Yano ●: CH_4-CD_4-Ar(6—6—88%) $\tau = 1$ ms
○: CH_4-Ar(12—88%) $\tau = 1$ ms
Skinner ▲: CH_4-Ar(12—88%) $\tau = 1$ ms
■: CH_4-Ar(12—88%) $\tau = 10$ ms

found to be 1.53±0.05 and 0.60±0.05, respectively (see Table 2, Mixt. B). These values are in good agreement with those obtained for the mixture A. As shown in Fig. 2, the effect of the trace amounts of oxygen (less than 300 ppm) is negligible. This conclusion is consistent with the calculation[9] after Meyerson.

As described in the previous paper, methane is converted into ethane in the early reaction stage and the latter is further transformed into ethylene, acetylene and higher hydrocarbons. When the products of the methane pyrolysis are assumed to be only C_2 hydrocarbons, the total hydrogen produced by the pyrolysis, ΣH ($=(H_2)+(HD)+(D_2)$), should be equivalent to the sum $\Sigma' C_2 (=(C_2H_6)+2(C_2H_4)+3(C_2H_2))$. ΣH is, however, always larger than $\Sigma' C_2$ in both the present and the previous works, and the ratio $\Sigma' C_2/\Sigma H$ decreases as the temperature increases as shown in Fig. 3. In order to confirm this, product analysis was made for three runs shock heated at higher temperature with a mixture of 12% CH_4 in argon. From Table 3, it is clear that at higher temperatures the ratio $\Sigma' C_2/\Sigma H$ decreased remarkably. This inclination may be explained by the formation of higher hydrocarbons during the pyrolysis of methane. Actually, a small amount of propylene was detected in the experimental runs 8 and 11 (see Table 2, Mixt. B).

9) Even if hydrogen molecules are produced by the methane pyrolysis *via* methylene mechanism and dissociated into hydrogen atoms, at the rate given by Meyerson and Watt under the presence of 1000 ppm oxygen, and if H and D atoms from this process may be converted into HD molecules by the abstraction reaction with CH_4 and CD_4, *i. e.*,

$$\left.\begin{array}{l} H+CD_4 \rightarrow HD+CD_3 \\ D+CH_4 \rightarrow HD+CH_3 \end{array}\right\} \quad k_1 = 1.5\times10^{11}\exp(-14000/RT) \ (\mathrm{mol^{-1}\cdot l\cdot s^{-1}}) \qquad (A),$$

the amount of HD molecules obtained through these processes will be only 1.4% of total hydrogen molecules initially produced. The reactions

$$\left.\begin{array}{l} H+D_2 \rightarrow HD+D \\ D+H_2 \rightarrow HD+H \end{array}\right\} \quad k_2 = 5\times10^{10}\exp(-7500/RT) \ (\mathrm{mol^{-1}\cdot l\cdot s^{-1}}) \qquad (B)$$

are ignored since the processes (A) are faster than (B).

This small value with respect to HD molecules, obtained on above assumptions, contradicts with the experimental results.

Table 3. $\sum'C_2/H_2$ at relatively high temperature in CH_4 (12% in Ar) pyrolysis

Discussion

The yield of HD molecules in products has great significance in judging the validity of a methyl mechanism, proposed by Skinner,[10] compared with a methylene mechanism by Kevorkian.[11] In the previous paper, the formation of only C_2 hydrocarbons was taken into consideration, and the product hydrogen was divided into two parts, the primary and the secondary hydrogen. That is, the primary hydrogen was produced from the process

$$2\,CH_4 \longrightarrow C_2H_6 + H_2, \tag{6}$$

and the secondary one was produced from the dehydrogenation process,

$$C_2H_6 \longrightarrow C_2H_4 + H_2$$
$$\longrightarrow C_2H_2 + H_2. \tag{7}$$

Then, the formation of one mole of ethane corresponded to one mole of the primary hydrogen. And one mole of ethylene in the products corresponded to one mole each of the primary and the secondary hydrogens. In the similar way, the formation of one mole acetylene is equivalent to one mole primary and two moles secondary hydrogens. According to a methylene mechanism, small amount of HD would be formed in the primary process, while in the secondary process HD would be appreciably formed. Yet, the previous experimental results have been inconsistent with methylene mechanism as far as only C_2 hydrocarbons are concerned, even if the equilibrium distribution of hydrogen isotopes among the secondary hydrogens is assumed.

As shown in Fig. 3, however, the formation of considerable amounts of higher hydrocarbons is revealed. Therefore, the contribution from the higher hydrocarbons must be considered in addition to C_2 hydrocarbons, and the problem should be discussed more precisely. The ratio of the primary hydrogen to total hydrogen $\sum H$, A, is now expressed,

$$A = (\sum C_2 + \sum F_n(C_n))/\sum H \qquad (n \gtrsim 3) \tag{8}$$

where $\sum C_2$ gives the sum of C_2 hydrocarbons, *i.e.*, $\sum C_2 = (C_2H_6) + (C_2H_4) + (C_2H_2)$, and $F_n(C_n)$ means the sum of the primary hydrogen corresponding to C_n hydrocarbons. When the concentration of the hydrocarbon C_nH_m is expressed by C_n,

$$F_n(C_n) = n \cdot C_n/2. \tag{9}$$

To simplify the notation, A is divided into two parts, A' and A'', or

$$A = (\sum C_2 + \sum nC_n/2)\sum H = \sum C_2/\sum H + \sum nC_n/2\sum H$$
$$= A' + A''. \tag{10}$$

A' can be directly obtained from experimental data but A'' cannot because nC_n is unknown. The minimum value of A'', however, can be estimated from the extreme case where the n-carbons skeleton is taking the place of C_n-hydrocarbons. That is, all of the hydrogen atoms, attached to the carbon atom of the reactant methane molecule, are converted into hydrogen molecules. When $g(C_n)$ gives the amount of the total hydrogen released through the formation of C_n-skeleton, following two equations are obtained,

$$g_n(C_n) = 2n \cdot C_n \tag{11}$$

$$\sum_{n \geq 3} g_n(C_n) = \sum H - \sum' C_2. \tag{12}$$

Since $\sum'C_2$ has a value between $0.60\sum H$ and $0.92\sum H$ (Table 2), $\sum nC_n$ comes between $0.20\sum H$ and $0.04\sum H$, therefore, the minimum value of A'' is given by,

$$A'' = \sum nC_n/2\sum H = 0.1 \sim 0.02. \tag{13}$$

The value of A' has proved to be between 0.43 and 0.79 (see Table 2, Mixt. A) and so, A is estimated to be between 0.53 and 0.81.[12] Therefore, from this A and eq. (4), $(H_2)_{prim}$ and the upper limit of $(HD)_{prim}$ are expected to be,

$$(H_2)_{prim} = (1.0/2.28)(\sum H)_{prim} = (1.0/2.28)(\sum H)A \tag{14}$$

$$(HD)_{prim} = (0.28/2.28)(\sum H)_{prim} = (0.28/2.28)(\sum H)A. \tag{15}$$

while, the isotopic distribution in the secondary hydrogen is assumed to be in equilibrium state. The amount of $(H_2)_{sec}$ and $(HD)_{sec}$ are given as,

$$(H_2)_{sec} = (1-A)(\sum H)/4 \tag{16}$$

$$(HD)_{sce} = (1-A)(\sum H)(2/4). \tag{17}$$

The ratio of HD to H_2 is now expressed as,

$$(HD)/(H_2) = \{(HD)_{prim} + (HD)_{sec}\}/\{(H_2)_{prim} + (H_2)_{sec}\}$$
$$= \{4(0.28/2.28)A + 2(1-A)\}/\{4(1.0/2.28)A + (1-A)\}$$
$$= 0.86 \sim 0.48. \tag{18}$$

Thus, even if the most favorable cases for the methylene mechanism are assumed, it cannot explain the observed high ratio of 1.53 for $(HD)/(H_2)$.

Since no carbon-soot was detected but actually propylene and also other hydrocarbons are expected, the value of calculated A'' should be higher and the ratio $(HD)/(H_2)$ should be lower than those calculated above for carbon skeletons.

The author wishes to thank Professor Kenji Kuratani for his helpful discussions and encouragement.

11) V. Kevorkian, G. E. Hearth and M. Boudart, *ibid.*, **64**, 964 (1960).

12) There is a positive correlation between $\sum'C_2/\sum H$ and $\sum C_2/\sum H$ in the present experimental conditions. That is, A' values of 0.43 and 0.79 correspond to $\sum'C_2/\sum H$ values of 0.69 and 0.92, respectively. So, the range of A value is 0.53~0.81.

An Investigation of a Surface Reaction between Pyrrhotite and the Hydrogen–Hydrogen Sulfide Mixture

Masayuki KATSUMOTO, Kazuo FUEKI, and Takashi MUKAIBO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 31, 1972)

The isotopic exchange between H_2S and D_2 has been studied in the temperature range from 480 °C to 551 °C on a pyrrhotite specimen. The isotopic exchange reaction proceeded *via* these steps:

$$H_2S + D_2 = D_2S + H_2$$
$$H_2 + D_2 = 2\,HD$$

From the analysis of the kinetic data, the rate constant of the sulfurization of $Fe_{1-x}S$ by "hydrogen sulfide,"[1] k_i, and that of reduction by "hydrogen,"[1] k_i', were determined. It was found that k_i is inversely proportional to the sulfur activity of $Fe_{1-x}S$, a_S, and that k_i' is independent of it. It was found that the rate equation for the sulfurization of $Fe_{1-x}S$ in the "hydrogen"–"hydrogen sulfide" gas mixture could be expressed in the form of $v = kP_{\text{"}H_2S\text{"}}a_S^{-1} - k'P_{\text{"}H_2\text{"}}$.[1] A possible mechanism of the reaction at the surface of $Fe_{1-x}S$ is discussed.

For the elucidation of the mechanism of the gas-solid interface reaction, it is necessary to determine the reaction rate as a function of the activity of chemical species in a solid as well as the partial pressure of the reactant gases. Such a study was first carried out by Kobayashi and Wagner[2] for the reduction of silver sulfide by "hydrogen." Several methods have been developed on the same basis of the theory proposed by them and have been applied to oxide and sulfide systems.[3–7]

The present work aims to study the reaction at the interface between β-$Fe_{1-x}S$ and a "hydrogen"–"hydrogen sulfide" gas mixture by using the isotopic exchange method.

Experimental

$Fe_{1-x}S$ Specimen. An iron specimen was taken from a Ferrovac E sheet (0.05 mm thick). After being polished with 1000-emery paper and cleaned by petroleum ether, it was sulfurized in a gas mixture of hydrogen sulfide and hydrogen at 580 °C. As the $Fe_{1-x}S$ was fragile, it could not be used in the form of "foil" through many runs. Therefore, it was crushed lightly and the powder larger than 170 mesh was used as a sample. The surface area was 133.3 $cm^2\,g^{-1}$.

Isotopic Exchange Method. The apparatus, the method of the purification of gases, and the experimental procedure were essentially the same as in the isotopic exchange experiment on Cu_2S.[7] As the pyrrhotite sample was a powder, a Pyrex glass reaction vessel with a G3 filter (Fig. 1) was used, and the temperature was measured at a position near the sulfide sample.

The isotopic exchange was carried out after the chemical equilibrium had been reached between the sulfide and the "hydrogen"–"hydrogen sulfide" gas mixture. Therefore, a_S, the sulfur activity of the solid, defined as the pressure ratio of "hydrogen sulfide" to "hydrogen," was kept constant throughout the isotopic exchange run, irrespective of the change in the concentration of isotopic species.

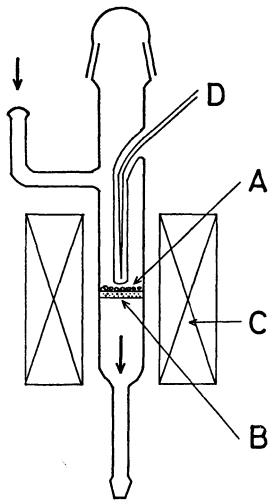

Fig. 1. Reaction vessel for the isotopic exchange experiment.
A $Fe_{1-x}S$ specimen B G3 filter
C furnace D Thermocouple

A blank test showed that, in the absence of $Fe_{1-x}S$, no exchange occurred below 528 °C, whereas a little exchange did occur at 551 °C. No deposition of sulfur occurred at the cold portions of reaction vessel over all the temperature and gas composition ranges studied.

Results and Discussion

Isotopic Exchange Reaction. Figures 2–4 give the change in x_{H_2}, x_{HD}, and x_{D_2}, the mole fractions of H_2, HD, and D_2 respectively, at different sulfur activities.

The following two mechanisms are possible for the formation of H_2 and HD. In the first mechanism, H and D atoms are formed by the dissociation of H_2S and D_2 *via* (1a) and (1b):

$$H_2S \rightleftharpoons HS(ad) + H(ad) \quad (1a)$$
$$D_2 \rightleftharpoons 2\,D(ad) \quad (1b)$$

where H(ad), D(ad), and HS(ad) represent H, D,

1) Terms such as "hydrogen" and "hydrogen sulfide" are used in a generic sense, irrespective of the isotopic species. The chemical symbols "H_2S" and "H_2" are employed for the chemical species of "hydrogen sulfide" and "hydrogen" respectively.

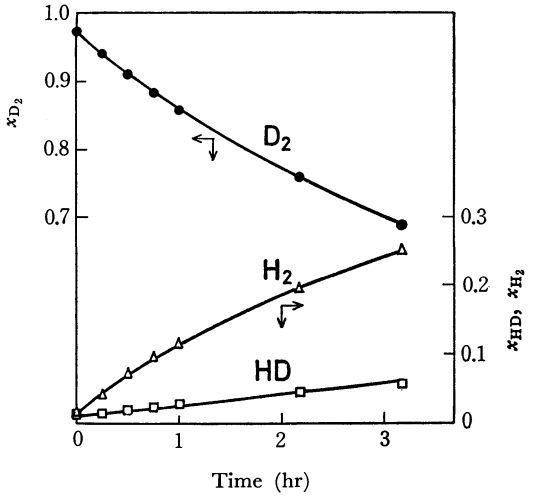

Fig. 2. Change in x_{D_2}, x_{HD} and, x_{H_2} with time. (551 °C, $P^o_{H_2S}=123.6$ mmHg, $P^o_{D_2}=30.9$ mmHg, $a_S=4$).

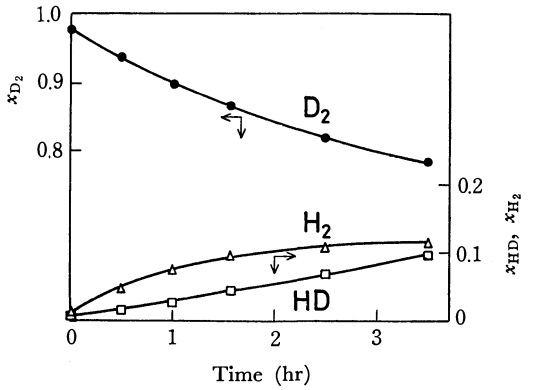

Fig. 3. Change in x_{D_2}, x_{HD}, and x_{H_2} with time. (551 °C, $P^o_{H_2S}=17.6$ mmHg, $P^o_{D_2}=70.4$ mmHg, $a_S=1/4$).

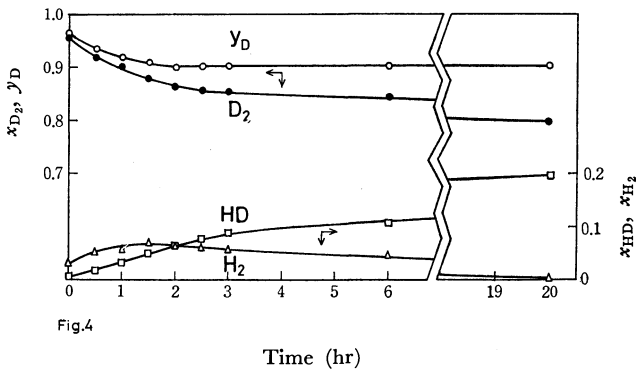

Fig. 4. Change in y_D, x_{D_2}, x_{HD}, and x_{H_2} with time. (551 °C, $P^o_{H_2S}=12.5$ mmHg, $P^o_{D_2}=125$ mmHg, $a_S=1/10$).

and HS adsorbed on the surface of $Fe_{1-x}S$. Then, H_2 and HD are formed by these reactions:

$$D(ad) + H(ad) \rightleftharpoons HD \quad (1c)$$

$$H(ad) + H(ad) \rightleftharpoons H_2 \quad (1d)$$

In the second mechanism, H_2S is directly converted to H_2, giving a sulfur atom to the lattice site on $Fe_{1-x}S$

$$H_2S \rightleftharpoons H_2 + S(lattice) \quad (2a)$$

The (2a) reaction is characterized as the redox reaction or as the two atom-direct exchange reaction. Then, H_2 and D_2 react to form HD:

$$H_2 + D_2 \rightleftharpoons 2\,HD \quad (2b)$$

As may be seen from Figs. 2—4, the rate of HD formation was smaller than that of H_2 in the initial period, and the formation of HD became remarkable only after the concentration of H_2 became high. These facts suggest that the (2a) and (2b) mechanisms are more predominant than (1a)—(1d). The second mechanism may also be confirmed as follows.

Let us define y_D, the fraction of D in "hydrogen," by:

$$y_D = x_{D_2} + \frac{1}{2}x_{HD} \quad (3a)$$

and y_H, the fraction of H in "hydrogen," by:

$$y_H = x_{H_2} + \frac{1}{2}x_{HD} \quad (3b)$$

At $a_s=1/10$, y_D decreases with time during the initial period, but it reaches a constant value at the time corresponding to the maximum of x_{H_2}; thereafter it remains unchanged, while x_{H_2}, x_{HD}, and x_{D_2} are still changing. When the value of a_s is 1/10, the ratio of H to D is also 1/10. Thus, after the isotopic equilibrium is attained between "hydrogen" and "hydrogen sulfide," the ratio of y_H to y_D is 1/10; *i.e.*, y_D is 0.909. Figure 4 shows that the constant value of y_D is equal to 0.909 within the limits of experimental error. The results clearly show that the H to D ratio attains equilibrium at the time x_{H_2} reaches its maximum and that, thereafter, only relative changes of x_{H_2}, x_{HD}, and x_{D_2} occur. That is, these results mean that H_2 and HD are formed by the mechanisms of (2a)—(2b) and not by (1a)—(1d).

At the beginning of the reaction, only H_2S and D_2 exist in the gas phase of the reaction system. Because the exchange reaction proceeds *via* (2a) and (2b), the amount of H in "hydrogen" at any time represents the amount of H transported from "hydrogen sulfide" to "hydrogen" *via* (2a). Similarly, the amount of D in "hydrogen sulfide" represents the amount of D transported from "hydrogen" to "hydrogen sulfide" *via* (2a). Accordingly, the change in the amount of D in "hydrogen" with time is given by this equation:

$$\frac{1}{A}\frac{dn_D}{dt} = \frac{RT}{V}(k_i n_D' - k_i' n_D) \quad (4)$$

where A is the surface area of $Fe_{1-x}S$, where k_i and k_i' are the rate constant of sulfurization and reduction respectively (mol atm^{-1} cm^{-2} hr^{-1}), and where V is the volume of the reaction system. n_D and n_D' are defined as follows:

$$n_D = n_{D_2} + \frac{1}{2}n_{HD} = n_{\text{"}H_2\text{"}}y_D \quad (5)$$

$$n_D' = n_{D_2S} + \frac{1}{2}n_{HDS} = n_{\text{"}H_2S\text{"}}y_D' \quad (6)$$

where n_{D_2}, n_{HD}, n_{D_2S}, and n_{HDS} represent the number of moles of D_2, HD, D_2S, and HDS respectively. $n_{\text{"}H_2\text{"}}$ and $n_{\text{"}H_2S\text{"}}$ are the number of moles of "hydrogen" and "hydrogen sulfide" respectively. y_D' is defined in the same manner as in the case of (3a) for "hydrogen sulfide."

At the beginning of the reaction:

$$n_D + n_D' = n_D^\circ = n_{\text{"H}_2\text{"}} x_{D_2}^\circ = n_{\text{"H}_2\text{"}} y_D^\circ \quad (7)$$

The insertion of Eq. (7) into Eq. (4) yields:

$$\frac{dn_D}{dt} = \frac{ART}{V}[k_i n_D^\circ - (k_i + k_i')n_D] \quad (8)$$

After the isotopic equilibrium between "hydrogen" and "hydrogen sulfide" has been attained, $dn_D/dt=0$ and $n_D=n_D^e$; *i.e.*,

$$\frac{dn_D}{dt} = \frac{ART}{V}[k_i n_D^\circ - (k_i + k_i')n_D^e] = 0 \quad (9)$$

Accordingly,

$$\frac{n_D^e}{n_D^\circ} = \frac{k_i}{k_i + k_i'} \quad (10)$$

By integrating Eq. (8) and using Eq. (10), we obtain:

$$-\log\frac{n_D - n_D^e}{n_D^\circ - n_D^e} = \frac{ART}{2.303\,V}(k_i + k_i')t \quad (11)$$

By replacing n_D, n_D°, and n_D^e by y_D, y_D°, and y_D^e respectively, Eq. (11) can be rewritten as:

$$-\log\frac{y_D - y_D^e}{y_D^\circ - y_D^e} = \frac{ART}{2.303\,V}(k_i + k_i')t \quad (12)$$

Figures 5—7 show the plot of $\log\{(y_D - y_D^e)/(y_D^\circ - y_D^e)\}$ *vs.* t for the data given in Figs. 2—4 respectively. The plots are linear irrespective of the HD formation. If we denote the slope of the plot of $-\log\{(y_D - y_D^e)/(y_D^\circ - y_D^e)\}$ against t by α, k_i and k_i' can be represented by the following equations:

$$k_i = \frac{2.303\,V}{ART}\alpha\frac{y_D^e}{y_D^\circ} \quad (13)$$

$$k_i' = \frac{2.303\,V}{ART}\alpha\left(1 - \frac{y_D^e}{y_D^\circ}\right) \quad (14)$$

The k_i and k_i' calculated by Eqs. (13) and (14) using α were independent of the total pressure.

Figure 8 gives the plots log k_i and log k_i' against log a_s. Both plots are linear at 551 °C and 480 °C. The slopes of log k_i *vs.* log a_s are −1.00 for 551 °C and −0.97 for 480 °C. The slopes of log k_i' *vs.* log a_s are 0.00 and 0.03 respectively.

The Arrhenius plot of k_i at $a_s=1$ is given in Fig. 9. The activation energy determined from the slope is 26.8 kcal mol^{-1}.

Reaction Mechanism of Sulfurization. From the results of this study, the rate of redox reaction proceeding *via* (2a) can be expressed by this equation:

$$v = k_i P_{\text{"H}_2\text{S"}} - k_i' P_{\text{"H}_2\text{"}} = k P_{\text{"H}_2\text{S"}} a_S^{-1} - k' P_{\text{"H}_2\text{"}} \quad (15)$$

where k and k' are constants.

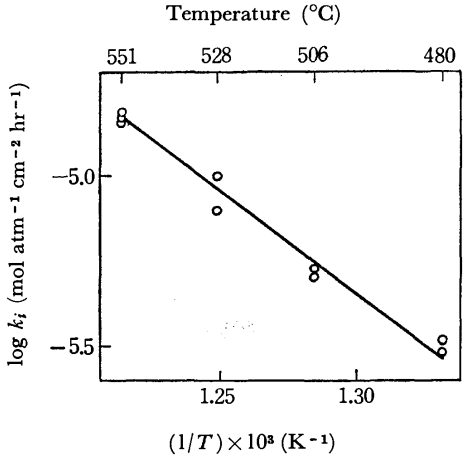

Fig. 9. Arrhenius plot for k_i at $a_S=1$.

Kobayashi and Wagner considered that e^-, S, S^-, and S^{2-} are reactants in Ag_2S and proposed the following three mechanisms for the reduction of Ag_2S by "hydrogen":

$$\text{"}H_2\text{"} + S \rightleftharpoons \text{"}H_2S\text{"} \quad (16A)$$

$$\text{"}H_2\text{"} + S^- \rightleftharpoons \text{"}H_2S\text{"} + e^- \quad (16B)$$

$$\text{"}H_2\text{"} + S^{2-} \rightleftharpoons \text{"}H_2S\text{"} + 2\,e^- \quad (16C)$$

where S, S^-, and S^{2-} are sulfur atom, mono-, and divalent sulfur ions respectively and where e^- is an electron. They showed that the rate equations for (16A) to (16C) can be expressed in a general formula:

$$v = k'P_{\text{"}H_2\text{"}}a_S^{m-} - kP_{\text{"}H_2S\text{"}}a_e^m \quad (17)$$

where m is integers characteristic of the reaction mechanism.

Let us first discuss the mechanism of the redox reaction on the pyrrhotite surface by the Kobayashi-Wagner mechanism.

Pyrrhotite is known as a semiconductor below the Néel temperature. However, the temperature coefficient of the conductivity is negative in the temperature range of this study, *i. e.*, above the Néel temperature[8–10], and the conductivity is independent of a_s.[10] As the conductivity is $\sim10^3$ mho-cm, we can conclude that β-$Fe_{1-x}S$ is a compound of metallic conduction. The metallic conduction is due to a half-filled narrow d-band. If the ratio of S to Fe changes, the number of electrons in the d-band also changes. However, we can expect that the Fermi level of electron will not be influenced because the density of the state of the narrow d-band is very high. Accordingly, we can assume that the activity of the electron, a_e, is nearly constant over the whole experimental range of a_s, *i. e.*,

$$a_e \cong \text{const.} \quad (18)$$

Among e^-, S, S^-, and S^{2-}, the following equilibrium relationships exist:

$$S^- \rightleftharpoons S + e^- \quad (19A)$$

$$S^{2-} \rightleftharpoons S + 2\,e^- \quad (19B)$$

i. e.

$$a_S{}^- \propto a_S \quad (20A)$$

$$a_S{}^{2-} \propto a_S \quad (20B)$$

Therefore, for mechanisms (16A) to (16C), the rate equation of the sulfurization reaction of the pyrrhotite should be expressed in this form:

$$v = kP_{\text{"}H_2S\text{"}} - k'P_{\text{"}H_2\text{"}}a_S \quad (21)$$

This dependence of the reaction rate on a_s does not agree with the results observed in this study.

Next, les us consider the Fe atom as a reactant in sulfide. In this case, the reaction mechanism is:

$$\text{"}H_2S\text{"} + \text{Fe(sulfide)} \rightleftharpoons \text{"}H_2\text{"} + FeS \quad (22)$$

and the rate equation is:

$$v = kP_{\text{"}H_2S\text{"}}a_{Fe} - k'P_{\text{"}H_2\text{"}}a_{FeS} \quad (23)$$

Since the activity of $Fe_{1-x}S$ is nearly constant, irrespective of nonstoichiometry,[11]

$$a_{Fe} = \text{const}\cdot a_S{}^{-1} \quad (24)$$

The insertion of Eq. (24) into Eq. (23) yields:

$$v = kP_{\text{"}H_2S\text{"}}a_S{}^{-1} - k'P_{\text{"}H_2\text{"}} \quad (25)$$

Therefore, it may be concluded that Eq. (22) is a possible mechanism for the redox reaction on the pyrrhotite surface.

Summary

(1) The isotopic exchange between H_2S and D_2 on $Fe_{1-x}S$ was investigated as a function of the temperature and of a_s, the sulfur activity of $Fe_{1-x}S$.

(2) It was found that the isotopic exchange reaction proceeds *via*:

$$H_2S + D_2 \rightleftharpoons D_2S + H_2$$

$$H_2 + D_2 \rightleftharpoons 2\,HD$$

(3) The rate equation for the sulfurization of $Fe_{1-x}S$ in the "hydrogen"-"hydrogen sulfide" gas mixture was

$$v = kP_{\text{"}H_2S\text{"}}a_S{}^{-1} - k'P_{\text{"}H_2\text{"}}$$

The activation energy was 26.8 kcal mol^{-1}.

(4) The reaction mechanism of redox reaction was discussed.

The authors wish to express their thanks to Dr. Masahiko Tsuchiya and Dr. Ju Kumanotani of the Faculty of Engineering, the University of Tokyo, for their help in carrying out the mass-spectroscopic analysis.

Studies on Fragment Ion Distribution and Reactions by the Use of a Charge Spectrometer. III. Reactivities of the Excited Ions from Methylamine after Charge Exchange with Positive Ions

Toshio NAGATANI, Kenji YOSHIHARA, and Takanobu SHIOKAWA

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received July 31, 1972)

The behavior of the excited ions produced by positive ion impact in methylamine has been studied in the reaction chamber of a double mass spectrometer at elevated pressure. The ion-molecule reactions have been discussed for three energy regions. Metastable transitions taking place in the reaction chamber and in the Giese lens have also been studied in the corresponding regions.

Ordinary mass spectrometry deals with cases in which molecular ions or their fragment ions initially produced in the ionization chamber collide with sample gases and form secondary or tertiary products when gas pressure is enhanced. Studies have been carried out on these phenomena using electron impact but only a few have been made using positive ion impact.[1,2,3]

Positive ions accelerated to the order of kilo electron volt are extremely useful for charge exchange reactions with neutral molecules.[4] If the reaction chamber is filled with methylamine, the fragment ions from the excited molecular ions after charge exchange with the positive ions react with methylamine having kinetic energy given by the repeller voltage.

This paper deals with the reaction of the ionic species which are pulled in the second optical system and various processes of ion-molecule reactions in the reaction chamber of the charge spectrometers. Flying ions in the Giese lens system have shown characteristic features because the lens is long and located in a position neighboring the reaction chamber of high pressure. The behavior of the excited ions in particular has been investigated.

Experimental

The charge spectrometer was described in detail.[5] It consists of a double mass spectrometer having a large source volume for the study of charge distribution. Two sets of mass analyzers are connected perpendicular to each other and there is a reaction chamber in the crossing. A Hitachi T-2 ion source was used. The pressure of the reaction chamber could not be measured directly since distribution of gas density was not at all uniform. However, relative values of pressure in the reaction chamber could be expressed by reading the McLeod gauge of the gas-inlet system which leads gases through an orifice (0.300 ml/s).

All the gases used were of high purity or purified several times before use when necessary. Other details were reported previously.[4]

An example of the relationship between gas pressure and the intensities of various ionic species after charge exchange is shown in Fig. 1. Methylamine molecules were subjected to the impact of Xe^+ ions. The pressure given in the abscissa is that of methylamine in the gas reservoir of the sample inlet system. The repeller field was set at a sufficient strength 15.0 V/cm) expected to protect it from the phenomena of an unsuitable reaction order as pointed out by Hamill for CD_4.[6] Fig. 1 shows satisfactory results for determination of the reaction order, the gradient of the straight line representing the reaction order. In the low pressure region all the ions except that of m/e=32(abbreviated as (32), see Table 2) have the gradient of unity. This indicates that they are primary fragment ions after charge exchange with Xe^+. On the other hand, (32) is observed when the pressure in the reaction chamber increases, and its gradient differs from that of others showing the value of 2. It is obvious that (32) is the secondary product of an initially formed ion with methylamine.

Results and Discussion

Impact of methylamine with various positive ions has been performed in the reaction chamber at elevated pressure. The results with C^+, Cl^+ and Xe^{++} are shown in Figs. 2–4. Similar experiments using benzene, Ne^{++}, Xe^+, CO_2^+, Kr^+, Ar^+, Kr^{++}, Ne^+, Ar^{++} and He^+ have been described.[7] Detailed features depend on the energy received by the charge exchange. The break down curve should be taken into consideration.[4] The relation between the appearance of certain ions and their energy region is indicated graphically (Fig. 5).

M* observed m/e ratio which can be calculated theoretically.[8]

tions may overlap with the ordinary ions. In the higher pressure region (Figs. 1-4), however, the behavior of the metastable ions seems to differ from that of the other ions.

The relation between excitation energy of methylamine molecule ion and the behavior of ionic species can be treated according to classification of the energy regions into three parts. Dominant ionic species are (31), (30) and (28).

i) 9.0—12.0 eV

Ion (31) collides with the parent molecule to give (32) through transfer of a hydrogen atom or a proton. A part of (31) releases a hydrogen atom or molecule to produce (30) or (29) during the flying path in the Giese lenses of 126 mm length. These species will be observed as the peaks of (29) or (27). This process is collision-induced dissociation as was reported by Melton and Well.[9]

ii) 12.1—14.7 eV

The products of ion-molecule reactions in this region are (32) and (31). (31) may be given by charge exchange or hydrogen atom transfer.[10]

The recombination energy of (30) is expected to be not so far from 13 eV, and charge exchange may be important in this case.

Metastable peaks of (28) and (26) are observed after release of a hydrogen atom or molecule from the most abundant ion (30).

A set of isomers $CH_2{=}N^+H_2$ and $C^+H_2{-}NH_2$ might exist for the mass peak (30).[11] Probably the former is formed in the low energy region not much above 9.0 eV which is the ionization potential of nonbonding nitrogen orbital [za']. The latter will be formed in the higher energy region. It is plausible that these isomers in the reaction chamber show different behavior at elevated pressure, though detection of the difference is difficult. The meatstable peak (28) is observed in the low energy region and (26) in the higher energy region (Fig. 5). It is not clear whether this difference is due to the different behavior of the isomers or to the difference of the excited states of the produced ion (30). It seems that the latter is more important for determining the number of hydrogen atoms eliminated from the ion, since this is possible for the other cases.

iii) 15.8—25.0 eV.

The fragment ion (28) is present most abundantly. This reacts with methylamine to produce three kinds of secondary ions (32), (31) or (30) through the processes of proton transfer.

The secondary ion (30) after the change exchange with Xe^{++} seems to be highly excited, being raised up to 2.8 eV above its appearance potential. This is rarely observed in usual molecules. Metastable transition in this energy region is observed not in the initially produced ions but in the secondary ions. No collision-induced dissociation takes place in the case of (28).

As the recombination energy of (28) is considered to be appreciably high, He^+ in the cascade-type mass spectrometer was used as the monitor of the collision induced reactions. It was shown that the maximum probability for the charge exchange was observed in acceleration of 100—200 eV. The ion flying through the Giese lenses will attain this acceleration energy

TABLE 2. CLASSIFICATION OF ION-MOLECULE REACTIONS IN METHYLAMINE AFTER CHARGE EXCHANGE WITH POSITIVE IONS

Energy range	Process	Mass Peak
9.0—12.0 eV	H transfer:	
	$CH_3NH_2^+ + CH_3NH_2 \rightarrow CH_3NH_3^+$	(32)
	H^+ transfer:	
	$CH_3NH_2^+ + CH_3NH_2 \rightarrow CH_3NH_3^+$	(32)
	Metastable transition:	
	$CH_3NH_2^+ \xrightarrow{-H} CH_2NH_2^+$	(29)
	$CH_3NH_2^+ \xrightarrow{-2H} CHNH_2^+$	(27)
12.1—14.0 eV	H^+ transfer:	
	$CH_2NH_2^+ + CH_3NH_2 \rightarrow CH_3NH_3^+$	(32)
	Electron transfer:	
	$CH_2NH_2^+ + CH_3NH_2 \rightarrow CH_3NH_2^+$	(31)
	H transfer:	
	$CH_2NH_2^+ + CH_3NH_2 \rightarrow CH_3NH_2^+$	(31)
	Metastable transition:	
	$CH_2NH_2^+ \xrightarrow{-H} CHNH_2^+$	(28)
	$CH_2NH_2^+ \xrightarrow{-2H} CHNH^+$	(26)
15.8—25.0 eV	H^+ transfer:	
	$CHNH^+ + CH_3NH_2 \rightarrow CH_3NH_3^+$	(32)
	Electron transfer:	
	$CHNH^+ + CH_3NH_2 \rightarrow CH_3NH_2^+$	(31)
	H^- transfer:	
	$CHNH^+ + CH_3NH_2 \rightarrow CH_2NH_2^+$	(30)
	Metastable transition:	
	$CH_2NH_2^+ \xrightarrow{-2H} CHNH^+$	(26)

10) When xenon ions of low recombination energy were bombarded to methylamine molecules filled in the source volume, it was indicated that more than 50% of total ionization is due to charge exchange above 12 eV.

11) H. Sjögren, *Arkiv Fysik*, **29**, 565 (1965).

very easily.

In the whole energy range from the ionization potential of methylamine to 25 eV, contributions from (15) and (29) are quite low.

The rate constant of the ion-molecule reaction $CH_3NH_2^+ + CH_3NH_2 \rightarrow CH_3NH_3^+ + CH_2NH_2(CH_3NH)$ is given as 0.6×10^{-9} cm^3 molecule^{-1} sec^{-1} by Jones and Harrison,[12] who carried out experiments by electron impact. In this study, however, this type of reaction can be neglected because in the energy region of the secondary product (30) there is no primary ion of (31) as shown in Fig. 5.

The ion- molecule reactions of various ionic species are classified in Table 2.

The authors' thanks are due to Mr. M. Hiraga and Mr. Y. Takita for their kind cooperation throughout this work.

Studies of the Surface of Rutile Single Crystals by Means of Electrical Conductivity

Toru IWAKI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received October 6, 1972)

The surface properties of rutile single crystals were studied by the measurement of the d.c. electrical conductivity. Upon successive thermal treatments *in vacuo* from 25 to 550 °C, the electrical conductivity on the (110) plane increased remarkable, while the activation energy decreased. The addition of oxygen decreased the conductivity according to the oxidation temperature, whereas the reduction by hydrogen above 300 °C increased the conductivity greatly. The number of carriers was also determined from the measurement of the Hall effect. These results, by reference to those of the photoconductivity, were interpreted in terms of the change in the energy band structure near the surface associated with the defect centers on the surface.

It is well known that titanium dioxide, though it is an insulator in the stoichiometric composition, becames an *n*-type semiconductor as a result of the removal of oxygen atoms when treated at a high temperature *in vacuo* or in a reducing gas, such as hydrogen or carbon monoxide.[1] The reduction process may bring about a remarkable change in the structure and properties of the surface and also in the bulk, since oxygen atoms are removed from the surface and also from the bulk through the surface region. A number of studies of reduced titanium dioxide have been made by means of measurements of the electrical conductivities,[2] photoelectronic properties,[3-5] dielectric properties,[6] and diffusion of foreign atoms[7,8] in order to clarify the electronic structure in the bulk, but few have taken into account the properties of the surface.[9,10] So far, the heat of immersion in water and the adsorption of water vapor on the surface were examined for the powder specimen with an anatase modification; it has been found that these phenomena are considerably affected by a departure from the stoichiometric composition.[10] The purpose of the present study is to examine the surface of a single crystal with a rutile modification by the measurement of the electrical conductivity along with the photoconductivity.

The crystal structure of rutile is tetragonal; a titanium ion is located in the center of eight oxygen ions, and an oxygen ion is surrounded by three titanium ions on the (110) plane, which is a cleavage plane. The bond length between a titanium ion and an oxygen ion is longer by 0.044 Å in the (110) direction than in the other two directions.[11] In this study, the electrical conductivity was measured mostly along the c-axis on the (110) plane. Since the value of the conductivity differs to some extent from one specimen to another, the conductivity was measured for a definite specimen treated successively in the following manner: outgassing from room temperature to an elevated temperature, oxidation with oxygen, and then reduction with hydrogen. As a result, it was clarified that the surface

conductivity varied remarkably with the treatment. Further, the surface properties of a rutile single crystal were examined by means of measurements of the Hall effect and the photoconductivity.

Experimental

Material. A single crystal of rutile grown by the Verneuil method was obtained from the Nakazumi Crystal Co., Ltd. According to the spectroscopic analysis, its purity was above 99.99%; the main impurity was sodium, the amount of which was less than 0.005%.[12] The (110) plane was obtained by cleaving the crystal at a high temperature and was polished smoothly with α-corundum 0.1~0.2 μ in diameter. The dimensions of the crystal were 10×10×2 mm³. The specimen was treated with a chromic acid mixture, washed thoroughly with distilled water, and then dried at room temperature.

Electrode. As an electrode for the measurement of the electrical conductivity, gold was evaporated onto the (110) plane held at 100 °C. Various types of electrodes as is illustrated in Fig. 1 were used. As to Type I in the figure,

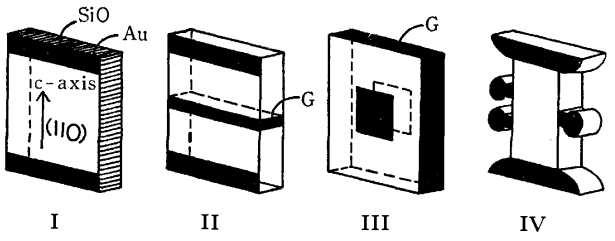

Fig. 1. Schematic drawing of four types of electrodes on the (110) planes of rutile single crystals.

all sides of the crystal were coated with evaporated SiO film in order to bring these surfaces to an insulator. Types II and III have guard-ring electrodes mounted to surround the surface in two ways. When the guard ring is grounded, the current which flows only in the bulk can be obtained since the surface current is intercepted by the guard ring, while both currents can be obtained when the guard ring is not grounded. Type IV, which was used for the measurement of the Hall effect, was formed by means of an ultrasonic cutter. The conductivity was measured parallel to the c-axis except for the case of Type III. Besides gold, several electrode materials such as In, Ti, and Ag, were evaporated on the surface of Type I in order to examine the contact between rutile and gold; further, the voltage-current character was examined at 25 °C under several treatments.

Treatments. A rutile single crystal connected with electrodes was placed in a quartz cell; in this the crystal was thermally treated as will be described below. Both the dark conductivity and the photoconductivity were measured below room temperature in the same cell after each treatment. The treatment of the sample was as follows: evacuation was carried out at 10^{-5} Torr at temperatures from 25 to 300 °C for 3 hr and above 400 °C for 1 hr, oxygen was added at temperatures varying between 25 and 500 °C for several minutes under a pressure of 20~50 Torr, followed by evacuation at 25 °C, and then hydrogen was added under the same conditions as in the case of oxygen, followed by evacuation at the temperature at which the hydrogen has been introduced. A liquid-nitrogen trap was used to protect the specimen from contamination by organic substances.[10]

Measurements. The electrical conductivity was measured at temperatures between −196 and 25 °C after helium gas had been introduced into the cell at 25 °C. A dry cell of about 1.5 V was used as the electric source. The electric current was measured with an Ohkura Electric Co. Model Am 5001 high-impedance microvoltammeter. The Hall e.m.f. was obtained in a three-electrode system under a magnetic field of about 4600 gauss. The photoconductivity was measured at −196 and 25 °C in the wavelength range between 350 and 600 mμ by using a tungsten lamp as the light source and interference filters. The intensity of the illuminating light was calibrated by means of a chemical actinometer using potassium ferrioxalate[13] and Rhodamine B.[14] The absorption spectrum was measured at −133 °C. and at room temperature over the wavelength range from 0.22 to 2.5 μ.

Results and Discussion

Contact between Rutile and Gold. When a metal and a semiconductor are brought into contact, a contact potential is formed by the difference between the work functions of these two materials. It was found that the electrical conductivity for the same specimen showed almost the same value regardless of the kind of electrode materials, such as In, Ti, Ag, and Au. The relationship between the electric current and the applied voltage indicated the Ohm law, as is shown in Fig. 2. From the above results, the Schottky barrier, which is generally seen in Si, GaAs, *etc.*[15], may not be formed in this contact. The measurement by the four-contact method, however, indicated a slight contact resistance at a low temperature when the specimen was evacuated above 300 °C.

According to the value of the electron affinity of rutile reported recently,[16] it is probable that the accumulation layer is formed near the surface by the contact with gold,[17] as is illustrated in Fig. 3, where the Fermi level of rutile is located below the conduction band, judging from the *n*-type semiconductor. The

energy level of the surface which is treated under various conditions may differ from that in the bulk because of the presence of impurities, lattice defects, and adsorbed gases, though the former may be identical with the latter if the surface is in an idealized state.

Changes in the Electrical Conductivity with Various Treatments. The changes in the electrical conductivity of the rutile treated successively at temperatures from 25 to 550 °C *in vacuo* are shown in Fig. 4(a) as a function of the reciprocal absolute temperature. The value of conductivity, σ, is expressed by the unit of mho/cm and also by that of mho; the latter unit is introduced on the basis of two-dimensional conductivity. It is clear from the figure that the conductivity increased remarkably with the outgassing temperature. A linear relation between log σ and $1/T$ was obtained over a considerably wide temperature range. The electrical conductivity can be expressed as $\sigma=\sigma_0 \exp(-\varepsilon/kT)$; ε is the activation energy for the electrical conductivity and is nearly equal to $E_d/2$ in this temperature range, where E_d is the donor level measured from the bottom of the conduction band, as will be discussed later. When the outgassing temperature increased from 25 to 550 °C, the conductivity at 25 °C, $\sigma_{25°C}$, increased by 10^5, while ε decreased from 0.25 to 0.10 eV. The oxidation at 500 °C lowered the value of $\sigma_{25°C}$ as low as below 10^{-13}. Not even evacuation at 500 °C restored the conductivity above 10^{-13}, but the introduction of hydrogen above 300 °C did. The reduction with hydrogen at 500 °C increased the conductivity remarkably and changed the sign of the temperature coefficient at around −25 °C, as can be seen in Fig. 4(b). On the other hand, when oxygen was added at a high temperature, σ decreased and ε increased. Moreover, when hydrogen was added at a high temperature after the oxidation, σ increased and ε

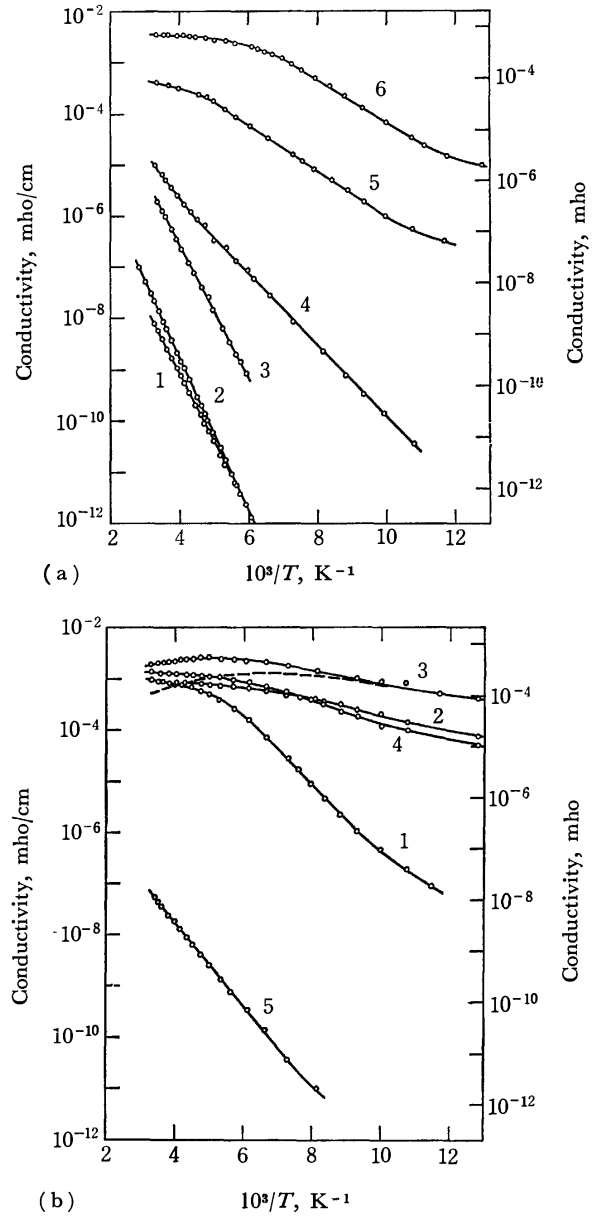

Fig. 4. Electrical conductivity of rutile treated under various conditions as a function of reciprocal absolute temperature.
(a) Successive evacuation at the following temperatures: (1) 25 °C, (2) 100 °C, (3) 200 °C, (4) 300 °C, (5) 400 °C, and (6) 550 °C.
(b) Successive introduction of oxygen or hydrogen as follows: (1) hydrogen, at 500 °C for 2 min after oxidation at 500 °C, (2) hydrogen, at 500 °C for 5 min, (3) hydrogen, at 500 °C for 5 min, (4) oxygen, at 25 °C for 2 min, and (5) oxygen, at 500 °C for 2 min.

decreased. This behavior observed by means of the reduction and oxidation cycle were reversible on the same sample, illustrating "Meyer's rule" that the larger the concentration of electrons, the lower the the activation energy becames.[18] The addition of oxygen at room temperature after the reduction also decreased the conductivity, which is represented by Curve 4 in Fig. 4(b). The decrement of the conductivity by the adsorption of oxygen is indicated by the dotted line in the figure. These results may indicate

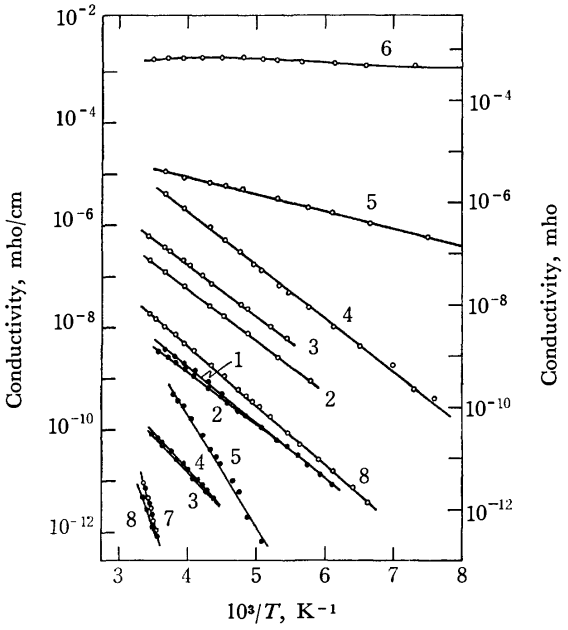

Fig. 5. Electrical conductivity of rutile with a guard ring treated under various conditions as a function of reciprocal absolute temperature. Successive treatments *in vacuo* and introduction of oxygen or hydrogen for 2 min at the following temperatures: (1) 25 °C, (2) 100 °C, (3) 200 °C, (4) 300 °C, (5) 500 °C, (6) hydrogen, 500 °C, after oxidation at 500 °C, (7) oxygen, 500 °C, and (8) hydrogen, 300 °C. In Figs. 5 and 6, open circle indicates that a guard ring was not grounded and closed one shows that it was grounded.

the effect of the adsorbed oxygen on the conductivity and the existence of the surface conductivity of the reduced rutile.

Contribution of Bulk Conductivity. The conductivity for the sample with a guard ring may clarify the problem of whether the remarkable variations in the electrical conductivity with pretreatments, as described above, occur predominantly on the surface region or in the bulk. The results for Type II presented in Fig. 1 are shown in Fig. 5. The closed circle given in the figure means that the guard ring was grounded, representing a bulk conductivity. The conductivity values obtained for the bulk were extremely small, though they differed to some extent according to the treatment. The conductivity with the guard ring not grounded shows a tendency similar to that in the case of Type I. The effect of the bulk on the conductivity seems negligibly small in the temperature range examined except for the case of the oxidation at high temperatures; the oxidation at high temperature makes the surface contribution extremely small.

The results of the conductivity in the case of Type III are shown in Fig. 6. When the specimen was evacuated at 100 and 200 °C, the bulk conductance became lower than 10^{-13} A/V. The bulk conductance increased after evacuation above 300 °C and increased significantly at 650 °C, though it is much smaller than the contribution of the surface. The oxidation at 500 °C after evacuation at 650 °C reduced the conductance extremely, as in the cases of Types I and II. Figure 6(b) demonstrates the dependence of the conductance

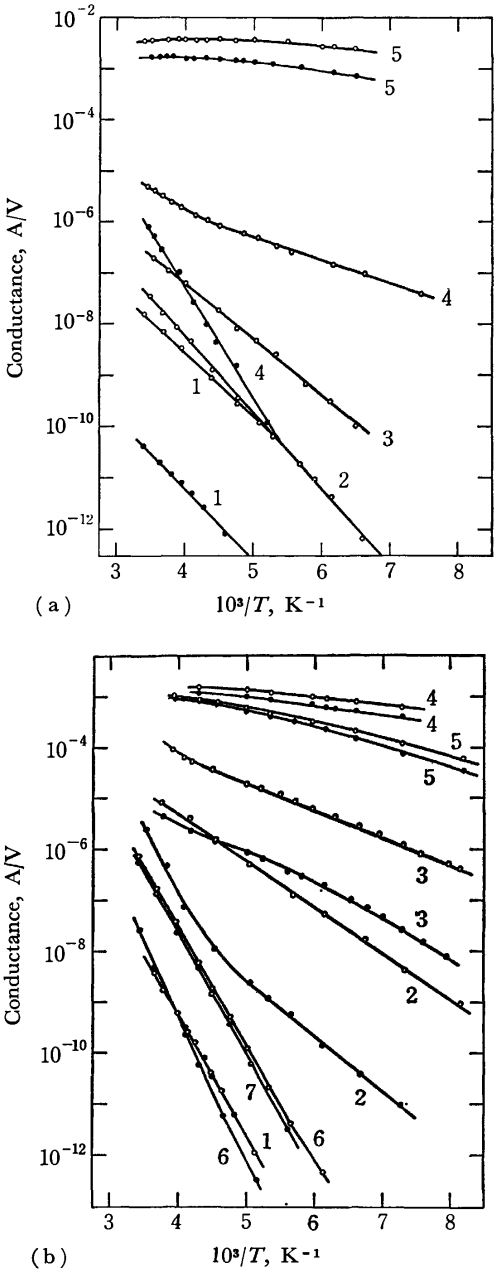

Fig. 6. Electric conductance of rutile with a guard ring under various treatments as a function of reciprocal absolute temperature.
(a) Successive evacuation at the following temperatures: (1) 25 °C, (2) 100 °C, (3) 200 °C, (4) 300 °C, and (5) 650 °C, (b) Successive introduction of oxygen or hydrogen for 2 min at the following temperatures: (1) hydrogen, 200 °C. after oxidation at 500 °C, (2) hydrogen, 300 °C, (3) hydrogen, 400 °C, (4) hydrogen, 500 °C, (5) oxygen, 100 °C, (6) oxygen, 400 °C, and (7) evacuation at 500 °C.

on the reduced state of rutile, which was treated by the reduction with hydrogen at temperatures between 200 and 500 °C. After the oxidation at 500 °C, outgassing at a high temperature did not recover the conductance, but the reduction by hydrogen did.

Surface State of Rutile. An idealized model of the (110) plane of rutile is illustrated in Fig. 7. The following three kinds of oxygen ions are present on the surface: A, above the titanium ion, B, between the titanium ions, and C, on the same plane as the

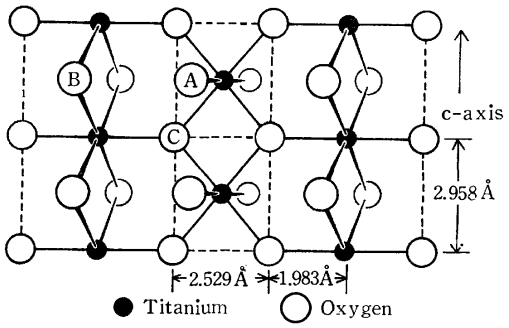

Fig. 7. Atomic model for the (110) plane of the surface of rutile.

titanium ions on the surface. Some of these oxygen ions can be excluded from the surface by virtue of the law of electric neutrality. The removal of the A oxygen is most probable because it is situated remotest from the plane composed of titanium ions. In general, the real surface of titanium dioxide is covered with hydroxyl groups which combine with titanium ions.[19] When titanium dioxide is evacuated at a high temperature, an oxo-structure similar to B in the figure is formed as a result of the condensation of these hydroxyl groups. As the surface oxo-structures thus produced are distorted,[10] these sites are considered to act as donors.

On the other hand, defect centers such as oxygen vacancies rather than interstitial titanium ions are produced by the removal of oxygen atoms when rutile is kept at high temperatures below 700 °C *in vacuo*[20] or in hydrogen.[21,22] The removal of one oxygen atom produces two electrons which reside in the oxygen vacancy or neighboring titanium ions of the lattice and which also serve as donors. Since the surface conductivity increased as the reduction proceeded, oxygen atoms, for example, B and C in the figure, may be removed from the surface. From the viewpoint of the band structure, the crystal imperfections on the surface create the energy level within the forbidden gap. This level is generally called the "surface state". When the donors in the surface state, such as the oxygen vacancy and Ti^{3+}, release the electrons to the conduction band at a moderate temperature, the surface is positively charged; the electrostatic potential for electrons bends down near the surface, in analogy with the scheme shown in Fig. 3. Therefore, as the accumulation layer is formed, the probability of the transition of the electron from the donor level to the conduction band becomes large and the concentration of the carrier electrons in the conduction band near the surface region may increase.

When oxygen molecules are admitted to the specimen at a high temperature after reduction, some are incorporated in the crystal lattice as O^{2-}, while the others adsorb as O^- and O_2^- on the surface. The incorporated oxygen may not be the defect center, but the anion radicals may form the surface state by drawing electrons from the conduction band and the donor level. As the surface is charged negatively, the surface potential bends upward to near the surface, resulting in the formation of the depletion layer.

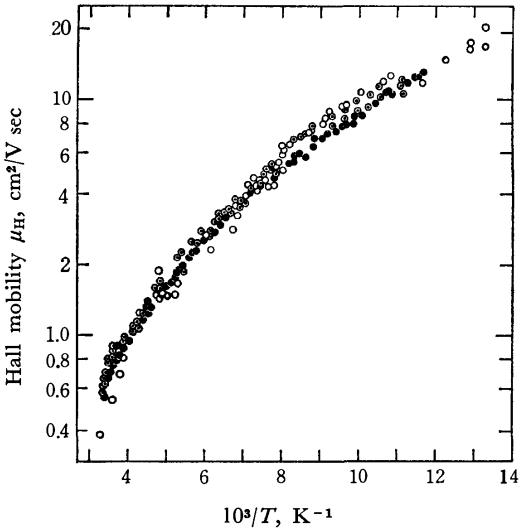

Fig. 8. Hall mobility of rutile treated under several conditions as a function of reciprocal absolute temperature. Treatments; ○: evacuation at 500 °C, ●: reduction by hydrogen at 450 °C for 2 min, and ⊙: reduction by hydrogen at 500 °C for 7 hr. The electrical conductivities at 25 °C, $\sigma_{25°C}$, of the specimens treated above are 1.6×10^{-3}, 3.5×10^{-3}, and 1.5×10^{-1} mho/cm, respectively.

Hall Mobility. The Hall e.m.f. was measured at temperatures between −196 and 25 °C for a specimen reduced under several conditions. The Hall mobility, μ_H, is given as the product of the Hall coefficient and the conductivity. The results are shown in Fig. 8. The value changed over the range from 0.4 to 20 cm²/V s, and the following relation was obtained in this temperature range: $\mu_H \propto T^{-5/2}$. In general, when carrier electrons in a semiconductor are scattered by the thermal vibration of the crystal lattice, the mobility can be expressed as follows: $\mu \propto T^{-3/2} m^{*(-5/2)}$, where m^* is the effective mass of an electron.[23] Since the oxygen ion in rutile is considerably polarizable,[24] lattice scattering by the optical mode of vibration as well as by the acoustical mode must be taken into account in a manner similar to that in the case of the mobility of hole carriers in Si or Ge.[25] The estimated value of m^* has been reported to be $10\sim30\ m$,[26] where m is the mass of a free electron. Yahia has suggested that the large effective mass at room temperature is due to a small polaron mass.[27] The low mobility may arise from the large effective mass. It should be noted that the mobility is not influenced even by the reduction with hydrogen for a long time, though the reduction may produce the defect centers

a) n_b is larger by 5 times than n_s.

b) Fermi levels ζ_b and ζ_s are estimated respectively from the following relations:

$$\zeta_b = \frac{1}{2}E_{d_b} - \frac{1}{2}kT\log\frac{2N_d}{N_0(T)(m^*/m)^{3/2}} \text{ and } \zeta_s = \frac{1}{2}E_{d_s} - \frac{1}{2}kT\log\frac{N_d}{4(m^*/m)[N_0(T)/2]^{2/3}}.$$

in bulk to a considerable extent. This implies that the mobility of the carrier electron in rutile is not affected by the lattice defect on the surface or in the bulk. Therefore, this may be due to a small mean free path of the carrier electrons compared with the scattering cross-section of such lattice defects as oxygen vacancies. When the mobility, μ, is known, the concentration of carrier electrons, n, can be estimated from the relation: $\sigma = en\mu$, where e is the electronic charge. When the Hall mobility is presumed to be equal to the true mobility and also to be independent of the treatments, it is revealed that the variation in the conductivity with the treatments *in vacuo* at temperatures between room temperature and 300 °C is caused mainly by the variation in the concentration of carriers, and that the reversion of the temperature coefficient of the conductivity for the case of the reduction by hydrogen as indicated in Fig. 4(b) is to be ascribed to a decrease in the mobility with an increase in the temperature. If the donor level is composed of a single level, the two-dimensional concentration of carrier electrons, n_s, and the three-dimensional one, n_b, in the temperature range studied can be given, respectively, by:

$$n_S = (m^*/m)^{1/2}N_{d_s}^{1/2}[N_0(T)/2]^{1/3}\exp(-E_{d_s}/2kT),$$

$$n_b = (m^*/m)^{3/4}[N_{d_b}N_0(T)/2]^{1/2}\exp(-E_{d_b}/2kT),$$

where:

$$N_0(T) = 2(2\pi mkT/h^2)^{3/2};$$

N_{d_s} and N_{d_b} are the two-dimensional and three-dimensional concentrations of donors respectively, and E_{d_s} and E_{d_b} are the two-dimensional and three-dimensional donor levels respectively. The values of N_{d_s} and E_{d_s} are obtained from the intercept and the slope of the relation between $n_s/T^{1/2}$ and $1/T$ respectively, and N_{d_b} and E_{d_b}, from those between $n_b/T^{3/4}$ and $1/T$. However, the donor concentration obtained from the intercept is overestimated, as has been revealed in ZnO.[28] As the donor centers were not completely exhausted at room temperature, the concentrations of the donor at 230 °C and 400 °C were estimated by the extrapolation of the relation between n and $1/T$ to these two temperatures, because an intrinsic conductivity of rutile occurred above 600 °C.[3a] The results are listed in Table 1. From the crystal structure of rutile, the number of titanium ions was calculated to be $3.2\times10^{22}/cm^3$. On the assumption that all the oxygen atoms were removed from the surface of the (110) plane, the amount of the released electrons was calculated to be $4.36\times10^{15}/cm^2$. It is clear from the table that the electrical conduction for the specimen evacuated at 500 °C occurs not only on the top layer of the surface, but also considerably beneath the surface. The table also contains the Fermi levels, whose values were calculated by estimating m^* to be 25 m.

Photoconductivity. The typical spectral responses of the photoconductivity of the rutile measured at room temperature and −196 °C are shown in Fig. 9. The maxima in the photoconductivity curves occurred at

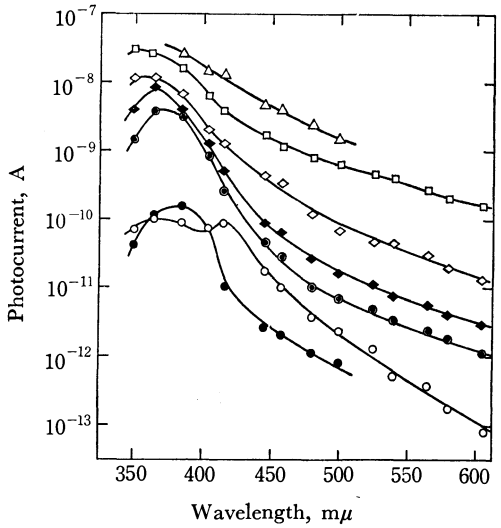

Fig. 9. Spectral responses of photoconductivity of rutile treated under several conditions at 25 and −196 °C. 28) S. E. Harrison, *Phys. Rev.*, **93**, 52 (1954).

the wavelengths between 350 and 400 mμ, which are near the fundamental absorption edge, as may be seen in Fig. 11. The photoconductivity increased as the out-gassing temperature rose from 300 to 500 °C. In particular, the photoconductivity in the wavelength region longer than the absorption edge increased when the rutile was reduced by hydrogen. This finding suggests that the large number of donors near the conduction band contribute to the photocurrent at the long wavelength. The rather sharper peak in the curve at −196 °C than that at room temperature may come from the more distinct band width of the forbidden gap, since most of the electrons are present in donor centers rather than in a conduction band at a low temperature. When the rutile was oxidized at 500 °C, a new maximum appeared at 415 mμ in the photoconductivity spectra at room temperature. This peak has also been observed for highly-oxidized rutile.[5,29] It may be presumed from the results of the conductivity measurements that donor levels are hardly present below the conduction band at the surface because of the formation of the depletion layer near the surface because of the presence of O^- or O_2^-. Therefore, this peak may be attributable to excitation from a level, such as O_2^- or O^-, near the valence band on the surface to the conduction band.

It is clear from Fig. 9 that the photocurrent of the rutile increases with an increase in the conductivity, *i.e.*, the dark current. The relationship between the photocurrent at 405 mμ and the dark current at room temperature is shown in Fig. 10. This implies that the population of electrons in the donor level on the surface may increase, since the accumulation layer becomes remarkable with a rise in the Fermi level on the surface. The photocurrents of both the specimen treated with hydrogen and that treated with oxygen decayed slowly when the illuminating light was cut off; This may be due to the existence of traps in the specimen treated with hydrogen and to the photodesorption of the adsorbed oxygen molecules from the specimen treated with oxygen.

Absorption Spectra. The absorption spectra of the rutile did not change upon the thermal treatment *in vacuo*, as is shown in Fig. 11. This finding is similar to that of Cronemeyer.[3a] The absorption edge shifted from 420 to 410 mμ as the temperature decreased from

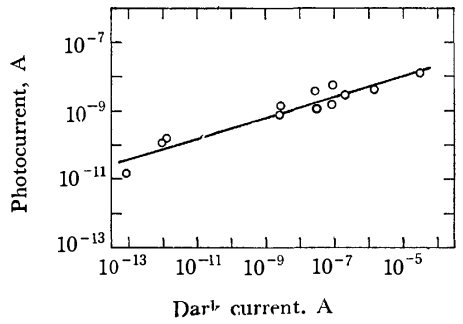

Fig. 10. Relation between the photocurrent at 405 mμ and the dark current at 25 °C.

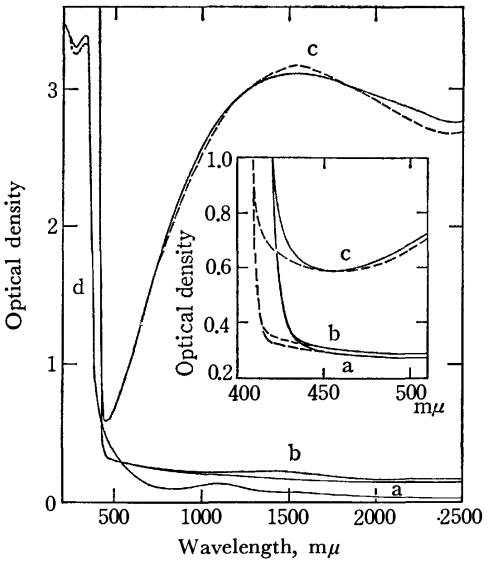

Fig. 11. Optical densities of a rutile single crystal and thin film treated under several conditions. Single crystal: (a) oxidation at 450 °C for 3 min, (b) reduction at 500 °C for 10 min, and (c) reduction at 500 °C for 3 hr. Thin film prepared by the oxidation of the evaporated film of titanium at 1100 °C: (d) oxidation and reduction at 500 °C. Full lines show the optical density measured at 25 °C and dotted lines at −133 °C.

room temperature to −133 °C. A broad absorption centered at 1.5 μ appeared upon the reduction with hydrogen and increased extremely remarkably with the reduction time, though the absorption edge did not change entirely. The absorption spectrum of a thin film of rutile showed maxima at 330 mμ and a slight peak at 1.1 μ. These peaks did not change with the temperature. The optical density near the band gap was not changed by the reduction, whereas the photoconductivity changed markedly.

It is clear from the results of the electrical conductivity and the photoconductivity that the electronic state near the surface of the rutile single crystal is changed remarkably by the contact with oxygen or hydrogen for a short time, while the electronic state in bulk is also changed. It has been considered that hydrogen atoms can diffuse into the bulk of rutile and act as donors.[7,30] However, the evacuation at a high temperature may remove the hydrogen atoms as in the case of ZnO.[31] The reversible change in the electrical conduction by the reduction-oxidation cycle indicates that oxygen atoms may be removed easily from the surface or bind to the surface even under the mild conditions studied. The change in the activation energy with the concentration of donors may be considered to depend on the position of the Fermi level in relation to the conduction band on the surface in addition to the effect of the interactions between donors.[3b] As oxygen atoms can not be removed below 300 °C, the increase in the electrical conductivity and

photoconductivity when rutile is evacuated below that temperature suggests that the active oxo-structure produced by the condensation of hydroxyl groups on the surface can act as donors in the electrical conduction on the surface.

(Received July 20, 1972)

The relationship between the rheological properties and the states of water in macromolecular gels is investigated by both the rheological and nuclear magnetic resonance methods. In accordance with the stress-strain curve, macromolecular gels are shown to be classifiable into: (1) an agarose type of gel which shows great gel strength and brittleness at breaking; (2) a κ-carrageenan type of gel showing great gel strength, but ductility at breaking, and (3) a λ-carrageenan type of gel, which has very little gel strength and is pasty. The dependence of the NMR line-width of water in gels on the polymer concentration and on the temperature reveals that the motional state of water in gels is restricted in this order: the agarose type of gel > the κ-carrageenan type of gel > the λ-carrageenan type of gel. These results show that the state of water is closely related with the rheological properties of macromolecular gels.

The states of water existing in polysaccharide gels, such as agarose-, κ- and λ-carrageenan-, and curdlan-type polysaccharide gels, have previously been studied by the electrochemical method,[1,2] by means of nuclear magnetic reasonance,[3,4] and by the dilatometric method.[5] These studies have revealed that so-called free water is a mixture of at least two different states of water; one is comparable with ordinary water except that it is prevented from flowing out, and the other is less mobile than ordinary water, but more mobile than so-called bound water.

On the other hand, various rheological types of gel can be found in polysaccharide gels. Agarose gels, for instance, exhibit brittleness, while k-carrageenan gels show ductility. It has not been clarified yet, however, what affects these rheological properties of macromolecular gels. This investigation was carried out with the aim of clarifying how to correlate the states of water to the rheological properties of macromolecular gels.

The states of water existing in gels are quite difficult to survey by means of spectroscopic measurements because of their poor transparency. Nuclear magnetic resonance (NMR) methods may be more suitable for such investigations, for the motional states of water can be estimated through the NMR line-width of the proton signal. Agarose-, κ- and λ-carrageenan-, and curdlan-type polysaccharide gels were measured for the NMR line-width of their water, and the line-widths were compared with their rheological properties.

Experimental

Samples. Agarose-, κ-carrageenan-, λ-carrageenan-, and curdlan-type polysaccharide gels prepared at the required water contents were used as the samples. Curdlan-type polysaccharide is a bacterial gel-forming β-1,3-glucan obtained from the culture filtrate of a mutant strain (NTK-U, IFO 13140) of *Alcaligenes faecalis var. myxogenes*, strain 10C3K.[6]

Gel Strength and Elasticity Measurement. The stress-strain curves for gels were obtained at 25 °C by the use of a gel-strength tester. The water contents of gels were measured before and after the mechanical test.

NMR Spectra. The proton NMR spectra were obtained using a JNM-C-60HL high-resolution NMR spectrometer, as has been described previously.[3] The sample was sealed in a standard sample tube (5 mm ϕ O.D.). The temperature was measured by means of a copper constantan thermocouple near the sample tube.

Results

Rheological Properties of Various Polysaccharide Gels. Gel strength is known as a gel property. It is not sufficient, however, as a basis for profiling the rheologi-

cal properties of gels, because it shows only the maximum at the breaking point. A stress-strain curve may be convenient as a basis for classifying the rheological properties of the various polysaccharide gels.

The stress-strain curves at 25 °C are shown in Fig. 1 for agarose-, κ-carrageenan-, λ-carrageenan-, and curdlan-type polysaccharide gels. The polysaccharide content of each is 2%. The strain is indicated as ε in the abscissa, showing the ratio of the contraction to the length of the gel which is free from stress.

In the range of low stress, the stress correlates linearly with the strain. The gradients of the stress-strain curves, *i. e.*, the elastic moduli, increase in the following order: λ-carrageenan<κ-carrageenan and curdlan-type polysaccharide<agarose. The end points of the curves show the stress at the breaking point, the so-called gel strength. The λ-carrageenan gel has very little gel strength. The other three kinds of gels exhibit comparable gel strengths.

The stress-strain curve of agarose gel has an inflection point at $\varepsilon=0.2$, following the abrupt rise between this inflection point and the breaking point. Thus, this type of gel shows brittleness. κ-Carrageenan gel gives an inflection point in the stress-strain curve around $\varepsilon=0.4$, and the slope of the line in the range from this inflection point to the breaking point is moderate compared to that of the agarose gel. The curdlan-type polysaccharide gel resembles the κ-carrageenan gels in its rheological properties.

On the other hand, the λ-carrageenan gel markedly contracts when subjected to even a slight stress, showing paste-like properties. Therefore, the polysaccharide gels investigated can be classified as follows:

(1) The agarose type of gel, which shows great gel strength and brittleness at breaking.

(2) The κ-carrageenan type of gel, which shows great gel strength and ductility at breaking, and

(3) The λ-carrageenan type of gel, which shows very little gel strength and paste-like properties.

NMR Line-width of Water in Gels. The polysaccharide gels can be classified into three groups according to the rheological properties mentioned above. As the NMR line-width is known to be related to the spin-spin relaxation time, T_2 which indicates the motional states of nuclear spin, and is known to become narrow when the nucleus is in a vigorous motional state,[7] the NMR line-width of water was investigated for these three types of polysaccharide gel.

For agarose-, κ- and λ-carrageenan-, and curdlan-type polysaccharide gels, the NMR line-width of water is illustrated at various concentrations in Fig. 2. The line-width is indicated in Hz units as the half-width of the maximum peak height. The line-width widens with the increase in the polysaccharide concentration for each gel. The concentration dependence of the line-width is most prominent for agarose gels, as is shown in Fig. 2. In contrast, the line-width changes only slightly with the increase in the λ-carrageenan concentration. The concentration dependences of the line-width of water in κ-carrageenan and curdlan-type polysaccharide gels lie between those agarose and λ-carrageenan gels. These results indicate that water is more restricted in the agarose type of gel than in the κ-carrageenan and λ-carrageenan types of gel.

Temperature Dependence of the NMR Line-width of Water in Gels. The temperature dependence of the NMR line-width of water can offer effective information concerning the states of water in gels. The temperature dependence of the line-width below 0 °C is shown in Fig. 3 for agarose, κ-carrageenan, and curdlan-type polysaccharide gels containing 92% of water by weight. The line-width increases with the temperature decrease, this shows the restriction of the motional state of water. Most water existing in gels changes in phase from a liquid into a solid at 0 °C, this accompanies the drastic change of the line-width. As the line-width of water in the solid state, frozen water, is too wide to be detected by a high-resolution NMR spectrometer, the NMR signal of water frozen at 0 °C may be eliminated below 0 °C. Therefore, the NMR line-width shown in Fig. 3 has been determined by studying the water molecules which remains unfrozen even in this temperature range. In Fig. 3, an anomalous temperature dependence of the line-width is found in the temperature range from 0 to −20 °C. This anomalous temperature depen-

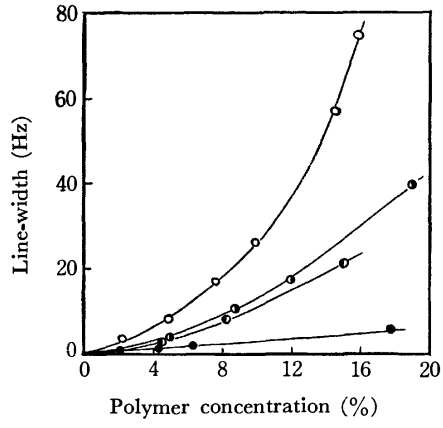

Fig. 2. NMR line-width of water in agarose (—○—), curdlan-type polysaccharide (—◑—), κ-carrageenan (—◐—) and λ-carrageenan (—●—) gels.

7) H. S. Gutowsky and G. E. Pake, *J. Chem. Phys.*, **18**, 162 (1950).

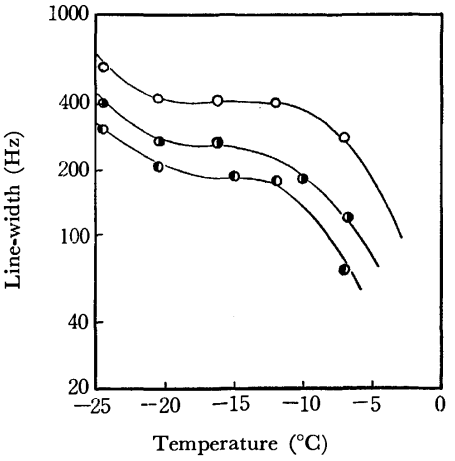

Fig. 3. Temperature dependence of NMR line-width of water in agarose (—○—), curdlan-type polysaccharide (—◑—) and κ-carrageenan (—◐—) gels containing 92% of water.

dence may be caused by the phase-transition of water which remains unfrozen below 0 °C.

Moreover, water in an agarose gel exhibits a wider line-width in this temperature range than the other two kinds of polysaccharide gel. This indicates that the motional state of water which remains unfrozen below 0 °C is restricted more extremely in an agarose gel than in the other two kinds of gel. The restriction of the motional state of water which remains unfrozen below 0 °C is in the order: agarose>curdlan-type polysaccharide>κ-carrageenan gels. This restriction order quite agrees with the results derived from the polymer-concentration dependence of the NMR line-width.

Generally, the NMR line-width gets narrower with an increase in the temperature (motional narrowing). On the contrary, the line-width of water existing in polysaccharide gels was found to become wider with the increase in the temperature above 0 °C, as has been reported previously.[4] Such an anomalous temperature dependence of the line-width can be expected to be closely related to the rheological properties of polysaccharide gels.

The temperature effects on the NMR line-width of water are presented in Fig. 4 for agarose-, κ-carrageenan-, λ-carrageenan-, and curdlan-type polysaccharide gels containing 92, 91, and 92% of water respectively. In Fig. 4, the line-width of water in an agarose gel is shown to increase with the increase in temperature up to approximately 35 °C, and then to decrease above this temperature. The anomalous temperature effect is the most prominent in the agarose gel. Water involved in the curdlan-type polysaccharide and κ-carrageenan gels increases the line-width, with a slight inclination, with the increase in the temperature, giving no maxima. This anomalous effect is not so marked, but is rather, negligible in a λ-carrageenan gel. The magnitude of the anomalous temperature effect on the line-width decreases in this order: agarose>curdlan-type polysaccharide and κ-carrageenan>λ-carrageenan gels.

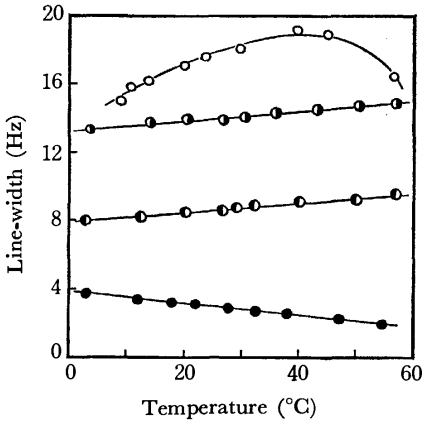

Fig. 4. Anomalous temperature dependence of NMR line-width of water in agarose (—○—), curdlan-type polysaccharide (—◑—), κ-carrageenan (—◐—) and λ-carrageenan (—●—) gels containing 92, 92, 91 and 92% of water respectively.

Discussion

The nuclear magnetic resonance properties of water in polysaccharide gels may be summarized as follows:

(1) For agarose gels, the line-width of water depends markedly on the polysaccharide concentration of the gel, the anomalous temperature effect on the line-width is the most prominent, and the line-width is wider than in the other gels at the same concentration and the same temperature.

(2) The line-width of water in λ-carrageenan gels is not so dependent on the polymer concentration, and the anomalous temperature effect on the line-width is rather negligible.

(3) The properties of the water involved in curdlan-type polysaccharide and κ-carrageenan gels are intermediate between those of the above two types of polysaccharide gels. As was shown in the previous papers,[3,4] these properties reflect the motional state of water in gels. These results indicate that the motional state of water is restricted in this order: agarose>curdlan-type polysaccharide and κ-carrageenan>λ-carrageenan gels.

The above order corresponds reasonably well to that of the rheological classification. In other words, the water involved in the rheologically-strong gels is extremely restricted or immobilized. Therefore, a close relationship between the rheological properties of gels and the states of water existing in it was revealed.

Summary

The nuclear magnetic resonance properties of water showed that the restriction effect on the motional state of water was the most marked in agarose gels among the polysaccharide gels surveyed, and that it was loosened in this order: agarose>curdlan-type polysaccharide, κ-carrageenan>λ-carrageenan gels. On the other hand, the polysaccharide gels were revealed to be classifiable into three groups according to their rheological properties: (1) the agarose type of gel, (2) the κ-carrageenan type of gel, and (3) the λ-carrageenan type of gel. A close relationship between the motional state of water and the rheological properties was found on the basis of the above results.

The 2288 Å Photolysis of Hydrogen Iodide in the Presence of Ethylene and Propylene

Yasuhisa SANO and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received August 15, 1972)

The photolysis of hydrogen iodide at 2288 Å has been investigated in the presence of ethylene or propylene. The combinations studied were DI–C_2H_4, HI–C_2D_4, and DI–C_3H_6. In all combinations, the formation of a large amount of HD was observed; this may be attributed to the reaction of hot hydrogen atoms. The pressure dependence of the relative yields of HD and total hydrogen suggested that, of the two possible hot hydrogen atom reactions with ethylene, the abstraction reaction,

$$D^* + C_2H_4 \longrightarrow C_2H_3 + HD \quad (2)$$

does not occur, while the substitution reaction,

$$D^* + C_2H_4 \longrightarrow C_2H_3D + H \quad (3)$$

is the important process. In the case of propylene, however, the abstraction of H by D* is important for the formation of HD. The measured ratios of C_2H_3D/HD in the DI–C_2H_4 system and of C_2D_3H/HD in the HI–C_2D_4 system were consistent with the above conclusion. Reaction (3) is probably not a real substitution reaction, but a combination of the addition reaction of a hydrogen atom to ethylene and the rapid decomposition of the excited ethyl radical produced.

When hydrogen iodide is photolyzed at 2288 Å, hot hydrogen atoms are produced.[1,2] The excess translational energy amounts to 2.3 eV if the iodine atoms produced are in their ground state ($^2P_{3/2}$). According to the estimation of Compton and Martin,[2] about 20% of total iodine atoms are produced in the first excited state ($^2P_{1/2}$) in the 2288 Å photolysis of hydrogen iodide. In this case, the excess energy of hydrogen atoms is reduced to 1.4 eV.

In a previous communication,[3] we have suggested that the deuterium atoms produced in the photolysis of deuterium iodide at 2288 Å undergo the following reaction:

$$D^* + C_2H_4 \longrightarrow C_2H_3D + H$$

The present paper will report the details of this experiment, and also the results with different combinations, HI–C_2D_4 and DI–C_3H_6.

Experimental

Materials. The deuterium iodide was synthesized by heating a mixture of deuterium (Takachiho Chemical Co.) and iodine (Koso Chemical Co.) on platinized asbestos in a Pyrex tube at 400 °C for two days. The DI thus produced was distilled three times from a bath at 200 K to that at 77 K, with the rejection of the head and tail fractions. The DI gas thus synthesized was stored in a bulb covered with Al-foil. During the storage, the HI content gradually increased, probably because of a proton-exchange reaction between DI and water in glass or in grease. The HI content was estimated from the H_2 : HD : D_2 ratio obtained in the photolysis of DI. Since the extinction coefficient of HI at 2288 Å is a little larger than that of DI,[4] the HI content will be overestimated. The initial content of HI was less than 5%. When the content reached 15%, the reactant gas was renewed.

The hydrogen iodide was prepared by dropping hydriodic acid (Yanagishima Pharmaceutical Co.) on phosphorus pentoxide (Kishida Chemical Co.) cooled at 0 °C in a flow of nitrogen gas.

The C_2H_4, C_3H_6 (Takachiho Chemical Co.) and C_2D_4 (Merck Sharp & Dohme Co.) were used after bulb-to-bulb distillations. Mass spectrometric analysis showed that C_2D_4 contained 4% C_2D_3H.

Apparatus and Procedure. Home-made cadmium resonance lamps[5] were used for irradiation. When, of the two resonance lines, the 2288 Å line was cut off with the Toshiba UV-D 25 filter, the reaction products were very few. Therefore, all the measurements were carried out without a filter. The contribution of the 3261 Å resonance line to the reaction must be less than a few percent, because the extinction coefficient of hydrogen iodide at 2288 Å is about 200 $l \cdot mol^{-1} \cdot cm^{-1}$ and that at 3261 Å is a hundred times smaller.[6]

Before irradiation, all the faces of the quartz reaction vessel, 5 cm long and 5 cm in diameter, were heated with a torch under a vacuum to remove any deposit; however, the complete removal of iodine could not be achieved. All the experiments were done at room temperature. Immediately before and after the run with hydrocarbons, the photolysis of DI or HI without hydrocarbons was made in order to estimate the intensity of the light and in order to obtain the HI content when DI was used as a reactant. If the two measurements, before and after the run with hydrocarbons, did not agree within the limits of experimental error, this series of measurements was discarded.

The amounts of the products were measured volumetrically with a Toepler pump, and their analyses were made by mass spectrometry. Before the analysis of the H_2 : HD : D_2 ratio, it was determined that no significant isotope exchange was induced during the mass-spectrometric analysis. When the amount of C_2H_3D or C_2D_3H in ethylene was estimated, the correction for the ^{13}C natural abundance was applied to the data. Because of the presence of a large amount of C_2H_4 or C_2D_4, the estimated values of C_2H_3D

and C_2D_3H are not accurate, the error probably being ±50%.

Results

DI-C_2H_4. Figure 1 shows the time dependence of the products, D_2, HD, H_2, and C_2H_3D, from the photolysis of DI-C_2H_4 mixture. The DI gas used here contained 15% HI. The initial pressure of deuterium iodide was 5 Torr, and the initial $[C_2H_4]_i/[DI]_i$ ratio was 0.85. Since the contamination of HI could not be avoided, the following procedure was applied to the experimental results as correction. In the first place, the ratios of $x=[HD]_0/[D_2]_0$ and $y=[H_2]_0/[D_2]_0$ were calculated. Here, the suffix 0 denotes the absence of C_2H_4. Then the following correction was applied to the data:

$$[HD]_{corr} = [HD]_e - [D_2]_e x$$

$$[H_2]_{corr} = [H_2]_e - [D_2]_e y$$

Here, the suffix e denotes the presence of C_2H_4, while the suffix corr denotes the corrected values. The $[H_2]_{corr}$ values thus obtained were always very close to zero.

Figure 2 shows the relative yields of D_2+HD, D_2, and HD as a function of the initial ratio of C_2H_4 to DI. Here, the initial pressure of DI was kept at 5 Torr and the pressure of C_2H_4 was changed. The conversion of DI was less than 20%. The yield of D_2 in the photolysis of DI was taken as unity. The correction described above has already been applied. Table 1 shows the $[C_2H_3D]/[HD]$ ratio, which was

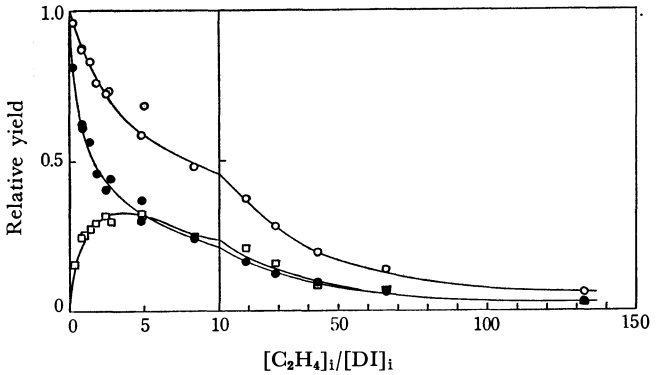

Fig. 2. The relative yields of D_2+HD (○), D_2 (●), and HD (□) as a function of the initial $[C_2H_4]_i/[DI]_i$ ratio.

obtained in the same series of data measurement as is shown in Fig. 2. At $[C_2H_4]_i/[DI]_i$ ratios higher than 10, the $[C_2H_3D]/[HD]$ ratios could not be measured because of a large amount of C_2H_4. In spite of the careful inspection of the mass spectrograms, no products other than C_2H_3D, such as acetylene or ethane, could be observed.

HI-C_2D_4. The relative yields of H_2+HD, H_2, and HD are shown in Fig. 3 as a function of the $[C_2D_4]/[HI]_i$ ratio. In this case, no correction except the contribution of 4% C_2D_3H in C_2D_4 to the observed yields was necessary. Table 2 shows the $[C_2D_3H]_i/[HD]_i$ ratio as a function of the $[C_2D_4]_i/[HI]_i$ ratio. Several measurements were made in the presence of the saturated vapor pressure of iodine, which was intentionally introduced in the system. Practically no difference between the data obtained in the presence and in the absence of iodine was observed. The

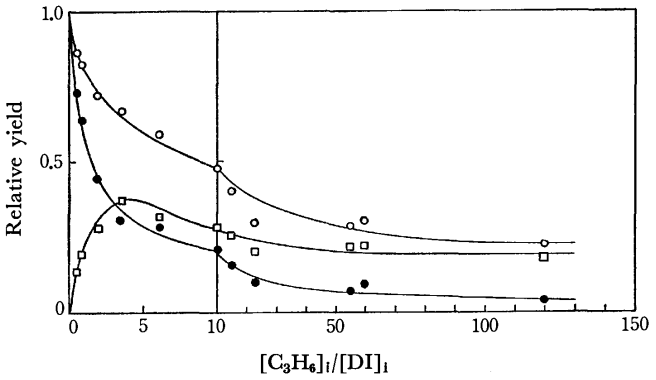

Fig. 4. The relative yields of D_2+HD (○), D_2 (●), and HD (□) as a function of the initial $[C_3H_6]_i/[DI]_i$ ratio.

$[C_2D_3H]/HD]$ ratios obtained in this series of experiments are also shown in Table 2.

DI-C_3H_6. Propylene was also used as a counterpart in the photolysis of DI. Figure 4 shows the relative yields of D_2+HD, D_2, and HD as a function of the $[C_3H_6]_i/[DI]_i$ ratio. A correction similar to that to the DI-C_2H_4 system has already been applied. Obviously the curves for D_2+HD, D_2, and HD are very similar to those obtained with C_2H_4; however, the [HD] values do not approach zero, but level off at about 0.2. The mass-spectrometric analysis for the formation of C_3H_5D could not be carried out because the attempt to separate propylene from deuterium iodide was not successful.

Discussion

It is well known that the reaction of thermal hydrogen atoms with ethylene or propylene leads almost exclusively to the formation of the ethyl or isopropyl radical. According to the estimation of Jennings and Cvetanović,[7] the k_a/k_b ratios are zero for ethylene and 0.045 for propylene.

$$H + RH \longrightarrow H_2 + R \qquad a$$

$$H + RH \longrightarrow RH_2 \qquad b$$

Woolley and Cvetanović reinvestigated these ratios and reported zero for ethylene and 0.082 for propylene. Therefore, the formation of a large amount of HD observed in the present experiment may be considered to be evidence for a hot hydrogen atom reaction. However, the reaction of the (a) type is not necessarily the only mechanism for the formation of HD. Another possible mechanism is the following substitution reaction:

$$D^* + RH \longrightarrow H + RD$$

followed by:

$$H + DI \longrightarrow HD + I$$

Such a substitution reaction has been observed with recoil tritium atoms from a nuclear reaction.[8] Which type of reaction is responsible for the formation of HD is one of the main concerns in this paper.

As Figs. 2 and 3 show, the formation of HD in the system containing ethylene approaches zero with the increase in the ratio of ethylene to hydrogen iodide. This result suggests that the hot hydrogen atom does not abstract a hydrogen atom from ethylene in the first collision. If it does, a certain fraction of HD should remain even at the higher $[C_2H_4]_i/[DI_i]$ ratios, because the $[DI]_i$ was kept at a constant value, 5 Torr. In the system containing propylene, on the other hand, the HD formation levels off at a constant value with the increase in propylene, as is shown in Fig. 4.

In order to discuss these reactions, the following reaction scheme was considered:

$$DI + h\nu \rightarrow D^* + I \qquad (0)$$

$$D^* + DI \rightarrow D_2 + I \qquad (1)$$

$$D^* + RH \rightarrow HD + R \qquad (2)$$

$$D^* + RH \rightarrow H + RD \qquad (3)$$

$$D^* + RH \rightarrow D + RH \qquad (4)$$

$$D^* + I_2 \rightarrow DI + I \qquad (5)$$

$$D + DI \rightarrow D_2 + I \qquad (6)$$

$$D + RH \rightarrow RHD \qquad (7)$$

$$D + RH \rightarrow HD + R \qquad (8)$$

$$D + I_2 \rightarrow DI + I \qquad (9)$$

$$H + DI \rightarrow HD + I \qquad (10)$$

$$H + RH \rightarrow RH_2 \qquad (11)$$

$$H + RH \rightarrow H_2 + R \qquad (12)$$

$$H + I_2 \rightarrow HI + I \qquad (13)$$

$$R + DI \rightarrow RD + I \qquad (14)$$

$$R + RH \rightarrow R_2H \qquad (15)$$

$$R + I_2 \rightarrow RI + I \qquad (16)$$

$$I + I + M \rightarrow I_2 + M \qquad (17)$$

For the discussion of the HI–C_2D_4 system, H and D in the scheme should be exchanged. In this reaction scheme, the moderation of D* atoms by DI and I_2 was not included, because the heavy molecules, such as DI and I_2, would not be effective moderators for hot hydrogen atoms. Table 3 summarizes the average fraction of energy lost per collision, assuming an elastic head-on collision. According to the estimation of Martin and Willard,[6] the average fractions of energy lost per collision in the systems of H*+C_2D_6 and of D*+C_2H_6 are, respectively, 0.19 and 0.51, values which are 1.5 and 2 times that of the energy lost per elastic head-on collision. Ob-

viously, even in the case of 2.3 eV D* in C_2H_4, several collisions are necessary for the complete thermalization. In the present treatment, however, it has been assumed that only one collision is effective enough to thermalize the hot hydrogen atom; otherwise, the kinetic treatment cannot easily be carried out.

When the conversion is not large, the steady-state-treatment on the reasonable assumptions that $k_3 \gg k_8$ and that $k_1[DI] \gg k_5[I_2]$ gives the following relationship: Here, ϕ denotes the relative yield of $[D_2]+[HD]$, and β stands for the following ratio:

$$\frac{1-\beta}{1-\phi} = 1 + \frac{k_2}{k_3+k_4} + \frac{k_1}{k_3+k_4}\frac{[DI]}{[RH]} \qquad \text{(I)}$$

$$\beta^{-1} = 1 + \frac{k_7[RH]}{k_6[DI]} + \frac{k_9[I_2]}{k_6[DI]}$$

$$= 1 + \frac{k_{11}[RH]}{k_{10}[DI]} + \frac{k_{13}[I_2]}{k_{10}[DI]} \qquad \text{(II)}$$

The equality between the second equation and the third in Eq. (II) is acceptable, because Reactions (6), (7), and (9) are the reactions of deuterium atoms DI, RH, and I_2 respectively, while Reactions (10), (11), and (13) are those of hydrogen atoms with DI, RH, and I_2 respectively.

Since Reactions (10), (11), and (13) are those of thermal hydrogen atoms, the specific rates are rather accurately known. According to the measurements of Penzhorn and Darwent,[9,10] the ratio of k's for the reactions of thermal hydrogen atoms with I_2 and HI is expressed by $4.96 \exp(640/RT)$, and $k(H+C_2H_4)/k(H+HI)$ is equal to $0.30 \exp(-845/RT)$. Cvetanović and Doyle reported $k(H+C_3H_6)/k(H+C_2H_4) = 1.53$ at 20 °C.[11] For the present calculations, the following values were used: 0.0738 for k_7/k_6 of ethylene, 0.113 for k_7/k_6 of propylene, and 14.3 for k_9/k_6. As has been described in the results for the system of HI–C_2D_4, the intentionally-introduced iodine did not affect the formation of H_2 and HD. Judging from this result and from the difficulty in completely removing iodine in the reaction vessel, it may be said that all the reactions reported here take place in the presence of iodine vapor. Therefore, the following calculations were carried out on the assumption that the iodine pressure in the reaction vessel was 0.195 Torr, the saturated vapor pressure of iodine at 20 °C.[12]

Figure 5 shows the plots of the left-hand side of Eq. (I) as a function of the [Deuterium iodide]/[Olefin] ratio. From these linear relationships, the values listed in Table 4 were obtained. It may be noticed here that the value of k_2 is very small in the case of ethylene.

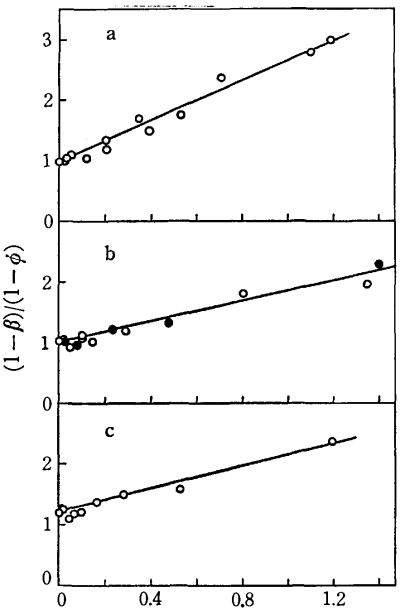

Fig. 5. The plots for Eq. (I).
a: $[DI]_i/[C_2H_4]_i$, b: $[HI]_i/[C_2D_4]_i$, c: $[DI]_i/[C_3H_6]_i$

TABLE 4. THE CALCULATED VALUES OF THE RATIOS OF k's

System	$k_2/(k_3+k_4)$	$k_1/(k_3+k_4)$	
C_2H_4–DI	0.0	1.6	$k_1 \gg k_2$
C_2D_4–HI	0.0	0.85	
C_3H_6–DI	0.2	1.0	$k_1 = 5k_2$

The steady-state treatment based on the reaction scheme proposed above also gives this relation:

$$\frac{\phi_D}{\phi_{HD}} = \frac{\beta k_4}{k_2+\beta k_3} + \frac{k_1}{k_2+\beta k_3}\frac{[DI]_i}{[C_2H_4]_i} \qquad \text{(III)}$$

In the system of DI–C_2H_4, the value of k_2 may be taken to be zero; then, the plots of ϕ_{H_2}/ϕ_{HD} as a function of $[DI]_i/\beta[C_2H_4]_i$ should give a straight line. Similarly, in the HI–C_2D_4 system the ϕ_{H_2}/ϕ_{HD} ratio should be linearly dependent on the $[HI]_i/\beta[C_2D_4]_i$ ratio. The results are shown in Fig. 6. The slopes and the intercepts of the straight lines give $k_4/k_3 \sim 0.7$ and $k_1/k_3 \sim 1.0$ for both systems. However, these values should not be taken too seriously, because in them errors from various sources are accumulated. Therefore, the only thing we can say is that all the values of k_1, k_3, and k_4 are in the same order.

Consequently, we can conclude from the above two analyses that the k_2 is much smaller than the k_3 in the system with ethylene and that the k_2 is more than 20% of the k_3 in the system with propylene.

In the experiments on the DI–C_2H_4 and HI–C_2D_4 systems, we measured the amounts of C_2H_3D and C_2D_3H produced. The ratios of $[C_2H_3D]/[HD]$ and $[C_2D_3H]/[HD]$ are listed in Tables 1 and 2. Although the data are very scattered, they may be enough to show that the ratios are between 1.0 and 2.0.

Since we know that thermal hydrogen atoms are about 10 times more reactive to hydrogen iodide than

9) R. D. Penzhorn and B. deB. Darwent, *J. Phys. Chem.*, **72**, 1639 (1968).
10) R. D. Penzhorn and B. deB. Darwent, *J. Chem. Phys.*, **55**, 1508 (1971).
11) R. J. Cvetanović and L. C. Doyle, *ibid.*, **50**, 4705 (1969).

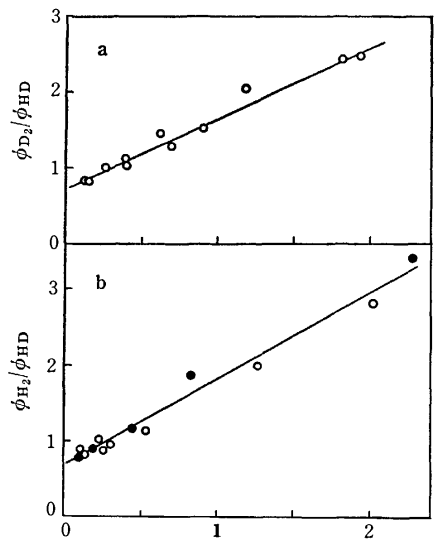

Fig. 6. The plots for Eq. (III).
a: $[DI]_i/\beta[C_2H_4]_i$, b: $[HI]_i/\beta[C_2D_4]_i$

to olefins, and since the C_2D_3H and C_2H_3D values were measured in the Olefin/Hydrogen Iodide ratio range of 0.4~8, we can derive the following relationship by using the steady-state treatment:

$$\frac{[RD]}{[HD]} = \frac{k_2+(1+\gamma)k_3}{k_3+(1+\gamma)k_2} \qquad (IV)$$

Here, γ stands for the following ratio:

$$\gamma = \frac{k_{13}[I_2]}{k_{10}[DI]} = \frac{k_{16}[I_2]}{k_{14}[DI]} \qquad (V)$$

The equality between the second term and the third in Eq. (V) may be admitted for the same reason as in the case of Eq. (II). At the temperature of 20 °C, the k_{13}/k_{10} ratio is equal to 14.3, as has already been stated. Therefore, the value of γ for the present experiment is calculated to be $0.6(=14.4\times0.195/5.0)$. In the above discussion, the inequality $k_2 \ll k_3$ has been derived in the DI–C_2H_4 and HI–C_2D_4 systems. The substitution of this relation into Eq. (IV) leads to the conclusion that the [RD]/[HD] ratio should be 1.6. This value is not inconsistent with the observed values.

In the discussion of the reactions of tritium atoms from a nuclear reaction with saturated hydrocarbons, Wolfgang indicated that the threshold energy of the substitution reaction is higher than that of the abstraction reaction.[13] If this rule is applicable to ethylene, the present conclusion, $k_2 \ll k_3$, is obviously inconsistent with the statement of Wolfgang. However, according to the paper presented by Turner and Cvetanović,[14] when D atoms produced by the mercury-photosensitized decomposition of n-C_4D_{10} add to C_2H_4, the isotopic exchange occurs, but it does not occur when H atoms add to C_2D_4. Comparing these results with ours, we believe that the substitution reaction observed in the present experiment occurs through the rapid decomposition of excited ethyl radicals produced, the internal energy of which is much higher than that of the ethyl radicals discussed by Turner and Cvetanović.

If the Kassel equation, $k=(1-\varepsilon_0/\varepsilon)^{s-1}$, is applicable to the unimolecular decomposition of ethyl radicals, the lifetime may be calculated to be in the order of 10^{-11} s by using the following values: $A=10^{13.6}$, $\varepsilon_0=40.7$ kcal mol^{-1},[15] $\varepsilon=40.7+50$, and $s=8$. This lifetime is obviously too short to be affected by the pressure used in the present experiment.

Laser Photolysis Studies on the Ionization of *N*-Vinylcarbazole and *N*-Ethylcarbazole in the Presence and Absence of Electron Acceptors[1)]

Yoshio TANIGUCHI, Yasuzo NISHINA, and Noboru MATAGA*

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 565

(Received November 22, 1972)

Formation of solvated ion radicals in the *N*-vinylcarbazole (VCZ)-and *N*-ethylcarbazole (ECZ)-electron acceptor systems in polar solvents has been studied by means of laser photolysis, transient photoconductivity and transient absorption measurements. Ion radical formation due to the encounter collision between an excited VCZ or ECZ and electron acceptor was confirmed directly. In the absence of electron acceptor, formation of cation radicals of carbazoles due to biphotonic process was observed in polar solvents. The $S_n \leftarrow S_1$ spectra of these molecules were observed both in polar and nonpolar solvents.

It was postulated that the photopolymerization of VCZ in the presence of electron acceptors is initiated by cation radicals formed by the electron transfer from VCZ molecules to acceptors in the excited state.[2)] However, no direct experimental evidence has been given on the mechanism of cation radical formation.

We have shown the ion radical formation due to the encounter collision between an excited pyrene and *N*,*N*-dimethylaniline (DMA) and also between an excited anthracene and DMA in moderately and strongly polar solvents by means of laser photolysis, transient photoconductivity and absorption measurements.[3,4)] We carried out analogous studies on VCZ, using 1,2,4,5-tetracyanobenzene (TCNB) and tetracyanoethylene (TCNE) as electron acceptors, and confirmed the formation of solvated cation radicals of VCZ and anion radicals of the acceptor due to the encounter collision between the excited VCZ and the ground state acceptor.

We also studied the photoionization of VCZ in polar solvents in the absence of the electron acceptor, since photopolymerization of VCZ can even thus be observed. The formation of VCZ cation radicals was found to be due to a biphotonic absorption process. $S_n \leftarrow S_1$ spectra of VCZ might be important for the elucidation of its excited state electronic structure.

We examined ECZ in detail for the purpose of comparison and obtained similar results to those of VCZ.

Experimental

The same Q-switched ruby laser as described previously[3,5)] was used. The ion radicals produced were observed by measurement of the transient photocurrent and the transient absorption spectra induced by laser excitation, the methods for these measurements being the same as before. For examining the effect of exciting light intensity on the photocurrent, the intensity of the laser pulse was reduced by using neutral filters composed of wire gauzes. Relative values of the exciting intensity were monitored by measuring the intensity of light partially reflected by means of a beam splitter with a photomultiplier. The absolute value was determined by a ballistic thermopile TRG model 100 (Hadron). Measurements of fluorescence decay times were carried out by using a nitrogen gas laser.

TCNB was the same sample as used before and recrystallized from ethanol several times before use. TCNB was purified by repeated recrystallization from monochlorobenzene and sublimation in a vacuum. Solvents were Merck spectrograde and used without purification. Concentrations of VCZ and ECZ in solutions for the measurements were *ca.* 1.0×10^{-3} M, where the optical density of the solution at 347 nm was *ca.* unity. Concentrations of the electron acceptors in solutions for the laser photolysis were *ca.* 1.0×10^{-2} M. All solutions were deaerated by repeated freeze-pump-thaw cycles.

Results and Discussion

A. Formation and Annihilation Mechanisms of VCZ and ECZ Cation Radicals under the Presence of Electron Acceptors. The transient photocurrents of VCZ–TCNB–acetonitrile and ECZ–TCNE–methylene chloride systems are shown in Figs. 1 and 2, respectively. We see that the dissociated and solvated ion radicals are produced by excitation with 347 nm laser pulse, and vanish due to bimolecular recombination reaction. In a more concentrated solution, there arises a charge transfer (CT) absorption band near 570 nm due to complex formation. However, in the present case, the interaction of VCZ with TCNB in the ground state can be ignored, since no CT absorption is observed. The ion radicals (Figs. 1 and 2) might be formed by the encounter collision between excited carbazoles and

acceptors. We examined the effect of the addition of acceptors on the fluorescence decay time and yield of VCZ in acetonitrile solution. The results can be reproduced by the simple Stern-Volmer equation, $\tau/\tau_0=1/(1+\tau_0 k[A])$, from which k values were evaluated to be $1.5\times10^{10}\,M^{-1}\,s^{-1}$ for VCZ–TCNB system and $1.3\times10^{10}\,M^{-1}s^{-1}$ for VCZ–TCNE system. These values of the rate constant of the quenching reaction indicate that the excited VCZ molecules make diffusion-controlled encounter collision with acceptor molecules. Analogous results were obtained by fluorescence yield measurements.

The ion radical formation can be confirmed also by transient absorption measurements. The transient absorption spectra of VCZ–TCNB–acetonitrile system are shown in Fig. 3. The decay of the optical absorption at 780 nm and the reciprocal of the absorbance *vs.* time relation are shown, respectively, in Figs. 4a and 4b, and the decay process at 460 nm in Figs. 5a and 5b. The absorbance *vs.* time relation at *ca.* 710 nm is similar to that at 780 nm. The decay curve of the absorption at *ca.* 620 nm consists of two components. The short lived component of the absorption at 540—680 nm may be ascribed to the transition from the lowest excited singlet (S_1) to the higher excited singlet (S_n) state of VCZ. The decay of the long lived component is the same as that at 780 nm. The transient absorption bands at 780, 710 and 620 nm with a rather long life may be ascribed to the VCZ cation radical since they are similar to those of the VCZ cation radical obtained by radiolysis at low temperatures.[7] The absorption band at *ca.* 460 nm can be ascribed to the TCNB anion radical. The results show that the ion radicals formed by the electron transfer from the excited VCZ to TCNB decay due to the bimolecular recombination reaction.

The photoionization of VCZ in the presence of TCNB was also examined for the tetrahydrofurane (THF) solution, the results being shown in Figs. 6 and 7. They are similar to those in the case of acetonitrile solution, except that the amount of produced ions is considerably smaller. We observed both dissociated ion radical

formation and fluorescent exciplex formation in the case of pyrene–*N*,*N*-dimethylaniline–THF system, but no fluorescent exciplex formation was observed in the present case. This was the same also in the case of ECZ–TCNB system.

It is possible that ionization of VCZ or ECZ due to double photon absorption occurs since the exciting light pulse we used is fairly strong. For the sake of confirmation we investigated the effect of exciting light intensity on the peak photocurrent, the results of which are given in Fig. 8. We see that the ionization is a one-photon process in the case of the VCZ–TCNB–acetonitrile system.

We can conclude that the photoionization process of the VCZ–acceptor system is the encounter collision between the excited VCZ and the acceptor molecule followed by one electron transfer from the excited VCZ to the acceptor leading to the dissociation into ions.

The results might be of some interest for the elucidation of the CT photopolymerization mechanisms. Only a very small part of the dissociated ion radicals which have escaped deactivation due to recombination might initiate the polymerization.

B. Photoionization of VCZ and ECZ in the Absence of Electron Acceptors. In the photoionization of VCZ and ECZ in polar solvents in the absence of electron acceptors, the formation of their cation radicals was confirmed by transient absorption and transient photoconductivity measurements. The decay process of the absorption of VCZ cation radical in acetonitrile solution is shown in Fig. 9 and the transient absorption spectra of ECZ–methanol system in Fig. 10.

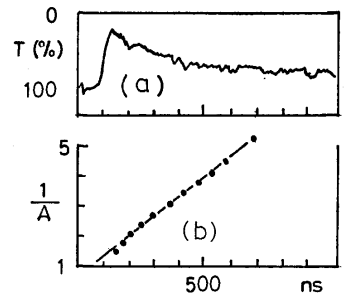

Fig. 9. The decay process of the absorption at 720 nm in the case of VCZ-acetonitrile system.

(b) The reciprocal of the absorbance *vs.* time relation.

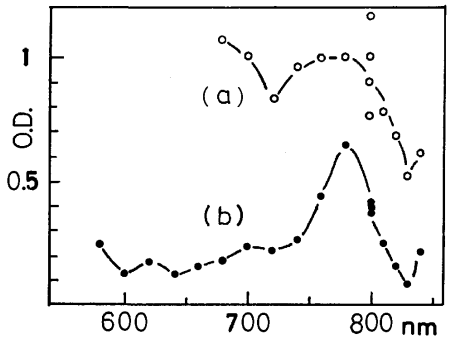

Fig. 10. Transient absorption spectra of ECZ-methanol system. The delay time from the laser pulse. (a) 0, (b) 100 ns.

The photocurrent in two-component system is similar to that of three-component systems, but in the former it is due to solvated cation radicals and solvated electrons.

We have confirmed that ionization is mainly due to the double photon process. The result in the case of VCZ–acetonitrile two-component system is shown in Fig. 8.

C. $S_n \leftarrow S_1$ Absorption Spectra of VCZ and ECZ. In order to examine the $S_n \leftarrow S_1$ transitions of VCZ and

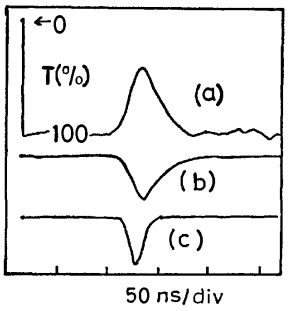

Fig. 13. The rise and decay curves of the transient absorption and fluorescence of VCZ-*n*-hexane system.
(a) Absorption at 620 nm.
(b) Fluorescence at 370 nm.
(c) Exciting laser pulse.

ECZ in detail, we carried out the laser photolysis and transient absorption measurements in n-hexane solution of these molecules, in order to avoid the formation of ion radicals.

The transient absorption spectra of VCZ-*n*-hexane and ECZ-*n*-hexane systems are shown in Figs. 11 and 12, respectively. The rise and decay curves of the transient absorption and the fluorescence of VCZ-*n*-hexane system are shown in Fig. 13. We can conclude that the observed transient absorption spectra are due to the $S_n \leftarrow S_1$ transitions, since the decay process of absorption is approximately the same as that of the fluorescence.

It might be of interest to note that the 620 nm band in the $S_n \leftarrow S_1$ spectra is similar to the absorption band of biphenyl anion. According to theoretical calculations on the electronic structures of carbazole[8,9] and VCZ[9], a considerable amount of charge transfer from nitrogen to the biphenyl part occurs in the S_1 state. Thus, the structure of these molecules in the equilibrium S_1 state might be highly polar where the biphenyl part is negatively charged, giving rise to $S_n \leftarrow S_1$ spectra similar to the absorption band of biphenyl anion. On the other hand, the wavelengths of the absorption bands in the $S_n \leftarrow S_1$ spectra are similar to those in the absorption spectra of cation radicals of VCZ and ECZ. Similarity of the $S_n \leftarrow S_1$ spectra of a molecule to those of its cation radical may be understood at least qualitatively on the basis of simple MO theory.

The authors wish to express their thanks to Dr. S. Tazuke, Kyoto University (presently at Tokyo Institute of Technology), for the VCZ and ECZ samples and for valuable discussions. They are indebted to Dr. K. Nishimoto, Osaka City University, for showing them his unpublished results of MO calculation.

A Kinetic Study of the Mutarotation of D-Xylose by the Polarographic Method[1]

Tokuji IKEDA and Mitsugi SENDA

Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606

(Received September 2, 1972)

The polarographic behavior of D-xylose in several buffer solutions was investigated. The rate constants, k_1, k_2, k_{-1}, and k_{-2}, of the mutarotation of α-D-xylose, assumed as $\alpha \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \gamma \underset{k_2}{\overset{k_{-2}}{\rightleftharpoons}} \beta$, were calculated by the use of Wiesner's method, but with a modified equation for the polarographic current. The overall mutarotation rate constant, k_o, which is defined by $k_o=(k_1k_{-2}+k_{-1}k_2)/(k_{-1}+k_{-2})$, was also determined. The rate constants, k_o, k_1, and k_2, were analyzed as a linear function of the buffer concentration. It was revealed that the catalytic effects of the buffer salts were mainly due to their basic components for all the buffer salts investigated. The Brönsted plots of k_1 and k_2 for all the basic components gave straight lines with the same slope of 0.42. The rate constants for several amines deviated from the slope; this deviation was ascribed to the steric hindrance caused by their large molecular sizes.

The mutarotation of reducing sugar in an aqueous solution is catalyzed by the use of acids and bases.[2-4] The measurements of the mutarotation velocity are usually made by polarimetry, NMR and other such methods, but the results are in most cases interpreted in terms of the mutarotation rate constant, k_o, defined by $k_o=k_\alpha+k_\beta$, where the reaction mechanism is assumed to be as in Eq. (1):

$$\alpha\text{-pyranose} \underset{k_\beta}{\overset{k_\alpha}{\rightleftharpoons}} \beta\text{-pyranose} \tag{1}$$

Los, Simpson, and Wiesner[5] have shown that, by the use of the polarographic method, four individual rate constants, k_1, k_2, k_{-1} and k_{-2}, of the mutarotation assumed as in Eq. (2):

$$\alpha\text{-pyranose} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \gamma\text{-form} \underset{k_2}{\overset{k_{-2}}{\rightleftharpoons}} \beta\text{-pyranose} \tag{2}$$

can be determined; here, the intermediate γ-form is assumed to be an electroactive free aldehyde form, and the polarographic current produced by a monosaccharide, such as D-glucose, is controlled by the kinetics of the formation of the γ-form from α- and β-pyranose. Experimental study of the isotope exchange of D-glucose C-1-^{18}O also supports the idea that the formation of the aldehydrol form is negligible in mutarotation kinetics.[2]

In this study, the individual rate constants of the base-catalyzed mutarotation of α-D-xylose are determined by the polarographic method; this method is based on Wiesner's assumption, but with a modified equation for the polarographic current. The results are discussed in view of the base-catalyzed reaction.

Expression for The Polarographic Current of D-*Xylose.* According to Los, Simpson, and Wiesner, the polarographic kinetic current, i_k, of monosaccharide when it is present in two forms, *e. g.*, α- and β-pyranose at the concentrations of C_α and C_β, is given by:

$$\bar{i}_k = nF\bar{q}(D/(k_{-1}+k_{-2}))^{1/2}(k_1C_\alpha+k_2C_\beta) \tag{3}$$

where n denotes the number of electrons consumed in the electrolysis per molecule; F, the Faraday; $\bar{q}$, the mean electrode surface area, and D, the diffusion coefficient of the monosaccharide. Eq. (3) was first derived by assuming a reaction layer on the electrode surface, the thickness of which was given by:

$$\mu = (D/(k_{-1}+k_{-2}))^{1/2} \tag{4}$$

We ourselves have previously shown[6] that Eq. (3) can be derived by a rigorous mathematical procedure on the following assumption:

$$\tau(k_{-1}+k_1) \gg 1 \qquad \tau(k_{-2}+k_2) \gg 1, \tag{5}$$

τ being the drop time, and

$$K_\alpha = k_{-1}/k_1 \gg 1 \qquad K_\beta = k_{-2}/k_2 \gg 1, \tag{6}$$

while k_1/k_2 is not extremely different from unity. This is actually the case with D-glucose.[5] A similar argument has also been advanced by Paldus and Koutecký.[7]

As will be demonstrated later in this study, however, the rate constants for D-xylose are not so large as Eq. (5) predicts. Accordingly, a modified equation has to be used in analyzing the polarograpnic current of D-xylose.

By a close investigation of the rigorous mathematical solution for the polarographic kinetic current reported by Koutecký and Brdička,[8] and by assuming the reaction layer given by Eq. (4), we may derive a modified equation of the polarographic current:

$$\bar{i}_l = \bar{i}_k + \bar{i}_{corr} \tag{7}$$

with:

$$\bar{i}_{corr} = \frac{\bar{i}_d}{K_\alpha+K_\beta} \times \frac{1-\exp(-\tau(k_{-1}+k_{-2}))}{\tau(k_{-1}+k_{-2})} \times \frac{1.13}{1.13+(\tau(k_{-1}+k_{-2}))^{1/2}} \tag{8}$$

and:

$$\bar{i}_d = \kappa(C_\alpha + C_\beta) \qquad \kappa\text{: Ilković constant,} \tag{9}$$

under the following conditions:

$$(\tau(k_{-1}+k_{-2}))^{1/2}/(K_\alpha + K_\beta) \ll 1 \tag{10}$$

and:

$$K_\alpha \gg 1, \qquad K_\beta \gg 1 \tag{11}$$

In these equations, $\bar{i}_k$ is defined by Eq. (3), $\bar{i}_{corr}$ is the correction term, and $\bar{i}_d$ is the diffusion current given by the Ilkovič equation, with the total bulk concentration of monosaccharide, being $C_\alpha + C_\beta$. Some details of the derivation of Eq. (7) are given in the Appendix.

As the mutarotation takes place in the bulk of the solution, the concentrations of α- and β-pyranose, C_α, and C_β, change with the time. For example, if we dissolve α-D-xylose in a solution at time $t=0$, C_α decreases with the time, whereas C_β increases with the time, in accordance with the following equation:[5]

$$C_\alpha = (C_\alpha)_{t\to\infty}(1 + K\exp(-k_o t)) \tag{12}$$

$$C_\beta = (C_\beta)_{t\to\infty}(1 - \exp(-k_o t)) \tag{13}$$

where:

$$k_o = (k_1 k_{-2} + k_{-1}k_2)/(k_{-1}+k_{-2}), \tag{14}$$

$$K = (C_\beta/C_\alpha)_{t\to\infty} = (C_\beta)_{t\to\infty}/(C_\alpha)_{t\to\infty} = K_\beta/K_\alpha, \tag{15}$$

and:

$$C_\alpha + C_\beta = C_{total} = (C_\alpha)_{t=0}, \tag{16}$$

where the concentration of the intermediate γ-form is assumed to be negligibly small. That is, the polarographic current, which is given by Eq. (7) or Eq. (3), changes with the time. The combination of Eqs. (12) to (16) with Eq. (7) to analyze the polarographic current, that was recorded as a function of the time, makes it possible to compute the four rate constants, k_1, k_{-2}, k_{-1}, and k_2, in Eq. (2).

Experimental

Materials. The α-D-xylose was recrystallized from an aqueous solution;[10] $[\alpha]_D^{25} = +96$, mp 146 °C, mutarotation rate const. $k_o = 1.30 \times 10^{-3}\ s^{-1}$ in water at 25±0.5 °C. All the other chemicals used were of a reagent grade. The solutions were prepared with bidistilled water. The buffer components were NaH_2PO_4–Na_2HPO_4, NH_3–NH_4Cl, Trys(hydroxymethyl)amino methane (TRIS), Tris(hydroxymethyl)methyl glycine (TRICINE), and N,N-bis(2-hydroxyethyl)glycine (BICINE). Potassium chloride was used to adjust the ionic strength to the desired values (usually 0.5).

Equipment. A Yanagimoto polaro-recorder type PA-103 was used for all the polarographic measurements. A Yanagimoto controlled-potential electrolyzer, type VE-3, was used for controlled-potential electrolysis, while the polarimetric measurements were carried out with a Yanagimoto polarimeter, type OR-20. The pH values were measured with a Hitachi Horiba M-5 pH meter.

An electrolysis cell (20 ml in capacity) was used; it was connected with a saturated calomel electrode (SCE) by means of an agar-gelatin bridge containing potassium chloride. All the experiments were carried out in a water thermostat controlled at 25±0.05 °C.

Method. A supporting electrolyte solution (15 ml) of the desired composition was freed of oxygen by passing a nitrogen stream through the solution. First, the residual current was recorded by means of the polarograph. Second, after the potential of the dropping mercury electrode has been set at −1.75 V *vs.* SCE, a weighed amount of α-D-xylose was dissolved in the deoxygenated electrolyte solution; the passing of the nitrogen stream through the solution was continued for about 30 seconds to complete the dissolution of the α-D-xylose. Then, the current intensity at −1.75 V *vs.* SCE was recorded as a function of the time. The recording of the current was continued until the current intensity reached a constant value. The nitrogen stream was passed over the solution during the measurement. Finally, after the mutarotation eqilibrium had been reached, a whole polarographic wave of the D-xylose was recorded. The current intensity was corrected for the residual current.

Results

General Polarographic Behavior of D-Xylose. The polarographic behavior of an equilibrated mixture of D-xylose was studied. At pH values lower than 9.5, no appreciable change in the polarogram of equilibrated solution of D-xylose was observed, at least not within two hours, at 25 °C. No appreciable change in specific rotation was observed, either. These results suggest that no hydrolysis, carbonyl amino reaction, or any complicated reaction of D-xylose occurs under the conditions used in the present experiment.

A few examples of the experimental results on the dependence of the limiting current, $\bar{i}_l$, on the height of the mercury reservior, h, are shown in Table 1. The limiting current was inclined to increase slightly with an increase in the height of the mercury reservior. An analysis of the current-time (i-t) curve for single drop has shown that the slope of the log i *vs.* log t plot is 1.8/3, which is slightly smaller than the theoretical value, 2/3, which is expected for a purely kinetic current defined by Eq. (3). These results support

Table 1. Dependence of the limiting current $\bar{i}_l$ on the height of mercury reservior h

9) Recently Nishihara and Matsuda have carried out more rigorous mathematical analysis of the problem by use of an electronic computer (Presented at 17th. Ann. Symp. Polarography, Fukuoka, Oct. 16—18, 1971). Preliminary examination showed that the errors resulted by use of Eqs. (7) to (9) did not exceed 8% for $(k\tau)^{1/2}<2$, under the condition (10) and (11).

10) K. Anno and N. Seno, "Jikken Kagaku Koza", Vol. 23, ed. by S. Akabori and S. Funahashi, (in Japanese) Maruzen, Tokyo, (1957), p. 336.

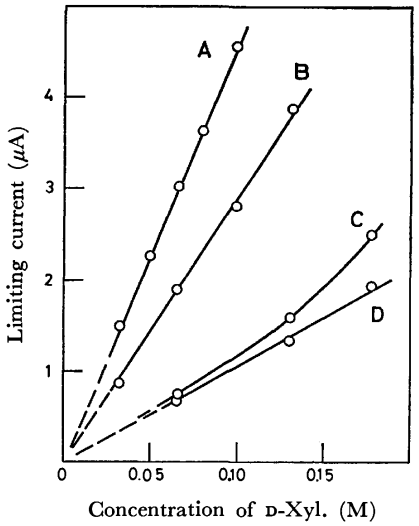

Fig. 1. Relationships between limiting current and the concentration of D-xylose. 25 °C, A: Ammonia buff. 0.100 M pH 8.79, B: TRIS buff. 0.020 M, pH 8.25, C: Phosphate buff. 0.005 M, pH 6.99, D: Phosphate buff. 0.070 M, pH 6.12.

the idea that the correction term, i_{corr}, in Eq. (7) should not be neglected in interpreting the kinetic current produced by D-xylose.

The limiting current is proportional to the D-xylose concentration in various supporting electrolyte solutions, as is shown by Curves A, B, and D in Fig. 1, but at a very low concentration of the buffer component a deviation from the linearity was observed, as is exemplified by Curve C in Fig. 1. Table 2 and Fig. 2 show the effects of the buffer concentration and the pH on the limiting current. In a basic solution, the limiting current increased exponentially with the pH. In an ammonia buffer solution with a pH of about 9, the limiting current decreased with a decrease in the concentration of the buffer component. On the contrary, in the phosphate buffer solution, the limiting current first decreased with a decrease in the concentration of the buffer component, but at a lower concentration (0.005 M) it began to increase and finally reached an unusually large value in an unbuffered solution. This last result might be explained by the autocatalytic effect of the hydroxy anion produced in company with the electro-reduction of D-xylose at the electrode surface. A simlar phenomenon has been reported by Brdička and his coworker[11-13] for the electro-reduction of formaldehyde at the dropping mercury electrode in an unbuffered solution.

A controlled potential electrolysis of D-xylose was carried out at the mercury-pool cathode in an ammonia buffer solution with a pH of 9.5. After about nine hours of electrolysis at −1.8 V *vs.* SCE, the kinetic wave of D-xylose disappeared almost completely (Fig. 3). During the electrolysis, the generation of

bubbles was observed on the mercury-cathode surface. This may be attributed to the evolution of hydrogen, which occurs parallel with the reduction of D-xylose. The electrolyzed solution was paper-chromatographed,[14] and the spot of D-xylitol was identified on the chromatogram. Provided that the number of electrons consumed per molecule of D-xylose is 2, calculation showed that about two thirds of the total electricity was consumed by the reduction of the D-xylose and one third, by the reduction of the hydrogen

ion, in the controlled-potential electrolysis on the mercury-pool electrode at −1.8 V.

Determination of Mutarotation Rate-Constants of α-D-Xylose. The composition and pH's of the buffer solution in which the mutarotation rate-constants were determined are summarized in Table 3. These conditions have been selected to avoid complexities arising from too high a basisity or too low a buffer concentration, as has been described above. Too high a concentration of buffer components resulted in an increase in the final ascending of the base current and made accurate measurement of the limiting current difficult.

The experimental results were analyzed by the use of the theoretical equations given above, and the individual rate constants, k_1, k_2, k_{-1}, and k_{-2}, were computed. In applying Eqs. (7), (8) and (4), a successive approximation method was employed. The computation was carried out by the use of an electronic computer, FACOM 230—60 (Kyoto University). The diffusion coefficient, D, was assumed to be 6.58×10^{-6} $cm^2\,s^{-1}$,[15] and the equilibrium constant, K (defined by Eq. (15)), to be 1.873.[2]

Examples of the four individual rate constants, k_1, k_2, k_{-1}, and k_{-2}, and the overall rate-constant, k_o, defined by Eqs. (2) and (14), are shown in Table 4. In general, the backword or ring-closing rate constants, k_{-1} and k_{-2}, could be determined with only a poor precision. Accordingly, a detailed analysis of the rate constants was made with the forward or ring-opening rate constants, k_1 and k_2, and the overall rate constant, k_o.

15) L. Friedman and P. G. Carpenter, *J. Amer. Chem. Soc.*, **61**, 1745 (1939).

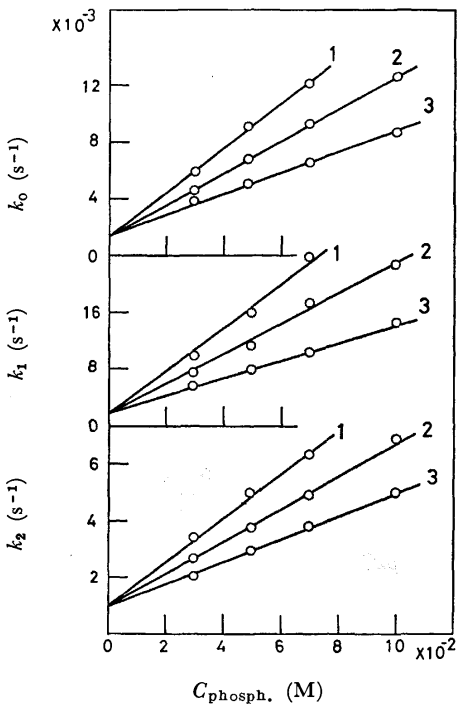

Fig. 4. The rate constants as a function of the concentration of phosphate buffer, $C_{phosph.}$ 25 °C, 1: pH 6.99, 2: pH 6.59, 3: pH 6.12.

At a constant pH, the rate constants, k_o, k_1, and k_2, increased linearly to the buffer concentration. Some representative results are shown in Fig. 4 and Fig. 5.

Generally, the rate constant of a catalyzed reaction can be expressed as follows:[3]

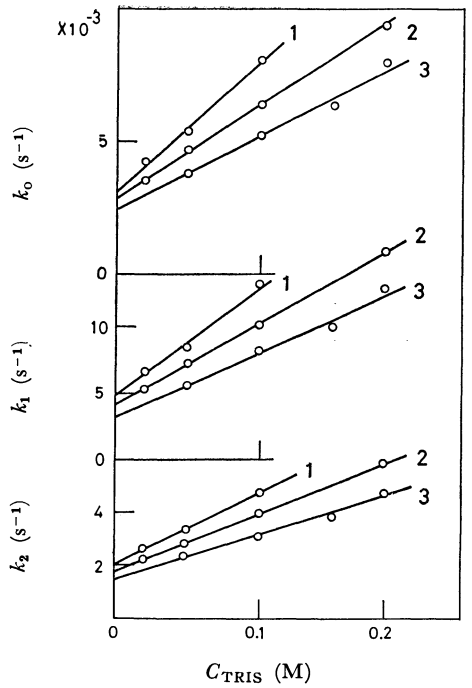

Fig. 5. The rate constants as a function of the concentration of TRIS buffer, C_{TRIS}. 25 °C, 1: pH 8.42, 2: pH 8.27, 3: pH 8.04.

$$k_i = k_{i,w} + k_{i,OH}(OH^-) + k_{i,A}(A) + k_{i,B}(B) \quad (17)$$
$$i=0,\ 1 \text{ and } 2$$

where $k_{i,w}$ represents the catalytic constant of the solvent molecule (water in our case), where $k_{i,OH}$, $k_{i,A}$, and $k_{i,B}$, represent the catalytic coefficients of the catalysts indicated by the subscripts, and where the symbols in brackets represent the concentrations (activities) of the catalysts, OH^-, A, and B, being the hydroxyl ion, acid, and the base of buffer components. In this expression, the concentration of the hydrogen ion is neglected because the measurements were made in neutral or basic solutions. The contribution of the D-xylose anion is also neglected. The significance of this approximation will be discussed later.

When the rate constant is plotted against the sum of the concentrations of the buffer components, $C_{buff}=(A)+(B)$, at a given pH, a straight line is obtained; the slope of this line is $(k_{i,A}M+k_{i,B})/(1+M)$, M being $(A)/(B)$, and the intercept on the k_i-axis is $k_{i,w}+k_{i,OH}(OH^-)$. A plot of this intercept against (OH^-) will give a straight line, from which $k_{i,OH}$ (slope) and $k_{i,w}$ (intercept) can be obtained. Fig. 4 shows a plot of k_i *vs.* C_{buff} for phosphate buffer solutions of pH 6.12, 6.59, and 6.99. Three straight lines with different slopes are obtained, but their intercepts on the k_i-axis coincide within the limits of experimental error. These results suggest that $k_{i,OH}(OH^-)$ is negligible in comparison with $k_{i,w}$ in such neutral solutions. Fig. 5 shows the same plot for the TRIS buffer; straight lines with different slopes and different intercepts on the k_i-axis are given for each solution at a given pH. Similar results were obtained for all the other basic buffers. The intercept values thus obtained from the k_i *vs.* C_{buff} curves are plotted against (OH^-) in Fig. 6. In accordance with theoretical

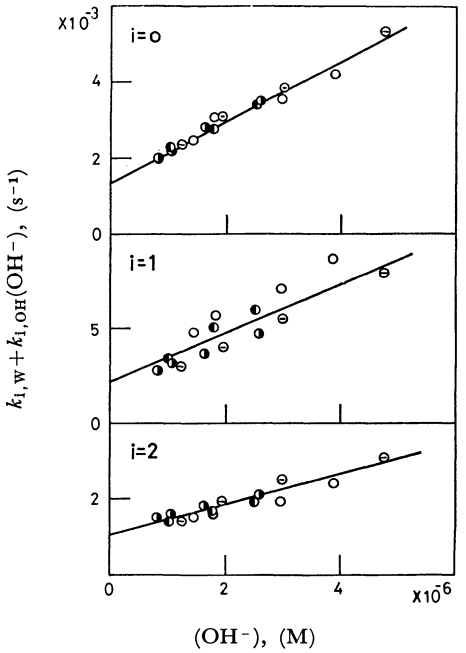

Fig. 6. The plot of $k_{i,w}-k_{i,OH}(OH^-)$ against the concentration of hydroxy ion, (OH^-).
○: NH_3, ◐: TRIS, ◑: TRICINE, ⊖: BICINE

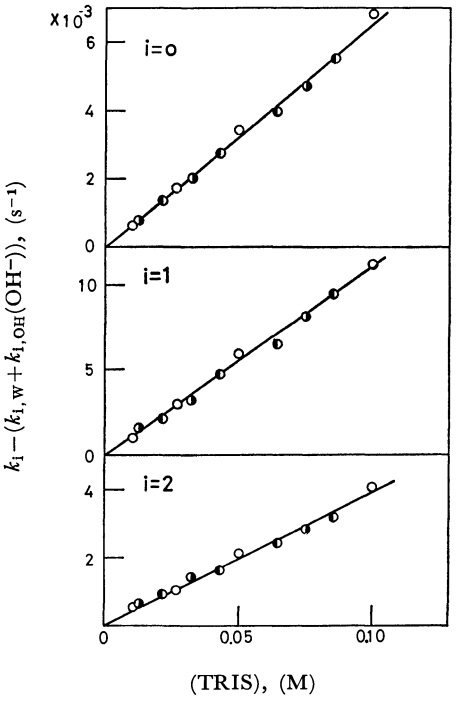

Fig. 7. The plot of $k_i-(k_{i,w}+k_{i,OH}(OH^-))$ against the concentration of the base conponent of TRIS buffer. (TRIS).
○: $M=1$, ◑: $M=4/6$, ◐: $M=6/4$.

considerations, all the data are distributed along the regression line, from which $k_{i,w}$ and $k_{i,OH}$ for overall as well as individual reaction rates are determined. The $k_{i,w}$ value obtained in this way is in good agreement with those obtained from the intercepts in Fig. 4 (*e. g.* $k_{o,w}=1.3\times10^{-3}$ s^{-1} from Fig. 6 and $k_{o,w}=1.4\times10^{-3}$ s^{-1} from Fig. 4).

Figure 7 shows a plot of $k_i-(k_{i,w}+k_{i,OH}(OH^-))$ against (B) for the TRIS buffer. A straight line with

a slope of $k_{i,B}+M\times K_{i,A}$ can be expected from each for a given M. As may be seen from the figure, however, all the points lie on a single straight line, irrespective of the M values. This suggests that $k_{i,B}\gg M\times k_{i,A}$ *i. e.*, that $k_{i,A}$ is negligibly small compared with $k_{i,B}$ for the buffer components examined. Similar results were obtained for all the other basic buffers examined.

Discussion

The values of the catalytic rate coefficients are summarized in Table 5. The coefficients, $k_{i,B}$'s, for B=TRIS, TRICINE, and BICINE are those for the base components of the amine buffers. The water molecule is both an acid and a base, but for the mutarotation of D-glucose in a neutral solution, the basic catalytic function is supposed to predominate over the acid one.[3] For the mutarotation of D-xylose, the same argument is justified on the basis of the Brönsted plot (Fig. 8). The HPO_4^{2-} and $H_2PO_4^-$ ions are also bifunctional, but in a neutral buffer solution the former ion functions as a base, and the latter, as an acid. Accordingly, their catalytic activities, as observed in a neutral solution, should in the first place be basic for HPO_4^{2-} and acidic for $H_2PO_4^-$. It may be seen in Table 5 that, except for the rate coefficients for $H_2PO_4^-$, the rate coefficients, $k_{i,B}$, for the $\alpha\rightarrow\gamma$ reaction are always larger than the $k_{2,B}$ for $\beta\rightarrow\gamma$, where B is a base catalyst. In Fig. 8, log $k_{i,B}$ and log $k_{2,B}$ are plotted against the pK_A value of the base catalyst, B. The rate coefficients for the water molecule, assumed to be a base catalyst, were calculated by means of $k_{i,w}/55.6$ M and plotted against pK_A= $-\log 55.6$.[3] The rate coefficients for H_2O, HPO_4^{2-}, NH_3 and OH^- are on a straight line with a slope of 0.42. The value of this slope seems reasonable in view of the value, 0.40 or 0.34, observed for the overall mutarotation rate constants of D-glucose.[3] The rate coefficients for the base components of TRIS, TRICINE, and BICINE are smaller than the theoretical values expected from the Brönsted plot and their pK's, and become smaller with an increase in their molecular size. These results should be attributed to the steric hindrance effect in the catalytic mutarotation reaction.[16,17] Smith[18] and Los and Simpson[19,20] have pointed out that the catalytic effect caused by sugar anion can generally not be neglected. According to these authors, the rate coefficient for (OH^-) in Eq. (17) should be rewritten as:

$$k_{i,OH} = k'_{i,OH} + k_{i,xyl}(xyl)K_{xyl}/K_w$$

where k'_{OH} and $k_{i,xyl}$ are the true rate coefficients for OH^- and the xylosate anion respectively, where (xyl) is the concentration of D-xylose where $K_{xyl}(=10^{-12.3})$[21] is the dissosiation constant of the Xylose⇌Xylosate Anion+H^+ reaction, and where K_w is the ionic product of water. Appling the Brönsted rule (Fig. 8) to D-xylose, we obtain $k_{i,xyl}\sim 30$ s^{-1} l/mol. In our experiments, (xyl) was 0.06 M, so that $k_{i,xyl}$ (xyl) $K_{xyl}/K_w\sim$ 90 s^{-1} l/mol, which is approximately 8% or less of $k_{i,OH}$. Accordingly, the effect by the xylosate anion may be considered to be of secondary significance in our case. In reality, no appreciable experimental indication was given of the significant contribution of the xylosate anion to catalysis, such as a nonlinear dependence of the polarographic current on (xyl).

The equilibrium constants of the γ-form to the α- and β-pyranose forms, $K_\alpha+K_\beta$, are given in Table 4. These values were found to change slightly with the change in the buffer concentration; for example, $K_\alpha+K_\beta$ for the TRIS buffer changed 4.5×10^2 to 2.5×10^2 with the change in the buffer concentration from 0.20 to 0.02 M, while $K_\alpha+K_\beta$ for the phosphate buffer changed from 4.2×10^3 to 2.1×10^3 with the change in the buffer concentration from 0.10 to 0.03 M. A similar downward trend of $K_\alpha+K_\beta$ with a decrease in the buffer concentration was also reported by previous authors.[5] The relatively large difference between the $K_\alpha+K_\beta$ values obtained from the phosphate buffer and the amine buffers should also be noted. These results suggest a further complicated structure of the intermediate form in the reaction mechanism of the mutarotation of monosaccharide. Further studies on the mechanism of mutarotation for monosaccharide are now in progress in this laboratory and will be

presented in another paper.[22]

This research was aided in part by a Scientific Reserch Grant from the Ministry of Education, to which the authors' thanks are due.

Appendix

The expression for the instantaneous limiting current, $i(t)$, of an electrode reaction with a preceding chemical reaction;

$$\underset{\text{(chem)}}{A} \underset{k_b}{\overset{k_f}{\rightleftharpoons}} \underset{\text{(el.)}}{Ox} \xrightarrow{ne} Red, \qquad (1')$$

at a stantionary plane electrode has been given by:[8]

$$\frac{i(t)}{nFq} = \frac{D^{1/2}C^*}{\pi^{1/2}(K^2-1)}\left[\frac{K\exp(-lt)-1}{t^{1/2}} + \frac{K^2(\pi k_f)^{1/2}}{(K-1)^{1/2}} \times \exp\left(\frac{k_f t}{K-1}\right)\left\{\operatorname{erf}\left(K\left(\frac{k_f t}{K-1}\right)^{1/2}\right) - \operatorname{erf}\left(\left(\frac{k_f t}{K-1}\right)^{1/2}\right)\right\}\right], \qquad (2')$$

where n indicates the number of electrons involved in the electrode reaction; q, the electrode surface area; D, the diffusion coefficient of the depolarizer; C^*, the sum of the concentrations of A and Ox; $K=k_b/k_f$, and $l=k_f+k_b$.

When $K \gg 1$ and when lt is in the order of unity or less, so that $(k_f t/K)^{1/2} \simeq (lt)^{1/2}/K$, $K\exp(-lt) \gg 1$, $\operatorname{erfc}((lt)^{1/2}/K) \simeq 1$, and $\exp(lt/K^2) \simeq 1$, Eq. (2') may be reduced in a good approximation to:

$$\frac{i(t)}{nFq} = \frac{D^{1/2}C^* l^{1/2}}{K} + \frac{D^{1/2}C^*}{K(\pi t)^{1/2}} \times \exp(-lt) \times \{1-(\pi lt)^{1/2}\exp(lt)\operatorname{erfc}((lt)^{1/2})\} \qquad (3')$$

Accordingly, the mean limiting current, $\bar{i}_l$, at the dropping mercury electrode is given by:

$$\bar{i}_l = \frac{1}{\tau}\int_0^\tau nFq\frac{D^{1/2}C^* l^{1/2}}{K}dt + \frac{1}{\tau}\int_0^\tau nFq\frac{D^{1/2}C^*}{K(\pi t)^{1/2}} \times \exp(-lt)\{1-(\pi lt)^{1/2}\exp(lt)\operatorname{erfc}((lt)^{1/2})\}dt \qquad (4')$$

22) In course of preparation.

The second term on the right-hand side of Eq. (4') could be given in the first approximation for a smaller value of $l\tau$ by:

$$g_2(\tau) = \frac{1-\exp(-l\tau)}{l\tau}\left[\frac{1}{\tau}\int_0^\tau nFq\frac{D^{1/2}C^*}{K(\pi t)^{1/2}}dt - \frac{1}{\tau}\int_0^\tau nFq\frac{D^{1/2}C^*}{K}l^{1/2}\exp(lt)\operatorname{erfc}((lt)^{1/2})dt\right] \qquad (5')$$

Furthermore, according to Matsuda[23] or Koutecký,[24] the second term in the brackets on the right-hand side of Eq. (5') should be replaced by $(\bar{i}_d/K)/(1+1.13(l\tau)^{-1/2})$ for the case of the dropping mercury electrode. In conclusion, the mean limiting current, $\bar{i}_l$, at the dropping mercury electrode may be given by:

$$\bar{i}_l = 0.81\frac{(l\tau)^{1/2}}{K}\bar{i}_d + \frac{\bar{i}_d}{K} \times \frac{1-\exp(-l\tau)}{l\tau} \times \left(1-\frac{1}{1+1.13(l\tau)^{-1/2}}\right) \qquad (6')$$

where $\bar{i}_d$ is the diffusion current given by the Ilkovič equation with the total bulk concentration, C^*.

If we proceed with the reaction scheme (2), $K_\alpha+K_\beta$ and $k_{-1}+k_{-2}$ should be substituted for K and l respectively.[6] we thus obtain Eq. (7'):

$$\bar{i}_l = 0.81\frac{(\tau(k_{-1}+k_{-2}))^{1/2}}{K_\alpha+K_\beta}\bar{i}_d + \frac{\bar{i}_d}{K_\alpha+K_\beta} \times \frac{1-\exp(-\tau(k_{-1}+k_{-2}))}{\tau(k_{-1}+k_{-2})} \times \left(1-\frac{1}{1+1.13(\tau(k_{-1}+k_{-2}))^{-1/2}}\right) \qquad (7')$$

The first term on the right-hand side of Eq. (7') corresponds to $\bar{i}_k$ in Eq. (7), and the second term, to $\bar{i}_{corr}$. It can easily be seen that $\bar{i}_l$ is reduced to $\bar{i}_k$ when $(k_{-1}+k_{-2}) \gg 1$, whereas $\bar{i}_l$ is reduced to $\bar{i}_d/(K_\alpha+K_\beta)$ when $\tau(k_{-1}+k_{-2})$ becomes zero.[9]

Ultrasonic Absorption in Aqueous Solutions of Octylamine. Kinetic Investigation of Proton Transfer Reaction

Sadakatsu NISHIKAWA, Tatsuya YASUNAGA, and Nobuhide TATSUMOTO

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received December 7, 1972)

The ultrasonic absorption in the mesomorphic state of octylamine water system was characterized by double relaxations. One in the lower frequency range has been explained by the structural relaxation theory of the two state model. In order to clarify the mechanism of the relaxation in the higher frequency range, the ultrasonic absorption in a relatively dilute aqueous solution was measured. The mechanism of the absorption was attributed to hydrolysis from the concentration dependence of the relaxation time. The rate constant k_f for the proton transfer reaction, the equilibrium constant $K=k_b/k_f$, and the standard volume change ΔV resulting from the reaction were determined to be 1.0×10^{10} M^{-1} sec^{-1}, 7.6×10^{-3} M, and 32 cc mol^{-1} respectively.

A large amount of data has been accumulated on the equilibrium properties of aqueous solutions of amines. However, the knowledge of their dynamic properties in the solutions is limited. An ultrasonic absorption method has provided the very useful informations on dynamic properties in the liquid phase. In recent years, the ultrasonic absorptions in aqueous solutions of various amines have been measured and some mechanism associated with the excess absorptions have been proposed.[1-10]

The ultrasonic absorption in the mesomorphic state of octylamine water system is characterized by double relaxations. One in the lower frequency range was explained by the structural relaxation theory of the two state model. The explanation of the other in the higher frequency range remains unclarified.

The purpose of the present investigation is to report the results of the ultrasonic absorption measurement in the relatively dilute aqueous solutions of octylamine, to elucidate the mechanism and to clarify the relation between the excess absorption in the higher frequency range in the mesomorphic state and that in the relatively dilute solutions of octylamine.

In addition, an octylamine water system is one of lyotropic liquid crystals related very closely to biological systems.[11] Clarification of its dynamic properties, therefore, is of interest for understanding the biochemical reactions.

Experimental

The octylamine was of guaranteed grade and purified by distillation. The purity was verified to be higher than 99.9% by the gas chromatography. Deionized and distilled water was used as a solvent. Measurements of ultrasonic absorptions were carried out at odd harmonic frequencies of 0.5, 5, and 20 MHz X-cut quartz transducers by the pulse technique.[12] The frequency range was 2.5—220 MHz. The ultrasonic absorption measurement cell was air-tight and dry nitrogen gas was passed over the solution. The sing-around method was employed at 1.92 MHz to measure the sound velocity. Two kinds of picnometers were used for the measurement of density. The pH values of the solutions were measured by a Hitachi-Horiba Type F-5 pH meter. The temperature range of the ultrasonic absorption measurement was 12—36 °C and the concentration range 0.501—4.76 M.

Results

In general, the sound absorption caused by several relaxation processes is given by

$$\alpha/f^2 = \sum_j \frac{A_j}{1+(f/f_{rj})^2} + B \qquad (1)$$

where f_{rj} is the relaxation frequency for the jth process and A_j and B are constants.

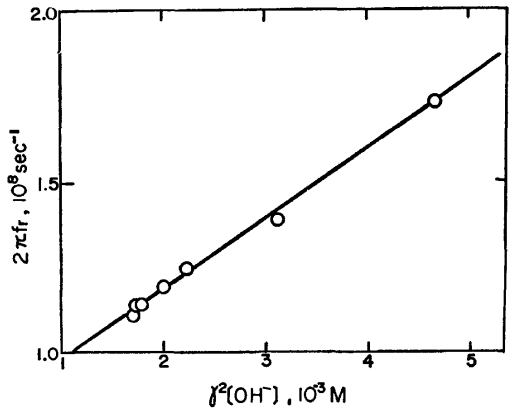

Fig. 3. The plots of $2\pi f_r$ *vs.* concentration at 20 °C. The straight line is a least-squares fit of the experimental points.

M (0.15 mol fraction of octylamine) at various temperatures are shown in Fig. 1. These spectra except one at 36 °C are characterized by double relaxations which correspond to the case of $j=1, 2$ in Eq. (1). The spectrum at 36 °C is described by the single relaxation equation which is the case $j=1$ in Eq. (1). The mesomorphic state of the octylamine water system is transformed to the isotropic one by heating. Since the transition temperature from mesomorphic to isotropic state is 35 °C at 3.79 M, the spectrum at 36 °C is that in the isotropic state. The excess absorption in the lower frequency range decreases abruptly as soon as the phase changes into the isotropic state, but that in the higher frequency range remains even in the isotropic state. The ultrasonic absorption spectra at various concentrations at 20 °C are shown in Fig. 2. The dashed lines are the spectra in the mesomorphic state, characterized by double relaxations. The solid lines are those for the relatively dilute solutions in the isotropic state, characterized by single relaxation. The values of relaxation frequency f_{rj} and constants A_j and B were determined so as to obtain the best fit of the data to Eq. (1). The values are listed in Table 1 together with the observed values of the sound velocity and density.

If the mechanism of the excess absorption in the relatively dilute solutions is attributed to the perturbation of the equilibrium[1-6]

$$R\text{-}NH_3^+ + OH^- \underset{k_b}{\overset{k_f}{\rightleftharpoons}} R\text{-}NH_2 + H_2O \qquad (2)$$

where k_f and k_b are forward and backward rate constants respectively, the relation between the relaxation frequency and the rate constants is given by

$$1/\tau = 2\pi f_r = k_f([R\text{-}NH_3^+]+[OH^-])\Pi\gamma_i + k_b \qquad (3)$$

where τ is relaxation time and γ_i an activity coefficient of species i. If the activity coefficient and concentration of $R\text{-}NH_3^+$ ion are equal to those of OH^- ion respectively at each concentration, Eq. (3) can be written as

$$1/\tau = 2\pi f_r = 2k_f\gamma^2[OH^-] + k_b \qquad (4)$$

where γ is the mean activity coefficient. The activity coefficients were calculated by the Davies equation[13]

$$-\log\gamma = 0.5\left[\frac{\sqrt{I}}{1+\sqrt{I}} - 0.3I\right] \qquad (5)$$

where I is the ionic strength. Figure 3 shows the plots of $2\pi f_r$ *vs.* $\gamma^2[OH^-]$. The forward and backward rate constants were determined from the slope and inter-

$(C_3H_7)NH_3^+ + OH^- \rightleftarrows (C_3H_7)NH_2 + H_2O$	3.0×10^{10}	1.2×10^{7}	4.0×10^{-4}	24.0	(2)
$(C_4H_9)NH_3^+ + OH^- \rightleftarrows (C_4H_9)NH_2 + H_2O$	4.1×10^{10}	1.1×10^{8}	2.5×10^{-3}	32	(6)
$(C_8H_{17})NH_3^+ + OH^- \rightleftarrows (C_8H_{17})NH_2 + H_2O$	1.0×10^{10}	7.6×10^{7}	7.6×10^{-3}	32	this work

cept, respectively, by the least-mean-squares method. The standard volume change ΔV resulting from the reaction could be determined as follows. The excess absorption per wavelength shows a maximum at a frequency $f=f_r$ and is given by

$$(\alpha\lambda)_{max} = \frac{1}{2}Af_r c \tag{6}$$

where $(\alpha\lambda)_{max}$ is the maximum excess absorption per wavelength and c the velocity of sound. For a chemical process of the type represented by Eq. (2), the maximum excess absorption per wavelength is given by

$$(\alpha\lambda)_{max} = \frac{1}{2}\pi\rho c^2V^2RT\Gamma_c\left\{\left(\frac{\beta\Delta H}{C_pRT}\right)-\left(\frac{\Delta V}{VRT}\right)\right\}^2 \tag{7}$$

$$\Gamma_c = \left(\frac{1}{[OH^-]}+\frac{1}{[R\text{-}NH_3^+]}+\frac{1}{[R\text{-}NH_2]}\right)^{-1} \tag{8}$$

where ρ is density, V the molar volume, R the gas constant, β the thermal expansion coefficient, C_p the specific heat at constant pressure, and T the absolute temperature. In the case of a relatively dilute solution of amine, the first term in the bracket of Eq. (7) is negligibly small compared with the second term. The standard volume change resulting from the hydrolysis of octylamine was calculated by means of Eqs. (6) and (7). The values of rate constants, equilibrium constant, and standard volume change are listed in Table 2 together with those for other monoamines.

Since the aqueous solution of octylamine is separated into two phases below 0.5 M at 20 °C, measurements were impossible below 0.5 M.

Discussion

The excess absorption mechanism in the mesomorphic state in the higher frequency range can not be interpreted quantitatively since the ionic concentration in that state is not determined accurately. However, excess absorption is observed even in the isotropic state as is seen in Fig. 1 and the relaxation frequencies seem to increase continuously with concentration as is seen in Fig. 2. The mechanism of the excess absorption in the mesomorphic state is therefore regarded to be identical with that in the relatively dilute solution. The linearity of the plots of $2\pi f_r$ *vs.* $\gamma^2[OH^-]$ in Fig. 3 indicates that the cause of the excess absorption is attributed to the perturbation of the equilibrium given by Eq. (2). The value of the rate constant k_f obtained is pertinent to the proton transfer reaction, since it is, in general, of the order 10^{10}—10^{11} M^{-1} s^{-1}. However, the equilibrium constant determined by the

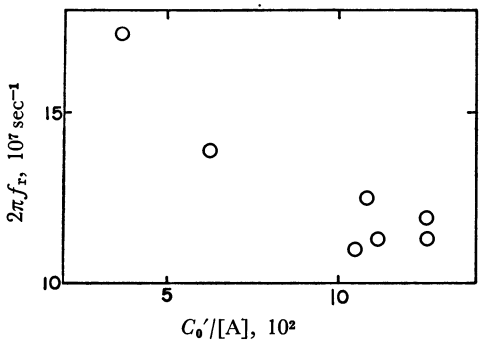

Fig. 4. The plots of $2\pi f_r$ *vs.* C_0'/[A] at 20 °C.

relation $K=k_b/k_f$ does not agree with the value reported 4.5×10^{-4} M at 25 °C[14] which was obtained in various dilutions of alcohol such as to permit satisfactory extrapolation to pure water in a concentration less than 0.016 M because of the limited solubility of octylamine in water. Since our investigation was carried out in concentrations higher than 0.5 M, a comparison of the results may not be suitable.

The process of hydrolysis of amine[3] is not so simple as that expressed by Eq. (2). It proceeds through a complex formation by hydrogen bonding as follows

$$R\text{-}NH_3^+ + OH^- \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} R\text{-}NH_3^+\cdots$$

$$OH^- \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} R\text{-}NH_2 + H_2O \tag{9}$$

Under the conditions[3] of $k_{23}\gg k_{21}$, the rate constants in Eq. (2) are expressed as follows

$$k_f = k_{12}, \quad k_b = k_{21}\frac{k_{32}}{k_{23}} \tag{10}$$

Consequently, the collision frequency of reaction partners, $R\text{-}NH_3^+$ and OH^- ions, might affect the magnitude of the rate constant k_f. The octylamine molecule consists of a long hydrophobic chain and a small hydrophilic group, *viz.*, the reaction site might be so small compared with the size of the molecule. Therefore, the effective collision frequency for the reaction might decrease. As is seen in Table 2, the rate constant k_f for octylamine is small compared with those for other monoamines.[2,3]

The excess absorption mechanism attributed to the perturbation of the equilibrium expressed as $nA \underset{k_2}{\overset{k_1}{\rightleftharpoons}} A_n$

14) C. W. Hoerr, M. R. McCorkle, and A. W. Rals, *J. Amer. Chem. Soc.*, **65**, 328 (1943).

by McKellar and Andreae[7] should be reconsidered. The relation between relaxation time and concentration for this mechanism is derived as follows.

$$1/\tau = 2\pi f_r = -k_2(n-1) + nk_2C_0'/[A] \quad (11)$$

where n is the aggregation number, [A] the concentration of monomer, k_2 the rate constant and $C_0' = [A]+n[A_n]$. If the cause of the excess absorption were attributed to the association-dissociation reaction, the plots of $2\pi f_r$ *vs.* $C_0'/[A]$ should be a straight line with a positive slope and a negative intercept according to Eq. (11). However, the results do not obey Eq. (11), *viz.*, the plots of $2\pi f_r$ *vs.* $C_0'/[A]$ seems to have a negative slope and positive intercept as is shown in Fig. 4. The mechanism due to the aggregation reaction might, therefore, be ruled out as that of the excess absorption.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1660—1663 (1973)

Dielectric Behavior of the Packing Bed of Alumina Granules with Adsorbed Water

Kaoru UMEYA and Takashi KANNO

Department of Chemical Engineering, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Sendai 980

(Received December 16, 1971)

Dielectric behavior of the packing bed of alumina granules with various amounts of adsorbed water were determined in the frequency range 30 Hz—3 MHz. The dielectric relaxations characterized by a distribution in relaxation time were attributed to interfacial polarizations due to the adsorbed ions accumulated around the non-conductive points (*i.e.*, discontinuous points on conducting paths consisting of water films adsorbed on alumina granules). Some of the adsorbed ions were carried away to the electrodes through the points of contact between the water films adsorbed on granules adjacent to each other (*i.e.*, continuous conducting paths), giving rise to d.c. conductance and electrode polarization. When insulating sheets were inserted between the electrodes and surfaces of the packing bed, both the d.c. conductance and electrode polarization disappeared and another dielectric relaxation was observed. This was attributed to the interfacial polarization due to the ions accumulated at the interfaces between insulating sheets and water adsorbed on alumina granules.

Dielectric studies of water adsorbed on inorganic oxides have been made.[1,2] In order to study the mechanism of adsorption of water vapor and the nature of the adsorbed water, dielectric isotherms have frequently been determined for several frequencies.[3,4] With increasing amounts of adsorbate, contribution of adsorbed ions becomes significant and dielectric relaxations due to the interfacial polarizations are observed if measurements are made over a wide frequency range.[5-7] However, their mechanism has not been discussed in detail.

In the present study we discuss the mechanism of dielectric relaxations observed for the packing bed of alumina granules with adsorbed water. Since such a system is an assembly of individual granules, the dielectric properties as well as electrical conductance are affected by packing conditions of alumina granules. The results also change with the conditions of the contact of the specimen with electrode, since electrical conduction can be prevented if the contact is incomplete. For the sake of confirmation measurements were also made on a system in which electrical conduction was prevented by inserting polyethylene sheets (0.07 mm in thickness) between the electrodes and surfaces of the packing bed. The dependence of dielectric properties upon particle size was also studied.

Experimental

Alumina granules, spherical particles of porous alumina granules containing 10% silica "Neobead D" supplied from Mizusawa Chemical Engineering Co., Ltd. were used. Their specific surface area is 300 m^2/g. True density and packing density are 3.10 and 0.5—0.6 g/cm^3, respectively. Granules of two different particle size, *i.e.*, about 0.3 mm and 1.0 mm in diameter, were used.

A Type TR-1B Transformer Bridge from Ando Electric Company was employed for measurements of capacitance and conductance over the frequency range 30 Hz—3 MHz.

Results and Discussion

Dielectric Constant and Dielectric Loss. Dielectric constant ε' and dielectric loss ε'' measured on the packing bed of alumina granules with adsorbed water are plotted against frequency in Fig. 1, and compared with those of the specimen with insulating sheets inserted between the electrodes and surfaces of the packing bed. The dielectric loss of the specimen without insulators was obtained by subtracting the d.c. conductance.

In the lower frequency range the dielectric constant

○: measured with insulating sheets.
●: measured without insulating sheets.

of the specimen with no insulating sheets increased rapidly with decreasing frequency. This can be attributed to the electrode polarization which arises from the electrolytic polarization of ions on electrode surfaces. In the same frequency range the dielectric constant of the specimen with insulating sheets had a tendency to reach a plateau with decreasing frequency accompanied by a distinct peak in the dielectric loss curve. This can be attributed to the dielectric relaxation due to the interfacial polarization which arises from the ions accumulated at the interfaces between insulating sheets and water adsorbed on alumina granules.

In a higher frequency range the dielectric constants of both specimens decreased gradually with increasing frequency. The dielectric dispersion can be attributed to the interfacial polarizations which arise from the adsorbed ions within the packing bed of alumina granules. A well-defined peak in the dielectric loss curve was observed for the specimen without insulating sheets, whereas in the case of that with insulators no distinct peak was found. It can be seen, however, that the dielectric loss curve of the specimen with insulating sheets almost coincides with that of the specimen without insulators in frequency range above 100 kHz.

Complex Plane Plots of ε' and ε''. The complex plane plots of ε' and ε'' measured on the specimen without insulators gave a circular-arc as shown in Fig. 2. Thus the complex dielectric constant of the packing bed of alumina granules with adsorbed water is represented approximately by the following equation:[8,9]

$$\varepsilon^* = \varepsilon_h + \frac{\varepsilon_l - \varepsilon_h}{1+(i\omega\tau)^\beta} + \frac{\kappa_1}{i\omega\varepsilon_v} \qquad (1)$$

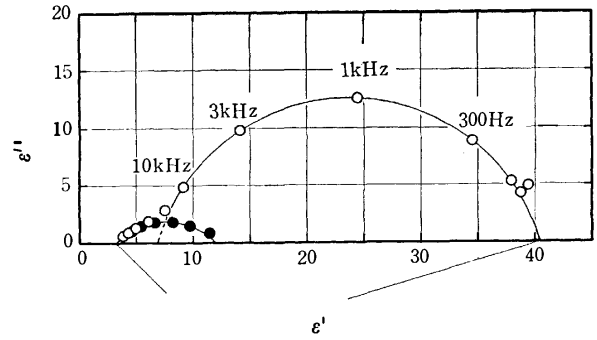

Fig. 2. Complex plane plots of ε' and ε''. Amount of water adsorbed: 200 mg/g. Particle diameter: 0.3 mm.
○: measured with insulating sheets.
●: measured without insulating sheets.

where ε_h and ε_l are the limiting dielectric constants at high and low frequencies, respectively; κ_1 is the limiting conductivity at low frequency (*i.e.*, d.c. conductivity) subtracted in calculating the dielectric loss; $\omega(=2\pi f)$ measuring angular frequency, $\tau(=1/2\pi f_0)$ mean relaxation time, f and f_0 measuring frequency and relaxation frequency for which the dielectric loss is a maximum, respectively; β parameter for the distribution of relaxation times, and $\varepsilon_v=8.8541\times10^{-14}$ F/cm and $i=\sqrt{-1}$.

In the case of the specimen with insulating sheets a large circular-arc corresponding to the relaxation in low frequencies was observed. Several plots in the high frequency range deviate from the ciruclar-arc and lie on that of the specimen without insulators. The tail appearing on the circular-arc reveals the presence of another dielectric relaxation in the high frequency range, which seems to be the same relaxation as that of the specimen without insulators. The complex dielectric constant of the specimen with insulating sheets, therefore, can be expressed by the following equation:

$$\varepsilon^* = \varepsilon_h + \frac{\varepsilon_l - \varepsilon_h}{1+(i\omega\tau_1)^\beta} + \frac{\varepsilon_l - \varepsilon_i}{1+(i\omega\tau_2)^\alpha} \qquad (2)$$

where ε_h, ε_l and ε_i denote the values of limiting dielectric constants at high and low frequencies and at an intermediate plateau, respectively; τ_1 and τ_2 are the mean relaxation times of polarizations at high and low frequencies, respectively; β and α are parameters for the distribution of relaxation time of individual polarization.

Since the relaxations in high and low frequencies overlapped partially, no distinct corresponding circular-arcs were observed. The circular-arc in low frequencies (Fig. 2) might not represent the one corresponding to the relaxation in low frequencies precisely, but involves a part of relaxation in high frequencies.

The dielectric relaxations overlapping each other were separated into two individual ones. The circular-arc corresponding to the relaxation at high frequencies was first drawn with respect to that of the specimen without insulators (broken line, Fig. 3). From this the numerical values of the first and second terms of the right side in Eq. (2) were determined. The dielectric constants and dielectric losses calculated by

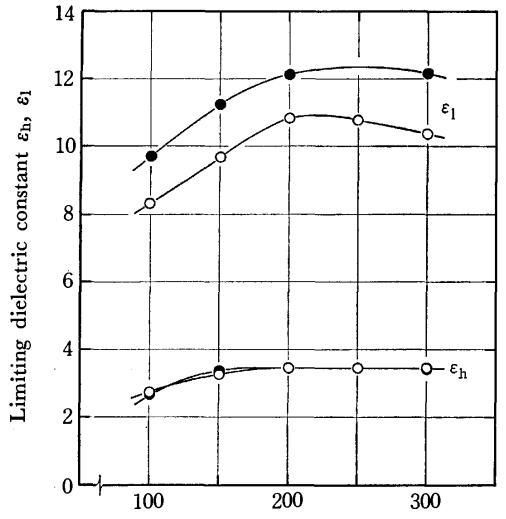

Fig. 4. Limiting dielectric constants ε_h, ε_l as a function of amount of adsorbed water. Particle diameter: 1.0(○), 0.3(●) mm.

use of this equation are plotted with open circles.

The dielectric constants of the relaxation in low frequencies can be obtained by adding the values equal to the dielectric decrements due to relaxation in high frequencies to those observed. The dielectric loss of relaxation in low frequencies can also be obtained by subtracting the values due to relaxation in high frequencies from those observed. The complex plane plots obtained by use of these values are shown by a broken line with full circles. These procedures can also be expressed in vector form (Fig. 3).

A similar behavior to that mentioned above was observed in different amounts of adsorbed water for both the specimens with and without insulating sheets.

For the specimen without insulators, dielectric measurements were also carried out on granules of about 1.0 mm in diameter. The experimental values of the parameters in Eq. (1) will be discussed in detail.

Limiting Dielectric Constants: The limiting dielectric constants at high and low frequencies ε_h and ε_l, respectively, are plotted against the amounts of adsorbed water in Fig. 4. The values of ε_h and ε_l increased first with increasing amount of adsorbed water, but for higher water content, the value of ε_l decreased with the increase of the amount of adsorbed water, and that of ε_h remained almost constant.

Murphy and Lowry proposed a mechanism of dielectric polarization for "Interstitial Conducting Systems."[10] The electrical conduction of moistened dielectrics takes place through interstitial conducting paths of water film containing ions in a certain concentration. The ions near the surface are adsorbed so strongly that they cannot be detached under the effect of an external field but can be displaced along the surface, giving rise to polarization.

Miles and Robertson,[11] and Schwarz[12] extended the Wagner theory[13] to a dispersed system of spherical particles with electrical double layer.

However, these theories cannot interpret the decrease of the values of ε_l observed in a large amount of adsorbed water. The dielectric relaxations observed in this study might be attributed to the interfacial polarization which arises from the ions accumulated around the non-conductive gaps between water films adsorbed on the granules adjacent to each other, *i.e.*, discontinuous points on conducting paths. At a higher water content these gaps are bridged with water films and the ions accumulated may be carried away to the electrode through the points of contact, giving rise to d.c. conductance and electrode polarization. Thus in higher water contents the values of ε_l decrease with increasing amount of adsorbed water.

The values of ε_l also change with particle size as shown in Fig. 4. This may be interpreted by the difference in number of non-conductive points. The packing bed of small granules may be expected to have a large number of non-conductive points, resulting in an increase in the value of ε_l.

The values of ε_h corresponding to polarization due to the ions strongly adsorbed were not affected by particle size. This is understandable since the specific surface area of the granules do not change with the difference in particle size as they have a porous structure.

Mean Relaxation Frequency: The mean relaxation frequency f_0 is plotted in Fig. 5 as a function of the

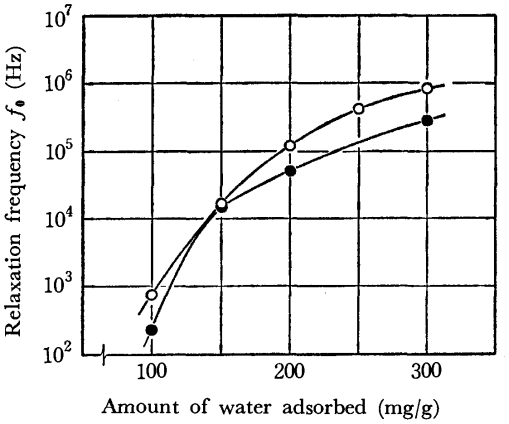

Fig. 5. Mean relaxation frequency f_0 as a function of amount of adsorbed water. Paticle diameter: 1.0(○), 0.3(●) mm.

13) K. W. Wagner, *Arch. Elektrotech.*, **2**, 371 (1914).

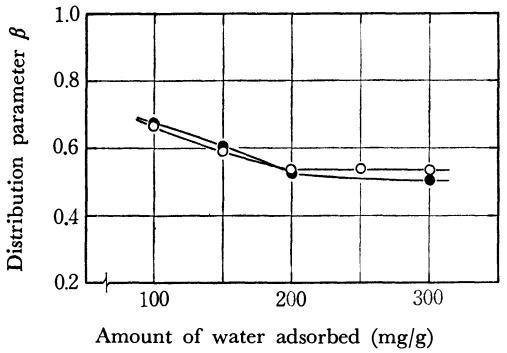

Fig. 6. Distribution parameter β as a function of amount of adsorbed water. Particle diameter: 1.0(○), 0.3(●) mm.

amount of water adsorbed. The increase in the value of f_0 with increasing adsorbate can be attributed to the formation of weakly adsorbed layers. The decrease in the rate of increase of f_0 in a higher water content can be attributed to the saturation or decrease in the polarization described above.

The mean relaxation frequency increases with the increase of particle size. This can be interpreted in terms of the difference in geometrical surface area as well as the difference in number of non-conductive points. As the particle size increases geometrical surface area decreases, and the effect of surface becomes smaller for the same water content.

Distribution Parameter: The distribution parameter β is plotted in Fig. 6 as a function of the amount of adsorbate. Decrease in the value of β at low water content can be interpreted in terms of the increase in polarization with a small relaxation time. For water content above 200 mg/g the value of β remained almost constant irrespective of the amount of adsorbate. This is attributed to the saturation or decrease in polarization. The value of β was not affected by particle size (Fig. 6).

Table 1. Values of ε_h, ε_l, ε_l, f_{01}, f_{02}, β and α in various amounts of water adsorbed on alumina

Amount adsorbed (mg/g)	ε_h	ε_l	ε_l	f_{01} (kHz)	f_{02} (kHz)	β	α
100	2.9	10.1	—	0.56	—	0.733	—
200	3.6	12.1	39.8	16.8	1.1	0.628	0.872
300	3.5	11.5	38.7	224	8.5	0.600	0.922

The results observed for the specimen with insulating sheets are shown in Table 1.

The limiting dielectric constants ε_h and ε_l, the mean relaxation frequency f_{01} and the distribution parameter β for the specimen with insulating sheets were almost coincident with those of the specimen without insulators. The limiting dielectric constant at low frequency ε_l and the mean relaxation frequency f_{02} can be explained by means of the Maxwell theory of a stratified model.[8] The distribution in relaxation time can be attributed to the heterogeneity in limiting conductivity at low frequency κ_l observed for the specimen without insulators.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1663—1667 (1973)

Kinetics of the Reaction at the Silver–Silver Sulfide Interface

Junichiro MIZUSAKI, Kazuo FUEKI, and Takashi MUKAIBO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 30, 1972)

The reaction rate at the Ag/Ag_2S interface was determined as a function of silver activity of Ag_2S in the temperature range 215—400 °C. The silver activity of Ag_2S at the interface was measured electrochemically by means of an Ag/AgI electrode. The reaction rate was measured by the direct sulfurization method (Wagner's pellet method) and by Rickert's method using $Ag/AgI/Ag_2S/Pt$ cell. The rates obtained by the two methods were in good agreement. It was found that this is a first-order reaction with respect to the activity of sulfur in Ag_2S and that the rate equation is given by

$$v = 1.0 \times 10^4 \{\exp(-18000/RT)\} a_S \text{ eqv cm}^{-2}\text{ s}^{-1} \quad \text{(i)}$$

The following reaction mechanism prevails at the interface.

$$2Ag(Ag) + S(Ag_2S) \longrightarrow 2Ag^+(Ag_2S) + S^{2-}(Ag_2S) \quad \text{(ii)}$$

Solid state reactions such as oxidation or sulfurization of metals or formation of spinels involve a solid–solid interface reaction as an elementary process. Because of the fact that the rate of reaction at a solid–solid interface is much higher than that of diffusion in a solid phase, the solid–solid interface reaction has not been studied kinetically yet. However, a few systems have been found recently in which the solid–solid interface reaction has an effect on the overall reaction rate.

Rickert and his co-workers showed that the sulfurization of silver is a mixed controlled reaction of three elementary processes, *i.e.*, reaction at the Ag/Ag_2S interface, diffusion in Ag_2S, and reaction at the $Ag_2S/S(g)$ interface. They tried to measure the reaction rate at the Ag/Ag_2S interface quantitatively by the coulometric titration method.[1-3] Schmalzried and his collaborators studied the formation of spinels,

1) H. Rickert, *Z. Phys. Chem., N. F.*, **23**, 355 (1960).
2) H. Rickert and C. D. O'Briain, *ibid.*, **31**, 71 (1962).
3) H. Rickert and K. H. Tostmann, *Werkstoffe und Korrosion* **21**, 965 (1970).

such as $ZnAl_2O_4$, from their constituent oxides, and discussed the influence of the reactions at the ZnO/$ZnAl_2O_4$ and $ZnAl_2O_4/Al_2O_3$ boundaries on the overall reaction rate.[4,5] Leute and Kalb investigated the interdiffusion for the system (Hg, Cd)Te/(Hg, Cd)Se, and discussed the influence of the interface reaction in the initial stage.[6] In these investigations, however, no quantitative treatment was performed.

The present study was undertaken to investigate the reaction at the Ag/Ag_2S interface kinetically.

Experimental

In order to obtain the reaction rate as a function of the silver activity of silver sulfide at the solid-solid interface, the direct sulfurization method (Wagner's pellet method[1,7]) and Rickert's coulometric titration method[2] were used.

Direct Sulfurization Method. A schematic diagram of the experimental arrangement is shown in Fig. 1. The sulfurization rate of silver by liquid sulfur was determined from the growth rate of the sulfide layer. The silver activity of silver sulfide at the interface was measured electrochemically with an Ag/AgI electrode. The rate equation was determined from the sulfurization rate and silver activity at the interface.

The essential part of the apparatus for the direct sulfurization method is shown in Fig. 2. A silver cylinder (10 mm in diameter) with a small hole (1.5 mm in diameter) along its axis was fabricated from a silver rod (99.9% pure). The surface in contact with the Ag_2S pellet was polished with No. 1000 emery papers and 0.3 μ alumina polishing powder. A compact silver sulfide rod (10 mm in diameter) prepared by direct sulfurization of the silver rod was sliced into pellets about 0.5 mm in thickness. The pellets were also polished to attain good contact with the silver cylinder. Sulfur of reagent grade was purified several times by distillation.

The Ag/AgI electrode consisting of a silver wire (0.2 mm in diameter) and silver iodide of reagent grade was assembled in a small alumina tube of 1.2 mm in outer diameter. The electrode was placed in the hole of the silver cylinder with its upper edge in contact with the Ag_2S pellet near the Ag/Ag_2S interface. A pyrex tube, with inner diameter 6—8 mm was used to press the Ag_2S pellet and to hold liquid sulfur in it. In order to assure good contact between the cylinder and the Ag_2S pellet, a pressure of about 3 kg/cm^2 was applied by a spring or weight through the pyrex tube.

An electric furnace was constructed by winding nichrome wires around the pyrex tube in order to follow the growth of Ag_2S layer continuously from the outside by means of a cathetometer. The reaction temperature was controlled by an electric controller within ± 1 °C. Measurements were performed in purified nitrogen atmosphere.

Coulometric Titration Method. The coulometric titration method was originated by Rickert and O'Briain.[2] The principle is schematically shown in Fig. 3. When a potential difference is given between Ag(II) and Ag_2S, silver is removed from Ag_2S to Ag(II) in the form of Ag^+ ions and electrons. Namely, Ag^+ ions are transported through the AgI pellet since silver iodide is a pure ionic conductor, and electrons are removed from Ag_2S to Ag(II) through a Pt wire. The rate of silver removal can thus be measured as an electric current by means of an ammeter A. As silver

is removed from Ag_2S to Ag(II), an equivalent amount of silver goes into the Ag_2S pellet across the Ag(I)/Ag_2S interface. When a steady state is established, the rate of reaction at the Ag(I)/Ag_2S interface is equal to that of removal of silver from the Ag_2S pellet. The silver activity of silver sulfide is measured electrochemically by means of an Ag/AgI electrode. An Ag_2S pellet of about 2 mm in thickness was used. The AgI pellet was prepared by pressing silver iodide powder of reagent grade in a die under the pressure of 7 t/cm^2. The pellet was 10 mm in diameter and about 7 mm in thickness. The electric furnace and other experimental apparatus were almost the same as those used in the direct sulfurization method.

Results

Direct Sulfurization Method. A typical result is shown in Fig. 4. E(mV) is the potential drop at the Ag/Ag_2S interface and x(mm) the thickness of the silver sulfide layer formed. The reaction rate v(eqv cm^{-2} s^{-1}) was calculated by the graphical differentiation of x-time curves. The silver activity of Ag_2S, a_{Ag}, is related to E as follows:

$$\log a_{Ag} = -\frac{EF}{2.3RT} \quad (1)$$

where F is the Faraday constant. The activity of metallic silver is taken as unity.

The plots of $\log v$ *vs.* $\log a_{Ag}$ were obtained at 250, 300, 340, and 400 °C by the direct sulfurization method.

Coulometric titration method. Fig. 5 shows the time dependence of E when silver was removed from Ag_2S to Ag(II) at constant currents. The reaction rate v(eqv cm^{-2} s^{-1}) was calculated from the electric current and the area of the Ag/Ag_2S interface. We see that the steady state was attained in a short time when the reaction rate was high.

The plots of $\log v$ *vs.* $\log a_{Ag}$ are given by open circles and solid lines in Fig. 6. Circles show the experimental average values. Empirical solid lines were calculated by the method of least-squares, bars showing the standard deviation from the solid line. The slope of the line is -1.9 ± 0.3, -2.1 ± 0.3, -2.3 ± 0.3, and -2.2 ± 0.6 for the temperatures 215, 250, 300, and 350 °C, respectively. Because of the difficulty in attaining a reproducible good contact between silver and silver sulfide, scattering of the experimental values could not be noticeably reduced.

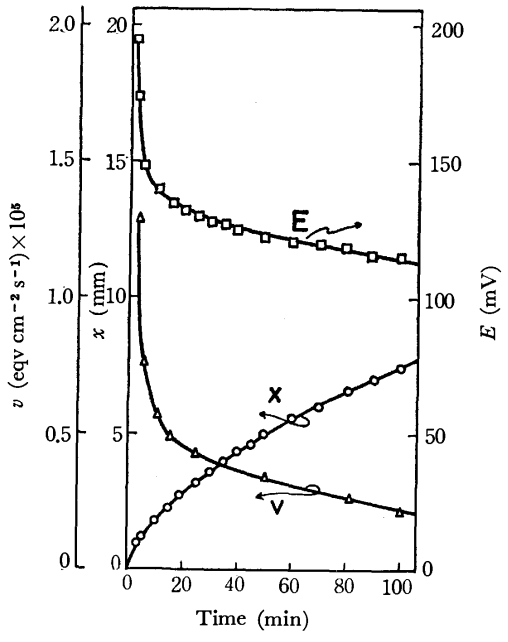

Fig. 4. Change of E, v, and x with time at 300 °C; direct sulfurization method.

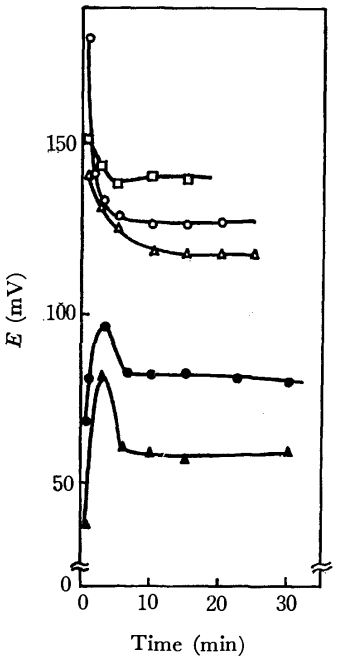

Fig. 5. Change of E with time at 300 °C; coulometric titration method.

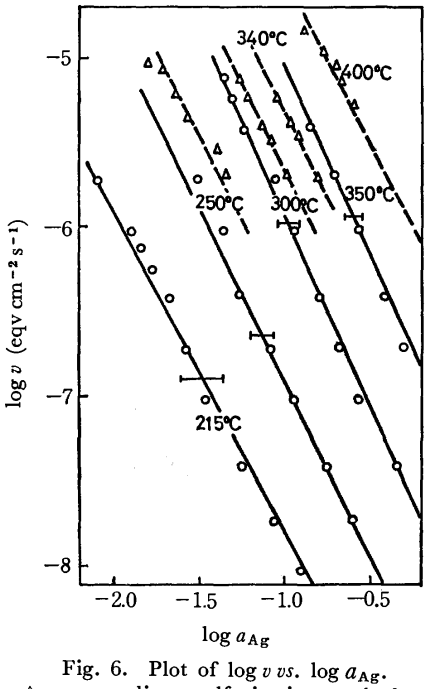

Fig. 6. Plot of $\log v$ *vs.* $\log a_{Ag}$.
△, ----; direct sulfurization method.
○, ——; coulometric titration method.

The results obtained by both methods are in fairly good agreement (Fig. 6).

Rickert and his co-workers showed that the relation between log v *vs.* log a_{Ag} is not linear at 220 and 300 °C, but we found a linear relation.

Discussion

Mechanism. Kobayashi and Wagner[8] studied the reduction of Ag_2S by H_2 at 300 °C and obtained the rate of reduction at the gas-solid interface as a function of a_S. They proposed three mechanisms wherein S, S^-, S^{2-}, and electrons are reactants in solid phase. If the same reactants take part in the reaction between silver and Ag_2S, the transfer of silver atom from metal sulfide would proceed by the most predominant of the following three mechanisms.

$$2Ag(I) + S(II) \rightarrow Ag_2S(II) \qquad (2.A)$$

$$2Ag(I) + S^-(II) \rightarrow Ag_2S(II) + e^-(II) \qquad (2.B)$$

$$2Ag(I) + S^{2-}(II) \rightarrow Ag_2S(II) + 2e^-(II) \qquad (2.C)$$

where (I) denotes the metal phase, (II) the sulfide phase, and e^- is electron.

The corresponding rate equations for these mechanisms are

$$v_A = K_A[a_{Ag}(I)]^2 a_S - K_A' a_{Ag_2S} \qquad (3.A)$$

$$v_B = K_B[a_{Ag}(I)]^2 a_{S^-} - K_B' a_{Ag_2S} a_{e^-} \qquad (3.B)$$

$$v_C = K_C[a_{Ag}(I)]^2 a_{S^{2-}} - K_C' a_{Ag_2S}(a_{e^-})^2 \qquad (3.C)$$

Since the reaction proceeds under the condition far from equilibrium in our case the reverse reactions can be neglected.

The silver activity of metal phase is unity and thus the rate equations (3.A)—(3.C) are rewritten as

$$v_A = k_A a_S \qquad (4.A)$$

$$v_B = k_B a_{S^-} \qquad (4.B)$$

$$v_C = k_C a_{S^{2-}} \qquad (4.C)$$

According to Wagner[9], a_{Ag_2S} and a_{Ag} of α-Ag_2S are constant irrespective of nonstoichiometry of the sulfide, *viz.*,

$$a_{Ag_2S} = \text{const} \qquad (5)$$

$$a_{Ag^+} = \text{const} \qquad (6)$$

Assuming the chemical equilibria between species in α-Ag_2S, we obtain

$$Ag = Ag^+ + e^-$$

$$a_{Ag^+} a_{e^-} = K_1 a_{Ag} \qquad (7)$$

$$S^{2-} = S + 2e^-$$

$$a_S (a_{e^-})^2 = K_2 a_{S^{2-}} \qquad (8)$$

$$S^- = S + e^-$$

$$a_S a_{e^-} = K_3 a_{S^-} \qquad (9)$$

$$2Ag + S = Ag_2S$$

$$a_{Ag_2S} = K_4 (a_{Ag})^2 a_S \qquad (10)$$

Where K_1, K_2, K_3, and K_4 are equilibrium constants.

From Eqs. (5)—(10), we get

$$a_S \propto (a_{Ag})^{-2} \qquad (11)$$

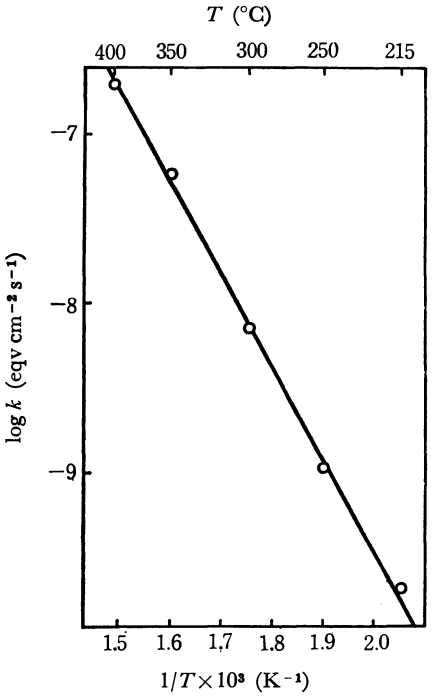

Fig. 7. Arrhenius plot of k.

$$a_{S^-} \propto (a_{Ag})^{-1} \qquad (12)$$

$$a_{S^{2-}} \propto (a_{Ag})^0 \qquad (13)$$

Thus, Eqs. (4.A)—(4.C) are expressed in the form

$$v = k(a_{Ag})^n \qquad (14)$$

where $n=-2$ for mechanism (A), $n=-1$ for mechanism (B) and $n=0$ for mechanism (C).

We found that n varies from −1.9 to −2.3. Thus, it is concluded that n is −2 and that mechanism (A) prevails for the reaction at the Ag/Ag_2S interface.

Rate Constants. The logarithms of the rate constants for each temperature can be obtained from extrapolation of the lines (Fig. 6) to the ordinate $\log a_{Ag} = 0$. Figure 7 shows the Arrhenius plot of k, which is expressed by

$$k = 251 \exp(-25000/RT) \quad \text{eqv cm}^{-2}\,\text{s}^{-1} \qquad (15)$$

Therefore the rate equation is

$$v = 251\{\exp(-25000/RT)\,(a_{Ag})^{-2}\}\text{eqv cm}^{-2}\,\text{s}^{-1} \qquad (16)$$

If the activities of sulfur of Ag_2S under reaction and in equilibrium with Ag are expressed in terms of a_S and a_S^0, respectively, we have

$$a_S (a_{Ag})^2 = a_S^0 \qquad (17)$$

Hence

$$(a_{Ag})^{-2} = \frac{a_S}{a_S^0} \qquad (18)$$

Substituting (18) into (16) we have

$$v = 251\{\exp(-25000/RT)\}(a_S/a_S^0)\ \text{eqv cm}^{-2}\,\text{s}^{-1} \qquad (19)$$

According to Kiukkola and Wagner[10] the standard free energy of formation of Ag_2S, ΔG^0, is

$$\Delta G^0 = -7.04 - 0.00735\,T \quad \text{kcal/mol} \qquad (20)$$

ΔG^0 is related to a_S^0 as follows.

$$\Delta G^0 = RT \ln a_S^0 \quad \text{kcal/mol} \qquad (21)$$

8) H. Kobayashi and C. Wagner, *J. Chem. Phys.*, **26**, 1609 (1957).
9) C. Wagner, *ibid.*, **21**, 1819 (1953).
10) K. Kiukkola and C. Wagner, *J. Electrochem. Soc.*, **104**, 379 (1957).

Eq. (19) can be written as

$$v = 1.00 \times 10^4 \{\exp(-18000/RT)\} a_S \text{ eqv cm}^{-2}\text{ s}^{-1} \quad (22)$$

Summary

(I) The solid-solid interface reaction between silver and silver-sulfide was investigated kinetically by the direct sulfurization and coulometic titration methods.

(2) The reaction rate was determined as a function of a_S, silver activity of silver-sulfide, at 215—400 °C.

The rate quation is

$$v = 1.00 \times 10^4 \{\exp(18000/RT) a_S\} \text{ eqv cm}^{-2}\text{ s}^{-1}$$

(3) The reaction mechanism was discussed on Kobayashi-Wagner's theory. The following mechanism was found to be predominant.

$$2Ag(Ag) + S(Ag_2S) \rightarrow 2Ag^+(Ag_2S) + S^{2-}(Ag_2S)$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1667—1669 (1973)

Chemical Analysis of Mixtures of Metals by a Logarithmic Extrapolation Method

Yukio NAGAOSA and Tatsuo YONEKUBO

Faculty of Engineering, Fukui University, Bunkyo, Fukui 910

(Received March 8, 1972)

Decomposition of the ternary molybdophosphoric acid of titanium(IV), vanadium(V), zirconium(IV) and niobium(V) by complexing agents such as oxalate, citrate or tartrate was found from a kinetic study to be of first-order with respect to each metal ion. The half lives and activation energies of decomposition were also examined. From the results chemical analysis of mixtures of the metals was studied by a logarithmic extrapolation method, utilizing the difference in decomposition rate. Metals in binary systems such as Zr–Nb, V–Zr, Nb–V, Ti–V and Ti–Nb could be determined simultaneously within a relative error of ±5%. Determination of 0.01∼0.2 mg of vanadium was carried out in the presence of titanium (0.1 mg), zirconium (0.5 mg), niobium (0.5 mg) and other diverse ions. Iron(III), aluminum, germanium(IV) and iodide interfered with the determination.

Spectrophotometric determination of titanium(IV), vanadium(V), zirconium(IV) and niobium(V) utilizing their chelate compounds, ternary heteropoly acids and peroxy compounds has been widely used.[1–5] The heteropoly acid method is sensitive in the determination of each metal, but can not be applied to mixtures of these metals because of their mutual interference.

For the chemical analysis of mixtures of these metals, the authors reported on a simultaneous determination of titanium(IV) and vanadium (V), based on the different rate of decomposition of each ternary molybdophosphoric acid in hydrochloric acid solution, without tedious separation procedure.[6] However, the method has the disadvantage that zirconium(IV) and niobium(V) should not be present since they form a precipitate.

The logarithmic extrapolation method has also been used for the analysis of mixtures of two components because of its simplicity and convenience.[7–10] Tanaka *et al.* used this method in the analysis of mixtures of some heavy metals, utilizing different rates of ligand substitution reactions.[11]

A method has been proposed for the simultaneous determination of two of the metal ions, titanium(IV), vanadium(V), zirconium(IV) and niobium(V) by the logarithmic extrapolation technique. This method is based on the different rates of decomposition of the ternary molybdophosphate of metal ions by complexing agents such as citrate, oxalate or tartrate. The kinetics of decomposition was examined by spectrophotometry, and a mixture of the four metal ions was analyzed in the presence of diverse ions.

General Considerations

The logarithmic extrapolation method[12–14] has been applied. After the faster reacting component(A) has reacted completely, the amount of the slower reacting component(B) at the initial time is determined by extrapolating the first-order plots to zero time, the amount of the former at the initial time being estimated by extrapolating logarithm of the difference between the

total absorbance and the absorbance due to B to zero time. The procedure is as follows.

Logarithm of the net absorbance, log E_t, is plotted against time, E_t being obtained by subtracting the blank absorbance from that of the sample solution containing A and B. With the lapse of time diagram (I) gives first a curve, then a straight line when the ratio of rate constants for A and B is large enough. The straight line in (I) is extrapolated (line II) to zero time, to give an intercept of log $E_{B,0}$, logarithm of the absorbance due to initial B. Next, logarithm of the difference in absorbance, obtained by subtracting the absorbance in (II) from that in (I), is plotted against time. The intercept at zero time is log $E_{A,0}$, logarithm of the absorbance due to initial A (diagram III). The concentrations of A and B are calculated from $E_{A,0}$, and $E_{B.0}$ with the aid of calibration curves.

Experimental

Reagent. All the chemicals were of analytical reagent grade. Water was deionized and distilled. The solutions prepared were 0.1 M potassium dihydrogen phosphate, 0.2 M sodium molybdate dihydrate, 0.1 mg metal ion per ml (Ti, V, Zr and Nb) and 0.25 M complexing agent solution (ammonium oxalate monohydrate, sodium citrate dihydrate and sodium tartrate dihydrate).

Apparatus. Spectrophotometric measurements were made on a Hitachi Recorder QPD$_{53}$ and a spectrophotometer Model 139, with 1 cm and 5.3 cm quartz cells. A pH meter, Toa Electronics Ltd., Model HA-5A was used.

Experimental Procedure. One ml phosphate solution was added to 10 ml molybdate solution in a 100 ml beaker, to which was then added a sample solution containing metal ions. The solution was diluted to *ca.* 40 ml with water, the pH being adjusted to 1.5 with 0.5 M sulfuric acid, and made up to 50 ml with water. The mixture was set aside for 2 hr and then 40 ml of the solution was transferred to a 50 ml cell. To this was added 10 ml of complexing agent solution, and the change in transmittance of the solution was recorded at 400 nm as a function of time. A blank solution containing phosphate and molybdate was treated in the same manner. All the experiments were carried out at 20±0.2 °C unless otherwise mentioned.

Results and Discussion

Molar Extinction Coefficients. The absorption spectra of the ternary molybdophosphoric acids and the reagent blank give peaks in the ultraviolet range.[15] Hence, all the absorbances were measured at 400 nm where the absorbance of the reagent blank was considerably low. The molar extinction coefficients of the ternary molybdophosphoric acids were kinetically determined. Figure 1 shows plots of log E_t *vs.* time t, which correspond to the decomposition of ternary molybdophosphoric acids by the complexing agent in 1 cm cells. The linear plots show that the decomposition follows the first-order rate law under the given conditions. The molar extinction coefficients of each ternary molybdophosphoric acid were estimated from the extrapolated intercept to time zero (log E_0). They

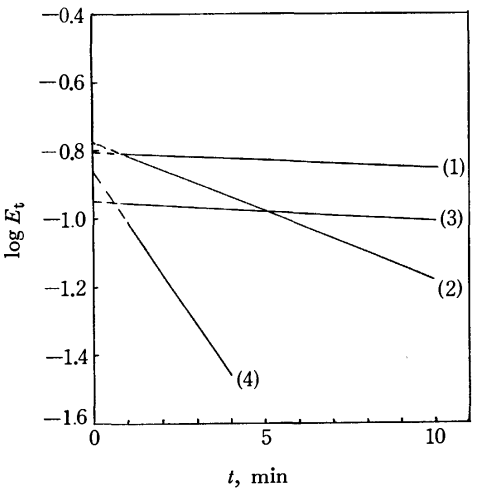

Fig. 1. Determination of E_0 for each metal.
(1) Ti(IV) 0.24 mg/50 ml (0.05 M citrate)
(2) V(V) 0.16 mg/50 ml (0.05 M citrate)
(3) Zr(IV) 0.40 mg/50 ml (0.50 M citrate)
(4) Nb(V) 0.40 mg/50 ml (0.05 M tartrate)
Cell length: 1 cm, temperature: 20 °C

were 1.57×10^3, 2.67×10^3, 1.28×10^3 and 1.52×10^3 for molybdotitanophosphoric, molybdovanadophosphoric, molybdozirconophosphoric and molybdoniobiophosphoric acid, respectively. Beer's law holds up to the concentration of 1 mg/50 ml of each metal at 400 nm.

