refluxing methanol (20 ml) for 17 hr under nitrogen. After removal of the solvent, the residue was treated with water and chloroform, and the chloroform solution gave amorphous product (57 mg), showing 2 spots. This was separated by preparative tlc (ether–benzene 1:2, and 3 plates). The main, more mobile crystalline fraction (30 mg), showing practically the same IR spectrum as **13**, was recrystallized from acetone–isopropyl ether to give the starting material (10 mg), mp 164—165 °C. The less mobile fraction (7.5 mg), oil, resisted crystallization and showed the following IR and NMR spectra, but was not further examined; IR ($CHCl_3$), ν_{max} 3580, 3450, 1706, 1644, and 1047 cm^{-1}; NMR, τ 8.98 (3H, s), 8.82 (3H, s), 8.29 (s, OH, checked by addition of D_2O), 7.97 (3H, s, 21-Me), 6.45 (1H, br W_H=25 Hz, H at C_3), and 4.64 (1H, br s W_H=11 Hz, H at C_6). This might be a 13ξ-hydroxyetiojervane derivative with a C/D *cis*-fused linkage.

Hydrogenation of **2**. *22,27-Imino-5α,12α,17β-jervane-3β,23β-diol (**14**) and 22,27-imino-5α,13β,17β-jervane-3β,23β-diol (**15**).*
a) A suspended, 3:1 mixture of rhodium and platinum oxide[11] (1.017 g) in acetic acid (20 ml) was prereduced with hydrogen for 2.7 hr, when 281 ml of hydrogen had been consumed. Compound **2** (2.501 g) in acetic acid (40 ml) was added to the mixture and then hydrogenated for 1 hr, when 286 ml of hydrogen (2.0 mol) had been absorbed. The reaction was further continued for 48 hr but without absorption of hydrogen and, after addition of the prereduced catalyst (217 mg) freshly prepared, for another 24 hr, when only 0.18 mol of hydrogen had been consumed. After filtration of the catalyst and subsequent evaporation of the acetic acid below 67 °C, the residue was mixed with water (10 ml), cooled, basified with 6M ammonium hydroxide (20 ml) to pH over 11, and mixed with chloroform (35 ml). The whole mixture was stirred vigorously at room temperature for 20 hr, when chloroform-addition compounds (3.83 g) remaining suspended between the aqueous and chloroform layers were collected by filtration and dissolved in methanol. The solution was evaporated to leave amorphous residue (2.266 g), showing a single spot, which crystallized on trituration with methanol–acetone (1:1) and was collected by filtration to yield **14** (1.905 g), mp 182.5—184.5 °C. This was identical with compound X[1b] obtained already, and recrystallized from the same solvent for analysis; mp 185.5—186 °C (lit,[1b] 185—187 °C); $[\alpha]_D$ −52.9° (MeOH) (lit,[1b] −28.5° in 95% EtOH); mass, *m/e* 417 (M^+) and 114; IR, ν_{max} 3400, 3285, and 1041 cm^{-1}.

Found: C, 77.68; H, 11.40; N, 3.29%. Calcd for $C_{27}H_{47}O_2N$; C, 77.64; H, 11.34; N, 3.35%.

Compound **14** (102 mg) was heated with acetic anhydride (2 ml) and pyridine (2 ml) at 90 °C for 2 hr. After removal of the solvents by azeotropization with benzene, the residue was refluxed with 5% potassium hydroxide in methanol (10 ml) for 1 hr. The reaction mixture was evaporated and mixed with water, when white precipitates separated out and were collected by filtration. These were washed with water, dried and dissolved in ethyl acetate. On being allowed to stand, the solution gave crystalline material (109 mg), mp 180—181 °C. This was recrystallized from ethyl acetate to give an analytical sample of the *N*-acetyl derivative (**14a**) of **14**, mp 180.5—182.5 °C; $[\alpha]_D$ −10.1° (MeOH); mass, *m/e* 459 (M^+) and 156; IR, ν_{max} 3285, 1641, 1611, 1041, 1030 (sh), and 1023 cm^{-1}; NMR, τ 9.26 (3H, s, 19-Me).

Found: C, 75.61; H, 10.61; N, 2.99%. Calcd for $C_{29}H_{49}O_3N$: C, 75.77; H, 10.64; N, 3.05%.

b) Compound **2** was hydrogenated over platinum in almost the same manner as reported;[1b] **2** (2.50 g) was reduced over prereduced platinum oxide (1.0 g) in acetic acid (55 ml) at room temperature for 47 hr, when 1.6 mol of hydrogen had been absorbed. The reaction was continued for another 47 hr after addition of the catalyst (0.55 g), and 2.1 mol of hydrogen was consumed in all. The mixture was worked up as usual and the product was separated into a chloroform-addition compound (**14**) and a chloroform-soluble fraction. The latter crystallized on trituration with acetone and was recrystallized to give **15**, mp 180—182 °C, which was identical with compound X′ obtained already.[1b] This was recrystallized from acetone for analysis; mp 183—185 °C (lit,[1b] 184—186 °C); $[\alpha]_D$ −7.8°; IR, ν_{max} 3270, 1056, and 1029 cm^{-1}; NMR, τ 9.26 (3H, s, 19-Me).

Found: C, 77.46; H, 11.57; N, 3.24%. Calcd for $C_{27}H_{47}O_2N$: C, 77.64; H, 11.34; N, 3.35%.

*17α-Acetyl-5α,12α-etiojervan-3β-ol 20-Oxime (**17**).* A solution of **14** (1.843 g) in THF (80 ml) was stirred with NCS (722 mg) at room temperature for 1.8 hr and, after removal of the solvent below 27 °C, the residue was dissolved in chloroform (200 ml). The solution was washed with water (3×55 ml), dried and evaporated to leave amorphous residue (2.383 g) after being dried over phosphorus pentoxide. To the cooled residue in methanol (50 ml) was added 2M sodium methoxide in methanol (50 ml) under nitrogen, and the solution was stirred for 2 hr and then concentrated to 20 ml below 35 °C for 50 min. The concentrate was mixed with 6M hydrochloric acid (50 ml) and water (200 ml) under cooling, stirred at room temperature overnight, and then extracted with chloform (4×50 ml). The chloroform solution was washed with water, dried and evaporated below 35 °C to give amorphous 20-aldehyde (**16**, 1.541 g), showing a single spot; IR ($CHCl_3$), ν_{max} 3605, 3420, 2710, 1723, 1067, and 1033 cm^{-1}; NMR, τ 9.20 (3H, s, 19-Me), 9.12 and 9.00 (each 3H, d J=7 Hz, 18- and 21-Me or *vice versa*), 6.39 (1H, m W_H=19 Hz, H at C_3), and 0.35 (1H, s, CHO).

A solution of **16** (1.492 g) in methanol (70 ml) was treated with *n*-butyl nitrite (6 ml) and sodium methoxide, prepared from sodium (2.9 g) and methanol (70 ml), in a refrigerator (0 °C) for 14 hr, acidified to pH 6.0 with concd hydrochloric acid (10.5 ml) under cooling, and allowed to stand for 1 hr. The whole mixture was shaken with water (100 ml) and chloroform (3×100 ml), and the chloroform solution gave

oily residue (1.671 g), which showed a single spot but resisted crystallization; IR ($CHCl_3$), ν_{max} 3600 (BuOH), 3300, 1651, 1066, and 1030 cm^{-1}. A part (45.5 mg) of the residue was purified by preparative tlc (ether–benzene 1:1, and 2 plates). The main fraction was extracted with acetone, and the solution gave crystalline material (32.7 mg), which was recrystallized from acetone–isopropyl ether to yield **17** (24 mg), mp 174—176 °C; $[\alpha]_D$ −80.3°; IR, ν_{max} 3650, 3410, 3250, 1643, 1065, 1036, and 1014 cm^{-1}.

Found: C, 75.55; H, 10.61, N, 4.45%. Calcd for $C_{21}H_{35}O_2N$: C, 75.63; H, 10.58; N, 4.20%.

17α-Acetyl-5α,12α-etiojervan-3β-ol (18). A solution of **17** (1.619 g in crude state) in ethanol (100 ml) and water (67 ml) was refluxed with sodium bisulfite (2.1 g) for 11 hr under stirring.[6] The solution was concentrated to 20 ml, cooled, mixed with 1M hydrochloric acid (64 ml) and chloroform (96 ml), and the mixture was stirred vigorously at room temperature for 2 hr. The organic layer was combined with chloroform washings of the aqueous layer, washed with water, dried and evaporated below 35 °C to leave amorphous residue (1.335 g), which crystallized on trituration with acetone and was collected by filtration to give **18** (825 mg), mp 133—135 °C. This was recrystallized from aqueous methanol for analysis; mp 135—137 °C; $[\alpha]_D$ −54.6°; IR, ν_{max} 3460, 1699, 1066, and 1041 cm^{-1}; NMR, τ 9.20 (3H, s, 19-Me), 9.18 (3H, d J=5.5 Hz, 18-Me), 7.89 (3H, s, 21-Me), and 6.40 (1H, m W_H=25 Hz, H at C_3). The afore-mentioned filtrate on crystallization was subjected to preparative tlc (ether–benzene 1:1, and 23 plates), and the main fraction extracted with acetone and then with methanol afforded amorphous substance (352 mg), which on trituration with acetone afforded an additional amount of **18** (168 mg), mp 129—134 °C. Compound **18** proved to be identical with an authentic sample already reported[14b] (the acetate[14a]) by direct comparison.

Compound **18** (30 mg) was treated with 1M sodium methoxide in refluxing methanol (20 ml) for 12 hr under nitrogen. The reaction mixture was worked up as usual and gave crystalline material (31 mg), which showed the same IR spectrum and R_f value on tlc as the starting material, and was recrystallized from aqueous methanol to yield **18** (20 mg), mp 135—136 °C; $[\alpha]_D$ −51.7°.

17α-Acetyl-5α,13β-etiojervan-3β-ol (21). Compound **15** was degraded into the corresponding methyl ketone (**21**) in the same manner as **14**. A solution of **15** (810 mg) in THF (30 ml) was converted into the *N*-chloro derivative by treatment with NCS (400 mg) for 1.7 hr. This in methanol (50 ml), on treatment with 2 M sodium methoxide in methanol (50 ml) under cooling for 3 hr followed by hydrolysis of the product with 2M hydrochloric acid at room temperature for 69 hr, produced crude 20-aldehyde (**19**, 786 mg), which on purification by preparative tlc (ether–benzene 1:1 and 36 plates) gave **19** (374 mg), amorphous; IR ($CHCl_3$), ν_{max} 3590, 3420, 2780, 1724, and 1028 cm^{-1}; NMR, τ 9.25 (3H, s, 19-Me), 9.04 and 9.03 (total 6H, each d J=7 and 5 Hz, 18- and 21-Me or *vice versa*), 6.46 (1H, br W_H=30 Hz, H at C_3), and 0.40 (1H, s, CHO).

20-Aldehyde (**19**, 270 mg) in methanol (15 ml) was treated with *n*-butyl nitrite (1.2 ml) and 1.3M sodium methoxide in methanol (20 ml) at 0 °C for 11 hr to yield 20-oxime (**20**, 334 mg), showing a single spot; IR ($CHCl_3$), ν_{max} 3600, 3280, and 1027 cm^{-1} (no C=O absorption). A solution of **20** (315 mg) in 40% aqueous ethanol was refluxed with sodium bisulfite for 10 hr[6] and, after removal of the solvent, stirred with 1M hydrochloric acid (9 ml) and chloroform (15 ml) at room temperature for 1.5 hr to give amorphous residue (278 mg). This was subjected to preparative tlc (ether–benzene 1:2, and 13 plates) and gave amorphous substance (**21**, 133 mg) as the main fraction, showing the same IR spectrum and R_f value as the analytical sample described below, which crystallized on trituration with acetone–*n*-hexane to yield **21** (41 mg), mp 70—72 °C; $[\alpha]_D$ +15.4°; IR ($CHCl_3$), ν_{max} 3600, 3435, 1704, and 1027 cm^{-1}; NMR, τ 9.26 (3H, s, 19-Me), 9.17 (3H, d J=6 Hz, 18-Me), 7.90 (3H, s, 21-Me), and 6.40 (1H, br W_H=22 Hz, H at C_3).

Found: C, 79.24; H, 10.58%. Calcd for $C_{21}H_{34}O_2$: C, 79.19; H, 10.76%.

Compound **21** (17 mg) was treated with 1M sodium methoxide in refluxing methanol for 12 hr, and the product (14 mg), amorphous, showed the same IR spectrum and R_f value on tlc as the starting material.

Reduction of N*-acetyl-22,27-imino-17β-jerva-5,12-diene-3β,23β-diol-11-one (23) with sodium borohydride. 3-*O,*23-*O,N*-Triacetyl-22,27-imino-17β-jerva-5,12-diene-3β,11β,23β-triol (24=7a) and Others (25 and 26).* A solution of **23**[16,18] (1.5 g) in dioxane (150 ml) was refluxed with sodium borohydride (NBH) (3.0 g) under stirring for 48 hr. After addition of acetone under cooling to decompose excess NBH, the mixture was further stirred for 15 min, insoluble material being filtered off. The filtrate was evaporated, shaken with water and chloroform. The chloroform solution afforded amorphous residue (1.71 g), which showed 2 spots on tlc; IR ($CHCl_3$), ν_{max} 3590, 3410, 1641, 1048 and 1020 cm^{-1} (no C=O absorption). A part (1.67 g) of the residue was acetylated with acetic anhydride (15 ml) and pyridine (15 ml) at room temperature for 21 hr. After being worked up in the usual way, the mixture gave amorphous residue, which was separated into 3 parts by preparative tlc (ether–benzene 1:1, and 62 plates). The most mobile fraction (**25a**, 535 mg), amorphous, resisted crystallization; NMR, τ 9.18 and 8.81 (each 3H, d J=6 and 5 Hz, 21- and 26-Me or *vice versa*), 8.89 (3H, s, 19-Me), 8.50 (3H, s, 18-Me), 8.00 (9H, s, OCO-CH_3), and 7.88 (3H, s, NCOCH_3). This was then hydrolyzed with 5% potassium hydroxide in refluxing methanol (50 ml) for 1 hr under nitrogen, and gave amorphous substance, which crystallized on trituration with methanol–acetone, was collected by filtration to yield *N*-acetyl-22,27-imino-17β-jerva-5,12-diene-3β,11α,23β-triol (**25**, 130 mg), mp 223—233 °C. This was recrystallized twice from the same solvent for analysis; mp 248—251 °C; $[\alpha]_D$ −22.8° (MeOH); IR, ν_{max} 3320, 1612, 1067, and 1024 cm^{-1}.

Found: C, 73.48; H, 9.50; N, 3.00%. Calcd for $C_{29}H_{45}O_4N$: C, 73.84; H, 9.62; N, 2.97%.

The middle fraction (**26a**, 355 mg), amorphous, showed the following IR and NMR spectrum; ν_{max} ($CHCl_3$) 1724, 1628, 1250, and 1025 cm^{-1} (no OH absorption); τ 9.12 and 8.96 (total 9H?, each d J=6.5 and 5 Hz, 18-, 21- and 26-Me or *vice versa*), 8.73 (3H, s, 19-Me), 7.97 (9H, s, OCOCH_3), and 7.87 (3H, s, NCOCH_3). This was hydrolyzed in the same manner as **25a** and gave amorphous substance, which crystallized on trituration with methanol–acetone and was collected by filtration to yield *N*-acetyl-22,27-imino-12ξ,13ξ,-17β-jerv-5-ene-3β,11β,23β-triol (**26**, 96 mg), mp 217—223 °C. This was recrystallized three times from the same solvent for analysis; mp 241—242 °C; $[\alpha]_D$ −30.2° (MeOH); mass, *m/e* 473 (M^+); IR, ν_{max} 3505, 3395, 1605, 1049, and 1024 cm^{-1}; NMR, τ 9.17, 8.98 and 8.78 (total 9H?, each d J=7, 5 and 6 Hz, 18-, 21- and 26-Me or *vice versa*), 8.76 (3H, s, 19-Me), 7.88 (3H, s, NCOCH_3), and 4.75 (1H, br s W_H=9.5 Hz, H at C_6).

Found: C, 73.27; H, 10.03; N, 2.84%. Calcd for $C_{29}H_{47}O_4N$: C, 73.53; H, 10.00; N, 2.96%.

The least mobile fraction (376 mg), crystalline, was recrystallized from acetone–isopropyl ether to give **24** (=**7a**,

215 mg), mp 213—215 °C; $[\alpha]_D$ −28.3°; mass, *m/e* 555 (M^+), 198 and 156; IR, ν_{max} 3570, 1741, 1635, 1239, and 1023 cm^{-1}; NMR, τ 9.18 and 8.80 (each 3H, d J=6 and 7 Hz, 21- and 26-Me or *vice versa*), 8.74 (3H, s, 19-Me), 8.23 (3H, s, 18-Me), 8.00 (6H, s, $OCOC\underline{H}_3$), 7.89 (3H, s, $NCOC\underline{H}_3$), and 6.58 (1H, br s W_H=5.5 Hz, H at C_{11}).

Found: C, 71.13; H, 8.83; N, 2.57%. Calcd for $C_{33}H_{49}O_6N$: C, 71.32; H, 8.89; N, 2.52%.

Oxidation of **24** *(=***7a***) with chromic anhydride and pyridine.* A solution of **24** (=**7a**, 26 mg) in pyridine (1 ml) was treated with chromic anhydride (96 mg) at room temperature overnight under stirring, and then shaken with water and chloroform. The chloroform solution was washed with 1M hydrochloric acid, a 5% sodium bicarbonate solution and water, dried and evaporated to leave oily residue, which showed a single spot but was further purified by preparative tlc (ether–benzene 4: 1, and 1 plate). The main fraction afforded crystalline material (22 mg), which was again dissolved in chloroform. The solution was worked up as usual and the product was recrystallized from acetone–isopropyl ether to give **23** (15 mg), mp 215.5—217 °C, which was identical with an authentic sample.[16,18]

Birch reduction of **24** *(=***7a***).* a) To a solution of **24** (=**7a**, 200 mg) in ethylamine (35 ml) was added finely divided lithium (250 mg), and the mixture was stirred vigorously under reflux for 1 hr. The reaction mixture on addition of ammonium chloride became colorless and was worked up in the same manner as for **4**, giving amorphous residue (198 mg), showing only 2 spots. This was acetylated with acetic anhydride (3 ml) and pyridine (3 ml) at room temperature for 28 hr. The product showed 4 spots and was separated into 4 parts by preparative tlc (ether–benzene 1: 2, and 9 plates). The first, mobile fraction (22 mg), amorphous, was not further examined but apparently differed from **6a**, judging from the R_f value. The second, main fraction (149 mg), crystalline, was recrystallized from aqueous methanol to give **2a** (89 mg), mp 191—194 °C, which was identical with the sample obtained from **4**. The third fraction (21 mg), amorphous, was a mixture of two compounds and not further examined. The last, least mobile fraction (48 mg), amorphous, crystallized on trituration with acetone–isopropyl ether to give the starting material **24** (28 mg), mp 208—212 °C.

b) A solution of **24** (=**7a**, 207 mg) in liquid ammonia (50 ml), dry dioxane (20 ml) and dry THF (20 ml) was stirred vigorously with lithium (130 mg) under reflux for 1 hr. After dropwise addition of ethanol (10 ml), the mixture was worked up as usual and gave amorphous substance. Since this contained a considerable amount of the unreacted material **24**, the reduction was again carried out under the same conditions as mentioned above. The resulting amorphous product (185 mg) showed 3 spots and was separated into 2 main fractions by preparative tlc (ether–methanol 9: 1, and 9 plates). The more mobile fraction crystallized on trituration with methanol–acetone and was collected by filtration. The crystalline material (18 mg), mp 220—222 °C, proved to be identical with **6**. The less mobile fraction apparently consisted of deacetylated derivatives of **2a** and **24**, but was not further examined.

Wolff-Kishner Reduction of **23**. A solution of diethylene glycol (20 ml) with dissolving sodium (620 mg) was heated to reflux with anhydrous hydrazine (4 ml) and cooled. Compound **23** (400 mg) was added to the solution, whcih was refluxed for 14.5 hr. The condenser was replaced by a distillation apparatus, and the whole solution was heated for 4.5 hr, 2.3 ml of hydrazine being removed. The resulting pale-yellow solution was poured into ice-water (200 ml) and allowed to stand overnight, when precipitates separated out, were collected by filtration, washed with water and dried (320 mg). On the other hand, the aqueous solution obtained on filtration and water washings were combined and extracted with chloroform. The chloroform solution gave amorphous residue (35 mg), which was combined with the afore-mentioned precipitates and acetylated with acetic anhydride (5 ml) and pyridine (5 ml) at room temperature for 17 hr. The product, showing 2 spots, was separated by preparative tlc (ether–benzene 3: 5, and 25 plates). The more mobile fraction (161 mg). amorphous, showed the same IR spectrum and R_f value on tlc as **6a**, and crystallized on trituration with isopropyl ether to give **6a** (69 mg), mp 173—174 °C, which was identical with the sample described already. The less mobile fraction (107 mg), amorphous, was crystallized from aqueous methanol to yield **2a** (71 mg), mp 193—194 °C, identical with the authentic sample.

Hydrogenation of **6a**. A solution of **6a** (91 mg) in acetic acid (6 ml) was hydrogenated over prereduced rhodium-platinum (3: 1) catalyst (104 mg)[11] in acetic acid (5 ml) at room temperature for 1.2 hr, when 2.3 mol of hydrogen had been absorbed. The mixture was worked up as usual and gave amorphous residue (113 mg). This was refluxed with 5% potassium hydroxide in methanol (15 ml) for 1.1 hr under nitrogen and afforded amorphous residue (93 mg), which showed 2 spots and was subjected to separation by preparative tlc (ether, and 6 plates). The more mobile fraction (7 mg), amorphous, was not further examined. The less mobile fraction (76 mg) crystallized on trituration with ethyl acetate, mp 180—182 °C, 55 mg. This compound was identical with **14a**.

Hydrolysis of **24** *(=***7a***).* A solution of diethylene glycol (5 ml) with dissolving sodium (180 mg) was refluxed with anhydrous hydrazine (1 ml) for 10 min and cooled. After addition of **24** (99 mg), the whole solution was refluxed for 17 hr, cooled and poured onto crushed ice (30 g), when precipitates separated out, were collected by filtration, washed with water and dissolved in methanol. The methanol solution was concentrated to give oily substance, which crystallized on addition of acetone, mp 232—233 °C, 46 mg. This compound was identical with **7** isolated from the Birch reduction products of **4**. This was recrystallized from acetone for analysis; mp 233—235 °C; $[\alpha]_D$ −65.4° (MeOH); mass, *m/e* 429 (M^+), 141 and 114; IR, ν_{max} 3420 and 1046 cm^{-1}.

Found: C, 75.19; H, 10.08; N, 3.19%. Calcd for $C_{27}H_{43}O_3N$: C, 75.48; H, 10.09; N, 3.26%.

The authors express their thanks to Mrs. S. Araki and Miss M. Shiozawa for the measurement of NMR spectra, to Misses H. Kakizawa and A. Maeda for the microanalysis, and to Miss Y. Imai for the measurement of mass spectra.

The Biosynthesis of Geraniol and Citronellol in *Pelargonium roseum* Bourbon[1]

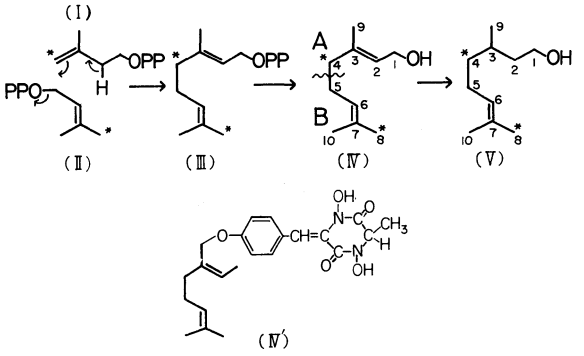
Takayuki SUGA and Tsuyoshi SHISHIBORI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received June 22, 1973)

Geraniol and citronellol were biosynthesized from [2-^{14}C]mevalonic acid by the leaves of *Pelargonium roseum* Bourbon. The degradation of the radioactive specimens revealed that the major radioactivity (70—80%) was located at C-4 in the skeleton derived presumably from isopentenyl pyrophosphate and the rest of the activity at C-8 (and/or C-10) in the moiety from 3,3-dimethylallyl pyrophosphate. The unbalance of labeling was distinct from the result observed for the monoterpenes biosynthesized from the same labeled precursor by the flowers of the rose. A discussion is given on factors causing such a discrepancy in the labeling pattern owing to the difference of the plant and/or the organ. Time-course experiments with the use of [2-^{14}C]mevalonic acid indicated the formation of geraniol prior to citronellol both in the intact plant and in the cell-free extract.

The biosynthesis of monoterpenes is said to involve the conversion of mevalonic acid (MVA) into isopentenyl pyrophosphate (IPP) (I) and 3,3-dimethylallyl pyrophosphate (DMAPP) (II), followed by the condensation of IPP (I) with DMAPP (II) directed toward the formation of geranyl pyrophosphate (III), the presumed precursor of monoterpenes. Incorporations of [2-^{14}C]MVA into geraniol (IV) and nerol and their β-glucosides in the petals of *Rosa dilecta*[2,3] and into pyrethrins in the flower heads of *Chrysanthemum cinerariaefolium*[4] have been reported to result in the almost balanced pattern of labeling in the parts generated from IPP (I) and DMAPP (II) respectively. The geranyl moiety of the fungal product, mycelianamide (IV'), has been shown to possess a labeling pattern resulting from the equilibration of a tracer from [2-^{14}C]MVA between the C-5 units.[5] On the other hand, the biosynthesis of cyclic monoterpenes, thujone,[6] camphor,[7] and pulegone,[8] in the leaves and stems of several higher plants has been reported to localize the tracer mainly in the part derived from IPP (I), although one exception has been observed for linalool, an acyclic monoterpene, which had the almost symmetrical pattern of labeling.[9,10] Recently, the symmetrical labeling was also observed for geraniol (IV) biosynthesized in the leaves of *Pelargonium graveolens* Ait.[3] We now have tested the labeling pattern in geraniol (IV) biosynthesized from [2-^{14}C]MVA in the leaves of the geranium, *Pelargonium roseum* Bourbon, as well as the labeling pattern of citronellol (V), the main component of an essential oil of the plant. Contrary to Banthorpe's result,[3] we observed the unbalanced pattern of labeling for both geraniol (IV) and citronellol (V).



PPO = a pyrophosphate group; * = ^{14}C

Scheme 1.

Results

Time-course of the Incorporation of a Tracer into Geraniol (IV) and Citronellol (V). Feeding experiments were carried out on the intact plant tissue and the cell-free extract obtained from *P. roseum* Bourbon. The incorporation of [2-^{14}C]MVA to the small branches of *P. roseum* Bourbon for periods of 2 hr to 2 days resulted in an accumulation of the tracer in the plant oil. The radioactivity of the monoterpenes in the plant oil was determined by thin-layer plate radiochromatography. Table 1 shows the radioactivities of geraniol (IV) and

Time of incubation (hr)	Radioactivities (cpm) Geraniol (IV)	Citronellol (V)	A_V/A_{IV}[a)]
2	156	82	0.53
24	100	84	0.84

a) A_V and A_{IV} denote the radioactivities of citronellol (V) and geraniol (IV) respectively.

citronellol (V) and the ratio (A_V/A_{IV}) of the activities of IV and V at predetermined time intervals after feeding. The contents of geraniol (IV) and citronellol (V) were estimated to be 23.6 and 33.3% of the total oil by means of gas chromatography respectively.

The cell-free extract prepared from *P. roseum* Bourbon was found to transform [2-^{14}C]MVA into the monoterpenes, geraniol (IV) and citronellol (V). Table 2 shows the radioactivities of IV and V and the ratio (A_V/A_{IV}) of their radioactivity at 2 hr and at 24 hr after feeding of the tracer.

Labeling Patterns. By means of elution chromatography on a silica gel column, geraniol (IV) and citronellol (V) were isolated from the leaf oil of *P. roseum* Bourbon to which [2-^{14}C]MVA had been administered. Incorporations of the MVA into IV and V were 0.038 and 0.041%, respectively, of the administered tracer.

Radioactive geraniol (IV) was degraded to acetone containing a tracer from C-7, C-8, and C-10 and to levulinic acid containing a tracer from C-3~C-6 and C-9 by permanganate-periodate oxidation.[11-13] By hypoiodite oxidation, then, the acetone was degraded to iodoform containing a tracer from C-8 (and/or C-10) and to acetic acid originated from C-7 and C-8 (and/or C-7 and C-10), while the levulinic acid to iodoform originated from C-9 and to succinic acid from C-3~C-6. This acid was further cleaved into carbon dioxide originated from C-3 and C-6 and into ethylenediamine from C-4 and C-5 by the Schmidt reaction.[14] The all degradation products, after the conversion into the solid derivative when the product is a liquid, were purified by recrystallization or sublimation. The purified degradation products and geraniol (IV) were converted to barium carbonate by Van Slyke-Folch oxidation[15] in order to determine their specific radioactivities. The results are shown in Table 3.

By permanganate-periodate oxidation,[11-13] radioactive citronellol (V) was degraded to acetone containing a tracer from C-7, C-8, and C-10 and to 6-hydroxy-4-methylhexanoic acid (VI) originated from C-1~C-6 and C-9. Acetone was degraded to iodoform

Table 3. Specific activities of geraniol (IV) biosynthesized from [2-^{14}C]MVA by the intact plant of *Pelargonium roseum* Bourbon and of its degradation products

Compounds (Carbons originated from IV)	Specific activities, dpm × 10^{-3}/mmol	(%)
Geraniol (C-1~C-10)	271	(100)
Levulinic acid (C-3~C-6 and C-9)	220	(81.3)
Iodoform (C-9)	4.2	(1.9)
Succinic acid (C-3~C-6)	210	(77.5)
Ethylenediamine (C-4 and C-5)	197	(72.7)
Carbon dioxide (C-3 and C-6)	14.5	(5.4)
Acetone (C-7,C-8, and C-10)	—	—
Iodoform (C-8 and/or C-10)	25.7	(9.5)
Acetic acid (C-7 and C-8, and/or C-7 and C-10)	23.6	(8.7)

Table 4. Specific activities of citronellol (V) biosynthesized from [2-^{14}C]MVA by the intact plant of *Pelargonium roseum* Bourbon and of its degradation products

Compounds (Carbons originated from V)	Specific activities, dpm × 10^{-3}/mmol	(%)
Citronellol (C-1~C-10)	701	(100)
6-Hydroxy-4-methylhexanoic acid (C-1~C-6 and C-9)	474	(67.6)
Acetone (C-7, C-8, and C-10)	72.3	(10.3)
Iodoform (C-8 and/or C-10)	78.2	(11.2)

containing a tracer from C-8 (and/or C-10) by hypoiodite oxidation. The radioactivities of the degradation products were assayed by counting aliquots of barium carbonate which was prepared from the products, after purified similarly, in the same manner as above. The results are shown in Table 4.

Discussion

The maximum incorporation of a tracer from [2-^{14}C]-MVA into geraniol and nerol of the petals of *Rosa dilecta* has been reported to be observed within 1 hr of feeding.[16] On the other hand, the incorporation of a tracer from the ^{14}C-labeled MVA into geraniol (IV) and citronellol (V) by the intact plant tissues of *P. roseum* Bourbon resulted in the increase in their radioactivities with time of feeding and then the maximum activity in 24 hr, as is shown in Table 1. The results of the incorporations are, although low, similar to those found in analogous experiments.[6-10,17] The low incorporation probably is not due to a rapid passage of the tracer through geraniol (IV) and citronellol (V), since the maximum in the radioactivity was observed for the compounds in the time-course examination, as is shown in Table 1. The increase in the activity ratio of A_V/A_{IV} with time of feeding of a tracer was observed for incubations not only in the intact plant

tissue but also in the cell-free extract, as is shown in Tables 1 and 2. The results indicate the formation of geraniol (IV) prior to that of citronellol (V) and subsequently the transformation of IV to V. This biosynthetic sequence may be supported by the fact that a geraniol-nerol reductase, which converts both geraniol and nerol into citronellol (V), has been isolated from the rose petals.[18]

The extensive degradation of geraniol (IV) biosynthesized from [2-^{14}C]MVA in the leaves of *P. roseum* Bourbon revealed, as is shown in Table 3, that more than 90 per cent of the total radioactivity was detected in ethylenediamine and iodoform derived respectively from C-4 and C-5 and from C-8 (and/or C-10) of IV. Since C-1, C-2, C-3, and C-9 were almost unlabeled and the rest of the C_5-isoprene unit is nothing other than C-4, the main site of labeling on geraniol (IV) is considered to be C-4 rather than C-5. Thus, the pattern of labeling observed for geraniol (IV) is consistent with the biosynthetic pathway depicted in the Scheme, which shows the formation of geraniol (IV) *via* geranyl pyrophosphate generated from the condensation of IPP (I) with DMAPP (II). Although the sites of labeling accord with the biosynthetic pathway shown in the Scheme, the radioactivities of C-4 and C-8 derived respectively from IPP (I) and DMAPP (II) were unbalanced; the former contained more than 70% of the total activity and the latter did only 20%. Such unbalanced labeling that the tracer predominantly resided in the moiety A of geraniol (IV) was in contrast to the balanced pattern of labeling in the moieties A and B of IV biosynthesized in the petals of the rose.[2,3]

The results of the degradation of citronellol (V) revealed that acetone and 6-hydroxy-4-methylhexanoic acid (VI) contained respectively about 10 and 70% of the total activity, as is shown in Table 4. The acetone and the hydroxy acid (VI) contain a tracer from C-8 (and/or C-10) and C-4, respectively, which should be labeled by a tracer from [2-^{14}C]MVA as shown in the Scheme. The unbalanced pattern of labeling in two positions observed in citronellol (V) is similar to that in geraniol (IV) described above.

The unbalanced labeling thus found in geraniol (IV) and citronellol (V) biosynthesized by the leaves of *P. roseum* Bourbon is of interest, since the phenomenon has not been observed yet for the polyisoprenoids, triterpenes and steroids;[19,20] these are said to be biosynthesized *via* the same precursor, geranyl pyrophosphate, as that in geraniol (IV). Such an unbalanced pattern of labeling may be rationalized in terms of the operation of several factors: a) a pool of DMAPP (II) in the plant may exist which can react with IPP (I) generated from exogenous radioactive MVA before the labeled IPP (I) can be isomerized to DMAPP (II), b) DMAPP (II) may not be the direct mevalonoid origin, c) compartmentation effects may intervene, and d) the excess of MVA unavoidably used may inhibit IPP-isomerase.[21] The incorporation of [2-^{14}C]-MVA into geraniol and nerol[2,3] in the petals of *Rosa dileca* and into pyrethrins[4] in *Chrysanthemum cinerariaefolium* resulted in the nearly balanced pattern of labeling in the moieties derived from IPP (I) and DMAPP (II). In the biosynthesis in leaves of several higher plants, on the contrary, the unbalanced pattern of labeling has been observed in thujane derivatives,[6] camphor,[7] pulegone,[8] and artemisia ketone,[22] as well as in geraniol (IV) and citronellol (V) as described above. These findings related to the labeling pattern suggest that the nature of the synthetic site in the leaves of the higher plants may be different from that in the petals. The presence of an oil gland in the leaves seem to be responsible for the unbalanced labeling. Our presently reported examples of the asymmetrical pattern of labeling differ from a recent report for geraniol (IV) biosynthesized by *P. graveolens*.[3] This discrepancy seems to be due to differences in the plants used, although both the plants belong to Geraniaceae, in the growth stage of the plants employed, and in feeding conditions of the precursor.

Experimental

Materials. Specimens of *P. roseum* Bourbon were grown from a young shoot obtained from the experimental farm of the Soda Perfumery Co., Ehime Prefecture, Japan. The small terminal branches (*ca.* 7 cm long) of the 15 week-old plants, grown outdoors from April to October, were used for feeding experiments. 3-RS-[2-^{14}C]MVA was obtained from the Daiichi Pure Chemicals Co., Ltd. (Tokyo) as the dibenzylethylenediamine salt. Adenosine triphosphate (ATP) was purchased from the Sigma Chemical Co., (St Louis, Mo., U.S.A.) as Sigma Grade Products.

Chromatographic Analyses. Tlc plates were prepared as follows: the end of a glass plate coated with silica gel G (0.25 mm; Merck) were dipped into 10% silver nitrate solution to permeate the solution through the plate and then the plate was dried at 105 °C for 45 min. Upon developing with a mixture of *n*-hexane and ethyl acetate (85: 15 or 50: 50 by volume, respectively), the plate resulted in the good separation of geraniol (IV) (R_f value 0.10 or 0.43) and citronellol (V) (R_f value 0.33 or 0.70). Column chromatography of the steam-volatile oil was performed on silica gel impregnated with 3% (w/w) silver nitrate, using a mixture of *n*-hexane with successively increasing amounts of ethyl acetate (0—25% by volume). Gas-liquid chromatographic analyses were made using a Hitachi Perkin-Elmer F6-D instrument attached with a column (1 m×3 mm) packed with 20% PEG-6000 on Celite (60—80 mesh) at 145 °C.

Measurements of Radioactivities. Thin-layer plate radiochromatograms were taken on an Aloka (Tokyo) JTC-203 instrument at a slit width of 1.5 mm. Radioactivities of geraniol (IV) and citronellol (V), shown in Tables 1 and 2, were determined by cutting the corresponding areas on the thin layer radiochromatogram obtained in the manner as mentioned above to weigh their pieces of paper and then by comparing the peak areas with those obtained with geraniol having the known radioactivity. In order to assay the specific activity, geraniol, citronellol, and all their degradation products were converted into barium carbonate by Van Slyke-Folch oxidation,[15] and aliquots of the barium carbonate

were counted on planchets at an infinite thickness under an Aloka (Tokyo) 2π-gas-flow low background counter, Model TDC R1361. The counting error for the values shown in Tables 3 and 4 is about $\pm 3\%$.

Incorporations of Tracer. *a) With Intact Plant Tissue*: The stems in the nearly same size (each 6 g) were cut under water, and a phosphate-buffered solution (5 ml, pH 7.3) of [2-^{14}C]MVA (20 μCi, 4 μmol) and ATP (4 mg) was fed through a cut-stem into twigs. Just after the tracer solution had been absorbed, two aliquots (each 0.5 ml) of water were given for completely sucking up all the tracer in the twigs. The time required for the complete administration of the tracer was *ca.* 1 hr. The twigs were then maintained under outdoor conditions on water. At predetermined intervals, two twigs were ground with solid carbon dioxide in a mortor and the crushed plant tissues were then steam-distilled. The yield of the volatile oil was 0.3—0.4% (w/w) of the plant employed, and the contents of geraniol (IV) and citronellol (V) were estimated by glc to be 23.6 and 33.3% of the total plant oil respectively. The oil was chromatographed on the tlc plate coated with silica gel G impregnated with silver nitrate. The plate was then subjected to thin-layer plate radiochromatography for counting radioactivities of the separated constituents. The results are shown in Table 1.

b) With Cell-free Extract: The leaves (30 g) of the geranium were ground with 0.1 M phosphate buffer (pH 7.3, 30 ml) and solid carbon dioxide in a mortar. The resulting slurry was filtered through a cheese cloth to give a green homogenate (30 ml). The homogenate was centrifuged for 30 min at 14000$\times$g and 0 °C. The supernatant film and the precipitate were discarded and the clear middle layer (20 ml) was used as a cell-free extract for incubations. [2-^{14}C]MVA (2 μCi, 0.4 μmol) dissolved in 1 ml of 0.1 M phosphate buffer (pH 7.3) containing 8 mg of ATP was incubated with the cell-free extract at 25 °C for 2 hr and for 24 hr with shaking in the air. The enzymic reaction was stopped by adding 2 M hydrochloric acid and then by heating the mixture for 3 min at 70 °C. The extraction of the mixture with *n*-hexane afforded, after removal of the solvent, an oily product; this was subjected to thin-layer plate radiochromatography. The results are shown in Table 2.

Labeling Patterns. Radioactive geraniol (IV) and citronellol (V) used for determining the labeling patterns were obtained as follows. A phosphate-buffered solution (4 ml, pH 7.3) of [2-^{14}C]MVA (0.1 mCi, 17 μmol) and ATP (5 mmol) was fed through a cut-stem into the small terminal branches (60 g) of *P. roseum* Bourbon for 4 hr. The leaves and stems were then subjected to steam distillation. The steam-volatile oil thus obtained (260 mg) was separated by a combination of column chromatography and tlc to give geraniol (IV) (24 mg) and citronellol (V) (33 mg). These were judged to be chemically and radiochemically pure on the basis of glc, tlc, and thin-layer plate radiochromatography.

a) Degradation of Geraniol (IV): Radioactive geraniol (206 mg) diluted 29 times with the carrier was oxidized with a permanganate-periodate reagent for 24 hr following the method reported in the literatures.[11-13] After the residual oxidant had been decomposed with sodium bisulfite, the weakly alkaline solution was subjected to steam distillation. After the residual alkaline solution was acidified with diluted sulfuric acid, the solution was extracted with ether by a continuous extractor to afford crude levulinic acid (70 mg). This acid was chromatographed repeatedly on a thin layer plate coated with silica gel G by a mixture of chloroform, acetone, methanol, and formic acid (45: 5: 5: 1 by volume) to give pure levulinic acid (39 mg; its *p*-bromophenacyl ester, mp 83—84 °C; lit,[23] mp 84 °C). On the other hand, the aqueous distillate was subjected to hypoiodite oxidation. Iodoform (290 mg) filtered off was purified by sublimation under reduced pressure. The filtrate was acidified with diluted sulfuric acid and then treated with silver sulfate to remove iodine liberated. The aqueous mixture was then steam-distilled. The evaporation of the neutralized distillate afforded acetic acid as the sodium salt, which was further converted into the silver salt; this salt was purified by recrystallization from ethanol–water.

The levulinic acid (100 mg) was oxidized with potassium hypoiodite, which was prepared by adding sufficiently a solution of potassium iodide and iodine (2: 1) to 14 ml of 5% potassium hydroxide until the color persisted. Iodoform (189 mg) filtered off was purified by sublimation under reduced pressure. The filtrate was acidified with diluted sulfuric acid and treated with silver sulfate to remove iodine. The continuous extraction of the aqueous solution with ether afforded crude succinic acid (84 mg). After washed with chloroform, the acid was recrystallized from water and then it melted at 184—186 °C. The succinic acid was degraded to ethylenediamine and carbon dioxide by a modified method[14] of the Schmidt reaction. The carbon dioxide was trapped as barium carbonate.

b) Degradation of Citronellol (V): Radioactive citronellol (220 mg) diluted 20 times with the carrier was oxidized with a permanganate-periodate reagent[11-13] for 6 hr as above. After the same treatment es in geraniol (IV), the mixture was subjected to steam distillation. The continuous extraction of the residual solution, after it was acidified with diluted sulfuric acid, with ether afforded crude 6-hydroxy-4-methylhexanoic acid (VI) (195 mg). The methyl ester of the acid was converted to its 3,5-dinitrobenzoate, mp 145—146 °C (lit,[11] mp 145—147 °C). A half of the aqueous distillate was subjected to hypoiodite oxidation. The yellow precipitate filtered off was sublimated under reduced pressure to give pure iodoform, mp 118—119 °C. From another half of the aqueous distillate, acetone was isolated as the 2,4-dinitrophenylhydrazone derivative, mp 125—126 °C.

The authors are thankful to the Soda Perfumery Co., Ltd., Tokyo, for its gift of the plant, and to Takasago Perfumery Co., Ltd., for its gift of the samples of citronellol and geraniol.

Oxidation of Carbon Monoxide over Transition Metal Ion-Zeolite Catalysts

Toshihiko KUBO, Hiroo TOMINAGA, and Taiseki KUNUGI

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received January 22, 1973)

Adsorption of oxygen and oxidation of carbon monoxide was investigated on several X and Y type zeolites, their Na^+ being replaced by transition metal ions. Oxygen adsorption was observed on Cr(II), Cu(I), and Fe(II) ions whose oxidation potentials are high, giving an oxygen atom to metal ion ratio of 0.43—0.62 or nearly 0.5. A small amount of oxygen was adsorbed on Tl(I), Co(II), and Mn(II), as expected from their standard oxidation potentials. No oxygen was adsorbed on Cu(II) and Ni(II), their valences being difficult to increase. The activities of these transition metal ions for oxidation of carbon monoxide increased exponentially with the increase of their standard oxidation potential. Kinetic studies on CO oxidation over Fe(II)–X and –Y zeolites have been made, and a Rideal mechanism is suggested where CO molecules in the gas phase attack the oxygen atoms dissociatively adsorbed in the bridged form of Fe^{3+}–O^{2-}–Fe^{3+}. The difference in the activities of Fe(II)–X and –Y catalysts is discussed.

Since some transition metal ions are easily reduced by hydrogen and hydrocarbons and re-oxidized by oxygen, transition metal ion zeolites are inherently active for the oxidation of hydrocarbons. Some papers have recently been published on catalysis by the transition metal ions loaded on zeolites. They include studies by Van Sickle and Prest,[1] Mochida,[2] and others.[3-9]

Furthermore, fundamental studies of the transition metal ions on zeolite were published by Delgass *et al.*,[10] Garten and Boudart[11] and Ward.[12] Boudart has studied the reversible oxidation and reduction of iron supported on zeolite (Y-type faujasite and mordenite) by Mössbauer spectroscopy, demonstrating that Fe(II)–Y(or M) is converted into Fe(III) in oxygen at 400 °C and the Fe(III) is then reduced to Fe(II) by hydrogenation at 400 °C. In this case, the net oxygen adsorption due to the ion corresponded to an oxygen atom to iron ratio of 0.5.

From an interest in the catalysis of adsorbed oxygen on metal ions on zeolite, we prepared zeolite catalysts by replacing the original sodium ions with transition metal ions in their defined valence states, and used them to investigate the chemisorption of oxygen and activity for oxidation of carbon monoxide.

Experimental

Catalyst Preparation. The zeolites used in this study were 13X and 13Y type Linde Molecular Sieves. Catalysts were prepared by the exchange of sodium ions of the zeolite with transition metal ions, Cr(II), Cr(III), Mn(II), Fe(II), Co(II), Ni(II), Cu(I), Cu(II), and Tl(I). The ion exchange with the transition metal ions in a higher valence state, namely Cu(II), Cr(III), and Ni(II), was carried out in atmosphere. On the other hand, the transition metal ions in a lower valence state, Co(II), Tl(I), Mn(II), and Fe(II), were incorporated into the zeolites by ion exchange in nitrogen stream following the procedure employed by Delgass *et al.* to prepare ferrous Y zeolite.[13]

Since chromous salts are unstable in oxidative atmosphere, Cr(II)-zeolites were prepared by ion exchange with the freshly prepared chromous chloride from chromic chloride[14] in nitrogen stream. Cu(I)-zeolites were prepared by ion exchange with cuprous iodide in liquefied ammonia according to the procedure by Reimlinger *et al.*[15]

After ion exchange, the transition metal ion zeolite were filtered and washed thoroughly with water. The zeolite was dried at 110 °C and compressed into a tablet under 300 kg/cm^2, and then crushed into 10—20 mesh. The cuprous zeolite was degassed at 400 °C for 3 hr under 10^{-3} mmHg to remove ammonia from the cuprous ammine complex ion before the catalytic activity test. The contents of the transition metal ion in the zeolites were determined, after ion exchange, by titration of the metal ion remaining in the filtrate with EDTA solution.

Oxygen Chemisorption. The oxygen chemisorption measurements were carried out on samples (2—3 g) of dehydrated zeolites using a conventional volumetric adsorption apparatus. The ion exchanged zeolite was admitted into the vessel and evacuated at 400 °C for 3 hr under 10^{-4} mmHg to remove the adsorbed water and gases. The zeolites prepared by ion exchange with transition metal ion in a lower valence state were further reduced in hydrogen at 400 °C and evacuated again at 400 °C for 3 hr under 10^{-4} mmHg.[13] After reduction, oxygen chemisorption on the transition metal ion in the zeolites was measured at 400 °C. The zeolites with the

metal ions in the higher valence states were not pretreated by hydrogen to avoid proton formation.[16]

CO Oxidation. The activity test was carried out at catalyst temperatures 200—300 °C at atmospheric pressure by use of a flow reactor (17 mm in diameter) where 2 g of catalyst diluted with glass beads (2 mm in diameter) was placed. The gaseous reactants, carbon monoxide and oxygen, and the diluent nitrogen were supplied from the respective cylinders to the reactor. Carbon dioxide was analyzed at 80 °C by gas chromatography using a silica gel column, 2 m in length.

Results and Discussion

Oxygen Chemisorption. It was shown that Fe(II) ions on zeolite Y (or M) activated and adsorbed oxygen dissociatively, Fe(II) being oxidized to Fe(III) at 400 °C.[10,11] We have found that Fe(II) ions on zeolite seem to be more easily oxidized by molecular oxygen in the presence of water. This is suggested by the change in color of Fe(II) zeolite X (or Y) from pale green to brown when the ion exchanged zeolite was washed with water in the atmosphere at room temperature. The catalysis of the activated O^{2-} on this zeolite is of particular interest, since the electronic structure and hence the reactivity of these Fe(III) and O^{2-} might differ from those in the lattice of iron oxides.