On the other hand, the absorbance of the reagent blank was approximately 1.0 at 400 nm under the given conditions, but it decreased after the addition of a complexing agent to the solution and finally reached a constant value of 0.01 after 1 min. It is clear that molybdophosphoric acid itself decomposes completely within 1 min.

Half Life. In order to predict the possibility of the simultaneous determination of these metals in their binary mixtures, it is necessary to know the half life of the decomposition of each ternary molybdophosphoric acid by the complexing agent. It can be obtained from the plot of log E_t *vs.* t required for the decomposition. The results are given in Table 1. The half lives decreased in the order V>Ti>Zr>Nb for oxalate system and Ti>Zr>V>Nb for citrate or tartrate system. The following conclusions can be drawn: (1) Of these metals vanadium gives the longest half life for the oxalate system, in good accordance with the previous results,[6,16] where molybdo-

vanadophosphoric acid is the most inert in aqueous solution. (2) For citrate and tartrate systems, the half lives of quadrivalent metal ions (Ti,Zr) are longer than those of quinquevalent metal ions (V, Nb).

Activation Energy. Influence of temperature on the decomposition rate was examined at 15, 20, 25, and 30 °C. Straight Arrhenius plots gave the activation energies summarized in Table 2. They indicate that the activation energies for decomposition by oxalate are 4.4 kcal mol^{-1} and 7.5 kcal mol^{-1} for molybdotitanophosphoric and molybdoniobiophosphoric acids, respectively, and 13.9～17.9 kcal mol^{-1} for the other decomposition systems.

Simultaneous Determination of Two Metal Ions. In order to carry out the extrapolation method successfully, the ratio of the decomposition rate constants of the ternary molybdophosphoric acids in the mixture, k_A/k_B, should be greater than 4 for the case in which the ratio of initial concentration of two metals $[A]_0/[B]_0$ is equal to unity.[9] Pairs of metals in which the differential kinetic determination seems possible were chosen from Table 1, and simultaneous determination of the metal ions was examined. The result for a mixture of zirconium and niobium is given in Fig. 2. From plots of log E_t *vs.* t, the concentrations of zirconium and niobium were determined from the intercepts obtained by extrapolation (Table 3). Synthetic samples of Zr–Nb, V–Zr, Nb–V, Ti–V, and Ti–Nb have been successfully analyzed within a relative error of ±5%.

a) Temperature 25 °C

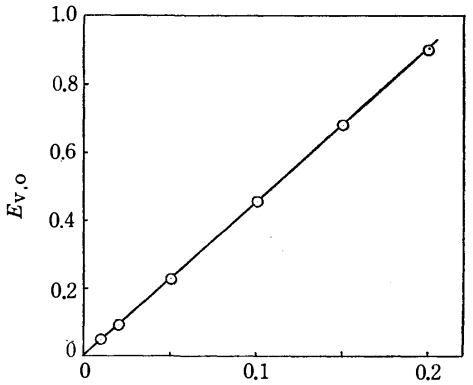

Fig. 3. Determination of V in the presence of Ti(0.1 mg), Zr(0.5 mg) and Nb(0.5 mg).
Oxalate: 0.05 M, cell length: 5.3 cm, temperature: 20 °C.

An attempt was made to analyze a mixture of titanium and zirconium using tartrate at 25 °C. Titanium was determined in the mixture but not zirconium (Table 3).

Determination of Vanadium in the Presence of Titanium, Zirconium and Niobium. We see from Table 1 that vanadium can be determined in the presence of titanium, zirconium and niobium by using oxalate as complexing agent, since the half life of molybdovanadophosphoric acid is more than six times greater than those of the other metals. Analysis of 0.01～0.2 mg of vanadium in the presence of titanium (0.1 mg), zirconium(0.5 mg) and niobium(0.5 mg) was examined at 20 °C. The plot of absorbance $E_{V,O}$, *vs.* the amount of vanadium gives a straight line (Fig. 3). The present method can be applied to the determination of vanadium in the presence of the other three metals.

Diverse Ions. The effect of diverse ions on the determination of 0.1 mg of vanadium was examined in the presence of titanium (0.1 mg), zirconium (0.5 mg) and niobium (0.5 mg). Five mg of Co(II), Ni(II), Mn(II), Cu(II), Cr(VI) and 0.1 mg of Si(IV), As(V) and W(VI) gave no interference, but 0.05 mg of Ge(IV) and 5 mg of iodide interfered with determination. Iron(III) and aluminum should not be present because of the formation of precipitate, and calcium for that of its oxalate.

Potential-step Anodic Stripping Voltammetry

Masahiro KOMATSU

Government Industrial Research Institute, Kyushu, Tosu, Saga 841

(Received August 7, 1972)

The application of anodic potential-step stripping voltammetry for the determination of metal ion was investigated. From the dependence of stripping current ($i_{a,d}$) on electrode radius, the rotational speed of the stirring rod in electrodeposition and electrodeposition time for Cd(II) in 1 M KCl, the diffusion-controlled process could be theoretically predicted. The calibration curves of Cd(II), Mn(II), Ni(II), Zn(II), and Sb(III) were found to be linear in the range 0.01—0.1 ppm, and those of Tl(I), Cu(II), Pb(II), Sn(II), Bi(III), and In(III) in the range 0.02—0.2 ppm, by analysis at time $t=1.25$ sec on current-time curves. The ratio $i_{a,d}/i_{a,p}$ increased in the order $n=3<2<1$, where $i_{a,d}$ is the anodic diffusion current obtained by the potential-step method, and $i_{a,p}$ the anodic peak current obtained by the linearly varying potential method. The ratio of irreversible electron transfer reaction differed from that of the reversible one. The coefficient of variation in the measurement of peak heights was ±3% for 0.1 ppm or 0.2 ppm of metal ion.

Anodic stripping voltammetry has been found to be a very sensitive means for the determination of trace metal ions.[1] The metal ion to be determined is first electrodeposited on a stationary electrode and then stripped from this electrode by reoxidation of mercury amalgam. In the latter process, many reoxidation methods such as linearly varying potential method,[2] a.c. polarography,[3] square wave polarography,[4] constant current electrolysis,[5,6] coulostatic method,[7] and pulse polarography[8] have been employed. Mamantov *et al.* used the potential-step method to reoxidize mercury amalgam and applied it for the determination of cadmium ion.[5] Anodic potential-step stripping voltammetry was applied for the determination of the diffusion coefficient of metal atom in a hanging mercury drop electrode by analyzing the anodic current-time curve.[9,10] However, no papers dealing with the determination of metal ion have appeared except for that of Mamantov *et al.* It appeared to be worthwhile to investigate the applicability of anodic potential-step stripping voltammetry to the determination of metal ions and to compare the result with that of anodic stripping voltammetry under lineraly varying potential.

Experimental

Reagents. Standard solution of metal ions were prepared by dissolving metal salts of analytical reagent grade, and were standardized by complexometric titration with EDTA, except for tin(II) which was standardized gravimetrically.[11] Nitrates were used for Tl(I), Pb(II), Ni(II), and Zn(II), and chlorides for others.

Potassium chloride was purified by extracting heavy metals with dithizone–chloroform system, being recrystallized twice and heated at 300 °C in an electric furnace for 3 hr.

All the other reagents were of reagent grade and used without purification. Water was deionized on a mixed-bed ion-exchange resin and then distilled from alkaline permanganate solution.

Apparatus. The instrument for anodic stripping voltammetry with potential-step was set up with an automatic potential controller(Type AP-1, Shimadzu Co., Ltd.) for electrodepositing process and a potentiostat(Type PS-2, Shimadzu Co., Ltd.) for reoxidizing process from mercury amalgams. Switching from electrodepositing potential to reoxidizing potential was done by a mercury-relay(Type MC-1, NEC Co., Ltd.). The load resistance was adjusted with a precision variable resistor(Type 2786, Yokogawa Elec. Work, Ltd.) inserted in series with the load resistor of the potentiostat. *IR* drop across the variable resistor was applied to the recorder input for measuring cell current. A preliminary test showed that the *IR* drop was linearly proportional to the load resistance from 0 to 3000 Ω and from 0 to 10000 Ω. Current-time curves were recorded on a recorder(Type D-5SN, Rikendenshi Co., Ltd.) with 480 mm/min chart speed, a full-scale sensitivity of 10 mV and a nominal full scale response time of 0.4 sec. For anodic stripping voltammetry at linearly varying potential, a conventional polarograph(Type p-8, Yanagimoto Co., Ltd.) with a 1 V/1.1 min sweep rate and 180 mm/min chart speed was used.

A balanced head stationary hanging mercury drop electrode (HMDE)[12] and a saturated calomel electrode with KNO_3 agar-bridge were arranged with a beaker type electrolysis cell (*ca.* 100 ml). The characteristics of HMDE used were: $t=4.25$ min, $m=3.6$ mg/min. The electrode surface area was 0.028 cm², unless otherwise stated. The characteristics of another HMDE used for examining the relation between anodic diffusion current and the electrode radius were: $t=22.25$ min, $m=1.1$ mg/min.

All the experiments were carried out at room temperature.

Procedure. The method followed standard anodic stripping procedure.[13] A 50 ml solution containing the desired amount of metal and supporting electrolyte was transferred into the electrolysis cell. High purity nitrogen gas was passed through the solution for at least 15 min to remove oxygen. The solution was stirred with 360 rpm (driven by a synchronous rotating motor, unless otherwise

stated). During the course of the experiment, the solution was kept under nitrogen atmosphere. The deposition and reoxidation potentials of each metal ion are given in Table 1.

After deposition for 5 min, stirring was stopped for 30 sec, the chart was driven to record the current-time curve and the potential was switched from electrodeposition potential to reoxidation potential by a mercury-relay.

Results and Discussion

Typical anodic current-time curves for Zn(II), Cd(II), Pb(II), Cu(II), and supporting electrolyte are shown in Fig. 1. Their residual currents which result from charging of the electrical double layer suddenly rise to a maximum and then decay to zero. Anodic current at constant potential electrolysis under the diffusion-controlled condition($i_{a,d}$) is given by[10]

$$i_{a,d} = nFAD_RC_R^* [-1/\sqrt{\pi D_R t} + 1/r_0 - (2/\sqrt{\pi D_R t}) \sum_{n=1}^{\infty} \exp - (n^2 r_0^2/D_R t)] \quad (1)$$

where C_R^* is the initial uniform concentration of deposited metal in the spherical mercury drop electrode, D_R the diffusion coefficient, t the time elapsed from beginning of stripping electrolysis, n the number of electron involved in the electron transfer reaction, r_0 the electrode radius, and A the area of electrode surface. The following semi-empirical equation for the electrodeposition process indicates that the limiting cathodic current i_c for an HMDE is a function of the radius of mercury drop r_0, the diffusion coefficient D_0(cm²/sec), the bulk concentration of the metal ion O to be determined C_o^*(mM), the rpm of the stirring rod U and constant k[1]:

$$i_c = (4\pi r_0 nFD_oC_o^* + knr_0^2D_o^{2/3}C_o^*U^{1/2}) \ \mu A \quad (2)$$

where the first term in the right hand side is the value

of i_c at $U=0$. This can be neglected if the rotational speed is high.[14] The concentration of the reductant C_R^* is expressed as follows by means of cathodic current i_c and electrodeposition time τ.[15]

$$C_R^* = \frac{3i_c\tau}{4\pi nFr_0^3} \quad (3)$$

Since the third term in the right hand side of equation (1) is small when t is less than about 30 sec,[10] anodic diffusion current ($i_{a,d}$) is expressed as follows from equations (1), (2) and (3).

$$i_{a,d} = 4\pi knFD_R\tau D_o^{2/3}C_o^*U^{1/2}\left(\frac{-1}{\sqrt{\pi D_R t}}r_0+1\right) \quad (4)$$

The dependence of $i_{a,d}$ upon r_0, $U^{1/2}$ and τ was examined for Cd(II) in 1 M KCl, Mamantov *et al.* having reported that its electrode reaction was dif-

fusion-controlled. The relation between $i_{a,d}$ and r_0 is shown in Fig. 2. The various radii of the stationary mercury drop electrode were obtained by changing mercury run-off time. The $i_{a,d}$ for all the fixed times of the current-time curve after the start of reoxidation was linearly proportional to r_0. When extrapolated to zero radius, each line intersected at the same point. Since the spherical diffusion process is divergent, spherical correction acts to reduce the current below the value expected for a plane electrode. As a result, the $i_{a,d}$ *vs.* r_0 and also $i_{a,d}$ *vs.* $1/\sqrt{t}$ plots(Figs. 5 and 6) were extrapolated to a positive value. The relation between $i_{a,d}$ and $U^{1/2}$ is shown in Fig. 3. The $i_{a,d}$ was measured at two rotational speeds (rpm 360 and

120), and was found to be linearly proportional to $U^{1/2}$ for two different electrode surfaces. The $i_{a,d}$ *vs.* $U^{1/2}$ plots for both surfaces pass through the origin. The relation between $i_{a,d}$ and τ is shown in Fig. 4, The $i_{a,d}$ at the fixed time of the current-time curves is linearly proportional to τ from 1 to 10 min. All these lines pass through the origin.

If the electrode reaction is diffusion-controlled, the $i_{a,d}$ *vs.* $1/\sqrt{t}$ plot should be linear. $i_{a,d}$ was plotted against $1/\sqrt{t}$ over the time interval 1.25—10 sec after the start of reoxidation for all the metals used. All the resulting curves are linear and their electrode reactions found to be diffusion-controlled. The results are shown in Figs. 5 and 6. Although Ni(II) can easily form intermetallic compounds, the current-time curve of Ni(II) decayed with $t^{-1/2}$ at 0.1 ppm

concentration, showing that the electrode reaction is diffusion-controlled. Calibration curves are shown in Figs. 7, 8 and 9. 5 min was chosen as electrodeposition time for all the metal ions. The reoxidation potential was chosen to have a positive value to make anodic diffusion current independent of potential. The $i_{a,d}$ was measured at $t=1.25$ sec on the current-time curve. The value at zero concentration for each metal ion was due to impurities in the supporting electrolyte. Straight lines were obtained from 0.01 to 0.1 ppm for Cd(II), Mn(II), Ni(II), Zn(II), and Sb(III), and from 0.02 to 0.2 ppm for Tl(I), Cu(II), Pb(II), Sn(II), In(III), and Bi(III). It is of interest that even 0.01 ppm Mn(II) was determined by this method. 0.1 ppm Mn(VII) at most was determined by colorimetric determination[16] and 0.05 ppm Mn(III) by square wave polarography.[17]

As anodic diffusion current decreases with $1/\sqrt{t}$, it will be possible to determine a wide range of concentration of the metal ion from a current-time curve. According to Mamantov's suggestion,[5] concentration below 10^{-7} M of metal ion could be determined, if the current at a shorter time than $t=1.25$ sec has been measured.

Anodic diffusion current($i_{a,d}$) obtained by the potential-step reoxidation method were compared with

16) JIS K 0102 (1971).
17) T. Fujinaga and K. Hagiwara, *Bunseki Kagaku*, **11**, 442 (1962).

anodic current($i_{a,p}$) obtained by the linearly varying potential method. The results, including the potential difference between anodic peak potential ($E_{a,p}$) and anodic half-peak potential($E_{a,p/2}$) are given in Table 1. In the case of Cu(II), the electrodeposition potential and reoxidation potential correspond to Cu(0)→Cu(I) or one electron reoxidation.[18]

The ratio $i_{a,d}/i_{a,p}$ of reversible electron transfer reaction in which $E_{a,p}-E_{a,p/2}$ is $58/n$, increases in the order $n=3<2<1$.

Although the ratios can be varied by changing the sweep rate, the order $n=3<2<1$ will not change. This is because $i_{a,d}$ is in direct proportion to n, and $i_{a,p}$ is in direct proportion to $n^{3/2}$ under the diffusion-controlled condition.[19]

The ratio $i_{a,d}/i_{a,p}$ of Ni(II), Mn(II), and Zn(II) is larger than that of reversible two electron transfer reaction, and the ratio of Zn(II) in 1 M KCl differs from that in 0.5 M NH_3+1 M NH_4Cl. This is because $i_{a,p}$ is affected by α which may have a different value depending on the kind of supporting electrolytes.[20,21] The $i_{a,d}$ value of irreversible electron transfer reaction is considered to be close to the value of the reversible electron transfer reaction, since the reoxidation potential was chosen so as to be far more anodic than the anodic half-wave potential in this experiment.[22] This is why the ratio $i_{a,d}/i_{a,p}$ of Sb(III) differs from the other reversible three electron transfer reactions. Jacobsen and Rojahn reported that Sb(III) was not a strictly reversible process in 1 M H_2SO_4+0.01 M KSCN.[23]

The value $i_{a,d}/i_{a,p}$ indicates that anodic stripping voltammetry with potential-step method is more sensitive than linearly varying potential method for metal ions of which electron transfer reaction is irreversible. However, it has the disavantage of being more difficult to render analysis of certain ion mixtures with proximate anodic peak potentials or adverse relative concentration.

Potentiometric Studies of Cadmium- and Zinc-Halide Complexes in Acetonitrile

Makoto AIHARA and Seizo MISUMI

Inorganic Chemistry Laboratory, Faculty of Science, Kyushu University, Fukuoka 812

(Received December 18, 1972)

The overall formation constants of cadmium- and zinc-halide complexes in acetonitrile were determined by potentiometric titration using a saturated metal amalgam indicator electrode. The effect of ion-pair formation was taken into consideration to elucidate the free halide ion concentration in the experiments. The values of log β_3 and log β_4 for cadmium-halide complex were found to be: I^-, 22.4 and 26.5; Br^-, 25.3 and 29.8; Cl^-, 29.2 and 34.0. The values for zinc-chloride complex were 20.1 and 23.4.

Cadmium-, zinc- and manganese(II)-iodide complexes were studied polarographically in acetonitrile and the overall formation constants of these complexes were evaluated.[1] The formation of some halide complexes in non-aqueous solvents was studied potentiometrically by a number of investigators, too.[2-4] As acetonitrile has the donor number of 14.1, many ligand-exchange reactions have been studied in this solvent.[5]

In this work, cadmium-, and zinc-halide complexes have been studied potentiometrically in acetonitrile. The overall formation constants of the halide complexes were determined and the free halide ion concentration was corrected for the effect of ion-pairing. The data obtained were compared with those previously reported by polarography.

Experimental

Materials. Tetraethylammonium halides (Et_4NX) were prepared, purified several times and dried at 60 °C *in vacuo*. Other reagents were prepared as described previously.[1]

Apparatus. Potentials were measured by YOKOGAWA 2802 digital voltmeter with a manual impedance converter. The cell for potentiometric titration had a stopper of silicone rubber which had openings for a microburet tip, nitrogen inlet and outlet tubes and an SCE.[1] The SCE was isolated from the solution by a bridge of 0.1 M Et_4NClO_4 in acetonitrile with ultrafine sintered-glass membranes. The indicator electrode was a saturated metal amalgam,

prepared by warming pure piece of reagent grade metal with thrice-distilled mercury under a stream of nitrogen.

Procedure. Potentiometric titration curve was obtained by the titration of 0.50 mM metal(II) ion with 0.05 M Et_4NX in acetonitrile. The titrant contained the same concentration of metal(II) ion as that in the cell. The concentration of Et_4N^+ was kept constant (0.1 M) for each solution of metal(II) ion and Et_4NX.

Et_4NClO_4[6] and Et_4NCl[7] were assumed to be completely dissociated in acetonitrile and the K_a values of the association constants used were 4.7 for Et_4NBr[6] and 5 for Et_4NI.[8]

The solution in the cell was deaerated by nitrogen gas presaturated with acetonitrile. All the potential measurements were made at 25.0±0.1 °C.

Results and Discussion

The potentiometric titration curves for cadmium-halide system are shown in Fig. 1. ΔE is the potential difference between cell potentials when halide is present and when it is absent. C_X and C_M are the total concentrations of halide and of metal(II), respectively. Each titration curve has an inflection point at $C_X/C_M=3$. Inflection at $C_X/C_M=4$ becomes larger in the order of iodide, bromide and chloride. The formation of CdX_3^- and CdX_4^{2-} (X=I, Br and Cl) was found to occur in acetonitrile.

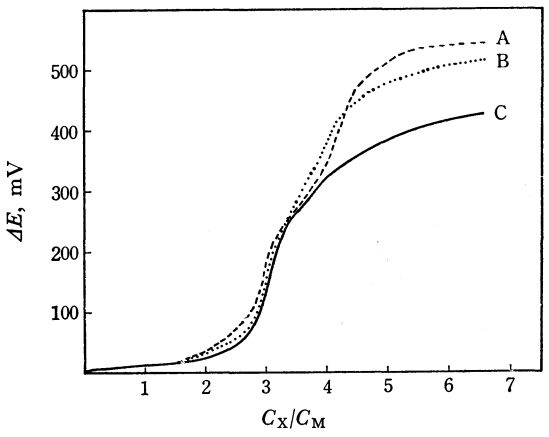

Fig. 1. Potentiometric titration curves for the titration of 0.5 mM Cd(II) with 0.05 M Et_4NCl (curve A), Et_4NBr (curve B) and Et_4NI (curve C).

The formation constants for cadmium- and zinc-halide complexes could not be calculated by Leden's method[9] because of the large inflection of titration curve but were determined in the following way.

In acetonitrile, the concentration of halide ion must be corrected for ion-pair formation. The total concentrations of metal(II) ion and halide are given by Eqs. (1) and (2).

$$C_M = [M^{2+}] + \sum_1^p [MX_p^{2-p}] \quad (1)$$

$$C_X = [X^-] + [Et_4NX] + \sum_1^p p[MX_p^{2-p}]$$

$$= [X^-] + K_a[Et_4N^+]_t[X^-] + \sum_1^p p[MX_p^{2-p}] \quad (2)$$

The total concentration of Et_4N^+, $[Et_4N^+]_t$ was kept to be 0.1 M by addition of the appropriate amount of Et_4NClO_4.

Assuming that the concentration of MX^+ and MX_2 to be negligible at $C_X/C_M \geq 3$, Eqs. (3) and (4) are derived from Eqs. (1) and (2).

$$YK_4[X^-]^2 + (Y+Y'K_4)[X^-] - Y'' = 0 \quad (3)$$

$$[MX_4^{2-}] = Y'' - Y[X^-] \quad (4)$$

where $Y=1+0.1K_a$, $Y'=4C_M-C_X-4[M^{2+}]$, $Y''=3[M^{2+}]+C_X-3C_M$ and $K_4=[MX_4^{2-}]/[MX_3^-][X^-]$

The potential shift (ΔE) by addition of halide is given by Eq. (5)

$$\Delta E = \frac{0.0591}{2} \log \frac{C_M}{[M^{2+}]} \quad (5)$$

and the overall formation constant β_4 is

$$\beta_4 = \frac{[MX_4^{2-}]}{[M^{2+}][X^-]^4} \quad (6)$$

A series of values was assumed for K_4 and corresponding values of β_4 were calculated by using Eqs. (3), (4), (5), and (6). The resulting values of log β_4 were plotted against the assumed value of log K_4. The different lines obtained from different points on the titration curve intersect at one point. For example, there can be seen the intersection point as shown in Fig. 2 for cadmium-iodide system. The value of β_3 was calculated from β_4 and K_4.

The plots for the other systems also intersect at one point.

The values of the formation constants for metal(II)-halide systems obtained by potentiometry and polarography[1] are summarized in Table 1.

The agreement between the values of the formation constant obtained for tetraiodocadmium(II) ion by potentiometry and by polarography is quite satisfactory.

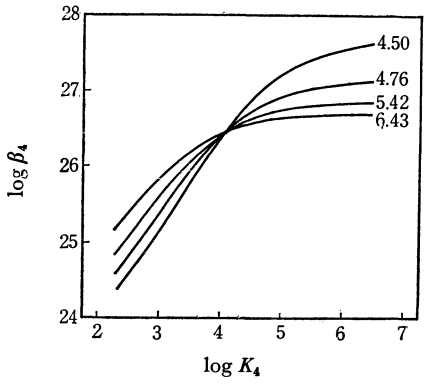

Fig. 2. Graphical solution of the formation constants (β_4 and K_4) for cadmium-iodide system.
Numbers on curves indicate mole ratio, C_I/C_{Cd}.

Table 1. Logarithms of the overall formation constants β_n for cadmium- and zinc-halide systems

System	β_n	Potentiometric data	Polarographic data
Cd(II)-I^-	β_3	22.4	
	β_4	26.5	26.2
-Br^-	β_3	25.3	
	β_4	29.8	29
-Cl^-	β_3	29.2	
	β_4	34.0	
Zn(II)-I^-	β_4		18.4
-Cl^-	β_3	20.1	
	β_4	23.4	

In the case of the cadmium-bromide system, β_3 and β_4 were obtained by potentiometry, whereas only a crude value of β_4 was obtained by polarography. The stability of metal-chloride complex in acetonitrile follows the natural order of stability, that is, Ni(II)< Cu(II)>Zn(II).[2,10]

10) I. V. Nelson and R. T. Iwamoto, *J. Electroanal. Chem.*, **6**, 234 (1963).

These data indicate increasing stability of tri- and tetra-halogeno complexes in the order I<Br<Cl.

The values of β_4 obtained for cadmium- and zinc-halide systems in acetonitrile (donor number,[5] DN= 14.1) were compared with those in other solvents such as dimethyl sulfoxide (DN=29.8), methanol (DN= 33.8) and formamide (DN=39.1).

In the cadmium-chloride system, the stability (log β_4) decreases in the order acetonitrile (34.0)≫methanol (6.1)[11]>formamide (5.5).[12] In the zinc-chloride system, the value of log β_4 is larger in acetonitrile (23.5) than that in dimethyl sulfoxide (16.25).[13] The stability for other systems decreases with increasing donor number of the solvent, too.

Thus, a solvent of low donor number such as acetonitrile was confirmed to be effective for the formation of halide complexes.

The authors are grateful to the Ministry of Education for financial support given for this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1676—1680 (1973)

The Internal Friction of Glasses Containing Alkali under an Electric Field

Hiroyasu SAKAMURA and Minoru IMAOKA

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received May 31, 1972)

The change of the internal friction of sodium silicate and sodium borate glasses under an electric field was studied by means of a torsion pendulum technique. It was found that the internal friction increased under an electric field and that the increase was related to the numbers of vibration, the strength of the electric field, and the Na_2O content. The increase in internal friction in the glasses with a high Na_2O content was large because of the electrolysis of the glasses, which resulted in the removal of sodium ions. It was proposed that the internal friction increased because the removal of sodium ions was promoted by torsional oscillation under an electric field and that the deformation of the network took place around holes which were left behind by the removal of the sodium ions.

In an experiment with a glass containing alkali, an internal friction peak caused by the diffusion of sodium ions has been observed near room temperature over a period of the order of seconds.[1,2] When an alternating voltage is applied to a glass containing alkali, an electric loss with an activation energy and relaxation time almost the same as those of the internal friction has been observed.[3] In this case, alkali ions under electric stress move back and forth through the network structure of a glass. When an electric field is applied to a glass, an absorption current appears first, and then a constant current flows. The former causes polarization in a glass. The latter is due to ionic conduction. Alkali ions move to the cathode side under an electric field, some of them, however, stop within the network. Though alkali ions are forced to move within a glass by external force, their movement is controlled by the glass network structures. It is interesting to study the combined effect of electric and mechanical forces on glasses.

In Copley's experiment, an electric field was applied between the center and the surface of a glass bar sample and electrolysis was carried out for a constant time at 250 °C.[4] We are, however, interested in the polarization phenomenon, so we measured the internal friction by applying an electric field between the two ends of a glass bar sample.

Experimental

The apparatus used in this work is almost the same as Forry's except that a torsion pendulum is hung by means

of a nylon string.[5-7] The influence from the twist of the string was minimized by using a long string (45 cm). Other advantages of hanging it with a nylon string are that the tension to a sample becomes smaller and the frequency of vibration can be easily varied as much as tenfold for the same sample.

The chuck holding a sample was insulated from metal parts by means of a Pyrex tube, as is shown in Fig. 1, lest an unnecessary vibration should be raised by coulombic force. A sample was connected with such thin copper wire lead (0.075 mm in diameter) that it affected nothing.

The glasses used were systems of SiO_2-Na_2O and B_2O_3-Na_2O. Each sample was about 1.5 mm in diameter and 30 mm in length. Since these glasses are hygroscopic and are apt to cause surface conduction, a drying box with silca gel was used, keeping the humidity low (below 10%).

Hot water within a plastic vessel was used instead of an electric furnace to raise the temperature. Below 0 °C, even a very little moisture was frozen, electrified, and stuck on the surface of a sample, so the temperature range was limited to from 0 to 40 °C.

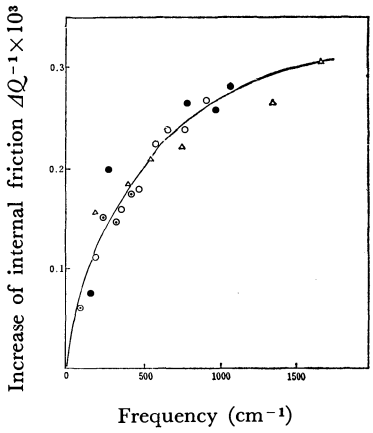

Fig. 6. Relationship between the increase of internal friction and numbers of vibration for a 0.35 Na_2O+0.65 SiO_2 glass at 18 °C. Electric field applied is 2700 V/cm.
○: 0.14 Hz, ⊙: 0.17 Hz, ●: 0.41 Hz, △: 0.69 Hz.

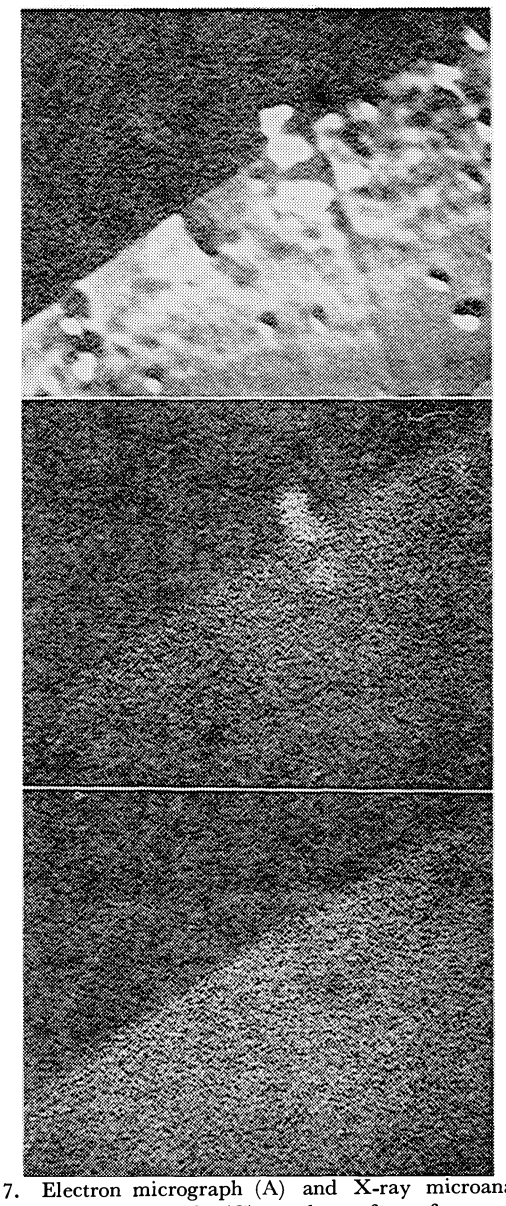

Fig. 7. Electron micrograph (A) and X-ray microanalysis by NaK_α (B) and Si-k_α (C) on the surface of a cut-edge of a 0.40 Na_2O+0.60 SiO_2 glass bar sample near cathode after an electric field was applied for a while. In B some sodium product can be seen at the edge of the surface but in C it can not be seen. Magnification is 1080.

the electric field and that without the electric field. When it reached a constant value, the electric field was removed. The ΔQ^{-1} value decreased gradually and approached zero under continuous torsional oscillation. The internal friction under an electric field was found to increase as the concentration of the sodium ion in a glass increased. The change in internal friction for the 0.4 Na_2O+0.6 SiO_2 glass was especially large, and the ΔQ^{-1} value did not return to zero after the removal of the electric field. This indicates that some irreversible change occurred in the sample.

Figure 3 shows the change in the internal friction versus the Na_2O content. There was little difference between the curves for the SiO_2–Na_2O and B_2O_3–Na_2O systems. Their curves were nearly parabolical. The internal friction, as measured in a drying box, was generally smaller than that in an ordinary room. The increase in internal friction was in proportion to the strength of the electric field. For instance, the ΔQ^{-1} values after the electric field was applied for 30 minutes were found to be proportional to the electric field in the range from 8×10^2 to 32×10^2 V/cm, as is shown in Fig. 4. The electric field had little influence on the peak position, but the background became higher than that obtained without an electric field, as is shown in Fig. 5.

When the ΔQ^{-1} values for various periods were plotted as a function of the numbers of vibration, it was found that the period had no influence, but that the numbers of vibration did influence the change in internal friction, as is shown in Fig. 6.

When a 0.4 Na_2O+0.6 SiO_2 glass was measured, a part of the sample near the chuck on the cathode clouded and then cracked before long. This is pro-

bably because of the presence of product obtained through electrolysis (see Fig. 7). This seems to be the reason why the curve of the internal friction for the 0.4 Na_2O+0.6 SiO_2 glass (Fig. 2) did not return to zero after the removal of the electric field.

Discussion

The curves in Fig. 2 were normalized at their saturated values, as is shown in Fig. 8. Among these curves for the increasing internal friction (solid lines), Curve 3 is quite different from Curves 1 and 2. The difference is caused by electrolysis. In the cases shown by Curves 1 and 2, very little electrolysis occurs, so their internal friction returns to the orginal value after the removal of the electric field. The returning curves 1 and 2, after the removal of an electric field (broken lines), are different from the increasing curves 1 and 2 (solid lines). During this experiment, torsional oscillation was always applied to a sample. If torsional oscillation is not applied under an electric field, the values of the internal friction will scarcely alter at all. The increase in internal friction will occur only when torsional oscillation and an electric field are applied to a sample simultaneously. When an electric field is removed after the internal friction reaches a saturated value, the internal friction decreases rapidly even without torsional oscillation. This suggests that sodium ions which have been raised to a higher potential energy level return to their original lower potential level by thermal vibration. This is one of the causes of the difference between a solid line and a broken line.

The increase in internal friction was scarcely observed in the glass with a low Na_2O content, below 15 mol%, but in the glass of Na_2O above 20 mol% it increased considerably with the Na_2O content, as is shown in Fig. 3. In the glasses of the SiO_2–Na_2O systems, the background of internal friction is large in a glass with a low Na_2O content (below 100 °C) and is large in one with a high content (over 100 °C).[5] It may be supposed that the background below 100 °C is affected by the deformation of the porous frame structure of SiO_2 while over 100 °C it is affected by the increase in the flexibility of the Si–O network due to sodium ions. The background in the temperature range of this experiment seems to be affected mostly by the deformation of the porous frame structure of SiO_2 and very little by the flexibility of the Si–O network. In a higher-Na_2O-content glass, the three-dimensional network structure is destroyed and the background becomes lower. When an Na_2O-containing glass is subjected to torsional oscillation under an electric field, the network structure is apt to be deformed around holes which are left behind by the removal of sodium ions. Thus, the internal friction must increase. The network structure will deform more easily near continuous holes than near an isolated hole. Such continuous holes can be made more in higher-Na_2O-content glasses. Moreover, electrolysis is also apt to occur. This is the reason why the increase in internal friction is high in the glass with a high Na_2O content and very low in the glass with a Na_2O content of less than 15 mol%.

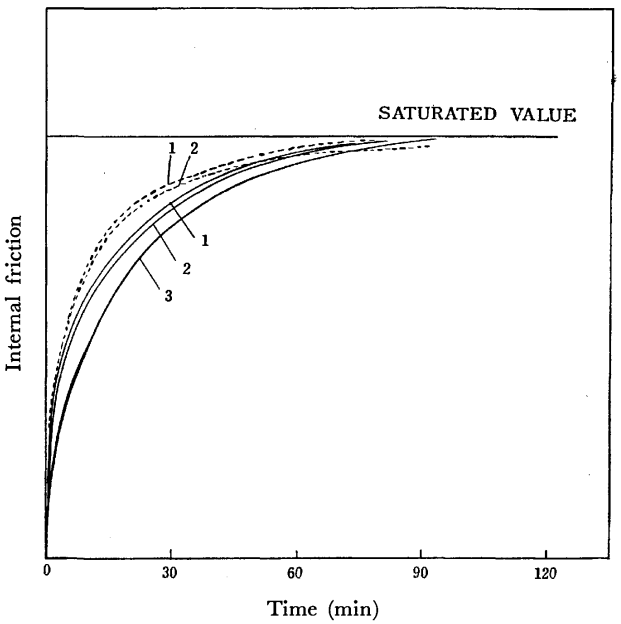

Fig. 8. Variation of internal friction with time. Each saturated value in Fig. 2 is normalized.
1: Na_2O 30 mol%, 2: Na_2O 35 mol%,
3: Na_2O 40 mol%
——: under electric field
----: after the removal of electric field

The results can almost all be explained in terms of Copley's proposal that the increase in background is characteristic of a more open, loosely-bound structure because of the removal of a certain number of sodium ions.[4] The internal friction was found to increase with the strength of the electric field. This means that the number of holes which are left behind by the removal of the sodium ions is proportional to the strength of the electric field, so that the background of internal friction rises in proportion to the number of holes. The characteristic of the increase in the background is, however, related to the network structure of glass composition. From the facts that the increase in background shows saturation with time and that it does not change with the period of torsional oscillation, but with the number of vibrations, a mechanism in which some of the sodium ions moving under an electric field are trapped somewhere in the network structure when the network is deformed can be proposed. As soon as an electric field is applied, some holes are produced by polarization, and hence the background increases, yet sodium ions are supposed to move from a hole to a hole which has nonbridging oxygen ions. When sodium ions are trapped somewhere in the network structure, the number of holes seems to increase. These sodium ions cannot slip easily from the traps without torsional oscillation after an electric field is removed. They can, however, slip gradually because of thermal vibration.

According to Copley's experiment, the peak position of the internal friction caused by sodium ions shifts slightly,[4] but we did not observe such a change. In Copley's experiment, the surface concentration of

the sodium ions changed by electrolysis. In our experiment, the change in the concentration of the sodium ions is caused by polarization and electrolysis occurs only near the cathode in the axial direction of a sample. Therefore, there is probably no influence on the peak position.

The Hydrolysis of Ferric Complexes. Magnetic and Spectrophotometric Studies of Aqueous Solutions of Ferric Salts

Masao KIYAMA and Toshio TAKADA

Institute for Chemical Research, Kyoto University, Kyoto 611

(Received December 3, 1971)

Ferric chloro, ferric aquo, and ferric sulfato complexes in acidic solutions have been hydrolyzed at temperatures below 70 °C to form polynuclear complexes of iron(III). Magnetic and spectrophotometric studies have then been carried out in order to clarify the nature of the polynuclear complexes. From these studies, their empirical formulas are presumed to be $Fe_2(OH)_2Cl_2O$, $Fe_2(OH)_3(NO_3)_3$, $Fe_2(OH)_3(SO_4)_{3/2}$, and $Fe_3(OH)_2(SO_4)_{7/2}$. The iron ions in these polynuclear complexes are in a high spin state, as are those in the ferric complexes, iron oxides, and oxyhydrates. It is proposed that, in all these polynuclear complexes except $Fe_3(OH)_2(SO_4)_{7/2}$, edge-shared octahedral dimer units are antiferromagnetically linked with one another by hydroxy or oxo bridging. When the hydrolysis temperature is raised, these polynuclear complexes are further hydrolyzed to form precipitates. The complexes of $Fe_2(OH)_2Cl_2O$, $Fe_2(OH)_3(SO_4)_{3/2}$, and $Fe_3(OH)_2(SO_4)_{7/2}$ give β-FeOOH, α-FeOOH, and $RFe_3(OH)_6(SO_4)_2$ (R=Na, K or NH_4) respectively, whereas the complex of $Fe_2(OH)_3(NO_3)_3$ gives α-FeOOH or α-Fe_2O_3, depending on the temperature.

When ferric salt solutions are heated or made alkaline, the ferric ions in them are hydrolyzed to form precipitates of various iron compounds. It is known that a ferric chloride solution gives β-FeOOH,[1-3] whereas a ferric nitrate solution gives α-FeOOH or α-Fe_2O_3, or a mixture of them, depending on the hydrolysis temperature.[4,5] Also, a ferric sulfate solution gives α-FeOOH or a basic sulfate, or a mixture of them, depending on the pH.[6] We consider that what kind of precipitate is formed by hydrolysis is closely connected with the nature of the ferric complexes present in the solutions just before the formation of precipitates.

The ferric complexes which are present as monomers in strongly acidic solutions of ferric salts have so far been studied by means of X-ray diffraction,[7,8] spectrophotometry,[9-13] magnetic measurement,[14-16] potentiometry,[17] *etc.* Among these methods the spectrophotometry in the region of electronic absorption has been used particularly for the study of Cl^-, SO_4^{2-}, and OH^- ligands. The electronic absorption curves of acidic solutions of ferric salts have been studied by many investigators. It has been clarified by these studies that such ferric complexes as chloro, sulfato, hydroxo, and aquo complexes are present in the strongly acidic solutions, depending on the kind and concentration of the anions in them. By decreasing the acidity of the solutions, polynuclear complexes of iron(III) are formed.

The polynuclear complexes formed in solutions of ferric perchlorate and ferric nitrate have also been studied by several investigators. From a potentiometric study, Hedstrom first proposed that the polynuclear complex formed by the hydrolysis of a diluted ferric perchlorate solution was a dimer.[17] The pH dependence of the magnetic susceptibilities and the optical absorption spectra of similar solutions was studied by Mulay and Selwood, who proposed that a diamagnetic dimer was formed by the hydrolysis of the same.[18] Also, Zvyagintsev and Loppato reported that a tetramer was formed by the hydrolysis of ferric nitrate.[19] The polynuclear complex in a ferric nitrate solution was studied in detail by Spiro *et al.* using various methods. Spiro *et al.* observed that the poly-

nuclear complex consisted of a great number of iron ions.[20] Further, the structure of this complex was discussed by Schugar *et al.*, who pointed out that it was not a diamagnetic complex, but a paramagnetic one with a spin angular moment of $S=1$ per iron, and presumed that it was composed of many aquo dimers, $Fe=(OH)_2=Fe$.[21]

In order to discuss the mechanism of precipitation in solutions of different ferric salts, further investigations of the nature of complexes present in the solutions are needed. In this paper, the possible structure and the chemical composition of the polynuclear complexes will be discussed on the basis of the spectrophotometric and magnetic data.

Experimental

Sample Solution. Chemical reagents of an analytica grade were used in the present experiments. Desired quantities of ferric chloride, ferric nitrate, and ferric sulfate were dissolved in 1.00 N hydrochloric acid, nitric acid, and sulfuric acid solutions respectively. To each of these strongly acidic solutions of ferric salts, alkali solutions were added in various ratios below the chemical equivalent. By this addition, a precipitate was formed. However, it disappeared on agitation. The resultant acidic solutions were diluted with distilled water to desired concentrations of the ferric ion and stored in polyethylene bottles. The magnetic susceptibilities and the absorption spectra of these acidic solutions, which contained no visible precipitates, were then measured.

Apparatus. The measurements of the optical absorption spectra were carried out using a Shimadzu spectrometer, Model QR-50. The optical path in its sample container was selected from among 0.003, 0.010, and 1.0 cm by the use of quartz spacers of different sizes according to the concentration of the ferric ion and the frequency of the light. The absorbance value was obtained at intervals of 0.5 mμ. The extinction coefficient was calculated using Lambert-Beer's formula.

The magnetic susceptibilities of the solutions were measured as follows. A schematic illustration of the magnetic balance used is shown in Fig. 1. Each solution was introduced into a double cylindrical vessel (A) 2.5 cm in external diam., 1.8 cm in internal diam., and 40 cm in length, which was placed between the pole pieces of a magnet (B). A cylindrical quartz rod (C) with a cross-sectional area of 0.48 cm^2 and a length of 20 cm was hung in the vessel by means of a platinum wire from one arm of a chemical balance (D). The lower end of the rod was brought to the center between the pole pieces.

The repulsion force, F, of the lower end of the rod was measured by the chemical balance in the magnetic field range 0.2—13.5 kOe. The magnetic susceptibility, K, per unit of volume of the solution was calculated as follows:

$$2F/(H_A^2-H_B^2)A = K - K_0$$

where H_A is the strength of the magnetic field at the lower end of the rod; H_B, that at the upper end (negligibly small); K_0, the magnetic susceptibility per unit of volume of the rod, and A, the cross sectional area of the rod. The magnetic susceptibility of the rod was calibrated with a standard solution of $NiCl_2$ and was found to be

$$-0.395\times10^{-6}/cm^2(-0.878\times10^{-6}/g).$$

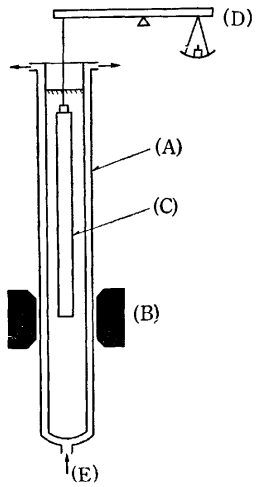

Fig. 1. Schematic illustration of vessel and magnetic balance used.
(A) Double cylindrical vessel, (B) Magnet, (C) Quartz rod, (D) Chemical balance, (E) Temperature-controlled water

The density of the solution was measured by using a density bottle, while the magnetic susceptibility per g-atom of the ferric ion in the solution was calculated making corrections for the diamagnetic elements in the solution. The magnetic moment, μ_{eff}, was calculated by the usual formula, $\mu_{eff}=2.84\sqrt{X_{Fe}\times T}$, where T is the absolute temperature. The pH was measured using a Horiba electrode pH meter.

Results

Spectrophotometric Data. Figures 2, 3, and 4 show the absorption curves of acidic solutions containing 0.3 N-ferric salt, 0.5 N-acid, and alkali in different concentrations from 0 to 0.7 N. There are absorption bands with peaks at 90 and 130×10^{13} Hz for the chloride, at 120×10^{13} Hz for the nitrate, and at 100 and 130×10^{13} Hz for the sulfate. When the acidity was decreased, the colors of these solutions (yellow for the chloride, light blue for the nitrate, and orange yellow for the sulfate) changed to reddish brown and these absorption bands broadened as may be seen in these figures. In order to find the relation between the frequencies of the peaks of absorption bands and the experimental conditions, optical measurements of acidic solutions with different concentrations of ferric salt, acid, and alkali were carried out in the frequency range from 70 to 140×10^{13} Hz at different temperatures. The results are given in Tables 1, 2, and 3.

Magnetic Data. Magnetic measurements of the same solutions were made in the range from 0.2 to 13.5 kOe at different temperatures. Their susceptibilities did not show any magnetic-field dependence at a given temperature. The magnetic moments, μ_{eff}, calculated from the magnetic data are given in the right-hand columns of Tables 1, 2, and 3.

In the above experiments, the pH values of the so-

Discussion

In strongly acidic solutions of ferric chloride, ferric sulfate, and ferric nitrate, ferric chloro, ferric sulfato, and ferric aquo complexes are formed respectively. These ferric complexes strongly absorb the light of frequencies in the ultraviolet region, the frequencies of the peaks of their absorption bands depending on the kind of ligands in them. Table 5 gives the frequencies and wavelengths of their peaks in the ultraviolet region.

Tables 1—3 indicate that the ferric complexes in

the strongly acidic solutions are paramagnetic in a high spin state, and that the frequencies of the peaks are determined by the kind and concentration of the anions in the solutions. Regardless of the concentration of ferric ions and the temperature, peaks appear at 89—90 $\times 10^{13}$ Hz, 120—125 $\times 10^{13}$ Hz, and 98—100 $\times 10^{13}$ Hz for strongly acidic solutions of ferric chloride, ferric nitrate, and ferric sulfate respectively. These peaks are due to ferric chloro, ferric aquo, and ferric sulfato complexes respectively. The strongly acidic solutions of ferric chloride and ferric sulfate show peaks (though not sharp) in the region of 132—137 $\times 10^{13}$ Hz, too. They are considered to be due to ferric chloro and ferric sulfato complexes respectively.

As the acidity of the strongly acidic solutions is decreased, the absorption bands become broad and obscure, as may be seen in Figs. 2, 3, and 4. This broadening may be due to the fact that a polynuclear complex containing a great number of ferric ions is formed in each solution and that its concentration increases with a decrease in the acidity, so that light in the ultraviolet region is strongly scattered. Also, the increase in the concentration of the polynuclear complex causes the magnetic susceptibility, X, of the ferric ions to decrease. The decrease in X may be due to the fact that the polynuclear complex contains antiferromagnetic couplings, though the ferric ions in the polynuclear complex as well as those in the strongly acidic solutions are in a high-spin state, as will be described later.

It is known that all the ferric ions present in crystals of α-FeOOH, β-FeOOH, and α-Fe_2O_3 are in a high spin state (S=5/2, five unpaired spins per iron) and are bound to O^{2-} and/or OH^- ions at angles of 90°

and either 120° or 180°.[22-25] When the bond angle between these ferric ions is between 120° and 180°, the spins can align themselves to each other by means of a superexchange interaction whose strength depends on the distance and angle between them. This bridging, called an antiferro magnetic coupling, causes the X value to decrease. Because both the iron ions in the ferric complexes and those in the final products of hydrolysis are in a high spin state, it is reasonable to consider that the iron ions in the polynuclear complexes, intermediates, are not in a low spin state, but in a high spin one, and that the polynuclear complexes must have antiferromagnetic couplings, causing the decrease in the X value.

It is known that upon a decrease in the acidity, the X decreases to a certain value. According to Mulay and Selwood's magnetic data, X of the ferric ions in a 0.04 M $Fe(ClO_4)_3$ solution at 16 °C decreased to 6.3 and 6.2×10^{-3} per g-iron atom when the pH was increased to 1.9 and 2.45 respectively.[18] Schuger et al. also reported that, in a 0.195 M $Fe(ClO_4)_3$ solution at 25 °C, X decreased to about 6.9×10^{-3} per g-iron atom.[21] It is supposed that when the solution reaches a state where a further decrease in its acidity causes hardly any decrease in X, most of the ferric complexes in it have been hydrolyzed to form a polynuclear complex.

The usual formula for the hydrolysis of the ferric ion is written as follows:

$$Fe^{3+} + nH_2O = Fe(OH)_n^{3-n} + nH^+$$

Let c represent the wt fraction of ferric ions as a polynuclear complex, $Fe(OH)_n^{3-n}$; X_{Fe}, the susceptibility/g-atom of the total ferric ions present at different acidities; X_T, that/g-atom of ferric ions present as a ferric complex, Fe^{3+}; and X_P, that/g atom of ferric ions present as the polynuclear complex. Assuming that $X_{Fe}=cX_P+(1-c)X_T$ and that X_P is independent of acidity, it is given as:

$$c = (X_T-X_{Fe})/(X_T-X_P)$$

In the present experiment, unfortunately, the X value independent of the acidity could not be obtained (the magnetic measurements were not made for the solutions with higher pH values than the values shown in Table 4, as the presence of a precipitate was observed). From the X_{Fe} values in Table 4, the c values at different acidities are calculated for the solutions at 17 °C using the $X_P=6.2\times10^{-3}$ obtained by Mulay and Selwood.[18] The c values thus obtained are plotted against the pH in Fig. 5. As may be seen in the figure, the points for the chloride and the nitrate are on straight lines, while those for the sulfate on a curved line. These lines have different slopes and intercepts. Since $\log K=\log(Fe(OH)_n^{3-n})\times(H^+)^n/(Fe^{3+})$ in the hydrolysis formula, the slope(n) and intercept ($\log K$) represent the OH^- (or $2O^{2-}$)/Fe^{3+} ratio in each polynuclear complex and its formation constant respectively. The n and $\log K$ values obtained are given in Table 6.

Table 6. Slopes (n) and intercepts ($\log K$) for each ferric salt solution in Fig. 5

Chloride		Nitrate		Sulfate			
n	$\log K$	n	$\log K$	n	$\log K$	n	$\log K$
2.2	−3.7	1.4	−2.5	0.7	−1.4	1.4	−3.0

It is supposed that the X_P value depends on the particle size and the structure of the polynuclear complex which are affected by the kind of ferric complex. Spiro *et al.* reported that the particle size of the polynuclear complex in the nitrate is nearly independent of the degree of hydrolysis of the aquo ferric complex.[20] The nature of the polynuclear complexes formed by the hydrolysis of the aquo ferric complex has been widely studied, but that of the polynuclear ones formed by the hydrolysis of other ferric complexes, such as the chloro ferric complexes, has not yet been sufficiently studied.

We believe that the X_P value of the polynuclear complex formed in the ferric chloride solution is not less than 3.4×10^{-3}, which is the room-temperature molar susceptibility of the final product, β-FeOOH, of the hydrolysis of the ferric chloro complexes. The c values for the chloride are also calculated using $X_P=3.4\times10^{-3}$. The n and pK values for the chloride obtained by the graphical method are 2 and 3.7 respectively.

These n values suggest that the polynuclear complex formed by the hydrolysis of the aquo ferric complex in the nitrate contains $[Fe_2(OH)_3]^{3+}$ cations. In the sulfate, a polynuclear complex containing $[Fe_2(OH)_3]^{3+}$ or one containing $[Fe_3(OH)_2]^{7+}$, or a mixture of them, is formed, depending on the pH. The polynuclear one formed in the chloride contains $[Fe(OH)_2]^+$ cations.

It is impossible to determine from the n values whether the ligand is OH^- or O^{2-}. Tables 2 and 3 show that when the acidity of ferric nitrate solutions is decreased, absorption peaks appear at 90—91 $\times10^{13}$ Hz, and that when a ferric sulfate solution is added to excess sodium acetate, a peak appears at 89×10^{13} Hz. It was found by Schugar *et al.* that a dimeric complex, $[Fe(pic)_2OH]_2$(pic=picolinic radical), contains a dihydroxo-bridged structural unit, $Fe_2(OH)_2$.[26] Also, Anderegg pointed out that $[Fe(pic)_2OH]_2$ and polynuclear complexes formed by the hydrolysis of a ferric aquo complex must have a similar bridging structure, because they exhibit similar electronic spectral bands at 87.5 and 89×10^{13} Hz respectively.[27] It is evident that the dihydroxo-bridged structural units exist in the polynuclear complexes containing $Fe_2(OH)_3$ cations. Where edge-shared octahedral dimers, $[Fe_2(OH)_2(H_2O)_8]^{4+}$, are weakly bound by water molecules to form a polynuclear complex, the decrease in the X value may, however, be slight at room temperature, since magnetic superexchange

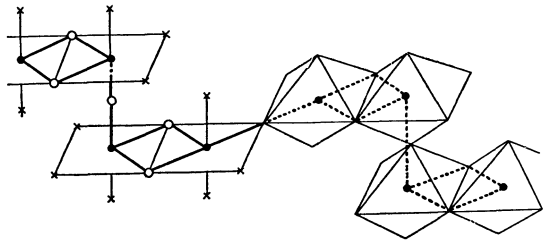
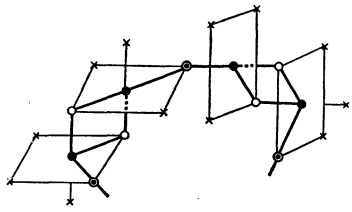
interaction is weak. We propose that the edge-shared octahedral dimers are antiferromagnetically bound together by monohydroxo-bridging to give a zigzag polynuclear cation of a structure such as is shown below:



where ●, O, and × are Fe^{3+}, OH^-, and H_2O respectively.

The ferric chloride solutions show absorption peaks at 90×10^{13} Hz regardless of the presence of polynuclear complexes. Therefore, it is impossible to determine from the spectroscopic data whether or not the polynuclear complex in the chloride contains the dimers. However, from the crystal structure and magnetic properties of the β-FeOOH formed by the hydrolysis of ferric chloride,[2,25] it can be presumed that the edge-shared octahedral dimers are antiferromagnetically bound together by oxo-bridging to give a ring-like polynuclear cation of a structure such as is shown below:



where ●, O, ⊙, and × are Fe^{3+}, OH^-, O^{2-}, and H_2O respectively.

The polynuclear complexes may be composed of the polynuclear cations and the acid ions, NO_3^-, $SO^2{}_4^-$, and Cl^-; they would thus be enabled to keep their electric neutrality. Among these anions, SO_4^{2-} and Cl^- are probably bound to the ferric ions as ligands in these complexes. The reactions by which the polynuclear complexes are formed may be roughly expressed by the following formulas, where the H_2O ligands are omitted:

$$2Fe(NO_3)_3 + 3H_2O = Fe_2(OH)_3(NO_3)_3 + 3HNO_3$$

$$Fe_2(SO_4)_3 + 3H_2O = Fe_2(OH)_3(SO_4)_{3/2} + (3/2)H_2SO_4$$

$$(3/2)Fe_2(SO_4)_3 + 2H_2O = Fe_3(OH)_2(SO_4)_{7/2} + H_2SO_4$$

$$2FeCl_3 + 4H_2O = Fe_2(OH)_2Cl_2O + 4HCl$$

On heating, these polynuclear complexes are further hydrolyzed. The $Fe_2(OH)_3(SO_4)_{3/2}$ and $Fe_2(OH)_3(NO_3)_3$ complexes form the precipitate of α-FeOOH, and the $Fe_2(OH)_2Cl_2O$ complex forms the precipitate of β-FeOOH. When Na^+, K^+, or NH_4^+ ion exists in the acidic solution of ferric sulfate, (Na, K or NH_4)-$Fe_3(OH)_6(SO_4)_2$ is formed as a crystalline precipitate of the basic sulfate.

When the temperature is raised, α-Fe_2O_3 is formed. Also, the formation temperature differs with the kind of polynuclear complex. For example, α-Fe_2O_3 began to be formed at about 60 °C in the ferric nitrate solution, and at about 90 °C in the sulfate and chloride solutions. Which is formed, α-Fe_2O_3 or FeOOH (α or β), may be determined by the change in the structures of the polynuclear complexes. It may also be supposed that the temperature at which the structural change begins is lower for the $Fe_2(OH)_3(NO_3)_3$ complex than for the others. The temperature dependence of the magnetic susceptibility of the ferric ions in acidic solutions of ferric nitrate, ferric chloride, and ferric sulfate was investigated by Bose at temperatures between room temperature and the boiling point.[15] His data suggest that the structure of the ferric ion in the nitrate solution varies with the temperature, since among these three kinds of ferric ions, the ferric ion in the nitrate solution has a magnetic transition point at about 343 K (70 °C) on the $1/X$ *vs.* temperature (K) curve.

Our proposal on the compositions and structures of the polynuclear complexes can well explain the experimental results obtained by many workers. It also gives a fundamental understanding of their nature. In order to clarify the mechanism of precipitation in ferric salt solutions, it will be necessary to determine precisely the compositions and structures of the polynuclear complexes present in them.

One of us (M. K.) is indebted to Professor Yuroku Yamamoto, Hiroshima University, for suggesting this problem and to Mr. Yoshihiro Onoda for his assistance in the experiments. Thanks are also due to Drs. Toshiro Tsuji, Yoshichika Bando and Teruya Shinjo for their valuable discussions.

Isomerism of the Metal Complexes Containing Multidentate Ligands. III. Geometric and Optical Isomers of the Tris(2-methyl-1,2-propanediamine)cobalt(III) Ion[1]

Masaaki KOJIMA, Yuzo YOSHIKAWA, and Kazuo YAMASAKI

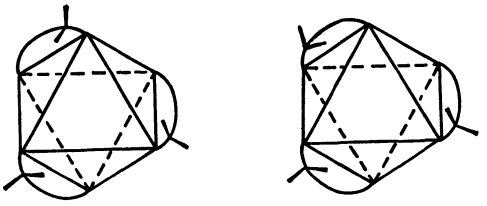
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received December 11, 1972)

The tris(2-methyl-1,2-propanediamine)cobalt(III) complex was prepared, and four possible isomers, geometrical and optical, were isolated by column chromatography on SP-Sephadex. Their configurations were assigned on the basis of the formation ratio and electronic, infrared, circular dichroism and PMR spectra: they were later confirmed by X-ray analysis.

For a tris(diamine) complex with a symmetrical bidentate ligand like ethylenediamine, only a pair of optical isomers are formed, whereas for a complex with an unsymmetrical bidentate ligand geometrical isomers can be expected in addition to optical isomers. In 1968 MacDermott[2] separated *mer* and *facial* isomers of Λ-[Co(*l*-pn)$_3$]$^{3+}$* as the chloride and bromide by the gradual evaporation of their aqueous solutions, and found that the physical properties were similar for these two isomers. More recently, Crossing and Snow[3] tried to study the *mer* isomer by X-ray structure analysis, but they failed to find good crystals for their purpose.

With unsymmetrical 2-methyl-1,2-propanediamine (*iso*-butylenediamine, abbreviated as ibn) as the ligand, the isolation and characterization of four isomers, geometrical and optical, of the tris(ibn)cobalt(III) complex will be described in this paper (*cf.* Fig. 1).



Λ(*facial*) Λ(*mer*)

Fig. 1. Geometric isomers of Λ-[Co(ibn)$_3$]$^{3+}$.

Experimental

Measurements. All the measurements were done in the same way as in the previous papers.[1]

Ligand. The *iso*-butylenediamine was obtained from the Aldrich Chem. Co., U.S.A., and was used without further purification.

Preparation of the Complex. To 3.8 g (10 mmol) of [CoBr(NH$_3$)$_5$]Br$_2$ suspended in 50 ml of water, 3 g (34 mmol) of the ligand was added. After 0.5 g of active charcoal had been added, the mixture was stirred for several days at room temperature; the brown solution thus obtained was directly subjected to column chromatography on SP-Sephadex after the removal of the charcoal.

Chromatographic Separation of the Isomers. A column chromatographic method on ion-exchange Sephadex developed by us[4] was used to separate and, at the same time, resolve the isomers. The SP-Sephadex C-25 used was a product of Pharmacia, Sweden, which has sulfopropyl groups as the cation-exchange group. An SP-Sephadex column of ϕ2.7 cm × 130 cm was prepared; on the top of the adsorbent layer, the same SP-Sephadex, saturated in advance with the prepared complex solution, was poured so as to make a layer about 5 mm thick. As the eluent we used a 0.15 M sodium (+)$_{589}$-tartrate solution with an elution velocity of 0.4—0.5 ml per minute. Under these conditions, 7—10 days were required for the complete elution of the complex, which produced three separate bands, I, II, and III (Fig. 2). The effluent was separated into fractions of 15 ml each, and the absorbance of each fraction at 475 nm (cell thickness, 1 cm) was plotted against the volume ratio of the effluent (V) *versus* the bed volume of the column (V_t=750 ml). The isomers corresponding to the fastest and

Table 1. Chemical compositions of the isomers

Complex	Elemental analyses (Calcd. value)			
	Co (%)	C (%)	H (%)	N (%)
A: $[Co(ibn)_3]Cl_3 \cdot 4H_2O$	11.84 (11.74)	28.71 (28.72)	8.53 (8.84)	16.87 (16.75)
B: $[Co(ibn)_3]Cl_3 \cdot 3H_2O$	12.11 (12.18)	30.08 (29.79)	7.84 (8.75)	17.15 (17.37)
C: $[Co(ibn)_3]Cl_3 \cdot 4H_2O$	11.85	29.06	8.35	17.03
D: $[Co(ibn)_3]Cl_3 \cdot 3H_2O$	11.84	29.76	8.02	17.04

middle peaks, I and II, were named A and B respectively. All these fractions were optically active, the signs of both I and II being plus, and that of the slowest III being minus for the Na-D line; their area ratio was 3 : 1 : 4. As the III peak had a small shoulder and seemed to be a mixture of isomers, the fractions corresponding to the III peak were diluted 4—5 times with water; then they were again adsorbed on SP-Sephadex, this time a 0.3 M sodium $(+)_{589}$-tartratoantimonate(III) being used as the eluent. The elution curve showed two peaks; these isomers were named C and D respectively (Fig. 3). Thus, the area ratio of the four peaks corresponding to the A, B, C, and D isomers was 3 : 1 : 3 : 1; no further separation was possible, not even by repeated chromatography.

Purification of the Isomers. The isomers separated as the tartrates and tartratoantimonates(III) were converted into chlorides by adsorption on SP-Sephadex, followed by elution by a 1 M sodium chloride solution. These chlorides were precipitated as hexacyanocobaltates; they were then again converted into chlorides by the anion-exchange resin, as has been described before.[1] The four isomers have the chemical compositions shown in Table 1.

Effects of Eluents on the Separation Order of the Isomers. As we have described above, these four isomers were eluted by sodium $(+)_{589}$-tartrate in the order of A, B, and (C+D); the subsequent separation of the last mixture into C and D was accomplished by sodium $(+)_{589}$-tartratoantimonate(III). If sodium $(+)_{589}$-tartratoantimonate(III) was used first, the order of separation was A, C, and (B+D), and the last mixture was further separated by sodium $(+)_{589}$-tartrate. Thus, sodium $(+)_{589}$-tartratoantimonate(III) is effective in separating geometric isomers, whereas sodium $(+)_{589}$-tartrate is effective in separating optical isomers. Sodium $(+)_{589}$-tartratoarsenate(III) was prepared and tested for separation with the same results as for sodium $(+)_{589}$-tartratoantimonate(III).

Results and Discussion

Absorption (AB) and Circular Dichroism (CD) Spectra. In Fig. 4 the AB and CD spectra of the B isomer are shown, while Tables 2 and 3 list their data. The maximum of the octahedral $^1T_{1g} \leftarrow {}^1A_{1g}$ absorption (480 nm) is at a longer wavelength than the $[Co(en)_3]^{3+}$ (467 nm) and Λ-$[Co(l\text{-pn})_3]^{3+}$ (467 nm) ions; the shift may be due to the two methyl groups of the ligand, since one of them is forced to be in the axial position regardless of the chelate-ring conformation(δ or λ). The CD band corresponding to the first absorption band is at 494 nm ($\Delta\varepsilon$=3.00), which splits into two at 503 nm ($\Delta\varepsilon$=2.16) and 450 nm ($\Delta\varepsilon$=−1.08) upon the addition of sodium phosphate, the presence of the

A_2 component being disclosed (Fig. 4). At the same time, a new CD band appears at 266 nm ($\Delta\varepsilon=0.98$) which corresponds to the charge-transfer absorption due to ion-pair formation. This CD band is characteristic of the *lel* conformation, and has never been observed for an *ob* conformation like *Δ*-$[Co(d\text{-pn})_3]^{3+}$ ion.[5] The CD spectrum of the A isomer is almost the same as that of B (Table 3). The C and D isomers show almost the identical CD spectra, with the sign opposite to that of the B isomer. The AB and CD spectral data of the four isomers are listed in Tables 2 and 3 respectively.

Infrared Spectrum. The infrared spectrum of the A isomer is slightly different from that of B in shape and position, but it is difficult to assign their configurations on the basis of the infrared spectrum alone. Some characteristic bands are listed in Table 4.

PMR Spectrum. As the *facial* isomer has a threefold axis and three equivalent chelate rings, two PMR signals due to the equatorial and axial methyl groups are expected to appear in the methyl region. On the other hand, the *mer* isomer, which has neither equivalent chelate rings nor an axis of rotation, should show more complicated methyl signals, consisting of up to six peaks. Figure 5 shows the signals observed for the A and B isomers. For the B isomer, only two peaks ($\tau=8.48$, 8.73 ppm) are found, with the area ratio 1 : 1. The peak in the higher field is attributed to the axial methyl group, since the axial proton of the methylene group was found to show signals in a higher field than the equatorial one as a result of the larger shielding by the central metal for $[M(en)_3]^{3+}$ and $[M(l\text{-pn})_3]^{3+}$, where M is Ru(II), Rh(III), Co(III), or Pt(IV).[6] The complicated signals observed for the A isomer at 60 MHz were resolved into five peaks ($\tau=8.44$, 8.58, 8.68, 8.74, 8.77 ppm) at 100 MHz, with the intensity ratio of 1 : 2 : 1 : 1 : 1 suggesting that the A isomer was the *mer* isomer (Fig. 5). MacDermott[2] reported that no difference was observed for two geometrical isomers of *Δ*-$[Co(l\text{-pn})_3]^{3+}$ at 60 MHz, but recently Sudmeier *et al.*[7] have measured the 251 MHz PMR spectrum by the Co-59 decoupling technique and have found a fine structure

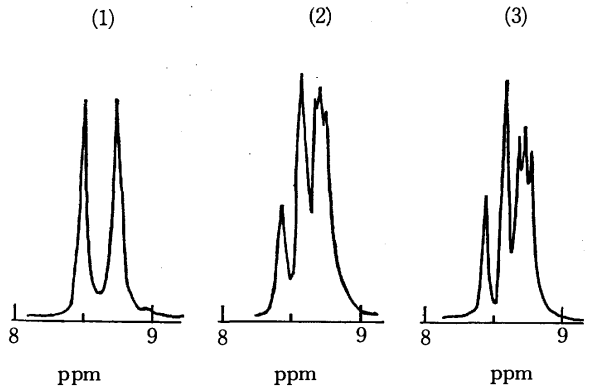

Fig. 5. PMR spectra of (1) the isomer B (60 MHz), (2) the isomer A (60 MHz) and (3) the isomer A (100 MHz) in DMSO-d_6 with TMS as an internal reference.

attributable to nonequivalent propylenediamine rings arising from the presence of geometrical isomers.

Assignment of the Structures. The configurations of the isomers isolated were assigned by means of the formation ratio and the CD and PMR spectra. The relationship between the absolute configuration and the CD spectrum of the tris(diamine)cobalt(III) complexes has been well established[8]; the complex which shows a major positive CD band in the region of the octahedral $^1T_{1g}\leftarrow{}^1A_{1g}$ absorption has the *Λ* configuration in terms of the IUPAC nomenclature. Further, the statistical formation ratio of the *mer* isomer to the *facial* isomer should be 3 : 1 under equilibrium conditions. Thus, the formation ratio, 3 : 1, actually found for the A and B isomers, both of which show a major positive CD band in the first absorption region, indicates that the A isomer is *Λ-mer* and B isomer *Λ-facial*. Similarly, the C and D isomers were identified as *Δ-mer* and *Δ-facial* respectively. The PMR spectral results support these assignments, too. The structure and the absolute configuration of the D isomer was determined by X-ray analysis[9] to be *Δ-facial* with three *lel* chelate rings, confirming the structures proposed above.

A part of the expenses was met by a Grant-in-Aid of the Ministry of Education.

Determination of Arsenic(III) by Anodic Stripping Method Using Co-deposition with Copper

Takeshi KUWABARA, Shigetaka SUZUKI, and Shun ARAKI

Department of Industrial Chemistry, Faculty of Engineering, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received June 10, 1972)

The determination of arsenic(III) by anodic stripping using co-deposition with copper was worked out. A 0.24 M hydrochloric acid containing arsenic(III) and copper(II) was electrolyzed with a rotating platinum electrode (rpm=800) at a constant current. The deposit on the electrode was stripped by linear potential sweep method in 4 M hydrochloric acid. The stripping voltammogram was recorded in the span voltage −0.2—+1.2 volt *vs.* SCE. The stripping voltammogram showed two peaks, at zero volt and 0.5 volt *vs.* SCE. The area of the second peak was proportional to the concentration of arsenic. Linear dynamic range was 1—20 microgram per milliliter. The method was rapid and simple, the time required for analysis being about 35 minutes (electrolysis temperature, 25 °C). X-ray and electron diffractions indicate that the second peak in the stripping voltammogram results from the dissolution of Cu_3As.

Stripping voltammetry was developed to increase the sensitivity of electroanalytical methods. Anodic stripping voltammetry consists of a preliminary concentration or deposition process and a dissolution or stripping (anodic oxidation) process. The deposition step is carried out for a definite time under reproducible conditions, and the stripping process mostly by means of voltammetric scanning. This method has been applied only to elements such as copper or silver, which are easily deposited alone on a working electrode.[1]

However, it is known that some elements such as arsenic and tellurium, which are hardly deposited alone on a working electrode, have been easily co-deposited with copper on a solid electrode. Some electrogravimetric analyses utilizing co-deposition of two elements have been reported.[2-6]

We have developed anodic stripping voltammetry for arsenic using co-deposition with copper. Arsenic(III) and copper were first deposited cathodically on a rotating platinum electrode, and the deposit was stripped in another electrolytic cell. The resulting stripping voltammogram showed two peaks. Arsenic was determined from the area of the second peak. Electrolysis conditions both in the stripping and deposition steps were studied, composition of the deposit being also investigated.

Experimental

Apparatus. The apparatus is shown schematically in Fig. 1. A Yanagimoto polarograph Model PA-101 was used as the source of scanning voltage and the recorder in the stripping step. A Yanagimoto controlled potential electrolyzer Model VE-3 was used as the source of constant current. A rotating platinum electrode(RPE) with surface area 0.35 cm^2 was used as a working electrode. The counter electrode was a platinum plate in the deposition step and a saturated calomel electrode (SCE) in the stripping step.

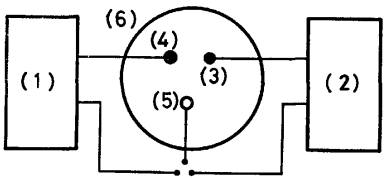

Fig. 1. Schematic diagram of anodic stripping apparatus. (1) Polarograph; (2) Galvano-stat; (3) Platinum plate electrode; (4) SCE; (5) RPE; (6) Electrolytic cell with sintered glass membrane

Reagents. Standard solution of copper: Pure copper (0.6406 g of four nine purity) was dissolved into concentrated nitric acid (7 ml). After evaporation of the solution to dryness, the residue was dissolved in 10 ml of concentrated hydrochloric acid and then the total volume was made up to 1 l. The concentration of copper was 1.008×10^{-2} M, or 0.6406 mg per ml.

Stadard solution of arsenic: A weighed amount of pure arsenic(III) oxide (0.6605 g) was dissolved in 100 ml of sodium hydroxide solution (0.46%) and acidified with concentrated hydrochloric acid. The total volume was then made up to 500 ml. One ml of this solution contained 1.000 mg of arsenic.

Deionized water was used throughout the experiment. All other reagents were of guaranteed grade.

Results

Stripping Voltammogram of Arsenic. A hydrochloric acid solution of arsenic(III) and copper(II) was electrolyzed with a RPE at a constant current of 100 mA for 30 minutes. The RPE was used as a cathode and a platinum plate as a counter electrode. The deposit on the RPE was stripped in a fresh hydrochloric acid solution by linear potential sweep method, the stripping voltammogram (SV-gram) being recorded. The range of span voltage was −0.2—+1.0 volt *vs.* SCE. The resulting voltammogram is shown in Fig. 2, curve 3, and the SV-gram obtained in the same way in the absence of arsenic, curve 2. No peak appeared in the absence of copper.

Thus, the first peak at 0 volt resulting from stripping of copper and the second peak at +0.5 volt *vs.* SCE indicate the presence of arsenic.

Experimental Conditions in the Stripping Step. The SV-gram showed two peaks resulting from dissolu-

electrolytes such as sodium sulfate, sodium chloride, perchloric acid and hydrochloric acid, the best SV-gram being obtained in hydrochloric acid solution.

The effect of concentration of hydrochloric acid on the SV-gram was examined under definite conditions in the deposition step. The results are shown in Fig. 3. We see that 3—4 M hydrochloric acid is preferable as regards the extent of the zero current range of the background (Fig. 2) and separation of two peaks in the SV-gram. Subsequent stripping was therefore carried out in 4 M hydrochloric acid.

The rotating platinum electrodes used are shown in Fig. 4. They were rotated at a constant speed by a synchronous motor. Type (a) was preferable to any other electrode because turbulence produced by rotation was less and the current more steady and reproducible. The current depends on the rate of rotation, which also affects reproducibility: the precision deteriorates if the rate of rotation is either too high or low. The rpm 800—1000 was preferable (Fig. 5). The rpm 800 was employed. The RPE was pre-

treated electrolytically in nitric acid solution by a controlled current of 400 mA. Its polarity was reversed every 5 minutes so that the electrode was in turn the anode, cathode and anode.

The electrolytic deposition was carried out from 0.25 M hydrochloric acid solution of arsenic and copper in a cell without a membrane. After deposition, the deposit was stripped in the same electrolyte. The stripping voltammogram is shown in Fig. 6, curve 1. The curve shows that a reduction current restricted by an oxidant was too large to obtain a SV-gram. The oxidant should be dissolved chlorine generated at the counter electrode during the course of deposition and diffused to the surface of the RPE. Curve 2 was obtained in a cell with a sintered glass membrane by stripping into the same electrolyte as that used in the deposition step. It is seen that the cell should have the membrane to prevent interfering electrode reaction.

Curve 3 was obtained by using 0.25 M HCl as the electrolyte in the deposition step and 0.5 M HCl in the stripping. The cell used had a membrane. The difference between curves 2 and 3 was accounted for by the change of the concentration of HCl in the stripping step. Two peaks appearing in the curve 3 were sharper than those in curve 2. Sharpness of the peak indicates the reversibility of the electrode process. Sharpness changed with the concentration of HCl. The stripping reaction seems to occur accompanied by the formation of a chloro-complex ion.

Experimental Conditions in the Deposition Step. Supporting electrolytes such as sodium sulfate, sodium chloride, perchloric acid and hydrochloric acid were used in the deposition step and the deposit was stripped under definite conditions. Hydrochloric acid was found to be the most suitable electrolyte. Under optimum conditions in the stripping step, the effect of concentration of hydrochloric acid was examined in the deposition bath containing definite amounts of arsenic and copper. Effects of concentration of the acid on the height of the second peak are shown in Fig. 7.

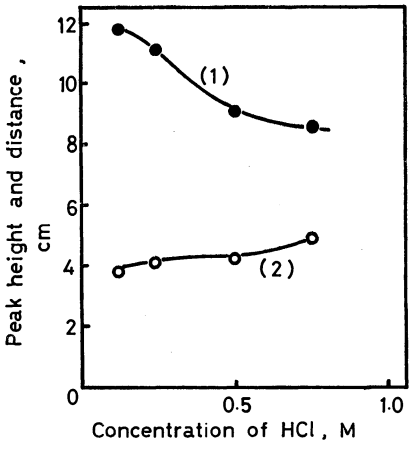

Fig. 7. Effect of concentration of HCl in the deposition step.

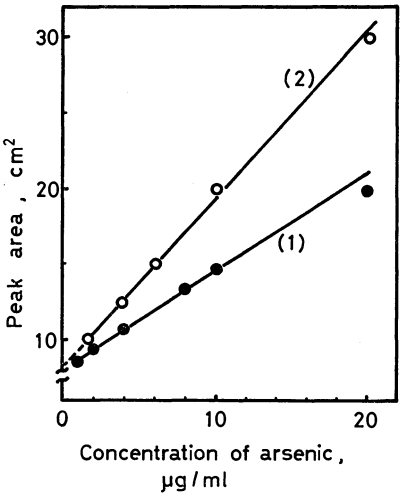

Fig. 9. Analytical curves.
Deposition: Electrolyte, 0.24 M HCl, 2×10^{-4} M Copper; Current, (1) 100 mA, (2) 150 mA
Other experimental conditions: Same as Fig. 2.

Taking into account the height of the second peak and distance between two peaks, 0.2—0.25 M hydrochloric acid solution was found to be preferable for the electrolyte in the deposition step. Hydrochloric acid of 0.24 M was employed. As regards the reproducibility of peak height, the optimum deposition current should be greater than 50 mA (current density 0.14 A/cm²). The results are shown in Fig. 8. The reproducibility deteriorated when the deposition current exceeded 150 mA. It seems that the current density 0.24—0.4 A/cm² is suitable. Current densities 0.28 and 0.42 A/cm² (100 and 150 mA, respectively) were employed.

The potential of a working electrode (RPE) was about −1.0 V *vs.* SCE at 100 mA of the deposition current.

Analytical Results. The second peak in SV-gram resulted from the presence of arsenic. A set of 0.24 M hydrochloric acid solutions containing arsenic in concentrations from 10^{-5} M to 2.6×10^{-4} M with copper (2×10^{-4} M) were prepared. Arsenic was co-deposited with copper on RPE at the constant current of 100 or 150 mA for 30 minutes. After

deposition, the deposit was stripped into 4 M hydrochloric acid by the linear potential sweep method and the SV-gram was recorded. The areas of the second peaks were calculated through the method of height times width at half height, taking zero current as the the base line (Fig. 2), and were found to be proportional to the amounts of arsenic (Fig. 9). Two analytical curves were obtained for two different deposition current densities. Arsenic was determined in the range $(1—20)\times10^{-6}$ g/ml with a relative deviation less than 10%. Analytical curves did not pass through the zero point because of the capacity current and the graphical method used for measuring the peak areas.

Discussion

Composition of the Deposit. Since it was difficult to obtain the X-ray diffraction pattern of the deposited film on the RPE directly, a platinum sheet (17 mm × 17 mm) was employed as the working electrode instead and the deposition process was carried out with different cathodic current densities, *viz.*, 0.10, 0.16, and 0.28 A/cm². The diffraction pattern was obtained with X-ray of CuK_α. It is thought that the phase structure of the deposited film is influenced not only by the cathodic potential but also the rate of cathodic reaction, but that no difference in diffraction pattern is observed with the change of current density. Thus, deposition was carried out with the current density 0.28 A/cm² for 25 hr in different solutions as follows:

(1) 2×10^{-4} M copper, 2.67×10^{-4} M arsenic (As, 2.02×10^{-5} g/ml), 0.24 M HCl

(2) 2×10^{-4} M copper, 2.67×10^{-5} M arsenic 0.24 M HCl

However, no difference in diffraction pattern was observed also in this case. Distances between planes, "*d*" values and their relative intensities were calculated from the diffraction patterns. On being compared with data from the ASTM powder data file, the results were found to indicate the presence of Cu_3As and/or Cu_2As in the deposit.

Electron diffraction pattern of the deposit showed that composition of copper arsenide in the deposit was Cu_3As, which was also the most stable in the phase diagram of Cu-As alloys.[7]

Electrode Reaction in the Stripping Step. The deposit on the RPE was first stripped at the constant potential of +0.25 volt *vs.* SCE into 4 M hydrochloric acid. The potential was satisfactory to complete the first anodic oxidation. The copper dissolved in electrolyte was determined by the spectrophotometric method with zinc dibenzyldithiocarbamate.[8] The number of coulombs in the electrode reaction were calculated from total amounts of copper dissolved and the areas under the first peaks.

Table 1. Amounts of copper in the first peak

Amounts of Cu, by colorimetry W, (μg)	Peak area (cm²)	Numbers of coulombs, Q (mC)	Valency, n[a]
36.0	39.0	56.2	1.03
35.2	37.8	54.5	1.02
32.8	36.1	52.0	1.04
39.6	42.4	61.0	1.01
39.6	41.5	59.8	1.00

Deposition: Electrolyte, 1.07×10^{-4} M arsenic in 2×10^{-4} M copper and 0.24 M HCl; Total volume, 10 ml; Current, 10 mA; Time, 28—30 min
Stripping: Scan rate, 0.21 V/min; Span volt. range, −0.2—+1.2 V *vs.* SCE

Table 2. Amounts of copper in the second peak

Amounts of Cu, by colorimetry W_1 (μg)	Peak area (cm²)	Amounts of Cu as Cu (II) by coulometry W_2 (μg)	W_2/W_1 (%)
21.8	30.2	14.3	65.5
21.0	30.0	14.2	67.6
17.8	24.8	11.8	66.3
11.8	17.0	8.1	68.5
10.8	16.3	7.7	71.0

Deposition: Electrolyte, 2.67×10^{-4} M arsenic in 2×10^{-4} M copper and 0.24 M HCl; Total volume, 10 ml; Current, 150 mA; Time, 25—32 min
Stripping: Conditions same as Table 1.

It was thought that the electrode reaction was oxidation of copper to univalent state(Table 1).

The deposit was thus stripped at the constant potential +0.75 volt *vs.* SCE into a new stripping bath of 4 M hydrochloric acid. This potential corresponded to that of completion of the second anodic oxidation. The total amount of copper dissolved into the electrolyte was determined by the spectrophotometric method and compared with the value calculated from the areas of the second peaks.

Copper was also found in the electrolyte in which the second anodic oxidation occurred, and aresnic was also detected in the electrolyte by Gutzeit's method (Table 2). The number of coulombs under the second peak was equal to two-thirds of the values calculated from oxidizing copper to copper(II) ion and did not coincide with them. The peak potential of the second peak deviated greatly from the half-wave potential in the polarography of arsenic (−0.45, or −0.88 volt) or of copper(II) (+0.03 volt *vs.* SCE) in 1 M HCl. It is considered that the second peak in the SV-gram resulted from dissolution of Cu_3As. The mechanism of the electrode reaction of the second anodic oxidation is not clarified.

Effects of Diverse Ions. The deposition of copper and arsenic was carried out in the presence of several ions by the same procedure employed in the determination of arsenic.

7) Hansen, "Constitution of Binary Alloys," 2nd Ed., McGraw-Hill, New York (1958).

8) T. Mukoyama and T. Hasebe, *Bunseki Kagaku*, **20**, 1033 (1971).

Sodium and calcium ions did not interfere in the deposition. We thought that barium would interfere in the deposition with formation of a stable alloy with copper, but no interference was observed. Zinc and nickel, however, had an effect on the area of the second peak in SV-gram.

No effects of foreign anions such as sulfate, nitrate and perchlorate ions were observed.

The authors thank Dr. Y. Tanabe for helpful discussions and suggestions in analysing X-ray and electron diffraction patterns.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1694—1698 (1973)

The Analytical Application of Sulfur Analogues of β-Diketones. II. The Separation of Mercury(II), Cobalt(II), and Zinc(II) as Their STTA (1,1,1-Trifluoro-4-(2-thienyl)-4-mercaptobut-3-en-2-one) Complexes by Extraction Chromatography

Takaharu HONJO and Toshiyasu KIBA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa, Ishikawa 920

(Received November 10, 1972)

The behavior of trace amounts of mercury(II), cobalt(II), and zinc(II) in liquid-liquid extraction have been investigated with 1,1,1-trifluoro-4-(2-thienyl)-4-mercaptobut-3-en-2-one in cyclohexane, and the results applied to the separation of the three metals as their STTA complexes by extraction chromatography. A chromatographic column in which 10^{-3} M STTA in cyclohexane supported on Kel-F(poly-trifluorochloroethylene) powder was the stationary phase has been employed throughout this work. After the metal ions had been retained on the column by passing a sample solution of pH 5.5—6.0 through the column, the zinc(II) was eluted with an aqueous solution of pH 5.0 and then the mercury(II) was eluted with 1M hydrochloric acid. Last of all, since the cobalt had been caught so tightly on the column that it could not be removed even with concentrated hydrochloric acid, acetone was poured down the column in order to wash down all the organic phase together with the cobalt. The relation between the extraction chromatography and the liquid-liquid extraction in batches has been discussed with regard to the metal-STTA system under the same conditions.

In recent years, extraction chromatography has received increasing interest as a powerful technique in the separation of various metal ions.[1] In this chromatography, the stationary phase is an organic extractant held on an inert support, while the mobile phase is a sample solution itself or an aqueous solution adjusted to an adequate condition. By this attractive method, it is possible to separate effectively inorganic compounds despite their low separability; further, it is a means of clarifying the extraction mechanism of the separation process. Because the extraction and back-extraction may recur many times throughout the chromatographic process, the separation of the difficultly-separable compounds can be achieved. The process is closely related to the ordinary batch extraction, so the optimum conditions for the chromatographic separation may be predicted from the distribution ratio (of the compound) given by the liquid-liquid extraction of the same system.

In extraction chromatography, the extraction systems involving ion association have been frequently applied, but the chelate extraction systems only rarely. For example, dithizone, TTA (thenoyltrifluoroacetone), and α-hydroxyoxime have been used in the extraction chromatography of several metal ions: In,[2,3] Zn,[4,5] and Hg,[6] by dithizone, some radio isotopes,[7] by dithizone; Fe–Co,[8] by dithizone; alkaline earth,[9] by TTA; alkali metals,[10] by TTA; Am–Ce–La,[11] by TTA and Cu,[12] by α-hydroxyoxime.

In this investigation, the behavior of trace amounts of mercury(II), cobalt(II), and zinc(II) in solvent extraction with STTA in cyclohexane has been examined in detail; in consequence, the separation of these metals has been achieved by extraction chromatography under the optimum conditions established by the present authors.

Experimental

Apparatus. A glass chromatographic column used was of 1 cm in diameter and 20 cm in length, with a coarse glass frit and a stopcock on the bottom and a separation funnel as an eluent reservoir on the top. The effluent was collected in fractions by means of a Toyo Kagaku Sangyo fraction collector, Model E–E, holding 200 tubes. The scintil-

lation counter, the pH meter, the shaking machine, and the spectrophotometer were ordinary ones.

Materials. The Daiflon-300 (trade name of polytrifluorochloroethylene) moulding powder, which is non-inflammable, exceptionally stable, and resistant to temperature as well as to chemicals, was purchased from Daikin Kogyo KK. The material was dried at 80 °C, stored in a silica gel desiccator, and then ground with a mixing grinder; the particles were then collected between 42 to 80 mesh by sieving them through screens. The STTA was synthesized by a modification by the present authors of the method reported by Berg and Reed.[13] The chlorides of such radioisotopes as ^{60}Co, ^{203}Hg, and ^{65}Zn were purchased from the Radiochemical Centre, Amersham, England, and from the New England Nuclear Corp., U.S.A. The cyclohexane was purified by distillation. All the other reagents were reagent-grade materials and were used without further purification.

Extraction. Extraction was carried out for a buffered solution containing a radioactive tracer (in a concentration of a few ppm); the solution was made to have 0.1 M acetic acid (in the acidic region) or 0.1 M boric acid (in the basic region), and its pH was adjusted to an appropriate value with a 0.1—1 M hydrochloric acid or a 0.1—1 M sodium hydroxide solution. Five or ten milliliters of this solution and an equal volume of 10^{-3} M STTA in cyclohexane were put in a 30-ml glass-stoppered centrifuge tube and shaken by means of a shaking machine (300 rpm in an amplitude of 4 cm) for 2—60 min at room temperature (25—29 °C). After centrifugation, an 3-ml aliquot of each phase was pipetted out into a test tube (14 mm in diameter), and the radioactivity was counted with the NaI(Tl) scintillation counter. The pH of the aqueous phase after the extraction was again measured.

Back Extraction. A 5-ml aliquot of an organic phase which had been prepared by the standard extraction procedure was shaken with a 5-ml portion of an aqueous solution adjusted to the desired pH for 2—60 min at room temperature.[14] The distribution was determined as in the case of the extraction.

Preparation of the Column and the Procedure in Extraction Chromatography. To 5 g of Kel-F powder of 42—80 mesh, a 20-ml portion of a solution containing 10^{-3} M STTA in cyclohexane was added; the mixture was then stirred in a small 100-ml beaker until it became homogeneous. Then, a 10-ml portion of distilled water adjusted to the desired pH and pre-equilibriated with a small portion of the 10^{-3} M STTA cyclohexane solution was added, and finally the mixture was allowed to stand for an hour.

After the excess of STTA-cyclohexane solution had been taken off by decantation, the mixture was poured into a column which had been filled with an eluting solution; the voids were eliminated by gently pressing the column with a glass rod. During the course of this manipulation, the stop cock was opened a little to make the eluting solution flow through the column spontaneously. Then, the stop cock was closed and the column was again filled with the eluting solution. These procedures were repeated so as to prevent the loss of the cyclohexane solution. The chromatographic column bed thus prepared (20 cm in height) was washed with 200 ml of pre-equilibrated water coming from the reservoir fitted at the top of the tube in order to eliminate the excess organic solution. Two milliliters of a solution containing a trace amount of radioisotopes were then poured onto the column, the metals were retained on the column by passing through an aqueous solution of pH 5.5—6.0 at a flow rate of 0.2 ml/min, and then the metals were released from the column by passing through at 0.5 ml/min, the eluting solution adjusted to the desired condition. The effluent was collected in 5-ml fractions by means of the automatic fraction collector, and the chromatographic behavior of the metals was examined by counting the radioactivity of each fraction.

Theoretical

Solvent Extraction. In the extraction system of divalent metal(M^{2+})–HR(STTA)–diluent(cyclohexane), the net distribution ratio of a metal, D, and that of the back-extraction, D^*, are generally described as follows:

$$D = \frac{(MR_2)_0}{\sum_{m=0}(MR_m^{(2-m)+}) + \sum_{i=0}(M(OH)_i^{(2-i)+}) + \sum_{j=0}(MX_j^{(2-j)+})} \quad (1)$$

$$D^* = 1/D \quad (2)$$

where ( ) and ( )$_0$ designate the concentration of chemical species in the aqueous phase and in the organic phase respectively, and where $M(OH)_i^{(2-i)+}$ and $MX_j^{(2-j)+}$ indicate the metal hydroxocomplexes and the water-soluble complexes formed with a masking agent, etc. The percentage of extraction, $\%E$, and the percentage of back-extraction, $\%E_{Back}$ were calculated by means of the following equations:

$$\%E = \frac{D}{(V/V_0)+D} \cdot 100 \quad (3)$$

$$\%E_{Back} = 100 - \%E \quad (4)$$

where V and V_0 are the volumes of the aqueous and the organic phase respectively.

Extraction Chromatography. The partition on the column, based on the theory of Martin and Synge,[15] seems to correspond to the counter-current system consisting of a series of plates. It has been demonstrated that the distribution ratio of metals in the extraction chromatography, D**, can be related by the following equation[15,16]:

$$D^{**} = \frac{V_m - V^*}{V_0^*} \quad (5)$$

where V_m is the volume of the eluate to the maximum of the eluted metal concentration, where V^* is the volume of the mobile phase, and where V_0^* is that of the stationary phase. In extraction chromatography, the extraction and the back-extraction of metals between the organic phase and the aqueous phase should be repeated many times; the $\%E$ and the $\%E_{Back}$ of metals in the column can be expressed by the following equation:

$$\%E = \frac{D^{**}}{(V^*/V_0^*)+D^{**}} \cdot 100 = \left(1 - \frac{V^*}{V_m}\right) \cdot 100 \quad (6)$$

If the extraction equilibrium is ideal and is attained

rapidly at any interval under certain extraction conditions, it may be established that $D=1/D^*=D^{**}$ and that $\%E=100-\%E_{Back}$ between the solvent extraction and the extraction chromatography.

Results and Discussion

The symbols in all the figures, A→O and O→A respectively, denote the extraction and the back-extraction of chemical species.

Distribution of STTA. The STTA in cyclohexane showed its absorption maximum at 365 nm and a molar absorption coefficient of 1.90×10^4.[13] The absorption spectra of STTA in cyclohexane and in an aqueous phase after the shaking of 10 ml of the 10^{-3} M STTA cyclohexane solution with 10 ml of an aqueous solution of pH 6.0 are shown in Fig. 1. The content of STTA in the aqueous solution was estimated by conventional spectrophotometry to be

Shaking time: 30—60 min.

3×10^{-5} M. The percentage of the back-extraction of STTA in cyclohexane as a function of the pH is shown in Fig. 2. The STTA was found to transfer itself partially into an aqueous solution from the cyclohexane phase at pH 6.0 and completely above pH 9.5. In the column extraction, an aqueous solution containing the metal ion to be extracted is always in contact with the fresh organic solvent on the column; the STTA in the organic phase will gradually dissolve in the aqueous phase and will be taken away from the extraction systems. Therefore, the eluting solutions should be pre-equilibrated with the STTA cyclohexane solution. The STTA was stable in both the aqueous and the organic phases for at least 10 hours under the present experimental conditions.

Liquid-liquid Extraction of Mercury(II), Cobalt(II), and Zinc(II). The extraction and the back-extraction of trace amounts of mercury(II), cobalt(II), and zinc(II) by 10^{-3} M STTA in cyclohexane were carried out; the results are shown in Fig. 3 as a function of the pH of the aqueous phase. It is enough to keep the concentration of 10^{-3} M STTA in cyclohexane to achieve the quantitative extraction of trace amounts of these metal ions in the acidic regions.[13,14] The extraction curves, show that the quantitative extractions of these metals are attained above pH 1.0 (Hg), pH 4.5 (Co), and pH 6.0 (Zn) respectively. The back-extractions of Hg and Zn from the organic phase were complete below pH 0 (1 M HCl) and pH 3.5 respectively, while that of Co is impossible in any pH region as has been described in the preceding paper.[13] The curves of the extraction and back-extraction of Hg and Zn obtained in the present extraction system were identical, indicating that the extraction equilib-

rium is reached within 30 minutes. The extraction and the back-extraction curves in Fig. 4 also demonstrate that the time required to reach the equilibrium is within 5 minutes in the extraction of the STTA chelates of Hg and Zn. The extraction of Co is quite rapid at pH 6.0, while it is quite show at pH 3.0, as can be seen in Fig. 4. The optimum pH for the extraction of Co into the STTA–cyclohexane seems to be above pH 5.5. However, the back-extraction of cobalt did not occur at all with any hydrochloric acid solution.[13] The extraction of cobalt(II) seemed to be accompanied by a transformation of the $Co(STTA)_2$ into an inert complex such as $Co(STTA)_3$.[14] The ratio of the volume of the stationary phase to the mobile phase in the extraction chromatography was 2.6 : 1, so the effect of the volume of the aqueous and organic phases in batch extraction was studied. When the volume of the aqueous phase was kept at 5 ml, when that of the volume of the organic phase of 10^{-3} M STTA in cyclohexane was varied from 5 ml to 15 ml, and when the $\%E$ and the $\%E_{Back}$ of metals were measured after every extraction, almost the same results were obtained in each case, as Figs. 3 and 4 show.

The Volume of the Stationary Phase. The volume of the stationary phase was determined by the following three methods: 1) In an Erlenmyer flask fitted with a glass stopper, 20 ml of a cyclohexane solution, 10 ml of distilled water, and 5 g of Kel–F powder were mixed together for a few minutes, and then the mixture was allowed to stand for one hour at room temperature. The unadsorbed solvent was subsequently drained through a small glass filter into a measuring cylinder placed in a slightly evacuated vessel. The difference between the volume of the cyclohexane solution initially taken and that measured in the cylinder showed the volume of the solvent adsorbed on the Kel–F. 2) Twelve milliliters of a cyclohexane solution, 10 ml of an eluting solution, and 5 g of Kel–F were put in a vessel with a stopper; the mixture was mixed well until it became homogeneous, and then it was allowed to stand for one hour. The slurry was then poured into the column tube and gently packed with a glass rod so as to be homogeneous. The column was then washed with 200 ml of the eluting solution at the flow rate of 2—3 ml/min, after which the excess of the solvent on the column was brought down into a receiver and the volume of the released solvent was measured by means of a measuring cylinder. The difference between the volume of the organic solvent initially taken and that of the released showed the volume of the stationary phase in ml. 3) The organic solution remaining on the column was completely taken out by passing 50 ml of acetone through the column, followed by washing with 100—150 ml of the eluting solution. All of the effluent was collected in a 250 ml flask fitted with a glass stopper, and shaken by hand so as to separate the two phases clearly. The volume of this organic phase seems to be the volume of the stationary phase of the column. The average of the values determined by the three methods was 9.3 ml for the stationary phase.

The Volume of the Mobile Phase. The space volume of the mobile phase of the column was determined by the elution of a ^{60}Co tracer in 0.1 M hydrochloric acid. The column bed was prepared in a glass tube as has been described above, and the eluting solution was drained until the liquid surface came just to the top of the column bed. One drop of a 0.1 M HCl solution containing ^{60}Co in a tracer quantity was placed at the top of the column bed, and the solution was eluted with the 0.1 M hydrochloric acid solution at the flow rate of 0.12 ml/min. Each five-drop portion (0.3 ml) of the effluent was collected in a test tube, and its radioactivity was counted by means of a NaI(Tl) scintillation counter. The volume of the eluting solution to the maximum peak of the elution curve of ^{60}Co appears to indicate the volume of

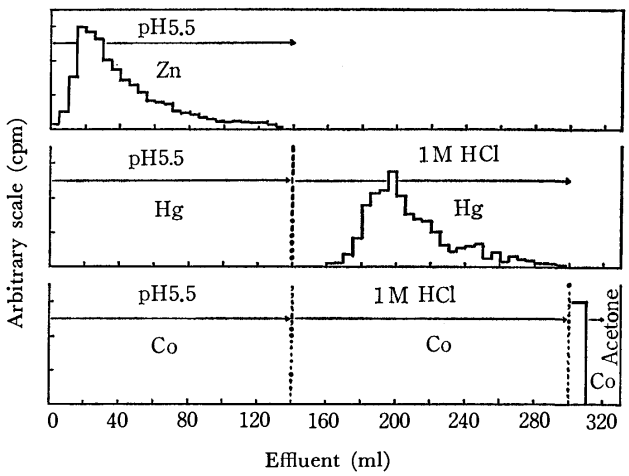

Fig. 5. Individual elution behavior of a trace amount of mercury(II), cobalt(II), and zinc(II) on a 10^{-3} M STTA–cyclohexane-Kel-F column.

the mobile phase in the column. The mean value of the mobile phase, as determined by the present method was 3.6 ml.

Chromatographic Behavior of Mercury(II), Cobalt(II), and Zinc(II). The chromatographic behavior of each metal ion was examined by loading 2 ml of a test solution containing only its radioactive tracer after it had been adjusted to pH 5.5. The results are shown in Fig. 5, in which Zn(II) is found to be completely eluted with 140 ml of the eluting solution of pH 5.5, while Hg(II) and Co(II) did not appear in the effluent under these conditions. When the eluting solution of 1 M HCl was passed through the column, Hg(II) was released in 160—300 ml of the effluent, while all of the cobalt was strongly held in the stationary phase as it was. The cobalt was not eluted even with a concentrated HCl solution, as could have been predicted from the extraction behavior. Therefore, the cobalt was finally washed down as metal chelates in cyclohexane by passing acetone through the column.

Mutual Separation of Mercury(II), Cobalt(II), and Zinc(II) from a Mixed Solution. Taking advantage of the results of the chromatographic behavior of an individual ion, the separation of the three metal ions from the mixed solution was carried out; the elution scheme is shown in Fig. 6. The cobalt was retained entirely on the column, while the zinc(II) was completely eluted with an aqueous solution of pH 5.0, and the mercury(II), with a 1 M HCl solution. Last of all, the cobalt was collected as metal chelates in the cyclohexane solution by passing acetone through the column. The average recovery for the three metal ions was 99.9%.

TABLE 1. $\%E$ AND $\%E_{Back}$ OF MERCURY(II), COBALT(II), AND ZINC(II) OBTAINED FROM THE EXTRACTION AND ELUTION CURVES

Metal	Acidity	Liquid-liquid extraction			Extraction chromatography
		$\%E$	$\%E_{Back}$		$\%E$
			Found	Calc.	
Zn	pH 5.5	85.0	26.0	15.0	79.4
Hg	1 M HCl	4.5	96.2	95.5	93.7
Co	12 M HCl	0.0	not back extracted		not eluted

The Relation of the Extraction Chromatography to the Liquid-liquid Extraction. The precentage of extraction ($\%E$) and the percentage of back-extraction ($\%E_{Back}$), as obtained from the liquid-liquid extraction and the extraction chromatography of the metals, are given in Table 1. The $\%E$ of zinc(II) which was obtained by means of liquid-liquid extraction differs somewhat from the value estimated by means of extraction chromatography, while that of mercury(II) is quite different in the two methods. Moreover, the $\%E_{Back}$ of Zn(II) and Hg(II) deviated a little from the theoretical values. These facts indicate that the ideal extraction equilibrium was not strictly established in either the batch or column extraction of the metal-STTA-cyclohexane system. A similar henomenon has been observed in alkali earth metal-TTA-MIBK systems.[9] This apparent discrepancy may be caused by the differences in the contact times of the two phases and/or by the time-lag in the complex formation in the extraction and the back-extraction processes.

Trinuclear Intermediates Isolated in the Reactions of Bis(acetylacetonato)-nickel(II) with Dry Hydrogen Bromide

Kiyoshi Isobe, Kenichiro Noda,* Yukio Nakamura, and Shinichi Kawaguchi
Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received September 25, 1972)

The reactions of bis(acetylacetonato)nickel(II) with restricted amounts of dry hydrogen bromide have been performed in appropriate mixtures of dichloromethane and petroleum ether at room temperature or lower in order to isolate the intermediary products, $Ni_3Br(acac)_5$, $Ni_3Br_2(acac)_4$, and $Ni_3Br_4(acac)_2$. The essentially octahedral trinuclear structure of $Ni_3Br(acac)_5$ was established on the basis of elemental analysis, by molecular-weight and magnetic-moment determinations, and by studying the electronic and IR spectra. $Ni_3Br_2(acac)_4$ and $Ni_3Br_4(acac)_2$ were characterized less satisfactorily because of their lower solubilities. The reactions of these mixed complexes with pyridine have also been examined; a new complex $NiBr(acac)(py)_3$ was thus obtained in addition to the known compound, $Ni(acac)_2(py)_2$.

As an extension of our studies of the reactions of various metal acetylacetonate complexes with bromine,[1-6] we have examined the reaction between bis(acetylacetonato)nickel(II) and bromine in dichloromethane.[7] Bis(acetylacetonato)cobalt(II) is known to exist as a tetrameric molecule in crystals[8] and to be trimeric in non-coordinating solvents.[9,10] Oligomeric mixed cobalt(II) complexes containing bridging acetylacetonate anions, such as $Co_3(acac)_6(H_2O)$,[11] $Co_2(acac)_4(py)$,[10] and $Co_2(acac)_4L_2$, where L is water,[12] pyridine,[10] or cyclohexylamine,[13] have also been reported. In a reaction of bis(acetylacetonato)-cobalt(II) with an equimolar amount of bromine in dichloromethane at 0 °C, a dimeric mixed complex, $Co_2Br_2(acac)_2$, was isolated,[6] but no other tetrameric or trimeric intermediary compound has yet been identified.

The trimeric nature of anhydrous bis(acetylacetonato)nickel(II) has also been well established for crystals[14] and in non-donor solvents,[15] The relative stabilities of the trimeric structure of $M(acac)_2$ in non-coordinating solvents are considered to be in the following order:[16] Ni(II)>Co(II)>Mn(II)>Zn(II). Thus, the reaction of bis(acetylacetonato)nickel(II) with bromine was expected to afford some trinuclear intermediary products preserving the bridging acetylacetonate anions. In fact, novel mixed complexes, $Ni_3Br_2(acac)_4$ and $Ni_3Br_4(acac)_2$, were obtained by the reactions of $Ni_3(acac)_6$ with restricted amounts of bromine in dichloromethane.[7] In such reactions monobromoacetylacetone is also produced; it is neither volatile nor stable, and gives some trouble in the purification of intermediates. To avoid this difficulty, hydrogen bromide was employed in place of bromine. Acetylacetone is produced instead, but the general pattern of the reaction is the same as with bromine.[2,3]

In the reaction of bis(acetylacetonato)nickel(II) with dry hydrogen bromide in dichloromethane, another trinuclear intermediary product, $Ni_3Br(acac)_5$, was obtained.[17] This paper will report in detail on the isolation and characterization of these three trinuclear complexes.

Experimental

Materials. Bis(acetylacetonato)diaquonickel(II) prepared by the method of Charles and Pawlikowski[18] was recrystallized three times from methanol, and then dehydrated to anhydrous $Ni_3(acac)_6$ by heating it at 100 °C *in vacuo* for 4 hr (Found: Ni, 23.45; C, 45.63; H, 5.55%). Dichloromethane was purified and dried by the standard method.[19] Hydrogen bromide was generated by a reaction between tetraline and bromine, and was dissolved in purified dichloromethane.[2] Petroleum ether was distilled over metallic sodium, and a fraction distilled at 40—50 °C was used. For optical measurements, the petroleum ether was purified according to the method of Tonberg and Johnston.[20] Pyridine was freshly distilled before use.

Reactions of Bis(acetylacetonato)nickel(II) with Dry Hydrogen Bromide. Bis(acetylacetonato)nickel(II) was dissolved in a mixture of dichloromethane and petroleum ether in

a three-necked flask equipped with a burette, a glass tube containing phosphorus pentoxide, and another glass tube connected to filtration equipment by means of polyethylene tubing. With vigorous magnetic stirring, a dichloromethane solution of hydrogen bromide (*ca.* 0.1 M) was gradually added from the burette. The precipitate thus formed was transferred *via* the polyethylene tubing to a vacuum filtration apparatus set up in a desiccator containing phosphorus pentoxide. When no precipitate was separated, the solvent was evaporated to some extent to obtain a precipitate.

If enough amount of hydrogen bromide is used, the ultimate product of the reaction is nickel(II) bromide (Found: Ni, 26.60; Br, 72.67%. Yield: 99%). However, when a restricted amount of hydrogen bromide is employed, three kinds of intermediary products are obtained, depending on the reactants' mole ratio. In each case, a mixed solvent containing appropriate portions of dichloromethane and petroleum ether was used to discriminate a desired intermediary product from other species.

Bromopentakis(acetylacetonato)trinickel(II), $Ni_3Br(acac)_5$. Two grams (2.6 mmol) of $Ni_3(acac)_6$ were dissolved in 200 ml of a mixture of dichloromethane and petroleum ether (1 : 10 by volume). Into this solution vigorously stirred, we then added, drop by drop, 26 ml of a dichloromethane solution of hydrogen bromide (2.6 mmol) from the burette. The solution was green throughout the reaction, showing no remarkable change. The solvent was evaporated up to about one fifth in volume, thus producing a green precipitate. Found: Ni, 23.21; Br, 10.24; C, 40.01; H, 4.86%. Calcd for $C_{25}H_{35}O_{10}BrNi_3$: Ni, 23.41; Br, 10.63; C, 39.91; H, 4.66%. Yield: 80%.

The $Ni_3(acac)_6$ reactant is highly soluble in dichloromethane and does not precipitate even when a solution of the same concentration as above is concentrated to one twentieth in volume. The possibility that the above reaction product may be a mixture of unreacted $Ni_3(acac)_6$ and some product can thus be rejected.

Dibromotetrakis(acetylacetonato)trinickel(II), $Ni_3Br_2(acac)_4$. (1) Two grams (2.6 mmol) of $Ni_3(acac)_6$ was dissolved in 100 ml of a mixture of dichloromethane and petroleum ether (2 : 15 by volume), and was then kept at $-5\sim-10$ °C by cooling with ice and salt. To this solution we then gradually added a 0.1 M solution of hydrogen bromide (5.2 mmol) in dichloromethane. After about 1.5 times as many moles of hydrogen bromide had been added, a yellow-green hygroscopic precipitate began to separate out. Found: Ni, 23.39; Br, 20.65; C, 32.05; H, 4.21%. Calcd for $C_{20}H_{28}O_8Br_2Ni_3$: Ni, 24.05; Br, 21.82; C, 32.77; H, 3.82%. Yield: 85%.

(2) Alternatively, 1.5 g (2 mmol) of $Ni_3Br(acac)_5$ was allowed to react with an equimolar amount of hydrogen bromide in dichloromethane–petroleum ether (1 : 1 by volume) at $-5\sim-10$ °C. A yellow green precipitate began to appear at about the middle of the overall reaction. The analytical data and infrared spectra of this product coincide completely with those of the specimen prepared in (1). Found: Ni, 23.00; Br, 20.90; C, 32.66; H, 4.38%. Yield: 92%.

Tetrabromobis(acetylacetonato)trinickel(II), $Ni_3Br_4(acac)_2$. (1) Two grams (2.6 mmol) of $Ni_3(acac)_6$ were dissolved in 40 ml of a mixture (1 : 3 by volume) of dichloromethane and petroleum ether. To this solution we then added a dichloromethane solution of four times as many moles of hydrogen bromide with cooling at $-5\sim-10$ °C. A very hygroscopic yellow powder precipitated; this powder turned brownish yellow on drying. Found: Ni, 25.45; Br, 50.21; C, 14.77; H, 2.20%. Calcd for $C_{10}H_{14}O_4Br_4Ni_3$: Ni, 25.37; Br, 48.91; C, 17.29; H, 2.01%. Yield: 95%.

(2) In 100 ml of a mixed solvent (7 : 3 by volume) of dichloromethane and petroleum ether, 1.5 g (2 mmol) of $Ni_3Br(acac)_5$ were allowed to react with three times as many moles of hydrogen bromide at $-5\sim-10$ °C. When about half the hydrogen bromide had been added, a yellow precipitate began to appear. Found: Ni, 24.41; Br, 49.10%. Yield: 93%.

The analytical data for $Ni_3Br_2(acac)_4$ and $Ni_3Br_4(acac)_2$ are very poor due to their very hygroscopic characters.

The Reaction of Bromopentakis(acetylacetonato)trinickel(II) with Pyridine. One gram (1.33 mmol) of $Ni_3Br(acac)_5$ was dissolved in 30 ml of dichloromethane. To this solution we then added, drop by drop, 15 ml of a dichloromethane solution containing 9.31 mmol of pyridine. The reaction mixture was kept standing for a week in a desiccator equipped with a glass tube containing calcium chloride. The solvent was thus vaporized almost to dryness. Two kinds of crystals resulted. Blue-violet crystals were dissolved in benzene, but other blue crystals remained insoluble and gave the following analysis. Found: Ni, 12.74; Br, 17.10; C, 50.98; H, 4.90; N, 8.66%. Calcd for $NiBr(acac)(py)_3=C_{20}H_{22}O_2N_3BrNi$: Ni, 12.36; Br, 16.82; C, 50.52; H, 4.63; N, 8.84%. Yield: 90% on the basis of Eq. (11), which will be shown in the Results and Discussion section. The benzene solution was evaporated to dryness, and the residue was recrystallized from methanol to give blue-violet crystals. Found: Ni, 14.46; C, 57.59; H, 5.85; N, 7.02%. Calcd for $Ni(acac)_2(py)_2=C_{20}H_{24}O_4N_2Ni$: Ni, 14.14; C, 57.81; H, 5.78; N, 6.74%. Yield of crystals: 60% on the basis of Eq. (11).

The Reaction of Dibromotetrakis(acetylacetonato)trinickel(II) with Pyridine. A dichloromethane solution (20 ml) of pyridine (5.44 mmol) was added, drop by drop, to a suspension of $Ni_3Br_2(acac)_4$ (0.5 g, 0.68 mmol) in dichloromethane (30 ml). The complex was dissolved gradually with an increase in the amount of pyridine added. The blue solution was kept standing for two days in an evacuated desiccator. The residue was extracted with benzene, and the remaining blue crystals were identified by the IR assay as $NiBr(acac)(py)_3$. Yield: 20% on the basis of Eq. (12). To the benzene extract, petroleum ether was added to separate an impure, pale green precipitate; the filtrate was evaporated to give blue violet crystals which were identified by the IR assay as $Ni(acac)_2(py)_2$. Yield: 65% on the basis of Eq. (12).

The Reaction of Tetrabromobis(acetylacetonato)trinickel(II) with Pyridine. A dichloromethane solution of excess pyridine was added to a dichloromethane suspension of $Ni_3Br_4(acac)_2$. A blue solution was concentrated by evaporation to give pale blue-green crystals. Found: Ni, 10.90; Br, 30.10; C, 44.34; H, 3.86; N, 10.32%. Calcd for $NiBr_2(py)_4=C_{20}H_{20}N_4Br_2Ni$: Ni, 10.98; Br, 29.88; C, 44.91; H, 3.77; N, 10.47%. Yield: 82% on the basis of Eq. (13). The filtrate was evaporated to dryness, and the residue was recrystallized from methanol to give blue-violet crystals of $Ni(acac)_2(py)_2$. Yield: 40% on the basis of Eq. (13).

Analysis and Measurements. All the solid samples were subjected to elemental analysis after drying *in vacuo* at room temperature. Nickel and bromine were determined gravimetrically as bis(dimethylglyoximato)nickel(II) and silver bromide respectively. To determine the concentration of hydrogen bromide in dichloromethane, an aqueous solution of sodium hydroxide was added to an aliquot of the hydrogen bromide solution, and the excess alkali was titrated with 0.1 N sulfuric acid, using phenolphthalein as an indicator.

The visible and ultraviolet absorption spectra were measured by means of a Hitachi EPS-3T autorecording spectro-

photometer. The molar absorption coefficients of trinuclear complexes are expressed on the basis of the gram-atom of nickel(II). The infrared spectra were taken in Nujol on JASCO IR-E (4000—700 cm^{-1}), Hitachi EPI-L (700—200 cm^{-1}), and FIS-3 (400—30 cm^{-1}) infrared spectrophotometers.

The magnetic susceptibility was measured at room temperature by the Gouy method by means of an automatically-recording magnetic balance (Shimadzu Seisakusho Co., Ltd.). Hexaamminechromium(III) chloride and mercury-(II) tetraisothiocyanatocobaltate(II) were used as the reference compounds.

The molecular weight was determined cryoscopically in benzene by means of an apparatus manufactured by Knauer, Germany. Tris(acetylacetonato)aluminium was used as the reference.

Results and Discussion

When six times as many moles of dry hydrogen bromide were allowed to react with $Ni_3(acac)_6$ in dichloromethane, anhydrous nickel(II) bromide precipitated in a 99% yield. The UV spectrum of the filtrate showed that six times as many moles of acetylacetone were produced in this reaction, certifying the following stoichiometry.

$$Ni_3(acac)_6 + 6HBr = 3NiBr_2 + 6acacH \quad (1)$$

Here, acacH stands for an acetylacetone molecule.

The overall reaction (1) must proceed *via* several consecutive steps, and it depends on the relative rates of these elementary steps whether or not some intermediary products can be isolated and characterized. Fortunately, the trinuclear framework of $Ni_3(acac)_6$ was strong enough, and the differences among the rates of the consecutive reaction steps were large enough, for three kinds of intermediary products to be isolated in satisfactory yields and purities. The reactions producing these mixed complexes may be represented by the following equations:

$$Ni_3(acac)_6 + HBr = Ni_3Br(acac)_5 + acacH \quad (2)$$

$$Ni_3Br(acac)_5 + HBr = Ni_3Br_2(acac)_4 + acacH \quad (3)$$

$$Ni_3Br_2(acac)_4 + 2HBr = Ni_3Br_4(acac)_2 + 2acacH \quad (4)$$

In principle, two more intermediates, $Ni_3Br_3(acac)_3$ and $Ni_3Br_5(acac)$, may be expected to be involved in the course of the conversion of $Ni_3(acac)_6$ to nickel(II) bromide. However, even the tribromo-intermediate could not be obtained. The reason for this is not clear, but $Ni_3Br_3(acac)_3$ might be especially unstable compared to $Ni_3Br_2(acac)_4$ and $Ni_3Br_4(acac)_2$.

The three isolated mixed complexes show a very remarkable trend in their properties. For instance, they show intermediate colors between the green of $Ni_3(acac)_6$ and the orange of nickel(II) bromide. $Ni_3Br(acac)_5$ is quite soluble in dichloromethane, but $Ni_3Br_2(acac)_4$ is much less soluble and $Ni_3Br_4(acac)_2$ is insoluble in the same solvent. The hygroscopic character is remarkably enhanced with an increase in the content of bromine.

Properties of $Ni_3Br(acac)_5$. As is shown in Table 1, the molecular weight determined cryoscopically in benzene indicates that this is a trinuclear complex. The ultraviolet absorption spectrum in Fig. 1 and the visible absorption spectrum in Fig. 2 also support the trinuclear and essentially octahedral structure of this compound. The ultraviolet spectra of bis(acetylacetonato)nickel(II) in dry dichloromethane have recently been reinvestigated in detail;[21] the more intense absorption band at 265 nm has been attributed to the trinuclear molecule, while the low-energy band at 300 nm has been attributed to the mononuclear dihydrated species. The high-energy band of Curve 2

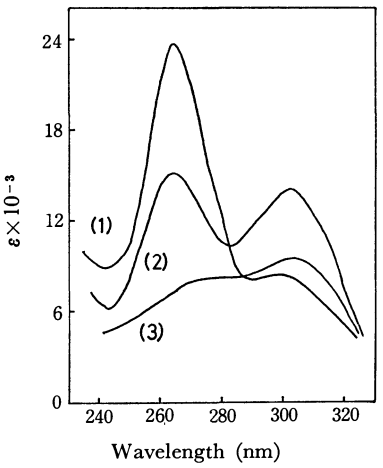

Fig. 1. The ultraviolet absorption spectra of $Ni_3(acac)_6$ (curve 1), $Ni_3Br(acac)_5$ (curve 2), and $Ni_3Br_2(acac)_4$ (curve 3) in dichloromethane.

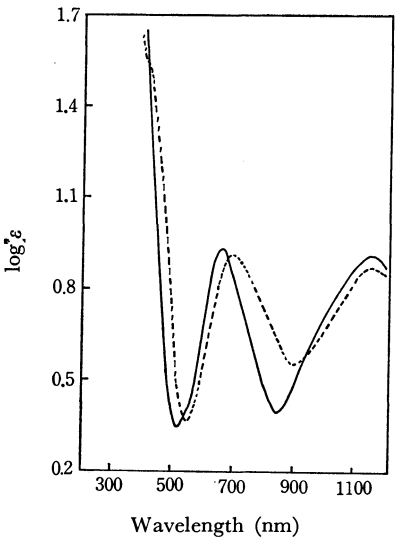

Fig. 2. The visible absorption spectra of $Ni_3(acac)_6$ (——) and $Ni_3Br(acac)_5$ (----) in dichloromethane.

in Fig. 1 indicates the existence of the trinuclear framework in $Ni_3Br(acac)_5$.

The visible absorption spectrum of $Ni_3(acac)_6$ in dichloromethane shows two maxima, at 1150 (ε=8.2) and 660 nm (ε=8.5), closely resembling the pattern in cyclohexane reported by Cotton and Fackler.[15b] The spectrum of $Ni_3Br(acac)_5$ also has two maxima, at 1140 (ε=7.4) and 695 nm (ε=8.2), revealing the essentially octahedral environment of the nickel(II) ion in this compound. The observed effective magnetic moment of 3.51 B.M. also indicates the high-spin state of the nickel(II) ion.

In order for $Ni_3Br(acac)_5$ to exist as a discrete trinuclear molecule, one of the three nickel ions must assume a pentacoordinate structure. In other words, it seems probable that one of the non-bridging acetylacetonate groups in $Ni_3(acac)_6$ was displaced by a bromide anion. The shoulder observed at 405 nm (Fig. 2) might reflect the five-coordinate nickel(II).[22] In fact, the shoulder disappeared on the addition of equimolar pyridine to the solution of $Ni_3Br(acac)_5$, presumably because of the completion of the totally octahedral structure.

As is shown in Fig. 3, the infrared spectrum of $Ni_3Br(acac)_5$ is much more complicated than that of $Ni_3(acac)_6$, suggesting the poorer symmetry of the former compound. Such a spectral feature also supports the above structural consideration.

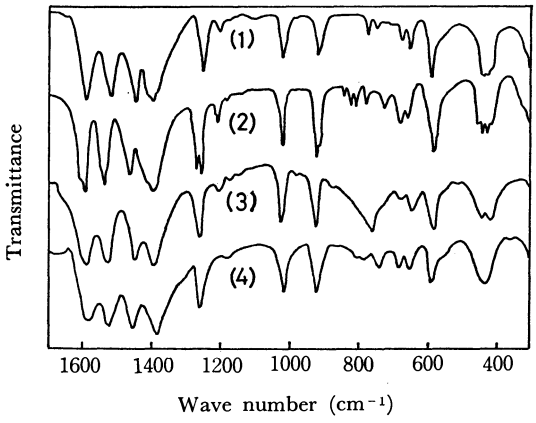

Fig. 3. The infrared absorption spectra in Nujol mull of $Ni_3(acac)_6$ (curve 1), $Ni_3Br(acac)_5$ (curve 2), $Ni_3Br_2(acac)_4$ (curve 3), and $Ni_3Br_4(acac)_2$ (curve 4).

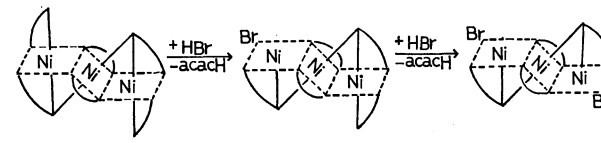
$Ni_3Br_2(acac)_4$ and $Ni_3Br_4(acac)_2$. The lower solubilities of these dibromo and tetrabromo complexes in the appropriate solvents prevented the molecular-weight determination. The ultraviolet spectrum of $Ni_3Br_2(acac)_4$ (Curve 3 in Fig. 1) has a broad band at 260—280 nm, indicating the maintenance of the trinuclear framework.

In a previous paper,[21] the peak-height ratio of the high-energy to low-energy bands for bis(acetylacetonato)nickel(II) was found to decrease with an increase in the water content of dichloromethane due to the depolymerization equilibrium:

$$Ni_3(acac)_6 + 6H_2O \rightleftharpoons 3Ni(acac)_2(H_2O)_2 \quad (5)$$

Although the three spectra in Fig. 1 were taken in dichloromethane of almost same water content (*ca.* 4.5×10^{-3} M), the low-energy band grows at the expense of the high-energy band as the bromine content of the mixed complex increases. A depolymerization equilibrium similar to (5) might be more favorable for $Ni_3Br(acac)_5$ than for $Ni_3(acac)_6$, and more favorable for $Ni_3Br_2(acac)_4$ than for $Ni_3Br(acac)_5$.

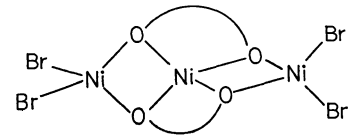
The effective magnetic moment of $Ni_3Br_2(acac)_4$ (3.38 B.M.) is appreciably lower than that, 3.51 B.M., for $Ni_3Br(acac)_5$; it is rather near to that, 3.37 B.M., for $Ni_3(acac)_6$. In the previous section it was presumed that a non-bridging acetylacetonate ligand was displaced by the attack of hydrogen bromide (Eq. (2)). If this presumption be extended to the second step of the reaction (Eq. (3)), another non-bridging acetylacetonate group will be displaced, as is illustrated by Eq. (6).



(6)

In order for $Ni_3Br_2(acac)_4$ to retain the trinuclear structure, both terminal nickel(II) ions must be in the five-coordinate environment. Of course, it is not at all clear whether a square-pyramidal or a trigonal-bipyramidal structure is preferred. The infrared spectrum of $Ni_3Br_2(acac)_4$ (Curve 3 in Fig. 3) is much simpler than that of $Ni_3Br(acac)_5$ and rather resembles that of $Ni_3(acac)_6$, indicating that the symmetry of $Ni_3Br_2(acac)_4$ is higher than that of $Ni_3Br(acac)_5$. It is very unfortunate that the visible absorption spectrum of $Ni_3Br_2(acac)_4$, which might exhibit the characteristic feature of the five-coordinate nickel(II), can not be observed because of its low solubility.

The tetrabromo-complex $Ni_3Br_4(acac)_2$ is more hygroscopic than $Ni_3Br_2(acac)_4$, and its low solubility in nondonor solvents prevented satisfactory characterization. The infrared spectrum of $Ni_3Br_4(acac)_2$ (Curve 4 in Fig. 3) is rather simple, resembling that of $Ni_3(acac)_6$. In order to retain the trinuclear structure, all three nickel(II) ions in $Ni_3Br_4(acac)_2$ must be in the four-coordinate environment. The observed paramagnetism (μ_{eff}=3.33 B.M.) clearly shows the square-planar arrangement to be impossible. Thus a tetrahedral structure such as the following may be imagined:



Adduct Formations. A methanolic solution of bis(acetylacetonato)nickel(II) shows an absorption maximum at 295 nm, accompanied by a shoulder on the longer-wavelength side. Cotton and Fackler[15b] presumed that the solute is entirely present as the sol-

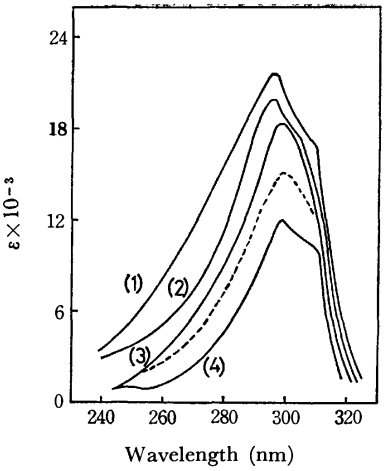

Fig. 4. The ultraviolet absorption spectra in methanol of $Ni_3(acac)_6$ (curve 1, λ_{max}=295 nm, ε=21710), $Ni_3Br(acac)_5$ (curve 2, λ_{max}=295 nm, ε=19818), $Ni_3Br_2(acac)_4$ (curve 3, λ_{max}=299 nm, ε=18560), and $Ni_3Br_4(acac)_2$ (curve 4, λ_{max}=299 nm, ε=11952). A dashed curve is a spectrum calculated for a presumed species $NiBr(acac)(CH_3OH)_3$ (λ_{max}=300 nm, ε=15885).

vated species, $Ni(acac)_2 \cdot 2CH_3OH$, which was recently prepared by the reaction of $Ni_3(acac)_6$ with methanol in petroleum ether.[21]

Fig. 4 shows the ultraviolet absorption spectra of bis(acetylacetonato)nickel(II) and of three bromo-complexes derived therefrom. All these spectra show quite a striking resemblance to each other except that the apparent molar extinction coefficient decreases with the decrease in the acetylacetonate anions involved. These spectral features clearly indicate that the trinuclear mixed complexes are also depolymerized in such a coordinating solvent, just as $Ni_3(acac)_6$ is. In analogy with Eq. (5), these reactions might be represented by the following equations:

$$Ni_3(acac)_6 + 6CH_3OH = 3Ni(acac)_2(CH_3OH)_2 \quad (7)$$

$$Ni_3Br(acac)_5 + 7CH_3OH = 2Ni(acac)_2(CH_3OH)_2 + NiBr(acac)(CH_3OH)_3 \quad (8)$$

$$Ni_3Br_2(acac)_4 + 8CH_3OH = Ni(acac)_2(CH_3OH)_2 + 2NiBr(acac)(CH_3OH)_3 \quad (9)$$

$$Ni_3Br_4(acac)_2 + 10CH_3OH = Ni(acac)_2(CH_3OH)_2 + 2NiBr_2(CH_3OH)_4 \quad (10)$$

The presumed complex, $NiBr(acac)(CH_3OH)_3$, has not yet been isolated, but its spectrum can be calculated from Curves 1 and 2 or from Curves 1 and 3 in Fig. 4. These two calculated spectra are very close to each other; an averaged curve is drawn in Fig. 4.

In order to study such depolymerization (adduct formation) reactions more precisely, the reactions of these trinuclear complexes with pyridine were examined in dichloromethane. As has been described in the Experimental section, addition products reconciled with the following equations were obtained in satisfactory yields:

$$Ni_3Br(acac)_5 + 7py = 2Ni(acac)_2(py)_2 + NiBr(acac)(py)_3 \quad (11)$$

$$Ni_3Br_2(acac)_4 + 8py = Ni(acac)_2(py)_2 + 2NiBr(acac)(py)_3 \quad (12)$$

$$Ni_3Br_4(acac)_2 + 10py = Ni(acac)_2(py)_2 + 2NiBr_2(py)_4 \quad (13)$$

The fact that $Ni_3Br(acac)_5$ gave $NiBr(acac)(py)_3$ in the reaction with pyridine supports the assumption that $Ni_3Br(acac)_5$ contains a five-coordinate nickel(II). Furthermore, the fact that $Ni_3Br_2(acac)_4$ also produced $NiBr(acac)(py)_3$ and not $NiBr_2(py)_4$ clearly indicates that the two bromine atoms are linked to different nickel atoms in $Ni_3Br_2(acac)_4$ in accordance with the formula in Eq. (6).

Bis(acetylacetonato)bis(pyridine)nickel(II) was identified by elemental analysis and by comparing the IR and electronic spectra with those in the literature.[23,24] Dibromotetrakis(pyridine)nickel(II) is also a known compound; it was identified by elemental analysis and studying its IR spectrum.[25] On the contrary, bromo(acetylacetonato)tris(pyridine)nickel(II) $NiBr(acac)(py)_3$ is a new compound. In Fig. 5, the infrared spectrum in the 100—700 cm^{-1} region is compared with that of $Ni(acac)_2(py)_2$. A combination band at 574 cm^{-1} which was previously assigned to ν(Ni–O) and ring vibrations in $Ni(acac)_2(py)_2$[24] is replaced by two peaks, at 571 and 557 cm^{-1}, in $NiBr(acac)(py)_3$, indicating weaker Ni–O bonding and poorer symmetry in the latter complex. The ν(Ni–O)+ν(CR) at 438 cm^{-1} in the former complex is also shifted to 433 cm^{-1} in the latter; a similar feature is also observed in the 200—300 cm^{-1} region. Three strong peaks are observed at 262, 247, and 235 cm^{-1} for $NiBr(acac)(py)_3$ instead of the ν (Ni–O) and ν(Ni–N) bands at 272 and 250 cm^{-1} in $Ni(acac)_2(py)_2$. It is not certain whether or not one of the three peaks in the former complex should be assigned to the ν(Ni–Br) vibration, although no other strong peak attributable to ν (Ni–Br) is noticed.

Supplemental Discussion. Fackler[26] prepared

tetrakis(acetylacetonato)pyridinedinickel(II) $Ni_2(acac)_4py$ by the reaction of $Ni_3(acac)_6$ with a restricted amount of pyridine in benzene. Bertrand *et al.* synthesized $Ni(acac)(OCH_3)(CH_3OH)$ by the reaction of $Ni_3(acac)_6$ with equimolar potassium hydroxide in refluxing methanol. This compound is tetrameric in chloroform and is isostructural with $[Co(acac)(OCH_3)(CH_3OH)]_4$, which takes a cubane-type structure.[27] However, no derivative retaining the trinuclear framework of $Ni_3(acac)_6$ has yet been reported except $Ni_3OH(acest)_5$ which was obtained by Hay and Hook[28] in the reaction between the aqueous nickel(II) ion and ethyl acetoacetate (acestH) in the presence of potassium hydroxide or ammonia. The trinuclear octahedral structure of this compound was established by the cryoscopic and spectral measurements in benzene; an OH-bridged structure was presumed on the basis of the very sharp OH stretching band at 3587 cm^{-1} and the preliminary NMR data in benzene. $Ni_3Br(acac)_5$ prepared in the present study might have a structure similar to that of this ester complex, but the possibility of a bromide-bridging contrary to the proposed structure in Eq. (6) can not be denied. The conclusive description of the molecular structures of these trinuclear mixed complexes must await X-ray studies.

We are indebted to Dr. Hanako Kobayashi of Kyoto University for her help in the magnetic measurements and also to Mr. J. Gohda for the elemental analyses. Financial aid by the Ministry of Education and the kind supply of acetylacetone by the Daicel Co., Ltd., are also acknowledged.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1704—1705 (1973)

Stability Constants of Lanthanoid(III) Complexes with 7-Bromo-8-hydroxy-5-quinolinesulfonic Acid

Gurcharan Singh MANKU
Hans Raj College, Delhi-110007, India

(Received September 21, 1971)

Stability constants of the tervalent yttrium and lanthanoid complexes with 7-bromo-8-hydroxy-5-quinolinesulfonic acid have been determined in aqueous medium containing 0.100 M sodium perchlorate at 25±1 °C by means of pH-titration. The trends in the order of the stability constants of these complexes are also discussed.

The metal complexes of 8-quinolinol have been extensively investigated, but those of 7-bromo-8-hydroxy-5-quinolinesulfonic acid do not appear to have been investigated in detail. This is especially the case with complexes with the tervalent lanthanoid ions. The present communication describes the results of pH-titration for the determination of stoichiometric stability constants K of the tervalent yttrium and the lanthanoid complexes with 7-bromo-8-hydroxy-5-quinolinesulfonic acid in aqueous solutions containing 0.100 M sodium perchlorate at 25° (±1°)C. The results indicate a stepwise formation of 1:1, 1:2, and 1:3 metal : ligand complexes. The $\log K_3$ values could not be determined with an accuracy better than ±0.8 because of the precipitate formation around $\bar{n}=1.9$—2.2.

Experimental

7-Bromo-8-hydroxy-5-quinolinesulfonic Acid was prepared from 8-quinolinol.[1] *Lanthanoid(III) perchlorate* solutions were prepared by dissolving 84—100 mg of the oxides (Johnson, Matthey & Co. Ltd., Specpure grade) in 5 ml of warm 0.84 M perchloric acid, and diluting the solutions to 100 ml with water. The concentration of perchloric acid in the metal solutions was determined by Gran's titrimetric method.[2] A 0.50 M sodium perchlorate (B.D.H.) solution was used to keep the concentration of the perchlorate ions at 0.100 M in the final solutions used for titration. *Sodium hydroxide* solution, free from carbonate, was prepared from sodium hydroxide pellets (B.D.H.) and standardized against potassium hydrogen phthalate.

Titration Procedure. The following solutions were prepared for the titration of a set of metal — ligand concentrations:

(1) 5.00 ml of E molar perchloric acid, 4.00 ml of 0.50 M sodium perchlorate, and 11.00 ml water,

(2) 5.00 ml of E molar perchloric acid, 4.00 ml of 0.50 molar sodium perchlorate, 1.00 ml of water, and 10.00 ml of T_L molar 7-bromo-8-hydroxy-5-quinolinesulfonic acid,

(3) 5.00 ml of T_M molar metal solution (prepared in E' molar perchloric acid) adjusted to E molar acid concentration (using sodium hydroxide or perchloric acid), (4.00—10 E') ml of 0.50 molar sodium perchlorate (10 E' ml of 0.50 molar sodium perchlorate solution compensating the perchlorate ions present in metal solutions, *i.e.*, for 5.00 ml of E' molar perchloric acid; E' was in the range 0.0437—0.0213 M for different metal solutions), (1.00+10 E') ml of water and 10.00 ml of T_L molar 7-bromo-8-hydroxy-5-quinolinesulfonic acid.

The value of E was kept at 1.00×10^{-3} M. Solution (1), (2), or (3) was then titrated against 1 M molar sodium hydroxide,

1) R. G. W. Hollingshead, "Oxine and Its Derivatives," Butterworths Scientific Publications (1959), Vol. 3.

2) G. Gran, *Analyst*, **77**, 661 (1962).

and the equilibrium pH of the solution at each addition of alkali was recorded. Each titration was repeated till the equilibrium pH of the solutions after each addition of alkali was found to be within 0.02 pH units. Titration of solution (3) was, however, discontinued at the appearance of opalescence in solution.

Calculations

The plots of $\bar{n}$, the ligand number, *vs.* pL, L being the equilibrium concentration of the ligand, for a metal complex were calculated from the results of titration using equations similar to those proposed by Irving and Rossotti:[3]

$$\bar{n}_h = \left(yT_L + \frac{(V_1-V_2)(N+E)}{V^0+V_1}\right)/T_L \quad (1)$$

$$\bar{n} = \frac{(V_3-V_2)(N+E+(y-\bar{n}_h)T_L)}{(V^0+V_2)\bar{n}_h T_M} \quad (2)$$

and

$$pL = -\log L = \log \frac{\sum_0^J \beta_j^H (H^+)^j}{T_L - \bar{n}T_M} \times \frac{V^0+V_3}{V^0} \quad (3)$$

where the symbols have their usual meanings.[3]

As the formation function for mononuclear complexes can be given by

$$\bar{n} = \frac{K_1L+2K_1K_2L^2+3K_1K_2K_3L^3}{1+K_1L+K_1K_2L^2+K_1K_2K_3L^3} \quad (4)$$

the corresponding stability constants K_n were calculated from the experimental points from the linear plots of the equations

$$\frac{\bar{n}}{1-\bar{n}}\cdot\frac{1}{L} = K_1 + \frac{2-\bar{n}}{1-\bar{n}}\cdot K_1K_2L \quad (5)$$

and

$$\left(\frac{\bar{n}}{2-\bar{n}}\cdot\frac{1}{L} + \frac{\bar{n}-1}{2-\bar{n}}\cdot K_1\right)\frac{1}{L} = K_1K_2 + \frac{3-\bar{n}}{2-\bar{n}}\cdot K_1K_2K_3L. \quad (6)$$

Results and Discussion

Assuming the ligand to be the bivalent anion of the unionized molecule (obtained by the ionization of the sulfonic acid and the hydroxyl groups), the *proton association constants* for the ligand were determined to be $\log K_1^H = 7.32 \pm 0.03$, $\log K_2^H = 4.38 \pm 0.03$, and $\log K_3^H$ less than 2 in aqueous solutions containing 0.100 M sodium perchlorate at 25 °C. The stability constants for yttrium(III) and lanthanoid(III) complexes with 7-bromo-8-hydroxy-5-quinolinesulfonic acid are given in Table 1.

We see that for the lanthanoid(III) complexes, $\log K$ increases regularly with the atomic number of the lanthanoid from lanthanum to europium, the values for gadolinium complexes being lower than those for the europium complexes, a trend established for the lanthanoid complexes.[4] In case of heavy lanthanoid complexes, however, two trends are observed:

(1) $\log K_1$ increases regularly from gadolinium to ytterbium,

(2) $\log K_2$ increases from gadolinium to holmium and then drops for the next members of the series.

The first trend is very common for the lanthanoid complexes. The less common second trend is also observed. This might be due to the steric factors involved in the introduction of the second ligand molecule to the 1 : 1 complex.

The $\log K$ values for lutetium complexes are lower than those for ytterbium complexes, probably due to the same factors as responsible for the gadolinium-break.

As a result of their observations on the stability constants of the lanthanoid and yttrium complexes with a common ligand, Yoneda *et al.*[5] concluded that the $\log K$ for yttrium complex is comparable to that for light lanthanoid complexes in case of monodentate ligands, but of the heavy lanthanoid complexes for multidentate ligands forming chelate structure. As expected for the present ligand, the stability constants for yttrium(III) complexes are among those of the heavy lanthanoid complexes.

The Atomic Absorption Spectrophotometric Determination of Arsenic and Selenium in Premixed Inert Gas(Entrained Air)-Hydrogen Flames with a "Multi-flame" Burner

Taketoshi NAKAHARA, Hirohito NISHINO, Makoto MUNEMORI*, and Sôichirô MUSHA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-umemachi, Sakai 591

** Laboratory of Environmental Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-umemachi, Sakai 591*

(Received August 21, 1972)

The determination of arsenic and selenium by atomic absorption spectrophotometry was established in premixed inert gas(entrained air)-hydrogen flames using a "multi-flame" burner. Arsenic and selenium electrodeless discharge lamps were used as the sources of radiation. The optimum operating conditions for the atomic absorption measurements for arsenic and selenium at 193.7 and 196.1 nm respectively were investigated. Under the optimum conditions, the sensitivities for 1% absorption were 0.17 and 0.15 ppm for arsenic and selenium respectively. Many other elements and acids interfered with the determination of arsenic and selenium in these low-temperature flames. Most of the interferences were found to be completely eliminated, in appearance, by adding a large amount (2000 ppm) of tin(II) chloride to the sample solutions. Furthermore, a gas-sampling technique for arsenic was studied in order to improve the arsenic sensitivity and in order to eliminate the interferences from other elements. The present method was applied to the determination of arsenic in sulfide ores and steels with satisfactory results.

There are two major difficulties in the determination of arsenic and selenium by atomic absorption spectrophotometry; the first is the high flame background absorption and the noise levels obtained at the resonance lines of these elements below 200 nm, and the second is the relatively low intensity and poor stability shown by many arsenic and selenium hollow-cathode lamps. By using a hollow-cathode lamp and an air-acetylene flame, the sensitivities have been reported to be 1.0 ppm for arsenic[1-3] at 193.7 nm and to be 1.0 ppm for selenium[1-4] at 196.1 nm. Later, the present authors[5] have described the determination of selenium in sulfur and obtained the sensitivity of 0.4 ppm for 1% absorption in an air-hydrogen flame with a total-consumption nebulizer-burner.

Several attempts have been made to overcome the difficulties due to the absorptions of arsenic- and selenium-radiations by the atmosphere, by optical components, and by flame gases. Arsenic and selenium may be atomized efficiently in argon-hydrogen flame[2] and nitrogen-hydrogen flame[6] burning with entrained air. These flames exhibit greater transparencies below 200 nm than do conventional air-hydrogen or air-acetylene flames, resulting in improved signal-to-noise ratios. However, the determination of arsenic and selenium in these cool flames may suffer from interferences from various foreign elements. Kirkbright and Ranson[7] have used the slightly fuel-rich nitrous oxide-acetylene flame to remove the interferences from foregin elements. Ando *et al.*[6] have employed long-path-length Vycor cells with a nitrogen(entrained air)-hydrogen flame to determine arsenic; they thus obtained the sensitivity of 0.006 ppm for 1% absorption. Massmann[8] has used an electrically-heated graphite cell in the argon atmosphere to show the possibility of determining arsenic down to 0.1 ppm. The use of electrodeless discharge lamps as an alternative to hollow-cathode lamps in atomic absorption spectrophotometry has been reported.[3,9-13] Potentially these line sources have the advantage of having a higher output intensity and a narrower emission line free from self-absorption or self-reversal; therefore, they may allow operation at low amplifier-gain and spectral-bandpass settings.

In this investigation, the determination of arsenic and selenium in premixed inert gas (entrained air)-hydrogen flames with a "multi-flame" burner[14] has been established by using arsenic and selenium electrodeless discharge lamps as sources of radiation. The performance characteristics of the electrodeless discharge lamps, the interferences, and their elimination in the determination of both elements have been studied in detail. Furthermore, a gas-sampling technique[15] for arsenic has been studied in order to improve the sensitivity and eliminate the interferences. The present method has then been applied to the determination of arsenic in several sulfide ores and steels.

Experimental

Apparatus. A Nippon Jarrell-Ash Model AA-1 atomic absorption/flame emission spectrophotometer fitted with a HTV R—106 photomultiplier was used on a single-pass

system. A "multi-flame" burner[14] constructed in the authors' laboratory in conjuction with a Techtron nebulizer-chamber was also used.

The line sources employed were arsenic and selenium electrodeless discharge lamps (EMI Electronics, Ltd., Great Britain), which were operated in a 3/4-wave resonant cavity, Model 211 L, at 2450 MHz with a "Microtron 200" power generator (Electro-Medical Supplies, Ltd., Great Britain) coupled with a reflected power meter. The discharge was initiated with a "Tesla" high-frequency vacuum tester.

The hydrogen, argon and nitrogen flow rates were controlled by means of needle valves and were measured on calibrated flow meters.

Reagents. A standard arsenic solution (1000 ppm) was prepared by dissolving 1.386 g of arsenious oxide of an analytical-reagent grade with 2 g of sodium hydroxide and 20 ml of distilled water, by neutralizing with hydrochloric acid, and by then diluting the solution to 1000 ml with distilled water.

A stardard selenium solution (1000 ppm) was prepared by dissolving 1.000 g of high-purity selenium metal in 5 ml of nitric acid and by then diluting the solution to 1000 ml with distilled water.

Diluted solutions of arsenic and selenium were prepared from the stock solutions as required.

All the acids and inorganic salts used were of either an analytical-reagent grade or the highest quality available.

Results and Discussion

Wavelengths and Flame Conditions. The relative intensities and sensitivities of the arsenic and selenium lines radiated from the electrodeless discharge lamps indicated that the arsenic 189.0-nm line was the most sensitive, but when we take the noise levels into consideration the arsenic 193.7-nm line was the most useful, while the selenium 196.1-nm line was the most sensitive and useful.

The effect of the flame composition and the flame height on the arsenic and selenium atomic absorptions was studied in premixed inert gas(entrained air)-hydrogen flames. The flame composition and the flame height had remarkable effects on the arsenic and selenium atomic absorptions in these flames. The optimum flame conditions obtained for arsenic and selenium are shown in Table 1.

Table 1. Optimum flame conditions for arsenic and selenium

	Arsenic	Selenium
Argon (entrained air)-hydrogen flame		
Hydrogen flow rate (l/min)	9.4	7.2
Argon flow rate (l/min)	4.5	4.5
Argon pressure (kg/cm²)	1.5	1.5
Sample aspiration rate (ml/min)	8.9	8.9
Flame height above burner head (mm)	4.0	2.0
Nitrogen (entrained air)-hydrogen flame		
Hydrogen flow rate (l/min)	9.4	6.5
Nitrogen flow rate (l/min)	5.0	5.0
Nitrogen pressure (kg/cm²)	1.5	1.5
Sample aspiration rate (ml/min)	9.0	9.0
Flame height above burner head (mm)	5.0	3.0

Optimization of Some Experimental Parameters in the Operation of Microwave-excited Electrodeless Discharge Lamps. Many workers have used microwave-excited electrodeless discharge lamps in atomic absorption and atomic fluorescence spectrophotometry, and have described their advantages and limitations.[11-13,16-18] Since the performance characteristics of the electrodeless discharge lamps are not always identical, it appeared necessary to establish the optimum operating conditions of each electrodeless discharge lamp employed. The efficiency with which the electrodeless discharge lamps were operated was found to depend to a large extent on the proper choice of resonant cavity. The electrodeless discharge lamps employed in this study were not discharged in a 3/4-wave resonant cavity Model 210 L (Electro-Medical Supplies, Ltd.) under any circumstance.

Although it had been expected[19] that tuning was dependent on the discharge characteristics and, consequently, dependent upon the microwave power applied, a change in the tuning characteristics with a variation in the microwave power is generally impossible to detect. Consequently, apart from occasional checks, the cavity was tuned to give as low a reflected power as possible. A reflected-power meter may be used to facilitate the tuning of the cavity and to ensure that the reflected power is not so high that the mag-

netron may be damaged. Provided that powers not higher than about 75 W are used, there is little possibility of damage being caused, and visual tuning to maximum lamp intensity is quite satisfactory.

The effect of microwave power (the power indicated on the microwave generator minus the reflected power (P–R) was taken) on the resonance-line intensity was examined for arsenic and selenium electrodeless discharge lamps. The results obtained are shown in Fig. 1. The cooling of electrodeless discharge lamps has been recommended by some workers.[20,21] As is shown in Fig. 1, a decrease in the line intensity was observed with both electrodeless discharge lamps when they were cooled with nitrogen. Furthermore, the maximum in the intensity of the 193.7-nm arsenic line shifted from a lower to a higher microwave power with an increase in the nitrogen flow rate. Although the line intensities were decreased with an increase in the nitrogen flow rate, the cooling produced an increased stability and considerably shorter warming-up periods by means of improved insulation from draughts. However, it was necessary for the flow rate of cooling nitrogen to be accurately regulated; otherwise, the cooling rather resulted in poor stability. In this study, the nitrogen from a cylinder was used as the cooling gas after drying with anhydrous calcium chloride instead of dry air, because a small pressure variation in an air compressor remarkably affected the line intensity with both elelectrodeless discharge lamps employed.

Then, the effect of the microwave power (P–R) on the atomic absorption signals of arsenic and selenium was examined. The absorbance variations obtained in the microwave power range from 8 to 70 W with and without the use of nitrogen cooling are shown in Fig. 2. The arsenic atomic absorption was remarkably increased with a decrease in the microwave power, while no or little variation with microwave power was observed for selenium. As is shown in Fig. 2, the nitrogen cooling produced an increase in the atomic absorption signals. However, a nitrogen flow rate of more than 2.0 l/min gave a constant absorbance for either arsenic or selenium. This phenomenon is presumably due to the fact that there is little or no self-absorption and/or self-reversal effects so long as the microwave power is small. Particularly for arsenic, this may be the case. A self-reversal effect has been noticed with some microwave-excited electrodeless discharge lamps,[22] but this may be readily overcome by using a slightly reduced operating microwave power and/or by cooling the lamp, as has been described above.

Thus, the optimization of the microwave power and the nitrogen cooling was important to the atomic absorption signal rather than the line intensity. The short-term stability of the lamps employed was similar, virtually better than 5% and often 2%, and the drift rate was less than 2% per hour for both arsenic and selenium lamps.

The optimum operating conditions for the atomic absorptions of arsenic and selenium may be summarized as follows. The microwave power(P–R) values were 8 and 20 W for arsenic and selenium respectively. The flow rate of nitrogen as a cooling gas was 2.0 l/min; it was accurately controlled with a needle valve and measured on a calibrated flow meter.

Calibration Graphs for Arsenic and Selenium. The calibration graphs for arsenic and selenium in the argon(entrained air)-hydrogen flame under the optimum experimental conditions described above were linear in the range of 0—10 ppm, as is shown in Fig. 3, with a precision of the mean relative standard deviation of about 3%, but the graph obtained at the 193.7-nm arsenic line with the higher microwave power (19 W) was bent slightly towards the concentration axis from 6 to 10 ppm. This bending is presumably due to self-absorption and/or self-reversal effects at a higher microwave power. The sensitivities (ppm for 1% absorption) over the linear ranges were found to be 0.17 and 0.15 ppm at the 193.7-nm arsenic line and the 196.1-nm selenium line respectively. No appreciable difference in the sensitivities between the argon(entrained air)-hydrogen flame and the nitrogen (entrained air)-hydrogen flame was observed.

Effects of Acids on the Atomic Absorptions of Arsenic and Selenium. The effects of the acids generally used for the dissolution of various practical samples in the determination of arsenic and selenium were examined in both the flames. The acids were hydrochloric, nitric, perchloric, phosphoric, and sulfuric acids. The concentrations of arsenic and selenium were 10 and 15 ppm respectively, and the concentration range of the acids was 0–3.0 N. The results obtained for arsenic in the argon(entrained air)-hydrogen flame are shown in Fig. 4. Similar results for selenium were obtained in both the flames. Hydrochloric, nitric, and perchloric acids had little effect on the atomic absorptions of arsenic and selenium, while sulfuric acid caused either an enhancement or depression, depending on its concentration. Phosphoric acid caused a depressing interference, independent of its concentration. The present authors have reported previously that hydrochloric, nitric, perchloric, and phosphoric acids, unlike sulfuric acid, had no effect on the selenium atomic absorption at the 196.1-nm line in the hotter air-hydrogen flame with a total-consumption nebulizer-burner.[5]

It was noted that the solutions containing nitric, perchloric, phosphoric, and sulfuric acids in the absence of both arsenic and selenium gave background absorptions at 193.7 and 196.1 nm in the inert gas(entrained air)-hydrogen flames under the optimum contions for the arsenic and selenium atomic absorptions. These background absorptions were not linear with respect to their concentrations. The background absorbances at 193.7 nm were found to be 0.101, 0.053, 0.026, and 0.019 in the argon(entrained air)-hydrogen flame for sulfuric, phosphoric, perchloric, and nitric acids respectively at a 3.0-N concentration level, and to be 0.107, 0.050, 0.021, and 0.011 in the nitrogen (entrained air)-hydrogen flame for sulfuric, phosphoric, nitric, and perchloric acids respectively at the same concentration level. The results shown in Fig. 4 have been corrected for the background absorptions at each concentration of the acids. The background absorption seems to be ascribable to the molecular absorption, the light scattering, and/or the variation in the refractive index within the flame caused by vaporization of concentrated solutions.[5]

Effects of Foreign Elements on the Determination of Arsenic and Selenium. The effects of various foreign elements on the determination of arsenic and selenium have been studied in an air-hydrogen,[5] an air-acetylene flame,[23] and a nitrogen-shielded air-acetylene flame.[3] The present authors have established that the determination of tin[24] and bismuth[25] in premixed inert gas(entrained air)-hydrogen flames suffer from interference from foreign elements because of the inability of the cool flames to vaporize or atomize the other elements present in the sample solutions. The interference effects of various other elements on the atomic absorptions of arsenic and selenium were studied in inert gas(entrained air)-hydrogen flames under the optimum conditions established above. The atomic absorptions were recorded in the presence of a 20-fold weight excess of diverse elements for 10 and 5 ppm of arsenic and selenium respectively. The results obtained in the argon(entrained air)-hydrogen flame are shown in Table 2. It can be seen from Table 2 that many elements produce depressing interferences with the determination of arsenic and selenium. The depressing interferences due to antimony, cadmium, manganese, selenium, and bismuth in the determination of arsenic, and those due to barium, lead, mercury, and zinc in the determination of selenium, were completely overcome by using a slightly acidic solution (0.2–0.5 N in hydrochloric acid). These interferences may also be overcome by using a hotter flame, such as a nitrous oxide-acetylene flame.[7]

However, further investigations of the depressing interferences indicated that most of the depressing interferences with the arsenic and selenium atomic absorptions were eliminated, in appearance, by adding a great amount (2000 ppm) of tin to the sample solutions, as is shown in Table 3. Although the

C: 0.1 μg of arsenic D: 0.2 μg of arsenic
E: 0.4 μg of arsenic

mechanism of the elimination of the depressing interferences in the presence of tin has not been explained satisfactorily, the present method could be applied to the determination of arsenic or selenium in some practical samples with satisfactory results.

Gas-sampling Technique for the Determination of Arsenic. Arsenic often needs to be determined in trace amounts, and an improvement in the sensitivity of the atomic absorption spectrophotometric method would be desirable. This can be achieved if arsenic is generated from the sample solution, col-

lected in a cold trap with, for example, liquid nitrogen, and then passed into the burner of an atomic absorption spectrophotometer; the atomic absorption signal is recorded as a function of the time. Holak[15] has reported this gas-sampling technique for arsenic determination by atomic absorption spectrophotometry, and obtained the detection limit of 0.04 μg of arsenic.

This gas-sampling technique was applied to the present method. Examples of response signals are shown in Fig. 5. A preliminary study indicated that the sensitivity for 1% absorption was 0.004 μg (4 ng) in quantities or 0.13 ppb in concentration, and Beer's law was established as holding between the absorbance and the amount of arsenic.

The main advantage of the gas-sampling technique is its suitability for trace analysis. The element is isolated from the matrix elements, and the total quantity is used to produce a sharp absorption signal. In addition, interferences often associated with solutions, such as those with high concentrations, and light scattering, as well as chemical interferences, are virtually eliminated.

Determination of Arsenic in Sulfide Ores and Steels. Based on the above-mentioned observations, the following procedures for the determination of arsenic in sulfide ores and steels were developed.

A 0.5-g ore sample was weighed and dissolved in 25 ml of diluted *aqua regia* by gentle heating on a hot plate. After the solution had then been cooled, the insoluble solids (sulfur and silicate) were filtered off with a filter paper. The filtrate was transferred to a 100-ml volumetric flask and diluted to volume with distilled water. Determinations were made by the standard addition method, and also by the calibration graph method. In either case the arsenic atomic absorptions were measured at 193.7 nm in the presence of 2000-ppm tin (as stannous chloride) as a suppressor of the interferences from other elements under the above-mentioned optimum operating conditions. The results of the determination of arsenic in sulfide ores by atomic absorption spectrophotometry are shown in Table 4.

Table 4. Results of the determination of arsenic in sulfide ores by atomic absorption spectrophotometry

Sample	Arsenic content (%)

Table 5. Results of the determination of arsenic by atomic absorption spectrophotometry in conjunction with a gas-sampling technique

Sample	Arsenic content (%)	
	Cert. value	Atomic absorption method
GK-9 Stainless steel[a]	0.012	0.011_8[b]
GK-10 Cast iron[a]	0.029	0.028_5[b]

a) Supplied by Kansai Bunseki Kenkyukai.
b) An average of 5 determinations.

A 0.1-g steel sample was weighed and dissolved in 10 ml of *aqua regia* by heating on a hot plate. After evaporation to dryness, the residue was dissolved in 10 ml of hydrochloric acid by gentle heating on a hot plate. The solution was transferred to a 100-ml volumetric flask and diluted to volume with distilled water. The resultant solution was employed as the sample solution. The determination of arsenic was followed below. A 5-ml portion of the sample solution was transferred into a 300-ml Erlenmeyer flask, and 0.5 ml of a 35% stannous chloride solution, 40 ml of 6 N hydrochloric acid, and 5 ml of a 20% potassium iodide solution were added. After about 10 min, 5 g of sandy zinc metal were added and the arsine generated was collected with a U-tube filled with glass beads in liquid nitrogen. The U-tube was removed from the liquid nitrogen and allowed to come to room temperature. The arsenic atomic absorption signals were measured at 193.7 nm in the argon(entrained air)-hydrogen flame. The results are shown in Table 5.

We would like to thank the Ministry of Education for its Scientific Research Grant to one of us (M. M.).

Peroxo-, Oxo-, and catena-Oxo-Manganese Complexes with *N,N'*-Ethylenebis(salicylideneimine) Analogues[1]

Takayuki MATSUSHITA, Tatsuo YARINO*, Isao MASUDA, Toshiyuki SHONO, and Koichiro SHINRA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka 565

(Received May 29, 1972)

By the reaction of Mn^{II}(salen) (salen=*N,N'*-ethylenebis(salicylideneiminato) dianion) and its analogues with molecular oxygen in organic solvents, three types of complexes including as structural units the Mn^{III}–O_2–Mn^{III}, –(–Mn^{IV}–O–)–$_n$, and Mn^{IV}=O bonds respectively, have been obtained, and characterized by means of their electronic and infrared spectra, by thermogravimetric analysis, and in terms of their magnetic properties. The lower magnetic moments for [Mn^{III}(salen)]$_2O_2$ and –[–Mn^{IV}(salen)–O–]–$_n$ than those expected have been interpreted in terms of antiferromagnetic interactions. The oxo complex was found to give the catena-oxo complex quantitatively in a DMF, DMSO, or Py solution. The effects of the oxygen partial pressure and the nature of the substituent in the organic part on the complex formation were investigated. A lower partial pressure of oxygen has the advantage of yielding the μ-peroxo complex in a higher yield. A discussion of the reaction mechanism is also included.

The Mn^{II}(salen)[2] was first reported by Tsumaki[3] to react with oxygen to yield Mn^{III}(salen)OH, for which Lewis *et al.*[4] later proposed a polymeric structure including unitary Mn^{III}(salen)–O–Mn^{III}(salen)·H_2O on the basis of the magnetic property. Recently, Johnson *et al.*[5] have reported that Mn^{II}(salpr)[2] takes up molecular oxygen in a benzene solution. In the present study, three types of complexes involving Mn^{III}-O_2-Mn^{III}, –(–Mn^{IV}–O–)–$_n$, and Mn^{IV}=O bonds respectively are shown to be obtainable upon reacting the Mn^{II}(salen) and its analogues with molecular oxygen in organic solvents.

Experimental

Manganese(II) Complexes. The preparation of Mn^{II}(salen) and Mn^{II}(3-MeO-salen)·H_2O[2] was carried out in a nitrogen atmosphere according to a modification of the procedure of the literature.[4] Mn^{II}(5-NO_2-salen)[2] was obtained by allowing the pyridine adduct, Mn^{II}(5-NO_2-salen)·2Py, which had been prepared by the reaction of 5-NO_2-salenH_2 with $MnCl_2$·$4H_2O$ in a *ca.* 50% aqueous pyridine solution, to stand *in vacuo* at 90—100 °C for 12 hours. The compounds were confirmed by elemental analyses.

Peroxo-, Oxo-, and catena-Oxo-Manganese Complexes. *μ-Peroxo-bis-*NN'*-ethylenebis(salicylideneiminato)manganese(III)*, [*Mn^{III}(salen)*]$_2O_2$: Mn^{II}(salen) (2.0 g) was dissolved in DMSO (150 ml) in a nitrogen atmosphere, and then the solution was kept in oxygen (1 atm) at room temperature for about 12 hours. Two grams of precipitates were thus separated. The precipitates were extracted with CH_2Cl_2 (1 l), and then the solvent was evaporated to *ca.* 50 ml to leave reddish-brown crystals. They were separated by filtration and then dried *in vacuo* at 50 °C for 6 hours. Yield: 0.2 g. When the solution of Mn^{II}(salen) was kept in a nitrogen atmosphere which contained about 2.0 vol% of oxygen, the crystals of the μ-peroxo complex could be obtained in a *ca.* 90% yield. The μ-peroxo complex is soluble in CH_2Cl_2 (*ca.* 0.4 g/l) and is slightly souble in DMSO and DMF.

*Oxo-*N,N'*-ethylenebis(3-methoxy-salicylideneiminato) manganese (IV) Methanol Adduct, O=Mn^{IV}(3-MeO-salen)·2MeOH*: Mn^{II}(3-MeO-salen)·H_2O (2.0 g) was suspended in absolute MeOH (200 ml), and then oxygen gas was bubbled through the mixture while it was being stirred for *ca.* 20 hours. The solution turned greenish-brown, and dark-green, crystalline needles were separated. The crystals were filtered and dried *in vacuo*. Further crystals were obtained by concentrating the filtrate. Yield: 1.4 g. The complex was recrystallized from methanol.

*Poly, catena-oxo-*N,N'*-ethylenebis(salicylideneiminato)manganese-(IV), –[–Mn^{IV}(salen)–O–]–$_n$*: Mn^{II}(salen) (1.0 g) was dissolved in Py (100 ml) under a nitrogen atmosphere, and then the solution was allowed to stand for about 20 hours in dry oxygen (1 atm). The brown precipitates thus separated were centrifuged, washed with MeOH, and then dried *in vacuo*. Yield: 0.95 g.

*Poly, catena-oxo-*N,N'*-ethylenebis(3-methoxy-salicylideneiminato)-manganese(IV), –[–Mn^{IV}(3-MeO-salen)–O–]–$_n$*: The complex was obtained from Mn^{II}(3-MeO-salen)·H_2O in the way described above. Yield: 93%.

*Poly, catena-oxo-*N,N'*-ethylenebis(5-nitro-salicylideneiminato)-manganese(IV) Dimethylformamide Adduct, –[–Mn^{IV}(5-NO_2-salen)–O–]–$_n$(DMF)$_n$*: The complex was prepared by a similar reaction of Mn^{II}(5-NO_2-salen) in a DMF solution. Yield: 90%.

These catena-oxo complexes are amorphous, and they are insoluble in water and in common organic solvents.

Measurements. The oxygen uptake was measured by using a Warburg manometer. The infrared spectra were obtained in Nujol mulls using a JASCO IR-L spectrophotometer in the 400—4000 cm^{-1} region, and a Hitachi EPI-L spectrophotometer in the 200—700 cm^{-1} region. The electronic spectra were recorded on a Hitachi EPS-3 spectrophotometer. The magnetic susceptibility was measured for a powder sample by the Faraday method, using a torsion balance[6] over the temperature range from 77 to 293 K,

and by the Gouy method at room temperature. The equipment was calibrated using a standard nickel chloride solution. Thermogravimetric and differential thermal analyses were carried out using a Rigaku Denki DG-CIH Thermoflex, at a heating rate of 5 °C/min or 2.5 °C/min, and under a nitrogen stream.

Results and Discussion

As is shown in Table 1, the analytical data of the aerial oxidation products of Mn^{II}(X-salen) are in fair agreement with the Mn(X-salen)O formula. The data of the manometric measurements shown in Table 2 indicate that the Mn^{II}(X-salen) uptake oxygen in a Mn : O_2 molar ratio of 1 : 0.5 is consistent with the above results. However, as will be discussed below, these products can be classified into three types of complexes, including Mn^{III}–O_2–Mn^{III}, $-(-Mn^{IV}-O-)-_n$, and $Mn^{IV}{=}O$ bonds respectively, on the basis of their physicochemical data.

Table 2. Oxygen uptake of Mn^{II} (X-salen)[a]

Complex	Solvent	Molar ratio: O_2/complex	Time:[b] min.
Mn^{II}(salen)	DMSO	0.53	30
	DMF	0.46	5
	MeOH	0.30	1440
Mn^{II}(3-MeO-salen)·H_2O	DMSO	0.48	40
	MeOH	0.40	1200
Mn^{II}(5-NO_2-salen)·2Py	DMF	0.40	2160

a) Measurements were carried out at 20 °C.
b) The time needed for attaining equilibrium.

Solubility. Complex I (*cf.* Table 1) is slightly soluble in such organic solvents as CH_2Cl_2, DMF and DMSO, while Complexes II and III are insoluble in these solvents. Complex IV is soluble in DMSO, but sparingly so. It should be noted that Complex V is soluble in MeOH without decomposition, whereas in a Py, DMF, DMSO, or CH_2Cl_2 solution it is converted to an insoluble complex, III, in an almost quantitative yield.

Thermogravimetric Analyses. Complexes II, III, and IV show a similar pattern in the TGA curves (Fig. 1), decreasing in weight in the 200—225 °C range and with subsequent decomposition. These weight losses correspond to that caused by the release of 0.5 mole of oxygen per manganese atom.

Though Complex I shows a similar weight loss at 198 °C which is thought to be caused by the liberation of 0.5 mole of oxygen per manganese atom (observed, 4.6%; calcd, 5.3%), no other remarkable decomposition is, in this case, observed to occur until *ca.* 250 °C. It should be noticed that, upon heating at about 200 °C for 1 hour *in vacuo*, the complex was converted to the Mn^{II}(salen) in an 85% yield.

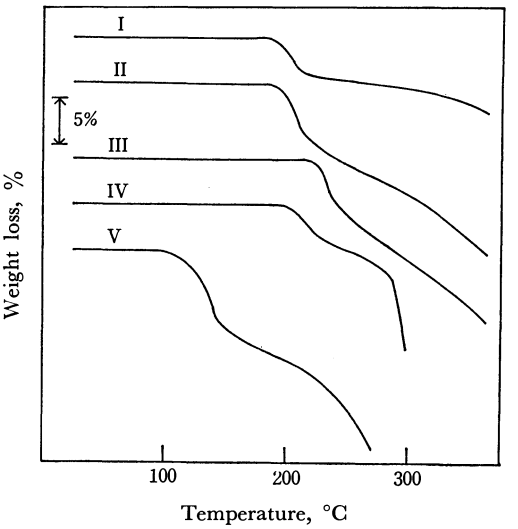

Fig. 1. TGA curves.
I: $[Mn^{III}(salen)]_2O_2$, II: $-[-Mn^{IV}(salen)-O-]-_n$, III: $-[-Mn^{IV}(3\text{-MeO-salen})-O-]-_n$, IV: $-[-Mn^{IV}(5\text{-}NO_2\text{-salen})-O-]-_n$, V: $O{=}Mn^{IV}(3\text{-MeO-salen})\cdot 2MeOH$.

Complex V decreases in weight corresponding to the release of two moles of MeOH per manganese atom between 70 and 140 °C, and then it decomposes.

Magnetic Properties. Lewis *et al.*[4] have reported that polymeric $[Mn(salen)-O-Mn(salen)]\cdot H_2O$ shows a room-temperature magnetic moment of 2.03—1.92 B.M., and that there exists a large antiferromagnetic interaction with $J=-90\ cm^{-1}$ for a binuclear cluster ($S=2$, $g=2.00$, and $N\alpha=0$ or $S=1$, $g=2.05$, and $N\alpha=0$). Complex I in the present work shows 1.96 B.M. (Table 3) at room temperature, a value which is considerably lower than those (4.96—4.98 B.M.) found for the Mn^{III}(salen)X-type complexes where X is Br^- or I^-.[7] Moreover, a significant deviation from the Curie-Weiss law is observed over the temperature range from 77 to 296 K (Fig. 2). Below *ca.* 130 K, the data fit fairly well a curve calculated by assuming a binuclear cluster, Mn–O_2–Mn, with $J=-85\ cm^{-1}$, $S=1$, $g=2.00$, and $N\alpha=O$. However, at higher temperatures they deviate from the curve and fit, rather, one calculated for $J=-90\ cm^{-1}$, $S=2$, $g=2.00$, and $N\alpha=0$. These magnetic data can

be understood by taking into consideration the thermal equilibrium between spin-free and spin-paired configurations in the complex. As for Complexes II and III, their room-temperature magnetic moments are lower than that (3.75 B.M.) of the spin-only value expected for the octahedral Mn(IV) complexes. Moreover, the magnetic susceptibilities deviate from the Curie-Weiss law (Fig. 2); this deviation is probably caused by antiferromagnetic interaction between manganese atoms bridged by the oxygen atom. Kubo *et al.*[8] have reported that the magnetic susceptibilities of ammonium pentafluoromanganate(III), which has a linear chain structure, fit the curve calculated for a one-dimensional array of Ising spins $S=2$ above 80 K, assuming a "reduced" spin magnetic moment. The data for Complexes II and III do not fit the curve calculated assuming Ising spins $S=3/2$. As is shown in Fig. 2, the data fit, rather, the curve calculated by

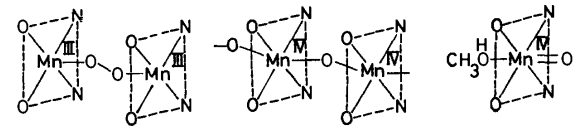
assuming a binuclear cluster including Mn–O–Mn bonding with $S=3/2$. Moreover, $J=-95$ cm^{-1} and -125 cm^{-1} are proposed Complexes II and III respectively. As for Complex V, the room-temperature magnetic moment, 3.81 B.M., is consistent with that expected for a high-spin Mn(IV). In this case, the magnetic susceptibilities fit the Curie-Weiss law well.

Infrared Spectra. Complexes I–IV show IR spectral frequencies which are comparable with those of the corresponding Mn^{II}(X-salen) in the 700—4000 cm^{-1} region. On the other hand, as is shown in Fig. 3 and Table 3, the spectra of the complexes in the 600—700 cm^{-1} region are characterized by two intense

absorption bands. The μ-oxo, $[Fe(salen)]_2O$,[4] and μ-peroxo, $[\{Co(NH_3)_5\}O_2](NO_3)_4$, including a metal-oxygen bond, show similar bands at 820 and 560 cm^{-1} respectively. In the case of Complex V, a new band is observed at 840 cm^{-1}. In view of the fact that the $[O=Mn(salen)]_2O_2$ complex, which is considered to involve both Mn=O and Mn–O_2–Mn bonds, shows the characteristic band at 884 cm^{-1} referred to the Mn=O, and those at 640 and 623 cm^{-1} referred to Mn–O bonds,[9] it is likely to ascribe the above bands in the 600—700 cm^{-1} to the Mn–O bond, and the band at 840 cm^{-1}, to the Mn=O bond.

Electronic Spectra. The electronic absorption spectra of the Mn^{II}(salen) and Complexes I and V in solution are represented in Fig. 4. The absorption bands appearing in the wave-number region higher than 25 kK are thought to be associated mainly with the ligand transitions. As may be seen in Fig. 4, the Mn^{II}(salen) shows no intense absorption band in the visible region. Information concerning the structure of the oxygenated complexes may be obtained by inspecting the visible spectral features. It has been reported that the spin-free manganese(III) complexes with an octahedral configuration give rise to a d–d transition band ($^5E_g \rightarrow {}^5T_{2g}$) with log ε=2.5 around 20 kK.[10] On the other hand, the spin-free penta-coordinate Mn^{III}(salen)X, where X is Br^- or I^-, shows two absorption bands, around 20 kK with log ε=3.0 and around 25 kK with log ε=3.5; these have been described by Prabhakaran *et al.*[7] as a d–d transition and a charge-transfer band respectively. As can be seen in Fig. 4, the spectral pattern of Complex I with two absorption bands at *ca.* 20.0 and *ca.* 23.2 kK resembles that of the penta-coordinate manganese(III)-complexes. Thus, as for Complex I, the visible and the IR spectral properties, as well as the thermal property, which indicates a reversible release of oxygen, led us to conclude that Complex I includes a μ-peroxo bond and that the structure can be depicted as is shown in Fig. 5-(a). As has been mentioned, the magnetic moment, 1.96 B.M., of Complex I (*cf.* Table 3), lower than that expected for the penta-coordinate manganese(III)-complexes with a square-pyramidal structure, can be explained in terms of an antiferromagnetic exchange which may be caused by the formation of a binuclear structure through the μ-peroxo bond. The magnetic moment, 3.81 B.M., of Complex V (*cf.* Table 3) agrees with the assumption that the complex includes a spin-free Mn(IV). The visible electronic spectrum of Complex V, unlike that of Complex I, shows only one peak, at 23.2 kK. This spectral feature is not inconsistent with those of such spin-free, octahedral manganese(IV) complexes as $[MnF_6]^{2-}$ and $[MnCl_6]^{2-}$, which show absorption maxima at 21.8 and 17.9 kK respectively.[11] On the basis of these facts, a proposed structure for Complex V is shown in Fig. 5-(c). The insolubility of Complexes II, III, and IV did not allow measurements of the electronic spectra in solution. However, the magnetic properties and the IR spectral data, as well as the fact that they are obtained from the oxo complexes, led us to propose the structure for the complexes shown in Fig. 5-(b).



(a) (b) (c)

Fig. 5. Schematic structures proposed for the complexes.

Effects of Oxygen Partial Pressure, Solvent, and Substituent on the Oxidation Reaction. As has been discussed above, three types of complexes containing a μ-peroxo-, catena-oxo-, or oxo-bond were isolated in the reactions of the Mn^{II}(X-salen) with oxygen in organic solvents. In this section we will consider the effects of the oxygen partial pressure and of the nature of the solvents and substituents, X, on the complex formation.

As has been descrived in the Experimental part, the Mn^{II}(salen) yielded, upon reaction with oxygen in a DMSO solution, the μ-peroxo complex as a precipitate plus precipitates of the catena-oxo complex. As can be seen in Table 4, the amount of the μ-peroxo complex of the above precipitates increases with a decrease in the partial pressure of oxygen applied in the reaction system; it increases up to 86% when oxygen diluted to 1.7 vol% by mixing with nitrogen is used. It can be noticed that, in Py and DMF solutions, the reaction using dilute oxygen gave the μ-peroxo complex, although the reaction using pure oxygen only afforded the catena-oxo complex.

Table 4. The effects of oxygen partial pressure and solvents on the formation of $[Mn^{III}(salen)]_2O_2$ and $-[-Mn^{IV}(salen)-O-]-_n$[a]

P_{O_2} (vol%)[b]	Yield[c]		
	DMSO	DMF	Py
1.7	86	82	21
10	—	50	—
20	—	16	0
100	10	0	0

a) The reactions were carried out using Mn^{II}(salen) (1 g) and solvent (50 ml), at room temperature for 15 hr.. $[Mn^{III}(salen)]_2O_2$ was separated as soluble part by extraction with CH_2Cl_2.

b) Represented in volume % of O_2 in mixed $O_2 + N_2$ at atmospheric pressure and room temperature.

c) Corresponds to $\frac{[Mn^{III}(salen)]_2O_2}{[Mn^{III}(salen)]_2O_2 + -[-Mn^{IV}(salen)-O-]-_n} \times 100$ in gram.

The above results (*cf.* Table 4) suggest that the formation of the μ-peroxo complex is favored in the solvents in the following order; Py<DMF<DMSO, and that it is also favored when oxygen with a lower partial pressure is reacted.

As for the Mn^{II}(3-MeO-salen)·H_2O and Mn^{II}(5-NO_2-salen)·2Py complexes, the corresponding μ-peroxo complex could not be obtained even if the reac-

11) A. B. P. Lever, "Inorganic Electronic Spectroscopy," Elsevier Publishing Co., (1963), p. 283.

tion was carried out in a DMSO solution using dilute oxygen of 1.7 vol%. The oxo complex, O=Mn^{IV}(3-MeO-salen)·2MeOH, was successfully isolated only for the 3-MeO-substituted complex in a MeOH solution. Further, it is of importance that, in a DMF, DMSO, or Py solution, the oxo complex is transformed to the insoluble catena-oxo complex,–[–Mn^{IV}(3-MeO-salen)–O–]$_n$, almost quantitatively, indicating that the reaction forming the catena-oxo complex proceeds *via* the oxo complex. The low solubility of the catena-oxo and μ-peroxo complexes did not allow kinetical measurements. However, in view of the results obtained in the present study, it can be interpreted by assuming that the reactions proceed as follows:

$$S\text{–}(Mn^{II})\text{–}S + O_2 \xrightarrow{k_1} S\text{–}(Mn^{III})\text{–}O_2 + S \quad (1)$$

$$S\text{–}(Mn^{III})\text{–}O_2 + O_2\text{–}(Mn^{III})\text{–}S \xrightarrow{k_2} 2S\text{–}(Mn^{III})\text{–}O\cdot + O_2 \quad (2)$$

$$S\text{–}(Mn^{III})\text{–}O\cdot \longrightarrow S\text{–}(Mn^{IV})\text{=}O \quad (2\text{-}1)$$

$$n[S\text{–}(Mn^{IV})\text{=}O] \longrightarrow \text{–}[\text{–}(Mn^{IV})\text{–}O\text{–}]_n\text{–} + n\cdot S \quad (2\text{-}2)$$

$$S\text{–}(Mn^{III})\text{–}O_2 + S\text{–}(Mn^{II})\text{–}S \xrightarrow{k_3} S\text{–}(Mn^{III})\text{–}O_2\text{–}(Mn^{III})\text{–}S \quad (3)$$

((Mn) represents a parent complex, Mn^{II}(X–salen).)

As is illustrated in Fig. 4, the Mn^{II}(salen) shows an electronic absorption maximum at 27.0 kK (log ε=4.5); this maximum is shifted to a lower frequency with the solvents in the order of MeOH (28.7 kK)< DMF (27.7 kK)<DMSO (27.6 kK)<Py (27.0 kK). Similar spectral behavior is observed for the substituted Mn^{II}(X-salen). These results seem to indicate that the complexes are coordinated with the solvent in solutions. In fact, an adduct with a solvent, *e.g.*, Mn^{II}(5-NO_2-salen)·2Py, is isolated. Hence, the reaction of the manganese (II) complexes with oxygen could be initiated by replacing a coordinated solvent molecule with oxygen, thus forming an intermediate superoxo complex, as is shown in Equation (1). When assuming that the unstable superoxo complex thus formed undergoes reactions to yield both oxo- and μ-peroxo complexes, following Equations (2), and (3) respectively, the reaction rate in respect to the superoxo complex can be given as:

$$d[S\text{–}(Mn^{III})\text{–}O_2]/dt = k_1[O_2][S\text{–}(Mn^{II})\text{–}S] - k_2[S\text{–}(Mn^{III})\text{–}O_2]^2 - k_3[S\text{–}(Mn^{II})\text{–}S][S\text{–}(Mn^{III})\text{–}O_2] \quad (4)$$

where k_1, k_2, and k_3 are the rate constants in Reactions (1), (2), and (3) respectively.[12] Reactions (2—1) and (2—2) are thought to follow Reaction (2) very rapidly in DMF, DMSO, and Py solutions. In view of the fact that the catena-oxo, and μ-peroxo complexes were separated out of the reaction system as precipitates, the concentration of the superoxo complex involved in solution must remain approximately constant during the reaction; that is,

$$d[S\text{–}(Mn^{III})\text{–}O_2]/dt \fallingdotseq 0 \quad (5)$$

Thus, the ratio of the yield of the catena-oxo complex to the μ-peroxo complex can qualitatively be described as:[12]

$$\frac{\text{catena-oxo complex}}{\mu\text{-peroxo complex}} \propto \frac{k_1k_2}{k_3^2}\cdot\frac{[O_2]}{[S\text{–}(Mn^{II})\text{–}S]} \quad (6)$$

proportional to the ratio of $[O_2]$ to $[S\text{–}(Mn^{II})\text{–}S]$. This relation can explain the experimental finding (*cf.* Table 4) that the yield of the catena-oxo complex decreases with a decrease in the oxygen concentration.

In a solvent such as Py, which tends to coordinate with a stronger affinity toward the central manganese ion, it is not unreasonable to expect a smaller k_1 than in another solvent. Hence, the higher yield of the catena-oxo complex by the reaction in the Py solution implies smaller k_3 and k_1 values. The failure to obtain the μ-peroxo compound of the Mn^{II}(3-MeO-salen)·H_2O may be attributed mainly to a larger k_1 caused by the electron-donating MeO group, which weakens the bonding of the central manganese ion with the solvent. The fact that the Mn^{II}(5-NO_2-salen)·2Py yielded the catena-oxo complex, even in the DMSO solution, can be explained in terms of a stronger bonding with the solvent due to the electron-withdrawing NO_2 group.

The authors wish to thank Associate Professor C. Miyake for the use of equipment for magnetic susceptibility measurements by means of the Faraday method.

12) From Eqs. (4) and (5), concentration of superoxo complex is given as follows,

$$[S\text{-}(Mn^{III})\text{-}O_2] = \frac{[S\text{-}(Mn^{II})\text{-}S]}{2k_2} \times(-k_3+\sqrt{k_3^2+4k_1k_2[O_2]/[S\text{-}(Mn^{II})\text{-}S]}). \quad (i)$$

And, the rate equation respect to catena-oxo-, and μ-peroxo-complexes are given by Eqs. (ii) and (iii), respectively:

$$d[\text{-}(\text{-}(Mn^{IV})\text{-}O\text{-})_n\text{-}]/dt = (1/n)\cdot d[S\text{-}(Mn^{III})\text{-}O\cdot]/dt = (k_2/n)\cdot[S\text{-}(Mn^{III})\text{-}O_2]^2 \quad (ii)$$

$$d[S\text{-}(Mn^{III})\text{-}O_2\text{-}(Mn^{III})\text{-}S]/dt = k_3[S\text{-}(Mn^{III})\text{-}O_2][S\text{-}(Mn^{II})\text{-}S] \quad (iii)$$

Then, from the Eqs. (i), (ii) and (iii) the ratio of reaction rate for catena-oxo complex to that for μ-peroxo complex is derived as,

$$\frac{d[\text{-}(\text{-}(Mn^{IV})\text{-}O\text{-})_n\text{-}]/dt}{d[S\text{-}(Mn^{III})\text{-}O_2\text{-}(Mn^{III})\text{-}S]/dt} = \frac{k_2[S\text{-}(Mn^{III})\text{-}O_2]}{nk_3[S\text{-}(Mn^{II})\text{-}S]} = (1/2n)\left(-1+\sqrt{1+(4k_1k_2/k_3^2)\frac{[O_2]}{[S\text{-}(Mn^{II})\text{-}S]}}\right) \quad (iv)$$

Eq. (iv) can be qualitatively transformed as shown by Eq. (6).

Pyrolysis-Gas Chromatographic Studies of Ionically-chlorinated Poly-α-methylstyrenes

Tadaoki OKUMOTO* and Tsugio TAKEUCHI**

** *Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464*

(Received October 7, 1972)

The microstructure of ionically-chlorinated poly-α-methylstyrene with or without a catalyst and the distribution of chlorine in the aromatic nucleus of the polymers were studied by means of pyrolysis-gas chromatography. The degradation products, such as α-methylstyrene, *p*-chloro-α-methylstyrene, and 3,4-dichloro-α-methylstyrene, gave good information about substitution reactions on the aromatic nucleus in original poly-α-methylstyrene. The differences between two series of ionically-chlorinated poly-α-methylstyrene were also discussed on the basis of yield of α-methylstyrene and *p*-chloro-α-methylstyrene.

Chlorinated polystyrenes and poly-α-methylstyrenes have been synthesized by both ionic and radical mechanisms. The chlorination of polystyrene has been the subject of a number of investigations.[1-4] However, only one study of the chlorinated poly-α-methylstyrene (CPMS) has been reported.[4]

Jenkins *et al.*[1] have examined the radically-chlorinated polystyrene by the use of an IR spectrometer, etc. They reported the determination of the change in the infrared spectrum, the glass transition temperatures, and the molecular weight of the polymers.

In our previous work[2] we have studied the distribution of chlorine atoms as a function of the degree of chlorination in the chlorinated polystyrene formed by radical chlorination by means of pyrolysis-gas chromatography(PGC).

Teyssie *et al.*[3] have investigated the structure of ionically-chlorinated polystyrene by both chemical and infrared spectrometric analyses and concluded that the chlorine is preferentially oriented in the para, and secondarily in the ortho, position, and that, with the further introduction of chlorine, 3,4-, 2,5- and, to a lesser extent, 2,4-dichloro-substituted phenyl groups are formed.

Bachman *et al.*[4] elucidated the depolymerization of ionically-chlorinated polystyrene and poly-α-methylstyrene and identified halogenated styrene and α-methylstyrenes, such as *p*-chlorostyrene, 3,4-dichlorostyrene and 3,4-dichloro-α-methylstyrene, after the fractional distillation of the depolymerized mixture.

In the present work, we have studied a pyrolysis-gas chromatographic method for elucidating the microstructure of ionically-chlorinated poly-α-methylstyrene, especially the distribution of chlorine in the aromatic nucleus of the polymers.

Experimental

Materials. The poly-α-methylstyrene was dissolved in chloroform and then purified. Chlorine gas was introduced into the polymer solution with constant stirring. Two series of ionically-chlorinated poly-α-methylstyrenes were prepared by the following methods of chlorination. The first method was a catalytic method where CPMS was synthesized by the chlorination of poly-α-methylstyrene in the iron powder, which acted as a catalyst in the dark. The second method was a direct method, where poly-α-methylstyrene was chlorinated in the absence of a catalyst. The samples were purified by the same procedure as that described in our previous work.[2] The polymers formed by the catalytic and direct methods will be abbreviated as "CPMS–Cat" and "CPMS–Direct" respectively. The chlorine content of the chlorinated polymers was chemically determined.

The degree of chlorination (DC) of the samples is defined as the number of chlorine atoms contained per monomer unit in the polymer as follows:

$$DC = \frac{118.19 \times Cl\ wt\%}{3545 - 34.4 \times Cl\ wt\%}$$

Pyrolysis-Gas Chromatographic Conditions. The pyrolysis of the polymer was carried out by means of a furnace-type pyrolyzer (Hitachi Model KP-1) which was directly attached to the inlet port of a gas chromatograph equipped with dual flame-ionization detectors. At the optimum pyrolysis temperature, 550 °C, reproducible and characteristic pyrograms were obtained.

The gas-chromatographic conditions were the same as those described in our previous work.[2] Separation columns (3 mm i. d. × 2 m) packed with Diasolid L (80—100 mesh) and coated with PEG-6000 (10 wt% to the support) were used at programmed temperatures ranging from 100 to 210°C at a rate of 5 °C/min. The peaks on the pyrograms were identified by the use of PGC–MS and Hitachi–RMS-4 apparatuses and by means of the retention data of the pure substances.

Infrared Spectrometry. The infrared absorbance curves were obtained on Hitachi Model EPI-S_2 spectrometer. The various chlorinated poly-α-methylstyrene samples were examined by the KBr disc method.

Results and Discussion

In the following discussion, α-methylstyrene, *p*-chloro-α-methylstyrene, and 3,4-dichloro-α-methylstyrene are briefly denoted by MS, *p*-CMS, and 3,4-CMS respectively.

Figure 1 shows typical pyrograms of poly-α-methylstyrene and CPMS–Cat at the pyrolysis temperature of 550 °C. Raw poly-α-methylstyrene yields, nearly quantitatively, the α-methylstyrene monomer, while, with the rise in the degree of chlorination, chlorinated

poly-α-methylstyrene yields two kinds of chlorine-substituted α-methylstyrene, such as *p*-CMS and 3,4-CMS. The relative yields of α-methylstyrene derivatives from the CPMS-Cat and -Direct methods are summarized in Tables I and II, where a small amount of styrene is added to the yield of α-methylstyrene. These values are calculated from the relative peak areas appearing on the pyrograms, considering the relative sensitivities of compounds for the flame-ionization detectors.

Figure 2 shows the relationships between the DC and the yields of the degradation products of the ionically CPMS-Cat and -Direct methods. The two series of CPMS differ generally from one another, especially in the yields of MS and *p*-CMS, as is shown in Fig. 2. It is apparent from the above observations that a chlorination reaction is taking place, mainly on the aromatic nucleus. The chlorine is nearly oriented in the para position and with the further introduction of chlorine, 3,4-dichloro-substituted phenyl group is formed.

Figure 3 shows the infrared spectrum of chlorinated poly-α-methylstyrene with various DC. The disappearance of the absorption bands at 700, 750, and 1030 cm^{-1} is indicative of chlorine substitution on the aromatic nucleus. On the other hand, sharp bands of 825 and 1010 cm^{-1} which are related to the position of the substitution in the nucleus appear on the spectrum with the rise in DC. These results are in

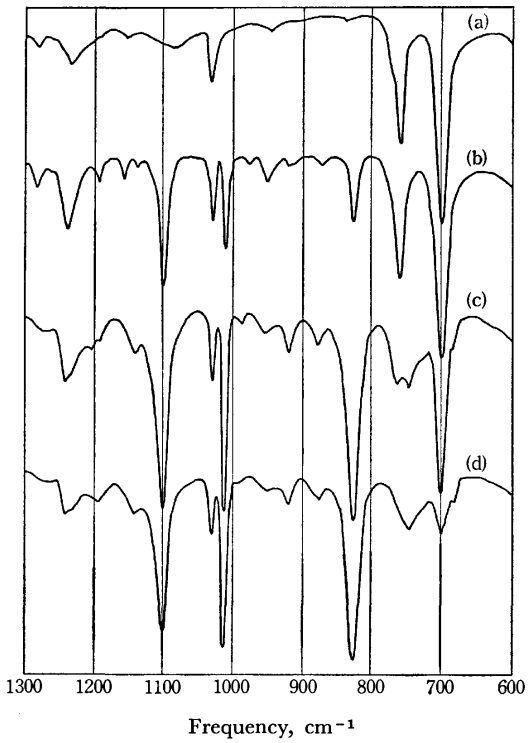

Fig. 3. Infrared spectra of CPMS-Cat.
(a): PMS, (b)—(d): CPMS; (b): DC=0.47, (C): DC=1.18, (d): DC=1.53

fairly good agreement with those of polystyrene reported by Teyssie et al.[3]

At a small degree of chlorination with or without a catalyst, only the yield of *p*-CMS through monochloro-substituted α-methyl styrene appeared on the pyrograms, while the yield of isomers did not appear. This is different from the case with chlorinated polystyrene. This is mainly due to the steric hindrance of methyl group in the polymer. This is also supported by the fact the yield of dichloro-substituted α-methylstyrene is almost 3,4-CMS.

The ionic chlorination of poly-α-methylstyrene mainly proceeds by means of the direct substitution of the aromatic nucleus under these conditions. At the beginning of chlorination, a substitution reaction takes place in nearly the para position. The second chlorine atom is preferentially directed into the phenyl ring

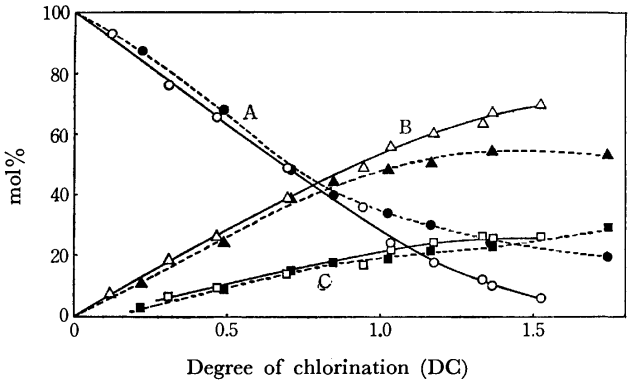

Fig. 2. Relationships between the degree of chlorination (DC) and relative yields of the degradation products of CPMS.

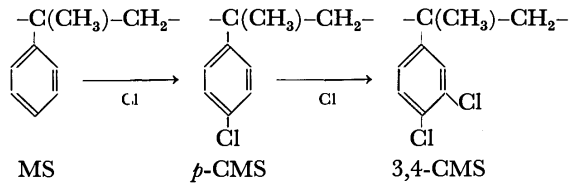
C: 3,4-dichloro-α-methylstyrene.

in the 3 positions for the para chloro-α-methyl styrene unit before all the phenyl ring is substituted. It is also thus apparent that the formation of *p*-CMS is locally competitive with the formation of 3,4-CMS.

Consequently, *p*-CMS is formed by the following mechanisms;



The two series of CPMS differ from one another, especially in the yields of α-methylstyrene and *p*-chloro-α-methylstyrene, as is illustrated in Fig. 2.

No appreciable differences are observed between the two series of CPMS with respect to the yields of dichloro-α-methylstyrene. However, the yields of MS and *p*-CMS change in different ways as a function of DC. The ratio of *p*-CMS to 3,4-CMS of CPMS-Cat is also larger than that of CPMS-Direct. These results suggest that the distribution of the chlorine introduced to the phenyl ring of CPMS-Cat is more homogeneous than that of CPMS-Direct.

The Hydrolysis of Y^{3+}, La^{3+}, Gd^{3+}, and Er^{3+} Ions in an Aqueous Solution Containing 3 M (Li)ClO_4 as an Ionic Medium

Toshihiko AMAYA*, Hidetake KAKIHANA, and Masunobu MAEDA**

(Received December 8, 1972)

The hydrolysis equilibria of Y^{3+}, La^{3+}, Gd^{3+}, and Er^{3+} ions have been studied at 25 °C in 3 M (Li)ClO_4 by measuring the hydrogen-ion concentration with a glass electrode. All the test solutions containing hydrolyzed species prepared by the addition of alkali were acidified by means of constant-current coulometry. The data, which indicate a slight hydrolysis of the relevant ions, can be explained by assuming the formation of the following complexes: $Y(OH)_2^{+}$, $\log \beta_{2,1} = -17.0 \pm 0.1$; $Y_2(OH)_2^{4+}$, $\log \beta_{2,2} = -14.04 \pm 0.01$; $LaOH^{2+}$, $\log \beta_{1,1} = -10.04 \pm 0.01$; $GdOH^{2+}$, $\log \beta_{1,1} = -8.20 \pm 0.01$; $Er(OH)_2^{+}$, $\log \beta_{2,1} = -17.4 \pm 0.1$; $Er_2(OH)_2^{4+}$, $\log \beta_{2,2} = -13.72 \pm 0.01$.

So far, very few quantitative investigations have been made of the hydrolysis of rare-earth ions.[1]

In 1946 Moeller[2] measured the acidity of a series of rare-earth sulfate solutions at 25 °C by the use of a glass electrode and found that only a small part of the rare-earth ions were transformed to hydrolysis species of $LnOH^{2+}$ before precipitation started.

Wheelwright, Spedding, and Schwarzenbach[3] titrated a 0.01 M $LaCl_3$ solution with NaOH using a glass electrode and reported the formation of $LaOH^{2+}$ with $\log \beta_{1,1} = -8.4$ (at 20 °C).

Tobias and Garrett[4] studied the hydrolysis equilibria of Nd^{3+} and Pr^{3+} ions at 25 °C and found that a very small part of the metal ions could be present as hydrolysis products in solution. They found $NdOH^{2+}$ and $PrOH^{2+}$ to have the same stability constant of $\log \beta_{1,1} = -8.5$.

In 1961 Biedermann and Ciavatta[5] investigated the hydrolysis of the La^{3+} ion by measuring the concentration of the hydrogen ion with a glass electrode. They explained the results in the $\log h$ range from −6.5 to −8.1 by assuming the formation of $LaOH^{2+}$, La_2OH^{5+}, and $La_5(OH)_9^{6+}$ (or $La_6(OH)_{10}^{8+}$), the corresponding stability constants being $\log \beta_{1,1} = -10.1$, $\log \beta_{1,2} = -9.9_5$, and $\log \beta_{9,5} = -71.4_5$ (or $\log \beta_{10,6} = -78.7_5$) (at 25 °C).

Biedermann and Newman[6] investigated the hydrolytic reaction of the Ce^{3+} ion and reported that only the $Ce_3(OH)_5^{4+}$ species with $\log \beta_{5,3} = -35.7_5$ was formed.

In 1964 Biedermann and Ciavatta[7] studied the hydrolysis equilibria of the Y^{3+} ion by the application of constant-current coulometry. Their data, which indicated that, at most 3% of the Y^{3+} ions were transformed to the hydrolysis species, without the formation of any precipitate, were explained by assuming the formation of a dimer, $Y_2(OH)_2^{4+}$, with $\log \beta_{2,2} = -14.30$ as the main species. As minor species they found the YOH^{2+} and $Y_3(OH)_5^{4+}$, the stability constants of which were $\beta_{1,1} = -9.1$ and $\log \beta_{5,3} = -33.8$.

From the previous investigations described above, it has been found that the hydrolytic reactions of rare-earth ions become measurable at $\log h \leq -5$, and that not more than a small percentage of the metal ions can be transformed to hydrolysis products without the formation of a precipitate.

In the present work, therefore, we made an effort to keep contamination with protolytic impurities to a minimum when preparing test solutions containing hydrolyzed species, and employed the "back titration" method with a constant current coulometer, which had been found to be suitable for the study of a slightly buffered solution.[7,8]

The present study will deal with the hydrolytic reactions of Y^{3+}, La^{3+}, Gd^{3+}, and Er^{3+} ions in 3 M (Li)ClO_4.

Symbols

h	concentration of the free hydrogen ion.
H	analytical excess of hydrogen ions $= [ClO_4^-] - 3B - [Li^+]$.
B	total concentration of metal ions.
b	concentration of the free metal ion.
z	average number of hydrogen ions set free per metal ion.
p	number of OH groups bound to hydrolyzed species.
q	number of metal present in hydrolyzed species.
$\beta_{p,q}$	equilibrium constant of the following reaction: $qLn^{3+} + pH_2O = Ln_q(OH)_p^{(3q-p)+} + pH^+$
(p, q)	Complex, $Ln_q(OH)_p^{(3q-p)+}$
E	emf (mV).

purity supplied by the Shin-estu Chemical Co. The oxide, which had been ignited at around 900 °C, was dissolved in a slight excess of hot perchloric acid, and the lanthanum perchlorate was recrystallized twice from water. In the stock solution thus prepared, no chloride, sulfate, or ferric ions could be detected. The La(III) content of the stock solution was determined by the precipitation of the La^{3+} ion as the oxalate and by ignition to the oxide. The total perchlorate concentration in the stock solution was determined by neutralization after passing a definite amount of the solution through a column of the cation exchange resin, Dowex 50W-12, of the H^+ form.

The other rare-earth perchlorate solutions were prepared and analyzed by the same procedures as those used for the $La(ClO_4)_3$ solution.

The lithium perchlorate was prepared by the method described by Biedermann and Ciavatta.[5]

Apparatus. The titration cell consisted of two Wilhelm-type half-cells[9] for emf measurements and for constant-current coulometry.

Glass electrodes of the Beckman type No. 40498 were employed.

The pH meter used was a Radiometer PHM-4C pH-meter (Copenhagen).

A Coulometric Analyzer (Leeds & Northrup Co., Philadelphia) was used as the constant-current power source.

Preparation of Test Solutions. The hydrolyzed test solutions of rare-earth ions were prepared by the following two methods. (1) For the system of the Y^{3+} ion, a slightly acidic yttrium perchlorate solution was electrolyzed to reduce the H^+ ions by constant-current coulometry to the point where the value of Z was around 0.015; this was found to be the highest value to be reached without precipitation. For the electrolysis, the same circuit as Ciavatta's[10] was used. In the test solution thus prepared, no colloidal precipitate could be detected nephelometrically.

(2) For the systems of La^{3+}, Gd^{3+}, and Er^{3+} ions, the test solutions were prepared as follows.

We started with a slightly acidic rare-earth perchlorate solution ($\log h \leqq -3$) which had been freed from CO_2 by passing purified nitrogen gas through. The solution was electrolyzed to reduce H^+ ions by using a d.c. power supply until precipitates appeared. Equilibration was made at 25 °C by stirring the mixture for about two days with a Teflon-covered bar; then, the precipitates were removed through G4 glass filters. These procedures were carried out under an atmosphere of nitrogen gas. In each case, the filtered solution was carefully examined for turbidity, but no suspended particle could be detected. No indication of slow precipitation was found in an aliquot of the filtered solution which was occasionally tested for turbidity over half a year's time.

Emf Measurements. The general composition of a test solution can be written as:
B M Ln^{3+}, H M H^+, $(3-3B-H)$ M Li^+, 3 M ClO_4^-, where H, the analytical hydrogen ion concentration is often negative.

The test solution was titrated by means of constant-current coulometry, a coulometric circuit similar to Ciavatta's[10] being used.

The potentiometric measurements were made by the use of this cell:

GE | test solution | Ref (A)

where GE denotes a glass electrode, and Ref, the reference half-cell | 3 M $LiClO_4$ | 2.99 M $LiClO_4$ + 0.01 M $AgClO_4$ | Ag-ClAg. The emf of the cell(A) at 25 °C can be described as;

$$E = E_0 + 59.15 \log h \quad (1)$$

where E_0 is a constant into which the term of the activity coefficient of the hydrogen ion and that of the liquid-junction potential are incorporated.

All the emf measurements were performed at 25.00±0.01 °C in a parrafin oil thermostat in a room thermostated at 25±1 °C.

Results and Discussion

The values of $Z(\log h)_B$ for each metal ion, which form the basis of the following calculations, are graphically shown in Fig. 1.

The experimental data were treated by graphical methods to determine the compositions of the hydrolysis species and the corresponding approximate stability constants; then, computer calculations were made to find the most probable values of the stability constants.

If the formation of a series of reaction products with the general composition of $Ln_q(OH)_p^{(3q-p)+}$ is assumed, the concentration of the hydrogen ion set free by hydrolysis, BZ, is given by the general form:

$$BZ = \sum_p \sum_q p\beta_{p,q}[Ln^{3+}]^q[H^+]^{-p} = \sum_p \sum_q p\beta_{p,q} b^q h^{-p} \quad (2)$$

Since the maximal value of Z never exceeds 0.02 in the solutions studied, we may simplify, without introducing any appreciable error, the preliminary calculations by using this approximation:

$$[Ln^{3+}] = b \simeq B \quad (3)$$

By substituting this relation into Eq. (2) and by rearranging, we obtain:

$$Zh = \sum_p pK_p h^{-(p-1)} \quad (4)$$

where:

$$K_p = \sum_q \beta_{p,q} B^{q-1} \quad (5)$$

Primary information on the compositions of the hydrolysis species and the corresponding stability constants was obtained by the use of Eqs. (4) and (5).

For the system of the Y^{3+} ion, the plots of Zh against h^{-1} gave a set of straight lines with various slopes and with a zero intercept. This indicates that p is equal to 2. In order to determine the values of q, the values of the $(K_2 = 2\sum_q \beta_{2,q} B^{q-1})$ slope were plotted against B. The plot closely approximated a straight line; this establishes that q is equal to 1 and 2 at $p=2$. Thus, the hydrolysis species formed are $Y(OH)_2^+$ and $Y_2(OH)_2^{4+}$. Their stability constants were estimated from the intercept and slope of the straight line according to Eq. (5).

For the system of the La^{3+} ion, the plots of Zh *vs.* h^{-1} showed a horizontal line independent of B; this indicates that p and q are equal to 1. The hydrolysis species formed is $LaOH^{2+}$. The stability constant was estimated from the intercept.

For the system of the Gd^{3+} ion, the plots of Zh *vs.* h^{-1} gave the same results as that for the system of the La^{3+} ion: p and q are equal to 1. The hydrolysis

9) W. Forsling, S. Hietanen, and L. G. Sillén, *ibid.*, **6**, 901 (1952).
10) L. Ciavatta, *Arkiv Kemi*, **20**, 417 (1962).

values for $\beta_{p,q}$ they obtained were log $\beta_{1,1}=-10.0\pm0.1$, $\beta_{1,2}=-9.9_5\pm0.1$, and log $\beta_{9,5}=-71.4_5\pm0.1$ (or log $\beta_{10,6}=-78.7_5\pm0.1$). The stability constants for the (1,1) species obtained by us was the same as that obtained by Biedermann and Ciavatta. None of the (1,2) and (9,5) (or (10.6)) complexes they found were detected in the present work.

The authors are indebted to Dr. Hitoshi Ohtaki for his valuable discussions.

Cobalt(II) Complexes of Diethylenetriamine-*N,N',N''*-triacetic Acid

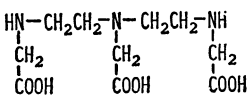
Toshio KAWATO, Hajime KANATOMI, and Ichiro MURASE

Laboratory of Chemistry, College of General Education, Kyushu University, Ropponmatsu, Fukuoka 810

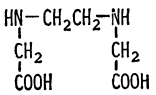
(Received November 28, 1972)

Cobalt(II) complexes of diethylenetriamine-*N,N',N''*-triacetic acid (DTTA) were prepared. From spectrophotometric and magnetic data, diaquo-DTTA-Co(II) was found to have an octahedral arrangement in which the *N,N'*-diacetate moiety and two water molecules are in the coordination sphere, and the terminal amino acid residue dangles outside. On heating the diaquo-complex, thermal rearrangement occurred with loss of water and the complex took a tetrahedral configuration. This was confirmed by its electronic spectrum and magnetic moment. The tetrahedral complex turned to another octahedral complex with absorption of water, the configuration of which seemed to differ from the original as judged by spectral difference. Cobalt(II) complexes of ethylenediamine-*N,N'*-diacetic acid (EDDA) were also prepared and investigated for the sake of comparison.

Diethylenetriaminepentaacetic acid(DTPA) is well-known as a potentially octadentate chelating ligand to form stable complexes with a number of metal ions. Many geometrical isomers are possible for Co(III) complexes of hexacoordination. Recently several Co(III)–DTPA complexes were isolated, the structure of the nitro complex being elucidated by means of PMR spectroscopy.[1] The terminal iminodiacetate group was found to be dangling and free from the coordination sphere. On the other hand, Co(III) complexes of diethylenetriamine-*N*-acetic acid and diethylenetriamine-*N'*-acetic acid were isolated as dinitro, dichloro and other derivatives, and their configurations were discussed on the bases of electronic spectra.[2] All the donor groups in these ligands were found to coordinate to the Co(III) ion.



DTTA



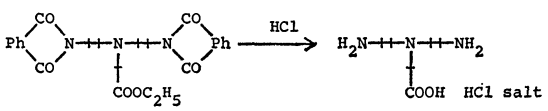
EDDA

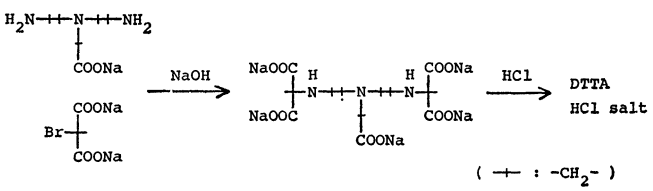
It is of interest to study the donor function of hexadentate diethylenetriamine-*N,N',N''*-triacetic acid (DTTA) with Co(III) ion. We therefore examined the reaction of DTTA with Co(II) ion to obtain a Co(II) complex which might be converted into a Co(III) complex by oxidation. Eventually, it was found that the Co(II) complex was fairly stable against oxidation and isolated as red-pink crystals. It was also found that the red-pink complex shows thermochromism at elevated temperature to blue-violet with loss of water, turning pink at room temperature in moist air. This paper deals with the structure determination of the Co(II) complexes by means of infrared and visible absorption spectra, magnetic moment, differential thermal analysis and thermogravimetric analysis, and the mechanism of thermochromism in terms of structure change. Co(II) and Co(III) complexes of ethylenediamine-*N,N'*-diacetic acid(EDDA) were also investigated for the sake of comparison.

Experimental

The infrared spectra were determined in potassium bromide disks with a Hitachi EPI-S2 spectrophotometer, while the electronic spectra were measured with a Hitachi EPS-3T spectrophotometer. Measurements of the magnetic moment were carried out at room temperature by the Gouy-method. The DTA curve was recorded under nitrogen stream with a Rigakudenki Thermoflex 8001 with a 5 mg sample on an aluminium cell at a heating rate of 10 °C/min using alumina as a reference.

Diethylenetriamine-N,N',N''-*triacetic Acid (DTTA).* The synthetic route of DTTA is shown in scheme. The terminal amino groups of diethylenetriamine-*N'*-acetic acid[2] were reacted with two equivalent bromomalonic acid in alkaline solution and the product was decarboxylated in dilute hydrochloric acid to give DTTA hydrochloride. It was thus confirmed that an acetic acid group attaches to each nitrogen atom of the diethylenetriamine molecule.





1) B. B. Smith and R. H. Betts, *J. Amer. Chem. Soc.*, **91**, 7749 (1969).

2) P. W. Schneider and J. P. Collman, *Inorg. Chem.*, **7**, 2010 (1968).

A mixture of 25.6 g (0.014 mol) of bromomalonic acid and 19 g (0.071 mol) of diethylenetriamine-*N'*-acetic acid trihydrochloride in 80 ml of water was carefully neutralized with 20% aqueous sodium hydoxide below 15 °C using phenolphthalein as an indicator. The solution was then heated at about 75 °C for an hour, being maintained its pink color by the dropwise addition of sodium hydroxide. After being heated at 85 °C for another hour, the solution was concentrated to 80 ml in a vacuum, the pH being brought to 2 with hydrochloric acid. The acidic solution containing diethylenetriamine-*N'*-acetic-*N,N''*-dimalonic acid was refluxed for 30 min until termination of the evolution of CO_2 and evaporated almost to dryness in a vacuum. The residue was extracted with ethanol containing a small amount of hydrochloric acid, the ethanol solution being evaporated to dryness in a vacuum. The product assumed to be DTTA trihydrochloride was a very hygroscopic glassy material. Since an attempt at crystallization failed, it was used directly for the preparation of the Co(II) complexes.

Diaquo-DTTA-Co(II): Red-pink Complex. To a solution of 5.4 g (0.014 mol) of DTTA trihydrochloride in 20 ml of water was added 3.33 g (0.014 mol) of cobalt(II) chloride hexahydrate in a minimum amount of water. The mixture was carefully neutralized at pH 7 with 20% aqueous sodium hydroxide. After filtration to remove a trace of violet precipitate, the filtrate was concentrated to 15 ml in a vacuum at 60 °C. On standing for a week, a red-pink crystalline powder was obtained, which was collected by filtration and washed with water and dried over calcium chloride at room temperature: yield 2 g. The complex could be recrystallized from boiling water. It was pure enough without further purification.

Found: C, 29.75; H, 5.95; N, 10.51%. Calcd for $[Co(dtta)(H_2O)_2]2H_2O$[3]: C, 29.56; H, 6.20; N, 10.34%.

The reaction conducted under nitrogen gave the same complex indicating that no oxidation took place in the air.

Thermochromisms. On being heated at 150 °C in an open vessel, the red-pink DTTA-Co(II) turned blue-violet, turned pink on cooling to room temperature. When the blue-violet complex was kept in a dry atmosphere, no color change took place even at room temperature.

Blue-violet complex, Found: C, 35.83; H, 5.00; N, 12.64%. Calcd for [Co(dtta)]: C, 35.94; H, 5.13; N, 12.57%.

Pink complex, Found: C, 29.48; H, 6.16; N, 10.44%. Calcd for $[Co(dtta)(H_2O)_2]2H_2O$: C, 29.56; H, 6.20; N, 10.34%.

*Ethylenediamine-*N,N'*-diacetic Acid (EDDA).* Although this compound is well-known, only one method of preparation has been reported with no mention of the yield.[4] We have prepared the hydrochloride in a different way with a fairly good yield.

To a suspension of 26.6 g of ethylenediamine dihydrochloride in 200 ml of ether was added with vigorous stirring 19.6 g of sodium cyanide in 30 ml of water at 2—5 °C. After standing for 10 min, 36 g of formalin (37%) was added dropwise over a period of 30 min at a temperature below 10 °C. The reaction mixture was further stirred for 2 hr at room temperature and 200 ml of methanol was added and chilled to 5 °C. The resulting sodium chloride was filtered and hydrogen chloride was saturated to the filtrate at 10 °C. The resulting precipitate was filtered and washed with methanol. Thus 40 g of ethylenediamine-*N,N'*-diacetonitrile dihydrochloride containing a small amount of sodium chloride was obtained.

3) (dtta) represents a dianion of DTTA.

To 700 ml of concentrated hydrochloric acid was added portionwise 40 g of freshly prepared dinitrile at 0—5 °C, and the mixture was stirred for 20 hr at room temperature and then diluted with 700 ml of water. The solution was boiled for 2 hr and concentrated in a vacuum until crystals began to deposit. The mixture was diluted with 150 ml of methanol and kept in a refrigerator overnight. The product was filtered and washed with methanol : yield 28 g. Recrystallization was carried out from dilute methanol containing a small amount of hydrochloric acid.

Found: C, 28.86; H, 5.73; N, 11.38%. Calcd for $C_6H_{12}N_2O_4 2HCl$: C, 28.93; H, 5.67; N, 11.25%.

Diaquo-EDDA-Co(II). The procedure was the same as in the preparation of diaquo-DTTA-Co(II) except that 3.5 g (0.014 mol) of EDDA dihydrochloride was reacted in place of DTTA trihydrochloride and the reaction and separation were carried out under nitrogen. The complex was obtained as pink crystals in a yield of 2 g which was then dried over calcium chloride and stored in a nitrogen atmosphere.

Found: C, 25.93; H, 5.35; N, 10.26%. Calcd for $[Co(edda)(H_2O)_2]1/2H_2O$[5]: C, 25.90; H, 5.45; N, 10.07%.

Aquo-hydroxo-EDDA-Co(III). Diaquo-EDDA-Co(II) was dissolved in water and air was bubbled through the solution at room temperature. Oxidation occurred within a few minutes and the solution turned to violet. It was concentrated to a small volume and kept standing in a refrigerator for a week to give violet needles. The sample was dried over calcium chloride in a vacuum.

Found: C, 26.51; H, 5.26; N, 10.19%. Calcd for $[Co(edda)(OH)(H_2O)]$: C, 26.88; H, 4.89; N, 10.45%.

Results and Discussion

DTTA is a tribasic acid and can behave as a hexadentate ligand with N_3O_3 arrangement. The Co(II) complexes obtained were neutral carrying no counter cation. Thus the possibility of hexacoordination with trinegative ligand species can be excluded. The infrared spectrum of red-pink DTTA-Co(II) is shown in Fig. 1. In the carbonyl stretching region, it exhibits two absorptions at 1585 cm^{-1} and 1645 cm^{-1} indicating the presence of two kinds of carboxylic acid groups. Since the stretching vibration of the free carboxylic acid groups is seen at 1740 cm^{-1} in

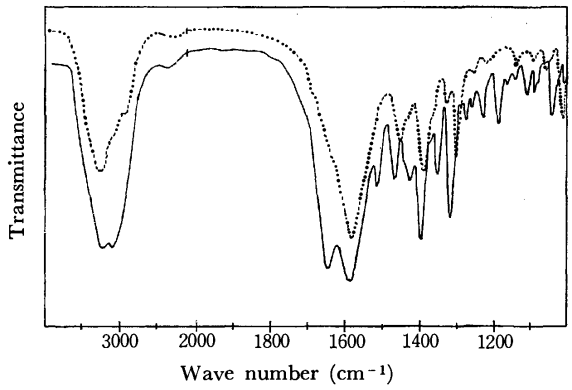


Fig. 1. IR spectra of diaquo-DTTA-Co(II) (——) and diaquo-EDDA-Co(II) (----).

4) M. Mori, M. Shibata, E. Kyuno and F. Maruyama, This Bulletin, **35**, 75 (1962).

5) (edda) represents a dianion of EDDA.

DTTA trihydrochloride and EDDA dihydrochloride, no such unionized groups are present in the complex. Thus the two absorptions can be assumed to be due to coordinated and uncoordinated but ionized carboxylate vibrations. The stretching mode of the coordinated carboxylate in a similar ligand can be seen in EDDA-Co(II) in which the two acetate groups undoubtedly coordinate to the metal ion. Diaquo-EDDA-Co(II) was sensitive against air-oxidation, though the infrared spectrum obtained under careful operation showed a single sharp peak at 1585 cm^{-1} which is attributed to COO-Co(II) stretching vibration (Fig. 1). Assuming that EDDA moiety in DTTA molecule coordinates to the Co(II) ion, the absorption at 1585 cm^{-1} in DTTA-Co(II) can be assigned to the coordinated carboxylate as well as that in EDDA-Co(II). The one at 1645 cm^{-1} seems to be due to the remaining carboxylate which exists as a dipolar ion with the α-amino group dangling outside the coordination sphere. This is supported by the fact that the area ratio of the absorption bands in the coordinated and uncoordinated carboxylate is approximately 2 : 1. In other words, DTTA coordinates to the Co(II) ion as a tetradentate ligand of linear O-N-N-O type and the remaining amino acid residue exists as a zwitter ion in crystals.

Since the red-pink complex shows a magnetic moment of μ_{effect}=4.96 B. M. which is normal for a high-spin octahedral Co(II) complex, the remaining two positions of the coordination sphere are occupied by water molecules, the presence of which was suggested from the elemental and thermal analyses. The charts of differential thermal analysis (DTA) and thermogravimetric analysis (TGA) of the red-pink complex are given in Fig. 2. The weight loss of 18% up to 150 °C corresponds very closely to four moles of water (calcd: 17.7%), which probably consists of two moles of coordinated and two moles of lattice water. However, no difference is observed between the curves of the two kinds of water. The DTA curve indicates two endothermic peaks at 133 °C and around 155 °C. The large peak at 133 °C is due to the elimination of water as judged from the TGA curve. The other broad peak may be due to some phase transition in the crystalline structure.

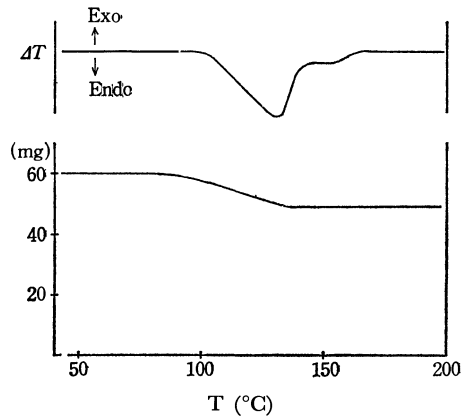

Fig. 2. DTA and TGA curves for diaquo-DTTA-Co(II).

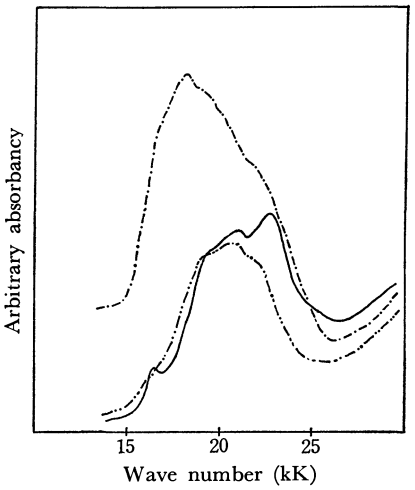

Fig. 3. Reflectance spectra of DTTA-Co(II) complexes: ——: red pink diaquo-DTTA-Co(II); —·—: blue violet anhydrous DTTA-Co(II); —··—: pink diaquo-DTTA-Co(II).

The blue-violet complex obtained by heating the red-pink one at 150 °C carries no water and shows a magnetic moment of μ_{effect}=4.66 B. M. Because of its high hygroscopicity, no well-defined infrared spectrum could be obtained. The broad absorption around 1590—1650 cm^{-1} suggests the presence of two kinds of carboxylate groups like those in diaquo-DTTA-Co(II). The electronic spectrum in solid exhibits d-d transition as a broad band around 18 kK (Fig. 3). This implies a high spin tetrahedral configuration of low symmetry for the complex, where O-N-N-O coordination occurs around the Co(II) ion and the terminal iminoacetate group dangles like that in diaquo-DTTA-Co(II).

When the blue-violet complex was allowed to come in contact with moist air, the color turned pink with absorption of four moles of water. The pink complex was rather sensitive against air-oxidation. The mag-

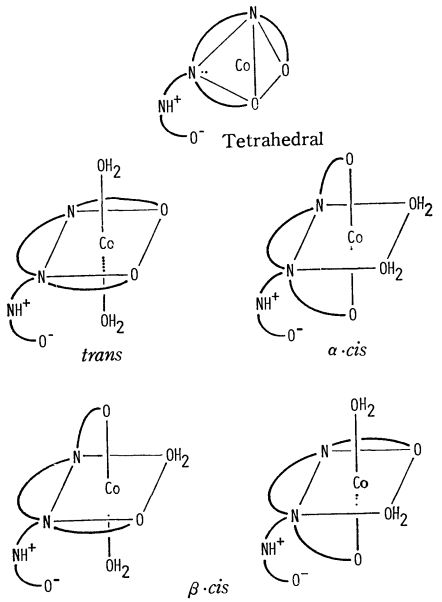

Fig. 4. Tetrahedral and possible four octahedral arrangements of DTTA-Co(II) complexes.

netic moment was slightly lower at μ_{effect}=4.83 B.M. decreasing gradually on standing in the air. The infrared spectral pattern was superimposable with that of the red-pink complex. An octahedral configuration is therefore reasonable for the pink complex in the same sense as in the red-pink one. On the other hand, the electronic spectrum of the former differs from that of the latter (Fig. 3).

In diaquo-DTTA-Co(II) in which the terminal iminoacetate group dangles, four stereoisomers are possible (Fig. 4). The difference in the electronic spectrum may be due to the fact that the red-pink and pink complexes are stereoisomers of this type. Exact assignment of their configurations, however, is impossible at present.

In diaquo-EDDA-Co(II), the EDDA anion coordinates as a tetradentate ligand. An octahedral configuration is provided, since its spectral pattern is similar to that of diaquo-DTTA-Co(II) (Fig. 5). However, the magnetic moment varied in each sample around an average value of μ_{effect}=4.4 B.M. which is lower than that for ordinary octahedral Co(II) complexes. This is due to a contamination by a Co(III) complex formed by inevitable air-oxidation during the course of measurements.

The pink coloration of diaquo-EDDA-Co(II) turned violet on heating at 150 °C in the absence of oxygen, returning to pink in a moist atmosphere at room temperature. In contact with air, the latter pink complex turned very quickly to deep violet. The thermochromism from pink to violet was probably due to dehydration. However, an extremely high sensitivity of the violet complex against air-oxidation and moisture made it impossible to confirm it. A tetrahedral configuration is suggested for the violet complex from the electronic spectrum in solid (Fig. 5). It exhibits a d–d transition band having a typical strong absorption at 19.1 kK.

The deep violet one caused by air-oxidation is undoubtedly a Co(III) complex. Elemental analysis indicates formula [Co(edda)(OH)(H_2O)]. This is supported by taking the formation condition into consideration, since no inorganic anion besides a hydroxide ion was present in the solution from which the crystals were obtained. The infrared spectrum shows a carboxylate stretching vibration due to COO–Co(III) at 1650 cm^{-1}. An octahedral configuration is seen in its electronic spectrum in solid which exhibits a typical d–d transition pattern having an absorption maxima at 18.7 kK and 26.3 kK (Fig. 5). Co(III) complexes of EDDA were investigated by several authors[6] and their stereochemistry has already been established. However, the geometry of the hydroxide ion and the water molecule in the octahedral arrangement is not clear in the present complex.

(Received July 4, 1972)

The reaction of α-nitroolefins with triethyl or diethyl phosphite was studied and structural assignment of the products was made by spectroscopic analyses. Ethyl α,β-unsaturated α-nitrocarboxylates (IV) and 1-nitroalkenes (V) reacted with triethyl phosphite to afford ethyl β-diethoxyphosphinyl-α,β-unsaturated-carboxylates (IX) and 2-diethoxyphosphinyl-1-alkenes (X), respectively. Compound (IV) reacted with diethyl phosphite to give ethyl β-diethoxyphosphinyl-α-nitrocarboxylates (VI). The geometrical isomerism in IX and the reaction mechanism were discussed.

Numerous reports have appeared on the deoxygenation and intramolecular cyclization reaction of aromatic nitro and nitroso compounds with tervalent organophosphorus reagents,[3-7] but little attention has been paid to that of aliphatic nitro compounds with the above reagents.[3]

The reaction of ethyl α,β-unsaturated α-nitrocarboxylates (IV)[8,9] with triethyl phosphite gives ethyl β-diethoxyphosphinyl-α,β-unsaturated-carboxylates (IX). Only two kinds of vinylphosphonates (IXa and IXb) have recently been prepared by nucleophilic substitution of the corresponding activated vinyl halides with triethyl phosphite, as useful intermediates (Arbuzov reaction).[10,11]

In the present paper, detailed studies on the reaction of α-nitro-olefins (IV and V) with triethyl or diethyl phosphite and on the structural assignment of products are described.

Results and Discussion

Reactions of α-Nitroolefins with Triethyl Phosphite. When a benzene solution of IV and triethyl phosphite was refluxed for about 3 hr, evolution of a gaseous substance was observed. This was trapped and identified by gas chromatography to be ethyl nitrite. Fractional distillation of the reaction mixture gave ethyl β-diethoxyphosphinyl-α,β-unsaturated-carboxylates (IX) as a colorless oil in good yield.

Similar reaction of ethyl 3-hydroxy (Id)-, 3-acetoxy (IId)- and 3-methoxy-2-nitrohexanoates (IIId) with triethyl phosphite also gave IXd and ethyl nitrite, together with a small amount of water, acetic acid and methanol, respectively. It is well-known that hydroxy, acetoxy and methoxy groups in the 3-position of 2-nitrocarboxylic esters are easily eliminated in the persence of base to afford the corresponding nitroolefins.[1,8,12,13] The reaction might thus be preceded by the elimination of the substituents in the presence of triethyl phosphite as Lewis base. In the cases of Id and IIId, the yield of IXd decreased a great deal.

Under similar experimental conditions, 1-nitroalkenes (V) also reacted with triethyl phosphite to afford 2-diethoxyphosphinyl-1-alkenes (X) as a colorless oil in good yield. The results are summarized in Table 1, 2, 3, and 4.

Structural Assignment of IX and X. The streeochemical assignment of IX and X was made on the basis of independent preparation from vinyl halides and triethyl phosphite,[11] elementary and spectroscopic analyses. NMR spectra of IX (Table 2) showed two kinds of vinyl hydrogen signals, one with smaller coupling constants ($J_{P,H}$=23.5—28.4 Hz) appearing in the lower magnetic field and the other in higher field with larger coupling constants ($J_{P,H}$=43.5—46.3 Hz) and were assigned to *cis* and *trans* isomers,[14] respectively.

Similarly, two vinyl hydrogen signals of *cis* and *trans* to the phosphorus atom appeared in lower and higher magnetic fields with smaller ($J_{P,H}$=22.5—23.8 Hz) and larger ($J_{P,H}$=46.3—50.0 Hz) coupling constants, respectively. The composition of *cis* and *trans* isomers in IX was evaluated from the intensity of the vinyl proton signals to be approximately 7/3.

The infrared spectra of IX showed a waek band of carbon-carbon double bond in the region 1615—1630 cm^{-1} and two strong bands of P=O and P-O-C groups at 1250 and 1020—1025 cm^{-1}, respectively (Table 2). The absorption pattern of X is essentially the same

as that of IX except for the lack of ethoxycarbonyl band (Table 4).

Reaction of α-Nitroolefins with Diethyl Phosphite. In contrast to triethyl phosphite, diethyl phosphite can add to the olefinic bond of IV easily. When a mixture of IV and the phosphite was heated at 100 °C for 2 hr, the expected ethyl α-nitro-β-diethoxyphosphinylcarboxylates (VI) were obtained in about 50% yield. Compounds (VI) keep the nitro group, which showed stretching bands at *ca* 1565 and 1370 cm^{-1} in the infrared spectra. The disappearance of the stretching band of carbon-carbon double bond in the region 1640—1665 cm^{-1} and the appearance of P=O and P–O–C groups at 1250 and *ca* 1020 cm^{-1} seem to support the formation of VI.

Reaction Mechanism. From the results, it is postulated that the triethyl phosphite attacked nucleophilically on the β-position of the nitro-olefins (aci-form; VII) and cyclized to afford five-membered intermediates, 3-ethoxycarbonyl-Δ^2-1,2,5-oxazaphospholine-2-oxide derivatives (VIII), and the subsequent concerted reaction in VIII occurred to give IX and X together with ethyl nitrite (Scheme 1). In fact, in the case of isopropyl derivative (VIIIe, R′=COOEt), an unstable intermediate was obtained under mild conditions and decomposed to IXe and ethyl nitrite during the course of redistillation.

On the other hand, diethyl phosphite added nucleophilically to β-position of the nitroolefins (nitro-form; IV) affords VI.

Experimental

All boiling points are uncorrected. The IR spectra were recorded on a Hitachi EPI-S2 spectrometer. The NMR spectra were measured with a JNM-4H-100 spectrometer (Japan Electron Optics Laboratory Co., Ltd.) at 100 MHz.

Materials. Ethyl α,β-unsaturated α-nitrocarboxylates were prepared by the reaction of ethyl α,β-unsaturated carboxylates with fuming nitric acid.[9] Ethyl α-nitrocinnamate was prepared according to the method of Dornow and Menzel.[15]

Reactions of IV with Triethyl Phosphite. A solution of IV (0.05 mol) in dry benzene (40 ml) was added dropwise, with stirring, to triethyl phosphite (0.05 mol) at a temperature below −5 °C. After being stirred for 3 hr at this temperature, the mixture was allowed to warm to room temperature, when stirring was continued for 1 hr. When the mixture was refluxed for about 3 hr, evolution of gaseous substance was observed. This was trapped in a U-tube fitted at the top of a condenser and cooled below −20 °C, and identified to be ethyl nitrite by gas chromatography. After concentration of the reaction solution, the residual oil was distilled under reduced pressure to afford a colorless oil, which was identified as ethyl β-diethoxyphosphinyl-α,β-unsaturated-carboxylates (IX). The results are summarized in Tables 1 and 2.

Reaction of IVe with Triethyl Phosphite below 30 °C. Ethyl 4-methyl-2-nitro-2-pentenoate (IVe; 5 g) was added dropwise, with stirring, to triethyl phosphite (10 g) at a temperature below −20 °C. After stirring for 2 hr, the mixture was allowed to warm slowly to room temperature and stirring was continued for 2 days at 30 °C. After concentration of the reaction mixture, the residual viscous oil was carefully distilled in a vacuum to afford 3-ethoxycarbonyl-4-isopropyl-Δ^2-1,2,5-oxazaphospholine-2-oxide (VIIIe) as yellow viscous oil (3.9 g, 41.5%), bp 95—105 °C/0.001 mmHg. IR (KBr disk): 1730 (-COOEt), 1625 (-C=N-), 1240 (-P-O-), and 1030 (P-O-C-) cm^{-1}.

Found: N, 4.14%. Calcd for $C_{14}H_{28}NO_7P$: N, 3.87%.

When a solution of VIIIe (2.8 g) in dry benzene (30 ml) was refluxed for 3 hr and the reaction solution was concentrated, residual oil was obtained accompanied by liberation of ethyl nitrite. The oil was distilled under reduced pressure to afford a colorless oil, which was identified as ethyl 3-diethoxyphosphinyl-4-methyl-2-pentenoate (IXe; 1.9 g, 74 %).

Reactions of V with Triethyl Phosphite. 1-Nitro-1-alkene (0.05 mol) was added dropwise, with stirring, to triethyl phosphite (0.07 mol) maintained below 15 °C. After stirring for 1 hr, the mixture was allowed to stand at 40 °C for about 2 hr when liberation of ethyl nitrite ceased. Concentration of the reaction mixture afforded residual oil, which was identified as 2-diethoxyphosphinyl-1-alkene (X). The results are summarized in Tables 3 and 4.

Reactions of Id-IIId with Triethyl Phosphite. Ethyl 3-acetoxy-2-nitrohexanoate[13] (IId; 0.03 mol) was added dropwise, with stirring, to a solution of triethyl phosphite (0.03 mol) in dry benzene (20 ml) cooled below 15 °C. After being stirred for 30 minutes at room temperature, the solution was refluxed for 1 hr. After concentration of the reaction solution, the residual oil was distilled under reduced pressure to afford a colorless oil, which was identified as ethyl 3-diethoxyphosphinyl-2-hexenoate (IXb). Yield 68.3%.

An analogous treatment of ethyl 3-hydroxy-2-nitrohexanoate (Id)[13] and ethyl 3-methoxy-2-nitrohexanoate (IIId)[9] with triethyl phosphite under reflux for 6 hr also afforded IXd, in 38.5 and 23.5% yields, respectively.

Reactions of IV with Diethyl Phosphite. Diethyl phosphite (0.03 mol) was added dropwise, with stirring, to ethyl 2-nitropentenoate (IVc; 0.03 mol) at room temperature, and the mixture was heated at 100 °C for 2 hr when it changed to brown. After concentration of the reaction mixture, the residual oil was distilled under reduced pressure to afford a colorless oil (68%, bp 130—135 °C/0.75 mmHg), which was identified as ethyl 3-diethoxyphosphinyl-2-nitropentanoate (VIc). IR(KBr disk): 1750 (-COOEt), 1565 and 1370 (-NO_2), 1250 (P=O), and 1020 (P-O-C) cm^{-1}. NMR ($CDCl_3$): 4.40—4.75 τ (double doublets, J=7.0 Hz) and 4.58 τ(doublet, J_{P-C-CH}=16.2 Hz).

Found: C, 42.84; H, 6.91; N. 4.33%. Calcd for $C_{11}H_{22}NO_7P$: C, 42.85; H, 7.07; N, 4.50%.

An analogous treatment of ethyl 2-nitrobutenoate (IVb) with diethyl phosphite also afforded ethyl 3-diethoxyphosphinyl-2-nitrobutanoate (VIb). Yield 41%, bp 126—128 °C/0.8 mmHg. IR: 1755 (-COOEt), 1565 and 1370 (-NO_2), 1250 (P=O), and 1020 (P-O-C) cm^{-1}. NMR: 4.60—4.73 τ(double doublets, J=6.8 Hz) and 4.66 τ(doublet, J_{P-C-CH}=12.5 Hz).

Found: C, 40.32; H, 6.83; N, 4.32%. Calcd for $C_{10}H_{20}NO_7P$: C, 40.40; H, 6.73; N, 4.71.%

Solvolysis of Organic Phosphates. VIII. γ-Elimination in the Spontaneous Hydrolysis of 2-Chloro-3-pyridylmethyl Phosphate[1]

Yukito MURAKAMI, Junzo SUNAMOTO, and Naomi KANAMOTO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received July 17, 1972)

2-Chloro-3-pyridylmethyl phosphate was hydrolyzed in aqueous media. All runs were carried out in a pH range 1—3 where the reactive species are essentially of neutral and monoanion forms. The main reaction product was 3-hydroxymethyl-2-pyridone, the reaction following an apparent first-order kinetics with respect to both pyridone formation and liberation of inorganic phosphate. The hydrolytic elimination of the 2-chlorine atom was catalyzed to a great extent by the phosphate group. The dephosphorylation was effected by the presence of the 2-chlorine atom as well. The hydrolysis of the neutral phosphate species, which is in general inert to hydrolysis, was much accelerated in the present hydrolysis. A plausible mechanism was presented in terms of the concerted elimination of both 2-chlorine atom and phosphate moiety by their mutual catalytic participation. Besides the main reaction process, a normal hydrolysis affording 2-chloro-3-pyridylmethanol was also detected to proceed to a minor extent.

In a series of studies on the hydrolysis of organic phosphates, we have shown some distinct types of neighboring group participation in dephosphorylation processes. Both pyridinium and quinolinium groups were observed to play an intramolecular general acid catalysis in the hydrolysis of 2-pyridylalkyl phosphates[2,3] and 8-quinolyl phosphate,[4] respectively, in their zwitterion forms. A neighboring hydroxyl group acted as a remarkable acid catalyst in the hydrolysis of 3-hydroxy-2-pyridylmethyl phosphate.[5]

The phosphate group occasionally provides a proximity effect on the elimination of another functional group in the molecule. The hydrolytic elimination of β-chlorine in 2,2,2-trichloroethanol was almost inhibited by the presence of a phosphate group, as apparent in the solvolysis study of 2,2,2-trichloroethyl phosphate.[6] This study on the hydrolysis mechanism of 2-chloro-3-pyridylmethyl phosphate provides another type of proximity effect caused by the participation of both γ-chlorine atom and phosphate. These groups located mutually in the neighboring space showed marked catalytic effects in their hydrolytic elimination.

Experimental

Materials. Details of synthesis and purification procedures for 2-chloro-3-pyridylmethyl phosphate are described elsewhere.[7] UV (in 0.02 M-perchloric acid at room temperature): 266 nm (ε 3100) and 273 nm (ε 2800). NMR (0.71 M in DMSO-d_6, TMS as internal reference): δ 5.03 (2H, d, $J_{CH_2-^{31}P}$=8.0 Hz, -C$\underline{H_2}$-), 6.61 (2H, s, -O$\underline{H}$), 7.54 (1H, q, J_{4-5}=7.5 Hz and J_{5-6}=5.0 Hz, H-5), 8.02 (1H, q, J_{4-6}=2.0 Hz, H-4), and 8.46 (1H, q, H-6).

2-Chloro-3-pyridylmethanol was prepared by LAH reduction of methyl 2-chloronicotinate.[7] UV (in 0.02 M-perchloric acid at room temperature): 266 nm (ε 4700) and 273 nm (ε 4400). NMR (0.40 M in DMSO, TMS as internal reference): δ 4.57 (2H, d, J_{CH_2-OH}=4.5 Hz, -C$\underline{H_2}$-), 5.49 (1H, t, -O$\underline{H}$), 7.43 (1H, q, J_{4-5}=7.5 Hz and J_{5-6}=4.5 Hz, H-5), 7.95 (1H, q, J_{4-6}=2.0 Hz, H-4), and 8.19 (1H, broad d, H-6).

3-Hydroxymethyl-2-pyridone was synthesized through diazotization of 2-amino-3-hydroxymethylpyridine followed by hydrolysis.[7] UV (in 0.02 M-perchloric acid at room temperature): 228 nm (ε 5300) and 297 nm (ε 5140). IR (0.2 M in 0.1 M-deuteroperchloric acid): 1640 cm^{-1} (C=O). NMR (0.40 M in DMSO, TMS as internal reference): δ 4.28 (2H, broad s, -C$\underline{H_2}$-), 4.91 (1H, broad s, -O$\underline{H}$), 6.17 (1H, t, J_{4-5}=J_{5-6}=6.5 Hz, H-5), 7.22 (1H, broad q, J_{4-6}=1.5 Hz, H-4), and 7.38 (1H, broad d, H-6).

Acid Dissociation Constants. The acid dissociation constants of the phosphate were obtained by the usual potentiometric titration.[2] The values found for pK_{H_2A} and pK_{HA} were 1.8 and 6.3 at 80 °C, and 2.17 and 5.97 at 25 °C, respectively, an ionic strength being maintained at 0.10 with potassium nitrate. The neutralization equivalence was 106.68 and 108.90 (calcd. 111.77) at 80 and 25 °C, respectively. The values of acid dissociation constants at elevated temperature were not sufficiently reproducible, especially for pK_{H_2A}. This was most likely caused by a trace hydrolysis of the phosphate during the course of titration to give off hydrochloric acid.

Product Analyses. The chromatographic solvent used was a mixture of *n*-propanol, concentrated aqueous ammonia, and water (6 : 3 : 1 by vol.). An acid molybdate spray reagent[8] was used for detection of phosphorus-containing spots. Paper chromatography and tlc were carried out with Toyo Roshi No. 50 filter paper and Tokyo Kasei spot film (silica gel), respectively, in combination with the above solvent and developing reagent. The R_f-values found for inorganic phosphate and 2-chloro-3-pyridylmethyl phosphate were ≈0.0 and 0.34, respectively, by paper chromatography, and 0.0 and 0.45 by tlc.

(i) A 2.02×10^{-3} M aqueous solution of 2-chrolo-3-pyridylmethyl phosphate was hydrolyzed in a sealed pyrex tube for 10.5 hr at 90 °C and pH 1.0 with an ionic strength of 0.10 ($HClO_4$). At the end the conversion was 30.0%, calculated from the determination of liberated inorganic phosphate. UV spectrum of the resulting hydrolyzate indicated the formation of 2-chloro-3-pyridylmethanol and 3-hydroxymethyl-2-pyridone (Fig. 1). No other organic phosphorus compounds besides the starting phosphate were

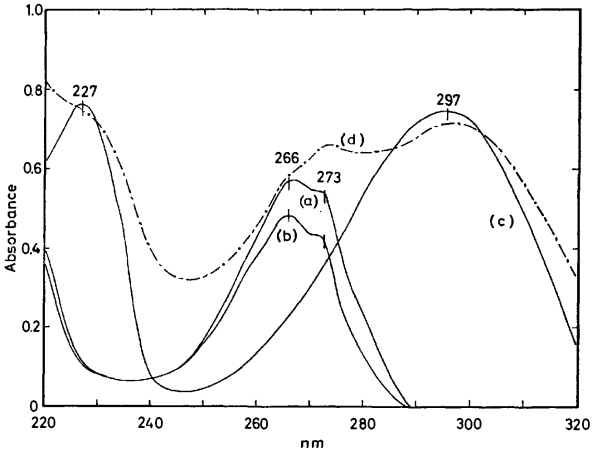

Fig. 1. Ultraviolet absorption spectra in 0.02 M-perchloric acid: (a) 2-chloro-3-pyridylmethyl phosphate, 1.58×10^{-4} M; (b) 2-chloro-3-pyridylmethanol, 1.26×10^{-4} M; (c) 3-hydroxymethyl-2-pyridone, 1.44×10^{-4} M; (d) the hydrolyzate of 2-chloro-3-pyridylmethyl phosphate, the initial phosphate solution of 0.103 M was treated at 90 °C and $-\log[H^+]=1.0$ for 23 hr and diluted 5/3 times for measurement.

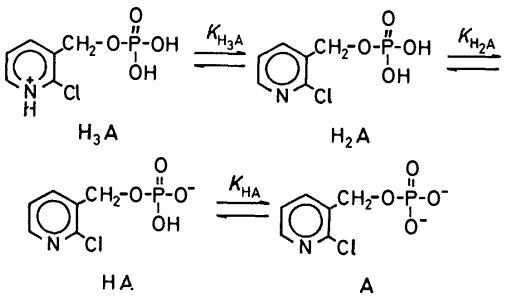
detected by means of paper and thin layer chromatographic techniques. (ii) A 0.103 M 2-chloro-3-pyridylmethyl phosphate solution in 0.1 M-deuteroperchloric acid was placed in a sealed Pyrex tube and allowed to stand for 23 hr at 90 °C. White precipitates formed were removed by filtration and the filtrate was subjected to IR measurement. The absorption band attributable to the carbonyl stretching mode was weak but observable at 1640 cm^{-1}. The white precipitates formed was identified as 3-hydroxymethyl-2-pyridone by tlc with the use of UV light for detection, R_f 0.65. A 0.196 M solution of 2-chloro-3-pyridylmethanol in 0.1 M-deuteroperchloric acid was treated under the same conditions. However, significant transformation of this alcohol was not detected by any analytical method. (iii) 2-Chloro-3-pyridylmethyl phosphate (47.32 mg) was dissolved in DMSO-d_6 (0.30 ml) containing 10 μl of deuterium oxide, placed in a sealed Pyrex tube and kept at 95 °C for 21 hr. The reaction was followed by NMR with TMS as an internal reference. A doublet signal of the methylene protons in the starting phosphate gradually decreased, whereas a singlet signal assignable to the methylene protons of 2-chloro-3-pyridylmethanol increased in intensity. Another signal due to the methylene protons appeared at 4.28 ppm and increased markedly in intensity with the progress of reaction. This signal was assigned to the methylene protons in 3-hydroxymethyl-2-pyridone with the aid of an authentic sample. No other methylene signal of a doublet nature was detected throughout the reaction. After 4 hr of the reaction period, a white crystalline mass (the pyridone) started to precipitate. The yield of the pyridone was approximately 90% at the end of the reaction.

Kinetic Procedures. The experimental and analytical procedures were essentially the same as those employed for the hydrolysis studies of 2-pyrdidylalkyl phosphates at higher temperature.[3] All runs were carried out in aqueous media at 90.0±0.1 °C with an ionic strength of 0.10 ($HClO_4$–$NaClO_4$) over the $-\log[H^+]$ range 1.0—3.0, where the phosphate exists in three forms, cation, neutral, and monoanion. The pH-deviation did not exceed ±0.02 during the course of reaction. The hydrolytic decomposition of the phosphate was followed by determination of the liberated inorganic phosphate.[2-5] The formation of 3-hydroxymethyl-2-pyridone was measured spectrophotometrically at 297 nm.

Results and Discussion

Acid Dissociation Process. The second acid dissociation constant found for the present phosphate ($pK_{H_2A}\approx2$) was comparatively smaller than those for the other pyridylalkyl phosphates (pK_{H_2A} 4-5).[2-6] Brown and McDaniel obtained spectrophotometrically the pK_a-values of chloropyridines in aqueous system at 25 °C; 0.72 for the 2-isomer and 2.84 for the 3-isomer.[9] The pK_a-values for dissociation of a pyridinium proton in pyridine[10] and 3-pyridylmethyl phosphate[11] are 5.45 and 4.86 at 25 °C, respectively. The phosphorylated hydroxymethyl group apparently tends to act as an electron-withdrawing substituent to some extent. Thus, the pK_a-value for dissociation of a pyridinium proton in the present phosphate should be less than that for 2-chloropyridine. The most plausible acid dissociation process is presented in Scheme 1. An intramolecular hydrogen bonding of



Scheme 1.

the phosphate moiety with the chlorine atom may cause the trapping of the phosphate proton, and consequently the pK_{H_2A}-value may become a little larger than that of ordinary alkyl phosphates.

Reaction Mechanisms. We may conclude from product analyses that 2-chloro-3-pyridylmethyl phosphate undergoes hydrolytic decomposition to afford 3-hydroxymethyl-2-pyridone as the major product

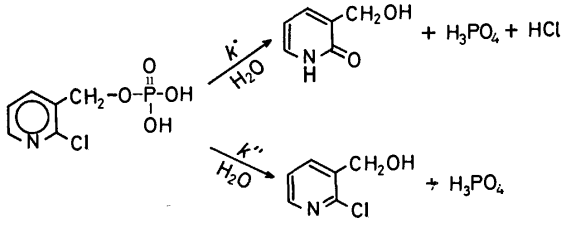
along with a small amount of 2-chloro-3-pyridylmethanol. The apparent first-order rate constants obtained from analysis of the liberated inorganic phosphate are listed in Table 1. A good first-order kinetics was also established for the pyridone formation. The rate constants obtained by both methods were almost comparable: for example, $k_{Pi}=1.02\times10^{-5}$ sec^{-1} for the liberation of inorganic phosphate and $k'=0.93\times10^{-5}$ sec^{-1} for the formation of the pyridone at 90.7±0.1 °C and $-\log[H^+]=1.0$ with an ionic strength of 0.10 ($HClO_4$). The difference between these two rate constants is significant since the presence of a small amount of 2-chloro-3-pyridylmethanol, the normal hydrolysis product, was no doubt detected by NMR. Thus, the whole reaction scheme consists of two competitive reactions as shown in Scheme 2. One may provide two possible mechanisms for the pyridone formation process; consecutive (Scheme 3) and concerted bimolecular (Scheme 4). Although other organic phosphates besides the starting one could not be detected in the course of hydrolysis reaction, we would not completely eliminate the possible formation of 2-hydroxy-3-pyridylmethyl phosphate (I or its keto-isomer, 1,2-dihydro-2-oxo-3-pyridylmethyl phosphate, II) as a labile intermediate in the pathway to the pyridone formation.

The neighboring acidic phosphate moiety seems to promote the elimination of the γ-chlorine atom through



Scheme 2.

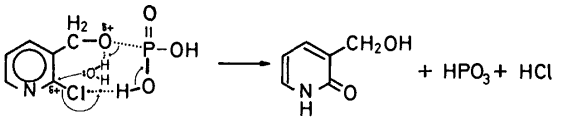

Scheme 4. (A concerted bimolecular mechanism).

the intramolecular Cl···H···O hydrogen bonding. Examination by the Dreiding-type model (Fig. 2) shows that the chlorine atom and the phosphate hydroxyl group can be favorably oriented in space to form a linear hydrogen bonding with the preferential orbital direction.

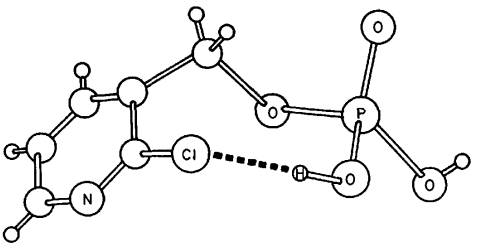

Fig. 2. Stereoview of the molecular configuration and the geometry for intramolecular hydrogen bonding between the chlorine atom and the phosphate moiety in 2-chloro-3-pyridylmethyl dihydrogen phosphate.

Using pK_a-values evaluated at 80 °C for each ionic species of the present phosphate[12] and the observed rate constants listed in Table 1, we calculated the apparent specific rate constants for the hydrolysis according to the usual computation procedures;[2-5] $k_{H_2A}=1.0\times10^{-5}$ and $k_{HA}=0.5\times10^{-5}$ sec^{-1} at 90 °C. It is well-known that the neutral alkyl dihydrogen phosphates are in general very inert to hydrolysis.[13,14] The hydrolysis rate constants for the neutral species of methyl and ethyl phosphates, for example, are 0.5×10^{-6} [13] and 0.7×10^{-6} sec^{-1} [14] at 100 °C, respectively. The hydrolysis reaction of the present neutral phosphate species, mainly giving rise to pyridone formation, was apparently much accelerated relative to the hydrolysis of those alkyl phosphates. The profound rate enhancement for the neutral phosphate hydrolysis can not be explained only by the usual electronic effect brought about by the 2-chloropyridyl group, but can be attributed to direct participation of the chlorine atom at the dephosphorylation site.

In conclusion, 2-chloro-3-pyridylmethyl phosphate was hydrolyzed primarily to afford the pyridone by the mutual participation of the chlorine atom and the phosphate group (Scheme 4).

12) The pK_{H_3A}-value for dissociation of the pyridinium proton was estimated to be 0.7 in reference to the value for 2-chloropyridine.[9] Care was taken to minimize the possible error in each specific rate constant caused by this estimation.

Methylene Analogs of Cyclobutenedione. VI.[1] Interconversion between 3,4-Dimethylcyclobut-3-ene-1,2-dione and 3,4-Dimethylenecyclobutane-1,2-dione

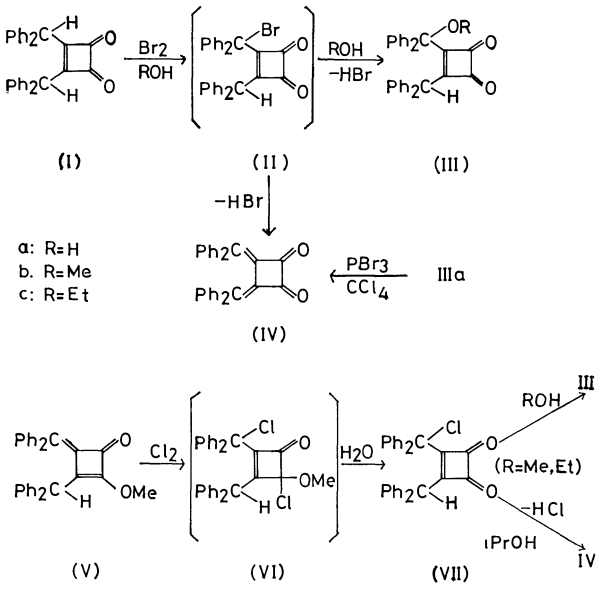
Fumio Toda and Nobuhiro Ooi

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

(Received July 10, 1972)

Treatment of 3,4-bis(diphenylmethyl)cyclobut-3-ene-1,2-dione (I) with bromine in ROH (R=H, Me, Et, and *i*-Pr) afforded 3,4-bis(diphenylmethylene)cyclobutane-1,2-dione (IV) and 3-diphenylmethyl-4-alkoxydiphenylmethylcyclobut-3-ene-1,2-dione (III) in various ratios depending on the steric bulkiness of R of ROH. Acidification of a solution of III in KOH–MeOH, in which III exists in the form of enolate anion (VIII), afforded III and IV in various ratios depending on the steric nature of the substituent R. Bromination of IV in 99% acetic acid afforded 3,4-bis(hydroxydiphenylmethyl)cyclobut-3-ene-1,2-dione (XI). Although the bromination of XI with phosphorus tribromide afforded IV, that with bromine afforded the 2,5-dihydrofuran derivative (XVII). The reaction of I with *o*-phenylenediamine to afford azamethylenecyclobutane derivatives XXV and XXVI is described.

The ring-hydrogen of 3-phenylcyclobut-3-ene-1,2-dione reacts with halogen to afford 4-halo-3-phenylcyclobut-3-ene-1,2-dione.[2-4] However, no reaction of hydrogen on the carbon bound to the cyclobutenedione ring has yet been reported. We have studied the reaction of 3,4-bis(diphenylmethyl)cyclobut-3-ene-1,2-dione (I) with electrophile and found that interconversion between I and 3,4-bis(diphenylmethylene)cyclobutane-1,2-dione (IV) occurs easily.



Scheme 1.

The reaction of I with bromine in 10% aqueous acetonitrile afforded 3-diphenylmethyl-4-hydroxydiphenylmethylcyclobut-3-ene-1,2-dione (IIIa) in a 45% yield. In methanol, 3-diphenylmethyl-4-methoxydiphenylmethylcyclobut-3-ene-1,2-dione (IIIb) was obtained in a 53% yield. On the other hand, the reaction of I with bromine in ethanol afforded 3-diphenylmethyl-4-ethoxydiphenylmethylcyclobut-3-ene-1,2-dione (IIIc) and IV in 39 and 13% yields, respectively, but that in 2-propanol afforded IV as the sole product (47% yield).

The reactions can be interpreted by assuming 3-diphenylmethyl-4-bromodiphenylmethylcyclobut-3-ene-1,2-dione (II) to be an intermediate. It is understandable that substitution of bromine of II with hydroxylic or alkoxylic nucleophile to afford III is in competition with the elimination of hydrogen bromide from II to afford IV (Scheme 1). The intermediacy of II is likely, since the bromination of IIIa with phosphorus tribromide in carbon tetrachloride afforded IV in a 52% yield. In order to confirm the intermediacy of II, preparation of its chloro-analog (VI) was attempted. Bubbling of chlorine through a solution of 2-methoxy-3-diphenylmethyl-4-diphenylmethylenecyclobut-2-en-1-one (V)[5] in ether afforded an oil. This was identified to be 3-diphenylmethyl-4-chlorodiphenylmethylcyclobut-3-ene-1,2-dione (VII) by means of IR and UV spectra, though the oil was too unstable for further purification. The strong IR absorption bands of VII, 1785 (νC=O) and 1640 cm^{-1} (νC=C), are charactaristic of cyclobutenedione derivatives as shown by I, III, and X. A possible reaction mechanism for the formation of VII is the hydrolysis of VI initially produced by the 1,4-addition of chlorine to V, since it has been established that α-halo-α-alkoxycyclobutanone is easily hydrolyzed into cyclobutenedione.[5] The reaction of VII with methanol and ethanol at room temperature afforded IIIb and IIIc in 64 and 59% yields, respectively. The reaction of VII with 2-propanol afforded IV in a 32% yield. It is thus reasonable to assume that II is an intermediate of the reaction of I with ROH in the presence of bromine. The reason for the difference between the reaction of VII with ethanol to afford IIIc and that of I with ethanol in the presence of bromine to afforded IIIc and IV is not clear.

UV spectra of IIIa, IIIb, and IIIc in 5% KOH–MeOH, 324 (18900), 323 (16000), and 323 nm (ε, 4700), respectively, were comparable with the spectrum of I in the same solvent, 330 nm (ε, 21700).[6]

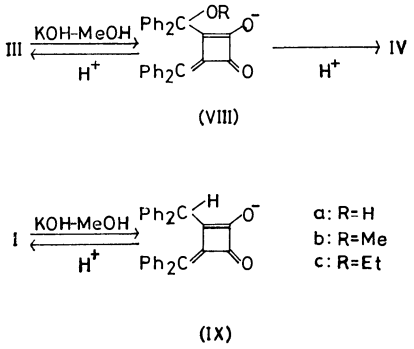
Since it has been established that I dissolved in KOH–MeOH in the form of enolate anion (IX), the enolate form of III is considered to be VIII. The wavelength of the absorption band of VIII is slightly smaller than that of IX. The greater the sterical bulkiness of R in VIII, the smaller the molecular extinction coefficient ε. This suggests that the steric crowding between alkoxydiphenylmethyl and diphenylmethylene moieties increases the transition energy but decreases the probability of the electronic excitation of VIII.

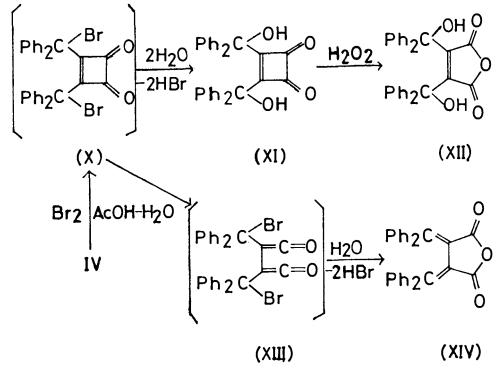


Scheme 2.

Acidification of IX affords I quantitatively,[6] but that of VIII was found to afford III and IV (Table 1). Major products obtained by the acidification of VIIIa and VIIIb were IIIa and IV, respectively. It seems possible that the ketonization of VIII leading to IV is predominant when R is relatively bulky. However, the ketonization of VIIIc afforded IIIc predominantly. A possible interpretation for the anomaly is that the ethoxy and enolate anion groups in IIIc are prevented from being arranged on an effective coplane for elimination.

Table 1. Yields (%) and products obtained by the ketonization of VIII

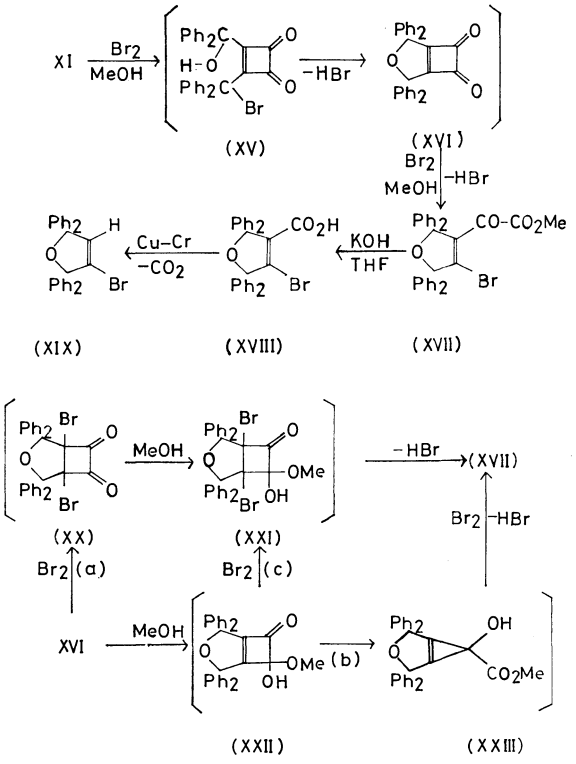
Enolate anion	Products (%)	
VIIIa	IIIa (60)	IV (5)
VIIIb	IIIb (25)	IV (56)
VIIIc	IIIc (83)	IV (8)



Scheme 3.

We reported that the reaction of IV with water in carbon tetrachloride in the presence of bromine affords 3,4-bis(diphenylmethylene)succinic anhydride (XIV) *via* the cyclobutenedione derivative (X) and the bisketene (XIII) successively[1] (Scheme 3). By means of a similar reaction in a protic solvent, one can expect the isolation of a stable cyclobutenedione derivative produced by the substitution of one or two bromines of X with nucleophile, instead of the conversion of X into XIII. The reaction of IV with bromine in 99% acetic acid afforded 3,4-bis(hydroxydiphenylmethyl)cyclobut-3-ene-1,2-dione (XI) and XIV in 55 and 6% yields, respectively. The formation of XI can be explained by the reaction of water and X initially produced by the 1,4-addition of bromine to IV. The production of X as an intermediate is supported by the isolation of XIV, though in a low yield (Scheme 3). The intermediacy of X was also confirmed by the reaction of XI with phosphorus tribromide in carbon tetrachloride to afford IV in a 43% yield. The reaction also gives structural evidence for XI. The structure of XI was further identified by its oxidation with hydrogen peroxide[2] to afford 3,4-bis(hydroxydiphenylmethyl)maleic anhydride (XII).

In order to prepare 3,4-bis(methoxydiphenylmethyl)-cyclobut-3-ene-1,2-dione, XI was made to react with methanol in the presence of bromine. However, 2,2,5,5-tetraphenyl-3-bromo-4-methoxalyl-2,5-dihydrofuran (XVII) was isolated in a 45% yield. The structure of XVII was identified by means of spectral data, and by its conversion into the known compound (XIX). Decarboxylation of 2,2,5,5-tetraphenyl-3-bromo-4-carboxy-2,5-dihydrofuran (XVIII), obtained by base-catalyzed hydrolysis followed by decarbonylation of XVII, afforded 2,2,5,5-tetraphenyl-3-bromo-2,5-dihydrofuran (XIX). The spectral data of XIX were



Scheme 4.

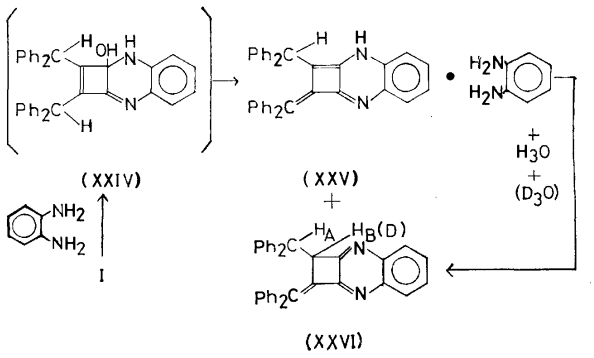
identical with those of an authentic sample.[7]

The reaction mechanism for the production of XVII can be explained by the intramolecular cyclization of XV into XVI followed by ring-opening, as shown in Scheme 4. The formation of the bicyclic intermediate (XVI) would precede the ring-opening of the cyclobutene-dione system, since the cyclobutenedione system was stable under the reaction conditions, as can be seen in the reaction of I with bromine in methanol to afford IIIb predominantly but not ring-opened product. The highly strained cyclobutenedione system of XVI would undergo ring-cleavage even under the acidic conditions of hydrogen bromide generated during the course of reaction, whereas the cyclobutenediones I and III were stable under such conditions (Scheme 2).

For the KOH-catalyzed ring-cleavage of phenylcyclobutenedione to afford benzylidenepyruvic acid, two mechanisms have been postulated, (a) addition-elimination[2,8] and (b) cyclopropenol mechanism.[2,9] However, (a) is unlikely since the addition of bromine to the double bond of cyclobutenedione system does not occur,[3,4] while (b) is also unlikely because of the highly strained nature of the bicyclic cyclopropene intermediate (XXIII). Another mechanism (c) can be applied to the present ring-cleavage of XVI. Since it is the ring-opening of XXI produced by the addition of bromine to XXII it might be considered the most probable mechanism.

Previous attempts to prepare the quinoxaline derivative having a fused cyclobutadiene ring, *i. e.*, 3,8-diazanaphtho[*b*]cyclobutadiene, have failed.[2,3,4,10] The reaction of I with *o*-phenylenediamine was carried out, with the expectation of obtaining the quinoxaline derivative of I. Contrary to expectation, the reaction afforded complex (XXV) and diazatrimethylenecyclobutane derivative (XXVI) in 15 and 17% yields, respectively. Their structures were identified by means of IR, UV, and NMR spectral data. The complex nature of XXV was confirmed by its acid-catalyzed reaction to afford XXVI in a 85% yield. Two protonation sites, β- and δ-carbon, are available for the protonation of dienamine.[11] The protonation on the β-carbon of XXV can afford XXVI. However, that on the δ-carbon of XXV which should produce the quinoxaline derivative of I, was not observed. The NMR spectrum of XXVI showed two AB-type doublets at 4.62 and 5.85 τ. Since the NMR spectrum of XXVI-d prepared by the reaction of XXV with DCl in D_2O showed one methine proton signal at 5.87 τ as a singlet, the structure of XXVI produced by the protonation on the β-carbon of XXV is determined.

The MS spectrum of the complex (XXV) showed the ion peak of each component at *m/e* 486 and 108, in addition to the parent ion peak at *m/e* 594. The fragmentation pattern of the azadimethylenecyclobutene component of XXV was similar to that of XXVI. In both cases, fragment ion peaks, *m/e* 319 (M^+-Ph_2CH), *m/e* 152 (M^+-2Ph_2CH) and an intense peak at *m/e* 167 (Ph_2CH) were observed.



Scheme 5.

Experimental

All the melting points were uncorrected. IR and NMR spectra were measured in Nujol mull and $CDCl_3$ respectively, unless otherwise stated. Mass spectra were measured with an ionization energy of 70 eV.

Reactions of I with ROH in the Presence of Bromine. With H_2O: A solution of I[6] (0.30 g) and bromine (0.66 g) in 10% aqueous acetonitrile (10 ml) was heated under reflux for 3 hr. The cooled reaction mixture was diluted with benzene (100 ml), and washed successively with aqueous sodium thiosulfate and water, and dried over anhydrous sodium sulfate. The crude product remaining after evaporation of benzene was recrystallized from methanol to afford IIIa (0.14 g, 45%) as colorless prisms, mp 140—141 °C. IR: 1780 and 1765 (C=O) and 1570 cm^{-1} (C=C); λ_{max}^{EtOH}: 258 sh (10400), 265 sh (8900), 275 sh nm (ε, 7000); NMR: 2.3—3.1 (m, Ph, 20 H), 4.39 (s, CH, 1H), and 6.80 τ (s, OH, 1H).

Found: C, 83.42; H, 5.08%. Calcd for $C_{30}H_{22}O_3$: C, 83.70; H, 5.15%.

With MeOH: A solution of I (0.30 g) and bromine (0.66 g) in methanol (30 ml) was heated under reflux for 1 hr. The crude crystals remaining after the evaporation of methanol were recrystallized from methanol to afford IIIb (0.17 g, 53%) as colorless needles, mp 127—128 °C. IR: 1775 (C=O) and 1570 cm^{-1} (C=O); λ_{max}^{EtOH}: 259 sh (10500), 265 sh (9200), and 274 sh nm (ε, 7700); NMR (CCl_4): 2.5—3.0 (d, Ph, 20 H), 3.95 (s, CH, 1H), and 6.97 τ (s, OCH_3, 3H).

Found: C, 84.01; H, 5.46%. Calcd for $C_{31}H_{24}O_3$: C, 83.76; H, 5.44%.

With EtOH: A solution of I (0.30 g) and bromine (0.66 g) in ethanol (30 ml) was heated under reflux for 1 hr. Recrystallization from ethanol of the crude product obtained by evaporation of ethanol afforded a mixture of two crystalline forms, colorless and green crystals, which were separated mechanically. Recrystallization of the colorless crystals from ethanol afforded IIIc (0.13 g, 39%), mp 155—156 °C. IR: 1780 (C=O) and 1580 cm^{-1} (C=C); λ_{max}^{EtOH}: 260 sh (10300), 266 sh (9200), and 273 sh nm (ε, 7800); NMR (CCl_4): 2.4—3.1 (m, Ph, 20H), 3.91 (s, CH, 1H), 6.86 (q, J=7 Hz, CH_2, 2H), and 8.76 τ (t, J=7 Hz, CH_3, 3H).

Found: C, 84.09; H, 5.62%. Calcd for $C_{32}H_{26}O_3$: C, 83.82; H, 5.72%.

Recrystallization of the green crystals from acetonitrile

11) G. H. Alt, "Enamines: Synthesis, Structure, and Reaction," ed. by A. G. Cook, Marcel Dekker, New York and London (1969), p. 118.

afforded IV (0.04 g, 13%) as green prisms, mp 206—207 °C (lit,[12] mp 206—207 °C).

With i-PrOH: A solution of I (0.30 g) and bromine (0.66 g) in 2-propanol (20 ml) was heated under reflux for 1 hr. The crude crystals separated out by the cooling of the reaction mixture were recrystallized from acetonitrile to afford IV (0.14 g, 47%) as green prisms, mp 206—207 °C.

The Reaction of IIIa with Phosphorus Tribromide. To a solution of IIIa (0.05 g) in carbon tetrachloride (3 ml) was added phosphorus tribromide (0.06 ml) at 0 °C, and the mixture was then stirred at 0 °C for 15 min. The crude product which crystallized out was recrystallized from acetonitrile to afford IV (0.025 g, 52%) as green prisms, mp 206—207 °C.

Synthesis of 3-Chlorodiphenylmethyl-4-diphenylmethylcyclobutene-1,2-dione (VII). Chlorine was bubbled through a solution of V[5] (0.30 g) in ether (20 ml) at room temperature for 5 min. The ethereal solution was washed successively with aqueous sodium thiosulfate and water, and dried over anhydrous sodium sulfate. Evaporation of the solvent afforded VII (0.30 g, 95%) as pale green oil. IR (liquid film): 1785 (C=O) and 1640 cm^{-1} (C=C); λ_{max}^{EtOH}: 243 sh (5700), 259 sh (3700), 266 sh (3300), and 273 sh nm (ε, 2900).

No satisfactory analytical data were obtained since the oil was too unstable for purification.

Reaction of VII with ROH. *With MeOH*: A solution of VII (0.30 g) in methanol (5 ml) was stirred at room temperature for 24 hr. The crude crystals separated out were recrystallized from methanol to afford IIIb (0.19 g, 64%) as colorless needles, mp 127—128 °C.

With EtOH: Treatment of VII (0.30 g) in ethanol (5 ml) by the same method as that employed for the reaction of of VII with methanol afforded IIIc, 0.18 g (59%) as colorless needles, after recrystallization from methanol, mp 155—156 °C.

With i-PrOH: Treatment of VII (0.30 g) in 2-propanol (5 ml) by the same method as that employed for the reaction of VII with methanol afforded IV, 0.09 g (32%) as green prisms, mp 206—207 °C, after recrystallization from acetonitrile.

Ketonization of The Enolate Anion VIII. To a solution of IIIa (0.1 g) in 10% methanolic potassium hydroxide (3 ml), was added concd hydrochloric acid (0.5 ml). The crude product separated out was washed with water. Recrystallization from methanol afforded a mixture of two crystalline forms, colorless needles and green prisms, which were separated mechanically. Recrystallization of the former from methanol afforded IIIa (0.06 g, 60%), mp 140—141 °C, while that of the latter from acetonitrile afforded IV (0.005 g, 5%), mp 206—207 °C.

The same treatment of IIIb and IIIc as that employed for IIIa afforded IV and the corresponding ketonization product (III), respectively, in the yields given in Table 1.

Reaction of IV with Bromine in Aqueous Acetic Acid. A mixture of IV (1.0 g), bromine (2.2 g) and 1% aqueous acetic acid (100 ml) was stirred at 70—75 °C for 1.5 hr. The reaction mixture was concentrated to dryness, and the residue was taken up in benzene (100 ml). The benzene solution was washed successively with aqueous sodium thiosulfate and water, and dried over anhydrous sodium sulfate. After removal of benzene, the residue was recrystallized from methanol to afford a mixture of two crystalline forms, colorless and red rhombs, which were separated mechanically. Recrystallization of the former from methanol afforded XI (0.6 g, 55%), mp 179—180 °C. IR: 3480 and 3360 (OH), 1810 and 1785 (C=O), and 1570 cm^{-1}.

Recrystallization of the latter from ethyl acetate afforded XIV (0.065 g, 6%), mp 230 °C (lit,[12] mp 230 °C).

Reaction of XI with Phosphorus Tribromide. To a solution of XI (0.1 g) in carbon tetrachloride (5 ml) was added phosphorus tribromide (0.12 ml) at 0 °C, and the mixture was then stirred at 0 °C for 15 min. Recrystallization from acetonitrile of the crude crystals which separated out afforded IV (0.04 g, 43%) as green prisms, mp 206—207 °C.

Oxidation of XI with Hydrogen Peroxide. A mixture of XI (0.15 g), 30% aqueous hydrogen peroxide (3 ml), and acetic acid (60 ml) was stirred at room temperature for 3 days. The crude crystals which separated out by the addition of water to the reaction mixture were washed with water. Recrystallization from methanol afforded XII (0.08 g, 51%) as colorless prisms, mp 205—206 °C. IR: 3480 and 3320 (OH), 1835 and 1770 (C=O), and 1590 cm^{-1} (C=C); λ_{max}^{EtOH}: 212 (24500), 255 (6700), and 285 sh nm (ε, 3500); NMR: 2.5—3.0 (m, Ph, 20 H) and 4.80 τ (s, OH, 2H).

Found: C, 78.06; H, 4.69%. Calcd for $C_{30}H_{22}O_5$: C, 77.91; H, 4.80%.

Reaction of IV with Bromine in Methanol. A solution of IV (0.11 g) and bromine (0.22 g) in methanol (10 ml) was heated under reflux for 45 min. The crude crystals formed by cooling the reaction mixture were recrystallized from acetone to afford XVII (0.06 g, 45%) as colorless prisms, mp 190—191 °C. IR: 1740 and 1690 (C=O), 1620 (C=C), 1235 (ester), and 1015 cm^{-1} (ether); $\lambda_{max}^{CHCl_3}$: 266 (8000) and 275 sh nm (ε, 7500); NMR: 2.6—2.9 (m, Ph, 20 H) and 6.20 τ (s, CO_2CH_3, 3H); MS: m/e 538 (M^+).

Found: C, 69.29; H, 4.15%. Calcd for $C_{31}H_{23}O_4Br$: C, 69.01; H, 4.26%.

Hydrolysis and Decarbonylation of XVII. A mixture of XVII (0.22 g), potassium hydroxide (0.42 g), tetrahydrofuran (8 ml) and acetone (7 ml) was heated under reflux for 7 hr. To the residue remaining after evaporation of the solvent of the reaction mixture to dryness was added dil hydrochloric acid and the crystalline solid obtained was washed with water. Recrystallization of the dried crude product from tetrahydrofuran–cyclohexane afforded XVIII (0.12 g, 61%), mp 278—279 °C. IR: 3000—2500 (CO_2H), 1690 (C=O), and 1600 cm^{-1} (C=C); λ_{max}^{EtOH} 238 sh (12400), 258 sh (5200), 264 sh (3500) and 268 sh nm (ε, 2400).

Found: C, 70.35; H, 3.94%. Calcd for $C_{29}H_{21}O_3Br$: C, 70.02; H, 4.22%.

Decarboxylation of XVIII. A mixture of XVIII (0.15 g), quinoline (5 ml), and a catalytic amount of copper chromite was heated under reflux for 4 hr. The cooled reaction mixture was diluted with ether (100 ml), and the ether solution was washed successively with dil hydrochloric acid and water, and dried over anhydrous sodium sulfate. The crude crystals obtained by evaporation of ether were recrystallized from methanol to afford XIX (0.08 g, 59%), mp 175 °C (lit,[7] mp 175 °C).

Reaction of I with o-Phenylenediamine. A mixture of I (1.00 g) and *o*-phenylenediamine (0.26 g) was allowed to remain at 130 °C for 40 min. The crude crystals obtained by the addition of methanol (1 ml) to the cooled reaction mixture were fractionated into two crystalline forms, pale yellow and yellow, by fractional recrystallization from tetrahydrofuran. Recrystallization of the former, relatively insoluble in tetrahydrofuran, from tetrahydrofuran–chloroform afforded XXV (0.22 g, 15%) as pale yellow prisms, mp 204—207 °C. IR: 3300 (NH) and 1610 cm^{-1} (C=N); $\lambda_{max}^{CHCl_3}$: 304 nm (ε, 5800); MS: *m/e* (rel intensity) 594 (4), 486 (23), 319 (9), 236 (18), 167 (100), 152 (8), and 108 (11).

Found: C, 84.75; H, 5.72; N, 9.39%. Calcd for

12) F. Toda and K. Akagi, *Tetrahedron*, **27**, 2801 (1971).

$C_{42}H_{34}N_4$: C, 84.85; H, 5.72; N, 9.43%.

Recrystallization of the latter, relatively soluble in tetrahydrofuran, from acetone afforded XXVI (0.2 g, 17%), mp 172—173 °C. IR: 1640 cm^{-1} (C=N); $\lambda_{max}^{CHCl_3}$: 275 (16800) and 385 nm (ε, 19000); NMR: 1.8—3.1 (m, Ph, 24H), 4.62 (d, J=2.5 Hz, H_B, 1H), and 5.85 τ (d, J=2.5 Hz, H_A, 1H); MS: *m/e* (rel intensity) 486 (34), 319 (10), 167 (100), and 152 (7).

Found: C, 88.67; H, 5.28%. Calcd for $C_{36}H_{26}N_2$: C, 88.86; H, 5.38%.

Reaction of XXV with Hydrochloric Acid. A suspension of XXV (0.1 g) in methanol (5 ml)–concd hydrochloric acid (0.6 ml) was stirred at room temperature for 30 min. The crude product obtained by concentration of the reaction mixture to dryness was suspended in water and then collected by filtration. The recrystallization of the dried crude product from acetone afforded XXVI (0.07 g, 85%), mp 172—173 °C. IR spectral data were identical with those of an authentic sample. Treatment of XXV (0.1 g) in methanol-d (2 ml)–concd deuteriochloric acid (0.6 ml) by the same method as that employed above, afforded XXVI-d (0.07 g, 85%). NMR: 1.8—3.1 (m, Ph, 24H) and 5.87 τ (s, H_A, 1H).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1737—1740 (1973)

Methylene Analogs of Cyclobutenedione. VII.[1] Photolysis of 2,3-Bis(diphenylmethylene)cyclobutanone and Its Derivatives

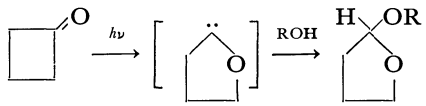
Fumio TODA, Hisao NAKAOKA, Kentaro YUWANE, and Eishiro TODO

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

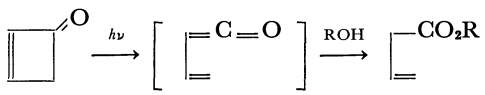
(Received July 29, 1972)

Photolysis of 2,2-dimethoxy-3,4-bis(diphenylmethylene)cyclobutanone (I), 2,3-bis(diphenylmethylene)cyclobutanone (XIV), and 3,4-bis(diphenylmethylene)cyclobutanedione (XXV) in methanol was investigated. Photolysis of I afforded tricyclic compound(II) and dimethyl cyclobutanedicarboxylate (III) in 48 and 35% yields, respectively. Photolysis of XIV and XXV afforded the dihydronaphthalene derivatives (XIX) (88% yield) and XXIV (72% yield), respectively. The mechanisms of these reactions were also studied.

Two types of reaction for the photolysis of the four-membered ketones in alcohol, *viz.*, photo ring-expansion of cyclobutanone to tetrahydrofuran derivative *via* oxacarbene intermediate (1)[2-8] and the photo ring-cleavage of cyclobutenone to ester *via* ketene intermediate (2),[9-11] have been reported. However, no



(1)



(2)

photolysis of 2,3-dimethylenecyclobutanone derivative has yet been reported, although 2,4-dimethylenecyclobutanone has been shown to be inert to the photolysis in alcohol.[8] We have studied the photolysis of 2,3-bis(diphenylmethylene)cyclobutanone derivatives, I, XIV, and XXV in methanol, in order to confirm which type of reaction is appropriate. The photochemical reaction between the two over-crowded diphenylmethylene moieties of the cyclobutanones is also of interest.

Photolysis of I[12] in methanol under nitrogen at room temperature afforded methanol-insoluble colorless needles ($C_{32}H_{26}O_3$) and methanol-soluble colorless prisms ($C_{32}H_{28}O_4$). The former was identified to be II by means of spectral data and chemical reactions. The IR spectrum of II showed all the three oxygen atoms to be of ether linkage. The NMR spectrum showed the presence of the two magnetically nonequivalent methoxy group, in addition to one quite deshielded (3.95 τ) methine proton, and nineteen aromatic protons. However, the UV spectrum of II in ethanol, 294 nm (ε, 7900), differed from that of 1,4-diphenylbuta-1,3-diene in benzene, 334 nm (ε,

40000).[13] The difference is attributable to the non-coplanarity of II, since studies on a molecular model of II show that the indene and the diphenylmethylene chromophores are prevented from being arranged on a coplane.

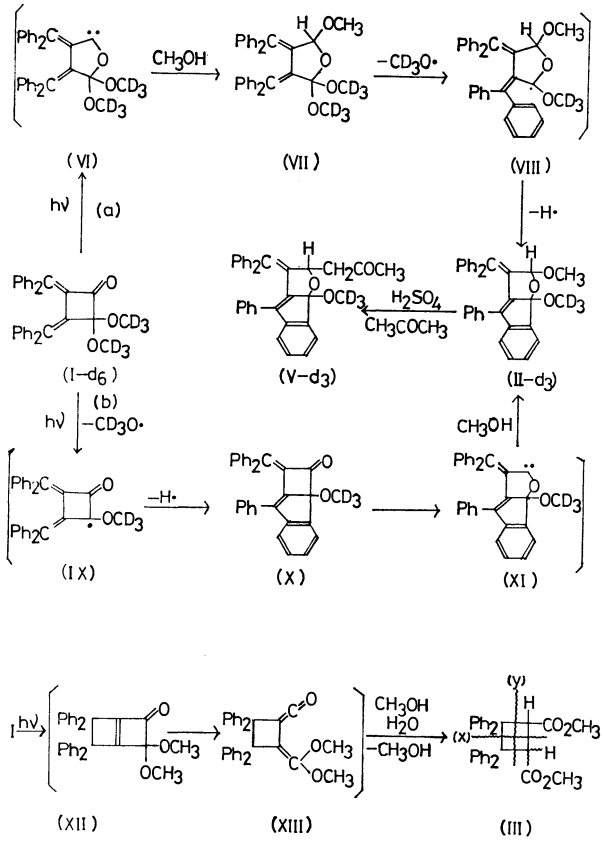
In order to distinguish the two methoxy groups of II, II was allowed to react with acetone in the presence of concd sulfuric acid to afford the substitution reaction product (V). The NMR spectrum of V showed the methine proton signal as a quartet centered at 4.12 τ, and the methylene proton signal at 7.6—7.9 τ as a multiplet, in addition to the methoxy methyl and the acetyl methyl proton signals as a singlet at 6.99 and 8.10 τ, respectively. The multiplicity of the methine and methylene proton signals is probably due to the spin-spin coupling between the methine proton and the two magnetically nonequivalent methylene protons (H_A and H_B). The nonequivalency of the two methylene protons is probably due to an asymmetric effect. Direct evidence for the coupling was obtained by using V-d_5 which was prepared by the reaction of II and acetone-d_6. In the NMR spectrum of V-d_5, a methine proton signal appeared at 4.20 τ as a singlet in addition to a singlet signal of methoxy at 7.02 τ.

In order to determine the origin of the two methoxy groups of II, the photolysis of I in ethanol was carried out, and the ring-expanded product (IV) was obtained. The structure of IV was identified by its reaction with acetone to afford V. The magnetic nonequivalency of the two methylene protons of the ethoxy of IV is also probably due to an asymmetric effect. The production of IV in the above photolysis shows that the methoxy on the bridge-head and the other methoxy of II were derived from I and methanol, respectively. This was further supported by the photolysis of I-d_6 in methanol to afford II-d_3 (Scheme 2). The acid-catalyzed reaction of II-d_3 with acetone afforded V-d_3. The structures of II-d_3 and V-d_3 were determined by means of the spectral data.

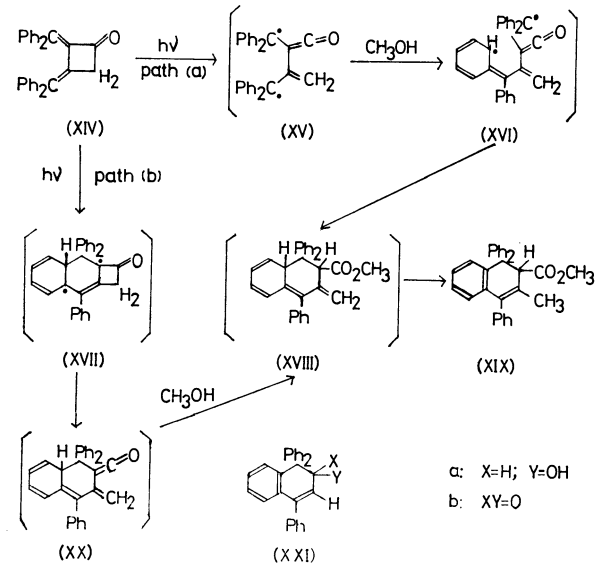
The photolysis of I to afford II corresponds to the type of reaction (1). The reaction might then proceed *via* an oxacarbene intermediate. Depending on whether or not the dihydrofuran-ring formation precedes the indene-ring formation, two reaction paths (a) and (b), and thereafter the oxacarbene intermediates, VI and XI, are applicable (Scheme 2). However, we could obtain no further evidence to distinguish the path.

The structure of the methanol-soluble compound accompanying II in the photolysis of I was identified by spectral data to be the cyclobutane derivative (III). The NMR data indicating that all the aromatic protons appear at a relatively higher field, 2.7—3.6 τ, agree with the structure of III, in which four phenyls are shielded each other. However, the geometry of the two carbomethoxy group could not be determined. The MS spectrum of III showed a fragment ion peak at *m/e* 238 which is just half of the mass of its parent ion. The data show that III undergoes ring-cleavage easily in the manner of (x) but not (y) (Scheme 2).

Formation of III can be interpreted by the photo ring-cleavage of XII initially produced by the photo ring-closure of I, to afford the ketene intermediate (XIII) and finally III. This type of photo reaction is analogous to (2). The conversion of XIII into III would proceed by the addition of methanol and water to the ketene and dimethoxyethylene moieties, respectively, followed by the elimination of methanol. Since II and III were obtained in 35 and 48% yields, respectively, when the photolysis of I was carried out in 95%



Scheme 2.



Scheme 3.

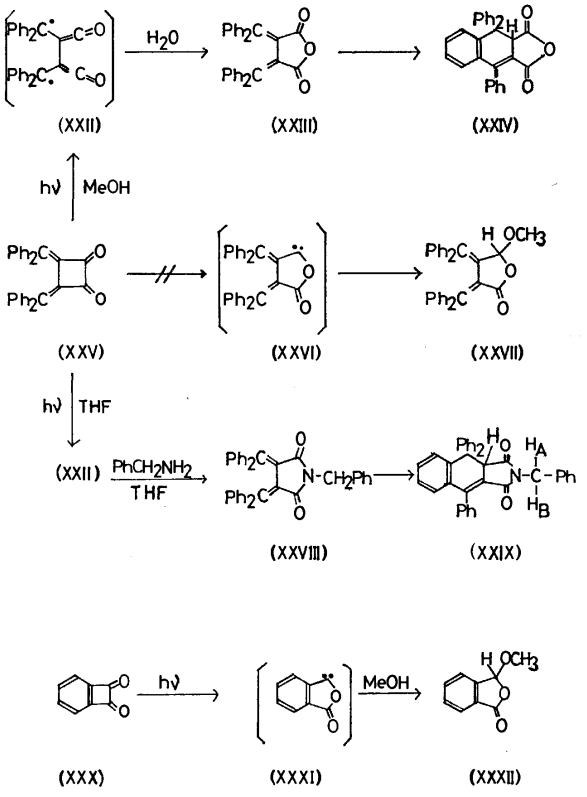
13) K. W. Hausser, R. Kuhn, and A. Smakula, *Z. Phys. Chem.*, **B29**, 384 (1935).

methanol, it is clear that water is essential for the formation of III.

In order to clarify the special role of the methoxy group of I in its photolysis, the photolysis of XIV[12] was carried out, under the same conditions as those employed for I, and afforded the dihydronaphthalene derivative (XIX) as the sole product (85% yield). Its structure was identified by means of spectral data. The UV spectrum of XIX, 285 nm (ε, 6900), was comparable to that of the analogous compound (XXIa),[14] 288 nm (ε, 6000).

Two possible reaction paths (a) and (b) can be written for the formation of XIX (Scheme 3). The choice of path depends on whether the ring-cleavage of the cyclobutanone-ring or the reaction between the two diphenylmethylene moieties occurs initially.

Although it is difficult to define the real mechanistic pathway, it is clear that the photo reaction of XIV proceeds *via* a pathway analogous to (2). From a comparison of the photolysis of I to afford II with that of XIV to afford XIX, the special role of the methoxy group of I in its photolysis is clear. (b) is therefore the more plausible path of the photolysis of I to afford II (Scheme 2).



Scheme 4.

The photolysis of the diketone (XXV)[12] is of interest as regards the photolysis of benzocyclobutenedione (XXX) to afford the benzolactone (XXXII), the product of the type of reaction (1). The photolysis of XXV in 99% methanol afforded the acid anhydride (XXIV) in a 72% yield, but no detectable amount of lactone (XXVII). The structure of XXIV was identified by means of spectral data. The UV spectral bands of XXIV in chloroform, 242 (14000) and 315 nm (ε, 14000), were comparable to those of XXIb in ethanol, 240 sh (8100) and 316 nm (ε, 8900).[14] Since the photolysis of XXIII[12] under the same conditions as employed for XXV afforded XXIV in a 82% yield, XXIII is a probable intermediate of the photolysis of XXV. A possible precursor of XXIII is the bisketene (XXII) which is produced by ring-cleavage of XXV of type (2). The reaction of the bisketene (XXII) with water to afford the acid anhydride (XXIII) is reasonable, since the reaction of XXV with water in the presence of bromine to afford XXIII *via* XXII has been postulated,[15] and the photochemical reaction of XXV with benzylamine in dry tetrahydrofuran afforded XXIX *via* XXVIII. The intermediacy of XXVIII in the latter photolysis was defined by a separate photolysis of XXVIII prepared according to a modified procedure to afford XXIX.

The structure of XXIX was identified by means of spectral data. The magnetic nonequivalence of the two methylene protons of XXIX (H_A and H_B) gives further structural evidence for XXIX which has asymmetric center.

Experimental

All the melting points were uncorrected. Photolysis was carried out at room temperature under nitrogen atmosphere, with a 100-W high-pressure mercury lamp (Riko Kagaku Sangyo Co.). IR, UV, and NMR spectra were measured in Nujol mull, EtOH, and $CDCl_3$ respectively, unless otherwise stated. Mass spectra were measured with an ionization energy of 70 eV.

Photolysis of I in Methanol. A suspension of finely-powdered I (1.09 g) in 99% methanol (100 ml) was irradiated under stirring for 17 hr. The crude product precipitated was collected by filtration, and recrystallized from ethyl acetate to afford II as colorless needles; 0.52 g (48%); mp 180—181 °C. IR: 1120, 1010, and 990 cm^{-1} (C-O-C); λ_{max}: 237 (20200) and 294 nm (ε, 7900); NMR: 1.85—2.00 (m, Ph, 1H), 2.2—2.9 (m, Ph, 18 H), 3.95 (s, CH, 1H), 6.85 (s, OCH_3, 3H), and 7.03 τ (s, OCH_3, 3H); MS: *m/e* (rel intensity) 458.1917 (M^+ 458.1882, 2), 427 (40), 426 (100), 411 (90), 381 (15), 367 (20), and 278 (20).

Found: C, 84.01; H, 5.65%. Calcd for $C_{32}H_{26}O_3$: C, 83.82; H, 5.72%.

Concentration of the mother liquor remaining after the separation of crude II by filtration afforded crude crystals. Their recrystallization from ethyl acetate afforded III as colorless prisms; 0.38 g (35%); mp 172—174 °C. IR: 1740 and 1725 (C=O), and 1230 cm^{-1} (ester); λ_{max}: 262 (1100), 269 (1100), and 275 nm (ε, 700); NMR: 2.7—3.6 (m, Ph, 20 H), 5.03 (s, CH, 2H), and 6.63 τ (s, CO_2CH_3, 6H); MS: *m/e* (rel intensity) 238.0982 ($M^+/2$ 238.0992, 100), 237 (22), 207 (53), 179 (30), and 178 (25).

Found: C, 80.71; H, 5.73%; mol wt (benzene), 471. Calcd for $C_{32}H_{28}O_4$: C, 80.64; H, 5.92%; mol wt, 476.

When the photolysis of I was carried out in 95% methanol, II and III were obtained in 35 and 48% yields, respectively.

Photolysis of I in Ethanol. A suspension of finely-powdered I (1.0 g) in 99% ethanol (100 ml) was irradiated

14) F. Toda and K. Akagi, *Tetrahedron*, **27**, 3795 (1969).

15) F. Toda and J. Fujita, This Bulletin, **45**, 1928 (1972).

under stirring for 17 hr. The crude product precipitated was recrystallized from ethyl acetate to afford IV as colorless needles 0.68 g (68%); mp 176—177 °C. IR: 1110, 1010, and 995 cm^{-1} (C–O–C); NMR: 1.95—2.00 (m, Ph, 1H), 2.2—2.9 (m, Ph, 18H), 3.86 (s, CH, 1H), 6.2—6.9 (m, OCH_2CH_3, 2H), and 7.02 (s, OCH_3, 3H), and 9.21 τ (t, OCH_2CH_3, 3H).

Found: C, 84.10; H, 5.83%. Calcd for $C_{33}H_{28}O_3$: C, 83.87; H, 5.97%.

Photolysis of I-d_6 in Methanol. A suspension of finely-powdered I-d_6 (0.45 g), prepared from XXV and methanol-d_4 in 99% methanol (50 ml) was irradiated under stirring for 17 hr.[12] The crude product precipitated was recrystallized from ethyl acetate to afford I-d_3; 0.2 g (45%). IR: 2080 cm^{-1} (OCD_3) and 1110, 1005, and 990 cm^{-1} (C–O–C); NMR: 1.85—2.00 (m, Ph, 1H), 2.2—2.9 (m, Ph, 18H), 3.92 (s, CH, 1H), and 6.82 τ (s, OCH_3, 3H).

Acid-catalyzed Reactions of II, IV, and I-d_3 with Acetone. A solution of II (0.2 g) and three drops of concd sulfuric acid in acetone (10 ml) was heated under reflux for 20 min. The crude crystals obtained by the evaporation of the solvent to dryness were washed with water, dried and recrystallized from ethyl acetate to afford V as colorless needles; 0.15 g (71%); mp 243—244 °C. IR: 1720 (C=O), and 1060 and 995 cm^{-1}(C–O–C); λ_{max} ($CHCl_3$): 249 (28100) and 297 nm (ε, 10200); NMR: 1.8—2.0 (m, Ph, 1H), 2.2—2.9 (m, Ph, 18H), 4.12 (q, CH, 1H), 6.99 (s, OCH_3, 3H), 7.6—7.9 (m, CH_2, 2H), and 8.10 τ (s, $COCH_3$, 3H).

Found: C, 84.27; H, 5.54%. Calcd for $C_{34}H_{28}O_3$: C, 84.27; H, 5.82%.

The same treatment of IV with acetone as for II afforded V in a 65% yield.

The same treatment of II with acetone-d_6 as for II afforded V-d_5 in a 70% yield. IR: 1715 (C=O) and 1065 cm^{-1} (C–O–C); NMR: 1.85—2.05 (m, Ph, 1H), 2.3—3.0 (m, Ph, 18 H), 4.20 (s, CH, 1H), and 7.02 τ (s, OCH_3, 3H).

The same treatment of II-d_3 with acetone as for II afforded V-d_3 in a 50% yield. IR: 1720 (C=O) and 1060 cm^{-1} (C–O–C); NMR: 1.8—2.0 (m, Ph, 1H), 2.2—2.9 (m, Ph, 18H), 4.10 (q, CH, 1H), 7.5—7.8 (m, CH_2, 2H), and 8.11 τ (s, $COCH_3$, 3H).

Photolysis of XIV in Methanol. A suspension of finely-powdered XIV (1.03 g) in 99% methanol (100 ml) was irradiated under stirring for 17 hr. The crude crystals obtained by the evaporation of the solvent to dryness were recrystallized from ethyl acetate to afford XIX as colorless needles; 0.91 g (88%); mp 146—147 °C. IR: 1700 and 1720 (C=O), and 1225 cm^{-1} (ester); λ_{max}: 228 (18600) and 285 nm (ε, 6900); NMR: 2.5—3.1 (m, Ph, 18H), 3.25—3.45 (m, Ph, 1H), 6.03 (s, CH, 1H), 6.62 (s, CO_2CH_3, 3H), and 8.26 τ (s, CH_3 3H); MS: *m/e* (rel intensity) 430.1938 (M^+, 430.1932, 100), 398 (7), 371 (57), 356 (18), 293 (32), 279 (14), 278 (14), and 215 (13).

Found: C, 86.33; H, 5.88%. Calcd for $C_{31}H_{26}O_2$: C, 86.48; H, 6.09%.

Photolysis of XXV in Methanol. A suspension of finely-powdered XXV (1.0 g) in 99% methanol (100 ml) was irradiated under stirring for 17 hr. The crude crystals remaining after the evaporation of solvent were recrystallized from ethyl acetate to afford XXIV as colorless prisms; 0.73 g (72%); mp 225—226 °C. IR: 1760 and 1820 cm^{-1} (C=O); λ_{max}($CHCl_3$): 315 (12200) and 340 sh nm (ε, 7400); NMR: 2.5—3.2 (m, Ph, 18H), 3.2—3.4 (m, Ph, 1H), and 4.91 τ (s, CH, 1H); MS: *m/e* (rel intensity) 428.1437 (M^+ 428.1412, 100), 384 (98), 355 (56), 350 (86), 330 (98), 307 (75), 279 (98), and 278 (98).

Found: C, 84.36; H, 4.81%. Calcd for $C_{30}H_{20}O_3$: C, 84.09; H, 4.71%.

Photolysis of XXIII in Methanol. A suspension of finely-powdered XXIII (1.0 g) in 99% methanol (100 ml) was irradiated under stirring for 2 hr. The crude crystals remaining after the evaporation of solvent to dryness were recrystallized from ethyl acetate to afford XXIV; 0.82 g (82%). The IR spectral data were identical with those of an authentic sample prepared by the photolysis of XXV in methanol.

Photo Reaction of XXV with Benzylamine in Tetrahydrofuran. A solution of XXV (1.26 g) and benzylamine (3.2 g) in dry tetrahydrofuran (150 ml) was irradiated under stirring for 17hr. The residue remaining after the evaporation of the solvent was taken up in ether. The ether solution was washed successively with dil hydrochloric acid and water, and dried over sodium sulfate. The crude product obtained by the evaporation of solvent was chromatographed on alumina with carbon tetrachloride as a solvent. The elution with benzene afforded XXIX as colorless plates; 0.18 g (11%); mp 221—222.5 °C. IR: 1760 and 1690 (C=O), 1630 (C=C), and 1430 cm^{-1} (CH_2); λ_{max}($CHCl_3$): 310 (16800) and 340 sh nm (ε, 8800). NMR: 2.9—3.0 (m, Ph, 24H), 5.22 (s, CH, 1H), and 5.41 τ (q, CH_2, 2H); MS: *m/e* (rel intensity) 517.2015 (M^+ 517.2041, 100), 440 (28), 439 (55), 384 (17), 356 (65), and 307 (38).

Found: C, 85.54; H, 5.27%. Calcd for $C_{37}H_{27}O_2N$: C, 85.85; H, 5.26%.

Preparation of XXVIII. A mixture of XXV (3.9 g), bromine (2 g), benzylamine (10 g) and dry carbon tetrachloride (300 ml) was stirred at room temperature for 30 min. After removal of the amine salt formed as a result of filtration, the filtrate was evaporated to dryness to afford crude crystals. Recrystallization of the crude crystals from acetone afforded XXVIII as yellow plates; 2.2 g (45%); mp 227—228 °C. IR: 1750 and 1690 (C=O), and 1430 cm^{-1} (CH_2); λ_{max}: 252 (29000), 309 (21800), and 400 nm (ε, 11100). NMR: 2.4—3.2(m, Ph, 25H) and 5.31 τ (s, CH_2, 2H); MS: *m/e* (rel intensity) 517.2059 (M^+ 517.2041, 81), 384 (100), 356 (36), and 307 (36).

Found: C, 85.65; H, 5.32%. Calcd for $C_{37}H_{27}O_2N$: C, 85.85; H, 5.26%.

Photolysis of XXVIII in Tetrahydrofuran. A solution of XXVIII (1.12 g) in dry tetrahydrofuran (100 ml) was irradiated for 7 hr. The crude crystals obtained by the evaporation of solvent was recrystallized from ethyl acetate to afford XXIX as colorless plates; 0.50 g (45%). The IR spectral data were identical with those of an authentic sample prepared by the photo reaction of XXV with benzylamine.

Oxygen-18 Scrambling Reaction of Aroyl Alkyl Carbonates

Shigeru Oae, Yuzuru Uchida,[1] Ken Fujimori, and Seizi Kozuka

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received August 9, 1972)

Specifically ^{18}O-labeled *p*-substituted benzoyl cyclohexyl carbonates (**1**) were prepared and heated at 45, 70 and 75 °C, and novel stepwise oxygen scrambling was found to take place in **1**. On being heated at 45 °C, the carbonic carbonyl oxygen atom and the oxygen atom sandwiched between the two carbonyl carbon atoms of **1** were found to scramble. The ^{18}O-scrambling among the above two and carboxylic carbonyl oxygen atoms of **1** was found to take place at 70 or 75 °C. A good first order kinetic dependence was observed for the first step of the scrambling at 45 °C but no substituent effect. An intramolecular mechanism involving two steps of equilibration is proposed.

We reported on the basis of ^{18}O-tracer studies of the decomposition of several diacyl peroxides[2] that the carboxy-inversion is the major pathway for the decomposition of *sec*- and *tert*-alkylformyl peroxides, while ^{18}O-scrambling is observed not only in the original peroxide but also in the intermediate of the decomposition, *i.e.*, acyl alkyl carbonates. We extended our ^{18}O-tracer study to the ^{18}O-scrambling of the aroyl alkyl carbonates,[3] specifically ^{18}O-labeled benzoyl l-apocamphyl carbonate being employed, and an intramolecular oxygen scrambling reaction was found. Although a zwitterion mechanism (scheme 1) has been suggested for the ^{18}O-scrambling, another intramolecular mechanism, *viz.*, an ion pair pathway is possible (scheme 2).[3] Kinetic determinations of the ^{18}O-scrambling with ^{18}O-labled substituted benzoyl l-apocamphyl carbonates are considered to be very helpful for making choice of the two mechanisms. We have studied the reactions of *p*-substituted benzoyl alkyl carbonates having a cyclohexyl group as the alkyl moiety instead of the l-apocamphyl group, and found an interesting stepwise scrambling of ^{18}O in these compounds. A discussion on detailed mechanism of the ^{18}O-scrambling reaction of the aroyl alkyl carbonates is given.

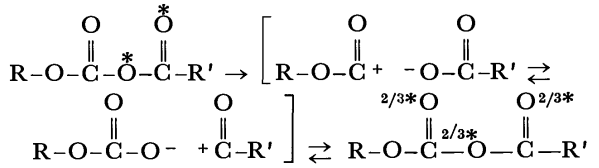
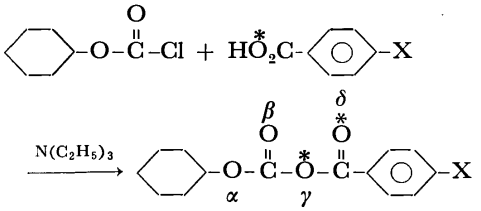
Ion pair mechanism



Scheme 2.

Results and Discussion

p-Substituted benzoyl cyclohexyl carbonates (**1**) specifically ^{18}O-labeled in γ- and δ-oxygen atoms were prepared as usual by the reaction of cyclohexyl chloroformate with the ^{18}O-labeled *p*-substituted benzoic acids in the presence of triethylamine in ethereal solution as in the following.[4]



(1)

1a X=CN, **b** X=H, **c** X=CH_3

The aroyl carbonates (**1**) thus prepared were dissolved in CCl_4 (0.04 M) and heated at 45 °C for 24 hr, at 70 °C for 12 hr or at 75 °C for 24 hr. The aroyl alkyl carbonate was recovered quantitatively without decomposition. ^{18}O-Distribution in the recovered carbonate (**1**) was analyzed according to the following cleavage reactions.[3,5]

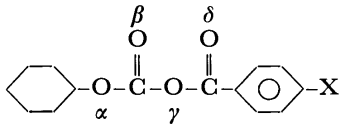
Table 1. ^{18}O-Distribution in the aroyl alkyl carbonates



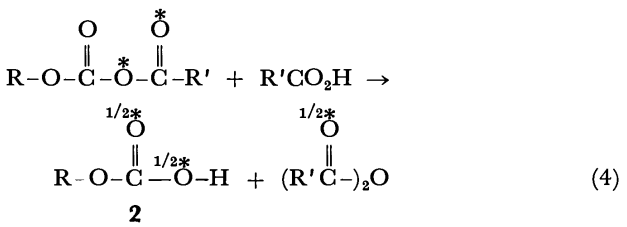
Aroyl alkyl carbonate	From starting material			^{18}O-Content (Excess atom %)[a] From recovered meterial			^{18}O-Distribution in oxygen atom (%)[b]			Reaction conditions	
	Carbamate	Acid	Anilide	Carbamate	Acid	Anilide	β[c]	γ[d]	δ[e]	Temp (°C)	Time (hr)
1a	0.00	0.84	0.81[f]	0.18	0.66	0.81[f]	21	29	50	45	24
1b	—	1.39	1.38	0.33	1.07	1.34	24	28	49	45	24
1c	0.00	1.04	1.02	0.24	0.80	0.99	23	27	49	45	25
1a	0.00	0.94	0.92	0.29	0.66	0.73	31	31	40	70	12
1b	—	1.39	1.38	0.44	0.97	1.03	32	32	37	70	12
1c	0.00	1.04	1.02	0.34	0.72	0.76	33	32	37	70	12
1a	—	0.87	0.85	0.29	0.59	0.57[g]	33	34	34	75	24

a) Estimated error ± 0.005 (excess atom %). b) Based on the total amount of ^{18}O. c) Calculated from the ^{18}O-content of the carbamate. d) Estimated from the ^{18}O-content of the acid and the anilide. e) Calculated from the ^{18}O-content of the anilide. f) Carbon dioxide obtained from reaction (2) contained 0.46 excess atom % of ^{18}O. g) Carbon dioxide obtained from the reaction with aniline contained 0.57 excess atom % of ^{18}O.

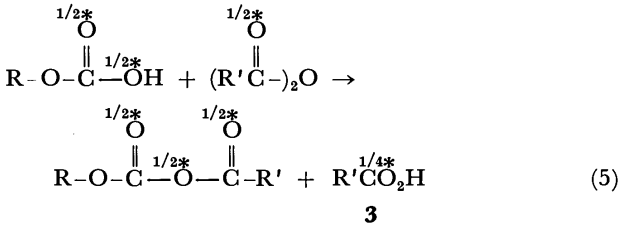
The ^{18}O-analytical data and percentages of ^{18}O-distributions are summarized in Table 1. There was no ^{18}O-scrambling during the preparation of the aroyl alkyl carbonates and the α-oxygen atom remained without scrambling even after being heated at 75 °C for 24 hr. We see that nearly all the original ^{18}O-label was retained in the δ-oxygen atom after heating at 45 °C for 24 hr, while scrambling was found between β- and γ-oxygen atoms. In addition, the δ-oxygen atom participates in the oxygen scrambling reaction on heating at 70 °C for 12 hr. These results suggest a stepwise ^{18}O-scrambling for the carbonates.

An intermolecular chain process (4)—(7) for the mechanism of ^{18}O-scrambling was ruled out on the basis of the ^{18}O-content of benzoic anhydride obtained from the reaction of ^{18}O-labeled benzoyl 1-apocamphyl carbonate with unlabeled benzoic acid.[3]

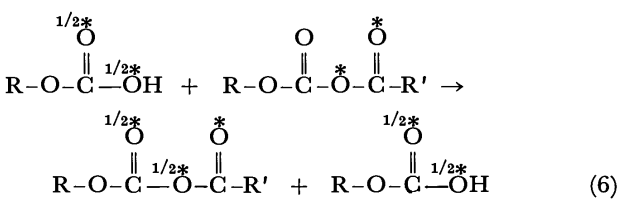
Intermolecular mechanism



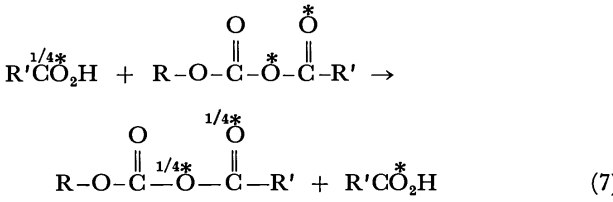
(4)



(5)



(6)



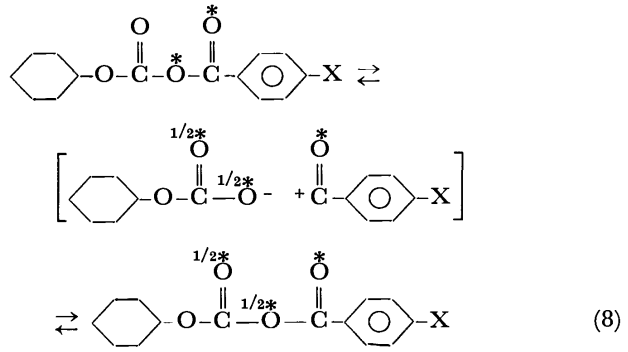
(7)

The intermolecular mechanism can be ruled out also in the present studies involving the following crossover experiments. If the reaction proceeds with the alkyl carbonic acid (**2**) as the chain carrier (5—6), ^{18}O would be incorporated into the recovered **1a** by the crossover experiment of unlabeled **1a** and labeled **1b**. On the other hand, if the carboxylic acid (**3**) is the chain carrier as shown in (4) and (7), labeled *p*-toluic acid would be expected in the reaction of labeled **1c** with unlabeled *p*-toluic acid. An equimolar amount of unlabeled **1a** was heated with ^{18}O-labeled **1b** in the γ- and δ-oxygen atoms at 45 °C for 48 hr in CCl_4. Although a complete ^{18}O-scrambling of β- and γ-oxygen atoms was found, no excess of ^{18}O was found in the *p*-cyanobenzoic acid obtained by the treatment of the recovered **1a** with *N*-methylaniline (3). The reaction of **1c** with an equimolar amount of unlabeled *p*-toluic acid was carried out at 70 °C for 12 hr in CCl_4. *p*-Toluic acid was recovered quantitatively, no excess ^{18}O being found in the recovered acid. The results show that the mode of oxygen scrambling reaction of aroyl alkyl carbonates is quite different from that of carboxylic anhydrides.[6] Another possible ^{18}O-scrambling mechanism of the β- and γ-oxygen atoms is one involving ionic dissociation in solvent cage in view of the stepwise nature of the reaction as shown below.

If this is the case, a large negative ρ value would be expected in the kinetics of the ^{18}O-scrambling for substituted benzoyl derivatives.

The rate of scrambling between β- and γ-oxygen atoms at 45 °C can be obtained by measuring the decreasing amount of ^{18}O in the carboxylic acids ob-

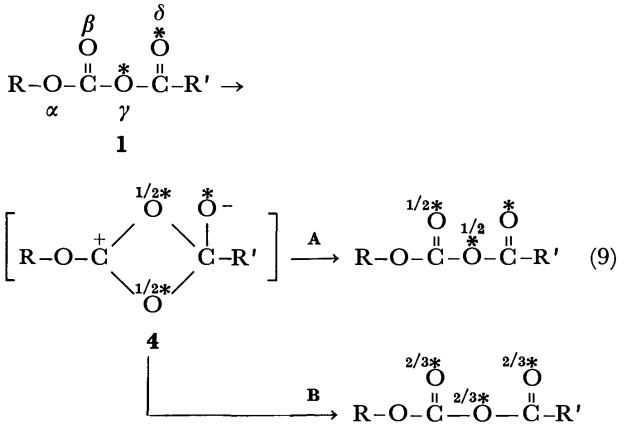
6) L. Ponticorvo and D. Rittenberg, *J. Amer. Chem. Soc.*, **76**, 1705 (1954).



(8)

tained by treatment of the recovered carbonate with *N*-methylaniline (3). Good first-order rate constants of the ^{18}O-scrambling of β- and γ-oxygen atoms were observed: $2.42\pm0.05\times10^{-5}$ sec^{-1} (**1a**); $2.85\pm0.28\times10^{-5}$ sec^{-1} (**1b**); $2.74\pm0.02\times10^{-5}$ sec^{-1} (**1c**). Since there is no substituent effect, the ion pair mechanism (8) can be ruled out. A mechanism involving homolytic cleavage of the C–O bond is also unlikely since the aroyl alkyl carbonates did not decompose at all under the reaction conditions.

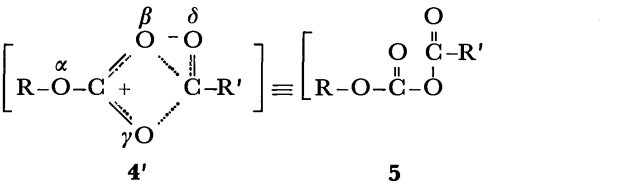
The only conceivable intramolecular mechanism to rationalize the observations is an intramolecular pathway involving nucleophilic attack of carbonic oxygen (β) on the carboxylic carbon as shown below.[3]



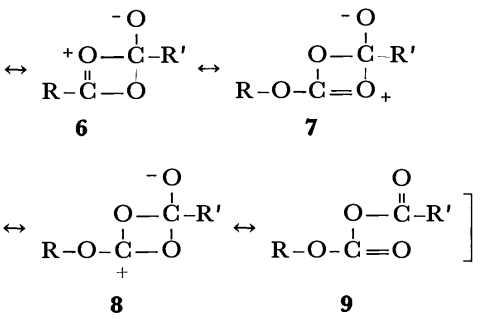
1

4

According to this mechanism, the nucleophilic attack of the β-oxygen on the carbon gives rise to the formation of an intermediate (**4**), which allows only the exchange of the β- and γ-oxygen atoms at the lower temperature (path **A**). In this process, the electron withdrawing group at the para position of the phenyl group would decrease the electron density at benzylic position of **1** and enhance the nucleophilic attack of β-oxygen atom on the carboxylic carbon atom. The structure of intermediate (**4**) is visualized as a resonance hybrid (**4'**) somewhere between the following five extremers.[7]



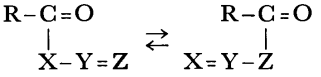
4' **5**



6 **7** **8** **9**

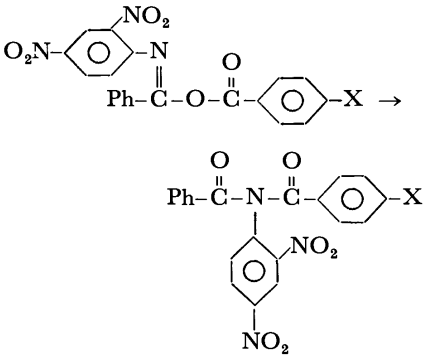
The rate of oxygen scrambling between β- and γ-oxygen atoms would therefore be determined by the stability of **4**, in which the substituent on R' which stabllizes positive charge on β- and γ-oxygen atoms instabilizes the negative charge on δ-oxygen atom. Since β-, γ- and δ-oxygen atoms are situated in the same position with respect to R', the opposite substituent effect would be canceled as a whole. The other possible explanation of no substituent effect of first step of oxygen scrambling is that polar canonical forms **6**, **7** and **8** hardly contribute to the structure of **4**, with respect to oxygen scrambling of acetyl peroxide (1, 3 sigmatropy) as suggested by Goldstein and Judson.[8]

The new oxygen scrambling in **1** can be regarded as an intramolecular 1, 3 acyl migration as shown by



(10)

Several examples of reaction (10) are summarized in Table 2. Curtin and Miller observed the small positive ρ-value, 0.6—0.7 and proposed a similar mechanism for the *O*- to *N*-acyl migration as in the following[7]



(11)

At higher temperatures, the δ-oxygen atom in the intermediate (**4**) attacks the carbonic carbon (Scheme 1) either *via* the concerted bond formation and breaking process or *via* formation of an alternative intermediate (**5**). The three oxygen atoms of the carbonates **1** (β, γ and δ) thus scramble completely (path **B**).

Experimental

Preparation of Cyclohexyl Chloroformate. To 45 g of phosgene cooled in an ice-bath was added 25 g of cyclohexanol, and the reaction mixture was allowed to stand overnight at room temperature. Excess phosgene was removed and cyclohexyl chloroformate was distilled under reduced pressure (90—91 °C/31 mmHg, 86%).

Preparation of ^{18}O-Labeled p-*Cyanobenzoyl Cyclohexyl Carbonate (**1a**).* In a flask equipped with a stirrer and a dropping funnel were placed 300 ml of dry ether, 10 g of ^{18}O-labeled *p*-cyanobenzoic acid and 6.8 g of triethylamine. The mixture was cooled to 0 °C with an ice-bath, 11.0 g of cyclohexyl chloroformate in 30 ml of dry ether being then added dropwise over a period of 1 hr. Stirring was continued for 4 hr. The amine hydrochloride was filtered off, and the filtrate was washed with dil HCl, dil aqueous $NaHCO_3$ and water and dried over Na_2SO_4. Evaporation of the solvent left 15.0 g of colorless crystals. Recrystallization from CCl_4–petroleum ether gave 12.6 g of **1a**, mp 54.5—55.0 °C. IR: 5.59 and 5.76 μ ($\nu_{C=O}$). Found: C, 66.08; H, 5.55; N, 5.03%. Calcd for $C_{15}H_{15}NO_4$: C, 65.92; H, 5.53; N, 5.13%.

*^{18}O-Labeled Benzoyl Cyclohexyl Carbonate (**1b**) and p-Toluyl Cyclohexyl Carbonate (**1c**)* were prepared from ^{18}O-labeled benzoic acid and *p*-toluic acid in the same way as for **1a** in 67 and 91% yields, respectively. **1b**: mp 21.0—21.5 °C resrystallized from pet. ether. IR: 5.59 and 5.76 μ ($\nu_{C=O}$). Found: C, 68.00; H, 6.32. Calcd for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50% **1c**: mp 25.5—26.5 °C, IR: 5.59 and 5.76 μ ($\nu_{C=O}$). Found: C, 68.90; H, 6.76%. Calcd for $C_{15}H_{18}O_4$: C, 68.68; H, 6.92%.

^{18}O-Scrambling in the Aroyl Alkyl Carbonates. A typical run is as follows: A solution of 2.73 g of **1a** in 1 l CCl_4 was warmed at 45 °C for 24 hr. The solvent was removed under reduced pressure at room temperature and the residue was used for the following cleavage reaction, the products being subjected to ^{18}O-analysis.[2)]

Reaction of Aroyl Alkyl Carbonates with Aniline. In a typical run, 0.40 g of aniline was added 10 ml CCl_4 solution of 0.82 g of **1a** at room temperature and the mixture was allowed to stand for 1.5 hr. *p*-Cyanobenzanilide was collected by filtration and recrystallized from chloroform, mp 180—180.5 °C, and subjected to ^{18}O-analysis. The filtrate was diluted with 30 ml of ether and washed with dil HCl, dil $NaHCO_3$ and water, and dried over Na_2SO_4. Solvent was removed and the residue was chromatographed through an activated alumina column with benzene and ether as eluents. A fraction which came out in the latter was identified as cyclohexanol and subjected to ^{18}O-analysis. In order to collect carbon dioxide, the reaction was carried out as follows: The aroyl alkyl carbonate (**1**) (0.30 g) and 5 ml of CCl_4 were placed in a flask with two necks, one equipped with a bent tube charged with 0.2 g of aniline and the other connected to a vacuum line. After evacuation of the flask with cooling in a dry ice-acetone bath, it was warmed up to room temperature and aniline was added by turning the bent tube. The carbon dioxide evolved was collected in a trap cooled with liquid N_2, sublimed three times in the vacuum line and then subjected to ^{18}O-analysis.

Reaction of Aroyl Alkyl Carbonates with N-*Methylaniline.* In a typical run, 0.4 g of *N*-methylaniline was added to a solution of 0.82 g of **1a** in 10 ml CCl_4 at room temperature. The reaction was allowed to continue for 1.5 hr. Solid material was collected by filtration, recrystallized from chloroform, identified as *p*-cyanobenzoic acid, mp 219.0—219.5 °C, and subjected to ^{18}O-analysis. The filtrate was washed with dil HCl dil aqueous $NaHCO_3$ and water, then dried over Na_2SO_4. CCl_4 was removed by distillation, and the residue was chromatographed on silica gel column with benzene as an eluent. The early fraction was distilled under reduced pressure (bp 135—136 °C/3 mmHg), identified as cyclohexyl *N*-methyl-*N*-phenyl carbamate with the authentic sample and subjected to ^{18}O-analysis.

Preparation of Cyclohexyl N-*Methyl*-N-*Phenyl Carbamate.* To a mixture of 6.0 g of *N*-methylaniline and 5.0 g of triethylamine in 40 ml of dry ether was added 8.2 g of cyclohexyl chloroformate in 10 ml dry ether with stirring at 0 °C. Stirring was continued for 1 hr. Amine hydrochloride was filtrated off and the filtrate was washed with dil HCl, dil $NaHCO_3$ and water, then dried over Na_2SO_4. The ether was removed by distillation and the residue was distilled under reduced pressure to yield 8.8 g of cyclohexyl *N*-methyl-*N*-phenyl carbamate, bp 135—136 °C/3 mmHg. Found: C, 71.88; H, 8.28; N, 5.72%. Calcd for $C_{14}H_{19}O_2N$: C, 72.02; H, 8.21; N, 6.00%.

*Reaction of ^{18}O-Labeled **1c** with* p-*Toluic Aicd.* A solution of 1.31 g of **1c**, labeled with 1.04 excess atom % of ^{18}O at γ- and δ-oxygen atoms, and 0.66 g of unlabeled *p*-toluic acid in 125 ml CCl_4 was heated at 70 °C for 12 hr. After heating the free acid was extracted with aqueous $NaHCO_3$. The water layer was acidified with HCl and extracted with ether. The etheral solution was washed with water and dried over Na_2SO_4. The ether was evaporated to give 0.66 g *p*-toluic acid which was recrystallized from benzene, mp 179.0—179.5 °C and subjected to ^{18}O-analysis.

*Crossover Experiment between Unlabeled **1a** and Labeled **1b**.* A mixture of 1.36 g of unlabeled **1a** and 1.20 g of labeled **1b** (1.39 excess atom % in the γ- and δ-oxygen atom) in 250 ml of CCl_4 was heated at 45 °C for 48 hr. The solvent was removed under reduced pressure at room temperature. **1a** (0.7 g) was recovered by the fractional recrystallization of the residue from CCl_4–pet. ether. **1a** recovered was treated with *N*-methylaniline (**3**) to yield 0.17 g of *p*-cyanobenzoic acid which was subjected to ^{18}O-analysis (0.00 excess atom %).

Preparation of ^{18}O-Labeled p-*Cyanobenzoic Acid.* In a flask equipped with a stirrer and a dropping funnel were placed 33 g of *p*-cyanobenzoyl chloride, 40 g of triethylamine and 300 ml of dry dioxane to which was added dropwise

4.0 g of ^{18}O-enriched water (1.5 atom%) in 10 ml of dry dioxane. Stirring was continued for 2 hr. The reaction mixture was filtered and the precipitate was washed with 100 ml of dioxane. The filtrate and washing solution were combined and the solvent was removed by distillation. The residue was dissolved in 300 ml of water and acidified with HCl. The precipitate was filtered, washed with water and dried. The acid was recrystallized from chloroform–acetone, mp 217.0—218.0 °C.

Kinetics of ^{18}O-Scrambling in the Aroyl Alkyl Carbonates. Kinetics of ^{18}O-scrambling between β- and γ-oxygen atoms were followed by measurement of the decreasing amount of ^{18}O in *p*-substiutted benzoic acids formed by cleavage reaction (3). The aroyl alkyl carbonates were heated at 45 °C in CCl_4 (0.04 mol/l).

^{18}O-Analysis was carried out in the same way as reported previously.[2)]

We wish to thank Professor S. Okazaki for the supply of ^{18}O-water which made this work possible.

Mechanism of Oxygen Exchange Reaction of Diaryl and Alkyl Aryl Sulfoxides in Sulfuric Acid*

Norio KUNIEDA and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received August 21, 1972)

The mechanistic investigations of the concurrent oxygen exchange and racemization reactions of ^{18}O-labeled and optically active methyl *p*-tolyl sulfoxide (I) and phenyl *p*-tolyl sulfoxide (II) in sulfuric acid of various concentrations have been carried out by the determination of detailed kinetics. The kinetic data were analyzed in the lights of k_{ex}/k_{rac} values, activation parameters, correlations between the rates and acidity functions, solvent isotope effects, polar effects of substituents, etc.. A gradual change of mechanism of the reaction from an S_N2 type process to a predominant A-1 like one (in above 95% sulfuric acid) with the increase of the concentration of sulfuric acid was observed. All these observations suggest that the A-1 like reaction takes place through a cation radical ($-\overset{+\cdot}{S}-$) or a dication ($-\overset{++}{S}-$) intermediate at higher concentrations of sulfuric acid, while the S_N2 type reaction that involves a water molecule as nucleophile in the rate-limiting step is the predominant path in less concentrated sulfuric acid.

The concurrent oxygen exchange and racemization reactions of optically active and ^{18}O-labeled (*on sulfoxide oxygen*) sulfoxides are advantageous to study the nature of nucleophilic substitution on the trivalent sulfur atom, which is one of the important subject in organic sulfur chemistry, and have attracted considerable attentions in recent years. Several studies have been reported on the acid-catalyzed oxygen exchange and racemization reactions of sulfoxides.[1-7] Among these, the concurrent oxygen exchange and racemization reactions of diaryl sulfoxides in concentrated sulfuric acid is the most extensitvely studied, since it was the first example discovered.[8-10] When ^{18}O-labeled and optically active sulfoxides are dissolved in a concentrated sulfuric acid, one observes the concurrent oxygen exchange and racemization of the sulfoxide.

However, in order to clarify the over-all feature of these reactions, in which the mode of the reaction displays a gradual change with the change of the concentration of sulfuric acid, more detailed kinetic investigations are desirable especially since it has recently been shown that the sulfoxides do not behave as Hammett bases.[19,20,31]

We now have investigated the oxygen exchange and racemization reactions of methyl *p*-tolyl sulfoxide (I) as well as phenyl *p*-tolyl sulfoxide (II) much more in detail in sulfuric acids of various concentrations. And a reinvestigation of our previous results[9,10] has also been carried out.

Results and Discussion

Careful kinetic experiments have been conducted mainly on the rates of concurrent oxygen exchange and racemization reactions of methyl *p*-tolyl sulfoxide (I), 1.08 *atom*%-^{18}O $[\alpha]_D^{23}+146°$ (Acetone), and phenyl *p*-tolyl sulfoxide (II), 1.12 *atom*%-^{18}O $[\alpha]_D^{20}+27.6°$ (EtOH), in sulfuric acid of various concentrations ranging from 52.4% to 94.8% at several temperatures. These results are listed in Table 1.

When the reaction proceeds through the A-1 type

	93.8	19.8	−5.94
	64.7	17.1	−25.1
C_6H_5[a]	95.5	24.0	+9.86[b]
	90.8	18.5	−10.8
	85.6	17.5	−17.5
	75.4	18.6	−18.9

a) These values are based on pseudo first-order rate constants. b) This is smaller than that reported in the previous report.[10]

route, each cleavage of S–O bond in the rate limiting step which results in oxygen exchange will cause racemization, and $k_{exchange}$ (k_{ex}) is equal to $k_{racemization}$ (k_{rac}), since it passes through a symmetrical intermediate such as $-\overset{+\cdot}{S}-$ or $-\overset{++}{S}-$. While, when the reaction proceeds through the S_N2 type route, the k_{ex}/k_{rac} value becomes 0.5.

The k_{ex}/k_{rac} values for I in 94.8% acid and for II in 95.5% acid were found to be 0.86 and 0.97, respectively. While the values for I in 58.5% acid and in 75.4% acid were 0.48 and 0.49, respectively. Thus the predominant path of the reaction in the less con-

centrated acid is an S_N2 type. And the k_{ex}/k_{rac} value increases gradually with the increase of the acid concentration. However, the values change drastically in above *ca.* 93% acid.

The energies and entropies of activation, E_a and $\Delta S^{\neq}$, obtained in sulfuric acid of several concentrations are listed in Table 3. The E_a value increases significantly while $\Delta S^{\neq}$ value changes from the large negative value to a small negative or positive one with the increase of the acid concentration. In the highly concentrated acid region, the $\Delta S^{\neq}$ values of I and II are −1.77 e.u. (in 94.2% acid) and +9.86 e.u. (in 95.5% acid), respectively. While in a less concentrated acid, the $\Delta S^{\neq}$ values are −25.1 e.u. (in 64.7% acid) for I and −18.9 e.u. (in 75.4% acid) for II, respectively. These values are typical for S_N2 type reactions.[11] The drastic change of the $\Delta S^{\neq}$ value is also observed in the higher concentrated acid region above ca. 93—95%.

In these concentrated sulfuric acids, the sulfoxides are considered to be protonated[13] almost completely (Eq. 2). Therefore, the rate can be expressed as a function of the concentration of the protonated sulfoxide, [S⁺–OH], (Eq. 3,4).

$$\mathrm{R{-}\underset{\underset{\mathrm{O}}{\downarrow}}{S}{-}R' + H^+ \overset{K_{SH^+}}{\rightleftharpoons} R{-}\overset{+}{S}{-}\underset{\underset{\mathrm{OH}}{|}}{R'}} \qquad (2)$$

$$\text{Rate} = k_1[\mathrm{S^+{-}OH}] \qquad (3)$$

$$k_1 = k_{obs}(h_0^m + K_{SH^+})/h_0^m \qquad (4)$$

where, K_{SH^+} and h_0^m[16] are the thermodynamic ionization constant of the sulfoxides and the acidity function fitted for the sulfoxide-bases, respectively.

In order to solve the rate equation, the accurate pK_{SH^+} values of the sulfoxides are necessary. The p*Ka* values of several sulfoxides have been determined.[17–20] However, it has known that the sulfoxides do not behave as Hammett bases, since the gradient of log [SH⁺]/[S] *vs.* H_0 for the sulfoxides were found to be smaller than unity.[19,20] For example, the average gradient for substituted diphenyl sulfoxides was found to be 0.59.[20b,c] The H_0 scale is based on substituted aniline indicators.[21] Therefore, an acidity function which is strictly appropriate to study especially the ionization behaviors of sulfoxides is most desirable, like the H_A for amide bases,[22,23] and H_0 for benzophenone bases.[24] However, it is difficult to determine the peculiar acidity function just fitted for sulfoxide-bases, and hence it has not been worked out. Yates and McClelland[26] have introduced the H_S function as the ester-base acidity function. And the H_S was obtained by the following empirical relationships, $\log [SH^+]/[S] = -H_s + pK_{SH^+}$; $\log [SH^+]/[S] = -mH_0 +$ const.; $H_S = mH_0$, where m is the slope of plot of the ionization ratio for acetates *vs.* the available H_0 scale. Here, we also undertook the same treatment for the sulfoxide-base. From the average gradient of log [SH⁺]/[S] vs H_0 measured by UV and NMR, mentioned above, we have chosen to use m=0.60 and 0.6 H_0 instead of H_0 in this study.[27] Recently, Landini *et al.*[31,33] have found that the H_A function developed by Yates *et al.*[22] satisfactorily represents the protonation behaviors of the sulfoxides. The H_A is about 0.65 H_0 (between 50 and 80% acid), which also corresponds closely to the approximation, $m=0.6$, for the value of sulfoxide-bases mentioned above. Then the rate constants, k_1, of both the oxygen exchange and racemization reactions were calculated by the eq. 4 using h_A and $h_0^{0.6}$ and the pK_{SH^+} values, where $h_0^{0.6}$ was used to conduct the kinetic data in higher than 80% acid.

The rate constants, k_1, obtained are listed in Table 1, which also increase with the increase of the acid concentration. The acid dependencies of the rates are collected in Table 4. At first, diagrams correlating the logarithmus of the rates of racemization of both I and II against H_A(or $0.6H_0$) were made. At highly concentrated acid regions, log k_1 was found to be in a

11) For example, the $\Delta S^{\neq}$ value for the racemization reaction of II with acetic anhydride which is a typical S_N2 type process was found to be −28.6 e. u.[12]

TABLE 4. CORRELATION BETWEEN ACIDITY FUNCTIONS AND RATE CONSTANTS OF RACEMIZATION OF p-CH_3-C_6H_4SOR IN SULFURIC ACID

R;	H_2SO_4 (wt%)[a]	log k_1 *vs.* H_A ($0.6H_0$)	log $k_{obs}+H_0$ *vs.* log a_{H_2O}	log $k_{obs}+H_A$ ($0.6H_0$) *vs.* log a_{H_2O}	log k_1+H_0 *vs.* $H_0+\log[H^+]$
CH_3	52.4—68.8	0.583	1.86(0.999)	0.388(0.988)	0.770(0.999)
	89.8—94.2	1.18(0.997)[b]	0.328(0.985)	−0.116[c]	0.336(0.986)
C_6H_4	64.7—74.4	0.750	1.44(0.999)	0.317(0.949)	0.701(0.991)
	93.3—96.3	1.44(0.990)	0.133[c]	−0.272(0.866)	0.300(0.880)

a) Range of sulfuric acid concentration. b) Correlation coefficient.
c) It's correlation showed as low value because the slope is very low.

linear relationship with $0.6H_0$. The slopes for I at above 89.8% acid and for II at above 93.3% acid were 1.18 and 1.44, respectively. This means that the reaction proceeds through a predominant A-1 type route, according to the Zucker-Hammett hypothesis.[34] As the concentration of acid decreases, the plot of log k_1 *vs.* acidity functions start to deviate markedly from the linear slopes to lower ones.

The Bunnett w-values,[35] at the range of less concentrated acid for I(below 68.8%) and for II(below 74.4%) are 1.86 and 1.44, respectively. Whereas, at sulfuric acids of above 89.9% for I and above 93.3% for II, the w-values are 0.328 and 0.133, respectively. Though the values are little larger than zero and cannot be classified strictly into the class $w \leqq 0$ of the criterion, the values seem to indicate that the reaction proceeds through a nearly A-1 type route in which water does not participate in the rate limiting step. According to the modified Bunnett hydration parameter treatment[23,25,36] using H_A or $0.6H_0$ for H_X, the slopes (r), at the highly concentrated acid region, show smaller values than zero (*i. e.* for I; −0.116 (above 89.8%), for II; −0.272 (above 93.3%)), and at the less concentrated acid region, however, the slopes show small positive values. However, the equation, log k_{obs}−log h_A (or $h_0^{0.6}$)/[$K_{SH^+}+h_A$ (or $h_0^{0.6}$)]$=r \log a_{H_2O}+$ const., gives a large negative r values at all range of the plot both for I and II, even at the less concentrated acid region.

The plot[32] of (log $k_{obs}+H_0$) against ($H_0+\log[H^+]$) also gave a linear slope at the less concentrated acid range. The ϕ values for I and II are 0.770 and 0.701, respectively. On the other hand, at the range of concentrated acid, the slopes for I, and II were larger than that expected from a typical A-1 mechanism. The plot of ($\log k_1+H_0$) *vs.* ($H_0+\log[H^+]$) showed a similar slope.[37] These results seem to indicate that the S_N2 type reaction takes place competitively in no small portion, even in the high acid region above 85%. The plot of $\log k_{obs}-\log h_0^m/(K_{SH^+}+h_0^m)$ *vs.* ($H_0+\log[H^+]$), where h_0^m is h_A or $h_0^{0.6}$, showed high negative ϕ values for both I and II at all ranges of the acid concentration, even including less concentrated acids. Similar large negative ϕ values have been observed, for instance, in the reduction of sulfoxides by halide ion(−1.2∼−1.6)[33] and Wallach rearrangement(−1.8∼−0.4),[38] which have been believed to involve two protons in the rate limiting step.

It would be difficult to apply the Bunnett[35] and the Bunnett and Olsen[32] criteria to analyze directly the reaction at the high acid region.

TABLE 5. EFFECT OF DEUTERIOSULFURIC ACID ON THE RACEMIZATION RATE OF I AND II

Sulfoxide	Sulfuric acid (mol/l)	Temp. (°C)	$\times 10^4$ s^{-1} [a]		k_H/k_D
			$k_{H_2SO_4}$	$k_{D_2SO_4}$	
I	17.48	10	18.6	13.9	1.34
	17.09	10	10.8	8.71	1.24
	14.61	25	3.10	2.60	1.19
	11.40	45	2.43	2.57	0.946
	10.27	30	0.306	0.322	0.950
	10.27	45	1.48	1.59	0.931
II	17.68	10	7.00	6.93	1.01
	13.02	45	1.97	1.78	1.11

a) Pseudo first order rate constants using Method B. These values are average ones for three or four measurements.

Table 5 summarizes the values of the ratio of the rate, k_H/k_D, *i. e.* the ratio of the rates of the racemization of I and II in D_2SO_4–D_2O media to those in ordinary H_2SO_4–H_2O media. The solvent isotope effect observed is not very large. As described earlier, in both highly and moderately concentrated sulfuric acids, the sulfoxides are considered to be protonated almost completely. Therefore, if the reaction proceeds through an A-1 type route, the isotope effect would be found only in the step of unimolecular S–O bond cleavage of the protonated sulfoxides, and its k_H/k_D value at the concentrated acid regions should be close to unity. In the case of II, the value is indeed 1.01 at the acid of 17.68 mol/l. However, the value of I was found to be a larger than one, *i.e.* 1.34, in the acid of similar concentration, *i.e.* 17.48 mol/l. This means that, in the case of I, an S_N2 type reaction involving the nucleophilic attack of water on the protonated sulfoxide takes place to substantial extent even at the high concentrated acid region, and hence the solvent

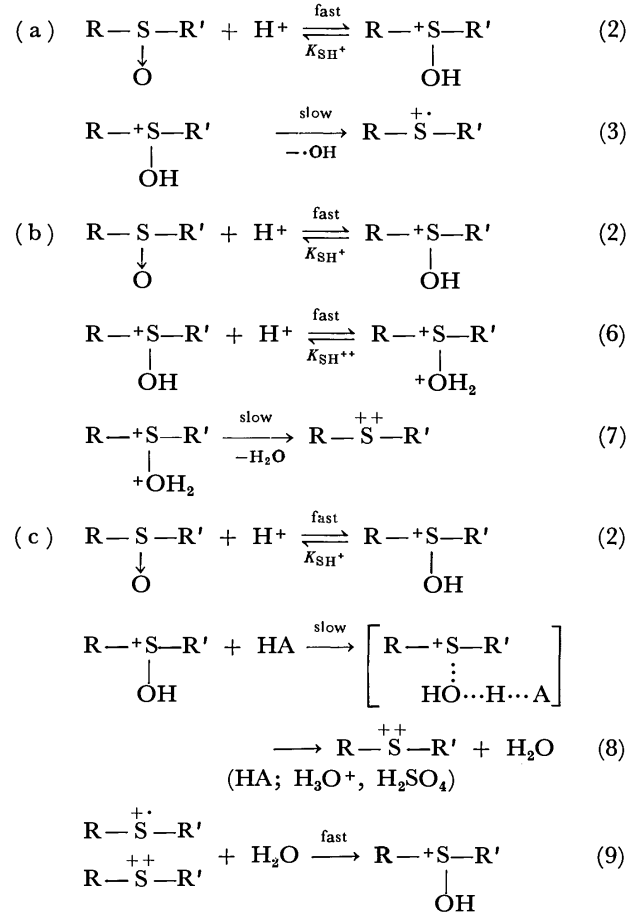
35) J. F. Bunnett, *ibid.*, **82**, 499 (1960); **83**, 4956 (1961); **83**, 4968 (1961); **83**, 4973 (1961); **83**, 4978 (1961).
36) K. Yates and J. C. Riordan, *Can. J. Chem.*, **43**, 2328 (1965).
37) Landini *et al.* applied the same treatment using k_1 into a study of the reduction of sulfoxides by halide ion in aqueous perchloric acid, and they gave the ϕ values in the range from −0.12 to +0.06.[33]
38) E. Buncel and B. T. Lawton, *Can. J. Chem.*, **43**, 862 (1965).



Scheme 1. A-1 like mechanism.

isotope effect due to the difference of the nucleophilicities between D_2O and H_2O would appear. As the acid concentration decreases, the k_H/k_D value of I also decreases gradually, and at 10.27 mol/l, the isotope effect is reversed, *i.e.* $k_H/k_D=0.931$. Thus it is clear that the initial protonation equilibrium controls the isotope effect, because in the less concentrated acids the protonation would not be complete.

There are a few concievable pathways for the A-1 type S–O bond cleavage that fit to these observations, as shown in Scheme 1.

The several ESR studies of the sulfur containing aromatic compounds have been done.[39] Shine *et al.*[40] revealed that noticeable ESR signals of the corresponding cation radical were observed from 96% sulfuric acid solutions of *p,p'*-disubstituted diphenyl sulfoxides. Recently, we have also found the ESR signals from 96.3% sulfuric acid solutions of *p,p'*-ditolyl sulfoxide and II,[9] though the signal from II has no hyperfine structure. These ESR results suggest that the route (a) involving the homolytic cleavage to form an incipient cation radical intermediate is the most likely possibility, in the case of diaryl sulfoxides. The polar effects of *p*-substituents on the oxygen exchange reaction rates are very small in comparison with that of the typical S_N1 type reactions (see Table 6). This rather small polar effect also seems to favor the route (a). While the 96% sulfuric acid solution of I is colorless,[41] and no noticeable ESR signal was detected for I from the 96% acid solution. It is dubious, therefore, that I undergoes the reaction depicted by route (a), in the acid below 96% concentration.

Table 6. Rate constants of ^{18}O-exchange of *p*-X-$C_6H_4S^{18}O$-C_6H_5[a] in 95.3% sulfuric acid at 5°C

Cl	1.53±0.05
NO_2	1.13±0.03

a) Sulfoxide=0.12 mol/l, by Method A.
b) These values are much the same as those of our previous work.[9]

The pathways (b) and (c), including the dication intermediate, must also be included among the A-1 type reactions. For the unimolecular S–O bond cleavage, the second protonation or a second proton transfer from acid media to the mono-protonated sulfoxide is considered to be neccessary, since, OH group being a poor leaving group, the S^+–OH should pick up one more proton before the heterolytic cleavage of S–O bond. Route (b) begins with a rapid protonation equilibrium (Eq. 2) and followed by a second protonation (Eq. 7) again on the oxygen. Then the rate-limiting step becomes the loss of a water molecule from the diprotonated sulfoxide. This dication intermediate is similar to the carbonium ion in the acid catalyzed oxygen exchange reaction of alcohols.[42]

If the reaction proceeds through the overall two-proton process, the rate is expressed by the use of the H_+ function.[43] The kinetic analyses with the H_+ function also permit the reaction in the concentrated acid to follow the route (b). Though we can find no value of H_+ available for this treatment, the parallelism has been found between H_+ and H_0 in the sulfuric acid media,[43-44] and hence H_A or $0.6H_0$ could be substituted for H_+ in this instance,[45] even though

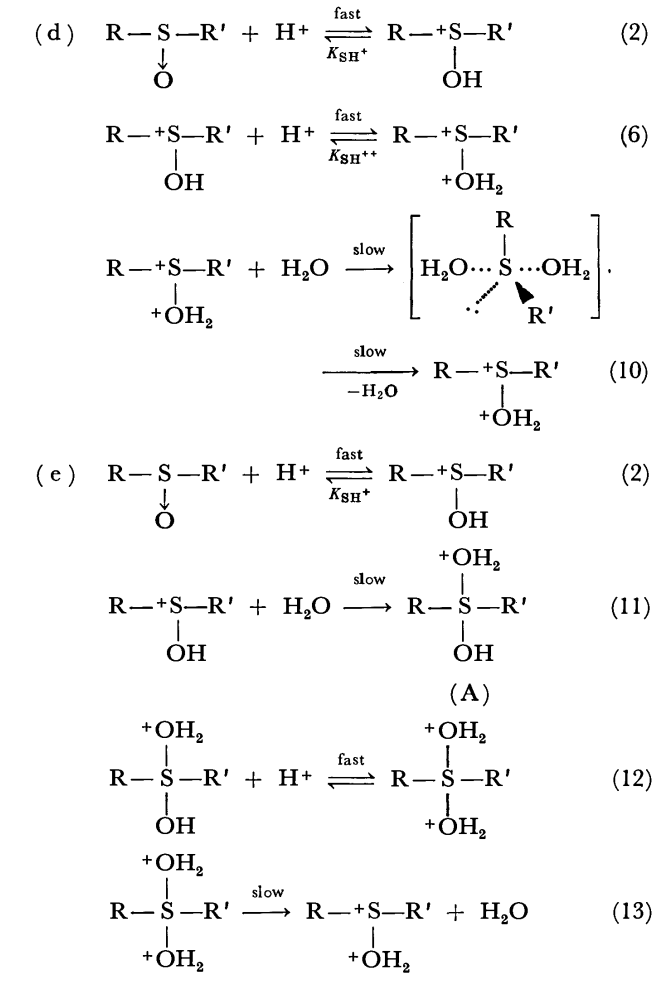
a) Sulfoxide=0.16 mol/l, at 30 °C. b) Sulfoxide=0.1 mol/l, at 0 °C.
c) In a 1 : 2 v/v mixture of 12 M aqueous HCl and dioxane at 25 °C (Ref. 1).
d) In 3.93 M-HCl in 80% dioxane-water, at 25 °C (Ref. 2). e) The relative rates are given in parentheses.

an error may be introduced.

Meanwhile, in the strong acid above *ca.* 93%, all acid species in the medium must take the form of either H_3O^+ or H_2SO_4. Then the route (c) including the general acid catalyzed removal of water would be conceivable. However, according to this mechanism, since it includes a proton transfer from the acid medium to the mono-protonated sulfoxide, a large isotope effect, $k_H/k_D>1$, must be expected. Actually, the isotope effect observed in the racemization of I in 17.68 mol/l is nearly one, as shown in Table 5. So this route (c) can be excluded.

All these results seem to suggest that sulfoxide I undergoes much less the A-1 reaction than II, and the legitimate A-1 type reaction takes place with I



Scheme 2. S_N2-like mechanism.

only in an extremely concentrated sulfuric acid close to 100%. This may be attributed to the higher stability of the monoprotonated sulfoxide I and the less stability of the intermediate such as cation radical or dication derived from I.

The following two alternative routes (d) and (e) (in Scheme II) may be postulated for the S_N2 type reaction.

There are differences between the two routes (d and e) in the second protonation step and in the degree of bonding of both entering and leaving groups on sulfur atom at the transition state. The reaction *via* route (d) includes the rate-limiting displacement of water molecules on the sulfur atom. And the every displacements cause the "Walden Inversion" at the sulfur atom, since both entering and leaving water molecules assume axial-axial positions at the trigonal bipyramidal transition.[47] The scheme *via* route (e) begins with the first equilibrium of mono-protonation, followed by the slow nucleophilic attack of water to form intermediate (A), and the subsequent fast second protonation to (A). The racemization may take place in the step 11 or 12 or both, and the oxygen exchange takes place at the step 13. Up to now, many reactions including tetracovalent pentacoordinate sulfur intermediates have been investigated. The acid catalyzed reduction of sulfoxides by halide ion[33,48] and recemization reaction of sulfoxides in aqueous hydrochloric acid[1,2] have been known to form a halohydrine intermediate ($R_1R_2S(OH)X$), and in these reactions, large steric effects on the rates by bulky substituents attacked to the central sulfur atom have been found owing to the tightness of the intermediate. If the title reaction would take place through the route (e), a similarly large steric effect must be expected. The steric effects observed in the racemizations of *p*-tolyl alkyl and *p*-tolyl aryl sulfoxides in 64.7% sulfuric acid were studied. However, as shown in Table 7, the steric effect is not so large and almost the same as that in 96.7% sulfuric acid. Thus, the route (e) including the intervention of a tight intermediate seems unlikely.

The rate constants, k_1, of the oxygen exchange of several *p*-substituted diphenyl and methyl phenyl sulfoxides were measured in the less concentrated acid.

CH_3[b]	*p*-CH_3	64.7	0.202	0.216
CH_3	H	64.7	0.238	0.257
CH_3	*p*-Cl	64.7	0.241	0.270

a) Sulfoxide=0.1 mol/l, at 50°C,[10] Method A.
b) Sulfoxide=0.1 mol/l, at 30°C, Method A.
c) k_1 was calculated using the pK_{BH^+} values established by Landini *et al.*[31] (for methyl phenyl sulfoxides), and by us (for diphenyl sulfoxides).

One finds in Table 8 that the polar effects of *p*-substituents on k_1 are not large. When log k_1 values obtained were plotted against σ^+, a good straight line was obtained (for diphenyl sulfoxides $\rho=0.412$, and for methyl phenyl sulfoxides $\rho=0.250$). However, the small positive values of ρ seems only to point out that the nucleophilic substitution of the protonated sulfoxide by water is the slow rate-limiting step of the reaction at a less concentrated sulfuric acid.

Experimental

Materials. *Optically Active Sulfoxides* were prepared from (−)menthyl (−) *p*-toluenesulfinate [mp 107—7.5 °C, $[\alpha]_D$ −200.4° ($c=1.85$, $l=0.5$ acetone)(lit,[49] mp 106—7 °C, $[\alpha]_D^{25}$ −199.2° (acetone)] and the corresponding aryl or alkyl Grignard's reagent according to the method developed by Andersen.[50] The mp or bp and specific rotations of sulfoxides obtained are as follows. *p*-Tolyl-SO-R; (R; mp or bp, specific rotation ($l=0.5$), (lit)[51]). CH_3; 74 °C, $[\alpha]_D^{23}$ +146.0° ($c=1.80$, acetone), (73—74.5 °C, $[\alpha]_D$ +145.5° (acetone)), C_2H_5; 95—97 °C/0.5 mmHg, $[\alpha]_D^{25}$ +184° ($c=1.3$, acetone), (123—126 °C/1.5 mmHg, $[\alpha]_D^{25}$ +186°(acetone)), C_6H_5; 92 °C, $[\alpha]_D^{20}$ +27.6°($c=1.53$, EtOH), (92—93 °C, $[\alpha]_D$ +27°(EtOH)), *o*-CH_3-C_6H_4; 78—78.5 °C, $[\alpha]_D^{20}$ −90.5°($c=1.21$, acetone), (77.8—78.5 °C, $[\alpha]_D$ −89.1° (acetone)), Mesityl; 107—107.5 °C, $[\alpha]_D^{22}$ −265.5° ($c=1.53$, EtOH), (107—107.5 °C, $[\alpha]_D$ −259° (EtOH)).

^{18}O-Labeled Sulfoxides were prepared by the bromine-oxidation of the corresponding sulfides in the presence of ^{18}O-enriched water(1.62 *atom*%-^{18}O) in acetic acid by the similar procedure described in our previous paper.[52] A sulfide (1 mol) was dissolved in a mixture of ^{18}O-enriched water(2—5 mol, 1.62 *atom*%-^{18}O), pyridine(5 mol) and acetic acid, and the solution was cooled under 0 °C, and then acetic acid solution of bromine (1 mol) was added dropwise over a period of 1 hr. After stirring for 1 hr, the mixture was poured into a large amount of ice-water, and the aqueous solution was neutralized with sodium bicarbonate. The resulted sulfoxide was extracted with chloroform, and the extract was washed with 10% aqueous solution of sodium thiosulfate and water, respectively, and dried. Finally, chloroform was distilled off and the crude ^{18}O-labeled sulfoxide was purified by distillation or recrystallization. Their mp or bp and *atom*%-^{18}O are as follows. $C_6H_5SOC_6H_4$-R; (R; mp or bp(lit)[53], *atom*%-^{18}O), *p*-CH_3; 71.5—72 °C (71 °C), 1.12, H; 70—71 °C(71 °C), 0.852, *p*-Cl; 45—46 °C (45—46 °C), 1.23, *p*-NO_2; 107 °C (106—107 °C), 0.996(This oxide was prepared using 3.50 *atom*%-$H_2^{18}O$). $CH_3SOC_6H_4$-R; (R; mp or bp(lit), *atom*%-^{18}O), *p*-CH_3; 42—43 °C (42—43 °C),[53] 1.08, H; 84 °C/0.25 mmHg(85 °C/0.5 mmHg),[54] 0.997, *p*-Cl; 46—48 °C(47—48 °C),[53] 0.983.

Kinetic Procedures. The rate of oxygen exchange and racemization were measured by the following two methods using YANAGIMOTO OR-10 TYPE polarimeter and HITACHI RMU-6E TYPE mass-spectrometer.

Method A(for both oxygen exchange and racemization). An ^{18}O-labeled or an optically active sulfoxide of a set mol was dissolved in sulfuric acid at a preset temperature. Aliquot portion(5 ml) of the solution was taken up from time to time for 5—7 times, and was quenched with 100 ml of ice-water. The sulfoxide recovered was then extracted with carbon tetrachloride or chloroform and the extract was washed with water, 10% aqueous solution of sodium carbonate and water, respectively, and dried over anhydrous sodium sulfate, and the solvent was then distilled off. The sulfoxide resulted was dried and subjected to both ^{18}O-analysis or specific rotation measurement. The ^{18}O-atom% was calculated from the mass peak heights 44 and 46 of carbon dioxide according to the method described by Samuel.[55] The rate constant for oxygen exchange were calculated from the equation, $\log \beta_0-\beta/\beta_t-\beta=kt/2.303$, where β_0 and β_t are atom% of ^{18}O at time 0 and t, respectively, and β is the atom% of ^{18}O of natural CO_2. The pseudo-first-order rate constant for the racemization was calculated from the equation, $\log \alpha_0'/\alpha_t'=kt/2.303$, where α_0' and α_t' are the specific rotation, $[\alpha]_D$, at time 0 and t, respectively.

Method B (for racemization): In the square shape cell (5 cm) was placed a sulfuric acid solution containing an optically active sulfoxide of a set mol, the rate was measured directly by checking the rotation, α, of polarimeter which was set at a desired temperature with a constant temperature bath connected. The pseudo-first-order rate constants were evaluated by the following equation, $\log \alpha_0/\alpha_t=kt/2.303$, where α_0 and α_t are the rotatory power at time 0 and t, respectively.

Sulfuric Acid. The concentration(wt%) of sulfuric acid medium was determined by titration with a standard alkali solution. The H_0 values of the media were obtained by interpolation from a graph of the data of Johnson *et al.*[30] D_2SO_4–D_2O solutions were prepared from MERCK D_2SO_4 (*min.* 99%-*d*) by dilution with D_2O (*min.* 99.75%-*d*). The concentration of acid was determined by titration of a weighed sample with a standard alkali solution. The molarity of the acid was calculated from the specific gravity. The specific gravities of ordinary acids used here are the values in the established table,[56] and these of deuterio acid media were newly determined by weight-method. The activity of water, $\log a_{H_2O}$, of the acid media was the value interpolated from the table of Giauque *et al.*[57]

Preparation, Polymerization, and Copolymerization of *N*-Vinyl Phthalimidine[1)]

Kenichi MURATA

Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda, Osaka 563

(Received August 30, 1972)

The preparation, polymerization, and copolymerization of *N*-vinyl phthalimidine were investigated. The monomer was prepared by the dehydrochlorination of *N*-(β-chloroethyl) phthalimidine. Polymerization was carried out in the presence of radical or cationic initiators in bulk and in solution. It was found that polymerizability with cationic initiators was larger than that with radical ones. The resulting polymers had a softening point in the range of 160—180 °C, the reduced viscosities being small. Copolymerization with acrylonitrile and styrene was carried out in dimethylformamide and benzene by radical initiators. The monomer reactivity ratios and Alfrey-Price Q and e values calculated from the copolymerization data of the monomer (M_1) and styrene (M_2) were $r_1=0.05$, $r_2=7.4$, $Q_1=0.30$, and $e_1=-1.80$. Values for *N*-vinyl pyrrolidone (M_1) were likewise determined for the sake of comparison, and found to be $r_1=0.02$, $r_2=12.0$, $Q_1=0.22$, and $e_1=-1.99$.

The polymerization and copolymerization of *N*-vinyl imides such as *N*-vinyl phthalimide and *N*-vinyl succinimide by radical process have been reported by many workers. In previous papers,[2-4)] the author reported on the polymerization and graft-copolymerization by γ-ray radiation, and the copolymerization by radical initiators.

N-Vinyl phthalimidine has been synthesized by Ooki,[5)] and Kato and Yoshida,[6)] but its polymerization and copolymerization have hardly been discussed at all.

In this paper the author reports a new preparative method of *N*-vinyl phthalimidine, and its polymerization and copolymerization.

Experimental

N-Vinyl Phthalimidine. The monomer was prepared *via* the dehydrochlorination of *N*-(β-chloroethyl) phthalimidine obtained after the condensation of monoethanolamine with phthalide and the following chlorination.

N-(β-Hydroxyethyl) Phthalimidine: To 16.0 g (0.26 mol) of monoethanolamine was added 35.0 g (0.26 mol) of phthalide, and the mixture was heated at 190—200 °C for about 6 hr to remove the water formed by condensation reaction. The amount of water removed was approximately 4 ml. The reaction product crystallized completely at room temperature. Recrystallization from benzene yielded 41.4 g (90%) of *N*-(β-hydroxyethyl) phthalimidine as colorless plates with a melting point of 119—120 °C (lit. mp 113—114 °C[6)]).

Found: C, 67.48; H, 6.06; N, 7.81%; mol wt (Rast), 181. Calcd for $C_{10}H_{11}NO_2$: C, 67.78; H, 6.26; N, 7.91%; mol wt, 177.2.

N-(β-Chloroethyl) Phthalimidine: To a solution containing 23.0 g (0.13 mol) of *N*-(β-hydroxyethyl) phthalimidine in 100 ml of benzene was added, drop by drop, 18.0 g (0.15 mol) of thionyl chloride with stirring at 5—10 °C for 30 min. After addition was completed, stirring was continued for 6 hr at room temperature. The solvent and volatile parts were removed as much as possible under reduced pressure, and the remaining part then began to crystallize. The crude crystals were also dissolved in a small amount of fresh benzene and the solution was poured into a large amount of petroleum benzine (bp 50—90 °C) to obtain 24.2 g (95%) of the crystals with a melting point of 78—82 °C. Recrystallization from petroleum benzine gave *N*-(β-chloroethyl) phthalimidine as colorless plates, mp 81—82 °C.

Found: C, 61.89; H, 5.06; N, 7.29%; mol wt (Rast), 199. Calcd for $C_{10}H_{10}NOCl$: C, 61.39; H, 5.15; N, 7.16%; mol wt, 195.7.

N-Vinyl Phthalimidine: To a solution containing 19.6 g (0.10 mol) of *N*-(β-chloroethyl) phthalimidine in 150 ml of benzene was added 10 g (0.18 mol) of potassium hydroxide pellets. The mixture was refluxed for 15 hr, while the liberated water was collected in a receiver. The reaction product was filtered to remove potassium chloride. The filtrate was concentrated under reduced pressure, and the remaining part then began to crystallize. Recrystallization from petroleum benzine gave 11.0 g (69%) of *N*-vinyl phthalimidine as colorless needles with a melting point of 66—67 °C (lit. mp 66—67 °C,[5)] mp 66.5 °C[6)]); its infrared absorption bands were at 1680 (phthalimidine carbonyl), 1610 (benzene ring), 1630, 1420, 975, 935 (vinyl), and 730 cm^{-1} (*o*-disubstituted benzene) (Fig. 1).

The ultraviolet absorption maxima in ethanol were: 228.5 (ε, 10900), 236 (8390), 276 (10000), and 280 nm (9860).

Found: C, 75.52; H, 5.52; N, 8.83%; mol wt (Rast), 164. Calcd for $C_{10}H_9NO$: C, 75.45; H, 5.70; N, 8.80%; mol wt, 159.2.

Other Materials. Commercial vinyl monomers such as acrylonitrile, styrene, and *N*-vinyl pyrrolidone were purified in the usual manners prior to use. Commercial initiators, azobisisobutylonitrile, benzoyl peroxide, boron trifluoride etherate, and stannic chloride were purified by reprecipitation, recrystallization, and distillation. Solvents, benzene and dimethylformamide were also purified according to the usual methods.

Polymerization Procedure. For polymerization and copolymerization in the presence of initiator, the required amounts of monomers, initiator, and solvent were weighed into a glass ampule, sealed under nitrogen atmosphere except for the cationic polymerization. In the radiation-induced polymerization, the ampule was irradiated by a cobalt-60 source for a given time.

After polymerization, the contents in the ampule were poured into a large amount of diethylether and methanol to precipitate the homopolymer and copolymer, respectively. The resulting polymers were filtered, washed with diethylether or methanol, dried under reduced pressure and weighed.

Elemental Analyses. The copolymers were purified by repeated precipitations. The copolymer compositions were determined by carbon and nitrogen analyses with a Yanagimoto C. H. N. Corder, Model MT-1.

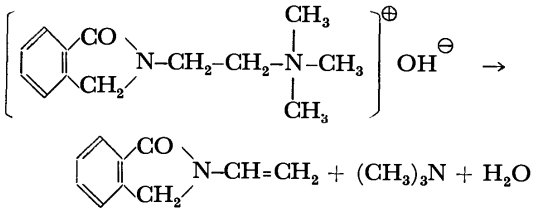
Viscosity Measurement. The reduced viscosity of the resulting polymer was determined at 30±0.01 °C as a 0.50% solution in dimethylformamide with an Ostwald viscometer.

Infrared Absorption Spectra. The infrared absorption spectra were obtained with a JASCO Infrared spectrophotometer, Model IR-G.

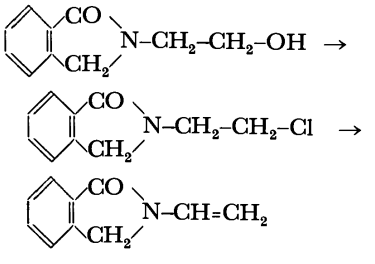
Results and Discussion

Preparation of N-*Vinyl Phthalimidine.* *N*-Vinyl phthalimidine was prepared by the olefin decomposition of the corresponding quaternary ammonium hydroxide by Ooki[5] for the first time with only a 43% yield. Kato and Yoshida[6] obtained the same monomer by the pyrolysis of *N*-(β-acetoxyethyl) phthalimidine, but the method when traced by the author gave a very poor yield.



A new method was worked out to improve the yield. The monomer was prepared by the dehydrochlorination of *N*-(β-chloroethyl) phthalimidine.

The chlorination reaction of *N*-(β-hydroxyethyl) phthalimidine with thionyl chloride in benzene afforded *N*-(β-chloroethyl) phthalimidine as colorless plates with a 119—120 °C melting point in a good yield. The dehydrochlorination reaction of the



chloride was carried out by the use of potassium hydroxide pellets in benzene to give *N*-vinyl phthalimidine as colorless needles with a melting point of 66—67 °C in a 69% yield. The infrared absorption spectrum was shown in Fig. 1.

Polymerization of N-*Vinyl Phthalimidine.* This was carried out in bulk or solution state. Initiators such as azobisisobutyronitrile (AIBN), benzoyl peroxide (BPO), boron trifluoride etherate, and stannic chloride, and also γ-rays from a cobalt-60 source were used. The results are shown in Table 1. We see that the polymerizability by AIBN is larger than that by BPO, the tendency being observed also in the polymerization of *N*-vinyl pyrrolidone. The *N*-vinyl phthalimidine was similarly polymerized by irradiation of γ-rays. Polymerization in the presence of cationic initiators was carried out more effectively compared with that in the presence of radical ones. This is because Alfrey-Price *e* value for *N*-vinyl phthalimidine is large and negative (Table 4).

The resulting polymer is a transparent resin having a 160—180 °C softening point, and soluble in benzene and insoluble in water in contrast to *N*-vinyl pyrrolidone polymer. The reduced viscosities of all the polymers were small, particularly in the polymers obtained by cationic polymerization.

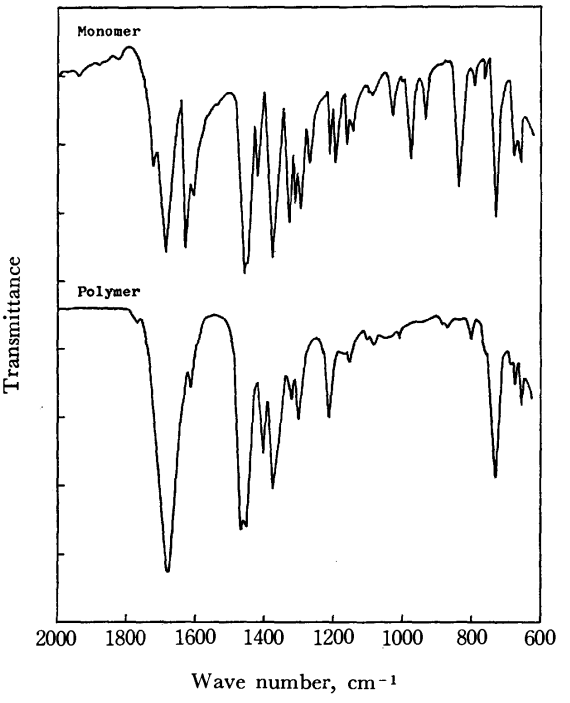


Fig. 1. Infrared absorption spectra of *N*-vinyl phthalimidine and its polymer in Nujol paste.

The infrared absorption spectrum of this *N*-vinyl phthalimidine polymer is shown in Fig. 1, no absorption bands (1630, 975, and 933 cm^{-1}) due to vinyl group in the original monomer being found.

Copolymerization of N-*Vinyl Phthalimidine.* The results of the copolymerization of *N*-vinyl phthalimidine with acrylonitrile and styrene by the use of BPO in dimethylformamide at 60 °C are shown in Table 2, together with those of *N*-vinyl pyrrolidone for comparison. The analytical data show that the *N*-vinyl phthalimidine can polymerize with the vinyl monomers, but *N*-vinyl phthalimidine is less reactive to enter the copolymer with styrene than that with acrylonitrile. The tendency was also observed in the copolymerization of *N*-vinyl pyrrolidone.

In an attempt to determine the monomer reactivity ratios for the system of *N*-vinyl phthalimidine and styrene, copolymerizations in dimethylformamide and in benzene were carried out statically at 60 °C. The monomer ratio in the initial stage was varied, while BPO or AIBN was used as the radical source at a concentration of 1.0 mol% in each case. All the procedures were carried out in less than 10% conversion to determine the initial stage of each copolymerization.

The results of copolymerization by BPO in dimethylformamide are given in Table 3. M_1 and M_2 denote the molar concentrations of *N*-vinyl phthalimidine and styrene, respectively, at the initial feeding, and m_1 and m_2 the molar fractions of the monomers

in the resulting copolymers calculated from the carbon and nitrogen analyses. According to the curve fitting method with use of all the average values of respective m_1 and m_2, the following was obtained.

$$r_1=0.05$$
and $$r_2=7.4.$$

The results of copolymerization by AIBN in benzene were close to those obtained above.

The copolymerization of *N*-vinyl pyrrolidone–styrene system was similarly carried out in the presence of BPO in dimethylformamide. The monomer reactivity ratios were calculated in the same way and found to be

$$r_1=0.02$$
and $$r_2=12.0.$$

Bork and Coleman[7] have dealt with the copoly-

Table 4. Alfrey-Price Q and e values of *N*-vinyl lactams and *N*-vinyl imides

Monomer	Q	e
N-Vinyl phthalimidine	0.30	−1.80
N-Vinyl pyrrolidone	0.22	−1.99
N-Vinyl phthalimide	0.09	−0.13
N-Vinyl succinimide	0.06	−0.17

merization of the same system by AIBN in benzene at 50 °C, their results being $r_1=0.045$ and $r_2=15.7$. These are close to the values obtained herewith.

In the copolymerizations of *N*-vinyl phthalimidine and *N*-vinyl pyrrolidone with styrene, it was also found that the rates of copolymerization decreased in proportion to the increase in the initial feedings of *N*-vinyl phthalimidine and *N*-vinyl pyrrolidone.

The Q and e Parameters. The Q and e parameters for these monomers were calculated according to the Alfrey-Price scheme[8] by using the values, r_1 and r_2, and $Q=1.0$ and $e=-0.8$ for styrene. The calculated Q and e values and those of *N*-vinyl imides[3] of related type are shown in Table 4. The respective pairs of the Q and e parameters of *N*-vinyl phthalimidine and *N*-vinyl pyrrolidone are very similar to each other. This indicates that the effects of the two substituents on the radical polymerization of such monomers closely resemble each other.

The e values of *N*-vinyl phthalimidine and *N*-vinyl pyrrolidone are much more negative than those of *N*-vinyl phthalimide and *N*-vinyl succinimide. This may be explained by the electron-attractive power (mesomeric effect) of carbonyl group in these monomers.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1755—1759 (1973)

The Synthesis of 4-Chloro-3-benzoyl-2-azetinone Derivatives and Their Conversion into *N*-Benzoyl-2,4-azetidinedione Derivatives

Kiyotada Matsui and Masatoshi Motoi

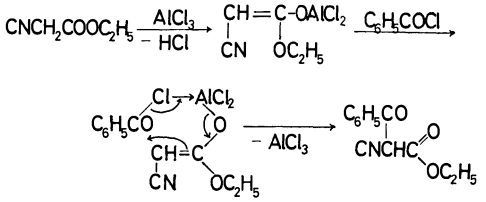
Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kodatsuno, Kanazawa 921

(Received September 14, 1972)

The treatment of ethyl α-cyanophenylacetate with benzoyl chloride in the presence of 2 equivalents of aluminum chloride in nitrobenzene afforded 4-chloro-3-benzoyl-3-phenyl- (6% yield) and 4-chloro-3-benzoyl-3-(*p*-benzoylphenyl)-2-azetinone (28%) at 50 °C. The same treatment of ethyl α-cyanopropionate afforded 4-chloro-3-benzoyl-3-methyl-2-azetinone (37%). The hydrolytic splitting of the chlorine atoms from the first two azetinones resulted in the formation of *N*-benzoyl-2,4-azetidinedione derivatives (36 and 20% respectively), whereas from the last we obtained *N*-benzoyl-α-carboxypropionamide (18%). These azetinone derivatives, when warmed with sodium methoxide in methanol, were converted into α-benzoyl α-cyano esters. The treatment of α-benzoyl α-cyano esters with aluminum chloride also afforded the azetinone derivatives in low yields.

Earlier studies of the aluminum chloride-catalyzed acylation[1] of active methylene compounds with acid chlorides were extended to the use of α-cyano esters as substrates. Thus, it was found that 4-chloro-3-benzoyl-2-azetinone derivatives could be formed from α-benzoylated α-cyano esters. The reconversion of the azetinone derivatives to the latter esters and their transannular, hydrolytic rearrangement to *N*-benzoyl-2,4-azetidinedione derivatives (*N*-benzoylmalonimides) were encountered.

When ethyl cyanoacetate was treated with benzoyl chloride in the presence of aluminum chloride in nitrobenzene at 55 °C, ethyl benzoylcyanoacetate was obtained as the main product. According to our previously-proposed mechanism,[1] the acylation can be explained in terms of an intramolecular condensation reaction which proceeds by means of the elimination of aluminum chloride from the coordination complex between acyl chloride and dichloroaluminum enolate as is shown in Scheme 1.

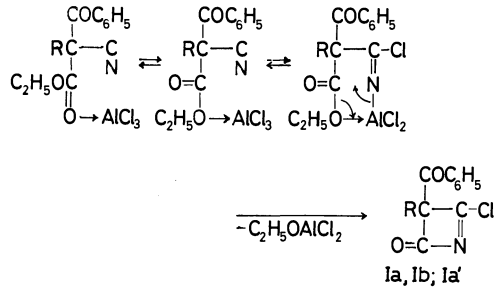


Scheme 1.

The benzoylation of ethyl α-cyanophenylacetate afforded a substance (Ia) in the presence of one equivalent of aluminum chloride at 50 °C, but the use of a larger amount of the condensing agent led to the formation of another substance (Ia′) besides Ia, while the benzoylation of ethyl α-cyanopropionate afforded only one product (Ib). The IR spectra of Ia, Ia′, and Ib are comparable to each other, none showing any band due to the cyano group. Their molecular formulas indicate that the α-benzoylated cyano ester is converted into Ia or Ib by losing its ethoxyl group and gaining a chlorine atom, and that Ia′ is a benzoylated

1) T. Nojiri and K. Matsui, *Nippon Kagaku Zasshi*, **87**, 880 (1966); T. Nojiri, I. Hashimoto, M. Motoi, and K. Matsui, This Bulletin, **42**, 3359 (1969); K. Matsui, M. Motoi, and T. Nojiri, *ibid.*, **46**, 562 (1973).

product from the Ia. Thus, each of the structures seems to have a 4-chloro-3-benzoyl-2-azetinone ring. The reaction seems to be a novel case of the Ritter reaction[2] known as the nucleophilic addition of a nitrile to a carbonium ion in the presence of sulfuric acid. By analogy with the mechanism proposed for the aluminum chloride-catalyzed transacylation[3] between β-diketones and esters, the mechanism for the present reaction can be depicted as in Scheme 2.

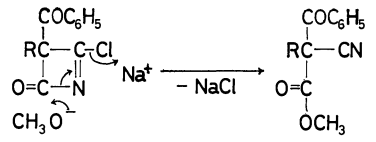


a: R=C_6H_5; b: R=CH_3; a′: R=*p*-$C_6H_5COC_6H_4$

Scheme 2.

The formation of Ia′ can be ascribed to the Friedel-Crafts benzoylation at the *para* position of the phenyl group of Ia, because the hydrolysis of Ia′ gives *p*-benzoylated compounds, as will be described in the Experimental section. The facile formation of the four-membered ring from the α-substituted, but not from the unsubstituted cyanoacetic ester, seems to be ascribable to a deviation from the normal valence angle by the introduction of a benzoyl group into the α position of the ester.

The treatment of 4-chloro-3-benzoyl-3-phenyl- (Ia), 4-chloro-3-benzoyl-3-(*p*-benzoylphenyl)- (Ia′), and 4-chloro-3-benzoyl-3-methyl-2-azetinone (Ib) with sodium methoxide in methanol gave their respective products, all of which show the IR spectra characteristic of α-benzoyl α-cyano esters, but the treatment of ethyl α-benzoyl-α-cyanophenylacetate and -α-cyanopropionate with aluminum chloride in nitrobenzene gave Ia and Ia′, and Ib, respectively, in low yields. These findings support the assigned structures. The formation of this Ia′ suggests that free benzoyl chloride is liberated from the reactants during the reaction because of the reversibility[1] of the aluminum chloride-catalyzed acylation with acyl chlorides. The formation of α-benzoyl α-cyano ester by ring-opening can be explained in terms of the 1,4 attack of sodium methoxide on the 4-chloro-2-azetinone ring, as is illustrated in Scheme 3.

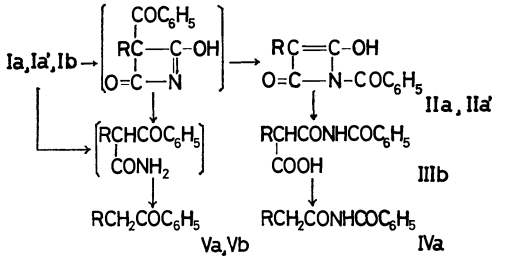


Scheme 3.

The hydrolytic splitting of the chlorine atom from Ia with glacial acetic acid containing a few drops of concentrated hydrochloric acid resulted in small amounts of *N*-benzoylphenylacetamide (IVa) and another substance (IIa), together with the unaltered Ia (47%), without giving a detectable amount of benzoic acid. The product IIa, with the composition of the expected 3-benzoyl-3-phenyl-2,4-azetidinedione, melts at 228.5—229.5 °C and is soluble in an aqueous sodium bicarbonate solution. In this solution, the IIa is partly converted into IVa on standing at room temperature, but remains unchanged to a certain extent. Obviously, the benzoyl group migrates from the carbon to the nitrogen atom.

The IR spectrum of Ia is somewhat similar to that of IIa, as will be described in the Experimental section. In the frequency region higher than 1200 cm^{-1}, however, a comparison of the two spectra shows that the absorption bands for Ia at 1745 cm^{-1} and at 1238 and 1217 cm^{-1}, which may be due to ClC=N and Ar-CO-C respectively, are replaced by the bands at 1660 and 1629 cm^{-1}, and at 1426, 1402, and 1276 cm^{-1}, which may be assigned mainly to NC=O and N≡C_3 respectively, in IIa, which has no absorption due to N-H. Thus, the benzoyl group in IIa must be situated on the nitrogen atom; hence, IIa may be characterized as *N*-benzoyl-3-phenyl-2,4-azetidinedione. A similar acidic hydrolysis of Ia′ provided a chlorine-free substance (IIa′) (mp 228—230 °C), which was characterized as *N*-benzoyl-3-(*p*-benzoylphenyl)-2,4-azetidinedione by its IR spectrum, which is similar to that of IIa. Moreover, under more drastic conditions, Ia′ as well as Ia was hydrolyzed to give benzamide derived from the rearranged products.

A solution of Ia in methanol containing sodium carbonate, on standing at room temperature, also afforded a small amount of IIa, a trace of IVa, and an oil which was soluble in an aqueous sodium hydroxide solution but not in a sodium bicarbonate solution. This oil reacted to give an unidentified 2,4-dinitrophenylhydrazone which was not formed from Ia, and it was converted into desoxybenzoin (Va) and benzil upon treatment with sodium nitrite and sulfuric acid. The formation of such a hydrazone or ketones suggests that, in an alkaline medium, a part of either Ia or intermediate 3-benzoyl-3-phenyl-2,4-azetidinedione can be hydrolyzed with ring-opening prior to the rearrangement, as is shown in Scheme 4.



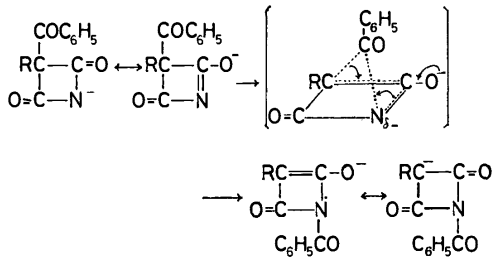
Scheme 4.

The rearrangement, being independent of the acidities of media, seems to proceed intramolecularly through both resonance-stabilized anions from the 3-benzoyl-

2) L. I. Krimen and D. J. Cota, "Organic Reactions," Vol. 17, p. 213 (1969).

3) K. Matsui and M. Motoi, This Bulletin, **46**, 565 (1973).

and *N*-benzoyl-azetidinedione derivatives. Accordingly, the transannular migration of the benzoyl group can be considered as being due to the relative unstability of the former anion which has a quaternary carbon atom linked to the three carbonyl groups. For this electrophilic rearrangement, the transition state shown in Scheme 5 may be passed through.



Sceheme 5

Ib, under conditions similar to those in the above acidic hydrolysis of Ia, was converted into *N*-benzoyl-α-carboxypropionamide (IIIb) (18%), benzoic acid, and a mixture, giving the unaltered Ib (75%). The acidic hydrolysis of the mixture gave a slight amount of propiophenone (Vb). It can be seen that Ib undergoes the same rearrangement and subsequent ring-opening to give IIIb; it is also subject to some acid cleavage.

Further work is required on the general preparation of *N*-acyl-2,4-azetidinediones.

Experimental

Materials. Commercial ethyl cyanoacetate was distilled at 206—207 °C before use. The ethyl α-cyanopropionate[4] and ethyl α-cyanophenylacetate[5] were prepared according to the literature, boiling at 86.4—87 °C/17 mmHg and at 125—127 °C/3.5 mmHg respectively. IR of the latter: 2250, 1747, 1240, 1028 cm^{-1}. Ethyl α-benzoyl-α-cyanophenylacetate was prepared from ethyl α-cyanophenylacetate by a modification of the method described in the literature[6]; bp 135—136 °C/0.03 mmHg. Found: C, 73.48; H, 5.13; N, 4.71%. Calcd for $C_{18}H_{15}NO_3$: C, 73.7; H, 5.17; N, 4.78%. IR: 2264, 1763—1749, 1696, 1218—1184, 1005 cm^{-1}. Ethyl α-benzoyl-α-cyanopropionate was also prepared as above; bp 116—117 °C/0.4 mmHg. Found: C, 67.54; H, 5.63; N, 5.94%. Calcd for $C_{13}H_{13}NO_3$: C, 67.51; H, 5.68; N, 6.06%. IR: 2207, 1752, 1709, 1259—1229, 1014 cm^{-1}.

General Procedure for Preparing Crude Ethyl Benzoylcyanoacetate and 4-Chloro-3-benzoyl-2-azetinone Derivatives. To a cold solution of aluminum chloride in dry nitrobenzene (10 ml), which was placed in a 50-ml flask equipped with a calcium chloride tube, we added the cyano ester (15 mmol) and then benzoyl chloride (4.2 g, 30 mmol) with cooling. The mixture was kept, with occasional swirling, in a thermostat. The reaction mixture was then stirred into a mixture of crushed ice and hydrochloric acid, after which the mixture was shaken with ether. The upper layer was washed with water to remove the aluminum chloride, and then shaken occasionally with a sodium bicarbonate solution until the Beilstein test for benzoyl chloride showed negligible results. The upper layer was then concentrated and steam-distilled *in vacuo* to leave a crude crystalline product.

a) Ethyl Benzoylcyanoacetate: The crude product obtained from ethyl cyanoacetate (1.7 g) by using aluminum chloride (4 g, 30 mmol) at 55 °C for 20 hr was found to consist of slight amounts of dibenzoyl- and tribenzoyl-methane by the use of the procedures described in our previous papers.[1] The aqueous sodium bicarbonate extract, after having been acidified with hydrochloric acid, was shaken with ethyl acetate. The upper layer was shaken with an aqueous copper acetate solution, and then the resulting product was filtered from copper benzoate. The upper layer of the filtrate was dried over sodium sulfate and concentrated to give a copper complex (mp 231—233 °C, ethanol), which was usually decomposed to give ethyl benzoylcyanoacetate. The aqueous solution containing aluminum chloride, after standing for a week, was extracted with ether. The evaporation of the ether extract gave an oil which was subsequently crystallized from ethanol to give ethyl benzoylcyanoacetate; mp 39—40 °C, (Found: N, 6.16%). The total yield was 41%.

b) 4-Chloro-3-benzoyl-3-phenyl-2-azetinone, Ia: The crude product obtained from ethyl α-cyanophenylacetate (2.84 g) by using aluminum chloride (15 mmol) at 50 °C for 48 hr was dissolved in a slight amount of benzene; then the solution was transferred onto a column packed with silica gel (60—200 mesh). Ia, eluted with benzene–petroleum ether (1 : 1), was recrystallized from ethanol as colorless needles (0.65 g, 15%), mp 184—185 °C. Found: C, 67.33; H, 3.56; Cl, 12.91; N, 4.91%. Calcd for $C_{16}H_{10}ClNO_2$: C, 67.73; H, 3.56; Cl, 12.49; N, 4.94%. MS: M^+=283, 285 (intensity ratio, 3 : 1). IR(KBr): 1745(s), 1707(sh), 1601(sh), 1592(s), 1567(s), 1547(s), 1491(m), 1446(m), 1350(s), 1314(w), 1238(s), 1217(m), 1176(w), 1043(m), 1020(m) cm^{-1}.

c) 4-Chloro-3-benzoyl-3-(p-benzoylphenyl)-2-azetinone, Ia': The crude product from the same treatment with 30 mmol of aluminum chloride was chromatographed successively with benzene–petroleum ether (1 : 1) and benzene–ether (3 : 1), giving 0.26 g (6%) of Ia and 1.64 g (28%) of Ia' respectively. The latter, on recrystallization from ethanol, melts at 164.5—165 °C. Found: C, 71.30; H, 3.68; Cl, 8.89; N, 3.64%. Calcd for $C_{23}H_{14}ClNO_3$: C, 71.23; H, 3.64; Cl, 9.14; N, 3.61%. MS: M^+=387, 389 (3 : 1). IR(KBr): 1754(s), 1704(sh), 1669(s), 1598(s), 1570(s), 1535(s), 1502(m), 1447(m), 1355(s), 1315(m), 1279(s), 1239(s), 1227(m), 1175(w), 1041(m), 1020(w) cm^{-1}.

d) 4-Chloro-3-benzoyl-3-methyl-2-azetinone, Ib: The crude product obtained from ethyl α-cyanopropionate (1.9 g) by using 30 mmol of aluminum chloride at 50 °C for 48 hr was recrystallized from ethanol to give Ib(1.22 g, 37%), mp 123—124 °C (ethanol). It decomposes, with the formation of benzoic acid, over a long period in air. Found: C, 60.22; H, 3.74; Cl, 16.06; N, 6.36%. Calcd for $C_{11}H_8ClNO_2$: C, 59.64; H, 3.61; Cl, 16.03; N, 6.32%. MS: M^+=221, 223 (3 : 1). IR(KBr): 1750(s), 1707(sh), 1603(s), 1575(m), 1554(s), 1489(w), 1448(m), 1387(m), 1349(m), 1313(w), 1247(m), 1223(m), 1050(m), 1015(w) cm^{-1}.

Ia and Ia', or Ib from the α-Benzoyl α-Cyano Ester. When ethyl α-benzoyl-α-cyanophenylacetate (2.9 g, 10 mmol) in a nitrobenzene solution (10 ml) of aluminum chloride (1.6 g, 12 mmol) was kept at 50 °C for 22 hr (as in the case of *c*) above), Ia and Ia' were obtained from the reaction mixture in trace and 7-mg amounts respectively. The yields were

4) N. Zelinsky, *Ber.*, **21**, 162 (1888).
5) E. C. Horning and A. F. Finelli, "Organic Syntheses," Coll. Vol. IV, p. 461 (1963).
6) A. Haller, *C. R. Acad. Sci. Paris*, **105**, 169 (1887).

increased to 0.5 mg and 12 mg respectively when the amount of aluminum chloride and the reaction temperature were decreased to 5 mmol and to 40 °C respectively. Under the former conditions, 70 mg of Ib were obtained from 2.3 g (10 mmol) of ethyl α-benzoyl-α-cyanopropionate. These azetinones were identified by the mixed-melting-point method.

α-Benzoyl α-Cyano Ester from Ia, Ia', or Ib. A benzene solution (2 ml) of Ia (2 mmol) was added to a sodium methoxide solution made from sodium (0.002 g atom) and methanol (3 ml). After 1 hr, the mixture was warmed at 40 °C for 1 hr. The cooled reaction mixture was acidified with an aqueous acetic acid and then shaken with ether. The ether layer, after having been washed with a sodium bicarbonate solution, was dried and concentrated; then the remaining oil was placed in a column packed with silica gel. Benzene–ether (14 : 1) was used as the eluent. The fractions, each showing a single spot on tlc, were collected. The resulting product was concentrated to leave an oil. The IR spectra for the oils from Ia and Ib were similar to those of ethyl α-benzoyl-α-cyanophenylacetate and -α-cyanopropionate respectively. In the same way, the IR spectrum of the oil from Ia' was found to be similar to that for Ia, so it seems to be due to methyl α-benzoyl-α-cyano-*p*-benzoylphenylacetate. No search for compounds with a methoxyl group in the products was made because of the small amounts involved.

Hydrolysis of Ia. a): Two drops of concd hydrochloric acid were added to a solution of Ia (0.3 g) in benzene (1 ml) and glacial acetic acid (5 ml); then the solution was warmed at 50—51 °C for 2 hr. The cooled reaction mixture was diluted with water and then shaken with ether–benzene (5 : 1). The upper layer, freed from acetic acid by washing with water, was shaken with a saturated sodium bicarbonate solution. The upper layer was then dried and evaporated to leave a crystalline mass, which was subsequently recrystallized from ethanol to give Ia (0.14 g). The lower layer, after the removal of the ether dissolved, was acidified to precipitate crude *N*-benzoyl-3-phenyl-2,4-azetidinedione (IIa) (0.1 g, 36%, mp 226—228 °C), which was collected by filtration. The crude IIa in ether was washed with an aqueous solution of a slight amount of sodium bicarbonate; then it was dried and concentrated by passing a stream of dry air, giving colorless crystals; mp 228.5—229.5 °C. Found: C, 72.67; H, 4.19; N, 5.42%. Calcd for $C_{16}H_{11}NO_3$: C, 72.44; H, 4.19; N, 5.28%. IR(KBr): 1710(sh), 1660(s), 1629(m), 1612(m), 1579(m), 1552(s), 1496(w), 1448(m), 1426(s), 1402(s), 1352(s), 1309(m), 1276(s), 1115(m) cm^{-1}.

The filtrate separated from the above crude IIa was extracted with ether. The resulting extract was dried and concentrated to give colorless crystals (20 mg, 8%), which were subsequently recrystallized from ether to give *N*-benzoylphenylacetamide; mp 138.5—139.5 °C. This melting point was undepressed on admixture with a synthesized sample melting at 139—140 °C (lit.[7] 129—130 °C). Found: N, 5.8%. IR(KBr): 3287, 1732, 1686, 1605 cm^{-1}.

b): A solution of Ia (50 mg) in benzene (1 ml) and ethanol (10 ml) was added to a mixture of an aqueous solution (4 ml) of sodium carbonate (35 mg) and methanol (30 ml). The resulting solution was stirred with a magnetic stirrer at room temperature for 6 hr. The reaction mixture was then steam-distilled *in vacuo* to remove the organic solvent. The residue was separated as above into an oil, IIa (7 mg), and *N*-benzoylphenylacetamide (a trace). The oil, containing a small amount of Ia, gave a 2,4-dinitrophenylhydrazone. The isolated products were identified by mixed-melting-point method.

c): A solution of Ia (100 mg) in benzene (2 ml) and ethanol (20 ml) was added to a warm mixture of methanol (40 ml) and an aqueous solution (5 ml) of sodium carbonate (100 mg). The resulting solution was warmed at 60—65 °C for 8 hr. The reaction mixture, after the removal of the organic solvent, was shaken with ether. The lower layer, on acidification, gave phenylacetic acid (mp 79—80 °C (water)) and benzoic acid (mp 119—120 °C). The upper layer, after extraction with a sodium hydroxide solution, was evaporated to give benzamide (mp 129—130 °C (ether)). The alkaline extract, after acidification, was reextracted with ether. The evaporation of the ether extract gave an oil. An excess amount of sodium nitrite powder was added in small portions to a solution of this oil in 80% sulfuric acid over a 12-hr period with occasional heating up to 50—60 °C; then the reaction mixture was diluted with warm water. The ether extract from the sulfuric acid solution was concentrated and then steam distilled. The residue was alkalized with a sodium hydroxide solution and then extracted with ether. An oil obtained from the ether extract gave a 2,4-dinitrophenylhydrazone melting at <195 °C (ethanol). A similar treatment of the above distillate led to crystals melting at <185 °C. The first and last melting points were undepressed on admixture with the 2,4-dinitrophenylhydrazone of benzil (mp 200—202 °C) and that of desoxybenzoin (mp 203—204 °C) respectively.