The transition metal ions with high oxidation potential such as Cu(I), Cr(II), Tl(I), Co(II), are supposed to exhibit a similar catalytic behavior to that of Fe(II) ions. Cu(I) and Cr(II) ion on zeolites were presumed to be oxidized in the atmosphere from the change of color in filtrating and washing procedures after ion exchange. However, no color change was observed in the zeolites incorporated with Tl(I) and Co(II).

The oxygen chemisorption data are shown in Tables 1 and 2. No oxygen was chemisorbed on either X or Y type Na^+. Accordingly, any oxygen chemisorption on the zeolites loaded with transition metal ions was attributed to the presence of metal ions. The amount of oxygen chemisorption on Co(II), Mn(II), or Tl(I) of both types was less than the other zeolite loaded with Fe(II), Cu(I), or Cr(II). All the latter transition metal ions are in their lower valence state in the ion exchange. The results are in line with the relative ease of oxidation predicted from the levels of oxidation potentials of the metal ions. On Fe(II), Cu(I), or Cr(II) zeolites of both X and Y type, oxygen chemisorption due to the metal ions gave an oxygen atom to metal ion ratio 0.430—0.618, which is not far from 0.5 observed for Fe(II)–Y(or M).[10,11] This may permit the supposition that the oxygen chemisorption in a bridged form like M^{n+1}–O^2–M^{n+1} applies for Cu(I) and Cr(II) as for Fe(II).

As shown in Table 2, the oxygen chemisorption on Fe(II) is affected by the degree of ion exchanged for the original sodium ion with Fe(II), namely the ratio of oxygen atom to Fe(II) approaches 0.5 with a rise in the ion exchange degree. An exceedingly high dispersion of Fe(II) in low concentration on zeolite might not be favorable for the formation of the bridged oxygen atom such as Fe(III)–O^{2-}–Fe(III) due to more frequent occurrences of an unduly long distance from neighbouring Fe(II) ions in zeolite.

Table 1. Oxygen chemisorption on the transition metal ion in the Y type zeolite at 400 °C and at 100 mmHg

Zeolite	Na(I) exchanged (%)	Oxygen chemisorbed, 10^{-4} mol/g-cat.	Oxygen atom to metal ion ratio
Na(I)	0	0.00	0.000
Co(II)[a]	48	0.53	0.106
Tl(I)[a]	54	0.07	0.006
Fe(II)[a]	36	1.89	0.500
Cu(I)[a]	34	3.12	0.436
Cr(II)[a]	34	1.52	0.430
Cu(II)	54	0.00	0.000

Mn(II)[a]	40	0.70	0.100
Ni(II)	39	0.00	0.000

a) Employed for its catalytic activity for oxidation of carbon monoxide.

Table 2. Oxygen chemisorption on the transition metal ion in the X type zeolite at 400 °C and at 100 mmHg

Zeolite	Na(I) exchanged (%)	Oxygen chemisorbed, 10^{-4} mol/g-cat	Oxygen atom to metal ion ratio
Na(I)	0	0.00	0.000
Co(II)[a]	41	0.07	0.013
Tl(I)[a]	26	0.00	0.000
Fe(II)	12	0.76	0.360
Fe(II)	35	3.00	0.488
Fe(II)[a]	42	3.62	0.490
Cu(I)[a]	18	3.86	0.618
Cr(II)[a]	28	2.33	0.474

a) Employed for its catalytic activity for oxidation of carbon monoxide.

Among the Y zeolites prepared by ion exchange with the transition metal ions in higher valence states (Table 1), oxygen chemisorptions were negligibly small for Cu(II) and Ni(II) whose valences are energetically difficult to enlarge. However, for Mn(II) whose valence can step up to a higher state, a slight oxygen chemisorption was observed.

CO Oxidation. The activities of catalysts for CO oxidation, tested under given conditions for 4 hr, were confirmed to be fairly constant for the duration of the experiment except for Fe(II)–Y catalyst which showed a slight decrease in its initial activity within the first 40 min.

Figure 1 shows the relative activity of transition metal ions, expressed by conversion of CO per metal ion, compared to that of Fe(II)–Y for oxidation of carbon monoxide. The standard oxidation potentials of the transition metal ions are chosen as the abscissa. The catalytic activities of the metal ions are closely related with their oxidation potentials. A very small amount of oxygen was adsorbed on Co(II), Mn(II), and Tl(I) standard oxidation potentials of which are −1.82, −1.51, and −1.25, respectively. The catalytic

Temperature 280 °C, except for the comparison between Cu(I) and Fe(II) carried out at 200 °C.

activities of these metal ion zeolites were also lower than those of Cu(I) and Fe(II) as expected from oxygen chemisorption data.

The activities of the transition metal ions increased exponentially with the increase in their standard oxidation potential. But the X and Y zeolite ions replaced by Cr(II) showed extremely low activities for CO oxidation. Reduction of bulk α-Cr_2O_3 and chromia on silica or alumina to CrO by hydrogen or carbon monoxide is known to be difficult below 500 °C.[17] Similarly, the oxidized chromic ion Cr(III)-O^2-Cr-(III) on zeolite does not seem to be reduced by carbon monoxide below 300 °C.

The marked difference in catalytic activities expressed in the term (produced CO_2 mol/Fe(II)·hr) of Fe(II) on X and Y type is described in the following section. The difference was also confirmed with other transition metal ions when they were on either X or Y zeolite. The key factor which controls the catalytic activity of a given transition metal ion should be ascribed to the structure of zeolite as ligand. Because of limited data obtained on only two types of zeolite, X and Y type, the correlation between catalytic activity and the structure has not been fully established yet.

The catalytic activities of some zeolite catalysts which were exchanged with transition metal ions in a higher valence state, Cu(II), Cr(III), Ni(II), were also examined (Table 3). The oxidation activity of Cu(II)

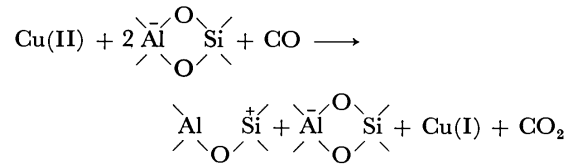
17) R. L. Burwell, Jr., G. L. Haller, K. C. Taylor, and J. F. Read, *Advan. Catal.*, **20**, 12 (1969).

Table 3. Catalytic activities of some zeolite Y catalysts for oxidation of carbon monoxide
Conditions: CO partial pressure 0.099 atm, O_2 partial pressure 0.179 atm
W/F 7.4 g-cat·hr/mol

Catalyst	Na(I) exchanged (%)	Reaction temperature (°C)	Conversion (%)
Fe(II)	36	280	17.2
Cu(I)	34	200	38.7
Cu(II)	54	200	0.8
Cr(III)	38	280	5.4
Ni(II)	39	300	0.93

and Ni(II) was much lower than that of Fe(II) and Cu(I). This is in line with the fact that oxygen is not adsorbed on Cu(II) and Ni(II) whose valences are difficult to enlarge.

A small amount of carbon monoxide was converted into carbon dioxide over Cu(II) zeolite Y, but the carbon monoxide does not seem to have reacted with oxygen activated by Cu(II) since no chemisorption of oxygen is observed (Table 1). Naccache and Taarit[18] showed that Cu(II) Y reduced by carbon monoxide gave no ESR signal of Cu(II) and that Cu(I) were detected by chemical analysis. They proposed a scheme for the reduction of Cu(II) Y by carbon monoxide as follows:



We have confirmed carbon dioxide formation when carbon monoxide was passed over the Cu(II) Y zeolite at 340 °C in the absence of oxygen. The amount of carbon dioxide produced was gradually reduced and the color of the Cu(II) Y catalyst turned from green to white. When the catalyst was allowed to stand in contact with air at room temperature its greenish color slowly reappeared.

It is not strange that Cr(III) showed a fairly good activity, because there is the possibility that heating of Cr(III) in the presence of oxygen can convert all or a part of it into Cr(VI).

Kinetics of CO Oxidation over Fe(II) Zeolite Catalysts. Some kinetic experiments have been made on the oxidation of carbon monoxide over Fe(II)–X and Fe(II)–Y catalysts, their degrees of sodium ion exchange being 42 and 36%, respectively. Experiments were carried out to study the difference in their activities quantitatively as a function of temperatu re (Fig.2). Dependence of the rate on carbon monoxide pressure was found to be nearly unity for both catalysts, while that on oxygen pressure was fractional, approximately 0.1 and 0.4 for Fe(II)–X and Fe(II)–Y, respectively (Fig. 3). These observations, together with the fact that no CO chemisorption was found on the catalysts, lead to a hypothesis that the reaction proceeds *via* the

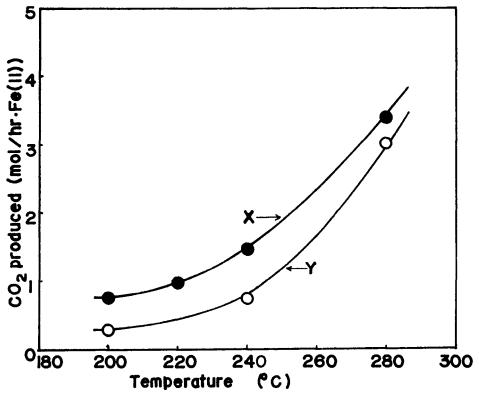

Fig. 2. Change of CO conversion against reaction temperature.
●: Fe(II)X, ○: Fe(II)Y
Conditions: P_{CO} 0.099 atm, P_{O_2} 0.179 atm
W/F 7.4 g-cat. hr/mol.

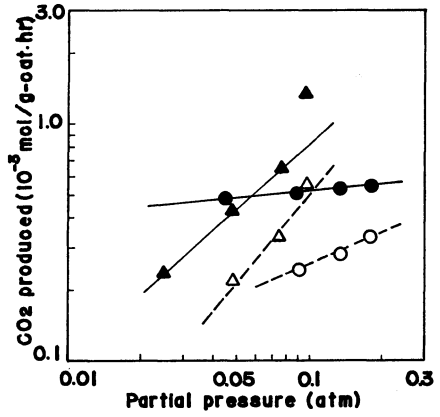

Fig. 3. Dependence of the rate on carbon monoxide and oxygen partial pressure.
Dependence on P_{CO}: ▲: Fe(II)X (220 °C), △: Fe(II)Y (240 °C) P_{O_2} 0.179 atm, W/F 7.4 g-cat. hr/mol
Dependence on P_{O_2} ●: Fe(II)X (220 °C), ○: Fe(II)Y (240 °C) P_{CO} 0.074 atm, W/F 7.4 g-cat. hr/mol

Rideal mecahnism, where carbon monoxide in the gas phase attacks oxygen which is adsorbed dissociatively on the catalysts. This is supported by the fact (Fig. 4) that the plot of reciprocal of the rate *vs.* reciprocal of the root of the oxygen partial pressure gives a straight line. Thus the following rate law holds.

$$r_{CO_2} = \frac{k\sqrt{K \cdot P_{O_2}}}{1+\sqrt{K \cdot P_{O_2}}} \cdot P_{CO}$$

By rearrangement we get

$$\frac{1}{r_{CO_2}} = \frac{1}{k\sqrt{K} \cdot P_{CO}} \cdot \frac{1}{\sqrt{P_{O_2}}} + \frac{1}{k \cdot P_{CO}}$$

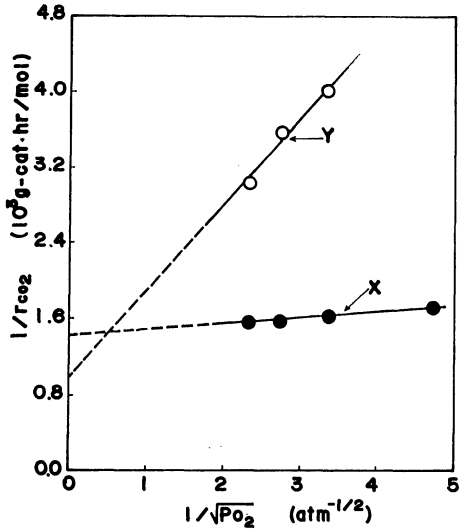

Fig. 4. Dependence of the rate on oxygen partial pressure.
●: Fe(II)X, (220 °C) ○: Fe(II)Y (240 °C)
Conditions: P_{CO} 0.074 atm, W/F 7.4 g-cat. hr/mol

The kinetic parameters obtained by a numerical analyis of the data are:

	Fe(II)X (220°C)	Fe(II)Y (240°C)
k(mol/g-cat.·hr·atm^{-1})	1.95×10^{-2}	2.73×10^{-2}
K(atm^{-1})	365	1.16

Because of the difference in reaction temperatures of the experiments for Fe(II)–X and Fe(II)–Y, comparison and interpretation of these kinetic parameters for carbon monoxide oxidation over the two catalysts would leave some ambiguities.

It might be tentatively concluded that Fe(II)–X catalyst adsorbs a larger amount of oxygen than Fe(II)–Y in their working states at temperatures 200—300 °C. This is supported by further findings on oxygen adsorption.

Skalkina *et al.*[7] reported that catalytic activity of X type zeolite incorporated with Fe(III) was higher than that of Y type for ammoxidation of propylene. Some reports suggested the difference to lie in the strength of electrostatic field near the metal ion for the corresponding X and Y types.[19,20] For carbon monoxide oxidation, the strength of electrostatic field may affect the catalytic activity.

The Methylenation of Several Allylbenzene-1,2-diol Derivatives in Aprotic Polar Solvents

Harushige FUJITA and Masataro YAMASHITA

Department of Chemistry, Faculty of Science and Technology, Kinki University, Kowakae, Higashi-Osaka 577

(Received February 3, 1973)

The aprotic polar solvents, such as DMF (*N,N*-dimethylformamide) and DMSO (dimethyl sulfoxide), accelerated very effectively the methylenation of 1,2-dihydroxy-4- (I), 1,2-dihydroxy-3,4-dimethoxy-5- (II), and 1,2-dihydroxy-3-methoxy-5-allylbenzene (III) in the presence of bronze and cupric oxide as catalysts.

Recently, there are many effective insecticides derived from safrole. There have been many studies undertaken in an attempt to form an ether linkage of methylenedioxy compounds,[1-10] and these derivatives are being commercially produced. However, studies of the methylenation of 1,2-dihydroxyallylbenzenes have been discontinued since Perkin and Trikojus.[4] Although some 1,2-dihydroxybenzene derivatives containing an aldehyde group were methylenated in the presence of copper and related catalysts,[3,10] the yields of the products were poor.

The present authors studied the conditions for synthesizing methylenedioxy derivatives from 1,2-dihydroxy-4- (I), 1,2-dihydroxy-3,4-dimethoxy-5- (II), and 1,2-dihydroxy-3-methoxy-5-allylbenzene (III) in aprotic polar solvents in the presence of bronze and copper oxides, as no studies of the methylenation of these 1,2-dihydroxyallylbenzene derivatives in the presence of such catalysts in aprotic polar solvents (DMF and DMSO) were available.

Results and Discussion

The results are shown in Tables 1—3.

As Table 1 shows, acetone, methanol, and pyridine gave only a small amount of the product, whereas the

Each reaction was carried out as is described in the footnote to Table 2.

yields of the product were more than 50% when DMF and DMSO were used. The addition of bronze and cupric oxide as catalysts increased the yields about 20%, while the yields of the products in the presence of copper powder and cuprous oxide were about the same as the yields in the reactions without any catalyst. Therefore, in the methylenation of (II) and (III) DMF and DMSO were used as solvents. In these cases, the addition of bronze and cupric oxide as catalysts also increased the yields about 20%, as is shown in Tables 2 and 3, and DMSO was a little better than DMF as a solvent.

From these results, the authors found that cupric oxide and bronze were better catalysts than other catalysts in methylenation using a definite amount of catalysts, though no remarkable difference was remarked between the two catalysts. The addition of anhydrous potassium carbonate to the reactions would give good results in the case of solvents, DMF and DMSO, that greatly accelerate the nucleophilic substitution reaction, judging from the results that these aprotic polar solvents, DMF and DMSO, gave 54—61% yields for (IV), (V), and (VI). Further, it appeared that DMSO accelerated the reaction more effectively than DMF, judging from the fact that DMSO, being more stable than DMF in a basic solvent, gave the best results in the presence of alkali in these reactions. Therefore, DMSO should be a very effective solvent in the methylenation of 1,2-dihydroxy-allylbenzene derivatives.

Experimental

Catalysts. The bronze (Cu 65%, Zn 23%, Sn 1.5%, Fe 2%, Pb 0.3%) and copper powder were commercial products. The cuprous and cupric oxide were prepared according to the methods of Tomita *et al.*[11]

Reagents. The potassium carbonate and methylene diiodide were commercial products.

Solvents. The acetone, methanol, pyridine, DMF, and DMSO were purified by the distillation of commercial products.

Materials. The 1,2-dihydroxy-4- (I), 1,2-dihydroxy-3,4-dimethoxy-5- (II), and 1,2-dihydroxy-3-methoxy-5-allylbenzene (III) were prepared according to the methods of Perkin, and Trikojus,[12] Baker *et al.*,[13] and Trikojus and White[14] respectively.

General Synthetic Procedure. The materials, the methylene diiodide, the anhydrous potassium carbonate, and the catalysts were added to the solvents; then the mixture was reacted on an oil bath with stirring, as is shown in the tables. The reaction mixture was extracted with ether, washed with 3% HCl, 3% NaOH and water successively, and dehydrated with anhydrous Na_2SO_4. Then the product was obtained by distillation *in vacuo* after the removal of the solvent.

1,2-Methylenedioxy-4-allylbenzene (Safrole). Bp 94.0—94.5 °C/4 mmHg (lit,[12] bp 100—101.5 °C/10—11 mmHg). Beilstein's test for halogen: negative. n_D^{20} 1.5380 (lit,[12] n_D^{20} 1.5381). Preparation of Reinforcing Fillers from Japanese Acid Clays with Lime and by Calcination. II. Optimum Conditions for the Preparation of Good Hard Clays and Evaluation of Their Reinforcing Properties

Hideki RAI and Junkichi YAMADA*

Engineering Research Institute, Fuculty of Engineering, The University of Tokyo, Yayoi, Bunkyo-ku, Tokyo 113

(Received March 22, 1973)

In order to find the optimum conditions for the preparation of good reinforcing filler from Matsune (**M**) and Nakajo (**N**) acid clays with lime and by calcination, investigations were carried out by changing the amount of alkali (1.25—60% CaO), the temperature of thermal treatment (110—800 °C) and the subsequent mechanical disintegration time (6—24 hr). The required conditions were found to be: amount of alkali, 3% for **M** and 6% for **N**; calcination at 600 °C for 1.5 hr; disintegration time around 18 hr. The deviation in the optimum amount of alkali was attributed to the difference of mineralogical constituents. The products pulverized gave the SBR-1502 compounds good reinforcing properties comparable to those of Dixie Clay. Investigation was also carried out on the influence of manual and mechanical mixing of the raw materials, the mode of disintegrating the calcined matter by either wet ball-milling or dry pulverization, and the effect of sieving the pulverized product in wet or dry state on the reinforcing properties of the prepared fillers. A variable loading test with hard clay **M** up to 150 PHR proved that its reinforcing properties are comparable to those of the reference filler. The maximum reinforcement for the elastomer was found to be about 50 PHR for hard clay **M** and about 100 PHR for the reference filler.

The availability of some Japanese acid clays as raw material for the preparation of a reinforcing filler of elastomers was reported previously.[1] Acid clays such as **M** and **N** containing normal and/or abnormal montmorillonite and α-cristobalite as principal constituents were found to be suitable. However, no reinforcing filler could be prepared from Kuramitsu (**K**) acid clay containing halloysite as a major component in the randomly mixed layers of kaolinite and montmorillonite with no excess silica. **M** provided less colored and much better reinforcing fillers than **N**.

Treatment with hydrated lime (10% CaO) followed by calcination (600 °C, 1.5 hr) causes irreversible contraction in the montmorillonite minerals as well as the formation of calcium silicates covering the surfaces of montmorillonite crystallites. This gives rise to favorable changes in the inherent properties such as adsorptivity, pH, swelling, bulk density and specific gravity. The products pulverized exhibit considerable reinforcing effects on SBR-1502, which exceed Silene EF in the tensile strength and elongation of the loaded compounds. However, the reinforcing character still falls short of Dixie Clay.

This paper deals with further investigations to find the optimum conditions for the preparation of a good hard clay from the acid clays, Matsune **M** and Nakajo **N**; the amount of alkali, temperature of thermal treatment and subsequent mechanical disintegration time. Effects of mixing the raw materials manually and mechanically and of sieving the pulverized product in wet and in dry state on the reinforcing properties of the prepared filler were also investigated. Variations in the reinforcing characters due to the loading amounts were examined up to 150 PHR with hard clay **M**. The reinforcing effects of the prepared fillers on SBR-1502 were evaluated in comparison with those of Dixie Clay. Excellent fillers comparable to the references were obtained from both specimens.

Experimental

Raw Materials. *Acid Clays*: The same acid clays, **M** and **N**, as in the preceding paper[1] were used. Table 1 shows the chemical composition of the specimens, from which the structural formulas and excess silica were estimated.

M, white and powdery, consists only of normal montmorillonite containing excess silica (34%), whereas **N**, light yellowish gray and crushed under 6 mesh, consists of montmorillonites containing excess silica (13%), in which the amount of abnormal montmorillonite is greater than that of normal one.

Quicklime: Calcium oxide lumps (10—30 cm^3) of reagent grade were pulverized and grains smaller than 60 mesh were chosen.

Preparation of Reinforcing Fillers. The method essentially the same as before[1] was followed. Treatment was modified as follows: The amounts of alkali were varied in the range 1.25—60% CaO in weight of the acid clay dehydrated at 110 °C for 4 hr; the temperature of thermal treat-

ment was 110—800 °C and the time of subsequent mechanical disintegration for the calcined matter 6—24 hr.

Effects of Mixing, Disintegration, and Sieving. The effect of mixing the raw materials according to the ball-milling method and that of manual grinding with a mortar and pestle was compared. The difference in mechanical disintegration in wet and dry states of the calcined matter was examined respectively by ball milling and dry pulverization with an atomizer (Tokyo Atomizer Co., Ltd). The effect of sieving the pulverized product in dry and wet states was also investigated.

Compounding Test. The same compounding test as described before[1] was carried out to screen the reinforcing fillers prepared. The effect of loading amounts of the best hard clay on the reinforcement of SBR-1502 was examined up to 150 PHR in comparison with those of Dixie Clay.

Results and Discussion

The Optimum Conditions for The Preparation of A Good Reinforcing Filler. A. Preparation and Reinforcing Properties of Hard Clay N: The amounts of alkali were made to be 3, 6, 10, 30, 50, or 60% CaO in weight. The raw materials were mechanically mixed in wet state with a porcelain ball mill for 1 hr. In view of the structural changes in acid clay revealed on the DTA and TGA thermograms,[1] the mixture dried at 110 °C was calcined at 400 °C to attain complete dehydration, at 600 °C for mid-dehydroxylation and

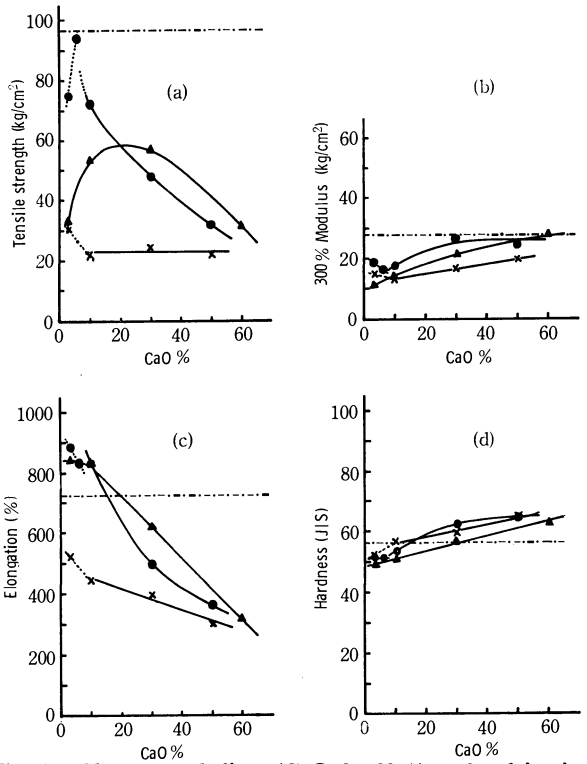

Fig. 1. Changes with lime (CaO 3—60%) and calcination (400—800 °C, 1—1.5 hr) in the reinforcing effects of **N** hard clay on SBR-1502 as compared with those of Dixie Clay.
×····× 800 °C, 1.5 hr: ●····● 600 °C, 1.5 hr; ▲—▲ 400 °C, 1.5 hr; ×—× 800 °C, 1 hr; ●—● 600 °C, 1 hr; ------ Dixie Clay

at 800 °C for complete dehydroxylation for 1 or 1.5 hr. The product was disintegrated by wet ball-milling at room temperature for 18 hr followed by filtration and drying at 110 °C. The dried matter was pulverized with an atomizer to give a reinforcing filler. The reinforcing effects of the prepared fillers on SBR-1502 are given in Table 2. Figures 1 (a)—(d) show the results obtained under the optimum conditions.

Tensile Strength (kg/cm²): The fillers prepared with hydrated lime (3—50% CaO) followed by calcination at 800 °C for 1 or 1.5 hr gave the lowest tensile strength which was almost independent of the variation in alkali corresponding to only 25% value of Dixie Clay (Fig. 1-(a)). Those treated with 3—60% CaO and by subsequent calcination at 400 °C for 1.5 hr exhibited a maximum tensile strength around 20% CaO, which was equivalent to about 60% value of Dixie Clay. Those prepared with 3—50% CaO followed by calcination at 600 °C for 1 or 1.5 hr showed a noticeable increase in the tensile strength with the decrease in the amount of alkali. The specimen treated with 6% CaO and by subsequent calcination at 600 °C for 1.5 hr exhibited the highest tensile strength comparable to that of Dixie Clay. However, the one treated with 3% CaO followed by the same calcination as the former showed an abrupt decrease in tensile strength about 78% value of Dixie Clay.

Modulus (300%, kg/cm²): Fillers prepared with 3—60% CaO and by subsequent calcination at 400 °C for 1.5 hr or 800 °C for 1 hr showed increase in the moduli with the increase in the amount of alkali (Fig. 1-(b)). The filler calcined at a lower temperature showed a greater rate in the increase in modulus than the one treated at a higher temperature with the same amount of alkali. Those prepared with 3—50% CaO followed by calcination at 600 °C for 1 hr exhibit an almost maximum modulus comparable to that of Dixie Clay with 30% CaO. The fillers prepared with CaO less than 10% and by calcination at temperatures 400—800 °C for 1 or 1.5 hr showed relatively lower modulus than that of Dixie Clay. This is in remarkable contrast to the case of hard clay **M**, and might be ascribed to the difference in the amounts of excess silica and abnormal montmorillonite.

Elongation (%): The fillers treated with CaO less than 10% followed by calcination at 400 or 600 °C for 1.5 hr gave considerably higher elongation than that of Dixie Clay (Fig. 1-(c)). The elongation decreases in proportion to the amount of alkali. When specimens were prepared with equal amount of alkali, the higher the calcinating temperature, the lower the elongation. The rate of decreasing elongation due to the amount of alkali was found to be great for the fillers calcined at 400 °C, but was relatively small for those treated at 800 °C.

Hardness (JIS): The fillers calcined at 400 °C for 1.5 hr or 800 °C for 1 hr showed a linear increase in hardness with the amount of alkali (Fig. 1-(d)). Those calcined at 600 °C for 1—1.5 hr afforded greater rate of increasing hardness with the amount of alkali than the former two series. A tendency to approaching a saturated value (64) was observable at 30% CaO, which was much greater than that (56) of Dixie Clay and comparable to that (65)[1] of Silene EF.

The optimum conditions of treatment with lime and by calcination for **N** may be concluded to be around 6% CaO and 600 °C for 1.5 hr, respectively. It is

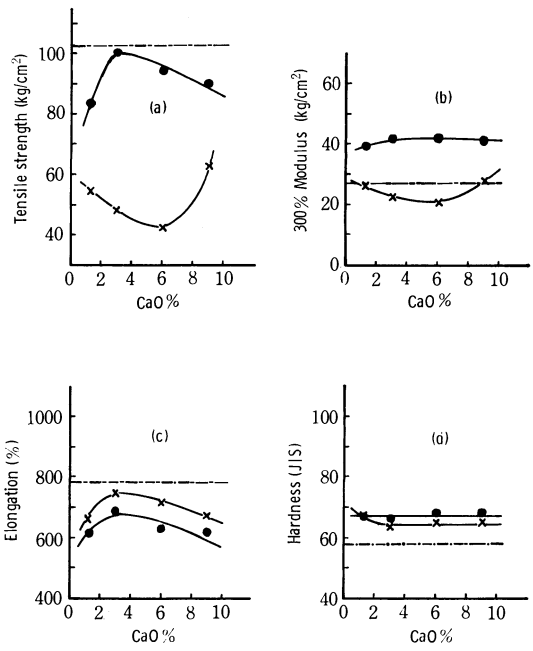

Fig. 2. Changes with lime (CaO 1.25—9%) and thermal treatment (110 °C, 5 hr; 600 °C, 1.5 hr) in the reinforcing effects of **M** hard clay on SBR-1502 as compard with those of Dixie Clay.

				12	102.6	27.3	783	58
				16	90.8	27.8	715	60

noticeable that regardless of the calcinating temperature, the reinforcing properties of the prepared fillers tend to approach their respective constant values around 60% CaO which much exceeds the amount of alkali equivalent to the excess silica estimated from the chemical composition of the original acid clay.

Curing Property: Owing to the remarkable adsorptivity[1] of the original acid clay, hard clay **N** tends to show a slow cure rate resulting in the poor reinforcing properties of the vulcanizates, which is attributable to the residual adsorptivity in the prepared filler. The 8 min vulcanizates containing the fillers treated with CaO less than 10% followed by calcination at 400 or 600 °C for 1.5 hr gave modulus and hardness lower than those of the 12 or 16 min vulcanizates (Table 2, No. 7, 10, 11, and 13). Treatment with CaO more than 10% and by calcination at 800 °C for 1 hr afforded the compounds normal cure. However, the formation of agglomerates, which were too hard to be disintegrated into sufficiently fine particles to give the desired strength, was unavoidable. Though the best sample (CaO 6%; calcination 600 °C, 1.5 hr; wet milling 18 hr) exhibited comparable tensile strength and higher elongation than those of Dixie Clay, its modulus was lower than that of the latter. Addition of some glycols or amines in the compounding may be expected to improve the lower modulus and tensile strength as well as the curing property like silica loading.[2]

B. Preparation and Reinforcing Properties of Hard Clay M: The preparation of good hard clay from **M** according to the same treatment with hydrated lime (3—60% CaO) and by subsequent calcination (400—800 °C, 1—1.5 hr) as mentioned above revealed that the optimum conditions were very close to those for **N**; the requisite amount of CaO lay in less than 10% and the calcination at 600 °C for 1.5 hr. Consequently **M** was treated with a less amount of CaO (1.25, 3, 6, or 9%) and then either calcined at 600 °C for 1.5 hr or dried at 110 °C for 5 hr in order to remove the moisture without calcination. Table 3 shows the reinforcing effects of the prepared fillers on SBR-1502 and Figs. 2 (a)—(d) demonstrate the results obtained under the optimum vulcanizing conditions.

Of all the fillers prepared from **M**, the one obtained with 3% CaO followed by calcination at 600 °C for 1.5 hr gave the loaded compound a maximum tensile strength comparable to that of Dixie Clay (Fig. 2-(a)). Although elongation 12% lower than that of Dixie Clay was observed, the modulus (300%) and hardness exceeded those of the reference filler by 52 and 14%,

2) Y. Hirata, "Science of New Industrial Materials for Rubber," A-4, ed. by T. Kuwata, Kanehara Publishing Co., Ltd., Tokyo, (1941), Chap. VI, p. 179.

respectively (Figs. 2 (b)—(d)). The increase in alkali above the optimum amount gave rise to a slow decrease in both tensile strength and elongation. The decrease in alkali gave an abrupt diminution in the reinforcing properties. However, nearly constant modulus (300%) and hardness were obtained irrespective of the variation in alkali. A remarkable difference in the reinforcement of SBR-1502 was found between the fillers calcined at 600 °C for 1.5 hr and those only dried at 110 °C for 5 hr without calcination. In spite of the relatively high elongation of the latter, the modulus and the hardness were lower than those of the former. Even the highest tensile strength at 9% CaO was found to be less than a 60% value of Dixie Clay. Investigations by DPG adsorption test and electron microscopy revealed that the noticeably low reinforcing properties could be attributed to the surface activity remaining in the filler, which causes the fine particles disintegrated in wet state to recondense into aggregates during the course of drying.

The optimum conditions can be concluded to be as follows. The optimum amount of quicklime is 3% for **M** and 6% for **N**; calcination at 600 °C for 1.5 hr. Variation in the optimum amount of alkali can be ascribed to the difference of the mineralogical constituents of the specimens, especially to the presence of abnormal montmorillonite, because it exhibits much greater adsorptivity and requires a greater amount of alkali than in normal one. The pulverized products thus prepared give the SBR-1502 compounds excellent reinforcing properties comparable to those of Dixie Clay.

C. Effects of Mixing, Disintegration, and Sieving: **M** (150 g) and quicklime (8.02 g, 6% CaO) were mixed for 1 hr manually with a mortar and pestle into a paste with 100 ml water (procedure M) or mechanically with a porcelain ball mill in slurry (procedure B).[1] After drying the mixture obtained by procedure M at 110 °C, the dried matter was calcined at 600 °C for 1.5 hr. The resulting product was ground by means of wet ball-milling for 6, 12, 18, or 24 hr. On being filtered off, the ground particles were dried again at

a) M_1 and B_1 denote manual or mechanical mixing of raw materials for 1 hr respectively with a mortar and pestle and with a ball mill.

b) B_w and A_d denote pulveriztion of the calcined matter by wet ball-milling and with an atmoizer in dry state, respectively.

c) W_{300} and D_{200} denote sieving of the pulverized product with a 300 mesh standard sieve (JIS) in wet state and with a 200 mesh in dry state, respectively.

d) 2* indicates pulverization repeated twice.

110 °C followed by pulverization with an atomizer (Table 4, Runs 1—4). Two samples mixed with alkali (3 and 6% CaO) by procedure B were prepared similarly by subsequent drying, calcination and wet ball-milling for 18 hr. In order to remove coarser particles, the disintegrated product was diluted with water to about 10% slurry and then made to pass through a 300 mesh standard sieve (JIS). Sieving after the milling for 18 hr, however, was found to be unnecessary. On being dried at 110 °C, the dehydrated product was pulverized with an atomizer to give a reinforcing filler (Table 4, Runs 5 and 6). Two more specimens mixed with alkali (6% CaO) by procedure B were obtained by the same treatment as above. Both calcined matters were disintegrated repeatedly in dry state with the atomizer. One of them was made to pass through a 200 mesh sieve before the compounding tests (Table 4, Run 8). The effects of the fillers thus prepared on the reinforcement of SBR-1502 were examined in comparison with those of Dixie Clay (Table 4). The results obtained under the optimum vulcanizing conditions are given in Figs. 3 and 4 (a)—(d).

So far as the calcined matter is concerned, the longer the wet milling time, the finer the resulting disintegrated particles. As disintegration proceeds sufficiently, a greater increase in the specific surface area contributes to a noticeable increase in the reinforcing capacity of the filler. The compound loading the filler, consequently, exhibited a considerable increase in tensile strength, modulus and hardness, accompanied by a remarkable decrease in the elongation as well (Fig. 3). The reinforcing properties were strictly or nearly in proportion to the wet milling time up to about 18 hr, and then approached a saturated value in the tensile strength or abrupt changes in the modulus (300%) and elongation. Both modulus and hardness far exceeded those of Dixie Clay, but the tensile strength and the elongation still fell short of the reference filler. This can be explained in terms of the effect of heterogeneous, manual mixing of the raw materials by procedure M as compared with the specimen (Table 3, No. 7) prepared by procedure B or mechanical mixing. A distinguishable difference in the reinforcing character between the fillers prepared by procedures B and M is ascribable to the high efficiency of the mechanical disintegration in mixing the raw materials (Table 4, Runs 3 and 5). Procedure B with a ball mill gives a homogeneous mixture leading to the promotion of the Pozzolanic reaction[3] between the acid clay and hydrated lime, which causes the formation of calcium montmorillonite as well as calcium silicate hydrates with the excess silica involved. As a result, the subsequent calcination proceeds so uniformly that any local sintering due to the polycondensation of acid clay itself can be avoided effectively. This should facilitate the pulverization of the calcined matter and contribute to the production of a better reinforcing filler.

The effect of sieving after the disintegration of calcined matter in dry or even in wet state on the reinforcing properties of the prepared filler was found to be relatively small or negligible as compared with that induced by the difference in procedure of mixing

and disintegration as well as the applied amount of alkali.

Thus pulverization of the calcined matters and the mixing of the raw materials are indispensable. Even if proper conditions are selected for treatment with lime and calcination as well as the raw materials, the filler prepared without being disintegrated sufficiently would not exhibit the maximum reinforcement of the elastomer. The reinforcement of an elastomer by loading inorganic fillers is caused by the interaction[4] between the filler and the elastomer. The greater the specific, effective surface area of the filler applied, *i.e.*, the smaller the fineness of the filler pulverized, the greater the reinforcing effects with a given amount of the prepared filler on the elastomer would be expected. Pulverization, therefore, is considered to be the most important process for the calcined matter and comprises a significant factor dominating the reinforcing character of the final product. From the viewpoint of the high efficiency of disintegrating the calcined matters, wet milling with a porcelain ball mill is more suitable than dry pulverization with an atomizer alone, and is considered to be indispensable for this purpose. Owing to its poor efficiency, the reinforcing properties of the fillers pulverized by the atomizer were hardly expect-

able. Regardless of the relatively high elongation and hardness observable in the loaded compounds, the tensile strength and modulus were only 20—30% as low as those of Dixie Clay (Figs. 4 (a)—(d)).

D. Variable Loading Test with Hard Clay M: For investigating the difference in the reinforcing properties between Dixie Clay and the best filler obtained, hard clay **M** prepared under the optimum conditions (CaO 3%; calcination 600 °C, 1.5 hr; wet milling 18 hr) was subjected to a variable loading test with SBR-1502 ranging 0, 50, 100, and 150 PHR in weight (Table 5). Figures 5 (a)—(d) give the results obtained under the optimum vulcanizing conditions.

It is evident that the reinforcement with the prepared hard clay is comparable to that with Dixie Clay. However, some differences can be seen in the maximum reinforcement of the elastomer; hard clay **M** exhibits it around 50 PHR, Dixie Clay around 100 PHR. The former thus undergoes a greater change due to the loading amount than the latter. The deviation seems to be attributable to the particle size as well as morphological, structural, and physicochemical properties originating from the mineralogical constituents of the fillers.

Curing Property: All samples of hard clay **M**, even the one treated with minor alkali (CaO 1.25%) and dried at 110 °C for 5 hr without calcination, showed no such delay of cure as hard clay **N**, and gave higher reinforcing properties than those of the latter treated with the corresponding conditions (Table 3). The best sample (CaO 3%; calcination 600 °C, 1.5 hr; wet milling 18 hr) showed favorable reinforcing properties in tensile strength, modulus, and hardness which were equivalent or even higher than those of Dixie Clay in the tested range. The elongation was somewhat higher at lower loading than 75 PHR and a little lower at higher loading than those of the reference filler, the maximum reinforcement being observable for the low ratio, 50 PHR (Fig. 5).

Evaluation of Reinforcing Properties: From a practical viewpoint, white fillers with high modulus and hardness are useful. If the tensile strength of vulcanizates as well as the recipe and vulcanizability of compounds were equivalent, the higher modulus given by a filler is considered to be a measure of the greater reinforcing capacity.[5] In a variable loading test, such a filler exhibits the maximum tensile strength at a relatively low ratio. Though negative effects of the filler on the tear resistance and flexing life of the vulcanizate are inevitable, better abrasion resistance can be expected as well. In case of hard clay **M**, however, the negative effects are assumed to be relatively small because of the less diminution of elongation and tensile strength in the variable loading test in spite of the high modulus and hardness.

Consequently hard clay **M** might excel as a reference filler in its reinforcing properties such as modulus, hardness, and abrasion resistance.

The authors are grateful to the late Prof. T. Kuwata and Assoc. Prof. J. Kumanotani for many helpful discussion and suggestions during the course of this work, and to Mr. Y. Sugawara, president of Mizusawa Industrial Chemicals Co., Ltd. for providing samples of acid clay.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3562—3565 (1973)

The Selective Hydrogenation of α-Methylcinnamaldehydes Catalyzed by Cobalt Carbonyl in the Presence of Amines

Kunio KOGAMI and Ju KUMANOTANI*

T. Hasegawa Co., Ltd, Nihonbashi, Chuo-ku, Tokyo 103

**Institute of Industrial Science, University of Tokyo, Roppongi, Minato-ku, Tokyo 106*

(Received May 9, 1973)

The selective hydrogenation of α-methylcinnamaldehydes to the hydrocinnamaldehydes, catalyzed by cobalt carbonyl and a limited amount of amines, has been investigated. The addition of such amines as diisopropylamine, diethanolamine, tributylamine, triethylamine, and pyridine showed a remarkable selectivity and gave the desired α-methylhydrocinnamaldehydes in 96.4—91.5% theoretical yields. Especially, diisopropylamine gave the best selectivity, in it the yields of *p-t*-butyl-α-methylhydrocinnamaldehyde and cyclamenaldehyde amounted to 96%. The optimum amount was found to be 1.0—1.3 equivalents of cobalt carbonyl.

p-t-Butyl-α-methylhydrocinnamaldehyde (lilyal) and *p*-isopropyl-α-methylhydrocinnamaldehyde (cyclamenaldehyde), the most appreciated synthetic perfumes, are prepared industrially by two well-known processes, *viz.*, the dehydrogenation of the corresponding alcohol using a Cu–Zn catalyst[1] and the selective hydrogenation of the cinnamaldehyde using a palladium-alumina catalyst containing potassium acetate.[2]

Previously we have reported a selective hydrogena-

1) S. Abe and T. Yasukawa, *Yuki Gosei Kagaku Kyokai Shi*, **22**, 144, 209 (1964).

2) D. Morris, E. Daniel J, and S. Alfred, U.S. 3520934 (1970).

tion of *p*-isopropyl-α-methylcinnamaldehyde to cyclamenaldehyde with a cobalt carbonyl catalyst or its ligand-substituted complex under oxo conditions.[3] It was found that a tris(2-bromoethyl) phosphite-substituted cobalt carbonyl gave the best yield (86.3%) among those substances unsubstituted and substituted with PR_3, $P(OR)_3$, and $PO(OR)_3$ (R=alkyl, aryl).

Wender *et al.*[4] have reported on the behavior of amines in the hydroformylation of cyclohexene as follows: 1) The rate of hydroformylation is increased by the addition of a small amount of organic amines, but decreased with a larger amount of them. 2) Both the basicity and the steric factor of the amines affect the rate of the reaction. Matsuda and Uchida[5] have proved that the addition of an appropriate amount of pyridine improves not only the selectivity for the hydroesterification of propylene with carbon monoxide and methanol, but also the rate of conversion. These findings urged us to study more closely the effect of organic amines upon the rate and the selectivity of the hydrogenation of the cinnamaldehyde under controlled oxo conditions.

The present paper will describe the selective hydrogenations of *p*-*t*-butyl-α-methylcinnamaldehyde and *p*-isopropyl-α-methylcinnamaldehyde using a cobalt carbonyl catalyst in the presence of various organic amines. Diisopropylamine was found to be the best and gave the highest yields, 96.4 and 96.2%, for lilyal and cyclamenaldehyde respectively.

Experimental

Materials. *p*-*t*-Butyl-α-methylcinnamaldehyde (I) was prepared according to the Knorr method[6] in the same manner as *p*-isopropyl-α-methylcinnamaldehyde (II).[3] I; bp 114—116 °C/1 mmHg, mp 69 °C, purity by gas liquid chromatography (glc) 100%. The dicobalt octacarbonyl (mp 51 °C) was the same as has been described in previous papers.[3,7] It was used with one of the following organic amines in an equimolar ratio or a little more in relation to dicobalt octacarbonyl in isopropyl ether:[5] Triphenylamine, 3-aminopropionitrile, quinoline, pyridine, dimethylaniline, diethanolamine, isopropylamine, cyclohexylamine, triethylamine, tributylamine, diisopropylamine, and piperidine. They were all chemically pure-grade reagents, purchased from the Tokyo Kasei Co., Ltd.

Procedure. I or II (0.3 mol, 60.6 or 56.4 g respectively) and a solution of dicobalt octacarbonyl (5.2 mmol, 1.8 g) in isopropyl ether (150 ml) containing a small amount of an amine were put into a 500 ml stainless steel autoclave equipped with an outlet for sampling. The air in the autoclave was flushed with nitrogen several times. Then the autoclave was filled with water gas (65 kg/cm², H_2: CO=12: 1) at room temperature, heated to 107 °C in 30 min, and stirred. The temperature was kept within a range of ±1 °C during the reaction. During the reaction, small amounts of the reaction mixture were withdrawn at prescribed time intervals for glc analysis. Hydrogenation was continued until the peak of I or II disappeared. The end point was checked from the gauge-time relation as well. The rate of hydrogenation was then estimated from the depression in the pressure. The rate constant (k) of hydrogenation was obtained according to the following equation:

$$k = 2.303 \log (P_o - P_f)/(P_t - P_f)/t$$

where P_o is the initial pressure at the beginning of stirring, where P_f is the final one at the end of the reaction, and where P_t is the one at time t.

In the case of constant-pressure experiments, hydrogen was continuously introduced from a pressure storage tank through a needle valve in order to keep the total pressure constant throughout the reaction. After the hydrogenation, the autoclave was cooled and the remaining gas was eliminated. An aqueous solution (150 ml) of 0.25 M iodine–potassium iodide and an acetic acid–isopropyl ether solution (1: 100 v/v, 150 ml) were stirred in 1 hr to decompose the cobalt carbonyl catalyst. The upper layer was separated, washed with 300 ml of 5% aqueous hydrosulfite and subsequently with 200 ml of 5% aqueous sodium carbonate, and dried over sodium sulfate. After the removal of the ether, an oily product was distilled *in vacuo*; this separated volatile products and a resinous matter (1—3% by weight) through a packed column-type rectifier.

Identification of the Products. Lilyal and the corresponding alcohol, *p*-*t*-butyl-α-methylhydrocinnamyl alcohol (III), in the products were separated by distillation through the packed column-type rectifier and identified by means of their NMR spectra in $CDCl_3$ with tetramethylsilane as the internal standard, on a JEOL 4H-10 spectrometer. As the NMR spectra and physical constants of cyclamenaldehyde and cyclamenalcohol, were described in a previous paper,[3] they will be omitted here. Lilyal: Bp 96—98 °C/1 mmHg, d_{25}^{25} 0.9385, n_D^{25} 1.5056. NMR spectrum: 1.05 ppm (d) doublet (J=2.5 Hz) methyl 3H; 1.30 ppm (s) singlet *t*-butyl 9H; 2.52 ppm (d) methylene 2H; 3.0 ppm (m) multiplet methine H; 7.10 ppm (m) phenyl 4H; 9.6 ppm (s) aldehyde H. III: Bp 106—108 °C/1 mmHg, d_{25}^{25} 0.9360, n_D^{25} 1.5068. NMR spectrum: 0.90 ppm (d) (J=3.0 Hz) methyl 3H; 1.30 ppm (s) *t*-butyl 9H; 1.55 ppm (d) methylene 2H; 1.82 ppm (bs) broad singlet hydroxy H; 1.87 ppm (m) methine H; 3.30 ppm (d) hydroxymethylene 2H; 7.10 ppm (m) phenyl 4H.

The composition of the aforementioned oily product and the volatile matter were determined by the normalization method with glc, using a gas chromatograph, Kotaki GU-21, equipped with a 2 m stainless steel column of KF 54 (5% by weight) on Celite 545 sk (60—80 mesh) at 180 °C. They were analyzed within a relative experimental error of ±1.5%. Authentic lilyal was prepared by the dehydrogenation of III with a Cu-Zn catalyst (bp 96—98 °C/1 mmHg, d_{25}^{25} 0.9387, n_D^{25} 1.5058) and III by the catalytic hydrogenation of I over a nickel diatomaceous earth catalyst (bp 106—108 °C/1 mmHg, d_{25}^{25} 0.9357, n_D^{25} 1.5065).

Results and Discussion

In the preceding paper,[3] we reported that the conversion of cinnamaldehyde into hydrocinnamaldehyde can be increased by both increasing the pressure of hydrogen in water gas and by the use of a 2.0—2.5-fold volume of solvent for the cinnamaldehyde.

On the basis of those results, the foregoing experiments were carried out using dicobalt octacarbonyl

with or without pyridine, often used in conventional hydroformylations, under the following favorable conditions:[3] At 107 ± 1 °C and 65 kg/cm² of the initial pressure of water gas (H_2: CO=12: 1). They revealed that the hydrogenation of I or II apparently obeyed a first-order kinetics in the partial pressure of hydrogen and that the addition of pyridine not only increased the rate of hydrogenation, but also improved the selectivity for forming lilyal or cyclamenaldehyde (Table 1). Equimolar pyridine to dicobalt octacarbonyl increased the rate and the selectivity of the hydrogenation; however, greater or lesser amounts had negative effects. The analysis of the hydrogenation products in the presence of pyridine proved the absence of the hydroformylates formed. Plots of the consumed amount of cinnamaldehyde against the reaction time gave a linear relation under a constant pressure of hydrogen, indicating that the hydrogenation was first order in the partial pressure of hydrogen, and zero order in the concentration of cinnamaldehyde, when a small amount of pyridine existed (Fig. 1).

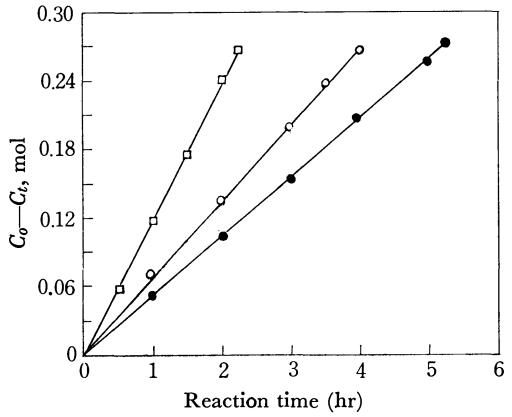

Fig. 1. Plots of the consumed amount of cinnamaldehyde, C_o-C_t, *vs.* reaction time at 107 ± 1 °C and 65 kg/cm² the total pressure of water gas (H_2: CO=12: 1) in the presence of pyridine.

●	2.9	2.9	89.5

C_0; the initial molar concentration of I.
C_t; the molar concentration of I at reaction time *t*.

Iwanaga[8] observed that the rate of the hydroformylation of methyl acrylate in benzene under an oxo condition is nearly doubled with only a small amount of pyridine, and that the pyridine accelerates the rate of the reaction by forming an intermediate complex (Eq. 2), which is then rapidly converted into cobalt hydrocarbonyl by the subsequent hydrogenation (Eq. 3). The amount of free cobalt hydrocarbonyl, however, decreases upon combination with amine (Eq. 4) and increases with the increased basicity of the amine applied. Some amines with low steric requirements, such as pyridine, can replace the free cobalt hydrocarbonyl (Eq. 5):[5]

$$Co_2(CO)_8 + H_2 \longrightarrow 2HCo(CO)_4 \quad (1)$$

$$Co_2(CO)_8 + 2B \longrightarrow (CO_4)Co\cdots Co(CO)_4 \quad (2)$$

$$HCo(CO)_4 + B \longrightarrow (BH)^+(Co(CO)_4)^- \quad (4)$$

$$HCo(CO)_4 + B \longrightarrow HCo(CO)_3B + CO \quad (5)$$

In the hydrogenation of α,β-unsaturated carbonyl compounds catalyzed by cobalt hydrocarbonyl, the saturated carbonyl compounds formed are very slowly transformed into the corresponding alcohols.[3,9] This indicates that the cobalt hydrocarbonyl coordinate more intimately around the carbonyl group of cinnamaldehyde than around that of hydrocinnamaldehyde, resulting in the formation of the π-oxapropenyl intermediate complex.[10] Furthermore, the slow transformation into the hydrocinnamyl alcohol can be interpreted in terms of the difficulty in the formation of the cyclic-transition-state intermediate between the cobalt hydrocarbonyl and the hydrocinnamaldehyde.[11] Consequently, the favorable selectivity in the formation of hydrocinnamaldehyde is considered to occur with the cobalt hydrocarbonyl produced by strong amines with appropriate steric factors. In order to

a) I or II (0.3 mol, 60.6 or 56.4 g, respectively) was hydrogenated in 150 ml of isopropyl ether at 107±1 °C and 65 kg/cm² of water gas (H_2: CO, 60: 5) with 5.2 mmol of $Co_2(CO)_8$ as catalyst.
b) Theoretical yield of lilyal or cylcamenaldehyde.

establish the optimum conditions for obtaining the hydrocinnamaldehydes, the hydrogenation was investigated with various organic amines such as diisopropylamine, tributylamine, triethylamine, and pyridine. The results obtained are shown in Table 2.

The applied amines showed increasing effects on the rate of hydrogenation as well as on the selectivity in the formation of the hydrocinnamaldehyde, in accordance with the order of basicity. The rates of hydrogenation were found to be as follows: Triphenylamine (pK_b=14.0)<3-aminopropionitrile (pK_b=11.9)<quinoline (pK_b=9.0), pyridine (pK_b=8.96) and dimethylaniline (pK_b=8.94)<diethanolamine (pK_b=5.52), isopropylamine (pK_b=3.34) and cyclohexylamine (pK_b=3.32)<triethylamine (pK_b=3.32)<tributylamine (pK_b=3.11)<diisopropylamine (pK_b=2.89), and piperidine (pK_b=2.79). Smaller rate constants were observed with triphenylamine and 3-aminopropionitrile, which gave almost the same selectivity in the formation of hydrocinnamaldehyde as in the absence of an amine. Quinoline, dimethylaniline, isopropylamine, cyclohexylamine, and piperidine had only feeble effects on increasing the selectivity, although larger rate constants of hydrogenation were obtained. This can be explained in terms of the persistency of activity for the further conversion of hydrocinnamaldehyde into hydrocinnamyl alcohol in the cases of amines with a relatively stronger basicity and less steric hindrance. Pyridine, diethanolamine, triethylamine, tributylamine, and diisopropylamine showed larger rate constants of hydrogenation, in good argeement with the order of basicity, and showed the best effects in producing hydrocinnamaldehyde. In spite of the weak basicity and small steric effect, pyridine affords good selectivity in the formation of hydrocinnamaldehydes. The knowledge[5] at present available on the catalytic behavior of $HCo(CO)_3Py$ can not make possible a satisfactory interpretation of the effect.

Among the effective amines, diisopropylamine gave the largest rate constants and the best selectivity; the yields of lilyal and cyclamenaldehyde amounted to 96%, suggesting the effectiveness of both the strong basicity and the appropriate bulkiness. The optimum amount of diisopropylamine was found to be 1.0—1.3 equivalents, based on the dicobalt octacarbonyl.

The authors wish to express their gratitude to Mr. Shozo Hasegawa, the President of T. Hasegawa, Co., Ltd, for his permission to publish this paper. The authors also wish to thank Professor Shigeo Nishimura, Tokyo University of Agriculture and Technology, for his valuable suggestions and helfpul discussions.

Modifying Effect of Acetic Acid or Triphenylphosphine on the Raney Cobalt Catalyst in the Liquid-phase Hydrogenation of an Aliphatic α,β-Unsaturated Aldehyde

Kazuhiko HOTTA and Teruo KUBOMATSU
The Osaka Municipal Technical Research Institute, Kita-ku, Osaka 530
(Received November 13, 1972)

In our previous papers,[1,2] we have reported that, in the hydrogenation of the α,β-unsaturated aldehyde, 2-methyl-2-pentenal(UD), over the Raney cobalt catalyst with or without modifiers, the products are the saturated aldehyde 2-methylpentanal(SD), saturated alcohol 2-methylpentan-1-ol(SA), and unsaturated alcohol 2-methyl-2-penten-1-ol(UA), and that the initial rates of formation of the three products, r_{SD}, r_{SA}, and r_{UA}, can be represented by the following Langmuir-type rate equations:

$$r_{SD} + r_{SA} = k_1 b_1 C_{UD}/(1+b_1 C_{UD})^2 \quad (1)$$

$$r_{UA} = k_2 b_2 C_{UD}/(1+b_2 C_{UD})^2 \quad (2)$$

where k and b denote the rate constant of the surface reaction and the adsorption parameter for UD and hydrogen[3] respectively; where the subscripts 1 and 2 represent the formation of SD and SA and that of UA respectively, and where C_{UD} refers to the liquid-phase concentration of UD. There it has also been shown that k_1 decreases with an increase in the amounts of Mn- and $CoCl_2$ added, while k_2 does not change or increases with the addition of a small amount of the modifiers.

In the present note, the variation in the kinetic parameters with the amounts of added acetic acid (AcOH) and triphenylphosphine(PPh_3) is examined. The variation of k_1 and k_2 over the AcOH-modified catalyst is found to be similar to that over the $MnCl_2$- and $CoCl_2$-modified catalysts, but both k_1 and k_2 are decreased by the addition of PPh_3. It can be concluded that the acidic modifiers, such as AcOH, $MnCl_2$, and $CoCl_2$, promote the formation of UA.

Experimental

The Raney cobalt catalyst was prepared as has previously been reported.[1] The catalyst was modified by injecting a hexane solution of AcOH or PPh_3 to the catalyst–hexane–hydrogen system and by stirring the mixture.

The rate measurements were carried out as has been reported in a previous paper.[1]

Results

The products of the reaction were found to be SD, SA, and UA. The dependence of the initial rates on C_{UD} over the AcOH-modified catalyst are shown for r_{SD} and r_{SA} in Fig. 1, and for r_{UA} in Fig. 2.

Since the formation of SD and SA and that of UA can be treated separately,[1,2] the rate data in Figs. 1 and 2 were analyzed by means of Eqs. (1) and (2) respectively, and the kinetic parameters, k_1, k_2, b_1, and

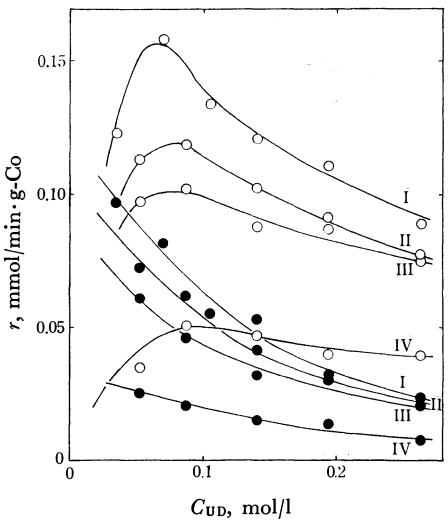

Fig. 1. Concentration dependence of the initial rate of formation of SD, ○; SA, ●, in the presence of AcOH of 0.0, I; 0.035, II; 0.070, III; 0.175 mmol/g-Co, IV at 40 °C.

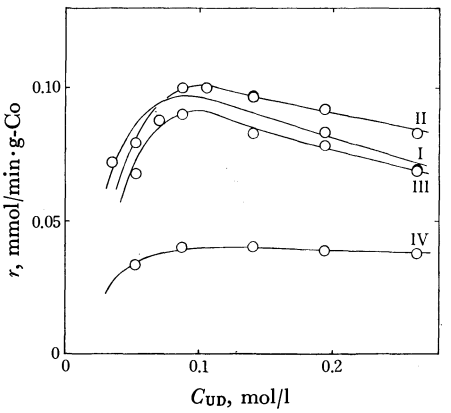

Fig. 2. Concentration dependence of the initial rate of formation of UA. Same notations as in Fig. 1.

1) K. Hotta and T. Kubomatsu, This Bulletin, **44**, 1348 (1971).
2) *Idem, ibid.*, **45**, 3118 (1972).
3) The accurate definition of b is: $b=K_{UD}/(K_H \cdot C_H)$, where C_H refers to the liquid phase concentration of hydrogen and is assumed to be constant at a given temperature, and where K_{UD} and K_H denote the adsorption equilibrium constants of UD and hydrogen, respectively.

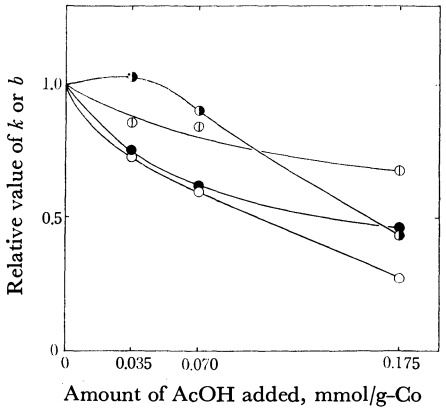

Fig. 3. Variation of the rate constant and adsorption parameter with the amount of AcOH, k_1, ○; k_2, ◑; b_1, ●; b_2, ⓘ.

b_2, were evaluated to see how the values of these parameters vary with the modification.

The values of the kinetic parameters/values without modifier are plotted against the amount of AcOH added in Fig. 3. The rate constant for the formation of SD and SA, k_1, and the adsorption parameters, b_1 and b_2, were found to decrease upon the addition of AcOH, while k_2 did not change upon the first addition of a small amount of AcOH, but then began to decrease upon further addition.

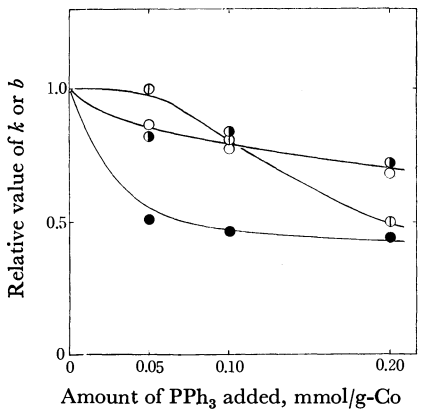

Fig. 4. Variation of the rate constant and adsorption parameter with the amount of PPh_3. Same notations as in Fig. 3.

The results obtained on the catalyst modified with PPh_3 are also shown in Fig. 4. It was found that k_2 as well as k_1 and b_1 decreased when the catalyst was modified with PPh_3, and that b_2 did not change on the first addition of a small amount of PPh_3.

Discussion

The behavior of the two kinetic parameters for the formation of SD and SA (k_1 and b_1) over the AcOH- and PPh_3-modified catalysts are found to be similar to each other.

It is interesting that the variation in the kinetic parameters for the formation of UA (k_2 and b_2) over the AcOH-modified catalyst is different from that over the PPh_3-modified one. It is also interesting that the variation in k_1 and k_2 over the AcOH-modified catalyst is the same as those previously observed over the $CoCl_2$- and $MnCl_2$-modified catalysts.[2] Taking into consideration the facts that AcOH has the Brönsted acidity and that Co- and $MnCl_2$ have the Lewis acidity, these results can be considered to indicate that the action of acids as modifiers differs from that of bases, especially in the effect on the formation of UA, although the reason is not yet well known. No detailed or quantitative discussion of the variation in the kinetic parameters observed in the present study is possible, since the effect of modifiers on the kinetic parameters is not simple.

If a modifier is adsorbed competitively with the reactants and without any interaction among them, the rate equation can be expressed as:[4]

$$r = k_a b_a C_{UD}/(1+b_a C_{UD})^2 \quad (3)$$

where k_a and b_a denote the apparent rate constant and the adsorption parameter respectively. The definitions of the apparent kinetic parameters are as follows:

$$k_a = k/(1+b_M C_M) \quad (4)$$

$$b_a = b/(1+b_M C_M) \quad (5)$$

where b_M and C_M denote the adsorption parameter and the liquid-phase concentration of a modifier respectively. It can thus be said from Eqs. (4) and (5) that the rate constants and adsorption parameters determined by Eqs. (1) and (2) apparently decrease with the addition of a modifier, provided that there is no interaction between the adsorbed modifier and the reactants. The variation in the kinetic parameters for the formation of SD and SA (k_1 and b_1) over the AcOH- and PPh_3-modified catalysts, therefore, seems to be explainable in terms of the above-described Langmuir-Hinshelwood mechanism.

Both of the adsorption parameters over the AcOH-modified catalyst were found to decrease, even on the first addition of a small amount of AcOH. This indicates that AcOH is adsorbed on the site responsible for the formation of UA as well as on that responsible for the formation of SD and SA. Therefore, the fact that k_2 did not change, or even increased, on the first addition of a small amount of acidic modifiers, such as AcOH, $MnCl_2$, and $CoCl_2$, can certainly be considered to be due to an increase in the rate constant, k, in Eq. (4). This indicates that the acidic modifiers promote the formation of UA, suggesting that an interaction exists among the adsorbed acidic modifier and adsorbed species responsible for the formation of UA.

Difficulty of Establishing Adsorption Equilibrium in *n*-Butylamine Titration of Solid Acid Surfaces

Jun-ichiro TAKE, Yasumasa NOMIZO,[1] and Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 6, 1972)

The Benesi or *n*-butylamine titration method[2] has widely been employed for determining the acid-strength distribution of solid acid surfaces. Applications[3,4] and variations[5] of the method have also been worked out. It was assumed so far that the adsorption equilibrium of both amine and indicator molecules with acid sites is attained on solid surfaces. However, no evidence has been given to show that the assumption is satisfied. Leftin and Hobson[6] showed that the intensity of a 550 mμ band due to benzeneazodiphenylamine (BADA) chemically adsorbed on silica-alumina became practically constant 30—40 hr after addition. Accomplishment of such a stationary state, however, does not necessarily indicate the validity of the assumption.

In the course of our studies we came across a remarkable phenomenon giving rise to a strong doubt about the validity of the assumption. The present paper deals with the findings.

A thin wafer (*ca.* 25 mg, 20×9 mm and about 0.1 mm thick) of a commercial silica-alumina catalyst (SA-1, Al_2O_3 13%)[3] was mounted on a holder, placed in a UV-cell,[7] and then activated by evacuation at 450 °C for 1 hr *in situ*. After transfer of highly dried and degassed decalin in a vacuum, followed by introduction of dried nitrogen gas, a decalin solution of *n*-butylamine was gently added through a pipette, without any agitation, into the cell in a dried nitrogen gas stream. The amount of addition was about 0.1 meq/g-catalyst, roughly corresponding to one-half of the acid content of SA-1 determined by *n*-butylamine titration with BADA as an indicator.[3] The cell was then allowed to stand at 50 °C without stirring. After 12 days, a solution of BADA in decalin (*ca.* 6×10^{-4} meq/g-catalyst) was admitted into the cell.

The resulting surface coloration and its change with time are shown schematically in Fig. 1. The indicator BADA is purple when adsorbed on acid sites, and yellow when adsorbed on poisoned acid sites or non-acidic sites.[3] Thus, in Fig. 1 yellow coloration indicates the poisoning of acid sites with the amine, the purple no poisoning with the amine, and no coloration the absence of BADA on the surface.

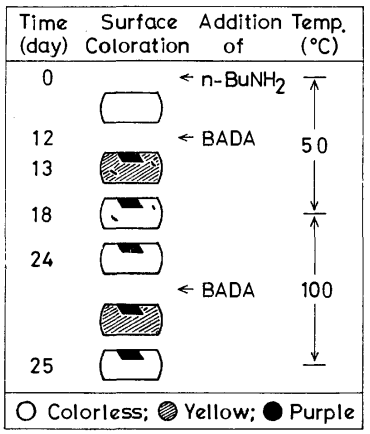

Fig. 1. Surface colorations of SA-1 wafer partially poisoned with *n*-butylamine.

In general, solid acid surfaces have been thought to have acid sites with different acid strengths. Acid sites of every acid strength should, on a macroscopic scale, be uniformly distributed over the surface of a wafer or of a catalyst particle. According to the prevailing theory of adsorption on such a heterogeneous surface,[8] at adsorption equilibrium basic molecules such as *n*-butylamine are distributed onto acid sites of every acid strength following the adsorption isotherm, a function of both the number and the strength of acid sites. Thus the adsorption of BADA onto the surface having reached adsorption equilibrium with *n*-butylamine will cause the surface to be uniformly colored at equilibrium. However, it should be noted that a macroscopically uniform distribution of basic molecules can be realized even though no adsorption equilibrium exists. The adsorption of basic molecules not followed with the desorption will yield an adsorption state far from equilibrium. Establishment of adsorption equilibrium thus needs desorption-readsorption cycles of basic molecules once adsorbed on the surface.

Macroscopic uniformity in the distribution of acid sites was proved by the fact that a uniform coloration occurred when BADA was added onto the wafer that had been immersed into a previously well-mixed decalin solution of *n*-butylamine (*ca.* 0.1 meq/g-catalyst) for 1—2 days at room temperature. The surface of a wafer partially poisoned with the amine would then have uniformly turned purple independently of the mode of poisoning, if there had existed adsorption equilibrium. However, this was not the case (Fig. 1). Essentially the same results were also obtained in separate experiments carried out in a similar way. No

uniform coloration appeared during the course of standing for 25 days, indicating that the amine once adsorbed on acid sites was hardly desorbed or hardly migrated even at 100 °C, a temperature higher than the boiling point of the amine (77.8 °C). This was confirmed by the reappearance of the yellow upon the second adidtion of BADA (see Fig. 1). Such difficulty is also demonstrated by the fact that ethylamine is desorbed with an activation energy as high as about 20 kcal/mol from silica gel,[9] which is usually nonacidic or much less acidic than silica-alumina catalyst. All the facts are strongly negative against the establishment of adsorption equilibrium. Therefore, the local coloration in Fig. 1 is best explained as being due to the fact that the added amine molecules approach the surface, as a whole, irregularly or non-uniformly (as in the motion of a drop of ink allowed to fall into standing water), and then remain, without reaching adsorption equilibrium, on adsorption sites at which they first arrived. In both cases where the amine is added with stirring and where a previously well-mixed solution of the amine is used without stirring, the amine molecules should be allowed to approach uniformly the surface of catalyst, hence the subsequent addition of BADA probably yields a uniform surface coloration. However, it is highly unlikely that the desorption of the once adsorbed amine is accelerated and adsorption equilibrium thus reached.

The ordinary conditions for equilibration used in the *n*-butylamine titration method are much milder than those employed here; in the former, the temperature ranges from room temperature to 30 °C and the standing period from several hours to several days. Under such conditions, therefore, the adsorbed amine is probably far from equilibrium even if agitation is applied.

The yellow coloration of the wafer surface faded gradually with time, this being accompanied by the deepening of the purple (Fig. 1), indicating that the physically adsorbed BADA migrated onto acid sites not poisoned with the amine. The completion of this migration took at least 5 days at 50 °C. In fact, physically adsorbed BADA is desorbed with an activation energy as high as 16 kcal/mol from silica gel.[7] Thus it is concluded that even physically adsorbed BADA is desorbed or migrates with considerable difficulty.

It is very difficult for either *n*-butylamine or indicators, particularly the former, to reach adsorption equilibrium with acid sites under the usual conditions in the *n*-butylamine titration method. The difficulty is not effectively diminished for *n*-butylamine by raising the temperature to 50—100 °C. Such will also be the case with catalysts in the form of powder. Disregard of this difficulty might lead to an overestimation of the acid contents.

The Formation of Benzene Dimer Cations on Synthetic Mordenite

Hiroji TOKUNAGA, Yoshio ONO, and Tominaga KEII

Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received February 19, 1973)

Extensive studies have been carried out on the formation of cation radicals from aromatic hydrocarbons on silica-alumina or synthetic zeolites, since the electron-transfer process seems to be closely relevant to the acid-base properties of the surfaces.[1-6] It has been established that the heat treatment of the catalyst and the presence of adsorbed oxygen have a marked effect on the formation of cation radicals. Recently, Kurita and co-workers[7] reported that benzene dimer cations were formed when synthetic mordenite was contacted with benzene in carbon tetrachloride. The effects of catalyst pretreatment and of adsorbed oxygen on the formation of dimer cations over the ammonium form of synthetic mordenite were investigated by means of ESR spectroscopy and the mechanism of the formation of the dimer cations is discussed in this paper.

Experimental

The Na form of mordenite was furnished by Nippon Kagaku and NH_4^+ form was prepared by the conventional cation-exchange procedures with ammonium chloride. The degree of ion exchange was found to be 32% by the gravimetric analysis of the eluted Na^+ ions. For easy introduction and evacuation of gases the adsorption of benzene was carried out from vapor phase no solvents being used. The zeolite (600 mg) was placed in an ESR sample tube (o.d. 10 mm) and evacuated at an appropriate temperature for 3 hr and then exposed to benzene vapor at room temperature. ESR measurements were carried out with a JEOL X-band spectrometer with a modulation frequency of 100 kHz. Radical ion concentrations expressed in terms of spins per gram of dry zeolite were determined by double integration using a benzene solution of 1,1-diphenyl-2-picrylhydrazyl.

Results and Discussion

Assignment of ESR Signals. The ammonium mordenite showed no ESR absorption when it was evacuated at 600 °C. A well-resolved spectrum was obtained when it was exposed to benzene vapor of 50 Torr for 5 min. The hyperfine coupling constant of 2.2 Oe agrees with that of benzene dimer cations in sulfuric acid.[8] The intensity distribution of lines was also in good agreement with that expected from radicals with 12 equivalent protons. Thus, the spectrum was unambiguously assigned to benzene dimer cations. The intensity of the spectrum decreased with time, the line shape being changed. The spectrum after 7 days was the same as that obtained on biphenyl adsorption on the mordenite. The results we obtained from the vapor phase adsorption of benzene are concluded to be essentially the same as those obtained by Kurita and co-workers[7] from the adsorption of benzene in carbon tetrachloride. The adsorption of benzene on the ammonium mordenite leads to the formation of benzene dimer cations which are converted into biphenyl cation on the surface.

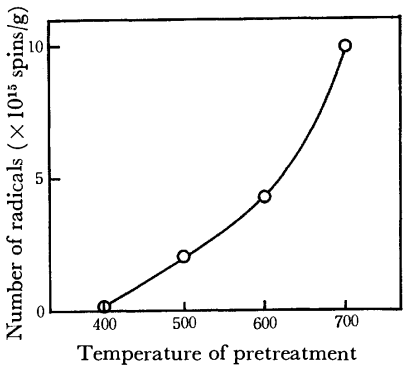

Fig. 1. Effect of pretreatment temperature on the number of benzene dimer cations.

Effect of Calcination Temperature. The effect of the temperature of zeolite activation on the generation of benzene dimer cation radicals on NH_4^+ mordenite is illustrated in Fig. 1. Generation of the radicals was observed only for samples evacuated above 500 °C, the radical amount increasing drastically with the rise in the activation temperature. It was reported[9] that the dehydroxylation of H mordenite starts at 450 °C. Since the activation temperature of the mordenite giving dimer cations corresponds to the temperature of the dehydroxylation which results in the formation of the three-coordinated aluminium, it is concluded that the dimer cations are formed by the transfer of an electron from two benzene molecules to the three-coordinated aluminium atoms. The same mechanism of the charge transfer was proposed by Stamires and Turkevich[5] for the formation of triphenylamine cation radicals on ammonium Y-zeolite.

Effect of Adsorbed Oxygen. *(a) Effect of the Introduction of Gaseous Oxygen*: Ammonium mordenite evacuated at 700 °C for 3 hr was exposed to benzene vapor for 5 min and evacuated for 2 min. The intensity of spectrum was then monitored with time. It decreased slowly with time. After 60 min, 6 Torr of oxygen was introduced into the system. This caused about five-time increase in ESR intensity as shown in Fig. 2. It was confirmed that this is not caused by the removal of the saturation of the ESR signal. It is thus concluded that the presence of oxygen enhances the dimer radical formation.

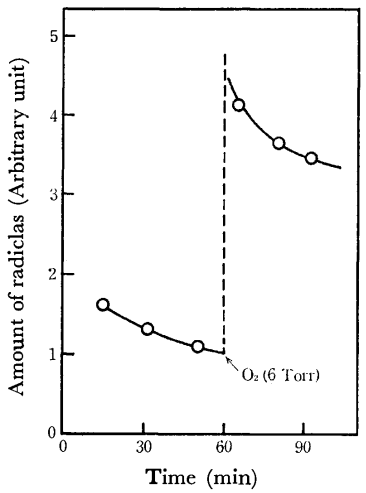

Fig. 2. Change in the radical amount on introduction of 6 Torr of oxygen.

(b) Effect of Oxygen Pretreatment: When ammonium mordenite treated at 700 °C was exposed to 25 Torr of oxygen and evacuated at room temperature for 5 min prior to adsorption of benzene, the ESR intensity of dimer cations was 1.5 times larger than that from the sample without oxygen treatment. When oxygen pretreatment was carried out at elevated temperatures (200 and 400 °C), the enhancement of the ESR intensity was enormous, as shown in Fig. 3. These results show that the adsorbed oxygen has an important role in the formation of the dimer cations as it does for monomer cation radical formation.[3,4,6] The adsorption of oxygen might be an activated process since the radical amount

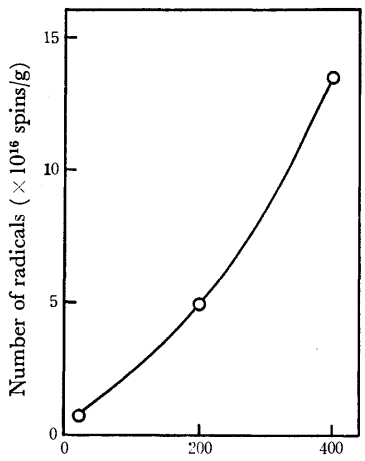

Fig. 3. Effect of oxygen pretreatment temperature on the number of benzene dimer cations.

increases with the temperature of oxygen pretreatment.

Enhancement of the radical formation by adsorbed oxygen could be caused by either or both of the following.

a) An increase in the electron-withdrawing power of the aluminium atoms due to the inductive effect of adsorbed oxygen. In this case, a negative charge would be shared by an aluminium atom and an adsorbed oxygen molecule.

b) The chemical reaction of benzene with chemisorbed oxygen. Actually, perylene in liquid $SbCl_3$ is stoichiometrically oxidized to the radical ion on the addition of oxygen according to[10]

$$O_2 + 4C_{20}H_{12} + 6SbCl_3 \longrightarrow 4C_{20}H_{12}^{+} + 4SbCl_4^{-} + 2SbOCl$$

The following experiments were carried out. When sulfur dioxide, instead of oxygen, was introduced into the catalyst with preadsorbed benzene at room temperature, a large increase in ESR signal of benzene dimer cations and, at the same time, the signal due to SO_2^- were observed. The ESR signal of SO_2^- (g_{xx}= 2.0012, g_{yy}=2.0025, g_{zz}=2.0071) was observed even in the absence of preadsorbed benzene, the amount depending considerably on the adsorption temperature. The temperature dependence was similar to the dependence of amount of benzene dimer cations on the temperature of the oxygen pretreatment. The results indicate that the role of oxygen and sulfur dioxide on the formation of dimer cations is similar. Thus, the possibility of chemical reaction with adsorbed oxygen can be eliminated since sulfur dioxide as well as oxygen enhance the formation. The formation of benzene dimer cations and sulfur dioxide anions at the same time on the same catalyst strongly suggests the important role of the inductive effect on the electron transfer process on the mordenite.

It is demonstrated that the radical amount increases with the activation temperature of the zeolite, the presence of the adsorbed oxygen drastically enhancing the formation of the benzene dimer cations. It is concluded that the three-coordinated aluminium atoms are responsible for the dimer cation formation, the role of oxygen being to increase the electronegativity of aluminium atoms by its inductive effect.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3571—3573 (1973)

An Electron Spin Resonance Study of the Carbonization of Acenaphthylene

Yoshio YAMADA and Sadaharu TOYODA

National Research Institute for Pollution and Resources, Kawaguchi, Saitama 332

(Received March 10, 1973)

Many Electron Spin Resonance (ESR) studies have been made on charred materials.[1-3] Since most of these experiments were carried out on solid state, however, only one signal was observed, and consequently the intermediate radicals produced in the process of carbonization could not be identified by the signal. Recently, Singer and Lewis[4-6] investigated the carbonization of acenaphthylene, 9,9′-bifluorene, and so forth in *m*-quinquephenyl, which is a high-boiling and inert solvent. They reported in their first paper[4] that the signal due to the perinaphthenyl radical is observed at the early stage of the pyrolysis of acenaphthylene and suggested that the 4,6-dimethylperinaphthenyl radical also appears during the carbonization. However, their discussion was chiefly confined to the identification of these radicals. The present investigation, therefore, was undertaken in order to clarify the reaction mechanism of the pyrolysis of acenaphthylene at from 200 to 500 °C on the basis of the variation in the signal intensity for the radicals identified by Singer and Lewis.[4] In this connection, decacyclene in *m*-quinquephenyl was carbonized in the same manner as acenaphthylene.

Experimental

The acenaphthylene was purified by recrystallization from ethanol. The decacyclene and *m*-quinquephenyl were purchased from the Aldrich Chem. Co. Inc. and K & K Laboratories, Inc., respectively. Samples were prepared by adding acenaphthylene to *m*-quinquephenyl at a weight ratio of 1:10 and then by degassing them at room temperature. These samples were heated in a furnace for 5 min at 30 °C intervals in the range from 200 to 500 °C. All of the ESR spectra were measured at 150 °C because *m*-quinquephenyl begins to melt at 125 °C. The ESR apparatus was a Japan Electron Optics Laboratory JES-ME-3X-type spectrometer with a temperature-varying attachment.

Results and Discussion

When the temperature of acenaphthylene dissolved in *m*-quinquephenyl was raised to 290 °C, the well-

resolved ESR spectrum shown in Fig. 1(a) was observed. It consists of two hyperfine structures; one structure is due to six equivalent protons, with a coupling constant of 6.32 gauss, and the other to three equivalent protons, with a constant of 1.81 gauss. It agrees closely with the spectrum observed by Singer and Lewis.[4] Thus, the substance in the solution can be identified as the perinaphthenyl radical (V).[7] Further heat-treatment up to 440 °C brings about the formation of a new radical, as may be seen in Fig. 1(b). The spectral lines derived by subtracting the signal due to the (V) radical from the spectral lines of Fig. 1(b) correspond to the 4,6-dimethylperinaphthenyl radical (VI) assigned by Singer and Lewis.[4] Though the spectral intensity due to the (V) radical is weak at this temperature, it increased again when the sample was heated to 500 °C. In addition, the broad line of 5 gauss became more intense. The variation in the spectral intensity of the (V) and (VI) radicals is represented in Fig. 2 as a function of the heat-treatment temperature. Since *m*-quinquephenyl boils near 540 °C, the samples were not heated above 500 °C. When the temperature of the sample was maintained at 500 °C, the signal intensity for the (V) radical decreased. Hence, the spectral intensity is probably lowered above 500 °C.

Acenaphthylene is well known to polymerize with pyrolysis at *ca.* 200 °C and then to decompose near 350 °C, resulting in biacenaphthylidene (II) (or dinaphthylenebutadiene), decacyclene (IV), and fluorocyclene (III).[8] Mueller[8] studied the acenaphthylene pyrolysis by thin-film chromatography and found that biacenaphthylidene (II) and fluorocyclene (III) disappear above 350 °C, while decacyclene (IV) is stable at 450 °C. On the basis of these facts, the increase in the radical concentrations of (V) and (VI) up to 350 °C may be explained in terms of the pyrolysis of biacenaphthylidene (II) and fluorocyclene (III). When the sample was heated at higher temperatures, the signal due to the (VI) radical remained almost constant, while that due to the (V) radical gradually decreased. Such a difference may be interpreted as follows: the (V) radical generally exists in equilibrium with its diamagnetic dimer.[9] Accordingly, a decrease in the amount of the (V) radical seems to be responsible for the dimerization. On the contrary, because of the steric hindrance, the (VI) radical is less mobile and less subject to dimerization than the (V) radical. Therefore, the (VI) radical may be thought to be present even at higher temperatures.

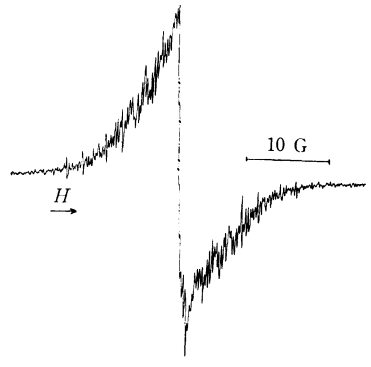

Fig. 3. ESR spectrum of decacyclene in *m*-quinquephenyl heat-treated up to 500 °C.

8) K. Mueller, Ph. D. Thesis, Karlsruke University, W. Germany, 1967.

9) F. Gerson, *Helv. Chim. Acta*, **49**, 1463 (1966).

When decacyclene (IV) dissolved in *m*-quinquephenyl was heated, the faint signals due to the (V) and (VI) radicals began to appear at from 440 to 470 °C. However, the signals were significantly weaker than those obtained from carbonized acenaphthylene and were superposed by a spectral line, the linewidth of which was *ca.* 2.5 gauss (Fig. 3). Therefore, it seems unreasonable to regard the increase in the radical concentration of (V) at from 440 to 500 °C as caused by decacyclene (IV) alone. According to the results of Madison and Roberts,[10] the liquid-phase pyrolysis of an alkyl-substituted aromatic compound leads to a cleavage of the alkyl group at *ca.* 470 °C. In this case, it is clear that the (VI) radical decomposes to produce the (V) radical and methane. With this view, the high value of concentration for the (V) radical at 500 °C may be concluded to be due not only to decacyclene (IV), but also to the (VI) radical. Figure 4 shows a reaction scheme for acenaphthylene proposed on the basis of the results mentioned above. However, the formation of zethrene described by Ruland[11] should also be taken into account in the pyrolysis of acenaphthylene, although it cannot be detected by the ESR technique.

Deformation of the Molecular Orientation of Nematic Liquid Crystals with Homeotropic Alignment in Electric Field

Sakumitsu SAKAGAMI, Akira TAKASE, and Minoru NAKAMIZO
National Industrial Research Institute of Kyushu, Tosu, Saga 841

(Received March 22, 1973)

It is well-known that the thin layer of nematic liquid crystals (NLC) with negative dielectric anisotropy shows the so-called Williams domain pattern at the threshold of an applied electric field, and gives dynamic scattering of light at a higher voltage, while NLC with positive dielectric anisotropy exhibit no such scattering.[1-8] Most measurements on electrically induced hydrodynamic instabilities have been carried out with a molecular orientation in which the long molecular axes of NLC are made to lie parallel to the glass surface, *i.e.*, perpendicular to the direction of an applied electric field.

In this paper we report on the behavior of NLC with homeotropic alignment[9] in the presence of an external DC electric field.

Experimental

Materials. 4-Methoxybenzylidene-4-*n*-butylaniline (MBBA, nematic range 21—41 °C) and 4-(4-*n*-butoxybenzylideneamino)benzonitrile (BBABN, nematic range 63—106 °C). MBBA[10] has a negative dielectric anisotropy ($\varepsilon_{//}-\varepsilon_{\perp}<0$) and BBABN a positive dielectric anisotropy ($\varepsilon_{//}-\varepsilon_{\perp}>0$).[11] The liquid crystal was sandwiched between two transparent tin-oxide-coated glass plates separated by a Mylar spacer about 20 μm thick. Homeotropic alignment of MBBA was achieved by coating a dilute aqueous solution of sodium dodecyl sulfate on the electrode surfaces. Uniform homeotropic alignment was attained by standing the solution for several hours. In the case of BBABN the electrode surfaces were coated with lecithin.[12] Domain patterns were observed under an ordinary polarizing microscope. A sensitive color plate ($R=530$ mμ) was used as the test plate to determine the retardation.

The measurement on light scattering was carried out by use of a He–Ne laser beam polarized through a polarizer and incident normally upon the sample cell. The scattered light from the NLC was passed through an analyzing polaroid and allowed to fall on a photographic film.

The experiments were carried out for MBBA at room temperature and for BBABN at 70—90 °C on the heater regulated.

Results and Discussion

When no electric field is applied, the nematic cell extinguishes the light transmission between crossed polarizers, corresponding to the homeotropic orientation. With the increase in electric field, circular domain patterns are observed at the threshold of the electric field between crossed polarizers (Fig. 1). Both MBBA and BBABN give circular domain patterns, the size of the domain for MBBA being dependent on the state of the electrodes. Each domain shows extinction, cross and quadrants, colored by interference. The first and third quadrants are blue, the second and fourth yellow. These results indicate that the direc-

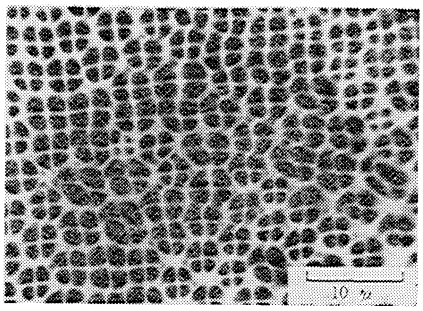

Fig. 1. Photomicrograph of circular domain patterns in MBBA at 2.6 V rms.

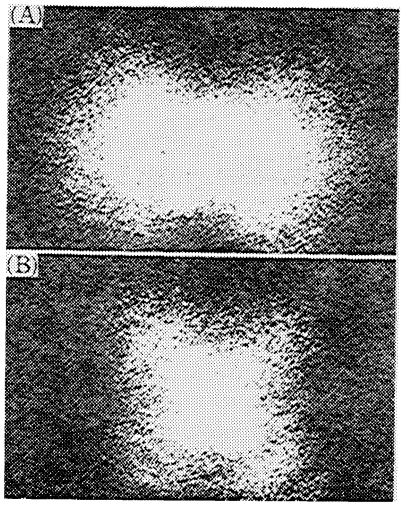

Fig. 2. Light scattering patterns for BBABN at 2.8 V rms with (A) parallel and (B) crossed polarization.

tions of the dipole moments of nematic molecules in the circular domain are arranged as a whole to radiate from the center of the domain.

Figure 2 shows typical light scattering patterns observed slightly above the threshold. The scattering pattern in crossed polars has a four-leaf clover shape which has its maximum intensity at 45 ° to the polarization direction. On the other hand, the pattern in parallel polars is of comparable intensity and has a cocoon-like shape elongated to the polarization direction. The light scattering patterns are associated with the formation of the circular domains, and are similar to those observed in spherulite.[13]

Heilmeier reported a similar circular domain pattern to that mentioned above using butyl *p*-(anisylideneamino)cinnamate and suggested that its formation can be ascribed to positive dielectric anisotropy of the nematic molecule.[14] However, the circular domain, as shown above, can be observed in both MBBA and BBABN, independent of the directional relation between the dipole moment and long molecular axis. Thus, we infer that the appearance of the circular domain is due to the homeotropic alignment subjected to the electric field, irrespective of positive or negative dielectric anisotropy of the nematic molecule. It is suggested from both the microscopic circular domain and light scattering pattern that the applied electric field causes an ellipsoidal molecular deformation (Fig. 3).

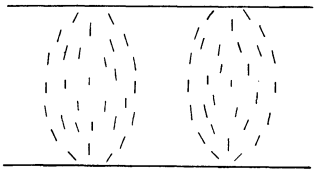

Fig. 3. Schematic representation of molecular orientation corresponding to the circular domains. Solid lines indicate the long molecular axes of nematic molecules.

As voltage is further increased, the circular domain is broken and a turbulent flow takes place. MBBA exhibits dynamic scattering of light, but not BBABN.

Temperature Dependence of Association of Methanol, Ethanol, and 1-Propanol

Yoshiro SAKAI, Yoshihiko SADAOKA, and Tsuguo YAMAMOTO

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Bunkyo-cho, Matsuyama, Ehime 790

(Received March 29, 1973)

Arnold and Packard[1] reported that the signal from the hydroxylic proton in the NMR spectra of methanol and ethanol moves towards high fields with temperature rise, but not those of CH_2 and CH_3 groups. The effect of temperature on the shifts of OH signals has been accounted for by the rupture of the hydrogen bonds. In the present paper, the variation of the relative concentrations of the monomer and the *n*-mer (linear or cyclic) with temperature calculated from the chemical shifts of OH protons are discussed.

Results and Discussion

In order to determine the state of association of alcohols, the method of Saunders and Hyne[2] was applied. The following equilibrium is assumed between monomer and a single species of *n*-mer:

$$n(\text{R-OH}) \rightleftarrows (\text{R-OH})_n$$

$$K_n = M_n/(nM_1^n). \quad (1)$$

The equilibrium constant K_n is given by means of Eq. (1) where M_1 and M_n are the molar concentrations of monomer and *n*-mer, respectively, in terms of monomer unit. The observed resonance frequency is given by

$$\delta_{\text{obsd}} = (\delta_1 M_1 + \delta_n M_n)/C \quad (2)$$

where δ_1 and δ_n represent characteristic shifts of a proton in monomer and *n*-mer, respectively. C is the total concentration of alcohol in mol/l. In order to determine δ_1, the variation of the shift of OH protons in dilute solution in cyclohexane characterized by a small effect on the shift of OH protons, was measured at relatively high temperatures near the boiling point of either alcohol or cyclohexane at concentrations 10^{-2}—10^{-4} (mol/l), where the shifts varied little with concentration. The value of δ_1 was obtained by extrapolation to infinite dilution. Since it was reported by Luck and Ditter[3] that there are few monomers in pure methanol and ethanol below about −80 °C, the shift of OH proton in pure alcohols just above the melting point was taken to be δ_n. The values of δ_1 and δ_n are given in Table 1 together with temperatures of measurements. The values of M_1 and M_n at various temperatures were calculated by substituting the shifts δ_1 and δ_n into Eq. (2). The logarithms of M_1 and M_n thus obtained from Eq. (2) were plotted against the reciprocal of the absolute temperature in Figs. 1 and 2.

Table 1. Chemical shift of monomer and *n*-mer

Alcohol	δ_1[a] / Hz	δ_n / Hz
Methanol	205 (+30 °C)	592 (−90 °C)
Ethanol	185 (+60 °C)	639 (−100 °C)
1-Propanol	199 (+70 °C)	640 (−90 °C)

a) Solvent: cyclohexane

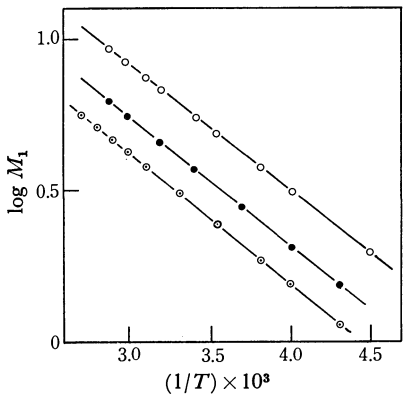

Fig. 1. Plot of logarithm of M_1 against reciprocal of absolute temperature.
○: methanol, ●: ethanol, ⊙: 1-propanol

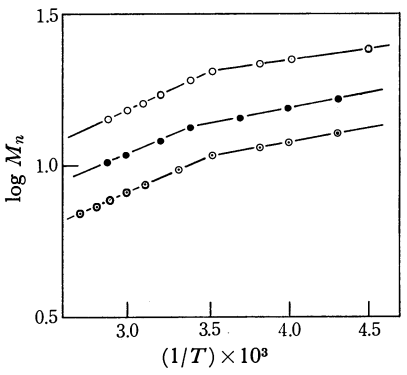

Fig. 2. Plot of logarithm of M_n against reciprocal of absolute temperature.
○: methanol, ●: ethanol, ⊙: 1-propanol

The plot of $\log(M_1)$ against $1/T$ gives a straight line for the three different alcohols, an inflection point appearing at about +30 °C for the plot of $\log(M_n)$ against $1/T$. According to the integrated van't Hoff equation

$$\ln(K_n) = -\Delta H/RT + D \quad (3)$$

where D is constant, it is expected that the plot of $\log(K_n)$ against $1/T$ will give a line which has an inflection point around +30 °C. By conbining Eq. (1) with Eq. (3), we have

1) J. T. Arnold and M. E. Packard, *J. Chem. Phys.*, **19**, 1609 (1951).
2) M. Saunders and J. B. Hyne, *ibid.*, **29**, 253, 1319 (1958), *ibid.*, **31**, 270 (1959).
3) W. A. P. Luck and W. Ditter, *Ber. Bunsenges. Phys. Chem.*, **72**, 365 (1968).

$$\ln (M_n) = -\Delta H/RT + D + \ln (n) + n \ln (M_1) \quad (4)$$

On the other hand, Fig. 1 gives the following empirical formula for the variation of the monomer concentration with temperature:

$$\ln (M_1) = A/T + B \quad (5)$$

where A and B are the constants characteristic of each alcohol. By substituting Eq. (4) into Eq. (5), we obtain

$$\ln (M_n) = (-\Delta H/R + nA)/T + nB + D + \ln (n) \quad (6)$$

The slope of the line for the plot of $\log(M_n)$ against $1/T$ in Fig. 2 corresponds to $(-\Delta H/R+nA)$ in Eq. (6). This indicates that the inflection at about +30 °C results from the change in $-\Delta H$ or/and n. For several values of n, we have calculated the values of $-\Delta H$ in high and low temperature ranges for each alcohol. The results are given in Table 2. Dividing the values of $-\Delta H$ by n (for cyclic form) and $n-1$ (for linear form), we obtained $-\Delta H$ per hydrogen bond for both cyclic and linear forms (Table 3). It is expected that $-\Delta H$ per hydrogen bond does not vary much with the form of aggregate. For the change of $-\Delta H$ at +30 °C, two possibilities can be considered from the results of Table 3; the increase of the size (n) of aggregates in linear state, and the change of the form from linear to a cyclic one with smaller value of n with increasing temperature. Thermodynamically the increase in the degree of association with temperature rise can not be considered. It could be concluded that the linear form is converted into the cyclic form of lower degree of association with a rise in temperature.

Table 2. $-nA$ and $-\Delta H$ for various values of n

Experimental

Methanol and ethanol of reagent grade were refluxed for 24 hr over calcium oxide and then fractionally distilled. It was then dried over calcium, and fractionally redistilled twice under nitrogen atmosphere. Similar procedures were applied to the purification of 1-propanol, except that sodium was used instead of calcium. Cyclohexane of reagent grade was dried over sodium and then fractionally distilled twice. From the results of the specific conductivity measurements of the alcohols and cyclohexane at +25 °C (methanol, 1.0×10^{-8} ohm^{-1}·cm^{-1}, ethanol, 1.5×10^{-9} ohm^{-1}·cm^{-1}, 1-propanol, 2.0×10^{-10} ohm^{-1}·cm^{-1}, cyclohexane, 1.0×10^{-14} ohm^{-1}·cm^{-1}), it was confirmed that the reagents were highly dried. For NMR measurements, the purified alcohols were sealed in NMR sample tubes. NMR measurements were carried out in a temperature range of from just above melting point to near boiling point of each alcohol, on an JNM-4H-100 NMR spectrometer (Japan Electron Optics Co.) operating at a frequency of 100 MHz. Tetramethylsilane was employed as an internal standard. No temperature dependence of the CH_2 and CH_3 proton signals was observed. Experimental errors were within ±0.5 Hz and ±0.5 °C.