Acid Hydrolysis of Ia'. a): Ia', when treated as has been described in the case of the hydrolysis of Ia, *a)*, was converted into *N*-benzoyl-3-(*p*-benzoylphenyl)-2,4-azetidinedione (20%); mp 228—230 °C (tetrahydrofuran). Found: C, 74.82; H, 4.03; N, 3.55%. Calcd for $C_{23}H_{15}NO_4$: C, 74.78; H, 4.10; N, 3.79%. IR(KBr): 1705(sh), 1662(sh), 1652(s), 1630(m), 1605(m), 1580(m), 1563(s), 1495(w), 1447(w), 1425(s), 1400(s), 1353(s), 1314(s), 1280(s), 1262(m), 1173(m), 1115(m) cm^{-1}.

b): To a solution of Ia' (100 mg) in glacial acetic acid (2 ml), we added one drop each of concd sulfuric acid and water; then the solution was refluxed for 0.5 hr. The reaction mixture was subsequently diluted with water, neutralized with sodium bicarbonate, and then shaken with ether. The evaporation of the upper layer left crystals, which were then triturated with water. The water-insoluble crystals were recrystallized from ether–methanol to give *p*-benzoylphenylacetamide; mp 140—141 °C (lit.[8] 136—137 °C). Found: C, 75.34; H, 5.66; N, 5.70%. From the aqueous solution, benzamide was separated; it was then crystallized from ether–petroleum ether; mp 127—128 °C. The above lower layer was acidified and then extracted with ether. The ether extract, freed from acetic acid, was evaporated to give crystals, which were then triturated with water. The water-insoluble crystals were recrystallized from benzene to give *p*-benzoylphenylacetic acid; mp 113—114 °C (lit.[8] 112—114 °C). Found: C, 75.18; H, 5.15%. From the aqueous solution, benzoic acid was isolated. The benzoic acid and benzamide were identified by the mixed-melting-point method.

Acid Hydrolysis of Ib. Six drops of concd hydrochloric acid were added to a solution of Ib (2 g) in benzene (5 ml) and glacial acetic acid (30 ml); then the solution

7) H. L. Wheeler, T. B. Johnson, and D. F. McFarland, *J. Amer. Chem., Soc.* **25**, 787 (1903).

8) R. P. Zelinski, B. W. Turnquest, and E. C. Martin, *ibid.*, **73**, 5521 (1951).

was warmed at 65—66 °C for 0.5 hr. The reaction mixture was separated as in the case of the hydrolysis of Ia, *a)*. The unaltered Ib weighed 1.5 g. The sodium bicarbonate extract, after acidification, was extracted with ether. The ether extract was evaporated to give a crystalline mass, which was triturated with ether–petroleum ether (1 : 4); then the insoluble crystals were collected by filtration. From the filtrate, benzoic acid was obtained. The organic solvent-insoluble crystals were treated with a sodium bicarbonate solution; then the product was filtered from an insoluble substance. The filtrate on acidification gave crystals. A solution of these crystals in ether was concentrated by passing dry air to give *N*-benzoyl-α-carboxypropionamide (0.36 g, 18%) in the form of colorless needles, which melted at 129 °C with decomposition. Found: C, 59.71; H, 5.04; N, 6.20%. Calcd for $C_{11}H_{11}NO_4$: C, 59.72; H, 5.01; N, 6.33%. IR (KBr): 3400—3370, 3306, 1712, 1682, 1602 cm^{-1}. The thermal decomposition of this carboxy amide gave *N*-benzoylpropionamide. It was crystallized from petroleum ether (mp 98—98.5 °C), giving no depression on admixture with a synthesized sample (lit.[9] mp 98 °C). IR(KBr): 3295, 1713, 1683, 1602 cm^{-1}.

The mother liquor from the crystallization of the above carboxy amide, the sodium bicarbonate-insoluble substance, and the aqueous acidic filtrates were combined; then the mixture, after the addition of a few mls of concd hydrochloric acid, was steam-distilled. The distillate gave 2,4-dinitrophenylhydrazone of propiophenone. It was recrystallized from ethanol (mp 197—199 °C), giving no depression on admixture with an authentic sample melting at 199—200 °C.

The present authors wish to express their thanks to Professor Hiroshi Suda and to Miss Michiko Araki of this faculty for their elemental analyses.

(Received September 20, 1972)

The photo-amination reaction of sodium 1-amino-4-bromoanthraquinone-2-sulfonate (I) was studied. The experimental results may be summarized as follows: 1) The photo-reaction is evoked by the absorption of light corresponding to the first absorption band (490 nm) of (I); 2) no dark reaction is observed: 3) aromatic amines appeared not to photo-react with (I); 4) the larger the polarity of the solvents used, the greater the yield of the product; 5) in the absence of oxygen, the photo-reaction was stopped. The possible reaction schemes were discussed.

The photochemistry of anthraquinone derivatives has attracted much attention in relation to the photo-tendering effects of vat dyes, and many studies concerning photo-reduction and photo-annelation have been reported.[1] However, the photo-substitution reactions of anthraquinones have rarely been reported on. Only two examples have been reported: the photolysis of 3-nitroalizarin in aerated methanol to give 4-methoxy-3-nitroalizarin, and the photolysis of anthraquinone-2-sulfonic acid in oxygen-free water to give hydroxyanthraquinones.[2,3] We ourselves have previously found that sodium 1-amino-4-bromoanthraquinone-2-sulfonate (bromamine acid) is photo-aminated to produce sodium 1,4-diaminoanthraquinone-2-sulfonate.[4] In this paper, details of the photo-amination will be reported and the most probable mechanism of the reaction will be discussed.

Experimental

Materials. The sodium 1-amino-4-bromoanthraquinone-2-sulfonate(bromamine acid) was purified by repeated salting out and by subsequent recrystalization from 1 : 1 ethanol-water. The sodium 1,4-diaminoanthraquinone-2-sulfonate was prepared by the hydrolysis of sodium 1-amino-

4(N-benzenesulfonyl)-aminoanthraquinone-2-sulfonate. The other authentic samples of sodium 1-amino-4-alkylamino-anthraquinone-2-sulfonate were prepared in an autoclave by an Ullmann condensation reaction from bromamine acid and the corresponding alkylamine in the presence of cupric sulfate as the catalyst.

Solvents. Water was passed through ion-exchange resin columns (specific resistance: 10^6 ohm/cm). The methanol was purified by repeated fractional distillations. The 1-propanol and tertiary butanol were refluxed over lime and fractionally distilled. The ethanol was distilled with 5 ml of concd sulfuric acid and 20 ml of water per liter; then it was refluxed with silver nitrate and potassium hydroxide, and finally fractionally distilled. The acetonitrile was refluxed with sodium carbonate and potassium permanganate, and then distilled. It was subsequently refluxed with phosphorus pentoxide, fractionally distilled, and finally distilled over potassium carbonate. The extra-pure reagent of dioxane (Tokyo Kasei Co.) was used without further purification.

Measurements. A Shimadzu recording spectrophoto meter, model MPS 50, was used for the measurements of the visible absorption spectra.

Isolation of the Product. After the irradiation of light, the solvent was distilled from the reaction system at 30 °C under reduced pressure; the blue-colored product was separated by the method of cellulose-column chromatography with a developing solution of water.

Results and Discussion

Photo-reaction of I with Various Amines. A solution of 0.990×10^{-4} mol/l of bromamine acid and 4.37×10^{-2} mol/l of ammonia in an aerated 4 : 1 2-propanol-water mixture was irradiated at 30 °C by means of a water-jacketed 500 W high-pressure mercury lamp filtered with a glass which allows a radiation of $\lambda>300$ nm. The color of the solution turned from red to blue upon the irradiation. The visible absorption spectrum of the reaction system is shown in Fig. 1. As the reaction proceeded, the absorption intensity at 490 nm(λ_{max}) decreased with the increase in the intensities at 565 nm(λ_{max}) and 607 nm(λ_{max}), and the isosbestic points were at 382 nm and 525 nm. The newly-appeared absorption bands of 565 nm(λ_{max}) and 607 nm(λ_{max}) agreed with those of the authentic sodium 1,4-diaminoanthraquinone-2-sulfonate(II). Hence, this result suggested that the photo-reaction of bromamine acid(I) with ammonia gives only sodium 1,4-diaminoanthraquinone-2-sulfonate(II). The IR spectrum of the blue product and the paper chromatogram also supported this suggestion. Similar photo-aminations of bromamine acid(I) by alkylamines such as methylamine, ethylamine, *n*-propylamine, *n*-butylamine, and the piperidine were also observed. The wavelengths of the maximum absorption in the visible region of products in 4 : 1 2-propanol-water are compared in Table 1. In the case of piperidine, the reaction proceeds rather fast as compared with the case of other alkylamines. As is shown in Fig. 2, when the irradia-

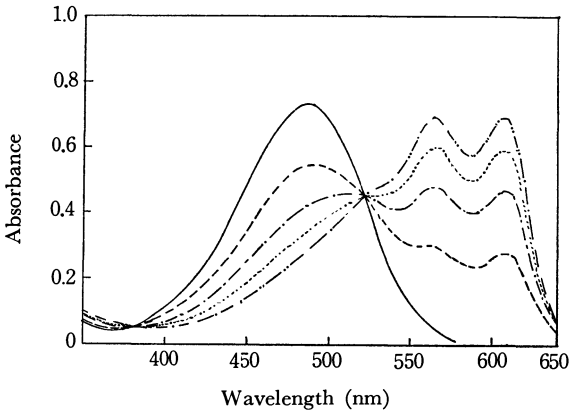

Fig. 1. Visible absorption spectra of the reaction system [I]~0.990×10^{-4} mol/l, [NH_3]~4.37×10^{-2} mol/l in 4 : 1 2-PrOH-H_2O.
——: 0 hr, ----: 2 hr, —·—: 4 hr, ·····: 6 hr, —··—: 8 hr.

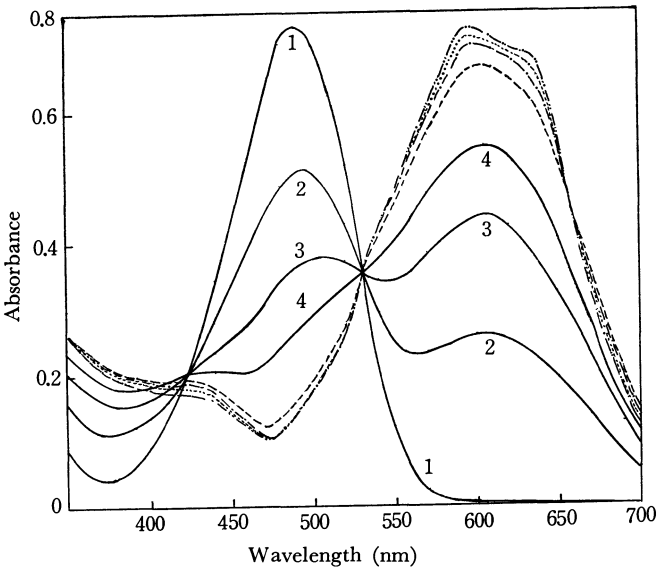

Fig. 2. Visible absorption spectra of the reaction system [I]~0.990×10^{-4} mol/l. [Piperidine]~5.00×10^{-2} mol/l in 4 : 1 2-PrOH-H_2O.
1: 0 min, 2: 20 min, 3: 40 min, 4: 60 min,
----: 2 hr, —·—: 4 hr, ----: 6 hr, —··—: 8 hr.

tion was carried out for more than 1 hr, the isosbestic point at 423 nm in the early stage of reaction disappeared and new two isosbestic points appeared in the neighbourhoods of 350 nm and 660 nm. Moreover, the broad absorption band of 605 nm(λ_{max}) split into two peaks; it resembles that in the spectrum of the reaction products of other alkylamines. These facts seem to indicate that bromamine acid may be photo-aminated by piperidine to produce sodium 1-amino-4-piperidinoanthraquinone-2-sulfonate, followed by the ring opening of the piperidine ring. When aromatic amines such as aniline and diphenylamine were used, the substitution reaction did not occur and (I) remained unchanged.

Photo-reaction of I with the Hydroxyl Ion. A solution of 0.990×10^{-4} mol/l of bromamine acid and 4.84×10^{-2} mol/l of sodium hydroxide in an aerated 4 : 1 2-propanol–water mixture was irradiated under the same conditions as have been given above. The absorption intensity of the first band(λ_{max}=490 nm) of bromamine acid decreased, and a new absorption band at 612 nm initially appeared and then decreased with the irradiation; that is, the photo-decomposition of bromamine acid by the hydroxyl ion takes place exclusively. Nothing about the new absorption band at 612 nm was made clear. However, this band seems likely to be caused by either of two possible intermediates. One is a photo-reduced intermediate, since the new absorption band has a tendency to disappear upon the bubbling in of air. The other is sodium 1-amino-4-hydroxyanthraquinone-2-sulfonate, which may be considered to be once produced and then soon decomposed, since it has an absorption peak at 612 nm in an alkaline solution.

Photolysis of I. A solution of 0.990×10^{-4} mol/l of bromamine acid in a 4 : 1 2-propanol–water mixture was irradiated under the same conditions as in the case of the reaction with ammonia. After 8 hrs' irradiation, no change was observed in the absorption spectrum of the reaction system; that is, bromamine acid remained unchanged in the absence of amines or hydroxyl ion.

Effect of the Solvent. The photo-substitution reactions of bromamine acid (I) with ammonia were carried out in various solvents. As is shown in Fig. 3, the yields of the aminated product decreased in the following order: 4 : 1 CH_3CN–H_2O>4 : 1 2-PrOH–H_2O>4 : 1 EtOH–H_2O>4 : 1 MeOH–H_2O>4 : 1 1-PrOH–H_2O>4 : 1 *t*-BuOH–H_2O>4 : 1 Dioxane–H_2O>H_2O; that is, bromamine acid is more reactive in polar solvents, such as acetonitrile and alcohols, than in less polar solvents, such as dioxane, except in the case of water. This seems to imply the existence of a polar intermediate, which may be stabilized by the polar solvents.

Effect of the Wavelength of Irradiation. When the substance was irradiated with light including the UV region (λ<300 nm), the photo-amination reaction did not take place and the photo-decomposition of bromamine acid predominated. When the irradiating light was λ>420 nm, including only the region of the first absorption band (λ_{max}=490 nm), the substitution reaction proceeded as well as in the case of the radiation of λ>300 nm. Moreover, no dark reaction was observed under the same conditions in the case of any amine. From these results it may be concluded that the amination of bromamine acid by ammonia is induced by the absorption of light corresponding to the first absorption band of bromamine acid.

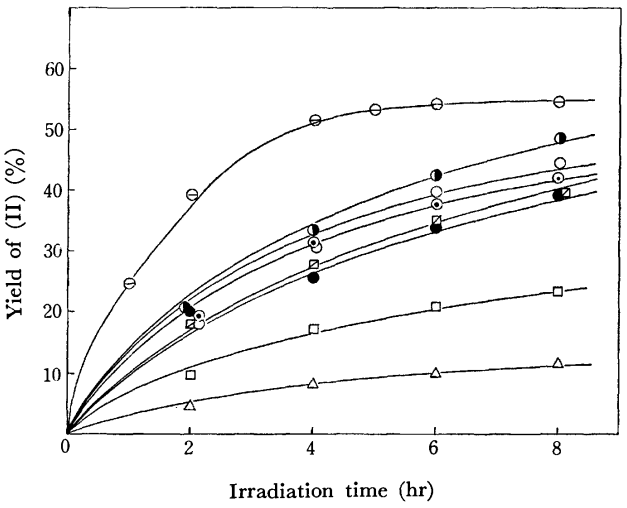

Fig. 3. Effect of the solvents on the yield of (II) [I]~0.990×10^{-4} mol/l, [NH_3]~4.37×10^{-2} mol/l.

Photo-reaction of 1-Bromoanthraquinone with Ammonia. A solution of 1-bromoanthraquinone (1.0×10^{-4} mol/l) and ammonia (4.37×10^{-2} mol/l) in a 4 : 1 2-propanol–water mixture was irradiated in the way described above. No change was observed in the near UV and visible absorption spectra of the reaction system, and it was concluded that 1-bromoanthraquinone was not photoaminated by ammonia. This eliminates the possibility that the photo-induced cleavage of the C–Br bond may take place in the early stage of the photo-amination of bromamine acid.[5] This is also supported by the fact that no debrominated product such as sodium 1-aminoanthraquinone-2-sulfonate was detected in the photo-amination reaction of bromamine acid.

Effect of Oxygen. The reaction almost stopped under nitrogen. This suggests that dissolved oxygen has an important role in the photo-amination of bromamine acid. As has been mentioned above, the photo-reduction of quinones is well known, and the photo-amination may be considered to proceed through the intermediates which may be produced by several photo-

5) Several examples of the photo-cleavage reactions of α-substituted aliphatic ketones, induced by the polarization of the C=O group in the excited n–π* state, are known to be;

$$-\overset{\overset{O}{\|}}{C}-\overset{\overset{X}{|}}{C}- \xrightarrow{h\nu} -\overset{\overset{O}{\|}}{C}-\overset{\overset{\pm}{|}}{C}- + \overset{\pm}{X} \quad (\pm\sim+,\ -,\ \text{or.})$$

where X is an electronegative species such as a halogen atom. (cf., for example, O. Jeger, K. Schaffner, and H. Wehrli, *Pure Appl. Chem.*, **9**, 555 (1964); J. A. Barltrop and A. Thomson, *J. Chem. Soc., C*, **1968**, 155; J. Hill, *Chem. Commun.*, **1966**, 260.)

reduction processes;[1,6,7]

a) $AQ^* + R\text{-}H \rightarrow AQH\cdot, AQH_2, AQ^{\cdot-}$

b) $AQ^* + OH^- \rightarrow AQ^{\cdot-}$

c) $AQ^* + R_1R_2\ddot{N}H \rightarrow [AQ^{\cdot-} \cdots\cdots R_1R_2\overset{+\cdot}{N}H] \downarrow AQ^{\cdot-}, AQH\cdot$

However, in the presence of oxygen it is well known that these intermediates are immediately oxidized and that the quinone is regenerated.[8,9] In the case of sodium anthraquinone-2-sulfonate, Bridge and Reed observed that the concentrations of the intermediate semiquinone radical and the radical anion decrease with the increase in the oxygene concentration.[10] Therefore, if the photo-amination proceeds through these intermediates, the reaction is expected to be enhanced under nitrogen and retarded under air. However, the experimental results were contrary to the above expectation. Therefore, it seems that this scheme is also invalid. Further, Cooper and Talbot observed that both oxygen and metal ions, such as Fe^{3+}, have oxidizing power for intermediate radicals which are generated from quinones by photo-reduction.[11] According to their report, the photo-reaction of bromamine acid with ammonia in a 4 : 1 2-propanol–water mixture was carried out under nitrogen in the presence of Fe^{3+} (about 10^{-2} mol/l of ferric chloride or potassium ferricyanide) in place of the molecular oxygen. If the photo-amination reaction proceeds through the process of oxidation by the molecular oxygen of intermediate radicals generated in the photo-reduction of the anthraquinone nucleus, the reaction may be expected to take place upon the addition of Fe^{3+} as an oxidizing agent under nitrogen. However, no reaction was observed. These results suggest that molecular oxygen does not act as a simple oxidizing agent, but plays a more complicated role in the photo-amination reaction. The following other possible photochemical schemes including interactions with oxygen were also considered:

i) the photo-amination through the interaction of bromamine acid with singlet oxygen, which may be produced by the sensitizing effect of the triplet state of bromamine acid;

ii) the photo-amination through the interaction of excited bromamine acid with ground-state oxygen to form some complex as below:[12]

$$AQBr^* + O_2 \longrightarrow [AQBr^{\oplus} \cdots\cdots O_2^{\ominus}]$$

$$\swarrow \qquad \searrow^{R_1R_2NH}$$

$$AQBr + O_2 \qquad \text{Amination}$$

etc.

It seems very difficult to deduce the mechanism of the photo-amination reaction of bromamine acid from only the above experimental results. A detailed kinetic study of the reaction will be reported in the near future.

6) In the study of the photo-reduction of 2-piperidinoanthraquinone, Phllips and his co-workers reported that, in a high concentration of the hydroxyl ion, the electron transfer from the hydroxyl ion to the excited 2-piperidinoanthraquinone can take place. (G. O. Phillips, A. K. Davies, and J. F. McKeller, *J. Chem. Soc.*, D, **1970**, 519).

(Received September 27, 1972)

5-Chloro-, bromo-, iodo-, *N*-ethylamino-, and *N,N'*-diethylamino-1-[(2'-dihydrogenphosphato)-ethyl]-uracil were synthesized from 1-(2'-hydroxyethyl)-uracil through the combination of halogenation, phosphorylation, and subsequent amination. These compounds were coupled with poly(vinyl alcohol) using *N,N'*-dicyclohexylcarbodiimide as a dehydrating agent to give polymers having 5-substituted uracils as pending groups.

In previous papers we have reported on the syntheses of oligonucleotide analogues from *N*-(2'-hydroxy-3'-dihydrogenphosphato)-propyl derivative of nucleic-acid bases.[1,2] These oligomers were very soluble in water and showed significant hypochromic effect, a typical spectroscopic behavior of natural polynucleotides. As another polymer we prepared poly(vinyl alcohol) having nucleic-acid bases as pending groups by the condensation of *N*-(2'-hydroxyethyl) derivatives of nucleic-acid bases with poly(vinyl al-

1) T. Seita, K. Yamauchi, M. Kinoshita, and M. Imoto, This Bulletin, **45**, 926 (1972).

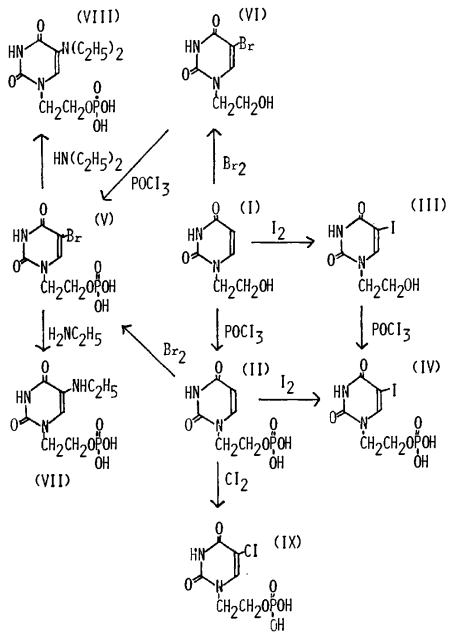
cohol). The polymers obtained were also hygroscopic and very soluble in water and showed the same hypochromic effect.[3] The excellent solubility makes it possible to use these polymers for biological systems as polymeric drugs. A most interesting utilization might be found in the incorporation of 5-halo-uracils, especially the important anti-cancer material 5-fluoro-uracil, into polymers.

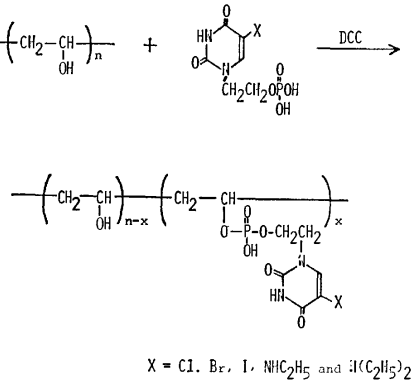
This paper deals with the syntheses of 5-substituted 1-[(2′-dihydrogenphosphato)-ethyl]-uracils and their coupling with poly(vinyl alcohol).

1-(2′-Hydroxyethyl)-uracil (I) was readily converted into 1-(2′-hydroxyethyl)-5-iodouracil (III) in good yield by refluxing with iodine in 1,4-dioxane and 0.5 M nitric acid. Reaction of compound (III) with phosphorus oxychloride in trimethyl phosphate and subsequent hydrolysis gave 1-[(2′-dihydrogenphosphato)-ethyl]-5-iodouracil (IV). Compound (IV) was also obtained by refluxing 1-[(2′-dihydrogenphosphato)ethyl]-uracil (II) with iodine in 1,4-dioxane and 0.5 M nitric acid. Bromination of (I) was carried out using the system bromine, carbon tetrachloride and 0.5 M nitric acid at room temperature. 1-[(2′-Dihydrogenphosphato)-ethyl]-5-bromouracil (V) was easily prepared by both the reactions a) of 1-(2′-hydroxyethyl)-5-bromouracil with phosphorus oxychloride and b) of the compound (II) with bromine. *N*-Ethylamino and *N,N*-diethylamino groups were introduced into uracil by the reaction of compound (V) with ethylamine and diethylamine, respectively. These reaction paths are shown in Scheme 1.



Scheme 1

As shown in Scheme 2, the condensation reaction of 5-substituted-1-[(2′-dihydrogenphosphato)-ethyl]-uracils with poly(vinyl alcohol) was carried out using *N,N′*-dicyclohexylcarbodiimide (DCC) as a dehydrating agent in refluxing dimethylformamide (DMF)-water mixture (9 : 1).



Scheme 2

The results of incorporation are given in Table 1. Nitrogen analysis showed that about half of the original hydroxy groups of poly(vinyl alcohol) was occupied by the uracil derivatives. The white powdery polymers obtained were very soluble in water and showed typical infrared absorptions at 1300—1000 cm^{-1} due to phosphoric ester. Ultraviolet absorptions were identical with those of the starting uracil derivatives.

Table 1. Condensation of 5-Substituted-1-[(2′-dihydrogenphosphato)-ethyl]-uracil (5-X-1-MOU) with PVA

Experimental

The melting points are uncorrected. The infrared (IR) spectra were obtained on a JASCO Model IR-G Spectrometer. The ultraviolet (UV) spectra were measured with a Hitachi Recording Spectrometer Model EPS-3T. Paper chromatography was carried out by the ascending technique using Toyo Roshi No 50 paper. Solvents for chromatography were a mixture of *n*-propanol, concd NH_4OH and water (6 : 2 : 2) (solvent A), and a mixture of concd NH_4OH, ethanol and water (10 : 15 : 2) (solvent B).

Poly(vinyl alcohol) used as stem polymer had a degree of polymerization of 300.

1-(2′-Hydroxyethyl)-5-iodouracil (III). Iodine 2.58 g (20 mmol) was added to a solution of 1-(2′-hydroxyethyl)-uracil (I) 1.7 g (10.9 mmol) in 0.5 M nitric acid (12 ml) and 1,4-dioxane (48 ml). The solution was heated at 100 °C for 4 hr. After the reaction mixture was allowed to cool to room temperature, the solvents were evaporated under reduced pressure. The residue was recrystallized from ethanol to give colorless prism crystals. Yield 85%; mp 197—200 °C; R_f of tlc 0.88 (solvent B); $\lambda_{max}^{H_2O}$, 217 mμ (ε=10440), 290 mμ (ε=8156); IR, 3350 (s), 1710(s), 1670(s), 1450(m), 1440(w), 1350(s), 1250(m), 1130(w), 1050(m),

1010(s), 900(w), 600(s) cm^{-1}; Found: C, 25.54; H, 2.51; N, 9.89%. Calcd for $C_6H_7O_3N_2I$: C, 25.58; H, 2.44; N, 9.93%.

1-(2'-Hydroxyethyl)-5-bromouracil (VI). Bromine 1.2 g (15 mmol) dissolved in 8 ml of carbon tetrachloride was added to a solution of (I) 1.5 g (9.6 mmol) in a mixture of 0.5 M nitric acid (8 ml) and 1,4-dioxane (32 ml), and the solution was stirred at room temperature for 5 hr. The solvent were evaporated to dryness under reduced pressure. The residue was recrystallized from ethanol to give colorless needle crystals. Yield 87%; mp 209—211 °C; R_f of tlc 0.86 (solvent B); $\lambda_{max}^{H_2O}$, 212 mμ (ε=9251), 281 mμ (ε=8980); IR, 3350(s), 1710(s), 1670(s), 1450(m), 1340(s), 1230(w), 1050(s), 930(m), 880(w), 860(m), 750(s) cm^{-1}; Found: C, 30.51; H, 3.04; N, 11.81%. Calcd for $C_6H_7O_3N_2Br$: C, 30.64; H, 3.01; N, 11.92%.

1-[2'-Dihydrogenphosphato)-ethyl]-5-iodouracil (IV). a) 2.4 g of iodine (18.9 mmol) was added to a solution of 1.2 g of 1-[2'-dihydrogenphosphato)-ethyl]-uracil (II) (5.09 mmol) in 0.5 M nitric acid (10 ml) and 1,4-dioxane (40 ml). The procedure was similar to that for (III). Colorless powdery crystals were obtained by recrystallization from a minimal amount of absolute ethanol. Yield 69%.

b) 0.46 g of phosphorus oxychloride (3 mmol) was added at 0 °C to a suspension of 0.7 g of (III) (2.48 mmol) in trimethyl phosphate (7 ml). After stirring for 6 hr, water (3 ml) was added and stirring was continued for 1 hr. The water added was removed under reduced pressure below 50 °C, and the residue was poured into ethanol–ether mixture. The white precipitate was recrystallized from a minimal amount of absolute ethanol to give colorless powdery crystals. mp 216—217 °C; R_f of paper chromatography 0.25 (solvent A); $\lambda_{max}^{H_2O}$, 217 mμ (ε=10655), 290 mμ (ε=8196); IR, 3000(s), 1700(s), 1650(s), 1470(m), 1430(w), 1240(m), 1060(w), 1040(s), 980(s), 850(w), 660(w), 620(m) cm^{-1}; Found: C, 20.31; H, 2.21, N, 8.18%. Calcd for $C_6H_9N_2O_6PI$: C, 19.90; H, 2.23; N, 7.74%.

1-[(2'-Dihydrogenphosphato)-ethyl]-5-bromouracil (V). a) 0.5 g of (II) (2.1 mmol) was dissolved in a hot mixture of 0.5 M nitric acid (4 ml) and 1.4-dioxane (16 ml). A solution of 0.48 g of bromine (6 mmol) in carbon tetrachloride (4 ml) was added to the above solution at room temperature. After being kept at room temperature overnight, the solvents were evaporated under reduced pressure. The residue was recrystallized from ethanol–ether mixture to give colorless needle crystals. Yield 68%.

b) 0.4 g of phosphorus oxychloride (3 mmol) was added to a suspension of 0.5 g of (VI) (2.13 mmol) in trimethyl phosphate (5 ml) and treated as the synthesis of (IV)-b). Colorless needle crystals were obtained by recrystallization from ether–ethanol mixture. mp 236—237 °C; R_f of paper chromatography 0.33 (solvent A); $\lambda_{max}^{H_2O}$, 212 mμ (ε=8414), 281 mμ (ε=8090); IR, 3000(s), 1700(s), 1650(s), 1470(m), 1430(w), 1350(w), 1040(s), 980(s), 650(w), 620(m), 530(m) cm^{-1}; Found: C, 23.39; H, 2.49; N, 9.28%. Calcd for $C_6H_9N_2O_6PBr$: C, 22.88; H, 2.56; N, 8.89%.

1-[(1'-Dihydrogenphosphato)-ethyl]-5-chlorouracil (IX). 5.35 g of chlorine (7.5 mmol) dissolved in carbon tetrachloride (10 ml) was added to a solution of 1.0 g of (II) (4.2 mmol) in acetic acid (60 ml) and the solution was kept at room temperature for 1 hr. The solution was then concentrated to half the volume and refluxed for 30 min. The solvents were evaporated to dryness under reduced pressure. The residue was recrystallized from the ether–ethanol mixture to give colorless crystals. Yield 90%, mp 212—214 °C, $\lambda_{max}^{H_2O}$, 213 mμ (ε=12000), 280 mμ (ε=9800); IR, 3050(m), 1690(s), 1640(s), 1460(m), 1420(m), 1060(w), 1030(s), 980(m), 660(w), 520(m) cm^{-1}; Found: C, 26.19; H, 2.89; N, 9.92; Cl, 12.34%. Calcd for $C_6H_8N_2O_6PCl$: C, 26.64; H, 2.98; N, 10.35; Cl, 13.10%.

1-[(2'-Dihydrogenphosphato)-ethyl]-5-(N-ethylamino)-uracil (VII). A solution of 0.35 g of (V) (1.0 mmol) in 50% ethylamine (10 ml) was stirred for 24 hr at room temperature. The reaction mixture was evaporated to dryness under reduced pressure. Colorless plate crystals were obtained by recrystallization from ethanol–water mixture. Yield 58%, mp 214—216 °C, R_f of paper chromatography 0.27 (solvent A), $\lambda_{max}^{H_2O}$, 212 mμ (ε=7090), 281 mμ (ε=6986): IR 3150(s), 1710(s), 1610(m), 1440(s), 1380(w), 1340(s), 1240(m), 1010 (s), 780(m), 640(w) cm^{-1}; Found: C, 27.84; H, 5.48; N, 16.07%. Calcd for $C_8H_{14}N_3O_6P$: C, 28.25; H, 5.53; N, 16.47%.

1-[(2'-Dihydrogenphosphato)-ethyl]-5-(N,N-diethylamino)-uracil (VIII). A solution of 0.35 g of (V) (1.0 mmol) in 50% diethylamine (12 ml) was refluxed for 5 hr and then treated as in the synthesis of (VI). Yield 53%, mp 235—236 °C, R_f of paper chromatography 0.22 (solvent A), $\lambda_{max}^{H_2O}$, 212 mμ (ε=9064), 281 mμ (ε=8953); IR, 2540(s), 1680(s), 1610(m), 1500(w), 1420(m), 1340(s), 1230(s), 1150(m), 1030(s), 890(s), 640(w) cm^{-1}; Found: C, 38.51; H, 5.79; N, 13.24%. Calcd for $C_{10}H_{18}N_3O_6P$: C, 39.10; H, 5.90; N, 13.68%.

Condensation of 5-Substituted 1-[(2'-Dihydrogenphosphato)-ethyl]-uracils with Poly(vinyl alcohol). 5-Substituted 1-[(2'-dihydrogenphosphato)-ethyl]-uracil (7.7 mmol) and PVA (0.22 g) were dissolved in boiling water. To the solution was added DMF (12 ml) and the water was then evaporated to substitute the solvent for DMF. DDC (30 g) was added to the DMF solution and the mixture was refluxed for 25—25 hr. After cooling the reaction mixture was poured into a large amount of water and allowed to stand at room temperature overnight. The mixture was filtered and the filtrate was evaporated under reduced pressure to obtain a white polymer as residue. The polymer obtained was purified by column chromatography with Sephadex G-25 eluted with water.

N-Halogen Compounds of Cyanamide Derivatives. I[1] Rearrangement of *N*-Alkylhaloamidines

Toshio FUCHIGAMI, Eiichi ICHIKAWA, and Keijiro ODO

Faculty of Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received October 13, 1972)

The reactions of *N*-chloroamidines with various dehydrochlorinating reagents were studied. *N*-Alkyl-*N'*-chloroamidines were treated with sodium alkoxide, sodium hydroxide, and silver oxide to form *O*-alkylisoureas, ureas, and carbodiimides, respectively. However, *N*-chloro-*N'*,*N'*-dialkylamidines did not afford corresponding products. The mechanisms for the rearrangements are discussed.

N-Haloamidines are unique in reactivity and useful as transient intermediates. A few reports on *N*-haloamidines have appeared, among which the synthesis of thiadiazoles by Goerdeler[2] and that of benzimidazoles by Grenda[3] are notable. However, no systematic examination of *N*-haloamidines has been made.

The present investigation was undertaken to prepare *N*-alkyl-*N'*-chlorobenzamidines and study their reactivity. We have attempted to prepare various *N*-chloroamidines and to reveal their chemical behavior with various kinds of dehydrochlorinating reagents and the relationship between their structure and reactivity.

Results and Discussion

Preparation of Amidines. *N*-Methyl-*N'*-phenylbenzamidine[4] was prepared from *N*-phenylbenzimidoylchloride and methylamine. The other amidine hydrochlorides were prepared from the corresponding iminoethers and amines by Pinner's method.[5]

Chlorination of Amidines. *N*-Chloroamidines were prepared from amidine hydrochlorides and sodium hypochlorite in water at −5—5 °C. Most of the *N*-chloroamidines were solids with low melting points, their active chlorine contents determined iodometrically being in good agreement with the corresponding calculated values. No effects of substituents were observed on the yield in chlorination except for *N*,*N*-pentamethylenebenzamidine.

Structure of N-*Alkyl*-N'-*chloroamidines.* The most possible structure of *N*-chloroamidine is (**K**) in consideration of the kinetic study of *N*-chlorination,[6] NMR spectra of *N*-haloamidines[7] and substitution reactions with thiocyanate or cyanide ion.[2,8]

$$\mathrm{R{-}\overset{\overset{\mathrm{NCl}}{\|}}{C}{-}NHR'} \qquad (\mathbf{K})$$

Reaction of N-*Chloroamidines with Alkaline Reagents. Reaction of* N-*Chloroamidines with Sodium Alkoxides*: Methoxide was mainly employed but other alkoxides such as ethoxide, isopropoxide, and *t*-butoxide were also tested in certain cases.

When *N*-alkylhaloamidine (**2**∼**5**) was treated with sodium alkoxide in alcohol at 60 °C (under reflux in case of sodium methoxide in methanol), an oily material was obtained. A larger part of the material was identified as a mixture of *N*-alkyl-*N'*-phenyl-*O*-alkylisourea (**A1**∼**7**) (main product) and benzoate (**B**). Products (**A6,7**) were isolated as their picrates but the others (**A1**∼**5**) were identified by means of preparative gas chromatography since they coud not be separated by distillation *in vacuo*. The yields of **A** and **B** were determined using glc. **5** gave a small amount of a by-product, cyaphenine (**C**).

An active chlorine did not disappear even when **7** was treated with such a strong base as sodium *t*-butoxide. The Neber rearrangement[9] was expected in the treatment of **10** which has an α-methylene group with sodium *t*-butoxide, but no product due to such a rearrangement was formed.

Structures of new compound (**A1**∼**7**) were established by the following examinations.

a) Acid hydrolysis: **A1**∼**7** were converted into the corresponding ureas.

b) Elemental analysis of their free bases or picrates.

c) Comparison of the IR spectra and glc retention times with those of authentic samples prepared by the reactions of carbodiimides and alcohols.

The boiling points of authentic samples (**A1**∼**5**) are shown in Table 4.

Reaction of N-*Chloroamidines with Sodium Hydroxide in a* 50% *Aqueous Methanolic Solution*: An aqueous solution of amidine hydrochloride was treated with sodium hypochlorite to form *N*-chloroamidine, which was refluxed with sodium hydroxide in aqueous methanol, yielding colorless crystalline solid and an oily material. The former was identified as *N*-alkyl-*N'*-arylurea (**D**) by comparison of its melting point and IR spectrum with those of the authentic sample. A larger part of the latter was identified as *N*-alkyl-*N'*-phenyl-*O*-alkylisourea (**A**) on the basis of IR spectrum and glc retention time.

In an aqueous methanolic solution, most *N*-chloroamidines gave **A**, while in the absence of methanol, they afforded **D** instead.

1 gave no **D** but sodium phenyl cyanamide (**F**), which was converted further into phenylurea by acid hydrolysis.

In the case of *N*,*N*-disubstituted amidines (**7**—**10**), no rearrangement took place and the products of hydrolysis (**E**) were obtained.

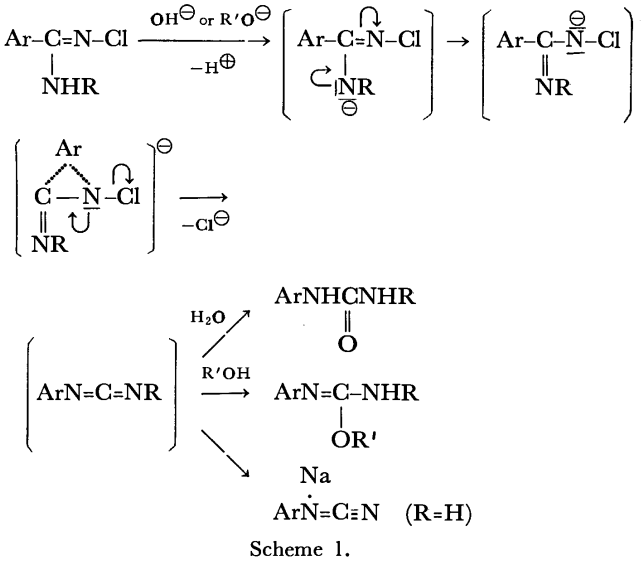
a) The structure has not been established yet. The same product can be obtained from alkaline hydrolysis of *N*-methyl-*N'*-phenylbenzamidine.

Mechanisms of Rearrangement. The basicity of alkoxide ions was found to have large effects on the rates of dehydrochlorination. The reactivity of alkoxide ions was found to be in the order *iso*-$PrO^{\ominus}$> $EtO^{\ominus}$> $MeO^{\ominus}$.

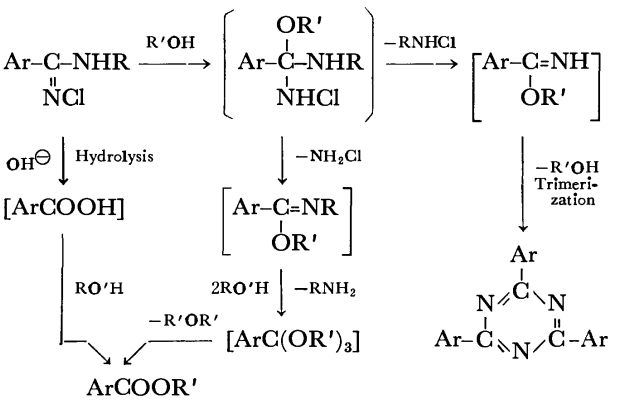
In the reactions of *N*-chloroamidines having no hydrogen on the nitrogen atom with sodium alkoxide in alcohol or sodium hydroxide in an aqueous alcohol, the active chlorine did not disappear and no rearrangement took place. (Tables 3 and 6).

This rearrangement may be initiated by removal of a proton from the NH group with an alkoxide ion or hydroxide ion. The loss of a chloride ion from the resulting anion and the migration of the aryl group to a nitrogen atom probably take place simultaneously to form a carbodiimide as an intermediate. The carbodiimide thus produced may react with water or alcohol to give urea or *O*-alkylisourea (Scheme 1), and by-products esters of benzoic acid and cyaphenine may be formed (Scheme 2).

Reaction of N-*Chloroamidines with Silver Oxide.* *N*-Alkyl-*N'*-chloroamidines were mixed with silver oxide in ligroin and then refluxed. This gave rise to rearrangement, giving carbodiimides (**G**). Their infrared spectra showed a characteristic carbodiimide absorption at 2150 cm^{-1} and agreed completely with those of authentic samples. When these carbodiimides were refluxed in dilute hydrochloric acid, the corresponding ureas were obtained.



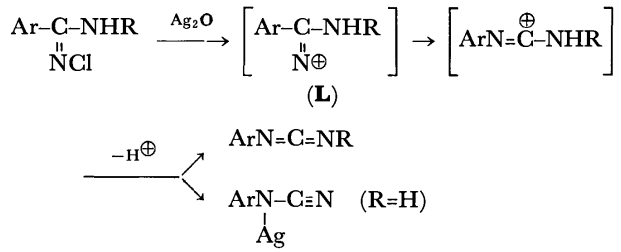
Scheme 1.



Scheme 2.

N-Methyl-*N'*-chloroamidine (**2**) gave no carbodiimide at all, but *N*-chlorobenzamidine (**1**) gave silver phenylcyanamide, which was converted into phenylurea by acid hydrolysis.

The rearrangement may proceed via a nitrenium cation (**L**) to form carbodiimide or cyanamide. The same mechanism was suggested by Haruki *et al.*[13]



Scheme 3.

Experimental

Amidines. *N*-Methyl-*N'*-phenylbenzamidine was prepared from *N*-phenylbenzimidoyl chloride in ethereal solution and aqueous methylamine.[4] The other amidine hydrochlorides were prepared from the corresponding iminoethers and amines in water or ethanol by Pinner's method.[5]

N-*Chloroamidines.* As a typical experiment the preparation of *N*-chloro-*N'*-methylbenzamidine (**2**) is given. To a stirred solution of *N*-methylbenzamidine hydrochloride[14] (3.14 g, 0.02 mol) in water–ether (20 ml–40 ml) was gradually added 0.024 mol of sodium hypochlorite, the temperature being kept below 5 °C. After about 5 min of continued stirring, the ether layer was separated and residual *N*-chloroamidine was extracted twice with 10 ml portions of ether. The combined ether extracts were dried (Na_2SO_4) for 2 hr, filtered, and evaporated under reduced pressure at room temperature. The yield of **2** was 3.06 g (91%), mp 69 °C. Recrystallization from ether–petroleum ether gave a pure product, mp 69.5—70 °C.

The other *N*-chloroamidines were prepared as above.

Reaction of N-*Chloroamidines with Sodium Alkoxide.* *Reaction of* ***5*** *with Sodium Methoxide in Methanol*: To a stirred so-

lution of sodium methoxide prepared from sodium (0.28 g, 0.012 mol) and 25 ml of absolute methanol was added 2.45 g of *N*-benzyl-*N'*-chlorobenzamidine (**5**).

The mixture was then refluxed for 2.5 hr when sodium chloride precipitated. The solvent was removed by distillation under reduced pressure and the residue was mixed with water (10 ml). The upper oily layer was extracted once with a 20 ml portion and twice with 10 ml portions of ether. After the combined ethereal extracts were dried (Na_2SO_4), filtered and concentrated under reduced pressure, colorless needle crystals of 2,4,6-triphenyl-*s*-triazine (**C**) and a yellowish oily material were obtained. **C** was separated by filtration and recrystallized from benzene, mp 230—235 °C. The yield was 0.04 g (1%). (Found: C, 81.53; H, 4.89; N, 13.58%. Calcd for $C_{21}H_{15}N_3$: C, 81.53; H, 4.85; N, 13.58%).

To an ethereal solution of the filtrate containing a yellowish oily material was added a saturated ethereal solution of picric acid. The picrate of *N*-benzyl-*N'*-phenyl-*O*-methylisourea (**A6**) precipitated was collected by filtration and recrystallized from methanol, mp 148—149 °C. The yield was 33%.

A small part of the above filtrate was subjected to glc analysis and methyl benzoate was detected.

Reaction of **2** *with Sodium Ethoxide in Ethanol*: A mixture of **2** (4.22 g, 0.025 mol) and sodium ethoxide prepared from sodium (0.69 g, 0.03 g atom) and 25 ml of absolute ethanol was stirred at 60 °C for 0.7 hr. After working up the mixture as described above, the oily material was distilled under reduced pressure to give a fraction, bp 80—88 °C/3—40 mmHg (2.86 g). The fraction was subjected to glc analysis. *N*-Methyl-*N'*-phenyl-*O*-ethylisourea (**A2**) and ethyl benzoate were isolated by preparative gas chromatography (Silicone H. V.).

The authentic sample of **A2** was prepared according to the method of Forman *et al.*[14]

Reactions with the other *N*-chloroamidines were carried out similarly. The products are given in Table 3.

Reaction of N-*Chloroamidines with Sodium Hydroxide. Reaction of* **2** *with Sodium Hydroxide in 50% Aqueous Methanol*: To a stirred solution of *N*-methylbenzamidine hydrochloride (1.71 g, 0.01 mol) in 12 ml of water was added sodium hypochlorite (0.012 mol) at −5—5 °C to yield a suspension of the intermediate *N*-chloro compound (**2**). After about 5 min of stirring, an aqueous methanolic solution (water-methanol, 5 ml—25 ml) of sodium hydroxide (0.48 g, 0.012 mol) was added and the mixture was refluxed for 2.5 hr. When the reaction mixture was evaporated under reduced pressure and methanol was almost removed, crystals precipitated and were washed with ether to yield *N*-methyl-*N'*-phenylurea, mp 149 °C (0.34 g, 23%). Recrystallization from aqueous methanol gave a pure product, which showed no depression of its melting point (149—150 °C) upon a mixed-melting-point determination with an authentic sample. The washings and ethereal extracts from the reaction mixture were combined, dried (Na_2SO_4) and filtered. **A1** was detected by glc.

Reaction of **2** *with Sodium Hydroxide in 50% Aqueous Dioxane*: **2** obtained from *N*-methylbenzamidine hydrochloride (1.71 g, 0.01 mol) according to the same procedure as above was refluxed in 50% aqueous dioxane (50 ml) for 10 hr. When the reaction mixture was evaporated under reduced pressure and dioxane was almost removed, crystals precipitated. *N*-methyl-*N'*-phenylurea, mp 149 °C (0.36 g, 24%).

Reaction of **3** *with Sodium Hydroxide in* 50% *Aqueous Methanol*: Yellowish oily material was similarly obtained from *N*-chloro-*N'*-ethylbenzamidine (**3**) (0.01 mol). The yields of *N*-ethyl-*N'*-phenyl-*O*-methylisourea (**A4**, 35%) and methyl benzoate (7%) were determined using glc.

Reaction of **1** *with Sodium Hydroxide in 50% Aqueous Methanol*: **1** similarly obtained from benzamidine hydrochloride (3.85 g, 0.02 mol) was refluxed for 10 hr. When methanol was almost removed by evaporation under reduced pressure from reaction mixture, colorless leaflets (benzamide, 2.12 g, 65%) precipitated and were separated by filtration. The filtrate was evaporated and the residue extracted with hot ethanol (29 ml). The extract was concentrated to give the residual solid (sodium phenylcyanamide, **F**). Its infrared spectrum showed characteristic absorption of the cyano group at 2200 cm^{-1}. The residue was refluxed in 2 N hydrochloric acid (6 ml) for 40 min. After cooling and addition of aqueous sodium hydroxide solution to make the reaction mixture neutral, phenylurea was separated. (0.24 g, 9%, mp 146—148 °C).

The other *N*-chloroamidines were treated with sodium hydroxide by a similar method.

Reaction of N-*Chloroamidines with Silver Oxide. Reaction of* **4** *with Silver Oxide*: A suspension of **4** (11.80 g, 0.06 mol) and silver oxide (30 g, 0.13 mol) in anhydrous ligroin (60 ml) was heated under reflux for 0.3 hr. The insoluble matter was separated by filtration and the filtrate was distilled under reduced pressure to give a fraction with a bp of 75—80 °C/2 mmHg (3.37 g, 35%), which was identified

14) S. E. Forman, C. A. Erickson, and H. Adelman, *J. Org. Chem.*, **28**, 2653 (1963).

as *N*-isopropyl-*N'*-phenylcarbodiimide by comparison of its infrared spectrum with that of an authentic sample prepared by the treatment of *N*-isopropyl-*N'*-phenylthiourea with HgO. The distillate was refluxed in 1 N hydrochloric acid for 0.25 hr. After cooling and addition of aqueous sodium hydroxide solution to make the reaction mixture neutral, solid *N*-isopropyl-*N'*-phenylurea was obtained.

Reaction of ***1*** *with Silver Oxide*: A suspension of **1** (3.09 g, 0.02 mol) and silver oxide (10 g, 0.043 mol) in anhydrous ligroin (50 ml) was refluxed for 2 hr. The insoluble matter separated by filtration showed characteristic absorption of the cyano group at 2200 cm^{-1} in its infrared spectrum. The solid refluxed in 6 N hydrochloric acid and the insoluble matter was separated by filtration. After cooling, colorless plates were precipitated, which were identified as phenylurea, mp 147 °C, 0.26 g, 10%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1770—1772 (1973)

Studies of Azo Colors. XI.[1] The Diazo-coupling Reaction of Pyrroles

Kazuo MITSUMURA, Yōji HASHIDA, Shizen SEKIGUCHI, and Kohji MATSUI

Department of Synthetic Chemistry, Faculty of Engineering, Gunma University, Tenjincho, Kiryu, Gunma 376

(Received October 18, 1972)

Kinetic studies have been made of the coupling reaction of several diazonium salts with pyrrole, *N*-methylpyrrole, and *N*-ethoxycarbonylpyrrole. In the case of pyrrole, it was found, from the dependence of the apparent rate constant on the pH values, that the undissociated pyrrole reacted with diazonium salts in the pH range from 4.7 to 8.2, whereas in the pH region higher than 10.0 the reactive species was the conjugate base of pyrrole. The reactivity of the pyrrole anion was higher by a factor of 8 powers of ten than that of the undissociated pyrrole. The effects of the substituents of diazonium salts on the reaction rates were also investigated. The ρ-values (4.3—4.6) obtained in the Hammett plots were practically the same as those of diazo-coupling reactions which involve ordinary aromatic amines as coupling components.

Normally, diazo-coupling reactions take place between diazonium salts and substituted aromatic hydrocarbons, especially phenols and aromatic amines. The mechanisms and the structural effects of these reactions have been studied kinetically.[2]

Heterocyclic compounds, such as pyrrole,[3,4] indole,[5] imidazole,[6] and indazole,[7] have also long been known to react with diazonium salts to form azo compounds. Although the kinetic studies of some of these reactions have been carried out,[8,9] no detailed information on their mechanism and reactivity has yet been reported. In this paper, we wish to report the kinetics of the reactions of pyrroles with diazonium salts.

Results and Discussion

Brown and his co-workers[8] investigated the kinetics of the reaction of imidazole with diazonium salts. They found that the reaction of the diazonium ion with the imidazole anion formed by the ionization of the N–H bond was the rate-determining step. On the other hand, in the reaction of indole with diazonium salts, Binks and his co-worker[9] suggested that the undissociated indole was the reactive species.

Pyrrole is known to react with a diazonium salt, preferentially at the 2-position in a neutral solution, to form a monoazo compound, and to form a 2,5-bisazo compound in an alkaline solution.[3] However, it was confirmed by thin-layer chromatography that only a monoazo compound was obtained under our kinetic conditions, as will be described below.

Kinetic experiments have been carried out on the reactions of diazonium salts with 50 to 100 as many pyrroles in an aqueous buffer solution; the apparent rate constants (k') were calculated from Eq. (1), where E_t and E_∞ are the optical densities of the azo-compound at time t and at infinity respectively.

$$k't = \ln \frac{E_\infty}{E_\infty - E_t} \quad (1)$$

In each kinetic run, an increase in the optical density of the azo-compound obeyed good pseudo-first-order kinetics. The reactions also showed a first-order dependence on the concentration of pyrrole. The dependences of the rate constants (k') on the pH values are listed in Tables 1, 2, and 3. In the pH range treated in Tables 1, 2, and 3, the diazonium salts are considered to exist practically as diazonium ions.[10] In the case of pyrrole, it has become apparent that the rate constant increases with increases in the pH values in the alkaline region. For example, in the reaction of pyrrole with *p*-methoxybenzenediazonium salt (Table 1) or benzenediazonium salt (Table 2), the reaction rate is independent of the pH values in

k' (min^{-1})	0.0672	0.118	0.172	0.201	0.532	0.861	1.33	3.48
k_2 ($l\,mol^{-1}\,min^{-1}$)	1.68×10^{1}	—	—	—	—	3.49×10^{9} (2.47×10^{-10}) a)	3.33×10^{9} (4.00×10^{-10})	3.55×10^{9} (9.84×10^{-10})

a) Values in parentheses are the concentration of pyrrole anion under experimental conditions.

Table 2. Dependence of the rate constant (k') for the reaction of pyrrole with benzenediazonium salt on pH at 20°C (Pyrrole 4×10^{-3} mol/l; Diazonium salt 4×10^{-5} mol/l)

pH	5.01	6.31	7.11	8.21	9.27	10.30
k' (min^{-1})	1.32	1.48	1.63	1.80	3.51	20.8

Table 3. Dependence of the rate constant (k') for the reaction of *N*-methylpyrrole with *p*-methylbenzenediazonium salt on pH at 20°C (Pyrrole 4×10^{-3} mol/l; Diazonium salt 4×10^{-5} mol/l)

pH	5.10	5.79	6.30	6.30	8.13	10.13
k' (min^{-1})	0.741	0.778	0.944	0.970	1.04	1.26

the pH range from 4.7 to 8.2; there is a slight dependence of k' on the pH values in the same range, which will be discussed later. However, the rate constant increased considerably when the pH value rose above 9.0.

The pK_a values of the pyrrole cation and pyrrole have been known to be 0.4[11] and 17.55[12] respectively. Therefore, pyrrole does not substantially dissociate in the pH range from 4.7 to 8.2. Thus, the fact that the reaction rate is independent of the pH may be explained by assuming that the undissociated pyrrole reacts with the diazonium salts (Eq. 2):

$$pH < 8.2 \qquad v = k_2(Ar\text{-}\overset{+}{N}_2)\left(\text{C}_4\text{H}_4\text{NH}\right) \qquad (2)$$

On the other hand, the reactive species is likely to be the pyrrole anion in an alkaline solution (Eq. 3), because the slope of the line between the log k' and pH values is close to unity in the pH region above pH 10.0. Furthermore, the observation that the reaction rates of *N*-methylpyrrole are essentially independent of the pH values, even in the alkaline region, supports the view mentioned above.

$$pH > 10.0 \qquad v = k_2(Ar\text{-}\overset{+}{N}_2)\left(\text{C}_4\text{H}_4\text{N}^-\right) \qquad (3)$$

Therefore, the second-order rate constants (k_2) were obtained according to Eq. (2) or (3) by dividing the first-order rate constants (k') by the undissociated pyrrole concentration or by the pyrrole anion concentration respectively. The results for the reaction of pyrrole with *p*-methoxybenzenediazonium salt are given in Table 1.

Table 4. Base catalyses in the reactions of substituted benzenediazonium salt with pyrroles at 20°C (Pyrrole 4×10^{-3}; Diazonium salt 4×10^{-5})

Pyrroles	Substituents	pH	Pyridine concn. (mol/l)	k' (min^{-1})
Pyrrole	*p*-OCH_3	6.3	0.0	0.0570
			0.1	0.0672
			0.2	0.0749
			0.4	0.0890
			0.6	0.104
Pyrrole	H	10.6	0.0	1.48
			0.1	1.72
			0.2	1.78
			0.4	2.00
			0.6	2.16
N-Methylpyrrole	*p*-CH_3	6.3	0.0	0.944
			0.1	1.03
			0.2	1.13
			0.4	1.30
			0.6	1.49

As can be seen from Table 1, the second-order rate constants (k_2) thus obtained are independent of the pH values of the medium, even in the alkaline region, suggesting that the application of Eq. (3) is reasonable. The pyrrole anion reacted faster by a factor of some 8 powers of ten than the undissociated pyrrole. The difference between the reactivities of these two species is similar to that observed between the reactivities of the naphthol and the naphtholate ion.[13] The reactivity of the pyrrole anion is greater by a factor of 5 orders than that of the naphtholate ion.[1]

It has been well known that some diazo-coupling reactions are accelerated by a base such as pyridine,[2] which acts as a proton acceptor from the intermediate of the substitution reaction. In order to confirm the base catalysis in the present study, the rate constants in the presence of the base (pyridine) have been measured. The results are given in Table 4. From these results, it can be seen that the reactions of pyrrole (pH 6.3), the pyrrole anion (pH 10.6), and *N*-methyl-

Table 5. Rate constants (k_2) for the reactions of pyrroles with substituted benzenediazonium salt at pH 6.3 (20°C)

Pyrrole	Substituent	k_2 ($l\,mol^{-1}\,min^{-1}$)
Pyrrole	*p*-OCH_3	1.43×10^1
	p-CH_3	6.65×10^1
	m-CH_3	1.77×10^2
	H	3.70×10^2
	m-OCH	8.85×10^2
N-Methylpyrrole	*p*-OCH_3	5.08×10^1
	p-CH_3	2.36×10^2
	m-CH_3	5.85×10^2
	H	1.03×10^3
	m-OCH_3	2.46×10^3
N-ethoxycarbonylpyrrole	*p*-CH_3	4.79
	m-CH_3	1.61×10^1
	H	2.92×10^1
	m-OCH_3	9.15×10^1
	p-Cl	3.58×10^2

pyrrole were slightly catalyzed by the base. As has been described previously, in our experiments the rate measurements were performed in buffer solutions; the buffer reagent may be assumed to act also as a base in these cases. Therefore, the slight dependence of k' on the pH values in the pH range from 4.7 to 8.2 may be ascribed to the difference in the catalytic actions of buffer solutions.

In the cases of pyrrole, *N*-methylpyrrole, and *N*-ethoxycarbonylpyrrole, the influence of substituents in the diazonium salts on the rate constants was also investigated (Table 5). The results may be expressed by the following Hammett equations*[20]:

Pyrrole	$\log k_2 = 4.63\sigma + 2.51$	$r=0.992$
N-Methylpyrrole	$\log k_2 = 4.28\sigma + 2.99$	$r=0.986$
N-Ethoxycarbonylpyrrole	$\log k_2 = 4.64\sigma + 1.48$	$r=0.985$

It can be seen from these results that the influence of the *N*-substituents in pyrrole on the reaction constant is small and that these ρ-values are similar to those in the coupling reactions of diazonium salts with ordinary aromatic amines, such as *N*,*N*-dimethylaniline (ρ; 4.34)[15] and 1-naphthylamine (ρ; 4.94).[15]

Experimental

Materials. The *N*-ethoxycarbonylpyrrole was prepared according to the method of Ciamician[16] from ethyl chloroformate and potassium salt of pyrrole. The commercial pyrrole, *N*-methylpyrrole, and aromatic amines used as diazo components were purified by distillation or by recrystallization prior to use. Their purities were checked by means of their physical constants and by gas-liquid chromatography.

Kinetic Measurements. The procedure was essentially the same as that described in an earlier paper.[17] The kinetic measurements were carried out in aqueous buffer solutions at 20 °C and at a constant ionic strength (0.04). Kinetic measurements in the presence of pyridine were carried out at a constant pH (6.3 or 10.3) according to the procedure of Zollinger *et al.*[8]

Phenanthro[4,5-*bcd*]furan Derivatives. I. A Synthesis of 5-Hydroxy-1-methoxyphenanthro[4,5-*bcd*]furan

Takahachi SHIMIZU, Takaaki HORAGUCHI, and Akio WATANABE

Department of Chemistry, Faculty of Science, Niigata University, Igarashi, Niigata 950–21

(Received October, 11, 1972)

5-Hydroxy-1-methoxyphenanthro[4,5-*bcd*]furan(I;R=MeO) was synthesized by dehydrogenation with 20% palladium on charcoal from 5,6,7,7a,8,9-hexahydro-1-methoxy-5-oxophenanthro[4,5-*bcd*]furan(XVII), which had itself been prepared *via* a naphthofuran derivative (XVI) starting from 5,8-dimethoxy-1-tetralone (VII).

Morphine gives a variety of non-nitrogenous degradation products,[1] including morphenol (I;R=H), which has not yet been synthesized. Burger and Avakian[2] failed to cyclize the acid (II;R=H, n=1) to a phenanthrol derivative (III; R=H); similarly, the acid (II; R=MeO, n=2) was converted to the indenone (IV)[3] rather than to a phenahthro[4,5-*bcd*]-furan. Dendy *et al.*[4] succeeded in cyclizing it with a partially hydroaromatic precursor (V; R=MeO) into the ketone (VI), but the yield was too poor for them to continue the project further. They ascribed these difficulties of cyclization to a strain in the fused-

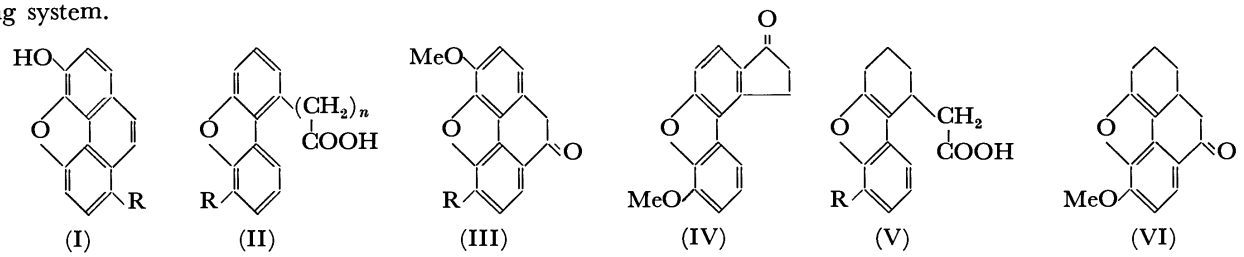
ring system.

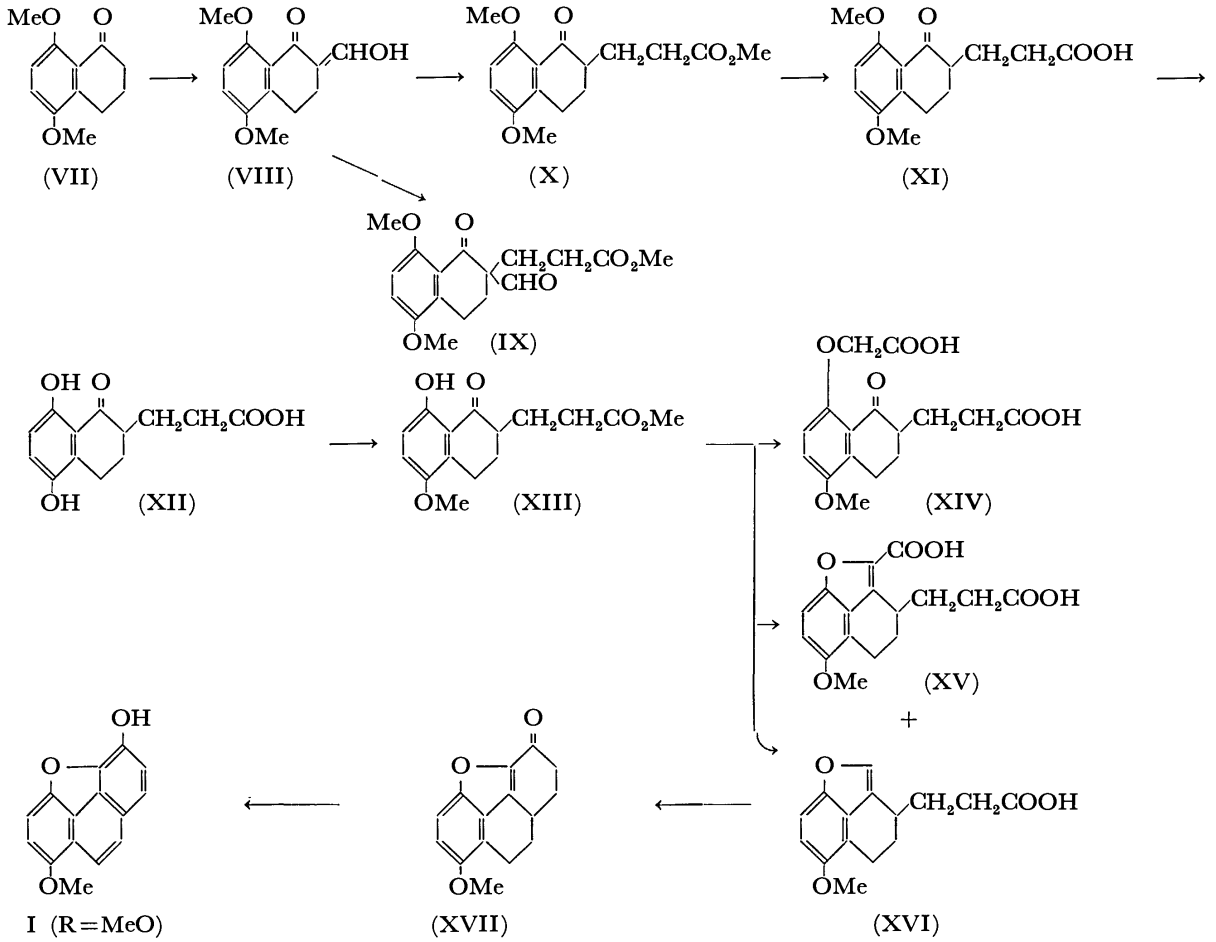


An approach to the synthesis of morphenol, not from a dibenzofuran, but from the naphtho[1,8-*bc*]furan derivative (XVI), was planned. In this paper, the results of a model experiment will be reported, this experiment led to a successful synthesis of a kind of methoxymorphenol, 5-hydroxy-1-methoxyphenanthro-[4,5-*bcd*]furan(I; R=MeO).

Results and Discussion

The naphtho[1,8-*bc*]furan derivative (XVI) was prepared from 5,8-dimethoxy-1-tetralone (VII) *via* a series of intermediate, as is shown in scheme 1.

5,8-Dimethoxy-1-tetralone (VII) was prepared starting from 3-(2,5-dimethoxybenzoyl)propionic acid (*cf.* the Experimental section). VII was formylated[5] to give VIII, with ethyl formate on the methylene group adjacent to the carbonyl group, becasue the methylene was not expected to be active enough to react with methyl acrylate because of the electronic effect of two methoxy groups on the benzene ring.[6] The addition reaction of VIII with methyl acrylate was performed in a refluxing methanol solution containing a small amount of triethylamine; this gave X in a good yield rather than IX. The propionic acid derivative (XI) was prepared from X by saponification. The heating of XI with pyridinium chloride[7] afforded a dihydric phenol derivative (XII). XII showed a absorption due to OH stretching at 3400 cm^{-1} in the infrared absorption spectrum and reacted with ferric chloride.



Scheme 1.

The reaction mixture changed in color from blue to brown in time. The reaction of XII with dimethyl sulfate afforded a good yield of a monohydric phenol, which then reacted with ferric chloride to result in a blue color. In spite of the color reaction, XIII did not manifest any OH stretching absorption in the infrared absorption spectrum above 3000 cm^{-1}; such a phenomenon is, though, often observed for *O*-acyl phenols.[8]

Let us turn now to a consideration of the building of the strained fused-ring; our first effort involved the transformation of XIII into the naphtho[1,8-*bc*]furan derivative (XVI). The reaction of the tetralone (XIII) with a mixture of ethyl bromoacetate and potassium carbonate in acetone at 100 °C, followed by saponification, afforded the dicarboxylic acid (XIV), which was then heated with a mixture of acetic anhydride and sodium acetate in the expectation that the naphthofuran would be formed. However, no evolution of carbon dioxide was observed, indicating no reaction, that these was not even under the above reaction conditions.

In the course of further studies of the formation of a furan ring, a convenient method for the direct synthesis of naphtho[1,8-*bc*]furan from 8-hydroxy-1-tetralone was discovered by accident: the heating of the tetralone in ethyl bromoacetate at 170 °C, followed by saponification, gave two crystalline products, 3-(4,5-dihydro-6-methoxy-3*H*-naphtho[1,8-*bc*]fur-3-yl)propionic acid (XVI) and 3-(2-carboxy-4,5-dihydro-6-methoxy-3*H*-naphtho[1,8-*bc*]fur-3-yl)propionic acid (XV), but XIV was not detected. The structures of XV and XVI were discussed on the basis of their spectral properties and subsequent transformations. The infrared spectrum for XV shows a conjugated-carbonyl band at 1693 cm^{-1} in addition to an unconjugated-carbonyl band at 1710 cm^{-1}. XV was transformed into XVI by heating with a mixture of quinoline and copper. The ultraviolet spectrum of XVI shows λ_{max}^{EtOH} 253 nm (ε 9300) and 292 nm (ε 3600), similar to those of the benzofurans, and the nuclear magnetic resonance absorption spectrum shows a sharp singlet at τ 2.43 which might be ascribed to a methine hydrogen on the furan ring. The acid (XVI), when heated at 90 °C in polyphosphoric acid, was transformed into the expected ketone (XVII) in a good yield; this substance showed an absorption band due to a conjugated-carbonyl group at 1660 cm^{-1} in the infrared absorption spectrum.

For aromatization[9] of XVII to the phenol I (R=MeO), palladium on charcoal was used as the catalyst; the yield was 20%. The resulting phenol decomposes at 187—191 °C and gives an intense blue fluorescence in an alkaline solution, much like morphenol I (R=H). The structure of I (R=MeO) was established on the basis of its spectral properties. The nuclear magnetic absorption spectrum showed the existence of a methoxyl group at τ 5.49 (s), two equivalently-situated hydrogens on the phenanthrene ring at τ 2.13 (s), four hydrogens on the phenanthrene ring at τ 2.23—2.82 (oct), and a hydroxyl group at τ 0.59 (s); moreover, the band at τ 2.23—2.82 (oct) could be explained as an assembly of two kinds of AB-type resonances. The ultraviolet absorption spectrum of I (R=MeO) is very similar to that of morphenol methyl ether.[10] The infrared absorption spectrum of I (R=MeO) posseses bands corresponding to three kinds of two adjacent hydrogens on the phenanthrene ring at 800 and 826 cm^{-1}—one of the three expected absorptions is overlapped with one of the two residual absorptions—and a broad band corresponding to the hydroxyl group at 3250 cm^{-1}.

This phenolic compound is believed to be the never-before-synthesized phenanthro[4,5-*bcd*]furan. The ketone (XVII) must be as strained as the ketone (VI) prepared by Dendy *et al.*,[4] since the two ketones are very similar to each other in fused-ring structure. From this point of view, it is surprising that we unexpectedly obtained good yields in two cyclizations, from XIII to a mixture of XV and XVI, and from XVI to XVII. However, that the latter cyclization proceeded under mild reaction conditions suggests that the strain was dominantly introduced in the former cyclization, in which a drastic reaction condition was required to give a lower yield. This suggestion is surported by the experiments of Royer *et al.*[11]

Experimental

All the melting point are uncorrected. The chromatography was performed over silica gel (WAKOGEL C-200, Wako Pure Chemical Industries, Ltd.). The polyphosphoric acid was prepared from 85% phosphoric acid (470 g) and phosphorus pentoxide (516 g) by heating at 160—165 °C for 5 hr. Unless otherwise stated, sodium sulfate was employed as the drying agent. The infrared spectra were determined with a JASCO Model DS 402 G infrared spectrophotometer. The ultraviolet spectra were determined with a Shimadzu Model MR-31 spectrophotometer. The nuclear magnetic resonance spectra were determined at 100 MHz with a JEOL Model 4H-100 NMR spectrometer, using tetramethylsilane as the internal standard. Their chemical shifts are presented in terms of the τ value.

4-(2,5-Dimethoxyphenyl)butyric Acid. In a vessel for reduction we placed a solution of 3-(2,5-dimethoxybenzoyl)-propionic acid (40 g) in acetic acid (120 ml), a solution of palladium chloride (0.25 g) in 0.1 M hydrochloric acid (32 ml), and active charcoal (12.0 g). The hydrogenation[12] was carried out at room temperature and at atmospheric pressure until the hydrogen uptake had ceased. The catalyst was then filtered out, and the filtrate was evaporated under

reduced pressure to leave a viscous oil. Trituration with ice-cold water, followed by the washing of the resulting crystals with water, gave a crude solid in a 76.5% yield (57.5 g). Recrystallization from 30% aqueous ethanol afforded the pure 4-(2,5-dimethoxyphenyl)butyric acid as colorless plates; mp 66—68 °C. The mixed melting point with an authentic sample[11] did not depressed.

5,8-Dimethoxy-1-tetralone (VII). A mixture of γ-(2,5-dimethoxyphenyl)butyric acid (25 g) and polyphosphoric acid (325 g) was stirred at 50 °C for 8.5 hr. The resulting yellow mixture was diluted with ice-cold water and extracted with ether. The ether was washed with 1M aqueous potassium carbonate and with water, and then dried. After the removal of the solvent the extract was crystallized from *n*-hexane–ether to give 13.4 g (58.2%) of VII as colorless needles; mp 62—63 °C (lit,[11] mp 61 °C).

Found: C, 69.82; H, 6.74%. Calcd for $C_{12}H_{14}O_3$: C, 69.90; H, 6.84%.

2-Hydroxymethylidene-5,8-dimethoxy-1-tetralone (VIII). In a 500-ml flask equipped with a stirrer and a dropping funnel we placed sodium methylate powder (from 6.6 g of sodium metal and 70 ml of absolute methanol) and benzene (200 ml). Into the suspension ethyl formate (36 ml) was stirred over a 5-min period under cooling in ice-cold water; the stirring was then continued for 1 more hr. The tetralone (VII, 15 g) in benzene (120 ml) was added, drop by drop, over 50-min period, during which the reaction temperature was kept below room temperature. The ice-bath was then removed, and the stirring was continued for an additional 2.5 hr. The reaction mixture was then acidified with 2 M hydrochloric acid (150 ml) to give crystals of VIII. Recrystallization from 60% ethanol afforded 13.7 g of the pure VIII as colorless needles; mp 85—86 °C. IR(KBr): 3270 cm^{-1} (OH), 1263 cm^{-1}(C=O). NMR($CDCl_3$): τ 1.67 (OH).

Found: C, 66.61; H, 6.08%. Calcd for $C_{13}H_{14}O_4$: C, 66.74; H, 6.03%.

Methyl 3-(1,2,3,4-Tetrahydro-5,8-dimethoxy-1-oxo-2-naphthyl)-propionate (X). To 20.0 g of VIII we added 12.0 g of methyl acrylate, 27.0 g of triethylamine, and 80% methanol (80 ml), after which the mixture was refluxed for 7.5 hr. The reaction mixture was then extracted with ether. To remove the triethylamine and the acidic compounds, the ether (800 ml) was washed with five 100-ml portions of 0.5 M hydrochloric acid and then with four 50-ml portions of 2 M aqueous patossium carbonate, and washed with water. The ether, after drying, was evaporated to an oil, which was warmed on a steambath under reduced pressure to remove the unreacted methyl acrylate. Crystallization from methanol gave 14.3 g (57.2%) of X as colorless needles; mp 64—65 °C. IR(KBr): 1737 ($COOCH_3$), 1692 cm^{-1} (C=O). NMR (CCl_4): τ 6.45 ($COOCH_3$, s).

Found: C, 65.88; H, 6.91%. Calcd for $C_{16}H_{20}O_5$: C, 65.75; H, 6.81%.

3-(1,2,3,4-Tetrahydro-5,8-dimethoxy-1-oxo-2-naphthyl)propionic Acid (XI). Into a saturated alcoholic solution of X (20 g) we stirred, drop by drop, 3 M aqueous potassium hydroxide until the last few drops no longer induced instantaneous milky turbidity. After standing for 30 min, the reaction mixture was diluted with water and acidified with 6 M hydrochloric acid to give precipitates of XI. Recrystallization from 60% ethanol afforded 15.8 g (83.0%) of the pure XI as colorless needles; mp 139—140.5 °C. IR (KBr): 1716 (COOH), 1685 cm^{-1} (C=O).

Found: C, 64.76; H, 6.55%. Calcd for $C_{15}H_{18}O_5$: C, 64.74; H, 6.47%.

3-(1,2,3,4-Tetrahydro-5,8-dihydroxy-1-oxo-2-naphthyl)propionic Acid (XII). A mixture of XI (10.0 g) and pyridinium chloride (45 g) was heated at 220 °C (bath temp.) for 2.5 hr. The reaction mixture was dissolved in 2 M aqueous sodium hydroxide and filtered. The filtrate was acidified with 6 M hydrochloric acid and then extracted with ether. The ether was washed with three 80-ml portions of 1 M hydrochloric acid to remove the pyridine; then it was further washed with water and dried. The ether was evaporated to yellow crystals. Recrystallization from 25% ethanol gave 7.8 g (86.8%) of XII as yellow needles; mp 125—126 °C. IR(KBr): 3390 (OH), 1722 (COOH), 1625 cm^{-1}(C=O).

Found: C, 62.02; H, 5.70%. Calcd for $C_{13}H_{14}O_5$: C, 62.40; H, 5.60%.

Methyl 3-(1,2,3,4-Tetrahydro-8-hydroxy-5-methoxy-1-oxo-2-naphthyl)propionate (XIII). A mixture of XII (10.0 g), dimethyl sulfate (18.5 g), potassium carbonate (22.5 g) and acetone (33.5 g) was heated under reflux for 2 hr. The reaction mixture was refluxed with water (150 ml) for 15 min and then extracted with ether. The ether extract was washed with water, dried, and evaporated to a yellow solid. Recrystallization from methanol gave 8.5 g (76.3%) of XIII as yellow needles; mp 66.5—67.5 °C. IR(KBr): 1728 ($COOCH_3$), 1638 cm^{-1} (C=O).

Found: C, 64.75; H, 6.11%. Calcd for $C_{15}H_{18}O_5$: C, 64.74; H, 6.47%.

3-(1,2,3,4-Tetrahydro-8-carboxymethoxy-5-methoxy-1-oxo-2-naphthyl)propionic Acid (XIV). A mixture of XIII (1.0 g), ethyl bromoacetate (3.1 g), potassium carbonate (3.4 g), and methyl ethyl ketone (50 ml) was heated under reflux for 3 hr; ethyl bromoacetate (2.0 g) was then added to the mixture, and the refluxing was continued for an additional 3 hr. The reaction mixture was filtered and thoroughly washed with hot acetone, and then the filtrate and washings were combined and evaporated to dryness. The residue was treated much as has been described in connection with the preparation of XI to give 150 mg of XIV (13% based on XIII) as colorless prisms; mp 179—185 °C (decomp.). IR(KBr): 1780 (OCH_2COOH), 1705 (COOH), 1659 cm^{-1} (C=O).

Found: C, 59.39; H, 5.70%. Calcd for $C_{16}H_{18}O_7$: C: 59.70; H, 5.59%.

3-(2-Carboxy-4,5-dihydro-6-methoxy-3H-naphtho[1,8-bc]fur-3-yl)propionic Acid (XV) and 3-(4,5-Dihydro-6-methoxy-3H-naphtho[1,8-bc]fur-3-yl)propionic Acid (XVI). A mixture of XIII (2.0 g), ethyl bromoacetate (6.2 g), potassium carbonate (2.3 g), and methyl ethyl ketone (2.2 g) was heated at 170 °C (bath temp.) for 3 hr; ethyl bromoacetate (2.0 g) was then added to the mixture, and the refluxing was continued for an additional 3 hr. The dark brown and almost dry reaction mixture thus obtained was extracted with hot acetone, and the acetone was evaporated. The residue was hydrolyzed much as has been described in connection with the preparation of XI, and the resulting alkaline solution was acidified with 6 M hydrochloric acid and extracted with ether. The ether was washed with water, dried, and evaporated to dryness. The solid mass was separated into two moieties, one of which is insoluble in benzene. The benzene-insoluble moiety was crystallized from tetrahydrofuran–benzene to give 0.95 g (43.5%) of XV as colorless needles; mp 195—196 °C. IR (KBr): 1710, 1693 cm^{-1} (COOH).

Found: C, 63.11; H, 5.43%. Calcd for $C_{16}H_{16}O_6$: C, 63.16; H, 5.26%.

The other moiety in benzene was chromatographed over silica gel and eluted with benzene–ether (97 : 3). A yellow fraction was collected, and the solvent was evaporated. The residue was crystallized from benzene–*n*-hexane to give 0.1 g (8.8%) of XVI as colorless needles; mp 123—124 °C. IR (KBr): 1705 cm^{-1} (COOH). NMR(CD_3COCD_3): τ 2.43

(H on the furan ring. UV: λ_{max}^{EtOH} 253 (ε 9300), 292 (ε 3600), 302 nm (ε 3200).

Found: C, 68.88; H, 6.10%. Calcd for $C_{15}H_{16}O_4$: C, 69.21; H, 6.15%.

Decarboxylation of XV. A mixture of 8.0 g of quinoline, 0.6 g of XV, and 0.6 g of copper powder was heated at 150 °C for 1.5 hr, during which carbon dioxide was evolved, and then at 155 °C for 10 more min. The mixture was acidified with 1 M hydrochloric acid and extracted with ether. The ether extract (500 ml) was washed four 50-ml portions of 2 M hydrochloric acid, and with water, and then dried, after which the ether was evaporated. The residue in benzene was chromatographed over silica gel and eluted with benzene–ether (93 : 7). An orange fraction was collected, and the solvent was evaporated. The residue was crystallized from benzene–*n*-hexane to give 0.23 g (44.9%) of XVI as colorless needles; mp 123—124 °C.

*5,6,7,7a,8,9-Hexahydro-1-methoxy-5-oxophenanthro[4,5-*bcd*]furan (XVII).* A mixture of 0.4 g of XVI and 36.5 g of polyphosphoric acid was stirred at 80 °C for 3.5 hr. The violet reaction mixture was poured onto ice and extracted with ether. The ether (500 ml) was washed with water, with four 70-ml portions of 1 M aqueous potassium carbonate, and with water, and then dried. The ether was evaporated to give crystals. Recrystallization from ethanol gave 0.25 g (67.1%) of XVII as colorless needles; mp 170—170.5 °C. IR(KBr): 1660 cm^{-1}(C=O).

Found: C, 74.03; H, 5.83%. Calcd for $C_{15}H_{14}O_3$: C, 74.37; H, 5.79%.

*5-Hydroxy-1-methoxyphenanthro[4,5-*bcd*]furan (*I: *R=MeO).* A mixture of 0.1 g of XVII, 0.2 g of 20% palladium on charcoal, and 2.0 g of α-methylnaphthalene was heated at 240 °C for 30 hr in a nitrogen atmosphere. The catalyst was then filtered out and washed with ether. The filtrate and washings were combined, and the ether was extracted with five 50-ml portions of 1 M potassium hydroxide. The alkaline solution was washed with two 30-ml portions of carbon tetrachloride and acidified with 6 M hydrochloric acid, and the resulting precipitates were extracted with ether. The ether extract was washed with water and dried, and the ether was evaporated. The residue was dissolved in benzene containing a little ether, chromatographed over silica gel, and eluted with benzene–ether (9 : 1). A yellow fraction was collected, and the solvent was evaporated to give crystals. Recrystallization from benzene gave 0.02 g (20.3%) of I (R=MeO) as colorless needles; mp 187—191 °C (decomp.). IR(KBr): 3240 (OH), 825, 800 cm^{-1} (2H). NMR(CD_3COCD_3): τ 4.59 (MeO, s), 2.82, 2.73, 2.31, 2.23 (q, 2H), 2.58, 2.53, 2.49, 2.44 (q, 2H), 2.13 (2H), 0.59 (OH). UV: λ_{max}^{EtOH} 242 (ε 56300), 265 (ε 23500), 313 (ε 11300), 327 (ε 15700), 351 (ε 8120), 370 nm (ε 14700).

Found: C, 75.45; H, 4.29%. Calcd for $C_{15}H_{10}O_3$: C, 75.76; H, 4.26%.

The authors wish to thank Prof. N. Fudaka for his interest and encouragement, Mr. Y. Takahashi for the elemental analyses, and Mr. H. Saisu for infrared analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1776—1779 (1973)

The Palladium-catalyzed Arylation of 4-Chromanone Enol Esters. A New Synthesis of Isoflavanones

Ryu-ichi SAITO, Taeko IZUMI, and Akira KASAHARA*

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa-shi, Yamagata 992

(Received October 31, 1972)

Heck's reaction of 4-chromanone enol esters with arylpalladium compounds in acetic acid afforded isoflavanones in a high yield. The structural elucidation of these products was accomplished by spectral inspections.

Isoflavanones (I) have been synthesized by the hydrogenation of the corresponding isoflavones,[1-4] by the oxidation of isoflavanes,[5] by the reduction of 3-hydroxyisoflavanones with zinc in aqueous acetic acid,[6] and by the action of methylene diiodide on *o*-hydroxydeoxybenzoin.[7] Recently, Heck[8] has reported that arylpalladium compounds, generated *in situ* from arylmercury compounds (II) and palladium salts, reacted with ketone enol esters to form α-arylketones as the major products. In this report we wish to report

the application of this new reaction to 4-chromanone enol esters (III); this method gave I in a high yield.

III was obtained in 80—90% yields by the reaction of 4-chromanones (IV) with isopropenyl acetate at reflux. In the presence of palladium acetate, III was treated with II in acetic acid at room temperature to produce I. For example, the reaction of 4-chromanone enol acetate (IIIa) with phenylmercuric acetate (IIa) resulted in the formation of isoflavanone (Ia) (yield=75%), which was identified by a comparison of its NMR and IR spectra with those of an authentic sample.[4] Similarly, 6-methoxy- and 7-methoxy-isoflavanone (Ig and Im) were synthesized from 6-methoxy- and 7-methoxy-4-chromanone enol acetate (IIIb and IIIc) respectively. The reactions carried out are summarized in Table 1.

Recent studies of the Heck reaction have shown that the reaction usually gives products consistent with a *cis* addition of the arylpalladium compounds to olefin, followed by a *cis* palladium hydride elimination and readdition.[9] In the reaction of III with arylpalladium compounds, the sterically-preferred direction of addition appears to be to add the aryl group to the least-substituted carbon atom (C_3) of the double bond. In the initially-formed adduct (V), the *trans* elimination of palladium with a neighboring hydride produces an arylated enol ester (VI), while the elimination of palladium with an acyl group produces a carbonyl compound (I). Previously it was suggested that, in the phenylation of enol esters, the elimination of palladium with an acyl group in the adduct appears to be produce the carbonyl compounds,[8] but Heck[10] has recently shown that the cupric chloride used as a co-catalyst is responsible for the formation of phenylacetaldehyde in the phenylation of vinyl acetate and that presumably the elimination of palladium with an acyl group does not occur. However, in the arylation reaction of III without using cupric chloride as a co-catalyst, the reaction mixtures produced little, if any, VI, affording only I. Moreover, since the enol ester, IIIa, can not be changed to the IVa ketone in an acetic acid solution of palladium acetate, it is clear that the I does not all come from the hydrolysis of VI and that the elimination of palladium with an acyl group produces I.

Experimental

All the melting points and boiling points are uncorrected. The IR spectra were taken with a Hitachi model 215 grating spectrometer. The NMR spectra were recorded on a Hitachi model H-60 spectrometer, operating at 60 MHz in a $CDCl_3$ solution; the chemical shifts were given in ppm from the TMS internal standard. The NMR signals in a singlet are designated as s; in a doublet, as d; in a triplet, as t, and in a multiplet, as m.

Materials. The palladium acetate was prepared according to the procedure of Wilkinson.[11] The following compounds were synthesized by the methods described in the literature: 4-chromanone (IVa), bp 120—122 °C/9 mmHg (lit,[12] bp 127—128 °C/13 mmHg); 6-methoxy-4-chromanone (IVb), mp 48—49 °C (lit,[13] mp 49 °C); 7-methoxy-4-chromanone (IVc), mp 52—53 °C (lit,[14] mp 52—54 °C); *p*-tolylmercuric chloride (IIb), mp 232—233 °C (lit,[15] mp 233 °C); *p*-anisylmercuric chloride (IIc), mp 173—174 °C (lit,[16] mp 173—174 °C); *m*-nitrophenylmercuric chloride

(IId), mp 218—220 °C (lit,[17] mp 218—221 °C); *p*-phenylphenylmercuric chloride (IIe), mp>360 °C (lit,[18] mp> 360 °C); and *p*-chlorophenylmercuric chloride (IIf); mp 223—225 °C (lit,[19] mp 225 °C). The phenylmercuric acetate (IIa) and isopropenyl acetate were of a commercial grade. The acetic acid was dried over phosphorus pentoxide and distilled before use.

Preparation of 4-Chromanone Enol Acetates (III). A mixture of 4.0 g of IV, 16 ml of isopropenyl acetate, and 0.4 g of *p*-toluene sulfonic acid was refluxed for 36 hr under nitrogen. After 200 ml of benzene was added to the reaction mixture, the benzene solution was washed successively with water, dilute aqueous sodium bicarbonate, and water. The benzene extracts were dried over anhydrous magnesium sulfate and evaporated to dryness *in vacuo*. The residue was distilled under reduced pressure to give enol acetates (III) (yield, 80—90%). The following compounds were prepared in this manner.

4-Chromanone Enol Acetate (IIIa, $R_1=R_2=H$). Bp 150—152 °C/13 mmHg. IR spectrum: 1760, 1210, and 743 cm^{-1}. NMR spectrum: δ 2.33 (s, 3H, CH_3COO–), 4.87 (d, 2H, J=4.2 Hz, protons on C_2), 5.46 (t, 1H, J=4.2 Hz, olefinic proton on C_3), and 6.81—7.83 *ppm* (m, 4H, aromatic ring protons).

Found: C, 69.61; H, 5.38%. Calcd for $C_{11}H_{10}O_3$: C. 69.46; H, 5.30%.

6-Methoxy-4-chromanone Enol Acetate (IIIb, $R_1=-OCH_3$, $R_2=H$). Bp 162—164 °C/7 mmHg. IR spectrum: 1765, 1210, 900, and 802 cm^{-1}. NMR spectrum: δ 2.15 (s, 3H, CH_3COO–), 3.69 (s, 3H, CH_3O–), 4.82 (d 2H, J= 4.8 Hz, protons on C_2), 5.29 (t, 1H, J=4.8 Hz, olefinic proton on C_3), and 6.96—7.38 ppm (m, 3H, aromatic ring protons).

Found: C, 65.57; H, 5.60%. Calcd for $C_{12}H_{12}O_4$: C, 65.44; H, 5.49%.

7-Methoxy-4-chromanone Enol Acetate (IIIc, $R_1=H$, $R_2=CH_3O$–). Bp 159—161 °C/6 mmHg. IR spectrum: 1760, 1208, 900, and 800 cm^{-1}. NMR spectrum: δ 2.18 (s, 3H, CH_3COO–), 3.67 (s, 3H, CH_3O–), 4.84 (d, 2H, J= 4.6 Hz, protons on C_2), 5.36 (t, 1H, J=4.6 Hz, olefinic proton on C_3), and 6.88—7.64 ppm (m, 3H, aromatic ring protons).

Found: C, 65.48; H, 5.58%. Calcd for $C_{12}H_{12}O_4$: C, 65.44; H, 5.49%.

General Procedures for the Arylation of III. A mixture of 10 mmol of III, 10 mmol of II, and 10 mmol of palladium acetate was stirred overnight in 80 ml of acetic acid at room temperature. After the resulting mixture has been filtered to remove the precipitated palladium metal, the filtrate was evaporated to dryness *in vacuo* to remove the acetic acid. The residue was poured into water and was extracted with chloroform. The chloroform solution was treated with dilute aqueous sodium bicarbonate, washed with water to free it from acetic acid, and then dried over anhydrous magnesium sulfate. After the evaporation of the solvent, the products were isolated by column chromatography on alumina with benzene and by crystallization from alcohol. The identities of the products formed were proved by mixed-melting-point determinations or by comparisons of the IR or NMR spectra with those of authentic samples. The analytical results and properties of the products are listed in Table 2.

The authers would like to express their thanks to Associate Professor Kaoru Hanaya and Mr. Hideaki Kudo of Yamagata University for the measurements of NMR spectra, and to the Kawaken Fine Chemical Co., Ltd., for a gift of palladium.

One-Electron Reduction of Carbonium Ions. III. The Effect of Added Anions on the Rate of Reduction of the Tropylium Ion with Cr(II)[1]

Kunio Okamoto, Koichi Komatsu, Susumu Tsukada, and Osamu Murai

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received October 30, 1972)

The one-electron reduction of tropylium fluoroborate with Cr(II) was carried out in aqueous solution containing various anions (Cl^-, Br^-, SO_4^{2-}, HSO_4^-, BF_4^- and ClO_4^-) which were added as proton acids or as sodium salts, and the reaction rate at 25 °C was measured by the use of the flow method. It was found that Cl^-, Br^-, and SO_4^{2-} exhibit the characteristic rate-accelerating effect, whereas BF_4^- and ClO_4^- show a slight rate-retarding effect. From the extrapolation of the anion concentration to zero, it was indicated that this reaction can proceed even in the absence of added anions. From these findings, together with the results of chemical and spectrophotometrical analyses of the Cr(III) species, it was concluded that the reduction of the tropylium ion with Cr(II) proceeds through an electron-transfer step where the anion (Cl^-, Br^-, or SO_4^{2-}) or the water molecule acts as a weakly interacting electron-transfer bridge. This mechanism is essentially analogous to the "inner-sphere mechanism" known in the field of inorganic metal complex chemistry.

In the preceding paper,[2] we have reported on the reactivities of the cycloheptatrienyl and triphenylmethyl cations with a series of metallic powders and of the low-valent metallic ions, and demonstrated that the spectra of the reduction product yields may be regarded as a measure of the reducibility of the respective carbonium ions. As an extension of this work, a more quantitative investigation of the reducibility by the use of kinetic measurements seems of interest. Among the various reductants examined in the previous work, Cr(II) was found to be a satisfactory reagent, especially for kinetic measurements, since the one-electron reduction with Cr(II) proceeds quite readily without forming any by-product, as has already been reported in the case of some carbonium ions.[2,3] Prior to the kinetic study with respect to the reducibility of various stable carbonium ions, it seems necessary to clarify the mechanistic characteristics of this reaction by the use of a single representative carbonium ion, *e.g.*, the cycloheptatrienyl cation (the tropylium ion).

In the field of inorganic chemistry, the mechanisms for the reduction of several transition-metal complexes with Cr(II) are well established and are, in general, classified into "inner-sphere" and "outer-sphere" mechanisms depending upon whether or not an electron-transfer bridge between the reductant and the oxidant exists.[4]

On the other hand, for organic compounds, Cr(II) is known to be a potent and versatile reducing agent and has been used in the reduction of carbonium ions,[2,3] organic halides,[3c,5] olefins,[6] and carbonyl compounds.[6a] Among these reactions, the reduction of organic halides was interpreted as proceeding through reaction sequences analogous to the inner-sphere mechanism mentioned above, with the halide ion acting as an electron-transfer bridge between the organic moiety and Cr(II):[5a-d,g]

$$RX + Cr^{2+} \rightarrow [R\cdots X\cdots Cr]^{2+} \rightarrow R\cdot + CrX^{2+} \qquad (1)$$

It is currently accepted that the produced radical species is rapidly captured by the second chromous ion to furnish an organochromic complexes, which subsequently dimerizes with an unchanged halide or undergoes protonolysis to give a monomeric hydrocarbon.[3c,5c,e] There is also an exceptional case in which the first-formed radical abstracts the hydrogen atom before the formation of the organometallic complex.[5g]

In contrast to the reduction of organic halides, the chromous-ion reduction of carbonium ions usually gives rise to only dimers of the corresponding radicals,[2,3] but no kinetic investigation of this reaction has been reported. We chose the tropylium ion as a representative of stable carbonium ions and successfully measured the reduction rate with Cr(II) in an aqueous solution by the use of flow method; some findings of the effect of various added anions upon the reduction rate were obtained. The Cr(III) species produced under the various conditions were also analyzed chemically and spectrophotometrically. From the results obtained by these experiments, we wish to clarify the mechanism and scope of the reaction in this paper.

Results

Kinetic Measurements of the Reaction of the Tropylium Ion with Cr(II). As has already been reported,[2,3d] the tropylium ion reacts with Cr(II) quite rapidly

and quantitatively to give the dimer, bitropyl. The kinetic measurement of this reaction was made at 25 °C by the use of the apparatus depicted in Fig. 1. The aqueous acid solutions of the tropylium ion and of Cr(II) were mixed in a T-shaped mixing chamber and then allowed to react while flowing down through a reaction tube. The reaction time was 0.2—1.5 sec, depending on the length of the tube. After the quenching of the reaction by the use of the instantaneous oxidation of the unchanged Cr(II) with an aqueous solution of $CuSO_4$,[7] bitropyl was extract-

7) It was ascertained that Cu(II) has no interaction with unchanged tropylium ion under these conditions; see the Experimental section. The reactions of Cu(II) with the tropyl radical, such as the one reported by Kochi and Rust (J. K. Kochi and F. F. Rust, *J. Amer. Chem. Soc.* **83**, 2017 (1961)), seem to be negligible, if present at all, because the coupling reaction of the tropyl radical is supposed to be so fast ($k_2\sim2\times10^7$ M^{-1} sec^{-1} (22 °C); M. L. Morrell and G. Vincow, *J. Amer. Chem. Soc.*, **91**, 6389 (1969)) that, at this stage of the reaction, the steady-state concentration of the radical must be negligibly small compared with the concentration of the tropylium ion or bitropyl.

ed with *n*-hexane and determined by ultraviolet spectroscopy. The initial concentrations of both the reagents were set so that the concentration of Cr(II) would be 1.5 to 3.0 fold greater than that of the tropylium ion. The results for the various reaction times were treated according to the ordinary second-order rate equation (first-order for each reagent) to give a good straight line through the point of origin, as is shown in Fig. 2. The reaction conditions and the graphically-obtained values of the second-order rate constants are listed in Tables 1 and 2.

In a representative run, the unchanged tropylium ion was determined from the ultraviolet spectrum of the aqueous layer, and the material balance was found to be >97.5%. The product, bitropyl, was characterized on the basis of its infrared spectrum, the purity being ascertained by thin-layer chromatography.

The Effect of Added Anions on the Reduction Rate. In order to obtain information on the mechanism operating, especially at the electron-transfer step, the reaction of the tropylium ion with Cr(II) was carried out in aqueous acid solutions containing various anions (Cl^-, Br^-, SO_4^{2-}, HSO_4^-, BF_4^-, and ClO_4^-), which were added as proton acids or as sodium salts; the effects of the concentrations and of the nature of the anions upon the rate of the reaction were then examined. Among the results shown in Tables 1 and 2 and in Figs. 3 and 4, the following are noteworthy: (a) Cl^-, Br^-, and SO_4^{2-} have the characteristic effect of increasing the rate of the reaction; (b) this rate-increasing effect approaches its maximum as the concentration of the anion is increased; (c) on the contrary, BF_4^- and ClO_4^- show only a slight rate-retarding effect; (d) the extrapolation of the concentration of each anion leads to the same intercept where $k_2=9$ (l/g.ion.sec) at 25 °C; (e) H_2SO_4 and HSO_4^- seemingly exhibit a rate-accelerating effect at lower concentrations and a rate-retarding effect at higher concentrations. Among these findings, the observation (d) clearly indicates that the presence of halide ions is not essential for the reduction of the tropylium ion, as has been reported in the cases of the triphenylmethyl and diphenylmethyl cations.[3c] This result is in sharp contrast to the observation made by Castro[6b] that the 1,1-diphenylethyl cation can not be reduced by Cr(II) unless the chloride ion is added. The characteristic effect shown by H_2SO_4 and HSO_4^- as described in (e) seems to be attributable to the equilibrium composition[8] of H_2SO_4, HSO_4^-, and SO_4^{2-} in an aqueous solution; at lower concentrations, the SO_4^{2-} ion, which is predominant as a result of the nearly complete dissociation of H_2SO_4 or HSO_4^-, exerts a rate-accelerating effect, whereas at higher concentrations, undissociated H_2SO_4 and HSO_4^- seem to retard the reaction.

The Analysis of Cr(III) Species. Although Cr(II) is labile to the substitution of its ligands, Cr(III) is known to be sluggish to ligand substitution.[9] Thus, the analysis of the group attached to Cr(III), which is produced as a result of Cr(II) reduction, makes it possible to deduce the nature of the activated complexes. Taking advantage of these properties, Taube and his coworkers[10] successfully demonstrated that one-electron transfer reactions from Cr(II) to several inorganic metallic complexes proceed through an activated complex in which a single anion or a molecule acts as an electron-transfer bridge. With the expectation of obtaining information on the function of the added chloride ion on the electron-transfer step, we conducted the reaction of Cr(II) with an excess of the tropylium ion in variable HCl concentrations at room

temperature and analyzed the Cr(III) species chemically and by their visible spectra.

An excess of the tropylium ion was allowed to react with Cr(II) in 0.1 to 2.9 M aqueous HCl for 10 min (more than 100 half-lives) under nitrogen; after the subsequent extraction of the organic product, the visible spectrum of Cr(III) was taken. As is shown in Table 3 and Fig. 5, the absorption maximum of Cr(III) at longer wavelengths was found to make a bathochromic shift to 605 mμ, which corresponds to $CrCl(H_2O)_5^{2+}$,[11] with an increase in the concentration of HCl. This indicates that the Cr(III) species formed at lower HCl concentrations is a mixture of $Cr(H_2O)_6^{3+}$ (λ_{max} 575 mμ[11]) and $CrCl(H_2O)_5^{2+}$, but at higher HCl concentrations most of the Cr(III) exists as $CrCl(H_2O)_5^{2+}$. The results of the chemical analysis of the chloride ion attached to Cr(III) exhibit qualitatively the same tendency, as is shown in Table 4.

Discussion

One of the simplest mechanisms for the formation of bitropyl by the reduction of the tropylium ion with Cr(II) is the radical mechanism shown below:

$$C_7H_7^+ + Cr(II) \rightarrow C_7H_7\cdot + Cr(III) \quad (2)$$

$$2C_7H_7\cdot \rightarrow (C_7H_7\text{–})_2 \quad (3)$$

At present, it still remains open whether the radical produced is entirely free or is loosely affiliated with the metal ion (Step (4)); consequently, the possibilities for the reactions through $[C_7H_7\cdots\overset{|\diagup}{\underset{\diagdown|}{Cr}}\cdots]^{2+}$, depicted in Steps (4) and (5) or in Steps (4) and (6), can not be rigorously eliminated:

$$C_7H_7\cdot + Cr(II) \rightarrow [C_7H_7\cdots\overset{|\diagup}{\underset{\diagdown|}{Cr}}\cdots]^{2+} \quad (4)$$

$$[C_7H_7\cdots\overset{|\diagup}{\underset{\diagdown|}{Cr}}\cdots]^{2+} + C_7H_7\cdot \rightarrow (C_7H_7\text{–})_2 + Cr(II) \quad (5)$$

$$[C_7H_7\cdots\overset{|\diagup}{\underset{\diagdown|}{Cr}}\cdots]^{2+} + C_7H_7^+ \rightarrow (C_7H_7\text{–})_2 + Cr(III) \quad (6)$$

Among these, however, Steps (2) and (3) seem most likely because, regardless of the acidity of the solvent, the reduction only gives the dimer, and no protonolysis product (tropilidene) which can be derived from $[C_7H_7\cdots\overset{|\diagup}{\underset{\diagdown|}{Cr}}\cdots]^{2+}$ is ever formed. Furthermore, the marked effect of the added anions on the reaction rate indicates that, in any case, the rate-determining step is Step (2), at which an anion can substantially participate.

A representative example of such an anion-affected reaction may be seen in the reduction of $[Co(NH_3)_5X]^{2+}$ with Cr^{2+}. In this case the transition state in which the anion, X, acts as an electron-transfer bridge has been proposed:[10]

$$[Co(NH_3)_5X]^{2+} + Cr^{2+} + 5H^+ \rightarrow Co^{2+} + CrX^{2+} + 5NH_4^+ \quad (7)$$

Also, in the present study, the fact that only such anions as Cl^-, Br^-, and SO_4^{2-}, which can coordinate with Cr(III), show the rate-accelerating effect would imply that these anions act as electron-transfer bridges between the tropylium ion and Cr(II). On the other hand, when the anion concentration is graphically extrapolated to zero, the rate constant still has the value of 9 (l/g.ion·sec), indicating that the electron transfer also takes place via the H_2O molecule as a bridge. Thus, in the reaction system, paths which proceed *via* an anion bridge and those which proceed *via* an H_2O bridge are both present; they give rise to $Cr(H_2O)_5X^{2+}$ and $Cr(H_2O)_6^{3+}$ respectively.

The effect of the added chloride ion on the reaction rate, however, is at most a factor of about 10 (see Fig. 4), much smaller than the factor of 10^6 found in the reaction (7) for the Cl bridging relative to the H_2O

bridging.[12] This may indicate that, although there is bridging by the chloride ion between $C_7H_7^+$ and Cr(II), it is much less effective than in the case of the reduction of $[Co(NH_3)_5X]^{2+}$, since even in the activated complex, the interaction between $C_7H_7^+$ and Cl^- is considered to be quite weak because of the complete delocalization of the positive charge in the tropylium ion.

When the reaction is conducted in the presence of HCl, the reacting species which gives rise to the chloride ion bridge is supposed to be $Cr(H_2O)_5Cl^{+}$[13] or the ion pair, $C_7H_7^+\cdots Cl^-$,[14] which is in equilibrium with $Cr(H_2O)_6^{2+}$ or with $C_7H_7^+$ respectively:

$$Cr(H_2O)_6^{2+} + Cl^- \rightleftharpoons Cr(H_2O)_5Cl^+ + H_2O \quad (8)$$

$$C_7H_7^+ + Cl^- \rightleftharpoons C_7H_7^+\cdots Cl^- \quad (9)$$

Therefore, it may be supposed that, among these species, the following reaction paths (Steps (10)—(12)) are competing with each other:

$$C_7H_7^+ + Cr(H_2O)_6^{2+} \rightarrow [C_7H_7\cdots \overset{H}{O}Cr(H_2O)_5]^{3+} \rightarrow C_7H_7\cdot + Cr(H_2O)_6^{3+} \quad (10)$$

$$C_7H_7^+\cdots Cl^- + Cr(H_2O)_6^{2+} \xrightarrow{-H_2O} [C_7H_7\cdots ClCr(H_2O)_5]^{2+}$$

$$C_7H_7^+ + CrCl(H_2O)_5^+ \rightarrow C_7H_7\cdot + CrCl(H_2O)_5^{2+} \quad (11)$$

$$C_7H_7^+\cdots Cl^- + CrCl(H_2O)_5^+ \xrightarrow{-Cl^-} [C_7H_7\cdots ClCr(H_2O)_5]^{2+} \rightarrow C_7H_7\cdot + CrCl(H_2O)_5^{2+} \quad (12a)$$

$$C_7H_7^+\cdots Cl^- + CrCl(H_2O)_5^+ \xrightarrow{-H_2O} [C_7H_7\cdots ClCrCl(H_2O)_4^+ \rightarrow C_7H_7\cdot + CrCl_2(H_2O)_4^+ \quad (12b)$$

Path (10) proceeds by means of bridging with H_2O, while Paths (11) and (12) make use of the chloride bridge. As for Path (12), it can not be determined from the analysis of Cr(III) which course, (12a) or (12b), is pertinent, since $CrCl_2(H_2O)_4^+$ is known to react readily ($k_2 \approx 10^2$ l/g.ion·sec at 2 °C[9]) with Cr^{2+} to give $CrCl(H_2O)_5^{2+}$, as is shown below:

$$CrCl_2(H_2O)_4^+ + Cr^{2+} \rightarrow CrCl(H_2O)_5^+ + CrCl(H_2O)_5^{2+} \quad (13)$$

The tendency of the rate-increasing effect of anions to approach its maximum with an increase in the anion concentration (shown in Figs. 3 and 4) can be ascribed to the shift of the equilibria (8) and (9) to the right, with the result that the reaction proceeds completely *via* the bridging with the chloride ion so that no more rate acceleration becomes observable. This is also consistent with the result, obtained from the chemical analysis, that the amount of the chloride ion attached to Cr(III) increases with an increase in the HCl concentration.

From these results, it is concluded that the one-electron reduction of the tropylium ion with Cr(II) in the aqueous acid of the appropriate concentration does not occur directly between the two reagents, but proceeds by means of the electron-transfer bridge mechanism. Therefore, it may be expected that, so long as the acid solution is used in a concentration sufficient for the bridging, the reactivity of the various stable carbonium ions in this reaction will mainly reflect the inherent electron affinity of the respective carbonium ions, and that the effect of the steric factor will be minimized. The investigation on the correlation of such a reactivity with the electron affinity of the various stable carbonium ions is now in progress and will be reported in the following paper.

Experimental[15]

Materials. Tropylium fluoroborate was prepared from tropilidene according to the method of Conrow.[16] The aqueous solutions of the chromous ion were prepared by the dissolution of chromium metal (99.99%, Nakarai Co., Ltd.) in 2.9 M respective acid solutions under nitrogen after activation in 2.9 M HCl and rinsing with distilled water. The transfer and dilution of the original chromous solution were done by the use of a hypodermic syringe; distilled water or acid solutions of appropriate concentrations had previously been deoxygenated with nitrogen. The aqueous solutions of hydrochloric, hydrobromic, sulfuric, perchloric, and fluoroboric acids, the sodium salts of the respective anions, and the sodium bisulfate were of a reagent grade and were used without further purification.

Kinetic Measurements for the Reaction of the Tropylium Ion with Cr(II). The reaction was carried out under a nitrogen atmosphere in the flow system shown in Fig. 1. Burettes and a reaction tube were covered with jackets circulated with water thermostated at 25.0±0.2 °C. The aqueous acid solutions of the tropylium ion and of the chromous ion, the concentrations of which had been determined by ultraviolet spectroscopy and by iodometry, respectively, were charged into each burette from the reservoirs and let stand for at least 10 min for temperature equilibration. The nitrogen pressure in the whole system was raised to 200 mmHg above atmospheric pressure, and then the main stopcock was opened for about 4 sec so that 20 ml each of the reagent solutions ran into a glass reaction tube 3.6 mm in inner diameter, through a mixing chamber made of T-shaped glass tube 1.0 mm in inner diameter. The reagents were allowed to react for 0.3—1.5 sec while flowing through reaction tubes of various lengths; then they flowed out into 20 ml of a magnetically-stirred "stop solution" containing 0.5 M $CuSO_4$. The operation of the main stopcock was synchronized with a buzzer switch; while the stopcock was opened the buzzer sound was recorded on a tape recorder, and from the distance of the recording tape between the starting and ending points of the buzzer sound the flowing time of the reagents was

14) The formation of such an ion pair can be well supposed from the observation that the charge-transfer complexes are formed between the tropylium ion and halide ions (K. M. Harmon, F. E. Cummings, D. A. Davis, and D. J. Diestler, *J. Amer. Chem. Soc.*, **84**, 120, 3349 (1962); E. M. Kosower, *J. Org. Chem.*, **29**, 956 (1964)).

15) The infrared and ultraviolet spectra were obtained on Shimadzu models IR-27 and UV-50M spectrometers respectively. The Kohlrausch bridge used for the conductometry was a Shimadzu apparatus, model BF-62.

16) K. Conrow, "Organic Syntheses," Vol. 43, p. 101 (1963).

determined. The time-distance calibration was made by the use of the standard time service of the Nippon Telegram and Telephone Corporation. Thus, when the time required for a total flow of 40 ml was determined to be 4.00 sec, for example, the reaction times were calculated to be 0.26, 0.36, 0.46, 0.60, 0.72, and 1.04 sec with reaction tubes of the length of 25.1, 35.1, 45.0, 58.8, 70.2, and 102.5 cm respectively. The reaction solution was extracted three times with 50-ml portions of *n*-hexane, washed with three 100-ml portions of 10% aqueous sodium chloride, and dried over magnesium sulfate. The solvent was evaporated under reduced pressure to give white crystals which were identified as bitropyl from the superimposability of the infrared spectrum with the spectrum of an authentic sample. The amount of the product was determined by ultraviolet spectroscopy in ethanol, using 255 mμ (ε=7080) as a characteristic band for bitropyl.[17] The rate constants were determined graphically from the ordinary second-order rate equation. The efficiency of mixing in the mixing chamber was examined by the method described by Roughton,[18] *i.e.*, the measurement of the heat of neutralization, which was evolved when equivalent aqueous solutions of HCl and NaOH were mixed together under the same conditions as in the chromous-ion reduction. It was confirmed that 100% mixing was attained within 0.02 sec after mixing.

Test for the Efficiency of the Quenching of Cr(II) with Cu(II). To 20 ml of a 2.9 M HCl solution of the tropylium ion (0.02 g.ion/l) and $CuSO_4$ (0.5 mol/l), was added 10 ml of a 2.9 M HCl solution of Cr(II) (0.04 g.ion/l) under an atmosphere of nitrogen at room temperature. After 10 min, the ultraviolet spectrum of an aliquot showed that the amount of the tropylium ion had not been affected.

The Analysis of Cr(III) Complex in Solution. By the use of an apparatus employed in the kinetic measurements, 40-ml portions each of a solution of the tropylium ion and of Cr(II) in aqueous hydrochloric acid of various concentrations were mixed and allowed to react for 10 min at room temperature under nitrogen in a Erlenmeyer flask, set under the mixing chamber. The initial concentrations of both reagents were set as is shown in Tables 3 and 4, so that the amount of the tropylium ion was a 1.5—1.8 fold excess. After the extraction of the organic product with three 60-ml portions of *n*-hexane, the aqueous layer was subjected to the measurement of its visible spectrum or to the chemical analysis of the chloride ion bound to Cr(III) as follows: the free chloride ions in the solution were first determined by conductometric titration with 0.1 M $AgNO_3$. The solution was then heated at 100 °C for 30 min and titrated again with 0.1 M $AgNO_3$. The differences in titers before and after the heating of the solution was regarded as corresponding to the amount of chloride ions bound to Cr(III).[9]

(Received November 2, 1972)

The one-electron reduction of the unsubstituted, methyl-, ethyl-, isopropyl-, *t*-butyl-, triphenylmethyl-, and phenyltropylium ions with Cr(II) in a 10% HCl solution gives, quantitatively, the dimer of the corresponding substituted tropyl radical. The measurements of the reaction rate at 25 °C exhibit this order of reactivity: *t*-butyltropylium (k_2=7.98 l/g·ion·sec), isopropyltropylium (8.22), ethyltropylium (10.3), methyltropylium (11.1), tropylium (74.0), phenyltropylium (144), and triphenylmethyltropylium (567) ions. The values of log k_2 have a linear correlation with the transition energies of the charge-transfer bands observed for these carbonium ions with pyrene, and also with the polarographic half-wave potentials of the respective cations. These correlations indicate that the reactivity of the carbonium ion in the reduction with Cr(II) is determined mainly by the electron affinity inherent in the respective cations. The values of log k_2 also have a good linear correlation with the pK_{R^+} values, implying a parallelism between the electron affinity and the electrophilicity of these stable carbonium ions.

Although the one-electron reduction of carbonium ions in the gas phase has raised much theoretical interest in the ionization of organic radicals to carbonium ions, the reducibility of stable carbonium ions in solutions has received rather little attention; quantitative studies of it have been restricted to electrochemical one, such as polarography[1] and emf measurements of the cells made of equilibrated solutions of the carbonium ions and the corresponding radicals.[2] We demonstrated in previous papers[3,4] that the reducibility of the stable carbonium ion can be estimated from the reactivity

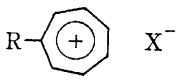
toward various metals and low-valent metallic ions, and that among these reductants Cr(II) is a suitable reagent for the kinetic study designed to estimate quantitatively the reducibility of stable carbonium ions in a solution.

Thus, the kinetics of the chromous-ion reduction of the substituted tropylium ions were studied with the idea that the change in the electron affinity of these ions caused by the introduction of various substituents will be reflected in the rate constants. The relative electron affinities of carbonium ions have been estimated from the transition energies of the charge-transfer bands, and also from the polarographic half-wave potentials. We will discuss the correlation of the reducibility of these carbonium ions with the relative electron affinities obtained, and also with the pK_{R^+} values measured for the respective cations, and will show the applicability of this method to the evaluation of the reducibility of stable carbonium ions of the tropylium system in a solution.

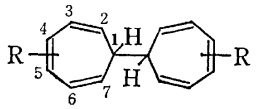
Results and Discussion

Reduction of the Substituted Tropylium Ions with Cr(II). It has been reported that the tropylium ion was readily reduced with Cr(II) to give a quantitative yield of the dimer, bitropyl.[3,5] We have ourselves examined the reduction of the substituted tropylium salts (Ia—f) with Cr(II) in 10% HCl (2.9 M);[6]



I

I a : R=CH_3, X=ClO_4 b : R=C_2H_5, X=ClO_4
c : R=i-C_3H_7, X=ClO_4 d : R=t-C_4H_9, X=ClO_4
e : R=C_6H_5, X=BF_4 f : R=$C(C_6H_5)_3$, X=BF_4



II

We ascertained that, in each case, the dimer (II) was obtained in a yield of more than 95% without the formation of any by-product. The elemental analysis of the respective reaction products gave satisfactory values for the dimers. The NMR spectra (60 MHz) of the dimers showed three groups of multiplets, centered at about τ 3.5, 3.9, and 4.8, along with a broad singlet at about 8.0, typical of a cycloheptatrienyl system, and also the signals corresponding to each substituent. The complex patterns of these multiplets and the multiplicity of the signals of the substituents suggest that the product is a mixture of isomers of x,x'-disubstituted bitropyl (II). The signals centered at τ *ca.* 3.5 ($H^{4,5}$) and at *ca.* 3.9 ($H^{3,6}$) were not fully separated; therefore, integration was made for these four protons (H^{3-6}) as one group. It was found that, although the average of from three to five integrations constantly gave the relative ratio of nearly 1 : 5 for $H^1 : H^{2-7}$, the averaged ratio for $H^{2,7} : H^{3-6}$ varied with the substituents, as is shown in Table 1. Though each integration includes the probable error of *ca.* 5%, there is still a clear tendency for the integrated value of H^{3-6} to decrease with the increase in the bulkiness of the substituent. This seems to reflect the steric hindrance exerted upon the coupling of the substituted tropyl radicals formed by one-electron transfer.[4] Each product mixture seemingly gave one or hardly separating two spots on a silica-gel thin-layer plate (*n*-hexane–benzene, 9 : 1, as the solvent), but all attempts to isolate the single isomer were unsuccessful.

Table 1. Ratio of the integrations for ring protons of x,x'-disubstituted bitropyl

Substituent	H^1	$H^{2,7}$	H^{3-6}
None	2.0	4.0	8.0
Methyl	~2[a]	2.94	7.06
Ethyl	~2[a]	3.36	6.64
Isopropyl	1.90	3.48	6.52
t-Butyl	1.80	3.76	6.24
Phenyl	1.88	4.10	5.90
Trityl	2.00	3.74	6.26

a) Not determined separately because of the substituent signals which appear at the same position.

Kinetic Measurements of the Reduction of the Substituted Tropylium Ions. In order to examine the influence of substituents on the reducibility, the rate of the chromous-ion reduction of various substituted tropylium salts (Ia—f) was measured by the use of the flow method previously described;[4] the reaction was carried out at 25 °C under a nitrogen atmosphere in 10% HCl for 0.2—1.5 sec; the conversion was determined by the ultraviolet spectroscopy of the dimers. The reaction was found to follow good second-order kinetics with respect to each substituted tropylium ion and Cr (II). The results shown in Table 2 demonstrate that, whereas the reactivity of the tropylium ion is markedly increased by the introduction of phenyl and triphenylmethyl substituents, it is suppressed by the introduction of the alkyl groups, among which the effect gradually increases in this order; methyl, ethyl, isopropyl, and *t*-butyl groups.

In a previous mechanistic study[4] it was indicated that the reduction of the tropylium ion with Cr(II) in 10% HCl proceeds through a transition state, in which the chloride ion acts as an electron-transfer bridge between the two reactants, rather than by direct interaction between them. Therefore, it was expected that the influence of the steric effect exerted by each substituent would be minimized and that the reactivity would mainly reflect the intrinsic reducibility of the

5) W. T. Bowie and M. Feldman, *J. Phys. Chem.*, **71**, 3696 (1967).

6) Throughout this work, 10% HCl was used as the standard solvent in order to ensure the enough stability of the respective tropylium ions in the aqueous solution; in the solutions with lower acidities (pH>1), slow decomposition was observed for the methyl-, ethyl-, and isopropyltropylium ions.

Table 2. Second-order rate constants for the reaction of substituted tropylium ions with Cr(II) in 10% HCl at 25 °C

respective carbonium ions. This supposition seems to be verified by the fact that the reduction of the tropylium ion with the bulkiest substituent, the triphenylmethyl group, still proceeds most rapidly. Thus, the results of the kinetic measurements should be interpreted in terms of the difference in the intrinsic reducibility of the respective cations. From the observed results, it also appears that the inductive effect of the substituents controls the reducibility sequence (*t*-Bu<*i*-Pr<Et<Me<H<Ph<Ph_3C) and that the π-conjugative stabilization exerts very little effect in the tropylium system.

Correlation of the Reducibility with the Relative Electron Affinity of the Carbonium Ions. It seems that it would be of interest to compare the observed reducibility of each substituted tropylium ion with the electron affinity determined by the other methods. As one of such methods we made use of the measurement of the charge-transfer bands observed between carbonium ions and an aromatic hydrocarbon.[7] From the interpretation according to the donor-acceptor theory of Mulliken,[8] it can be expected that the frequency of the charge-transfer band, ν_{max}, for a series of similar stable carbonium ions with a given donor molecule would correlate with the electron affinities of these carbonium ions. Actually, Feldman and Winstein[7e] estimated the electron affinities of various organic cations, applying the principle mentioned above. In the present study, it was observed that the dissolution of each substituted tropylium salt in a 1,2-dichloroethane solution of a condensed aromatic hydrocarbon, pyrene, immediately gave a red-colored solution. It exhibits a band in the visible region which is not found in the spectrum of either component and which can be regarded as a charge-transfer band. The results are shown in Table 3, along with the values of log k_2 for the chromous-ion reduction. A plot of log k_2 against ν_{max} exhibits a linear correlation between them, as is shown in Fig. 1.

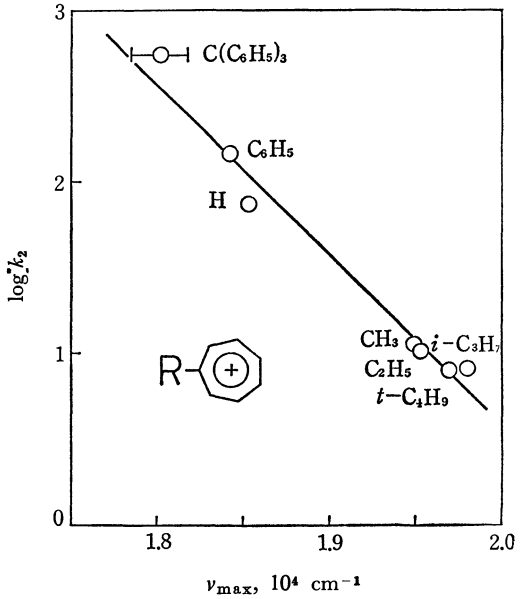

Fig. 1. The correlation of log k_2 with CT transition energies (ν_{max}).

As another measure of the electron affinity of the carbonium ions, electrochemical reduction potentials were determined by polarography with the dropping mercury electrode. The polarography of the tropylium ion was reported to include an irreversible reduction step.[1a-c] While some effects (solvation energy, *etc.*) other than electron affinity are regarded as being reflected in the half-wave potentials for such an irreversible step, for a series of similar cations the relative potentials will serve as a measure of readiness to accept an electron. The half-wave potentials measured in acetonitrile are listed in Table 3, while the correlation with log k_2 is shown in Fig. 2. The linear correlation observed in Figs. 1 and 2 clearly demonstrates that the reactivity of carbonium ions toward Cr(II) can be used satisfactorily as a measure of the electron affinity.

Correlation of the Reducibility with pK_R^+. In order to examine the correlation between the reducibility and the stability of carbonium ions, the pK_R^+ values of some representative substituted tropylium ions[9] were determined in 23% aqueous ethanol by

the spectrophotometric method described by Breslow and Chang.[10] From the results shown in Table 3, it can be seen that, whereas the alkyl substituent increases the stability, the phenyl group rather destabilizes the cation by means of its electron-withdrawing inductive effect, as is shown by the least stability of the triphenylmethyltropylium ion. The greater contribution to the stabilization of the cation by the alkyl group than by the phenyl group has been also observed in a cyclopropenyl system.[11]

A plot of $\log k_2$ against pK_{R^+}, again, gave a good linear correlation, as is shown in Fig. 3. Since the equation for pK_{R^+} is written as Eq. (2), with the rate constants for the forward and backward reactions (k_f and k_b respectively), and since it can be assumed that the backward reaction is not greatly affected by the structural change, this correlation may be generalized to imply that the readiness of the carbonium ion to accept one electron is parallel with the reactivity of the ion toward the electron pair of the nucleophile.

$$R^+ + H_2O \underset{k_b}{\overset{k_f}{\rightleftharpoons}} ROH + H^+ \quad (1)$$

$$pK_{R^+} = \log k_b - \log k_f \quad (2)$$

12) The melting points and boiling points are uncorrected. The microanalyses were performed by the Microanalytical Center, Kyoto University, Kyoto. The infrared and ultraviolet spectra were recorded with Shimadzu spectrometers, models IR-27 and UV-50M respectively. The NMR spectra were obtained by the use of a JEOL model JNM-3H-60 spectrometer with tetramethylsilane as the internal standard. The polarograms were obtained with a Yanagimoto polarograph, model P8-DP.

nitrile and ethyl acetate were refluxed over phosphorus pentoxide and then distilled; acetonitrile, bp 81.0—81.5 °C; ethyl acetate, bp 77.0—77.4 °C.

Tropylium fluoroborate was prepared from tropilidene according to the method of Conrow.[13]

7-Methyl-, 7-ethyl-, 7-isopropyl-, and 7-*t*-butylcycloheptatrienes were obtained by the reaction of 7-ethoxycycloheptatriene with the corresponding alkyl magnesium halides, as has been reported by Nozoe and his co-workers;[14] 7-methylcycloheptatriene, bp 53 °C/63 mmHg (lit, bp 63 °C/80 mmHg[14]); 7-ethylcycloheptatriene, bp 84 °C/35 mmHg; 7-isopropylcycloheptatriene, bp 88 °C/36 mmHg (lit, bp 74 °C/33 mmHg[14]); 7-*t*-butylcycloheptatriene, 90 °C/24 mmHg (lit, bp 95—98 °C/45 mmHg.[14])

7-Phenylcycloheptatriene was prepared by the reaction of tropylium fluoroborate with phenyllithium according to the method of Doering and Knox;[15] bp 76 °C/0.4 mmHg.

7-Triphenylmethylcycloheptatriene was synthesized by reference to the thesis of Rifi.[16] In a 100-ml four-necked flask equipped with a mechanical stirrer, a thermometer, and a nitrogen inlet and outlet, there was stirred a suspension of 1.467 g (8.74 mmol) of tropylium fluoroborate in 40 ml of dry ethyl ether. To this mixture was slowly added 63 ml of a 0.14 M ethereal solution of triphenylmethylsodium (8.8 mmol), prepared from triphenylmethyl chloride and 1% sodium amalgam according to the method of Renfrow and Hauser,[17] over a 10-min period by the use of a hypodermic syringe. The dark red color of the solution of triphenylmethylsodium was instantaneously discharged when it was added to the ethereal suspension of tropylium fluoroborate. The yellowish gray mixture was stirred for a further 2 hr at 24—26 °C under nitrogen. After the addition of 100 ml of distilled water, the organic layer was separated and worked up in the usual way to give 2.928 g of a yellowish white solid, which was then chromatographed over 100 g of silica gel (Nakarai, No. II-A, 100—200 mesh). Elution with *n*-hexane–benzene (4 : 1) gave 1.263 g (3.78 mmol) of 7-triphenylmethylcycloheptatriene as white crystals; the same infrared spectrum as the authentic sample; 43.3% yield; mp 166.6—170.7 °C (dec) (lit, mps 167—170 °C (dec)[18] and 156 °C[16]).

The isomerization of 7-substituted cycloheptatrienes to the mixtures of 1-, 2-, and 3-substituted cycloheptatrienes was effected thermally by successive sigmatropic 1—5 hydrogen shifts,[19] so that the steric hindrance at the step of hydride abstraction by the triphenylmethyl cation (*vide infra*) might be diminished. 7-Methyl-, 7-ethyl-, 7-isopropyl-, 7-*t*-butyl, and 7-phenylcycloheptatrienes were sealed in Pyrex ampoules under a vacuum ($<10^{-3}$ mmHg), heated in an oil bath at 175 °C for 1.5 hr,[14] and distilled under reduced pressure; methylcycloheptatrienes, bp 65—67 °C/72 mmHg; ethylcycloheptatrienes, bp 95—98 °C/41 mmHg; isopropylcycloheptatrienes, bp 90—94 °C/35 mmHg; *t*-butylcycloheptatrienes, bp 79—80 °C/24 mmHg; phenylcycloheptatrienes, bp 77—79 °C/0.4 mmHg. 7-Triphenylmethylcycloheptatriene was dissolved in *m*-xylene and similarly sealed in a Pyrex ampoule under a vacuum. After heating at 145 °C for 5 hr, the isomer mixtures were recovered as white crystals by chromatography over silica gel (Nakarai, No. II-A, 100—200 mesh), with *n*-hexane–benzene (4 : 1) as the eluent.

Methyltropylium perchlorate (Ia) was synthesized following the method of Conrow.[20] Into a suspension of 7.00 g (0.0204 mol) of triphenylmethyl perchlorate in 40 ml of acetonitrile, we added 2.079 g (0.0195 mol) of thermally-isomerized methylcycloheptatrienes with magnetical stirring at room temperature. In 1 min, the precipitates of triphenylmethyl salt all dissolved. After 10 min, the solvent was evaporated under reduced pressure, a 50-ml portion of ethyl acetate was added, and the yellow solid mass was pulverized. Then the mixture was evaporated again, followed by the addition of another 100 ml of ether acetate and by the trituration of the solid. This time the precipitates were collected under a stream of nitrogen, washed with ten 10-ml portions of ethyl acetate, and dried in a vacuum desiccator to give 3.879 g (0.0190 mol) of crude Ia; 97.4% yield. Recrystallization from acetonitrile–ethyl ether under nitrogen gave white crystals, which rapidly decompose on exposure to air; mp 110.0—111.5 °C (lit, mp 111—112 °C[20], mp 109 °C[21]); $\lambda_{max}^{0.1\,M\,HCl}$ 287 mμ (ε, 4760) (lit, $\lambda_{max}^{conc\ H_2SO_4}$ 288 mμ (ε, 3500)[21]).

Ethyltropylium perchlorate (Ib) was obtained by the same method as white crystals with a pink tinge from the isomerized ethylcycloheptatrienes; 90.5% yield; mp 84.0—84.3 °C; $\lambda_{max}^{0.1\,M\,HCl}$ 292 mμ (ε, 4880).

Isopropyltropylium perchlorate (Ic) was similarly prepared as brownish-white crystals from the isomerized isopropylcycloheptatrienes, except that dry ethyl ether was employed instead of ethyl acetate for the washing of the product; 76.7% yield; mp 35.8—39.8 °C; $\lambda_{max}^{0.1\,M\,HCl}$ 294 mμ (ε, 5030).

t-Butyltropylium perchlorate (Id) was obtained as white crystals by the same procedure as was used in the preparation of Ia except that the reaction time was prolonged to 2 hr; 64.0% yield; mp 179.0—180.0 °C (dec); $\lambda_{max}^{0.1\,M\,HCl}$ 293 mμ (ε, 4880).

Phenyltropylium fluoroborate (Ie) was prepared as yellow crystals by the same method, except that triphenylmethyl fluoroborate was used instead of perchlorate salt; 74.9% yield; mp 151.0—152.0 °C (lit, mp 153—154 °C[22]); $\lambda_{max}^{0.1\,M\,HCl}$ 226 mμ (ε, 37700), 270.5 mμ (14800), 368 mμ (16200).

Triphenylmethyltropylium fluoroborate (If) was synthesized by an essentially similar method. In a 100-ml two necked flask equipped with a thermometer and a reflux condenser connected to soda lime tube, we charged a solution of 0.330 g (1.00 mmol) of triphenylmethyl fluoroborate in 15 ml of acetonitrile. To this solution was then added 0.336 g (1.04 mmol) of thermally-isomerized triphenylmethylcycloheptatrienes, and the whole mixture refluxed for 6.5 hr. The reaction mixture was then evaporated *in vacuo*, pulverized in 7 ml of freshly-added ethyl acetate, and evaporated again. Then an 18-ml portion of ethyl acetate was added;

The solution of chromous chloride in 10% HCl was prepared as has previously been reported.[3]

One-Electron Reduction of the Substituted Tropylium Ions with Cr(II). In a 100-ml, four-necked flask equipped with a magnetic stirring bar, a serum rubber cap, and a nitrogen inlet and outlet, there was charged a solution of 0.258 g (1.05 mmol) of Id in 40 ml of 10% HCl. To this solution was then added 5 ml of 1 M solution of chromous chloride in 10% HCl (5 mmol) by the use of a hypodermic syringe under an atmosphere of nitrogen. The reaction mixture immediately became cloudy with an organic substance dispersed in the solution. The mixture was stirred for 10 min and worked up in the usual way to give 0.157 g (0.534 mmol) of *x,x'*-di-*t*-butylbitropyl as a viscous oil; 100.1% yield; NMR, τ_{CCl_4} 3.3—4.1 (m, 6.2H, H^{3-6}), 4.7—5.1 (m, 3.8H, $H^{2,7}$), 8.2 (s, 2H, H^1), 8.8, 8.9 (two s, 18H, *t*-butyl). Reductions of Ia, b, c, e, and f were carried out in the same way. The ultraviolet spectra and the results of the elementary analyses of all the products are tabulated in Table 4.

Kinetic Measurements. The reaction rate was measured in 10% HCl at 25.0±0.2 °C by a method reported previously.[3] The products were determined by ultraviolet spectroscopy using the characteristic bands listed in Table 4.

Measurements of the Charge-Transfer Bands with Pyrene. In 5 ml of the solution of pyrene in 1,2-dichloroethane (0.2 M) was dissolved 2—4 mg of the purified sample of the substituted tropylium ion salt, so that the concentration of the cation became 2×10^{-3} g-ion/l. A red color immediately developed; the visible spectrum was then recorded to give the results shown in Table 3.

Determination of pK_{R^+}*'s.* The determination of the pK_{R^+} in 23% aqueous ethanol was carried out spectrophotometrically following the method of Breslow and Chang.[10] The ultraviolet spectrum was recorded on each cation in nine or ten solutions of buffer spaced through a pH range of about two units on each side of the pK_{R^+}. The buffer solutions were made up from various mixtures of 0.1 M citric acid and 0.2 M Na_2HPO_4 according to the procedure of Gomori.[23] The absorbancy at a wavelength characteristic of the cation, described above, was plotted against the pH to give a classical titration curve, whose mid-point was taken as the pK_{R^+}. The pH's were read on a Horiba model H pH meter calibrated with standard buffers before use.

Polarography. The polarograms were obtained on the solutions of the respective cations in acetonitrile (1.0×10^{-3} g-ion/l) containing $Et_4N^+ClO_4^-$ (0.5 M) as the supporting electrolyte at 25 °C. As the reference electrode, we used the Ag/AgCl electrode described by Popov and Geske,[24] whose potential was found to be −0.162 V *vs.* SCE.

The Nickel-catalyzed Cyclodimerization of Butadiene. The Synthesis of 2-Methylenevinylcyclopentane and the Isomerization of 1,3,7-Octatriene

Jitsuo KIJI, Kazuyoshi YAMAMOTO, Shin-ichi MITANI, Susumu YOSHIKAWA, and Junji FURUKAWA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received November 10, 1972)

A catalyst system of $NiX_2(R_3P)_2$–$NaBH_4$ or –R'ONa (X=halogen, R and R'=alkyl) was found to yield 2-methylenevinylcyclopentane (MVCP) and *n*-octatrienes (OT), depending on the amount of $NaBH_4$ or R'ONa, which act as a reducing agent for the nickel halide. Less than an equimolar amount of the reducing agent provides a catalyst for MVCP, whereas an excess amount provides that for *n*-octatrienes. In the latter case, the nickel halide is reduced to zero-valent nickel, which then reacts with hydrogen halide to give a catalyst for MVCP again. The catalyst (<2 : 1 ratio of reducing agent : Ni) was also effective in the isomerization of 1,3,7-octatriene to MVCP.

Some nickel catalysts have been reported to be effective catalysts for the novel cyclodimerization of butadiene to give 2-methylenevinylcyclopentane (MVCP).[1-3] Organonickels, such as arylnickel- or π-allylnickel halide, are typical catalysts which are used in the presence of a controlled amount of alcohol. The other type of the catalyst is a phosphine complex of nickel halide combined with organolithium. In both cases, the nickel compounds might be reduced by alcohols or organolithium to an active nickel species. On the other hand, sodium borohydride is an effective reducing agent for the preparation of transition-metal catalysts and is also used for the linear dimerization of butadiene by a nickel catalyst.[4,5] A mixture of cobalt halide and sodium borohydride is also effective for the dimerization of butadiene; an important intermediate has been isolated, and its structure has been studied crystallographically.[6]

It is well-known that the phosphine complex of platinum halide is also reduced to a stable platinum hydride by the action of alcoholic potassium hydroxide.[7] A similar reduction can be anticipated for nickel salts.

$$PtCl_2(Et_3P)_2 + CH_3CH_2OH + KOH \rightarrow PtHCl(Et_3P)_2 + CH_3CHO + KCl + H_2O \quad (1)$$

It has now been found that tri-*n*-butylphosphine complexes of nickel halides $NiX_2(n\text{-}Bu_3P)_2$, combined with sodium borohydride or sodium alkoxide, are also effective for the cyclodimerization of butadiene to MVCP, when the reducing agent is controlled to an equimolar amount. This paper will deal with the cyclodimerization of butadiene and the isomerization of 1,3,7-octatriene. An effort has been made to find the relationship between the two catalysts, which give linear dimers or MVCP.

Results and Discussion

When bis(tri-*n*-butylphosphine)dibromonickel and sodium borohydride or sodium alkoxide were mixed in equimolar quantities in alcohol, a yellowish-brown solution was obtained. This solution smoothly dimerized butadiene under a slightly high pressure at between 80 and 100 °C to give 2-methylenevinylcyclopentane(MVCP). In the catalyst system, the amount of sodium borohydride or sodium alkoxide plays an important role and has a strong influence on the product distribution. First, the conditions were decided under which MVCP could be formed selectively. Table 1 summarizes the effect of the amount of the reducing agent on the distribution of the dimers. In most cases, butadiene was not unchanged by the reaction. The product other than the dimers was *trans*-1,4-polybutadiene. To obtain MVCP selectively, an amount of sodium borohydride or sodium alkoxide equimolar to the nickel salt was necessary. The effect of the amount of alkoxide is shown in Fig. 1. If the nickel salt was combined with an excess (more than 1 mol) of the reducing agent, a conventional linear dimerization occurred and *n*-octatrienes were the main products.

By analogy to the reaction of platinum with alcoholic potassium hydroxide, the formation of the

a) At 80 °C for 24 hr. b) MVCP, 2-methylenevinylcyclopentane; OT, mixture of isomeric *n*-octatrienes; VCH, 4-vinyl-1-cyclohexene; COD, 1,5-cyclooctadiene.

nickel hydride caused by alkoxide may be assumed (Eq. 2) when an equimolar amount of alkoxide is used. Until now only a few nickel hydrides have, however, been isolated in a stable form.

$$NiBr_2(n\text{-}Bu_3P)_2 + CH_3ONa \rightarrow [HNiBr(n\text{-}Bu_3P)_2] + NaBr + CH_2O \quad (2)$$

It has been reported that bis(tri-propylphosphine)-hydridochloronickel, $HNiCl(i\text{-}Pr_3P)_2$, is unstable and decomposes at room temperature.[9] Therefore, the hydride transiently formed according to Eq. 2 may be assumed to decompose at the reaction temperature, probably through the reductive elimination of hydrogen bromide to give an active nickel catalyst for the cyclodimerization.

$$HNiBr(n\text{-}Bu_3P)_2 \rightarrow HBr + [Ni(n\text{-}Bu_3P)_2] \quad (3)$$

Another possibility for the activation of the catalyst is that the nickel-hydrogen bond is activated by the coordination of butadiene, as in the case of the alkylnickel catalyst.[10,11] Stable $HNiCl[(C_6H_{11})_3P]_2$ has been synthesized by the reaction of $NiCl_2[(C_6H_{11})_3P]_2$ with sodium borohydride,[8] but it has no catalytic activity by itself. However, it shows a catalytic activity for the linear dimerization of butadiene in the presence of alcohol, although not for that of amine and phenol, and gives octatrienes.[12] The cyclodimerization proceeds satisfactorily in the presence of strong donor phosphines, such as tri-*n*-butylphosphine. Tricyclohexylphosphine possesses a basicity similar to that of tri-*n*-butylphosphine.[13] In the dimerization of butadiene, the bulky cyclohexyl group on phosphorus prevents the cyclodimerization to the five-membered cycle.[3] It seems reasonable to assume, on the basis of the reduction of organometals by alcohol,[14] that stable $HNiCl[(C_6H_{11})_3P]_2$ is reduced further by alcohol in the presence of butadiene, and that only after the reduction does it show the catalytic activity for the dimerization.

$$HNiCl[(C_6H_{11})_3P]_2 + C_2H_5OH \rightarrow H_2 + \{Ni[(C_6H_{11})_3P]_2\} + CH_3CHO + HCl \quad (4)$$

During this reduction or during the decomposition described above, hydrogen halide is liberated; it appears to play an important role as a cocatalyst, and

the product distribution seems to vary with the concentration of hydrogen bromide. To confirm this, we examined the effect of hydrogen halide on the catalyst composed of $NiBr_2(n\text{-}Bu_3P)_2$ and an excess of sodium alkoxide. Hydrogen bromide was added incrementally to the catalyst, which gives linear dimers. The results of this study are shown graphically in Fig. 2; the reversibility of the cyclodimerization catalyst formation is there demonstrated.

The catalyst was prepared by the reaction of $NiBr_2(n\text{-}Bu_3P)_2$ with sodium methoxide (molar ratio 1 : 5) in 2-propanol. After confirming that the catalyst of this composition is effective for the linear dimerization, but not for MVCP, dry hydrogen bromide was added; the cyclodimerization catalyst was found to be thus regenerated. It is assumed that the decomposition or the reduction of the nickel hydride proceeds according to Eq. 3 or 4, and that the hydrogen bromide formed during this process in neutralized with the excess of alkoxide. It has been observed that the addition of hydrogen bromide in a 3 : 5 molar ratio of HBr: alkoxide (point (b) in Fig. 2) is still ineffective for the cyclodimerization and that *n*-octatrienes are thus formed mainly. In this region (from (a) to (b)), the isomerization of 1,3,7-octatriene to 2,4,6-octatriene decreases with an increase in the amount of hydrogen bromide, because the isomerization is catalyzed by a strong base.[15] Under these conditions, all the hydrogen bromide is neutralized by alkoxide; thus, the solution is "basic." When more hydrogen bromide (point (c)) is added, the solution reveals the catalytic activity for the cyclodimerization. At this point the molar ratio of free hydrogen bromide to nickel is assumed to be 1 : 1. Beyond this point, the further addition of hydrogen bromide produces a color change from yellow to green; this change can reasonably be attributed to the formation of the original nickel bromide, and no reaction of butadiene occurs. These observations lead to a conclusion concerning the hydrogen bromide (generally speaking, hydrogen halide) stoichiometry for the activation of the catalyst. The ratio of hydrogen bromide to zero-valent nickel must be 1 : 1 for the cyclodimerization. This reaction is demonstrated by Eq. 2. Zero-valent nickel and hydrogen bromide are formed through the transient formation of the nickel hydride, followed by rapid decomposition (Eq. (3)) or by further reduction by alcohol (Eq. (4)), when the catalyst is prepared by the equimolar reaction of $NiBr_2(n\text{-}Bu_3P)_2$ with sodium borohydride or sodium alkoxide in alcohol. The catalyst which have been reported in the previons paper[3] also satisfy these conditions. Once zero-valent nickel is formed, the formation of the bis-π-allylic intermediate (II), which is described below, is a well-known reaction.[16,17] The stabilization by forming a chelating bis-π-allylic complex seems to be a driving force for this reaction.

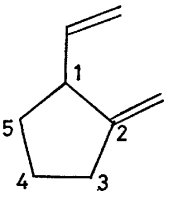
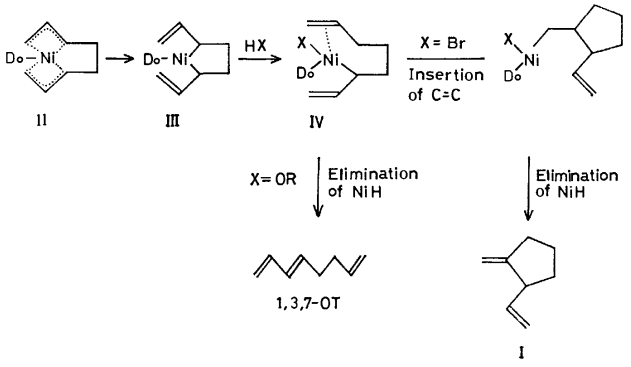
If butadiene reacts with the nickel hydride before the reduction (Eq. (4)) or the decomposition (Eq. (3)), it forms a π-crotyl nickel.[18] This possibility can also be excluded by the observation that the position of the deuteration of the dimer (I) is at the 3-carbon atom when the dimerization is carried out in deuterium-labelling alcohol.[1]



I

Therefore, in contrast to the rhodium-catalyzed dimerization of ethylene studied by Cramer,[19] where a metal hydride initiates the dimerization, nickel hydride or hydrogen bromide does not participate in the initiation reaction. Detailed information on the role of hydrogen bromide could not be obtained from the present study, but it appears that the bromide promotes the further insertion of one terminal double bond into the Ni–C bond to give the cyclic dimer before the elimination of nickel hydride.



Scheme 1

Solvent. This cyclodimerization involves the migration of one hydrogen atom. It has been already proposed that alcohol participates in this reaction.[3] For this reason, in most of our studies alcohol was employed. Primary and secondary alcohols were effective for the reaction, but tertiary alcohol, benzene, tetrahydrofuran, and dimethyl sulfoxide were ineffective. In *t*-butylalcohol and dimethyl sulfoxide, *trans*-1,4-polybutadiene was the main product, while in benzene and tetrahydrofuran no appreciable reaction occurred and butadiene was recovered unchanged. In triethylsilane, no reaction of the nickel salt with sodium borohydride occurred, butadiene and triethylsilane being recovered. However, if ethanol was present in the silane, MVCP was formed in a considerable amount (≈30%). In this case, though, no product due to hydrosilation was detected.

Other Nickel Salts. The best results were obtained with tri-*n*-butylphosphine complexes of nickel

18) C. A. Tolman, *J. Amer. Chem. Soc.*, **92**, 6777 (1970).
19) R. Cramer, *ibid.*, **87**, 4717 (1965).

bromide and chloride. Since a crystalline complex could not be obtained by the reaction of nickel iodide with tri-*n*-butylphosphine, the catalytic activity of the iodide analogue has not been examined. However, it has been previously reported that (*o*-tolyl)NiI-$[(C_2H_5)_3P]_2$ is highly effective for the cyclodimerization in the presence of alcohol.[2] Therefore, hydrogen iodide has a similar effect on the reaction. The tri-*n*-butylphosphine complex of the nitrate and triphenylphosphine complexes of the bromide and the chloride gave a mixture of MVCP, *n*-octatrienes, and low-molecular-weight polybutadiene. No reaction of butadiene occurred when the isothiocyanate was used as a catalyst. The cyanate complex gave polybutadiene.

The effects of the other electron donors as auxiliary ligands have also been studied. Strong electron donors, such as tri-*n*-butylphosphine and diethylphenylphosphine, are best. The presence of an excess amount of phosphine (>2 : 1 ratio of phosphine : Ni) suppresses the formation of the dimers. The strong electron donors favor the formation of the σ-allyl complex (III), which is a transient form occurring before the alcoholysis and the cyclization. Bidentate phosphines and amines are not effective.

Isomerization of 1,3,7-*Octatriene.* 1,3,7-Octatriene may be expected to react further in the presence of the catalyst. One possibility is an isomerization through the π-allyl nickel intermediate (II), which is assumed to be formed by an intramolecular transfer of hydrogen, followed by alcoholysis. Another possibility is the direct reaction of 1,3,7-octatriene with nickel hydride to form the intermediate (IV). If this is true, it is possible to isomerize 1,3,7-octatriene to MVCP. From this point of view, the isomerization has been studied. The results are shown in Fig. 3. The nickel complex, when combined with less than 2 moles of alkoxide, isomerized 1,3,7-octatriene to MVCP. If more alkoxide was used, only the isomerization of the double bond occurred to give 2,4,6-octatriene; *e. g.*, the base-catalyzed isomerization was predominant. The other products were high-boiling oligomers.

To gain insight into the isomerization, the deuterium-labelling experiment was particularly instructive; it will, therefore, be described in some detail. Hexadeutero-1,3-butadiene and its dimer (1,3,7-OT) were used for this purpose. A solution of 0.5 mmol of $NiBr_2(n\text{-}Bu_3P)_2$, 10 mg of sodium borohydride, and 1 ml of liquified hexadeuterobutadiene were heated in 1 ml of ethanol in a sealed glass tube at 80 °C for 24 hr. The deuterated MVCP thus formed showed only one broad singlet, around 7.7 τ. Isotope (H)-labelling occurred on the 3-carbon atom. The position of the hydrogen can be explained by the assumption that the reaction proceeds through the bis-allylic nickel intermediate (II), which has been discussed previously.[1] On the other hand, 0.5 ml of perdeutero-1,3,7-octatriene was treated with 1 mmol of $NiBr_2(n\text{-}Br_3P)_2$ and sodium ethoxide in 1 ml of ethanol at 80 °C for 24 hr. The MVCP which was obtained from this isomerization showed a broad singlet around 8.2 τ. This signal is assigned to a hydrogen on the 4- or 5-carbon atom (in I). In a separate experiment we have confirmed that MVCP is stable toward the action of the catalyst under these conditions and that no appreciable exchange of hydrogen with a solvent occurs after it is formed.[20] Thus, the position of the hydrogen is quite different between these two experiments. This fact shows that the isomerization of 1,3,7-octatriene to MVCP does not proceed through the bis-π-allylic intermediate (II), which is anticipated to be formed by the nickel-catalyzed C_6—C_4 shift of hydrogen. In this case, an addition of nickel hydride occurs on the 3- and 4-carbon atoms, followed by cyclization to give the five-membered cycle, *i. e.*, nickel hydride-initiated isomerization.

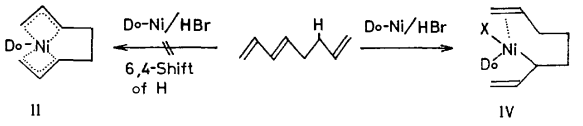

Scheme 2

This is different from the cyclodimerization of butadiene described above, which is not initiated by the addition of butadiene to the nickel hydride.

Experimental

The phosphine complexes of nickel salts were prepared by a method described earlier.[3] Commercially-available butadiene was dried over a 3A Molecular Sieve. The hexadeuterobutadiene was prepared from hexachlorobutadiene by the method of Morse.[21] The 1,3,7-octatriene was synthesized by the dimerization of butadiene with a palladium catalyst.[22] The dry hydrogen bromide was generated by adding bromine to tetralin.[23] All the solvents were purified by the conventional method and were distilled under a nitrogen atmosphere.

Gas-chromatographic analyses were carried out on a column, Silicone DC 550 on Celite, 3 m, at 100 °C. The products were identified by comparing the retention times and,

if necessary, the infrared and NMR spectra with those of authentic samples after separation by gas chromatography.

Cyclodimerization of Butadiene. *(i) Sodium Borohydride Method*: The nickel phosphine complex and the sodium borohydride were placed in a glass tube (20 mm in diameter). The tube was immediately fitted with a three-way stapcock. The system was placed under nitrogen by evacuating and by then filling it with nitrogen several times. When the solvent was added at room temperature, the solution turned brown or yellow, depending on the amount of sodium borohydride used. The reaction was instantaneous. The tube was cooled to −78 °C in a dry ice–acetone bath; then, liquified butadiene was added by means of a syringe through the three-way stopcock under a nitrogen atmosphere. The tube was sealed with a flame and heated. The yields of the products were determined gas chromatographically.

(ii) Alkoxide Method: To an alcoholic solution of the nickel complex in the glass tube we slowly added a 1 M solution of alkoxide by means of a syringe. At −78 °C, liquified butadiene was added, after which the tube was sealed with a flame and heated. The detailed reaction conditions and the results are given in Table 1.

Studies on Reversibility of Catalyst. The catalyst solution was prepared by the reaction of 10 ml of a 0.15 M 2-propanol solution of $NiBr_2(PBu_3)_2$ with 1.5 ml of a 5 M methanol solution of sodium methoxide. To this solution, a small amount of butadiene was then added; the mixture was allowed to stand overnight at room temperature. Five sets of experiments were made with this solution. After confirming that the only products were *n*-octatrienes and octadienyl ether, 2 ml of this solution was transferred to the glass tube under a nitrogen atmosphere. To each solution a definite amount of dry hydragen bromide was added as a 1.5 M 2-propanol solution, and then a 20-mmol portions of liquified butadiene was added at −78 °C. The tube was subsequently sealed and heated at 80 °C for 18 hr. The results are shown in Fig. 2.

Isomerization of 1,3,7-Octatriene. To the catalyst solution, 1,3,7-octatriene, instead of butadiene, was added. The mixture was then allowed to react in the sealed tube. The results are shown in Fig. 3.

Solvolysis of *cis*- and *trans*-4-*t*-Butylcyclohexyl Tosylates in *N*-Methylacetamide. Rates and Products Distribution

Seiki Saitô, Tatsumi Yabuki, Toshio Moriwake, and Kunio Okamoto*

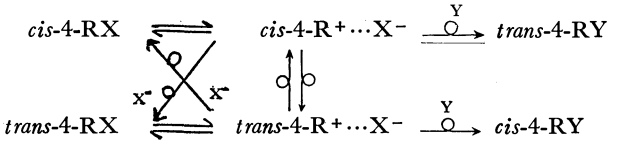
Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700

**Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606*

(Received November 16, 1972)

Solvolysis of *cis*- and *trans*-4-*t*-butylcyclohexyl tosylates (RX) in wet *N*-methylacetamide (H_2O content: 0.06—0.94 wt%) was carried out to give olefins (77—93%), 4- and 3-*t*-butylcyclohexyl acetates (ROAc) (6—22%), and 4- and 3-*t*-butylcyclohexanols (ROH) (2—4%). In *N*-methylacetamide with water (0.06%, wt) *trans*-4-RX gave *cis*-4-ROAc containing 18% *trans*-4-ROAc whereas *cis*-4-RX yielded *trans*-4-ROAc containing only 3% of *cis*-4-ROAc. In the course of solvolysis (75% completion) *trans*-4-RX was isomerized to *cis*-4-RX (5.9%), whereas *cis*-4-RX gave only 0.3% *trans*-4-RX. These results are characteristic of solvolysis in this amide solvent when compared with those in other hydroxylic solvents. Stereochemical results obtained from the present studies on the solvolysis in *N*-methylacetamide can not be explained by the hypothetical hydrogen-bridged carbonium ion intermediate proposed for the solvolysis of *cis*-4-RX. The nature of *N*-methylacetamide as a solvolytic solvent is discussed especially with regard to the effect of its polymeric structure on the steric course of solvolysis.

In previous studies on the solvolysis of *cis*- and *trans*-4-*t*-butylcyclohexyl tosylates (RX) in various hydroxylic solvents such as phenol, acetic acid, or 60% aqueous acetone, we demonstrated that the solvolytic *cis-trans* isomerization and 1,2-rearrangement of these tosylates, which respectively afford their geometrical isomers and their 3-derivatives (*cis*-and *trans*-3-RX), occur concurrently.[1] It was concluded that an appreciable part of the retained products is actually produced by double inversion, as is shwon in the following scheme, and the hypothesis of the hydrogen-bridged carbonium ion intermediate[2] is not necessary for an explanation of the formation of the retained products.



(X=OTs, Y=Nucleophile)

Scheme 1.

An investigation of these phenomena was extended to a non-hydroxylic solvent, solvolysis of this system in *N*-methylacetamide being carried out. This amide is known to possess a large dielectric constant[3] and

would be a typical solvolytic solvent. It is anticipated that the negative end of the dipole could probably solvate the carbonium ion more strongly than that of the hydroxylic solvents.

In this paper we report on the results of examination of solvolytic *cis-trans* isomerization and 1,2-rearrangement of tosylates, as well as of the rates and products studies on the solvolysis of *cis*- and *trans*-4-RX in *N*-methylacetamide. The factors determining the steric course of solvolysis are discussed in connection with the nature of the amide as a solvolytic solvent.

Results and Discussion

The solvolysis of both *cis*-4-RX and *trans*-4-RX was carried out in *N*-methylacetamide containing a small amount of water (0.06—0.94 wt%) and pyridine (equimolar amount to the tosylate). The yields and compositions were determined by means of vpc. The compositions of recovered tosylates from partially-solvolyzed reaction mixtures were determined by the method previously reported.[1b] The data are summarized in Tables 1 and 2 together with data pertinent to other solvent systems.

Both tosylates displayed good first-order behavior and the reaction proceeded at a similar rate to that of ethanolysis.[2a] This is in line with the expectation based on the Y value of *N*-methylacetamide.[4,5] As observed in S_N1 solvolysis in other solvents,[2,6] *cis*-4-RX is solvolyzed more rapidly than *trans*-4-RX in

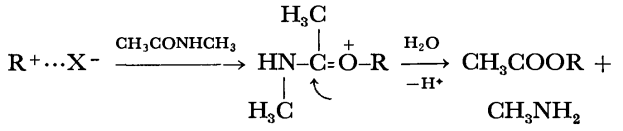
the amide by a factor of 4.0 at 75 °C (2.5—3.1 for other solvents) (Table 1). The kinetic results imply that *N*-methylacetamide is a typical solvolytic solvent.

The major product of solvolysis in the amide for both tosylates has been proved to be an olefin, exclusively 4-*t*-butylcyclohexene. This is in sharp contrast to the case of other solvent systems in which small amounts of isomeric 3- and 1-*t*-butylcyclohexenes are accompanied with 4-*t*-butylcyclohexene.

The substitution products for both tosylates are composed of a major portion of 4- and 3-*t*-butylcyclohexyl acetates (ROAc) and a minor portion of 4- and 3-*t*-butylcycohexanols (ROH). The formation of ROAc could be elucidated by a mechanism similar to the nucleophilic intervention by acetone to furnish an oxonium ion in the solvolysis of 2-octyl brosylate in 80% methanolic acetone.[7] Thus, nucleophilic attack by the amide on $R^+\cdots X^-$ would be likely to produce an oxonium ion whose subsequent reaction with water furnishes ROAc as follows.



The yields of ROAc for solvolysis in the amide containing various amounts of water is a function of water concentration. This means that the second step in the above scheme is $B_{AC}2$ between the carbonyl-carbon in the pre-formed oxonium ion and water.

The composition percentage of the retained ROAc (18%) produced from the *trans*-4-RX (H_2O content: 0.06 wt%) significantly exceeds that of ROAc (3.1%) produced in the *cis*-4-RX solvolysis (H_2O content: 0.06 wt%), the formation of the rearranged ROAc being substantially less favored particularly in the case of *cis*-4-RX solvolysis. The results differ from those for the other solvent systems[2,6] (Table 1). It should be noted that the abnormal stereochemical results are incompatible with the expectation from the hypothetical hydrogen-bridged carbonium ion intermediate,[2] since such a carbonium ion should produce much of the retained or rearranged products *in the cis-4-RX solvolysis.*

The nature characteristic of this amide solvent became more evident when the composition of the recovered tosylates was examined (Table 2).

The extent of 1,2-rearrangement of the tosylate is greatly diminished, being comparable with the significant decrease in the rearranged products. Solvation of the cation by the amide in $R^+\cdots X^-$ may suppress the migration of β-hydrogen.

With regard to the superiority of *trans-cis* isomerization (5.9%) over *cis-trans* isomerization (0.3%), the following explanations are given. The amide might be operative as a nucleophile in the form of an extended polymer,[8] which would diminish the extent of attack by amide on *trans*-4-$R^+\cdots X^-$ from the back, since the approach of such a bulky nucleophile should enlarge the steric repulsion toward 1,3,5-triaxial hydrogens.[9] This would make it possible for the released tosylate anion (X^-) to compete affectively with polymerized amide to produce *cis*-4-RX from *trans*-4-RX by the S_N2-like attack on *trans*-4-$R^+\cdots X^-$ from the back (Scheme 1).

The decrease in the extent of retention for ROAc in the higher water contents, observed in the case of *trans*-4-RX solvolysis, might be explained as follows. The increase in water content lowers the degree of association of amide, increasing the extent of attack by the amide from the back on *trans*-4-$R^+\cdots X^-$, and decreasing the retained ROAc (Table 1).

The fact that the compositions of ROAc and ROH vary with the change in water content of the amide suggests the existence of an intermolecular complex between water and the amide, which competes with polymerized amide as a nucleophile to produce ROH.

Experimental

Materials. *N*-Methylacetamide was prepared according to Alelio and Ried,[10] and the water content was determined by means of Karl Fischer titration. *trans*-4-*t*-Butylcyclohexanol was prepared by the method of E. L. Eliel *et al.*,[11] other reagents being provided by the methods previously reported.[6]

Rate Measurements. Titrimetric rates were followed by placing the flask containing reaction mixture into an oil bath (75 °C±0.03) and removing 1 ml of an aliquot at various time intervals. The aliquots were transferred to a separatory funnel using 20 ml of ether and the ether solution was extracted three times with 10 ml of water. The aqueous solution was titrated with a standard aqueous sodium hydroxide using phenolphthalein as an indicator. It was not possible to obtain an experimental infinity titer, and therefore, tosylate concentrations at time t were calculated on the basis of the theoretical infinity titer. The rate constants were calculated graphically and are shown in Table 1, footnote (d).

Product Analysis and Unchanged Tosylate Analysis. The procedures were carried out as reported.[1b] except for the use of tlc for the separation of mixtures of products instead of column chromatography. The results are shown in Tables 1 and 2.

7) H. Weiner and R. A. Sneen, *J. Amer. Chem. Soc.*, **85**, 2181 (1963); **87**, 287 (1965).

8) It is considered that the much higher dielectric constant of *N*-methylacetamide is due to the formation of extended polymer by hydrogen bonding (Ref. 3).

9) The axial approach of the incoming amide should be hindered to a greater extent than the equatorial approach. For instance, S_N2 rate ratio ($k_{cis}/k_{trans}=31$ for the reaction of 4-*t*-butylcyclohexyl system with sodium thiophenoxide in 87% ethanol) is much greater than the value *ca.* 3 as expected from the ground-state energy differences alone (E. L. Eliel and R. S. Ro, *J. Amer. Chem. Soc.*, **79**, 5995 (1957)). Thus, the equatorial derivative undergoes S_N2 displacement more slowly, owing to its larger steric hindrance to the approach of the nucleophile in addition to its lower ground-state energy than the axial isomer. Synthesis and Reactions of α-Bromoaroylacetarylamides

Ahmad S. SHAWALI,* Mohammed I. ALI, and Abdelgawad A. FAHMI
Department of Chemistry, Faculty of Science, University of Cairo, Giza, Egypt
(Received April 20, 1972)

Benzoylacetanilide and fourteen of its substituted derivatives were brominated to give α-bromobenzoylacetanilides (I). The spectral data of I indicate that they exist mainly in the keto form. Reaction of I with phenylhydrazine yielded 4-phenylazo-1,3-diaryl-2-pyrazolin-5-ones (IV). Treatment of I with thiourea and thioacetamide gave 2-amino-4-arylthiazole-5-carboxanilides (XII) and 2-methyl-4-arylthiazole-5-carboxanilides (XIII), respectively. With excess of concentrated sulfuric acid or polyphosphoric acid, α-bromobenzoylacetanilides (I) were converted into 3-bromo-4-aryl-2-quinolones (XVI). Structural assignments were based on the elemental and spectral analyses.

Aroylacetarylamides are readily available,[1] but there have been no reports on the preparation and reactions of α-bromoaroylacetarylamides (I) and their α-iodo analogs (II). Very little is known about α-chloro derivatives (III).[2] Thus, from an interest in the chemistry of aroylacetarylamides,[1,3] we have studied the preparation of two series of the α-halo derivatives (I—II) and some of their reactions.

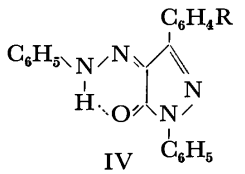
When benzoylacetanilide in acetic acid solution was treated with an equimolar amount of bromine in the same solvent, α-bromo derivative (Ia) was obtained in 80% yield. The other α-bromobenzoylacetanilides (Ib—o) were prepared from the corresponding benzoylacetanilides in a similar manner.

The structure assignment of I was based on elemental and spectral analyses. Thus, the NMR spectrum of Ia ($CDCl_3$) showed a multiplet absorption due to ten protons at δ 8.25—7.65 ppm and two one proton singlets at δ 4.90 (–COCHBr–) and 9.43 (–CONH–) ppm. Its IR spectrum (KBr) showed a benzoyl CO band at 1715 cm^{-1} and an anilide CO band at 1665 cm^{-1}. The high frequency position for the benzoyl carbonyl, which ordinarily falls near 1705 cm^{-1}, might be expected in view of the presence of bromine substituent on the α-carbon atom. The identity of the bromination products was also confirmed by treatment of I with acidified potassium iodide[4] to give the parent benzoylacetanilides.

It has been reported[1] that the electronic absorption pattern of benzoylacetanilides in ethanol was in each case characterised by the presence of two maxima in the 305—350 and 240—280 nm regions. These were assigned to the cinnamoyl and benzoyl chromophores of the enol and keto froms, respectively. In the UV spectra of the α-bromoanilides (Ia—o), the cinnamoyl band was absent; each exhibited only one band in the 240—270 nm region. This suggests that the α-bromobenzoylacetanilides (Ia—o), unlike their parent compounds, exist mainly in the keto form in ethanol. This might be ascribed to the instability of the enol form of I which probably results from the large steric interaction between the voluminous bromine atom and the benzene nuclei.[5]



IV

a, R=H; b, R=4-Cl; c, R=4-Br; d, R=4-CH_3O

When Ia was heated with phenylhydrazine in acetic acid for 3 hr, it gave 1,3-diphenyl-4-phenylazo-2-pyrazolin-5-one (IVa). The structure of IVa was established by comparing it with an authentic sample prepared by coupling 1,3-diphenyl-2-pyrazolin-5-one with benzenediazonium chloride.[6] They were found to be identical. In order to explain this, we propose the two mechanisms represented in scheme 1 for the reaction of I with phenylhydrazine. The conversion of V into VI (or X into VIII) is similar to that for the preparation of 2-pyrazolin-5-one derivatives by the reaction of β-keto esters with phenylhydrazine.[7] This was also supported by our finding that the α-bromoanilides, If and Ij yielded IVa only when they were similarly treated with phenylhydrazine. The oxidation of the proposed hydrazine intermediates VII or IX into VIII or X, respectively, is probably effected by

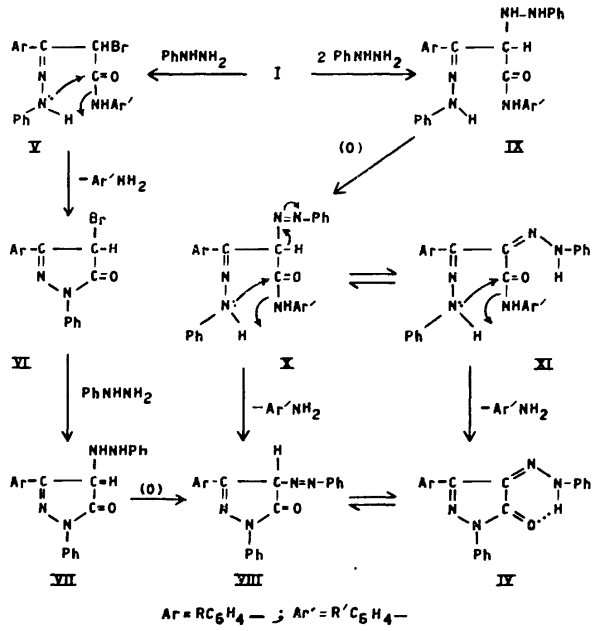

Scheme 1.

atmospheric oxygen during the course of refluxing the reaction mixture. In many cases, atmospheric oxygen suffices for such oxidation of hydrazines.[8]

Treatment of the other α-bromobenzoylacetanilides (Il, In, and Io) with phenylhydrazine in the manner described above afforded the corresponding 4-arylazo-2-pyrazolin-5-ones (IVb, IVc, and IVd), respectively. The structures of the unreported compounds in series IV were derived from their analytical and spectral data. The NMR spectrum of IVc in $CDCl_3$, as an example, exhibited a multiplet at δ 7.33 ppm due to aromatic protons and a singlet due to a highly deshielded proton at δ 13.89 ppm. The low field signal was assigned to hydrogen bonded NH group.[9] Such data indicate that the products IVa—d thus prepared exist in the assigned hydrazone structure IV. The IR spectra of IV are also compatible with this structure. Thus, each of the compounds (IVa—d) exhibited three characteristic bands at 1680 (lactam CO), 1610 (C=N), and 3280 (weak, hydrogen bonded NH) cm^{-1}.

α-Bromobenzoylacetanilides (I), when heated with thiourea, readily gave 2-amino-4-phenylthiazole-5-carboxanilides (XII). α-Bromoanilides (I) also, reacted with thioacetamide to give 2-methyl-4-phenylthiazole-5-carboxanilides (XIII). Both compounds XII and XIII have not yet been reported. Their structures were established by elemental analysis and a study of their spectral data. The UV absorption pattern of XII was in each case characterised by the presence of two maxima: one in the 320—327 (log ε 4.15$\pm$0.02) nm region and the other located between 240 and 245 nm (log ε 4.33$\pm$0.03). The 2-methyl analogs (XIII) absorb fairly intensively in the regions 306—315 (log ε 4.08$\pm$0.1) and 240—280 (log ε 4.29$\pm$0.6)

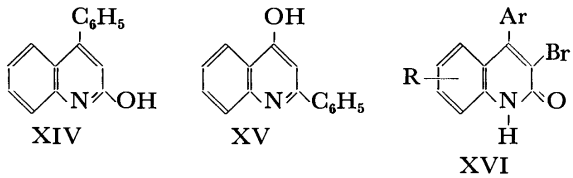
nm. All compounds (XII—XIII) showed amide-I band near 1660 cm^{-1} and an absorption band due to the C=N double bond stretching near 1620 cm^{-1} in their IR spectra. Compounds of series XII exhibited also absorption bands in the 3400—3285 cm^{-1} region due to the NH_2 stretching.

Benzoylacetanilide undergoes cyclization when heated with concentrated sulfuric acid or polyphosphoric acid (PPA) to give XIV or XV depending on the anilide to acid ratio.[10] Utilization of a higher proportion of acid in the reaction favours the formation of XIV. Cyclization of α-bromobenzoylacetanilides (Ia—o) is now being considered. With an anilide–acid (H_2SO_4 or PPA) ratio of 1: 10, the anilides I were converted into the corresponding 3-bromo-4-aryl-2-quinolones (XVI) in 60—80% yields. Attempts to cyclize α-bromoanilides If and Ij were, however, unsuccessful. This indicates that the ease of cyclization of substituted benzoylacetanilides is influenced by both the position and nature of the substituent present. In line with this finding is the observation that the nitro- and chloro-acetoacetanilides are appreciably decomposed to arylamines even with excess acid reagent.[10]



XIV XV XVI

Staskun[10] has assigned the 2-hydroxy structure XIV for the cyclized product of benzoylacetanilide. However, the spectral data of the compounds XVIa—d prepared revealed that they have the 2-oxo form (XVI). Thus, all compounds exhibited an NH stretching bands at 3312 and 3156 cm^{-1} and a strong CO band at 1650 cm^{-1}. The products XVIa—d gave no colour with alcoholic ferric chloride. The UV absorption maxima of XVIa, as a typical example of the series, in a series of different buffer solutions were not affected by a change in pH, a fact which seems to be compatible with the proposed 2-oxo form (XVI).

Experimental

Melting points are uncorrected. IR spectra were obtained for new compounds and were recorded on a Unicam SP 200G infrared spectrophotometer (1 mg/300 mg KBr). UV

spectra were determined from a Beckman DK spectrophotometer. NMR spectra were recorded on a Varian A-60 spectrometer with TMS as internal reference. Benzoylacetanilides were prepared from the appropriate arylamine and ethyl benzoylacetate.[11] Aroylacetanilides were reported by Shawali *et al.*[1]

Preparation of α-Bromoaroylacetarylamides (Ia—o). General Procedure: A solution of bromine (4.8 g, 0.03 mol) in glacial acetic acid (30 ml) was added dropwise over a period of 1 hr to the appropriate aroylacetarylamide (0.03 mol) dissolved in the same solvent (60 ml) with stirring at room temperature. After 2 hr, the mixture was poured into water and the precipitated solid was filtered. In some cases the resulting solid precipitated before dilution. The crude product was washed with water and recrystallized from dilute ethanol. The results are given in Table 1.

Preparation of 1-Phenyl-3-aryl-4-phenylazo-2-pyrazolin-5-ones, (IVa—d). A mixture of α-bromobenzoylacetanilide (Ia) (1.6 g, 0.005 mol) and phenylhydrazine (2 ml) in acetic acid (10 ml) was refluxed for 3 hr and cooled. The precipitated product was collected and recrystallized from acetic acid. The product obtained was identified as 4-phenylazo-1,3-diphenyl-2-pyrazolin-5-one (IVa), mp 172—173 °C. Mixed mp with an authentic sample (prepared by coupling of benzenediazonium chloride with 1,3-diphenyl-2-pyrazolin-5-one as described before[6]) showed no depression. When each of the α-bromoanilides Il, In, and Io was treated with phenylhydrazine following the same procedure as for Ia, compound IVa was the only product obtained.

The other α-bromoaroylacetanilides If, Ih, and Id reacted with phenylhydrazine and yielded the following derivatives of 5-pyrazolones: IVb, mp 205 °C (55%) (lit,[6b] 203—205 °C); IVd; mp 177 °C (70%) (lit,[6c] mp 176—177 °C) and IVc, mp 201°C (65%). a) Found: C, 59.89; H, 3.40; N, 4.58%. Calcd: C, 60.01; H, 3.33; N, 4.67%.

Conversion of I to 3-Bromo-2-quinolones (XVI). α-Bromoaroylacetanilide (0.005 mol) was added portionwise over a period of 20—30 min to warm concentrated sulfuric acid (10 g, *d*, 1.84, 98%) at 75—80°C, with manual stirring. Heating was continued for another 30 min at 95°C with stirring; the reaction mixture was then cooled and triturated with water. The resulting solid was collected by filtration and washed with 20 ml of aqueous sodium hydroxide (0.5M). Purification of the alkali insoluble product was effected by recrystallisation from ethanol. The mp and elemental analyses of the 3-bromo-2-quinolones prepared are given in Table 3. The same products XVIa—d were obtained when polyphosphoric acid was used in place of sulfuric acid. Anilides If and Ij could not be cyclized and were recovered unchanged when heated with concentrated sulfuric acid. When α-bromobenzoylacet-*p*-anisidide (Id) was similarly treated with the acid reagent, it gave a water solution product which could not be isolated.

A New Route for the Preparation of Pyrazolo[4,3-*c*]pyridines

Abdou Ahmed EL-SAYED and Masaki OHTA

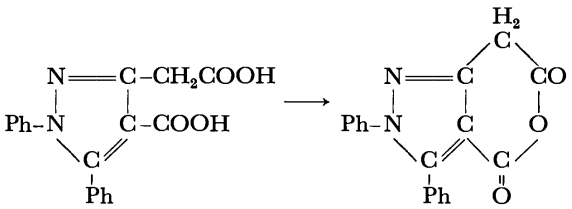
Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 16, 1972)

The anhydride (II) of 4-carboxy-1,5-diphenylpyrazole-3-acetic acid (I) has been prepared. The reactions of II with primary amines resulted in the formation of the monoamides IIIa—c. 2,3-Diphenylpyrazolo[4,3-*c*]-pyridine-(5*H*,7*H*)-4,6-dione (VIIa), has been obtained by heating the ammonium salt of I in a vacuum at 220 °C. The ring closure of IIIc with acetyl chloride in benzene afforded VIIb. Compound VIIb was coupled with benzenediazonium chloride to give the 7-phenylazo derivative (XII) and also condensed with aromatic aldehydes giving 7-arylidene derivatives (XV).

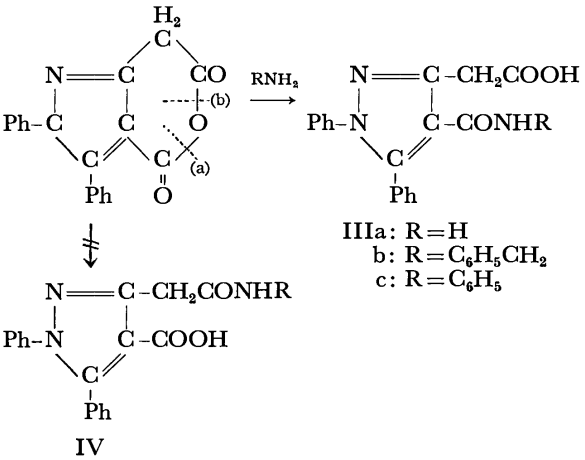
We recently, prepared 4-carboxy-1,5-diphenylpyrazole-3-acetic acid (I) through the condensation of 1-benzoyl-1-phenylhydrazine with diethyl acetonedicarboxylate.[1] We wish to report on some reactions of this acid.

We have found that the acid anhydride (II) was directly obtained by dehydration of the dibasic acid (I) with acetyl chloride in anhydrous dioxane.



I II

The reaction of II with primary amines in anhydrous dioxane resulted in the ring opening of the anhydride at position (a) with the formation of the corresponding amides IIIa—c, rather than at position (b) to give IV.

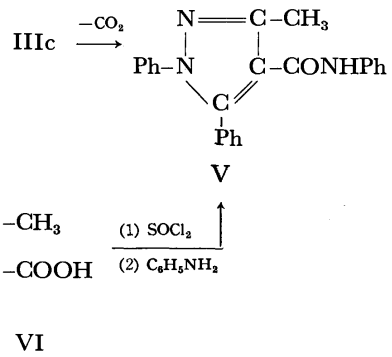


IIIa: R=H
b: R=$C_6H_5CH_2$
c: R=C_6H_5

IV

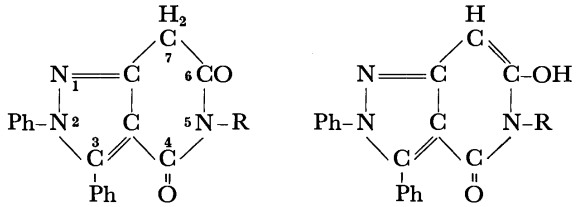
The structural elucidation of compounds III and confirmation of the ring opening of the anhydride (II) at position (a) were carrid out as follows:

Decarboxylation of the monoanilide (IIIc) at 250 °C yielded 1,5-diphenylpyrazole-4-carboxanilide (V) prepared from 4-carboxy-1,5-diphenyl-3-methylpyrazole *via* the acid chloride.[2]



V VI

Heating of the ammonium salt of I at 220 °C in a vacuum gave 2,3-diphenylpyrazolo[4,3-*c*]pyridine-(5*H*, 7*H*)-4,6-dione (VIIa). The 5-phenyl analogue (VIIb) was obtained by the action of acetyl chloride on the monoanilide (IIIc).

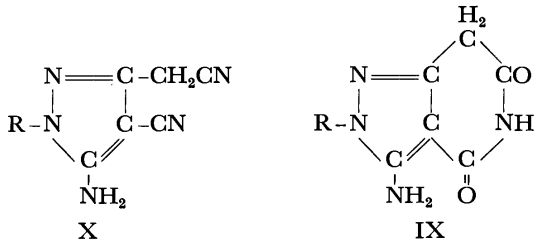


VIIa: R=H
b: R=C_6H_5

VIII

Compounds VII can also exist in the tautomeric structure VIII. However, the IR spectrum of the product shows two bands at 1720 and 1680 cm^{-1} assignable to two carbonyl groups but no absorption in the OH region. This is in favor of the keto structure VII.

A similar compound (IX) which has the same ring structure as VII was prepared by acidic hydrolysis of compound X.[3-5]



X IX

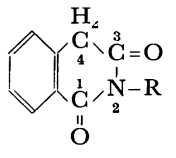
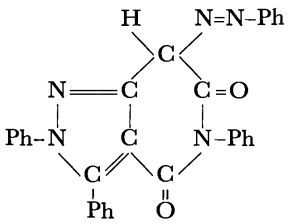
2) K. V. Auwers and H. Holleman, *Ber.*, **18**, 313 (1885).
3) T. Sato, *J. Org. Chem.*, **24**, 963 (1959).
4) E. C. Taylor and K. S. Hartke, *J. Amer. Chem. Soc.*, **81**, 2452 (1959).
5) E. C. Taylor and K. S. Hartke, *ibid.*, **81**, 2456 (1959).

The reactivity of the methylene group at position 7 in pyrazolo[4,3-*c*]pyridine derivatives (VII) proved to be similar to that of the 4-methylene group in homophthalimides (XI).[6,7]

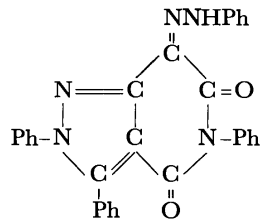


XI

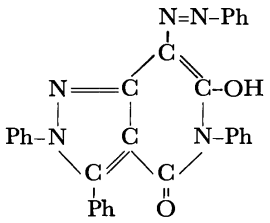
Thus, compound VII was coupled with benzenediazonium chloride to give the 7-phenylazo derivative (XII) which can also be formulated as either hydrazone (XIII) or azo-enol (XIV).[8]



XII



XIII



XIX

However, the IR spectrum of the product shows two absorption bands in the carbonyl region (1710, 1680 cm^{-1}), but not in either the OH or NH regions. This indicates that it exists mainly in keto-azo form XII.

Compound VIIb was also condensed with aromatic aldehyde in acetic acid to furnish the 7-arylmethylene derivatives XV in the presence of sodium acetate.

b: Ar = $C_6H_4Cl(p)$

Experimental

4-Carboxy-1,5-diphenylpyrazole-3-acetic Acid Anhydride (II). To a solution of 2 g of 4-carboxy-1,5-diphenylpyrazole-3-acetic acid (I) in 50 ml of anhydrous dioxane was added 10 ml of acetyl chloride and the mixture was boiled on a water bath for 30 min. The solution was concentrated and cooled and the solid that separated (1.9 g) was crystallized from benzene to give II as colorless prismatic crystals, mp 158 °C. Found: C, 71.32; H, 3.79; N, 9.41%. Calcd for $C_{18}H_{12}O_3N_2$: C, 71.04; H, 3.98; N, 9.21%. IR: 1795, 1760 cm^{-1}.

3-Carboxymethyl-1,5-diphenylpyrazole-4-carboxamide (IIIa). Dry ammonia gas was bubbled slowly through a solution of 1.0 g of the anhydride (II) in 30 ml of anhydrous dioxane solution. The ammonium salt of the product IIIa was separated within a few minutes. Water was added after the dioxane solution has been saturated with ammonia and the clear light yellow solution was acidified with 10% hydrochloric acid solution. The resulting precipitate was filtered off to yield 0.8 g of IIIa, which was recrystallized from dilute acetic acid as colorless crystals, mp 228—230 °C. Found: C, 67.15; H, 4.50; N, 12.59%. Calcd for $C_{18}H_{15}O_3N_3$: C, 67.27; H, 4.71; N, 13.08%. IR: 3430, 3330, 1685, 1635 cm^{-1}.

3-Carboxymethyl-1,5-diphenylpyrazole-4-carboxamides (IIIb, c). A solution of II (3 g; 1 mol) in anhydrous dioxane (50 ml) was treated with appropriate amines (2.2 mol) and the mixture was refluxed for 15 min and then cooled. The reaction mixture was diluted with water (20 ml) and acidified with 10% hydrochloric acid solution. The solid that separated was collected and crystallized from the proper solvent to give IIIb, c.

3-Carboxymethyl-1,5-diphenylpyrazole-4-carboxybenzylamide (IIIb). Colorless crystals from ethanol, mp 185 °C (85%). Found: C, 72.74; H, 5.70; N, 10.10%. Calcd for $C_{25}H_{21}O_3N_3$: C, 72.98; H, 5.14; N, 10.21%. IR: 3280, 1720, 1620 cm^{-1}.

3-Carboxymethyl-1,5-diphenylpyrazole-4-carboxyanilide (IIIc). Colorless crystals from ethanol, mp 232—234 °C. Found: C, 72.22; H, 4.62; N, 10.64%. Calcd for $C_{24}H_{19}O_3N_3$: C, 72.53; H, 4.82; N, 10.57%. IR: 3400, 1698, 1665 cm^{-1}.

1,5-Diphenyl-3-methylpyrazole-4-carboxanilide (V). (Method A): Half a gram of IIIc was heated in a metal bath at 250 °C until the evolution of carbon dioxide stopped. The residue was triturated with ethanol and then crystallized from ethanol as colorless crystals, mp 178—180 °C.

(Method B): A suspension of 1.0 g of 4-carboxy-1,5-diphenyl-3-methylpyrazole (VI) in 20 ml of anhydrous benzene was treated with 3 ml of thionyl chloride and the mixture was refluxed until hydrogen chloride evolution stopped. The reaction mixture was distilled to dryness and the residue was dissolved in 50 ml of anhydrous benzene and treated with 0.7 g of aniline (2 mol). The reaction was refluxed for 2 hr, cooled and filtered to remove aniline hydrochloride. The filtrate was concentrated and cooled, and the precipitate formed was collected and recrystallized from ethanol, mp 180—181 °C. The products obtained by methods A and B were identical, as judged by mixed melting point determination and by comparison of infrared spectra. Found: C, 77.88; H, 5.38; N, 11.88%. Calcd for $C_{23}H_{19}ON_3$: C, 78.16; H, 5.42; N, 11.89%. IR: 3389, 1665 cm^{-1}.

2,3-Diphenylpyrazole[4,3-c]pyridine-(5H,7H)-4,6-dione (VIIa). Three grams of acid I was treated with 10 ml of concentrated ammonium hydroxide solution and the resulting solution was heated on a boiling water bath to dryness and then heated in a metal bath at 220 °C under reduced pressure. The residue obtained was triturated with ethanol to give a yellow solid (1.8 g) of VIIa, which was recrystallized from ethanol as yellow crystals, mp 251—252 °C. Found: C, 71.08; H, 4.40; N, 13.80%. Calcd for $C_{18}H_{13}O_2N_3$: C, 71.27; H, 4.32; N, 13.86%. IR: 3180, 3055, 1715, 1685 cm^{-1}.

2,3,5-Triphenylpyrazolo[4,3-c]pyridine-(5H,7H)-4,6-dione (VIIb). A suspension of 2 g of IIIc in 50 ml of anhydrous benzene was treated with 10 ml of acetyl chloride and the mixture was boiled on a water bath for 2 hr. The

solution obtained was concentrated to dryness and the residue was triturated with ethanol to give a pale yellow solid (1.3 g) which was crystallized from acetic acid as pale yellow crystals, mp 217—219 °C. Found: C, 75.56; H, 4.37; N, 11.22%. Calcd for $C_{24}H_{17}O_2N_3$: C, 75.97; H, 4.52; N, 11.08%. IR: 1720, 1680 cm^{-1}.

2,3,5-Triphenyl-7-phenylazopyrazolo[4,3-c]pyridine-(5H,7H)-4,6-dione (XII). A solution of 0.5 g of VIIb in 50 ml of pyridine was cooled in ice and treated with a solution of an equimolar amount of benzenediazonium chloride (prepared from 0.15 g of aniline in 2 ml of concentrated hydrochloric acid, 2 ml of water and 0.1 g of sodium nitrite), left to stand in ice for 1 hr and then diluted with water (100 ml). The product that separated was filtered off,washed thoroughly with water and crystallized from dioxane as orange voluminous crystals, mp 262—266 °C. Found: C, 74.22; H, 4.44; N, 14.27%. Calcd for $C_{30}H_{21}O_2N_5$: C, 74.52; H, 4.38; N, 14.49.% IR: 1710, 1680 cm^{-1}.

Condensation of Compound VIIb with Aromatic Aldehyde. A solution of VII (1 g) and anhydrous sodium acetate (2g) in glacial acetic acid (100 ml) was treated with an equimolar amount of appropriate aldehydes, and the mixture was refluxed for 1 hr. It was then cooled and the crystalline precipitate was filtered off. The arylidene derivatives XVa, b were yellow and gave red coloration with concentrated sulfuric acid.

7-Benzal-2,3,5-triphenylpyrazolo[4,3-c]pyridine-(5H,7H)-4,6-dione (XVa). This was recrystallized from acetic acid, mp 256—257 °C. Yield 90%. Found: C, 79.34; H, 4.46; N, 9.10%. Calcd for $C_{31}H_{21}O_2N_3$: C, 79.64; H, 4.53; N, 8.99%. IR: 1715, 1680 cm^{-1}.

7-p-Chlorobenzal-2,3,5-triphenylpyrazolo[4,3-c]pyridine-(5H,7H)-4,6-dione (XVb). This was recrystallized from acetic acid, mp 250—252 °C, yield 82%. Found: C, 73.88; H, 4.08; N, 8.29%. Calcd for $C_{31}H_{20}O_2N_3Cl$: C, 74.12; H, 3.95; N, 8.37%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1803—1806 (1973)

Spectroscopic Investigations of α-Keto Phosphorus Compounds

Takayoshi OSAKI, Junzo OTERA, and Yoshikane KAWASAKI
Department of Applied Chemistry, Osaka University, Yamadakami, Suita, Osaka 565

(Received November 18, 1972)

The NMR, IR, and UV spectra of some α-keto phosphorus compounds, $(C_2H_5)_2PCOR$, $(C_2H_5)_2P(S)COR$, and $[(C_2H_5)_2CH_3PCOR]^+I^-$ ($R=C_6H_5$ and CH_3), were measured. The carbonyl stretching frequency and the n-π^* transition show considerable red shifts, but the shifts are smaller than those of α-keto organosilicon compounds. The lowering of the carbonyl π^* level, which resulted from the interaction with a vacant d orbital of the phosphorus atom, was found to be largely responsible for the red shift of the n-π^* transition in the α-keto phosphorus compounds, particularly in $[(C_2H_5)_2CH_3PCOR]^+I^-$. The rise in the n level of the carbonyl group was found to be rather small.

Two of the characteristic properties of the α-keto derivatives of organometalloids are a large red shift of the n-π^* transition and a low carbonyl stretching frequency relative to those of the carbon analogs.[1,2] To explain these unusual red shifts of the n-π^* transition, several suggestions, especially for silicon compounds, have been put forward:

a) A large π^*-d splitting and a slight rise in the n level of the carbonyl oxygen caused by an inductive effect of the triorganosilyl group have been suggested on the basis of molecular orbital considerations.[3,4]

b) The simultaneous operation of the σ-donor and π-acceptor effects of the triorganosilyl group has been proposed.[5] Bock *et al.*[6] deduced, from a variety of experimental measurements, that the unusual red shift is due to the strong inductive rise in the n level as well as to considerable excited-state interactions, Si←π^*.

c) The inductive rise in the n level is considered to be the primary cause of the long-wavelength shift of the n-π^* transition.[7–10] Agolini *et al.*[11] have drawn the conclusion, from simple and extended Hückel molecular orbital calculations with and without d orbitals, that it is the σ-donor properties of silicon which are primarily responsible for the observed spectral shift, and that any possible p_π-d_π interactions are of minor importance.

These studies, however, were mainly made on α-keto derivatives of Group IVb organometalloids, which are very limited in organophosphorus derivatives.[12–15] In

the present report, the effects of the organophosphorus group on the UV and IR spectra of the carbonyl group have been studied. For this purpose, three types of α-keto organophosphorus compounds, $(C_2H_5)_2PCOR$, $(C_2H_5)_2P(S)COR$, and $[(C_2H_5)_2CH_3PCOR]^+I^-$ (R= C_6H_5 and CH_3), have been prepared. Because the valence state of the phosphorus atom is different in these compounds, some distinguishable effects on the spectra of the carbonyl group can be expected. The internal chemical shift of the ethyl group was also measured for these compounds.

Experimental

All the experiments were performed in an oxygen-free dry nitrogen atmosphere. The solvents were purified in a stream of nitrogen prior to use.

Preparation. Benzoyldiethylphosphine (I), Benzoyldiethylmethylphosphonium Iodide (III), Acetyldiethylphosphine (IV), and Acetyldiethylmethylphosphonium Iodide (VI): These substances were synthesized by Issleib's method.[16] I, bp 102—103 °C /2.5 mmHg) (reported 98—100 °C/2 mmHg). III, mp 68—69 °C (reported 68 °C). IV, bp 58 °C/11 mmHg (reported 168 °C/760 mm and 53—54 °C/10 mmHg[14]). VI, mp121°C (reported 122 °C).

Benzoyldiethylphosphine Sulfide (II). I (2.70 g, 13.9 mmol) and trimethylstibine sulfide, $(CH_3)_3SbS$[17] (2.76 g, 13.9 mmol), were treated in dichloromethane at room temperature for 12 hr. The trimethylstibine formed was removed with a solvent *in vacuo*, and the residual liquid was extracted with *n*-hexane. After the removal of the solvent *in vacuo*, 2.63g (83%) of II were obtained as a viscous liquid, which was then gradually hydrolyzed by moisture in the air (Found: C, 58.27; H, 6.90%. Calcd for $C_{11}H_{15}OSP$: C, 58.39; H, 6.68%.). The compound could not be distilled below 100 °C under a high vacuum (1.3×10^{-3} mmHg), and it decomposed at a higher temperature. In the treatment of I with equimolar amounts of sulfur powder in tetrahydrofuran at room temperature, an exothermic reaction occurred immediately. The liquid obtained after the removal of the solvent contained II, with significant amounts of impurities.

Acetyldiethylphosphine Sulfide (V). As in the case of II, equimolar amounts of IV and trimethylstibine sulfide were treated, the liquid thus obtained was then distilled *in vacuo*, yielding 85% of V (bp 47 °C /1.1×10^{-3} mmHg); it was a faintly pale yellow liquid and was readily hydrolyzed in air (Found: C, 43.88; H, 8.05%. Calcd for $C_6H_{13}OSP$: C, 43.89; H, 7.98%.). A similar reaction took place between IV and sulfur, yielding 25% of V.

Diethylphosphine Sulfide. Soon after the mixing of diethylphosphine[18] (2.0 g, 22.2 mmol) and sulfur powder (0.64 g, 20.0 mmol) in dry ether, a vigorous reaction occurred and the sulfur powder disappeared. After the removal of the solvent, the residue was distilled *in vacuo*, yielding 1.95 g (80%) of the product (bp 57 °C/1 mmHg), which was readily hydrolyzed in air. Found: C, 39.03; H, 8.86%. Calcd for $C_4H_{11}SP$: C, 39.33; H, 9.08%. IR spectrum (neat) ν_{PH} 2297, ν_{PS} 586 cm^{-1}.

Physical Measurements. The infrared spectra in dichloromethane were measured on a Hitachi 225 grating spectrophotometer in airproof cells provided with KRS-5 windows. The electronic spectra were obtained by means of a Hitachi 124 spectrophotometer in 1 cm quartz airproof cells in cyclohexane, dichloromethane, and acetonitrile. The NMR spectra were recorded on JNM-3H-60 and JNM-PS-100 spectrometers operating at 60 and 100 MHz, respectively, at 25 °C in dichloromethane.

Analysis of the NMR Spectra. The NMR spectra of ethyl protons of I and IV were analyzed by the use of Corio's theoretical formula[19] of A_3B_2X. In other cases, the first-order analysis was performed. The reliability of the internal chemical shifts of the ethyl group was found to be ±0.02 ppm at most.

Results and Discussion

NMR Spectra. As can be seen from Table 1, the values of the internal chemical shift of the ethyl group and the indirect spin-spin coupling constants between the ethyl protons and the phosphorus nucleus increase in the following order for I—VI; tertiary phosphine<phosphine sulfide<phosphonium iodide in both benzoyl and acetyl series. The results are quite similar to those obtained for organophosphorus compounds without the keto group.[20-22] The electron-withdrawing effect on the internal chemical shift of these phosphorus compounds is considered to increase

in the above order.[23] The internal chemical shifts of I—VI are always larger than those of the corresponding phosphorus compound not containing the keto group. This is considered to be due mainly to the difference in the electron withdrawing property of the ethyl and the keto groups, although there might be some contributions of the magnetic anisotropy of the carbonyl group.

One of the most notable results is that the $^3J_{PH}$ value for the acetyl group in IV—VI is very small compared with that of the methyl protons in the ethyl group; it is almost the same for the three compounds.

IR Spectra. The carbonyl stretching frequency of I—VI is shown in Table 2, together with the carbon[6,24] and silicon[9] analogs. The low-frequency shift of the carbonyl stretching of the α-keto organosilicon compounds relative to the carbon analogs is considered to be due mainly to a small electronegativity of silicon.[1] The stretching frequency of I—VI is smaller than that of carbon analogs, but larger than that of silicon, and it increases as in the internal chemical shift in this order: I<II<III and IV<V<VI. The results are considered to be due to the increase in the electron withdrawing property of the phosphorus group. In spite of the large effective electronegativity of the phosphorus atom in III and VI relative to that of carbon as revealed from NMR spectra, the stretching frequency is a little smaller than that of the carbon analogs. These results seem to suggest that there are some p_π-d_π interactions[25] in the ground state in III and VI.

23) If we use the relation between the internal chemical shift of the ethyl group and the electronegativity of the atom bonded to this group proposed by Narasimhan and Rogers (*J. Amer. Chem. Soc.*, **82**, 5983 (1960)), the effective electronegativities of the phosphorus and silicon atoms are found to be 2.2, 2.5, 2.8, and 1.8 for $(C_2H_5)_3P$, $(C_2H_5)_3PS$, $(C_2H_5)_4P^+$, and $(C_2H_5)_4Si$ respectively.

24) J. I. Adelfang, P. H. Hess, and N. H. Cromwell, *J. Org. Chem.*, **26**, 1402 (1961).

25) Hoffmann *et al.* have indicated that, in Extended Hückel MO calculation, the large charge separation is considerably reduced by the inclusion of the P 3d orbital in phosphonium ylide (R. Hoffmann, D. B. Boyd, and S. Z. Goldberg, *J. Amer. Chem. Soc.*, **92**, 3929 (1970)).

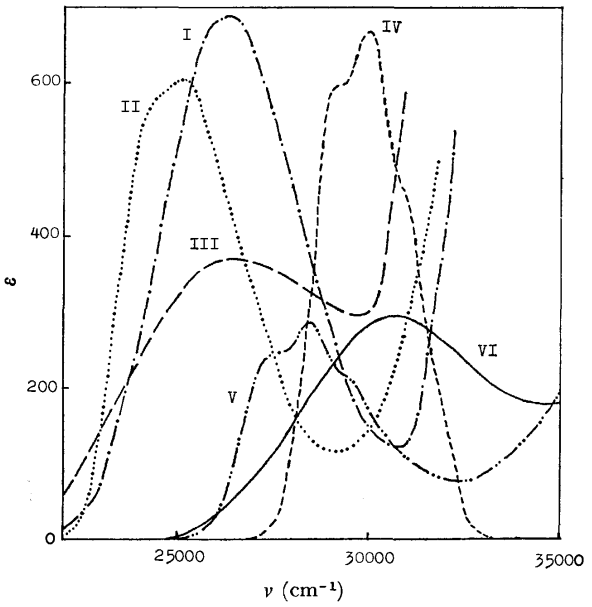

Fig. 1. The absorption bands of the n-π^* transition measured in dichloromethane.

UV Spectra. The positions and intensities of the absorption maxima of I—VI are summarized in Table 3. The values of the carbon and silicon analogs are added for the sake of comparison. Each compound exhibits several absorption bands in the 23000—50000 cm^{-1} region, these bands can be classified into six types depending on their positions and intensities. The band at the lowest frequency (A) shows a blue shift as the polarity of solvent increases, and, as is shown in Fig. 1, it has somewhat fine structure. One of the most remarkable results is that the intensity of the band is rather large as compared with that of carbon analogs. This band is presumably due to the n-π^* transition involving the carbonyl group. The band with a medium intensity or the shoulder (B) at 35000—36000 cm^{-1} in I and II is probably due to the ^1L_b band.[26] The band (B) in III may be hidden by a strong band, C. The origin of the absorption band (B) at 38000—41000 cm^{-1} in IV and V is not clear. A possible assignment of this band is a transition of the n electrons on phosphorus and sulfur to the π^* orbital of the carbonyl group. The intense band (C) at 38000—42000 cm^{-1} in I—III is probably due to the allowed ^1L_a band with an intramolecular charge-transfer character of the benzoyl group.[26] The intense band (D) at 41000—42000 cm^{-1} in III and VI was assigned tentatively to an intramolecular charge-transfer transition from the carbonyl n level to the vacant d orbitals of the phosphorus atom, because, in these compounds, the energy level of the d orbitals seems to be considerably lowered as a result of a net positive charge on the molecule. The band with medium intensity (E) at 43000—45000 cm^{-1} in II and V may be due to the P–S group, because a similar band was observed in diethylphosphine sulfide. Finally, in the highest frequency region, an intense band (F) was observed in all the compounds. The band in I—III is probably due to the intramolecular charge-transfer band with the ^1B-band character.[26] The nature of the band not containing the phenyl group IV—VI has never been definitely established. This band may be due to either the π-π^* transition or the n-σ^* transition of the carbonyl group. One notable result of this band is that, in V and VI, the intensity is very large compared with that of pinacolone or acetyltrimethylsilane.

As can be seen from Table 3, the n-π^* transition band of I—VI shows a large red shift as compared with that of the carbon analogs, but the shift is smaller than that of the silicon analogs. II and V show the largest red shift among the phosphorus compounds. The red shifts of I and III, and those of IV and VI, relative to the carbon analogs are almost the same, although the valence state of the phosphorus atom is different. As has been shown in connection with the NMR and IR spectra, the electron withdrawing property of the phosphorus group is larger than that of the silyl group. Therefore, the inductive rise in the n level of the carbonyl group may be smaller in I—VI, particularly in III and VI, than in α-keto silicon compounds. The red shift of the n-π^* transition band in III and VI may be largely responsible for the lowering of the π^* level of the carbonyl group as a result of interaction with the vacant d orbital of the phosphorus atom. In I and IV, in addition to the lowering of the carbonyl π^* level, there may be some contribution of the n level rising to the red shift. The largest red shift in II and V is also considered to be due to the large lowering of the carbonyl π^* level by the interaction with that of the P=S group. The lowering of the π^* level in the phosphorus compounds is partly supported by the following fact. In spite of the smaller red shift of the n-π^* transition in the phosphorus compounds relative to that of the silicon, the red shifts of the π-π^* transitions are larger in phosphorus compounds (see Table 3). These results seem to reveal that the d-π^* interaction occurs more easily in α-keto organophosphorus compounds than in organosilicon compounds.

We wish to express our hearty thanks to Professor Rokuro Okawara for his continuous encouragement throughout this study. We are also grateful to Drs. Masanori Wada and Yoshio Matsumura of Osaka University for their helpful discussions. The calculations needed for obtaining the NMR parameters were carried out on an NEAC-2200 at the Computation Center of Osaka University.

Reactions of Vinyloxyboranes.[1] A Convenient Method for the Preparation of β-Hydroxy Thiolesters, Esters and Ketones

Katsuhiko INOMATA, Masayoshi MURAKI, and Teruaki MUKAIYAMA

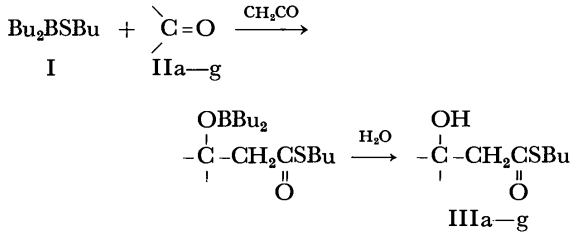
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 27, 1972)

It was found that the reaction of thioboronites with carbonyl compounds and ketene proceeds with the initial formation of vinyloxyboranes (VII). The boranes were found to be important intermediates for the formation of β-hydroxythiolesters by the reaction with various carbonyl compounds. Vinyloxyborane derivatives can be alternatively prepared by the reactions of trialkylboranes and α-diazocarbonyl compounds. The boranes similarly reacted with carbonyl compounds to give β-hydroxyketones and β-hydroxyesters.

In a previous paper,[2] it was reported that the reaction of thioboronite with carbonyl compounds and ketene afforded β-hydroxyalkanethioates in excellent yields. This paper deals with an extention of earlier works.[2,3]

A typical reaction of thioboronite with carbonyl compounds and ketene is shown in the following. When equimolar amounts of *n*-butyl di-*n*-butylthioboronite (I) and various carbonyl compounds (IIa—g) in dry ether were treated with excess gaseous ketene at 0 °C for 2 hr followed by hydrolysis, the corresponding β-hydroxyalkanethioates (IIIa—g) were obtained in excellent yields (Scheme 1). The results are summarized in Table 1.



Scheme 1

In the same way, β-hydroxyalkanethioates (Va—e) were obtained by the treatment of other thioboronites (IVa—e) prepared from tri-*n*-butylborane and thiols with benzaldehyde and ketene, followed by hydrolysis, in excellent yields (Table 2). Thus, it became clear that the reaction of thioboronites with carbonyl compounds and ketene is an excellent method of preparing various β-hydroxyalkanethioates.

By utilizing this reaction, *S*-*n*-butyl ethyl β-hydroxy-β-methyl-thioglutarate (VI), the analog of β-hydroxy-β-methyl-glutaryl coenzyme A (HMG-CoA), was obtained in 81% yield from ethyl acetoacetate by the following procedure (Scheme 2).

a) In ether at 0 °C. b) This is an oily substance and decomposed during the course of vacuum distillation.

It was postulated that the above reaction of thioboronites with carbonyl compounds and ketene proceeds with the initial formation of a coordination complex of thioboronite and a carbonyl compound, followed by a nucleophilic attack of the thiolate anion on ketene.[2] However, the present results show that this reaction proceeds through vinyloxyborane (VII), formed from thioboronite and ketene, as sketched in the following scheme.

$$H_2C{=}C{=}O + RSBR_2' \longrightarrow H_2C{=}C(SR)(OBR_2') \xrightarrow{H_2O} CH_3CSR$$

VII VIII

$$VII + \text{>C=O} \longrightarrow \left[\text{>C(H}_2\text{)–C(SR)=C(O–B(R}_2'\text{)–O)–C<}\right] \xrightarrow{H_2O} -C(OH)-CH_2CSR$$

IX

When nearly one equivalent of gaseous ketene was passed through a solution of phenyl di-*n*-butylthioboronite in carbon tetrachloride at −20——30 °C under argon, formation of VII (R=C_6H_5, R′=*n*-C_4H_9) was confirmed by the PMR spectrum of the reaction mixture which displayed two doublets for the vinyl hydrogens at δ 4.57 and 4.63 (*J*=*ca.* 1.5 Hz). On hydrolysis of this reaction mixture, phenyl thioacetate (VIII, R=C_6H_5) was isolated by preparative tlc.

It was established that the treatment of VII (R=C_6H_5, R′=*n*-C_4H_9) with acetone in ether, followed by hydrolysis, afforded phenyl β-hydroxy-isovalerothioate (IX, R=C_6H_5) in 67% yield.

Excess gaseous ketene was bubbled into a solution of equimolar amounts of thioboronites and carbonyl compounds at 0 °C in dry ether. Completion of the reaction by this procedure took a longer time as compared with the above procedure of treating vinyloxyboranes with carbonyl compounds. This might be attributed to the presence of the coordination complex of thioboronite with carbonyl compound and the necessity of ligand exchange of the carbonyl compound and ketene to proceed further.

The reactions of vinyloxyboranes prepared by other methods were studied with the expectation that these compounds would be important synthetic intermediates.

Hooz and Linke reported that the reaction of trialkylboranes and α-diazo ketones[4] or esters,[5] followed by hydrolysis, gave the corresponding α-alkyl carbonyl compounds, the intermediate being β-ketoborane.[4] Pasto and Wojtkowski[6] proposed vinyloxyborane to be an intermediate by means of NMR and UV spectra. It was found that the vinyloxyboranes (XI, Y=C_6H_5; XI′, Y=OC_2H_5), obtained from α-diazo carbonyl compounds and tri-*n*-butylborane, gave β-hydroxy ketones (XII) and β-hydroxy esters (XII′), respectively, on treatment with carbonyl compounds in THF at room temperature as follows. The results are summarized in Tables 3 and 4.

$$N_2CHCY + Bu_3B \xrightarrow{-N_2} BuCH{=}C(Y)(OBBu_2)$$

X, Y=C_6H_5; X′, Y=OC_2H_5 XI or XI′

$$XI \text{ or } XI' + \text{>C=O} \xrightarrow{H_2O} -C(Bu)-CHCY \quad (OH,\ O)$$

XII or XII′

It was found that the vinyloxyborane (XIV) prepared from tri-*n*-butylborane and ethyl α-diazohydrocinnamate (XIII)[7] reacted with benzaldehyde to give ethyl 2-*n*-butyl-2-benzyl-3-hydroxy-hydrocinnamate (XV) in 70% yield under similar conditions.

$$N_2C(CH_2C_6H_5)CO_2C_2H_5 + Bu_3B \xrightarrow{-N_2} C_6H_5CH_2(Bu)C{=}C(OC_2H_5)(OBBu_2)$$

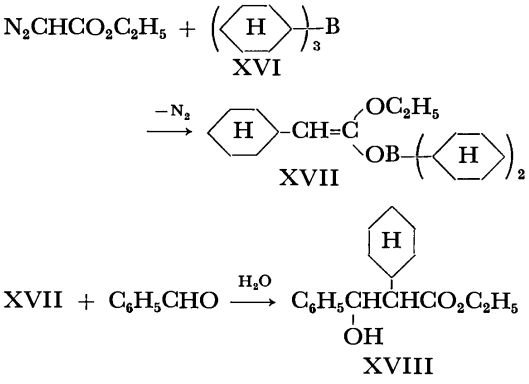
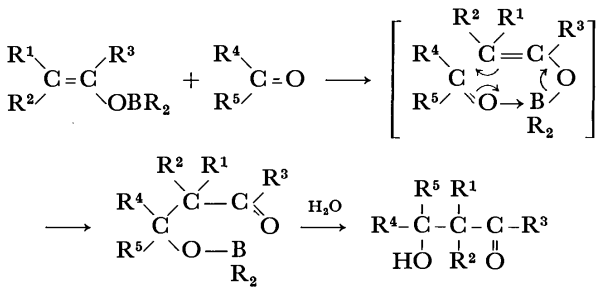
XV

Tricyclohexylborane (XVI) also reacted with ethyl diazoacetate to afford another vinyloxyborane (XVII) which further reacted with benzaldehyde to give ethyl 2-cyclohexyl-3-hydroxyhydrocinnamate (XVIII) in 87% yield.



XVI XVII XVIII

It is to be noted that vinyloxyboranes, which afford the corresponding β-hydroxycarbonyl derivatives by the reaction with carbonyl compounds according to the following scheme, are useful intermediates in organic synthesis because of their high reactivity with carbonyl compounds and their availability.[6,8,9]



Experimental[10]

Materials. Tri-*n*-butylborane was prepared from boron trifluoride diethyl etherate and *n*-butylmagnesium bromide in dry ether under argon. Tricyclohexylborane was prepared by hydroboration of cyclohexene in THF.

s-Butyl Di-n-butylthioboronite (IVe).[11] *s*-Butylmercaptan (1.65 g, 18.3 mmol) was added to tri-*n*-butylborane (3.42 g, 18.8 mmol) in the presence of some boiling stone at room temperature under argon. The reaction mixture was then heated at 150 °C for 1 hr and distilled *in vacuo* under argon. Bp 100—103 °C/7 mmHg. 3.19 g (81.5%). PMR ($CDCl_3$) δ 0.7—1.8 (m, 26H), 3.23 (q, J=7 Hz, 1H).

Other thioboronites (IVa—e) were prepared from tri-*n*-butylborane and the corresponding mercaptans in a similar way. The results are listed in Table 5.

Table 5. Yields of thioboronites[a)]

$n\text{-}Bu_3B + RSH \longrightarrow n\text{-}Bu_2BSR$ IVa—e

Mercaptan	Conditions	Yield, %	Bp °C/mmHg

Preparation of S-n-*Butyl Ethyl β-Hydroxy-β-methyl-thioglutarate (VI).* Ketene was bubbled into a solution of *n*-butyl di-*n*-butylthioboronite (973 mg, 4.55 mmol) in 15 ml dry ether at 0 °C for 15 min with stirring, and ethyl acetoacetate (545 mg, 4.19 mmol) in 10 ml dry ether was added. After bubbling ketene for 1 hr, the reaction mixture was worked up as in the preparation of IIIb to give a crude oil. The residue was separated by preparative tlc (silica gel) using methylene chloride. Elution of the main band and the evaporation under reduced pressure at *ca.* 50 °C gave 891 mg (81%) of *S-n*-butyl ethyl *β*-hydroxy-*β*-methyl-thioglutarate (VI); IR 3510, 1740, 1720 (shoulder), 1690 cm^{-1}. PMR (CCl_4) δ 0.6—1.8 (m, 13H), 2.54 (s, 2H), 2.6—3.0 (m, 2H), 2.83 (s, 2H), 3.4—3.8 (br s, 1H), 4.14 (q, J=*ca.* 7.5 Hz, 2H). Bp 119 °C/1.5 mmHg. Found: C, 54.87; H, 8.55; S, 12.48%. Calcd for $C_{12}H_{22}O_4S$: C, 54.95; H, 8.45; S, 12.20%.

Reaction of Vinyloxyborane (XI) with Benzaldehyde. To a stirred solution of diazoacetophenone (154 mg, 1.05 mmol) in 5 ml THF (dried $LiAlH_4$) was added tri-*n*-butylborane (216 mg, 1.19 mmol) at room temperature under argon. N_2 was immediately evolved. After being stirred for 45 min, the reaction mixture was treated with a solution of benzaldehyde (92 mg, 0.87 mmol) in 5 ml THF for 10 min at room temperature. The mixture was worked up as in the preparation of IIIb to give a crude oil. It was purified by preparative tlc (silica gel) using methylene chloride to give 240 mg (98%) of 2-hydroxybenzyl-1-phenylhexan-1-one (XIIb, oil); IR 3440, 1660 cm^{-1}. PMR (CCl_4) δ 0.3—2.0 (m, 9H), 3.4—3.9 (m, 2H), 4.6—4.9 (m, 1H), 6.8—7.4 (m, 8H), 7.5—8.0 (m, 2H).

The IR and PMR spectra of other *β*-hydroxyketones (XIIa—d) are consistent with the assigned structure: XIIa; IR 3430, 1660 cm^{-1}. PMR (CCl_4) δ 0.4—2.1 (m, 16H), 3.1—4.1 (m, 3H), 7.1—7.6 (m, 3H), 7.7—8.1 (m, 2H). XIIc; IR 3480, 1650 cm^{-1}. PMR (CCl_4) δ 0.3—2.4 (m, 19H), 3.19 (s, 1H), 3.50 (dd, J_A=6 Hz, J_B=8 Hz, 1H), 7.2—7.6 (m, 3H), 7.7—8.2 (m, 2H). XIId; IR 3460, 1660 cm^{-1}. PMR (CCl_4) δ 0.5—2.1 (m, 15H), 2.98 (s, 1H), 3.47 (dd, J_A=5 Hz, J_B=8 Hz, 1H), 7.1—7.6 (m, 3H), 7.7—8.1 (m, 2H).

Reaction of Vinyloxyborane (XI') with Benzaldehyde. To a solution of tri-*n*-butylborane (346 mg, 1.9 mmol) and benzaldehyde (169 mg, 1.6 mmol) in dry THF (3 ml) was added a solution of ethyl diazoacetate[12] (195 mg, 1.7 mmol, dried over P_2O_5) in THF (1 ml) at room temperature under argon with stirring. N_2 was immediately evolved and the yellow coloration characteristic of ethyl diazoacetate disappeared. The reaction mixture was allowed to stand at room temperature for 1 day. After removal of THF, the residue was treated with 30% H_2O_2 (1 ml) in MeOH (3 ml) for 2 hr and water was added. The mixture was concentrated *in vacuo* to remove most of the methanol and extracted with ether. The ether layer was washed with 5% solution of $NaHCO_3$ and saturated solution of NaCl, dried over Na_2SO_4 and the solvent was removed. The crude oil was purified by preparative tlc (silica gel, CH_2Cl_2) to give the pure oil of ethyl 2-*n*-butyl-3-hydroxyhydrocinnamate (XII'b, 320 mg, 81%); IR 3450, 1710 cm^{-1}. PMR (CCl_4) δ 0.6—1.6 (m, 9H), 1.18 (t, J=7 Hz, 3H), 2.5—2.9 (m, 1H), 3.05 (br s, 1H), 4.15 (q, J=7 Hz, 2H), 4.75 (d, J=7 Hz, 1H), 7.25 (s, 5H). Found: C, 72.02; H, 8.96%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%.

The IR and PMR spectra of other *β*-hydroxyesters (XII'a—d) are consistent with the assigned structure: XII'a; IR 3430, 1710 cm^{-1}. PMR (CCl_4) δ 0.7—1.6 (m, 16H), 1.25 (t, J=7 Hz, 3H), 2.25 (m, 1H), 2.68 (br s, 1H), 3.55 (m, 1H), 4.16 (q, J=7 Hz, 2H). XII'c; IR 3500, 1710 cm^{-1}. PMR (CCl_4) δ 0.65—1.9 (m, 19H), 1.25 (t, J=7 Hz, 3H), 2.30 (t, J=7 Hz, 1H), 2.79 (s, 1H), 4.15 (q, J=7 Hz, 2H). XII'd; IR 3450, 1710 cm^{-1}. PMR (CCl_4) δ 0.7—1.5 (m, 9H), 1.15 (s, 6H), 1.26 (t, J=7 Hz, 3H), 2.1—2.4 (m, 1H), 2.9 (br s, 1H), 4.14 (q, J=7 Hz, 2H). XII'e; IR 3480, 1700 cm^{-1}. PMR (CCl_4) δ 0.4—1.5 (m, 17H), 2.85 (t, J=9 Hz, 1H), 3.79 (q, J=7 Hz, 2H), 3.8 (s, 1H), 7.25 (s, 5H).

Studies of the Synthetic Model Enzyme. The Synthesis of Cyclo(His-Glu-Cys-D-Phe-Gly)$_2$ as the Esterase Model[1]

Kiichiro NAKAJIMA and Kenji OKAWA

Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Nishinomiya 662

(Received December 2, 1972)

To study the mechanism of enzyme action, cyclo(His–Glu–Cys–D–Phe–Gly)$_2$ was prepared as an esterase model from the corresponding linear decapeptide by the azide methods. The esterase-like activity of this cyclic decapeptide in reaction to *p*-nitrophenyl acetate was three times greater than that of the linear decapeptide, the curve of the catalytic coefficient *versus* the different pH is of a bell type, and the optimum pH was recorded at about 7.6. The kinetics of the hydrolysis obeyed Michaelis-Menten's typical equation.

In spite of all our knowledge of the structures of enzymes and the kinetics of enzyme-catalyzed reactions, we are still far from an adequate understanding of the mechanisms of enzyme action. To answer this problem, approaches have been made by many workers through synthetic research into model enzymes. In these cases, linear amino acid peptide[2] or polyamino acid,[3] with active sites of amino acid residues, have mostly been used as the model substances, these studies attained their first purpose to some extent.

In the present study, the authors proposed to synthesize the cyclic peptide as a model enzyme; it has a relatively low molecular weight and will have hydrolytic activity. For the above purpose, histidine, cysteine, and glutamic acid were chosen as the active-site amino acids of synthetic cyclic peptide; they are arranged along the cyclic decapeptide chain with an antiparallel structure, as is shown in Fig. 1.

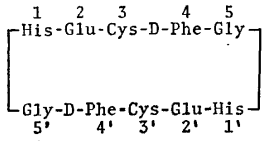

Fig. 1. Enzyme model (I)

Moreover, the cyclic decapeptide (I) could be successfully obtained by the removal of the protecting groups, followed by the cyclization of the linear decapeptide azide by using the high-dilution method. The hydrolytic activity of the synthetic model peptide has been investigated in detail by using the linear and cyclic decapeptide.

Synthesis of the Linear Decapeptide Derivative. The synthetic route of the linear decapeptide derivative (XV) is summarized in Figs. 2 and 3. Boc-dipeptide methyl ester (II) was prepared by the DCC method; then II was converted into tripeptide (IV) by the azide method. Boc-pentapeptide (X) was successively obtained from the tripeptide (V), Boc–Glu(OBzl)–OSu (VI), and Boc–His(*im*-Dnp)–OSu (IX) by the succinimide ester method. The preparation of Boc-decapeptide (XV) from X and the free pentapeptide (XII) failed, because of the difficulties of isolating the decapeptide from the reaction mixture. Also, the pure XV could be obtained by the coupling of IX and nonapeptide (XIV), which has been prepared from the Boc-tetrapeptide *p*-nitrophenyl ester (XI) and free pentapeptide (XII).

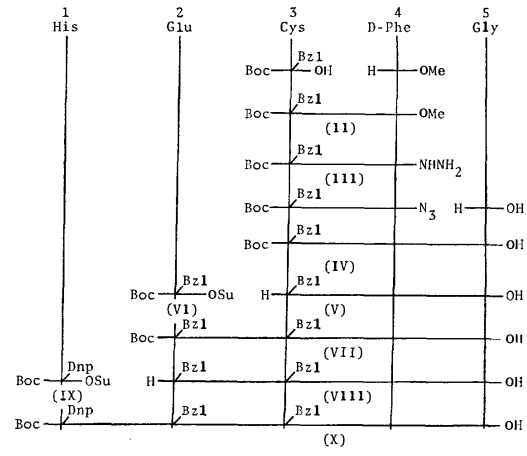

Fig. 2. Synthesis of Boc-pentapeptide (X)

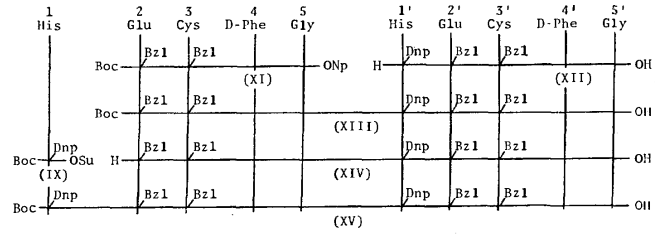

Fig. 3. Synthesis of Boc-decapeptide (XV)

The Cyclization of Linear Decapeptide Derivatives. Three different methods, using the *p*-nitrophenyl ester, *N*-hydroxysuccinimide ester, and azide, were used in the cyclization procedure (Fig. 4); the results are summarized in Table 1. The Boc-decapeptide *p*-nitrophenyl ester was obtained in a higher yield by the di-*p*-nitrophenyl sulfite method than by the DCC method, but the cyclization did not proceed satisfactorily. The Boc-decapeptide succinimide ester could be prepared in good yield by the DCC method, but

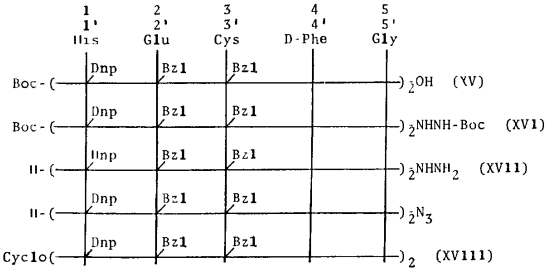

Fig. 4. Synthesis of Cyclic decapeptide (XVIII) by azide method

its active ester was not cyclized and the cyclic decapeptide derivative (XVIII) was not obtained. It was, therefore, concluded that the cyclization by the azide was the most favorable method in the present experiment, as is shown in Table 1.

TABLE 1. THE RESULTS OF THE CYCLIZATION REACTION

Method	Reaction temp. (°C)	Reaction time (hr)	Cyclo decapeptide (%)
ONp ester	60	6	52
OSu ester	rt	12	trace
Azide	0	24	87

XVIII was purified by the use of ion-exchange and gel filtration. The pure cyclic decapeptide (XVIII) was identified by thin-layer chromatography, by elemental analysis, and by molecular-weight measurements.

The Removal of the Protecting Groups from the Linear and Cyclic Decapeptide Derivatives. The benzyl ester and *s*-benzyl groups were removed from XV and XVIII by treating them with anhydrous hydrogen fluoride, and the dinitrophenyl group of the imidazole was removed by use of 2-mercaptoethanol[4] as is shown in Fig. 5.

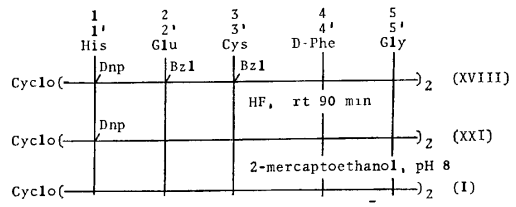

Fig. 5. Removal of the protecting groups from cyclic decapeptide (XVIII)

The free linear (XXIII) and cyclic decapeptide (I) thus obtained were purified with Sephadex G-15, and their purity was checked by means of a ninhydrin reaction, a Pauly reaction, and a nitroprusside reaction on thin-layer chromatography and paper electrophoresis. No disulfide groups were detected by the Ellman[5] and iodoacetamide methods.[6]

Hydrolytic Activity of the Synthetic Peptides, as Studied Using p-*Nitrophenyl Acetate as the Substrate.* The measurement of the catalytic action of the cyclic and linear decapeptide against *p*-nitrophenyl acetate was carried out by the method of Katchalski *et al.*;[3] the results are summarized in Table 2.

TABLE 2. HYDROLYSIS OF *p*-NITROPHENYL ACETATE IN 1/15M PHOSPHATE BUFFER, pH 7.73, CONTAINING 3.23% DIOXANE AND DMF (v/v) AT 24°C. [*p*-NITROPHENYL ACETATE]=3.23×10⁻⁵M.

Catalyst	Concn of catalyst mol l⁻¹ ×10⁴	k_1 min⁻¹ ×10³	c mol l⁻¹	k_2 l mol⁻¹ min
none		1.75

XXIII·3AcOH	3.00	5.26	6.00	6.05
Chymotrypsin				10⁴

The value of the catalytic coefficient of the cyclic decapeptide was greater than those of the linear decapeptide and histidine hydrochloride, but smaller than that of cysteine hydrochloride. The results show that the active sites of the amino acid placed opposite to each in the cyclic molecule have a more effective interaction between the catalyst and the substrate than those of the linear peptide.

The initial rate of hydrolysis was determined at several concentrations of the substrate under a constant concentration of I; it was found that the reaction rate increased in parallel with the substrate concentration at a relatively lower concentration, but thereafter gradually reached the maximum rate, as is shown in Table 3.

TABLE 3. EFFECT OF CONCENTRATION ON THE RATE (V) OF *p*-NITROPHENYL ACETATE IN 1/15M PHOSPHATE BUFFER, pH 7.73, CONTAINING 3.23% DIOXANE AND DMF (v/v) AT 24°C. [DECAPEPTIDE-1]=47.6 μM

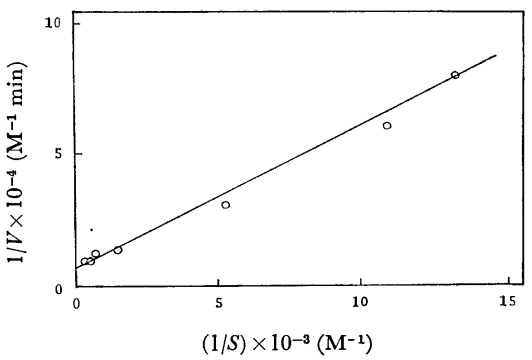

Fig. 6. Lineweaver-Burk plot for the hydrolysis of *p*-nitrophenyl acetate catalysed by Cyclic decapeptide (I) under condition indicated in Table 3

4) S. Shaltiel and M. Fridkin, *Biochemistry*, **9**, 5122 (1970).
5) G. Ellman, *Arch. Biochem. Biophys.*, **82**, 70 (1959).
6) S. Akabori, T. Kaneko, and K. Narita, "Chemistry of Proteines", Vol. 1, Kyoritsu Shuppan CO., Tokyo, (1969), p. 338.

Moreover, the Lineweaver-Burk plot of the data in Table 3 gives a straight line, as is shown in Fig. 6; the Michaelis-Menten constant, K_m, and the catalytic constant, K_{cat}, were 2.7 mM and 0.168 min^{-1} respectively. When the catalytic coefficient, K_2, was plotted against different pH values in the presence of a large excess of the substrate, the curve of K_2 was of a bell type and has an optimum pH at about 7.6, as is shown in Fig. 7.

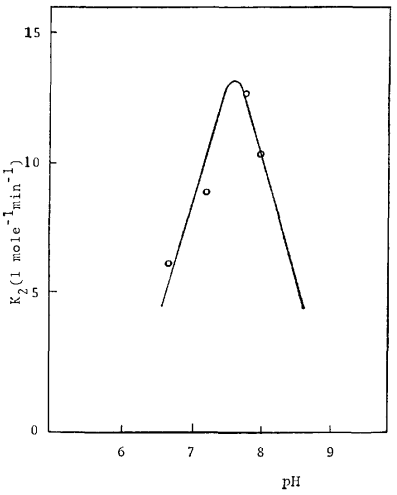

Fig. 7. PH dependance of catalytic coefficient for hydrolysis of *p*-nitrophenyl acetate by the cyclic decapeptide (I) in 1/15 M phosphate buffer containing 3.23% dioxane and DMF (v/v) at 24°C: [NPA]=1.57 mM, [Decapeptide-I]= 2.37 mM

From the above results, it may be concluded that the cyclic decapeptide behaves as an acid-base type catalyst; it seems that the reaction proceeds through a soft binding intermediate (the so-called E-S complex), as in a usual enzyme system. The kinase-like activity will be investigated by using this same cyclic decapeptide in the near future.

Experimental

All the melting points are uncorrected. The infrared spectra were measured on a Hitachi Infrared Spectrophotometer, EPI-G3. The kinetics were followed with a Hitachi Photo-Electric Spectrophotometer, EPU-2. The purity of the compound was confirmed by thin-layer chromatography on Kieselgel G.

Boc-Cys(SBzl)-D-Phe-OMe (II). Boc-Cys(SBzl)-OH[7] (from the cyclohexylamine salt; 19.8 g, 50 mmol) was treated with DCC (11.4 g, 55 mmol) and H-D-Phe-OMe (from hydrochloride; 11.9 g, 55 mmol) in methylene chloride (250 ml) at 0 °C. After the reaction mixture had been allowed to stand overnight in the refrigerator, acetic acid (2 ml) was added and the mixture was stirred for 15 min. The dicyclohexyl urea thus produced was then filtered off, and the filtrate was washed with M sodium bicarbonate, M hydrochloric acid, and water successively, dried over anhydrous sodium sulfate, and concentrated under reduced pressure. II was obtained from ethyl acetate–*n*-hexane in a 90.5% yield (21.4 g); mp 79 °C, $[\alpha]_D^{23}$ −33.3° (*c* 2.0, AcOH).

Found: C, 63.40; H, 6.90; N, 6.01; S, 6.89%. Calcd for $C_{25}H_{32}N_2O_5S$: C, 63.53; H, 6.83; N, 5.93; S, 6.78%.

Boc-Cys(SBzl)-D-Phe-NHNH$_2$ (III). 80% hydrazine hydrate (18.15 g, 300 mmol) was added to a solution of II (14.16 g, 30 mmol) in methanol (80 ml), and the solution was stirred for 30 min in an ice bath. After the reaction mixture had been kept at room temperature for one day, the addition of water to this reaction mixture gave white crystals. III was yielded; 13.9 g (98%); mp 110 °C, $[\alpha]_D^{23}$ −23.0° (*c* 2.0, AcOH).

Found: C, 60.92; H, 6.87; N, 11.59; S, 6.96%. Calcd for $C_{24}H_{32}N_4O_4S$: C, 60.99; H, 6.83; N, 11.80; S, 6.78%.

Boc-Cys(SBzl)-D-Phe-Gly-OH (IV). Into a solution of III (16.54 g, 35 mmol) in DMF (300 ml) and M hydrochloric acid (70 ml), was added, drop by drop, M sodium nitrite (35 ml, 35 mmol) under cooling at −15 °C. After stirring for 40 min, the reaction mixture was neutralized by the addition of triethylamine. A solution of glycine (7.88 g, 105 mmol), triethylamine (14.65 ml, 105 mmol), and water (35 ml) was added, drop by drop, into an azide solution at −10 °C. After the reaction mixture had then been stirred at −10 °C for 2 hr and allowed to stand overnight in a refrigerator, the mixture was acidified to pH 2 with 2 M hydrochloric acid, the precipitate appeared was collected and washed with water. The product was recrystallized from methanol-water. IV was yielded; 17.3 g (95.5%); mp 186.7—187 °C, $[\alpha]_D^{23}$ −22.0° (*c* 0.5, pyridine).

Found: C, 60.59; H, 6.55; N, 8.07; S, 6.50%. Calcd for $C_{20}H_{33}N_3O_6S$: C, 60.57; H, 6.45; N, 8.15; S, 6.22%.

H-Cys(SBzl)-D-Phe-Gly-OH·HCl (V·HCl). The dry hydrogen chloride was bubbled through a suspended solution of IV (7.73 g, 15 mmol) in ethyl acetate (90 ml) for 30 min at 0 °C; the solution was then allowed to stand in an ice bath for an additional 30 min. After the solvent had been removed under reduced pressure, anhydrous ether was added to the residual oil. The crystals (V·HCl) produced were obtained in the theoretical yield; mp 183—184 °C. $[\alpha]_D^{23}$ + 16.0° (*c* 0.5, AcOH).

Found: C, 55.82; H, 5.87; N, 9.18; S, 7.05; Cl, 7.74%. Calcd for $C_{21}H_{26}N_3O_4SCl$: C, 55.81; H, 5.80; N, 9.30; S, 7.09; Cl, 7.84%.

Boc-Glu(OBzl)-OSu (VI). Boc-Glu(OBzl)-OH[7] (from dicyclohexylamine salt, 25.94 g, 50 mmol) was treated with HOSu (6.33 g, 55 mmol) and DCC (11.4 g, 55 mmol) in methylene chloride (100 ml) at −5 °C while being stirred for 5 hr. After the reaction mixture had then been allowed to stand overnight in a refrigerator and acetic acid (1 ml) had been added, the dicyclohexyl urea thus produced was filtered off and the filtrate was washed with 0.5 M sodium bicarbonate, 0.5 M hydrochloric acid, and water successively, dried over anhydrous sodium sulfate, and concentrated under reduced pressure. The residual oil was crystallized from 2-propanol; 17.97 g (83.6%); mp 101 °C. $[\alpha]_D^{23}$ −23.4° (*c* 2.0, dioxane). ν_{max}^{KBr} 1815, 1785, 1740 cm^{-1} (ester).

Found: C, 58.35; H, 6.18; N, 6.58%. Calcd for $C_{21}H_{26}N_2O_7$: C, 58.06; H, 6.08; N, 6.48%.

Boc-Glu(OBzl)-Cys(SBzl)-D-Phe-Gly-OH (VII). The solid VI (13.1 g, 30 mmol) was added to a solution of V(from hydrochloride, 14.94 g, 33 mmol) and triethylamine (9.24 ml, 66 mmol) in 65% dioxane (100 ml) at room temperature. After stirring for 48 hr, the reaction mixture was acidified to pH 2 with M hydrochloric acid. The precipitate thus formed was extracted with ethyl acetate; the ethyl acetate solution was dried over anhydrous sodium sulfate and was concentrated under reduced pressure. The residual product was crystallized from methanol-water. VII was

thus yielded; 19.3 g (88%); mp 154—154.5 °C, $[\alpha]_D^{23}$ −1.83° (*c* 0.5, pyridine).

Found: C, 62.05; H, 6.28; N, 7.39; S, 4.57%. Calcd for $C_{38}H_{46}N_4O_9S$: C, 62.11; H, 6.31; N, 7.62; S, 4.36%.

*H–Glu(OBzl)–Cys(SBzl)–*D*-Phe–Gly–OH·HCl (VIII·HCl).* The dry hydrogen chloride was bubbled through a suspended solution of VII (11.01 g, 15 mmol) in dioxane (140 ml) at 0 °C for 30 min and was then allowed to stand in an ice bath for an additional 30 min. After the solvent had been removed under reduced pressure, anhydrous ether was added to the residue. White crystals were obtained in the theoretical yield; mp 178—178.5 °C. $[\alpha]_D^{23}$ +1.0° (*c* 0.5, AcOH).

Found: C, 59.25; H, 5.73; N, 8.17; S, 4.63; Cl, 5.20%. Calcd for $C_{33}H_{39}N_4O_7SCl$: C, 59.05; H, 5.86; N, 8.35; S, 4.78; Cl, 5.28%.

*Boc–His(*im*-Dnp)–OSu (IX).* Boc–His(*im*-Dnp)–OH[8] (1.58 g, 3.7 mmol) was treated with HOSu (472 mg, 4.1 mmol) and DCC (846 mg, 4.1 mmol) in dimethoxyethane (20 ml) and methylene chloride (10 ml) at 0 °C while being stirred for 10 hr. From the reaction mixture, IX was obtained by the method used in the case of VI. The product was recrystallized from ethyl acetate–ether–*n*-hexane. IX was obtained in an 83% (1.59 g) yield; mp 146—146.5 °C. $[\alpha]_D^{23}$ −3.37° (*c* 0.9, DMF). ν_{max}^{KBr} 1819, 1780, 1745 cm^{-1} (ester).

Found: C, 47.27; H, 4.25; N, 15.32%. Calcd for $C_{21}H_{22}N_6O_{10}\cdot H_2O$: C, 47.02; H, 4.51; N, 15.67%.

*Boc–His(*im*-Dnp)–Glu(OBzl)–Cys(SBzl)–*D*-Phe–Gly–OH (X).* Into a solution of VIII·HCl (6.4 g, 9 mmol) in DMF (20 ml) and water (2 ml), we stirred a solution of triethylamine (2.5 ml, 18 mmol) in DMF (5 ml) over a 20 min period at 0 °C; solid IX (7.33 g, 13.5 mmol) was then added to the above solution. After the reaction mixture had been stirred for 48 hr at room temperature, the reaction mixture was acidified to pH 2 with M hydrochloric acid, and water was added. The yellow precipitate was recrystallized from methanol–methylene chloride–ether. The yellow crystals were thus obtained in an 87.6% (8.18 g) yield; mp 153—154 °C. $[\alpha]_D^{23}$ −12.5° (*c* 0.3, DMF).

Found: C, 55.93; H, 5.18; N, 11.53; S, 3.10%. Calcd for $C_{50}H_{59}N_9O_{16}S$: C, 55.91; H, 5.54; N, 11.74; S, 2.98%.

*Boc–Glu(OBzl)–Cys(SBzl)–*D*-Phe–Gly–ONp (XI).* A solution of VII (7.35 g, 10 mmol) and *p*-nitrophenol (2.78 g, 20 mmol) in methylene chloride (10 ml) and acetonitrile (10 ml) was treated with DCC (2.27 g, 11 mmol) at 0 °C for 4 hr with stirring. After the dicyclohexyl urea thus produced had been filtered off, the reaction mixture was washed with M sodium bicarbonate, 0.1 M hydrochloric acid, and water successively, and then dried over anhydrous sodium sulfate. The solvent was evaporated under reduced pressure. The residual crystals were recrystallized from methylene chloride–ether–*n*-hexane (6.74 g, 78.7%); mp 127—128 °C, $[\alpha]_D^{24}$ −5.8° (*c* 0.3, DMF), R_f[9] 0.92 (aqueous AcOEt). ν_{max}^{KBr} 1780 cm^{-1} (ester).

Found: C, 61.53; H, 5.83; N, 7.88; S, 4.01%. Calcd for $C_{44}H_{49}N_5O_{11}S$: C, 61.74; H, 5.77; N, 8.18; S, 3.75%.

*H–His(*im*-Dnp)–Glu(OBzl)–Cys(SBzl)–*D*-Phe–Gly–OH·HCl (XII·HCl).* The dry hydrogen chloride gas was bubbled through a solution of X (1.15 g, 1.1 mmol) in ethylacetate (30 ml) containing anisole (1.5 ml) for 10 min at 0 °C; the reaction mixture was then allowed to stand at room temperature for 30 min. After the solvent had been evaporated under reduced pressure, anhydrous ether was added; the crystals thus formed were collected in the theoretical yield. The products were used immediately for the next reaction.

*Boc–Glu(OBzl)–Cys(SBzl)–*D*-Phe–Gly–His(*im*-Dnp)–Glu(OBzl)–Cys(SBzl)–*D*-Phe–Gly–OH (XIII).* The solid XI (486 mg, 0.568 mmol) was added to a solution of XII·HCl (609 mg, 0.625 mmol) and triethylamine (0.26 ml, 1.875 mmol) in DMF (5 ml). After the reaction mixture had been stirred for 3 days at room temperature, it was acidified to pH 2 by the use of M hydrochloric acid in an ice bath and the precipitate thus formed was collected by filtration. The recrystallization from DMF–water gave a pure XIII; 881 mg, (92.7% yield); mp 187 °C (decomp.), $[\alpha]_D^{32}$ −4.2° (*c* 0.4, DMF). R_f[9] 0.80 (PW), 0.80 (BAW).

Found: C, 59.58; H, 5.44; N, 10.86; S, 4.03%. Calcd for $C_{87}H_{93}N_{13}O_{21}S_2$: C, 59.59; H, 5.60; N, 10.86; S, 3.83%.

*H–Glu(OBzl)–Cys(SBzl)–*D*-Phe–Gly–His(*im*-Dnp)–Glu(OBzl)–Cys(SBzl)–*D*-Phe–Gly–OH (XIV).* The dry hydrogen chloride gas was bubbled through a solution of XIII (1 g, 0.6 mmol) in dioxane (20 ml) and methylene chloride (20 ml) containing anisole (1.5 ml) for 30 min in an ice bath. After the reaction mixture had then been allowed to stand for 1.5 hr, the solution was concentrated under reduced pressure. The addition of anhydrous ether gave yellow crystals of XIV·HCl in the theoretical yield. Free XIV was obtained by the isoelectric point precipitation method; mp 175—177 °C. $[\alpha]_D^{23}$ −21.0° (*c* 1.1, DMF).

Found: C, 58.00; H, 5.43; N, 11.68; S, 3.63%. Calcd for $C_{78}H_{89}N_{13}O_{21}S_2$: C, 58.23; H, 5.58; N, 11.32; S, 3.99%.

*Boc–(His(*im*-Dnp)–Glu(OBzl)–Cys(SBzl)–*D*-Phe–Gly)$_2$–OH (XV).* Into a solution of XIV·HCl (2.168 g, 1.347 mmol) in DMF (10 ml) and water (1 ml), we stirred triethylamine (0.376 ml, 2.7 mmol) over a 20 min period in an ice bath. Solid IX (1.4 g, 2.7 mmol) was then added to the above solution. After the reaction mixture had been stirred at room temperature for an additional 3 days, the reaction mixture was acidified to pH 2 by the addition of M hydrochloric acid and the precipitate thus fromed was collected by filtration. The recrystallization form DMF–water gave pure yellow crystals in a 90% yield (2.37 g); mp 200 °C (decomp.). $[\alpha]_D^{24}$ −10.7° (*c* 0.3, DMF). R_f[9] 0.84 (PW), 0.86 (BAW).

Found: C, 56.63; H, 4.98; N, 12.13; S, 3.53%. Calcd for $C_{95}H_{105}N_{18}O_{28}S_2$: C, 56.71; H, 5.31; N, 12.53; S, 3.19%.

*Boc–(His(*im*-Dnp)–Glu(OBzl)–Cys(SBzl)–*D*-Phe–Gly)$_2$–NH–NH–Boc (XVI).* Into a solution of XV (1.96 g, 1 mmol), Boc–NHNH$_2$ (146 mg, 1.1 mmol), HOSu (230 mg, 2 mmol) in DMF (10 ml), we stirred, drop by drop, a solution of DCC (247 mg, 1.2 mmol) in DMF (3 ml) at 0 °C; the reaction mixture was then allowed to stand for 72 hr in a refrigerator. After the addition of acetic acid (0.5 ml), the dicyclohexyl urea thus produced was filtered off and was washed with cold DMF (3 ml). The filtrate was concentrated under reduced pressure, and the residual oily product was scratched by anhydrous ether. The powder-like product was recrystallized from DMF–water in a 97% yield (2.0 g); mp 192—192.3 °C (decomp.). $[\alpha]_D^{23}$ −6.53° (*c* 0.45, DMF). R_f[9] 0.73 (aqueous AcOEt).

Found: C, 58.05; H, 5.80; N, 13.32; S, 3.37%. Calcd for $C_{100}H_{110}N_{20}O_{26}S_2$: C, 57.96; H, 5.35; N, 13.52; S, 3.09%.

*Cyclo(His(*im*-Dnp)–Glu(OBzl)–Cys(SBzl)–*D*-Phe–Gly)$_2$ (XVIII).* *a)* Via *the Azide Method*: The dry hydrogen chloride gas was bubbled through a suspended solution of XVI (1.036 g, 0.5 mmol) in anhydrous dioxane (20 ml) con-

8) F. Chillemi and R. B. Merrifield, *Biochemistry*, **8**, 4344 (1969).

9) The thin layer chromatography solvent system. aqueous AcOEt: water saturated with ethyl acetate, PW: pyridine-water (4:1 v/v), BAW: *n*-butanol–acetic acid–water (4:1:1 v/v), BAPW: *n*-butanol-acetic acid–pyridine–water (4: 1: 2: 1 v/v).

taining anisole (1 ml) for 30 min at 0 °C. After the reaction mixture had been allowed to stand for 45 min at room temperature, the solvent was removed under reduced pressure; the addition of anhydrous ether to the residual oil gave a pure yellow product of decapeptide hydrazide di-hydrochloride (XVII·2HCl) in the theoretical yield.

Found: C, 52.27; H, 5.20; N, 13.86; S, 3.39%. Calcd for $C_{90}H_{110}N_{20}O_{29}S_2Cl_2$: C, 52.19; H, 5.35; N, 13.52; S, 3.10%.

The hydrazide was used immediately in the following cyclization procedure. Into a solution of XVII·2HCl (850 mg, 0.415 mmol) in DMF (10 ml) and acetic acid (10 ml), we stirred M sodium nitrite (0.45 ml, 0.45 mmol) and M hydrochloric acid (0.415 ml, 0.415 mmol) cooling at −10—−15 °C over a 60 min period. The reaction mixture was added, drop by drop, into cold pyridine (320 ml) at 0 °C over a 5 min. After the reaction mixture was stirred for an additional 24 hr at 0 °C. After the solvent had been evaporated under reduced pressure and water had been added to the residual oil, the product was collected by filtration and was dissolved in a mixed solvent of methanol–methylene chloride–DMF–water (17: 32: 5: 6 v/v). The solution was then treated with IRC-50 (1.5×25 cm) and IR-45 (1.5×25 cm) columns. The effluent (200 ml) was concentrated under reduced pressure, and the products were purified with Sephadex LH-20 by a mixed solvent of DMF–methylene chloride (1: 1 v/v). XVIII was obtained as crystals from DMF–water in an 87.6% yield (610 mg); mp 165—166.5 °C. $[\alpha]_D^{23}$ −21.4° (*c* 0.35, DMF). R_f[9] 0.94 (PW), 0.88 (BAW).

Found: C, 55.34; H, 5.12; N, 12.46; S, 3.61%. Calcd for $C_{90}H_{90}N_{18}O_{22}S_2\cdot 6H_2O$: C, 55.49; H, 5.28; N, 12.94; S, 3.29%. Mol wt Found:[10] 1880. Calcd for $C_{90}H_{90}N_{18}O_{22}S_2$: 1840.

b) Via *the ONp Method*: Di-*p*-nitrophenyl sulfite (4 g, 12.9 mmol) was added to a solution of XV (587 mg, 0.33 mmol) in pyridine (4 ml). After the mixture had been allowed to stand for 4 days at room temperature, the solvent was evaporated under reduced pressure. The residual product (XIX) was collected by using anhydrous ether (432mg); ν_{max}^{KBr} 1775 cm^{-1} (ester). XIX was treated with formic acid (5 ml) containing anisole (1 ml) at 20 °C. After the reaction mixture had been allowed to stand for 4 hr, the solution was concentrated under reduced pressure, and the *p*-nitrophenyl ester formate was immediately dissolved in DMF (10 ml) containing a small amount of acetic acid. The DMF solution was stirred, drop by drop, into prydine (148 ml) at 60 °C over a 4 hr period; the stirring was then continued for an additional 2 hr. Cyclic decapeptide (XVIII) was obtained in a 52% yield (334 mg) by the purification procedure described in a).

c) Via *the OSu Method*: The solution of XV (1.96 g, 1 mmol) and HOSu (253 mg, 2.2 mmol) in DMF (10 ml) was treated with DCC (453 mg, 2.2 mmol) at 0 °C for 4 hr. After the dicyclohexyl urea had been filtered off, the reaction mixture was concentrated under reduced pressure and the product (XX) was collected by using anhydrous ether; ν_{max}^{KBr} 1820, 1785, and 1742 cm^{-1} (C=O and ester). The active ester was dissolved in TFA (10 ml) containing anisole (1 ml). After the mixture had been allowed to stand at 0 °C for 2 hr, the solvent was removed under reduced pressure. The addition of anhydrous ether to the residual product gave decapeptide succinimide ester trifluoroacetate. The active ester was used immediately in the following cyclization procedure. A solution of the active ester dissolved in DMF (10 ml) containing 6 drops of acetic acid was added drop by drop into anhydrous pyridine (755 ml) at room temperature over a period 12 hr with stirring. The reaction mixture was also treated by the same purification procedure as has been described in a), but XVIII was not isolated; it was only detected by thin-layer chromatography.

*Cyclo(His–Glu–Cys–*D*-Phe–Gly)$_2$·2AcOH (I·2AcOH).* *i) Removal of the Benzyl Ester and the* s*-Benzyl Group*: XVIII (1.27 g, 0.7 mmol) was treated with anhydrous HF (10 ml) containing anisole (1.5 ml) at room temperature for 90 min. After the reaction mixture had been concentrated under reduced pressure, the residual oil was dissolved in aqueous acetic acid and the residual anisole was extracted with ether from the aqueous acetic acid layer. Also, the acetic acid layer was treated with an IR-45 (1.5×30 cm, acetate form) column. The effluent (100 ml) was concentrated under reduced pressure; the addition of peroxide-free anhydrous ether to the residual oil gave a white powder (XXI).

ii) Removal of the Dinitrophenyl Group: XXI was dissolved in DMF (10 ml), and the solution was adjusted to pH 8 with 10% sodium carbonate. After 2-mercaptoethanol (60 ml)[4] had been added to the above solution, the reaction mixture was allowed to stand at room temperature for 3 hr. The reaction mixture was then neutralized by acetic acid and was concentrated under reduced pressure. The residual product was immediately treated by the use of a Sephadex G-15 (5×50 cm) column by using 50% aqueous acetic acid. When the effluent was concentrated under reduced pressure and the residue was treated with peroxide-free ether, the free cyclic decapeptide (I) was obtained in a 64.9% yield (606 mg). $[\alpha]_D^{23}$ +3.5° (*c* 0.3, DMF). The purity of I was checked by thin-layer chromatography on Kieselgel G and by paper electrophoresis. The thin-layer chromatography of I showed a single spot; R_f[9] 0.56 (BAW): Pauly reaction, nitroprusside reaction positive; ninhydrin negative. On the paper electrophoresis, I moved as a single band toward the cathode; R_{His} 0.24.[11] No disulfide bond at all was detected in I by either the Ellman[5] or iodoacetamide method.[6]

Found: C, 45.64; H, 5.94; N, 13.71; S, 4.73%. Calcd for $C_{50}H_{62}N_{14}O_{14}S_2\cdot 2AcOH\cdot 8H_2O$: C, 45.95; H, 6.14; N, 13.89; S, 4.54%.

*H–(His–Glu–Cys–*D*-Phe–Gly)$_2$–OH·3AcOH (XXIII·3AcOH).* XV (964 mg, 0.5 mmol) was treated with anhydrous HF (15 ml) containing anisole (1.5 ml) at room temperature for 1 hr. After the reaction mixture had been treated in the same way as in the case of the cyclic decapeptide (I), the debenzylated product (XXII) was obtained in a 78% yield (609 mg). XXII (151 mg, 0.1 mmol) was treated with 2-mercaptoethanol (1.56 g, 20 mmol) in DMF (5 ml) at pH 8. XXIII was purified by the same method used for the cyclic decapeptide (I). XXIII·3AcOH was thus obtained in a 44.7% yield (65 mg). $[\alpha]_D^{23}$ +1.7° (*c* 0.3, DMF). R_f[9] 0.08 (BAW). R_{His} 0.58.[11] The amount of the free thiol group was measured by the Ellman method.[5]

Found: C, 46.03; H, 5.74; N, 13.56; S, 4.70%. Calcd for $C_{50}H_{64}N_{14}O_{15}S_2\cdot 3AcOH\cdot 6H_2O$: C, 46.27; H, 6.10; N, 13.49; S, 4.43%.

Kinetic Method of Catalytic Activity. A solution of a 1/15 M phosphate buffer containing dioxane and DMF was used for all the kinetic measurements, and all the experiments were carried out at 24±1 °C. DMF was used to increase the solubility of the peptide (I or XXIII) in the buffer solution.

The linear (XXIII) and the cyclic decapeptide (I) were

10) Molecular weight was measured by a Knauer Thermoelectric Cooling Unit for cryoscopic measurements using formic acid as a solvent.

11) Solvent system: pH 1.8 (HCOOH–AcOH–MeOH–water, 1: 3: 6: 10 v/v), 1000 v/20 cm, 1 hr, Toyo Roshi No. 50.

weighed and dissolved in DMF (1 ml) and the buffer (29 ml). The buffer solution was pretreated with nitrogen gas to remove the oxygen in the solution. A solution (0.1 ml) of *p*-nitrophenyl acetate in peroxide-free dioxane was added to the peptide solution (3 ml). The reaction mixture was rapidly stirred and the liberated *p*-nitrophenol was detected by the use of a Hitachi Photo-Electric Spectrophotometer (at 400 nm[3]).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1816—1819 (1973)

The Formation and Chelate-forming Properties of 2-Chloriminocyclohexanone Oxime and Its Hydrochloride

Yoshinari KOBAYASHI and Shigeru WAKAMATSU

Chemicals Research and Development Laboratories, Toray Industries, Inc., Minato-ku, Nagoya 455–91

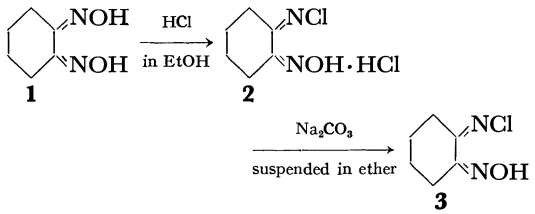
(Received December 4, 1972)

Cyclohexane-1,2-dione dioxime (**1**) in absolute ethanol containing hydrogen chloride was subjected to an irreversible dehydration to afford 2-chloriminocyclohexanone oxime hydrochloride (**2**), which could be liberated by cautious neutralization with sodium carbonate. The novel free and salt-form compounds thus obtained reacted with metal ions, such as Cu(II), Co(II), Ni(II), and Pd(II), to afford stable complexes. The molar ratio and the consecutive stability constants of a Ni(II) complex of **2** were determined and compared with those of a complex of **1** with Ni(II). An approximate linear relationship between the logarithm of the rate constant of the *N*-chlorimination and the acidity function, H_0, was observed.

The ordinary reaction of oximes with hydrogen chloride in nonaqueous solvents affords the corresponding stable salts, which can be reversibly set free with strong bases. Cyclohexanone oxime[1a,b] and its 2-substituted derivatives,[1c,d] the substituents of which are alkyl, alkoxyl, hydroxyl, piperidinyl, morpholinyl, and so on, are typical examples. In an attempt to prepare cyclohexanedione dioxime dihydrochlorides, we have found that cyclohexane-1,2-dione dioxime (**1**) can readily be transformed into novel 2-chloriminocyclohexanone oxime hydrochloride (**2**). The conventional synthetic routes to *N*-chlorimines are the chlorination of the corresponding imines with hypochloric acid or its derivatives,[2–5] the reaction of carbonyl compounds with chloramine[6,7] and the dehydrochlorination of *N,N*-dichloro-*sec*-alkylamines by the action of strong bases.[8–10] There are few papers[11] reporting the direct conversion of hydroxyimino group into *N*-chlorimine. The present paper will report the formation of **2** from **1** by the direct displacement of one of the hydroxyl groups of the hydroxyimino groups with chloride and the chemical properties, especially, related to a ligand in chelate complexes.

Results and Discussion

Formation of 2-Chloriminocyclohexanone Oxime and Its Hydrochloride. It was found that when an absolute ethanolic solution of cyclohexane-1,2-dione dioxime (**1**) was, after the introduction of dry hydrogen chloride to saturation at temperatures between −1 and 1 °C, allowed to stand for several days at a low temperature colorless-needle-form crystalline 2-chloriminocyclohexanone oxime hydrochloride (**2**) was precipitated with the formation of its equivalent molar water.



1 **2** **3**

As is shown in Fig. 1, the chloride titrations of **2** with silver nitrate indicates that the ionic chloride in **2** is equal to half of the total chlorine content. The successful liberation of **2** to 2-chloriminocyclohexanone oxime (**3**) proceeded by means of the neutralization of 2 suspended in diethyl ether with an aqueous sodium carbonate solution at temperatures between −10 and 5 °C.

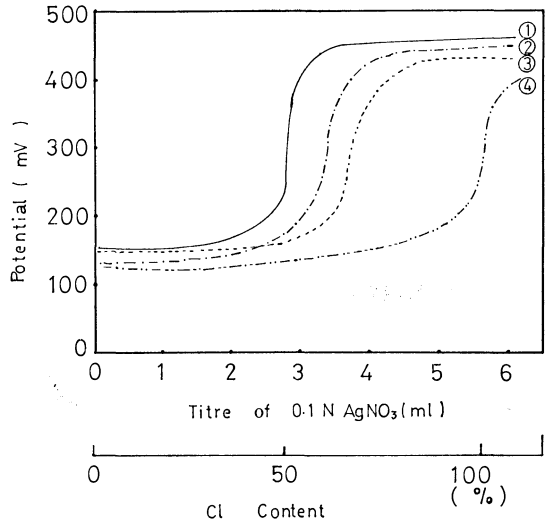

Fig. 1. $AgNO_3$ titration curves of 2-chloriminocyclohexanone oxime hydrochloride.
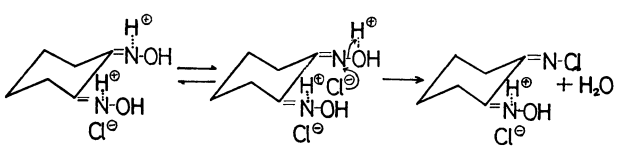
Condition: Sample 55.5 mg/30 ml H_2O; Temp. 25°C
1: Without buffer solution (pH 2.3); 2: Buffer solution pH 4.6; 3: Buffer solution pH 6.3—7.3; 4: Hydrolysis in alkaline solution.

The structures of **2** and **3** were supported not only by the results of the elemental analysis, the molecular-weight determinations, the titration curves and the UV and IR spectra, but also by the formation of such derivatives as cyclohexane-1,2-dione bis-(2,4-dinitrophenylhydrazone) and 1,2,3,4,6,7,8,9-octahydrophenazine: the latter was obtained by the hydrogenation of **2** in ethanol over palladium chloride. Compounds **2** and **3** also retained such chelate-forming properties as those in **1**.

Acyclic vicinal dioximes, such as dimethylglyoxime, diphenylglyoxime and di-α-furylglyoxime, normally gave the corresponding dihydrochlorides by reactions with hydrogen chloride under the same anhydrous conditions. Cyclohexane-1,3-dione dioxime monohydrochloride was immediately precipitated from an absolute ethanolic solution as soon as dry hydrogen chloride was introduced. Simple dihydrochloride, however, could not be isolated even from the solution saturated with hydrogen chloride. This result is in marked contrast with that of cyclohexane-1,4-dione dioxime, which affords the normal dihydrochloride.

From these results, we can conclude that the *N*-chlorimine formation is limited to **1**. The structure of cyclohexanone oxime hydrochloride has been reported to be one in which proton is donated to the nitrogen atom.[1] In the case of **1**, the proton transfer to the oxygen atom in one of the hydroxyimino groups is supposed to bring about a partial ionization of the hydroxyimino group as in an intermediate of the Beckmann rearrangement. The electron deficient nitrogen or nitronium thus formed may then be nucleophilically attacked by chloride to afford the *N*-chlorimine.



The peculiar reactivity of **1** may be ascribed to the fact that the rigid co-planarity of vicinal dioxime groups where protons donate and when counter anions, chloride anions, exist, makes the salt unstable and so likely to undergo the α-displacement described above.

Table 1. Rate constants of 2-chloriminocyclohexanone oxime hydrochloride formation from cyclohexane-1,2-dione dioxime[a] in ethanol

Temperature (°C) (±0.1)	Rate constants (hr^{-1}) × 10^{-2}		
	From the dioxime	From H_2O formed	Mean
0.0	1.72	1.48	1.60
10.0	2.88	3.22	3.05
20.0	7.66	5.27	6.45

a) The concentration of hydrogen chloride was 34.0—34.8% by weight.

Table 2. Determination of thermodynamic quantities in the formation of 2-chloriminocyclohexanone oxime hydrochloride

Solvent	E_a (kcal/mol)	(e.u.)$\Delta S^{\neq}$	Concentration of HCl (wt%)
Ethanol	11.1	−19.4	34
Dioxane	19.4	− 8.4	10
Cyclohexanone oxime dihydrochloride	7.1	−39.1	36

Kinetics. The rate of the conversion of **1** into **2** was of the first order in a non-aqueous solution at a given concentration of hydrogen chloride. Table 1 shows that the decreasing rate of **1** was approximately equal to the rate of the formation of water. The activation energy was measured in ethanol, dioxane and cyclohexanone oxime;[14] the results are shown in Table 2. These substances are all solvent-dependent, *i.e.*, smaller in more polar solvents. The rate of the *N*-chlorimination increased with an increase in the concentration of hydrogen chloride in absolute ethanol, but there was no linear relationship between them. However, when the acidity function, H_0, was measured in an absolute ethanol solution of hydrogen chloride at 10 °C, an approximate linear relationship between the logarithm of the rate constant, k, and the acidity function, H_0, was observed (Fig. 2). In discussing the probable transition state from the relationship between the rate constant and the acidity function, H_0, Hammett[15] suggested that when the conjugate acid of the reactant takes part in the rate-determining step, the $\log k = -H_0 + \text{const.}$ relation should hold. This prediction of the unit slope relationship was not realized in the authors' experiments, but there may be some significance in the approximate linear relationship between $\log k$ and H_0.

Chelate-forming Properties. The *N*-chlorimines **2** and **3** co-ordinate to various metal ions, *e.g.*, copper-

14) Cyclohexanone oxime dihydrochloride forms an oily material.[1a,1b]

15) L. P. Hammett, "Physical Organic Chemistry," McGraw-Hill Book Co., Inc., New York, N. Y. (1940), p. 273.

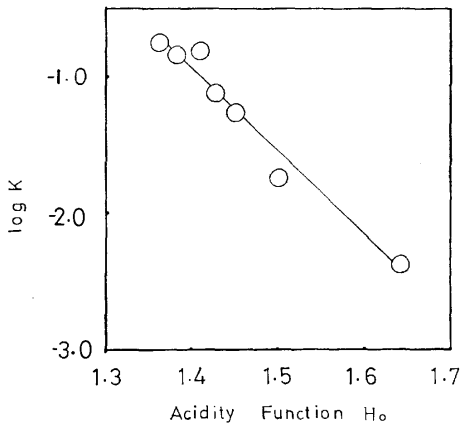


Fig. 2. The relationship between acidity H_0 and log k in 2-chloriminocyclohexanone oxime hydrochloride formation.

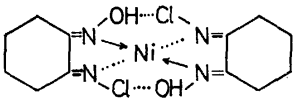
(II), nickel(II), cobalt(II), and palladium(II) ions, such as **1** does. However, the *N*-chlorimines are not polarographically active.

Copper(II) Complex of 2. The absorption spectra change on the change in the molar ratio of **2** to the copper(II) ion and the pH of its aqueous solution. In a neutral solution, the complex has its maximum absorption at 264 nm in the presence of an excess of copper(II) ion. However, when the molar ratio is higher than two, the complex shows its maximum at 545 nm ($\varepsilon=1.03\times10^2$). At pH values below three, the complex is not formed. A stable violet complex solution is obtained at pH value from 5 to 6. By Job's continuous variation method,[16] the molar ratio was determined to be two in the stable complex in solution.

Nickel(II) Complex of 2. The formation of the nickel(II) complex was considerably affected by the pH, and the chelate could be formed only in the alkaline range. The absorption spectrum has no maximum at pH 10, but a shoulder at 420 nm ($\varepsilon=7.10\times10^2$). In a buffer solution at pH 8.0, the molar ratio was determined to be two by Job's method. By means of Bjerrum's pH measurement method[17] and Block-McIntyre calculations[18] the consecutive stability constants were measured in 75% aqueous dioxane at 20 °C and found to be $\log k_1=7.90$ and $\log k_2=4.81$. Accordingly, appreciable amounts of the mono complex must exist in the presence of an excess of nickel(II). In contrast, vicinal dioximes give the $k_1<k_2$[19] stability constants. Especially, the nickel(II) complex of **1** has stability constants at 25 °C $\log k_1=8.52$ and $\log k_2=8.82$. Therefore, the overall stability constant ($\log k_1\cdot k_2=12.71$) of the nickel(II) complex of **2** is much smaller than that ($\log k_1\cdot k_2=17.34$) of the corresponding complex of **1**. From analogy with the metal (II)-vicinal dioxime complexes,[20] the complex was supposed to have the following structure:



The relative instability of the nickel(II) complex of **2** and the $k_1\gg k_2$ relationship can be attributed to the weaker hydrogen bonding in the –OH···Cl bond in the complex than in the –OH···O bond in the nickel(II) complex of **1**, and to the steric effect of chlorine.

Cobalt(II) and Palladium(II) Complexes. The *N*-chlorimine **2** formed a stable complex with the cobalt(II) ion in an alkaline solution, the absorption spectrum of which had neither maximum nor shoulder. The molar ratio was also shown to be two. The palladium(II) ion readily reacted with **2** to precipitate a yellow complex.

Experimental

Apparatus. The IR spectra were measured on a Shimadzu IR spectrometer IR-27A. The electronic spectra were recorded by means of a Hitachi Spectrometer EPS-2. The pH measurements were made with a Horiba pH Meter, type M. The potentiometric titration curves were obtained by the use of a Metrohm Potentiograph E-336. The molecular weights were determined by means of a Mechrolab Vapor-pressure Osmometer.

Materials. The cyclohexanedione dioximes were prepared by the procedure described in a previous paper.[21] The copper(II), nickel(II), cobalt(II), and palladium(II) ions used were $Cu(OCOCH_3)_2\cdot H_2O$, $NiCl_2\cdot6H_2O$, $CoCl_2\cdot6H_2O$, and $PdCl_2$ respectively, all were of analytical grade purity and were used without further purification.

2-Chloriminocyclohexanone Oxime Hydrochloride (2). To a solution of **1** (90 g) in absolute ethanol (200 ml) on a brine bath at −1—1 °C, we introduced dry hydrogen chloride until the point of saturation (about 33—34% by weight). After the mixture had stood for several days in a refrigerator, colorless needle crystallines were precipitated; they were filtered off and washed with anhydrous diethyl ether. Yield, 80 g (64%). Mp 130 °C (decomp.). UV (ethanol): 224 (log $\varepsilon=4.66$), 265 nm (log $\varepsilon=4.46$). IR (KBr): 3240 (OH), 2600 (N^+–H), 1665 cm^{-1} (C=N). Found: C, 36.45; H, 4.95; O, 8.65; N, 13.69; Cl, 36.64. Calcd for $C_6H_{10}N_2OCl_2$: C, 36.57; H, 5.11; O, 8.12; N, 14.22; Cl, 36.64%. The potentiometric titration curves obtained by the use of silver nitrate are shown in Fig. 1. No such polarographic activity as that of **1**[22] was observed.

2-Chloriminocyclohexanone Oxime (3). Into a suspension of **2** (10.5 g) in diethyl ether (100 ml) on a brine bath at −5—−10 °C, was added drop an aqueous 10% sodium carbonate solution with stirring to bring the pH of the aqueous phase to about 10. After the separation of the ether phase the aqueous phase was extracted with four 25 ml portions of diethyl ether. The ether fractions were then combined and dried over anhydrous sodium sulfate. The solvent was

distilled off, and the residue was recrystallized from water to afford colorless needles. Yield, 6.8 g (85%). Mp 115.0—116.5 °C. UV (water): 265 nm ($\log \varepsilon = 3.99$), IR (KBr); 1655 cm^{-1} (C=N). (mol. wt. by vapor-pressure osmometry in ethanol): 162 (Calcd for 160.2). Found: C, 44.55; H, 5.68; N, 17.47; O, 10.36; Cl, 22.07%. Calcd for $C_6H_9N_2OCl$: C, 44.87; H, 5.65; N, 17.44; O, 9.96; Cl, 22.08%.

Cyclohexane-1,2-dione-bis-(2,4-dinitrophenylhydrazone) from **2**. To a solution of 2,4-dinitrophenylhydrazine (2.0 g) in 95% ethanol (140 ml), conc. hydrochloric acid (100 ml) and **2** (2.0 g) were successively added. The mixture was then refluxed for 30 min with occasional stirring. After the mixture had stood overnight in a refrigerator, an orange precipitate was formed; this was filtered off and recrystallized from ethanol. Yield, 4.9 g. Mp 220—222.5 °C (decomp.); undepressed by admixture with an authentic sample derived from **1** (lit,[23] mp 220 °C). IR: superimposable with that of an authentic sample. Found: C, 45.47; H, 4.02%. Calcd for $C_{18}H_{16}O_8N_8$: C, 45.77; H, 3.42%.

1,2,3,4,6,7,8,9-Octahydrophenazine from **2**. Nine grams of **2** in absolute ethanol (220 g) were hydrogenated by palladium chloride (0.6 g as Pd) under atmospheric pressure at room temperature with constant shaking. About 2.7 l of hydrogen was absorbed. After the removal of the catalyst, the solvent was distilled off and benzene was added. The precipitated ammonium chloride was then filtered off, and the filtrate was neutralized with sodium hydroxide solution and steam-distilled. The water was removed *in vacuo*, and the residue was recrystallized from benzene or acetone to afford colorless plate crystalline: 1,2,3,4,6,7,8,9-octahydrophenazine hydrochloride hydrate (0.65 g). Mp 124—126 °C. UV (ethanol): 214 ($\log \varepsilon = 3.76$), 291 ($\log \varepsilon = 3.90$), 310 nm ($\log \varepsilon = 3.93$). IR (KBr): 2380, 1980 cm^{-1} (N^+–H), H_2O content: 8.1% (requires 7.42%), as determined by Karl Fischer's method. Found: C, 59.06; H, 7.89; N, 11.53; Cl, 14.86; O, 5.65%. Calcd for $C_{12}H_{16}N_2 \cdot HCl \cdot H_2O$: C, 59.37; H, 7.89; N, 11.54; Cl, 14.61; O, 6.59%. The base was successfully liberated by neutralization with an anionic exchanger Amberlite CG-400 (OH type), followed by steam distillation. Mp 109 °C (lit,[24] 108—109 °C). Found: C, 76.73; H, 8.44; N, 14.26%. Calcd for $C_{12}H_{16}N_2$: C, 76.55; H, 8.57; N, 14.88%.

Determination of the Rate Constants of the Dehydration Reaction of **1** *with HCl*. To a 200 ml Erlenmeyer flask with a grinding stopper containing absolute ethanol (150 ml) saturated with dry hydrogen chloride, **1** (4.5 g) was introduced with vigorous shaking. The flask was then placed in a desiccator and kept in a refrigerator at a constant temperature. The contents of both **1** and water were determined at given intervals.

Determination of **1**. About 2 g of the sample were pipetted out, accurately weighed, and then poured into water (200 ml). A 20% ammonium acetate solution was added to adjust the pH to 5.5—6.0. Then, 10 ml portion of an aqueous nickel(II) chloride solution (1 mg as Ni(II)/ml) was added, and the whole was kept standing for 3—4 hr at 40 °C. The red precipitates were filtered off with a glass-filter G4 and gravimetrically determined.

Determination of the Water Formed. About 5 g of the sample were pipetted out, poured into a mixture of absolute ethanol (10 ml) and anhydrous pyridine (5 ml), and accurately weighed. The water concentration in the solution was determined by Karl Fischer's method.

Determination of the Acidity Function, H_0. The acidity functions of the absolute ethanol–hydrogen chloride system were determined spectrophotometrically with *p*-nitroaniline at 360 nm.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1819—1822 (1973)

The Structure of the Crystalline Adduct of Nitrosobenzene and 2,3-Dimethyl-1,3-butadiene

Eizo OIKAWA and Suguru TSUBAKI

Faculty of Engineering, Niigata University, Nagaoka, Niigata 940

(Received December 9, 1972)

The structure of the crystalline product obtained in up to an 18% yield in the reaction of nitrosobenzene with 2,3-dimethyl-1,3-butadiene in diethyl ether was determined to be the nitrone, II, by means of NMR, IR, and a series of reductions with lithium aluminum hydride and zinc–acetic acid, and by the ozonization of the reduction product.

Nitrosobenzene (NB) has been used as a dienophile in the Diels-Alder reaction with dienes. In the reaction with 2,3-dimethyl-1,3-butadiene (DMB) in diethyl ether, a white precipitate was obtained in a few minutes at from 0 °C to room temperature, in addition to the normal Diels-Alder adduct. This product was first reported by Arbuzov and his co-workers[1] although they did not give any structure, just the molar composition of 2NB: DMB. Hamer and Bernard[2] have carried out a very similar reaction of *p*-nitronitrosobenzene with DMB in nitromethane and obtained an orange precipitate at 0 °C in 15 min. They identified the product as 4,5-dimethyl-1,2-bis(*p*-nitrophenyl)-1,2,3,6-tetrahydropyridazine 1,2-dioxide. The present authors have now investigated the structure of the

2) J. Hamer and R. E. Bernard, *J. Org. Chem.*, **28**, 1405 (1963).

white product (**A**) of NB and DMB and determined it to have a nitrone structure.

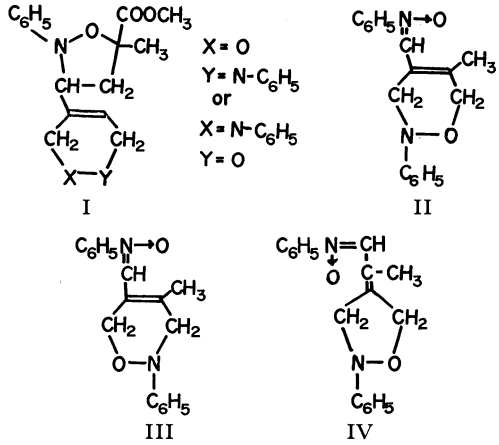
Results and Discussion

The product, **A**, was obtained in a higher yield (up to 18%, based on 2 mol of NB and 1 mol of DMB) in diethyl ether and in a poor yield (5%) in benzene, but in nitromethane nothing but the normal Diels-Alder adduct was obtained. The thin-layer chromatography of **A** gave just one spot, indicating that the product was a pure material, not a mixture. The most striking characteristics of **A** were given in NMR, in which 18 protons, including 3 methyl protons, were found. This showed a clear difference in the phenyl and methyl region from the NMR of the Diels-Alder adduct of NB–DMB, 2-phenyl-4,5-dimethyl-3,6-dihydrooxazine (**B**), and from that of DMB–4,4′-dinitroazobenzene, 4,5-dimethyl-*N*,*N*-(4,4′-dinitrophenyl)-1,2,3,6-tetrahydropyridazine,[3] both of which contained 6 methyl protons. One methyl group per molecule of **A** means that one of the two initial methyl groups from DMB has reacted. This rules out a pyridazine dioxide structure. Eleven protons in the phenyl region were well observed in a $(CD_3)_2SO$ solution, as will be described in the Experimental section. The peak at δ 8.07 may be assigned to the aldo-nitrone structure, $-CH{=}N(O)Ph$.[4] These NMR analyses can give $C_{18}H_{18}N_2O_2$ as the molecular formula of the product; this formula is closer to the observed analysis that is $C_{18}H_{20}N_2O_2$ (2NB: DMB).

The nitrone structure was supported by the following experimental results. Irradiation with ultraviolet light yielded an isonitrile odor, reduced the strong peak at 1535 cm^{-1} assigned to N→O, and concurrently increased the peaks at 1665 and 1267 cm^{-1} attributed to C=O and C–N respectively. The treatment with

PCl_3 or $POCl_3$ in chloroform at room temperature overnight also reduced the peak at 1535 cm^{-1} and afforded a new peak at 1681 cm^{-1} which can be attributed to the amide group. These characteristics are generally observed in nitrone compounds.[5] One of the characteristic reactions of nitrone is the 1,3-dipolar addition to an alkene.[6] The treatment with an excess of methyl methacrylate gave colorless crystals. The NMR and elemental analyses are in good agreement with the structure of the isoxazolidine, I.

The formation of a nitrone from NB and alkene was reported long ago by Alessandri[7] in the reaction of NB with safrole and similar compounds; since then, however, very few articles have appeared.[5,8]



I II III IV

The possibility of the existence of a ring containing N–O from NB in **A** was indicated by the strong IR peaks at 1067 and 1082 cm^{-1}, since **B** has strong absorptions at 1047 and 1065 cm^{-1} attributable to the oxazine ring.[9] The existence of such a ring was supported by the fact that the reduction of **A** with zinc–acetic acid under conditions similar to those in the case of **B**[10] gave a solid whose IR showed no absorption at 1535 and markedly reduced absorptions at 1065 and 1082 cm^{-1}; subsequent treatment with acetic anhydride produced an acetylated solid whose IR had two carbonyl absorptions at 1735 (ester) and 1650 cm^{-1} (amide), the latter being remarkably decreased after hydrolysis with K_2CO_3 in methanol–water. The same behavior was observed in the case of **B**, and the IR absorptions of the acetylated product of **A** and **B** had nearly the same wave number and relative intensity. Furthermore, a structure which does not contain any cyclic N–O bond can not satisfy the elemental composition.

The double bond in **A** was detected with potassium permanganate and bromine.

All the foreging results obtained from the spectra, functional tests, and reduction suggest three probable structures, II, III, and IV, for **A**, but could not decide the correct structure. The final structure was determined by reduction with lithium aluminum hydride in tetrahydrofuran[8] and subsequently with zinc–acetic acid, followed by acetylation with acetic anhydride and the ozonization of the acetylated product in acetic acid. The colorless product thus obtained was identified as bis(*N*-acetylanilino)acetone, VIII. The acetoxyacetone, IX, was identified by gas chromatography.

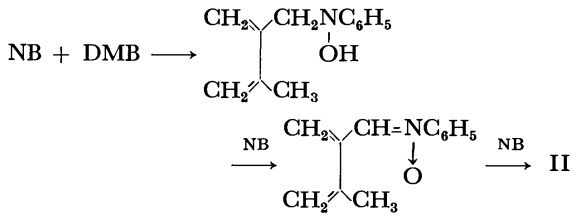
VII VIII IX

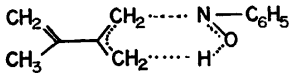
Consequently, the crystalline product, **A**, from NB and DMB was found to be the nitrone, II. This structure is also in accord with the results of catalytic hydrogenation, in which one mole of **A** consumed 6 mol of hydrogen, 3 mol for the nitrone part and the other 3 for the oxazine part.

The nitrone formation from DMB seems important because simple alkenes such as propylene, butenes, and octenes have not thus far given a nitrone.

The reaction may proceed *via* intermediate secondary hydroxylamine:[11]



Since the first step is an "ene" reaction, the isopropenyl group may contribute to the stabilization of the transition state, facilitating the production of a nitrone in the reaction with NB:



Experimental

All the melting points were corrected.

Materials. The nitrosobenzene was prepared by the reduction of nitrobenzene;[12] it was purified by sublimation before use. The 2,3-dimethyl-1,3-butadiene was prepared from acetone.[13,14] A guaranteed grade of nitromethane was purchased and was used without further purification. The other organic solvents for the reactions and for recrystallization were distilled before use. The 4,5-dimethyl *N,N*-(4,4′-dinitrophenyl)-1,2,3,6-tetrahydropyridazine was prepared by the Diels-Alder addition of 2,3-dimethyl-1,3-butadiene and 4,4′-dinitroazobenzene;[3] NMR ($(CD_3)_2SO$) δ 8.13 (d, 4, benzene ring), 7.04 (d, 4, benzene ring), 4.14 (q, J=16, 4, NCH_2), 1.67 (s, 6, CH_3).

Formation of Nitrone, II (A). A typical procedure was as follows; in a 100 ml, three-necked flask fitted with a thermometer, was placed 13.47 g (125.8 mmol) of NB and 80 ml of diethylether. After all of the nitrosobenzene had been dissolved with occasional warming, the solution was cooled to 5 °C and 9.91 g (120.5 mmol) of distilled DMB was added. The mixture was then stirred magnetically at room temperature (16 °C) for 6 hr. The white precipitate was formed within several minutes after the addition of the diene. The mixture was allowed to stand in a refrigerator overnight. The precipitate was filtered and recrystallized from ethanol or carbon tetrachloride into needles. Yield, 3.15 g (17.9% based on 2NB: DMB), mp 160.0—160.5 °C. Found: C, 73.50; H, 6.01; N, 9.29%; mol wt (cryoscopically in nitrobenzene), 294. Calcd for $C_{18}H_{20}N_2O_2$ (2NB: DMB): C, 73.00; H, 6.76; N, 9.12%; mol wt, 296; for $C_{18}H_{18}N_2O_2$: C, 73.45; H, 6.16; N, 10.87%; mol wt, 294. NMR ($CDCl_3$): δ 7.7—7.0 (m, 11), 4.75 (s, 2, OCH_2), 4.56 (s, 2, NCH_2), 1.86 (s, 3, CH_3). Phenyl region in $(CD_3)_2SO$: δ 8.07 (s, 1), 7.91—7.81 (m, 2), 7.58—7.47 (m, 3), 7.41—6.92 (m, 5).

The Diels-Alder adduct of NB–DMB, 2-phenyl-4,5-dimethyl-3,6-dihydrooxazine (**B**), was obtained from the filtrate; *i.e.*, the brown filtrate was concentrated and a small amount of ethanol was added. The solution was then cooled to about −20 °C. The white solid thus formed amounted to 9.34 g (40.9%) and was recrystallized from ethanol. Mp 37.5—38.5 °C; NMR ($CDCl_3$) δ 7.4—6.7 (m, 10, phenyl), 4.34 (s, 2, OCH_2), 3.67 (s, 2, NCH_2), 1.73 (s, 3, CH_3), 1.64 (s, 3, CH_3).

The reaction of 2 mol of NB with 1 mol of DMB and a nitrogen atmosphere did not increase the yield of **A**.

A similar treatment of 10.70 g (100 mmol) of NB and 8.10 g (98.8 mmol) of DMB in 60 ml of benzene gave 0.79 g (5.4%) of **A** and 5.84 g (31.1%) of **B**.

In nitromethane no precipitation occurred. A brown reaction mixture of 1.0 g (9.35 mmol) of NB and 0.80 g (9.73 mmol) of DMB in 40 ml of nitromethane was concentrated under reduced pressure, after which a large amount of diethyl ether was added. The solution was subsequently cooled to −10 °C, but no precipitate was formed. The evaporation of the solvent gave 0.33 g (18.7%) of **B**.

Measurements. The NMR spectra were recorded with a Japan Electron Optics Lab. Model JNM-4H-100 high-resolution spectrometer at 100 MHz at room temperature, with tetramethylsilane as the internal standard. The infrared spectra were recorded on a KRS-5 plate or by the KBr method with a Hitachi EPI-S2 double-beam spectrometer.

Thin-layer chromatography was carried out on silica gel (WAKOGEL B-5 UA) which was put on a glass plate (0.25 mm thick) and activated at 110 °C for 3 hr. A small drop of an about 1% chloroform solution of **A** was placed on the plate and developed with a mixture of chloroform–acetone (85 to 15 vol%) for 50 min. Coloring with sulfuric acid gave one spot with an R_f value of 0.59. A similar treatment with benzene–acetone (90 : 10 vol%) for 30 min gave one spot again, with an R_f value of 0.53.

Qualitative Tests of A. Irradiation by Ultraviolet Light: A small amount of **A** was placed in a quartz test tube, after which the test tube was stoppered and irradiated with a 100 W high-pressure mercury arc lamp for about half an hour. The initial white solid turned brown, and an isonitrile odor was perceived. The IR spectrum of the brown solid was recorded by the KBr pellet method.

Treatment with $POCl_3$ or PCl_3: 0.44 g of **A** was dissolved in 30 ml of chloroform, and then the mixture was ice-cooled. $POCl_3$ or PCl_3 (3 ml) was added to the cooled solution, which then turned red brown; the solution was allowed to stand overnight at room temperature. The subsequent evaporation of the solvent and an excess of the phosphorus compound gave a deep brown semisolid. It was dissolved in ethanol and cooled at −20 °C for 2 days, but no precipitate was yielded. The solution was then distilled at 60 °C under

reduced pressure, and 0.38 g of a pale yellow liquid was obtained.

Detection of Unsaturated Group: To an acetic acid solution of **A** was added a few drops of a 0.5% potassium permanganate solution. The purple color was immediately lost. A carbon tetrachloride solution of bromine (1—2%) was added dropwise to 0.5 ml of a 1% acetic acid solution of **A**. More than two drops were needed before the color of bromine stayed.

Reaction with Methyl Methacrylate. In a 100 ml three-necked flask equipped with a condenser and a thermometer, was placed 0.50 g of **A** and an excess of methyl methacrylate (20 ml) containing a small amount of hydroquinone. The solution was then heated at 55 °C for 15 hr and at 80 °C for 2 hr. The excess methyl methacrylate was removed under reduced pressure, and the remaining pale yellow liquid was poured into petroleum ether. After a while, a white crystalline solid (I) was precipitated (0.39 g). The filtrate was concentrated, and another 0.23 g of the solid was obtained. Yield, 0.62 g (92.8%). It was recrystallized from methanol. Mp 118.0—118.5 °C. Found: C, 69.76; H, 6.29; N, 6.99%. Calcd for $C_{23}H_{26}N_2O_4$: C, 70.03; H, 6.64; N, 7.10%. NMR ($CDCl_3$): δ 7.37—6.90 (m, 10, phenyl), 4.75 (t, 1, CH), 4.39 (s, 2, OCH_2), 3.95 (s, 2, NCH_2), 3.58 (s, 3, OCH_3), 2.70 (q (two pairs), J=13, 2, CH_2(MMA)), 1.74 (s, 3, CH_3C=), 1.67 (s, 3, CH_3(MMA)).

Reductions and Acetylation. In a 100 ml Erlenmeyer flask was placed 2.14 g of lithium aluminum hydride and 60 ml of dry tetrahydrofuran; the stoppered flask was then cooled in an ice bath with magnetic stirring. To the flask was then added 3.14 g of **A** in small portions. The ice bath was removed, and the mixture was allowed to stand at room temperature for 4.5 hr with stirring. The excess of the hydride was then destroyed by adding water slowly. Diethyl ether was added to extract the product with shaking; the solution was collected by decantation. This procedure was repeated several times. The combined ether solution was dried over anhydrous sodium sulfate. The ether was removed under reduced pressure to give 2.55 g of an orange viscous liquid. About 30 ml of *n*-hexane was added to the liquid, and the mixture was heated. Because some of the liquid remained undissolved, ethanol was added with shaking until all the liquid had been dissolved. The solution was allowed to stand in a refrigerator (*ca.* 5 °C) for 2 days. The crystalline solid which formed at the bottom was removed by decantation and was found to be unreacted **A** by the measurement of the mp and IR spectra. The solution was subsequently evaporated to give 1.99 g of V.

In a 100 ml Erlenmeyer flask was placed 1.99 g of V and 25 ml of acetic acid; 6.08 g of zinc dust was then added slowly under water cooling (22 °C) and with magnetic stirring. Stirring was continued at room temperature (26 °C) for 5 hr. The mixture was then filtered, and the solid was washed with a small amount of acetic acid and then with diethyl ether. The filtrate and washings were combined, neutralized with a NaOH solution under ice cooling, and then extracted with diethyl ether. The extract was washed with water and dried over anhydrous sodium sulfate. The ether was then evaporated to give 1.42 g of VI. It was purified by distillation in a bent glass tube under highly reduced pressure. Yield, 1.28 g of a pale yellow semisolid. Found: C, 76.57; H, 7.67; N, 9.51%. Calcd for $C_{18}H_{22}N_2O$: C, 76.56; H, 7.85; N, 9.92%.

In a round-bottomed flask with a condenser was placed 1.28 g of VI, 80 ml of acetic anhydride, and about 0.2 g of anhydrous potassium acetate. The mixture was heated at 105 °C in an oil bath for 7 hr. The solution was then concentrated and neutralized with potassium carbonate. The brown crystals which came out were then dissolved in benzene. The solution was washed with water, dried over anhydrous sodium sulfate, filtered, and evaporated to dryness to give 1.76 g of crude VII. It was purified by recrystallization from *n*-hexane–diethyl ether as white crystals. Yield, 1.33 g; mp 106.0—106.5 °C. Found: C, 70.44; H, 6.61; N, 6.75%. Calcd for $C_{24}H_{28}N_2O_4$: C, 70.57; H, 6.91; N, 6.86%.

A (2.0 g) was also treated with zinc–acetic acid in a manner similar to that described above, yielding 1.1 g of a pale brown solid (softening point, 75 °C). Found: C, 77.72; H, 7.31; N, 8.51%. Calcd for $C_{18}H_{20}N_2O$: C, 77.14; H, 7.14; N, 10.00%. The subsequent acetylation of the reduction product (0.50 g) was carried out similarly, yielding 0.46 g of a brown solid (softening point, 85 °C). Found: C, 72.34; H, 6.57; N, 6.49%. Calcd for $C_{22}H_{24}N_2O_3$: C, 72.53; H, 6.59; N, 7.69%. The hydrolysis of the amide group was carried out as follows; to a methanol solution of this solid was added an aqueous potassium carbonate solution until a slight cloudiness was observed. The mixture was then heated to boil for a few minutes, and then acidified with sulfuric acid. The white precipitate thus formed was filtered and dried *in vacuo*.

Catalytic Hydrogenation. **A** was hydrogenated over a Raney Ni or Pd–$BaSO_4$ catalyst. Raney Ni was used as an isobutyl alcohol suspension after the Raney Ni alloy (Ni: Al= 1:1) had been treated with an aqueous solution of sodium hydroxide. Pd–$BaSO_4$ was prepared from palladium chloride in hydrochloric acid and a water suspension of barium sulfate from barium hydroxide and sulfuric acid. Styrene was used in a control reaction for the calibration of the results.

In a 30 ml reaction flask was placed a stirring bar and 10 ml of isobutyl alcohol containing 0.4—0.5 g of the catalyst. About 15 mg of **A** was weighed accurately in a small aluminum basket and hung on a hook in the flask. After the complete absorption of hydrogen by the catalyst and the solvent (about 3 hr), the basket was dropped and stirring was continued for from 3 to 4 hr until the manometer showed no further change. The average absorption was 6.21 mol of hydrogen per mol of **A** (294 as mol wt). When α,*N*-diphenylnitrone and **B** were treated similarly, they absorbed 3 mol of hydrogen per mol of the sample. In the former case, a primary amine was detected in the reduction mixture by a carbylamine test and a diazo test.

Ozonization. The acetylated product, VII (0.60 g), was dissolved in 4 ml of acetic acid, and an oxygen stream containing ozone was bubbled through the solution at 0 °C. The reaction was continued for 16.5 hr until the color of the solution changed from the red-brown of the initial stage to a very pale yellow. Into the solution was then added 3.0 g of zinc dust with stirring. The solution did not change the color of KI-starch paper. A gas chromatogram of the solution, recorded by using a 75 cm column of SE-30 on celite at 176 °C, had a peak at the same retention time (1.4 min) as that of the solution containing acetoxyacetone obtained by the ozonization of acetylated **B**. The acetic acid solution was filtered, and the zinc was washed with a small amount of acetic acid and then diethyl ether. The filtrate and washings were then combined and evaporated to give a white crystalline solid, VIII. It was recrystallized from ethanol. Yield, 0.23 g (48.0%); mp 137.5—138.0 °C. Found: C, 69.72; H, 6.20; N, 8.41%. Calcd for $C_{19}H_{20}N_2O_3$: C, 70.35; H, 6.21; N, 8.64%. NMR ($CDCl_3$): δ 7.36 (m, 10, phenyl), 4.49 (s, 4, NCH_2), 1.91 (s, 6, CH_3). IR: 1744 (C–C=O), 1646 (N–C=O), 1418, 1382 (δ(C–H)), 1305 (ν(N–C=)), 1596, 1496, 740, 700 cm^{-1} (benzene ring).

Synthesis and Structural Investigation of *trans*-8-Oxabicyclo[4.3.0]nonan-3-ols

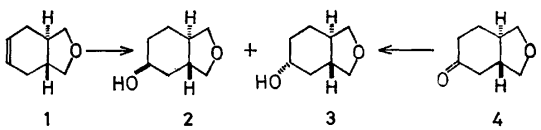
Ta-Yan LEONG, Takeshi IMAGAWA, and Mituyosi KAWANISI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received December 13, 1972)

Various methods of the synthesis of *trans*-8-oxabicyclo[4.3.0]nonan-3-ols were examined; the best method for *c*-3-hydroxy-*r*-1-*trans*-8-oxabicyclo[4.3.0]nonane (**2**) was found to be the LAH reduction of the epoxide of *trans*-8-oxabicyclo[4.3.0]non-3-ene (**1**), while *t*-3-hydroxy-*r*-1-*trans*-8-oxabicyclo[4.3.0]nonane (**3**) could be obtained in a high stereoselectivity by the LAH reduction of *trans*-8-oxabicyclo[4.3.0]nonan-3-one (**4**). The structures of the two isomeric alcohols were investigated by means of nuclear magnetic resonance spectroscopy using the paramagentic shift reagent. The C-1 proton of **2** is shifted to a much greater extent than that of **3**. Much as in the case of the *cis* analogues, there is almost no difference in the coordination abilities of europium ions with the alcoholic and ethereal oxygen atoms in these compounds.

We have recently reported on the synthesis and structural investigation of *cis*-8-oxabicyclo[4.3.0]nonan-3-ols.[1] In connection with the studies of the photo-induced addition of acetic acid to *trans*-8-oxabicyclo-[4.3.0]non-3-ene (**1**),[2] the hydrolysis of the adducts has been found to afford the title compounds. As an extension of this research, and also in order to compare these results with those obtained for the *cis* compounds, the synthesis of *c*-3-hydroxy-*r*-1-*trans*-8-oxabicyclo-[4.3.0]nonane (**2**) and *t*-3-hydroxy-*r*-1-*trans*-8-oxabicyclo[4.3.0]nonane (**3**)[3] has been undertaken, and the structures of the two isomeric alcohols have been investigated by means of nuclear magnetic resonance spectroscopy using the paramagnetic shift reagent.



Scheme 1

Results and Discussion

As is shown in Table 1, the hydroboration of **1** with diborane gave almost an equal isomeric ratio of **2** and **3**, while hydroboration with diisopinocampheylborane did not improve the isomeric ratio. The lithium aluminum hydride (LAH) reduction of the epoxide of **1** obtained by the reaction of **1** with *m*-chloroperbenzoic acid gave **2** predominantly. The isomer **3** was obtained in a high isomeric ratio by the reduction of *trans*-8-oxabicyclo[4.3.0]nonan-3-one (**4**) with sodium in ethanol, lithium aluminum hydride, sodium borohydride, and catalytic hydrogenation over platinum oxide in acetic acid. To summarize these results, the LAH reduction of the epoxide of **1** seems to be the best method for the synthesis of the isomer **2**, while the LAH reduction of the ketone, **4**, provides the most convenient route to **3**.

A comparison of the above results with those for the *trans*-bicyclo[4.3.0]nonan-3-one[4] is included in Table 1; it can be deduced that, in this case, much as in

TABLE 1. REACTIONS OF **1** AND **4**

Starting materials	Methods of preparation		Alcohol ratio[a]	
			2(%)	**3**(%)
1	A	B_2H_6, H_2O_2	46	54
	B	DICB, H_2O_2[b]	43	57
	C	MCPBA, LAH[c]	93	7
4	D	LAH	6	94
	E	H_2, PtO_2/AcOH	20	80
	F	Na/EtOH	8	92
	G	$NaBH_4$	14	86
			β-ol	α-ol
	H	Na/EtOH	4	96
trans-Bicyclo[4.3.0]nonan-3-one	I	LAH	12	88
	J	H_2, PtO_2/AcOH	44	56

a) Percentage of ratio of alcohols **2** and **3** were determined by glc analysis.
b) DICB stands for diisopinocampheylborane.
c) MCPBA stands for *m*- chloroperbenzoic acid and LAH stands for lithium aluminum hydride.

that of *cis*-8-oxabicyclo[4.3.0]nonan-3-one,[1] there seems to be no difference in the reactivities of the ketones in reductions even when one methylene group of the five-membered ring is replaced by an oxygen atom.

In order to determine the axial or equatorial nature of the protons adjacent to the hydroxyl or acetate moieties, it is helpful to observe the half-band widths of the proton NMR signal. The half-band widths of the carbinyl protons of **2** and **3** cannot be observed directly because of the overlapping with the signals of the protons α to the ethereal oxygen, even when the NMR shift reagent, Eu(DPM)$_3$, is added.[5] However, those of the respective acetates of **2** and **3** are observed to be 8 and 14 Hz[6] respectively, indicating the axial and equatorial arrangements for the acetoxy groups in the acetates of **2** and **3** respectively. Thus, the structures of **2** and **3** are unambiguously proved to have the structures shown in Figs. 1 and 2, since the fused systems have a *trans* configuration and since an inversion of the structure is impossible.

The above structures of **2** and **3** are further studied by the use of Eu(DPM)$_3$. The relationship between

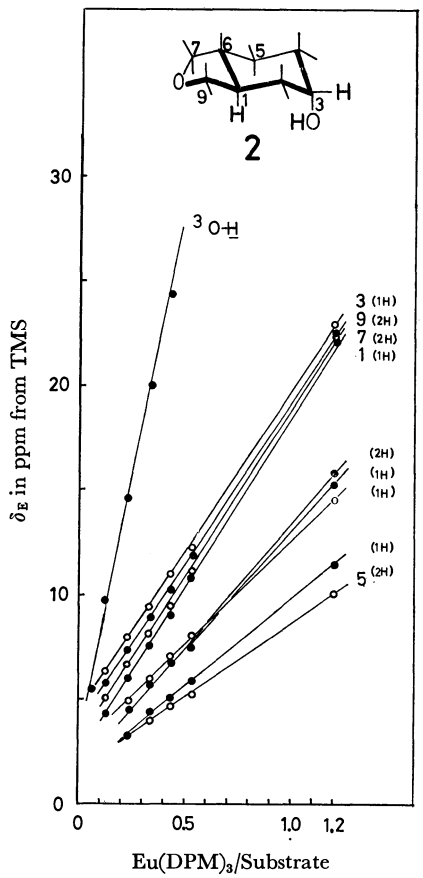

Fig. 1. Variation of chemical shift with molar ratio of Eu(DPM)$_3$/substrate for **2** in $CDCl_3$ solution.
The numerals on the lines represent protons assigned to those attached to the numbered ptorons. Numerals in parenthesis stand for the number of respective proton(s).

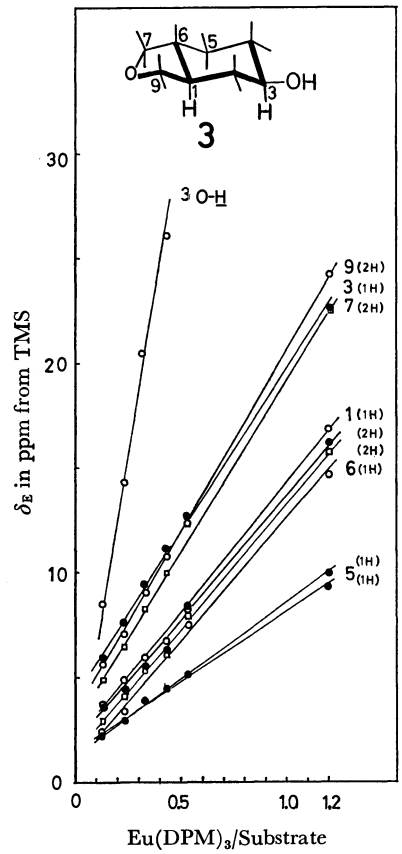

Fig. 2. Variation of chemical shift with molar ratio of Eu(DPM)$_3$/substrate for **3** in $CDCl_3$ solution.
The numerals on the lines represent protons assigned to those attached to the numbered protons. Numerals in parenthesis stand for the number of respective proton(s).

the variation in chemical shifts (δ_E) and Eu(DPM)$_3$/substrate (molar ratio) for the two isomers of **2** and **3** is shown in Figs. 1 and 2, demonstrating the linearity between δ_E and Eu(DPM)$_3$/substrate for the different protons in both isomers.

The linearities, even at the high concentration of a 1.2 molar ratio for the carbinyl protons and the four methylene protons adjacent to the oxygen atom of the five-membered rings indicate that there is no great difference in the equilibrium constants of complex formation for the alcoholic and the ethereal oxygen atoms. The same tendency has been observed in the behavior of the *cis*-8-oxabicyclo[4.3.0]nonan-3-ols toward Eu(DPM)$_3$.[1]

As is shown in Figs. 1 and 2, it is clear that the H_1 of **2** is shifted much more than that of **3**; this is the most distinct difference in the behavior of **2** and **3** upon the addition of Eu(DPM)$_3$. At the high concentration of a 1.2 molar ratio, the H_1 of **2** is unexpectedly shifted as much as H_3, H_7, and H_9, which are protons nearest to the two sites of coordination with the europium ions, whereas the H_1 of **3** is shifted to a much smaller degree. This observation supports the conformation of **2** and **3** as set forth in Figs. 1 and 2. It also implies that competitive coordination occurs at almost the same degree at the two sites in both **2** and **3**. This similar degree of competitive coordination for the two sites has been confirmed by an intermolecular

competitive experiment on an equal molar mixture of tetrahydrofuran and cyclohexanol, as has previously been reported.[1]

Experimental

All the temperatures are uncorrected. The microanalyses were performed by Mrs. Kiyoko Fujimoto of our laboratory. The IR spectra were obtained on a Shimadzu IR-27-C spectrophotometer. The NMR spectra were taken on a JEOL C-60H spectrometer, using tetramethylsilane as the internal standard, and $CDCl_3$ as the solvent. Tris(dipivalomethanato)europium (III), $Eu(DPM)_3$, was prepared in a manner similar to that of Eisentraut;[7] it had a mp of 189.5—190 °C (lit,[8] mp 190—191 °C). The glc analyses and separations were carried out on a Shimadzu GC-4APT apparatus using a 3 m×3 mm column of Dowfax 9N9 10% on Neopak 1A, operating at 150 °C with a He flow rate of 40 cc/min. For the preparative tlc, a 1.0 mm thickness of Merck GF-254 silica gel was employed with the solvent system of diethyl ether–benzene (50: 50). The mass spectra were recorded with a Hitachi RMS-4 mass spectrometer, with an ionizing energy of 70 eV and a source temperature of 150 °C.

Starting Material. Compound **1** was prepared from dimethyl *trans*-Δ^4-tetrahydrophthalate using the method described by Eliel;[9] it had properties identical with those reported by Christol.[10]

Reactions of trans-*8-Oxabicyclo[4.3.0]none-3-ene (1).* *Hydroboration with Diborane*: Dibroane generated by adding a solution of 14 g of $BF_3 \cdot Et_2O$ in 25 ml of diglyme to 1.9 g of sodium borohydride in 50 ml of diglyme was passed over a 75 min period into a stirred solution of 5.9 g of **1** in 50 ml of THF, cooled in an ice bath. The solution was then left for 75 min at room temperature, the excess diborane was decomposed with water (15 ml), 15 ml of 3M sodium hydroxide was added, and subsequently 15 ml of 30% hydrogen peroxide was added drop by drop. The reaction mixture was then stirred for an additional hour at room temperature and extracted with dichloromethane. After the evaporation of the solvent, distillation yielded 4.1 g of a mixture of **2** and **3** (bp 120 °C/10 mmHg); the isomeric ratio of **2** to **3** was shown by glc to be 46: 54.

Hydroboration with Diisopinocampheylborane: Hydroboration with diisopinocampheylborane was carried out with 680 mg of **1** according to the method of Brown;[11] a 580 mg portion of a mixture of **2** and **3** was thus obtained, its isomeric ratio being shown by glc to be 43: 57.

Reaction of 1 with m-*Chloroperbenzoic Acid Followed by Reduction with Lithium Aluminum Hydride (LAH)*: A solution of 1.8 g of 85% *m*-chloroperbenzoic acid in 40 ml of dry chloroform was added dropwise to a stirred solution of 1 g of **1** in 10 ml of dry chloroform. The reaction mixture was stirred overnight at room temperature. The solution was then washed 2 times each with 100 ml of a 10% sodium sulfite solution, 2 times each with 100 ml of a 5% sodium bicarbonate solution, and finally with a saturated sodium chloride solution, and dried (Na_2SO_4). The chloroform was driven off at reduced pressure, and a white solid was obtained on standing. Recrystallization from petroleum ether gave the epoxide of **1** in needles; mp 53.5—54 °C, IR (KBr): 2924, 2870, 1435, 1425, 1348, 1269, 1195, 1110, 1080, 990, 885, 875, 805, 780 cm^{-1}; NMR (CCl_4): δ 4.00—3.50 (m, 2H), 3.40—2.75 (m, 4H), 2.55—1.15 (m, 6H); MS: *m/e* 140 (M^+, 23%), 110 (100), 95 (69), 82 (72), 81 (70), 79 (71%). Found: C, 68.29; H, 8.59%. Calcd for $C_8H_{12}O_2$: C, 68.54; H, 8.63%.

A solution of 640 mg of the above epoxide in 10 ml of ether was added dropwise to a stirred slurry of LAH in 10 ml of ether; the mixture was then stirred overnight at room temperature. Aqueous hydrochloric acid (10%) was added to destroy the excess hydride. Extraction (ether) and drying (Na_2SO_4), followed by evaporation, afforded 520 mg of a mixture of **2** and **3**, which was shown by glc to have an isomeric ratio of 93: 7.

Reduction of trans-*8-Oxabicyclo[4.3.0]nonan-3-one (4).* The ketone, **4**, was prepared by oxidizing the mixture of **2** and **3** obtained in the hydroboration (with diborane) of **1**. A solution of 2.84 g of a mixture of **2** and **3** in a small volume of dichloromethane was oxidized with the chromium trioxide-pyridine complex, as has been described by Ratcliffe,[12] to yield 2.2 g of **4**; bp 120—121 °C/18 mmHg, IR: 2955, 2900, 1720, 1420, 1322, 1201, 1072, 1020, 996 cm^{-1}; NMR (CCl_4): δ 4.06—3.70 (m, 2H), 3.55—3.07 (m, 2H), 2.70—1.15 (m, 8H); MS: *m/e* 140 (M^+, 100), 96 (22), 84 (41), 82 (70%). Found: C, 68.46; H, 8.88%. Calcd for $C_8H_{12}O_2$: C, 68.54; H, 8.63%.

A solution of **4** (170 mg) in 10 ml of ether was added dropwise to a stirred slurry of 60 mg of LAH in 10 ml of ether. The mixture was then stirred overnight at room temperature, dilute hydrochloric acid was added to destroy the excess hydride, and the aqueous phase was extracted with ether. After drying (Na_2SO_4), the solvent was removed; the alcohols **2** and **3** were found to have been formed in a ratio of 6: 94.

Hydrogenation of 4 over Platinum Oxide. A solution of **4** (100 mg) in 5 ml of glacial acetic acid was added to 50 mg of platinum oxide in 10 ml of glacial acetic acid, 3 drops of concentrated hydrochloric acid were added, and hydrogenation was carried out under normal atmospheric hydrogen at room temperature. A rapid uptake of hydrogen occurred, and the theoretical amount of hydrogen was absorbed in 20 min. The reaction mixture was then neutralized with aqueous sodium bicarbonate and extracted with ether. An analysis of the reaction product by glc showed that **2** and **3** were formed in a ratio of 20: 80.

Reduction of 4 with Sodium in Ethanol. A solution of 320 mg of **4** in 100 ml of absolute ethanol was placed in a flask fitted with a reflux condenser, and 1.75 g of small pieces of sodium were added to maintain reflux. After the addition of sodium had been finished, the reaction mixture was refluxed for an additional hour; it was then cooled and acidified with 10% aqueous hydrochloric acid. The ethanol was removed under diminished pressure, and the aqueous phase was extracted with ether. The ethereal solution was dried and evaporated. An analysis of the residue by glc showed that the isomers **2** and **3** were formed in a ratio of 8: 92.

Reduction of 4 with Sodium Borohydride. A solution of 170 mg of **4** in 20 ml of absolute methanol was cooled in an ice bath, and then 110 mg of sodium borohydride were slowly stirred in. After the reaction mixture had been stirred at room temperature overnight, the methanol was removed under

diminished pressure, and ice water was added. Extraction (CH_2Cl_2) and drying (Na_2SO_4), followed by evaporation, afforded the reaction products, an analysis of which by glc showed that the isomers **2** and **3** were formed in a ratio of 14: 86.

Pure samples of **2** and **3** were secured from the reduction of epoxide of **1** and LAH reduction of **4**, respectively; by separation with preparative tlc and glc, followed by bulb-to-bulb distillation under reduced pressure, we obtained the following results, For **2**: IR (CCl_4) 3620, 3385, 2940, 2855, 1085, 1015, 995 cm^{-1}, NMR ($CDCl_3$): δ 4.40—3.80 (m, 3H), 3.60—3.18 (m, 2H), 2.40—1.30 (m, 9H), MS: *m/e* 142 (M^+, 26%), 124 (M^+-18, 30%), 69 (100%). Studies of the Synthesis of Furan Compounds. XXIX.[1] Syntheses of 2-(5-Nitro-2-furyl)vinyl-1,8-naphthyridines[2]

Ichiro HIRAO, Yasuhiko KATO, Yoshimasa FUKANO, and Shinpei YANAI

Laboratory of Organic Synthesis, Department of Industrial Chemistry, Kyushu Institute of Technology, Tobata-ku, Kita-Kyushu 804

(Received December 16, 1972)

In continuing our study of the relationship between structures and antibacterial activity, 2-[2-(5-nitro-2-furyl)vinyl]-5-hydroxy- and 4-[2-(5-nitro-2-furyl)vinyl]-2,7-dihydroxy-1,8-naphthyridine and their related derivatives have been synthesized. In these compounds, 2-[2-(5-nitro-2-furyl)vinyl]-5-hydroxy- (I) and 2-[2-(5-nitro-2-furyl)vinyl]-5-hydroxy-6-ethoxycarbonyl-1,8-naphthyridine (II) showed broad spectra of antibacterial activity, and the activity of I was greater than that of II. Other compounds exhibit a strong antibacterial activity against *Diplococcus pneumoniae*, *Streptococcus hemolyticus*, and *Staphilococcus aureus*, but they show a weak activity against the other microorganisms tested.

In 1,8-naphthyridine compounds, nalidixic acid (1-ethyl-4-oxo-7-methyl-1,8-naphthyridine-3-carboxylic acid) has been known as an effective chemotherapeutic drug for Gram-negative infections. Nishigaki *et al.* reported that the derivatives of nalidixic acid and its related methyl-1,8-naphthyridines, whose methyl groups were condensed with 5-nitrofurfural, showed a broad spectrum of antibacterial activity greater than that of the parent nalidixic acid; another excellence of these compounds is that the nalidixic acid resistant-strain of *Escherichia coli* K-12 and *Shigella dysenteriae* Hanabusa are still as susceptible to these compounds as the original strains.[3,4] Several patents concerning the syntheses and the use of 2-(5-nitro-2-furyl)vinyl-1,8-naphthyridines have been granted.[5–10]

In order to compare the antibacterial activity, 2-[2-(5-nitro-2-furyl)vinyl]- and 4-[2-(5-nitro-2-furyl)-vinyl]-1,8-naphthyridine derivatives were prepared.

Results and Discussion

2-[2-(5-Nitro-2-furyl)vinyl]-5-hydroxy-1,8-naphthyridine (I) was obtained by the condensation of 2-methyl-5-hydroxy-1,8-naphthyridine[11] with 5-nitrofurfural in refluxing acetic anhydride. In a similar manner, 2-[2-(5-nitro-2-furyl)vinyl]-5-hydroxy-6-ethoxycarbonyl-1,8-naphthyridine[4] (II) was obtained from the corresponding 2-methyl-1,8-naphthyridine. I and II were converted into the corresponding 5-chloro derivatives (Ia and IIa respectively) by being heated in phosphoryl chloride. On the other hand, Ia was also obtained from 2-methyl-5-chloro-1,8-naphthyridine[11] and 5-nitrofurfural. When Ia or IIa was heated with phenol, the 5-chlorine atom was replaced by a phenoxy group to give 2-[2-(5-nitro-2-furyl)vinyl]-5-

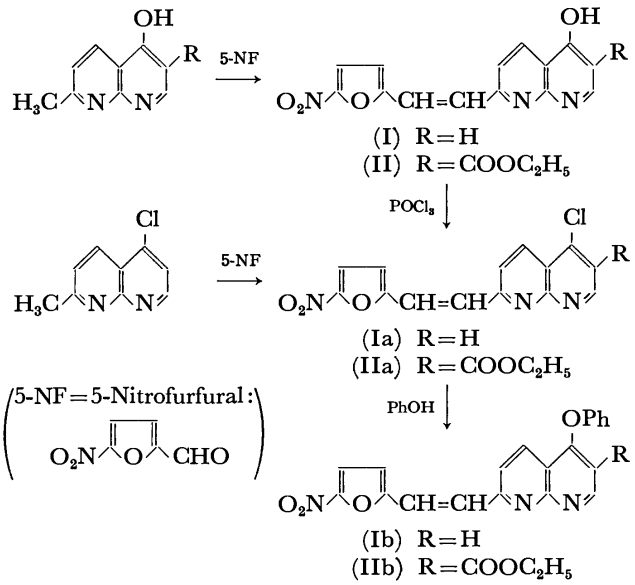
phenoxy-1,8-naphthyridine (Ib) and 2-[2-(5-nitro-2-furyl)vinyl]-5-phenoxy-6-ethoxycarbonyl-1,8-naphthyridine (IIb) (Scheme 1).



Scheme 1

It was found that the reactivity of the methyl group at the γ-position on the 1,8-naphthyridine nucleus is smaller than that at the α-position. An attempt to prepare 2-hydroxy-7-amino- (III) or 2,7-dihydroxy-4-[2-(5-nitro-2-furyl)vinyl]-1,8-naphthyridine (IV) from the corresponding 4-methyl-1,8-naphthyridines and 5-nitrofurfural was unsuccessful, although Herbert *et al.*[6] have described the preparation of the same compounds (III and IV) by this method. In our results, the raw materials were recovered as 5-nitrofurfural diacetate and 2-hydroxy-7-acetamido- or 2,7-dihydroxy-4-methyl-1,8-naphthyridine themselves in place of the desired III or IV. Another method for preparation of III and IV is the decarboxylation of 3-(5-nitro-2-furyl)-2-(2-hydroxy-7-acetamido-1,8-naphthyridin-4-yl)acrylic acid (V) and 3-(5-nitro-2-furyl)-2-(2,7-dihydroxy-1,8-naphthyridin-4-yl)acrylic acid (VI), which had themselves been prepared by the reaction of 2-hydroxy-7-amino- and 2,7-dihydroxy-1,8-naphthyridine-4-acetic acid[12] respectively with 5-nitrofurfural. While the decarboxylation of V and VI did not occur in the presence of copper bichromate in hot quinoline or in the presence of benzoyl peroxide in dimethylformamide, IV was produced as the main product in the preparation of VI. It can be assumed that IV was formed by condensation of 2,7-dihydroxy-1,8-naphthyridine-4-acetic acid with 5-nitrofurfural involved in the decarboxylation.

When IV was heated with phosphoryl chloride, the corresponding 2,7-dichloro derivative (IVa) was obtained. IVa gave 2,7-diphenoxy (IVb) and 2,7-dianilino (IVc) compounds when heated with phenol and aniline respectively.

In the IR spectra of I, II, IV, V, and VI, the C=O stretching absorption band was observed in the 1660—1650 cm^{-1} region, while it disappeared in the corresponding chloro derivatives (Ia, IIa, and IVa); this suggests that the hydroxy-naphthyridine part takes the keto structure in the solid state. The *trans*-configuration of I, Ia, b, II, IIa, b, IV, and IVa—c is supported by the presence of a C–H out-of-plane deformation vibration band in the 960—950 cm^{-1} region.

Microbiological Assays.[13] The antibacterial activities of these compounds in response to ten microorganisms were examined. The minimum amount of

a) 3-(5-Nitro-2-furyl)-2-(2-furyl)acrylic amide was used in the test.

each compound necessary for the complete inhibition of growth was determined by the dilution method, using the usual bouillon agar medium (pH 6.8—7.0); some of the results are shown in Table 1. The compounds employed in this test consist of three types (Table 1). I, Ib, II, and IIa are the compounds substituted by the 5-nitro-2-furylvinyl group at the 2-position on the 1,8-naphthyridine nucleus (type A), IV and IVa—c are those substituted at the 4-position (type B), and V and VI are acrylic acid derivatives (type C). The three types of compounds showed a decreasing tendency of activity in the order: type A> type B>type C.

All the compounds of type A, except for Ib, showed broad spectra of antibacterial activity; I was the most active antibacterial against all the microorganisms employed. All the compounds of type B, except IVb, showed a strong activity against *Diplococcus pneumoniae*, *Streptococcus hemolyticus*, *Staphilococcus aureus*, and *Bacillus subtilis*, but they exhibited no activity against the other microorganisms. The lack of activity in Ib and IVb may be due to the substituent (phenoxy group). The compounds of type C include almost no active antibacterial.

Experimental[14]

2-[2-(5-Nitro-2-furyl)vinyl]-5-hydroxy-1,8-naphthyridine (I). A mixture of 2-methyl-5-hydroxy-1,8-naphthyridine[11] (1.6 g, 10 mmol), 5-nitrofurfural (1.6 g, 11 mmol), and acetic anhydride (10 ml) was refluxed for 5 hr. Cooling provided 1.8 g of a crude product; when the mother filtrate was then allowed to stand for several days at room temperature, an additional 0.2 g of the product was obtained. Recrystallization from ethylene glycol monomethyl ether afforded 1.8 g (63.6%) of I as pale yellow needles; mp 316—317 °C (decomp.). IR (KBr) cm^{-1}: 1650 (ν C=O), 965 (δ C–H; *trans*).

Found: C, 59.19; H, 3.07; N, 14.60%. Calcd for $C_{14}H_9N_3O_4$: C, 59.36; H, 3.20; N, 14.83%.

2-[2-(5-Nitro-2-furyl)vinyl]-5-hydroxy-6-ethoxycarbonyl-1,8-naphthyridine (II). 2-Methyl-5-hydroxy-6-ethoxycarbonyl-1,8-naphthyridine[15] (2.6 g, 12.2 mmol) and 5-nitrofurfural (1.8 g, 12.5 mmol) were heated in acetic anhydride (10 ml) under reflux for 1.5 hr. On cooling, the precipitated product was collected and washed with ether and methanol. Crystallization from ethylene glycol monomethyl ether gave 3 g (76.5%) of II as pale yellow needles which melted, with decomposition, at 285 °C. IR (KBr) cm^{-1}: 1730 and 1710 (shoulder) (ν C=O), 960 (δ C–H; *trans*).

Found: C, 57.42; H, 3.85; N, 11.53%. Calcd for $C_{17}H_{13}N_3O_6$: C, 57.47; H, 3.69; N, 11.83%.

2-[2-(5-Nitro-2-furyl)vinyl]-5-chloro-1,8-naphthyridine (Ia). *Procedure A*: Compound I (0.4 g, 1.7 mmol) was heated in phosphoryl chloride (5 ml) for 4 hr under reflux. The reaction mixture was then poured into cold water, and the product was collected, washed with water, and then dried. Recrystallization from ethylene glycol monomethyl ether gave 0.23 g (54%) of Ia as pale yellow needles; mp 231—232 °C (decomp.). IR (KBr) cm^{-1}: 960 (δ C–H; *trans*).

Found: C, 55.76; H, 2.53; N, 13.54%. Calcd for $C_{14}H_8N_3O_3Cl$: C, 55.74; H, 2.67; N, 13.93%.

Procedure B: 2-Methyl-5-chloro-1,8-naphthyridine[11] (1 g, 5.6 mmol) and 5-nitrofurfural (0.9 g, 6.4 mmol) were heated in acetic anhydride (5 ml) under reflux for 1.5 hr. Cooling provided 1.2 g of the crude product. Work-up as above afforded 0.8 g (58.9%) of Ia; mp 231—232 °C (decomp.), undepressed on admixture with a sample prepared by *Procedure A* as has been described above for Ia.

2-[2-(5-Nitro-2-furyl)vinyl]-5-chloro-6-ethoxycarbonyl-1,8-naphthyridine (IIa). II (0.6 g, 2.12 mmol) was covered with phosphoryl chloride (*ca.* 10 ml) and refluxed for 1 hr. After cooling the reaction mixture was poured into ice water and neutralized with aqueous ammonia. The precipitated product was filtered and washed with water. Crystallization from pyridine gave 0.3 g (47.5%) of IIa as pale yellow needles

14) All the melting and decomposition points are uncorrected. The elemental analyses were carried out with a Yanagimoto CHN Corder, MT-2 type. The infrared absorption spectra (IR) were recorded with a JASCO Model IRA-2 grating infrared spectrophotometer.

15) G. R. Lappin, *J. Amer. Chem. Soc.*, **70**, 3348 (1948).

which did not melt below 300 °C. IR (KBr) cm^{-1}: 1730 (ν C=O), 960 (δ C–H; *trans*).

Found: C, 54.95; H, 3.24; N, 11.14%. Calcd for $C_{17}H_{12}N_3O_5Cl$: C, 54.63; H, 3.24; N, 11.24%.

2-[2-(5-Nitro-2-furyl)vinyl]-5-phenoxy-1,8-naphthyridine (Ib). A mixture of Ia (0.5 g, 1.7 mmol) and phenol (5 ml) was refluxed for 15—20 min. After cooling, aqueous sodium carbonate was added to the reaction mixture, and the precipitated product was filtered. Recrystallization from tetrahydrofuran afforded 0.45 g (76.5%) of Ib as a pale yellow powder which melted at 223—224 °C. IR (KBr) cm^{-1}: 950 (δ C–H; *trans*), 734 and 690 (δ C–H; mono-substituted benzene).

Found: C, 66.92; H, 3.70; N, 11.56%. Calcd for $C_{20}H_{13}N_3O_4$: C, 66.85; H, 3.65; N, 11.69%.

2-[2-(5-Nitro-2-furyl)vinyl]-5-phenoxy-6-ethoxycarbonyl-1,8-naphthyridine (IIb). The chloro compound, IIa (0.15 g, 4 mmol), was heated in 2 ml of phenol under reflux for 40 min. Aqueous sodium carbonate was then added to the reaction mixture, and the precipitates were filtered. They were subsequently crystallized from ethylene glycol monomethyl ether to afford 0.08 g (63.8%) of IIb as pale yellow granules; mp>300 °C. IR (KBr) cm^{-1}: 1730 (ν C=O), 955 (δ C–H; *trans*), 730 and 690 (δ C–H; mono-substituted benzene).

Found: C, 64.72; H, 3.98; N, 9.51%. Calcd for $C_{23}H_{16}N_3O_6$: C, 64.88; H, 3.75; N, 9.76%.

4-[2-(5-Nitro-2-furyl)vinyl]-2,7-dihydroxy-1,8-naphthyridine (IV) and 3-(5-Nitro-2-furyl)-2-(2,7-dihydroxy-1,8-naphthyridin-4-yl)acrylic Acid (VI). A mixture of potassium salt of 2,7-dihydroxy-1,8-naphthyridine-4-acetic acid[12] (4.2 g, 16.3 mmol), 5-nitrofurfural (2.6 g, 18.4 mmol), and acetic anhydride (40 ml) was heated at 66—70 °C for 4 hr. After cooling, 40 ml of glacial acetic acid was added to the reaction mixture, and then this was poured into cold water. The precipitated product was filtered and recrystallized from dimethyl sulfoxide to give 2.3 g (42%) of IV as a yellow powder; mp 317 °C (decomp.). IR (KBr) cm^{-1}: 3100—2800 (ν O–H; associated), 1663 (ν C=O), 957 (δ C–H; *trans*).

Found: C, 55.97; H, 3.24; N, 13.98%. Calcd for $C_{14}H_9N_3O_5$ (IV): C, 56.19; H, 3.03; N, 14.04%.

The mother filtrate was concentrated under reduced pressure, after which the precipitated product was collected on a filter and washed with water. Recrystallization from aqeuous acetic acid afforded 1.5 g (24%) of VI as a yellow powder; mp>320 °C. IR (KBr) cm^{-1}: 3140—2800 (ν O–H; associated), 1706 and 1658 (ν C=O).

Found: C, 52.33; H, 2.67; N, 12.45%. Calcd for $C_{15}H_9N_3O_7$ (VI): C, 52.48; H, 2.64; N, 12.24%.

4-[2-(5-Nitro-2-furyl)vinyl]-2,7-dichloro-1,8-naphthyridine (IVa). IV (1 g, 3.3 mmol) was heated in phosphoryl chloride (20 ml) under reflux for 3 hr. After cooling, the reaction mixture was poured into ice water and the precipitated product was filtered. This product was recrystallized from ethylene glycol monomethyl ether to give 0.83 g (75%) of IVa as a yellow powder which melted at 259—260 °C. IR (KBr) cm^{-1}: 957 (δ C–H; *trans*).

Found: C, 50.28; H, 2.40; N, 12.49%. Calcd for $C_{14}H_7N_3O_3Cl$: C, 50.00; H, 2.08; N, 12.50%.

4-[2-(5-Nitro-2-furyl)vinyl]-2,7-diphenoxy-1,8-naphthyridine (IVb). IVa (1 g, 3 mmol) was heated in phenol (10 ml) under reflux for 30 min. After cooling, the reaction mixture was diluted with ether, and the precipitates were collected and washed with ether. Subsequent crystallization from ethylene glycol monomethyl ether gave 0.5 g (33%) of IVb as yellow needles; mp 216—217 °C. IR (KBr) cm^{-1}: 953 (δ C–H); *trans*), 750 and 690 (δ C–H; mono-substituted benzene).

Found: C, 69.24; H, 3.64; N, 9.45%. Calcd for $C_{26}H_{17}N_3O_5$: C, 69.18; H, 3.77; N, 9.31%.

4-[2-(5-Nitro-2-furyl)vinyl]-2,7-dianilino-1,8-naphthyridine Monohydrochloride (IVc). Aniline (0.3 g, 3.2 mmol), IVa (0.5 g, 1.5 mmol), and ethylene glycol monomethyl ether (10 ml) were refluxed for 1 hr. After cooling, concentrated hydrochloric acid was added to the reaction mixture. The isolated product was then collected and washed with water. Recrystallization from aqueous methanol afforded 0.35 g (48.5%) of IVc as a crimson-colored powder; mp 147—148 °C. IR (KBr) cm^{-1}: 959 (δ C–H; *trans*), 755 and 690 (δ C–H; mono-substituted benzene).

Found: C, 64.91; H, 3.98; N, 14.04%. Calcd for $C_{26}H_{19}N_5O_3 \cdot HCl$: C, 64.26; H, 4.12; N, 14.41%.

3-(5-Nitro-2-furyl)-2-(2-hydroxy-7-acetamido-1,8-naphthyridin-4-yl)acrylic Acid (V). A mixture of potassium salt of 2-hydroxy-7-amino-1,8-naphthyridine-4-acetic acid[12] (11.7g, 45 mmol), 5-nitrofurfural (7.1 g, 50 mmol), and acetic anhydride (10 ml) was heated at 50—55 °C for 4 hr. The reaction mixture was then poured into ice water, and the separated product was filtered and washed with water. Recrystallization from glacial acetic acid gave 11.5 g (62.5%) of V as a yellow powder; mp>320 °C. IR (KBr) cm^{-1}: 3230 (ν N–H), 2925 (ν CH_3), 1707, 1693, and 1660 (ν C=O).

Found: C, 53.26; H, 3.38; N, 15.06%. Calcd for $C_{17}H_{12}N_4O_7$: C, 53.13; H, 3.13; N, 14.58%.

Studies on 3,5-pyrazolidinediones. IV. Addition of 4-Arylazo-3,5-pyrazolidinediones to Ethyl Acrylate

Mohamed Helmi ELNAGDI and Masaki OHTA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

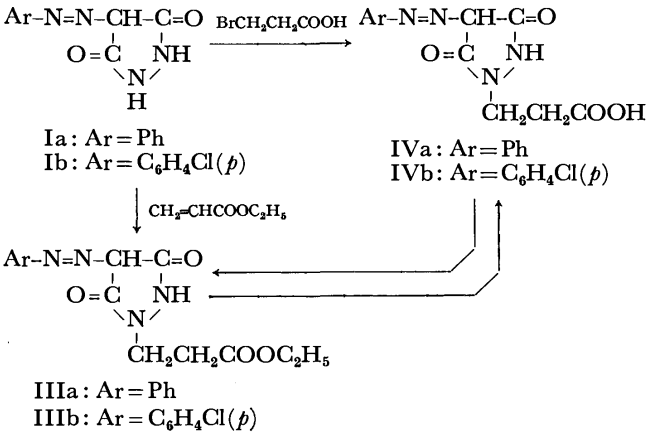
(Received December 22, 1972)

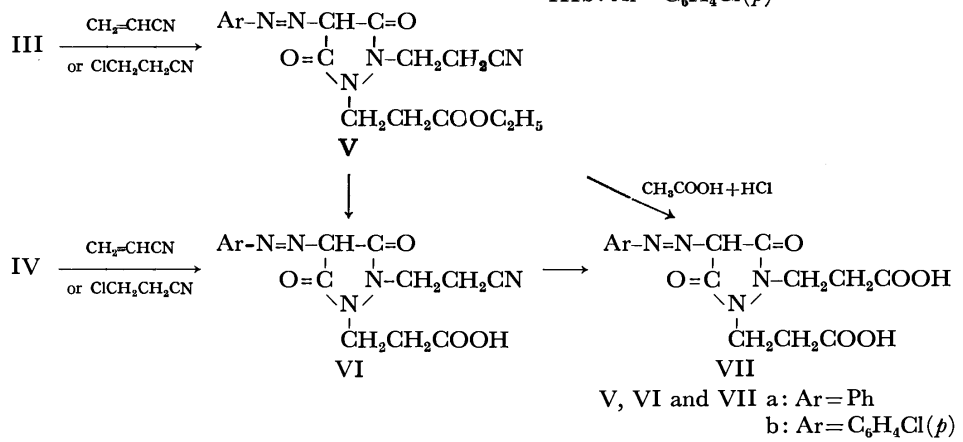
4-Arylazo-3,5-pyrazolidinediones (I) react with ethyl acrylate to yield the corresponding 1-β-ethoxycarbonylethyl derivatives (III), which were readily hydrolyzed into the acids IV. Compounds III and IV were found to react with acrylonitrile to yield the corresponding 1-substituted 2-β-cyanoethyl derivatives V and VI respectively. Whereas III and IV were recovered unchanged upon treatment with aniline or piperidine, the arylazomalonic acid dihydrazide (IX) were formed upon treatment of III or IV with hydrazine hydrate. 2-*p*-Chlorophenylazotetrahydropyrazolo[1,2-*a*]pyrazole-1,3,7-trione (XI) has been prepared by the action of phosphorus oxychloride on IVb. 3-Amino-4-phenylazo-2-pyrazolin-5-one (II) react with ethyl acrylate to yield the pyrazolo[1,5-*a*]pyrimidine derivative XII.

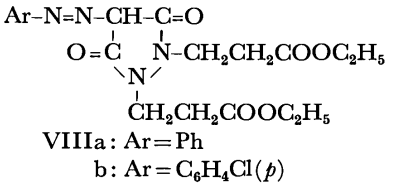
In a previous paper[1] it has been shown that 4-arylazo-3,5-pyrazolidinediones (I) react with acrylonitrile to yield either the 1-β-cyanoethyl or the 1,2-di(β-cyanoethyl) derivatives depending on the reaction conditions. It has also been shown that 3-amino-4-phenylazo-2-pyrazolin-5-one (II) react with the same reagent to yield a pyrazolopyrimidine derivative. As an extention of this work, it was thought worthwhile to investigate the behavior of compounds I and II toward other systems containing activated double bond. In the present paper, the behavior of I and II toward ethyl acrylate is reported.

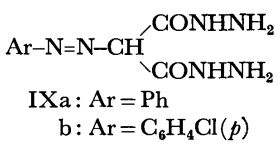
Upon treatment of I with ethyl acrylate in molecular proportions the 1-β-ethoxycarbonylethyl derivatives (III) were formed.[2] The structure of these derivatives was established from their IR spectra and from identity with authentic specimens prepared by the action of ethanol and concentrated sulfuric acid on 4-arylazo-1-β-carboxyethyl-3,5-pyrazolidinediones (IV),[2] now obtained by the action of β-bromopropionic acid on I. Furthermore, compounds IV were formed upon treatment of III with acetic acid–hydrochloric acid mixture.

In contrast to the reported unreactivity of 4-arylazo-1-phenyl-3,5-pyrazolidinediones toward the action of acrylonitrile,[1] compounds III and IV were found to add readily to acrylonitrile to yield the 1,2-disubstituted 3,5-pyrazolidinedione derivatives, V and VI respectively. Compounds V and VI were also obtained upon treatment of III and IV with β-chloropropiononitrile respectively.









1) M. H. Elnagdi, N. A. L. Kassab, S. M. Fahmy, and F. A. El-All, *J. Prakt. Chem.*, in press.

2) For the sake of convenience, all compounds described in this paper are referred to as arylazo-3,5-pyrazolidinediones derivatives, irrespective of their actual structure.

Compounds V were readily hydrolyzed with aqueous sodium hydroxide to the corresponding VI. On the other hand, treatment of V and VI with acetic acid–hydrochloric acid mixture results in the formation of the known[1] 4-arylazo-1,2-di(β-carboxyethyl)-3,5-pyrazolidinedione derivatives (VII).

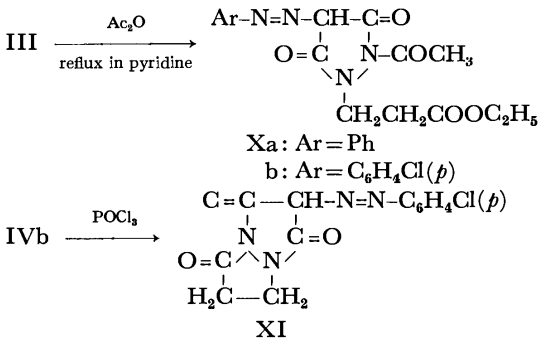
Compounds III react also with ethyl acrylate to yield the corresponding 4-arylazo-1,2-di(β-ethoxycarbonylethyl)-3,5-pyrazolidinediones (VIII). Compounds VIII are readily converted into VII by the action of acetic acid–hydrochloric acid mixture.

Whereas the compounds III and IV were recovered unchanged upon treatment with aniline or piperidine, the arylazomalonic acid dihydrazides (IX) were formed upon treatment of III with hydrazine hydrate. The stability of the pyrazolidinedione ring in III and IV toward the action of piperidine is in contrast to the reported[3,4] hetero-ring opening of 4-arylazo-1-phenyl- and 1,2-diphenyl-3,5-pyrazolidinediones by the action of the same reagent.

In a trial to effect cyclization of III into a pyrazolo-[1,2-*a*]pyrazole derivative by the action of acetic anhydride, the acetyl derivatives (X) were obtained. Although compounds III have three sites for acylation to occur,[5] compounds X were assigned the *N*-acetyl structure based on their stability toward the action of acetic acid[6] and from a study of their spectral data. The IR spectra of compound Xb, taken as an example, reveals the presence of four carbonyl sretching absorption bands at 1740, 1730, 1690, and 1675 cm^{-1}. The former two were considered to be due to the acetyl and ester carbonyl groups and the latter due to the ring carbonyl groups. Compounds X were converted readily into III on reflux with pyridine.

2-*p*-Chlorophenylazotetrahydropyrazolo[1,2-*a*]pyrazole-1,3,7-trione (XI) has now been prepared through cyclization of the acid (IVb) by the action of phosphorus oxychloride. The structure XI, presented here, finds support from analytical and spectral (IR) data. Thus, the IR spectrum was characterized by the presence of three carbonyl bands at 1770, 1710, and 1680 cm^{-1} and revealed the absence of absorption in the region of 2500—3000 cm^{-1} present in the spectrum of the starting acid (IVb).

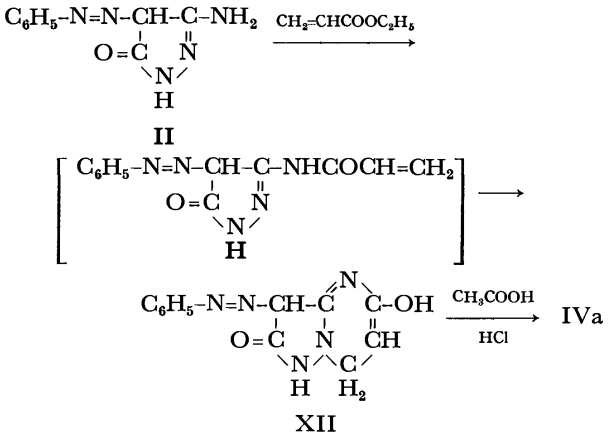
The behavior of 3-amino-4-phenylazo-2-pyrazoline-5-one (II) toward ethyl acrylate shows that II did not add to ethyl acrylate in aqueous pyridine solution, while it react with the same reagent in the presence of catalytic amount of potassium hydroxide to yield the pyrazolo-[1,5-*a*]pyrimidine derivative (XII). This is in analogy with the recently reported behavior of 3-phenyl-5-



aminopyrazole toward methyl phenylpropiolate.[7] The structure proposed for compound XII finds support from analytical data, IR spectrum, and its conversion into IVa through the action of acetic acid–hydrochloric acid mixture.

The IR spectrum of compound XII does not show free hydroxyl absorption around 3600 cm^{-1} and shows a broad band (2430—2800 cm^{-1}) similar to the OH group absorption of fatty acid dimers. Similar behavior has been reported for β-keto-enols and was attributed to intramolecular conjugate chelation.[8] However, in compound XII steric considerations will prevent a direct intramolecular hydrogen bond. This may lead to the conclusion that XII, at least in solid state, exists in a highly stable dimeric structure capable of similar resonance stabilization. Similar system in which such conjugate chelation could arise from intermolecular hydrogen bond has been reported in case of 5,5-dimethyl-1,3-cyclohexanedione.[9]

In part III of this series[1] it has been shown that position 1 in compound II is the most reactive position for cyanoethylation. That this position is not involved in the reaction of II with ethyl acrylate may lead to the assumption that in case of ethyl acrylate the first step in the reaction is acylation of the amino group followed by cyclization to yield XII.



Experimental

All melting points were determined on a micro hot stage and are uncorrected. The infrared spectra were recorded

with Hitachi Grating Infrared Spectrometer Model EPI-G3. Ultraviolet spectra were measured in ethanol with Hitachi 124 Spectrophotometer.

4-Arylazo-1-β-ethoxycarbonylethyl-3,5-pyrazolidinediones (IIIa and IIIb). From I and Ethyl Acrylate: Ten mmol of I was added to a solution of ethyl acrylate (0.01 mol) in pyridine (50 ml) and water (10 ml). The reaction mixture was refluxed for 6 hr and evaporated *in vacuo* to leave a residue which was purified by recrystallization from ethanol.

IIIa. Yellow crystals, yield 80%, mp 115 °C. IR: 3150 (NH), 1725 (ester CO), 1690 and 1660 cm^{-1} (ring CO). Found: C, 55.50; H, 5.37; N, 18.69%. Calcd for $C_{14}H_{16}N_4O_4$: C, 55.25; H, 5.30; N, 18.41%.

IIIb. Orange crystals, yield 85%, mp 164 °C. IR: 3120 (NH), 1730 (ester CO), 1690 and 1660 cm^{-1} (ring CO). Found: C, 49.60; H, 4.50; N, 16.55%. Calcd for $C_{14}H_{15}N_4O_4Cl$: C, 49.63; H, 4.46; N, 16.54%.

From IV by Esterification: A suspension of IV (see below) in ethanol (30 ml) containing sulfuric acid (1.5 ml; 98%) was refluxed for 16 hr, cooled and poured into ice water. The solid product, so formed, was purified by recrystallization and identified (mp and mixed mp) as IIIa or IIIb. Yields, 60 and 67% respectively.

4-Arylazo-1-β-carboxyethyl-3,5-pyrazolidinediones (IVa and IVb). From I and β-Bromopropionic Acid: Ten mmol of I was added to a solution of β-bromopropionic acid (0.01 mol) in 100 ml of aqueous ethanol (1 : 1) containing 2.0 g of sodium carbonate and refluxed for 3 hr. Evaporation of the solvent *in vacuo* afforded a solid product which was dissolved in water (100 ml), washed with ether, and then acidified with concentrated hydrochloric acid to give crude IV.

IVa. Yellow crystals (from ethanol), yield 82%, mp 230 °C (decomp.). IR: 3000—2600 (OH), 1752 (carboxyl CO), 1690 and 1660 cm^{-1} (ring CO). Found: C, 51.94; H, 4.09; N, 19.95%. Calcd for $C_{12}H_{12}N_4O_4$: C, 52.17; H, 4.38; N, 20.28%.

IVb. Yellow needles (from acetic acid), yield 87%, mp 248 °C (decomp.). IR: 3030—2600 (OH), 1758 (CO), and 1690, 1660 cm^{-1} (CO). Found: C, 46.54; H, 3.54; N, 18.08%. Calcd for $C_{12}H_{11}N_4Cl$: C, 46.38; H, 3.56; N, 18.03%.

From III by Hydrolysis: A solution of III (2.0 g) in acetic acid (20 ml) containing concentrated hydrochloric acid (5.0 ml) was refluxed for 3 hr, allowed to cool and poured into ice-water. The solid product, so formed, was collected, crystallized and identified (mp and mixed mp) as IVa or IVb. Yields, 90 and 93% respectively.

4-Arylazo-1-β-cyanoethyl-2-β-ethoxycarbonylethyl-3,5-pyrazolidinediones (Va and Vb). From III and Acrylonitrile: Ten mmol of III was added to a solution of pyridine (50 ml) and water (10 ml) containing acrylonitrile (3 ml) and the reaction mixture was refluxed for 12 hr, left overnight at room temperature, and then evaporated *in vacuo*. The resulting oily product was triturated with petrolum ether and crystallized from ethanol.

Va. Yellow crystals, yield 75%, mp 58 °C. IR: 3154 (NH), 2230 (CN), 1730 (ester CO), 1710 and 1670 cm^{-1} (ring CO). Found: C, 57.23; H, 5.30; N, 19.26%. Calcd for $C_{17}H_{19}N_5O_4$: C, 57.13; H, 5.36; N, 19.60%.

Vb. Yield 90%, mp 100 °C. IR: 3150 (NH), 2230 (CN), 1730 (CO), 1715 and 1675 cm^{-1} (CO). Found: C, 52.03; H, 4.57; N, 17.58%. Calcd for $C_{17}H_{18}N_5O_4Cl$: C, 52.11; H, 4.63; N, 17.63%.

From III and β-Chloropropiononitrile: A mixture of III (0.01 mol), β-chloropropiononitrile (0.01 mol), sodium acetate (2.0 g) and ethanol (30 ml) was refluxed for 5 hr. The solvent was removed *in vacuo* and the remaining solid was washed with dilute hydrochloric acid and then water. The crude product was purified by recrystallization from ethanol and identified (mp and mixed mp) as Va or Vb. Yields, 70 and 72% respectively.

4-Arylazo-1-β-carboxyethyl-2-β-cyanoethyl-3,5-pyrazolidinedione (VIa and VIb). From IV and Acrylonitrile: To a solution of pyridine (50 ml) and water (10 ml) containing acrylonitrile (3 ml) 2.0 g of IV was added and refluxed for 3 hr and then evaporated *in vacuo*. The resulting crystalline mass was purified by recrystallization.

VIa. Yellow crystals (from ethanol), yield 72%, mp 195 °C. IR: 3150 (NH), 2400—2900 (OH), 2238 (CN), 1732 (carboxyl CO), 1670 and 1660 cm^{-1} (ring CO). Found: C, 54.41; H, 4.49; N, 21.14%. Calcd for $C_{15}H_{15}N_5O_4$: C, 54.71; H, 4.59; N, 21.27%.

VIb. Yellow crystals (from acetic acid), yield 75%, mp 205 °C. IR: 3125 (NH), 2400—2900 (OH), 2240 (CN), 1735 (carboxyl CO), 1660 and 1670 cm^{-1} (ring CO). Found: C, 49.16; H, 3.82; N, 19.44%. Calcd for $C_{15}H_{14}O_4N_5Cl$: C, 49.52; H, 3.87; N, 19.25%.

From V by Hydrolysis: A solution of V (2.0 g) in ethanolic aqueous sodium hydroxide (30 ml of 50% ethanol containing 1.0 g of NaOH) was refluxed for 45 min. The reaction mixture was allowed to cool and then acidified with concentrated hydrochloric acid to produce a solid product which was purified and identified as VIa or VIb.

From IV and β-Chloropropiononitrile: A mixture of IV (0.01 mol), β-chloropropiononitrile (0.01 mol), sodium carbonate (2.0 g) and ethanol (30 ml, 75%) was refluxed for 6 hr and then evaporated *in vacuo*. The remaining solid was dissolved in water and acidified with concentrated hydrochloric acid. The precipitates were purified by recrystallization and identified as V. Yields, 60 and 62% respectively.

4-Arylazo-1,2-di(β-carboxyethyl)-3,5-pyrazolidinedione (VIIa and VIIb). From V by Hydrolysis: A suspension of V (1.0 g) in acetic acid (20 ml) and hydrochloric acid (5 ml, 35%) was refluxed for 4 hr and then the solvent was removed under vacuum. The resulting crude product was treated with water, filtered and identified as VIIa or VIIb[1] after crystallization. Yields are 62 and 68% respectively.

From VI by Hydrolysis: In a similar manner as described above, hydrolysis of VI afforded VIIa or VIIb. Yields are 72 and 75% respectively.

From VIII by Hydrolysis: The procedure described above was used and the product proved to be VIIa of VIIb by mp and mixed mp.

4-Arylazo-1,2-di(β-ethoxycarbonylethyl)-3,5-pyrazolidinediones (VIIIa and VIIIb). Ten mmol of III was added to a solution of pyridine (50 ml) containing ethyl acrylate (0.02 mol) and was refluxed for 16 hr. The reaction mixture was left for two days at room temperature and then evaporated *in vacuo*. The resulting oily residue was dissolved in hot ethanol. After cooling, a small amount of unchanged material was removed by filtration. Evaporation of the filtrate afforded a crude product which was purified and identified as VIII.

VIIIa. Yellow crystals (from benzene–petroleum ether), yield 60%, mp 55 °C. Found: C, 56.69; H, 5.85; N, 13.70%. Calcd for $C_{19}H_{24}N_4O_6$: C, 56.43; H, 5.98; N, 13.86%.

VIIIb. Yellow crystals (from benzene–petroleum ether), yield 64%, mp 95 °C. IR: 1740, 1730 (ester CO), 1700 and 1680 cm^{-1} (ring CO). Found: C, 52.07; H, 5.10; N, 12.59%. Calcd for $C_{19}H_{23}N_4O_6Cl$: C, 51.99; H, 5.28; N, 12.76%.

Reaction of III or IV with Hydrazine Hydrate. Two grams of III or IV was added to a solution of ethanol (30 ml) containing hydrazine hydrate (2.0 ml) and refluxed for 3 hr. After cooling, the product was collected, recrystallized from

dioxane and proved to be arylazomalonic acid dihydrazide by mixed mp determination with an authentic sample.[3]

4-Arylazo-1-β-ethoxycarbonylethyl-2-acetyl-3,5-pyrazolidinedione (X). A mixture of III (2.0 g) and acetic anhydride (30 ml) was refluxed for 3 hr. After cooling, the reaction mixture was poured into water and stirred to decompose the excess acetic anhydride. The product, which separated out, was collected and recrystallized from ethanol.

Xa. Yellow crystals, mp 95 °C. IR: 3155 (NH), 1742 (acetyl CO), 1718 (ester CO), 1690 and 1665 cm^{-1} (ring CO). Found: C, 55.81; H, 5.26; N, 16.61%. Calcd for $C_{16}H_{18}N_4O_5$: C, 55.48; H, 5.24; N, 16.18%.

Xb. Yellow needles, mp 127 °C. IR: 3150 (NH), 1740 (acetyl CO), 1730 (ester CO), 1690 and 1675 cm^{-1} (ring CO). Found: C, 50.46; H, 4.50; N, 14.59%. Calcd for $C_{16}H_{17}N_4O_5Cl$: C, 50.46; H, 4.47; N, 14.71%.

2-p-Chlorophenylazotetrahydropyrazolo[1,2-a]pyrazole-1,3,7-trione (XI). A suspension of IVb (2.0 g) in phosphorus oxychloride (20 ml) was heated on a water bath for 3 hr. The resulting solution was then poured into ice-water and the resulting solid product was crystallized from ethanol. Yield was 50%. Yellow crystals, mp 275 °C. IR: 1770, 1710, and 1680 cm^{-1} (ring CO). Found: C, 49.09; H, 3.33; N, 18.77%. Calcd for $C_{12}H_9N_4O_3Cl$: C, 49.23; H, 3.09; N, 19.14%.

1, 2-Dihydro-5-hydroxy-3-phenylazopyrazolo[1, 5-a]pyrimidine-2-one (XII). Two grams of II was added to a solution of pyridine (50 ml) and water (10 ml) containing 1 ml of ethyl acrylate and then one drop of potassium hydroxide solution was added. The mixture was refluxed for 14 hr and then left overnight at room temperature. Removal of the solvent *in vacuo* afforded an oily residue which was dissolved in ethanol and acidified with concentrated hydrochloric acid. The crystals, which separated out, were collected and recrystallized from dimethylformamide to give 1.2 g (60%) of XII. Mp 301 °C. IR: 1690 (CO), 2430—2900 cm^{-1} (OH). Found: C, 55.62; H, 4.39; N, 27.30%. Calcd for $C_{12}H_{11}N_5O_2$: C, 56.02; H, 4.31; N, 27.23%.

Compound XII produces a red color with ferric chloride solution and is soluble in sodium carbonate solution. In the absence of potassium hydroxide, compound II was recovered unchanged after being refluxed with ethyl acrylate for 36 hr.

The Reaction of Dicyclopentadiene with Ethyl Diazoacetate

Tadashi SATO, Tamio MORI, and Junichi SHINODA

Department of Applied Chemistry, Waseda University, Shinjuku-ku, Tokyo 160

(Received October 5, 1972)

The reaction of *endo*-dicyclopentadiene (**1**) with ethyl diazoacetate (**3**) was carried out in the presence of several copper compounds. Two patterns of reaction were observed, depending on the type of copper compound used; the following schemes were proposed for the two reactions. I: The reaction proceeds through a coordination of the olefinic group to copper to form an olefin-copper complex, followed by an attack of the diazo compound on the complex. II: The reaction proceeds through a coordination of the diazo compound to copper to form an inversed ylide (**11**), followed by an electrophilic attack of the carbonium-ion center in **11** on the olefin to form a three-membered cyclic transition state, **12**.

It has been believed that the copper-catalyzed reactions of aliphatic diazo compounds with olefins involve copper-carbene-olefin complexes in the final stage of the reaction.[1] The scheme has been confirmed by the stereochemical relation of products with the variation in the electronic and steric factors of the ligands in the catalyst,[2] and by the introduction of chirality into the products in the reaction catalyzed by the chiral copper compounds.[3] With a view to clarifying how copper compounds participate in the transition state in these reactions, the reaction of *endo*-dicyclopentadiene with ethyl diazoacetate was carried out under several conditions.

Results

When *endo*-dicyclopentadiene (**1**) or its copper(I) chloride complex (**2**) was reacted with ethyl diazoacetate (**3**), compounds **4**—**8** were obtained in the yields shown in Table 1. Compound **9** was obtained when the reaction was carried out in the presence of triethyl phosphite (**10**). The yields were obtained by gas-chromatographic analysis, and the product identifications for new compounds were carried out as follows.

The structures of **6** and **7** were speculated to have a cyclopropane ring fused to a cyclopentane ring, judging from the IR bands characteristic of the double bond in a strained norbornene system,[4] which appeared at 1570 cm^{-1} for **6** and at 1574 cm^{-1} for **7**. The struc-

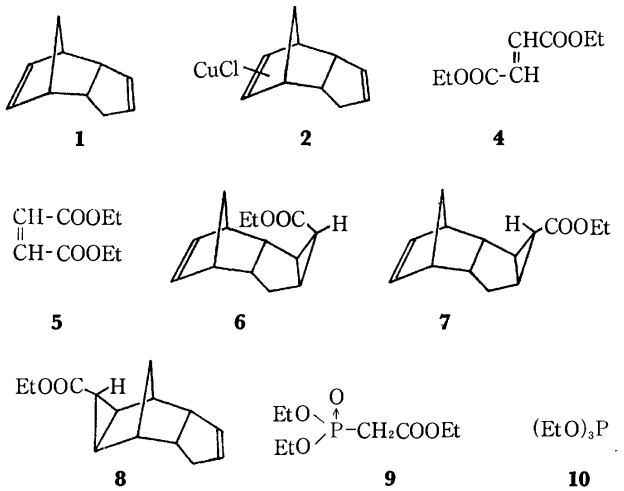
a) No account was taken of the low-boiling fractions (for instance, ethyl chloroacetate).
Although the mass balance of the reaction is not satisfactory, we consider the ratio **8**/(**6**+**7**) represented in this table is still meaningful, because the ratio is independent of the reaction conditions (reaction time or length of induction period) in a respective reaction, while the actual yields of products are more or less influenced.
b) Unless otherwise stated, equimolar amount to substrate was used.
c) AN: acetonitrile; D: dioxane; D–W: dioxane–water (1:1).
d) One-tenth equivalent was used.
e) **9** (8.5%) was also obtained.
f) The peak on the gas chromatogram overlapped with that of a phosphorus-containing substance.



1 **2** **4** **5** **6** **7** **8** **9** **10**

Chart 1

tures were also supported by the deformation bands of C–H in a cyclopropane ring fused to a cyclopentane ring,[5)] which appeared at 999 cm^{-1} for **6** and at 1011 cm^{-1} for **7**. The *exo*-configuration of the cyclopropane ring was tentatively assigned on the basis of the steric consideration that the alternative configuration would result in an enormous nonbonded steric repulsion.[5)] Since the steric repulsion created by the ethoxycarbonyl group and the hydrogen atoms in the norbornene system would be more serious in **6** than in **7**, the structure **7** was assigned to the major product.

The structure of **8** was supported by the elemental analysis and by an IR band at 1612 cm^{-1}, characteristic of the double bond in a cyclopentene ring, and a band at 1026 cm^{-1}, the deformation band of C–H in a cyclopropane ring fused to a norbornane system.[5)] The stereochemistry of the cyclopropane ring and the ethoxycarbonyl group was assigned in a similar way.

The structure of **9** was assigned on the basis of the elemental and spectroscopic analyses. The IR spectrum showed an ester carbonyl band at 1745 cm^{-1}. The NMR spectrum showed a doublet at δ 2.73 (2H, J=20 Hz) for $-CH_2-P$, besides signals corresponding to three ethyl groups.

Discussion

Referring to the ratio of **8**/(**6**+**7**), we can classify the reactions into three groups: Class I (Reactions 1—2) with higher ratios, Class II (Reactions 3—5) with intermediate ratios, and Class III (Reactions 6—8) with lower ratios. This fact suggests that more than one mode of the participation of copper in the reaction is present. We assume that the diversity arises from the different ability of copper catalysts to coordinate to a double bond. It has been established that an olefinic ligand coordinates to a metal more readily when the metal is in a low oxidation state than when it is in a high oxidation state.[6)] The rationale behind this might be that a metal with a lower valency, because of its formal abundance of electrons, back-donates its electrons into the antibonding orbital of the ligand more efficiently than does the same metal with a higher valency, thus providing a further stabilization for the metal-olefin complex. The donation and back-donation between the metal and the olefin might result in a net excitation of electrons from bonding to antibonding orbitals in the olefin, hence stabilizing the complex, particularly when the original olefin has much I-strain.[7)] Actually, it has been established that, in the copper(I) complex of **1**, the copper atom coordinates selectively to the double bond in the strained norbornene ring, as is shown in **2**.[4)] It may be suggested that, in Reaction 1, the catalyst participates in the reaction in the state of copper(I) with a strong coordinative power. The preferential formation of **8** over **6** and **7** can be explained by assuming an initial coordination of the strained double bond to the copper(I) atom, followed

by the attack of the diazo compound on the complex. That the reaction occurred in the near vicinity of the copper atom is evident from the fact that the complex **2** reacted with ethyl diazoacetate to form **8** predominantly (Reaction 2).

In reactions of Class III, on the other hand, both double bonds in **1** are involved in the reaction to a similar extent, thus indicating that the coordination of the metal has not played any important role in the reaction. Unlike the reactions in Class I, reactions in this class exhibit an induction period: the reactions proceeds smoothly at 40—65 °C only after the reaction has started at a higher temperature with the addition of one-third of the total amount of diazo compound. This indicates that the catalyst as such is not the actual species catalyzing the reaction. Although the exact state of this species is uncertain, we consider that copper is involved in the reaction in a state with a poor coordinative power. This consideration is consistent with the fact that the ratio (**8**/(**6**+**7**)) is quite low in Reaction 8, where the copper compound has been coordinatively saturated with the phosphorus ligand, although we observed no induction period.

Both reaction schemes (with strong and poor coordinative power of the metal) seem to occur competitively in reactions in Class II. This seems reasonable in view of the fact that copper(II) chloride is reduced partly to copper(I) chloride by ethyl diazoacetate.[8] Probably the same situation is also found with copper(II) sulfate. Furthermore, the reaction pattern of **2** (Reaction 2) was altered from Class I to Class II when the solvent was changed from dioxane to DMSO (Reaction 5). It is conceivable that a strongly coordinative solvent might partly expel copper from the complex, **2** thus providing a reaction pattern typical of reactions in Class III.

Chart 2

We feel that Moser's model,[2] which places emphasis on the coordination of copper to a double bond, is not suitable to explain the results we have presented thus far; we propose the following scheme for the reactions in Class III: the diazo compound attacks the copper compound to form an inversed ylide, **11**, and then the carbonium-ion center in **11** undergoes an electrophilic attack on the olefin to form a three-membered cyclic transition state, **12**. A three-membered cyclic transition state was proposed in view of the general belief[9] that a norbornene double bond should react in preference to a cyclopentene double bond as long as the reaction proceeds through a four-, five-, or six-membered cyclic transition state. In a separate experiment, we observed that the epoxidation of **1** with peracid, which has been confirmed to proceed through a three-membered cyclic transition state,[10] afforded **13a** and **14a** in a ratio of 1.3 (**13a**/**14a**), while epoxidation through a radical mechanism, which involves the double-bond opening,[11] afforded **13a** in preference to **14a** by a factor of 9.5.[12] Moser[2] proposed a copper-containing four-membered cyclic transition state rather than a three-membered cyclic transition state such as **12** for the present type of reaction, because no interaction causing the observed steric effects of ligands can be expected with the latter model. We are, however, of the opinion that the reaction scheme through the transition state **12** could also be susceptible to the steric effects, since the size of ligands in the copper compound **11** would sterically control the mode of approach of **11** to an olefinic group. Moreover, we consider that a transition state in which steric interaction between the reagent and the substrate are effective *to only a minor extent* is preferable in view of the following facts. The selective additions of dichlorocarbene[13] and dichloroketene[14] to the cyclopentene ring of **1** have been reported, and the unusual behavior in these cases has been interpreted in terms of the steric interaction between reagents and the hydrogen atoms in the norbornene system. Apparently, if the reaction between **1** and **3** proceeded through a transition state in which a considerable ligand effect can be expected, the formations of **6** and **7** would predominate, in contrast with the observed results. A good example favoring the present transition state, **12**, which is basically the same as that proposed for the Simmons-Smith reaction, has been provided by the observation[5] that the Simmons-Smith reaction of **1** afforded **13b** and **14b** in 12 and 11% yields respectively, as well as 63% of the diadduct.

Experimental

The IR spectra were obtained on JASCO IRS and Hitachi EPI-G3 spectrometers. The NMR spectra were measured on a JEOL MH-60 (60 MHz) spectrometer; the chemical shifts are represented in δ values relative to the internal TMS standard. The mass spectra were measured on a Hitachi RMS-4 mass spectrometer.

endo-*Dicyclopentadiene-copper(I) Chloride Complex (2).* This complex was prepared from **1**, $CuCl_2 \cdot 2H_2O$, and SO_2 in 95% ethanol by the method used for the preparation of the 1,5-cyclooctadiene-CuCl complex reported by Baird.[15] Mp 112 °C (decomp.). Lit[4]: mp 115 °C (decomp.).

Reactions of ***1*** *with* **3**. A solution of **1** (1.32 g) and copper compounds (specified amounts shown in Table 1) in 25 ml of a solvent was kept at an appropriate temperature. A solution of **3** (1.14 g) in 5 ml of the corresponding solvent was then added dropwise over a period of 2 hr. In cases where no nitrogen evolution was observed, the reaction mixture was heated to 70—80 °C after one-third of the total amount of diazo compound had been added. After the nitrogen evolution had been observed (usually in 20—90 min), the reaction mixture was cooled to the original temperature and the remainder of the diazo compound was added. The reaction mixture was poured into cold hydrochloric acid (200 ml of ice water containing 20 ml of concentrated hydrochloric acid) and shaken with ether. Ether was then removed, the residue was distilled under a vacuum, and the distillate was analyzed by gas chromatography. The six fractions, in the order of retention time, were as follows:

4 and **5**: Their retention times on gas chromatography and NMR and IR spectra were identical with those of authentic samples.

9: IR (CCl_4): 1745 (vs), 1275—1255 (b, s) and 1060—1020 cm^{-1} (b, s); NMR (CCl_4): δ 4.3—3.7 (m, 6H), 2.73 (d, J=20 Hz, 2H) and 1.4—1.1 (m, 9H).

Found: C, 43.1; H, 7.8%. Calcd for $C_8H_{17}O_5P$: C, 42.9; H, 7.6%.

6: MS: *m/e* 218 (M), 189 (M−C_2H_5), 173 (M−OC_2H_5), and 152 (base peak, M−C_5H_6); IR (CCl_4): 2940 (vs), 1730 (vs), 1570 (w), 1145 (b, vs) and 999 cm^{-1} (m).

7: MS: *m/e* 218 (M), 189 (very weak, M−C_2H_5), 173 (M−OC_2H_5), 153 (base peak, M−C_5H_5) and 152 (M–C_5H_6); IR (CCl_4): 2960 (vs), 1730 (vs), 1574 (w), 1160 (b, vs), and 1011 cm^{-1} (m); NMR (CCl_4): δ 6.15—6.0 (m, 2H), 3.95 (q, 2H), 2.9—2.6 (m), 1.7—1.0 (m), and 1.2 (t).

8: MS: *m/e* 218 (M), 189 (M−C_2H_5), 173 (M–OC_2H_5) and 152 (M–C_5H_6); IR (CCl_4): 2930 (vs), 1728 (vs), 1612 (w), 1170 (b, vs) and 1027 cm^{-1} (m); NMR (CCl_4): δ 5.8 (q, 2H), 4.2 (q, 2H), 2.7—2.2 (m), 1.7—0.9 (m), and 1.25 (t).

Found: C, 76.8; H, 8.5%. Calcd for $C_{14}H_{18}O_2$: C, 77.0; H, 8.5%.

Reactions of ***2*** *with* **3**. A solution of **2** (2.3 g) in 25 ml of a solvent was kept at an appropriate temperature. A solution of **3** (3.2 g) in 10 ml of the corresponding solvent was then added drop by drop over a period of 2 hr, after which the mixture was stirred for an additional hour. The reaction mixture was then worked-up in the way described above.

(Received November 4, 1972)

The treatment of 6-amino-5-nitrosopyrimidines with Vilsmeier-type reagents (substituted formamides and phosphorus oxychloride) afforded substituted 8-aminopurines; the treatment of 6-amino-4-hydroxy-2-methyl-5-nitrosopyrimidine gave 2-chloromethyl-8-dimethylamino-6-hydroxypurine.

Most substituted 8-aminopurine derivatives have been synthesized by the following two routes: the introduction of substituted amino groups into the preformed 8-chloro- or 8-methylmercapto-purine derivatives,[2] and the dehydrative or dethiohydrative cyclization of the 5-ureido- or 5-thioureido-6-aminopyrimidines obtained by the reaction of 5,6-diaminopyrimidines with substituted isocyanates or isothiocyanates.[3] We wish now to report a convenient new method of synthesizing substituted 8-aminopurine derivatives; the method consists of the treatment of 6-amino-5-nitrosopyrimidines with a mixture of substituted formamides and phosphorus oxychloride (Vilsmeier-type reagent).

The heating of 6-amino-1,3-dimethyl-5-nitrosouracil (**1**) with phosphorus oxychloride in dimethylformamide at 180 °C for 1 hr, the concentration of the reaction mixture by partial evaporation, and then dilution with water caused the separation of 8-dimethylaminotheophylline (**2a**) in a good yield. The structure of **2a** was established by a comparison of it with an authentic sample prepared by the treatment of 8-chlorotheophylline with dimethylformamide. This procedure is an application of the known dimethylamination of active chloro compounds using dimethylformamide.[4] Analogous reactions were observed in the condensation of **1** with methylformamide, diethylformamide, and *N*-methylformanilide in the presence of phosphorus oxychloride; in all cases, the substituted amino groups of the formamides were introduced into the 8-position of the final theophyllines. However, formamide did not react in the same way as substituted formamides to give the desired 8-aminotheophylline; rather, the formation of a small amount of 1,3-dimethylpyrimido-

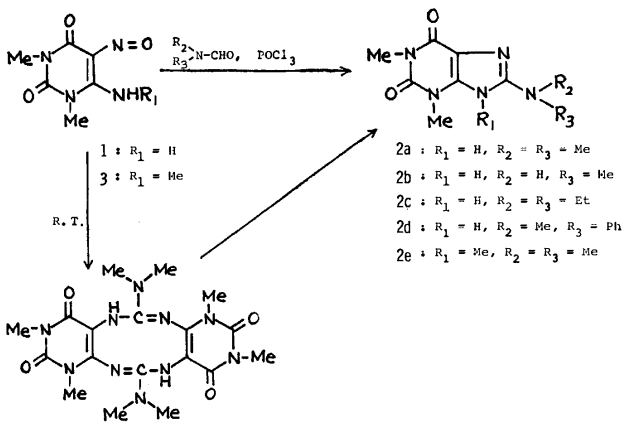
[4,5-*d*]pyrimidine-2,4-(1*H*,3*H*)-dione[5] was observed. The treatment of 1,3-dimethyl-6-methylamino-5-nitrosouracil (**3**) with a mixture of dimethylformamide and phosphorus oxychloride led to the formation of 8-dimethylaminoisocaffeine (**2e**). The results are summarized in Table 1.

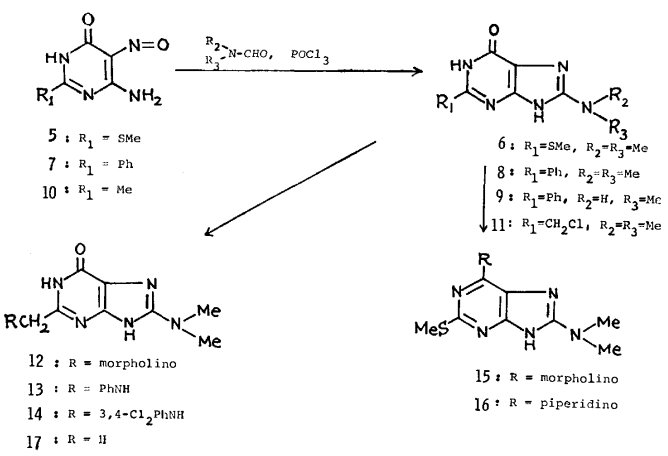
When **1** was treated with a mixture of dimethylformamide and phosphorus oxychloride at room temperature, a dimeric product (**4**) was obtained. The latter was converted into **2a** by further heating in the same reagent or by sublimating *in vacuo*. The structure of **4** was deduced from the following evidences; the molecular ion peak at *m/e* 446 in the mass spectrum and the elemental analysis correspond to the assigned formula. The NMR spectrum (CF_3COOH) displays a pair of six-proton singlets at 3.27 and 3.74 δ corresponding to the *N*-methyl groups of uracil and a twelve-proton singlet at 3.61 δ corresponding to the dimethylamino groups. Two two-proton broad singlets, at 5.77 and 5.94 δ, were assigned to the NH and NH^+ protons respectively.



Scheme I.

The heating of 6-amino-4-hydroxy-2-methylthio-5-nitrosopyrimidine (**5**) with a mixture of dimethylformamide and phosphorus oxychloride at 130 °C for 1 hr, the subsequent concentration of the reaction mixture by partial evaporation, and the treatment of the residue with ethanol gave 8-dimethylamino-6-hydroxy-2-methylthiopurine (**6**). Similarly, 6-amino-4-hydroxy-5-nitroso-2-phenylpyrimidine (**7**) and a mixture of dimethylformamide or methylformamide and phosphorus oxychloride led to 8-dimethylamino-6-hydroxy-2-phenylpurine (**8**) or 6-hydroxy-8-methylamino-2-phenylpurine (**9**). It is interesting to note that the reaction of 6-amino-4-hydroxy-2-methyl-5-nitrosopyrimidine (**10**) with a mixture of dimethylformamide and phosphorus oxychloride under the same conditions gave 2-chloromethyl-8-dimethylamino-4-hydroxypurine (**11**) (Table 2). The nuclear magnetic resonance spectrum (CF_3COOH) of **11** shows singlets at 3.57 (NMe_2) and 4.86 δ (CH_2Cl). The mass spectrometry reveals a parent ion (*m/e* 227) and the M+2 ion, suggesting that one chlorine atom is contained in the molecule.

The new synthesis of substituted 8-aminopurines can best be explained by assuming an initial nucleophilic attack of the oxime of the imino oxime tautomeric form (**18**) of the 6-amino-5-nitrosopyrimidines on the Vilsmeier-type reagent to form the adduct (**19**). Prototropic rearrangement would then give the protonated nitrone (**20**), which is suited for intramolecular cyclization to **21**. The subsequent elimination of a dichlorophosphoric acid and deoxygenation of the purine 7-oxide (**22**) would lead to the substituted 8-aminopurine. The formation of a dimeric product (**4**) in



Scheme II.

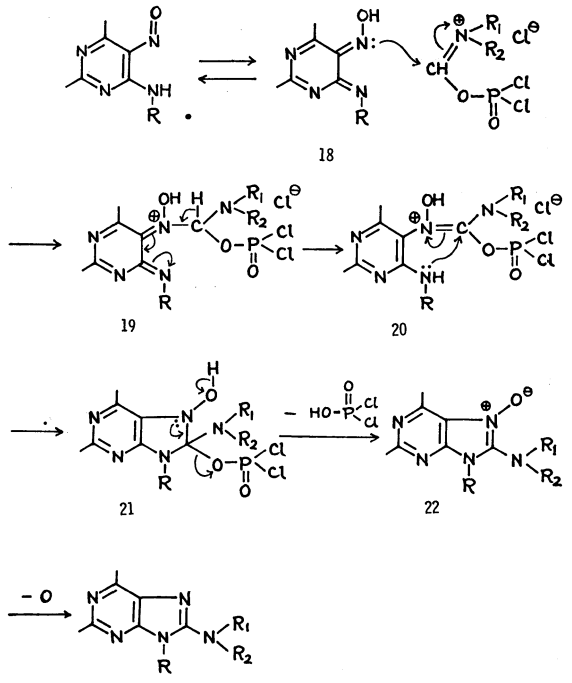
the reaction at a low temperature can be explained in terms of an alternative course *via* the dimerization of the initially formed nitrone (**20**), followed by the elimination of dichlorophosphoric acid and oxygen.

Compounds **6** and **11** served as starting materials for several nucleophilic reactions. For example, the displacement of the chlorine in **11** by morpholino and anilino groups yielded the respective 2-morpholinomethyl- (**12**) and 2-anilinomethyl-purine derivatives (**13** and **14**). It will be noted that the methylthio group of **6** was stable against nucleophilic substitutions. That is, in the reaction of **6** with morpholine the methylthio group survived completely and the product was 8-dimethylamino-2-methylthio-6-morpholinopurine (**15**), whose structure was established by the analytical and spectral data. Similarly, the heating of **6** with piperidine gave the corresponding 6-piperidinopurine (**16**). The reduction of **11** with triphenylphosphine in dimethylformamide gave 8-dimethylamino-6-hydroxy-2-methylpurine (**17**).



Scheme III.

Experimental

All the melting points are uncorrected. The NMR spectra were determined at 60 MHz, using tetramethylsilane as the internal standard. The chemical shifts were expressed in δ values (s: singlet, bs: broad singlet).

8-Dimethylaminopurines. General Procedure: A solution of 0.01 mol of 6-amino-5-nitrosopyrimidine and 0.015 mol of phosphorus oxychloride in 15 ml of dimethylformamide was heated at 150—180 °C for 1 hr and evaporated *in vacuo*, and water was added to the resulting residue. The solid separated was collected by filtration, washed with water, dried, and recrystallized from solvents as specified in Table 1 to give colorless needles.

8-Methylaminotheophylline (2b). A mixture of 1.84 g (0.01 mol) of 6-amino-1,3-dimethyl-5-nitrosouracil (**1**) and 2.3 g (0.015 mol) of phosphorus oxychloride in 5 ml of methylformamide was heated at 130 °C for 1 hr. The reaction mixture was diluted with methanol, and then the crystals separated were collected by filtration, washed with water, dried, and recrystallized to give colorless prisms.

8-Diethylaminotheophylline (2c). To a mixture of 0.92 g (0.005 mol) of **1** and 1 g (0.005 mol) of diethylformamide was added, 2.3 g (0.015 mol) of phosphorus oxychloride drop by drop at room temperature; the mixture was then heated at 120 °C for 30 min. After cooling, the reaction mixture was neutralized with 5% aqueous ammonia. The crystals precipitated were collected by filtration, washed with water, dried, and recrystallized to give colorless needles.

8-N-Methylanilinotheophylline (2d). To a mixture of 0.92 g (0.005 mol) of **1** and 1.35 g (0.01 mol) of *N*-methylformanilide, a 2.3 g portion (0.015 mol) of phosphorus oxychloride was added, drop by drop, at room temperature, and then the mixture was heated at 140 °C for 30 min with stirring. The reaction mixture was poured into 200 ml of ice water, and the crystals thus precipitated were collected by filtration, washed with water, dried, and recrystallized to give colorless needles.

8-Dimethylaminoisocaffeine (2e). To a mixture of 0.59 g (0.003 mol) of 1,3-dimethyl-6-methylamino-5-nitrosouracil (**3**) in 5 ml of dimethylformamide, 0.92 g (0.009 mol) of phosphorus oxychloride was added, drop by drop, at room temperature, and then the mixture was heated at 160 °C for 30 min. After the reaction mixture had been evaporated under reduced pressure, the resulting syrup was diluted with 20 ml of water, neutralized with 5% aqueous ammonia, and extracted with chloroform. The chloroform extracts were dried over anhydrous sodium sulfate, filtered, and evaporated to dryness. The residue was recrystallized from aqueous methanol to give colorless needles.

Formation of the Dimeric Product (4). Into a suspension of 1.84 g (0.01 mol) of **1** in 20 ml of dimethylformamide, 3.1 g (0.02 mol) of phosphorus oxychloride was added portionwise with stirring. The resulting clear solution was stirred at room temperature for 3 hr, during which time colorless needles were gradually separated. The crystals were collected by filtration, washed with water, dried, and recrystallized from dimethylformamide to give 1.18 g (53%) of colorless needles; mp>330 °C. MS 446 (M^+). Found: C, 48.72; H, 5.79; N, 31.09%. Calcd for $C_{18}H_{26}N_{10}O_4$: C, 48.42; H, 5.87; N, 31.38%.

Conversion of 4 into 2a. (A) A suspension of 0.8 g (0.0018 mol) of **4** and 0.77 g (0.005 mol) of phosphorus oxychloride in 10 ml of dimethylformamide was heated with stirring at 180 °C for 2 hr and then allowed to stand overnight. The crystals separated were collected by filtration and washed with ethanol to give 0.4 g (50%) of **2a**.

(B) **4** was sublimed at 260 °C under reduced pressure (10 mmHg) to yield **2a** in a good yield.

8-Dimethylamino-2-methylthio-6-morpholinopurine (15). A mixture of 0.3 g (0.0013 mol) of **6** in 10 g (0.12 mol) of morpholine was heated under gentle reflux for 1.5 hr. After the excess morpholine had been evaporated under reduced pressure, the residue was recrystallized from aqueous methanol to give 0.2 g (53%) of colorless prisms; mp>320 °C. NMR ($CDCl_3$) 2.62 (s, 3H, SMe), 3.28 (s, 6H, NMe_2), 4.01 (bs, 8H, morpholino CH_2). MS 294 (M^+). Found: C, 49.02; H, 6.15; N, 28.37%. Calcd for $C_{12}H_{18}N_6OS$: C, 48.97; H, 6.17; N, 28.56%.

8-Dimethylamino-2-methylthio-6-piperidinopurine (16). A mixture of 0.8 g (0.0036 mol) of **6** in 10 g (0.12 mol) of piperidine was treated under the same conditions to yield 1 g (95%) of colorless needles after recrystallization from aqueous methanol. MS 292 (M^+). Found: C, 53.22; H, 6.84; N, 28.49%. Calcd for $C_{13}H_{20}N_6S$: C, 53.41; H, 6.90; N, 28.75%.

2-Anilinomethyl-8-dimethylamino-6-hydroxypurine (13). A mixture of 1.5 g (0.0067 mol) of **11** and 4 g (0.043 mol) of aniline in 10 ml of dimethylformamide was heated at 130 °C for 1 hr. The reaction mixture was then evaporated under reduced pressure, and the resulting residue was recrystallized from ethanol to give 1.1 g (58%) of colorless needles; mp> 330 °C. MS 284 (M^+). Found: C, 58.97; H, 5.70; N, 29.32%. Calcd for $C_{14}H_{16}N_6O$: C, 59.14; H, 5.67; N, 29.56%.

2-(3,4-Dichloroanilino)methyl-8-dimethylamino-6-hydroxypurine (14). A mixture of 1.5 g (0.0067 mol) of 11 and 5 g (0.031 mol) of 3,4-dichloroaniline in 10 ml of dimethylformamide was heated at 160 °C for 2 hr and then treated in the manner described above to give 1.2 g (51%) of colorless needles; mp>330 °C. Found: C, 47.68; H, 4.04; N, 23.63%. Calcd for $C_{14}H_{14}H_6OCl_2$: C, 47.60; H, 3.99; N, 23.80%.

8-Dimethylamino-6-hydroxy-2-morpholinomethylpurine (12). A mixture of 0.8 g (0.0035 mol) of **11** and 10 g (0.12 mol) of morpholine was heated under reflux for 1 hr; then it was treated in the manner described for the preparation of **13** to yield 0.4 g (41%) of colorless needles (mp 260 °C) after recrystallization from methanol. MS 278 (M^+). Found: C, 51.62; H, 6.49; N, 30.31%. Calcd for $C_{12}H_{18}N_6O_2$: C, 51.78; H, 6.52; N, 30.20%.

8-Dimethylamino-6-hydroxy-2-methylpurine (17). A mixture of 0.3 g (0.0013 mol) of **11** and 0.45 g (0.0017 mol) of triphenylphosphine in 15 ml of dimethylformamide was heated under a mild reflux for 2 hr. The reaction mixture was then evaporated under reduced pressure, and the residue was diluted with 30 ml of methanol. The crystals precipitated were collected by filtration, washed with water, dried, and recrystallized from dimethylformamide to give 0.1 g (40%) of colorless prisms; mp>330 °C. MS 193 (M^+). Found: C, 50.02; H, 5.73; N, 36.03%. Calcd for $C_8H_{11}N_5O$: C, 49.73; H, 5.74; N, 36.25%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1839—1844 (1973)

The Synthesis and the Stereochemistry of 4-Chromanones and 4-Chromanols with Bulky Substituents

Kuninobu KABUTO, Yoriko KIKUCHI, Shozo YAMAGUCHI, and Naoto INOUE

Department of Chemistry, College of General Education, Tohoku University, Kawauchi, Sendai 980

(Received November 13, 1972)

The synthesis and the stereochemistry of 4-chromanones and 4-chromanols with bulky substituents have been investigated. In 3-substituted chromanones, the *t*-butyl group exists mainly in the *quasi*-axial position, while the phenyl group is still in the *quasi*-equatorial environment. The preferred conformations of the isopropyl, and of the *t*-butyl group in *cis*- and *trans*-2-substituted chromanols, are equatorial, whereas *trans*-3-*t*-butylchromanol and its benzoate exist mainly as the conformations in which the *t*-butyl group is in the axial position. The conformational preference of these compounds can reasonably be explained by considering the steric interactions ($A^{(1,3)}$ strain, *gauche*, and diaxial repulsion) of these groups. The magnitude of the $A^{(1,3)}$ strain due to the hydroxyl group was estimated to be 1.3 kcal/mol.

In a previous paper,[1] we have reported that the conformational equilibria of 3-methyl- and 3-phenylchroman-4-ols can be well interpreted on the basis of the $A^{(1,3)}$ strain together with the 1,3-diaxial repulsion.

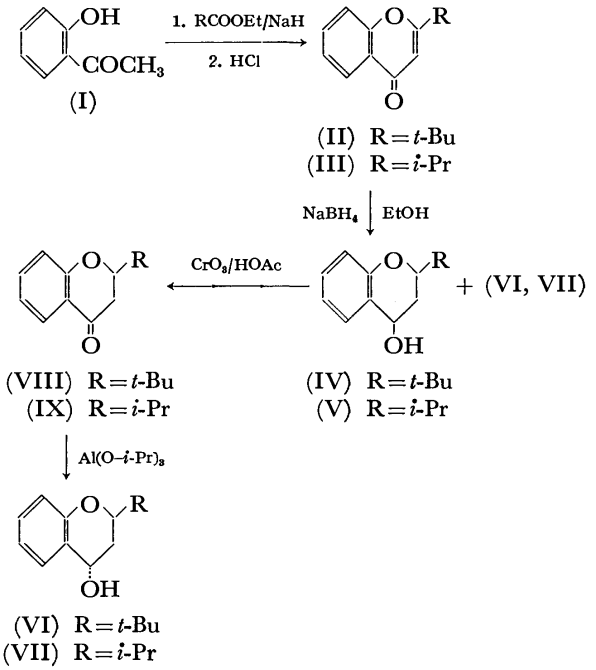
It is still not obvious, however, how the above interaction may affect the conformational equilibrium when the bulky groups are substituted on the 2- or 3-position of 4-chromanone and 4-chromanol.

In this paper, we wish to report on the synthesis and

1) S. Yamaguchi, K. Kabuto, Y. Ninomiya, and N. Inoue, This Bulletin, **43**, 3952 (1970).

the stereochemistry of 4-chromanones and 4-chromanols with bulky groups on the heterocyclic ring.

2-*t*-Butyl-(VIII), 2-isopropylchromanone (IX) and the corresponding chromanols (IV, VI; V, VII) were synthesized according to Scheme 1. *o*-Hydroxyacetophenone was allowed to react with ethyl pivalate in the presence of sodium hydride to give the diketone, which was in turn converted to the corresponding chromone (II) with concentrated hydrochloric acid.

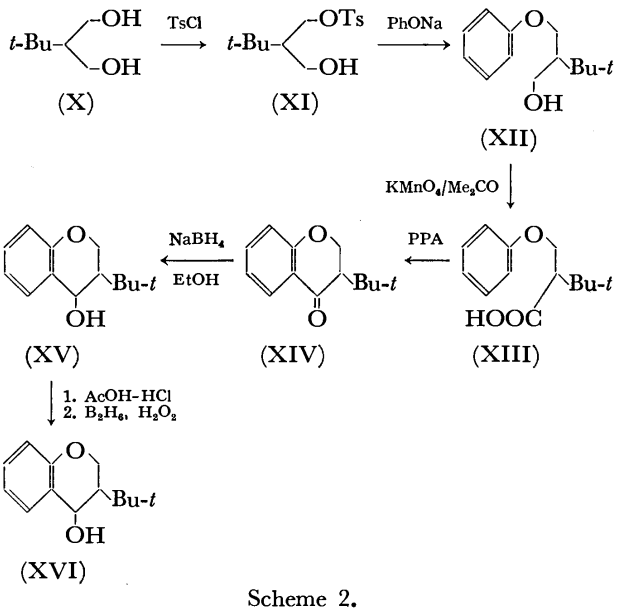


Scheme I.

When II was treated with excess sodium borohydride in boiling ethanol,[2] *cis*-2-*t*-butyl-4-chromanol (IV) was obtained as the main product. Compounds (IV) was easily oxidized by chromic acid in an acetic acid solution below 30 °C, yielding the chromanone (VIII), which subsequently afforded a mixture of *trans*- (VI, 58%) and *cis*-chromanols (IV, 22%) by Meerwein-Pondorf reduction. The NMR spectra (Table 2) of IV and VI indicate that the configurations of these compounds are *cis* and *trans* respectively. The purification of these chromanols by column or thin-layer chromatography was unsuccessful; hence, they were purified by preparative gas chromatography, using PEG 20M as the stationary phase.

The application of the synthetic route to isoflavanone[3] *via* phenoxyacetophenone cyanohydrin did not afford satisfactory results in preparing 3-*t*-butylchromanone (XIV). The chromanone (XIV) was successfully synthesized following Scheme 2, which is considered to be a suitable way for preparing chromanones with a bulky group such as the *t*-butyl group because the reaction is not so subject to steric hindrance by a bulky group.

2-*t*-Butyl-1,3-propanediol (X) was partially tosylated with tosyl chloride to give monotosylate (XI), which



Scheme 2.

was then transformed to phenoxyalcohol (XII) with sodium phenoxide in a dimethyl sulfoxide solution. 3-*t*-Butylchromanone (XIV) was prepared by the oxidation of XII with potassium permanganate, followed by the ring closure of carboxylic acid (XIII) in PPA.

The reduction of XIV with sodium borohydride resulted almost exclusively in the formation of *cis*-3-*t*-butylchromanol (XV). Compound (XV) was easily dehydrated with boiling acetic acid–hydrochloric acid to 3-*t*-butylchromene, which was then converted to the other isomer (XVI) by hydroboration, indicating that the configurations of XV and XVI are *cis* and *trans* respectively. These results are in accordance with the findings[4] that the formation of the *cis* isomer in the hydride reduction of 3-substituted chromanones increases with an increase in the size of the substituents.

The NMR spectra of substituted 4-chromanones are summarised in Table 1.

Table 1. NMR Spectra of substituted 4-chromanones

Chromanone		Preferred conformation of alkyl group
2-*t*-Bu (VIII)	$J_{2,3}$:~13.0;[a] $\lvert J_{2,3}+J_{2,3'}\rvert=16.0$	e
2-*i*-Pr (IX)	$\lvert J_{2,3}+J_{2,3'}\rvert=16.0$	e
3-*t*-Bu (XIV)	$J_{2,3}$: 4.6, 4.2; $\lvert J_{2,3}+J_{2',3}\rvert=8.8$	a'
3-Ph	$\lvert J_{2,3}+J_{2',3}\rvert=14.0$	e'
3-Me	$J_{2,3}$: 10.8, 5.4; $\lvert J_{2,3}+J_{2',3}\rvert=16.2$[5]	e'

a) Spectrum was taken in the presence of 0.30 molar ratio of $Pr(fod)_3$ in CCl_4.

The signals of 2-H and 3-H portion of 2-*t*-butylchromanone (VIII) did not appear as the typical ABX pattern; hence the spectrum was analysed as the first-order spectrum in the presence of $Pr(fod)_3$.[5] The

2) S. Yamaguchi, S. Ito, A. Nakamura, and N. Inoue, This Bulletin, **38**, 2187 (1965).

3) N. Inoue, *Nippon Kagaku Zasshi*, **79**, 218 (1958).

4) N. Inoue, This Bulletin, **37**, 601 (1964); K. Hanaya, *ibid.*, **43**, 442 (1970).

5) Since the separation between the two strong outer lines of X part of ABX pattern is almost same to that in the absence of $Pr(fod)_3$, the geometry of chromanone ring seems not to be altered by the shift reagent.

Fig. 2.

large $J_{2,3}$ value (13 Hz) and the distance between the two outside peaks of the X part of the ABX pattern[6] indicate that VIII exists exclusively in the VIIIe conformation, though there seems to be no remarkable interaction which forces VIIIa to be unfavorable.

The line separation of the X part in 2-isopropylchromanone (IX) is almost the same as that of VIII; therefore, the isopropyl group in IX also favors the equatorial orientation.

The NMR spectrum of 3-*t*-butylchromanone (XIV) was analysed as being the ABX pattern[7] ($J_{2,3}$: 4.6 and 4.2 Hz), indicating that XIV exists mainly as the XIVa conformation with the *quasi*-axial *t*-butyl group, contrary to the case of 3-methylchromanone,[8] in which the methyl group is *quasi*-equatorial.

The dihedral angle (32°) between the carbonyl group and the benzene ring, calculated from the absorbance in the ultraviolet region[9] in XIV, is almost the same as those of chromanone and 2-methylchromanone,[10] suggesting that the geometry of the chromanone ring is unchanged by the *t*-butyl group.

Although the magnitude of the 2-alkylketone effect due to the *t*-butyl group (the repulsion between the *quasi*-equatorial 3-*t*-butyl and the carbonyl group) has not yet been determined, it may be presumed to be considerably larger than that of the isopropyl group (1.7 kcal/mol).[11a] Since the 2-alkylketone effect anticipated for XIVe is considered to be considerably larger than the interaction between the *quasi*-axial *t*-butyl group and the ring oxygen in XIVa, XIVa seems more likely than XIVe.

The above considerations seem to be reasonable in the following points: (1) The interaction of an axial group with a ring oxygen is smaller than its interaction with an axial hydrogen,[12] and the repulsion between the axial *t*-butyl group and the ring oxygen in 5-*t*-butyl-2-alkyl-1,3-dioxane is estimated to be 1.4 kcal/mol,[13] which is quite small compared to the interaction with the axial hydrogen on the cyclohexane ring (4.4 kcal/mol).[13] (2) Since the interaction of an axial group with one axial hydrogen atom is reduced to one-half its normal conformational free energy,[11a,b] it may be considered that the interaction of the *quasi*-axial 3-*t*-butyl group with the ring oxygen in XIVa would be around 0.7 kcal/mol, which is considerably smaller than the 2-alkylketone effect because there is only one oxygen in the chromanone ring.

An attempt to determine the conformational equilibrium of 3-*t*-butylchromanone by studying the IR spectra using 3-d_2-chromanone and 3-*d*-3-*t*-butylchromanone was unsuccessful because of the anbiguity of the C–D stretching vibrations of these compounds.

The methylene signal in 3-phenylchromanone did not separate even in the presence of $Pr(fod)_3$. The line separation of the two strong outside peaks of the X part, however, is very close to that of 3-methylchromanone;[10] therefore, the 2-alkylketone effect in 3-phenylchromanone seems not to be sufficiently large to cause the phenyl group to occupy the axial position.

The preferred conformations of *cis*-2-isopropyl- and *cis*-2-*t*-butylchromanol are expected to be almost fixed at Ve and IVe respectively, because severe diaxial repulsion due to the bulky substituents would be considerably larger than the $A^{(1,3)}$ strain (the repulsion of *quasi*-equatorial 4-hydroxyl group with 5-H).

The magnitude of the $A^{(1,3)}$ strain for the hydroxyl group was calculated to be 1.3 kcal/mol by the procedure described in the previous paper;[1] this value was almost the same as that for the acetoxyl group.