An Application of the 0s-Function to Molecular Systems of H_2^+ and H_2

Shingo ISHIMARU, Kazuyoshi TANAKA, and Tokio YAMABE

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received April 17, 1973)

Recently, several authors[1-8] have pointed out the usefulness of 0s- and other so-called Hulthén functions for atoms. The Hulthén function often gives a better approximation to the Hartree-Fock wavefunction than the conventional Slater-type function. This has been shown not only by the numerical results, but also by analytical approaches.[9-13] Among these investigations, the work by McWeeny[10] is particularly instructive, because his results suggest the applicability of the 0s-function to molecular systems. However, as far as we know, there has been no numerical application of the 0s-function to molecular systems. Furthermore, since the 0s-function is the lowest eigenfunction of an s-electron in a kind of screened Coulomb potential (Hulthén potential) which has Jacobi polynomials as its eigenfunctions,[14] it seems that it would be interesting to investigate the usefulness of 0s- or other subsequent functions for molecular systems:

$$V_{\mathrm{Hu}}(r) = -[(\beta^2-\alpha^2)/2]e^{-(\beta-\alpha)r}/(1-e^{-(\beta-\alpha)r}), \quad (1)$$

$$\left.\begin{aligned}\psi_1(r) = 0s_{\alpha\beta}(r) &= N(e^{-\alpha r}-e^{-\beta r})/r,\\ N^2 &= \alpha\beta(\alpha+\beta)/2\pi(\alpha-\beta)^2 \quad (\alpha<\beta)\end{aligned}\right\} \quad (2)$$

$$E_1 = -\alpha^2/2. \quad (3)$$

We calculate here the energies of the hydrogen molecule ion and the hydrogen molecule variationally, using the 0s-function.

TABLE 1. THE ENERGY OF HYDROGEN MOLECULE ION (in a.u.)

R	1s+1s[a] ($\zeta=1.0$)	1s+1s[a] ($\zeta=1.228$)	0s+0s	Hylleraas[a]
1.0			−0.441004	−0.45230
2.0	−0.565050	−0.582691	−0.586380	−0.60263
3.0			−0.564483	−0.57755
4.0			−0.537356	−0.54608
5.0			−0.519217	−0.52442

a) Ref. 15, p. 336.

TABLE 2. THE VALUES OF THE PARAMETERS, α AND β, AT EACH R

R (a.u.)	1.0	2.0	3.0	4.0	5.0
α	1.453	1.162	1.079	1.016	0.992
β	1.643	1.351	1.112	1.041	1.012

a) As a matter of course, α and β which give the optimal energy are not equal (though not so different) to the values used by McWeeny (Ref. 10), namely 1.228 and 1.485, respectively.

In Table 1, the energies of the hydrogen molecule ion at several R values (the internuclear distances) are listed alone with other results, while Table 2 shows the values of the parameters, α and β, at each R. The present calculation gives energies improved by the amounts of 0.021 and 0.004 in a.u. at the equilibrium internuclear distance of 2.0 a.u. when compared with those of the 1s-function with the exponents (ζ) of 1.0 and 1.228 respectively. The behavior of α and β shows that, when the internuclear distance increases, the 0s-function approaches the 1s-function.

TABLE 3. THE ENERGY OF HYDROGEN MOLECULE AT THE EQUILIBRIUM DISTANCE R (in a.u.)

	VB(1s)[a] ($\zeta=1.0$)	VB(1s)[b] ($\zeta=1.166$)	VB(0s) ($\alpha=1.13$, $\beta=1.20$)	Exact[c]

R	1.4	1.406	1.416	1.400

a) Ref. 15, p. 349.
b) The energy value was recalculated in our laboratory.
c) Ref. 16.

In Table 3, the results for the hydrogen molecule obtained by the use of the valence bond method are listed. In the calculation, the exchange integral $\langle 0s_{\alpha\beta}(r_{a1})0s_{\alpha\beta}(r_{b2})|1/r_{12}|0s_{\alpha\beta}(r_{a2})0s_{\alpha\beta}(r_{b1})\rangle$, was easily obtained by the use of the formula given by Kotani *et al.*,[17] but a part of the Coulomb integral, $\langle 0s_{\alpha\beta}(r_{a1})0s_{\alpha\beta}(r_{b2})|1/r_{12}|0s_{\alpha\beta}(r_{a1})0s_{\alpha\beta}(r_{b2})\rangle$, was not so easily obtained (r_{a1} is the distance between the nucleus, a, and the electron, 1, and so forth). Therefore, after some modification, we expanded the part in the form of an infinite series and got a value with the required accuracy. The error of the energy given by the 0s-function is 2.05% smaller than that of the 1s-function with an exponent of 1.0, and the improvement over

the Wang's result is small but definite.

In comparing the two cases where a proton or a hydrogen approaches a hydrogen atom, it is clear that the perturbation in the former should be greater than in the latter.[18] Therefore, the deviation from the 1s-function should be more significant in the hydrogen molecule ion; this is reflected in the difference between α and β and in the improvement of the energies in the two cases.

Thus, taking the examples of the hydrogen molecule ion and the hydrogen molecule, we have numerically shown that the 0s-function is more effective not only in the atomic system, but also in the molecular one, than the conventional 1s-function. Of course, further improvement in the energy could be achieved by using wavefunctions with angular dependencies.

We wish to thank to Professor Kenichi Fukui for his helpful discussions.

18) α and β for the hydrogen molecule ion in the treatment by McWeeny (Ref. 10) correspond to the momenta of an electron in the hydrogen isolated and that perturbed by a proton, respectively.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3578—3580 (1973)

Anomalous Magnetic Properties of Crystalline Galvinoxyl Radical. IV. Effect of the Deuterium Substituent

Kazuo MUKAI, Manami IIZUKA, and Kazuhiko ISHIZU
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790

(Received April 24, 1973)

The stable organic galvinoxyl radical is known to undergo a first-order phase transition induced magnetically at 82 K, accompanied by pairing of magnetic spins, as is recognized from the results of magnetic susceptibility[1,2] and heat capacity[3] measurements. The Galvinoxyl radical is paramagnetic above the magnetic transition point, 82 K, where the susceptibility drops very sharply on cooling, and shows a weak paramagnetism below this point, with positive Weiss constants in both regions above and below the transition temperature. The entropy change at the transition point, which corresponds to R ln 9.45, cannot be explained by taking only the magnetic contribution. On the other hand, the phenol derivative, the corresponding diamagnetic substance, has no thermal anomaly in the temperature region 12—300 K.

It has been reported[4-7] that deuterium substitution causes two effects on the ESR spectrum of native undeuterated radicals. First, the proton splittings at the undeuterated positions are altered, and second, the ratio of the deuteron to the proton splitting differs from the ratio $(a^D/a^H)=0.1535$ calculated on the basis of the magnetic moments and spins of the two nuclei. Both isotope effects should result from the difference in mass of the proton and deuteron, and this difference can be manifested only through the molecular vibrations. The above results were successfully analyzed[6,8] in terms of a model for the effect of the difference in the CH and CD out-of-plane bending motion. This vibration can affect the sigma-pi coupling, the pi-electron spin-density distribution, or both.

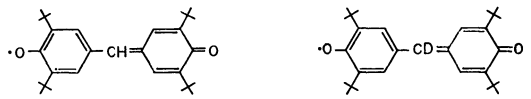

Fig. 1. Structures of galvinoxyl and D-galvinoxyl radicals.

We have synthesized the deuterium derivative (D-galvinoxyl, see Fig. 1) of the galvinoxyl radical, and studied its magnetic properties in order to see the effect of deuterium substitution on the anomalous magnetic property of galvinoxyl by ESR and magnetic susceptibility measurements.

Experimental

Materials. D-Galvinoxyl was synthesized following the method of Kharasch and Joshi[9] or Coppinger.[10] After condensation of 2,6-di-*t*-butylphenol with dideuteroformaldehyde (Merck, deuterierungsgrad 99%), the deuterized bisphenol, 3,3′,5,5′-tetra-*t*-butyl-4,4′-dihydroxydiphenyldideuteromethane, was synthesized, and it was recrystallized from ethanol. Mp 157.0—157.7 °C. The ultraviolet absorption spectrum in ethanol with $\lambda_{max}=278$ mμ (ε 3990) and proton NMR spectrum with $\tau_{C(CH_3)_3}=1.42$ ppm, $\tau_{OH}=4.87$ ppm, and $\tau_{m-H}=6.85$ ppm are in good agreement with those of the corresponding bisphenol, except for the disappearance of the proton NMR absorption due to center methylene

protons of the undeuterized bisphenol ($\tau_{CH_3}=3.75$ ppm). The D-galvinoxyl radical was prepared by the oxidation of the bisphenol with lead peroxide in ether under nitrogen atmosphere. Mp 154—159 °C. The absorption spectrum in ethanol with $\lambda_{max}=424$ mμ (ε 175000) of the D-galvinoxyl is also in good agreement with that of the galvinoxyl.

Apparatus. Magnetic susceptibility measurements were carried out in the continuous temperature range 59—290 K, using a Shimadzu MB-2 type magnetic torsion balance field up to 10 kOe. The ESR measurements were carried out using a JES-ME-3X spectrometer equipped with Takeda-Riken microwave frequency counter. ESR hyperfine splittings and g values were measured relative to those of $(KSO_3)_2$-NO ($a^N=13.05\pm0.03$ G; $g=2.0054$[11]).

Results and Discussion

The ESR spectra of galvinoxyl and D-galvinoxyl in THF at room temperature are shown in Figs. 2-(a) and -(b), respectively. The observed hyperfine splitting constants and g values of galvinoxyl[12] and D-galvinoxyl are listed in Table 1. The g value of D-galvinoxyl, $2.0052_1\pm0.0000_2$, is in agreement with that of Galvinoxyl, $2.0051_8\pm0.0000_2$. The hyperfine splitting (a_m^H) due to the *meta* ring hydrogen atoms of D-galvinoxyl is also the same as that of galvinoxyl, within experimental error. In contrast, the ratio 0.149 ± 0.002 of the deuteron to the proton splittings at center methylene position differs from the theoretical ratio $(a^D/a^H)=0.1535$ expected on the basis of the magnetic moments and spins of the two nuclei. The result can be explained as due to the difference in the CH and CD out-of-plane bending motion in these radicals.[6]

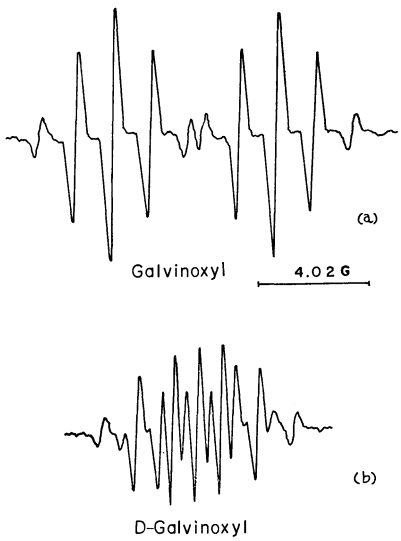

Fig. 2. ESR spectra of (a) galvinoxyl and (b) D-galvinoxyl radicals in THF at room temperature.

Table 1. Hyperfine splittings and g values of galvinoxyl and D-galvinoxyl radicals

	a_m^H	$a_{CH(CD)}^{H(D)}$	g value
Galvinoxyl	1.38±0.02G	5.94±0.02G	$2.0051_8\pm0.0000_2$
D-Galvinoxyl	1.38±0.02G	0.89±0.02G	$2.0052_1\pm0.0000_2$

The measured molar paramagnetic susceptibility, χ_P, as shown in Fig. 3 as a function of the temperature, has been corrected for the diamagnetic contribution of $\chi_{dia}=-0.276\times10^{-3}$ emu/mol calculated by Pascal's method. Between 84 and 290 K, χ_P follows the Curie-Weiss law, with a Weiss constant of $\theta=+6\pm3$ K and a spin concentration of $102\pm3\%$. At 84 K χ_P rapidly decreases by about 70 percent of its maximum value within about ten degrees, and afterward falls gradually to 68 K and again increases to 59 K.

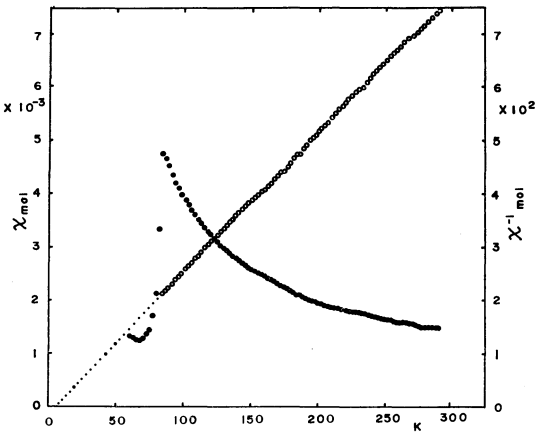

Fig. 3. (●) Molar and (○) inverse molar susceptibilities of the D-galvinoxyl radical *versus* temperature (59—290 K).

Since the anomaly in galvinoxyl is known to result from a transition accompanied by a pairing of the magnetic spins at around the position of the -CH= group as reported before, we can expect that the difference in the CH and CD out-of-plane bending motion in galvinoxyl and D-galvinoxyl, as observed in ESR measurement of the ratio (a^D/a^H), may induce some change in the anomaly in the magnetic susceptibility of galvinoxyl. However, the magnetic behavior is the same as that of galvinoxyl within experimental error, in contrast to our expectation. The result, together with the agreement of position and intensity of absorption maxima in optical spectra and of hyperfine splitting at undeuterated positions, indicates that the perturbation on the structure of galvinoxyl radical by deuterium substitution is too small to induce a change in the anomaly in magnetic susceptibility.

Paramagnetic susceptibility measurements of most crystalline aromatic free radicals usually give negative Weiss constants, showing that the spins on adjacent free radicals in the crystal lattice antiferromagnetically couple with each other. As far as we are aware, the positive Weiss constant observed with both galvinoxyl and D-galvinoxyl radicals is the first example of a positive Weiss constant in solid organic free radicals. McConnell[13] pointed out the possibility of a ferromagnetic exchange interaction favoring parallel (total) spin angular momentum on neighboring molecules in

certain aromatic and olefinic free radicals (especially odd-alternant radicals) in which there are large positive and negative atomic π-spin densities. The unpaired electron distribution on galvinoxyl really corresponds to this case as calculated[14] by the conventional valence-bond method. In addition, the result of X-ray analysis[15] of galvinoxyl shows that galvinoxyl may stack in the crystal lattice so that the atoms of positive spin density are exchange-coupled most strongly to the atoms of negative spin-density in neighboring molecules. This gives a ferromagnetic exchange interaction, that is, positive Weiss constant in both radicals.

Effective Ionic Charges of Lithium Niobate Crystal Obtained from the TO-LO Splittings of Infrared Active Lattice Vibrations

Jiro HIRAISHI

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received May 4, 1973)

In ionic crystals, the frequency splittings of the transverse (TO) and the longitudinal (LO) modes are observed for the infrared active vibrations due to long range electrostatic interaction. The values of effective ionic charges of cubic crystals such as sodium chloride, caesium chloride or zinc blende type have been obtained by using the TO–LO splittings.[1] In a previous paper[2] a simple equation useful for obtaining the effective ionic charges of cubic and non-cubic crystals was derived and applied to wurtzite and rutile type crystals. In the present paper the equation is applied to the $LiNbO_3$ crystal.

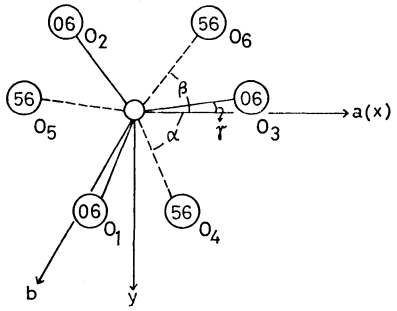

Fig. 1. Atoms in the Bravais lattice of $LiNbO_3$. The larger circles represent the oxygen atoms and the smaller circles the niobium and lithium atoms. The niobium atoms occupy the positions (0, 0, 0) and (0, 0, 1/2), and the lithium atoms the positions (0, 0, 0.2829) and (0, 0, 0.7829). The hexagonal axes are shown in the figure. The numbers in the circles represent the height along c axis.

The space group of the $LiNbO_3$ crystal at room temperature is R3c–C_{3v}^6, two formula units being in a unit cell.[3] The structure is shown in Fig. 1. By factor group analysis the lattice vibrations are classified into $5a_1+5a_2+10e$. Acoustic modes belong to the a_1 and e species. The vibrations of a_1 and e are active in both infrared and Raman spectra. The infrared reflection and polarized Raman spectra for the crystal were measured and assignments of the transverse and longitudinal modes of a_1 and e were made by several investigators.[4-8] In the present paper the assignments by Claus *et al.*[8] are used in the calculation of the values of the effective ionic charges.

The effective ionic charges Z_{Li}, Z_{Nb}, and Z_O are connected to the TO–LO splittings by the equation

$$\sum_i \omega_i^2(\mathrm{L}) - \sum_i \omega_i^2(\mathrm{T}) = 8\pi(Z_{Nb}^2/m_{Nb} + Z_{Li}^2/m_{Li} + 3Z_O^2/m_O)e^2/v_a \quad (1)$$

where $\omega(\mathrm{L})$ and $\omega(\mathrm{T})$ represent the frequencies of the longitudinal and transverse modes, respectively. The summation is carried out for all vibrations of either the a_1 or e species. Equation (1) was derived according to the procedure described previously.[2] The Cartesian symmetry coordinates are given in Table 1. It is noteworthy that $\sum_i \omega_i^2(\mathrm{L}) - \sum_i \omega_i^2(\mathrm{T})$ for the wurtzite, rutile and $LiNbO_3$ type crystal structures is given by

$$\sum_i \omega_i^2(\mathrm{L}) - \sum_i \omega_i^2(\mathrm{T}) = (4\pi e^2/v_a) z_a \sum_k n_k Z_k^2/m_k \quad (2)$$

where z_a and v_a represent the number of the formula unit in the unit cell and the volume of the unit cell, respectively, Z_k and m_k the effective ionic charge and the mass of particle k, respectively, and n_k is the number of particle k in the formula unit. Since the crystal should be electrically neutral, we have

$$Z_{Li} + Z_{Nb} + 3Z_O = 0 \quad (3)$$

However, the values of Z_{Li}, Z_{Nb}, and Z_O can not be definitely determined from Eqs. (1) and (3), and a third equation is introduced by taking into account the spontaneous polarization of the crystal. Spontaneous polarization P_S can be calculated by

$s_5 = [2z(O_1)-z(O_2)-z(O_3)-2z(O_4)+z(O_5)+z(O_6)]/2\sqrt{3}$

$s_6 = [z(O_2)-z(O_3)+z(O_5)-z(O_6)]/2$

$s_7 = [2ac\cdot x(O_1)-2as\cdot y(O_1)-bc\cdot x(O_2)-bs\cdot y(O_2)+cc\cdot x(O_3)-cs\cdot y(O_3)+2ac\cdot x(O_4)+2as\cdot y(O_4)-bc\cdot x(O_6)+bs\cdot y(O_6)+cc\cdot x(O_5)+cs\cdot y(O_5)]/2\sqrt{3}$

$s_8 = [cc\cdot x(O_3)-cs\cdot y(O_3)+bc\cdot x(O_2)+bs\cdot y(O_2)+cc\cdot x(O_5)+cs\cdot y(O_5)+bc\cdot x(O_6)-bs\cdot y(O_6)]/2$

$s_9 = [bs\cdot x(O_2)-bc\cdot y(O_2)-cs\cdot x(O_3)-cc\cdot y(O_3)+bs\cdot x(O_6)+bc\cdot y(O_6)-cs\cdot x(O_5)+cc\cdot y(O_5)]/2$

$s_{10} = [2as\cdot x(O_1)+2ac\cdot y(O_1)+bs\cdot x(O_2)-bc\cdot y(O_2)+cs\cdot x(O_3)+cc\cdot y(O_3)+2as\cdot x(O_4)-2ac\cdot y(O_4)+cs\cdot x(O_5)-cc\cdot y(O_5)+bs\cdot x(O_6)+bc\cdot y(O_6)]/2\sqrt{3}$

a) $as=\sin\alpha$, $ac=\cos\alpha$, $bs=\sin\beta$, $bc=\cos\beta$, $cs=\sin\gamma$ and $cc=\cos\gamma$. α, β, and γ are shown in Fig. 1. The coordinates of a_2 species and those of y-components of e species are not given in this table.

$$P_s = \iiint_{\substack{\text{whole}\\ \text{crystal}}} \rho(\boldsymbol{r})\boldsymbol{r}\,dv/V = \iiint_{\substack{\text{unit}\\ \text{cell}}} \rho(\boldsymbol{r})\boldsymbol{r}\,dv/v_a \qquad (4)$$

where $\rho(\boldsymbol{r})$ represents the charge density at $\boldsymbol{r}$ in the crystal and V the volume of the crystal. On the basis of the point charge model, P_S for $LiNbO_3$ is written as

$$P_s = \{Z_{Li}(1/2+2x_{Li})c_0 + Z_{Nb}c_0/2 + Z_O(3/2+6x_O)c_0\}e/v_a \qquad (5)$$

where c_O, x_{Li}, and x_O are 13.8631, 0.2829 and 0.0647 Å, respectively. The values of Z can be obtained by using the three Eqs. (1), (3), and (5).

Although spontaneous polarization is temperature dependent, that of $LiNbO_3$ can be reasonably assumed to be temperature independent near room temperature, since the ferroelectric phase transition temperature is 1210 °C,[9] which is very much higher than room temperature. In the present calculation the value of P_S 0.71 C/m² measured by Camlibel[10] at room temperature was used. The assignments by Claus *et al.*[8] for the TO and LO frequencies slightly differ from those by Kaminow and Johnston.[6] The values from the two assignments do not differ so much since the effective ionic charges depend on the difference of TO and LO frequencies as shown in Eq. (1).

As Eq. (1) is the second order with respect to Z and the sign of spontaneous polarization has not been determined, four sets of solutions were obtained as shown in Table 2. The solution of set 1 is most reasonable since abnormal signs of Z in set 2 and set 3 are given and the value of Z_{Li} is greater than +1.0 in set 4. These values were obtained on the basis of the TO–LO splittings of the a_1 species. The values determined from the splittings of the e species, which are close to those obtained from the a_1 species, are also given in Table 2. The results indicate that the spontaneous polarization of $LiNbO_3$ defined by Eq. (5) is −0.71 C/m². The value (0.347) of Z_{Li} in set 1 suggests the covalent character of Li–O bonds.

Table 2. The values of effective ionic charges and experimental values used in the calculation

(1) The frequencies of TO and LO modes[8] (in cm^{-1})

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3582—3583 (1973)

Anodic Oxidation of *N,N*-Dimethyl-*p*-phenylenediamine with Sodium Sulfite

Tatsuo ERABI, Fumihiro ARIFUKU, and Masaya TANAKA

Department of Industrial Chemistry, Faculty of Engineering, Tottori University, Koyamacho, Tottori 680

(Received May 24, 1973)

The sulfonation reaction occurs in the anodic oxidation of *N*-methyl-substituted-*p*-phenylenediamine, in the presence of sodium sulfite,[1-3] and the electrode reaction proceeds through the so-called ECE mechanism: that is the electro-oxidation of *N*-methyl-substituted-*p*-phenylenediamine, followed by a chemical sulfonation reaction with sodium sulfite and furthermore with a successive electro-oxidation of the sulfonated compound. However, the reaction intermediate with sodium sulfite has still not completely been revealed. The present paper aims to clarify the reaction intermediate, and to examine whether any regularity is found in these sulfonation mechanisms or not.

Apparatus for voltammetry have been described previously.[3]

When *N,N*-dimethyl-*p*-phenylenediamine (DMPPD) was oxidized anodically, two successive waves were observed in the region between pH 3.75 and 6.50, and only one wave was observed in its upper and lower regions. In addition, when the comparison of the wave height of DMPPD oxidation to the one of *p*-phenylenediamine (PPD) oxidation was attempted using the rotating electrode, the first wave height for DMPPD oxidation in the region between pH 3.75 and 6.50 was equal half to the wave height for PPD oxidation, and therefore the number of electron transfer involved in the reaction for the first wave was estimated to be 1. In its upper and lower regions, the wave height of DMPPD was equal to that of PPD, and therefore the number of electron transfer was estimated to be 2. However, it has been known that DMPPD forms the stable cation radical (so-called Wurster's red) in the measured pH region.[4] Moreover, from the analysis of the products by the controlled-potential electrolysis at the half-wave potential at pH 2.70, it was observed that DMPPD cation radical produced partly. Therefore, it seems probable that two successive one-electron transfers actually occurred in these pH regions. Furthermore, when the Tafel plots were tried for the polarograms obtained with the rotating electrode, α n values were estimated to be about 0.5. Hence, α was equal to 0.5 since the number of electron transfer for the initial reaction was estimated to be 1, and therefore the initial reaction is an oxidation of DMPPD with reversible one-electron transfer.

The anodic oxidation of DMPPD with sodium sulfite was carried out at pH 2.70, 4.00, 6.00, 8.00, and 10.00. As the typical examples, the anodic polarograms at pH 2.70 and 6.00 were shown in Figs. 1 and 2, and the relationships of half-wave potentials and peak currents to concentration of sodium sulfite based on the polarograms in Figs. 1 and 2 were illustrated in Figs. 3 and 4.

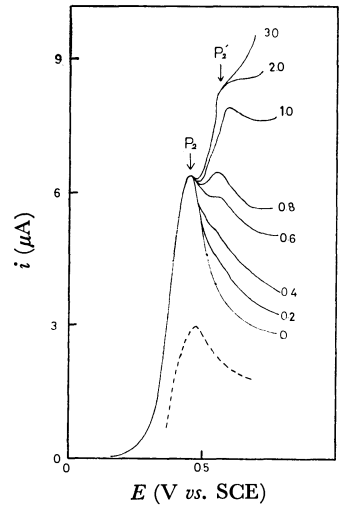

Fig. 1. Typical polarograms of DMPPD oxidation at pH 2.70. Numbers in the figure represent the mole ratio of Na_2SO_3 to DMPPD. The dotted line shows oxidation wave of DMPPD monosulfonate.[5,6]

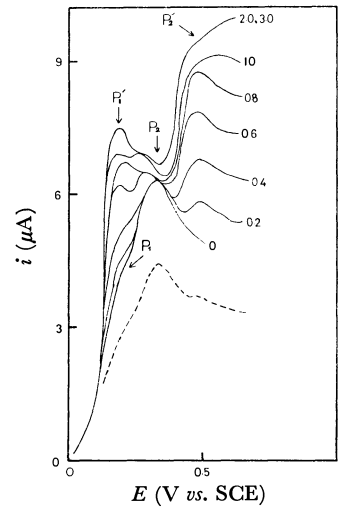

Fig. 2. Typical polarograms of DMPPD oxidation at pH 6.00. Numbers in the figure represent the mole ratio of Na_2SO_3 to DMPPD. The dotted line shows oxidation wave of DMPPD monosulfonate.

The results with DMPPD oxidation can be summarized as follows;

1) The species formed at the first wave (P_1) is DMPPD cation radical, since the initial reaction is oxidation of DMPPD with reversible one-electron transfer. (P_1 is not observed in Fig. 1.)

2) The product at the first wave, DMPPD cation radical, undergoes rapid chemical reaction with SO_3^{--} (or HSO_3^-), and forms DMPPD monosulfonate.

3) This resulting DMPPD monosulfonate is anodically oxidized through second successive one-electron transfers at the same potential range of DMPPD oxidation (P_1'), and forms DMPPD monosulfonate cation radical.

4) The product at P_1', DMPPD monosulfonate cation radical, again undergoes chemical reaction with SO_3^{--} (or HSO_3^-), and forms DMPPD disulfonate.

5) This resulting DMPPD disulfonate is anodically oxidized at the potential of P_2', and forms DMPPD disulfonate cation radical.

That is to say, the sulfonation reaction with DMPPD electro-oxidation seems to proceed through the ECE mechanism. These results are also supported by paper chromatography and spectrophotometric analysis of the products obtained by the controlled-potential electrolysis of DMPPD with sodium sulfite (Table 1).

The Dimorphism and Electronic Spectra of Anisyl-*p*-benzoquinones

Jun-ichi AIHARA, Goichi KUSHIBIKI,* and Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 25, 1973)

The coexistence of orange-yellow crystals (mp 58—59 °C) and red crystals (64—65 °C) has been noted by Brassard and L'Ecuyer in an *o*-anisyl-*p*-benzoquinone sample recrystallized from a mixture of acetone, methanol, and water (1: 1: 1 by volume).[1] We have examined the electronic spectra of these dimorphic forms and also those of some closely-related compounds in the first of our attempts to study self-complexing by a charge-transfer interaction in solids.

Phenyl-*p*-benzoquinone and its *o*- and *p*-MeO derivatives were prepared by the method of the above-mentioned authors. The preparation of the *m*-MeO and *o*- and *p*-EtO derivatives was similarly attempted. The purification of these three substances was found not to be easy. The crude products were repeatedly recrystallized, then sublimed in a vacuum, and finally recrysallized again. Their melting points were 121,81, and 115 °C respectively. The diffuse reflectance (R) of solid samples diluted with sodium chloride was measured at a concentration of 1.00% by means of a Beckman DK-2A spectroreflectometer. The spectra were plotted using the Kubelka-Munk function $f(R)=(1-R)^2/2R$.

The orange-yellow form of *o*-anisyl-*p*-benzoquinone could be isolated, by chance, during the processes of recrystallization, sublimation in a vacuum, and also solidification of the melt. Except for a shift of the absorption maximum to the wavelength side longer by about 25 nm, the spectrum is very similar to that displayed by the compound dissolved in ethanol (see Fig. 1). On the other hand, the red form shows an additional absorption with its maximum located around 500 nm.

p-Anisyl-*p*-benzoquinone recrystallized from an aqueous ethanol solution is orange-red, as has been reported

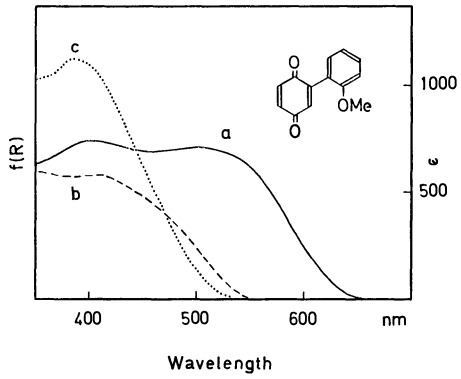

Fig. 1. Diffuse reflection spectra of (a) the red form and (b) the orange-yellow form of *o*-anisyl-*p*-benzoquinone and (c) the absorption spectrum in ethanol.

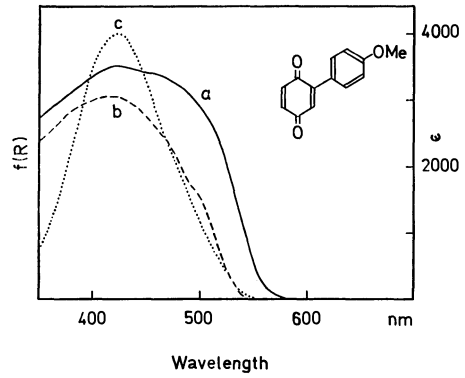

Fig. 2. Diffuse reflection spectra of (a) the orange-red form and (b) the yellow form of *p*-anisyl-*p*-benzoquinone and (c) the absorption spectrum in ethanol.

by Brassard and L'Ecuyer. When the melt is quickly cooled, the yellow form is obtained. Although this form can be kept for months without noticeable change, it is not so stable as the orange-yellow form of the *o*-anisylquinone. The color immediately turns orange-red when it is exposed to acetone vapor. Furthermore, the conversion to the stable form is markedly accelerated by grinding. As is shown in Fig. 2, the solid-state spectrum of the yellow form resembles the solution spectrum. The absorption maximum is located at about 420 nm in both of the states. The feeble structure observed around 500 nm in the solid-state spectrum can be assigned to the n-π transition. The appearance of a shoulder around 470 nm was noted in the spectrum of the orange-red form. The stable form melts at 126—127 °C, and the unstable form, at 118—119 °C. Curiously, the value reported by Brassard and L'Ecuyer, who observed only the orange-red form, agrees with the latter.

As the anisyl groups are excellent electron-donors, and as the quinone nucleus is a fairly good electron-acceptor, the absorptions appearing around 400 nm may be regarded as intramolecular charge-transfer transitions involving the transfer of an electron from a level which is akin to the highest occupied orbital of the anisyl group to the lowest vacant orbital, which is essentially of the quinone nucleus. The locations are shifted to the longer-wavelength side compared with that of the intermolecular charge-transfer absorption band in the anisole-*p*-benzoquinone complex, which has been located by Kuboyama at about 355 nm in carbon tetrachloride.[2] This assignment is supported by the observations that the absorption maximum in solid phenyl-*p*-benzoquinone is at 375 nm, while that in the *p*-NO_2 derivative is below 325 nm. In these two cases, the n-π transitions are well separated from

the intramolecular charge-transfer bands. There is little doubt that the *o*-anisyl-*p*-benzoquinone molecule is farther from co-planarity than the *p*-anisylquinone molecule because of the increased steric hindrance. This accounts for the fact that the extinction coefficient of the charge-transfer absorption band in the former compound is approximately one-fourth of that in the latter. The additional absorptions observed in the deeply-colored forms disappear upon melting. Thus, they may be attributed to the intermolecular charge-transfer interaction between the anisyl group in one molecule and the quinone nucleus in the neighboring molecule. Such a head-to-tail overlap in solids seems to be specific to these two compounds. The *m*-MeO and *o*- and *p*-EtO derivatives are all yellow-colored and exhibit no additional absorption on the longer-wavelength side of the intramolecular charge-transfer absorption band.

The Solid Molecular Complex Formed between Phenothiazinyl Neutral Radical and Bromine

Subray N. BHAT and Haruo KURODA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received July 24, 1973)

The optical and magnetic properties of the phenothiazine-bromine solid complex have been studied by several authors,[1-4] and it has been reported that the solid is a cation radical salt composed of phenothiazine cation radical and bromine anion, although it is diamagnetic at the room temperature. The apparent diamagnetism is considered to be the result of the reduction of paramagnetism by the strong interaction between phenothiazine cations. However, depending on the preparing conditions, possibly by the effect of the oxidizing agents contained in the used solvent, we sometimes obtain a paramagnetic phenothiazine-bromine solid complex. In this note, we will report the properties of this paramagnetic complex.

Experimental

Phonothiazine was recrystallized from an ethanol solution, and then sublimed *in vacuo* (mp 184 °C). A solution of 0.4 g bromine in 20 ml ethyl ether was added slowly to a solution of 1.0 g phenothiazine in 30 ml ethyl ether, cooling the reaction mixture with the ice-salt mixture. The solid precipitate thus obtained, was filtered, washed several times with cold ether, and dried under vacuum. The ethyl ether commercially obtained was distilled once before use, but no special precaution was done to exclude oxygen and other oxidizing agents.[5]

The result of the elemental analysis of the solid complex was as follows; Found: C, 51.64; H, 2.99; N, 4.79; S, 11.27; Br, 30.35%. Calcd[6] for $C_{12}H_9NS \cdot Br$: C, 51.62; H, 3.25; N, 5.02; S, 11.49; Br, 28.63%.

The ESR spectra were recorded by use of JES-ME-X ESR Spectrometer on a powder sample sealed in a glass tube under vacuum. The spin concentration was determined by using DPPH as the reference, and the *g*-value was determined by comparing with the standard signals of Mn^{2+}. The infrared and visible absorption spectra were measured on the powder sample by using the Nujol-mull method.

Results and Discussion

In contrast with the diamagnetic behaviors of the cation radical salt, the solid complex obtained in the present study, showed a strong paramagnetism, and gave a broad ESR signal with a half-width of about 15 Gauss at the room temperature. The *g*-value was 2.0015 ± 0.0005, and the spin concentration at the room temperature was 6.45×10^{19} spin/g. As shown in Fig. 1, the integrated intensity of ESR signal increased on lowering the temperature and, at the same time, there occurred a decrease of the line width. The temperature dependence of the spin concentration nearly obeys the Curie-Weiss law with the Weiss constant of approximately 70 K.

As shown in Fig. 2, the infrared spectrum of this paramagnetic solid complex considerably differs from that of the cation radical salt. In particular, the N–H stretching band which is observed at 3270 cm^{-1} in

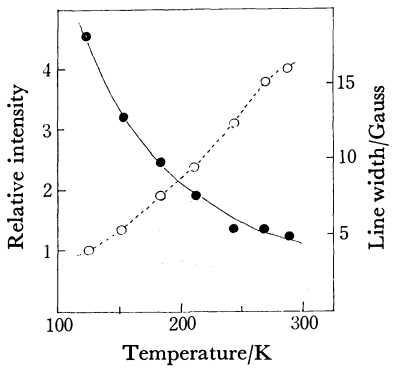

Fig. 1. The temperature dependences of the ESR intensity (—●—) and line width (---○---).

4) Y. Iida, *ibid.*, **44**, 663 (1971).

5) When we carefully excluded oxygen and other oxidizing agents from the solvent, we obtained the cation radical salt.

6) The values calculated for 2(phenothiazinyl)–Br_2 are as follows: C, 51.81; H, 2.89; N, 5.04; S, 11.53; Br, 28.73%.

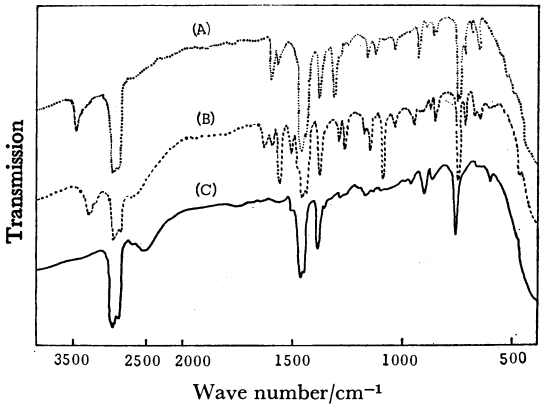

Fig. 2. Infrared absorption spectra of the phenothiazine (A), the cation radical salt, phenothiazine bromide (B) and the paramagnetic complex (C).

the case of the cation radical salt and at 3440 cm^{-1} in the case of pure phenothiazine, is missing in the spectrum of the paramagnetic complex. This seems to indicate that the hydrogen atom attached to nitrogen has been taken off from phenothiazine molecule. In the region below 500 cm^{-1}, the complex gives a broad band at 305 cm^{-1}, which can be attributed to Br–Br stretching vibration.[7,8]

The visible absorption spectrum of the paramagnetic complex is shown in Fig. 3, together with the spectrum of the cation radical salt. In the latter, the 20×10^3 cm^{-1} band has been attributed to the one corresponding to the 18×10^3 cm^{-1} band of the phenothiazine cation, and the near-infrared band at 11×10^3 cm^{-1} to the charge-transfer band associated with the interaction between phenothiazine cations.[4] The spectrum of the paramagnetic complex is considerably different from this; the first band is located at 8×10^3 cm^{-1}, and the second one at about 18×10^3 cm^{-1}.

It has been reported that the oxidation of phenothiazine in solution gives either phenothiazine cation radical (I) or phenothiazinyl neutral radical (II)

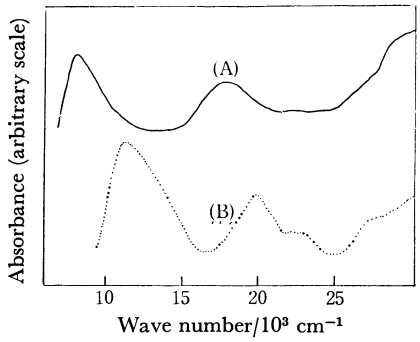

Fig. 3. Powder absorption spectra of the paramagnetic complex (A) and cation radical salt (B).

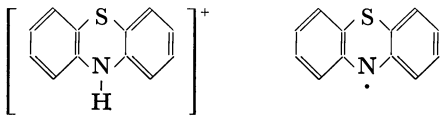
depending on the condition of oxidation.[9–11] The latter exhibits a strong visible absorption band at about 16×10^3 cm^{-1}.



(I) (II)

The strong paramagnetism and the absence of the N–H stretching band in the infrared spectrum, seem to indicate that phenothiazine is in the state of the phenothiazinyl neutral radical in the paramagnetic solid complex obtained in the present study. If this is the case, the solid is likely to be composed of the phenothiazinyl radical and bromine molecule with the mole ratio, 2: 1. This is in accord with the appearance of the Br–Br stretching band in the infrared spectrum. As for the visible spectrum, one could assign the 18×10^3 cm^{-1} band to the one due to phenothiazinyl radical and the 8×10^3 cm^{-1} band to a charge-transfer band.

Thanks are due to the Japan Society for the Promotion of Science for giving the fellowship to one of the authors (S.N.B.).

7) The Br–Br stretching band is infrared inactive in the free bromine molecule, but known to appear in a molecular complex such as the benzene–Br_2 complex.[8]

Torsional Braid Analysis of Magnesium Highpolyphosphate Coacervates

Takao UMEGAKI and Takafumi KANAZAWA

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received November 15, 1972)

Magnesium highpolyphosphate (MP) solutions with high viscosity (10—10^3 poise) and transparency were prepared by coacervation from mixed solutions of sodium highpolyphosphate and $MgCl_2$ under appropriate conditions.[1]

The physicochemical properties of alkali salts of highpolyphosphate have been described in detail by many researchers, but not those of other metal salts. Thermal changes of MP coacervates at temperatures from room temperature to about 1000 °C were examined by means of DTA, TGA and high temperature X-ray diffraction technique as a part of studies on non-alkali condensed phosphates.[2,3]

The present paper deals with temperature dependence of visco-elasticity of magnesium highpolyphosphate obtained by coacervation. Phase transition, thermal degradation and some other thermal changes of the MP at temperatures, from −120 to +80 °C were discussed on the basis of measurements of relative rigidity and logarithmic decrement by a torsional braid analyzer.

Experimental

Preparation of Magnesium Highpolyphosphate Coacervates. A 20% $MgCl_2$ solution (139 parts) was poured into a 15% solution (400 parts) of sodium methaphosphate (both guaranteed reagents of Kanto Chemical Co., Inc.) at room temperature. A white and opaque coacervate was obtained when ethyl alcohol was added to the well-stirred mixture of the two solutions. Addition of alcohol was continued until the coacervate no longer formed in clear liquid phase of the mixture. The MP coacervate (Sample I) was then accumulated by decantation.

Another MP coacervate (Sample II) was prepared by addition of distilled water to Sample I, in a ratio of 1:1 in weight. The chemical compositions of the two coacervates used are shown in Table 1.

TABLE 1. CHEMICAL COMPOSITION OF MAGNESIUM HIGHPOLYPHOSPHATE COACERVATES

Coacervate	Contents (%)			
	MgO	P_2O_5	Na_2O	H_2O
Sample I	6.8	36.8	4.1	52.9
Sample II	3.4	18.2	2.1	76.4

Measurement of Damped Oscillation. Magnesium coacervates settled in a week after preparation, the white, opaque coacervates becoming transparent. The samples were made to adhere to strips of glass cloth. The composite specimen of coacervate and glass cloth was suspended in a torsional pendulum type visco-elastometer (type RD-100, Applied Electric Laboratory, Ohyo Denki Kenkyujo Ltd.). For the experiments at low temperatures, liquid nitrogen was introduced into the visco-elastometer evacuated in advance and passed over the specimen. Damped oscillation was initiated manually at the desired temperature and recorded with a pen-writing oscillograph.

Calculation of Logarithmic Decrement and Relative Rigidity. Logarithmic decrement α_T and relative rigidity G_r were calculated as follows:[4]

$$\alpha_T = \ln A_n/A_{n+1}, \qquad G_r = (P_0/P_1)^2$$

where A_n is the n-th amplitude of damped sine wave, and P_0 and P_1 are periods of the oscillations of MP coacervate sample at temperatures T_0 and T_1, respectively. A certain period P_0 is fixed as a standard.

Results and Discussion

The thermomechanical spectra for MP coacervates are given in Figs. 1 and 2. No change in the logarithmic decrement and relative rigidity for Sample I was found over a temperature range between −120 and −60 °C, the solid phase of MP coacervate being retained without any thermal transformation. Relative rigidity for Sample I (Fig. 1) decreased with temperature rise, the lowering of the rigidity in the vicinity of 0 °C being remarkable. An inflection point of rigidity-temperature curve was found between 20 and 30 °C.

In this type of dynamic experiment the logarithmic decrement is directly related to the phase angle between the stress and strain, providing a measure of the mechanical energy dissipated per cycle compared with

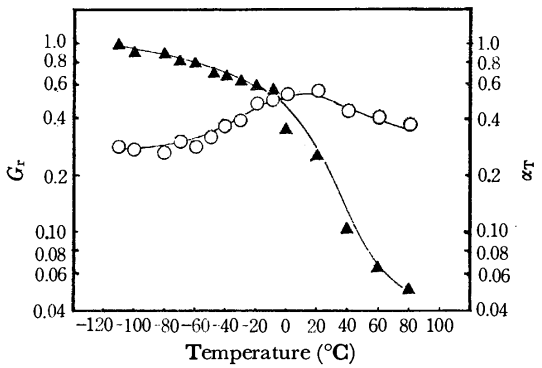

Fig. 1. TBA of sample I.
▲: G_r (relative rigidity), ○: α_T (logarithmic decrement)

4) J. K. Gillham, *Appl. Polym. Symp.*, No. 2, 45 (1966).

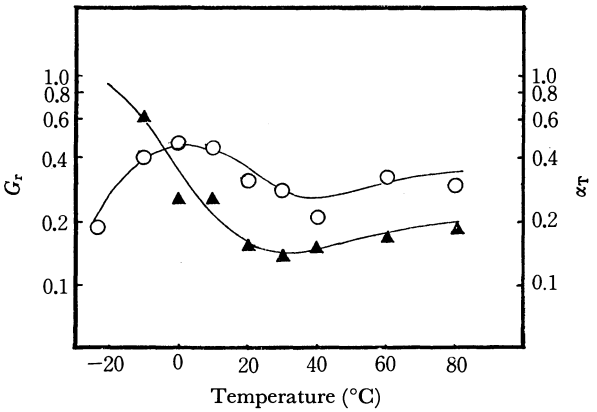

Fig. 2. TBA of Sample II.
▲: G_r (relative rigidity), ○: α_T (logarithmic decrement).

that recovered.[4] At the temperature of the peak for the decrement the MP coacervate was believed to be in the most random state of anion chains of the phosphate polymer.

It seems that the peak of logarithmic decrement and the drastic decrease of relative rigidity between 0 and 60 °C indicate melting of the MP coacervate.

Owing to the wide distribution in the chain length of polyphosphate ions, the peak of the decrement (Fig. 1) is broadened, which is almost unavoidable on the wet preparation of magnesium polyphosphates.

The maximum value of logarithmic decrement and the inflection point in rigidity-temperature curve shift to lower temperature compared with those of Sample I (Fig. 2). The thermomechanical behavior in the vicinity of 0 °C suggests melting of Sample II as well as Sample I. The gradual increase in rigidity and the decrement above 40 °C indicate stiffening of the specimen. Probably magnesium polyphosphates in water-rich coacervate are easily concentrated by vaporization of water, as compared with Sample I with lower content of water.

Besides the concentration of the polyphosphates, the above increase may be explained in terms of partial crystallization of orthophosphates formed in the course of thermal degradation of polyphosphates. However, a temperature of about 40 °C is believed to be somewhat low for initiation of the degradation.

The thermomechanical properties of the MP coacervates were described over a temperature range from −120 to +80 °C. Both coacervates settled in a week and the change of visco-elasticity with time was not examined. It is necessary to measure the time dependence of the rigidity and the decrement under controlled vapor pressure.

This work was supported by a grant from the Asahi Glass Foundation for Contribution to Industrial Technology, for which the authors wish to express their sincere appreciation. Thanks are due to Mr. Nobuhiro Sasaki, Manager of Technical Division, Applied Electric Laboratory (Ohyo Denki Kenkyujo), Ltd. for cooporation in the measurement of visco-elasticity.