On the other hand, *trans* isomers should be VIa and VIIa, for the sum of the diaxial repulsion (*e.g.*, 2-*t*-Bu~4-H; 2.2 kcal/mol) and the $A^{(1,3)}$ strain is much larger than the interaction due to the *quasi*-axial hydroxyl group (0.4 kcal/mol). The above considerations are supported by the NMR spectra (Table 2) of these compounds.

It is difficult to determine the preferred conformation

6) It is well known that the distance between the outermost lines of X part of ABX pattern may be used as convenient method for determining the stereochemistry: L. M. Jackman and S. Sternhell, "Application of Nuclear Magnetic Resonance Spectroscopy in Organic Chemistry," Pergamon Press, (1969), p. 133; B. J. Bolger, A. Hirwe, K. G. Marathe, E. M. Philbin, M. A. Vickers, and C. TABLE 2. NMR SPECTRA OF SUBSTITUTED 4-CHROMANOLS AND ITS DERIVATIVES

Chromanol	$\lvert J_{2,3}+J_{2,3'}\rvert$	$\lvert J_{3,4}+J_{3',4}\rvert$	Preferred conformation of alkyl group
cis-2-*t*-Bu (IV)	14.1	17.4	e
cis-2-*i*-Pr (V)	13.6	17.2	e
trans-2-*t*-Bu (VI)	13.8	6.0	e
trans-2-*i*-Pr (VII)	13.8	6.0	e
cis-3-*t*-Bu (XV)	$J_{3,4}$: 3.0; $\lvert J_{2,3}+J_{2',3}\rvert$=15.0		e
Benzoate of XV	$J_{3,4}$: 2.6; $\lvert J_{2,3}+J_{2',3}\rvert$=16.0		e
trans-3-*t*-Bu (XVI)	$J_{3,4}$: 4.3; $\lvert J_{2,3}+J_{2',3}\rvert$=8.6		a
Benzoate of XVI	$J_{3,4}$: 3.0; $\lvert J_{2,3}+J_{2',3}\rvert$=6.0		a

of *cis*-3-*t*-butylchromanol (XV) by the $J_{3,4}$ value (3.0 Hz) alone; however, the separations between the two strong outerlines ($\lvert J_{2,3}+J_{2',3}\rvert$) of XV and of its benzoate are 15.0 and 16.0 Hz respectively. In XV and its benzoate, the $A^{(1,3)}$ strain and the interaction of the axial *t*-butyl group with the ring oxygen would tend not to favor the XVe conformation, and the *t*-butyl group should be fixed in the equatorial environment

It is particularly interesting that the $J_{3,4}$ values in *trans*-3-*t*-butylchromanol (XVI) and its benzoate (XVI') were 4.3 and 3.0 Hz respectively, and the diaxial coupling constant expected for the XVIe conformation was not observed. Taking into account the facts that $J_{3a,4e'}$ in chromanols is as same as that of $J_{3e,4e'}$[1] and that the conformations of XV and its benzoate are homogeneous with $J_{3a,4e'}$: 3.0 and 2.6 Hz respectively, XVI and its benzoate ($J_{3,4}$: 4.3 and 3.0 Hz) can be considered to exist predominantly in the diaxial conformations (XVIa and XVI'a).

There are $A^{(1,3)}$, *gauche* (4-OR~3-*t*-Bu), and two methylhydrogen interactions due to the *t*-butyl group and C_2-methylene in XVIe and XVI'e. On the other hand, the above interactions are replaced by smaller steric interactions (4-OR~2-H, 3-*t*-Bu~ring oxygen, and one methyl-hydrogen interaction) in XVIa and XVI'a.

It is still obscure whether the chromanol ring in *trans*-3-*t*-butylchromanol has a half-chair or a half-boat conformation. If one may assume, however, that the energy difference between the half-chair and the half-boat conformation in the chroman ring is almost the same as that in the cyclohexene ring (2.7 kcal/mol),[14] the contribution of the half-boat conformation would be ruled out, because the unfavored interaction in XVIa is considered to be approximately 1.1 kcal/mol (0.4 kcal/mol: 1,3-diaxial repulsion due to 4-OH, 0.7 kcal/mol: *t*-Bu~ring oxygen).

Experimental

All the melting points are uncorrected. The NMR spectra were recorded on Varian A-60D (60 MHz) and HA-100 (100 MHz) spectrometers, using TMS as the internal standard.

2-t-Butylchromone (II). To a stirred solution of *o*-hydroxyacetophenone (I, 11 g) in ethyl pivalate (80 ml) was added, portion by portion, sodium hydride (50% in mineral oil, 15 g) at room temperature. The mixture was then stirred at 75—85 °C on a water bath for 4 hr and allowed to stand overnight at room temperature. After the excess hydride has been decomposed with a small amount of water, the reaction mixture was poured into ice water (400 ml); the separated sodium salt was then collected, decomposed with 6 M hydrochloric acid, and extracted with ether. The organic layer was washed with saturated sodium bicarbonate and water successively, and dried over sodium sulfate.

The removal of the solvent afforded pivalyl *o*-hydroxyacetophenone as a pale yellow crystals (13 g, 72%). Needles from hexane, mp 57.5—58 °C. Found: C, 70.92; H, 7.11%. Calcd for $C_{13}H_{16}O_3$: C, 70.89; H, 7.32%.

The diketone (13 g) was dissolved in concentrated hydrochloric acid (60 ml) and warmed at 40 °C for 1 hr. The solution was diluted with water (220 ml) and then extracted with ether. The organic layer was then worked up according to the usual procedure. The removal of the solvent afforded crude II, which subsequently purified by recrystallization from petroleum ether (bp 40—60 °C), mp 72—73 °C.

Found: C, 76.90; H, 6.79%. Calcd for $C_{13}H_{14}O_2$: C, 77.20; H, 6.98%. IR (KBr): 1660 cm^{-1}. NMR (CCl_4): δ 1.35 (s, 9H, *t*-Bu), 6.08 (s, 1H, C_3–H) ppm.

cis-2-t-Butyl-4-chromanol (IV). A solution of II (5 g) and sodium borohydride (5 g) in ethanol (100 ml) was refluxed for 5 hr. After the reaction mixture had then stood overnight at room temperature, the solvent was removed under reduced pressure; the residue was dissolved in 50% acetic acid (50 ml) and water (150 ml). The solution was extracted with ether, and the extract was treated as usual to give colorless crystals (4.6 g, 88%), whose vpc (20% PEG 20 M at 180 °C) showed that it was a mixture of *cis*- (94.7%) and *trans*-2-*t*-butyl-4-chromanol (5.3%). Recrystallization from pentane gave *cis*-2-*t*-butyl-4-chromanol as colorless needles; mp 58.5—60 °C.

Found: C, 75.82; H, 8.74%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%. IR (KBr): 3270 cm^{-1}. NMR ($CDCl_3$+D_2O): δ 1.00 (s, 9H, *t*-Bu), 3.64 (dd, 1H, C_2–H), 4.77 (dd, 1H, C_4–H) ppm.

The acetate of IV was prepared according to the usual manner with acetyl chloride and pyridine: Colorless oil. IR (neat): 1738 cm^{-1}. NMR ($CDCl_3$): δ 1.4—2.6 (m, 5H, C_3–H and –OAc), 3.76 (dd, 1H, C_2–H), 6.10 (dd, 1H, C_4–H) ppm. $\lvert J_{2,3}+J_{2,3'}\rvert$=13.6, $\lvert J_{3,4}+J_{3',4}\rvert$=16.7 Hz.

2-t-Butyl-4-chromanone (VIII). To a stirred solution of IV (3.0 g) in 80% acetic acid (20 ml) was added chromic acid (1.68 g) in the same solvent (18 ml) below 30 °C. After the stirring has been continued for an additional hour, the reaction mixture was poured into ice water (300 ml) and extracted with ether. The extract was washed according to the usual manner. The solvent was then removed to give pale yellow crystals (2.5 g, 83%); subsequent recrystallization from hexane gave colorless crystals; mp 64.5—66 °C.

Found: C, 76.59; H, 7.80%. Calcd for $C_{13}H_{16}O_2$: C,

14) C. W. Beckett, N. K. Freeman, and K. S. Pitzer, *J. Amer. Chem. Soc.*, **70**, 4227 (1948).

76.44; H, 7.90%. IR (CCl_4): 1694 cm^{-1}. NMR (CCl_4): δ 1.08 (s, 9H, *t*-Bu), 2.58 (AB part of ABX, C_3–H), 4.06 (dd, 1H, C_2–H) ppm.

trans-*2-t-Butyl-4-chromanol (VI).* A solution of VIII (2.0 g) and aluminum isopropoxide (4.0 g) in isopropyl alcohol (8.0 ml) was refluxed for 3 hr. The solution was then poured into ice water (200 ml) containing concentrated hydrochloric acid (10 ml) and extracted with ether. The ethereal layer was washed as usual. The vpc of the extract showed that it was a mixture of *trans*- (58%), *cis*-2-*t*-butyl-4-chromanol (22%), and VIII (20%). The removal of the solvent gave a pale yellow oil (1.9 g), which was then purified by preparative vpc (20% PEG 20M 3/8″ 1.2 m, at 180 °C) to yield VI. Recrystallization from pentane gave VI as colorless prisms; mp 81—82 °C.

Found: C, 75.64; H, 8.82%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%. IR (KBr): 3280 cm^{-1}, NMR ($CDCl_3$+D_2O): δ 1.00 (s, 9H, *t*-Bu), 3.78 (dd, 1H, C_2–H), 4.70 (t, 1H, C_4–H) ppm.

Acetate of VI: Colorless oil. IR (neat): 1736 cm^{-1}. NMR ($CDCl_3$): δ 1.5—2.1 (m, 5H, C_3–H and –OAc), 3.85 (dd, 1H, C_2–H), 6.00 (t, 1H, C_4–H) ppm. $|J_{2,3}+J_{2,3'}|=14.0$, $|J_{3,4}+J_{3',4}|=6.0$ Hz. By a procedure similar to that described above, 2-*i*-propylchromone (III, 44%), 2-*i*-propyl-4-chromanone (IX, 83%), *cis*-2-*i*-propyl-4-chromanol (V, 88%), and *trans*-2-*i*-propyl-4-chromanol (VII, 61%) were prepared.

III: Mp 42—43 °C; recrystallized from hexane. Found: C, 76.40; H, 6.39%. Calcd for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43%. IR (KBr): 1660 cm^{-1}. NMR (CCl_4): δ 1.32 (Me of *i*-Pr), 6.00 (s, 1H, C_3–H) ppm.

IX: Colorless oil. Found: C, 75.79; H, 7.45%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%. IR (CCl_4): 1690 cm^{-1}. NMR ($CDCl_3$): δ 1.05 (Me of *i*-Pr), 2.5—2.8 (AB part of ABX, C_3–H), 4.17 (ddd, 1H, C_2–H) ppm.

V: Mp 88.5—89 °C, recrystallized from hexane. Found: C, 74.67; H, 8.27%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%. IR (KBr): 3250 cm^{-1}. NMR ($CDCl_3$+D_2O): δ 1.00 (Me of *i*-Pr), 3.82 (ddd, 1H, C_2–H), 4.83 (dd, 1H, C_4–H) ppm.

Acetate of V: Colorless oil. IR (neat): 1739 cm^{-1}. NMR ($CDCl_3$): δ 1.7—2.6 (m, 6H, methine of *i*-Pr, C_3–H, and –OAc), 3.90 (ddd, 1H, C_2–H), 6.07 (dd, 1H, C_4–H) ppm. $|J_{2,3}+J_{2,3'}|=13.2$, $|J_{3,4}+J_{3',4}|=16.5$ Hz.

VII: Colorless oil. Found: C, 74.70; H, 8.54%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%. IR (neat): 3350 cm^{-1}. NMR ($CDCl_3$+D_2O): δ 1.02 (Me of *i*-Pr), 3.91 (ddd, 1H, C_2–H), 4.67 (t, 1H, C_4–H) ppm.

Acetate of VII: Colorless oil. IR (neat): 1740 cm^{-1}. NMR ($CDCl_3$): δ 1.8—2.2 (m, 6H, methine of *i*-Pr, C_3–H, and –OAc), 3.96 (ddd, 1H, C_2–H), 5.98 (t, 1H, C_4–H) ppm. $|J_{2,3}+J_{2,3'}|=13.2$, $|J_{3,4}+J_{3',4}|=6.0$ Hz.

2-t-Butyl-1,3-propanediol Monotosylate (XI). To a stirred solution of 2-*t*-butyl-1,3-propanediol (X, 14 g) in dry pyridine (80 ml) was added, drop by drop, *p*-toluenesulfonyl chloride (20.2 g) in dry chloroform (100 ml) under ice cooling over a period of 5 hr. After the reaction mixture had then been left to stand for 2 days in a refrigerator, it was poured into ice water (500 ml) containing concentrated hydrochloric acid. The organic layer was treated in the usual way to afford a pale yellow oil (28.3 g), which was subsequently chromatographed on silica gel (400 g). Elution with benzene–ether (4: 1) afforded 2-*t*-butyl-1,3-propanediol ditosylate (8.2 g, 17.5%); mp 69.0—69.5 °C.

Found: C, 57.19; H, 6.68%. Calcd for $C_{21}H_{28}O_6S_2$: C, 57.25; H, 6.41%.

Subsequent elution gave monotosylate (XI) (16.3 g, 57.5%) as a colorless oil.

Found: C, 58.56; H, 7.93%. Calcd for $C_{14}H_{22}O_4S$: C, 58.72; H, 7.74%. IR (neat): 3450 cm^{-1}. NMR ($CDCl_3$): δ 0.90 (s, 9H, *t*-Bu) ppm.

2-t-Butyl-1,3-propanediol Monophenyl Ether (XII). To a solution of sodium ethoxide in ethanol prepared from absolute ethanol (70 ml) and sodium (1.56 g) was added phenol (6.42 g); then the solvent was removed. To the stirred suspension of sodium phenoxide in dimethyl sulfoxide (40 ml), heated at 50—60 °C, was added, drop by drop, XI (16.3 g) in dimethyl sulfoxide (30 ml) over a period of 45 min. Stirring was continued for 2 hr at 50—60 °C, and then the mixture was allowed to stand overnight at room temperature. The reaction mixture was poured into ice water (350 ml), saturated with sodium chloride, and extracted five times with ether. The combined extract was then treated as usual to give a pale yellow oil (10.6 g), which was subsequently purified by distillation, 9.7 g (83%), bp 145—147 °C/4 mmHg.

Found: C, 74.65; H, 10.05%. Calcd for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68%. IR (neat): 3350 cm^{-1}. NMR ($CDCl_3$): δ 1.00 (s, 9H, *t*-Bu), 6.8—7.4 (m, 5H, aromatic-H) ppm.

p-*Nitrobenzoate of XII*: Colorless needles from ethanol–water, mp 63—63.5 °C. Found: N, 4.02%. Calcd for $C_{20}H_{23}NO_5$: N, 3.92%.

α-t-Butyl-β-phenoxypropionic Acid (XIII). To a stirred solution of XII (6.80 g) in acetone (360 ml) warmed to 30 °C was added, portion by portion, finely-powdered potassium permanganate (14 g). After the addition was complete, the stirring was continued for 24 hr. The manganese dioxide was filtered off and washed well with hot water (total volume, 300 ml). The filtrate and the washings were then combined and concentrated under reduced pressure. After 2 M sodium hydroxide (30 ml) had been added, the mixture was extracted with ether to remove the unreacted XII; the water layer was acidified with concentrated hydrochloric acid to give XIII, which was filtered, washed with water, and dried (2.67 g, 37%). Recrystallization from aqueous ethanol gave fine needles; mp 88.5—89.5 °C.

Found: C, 70.07; H, 8.12%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%. IR (KBr); 3300—3000 cm^{-1}. NMR ($CDCl_3$): δ 1.10 (s, 9H, *t*-Bu) ppm.

From the ether extract XII was recovered (2.85 g, 42%).

3-t-Butyl-4-chromanone (XIV). A mixture of XIII (2.85 g) and polyphosphoric acid (50 g) was kept at 90 °C for 5 hr and then poured into ice water (250 ml). Colorless crystals were collected and dissolved in ether; they were then washed with 1 M sodium hydroxide and water, and dried over sodium sulfate. The solvent was removed to give crude XIV (2.2 g, 88%) as colorless crystals, which were then distilled under reduced pressure (bath 120 °C/1 mm Hg) to yield colorless crystals; mp 37—39 °C. Recrystallization from pentane gave pure XIV; mp 41.5—42 °C.

Found: C, 76.40; H, 8.11%. Calcd for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90%. IR (CCl_4): 1684 cm^{-1}. NMR ($CDCl_3$): δ 1.09 (s, 9H, *t*-Bu), 2.29 (t, 1H, C_3–H), 4.40—4.75 (AB part of ABX, C_2–H) ppm. UV (95% EtOH nm ε): 254 (8950), 324 (3360).

The alkaline extract was acidified with dilute hydrochloric acid to give unreacted XIII (145 mg, 5%).

cis-*3-t-Butyl-4-chromanol (XV).* A solution of XIV (510 mg) and sodium borohydride (70 mg) in ethanol (5 ml) was refluxed for 3 hr. The removal of the solvent afforded an oily residue, which was then dissolved in dilute acetic acid. The mixture was extracted with ether, and the organic layer was worked up according to the usual procedure to yield crude product as colorless crystals (462 mg, 90%); whose vpc indicated that it was a mixture of XV (94.4%) and

trans-3-*t*-butyl-4-chromanol (XVI, 5.6%). Recrystallization from pentane gave pure XV; mp 60.5—61.0 °C.

Found: C, 75.56; H, 8.80%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%. IR (KBr): 3450 cm^{-1}. NMR ($CDCl_3$+D_2O): δ 1.11 (s, 9H, *t*-Bu), 1.4—1.8 (ddd, 1H, C_3–H), 4.1—4.3 (AB part of ABX, C_2–H), 4.83 (d, 1H, C_4–H) ppm.

Benzoate of XV: Colorless crystals from pentane–benzene; mp 155 °C.

Found: C, 77.52; H, 7.15%. Calcd for $C_{20}H_{22}O_3$: C, 77.39; H, 7.14%. IR (KBr): 1710 cm^{-1}. NMR ($CDCl_3$): δ 1.06 (s, 9H, *t*-Bu), 1.8—2.2 (ddd, 1H, C_3–H), 4.4—4.6 (AB part of ABX, C_2–H), 6.50 (d, 1H, C_4–H) ppm.

trans-*3*-t-*Butyl-4-chromanol (XVI)*. A solution of XV (675 mg) in acetic acid (8 ml)-concentrated hydrochloric acid (2 ml) was kept at 120—130 °C for 20 min. The reaction mixture was then poured into ice water and extracted with ether, and the extract was washed as usual. The removal of the solvent afforded 3-*t*-butylchromene as a yellow oil (582 mg, 95%), which was then distilled under reduced pressure (bath 80—110 °C/1 mmHg). NMR ($CDCl_3$): δ 1.14 (s, 9H, *t*-Bu), 4.75 (d, 2H, C_2–H), 6.24 (bs, 1H, C_4–H) ppm.

To a stirred solution of 3-*t*-butylchromene (470 mg) and sodium borohydride (85 mg) in diglyme (3 ml) was added, drop by drop, boron trifluoride etherate (0.38 ml) in diglyme (0.4 ml) under a nitrogen atmosphere over a period of 15 min. After the reaction mixture had been stirred for 1 hr, water (1 ml) was added to decompose the excess diborane. To the above stirred solution, there were added 3 M sodium hydroxide (0.8 ml) and then, drop by drop, 30% hydrogen peroxide (0.8 ml) at 40—50 °C. After the stirring had been continued for an additional hour, the solution was poured into water and extracted with ether. The extract was treated in usual manner to give a colorless oil (450 mg, 87%) which crystallized on standing. Recrystallization from pentane afforded colorless prisms; mp 64.0—64.5 °C.

Found: C, 75.46; H, 8.88%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%. IR (KBr): 3260 cm^{-1}. NMR ($CDCl_3$+D_2O): δ 0.98 (s, 9H, *t*-Bu), 1.66 (q, 1H, C_3–H), 4.25 (d, 2H, C_2–H), 4.74 (d, 1H, C_4–H) ppm.

Benzoate of XVI: Colorless oil.

Found: C, 77.64; H, 7.34%. Calcd for $C_{20}H_{22}O_3$: C, 77.39; H, 7.14%. IR (neat): 1710 cm^{-1}. NMR ($CDCl_3$): δ 1.01 (s, 9H, *t*-Bu), 1.87 (q, 1H, C_3–H), 4.42 (AB part of ABX, C_2–H), 6.31 (bd, 1H, C_4–H) ppm.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1844—1847 (1973)

Chemistry of α-Haloaldehydes. II.[1] Base-catalyzed Condensation of α-Haloaldehydes with Methyl Chloroacetate

Akira TAKEDA, Sadao TSUBOI, and Tōru HONGO

Department of Synthetics Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700

(Received December 15, 1972)

The Darzens-type condensation of α-haloaldehyde (**2**) with methyl chloroacetate has been studied. The reaction of aliphatic α-chloroaldehydes afforded 4-chloro-2,3-epoxyalkanoates (**4**). The reaction of 2-bromo-2-methylpropanal (**2d**) with methyl chloroacetate gave α-chloro-γ,γ-dimethyl-$\Delta^{\alpha,\beta}$-butenolide (**7**) as a major product. α-Bromo-*n*-alkanal gave a mixture of many minor products.

Two diastereomeric isomers of 4,5-dihydroxyhexanoic acid gamma lactone (**1**) have been isolated as major constituents of the aroma extracts of flour sherries.[2] In order to carry out the attempted synthesis of **1** and their derivatives we needed 4-halo-2,3-epoxys alkanoates (**4**) as starting materials. The Darzen-condensation of aldehydes and ketones may be the most convenient and common procedure for the one-step synthesis of 2,3-epoxyalkanoates, but there have been few reports on the title reaction of α-haloaldehydes (**2**).

We have been studying the reactions of α-haloaldehydes with active hydrogen compounds and reported on the Darzens-type condensation of **2** with dichloroacetate[1] giving 2,4-dichloro-2,3-epoxyalkanoates. As an extension of the previous work[1] we carried out the reaction of **2** with monochloroacetate in the presence of sodium alkoxide to prepare 4-halo-2,3-epoxyalkanoates. Ether or THF was used as solvent to prevent **2** from being transformed into α-hydroxy acetal.[3] In this paper the results of the reaction and a discussion of the reaction mechanism are given. The yields, boiling points and the analytical data are summarized in Table 1.

The cyclization of the possible intermediate (**3**) to an epoxyalkanoate may occur in such a way that the α- and γ-halogen atoms compete with each other as a leaving group to produce either 4-halo-2,3-epoxyalkanoate (**4**) (route 1) or 2-halo-3,4-epoxyalkanoate (**5**) (route 2). In the reaction of α-chloroaldehydes only 2,3-epoxyalkanoate (**4**) was obtained[4] in a 9—40% yield indicating that the oxyanion of **3** attacked more readily its α-carbon atom which was made more electron-deficient by the electron-withdrawing effect of the carboxyl group. The reaction sequence is given

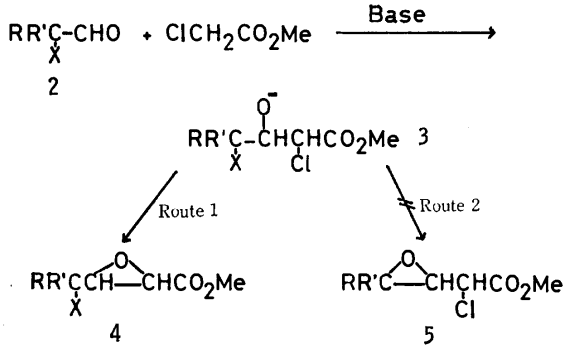
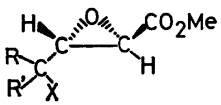
a) All the compounds are new.



Scheme 1.

in Scheme 1. The structure of **4** was confirmed by IR spectra, NMR spectra, MS, and microanalyses. The IR bands of **4** at 1750—1755, 900—910, and 820—825 cm^{-1} [1,5a,b] are characteristic of the epoxyester. The singlets or doublets at δ 3.28—3.24 (J=0—2.3 Hz) in the NMR spectrum of **4** represent the signal from the C_2-proton. The geometry of **4** can be estimated to be *trans* from the small value of the coupling constants due to epoxy-ring protons.



On account of a higher reactivity toward nucleophiles than their chlorine homologs α-bromoaldehydes tend to react in different ways. In contrast with α-chloroaldehydes, it is expected that in the reaction of α-bromoaldehydes the bromine atom attached to the γ-carbon of the intermediate **3** becomes a better leaving group as in the base-catalyzed condensation of α-bromoheptanal with methyl dichloroacetate.[1] As expected, the reaction of 2-bromo-2-methylpropanal (**2d**) with methyl chloroacetate gave α-chloro-γ,γ-dimethyl-$\Delta^{\alpha,\beta}$-butenolide (**7**) in a 14% yield, together with a small amount (9% yield) of methyl 4-bromo-4-methyl-2,3-epoxypentanoate (**4d**). α-Bromoheptanal (**2f**) only underwent displacement to yield α-hydroxyheptanal dimethyl acetal (**8**) and not the desired product, when methanol was used as solvent. It is not likely that acetal **8** was derived from acetal (**9**) of α-bromoaldehyde (**2f**) since α-bromoaldehyde acetal appears inactive toward nucleophiles such as sodium methoxide and sodium ethoxide as suggested by the reaction of α-bromopropanal acetal. It is reasonable to consider that the transformation of **2f** into **8** involves epoxy-ring intermediate.[3]

The $\Delta^{\alpha,\beta}$-butenolide structure of **7** is supported by IR and NMR spectra. The IR band of **7** at 1730 cm^{-1} is characteristic of the conjugated lactone carbonyl,[6] two singlets at δ 1.50 (methyl proton) and 7.35 (olefinic proton) in the NMR spectrum of **7** being indicative of butenolide structure. A possible pathway of the formation of **7** is shown in Scheme 2.

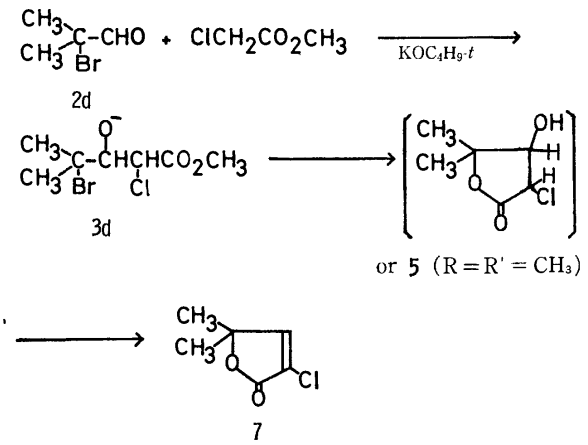

Scheme 2.

Experimental

All the boiling points and the melting points are uncorrected. α-Haloaldehydes were prepared by the method described previously.[1] The analytical determinations by glpc were performed on a Hitachi K-53 model gas chromatograph (3 mm o.d.×1 m, 10% Apiezon Grease L on Chromosorb W column); carrier gas, N_2 (0.5 kg/cm², 42 ml/min); detector, FID. The preparative glpc was performed on a Yanagimoto GCG-550T model gas chromatograph (3 mm o.d.×2.25 m, 10% Apiezon Grease L on Chromosorb W). Mass spectra were measured with a Hitachi RMS-4 model mass spectrometer and NMR spectra on a Hitachi R-24 NMR model spectrometer. Liquid samples were purified by glpc or tlc for analyses and spectral measurements.[7] The following experiments are shown as an example.

*Methyl 4-Chloro-2,3-epoxypentanoate (**4a**).* Powdered sodium methoxide (5.9 g, 0.11 mol) was added in several portions to a mixture of α-chloropropanal (9.3 g, 0.1 mol) and methyl chloroacetate (12.2 g, 0.1 mol) in dry ether (50 ml), at −30 °C.[8] After the mixture was stirred for 2 hr, it was allowed to cool to room temperature, stirring being continued for 4 hr. The reaction mixture was allowed to stand overnight and then treated with water. The ethereal layer was separated, washed several times with water and dried over $MgSO_4$. After removal of the solvent it was distilled giving 1.6 g (10%) of **4a**: bp 87—97 °C/8 mmHg; IR (cm⁻¹, liquid) 1755 (ester C=O), 900 and 825 (epoxide ring); NMR (CCl_4) δ 1.57 (d, 3H, J=6.5 Hz, $C\underline{H}_3CHCl$–), *ca.* 3.19 (q, 1H, J=1 Hz, –C<u>H</u>(O)–C<u>H</u>CO_2CH_3), 3.30 (s, 1H, –CH(O)–C<u>H</u>CO_2CH_3), 3.65 (m, 1H, >CHCl), and 3.75 (s, 3H, CO_2CH_3).

*Methyl 4-Chloro-4-methyl-2,3-epoxypentanoate (**4b**).* Powdered sodium methoxide (5.4 g, 0.1 mol) was added gradually to a solution of freshly-distilled 2-chloro-2-methylpropanal (10.6 g, 0.1 mol) and methyl chloroacetate (12.2 g, 0.1 mol) in dry ether (60 ml), at 0—3 °C. After the mixture was stirred at room temperature for 12 hr and then refluxed for 1 hr, it was treated with water. The ethereal layer was separated, washed several times with water and dried over Na_2SO_4. After removal of the solvent it was distilled to give 7.2 g (40%) of **4b**: bp 100—103 °C/12 mmHg; IR (cm⁻¹, liquid) 1750 (ester C=O), 910 and 828 (epoxide ring); NMR (CCl_4) δ 1.53 (s, 3H, >C(<u>C</u>H_3)$_2$), 1.59 (s, 3H, >C(C<u>H</u>$_3$)$_2$), 3.33 (d, 1H, J=1.7 Hz, –CH(O)–C<u>H</u>–), 3.40 (d, 1H, J=1.7 Hz, –C<u>H</u>(O)–CH–), and 3.74 (s, 3H, CO_2CH_3).

*Methyl 4-Chloro-2,3-epoxyhexanoate (**4c**).* Powdered sodium methoxide (5.4 g, 0.1 mol) was added in several portions to a mixed solution of freshly-distilled α-chloro-*n*-butanal (10.6 g, 0.1 mol) and methyl chloroacetate (10.9 g, 0.1 mol) in dry ether (30 ml) at 0—3 °C. The mixture was allowed to warm up to room temperature and then refluxed for 4 hr. The ethereal extract was worked up as usual and distilled to give 3.3 g (10% yield[9]) of the liquid, which was collected at 90—94 °C/5 mmHg. Glpc analysis showed it to consist of five components. The peaks, retention times (min), and integrated percentages[10] were: 1, 4.6, 55; 2, 6.6, 31; 3, 7.7, 5; 4, 8.3, 5; 5, 9.4, 4. Component 1 was collected by preparative glpc and identified as **4c**: IR (cm⁻¹, liquid) 1750 (ester C=O), 900 and 820 (epoxide ring); NMR (CCl_4) δ 1.10 (t, 3H, J=7.5 Hz, $C\underline{H}_3CH_2$–), 1.91 (m, 2H, $CH_3C\underline{H}_2$–), 3.19 (q, 1H, J=1 Hz, –C<u>H</u>(O)–C<u>H</u>CO_2CH_3), 3.33 (d, 1H, J=1 Hz, –CH(O)–C<u>H</u>CO_2CH_3), 3.40 (m, 1H, >CHCl), and 3.77 (s, 3H, CO_2CH_3).

Reaction of 2-Bromo-2-methylpropanal with Methyl Chloroacetate. Powdered potassium *tert*-butoxide (29.6 g, 0.26 mol) was added to a solution of freshly distilled 2-bromo-2-methylpropanal (19 g, 0.13 mol) and methyl chloroacetate (28.6 g, 0.26 mol) in dry THF (50 ml) at −5—0 °C. After addition was completed, stirring was continued for 1 hr. The reaction mixture was stirred for 5 hr at room temperature. It was allowed to stand overnight, refluxed for 1 hr and then treated with water. After the mixture was acidified with 10% HCl, the organic layer was extracted with ether, and the ethereal extract was washed several times with water and dried over Na_2SO_4. After removal of the solvent the residue was distilled to give 7 g of a liquid boiling at bp 93—125 °C/6 mmHg. The solidified material (0.9 g) was separated from the liquid, and recrystallized from *n*-hexane to give lactone **7**: mp 94—95 °C; IR (cm⁻¹, Nujol) 1730 (conjugated C=O), 1605 (conjugated C=C); NMR ($CDCl_3$) δ 1.50 (s, 6H, $(CH_3)_2C$<), and 7.35 (s, 1H, =C–H); MS (70 eV) *m/e* (relative intensity) 146 (13, M^+, 1Cl), 131 (100, M^+-CH_3), 111 (43, M^+-Cl), 103 (61), 68 (48), and 43 (73). Glpc analysis of the filtrate showed the presence of two major and six minor components. The peaks, retention times, and integrated percentages[11] were: 1, 6.0, 21%; 2, 10.6, 49%. Component 1 was collected by preparative glpc and identified as **7** by comparison of the retention times (min) and the IR spectrum with those of an authentic sample.

Component 2 was collected similarly and identified as **4d**: IR (cm⁻¹, liquid) 1750 (ester C=O), 905 and 820 (epoxide ring); NMR (CCl_4) δ 1.68 (s, 3H, $-CH_3$), 1.79 (s, 3H, $-CH_3$), 3.36 (d, 1H, J=2.3 Hz, –CH(O)–C<u>H</u>–), 3.42 (d, 1H, J=2.3 Hz, –C<u>H</u>(O)–CH–), and 3.76 (s, 3H, CO_2CH_3): MS (70 eV) *m/e* (relative intensity) 190 (1, M^+-CH_3OH), 164 (25), 162 (20), 142 (100, M^+-HBr), 135 (82), 133 (82), 104 (85), 88 (79), 54 (82), and 38 (80).

*Methyl 4-Chloro-2,3-epoxynonanoate (**4e**).* Into a solution

7) Microanalyses were carried out by Mr. Eiichiro Amano.

8) When the reaction was carried out at 0 °C, glycidate **4a** was obtained only in a poor yield, many unknown substances being obtained.

9) Estimated as compound **4c**.

10) Column temp., 150 °C.

11) Column temp., 120 °C.

of α-chloroheptanal (14.8 g, 0.1 mol) and methyl chloroacetate (12.2 g, 0.1 mol) in dry ether (60 ml), sodium methoxide (5.4 g, 0.1 mol) was added in several portions at 0—3 °C. The mixture was worked up as in the preparation of **4b** and 5.6 g (25%) of **4e** was obtained: bp 130—133 °C/5 mmHg; IR (cm^{-1}, liquid) 1755 (ester C=O), 900 and 825 (epoxide ring); NMR (CCl_4) δ 0.93 (t, 3H, $J=5$ Hz, $C\underline{H}_3(CH_2)_4$–), 1.15—2.15 (m, 8H, $CH_3(C\underline{H}_2)_4$–), 3.28 (s, 1H, –CH(O)–C<u>H</u>CO_2CH_3), 3.15—3.50 (m, 1H, –C<u>H</u>(O)–CHCO_2CH_3), 3.50 (m, 1H, >CHCl), and 3.75 (s, 3H, $CO_2C\underline{H}_3$).

*Reaction of α-Bromoheptanal (**2f**) with Methyl Chloroacetate in Methanol.* To a mixed solution of α-bromoheptanal (15.7 g, 0.081 mol) and sodium methoxide (4.4 g, 0.081 mol) in 60 ml of methanol was added 8.7 g (0.081 mol) of methyl chloroacetate with stirring, at −4 °C. Stirring was continued for 2 hr at room temperature and 0.5 hr at reflux temperature. The reaction mixture was diluted with 200 ml of water and then extracted with ether. The ethereal layer was washed several times with water, dried with $MgSO_4$ and the solvent was evaporated. The residual oil was distilled to give 10.9 g of a fraction boiling at 45—109 °C/17 mmHg. Glpc analysis of this fraction showed one major peak (58%)[12] and six minor (42% in total) peaks. The major constituent with the retention time of 8 min was collected by preparative glpc and identified as α-hydroxyheptanal dimethyl acetal (**9**) on the basis of the IR spectrum and analysis: IR (cm^{-1}, liquid) 3450 (OH), 1200, 1125, and 1070 (acetal C–O–C–O–C). Found: C, 61.06; H, 11.03%. Calcd for $C_9H_{20}O_3$: C, 61.32; H, 11.44%. Other minor products were not investigated further.

Treatment of α-bromopropanal diethyl acetal with sodium methoxide or sodium ethoxide in absolute alcohols only resulted in the recovery of starting materials.

12) Calculation based on peak area.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1847—1850 (1973)

Synthesis of Alanosine

Yoshikazu Isowa, Hideaki Kurita, Muneki Ohmori, Masanari Sato, and Kaoru Mori

Sagami Chemical Research Center, Nishiohnuma, Sagamihara, Kanagawa 229

(Received January 13, 1973)

DL-2-Amino-3-(*N*-tosyl-*N*-benzyloxyamino)propionic acid (DL-V) was synthesized starting from ethyl 2,3-dibromopropionate and *N*-tosyl-*O*-benzylhydroxylamine. L-2-Benzoylamino-3-(*N*-benzoyl-*N*-hydroxyamino)propionic acid anilide (L XIV) obtained *via* the enzymatic resolution of DL-2-benzoylamino-3-benzyloxyaminopropionic acid (DL-IX) was converted by acid hydrolysis to L-2-amino-3-hydroxyaminopropionic acid (L-II). The nitrosation product of the amino-hydroxyamino acid (L-II) was identical with alanosine (L-I).

Alanosine[1,2] (L-I) is an antimicrobial agent isolated from a Streptomyces. The structure[2] of L-I was determined to be a 3-*N*-nitroso-derivative of L-2-amino-3-hydroxyamino-propionic acid (L-II), one of the α-amino-ω-hydroxyamino acid.[3-5]

A route for the synthesis of L-II starting from methyl 2-acetamino-3-chloropropionate and hydroxylamine has been reported by Lancini *et al.*[6,7] The optically active amino-hydroxyamino acid (L-II) has been obtained by the acid hydrolysis of the cinchonine salt of L-2-benzoylamino-3-(*N*-benzoyl-*N*-hydroxyamino)propionic acid (L-XI). Nitrosation of L-II with sodium nitrite in the equimolar amount of cold M hydrochloric acid gave alanosine (L-I).

In our previous paper,[8] we described the syntheses of 5-(*N*-tosyl-*N*-benzyloxy)-DL-ornithine and 5-*N*-hydroxy-L-ornithine, a higher homolog of L-II. The present paper deals with the synthesis of L-II from DL-2-amino-3-(*N*-tosyl-*N*-benzyloxy-amino)propionic acid (DL-V), which was prepared from *N*-tosyl-*O*-benzylhydroxylamine (III) and ethyl 2,3-dibromopropionate. The reaction paths were outlined in Fig. 1.

Papain-catalyzed resolution[8-11] of DL-2-acetamino-3-(*N*-tosyl-*N*-benzyloxyamino)propionic acid (DL-VI) under the same conditions (38 °C, pH 6.1, or 7.3) as in the case of 2-*N*-acetyl-5-(*N*-tosyl-*N*-benzyloxy)-DL-ornithine in the presence of aniline was unsuccessful. But optically active 2-acetamino-3-(*N*-tosyl-*N*-benzyloxyamino)propionic acid anilide (VII), $[\alpha]_D^{23}$ −113.4° (*c* 1, chloroform) was obtained at 50 °C and pH 7.3 in spite of the bulkiness of the hydroxyamino-protecting tosyl and benzyl groups at the β-position of the molecule.

On the other hand, the detosylation product of the amino acid (DL-V), DL-2-amino-3-benzyloxyamino-propionic acid (DL-VIII), which was obtained from DL-V by the action of 36% hydrogen bromide–acetic

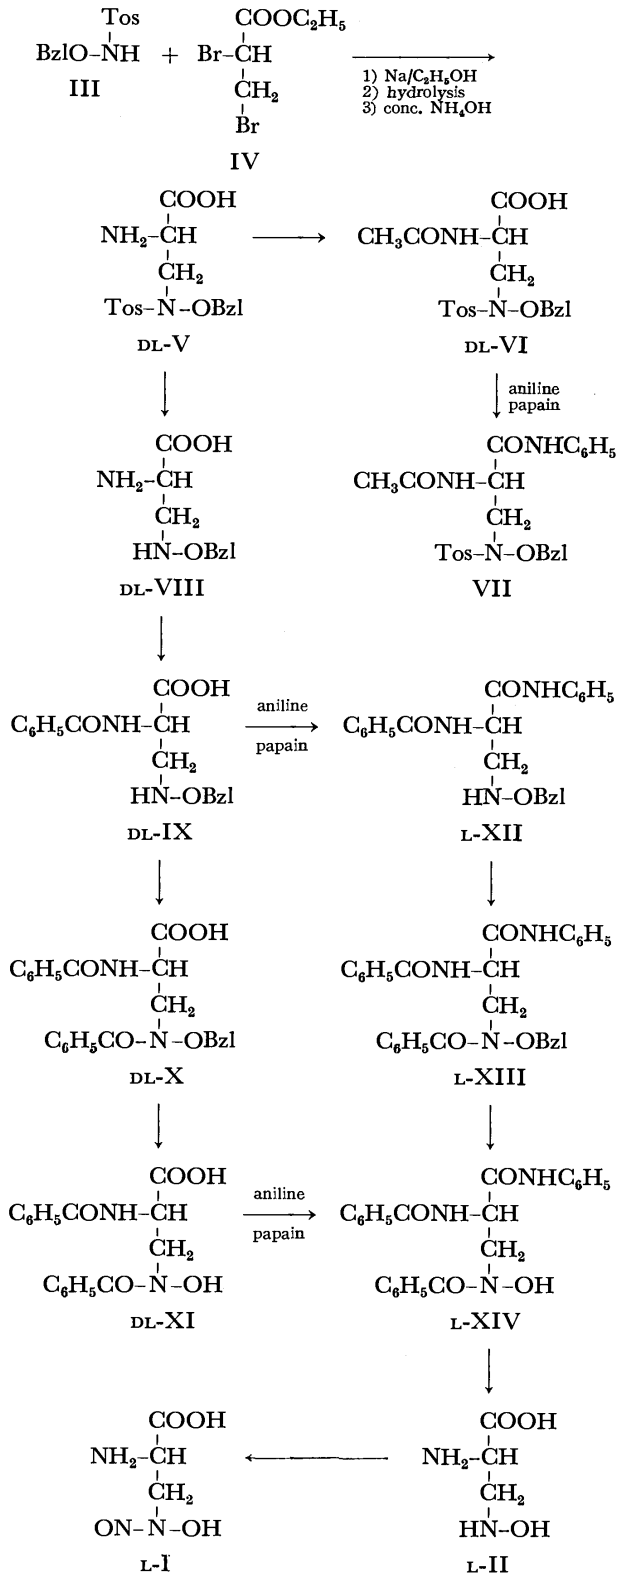

Fig. 1

acid in the presence of phenol, followed by the 2-*N*-benzoylation with *N*-benzoyloxysuccinimide, was resolved into derivatives of its optical isomers with the aid of cysteine-activated papain in the presence of aniline at 38 °C and pH 6.1; L-2-benzoylamino-3-benzyloxyaminopropionic acid anilide (L-XII), $[\alpha]_D^{26}$ −108.9° (*c* 1, chloroform) and D-2-benzoylamino-3-benzyloxyaminopropionic acid (D-IX), $[\alpha]_D^{26}$ −18.2° (*c* 1, acetic acid) were obtained.

3-*N*-Benzoylation of L-XII in pyridine with benzoyl chloride, followed by hydrogenation, yielded L-2-benzoylamino-3-(*N*-benzoyl-*N*-hydroxyamino)propionic acid anilide (L-XIV). The L-dibenzoyl derivative (L-XIV) was also obtained by resolution of DL-2-benzoylamino-3-(*N*-benzoyl-*N*-hydroxyamino)propionic acid (DL-XI), which was prepared by 3-*N*-benzoylation of monobenzoylamino acid (DL-IX) in ethyl acetate with benzoyl chloride in the presence of *N*-methylmorpholine and subsequent debenzylation.

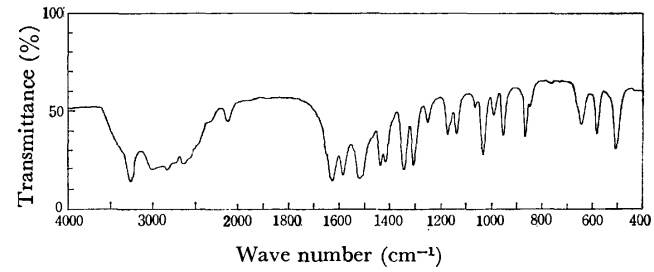

Fig. 2. L-2-Amino-3-hydroxyaminopropionic acid

Acid hydrolysis of the protected amino-hydroxyamino acid derivative (L-XIV) gave L-2-amino-3-hydroxyaminopropionic acid (L-II), which was identical, in respect of optical rotatory power, with an authentic sample obtained by another route.[6,7] The IR spectrum of L-II is shown in Fig. 2. Nitrosation of the amino-hydroxyamino acid (L-II) by the method reported by Lancini *et al.*,[7] gave L-2-amino-3-(*N*-nitroso-*N*-hydroxyamino)propionic acid, alanosine (L-I). The identity of the synthetic alanosine with natural one was confirmed by color reaction, optical rotation, and elemental analysis. The IR spectrum of L-I is shown in Fig. 3.

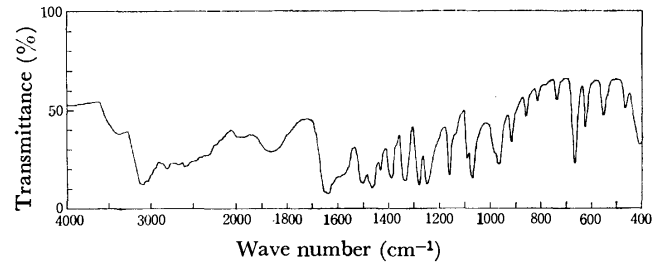

Fig. 3. L-2-Amino-3-(*N*-nitroso-*N*-hydroxyamino)propionic acid; alanosine

Experimental

Melting points were all determined with a Yanagimoto electric micromelting point apparatus, unless otherwise indicated, and are uncorrected. Optical rotations were measured with a Yanagimoto automatic polarimeter OR-50. Infrared spectra were recorded on a Hitachi EPI G-3 spectrophotometer as KBr disk. Nuclear magnetic resonance spectra were run on a Hitachi Perkin-Elmer R-20 High Resolution spectrometer, using tetramethylsilane as an internal standard. Concentration and evaporation of solutions were always carried out under reduced pressure.

DL-*2-Amino-3-(*N*-tosyl-*N*-benzyloxyamino)propionic Acid* (DL-*V*). To a solution of sodium (23 g, 1g-atom) in ethanol

(1 l) was added *N*-tosyl-*O*-benzylhydroxylamine (277 g, 1 mol). To the resultant mass, under ice-cooling and occasional shaking, ethyl 2,3-dibromopropionate (260 g, 1 mol) was added over a period of 2 hr. After stirring for 12 hr at room temperature, 5 M sodium hydroxide (210 ml) was added slowly at 0 °C and stirred for 12 hr at room temperature. Thereafter 2.5M sulfulic acid (*ca.* 210 ml) was added to the solution until pH 4 under ice-cooling and the solvent was evaporated. To the residue, ethyl acetate (1.5 l) and water (200 ml) were added, the organic layer was dried over sodium sulfate and the solvent was removed. To the viscous oily residue conc. aqueous ammonia (3 l) was added and the solution saturated with ammonia gas was stored at room temperature for 10 days. Thereafter the solution was concentrated. The crystalline deposit was collected and washed with water and methanol. Yield, 273 g (75%);mp 184—186 °C (decomp.). This crude product was used without recrystallization in the subsequent preparation. A part of the product was recrystallized from acetic acid–water to give an analytical sample, mp 187—188 °C (decomp.).

Found: C, 55.96; H, 5.23; N, 7.56%. Calcd for $C_{17}H_{20}N_2O_5S$: C, 56.03; H, 5.53; N, 7.69%.

DL-*2-Acetamino-3-(*N-*tosyl*-N-*benzyloxyamino)propionic Acid (*DL-*VI).* Crude amino acid (DL-V) (164.1 g, 0.456 mol) was mixed with glacial acetic acid (1.5 l) and acetic anhydride (60 ml) was added dropwise under stirring. After the clear solution was resulted, it was stirred for 6 hr at room temperature and then evaporated. The syrupy residue was taken up in a minimum quantity of ethyl acetate and the solution was chilled for 12 hr in a refrigerator. The resulting solid was collected by filtration. Yield, 161.0 g; mp 152—153 °C. Recrystallization from ethyl acetate gave an analytical sample, mp 156—157 °C.

Found: C, 56.11; H, 5.36; N, 6.88%. Calcd for $C_{19}H_{22}N_2O_6S$: C, 56.14; H, 5.46; N, 6.89%.

Resolution of DL-*2-Acetamino-3-(*N-*tosyl*-N-*benzyloxyamino)propionic Acid (*DL-*VI); 2-*N-*Acetamino-3-(*N-*tosyl*-N-*benzyloxyamino)propionic Acid Anilide (VII).* To the solution of the acetylamino acid (DL-VI) (20.3 g, 50 mmol) in 0.5M sodium hydroxide (300 ml) was added 0.5 M citric acid and the solution was adjusted to pH 7.3—7.35. The resultant clear solution was diluted to 500 ml and aniline (10 ml) was added together with papain (5 g) and L-cysteine hydrochloride monohydrate (5 g). The mixture was incubated at 50 °C for 48 hr. The precipitated crystals were collected, washed with 7% aqueous ammonia and water and dried. Recrystallization from *n*-propyl alcohol gave colorless crystals. Yield, 5.8 g (48.5%); mp 209—210 °C; $[\alpha]_D^{20}$ −110.2° (*c* 1, chloroform). Another recrystallization from the same solvent afforded an analytical sample, mp 211—212 °C and $[\alpha]_D^{23}$ −113.4° (*c* 1, chloroform).

Found: C, 62.05; H, 5.42; N, 8.79%. Calcd for $C_{25}H_{27}N_3O_5S$: C, 62.35; H, 5.65; N, 8.73%.

The above filtrate was adjusted to pH 1 with conc. hydrochloric acid and the deposited crystals were collected, washed with water and dried. Recrystallization from ethyl acetate gave colorless crystals, 7.45 g, mp 150—151 °C, which was identified DL-acetylamino acid (DL-VI) from the fact that this compound and the hydrolysis product, 2-amino-3-(*N*-tosyl-*N*-benzyloxyamino)propionic acid, were optically inactive and this compound gave the anilide (VII) under the above-described condition.

DL-*2-Amino-3-benzyloxyaminopropionic Acid (*DL-*VIII).* To a solution of phenol (54 g) and 36% hydrogen bromide-acetic acid (300 ml) in a glass-stoppered bottle, was added DL-V (64.5 g, 0.18 mol). After stirring for 84 hr at room temperature, the solution was evaporated to dryness at 45 °C. The residual crystals were triturated with ether and then dissolved in water (300 ml). The solution was adjusted to pH 7 with 7% aqueous ammonia under ice-cooling. After the removal of the precipitated crystals, the filtrate was concentrated to a small bulk and deposited crystals were collected. Yield, 20.55 g (54%); mp 206—210 °C (decomp.). An analytical sample was obtained by recrystallization from water, mp 210—211 °C (decomp.). IR; 3240 cm^{-1}. NMR (CF_3COOH): δ 4.46 (d, 2H), 5.12 (t, 1H), 5.53 (s, 2H), and 7.50 (s, 5H). Ninhydrin reaction was positive and triphenyltetrazolium negative.

Found: C, 57.16; H, 6.68; N, 13.54%. Calcd for $C_{10}H_{14}N_2O_3$: C, 57.13; H, 6.71; N, 13.33%.

DL-*2-Benzoylamino-3-benzyloxyaminopropionic Acid (*DL-*IX).*

a) To the suspension of DL-VIII (2.1 g, 10 mmol) in methanol (20 ml) were added 40% Triton B (4.7 ml) and *N*-benzoyloxy succinimide[12] (2.2 g, 10 mmol). After stirring for 12 hr at 50 °C, the solvent was removed and the residual oil was dissolved in water (30 ml). The water layer, after extracted with ethyl acetate, was acidified with conc. hydrochloric acid under cooling to pH 3.5. The resulting oil was scratched after standing in an ice box for 5 hr and then crystallized. Yield, 0.7 g (22.3%). Recrystallization from much water gave an analytical sample, mp 124—126 °C. NMR (CF_3COOH): 4.28 (2H), 5.32 (3H, benzylmethylene and α-methine protons), 7.49 and 7.68 (13H), and 8.16 (d, 1H, amide proton). Ninhydrin and triphenyltetrazolium test were negative.

Found: C, 65.02; H, 5.79; N, 8.93%. Calcd for $C_{17}H_{18}N_2O_4$: C, 64.95; H, 5.77; N, 8.91%.

b) The resulting oil was crystallized by adding a part of the product obtained as a) under stirring at room temperature. Yield, 64%; mp 143—147 °C. A part of the product was recrystallized from water to give an analytical sample, mp 147—149 °C. IR: 3370, 3250 cm^{-1}. NMR spectrum in trifluoroacetic acid was identical with that of the low-melting benzoylamino acid obtained as a). Ninhydrin test was negative. For the subsequent reaction this high-melting benzoylamino acid was used.

DL-*2-Benzoylamino-3-(*N-*benzoyl*-N-*benzyloxyamino)propionic Acid (*DL-*X).* To the stirred solution of DL-IX (6.28 g, 20 mmol) and *N*-methylmorpholine (2.22 g, 22 mmol) in ethyl acetate (100 ml) was added benzoyl chloride (3.08 g, 22 mmol) in ethyl acetate (20 ml) over 15 min at room temperature. The deposited crystals were collected after 12 hr and washed with ether and water. Yield, 6.84 g (81.5%); mp 175—177 °C. An analytical sample was obtained by recrystallization from ethyl acetate–ether, mp 182—183 °C.

Found: C, 68.53; H, 5.33; N, 6.79%. Calcd for $C_{24}H_{22}N_2O_5$: C, 68.89; H, 5.30; N, 6.70%.

DL-*2-Benzoylamino-3-(*N-*succinyl*-N-*benzyloxyamino)-propionic Acid.* To the stirred solution of the benzyloxyamino acid (DL-IX) (0.94 g, 3 mmol) and *N*-methylmorpholine (0.31 g, 3 mmol) in ethyl acetate (20 ml) was added succinic anhydride (0.3 g, 3 mmol). After 3 hr, water (20 ml) was added to the clear solution and the water layer was adjusted to pH 3 with 1 M hydrochloric acid. The precipitated oil was stored in an ice box for 12 hr and the resulting crystals were collected. Yield, 0.7 g (56.5%); mp 154—155 °C. Recrystallization from ethyl acetate–*n*-hexane gave an analytical sample, mp 153—154 °C. IR: 3300, 1710, 1650, 1525 cm^{-1}.

Found: C, 60.60; H, 5.24; N, 6.73%. Calcd for $C_{21}H_{22}N_2O_7$: C, 60.86; H, 5.35; N, 6.76%.

DL-2-Benzoylamino-3-(N-benzoyl-N-hydroxyamino)propionic Acid (DL-XI). DL-X (4.18 g, 10 mmol) in methanol (130 ml) was hydrogenated in the presence of 5% palladium-charcoal (0.5 g). After 36 hr, the catalyst was removed and the filtrate was evaporated. The residual oil was dissolved in hot water and the crystalline debenzylation product was collected. Yield, 2.7 g (82.5%); mp 173—175 °C (lit,[7] mp 170 °C). Ferric chloride test was positive.

Found: C, 62.18; H, 4.90; N, 8.38%. Calcd for $C_{17}H_{16}N_2O_5$: C, 62.19; H, 4.91; N, 8.53%.

Resolution of DL-2-Benzoylamino-3-benzyloxyaminopropionic Acid (DL-IX); L-2-Benzoylamino-3-benzyloxyaminopropionic Acid Anilide (L-XII) and D-2-Benzoylamino-3-benzyloxyaminopropionic Acid(D-IX). To the suspension of DL-IX (9.42 g, 30 mmol) in 0.5 M sodium hydroxide (160 ml) was added 0.5 M citric acid and the solution was adjusted to pH 6.15. The resulting clear solution was diluted with water to 500 ml. Aniline (6 ml) was added to the solution together with papain (6 g) and L-cysteine hydrochloride monohydrate (6 g). The mixture was incubated at 38 °C. After 30 hr, the deposited L-anilide (L-XII) was collected, washed with water and recrystallized from *n*-propyl alcohol. Yield, 4.87 g (83.5%); mp 129—131 °C; $[\alpha]_D^{26}$ −108.9° (*c* 1, chloroform). IR: 3280, 1670 1630 cm^{-1}.

Found: C, 71.15; H, 6.03; N, 10.85%. Calcd for $C_{23}H_{23}N_3O_3$: C, 70.93; H, 5.95; N, 10.79%.

The above filtrate, combined with the washings was adjusted to pH 3.5 with conc. hydrochloric acid. The precipitated D-amino acid (D-IX) was collected, washed with water and recrystallized from ethyl acetate. Yield, 2.45 g (52%); mp 147—149 °C; $[\alpha]_D^{26}$ −18.2° (*c* 1, acetic acid).

Found: C, 64.89; H, 5.77; N, 8.93%. Calcd for $C_{17}H_{18}N_2O_4$: C, 64.95; H, 5.77; N, 8.91%.

L-2-Benzoylamino-3-(N-benzoyl-N-benzyloxyamino)propionic Acid Anilide (L-XIII). To the solution of the benzyloxyamino compound (L-XII) (3.89 g, 10 mmol) in pyridine (30 ml) was added benzoyl chloride (1.82 g, 13 mmol) under ice-cooling. After stirring for 12 hr at room temperature, the solvent was evaporated. The residual oil was taken up in ethyl acetate (100 ml) and washed with 1 M hydrochloric acid and water. The organic layer was dried over sodium sulfate and then evaporated. The residual crystals were recrystallized from *n*-propyl alcohol. Yield, 3.80 g (77%); mp 173—174 °C; $[\alpha]_D^{30}$ −82.6° (*c* 0.5, chloroform).

Found: C, 72.94; H, 5.45; N, 8.66%. Calcd for $C_{30}H_{27}N_3O_4$: C, 73.00; H, 5.51; N, 8.51%.

L-2-Benzoylamino-3-(N-benzoyl-N-hydroxyamino)propionic Acid Anilide (L-XIV). a) L-XIII (4.9 g, 5 mmol) in methanol (500 ml) was hydrogenated in the presence of 5% palladium-charcoal (0.5 g) at room temperature. After 72 hr, the catalyst was removed and the filtrate was evaporated. The residual crystals were recrystallized from *n*-propyl alcohol. Yield, 2.88 g (71.5%); mp 192—193 °C; $[\alpha]_D^{31}$ +55.2° (*c* 0.5, chloroform). IR: 3300, 3110, 1670, 1635 cm^{-1}. Ferric chloride test was positive.

Found: C, 68.19; H, 5.35; N, 10.72%. Calcd for $C_{23}H_{21}N_3O_4$: C, 68.47; H, 5.25; N, 10.42%.

When this reaction was performed in the presence of 10% palladium-charcoal at 40 °C, the deoxygenated product of L-XIV, L-2,3-dibenzoylaminopropionic acid anilide was obtained. Mp 257—258 °C (methanol). This compound gave a negative ferric chloride test and was sparingly soluble in chloroform, ethyl acetate, *n*-propyl alcohol and methanol.

Found: C, 70.78; H, 5.42; N, 10.60%. Calcd for $C_{23}H_{21}N_3O_3$: C, 71.30; H, 5.46; N, 10.85%.

b) To the solution of the benzoylamino acid (DL-XI) (1.64 g, 5 mmol) in 0.5 M sodium hydroxide (30 ml) was added 0.5 M citric acid and the solution was adjusted to pH 6.15. The resultant clear solution was diluted to *ca.* 60 ml and aniline (1 ml) was added together with papain (0.5 g) and L-cysteine hydrochloride monohydrate (0.5 g). The mixture was incubated at 38 °C for 30 hr. The deposited crystals were collected and washed with water and ether. Recrystallization from *n*-propyl alcohol with the aid of charcoal gave an analytical sample. Yield, 0.45 g (44.5%); mp 193—194 °C; $[\alpha]_D^{29}$ +57.6° (*c* 0.5, chloroform).

Found: C, 68.40; H, 5.30; N, 10.21%.

L-2-Amino-3-hydroxyaminopropionic Acid (L-II). The protected amino-hydroxyamino acid (L-XIV) (1.7 g, 5 mmol) was stirred with 6M hydrochloric acid (100 ml) at 90—95 °C for 8 hr. After standing at room temperature for 3 hr, the deposited crystals were removed and the filtrate, after extracted with ether, was evaporated. Water (20 ml) was added and evaporated. The residual oil was dissolved in water (5 ml) and neutralized with 7% aqueous ammonia under cooling. Ethanol was added until the solution was cloudy. The precipitated crystals were collected, after the solution was stored in an ice box for 5 hr. Yield, 260 mg (43.5%). An analytical sample was prepared by recrystallization from water–ethanol. Mp 160—161 °C (decomp.) in a sealed capillary in a liquid bath (lit,[7] mp 161—163 °C (decomp.)); $[\alpha]_D^{27}$ +12.6° (*c* 0.5, M hydrochloric acid) (lit,[7] $[\alpha]_D$ +15.7°) IR: Fig. 2 in the text. Triphenyltetrazolium and ninhydrin test were positive.

Found: C, 30.26; H, 6.63; N, 22.97%. Calcd for $C_3H_8N_2O_3$: C, 30.00; H, 6.71; N, 23.33%.

L-2-Amino-3-(N-nitroso-N-hydroxyamino)propionic Acid; Alanosine (L-I). To a stirred clear solution of the amino-hydroxyamino acid (L-II) (240 mg, 2 mmol) in M hydrochloric acid (2 ml), sodium nitrite (138 mg, 2 mmol) was slowly added at 0 °C. After 30 min, the precipitated crystals were collected and washed with ethanol and ether. Yield, 190 mg (63.7%); mp 196—198 °C (decomp.). An analytical sample was obtained by recrystallization from 1 M sodium hydroxide–acetic acid. Mp 196—197 °C (decomp.) (lit,[7] mp 190 °C (decomp.); $[\alpha]_D^{27}$ −43.2° (*c* 0.5, 0.1 M sodium hydroxide) (lit,[7] $[\alpha]_D$ −46.0°). IR: Fig. 3 in the text. Ninhydrin and ferric chloride test were positive and the characteristic reaction of the *N*-nitroso group[13] with sulphanilic acid and α-naphtylamine was also positive. Triphenyltetrazolium test was negative.

Found: C, 24.00; H, 4.95; N, 28.19%. Calcd for $C_3H_7N_3O_4$: C, 24.16; H, 4.73; N, 28.18%.

Photochemical Substitution of Ferrocene in Halogenated Hydrocarbon-Ethanol Solutions

Takeo AKIYAMA, Yoshiyuki HOSHI,* Satoshi GOTŌ,** and Akira SUGIMORI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho 7, Chiyoda-ku, Tokyo 102

(Received January 20, 1973)

The photochemical substitution of ferrocene in several halogenated hydrocarbon–ethanol solutions was investigated. Ethoxycarbonyl, formyl, ethoxymethyl, benzyl and allyl groups were photochemically introduced into ferrocene in 25—53% yields by the UV-irradiation of ferrocene in carbon tetrachloride–, chloroform–, dichloromethane–, benzyl chloride–, and allyl bromide–ethanol solutions, respectively. The reactions proceeded effectively by the excitation of the charge transfer complexes formed between ferrocene and halogenated hydrocarbons.

Investigations have been made on the chemistry of ferrocene but only a few reports have appeared on the photochemical reactions of ferrocene. Nesmeyanov and his co-workers reported on the photochemical decomposition of several ferrocene derivatives.[1a-c]

van Riel *et al.* reported on the elimination of boric acid in the photolysis of ferroceneboronic acid in an aqueous alkaline solution.[2] Brand and Snedden observed a dissociative charge transfer absorption of ferrocene in a carbon tetrachloride solution.[3] Körner von Gustorf and his co-workers found that UV-irradiation of ferrocene in carbon tetrachloride gave ferrocenium tetrachloroferrate (III) almost quantitatively and they discussed the mechanism of its formation.[4] Spilners also reported the formation of ferrocenium tetrachloroferrate (III) in the photolysis of ferrocene in hexachlorocyclopentadiene.[5] Traverso and Scandola reported on the photochemical oxidation of ferrocene to ferrocenium ion in a carbon tetrachloride–ethanol solution, but they did not refer to the reaction product.[6] We reported the photochemical substitution of ferrocene in several organic halide–ethanol solutions.[7] The present paper deals with the photochemical introduction of ethoxycarbonyl, formyl, ethoxymethyl, benzyl, and allyl groups into ferrocene nucleus by UV-irradiation.

Experimental

Materials. Ferrocene was prepared from cyclopentadiene and iron(III) chloride by the method of Wilkinson *et al.*,[8] and was purified by column chromatography on silica gel. Mp 172—173 °C (lit,[9] 174 °C).

Carbon tetrachloride, chloroform and dichloromethane were purified by the method given in literature.[10] Benzyl chloride, benzal chloride, benzotrichloride, chlorobenzene, *n*-butyl chloride, *t*-butyl chloride, allyl chloride and allyl bromide were washed with aqueous alkaline solution and water, dried over calcium chloride and then distilled under reduced pressure just before use. Commercial *p*-nitrobenzyl chloride (Tokyo Kasei, Reagent Grade) was used without further purification.

Irradiation (General Procedure). A sample solution in a vessel equipped with gas inlet tube was irradiated internally with a high pressure mercury lamp (100 W high pressure mercury lamp, Ushio Denki, or 150 W high pressure mercury lamp, Taika Kogyo) with a quartz or a Pyrex jacket for cooling water, or a low pressure mercury lamp (120 W low pressure mercury lamp, Taika Kogyo) immersed in a sample solution. The reaction vessel was cooled externally by current water. During the course of irradiation nitrogen was bubbled through the solution. For irradiation of a comparatively small amount of solution, the sample solution in a quartz vessel was irradiated externally at the center of the spiral light source (16 W low pressure mercury lamp, Taika Kogyo) which was placed in a water bucket for cooling.

Separation of the Photoproducts (General Procedure). The irradiated solution was immediately washed with 0.1 M aqueous hydrochloric acid solution and extracted with *n*-hexane. The *n*-hexane solution was concentrated under reduced pressure below 45 °C and the residue was subjected to column chromatography on silica gel.

In the treatment of the reaction mixture from the photoreaction with less volatile chlorides such as benzyl, benzal and benzotrichloride, ether solution of anhydrous iron(III) chloride was added to the *n*-hexane solution to convert all the ferrocene and its derivatives into the corresponding ferrocenium salts. Ferrocenium salts and excess iron(III) chloride were extracted with water and then the ferrocenium salts were reconverted into ferrocene derivatives with sodium bisulfite. The reduced compounds were again extracted with *n*-hexane and dried over anhydrous sodium sulfate. After the solvent was removed, the residue was subjected to column chromatography on silica gel.

Identification of the Photoproducts. *Ethyl Ferrocenecarboxylate*: The compound was obtained in the photoreaction of ferrocene in carbon tetrachloride–ethanol solution. It was obtained as a yellow crystalline solid from the benzene fraction of column chromatography. Mp 58—61 °C. IR (KBr), 1690 cm^{-1} ($\nu_{C=O}$), 1100, 1040, 1000 cm^{-1} (mono substituted ferrocene). NMR (CCl_4), δ 4.70 (t), 2H (2,5H of the cyclopentadienyl ring of ferrocene); 4.22 (q), 2H (3,4H of the cyclopentadienyl ring of ferrocene); 4.10 (s), 5H (C_5H_5); 4.1 (q), 2H ($-CH_2-$); 1.32 (t), 3H ($-CH_3$).

Found: C, 58.0; H, 5.51%.

Formylferrocene: The compound was obtained in the photoreaction of ferrocene in chloroform–ethanol solution. Yellow orange substance was eluted with benzene on column chromatography. Mp 124—125 °C (lit,[11] 124.5 °C). IR spectrum was identical with that of the sample prepared by the method given in literature.[11]

Ethoxymethylferrocene: The compound was obtained in the photoreaction of ferrocene in dichloromethane–ethanol solution. It was eluted with *n*-hexane–benzene (9: 1) on column chromatography. Deep orange oil. Bp 112—113 °C/2 mmHg (lit,[12] 112—113.5 °C/2 mmHg). IR (direct), 2850, 1090, 920 cm^{-1} (ether), 1480, 1380 cm^{-1} ($-CH_2-$), 1100, 1020, 1000 cm^{-1} (mono substituted ferrocene). NMR (CCl_4), δ 4.11 (m), 6H ($C_5H_4-CH_2-$); 4.00 (s), 5H (C_5H_5); 3.39 (q), 2H ($-CH_2-$); 1.13 (t), 3H ($-CH_3$).

Found: C, 61.35; H, 6.39%.

1,1'-Diethoxymethylferrocene: The compound was obtained in the photoreaction of ferrocene in dichloromethane–ethanol solution. It was eluted with *n*-hexane–benzene (1: 1) after monoether had been eluted. Yellow oily substance. IR (direct), 2840, 1090, 930 cm^{-1} (ether), 1450, 1380 cm^{-1} ($-CH_2-$). The IR spectrum of this compound was nearly the same as that of monoether except for the peak at 1000 cm^{-1} which is characteristic of mono substituted ferrocene and ferrocene. NMR (CCl_4), δ 4.10 (m), 12H ($C_5H_4-CH_2-$); 3.96 (q), 4H ($-CH_2-$); 1.12 (t), 6H ($-CH_3$).

Found: C, 63.36; H, 7.14%. Calcd for $C_{16}H_{22}O_2Fe$: C, 63.59; H, 7.14%.

Benzylferrocene: The compound was obtained in the photoreaction of ferrocene in benzyl chloride–ethanol (20: 140 v/v) solution. It was obtained as a yellow orange crystalline solid (160 mg) from *n*-hexane–benzene (1: 1) fraction of column chromatography. Mp 75—76 °C (lit,[13] 74.5—76 °C). IR (KBr), 3020, 2920, 1603, 1495, 720, 699 cm^{-1} ($-CH_2-C_6H_5$), 1100, 1020, 1000 cm^{-1} (mono substituted ferrocene). NMR (CCl_4), δ 7.12 (s), 5H (C_6H_5-); 4.00 (s), 9H (C_5H_4-, C_5H_5); 3.64 (s), 2H ($-CH_2-$).

Found: C, 74.31; H, 6.39%.

Dibenzylferrocene: The compound was obtained as in the reaction described above. It was obtained as a yellow crystalline solid (50 mg) from benzene fraction of column chromatography, and was found to be a mixture of 1,2- and 1,3-dibenzylferrocene. IR (KBr), 3027, 2920, 1603, 1495, 700 cm^{-1} ($C_6H_5-CH_2-$), 1100, 1035, 1020, 1000, 940, 925, 920 cm^{-1} (homo annularly substituted ferrocene.[14]) NMR (CCl_4), δ 7.13 ($C_6H_5-CH_2-$); 7.05 ($C_6H_5-CH_2-$); 3.93 (s), (C_5H_5, C_5H_3-); 3.69 ($-CH_2-$); 3.60 ($-CH_2-$).

p-*Nitrobenzylferrocene*: The compound was obtained in the photoreaction of ferrocene with *p*-nitrobenzyl chloride in ethanol. It was obtained as a brown red substance (3.0 mg) from benzene fraction. IR (KBr), 2900, 1603, 1590, 1510, 1340, 710 cm^{-1} (p-$NO_2C_6H_4-CH_2-$), 1100, 1020, 1000 cm^{-1} (mono substituted ferrocene).

Phenylferrocene: The compound was obtained in the photoreaction of ferrocene in chlorobenzene–ethanol (10:110 v/v) solution. It was obtained as an orange crystalline solid (15 mg) from *n*-hexane–benzene (1: 1) fraction of column chromatography. IR (KBr), 3027, 1603, 1510, 690 cm^{-1} (C_6H_5-), 3080, 1100, 1020, 1000 cm^{-1} (mono substituted ferrocene). NMR (CCl_4), δ 7.20 (m), 5H (C_6H_5-); 4.50 (t), 2H (2,5H of the cyclopentadienyl ring of ferrocene); 4.16 (t), 2H (3,4H of the cyclopentadienyl ring of ferrocene); 3.90 (s), 5H (C_5H_5).

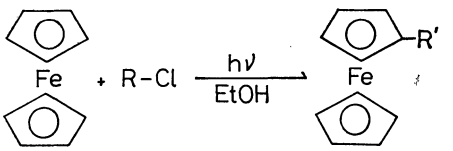
Found: C, 73.72; H, 5.20%.

Allylferrocene: The compound was obtained in the photoreaction of ferrocene in allyl bromide–ethanol (30: 250 v/v) solution. It was obtained as a dark orange liquid substance (900 mg) from *n*-hexane–benzene (2: 1) fraction of column chromatography. IR (direct), 3080, 3010, 2910, 1640, 1430, 1410 cm^{-1} (allyl group), 1100, 1020, 1000 cm^{-1} (mono substituted ferrocene). NMR (CCl_4), δ 5.70 (m), 1H ($-C\underline{H}=CH_2$); 4.90 (m), 2H ($-CH=C\underline{H}_2$); 3.96, 9H (C_5H_4-, C_5H_5); 2.98 (d), ($-CH_2-$).

Measurement. The electronic absorption spectra were measured with a Hitachi Model 124 UV–VS spectrophotometer. The NMR and IR spectra were obtained on a JEOL H-60 NMR spectrometer and a Hitachi Model 215 grating infrared spectrophotometer, respectively.

Results and Discussion

Although the UV-irradiation of ferrocene in carbon tetrachloride gave blue-gray precipitate of ferrocenium tetrachloroferrate (III) as was reported by Körner von Gustorf and his co-workers,[4] the UV-irradiation of ferrocene in a carbon tetrachloride–ethanol solution in the atmosphere of nitrogen gave ethyl ferrocenecarboxylate, a substitution product. Similar reactions were observed in the UV-irradiation of ferrocene in chloroform– and dichloromethane–ethanol solutions. Results of the reactions in these solvents are summarized in Table 1. The photoreactions can be generalized as follows.



R=$-CCl_3$ R'=$-CO_2Et$
R=$-CHCl_2$ R'=$-CHO$
R=$-CH_2Cl$ R'=$-CH_2OEt$

These reactions are formally the substitution at the cyclopentadienyl ring of ferrocene by halomethyl radicals formed by the fission of R–Cl bond of halomethanes, followed by the ethanolysis of halomethyl groups. This type of reaction affords a new route for the introduction of ethoxycarbonyl, formyl and ethoxymethyl groups into ferrocene ring.

However, it was not effective for alkyl and aryl monochlorides such as *t*-butyl chloride and chlorobenzene. Of phenyl substituted chloromethanes,

benzyl chloride gave photoproducts in considerable yields in the photoreaction with ferrocene, but benzal chloride and benzotrichloride gave only a trace of the substitution products. The results of the photoreactions of ferrocene with chlorides other than chloromethanes are listed in Table 2.

In the photoreactions of ferrocene with halides listed in Table 2, the yields of the photoproducts are lower than those shown in Table 1, except for allyl bromide.

In ferrocene–dichloromethane–ethanol system and ferrocene–benzyl chloride–ethanol system, disubstituted ferrocenes were obtained. However, the yields of the substitution products were lower in the latter system. This type of photoreaction is closely related to the formation of charge transfer complexes between ferrocene and halogenated hydrocarbons.

Brand and Snedden reported that the charge transfer absorption of ferrocene at 300—340 nm in several halogenated hydrocarbon solvents can be attributed to the electron transfer from ferrocene to the solvents.[3] The UV-spectra of ferrocene in ethanol and halogenated hydrocarbon–ethanol solutions are shown in Figs. 1 and 2. The UV-spectra of ferrocene in carbon tetrachloride, chloroform, dichloromethane, allyl bromide, ben-

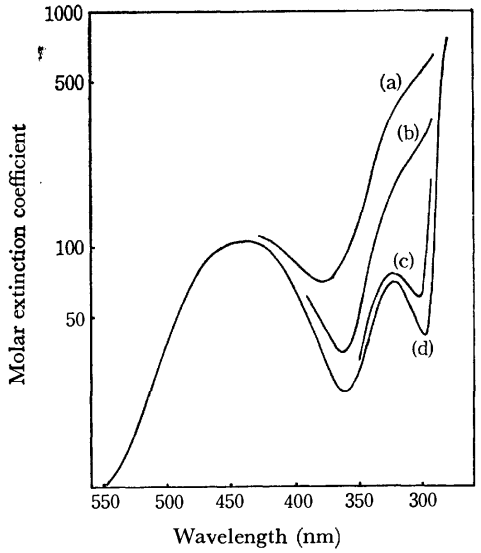

Fig. 1. UV-Spectra of ferrocene in halogenated hydrocarbon–ethanol solutions
(a) Ferrocene (5×10^{-3}mol/l) in carbon tetrachloride–ethanol (1: 1 v/v) solution.
(b) Ferrocene (5×10^{-3}mol/l) in allyl bromide–ethanol (1: 1 v/v) solution.
(c) Ferrocene (5×10^{-3}mol/l) in dichloromethane.
(d) Ferrocene (5×10^{-3}mol/l) in ethanol.
* The UV-spectra of ferrocene (5×10^{-3}mol/l) in chloroform–ethanol (1: 1 v/v) solution was nearly the same as those shown in (b). The UV-spectra of ferrocene (5×10^{-3}mol/l) in allyl chloride–ethanol (3.5×10^{-2}mol/l in ethanol) solution was nearly the same as those shown in (d).

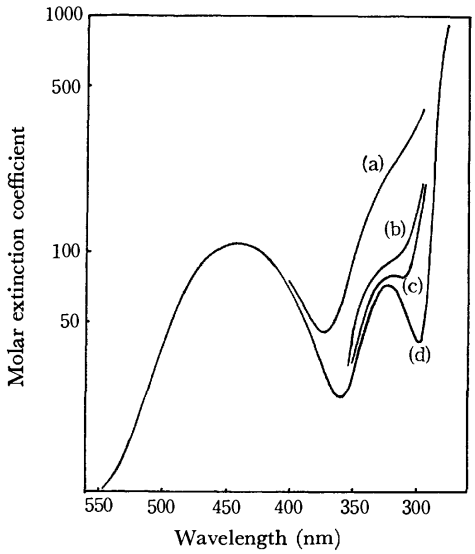

Fig. 2. UV-Spectra of ferrocene in halogenated hydrocarbon–ethanol solutions.
(a) Ferrocene (5×10^{-3}mol/l) in benzyl chloride–ethanol (7.0×10^{-1}mol/l in ethanol) solution.
(b) Ferrocene (5×10^{-3}mol/l) in benzal chloride–ethanol (5.5×10^{-1}mol/l in ethanol) solution.
(c) Ferrocene (5×10^{-3}mol/l) in benzotrichloride–ethanol (6.8×10^{-1}mol/l) solution.
(d) Ferrocene (5×10^{-3}mol/l) in ethanol.
* The UV-spectra of ferrocene (5×10^{-3}mol/l) in *n*-butyl chloride– and *t*-butyl chloride–ethanol solutions (1: 1 v/v) were nearly the same as those shown in (d). In chlorobenzene–ethanol (3.5×10^{-2}mol/l), it is similar to that in ethanol.

zyl chloride, benzal chloride, benzotrichloride and *p*-nitrobenzyl chloride showed the charge transfer absorption at 300—380 nm, but other chlorides, such as *n*-butyl chloride, *t*-butyl chloride, allyl chloride and chlorobenzene showed no charge transfer absorption.

As seen from Tables 1 and 2 and Fig. 1, the system showing charge transfer absorption afforded the photoproducts in higher yields in the irradiation with a high pressure mercury lamp (runs 1—7, Table 1, and runs 12—16, 21, 22, Table 2) than in that with a low pressure mercury lamp. Therefore, the charge transfer complex between ferrocene and halogenated hydrocarbons thus plays an important role.

In the ferrocene–chloroform–ethanol system, the low yield of the photoproducts is due to its sensitivity to 313 nm light which causes secondary decomposition.

In the ferrocene–*p*-nitrobenzyl chloride–ethanol system, the observed charge transfer absorption might be due to the interaction between ferrocene and nitro group, since the formation of ferrocenium ion was not observed and the percentage of loss of ferrocene and that of the product yield were extremely low. In the ferrocene–benzotrichloride–ethanol system, despite the high percentage of loss of ferrocene in irradiation with both high and low pressure mercury lamps, absence of the photoproduct might be due to the photo-sensitivity of benzotrichloride itself. The absorption of incident light by benzyl chloride, benzal chloride and benzotrichloride in the 300—340 nm region causes decomposition of the chlorides in irradiation with a high pressure mercury lamp. The high percentage of loss of ferrocene (runs 12—18, Table 2) might be due to the decomposition of ferrocene by the attack of chlorine atom produced by direct decomposition of the chlorides.

The Mechanism of Photo-substitution of Ferrocene in Haloalkane-Ethanol Solutions

(Received January 20, 1973)

The mechanism of photo-substitution of ferrocene in haloalkane–ethanol solutions was investigated by the flash photolysis technique and other chemical methods mainly on the ferrocene–carbon tetrachloride–ethanol system. The photoreaction is initiated by the excitation of charge transfer state (electron transfer from ferrocene to carbon tetrachloride). In the absence of ethanol, CT-excitation leads to the decomposition of ferrocene to $FeCl_3$ with first order reaction kinetics of $k=(1.6\pm0.5)\times10^5\ s^{-1}$. The formation of $FeCl_3$ was inhibited by ethanol effectively to give ethyl ferrocenecarboxylate. Diethylamine quenched the formation of $FeCl_3$, whereas dimethyl sulfoxide, a stronger base than ethanol, is a less effective quencher than ethanol. These facts suggest that the most important role of ethanol is to ethanolyse trichloromethylferrocene, which otherwise decomposes to $FeCl_3$.

The solutions of ferrocene in haloalkanes are photochemically interesting systems. Brand and Snedden observed a CT-absorption ("dissociative charge transfer band") in ferrocene–haloalkane systems.[1] Körner von Gustorf and his co-workers reported that the irradiation of the system leads to the oxidation of ferrocene, to give $[Fe(C_5H_5)_2]^+[FeCl_4]^-$.[2]

Hoshi *et al.* and Akiyama *et al.* observed photochemical substitution of ferrocene in ferrocene–haloalkane–ethanol systems.[3] Ethyl ferrocenecarboxylate, ferrocenecarboxaldehyde and ethoxymethylferrocene (accompanied by di(ethoxymethyl)ferrocene) were isolated after the irradiation of ferrocene in carbon tetrachloride–ethanol, chloroform–ethanol and dichloromethane–ethanol solutions, respectively.

In order to elucidate the mechanism of photosubstitution and especially to clarify the role of ethanol, flash photolysis and several chemical methods were applied to ferrocene–carbon tetrachloride systems containing ethanol and other bases.

Experimental

Materials. For the flash photolysis study, commercial ferrocene (Rheinelbe Bergbau A.G.) was recrystallized twice from ethanol, mp 174—175 °C.

Spectro-grade carbon tetrachloride, acetonitrile and dimethyl sulfoxide, analytical-grade ethanol, dioxane and methanol and reagent-grade diethylamine (Merck A.G.) were used without further purification.

The materials used for other investigations by chemical methods were the same as described elsewhere.[3]

Flash Photolysis. The argon flash tube employed for photolysis discharged 50% of the total energy within 1.4 μs and 90% within 4.2 μs. The energy for a flash was about 10 J. The spectro-flash was similar except in energy. The spectral separation of the monitoring light was achieved by passing it through a Carl Zeiss double monochrometer equipped with a quartz prism. The light intensity was recorded photographically. The intensity of light was calibrated with standard filters. For kinetic measurements a monitoring flash lamp (G. 431 Vakuumtechnik, Erlangen) was used. The intensity of the transmitted light was followed with an oscillograph.

Solutions of ferrocene ($2—5\times10^{-4}$ mol/l) in ethanol or carbon tetrachloride containing various additives were flash photolyzed in a suprasil cell (50 mm in length and 7 mm in diameter). When necessary, the solution was deoxygenated by bubbling argon for 30 minutes.

Wavelength Dependence of Photoreaction. Monochromatic light of 436, 366, and 313 nm was obtained by passing the light from a high pressure 150 W mercury lamp (Ushio Denki Co.) through interference filters (Carl Zeiss monochromatic filter; M-436, M-365, and M-313). Light of 254 nm was obtained by passing the light from a low pressure mercury lamp (Ushio Denki Co.) through a filter solution containing potassium iodide and iodine.[4]

A deaerated ferrocene solution (279 mg ferrocene in 30 ml carbon tetrachloride–ethanol 1 : 1 v/v) was irradiated in a quartz vessel by monochromatic light while being stirred continuously with a magnetic stirrer. The quantities of ethyl ferrocenecarboxylate and ferrocene were determined gas chromatographically (column; SE-30 on Diasolid L of Gaschro-kogyo Co.; temperature, 176 °C) with a Perkin-Elmer gas chromatograph Model F-6.

Actinometry was performed with a potassium trioxalatoiron(III) actinometer.[5]

tetrachloride and in carbon tetrachloride–ethanol are shown in Fig. 1.[1] Scott and Becker assigned the absorption band of ferrocene at 440 nm to d-d* transition and that at 325 nm to 3d-MO*, ring MO–MO* or symmetry forbidden π-π* transition. According to them the absorption at shorter wavelength is due to π-π* or n-π* transition.[6] The absorption at 307 nm observed in carbon tetrachloride solution is due to the charge transfer excitation.[1]

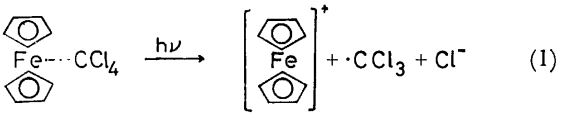
Table 1. Quantum yields in the photoreaction of ferrocene in a carbon tetrachloride–ethanol solution at various wavelengths

Wavelength (nm)	Quantum yield of ethyl ferrocenecarboxylate	Quantum yield of the decomposition of ferrocene
254	0.13	0.28
313	0.13	0.18
366	0.11	0.14
436	0.00	0.00

Wavelength dependence of the photo-substitution shown in Table 1 indicates that the excited state formed by d-d* absorption leads to no photoreaction, while the excitation of charge transfer state efficiently affords ethyl ferrocenecarboxylate. The excitation by light of a shorter wavelength brings about an increase in side reactions. Therefore, the photo-substitution arises from the electron transfer from ferrocene to carbon tetrachloride.

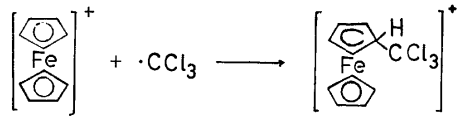
Reaction Succeeding CT-Excitation. It is known that the CT-excitation gives ferrocenium tetrachloroferrate (III) in the absence of ethanol.[2] However, the substitution product was obtained when ethanol is added to the above system. The problem is to clarify the role of ethanol which inhibits the decomposition of ferrocene and leads to the formation of ethyl ferrocenecarboxylate.

As reported by Brand and Snedden[1] the CT-excitation yields a radical pair.



(1)

According to Beckwith and Leydon[7] ferrocenium cations are reactive toward free radicals, in contrast with ferrocene. Therefore, a reaction of the trichloromethyl radical with ferrocenium cation is plausible.



(2)

The reaction within a solvent cage would be important. The following sequence of reactions would not play an important role in this photoreaction.

(i) The formation of ferrocenium tetrachloroferrate (III), the end product in the absence of ethanol.[2]

(ii) The reaction of ferrocenium tetrachloroferrate (III) with trichloromethyl radicals.

The reasons are:

(1) The formation of ethyl ferrocenecarboxylate is linear with respect to the light absorbed (Fig. 2), excluding a two step reaction.

(2) The UV-irradiation of ferrocenium tetrachloroferrate (III) in carbon tetrachloride–ethanol solution gave no substitution product, but ferrocene, a reduction product. In this case, we obtained a comparatively large amount of hexachloroethane, the dimerization product of trichloromethyl radicals. This indicates that ferrocenium tetrachloroferrate(III) itself has a different reactivity from normal ferrocenium ions and is unreactive toward trichloromethyl radicals.

In order to complete the substitution reaction, two reaction steps are necessary, namely;

(i) proton elimination

(ii) alcoholysis of the trichloromethyl group

The results of flash photolysis are informative. Flash

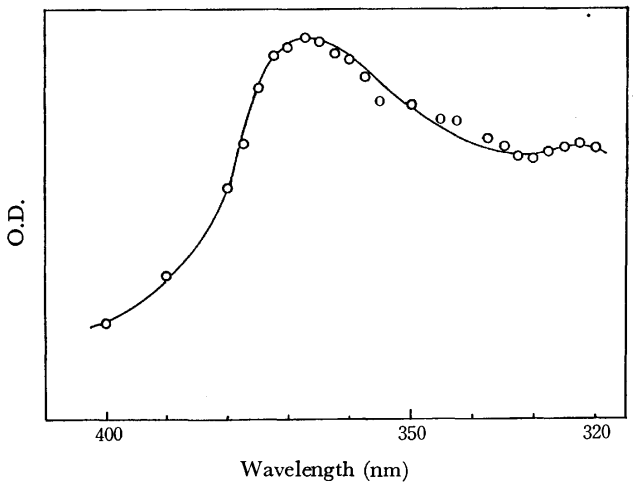

Fig. 3a. UV-Spectra of the product formed in the flash photolysis of ferrocene–CCl_4 system.

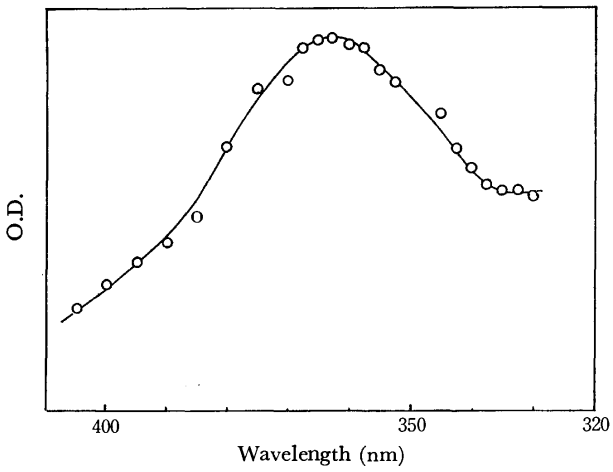

Fig. 3b. UV-Spectra of the product formed in the flash photolysis of ferrocene–CCl_4–DMSO system.

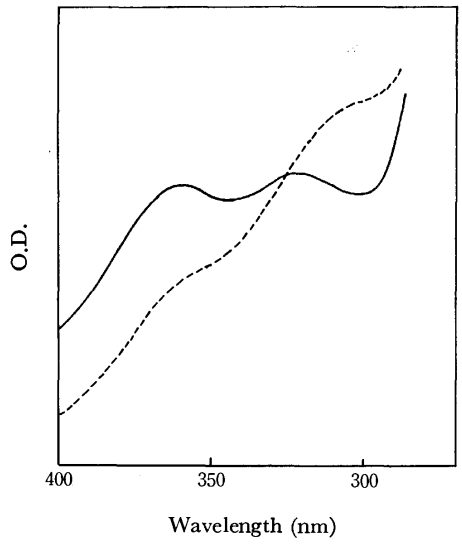

Fig. 3c. UV-Spectra of iron(III) chloride (——) and ferrocenium tetrachloroferrate (III) (- - -) in carbon tetrachloride–DMSO (DMSO 0.3 mol/l).

photolysis of ferrocene in an ethanol solution gave rise no spectral change, but that in carbon tetrachloride showed new absorption bands at 370 and 325 nm with a delay of $\sim\mu$s after the photolysis flash, though no transient absorption was observed. The absorption spectra are shown in Fig. 3a. They agree with those of iron(III) chloride (λ_{max} of the UV-spectra of iron(III) chloride are 375 and 325 nm in carbon tetrachloride solution.). The spectra of the product in carbon tetrachloride containing dimethyl sulfoxide (0.3 mol/l) also agree qualitatively with those of iron(III) chloride and not with those of ferrocenium tetrachloroferrate(III), the other possible product (Figs. 3b and 3c).

The formation of iron(III) chloride was completed in about 10 μs. An example of the intensity change of the transmitted light at 370 nm through a ferrocene solution with and without photolysis flash is shown in Fig. 4.

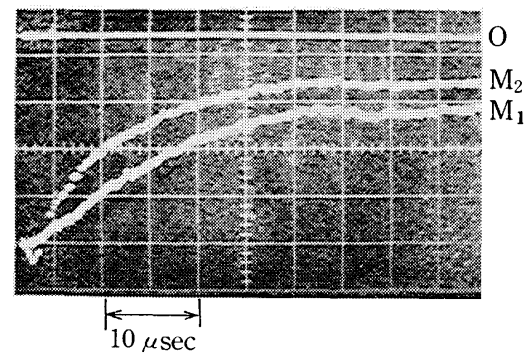

Fig. 4. The change in the intensity of the transmitted light at 370 nm.
M_1: Without photolysis flash
M_2: After photolysis flash

Kinetic analysis of the formation of iron(III) chloride is made in the following way. M_1 and M_2 are the intensities of the transmitted light without and with a photolysis flash, respectively. M_2 is smaller than M_1 due to the formation of the product. For the kinetic analysis, we should know the initial concentration of a precursor. However, the value could not be obtained in this experiment. We assume that the concentration of the precursor is equal (or proportional) to the end concentration of iron(III) chloride. Thus, we obtain the following equation for first order reaction kinetics.

$$k_1 t = \ln \frac{[FeCl_3]_\infty}{[FeCl_3]_\infty - [FeCl_3]_t}$$

where k_1 is the rate constant for a first order reaction, and $[FeCl_3]_\infty$ and $[FeCl_3]_t$ are the concentrations of iron(III) chloride after the completion of the reaction and at time t, respectively.

The expression in terms of the intensities of the transmitted light is

$$k_1 t = \ln \frac{\log (M_1/M_2)_\infty}{\log (M_1/M_2)_\infty - \log (M_1/M_2)_t}$$

In the same way, we obtain the expression for second order kinetics:

$$k_2 t = \frac{\log (M_1/M_2)_t}{\log (M_1/M_2)_\infty \{\log (M_1/M_2)_\infty - \log (M_1/M_2)_t\}}$$

Table 2. Effects of additives on the formation of $FeCl_3$ in the flash photolysis of ferrocene–CCl_4 system

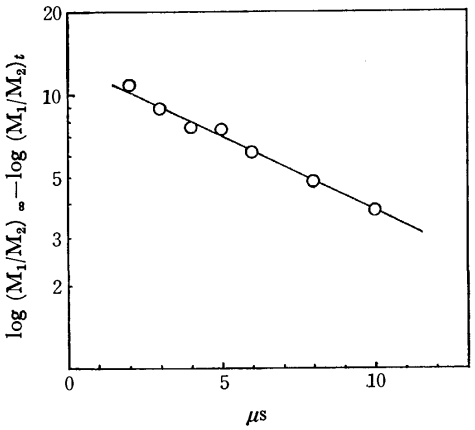

Fig. 5. First order kinetics for the formation of the product (λ_{max}=370 nm) in the flash photolysis of ferrocene–CCl_4 system.

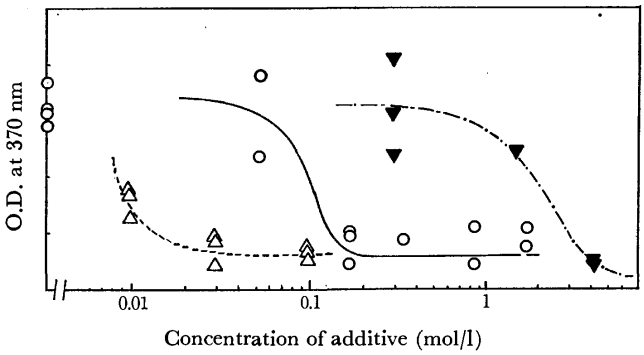

Fig. 6. Effects of additives on the formation of $FeCl_3$
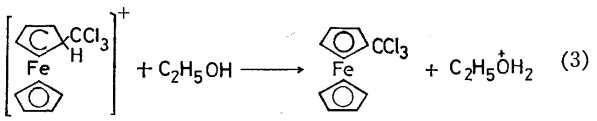
△---△: Diethylamine, -○—○-: Ethanol,
▼---▼: Dimethyl sulfoxide.

The experimental data fit first order reaction kinetics as is thown in Fig. 5. The average first order rate constant is: $k_1=(1.6\pm0.5)\times10^5\ s^{-1}$.

The formation of iron(III) chloride was quenched by several additives. Figure 6 shows the quenching by ethanol, diethylamine and dimethyl sulfoxide in the function of the concentration of the additives. The quenching effect of ethanol is remarkable above 10^{-1} mol/l of ethanol concentration. Diethylamine is more effective and dimethyl sulfoxide less effective than ethanol. The quenching effect of other additives are summarized semi-quantitatively in Table 2.

If the most important role of ethanol in the photoethoxycarbonylation were to abstract the proton according to Eq. (3), the basicity of the proton acceptor would affect the quenching effect.



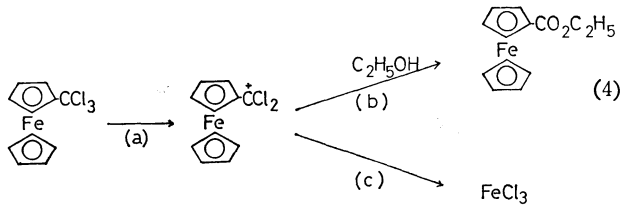
Dimethyl sulfoxide is a stronger base (pK_a of the conjugate acid of dimethyl sulfoxide is 0[8]) than alcohol (pK_a of the conjugate acid of methanol is equal to −2.[8]). The quenching effect of dimethyl sulfoxide is, however, lower by one order than ethanol and methanol. This indicates that the proton abstraction step does not determine the fate of the photoreaction.

Alcohols can solvolyze trichloromethylferrocene to give a stable product, namely, the corresponding ester of ferrocenecarboxylic acid, but dimethyl sulfoxide can not perform such a reaction. The difference in quenching effect would arise from this process.

An abnormaly high rate of solvolysis was reported for α-ferrocenylethyl chloride by Hill.[9] The solvolysis is of first order with respect to the chloride. The rate constant in ethanol (40%)–ethyl ether (60%) solution at −42.8 °C and the activation energy of the reaction are $8.9\times10^{-3}\ s^{-1}$ and 10.9 kcal/mol, respectively. Hill ascribed the high rate of solvolysis to the participation of the iron atom of ferrocene.

8) E. M. Arnett, "Progress of Physical Organic Chemistry," Vol. 1, ed. by S. G. Cohen, A. Streitwieser, and R. W. Taft, Interscience Publishers, New York, N. Y. (1963), p. 223.
9) E. A. Hill, *J. Org. Chem.*, **28**, 3586 (1963).

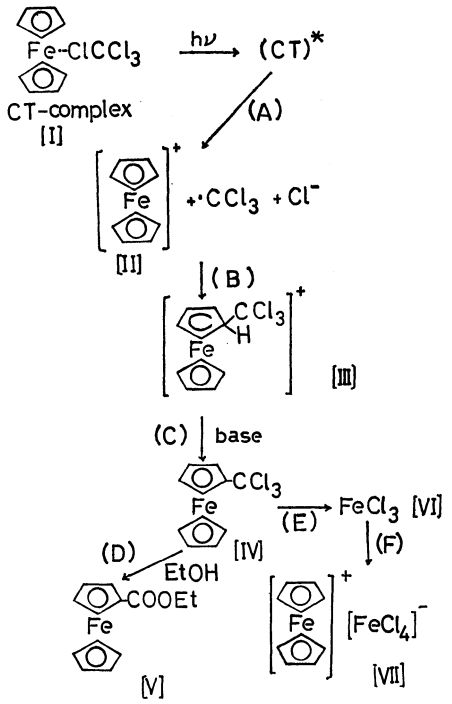
If the solvolysis of trichloromethylferrocene is an S_N1 type reaction, the following sequence of reactions should be considered.



Where (a) is the rate determining process and (b) and (c) are competing processes. If this is the ca, the rate constant for process (a) should be 1.6×10^5 sec^{-1} according to our experiment. This value is large compared with that for α-ferrocenylethyl chloride (the calculated rate constant for α-ferrocenylethyl chloride at 30 °C from the data of Hill is 2.8 s^{-1}). An alternative reaction mechanism would be S_N2. We have no means of distinguishing which of these two processes actually takes place.

The presence of oxygen affects to a great extent the photochemical behavior of ferrocene, the increase in absorption at ~370 nm being greater. Alcohols hardly inhibit the increase in absorption. The shape of the spectra remained the same. This finding corresponds to the fact that the photo-substitution proceeds with no side reactions only under anaerobic conditions.

The reaction mechanism of the photo-substitution is summarized in Scheme 1.



Scheme 1.

The authors wish to thank Prof. D. Schulte-Frohlinde, Dr. G. Koltzenburg and Dr. E. Körner von Gustorf of Max Planck-Institut für Kohlenforschung for their helpful discussions. Reaction of Alkylbenzene. IX.[1] A Study of the Reaction of Methylbenzenes under the Influence of Aluminum Chloride-Hydrogen Chloride by Means of NMR

Yoshihide Okami, Noboru Otani, Daigo Katoh, Sawako Hamanaka, and Masaya Ogawa

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka 564

(Received April 3, 1972)

The ^{1}H and ^{13}C NMR spectra of the complex layers obtained by the reaction of several methylbenzenes with aluminum chloride were measured at room temperature, and the proton exchanges were investigated. The ring ^{1}H signal shifted to a higher field as a result of fusion with the signal of the aliphatic CH_2 group of the methylbenzenonium ion, which resulted from the protonation to ring carbons. Thus, the proton exchange is considered to proceed among the ring carbons of aromatic hydrocarbon and its benzenonium ion in the complex layer intermolecularly as well as intramolecularly. This finding agrees with the results obtained from the ^{13}C NMR spectra of the complexes. The ^{13}C spectral data showed that the ease of the protonation to ring carbons depends upon the differences in the chemical shifts between the complex layer and the starting aromatic hydrocarbon, and some facts concerning the isomerization of methylbenzenes were discussed.

Investigations concerning benzenonium ions have been reported by many workers.[2-5] The presence of the benzenonium ion was supported first by measurements of vapor pressure and conductivity. The addition of the proton to an aromatic carbon atom, thus forming an "aliphatic" CH_2 group, was confirmed by observations of electronic[6] and infrared[7] spectra. More direct evidence for the structure of benzenonium ions was mainly obtained from the ^{1}H NMR spectra.

The ^{1}H NMR spectra of some methylbenzenonium ions were obtained by using $HF-BF_3$,[8,9] $HFSO_3$[10] or $HF-SbF_5$.[11] In all these experiments the spectra of benzenonium ions were measured at a low temperature in order to obtain well-resolved signals, since proton exchange occurred at higher temperatures.

Recently, Koptyug and his co-workers[12] measured the ^{13}C NMR spectrum of the mesitylenonium ion at room temperature by using aluminum chloride with hydrogen chloride and discussed how the positive charges on the ring-carbon atoms of the ion can be calculated on the basis of the relative shift differences between the mesitylenonium ion and mesitylene.

In the present work the ^{1}H and ^{13}C NMR spectra of the complex layers obtained by the reaction of several methylbenzenes with aluminum chloride were measured at room temperature in order to clarify the behavior of the methylbenzenonium ion under the influence of proton exchange.

Experimental

Preparation of the Complexes. The reaction was carried out in a long necked flask with a long side tube, as is shown in Fig. 1. About 3 g of aromatic hydrocarbon was placed in the reaction vessel (3) and about the same amount of pulverized aluminum chloride in the side tube (4). After the open end of the side tube had been sealed, the aluminum chloride was sublimed slowly under the reduced pressure of 3 mmHg by means of a ribbon heater. One-third to one-half of the aluminum chloride in the side tube was transferred into the reaction vessel, which contained the aromatic hydrocarbon which had been held at 2 °C with stirring by means of a magnetic stirrer. During the sublimation, the hydrogen chloride produced by the reaction of aluminum chloride with the moisture which existed in the system was absorbed in the aromatic hydrocarbon. Then the reaction mixture is gradually turned from a light yellow to a light vermilion as a result of the dissolving of the aluminum chloride. When the reaction mixture was left standing for a while, a colored complex of a

a) Al: ±0.3 wt%, Cl: ±1.0 wt%.

high viscosity was separated as a lower layer, leaving colorless hydrocarbon as the upper layer. The lower complex layer was examined by NMR and then quenched with water before submitting it to the vpc analysis for hydrocarbons.

Measurements. The ^1H NMR spectra were measured at 22.5 °C on a JEOL JNM-3H-60 spectrometer with 60 MHz, using a neat liquid. Tetramethylsilane was used as the external standard.

The ^{13}C NMR spectra were measured at 26 °C on a JEOL C-60HL spectrometer with a 15.09 MHz RF unit. The ^1H-decoupled ^{13}C spectra were obtained by means of a single scan. The chemical shifts were measured relative to CS_2.

Analyses of Hydrocarbons. The hydrocarbons in the complex layer were analyzed by means of vpc after the complex had been decomposed with water. The analyses were made at 100—130 °C by employing a vapor-phase chromatograph (Shimadzu Model GC-3AF) with a flame ionization detector and a 3 mm×3 m column packed with Benton-34 or Ucon-LB-550X; nitrogen was used as the carrier gas.

Analyses of Aluminum and Chlorine. The aluminum and chlorine in the complex layer were determined by the oxine- and the mercurimetric-titration methods,[13] respectively.

Results and Discussion

It is well known that, in the presence of hydrogen chloride, aluminum chloride dissolves in aromatic hydrocarbon by forming a benzenonium ion. In the present work, when aluminum chloride was heated, a certain amount of hydrogen chloride which was produced from the reaction of aluminum chloride with moisture evolved and was absorbed in the aromatic hydrocarbon. As more hydrogen chloride was not added in the reaction system, the amount of the complex layer seems to be proportional to that of the evolved hydrogen chloride. When both the reactants had been dehydrated extremely, aluminum chloride did not dissolve at all in aromatic hydrocarbon. Therefore, it seems that the dissolved aluminum chloride may form a certain protonic acid by reacting with hydrogen chloride or other proton donors. In each run, about a half of the aluminum chloride in the side tube dissolved in the aromatic hydrocarbon, but the excess aluminum chloride did not dissolve. Therefore, the complex layer seems to have similar constituents in each preparation under the given reaction conditions.

Analyses of Complex Layers. The constituents of the complex layers obtained by the reaction at 2 °C are shown in Table 1. Some methylbenzenes isomerized to the most stable isomer in a small amount. The ratio of Cl/Al is about 3.5. This value means that the protonic acid produced from aluminum chloride in the complex layer is not only $H^+AlCl_4^-$ but also some other acids, such as $H^+ AlCl_3OH^-$ and $H^+ Al_2Cl_7^-$.

On the other hand, the ArH/Al ratio for each complex is estimated to be between 2.24 and 3.14. This indicates that the aromatic hydrocarbon which exists in the complex layer is represented by the following equation:

$$\alpha ArH + HB + AlCl_3 \longrightarrow (\alpha - 1)ArH + ArH_2^+ \cdot AlCl_3 \cdot B^-$$

where HB is HCl or H_2O and where α is not necessarily an integer. Accordingly, the excess aromatic hydrocarbon which does not form benzenonium ions is considered to react as a solvent. The fluctuation of

Mesitylene	1.60	1.92	−21.0	6.06	5.96	+6.0

a) All the chemical shifts are referred to tetramethylsilane as an external standard.
b) The differences in chemical shifts between aromatic hydrocarbons and complexes are shown by Hz (positive; higher field shift, negative; lower field shift).
c) The intensity of the signal was about half of that of the signal at 1.96 ppm, and the signal could not be assigned.
d) This signal was assigned to the 1-CH_3 and 2-CH_3 groups, but it split into a doublet with an equal intensity in the complex.

the amount of such an aromatic hydrocarbon could not be interpreted.

^1H NMR Spectra. The ^1H NMR spectra of the starting aromatic hydrocarbons (A) and the complexes (B) are shown in Fig. 2. Each ^1H chemical shift (δ) of the complexes, and the difference ($\Delta\nu$) of each chemical shift between the aromatic hydrocarbon and its complex, are given in Table 2.

The proton signals of methyl groups in all of the complexes shifted about 20 Hz to a lower field. However, when cyclohexane was used as an internal reference in the complex layer, the proton signal of cyclohexane also shifted about 20 Hz to a field lower relative to the external reference. Therefore, the differences in the shifts of the methyl groups are considered to result mainly from the use of an external reference; thus, it seems that the methyl protons are not significantly affected by the formation of methylbenzenonium ions.[14]

On the other hand, the shifts of ring protons given in Table 2 are apparently up-field shifts, considering the influence of the external reference. MacLean and his co-workers,[9] who measured the NMR spectra of a mixture of aromatic hydrocarbon and its benzenonium ion in HF–BF_3, using excess HF as the solvent at various temperatures, found that signals of the ring and the methylene protons fused into a single signal at temperatures above −30 °C; this fused signal was observed between both the resolved signals.

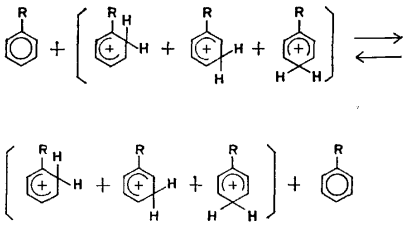
In the present observation, the up-field shift of ring protons seems to be caused by the fusing of the signals of the ring and methylene protons.[15]

The up-field shifts of the ring protons of each complex are in the following order:

Mesitylene>Hemimellitene>Pseudocumene>*m*-Xylene>*p*-Xylene>Toluene

This order is proportional to the basicity of methylbenzenes.[2] Consequently, the proton signals of more basic benzene rings are shifted to a higher field by the fusion with the methylene signal.

The fusion of signals may result from the proton exchange. As the observed signal of the ring protons in the complex layer is a singlet, the proton exchange is considered to occur not only among the ring carbons of the same benzenonium ion intramolecularly, but also among the ring carbons of aromatic hydrocarbon and those of its benzenonium ion intermolecularly as follows:



^{13}C NMR Spectra. Figure 3 shows diagrams of the ^{13}C NMR spectra of the starting aromatic hydrocarbons (A) and the complexes (B). Their chemical shift values are listed in Table 3. The assignments of the ^{13}C signals of each starting aromatic hydrocarbon were determined by reference to the literature.[16–18] The assignments of signals for the ring carbons of

14) The lowerings of the chemical shift based on the external reference are considered to be caused by some physical factors. The volume magnetic susceptibility of aluminum chloride, considered to be one of the physical factors, was determined to be $(0.70\pm0.05)\times10^{-6}$ cgs unit (measured at 100 MHz), by using hexamethyldisilane as the reference. The magnitude of the susceptibility corresponds to a lowering of the chemical shift of about 6 Hz.

15) M. Strohmeyer and C. Witte (*Ann. Chem.*, **729**, 21 (1969)) reported that aromatic hydrocarbon, which forms a stable methylbenzenonium ion in $AlCl_3$–HCl at −30 °C, must possess at least three methyl groups at the 1,3,5-positions.

a) Referred to $^{13}CS_2$.
b) The calculated values of the chemical shifts were based on the additivity relations reported by Savitsky[19] and by Lauterbur.[17]
c) These data were assigned with Refs. 16 and 17.
d) See footnote c, Table 2.

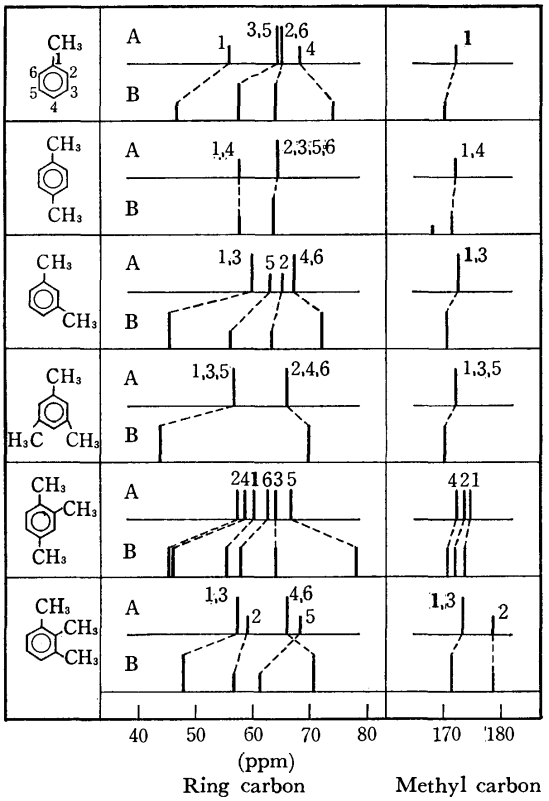

Fig. 3. The diagrams of the ^{13}C NMR spectra of the starting aromatic hydrocarbons (A) and the complexes (B).

pseudocumene and hemimellitene, the chemical shifts of which have not been reported, were performed on the basis of the peak intensities and then by using the additivity relations of chemical shifts postulated for disubstituted benzenes by Savitsky[19] and by Lauterbur.[17] The calculated values of the chemical shifts of ring carbons based on the additivity relations are also listed in Table 3. As can be seen in Table 3, the small differences between the calculated values and the observed values indicate that the above assignments of chemical shifts are acceptable.

Each ring ^{13}C signal of the complexes was also assigned by considering the peak intensities and the basicity of each ring carbon. The signals of each ring carbon were observed in the same order as those of the starting aromatic hydrocarbons, except for the signals of hemimellitene, which were ascertained by means of the peak intensities. On the other hand, the signals of the methyl groups were easily assigned by examining the peak intensities.

The mesitylenonium ion was independently prepared by introducing HCl gas into a mixture of mesitylene and two times as many moles of aluminum chloride in a stream of nitrogen. Figure 4 shows the diagrams of the ^{13}C NMR spectra of mesitylene (a), the mesitylenonium ion (b), and the complex of mesitylene (c). From the spectrum of the mesitylenonium ion (b), it

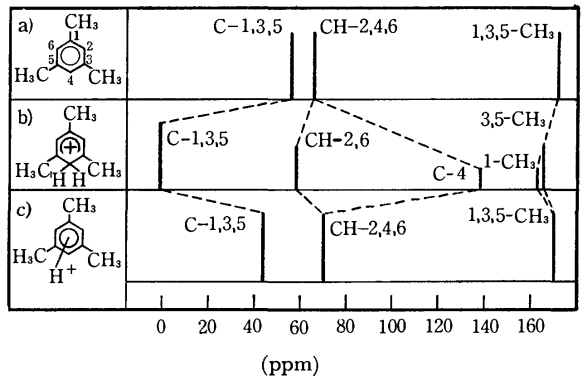

Fig. 4. The diagrams of the ^{13}C NMR spectra of mesitylene, the mesitylenonium ion and the complex of mesitylene.
a) mesitylene b) mesitylenonium ion (ArH^+_2, measured at −20 °C) c) complex (ArH: ArH_2^+)

was found that the ^{13}C signal of the methylene group resulted from the protonation to the C-4 ring carbon shifted to a higher field, similar to that of the alicyclic CH_2 group of cyclohexane (165 ppm), while the signals of the other ring carbons and of the methyl ones shifted to a lower field because of the decrease in the electron density caused by the protonation. These facts well agreed with Koptyug's findings concerning the ^{13}C NMR spectrum of the mesitylenonium ion. On the other hand, as is shown in Fig. 4 (c), the CH-2,6 and CH-4 signals of the complex were fused into a single signal, and all three signals of the complex shifted less than did the resolved signals of the mesitylenonium ion. These relations hold generally on the fused spectra of other complexes.

The following results were drawn from the data of the fused spectra in Fig. 3:

a) The protonation occurred more easily on the more basic ring carbon. Then the ring carbon signal shifted to a higher field.

b) The signals of the ring carbons with less basicity are shifted to a lower field by the decrease in electron density. Of course, such carbons also have a chance to be protonated, but the contribution of the protonation is less than that of the more basic carbon.

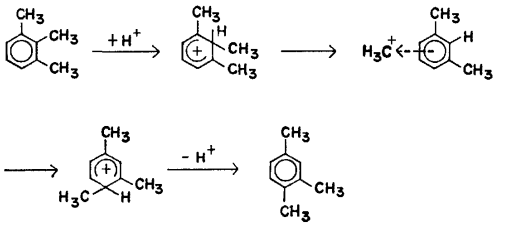
c) The methyl-substituted ring carbons are considered to be protonated to a small extent. Thus, their signals are shifted to a much lower field.

d) The signals of the methyl groups are shifted to a lower field, since the methyl groups are charged somewhat positively because of the decrease in the electron density through I- and H-effects.

Isomerization Mechanism. As is shown in Table 1, the complexes of some methylbenzenes, such as *p*-xylene, pseudocumene, and hemimellitene, gave small amounts of isomerized products after decomposition with water. The isomerization of methylbenzenes is known to proceed usually by means of the intramolecular 1,2-shift of methyl group;[20,21] the ease of the isomerization depends upon the ease of the protonation to the methyl-substituted carbons.

In the above three methylbenzenes, the signals of the methyl-substituted carbons showed an interesting behavior. The signals of the ring carbons, such as the C-1,4 of *p*-xylene, the C-1 of pseudocumene, and the C-2 of hemimellitene, showed small differences (w−x) compared with those of other methyl-substituted carbons. The small differences mean that such carbon atoms were protonated to a substantial extent and that then the methyl groups substituted for these atoms might have been easily rearranged to other positions. Moreover, the signals of the methyl groups attached to the above-mentioned carbons, such as the 1,4-CH_3 of *p*-xylene, the 1-CH_3 of pseudocumene, and the 2-CH_3 of hemimellitene, also shifted very slightly to a lower field compared with those of other methyl carbons. This finding indicates that the above methyl groups are charged less positively than the others and that, therefore, they may rearrange more easily.

The isomerization of hemimellitene is generally considered to proceed by means of the 1,2-shift of 1-CH_3 or 3-CH_3 groups. However, the above results suggest that hemimellitene may be isomerized by the rearrangement of the 2-CH_3 group according to the following scheme:



We are currently investigating this reaction further in an attempt to elucidate this mechanism.

The authors wish to thank Dr. Koichi Hatada of the University of Osaka for helpful discussions. The authors also wish to thank Mr. Hiroshi Okuda and Mr. Yoshio Terawaki of the University of Osaka for the measurements of the NMR spectra.

Sterically Controlled Syntheses of Optically Active Organic Compounds. XIX. Asymmetric Syntheses of Amino Acids by the Strecker Reaction[1]

Kaoru HARADA, Tadashi OKAWARA, and Kazuo MATSUMOTO

Institute for Molecular and Cellular Evolution, and Department of Chemistry, 521 Anastasia Avenue, Coral Gables, Florida 33134, U.S.A.

(Received September 11, 1972)

The Strecker type syntheses of optically active alanine, butyrine, valine, and leucine by the use of the corresponding aldehydes, hydrogen cyanide, and optically active α-alkylbenzylamines and α-(1-naphthyl)ethylamine were carried out (reaction A). The optical purities were in the range 22—51%. The modified Strecker type syntheses of alanine from acetaldehyde cyanohydrine and optically active amines were also carried out (reaction B). The optical purities of alanine were in the range 44—48%. In reaction B, optically active phenylglycine was also used as an amino source. The optical purities of the synthesized alanine were in the range 12—17%.

Synthesis of optically active alanine by the Strecker reaction using optically active α-methylbenzylamine, acetaldehyde, and hydrogen cyanide has been reported.[2] Optically active alanine was similarly synthesized from the same amine and racemic acetaldehyde cyanohydrine.[3] In these syntheses, the isolated alanine had rather high optical purities (80—95%), but the final products were isolated from the solution by crystallization. Thus, fractionation of optical isomers of alanine would be expected to take place during the crystallization process. Recently, the addition reaction of hydrogen cyanide to the Schiff bases of several aldehydes with optically active α-methylbenzylamines was studied.[4] It was reported that the isolated amino acids were almost optically pure. Although they claimed that there was no fractionation of the synthesized optical isomers during the isolation and purification processes, it was shown that fractionation could take place in three steps.[5] The real optical purities of amino acids prepared by the addition reactions of hydrogen cyanide were found to be much lower. Similar addition reactions of benzoyl cyanide to Schiff bases composed of various aldehydes and optically active α-alkylbenzylamine were studied.[6]

In the study of syntheses of optically active amino acids by the Strecker reaction, 1) the effect of the optically active moiety, 2) the effect of the aldehyde, and 3) the optical purity of the synthesized amino acids were investigated. Two kinds of reaction were carried out. A) the Strecker reactions of aldehydes, hydrogen cyanide, and optically active amines, and B) the modified Strecker reactions of racemic aldehyde cyanohydrine with optically active amines. The optically active amines used were: *R*-(+)-α-methylbenzylamine, *S*-(−)-α-methylbenzylamine, *S*-(−)-α-ethylbenzylamine, *S*-(−)-α-(1-naphthyl)ethylamine, and *R*-(−)-phenylglycine. The aldehydes used in reaction A were: acetaldehyde, propionaldehyde, isobutyraldehyde, and isovaleraldehyde. Reaction A was carried out in absolute ethanol at room temperature, except when the reactants were mixed at −10°C. Reaction B was carried out under similar conditions, except in reactions in which (*R*)-(−)-phenylglycine was used in aqueous alkaline conditions.

Reaction (A): $RCHO + R'NH_2 + HCN \xrightarrow[H^+]{H_2O} R\text{-}\overset{*}{C}H\text{-}CN \xrightarrow[H^+]{H_2O} \xrightarrow[Pd(OH)_2/C]{H_2} R\text{-}\overset{*}{C}H\text{-}COOH$ (NHR′ / NH_2)

Reaction (B): $CH_3\text{-}CH(OH)\text{-}CN + R'NH_2 \xrightarrow[H^+]{H_2O} \xrightarrow[Pd(OH)_2/C]{H_2} R\text{-}\overset{*}{C}H\text{-}COOH$ (NH_2)

R: CH_3–, CH_3CH_2–, $(CH_3)_2CH$–, $(CH_3)_2CHCH_2$–

R′: (±)-C_6H_5-CH(CH$_3$)–, (*R*)-(+)-C_6H_5-CH(CH$_3$)–, (*S*)-(−)-C_6H_5-CH(CH$_3$)–, (*S*)-(−)-C_6H_5-CH(C_2H_5)–, (*S*)-(−)-$C_{10}H_7$-CH(CH$_3$)–, (*R*)-(−)-C_6H_5-CH(COOH)–

The resulting *N*-alkylaminonitriles synthesized in reactions A and B were hydrolyzed with 6 M hydrochloric acid. The resulting *N*-alkyl amino acids were then hydrogenolyzed with palladium hydroxide on charcoal to remove the *N*-alkyl residue. Free amino acids were isolated by the use of a Dowex 50 column. The free amino acids obtained were then converted into DNP-derivatives with 2,4-dinitrofluorobenzene, and the DNPylated amino acids were purified by means of celite column chromatography to avoid any fractionation of optical isomers. The optical purities of the resulting amino acids were measured using the DNP-amino acids.

The specific rotations, optical purities, and over-all yields of alanine, α-aminobutyric acid, valine, and leucine, by using optically active α-methylbenzylamine, α-ethylbenzylamine, and α-(1-naphthyl)ethylamine are given in Table 1. The over-all yields were in the range 19—47%. The optical purities of amino acids were in the range 22—51%. It seems that the optical purity of amino acids decreased as the size of the

(*R*)-(−)-Phe-Glycine (0.01 mol)	Racemic lacto-nitrile (0.01 mol)	Yield[a] (%)	DNP-(*S*)-Alanine $[\alpha]_D^{25}$ (1M NaOH) (*c*, 0.3—0.5)	Optical purity[b] (%)
4	1	77	+17.8	12
3	1	73	+23.2	16
2	1	62	+20.0	14
1	1	56	+24.1	17
1	2	67	+23.8	17
1	3	82	+21.6	15
1	4	85	+20.0	14
1	5	75	+21.9	15

a) The yields are calculated from the least reactant (0.01 mol).
b) Optical purity defined as $[\alpha]_D$ obsd/$[\alpha]_D$ of the compound × 100. DNP-(*S*)-(+)-alanine, $[\alpha]_D^{25}$ +143.9° (1M NaOH).

α-carbon of (*R*)-cyanohydrine than (*S*)-cyanohydrine because of steric factors. The (*S*)-amine reacts with (*R*)-cyanohydrine to form *N*-(*S*)-α-methylbenzyl-(*S*)-aminopropionitrile which was hydrolyzed and hydrogenolyzed to form (*S*)-alanine. However, this mechanism is not likely, because reactions carried out at a higher ratio of cyanohydrine to amine did not yield higher optical purities of alanine, but rather lower values as shown in Tables 3 and 4. On the other hand, the dissociation of cyanohydrine to aldehyde and hydrogen cyanide should be considered. The yields and optical purities of alanine prepared from reactions A and B are almost the same; therefore, these reactions might proceed by the same reaction mechanism. The addition of hydrogen cyanide to Schiff bases composed of aldehydes and amines is a possible mechanism. Such a steric course has been described[7] but the mechanism is arbitrary. In order to understand the steric course of this reaction, *syn* and *anti* structures of the Schiff base must be determined under the reaction conditions. The results shown in Tables 1 and 2 indicate that the high optical purity of isolated alanine in the earlier reports[2,3] would be due to the fractionation during the final crystallization stage.

The Strecker type reaction was also carried out by the use of racemic lactonitrile with (*R*)-(−)-phenylglycine in aqueous conditions. The resulting *N*-substituted aminonitrile was hydrolyzed and hydrogenolyzed to convert the product into optically active alanine. The yields were rather high (56—85%); however, optical purities were low (12—17%). When (*R*)-(−)-phenylglycine was used, (*S*)-alanine was produced as in the case using (*S*)-(−)-α-methylbenzylamine.[8] The results are summarized in Table 4.

Experimental

All hydrogenolyses were carried out with a Parr 3910 Shaker type hydrogenation apparatus by using palladium hydroxide on charcoal or palladium on charcoal as a catalyst. All optical activity measurements were carried out on a JASCO ORD-CD-UV 5 spectropolarimeter.

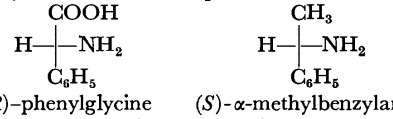
The specific rotations of optically active amines used were:
(*R*)-(+)-methylbenzylamine $[\alpha]_D^{25}$ +39.0°, benzene
(*S*)-(−)-methylbenzylamine $[\alpha]_D^{25}$ −38.5°, benzene
(*S*)-(−)-ethylbenzylamine $[\alpha]_D^{25}$ −20.0°, benzene
(*S*)-(−)-α-(1-naphthyl)ethylamine $[\alpha]_D^{25}$ −88.2°, benzene
(*R*)-(−)-phenylglycine $[\alpha]_D^{25}$ −168.0°, 5M HCl
Some of them are not completely optically pure (~95%); however, the optical purities of the resulting alanine are listed in the tables without corrections.

Syntheses of Amino Acids (Reaction A). To the solution of amine (0.012 mol) in absolute ethanol (20 ml) was added 1 ml of liqiud hydrogen cyanide (0.052 mol) at −10°C. Aldehyde (0.01 mol) was then added to the cold ethanolic solution. The sealed reaction mixture was shaken to homogenize the solution and was allowed to stand for 2 days at room temperature.

After the reaction was over, excess hydrogen cyanide and ethanol were evaporated under reduced pressure. The residue was refluxed with 20 ml of 6M hydrochloric acid for 12 hr. The hydrolyzate was extracted with ether to remove

7) In "Asymmetric Organic Reactions," by J. M. Morrison and H. S. Mosher, Prentice-Hall, Inc., Englewood Cliffs, New Jersey (1971), p. 328.

8) The steric structure of (*R*)-(−)-phenylglycine and (*S*)-(−)-α-methylbenzylamine could be expressed as shown below:



(*R*)-phenylglycine (*S*)-α-methylbenzylamine

If we regard the carboxyl and methyl groups as equivalent, the steric structures of (*R*)-(−)-phenylglycine and (*S*)-(−)-α-methylbenzylamine are the same.

Table 5. Elemental analyses of amino acids and *N*-alkyl amino acids

colored material. The hydrochloric acid was evaporated to dryness under reduced pressure. The residue was dissolved in a small amount of water and was applied to a Dowex 50 column (1.9 cm×23 cm, H^+ form) and eluted with 1.5 M aqueous ammonia. The fractions containing the amino acid were combined and the solution was evaporated under reduced pressure.

When optically active amines were used, the reaction products were treated in the same way. However, the resulting *N*-alkyl amino acids were not isolated to avoid fractionation of the diastereomeric mixture. The *N*-alkyl amino acids were dissolved in a mixture of ethanol and water (*ca.* 70 ml) and were hydrogenolyzed with 0.7 g of palladium hydroxide on charcoal for 12 hr. After hydrogenolysis was over, the catalyst was removed by filtration. The solution was evaporated under reduced pressure to give free α-amino acid. A part of the α-amino acid was converted into DNP-derivatives in the usual way. The resulting DNP-α-amino acids were purified by the use of a celite column treated with pH 7 citrate-phosphate buffer[9] to measure optical purities of resulting amino acids.

When racemic α-methylbenzylamine was used, the resulting racemic *N*-α-methylbenzylamino acids were isolated by means of a Dowex 50 column. Hydrogenolysis of these compounds with palladium hydroxide on charcoal resulted in the formation of racemic amino acids. The analytical results of these amino acids are summarized in Table 5. All of these *N*-substituted amino acids are sublimable at higher temperature.

Syntheses of Alanine (Reaction B). The freshly distilled racemic acetaldehyde cyanohydrine (0.71 g, 0.01 mol) and racemic amine were mixed with 20 ml of absolute ethanol under ice cooling. The reaction mixture was then kept at room temperature for 48 hr. After the reaction was over, ethanol was evaporated under reduced pressure. After evaporation of ethanol from the reaction mixture, the residue was dissolved in 20 ml of ethyl acetate. The solution was washed twice, with 20 ml of 1% aqueous sodium hydrogen carbonate, once with 20 ml of water and was dried over anhydrous sodium sulfate. The solution was evaporated under reduced pressure and distilled. When DL-α-methylbenzylamine was used, the DL-*N*-α-methylbenzylaminonitrile was isolated. Bp. 94—97°C/1.7 mmHg, yield, 1.2 g (66%). This was converted into its hydrochloride in ether treating with gaseous hydrogen chloride. The hydrochloride was recrystallized from ethanol. Mp. 141—142°C (decomp.).

Found: C, 62.43; H, 7.27; N, 13.40%. Calcd for $C_{11}H_{15}N_2Cl$: C, 62.70; H, 7.18; N, 13.30%.

The *N*-alkyl amino nitrile was hydrolyzed with 6 M hydrochloric acid. A part of the racemic *N*-α-methylbenzylalanine was isolated by means of a Dowex 50 column and recrystallized from ethanol and water for elemental analysis. Mp 270—273°C (sublime).

Found: C, 68.02; H, 7.71; N, 7.04%. Calcd for $C_{11}H_{15}NO_2$: C, 68.37; H, 7.82; N, 7.25%.

The rest of the *N*-substituted alanine was then hydrogenolyzed by use of palladium hydroxide on charcoal and the alanine was isolated as in reaction A (Found: C, 40.47; H, 8.05; N, 15.77%).

Optically active alanine was prepared in a similar way to that described above. This was recrystallized from water and ethanol for elemental analysis (Found: C, 40.24; H, 8.00; N, 15.71%).

A part of the unfractionated alanine was converted into DNP-derivative, and was purified by the use of a celite column as in reaction A. The results are summarized in Table 2.

Synthesis of Alanine (Reaction B). Using (R)-(−)-Phenylglycine: (*R*)-(−)-Phenylglycine, 1.51 g (0.01 mol) was dissolved in 25 ml of water containing 0.01 mol of sodium hydroxide. To this solution, 0.71 g (0.01 mol) of racemic acetaldehyde cyanohydrine was added under cooling in an ice bath. The mixture was allowed to stand for 2 days at room temperature. To this, 30 ml of 6 M hydrochloric acid was added and refluxed for 6 hr. The hydrolyzate was evaporated to dryness under reduced pressure. The residue was dissolved in 50 ml of water containing 0.02 mol of sodium hydroxide. The solution was subjected to hydrogenolysis by using 2.0 g of 5% palladium on charcoal for 12 hr. After the hydrogenolysis was over, the catalyst was removed by filtration and the aqueous solution was acidified to a pH of about 2.0—1.5 and then evaporated to dryness. Synthesized alanine hydrochloride was extracted with absolute ethanol. The ethanolic solution was evaporated. The alanine hydrochloride was applied on a Dowex 50 column (H^+ form) and eluted with 1.5 M aqueous ammonia. Fractions containing alanine were combined and evaporated to obtain free alanine. A part of the alanine was DNPylated and the optical purity of alanine was measured as described earlier. The results are summarized in Table 4.

This work was supported by Grant No. NGR-10-007-052 from the National Aeronautics and Space Administration.

Sterically Controlled Syntheses of Optically Active Organic Compounds. XX. Synthesis of Optically Active Alanine from α-Bromopropionamides[1]

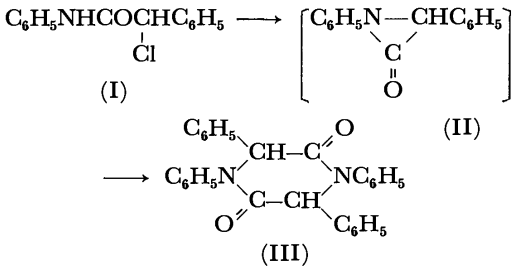
Tadashi OKAWARA and Kaoru HARADA

Institute for Molecular and Cellular Evolution, Department of Chemistry, University of Miami, 521 Anastasia Avenue, Coral Gables, Florida 33134, U.S.A.

(Received September 11, 1972)

The treatment of *N*-benzylchloroacetamide with sodium hydride resulted in the formation of *N,N'*-dibenzyldiketopiperazine which was converted to glycine after hydrolysis and hydrogenolysis. In a similar way, *N*-alkyl-α-bromopropionamides, in which the alkyl groups were chiral, were treated with sodium hydride and optically active alanine was obtained after hydrolysis and hydrogenolysis. When an optically active (*S*)-(−)- or (*R*)-(+)-α-methylbenzyl group was used as a chiral center, the optical activity of alanine was very low. When (*S*)-(−)-α-ethylbenzylamine was used, optically active (*S*)-alanine (optical purity 6—25%) was obtained. The use of (*S*)-(−)-α-(1-naphthyl)ethylamine resulted in the formation of (*R*)-alanine (opposite configuration, optical purity 23—27%). The overall yield of optically active alanine is in the range 11—36%.

It has been reported by Sarel and Ben-Shoshan that the α-chloropropionanilide was converted to *N*-phenyl-α-lactam by the action of sodium amide in liquid ammonia.[2] Sarel and Greenberger further reported[3] the chemical reaction of sodium hydride with α-chloro-α-phenylacetanilide (I) in dry benzene. The major product of this reaction was 1,3,4,6-tetraphenylpiperazine-2,5-dione (III), which could be converted to *N*-phenyl phenylglycine upon hydrolysis. In this reaction it was assumed that the three membered reactive intermediate (α-lactam) (II) dimerized to form a more stable six-membered ring product (III). In the inert solvent, only the dimerization reaction could take place to form the diketopiperazine derivative. Later it was reported that the postulated α-lactam and its corresponding diketopiperazine were isolated.[4] However, Sheehan and Frankenfeld[5] established that α-lactam was not found among the final products of the reaction of α-chloroanilides with sodium hydride. Baumgarten *et al.*[6] confirmed the existence of α-lactam spectroscopically. Since then, several α-lactam formations and their chemistry have been studied.[7-17]



(I) (II) (III)

In this paper, the syntheses of glycine and alanine from α-haloacylamides were examined. The α-haloacylamides were prepared from several benzylic amines by acylation with α-chloroacetyl anhydride or with α-bromopropionyl bromide. The benzylic amines used were benzylamine, (±)-α-methylbenzylamine, (*R*)-(+)-α-methylbenzylamine, (*S*)-(−)-α-methylbenzylamine, (*S*)-(−)-α-ethylbenzylamine, and (*S*)-(−)-α-(1-naphthyl)-ethylamine.

In the glycine synthesis, *N*-benzyl-α-chloroacetamide (IV, X=Cl, R_1=H, R_2=H, R_3=phenyl) was treated with sodium hydride in anhydrous tetrahydrofuran at varying temperatures (0, 25, and 50°C). After evaporation of the solvent and recrystallization of the residual material, *N,N'*-dibenzylpiperazine-2,5-dione (VI) was isolated. The VI was hydrolyzed and hydrogenolyzed to form glycine (overall yield 17 to 52%).

b) Specific rotation of DNP-anlanine was measured in 1M NaOH.
c) Defined as $[\alpha]_D$ obsd/$[\alpha]_D$ of the compound ×100. DNP-(*S*)-(+)-Alanine, $[\alpha]_D^{25}$ +143.9° (1M NaOH).
d) The yields are calculated from *N*-alkyl-α-haloacidoamide by using automatic amino acid analyzer.

In a similar way, several α-bromopropionamides (IV, X=Br, R_1=CH_3, R_2=Me or Et, R_3=phenyl or naphthyl) were prepared from racemic α-bromopropionyl bromide with racemic and also optically active α-alkylbenzylamines and optically active α-(1-naphthyl)ethylamine. Table 1 shows the physical properties and elemental analyses of *N*-alkyl-α-bromopropionamides prepared. At varying temperatures, the compounds (IV) were treated with sodium hydride in dioxane as in the synthesis of glycine. After hydrolysis and hydrogenolysis of the reaction products, alanine was obtained in 11 to 36% yield. The reaction conditions, configurations, optical purities, and yields of alanine are summarized in Table 2.

As shown in Table 1, *N*-α-methylbenzyl-β-bromopropionamides were prepared using (*S*)-(−)-α-methylbenzylamine and (*R*)-(+)-α-methylbenzylamine. The melting points of these amides are identical and the magnitude of specific rotations are the same (the signs of rotation are opposite each other). However, this might not mean that the configurations of α-bromopropionyl residue of the prepared amides are racemic. It could be possible that the fractionation took place during amide formation, isolation, and purification. However, from the results shown in Table 2, the possible fractionation of the diastereomeric starting material seems not great.

The reactions were carried out at 0, 25, and 50°C. The yields of optically active alanine at these temperatures are not much different. The optical purities of alanine by the use of α-methylbenzylamine are usually low (0—2.5%) at all temperatures. The optical purity of alanine prepared using (*S*)-(−)-α-ethylbenzylamine at 0°C is rather low (6%); however, it increased considerably at higher temperatures (25% at 25°C, 22% at 50°C). The optical purities of alanine prepared

with (*S*)-(−)-α-(1-naphthyl)ethylamine are rather high at all temperatures (24—27%) and the configuration of alanine is opposite to that prepared with (*S*)-(−)-α-ethylbenzylamine.

As shown in Table 2, the yields and optical purities of the resulting optically active alanine depending on the reaction time do not show a clear relation with the reaction time. This suggests that the reactions do not follow a simple kinetic resolution type mechanism.

In this experiment, the resulting partially optically active alanine was isolated by the use of an ion exchange resin and the resulting crude alanine was converted to DNP-alanine. The partially optically active DNP-alanine was purified by the use of celite column chromatography[18] without fractionation of optical isomers.[19]

Experimental

The specific rotations of optically active amines were:
(*R*)-(+)-α-methylbenzylamine, $[\alpha]_D^{25}$ +41.5° (benzene)
(*S*)-(−)-α-methylbenzylamine, $[\alpha]_D^{25}$ −42.3° (benzene)
(*S*)-(−)-α-ethylbenzylamine, $[\alpha]_D^{25}$ −21.0° (benzene)
(*S*)-(−)-α-(1-naphthyl)ethylamine, [α]- −86.5° (benzene)

Hydrogenolysis was carried out using the Parr 3910 shaker type hydrogenation apparatus. The accuracy of reaction temperatures is about ±1°C. All optical activity measurements were carried out on the JASCO ORD-CD-UV 5 spectropolarimeter.

N-Benzylchloroacetamide (IV, X=Cl, R_1=H, R_2=H, R_3=phenyl). Benzylamine, 10.7 g (0.10 mol) and monochloroacetic anhydride, 17.1 g (0.10 mol), were dissolved in 200 ml of dry benzene and the solution was refluxed gently for 3 hr. After the reaction was over, the benzene solution was washed with 100 ml each of 1 M hydrochloric acid, 7% sodium hydrogen carbonate, and water. The benzene solution was dried with anhydrous sodium sulfate and the benzene was removed under reduced pressure. The residual material was recrystallized from 95% ethanol, yield 14.2 g (77%) mp 92—93°C.

Found: C, 58.68; H, 5.41; N, 7.30%. Calcd for $C_9H_{10}NOCl$: C, 58.86; H, 5.49; N, 7.63%.

N,N'-Dibenzylpiperazinedione (VI, R_1=H, R_2=H, R_3=phenyl). Sodium hydride (60%, 0.4 g, 0.01 mol) was suspended in 50 ml of anhydrous tetrahydrofuran (THF). To this was added slowly a solution of 1.84 g (0.01 mol) of IV in 30 ml of anhydrous THF during a period of 2 hr under cooling with ice water. After the addition was over, the solution was kept at room temperature under agitation for an additional 12 hr. After the reaction was over, precipitated sodium chloride was removed by filtration. The filtrate was divided equally into two portions. One portion was evaporated to dryness and the residue was recrystallized from ethanol, yield of VI, 0.23 g (yield 32% from IV), mp 178—180°C.

Found: C, 73.52; H, 6.21; N, 9.32%. Calcd for $C_{18}H_{18}N_2O_2$: C, 73.45; H, 6.16; N, 9.52%.

The other portion of the filtrate was evaporated to dryness under reduced pressure, and the residue was refluxed with 20 ml of 6 M HCl for 6 hr. After the hydrolysis was over, hydrochloric acid was removed under reduced pressure and the residue was applied to a Dowex 50 column (H^+ form, 19×23 cm) and *N*-benzylglycine was eluted with 1M aqueous ammonia after washing with water. The fractions containing *N*-benzylglycine were combined and evaporated. The residue was dissolved in ethanol–water mixture (1 : 1 in volume) and was hydrogenolyzed by the use of 5% palladium on charcoal. After removal of the catalyst by filtration, the filtrate was evaporated under reduced pressure. The yield of glycine was measured by automatic amino acid analyzer after appropriate dilution, yield 17.3% from I. The glycine was recrystallized from water and ethanol for elemental analysis (Found: C, 31.74; H, 6.78; N, 18.63%).

N-(+)-α-Methylbenzyl-(±)-α-bromopropionamide (IV, X=Br, R_1=Me, R_2=Me, R_3=Phenyl). The solution of (±)-α-methylbenzylamine, 12.1 g (0.1 mol), was added slowly to the solution of (±)-α-bromopropionylbromide, 10.8 g (0.05 mol), in 20 ml of benzene over a period of 1 hr under cooling with ice water. The racemic α-methylbenzylamine hydrochloride was crystallized out during the reaction. The reaction mixture was stirred for 2 hr at room temperature. The precipitated compounds were filtered and washed with benzene (60 ml) to remove amide. The benzene solution was washed with 50 ml each of 1 M hydrochloric acid, 5% sodium hydrogen carbonate, and then with water. The benzene solution was dried by anhydrous sodium sulfate. After the sodium sulfate was removed by filtration, the filtrate was evaporated to dryness under reduced pressure. The residue was recrystallized from 95% ethanol, yield 7.8 g (61%), mp 129—130°C.

Other amides were prepared in a similar way. The physical properties and elemental analyses of these α-bromopropionamides are summarized in Table 3.

(S)-Alanine (VII) from N-Alkyl-α-bromopropionamide (IV, X=Br, R_1=Me, R_2=Me, R_3=phenyl). The solution of *N*-(*S*)-(−)-α-methylbenzyl-α-bromopropionamide (IV), 1.3 g (0.005 mol), in anhydrous dioxane (20 ml) was added slowly to a suspension of sodium hydride (60%, 0.2 g, 0.005 mol) in anhydrous dioxane (20 ml) during a period of 1 hr at room temperature. After the addition was over, the reaction mixture was stirred at room temperature for another 36 hr.

The precipitated sodium bromide was removed by filtration. The filtrate was evaporated under reduced pressure and the residue was refluxed with 30 ml of 6 M HCl for 6 hr. The hydrolyzate was extracted with ether and the hydrochloric acid was evaporated to dryness under reduced pressure. The residue was dissolved in a small amount of water and was applied on a Dowex 50 column (H^+ form). The column was eluted with 1 M aqueous ammonia after washing the column with water. The fractions containing *N*-alkylalanine were combined and evaporated to dryness. The residual *N*-alkylalanine was dissolved in water and alcohol mixture (1: 1) and was hydrogenolyzed with 0.5 g $Pd(OH)_2/C$ for 12 hr. After the hydrogenolysis was complete, the catalyst was removed by filtration. Part of the solution was diluted in the proper way and was analyzed by an automatic amino acid analyzer to determine the yield of alanine, 19.7%. The other part of the alanine solution was evaporated to dryness and the residue was recrystallized from water and ethanol for elemental analysis of alanine (Found: C, 40.03; H, 7.84; N, 15.34%).

The other part of the alanine solution was converted to its DNP-derivative in the usual manner. The resulting DNP-alanine was purified by the use of a celite column treated with pH 7 citrate-phosphate buffer.[18] The yields, specific rotations, and optical purities of alanine preparations are summarized in Table 2.

This work was supported by Grant No. NGR-10-007-052 from the National Aeronautics and Space Administration. The authors wish to express their thanks to Dr. Kazuo Matsumoto for discussions and to Mr. Charles R. Windsor for amino acid analyses.

A Theoretical Treatment of the Fragmentation Rules in the Mass Spectrometry of Organic Compounds[1]

Hiroshi ICHIKAWA and Michihiko OGATA

Hoshi College of Pharmacy, Ebara, Shinagawa-ku, Tokyo 142

(Received September 27, 1972)

The statistical theory of mass spectra[2-4] (QET) has clearly accounted for the fragmentation of saturated hydrocarbons. This approach, however, seems not to be readily adaptable to a general appreciation of the fragmentation of complex organic molecules, such as those of particular interest to organic chemists. Meanwhile, independently of the theoretical works,[5] organic chemical approaches[6] have provided some simple rules for break-down processes. These rules have been successful in predicting the major fragmentation paths of various compounds.[7] We will here propose a theoretical treatment of the fragmentation rules in terms of the QET and, at the same time, an interpretation of the relationship between the fragmentation rules and the QET.

Theory

According to the Bell[8] and Evans and Polanyi[9] (BEP) principle, the activation energy, ΔE, for a given reaction can be written in a linear form:

$$\Delta E = X + Y\Delta H, \tag{1}$$

where X and Y are constants in the same system and where ΔH is the heat of the reaction.

The QET provides several correlation formulae between the rate constant (k) and the activation energy (ΔE). Among them, for the model composed wholly of harmonic oscillators the general expression[3] in the rate constant is simply:

$$k = \nu\left(\frac{E-\Delta E}{E}\right)^{s-1}, \tag{2}$$

where E is the internal energy, ν is a constant with the dimension of cm^{-1}, and s is the effective number of degree of freedom.

If Eq. (1) holds in the mass-spectral reactions, then the ratio of the rate constants, k_1/k_2, for any two of the fragmentation paths:

$$\begin{array}{ccc} (\text{P–Q–R})^{\cdot+} & \xrightarrow[\text{Path A}]{k_1} & (\text{P–Q} + \text{R})^{\cdot+} \\ \text{Path B}\ \downarrow k_2 & & \\ (\text{P} + \text{Q–R})^{\cdot+} & & \end{array}$$

will be given by:

$$\frac{k_1}{k_2} = \left(\frac{E'-\Delta H_1}{E'-\Delta H_2}\right)^{s-1}, \tag{3}$$

where $E'=(E-X)/Y$.

Equation (3) indicates that the fracture occurs more predominantly at the position which gives the smallest ΔH; one can predict the most probable position of bond-scission by simply comparing the sum of the total energies of the fragments. That is, if the total energy of the $(\text{P–Q} + \text{R})^{\cdot+}$ state is lower than that of the $(\text{P} + \text{Q–R})^{\cdot+}$ state, the fragmentation path A will be more important.

a) Calculated by the open-shell CNDO/2 method.
b) The difference of the energies, E(radical)+E(cation)−E(molecule ion).
c) Asterisk indicates the most abundant fragmentation. See Ref. 7.

The adaptability of Eq. (3) may be responsible for the BEP principle. This principle has proved extremely valuable in a variety of chemical reactions.[10] With regard to mass-spectral reactions, some authors[11] have pointed out that the stability of the produced fragments plays an important role in the cleavage reaction. Actually, it should be pointed out that in the establishment of the fragmentation rules,[6,7] the stability of the produced fragments, based on the consideration of the ground-state chemical structure, has always been taken into account. These facts indicate that the fragmentation rules represent the approximate reactions of the electronically ground-state ion,[12] that the BEP principle mostly holds in the mass-spectral reactions, and that, therefore, the fragmentation rules suggest the path with the lower activation energy.

Results

The total energies of several cations and radicals obtained by means of the CNDO/2 method are listed in Table 1. The combination of these fragments would give a variety of fragmentation modes. Shown as examples in Table 2 are ΔH values calculated for the fragments given by the skeletal-bond cleavages of some simple amines and 1-butene, which are selected as model compounds showing the β-bond cleavage.[13] The positive charge should be put on the fragment with the lower I_p value so that the total energy of the system is made as low as possible.

The sum of the total energies of the fragments which are formed by the β-bond cleavage is generally the least, indicating that such a β-bond is most inclined to cleave. Though being qualitative, these results, of course, agree with the experimental results. We believe that the application of this method to various compounds will prove its validity and that it is possible to some extent to predict the quantitative abundance of the bond-scission for the ground-state molecule ion. Finally, though the CNDO/2 method is not well adaptable to the estimation of the total energy, as the results indicate, the method is sufficiently useful for such a qualitative problem as bond-scission.

The calculations were carried out on a HITAC 5020E computer at the Computation Center of the University of Tokyo.

Phase Diagram of the Phenanthrene/Carbazole-Picric Acid System

Shigeo KOIZUMI* and Yoshio MATSUNAGA**

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received October 20, 1972)

By means of differential scanning calorimetry, it has been found that phenanthrene picrate exhibits an enantiotropic transition at 77 °C in addition to the one at 106 °C reported by Kofler.[1,2] The recovery of the low-temperature form is so slow that the newly-found transition cannot be observed in the second run if it is examined immediately after the first heating. Furthermore, the addition of anthracene, a major impurity in phenanthrene, has been found to slow down the recovery. As carbazole is another major impurity in phenanthrene, an examination of the phenanthrene/carbazole picrate seemed to be desirable in order to confirm the effects of impurities on the above-mentioned phase-transition.

Phenanthrene, Eastman white label, was purified according to the method reported by Feldman *et al.*,[3] and then by zone-refining. After these processes, the content of anthracene was estimated to be less than 10^{-4} mol%, because the electronic absorption maximum located at 376 nm characteristic of anthracene was no longer detectable in a cyclohexane solution. Carbazole from the Koso Chemical Co. was refluxed with acrylonitrile in toluene for ten hours to remove the anthracene, and was then recrystallized twice from benzene. Picric acid, Wako special reagent grade, was purified by recrystallization from ethanol. The picrates were crystallized from methanol containing equimolar amounts of the component compounds. Although mutual solid solubility in many pairs of molecular complexes has been examined by Rheinboldt and Senise[4] and by Lower,[5] phenanthrene/anthracene-*s*-trinitrobenzene is the only system for which a phase diagram has been described in detail. Consequently, we decided to look into the whole system rather than just the phenanthrene-rich region. Samples were prepared by melting powdered mixtures with known ratios of the parent complexes. The composition is quoted in the mole percentage of the carbazole. After storage at room temperature for a week, the melting points and transition temperatures were determined using a Rigaku Denki differential scanning calorimeter, Model 8001 SL/C, at a heating rate of 3 °C/min. X-Ray measurements on powdered samples were made at room temperature with a Toshiba recording diffractometer, Model ADG-301, using filtered copper radiation.

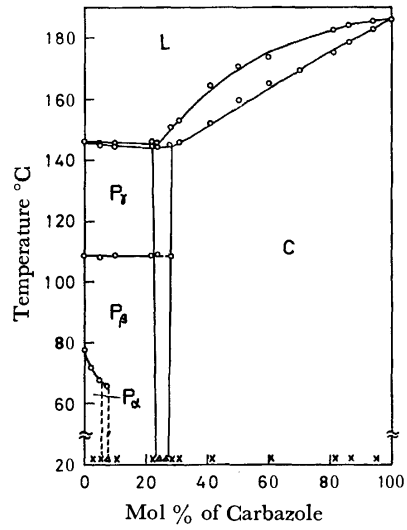

Fig. 1. The phenanthrene/carbazole-picric acid phase diagram.
○: calorimetric points, ×: single phase by X-ray diffraction, △: two phases by X-ray diffraction.

The experimental points determined by calorimetry are plotted in Fig. 1. This diagram is of the same type as that of the phenanthrene/anthracene-*s*-trinitrobenzene reported by Lower,[5] and shows the formation of two series of solid solutions, P and C, based on the two parent complex lattices, which have not previously been known. A eutectic occurs at about 24 mol% carbazole and at 145 °C. This temperature is nearly the same as the melting point of pure phenanthrene picrate. Therefore, the solidus and liquidus are almost flat and coincide with each other in the phenanthrene-rich region. The first phase-transition in the phenanthrene picrate is markedly lowered by the addition of small amounts of the carbazole picrate; *e.g.*, it becomes 66 °C at 6.86 mol%. Above this composition, the $P_\alpha \rightarrow P_\beta$ transition could not be detected by calorimetry. This result is similar to that reported for the phenanthrene/anthracene picrate.[1] Therefore, it is certain that carbazole can affect the rate of recovery as much as anthracene does. The X-ray examination revealed that the solid solution containing 5.12 mol% carbazole is single-phase, while those containing 5.91 and 6.86 mol% are mixtures of the P_α and P_β terminal solid solutions, indicating that the equilibrium condition could not be established by one week's storage. If the solid solutions containing more carbazole could be well annealed, the phase boundary between P_α and P_β would extend to about 22 mol%. On the other hand, the second phase-transition temperature is essentially independent of the composition and is detectable as

far as 28 mol% carbazole. Above 26 mol%, the X-ray diffraction pattern recorded at room temperature is clearly that of the carbazole picrate, although the lattice constants increase more or less upon the addition of phenanthrene; *e.g.*, a diffraction peak located at 12.82° in the pure carbazole picrate moves to 12.30° at 30 mol% carbazole. This change corresponds to an increase of 0.30 Å in the distance of 6.91 Å in the pure carbazole picrate. The presence of a narrow miscibility gap, the width of which could be influenced by non-equilibrium effects, was confirmed by the X-ray data, as is indicated in Fig. 1.

The authors wish to express their thanks to Professor Toshio Yokokawa for letting them use the X-ray diffractometer and to Dr. Eiji Osawa for his advice concerning the purification of carbazole.

Infrared Spectra of CO and O_2 Adsorbed on Tungsten

G. BLYHOLOER and Masako TANAKA*

Department of Chemistry, University of Arkansas, Fayetteville, Arkansas 72701, U.S.A.

(Received January 17, 1973)

While adsorption on tungsten surfaces has received much attention[1] from workers using field emission and field ionization microscopy, LEED and flash desorption techniques there has been no successful room temperature infrared spectroscopic work reported for species chemisorbed on tungsten. Since no single technique gives a definitive view of chemisorption, it is desirable to have information from as many different techniques as possible. The main difficulty to applying the usual infrared methods[2] in surface chemistry to tungsten is its refractory nature which makes obtaining it in a highly dispersed form difficult. In the only reported[3] attempt to work with tungsten, a technique which involves evaporating a thin film of metal onto a salt plate at 170 K and then admitting the adsorbate was tried. This method produced spectra for CO on Ni, Co, Fe, and Ir but not for tungsten. If the tungsten was evaporated in 10^{-2} Torr of CO, a weak band appeared at 1970 cm^{-1} but this disappeared upon warming to room temperature. This raises the question as to whether tungsten is different from the other transition metals for which infrared spectra of adsorbed CO and other gases have been obtained.

The wide spectral range experimental technique, which has been described in detail elsewhere,[4] consists of evaporating tungsten from a filament made by twisting together 4 strands of 0.06″ diameter tungsten wire. The evaporated metal deposits in a purified hydrocarbon oil film on the salt windows of an infrared cell. Spectra are recorded before and after admission of the gas to be studied. The spectra were recorded on a Perkin-Elmer Model 457 spectrometer.

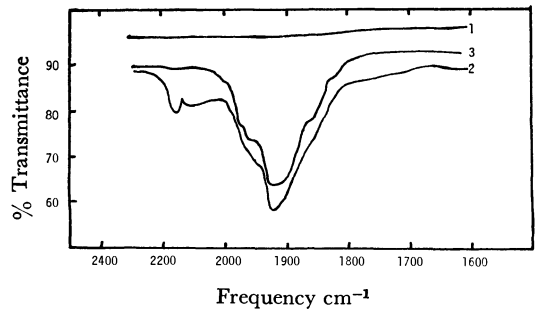

Fig. 1. Infrared spectra of CO adsorbed on tungsten. 1) background; 2) 50 Torr CO for 16 hr at room temperature; 3) evacuated at 10^{-5} Torr for 1.5 hr.

Infrared spectra of CO adsorbed on tungsten are shown in Fig. 1. After exposure to 50 Torr of CO for 16 hr at room temperature the result is curve 2, which has a band maximum at about 1920 cm^{-1} and a major shoulder at 1950 cm^{-1} as well as several lesser shoulders. The bands in the 2100—2200 cm^{-1} region are due to gas phase CO. The intensity of the band in the 1900 cm^{-1} region did not decrease appreciably after evacuation of the cell for 1.5 hr as shown in curve 3.

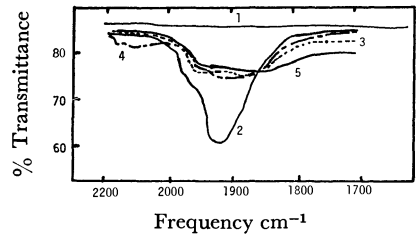

Fig. 2. Effect of heating. 1) background; 2) chemisorbed CO; 3) evacuated at 100°C for 1 hr.; 4) reexposed to 50 Torr CO for 16 hr.; 5) additional evacuation at 150 °C for 45 min.

The effect upon the spectra of mild heating is shown in Fig. 2, where curve 2 is for chemisorbed CO in an evacuated cell at room temperature. Evacuating and heating at 100 °C for 1 hr greatly decrease the band

intensity in the 1920 cm^{-1} region as shown in curve 3. The permanent nature of the change caused by heating is demonstrated by exposing the cell to 50 Torr of CO for 16 hr and observing that curve 4 shows little change after this treatment. Again the bands in the 2100 cm^{-1} region are due to gas phase CO. Curve 5 shows the sample after further evacuation at 150 °C for 45 min. After noting that the background at lower wave numbers has been shifted it is evident that this last treatment has further reduced the absorption in the 1920 cm^{-1} region while that at 1970 cm^{-1} is much less decreased by the heat treatments.

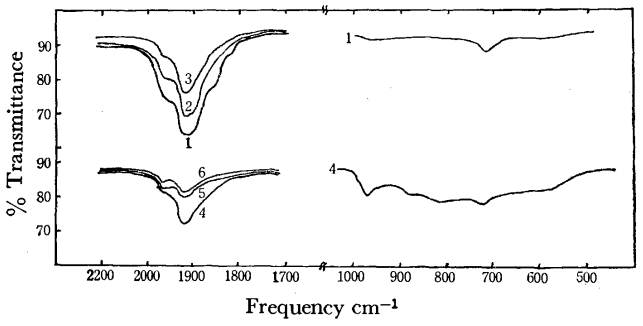

Fig. 3. O_2 addition to chemisorbed CO. 1) chemisorbed CO; 2) exposed to 30 Torr O_2 at room temperature; 3) after 6.5 hr exposure to O_2; 4) after 12 hr with 90 Torr O_2; 5) after 90 Torr O_2 at 100 °C for 30 min.; 6) evacuation at 100 °C for 5 min.

The effect of added O_2 on the chemisorbed CO is shown in Fig. 3, where curve 1 is for chemisorbed CO and the band at 720 cm^{-1} is a background oil band. After exposure to 30 Torr of O_2 at room temperature the chemisorbed CO band intensities decreased as shown in curve 2. Further exposure to O_2 for 6.5 hr gives curve 3 while 90 Torr of O_2 for 12 hr results in curve 4. By this time a broad band from 500 to 1000 cm^{-1} and a sharper band around 965 cm^{-1} have become evident. Heating the cell at 100 °C with 90 Torr of O_2 for 30 min further reduced the intensity around 1920 cm^{-1} while not changing the intensity near 1970 cm^{-1} as indicated by curve 5. Evacuation for 5 min at 100 °C resulted in curve 6.

In order to understand the bands resulting from the O_2 treatment of chemisorbed CO, a freshly evaporated tungsten surface was exposed to 115 Torr of O_2 at room temperature. The spectra obtained after 1.5 and 5 hr, shown in Fig. 4, reveal the formation of a broad absorption from 500 to 1000 cm^{-1} and a peak at 970 cm^{-1}.

In reviewing these results it is evident that tungsten

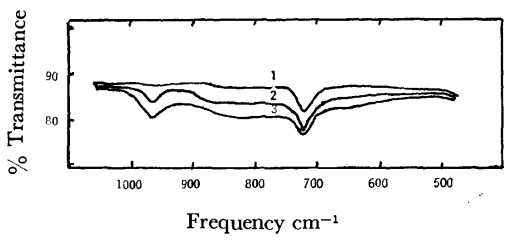

Fig. 4. O_2 adsorption on tungsten. 1) background; 2) 115 Torr O_2 at room temperature for 1.5 hr.; 3) 115 Torr O_2 at room temperature for 5 hr.

does indeed behave similarly to other transition metals with respect to the infrared spectra of chemisorbed CO. Since so much work has been done by other techniques on tungsten, it is good to have this additional evidence that tungsten is not unrepresentative of transition metals in general. The question may arise as to whether the oil matrix changes the chemical character of the metal surface. At least with respect to CO adsorption the answers seems to be no. Infrared spectra, where obtainable, for CO adsorbed on metals evaporated in high vacuum onto salt plates[3,5-7] or into an argon matrix[8,9] are like those for oil-matrix metals.[10] The spectrum obtained here by CO on tungsten is most like those for Cr, which is directly above it in the periodic table, and V which is above and one group to the left.

The decrease in infrared band intensity upon heating is more likely due to sintering than to simple thermal desorption since it occurs at 100 °C whereas the first major desorption in flash filament work occurs in the 150 to 200 °C range. That sintering can be a major cause of an infrared band intensity decrease is also shown in work with Ni in an argon matrix.[9] Noting the sintering effect and the fact that for spectra of CO on metals evaporated directly onto salt plates the intensities are always very low, it appears that most of the CO causing the large broad band centered around 1920 cm^{-1} is on surface tungsten atoms that have a low coordination number, *i.e.* that are not part of a high atom density surface plane. In view of the metal being evaporated in such a way as to inhibit sintering it is not surprising that there is large number of such sites. The band intensity around 1970 cm^{-1} suffers a less drastic decrease upon heating and oxygen treatment, suggesting that a part of this intensity is due to CO on the high atom density surface planes.

The spectral results of oxygen addition to chemisorbed CO shown in Fig. 3 indicate that the CO is displaced by the oxygen and new bands for surface species are produced in the 500 to 1000 cm^{-1} region. Subsequent adsorption of O_2 on fresh tungsten shows these bands to be entirely due to oxygen on tungsten. Thus tungsten does not behave like Ni where O_2 addition to surface CO produces a surface CO_3 species.[11]

The infrared bands produced by oxygen adsorption are quite similar to bands for tungsten oxides. Weltner and McLeod[12] report that the frequency of the terminal W=O stretch in W_2O_6 and W_3O_8 is at 989 cm^{-1} and

that WO_3 has a strong band at 1007 cm^{-1}. This leads to our assigning the 970 cm^{-1} band to a terminal W=O structure at the surface. The broad band in the 500—1000 cm^{-1} region is presumed due to the W–O–W structure since many W_nO_m compounds have several weak bands in this region. Thus on tungsten samples suitable for infrared studies the adsorption of O_2 is clearly dissociative. No infrared bands corresponding to O–O stretches were found. The formation of a surface structure in which an oxygen atom has a double bond to a metal atom has been found previously for V[13] and Cr[14] but not for transition metals to the right of group VIB such as Mn, Fe, Co, and Ni, which we have investigated.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1878—1880 (1973)

The Synthesis of Some New Europium(II) Vanadites

Tsutomu SHIN-IKE, Ginya ADACHI,* and Jiro SHIOKAWA*

Department of Chemistry, Osaka Dental Universtiy, Makino-honmachi, Hirakata-shi, Osaka 573

(Received May 12, 1972)

This paper is concerned with the preparation of some new europium (II) double oxides by reactions between europium (II) and vanadium (III) oxides, and with the determination of their crystal structures.

Europium (III) double oxides with vanadium have been prepared previously,[1,2] but no report has appeared regarding the double oxide containing the bivalent europium ion.

We succeeded in synthesizing the double oxides containing the bivalent europium ion. The crystal structures of the double oxides were determined by an X-ray diffraction method.

Experimental

Materials. Europium sesquioxide of a 99.9% purity from the Lindsay Chemical Division, American Potash & Chemicals, vanadium trioxide of a special reagent grade, and graphite of a spectroscopic grade were all used without further purification.

The europium mono-oxide (EuO) was prepared by reducing europium sesquioxide with graphite, as has been described in the literature.[3]

Procedure. The europium mono-oxide was thoroughly mixed with vanadium trioxide by grinding in a mortar, and then pressed at 100 kg/cm^2 to a pellet. The pellet was placed in a graphite crucible and heated in an induction furnace at 1500 °C for a few minutes *in vacuo* ($\sim 10^{-4}$ mmHg).

Analyses. X-Ray diffraction patterns of the products were obtained with a Rigaku Denki Geiger-Flex D-6C diffractometer, using Ni-filtered Cu-Kα radiation at a scanning rate of 1° (2θ)/min.

The atomic ratios of europium to vanadium were determined by means of a Rigaku Denki X-ray fluorescent spectrograph unit with an NaI(Tl) scintillator, a tungsten target X-ray tube, and a lithium fluoride analyzing crystal.

Results and Discussion

The products, the color of which was black, were examined by the X-ray diffraction method. The X-ray diffraction patterns of the samples and the analyzed atomic ratios of europium to vanadium are shown in Fig. 1. The X-ray diffraction pattern, shown in Fig. 1 (a), is similar to that of Eu_2TiO_4,[4] which belongs to a tetragonal system. It seems, therefore, that the crystal structure of this compound is the same as that of Eu_2TiO_4. The arrangement of the ions in this compound may be considered to consist of alternate layers of rocksalt EuO and perovskite $EuVO_3$, as is shown in Fig. 2. Thus, by assuming that the unit cell dimensions of the product are a_0=3.856 Å and

a) Relative intensities.

The density of this compound as observed by the conventional pycnometric method was 3.76 g cm^{-3}, very close to the value of 3.79 g cm^{-3} calculated using the unit cell dimensions and supposing the existence of two molecules of Eu_2VO_4 per unit cell.

When this compound was heated at 1400 °C *in vacuo* for more than 10 min, the peaks in the X-ray pattern assigned to Eu_2VO_4 gradually disappeared, while new peaks appeared. These peaks seemed to be due to another new double oxide, $Eu_3V_2O_7$, in which a

rocksalt-type EuO might be located at every two layers of perovskite-type $EuVO_3$. The X-ray diffraction data, given in Table 2, are indexed on a tetragonal cell with a_0=3.94 Å and c_0=19.52 Å. The reason why $Eu_3V_2O_7$ was formed may be that EuO was volatile at high temperatures, if so, the following reactions would occur:

$$2Eu_2VO_4 \longrightarrow Eu_3V_2O_7 + EuO\uparrow \quad (1)$$

The $Eu_3V_2O_7$ does not seem to be quite stable at such high temperatures, since the X-ray pattern of this compound gradually disappeared during the long period of heating. The final product was $EuVO_3$, which has the same distorted perovskite structure as the lanthanide-vanadites.[5] The $EuVO_3$ must be formed as follows:

$$Eu_3V_2O_7 \longrightarrow 2EuVO_3 + EuO\uparrow \quad (2)$$

The cell constants of $EuVO_3$ were a_0=3.88 Å, b_0=3.84 Å, c_0=3.88 Å, and β=92.50° in a monoclinic system. Both the calculated and the observed *d*-values are shown in Table 3.

5) S. Geller, *Acta Crystallogr.*, **10**, 219 (1957).

When the Eu_2VO_4 prepared was heated in air, both $EuVO_4$ and Eu_2O_3 were formed by oxidation. This fact was confirmed by X-ray diffraction analyses. If the following reaction is supposed to occur, the weight gain should be 5.73%:

$$2Eu_2VO_4 + \frac{3}{2}O_2 \longrightarrow 2EuVO_4 + Eu_2O_3 \qquad (3)$$

The observed weight gain, on the contrary, was 7.8% Therefore, it seems that the product was a non-stoichiometric compound, like Eu_2VO_{4-x} ($0.5 \geq x \geq 0$), in which the oxygen-deficient perovskite-type $EuVO_{3-x}$ was contained, and that the reaction was as follows:

$$4EuO + V_2O_3 \longrightarrow 2Eu_2VO_{3.5} \qquad (4)$$

If excess vanadium trioxide was added, or if the reaction time was prolonged, both Eu_2VO_4 and $Eu_3V_2O_7$ were formed (see Fig. 1 (b)). If much more vanadium trioxide was used, $EuVO_{3-x}$ was formed in addition to Eu_2VO_4 and $Eu_3V_2O_7$ (see Fig. 1 (c) and (d)).

By another procedure, one in which Eu_2O_3, V_2O_3, and graphite were mixed together, in spite of using EuO and V_2O_3, and then heated in an induction furnace at 1400 °C for an hour *in vacuo*, Eu_2VO_{4-x} was also obtained.

Nonbridging Ligand Effects on the Reduction of Nitrilopolyaminocarboxylato-cobalt(III) Complexes by Iron(II)

Kousaburo OHASHI

Department of Chemistry, Ibaraki University, Mito 310

(Received August 19, 1972)

The effects of the nonbridging ligand on the rate of electron-transfer reactions between $Co(ox)N_4^+$-type complexes ($N_4=(NH_3)_4$, $(en)_2$, trien, $(phen)_2$, and $(dpy)_2$) and Fe^{2+} have been reported in a previous paper.[1] The results show that the variation in the rate is mainly due to the change in the enthalpy of activation. It is of interest to investigate systematically how the nonbridging ligands affect the enthalpy and entropy of activation in the Fe^{2+} reduction of the cobalt(III) complexes. The author wishes now to report on the nonbridging ligand effects on the reactivities of the nitrilotriacetato- and ethylenediamine-*N*,*N*′-diacetatocobalt(III) complexes with Fe^{2+}.

Experimental

Materials. The *cis*-α-$[Co(edda)(NH_3)_2]ClO_4$,[2,3] *cis*-α-$[Co(edda)(en)]ClO_4$,[2] $[Co(nta)(en)]$,[4,5] *trans*-(N)-K$[Co(nta),(am)]$,[6] (am=glycine, β-alanine, and γ-aminobutyric acid) were prepared by methods similar to those described in the references cited. The $Co(nta)(H_2O)(NH_2CH_2CH_3)$ solution was prepared by the dissolution of $K[Co(nta)(NH_2CH_2CH_3)(OH)]$, which has itself been prepared by modifying the method of the preparation of $[Co(nta)(en)]$[4] into a perchloric acid solution. The $Co(edda)(H_2O)_2^+$ and the $Co(nta)(H_2O)_2$ solutions were prepared by the equation of *cis*-α-Na$[Co(edda)Cl_2]$ and the dissolution of $K[Co(nta)(H_2O)(OH)]$ respectively into the perchloric acid solution.

The preparation of the iron(II) solution and the determinations of the concentrations of iron(II), the perchlorate ion, and the hydrogen ion were carried out by methods similar to those described in a previous paper.[7] Reagent-grade chemicals were used for the preparation of the reaction mixtures.

Kinetic Measurements. The reactions were followed spectrophotometrically by observing the decrease in the absorbance of the Co(III) complexes at a wavelength in the vicinity of the first absorption maximum. The determinations of the rate constants of *cis*-α-$Co(edda)(NH_3)_2^+$ and *cis*-α-$Co(edda)(en)^+$ were performed in the temperature range of 50—80 °C because of the very small solubility and reactivities of these complexes. The rate constants at 25 °C were obtained by the extrapolation of the Arrhenius plots. In the course of the reactions, the decompositions of none of the complexes were observed under the conditions adopted.

Results and Discussion

The rate constants and the activation parameters are listed in Tables 1 and 2. The reactions of *cis*-α-$Co(edda)(en)^+$ were followed under the conditions of $[H^+]=0.86$ M and $\sum[ClO_4^-]=2.45$ M; the rate constant at $\sum[ClO_4^-]=1.00$ M, $[H^+]=0.36$ M, and 25 °C should be slightly smaller than 1.65×10^{-3} $M^{-1}\cdot s^{-1}$.

The relationship between the second-order rate constant and the hydrogen ion concentration for Co(nta)(en) is shown in Fig. 1. Similar hydrogen ion effects were also observed for the *cis*-α-$Co(edda)(H_2O)_2^+$ and *cis*-α-$Co(edda)(NH_3)_2^+$. In the cases of the Fe^{2+} reduction of the positively-charged and noncharged Co(III) complexes, not such a large effect of the hydrogen ion is observed, though it has been found that the hydrogen

ion slightly accelerates the Fe^{2+} reduction rates of some negatively-charged Co(III) complexes.[8,8a] The mechanism of the hydrogen-ion dependence has not yet been made clear.

Though the electron-transfer mechanism could not be ascertained directly, it is reasonable to assume that these reactions occure *via* an inner-sphere mechanism, since the reductions of Co(HY)(H_2O), and Co(YOH)(H_2O) (Y^{4-}=the ethylenediaminetetraacetate ion and YOH^{3-}=the hydroxyethylenediaminetriacetate ion) with Fe^{2+} proceed *via* the carboxylato-bridged activated state.[8]

The experimental results presented above serve to establish how the enthalpy and entropy of the activation and reactivities change when the nonbridging ligands are varied (Table 1). The variations in the reactivities of *cis*-α-Co(edda)A_2^+ (A_2=(H_2O)$_2$, (NH_3)$_2$, and (en)), Co(nta)B_2 (B_2=(H_2O)$_2$, (H_2O)($NH_2CH_2CH_3$), and (en)), and Co(nta)(am)$^-$ (am=glycine, β-alanine, and γ-aminobutyric acid) are due primarily to the changes in the enthalpies of activation. The entropies of activation increase slightly with a decrease in the reactivities of the Co(III) complexes in the three series.

The reactivities of the Co(nta)(am)$^-$ series decrease in this order: γ-aminobutyric acid>β-alanine>glycine. In a previous paper,[9] it was mentioned that the strain on the chelate ring of the nonbridging ligand accelerates the Fe^{2+} reduction rate. The decreasing order of reactivity is consistent with that of the strain on the chelate ring of the amino acid.

It is of interst to note here that the entropies of activation of the Co(nta)(am)$^-$ and Co(nta)B_2 complexes are almost the same, though the enthalpies of the activation decrease with the reactivities of the complexes.

Co(edta)$^-$	6.00×10^{-4}[b]	11.2±1.4	−36±5

a) This work, $\sum[ClO_4^-]=1.00$ M, $[H^+]=0.36$ M, 25 °C.
b) From Ref. 8, 25 °C, Ionic strength=1.00.

The rate constants and the activation parameters for the reductions of nitrilopolycarboxylato-Co(III) complexes by Fe^{2+} are listed in Table 2. The reactivity of the Co(nta)(H_2O)$_2$ complex is much larger than those of the other complexes. In these complexes, the efficiency of the nitrilopolycarboxylato ligand as the mediator in the electron-transfer is of almost the same degree. Therefore, the large reactivity of the Co(nta)(H_2O)$_2$ complex must be due to the smaller reorganization energy of the nonbridging ligand before electron transfer occurs. The small enthalpy of activation for the Co(nta)(H_2O)$_2$ complex supports the above-mentioned interpretation.

The author wishes to express his thanks to Professor Katsumi Yamamoto and Professor Yoshimi Kurimura for their helpful discussions, and to Mr. Takatsugu Fujita for his assistance in this work.

Recoil ^{82}Br Reactions with Liquid Chlorofluorocarbons

Takeshi TOMINAGA, Ren IWATA, and Yoshihiro MAKIDE*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

**The Institute of Physical and Chemical Research, Wako-shi, Saitama 351*

(Received November 10, 1972)

The study of recoil halogen reactions with chlorofluorocarbons appears to be interesting since one can make an intramolecular comparison of the reactivities of different types of bonds, such as C–C, C–Cl, and C–F. While recoil iodine and chlorine reactions with chlorofluoromethanes have been investigated,[1,2] the study of recoil bromine reactions with similar systems had not been reported before our preliminary work.[3] In the present article we wish to report our recent data on the recoil ^{82}Br reactions with chlorofluorocarbons, such as CF_2Cl_2, $CFCl_3$, and CF_2ClCF_2Cl.

Experimental

The samples for neutron irradiation were prepared by sealing one of the chlorofluorocarbons (CF_2Cl_2, $CFCl_3$, or CF_2ClCF_2Cl) *in vacuo* in quartz capillaries, along with varying amounts of bromine. These liquid samples were irradiated with thermal neutrons (flux: 5×10^{11} n/cm^2·s) for 5 min at room temperature in the rotary specimen rack of the TRIGA Mark II reactor at Rikkyo University. The accompanying γ dose was approximately 7×10^4 R.

The irradiated samples were analyzed after the decaying out of the shorter-lived bromine activities other than ^{82}Br. Hence, the observed radiochemical yields of recoil products were predominantly the results of the isomeric transition of ^{82m}Br.[4] The samples were directly introduced into a gas chromatograph and analyzed by means of a 5 m Silicone DC 550 column. The inorganic bromine was removed by means of a short column packed with dehydrated potassium ferrocyanide powder and placed before the main column. Procedures for the radioactivity measurement and determination of the ^{82}Br radiochemical yields of these products were the same as those in the previous work.[3]

Results and Discussion

Since radiogas chromatograms of irradiated CF_2Cl_2–Br_2 and $CFCl_3$–Br_2 systems were reported previously,[3] a typical radiogas chromatogram of ^{82}Br-labeled products from the irradiated CF_2ClCF_2Cl–Br_2 system is illustrated in Fig. 1. In the thermal conductivity measurements, only the mass peak of the parent compound could be observed (the position of the parent mass peak is indicated by an arrow in Fig. 1). The unknown radioactivity peaks were identified either by comparing their retention times with those of known

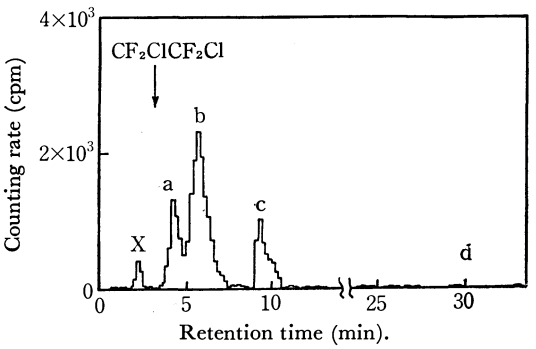

Fig. 1. Radiogas chromatogram of ^{82}Br-labeled products from the neutron-irradiated CF_2ClCF_2Cl—Br_2 system.
a: $CF_2Cl^{82}Br$; b: $CF_2ClCF_2{}^{82}Br$; c: $CF_2Br^{82}Br$; d: $CF_2ClCFCl^{82}Br$ (expected position, but not observed); X: presumably $CF_3{}^{82}Br$.

compounds added as carriers, or by applying the known correlation between the logarithm of the retention time and the composition of halogen atoms in bromochlorofluorocarbons.[5] If the carrier compounds are neither commercially available nor readily prepared by ordinary chemical syntheses, γ-irradiations up to a heavy dose of similar systems (*i.e.*, the mixtures of chlorofluorocarbons with bromine) appear to be useful

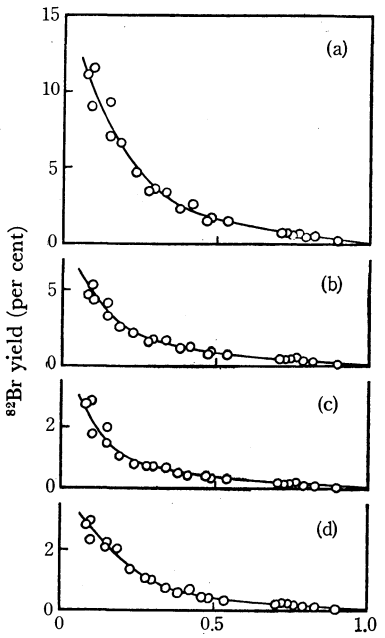

Fig. 2. Yields of major ^{82}Br-labeled products from CF_2ClCF_2Cl—Br_2 system *vs.* molar fraction of bromine.
(a) Total organic yield; (b) $CF_2ClCF_2{}^{82}Br$; (c) $CF_2Cl^{82}Br$; and (d) $CF_2Br^{82}Br$.

2) S. C. Lee and C. O. Hower, *J. Phys. Chem.*, **75**, 2685 (1971).
3) T. Tominaga, Y. Makide, S. Okada, Y. Kunimasa, and K. Wada, *Radioisotopes*, **20**, 541 (1971).
4) Since the reactivities of recoil ^{82}Br produced by either isomeric transition of ^{82m}Br(91%) or $^{81}Br(n,\gamma)^{82}Br$ reaction (9%) are qualitatively similar, the contribution from $^{81}Br(n,\gamma)^{82}Br$ reaction may be less than one-tenth of the overall observed results.
5) Y. Makide and N. Saito, presented at the 24th National Meeting of the Chemical Society of Japan (April 1971, Osaka).

for the preparation of the desired compounds in reasonable yields.[6] Hence, we have used mixtures of radiolysis products from the CF_2Cl_2–Br_2, $CFCl_3$–Br_2, and CF_2ClCF_2Cl–Br_2 systems preirradiated with γ-rays up to a total dose of about 10^{22} eV/g, as special samples for neutron irradiation in order only to identify the peaks of the ^{82}Br-labeled products from such systems.[7]

Figure 2 represents the radiochemical yields of the major ^{82}Br-labeled products from the CF_2ClCF_2Cl–Br_2 system as a function of the molar fraction of bromine. Very similar curves were observed for the radiochemical yields of the major ^{82}Br-labeled products from the CF_2Cl_2–Br_2 and $CFCl_3$–Br_2 systems. Bromine in these systems can scavenge carbon mixed halide radicals[6] as well as thermal ^{82}Br atoms or ions. A simple analysis of these curves, *i.e.*, an extrapolation of the almost linear portion of the curves to the yields at zero molar fraction of bromine, may reveal approximately the ^{82}Br yields from hot processes. Table 1 summarizes the ^{82}Br yields (estimated by extrapolation) of the major recoil products from the neutron-irradiated CF_2Cl_2–Br_2, $CFCl_3$–Br_2, and CF_2ClCF_2Cl–Br_2 systems. The following conclusions may be drawn from the results:

Table 1. Yields of major ^{82}Br-labeled recoil products from liquid CF_2Cl_2–Br_2, $CFCl_3$–Br_2 and CF_2ClCF_2Cl–Br_2 systems

	Product	^{82}Br yield (%)[a]
(1)	Liquid CF_2Cl_2–Br_2 system.	
	$CF_2Cl^{82}Br$	2
	$CF_2Br^{82}Br$	0.8
	$CFCl_2{}^{82}Br$	0.4
	$CFClBr^{82}Br$	0.2
(2)	Liquid $CFCl_3$–Br_2 system.	
	$CFCl_2{}^{82}Br$	6
	$CFClBr^{82}Br$	2
	$CCl_3{}^{82}Br$, $CCl_2Br^{82}Br$	not observed
(3)	Liquid CF_2ClCF_2Cl–Br_2 system.	
	$CF_2ClCF_2{}^{82}Br$	1.6
	$CF_2Cl^{82}Br$	0.6
	$CF_2Br^{82}Br$	0.7
	$CF_2ClCFCl^{82}Br$, $CFClBr^{82}Br$	not observed
	X ($CF_3{}^{82}Br$)[8]	<0.2

a) Estimated ^{82}Br yield from hot processes.

CF_2Cl_2–Br_2 System. At least four ^{82}Br-labeled species, *i.e.*, $CF_2Cl^{82}Br$, $CF_2Br^{82}Br$, $CFCl_2{}^{82}Br$, and $CFClBr^{82}Br$, were obtained from the recoil ^{82}Br reactions with CF_2Cl_2; of those the yield of $CF_2Cl^{82}Br$ (derived from ^{82}Br-for-Cl substitution) was larger than that of $CFCl_2{}^{82}Br$ (dreived from ^{82}Br-for-F substitution). Although the mechanisms for the formation of CF_2Br-^{82}Br and $CFClBr^{82}Br$ are not yet clear, it is likely that they are produced *via* radicals arising from the decomposition of the excited $CF_2Cl^{82}Br$ and $CFCl_2{}^{82}Br$ molecules.

$CFCl_3$–Br_2 System. The main ^{82}Br recoil products from the $CFCl_3$–Br_2 system were $CFCl_2{}^{82}Br$ and $CFClBr^{82}Br$, both originating from ^{82}Br-for-Cl substitution, whereas no ^{82}Br-for-F substitution product, such as $CCl_3{}^{82}Br$, was observed.

CF_2ClCF_2Cl–Br_2 System. $CF_2ClCF_2{}^{82}Br$, CF_2Cl-^{82}Br, and $CF_2Br^{82}Br$ were the major products from the CF_2ClCF_2Cl–Br_2 system,[8] indicating that ^{82}Br-for-Cl or ^{82}Br-for-CF_2Cl substituion took place predominantly. The ^{82}Br-for-F substituion product, $CF_2ClCFCl^{82}Br$, was not obtained.

In conclusion, the C–Cl and C–C bonds appear to be more reactive than the C–F bond in the recoil ^{82}Br reactions with these chlorofluorocarbons. It is worth mentioning that the C–Cl and C–C bonds are broken more readily than the C–F bond in the γ-radiolysis of these systems.[6] However, there is one point still to be clarified: whether or not such an apparent similarity between the isomeric-transition-induced ^{82}Br reactions and the γ-radiolysis reactions reflects the essential similarity of their reaction mechanisms.

Further work is in progress on the general application of the recoil technique to the selective preparation of labeled bromochlorofluorocarbons.

The present authors wish to express their thanks to Professor Nobufusa Saito, the University of Tokyo, for his encouragement and support.

6) T. Tominaga, R. Iwata, and Y. Makide, *Chem. Lett.*, **1972**, 871.

7) A variety of carbon mixed halides were produced by γ-irradiation up to a heavy dose, whereas no radiolysis products could be observed after 5 minutes' neutron irradiation in the reactor.

8) Another small unidentified peak (X) in Fig. 1 may presumably be $CF_3{}^{82}Br$, yet its origin is not fully understood.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1884—1885 (1973)

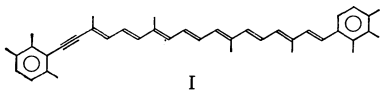
Two Natural Acetylenic Aromatic Carotenoids

Toshio HAMASAKI,* Nobuhisa OKUKADO, and Masaru YAMAGUCHI

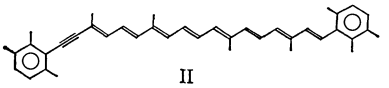
Department of Chemistry, Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812

(Received July 6, 1972)

Among seven carotenoid hydrocarbons[1] isolated from a sea-sponge "*Reniera japonica*," five major pigments, α-carotene,[1] β-carotene,[1] renieratene,[2] isorenieratene,[3] and renierapurpurin,[4] have been identified or structurally elucidated. Two other minor pigments (mp 205 and 194 °C) have remained structurally unsolved because of the paucity of materials. Recently, a considerable amount of the samples has been isolated, and, as will be shown below, enough evidence has been obtained to conclude that they have structures of acetylenic aromatic carotenoids, I (mp 205 °C) and II (mp 194 °C), respectively.



I



II

This is the first establishment of the natural occurrence of acetylenic aromatic carotenoids.

Experimental

Isolation of the Pigments. The extraction and isolation of the pigments were carried out according to the method described in the previous paper.[1] The pigment with a mp of 205 °C was adsorbed between renierapurpurin and renieratene in the chromatogram of the crude pigment mixture, on development on neutral alumina [Merck, deactivated by the addition of water (4%)] with a petroleum ether–benzene mixture (the benzene content being gradually increased from 30 to 75%). The pigment with a mp of 194 °C was adsorbed between renieratene and isorenieratene. Repeated chromatographic separations were necessary to obtain homogeneous zones. Several recrystallizations of the residue of each elute from a mixture of dichloromethane and petroleum ether gave a pure pigment.

Purplish red needles (referred to as the "mp 205 °C pigment"); mp 204—205 °C (uncorr.). UV max. 512, 480, 450 (benzene); 496, 465, 437 nm (*n*-hexane). IR max. (KBr disk); 3024, 2940, 2915, 2850, 1783, 1592, 1560, 1473, 1459, 1440, 1392, 1375, 1318, 1250, 1160, 1005, 960, 883, 830, 803, 776, 728 cm^{-1}.

Red needles (referred to as the "mp 194 °C pigment"); mp 194—194.5 °C (uncorr.). UV max. 500, 470, 442 (benzene); 485, 456, 431 nm (*n*-hexane). IR max. (KBr disk); 3020, 2940, 2910, 2845, 1782, 1620, 1560, 1455, 1436, 1392 1375, 1359, 1158, 997, 960, 878, 830, 805, 723 cm^{-1}.

Instruments. UV Spectra: Hitachi, Model EPS-3T. IR Spectra: Hitachi, Model 215. NMR Spectra: Hitachi, Model R-20B (60 Mc). Mass spectra: Hitachi, Model RMS-4.

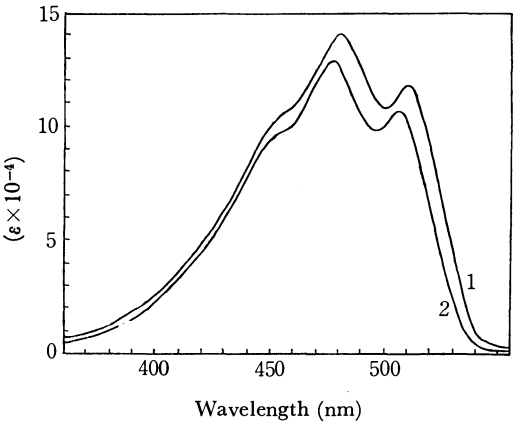


Fig. 1. Absorption spectra of the pigment, mp 205° (1) and renieratene (2) (benzene).

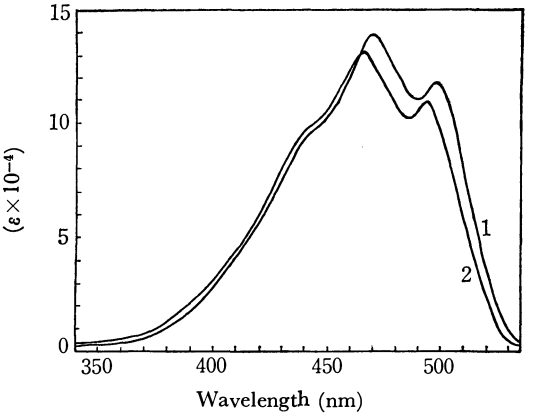

Fig. 2. Absorption spectra of the pigment, mp 194° (1) and isorenieratene (2) (benzene).

Results and Discussion

The Mp 205 °C Pigment. A brief examination of the UV, IR, NMR, and mass spectra of the pigment indicated a structurally very close relationship between the pigment and renieratene [1-(2,3,6-trimethylphenyl)-18-(2,3,4-trimethylphenyl)-3,7,12,16-tetramethyloctadecanonaene].

The mass spectrum of the pigment shows the ions [526(M), 511(M−15), 447(M−79), 434(M−92), 420 (M−106), 405(M−106−15), 393(M−133), 368(M−

158), 328(M−106−92), 301(M−133−92), 287(M−106−133), and 133(base peak)] characteristic of aromatic carotenoids.[5] The ions associated with *m/e* 133 give strong support to the presence of the trimethylphenyl group.[6] Most of the fragments are smaller by two mass units than the corresponding fragments of renieratene [528(M), 449(M−79), 436(M−92), 422(M−106), 395(M−133), 370(M−158), 330(M−106−92), 303(M−133−92), 289(M−106−133), and 133 (base peak)]. This suggests, besides other less likely structures, a possible formula where one of the double bonds of renieratene is replaced by a triple bond.

The NMR spectrum of the pigment [in $CDCl_3$, an average of 223 times: δ 2.02 (s, 6H) and 2.11 (s, 6H) ("in chain" methyl groups); 2.25 (s, 3H), 2.27 (s, 3H), and 2.34 (s, 6H) (four aromatic methyl groups); 2.45 (s, 6H) (two aromatic methyl groups); 6.10—6.90 (m, 12H) (polyene protons); 6.97 (s, 2H) (ring protons on the 2,3,6-trimethylphenyl group); double doublet centered at 6.99 (H) and 7.30 (H) (J=7.2 Hz, ring protons on the 2,3,4-trimethylphenyl group)] is quite similar to that of renieratene [in $CDCl_3$, an average of 214 times: δ 2.02 (s, 6H); 2.10 (s, 6H); 2.27—2.33 (m, 18H); 6.04—6.84 (m, 14H); 6.97 (s, 2H); 6.99 (H), and 7.29 (H) (dd, J=7.2 Hz)], indicating the presence of 2,3,6- and 2,3,4-trimethylphenyl groups.[7] It is noteworthy, however, that two (δ 2.45) out of six aromatic methyl groups are significantly deshielded when compared with those of renieratene. If the pigment is actually an acetylenic analogue of renieratene, this shift can be reasonably explained by assuming that the location of the triple bond in the polyene chain is in the moiety including the 2,3,6-trimethylphenyl group, probably neighbouring it, as is depicted in I.

The two *ortho*-standing methyl groups are considered to become more deshielded when a double bond attached to the benzene ring is replaced by a triple bond. Similar trends have been observed in alicyclic acetylenic carotenoids.[8,9] The relative abundance of the M−106 or M−92 ion (which stems from the central part of the polyene chain) in the mass spectrum also supports the conclusion.[10] This is also confirmed by the UV spectrum (Fig. 1). The small red shift of λ_{max} (3 nm in benzene) observed in going from renieratene to the pigment can be explained only by assuming that the pigment contains the triple bond in the terminal position of the central conjugated double bond system, as is observed in didehydroastaxanthin relative to astaxanthin[11] or in diatoxanthin[12] and alloxanthin[9,13] relative to zeaxanthin,[14] for example. A triple bond in other positions should give rise to a considerable hypsochromic shift.[15]

The IR spectrum also supports the (I) structure. The absence of $\nu_{C\equiv C}$ can be ascribed to the absence of polar functionality in this disubstituted acetylene. The possibility of the allenic structure, which is often encountered in natural carotenoids,[16] can be completely eliminated by a study of the IR and UV spestra.

The Mp 194 °C Pigment. The same arguments can apply to the pigment with a mp of 194 °C. The mass spectrum [526(M), 511(M−15), 447(M−79), 434(M−92), 420(M−106), 393(M−133), 301(M−133−92), 287(M−133−106), and 133(base peak)] clearly indicates that the compound can be interpreted as a dehydro derivative of isorenieratene [1,18-bis-(2,3,6-trimethylphenyl)-3,7,12,16-tetramethyloctadecanonaene; characteristic ions in the mass spectrum, 528(M, base peak), 513(M−15), 449(M−79), 436(M−92), 422(M−106), 395(M−133), 370(M−158), 330(M−106−92), 303(M−133−92), 289(M−106−133), and 133]. The NMR spectrum [in $CDCl_3$, an average of 597 times: δ 2.01 (s, 6H), 2.10 (s, 6H), 2.27—2.30 (12H), 2.44 (s, 6H), 6.05—6.90 (m, 12H), and 6.97 (s, 4H)] coincides well with that expected for the proposed formula, II, which has two 2,3,6-trimethylphenyl groups on both ends of the molecule, when compared with the spectrum of isorenieratene [in $CDCl_3$, an average of 223 times: δ 2.02 (s, 6H), 2.10 (6H), 2.31 (18H), 5.95—6.95 (m, 14H), and 6.97 (s, 4H)]. In this case again, a low-field shift by *ca.* 0.16 ppm of the signal of the *ortho*-standing methyl protons can be observed. The UV (Fig. 2) and IR spectra also prove the correctness of the (II) structure. The highest UV max. of the acetylenic analogue is again at a 3—4 nm-longer wavelength location in a benzene solution than that of isorenieratene in the same solvent.

The authors wish to thank Professor Otohiko Tsuge, Research Institute of Industrial Science, of this University, for the help he gave them in the measurements of the mass spectra.

The Synthesis of Optically-active Valine by the Stereoselective Decarboxylation of α-(α-Methylbenzylamino)-α-isopropylmalonic Acid*

Tadao HAYAKAWA and Kazuaki SHIMIZU

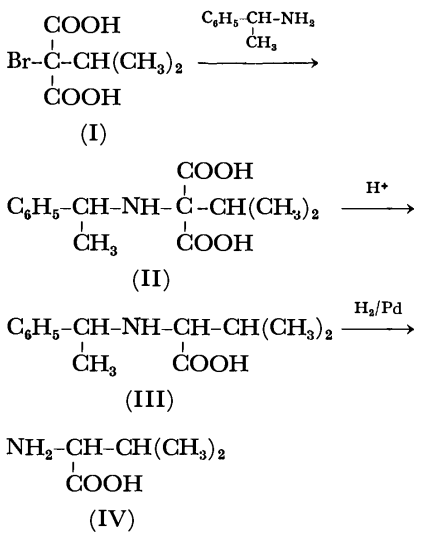
Institute of High Polymer Research, Faculty of Textile Science and Technology, Shinshu University, Ueda 386

(Received July 14, 1972)

Many studies of the syntheses of optically-active α-amino acids have been reported.[1-2] Syntheses using optically-active α-methylbenzylamine as an optically-active moiety have been reported in many types of stereochemical studies.[2]

In this study, the synthesis of optically-active valine was examined by the stereoselective decarboxylation of (*S*)(−)- and (*R*)(+)-α-(α-methylbenzylamino)-α-isopropylmalonic acids.

The route of synthesis is as follows:



α-(α-Methylbenzylamino)-α-isopropylmalonic acid (II) was prepared by the reaction of α-brom-α-isopropylmalonic acid (I)[3] with optically-active α-methylbenzylamine. The product, II, was decarboxylated by heating it in 6 M hydrochloric acid to give *N*-(α-methylbenzyl)-valine (III). In order to check the influence of the reaction temperature on the steric effect of the decarboxylation, the reactions were carried out at various temperatures. The resulting *N*-(α-methylbenzyl)-valine was hydrogenolyzed into valine by the use of palladium hydroxide on charcoal. A part of the isolated valine (IV) was converted to DNP-valine by the use of 2,4-dinitrofluorobenzene in the usual manner.[4] The reactions of II→III→IV proceeded to give a quantitative yield. To avoid the fractionation of the partially-active valine and its methylbenzyl derivative thus synthesized, the purification of the compounds was carried out by the use of a Dowex 50×2 column (hydrogen form). The optical rotations of the valine and DNP-valine thus isolated, their optical purities, and the experimental conditions are listed in Table 1. When a decarboxylation reaction was carried out at room temperature, the higher optically-active valine (20—26%) was obtained. The optical purities of the resulting valines decreased with the rise in the reaction temperature. It is considered that, at lower reaction temperatures, the steric hindrance between the methylbenzyl group and the two carboxyl groups of the malonic acid derivative may contribute to the stereoselective decarboxylation more than at higher temperatures. The configurations of the resulting valines are also shown in Table 1. When (*S*)(−)-amine was used, (*R*)-rich valines were obtained, while (*R*)(+)-amine gave (*S*)-rich valines. In order to clarify the mechanism of this selective decarboxylation, the synthesis of another optically-active α-amino acid is now under investigation.

Experimental

α-[(S)(−)-α-Methylbenzylamino]-α-isopropylmalonic Acid (II) To a solution of 2.0 g of α-brom-α-isopropylmalonic acid (I)[3] in 7.12 ml of a 10% sodium hydroxide solution, 5.40 ml of (*S*)(−)-methylbenzylamine was added. After the mixture had been allowed to stand for 3 weeks, the unreacted amine was extracted with ether, and an aqueous layer was placed in a Dowex 50×2 column (hydrogen form). The column was washed with water. Then methylbenzylaminomalonic acid was eluted with 3 M aqueous ammonia and evaporated to dryness *in vacuo*. The residual product was dissolved in 20 ml of water, and the insoluble material was removed by filtration. After the filtrate had been acidified to congo red by the addition of dilute hydrochloric acid, the crystals thus precipitated were filtered and dried; yield, 1.0 g (38%); mp 181—183 °C (decomp.), $[\alpha]_D^{20} = -33.5°$ (*c* 1.01, 1 M NaOH).

Found: C, 63.66; H, 7.24; N, 5.31%. Calcd for $C_{14}H_{19}O_4N$: C, 63.88; H, 7.22; N, 5.28%.

α-[(*R*)(+)-α-Methylbenzylamino]-α-isopropylmalonic acid was prepared from I (2.0 g) and (*R*)(+)-methylbenzylamine

	R(+)	*S*	+6.5	23.0	+28.8	26.4

a) (*S*) (−)-α-Methylbenzylamine ($[\alpha]_D^{25}$ −41.5°, benzene); (*R*) (+)-α-Methylbenzylamine ($[\alpha]_D^{25}$ +41.0°, benzene).
b) Defined as ($[\alpha]_D$ obsd/$[\alpha]_D$ lit) × 100. *S*-Val, $[\alpha]_D^{25}$ +28.3° (5 M HCl); DNP-(*S*)-Val, $[\alpha]_D$ +109.2° (1 M NaOH). (J. P. Greenstein and M. Winitz, "Chemistry of the Amino Acids," John Wiley and Sons Inc., New York, N. Y., 1961. valine, Vol. 3 p. 2368; DNP-valine, Vol. 2 p. 1564.)

(5.40 ml) in the same way as above. Yield, 0.8 g (30%); mp 180—183 °C (decomp.), $[\alpha]_D^{20}$ = +34.0° (*c* 1.02, 1 M NaOH).

Found: C, 63.73; H, 7.18; N, 5.35%. Calcd for $C_{14}H_{19}O_4N$: C, 63.88; H, 7.22; N, 5.28%.

N-[(S)-α-Methylbenzyl]-valine (III). A solution of 0.3 g of α-[(*S*)(−)-α-methylbenzylamino]-α-isopropylmalonic acid (II) in 30 ml of 6 M hydrochloric acid was heated at room temperature (20 °C) for 24 hr, at 50 °C for 6 hr, at 60 °C for 5 hr, at 70 °C for 4 hr, and at 90 °C for 3 hr. The solution was then evaporated to dryness *in vacuo*, and the residue was dissolved in 10 ml of water. The solution was then placed in a Dowex 50×2 column (hydrogen form). The column was washed with water until the effluent became neutral. Then the methylbenzylvaline was eluted with 3 M aqueous ammonia. The effluent was evaporated to dryness *in vacuo*. The yield was nearly quantitative.

Found: C, 70.37; H, 8.63; N, 6.27%. Calcd for $C_{13}H_{19}O_2N$: C, 70.56; H, 8.65; N, 6.33%.

The *N*-[(*R*)-α-methylbenzyl]-valines were prepared by the decarboxylation of α-[(*R*)(+)-α-methylbenzylamino]-α-isopropylmalonic acids at various temperatures in the same way as above. The yields averaged 95—99%. The elemental analytical values were in good agreement with the theoretical value.

(R)(−)-Valine (IV) and DNP-(R)(−)-valine. To a solution of 0.25 g of *N*-[(*S*)-α-methylbenzyl]-valine in 30 ml of 50% ethanol containing 0.096 ml of 12 M hydrochloric acid, 0.3 g of 10% palladium hydroxide on charcoal was added; the solution was then hydrogenated at room temperature until the absorption of gas had ceased. The catalyst was removed by filtration and washed with hot water. The combined solution was evaporated to dryness *in vacuo*. After the residue had then been dissolved in 10 ml of water, the solution was placed in a Dowex 50×2 column (hydrogen form) and the valine was eluted with 3 M aqueous ammonia. The effluent was evaporated to dryness; the yields averaged 95—99%. This valine was found by paper chromatography to have the same purity as the authentic optically-active valine. The analytical sample was obtained by one recrystallization from water and ethanol.

Found: C, 51.02; H, 9.50; N, 11.84%. Calcd for $C_5H_{11}O_2N$: C, 51.26; H, 9.47; N, 11.96%.

A part of the unrecrystallized valine was converted into DNP-valine in the usual manner,[4)] and the resulting DNP-valine was purified by the use of a Celite column treated with a pH 7.0 citrate buffer.[5)] The DNP-valine was extracted with ether and crystallized.

Found: C, 46.81; H, 4.58; N, 14.71%. Calcd for $C_{11}H_{13}O_6N_3$: C, 46.64; H, 4.62; N, 14.84%.

The (*S*)(+)-valines were prepared by the hydrogenation of *N*-[(*R*)-α-methylbenzyl]-valines obtained under several conditions and were then converted to DNP-(*S*)(+)-valine by dinitrophenylation in the way described above. The optical rotations of the resulting valines and DNP-valines, and their optical purities and configulations, are shown in Table 1.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1888—1890 (1973)

Cis- and *Trans*-Chlorination of Cyclohexene by Antimony Pentachloride and Triethyloxonium Hexachloroantimonate

Fuminori AKIYAMA, Toshio HORIE, and Minoru MATSUDA
Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai 980

(Received July 20, 1972)

Various methods for the preparation of *trans*-1,2-dichlorocyclohexane from cyclohexene have been reported by many investigators.[1-6] On the other hand, the formation of *cis*-1,2-dichlorocyclohexane was reported by Kawamoto and Komatsu[7] only in the case of the chlorination of cyclohexene by chlorine gas in the presence of cuprous chloride. However, the physical properties of the *cis*-1,2-dichloride reported by them are different from those reported by other investigators.[8,12] The chlorinations of cyclohexene by cupric chloride have been reported to yield *trans*-1,2-dichlorocyclohexane.[6,9] Therefore, we may suppose that the chlorination by chlorine in the presence of cuprous chloride does not give *cis*-1,2-dichloride. When we chlorinated cyclohexene by many metal halides without chlorine gas, we obtained *cis*-1,2-dichlorocyclohexane only in the case of chlorination by antimony pentachloride. While we were studying the chlorination of cyclohexene by antimony pentachloride, Uemura *et al.* reported the selective *cis*-chlorination of olefins by antimony pentachloride in carbon tetrachloride.[10] In this paper we wish to report some results on the chlorination of cyclohexene in liquid sulfur dioxide by antimony pentachloride and triethyloxonium hexachloroantimonate.

Experimental

General Procedure. The cyclohexene and antimony pentachloride were distilled into glass phials under a vacuum. The liquid sulfur dioxide was distilled into a reaction vessel in which the phials of the reactants have previously been placed. Breaking the phials, the chlorination reaction was started. After an appropriate time, an aliquot of the reaction solution was poured into a dilute alkaline aqueous solution. The products of the chlorination were analyzed by gas chromatography.

Materials. The triethyloxonium hexachloroantimonate was prepared according to the method of Meerwein *et al.*[11] Found: C, 16.26; H, 3.25%. Calcd for Et_3OSbCl_6: C, 16.46; H, 3.40%. Commercially-available metal halides and cyclohexene were purified by the usual methods. The liquid sulfur dioxide was distilled over phosphorous pentoxide.

Identification of the Chlorides. The products of the chlorination of cyclohexene were separated using 2.0 m silicone gum SE 30, 15% on a chromosorb w, column. The NMR or IR spectrum of each separated chloride coincided well with that of the respective authentic sample or that recorded in the literature.[12-14]

A. Monochlorocyclohexane

Found: C, 60.68; H, 9.25%. Calcd for $C_6H_{11}Cl$: C, 60.75; H, 9.35%.

B. *trans*-1,2-Dichlorocyclohexane——NMR: δ 3.9—4.20 (2H), 2.60—1.2 (8H); IR: 692, 738, 745 cm^{-1}.

Found: C, 47.39; H, 6.66%. Calcd for $C_6H_{10}Cl_2$: C, 47.08; H, 6.58%.

C. *cis*-1,2-Dichlorocyclohexane——NMR: δ 4.10—4.35 (2H), 1.20—2.40 (8H); IR: 696, 744 cm^{-1}.

Found: C, 47.28; H, 6.39%. Calcd for $C_6H_{10}Cl_2$: C, 47.08; H, 6.58%.

D. *trans*-1,3-Dichlorocyclohexane——NMR: δ 4.0—4.5 (2H), 1.0—2.5 (8H).

Found: C, 47.61; H, 6.60%. Calcd for $C_6H_{10}Cl_2$: C, 47.08; H, 6.58%.

Results and Discussion

We obtained only monochlorocyclohexane in the chlorination of cyclohexene by aluminum trichloride, stannic chloride, molybdenum pentachloride, and phos-

a) Initial reaction products. b) Reaction products at 2040 min.

phorous pentachloride. However, in the chlorination by antimony pentachloride, we obtained four chlorination products—monochlorocyclohexane, *trans*-1,2-dichlorocyclohexane, *trans*-1,3-dichlorocyclohexane, and *cis*-1,2-dichlorocyclohexane. As the reaction of monochlorocyclohexane with antimony pentachloride did not give the dichloride under our experimental conditions, the dichlorides were considered to result from the reaction of cyclohexene with antimony pentachloride. The yields of these products in liquid sulfur dioxide at 25 °C are plotted against the reaction time in Fig. 1. The yield of monochlorocyclohexane increased with the reaction time, but the yields of the dichlorides did not change with the reaction time. In the chlorination in *n*-hexane, we observed similar time-conversion curves. The distribution of the initial reaction products is listed in Table 1. At −70 °C in liquid sulfur dioxide, the chlorination reaction was very slow. As the reaction mixture prepared and kept for several hours at −70 °C was warmed up to 25 °C, however, the yield of the chlorination increased. In this case, however, only the chlorination product was monochlorocyclohexane, as is shown in Fig. 2. These

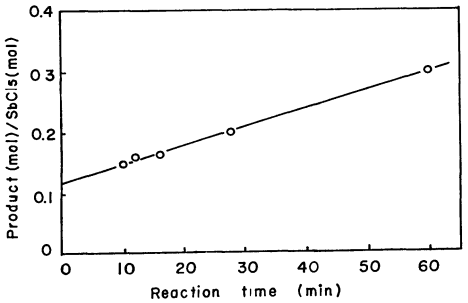

Fig. 2. The chlorination in the case that the reaction mixture was prepared at −70°C and then was warmed up to 25°C in liquid sulfur dioxide.

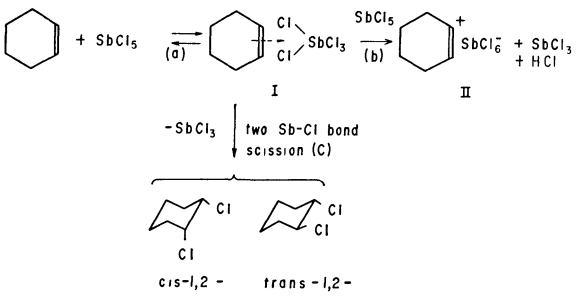
○: monochlorocyclohexane.

results may be tentatively represented by the sequence of the reactions in Scheme 1. Path (c) may resemble the Diels-Alder reaction. As Path (c) does not occur at −70 °C, all of the antimony pentachloride may be converted to an intermediate, II. The hydrochlorination of cyclohexene may be a slow reaction at −70 °C. Scarecely no change of II to I may occur with an increase in the reaction temperature from −70 to 25 °C. The II intermediate is supposed not to be able to give dichlorides. Therefore, only monochloro-



Scheme 1.

cyclohexane was obtained upon increasing the reaction temperature from −70 to 25 °C. Upon the mixing of the reagents at 25 °C, two path, (b) and (c), may occur, thus giving both mono- and dichlorides. We obtained dichlorides in the chlorination by triethyloxonium hexachloroantimonate, as is shown in Fig. 3. The product distribution at 2040 min is shown in Table 1. Since the triethyloxonium cation is more stable than the cyclohexenyl cation, a little of the free hexachloroantimonate anion can exist in the case of triethyloxonium hexachloroantimonate, but in the case of the II intermediate none can exist. The free hexachloroantimonate anion may react with cyclohexene to give

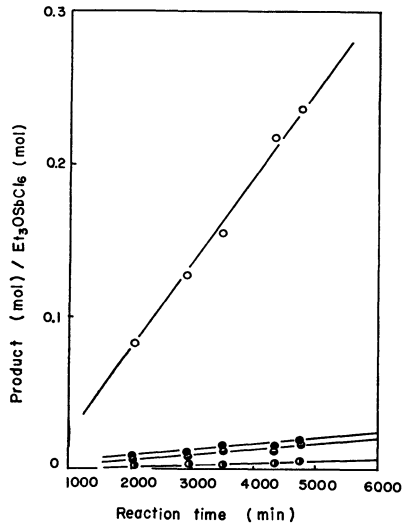


Fig. 3. The chlorination of cyclohexene by triethyloxoinum hexachloroantimonate in liquid sulfur dioxide at 25°C.

dichlorides. However, contact-ion pairs of triethyloxonium salt or the II intermediate are considered not to give dichlorides.

The solvent effect of dichlorination is shown in Table 1. The predominance of the *cis*-chlorination is somewhat clearer in the less polar solvent, *n*-hexane, than in the more polar solvent, liquid sulfur dioxide.

At present, the mechanism of the formation of *trans*-1,3-dichlorocyclohexane is not yet clear.

The Synthesis of Some 2*H*-Pyrazino[2,3-*e*][1,2,4]thiadiazine 1,1-dioxides

Mitsuo HATTORI, Michiaki YONEDA, and Miki GOTO
Department of Chemistry, Gakushuin University, Toshima-ku, Tokyo 171

(Received September 29, 1972)

Some benzothiadiazine derivatives are nowadays used as potential diuretics. The object of this research is to synthesize the corresponding pyrazinothiadiazine derivatives,[1] analogues of benzothiadiazine diuretics. The ring system of pyrazinothiadiazine has not hitherto been reported. This paper deals with the synthesis of some compounds of the new heterocycles.

For the synthesis of aminopyrazine-3-sulfonamides, the conventional method applied to the synthesis of benzenesulfonamides starting from sulfonyl chloride is not adequate, as pyrazines have little tendency to react with electrophilic reagents. Aminopyrazine-3-thiols (**2**) were first converted into aminopyrazine-3-sulfonamides (**4**) *via* aminopyrazine-3-sulfenamides by a method similar to that described by Korman.[2] The sulfonamides thus obtained were condensed with ethyl orthoformate to give 2*H*-pyrazino[2,3-*e*][1,2,4]thiadiazine 1,1-dioxides (**6**).

Similarly 2*H*-quinoxalino[2,3-*e*][1,2,4]thiadiazine 1,1-dioxide (**7a**) and its 3-methyl derivative (**7b**) were synthesized from 2-aminoquinoxaline-3-thiol (**3**) as a starting material.

6,7-Dimethyl-2*H*-pyrazino[2,3-*e*][1,2,4]thiadiazine

1,1-dioxide (**6c**) was converted into the corresponding 3,4-dihydro-compound (**8**) by reduction with sodium borohydride.

Experimental

Aminopyrazine-3-thiols (2). A mixture of aminopyrazinol[3] (**1**) (10 mmol) and phosphorus pentasulfide (1.5 g) in β-picoline (30—50 ml) was refluxed for 1.5 hr. After chilling, the solvent was evaporated *in vacuo*, and the residue was dissolved in 1 M sodium hydroxide (30—50 ml). The solution was filtered and adjusted to pH 3 with concd hydrochloric acid. After the mixture was chilled overnight, the product was collected.

Aminopyrazine-3-sulfonamides (4). Concd ammonia (15 ml) was added to aminopyrazinethiol[4] (**2**) (5 mmol) in 1.5 M sodium hydroxide (5 ml). Into the solution was then poured 10% sodium hypochlorite (3.7 ml) with stirring at 5 °C. The precipitate was collected and washed well with ice water to remove ammonia. The moist product was suspended in water (30 ml) and 5% aqueous potassium permanganate solution (15 ml) was added with vigorous stirring at room temperature. The solution was filtered, neutralized with concd hydrochloric acid and concentrated to dryness *in vacuo*. The residue was crystallized from water.

2-Aminoquinoxaline-3-sulfonamide (5). Aminoquinoxalinethiol[5] (**3**) was treated as in the synthesis of **4**. The filtered solution was concentrated to a half volume and adjusted to pH 3 with concd hydrochloric acid. After the mixture had been put to stand for 1 hr, the product was collected by filtration. The product is fairly unstable against alkaline media and boiling water. For the analysis, a small portion was recrystallized from a large amount of water (85 °C).

2H-Pyrazino[2,3-e][1,2,4]thiadiazine 1,1-Dioxides (6). A mixture of aminopyrazinesulfonamide (**4**) (5 mmol) and ethyl orthoformate (7.5 ml) was heated at 130 °C for 6 hr. After the mixture had been chilled well, the product was collected and washed with ethanol.

2H-Quinoxalino[2,3-e][1,2,4]thiadiazine 1,1-Dioxide (7a). Aminoquinoxalinesulfonamide (**5**) was treated at 110 °C for 4 hr as in the synthesis of **6**.

3-Methyl-2H-quinoxalino[2,3-e][1,2,4]thiadiazine 1,1-Dioxide (7b). A mixture of aminoquinoxalinesulfonamide (**5**) (667 mg) and ethyl orthoacetate (9 ml) was heated at 100 °C for 3 hr. After the mixture had been chilled, the product was collected and washed with ethanol.

3,4-Dihydro-6,7-dimethyl-2H-pyrazino[2,3-e][1,2,4]pyrazinothiadiazine 1,1-Dioxide (8). To sodium borohydride (47.5 mg) in water (2.25 ml) was added dimethylpyrazinothiadiazine 1,1-dioxide (**6c**) (212 mg) over a period of 30 min at room temperature. After the mixture had been put to stand for 6 hr, the product was collected.

The authors wish to express their thanks to Professors T. Nagatsu and H. Kuzuya, Aichigakuin University, for testing the enzyme.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1892—1893 (1973)

Asymmetric Reactions. VIII. Stereoselectivities in Several Organometallic Reactions with *N*-Benzyl-2,3-*O*-isopropylidene-D-glyceraldimine[1]

Yoshiaki OHGO, Yaeko KONDA,[2] and Juji YOSHIMURA

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received October 17, 1972)

The present authors have previously reported differences in stereoselectivity between phenyllithium and phenylmagnesium bromide reactions with α-aminonitriles bearing 1,3-dioxolane rings at α-positions,[3] 2,3-*O*-isopropylidene-D-glyceraldimines,[3,4] or 2,3-*O*-isopropylidene-D-glyceraldehyde,[5] *i.e.*, phenyllithium reactions gave *threo* products and Grignard reactions *erythro* products predominantly. The stereoselectivity of the phenyllithium reactions is consistent with Cram's rigid model,[6] but that of the Grignard reaction cannot be explained by this model. The anomalous stereoselectivity has been explained[3-5] in terms of the coordination ability of magnesium to C_3-oxygen, together with C_1-oxygen or C_1-nitrogen, and C_2-oxygen (Fig. 1). Support for this assumption was obtained[1] from the fact that no stereoselectivity difference was observed between the tworeactions with substrates having no C_3-oxygen.

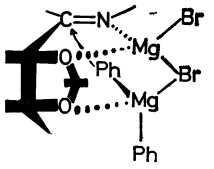

Fig. 1.

It is of interest to investigate other organometallic reactions in connection with the stereoselectivity which might result from the coordination ability of the attacking species. This paper will report on the stereoselectivity exhibited by organometallic compounds of Be, Ca, and Zn.

The phenylcalcium iodide was prepared in ether according to Gilman's method.[7] The other organometallic reagents were prepared by the addition of the corresponding metal halides into an ether solution of phenyllithium.[7]

N-Benzyl-D-glyceraldimine was treated with 2—3 molar equivalents of the reagents in ether. The reaction mixture was then decomposed with ice water, and the addition products obtained from ether layer were hydrolyzed to give a diastereomeric mixture of 1-benzylamino-1-deoxy-1-*C*-phenyl-*threo*- and -*erythro*-D-glyceritols. The product was confirmed by thin-layer chromatography. The analytical results agreed. In the case of the reaction with phenylcalcium iodide, there appeared in the thin-layer chromatography two spots other than the desired products. Therefore, the sample was purified by preparative thin-layer chromatography. The purified sample gave a single spot and agreeing analytical results.

The diastereomeric ratio was calculated from the optical rotation of the product by reference to that of each sample of the *threo* and *erythro* isomers. The results are shown in Table 1.

Table 1. Diastereomer ratios produced by the reaction with organometallic reagents

Run	Reagent (moles to substrate)	$[\alpha]_D$	Products *threo* (%)	Products *erythro* (%)
1	PhCaI (3)	−31.5	67	33
2	Ph_2Be+$BeCl_2$ (3) (0.6)	+15	35	65
3	Ph_2Zn (2)	+17	34	66
4	Ph_2Zn+$ZnCl_2$ (1.5) (1.5)	+34	23	77

As is shown in Table 1, the reactions with organometallics of Be and Zn showed a stereoselectivity similar to that of the organomagnesium reaction (giving the *erythro* product predominantly). It is worthy of mention that, in contrast to these reactions, the organocalcium reaction gives *threo* product predominantly, despite the fact that calcium belongs to the alkaline earth group (like Be and Mg) in the periodic table. Investigations[7] of the relative reactivities of organoalkaline and -alkaline earth metal compounds suggested that organocalcium has a rather ionic character, which could explain the stereoselectivity of the organocalcium reaction. At this stage, however, no clear explanation can be given.

Experimental

Reaction of N-*Benzyl-2,3-*O-*isopropylidene-*D-*glyceraldimine with Phenylcalcium Iodide.* An ethereal solution of *N*-benzyl-2,3-*O*-isopropylidene-D-glyceraldimine (10 g) was added with stirring at 0—5 °C into an ethereal solution of phenylcalcium iodide prepared from calcium (5.5 g) and phenyliodide (28 g). The reaction mixture was refluxed with stirring for 10 hr and then decomposed with ice water. The products were extracted with ether. The ether layer was concentrated *in vacuo* to a syrup. The syrup was hydrolyzed with 6 M hydrochloric acid (30 ml) at 100 °C for 2 hr, thereafter the hydrolysate was decolorized with activated carbon and then extracted four times with 50 ml portions of ethyl acetate after the adjustment of the pH to about 10 with a sodium hydroxide solution. The combined ethyl acetate solution was washed with water, dried over anhydrous sodium sulfate, and concentrated under reduced pressure to give crude products which showed two spots on a tlc besides those of the desired products. The crude products were purified by preparative thin-layer chromatography. The purified sample gave a single spot on a tlc (R_f, 0.45; solvent, acetone–benzene (3:5)). Found: C, 74.83; H, 7.20; N, 5.93%. Calcd for $C_{16}H_{19}O_2N$: C, 74.68; H, 7.44; N, 5.44%. The specific rotation of the sample was also measured; the result is shown in Table 1.

Reaction of N-*Benzyl-2,3-*O-*isopropylidene-*D-*glyceraldimine with Organoberyllium and Organozinc Compounds.* Organoberyllium and organozinc compounds were prepared from anhydrous beryllium chloride or zinc chloride, and phenyllithium according to the Gilman method.[7] For example, beryllium chloride (9 g) was added, portion by portion,into a stirred solution of phenyllithium prepared from lithium (2.7 g) and phenylbromide (20.1 ml). The mixture was refluxed for 30 min after the addition has been completed. To the resulting solution was added an ethereal solution of *N*-benzyl-2,3-*O*-isopropylidene-D-glyceraldimine with cooling and stirring; subsequently, the same procedure as was used in the phenylcalcium iodide reaction gave a diastereomeric mixture. Each sample gave a single spot on a tlc (R_f, 0.45; solvent, acetone–benzene (3:5)). The diastereomeric ratios produced by each reaction were calculated from the optical rotation of the sample and pure D-*threo* and D-*erythro* isomers. The analytical results agreed. Found: [C, 74.64; H, 7.20; N, 5.73% (Run 2)], [C, 74.21; H, 7.64; N, 5.97% (Run 3)], [C, 74.57; H, 7.56; N, 6.24% (Run 4)]. Calcd for $C_{16}H_{19}O_2N$: C, 74.68; H, 7.44; N, 5.44%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1893—1895 (1973)

The Synthesis of a Sweet Peptide, α-L-Aspartyl-L-phenylalanine Methyl Ester, without the Use of Protecting Groups

Yasuo ARIYOSHI, Tetsuo YAMATANI, Noboru UCHIYAMA, Yohko ADACHI, and Naotake SATO

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki-ku, Kawasaki 210

(Received November 6, 1972)

The large-scale preparation of α-aspartyl peptides which are entirely free from the corresponding β-isomers is not easily accomplished. In a previous paper the present authors reported a convenient one-step preparation of the hydrochloride and hydrobromide of L-aspartic anhydride, which might be useful intermediates for preparing aspartyl peptides.[1] It then appeared of interest to prepare α-L-aspartyl-L-phenylalanine methyl ester (α-APM), which has a sweet taste,[2] by the direct condensation of L-aspartic anhydride hydrochloride with methyl L-phenylalaninate. Although Kovacs *et al.* described the condensation of L-aspartic anhydride hydrobromide with ethyl glycinate to give a mixture of α- and β-aspartyl glycine ethyl esters,[3] its practical use for peptide synthesis has not yet been reported in the literature.

Simply by mixing L-aspartic anhydride hydrochloride and methyl L-phenylalaninate in an organic solvent, we can obtain a mixture of α- and β-APM in a fairly good yield. This coupling reaction, however, is always accompanied with side-reactions, such as the self-condensation of L-aspartic anhydride and the further condensation between the unchanged anhydride and the resulting dipeptide ester, since the amino group of the aspartyl residue is unprotected. In order to overcome these disadvantages and, in particular, to increase the formation of the α-isomer, the reaction conditions, such as the temperature, the solvent effects, and the molar ratios of the two reactants, were investigated. It was found that the reaction could be effected by adding such weak acids as acetic acid, by employing an excess of methyl L-phenylalaninate, and by conducting it at a low temperature. This method would appear to have considerable promise for conveniently preparing α-APM on a large scale, but it is necessary to separate the α-APM from the reaction mixture.

In the course of investigations of this peptide, we had occasion to attempt to hydrolyze the methyl ester group of α-APM in dilute hydrochloric acid. Contrary to expectations, α-APM hydrochloride (α-APM·HCl) readily crystallized out when α-APM was dissolved in dilute hydrochloric acid. This finding is interesting, since most peptides usually increase their

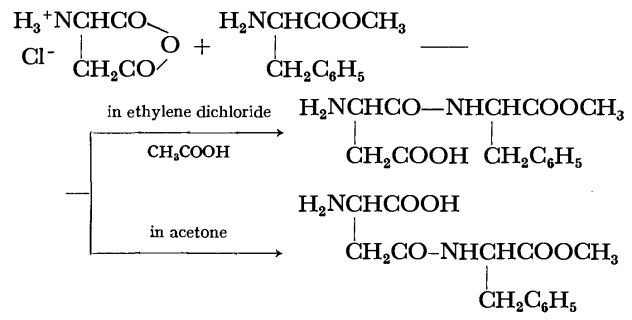
solubilities in such an acidic solution; *e.g.*, some closely related compounds, such as α-L-aspartyl-D-phenylalanine methyl ester hydrochloride and α-L-aspartyl-L-phenylalanine ethyl ester hydrochloride, are too soluble to be isolated. α-APM was also sparingly soluble in aqueous hydrobromic acid, while β-APM was almost freely soluble in both dilute hydrochloric and hydrobromic acids.

This characteristic was used successfully in the separation of α- and β-APM. After the separation, the recovery of the α-APM from the salt, and that of the β-APM from the mother liquor, could be accomplished easily and in an excellent yield by conventional neutralization. The ester group and the peptide bond were stable enough for the separation procedure.

The treatment of L-aspartic anhydride hydrochloride with 4 molecular equivalents of methyl L-phenylalaninate in the presence of acetic acid in ethylene dichloride at −20 °C gave a mixture of α- and β-APM, from which α-APM was isolated in a 37% yield (from the anhydride) by separation through its hydrochloride, followed by the neutralization of the salt with sodium carbonate and subsequent column chromatography.

On the other hand, when the reaction was conducted in acetone in the absence of acids, β-APM was formed predominantly and was isolated in a 36% yield.



Experimental

All the melting points are uncorrected. The peptides used here were left over from a previous investigation.[4] The optical rotations were measured by means of a visual polarimeter. The determination of the α- and β-APM by paper electrophoresis was carried out according to the method described in a previous paper.[5]

α-L-Aspartyl-L-phenylalanine Methyl Ester Hydrochloride Dihydrate (α-APM·HCl). α-APM (5.0 g) was dissolved in 1 M hydrochloric acid (50 ml) with slight warming, and then the solution was kept in a refrigerator overnight. The crystals thus formed were collected by filtration; yield, 5.2 g (86%); mp 127—128 °C (decomp., partly melted at 103 °C); $[\alpha]_D^{25}$ +1.3° (*c* 2, water). Lit,[6] mp 105—110 °C. Found: C, 45.86; H, 6.18; N, 7.55; Cl, 9.73%. Calcd for $C_{14}H_{18}O_5N_2 \cdot HCl \cdot 2H_2O$: C, 45.84; H, 6.32; N, 7.64; Cl, 9.67%.

α-L-Aspartyl-L-phenylalanine Methyl Ester Hydrobromide Dihydrate (α-APM·HBr). This salt was obtained from a solution of α-APM (5.0 g) in 1M hydrobromic acid (100 ml) by the procedure used in the preparation of α-APM·HCl; yield, 4.3 g (63%); mp 155 °C (decomp.); $[\alpha]_D^{2.5}$ +1.0° (*c* 2, water). Found: C, 41.13; H, 5.76; N, 6.85; Br, 19.39%. Calcd for $C_{14}H_{18}O_5N_2 \cdot HBr \cdot 2H_2O$: C, 40.89; H, 5.64; N, 6.81; Br, 19.43%.

Separation of α- and β-APM. α-APM (10 g) and β-APM (10 g) were dissolved in 1 M hydrochloric acid (100 ml) with slight warming. The solution was then kept in a refrigerator overnight. The crystals thus formed were collected by filtration; yield, 9.4 g (78%). The IR spectrum (Nujol) of the crystals was identical with that of the authentic α-APM·HCl. The crystals (9.3 g) were dissolved in water (90 ml), and the solution was adjusted to pH 4.8 with a 5% aqueous sodium bicarbonate solution while being stirred at 50 °C. The solution was then kept in a refrigerator overnight. The crystals thus formed were collected by filtration and washed with a small amount of chilled water; yield, 6.7 g (67%). The crystals were found by paper electrophoresis to be free from the β-isomer. For elemental analysis, the crystals were recrystallized from water; mp 235—236 °C (decomp.); $[\alpha]_D^{25}$ +32.0° (*c* 1, acetic acid). Lit,[2] mp 95 °C and 245—247 °C. Lit,[7] mp 246—247 °C. Lit,[4] mp 235—236 °C; $[\alpha]_D$ +32° (*c* 1, acetic acid). Found: C, 55.52; H, 6.13; N,9.32%. Calcd for $C_{14}H_{18}O_5N_2 \cdot 1/2H_2O$: C, 55.44; H, 6.31; N, 9.24%.

The filtrate from the α-APM·HCl was adjusted to pH 4.8 with a 5% aqueous sodium bicarbonate solution while being stirred at 50 °C; then the solution was treated in the manner described above to give 5.3 g (53%) of β-APM as needles. These needles were found by paper electrophoresis to be free from the α-isomer; mp 198—199 °C; $[\alpha]_D^{23}$ +40.5° (*c* 1, acetic acid). Lit,[2] mp 196—197 °C. Lit,[4] mp 198—199 °C; $[\alpha]_D$ +40.5° (*c* 1, acetic acid). Found: C, 55.29; H, 6.36; N, 9.27%. Calcd for $C_{14}H_{18}O_5N_2 \cdot 1/2H_2O$: C, 55.44; H, 6.31; N, 9.24%.

Synthesis of α-APM. A solution of methyl L-phenylalaninate hydrochloride (90 g) in water (450 ml) was neutralized with sodium carbonate (24 g), and the resulting free ester was extracted with two 350-ml portions of ethylene dichloride. To the organic solution there were then added acetic acid (9 g) and methanol (8 ml). Into this solution, L-aspartic anhydride hydrochloride (15.2 g)[1] was stirred at −20 °C. After stirring for 30 min at this temperature, hot water (350 ml, 70—80 °C) and an aqueous solution (300 ml) of sodium carbonate (5.7 g) were added successively to the reaction mixture. After the removal of the excess of methyl L-phenylalaninate by two extractions with 150-ml portions of ethylene dichloride, the aqueous layer was adjusted to pH 4.8 with dilute hydrochloric acid. The solution was found by paper electrophoresis to contain 18.2 g (60%) of α-APM and 6.1 g (20%) of β-APM. The solution was concentrated *in vacuo* to about 100 ml, and 36% hydrochloric acid (30 ml) was added to the concentrate. The solution was kept in a refrigerator overnight. The crystals (α-APM·HCl, 21.3 g, 58%) thus formed were collected by filtration and dissolved in water (200 ml). The solution was adjusted to pH 4.8 with a 5% aqueous sodium carbonate solution while being stirred at 50 °C, and then kept in a refrigerator overnight. The crystals thus formed were collected by filtration; yield, 13.0 g (43%). The crystals were dissolved in water (500 ml) and passed through a column (1×20 cm) of Dowex 1×4 (acetate form) maintained at 45 °C, and then the column was washed with water (20 ml). The eluate and washings were concentrated *in vacuo* to give α-APM, which was recrystallized from water; yield, 11.2 g (37%); mp 235—236 °C (decomp.); $[\alpha]_D^{22}$ +32.0° (*c* 1, acetic acid).

Synthesis of β-APM. To a stirred solution of methyl L-phenylalaninate (72 g) in acetone (750 ml), there was added L-aspartic anhydride hydrochloride (30.3 g) at −30 °C. After having been stirred for 1 hr at this temperature, the reaction mixture was allowed to attain room temperature and then concentrated *in vacuo*. The residue was dissolved in water (750 ml) containing sodium bicarbonate (20 g). The aqueous solution was extracted with two 500-ml portions of ethylene dichloride to remove the excess methyl L-phenylalaninate. The aqueous layer was adjusted to pH 4.8 with dilute hydrochloric acid and then concentrated to about 400 ml *in vacuo*. After storage in a refrigerator overnight, the crystals thus formed were collected by filtration; yield, 27.0 g (45%). Recrystallization from water gave 23.5 g (36%) of β-APM as needles, which were confirmed by paper electrophoresis to be free from the α-isomer; mp 198—199 °C; $[\alpha]_D^{28}$ +40.5° (*c* 1, acetic acid). Found: C, 55.79; H, 6.07; N, 9.39%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1895—1896 (1973)

The Inhibitory Effect of Several Olefins on the Formation of the Zinc-carbenoid Reagent from Diethylzinc and Chloroiodomethane

Sotaro MIYANO and Harukichi HASHIMOTO

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980

(Received November 16, 1972)

In a previous paper[1] we reported that styrene greatly inhibits the formation of the zinc-carbenoid reagent from diethylzinc and diiodomethane or chloroiodomethane. In this respect, it appeared of interest to examine the effects of several olefins on the zinc-carbenoid reaction of cyclohexene with diethylzinc and chloroiodomethane (Table 1). Norcarane was obtained

TABLE 1. EFFECT OF THE ADDITION OF AN OLEFIN ON THE ZINC-CARBENOID REACTION[a)]

Added olefin	Norcarane yield[b)], (%)	Reacted CH_2ClI (mmol)
None	67	9.8
2-Heptene	65	9.7
1-Heptene	64	10
Isoprene	45	8.3
trans-Stilbene	34	5.8
1,4-Diphenyl-1,3-butadiene	25	4.7
Styrene	22	4.6
α-Methylstyrene	16	3.1
1,1-Diphenylethylene	12	2.3
1-Phenyl-1,3-butadiene	8	1.8

a) Reaction conditions: diethylzinc; 10 mmol, chloroiodomethane; 15 mmol, cyclohexene; 10 mmol, added olefin; 5 mol % based on cyclohexene, 35°C, 5 hr, under a nitrogen atmosphere.
b) Based on cyclohexene.

in a good yield when diethylzinc was allowed to react with a mixture of cyclohexene and chloroiodomethane under a nitrogen atmosphere. On the other hand, in the presence of 5 mol % of 1-phenyl-1,3-budadiene only 18% of the initial chloroiodomethane was consumed within 5 hr. When dry air was introduced into the reaction mixture, chloroiodomethane completely reacted within 0.5 hr, giving norcarane in the yield of 98%.[2] This shows that 1-phenyl-1,3-butadiene retards the step of the formation of the zinc-carbenoid reagent from diethylzinc and chloroiodomethane. The order of the inhibiting effect of an added olefin on the zinc-carbenoid reaction seems to be in accordance with that of the reactivity of the olefin toward radicals. These results are consistent with the proposed radical-chain mechanism for the formation of the zinc-carbenoid reagent (Eqs. (1)—(3));[1] that is, the more reactive the olefin is toward radicals, the more the olefin seems to trap the ethyl or chloromethyl radiacl, and stop the chain:

$$EtZnR \xrightarrow{\text{initiator}} Et\cdot \quad (1)$$

$$Et\cdot + CH_2ClI \longrightarrow EtI + \cdot CH_2Cl \quad (2)$$

$$\cdot CH_2Cl + EtZnR \longrightarrow ClCH_2ZnR + Et\cdot \quad (3)$$

(R = Cl or Et)

The reason why isoprene was not so effective as was expected from its reactivity toward the methyl radical[3] or from the Q-value is not yet obvious, but the absence of a conjugating phenyl group and/or its volatility (bp 34 °C, while the reaction temperature was 35 °C) may be partly responsible.

Experimental

Materials. The 1-phenyl-1,3-butadiene[4] (bp 81.5 °C/9 mmHg), 1,4-diphenyl-1,3-butadiene[5] (mp 152—152.5 °C), and 1,1-diphenylethylene[6] (bp 111—113 °C/2 mmHg) were

prepared by conventional methods. The other materials were purified by methods which have been reported before.[1]

Reaction Procedure. The following procedure is representative. The reaction was carried out in a 100 ml, round-bottomed flask equipped with a magnetic stirrer, a reflux condenser, a pressure-equilibrating dropping funnel topped with a gas inlet cock, thermometer, and inlet carrying a rubber septum cap. The flask was flushed with nitrogen. In the flask was placed 30 ml of benzene containing 15.4 mmol of chloroiodomethane, 10.2 mmol of cyclohexene, and 0.865 g of ethylbenzene. To the solution we then added 67.2 mg 1-phenyl-1,3-butadiene (5.2 mmol). The temperature of the solution was kept at 35 °C, and 1 ml of diethylzinc (10 mmol) was injected into the solution with a hypodermic syringe through the septum cap. The reaction was then carried out under a nitrogen atmosphere for 5 hr at 35 °C. At the end of the reaction period, a sample (*ca.* 1 ml) was withdrawn through the septum cap with a hypodermic syringe and quenched with 3 ml of a dilute hydrogen chloride solution which had been saturated with nitrogen. After three extractions of the aqueous layer with benzene, the combined organic phase was analysed by glc. The amounts of the products were estimated from the peak areas, using ethylbenzene as the internal standard. Dry air was passed into the space above the remaining reaction mixture at a rate of 10 ml/min for 0.5 hr, after which the reaction products were analysed similarly.

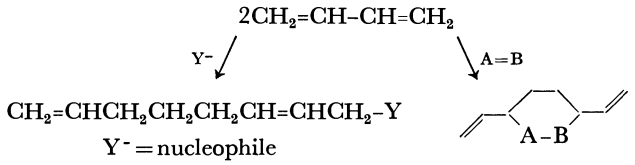
Organic Synthesis by Means of Noble Metal Compounds. L.[1] Palladium Catalyzed Reactions of Enamines with Butadiene and Allyl Acetate

Jiro TSUJI

Basic Research Laboratories, Toray Industries, Inc., Kamakura 248

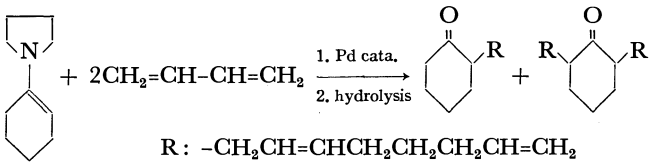
(Received February 16, 1973)

Recently extensive studies have been carried out on the palladium catalyzed dimerization reactions of butadiene, which can be classified into two types.[3] The first one is the dimerization reaction, especially with incorporation of a nucleophile such as water, alcohols, carboxylic acids, ammonia, amines, and some active methylene compounds to give 1-substituted 2,7-octadienes. Another one is the cocyclization reaction with a dipolar double bond such as aldehydes and isocyanates to give six-membered heterocyclic compounds.



We have investigated a reaction of enamine with butadiene in the presence of a palladium catalyst based on the following considerations. Enamines are considered to be a strong nucleophile and their nucleophilic reactions are well known.[4] In addition, enamines have dipolar double bond, which takes part in cyclization reactions to form six- or four-membered rings. Thus with these dual reactivities of butadiene and enamines in mind, we have carried out the reaction of enamine with butadiene in the presence of a palladium catalyst in order to determine which type of the reaction, namely nucleophilic attack or cocyclization of enamine, takes place. Concerning the interaction of enamine with a palladium complex, we have shown before that enamines are allylated with π-allylpalladium chloride.[5]

Pyrrolidine enamine of cyclohexanone was allowed to react with butadiene by using palladium acetate combined with triphenylphosphine as the catalyst. The reaction observed was not the cocyclization, but the introduction of 2,7-octadienyl moiety at the α position of cyclohexanone took place. In addition, 2,6-disubstituted cyclohexanone was obtained as a minor product. Pyrrolidine enamine of cyclopentanone behaved similarly giving 2-(2,7-octadienyl)cyclopentanone as a main product, accompanied by 2,5-di(2,7-octadienyl)-cyclopentanone.



The reaction undoubtedly proceeds through nucleophilic attack of the enamine on an intermediate π-allylic palladium complex formed from butadiene and the palladium compound. Formation of the intermediate π-allylic complex was proposed by Hagihara and his co-workers for dimerization of butadiene in the presence of nucleophiles.[6] Allyl acetate is known to form the most simple π-allylpalladium complex,

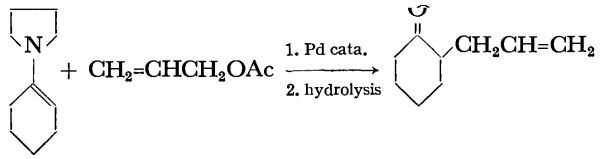
which is expected to react with enamines in the presence of the palladium catalyst. Thus we carried out the reaction of allyl acetate with the enamine of cyclohexanone, and 2-allylcyclohexanone was obtained as expected.[7]



Experimental

Reaction of the Cyclohexanone Enamine. A solution of 1-pyrrolidinocyclohexene (15 g), palladium acetate (100 mg), triphenylphosphine (200 mg) in acetonitrile (40 ml) was placed in an autoclave, and butadiene (12 g) was introduced. The autoclave was shaken for 3 hr at 80 °C. Two layers were formed, which were subjected to hydrolysis with hydrochloric acid at 50 °C for 30 min. Dichloromethane (100 ml) was added and the solution was washed with water. After being dried, the solvent was evaporated. The residue was distilled to give 2-(2,7-octadienyl)cyclohexanone (13.5 g) and 2,6-di(2,7-octadienyl)cyclohexanone (6.8 g), which were identified by the following data.

2-(2,7-Octadienyl)cyclohexanone. Bp 130—135 °C/3 mmHg, IR (neat); 993, 911 ($CH=CH_2$), 968 cm^{-1} (*trans* olefin). The NMR spectrum (CCl_4) showed complex olefin bands at τ 3.5—4.8 (=CH–) and τ 4.8—5.4 ($=CH_2$), which were identical with the olefin bands of the NMR spectrum of the known methyl 2,7-octadienyl ether.[8]

Found: C, 81.66; H, 10.73%; mol wt (mass spectrum), 206. Calcd for $C_{14}H_{22}O$: C, 81.50; H, 10.75%; mol wt, 206.32.

2,4-Dinitrophenylhydrazone, mp 93—94 °C. Found: C, 62.54; H, 6.81; N, 14.51%. Calcd for $C_{20}H_{26}O_4N_4$: C, 62.16; H, 6.78; N, 14.50%.

2,6-Di(2,7-octadienyl)cyclohexanone. Bp 170—175 °C/1 mmHg, showed the similar NMR olefinic bands as those of the above-shown monoderivative. Found: mol wt, 314. Calcd for $C_{22}H_{34}O$: 314.49. Hydrogenation over platinum oxide absorbed 4 mol of hydrogen to give 2,6-dioctylcyclohexanone, bp 160—165 °C/0.5 mmHg, mp 37—38 °C (from methanol–ether).

Found: C, 82.16; H, 12.84%; mol wt, 322. Calcd for $C_{22}H_{42}O$: C, 81.91; H, 13.13%; mol wt. 322.56.

Reaction of Cyclopentanone Enamine. A mixture of the enamine (10 g), butadiene (9 g), dimethylformamide (30 ml), palladium acetate (100 mg), and triphenylphosphine (200 mg) was allowed to react at 85 °C for 5 hr. After the usual work-up, 2-(2,7-octadienyl)cyclopentanone (8.2 g) and 2,5-di(2,7-octadienyl)cyclopentanone (4.2 g) were obtained.

2-(2,7-Octadienyl)cyclopentanone. Bp 100—105 °C/3 mmHg. The NMR spectrum showed the similar olefinic pattern as that of the corresponding cyclohexanone derivative.

Found: C, 81.36; H, 10.60%; mol wt. 192. Calcd for $C_{13}H_{20}O$: C, 81.20; H, 10.48%; mol wt. 192.29.

2,5-Di(2,7-octadienyl)cyclopentanone. Bp 155—165 °C/2 mmHg.

Found: C, 83.76; H, 10.68%; mol wt. 300. Calcd for $C_{21}H_{32}O$: C, 83.94; H, 10.73%; mol wt. 300.47.

Hydrogenation gave 2,5-dioctylcyclopentanone, mp 45—47 °C.

Found: C, 81.86; H, 12.90%; mol wt. 308. Calcd for $C_{21}H_{40}O$: C, 81.75; H, 13.07%; mol wt. 308.53.

Reaction of Allyl Acetate and Cyclohexanone Enamine. A mixture of 1-pyrrolidinocyclohexene (18 g), allyl acetate (15 g), acetonitrile (30 ml), palladium acetate (100 mg), and triphenylphosphine (200 mg) was stirred at 80 °C for 5 hr. Then 10 ml of concd hydrochloric acid and 10 ml of water were added and the mixture was stirred for 30 min. After the usual work-up, distillation gave 2-allylcyclohexanone (7.2 g, 70—73 °C/3 mmHg) and 2,6-diallylcyclohexanone (3 g, 85—95 °C/3 mmHg). They were identified with authentic samples prepared by the known method[9] by NMR and IR spectra and mixed mp determination of 2,4-dinitrophenylhydrazones (148—150 and 113—115 °C).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1898—1899 (1973)

The Preparation of *N*-(Alkylthio)- and *N*-(Arylthio)succinimides[1]

Yasuo ABE, Takeshige NAKABAYASHI, and Jitsuo TSURUGI
Radiation Center of Osaka Prefecture, Shinke-cho, Sakai 593

(Received December 19, 1972)

N-(Organothio)succinimides have been known as useful starting materials for syntheses of various organic sulfur compounds and have previously been synthesized by the reactions of: (1) organic sulfides with *N*-bromosuccinimide (NBS),[2] (2) organic disulfides with NBS,[3] and with NBS in the presence of benzoyl peroxide[4] or pyridine,[5] and organic disulfides and trisulfides with *N*-chlorosuccinimide (NCS) in the presence of pyridine,[6] (3) sulfenyl halides with potassium succinimide[5] and with succinimide in the presence of triethylamine,[7] and (4) lead bisthiolates with NBS or NCS.[8] It has been reported that mercaptans react with NBS or NCS to give disulfides,[5] sulfenyl bromides, or chlorides.[9] In a benzene solution, thiophenol was reacted with NCS to give phenylsulfenyl chloride and succinimide at room temperature.[9]

However, we have found that an exactly equimolar mixture of mercaptans and NCS, after the addition of triethylamine, gives *N*-(organothio)succinimides. Aryl, aralkyl and alkyl mercaptans can give the corresponding *N*-(organothio)succinimides in good yields. The identification was performed by studying the IR spectra and by elemental analyses. Table 1 gives the various types of thiosuccinimides prepared by this method, together with the yields, melting points, and IR data.

The reaction of disulfide and trisulfide with NCS in the presence of pyridine as a catalyst was proposed by Hayashi to proceed by a radical mechanism which involved the cleavage of NCS to a succinimido radical and a chloro radical in the first step.[6] The present reaction between mercaptan and NCS would then seem to proceed through the initial formation of sulfenyl chloride by the electrophilic chlorination of mercaptan.[8] It follows that the sulfenyl chloride and succinimide produced simultaneously would be dehydrochlorinated by the addition of triethylamine, much as in the reaction of sulfenyl chloride and succinimide:[7]

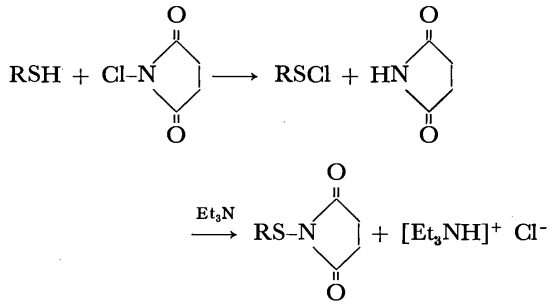

TABLE 1. THE YIELDS, MP, AND IR SPECTRA OF THE PREPARED *N*-(ALKYLTHIO)- AND *N*-(ARYLTHIO)SUCCINIMIDES[a]

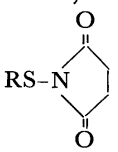

R	Yield (%)	Mp (°C)	(lit mp) (°C)	IR (C=O)[b] (cm^{-1})
Phenyl	78.2	117—117.5	(118—119)[5]	1740
o-Tolyl	71.2	88—88.5	(85.5—86)[2]	1730
m-Tolyl	86.4	108—109	(100—102)[7]	1725
p-Tolyl	75.6	114.5—115	(113.5)[2]	1725
p-Chlorophenyl	79.3	146—147	(142.5—143.5)[2]	1730
Benzyl	66.4	164—165	(165—166)[3]	1725
Benzhydryl	64.7	155—156		1725
Ethyl	34.2	48—49		1725
Isopropyl	68.6	48.5—49.5		1725
t-Butyl	79.6	156.5—157.5		1725
Cyclohexyl	74.5	106.5—107	(99)[7]	1725

a) Satisfactory elemental analyses were obtained for all compounds. Analytical data for the new compounds are shown in Experimental section.
b) All IR spectra were measured in KBr pellets.

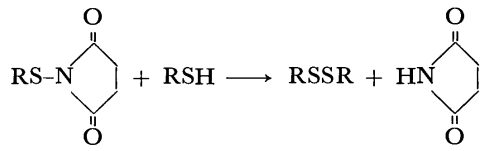
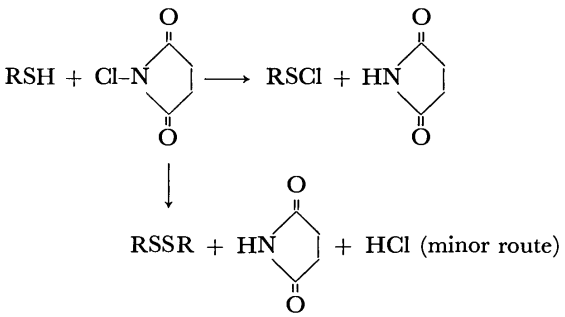
The red or orange coloration in the mixture solution of mercaptan, NCS, and benzene may be attributed to the formation of sulfenyl chloride. After the addition of triethylamine to this solution, the color of the reaction mixture fades. This indicates the consumption of sulfenyl chloride.

The use of an excess of mercaptan must be avoided. Otherwise, the product will be obtained in a lower yield than that shown in Table 1, because the *N*-(organothio)succinimide produced will react with the excess mercaptan to produce disulfide.[10,11]



Therefore, the purity of NCS must be determined by iodometrical titration and a calculated equimolar amount of NCS must be used. For example, in the case of the preparation of *N*-(phenylthio)succinimide, the yield increased from 55.1 to 78.2% as the NCS became more pure. The yield is still not quantitative, however. This may be because a part of the mercaptan is oxidized to disulfide by the reaction with NCS in spite of the major route to sulfenyl chloride. In fact disulfides were detected as by-products in all runs.



This method for the preparation of *N*-(organothio)-succinimide is superior to the method using chlorine gas[7] because the amount of NCS required as a chlorinating agent can be exactly and conveniently weighed, and it needs only one reaction vessel, even though the method involves two steps.

Experimental

All the melting points are uncorrected. The IR spectra were recorded with a JASCO IR-S spectrometer. The mercaptans were used without further purification. The purity of the NCS was determined by iodometrical titration before use.

General Procedure for the Preparation of N-*(Alkylthio)- and* N-*(Arylthio)succinimides.* A solution of mercaptan (20 mmol) in benzene (20 ml) at room temperature (*ca.* 20 °C) was added, all at once, to a suspension of NCS (20 mmol) in benzene (110 ml). After being stirred for 5 min, the mixture turned red or orange and the temperature rose to 30—35 °C. After the temperature had been depressed to 25 °C, a solution of triethylamine (21 mmol) in benzene (20 ml) was added, drop by drop, over a period of 5 min at 20—30 °C with cooling. The reaction mixture faded; it was then allowed to stand for 30 min, was washed thoroughly with water, and was then dried over anhydrous sodium sulfate. After the removal of the solvent, it was recrystallized from ethanol.

N-*(Benzhydrylthio)succinimide.* Found: C, 68.22; H, 5.02; N, 4.43; S, 10.52%. Calcd for $C_{17}H_{15}NO_2S$: C, 68.66; H, 5.08; N, 4.71; S, 10.78%.

N-*(Ethylthio)succinimide.* Found: C, 45.33; H, 5.74; N, 8.75; S, 20.04%. Calcd for $C_6H_9NO_2S$: C, 45.27; H, 5.70; N, 8.80; S, 20.14%.

N-*(Isopropylthio)succinimide.* Found: C, 48.36; H, 6.48; N, 8.11; S, 18.72%. Calcd for $C_7H_{11}NO_2S$: C, 48.53; H, 6.40; N, 8.09; S, 18.51%.

N-*(t-Butylthio)succinimide.* Found: C, 51.39; H, 7.04; N, 7.45; S, 17.14%. Calcd for $C_8H_{13}NO_2S$: C, 51.31; H, 7.00; N, 7.48; S, 17.12%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1900 (1973)

Dielectric Relaxation in α,ω-Dichloroalkanes in Benzene Solution

Suresh CHANDRA* and R. A. YADAV
Physics Department, University of Gorakhpur, Gorakhpur, India
(Received June 16, 1972)

We have recently reported the asymmetric dielectric behaviour for α,ω-dichloroalkanes in pure liquid.[1] In order to confirm the behaviour, dielectric studies have been made in dilute solutions since the result would give an idea of the molecular structure in quasi-isolated state. Dielectric constants and loss of five α,ω-dichloroalkanes (1,2-dichloroethane; 1,4-dichlorobutane; 1,6-dichlorohexane; 1,8-dichlorooctane; and 1,10-dichlorodecane) have been measured at frequencies 450 KHz, 1.8 GHz, 4.0 GHz, and 23.7 GHz in dilute benzene solution at 35°C. The experimental arrangement and procedure are the same as described earlier.[2,3] An asymmetric distribution of relaxation time has been obtained for all cases giving skewed arcs when the dielectric loss slope is plotted against the dielectric constant slope (Fig. 1).

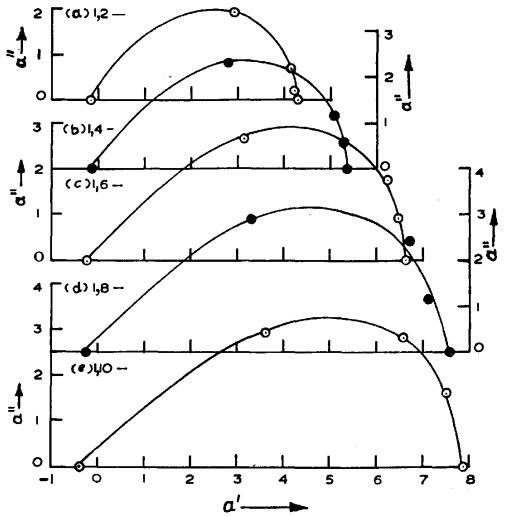

Fig. 1. Complex plot between a'' and a' for some α,ω-Dichloroalkanes in benzene solution.

The results have been analysed in terms of the Davidson-Cole plot.[4] They indicate the presence of some cooperative phenomenon in case of associated liquids[7,8] with a few exceptions.[1,5,6] Skewed arc behaviour in α,ω-dichloroalkanes can be understood in terms of intramolecular cooperative relaxation mechanism, *viz*; the intramolecular group rotations are such that the rotating electric moments interact sufficiently with one another and the reorientation of one segment triggers many other reorientations. Thus this intramolecular cooperative phenomenon has similar effect to that of intermolecular cooperative phenomena known to give skewed arc dielectric behaviour.

TABLE 1. DIELECTRIC RELAXATION PARAMETERS OF α,ω-DICHLOROALKANES IN BENZENE SOLUTION AT 35°C ASSUMING A DAVIDSON-COLE TYPE DISTRIBUTION

Parameters	1,2-DCE	1,4-DCB	1,6-DCH	1,8-DCO	1,10-DED
$\tau_{cs} \times 10^{12}$ (s)	7.3	11.6	16.5	23.6	31.6
β_{sol}	0.67	0.64	0.61	0.59	0.57

The characteristic relaxation time (τ_{cs}) and asymmetric distribution parameter (β_{sol}) in solution are presented in Table 1. We see that the value of τ_{cs} increases with increasing chain-length. The value of β_{sol} increases with decreasing chain-length suggesting more rigid structure with decreasing chain-length.

The authors are thankful to Prof. D. Sharma for his interest in the work.

Sterically Controlled Syntheses of Optically Active Organic Compounds. XXI. The Temperature Dependence of Hydrogenolytic Asymmetric Transamination between Optically Active Phenylglycine and α-Keto Acids*

Kaoru HARADA, Tameo IWASAKI, and Tadashi OKAWARA

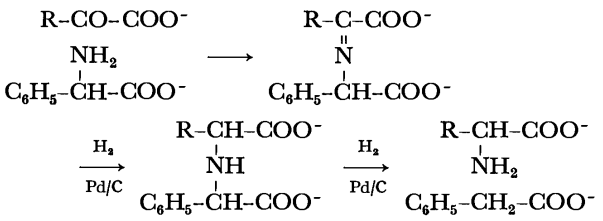
Institute for Molecular and Cellular Evolution, Department of Chemistry, University of Miami, 521 Anastasia Avenue, Coral Gables, Florida 33134, U.S.A.

(Received September 25, 1972)

Generally, temperature is one of the most important factors in determining the molecular conformation in asymmetric syntheses. Several studies of the effect of temperature on asymmetric syntheses have been recorded in the literature.[1-7]

A temperature dependent asymmetric synthesis by hydrogenolytic asymmetric transamination between ethyl pyruvate and optically active benzylic amines was reported from this laboratory.[8,9] It was found that the difference of entropy of activation ($\Delta\Delta S^{\neq}$) for the diastereomeric transition states was the important factor in the asymmetric synthesis. These facts agreed with the previously proposed explanation (chelation hypothesis) for the steric course of the sterically controlled reaction.[10-12]

In the previous study from this laboratory, the hydrogenolytic asymmetric transamination between α-keto acids and optically active α-phenylglycine in aqueous alkaline solution was examined.[13,14] The possible steric course of this asymmetric synthesis was discussed.[14] The chelated intermediate formed between the substrate and the catalyst would not be expected to be as important in this reaction as in similar asymmetric reactions using organic solvents[10-12] because of the high dielectric constant of the solvent used.



This investigation examines the temperature dependence of the hydrogenolytic asymmetric transamination between (*R*)-α-phenylglycine and (A) pyruvic acid or (B) α-ketoglutaric acid. The reaction temperatures used ranged from 0 to 70°C. The hydrogenation reactions were carried out at 1 atmosphere of hydrogen using palladium on charcoal (5%) in an aqueous solution that contained an equimolar amount of sodium hydroxide to the carboxyl groups in the substrate. The reaction procedures are similar to those described in an earlier paper.[13,14] The results are summarized in Table 1. When (*R*)-phenylglycine was used, (*R*)-alanine and (*R*)-glutamic acid were synthesized. The optical purities ranged from 31 to 57% for alanine and from 4 to 46% for glutamic acid. At 0°C, the optical purities of amino acids were the highest and the optical purities decreased as the reaction temperature was increased.

Formation of optically active amino acids in the asymmetric synthesis is due to the difference between the rates of formation of the two diastereomers from the starting material (substrate*). The rates of formation of the diastereomeric activated complexes are determined by the difference of the free energies of activation ($\Delta G^{\neq}$) for two diastereomeric transition states. According to the transition state theory, the rate of formation of an activated complex [(*R*)-substrate* complex]$^{\neq}$ in the transition state is expressed as follows:[2,15-18]

$$k_R = \kappa_R \frac{kt}{h} e^{-\Delta G_R^{\neq}/RT}$$

If we assume that the transmission coefficient κ_R is equal to κ_S, the *R*-product*/*S*-product* is expressed as shown below:

$$R\text{-product}^*/S\text{-product}^* = \frac{R}{S} = \frac{k_R}{k_S} = \exp\frac{\Delta S_R^{\neq} - \Delta S_S^{\neq}}{R} \exp\frac{-(\Delta H_R^{\neq} - \Delta H_S^{\neq})}{RT}$$

$$= \exp\frac{\Delta\Delta S_{R\text{-}S}^{\neq}}{R} \exp\frac{-\Delta\Delta H_{R\text{-}S}^{\neq}}{RT}$$

$$\log\frac{R}{S} = \log\frac{k_R}{k_S} = \frac{\Delta\Delta S_{R\text{-}S}^{\neq}}{2.3R} - \frac{\Delta\Delta H_{R\text{-}S}^{\neq}}{2.3RT}$$

TABLE 1. ASYMMETRIC SYNTHESIS OF AMINO ACIDS AT VARYING TEMPERATURES

Reaction		Reaction temp. (°C)	Phegly config.	Synthesized amino acid		DNP-Amino acid	
				Config. of amino acid	Yield[a] (%)	$[\alpha]_D^{25}$[b]	Optical purity[c] (%)
A	Ala	10	*R*	*R*	—[d]	−82.0	57
		20	*R*	*R*	33	−74.5	52
		30	*R*	*R*	29	−66.0	46
		40	*R*	*R*	26	−59.8	42
		50	*R*	*R*	46	−56.2	39
		60	*R*	*R*	44	−44.8	31
		70	*R*	*R*	40	−50.8	35
B	Glu	10	*R*	*R*	30	+37.4	46
		20	*R*	*R*	24	+31.0	38
		30	*R*	*R*	29	+21.8	27
		40	*R*	*R*	27	+16.6	20
		50	*R*	*R*	36	+10.8	13
		60	*R*	*R*	34	+ 9.8	12
		70	*R*	*R*	35	+ 3.2	4

a) Yields were calculated from phenylglycine.
b) Specific rotation of DNP-alanine was measured in 1M NaOH. Specific rotation of DNP-glutamic acid was measured in glacial acetic acid.
c) Optical purity was defined as $[\alpha]_D$ obsed/$[\alpha]_D$ of the compound ×100; DNP-(*R*)-(−)-alanine, $[\alpha]_D^{25}$ −143.9° (1M NaOH), DNP-(*R*)-(+)-glutamic acid, $[\alpha]_D^{25}$ +80.8° (AcOH).
d) A part of the sample was lost.

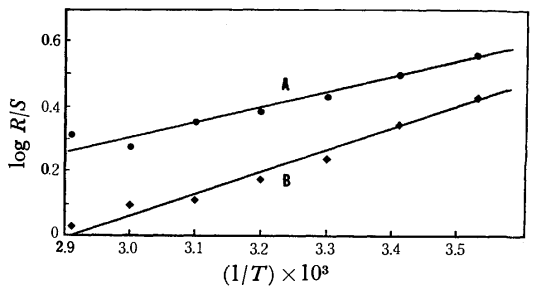

Fig. 1. Temperature dependence of hydrogenolytic asymmetric transamination. Reaction A, alanine: Reaction B, glutamic acid.

Figure 1 shows the plot of log R/S against $1/T$ from the results obtained in the asymmetric transamination reactions. In both reactions A and B, the plots are almost linear in the range from 10 to 70°C. From this plot, $\Delta\Delta H^{\ddagger}_{R-S}$ and $\Delta\Delta S^{\ddagger}_{R-S}$ of reactions A and B were calculated.

reaction A $\Delta\Delta H^{\ddagger}_{R-S} = -5.0$ kcal mol^{-1}

$\Delta\Delta S^{\ddagger}_{R-S} = -11.8$ cal mol^{-1} deg^{-1}

reaction B $\Delta\Delta H^{\ddagger}_{R-S} = -7.5$ kcal mol^{-1}

$\Delta\Delta S^{\ddagger}_{R-S} = -22.0$ cal mol^{-1} deg^{-1}

These results indicate that the free energy of activation ($\Delta G^{\ddagger}$) is independent of the reaction temperature and that the asymmetric hydrogenation reaction proceeds by a single mechanism in this temperature range.

Experimental

All the asymmetric transamination reactions were carried out as described in reference 14, except for the reaction temperature and the apparatus. Hydrogenation and hydrogenolysis were carried out in a three neck flask (100 ml) at one atmosphere with magnetic stirring at varying temperatures. The accuracy of the reaction temperature is about ±1°C. (*R*)-Phenylglycine (1.5 g, 0.001 mol, $[\alpha]_D^{25}$ −168.0°, *c* 1.11, 5M HCl) and 0.01 mol of α-keto acids were dissolved in 20 ml (30 ml in the case of α-ketoglutaric acid) fo aqueous sodium hydroxide (1M). Palladium on charcoal (5%, 2.5 g) was added to the solution and hydrogenation and hydrogenolysis were carried out. The hydrogenation and hydrogenolysis reactions proceeded at different rates depending on the temperature used. At 70°C, 20 min was sufficient to complete the reaction; however, at 10°C, more than 100 hr was necessary. After hydrogenolysis, the resulting amino acids were isolated by the use of a Dowex 50 column. A part of the amino acid was converted to DNP-amino acid by the use of 2,4-dinitrofluorobenzene. The resulting amino acids were purified by the use of Celite column chromatography in the usual manner[19] without fractionation of optical isomers. The DNP-amino acids were used for measurement of optical purity of amino acid. The dinitrophenylation was especially necessary in these asymmetric syntheses because the resulting crude amino acids contained impurities which had amphoteric properties. Therefore, the yield of alanine and glutamic acid was determined by the use of an automatic amino acid analyzer after appropriate dilution. The elution pattern of alanine in the amino acid analyzer showed 4—7 peaks other than alanine. However, the elution pattern of glutamic acid showed a single peak.

This work was supported by Grant No. NGR-10-007-052 from the National Aeronautics and Space Administration. The authors wish to express their thanks to Mr. Charles R. Windsor for amino acid analyses.

(Received June 12, 1972)

Ionic photodissociation of electron donor-acceptor (EDA) complexes of *s*-tetracyanobenzene (TCNB) and pyromellitic dianhydride (PMDA) with 2-methyltetrahydrofuran (MTHF) has been investigated by means of nsec flash photolysis and transient photocurrent measurements. The solvent-shared ion-pair of TCNB anion and MTHF cation is formed from the excited charge-transfer (CT) singlet state of a TCNB–MTHF complex, dissociating into solvated ions. TCNB complexes with aromatic hydrocarbons dissociate directly into ions from the lowest excited CT singlet state. Dissociation of PMDA complexes occurs in the CT triplet state in nonpolar solvents and mainly in the excited CT singlet state in polar solvents. The relative rate constant of radiationless process, which competes with ionic dissociation in the excited singlet state, can be deduced from the effect of solvent on ionic photodissociation. It has been confirmed for the first time that the ionic dissociation of a TCNB–benzene–1,2-dichloroethane (DCE) system occurs in the excited Franck-Condon (FC) state. It is pointed out that the latter dissociation mechanism is not inconsistent with all the results obtained for TCNB and PMDA complexes under various conditions.

Ionic photodissociation is one of the most important processes of EDA complexes. At the present stage of our investigation on the electronic structures and dynamic behaviors of EDA complexes in the excited state, the results on weak EDA complexes may be summarized as follows. TCNB complexes with methyl-substituted benzenes as well as some other aromatic donors such as naphthalene in polar solvents dissociate into ions in the excited singlet state, while in nonpolar solvents, ionic dissociation does not occur but only the CT fluorescence is observed.[1,2] It has become clear that a TCNB–α-methylstyrene complex in amylalcohol at low temperature dissociates in the CT triplet state.[3] Dissociation of PMDA complexes with mesitylene and hexamethylbenzene (HMB) occurs also in the CT triplet state.[4] The dissociative state of tetracyanoethylene (TCNE) complexes with tetrahydrofuran (THF), dimethylsulfoxide, *N*,*N*-dimethylformamide and acetone donors was concluded to be CT triplet state by means of ESR experiments.[5,6] A flash photolysis study on a TCNE–THF complex gave the same conclusion.[7] The present work deals with the complex formation and ionic dissociation of TNCB–MTHF and PMDA–MTHF complexes. The dissociation mechanism of TCNB complexes will be discussed in detail on the basis of present and previous results.

Experimental

Experimental methods are the same as reported previously.[2] Acetonitrile and butyronitrile were refluxed over phosphorus pentoxide and distilled from anhydrous calcium carbonate. MTHF was refluxed over metallic sodium for a few hours, distilled and stocked in a vacuum. Spectrograde DCE, 1,4-dioxane, THF, ethanol (Nakarai Chemicals) and benzene (Merck) were used without further purification. TCNB, PMDA and naphthalene were the same samples as used before.[2] All the solutions were degassed by the usual freeze-pump-thaw method.

Results

Absorption and Luminescence Spectra of MTHF Complexes. The absorption spectra of TCNB–MTHF–DCE and PMDA–MTHF–DCE systems are given in Figs. 1 and 2, respectively. As the concentration of the donor increases, the intensity of the absorption band of the acceptor decreases, the swelling and tail appearing at 280 and 330 nm, respectively. The isosbestic points can be recognized in both systems. A spectrum, obtained by normalizing spectra (a) and (c) at the 320 nm peak and subtracting the former from the latter, has broad bands with peaks at 280 and 323 nm. Both bands satisfy approximately the relation between the absorption maxima of TCNB complexes and the ioniza-

tion potential of the donor,[8] although the precise value of the ionization potential of MTHF is not known. Hence, they may be assigned to CT transitions of MTHF complexes with TCNB and PMDA. Absorption spectra were measured with a high concentration of the acceptor, and the molar extinction coefficient of the CT band as well as the equilibrium constant of the complex formation were evaluated. Since the original band of the acceptor has a small absorption intensity in the wavelength region examined, the following equation was used.

$$\varepsilon^* - \varepsilon_A = (\varepsilon - \varepsilon_A)/(1 + 1/Kc_D)$$
$$\varepsilon^* = D/c_A l$$

where D is the absorbance at the wavelength examined and l is the optical path length of the cell in cm. ε_A and ε represent molar extinction coefficients of the acceptor and the EDA complex at that wavelength, respectively. c_A and c_D are the concentrations of the donor and the acceptor, respectively. K is the equilibrium constant. The results for the TCNB–MTHF–DCE system are shown in Fig. 3, where the measure-

ments were made at 350 nm. The complex formation of MTHF, a weak electron-donor reagent, with TCNB and PMDA is thus confirmed. K was obtained as 0.45 and ε was calculated to be 6 at 350 nm. The extinction coefficients of CT bands at 323 and 280 nm were 700 and 1100, respectively.

Fluorescence spectra of the TCNB–MTHF complex observed at room temperature and at 77 K by exciting the CT absorption band are shown in Fig. 4. The fluorescence lifetime at room temperature is *ca.* 5 ns at all the wavelengths in the fluorescence band, while at 77 K the lifetime depends on the fluorescence wavelength. It increases from *ca.* 20 to 40 ns as the wavelength increases. A re-absorption of the CT fluorescence by the excited complex or by photoproduced transients was observed in the case of laser excitation. A phosphorescence spectrum of the TCNB–MTHF complex has a peak at about 500 nm with a lifetime 28.4 ms. Flourescence of the PMDA–MTHF complex has a peak at 390 nm with a very short lifetime (a few ns). No re-absorption effect by laser excitation was observed.

Ionic Dissociation of MTHF Complexes. The transient absorption spectrum obtained by exciting the TCNB–MTHF complex at 347 nm is shown in Fig. 5. Since the absorption spectrum on the wave-

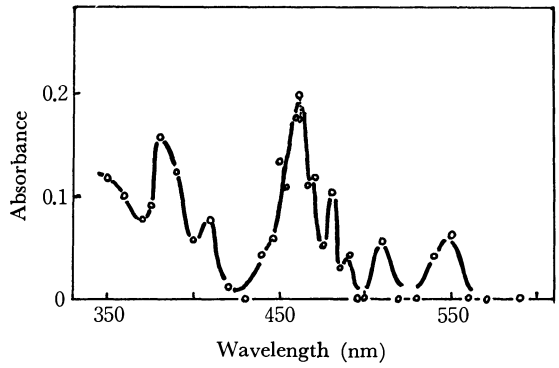

Fig. 5. The transient absorption spectra observed immediately after excitation of a TCNB–MTHF complex; the concentration of TCNB is 0.1 M.

length region smaller than 500 nm is similar to that of TCNB anion, it is confirmed that the excitation of the complex leads to ionic dissociation. On the other hand, the bands in the wavelength region greater than 500 nm, which cannot be observed by the ordinary stationary measurements, may be due to the excited state of a photoproduct, since the absorbances of these bands increase by the irradiation of CT band with a steady Xe-lamp. The kinetic relation between the transmittance at 462 nm and the transient photocurrent is given in Fig. 6. The transimittance is almost constant in the course of several μs after excitation, while the peak photocurrent is attained during *ca.* 2 μs. The current decays slowly ($\tau_{1/2}\sim 10$ μs). The difference between transmittance and photocurrent may be ascribed to a transient, which gives no current but shows an absorption spectrum similar to that of TCNB anion. The transient is deemed to be an ion-pair of TCNB anion and MTHF cation, which is produced rapidly by laser excitation, dissociating gradually into ions. The results in the case of the aerated system are the same as those in the degassed case.

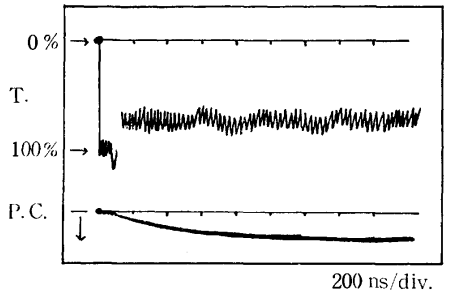

Fig. 6. The kinetic relation between the transient photocurrent and the transmittance of a TCNB anion at 462 nm, induced by exciting TCNB–MTHF complex.

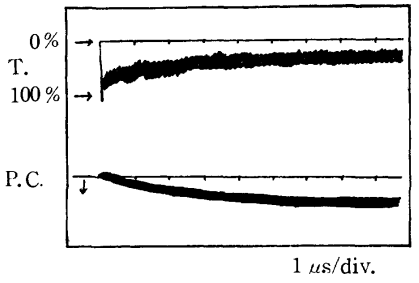

Fig. 7. The kinetic relation between the transient photocurrent and the transmittance of a PMDA anion at 660 nm, induced by exciting a PMDA–MTHF complex.

The dissociation process was also examined in an ethanol solution, where the volume ratio of MTHF to ethanol was 1:1. The transient absorption was similar to that of a TCNB anion. The transmittance was constant with respect to time, while most of the photocurrent was induced rapidly, the delayed ($\sim$100 ns) photocurrent being also detected.

Assuming that an extinction coefficient of the ion-pair is equal to that of the dissociated ions, the quantum yields of dissociation as well as ion-pair formation for the systems of TCNB–MTHF and TCNB–MTHF–ethanol were estimated according to the same method as reported previously.[2] Values for the quantum yield were 0.03 and 0.089, respectively.

Since all the measurements were carried out under a high concentration of TCNB, effect of the direct excitation of the tail of the original TCNB band should be examined. A small and rapidly rising photocurrent was induced in the TCNB–DCE system, which may be due to ionization of TCNB itself. A slowly rising curve of laser-induced photocurrent similar to that of the TCNB–MTHF system was observed by exciting the TCNB–MTHF–DCE system, where the concentration of TCNB was equal to that of the TCNB–DCE system. Thus, it might be concluded that the present results are due to the ionic dissociation of the TCNB–MTHF complex.

We have confirmed that a PMDA anion is produced by exciting a PMDA–MTHF complex with a 347 nm laser pulse at room temperature. Oscillograms showing the transmittance at the wavelength of the PMDA anion absorption (660 nm) as well as a laser-induced photocurrent are given in Fig. 7. The peak photocurrent was measured at *ca.* 8 μs after excitation. It decayed slowly ($\tau_{1/2}\sim 300$ μs). The rise curve of the photocurrent is in good agreement with that of absorption band of a PMDA anion. At 77 K the measurement of transient absorption spectra is impossible because of a laser-induced cracking of an MTHF rigid solution. No appropriate condition could be found in which the rise of a PMDA anion can be related to the decay of the phosphorescence. In the aerated system the peak photocurrent was measured at *ca.* 2.5 μs after excitation, its value being *ca.* one fifth of that in the degassed system.

The effect of solvents on the dissociation of a PMDA–MTHF complex was examined by photocurrent measurement. A schematic representation of oscillograms is given in Fig. 8. In a DCE solution, the peak photocurrent was reached slowly, while in polar solvents such as acetonitrile and butyronitrile rapid as well as slow productions of ions were observed. The rise of a laser-induced photocurrent is in good agreement with

that of transmittance of a PMDA anion in the case of a PMDA–MTHF–acetonitrile system. The photocurrent of a PMDA–acetonitrile system was also confirmed under the same concentration of PMDA as that of a PMDA–MTHF–acetonitrile system. Only rapid rise of the photocurrent was observed, which is *ca.* one fifth of that of a PMDA–MTHF–acetonitrile system. Hence, the present result is concluded to be due to the dissociation of a PMDA–MTHF complex.

We also made an investigation on TCNB–1,4-dioxane, PMDA–1,4-dioxane and PMDA–THF complexes in DCE solutions. The peak photocurrents were observed at several μs after excitation, the delayed formation of ions being confirmed. The effect of excitation light intensity on the production of ions was examined by transient photocurrent measurement. Since the decay of a photocurrent is slower than the rise, the peak photocurrent is approximately proportional to the concentration of dissociated ions. The linear relations obtained between the excitation light intensity and the peak photocurrent show that the ionic dissociation of the present complexes in several solvents is a one-photon process.

Ionic Dissociation of TCNB and PMDA Complexes with Benzene and Naphthalene Donors. TCNB complexes with benzene and naphthalene donors and a PMDA–benzene complex were investigated in several solvents. The transient photocurrent measurements show that these complexes dissociate into ions immediately after excitation. The PMDA–benzene complex was examined in DCE and acetonitrile, where the volume ratio of benzene donor *vs.* solvent was fixed to 1:2. The results obtained on the TCNB–naphthalene complex are listed in Table 1, where the values of dielectric

constant and viscosity coefficient are corrected by the method described previously. Although the measurement of the photocurrent has been reported,[2)] we examined the TCNB–benzene–DCE system in more detail, with a 1:2 volume ratio of benzene to DCE. The rise and decay curves obtained for the fluorescence and photocurrent are shown in Figs. 9A and B. The observed fluorescence lifetime is about 20 ns. The simulated curves, considering a duration of an exciting pulse, are given in Fig. 9C, where (a), (b), and (c) represent the observed exciting pulse and the rise curves of radical ions from the fluorescent state ($\tau\sim$20 ns) and excited FC states, respectively. The present observation of photocurrent agrees with (c). From an

examination of the effect of excitation light intensity upon photocurrent, it has been confirmed that this ionic dissociation is a one-photon process. The photocurrent of TCNB in DCE was confirmed to be much smaller than that of the present system.

Discussion

The Electronic Structure of a TCNB–MTHF Complex in the Ground and Excited States. It has been shown that the 1st and the 2nd CT absorption bands of TCNB–mesitylene and TCNB–HMB complexes are due to transitions from the highest occupied molecular orbital (MO) of the donor to the lowest and the 2nd lowest vacant MO's of the acceptor, respectively.[9)] In the case of benzene and toluene donors the 2nd CT band was not observable since there are absorption bands of the donor in this wavelength region. In the case of the TCNB–MTHF complex, two CT bands were observed since there is no absorption band of the donor. The energy gap between the 1st and the 2nd new bands was estimated to be 0.56 eV, from the observed frequencies of the two bands. The value differs somewhat from the gap between the lowest and the 2nd lowest MO's of TCNB (0.68 eV). The difference may be related to the relative locations of the CT and the original bands of TCNB. In the case of mesitylene and HMB donors, two CT's are observed in the wavelength region longer than the original TCNB band, which results in the small configuration interaction (CI) between the CT and the locally excited (LE) configurations. On the other hand, the CT bands of

9) S. Iwata, J. Tanaka, and S. Nagakura, *J. Amer. Chem. Soc.*, **88**, 894 (1966).

the present complex were observed in the same wavelength region as that of the original bands of the acceptor. Hence, it is expected that the extent of CI between the CT and the LE configurations is rather large. Thus, the energy gap between the two bands of the TCNB–MTHF complex is not connected directly with the gap between two MO energies.

According to Iwata *et al.*,[9] the CT degree in the excited singlet FC state of TCNB complexes increases as the ionization potensial of the donor decreases. The ionization potential of MTHF is not known but may be larger than that of benzene (9.24 eV), since the ionization potensial of THF is 9.49 eV. The large interaction between the CT and the LE configurations is expected in the TCNB–MTHF complex. The LE character in the excited FC state may be rather high.

Fluorescence spectra of a TCNB–MTHF complex at room temperature show a large Stokes shift of about 10200 cm^{-1}. This can be explained by the same consideration as that on TCNB complexes with other donors. The large Stokes shift of TCNB–methylsubstituted benzene complexes was concluded to be due to differences in energy and geometrical structure between the excited FC and the fluorescent state. This conclusion was deduced from fluorescence studies as well as from direct observations of excited singlet-singlet absorption spectra.[8,10–12] Since the LE character of the excited FC state of the TCNB–MTHF complex seems to be high and the value of Stokes shift is quite large, it is considered by analogy to the case of the TCNB–methylsubstituted benzene complexes that the CT character of the fluorescent state is rather high. The fluorescence spectrum of a TCNB–MTHF complex by laser excitation are re-absorbed by some transients photoproduced from the excited FC state. Absorption spectra of the transient estimated from the re-absorption are similar to those of TCNB anion. Due to the short fluorescence lifetime it was difficult to analyze fluorescence decay curves at several wavelengths, though this is necessary for assigning the transient to the fluorescent state of the complex.[13] Nevertheless, similarity of the spectra of the fluorescent state to those of a TCNB anion is consistent with the large value of the Stokes shift and with the above argument concerning the high CT character of the fluorescent state. Hence, the changes in energy as well as electronic structure of the TCNB–MTHF complex occur in the course of the process from the excited FC to the relaxed fluorescent states, just as in the case of TCNB–methylsubstituted benzene complexes.

The Stokes shift of the present complex at 77 K is almost the same as that at room temperature, differing from the case of TCNB complexes with methylsubstituted benzenes.[8,10] Dependence of fluorescence lifetime on the observed wavelength was not observed in the case of the latter TCNB complexes at 77 K. The fact that the lifetime increases with the fluorescence wavelength may be ascribed to the relaxation process including surrounding molecules from the excited FC state to the equilibrium state. This particular behavior might be due to the fact that the electron donating orbital is the lone pair orbital of oxygen atom and the structural change involving environments is possible even at 77 K.

Ionic Dissociation of TCNB Complexes. Dissociation mechanism of TCNB complexes should be discussed in detail in consideration of the results of previous[2] and present works. All these complexes with cyclic ethers, methylsubstituted benzenes and naphthalene have a quite polar structure in the fluorescent state and form ion-pair or dissociate into ions rapidly in various solvents. In the case of cyclic ether donors, ions are produced rather slowly through the ion-pair state from the excited CT singlet state in nonpolar and slightly polar solvents. In moderately and strongly polar solvents the new process of direct dissociation, not through the ion-pair, is observed in addition to the above delayed process. Stabilization of ion-pair state may be partially due to the Coulomb attraction force between the cation and the anion. Since the positive charge is localized on an oxygen atom, this attractive force may be rather large. In the case of TCNB complexes with methylsubstituted benzenes, dissociation occurs spontaneously in the lowest excited CT singlet state in various solvents and the ion-pair is not observed. We have pointed out that the ionic dissociation yield increases with the increase of ionization potential of the donor.[2] However, the dissociation yield of a TCNB–naphthalene complex in acetonitrile is larger than that of a TCNB complex with mesitylene, although the ionization potential of naphthalene is lower than that of mesitylene. This may be ascribed to the difference of the Coulomb attractive force between the donor cation and the acceptor anion, if one assumes that the larger Coulomb attraction leads to the stronger nondissociative quenching of the excited state. The Coulomb force between a TCNB anion and a naphthalene cation seems to be rather small, since the positive charge in naphthlene is more delocalized than that in methylsubstituted benzene as well as in cyclic ether. From this consideration and the solvent effect on ionic dissociation of some TCNB complexes, it is concluded that the ionic dissociation of TCNB complexes depends upon the solvation energy on the one hand and upon the Coulomb force between ions on the other.

In the above discussion, the difference of solvation energies of different donor cations was not considered explicitly. The particular behavior of TCNB–cyclic ether complexes may be attributed partly to the property of the donor solvent itself, since cyclic ether is a well-known solvent which stabilizes ion-pair rather than dissociated ions. For example, Briegleb and Lind showed the ion-pair formation in the case of THF–nitrosubstituted benzenes by analyzing an ESR hyperfine pattern.[14] The ion-pair formation was reported

also by Pilette and Weiss by analysing the decay of a PMDA anion,[15] produced by exciting the CT bands of PMDA complexes. They interpreted the results in terms of the equilibrium between ion-pair and dissociated ions as well as of the degradation of ion-pairs. In the case of TCNB–methylsubstituted benzene complexes, it is not certain whether the ion-pair was produced or not. Direct observation of the rapid formation of ion-pair was achieved for the first time for a TCNB–MTHF complex.

It should be noted that the ion-pair is a solvent-shared one. From the study on the electronic structure of the EDA complexes we have made it clear that the fluorescent state of these complexes is a contact ion-pair.[11,12] The excited equilibrium state of a TCNB–MTHF complex also seems to be quite polar. The lifetime of this fluorescent ion-pair is *ca.* 5 ns while that of the other ion-pair deduced from the absorption as well as the photocurrent measurement is a few μs. Since the difference of lifetime is very large, the difference between both ion-pairs cannot be ascribed to the difference of relative orientation of the donor cation and the acceptor anion. The long-lived ion-pair observed in μs time region is concluded to be a solvent-shared ion-pair.

Ionic Dissociation of PMDA Complexes. From the delayed formation of a PMDA anion and the oxgen effect on the dissociation, it is concluded that the PMDA–MTHF complex dissociates in the CT triplet state. Ions were produced not through the ion-pair state with rather long life, which differs from that of a TCNB–MTHF complex. This different behavior can be interpreted as follows. In the case of a PMDA–MTHF complex the rate constant of ion-pair formation might be small and in the same order as the dissociation of an ion-pair. Thus, the concentration of the latter is low and not detectable. In polar solvents, however, rapid production of a PMDA anion was observed in addition to the slow formation process. Due to the strong solvation of the donor cation and the acceptor anion by polar solvents, ionic dissociation may compete with intra-complex processes including intersystem crossing in the excited state. This suggests also a delicate balance between intra-complex interaction and solvation.

In the case of benzene and its derivative donors, dissociation has been confirmed to occur in the lowest CT triplet state. Potashnik *et al.* reported the dissociation from the CT triplet states of PMDA–mesitylene and PMDA–HMB complexes.[4] Recently, this dissociation from the triplet state has been demonstrated also by energy transfer experiments in some solvents.[7] In the present work, we observed the rapid dissociation of a PMDA–benzene complex in DCE as well as in acetonitrile. The rapid dissociation of a PMDA–mesitylene complex in acetonitrile was confirmed previously.[2] In the case of the latter system Achiba *et al.*,[7] have pointed out no participation of the CT triplet state to ionic dissociation. All these results on the PMDA complexes show a delicate effect of environments on the dissociation

15) Y. P. Pilette and K. Weiss, *J. Phys. Chem.*, **75**, 3805 (1971).

The relative rate constant of radiationless processes such as direct degradation as well as intersystem crossing, which compete with ionic dissociation in the excited singlet state, can be deduced from the effect of a solvent on ionic photodissociation. Assuming the same rate constants of photodissociation of TCNB and PMDA complexes, the intersystem crossing process of PMDA complexes may be faster than those of TCNB complexes. The process of PMDA–MTHF is faster than that of PMDA–methylsubstituted benzenes.

Ionic Dissociation from the Excited FC State. Although the dissociative states of EDA complexes have been classified as CT singlet or CT triplet state, the following experimental results seem to suggest the possibility of ionic dissociation in the excited FC state. (1) The electronic structure and geometrical configuration of the fluorescent state differ considerably from those of excited FC state in the case of TCNB complexes. The fluorescent state is therefore produced in nonpolar solvent through relaxation from the excited FC state.[12] In polar solvents, ionic dissociation was observed instead of fluorescence. (2) The intersystem crossing process of TCNB complexes is very rapid and direct formation of the phosphorescent state from the FC state was observed by means of ns flash photolysis studies on the rigid solution of TCNB–toluene complex in the mixture of 2- and 1-propanols.[16] In liquid mixture, ionic dissociation was observed, but not the formation of phosphorescent state. These results suggest that ionic dissociation and intersystem crossing compete with each other in the excited FC state. (3) The solvent effect on the fluorescence quantum yield and lifetime of a TCNB–benzene complex was examined and direct radiationless process was proved to occur from the excited FC state as well as in the course of the relaxation from the excited FC to the relaxed fluorescent states.[2] (4) Energy levels of several states of a TCNB–MTHF complex are given in Fig. 10. The energy levels of a solvent-shared ion-pair as well as dissociated ions are cited from results by Taniguchi *et al.*[17] It should be noted that there is a large gap between the fluorescent and solvent-shared ion-pair states. The ion-pair may be formed from the excited FC state.

We have directly confirmed that ions are produced immediately after exciting the CT band of a TCNB–benzene complex in DCE, not through the fluorescent state. It is concluded that the ionic dissociation of the present complex occurs in the excited FC state. This is the first direct observation of rapid dissociation of EDA complexes which are stable in the ground state. In more polar solvents the fluorescence lifetime of this complex is too short to be analysed, while no photocurrent is observed in less polar solvents.[18] Investigations on other systems are difficult because of short fluorescence lifetime. Hence, a TCNB–benzene–DCE system is the only example at the present stage of investigations. All the results obtained for TCNB and PMDA complexes under various conditions are not inconsistent with the present mechanism of dissociation in the excited FC state.

18) We used a 50Ω resistor for obtaining ns time resolution.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1909—1913 (1973)

Reaction of Mo^{5+} Formed on Supported Molybdena Catalysts with Oxygen or Water

Masamichi AKIMOTO and Etsuro ECHIGOYA

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received August 4, 1972)

Reactivity of Mo^{5+} formed on supported molybdena catalysts with oxygen or water was investigated by means of ESR spectroscopy. Mo^{5+} formed on the alumina carrier could not be oxidized with gaseous oxygen even at 450 °C and was poisoned by water at 200 °C losing its ESR signal. The Mo^{5+} formed on the titania carrier disappeared by reaction with either oxygen or water. The mechanism for the reactions was investigated and the different reactivities of Mo^{5+} with oxygen as regards carrier effect on the structure were discussed.

The surface area of a catalyst determined by the BET method has long been used as a measure of catalytic activity. However, in the case of supported catalysts, the surface area also contains that of carrier and does not give the actual surface area of the active site. The need to determine this area increases particularly in the case where catalysts of the same or similar compositions show different activity and selectivity. Various methods have been presented to determine the number of active sites. As an example, adsorption of hydrogen or carbon monoxide was used to estimate the active surface area of platinum supported on alumina. Carbon monoxide was also utilized in the analysis of real surface area of supported nickel catalyst. For the case of supported metal oxide catalysts, the actual surface area of chromic oxide[1] supported on either alumina, silica or silica-alumina and of bismuth molybdate[2] on silica was estimated by reducing these catalysts with hydrogen followed by the determination of the amount of oxygen required for reoxidation.

We observed Mo^{5+} which cannot be oxidized even at 450 °C, denoted as Mo^{5+} (A), in molybdena catalysts supported on alumina and magnesia.[3] Mo^{5+} formed on silica and zinc oxide carrier, denoted as Mo^{5+} (B), was easily oxidized and showed good selectivity for maleic anhydride in the vapor phase oxidation of butadiene. Both Mo^{5+} (A) and Mo^{5+} (B) appeared in titania supported molybdena catalyst. In order to investigate the mechanism for carbon dioxide and maleic anhydride formation during the course of oxidation of butadiene, a method is desirable for estimating the amount of Mo^{5+} on the surface of supported molybdena catalysts. Thus, the reaction of Mo^{5+} formed in supported molybdena catalysts with oxygen or water was investigated by means of ESR, their structure being discussed with respect to different reactivities.

Amounts of Mo^{5+} (A) and Mo^{5+} (B) formed in MoO_3–TiO_2 catalyst and their distribution on the surface and in bulk were also determined.

Experimental

The reactivity of Mo^{5+} formed in a supported molybdena catalyst was investigated by means of ESR with a glass instrument consisting of a 5 mm o.d. quartz tube, 150 mm long with a glass cock. The amount of catalyst was 0.100 g. Evacuation was carried out with a conventional apparatus consisting of an oil diffusion pump. Heating was carried out by means of a cylindrical thermal air bath. Oxygen was introduced into the reaction vessel from a reservoir connected with the evacuation apparatus and water as saturated vapor at room temperature. First, the catalyst was evacuated for 30 min at 10^{-4}—10^{-5} mmHg and the Mo^{5+} was determined at room temperature by means of ESR using Mn^{2+} as an internal standard. Oxygen or water was then introduced into the vessel at room temperature and the vessel was heated to start the reaction. After the elapse of a certain time, the reaction mixture was cooled to room temperature and evacuated for 30 min. The amount of decreased Mo^{5+} was also determined by ESR at room temperature. The effect of temperature on the amount of

adsorbed oxygen species was also measured by a similar method to that described above. However, in this case the catalyst (50 mg) was evacuated at 540 °C for 1 hr, and oxygen was introduced at a pressure of 5 mmHg at about −100 °C. A temperature-programmed cavity was used for ESR studies at −100—+250 °C. For temperatures above 250 °C, the vessel was heated at various temperatures for a fixed time followed by the determination of the amount of adsorbed oxygen species at room temperature. The catalysts were prepared by wet mixing of alumina sol or titania gel with an aqueous solution of ammonium paramolybdate.[3]

The surface area of the catalysts was determined by the BET method using nitrogen adsorbate. The structure of these catalysts was investigated by X-ray diffraction using nickel-filtered Cu$K\alpha$ radiation. It was found that molybdena can dissolve in anatase titania to the extent of 25—30 mol% and MoO_3–Al_2O_3 catalyst is amorphous within a 66.7 mol% molybdena content.

Results and Discussion

Reaction of Mo^{5+} with Oxygen or Water. Figure 1 shows the effect of reaction temperature and time on the amount of Mo^{5+} decreased as a result of the reaction. Mo^{5+} was formed by the evacuation of MoO_3–TiO_2 (1 : 3) catalyst at 365 °C for 30 min and then reacted. The same result was previously obtained for oxygen pressures of 20 and 200 mmHg. Therefore, gaseous oxygen of 20 mmHg was used in all experiments. We see that water does not react with Mo^{5+} at 100 °C but easily does so at 200 °C. Mo^{5+} is oxidized rapidly with oxygen at 200 °C in contrast with the case at 100 °C.

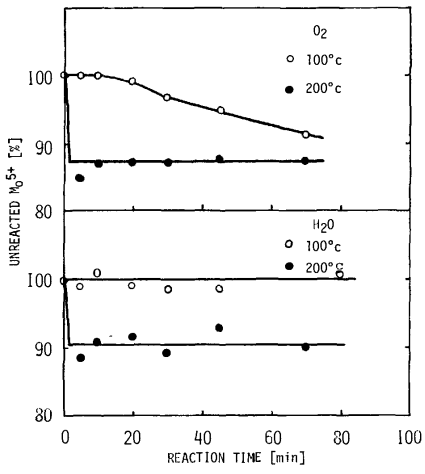

Fig. 1. Reaction of Mo^{5+} with oxygen or water. Effect of reaction time.
catalyst: MoO_3–TiO_2 (MoO_3 25.0 mol%)

The effect of reaction temperature is shown in Fig. 2. Decrease in the amount of Mo^{5+} was observed on reaction with water above 200 °C but not below 175 °C. However, the amount above 250 °C was found to exceed the initial amount presumably due to the formation of new Mo^{5+} in the bulk with a loss of lattice oxygen above 250 °C.

Based on the oxidation temperature, the reaction step can be broadly divided into (a) 57—150 °C, (b) 150—300 °C, and (c) 300—450 °C, attributable to the different reactivities of Mo^{5+} formed on the surface and in the bulk. At 57—150 °C, Mo^{5+} (B) on the surface seems to be oxidized slowly in contrast with the oxidation at 150—300 °C. However, when the temperature exceeds 300 °C, oxygen is assumed to penetrate into the bulk and oxidize Mo^{5+} (B) formed in the lattice. It is notable that the amount of Mo^{5+} decreased on reaction with water at 200—250 °C is approximately equal to that with oxygen. This suggests that water also reacts with surface Mo^{5+} (B) at 200—250 °C. Stable Mo^{5+} was observed in the catalyst not oxidized even at 450 °C. This is in accordance with Mo^{5+} (A) in MoO_3–Al_2O_3 catalyst.

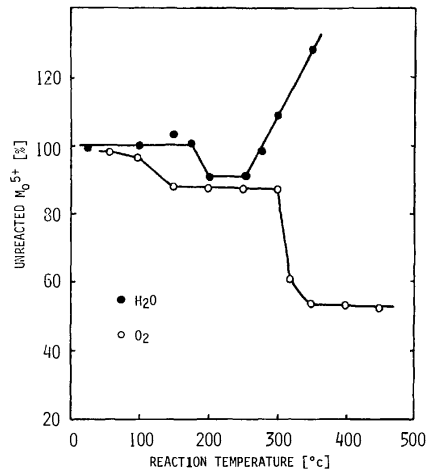

Fig. 2. Reaction of Mo^{5+} with oxygen or water. Effect of reaction temperature.
catalyst: MoO_3–TiO_2 (MoO_3 25.0 mol%)
reaction time: 30 min

The effect of evacuation temperature on the formation of Mo^{5+} in MoO_3–TiO_2 (1 : 3) catalyst is shown in Fig. 3. The catalyst was evacuated for 30 min at 10^{-4}—10^{-5} mmHg and Mo^{5+} was oxidized at 350 °C. The Mo^{5+} disappearing on oxidation is accordingly Mo^{5+} (B) and the rest is Mo^{5+} (A). Mo^{5+} (B) is possibly formed at the sites where lattice oxygen is lost by evacuation. The amount of Mo^{5+} (A) was found to be independent of evacuation temperature, thus suggesting that Mo^{5+} (A) is formed during the preparation of the catalyst. It is possible that water penetrates into the bulk and dissociates to form a bond M–OH (M: Mo^{6+} or Ti^{4+}) during the preparation and that these hydroxyl groups are dehydrated to give water with formation of a bond $-Ti^{4+}$–O–Mo– on heating in water-free atmosphere at higher temperatures. This molybdenum ion is expected to be Mo^{5+} (A). This gives an evidence for the amount of Mo^{5+} (A) exceeding the total amount formed on evacuation below 200 °C.

Figure 3 also shows that the total amount of Mo^{5+} formed on evacuation at 200 °C is nearly equal to that of Mo^{5+} (A), formation of Mo^{5+} (B) being negligible, thus suggesting that dehydration occurs above 200 °C in accordance with the formation of Mo^{5+} (B). From these results, it can be concluded that the Mo^{5+} disappearing on reaction with oxygen or water at 200—250 °C is surface Mo^{5+}.

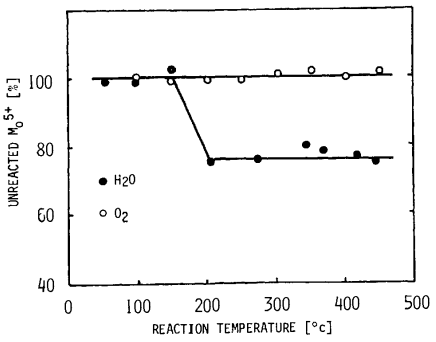

Fig. 4. Reaction of Mo^{5+} with oxygen or water.
catalyst: MoO_3–Al_2O_3 (MoO_3 18.2 mol %)
reaction time: 30 min

Figure 4 shows the result of reaction of oxygen or water with Mo^{5+} formed in MoO_3–Al_2O_3 (2: 9) catalyst, in which the intensity of ESR signal attributable to Mo^{5+} (A) does not decrease on reaction with oxygen even at 450 °C but does so with water above 200 °C. The reactivity of Mo^{5+} (A) with water was thus found to be similar to that of Mo^{5+} (B) on MoO_3–TiO_2 catalyst. The Mo^{5+} (A) disappearing on reaction with water is surface Mo^{5+} (A) since hydroxyl groups are dehydrated easily at higher temperatures and water cannot penetrate into the bulk.

Structure of Mo^{5+}. The amount of Mo^{5+} formed on MoO_3–TiO_2 catalyst was measured by the above method (Table 1). It is of interest to note that the amount of surface Mo^{5+} determined by means of oxidation is approximately equal to that obtained by reaction with water. Decrease in the amount of Mo^{5+} was not observed on reaction with water at 200 °C when Mo^{5+} was previously oxidized at 225 °C. These results suggest that most of Mo^{5+} on the surface is Mo^{5+} (B). The amount of Mo^{5+} (A) increases with a rise in molybdena content to reach a maximum amount at MoO_3 30 mol%, *i.e.*, at a maximum solubility of molybdena in anatase titania, which provides an evidence for the conclusion that most of Mo^{5+} (A) is present in the bulk as predicted by the mechanism for its formation.

a) Evacuated at 365 °C for 30 min.
b) Oxidized with oxygen at 350 °C for 30 min.

Asmolov and Krylov[4,5] investigated the structure of molybdena supported on magnesia or alumina by means of ESR and optical diffuse reflactance spectroscopy, and revealed that Mo^{6+} and Mo^{5+} on the surface are present in octahedric or tetrahedric and square-pyramid coordination, respectively. Mo^{4+} and Mo^{3+} were also found to occupy the lattice points in these carriers in octahedric coordination. It is possible that Mo^{5+} (A) in the bulk has a similar structure to that of Mo^{4+} and Mo^{3+}. Thus, the structure of surface or bulk Mo^{5+} is assumed to be that shown in (1). The structure of Mo^{5+} (B) in the bulk seems to be similar to that of Mo^{5+} (A) in the bulk, but at least one of the oxygen surrounding molybdenum ions is lost with formation of anion vacancy and M is not always metal ion of carrier. In the case of surface Mo^{5+}, M is expected to be metal ion of carrier (Mo^{5+} (A)) or molybdenum ion and metal ion of carrier (Mo^{5+} (B)). Thus, most of Mo^{5+} (A) in the bulk is presumably formed by dispersion and dissolution of molybdena into these carriers followed by the occupation of molybdenum ion at the lattice points of Al^{3+} or Ti^{4+}. Excess electrons appear around the molybdenum ion and are trapped by Mo^{6+} rather than by Al^{3+} or Ti^{4+} forming Mo^{5+} (A). This mechanism is similar to that of acid and base formation in aluminosilicate.[6] Mo^{5+} (A) in the bulk does not seem to be oxidized even at higher temperatures, which agrees with our result. On the contrary, Mo^{5+} (B) is presumably formed with a loss of lattice oxygen at the sites where molybdena is not so dispersed as in the case of Mo^{5+} (A) formation in MoO_3–TiO_2 catalyst. Decrease in the amount of Mo^{5+} on MoO_3–Al_2O_3 and MoO_3–TiO_2 catalyst was observed on reaction with water in contrast with the oxidation. This suggests that the reactions of water with Mo^{5+} (A) and Mo^{5+} (B) follow the same mechanism.

Mechanism for the Reaction of Mo^{5+} with Water.

Basolo and Pearson[7] showed that $(MoO)^{3+}$ is a hard Lewis acid which interacts more easily with a hard Lewis base than with a soft one. Based on this conception, Mo^{5+} formed on MoO_3–TiO_2 (1 : 3) catalyst by evacuation at 365 °C was reacted with either pyperidine, *n*-butylamine or tetrahydrothiophene as hard Lewis bases or toluene or benzene as soft Lewis bases at 200—250 °C. Pyridine was also used as a hard and soft Lewis base. However, decrease in the signal intensity was not observed in these reactions, thus suggesting that Mo^{5+} does not shift to Mo^{4+} even by the formation of a coordination bond between acidic Mo^{5+} and these Lewis bases. Accordingly, disappearance of the ESR signal on reaction with water can not be attributed to the formation of a complex (2) but to some other mechanism.

It is very possible that coordinated water in (2) dissociates above 200 °C to make a σ-bond with molybdenum ion as shown in (3). In proportion to the evacuation temperature, the amount of Mo^{5+} (A) formed in MoO_3–Al_2O_3 catalyst was found to increase with a decrease in the intensity of a broad absorption band due to OH stretching (3000—3600 cm^{-1}). IR measurement also revealed the presence of molecular water on MoO_3–Al_2O_3 catalyst on admission of water. These results provide a powerful evidence for the mechanism (3). Hence, it is concluded that Mo^{5+} shifts to Mo^{6+} with disappearance of its ESR signal by formation of the σ-bond with OH and extraction of electron by a neighboring oxygen. This mechanism is similar to that of Brønsted acid formation from Lewis acidic site in the presence of water at higher temperatures.[8]

Mechanism for the Reaction of Mo^{5+} with Oxygen.

It is interesting to note that Mo^{5+} on MoO_3–TiO_2 is oxidized with oxygen in contrast with Mo^{5+} on MoO_3–Al_2O_3 catalyst. For the purpose of clarifying this carrier effect, the mechanism for oxidation was studied by observation of adsorbed oxygen species with ESR.

Many papers[9] have appeared on the ESR spectra of oxygen species adsorbed on metal oxides. Shvets and Kazansky[10] investigated the spectra of oxygen species adsorbed on reduced molybdena and identified the triplet signal with $g=2.018$, 2.010, and 2.004 with O_2^-. Ishii and Matsu-ura[11] also studied the spectra on molybdena and ascribed the triplet signal with $g=2.04$, 2.01, and 2.00 to O_2^- and a sharp singlet signal with $g=2.00$ to O^-.

In our experiments, no ESR signal of adsorbed oxygen species appeared on alumina and silica even at −100 °C, but the signal was observed on supported molybdena catalysts. At room temperature, a triplet signal with $g=2.019$, 2.009, and 2.003 was observed on MoO_3–TiO_2 (1 : 99) catalyst on admission of oxygen. At 60—100 °C, the signal intensity at $g=2.019$, and 2.009 decreased and at the same time the signal with $g=2.002$ became sharp and increased. When N_2O was adsorbed on the MoO_3–TiO_2 catalyst at 100 °C, a sharp singlet signal with $g=2.002$ was obtained. Thus, the triplet signal with $g=2.019$, 2.009, and 2.003 can be ascribed to O_2^-, and a sharp singlet signal with $g=2.002$ to O^-. This signal of O^- is similar to that of Setaka and Kwan[9] and of Ishii and Matsu-

V: volume of adsorbed oxygen (NTP ml)

ura[11] but does not agree with the results of Shvets and Kazansky.[10] In the case of anatase titania, there appeared only one adsorbed oxygen species O_2^- which showed the maximum amount at 50 °C and disappeared at 230 °C. On the contrary, the MoO_3–TiO_2 catalyst showed the maximum amount of O_2^- at −20 °C and the ion disappeared at 100 °C with formation of a great amount of O^- which showed a maximum at 150 °C, thus suggesting that these oxygen species are not formed on titanium ions but on molybdenum ions.

The effect of temperature on the amount of adsorbed oxygen species formed on MoO_3–Al_2O_3 (2: 9) and MoO_3–TiO_2 (1: 99) catalyst is shown in Figs. 5 and 6, the amount of Mo^{5+} modified with temperature also being shown. Only O_2^- was observed on the MoO_3–Al_2O_3 catalyst, the ion disappearing at 130 °C without any decrease in the amount of Mo^{5+} (Fig. 5). In the case of the MoO_3–TiO_2 catalyst, the amount of Mo^{5+} and O_2^- decreased at higher temperatures with formation of O^-. Thus, the following reaction can be assumed to proceed on the catalyst surface at higher temperatures.

$$O_2(g) \xrightarrow{e} O_2^- \xrightarrow{e} 2O^- \xrightarrow{2e} 2O^{2-} \qquad (4)$$

O^{2-} combines with molybdenum ion to form Mo^{6+}.

Adsorption of oxygen on Mo^{5+} (B) at higher temperatures follows a dissociative mechanism of Langmuir type (Fig. 7), which supports the above reaction mechanism. In contrast with Mo^{5+} (B), this reaction does not seem to proceed on Mo^{5+} (A) formed on MoO_3–Al_2O_3 catalyst, to which the inactivity of Mo^{5+} (A) for oxygen is attributable.

As shown in Figs. 5 and 6, increase in the amount of Mo^{5+} was observed at −100—+20 °C, which is presumably due to formation of Mo^{4+} on these catalysts on evacuation at 540 °C and of Mo^{5+} and O_2^- on admission of oxygen.

These different reactivities of Mo^{5+} with oxygen are presumably attributed to the different dispersions of molybdena in the carriers, *i.e.*, molybdena seems to be finely dispersed in alumina and magnesia with formation of the molybdates in contrast with anatase titania and silica. Accordingly, it is possible that the bond Mo–O–Al^{3+} in MoO_3–Al_2O_3 is strong and difficult to be cut off in contrast with Mo–O–Mo in MoO_3–TiO_2 catalyst. Hence, Mo^{5+} (B) on the latter catalyst is expected to be oxidized with oxygen through cutting off the weak Mo–O–Mo bond followed by formation of the double bond as shown in (5). By IR analysis, the double bond type lattice oxygen was proved to be reduced easily with hydrogen and recovered by reoxidation,[12] which supports the above mechanism for the oxidation of surface Mo^{5+} (B). The formation of this double bond is presumably impossible in the case of alumina and magnesia carriers.

In conclusion, the nature of the Mo^{5+} formed when molybdena is supported on a carrier is remarkably affected by the property of the carrier through its dispersion and formation of the chemical bond. Mo^{5+} (A) on the surface has extra ability in making a single bond, while Mo^{5+} (B) on the surface can make, in addition, a double bond.

Equilibrium Composition of 1-Butanol-Water-Alkali Hydroxide System and Distribution of the Base

Norio YUI, Yoichi KUROKAWA, and Isozi SAKURABA

Department of Applied Science, Faculty of Engineering, Tohoku University, Aoba, Aramaki, Sendai 980

(Received September 6, 1972)

Equilibrium compositions of 1-butanol–water–MOH systems were studied at 25 °C, where MOH represents LiOH, NaOH, and KOH. Water and 1-butanol were determined by means of gas chromatography and the bases by titration. Apparent distribution ratio K_{obs} (molality of MOH in the aqueous phase/molality of MOH in the 1-butanol phase) was dependent on the concentration of base. A considerable amount of water was transferred from 1-butanol to the aqueous phase giving rise to an increase of base concentration. This suggests that the variation of K_{obs} depends principally on the variation of solvent composition. K_{obs} was expressed semi-empirically, considering the activity coefficients calculated by Miller's equation and also the change in the standard free energy resulting from the variation in solvent composition. Decrease of 1-butanol in the aqueous phase with the base concentration obeyed the salting-out equation. The calculated salting-out coefficients were: LiOH 0.176, NaOH 0.192, and KOH 0.184. These values are correlated to Gurney's unitary entropy. The results were compared with those previously obtained for alkali halides.

Solvent extraction of inorganic species was reviewed by Marcus,[1] a good summary being given by Marcus and Kartes.[2] There are a few theoretical treatments on extraction including a thermodynamical treatment by Dyrssen *et al.*[3] and Friedman and Haugen,[4] and a regular solution treatment by Skytte-Jensen.[5]

The authors investigated the change of solvent composition with salt concentration for the distribution of alkali halides between the 1-butanol and aqueous phases at atmospheric pressure and room temperature.[6–10] The relation between solvent composition and distribution ratio or salting-out coefficient was described. It was found that the changes in distribution ratio accompanied by the change of solvent composition could be classified into two groups; one showing a decrease of distribution ratio with an increase of salt concentration and the other an increase of distribution ratio. The greater the change of distribution ratio, the greater the change of solvent composition. Namely, the water transfer from 1-butanol to the aqueous phase increased with an increase of salt concentration. As to 1-butanol, the increase of it in the 1-butanol phase and the decrease in the aqueous phase were observed.

A semi-empirical treatment of distribution was made by using Miller's equation for the activity coefficient and also by assuming that the standard free energy depends linearly on the mole fraction of water in the 1-butanol phase.[9] It was found that the decrease of 1-butanol in the aqueous phase is represented by the salting-out equation, the decrease being correlated to Gurney's unitary partial molar entropy.[10] This study was undertaken to examine the applicability of the above treatment to the 1-butanol–water–alkali hydroxide systems.

Experimental

Reagents. Lithium Hydroxide, Sodium Hydroxide, Potassium Hydroxide, and 1-Butanol: Chemicals of reagent grade were used without purification. Conductivity water was prepared by passing distilled water through a mixed bed of ion exchange resins. The specific conductance was less than 2×10^{-7} ohm^{-1} cm^{-1}.

Procedure. 100 ml of aqueous and 1-butanol solutions of known composition were shaken mechanically in a thermostat for one hour at 25±0.1 °C and then let to stand in the thermostat for one hour. Distribution equilibrium was reached within 15 min. A portion of each solution was taken for analysis.

Analysis. The method has been described.[7] Solvents were analyzed by gas chromatography, and alkali hydroxide by titration with standard hydrochloric acid using phenolphthalein. A mean of three determinations was taken. The solvent was separated from the base by vacuum distillation for avoiding attachment of the base to gas chromatography detector. *t*-Butanol was added to the sample, separated into two phases on removal of base in order to bring about a single phase. Analysis was then carried out. For molality and wt % calculation, density of the solution was determined with a pycnometer (10 ml).

Various stationary liquids for analyzing a water–alcohol mixture have been reported.[11] We found that cetyl alcohol containing a small amount of triethanol amine gave a satisfactory result. The packing column had a support with 60—80 mesh cellite containing stationary liquid (20 wt%). The column was 100 cm long and made of a ϕ 6 mm stainless steel tube bent into a U shape. This was installed in a HITACHI KGL-2A type gas chromatography apparatus equipped with a thermal conductivity detector. Conditions of operation were: Column temperature 95 °C, carrier gas

(He) flow rate 50 ml/min, bridge current 180 mA and output signal 16 mV. A peak ratio was adopted for the analysis, since a linear relation holds between the peak ratio of solvent and its weight ratio, when the peak of 1-butanol is kept constant. A different method was used for the analysis of the aqueous phase to avoid tailing of the water peak. Weighed toluene and sodium chloride as salting-out agent were added to a weighed sample with shaking, causing the separation into two layers. The toluene phase containing the salted-out 1-butanol was analyzed by gas chromatography. Water was determined by subtracting the amounts of solute and 1-butanol from the total amount.

Results and Discussion

Mutual solubilities of the 1-butanol–water system in the absence of alkali hydroxide are given in Table 1.

Table 1. Mutual solubilities of 1-butanol and water at 25 °C

	Aqueous phase	1-Butanol phase
Water	92.69 (98.12)	20.36 (51.24)
1-Butanol	7.31 (1.88)	79.64 (48.76)

wt% (mol %)

Our result is consistent with those of Butler *et al.*,[12] and Hill and Malisoff.[13] The equilibrium composition of the system in the presence of alkali hydroxide is given in Tables 2—4, where m denotes molality, suffixes a and b indicate the aqueous and 1-butanol phases, respectively. The apparent distribution ratio K_{obs} is defined by m_a/m_b. Its determination is restricted to the system in the liquid-liquid distribution region. No determination was carried out in the vicinity of saturated solution and in higher concentration of lithium hydroxide for the sake of precision (particularly aqueous phase). We see that as the base concentration increases, in the 1-butanol phase the amount of water decreases and that of 1-butanol increases, and in the aqueous phase 1-butanol decreases. The behavior of each base shows the same trend as in the case of alkali halides.[6-8]

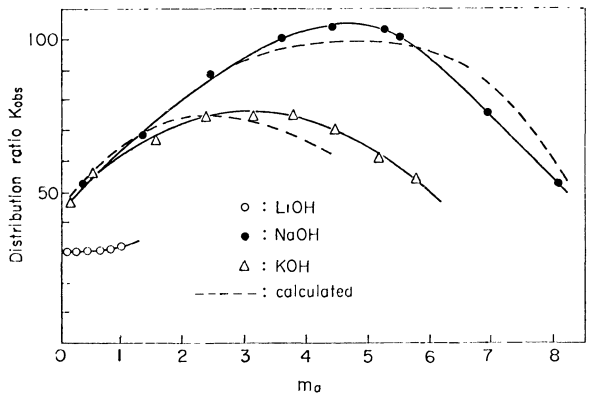

Fig. 1. Distribution ratio of base *vs.* molality in the aqueous phase at 25 °C.

The plots of K_{obs} against m_a are shown in Fig. 1. The distribution ratio of lithium hydroxide is almost constant at 31—33. At a higher concentration the same behavior as in sodium hydroxide and potassium hydroxide is expected. The ratios for sodium hydroxide and potassium hydroxide reach maximum at around 5 m_a and 3 m_a respectively, and then decrease. With the increase of base concentration the base tends to go into the 1-butanol phase. At a low concentration, the base might undergo primary solvation with water molecules even in the 1-butanol phase and secondary solvation with 1-butanol or more water molecules through primary solvation shell. The hydrated base may form bonds with an appreciable portion of 1-butanol molecules and the butanol phase loses its availability for extracting more base. Thus K_{obs} increases with the increase of base concentration. However, at a higher concentration any change in solvation and increase of ionic association might occur. The base might undergo primary solvation with both water and 1-butanol molecules, and is extracted to a greater extent into the 1-butanol phase, making K_{obs} decrease. The m_a at the maximum of K_{obs} is not identical with m_a at the minimum of activity coefficient in the aqueous phase.[14] A ternary diagram for the 1-butanol–water–sodium hydroxide system is given in Fig. 2. **A** indicates two liquid phases and one solid one, **B** one liquid and one solid phase in the aqueous region, **C** and **D** homogeneous phases. Oblique lines are the tie lines and the region is the range of separation of two liquids. An exact comparison of the results with the iso-butanol–water–sodium hydroxide system by Fritzche can no tbe made, but they seem to show a similar trend.[15]

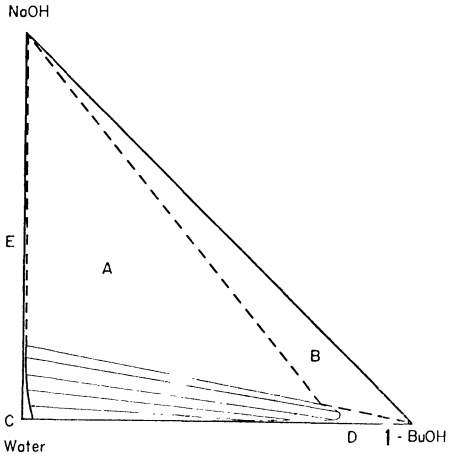

Fig. 2. Ternary diagram for 1-butanol–water–NaOH system at 25 °C, mol %.

The amounts of transfer of 1-butanol and water were determined. 50 mol of 1-butanol and 100 mol of water were taken. Alkali hydroxide was added to the latter and the resulting change of distribution of solvents between the two phases was determined. The result

of calculation is shown in Fig. 3. The number of moles of 1-butanol in the 1-butanol phase 49 is almost constant, but transfer of a greater amount of water took place from 1-butanol to the aqueous phase. The decrease of 1-butanol in the aqueous phase appears to be due to the salting-out effect but can not be attributed apparently to the salting-out effect.

Distribution Ratio. Alkali halides can be classified into two groups according to their distribution ratio between 1-butanol and water phases: (a) chlorides, fluorides and bromides which show a significant variation of ratio with the salt concentration, and (b) iodides which show no variation.[9] A semi-empirical treatment was made by assuming that the standard free energy of salt changes linearly with the mole fraction of water in the 1-butanol phase and Miller's equation is applicable to the calculation of activity coefficient. A reasonable agreement was obtained between calculated and observed values. Assuming the equilibrium in which electrolyte is completely dissociated in 1-butanol phase and also in the aqueous phase, we obtain

$$M_b^+ + OH_b^- \overset{K}{=} M_a^+ + OH_a^- \qquad (1)$$

where the subscripts a and b refer to the aqueous and 1-butanol phases, respectively. Thus, the equilibrium constant K is obtained as

$$K = \frac{a_a^+ \cdot a_a^-}{a_b^+ \cdot a_b^-} = \frac{(\gamma_\pm)_a^2}{(\gamma_\pm)_b^2} K_{obs}^2 \qquad (2)$$

where a: activity, γ: mean activity coefficient. It follows that

$$K_{obs} = \frac{(\gamma_\pm)_b}{(\gamma_\pm)_a} \exp\left\{\frac{(\mu_\pm^0)_a - (\mu_\pm^0)_b}{2RT}\right\} \qquad (3)$$

where $\mu_\pm^\circ$: the standard free energy term in chemical potential. Thermodynamic relations have been derived for the distribution of salts between the two phases, assuming that the salts in the organic phase are completely associated. However, this is not always valid in the phase with higher dielectric constant or high water content. Hesford and Mckay reported that perchloric acid is largely ionized when extracted into TBP alone.[16] Conductivity measurements on the 1-butanol phase containing alkali halides indicate that the salts are appreciably dissociated.[17] Friedman and Haugen showed that alkali perchlorates are strong electrolytes in the nitromethane phase.[18]

The standard free energies of transfer of various alkali halides from 1-butanol to aqueous phase were calculated, by assuming Eq. (1) and by applying the modified Born's equation proposed by Stokes.[19] The distribution ratio is independent of the concentration of the salts only in the case of complete immiscibility of phases and non-existence of any interaction between the salts and solvents. Dependency of K_{obs} on concentration might result from variation of activity coefficients and that of solvent composition with salt concentration. Solvent composition changes considerably with the addition of alkali hydroxide (Tables 2—4). Identification of the butanol phase containing a large amount of salt with one containing no salt is no longer valid. We assume that the standard free energy term in chemical potential of salt changes linearly with the mole fraction of water in the 1-butanol phase. Thus

$$\{(\mu_\pm^0)_a - (\mu_\pm^0)_b\}/2RT = -A_1 N_b + A_2 \qquad (4)$$

where N_b: mole fraction of water in the 1-butanol phase, A_1, A_2: adjustable parameters empirically determined. The variation of solvent composition in the aqueous phase which was considerably less than that

in the 1-butanol was neglected. Dielectric constants of the 1-butanol phase change a great deal with the presence of water. These values for the calculation of the theoretical slope were estimated from those for pure water and 1-butanol assuming that the dielectric constant of the 1-butanol–water mixture is given by a linear function of the weight fraction analogous with the behavior of ethanol–water mixture.

Of the theories on the activity coefficient of salt, those of Robinson-Stokes[20] and Miller[21] are useful. Miller's theory has no solvent activity term, and is convenient for computation. He derived an equation for the molality activity coefficient in terms of the hydration number n and ion size a. We assumed that the ions solvate water molecules selectively, both in the 1-butanol and aqueous phases. Thus, for calculation of γ in the two phases, the hydration number and ion size parameters given by Miller[21] were used. Water molecules are much smaller in size than 1-butanol molecules in the solution. More water than 1-butanol dipoles can pack around a cation to form its primary solvation shell.[22] Thus, the energy of the primary solvation by water is greater than that of 1-butanol. This means that the cation carries its primary water shell with it, and then in the 1-butanol phase undergoes further solvation of the hydrated species by 1-butanol. The following semi-empirical equations were obtained for K_{obs} as

$$\text{NaOH: } K_{obs} = (\gamma_\pm)_b/(\gamma_\pm)_a \exp(-6.60N_b + 7.30) \quad (5)$$

$$\text{KOH: } K_{obs} = (\gamma_\pm)_b/(\gamma_\pm)_a \exp(-9.34N_b + 8.45) \quad (6)$$

The values obtained by means of these equations are given in Fig. 1. The agreement between the calculated and observed values is reasonable. Parameters A_1 and A_2 were determined to fit K_{obs} by combining Eqs. (3) and (4). Theoretically, A_1 should be equivalent to A_2. However, it is not as is evident from the calculation for alkali halides.[9] The errors resulting from the calculation of activity coefficient and the inadequacy of assumption at high concentration are included in A_1 and A_2. This treatment might not be always applicable to other extraction systems. But it is thought to be advisable to investigate the treatment of the two liquid phase system accompaning a great change of solvent composition.

Salting-out Coefficient. The decrease of 1-butanol in the aqueous phase by the addition of salt follows the Setchenow equation[23,24]

$$\log f = \log S^0/S = kc \quad (7)^{25}$$

where f is the activity coefficient of non-electrolyte, S^0 and S are the solubility of non-electrolyte in pure water (mol/l) and in salt solution (mol/l), respectively, k is the salting-out coefficient and c is the concentration

of salt in mol/l. In general, the salting-out effect is influenced by the kind of non-electrolyte, but not by concentration and temperature. The values of k determined by means of Eq. (7) are as follows: LiOH 0.176, NaOH 0.184, KOH 0.192. The data of alkali halides and alkali hydroxides are well represented by Eq. (7), and this linear relation holds up to the salt concentration of one mole. On comparing the coefficients of alkali hydroxides with those of alkali halides, we see that the values are larger found for the latter. The values of k decrease in the order LiOH<NaOH<KOH, similar to that for alkali halides.[10] The above order is virtually the same for other non-electrolytes. In the case of alkali metal cations, the order of salting-out is generally Cs<Rb≃Li<K<Na and for the anion I<Br<Cl<F.[24] The small or highly charged ions which are strongly hydrated show a greater salt effect. There are, however, exceptions such as lithium and hydrogen ions. It is well-known that the tendency for complex ion formation between cation and non-electrolyte is greater for lithium ion.[26]

The relation of k to Gurney's unitary entropy will be discussed. The standard free energy change per mole for transfer of 1-butanol from a solution in pure water to one in which electrolyte is added is given by multiplying Eq. (7) by RT.[27] Combining the latter and the thermodynamic relation we have [10,27]

$$2.3kc = \Delta H/RT - \Delta S/R \qquad (8)$$

where ΔH, temperature slope, is small and almost of the same order as for the alkali hydroxides and alkali halides studied, ΔS being dominant. Gurney succeeded in correlating many properties of electrolytes using the partial entropy of salts. He showed that entropy of salts in water contained a constant or a cratic term depending not on the species of particles but only on the number of particles that have been mixed.[28]

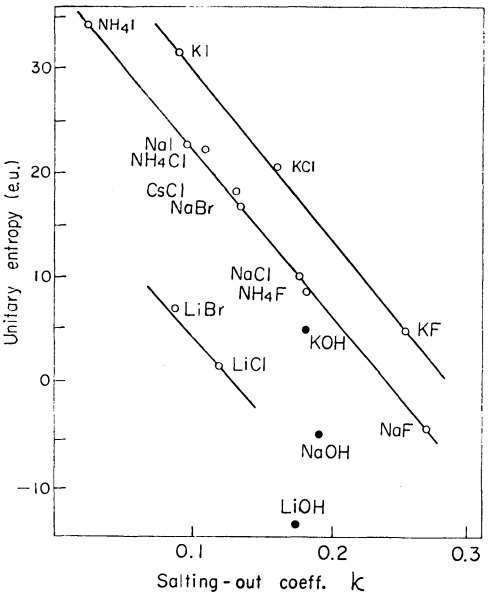

Fig. 4. Unitary entropies *vs.* salting-out coefficients at 25 °C

Subtracting the cratic term 8 e.u. from the observed partial molal entropy, he obtained the values as a unitary term which should be characteristic of ion. Higgins correlated salting-out coefficient with unitary entropy, assuming that all the cations beyond lithium behaved as if they were protons.[5] However, his assumption appears to be oversimplified. Without using it we compared unitary entropies for salts against the corresponding salting-out coefficients and consequently obtained three linear relationships, Li, K, and an other ion group.[10] It is interesting to see to what extent our approach could be applied to the problem of alkali hydroxides. Considerable deviation from lineality were seen for hydroxides as shown in Fig. 4. This might be due to specific interaction between hydroxides and 1-butanol, and to significant difference between temperature effects on salting-out coefficients of alkali halides and alkali hydroxides. The situation may be more complicated than this classification implies.

An Interstitial-Electron Model for the Structure of Metals and Alloys. III. Interpretation and Correlation of Properties of Group I—V Metals

Oliver JOHNSON*

Research Institute for Catalysis, Hokkaido University, Sapporo 060

(Received August 9, 1971)

The interstitial-electron model for metals supplements the concepts of band theory to give a detailed interpretation of the properties of metals. The instantaneous picture of vacant and electron-occupied interstices given by the model clarifies the complex gradations in electrical conductivity which are not explained by an electron per unit volume term. The consideration of polarization of the itinerant electron cloud by ion cores with high positive fields and of interpenetration of the more deformable ion cores by itinerant electrons is another new feature of the model. The interstitial-electron model leads to the expectation of parallel gradations for electronic heat capacity and magnetic susceptibility and an inverse relation of both of these properties with electrical conductivity. The presence of ($\bar{e}_2$) in the metal structure is associated with a positive Hall Coefficient for a metal, and a new correlation between positive Hall Coefficient and superconductivity for a metal is pointed out.

The interstitial-electron model for metals postulates an interstitial localization of electron density in close-packed metal structures.[1] The different interstice distances, the degree to which an $\bar{e}$ in an interstice is screened by ion cores, and requirement of alternating electron spin in adjoining interstices leads to variations in occupation of octahedral and tetrahedral interstices in metals. It was shown[2] that electron occupancy of interstices could be specified quite closely for metals of Group I—V. The definition of an electron in an interstice as an itinerant electron moving predominantly in a binding region provides a rigorous basis for handling interactions of $\bar{e}$ and ion cores on an electrostatic basis.[1]

The difference in the present interpretation with those of the band theory of metals is illustrated by the lack of a "density of states" term in the present paper. This arises because band theory uses energy and momentum coordinates while the interstitial model uses space coordinates. Band theory has given quantitative accounting of many properties of lower valent metal and much work is currently published on more complex metals.[3]

Electrical Conductivity of Metals

The four major factors which determine electrical conductivity of metals are (1) the number of electrons moving under the influence of the electric field, (2) the velocity of these electrons, (3) the scattering of electrons by metal ion cores due to their displacement during lattice vibrations, and (4) the degree of interpenetration of the ion cores by itinerant electrons. From the interstitial-electron model it is obvious that the number of electrons which can move under the influence of the electric field is directly proportional to the number of vacant interstices in the metal structure. The velocity of electrons will depend on electron energy, and the maximum electron velocities are for electrons at the Fermi Surface. The relative velocities of electrons in two metals can be compared from estimates of Fermi energies.[4] Electrons moving with maximum velocity will dominate the conduction process. The spin requirements of the lattice must be obeyed in relation to both factors (1) and (2). The greater the amplitude of lattice vibration, the greater the scattering of itinerant electrons by ion cores, and thus lowering of electrical conductivity. Lattice displacements are known experimentally.[5] Interpenetration of ion cores will reduce conductivity and, as discussed in part II, is expected to be largest for ion cores containing d-electrons (non-rare gas shells).

Conductivity Trends in Metals. The new concept in the interstitial-electron model is the presence of vacant interstices, and it is of interest to demonstrate the role of vacant interstices in the conductivity process. Electrical conductivity will be discussed in this paper in terms of molar conductivity (specific conductivity × atomic volume).

The molar conductivity for alkali metals increases from Li to K and then declines to Rb and Cs. See Fig. 1. The interstitial-electronic structures are the

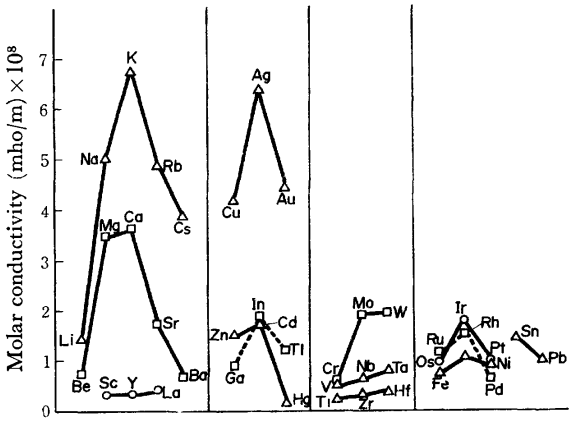

Fig. 1. Variations in molar conductivity for groups of metals.

same for all the alkali metals, and the number of vacant interstices is the same. Electron velocities are expected to increase monotonically from Li to Cs, with the decrease in positive field of the ion core with increase in size. The amplitude of lattice vibrations also increases monotonically from Li to Cs, but this is expected to lead to the opposite effect, a decrease in conductivity. The combination of these two opposing factors leads to the maximum at K (See Fig. 1) with decreasing conductivity for Rb and Cs due to larger effect of lattice vibrations. These same two factors account for the maximum at Ca in the series Be to Ba (See Fig. 1). For the latter series changes in crystal structure modify the trends of Mg to Ca as shown in Fig. 1. The maximum for Ag in the series Cu, Ag, Au cannot have the same explanation since the lattice displacements are very nearly the same for Ag and Au. There is an unusually high positive field in case of Au,[6] leading to lower electron velocity and lower conductivity. These are all manifestations of greater interpenetration of the Au^{25+} ($4f^{14}$, $5d^{10}$) ion core by itinerant electrons.

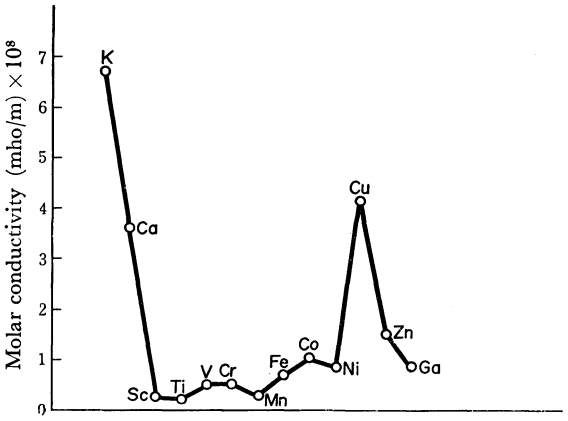

Fig. 2. Gradations in molar conductivity for metals.

It is of interest to note the relatively few metals with high molar conductance in Figs. 1 and 2. Those with values above 3.5 are Na, K, Rb, Cs, Cu, Ag, Au, Mg, Ca, and Al. All of the other metals including many not shown in Figs. 1 and 2 have molar conductivities below 2. Since there is a large variation in both E_f and amplitude of lattice vibration in both groups, the preponderance of metals with high conductivity which have large number of vacancies is a strong support for emphasis of this property of metals.

The sharp decrease in the order K, Ca, Sc, in Fig. 2 has not been explained previously. It will be noted that conductivities remain low for the series of 1st row transition metals until Cu is reached. For the series K, Ca, Sc the lattice displacements decrease so this factor should lead to increased conductivity. There is an increase in positive field, and this factor could cause a small decrease in conductivity (perhaps 2-fold). However, the 20-fold drop in conductivity is unexpected and must be connected with the decline in number of vacant interstices. There are 5 vacant interstices per metal ion core in K, 4 in Ca and only 1 in Sc (See Part 1). The series Cu, Zn, Ga represents a similar series, but the non-close packed structure of Ga may have influence here.

The gradations in conductivity Na>Cu and Mg>Zn show the effect of d-shell ion cores in lowering electron velocities due to the interpenetration of the d-shell by itinerant electrons.[2] The similar conductivities of Mg and Al are in sharp contrast to the sharp decline from Ca to Sc. In the above example there is a change from HCP to CCP for Mg to Al and from CCP to HCP for Ca to Sc. Due to pairing in the Al structure (See Part 1) there are a larger than normal number of vacant interstices. The especially low conductivities of Sc, Y, and La can all be traced to the distortion of the HCP lattice for these metals which reduces the number of tetrahedral interstices from 2 to 1 (bipyramical interstice) and thus reduces the total number of interstice vacancies. Vacancies listed above are based on 6 $\bar{e}$ (or 3 $\bar{e}_2$) in the normal 2 tet and 1 oct interstice per ion cores. A 1-electron vacancy and a 2-electron vacancy could be distinguished.

The interstitial-electron model also leads to the expectation of a dependence of conductivity on lattice structure. It is especially clear from the geometry that the pathways for itinerant electrons are more direct in HCP than CCP for non-distorted lattices (See Part I and II). This can explain the low position of Ca (CCP) in Fig. 1 as compared to Mg (HCP). A greater conductivity would be expected in normal HCP metals parallel to the c-axis than perpendicular to the axis. This is as observed for HCP magnesium.

Comparison of Interpretations of Conductivity. Band theory has accounted for the major effects observed experimentally for electrical conductivity, and it is generally assumed that it gives a quantitative interpretation. This is the case for Na and K metals, but with Li, Rb, and Cs there are 2—4 fold differences between calculated electrical conductivity and observed values, similar discrepancies for noble metals and poor results for higher valent metals.[7] From the interpretations of the interstitial-electron model it would appear that two factors have not been taken into account in the band theory treatment of conductivity. One is the concept of vacant interstices (on an instantaneous picture) although a term for $\bar{e}$ per unit volume partially takes care of this. The second factor is the polarization of the itinerant electron cloud by ion cores of strong positive field and interpenetration of deformable ion cores by itinerant electrons. The latter factor explains the very low conductivities for Li and Be and the trends for the noble metals.

The marked advantage of the Interstitial-Electron Model over previous attempts to account for gradations in electrical conductivity is demonstrated in Table 1. The first comparison is Bardeen's[7] Band Theory calculation where only Na and K show calculated values within 20% of the experimental conductivity. The second comparison is that of Ziman's[8] reduced re-

a) (Vac)=Vacant interstices

sistivity values where Na and Al give the only close correlation with the theoretical values. A correlation of electrical conductivity and *square* of number of vacancies is given for the interstitial-electron model. The reason for using $(\text{vac})^2$ involves the direct dependence of conductivity on vacancies *via* number of electrons moving and an indirect dependence since the velocity of electrons is also directly dependent on the number of vacancies. In the table the deviations of the ratios of $\text{cond}/(\text{vac})^2$ from the mean value of about 0.23 are all within 20% except for Li, Zn, and Al. This is a rather remarkable correlation when it is considered that a single parameter is used and that effects of lattice vibrations have not been directly included. The latter become important *e.g.* in extending the comparisons to Rb, Cs.

Thermal Conductivity of Metals

The same factors responsible for the gradations in electrical conductivity influence thermal conductivity: (1) the number of electrons moving as a result of the temperature gradient is directly proportional to the number of vacant interstices, (2) the velocity of electrons which move depend on the Fermi Energy, and those at the Fermi Level dominate the thermal conduction, (3) lattice vibration and (4) ion core interpenetration reduces thermal conductivity. In addition there is an influence of temperature since the number of electrons involved in heat conduction is a function of kT.

Electronic Heat Capacity of Metals

The interstitial-electron model accounts for the abnormally low value of the electronic heat capacity of metals in the same way as does band theory. While the movement of electrons which accounted for electrical conductivity did not depend on an excitation of electrons, the heat absorption by electrons does depend on excitation of electrons to a higher energy level. The electronic heat capacity, γ, depends also on the number of electrons at the Fermi Level which can be excited (absorb heat). Since kT is very small (0.02 eV at room temperature) relatively few electrons will be excited, and the expected electronic heat capacity will be a small fraction of 3/2 k. Because kT is small, the number of electrons at E_f is expected to be the decisive factor in determining electronic heat capacities of metals. From the interstitial model the number of electrons is directly proportional to the occupied interstices (and inversely proportional to the number of vacancies). This leads to the expectation of an inverse relation between electrical conductivity and electronic heat capacity since the conductivity is directly proportional to the number of vacancies. The influence of energy of excitation will be expected to show up in series of metals with the same number of vacancies (*e.g.* alkali metals).

The interstitial-electron model accounts for the major trends in γ for the metals as follows: (1) The small increase in γ in the order Na–Cs, metals which all have the same number of $\bar{e}$ at E_f is due to a decrease in the energy of excitation of $\bar{e}$. This is expected for the larger ion cores and indicated by band widths, but the larger value of Li than Na is due to an unexpectedly weak field of Li^+. This comes about by polarization of the $\bar{e}$ cloud and has been commented on in part II. (2) There is a monotonic increase from Be to Sr followed by a drop in γ at Ba. The first increase parallels the increase observed for the alkalis. The low value for Ba is associated with the change to BCC structure with a greater energy for excitation of $\bar{e}$ as compared to HCP. (3) The noble metals have γ values about 4 times smaller than the corresponding alkali metals and there also is lower electronic heat capacity for Zn, Cd, and Hg than the alkaline earths. This also is due to the larger excitation energy resulting from the 18-shell ion cores of the noble metals and Zn, Cd, and Hg. (4) In group 3 metals there is a large increase in γ from Al to Sc, Y, and La. In this case the distorted HCP lattice of the latter three metals leads to high occupancy of the fewer interstices. The larger number of $\bar{e}$ at E_f leads to the higher γ values. (5) The relatively high values of γ for group IV and group V metals also reflects the high occupancy of interstices in these metals. It is believed that across a row in the periodic table the increase Ca to Sc and Zr to V represents the normal trend of increased interstice occupancy, and the very high values for Sc, Y, and La are abnormal and due to restricted number of interstices in the distorted HCP lattice. (6) In general γ increases from M^+ to M^{2+} to M^{3+}, *etc.*, in proportion to the occupancy of interstices even though excitation energy increases in that order. The close proximity of tet interstices in HCP leads to the expectation of higher electronic heat capacity for HCP than BCC or FCC at least for high

occupancy of interstices. This is the observation for Ti and Zr.[9] The γ values for BCC Fe and Mn are higher than for FCC structures.

The discussion of electronic heat capacity has considered the number of $\bar{e}$ at E_f (occupied interstices) as well as the difference in energy of electron energy levels. These are usually considered as "density of states" in band theory. The density of states which is defined as the number of electron energy levels per ev is a theoretically derived concept and not an experimental number. There does appear to be a direct relation of the intensity of X-ray spectra to density of states.

Magnetic Susceptibility of Metals

The reason for weak paramagnetism in many metals is that only the $\bar{e}$ near E_f can have the spins reversed by the applied magnetic field. The gradations in paramagnetic susceptibility as for γ will depend primarily on the number of $\bar{e}$ at E_f but also on the energy required to reallign the electron spin. Thus, magnetic susceptibility should parallel the gradations in γ with the additional effect that electron pairs among the itinerant electrons can reduce the paramagnetism of the metal. Figure 3 shows the expected parallel behavior of γ and χ.

The diamagnetism of Be is an example of a divergence of magnetic properties from the observed gradation of γ. The diamagnetism of Be is undoubtedly the result of greater electron pairing of $\bar{e}$ in the distorted HCP structure ($c/a=1.567$) of Be (See Part II). There is a minimum in magnetic susceptibility at Na for the alkali metals which reflects the abnormally high value for Li. This is due to polarization of the itinerant electron cloud by the high field of Li^+. It can be looked on as the result of an increase in electron density around the Li^+ core. The trends in magnetic susceptibility for the heavier metals are difficult to interpret because of the large correction for the diamagnetism of the ion core. The χ values in Fig. 3 are not corrected for core diamagnetism.

Hall Coefficients of Metals

When a magnetic field is applied to a metal through which an electric current is passing, there is a drift of electrons in the direction of the magnetic field. The derived Hall Coefficients of metals have been taken as a measure of whether there are + or − carriers of electric current.

The alkali metals, noble metals, Mg, Ca, Al, and several other metals have −Hall Coefficients, while Be, Zn, Cd, V, Cr, Mn, Fe, and a number of other metals have +Hall Coefficients.[9] The explanation has been given tha tthe metals with +Hall Coefficient have positive hole conduction. The interstitial-electron model gives the following different interpretation. It is noticeable that the metals with +Hall Coefficients are those which contain electron pairs in their structure. It is proposed that in the conduction process an $\bar{e}$ dissociates from an $(\bar{e})_2$ and moves to an adjacent interstice. Then an $\bar{e}$ from a neighboring $(\bar{e})_2$ takes the place of the first $\bar{e}$. This process can continue and the resulting chain is equivalent to the movement of an $\bar{e}$ in the direction opposite to the movement of the first $\bar{e}$. This parallels the hole conduction explanation, but there are additional consequences of $(\bar{e})_2$ in metal lattices which are completely different from those of "holes" and which have been discussed in connection with other metal properties.

It is of great interest that with very few exceptions the metals with +Hall Coefficients are superconducting metals. The exceptions, *i.e.* superconductors which have −Hall Coefficients are La, Ga, In, Sn, all of which have unusual or distorted lattices. Th and Ti, also exceptions, have very low Hall Coefficients. This correlation between superconductivity and +Hall Coefficient has not been pointed out previously, and the role of $(\bar{e})_2$ in the superconducting state will be discussed in detail in Part VI of this series of papers.

Physical Properties of Metals

Only some general comments will be made relating to the very extensive area of physical and metallurgical properties of metals. The greater the degree of localiza-

9) R. J. Weiss, "Solid State Physics for Metallurgists," Pergamon, Oxford (1963).

tion of $\bar{e}$ density in a metal structure, the more brittle and hard the metal or alloy. This shows up in some of the metal alloys with large number of $(\bar{e})_2$ postulated for their structures and will be discussed in Part V for intermetallic phases. The localization of $\bar{e}$ density can also come *via* electron preference for occupancy of one type of interstice, or by asymmetry in $\bar{e}$ density in an interstice. The greater ductility of CCP metals as compared to HCP or BCC is probably connected to with the greater symmetry of $\bar{e}$ distribution in CCP.

An Interstitial-Electron Model for the Structure of Metals and Alloys. IV. Magnetic Properties of Metals and Electronic Structures of Group VI—VIII Metals

Oliver JOHNSON*

Research Institute for Catalysis, Hokkaido University, Sapporo 060

(Received August 9, 1971)

The interstitial-electron model leads to localization of d-electrons on the metal ion cores starting with group 6 metals which would have all the tetrahedral and octahedral interstices occupied by itinerant electrons. In the model the itinerant electrons play the role of ligands and determine the degeneracy of the d-orbitals localized on the ion core. There are mutual accomodations as far as location of itinerant electrons in specific interstices and d-electrons in preferred orbitals. Consideration of metal properties, especially Hall Coefficients, leads to reasonable values for both localized and itinerant magnetic moments. The relatively large spatial extension of 3d-orbitals at low intermetallic distances accounts for the magnetic moments in Cr, Mn, Fe, Co, and Ni. A striking consequence of the application of the interstitial-electron model to Fe is that it reproduces in detail the regions of positive and negative magnetization (including the interlocking rings on edges and faces) observed in neutron diffraction studies by Shull and Mook.

This paper will treat the magnetic properties of metals and show how the interstitial-electron model[1] accounts for the very complex magnetic behavior of metals like Cr and Mn, the ferromagnetism of Fe, Co, and Ni and the lack of a magnetic moment for metals of 2nd and 3rd transition series.

The first paper in the series indicated that the model would require localization of d-electrons on the metal ion core at M^{6+} since 6 itinerant electrons would completely fill the 2 tetrahedral and 1 octahedral interstice with electron pairs. The problem then for the metals starting with chromium (Cr^{6+} ion core) is to decide how many d-electrons are localized. Since it is desirable to predict magnetic moments, the starting point will be to examine the metal properties to see if the number of itinerant electrons can be specified as they were in Group I—V metals. Properties such as electrical conductivity, electronic heat capacity and Hall Coefficient are indicative of number and kind of itinerant electrons.

Itinerant Electrons and d-Electrons in Metals

Just as for non-transition metals there will be a structure determined preference for electron occupancy of octahedral or tetrahedral interstice, but extension of d-orbitals into each type of interstice can influence the distribution of itinerant electrons. A localization of itinerant electron density in binding regions (interstices) has been described in detail.[1] The alternate "instantaneous" description of electrons in interstices is the unique new feature of the interstitial-electron model. These electrons or $(\bar{e})_2$ can be treated as ligands in determining the degeneracy of the localized d-orbitals on the metal ion cores. This differs from the use of ligand field theory in metals by both Trost[2] (orbital constructions) and Goodenough.[3] It is believed that the objection made by Brooks to the use of ligand field theory in metals does not hold for this model, since his objections were directed toward the use of d-orbitals on other ion cores as ligand fields. Elliot[4] also discusses crystal fields in metal and suggests methods for their use.

Thus, ligand field theory can give the value of the magnetic moment on the ion core once the electronic structure with number of itinerant electrons and localized d-electrons and orientation of d-orbitals with respect to lattice axes is decided. In cases where there is unequal distribution of itinerant electrons among octahedral ($\uparrow$) and tetrahedral interstices ($\downarrow$), there can be a magnetic moment of itinerant electrons. The combination and interaction of these two kinds of moments can lead to ferromagnetism, antiferromagnetism and itinerant ferromagnetism.

The nature of interaction between itinerant electrons and d-electrons has not been specified. The simple picture of ion cores and itinerant electrons in binding regions (See Part I) no longer holds for metals with localized d-electrons. It is assumed that the extension of 3d-orbitals at least is such that itinerant electrons in the interstice involved would have an electron spin *opposite* to that of the d-electron. This also assumes that the two electron energies are about equal which is a reasonable assumption and consistent with the band theory of metals. This description of the interaction of $\bar{e}$ and d-electrons is essentially the "indirect exchange" used by Zener[5] but with antiparallel spin allignment as proposed by Vonsovsky and Vlasov[6] and Mott and Stevens.[7]

Trost[2] has argued for a strong interaction of adjacent 3d-orbitals on adjoining metal ion cores. He points out that the ratio of size of the $(n-1)$ shell to the n shell has the smallest value for the first transition period. The two factors involved are the decreasing separation of ns, np, and $(n-1)$ d atomic orbital energy and the increasing relative size of the $(n-1)$ d-orbitals as n increases. This implies that the $(n-1)$ d-orbitals become more important for binding and explains the increase in mp, bp, in transition metals as n increases (it decreases for non-transition metals). This effect of size and separation of d-orbitals reaches its maximum around Mn, Fe, and Co. It is believed that Trost's analysis is an even stronger argument for interaction of 3d electrons with itinerant electrons than his proposed interactions of 3d-3d on adjacent ion cores. In the present paper it is assumed that there are potential interactions between itinerant $\bar{e}$ and d-electrons of all 3 transition series, but that the very low intermetallic distances for the 1st transition series is crucial for determining magnetic properties.

In a metal lattice the ion cores can have an orientation such that its d-orbital axes are identical to the crystal axes or they may be at an appropriate angle, *e.g.* 45°. This orientation will be determined by the magnitude of repulsive interactions between itinerant electrons and d-electrons as compared to interactions between d-electrons on two adjacent ion cores. It is assumed that the onset of magnetic properties corresponds to the condition where the d-electron interactions determine the orientation, and empirically this occurs for metals with interatomic distances of 2.6 Å or less. This can now be compared directly to the treatment of magnetic properties by Goodenough.[3] Goodenough assumes a critical separation of $R_c = 2.9 \pm 0.1$ Å, below which there is localization of d-electrons on ion cores and above which the d-electrons are considered itinerant. The treatment by the interstitial-electron model proposed the localization of d-electrons to occur after M^{5+} and at M^{6+} (the intermetallic distances here are close to R_c above). The additional criterion is that at $R \leq 2.6$ Å, the $M^{n+}(d) - M^{n+}(d)$ interactions become more important than the $M^{n+}(d)$–$\bar{e}$ interactions in determining the orientation of the axes of the d-orbitals on the ion core.

The above principles will now be used in formulating interstitial-electron structures, and thus magnetic properties, for metals of Groups VI—VIII.

Interstitial-Electron Structures for Group VI Metals

Chromium metal has many unusual properties such as a very high positive Hall Coefficient, low electronic heat capacity (γ) for a transition metal, high work function, low electric conductivity and small amplitude of lattice displacement. It is also likely that the Cr structure differs from that of Mo and W since it exhibits a complex antiferromagnetism and the latter two are paramagnetic. To assign a valence to Cr, and thus an ion core charge and the number of localized d-electrons, it is pertinent to note that Cr has the BCC structure as does V^{5+} and Ti^{4+} (at high temperatures). The relatively low value of γ, comparable to that of Ti, suggests an ion core charge of 4. The very high positive Hall Coefficient (+36) suggests at least 4 as the number of itinerant electrons to account for a large number of ($\bar{e}_2$) (or filled interstices) in the structure. Tentatively, the structure will be taken as:

$$\left| \begin{matrix} Cr^{6+}(d^2),\ 4\bar{e} \\ \text{tet rings} \end{matrix} \right|_{BCC}$$

It is inherent in the BCC crystal structure that the corner and body center ion cores are not equivalent. However, for an equal distribution of itinerant electron in the face tetrahedral and edge tetrahedral rings (See Part I) there is the same degeneracy of d-orbitals on both corner and body center ion cores. The degeneracy given below is based on $\bar{e}$ in tet rings as ligands with equal $\bar{e}$ density on all faces and d-orbital axes 45° to crystal axes:

$\overline{xz}$ $\overline{yz}$ (directed to Cr)

$\overline{xy}$ $\overline{z^2}$ (directed to edges)

$\overline{x^2-y^2}$ (directed to face center)

Corner or Body Center $Cr^{6+}(d^2)$

This degeneracy is based on usual crystal field theory considerations. The 45° orientation is chosen since it conforms to the observed magnetic properties and has no occupied d-orbitals directed to Cr.

The degeneracy of d levels is such that the d^2 configuration of the Cr ion core leads to pairing of these localized d-electrons, and spatially they extend from corner ion cores (atoms) diagonally along horizontal faces and from body center ion cores perpendicular to the vertical face centers. The proposed structure for chromium has the following instantaneous distribution (See Part I[1]) of itinerant electrons in tetrahedral rings: 3 $\bar{e}$ in each tet ring on 4 faces of the Cr unit cell (xz, yz planes) and 2 $\bar{e}$ in each tet ring on two faces (xy plane). This is a total of 16 $\bar{e}$ on faces, 8 $\bar{e}$ per unit cell or 4 per Cr ion core. The e in tet rings on the 2 horizontal faces will be paired and the remain-

ing 6 ē do not have any spin allignment except that adjacent ē in tet rings will have opposite spins. Thus, there can be 1 ē on each of 4 faces with undetermined spin, and this can lead to 0,1 or 2 ē with the same spin per unit cell or 0, 1/2 or 1 unpaired spin per Cr. This lies within the observed magnetic moment for Cr of 0.54 μ_B per Cr.

The model proposes that any itinerant moment is to be distributed among the 4 vertical faces of the unit cell. The theoretical prediction of an helical spin state as the ground state for magnetic systems,[8] and consideration of linear spin density waves for Cr makes it reasonable that the undetermined spin above leads to an itinerant moment on Cr of approximately 0.5 μ_B per Cr.

Neutron diffraction studies show that below 312K Chromium exhibits a complex antiferromagnetic behavior. There are not the usual two sublattices associated with antiferromagnetism but a sinusoidal modulation of moment over at least 21 unit cells *i.e.* the total moment varies with position. The model gives a physical picture of this complex behavior in terms of electrons with free spins in each of the 4 vertical faces of the Cr unit cell. It is understandable that this could easily revert to a paramagnetic state as temperature is increased and as is observed above 312K.

The smaller Hall Coefficient and greater electrical conductivity suggest fewer itinerant electrons for *Mo and W* than for Cr. This leads to the proposal of a d^4 localization of d electrons on Mo and W. A different localization is expected as well on the basis of the non-magnetic properties of Mo and W. The proposed itinerant-electron structure for Mo and W is:

$$\left| \begin{matrix} M^{6+}(d^4),\ 2\bar{e} \\ \text{tet rings} \end{matrix} \right|_{BCC}$$

The intermetallic distance for Mo and W (1.39 and 0.41 Å) places it in the group of metals where the interaction of localized d-electrons is expected to be larger than between ē and localized d-orbitals on adjacent ion cores. A 45° orientation of the axes of d-orbitals in respect to the crystal axis gives the minimum ē-d interaction, and the degeneracy of d levels is as follows:

$\underline{z^2}$ $\underline{xy}$ (to edge tet ring)

$\underline{x^2-y^2}$ (to face tet ring)

$\underline{\uparrow\downarrow xy}$ $\underline{\uparrow\downarrow yz}$ (directed to M^{n+})

This degeneracy leads to complete pairing of d-electrons for d^4 and accounts for the normal metallic paramagnetism of metallic Mo and W. The degeneracy is based on distribution of itinerant electrons as 1 ē per tet ring on each of 2 horizontal faces (xy plane) and 1 ē per tet ring on each of 4 edges (z^2 and xy of d-orbital axes). In such an arrangement electron spins can be random as in the cases of Ba metal (also BCC). Each ē has 4 interstitial locations and different spins in adjoining interstices. This contrasts with the greater restriction of ē spin in Cr. No itinerant moment (or SDW) have been observed in neutron diffraction studies of Mo or W.

Interstitial-Electronic Structures for Group VII Metals

α-Manganese, the form of manganese metal stable from ordinary temperature to 710°C, has more than one type of Mn ion core in the structure. β-Manganese is paramagnetic and stable from 710—1079°C. It has 20 atoms per unit cell of which 8 are of higher valence (smaller size) than the remaining 12. A structure similar to those proposed for β-phases which have the same structure[9] is the following:

$$\left| 8Mn^{7+}(d^4),\ 12Mn^{7+}(d^6),\ 36\bar{e} \right|_{\beta\text{-Mn}}$$

This gives a number of itinerant electrons per unit cell which is close to the *e/a* ratio of 3/2 observed in β-phases. The structure has interstices which are not homogeneous in terms of ion cores around an interstitial electron. This is discussed in detail in Part V,[9] and in the case of Mn it leads to localization of ē in the structure as electron pairs and is associated with the hardness and brittleness of β-Mn.

γ-Manganese, stable in the temperature range 1079—1143°C, has a face-centered tetragonal structure when stabilized at room temperature and is CCP in its normal state. The room temperature modification has been observed to be antiferromagnetic[7] with a magnetic moment of 2.4 μ_B. The only data available to help establish the ion core charge is the relatively low atomic volume of 12.7 Å^3. This is reasonable for a divalent ion core, $Mn^{7+}(d^5)$, also indicated by magnetic properties. In the antiferromagnetic face-centered tetragonal structure, Mn has 8 neighbors at 2.58 Å and 4 neighbors at 2.67 Å. It is proposed that in a distorted structure like this, the Mn ion cores in the top and bottom faces (short distances) have a 45° orientation of d-orbital axes which minimizes Mn–Mn interactions, and the face center Mn on vertical faces (larger distance) have a 90° orientation of d-orbital axes with respect to the tetragonal cell. This leads to the following degeneracy for $|Mn^{7+}(d^5),\ 2\bar{e}|$ FCTetr.

$\overline{z^2-y^2}$ (Mn–Mn face)

$\underset{xz}{\uparrow}$ $\underline{yz}$ (tet)

$\underline{\uparrow\downarrow}$ xy (oct)

$\underline{\uparrow\downarrow}$ z^2 (oct, large d)

Mn ion cores on top and bottom face

$\overline{xy}$ (Mn–Mn, short d.)

$\overline{x^2-y^2}$ (oct)

$\underline{\downarrow}$ z^2 (oct, large d.)

$\underline{\uparrow\downarrow}$ xz $\underline{\uparrow\downarrow}$ yz (Mn–Mn, large d.)

Mn ion cores on Vert. Face Centers

8) A. W. Overhauser and A. Arrott, *Phys. Rev. Lett.*, **4**, 226 (1960).

9) O. Johnson, This Bulletin, **46**, 1929 (1973).

This degeneracy leads to one unpaired ē localized on the Mn ion cores of the top and bottom faces of a tetragonal unit cell and one unpaired ē on the Mn ion cores on centers of vertical faces. The former are directed into tet interstices and the latter into oct interstices so they will have opposite spins, and the total moment difference corresponds to 2 μ_B. In addition there is the chance of considerable imbalance in the itinerant electron spins since there is much more ē density from d-electrons directed into oct interstices. A distribution, *e.g.* of 1/2 ē in oct and 1 1/2 ē in tet would lead to an itinerant moment of 1 ↑/unit cell or 0.25 ↑ per Mn ion core.

Tc and Re both form HCP lattices with *c/a* values close to normal. Little data is available on Tc, but Re has a high Hall Coefficient and moderate electronic heat capacity; both metals have low conductivity. The structure proposed below with 3 itinerant electrons is reasonable for these properties:

$$\left|M^{7+}(d^4),\ 3\bar{e}\right|_{HCP}$$

The degeneracy of d levels, discussed in detail for Co, leads to pairing of localized d-electrons and thus normal paramagnetism for these metals.

Interstitial-Electron Structures for Fe, Ru, and Os

The Hall Coefficient for metallic iron is positive but not as high as that of Cr. It also has a high electronic heat capacity for a group 8 metal. These properties suggest an electronic structure with at least 4 itinerant electrons as follows:

$$\left|Fe^{8+}(d^4),\ 4\bar{e}\right|_{BCC}$$

A d^2 structure as proposed by Lomer and Marshall[10] is not compatible with the interstitial electron model since it would have 6 itinerant electrons, postulated not to give metallic properties.

In deriving the degeneracy of d-orbitals it is assumed that the 4 ē are distributed evenly among the tet rings on faces and edges of the BCC unit cell. An orientation of d-orbital axes of the Fe ion cores at 45° to the crystal axes leads both to the expected localized moment on the Fe ion cores and to the location of the magnetic lobes according to neutron diffraction studies.[11] The following degeneracy holds for both body-center and corner ion cores:

$\overline{xz}$ $\overline{yz}$	(directed to Fe)
$\uparrow$ $\uparrow$	
$\overline{z^2}$ $\overline{xy}$	(along edges or to face centers)
$\uparrow\downarrow$	
$\overline{x^2-y^2}$	(directed diagonally to tet rings)

The above electronic structure and degeneracy of d levels leads to d^2-orbitals along horizontal faces and directed to vertical edges from the body-centered ion cores. Unpaired d-electrons extend along all edges and from the body center Fe ion core to centers of all faces. The 4 itinerant electrons (or 8 ē per unit cell) on an instantaneous picture can be pictured as occupying 4 face tet with 3 ē each and the remaining 2 face tet per unit cell with 2 ē each. Thus, the small negative magnetization (0.2 μ_B) is associated with the interlocking tet rings. It is striking that the model proposed here reproduces in detail the spatial arrangement of localized moments on Fe ion cores as well as the itinerant moment found by Shull and Mook,[11] in neutron diffraction studies of Fe.

The difference in magnetic properties of Fe and Cr requires comment. The lack of a localized moment in Cr is accounted for on the basis of its d^2 configuration. The two metals in BCC have the same number of itinerant electrons according to the proposed structures. The unpaired d-electrons in Fe must greatly restrict the location of itinerant electrons in tet ring interstices. This restriction of ē in Fe is in keeping with the normal value of magnetic entropy ($k \ln 3$) observed for Fe and the very low magnetic entropy in the case of Cr.[11]

Os and Ru have HCP structures with *c/a* values of 1.57 and 1.59 and are expected to have 1 oct interstice and 1 Bipyramidal interstice per M^{n+}. This accounts for the very high Hall Coefficient of Ru if it has a d^4 structure (like Fe). The lower Hall Coefficient and electronic heat capacity suggest the following d^6 structure for Os:

$$\left|Os^{8+}(d^6),\ \bar{e}_{oct},\ \bar{e}_{BP}\right|_{HCP}$$

The degeneracy in HCP (see discussion, Part II[1]) leads to complete pairing of electrons for both Ru and Os, and the structure accounts for the normal paramagnetism of these metals.

Interstitial-Electron Structures for Co, Rh, and Ir

The Hall Coefficient is strongly negative for cobalt metal, an indication of lower electron occupancy of interstices and much less liklihood for presence of electron pairs in interstices. The electrical conductivity is higher than for iron, an indication of lower interstice occupancy than iron or of less interference in the conduction process by d-electrons.

These properties suggest a low ion core charge for Co relative to Fe, and the stability of Co^{2+} makes it a reasonable choice. The ion core structure below has the high d localizations as has been used by Lomer and Marshall[10] and others and applies to paramagnetic Co.

$$\left|Co^{9+}(d^7),\ 2\bar{e}\right|_{HCP}$$

The axes of the d-orbitals are placed so the z-axis corresponds to the c-axis of the hexagonal cobalt structure, the x-axis is placed along a line connecting 2 cobalt ion cores and the y-axis then passes 1/2 way between two other cobalt ion cores. This gives rise

10) W. M. Lomer and W. Marshall, *Phil. Mag.*, **3**, 185 (1958).
11) G. G. Shull and H. A. Mook, *Phys. Rev. Lett.*, **16**, 14 (1966); *Phys. Rev.*, **136**, A195 (1964); *ibid.*, **148**, 495 (1966).

to the following degeneracy for ferromagnetic Co:

$\overline{x^2-y^2}$ (to M^+)

$\underline{\uparrow(\downarrow)_{0.2}}_{yz}$ $\underline{\uparrow}_{z^2}$ (M^+, oct) (tet)

$\underline{\uparrow\downarrow}_{xz}$ $\underline{\uparrow\downarrow}_{xy}$ (no $\bar{e}$ or ion cores)

The above degeneracy of d levels for $Co^{9+}(d^7)$ leads to unpaired d-electrons extending into tet interstices and 0.8 unpaired d-electrons extending near oct and another ion core. It is not likely that other orientations of the d-axes would lead to more favorable d-electron distribution as far as ion core interactions are concerned.

The spin requirements of oct interstices[1] in HCP leads to only 0.4↑ occupancy since an unpaired d-electron from the Co ion core directed to oct requires an opposite itinerant electron spin. This gives the following interstitial-electron structure for cobalt metal:

$$\left| Co^{9+}(d^{6.2}),\ \bar{e}_{0.4}(\bar{e}_2)_{0.6oct},\ \bar{e}_{1.2tet} \right| HCP$$

This placement of additional $\bar{e}$ in tet is also in keeping with the preference for tet occupancy in HCP lattices below 2 $\bar{e}$ and accounts for a negative moment on $\bar{e}$.

The proposed structure has a magnetic moment corresponding to 1.8↑ on each Co ion core with spins alligned *via* tet electrons. The oct $\bar{e}$ (0.4 $\bar{e}$) have all one spin and the $\bar{e}$ in tet interstices can have a range of unpaired spins. Depending on whether these spins cancel or add, there could be no itinerant moment in Co or a maximum of 0.4↑. The observed moment of 1.7 μ_B lies within the range allowed by the above structure. The model would not give structures which would have more than 2 unpaired electrons localized on Co.

Rhodium and Iridium have a small positive Hall Coefficient so higher occupancy of interstices by electrons is indicated. The normal valence of 3 is thus indicated for the CCP structures of Rh and Ir.

$$\left| Rh^{9+}(d^6),\ \bar{e}_{oct},\ \bar{e}_{tet},\ (\bar{e}_2)_{1/2tet} \right| CCP$$

The distribution of electrons in interstices is that normally required in the CCP lattice to give balanced spins and preference for tet occupancy. The degeneracy for the d-electrons in this structure and the comparable Ir structure is:

$\underline{z^2}$ $\underline{x^2-y^2}$ (directed to edges)

$\underline{\uparrow\downarrow}_{xy}$ $\underline{\uparrow\downarrow}_{xz}$ $\underline{\uparrow\downarrow}_{yz}$ (directed to M^{n+})

The degeneracy given above is for placement of axes of d-orbitals coincident with crystal axes. This leads to non-magnetic properties for Rh and Ir.

Interstitial-Electron Structures for Ni, Pd, and Pt

Mook[11] has shown by neutron diffraction for Ni a ferromagnetic moment of 0.71 μ_B (0.656, 3d and 0.055, orbital) is localized around the ion core with a negative magnetization of 0.105 μ_B. It has also been maintained that the moment is itinerant[12,13] for Ni. In the following a structure is proposed which attempts to resolve these conflicting interpretations.

As with cobalt metal, the negative Hall Coefficient, relatively low electronic heat capacity and moderate electrical conductivity make it reasonable that Nickel has a Ni^{2+} ion core. The following ion core structure is proposed:

$$\left| Ni^{10+}(d^8),\ 2\bar{e} \right| CCP$$

To determine the d level degeneracy, the d-orbital axis is placed at 45° to the crystal axis since this gives the minimum extension of d-orbitals toward other Ni ion cores (R=2.5 Å). The degeneracy is as follows:

$\overline{x^2-y^2}$ (toward Ni)

$\underline{\uparrow\downarrow}_{xz}$ $\underline{\uparrow(\downarrow)_{0.3}}_{yz}$ (toward tet)

$\underline{\uparrow\downarrow}_{xy}$ $\underline{\uparrow\downarrow}_{z^2}$ (toward oct)

The degeneracy has occupied d-orbitals extending into both oct and tet interstices. The resultant repulsive interaction between d^2 electrons and itinerant electrons could lead to a shift of $\bar{e}$ from tet to oct (greater distance from ion core) or to a transfer of some d-electrons to tet interstices as itinerant electrons. The former requires $\bar{e}$ pairing so the latter is considered more likely. Assuming a transfer of 0.7 $\bar{e}$ from a localized d-orbital to tet interstice, the following structure results:

$$\left| Ni^{10+}(d^{7.3}),\ \bar{e}_{oct},\ (\bar{e}_2)_{0.3}\bar{e}_{1.1tet} \right| CCP \quad \text{(Ferromagnetic Ni)}$$

This electronic structure accounts for the observed moment around the Ni ion core observed by Mook and also its itinerant character. The equilibrium state can be looked on as having an occupied d-orbital extending into a tet interstitial region with a d-electron of one spin near the ion core and a d-electron of the opposite spin (and now indistinguishable from an itinerant electron) near the centre of a tet interstice. On an instantaneous basis there will be 30% regions of $Ni^{10+}(d^8)$, 1 $\bar{e}_{tet}$ (no magnetic moment) and 70% regions of $Ni^{10+}(d^7)$, 2 $\bar{e}$ (with 1 unpaired electron). Above 700° where Ni shows paramagnetism a small additional shift of electrons can give the following structure with no coupling of spins:

$$\left| Ni^{10+}(d^7),\ \bar{e}_{oct},\ \bar{e}_{tet},\ (\bar{e}_2)_{1/2tet} \right| CCP \quad \text{(Paramagnetic Ni)}$$

A similar equilibrium between d^2 electrons localized on Co ($d^{4.2}$) and tet itinerant electrons can explain the total localized moment and form factor for Co.

Palladium and Platinum have higher electronic heat capacities and lower electrical conductivities than expected for these group 8 metals. This suggests more itinerant electrons than ferromagnetic Ni. An ion core structure with M^{3+} can account for the above properties and the paramagnetism of these metals.

$$\left| M^{10+}(d^7),\ \bar{e}_{oct},\ \bar{e}_{tet},\ (\bar{e}_2)_{1/2tet} \right| CCP$$

12) A. Arrott, "Magnetism," Vol. 2B, Ed. by G.T. Rado and H. Suhl, Acad. Press, New York (1966), Chap. 4.

13) C. Herring, "Magnetism," Vol. 4, Ed. by G. T. Rado, H. Suhl, Acad. Press, New York (1966).

This structure is the same as that proposed for paramagnetic Ni. This proposed structure has the same degeneracy as shown for Rh and Ir and leads to d^2 electrons directed toward other M^{n+} and an unpaired electron directed toward 1/2 of the oct interstices. No coupling of spins is expected.

Discussion

The interstitial-electron model has been used to formulate structures for the magnetic and non-magnetic metals of groups VI—VIII. Ion core charges were established by comparison of properties of these metals (Hall Coefficient, electronic heat capacity and electrical conductivity) with metals of known ion core charge. The view is taken that when d-orbitals of the ion core extend into interstices, electrons occupying these two positions will have anti-parallel spins. The placing of the axes of the d-orbitals of the ion cores is based on empirical choice of an intermetallic distance of 2.6 Å above which interactions between d-electrons on adjacent ion cores becomes less important than interactions between these d-electrons and itinerant electrons in metal interstices. The itinerant electrons are treated as ligands to establish the d level degeneracy for d-electrons localized on the ion cores. The more complex splitting of d-levels than the usual e_g-t_{3g} splitting provides a new basis for discussing magnetic form factor.

The model leads to a magnetic structure of iron which has 2 unpaired electrons localized on the ion core, and a small additional moment associated with itinerant electrons. The magnetic entropy value and the spherical form factor found in neutron diffraction studies support this structure. The model proposes a magnetic moment originating on the itinerant electrons for nickel. This is supported by the observation that for Ni and Co metals, orbital magnetic moments are completely quenched (g value approx 2) and by the anisotropic form factor observed in neutron diffraction. For cobalt the model leads to 1.8 unpaired electron localized on the ion core and an additional moment on itinerant electrons. There have been unsuccessful attempts to locate itinerant electron spin density waves in Ni and Co. The experiments appear to have been scans in the 1, 1, 1 direction. The model indicates, *e.g.*, for Ni that unpaired electrons would be in tet interstices which are not centered on the 1, 1, 1 plane. The interpretation of the antiferromagnetism of Chromium offers a useful physical picture of the unusual itinerant magnetism (spin density waves). The model suggests that the antiferromagnetism of γ-Manganese is like that of an oxide system with itinerant electrons providing the antiferromagnetic allignment of spins.

The scheme of localization of electrons in interstices has provided a basis for explaining the complex magnetic properties of group VI—VIII metals. The electron distributions formulated for metals in this paper have been the result of mutual accomodations of localized d-electrons and itinerant electrons as is inherent in ligand field theory. This resultant more uniform electron density is an important property of the transition metals, and it is anticipated that it will give valuable insight into metal properties.

An Interstitial-Electron Model for the Structure of Metals and Alloys. V. Metal Alloys and Intermetallic Compounds

Oliver JOHNSON*

Research Institute for Catalysis, Hokkaido University, Sapporo 060

(Received September 17, 1971)

On the basis of the interstitial-electron model for metals the essential feature of the metallic state is the relatively free movement of electrons, ($\bar{e}$), between interstices in a close-packed array of metal ions (positive cores). For a solid solution of one metal in another in which the metal ions have nearly the same size and core charge, the interstitial-electron structures which incorporate spatial and spin correlation of electrons are the same as for metals. Metallic properties can also result when the ratios of two less similar metals in an alloy are such as to give interstices with a constant ratio of the two metals surrounding them. Occupancy of such "homogeneous interstices" is the basis for intermetallic compounds and accounts for the Hume-Rothery rules. Intermetallic compounds such as γ phases (*e.g.* Cu_5Zn_8) are unique in that $\bar{e}$ and electron pairs must be assigned to two or more types of interstices which have different ratios of the two metal ions around them. This localization of $\bar{e}$ density explains the very poor conductivity, the hardness, the brittleness and the large diamagnetic susceptibility of γ phases. The structural framework of the interstitial-electron description accounts for the large composition range of the interstitial phases and can naturally include effects of ion core size and charge. Interpenetration of d^{10} ion cores by itinerant electrons which gives a balancing of the positive fields of the 2 ion cores accounts for the preponderance of d^{10} metals among intermetallic phases.

Of the metals, only Manganese has ions of two different core charges (and sizes), and Mn has unusual properties for a metal. However, with metal alloys there are always two or more ions of different size or core charge to be accomodated into the metallic structure. Where there are not large differences in effective positive fields of the metal ions making up the alloy the disruption of the periodic field will not be great enough to lead to large changes in properties. This situation holds for a great many alloys of similar metals. When the differences in positive field are very large, metallic salts or alloy salts[1] are formed. Some examples are Li_3B, Mg_3Sb_2, and Mg_2Sn. They have a metallic appearance but have unusually high melting points, are brittle and are very poor conductors of electricity. The alloy salt CsAu has been given[1] the structure Cs^+Au^-.

Between these two extremes of alloys, the solid solutions of one metal in another and the metallic salts, there are a large number of intermediate alloys which are called secondary alloys or intermetallic compounds. They are clearly metal-like but may deviate from metals in some property *e.g.* the intermetallic compound may be less ductile, it may be harder or brittle, or it may be a poor conductor.

There are a large number of different types of intermetallic compounds. The best known of these are the ones classified by Hume-Rothery[2] on the basis of the number of electrons per atom in the compound (or intermetallic phase). This ratio is 3/2 for β phases, 21/13 for γ phases and 7/4 for ε phases. All three types of intermetallic compounds form over rather wide composition ranges so the ratios are only approximate. In addition it has to be assumed that group VIII metals contributed no electrons in order to fit them into the ratio pattern.

Recent reviews[3–5] show the highly complex behavior and interrelations of α, β, γ, μ, and ε phases including both size effects and electronic effects.

The relations between the electronic structures of intermetallic compounds and that of metals, as well as the inter-relation between the various phases still remains obscure. Since the intermetallic compounds all form close-packed or nearly close-packed structures, it is anticipated that the interstitial-electron model[6] of metal structure can be applied to understanding the binding in intermetallic compounds as well as in metals. The term electron in an interstice refers to electron density considered to be localized in the interstitial binding region of the close-packed metal structure.[6]

Interstices in Intermetallic Compounds

It is proposed that a stable metallic structure can result for intermetallic compounds if the ratio of the two metal ions around an interstice is the same throughout the structure. This homogeneity of interstices can lead to the same free movement of electrons through the intermetallic structure as is observed for the metals themselves. The observed deviations from stoichiometry are understandable since a given structure can accomodate some deviation from homogeneity of interstices just as is the case for the solid solutions.

With this postulated basis for the formation of intermetallic compounds the structures for the various types of intermetallic phases can be considered and formulated using the Interstitial Electron Model.

β Phases

A typical example of a β phase occurs with a 50–50 Cu–Zn alloy which is known as β-brass. Other examples are Cu_3Ga, AlFe, and Cu_5Sn. They have Body-Centered Cubic (BCC) structures and ordinarily form a random structure of the two metals (β-form); tempering converts them to an ordered structure known as a "superlattice" (β′-form). For CuZn each ion forms its own simple cubic lattice. For Cu_3Al a double unit must be taken, and no superlattice has been observed for Cu_5Sn.

In formulating an electronic structure for the BCC β-phases based on the interstitial-electron model, the first question is which interstices are most likely to be occupied. Unsymmetrical oct interstices are chosen as most likely to be occupied by electrons in an unsymmetrical structure with two different metal ion cores. The relatively poor conductivity compared to pure metals and the low ductility of β-phases also makes it unlikely that tet rings of interstices are occupied by $\bar{e}$.

For CuZn (β-brass) the ion cores Cu^+ and Zn^{2+} give up 3 itinerant electrons to the BCC lattice of the intermetallic compound. The two unsymmetrical oct interstices can be designated as (Cu_2Zn_4) and (Cu_4Zn_2). A preference for electron occupancy of (Cu_2Zn_4) interstices is expected because of the stronger positive field exerted by Zn^{2+} as compared to Cu^+. There are 2 such interstices per unit cell of CuZn, and there can be occupancy of all 3 by $\bar{e}$. The geometry of interstices is discussed in detail in Part I.[6]

In such an arrangement of electrons, the $\bar{e}$ are separated widely enough to have random spins (see Part I).[6] Thus, the proposed low occupancy by $\bar{e}$ would give low paramagnetic susceptibility for the itinerant electrons and is in keeping with the diamagnetism of the β-phases. As far as the structure as a whole is concerned there is a network of adjoining homogeneous interstices, in this case the (Cu_2Zn_4), through which electrons can move as in other metallic structures.

The model characterizes β-phases as having occupancy of one of the two types of oct interstices which gives an electron/atom ratio of 3/2. The 3 interstices of one type can accomodate as few as 1 $\bar{e}$ or with electron pairing as many as 6 electrons per unit cell. This would give e/a ratios of 1/2 to 3 with the major number expected at 3/2 which is occupancy by $\bar{e}$ of one type of the oct interstices in BCC and presumably the occupancy with optimum binding energy for a metal. The 3/2 ratio is found for CuZn, Cu_3Al, Cu_5Zn, PdCu and related compounds. It is 5/2 for AlCo, FeAl, NiAl, NiGa, and NiIn and 6/2 for TiFe, VFe, and AlNd.

Some β-phases are ferromagnetic and offer an additional test for the model. There are also intermetallic compounds containing Fe, Co, or Ni which are not ferromagnetic. The compound NiAl is one such example. According to the interstitial-electron model the electronic structure for NiAl would be $|Al^{3+}, Ni^{10+}(d^8), 5e_{oct}|_{BCC}$. If the Ni ion cores occupy body center positions, electron occupancy will be of the (Ni_2Al_4) interstices on faces of the unit cell. The d-orbital axis of the $Ni^{10+}(d^8)$ core will be at 45° to the lattice axis because this directs d-orbitals toward Al^{3+} and not to itinerant electrons. The degeneracy of d-orbitals will be:

$\overline{xy}$ (to $\bar{e}_2$ on faces)

$\overline{z^2}$ (to $\bar{e}$ on faces)

$\underline{\uparrow\downarrow}$ $\overline{x^2-y^2}$ (to edges)

$\underline{\uparrow\downarrow}$ $\overline{xz}$ $\underline{\uparrow\downarrow}$ $\overline{yz}$ (toward Al)

This leads to complete pairing of d-electrons so no magnetic moment is expected on the Ni ion core. Electron occupancy of the (Ni_2Al_4) interstices by $5\bar{e}$ requires $2(\bar{e})_2$ and $\bar{e}$ per unit cell. This high ratio of $\bar{e}_2/\bar{e}$ is in keeping with the +Hall Coefficient observed for NiAl. For FeAl the structure $|Fe^{8+}(d^6), Al^{3+}, \bar{e}, 2(\bar{e}_2)_{oct}|_{BCC}$ is proposed and leads to all paired d-electrons for Fe iron cores as corner atoms in the unit cell and $\bar{e}$ and $(\bar{e})_2$ on faces. This is in agreement with the observed paramagnetism of FeAl. The magnetic properties of the compound CoAl have not been reported. The structure expected from the interstitial-electron model is $|Co^{9+}(d^7), Al^{3+}, \bar{e}, 2(\bar{e}_2)_{oct}|_{BCC}$, and the same degeneracy of d-orbitals to the NiAl and FeAl leads to 1 unpaired electron in an orbital toward a face. This alligns with an itinerant electron so this alloy is expected to be ferromagnetic. A $Co^{9+}(d^6)$ ion core would lead to no magnetic moment on cobalt. The background for this method of interpreting magnetic properties is given in Part IV.[7]

Magnetic properties are known for the series TiFe, VFe, and CrFe. Both TiFe and VFe form ordered β-phases. TiFe is not ferromagnetic while VFe has a saturation moment of 0.80 μ_B localized on Fe. Cr does not form a β-phase but is related and will be considered as having similar oct interstices; it has a saturation magnetization of 1.8 μ_B per iron atom. The interstitial-electron structure proposed for TiFe has a high d-localization which is necessary to limit the number of itinerant electrons to 6 which appeared to be the maximum observed for β-phases.

$$\left|Ti^{4+}, Fe^{8+}(d^6), 3(\bar{e}_2)_{oct}\right|_{BCC}$$

When Fe ion cores are at body-centered positions the electron pairs are expected to be on face oct interstices (Ti_4Fe_2). The degeneracy expected is

$\overline{z^2}$ $\overline{xy}$ (to $2\bar{e}$ on faces)

$\underline{\uparrow\downarrow}$ $\overline{x^2-y^2}$ (to $\bar{e}$ on edge)

$\underline{\uparrow\downarrow}$ $\overline{xz}$ $\underline{\uparrow\downarrow}$ $\overline{yz}$ (to Ti).

There is no magnetic moment associated with this structure, in agreement with experimental data.

For VFe there must be still greater localization of d-electrons to keep within the maximum of 6 itinerant electrons. Thus an ion core $Fe^{8+}(d^7)$ is proposed for VFe.

7) O. Johnson, This Bulletin, **46**, 1923 (1973).

$$\left|V^{5+},\ Fe^{8+}(d^7),\ 3(\bar{e}_2)_{oct}\right|_{BCC}$$

This degeneracy of d-orbitals is the same as for TiFe, and with 7 d-electrons there will be one unpaired electron on the iron core. This is close to the observed magnetic moment for VFe. The increase in lattice contraction[3] from VFe to TiFe is probably due to the removal of some screening of the Fe ion core in going from 7 to 6 d-electrons (core charge from Fe^+ to Fe^{2+}).

The following structure is proposed for FeCr assuming it has the same occupancy of interstices as the β-phases:

$$\left|Fe^{8+}(d^6),\ Cr^{6+}(d^4),\ (\bar{e}_2),\ 2\bar{e}\right|_{oct}$$

Using the model, the unsymmetrical distribution of $\bar{e}$ and $(\bar{e})_2$ leads to 2 unpaired electrons on Fe and paired electrons on Cr. The data of Shull and Wilkenson[8] show a moment of 2 μ_B on Fe and no moment on Cr for the 50% alloy of Cr and Fe. The proposed structure for FeCr has fewer itinerant electrons (lower total ion core charges) than TiFe or VFe and weaker binding is expected. This agrees with the absence of lattice contraction[3] in FeCr.

There is a preponderence of intermetallic phases containing metal ion cores with d-electrons (*e.g.* Cu, Ag, Zn, Cd, *etc.*). This has been discussed by Nevitt[3] for β-phases. He suggests a special affinity for β-phase formation by the combination Group IV (*e.g.* Ti) and the Fe group and by Sc and the Cu, Zn group. There are two differences in the ion cores which contain d-electrons which may be responsible for stability of intermetallic phases with d-shell metals. One is the presence of d-electrons which can add to the binding strength. These d-electrons will be directed spatially in regions not occupied by interstitial electrons. The other difference is that d-shells are more easily deformed by positive fields of other ion cores and are more penetrable by itinerant electrons. This makes it possible for them to adapt to structures with another metal ion core and give greater homogeneity of interstices.

β-Manganese Phases

The β-Manganese type of compound has the same electron/atom concentration as the β-phases just discussed and will be included here for comparison. The crystal structure of β-Mn phases is a complex cubic type (tetragonal) with 20 atoms per unit cell. There are relatively few intermetallic compounds of this type which are also referred to as μ-phases.[4] These phases do not form superlattices. The interstitial-electron structures are given in Table 1.

Examination of the β-Mn structure indicates that interstices are approximately as in a face-centered cubic lattice, *i.e.* an oct edge interstice surrounded by 4 face and 2 corner ion cores and a central oct interstice surrounded by 6 face-centered ion cores. This is the basis for the interstices given in Table 1 and occupancy of a preferred 3/4 of the oct interstices (and the equivalent number of tet interstices) is the key to the 3/2 electron to atom ratio.

The interstitial-electron structure for Cu_5Si has three types of interstices. The stoichiometry requires that there is a 2/1 ratio of Cu/Si as corner atoms in the CCP scheme applied to interstices. In this case it is assumed that occupancy of 2 types of oct interstices is preferred to $\bar{e}$ pairing in tet. This provides an explanation for the difference in composition[4] for Cu_5Si as compared to Ag_3Al and $CoZn_3$.

It appears that $CoZn_3$ fits into the series by having additional $\bar{e}$ in tet interstices when the homogeneous oct interstices are occupied. The interstitial-electron structure proposed for $CoZn_3$ is

$$\left|Co^{9+}(d^7),\ 3Zn^{2+},\ 3\bar{e}_{oct},\ 3\bar{e},\ \bar{e}_{2tet}\right|\ \beta\text{-Mn}$$

The degeneracy of d-orbitals for a corner cobalt ion core is as follows (where d-orbital axes are in coincidence with lattice axes):

$$\underset{z^2}{\uparrow} \qquad \underset{x^2-y^2}{\overline{}} \qquad \text{(to edges, } \bar{e} \text{ in oct)}$$

$$\underset{xy}{\uparrow\downarrow} \qquad \underset{xz}{\uparrow\downarrow} \qquad \underset{yz}{\uparrow\downarrow} \qquad \text{(to Zn)}$$

This gives a magnetic moment on Co of 1 unpaired $\bar{e}$ which is directed to oct $\bar{e}$. This makes the additional $\bar{e}$ in tet interstices a reasonable structure for balancing $\bar{e}$ distribution. The $CoZn_3$ (β-Mn phase) has been observed to be ferromagnetic by Koster and Schmidt.[9] The structure for $CoZn_3$ is a further demonstration of the limited nature of the electron concentration/atom approach which requires Group VIII metals to be zero valent to fit the ratios.

The structure for β-Mn was given in Part IV[7] as $|8Mn^{3+}, 12Mn^{+}, 36e|\beta$-Mn. This fits the present scheme with 15 $\bar{e}$ in oct interstices, 15 $\bar{e}$ and 3 $\bar{e}_2$ in tet interstices. This fits the paramagnetism observed (assume the d^4 and d^6 ion cores have d-electrons paired), and the

localization of e_2 in tet accounts for the brittleness and hardness.

ε-Phases

The ε-phase for brass occurs at approximately 75 atomic % zinc, and the structure is written $CuZn_3$. ε-Phases have hexagonal close packing (HCP) with less than the normal ratio for c/a, and the metal ion cores are randomly arranged in HCP ε-phases. The lattice distortion of HCP gives the structure 4 oct and 4 bipyramidal interstices[6] per 4 ion cores ($CuZn_3$). For bipyr interstices to be completely occupied there must be only 1/2 occupancy of oct interstices because of the specific electron spin restrictions of the distorted HCP (see Part I).[6] The other restrictions on interstice occupancy, *e.g.* for $CuZn_3$, are (1) there is preferential occupancy of $CuZn_5$ oct interstices over $CuZn_4$ oct due to the difference in fields of the ion cores. (2) There is preferential occupancy of $CuZn_4$ bipyr over Cu_2Zn_3 bipyr which are in ratio of 3 $CuZn_4$ to 1 Cu_2Zn_3. In placing itinerant electrons in the interstices the maximum of 3 $\bar{e}$ are placed in $CuZn_4$ bipyr and the remaining 4 as $\bar{e}$ and $\bar{e}_2$ in $CuZn_5$ oct and $\bar{e}$ in $CuZn_4$. Thus, the electronic structure for $CuZn_3$, a typical example of the β-phase is:

$$\left|Cu^{+},\ 3Zn^{2+},\ \bar{e}_2,\ 2\bar{e}_{oct},\ 3\bar{e}_{bipyr}\right|_{HCP}$$

The unique requirements of the distorted HCP lattice explains the 7/4 e/a ratio of Hume-Rothery for most of the ε-phases, and the greater electron density in oct interstices is as expected for distortion of the HCP lattice in the non-axial direction (see Part II).[6] See Table 2.

Table 2. Interstitial-electron structures for ε-phases

Intermetallic compound	Electron/atom conc. range	Fractional occupancy of interstices		Electron/atom ratio
		bipyr.	Oct	
$CuZn_3$[a]	1.78—1.85	3/4	$1/2\bar{e}$, $1/4\bar{e}_2$	7/4
Cu_3Sn[b]	1.75	3/4	$1/2\bar{e}$, $1/4\bar{e}_2$	7/4
Ag_5Al_3[c]	1.54—1.86	3/4	$1/2\bar{e}$, $1/4\bar{e}_2$	7/4
$FeZn_7$	—	$5/8(\bar{e}_2)$	$3/4\bar{e}$	8/4
Sb_3Cu_{13}[d]	—	3/4	$1/2\bar{e}$, $1/4\bar{e}_2$	7/4

a) Also $CuBe_3$, $CuCd_3$, $AgZn_3$, $AgCd_3$, $AuZn_3$, $AuCd_3$.
b) Also Cu_3Ge, Ag_3Sn, Au_3Sn, Cu_3Si.
c) Also Au_5Al_3.
d) Also Sb_3Ag_{10}.

The interstitial-electron structure proposed for FeZn is (where bp=bipyramidal interstice)

$$\left|Fe^{8+}(d^6),\ 7Zn^{2+},\ 6\bar{e}_{oct},\ (5\bar{e}_2)_{bp}\right|_{HCP}$$

This stoichiometry $FeZn_7$ gives a ratio of $5(FeZn_4)$ and $3(Zn_5)$ bp interstices and a ratio of $6(FeZn_5)$ and $2(Zn_6)$ oct interstices. To place 16 $\bar{e}$ in conformity with lattice restrictions requires 5 $\bar{e}_2$ in B.P. and 6 $\bar{e}$ in oct. The degeneracy of d-orbitals on Fe in $FeZn_7$ is expected to be the same as for Ru metal in HCP (see Part IV),[7] and the six d-electrons are all paired. The Ag_5Al_3 ε-phase has a still different pattern of interstices, and Massalski[4] has not included it with the ideal ε-phases. A possible electron structure is

$$\left|5Ag^{+},\ 3Al^{3+},\ 2(\bar{e}_2),\ 4\bar{e}_{oct},\ 6\bar{e}_{bipyr}\right|_{HCP}$$

Here the bp interstices are in a ratio of $7Ag_3Al_2$ to one Ag_4Al and the oct interstice $6Ag_4Al_2$ to $1Ag_3Al_3$. A greater range of composition is expected since one more $\bar{e}$ can be accommodated in bp interstices. The Cu_3Sn phase fits the scheme for the other ε-phases if Cu is taken to have the stronger field in influencing preference within the bipyr interstices. This may be the case since the work function for Cu (4.4) is greater than that of Sn (4.2 eV).