Electron-transfer Reactions of Multidentate Ligand Cobalt(III) Complexes. VI. The Effect of the Chelation of Nonbridging Ligands on the Iron(II) Reductions of Chlorocobalt(III) Complexes

Yoshimi KURIMURA, Kousaburo OHASHI,* and Sachiko OHKUBO

College of General Education, Ibaraki University, Mito, Ibaraki 310

**Department of Chemistry, Ibaraki University, Mito, Ibaraki 310*

(Received January 23, 1973)

An earlier kinetic study of the reductions of several chlorocobalt(III) complexes, which proceed *via* the bridged activated states, suggested that the predominant factors controlling the rate of electron-transfer reactions are the energy for stretching the *trans*-ligand to the bridging one[1-3] and the effect of solvation.[4-6] More detailed data are necessary, however, to discuss the effect of nonbridging ligands on the rate. Therefore, the effects of the chelation of nonbridging ligands on the rate of the Fe^{2+} reductions of cobalt(III) complexes of the CoN_5Cl^{2+} and $CoN_4Cl_2^+$ types were investigated; the results will now be discussed.[7]

Experimental

trans-$[Co(en)(NH_3)_2Cl_2]Cl$,[7,8] *trans*-$[Co(en)_2Cl_2]Cl$,[9] and *cis*-$[Co(trien)NH_3Cl]Cl_2$[10] were prepared by the methods

described in the references cited. *cis*-$[Co(pn)_2NH_3Cl]Cl_2$, *trans*-$[Co(pn)_2Cl_2]Cl$, and $[Co(dien)ACl]Cl_2$ (A=pn and tn) were prepared by methods similar to those used for *cis*-$[Co(en)_2NH_3Cl]Cl_2$,[11] *trans*-$[Co(en)_2Cl_2]Cl$,[9] and $[Co(dien)(en)Cl]Cl_2$[10] respectively. The purity of the Co(III) complexes was ascertained by the elementary analysis of carbon, nitrogen, and hydrogen. The kinetics were followed by observing the change in the absorbance of the reaction mixture of the complex. The preparation of the ferrous perchlorate solution was described previously.[4] For all cases, rate studies were carried out with an excess of a reductant as pseudo-first order conditions. For the case of *trans*-$Co(en)(NH_3)_2Cl_2^+$, a lower concentration of the Co(III) ($\sim 2\times10^{-4}$ M) was employed for the kinetic measurements because of its lower solubility; thus, scale-expander attachement for a Hitachi Model 124 spectrophotometer was used. The ionic strength of the reaction mixture was adjusted by the addition of sodium perchlorate.

Results and Discussion

The rate constants for the Fe^{2+} reduction, and the relative rates for the Fe^{2+} reduction and acid hydrolysis of the Co(III) complexes, are presented in Tables 1 and 2 respectively. It is safe to assume that the Fe^{2+} reduction of CoN_5Cl^{2+} and $CoN_4Cl_2^+$ proceeds *via* the chloride-bridged mechanism.[3,5,6]

In previous discussions it was suggested[4,5] that the free energy for the bond stretching of the Co–N bond, especially that of the *trans*-N to the bridging ligand, is an important factor in the Fe^{2+} reduction of the CoN_5Cl^{2+}, and that both free energy for the bond stretching and the solvation effect[4-6] are major factors in the Fe^{2+} reduction of the $CoN_4Cl_2^+$ in determining the rate of electron-transfer reaction.[15] It is clear from Table 2 that an increase in chelation, such as replacing two NH_3 ligands by one ethylenediamine molecule, shows a progressive decrease in the rate of the reduction.

The relative rate constant of the *cis*-$Co(en)_2NH_3Cl^{2+}$ is about four times smaller than that of the *trans*-isomer. This suggests that the reduction rate is much more sensitive to the free energy for the reorganization of the *trans*-ligand than that of the *cis*-ligand for the CoN_5Cl^{2+} type: the effectiveness of *cis*-$Co(en)_2NH_3Cl^{2+}$ would be lower than that of the *trans*-isomer, since the reorganization energy for the *trans*-N ligand (en) of the former would be greater than that for the *trans*-ligand (NH_3) of the latter.

An appreciable decrease in the rate can also be seen when we replace the four NH_3 ligands of the *trans*-$Co(NH_3)_4Cl_2^+$ by two ethylenediamines. That is, the reduction rate is as sensitive to the chelation of the *cis*-ligands as that of the *trans*-ligand for the $CoN_4Cl_2^+$ type (Tables 2, 10 and 12, and 14 and 15). This may be due to (a) the effect of solvation, and (b) the effect of free energy on the reorganization of the non-bridging ligands. The effect of (a) may be explained as follows. The larger the complex ion, the less its solvation energy will be. Therefore, the rate is reduced by chelation because of the reduced stability of the transition state resulting from less efficient solvation.[4,6,14] A similar solvation treatment was given

Table 1. Rate constants for the iron(II) reduction of cobalt(III) complexes

Complex ion	k[a]/$M^{-1}sec^{-1}$

15) In the $CoN_5Cl^+ + Fe^{2+} \rightarrow Co^{2+} + 5N + FeCl^{2+}$ reaction the over-all charges on the Co(III) and Co(II) are not identical, so the solvation effect is considered to be an important factor in the reaction.[6]

in order to explain the effect of the chelation on the acid hydrolysis of the Co(III) complexes, though this theory does not distinguish between S_N1 and S_N2 mechanisms.[14] An interesting fact is that the values of $(R_{Fe})_2$ for *trans*-$CoN_4Cl_2^+$ are almost parallel to those of $(R_{aq})_2$: the rate constants of the Fe^{2+} reduction and those of the acid hydrolysis decrease by a factor of about one by replacing the two NH_3 ligands by one ethylenediamine. The $(R_{Fe})_1$, $(R_{Fe})_2$, and $(R_{Fe})_3$ represent the ratios of the rate constant for the Fe^{2+} reduction to those of $Co(NH_3)_5Cl^{2+}$, *trans*-$Co(NH_3)_4Cl_2^+$, and *cis*-$Co(NH_3)_4Cl_2^+$ respectively, while $(R_{aq})_1$ and $(R_{aq})_2$ represent the ratios of the rate constants for the aquation to those of $Co(NH_3)_5Cl^{2+}$ and *trans*-$Co(NH_3)_4Cl_2^+$ respectively.

Table 2 also shows the effect on the rate of increase in the size of the chelate ring from five members to six when trimethylenediamine is used instead of ethylenediamine. For both the CoN_5Cl^{2+} and $CoN_4Cl_2^+$ types, the rates are little affected by using the propylenediamine instead of ethylenediamines (Table 2, Nos 3 and 4, 5 and 6, and 12 and 13). However, the rate is doubled by replacing two ethylenediamines by two trimethylenediamines. This increase in the rate may be related to the fact that complexes with six-membered chelate rings are much less stable than those with five-membered chelate rings.[14,16]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3590—3591 (1973)

The Mössbauer Effect of Several Iron(II) Octahedral Complexes of α-Dioxime

Yoshihiro SASAKI and Tsunenobu SHIGEMATSU
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received April 20, 1973)

The Mössbauer effect has been used to study the electronic structure of iron porphyrins. The measurement is, however, difficult because of the small quantities of iron present. Therefore, an empirical approach, using simple model compounds, appears to be necessary. Since bis(dimethylglyoximato)diimidazoleiron(II) possesses unsaturated equatorial ligands containing nitrogen donor atoms and biologically-important axial ligands, it is regarded as a model complex of iron porphyrins.

We have studied the electronic structure of iron(II)-α-dioxime complexes containing pyridine or imidazole as axial ligands by Mössbauer spectroscopy and will report the results here.

Experimental

1,2-Cyclohexadione-dioxime(CdH_2), dimethylglyoxime(DgH_2), α-furyldioxime(FrH_2), and α-benzyldioxime(BzH_2) were used as the equatorial ligands, and pyridine(Py) and imidazole(Im), as the axial ligands. The pyridine complexes were synthesized as has been described by Matsumoto *et al.*,[1] while the imidazole adducts were prepared by analogous procedures.

The Mössbauer spectra were obtained with scanning velocity spectrometers operating in the time mode. The radiation source was ^{57}Co diffused into a copper or palladium foil and kept at room temperature throughout the measurements. The powdered samples, containing about 8 mg/cm² of natural iron, were mounted on aluminum foil, and the spectra were taken at 77 K, at *ca.* 100 K, and at room temperature. The velocity scale was calibrated with metallic iron, and the velocity was determined to an accuracy of ±0.04 mm/s.

Results and Discussion

The isomer shift, δ, and the quadrupole splitting, ΔE_Q, are listed in Table 1. Some typical Mössbauer spectra of bis(α-furyldioximato)dipyridineiron(II) are shown in Fig. 1.

Isomer Shift. The isomer shift of the present samples lies within a range normally found for low-spin complexes.[2] The complexes with α-furyldioxime

(a) room temperature (b) about 100 K

or α-benzyldioxime exhibit a smaller isomer shift than those with dimethylglyoxime or 1,2-cyclohexadionedioxime. Changes in the isomer shift reflect (a) changes in the s orbital populations due to involvement in covalent bonding, and (b) changes in the shielding of electrons in s orbitals by other electrons, notably those in 3d orbitals whose population and distribution are affected by the details of bonding. α-Furyl and α-benzyl groups, which are π-electron-attractive groups, will lead to a stronger interaction between the 3d orbitals of the central iron and the π* orbitals of the α-dioxime, causing a greater delocalization of the electrons in the 3d orbitals of the iron. This will weaken the shielding of s-electrons by 3d-electrons and decrease the isomer shift. Pyridine has a stronger π-accepting capability, while imidazole has a stronger σ-donor power. Both the effects by the axial ligands will decrease the isomer shift. Thus, the isomer shift of the complexes with the same α-dioxime may be changed little by the axial ligands.

Quadrupole Splitting. For metal-organic complexes, the electric-field gradient consists of both terms of the valence electrons of the Mössbauer nucleus and the ligands.[3] The electronic distribution of a ferrous ion in a strong crystal field has a cubic symmetry. Thus, octahedral low-spin iron(II) complexes show a single absorption peak or a doublet exhibiting a small quadrupole splitting.

The present complexes have a low-spin d^6 electronic configuration, while their observed quadrupole splittings are relatively large, especially in the pyridine adducts. Recently the Mössbauer spectrum of $Fe(II)(CdH)_2Im_2$ was measured in the magnetic field.[4] The results indicate that the asymmetry parameter for this complex is quite large. On the other hand, the quadrupole splitting of the complexes containing CO or CN^- as axial ligands is normally small.[5] These findings suggest that we should consider the effects of π bonding on the axial ligands. According to the X-ray analyses of $Fe(II)(CdH)_2Im_2$ and $Fe(II)(DgH)_2Im_2$,[6,7] the π rings of imidazole are coplanar and are perpendicular to the hydrogen bond. The structure of these complexes is shown in Fig. 2. We assume that the central iron is in a nearly D_{2h} symmetry. Then, the π orbitals of the axial ligands may interact with only the 3d(xz) orbital. As pyridine has a stronger π-accepting capability than imidazole, the electrons in the 3d(xz) orbital of pyridine adducts will migrate more to the axial ligands. Thus, this may give a larger quadrupole splitting in pyridine complexes.

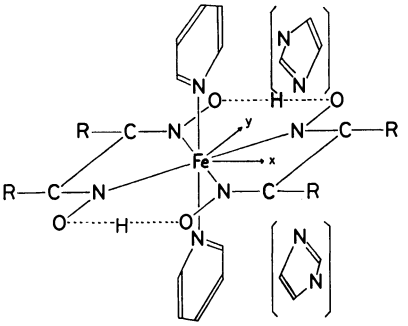

Fig. 2. The structure of the complex $Fe(II)(\alpha\text{-dioxime})_2X_2$.
(X=pyridine or imidazole)

The quadrupole splitting of the pyridine adducts increases in the order of: CdH_2, DgH_2, FrH_2, and BzH_2; the isomer shift decreases in the same order. In the imidazole complexes, CdH_2 and DgH_2 change places with each other.

An additional characteristic of the Mössbauer spectra of $Fe(II)(FrH)_2Py_2$, $Fe(II)(BzH)_2Py_2$, and $Fe(II)(FrH)_2Im_2$ is found in the differences in the peak intensities of the doublet lines. Such an asymmetry can be ascribed to (1) crystal orientation,[8] (2) anisotropic recoilless fraction,[9,10] or (3) relaxation phenomena.[11] Because these complexes are diamagnetic, relaxation phenomena are not taken into account. As the samples were finely powdered, any effects due to crystal orientation would be eliminated. The temperature dependency of the Mössbauer spectra predicts, then, that there is an anisotropic recoilless fraction in these complexes.

The authors wish to thank Drs. T. Shinjo and Y. Maeda for permitting us to use the equipment for the Mössbauer measurements and for their helpful discussions.

Photochemical Reactions of 1,1-Diphenyl-2-picrylhydrazyl with Gold(III) Complexes

Michihiko Asai and Shigeo Tazuke*

Department of Polymer Chemistry, Kyoto University, Kyoto 606

(Received May 1, 1973)

The reactions of 1,1-diphenyl-2-picrylhydrazyl(DPPH) with some metal salts have recently aroused interest. DPPH has been reported to undergo certain types of oxidation-reduction reaction with various metal ions[1,2] as well as chelates,[3,4] or charge transfer (CT) complex formation with CuCl.[5] All these systems, however, were treated under thermal conditions. No photochemical reactions of DPPH with metal salts have so far been reported. In the course of studies on the photo-cationic polymerization of *N*-vinylcarbazole sensitized by $(n\text{-}C_4H_9)_4NAuX_4$(X=Cl$^-$, Br$^-$),[6] we found that under irradiation of a solution containing DPPH and Au(III) complexes the characteristic purple color of the former disappeared. This communication describes the novel reaction in acetophenone as a solvent in connection with the photochemistry of Au(III) complexes, which has not been investigated quantitatively in spite of their extreme photosensitivities. Experimental methods are the same as described elsewhere.[6] All reactions were carried out without eliminating dissolved air.

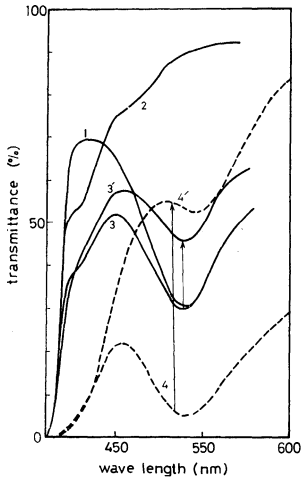

Fig. 1. Photochemical reactions between AuX_4^- and DPPH in acetophenone.
1; [DPPH]=5×10^{-5}M, 2; [$AuBr_4^-$]=5×10^{-5}M, 3; [DPPH]=5×10^{-5}M, [$AuBr_4^-$]=5×10^{-5}M, 4; [DPPH]=5×10^{-5}M, [$AuCl_4^-$]=2×10^{-3}M, 3′ and 4′; after irradiation of 3(30 min) and 4(45 min) irradiation at 436 nm, 30 °C.

When an acetophenone solution containing equimolar amounts (5×10^{-5} M) of DPPH and $AuBr_4^-$ was irradiated by 436 nm light for 30 min at 30 °C, the characteristic purple color (λ_{max} 540 nm) of DPPH faded as shown in the figure. This was also observed under thermal conditions, although the rate of disappearance was negligibly small. No interaction between DPPH and $AuBr_4^-$ species was observed spectroscopically and irradiation of a solution of DPPH alone induced no fading of its color. Irradiation at 546 nm was ineffective. These facts indicate that effective light absorbing species leading to the reaction is not DPPH but $AuBr_4^-$ itself. The quantum yield (ϕ_{-DPPH}) for the disappearance of DPPH was calculated from the plots of its absorbance at 540 nm against time to be 0.17 after correcting for the inner filter effect:

$$I_{abs,A} = \frac{\varepsilon_A[A]}{\varepsilon_A[A]+\varepsilon_D[D]} I_0[1-\exp\{-(\varepsilon_A[A]+\varepsilon_D[D])\}]$$

where A and D denote $AuBr_4^-$ and DPPH, and $I_{abs,A}$, I_0 and ε denote amounts of light absorbed by $AuBr_4^-$, the intensity of incident light and molar extinction coefficient, respectively. The quantum yield ($\phi_{-AuBr_4^-}$) for the photodecomposition of $AuBr_4^-$ under irradiation at 436 nm at 30 °C has been obtained as 0.20.[6] It is interesting that both ϕ_{-DPPH} and $\phi_{-AuBr_4^-}$ are nearly the same, indicating that the photodecomposition of $AuBr_4^-$ corresponds to the equimolar fading of DPPH.

A similar fading reaction of DPPH was also observed by the use of $AuCl_4^-$ as shown in the figure. In this case, however, thermal reaction should be considered because of the high concentration of $AuCl_4^-$. The value of $\phi_{-AuCl_4^-}$ was calculated to be 0.24 on the assumption of 1 : 1 correspondence between $\phi_{-AuCl_4^-}$ and ϕ_{-DPPH}.

The characteristic absorption band at 540 nm of DPPH radical has been reported[5] to be probably due to the picryl ring having an appreciably delocalized unpaired spin. Metal ions or chelates have been assumed[2] to react with equimolor proportion of DPPH with production of 1,1-diphenyl-2-picrylhydrazine ($DPPH_2$) *via* hydrogen atom transfer mechanism or election transfer accompanied by proton transfer mechanism. Alternatively, it has been known[5] to form CT complex with metal ion coordinating to the picryl ring. The purple color of DPPH has been reported to disappear in these systems, whereas the absorption maximum attributed to hydrazine or CT complex appears in ultraviolet region. In the present system, the solution became pale yellow by prolonged irradiation although the absorption maximum was not observable due to hindrance of the absorption band of solvent.

As to the photodecomposition of AuX_4^- under irradiation of its CTTM band, its primary process seems to be intramolecular photoredox reaction as suggested[7] from the flash photolysis studies in which transient spectrum of X_2^- was detected. The mechanism of primary processes is proposed as follows:

$$Au^{III}X_4^- \xrightarrow{h\nu} A^{II}X_3^- + X \xrightarrow{\text{free } X^-} X_2^-$$

The reaction of DPPH with either transient species Au(II) or X (or X_2^-) formed photochemically may be explained from the viewpoint of the electron-transfer reaction in which DPPH acts as an oxidant. The direction of the electron-transfer may be controlled by the relative magnitude of the redox potential (E°) of the reacting species. The E° for the DPPH system[2] and the Au(III)/Au(II) couple[8,9] have been estimated to be -1.1——-1.2 V and -0.5——-0.96 V, respectively. The halogen atom, a strong oxidant, has not been reported to act as a reductant presumably because of difficulty in the formation of X^+ cation from X atom. X_2^- anionradical has been reported to be a stronger oxidant than X_2 molecule.[10] Thus, electron-transfer from these halogen species to DPPH seems to be highly unlikely. This might be supported by the results obtained in the flash photolysis of $AuBr_4^-$, *i.e.* the amount of Br_2^- was less than that of photodecomposed $AuBr_4^-$ by a factor of about ten, which is not in line with the results where both ϕ_{-DPPH} and $\phi_{-AuBr_4^-}$ are of nearly the same value. The electron-transfer reaction between Au(II) and DPPH seems to be energetically more favorable. If Au(II) is reoxidized to Au(III), the dark red color of $AuBr_4^-$ should be restored. However, the presence of hydrazine derivatives as a result of the reduction of DPPH would cause the formation of a colorless complex with Au(III). The Au(III) complexed with amine is colorless as shown for the tetramine-[11] and bisethylenediamine-[12] Au(III) complexes.

Another possibility is that formation of the charge-transfer complex between DPPH radical with the halogen-Au(I) species may result from the spontaneous reduction of Au(II) species. This case is similar to the DPPH/CuCl complex reported by Leh and Wan.[5] It seems most likely that some gold species is responsible for the fading reaction of DPPH.

The authors express their gratitude to Professors Seizo Okamura and Toshinobu Higashimura for their encouragement and valuable discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3593—3594 (1973)

The Chelation-induced Deceleration of the Methyl Proton Exchange in the Bisacetylacetoneethylenediimine Ligand

Ichiro TAKAGI and Hayami YONEDA*

Department of Chemistry, Faculty of Education, Wakayama University, Masagocho, Wakayama 640
**Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730*

(Received May 18, 1973)

Organic ligands in chelate compounds are subject to the influence of the electron-withdrawing effect of a central metal ion, and, as a result, proton dissociation from the ligand is more or less facilitated. Therefore, hydrogen-deuterium exchange can be observed in some complexes when they are dissolved in deuterium oxide. This kind of exchange can easily be detected and followed by measuring the intensity decrease in the PMR signal of the coordinated ligand. We have found several such examples, *i.e.*, in the methylene of the malonato[1] and glycinato[2] cobalt(III) complexes, in the ethylene of the EDTA cobalt(III) complex,[3] and in the methyl of dimethylglyoximatocobalt(III) complexes.[4] In all these cases, the free ligand itself does not show such an exchange, and chelation is considered to accelerate it.

Here we would like to report another type of chelation effect, one which slows down the rate of proton exchange. The complexes studied are four kinds of bisacetylacetoneethylenediiminecobalt(III) with the formula of $[CoX_2acac\text{-}en]^{n+}$, where X is NO_2^-, pyridine, NH_3, and CH_3NH_2. These complexes were dissolved in a 2% NaOD deuterium oxide solution, and the PMR spectra were measured at 60 °C at appropriate time intervals. For comparison, the time change in the PMR spectrum of the free ligand itself was also recorded under the same conditions. Figure 1 shows the spectra of $[Co(NH_3)_2acac\text{-}en]NO_3$ measured (a) immediately and (b) 240 min after dissolution. A comparison of

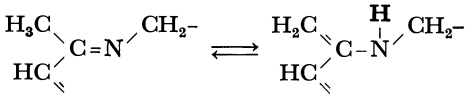
3) H. Yoneda and Y. Morimoto, This Bulletin, **42**, 1160 (1969).
4) H. Yoneda, I. Takagi, and Y. Morimoto, *ibid.*, **44**, 2863 (1971).

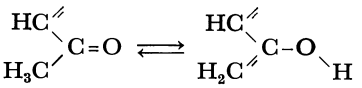
the two spectra, (a) and (b), reveals that the H–D exchange occurred at two sites of the ligand, namely, at the vinyl and at one of the two methyls. At present we have no unambiguous evidence with which to decide which methyl of the two (one adjacent to C=N and the other adjacent to C–O) is exchange-active. However, the exchange-rate constant in the methyl can easily be determined from the slope in Fig. 2.

The rate constants obtained for the free ligand and for the four complexes (10^{-3} min^{-1} unit) are 57.7 (free ligand), 6.6 (CH_3NH_2), 2.9 (NH_3), 1.6 (pyridine), and 0.7 (NO_2^-).

Here it should be noted that the exchange rate for the free ligand is ten times as large or larger than those for the complexes. This large exchange rate in the methyl of the free ligand can be understood by means of the following tautomeric mechanism:



or



This kind of tautomerism is depressed by chelation, which results in a decrease in the exchange rate in the complexes. In other words, chelation fixes the planar atomic arrangement of the acetylacetone group and gives it a pseudoaromatic character, which then serves to reduce the contribution of the electronic state favorable for the above-mentioned tautomerism. The decreasing order of the rate constants for the four complexes is; $CH_3NH_2 > NH_3 >$ pyridine $> NO_2^-$ and corresponds to the increasing order of the degree of the charge neutralization of the metal ion caused by the ligand, X. Therefore, this trend suggests that the electron-withdrawing effect of the metal ion is the only driving force for the proton exchange in the complexes.

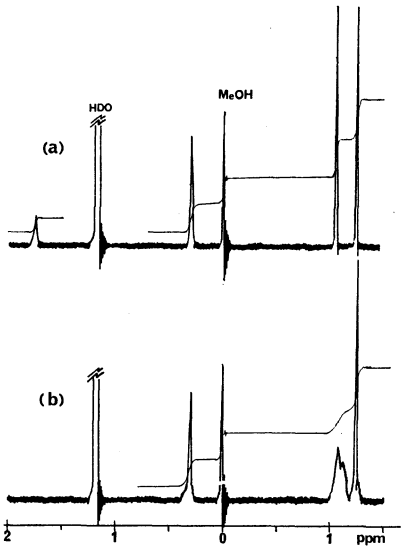


Fig. 1. The PMR spectra of $[Co(NH_3)_2acac\text{-}en]NO_3$ in 2% NaOD–D_2O solution at 60 °C recorded (a) immediately and (b) 240 min after dissolution.

△: $[Co(NH_3)_2acac\text{-}en]^+$, ■: $[Co(py)_2acac\text{-}en]^+$,
○: $[Co(NO_2)_2acac\text{-}en]^-$.

Experimental

Materials. The $[CoX_2acac\text{-}en]ClO_4$ (X=CH_3NH_2, NH_3, and pyridine) and $Na[Co(NO_2)_2acac\text{-}en]$ complexes were prepared according to the method reported by Fujii.[5]

NMR Measurements. The spectra were recorded in a 2% NaOD deuterium oxide solution on a Jeol JNM-C-60HL spectrometer. Methanol was added to the solution as an internal standard for the chemical shift and the intensity.

One of the authors especially, Dr. Takagi, is grateful to the Ministry of Education for a Grant in Aid for Scientific Research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3595—3596 (1973)

Indirect Determination of Tantalum by Atomic Absorption Spectrophotometry

Tsutomu MATSUO, Junichi SHIDA, and Seiichi KUDO

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Jonan-4, Yonezawa, Yamagata 992

(Received May 22, 1973)

Reports have recently been given on indirect determination of arsenate,[1] germanate,[2,3] phosphate,[4,5] silicate,[5] and niobate,[6] based on the extraction of heteropolymolybdate with the organic extractant and subsequent measurement of the molybdenum contained in the extract by atomic absorption spectrometry. Guyon *et al.* reported the spectrophotometric methods for determination of niobium[7] and tantalum,[8] in which heteropolymolybdate complex was used. The authors investigated an indirect determination of tantalum by atomic absorption spectrometry. The essential steps in this method are; formation of molybdotantalate, extraction of the molybdotantalate with methyl isobutyl ketone (MIBK) and measurement of molybdenum by aspirating the MIBK extract directly into the burner of the atomic absorption spectrophotometer.

Experimental

Apparatus. Atomic absorption spectrometric measurements were carried out with a Hitachi model 207 atomic absorption spectrophotometer equipped with a molybdenum hollow cathode lamp (Hitachi, HLA-3) as a light source at 3133 Å molybdenum line. Lamp current was 15 mA. An air-acetylene flame was used with flow rates 13 l/min and 3 l/min.

Standard Tantalum Solution (1.0×10^{-2} *M*). Dissolve 0.1809 g of tantalum metal (99.7%) in hydrofluoric acid containing a small amount of nitric acid and evaporate it to dryness. Add 5 ml of hydrofluoric acid and 5 ml of sulfuric acid, and heat until fumes of the sulfuric acid are evolved. After cooling, dilute to 100 ml with distilled water.

Procedure. Transfer 10 ml of 0.2 M ammonium molybdate solution to a 100 ml separatory funnel, add 2 ml of 6 M hydrochloric acid and swirl to mix. Add known amounts of tantalum solution and dilute with distilled water to 20 ml. After standing the solution 15 min, add 20 ml of MIBK and shake vigorously for 5 min. Separate the layers, wash the MIBK extract three times with 25 ml portions of 0.6 M hydrochloric acid and measure molybdenum by aspirating the MIBK extract of molybdotantalate into the burner of the atomic absorption spectrophotometer. A blank containing all the reagents except the tantalum sample is prepared by a similar procedure.

Results

Acidity for Extraction of Molybdotantalate. The optimum acidity of aqueous solution for the extraction of molybdotantalate with MIBK was examined. The results are shown in Fig. 1. The acidity range 0.5—0.7 M hydrochloric acid was found to be suitable, the absorbance value being constant in this range.

Effect of Molybdate Concentration. The effect of ammonium molybdate for the extraction of molybdotantalate was studied. The results are shown in Fig. 2. A constant absorbance value was obtained when 9 ml of 0.2 M ammonium molybdate was added.

7) J. C. Guyon, G. W. Wallace, Jr., and M. G. Mellon, *Anal. Chem.*, **34**, 640 (1962).
8) J. C. Guyon, *Anal. Chim. Acta*, **30**, 395 (1964).

In the determination of tantalum, 10 ml of molybdate solution was used.

Washing of the MIBK-Extract. Molybdotantalate was extracted into MIBK with a trace of excess molybdate.[2,3] To remove the trace of excess molybdate, washing of the MIBK extract with hydrochloric acid was examined. Washing three times with 25 ml portions of 0.6 M hydrochloric acid solution was sufficient to remove the excess molybdate. Shaking time for washing was 3 min.

Effect of Standing Time. The rate of formation of heteropolymolybdate was relatively slow at room temperature. The effect of standing time prior to extraction of molybdotantalate was examined. Fifteen minutes was found to be the best for quantitative extraction.

Stability of Extract. No change in absorbance value was observed for at least two hours in the MIBK extract.

Calibration Curve. The calibration curve of absorbance value *versus* concentration of tantalum was linear for 2.5×10^{-6}—2.0×10^{-5} M of tantalum.

Effect of Diverse Ions. An atomic absorption spectrometric method for the determination of niobium based on the formation of molybdoniobophosphate was reported by Kirkbright *et al.*[6] Niobium also forms molybdoniobate, which should be removed before the tantalum determination. It was found that niobium could be determined by the proposed method (Figs. 1 and 2) and that the linear relationship was obtained in the niobium concentration range 1.0×10^{-5}—5.0×10^{-5} M. The sensitivity of molybdoniobate is about five times less than that of molybdotantalate. Heteropolymolybdates which give positive errors are arsenate, germanate, phosphate and silicate.

The Rapid Collection of Traces of Silver with Mercury in an Ultrasonic Field

Atsushi MIZUIKE, Katsuaki FUKUDA, and Takeshi SAKAMOTO
Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received May 31, 1973)

Previously we reported that microgram quantities of silver deposit quantitatively into numerous mercury globules from 1 to 3 mm in diameter from stirred aqueous solutions, leaving large amounts of such base metals as iron, copper, and lead in the solutions.[1,2] Because mercury is removed by evaporation from the resulting dilute amalgam, this separation method is useful as a preconcentration technique in trace analysis. The procedure, however, is rather time-consuming. The present note will describe a more rapid separation method using a mercury-in-water emulsion in an ultrasonic field. This method has been applied to the atomic absorption spectrometric determination of silver at a low ppm level in lead.

Experimental

Apparatus. A Kaijo Denki model MA-2302 ultrasonic generator (29 kHz, 45 W) with a cylindrical transducer (13 mm diam. × 100 mm) coated with epoxy resin. A Hitachi model 139 spectrophotometer with a model 139-0420 atomic absorption attachment and a model QPD-53 recorder.

Solutions. Ammoniacal sample solutions were prepared by mixing 2 ml of nitric acid, 1.5 ml of hydrochloric acid, and 10 ml of aqueous ammonia and by then diluting to 25 ml with water, or by dissolving 5 g of high-purity copper in 40 ml of 7 M nitric acid, adding 15 ml of hydrochloric acid and 100 ml of aqueous ammonia, and diluting to 200 ml with water.

Standard Procedure. Place 25 ml of water and 34 g of mercury in a 50 ml beaker, immerse an ultrasonic transducer about 2 mm deep in the water, and apply ultrasonics for 30 s to obtain a gray emulsion containing about 150 mg of mercury. Within 3 min add this emulsion to a 100 ml, round-bottomed centrifuge tube containing 25 ml of the sample solution and apply ultrasonics for 30 s as has been described above. Centrifuge for 3 min at 4000 rpm and then discard the supernatant liquid. Add 5 ml of acetone and stir vigorouly with a glass rod for 10 s to effect coalescence into a single mercury droplet (about 3 mm in diameter)

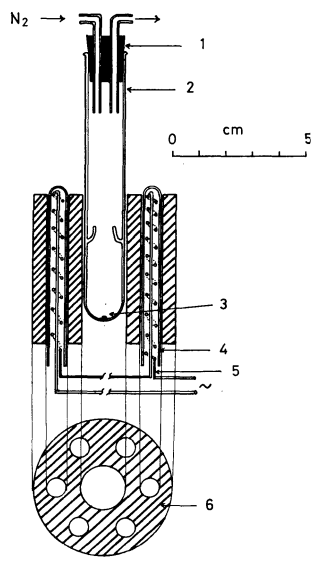

Fig. 1. Apparatus for evaporation of mercury.

with a metallic luster. Discard the acetone, wash the droplet with 2 ml of acetone two or three times, and discard the washings. Transfer the mercury droplet to the bottom of an evaporation tube with a dropping pipet, and then evaporate the mercury at 350 °C (Fig. 1). Cool, and then remove the mercury condensed on the walls of the evaporation tube using a mercury-plated copper wire. Add 1 ml of nitric acid to the evaporation tube to dissolve the residue.

Results and Discussion

Preparation of Mercury-in-Water Emulsions. Mercury-in-water emulsions were prepared with from 7 to 68 g of mercury and 25 ml portions of water with the aid of ultrasonics; the mercury in the emulsion was then separated as a single droplet by centrifugation and by washing with acetone as has been described under *Standard Procedure*, and determined by weighing or EDTA titration. As is shown in Fig. 2, saturation was reached after 20 s of ultrasonic irradiation. The reproducibility for 40 s of ultrasonic irradiation was as follows: 127, 122, 114, 125, and 125 mg of mercury in an emulsion (with 20 g of mercury), and 155, 150, 146, 152, and 138 mg (with 34 g of mercury). The diameter of the mercury droplets was from 1 to 4 μm after 20 s, and the emulsion was stable for about 5 min.

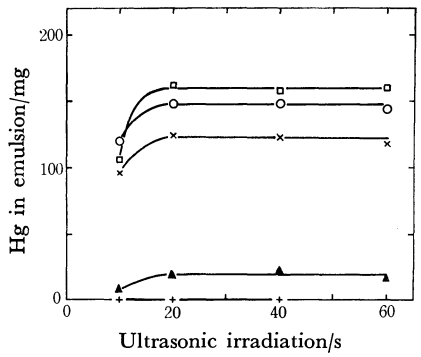

Fig. 2. The quantity of mercury in emulsion as a function of time of ultrasonic irradiation.
Hg used: (□) 68 g, (○) 34 g, (×) 20 g, (▲) 14 g, (+) 7 g.

Collection of Silver. A mercury-in-water emulsion (25 ml) was added to 25 ml of a sample solution containing from 5 to 10 μg of ^{110m}Ag-labeled silver; the silver was then collected as has been described under *Standard Procedure* except that the quantity of mercury and the collecting time were changed, and the gamma activity of the mercury droplet was measured. The results are summarized in Fig. 3. A silver recovery of greater than 96% was attained with from 125 to 150 mg of mercury between 20 and 40 s. In the case of nitric acid solutions, the silver recovery then decreased with the time because of the dissolution of mercury in the solutions, as is shown in Fig. 4. The dissolved mercury was determined by EDTA titration after the removal of the mercury droplets by means of a centrifuge.

Separation of Silver from Matrix Elements. Table 1 shows that ppm quantities of silver in lead and copper matrices can be separated with recoveries of greater than 96% and concentration factors of greater than 10^5 by the standard procedure. In this experiment,

both the silver recovery and the quantity of the matrix elements accompanying the silver were measured after the removal of the mercury by evaporation.

The proposed method may also be applied to the separation of traces of gold or palladium from copper and other base metals in ammoniacal or nitric acid solutions.

Table 1. Separation of silver from matrix elements in 0.1 M nitric acid solutions[a)]

b) Determined by square-wave polarography.

Determination of Traces of Silver in Lead. A 5 g lead sample was dissolved in 15 ml of 7 M nitric acid. The solution was then evaporated to dryness, and the residue was dissolved in 50 ml of 0.5 M nitric acid. A 1/10 or 1/5 aliquot was taken and diluted to 25 ml with 0.12 M nitric acid or water (final acidity, 0.2 M). The silver in the solution was separated by the standard procedure, and the residue in the evaporation tube was dissolved in 1 ml of 7 M nitric acid. The solution was then evaporated to dryness, and the residue was dissolved in 0.80 ml of 2 M nitric acid and then in 1.20 ml of acetone. The silver in the solution was then determined by atomic absorption spectrometry at 328.1 nm.[2] The analytical results are shown in Table 2. The time required for a determination was about 2 hr.

The Sublimation Pressure of Tetrasulfur Tetranitride

Shuichi HAMADA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received June 12, 1973)

Tetrasulfur tetranitride, S_4N_4, is stable contrary to expectation in air at room temperatures, but it decomposes explosively when struck or when heated above its melting point. Goehring and Voigt[1] pointed out that tetrasulfur tetranitride decomposes into its elements at approximately 130 °C. The concrete values of the sublimation pressure of tetrasulfur tetranitride have not been reported because of its instability, although Meuwsen[2] stated that the compound can be sublimed below 130 °C at 0.1 mmHg.

In this work, the sublimation pressure of tetrasulfur tetranitride was studied at temperatures below 90 °C by means of the method of transpiration.

Experimental

Materials. The tetrasulfur tetranitride was prepared by the method described by Villena-Blanco and Jolly[3] without further purification.

Argon was obtained from the Nippon Sanso Company, which guaranteed a purity better than 99.994%, as a carrier gas. The carrier gas was passed through a cylinder containing silica gel before it was admitted into the reaction vessel.

Procedure. A flow diagram of the apparatus is shown in Fig. 1. The reaction vessel was heated at temperatures from 70 to 90 °C with a precision of ±0.3 °C by mounting it in a thermostated aluminum block. The preheated carrier gas was made to flow, at specified flow rates, through about 3 g of the tetrasulfur tetranitride put on a glass filter in the reaction vessel. The accuracy of the specified flow rates,

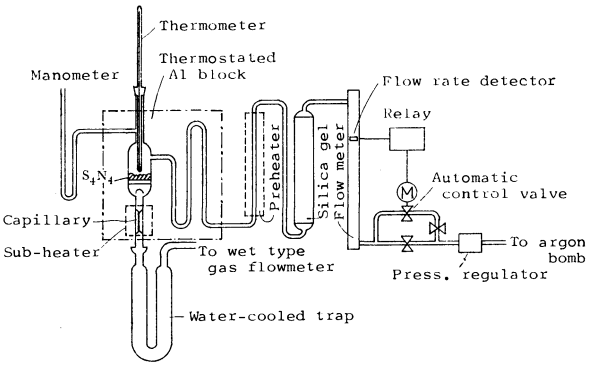

Fig. 1. Schematic diagram of apparatus.

obtained by using an automatic control valve model BM-N, the Nisshin Kagaku Company, and an argon bomb with a regulator, was of the order of 0.5%. The excessive pressure in the reaction vessel against the atmospheric pressure was measured with a manometer containing a Silicone oil with a low vapor pressure. The pressure control of the carrier gas was not carried out, because the maximum variation in the atmospheric pressure during the runs was 2.5 mmHg (corresponding to about 0.3%). The temperature of the flow gas in the reaction vessel was measured with a thermometer and was maintained within ±0.3 °C. The carrier gas containing the tetrasulfur tetranitride vapor was discharged through a capillary (2 cm in length and 0.1 cm in diameter) into a water-cooled trap. The capillary was heated at slightly higher temperatures than that of the reaction vessel to prevent a deposition of the tetrasulfur tetranitride on it. The total volume of the carrier gas was measured with an accuracy of ±0.4% by using a wet-type gas flowmeter, model WK-0.5, which can be read to an order of 1 ml (Shinagawa Seisakusho).

The small amount of the trapped tetrasulfur tetranitride was estimated from the optical absorbance of its benzene solution at 350 mμ by using a working curve previously

determined (the molar extinction coefficient at 350 mμ was 1057).

Results and Discussion

The melting point of the sample was determined microscopically to be 179 °C by using materials of known melting points as references. The value of the melting point for the tetrasulfur tetranitride which was prepared by the Jolly method was found to be 178—179 °C.[4] The IR spectrum[5] and the X-ray powder diffractogram[6] of the sample showed patterns attributable to tetrasulfur tetranitride only. Therefore, the sample obtained in this work was considered to be pure enough to measure the sublimation pressure of tetrasulfur tetranitride.

An abrupt weight loss and an exothermic change in the thermal gravimetric analysis and the differential thermal analysis on tetrasulfur tetranitride[6] occurred at temperatures above approximately 125 °C. These results were not affected by the presence of air. It is, then, considered that tetrasulfur tetranitride decomposes at temperatures higher than 125 °C. Therefore, the partial pressures of the sample were estimated in the temperature range from 70 to 90 °C.

Quantities of the argon sufficient to trap about 1 mg of the tetrasulfur tetranitride were used in all the runs; *i.e.*, they were in the ranges from 15.30 to 17.03 l (the passing times were from 160.0 to 600.0 min), from 9.274 to 10.99 l (from 105.0 to 510.0 min), from 5.712 to 7.632 l (from 70.0 to 420.0 min), from 3.442 to 5.151 l (from 45.0 to 180.0 min), and from 2.877 to 3.117 l (from 30.0 to 110.0 min) as the standard state at 70, 75, 80, 85, and 90 °C respectively, while the amounts of the trapped tetrasulfur tetranitride were estimated to be in the range from 0.899 to 1.30 mg. The tetrasulfur tetranitride deposited immediately on the neck of the trap as a fine powder after its vapor had passed through the thermostated aluminum block.

The partial pressure, p, of the tetrasulfur tetranitride at the specified temperature and flow rate was calculated by means of the following equation, being assumed to obey the law of partial pressures:

$$p = (P+p')/[1+(184.3/w)(P+p''-p_w)V/RT]$$

where P is the atmospheric pressure; p', the excessive pressure in the reaction vessel; p'', the excessive pressure in the gas flowmeter; p_w, the vapor pressure of water in the gas flowmeter; w, the weight of the trapped tetrasulfur tetranitride; V, the observed total volume of the carrier gas; T, the temperature of the carrier gas in the gas flowmeter, and R, the gas constant.

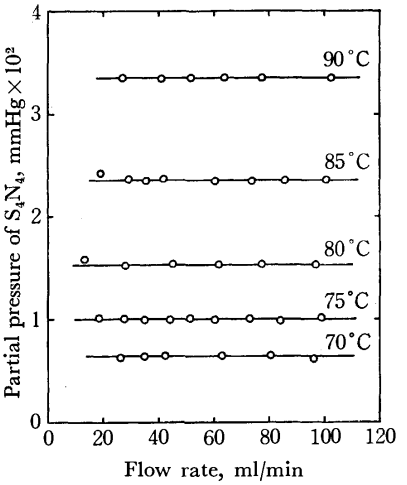

Fig. 2. Dependence of partial pressure of S_4N_4 on flow rate.

The relationship between the partial pressures and the flow rates, which were expressed as the standard states, is shown in Fig. 2. The values of the partial pressure were almost equal to each other at all the temperatures under those conditions except for those at the flow rates of 13.60 ml/min (80 °C) and 19.12 ml/min (85 °C), which were considered to arise from a diffusion[7] of the tetrasulfur tetranitride vapor. Therefore, the average values of the partial pressure can be accepted as those of the sublimation pressure of tetrasulfur tetranitride; they are shown in Table 1. No changes in the structure or chemical components of the sample remaining in the reaction vessel were found by X-ray powder diffraction analysis after the measurements.

Table 1. Sublimation pressures of tetrasulfur tetranitride

Temp., °C	Sublimation Press., mmHg
70	6.42×10^{-3}
75	1.00×10^{-2}
80	1.53×10^{-2}
85	2.35×10^{-2}
90	3.51×10^{-2}

The heat of the sublimation, ΔH^s, of tetrasulfur tetranitride in the temperature range from 70 to 90 °C was estimated to be 21.2 kcal/mol from the excellent linear relationship of the Clausius-Clapeyron plot. Although Barker *et al.*[8] deduced the heat of the sublimation of tetrasulfur tetranitride to be 15±5 kcal/mol from the results obtained by using a bomb calorimeter, the value estimated in this work is slightly larger than that obtained by Barker.

A Synthetic Approach to DL-α-(2-Thiazolyl)glycines

Minoru HATANAKA and Toshiyasu ISHIMARU

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka 565

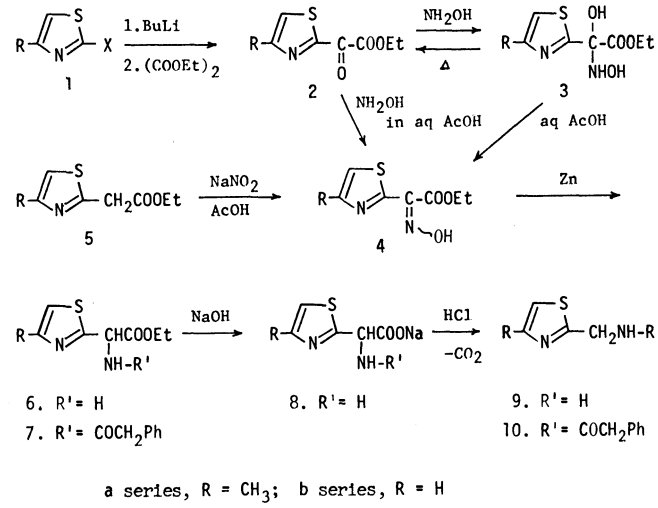
(Received January 26, 1973)

As a part of the investigation of the synthesis of the α-substituted glycine derivatives with heterocyclic rings,[1] the synthesis of 2-thiazolylglycine was studied. Since 2-thiazolylacetic acid has been reported to show a remarkable ease of decarboxylation,[2] we adopted a synthetic route *via* the amino acid esters, **6**. The unusual behavior of the 2-thiazolylglycines, which were decarboxylated too rapidly to be isolated, is the subject of this note.

The starting materials, ethyl 4-methylthiazole-2-glyoxalate (**2a**) and ethyl thiazole-2-glyoxalate (**2b**), were prepared from 4-methylthiazole (**1a**, R=CH_3, X=H) and 2-bromothiazole (**1b**, R=H, X=Br) respectively by lithiation, followed by the addition of the 2-lithio compounds to an excess of ethyl oxalate. The subsequent treatment of **2a** with hydroxylamine in aqueous methanol at 0 °C gave a crystalline product, **3a**, in a high yield; its empirical formula, $C_8H_{12}N_2O_4S$, corresponded to that of a monohydrate of the expected oxime. The IR spectrum, in addition to one carbonyl band at 1720 cm^{-1}, exhibited a very broad and strong band at 3150 cm^{-1}. Under the same conditions, **2b** yielded **3b** as a sirup; the IR spectrum of **3b** was similar to that of **3a**. Compounds **3a** and **3b**, when heated in refluxing benzene, regenerated the starting glyoxalates, **2a** and **2b** respectively, while upon treatment with aqueous acetic acid they gave the desired oximes, **4a** and **4b** respectively, which were mixtures of geometrical isomers, separable by column chromatography. These oximes were also formed when the reaction of **2a** and **2b** with hydroxylamine was carried out in aqueous acetic acid. From these results, it is evident that **3a** and **3b** are carbinolamine intermediates. Their having stability enough to permit isolation can be ascribed to the strong electron-withdrawing influence of both the carboxyl and the 2-thiazolyl moieties.[3]

The oxime, **4a**, was more conveniently prepared from ethyl 4-methylthiazole-2-acetate (**5a**) by isonitrosation with sodium nitrite in aqueous acetic acid at 0 °C. This reaction gave, stereoselectively, a single isomer in a high yield.

The reduction of **4a** with zinc dust in aqueous formic acid produced the amino acid ester, **6a** (*N*-phenylacetyl derivative **7a**; mp 80—81 °C). However, attempts to isolate the free amino acid after the alkaline



hydrolysis of **6a** failed. When the sodium salts, **8a**, were neutralized with hydrochloric acid at 0 °C, a vigorous evolution of CO_2 gas occurred to give the amine, **9a** (*N*-phenylacetyl derivative **10a**; mp 112—114 °C). Upon a similar treatment, the amino acid ester, **6b**, prepared by the reduction of **4b** with zinc dust, also furnished the amine, **9b** (*N*-phenylacetyl derivative **10b**; mp 102—104 °C). Figure 1 illustrates

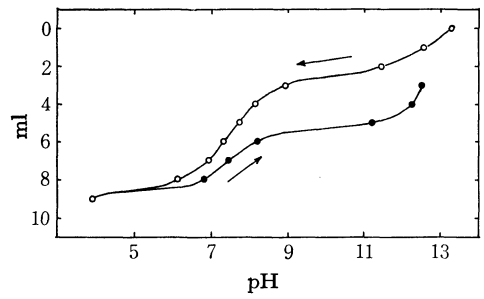


Fig. 1. Potentiometric titration of the sodium salt (**8a**) with 0.1 M hydrochloric acid (open circles) followed by a back titration with 0.1 M sodium hydroxide (filled circles).

the titration of **8a** with 0.1 M hydrochloric acid, followed by back titration with 0.1 M sodium hydroxide. The back-titration curve delineates the neutralization of the conjugate acid of the amine, **9a**. The amount of alkali required to neutralize the conjugate acid was almost equal to a half of that of acid needed for the initial titration, indicating that the decarboxylation takes place simultaneously with the transformation of the sodium salt to the free amino acid. The unusual instability of 2-thiazolylglycines is of interest in comparison with the 4- and 5-thiazolylglycines previously prepared by us;[1] the latter substances are stable and can be recrystallized from boiling water.

Similar differences have been found among thiazolylacetic acids; the activation energy of the decarboxyla-

1) M. Hatanaka and T. Ishimaru, *J. Med. Chem.*, **16**, 978 (1973).

2) H. Schenkel and R. Mory, *Helv. Chim. Acta*, **33**, 16 (1950).

3) In particular, the strong electron-withdrawing effect of the 2-thiazolyl moiety should be noted, for ethyl 3-methylisothiazole-5-glyoxalate was directly converted to the oxime by treatment with hydroxylamine under the same conditions as described for **3a** (see Ref. 1). Isolation of an analogous carbinolamine intermediate in the formation of 2-formyl-1-methylpyridinium iodide oxime has also been reported [E. J. Poziomek, D. N. Kramer, B. W. Fromm, and W. A. Mosher, *J. Org. Chem.*, **26**, 423 (1961)].

tion of 2-thiazolylacetic acid is much smaller than those for the 4- and 5-acetic acids.[2] Our finding indicates that the substitution of the amino group at the α-position of 2-thiazolylacetic acid makes the decarboxylation easier.

Experimental

Ethyl 4-Methylthiazole-2-glyoxalate (2a). A stirred solution of 4-methylthiazole (25.6 g, 0.259 mol) in dry ether (150 ml) was cooled at −70 °C in a Dry Ice-acetone bath, and then a 15% ethereal *n*-butyllithium solution (150 ml) was added at such a rate that the temperature was maintained below −65 °C. The cold mixture was then added through a glass tube to a stirred and cooled (−65 °C) solution of diethyl oxalate (58 g, 0.39 mol) in dry ether (200 ml). After an additional hour at −60 °C, 10% hydrochloric acid (260 ml) was added and the aqueous layer was neutralized with K_2CO_3 and extracted with ether. The evaporation of the ether, and distillation of the residue gave a yellow liquid (27.4 g, 53%); bp 106—107 °C/0.4 mmHg; IR (liquid film) 1740 (C=O) and 1700 (C=O) cm^{-1}; NMR ($CDCl_3$, TMS) δ 1.40 (*t*, 3H), 4.50 (*q*, 2H), 2.59 (*s*, 3H), and 7.38 (*s*, 1H).

Ethyl Thiazole-2-glyoxalate (2b). By a similar procedure, this was prepared from 2-bromothiazole (30 g, 0.183 mol); yield, 15.8 g (46.6%); bp 102—108 °C/0.6 mmHg; IR (liquid film) 1740 (C=O) and 1690 (C=O) cm^{-1}; NMR ($CDCl_3$, TMS) δ 1.42 (*t*, 3H), 4.44 (*q*, 2H), 7.92 (*d*, J=2.8 Hz, 1H), and 8.08 (*d*, J=2.8 Hz, 1H).

Ethyl α-Hydroxy-α-hydroxamino-4-methylthiazole-2-acetate (3a). A mixture of **2a** (6 g, 0.03 mol) and hydroxylamine hydrochloride (3.15 g, 0.045 mol) in methanol (15 ml) was cooled in an ice bath, and then a 2 M sodium hydroxide solution (17 ml) was slowly stirred in. After stirring for 6 h at 0 °C, the precipitate was collected by filtration; it yielded white crystals (5.2 g). An additional crop was obtained by the extraction of the filtrate with chloroform; total yield, 5.4 g (77.7%); mp 120—121 °C (from chloroform); IR (Nujol) 3150 (NH, OH) and 1720 (C=O) cm^{-1}. Found: C, 41.56; H, 5.22; N, 12.38%. Calcd for $C_8H_{12}N_2O_4S$: C, 41.37; H, 5.21; N, 12.06%.

Ethyl α-Oximino-4-methylthiazole-2-acetate (4a). A. From the Glyoxalate, 2a. A mixture of **2a** (2.6 g, 0.013 mol) and hydroxylamine hydrochloride (1.5 g, 0.0216 mol) in acetic acid (4 ml) was cooled in an ice bath, and then a 1 M sodium hydroxide solution (14 ml) was stirred in, drop by drop. After stirring overnight, the precipitate was collected by filtration. The pale yellow solid (2.43 g, 87%) thus obtained was chromatographed on silica gel. Elution with chloroform gave pale yellow prisms (1.5 g); mp 111—112 °C (from ether-petroleum ether); IR (KBr) 1709 (C=O)cm^{-1}. Found: C, 44.79; H, 4.74; N, 13.16%. Calcd for $C_8H_{10}N_2O_3S$: C, 44.85; H, 4.71; N, 13.08%.

Further elution with chloroform-methanol gave white needles (820 mg); mp 140—141 °C (from benzene-petroleum ether); IR (KBr) 1734 (C=O) cm^{-1}. Found: C, 44.99; H, 4.96; N, 13.04%. Calcd for $C_8H_{10}N_2O_3S$: C, 44.85; H, 4.71; N, 13.08%.

B. Isonitrosation of Ethyl 4-Methylthiazole-2-acetate (5a). Into an ice-cooled solution of **5a** (2.8 g, 0.015 mol) in acetic acid (4 ml), a solution of sodium nitrile (1.2 g, 0.0174 mol) in water (3 ml) was slowly stirred over a period of 30 min. After an additional 30 min, the mixture was diluted with water (10 ml) and then stirred for 2 h at 0 °C. The yellow precipitate was collected by filtration, washed with cold water, and dried *in vacuo*; yield, 2.3 g (71.2%). Recrystallization from ether-petroleum ether gave yellow prisms, which were identical with crystals (mp 111—112 °C) obtained by means of Method A (IR and NMR).

Ethyl α-Oximino-thiazole-2-acetate (4b). This was prepared from **2b** (1.85 g, 0.01 mol) according to the procedure (Method A) described for **4a**. The crude product was chromatographed on silica gel. Elution with chloroform gave pale yellow needles (537 mg); mp 58—59 °C (from ether-petroleum ether); IR (KBr) 1709 (C=O) cm^{-1}. Found: C, 42.33; H, 3.99; N, 14.19%. Calcd for $C_7H_8N_2O_3S$: C, 41.99; H, 4.02; N, 13.99%.

Further elution with chloroform-methanol gave white needles (139 mg); mp 121—122.5 °C (from ether-petroleum ether); IR (KBr) 1735 (C=O) cm^{-1}. Found: C, 42.07; H, 4.02; N, 14.20%. Calcd for $C_7H_8N_2O_3S$: C, 41.99; H, 4.02; N, 13.99%.

Ethyl α-Amino-4-methylthiazole-2-acetate (6a). Into an ice-cooled solution of **4a** (1.0 g, 4.66 mmol) in methanol (5 ml) and 40% formic acid (9 ml), zinc dust (1.0 g, 15.3 mmol) was stirred, portion by portion. The mixture was stirred at 5 °C for an additional 5 h, and then filtered. After the addition of 2 M hydrochloric acid (5 ml), the filtrate was evaporated *in vacuo*. The oily residue was dissolved in water (10 ml), neutralized with K_2CO_3, and extracted with chloroform. Drying (K_2CO_3) and evaporation of the chloroform *in vacuo* left 0.9 g of a pale-brown oil, pK_a 5.55 (in 50% ethanol), which showed one spot on tlc.

N-Phenylacetyl Derivative (7a). A solution of the crude **6a** (0.9 g) in chloroform (10 ml) was shaken with a 1 M sodium bicarbonate solution (20 ml), and then phenylacetyl chloride (900 mg, 5.8 mmol) was added gradually. After stirring for 24 h, the aqueous layer was extracted with chloroform. The combined organic layers were dried ($MgSO_4$) and evaporated *in vacuo*. The remaining sirup (1.5 g) was chromatographed on silica gel with chloroform to give **7a** as pale-brown crystals (1.2 g); mp 80—81 °C (from benzene); IR (Nujol) 3320 (NH), 1750 (C=O), and 1650 (CONH) cm^{-1}. Found: C, 60.59; H, 5.91; N, 8.66%. Calcd for $C_{16}H_{18}N_2O_3S$: C, 60.35; H, 5.70; N, 8.80%.

Hydrolysis of Ethyl α-Amino-4-methylthiazole-2-acetate (6a). Into an ice-cooled solution of the crude **6a** [prepared from **4a** (1.0 g, 4.66 mmol)] in methanol (20 ml), a 1 M sodium hydroxide solution (5.7 ml) was stirred, drop by drop. The mixture was stirred overnight at room temperature, and then evaporated *in vacuo*. The residue was dissolved in water (15 ml). The solution was washed with chloroform and cooled in an ice bath, and then 2 M hydrochloric acid was gradually added. When the pH of the solution reached 7, a vigorous gas evolution took place; stirring was continued at pH 6 for 30 min until the gas evolution ceased. The cold mixture was then washed with chloroform, saturated with K_2CO_3, and extracted with chloroform. The evaporation of the chloroform left the amine, **9a**, as a brown liquid.

This material was converted to the *N*-phenylacetyl derivative **10a** according to the procedure described for **7a**; yield, 0.6 g; mp 112—114 °C (from ether-petroleum ether); IR (Nujol) 3300 (NH) and 1650 (C=O) cm^{-1}. Found: C, 63.18; H, 5.61; N, 11.55%. Calcd or $C_{13}H_{14}N_2OS$: C, 63.38; H, 5.73; N, 11.37%.

Hydrolysis of Ethyl α-Amino-thiazole-2-acetate (6b). **6b**, prepared from **4b** (1.0 g, 5 mmol), was hydrolyzed in a manner similar to that described for **6a**. The resulting amine, **9b**, was converted to the *N*-phenylacetyl derivative, **10b** (yield, 540 mg); mp 102—104 °C (from benzene-petroleum ether); IR (Nujol) 3300 (NH) and 1640 (C=O) cm^{-1}. Found: C, 61.90; H, 5.06; N, 12.19%. Calcd for $C_{12}H_{12}N_2OS$: C, 62.04; H, 5.20; N, 12.05%.

Photochemical Behavior of 1,1-Diphenylethylene in Polychloroalkane Solvents: Preferential Abstraction of Chlorine Atom[1]

Kinjiro MATSUNAGA and Mituyosi KAWANISI*

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received February 16, 1973)

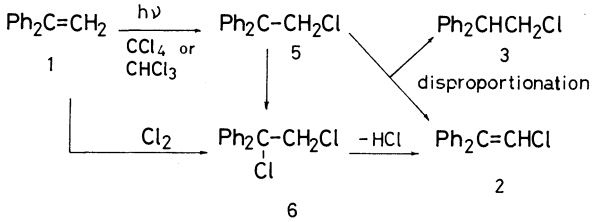
Kinetic evidence indicates that 1,1-diphenylethylene (**1**) in the triplet excited state behaves to some extent like a biradical species.[2] Irradiation of **1** induced abstraction of hydrogen atom from 2-propanol in a radical fashion.[3] We have investigated the photochemical reactions of **1** in several polychloroalkanes and chloroalkenes and found that the chlorine atom was abstracted by **1** in the triplet excited state.[4]

When a carbon tetrachloride solution of **1** was irradiated under nitrogen by means of a medium pressure mercury arc at room temperature for 140 hr, glc analysis of the reaction mixture showed the presence of two products. The residue of the distillation was chromatographed on a silica-gel column to give 2-chloro-1,1-diphenylethylene[5] (**2**) (92% based on the starting material consumed) and 2-chloro-1,1-diphenylethane[6] (**3**) (trace). Hydrogen chloride was found in the reaction mixture. The structures of the photoproducts were confirmed by direct comparison with authentic samples. It is of interest that no hexachloroethane which would result from trichloromethyl radical was detected in the reaction mixture.

Irradiation of a chloroform solution of **1** for 180 hr gave **2** (74%), **3** (trace), and HCl. Neither 1,1-diphenylethane (**4**) which is expected to be produced by hydrogen abstraction, nor products derived from trichloromethyl radical were found. Photolysis of a solution of **1** in dichloromethane for 180 hr gave **2** (6%), **3** (3%) together with only a trace amount of **4**. Photoreactions of **1** in 1,2-dichloroethane, *t*-butyl chloride, cyclohexyl chloride, and 3-chlorocyclohexene were sluggish, only a trace of **4** being detected in each reaction mixture even after prolonged irradiation. These facts suggest that the preferential mode of photochemical reaction of **1** in polychloroalkanes appears to be the abstraction of chlorine atom rather than that of hydrogen atom.

In chloroform molecule C–H bond fission usually occurs under radical reaction conditions[7] or by irradiation in nitrogen or argon matrix.[8] In the present investigation, however, only chlorine abstraction was observed. The cause is still open to discussion and the fate of the residual radical from the solvents remains unclarified.

In order to obtain information on the reactive excited species involved in the reaction between **1** and carbon tetrachloride, quenching and sensitization experiments were performed. Irradiation reaction (>330 nm) conducted in a Pyrex vessel was successfully sensitized by triphenylene, and the product distribution was not affected. The unsensitized reaction did not occur upon photolysis at this wavelength region. It was also found that the reaction could be quenched by the addition of piperylene. Since carbon tetrachloride itself absorbs light in this wavelength region[9] the possibility of the primary dissociation of the photoexcited carbon tetrachloride to give reactive species cannot be ruled out. Actually, however, light which passes a carbon tetrachloride filter induces the reaction. This indicates that at least the excited triplet state of **1** was involved in the photochemical reaction of **1** in carbon tetrachloride.



1 5 3 2 6

One might explain the formation of **2** and **3** by assuming intermediacy of radical species **5** which could undergo disproportionation and chlorine-abstraction (Scheme). Facile elimination of hydrogen chloride from a dichloroethane derivative (**6**) will give the final product **2** in a larger amount. An attempted chlorination of **2** by molecular chlorine[5] to obtain **6** resulted in the formation of **2** as the only isolable product. The result suggests the reaction pathway *via* **6** which, once formed, turns into **2** by ready loss of hydrogen chloride.

Experimental

All temperatures are uncorrected. Microanalyses were performed by Mrs. Kiyoko Fujimoto. The spectra were recorded in neat liquid films on a Shimadzu IR-27C spectrometer. The NMR spectra were determined on a JOEL C-60-H spectrometer using TMS as an internal standard and CCl_4 as solvent. The mass spectra were recorded with

a Hitachi RMS-4 mass spectrometer at 70 eV. The UV spectra were obtained in ethanol solutions on a Shimadzu MPS-50L spectrophotometer.

Reagents. 1,1-Diphenylethylene (**1**) was prepared by the method of Allen and Converse,[10] bp 143—145 °C/20 mmHg (lit,[10] bp 156 °C/25 mmHg). Carbon tetrachloride,[11] chloroform,[12] dichloromethane,[13] 1,2-dichloroethane,[14] *t*-butyl chloride,[15] cyclohexyl chloride,[16] and 3-chlorocyclohexene[17] were prepared and/or purified by published methods.

General Irradiation Procedure. After a solution of **1** (0.035 M) in the solvents was bubbled with commercial nitrogen for 1 hr, it was irradiated in a quartz tube by a Haros PIH-300 medium pressure mercury arc at room temperature for specified periods. The progress of the photoreaction was monitored by glc. After irradiation the solution was washed with an aqueous NaOH solution, the latter being then titrated with an aqueous HCl solution. The excess solvent was distilled off and the distillate was carefully checked by glc to scrutinize low boiling materials. The residue was chromatographed on silica gel to give the starting material, 2-chloro-1,1-diphenylethylene (**2**),[5] 2-chloro-1,1-diphenylethane (**3**),[6] and 1,1-diphenylethane (**4**)[18] which were further purified by glc to obtain analytical samples.

Sensitization with Triphenylene. A solution of **1** (36 mg, 0.2 mmol) in carbon tetrachloride (10 ml) was divided into two equal portions after bubbling with nitrogen. Triphenylene (23 mg, 0.1 mmol) was added to one portion, and the two solutions were irradiated (>330 nm) in Pyrex tubes through a filter of NaBr–$Hg(NO_3)_2$ solution[19] for 40 hr. The progress of the reaction was monitored by glc. The reaction with added triphenylene proceeded to almost 100% completion, whereas the unsensitized reaction showed the formation of only traces of the products.

Quenching with Piperylene. A solution of **1** (90 mg, 0.5 mmol) in carbon tetrachloride (10 ml) was divided into two equal portions after bubbling with nitrogen. Piperylene (170 mg, 2.5 mmol) was added to one portion and the two solutions were irradiated in quartz vessels with a medium pressure mercury arc for several hours. Glc monitoring of the progress of the reaction showed that the unquenched reaction was about 8 times as rapid as the quenched one.

Our thanks are due to Professor Hitosi Nozaki for his help and encouragment.

Chlorinated 2,3′-Dithienyls. The By-products Formed in the Coupling of Thiophene with Sulfuryl Chloride and Iron Powder[1,2]

Tyo Sone and Yukio Abe

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received March 28, 1973)

The reaction of thiophene with sulfuryl chloride has been known to give chlorothiophenes. In the presence of iron powder or a Friedel-Crafts-type catalyst, however, the reaction affords the chlorinated 2,2′-dithienyls (**1b—e**) as the main product.[2] In addition to **1b—e**, the product has been shown by vapor-phase chromatography (vpc) to contain 10—20% of unidentified materials, in which one component (**2c**) predominates. Although there have been several papers concerning the coupling of aromatic nuclei, little has been known about that of thiophene nuclei. The present work was undertaken in order to isolate and identify the by-products and to obtain information concerning the coupling of thiophene nuclei.

The crystalline product was sublimed repeatedly under reduced pressure, and the more volatile part was submitted to fractional recrystallization from petroleum ether. Compound **2c** (mp 53—54 °C), isolated from the more soluble part, seems to be 2′,5-dichloro-2,3′-dithienyl, judging from its UV and NMR spectral data and elemental analysis. Thus, the observed maximum (298 nm) of the UV absorption is a little lower than that of 2,2′-dithienyl (**1a**) itself and is rather similar to that of 2,3′-dithienyl (**2a**), while in the NMR spectrum, the coupling constants of two sets of double-doublets (J=3.9 and 5.9 Hz) in the ring-proton region and the relative peak intensities indicate the presence of both one 2,3-di-, and one 2,5-disubstituted thiophene rings in **2c**.[3] The assignment was finally confirmed by comparison with the authentic sample prepared by the chlorination of **2a**. The presence of 2′-chloro- (**2b**), and 2′,3,5-trichloro-2,3′-dithienyls (**2d**) as minor products was also detected by vpc. Some representative results of the coupling reaction are shown in Table 1. It is worth noting that considerable amounts of 2,3′-dithienyl derivatives are formed in the coupling of the thiophene nuclei, the

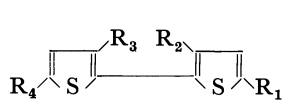
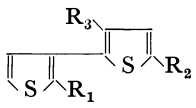
a) Reaction conditions: Dithienyl, 5 mmol in carbon tetrachloride (5 ml); 30 min at room temperature and additional 30 min at the boiling point of the reaction mixture.
b) Based on the dithienyl used.
c) Figures in the parentheses represent the yields obtained by the addition of ferric chloride (0.2 g, 1.233 mmol) in the reaction. In the presence of ferric chloride, the reactions are usually accompanied with the formation of a resinous material.
d) Besides **2b—d**, a small amount of higher chlorinated products were formed, when the reaction was carried out in the presence of ferric chloride.

proportion of 2,3′- to 2,2′-dithienyl derivatives being of the order of about 1 to 4.

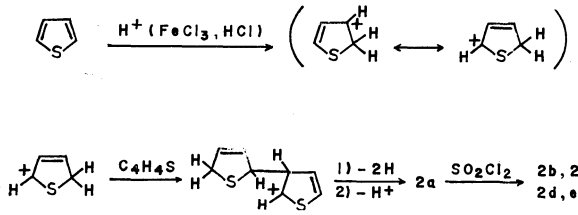




1a: $R_1=R_2=R_3=R_4=H$ **2a**: $R_1=R_2=R_3=H$
1b: $R_1=Cl$, $R_2=R_3=R_4=H$ **2b**: $R_1=Cl$, $R_2=R_3=H$
1c: $R_1=R_4=Cl$, $R_2=R_3=H$ **2c**: $R_1=R_2=Cl$, $R_3=H$
1d: $R_1=R_2=R_4=Cl$, $R_3=H$ **2d**: $R_1=R_2=R_3=Cl$
1e: $R_1=R_2=R_3=R_4=Cl$

In order to prepare authentic samples and to seek explanation for the formation of the chlorinated dithienyls, a brief study of the chlorination of **1a** and **2a** with sulfuryl chloride was carried out (Table 2); the chlorination occurs preferentially at the 5-position of **1a** and the 2′-position of **2a**, and successively at the 5′-, the 3-, and the 3′-positions for **1a**, and at the 5-, and the 3-positions for **2a**. The results are of interest, as only a little has been known concerning the substitution reactions of dithienyls, particularly those of **2a**. The reaction is promoted by the presence of ferric chloride to give the polychlorinated dithienyls in a higher proportion and a resinous material to some extent; the normal course of the chlorination is essentially unaltered.

In the previous paper, it was suggested that **1b—e** were formed by the coupling of the thiophene nuclei *via* a cationic mechanism, the reaction being initiated by the protonation of thiophene, followed by the chlorination of the resulting **1a**.[4] Taking into account the appreciable 3-substitution in certain electrophilic alkylations of thiophene and the results of the chlorination of **2a**, the formation of **2b—d** may be explained by the same mechanism, as is shown in Scheme 1.

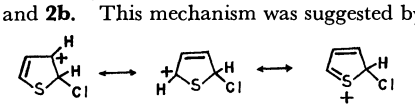


Experimental[5]

Isolation of 2′,5-Dichloro-2,3′-dithienyl (2c) from the Coupling Proauct. The crystalline coupling product[2] (60 g) was sublimed repeatedly under reduced pressure (110—130 °C/2—4 mmHg; the more volatile part (15 g) was then triturated with cold petroleum ether. The solvent was evaporated from the washings, and the residue was treated several times in a similar manner and finally recrystallized from the same solvent to give crude **2c** (2 g), which was subsequently purified by column chromatography on silica gel, using petroleum ether as the eluant; colorless needles, mp 53—54 °C. UV (MeOH) λ_{max} nm (log ε): 298 (4.25), 249 (4.10). NMR (Me_2CO) δ: 7.06 (d, J=3.9 Hz, 4-H), 7.38 (d, J=3.9 Hz, 3-H), 7.30 (d, J=5.9 Hz, 4′-H), 7.47 (d, J=5.9 Hz, 5′-H). Found: C, 40.92; H, 2.10%. Calcd for $C_8H_4Cl_2S_2$: C, 40.85; H, 1.71%.

Chlorination of 2,2′- (1a) and 2,3′-Dithienyls (2a). a) General Procedure. Sulfuryl chloride was added to a stirred solution of the dithienyl (0.84 g, 5 mmol) in carbon

4) Another possibility is the intermediary formation of the carbonium ions, **3a—c**, from thiophene through a reaction with the chlorinium ion, which attacks the 2-position of a thiophene molecule, followed by dehydrogenation and by the loss of a proton to yield **1b** and **2b**. This mechanism was suggested by the referee.



3a 3b 3c

5) All the melting and boiling points are uncorrected. The UV spectra were obtained on a Hitachi EPU-2A spectrophotometer, and the NMR spectra, on a Hitachi R-20A spectrometer, at 60 MHz, using tetramethylsilane as the internal reference.

tetrachloride (5 ml), and then the reaction mixture was stirred for 30 min. After being stirred for an additional 30 min at the boiling point, the mixture was poured into ice water (30 g) and extracted with carbon tetrachloride (30 ml). The organic layer was washed with a dilute sodium bicarbonate solution and then with water, and dried. The solvent was evaporated, and the residue was analyzed by vpc as has been described previously.[2] The reactions in the presence of anhydrous ferric chloride (0.2 g, 1.233 mmol) were carried out in a similar manner. The results are given in Table 2.

b) 2',5-Dichloro-2,3'-dithienyl (2c). The product (2.0 g) obtained by the reaction of **2a** (1.7 g, 0.01 mol) with two molar equivalents of sulfuryl chloride (2.7 g) was recrystallized twice from light petroleum ether to give **2c** (mp 53—54 °C, 0.6 g). This compound was proved to be identical with the **2c** isolated from the coupling product by a comparison of their IR and UV spectra and by a mixed-melting-point determination.

c) 2'-Chloro-2,3'-dithienyl (2b). A solution of sodium acetate trihydrate (67 g) in water (100 ml) was added to the mixture (5 g) of **2b** and **2c** in ethanol (380 ml) which had been obtained by the reaction of **2a** with two molar equivalents of sulfuryl chloride; to the resulting solution was then added a saturated solution of mercuric chloride (200 ml). The reaction mixture was allowed to stand for 3 days, after which the precipitates (3.4 g) were filtered off and recrystallized from chloroform to yield the chloromercury derivative of **2b** (2.3 g, mp 210—250 °C). The mercury derivative was heated with a mixture of hydrochloric acid (15 ml) and water (30 ml) on a water bath for 30 min, and the oil (1.0 g) thus separated out was extracted with chloroform. The extract was washed with a sodium bicarbonate solution and then with water, and dried. The solvent was evaporated and the residue distilled to afford **2b** (0.8 g); bp 103—104 °C/4 mmHg, n_D^{20} 1.6625. UV (MeOH) λ_{max} nm (log ε): 287 (4.14), 244 (4.10). NMR (Me_2CO) δ: 7.13 (q, J=3.7 Hz, J=5.0 Hz, 4-H), 7.51 (q, J=5.0 Hz, J=1.1 Hz, 5-H), 7.53 (q, J=3.7 Hz, J=1.1 Hz, 3-H), 7.31 (d, J=5.9 Hz, 4'-H), 7.42 (d, J=5.9 Hz, 5'-H).[6] Found: C, 48.06; H, 2.26%. Calcd for $C_8H_5ClS_2$: C, 47.87; H, 2.51%.

d) 2',3,5-Trichloro-2,3'-dithienyl (2d).[7] The further chlorination of a mixture of **2b** and **2c** with a large excess of sulfuryl chloride (6 times by weight) in carbon tetrachloride gave **2d**; colorless crystals; mp 77—78 °C (from petroleum ether). UV (MeOH) λ_{max} nm (log ε): 278 (4.05), 249 (4.10). NMR (Me_2CO-d_6) δ: 7.11 (s, 4-H), 7.21 (d, J=5.7 Hz, 4'-H), 7.50 (d, J=5.7 Hz, 5'-H). Found: C, 35.87; H, 0.82%. Calcd for $C_4H_3Cl_3S_2$: C, 35.63; H, 1.12%.

The authors wish to express their thanks to Mr. Kunimi Fujieda of the Naka Works, Hitachi, Ltd., for his NMR spectral measurements and to Mr. Kenji Abe for his assistance in the experiments.

6) The spectrum was analyzed by Professor Kensuke Takahashi (Nagoya Institute of Technology), to whom the authors are indebted.

7) It is interesting to note that, unlike the chlorination, the tribromination of **2a** with *N*-bromosuccinimide has been reported to give the 2',5,5'-trisubstituted derivative.[8]

Thermal and Photochemical Decompositions of 4,5,6,7-Tetrahydro-1,2,3-benzotriazole Analogues

Kazuo TSUJIMOTO, Mamoru OHASHI, and Teijro YONEZAWA*

Department of Materials Science, The University of Electro-Communications, Chofu, Tokyo 182
**Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606*

(Received May 17, 1973)

In our previous paper[1] we reported that the photolysis of various benzotriazoles gave products different from those of the thermal decompositions. Burgess and his co-workers have observed that both the thermal and photochemical decompositions of monocyclic 1,2,3-triazoles give 1,3-biradical intermediates which undergo the Wolff rearrangement to give the same ketenimine.[2] We wish now to report that the thermolysis and photolysis of 4,5,6,7-tetrahydro-1,2,3-benzotriazole analogues give the cyclized and the ring-contracted products in different ratios.

Results and Discussion

In the thermolysis of 1-phenyl-4,5,6,7-tetrahydrobenzotriazole (I), a preparative flash thermolysis apparatus was used at a pressure below 0.01 mmHg; the vapor of I was passed through a quatrz tube (10 mm diam.) at 590—630 °C. The thermolyzed mixture collected in a trap cooled by liquid nitrogen was column-chromatographed on silica gel to give 1,2,3,4-tetrahydrocarbazole (II) and cyclopentanecarboxanilide (III) in yields of 17 and 20% respectively.

The ring-contracted product (III) must be formed through a ketenimine (IV), followed by the addition of water in the course of separation. When the reaction was carried out in an atmosphere of dry nitrogen, the reaction mixture showed an IR absorption[3] at 2020 cm^{-1}. The intensity of the absorption decreased when the mixture was allowed to stand in the air for several minutes. This fact suggests that the ketenimine (IV) must be present as an intermediate.

Similarly, the thermolysis of 1-phenyl-4,5,6,7-tetrahydrocyclohepta[*d*]-1,2,3-triazole (V) gave an indole

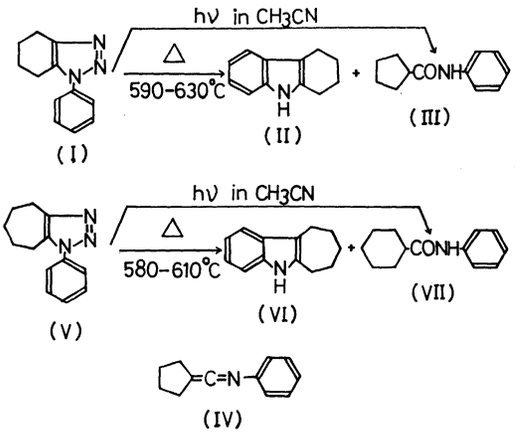
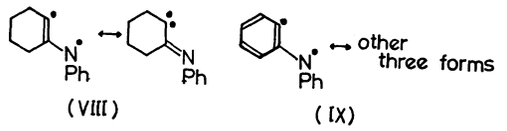
derivative (VI) and cyclohexanecarboxanilide (VII) in yields of 25 and 29% respectively. Again, the strong absorption at 2000 cm^{-1} in the IR spectrum of the reaction mixture suggested the presence of the ketenimine intermediate.



On the other hand, the photolysis of I in acetonitrile by means of a low-pressure mercury arc gave III as the major product (62% yield), along with a trace amount of II (less than 5%). The irradiation of a solution of I in benzene also gave III in a 25% yield, but no cyclized product was obtained. Similarly, the irradiation of V in acetonitrile afforded VII as the major product. From these results it became clear that the photolyses of 4,5,6,7-tetrahydro-1,2,3-benzotriazole analogues produce mainly their corresponding ring-contracted products, while their thermolyses give both the cyclized and the ring-contracted products in nearly the same yield. These results imply that the thermally- and the photochemically-generated intermediates have either (i) a different electronic configuration from each other or (ii) the same configuration giving different products in the succeeding dark reactions depending on the reaction environment. Such a behavior as (ii) is frequently observed in the photo-induced decarbonylation of carbonyl compounds.[4] Since, as was demonstrated in our previous paper,[1] the electronic configuration of a 1,3-biradical intermediate such as IX is sensitive to the environment, at this stage we can not judge which one of these two cases has actually occurred in the reactions.



The thermolysis[5] and the photolysis[2] of 1-phenyl-1,2,3-benzotriazole give the same cyclized product quantitatively. The difference in the behavior of the intermediates, VIII and IX, can be explained in terms of the reactivity of the carbene-like character for the Wolff rearrangement;[6] the reactivity of IX is smaller because of the delocalization of the unpaired π-electron on the nitrogen.

Experimental

All the melting points were determined on a micro hot stage and are not corrected. The IR and mass spectra were measured using a Hitachi Model 215 grating spectometer and a double-focussing mass spectrometer (Model JMS-01SG) respectively. The NMR spectra were obtained on a Varian HR-220 spectrometer, using TMS as the internal standard. The starting materials, I and V, were prepared by means of Fusco's method.[7] The pure samples of both I and V were obtained by crystallization from ligroin. A quartz tube (10 mm diam.) was used for the preparative flash vacuum thermolysis at a pressure below 0.01 mmHg and at a temperature of about 600 °C.

1-Phenyl-4,5,6,7-tetrahydrobenzotriazole (I): mp 116.0—116.5 °C (lit: 116 °C)[7].

1-Phenyl-4,5,6,7-tetrahydrocyclohepta[d]-*1,2,3-triazole (V)*: mp 115.8—116.1 °C (lit: 113 °C)[7].

Thermolysis of 1-Phenyl-4,5,6,7-tetrahydrobenzotriazole (I): I (122 mg) was thermolyzed at 590—630 °C (below 0.01 mmHg). The pyrolyte (90 mg) was column-chromatographed on silica gel (20 g, Mallinckrodt, AR-100, 100 mesh). Elution with dichloromethane gave II(17 mg), a tarry material(4 mg), and III(22 mg). II was identified as tetrahydrocarbazole by a comparison of its IR spectrum with that of an authentic specimen. The mixed melting point of these compounds showed no depression. III was a solid which had an mp of 159—160 °C (lit: 159—160 °C)[7]: M^+: 189.117 (calculated for $C_{12}H_{15}NO$ 189.115); NMR ($CDCl_3$) δ 1.5—2.0 (8H, m), 2.68 (1H, quintet, J=1.5 Hz), 4.84 (1H, br. s) and 7.1—7.6 (5H, m) ppm; IR (KBr) 3200 (ν NH), 1650 (amide ν C=O), 1540 (δ NH) and 750 (phenyl ring) cm^{-1}. Cyclopentanecarboxanilide was prepared from cyclopentanecarboxylic acid chloride and aniline. Its IR spectrum coincided with that of III. The mixed melting point showed no depression.

Thermolysis of 1-Phenyl-4,5,6,7-tetrahydrocyclohepta[d]-*1,2,3-triazole (V)*. V (123 mg) was thermolyzed at 580—610 °C as has been described above. The reaction mixture (90 mg) was column-chromatographed on silica gel, 7 g (Mallinckrodt, AR-100, 100 mesh). Elution with dichloromethane then gave VI(23 mg), VII(32 mg), and 27 mg of a tarry material. VI was identified as 5,6,7,8,9,10-hexahydrocyclohepta[*d*] indole on the basis of the following information: M^+: 185.116 (185.120 calculated for $C_{13}H_{15}N$); IR (KBr) 3400 (ν NH), 740 (phenyl ring) cm^{-1}; NMR ($CDCl_3$) δ 1.68—1.93 (6H, m), 2.80 (4H, s), 7.05—7.50 (4H, m) and 7.68 (1H, br. s) ppm. VII had an mp of 145.5—146.3 °C after recrystallization from ligroin. The spectral data are shown below: M^+: 203.127 (203.131 calculated for $C_{13}H_{17}NO$); IR (KBr) 3320 (ν NH), 1660 (ν C=O) and 730 (phenyl ring) cm^{-1}. The IR spectrum of VII coincided with that of cyclohexanecarboxanilide, which had been synthesized by the reaction of cyclohexanecarboxylic acid chloride with aniline.

Photolysis of 1-Phenyl-4,5,6,7-tetrahydrobenzotriazole (I) in Acetonitrile. A solution of I (123 mg) in 80 ml of purified acetonitrile was irradiated by means of a 5-W low-pressure

mercury arc lamp for 2 hr. After the removal of the solvent, the reaction mixture was column-chromatographed on silica gel. Elution with dichloromethane gave 17 mg of III, and further elution with ethyl acetate gave 94 mg of the unreacted material. III was identified as cyclopentanecarboxanilide by the method which has been described above.

Photolysis of 1-Phenyl-4,5,6,7-tetrahydrobenzotriazole (I) in Benzene. A solution of I (198 mg) in benzene (80 ml) was irradiated with a 100-W high-pressure mercury arc lamp for 10 hr. After the solvent had then been removed *in vacuo*, the residue was column-chromatographed on silica gel. Elution with dichloromethane gave 22 mg of III. The starting material (100 mg) was recovered by elution with ethyl ether. The tarry materials were not identified. A gas chromatograph of the reaction products did not exhibit the presence of tetrahydrocarbazole.

Photolysis of 1-Phenyl-4,5,6,7-tetrahydrocyclohepta[d]-*1,2,3-triazole (V) in Acetonitrile.* An acetonitrile solution (80 ml) of 122 mg of V was irradiated with a 5-W low-pressure mercury arc lamp for 3 hr under a stream of nitrogen gas. After the solvent had then been removed *in vacuo*, the reaction mixture was column-chromatographed on silica gel. Elution with dichloromethane gave 2 mg of an unidentified material, 22 mg of VII, 54 mg of the starting material, and 38 mg of a tarry product. The VII was identified as cyclohexane carboxanilide by a comparison of its spectrum with that of an authentic specimen which had been prepared by the reaction of cyclohexanecarboxylic acid chloride with aniline.

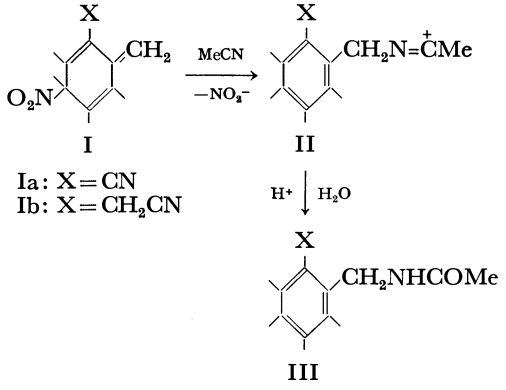
Nitration of Polyalkylbenzenes in Acetonitrile. Another View on Side-chain Acetamidation[1]

Hitomi SUZUKI and Terukiyo HANAFUSA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

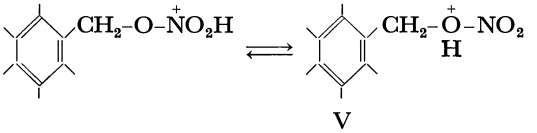
(Received May 21, 1973)

Nitration of polyalkylbenzenes in acetonitrile is known to give *N*-benzylacetamides in a good yield. The reaction was explained to proceed through the nucleophilic attack by the solvent on the nitro-methylenecyclohexadiene intermediate (I) followed by the release of a nitrite ion to give the carbonium ion (II), which was hydrolyzed to give *N*-benzylacetamide (III).[2]



In inert solvents such as dichloromethane and chloroform, the major process was the side-chain nitrooxylation, for which we have proposed a mechanism involving the rearrangement of nitro-methylenecyclohexadiene to benzyl nitrite.[3] In view of the high potency of polyalkylbenzylic compounds,[4] especially benzyl nitrite, to act as a benzylating agent in the presence of an acid catalyst, the possibility that the *N*-benzylacetamides are derived from the reaction of the initially formed benzyl nitrite with acetonitrile cannot be ruled out.

Hexamethylbenzene was nitrated with excess fuming nitric acid (d=1.5) in acetonitrile at 0—10 °C to give *N*-(pentamethylbenzyl)acetamide (IV) as the major product. Yields based on the unrecovered hydrocarbon often exceeded 50%. When pentamethylbenzyl nitrite was similarly treated in the same solvent, the product was a mixture of IV, pentamethylbenzyl nitrate, pentamethylphenylnitromethane, and 1,2-bis(nitrooxymethyl)-3,4,5,6-tetramethylbenzene in the approximate ratio 3:3:1:2. Formation of IV can be rationalized by assuming that the nucleophilic attack of the solvent upon the benzylic carbon atom of the conjugate acid (V) produces an imino-carbonium ion type intermediate (II; X=Me).



V

On treatment with excess fuming nitric acid in dichloromethane at room temperature, pentamethylbenzonitrile gave 1-cyano-2-nitrooxymethyl-3,4,5,6-tetramethylbenzene (VI) in 85% yield. Similarly, pentamethylbenzyl cyanide readily gave 1-cyanomethyl-2-nitrooxymethyl-3,4,5,6-tetramethylbenzene (VII) in 62% yield. The structures of VI and VII were determined by their conversion into 4,5,6,7-tetramethylphthalide (VIII) and 1,2-bis(cyanomethyl)-3,4,5,6-tetramethylbenzene (IX), respectively. Acid-catalyzed hydrolysis of VII yielded 5,6,7,8-tetramethyl-1,4-dihydro-3*H*-2-benzopyran-3-one (X), and the structure was deduced from the elemental analysis and spectral data.

The initial attack by nitronium ion on these compounds should occur at an aromatic carbon atom at 3-position, since the benzenium ion intermediates can be most effectively stabilized by three methyl groups. The nitro-methylenecyclohexadienes Ia and Ib should then be formed, and should be subject to some intramolecular interaction between the neighboring cyano and methylene groups, according to the reaction squence proposed.[2] The present results were contrary to this; the cyano group remained intact.

Benzyl nitrites are readily hydrolyzed to the corresponding benzyl alcohols. In organic mediums containing nitrite or acetate ions, they can be partly converted into phenylnitromethanes and benzyl acetates, respectively. Nitration of hexamethylbenzene with fuming nitric acid in acetic anhydride gives a mixture of varying amounts, depending on the conditions employed, of pentamethylbenzyl nitrate, pentamethylphenylnitromethane, and pentamethylbenzyl acetate. The latter two compounds can arise either from the anion-exchange of the benzylic intermediate-nitrite ion pair, or from the nucleophilic displacement on the benzylic carbon atom of the conjugate acid (V). These findings seem to favor our view that the side-chain acetamidation products arise from the reaction of the initially formed benzyl nitrite with the solvent rather than that proposed by previous workers.[2]

Experimental

All melting points are uncorrected. ^1H NMR spectra were determined in deuteriochloroform on a Varian T-60 spectrometer using TMS as an internal standard. IR spectra were recorded in Nujol on a Perkin-Elmer Model 137 spectrophotometer, only prominent peaks being given. Pentamethylbenzonitrile was prepared by heating iodopentamethylbenzene with cuprous cyanide in hexamethylphosphoric triamide. Pentamethylbenzyl cyanide and pentamethylbenzyl nitrite were prepared by treating the corresponding chloride with sodium cyanide and silver nitrite, respectively, in acetonitrile.

N-(Pentamethylbenzyl)acetamide (IV). A mixture of hexamethylbenzene (4.1 g) and acetonitrile (30 ml) was cooled in an ice-bath, fuming nitric acid ($d=1.5$; 8.4 g) being added with vigorous stirring over a period of 30 min. After the mixture was left to stand for several hours at room temperature, it was poured into water, and the precipitated solid was filtered off, washed with cold carbon tetrachloride, and crystallized from ethanol to give amide as fine white needles, mp 229—231 °C. Yields based on unrecovered hydrocarbon ranged from 28 to 60%. *m/e* 219 (M^+); NMR: 8.03 (s, 3H), 7.77 (s, 6H), 7.74 (s, 9H), 5.52 (d, 2H), and *ca.* 4.7 τ (broad, 1H); IR: 593, 1059, 1272, 1349, 1535, 1642, and 3300 cm^{-1}. Found: C, 76.52; H, 9.63%. Calcd for $C_{14}H_{21}NO$: C, 76.67; H, 9.65%.

1-Cyano-2-nitrooxymethyl-3,4,5,6-tetramethylbenzene (VI). Fuming nitric acid ($d=1.5$; 6.3 g) was added dropwise to a magnetically stirred solution of pentamethylbenzonitrile (1.73 g) in dichloromethane (15 ml) at 0—5 °C over a period of 30 min. The solution rapidly turned yellow, the color being intensified to dark brown. After the addition, the mixture was left to stand at room temperature for 5 hr, and then diluted with water. The organic layer was taken up, thoroughly washed with water and dilute aqueous sodium hydrogen carbonate, and evaporated to give a light brown pasty cake (*ca.* 2.3 g) which, on crystallization from a mixture of dichloromethane and light petroleum, yielded nitrate as colorless fine needles (1.98 g; 85%), mp 85—86 °C. NMR: 7.70 (s, 6H), 7.69 (s, 3H), 7.49 (s, 3H), and 4.29 τ (s, 2H); IR: 705, 858, 870, 970, 1281, 1638, and 2218 cm^{-1}.

Found: C, 61.57; H, 6.08; N, 11.66%. Calcd for $C_{12}H_{14}N_2O_3$: C, 61.53; H, 6.02; N, 11.96%.

VI was heated under gentle reflux with hydrochloric acid in ethanol to give *4,5,6,7-tetramethylphthalide (VIII)*, identical with the authentic sample obtained from the zinc chloride-catalyzed condensation of chloromethyl methyl ether with 2,3,4,5-tetramethylbenzoic acid. Mp 233—235 °C. NMR: 7.78 (s, 3H), 7.72 (s, 3H), 7.70 (s, 3H), 7.37 (s, 3H), and 4.91 τ (s, 2H); IR: 780, 966, 1016, 1126, 1264, 1297, 1350, and 1741 cm^{-1}. Found: C, 75.66; H, 7.38%. Calcd for $C_{12}H_{14}O$: C, 75.76; H, 7.42%.

1-Cyanomethyl-2-nitrooxymethyl-3,4,5,6-tetramethylbenzene (VII). Pentamethylbenzyl cyanide was similarly treated with the nitrating agent to give VII as fine needles, mp 116—118 °C. NMR: 7.75 (s, 6H), 7.67 (s, 6H), 6.26 (s, 2H), and 4.37 τ (s, 2H); IR: 702, 870, 957, 1283, 1296, 1629, and 2248 cm^{-1}.

Found: C, 62.54; H, 6.70; N, 11.44%. Calcd for $C_{13}H_{16}N_2O_3$: C, 62.89; H, 6.50; N, 11.28%.

VII was agitated with saturated aqueous sodium cyanide in acetonitrile to give *1,2-bis(cyanomethyl)-3,4,5,6-tetramethylbenzene (IX)*, mp 178—179 °C, identical with the compound obtained by the action of sodium cyanide on 1,2-bis(chloromethyl)-3,4,5,6-tetramethylbenzene. NMR: 7.75 (s, 6H), 7.69 (s, 6H), and 6.28 τ (s, 4H); IR: 801, 1068, 1286, 1302, and 2245 cm^{-1}. Found: C, 79.43; H, 7.50; N, 12.87%. Calcd for $C_{14}H_{16}N_2$: C, 79.21; H, 7.60; N, 13.19%.

VII was heated with a mixture of hydrochloric acid and ethanol to give white needles of formula $C_{13}H_{16}O_2$, which exhibited ^1H NMR peaks at 7.78 (s, 6H), 7.75 (s, 6H), 6.32 (s, 2H), and 4.63 τ (s, 2H); IR bands at 1026, 1226, 1261, and 1743 cm^{-1}. On heating with dilute sodium hydroxide it went into solution and was again precipitated on acidification. From the mode of reaction and spectral data, it was formulated as *5,6,7,8-tetramethyl-1,4-dihydro-3H-2-benzopyran-3-one (X).* Found: C, 76.14; H, 7.83%. Calcd for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90%.

Pyrrolizidine Alkaloids: The Synthesis and Stereochemistry of α- and β-Retusanecic Acids

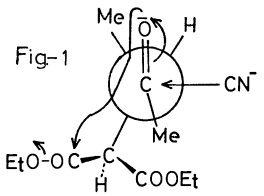
Shun'ichi KIYOOKA* and Tsunao HASE

Department of Chemistry, Faculty of Science, Kagoshima University, Kamoike, Kagoshima 890

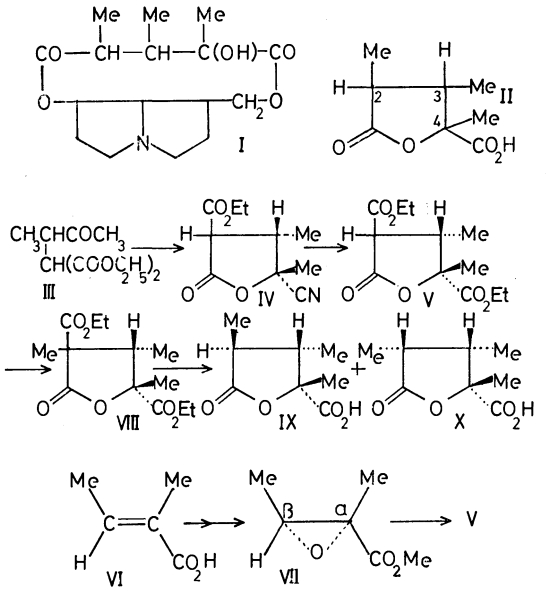
(Received May 28, 1973)

Retusine (I) was isolated from *Crotalaria retusa* L. by Culvenor and Smith,[1] the alkaline hydrolysis of I gave two acids, named α- and β-retusanecic acids. These acids agreed with the epimeric 2,3,4-trimethyl-4-hydroxyglutaric acid 1,4-lactones synthesized by Adams and Hauseman.[2] They have shown that the isomeric acids differ in the configuration of the carbon (C_2) alpha to the lactone and that the interconversion between α- and β-acids caused by refluxing with concentrated hydrochloric acid proceeds to an equilibrium wherein the β-acid predominates. Since the β-acid is thermodynamically more stable than the α-acid, the *trans*-cofiguration of the C_2–CH_3 group relative to the C_3–CH_3 group in the β-acid can be presumed. However, they have not referred to the relation between two methyl groups at C_3 and C_4. This note will discuss the new synthesis of α- and β-retusanecic acids and their stereochemistry. III was chosen as the starting material because an active hydrogen of the malonyl group would be available for alkylation after a ring-closure reaction. Cyano-lactone (IV) was obtained as the only product by the addition of HCN to the keto-ester (III). Moreover, IV was converted to the ester-lactone (V) by the usual method. In order to confirm the configuration of the two methyl groups at C_3 and C_4 in V, another synthesis of V was carried out. It is known that epoxide ring opening[3] by nucleophilic attack proceeds in a *trans* manner. Epoxide (VII) obtained from tiglic acid (VI) was reacted with sodium diethyl malonate to give a lactone compound. Moreover, it was identical with V (bp, IR, NMR). Therefore, the two methyl groups at C_3 and C_4 in V must be in *trans*-configuration. It was assumed that the formation of IV from III was begun by the attack of cyanide on the less hindered side, followed by ring closure, as if shown in Fig. 1. VIII

Fig-1



was obtained by the methylation of V. After acid hydrolysis and decarboxylation, two isomeric acids were given in a 17: 1 ratio by fractional crystallization. The IR spectrum ($CHCl_3$) of the (±)major product of IX was superimposable with that of β-retusanecic acid. Also, the IR spectrum ($CHCl_3$) of the (±)minor product of X was superimposable with that of α-retusanecic acid. Consequently, it is confirmed that the configuration of the two methyl groups at C_3 and C_4 in α- and β-retusanecic acids is *trans*.



Experimental

Diethyl 1-Methyl-2-oxo-propylmalonate (III). Twelve grams of sodium were added to a solution of 85 g of diethyl malonate in 450 ml of dry ether. The solution was then refluxed for 8 hr until the sodium had completely dissolved, and then it was cooled. To the cooled solution, 75 g of methyl α-bromoethyl ketone were added all at once. The mixture was then refluxed for 2 hr. The ether solution was washed with ice cold water, and then dried with calcium chloride. After the solvent had been distilled, the residue was distilled at 144—149 °C (18 mmHg) to give 64 g of III (52% yield). IR (neat): 1760—1740 cm^{-1} (broad); NMR ($CDCl_3$) (δ): 2.30 ($-COC\underline{H}_3$). Found: C, 57.37; H, 7.93%. Calcd for $C_{11}H_{18}O_5$: C, 57.38; H, 7.88%.

β-Methyl-α-ethoxycarbonyl-γ-cyano-γ-valerolactone (IV). Twenty grams of III, 2.5 g of powdered CaO, and 8.6 g of HCN were placed in a flask in an ice bath. The flask was sealed and warmed at 50 °C for 3 hr. The excess HCN was then evaporated *in vacuo*. To the residue, 20 ml of chloroform were added. The chloroform solution was separated from an inorganic substance. After the solvent had been removed, 17 g of a dark-colored oil was obtained and chromatographed over a silica-gel column. Elution with chloroform gave a

colorless oil. The oil was distilled at 120—122 °C (3 mmHg) to give 7 g of IV (50% yield). IR (neat): 1815, 1750 cm^{-1}; Found: C, 56.88; H, 6.05; N, 6.25%. Calcd for $C_{10}H_{13}O_4N$: C, 56.86; H, 6.20; N, 6.63%.

β-Methyl-α,γ-diethoxycarbonyl-γ-valerolactone (V). A cold solution (0 °C) of 2 g of IV, 1 ml of absolute ethanol, and 1 ml of dry ether were saturated with dry hydrogen chloride, allowed to stand at 0 °C overnight, and then neutralized with a saturated solution of potassium carbonate. After extraction with ether, the ether solution was dried with anhydrous sodium sulfate. After the ether had been removed, the residue was distilled at 150—153 °C (4 mmHg) to give 1.2 g of V (50% yield). IR (neat): 1800, 1745 cm^{-1}; NMR ($CDCl_3$) (δ): 1.60 (-C(COOC$_2$H$_5$)-CH$_3$). Found: C, 55.57; H, 7.10%. Calcd for $C_{12}H_{18}O_6$: C, 55.80; H, 7.03%.

V from Methyl α-Methyl-α,β-epoxy-butyrate (VII). To solution of 0.288 g of sodium in 30 ml of absolute ethanol, 1.98 g of diethyl malonate were added. After 1 hr, 1.6 g of VII were added to the solution. The mixture was then refluxed for 35 hr, and the ethanol was evaporated *in vacuo*. After the residue had been extracted with ether, the solution was dried with anhydrous sodium sulfate. After the distillation of the solvent, 1.3 g of a colorless oil was given. The oil was chromatographed over a silica-gel column and eluted with chloroform. The first fraction (1200 ml) was concentrated to give 0.7 g of an oily product which was identical with V (bp, IR, NMR).

α,β-Dimethyl-α,γ-diethoxycarbonyl-γ-valerolactone (VIII). One gram of V was added to a solution of 0.1 g of sodium in 25 ml of absolute ethanol. After 1 hr, 0.63 g of methyl iodide in 2 ml of absolute ethanol was added to the solution. The mixture was then refluxed for 25 hr, and the ethanol was evaporated *in vacuo*. After the residue had been extracted with ether, the ether solution was dried with anhydrous sodium sulfate. After the evaporation of the solvent, the residual oil was distilled at 133 °C (2 mmHg) to give 0.93 g of VIII (88% yield). IR (neat): 1795, 1750 cm^{-1}. Found: C, 57.56; H, 7.57%. Calcd for $C_{13}H_{20}O_6$: C, 57.34; H, 7.40%.

2,3,4-Trimethyl-4-hydroxy-glutaric Acid-1,4-lactone, IX and X. A solution of 2.565 g of VIII in 25 ml of conc. hydrochloric acid was refluxed for 15 hr. After the evaporation of the solvent, the residue was heated on an oil bath at 170—190 °C to give 1.385 g of a solid. Fractional crystallization with benzene gave 0.85 g of plate crystals (mp 117—118 °C) of IX and 0.05 g of needle crystals (mp 129—130 °C) of X. IX: IR ($CHCl_3$): 1790, 1738 cm^{-1}; NMR (pyridine-d_5) (δ): 1.75 (-C(COOH)-CH$_3$). Found: C, 55.93; H, 7.10%. Calcd for $C_8H_{12}O_4$: C, 55.80; H, 7.03%. δ: IR ($CHCl_3$): 1790, 1742 cm^{-1}; NMR (pyridine-d_5) (δ): 1.70 (-C(COOH)-CH$_3$). Found: C, 55.87; H, 6.97%. Calcd for $C_8H_{12}O_4$: C, 55.80; H, 7.03%.

Reaction of *trans*-Stilbene with Methanesulfenyl Chloride

Michinori Ōki, Atsuko Nakamura, and Keiji Kobayashi
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received June 8, 1973)

We have treated *trans*-stilbene (**1**) with excess methanesulfenyl chloride and obtained a mixture of α-chloro-α-methylthiostilbenes which are formally the dehydrogenation products of the adduct. This paper presents characterization of the products and a discussion on the reaction.

Experimental

Reaction between trans-*Stilbene and Methanesulfenyl Chloride in 1: 1 Molar Ratio.* To a solution of 4.0 g. (0.022 mol) of *trans*-stilbene in 300 ml. of toluene was added 1.8 g (0.022 mol) of methanesulfenyl chloride at −78 °C. After the color of the chloride had faded, the mixture was warmed to room temperature and evaporated *in vacuo*. The remaining mixture was fractionally recrystallized from petroleum ether to give 48% *erythro*-1-chloro-2-methylthio-1,2-diphenylethane,[1] mp 123 °C.

Reaction of trans-*Stilbene with Excess Methanesulfenyl Chloride.* *trans*-Stilbene (4.5 g or 0.025 mol) was added to 6.2 g (0.075 mol) of methanesulfenyl chloride at −78 °C and the mixture was slowly warmed up to room temperature. During this period a vigorous reaction set in and evolution of hydrogen chloride took place. The excess of methanesulfenyl chloride was decomposed by pouring into methanol. The product chromatographed on alumina gave a mixture in 77% yield (by weight). NMR spectra of the mixture indicated that it consists of *cis*- and *trans*-α-chloro-α′-methylthiostilbenes, the composition being *ca.* 4: 1 in favor of the *cis*-isomer. Rechromatography of the mixture gave the *trans* compound, mp 74 °C, and the *cis*, mp 52 °C.[2]

trans-*α-Chloro-α-methylthiostilbene.* Methanesulfenyl chloride (5 g or 0.06 mol) was added to 9 g (0.05 mol) of tolane in 20 ml of ether containing 2 ml of boron trifluoride etherate. The mixture was washed with water, evaporated and chromatographed on alumina to give 70% *trans*-α-chloro-α′-methylthiostilbene, mp 74 °C, which was identical with one of the products obtained above. Found: C, 69.00; H, 5.19%. Calcd for $C_{15}H_{13}ClS$: C, 69.14; H, 5.01%.

trans- *and* cis-*α-chloro-α′-methylsulfonylstilbenes.* The corresponding thioethers were oxidized with peracetic acid in acetic acid at 70 °C for 1 hr. The *trans* form, mp 158.5—159 °C. Found: C, 61.40; H, 4.58%. The *cis* form, mp 123—126 °C. Found: C, 61.44; H, 4.52%. Calcd for $C_{15}H_{13}ClO_2S$: C, 61.53; H, 4.44%.

Reaction of erythro-*1-Chloro-2-methylthio-1,2-diphenylethane with Methanesulfenyl Chloride.* To a solution of 0.52 g (2 mmol) of *erythro*-1-chloro-2-methylthio-1,2-diphenylethane in 10 ml of carbon tetrachloride was added 0.33 g (4 mmol) of methanesulfenyl chloride at room temperature. After the reaction was over, as indicated by fading of the color, the solution was washed with aqueous sodium carbonate and the

1) M. Ōki and A. Kimura, This Bulletin, **38**, 682 (1965).

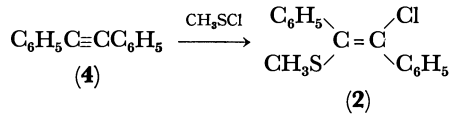
2) Since purification of this compound was rather tedious, elemental analysis was performed with the sulfone.

solvent was evaporated. NMR spectrum indicated the presence of *cis*- and *trans*-α-chloro-α'-methylthiostilbenes and dimethyl disulfide. The ratio of the isomers was paractically the same as the one obtained by the reaction of *trans*-stilbene with excess methanesulfenyl chloride.

Thermal Equilibration of α-Chloro-α'-methylthiostilbenes. The *trans* form of this compound was dissolved in carbon tetrachloride and sealed in an NMR sample tube. The whole was heated at 195 °C and the NMR spectra were determined at appropriate intervals. The *trans* compound had a sharp singlet at 1.77 ppm from internal TMS and a fairly sharp signal at 7.31 ppm, the latter being characteristic of *trans*-stilbene derivatives. After heating for 5 hr, the equilibrium was reached. The signals for the *cis* compound were observed at 1.83, 6.98, and 7.08 ppm. The latter two signals can be taken as an evidence for the *cis*-stilbene structure. The area ratio was *ca.* 2:1 in favor of the *cis*.

Discussion

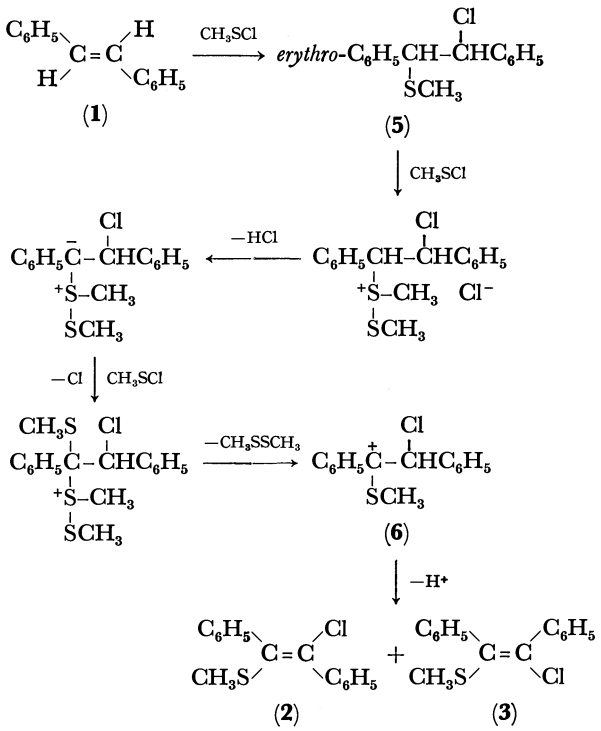
The reaction of *trans*-stilbene with excess methanesulfenyl chloride afforded a mixture of two compounds containing both sulfur and chlorine. One of the products was found to be identical with a product from the reaction of tolane with methanesulfenyl chloride. Since the ionic addition to tolane (**4**) has been known[3] to give mainly the *trans* isomer, it is most reasonable to assume that this compound is *trans*-α-chloro-α'-methylthiostilbene (**2**).



Analytical data of the other product suggest it to be an isomer of the *trans* compound, whose structure might be reasonably assigned to *cis*-α-chloro-α'-methylthiostilbene (**3**). Further evidence for the assignment of the structure was obtained by thermal equilibration with the *trans* compound and by refluxing the compound with Raney nickel in acetone: *cis*-stilbene, as identified by the corresponding signals in NMR spectra, was found.

The favored formation of the *cis* isomer over the *trans* is of interest. Although it is difficult to verify the reasons, there are many such examples. Among 1,2-dihaloethylenes, the *cis* isomer is known to be more stable than the *trans*.[4-6] In substituted enedithiol derivatives, the *cis* form is more stable,[7] although steric factor may operate to some extent in that *cis-trans* pair. Since the system in question possesses chlorine and sulfur atoms at both ends of the vinylene groups, the stability of the *cis* compound can be explained similarly. Thus the results appear as a result of thermodynamic control and the thermal equilibration agrees with expectation. The presence of hydrogen chloride, as one of the reaction products, will catalyze the equilibration between *cis*- and *trans*-isomers.

Since *erythro*-1-chloro-2-methylthio-1,2-diphenylethane (**5**), when treated with methanesulfenyl chloride, gives almost the same mixture as the products from *trans*-stilbene and excess methanesulfenyl chloride, the reaction may be assumed to proceed *via* compound **5**. The mechanism of the dehydrogenation reaction will then be similar to that reported:[8] a Pummerer type intermediate (**6**) intervenes and the deprotonation from beta to the sulfur atom takes place. A probable mechanism is as follows.



No evidence for further addition[9] of the sulfenyl chloride to **2** and **3** was obtained.

Note Added in Proof: Equilibration of *cis* and *trans* isomers of a similar system catalyzed by hydrogen chloride was reported recently. See G. Modena, G. Scorrano, and U. Tonellato, *J. Chem. Soc. Perkin II*, **1973**, 493.

Synthesis and Reaction of 1-Substituted-4-benzylpiperazin-2-ones

Hiroaki UCHIDA and Masaki OHTA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received June 14, 1973)

Introduction of a functional substituent at position 1 of 4-substituted piperazine-2-one (I) has been reported to be effected by two methods. Method A is an addition of I to an olefinic compound in the presence of base[1] or to an acetylenic compound at high temperature and pressure.[2] Method B is a reaction of sodium salt of I with an appropriate halide.[3]

However, the compounds thus prepared are quite few and are special types for practical application. In this note, preparation of 4-benzylpiperazin-2-ones (IV—XII) having a functional substituent at position 1 and their derivation and cyclization are described.

The starting material, piperazin-2-one (II), was prepared by Aspinall[4] by condensing ethyl chloroacetate with large excess of ethylenediamine, followed by cyclization. We found that the cyclization of the intermediate occurred during removal of excess of ethylenediamine at 100 °C instead of heating at 200 °C as described by Aspinall. 4-Benzylpiperazin-2-one (III) was readily available by reacting II with benzyl chloride.

Reaction conditions and yields in the preparation of IV—XII were tabulated in Table 1. In Table 2 were shown physical constants of the products and their salts respectively.

Reaction of ethyl 1-(4-benzyl-2-oxo)piperazinepropionate (VI) with concentrated ammonium hydroxide led to the formation of the corresponding amide (XIII) [mp 107—109 °C. Found: C, 64.25; H, 7.33; N, 16.01%. Calcd for $C_{14}H_{19}O_2N_3$: C, 64.34; H, 7.33; N, 16.08%]. Methyl 1-(4-benzyl-2-oxo)piperazinepropionate (V) and ethyl 1-(4-benzyl-2-oxo)piperazineacetate (XI) were allowed to react with hydrazine hydrate to give the corresponding hydrazides [V hydrazide was characterized as *m*-nitrobenzylidene derivative; mp 146—147 °C. Found: C, 61.82; H, 5.57; N, 17.17%. Calcd for $C_{21}H_{23}O_4N_5$: C, 61.60; H, 5.66; N, 17.11%. XI hydrazide; mp 108—109 °C. Found: C, 59.16; H, 6.87; N, 21.52%. Calcd for

Hydrogenation of 4-benzyl-1-cyanomethylpiperazin-2-one (X) and 4-benzyl-1-(2-cyanoethyl)piperazin-2-one (IV) in the presence of Raney nickel gave easily cyclized products, 7-benzyl-2,3,5,6,7,8-hexahydroimidazo[1,2-*a*]pyrazine (XIV) and 8-benzyl-2,3,6,7,8,9-hexahydro-4*H*-pyrazino[1,2-*a*]pyrimidine (XV) respectively. As an alternative route leading to the fused compound XV, selective reduction of nitrile group in IV or amide group in XIII was attempted using lithium aluminium hydride. However, the reduction of ring carbonyl group occurred simultaneously yielding 1-(3-aminopropyl)-4-benzylpiperazine (XVI) [bp 155—157 °C/1 mmHg. Picrate; mp 254—255 °C. Found: C, 41.92; H, 3.67; N, 17.64%. Calcd for $C_{32}H_{32}O_{21}N_{12}$ (tripicrate): C, 41.75; H, 3.50; N, 18.26%]. Hydrogenation of IV using 10% Pd–C in methanol containing hydrogen chloride was unsuccessful.

Experimental

4-Benzylpiperazin-2-one (III). A mixture of II(24.3 g), benzyl chloride(30.8 g) and sodium bicarbonate(24.5 g) in ethanol(300 ml) was gently refluxed for 5 hr. Upon cooling to room temperature, crystals of III separated out were collected by filtration. Concentration of the filtrate gave additional product. The combined crystals were recrystallized from benzene to give colorless prisms of III, mp 155—157 °C(lit,[6] mp 149—150 °C), 40.4 g (88%). Found: C, 69.50; H, 7.51; N, 14.89%. Calcd for $C_{11}H_{14}ON_2$: C, 69.44; H, 7.42; N, 14.73%.

4-Benzyl-1-(2-cyanoethyl)piperazin-2-one(IV) [*by Method A*]. A mixture of III(3.8 g), acrylonitrile(1.2 g) and powdered potassium hydroxide(20 mg) in acetonitrile(100 ml) was gently refluxed for 6 hr with stirring. The reaction mixture was concentrated, and to the residual oil was added 200 ml of ether. The ether insoluble substance was removed by filtration. The ethereal solution was concentrated and the residue was distilled under vacuum to obtaine 4.5 g of IV as a viscous pale yellow oil.

V and VI were prepared by this method.

*4-Benzyl-1-*n*-butylpiperazin-2-one(VII)* [*by Method B*]. A mixture of III(2.9 g) and finely pulverized sodium(0.35 g) in dry toluene(200 ml) was heated with vigorous stirring. At around 75 °C, III was completely dissolved and reaction mixture began to become turbid after 3 hr refluxing. After 7—8 hr refluxing the reaction mixture became gruel-like and all of the sodium was consumed. *n*-Butyl bromide(2.7 g) was added to the above mixture at room temperature. The mixture changed to a clear solution after 1 hr heating at 90 °C with stirring and additional 3 hr heating was continued. The reaction mixture was concentrated and ether(200 ml) was added to the oily residue. The ether-insoluble substance was removed by filtration and the ethereal solution was concentrated and then distilled under vacuum to give 1.9 g of VII as a viscous slightly yellow oil.

VIII-XII were prepared by this method.

7-Benzyl-2,3,5,6,7,8-hexahydroimidazo[1,2-a]pyrazine (XIV). X(4.0 g) in methanol(30 ml) containing ammonia(2 g) was hydrogenated at 95 °C in the presence of Raney nickel(1 g) and hydrogen at an initial pressure of 140 atm. The catalyst was removed by filtration and the filtrate was concentrated. The residue was distilled to give colorless oil of XIV, bp 176—179 °C/1 mmHg, 3.4 g(94%), hygroscopic. Found: C, 71.59; H, 8.13; N, 19.25%. (Calcd for $C_{13}H_{17}N_3$: C, 72.52; H, 7.96; N, 19.52%). IR(NaCl) cm^{-1}: 3350, 1635, 1492, 743, 701.

The picrate was recrystallized from acetonitrile, mp 197—199 °C. Found: C, 44.72; H, 3.50; N, 19.50%. Calcd for $C_{25}H_{23}O_{14}N_9$ (dipicrate): C, 44.58; H, 3.44; N, 18.71%.

8-Benzyl-2,3,6,7,8,9-hexahydro-4H-pyrazino[1,2-a]pyrimidine (XV). Hydrogenation of IV(6.1 g) by the same procedure as the preceding experiment gave colorless viscous oil of XV, bp 177—181 °C/1 mmHg, 5.5 g(96%), hygroscopic. Found: C, 72.24; H, 8.57; N, 18.28%. (Calcd for $C_{14}H_{19}N_3$: C, 73.32; H, 8.35; N, 18.33%). IR(NaCl) cm^{-1}: 3300, 1643, 1495, 750, 705. Picrate: mp 193—195 °C(methanol). Found: C, 45.33; H, 3.67; N, 18.25%. Calcd for $C_{26}H_{25}O_{14}N_9$(dipicrate): C, 45.42; H, 3.67; N, 18.34%.

Intramolecular Charge-transfer Interaction in Substituted Diphenylmethanes

Hiroyasu INOUE, Yoichiro MIKAMI, and Toshiji YOKOTANI

Department of Applied Chemistry, Faculty of Technology, Kanagawa University, Kanagawa-ku, Yokohama 221

(Received June 16, 1973)

In a previous paper,[1] we have reported that aniline and nitrobenzene in cyclohexane form a loose contact pair, are giving rise to the charge-transfer (CT) absorption as the tail of the long wavelength band of nitrobenzene when the concentrations of both are very high. According to White,[2] in the case of 4-amino-4′-nitrodiphenylmethane the across-space CT interaction between aniline and nitrobenzene parts causes a new band at 324 nm (30.9 kK), which is hidden under the intense band of nitrobenzene. Therefore, the presence of the CT band was revealed by the subtraction of the absorption spectra of the reference compounds *i.e.*, *p*-toluidine and *p*-nitrotoluene, from that of 4-amino-4′-nitrodiphenylmethane. For many compounds, the intramolecular CT interaction between two moieties separated by a saturated hydrocarbon chain has been established.[3-7]

In this paper, we will deal with the absorption and fluorescence spectra of 4-hydroxy-4′-nitrodiphenylmethane (HN) and 4-amino-4′-nitrodiphenylmethane (AN), aiming to give further evidence for the intramolecular CT interaction in these compounds.

Experimental

Materials. The HN was prepared by the diazo-decomposition of AN according to the method of Tsekhanskii and Fedorov[8] and was purified by repeated recrystallizations from an ethanol–water mixed solvent; mp 118.5 °C (lit,[8] 119 °C). The AN was prepared by the partial reduction of 4,4′-dinitrodiphenylmethane according to the method of Litvinenko and Levchenko[9] and was purified by repeated recrystallizations from a methanol–water mixed solvent; mp 98 °C (lit,[9] 98 °C). Cyclohexane was purified by standard procedures.

Measurements. The ultraviolet absorption spectra were measured with a Shimadzu Spectrophotometer, D-40D, using 1 cm quartz cells. The fluorescence and excitation spectra were recorded on a Hitachi Fluorescence Spectrophotometer, MPF-2A. The concentrations of solutions were of the order of 10^{-4} mol/l. No correction for the sensitivity of the instrument was made. The excitation wave number was 41.7 kK. All the measurements were carried out at room temperature.

Results and Discussion

The ultraviolet absorption spectrum of HN in cyclohexane does not coincide with that of *p*-nitrotoluene in the wave number region lower than 37.0 kK. When the latter is subtracted from the former, a weak broad band appears at 33.3 kK (ε=1700). Similarly, in the case of AN, a weak band appears at 32.3 kK (ε=1950) as an extra band. Since the shapes of these extra bands are not dependent on the concentrations of the solutions, they can not be attributed to intermolecular interaction. The extra bands are, therefore, considered to be the intramolecular CT bands. In fact, the CT band of HN appears at a higher wave

number than that of AN, because the ionization potential of HN (8.97 eV) is higher than that of AN (8.14 eV).[10]

When the absorption spectrum of HN is measured in alkaline aqueous ethanol (pH 13), the CT band is observed explicitly at 27.0 kK, as is shown in Fig. 1. In this case, the *p*-methylphenolate-ion part acts as the electron donor and its ionization potential seems to be very low compared with those of *p*-cresol and *p*-toluidine.

The presence of the intramolecular CT interaction in HN and AN is confirmed by the fluorescence spectra. That is, new fluorescence bands, which could not be assigned to the reference compounds, appeared at 29.0 and 25.5 kK for HN and AN respectively in cyclohexane. The fluorescence spectrum of AN, for example, is shown in Fig. 2, in which the excitation spectrum is also presented. As may be seen from this figure, the excitation spectrum agrees well with the extra absorption band. Therefore, this emission is not an excimer fluorescence such as those reported on some diphenyl alkanes,[11] but can be attributed to the presence of the intramolecularly-interacting species in the ground electronic state.

It may be expected that the dissociation constant of HN differs from that of *p*-cresol. Accordingly, the pK_a values were determined in a mixed solvent of methanol–water at 25 °C. The pK_a values were 10.8 and 11.1 for HN and *p*-cresol respectively. This can be interpreted in terms of the charge migration from the *p*-cresol part to the *p*-nitrotoluene part in HN.

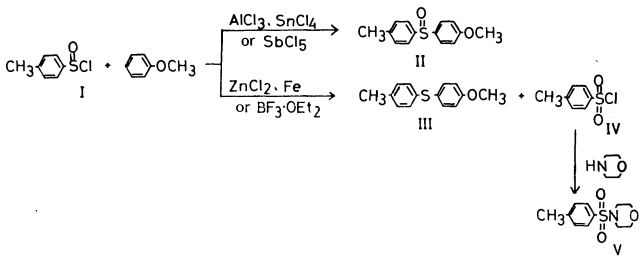
On the Reaction of *p*-Toluenesulfinyl Chloride with Anisole

Tamotsu FUJISAWA, Masami KAKUTANI, and Norio KOBAYASHI
Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229

(Received May 28, 1973)

Concerning the Friedel-Crafts-type reaction, sulfonyl chloride and sulfenyl chloride have been well known to give aromatic sulfone[1] and sulfide[2] respectively; however, with one exception,[3] the reaction of sulfinyl chloride with aromatics has not been reported. In this experiment, the reaction of *p*-toluenesulfinyl chloride (I) with anisole was studied with various catalysts as a series of electrophilic aromatic substitutions with the chlorides of organic sulfur acids.[2]



Scheme 1.

When the reaction of anisole with I in the presence of aluminum chloride was conducted in carbon disulfide or excess anisole at −15—20 °C, *p*-anisyl *p*-tolyl sulfoxide (II) was obtained in a good yield after the hydrolysis of the reaction product. The use of antimony pentachloride or stannic chloride in place of aluminum chloride led also to the formation of II. On the other hand, when a 10% excess molar amount of zinc chloride or boron trifluoride etherate, or a catalytic amount of iron powder, was used as the catalyst, the sulfoxide II was not obtained; instead, *p*-anisyl *p*-tolyl sulfide (III) and *p*-toluenesulfonyl chloride (IV) were formed. Compound IV was identified as *N*-(*p*-toluenesulfonyl) morpholine (V). The seresults are summarized in Table 1.

The sulfoxide formation may be explained by a mechanism similar to that of the Friedel-Crafts acylation.[1] This assumption was supported by the IR spectra of mixtures of I and the catalysts (*vide infra*) and by the isolation of a 1 : 1 complex of II with antimony pentachloride. The sulfide formation is ascribed to the reduction of the initially-formed II with I. In fact, control experiments revealed that II and the complexes of II with the catalysts for sulfide formation were reduced by I at room temperature in accord with the following equation.[4]

Scheme 2.

This is the first example of the reduction of sulfoxide by sulfinyl chloride, although there is one precedent for sulfinyl chloride functioning as a reducing agent; it is the reduction of pyridine *N*-oxide with *p*-nitrobenzene-

sulfinyl chloride at 180 °C.[5]

The catalyst dependence of the products may be due to the difference in the interaction between the catalysts and I. The IR spectra of mixtures of I and aluminum chloride, stannic chloride, or antimony pentachloride in carbon disulfide showed shifts of absorption due to the sulfinyl group to wave numbers lower by 129—179 cm^{-1}, but no such shifts were observed in the case of zinc chloride, boron trifluoride etherate, or iron powder. These findings suggest that the sulfinyl group of I interacts with the catalysts for the sulfoxide formation,[6] and that free sulfinyl chloride effects the reduction of sulfoxides.

The sulfide formation was observed also in the absence of a catalyst. Although the reaction of anisole with I did not occur at room temperature, the reaction in boiling anisole gave III in a 70% yield. This reaction path is different from that of the catalyzed reaction; *i.e.*, the formation of III is to be ascribed to the electrophilic aromatic substitution of *p*-toluenesulfenyl chloride (VI),[7] which may itself be formed by the disproportionation of I. Concerning the disproportionation of a sulfinyl chloride, it has been described that methanesulfinyl chloride decomposes to the corresponding sulfenyl and sulfonyl chlorides on standing for several months.[8] *p*-Toluenesulfinyl chloride (I) did not undergo the disproportionation at room temperature, not even in the presence of a catalyst, but it gave the corresponding sulfonyl chloride, IV, on heating at 140 °C.[9]

9) *p*-Toluenesulfenyl chloride could not be isolated because of instability at the temperature.

Experimental

The melting points are uncorrected. The infrared spectra were run on a Perkin-Elmer 337 spectrophotometer. All the NMR spectra were recorded on a Varian HA-100 spectrometer. The chemical shifts of the NMR spectra are reported in parts per million downfield from the internal TMS (δ). The glpc analyses were conducted using a Hitachi K-53 chromatograph with a 3% SE-30 column. *p*-Toluenesulfinyl chloride (I) was prepared by treating sodium *p*-toluenesulfinic acid with thionyl chloride according to the method of Kurzer.[10]

Reaction of I with Anisole in Carbon Disulfide in the Presence of Aluminum Chloride. Aluminum chloride (3.70 g, 28 mmol) was added to a solution of I (4.36 g, 25 mmol) and anisole (2.70 g, 25 mmol) in carbon disulfide (20 ml) cooled to −30 °C. The mixture was stirred for 5.5 hr at 0—−15 °C and then heated under reflux for 30 min to complete the reaction. The reaction mixture was poured into a mixture of ice and water. The carbon disulfide layer was separated and dried with calcium chloride. The removal of the carbon disulfide afforded *p*-anisyl *p*-tolyl sulfoxide[11] (4.6 g, 75%), which was subsequently recrystallized from *n*-hexane; mp 68—70 °C; IR (KBr) 1030 cm^{-1}; NMR ($CDCl_3$) δ 2.33 (s, 3H), 3.77 (s, 3H), 6.90 (d, 2H), 7.19 (d, 2H), 7.47 (d, 2H), 7.52 (d, 2H).

Found: C, 68.26; H, 5.73; S, 13.02%. Calcd for $C_{14}H_{14}O_2S$: C, 68.35; H, 5.87; 13.09%.

When antimony pentachloride was used as a catalyst in this reaction, a 1:1 complex of *p*-anisyl *p*-tolyl sulfoxide with antimony pentachloride (14 g, 86%) was obtained. The complex was recrystallized from chloroform–*n*-hexane; mp 178—179 °C; IR (KBr) 850 cm^{-1} (sulfoxide); NMR ($CDCl_3$) δ 2.47 (s, 3H), 3.91 (s, 3H), 7.07 (d, 2H), 7.40 (d, 2H), 7.65 (d, 2H), 7.72 (d, 2H). Found: C, 30.90; H, 2.62; S, 6.06; Cl, 32.75%. Calcd for $C_{14}H_{14}O_2SSbCl_5$; C, 30.83; H, 2.59; S, 5.88; Cl, 32.51%. When the complex was subjected to column chromatography (silica gel–chloroform), *p*-anisyl *p*-tolyl sulfoxide (22%) was obtained.

In a similar way, when stannic chloride was used as the catalyst in the reaction, the sulfoxide was also obtained (see Table 1).

Reaction of I with Anisole in Carbon Disulfide in the Presence of Boron Trifluoride Etherate. To a solution of I (4.36 g, 25 mmol) and anisole (2.70 g, 25 mmol) in carbon disulfide (20 ml) was added boron trifluoride etherate (3.9 g, 28 mmol)

10) K. Kurzer, "Organic Syntheses," Coll. Vol. IV, p. 937 (1964).
11) The preparation of the corresponding optically active sulfoxide has been reported, K. K. Andersen, W. Gaffield, N. E. Papanikolaou, J. W. Foley, and R. I. Perkins, *J. Amer. Chem. Soc.*, **86**, 5637 (1964).

at room temperature. The solution was stirred for 24 hr at room temperature and then heated under reflux for 1 hr. After the removal of the carbon disulfide by distillation, morpholine (5 ml) was added, and then the reaction mixture was poured into water. The mixture was extracted with chloroform. After the removal of the chloroform and excess morpholine under reduced pressure, the oily residue was recrystallized from ether to give *N*-(*p*-toluenesulfonyl)morpholine (0.35 g, 11%). A glpc of the remaining residue after the removal of the ether indicated the presence of *p*-anisyl *p*-tolyl sulfide (46%).

In a similar way, when equimolar amounts of zinc chloride and a catalytic amount of iron powder were used as catalyst in the reaction, the sulfide was also obtained (see Table 1).

Reaction of I with Anisole in the Absence of a Catalyst. A solution of anisole (27 g, 250 mmol) and I (4.36 g, 25 mmol) was heated under reflux for 3 hr. Morpholine (5 ml) was added to the reaction mixture, and then it was poured into water. The mixture was treated in the same manner described above. The results were recorded in Table 1.

Reduction of II with I. The general procedures were as follows: equimolar amounts of Lewis acid and *p*-anisyl *p*-tolyl sulfoxide were added to carbon disulfide, and the mixture was stirred for 2 hr at room temperature. Then equimolar amounts of I were added, and the mixture was stirred for 24 hr at room temperature, followed by refluxing for 1 hr. Morpholine was then added to the mixture. After the hydrolysis of the mixture with ice-water, the organic layer was analyzed by glpc. The results are summarized in Table 2.

Rearrangement of Potassium *o*-Hydroxybenzoate as Revealed by Microthermal Analyses

Koki OTA

Department of Chemistry, Kyushu Institute of Technology, Sensui-cho, Tobata-ku, Kitakyushu 804

(Received June 5, 1972)

It is well-known that potassium *o*-hydroxybenzoate (mono-potassium salicylate, SA–K), the main product of the Kolbe-Schmitt reaction, undergoes rearrangement ultimately to di-potassium *p*-hydroxybenzoate (POB–K_2).[1]

$$2SA\text{–}K \longrightarrow POB\text{–}K_2 + PhOH + CO_2 \quad (1)$$

The following reaction schemes were suggested by Ueno and Muramoto for the thermal behavior of SA–K.[2]

$$\begin{aligned} &SA\text{–}K \longrightarrow PhOK + CO_2 \\ &SA\text{–}K + PhOK \longrightarrow SA\text{–}K_2 + PhOH \quad (2) \\ &SA\text{–}K_2 \longrightarrow POB\text{–}K_2 \end{aligned}$$

However, we found by means of microthermal analysis that the thermal reaction of SA–K cannot be satisfactorily interpreted by the above schemes and a hydroxy dicarboxylic acid exists as an intermediate of the rearrangement reaction.

We undertook to elucidate the mechanism of the rearrangement by a combination of micro differential thermal analysis (DTA), detection and analysis of evolved gas, thermogravimetry (TG), and UV analysis.

Measurements were carried out in a stream of N_2. The results of thermal analyses are shown in Fig. 1.

Small, sharp DTA peaks 1, 2, and 3 in a large endothermic background and the three corresponding peaks of generated gases were observed. The amounts of CO_2 and PhOH simultaneously evolved were determined. It is evident from the analysis of the residues that peak 1 is partly due to the formation of 4-hydroxy isophthalic acid (4-OIP).

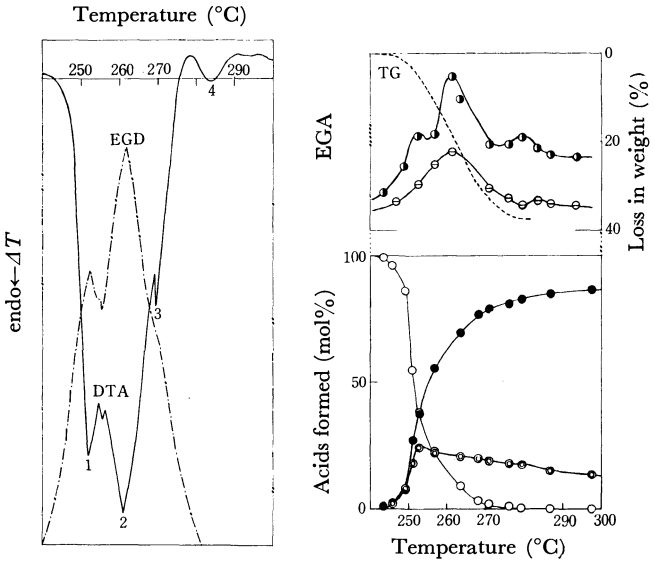

Fig. 1. Rearrangement of SA-K in N_2 stream.
⊖ CO_2, ◑ PhOH, ○ SA, ● POB, ◎ 4-OIP

The formation rate of POB increases greatly at temperatures between peaks 1 and 2. CO_2 and gaseous

2) R. Ueno and Y. Muramoto, *Kogyo Kagaku Zasshi*, **64**, 1317 (1961).

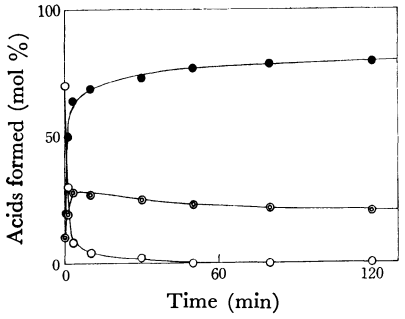

Fig. 2. Rearrangement of SA–K at 250 °C (N_2 stream).
○ SA, ● POB, ◎ 4-OIP

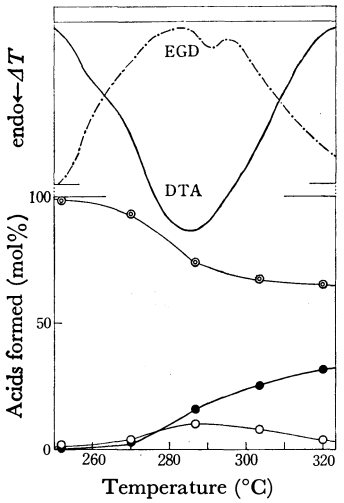

Fig. 3. Thermal reaction of 4-OIP–K_2 in N_2 stream.
○ SA, ● POB, ◎ 4-OIP

PhOH are evolved vigorously at about the same temperature (peak 2). These findings indicate that decarboxylation of SA takes place together with rearrangement of SA to POB. The changes of the DTA curve from peak 2 to peak 3 are characterized by the decrease in gases evolved, a loss in quantity of 4-OIP and the increasing amount of POB, suggesting a conversion of 4-OIP into POB. The curve TG shows that 37.0—37.4% of the original weight was lost (the theoretical value of Eq. (1) is 39.2%). This coincides with the result where acids formed contain 13—19% 4-OIP.

A small decrease in the TG curve at temperatures above 270 °C suggests that evolution of gases and the formation of POB are almost complete. When the DTA curve is restored to the initial level, the remaining amount of SA is about zero.

After this, the formation of POB occurs slightly from 4-OIP with small amounts of evolved gases as shown by evolved gas analysis and UV analysis.

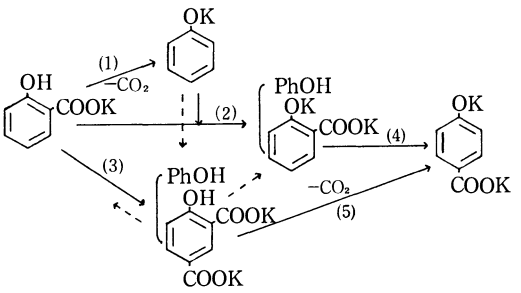
It seems that the rearrangement of SA–K proceeds partly through the formation of 4-OIP–K_2. For the sake of confirmation, the effect of reaction time at 250 °C on the reaction of SA–K was investigated.

The result is shown in Fig. 2.

At the initial stage of reaction, POB is formed and SA–K decomposes rapidly. This confirms the reaction route from SA–K to POB.[2] However, 4-OIP is also formed in this period and later slowly decomposes. This also confirms the view that the reaction proceeds from SA-K to POB *via* 4-OIP as a reaction intermediate, although 4-OIP is fairly stable under such conditions. It was confirmed that 4-OIP is formed in the thermal reaction of SA–K and is rearranged into POB at a lower rate.

The results for 4-OIP are shown in Fig. 3. We see that 4-OIP–K_2 undergoes rearrangement to POB and SA, and then SA–K_2 is converted into POB–K_2 at high temperatures. The amount of POB–K_2 formed nearly equals the loss of 4-OIP–K_2 (in weight). Evolution of a small amount of PhOH and excess CO_2 was observed (peak 4, Fig. 1).

The following reaction scheme is proposed.



The reaction rate of step (1) is high, step (2) being coupled with (1). Step (3) occurs in the earlier stage of reaction. The rate of rearrangement (4) is high, and that of (5) rather low. For the completion of reaction, it is necessary to remove PhOH and CO_2 formed.

Experimental

Sample. SA–K was prepared as reported previously[3] and 4-OIP–K_2 by purification of 4-OIP (Tokyo Kasei Kogyo Ltd.).

Apparatus. A Shimadzu EGD-20 and DT-GC system was used. TG was recorded with a TGC-20. Gas analysis was performed by gas-chromatography (GC). GC columns were packed with Shimalite-Q, MS-5A and active carbon for measurement of CO_2 and Shimalite-W (DEGS 10%+ H_3PO_4 1%) for PhOH.

QV-50 was used for UV analysis.

Methods. A sample (*ca.* 5 mg) was accurately weighed and set in an Al-sample holder. The heating rate was 10 °C/min.

The flow rate of gas was 30 ml/min, being regulated in the range 10—60 ml/min, when necessary.

The author would like to thank Dr. M. Senō, Tokyo University, for guidance and encouragement and Dr. T. Seiyama, Kyushu University, for advice.

An *ab initio* MO Study of the Hydrogen Bond in NH_3·HF

Shinichi YAMABE, Shigeki KATO, Hiroshi FUJIMOTO, and Kenichi FUKUI
Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received April 13, 1973)

The structure and properties of the hydrogen bond have been of long-standing interest to both theoretical and experimental chemists.[1] Especially by the use of the molecular orbital (MO) method, many studies have been carried out of relatively simple systems including, for example, the O—H···O, N—H···N, N—H···F bonds.[2]

Among the systems, a mixed dimer, NH_3···HF, is regarded as a strong complex, compared with such other dimers as $(NH_3)_2$ and $(HF)_2$. The several geometries of the complex were extensively studied by Kollman and Allen,[3] who found the *linear* structure to be the most stable one.

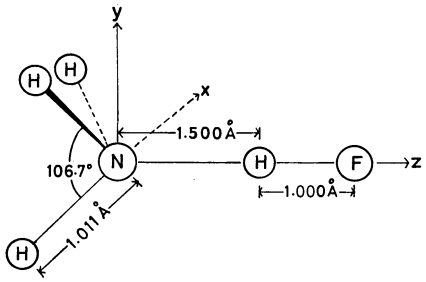

Fig. 1. The geometry of the NH_3·HF complex taken in this calculation from Ref. 3.

We thought it would be an interesting subject to detect the nature of the *strong* N···H bond in Fig. 1, taken from the results of Ref. 3. In order to analyze this in the frame of the MO method, we have used the technique which regards the MO's of NH_4F as the product of the orbital mixing of the MO's of NH_3 with those of HF.[4,5] In other words, the occupied MO's of the NH_4F system (Ψ_g, $g=1, 2, \cdots, 10$) are approximated as linear combinations of occupied MO's (a_i, $i=1, 2, \cdots, 5$ in NH_3 and b_k, $k=1, 2, \cdots, 5$ in HF) and unoccupied MO's (a_j, $j=6, 7, 8$ in NH_3 and b_l, $l=6$) of its two subsystems:

$$\Psi_g = \sum_{i=1}^{5} C_i^{(g)} a_i + \sum_{j=6}^{8} C_j^{(g)} a_j + \sum_{k=1}^{5} C_{k+8}^{(g)} b_k + C_{l+8}^{(g)} b_l \quad (1)$$

The MO's used here are constructed by means of the minimal-basis set of Slater-type Orbitals (STO's) expanded into *three* Gaussian-type Orbitals (GTO's).[6,7] Then, all the integrals of STO's necessary for composing the Fock matrix can easily be evaluated by this expansion.

In Table 1 the calculated results of the MO's are shown in relation to the equilibrium geometry in Fig. 1, except that the configuration of NH_3 is taken from the experimental one.[8] ($-E_K/E_T$) shows satisfactory optimization with respect to the exponents of STO's[9] adopted here (Virial Theorem).

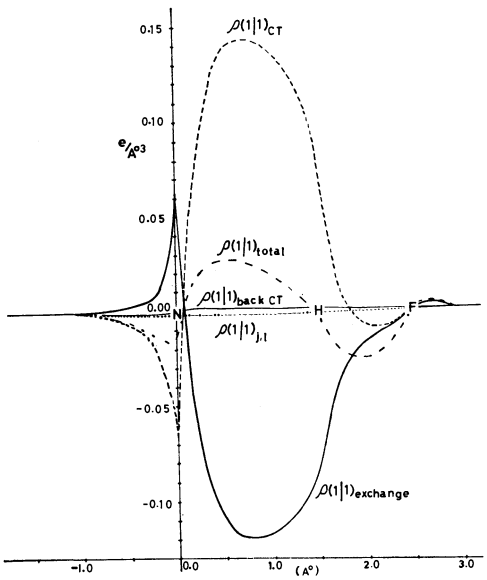

Fig. 2. The profile of the *intermolecular* charge density between NH_3 and HF.

By the use of the calculated MO's, the charge density in the *intermolecular* part as regards the two monomers (N···H region) can be obtained in the frame of the above-mentioned technique. In Fig. 2 the profile of the intermolecular charge density ($\rho(1|1)_{\text{total}}$), cut n x-y plane, is depicted in the following partitioned form:

$$\rho(1|1)_{\text{total}} = \rho(1|1)_{\text{exchange}} + \rho(1|1)_{\text{CT}} + \rho(1|1)_{\text{back CT}} + \rho(1|1)_{j,l} \quad (2)$$

$$\rho(1|1)_{\text{exchange}} = 2\sum_{g=1}^{10}\Big[\sum_{i=1}^{5}\sum_{k=1}^{5} C_i^{(g)} C_{k+8}^{(g)}\{a_i(1)b_k(1) + b_k(1)a_i(1)\}\Big] \quad (3)$$

$$\rho(1|1)_{\text{CT}} = 2\sum_{g=1}^{10}\Big[\sum_{i=1}^{5} C_i^{(g)} C_{i+8}^{(g)}\{a_i(1)b_i(1) + b_i(1)a_i(1)\}\Big] \quad (4)$$

$$\rho(1|1)_{\text{back CT}} = 2\sum_{g=1}^{10}\Big[\sum_{k=1}^{5}\sum_{j=6}^{8} C_{k+8}^{(g)} C_j^{(g)}\{a_j(1)b_k(1) + b_k(1)a_j(1)\}\Big] \quad (5)$$

TABLE 1. THE RESULTS OF MO CALCULATION[a)]

NH_3		HF		NH_4F	
a_i	$1a_1$ −15.3058	b_k	$1a_1$ −25.8878	Ψ_g	$1a_1$ −25.6837
	$2a_1$ −1.1050		$2a_1$ −1.4523		$2a_1$ −15.3799
	1e −0.5680		$3a_1$ −0.5560		$3a_1$ −1.3270
	$3a_1$ −0.3651		1e −0.4555		$4a_1$ −1.1657
a_j	$4a_1$ 0.6607	b_l	4a 0.5520		1e −0.6260
	2e 0.7151				$5a_1$ −0.5540
					$6a_1$ −0.3363
					2e −0.3193
					$7a_1$ 0.6080
					3e 0.6560
					$8a_1$ 0.8199
$E_K=55.2705$		$E_K=97.9823$		$E_K=153.6836$	
$E_T=-55.4450$		$E_T=-98.5556$		$E_T=-154.0059$	
$(-E_K/E_T)=0.9969$		$(-E_K/E_T)=0.9942$		$(-E_K/E_T)=0.9979$	

a) E_K means the kinetic energy, and E_T the total energy. The exponents of STO's are the *standard* values by Pople *et al.* in Ref. 9. The signs of MO's (a_1 and e) are termed according to the irreducible representation of C_{3v} symmetry at the whole system. Energies are in atomic unit.

$$\rho(1|1)_{j,l} = 2\sum_{g=1}^{10}[\sum_{j=6}^{8} C_j^{(g)} C_{l+8}^{(g)}\{a_j(1)b_l(1)+b_l(1)a_j(1)\}] \quad (6)$$

First, in this figure $\rho(1|1)_{exchange}$ shows a negative component which is unfavorable for the bond formation and is originated from the orbital interaction between the occupied orbitals in NH_3 and the occupied orbitals in HF. The operation of this orbital interaction essentially corresponds to the *exchange* repulsion force, shown in the example of the helium molecule.

On the other hand, $\rho(1|1)_{CT}$ stands for the density caused by the charge-transfer (CT) interaction between the occupied orbitals in NH_3 and the unoccupied orbitals in HF; it has enough density to strengthen the N···H bond. The mixing of the highest occupied (HO) MO, *i.e.*, $3a_1$ in NH_3, with the lowest unoccupied (LU) one, *i.e.*, $4a_1$ in HF, is found to contribute remarkably to this available density for the N···H bond (96.31% of $\int\rho(1|1)_{CT}dv_1$).

The residual two terms in Eq. (2), $\rho(1|1)_{back\ CT}$ and $\rho(1|1)_{j,l}$, have no serious effect on the intermolecular charge density:

$$|\rho(1|1)_{back\ CT}|<0.0016\ e/A^{\circ 3},\ |\rho(1|1)_{j,l}|<0.0003\ e/A^{\circ 3} \quad (7)$$

Here, the former corresponds to the density by the *back donation* from HF to NH_3, and the latter is the density coming from the orbital interaction between both originally unoccupied MO's in NH_3 and HF.

Thus, we come to the conclusion, apart from the electrostatic effect here, that among the several modes of orbital interaction, the particular HOMO–LUMO interaction supplies the considerable charge density in the intermolecular N···H region which overcomes the negative exchange density and results in the stabilization of the complex system.

One of the authors (S. Y.) especially grateful to Mr. Kazuhiro Ishida for his helpful advice in making the FORTRAN program of MO calculations.

We wish also to express our appreciation to the Data Processing Center of Kyoto University for its generosity in letting us use the FACOM 230-60 computer.

Methyl Signals in the PMR Spectra of Nigakilactones and Nigakihemiacetals

Tatsushi MURAE, Tôru IKEDA, Akihiko SUGIE, Tadaaki NISHIHAMA, Takahiko TSUYUKI, and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received May 4, 1973)

In connection with the structure determination of bitter principles isolated from *Picrasma ailanthoides* Planchon (*P. quassioides* Bennett),[1,2] the PMR spectra of nigakilactones A (I), B (II), C (III), D (IV) (= quassin[3]), E (V), F (VI),[1a,b] H (VII),[1c] J (VIII), K (IX), L (X), M (XI), and N (XII)[1d] were measured. The spectra of nigakihemiacetals A (XIII), B (XIV) (=neoquassin[3]), and C (XV)[1c] were also recorded. The PMR spectra of picrasin B (XVI)[2a] (=nigakilactone I[1c]), picrasin D (XVII),[2b,4] picrasin E (XVIII),[2b,4] a monoacetate of nigakilactone J (XIX),[1d] a deacetyl derivative of nigakilactone J (XX),[1d] and dehydroquassin (XXI)[3] were determined as references.

All of these compounds have a quassolidane skeleton (XXII) which possesses four methyl groups at C-4, C-8, C-10, and C-13. We wish to describe an assignment of the methyl signals of these compounds. The result is summarized in Table 1.

a) Chemical shifts and coupling constants are expressed in δ value and in Hz, respectively. b, c) Values may be reversed. d) Values may be interchanged. e) These assignments are in accord with those obtained from PMR experiments including NOE.[1b] f) Reversed values had been described.[8]

The method utilized for steroids[5] and triterpenes[6] was applied to the present investigation,[7] admitting that the effect caused by a change in a functional group is particularly observed on the signals of methyl groups situated nearly to this functional group, and the effect diminishes rapidly with the distance.

Methyl Group at C-4. A secondary methyl group at C-4 resonates at δ 1.07—1.17 as a doublet for the compounds with a methylated diosphenol moiety in ring A (I—VII, IX—XV, XVII, XVIII, and XXI). A doublet signal of this methyl group appears at δ 0.90—0.96 when ring A is saturated (VIII, XVI, XIX, and XX).

The signal due to the methyl group at C-4 is not practically affected by a structural change in rings C and D.

Methyl Group at C-13. A doublet at δ 1.00—1.10 is observed for a methyl group at C-13 of the compounds with R_3=H (I—III, VIII, XI, XV, and XVII—XX).

4) The PMR spectra of XVII and XVIII had been determined in pyridine by Hikino *et al.*[2b] Measurements in $CDCl_3$ were effected for the present communication.

5) *Cf.* N. S. Bhacca and D. H. Williams, "Application of NMR Spectroscopy in Organic Chemistry," Holden-Day Inc., San Francisco (1964), Chapter 2.

6) *Cf.* J. M. Lehn and G. Ourisson, *Bull. Soc. Chim. Fr.*, **1962**, 1137; Y. Tanahashi, Y. Moriyama, T. Takahashi, F. Patil, and G. Ourisson, *ibid.*, **1966**, 2374, and references therein.

7) PMR spectral measurements using $Eu(dpm)_3$ as a shift reagent resulted in coordinations of the reagent to at least two positions of a compound. The obtained spectra gave no information.

8) B. Viala and J. Polonsky, *C. R. Acad. Sci. Paris, C*, **271**, 410 (1970).

When a hydroxyl group is located on C-13, this methyl signal is shifted downfield (Δ+0.20—+0.27 ppm) and resonates as a singlet (compare V with III, VI with II, XII with I, and X with XVII). An introduction of a double bond between C-14 and C-15 causes a downfield shift (Δ+0.26 ppm) of this methyl signal (compare IX with VI).

The signal due to an olefinic methyl group at C-13 appears at δ 1.83—1.91 as a singlet for the compounds with a methylated diosphenol moiety in ring C (IV, XIV, and XVI). This olefinic methyl signal is shifted downfield (Δ+0.15 ppm) on introduction of a double bond between C-14 and C-15 (compare XXI with IV).

Practically, no effect is observed for the signal due to the methyl group at C-13, when a structural change is effected in ring A.

Methyl Group at C-10. A tertiary methyl group at C-10 appears at δ 1.40—1.50 as a singlet when the substituent at C-11 is a hydroxyl group (I, II, VI, VII, IX, XI—XIII, XV, and XX). Similar chemical shift values are observed for the methyl signal of the compounds with a methylene dioxy grouping (δ 1.43—1.47; X, XVII, and XVIII), and for the signal of the substances with a methylated diosphenol moiety in ring C (δ 1.45—1.54; IV, XIV, XVI, and XXI).

The signal due to the methyl group at C-10 is not affected by introduction of a hydroxyl group at C-13 (compare V with III, and VI with II) nor by location of a hydroxyl group on C-14 (compare VII with VI). An upfield shift (Δ—0.14——0.20 ppm) is observed for this methyl signal on acetylation of the hydroxyl group at C-11 (compare III with II, V with VI, and VIII with XX). Practically, no effect is observed for this signal on methylation of the hydroxyl group at C-12 (compare II with I, and VI with XII).

Methyl Group at C-8. A singlet at δ 1.16—1.28 is observed for a tertiary methyl group at C-8 of the compounds with both a hydroxyl (or an acetoxyl) group at C-11 and the substituent R_3=H (I—III, VIII, XI, XV, XIX, and XX).

An introduction of a hydroxyl group at C-13 causes a downfield shift (Δ+0.24—+0.29 ppm) of the signal due to the methyl group at C-8; this methyl group and the hydroxyl group at C-13 are in a 1,3-diaxial relationship (compare V with III, VI with II, XII with I, and X with XVII). Some downfield shifts are observed for this methyl signal on acetylation of the hydroxyl group at C-11 (Δ+0.06—+0.07 ppm; compare III with II, V with VI, and VIII with XX), on formation of a methylene dioxy ring (Δ+0.07 ppm; compare X with VI, and XVII with II), and on introduction of a double bond between C-14 and C-15 (Δ+0.04—+0.09 ppm; compare IX with VI, and XXI with IV). The methyl signal suffers some upfield shifts when a hydroxyl group is substituted on C-14 (Δ—0.04——0.11 ppm; compare VII with VI, XI with I, and XVIII with XVII), and when a hydroxyl group at C-12 is methylated (Δ—0.03——0.07 ppm; compare II with I, and VI with XII). Replacement of a lactone grouping in ring D by a hemiacetal moiety causes an upfield shift (Δ—0.08——0.13 ppm) of this methyl signal (compare VI with XIII, I with XV, and IV with XIV). The signal due to the methyl group at C-8 is not affected by a structural change in ring A (compare II with XX, III with VIII, and III with XIX).

Nigakihemiacetal D. As an example of application of the result shown above, the structure determination of a new bitter principle, nigakihemiacetal D (XXIII), isolated recently from *Picrasma ailanthoides* Planchon is described.

The presence of an acetoxyl, a hydroxyl and two methoxyl groups, one secondary and three tertiary methyl groups, and a hemiacetal[1c] and an α,β-unsaturated ketone[1a] moieties was suggested for XXIII from its spectral data (Experimental) and the molecular formula ($C_{24}H_{36}O_8$). As the spectral data of XXIII are similar to those of bitter substances hitherto isolated[1] from the same plant, XXIII is assumed to be a hemiacetal derivative related to the quassolidane (XXII).

As the methyl groups at C-8 and C-10 are tertiary ones (*Cf.* XXII), a secondary methyl resonating at δ 1.03 (J=7 Hz) must locate on either C-4 or C-13; the latter case is excluded as shown later. Therefore, this signal can be assigned to the methyl group at C-4 (not on a saturated ring A) (*Cf.* I—VII, IX—XV, XVII, XVIII, XXI). A tertiary methyl signal at δ 1.20 can be best assigned to the methyl group at C-13 to which a hydroxyl group is substituted (*Cf.* V—VII, XII, XIII). Chemical shift value (δ 1.36) observed for another tertiary methyl signal shows that this methyl group is in a 1,3-diaxial relationship with the hydroxyl group at C-13 and located on C-8 (*Cf.* XIII; with a hemiacetal grouping in ring D). The UV maximum at 262.5 nm[1a,c] of XXIII provides support for the location of an acetoxyl group on C-11. Thus a tertiary methyl signal at δ 1.24 could be assigned to the methyl group at C-10 (*Cf.* III, V; with an acetoxyl group at C-11).

These observations can be well interpreted based on a hemiacetal structure related to nigakilactone E (V) and lead to the structure XXIII for nigakihemiacetal D. This was confirmed by the formation of nigakilactone E (V)[1a] on oxidation of this hemiacetal (XXIII) with silver oxide.

Experimental

PMR spectra were taken on a JEOL JNM-C-60 spectrometer at 60 MHz in $CDCl_3$ solution containing TMS as an internal standard.

Isolation of XXIII. Extraction and subsequent separation procedures of crude material (200 g) from the stemchips (160 kg) of *Picrasma ailanthoides* Planchon were decribed elsewhere.[1d] After chromatographic separation of the fractions 2 and 3[1d] containing picrasin D, the Fractions 4—6 were eluted with acetone-benzene (1: 2) to give nigakihemiacetal D (XXIII) (15 mg), amorphous solid, $[\alpha]_D$+46° (c 0.1, MeOH); UV (MeOH): λ_{max} 262.5 nm (ε 2000), IR (Nujol): 3450, 1735, 1708, 1640, 1245 cm^{-1}; PMR ($CDCl_3$): δ 1.93 (3H, s; -OCOC$\underline{H}_3$), δ 3.27 (1H, d, J=9 Hz, -C$\underline{H}$OCH$_3$), δ 3.51 (3H, s; -OC$\underline{H}_3$), δ 3.56 (3H, s; -OCH$_3$), δ 3.72 [1H, m; -C$\underline{H}$-O-CH(OH)-], δ 5.44 (1H, q; J=11 and J=9 Hz; -C$\underline{H}$-OCOCH$_3$), δ 5.07 (1H, d, J=2.5 Hz; -C=C$\underline{H}$).

Oxidation of XXIII with Silver Oxide. Compound XXIII (10 mg) was treated with silver oxide as usual[1d] to give nigakilactone E (V)[1a,b] (7mg) identified by IR, PMR, $[\alpha]_D$ and tlc.

Kinetics and Mechanism of the Oxidation of Aliphatic Alcohols by Acid Permanganate

Kalyan K. BANERJI*

The Dyson Perrins Laboratory, University of Oxford, Oxford OX1 3QY, U.K.

(Received August 25, 1972)

Barter and Littler[1] suggested, on the basis of similar rate laws, that the oxidation of alcohols by acid permanganate, bromine and other two-electron oxidants follow similar mechanisms. The oxidation of alcohols by bromine involves removal of hydride ion in the rate-determining step.[2] A similar mechanism also was suggested for the oxidation of benzyl alcohol by acid permanganate.[3] The chromic acid oxidation, another two-electron process, however, is proposed to involve a proton transfer.[4] No conclusive evidence is available in literature about the form of hydrogen removed from the alcohol in permanganate oxidation.

If α-C–H bond is ruptured in the rate-determining step, then an unequivocal evidence about the flow of electrons leading to the transition state can be obtained by studying the effect of polar substituents on the rate of the oxidation of a suitable alcohol.

This paper reports the kinetics of the oxidation of some primary alcohols and evaluates the reaction constant. The mechanistic conclusions are discussed.

Results

Product Analysis. The oxidation of ethanol by acid permanganate eventually gives acetic acid. An estimation of the carboxylic acid formed indicated the following stoichiometry:

$$4MnO_4^- + 12H^+ + 5CH_3CH_2OH \longrightarrow 5CH_3COOH + 4Mn^{+2} + 11H_2O$$

Rate Laws. The oxidation of alcohols by acid permanganate is autocatalytic and this may be due to the effect of Mn(III)/Mn(IV). Addition of sodium fluoride suppresses the autocatalysis, though it does not affect the initial rate. Therefore, an excess of sodium fluoride was added to each reaction mixture.

The reaction were followed under pseudo-first-order conditions by keeping a large excess of the alcohol over permanganate. The rate of disappearance of permanganate, under these conditions, is of first order. The order with respect to the alcohol is also one (Table 1). The rate varies linearly with acidity, at constant ionic strength.

Table 1. Substrate dependence of the reaction rate

$[KMnO_4]$ 1×10^{-4} M	$[H^+]$ 1.0M	[NaF] 0.01M	Temp. 25 °C		
10^2 [EtOH]M	1.0	2.0	4.0	6.0	8.0
10^4 $k_1(s^{-1})$	9.55	19.0	37.5	57.0	76.8
10^2 k_1/[EtOH]	9.55	9.50	9.40	9.50	9.60

The rate constants for the oxidation of ethanol and α,α-dideuterioethanol at 30 °C are $10^2k=13.0$ and 5.0 l^2 mol^{-2} s^{-1} respectively. The kinetic isotope effect, $k_H/k_D=2.60$ at 30 °C.

The oxidation of ethanol, under nitrogen, failed to induce the polymerization of acrylonitrile. The formation of free radicals is, therefore, unlikely.

The rate constants for the oxidation of ethanol in deuterium oxide and in water at 30 °C are $10^2k=12.5$ and 13.0 l^2 mol^{-2} s^{-1} respectively. The solvent isotope effect, $k(H_2O)/k(D_2O)=1.04$.

The rate of the acid permanganate oxidation of ten primary aliphatic alcohols were obtained at different temperatures and the activation parameters evaluated (Tables 2 and 3).

Table 2. Oxidation of alcohols, RCH_2OH, by acid permanganate

R	10^4 k (l^2 mol^{-2} s^{-1})				
	25 °C	30 °C	35 °C	40 °C	45 °C

ΔH^* kcal/mol	10.0	13.5	14.0	16.0	15.8
$-\Delta S^*$ e.u.	29.1	23.3	22.0	20.0	20.2

Discussion

The linear dependence of the oxidation rate on acidity, may be attributed to the protonation of permanganate anion to give permanganic acid, a more

powerful oxidant.[3,5]

The kinetic isotope effect shown in the oxidation of ethanol is very close to the value obtained by Littler[6] in the oxidation of cyclohexanol ($k_H/k_D=2.41$). It confirms that α-C–H bond is ruptured in the rate-determining step. There is no kinetic evidence that the alcohol and the oxidant are involved in any pre-equilibrium. The formation of a permanganate ester is unlikely in view of the almost equal ease of the oxidation of alcohol and ethers.[1]

No systematic study on the effect of structure in the permanganate oxidation of alcohols has been reported. Barter and Littler reported the rate data of the oxidation of methanol, ethanol and 2-methoxyethanol.[1] However, no reaction constant could be evaluated with those limited data. In the present investigation, the rate of the oxidation of the ten alcohols give a good correlation ($r=0.993$) in the Taft plot with a reaction constant $\rho^*=-2.02\pm0.08$ at 30 °C. The negative ρ^* points to an electron-deficient carbon centre in the transition state. The magnitude of the reaction constant decreases with temperature, as expected.

The activation entropies and enthalpies of the ten compounds are linearly related ($r=0.988$), the value of isokinetic temperature being 650 ± 40 K. Present views do not attach much significance to the value of isokinetic temperature,[7] though a linear correlation between ΔH^* and ΔS^* is usually a necessary condition for the validity of the Taft equation.[2]

The results reported in this paper supports the hydride transfer mechanism. The small magnitude of the solvent isotope effect suggests that the removal of the hydroxylic proton simultaneously with the hydride ion transfer is unlikely and is more so in view of the magnitude of the reaction constant. The polar requirement on the carbinol carbon of hydride release from C–H is opposite to that of proton release from O–H and in a fully concerted process, the reaction constant should be nearer zero.

Experimental

Materials. Methanol, ethanol, 1-propanol, 1-butanol, 2-chloroethanol, 2-methyl 1-propanol, and 2,2-dimethyl 1-propanol were commercial products and were purified by the usual methods. Cyclohexylmethanol,[8] 2-bromoethanol,[9] and 2-methoxyethanol[10] were prepared by the methods described in literature.

α,α-Dideuterioethanol (CH_3CD_2OH) was prepared by the method reported by Kaplan.[11] Perchloric acid (Baker) was used as a source of hydrogen ions. All reagents used were of analytical grade.

Product Analysis. Acetic acid produced in the oxidation of ethanol was estimated colorimetrically as ferric hydroximate.[12]

Kinetic Measurements. The reactions were followed by estimating permanganate spectrophotometrically at 532 nm. The rate constants reported are averages of multiple runs and are reproducible within ±4%.

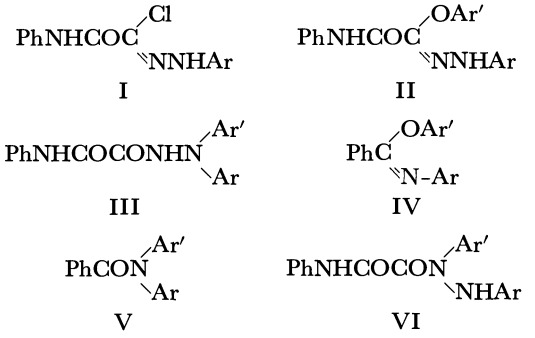
Synthesis and Rearrangement of Oxanilic Esters Arylhydrazones

A. Sami SHAWALI and M. Kamal AHMAD
Department of Chemistry, Faculty of Science, University of Cairo, Giza, Egypt

(Received February 15, 1973)

The reactivity of phenylcarbamoylarylhydrazidic chlorides (I) with various nucleophiles involving carbon and nitrogen atoms has recently been reported.[1] This communication describes the reaction of I with phenols to get the title compounds (II), which do not seem to have been reported, and the thermal rearrangement of II into III, a new Chapman-like rearrangement[2] in the hydrazone series.



Synthesis of II was most conveniently performed as follows. An equivalent amount of I was added to a suspension of sodium phenolate in benzene. After refluxing the mixture for 30 min, the solvent was distilled off and the residue was crystallized from methanol (Method A). Alternatively, to an ethanolic sodium phenolate solution (prepared by the addition of the appropriate phenol to sodium ethoxide in ethanol) was added an equivalent amount of I with stirring at room temperature. After standing for 24 hr, the mixture was diluted with water and the resulting product was filtered and crystallized from methanol (Method B). By the use of either method it was possible to prepare a series of aryl oxanilate arylhydrazones (IIa—j). The properties of these compounds are given in Table 1. The spectral and elemental analyses support structure II for the products listed.

Aryl imidates (IV) underwent rearrangement on heating to give *N*-aroyldiarylamines (V) (Chapman-rearrangement).[2] Aryl oxanilate arylhydrazones (II) were found to undergo a similar rearrangement to give oxanilic arylhydrazides (III) when refluxed in inert solvents. Thus, when IIa (Ar=C_6H_5; Ar'=4-$CH_3C_6H_4$) was refluxed in nitrobenzene for 4 hr, giving a product which was analyzed as $C_{21}H_{19}N_3O_2$. Its IR spectrum revealed the absence of the C–O–Ar band present in the IR spectra of all compounds in the series II. Furthermore, the UV spectrum of the compound obtained in ethanol differed from that of the starting

Table 1. Aryl oxanilate arylhydrazones (II) and their rearrangement products (III)

a) from Method A.

ester IIa, no band characteristic of the hydrazone chlomophore being present. Two possible structures IIIa and VIa (Ar=C_6H_5; Ar'=4-$CH_3C_6H_4$) were formulated. For the sake of confirmation we studied the rearrangement of the isomeric ester IIb (Ar=4-$CH_3C_6H_4$; Ar'=C_6H_5). It was found to give only one product identical with that obtained from IIa. This suggests strongly that the actual structure of the product is IIIa and not VIa. The correctness of such an assignment was further proved by the identity of the product IIIe (Ar=Ar'=C_6H_5) obtained by thermolysis of IIe (Ar=Ar'=C_6H_5) with an authentic sample of *N*-oxanilyl-*N'*,*N'*-diphenylhydrazine prepared by the reaction of oxanilyl chloride with asymmetric diphenylhydrazine.

When a mixture of the iosmeric esters IIa and IIb was heated, it gave only hydrazide IIIa (Ar=C_6H_5; Ar'=4-$CH_3C_6H_4$) in an almost quantitative yield. This indicates that the II—III conversion is an intramolecular rearrangement. The results of thermolysis of the isomeric esters IIc (Ar=C_6H_5; Ar'=4-ClC_6H_4) and IId (Ar=4-ClC_6H_4; Ar'=C_6H_5) either separately or in mixture confirm such a conlcusion.

The foregoing results indicate that the thermal rearrangement of II to III involves a 1,4-shift of an aryl group from oxygen to nitrogen probably *via* a five-membered cyclic transition state of type VII. No formation of VI might be attributed to the lower stability of the four-membered cyclic transition state (VII) required for the formation.

Group Interactions in Polyelectrolytes. VII.[1] Amination Kinetics of Chloromethylated Polystyrene with Butylamine Isomers

Hiroshi KAWABE and Masaya YANAGITA

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received October 19, 1972)

The amination of chloromethylated polystyrene (CMPS) and benzyl chloride with butylamine isomers and diethylamine was investigated kinetically in dioxane, methyl ethyl ketone (MEK), and *N,N*-dimethylformamide (DMF). Although the amination of *i*- and *s*-butylamine conformed to the ordinary second-order kinetics in all the solvents, deceleration was observed during the course of the amination of CMPS with *n*-butylamine in MEK as well as in dioxane, with *t*-butylamine in DMF, and with diethylamine in both dioxane and DMF. The intrinsic rate constants of the amination of CMPS were generally almost the same as those of benzyl chloride. The magnitudes of the rate constants in each solvent were in this order; *n*-butyl > *i*-butyl > *s*-butyl > *t*-butyl; it was in the order of DMF ≫ MEK ≈ dioxane with all the amines investigated. These results were interpreted in terms of both the structures of the amines and the interaction between the amine and the solvent molecules.

The kinetics of the amination of chloromethylated polystyrene (CMPS) with several primary and secondary amines was investigated by Kawabe and Yanagita.[1-3] They found that the apparent second-order rate constant of the amination with *n*-butylamine in dioxane decreased as the amination proceeded and that the rate constant of the amination with 2-aminobutanol increased in dioxane, though both the aminations obeyed the ordinary second-order kinetics in *N,N*-dimethylformamide (DMF). On the other hand, the rate constant of the amination with di-*n*-butylamine decreased in both dioxane and DMF. The amination of benzyl chloride with all the above amines obeyed the ordinary second-order kinetics. If the decrease in the rate constant during the amination of CMPS is caused by the steric effect of the already-aminated neighbors with bulky amine, this decrease must be related to the bulkiness of the amine. In the present study, the kinetics of the aminations of CMPS and benzyl chloride with butylamine isomers and diethylamine have been investigated in dioxane, methyl ethyl ketone (MEK), and DMF. The authors have found that the rate constant decreases slightly in the amination of CMPS with *t*-butylamine and appreciably in the amination of CMPS with diethylamine. It has also been found that the magnitudes of the rate constants in the aminations of both CMPS and benzyl chloride are greatly affected by the species of amine and solvent.

Experimental

Materials. Chloromethylated polystyrene (CMPS) was prepared and purified by the procedures described in the previous papers.[1-3] The chlorine contents and the molecular weights of the CMPS used in the present study are tabulated in Table 1. The amines and the solvents, all of a reagent grade, were distilled before use; they were proved to be pure by their refractive indices. All the other chemicals were of a reagent grade, and deionized, decarbonized water was used.

Kinetic Measurements. The procedures of the kinetic measurements in the amination of CMPS and benzyl chloride were almost the same as those described in a previous paper.[1]

Table 1. Chloromethylated polystyrene

Code	Content of Cl %	Degree of chloromethylation	Molecular weight
SC-3	22.87	0.98	—
SC-5	21.15	0.87	10.2×10^4
SC-7	22.04	0.93	7.3×10^4
SC-8	22.11	0.93	9.2×10^4
SC-9	21.83	0.91	9.6×10^4
SC-10	21.07	0.87	11.6×10^4

The experimental conditions in the amination of CMPS are listed in Table 2. The temperature of a reaction mixture was kept constant by means of a thermostat (within±0.1°). In the amination of benzyl chloride, the initial concentrations were almost the same as those in the amination of CMPS. All the reactions except Run 9 were homogeneous and reached completion. In Run 9, since hydrochloric acid salt of diethylamine was deposited during the amination, the reaction mixture was previously distributed in test tubes dipped in a thermostat to avoid uneven sampling.

Viscometric Measurements. In the amination of CMPS, the change in the viscosity of the reaction mixture was also checked for Runs 1—8 by the procedures described in the previous paper.[1]

Results

The aminations of chloromethylated polystyrene (CMPS) and benzyl chloride with butylamine isomers and diethylamine were investigated kinetically in dioxane, MEK, and DMF.[4] The kinetic measurements could not be carried out in dimethyl sulfoxide, because all the aminations of CMPS with these amines in the solvent were accompanied by the precipitation of the polymer in an earlier stage of the reaction.

The amination of benzyl chloride could be expressed by the ordinary second-order equation:

$$kt = \frac{1}{(a-b)t}\ln\frac{b(a-x)}{a(b-x)} \equiv \overline{kt} \qquad (1)$$

2) H. Kawabe and M. Yanagita, *ibid.*, **41**, 1518 (1968).

3) H. Kawabe and M. Yanagita, *ibid.*, **44**, 896 (1971).

4) Several aminations of CMPS were carried out by using different CMPS samples (Suns 4 and 24, Runs 7 and 19, and Runs 8 and 16 for butylamine isomers; and also Runs 9 and 10 for diethylamine), and almost the same value of rate constant was obtained in each case. It was also shown in these cases that difference in concentration of amine revealed no difference in the rate constant.

a) A: *n*-butylamine, B: *i*-butylamine, C: *s*-butylamine, D: *t*-butylamine, E: diethylamine. b) a: Initial concentration of amine. c) b: Initial concentration of the polymer expressed in moles of chloromethyl group per liter.

where a and b are the initial concentrations of an amine and the chloromethyl group respectively, while x is the concentration of the chloride ions after time t.

Although most of the aminations of CMPS conformed to Eq. (1), deceleration during the amination was observed in the following cases: *n*-butylamine in dioxane and MEK, *t*-butylamine in DMF, and diethylamine in dioxane and DMF. In these cases, the plot of $\overline{kt}$ against t was expressed substantially by straight lines which intersected nearly at half-amination, and the over-all kinetics in the presence of a large excess of amine ($a \gg b$) could be expressed by Eq. (2):[2]

$$\beta = x/b = 1 - \frac{k_1-k_2}{2k_1-k_2}e^{-k_1at} - \frac{k_1}{2k_1-k_2}e^{-k_2at} \quad (2)$$

$$k_1 = \frac{1}{[(2-k_2/k_1)a-b]} \ln \frac{1-\beta}{1-(2-k_2/k_1)\alpha} \quad (3)$$

$$k_2 = \frac{1}{(a-b)(t-\tau)}\left(\ln\frac{1-\alpha}{1-\beta}\ln\frac{1-\chi/a}{1-\chi/b}\right) \quad (4)$$

where k_1 and k_2 are the rate constants of the elementary reactions which are independent of the neighboring groups and which are dependent on their steric effect respectively. In Eq. (4), $\alpha=x/a$, τ and χ are the values of t and x respectively when $x_1 \simeq b/2$, and x_1 is the concentration of the group which was aminated independently of its neighbors. By combining Eqs. (1) and (4), we get Eq. (5):

$$\overline{kt} = k_2t + C \quad (5)$$

where C is a constant in a given system: $C=\ln[(1-\chi/a)/(1-\chi/b)]-k_2(a-b)\tau$. The value of k_2 can be determined, therefore, directly as the slope of the $\overline{kt}$ vs. t plot: $k_2=\Delta\overline{kt}/\Delta t$. With regard to k_1, on the other hand, the slope of the plot gives merely an approximate value of k_1. The real value of k_1 can be determined only by repeated computations by means of Eq. (3).[2]

Amination with Butylamine Isomers. The rate constants of the amination of CMPS and benzyl chloride with butylamine isomers at 50°C are tabulated in Table 3.[4] It is clearly shown in the table that the rate constant, k or k_1, in any solvent is in this order: *n*-butyl>*i*-butyl>*s*-butyl>*t*-butyl. It is also shown for any amine that the numerical value of the rate constant in MEK is almost the same as that in dioxane, while the value in DMF is much higher than those in dioxane and MEK.

Table 3 shows three cases in which the deceleration was observed; the values of k_2/k_1 are cited in parentheses. The course of the amination of CMPS with *n*-butylamine in MEK at 50 °C is shown in Fig. 1, where the solid line was calculated on the basis of Eq. (2) by using these rate constants:

$$k_1 = 2.85\times10^{-3},\ k_2 = 1.77\times10^{-3}\ \text{l/mol·min}$$

which were obtained on the basis of Eqs. (3) and (4) (or Eq. (5)) respectively. The white circles in Fig. 1, which represent the observed values, are substantially on the calculated curve. The value of k_2/k_1 in MEK, 0.62, is comparable to that in dioxane, 0.65 (the aver-

age value at various temperatures).

Deceleration was also observed in the amination of CMPS with *t*-butylamine in DMF. The results of kinetic measurements at various temperatures are shown in Fig. 2, where open circles represent the observed values and where the solid lines show the values calculated on the basis of Eq. (2) by the use of the values of k_1 and k_2 tabulated in Table 4. The rate constants of the amination of benzyl chloride, k_B, and the activation energies, E_a, and the frequency factors, A, which were computed by the least-squares method, are also listed in Table 4. The average value of k_2/k_1 is 0.79, higher than those of *n*-butylamine in dioxane and MEK. The amination of CMPS with *s*- and *i*-butylamine conformed to Eq. (1) in all the solvents. The results of the amination of CMPS and benzyl chloride with these amines are summarized in Tables 5 and 6.

Amination with Diethylamine. In the amination of CMPS with diethylamine, the deceleration during the amination was observed in both dioxane and DMF. The results at 30 °C are shown in Figs. 3 and 4, where

the observed values, represented by the white circles, are substantially on the curves calculated on the basis of Eq. (2) by the use of the following values of k_1 and k_2:

(in dioxane) $k_1 = 1.71\times10^{-3}$ l/mol·min, $k_2 = 3.96\times10^{-4}$ l/mol·min; $k_2/k_1 = 0.43$

(in DMF) $k_1 = 3.48\times10^{-2}$ l/mol·min, $k_2 = 1.81\times10^{-2}$ l/mol·min; $k_2/k_1 = 0.52$

In DMF, the rate constant of benzyl chloride was also measured at 30 °C as:

(in DMF) $k_B = 2.82\times10^{-2}$ l/mol·min

Viscosity Change in the Reaction Mixture During the Amination of CMPS with Butylamine Isomers. The change in the viscosity in the amination of CMPS was measured in various solvents; the results in DMF are shown in Fig. 5, where H, the viscosity ratio defined in the previous paper,[1] is plotted against β. The values of H are in this order: *t*-butyl>*s*-butyl>*i*-butyl>*n*-butyl. In the other solvents, the order was

the same; however, the viscosity changes do not seem to be related to the kinetic behavior of the aminations.

Discussion

Deceleration During the Amination of CMPS. In the amination of CMPS with butylamine isomers,

the amination with *i*- and *s*-butylamine conformed to the ordinary second-order kinetics in dioxane, MEK, and DMF; however, deceleration during the reaction was observed with *n*-butylamine in dioxane and MEK, and not in DMF, though a slight deceleration was observed with *t*-butylamine in DMF. On the other hand, a stronger deceleration was observed in the amination with diethylamine in both dioxane and DMF. Since all the aminations of benzyl chloride proceeded normally, and since the formation of charged groups on the polymer is not likely to take place during the reaction,[5] this deceleration seems to be caused by the steric effect of the already-aminated neighboring groups; this kinetic behavior can be fully expressed by Eq. (2). The kinetic behavior of the amination of CMPS is dependent on the species of amine and the solvent. The experimental results may be explained in terms of the geometry of amines, which is itself determined by the structural factors of the amines, such as the branching and the flexibility through the rotation around the bond axes, and also by the interactions between amine and solvent molecules and by the conformational change in the amine molecules (or groups) at the transition state of the reaction. The steric effect must be mainly determined by the conformational free energy, that is, the difference in the free energy of amine molecules (or groups) at the transition state under the influence of the neighboring groups from that at the initial state; it consists of the difference in the potential energies of the molecules between the two states and the difference between the conformational entropies.

In the case of diethylamine, an appreciable deceleration was observed in both dioxane ($k_2/k_1=0.43$) and DMF ($k_2/k_1=0.52$), though it was not so marked as the cases of di-*n*-butylamine, a higher homologue of the former, in dioxane ($k_2/k_1=0.23$)[2] and in DMF ($k_2/k_1=0.27$).[1] These results may be related to the bulky structure of secondary amines, in which two alkyl groups occupy the apices of the trigonal pyramid, and in which, therefore, the steric obstruction is pronounced with secondary amines, irrespective of the species of solvent. A weaker deceleration was observed in some cases of butylamine isomers. The slight deceleration with *t*-butylamine in DMF ($k_2/k_1=0.79$) may be asascribed to its rigid and bulky structure. The difference in kinetic behavior between *n*-butylamine and *i*- and *s*-butylamine may be supposed to be mainly due to the difference in their conformational entropies.

In the case of *n*-butylamine, the deceleration was observed in dioxane ($k_2/k_1=0.65$) and MEK ($k_2/k_1=0.62$), but it was not observed in DMF. Since the value of the solubility parameters, δ,[6] of *n*-butylamine ($\delta=9.15$) is almost the same as those of dioxane ($\delta=9.95$) and MEK ($\delta=9.16$), the amine molecules in these solvents may be considered to be statistically elongated and their conformational change at the transition state will require an increase in energy and a loss of entropy. On the other hand, the *n*-butylamine molecule in DMF ($\delta=12.11$) is considered to be contracted as a result of the intramolecular interaction among the segments; therefore, its conformational change at the transition state will require less energy and less entropy loss than those in dioxane and MEK. The normal kinetic behavior with *i*- and *s*-butylamine in both dioxane and DMF is properly to be ascribed to the branching structure of these molecules, the conformational entropies of which are much smaller than that of *n*-butylamine.

Comparison Between the Rates of CMPS and Benzyl Chloride. The values of k_1 or k of CMPS are generally almost the same as the corresponding values of benzyl chloride. The effects of the species of amine and solvent are, therefore, essentially the same for both CMPS and benzyl chloride. The ratios of the intrinsic rate constants of CMPS (denoted as k_P) to the corresponding rate constants of benzyl chloride (k_B) are somewhat higher than unity in dioxane and MEK. In DMF, the relative rates are slightly less than unity except in case of diethyl amine. Table 7 shows the numerical values of thermodynamic quantities, $\Delta H^{\ddagger}$; the enthalpy of activation, $\Delta S^{\ddagger}$; the entropy of activation, and $\Delta G^{\ddagger}$, the free energy of activation, all of which have been calculated at 25 °C by means of the equations described in the previous paper.[1] As is shown in Table 7, all the reactions in DMF have a tendency to be accompanied by a decrease in $\Delta S^{\ddagger}$ as well as the increase in $\Delta H^{\ddagger}$ from benzyl chloride to CMPS. This is also the case with the amination with 2-aminobutanol in DMF ($k_P/k_B=0.81$) or in DMSO ($k_P/k_B=0.76$).[1] On the other hand, in dioxane, the change in $\Delta S^{\ddagger}$ is not significant in the amination with *n*-butylamine or 2-aminobutanol.[1] Thus, this tendency of $\Delta S^{\ddagger}$ to decrease from benzyl chloride to CMPS seems to be characteristic of dipolar aprotic solvents, in which the solvation of the transition state plays an important role in the determination of the amination rate.

Effect of Amine on the Amination Rate. The intrinsic rate constants of CMPS as well as of benzyl chloride are dependent on the species of amine—*e.g.*, in butylamine isomers, in the following order: *n*-butyl>*i*-butyl>*s*-butyl>*t*-butyl. The values of the relative rate with respect to an amine are approximately the same, irrespective of the species of solvent and chloride (CMPS or benzyl chloride). This order among butylamine isomers is not likely to be dependent on their basicities, because the pK values of the conjugated acids are almost the same: 10.64; (*n*), 10.42 (*i*), 10.56 (*s*), and 10.45 (*t*). It seems rather dependent on the branching structures of the alkyl groups of the amines; this dependence produces the difference in the steric hindrance of the benzene ring to the alkyl group of amine in the transition state. This is supported, especially in the case of *t*-butylamine, by the fact, shown in Table 7, that the increase in $\Delta G^{\ddagger}$ from

5) In fact, a completely aminated CMPS sample, which was obtained simply by pouring the reaction mixture into a poor solvent, was proved to contain no chlorine by its elementary analysis for halogen. This may be ascribed to that the aminated group on the polymer is the *N*-benzyl substituent of an alkylamine used as a reagent and it is a weaker base than the alkylamine which is used in a large excess in the present study.

6) The δ values were calculated at 25 °C on the basis of the data shown in the book: J. A. Riddick and W. B. Bunger, "Organic Solvents," third edition, Wiley Interscience, New York, N. Y. (1970).

TABLE 7. THERMODYNAMIC QUANTITIES AT 25 °C IN THE AMINATION OF CHLOROMETHYLATED POLYSTYRENE AND BENZYL CHLORIDE

Solvent	Amine	Chloride	$\Delta H^{\neq}$ kcal/mol	$\Delta S^{\neq}$ e.u.	$\Delta G^{\neq}$ kcal/mol
Dioxane	*n*-Butyl[a]	CMPS, k_1	11.5±0.1	−41.2±0.3	23.8
		CMPS, k_2	11.5±0.9	−42.2±2.6	24.1
		Benzyl	12.0±0.2	−41.5±0.6	24.3
DMF	*n*-Butyl[a]	CMPS	10.8±0.1	−38.1±0.4	22.2
		Benzyl	11.0±0.2	−37.2±0.7	22.1
	i-Butyl	CMPS	11.0±0.2	−37.9±0.7	22.3
		Benzyl	11.2±0.1	−36.8±0.2	22.2

		Benzyl	11.7±0.1	−37.3±0.3	22.8
	t-Butyl	CMPS, k_1	11.4±0.0$_3$	−40.4±0.1	23.5
		CMPS, k_2	11.6±0.4	−40.3±1.3	23.6
		Benzyl	11.8±0.1	−38.5±0.3	23.3
	2-Amino-butanol[a]	CMPS,	12.5±0.2	−35.8±0.7	23.1
		Benzyl	12.7±0.1	−34.5±0.2	23.0

a) Data in Ref. 1.

n-butyl to *t*-butylamine is based on the decrease in $\Delta S^{\neq}$ as well as by the increase in $\Delta H^{\neq}$. It is also shown in Table 7 that the $\Delta H^{\neq}$ of 2-aminobutanol is considerably higher than that of *s*-butylamine (2-aminobutane); this is probably related to an inductive effect of the hydroxyl group.

Effect of Solvent on the Amination Rate. The intrinsic rate constant of CMPS as well as the rate constants of benzyl chloride are also dependent on the species of solvent. In dioxane and MEK, the rates are approximately the same, but that in DMF is very high. Since the dielectric constants (D) are 2.21 (dioxane), 18.51 (MEK), and 36.71; (DMF), no relation between k and D can be established in this case. The high rate constants in DMF are considered to be due to the solvation of the transition state in this dipolar aprotic solvent, as has been discussed in the previous paper.[1] Since the δ value of MEK is almost the same as that of dioxane, the contributions of both solvents to $\Delta H^{\neq}$ and $\Delta S^{\neq}$ are expected to be almost the same.

The authors wish to express their thanks to Mr. Akihiro Kishi, Mr. Kazuaki Kawamura, Mr. Masahiro Uchiyama and Mr. Masayuki Takahashi for their helpful assistance in preparing the polymer and in carrying out the measurements.

Kinetics of Oxygen Exchange between Arsenate Ions and Water. II. Catalysis by Arsenious Acid

Akiko OKUMURA, Noriko YAMAMOTO, and Nobukazu OKAZAKI
Department of Chemistry, Nara Women's University, Nara 630
(Received March 22, 1973)

Oxygen exchange between arsenate ions and water is catalyzed by arsenious acid. The catalytic effect has been studied at 14.5 °C and 30.0 °C over the pH region of 7.5—10.2. The increase in the exchange rate due to the addition of arsenious acid, R_c, may be expressed as: $R_c \approx k[H^+][As(III)][As(V)]$. The results are interpreted in terms of the rapid reversible condensation of the As(III) with the As(V) species to form the arsenitoarsenate ions.

In a previous study of the oxygen exchange between arsenate ions and water,[1] it has been shown that the reversible condensation of the arsenate ions to form diarsenate ions occurs in aqueous solutions. Itse ems that it would be interesting to see whether or not the arsenate ion reacts with other oxyanions to form heteropolyanions, and to compare the reactivities of these oxyanions towards the arsenate ions. These reaction open an additional path for the oxygen exchange of arsenate ions, and, if the reactions are reversible and sufficiently rapid, the exchange reaction can be catalyze by these oxyanions. In the present paper, catalysis by arsenious acid will be reported.

Experimental

Materials. The arsenic trioxide (Guaranteed reagent, JIS) and perchloric acid(Guaranteed reagent, JIS) were used without further purification. All the other chemicals were the same as those used in the previous work.[1]

Procedure. The procedures were almost the same as those used in the previous work.[1] The exchange reaction was started by diluting an isotopically-equilibrated solution of Na_2HAsO_4 in oxygen-18 water with a relatively large amount of isotopically normal water, a proper amount of an arsenious acid solution being added. The pH of the solution was adjusted by the addition of a small amount of perchloric acid or of a sodium hydroxide solution. After appropriate intervals, the arsenate ions were precipitated by the addition of a barium chloride solution. The precipitate, after being washed three times with absolute ethanol and dried, was converted into carbon dioxide by the guanidine hydrochloride method. The isotopic analysis of the carbon dioxide was made on a Hitachi RMS-I-type mass spectrometer. The contribution of a small amount of the precipitate of barium arsenite to the ^{18}O-content of the carbon dioxide was neglected. Oxygen exchange between arsenious acid and water is very rapid at room temperature, and is completed within the time necessary for the separation. The rate of the oxygen exchange of arsenate ions was calculated by means of the formula:

$$R = -\frac{[As(V)][H_2O]}{4[As(V)] + [H_2O]} \cdot \frac{1}{t} \cdot \ln\left\{1 - \frac{O_0 - O_t}{O_0 - O_\infty}\right\},$$

where O_0, O_t, and O_∞ are the ^{18}O-contents of the carbon dioxide at times 0, t, and infinity respectively, and where [As(V)] and $[H_2O]$ are the concentrations of the arsenate and water respectively.

Determination of Dissociation Constants. The dissociation constants of arsenious and arsenic acid under the conditions of the kinetic experiments were determined by potentiometric titration with a glass electrode. The pK_2 of arsenic acid was determined by titrating a solution of Na_2HAsO_4 containing the amount of sodium chloride necessary to maintain the desired ionic strength with hydrochloric acid. For the determination of the pK_1 of arsenious acid, a solution of arsenious acid was titrated with a solution of sodium hydroxide, an appropriate amount of sodium chloride being added to adjust the ionic strength. The pH of the solution was measured with a Radiometer PHM-26 pH meter. The results obtained from two series of titrations at I=0.2 M, where I is the ionic strength, are shown in the following table. For the definition of the pK's, see Part I of this series.

TABLE 1. THE DISSOCIATION CONSTANTS OF ARSENIC ACID (pK_2) AND ARSENIOUS ACID (pK_1) AT I=0.2 M.

	14.5°C	30.0°C
pK_2 of arsenic acid	$6.59_6 \pm 0.00_4$	$6.55_6 \pm 0.00_6$
pK_1 of arsenious acid	$9.34_1 \pm 0.00_3$	$9.10_8 \pm 0.01_7$

Results and Discussion

pH *Dependence.* Fig. 1 shows the pH-rate profile of the oxygen exchange of arsenate ions with and without the added arsenious acid at 14.5 °C and 30.0

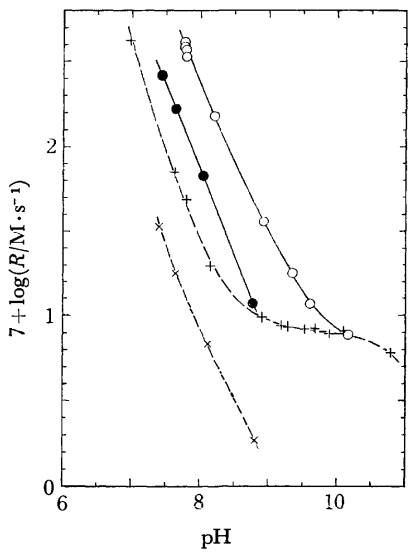

Fig. 1. pH-rate profiles of the oxygen exchange between arsenate ions and water ([As(V)]=0.07 M, I=0.2 M): + (30 °C), × (14.5 °C), without added arsenious acid. ○ (30 °C), ● (14.5 °C), with added arsenious acid ([As(III)] $\simeq 1.2 \times 10^{-4}$ M).

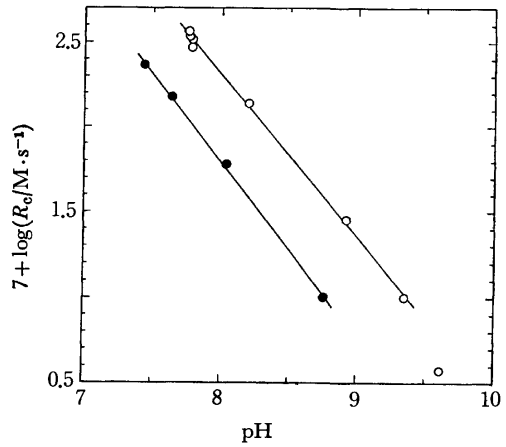

Fig. 2. pH dependence of the catalysed portion of the exchange rate R_c: ○ 30 °C, ● 14.5 °C.

°C([As(V) : [As(III)]≈50 : 1).[2] The addition of arsenious acid increases the exchange rate about 8-fold at pH 7.44. The catalytic effect decreases with the increase in pH, and it disappears above pH 10. From the pH-rate profile and the values of the dissociation constants of arsenic and arsenious acids, it may be inferred that $H_2AsO_4^-$ and H_3AsO_3 are the active species in the catalytic process.

Figure 2 shows a plot of the logarithm of $R_c(=R-R_0)$ against pH, where R and R_0 are the exchange rates observed with and without the addition of arsenious acid. The slopes of the lines passing through the plots are -0.96 ± 0.01 at 30.0 °C and -1.01 ± 0.02 at 14.5 °C. The catalyzed portion of the exchange rate, R_c, depends upon the first power of the hydrogen-ion concentration. The role of the hydrogen ion is to shift the pre-equilibrium:

$$H_2AsO_4^- \rightleftharpoons HAsO_4^{2-} + H^+,$$

in favor of $H_2AsO_4^-$, which is the active species in the exchange reaction.

Dependence of the Catalytic Rate R_c on [As(III)]. This has been studied at 30 °C, pH 7.83, [As(V)]= 0.07 M, and I=0.2 M. [As(III)] was varied between 3×10^{-4} and 13×10^{-4} M. The observed rates were

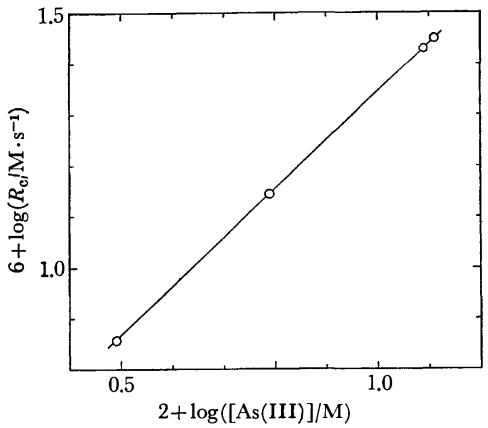

Fig. 3. Dependence of log R_c on log [As(III)] (30 °C, pH 7.83, [As(V)]=0.07 M, I=0.2 M).

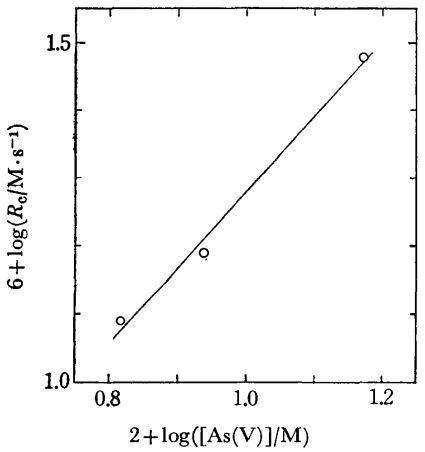

Fig. 4. Dependence of log R_c on log [As(V)] (30 °C, pH 7.78, [As(III)]=6.2×10^{-4} M, I=0.4 M).

corrected for the small differences in pH(<0.05) and in [As(V)](<0.0015 M). A plot of log R_c against log [As(III)] is shown in Fig. 3. A line drawn through the plots has a slope of $0.95\pm0.00_1$. The catalytic rate, R_c, depends on the first power of [As(III)].