None of the pairs of occupied interstices in ε-phases can be considered to be homogeneous, and there is relatively large localization of $\bar{e}$ in certain interstices proposed in the above structure so the movement of electrons from the occupied to vacant interstices will be more difficult than in pure metals. This restriction of electrons is reflected in the greater hardness and brittleness and relatively low electrical conductivity of ε-phases as compared to β-phases.

γ-Phases

As seen in Table 3 the compositions of γ-phases are rather complicated. These intermetallic compounds are exceptionally hard and brittle, and they have low electrical conductivity. They show a pronounced maximum in diamagnetic susceptibility over the small increases shown *e.g.* for brass by the β and ε phases.

A neutron diffraction study[10] has confirmed the structure of Cu_5Cd_8 and Cu_9Al_4, and the authors discussed the arrangement of ions in terms of inner and outer tetrahedral and octahedral positions in agreement with recent X-ray data[11] indicating a close-packed structure. The symmetry of Cu_9Al_4 is slightly different than that of the two other intermetallic phases. The γ-phase structure can also be discussed in terms of the small BCC units, and as in β-phases it is assumed that $\bar{e}$ will occupy the unsymmetrical octahedral interstices of these individual BCC unit cells. This can be done in a straight-forward manner even for these complex lattices if the true unit cell of 52 ions is broken up into individual AB unit cells with corner and body center ions assigned so as to give the correct over all composition.

For Cu_5Zn_8 (unit cell is $Cu_{20}Zn_{32}$) the structure can be divided into the following groups of BCC unit cells:

$$\left|8(Cu_7Zn_1,\ Zn_8),\ 1(Cu_5Zn_3,\ Zn_8),\ 1/2(Cu_2Zn_2,\ Zn_4)\right|$$

where for each group the first two atoms listed are the corner atoms and the last one the body center atoms. All of the face oct and edge oct interstices in these units can be listed and when grouped together they are:

face oct; $\underline{18(Cu_2Zn_4)}$, $24(Cu_4Zn_2)$ and $36(Cu_3Zn_3)$ total=78
edge oct; $\underline{42(Cu_2Zn_4)}$ and $36(CuZn_5)$ total=78

Fe_5Zn_{21}[d]	$1(Zn_6Fe_2, Zn_8)$	$84Fe_2Zn_4$	$\underline{120FeZn_5}$		$48\bar{e}_2$
$(Fe_{20}Zn_{84})$	$4(Zn_5Fe_3, Zn_8)$	$\underline{72FeZn_5}$	$36Zn_6$	$72\bar{e}\uparrow$	$72\bar{e}\downarrow$
	$1\ 1/2(Zn_4Fe_4, Zn_8)$				

a) Also Cu_5Cd_8, Ag_5Zn_8, Ag_5Cd_8, Au_5Zn_8, Au_5Cd_8, and Au_5Hg_8.
b) Also Cu_9Ga_4, Cu_9In_4, and Ag_9Al_4.
c) Also $Ag_{31}Sn_8$ and $Na_{31}Pb_8$ (unit of $Cu_{62}Sn_{16}$ has 117 unit cells, 128 $\bar{e}$)
d) Also Ni_5Zn_{21}, Rh_5Zn_{21}, Pd_5Zn_{21}, Pt_5Zn_{21}, and Ni_5Cd_{21}. (Ternary systems are $Cu_7Zn_4Al_2$, Cu_6Zn_6Al, and $Cu_2Al_3Zn_2$.)
e) Underlined interstices assumed to be occupied by electrons.
f) Most frequent e/a ratio is 21/13. The exceptions are $Li_{10}Ag_{13}$ (13/13), $Li_{10}Pb_3$ (22/13) and Fe_5Zn_{21} (26/13).

The criteria for deciding electron occupancy will be (1) the greatest homogeneity of interstices, (2) the maximum field of ions and (3) the balancing of electron spins. These preferred interstices are underlined above and in Table 3. The following distribution of electrons places the maximum number of $\bar{e}$ in these two interstices with the additional interstices occupied by electron pairs (there is complete occupancy of the preferred interstices):

$\underline{18Cu_2Zn_4}$ (face oct), $18\bar{e}$ $\underline{42Cu_2Zn_4}$ (edge oct), $18\bar{e}$, $24(\bar{e})_2$

This assignment of the 84 $\bar{e}$ of $Cu_{20}^{+}Zn_{32}^{2+}$ gives a structural explanation of the 84/52 or 21/13 Hume-Rothery ratio for γ-phases. The localization of $\bar{e}$ in certain interstices and presence of a large number of electron pairs is in keeping with the extreme hardness and brittleness and the low electrical conductivity of γ-phases as well as their high diamagnetic susceptibility (reduction in paramagnetic susceptibility). (An alternate placement of $\bar{e}$ as 24 $\bar{e}$ in Cu_4Zn_2, 18 $\bar{e}$ in Cu_2Zn_4 face oct and 42 $\bar{e}$ in Cu_2Zn_4 edge oct is also a possibility but would not account for the unusual properties.)

Table 3 lists some other γ-phases and lists the interstices in the same way as illustrated above for Cu_5Zn_8. The interstice pattern accounts for the electron/atom ratio is all of the cases except $Li_{10}Ag_3$. Here it is considered that this compound is an exception due to the weak forces of the two metal ion cores. It has an electron to atom ratio of 13/13. A 1/3 occupancy of edge and face oct can explain the electron/atom ratio. It would appear that the similarity to other γ-phases is coincidental for $Li_{10}Ag_3$.

The structure for $Li_{10}Pb_3$ suggests similarity to other γ-phases, but the Hume-Rothery e/a ratio is 22/13. The structure given in Table 4 requires placement of 4 additional electrons (out of 88). It may be that the stoichiometry $Li_{10}Pb_3$ is not exact, or it may be that the large difference in ion cores leads to occupancy of more than one type of interstice.

The compound Fe_5Zn_{21} is also included in the same interstice scheme as the majority of γ-phases with an ion core of $Fe^{8+}(d^4)$. This leads to no unpaired electrons on the iron since the degeneracy of d-orbitals is the same as for β-phases. As given in Table 3 the preferred interstices for Fe_5Zn_{21}, are 8 $\bar{e}$ (out of 248) short of being completely occupied. This can reflect the extension of $\bar{e}$ in d-orbitals into interstices and a small stoichiometry change would be indicated. Another possibility is that interstices surrounded only by Zn are preferred by itinerant electrons because of absence of d-electrons directed into these interstices.

The small Hall Coefficient[4] for γ-phases can be explained by the presence of both $\bar{e}_2$ and vacancies in the structure. In cases like this electric current can be carried both by dissociation of $\bar{e}_2$ and by $\bar{e}$ movement through interstices. The strong interstice preference in γ-phases with resultant presence of many $(\bar{e})_2$ leads to a polarity in the structure; regions of vacant interstices have a net positive charge and regions with $(e)_2$ a net negative charge.

Laves Phases

A special group of intermetallic compounds which is composed of metal ions of different sizes and which have more exact compositions than the intermetallic phases considered above are the Laves phases. These compounds are all close-packed structures and include both binary (AB_2) and ternary (A, BC) compounds. As an example of structure, $MgCu_2$ has cubic close packing, and the two metal ions form two interpenetrating lattices; Mg^{2+} is surrounded by 12 Cu^{+} and Cu^{+} by 6 Mg^{2+}. A few Laves phases are listed in Table 4 with proposed interstitial electron structure.

TABLE 4. INTERSTITIAL-ELECTRON STRUCTURES FOR LAVES PHASES

	Compound (AB_2)	Occupancy of interstices[b]		
		Tetrahedral		Octahedral
		($4AB_3$)	($2A_2B_2$)	$3(A_2B_4)$
Type 1 (CCP)	$MgCu_2$	—	$2\bar{e}\uparrow$	$2\bar{e}\downarrow$
	$AgBe_2$	$2\ 1/2\bar{e}\uparrow$	—	$2\ 1/2\bar{e}\downarrow$
	$NaAu_2$	—	$1\ 1/2\bar{e}\uparrow$	$1\ 1/2\bar{e}\downarrow$
	Mg(NiZn)	$3\bar{e}\uparrow$	—	$3\bar{e}\downarrow$
	KBi_2	$\uparrow 3\bar{e}, 1/2\bar{e}_2$	—	$3\bar{e}\downarrow$
	ZrW_2	$\uparrow 3\bar{e}$	—	$3\bar{e}\downarrow$
	$ZrZn_2$[a]	$\uparrow 3\bar{e}$, $(\bar{e})_2$ or $(\bar{e})$?		$3\bar{e}\downarrow$
Type 2 (HCP)	$MgZn_2$	$3\bar{e}\uparrow$	—	$3\bar{e}\downarrow$
	$CaMg_2$	$3\bar{e}\uparrow$	—	$3\bar{e}\downarrow$
	Ca(AgAl)	$3\bar{e}\uparrow$	—	$3\bar{e}\downarrow$
	$TiFe_2$	$\uparrow 3\bar{e}, \bar{e}_2$	—	$3\bar{e}\downarrow$
Type 3	$MgNi_2$	$3\bar{e}\uparrow$	—	$3\bar{e}\downarrow$
	Mg(CuAl)	$3\bar{e}\uparrow$	—	$3\bar{e}\downarrow$
	$TiCo_2$	$\uparrow 3\bar{e}, \bar{e}_2$	—	$3\bar{e}\downarrow$
	$ScFe_2$	$\uparrow 3\bar{e}, 1/2\bar{e}_2$	—	$3\bar{e}\downarrow$
	$ThMg_2$	$\uparrow 3\bar{e}, \bar{e}_2$	—	$3\bar{e}\downarrow$
	$NbZn_2$	$\uparrow 3\bar{e}, 1/2\bar{e}_2$	—	$3\bar{e}\downarrow$

a) Ferromagnetic Laves Phase (S. J. Pickart, H. A. Alperin, G. Shirane, and R. Nathans, *Phys. Rev. Lett.*, **12**, 444 (1964)).
b) Fractions used for a single unit cell.

Close-packed structures of the type AB_2 have octahedral interstices (A_2B_4 neighbors) which are all identical, but the tetrahedral interstices are of two types (AB_3 and A_2B_2 neighbors). It appears most likely that the electrons will occupy octahedral interstices and those tetrahedral interstices with highest + fields. When ion core A has the highest+field, the tet interstice A_2B_2 is occupied; when ion core B has the highest+ field, interstice AB_3 is occupied. This is done for the compounds in Table 4. These compounds cover a wide range of electron/atom ratios (given by Nevitt[3]). The compounds which have more electrons than the number which fill the preferred octahedral and tetrahedral interstices with single $\bar{e}$ are those with ions having unfilled d-shells. This is a classification pointed out by Raynor,[12] and these compounds also show considerable lattice contraction upon formation. The proposed structures for these latter compounds have $\bar{e}_2$ in tet interstices.

The Laves phase KBi_2 represents an exceptional compound. It has a melting point of 553°C, and there is a very large lattice contraction upon formation of KBi_2. Since Bi metal does not have a close-packed structure and may have electron pairs within the layer of bismuth ions[6] there may be a greater change in pattern of $\bar{e}$ in interstices of KBi_2 than in formation of other Laves phases. The structure as given in Table 4 assumes an ion core of Bi^{3+} for Bismuth and does have $\bar{e}_2$ in the tet interstice.

When a transition metal with localized d-electrons is present there is interaction between the ($\bar{e}$) of the interstices and the localized d-electrons. This could explain the non-existence of $TiNi_2$ whereas $TiFe_2$ and $TiCo_2$ both form. This probably comes about because the degeneracy of d-orbitals in the HCP lattice (see Part IV) directs d-electrons toward tet interstices for Fe(d^6) and Co(d^6) but to both oct and tet for Ni(d^8).

The interstitial-model indicates that the key to the $\bar{e}$ distribution in Laves phases is the change in occupancy of A_2B_2 tet interstices as there is a change from B to A as the ion core with highest+field. Lattice contractions appear to be associated with $(\bar{e})_2$ in the structure. It is of interest that the Laves phase $ZrZn_2$ exhibits itinerant ferromagnetism. As indicated in Table 4 this could come about if an unpaired $\bar{e}$ went into the A_2B_2 tet interstice instead of $\bar{e}_2$ in AB_3. Pairing of $\bar{e}$ is observed for Laves phases with d-electrons localized on ion cores and for KBi_2, $ThMg_2$, and $NbZn_2$ and may not occur in the case of $ZrZn_2$.

Miscellaneous Alloy Phases

The Na–Pb System is of interest because there are maxima in the phase diagram, but $Na_{31}Pb_8$ (a γ-phase) appears to be the only definite intermetallic compound. The special stability for certain compositions can be accounted for on the basis of the interstitial-electron model in the following way. The Na–Pb system forms a CCP lattice ($AuCu_3$ structure) with Na in corner positions and with a small portion of the Pb face center ions replaced by Na. The ideal phase $NaPb_3$ would have 13 $\bar{e}$ to be distributed among 4 oct and 8 tet interstices and is not observed. The phase maximum at Na_2Pb_5 represents replacement of 1Pb out of 18 (5.5%) by Na. Such a structure of 7 ion cores would have 7 oct and 14 tet interstices (11 of which are homogeneous with oct). Occupancy of oct by $7\bar{e}(\uparrow)$ and tet by $7\bar{e}(\downarrow)$ and $4(\bar{e})_2$ gives complete occupancy of preferred interstices. Greater % of Na leads to insufficient $\bar{e}$ to occupy all preferred interstices for an $AuCu_3$ structure. It appears that there is a stability for Na_2Pb_5 based on interstice occupancy which is similar to other intermetallic phases, but the small fraction of (or random nature of) face-centered Pb replaced by Na is insufficient to lead to a definite compound.

Discussion

The Interstitial-Electron Model gives reasonable structures for the wide variety of alloy phases and accounts for the existence and stability of intermetallic phases in the following way. A combination of 2 or more metal ion cores can achieve stability and metallic properties when a given structure provides an appropriate number of homogeneous interstices for the number of itinerant electrons available. A given structure will have an optimum number of interstices and variations in this optimum are expected with variations in core charge and ion core size. In this way the model incorporates the Hume-Rothery *e/a* ratio as a special case, and makes it possible to include discussion of the effect of d-electrons, of lattice contraction and changes in many properties in the framework of a comprehensive model for metals and alloys.

12) G. V. Raynor, "Physical Chemistry of Metallic Solutions and Intermetallic Compounds, Symposium," Vol. 1, Chemical Publishing Co., New York (1960).

The focussing on electrons in interstices gives insight into the variation in properties of an intermetallic compound in cases where electron concentration or radius-ratio failed to account for changes in properties. An example given by Nowotny *et al.*[13] is $LaNi_2$, a Laves phase which shows a strong lattice contraction. Nowotny suggests the polarity of La^+Ni^- but points out that Pauling assumed the opposite polarity on the basis of his interatomic distance relationships. The polarity arising in the Interstitial-Electron Model requires neither of these extremes. As pointed out for γ-phases for structures with strong preference for $\bar{e}$ occupancy of certain interstices, there will be interstitial regions with net + charge and others of net − charge. Lattice contractions to compensate for this lead to more uniform charge distribution.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1935—1940 (1973)

An Interstitial-Electron Model for the Structure of Metals and Alloys. VI. Interpretation of Superconductivity

Oliver JOHNSON*

Research Institute for Catalysis, Hokkaido University, Sapporo 060

(Received September 17, 1971)

A physical interpretation of the superconducting state based on the interstitial-electron model for metals is given within the framework of the BCS theory. The following conditions for itinerant electrons ($\bar{e}$) and metal ion cores (M^{n+}) are postulated as necessary for superconductivity: (1) There must be a matching of $\bar{e}$ energies (velocity) and binding strength of M^{n+} so $\bar{e}$ initiation of a lattice vibration is possible. (2) Movement of $\bar{e}$ and M^{n+} must be synchronized so there is enhancement of $\bar{e}$-phonon coupling. (3) There must be $\bar{e}$ of one spin available to enter such $\bar{e}$-phonon "chains". The model leads to $\bar{e}$ of opposite spin in phonon chains 500—5000 Å apart. It gives physical interpretations of the thermodynamic properties of superconductors and clearly shows that type of lattice influences superconductivity. It shows the basis for the new correlation observed between superconductivity and a positive Hall Coefficient. Since the model can incorporate the presence of anions as well as $\bar{e}$, it provides a related explanation for superconductivity in non-metals.

The phenomenon of superconductivity has been known since 1911[1] and major efforts have been expended to discover superconducting materials with the highest possible T_c. The range of T_c for materials now known is from a fraction of a degree K to the region of 20K. The major advances have been achieved by Matthias and coworkers[2] whose experiments were based on very careful considerations of the periodic relationships involved. There are several different types of superconductors, and the BCS theory[3] does not explain all of them.[4] It was therefore of great interest to see what additional information and insight the interstitial-electron model[5] might offer for the understanding of superconductivity. It was anticipated that the spatial location of electrons as well as the inherently chemical approach would supplement the correlations of Matthias.[2,4]

Theoretical discussions on superconductivity have emphasized that it is a quantum phenomenon not to be understood on a classical basis. The interpretation presented in this paper is largely in classical terms, but the interstitial-electron model does incorporate all of the essential elements of quantum chemistry and indicates how a microscopic quantum state arises. This is possible because the model introduces spin correlation of electrons in its fundamental postulate of localization of $\bar{e}$ density in interstitial positions (or binding regions).[5] If this approximation of $\bar{e}$ density is reasonably accurate it should lead to the same interpretations of metal properties as the approximations of band theory using wave mechanical calculations involving overlap and exchange terms for atomic wave functions. The viewpoint in this paper follows from the ideas of Föhlich,[6] London[7] Pippard,[8] and Matthias[4] and it contains the essential energy gap[9] of the BCS theory.[3]

Description of the Superconducting State

The basis idea of an electron-phonon interaction,[6] which was incorporated into the BCS theory,[3] will be

used in the physical picture for superconductivity according to the Interstitial-Electron Model. The treatment of metal properties in Parts I—V of this series of papers emphasized an instantaneous picture of a small degree of localization of electron density as "electrons-in-interstices". The Hellmann-Feynman Theorem was used to justify the electrostatic treatment of the quantum-mechanical electron distribution, and the interstitial electrons were pictured as moving between octahedral (oct) and tetrahedral (tet) binding regions separated by a triangle of 3 M^{n+} (positive ion cores). To treat the phenomenon of superconductivity the dynamic movement of electrons and ion cores must be included. In the normal metal, dynamic movement of $\bar{e}$ throughout the lattice is seen as part of a continuous reestablishment of equilibrium as $\bar{e}$ move to new positions in response to lattice vibrations. All of the properties of $\bar{e}$, including interstice preference and spin correlation are postulated to persist in the dynamic picture.

The concept of an electron initiating a lattice vibration[3,6] is used in qualitative discussions of superconductivity, but the details have not been explored beyond the postulate that upon movement of 2 M^{n+} closer together a second electron will be attracted to this region. At the critical temperature for superconductivity (T_c) the conditions must be such that electron motion can influence lattice vibrations. The Interstitial-Electron Model requires that the following conditions be fulfilled for superconductivity:

(1) There must be a matching of energy of electrons (velocity) and binding strength of M^{n+} for initiation of lattice vibrations. Taking a fixed electron velocity at T_c, when the amplitude of lattice vibrations is larger than optimum (low binding strength of M^{n+}) the lattice will not be significantly modified by motions of $\bar{e}$ in the vicinity of M^{n+}; when the amplitude is smaller than optimum (high binding strength), lattice vibrations cannot be initiated.

(2) The movement of $\bar{e}$ and M^{n+} must be synchronized so an $\bar{e}$ passes between $2M^{n+}$ at the precise time to give enhancement of lattice vibration. This condition includes the requirement of availability of a sufficient number of $\bar{e}$ at such critical positions and thus has a geometric component. This condition also implies that electrons not involved in the superconduction process do not scatter the phonons. This condition is in keeping with the treatment of superconductivity as a many body problem.[6]

(3) There must be a sufficient number of electrons of 1 spin in the above positions to sustain an electron-phonon chain. The detailed way in which these conditions lead to superconductivity can best be described by the interpretation of the persistent current and diamagnetism of the superconducting state.

The existence of the *persistent current* is the most spectacular consequence of the postulated electron-phonon coupling. The situation before application of an electric field is that there is relatively small amplitude of lattice vibration and random movement of $\bar{e}$. When electrons are set into motion by the electric field they will move from oct to tet between 2 (or 3) ion cores. Under conditions favorable for superconductivity the $\bar{e}$ will attract the ion cores toward each other and initiate or enhance a lattice vibration at that point. The initial moving electron, now moving faster than thermal velocity, continues on its path while a second electron is attracted to the region where the ion cores have moved even closer together. Thus, there is a phonon induced by the electron movement, and it has been proposed above that each phonon involves electrons of one spin type. This follows from the association of electron spin with an interstice type in the interstitial-electron model.[5] Thus, the second electron moving into the interstice vacated by the first moving electron must have the same spin. The same is true of subsequent electrons which are attracted. Along with the phonon, then, there is a group of $\bar{e}$ of the same spin moving through the lattice, and this has been termed an $\bar{e}$-phonon chain.

When the lattice vibration induced by the first moving electron is at minimum displacement (1/2 way through the vibration cycle), it will begin to move closer to metal ion cores in the adjoining layer in the lattice and thus attract an electron there, this time an electron of the opposite spin since it involves an adjoining interstice separated by an ion core. A new phonon chain is induced by the movement of electrons of spin opposite to the initial phonon chain and follows it by 1/2 of a vibration cycle, and a second group of $\bar{e}$ of opposite spin move in the same direction as the first group. If the vibration frequency induced is 10^{13} sec^{-1}, and the velocity of the electrons 10^8 cm/sec, the spacing of the two groups of $\bar{e}$ will be about 500 Å. For electrons of 10^9 cm/sec, the distance between these groups of $\bar{e}$ of opposite spin would be 5000 Å. These electron groups of opposite spins, in a sense bound together by induced phonons, are the counterpart to "Cooper Pairs" in the interstitial-electron model. It is easily seen that in a lattice like those of metals there is mutual reinforcement of all the phonons and consequently a persistent current in the superconducting state. It is also obvious that a metal surface as well as interstice vacancies or impurities will modify this effect, and this will be discussed in the next section. The range of distances of Cooper Pairs would represent a minimum since the lattice vibration in the adjoining layer may not always initiate a phonon.

Since lattice vibrations are a sensitive function of temperature it is reasonable that at a sufficiently low temperature (T_c for superconductivity), the optimum conditions for initiation of a phonon by an $\bar{e}$ would be reached. At T_c it becomes energetically more favorable for $\bar{e}$ of one spin to move in groups through the lattice as parts of a phonon chain than for $\bar{e}$ to move *via* the normal means of consecutive occupancy of vacant lattice interstices (energy gap). Since the new path has zero resistance there is a sharp drop in resistance over a small temperature interval as the electron transport shifts more and more to the new pathway.

The postulated $\bar{e}$-phonon chains with alternating spins associated with the moving itinerant electrons in a superconductor means that the superconducting metal

will exhibit *perfect diamagnetism* (Meissner Effect[10]). The interstitial-electron model gives a picture of the superconducting metal as a giant diamagnetic molecule which is a macroscopic manifestation[11] of the quantization of electrons (Pauli Principle). The diamagnetism of a superconductor is probable its most important property.

Properties of the Superconducting State

The model leads to a unique interpretation of the influence of crystal lattice on superconductivity and also to a new correlation with positive Hall Coefficient. These will be presented in detail, and then some major properties of the superconducting state will be briefly listed and commented on.

It has been observed that with few exceptions *superconducting metals have positive Hall Coefficients*. This appears to be an important correlation which has not been reported previously (See Paper III in Series). The interstitial-electron model for metals has interpreted a positive Hall Coefficient as indicative of electron pairs in the interstices of the metal in question. The presence of electron pairs goes along with high occupancy of interstices, large field of the metal ion core and fewer spin restrictions to the arrangement of electrons, all properties which favor the transition to a superconducting state. A small Hall Coefficient indicates nearly equal numbers of $\bar{e}$ and $\bar{e}_2$ in the interstices of the metal lattice, and metals with small Hall Coefficients are also expected to be potential superconductors. Another possibility is that the remaining $\bar{e}$ in the structure are more restricted (less phonon scattering) by the surrounding $(e)_2$ than in metals without these electron pairs. The $(e)_2$ also provide a source of $\bar{e}$ for the phonon interaction. Somewhat the same restriction may obtain in superconducting compounds such as NbN or MoC. The C^{4-} and N^{3-} anions in the structure restrict the movement of $\bar{e}$ which are present in the metallic structure and at the same time provide a source of additional $\bar{e}$ to propagate the phonon (*via* dissociation of electrons from the relatively unstable anion). The absence of a Hall Effect in the superconducting state provides confirmation of the proposed mechanism of superconductivity. A movement of chains of electrons of alternating spin with $\bar{e}_2$ as a major source of these electrons would not be affected by a magnetic field.

The type of crystal lattice is also expected to influence

Properties of Superconductor (S) Compared to Normal Metal (M)	Comments
1) There is an energy gap of approximately $3.5\,kT_c$ between S and M.	The $\bar{e}$-phonon chains give a pathway of lower potential energy; $\bar{e}$ kinetic energy may be higher.[12]
2) S has lower thermal conductivity than M.	Lattice vibrations are enhanced in S; this scatters $\bar{e}$ and there is lower dissipation of thermal energy.
3) At T_c, the electronic heat capacity (ν) increases for S.	In S, electrons require greater energy for excitation and more electrons are available. (See Text, Sect IV)
4) Penetration Depth for S is observed to be approximately 500 Å.	The 10—30% greater amplitude of lattice vibrations at the surface can disrupt phonon chains; proposed reinforcement at 1/2 of a vibration will be out of phase, effect is expected to extend at least 500 Å below the surface.
5) Coherence length (ε) of Pippard[8] (or correlation distance of BCS Theory) has been calculated[13] from the relation, $\varepsilon = 0.18\hbar V_f/kT_c$ to be (in Å) 830 for Pb, 2300 for Sn, 3800 for Nb, 7600 for Cd and 16000 for Al.	This is the spatial definition of the superconducting electron and is proposed to be in the range 500—5000 Å by the model. Gradation appears consistent with frequency of vibration expected for different M^{n+}.
6) For non-transition metals $T_c \propto m^{-1/2}$. For transition metals, no mass dependence or small dependence.	This isotope effect was the first demonstration of a relation between lattice vibration (frequency $\propto m^{-1/2}$) and S. Model suggests interaction of $\bar{e}$ and localized d-electrons in transition metals may provide a source of $\bar{e}$ of 1 spin and thus a modified mechanism of S.
7) Ferromagnetic or anti-ferromagnetic materials are not S.	The allignment of $\bar{e}$ with spin of d-electrons localized on ion cores interferes with $\bar{e}$-phonon chains.
8) S can be quenched by passing a critical transport current (Silsbee effect).	The greater number of moving $\bar{e}$ can disrupt $\bar{e}$-phonon chains.

the possibility of superconductivity both by its determining influence on phonon paths but also by its indirect affect on localization of electrons in interstices. The cubic close-packed lattice (CCP) is expected to offer favorable pathways for $\bar{e}$ of one spin through the lattice because it has the largest number of interconnected oct and tet interstices. Of the various hexagonal close-packed lattices (HCP), the La structure (ABACAB arrangement of layers) is more favorable than normal HCP or HCP with c/a greater than 1.632. The HCP structure with c/a less than 1.632 is less favorable because with bipyramidal interstices occupied by $\bar{e}$ the oct interstices can be only 1/2 occupied with $\bar{e}$. This restriction is removed, however, when $\bar{e}_2$ occupy these interstices. The details of the symmetry of interstices was given in paper I.[5] In the BCC structure the $\bar{e}$ are well dispersed in interlocking tet rings and would be favorable for superconductivity only for high occupancy of interstices. Tendency for superconductivity is expected to decrease in the order CCP>HCP-(La)>HCP($c/a \geq 1.632$)>HCP($c/a < 1.632$)>BCC.

TABLE 1. SUPERCONDUCTING TRANSITION TEMPERATURE AND LATTICE TYPE

CCP	HCP (La)	HCP ($c/a>1.632$)		HCP ($c/a<1.632$)	BCC	
La 6.3	La 4.9	Ti 0.4	Zn 0.9	Be 8.0	V	5.0

		Ru 0.5				
		Os 0.65				

Several examples with values for T_c (in K) are tabulated below. In general these expectations agree with the observations of Matthias[2,4] as far as frequency of superconductors of various lattice types. Superconductors with high T_c values do occur for all types of metal lattices. It is the frequency of occurrence of superconductivity in many alloy systems and compounds which is the criterion for the gradations with lattice type. Matthias[4] mentions that the β-tungsten structure is particularly favorable and that it has strings of transition metal ions which do not intersect. This observation is in keeping with the postulation of phonon chains as one of the requirements of superconductivity.

Correlation of Physical Properties with T_c

The three interrelated conditions postulated for superconductivity in a metal can be best related to the transition temperature (T_c) through well-known metal properties. The onset of superconductivity must represent a very delicate balance of electron energies since the lowering of energy in the superconducting state is very small.

Electron velocity can be estimated from band width (X-ray spectra), but the data is sometimes controversial. *Lattice energy* will also reflect electron velocity, and Fig. 1 shows that there is a rough correlation of T_c and lattice energy. Lattice energy should be a good correlating parameter since it is a measure of $\bar{e}$-lattice interaction. The deviations in Fig. 1 may indicate some optimum favorable lattice energy.

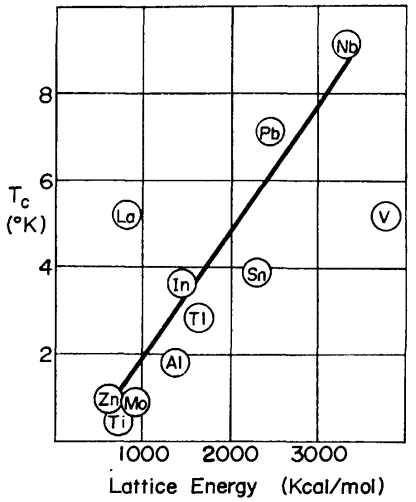

Fig. 1. Dependence of T_c on lattice energy of metal.

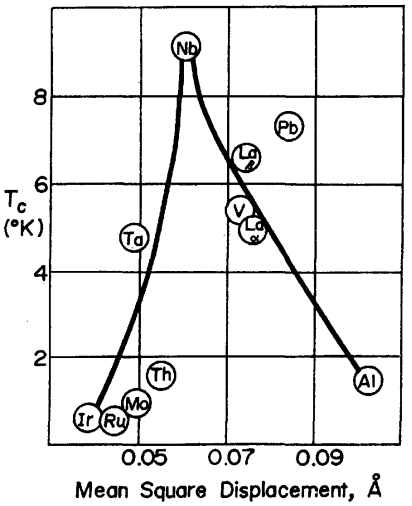

Fig. 2. Dependence of T_c on lattice displacement in thermal vibration.

Lattice displacement is directly related to ion core repulsion, and there is expected an increase in T_c as lattice displacement decreases followed by a decrease in T_c for ion core repulsions beyond the optimum for superconductivity. The data in Fig. 2 can be interpreted as showing such an optimum. The optimum may well be different for ion cores with completed d-shells. The relations in Fig. 2 show that T_c is inversely proportional to lattice displacement above values of 0.06 and directly proportional to $\sqrt{\bar{u}_0^2}$ for values below 0.06. The optimum may be 0.08 for d^{10} metals. In connection with the suggested optimum in Hall Coefficient it should be mentioned that although $\bar{e}_2$ are proposed to exist in the lattices of all superconducting metals, these $\bar{e}_2$ are not the "Cooper pairs" referred to above. The unusual gradation of T_c for group V metals (Nb>V≥Ta), not previously explained, appears to be due to an optimum lattice

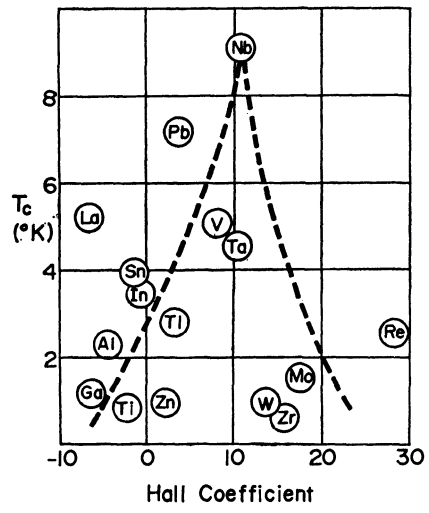

Fig. 3. Suggested dependence of T_c on Hall coefficient.

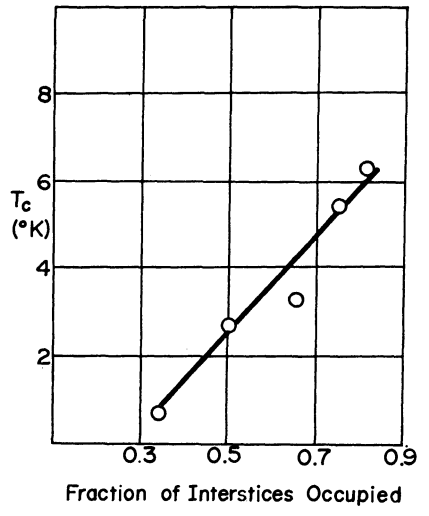

Fig. 4. Dependence of T_c on occupancy of metal interstices (average values)

displacement for Nb, less than optimum for Ta and more than optimum for V. The high T_c observed for La (as seen in Figs. 1 and 3) is due to the high favorability for superconductivity of the La-type packing in the lattice according to the interstitial-electron model.

The correlation with electron occupancy is shown in Fig. 4 and is based on values of electron occupancy of interstices given in Part II.[5] This appears to be a good correlation as expected. The largest deviations from the average line in Fig. 3 are for metals where other factors have a strong effect, *e.g.* for Pb (T_c= 7.2) and Ti, Zr, and Hf (0.2—0.6K) with 2/3 occupancy of interstices and for La (T_c=6.3) and Ir (0.14) both with 1/2 occupancy of interstices. The correlation with *Hall Coefficient* is shown in Fig. 3, where a maximum is suggested. This is a rough correlation and is given for illustration purposes. The interstitial-electron model clarifies the partial relation between *electronic heat capacity* (γ) and T_c. Qualitatively T_c and γ correlate[14] for M^{4+} to M^{6+} metals. There are opposite trends for M^{3+} (Sc, Y, and La) and for M^{7+}-M^{10+} ion cores. The lack of correlation for M^{3+} results from special $\bar{e}$ distribution due to lattice distortion in these metals (see Part II).[5] In groups 7 and 8 the localized d-electrons influence γ and no correlation with T_c is expected. These conclusions are related to the findings of Ishikawa and Totts[15] that a superconducting electron-phonon interaction parameter has a different behavior for d^{10} metals and transition metals. These authors use a correlation of T_c with a parameter combining γ and θ_D (Debye temperature).

The correlations given above offer a means of relating metal properties to the onset of superconductivity. It may be possible as well to relate these factors to superconductivity in non-metal materials. Factors which are more specific are the effects of type of lattice (sect. III) and effect of d-electrons localized on the ion core. Partially filled d-shells may lead to an interference with superconductivity due to asymmetry of ion core fields. For the ion cores with completed d-shells (Zn, Cd, Ga, In, Tl, Sn, Pb) the high positive field which results from the poor screening by d-electrons increases the chances of superconductivity. The greater $\bar{e}$ penetrability of the d^{10} ion cores also increases the chances of e-phonon interaction. Matthias[4] has pointed out the greater ease of preparing this group of superconductors.

Discussion

The interstitial-electron model for metals gives a detailed interpretation of the superconducting state as based on phonons induced by $\bar{e}$, very much as the general suggestions made by Fohlich[6] and Bardeen.[17] It also gives a qualitative physical interpretation of the energy gap which is the essential element of the BCS Theory. The model makes it possible to relate metal properties such as lattice energy, electron velocity, lattice displacement, type of metal lattice, and electron occupancy of interstices to the critical temperature(T_c) for superconductivity. These correlations can be the basis for further explorations for superconducting metals.

On the basis of the model all metals are not expected to become superconductors even at the lowest temperatures attainable. It is believed that the alkali metals and Cu, Ag, and Au have too many vacant interstices to allow superconductivity. In addition, certain intermetallic compounds with strong localization of $\bar{e}$ and $\bar{e}_2$ (inhomogeneous interstices, see Part IV) are not expected to allow superconductivity. The model does suggest that compounds with unstable anions (dissociable electrons) such as O^{2-}, S^{2-}, Se^{2-}, Te^{2-}, N^{3-}, P^{3-}, and C^{4-} are all possible superconductors when in metal-like compounds. (High pressure CS is superconducting.)

The present model gives a different interpretation from that of Matthias[18] for the gradations of T_c across

the rows in the periodic table. The maximum at Group V and VII and for Group IVB are considered to be the result of optima in lattice displacements and only indirectly a function of place in the periodic table. For example, the decreases from Nb to Mo followed by an increase to T_c are taken as due to changes in lattice displacement which reflect the different localization of d-electrons on the ion cores for Mo and T_c whereas Nb has no localized d-electrons. As mentioned earlier the maximum in T_c for Nb (and Pb) at a lattice displacement of approximately 0.06 Å (0.08 for Pb) represents the point at which strong ion core repulsion leads to low amplitude of lattice vibration but is not sufficiently strong to prevent initiation of phonons by $\bar{e}$. In the d^{10} group the inherently stronger forces lead to a larger optimum displacement and also lead to distorted structures and non-metallic properties beyond Group IV.

There are many superconductors not discussed in this paper. A detailed analysis of data on superconducting alloys would be needed to determine the effect of more than one ion core on superconductivity. It is anticipated for alloys with transition metals that the way the model allows ligand field theory to be used would be helpful in interpreting the effect of localized d-electrons in alloys on superconductivity.

The author wishes to thank the Japan Society for the Promotion of Science for the invitation to Hokkaido University as a Visiting Scientist (1971—1972) and to express appreciation to Professor Toya and the Staff of the Research Institute for Catalysis for valuable suggestions during Seminar discussions of this series of papers. The assistance of Miss M. Azuma, Miss T. Kawai, and Miss A. Hiratsuka in preparation of this series of manuscripts is much appreciated.

Dipole Correlation Functions of Non-interacting Symmetric Vib-rotors

Teruyo YAMASHITA* and Hiroshi SHIMIZU**

Faculty of Pharmaceutical Sciences, Kyushu University, Katakasu, Fukuoka 812

(Received September 13, 1972)

Dipolar correlation functions of non-interacting symmetric top molecules were obtained by quantum mechanical calculation. The effect of the rotation-vibration interaction on the correlation function is discussed, taking the constant ζ of the Coriolis coupling and the asymmetry I_x/I_z as parameters. It is shown that the decay of the correlation function for perpendicular vibrations very much depends on the sign and the magnitude of ζ. Some relationships between the shape of the correlation function and the value of the parameters are given.

Detailed information on the reorientational motion of molecules in the liquid state is obtained by infrared spectroscopy; the dipolar correlation function $\Xi(t)$ is given[1,2] from infrared spectrum $I(\omega)$ according to the Fourier transform

$$\Xi(t) = \int_{-\infty}^{+\infty} I(\omega) \exp(i\omega t) d\omega.$$

A number of studies[1-13] have shown that molecular reorientation of small molecules is not of rotational diffusion as described by Debye[14] but to some extent of free rotation. Contribution from this deviates the form of correlation function $\Xi(t)$ from exponential decay curves. Qualitatively, the function $\Xi(t)$ is represented by that of free rotors followed by an exponential curve.[2,5] The molecular motion can be treated more quantitatively, considering the effect of free rotation rigorously.[3,14-19] The form and the relaxation time of $\Xi(t)$ for non-interacting molecules give useful information for the study of observed functions. Thus, $\Xi(t)$ has been calculated for free diatomic,[1,2] spherical[5,20] and symmetric top[21] molecules.

The most important merit of the IR method may be that detailed and quantitative information is obtained on the anisotropy in molecular reorientation as predicted by theories.[1,2] Shimozawa and Wilson[4] first reported the observation of the anisotropic rotation in liquids by the IR method by using *trans*-dichloroethylene. The reorientational motion of acetone in various polar and non-polar solution was recently studied by Koga *et al.*[22] They found that the anisotropy was influenced by the density and polarizability of the solvent.

Observation of the anisotropy is difficult, however, because observed functions often differ much from theoretical ones.[14,22] The most significant contribution to the difference seems to result from the Coriolis' coupling as pointed out by Rothschild.[23] In the present paper we will show how the function $\Xi(t)$ of free symmetric top molecules is influenced by the Coriolis' coupling, taking the coupling constant ζ and the ratio of the moments of inertia, I_x/I_z, as parameters.

Methods of Calculation

In order to take into account the Coriolis' coupling at full length, we may write the Hamiltonian of a vib-rotor[24] as

$$H = H_v + H_r + H', \tag{1}$$

where

$$H_v = (1/2)\sum_i p_i^2 + V_0 + (1/2)l_z^2/I_z, \tag{2}$$

$$H_r = (1/2)(J_x^2/I_x + J_y^2/I_y + J_z^2/I_z) \tag{3}$$

and

$$H' = -J_z l_z/I_z. \tag{4}$$

x, y, and z in (2)—(4) refer to the principal inertial axes of molecule with components of the moment of inertia I_x, I_y, and I_z, respectively; J_x, J_y, and J_z are the components of the total angular momentum $\boldsymbol{J}$ onto the same axes; l_z is the z component of the vibrational angular momentum $\boldsymbol{l}$; p_i is the momentum conjugate to the i-th normal coordinate; and V_0 is the intra-molecular potential. We neglect anharmonicity in vibrations as well as vibration-rotation interactions higher than the first order one H'. We are interested only in the relative frequency of component lines to the center of vibration-rotation bands and not in absolute value. The anharmonicity can therefore be neglected, since it contributes mainly to shifting the whole band spectrum with band center. Vibration-rotation interactions of higher order shift energy levels of vibrationally excited states in the wave number of the order of the rotational constant B ($=\hbar/4\pi cI_x$, where c is the light velocity). The energy change in wave number is of the order of 10^{-2} cm^{-1} for an ordinary molecule. Displacements of the component line of the order of 10^{-2} cm^{-1} can be safely neglected, since neighboring lines are generally separated from each other about the wave number of the order of 1 cm^{-1}.

The eigenfunctions and eigenvalues for the Hamiltonian H may be rewritten in terms of conventional notation corresponding to (1) as follows.

$$H|v, l, k, M) = \hbar\omega(v, l, J, k)|v, l, k, M) \tag{5}$$

with

$$\omega(v, l, J, k) = \omega_v(v, l) + \omega_r(J, k) + \omega'(k, l) \tag{6}$$

$$\omega_v(v, l) = \begin{cases} (v+1/2)\omega_v \\ \qquad \text{for non-degenerate vibrations} & \text{(7a)} \\ (v+1)\omega_v + \hbar\zeta^2 l^2/2I_z \\ \qquad \text{for degenerate vibrations} & \text{(7b)} \end{cases}$$

$$\omega_r(J, k) = \hbar J(J+1)/2I_x + \hbar k^2/[2(1/I_z - 1/I_x)]$$
$$\omega'(k, l) = \hbar\zeta kl/I_z, \tag{8}$$

where $l=\pm 1$ is the quantum number for l_z, *viz.*, the projection of vibrational angular momentum $\boldsymbol{l}$ onto the molecular axis. The Coriolis' coupling appears only when vibrational states are degenerated. Such degenerate vibrations have an induced dipole moment in the x-y plane perpendicular to the molecular axis. In the following treatment the set of quantum numbers v, l, J, k, and M may be concisely represented in a symbolic way by a single letter n. In other words, all the possible quantum states are properly numbered from $n=1$ to infinity. The Schrödinger equation (4) is briefly rewritten as

$$H|n) = \hbar\omega_n|n) \tag{9}$$

with

$$|n) = |n_v)|n_r) \equiv |v, l)|J, k, M).$$

The dipole correlation function $\Xi(t)$, a normalized and dimensionless quantity, may be defined by

$$\Xi(t) = N\langle\mu_z(0), \mu_z(t)\rangle, \tag{10}$$

where μ_z refers to the projection of the induced moment μ onto the space fixed Z-axis which is taken arbitrarily in a plane perpendicular to the direction of propagation of the IR light; $\langle A, B\rangle$ represents the canonical average between variables A and B; and $N=\langle\mu_z(0), \mu_z(0)\rangle^{-1}$ is the normalization constant which makes $\Xi(0)=1$. When molecules are free from intermolecular interactions, energy H is a constant of motion. The correlation function is then conveniently expressed in terms of eigenfunctions $|n)$ and eigenvalues ω_n as follows.[25]

$$\Xi(t) = N\sum_{n,n'}(\beta\hbar\omega_{nn'})^{-1}\exp(-\beta\hbar\omega_n)\{\exp(\beta\hbar\omega_{nn'})-1\} \times \exp(i\omega_{nn'}t)(n|\mu_z|n')(n'|\mu_z|n), \tag{11}$$

where

$$\omega_{nn'} \equiv \omega_n - \omega_{n'}$$

and $\beta\equiv 1/kT$ with Boltzmann constant k and absolute temperature T. The angular frequency $\omega_{nn'}$ may be given by

$$\omega_{nn'} = \omega_{nn'}^c + \omega_{nn'}^* \tag{12}$$

where $\omega^c(n; n')\equiv\omega_{nn'}^c$, the angular frequency of the center of fundamental band $\{n\to n'\}$, is independent of the sets of rotational quantum numbers n_r and n_r' in the present approximation; namely,

22) K. Koga, Y. Kanazawa, and H. Shimizu, *J. Molec. Spectrosc.* (in press).
23) W. G. Rothschild, *J. Chem. Phys.*, **57**, 991 (1972).
24) H. H. Nielsen, *Phys. Rev.*, **60**, 794 (1941).
25) R. Kubo and K. Tomita, *J. Phys. Soc. Jap.*, **9**, 45 (1954).

$$\omega^c(n, n') = \omega^c(n_v; n_{v'}) \tag{13}$$

with $v=0$ and $v'=1$. By utilizing (12) the correlation function (11) may be rewritten as

$$\Xi(t) = \Xi^*(t) \exp [i\omega^c(n_v; n_{v'})t]$$

with

$$\Xi^*(t) = N'\sum_{n,n'}(\beta\hbar\omega_{nn'})^{-1} \exp(-\beta\hbar\omega_{n_r}) [\exp(\beta\hbar\omega_{nn'})-1] \times \exp(i\omega^*_{nn'}t)(n|\mu_z|n')(n'|\mu_z|n), \tag{14}$$

where N' is the normalization factor of $\Xi^*(t)$. The Fourier transform of $\Xi^*(t)$ gives the "normalized" and dimensionless rotation-vibration spectrum $S^*(\omega)$ relative to the band center ω^c. The inverse Fourier transformation of $S^*(\omega)$ results in $\Xi^*(t)$. In classical limit $\beta\hbar\omega_{nn'} \ll 1$, (14) is reduced to

$$\Xi^*_{cl}(t) = N'\sum_{n,n'} \exp(-\beta\hbar\omega_{n_r}) \times \exp(i\omega^*_{nn'}t)(n|\mu_z|n')(n'|\mu_z|n). \tag{15}$$

Further calculation of $\Xi(t)$ is possible when μ_z in the matrix elements of (11) is given in terms of variables defined in molecular-fixed coordinate systems. Wigner's rotation matrix $A_{mm'}{}^{(1)}(\Omega)$ can be most conveniently used for this purpose:[26]

$$\mu_z = \sum_{m=-1}^{1} A^{(1)}_{m0}(\Omega)\mu_m \tag{16}$$

with

$$\begin{pmatrix}\mu_{+1}\\ \mu_0\\ \mu_{-1}\end{pmatrix} = \begin{pmatrix}-1/\sqrt{2}\,(\mu_x+i\mu_y)\\ \mu_z\\ 1/\sqrt{2}\,(\mu_x-i\mu_y)\end{pmatrix} \tag{17}$$

and Ω refers to Eulerian angles between the space-fixed and molecule-fixed coordinate systems. We obtain

$$(n'|\mu_z|n) = \sum_{m=-1}^{1}(n_r'|A^{(1)}_{m0}(\Omega)|n_r)(n_v'|\mu_m|n_v), \tag{18}$$

where $(n_{v'}|\mu_m|n_v)$ have non-vanishing values only when $v'=v\pm1$ and $l'=l+m$.

We obtain the function $\Xi(t)$ corresponding to fundamental bands from (11) by confining ourselves to states $|n)$ with $v=0$ and $l=0$, or such states where $|n_v)=|n_0)$. Hence, non-vanishing elements appear when $v'=1$ and $l'=m$. Since the induced moment μ_m is given in terms of the normal coordinate Q_i by

$$\mu_m \simeq Q_i(\partial\mu_m/\partial Q_i)e, \tag{19}$$

nonvanishing elements become

$$(1, 0|\mu_0|0, 0) = [\hbar/2\omega_v]^{1/2}(\partial\mu_0/\partial Q_i)_e$$
$$(1, \pm1|\mu_{\pm1}|0, 0) = \mp[\hbar/\omega_v]^{1/2}(\partial\mu_{\pm1}/\partial Q_i)_e. \tag{20}$$

Matrix elements $(n_r'|A_{m0}{}^{(1)}|n_r)$ may be conveniently given in terms of Clebsch-Gordan coefficients[15] as

$$(J', K', M'|A^{(1)}_{m0}|J, K, M) = [J+1]^{1/2}C(J, 1, J'; K, m), \tag{21}$$

which have non-vanishing values only when

$$\Delta J \equiv J' - J = 0, \pm1 \tag{22}$$

and

$$\Delta K \equiv K' - K = m.$$

Results and Discussion

Parallel Bands. The excited states in the present case have no vibrational angular momentum, *i.e.* $l'=0$. Thus (18) is transformed into

$$(n'|\mu_z|n) = (n_r'|A^{(1)}_{00}(\Omega)|n_r)(n_v'|\mu_0|n_v) \tag{23a}$$
$$= (J', K, M'|A^{(1)}_{00}(\Omega)|J, K, M)(1, 0|\mu_0|0, 0)$$
$$= C(J, 1, J'; K, 0)[\hbar(J+1)/2\omega_v]^{1/2}(\partial\mu_0/\partial Q_i)_e \tag{23b}$$

by utilizing (20), (21) and (22). The quantity C in (23b) is non-vanishing only when $J'=J-1$, J, and $J+1$:

$$C(J, 1, J-1; K, 0) = [J^2-K^2]^{1/2}/[J(2J+1)]^{1/2}$$
$$C(J, 1, J; K, 0) = K/[J(J+1)]^{1/2}$$
$$C(J, 1, J+1; K, 0) = [(J+1)^2-K^2]^{1/2}/[(J+1)(2J+1)]^{1/2}. \tag{24}$$

We have

$$\omega^*_{nn'} = \begin{cases}-2BJ & \text{for } J' = J-1\\ 0 & J' = J\\ +2BJ & J' = J+1.\end{cases} \tag{25}$$

The reduced correlation function $\Xi^*(t)$ is easily obtained from (7), (14), (23b), (24), and (25).

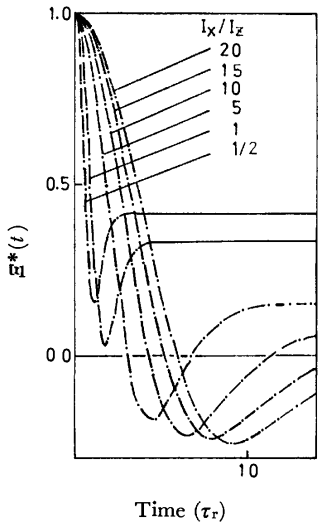

Fig. 1. Time correlation functions $\Xi^*(t)$ for parallel band obtained at $T=300$ K and $\omega_{nn'}{}^c=2{,}000\ \mathrm{cm}^{-1}$ in units of $\tau_r \equiv (I_z/kT)^{1/2}$, the mean period of rotation.

The functions $\Xi^*(t)$ at 300 K and $\omega_{nn'}{}^c=2000\ \mathrm{cm}^{-1}$ are shown in Fig. 1, taking the ratio I_x/I_z as a parameter. The value of I_z is assumed to be 5×10^{-40} g·cm^2, which is nearly the same with the moment of inertia of CH_3X. The calculated functions are clearly of non-exponential form with non-vanishing limiting value $\Xi^*(\infty)$, which results from the Q branch of spectrum. The limiting value $\Xi^*(\infty)$ is directly related to the relative intensity the Q branch. The proof is very simple. The spectrum $S^*(\omega^*)$ may be composed of the sum of the P and R branches, $S_1{}^*(\omega^*)$, and the Q branch, $S_2{}^*(0)\delta(\omega^*)$. The Fourier transform of $S^*(\omega^*)$ gives

$$\Xi^*(t) = \int_{-\infty}^{\infty} S_1{}^*(\omega^*)e^{i\omega^*t}d\omega^* + S_2{}^*(0)\int_{-\infty}^{\infty}\delta(\omega^*)e^{i\omega^*t}d\omega^*,$$

where the first term in the RHS vanishes when $t\to\infty$. Hence, $\Xi^*(\infty)=S_2^*(\omega_{nn'^c})$.

It is noted that the magnitude of the transition moment $(n|\mu_z|n')$ is independent of the moment of inertia of molecule as indicated by (23) and (24). This means that the relative intensity S_2^* of the Q branch is varied only by the statistical factor, the Boltzmann distribution factor $\exp(-\hbar\omega_n/kT)$, which is a function of the ratio of ω_n and temperature T. The eigenvalues (6)—(8) lead to the result that an increase in the moment of inertia I_x decreases the magnitude of ω_n/T and, hence, the relative intensity S_2^*. A similar effect is expected by increasing temperature T instead of I_x. On the other hand, there is the relation $\Xi^*(\infty)=S_2^*$ as shown above. Therefore, $\Xi^*(\infty)$ is a decreasing function of I_x as well as T.

It was shown by one of us (H.S.)[5] that the non-dissipative relaxation of the dipolar correlation $\Xi^*(t)$ is characterized by two dynamical factors, the mean period τ_f of rotation and the relaxation time τ_p of the phase coherence among dipole moments which are in phase at initial time $t=0$. The rate of the initial decay of the correlation function $\Xi^*(t)$ for non-interacting molecules is inversely proportional to τ_f, or estimated qualitatively by $<|\hbar/\omega_{nn'}^*|>$, where $<\ >$ refers to the ensemble average. In other words, the rate of the initial decay of the function $\Xi^*(t)$ is proportional to $<|\omega_{nn'}^*|>$ in a qualitative sense. The results (25) leads to $<|\omega_{nn'}^*|>\propto B\propto 1/I_x$, indicating that the smaller the moment of inertia I_x for a fixed value of I_z, the larger the rate of initial decay. The tendency is demonstrated in Fig. 1. The relaxation of the phase coherence gives rise to the disappearance of the oscillatory behavior of the correlation function and makes the function approach zero. The depth of the minimum Ξ_m^* of the correlation function is, therefore, an increasing function of τ_p, or the relaxation time of the phase coherence and is inversely proportional to $<|\Delta\omega_{nn'}^*|>\equiv<|\omega_{nn'}^*-<\omega_{nn'}^*>|>$. The rates of reorientation of molecular frame, (25), indicate that $<|\Delta\omega_{nn'}^*|>$ is further proportional to B or $1/I_x$. Thus, the larger the ratio I_x/I_z in Fig. 1 the deeper the minimum of the correlation function. The time t_m where the correlation function takes the minimum value Ξ_m^* is linearly proportional to $[I_z/I_x]^{1/2}$ as shown in Fig. 2. t_m is given in Fig. 3 as a function of $[I_z/I_x]^{1/2}$, indicating that it is proportional to $[I_z/I_x]^{1/2}$. In other words, t_m multiplied by Ξ_m^* is constant.

In classical limit, $\beta\hbar\omega_{nn'}\ll 1$, no vibrational effect

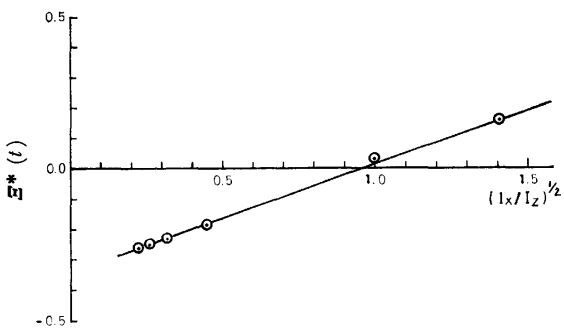

Fig. 2. The minimum values of Fig. 1 as a function of $(I_z/I_x)^{1/2}$.

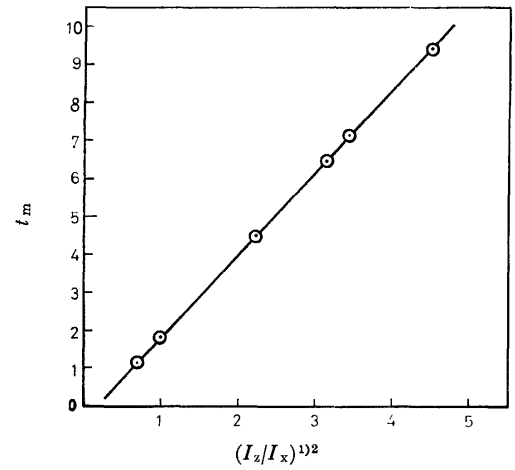

Fig. 3. The position of the minimum of $\Xi^*(t)$ in units of $t_m=t(I_z/kT)^{1/2}$ as a function of $(I_x/I_z)^{1/2}$.

exists in the correlation function $\Xi^*(t)$, because matrix elements $(n'|\mu_z|n)$ in (15) can be replaced by $(n_r'|A_{00}^{(1)}|n_r)$ and, the vibrational contributions, $(n_v'|\mu_0|n_v)$, can be included in the normalization factor N'. Hence, the correlation function in classical limit $\Xi_{cl}^*(t)$ represents the dipole correlation of rotor but not of vib-rotor. On the other hand, $\Xi^*(t)$ describes that of free vib-rotor.

Perpendicular Bands. In the present case where $l'\geq 1$, vibrations interact with molecular rotation through the Coriolis' coupling and vibration and rotation are often influenced substantially. From (20), (21) and (22), (18) becomes

$$(n'|\mu_x|n)=(n_r'|A_{\pm 10}^{(1)}(\Omega)|n_r)(n_v'|\mu_{\pm 1}|n_v) \tag{26a}$$

$$=(J',K',M|A_{\pm 10}^{(1)}(\Omega)|J,K,M)(1,\pm 1|\mu_{\pm 1}|0,0)$$

$$=C(J,1,J';K,\pm 1)[\hbar(2J+1)/\omega_v]^{1/2}(\partial\mu_{\pm 1}/\partial Q)_e. \tag{26b}$$

The coefficients C in (26b) have non-vanishing values only when $J'=J-1$, J, and $J+1$ and $K'=K-1$, and $K+1$:

$$\begin{aligned}&C(J,1,J-1;K,\pm 1)\\&\quad=[(J\mp K+1)(J\mp K)]^{1/2}/[2J(2J+1)]^{1/2}\\&C(J,1,J;K,\mp 1)\\&\quad=-[(J\mp K+1)(J\pm K)]^{1/2}/[2J(J+1)]^{1/2}\\&C(J,1,J+1;K,\pm 1)\\&\quad=[(J\pm K+1)(J\pm K)]^{1/2}/[2(J+1)(2J+1)]^{1/2}.\end{aligned} \tag{27}$$

We have[27]

$$\omega_{nn'}=\omega_v-B+\zeta(\zeta-2)A\pm 2K[(1-\zeta)A-B]\mp 2BJ, \tag{28a}$$

where the upper sign refers to $J'=J+1$, $K'=K-1$ and $l'=l-1$, and the lower one to $J'=J-1$, $K'=K+1$ and $l'=l+1$, and $A=\hbar/4\pi cI_z$. Similarly, we have

$$\omega_{nn'}=\omega_v-B+\zeta(\zeta-2)A\pm 2K[(1-\zeta)A-B], \tag{28b}$$

where the upper sign refers to $J'=J$, $K'=K+1$ and $l'=l+1$, and the lower $J'=J$, $K'=K-1$ and $l'=l-1$. For $J'=J+1$, $K'=K+1$ and $l'=l+1$ and for $J'=$

27) H. H. Nielsen, "Handbuch der Physik," Band 37-1, Atom 3-Molekül 1, Springer-Verlag Berlin, Göttingen, Heidelberg (1959), p. 254.

$J-1$, $K'=K-1$ and $l'=l-1$ we write

$$\omega_{nn'} = \omega_v - B + \zeta(\zeta-2)A \pm 2K[(1-\zeta)A-B] \pm 2BJ. \quad (28c)$$

From (7), (14), (26b), (27), (28a), (28b), and (28c), the reduced correlation function $\Xi^*(t)$ is easily calculated. In Figs. 4—9 are shown the dipole correlation functions at $T=300$ K and $\omega_{nn'^c}=2000$ cm^{-1}, regarding the Coriolis' coupling constant ζ as a parameter. When $\zeta \neq 0$, correlation function is affected not only by rotational state but also by interactions of the vibration and the rotation. Generally, the correlation function of degenerate vibrations obtained from infrared spectrum significantly differs from the dipole correlation functions of rotors as shown in Figs. 4—9.

Symmetric top molecules are classified into two groups, the oblate symmetric top (in the case of $I_z>I_x$)

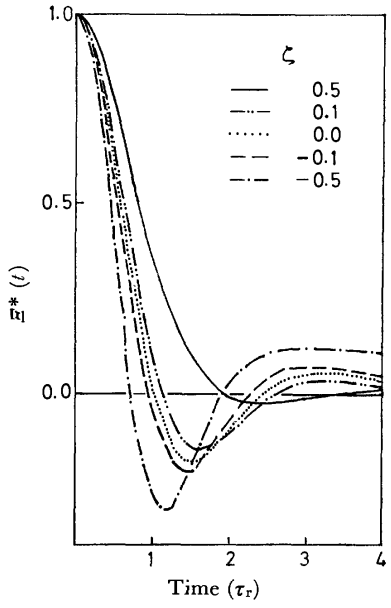

Fig. 4. Time correlation fuctions $\Xi^*(t)$ for perpendicular band at $I_x/I_z=1/2$, $T=300$ K and $\omega_{nn'^c}=2,000$ cm^{-1} in units of $(I_z/kT)^{1/2}$.

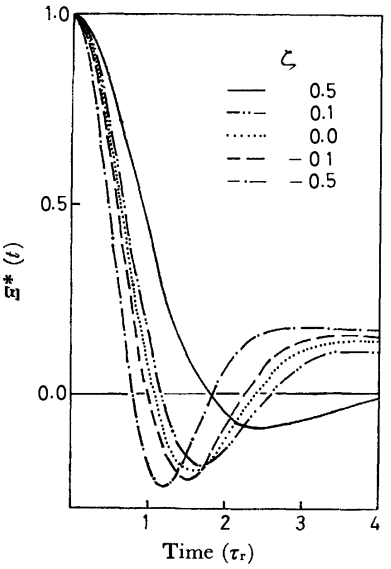

Fig. 5. Time correlation fuctions $\Xi^*(t)$ for perpendicular band at $I_x/I_z=3/4$, $T=300$ K and $\omega_{nn'^c}=2,000$ cm^{-1}.

and prolate symmetric top ($I_z<I_x$), the functions $\Xi^*(t)$ for the oblate and prolate molecules being shown in Figs. 4—5 and in Figs. 6—9, respectively. The dependence of the correlation function on I_x/I_z is more pronounced in oblate molecules than in prolate ones.

We will discuss the form of the correlation function more in detail by considering the two dynamical factors as in the case of parallel bands. In the present case the orientation of the dipole moment is changed by molecular vibrations with non-vanishing angular momentum as well as by molecular rotations. When $\zeta<0$ vibration and rotation change the orientation of the dipole moment in the same direction whereas in opposite directions for $\zeta>0$. Therefore, the rate of the initial decay of the function $\Xi^*(t)$ is evidently larger when $\zeta<0$ than when $\zeta>0$. Relations (28) demonstrate that $\omega_{nn'}^*\equiv\omega_{nn'}-\omega_v$ decreases as Ξ is increased for constant A and B from -1 to $+1$. This means that $<|\omega_{nn'}^*|>$ or the rate of the initial decay is also a decreasing function of ζ when the values of I_x and I_z are fixed. On the other hand, when I_x changes with constant I_z and ζ, the variable part of $\omega_{nn'}^*$ is $\mp 2(J+K)B$. This indicates that $<|\omega_{nn'}^*|>$ or the rate of the initial decay of the correlation function decreases as B is decreased, *i.e.*, as I_x/I_z is increased. Equations (28) show that the ζ-dependence of the rate of the initial decay becomes sharper as the ratio $I_x/I_z=A/B$ is increased.

In contrast to the case of parallel bands, the larger the rate of the initial decay of the function $\Xi^*(t)$ the deeper the minimum Ξ_m^* as seen in Figs. 4—9. The tendency may be explained as follows in terms of the relaxation of the phase coherence among dipole moments.

The rate of the change of the orientation of induced moments depends not only on the rotational quantum number J but also on the quantum number K of component of angular momentum along molecular axis. To estimate the effect caused by the K-dependence of molecular reorientation on τ_p, it will be convenient to utilize the relation $\tau_p\simeq\hbar/<\Delta\omega^*>$, where $<\Delta\omega^*>$ is the width of band spectrum in angular frequency units. Equations (28) together with (27) give an inhomogenous distribution of component lines and the spectrum is made from a subband structure. The wings of the whole spectrum are mainly contributed from P and Q branches of sub-bands, respectively, and give rapidly relaxing components in the phase correlation, since separations from the band center are large. The relaxation time τ_p is, therefore, contributed most effectively by Q branches which gather rather closely in the central part of the spectrum and gives a slowly relaxing component. In other words, the width of the spectrum is contributed most effectively from the Q branches as far as the phase relaxation is concerned. Hence, we have in a rough measure

$$\tau_p\simeq\hbar/\langle|\Delta\omega_{nn'}^*(Q)|\rangle, \tag{29}$$

where $\Delta\omega_{nn'}^*(Q)$ is the position of the Q branches relative to the center of the spectrum, namely,

$$\Delta\omega_{nn'}^*(Q)=2AK[(1-\zeta)-I_z/I_x], \tag{30}$$

from (28) for a fixed value of I_z.

When the ratio I_x/I_z is increased from zero, we obtain a decrease in the value of $<|\Delta\omega_{nn'}^*(Q)|>$ and its minimum value, *i.e.* the maximum value of τ_p, at

$$I_x/I_z=1/(1-\zeta). \tag{31}$$

Further increase of I_x/I_z leads to an increase of $<|\Delta\omega_{nn'}^*(Q)|>$ or a decrease of τ_p. Equation (30) indicates that the main contribution to τ_p results from the term $1-\zeta$, provided that

$$I_x/I_z\gg 1/(1-\zeta). \tag{32}$$

Equation (31) leads to the result that the larger the Coriolis' coupling constant ζ the larger the ratio I_x/I_z which gives the maximum τ_p. Comparison of the correlation functions for $=-0.5$ and $=0.5$ in Figs. 4—9 support the above discussion.

One of the authors, T. Yamashita, wishes to express her sincere thanks to Dr. K. Nishiyama and Mr. K. Kometani, Faculty of Science, Kyushu University, for discussions. Yano, Daiichi College of Pharmaceutical Sciences, for their continuous encouragement.

On the Interaction of Sodium Alkyl Sulfate with Alkylpyridinium Chloride and with Alkyltrimethylammonium Bromide in a Solution

Masaru MITSUISHI and Mieko HASHIZUME

Faculty of Textile Science and Technology, Shinshu University, Ueda, Nagano 386

(Received September 21, 1972)

The interaction between sodium alkyl sulfate and alkylpyridinium chloride or alkyltrimethylammonium bromide has been studied quantitatively by means of the conductometric method. The equilibrium constants of the reactions between them have been found to increase with an increase in the length of the alkyl chain. When the sum of the carbon atoms in an alkyl sulfate and of those of an alkylpyridinium chloride or of alkyltrimethylammonium bromide is less than twenty, no reaction has been found to take place. When it is larger than twenty-six, precipitates of the complex have been found. The interaction has been found to depend greatly on the length of the alkyl chain. The interaction decreases the heat content and increases the entropy.

The interaction between the oppositely-charged organic ions in aqueous solution have been examined by means of UV-spectroscopic,[1-5] NMR-spectroscopic,[6] conductometric,[7] and polarographic procedures.[8] The experimental evidence suggests that the hydrophobic groups in the organic ions play an important role in the ion-pair formation between oppositely-charged organic ions. However, very few quantitative investigations of the ion-pair formation between oppositely-charged organic ions, and of the factors involved in the determination of the interactions between them, have been carried out. Therefore, it seems valuable to make a quantitative examination of the role of the hydrophobic groups in the ion-pair formation between oppositely-charged organic ions by means of conductometric measurements of the solution.

Experimental

Materials. The alkyltrimethylammonium bromides (ATB) and alkylpyridinium chlorides (APC) used were as follows: hexyltrimethylammonium bromide (C_6TB), octyltrimethylammonium bromide (C_8TB), decyltrimethylammonium bromide ($C_{10}TB$), dodecyltrimethylammonium bromide ($C_{12}TB$), tetradecyltrimethylammonium bromide ($C_{14}TB$), hexadecyltrimethylammonium bromide ($C_{16}TB$), dodecylpyridinium chloride ($C_{12}PC$), and hexadecylpyridinium chloride ($C_{16}PC$).

The ATB was obtained by boiling a mixture of trimethylamine and the corresponding alkyl bromide in ethanol, by removing the ethanol, and by then recrystallizing it from acetone and/or benzene.

The APC was obtained by recrystallizing commercial agents from acetone and benzene.

The sodium alkyl sulfates (SAS) used were as follows: sodium amyl sulfate (SC_5S), octyl sulfate (SC_8S), sodium decyl sulfate ($SC_{10}S$), sodium dodecyl sulfate ($SC_{12}S$), sodium tetradecyl sulfate ($SC_{14}S$), sodium hexadecyl sulfate ($SC_{16}S$), and sodium octadecyl sulfate ($SC_{18}S$). They were prepared by adding an excess of sulfuric acid to a solution of the corresponding alkyl alcohol, by neutralizing alkyl sulfate with sodium hydroxide, and by then recrystallizing the sodium alkyl sulfate from ethanol.

Conductance Measurements of a Solution. A solution of alkyl sulfate and one of alkylpyridinium chloride or alkyltrimethylammonium bromide were mixed in varied proportions; the conductance measurements on the mixtures were made with a Yokogawa-Hewlett Packard Universal Bridge BV-Z-13B at 15, 25, 35 and 45 ± 0.01 °C. A simple dilution cell with a cell constant of 0.0514 at 25 °C was used.

Results and Discussion

The interaction of SAS with APC or ATB may be represented by Eq. (1), since all the examinations of the reactions between them have been carried out on a solution below the CMC of each electrolyte;

$$C^+ + nA^- \rightleftarrows CA_n \qquad (1)$$

Here, C^+ is an organic cations, like the alkylpyridinium ion (AP^+) or the alkyltrimethylammonium ion (AT^+), and A^- is an organic anion, like the alkyl sulfate ion (AS^-). The counter ion of AP^+ or AT^+, like Cl^- or Br^-, and the counter ion of AS^-, like Na^+, are assumed not to take part in the reaction at all, because the concentrations of the electrolytes are very low and the electrolytes are supposed to dissociate completely. In order to determine the n in Eq. (1) by the conductometric continuous-variation method,[9] a solution of C and one of A with the same molar concentration are mixed in various proportions and the conductances of the mixtures are measured.

Figure 1 shows the results obtained by the conductometric continuous-variation method for the interaction of $C_{16}TB$ with SC_8S. The mixture is made by the addition of x_1 liter ($x_1 \leqq 1$) of SC_8S of 1.0×10^{-4} mol/l to x_2 liter ($x_2=1-x_1$) of $C_{16}TB$ of 1.0×10^{-4} mol/l, the conductance measurement is carried out, and then specific conductance of the mixture is plotted against the composition. The straight lines, AB and CD, indicate the specific conductances of the SC_8S and $C_{16}TB$ solution respectively. When no reaction between SC_8S and $C_{16}TB$ takes place, the specific conductance of the mixture must be on the straight line BD. Since the

Table 1. Equilibrium constants of the interactions between sodium alkyl sulfates and alkylpyridinium chlorides

Alkyl-pyridinium chlorides	Sodium alkyl sulfates	Temperature (°C) 15	25	35	45
$C_{12}PC$	$SC_{10}S$	1.19×10^5	9.06×10^4	7.22×10^4	
	$SC_{12}S$		1.11×10^6	8.11×10^5	6.28×10^5
$C_{16}PC$	SC_8S	1.43×10^6	1.07×10^6	7.22×10^5	

specific conductance is found to be the smallest in the equimolar mixture, the n in Eq. (1) is 1, *i.e.*, an equimolecular complex with no charge is formed in the mixture.

Figure 2 shows the specific conductance *vs.* composition plot of a mixture of SC_5S and $C_{12}PC$ at 25 °C. The specific conductance of the mixture is equal to the sum of the specific conductances of SC_5S and $C_{12}PC$ with the corresponding concentrations. The results

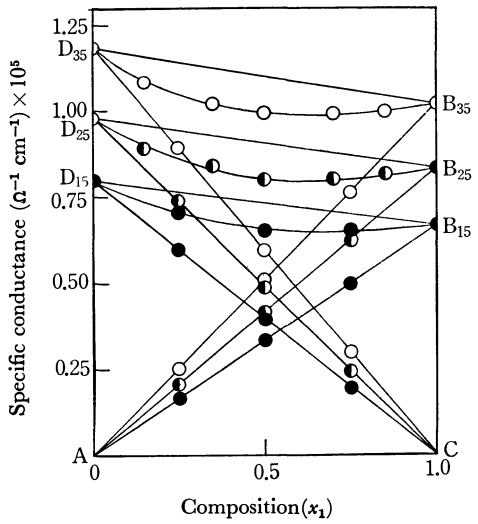

Fig. 1. The specific conductances of the mixture of x_1 liters of sodium octyl sulfate of 1.0×10^{-4} mol/l and $(1-x_1)$ liters of hexadecyltrimethylammonium bromide of 1.0×10^{-4} mol/l at 15 (●), 25 (◐), and 35 °C (○).

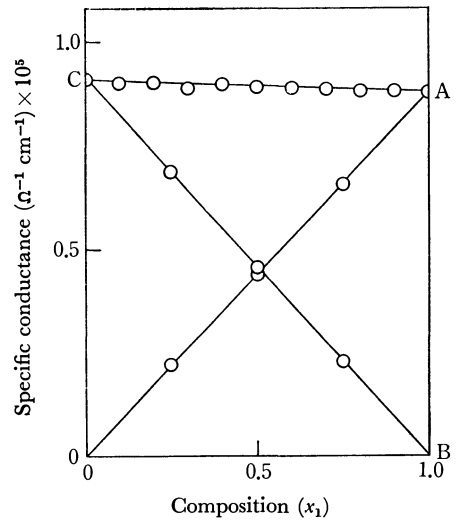

Fig. 2. The specific conductances of the mixture of x_1 liters of sodium amyl sulfate of 1.0×10^{-4} mol/l and $(1-x_1)$ liters of dodecylpyridinium chloride of 1.0×10^{-4} mol/l at 25 °C.

indicate that no reaction between SC_5S and $C_{12}PC$ takes place in the mixture.

The specific conductance *vs.* composition plots for the mixtures of the other substances, SAS and APC or ATB, are to be similar to either Figs. 1 or 2.

When the reaction between SAS and APC or ATB takes place, only the equimolecular complex is formed in the solution. The equilibrium constant, K, of Eq. (1) is given by Eq. (2);

$$K = \frac{X_{CA}}{X_{C^+}X_{A^-}} \tag{2}$$

Here, the X denotes the mole fraction of each component.

When the reaction takes place in a mixture of x_1 liter of C of c mol and x_2 liter of A of c mol, the specific conductance, κ, of the mixture is given by Eq. (3);

$$\kappa = (cx_1-z)\frac{\alpha}{10^3} + (cx_2-z)\frac{\beta}{10^3} + \frac{z(\gamma_-+\delta_+)}{10^3} \tag{3}$$

Here, z is the concentration of the product, CA, in the reaction. The α and β symbols are the equivalent conductances of the C electrolyte and the A electrolyte respectively. The γ_- and δ_+ symbols are the equivalent ionic conductance of the counter ion of C^+ and that of A^- respectively.

The concentration of the product, z, is obtained by means of Eq. (4);

$$z = \frac{c(x_1\alpha+x_2\beta)-10^3\kappa}{(\alpha+\beta)-(\gamma_-+\delta_+)} \tag{4}$$

The equilibrium constants shown in Tables 1 and 2 were calculated from Eqs. (4) and (2). It may be seen that the equibrium constants increase with the number of carbon atoms in the alkyl chain.

Table 2. Equilibrium constants of the interactions between sodium alkyl sulfates and alkyltrimethyl ammonium bromides

$CT_{16}B$	SC_8S	1.17×10^6	8.89×10^5	6.72×10^5

Table 3. Thermodynamic parameters of the interactions between sodium alkyl sulfates and alkylpyridinium bromides at 25 °C

Alkyl-pyridinium chlorides	Sodium alkyl sulfates	K_{298}	$-\Delta H°$ (kcal/mol)	$-\Delta G°$ (kcal/mol)	$\Delta S°$ (cal/K mol)
$C_{12}PC$	$SC_{10}S$	9.06×10^4	2.4	6.8	15
	$SC_{12}S$	1.11×10^6	5.0	8.2	11
$C_{16}PC$	SC^3S	1.07×10^6	5.5	8.2	9

Let N_1 and N_2 be the carbon atoms of the alkyl groups of SAS and APC or ATB respectively. When the sum of the carbon atoms of N_1 and N_2 is less than twenty, as in the mixture of SC_5S and $C_{12}PC$, no reaction takes place between SAS and ATB in the solution. When the sum is twenty-two, the equilibrium constant is smaller than 6×10^5, whereas it is larger than 6×10^5 when the sum reaches twenty-four. At a value for the sum of more than twenty-six, the reaction is found to be heterogeneous, for precipitates appear.

It is obvious from Tables 1 and 2 that the interaction of SAS with APC or ATB is highly dependent on the length of the alkyl group, though the behavior of the hydrophobic group in the complex is not clear.

The enthalpy changes, $\Delta H°$, in the reaction of SAS with APC or ATB were obtained from the slopes of the straight lines of the $\log K$ *vs.* $1/T$ plot over the whole temperature range; they are shown in Tables 3 and 4. The $\Delta H°$ values, which are always negative, are comparable with those of the interactions between the acid dye (C. I. Acid Blue 120) and some nonionic surface-active agents,[10] and with those of the interactions between the oppositely-charged organic ions, such as ionic dyes and ionic surface-active agents.[7]

	$SC_{14}S$	8.28×10^5	3.5	8.1	15
$C_{12}TB$	$SC_{10}S$	5.78×10^4	4.6	6.5	6
	$SC_{12}S$	9.28×10^5	2.2	8.1	20
$C_{14}TB$	SC_8S	4.76×10^4	4.5	6.4	6
	$SC_{10}S$	1.17×10^6	4.6	8.3	12
$C_{16}TB$	SC_8S	8.89×10^5	4.9	8.1	11

The $\Delta S°$'s of the interaction between SAS and APC or ATB are found to be positive, as are shown in Tables 3 and 4. It can be presumed that the iceberg structure of water around the hydrophobic groups in the organic ions weakens when alkyl chains in both the ions are held together.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1948—1953 (1973)

The Photoconductivity of Poly(*N*-vinylcarbazole). I. The Photoconductivity in a Surface-type Cell*

Kenichi OKAMOTO,** Shigekazu KUSABAYASHI,** and Hiroshi MIKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received June 19, 1972)

The photoconductivity of poly-*N*-vinylcarbazole in a surface-type cell was measured both in a high vacuum and in the air. Fresh films showed a large photocurrent in the lower π-π^* absorption region and a small photocurrent in the visible region. The threshold of the photocurrent was found at about 600 mμ. By heat treatment or by pre-irradiation with UV-light or γ-ray, the photocurrent increased throughout the spectral region and its threshold shifted to a longer wavelength. Both the dark current and the photocurrent in the visible and the near IR regions must be due to the thermal or optical reexcitation of the trapped carriers. The activation energies of the dark current (0.4—1.3 eV) and the photocurrent (0.06—1.0 eV) differ according to the temperature range, the light wavelength, and the film history (whether fresh film or one of various pre-treated films). The activation energies are needed for carrier migration and can be explained by the "trapping conduction mechanism".

Recently many vinyl polymers with large pendant π-electron systems have been synthesized in expectation of their having good photoconductive properties. These polymer materials will be useful for electrophotography. The polymers synthesized and examined for photoconductivity measurements are poly-*N*-vinylcarba-

* The experimental results in this paper were presented at the 22th Symposium of the Society of Electrophotography of Japan, Kyoto, November, 1968.

zole (PVCz),[1-9] polyvinylanthracene,[10,11] polyvinylpyrene,[12] polypyrenylmethylvinylether,[13] polyvinylacridine,[14] and polyacenaphthylene.[15] PVCz is one of the most photoconductive polymers, and it is now being used as a material for electrophotography.

In the present series of papers on the electrical properties of PVCz, the authors have examined the photoconductivity of PVCz purified as far as possible, especially under a high vacuum, for the purpose of clarifying the origin of the photoconductivity of PVCz. These studies can be expected to give us some guiding principles for preparing new photoconductive polymers with high sensitivity.

This paper will deal with the photoconductivity of fresh films in a surface-type cell. The effect of air, heating, or pre-irradiation with UV light or γ-rays will also be investigated.

Experimental

Materials. *N*-Vinylcarbazole was recrystallized three times from methanol and three times from *n*-hexane; it was then polymerized by heating it together with azobisisobutyronitril in benzene at 70 °C for 2 hr. The polymer was purified three times by reprecipitation from benzene–methanol. The molecular weight was determined to be 110000 by means of a membrane osmometer.

Measurements. The following four kinds of films were used.

a) Fresh film. A 0.2 ml portion of a 5 wt% benzene solution of the polymer was placed on a quartz plate (20×25 mm^2), and the solvent was evaporated slowly in the dark under a nitrogen atmosphere. The thickness of the film was determined to be about 15 μ by studying the UV absorption. The film showed an absorption edge at 357 mμ.

b) Film irradiated with UV light. A fresh film was irradiated with UV light in the air for 15 hr, 50 cm distant from a 500 W xenon lamp without a condenser lens.

c) Film irradiated with γ-rays. A fresh film was irradiated with γ-rays (^{60}Co) in the air for 1—50 hr (dose amount; 5×10^4—2×10^6 R).

d) Hot-pressed film. The powder of the polymer was compressed to a disk under a pressure of 80 kg/cm^2 and then hot-pressed at 220—240 °C in the air to a transparent film. There was no difference in either the IR spectrum or the UV spectrum among these four kinds of films. The γ-irradiated film showed a broad ESR signal ($g=2.0$) which was very stable and which did not disappear even after the film has been heated at 100 °C for 2 hr in a high vacuum.

In order to prepare a surface-type cell, Au or Ag comb-type electrodes (50 mm in length and 0.18 mm in electrode distance) were evaporated on the film, and then lead wires were placed in these electrodes by means of silver paste. A high-vacuum evaporation apparatus was prepared to obtain a clean vacuum of the order of 10^{-8} mmHg, according to the method reported by Maruyama *et al.*[16] This enabled us to measure photo- and dark-currents larger than 5×10^{-16} A in a high vacuum at 10—200 °C. The DC conductivity was measured by means of a vibrating-reed electrometer (Takeda Riken TR 84M). A stabilized 500 W xenon lamp was used as the light source; it was monochromatized by means of a prism monochromator. The light intensity was measured by means of a thermopile (Kipp and Zonen CA 1) or an actinometer by the use of potassium ferric oxalate. The intensity was changed by the use of neutral filters. The following data were taken using cells left for more than a few hours in the dark with an applied DC voltage.

Results

Shape of the Photoresponse Curve. In the pattern of photoresponse, the time required to reach the steady-state was between a second and a few minutes for the fresh films in a high vacuum. For the samples exposed in the air and also for the pre-treated ones, the response time was a little longer than that of the fresh film.

The decay curve of the photocurrent after the light had been turned off did not obey either the first- or second-order decay, and it showed a long tail, especially in the case of pre-treated films.

Voltage-dependence. The dark current of the fresh film left in the dark for a long time was too small to be observed at room temperature in a high vacuum. Its surface specific resistivity (ρ_{20}) was larger than $10^{19}\Omega$. On the other hand, the dark current of the pre-treated film was large enough to be measured (for instance, $\rho_{20}=1\times10^{18}\Omega$ for a UV-light-irradiated film in a high vacuum) and obeyed Ohm's law.

The photocurrents of both films obeyed also Ohm's law regardless of the wavelength of the illuminating light and the ambient gas.

Light-intensity Dependence. Figure 1 shows the light-intensity dependence of the photocurrent. The α value in the equation $i_{ph}\propto L^{\alpha}$, where L is the light intensity, was 1.0 in a high vacuum and 0.6—0.8 in the air for the fresh film. On the other hand, for the pre-treated films the α values were 0.6—0.9 both in a high vacuum and in the air. The lowering of the α value may be due to the introduction of some shallow trap levels by air or by pre-treatment, as has been reported in the case of polyethylene film by Yahagi *et al.*[17]

360 mμ (or 500 mμ) light at 24 °C under 3000 V/cm.
(1) a fresh film in high vacuum, (2) a fresh film in the air, (3) a film irradiated with γ-ray in high vacuum, (4) a film irradiated with γ-ray in high vacuum (500 mμ illumination), and (5) hot-pressed film in the air.

Spectral Response. Figures 2 and 3 show the spectral responses of the photocurrent for various films, the current being normalized for the relative light

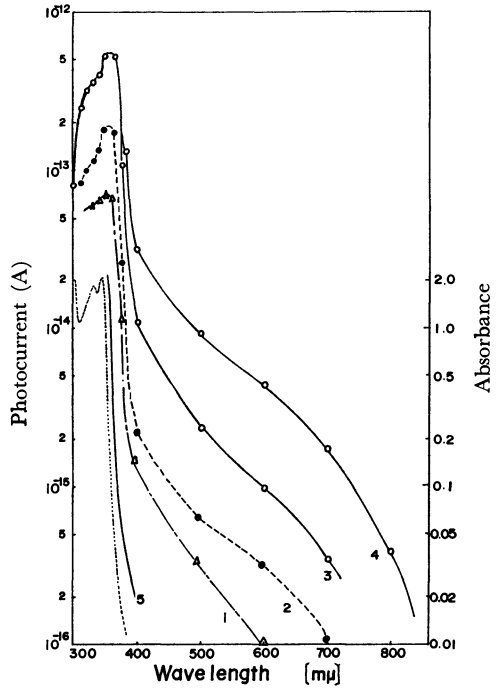

Fig. 2. Spectral dependence of the photocurrent of the fresh film in a surface-type cell for the light of 2×10^{13} photons/cm^2 s under 3000 V/cm at 23 °C.
(1) first run in high vacuum, (2) after heat treatment at 120 °C for 10 hr in high vacuum, (3) first run in the air, (4) after standing for a long time in the air, (5) absorption spectrum of the film 15 μ thick (The absorption spectrum of a film 3 μ thick is also given by a dotted line order to show the π–π^* absorption band).

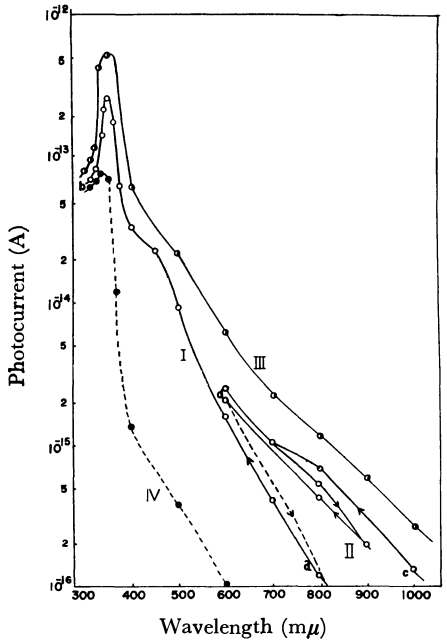

Fig. 3. Spectral dependence of the photocurrent in surface-type cells of the pre-treated films for the light of 2×10^{13} photons/cm^2 s. Effect of the repeated illumination of near-IR light was investigated. 3000 V/cm in high vacuum at 20 °C.
(I) The photocurrent of a UV-light irradiated film was measured from the wavelength (a) to (b). (II) Immediately after (b), the photocurrent was measured in the near-IR region from (c) to (d). This shows that the repeated illumination with near-IR light lowers the photocurrent progressively to the curve (I). (III) a film irradiated with γ-ray (2×10^6R). (IV) Fresh film, for comparison.

intensity according to the results shown in Fig. 1.

Fresh films have the photocurrent peak at 350—360 mμ and the threshold at 600 mμ. The wavelength for the minimum detectable photocurrent, 10^{-16} A, was taken as a threshold. After the film had been heated for a long time in a high vacuum (120 °C, 10 hr) or illuminated many times with UV light in a high vacuum, the photocurrent became larger in the UV as well as in the visible region and the threshold shifted to a longer wavelength region. The introduction of air had the same effect. As is shown by Curve (4) in Fig. 2, the photocurrent became larger in the air and the threshold shifted to 900 mμ. This effect of air was reversible so long as the cell was not exposed to UV illumination for a long time in the air.

In the case of the pre-treated films, the photocurrent was larger than that of the fresh film in all the wavelength regions, especially in the visible and near-IR regions, and showed the threshold at 1000 mμ even in a high vacuum, as is shown in Fig. 3. This large photocurrent in the visible and near-IR regions became still larger with pre-illumination by UV light and gradually became smaller with repeated illuminations by visible or near-IR light, as is shown in Fig. 3. Films with large photocurrents in the visible and near-IR regions showed quite large dark currents compared with that of the fresh film. Thus, there was a resemblance in the effect of the pre-treatments on the photocurrent in the visible or near-IR regions and on the dark

current.

Temperature-dependence and Activation Energies. Figures 4 and 5 show the temperature dependence of the photo and dark currents for the fresh film as well as for the pre-treated films. In these figures, the photocurrent in the first heating run increases steeply at first, reaches the saturation point, and finally even decreases in some cases. This initial increases must be due to some unknown heat effect, while the subsequent saturation or decrease (at higher temperatures, above 120 °C) must be due to the desorption of oxygen. It has been reported that, in molecular crystals, the complete elimination of the adsorbed oxygen molecules was possible only by sublimation in a high vacuum.[16] The temperature dependence of dark and photo currents observed after two or three heating cycles was inferred to be free from the above-mentioned heat effect and oxygen desorption effect. The values of activation energies (ΔE_d and ΔE_{ph}) shown in Table 1 were thus obtained.

Discussion

Effects of Air, Hot-press, and Irradiation with UV light or γ-Rays. It is well known that the ambient gas exerts significant effects on the electrical conduction

Table 1. Activation energies for dark and photo conductivities (ΔE_d and ΔE_{ph}) in a PVCz surface-type cell[a]

Sample	ΔE (eV)					
	ΔE_d		ΔE_{ph} (Visible light illumination)		ΔE_{ph} (UV light illumination)	
	low	high	low	high	low	high
Fresh film[c]	(b)	1.0—1.3 (120—200 °C)	0.06—0.20 (20—120 °C)	0.7—1.0 (~200 °C)	0.16—0.22 (20—120 °C)	0.16—0.22 (~200 °C)
Fresh film[d]	0.7—0.8 (50—120 °C)	—	0.3—0.6 (20—120 °C)	—	0.5—0.6 (20—120 °C)	—
Film irradiated with UV light[c]	0.47 (50—100 °C)	0.80 (80—200 °C)	0.20 (20—100 °C)	0.70 (~200 °C)	0.23 (20—130 °C)	0.68 (~200 °C)
Film irradiated with γ-rays[c]	0.4—0.5 (40—110 °C)	0.8—1.0 (~200 °C)	0.24 (20—130 °C)	0.40 (~200 °C)	0.23 (20—140 °C)	0.40 (~200 °C)

a) Activation energy (ΔE) is represented by the equation $i \propto \exp(-\Delta E/kT)$.
b) Only on the first heating, a fresh film showed a small dark current similar to the thermally stimulated current at this low temperature range. Thereafter, the current was too small to be measured.
c) In high vacuum under 3000 V/cm.
d) In air under 3000 V/cm.

in a surface-type cell.[18] The following effects of air on the electrical conduction were observed in a PVCz film: (a) an increase in the dark current with a lowering of ΔE_d; (b) an increase in the photocurrent in all the wavelength regions and a red shift of the threshold of the photocurrent; (c) a lowering of the α value of the light-intensity dependence of the photocurrent; (d) an increase in ΔE_{ph}, and (e) an increase in the rise time of the photocurrent and a long tail in the decay curve of the photocurrent.

The oxygen molecule acts as an electron acceptor because of its large electron affinity, and the resulting O_2^- molecule may act as a hole-trapping center.[19] These effects of air may be explained by supposing that, in the air, impurity levels acting as shallow hole-trapping centers are introduced into a PVCz film by oxygen molecules.

Such pre-treatments in the air as hot-press and irradiation by UV light or γ-rays had effects on the photocurrent similar to the effects of air. Any electron-accepting or hole-trapping levels may be introduced by these pre-treatments.

Origin of Both the Dark Current and the Photocurrent in the Visible and Near-IR Regions. The resemblance in the effects of the pre-treatments on the photocurrent in the visible and near-IR regions and on the dark current suggest that, in both cases, the carriers are generated from the same origins, which are increased by air, hot-press, or irradiation with UV light or γ-rays. In every film the value of ΔE_d was less than 1.3 eV. As this value is much smaller than the estimated band gap energy (~4.4 eV[20]), the intrinsic carrier generation must be ruled out. Other possible carrier generation process in the dark are (1) carrier injection from the electrode and (2) the ionization of acceptors or donors, which can release carriers by means of the thermal process.

The possibility of the carrier injection from the electrode can be ruled out on the basis of the following findings: (a) the dark current did not obey the Schottky equation, but Ohm's law[21]; (b) the electrode materials (Au, Ag, Cu, and Al) had no effect on the dark and photo currents,[21] and (c) the magnitude of the dark and photo currents was strongly influenced by UV pre-illumination or by repeated near-IR illuminations.

In a PVCz surface-type cell the dark current and the photocurrent may, therefore, be mainly due to the thermal or optical reexcitation of trapped carriers. In the pre-treated films, trapped carriers will increase with an increase in the number of trap centers introduced by the pre-treatments, thus resulting in an enhanced dark current and photocurrent in the visible and near-IR regions.

Activation Energy for Dark and Photo Conductions. As is evident from Table 1, the values of ΔE_d and ΔE_{ph} change considerably both with the temperature and with the wavelength of illuminated light. Except in the case of ΔE_{ph} for UV illumination in a fresh film, in every film the values of ΔE_d and ΔE_{ph} in the high temperature range are considerably larger than the values in low temperature range; the former values are also large as compared with those in the case of such aromatic hydrocarbons as anthracene. A similar phenomenon has been reported for polyethylene[23] and for the polymers prepared by glow-discharged polymerization.[24] In polyethylene Tanaka *et al.* have explained this phenomenon in terms of a "trapping conduction mechanism".[23] As has been mentioned above, both the dark current and the photocurrent in the visible and near-IR regions are due to the reexcitation of trapped carriers. The process of the reexcitation by light must not need a large activation energy. The large values of ΔE_{ph} in the high temperature range, therefore, suggest that these activation energies are needed mainly for carrier migration. A trapping conduction mechanism similar to the case of polyethylene is applicable to the photo- and dark-conductions in a PVCz surface-type cell as follows.

The exact profile of trap distribution is not yet available. However, if one considers a "hypothetical trap" which is defined as a discrete level corresponding to a special distribution of trapped carriers under conditions leading to a measured ΔE_d or ΔE_{ph}, then one can draw an energy diagram such as is shown in Fig. 6. In this diagram, a deep trap (E_{t4}) is also shown, though it has not been dicussed in this paper.

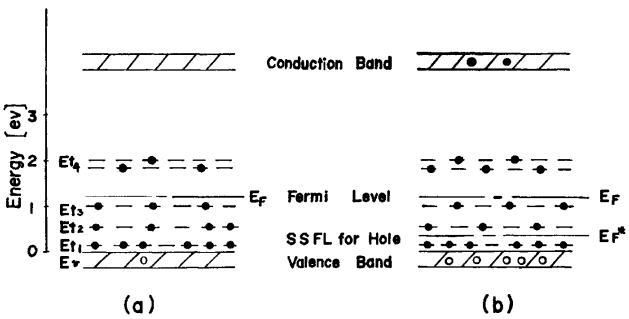

Fig. 6. Energy level model for a PVCz fresh film in high vacuum. As concerns the levels (E_{t1}~E_{t4}), see text.
(a) in the dark in low temperature range. (b) under UV or visible illumination in low temperature range.

Supposing that the Fermi level (E_F) exists between E_{t2} and E_{t3} or a little higher than E_{t3} below 120 °C, as the reexcitation of holes from the energy states much higher than E_F (E_{t3} or E_{t4} in the present case) is negligible, the energy states a little lower than E_F (E_{t2} or E_{t3} in the present case) will play an important role in

21) As will be reported in the succeeding paper of this series,[22] sandwichtype cells were examined over a wide range of field strengths up to 330000 V/cm with several kinds of electrode materials. The information thereby obtained also suggests the impossibility of electrode injection.

trapping hole carriers. The ΔE_d value in this temperature range, which could not be measured in the present study, may thus be estimated to be E_{t2} or E_{t3}, that is, 0.7—1.0 eV or 1.0—1.3 eV. With UV illumination, some holes and electrons are created by the extrinsic mechanism[25] and the distribution of holes in the dark (Fig. 6(a)) changes, thus resulting in Fig. 6(b). The increasing concentration of holes in the valence band leads to a lowering of the Fermi level to the steady-state Fermi level for hole (E_F*), and the trap level below E_F* acts as a shallow trap and the level above E_F* as a deep trap.[26] Now, supposing that E_F* exists between E_{t1} and E_{t2}, the trap levels associated with E_{t2} must be filled with holes and the levels associated with E_{t1} must act as effective trapping centers for migrating holes. Therefore, the ΔE_{ph} value under UV illumination is 0.1—0.2 eV ($=E_{t1}$) in the low-temperature range.

In the case of visible illumination in the low-temperature range, the photocurrent is much larger than the dark current. Therefore, the steady-state Fermi level must be lowered so far as below E_{t2} according to the increase in the current under visible illumination. The trap levels associated with E_{t1} act as effective trapping centers for migrating holes, and the ΔE_{ph} value under visible illumination is 0.1—0.2 eV in the low-temperature range. Above 120 °C the Fermi level probably rises to much above E_{t3}. In the dark the trap levels associated with E_{t3} act as effective trapping centers and the ΔE_t value is 1.0—1.3 eV.

Under UV illumination the steady-state Fermi level is probably lowered so far as below E_{t2} according to the number of holes created, in the same manner as in the case of the low-temperature range, and the ΔE_{ph} value is 0.1—0.2 eV even at high temperatures. In the case of visible or near-IR illumination, the photocurrent is not so large as the dark current in the high-temperature range and the steady-state Fermi level for hole is lowered to near E_{t3} or E_{t2} at most. The ΔE_{ph} value in this case becomes 0.7—1.0 or 1.0—1.3 eV.

A similar explanation is possible for the conductions in the pre-treated films.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1953—1959 (1973)

The Photoconductivity of Poly(*N*-vinylcarbazole). II. Dark Conductivity in a Sandwich-type Cell

Kenichi OKAMOTO,* Shigekazu KUSABAYASHI,* and Hiroshi MIKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received January 17, 1972)

The dark conductivity in a sandwich-type cell of PVCz films was investigated in a high vacuum, taking the temperature, the applied voltage, and the film thickness as parameters. In low fields, the conductivity was proportional to the applied voltage. In high fields, however, it was proportional to the fourth power of the applied voltage. This nonohmic dark conductivity in high fields may be attributed to the Pool-Frenkel effect. A model of the energy-level diagram is presented which can explain the dark conductivity in both low and high fields.

In the previous paper the authors have reported the photo and dark conductivities in a surface-type cell of poly-*N*-vinylcarbazole (PVCz) films.[1] Although PVCz has a large π-electron system as a pendant group, its dark conductivity is too small to be measured at moderate temperatures in a high vacuum. In the present paper, the dark conductivity was investigated in a sandwich-type cell. Interesting behavior was observed in the high-field conductivity, as will be mentioned below.

Experimental

PVCz was prepared as has been described in the previous paper.[1] A certain amount of a 5 wt% benzene solution of the polymer was poured onto a nesa-coated quartz plate, and the solvent was evaporated slowly in the dark. Films 8, 15, and 24 μ thick were thus prepared, to which three lead wires were attached by using silver paste, as is shown in Fig. 1 (a). The film with lead wires was set in the apparatus

(1) metal electrode lead wire, (2) nesa-electrode lead wire, (3) guard ring lead wire, (4) evaporated metal electrode, (5) evaporated guard ring electrode, (6) PVCz film, (7) nesa-electrode coated on quartz plate, (8) quartz plate (20×25×1 mm).

* Present address: Department of Chemical Engineering, Faculty of Engineering, Yamaguchi University, Ube, Yamaguchi 755.

1) K. Okamoto, S. Kusabayashi, and H. Mikawa, This Bulletin, **46**, 1948 (1973).

for the electrical measurement described in the previous paper and was kept in a high vacuum (10^{-7} mmHg) for several hours. Semitransparent main and guard electrodes were evaporated on the film to prepare the sandwich-type cell, as is shown in Fig. 1 (b, c). Several kinds of metals, such as Au, Ag, Cu, and Al, were used as the electrode material. The sandwich-type cell thus prepared was subjected to the electrical conductivity measurements after it had stood for a day in the dark in a high vacuum, without exposure to air after the evaporation of the metal electrodes. The measurements were carried out by means of a vibrating-reed electrometer (Takeda Riken TR 84M) in a high vacuum (10^{-7} mmHg).

Results

Time-dependence of the Dark Current. The dark current slowly decreased with the time after applying the voltage, as is shown in Fig. 2. The dark current requires from several hours to a day to reach a steady-state value. After the voltage was taken off, a fairly large back current was observed in the short circuit.

In low fields the dark current showed the time-dependence given by Eq. (1), where n was 0.4—0.7, and reached the steady-state value in scores of minutes or in a few hours at room temperature, as is shown in Fig. 3.

$$i_d \propto t^{-n} \qquad (1)$$

In high fields the dark current obeyed Eq. (1) for only a short period after the voltage was applied and the current continued to decrease slowly with the time even after ten hours. It reached the steady-state value after more than 20 hr at room temperature.

Voltage-dependence of the Dark Current. The voltage-dependence of the forward dark current (abbreviated as "dark current") is shown in Fig. 4(a), taking the time after the application of voltage as a parameter, and in Fig. 4(b), taking the temperature and the polarity of the electrode as parameters. The voltage-dependence of the dark current showed a dramatic change at a certain voltage (transition voltage, V_t); that is, the dark current was proportional to the applied voltage below the transition voltage and to the fourth power of the applied voltage above that. This voltage-dependence

was observed for the dark current (charging absorption current) within several minutes after the application of the voltage as well as for the steady-state dark current. The transition voltage changed with the temperature, the polarity of the electrode, and the thickness of the film. In the asymmetric Au–PVCz–Nesa sandwich-type cell of the film 15 μ thick, the transition voltage was about 35 V at room temperature or 60 V at 106 °C when the nesa-electrode was biased positively, while the transition voltage was about 90 V when the nesa-electrode was biased negatively at 20 °C. On the other hand, it was 60—80 V at 20 °C in the symmetric Au–PVCz–Au sandwich-type cell. Sandwich-type cells with other electrode materials (Ag, Cu, and Al) acted the same.

At a constant applied voltage, the dark current was inversely proportional to the thickness of the film below the transition voltage and apparently so to the fourth power of the thickness above the transition voltage, as is shown in Fig. 5(a). The transition voltage was proportional to the thickness of the film, as is shown in Fig. 5(b).

Temperature-dependence of the Dark Current. Figure 6(a) shows the temperature-dependence of the ohmic dark current below the transition voltage. Though the measurement was carried out after the cell had stood with an applied voltage of 7000 V/cm for a day in the dark, on the first heating the dark current behaved in a manner similar to that of the thermally stimulated current. After the subsequent cooling and heating cycles, the dark current showed a reproducible temperature-dependence. The activation energy[2] was

2) The activation energy (ΔE) is represented by the equation: $i_d \propto \exp(-\Delta E/kT)$.

1.1—1.3 eV, which was identical with that measured in the surface cell in the high-temperature range (100—200 °C) in a high vacuum. After the thermodynamic equilibrium had been built up, the dark conductivity was very small; the specific conductivity was only $1\times10^{-18}\ \Omega^{-1}\,cm^{-1}$ at 90 °C.

Figure 6(b) shows the temperature-dependence of the nonohmic dark current above the transition voltage. In the applied field (200000 V/cm), the activation energy of this dark current was 0.6—0.8 eV, which was considerably smaller than that of the ohmic dark current.

Discharging Absorption Current. When the applied voltage was taken off, the back dark current was observed in the short circuit. This back dark current is referred to the discharging absorption current. For many cells this current followed Eq. (1), as is shown in Fig. 7(a), and the n value was 1.0—1.4 regardless of the field strength. The discharging absorption current, was proportional to the pre-applied voltage in any voltage region, as is shown in Fig. 7(b). It should be noted that the discharging absorption current showed a linear dependence on the pre-applied voltage even in the high-voltage region, where the dark current showed the nonohmic dependence.

The temperature-dependence of the discharging absorption current was small in comparison with that of the dark current; that is, the discharging absorption

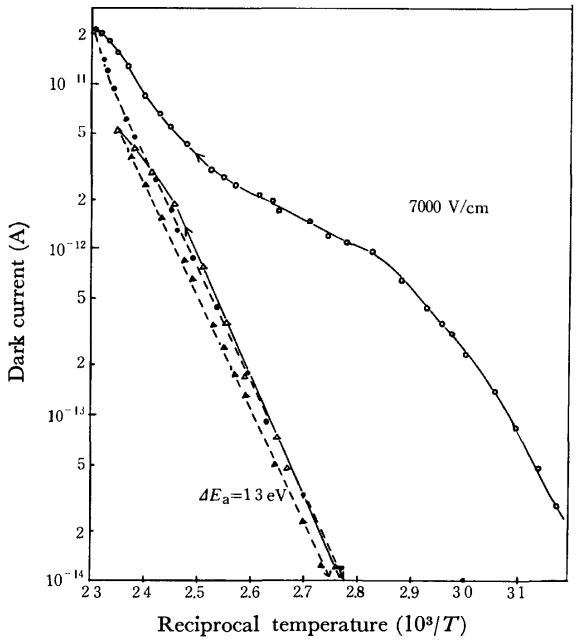

Fig. 6(a). Temperature dependence of the ohmic dark current at low field in the PVCz sandwich-type cell.

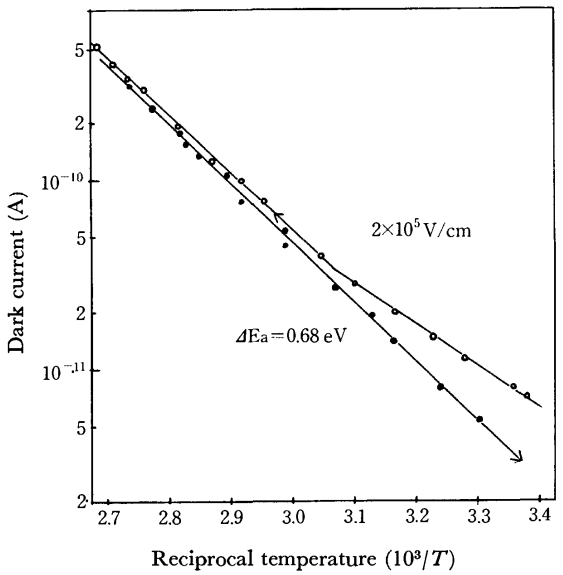

Fig. 6(b). Temperature dependence of the nonohmic dark current at high field in the PVCz sandwich-type cell.

current was approximately doubled in magnitude with a rise in the temperature from 20 to 100 °C.

The amount of the electric charge carried by the charging absorption current, which is indicated by the symbol Q_C in Fig. 2, did not depend on the structure of the electrodes, but that carried by the discharging absorption current (Q_{DC} in Fig. 2) was affected by the structure of the electrodes. In the asymmetric Au–PVCz–Nesa sandwich-type cell, the Q_{DC} value was about three times that in the symmetric Au–PVCz–Au sandwich-type cell. Furthermore, the Q_{DC} value was much smaller than the Q_C value; that is, the Q_{DC}/Q_C ratio was 1 : 2 in the asymmetric sandwich-type cell and 1 : 6 in the symmetric one in the ohmic voltage region.

Discussion

Absorption Current. It is well known that, for many insulating polymers, both charging and discharging absorption currents obey Eq. (1), where the n value is equal to 0.7—1.1.[3-5] In the case of the polymers such as polymethylmethacrylate, the two absorption currents equal one another in magnitude (superposition principle) and are attributable to the slow orientation of the permanent electric dipoles or ionic charges by the applied voltage.[3] On the other hand, for the polymers such as polyethylene the superposition principle fails to hold and the Q_C value is usually several times larger than the Q_{DC}. Another mechanism besides the orientation of the permanent electric dipoles (for example, the accumulation or dissipation of space charge) must, therefore, be used

5) G. Lengyel, *J. Appl. Phys.*, **37**, 807 (1966).

for both absorption currents of these polymers.[3,6]

In the case of PVCz, the discharging absorption current had an n value, 1.1—1.4, similar to those of polyethylene and others, but the charging absorption current showed a very small n value, 0.1—0.7, especially in the high-voltage region. The Q_C value was two or six times larger than the Q_{DC} value, and the superposition principle failed to hold. Both absorption currents in a PVCz sandwich-type cell, therefore, should not be attributed to the orientation of the permanent dipoles by the applied voltage, but to another mechanism in the same manner as in the case of polyethylene. The accumulation of space charges could be the reason for the charging absorption current in the low-voltage ohmic region, but not for that in the high-voltage nonohmic region, because the back electromotive force which would be caused by that is too large compared with the applied voltage.

Lindmayer has applied Eq. (2) to the discharging absorption current in the Au–SiO_2–Si system; he attributed this relation to the asymmetric field caused by the space charges trapped inhomogeneously in the bulk by the trap levels distributed energetically:[7]

$$I_{ext}(=i_{DAC}) = f \cdot g \cdot C \cdot V_a/t \qquad (2)$$

where I_{ext}, is the discharging absorption current; C, the capacity of the sandwich-type cell; f, the charge in the insulator divided by $C \cdot V_a$; V_a, the applied voltage; g, the charge appearing in the discharging current (Q_{DC}) divided by $C \cdot V_a$ and t, the time after the electrodes were short-circuited. Now, Eq. (2) was used for the PVCz sandwich-type cell the following $f \cdot g$ values were obtained; $f \cdot g = 0.8—1.0 \times 10^{-3}$ (20 °C) or $1.2—1.6 \times 10^{-3}$ (106 °C). These values are in agreement with the requirement that $f \cdot g < 0.06$.[7]

The Q_{DC} value in the asymmetric Au–PVCz–Nesa sandwich-type cell was larger than that in the symmetric Au–PVCz–Au one. The asymmetric structure of the electrodes, therefore, seems to contribute to the formation of the asymmetric field to a fairly large extent.

Ohmic Dark Current under a Low Field Strength. The ohmic dark current under a low field strength in a sandwich-type cell showed a behavior similar to that in a surface-type cell described in the previous paper.[1] The dark current increased upon UV-light pre-illumination and decreased upon repeated IR-light illumination. The activation energy of the ohmic dark current was quite small, while the dark current was fairly large, because of the effect of the previous history. After the thermodynamic equilibrium was achieved, it was, however, the same value, 1.0—1.3 eV, as that observed in a surface-type cell in a high vacuum in the high-temperature range.[1] These facts suggest that the ohmic dark current in a sandwich-type cell may be due to the thermal reexcitation of the trapped carriers, just as in the case of a surface-type cell.

On the other hand, the considerable effect of air on the dark conductivity observed in a surface-type cell was not observed for a sandwich-type cell; that is, there were no significant differences in the magnitude of the dark current and the dark activation energy between that in the air and in a high vacuum. This suggests that the trap level which gave an activation energy of 0.7—1.0 eV in a surface-type cell (trap level E_{t2} shown in Fig. 6 in the previous paper[1]) is negligibly small in a sandwich-type cell. This trap level was introduced by air or the irradiation of UV-light or γ-ray, and may, therefore, be attributed to some surface impurity. In a sandwich-type cell, the layer containing both some surface impurity and adsorbed oxygen molecules will be covered by the evaporated electrode layer.

Nonohmic Dark Current under a High Field Strength. The nonohmic dark current under a high field strength was different from the ohmic dark current under a low field strength in the following three characteristics; (1) $i_d \propto V^4$, (2) a small activation energy, and (3) the dark current decreased very slowly with time. The dark current with a superlinear dependence on the applied voltage has often been attributed to the space-charge limited current (SCLC), the Schottky conductivity, or the Poole-Frenkel conductivity.[8]

When there are trap levels with an energetic distribution such as an exponential one, the SCLC is proportional to the n-th power ($n>1$) of the applied voltage and the transition voltage from the ohmic current to the SCLC is proportional to the second power of the film thickness.[9,10] This kind of SCLC has been reported for anthracene,[10] stilbene,[11] and polyethyleneterephthalate.[12] In a sandwich-type cell of PVCz film, the nonohmic dark current was proportional to the fourth power of the applied voltage and inversely proportional to the same power of the film thickness. The nonohmic dark current, therefore, showed the same value for films with different thicknesses under the same field strength; that is, there was no effect of the film thickness. Furthermore, the transition voltage was

proportional to the film thickness. The carrier injection from the electrodes is difficult, as will be discussed below. The nonohmic dark current can not, therefore, be explained by the SCLC for these three reasons.

Figure 8 shows the energy diagram for the Au–PVCz–Nesa sandwich-type cell. The work function of gold is 4.83 eV.[13] The ionization potential and the electron affinity of nesa coating are 7.2 and 3.6 eV respectively.[14] The ionization potential of PVCz has been reported to be 6.1 eV from the measurement of the photoinjected hole current from the gold electrode,[15] and its electron affinity has been estimated to be only the polarization energy, the estimated value being 1.5 eV.[16] From Fig. 8 the hole injection from a gold electrode to PVCz is most conceivable, and the electron injection from a gold or nesa electrode to PVCz is not conceivable. As the nesa coating is a *n*-type semiconductor, the possibility of a hole injection from a nesa electrode to PVCz can be neglected. When a nesa-electrode was biased positively, the transition voltage was usually smaller and the nonohmic dark current was usually larger, as is shown in Fig. 4(b). For the nonohmic dark current to be attributed to the Schottky emission, an electron injection from a gold electrode to PVCz must be supposed. This injection, however, is difficult, as has been discussed above. The other electrode materials (Ag, Al, and Cu) which have a lower work function than that of Au, did not affect either the magnitude of the dark current or the transition voltage. From these facts, it can be said that the nonohmic dark current can not be explained by the Schottky emission from the electrode.

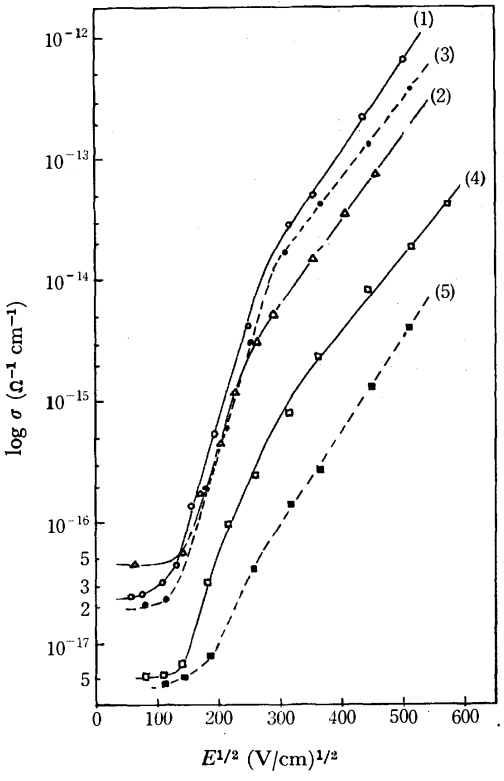

Fig. 9. Poole-Frenkel plot of dark conductivity *vs.* applied field for the PVCz sandwich-type cell.
(1) 8μ thick, 27 °C, 15 min. after application of voltage.
(2) 15 μ thick, 27 °C, 15 min. after application of voltage.
(3) 24 μ thick, 27 °C, 15 min. after application of voltage.
(4) 15 μ thick, 20 °C, 20 min. after application of voltage.
(5) 15 μ thick, 20 °C, steady state value.

Now the application of the Poole-Frenkel effect was attempted in the case of the nonohmic dark current. This effect is not concerned with the electrode limited conductivity, but with the bulk conductivity. The Poole-Frenkel effect gives the conductivity a field dependence of this form:[17]

$$\sigma_{PF} = \sigma_0 \exp(\beta_{PF} E^{1/2}/kT) \quad (3)$$

$$\beta_{PF} = (q^3/\pi K \varepsilon_0)^{1/2} \quad (4)$$

where σ_0 is the low-field conductivity of the system, q is the unit of electric charge, ε_0 is the permitivity of free space, K is the high-frequency dielectric constant of the film, and E is the electric field strength in the film. When the voltage-dependence of the dark current given in Figs. 4 and 5 is replotted, with log σ as ordinate and $E^{1/2}$ as abscissa, a straight line is obtained in the high field strength region, as is shown in Fig. 9. The Poole-Frenkel constant, β_{FP}, was obtained from the slope of the straight line in Fig. 9; it is shown in Table 1. On the other hand, this constant is calculated to be 4.1×10^{-5} eV m$^{1/2}$ V$^{-1/2}$ from Eq. (4) by assuming K as 3.0.[18] As is shown in Table 1, the agreement between the calculated and the experimentally found values of the β_{PF} constant are very good. The nonohmic dark current under the high-field strength in the sandwich-type cell of the PVCz film thus satisfies well Eqs. (3) and (4) and may, therefore, be attributed to the Poole-Frenkel conductivity. A similar behavior has been reported for the high-field conductivity of the polymers, such as polyethylene[19] and polyacrylonitrile,[20] and has been attributed to the Poole-Frenkel effect.

In order to exhibit the Poole-Frenkel conductivity under a high-field strength, a trap is required to be

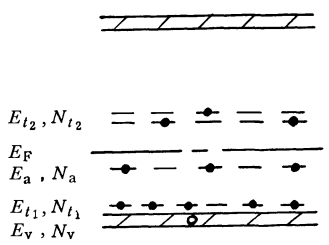

Fig. 10. Energy level diagram explaining the dark conductivity in PVCz sandwich-type cell.
The symbols E_v (=0), E_{t_1} (=0.1—0.3 eV), E_{t_2} (=2 eV), E_a (=1.0—1.3 eV) and E_F express the potential energy of each level measured above the valence band edge. The values in parentheses were obtained from the activation energy for the dark current. The symbols N_v, N_{t_1}, N_{t_2}, and N_a express the density of each level.

positively (or negatively) charged; that is, it must be charged when empty and uncharged when filled (donor or aceeptor), and these traps must be the main source of the dark conductivity under a low-field strength. A model must, therefore, be presented which can explain both the low-field and high-field conductivities. The energy level, 0.7—1.0 eV, above the valence band was negligibly small in the sandwich-type cell, as has been mentioned above, and so it has been excluded from Fig. 10. An acceptor level was considered as the trap level causing the Poole-Frenkel effect, because holes are the majority carriers in PVCz.

We located the position of the Fermi level by equating e number of holes missing from the acceptor centers with the number of the deep traps occupied by holes, the number of holes in the valence band being negligibly small. The thermodynamic Fermi level, E_F, as measured above from the valence band edge, is therefore, given by Eq. (5).

$$E_F = E_a - kT\log\{(N_a - N_{t2})/N_a\} \quad (5)$$

At a zero (or low) field, the number of free holes, p, is given by:

$$P = \{N_v(N_a - N_{t2})/N_a\}\exp(-E_a/kT) \quad (6)$$

The low-field conductivity σ_0 is, therefore, given by:

$$\sigma_0 = Pq\mu_h = \{q\mu N_v(N_a - N_{t2})/N_a\}\exp(-E_a/kT) \quad (7)$$

where μ_h is the hole carrier mobility. In the high field, the acceptor barrier is lowered by the Poole-Frankel effect, so that the number of free holes in the valence band increases to:

$$P = \{N_v(N_a - N_{t2})/N_a\}\exp\{-(E_a - \beta_{PF}E^{1/2})/kT\} \quad (8)$$

and the dark conductivity is given by Eq. (3). The magnitude of the lowering of the activation energy for the dark conductivity was 0.3—0.5 eV at the field strength of 2×10^5 V/cm, which is in approximate agreement with the calculated value, 0.2 eV. Thus, the energy-level model given in Fig. 10 can give a reasonable explanation of the dark conductivity in the sandwich-type cell of the PVCz film in both low- and high-fields.

The authors wish to thank the Fuji Photo Film Co. for its finacial support of this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1959—1963 (1973)

Lone Pair Ionization Potentials of Carboxylic Acids Determined by He(I) Photoelectron Spectroscopy

Iwao WATANABE, Yu YOKOYAMA, and Shigero IKEDA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received October 2, 1972)

Photoelectron spectra of some simple carboxylic acids and halogen substituted acetic acids were observed. Each spectrum contains a band which is associated with the ionization from an oxygen lone pair (n_O) orbital of carboxyl group. The band associated with the n_O orbital is clearly separated from other bands, and its shape and width are quite similar among the various carboxylic acids. In the spectra of halogen substituted acetic acids, n_O band appears around the region of the lone pair bands of halogen atoms. The ionization potentials for oxygen lone pair orbital of carboxylic acids are measured and compared with the results of some semi-empirical SCF MO calculations. The agreements are quite satisfactory when ionization potentials are obtained from the difference of total energies of neutral molecule and its corresponding cation calculated using CNDO/2 or INDO method. MINDO/2 method also gives excellent values when Koopmans' theorem is applied.

When a certain functional group of a molecule is expected to play a special role in a chemical reaction, it is desired to know the intrinsic properties of the group. There are many physicochemical techniques being used for that purpose, *e.g.* IR, Raman, UV, NMR, *etc.* If a functional group has electron orbitals which are considered to be essentially localized on the group, the orbital energies should be a measure of the intrinsic properties of the group, too. The orbital energies have usually been determined experimentally as ionization potentials of molecules from vacuum ultraviolet absorption spectrum, electron impact, or

photoionization method. Photoelectron spectroscopy, developed by Turner *et al.*,[1] has recently been recognized to have great potentialities as a tool which measures ionization potentials of various free molecules. It enables us to observe all orbitals of molecules which have less binding energy than the energy of irradiating light, frequently helium resonance line 584 Å (21.22 eV). The shape and/or structure of each band in the high resolution photoelectron spectrum are useful for the assignment of the bands.

Carboxyl group is known to have an oxygen lone pair (n_o) orbital and π orbitals. Theoretical calculations predict that the n_o orbital is composed mainly (50—80 per cent) of carbonyl oxygen atomic orbitals in various carboxylic acids.

It was our interest to study the extent of disappearance of the feature of these particular bands in the photoelectron spectra and the orbital energy variation as carboxylic acid molecule becomes larger. This paper deals with the results of some simple mono carboxylic acids and halogen substituted acetic acids. They are compared with the results of semi-empirical molecular orbital calculations such as CNDO/2,[2] INDO,[2] and MINDO/2[3] method to know how well these calculations can predict the ionization potentials of various carboxylic acids.

Experimental

The details of the photoelectron spectrometer used have already been reported.[4] The exciting light was He(I) resonance line which was produced by DC discharge through a glass capillary with a hollow cathode. The electron energy analyser was of an electrostatic type with parallel plates coated with benzene soot. With this spectrometer the peak width of Xe $^2P_{3/2}$ was 27.5 meV. Although the most of the sample gases were measured at this resolution, we had to decrease the resolution to about 50 meV for measuring monoiodo acetic acid, since its vapor pressure was small.

All samples were of G.R. grade and used without any further purification. Variations of appearance potentials of photoelectron peaks for carboxylic acids during measurements were so large that preliminary mixing of reference gas, xenon, into the sample gas was essentially needed to measure the ionization potentials accurately. Usually the spectra were measured after more than 30 min running of sample gas, since shift of the kinetic energy of photoelectron to lower energy side with the elapse of time was always noticed.

Results and Discussion

In Fig. 1, the photoelectron spectrum of formic acid is shown. At least five bands are distinguishable and three of them have clear vibrational structures. The spectrum appears quite similar to the spectrum

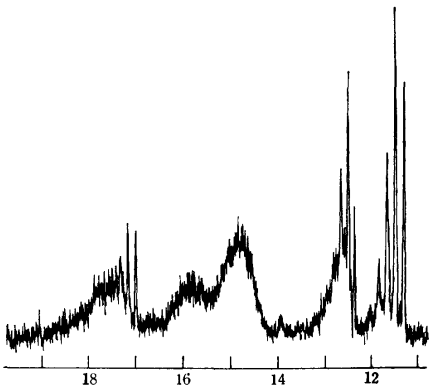

Fig. 1. Photoelectron spectrum of formic acid.

reported by Turner and co-workers.[1,5] However the structures of the second band are somewhat different from their results. Measurements for DCOOD, DCOOH, and HCOOD have also been performed and their vibrational structures have been studied. The details of the results will be reported elsewhere.[6]

In Figs. 2—5, the spectra of a series of aliphatic carboxylic acids are shown. The larger the alkyl group, the less clear the vibrational structures, and the closer the bands overlap. However it is observed that the first band is always separated from the second, that its shape and width are much the same, and that there always appears a band at a potential of 16—18 eV.

The spectra of trifluoro-, monochloro-, monobromo-,

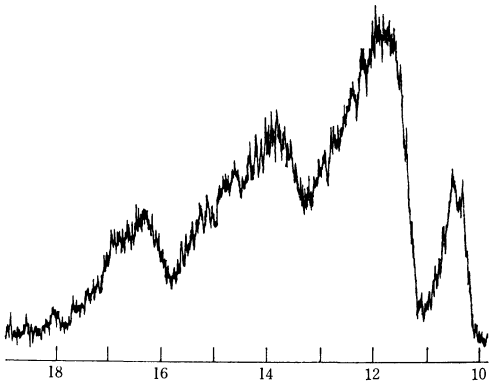

Fig. 4. Photoelectron spectrum of *n*-butyric acid.

and monoiodo-acetic acids are shown in Figs. 6, 7, 8, and 9, respectively. Although the intensity of the peaks of trifluoroacetic acid is relatively weak and the spectrum has a lot of noise, six bands are clearly separated. In this spectrum no vibrational structure is distinguishable. The first and the second bands are a little broader than those of acetic acid and, however, the band shapes and the separation of these bands are almost identical. The molecular orbital calculations indicate these bands are associated with the ionizations from n_0 and antisymmetric π (π_2) orbital of carboxyl group.

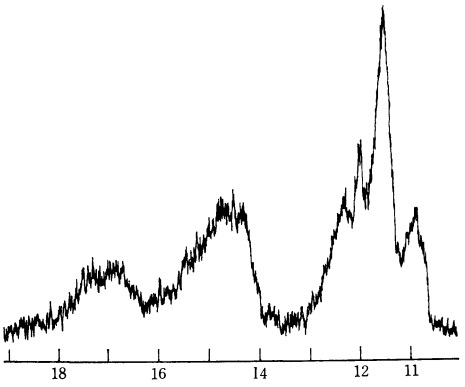

Fig. 7. Photoelectron spectrum of monochloroacetic acid.

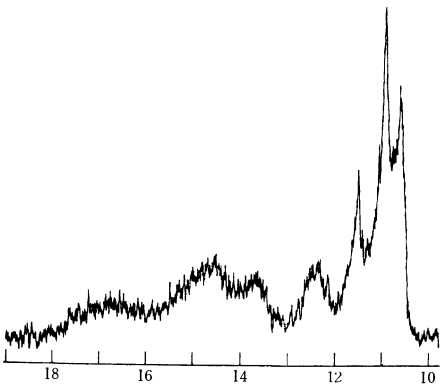

Fig. 8. Photoelectron spectrum of monobromoacetic acid.

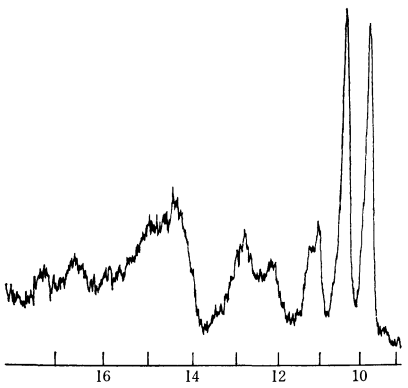

Fig. 9. Photoelectron spectrum of monoiodoacetic acid.

The spectra of the other three halogen substituted acetic acids are more complex, since around the bands from the orbitals localized mainly on the carboxyl group appear halogen lone pair bands which split into two components by the effect of the spin-orbit interaction. The spin-orbit splittings for many molecules containing halogen atoms have been reported to be about 80 meV for chlorine, 0.3 eV for bromine, and 0.6 eV for iodine.[1,7] With the aid of these values the

spectra are interpreted.

The first band in the spectrum of monochloro acetic acid is originated from n_O orbital of carboxyl oxygen and the next sharp peak from chlorine lone pair orbital. The spin-orbit splitting for chlorine atom is not observed because of the broadness of the peak. The order of halogen lone pair orbital and n_O orbital of carboxyl group is reversed in the case of monoiodoacetic acid. In the spectrum of monobromoacetic acid, the first two bands are originated from bromine lone pair orbital and the n_O band is considered to coincide with the second peak of the bromine lone pair bands.

Comparison of the Results Obtained by Photoelectron Spectroscopy and Photoionization Method. In Table 1, ionization potentials for various mono carboxylic acids determined by the photoelectron spectroscopy and photoionization method[8] are listed. The photoionization method always gives smaller adiabatic ionization potentials by 0.28—0.31 eV than the photoelectron spectroscopy does. The differences are quite the same. The first band of all of these molecules originates from oxygen lone pair orbital and photoelectron spectra show that the bands so much resemble each other in both shape and band width, and that the first band is clearly separated from the second. Since the photoionization method is particularly sensitive to the structure around the onset potential for the highest occupied orbital, these special conditions should be the main reason for the differences of the ionization potentials obtained by the photoionization method from our results to be constant.

Ionization Potentials Predicted from MO Calculations. In many cases, ionization potentials have been estimated by applying Koopmans' theorem to the results of molecular orbital energy calculation. When semi-empirical SCF MO calculations, such as CNDO or INDO, are performed, it is well known that each eigen value after multiplication by about 0.8[9] or subtraction of about 4 eV[10] approximately agrees with ionization potential experimentally measured. It is also known that the correlation between the eigen values calculated by MINDO/2 method and ionization potentials is quite satisfactory.[3]

We have performed CNDO/2, INDO, and MINDO/2 calculations. Ionization potentials have been estimated by the use of Koopmans' theorem. In addition, ionization potentials have been obtained from the difference between the total energy of the neutral molecule, E^0, and that of the corresponding cation radical in the same geometry, E^+, calculated by the unrestricted CNDO/2 and INDO method. The values obtained are listed in Table 1 and should be compared with the vertical ionization potentials observed.

The orbital energies by CNDO/2 and INDO method are steadily larger than the observed ionization potentials, and the agreement of the differences, E^+-E^0, with the observed ionization potentials is excellent. On the occasion of application of Koopmans' theorem to calculation by CNDO/2 and INDO methods, the discrepancy of energy in calculated and observed values is derived from errors due to arbitrariness of parameters used in calculation by CNDO/2 and INDO methods as well as both neglect of reorganization energy and assumption of constancy of relativistic and correlation energies.[11] On the other hand, the errors could successfully be cancelled in the difference, E^+-E^0.

Ionization potentials taken as the difference, E^+-E^0,

using CNDO/2 method are larger than the observed ones. The same procedure using INDO method gives smaller values. MINDO/2 method is superior in predicting ionization potentials to the above methods from the view point of simplicity of calculation. Our computer program for INDO method was available only for trifluoroacetic acid and CNDO/2 program for trifluoro- and monochloroacetic acid among the halogenated acids. The difference method using INDO predicts excellent value for trifluoroacetic acid.

All calculations we have performed predicted that the level of n_O orbital is higher than that of π_2 orbital in all carboxylic acids, and that the n_O orbital is the highest occupied orbital in the aliphatic carboxylic acids.

Difference of n_O-π_2 Levels. In RCOX where X is OH, OR′, or NR′$_2$, it has been reported that the separation between n_O and π_2 orbital varies with R and X groups and that the π_2 orbital is particularly sensitive to changes in the X group and the n_O orbital is sensitive to changes in the R group, since the π_2 orbital has a large population on the X group and the n_O orbital has a greater population on the carbonyl carbon than the π_2 does.[12]

In the present work, as the alkyl group of the carboxylic acid becomes larger, the separation between the first and the second band increases. The gap between the first and the second band in the *iso*-tutyric acid is wider by 0.2 eV than that in the *n*-butyric acid. The electron releasing effect of the alkyl group and the atomic orbital population analysis seem to explain these results. However, such an explanation is not always applicable, since the substitution of all hydrogen atoms in the methyl group in acetic acid with fluorine atoms which have a strong electron withdrawing effect considerably shifts the n_O and π_2 bands to greater energy side but the gap in trifluoroacetic acid is almost the same as in acetic acid.

The molecular orbital calculations have been carried out on a NEAC 2200/N700 computer at Osaka University Computer Center.

Notes Added in Proof

After the completion of this paper came to hand two very important papers dealing with the photoelectron spectra of carboxylic acids.[13,14] Ionization potentials reported in these papers are added in a margin of Table 1. The spectra of dimers and complexes of carboxylic acids have been reported by Thomas.[14] From his calculated dimer-monomer ratios and spectra of dimers, we believe that contribution of dimers in the present work is negligible.

From our expanded spectrum of n_O band of acetic acid, from which we have determined the ionization potentials, it appears that the band has at least three vibrational components and is more complex than the one reported by Sweigart and Turner.[13] This might cause the ionization potentials of acetic acid in the present work to be a little smaller than the values reported by them.

It was recognized that the spectrum of the second band (π_2) of formic acid reported by Turner and co-workers[1] may contain a peak (12.61 eV) from impurity water.[15]

Effect of Additives on Thermal Decomposition of Basic Magnesium Carbonate[1]

Kayoko AMITA and Genzo HASHIZUME

Industrial Research Institute of Hyogo Pref., Yukihira-cho, Suma-ku, Kobe 654

(Received January 31, 1972)

The effect of eleven halides on the thermal decomposition of basic magnesium carbonate ($4MgCO_3 \cdot Mg(OH)_2 \cdot 4H_2O$) has been studied by means of thermogravimetry (TG), differential thermal analysis (DTA) and gas chromatography. The size of crystallite of magnesium oxide prepared by heating the carbonate containing halide was determined by X-ray diffractometry, the oxides being studied by transmission electron microscopy. The thermal decomposition of basic magnesium carbonate was influenced by the addition of beryllium chloride tetrahydrate, magnesium chloride hexahydrate, calcium chloride hexahydrate and magnesium bromide hexahydrate. The DTA curve was changed with the amount of additive, *i.e.*, three endothermic peaks (at about 300, 430, and 530 °C) and an exothermic peak (at 490 °C) turned to only two endo-thermic peaks in the case where the molar ratio of an additive to the carbonate exceeded 0.005, the peak at higher temperature becoming sharp with shift toward lower temperature. The results of TG of basic magnesium carbonate corresponded to those of DTA. Gas chromatographic data showed that the composition of evolved gas varied with temperature. The activation energies of decarbonation and dehydration were obtained by gas chromatography by use of Freeman-Carroll's technique. Increase in the amount of additive caused a decrease in the activation energy of decarbonation, but not in that of dehydration except for magnesium bromide hexahydrate. The size of crystallite of magnesium oxide prepared by calcination at 600 °C for 2 hr, increased with the increase in the amount of additive.

The effect of impurities or additives on the thermal properties of compounds and the characteristics of materials produced by thermal decomposition have been extensively investigated.[2-4]

Basic magnesium carbonate shows the DTA curve as seen in Fig. 1c, which is similar to that given by Mackenzie.[5] We also reported that the DTA curve was influenced by the addition of magnesium chloride hexahydrate and environmental atmosphere.[6] Sawa reported that the addition of lithium fluoride also affected the shape of the curve.[7]

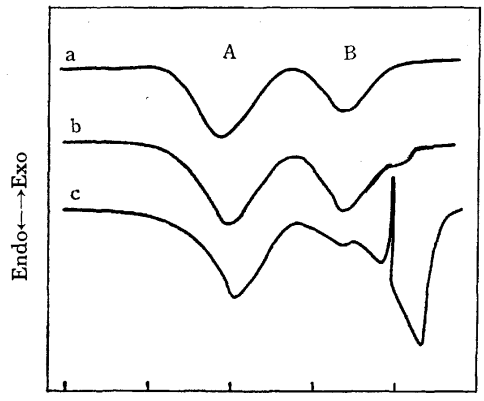

Fig. 1. DTA curves of basic magnesium carbonate Heating rate of a, b, and c was 1, 3, and 20 °C/min respectively. Sample weight was about 18 mg.

In this paper, the effect of halides (mainly chlorides) which affect the decomposition of magnesium hydroxide prepared from sea salt,[8] on the decomposition of basic magnesium carbonate was investigated by the measurement of DTA and TG curves, the calculation of apparent activation energy (referred to hereafter as "activation energy") of decarbonation and dehydration, and the determination of the size of crystallite of magnesium oxide prepared from basic magnesium carbonate.

Experimental

Materials. Basic magnesium carbonate (Earth Seiyaku Co., Ltd.) and additives of reagent grade were used. X-Ray diffractometry showed the structure of basic magnesium carbonate to be $4MgCO_3 \cdot Mg(OH)_2 \cdot 4H_2O$ although the composition is known to be either $5MgO \cdot 4CO_2 \cdot 5H_2O$ or $4MgO \cdot 3CO_2 \cdot 5H_2O$ according to the mode of preparation.

The following additives were used. Alkali metal chlorides (lithium chloride, sodium chloride, potassium chloride, and rubidium chloride) alkaline earth metal chlorides (beryllium chloride tetrahydrate, magensium chloride hexahydrate, strontium chloride hexahydrate, and barium chloride dihydrate), and magnesium halides (magnesium fluoride, magnesium bromide hexahydrate, and magnesium iodide).

Procedure. A given volume of methanolic solution of additive or a given weight of solid additive was mixed with a given weight of basic magnesium carbonate in an automatic mortar for a short time.

Simultaneous DTA–TG was performed with a Rigaku Denki Thermoflex 8002. DTA–TG runs were made at a

heating rate of 3 °C/min under dry nitrogen flow of 100 ml/min, except for that of 20 °C/min in the measurement of a sample containing 1 mol% of an additive. The weight of sample was about 18 mg.

Gas evolved during the course of decomposition was measured with a gas chromatograph (Hitachi Ltd., Model 063) connected with DTA–TG apparatus equipped with an automatic gas sampler. A katharometer was used as a detector. The glass column was packed with Porapak-Q 80/100 (Water Associate Inc.). The column temperature was 110 °C. The time interval to collect a gas sample was 15 s.

The size of crystallite was determined by a Rigaku Denki Geigerflex X-ray diffractometer. Ni-filtered CuKα-radiation was used. The size of magnesium oxide samples was calculated from half width of diffraction peak by Sherrer's equation, taking that of magnesium oxide prepared by the combustion of magnesium metal as a standard.

Particle forms were observed with a transmission electron microscope (Japan Electron Optics Laboratory Co., Ltd., model JEM-T6S). A specimen was prepared by placing a sample on a collodion membrane, and carrying out vacuum-evaporation with carbon to prevent sintering of the sample by an electron beam. Samples used for X-ray diffractometry and transmission electron microscopy were prepared by calcination at 600 °C for 2 hr.

Results and Discussion

Effect of Additives on DTA Curve. The DTA curve of basic magnesium carbonate changes with environmental atmosphere[9] and heating rate. Four transitions were observed on the DTA curve at a heating rate of 20 °C/min (Fig. 1c): Endothermic peak (1) at about 300 °C due to dehydration, (2) at about 430 °C due to partial decarbonation, (3) at about 520 °C due to decarbonation, and an exothermic peak at 490 °C attributable either to crystallization of amorphous magnesium oxide or recombination of magnesium oxide with carbon dioxide evolved. When the heating rate decreased, the DTA curve showed two endothermic peaks (Fig. 1a).

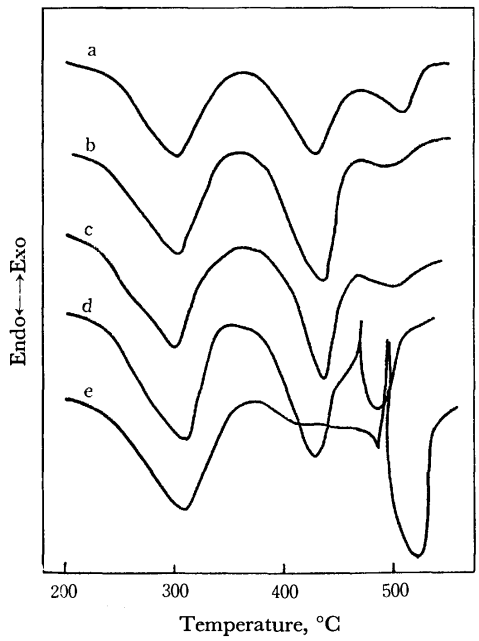

Fig. 2. Comparison of DTA curves of basic magnesium carbonate with those of additives.
a: $BeCl_2 \cdot 4H_2O$, b: $MgCl_2 \cdot 6H_2O$, c: $CaCl_2 \cdot 6H_2O$,
d: $SrCl_2 \cdot 6H_2O$, e: $BaCl_2 \cdot 2H_2O$.

The DTA curves of the sample containing 1 mol% of alkali earth metal chlorides are given in Fig. 2. Decomposition was greatly influenced by the addition of beryllium chloride tetrahydrate, magnesium chloride hexahydrate, calcium chloride hexahydrate and magnesium bromide hexahydrate, but the effect of strontium chloride hexahydrate was small and no effects were observed by other additives.

We see that all the additives with considerable effect contain four or six molecules of water of crystallization which would cause the hydrolytic cleavage of hydrogen chloride from the halides at relatively low temperature, as suggested from the following reaction scheme.[10]

$$MgCl_2 \cdot 6H_2O \longrightarrow MgCl_2 \cdot 4H_2O + 2H_2O \quad 95—115°C$$
$$MgCl_2 \cdot 4H_2O \longrightarrow MgCl_2 \cdot 2H_2O + 2H_2O \quad 135—180°C$$
$$MgCl_2 \cdot 4H_2O \longrightarrow MgOHCl + HCl + 3H_2O$$
$$MgCl_2 \cdot 2H_2O \longrightarrow MgCl_2 \cdot H_2O + H_2O \quad 185—230°C$$
$$MgCl_2 \cdot 2H_2O \longrightarrow MgOHCl + HCl + H_2O$$
$$MgCl_2 \cdot H_2O \longrightarrow MgCl_2 \cdot H_2O \quad \text{over above } 230°C$$
$$MgCl_2 \cdot H_2O \longrightarrow MgOHCl + HCl$$
$$MgOHCl \longrightarrow MgO + HCl$$

Evolution of hydrogen chloride or hydrogen bromide was also detected from three other additives by gas chromatography. The temperature of liberation of hydrogen chloride was the same as or very close to that of decarbonation and dehydration of basic magnesium carbonate.

Effect of the Amount of Additive on DTA Curve. Concentrations of four additives greatly influenced DTA curves. The DTA curves for various concentrations of magnesium chloride hexahydrate are shown in Fig. 3. The other three additives also show similar tendency. With increase in the amount of additive endothermic peak A at a lower temperature shifted somewhat to a higher temperature and peak B at a higher temperature shifted considerably to a lower temperature. The change in the maximum temperature of peak B is illustrated in Fig. 4. Of the four additives, magnesium bromide showed the largest temperature shift (80°) to lower side.

Effect of Additive on the TG Curve. In Fig. 5 are shown the TG curves of the sample containing magnesium chloride hexahydrate in the region 300—500 °C, where decarbonation, partial dehydration from basic magnesium carbonate and decomposition of additive are known to occur. The other three additives also show a similar tendency. It is thus evident that the TG curve is also influenced by additive. It appears that the rate of decomposition increases with the increase in the amount of additive.

Effect of Additive on the Activation Energy. To evaluate the activation energy from the TG curve, we employed Freeman-Carroll's technique[11] and Coat's technique.[12] An abnormally high activation energy was obtained for decomposition of the sample containing additive at about 450 °C, although the decomposition occurred more abruptly and at a lower temperature than that for an additive-free sample. Reason why the above high value was obtained was considered as follows: Weight loss obtained by TG might be attributed to the decomposition of basic magnesium carbonate and additive. Not only the rate of decomposition but also the composition of the evolved gas varied with the amount of additive (Fig. 6).

11) E. S. Freeman and B. Carroll, *J. Phys. Chem.*, **62**, 394 (1958).
12) A. W. Cats and J. P. Redfern, *Nature*, **201**, 68 (1964).

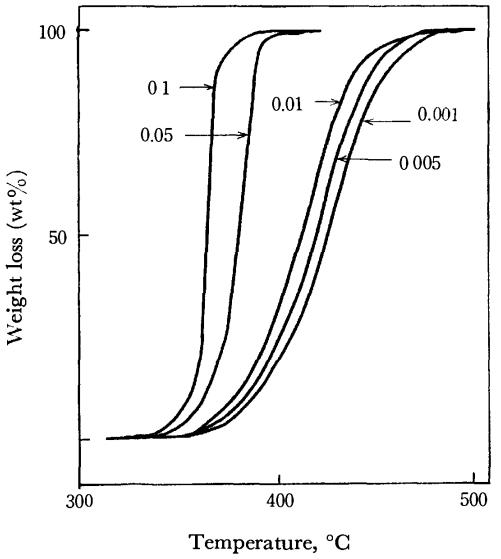

Fig. 5. Effect of magnesium chloride hexahydrate on TG curve of basic magnesium carbonate in the region of 300 to 500 °C.
0.001—0.1: $[MgCl_2 \cdot 6H_2O]/[4MgCO_3 \cdot Mg(OH)_2 \cdot 4H_2O]$

We employed gas chromatography for the evaluation of activation energy using the Freeman-Carroll equation:

$$\frac{-E}{2.3R}\frac{\Delta\frac{1}{T}}{\Delta \log Wr} = -x + \frac{\Delta \log \frac{dw}{dt}}{\Delta \log Wr}$$

where E, T, R, and x represent the activation energy, the absolute temperature at which gas is collected, the gas constant and the order of reaction with respect to the component, respectively, dw/dt being the rate of

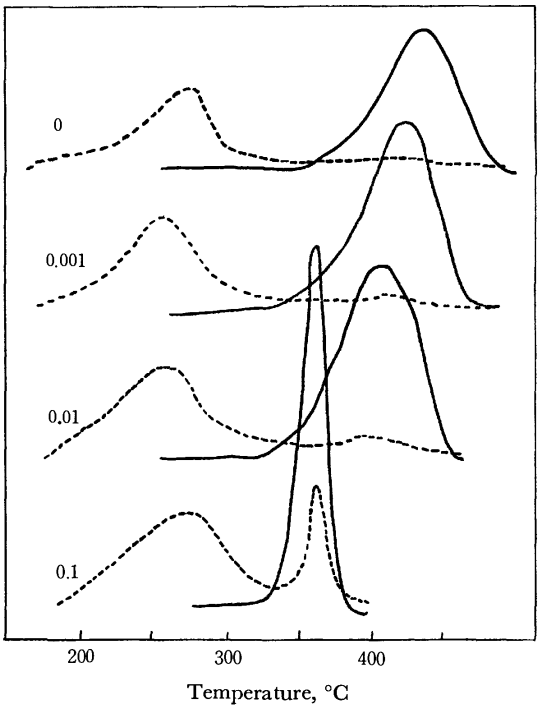

Fig. 6. Rate of dehydration and decarbonation
0—0.1: $[MgCl_2 \cdot 6H_2O]/[4MgCO_3 \cdot Mg(OH)_2 \cdot 4H_2O]$
——: CO_2, ------: H_2O

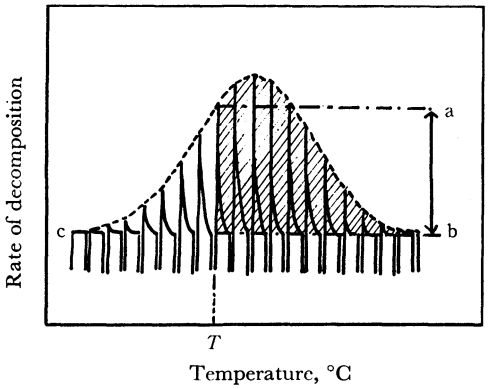

Fig. 7. Gas chromatogram obtained by thermal decomposition.

decomposition at T K, and Wr the difference between the weight loss at completion of reaction and total weight loss up to T K. Gas chromatograms obtained are shown in Fig. 7. The differential curve given by a dotted line (namly dw/dt *vs.* t) corresponds to the rate of decomposition. The length from (a) to (b) is the rate of decomposition reaction (dw/dt) at T K. The areas bound by a dotted line and basement (b—c) represent the total amount of water or carbon dioxide. Wr corresponds to the shaded part. Thus dw/dt and Wr can be determined directly from the curve (dotted line), and the activation energy could be readily calculated by plotting $(\Delta\log dw/dt)/\Delta\log Wr$ against $(T^{-1})/\Delta\log Wr$.

Validity of this gas chromatographic method is clear from the following evidences. Although basic magnesium carbonate evolved water vapor only in a very small amount in the range 350—500 °C, this does not seem to affect the evaluation of activation energy. Thus the values of $\Delta\log dw/dt$ and $\Delta\log Wr$ determined by gas chromatography for the additive-free sample seems to be the same as those by TG. The activation energies calculated from gas chromatogram agreed with the one from the TG curve, *viz.*, 47.7 and 47 kcal/mol.

The activation energies of decarbonation obtained by gas chromatography are shown in Fig. 8. The rate of decomposition was too large for the evaluation of activation energy for the sample containing an additive in a molar ratio greater than 0.05.

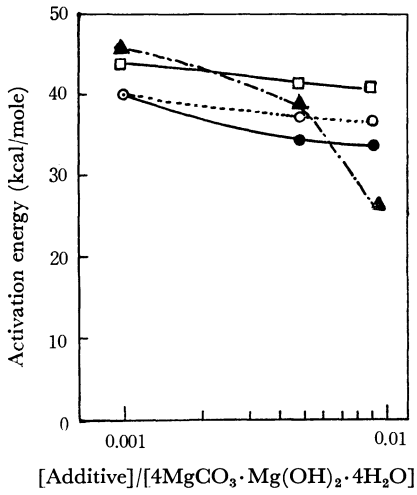

Fig. 8. Variation of the activation energy of basic magnesium carbonate with additives
○---○ $BeCl_2\cdot4H_2O$ ●—● $MgCl_2\cdot6H_2O$
□—□ $CaCl_2\cdot6H_2O$ ▲-·-▲ $MgBr_2\cdot6H_2O$

Although the effect of additive on dehydration at about 200 °C of basic magnesium carbonate is not clear since dehydration of the additive took place in a similar temperature range, the influence on the activation energy of dehydration would be neglected due to a very low concentration of additive. The activation energies of dehydration of the sample containing beryllium chloride tetrahydrate, magnesium chloride hexahydrate, calcium chloride hexahydrate, and additive-free were 13, 15, 23, and 25 kcal/mol, respectively. They were not affected by the amount of additive. On the other hand, the values for the sample containing magnesium bromide hexahydrate in the molar ratio range 0.001—0.01 varied from 25 to 15 kcal/mol.

The amount of magnesium bromide hexahydrate affects the activation energies of both decarbonation and dehydration remarkably. The effect might be mainly ascribed to hydrogen bromide generated in addition to the difference in the mode of decomposition of additive.

Effect of Additive on the Size of Crystallite of Magnesium Oxide. Sizes of the crystallite of magnesium oxide are shown in Fig. 9.

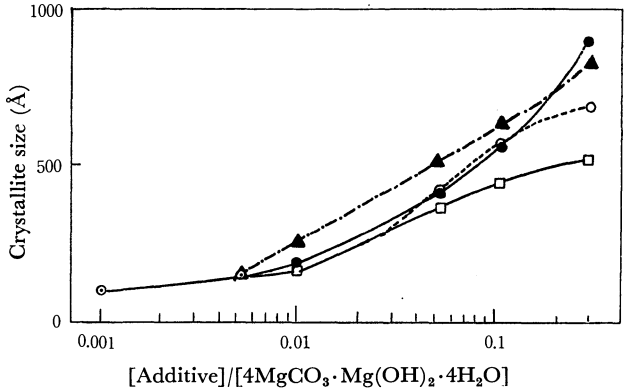

Fig. 9. Variation of the crystallite size of MgO with concentration of additives
○---○ $BeCl_2\cdot4H_2O$ ●—● $MgCl_2\cdot6H_2O$
□—□ $CaCl_2\cdot6H_2O$ ▲-·-▲ $MgCl_2\cdot6H_2O$

Transmission electron micrographs of basic magnesium carbonate and magnesium oxides are shown in Fig. 10. Magnesium oxide exists as an aggregate of small particles of the oxide. The shape of the aggregate is similar to that of basic magnesium carbonate, the particle size of magnesium oxide increasing with the increase of the amount of additive. The results obtained the micrographs (Fig. 10) are in line with those obtained with X-ray diffractometry. Since it is known that sintered magnesia of large size is prepared by heating magnesium oxide under a flow of hydrogen chloride,[13] it seems that the growth of crystal of magnesium oxide is influenced by hydrogen halide evolved

by the decomposition of an additive.

It should be noted that thermal decomposition of basic magnesium carbonate and the size of the crystallite of magnesium oxide prepared from basic magnesium carbonate are influenced by hydrogen halide evolved from an additive.

Spectroscopic and Coordination Behavior of α-Cyanothioacetamide

Arabinda RAY and D. N. SATHYANARAYANA

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore-12, India

(Received June 14, 1972)

α-Cyanothioacetamide (CTAM) complexes of cuprous chloride CuCl–2CTAM and cuprous bromide CuBr–2CTAM have been prepared. The infrared spectra of CTAM and its complexes, and the laser Raman spectrum of CTAM have been recorded. Assignment of the frequencies of the ligand has been made on the basis of a normal coordinate analysis using the Urey-Bradley force field. The copper (I) complexes are inferred to have thiocarbonyl sulfur and amide nitrogen bonded CTAM as evidenced from infrared and electronic spectra.

α-Cyanothioacetamide is a potentially tridentate ligand. The coordination complexes of its oxygen anologue α-cyanoacetamide have been studied recently.[1,2] The results of detailed spectroscopic investigations of thioacetamide[3] and malononitrile[4] are also available. In this connection, we considered it interesting to study in detail the spectroscopic and coordination behavior of α-cyanothioacetamide (CTAM). The location of thiocarbonyl stretching frequency was also of considerable interest. We report here the infrared and laser Raman spectra of CTAM and the assignment of its vibrational frequencies with the aid of a normal coordinate treatment. The complexes of CTAM with cuprous chloride and cuprous bromide are also included. The assignment of the vibrational frequencies and the frequency shifts in metal complexes are discussed.

Experimental

Materials. α-Cyanoacetamide was prepared by reacting ethylcyanoacetate (Boehringer Ingelheim reagent) with liquor ammonia.[5] CTAM was synthesised from α-cyanoacetamide by being refluxed with phosphorus pentasulfide (Fluka) in ethylacetate[6] (BDH reagent). The product was recrystallized from A.R. benzene. The salts $CuCl_2 \cdot 2H_2O$ and $CuBr_2$ were of A.R. grade. Ethanol (99%) was used for the preparation.

Preparations. *CuCl–2CTAM*: An ethanol solution of the ligand was mixed with cupric chloride dihydrate in ethanol when cupric chloride was reduced and a yellow precipitate of the cuprous chloride complex was obtained. It was filtered off, washed with ethanol and dried in a vacuum. Found: Cu, 20.73; S, 20.99%. Calcd for CuCl–2CTAM: Cu, 21.26; S, 21.4%.

CuBr–2CTAM: The above procedure was followed for the preparation of CuBr–2CTAM. The resulting yellow precipitate was filtered, washed with ethanol and dried in a vacuum. Found: Cu, 18.70; S, 18.33%. Calcd for CuBr–2CTAM: Cu, 18.48; S, 18.63%.

Analysis. Copper in the complexes was estimated by the thiosulfate method and sulfur as barium sulfate.

Infrared Spectra. The infrared spectra of CTAM and its complexes were taken in Nujol mull and KBr pellets on a Carl-Zeiss UR 10 spectrophotometer in the range 4000—400 cm^{-1}, and on a Perkin-Elmer 521 grating spectrophotometer in the range 400—250 cm^{-1}.

Raman Spectra. The Raman spectrum of the powdered sample of CTAM sealed in a thin capillary tube was taken on a Cary 81 Raman spectrophotometer equipped with an argon ion laser.[7]

Electronic Spectra. The electronic spectrum of CTAM in acetonitrile was taken on a Unicam SP 700A recording spectrophotometer. The electronic spectra of the complexes were recorded in Nujol mull.

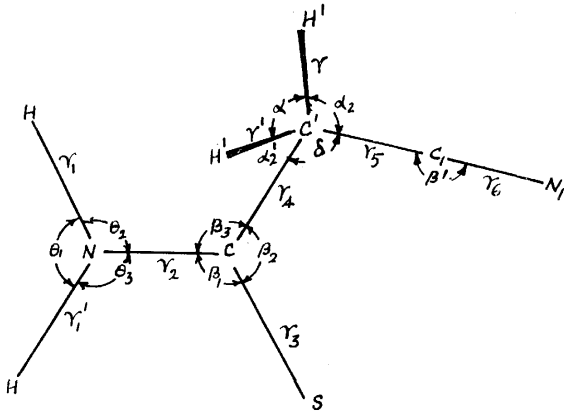

Fig. 1. Internal coordinates.

Normal Coordinate Analysis. The molecule CTAM belongs to the point group C_s and its 24 fundamental vibrations are distributed as 16 A′ and 8 A″ types. Calculations have been carried out for the A′ vibrations only since the frequencies of interest in the present study belong to this species. The internal coordinates are defined in Fig. 1 and the internal symmetry coordinates are given in Table 1. The molecular parameters of CTAM based on the available structural data for formamide,[8] α-cyanoacetamide,[9] and thioacetamide[10] are given in Table 2. The secular equation of Wilson's GF matrix was solved using Miyazawa's method[11] on a IBM 360/44 computer.

Force Field. Because of its effectiveness for thio-

amides,[3,12-14] the Urey-Bradley force field (UBFF) was chosen for the calculations. The initial set of force constants were taken from thioacetamide (TAM)[3] and malononitrile (MNL, set I).[4] From the results of calculation, the force constants were modified by an iterative procedure so as to get the best fit between the calculated and the observed frequencies. Table 3 shows the final force constants thus obtained. A comparison of the force constants of CTAM with those of TAM and MNL indicates that only three bending force constants differ considerably while all other force constants are nearly the same as those in either TAM or MNL. Thus the transferability of these force constants is good.

a) Percentage deviation.
b) Contribution less than 10 per cent is not included.
c) Taken from Raman data.

The calculated frequencies are compared with the observed ones in Table 4, in which the assignments of the bands based upon the calculated potential energy distribution (PED) are also given.

Results and Discussion

The assignments are compared with those of the closely related TAM and MNL molecules.

3400—2000 cm^{-1} Region. The bands at 3375 and 3295 cm^{-1} in CTAM are due to N–H asymmetric and symmetric stretching vibrations. The CH symmetric and antisymmetric (A″) modes are located at 2895 and 2930 cm^{-1}, respectively. The C≡N stretching occurs at 2268 cm^{-1}.

1650—1000 cm^{-1} Region. The 1630 cm^{-1} band is due to NH_2 bending. The C–N stretching mode is coupled and is distributed in the frequencies at 1630, 1460, and 1385 cm^{-1}, its contribution being maximum (41 per cent) in the 1460 cm^{-1} band. In TAM, NH_2 bending and C–N stretching modes occur, respectively, at *ca.* 1630 and 1400 cm^{-1}. The bands at 1415 and 1385 cm^{-1} due to CH_2 bending and CH_2 wagging, respectively, are compatible with those in MNL[4] and other related molecules.[15]

In the 1300—1250 cm^{-1} region, there are two intense absorptions at 1260 and 1295 cm^{-1}. The 1260 cm^{-1}

a) Values in parantheses are Raman frequencies. Because of poor signal/noise ratio in the Raman spectrum, only the prominent bands are given.

band has been included in A′ vibrations in preference to the 1295 cm^{-1} one. The 1260 cm^{-1} band has a complicated mode of coupling with a slightly higher contribution from NH_2 rocking (Table 4). The 1295 cm^{-1} band has been assigned to CH_2 twisting (A″) in accordance with the CH_2 twisting mode at 1225 cm^{-1} in MNL.[4] The 1295 cm^{-1} band is not much affected on complex formation with metals while that at 1260 cm^{-1} shows a large red shift (Table 5). The infrared spectra of the deuterated ligand and the reaction product with HCl gas also showed that the 1295 cm^{-1} band is not affected while the 1260 cm^{-1} band showed a large variation. These findings might support the assignments.

The bands at 1001 and 1260 cm^{-1} have, respectively, 50 and 30 per cent NH_2 rocking mode. Comparable frequencies in TAM appear at 1310, 1030, and 965 cm^{-1} having, respectively, 50, 20, and 16 per cent contribution from NH_2 rocking vibration.[3]

950—700 cm^{-1} Region. The asymmetric C–C stretching mode in CTAM is observed at 955 cm^{-1} while the symmetric mode is distributed amongst 1001, 955, and 630 cm^{-1} bands. The asymmetric mode is comparable with the 985 cm^{-1} band in MNL.[4] The symmetric C–C stretching in MNL occurs as a pure band around 890 cm^{-1}. The symmetric C–C vibration in CTAM is comparable with the C–C stretching mode in TAM, where it is distributed in the bands in the 1400—700 cm^{-1} region.[3]

The band at 760 cm^{-1} is of considerable interest and is due, mainly, to C=S stretching in agreement with an earlier empirical assignment.[16] The C=S stretching occurs at 720 cm^{-1} in TAM.[3] Occurrence of C=S stretching at a higher frequency in CTAM could be attributed to the electron withdrawing effects of the CN group. This band shifts to lower frequency in metal complexes (where sulfur is presumed to be the donor) which may be taken as a support to the above assignment.

650—100 cm^{-1} Region. The CCC bending mode is observed at 580 cm^{-1} in MNL, while in the present case, it is highly coupled and appears in the bands at 1001, 335, and 105 cm^{-1}, the contribution being the largest (36 per cent) in the 105 cm^{-1} band.

The assignment of bands at 421 and 335 cm^{-1} to predominantly NCS and CCS bending modes needs some comment. The corresponding bands in TAM have been observed at 470 and 390 cm^{-1}. One would be inclined therefore to assign empirically the 495 and 421 cm^{-1} in CTAM to NCS and CCS bending vibrations, respectively. The frequencies obtained from the initial trial set were very close to 420 and 330 cm^{-1}. To raise these bands to 495 and 420 cm^{-1}, it was necessary to employ unusually large bending force constants. When this was done, the assignments obtained for some of the higher frequencies were of "unacceptable" nature. Hence, the present assignments for 421 and 335 cm^{-1} were preferred. The lowering of NCS and CCS bending frequencies in CTAM may be attributed to its coupling with CC≡N bending. The CC≡N "in-plane" bending modes in MNL[4] occur at 365 and 165 cm^{-1}.

Out-of-plane Vibrations. Mention should be made of the A″ vibrations although no calculations have been carried out to assign the frequencies to these modes. There are 8 A″ vibrations. The CH_2 antisymmetric stretching occurs at 2930 cm^{-1}. A band at 1295 cm^{-1} is assigned to CH_2 twisting. The CH_2 rocking mode is assigned at 905 cm^{-1} in comparison with that at 936 cm^{-1} in MNL.[4] A strong band at 695 (715) cm^{-1} is assigned to NH_2 wagging in agreement with that in TAM[3] and acetamide,[17] while a very weak band at 855 cm^{-1} is assigned to NH_2 torsional vibration in comparison with that around 800 cm^{-1} in acetamide.

Of the remaining four modes, the band at 495 cm^{-1}

16) K. A. Jensen and P. H. Nielsen, *Acta. Chem. Scand.*, **20**, 597 (1966).

17) T. Uno, K. Machida, and Y. Saito, *Spectrochim. Acta*, **27A**, 833 (1971).

may be due to C–C out-of-plane bending and is compatible with that at 530 cm^{-1} in TAM.[3] An out-of-plane C–C≡N bending mode is assigned to 365 cm^{-1} in comparison with the one at 371 cm^{-1} in MNL.[4] The C=S out-of-plane bending is tentatively placed at 380, 390 cm^{-1}. The bands below 150 cm^{-1} in Raman spectrum (excepting 105 cm^{-1}) may be due to lattice modes.

Metal Complexes. Except for the copper(I) complexes, the initial efforts to prepare complexes of other metals were unsuccessful. The cuprous complexes are insoluble in most solvents, thus restricting the studies. The site of coordination of CTAM in the complexes were inferred from the infrared data based on the assignments for the ligand bands discussed above. The changes in the infrared frequencies of CTAM on coordination to copper(I) can be seen in Table 5.

A strong band at 760 cm^{-1} due mainly to C=S stretching is lowered by 50 to 60 cm^{-1} in the complexes. This large red shift clearly indicates the coordination of CTAM through sulfur.

The NH_2 stretching modes are found to shift to lower frequencies by about 100 cm^{-1} in the complexes. No perceptible variation is observed in the NH_2 bending frequency. The NH_2 rocking frequencies at 1260 and 1001 cm^{-1} are affected differently. The 1260 cm^{-1} band which has considerable C=S stretching decreases to ~1200 cm^{-1} while the 1001 cm^{-1} shows two or three bands at higher frequencies at 1030—1100 cm^{-1}. Similar variations in the $-NH_2$ group frequencies have been noted in the case of (glycine[18]), urea[19] and thiourea[20] complexes of metals when coordination is said to have taken place through nitrogen. This indicates that in CTAM the bonding to copper(I) through amide nitrogen is likely.

The decrease in C≡N stretching frequency at 2268 cm^{-1} to ~2200 cm^{-1} in metal complexes is puzzling. Normally, coordination through the nitrogen of the cyanide group should increase the C≡N frequency, as has been observed in almost all the cases, including α-cyanoacetamide.[1,21] A decrease in C≡N stretching frequency has been found in cases where the coordination to the metal is through the π-bonding of the CN group.[21] Such a possibility is not thought of seriously in this case, although it cannot be completely ruled out. The intense broad band at 630 cm^{-1} in CTAM disappears in the complexes or appears as a weak band at 525 cm^{-1}. If the latter is the case, the unusually large shift is rather difficult to explain, if CN group is not coordinated.

The complexes of α-cyanothioacetamide are likely to be polymeric and may have complicated stereochemistry.

Electronic Spectra. The electronic spectrum of CTAM in acetonitrile shows bands at 270 mμ (ε 10000) and at 358 mμ (ε 200). These are due to $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions of the C=S chromophore. The electronic spectra of the complexes in solid state give a well-defined peak ~225 mμ. This band may correspond to the π—π^* transition at 270 mμ of the ligand. This blue shift may be attributed to the coordination of the thiocarbonyl sulfur to the metal.

The authors thank Prof. C. C. Patel for helpful discussions, and Prof. A. R. Vasudeva Murthy for his keen interest and encouragement.

A Study of Solute-Solvent Interaction in Solvents of Medium Dielectric Constant from the Apparent Molal Volume Data. I

Ram GOPAL,* D. K. AGARWAL, and Rajendra KUMAR
Department of Chemistry, Lucknow University, Lucknow, India
(Received July 28, 1972)

A study of the apparent molal volume (ϕ_v) of some common salts and the tetraalkylammonium iodides in DMSO has been reported in this communication. All the salts studied here, including those containing the larger R_4N^+ ions, have a positive slope in the ϕ_v *vs.* $\sqrt{C}$ curves, indicating a strong ionic interaction, apparently due to the medium dielectric constant of the solvent. This dielectric constant also promotes ion-association at higher concentrations and thus mutual penetration of the R_4N^+ ions is prevented. As a result, no negative slope in the ϕ_v *vs.* $\sqrt{C}$ curves of the larger R_4N-iodides is observed in this solvent. The effect of temperature on the limiting apparent molal volume, $\phi°$, reveals that the ion-solvent interaction is comparatively stronger in the non-hydrogen bonded solvents like DMSO and DMF than that in strongly hydrogen-bonded solvents like NMA and NMP. Addition of a CH_2-group to each of the four R-chains of the R_4N^+ ion increases its volume by about 70 ml per mole in DMSO, DMF, and NMA.

Dependence of the apparent molal volume, ϕ_v, on concentration and temperature has been employed as a tool to study ion-ion and ion-solvent interactions in some non-aqueous solvents of high dielectric constant during the last few years.[1-8] The usual idea that the salts, containing the small common ions have only a positive slope in the linear ϕ_v *vs.* $\sqrt{C}$ curves, is not universally true and the slope for some of these salts in the solvents of very high dielectric constant, like *N*-methylacetamide (NMA, $\varepsilon_{25°}=171.7$) and *N*-methylpropionamide (NMP, $\varepsilon_{30°}=164.3$) is negative.[5-8] It was suggested that in such cases, perhaps, the small ions are accommodated inside the voids left in the packing of the large solvent molecules. Because of the weak ion-ion interaction, due to the very high dielectric constant of the solvents, such systems would behave, more or less, like a mixture of two molecular species widely different in size. This fact and some electrostatic ion-solvent interaction somehow combine to give a negative slope even for the salts containing small and compact ions. It was believed that the extension of studies on apparent molal volumes in solvents of medium dielectric constant[9] should prove useful and may give a better insight into ion-ion and ion-solvent interaction in general. Hence dimethylsulphoxide ($\varepsilon_{25°}=46.6$) has been chosen as the solvent for the present study in which the apparent molal volumes of some salts containing small common ions and of some tetraalkylammonium iodides have been determined and examined.[10]

Experimental

Dimethylsulphoxide (Fluka, purum) was refluxed for several hours on freshly ignited quicklime and then distilled under reduced pressure, the middle fraction being retained; this was again distilled under reduced pressure and the middle fraction was collected. This process was continued until the electrical conductance of the sample was reduced to 10^{-7} mho or less. The purified sample was stored in dark colored

bottles and kept in a dry box until used. The tetraalkylammonium iodides and the common salts, used in the present study, were purified in the usual manner, dried and kept in a vacuum desiccator. The rest of the experimental procedure for determining the density of the solutions and calculating the apparent molal volume therefrom, was the same as detailed in some earlier communications.[3,4]

From the ϕ_v-data, thus obtained, ϕ_v *vs.* $\sqrt{C}$ curves were drawn and are given in Fig. 1a for NaI and in Fig. 1b for Bu_4NI. The ϕ_v *vs.* $\sqrt{C}$ curves for other salts are very much similar to those given in Figs. 1a and 1b and hence have been omitted.

From these figures it is clear that the ϕ_v *vs.* $\sqrt{C}$ curves are almost linear with a positive slope[11] for all the salts studied here. Obviously, the Masson's empirical relation, namely,

$$\phi_v = \phi^\circ + S_v\sqrt{C}$$

is satisfied within the concentration range studied here. The limiting apparent molal volumes, ϕ°, obtained from extrapolation of the ϕ_v *vs.* $\sqrt{C}$ curves to infinite dilution, for various salts at different temperatures, are given in Tables 1 and 2. The ϕ°-values of some salts in DMF are also included in these Tables for the sake of comparison (quoted from Ref. 9).

Note: Due to limited range of concentrations that could be studied in many cases on account of low solubility and also because of our inability to handle dilute solutions (<0.1 m) for want of proper equipment, values of ϕ° given in Tables 1 and 2 should be considered only approximate.

Discussion

Variation of the Apparent Molal Volume with Concentration. As has been pointed out earlier, both the common salts and the R_4N iodides, have a positive slope in the ϕ_v *vs.* $\sqrt{C}$ curves in DMSO and DMF[11] both of which have a medium dielectric constant. It may also be recalled that the slope for some R_4N bromides (R= CH_3 to C_4H_9) and common salts is positive in methanol.[12,13] The positive slope, even for the larger R_4N-salts in these solvents is rather surprising since the interionic penetration[14] which is expected to occur when the large R_4N^+ ions are involved, should also be present in DMSO and DMF. These solvents, of course differ from solvents like water, formamide, NMA and NMP (in which negative S_v values have been reported) in having a much lower dielectric constant and negligible hydrogen bonding.

A comparison of the results obtained in DMSO and DMF on the one hand and in water, formamide, NMA and NMP on the other, suggests a possible explanation for the absence of the negative S_v values (*i.e.* the negative slope) for the R_4N-salts, in the former set of solvents. Although at infinite dilution, R_4N- and common salts are completely dissociated in all these solvents, the situation in the two types would be different at the higher concentrations. While in the solvents of high dielectric constant like water, the salts would remain completely ionized, even at fairly high concentrations, so that appreciable interionic penetration may occur and this may give rise to a negative slope in the ϕ_v *vs.* $\sqrt{C}$ curves in salts containing the larger R_4N^+ ions, the situation would be somewhat different in solvents of medium dielectric constant in which the ionic association would be quite appreciable at the higher concentrations and this would result in weakening of the ion-solvent interaction. So the ion-solvent interaction, which would be maximum at infinite dilution and would cause maximum electrostriction and contraction of the solvent, would be significantly lowered at higher concentrations. This would result in net positive volume changes per mole of the added solute since now electrostriction is less as compared to that at the lower concentrations, even if some interionic penetration, involving the large uncommitted R_4N^+ ions, occurs. As far as the common ions of small radii and compact nature are concerned,

11) It may be mentioned that similar results, *i.e.* a positive slope in the ϕ_v *vs.* $\sqrt{C}$ curves of some common as well as tetraalkylammonium salts have been obtained in dimethylformamide (DMF); see Ref. 9.

12) J. Padova and L. Abrahamer, *J. Phys. Chem.*, **71**, 2112 (1967).

13) J. B. Stark and E. C. Gilbert, *J. Amer. Chem. Soc.*, **59**, 1818 (1937); W. C. Vosburgh, L. C. Connell, and J. A. V. Butler, *J. Chem. Soc., A*, **1933**, 933.

14) This concept has been used to explain the negative slope in the ϕ_v *vs.* $\sqrt{C}$ curves and other properties of the larger R_4N-salts in different solvents.

the question of interionic penetration does not arise; at the higher concentrations, strong electrostatic ion-ion interaction would cause ionic association and weaken the ion-solvent interaction and this would result in positive S_v values.

Variation of Limiting Apparent Molal Volume, ϕ°, with Temperature. The effect of temperature on ϕ° of the salts in DMSO is shown in Figs. 2a and 2b. Similar results have been obtained in DMF also. It may be noted that as far as the salts containing the small common ions are concerned, ϕ° *vs.* t curves pass through a maximum around 35—45°C, after which ϕ° steadily decreases with the rise in temperatures. The nature of the curves clearly suggests strong ion-solvent dipole interaction so that some of the solvent molecules remain firmly associated with the solute ions even at higher temperatures and hence are not available for expansion so that the solution expands less rapidly than the pure solvent. This behavior is somewhat similar to that in water, formamide *etc.* except that the maximum in the ϕ° *vs.* t curves occurs at lower temperatures in DMSO and DMF.

Turning now to the R_4N-iodides, it may be noted that the ϕ° *vs.* t curve for Et_4NI salt almost passes through a maximum around 60°; however, for the larger R_4N iodides, although ϕ° increases with the rise in temperature throughout the temperature range

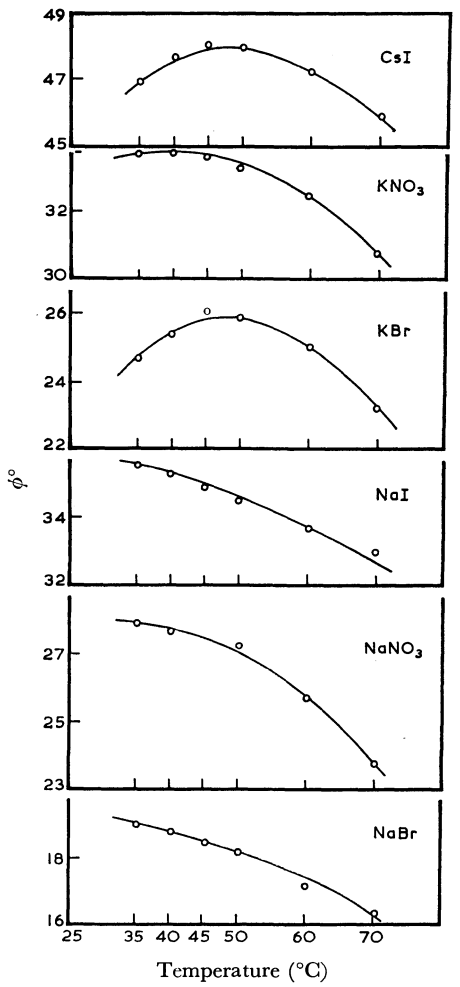

Fig. 2a. ϕ° *vs.* t curves of some common salts in DMSO.

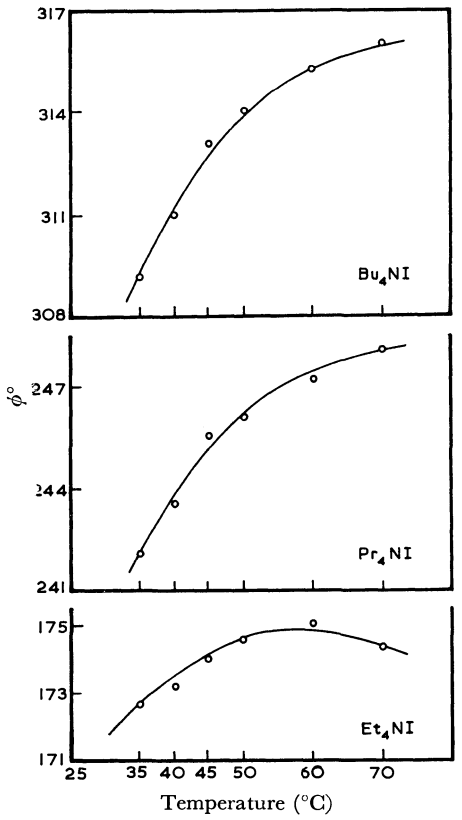

Fig. 2b. ϕ° *vs.* t curves of Et_4NI, Pr_4NI, and Bu_4NI in DMSO.

studied here, $d\phi^\circ/dt$ appears to decrease significantly, indicating the occurrence of a maximum at somewhat higher temperatures.[15] Thus the nature of the ϕ° *vs.* t curves appears to show that ion-solvent interaction is quite appreciable for the R_4N^+ ions in DMSO, the extent of interaction decreasing with increase in the radius of the R_4N^+ ion. It may be recalled that for the larger R_4N iodides, $d\phi^\circ/dt$ is almost a constant in protic solvents like formamide, NMA and NMP (not water in which ϕ° increases almost exponentially with temperature[3]), perhaps, due to release of the solvent molecules loosely bound to the R_4N^+ ions and of the solvent molecules which may be accomodated inside the larger R_4N^+ ions as well as due to uncoiling of the long coiled-up R-chains at higher temperatures. The same should be true in DMSO and DMF as well and the observed appreciable decrease in the $d\phi^\circ/dt$ values for the R_4N iodides in these solvents at higher temperatures indicates electrostatic interaction. Some other factors also appear to play an important role in controlling the general variation of ϕ° with temperature in different solvents.

A close look into the two types of the solvents appears to suggest a solution to this riddle. While DMSO and DMF are, more or less, non-hydrogen bonded-solvents, formamide, NMA and NMP, are strongly hydrogen bonded. The ion-solvent dipole interaction energy in DMF and DMSO, in the absence of any appreciable hydrogen-bond breaking energy, would be appreciable and the attachment of the solvent molecules even to

15) The ϕ° *vs.* t curves for Pen_4NI and Hep_4NI are almost similar to those for Bu_4NI although slightly steeper.

the R_4N^+ ions may not be loose; at the same time, no structure formation would occur in the solvents around the ions.[16] On the other hand, in formamide, NMA and NMP, a similar ion-solvent dipole interaction will lead to the breaking of the strong intermolecular hydrogen bonds and loosening up of the solvent structure around the ions so that the attachment of the solvent molecules to the R_4N^+ ions should be weaker, on account of the competing intermolecular hydrogen-bondre formation energy. The net result will be a weaker solvation[17] and loosening of the hydrogen bonded structure of the solvent[15,16] around the ions. Now in DMF and DMSO, some solvent molecules would be associated with the R_4N^+ ions while outside the ion-sphere, the solvent structure would be almost the same as in the pure solvent; so the expansion of the solution on heating would be comparatively less than that of the pure solvent and $d\phi^\circ/dt$ would decrease with the rise in temperature. In formamide, NMA and NMP, due to net structure breaking of the solvent[16,18] in presence of the R_4N^+ ions and their comparatively weaker solvation, solution may expand more rapidly than the pure solvent and $d\phi^\circ/dt$ may remain almost a constant (if the R_4N^+ is not too small like Me_4N^+ and Et_4N^+ ions). Thus it appears that the variation of ϕ° with temperature in different solvents can be satisfactorily explained on the concept of the ion-solvent interaction alone without invoking the idea of the release of the solvent molecules locked inside the large R_4N^+ ions or of the uncoiling of the coiled up large R-chains[4,5] of the R_4N^+ ions at the higher temperatures.

Some Remarks on the Values of ϕ° of R_4N Iodides in Various Solvents. An interesting fact to which the attention may now be drawn is that the difference $(\phi^\circ_{(RR_{n+1})_4NI} - \phi^\circ_{(R_n)_4NI})$ in formamide,[5] NMA[4,8] DMF[9] and DMSO is around 70 and is almost independent of temperature. Further, this difference *i.e.* 70 ml, very nearly corresponds to the difference in the intrinsic volumes, obtained from the relation $4\pi r^4N/3$ (r being the radius of the ions in question) of the R_4N^+ ions, using the radius as given by Robinson and Stokes.[19] This observation suggests that the electrostriction in presence of the R_4N^+ ions is very little in these solvents and also that the addition of one CH_2-group to the R-chains of the R_4N^+ ions, increases the volume of the ion by about 70 ml per mole. Since our ϕ° data have been obtained by extrapolation of the ϕ_v *vs.* $\sqrt{C}$ curves from higher concentrations and in many cases, density could be measured only within a very narrow range of concentrations due to solubility restrictions, it would be safer not to make any quantative deductions. However, since the results indicate that R_4N^+-solvent interaction is very slight, one wonders whether the variation of ϕ° with temperature, in the case of the larger R_4N iodides, is only governed by I^--solvent interaction alone. It is hoped that studies on apparent molal volumes in dilute solutions would throw more light on the behavior of the R_4N^+ ions.

The Bromination of *p*-Nitrophenol in Acetic Acid

N. SRIDHAR, J. RAJARAM, and J. C. KURIACOSE
Department of Chemistry, Indian Institute of Technology, Madras, India
(Received April 1, 1972)

Bromination of aromatic substrates like *p*-bromophenol, anisole, *etc.* by molecular bromine in acetic acid follows the rate expression, Rate=k[ArH][Br_2]+k'[ArH][Br_2]^2. For the bromination of *p*-nitrophenol in acetic acid, variable orders in bromine and *p*-nitrophenol have been observed on varying the concentrations of reactants. A rate expression of the type, Rate=k[ArH][Br_2]+k'[ArH][Br_2]^2+k''[ArH]^2[Br_2] has been proposed. The observations conform to a general mechanism for bromination provided a bromine molecule, a substrate molecule or solvent molecules can be the electrophile in the rate determining step, depending upon the conditions employed for the reaction.

Bromination of aromatic compounds by molecular bromine in acetic acid medium usually exhibits complex kinetics, the overall orders being dependent on the relative concentration of substrate and bromine.[1,2] The rate is usually expressed in the form

$$\text{Rate} = k[\text{ArH}][Br_2] + k'[\text{ArH}][Br_2]^2.$$

The accepted mechanism for the third order process involves the electrophilic attack of the complex formed between the substrate and bromine by a molecule of bromine in the rate-determining step.[3] In the second order process, it has been suggested that the complex undergoes electrophilic attack by the solvent molecules.[2] That certain substrates can also act as electrophiles has been shown in the bromination of *p*-bromophenol in CCl_4.[4] In acetic acid however, it has not been possible to establish conditions where *p*-bromophenol acts as an electrophile. A more powerful electron-withdrawing group like $-NO_2$ in the *para* position of phenol might make it function as an electrophile capable of competing with both Br_2 and CH_3COOH, leading to a second order in substrate and first order in Br_2. The bromination of *p*-nitrophenol (ArH) in acetic acid has been taken up to investigate this possibility.

Experimental

Glacial acetic acid (GR, SM) was purified according to Orton's procedure,[5] potassium permanganate being used instead of chromic acid. Bromine (AR, BDH) was used without further purification. *p*-Nitrophenol was recrystallized from two percent hydrochloric acid. The kinetics of the bromination of *p*-nitrophenol was followed by determining the concentration of bromine iodometrically as a function of time. The reactions were carried out by the batch method.[6] The orders have been determined by the isolation method using the initial rates. This procedure eliminates the influence of the products formed in the reaction. The slopes at various concentrations were taken from the concentration-time curve by the mirror method.[7] For each experiment a plot of log rate *vs.* log concentration was made from which the initial rate was obtained for the corresponding initial concentration. The initial rate was also evaluated by the method of least-squares. The values obtained for initial rates by both methods were within 5% deviation. With the use of these initial rates, orders were obtained by plotting the logarithms of initial rates against the corresponding initial concentrations. The orders and rate constants were again evaluated by the least-squares analysis of the data. The deviations in rate constants in most cases were within 10%.

Results and Discussion

The interaction of *p*-nitrophenol with bromine in acetic acid follows 1:1 stoichiometry. At higher concentrations of reactants (0.29—0.14M) under equimolar conditions, the overall order is three and at lower concentrations of reactants (0.099—0.018M) it is less than three (Fig. 1). It is apparent that the reaction is complicated by the occurence of variable orders. The individual ordres are given in Table 1.

The variation in order in ArH from 0.80 to 1.58 is more than to be expected from experimental error.

TABLE 1. INDIVIDUAL ORDERS AT DIFFERENT CONCENTRATION RANGES

Order in *p*-nitrophenol (Fig. 2)			Order in bromine (Fig. 3)		
Concentrations (mol/l)		order	Concentrations (mol/l)		order
ArH	Br_2		ArH	Br_2	
0.43—0.20	0.020	1.40	0.43	0.03—0.005	1.56
0.43—0.25	0.010	1.58	0.30	0.03—0.005	1.50
0.43—0.20	0.005	1.40	0.20	0.03—0.005	1.64
0.20—0.10	0.010	0.80			

The fractional orders observed in ArH and bromine at different concentrations of reactants suggest the possibility of either substrate molecules or bromine molecules or solvent molecules playing a vital role in the rate-determining step of the general mechanism:

$$ArH + Br_2 \rightleftharpoons ArHBr_2$$

$$ArHBr_2 + E \xrightarrow{slow} ArHBr^+ + EBr^-$$

$$ArHBr^+ \xrightarrow{fast} ArBr + H^+$$

$$H^+ + EBr^- \xrightarrow{fast} HBr + E$$

E can be ArH, bromine or solvent. When the bromine concentration is comparatively high, the electrophile will be bromine itself. As the concentration of ArH is increased, the substrate, being in excess, may satisfy the role of electrophile. This is possible in the case of *p*-nitrophenol, due to the highly electron-withdrawing nature of the nitro group which will make the molecule more electrophilic towards the removal of Br^- from the $ArHBr_2$ complex. Hence the fractional orders in reactants observed in the bromination of *p*-nitrophenol suggest a rate expression of the type

$$\text{Rate} = k[ArH][Br_2] + k'[ArH][Br_2]^2 + k''[ArH]^2[Br_2]$$

This equation can be rearranged as

$$\frac{\text{Rate}}{[ArH][Br_2]} = k + k'[Br_2] + k''[ArH]$$

At constant concentrations of bromine, the values on the left hand side of this equation can be plotted against [ArH]. The value of k'' can be obtained from the slope (Fig. 4). Different values of intercepts will be

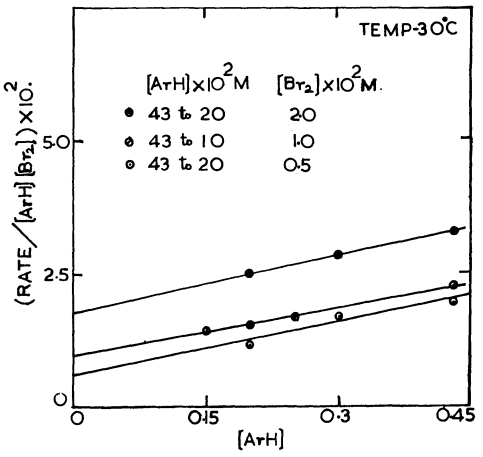

Fig. 4. Composite order plots.

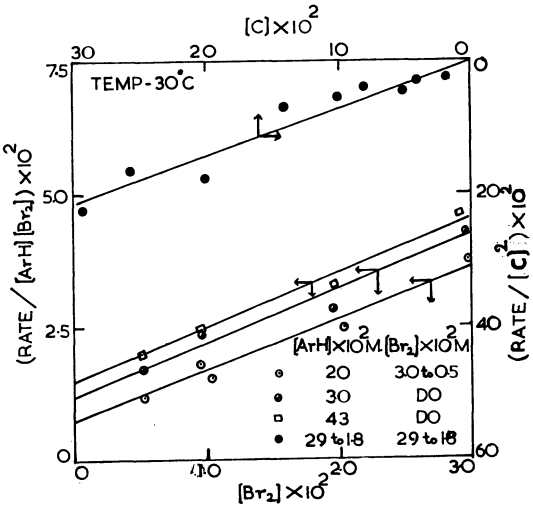

Fig. 6. Composite order plots.

obtained for different constant concentrations of bromine. A plot of the values of the intercepts obtained against the corresponding $[Br_2]$ should give a straight line with a slope k' and an intercept k (Fig. 5). Similar analysis of the data can be made for experiments where the concentration of ArH is kept constant and that of bromine is varied. The linear relationship is actually verified (Fig. 6) and another set of values of k, k', and k'' are obtained (Table 2). There is satisfactory agreement between these two sets of values. For the experiments carried out to determine the overall order, since equimolar concentrations are used, the rate expression can be written as

$$\text{Rate} = k[C]^2 + (k'+k'')[C]^3$$

where $[C]=[ArH]=[Br_2]$. The plot of Rate/$[C]^2$ *versus* [C] should be a straight line. This is verified as can be seen in Fig. 6. The intercept in agreement with value of k already determined is almost zero. The value of $(k'+k'')$ obtained is presented along with the rate constants obtained from the other analysis, in Table 2. The overall second order process may not be significant under these conditions.

The values of the rate constants indicate that the process in which bromine acts as the electrophile is much faster than the one in which ArH acts as the electrophile, which in turn is faster than the one in which the solvent molecules take an active part. The appearance of higher orders in substrate indicates that structural features induce a molecule to play an active role in the rate-determining step. In the case of *p*-nitrophenol, this may be due to the inductive effect of the nitro group which makes the substrate more electrophilic for the removal of Br^- from the $ArHBr_2$ complex than *p*-bromophenol.

Since ArH is in excess of bromine, even if there is a significant complex formation between the reactants, the total concentration of ArH and the free concentration of ArH are not different. But the total bromine concentration and the free bromine concentration will be different. Hence

$$\text{Rate} = \frac{k_1[ArH][Br_2]_T}{1+K[ArH]} + \frac{k_1'[ArH][Br_2]_T^2}{(1+K[ArH])^2} + \frac{k_1''[ArH]^2[Br_2]_T}{1+K[ArH]}$$

where K is the equilibrium constant for the complex formation. On transformation this expression can be written as

$$\frac{\text{Rate}}{[ArH][Br_2]_T} = \frac{k_1}{1+K[ArH]} + \frac{k_1'[Br_2]_T}{(1+K[ArH])^2} + \frac{k_1''[ArH]}{1+K[ArH]}$$

At constant concentration of ArH, the left hand side of the above expression can be plotted against $[Br_2]_T$ to give a straight line. The experimental results plotted in this manner yields a straight line with an intercept equal to $(k_1+k_1''[ArH])/(1+K[ArH])$. From the different values of the intercepts for different concentrations of ArH, the values of K, k_1, and k_1'' can be calculated. The value of K thus obtained is about 23. Eventhough the value of k_1'' obtained is positive, the value of k_1 is negative which is absurd. A similar plot made for the results obtained for varying concentrations of ArH but constant concentration of bromine is also a straight line. This should not be so if there is significant complex formation. Spectroscopic studies also suggest that the concentration of the complex is very small. It is therefore justified to consider that actually K is very small and the free bromine concentration can be taken to be equal to the total bromine concentration.

Neutral Salt Effect on the Interaction of Poly-α,L-glutamic Acid with Acridine Orange

Yukio SATO, Masahiro HATANO, and Michio YONEYAMA*

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received October 7, 1972)

The effect of potassium chloride on the absorption and optical rotatory properties of the poly-α,L-glutamic acid-acridine orange system in an aqueous solution was studied under various conditions. The stability of the helical conformation of poly-α,L-glutamic acid in this system was examined at different potassium chloride concentrations by estimating the helix fraction of the polymer. At pH 4.5, where poly-α,L-glutamic acid exists in the helix, it was found that the added potassium chloride raised the stability of the helical conformation of the polymer in this system. In this case, it was assumed that the added potassium chloride lowers the disturbance of helix formation by the bound acridine orange cation. However, when the solution's pH was raised, the added potassium chloride lowered the extent of the helix fraction in this system. These phenomena were discussed on the basis of several experimental findings on the circular dichroism of the systems. Furthermore, from the change in the intensities of the circular dichroism with the variation in the potassium chloride concentration, it was presumed that the positive circular dichroism band at about 520 nm was due to the binding of dimeric acridine orange molecules to the polymer.

Many investigators[1-3] have studied the interaction of biopolymers, such as polynucleotides,[4,5] or polypeptides,[6,7] with dyes. It is well known that an extrinsic optical activity is induced in the region corresponding to the absorption bands of acridine orange (AO) only when the dye combines with the helical form of poly-α,L-glutamic acid (PLGA) in an acidic solution. Furthermore, in the course of studies of the interaction of PLGA with AO under conditions of various pH or R/D (the ratio of glutamyl residues to dye molecules) ratios,[8,9] we found that, in the case of a R/D of around unity, the induced Cotton effects can also be observed even when the AO molecules are bound to PLGA in the neutral and alkaline pH region.[8] In this case, it was confirmed that the PLGA–AO complex had a helical conformation. Thus, extrinsic optical activity can be expected in the aqueous solution system of PLGA–AO, in which PLGA forms a helix.[10] Ballard *et al.*[2] assigned the induced circular dichroism (CD) bands of the PLGA–AO complex in an aqueous solution by measuring the CD spectrum of the complex under streaming conditions. Yamaoka and Resnik[11] discussed the optical activity in this system at very large R/D values. They proposed that the induced Cotton effects could arise from monomeric dye bound near the asymmetric environment of the α-carbon atom of the peptide residue.

In this paper, we will discuss the effect of potassium chloride on the interaction of PLGA with AO. The origin of the CD band at 520 nm will also be considered on the basis of the effect of potassium chloride at small R/D values, and will be compared with the dimer formation of AO.

Experimental

Materials. The sodium poly-α,L-glutamate used here was supplied by the Ajinomoto Co., Inc. The degree of polymerization of the polymer was 650. The AO was purified according to the method described in previous paper.[9]

Procedure. The mixtures were prepared by adding an aqueous AO solution to an aqueous PLGA solution with a pH of 4.5 in the presence or absence of potassium chloride, and then the pH of the mixed solutions was brought to the desired value by the addition of 1/10N NaOH. The R/D value was varied from 1 to 10, but the final concentration of AO was fixed at 2×10^{-5} M. The spectra of all the mixed solutions were measured within a few hours after their preparation. The CD and absorption spectra were measured by means of a JASCO Model ORD/UV-5 dichrograph with a CD attachment and by means of a Hitachi Model EPS-3T spectrometer respectively, both times at room temperature. The pH values of the solutions were measured by means of a Toa Denpa Kogyo Model HM-8 pH meter under a streaming of nitrogen gas. All the data presented below are reduced to the molar basis of the total dye concentration or the glutamyl residue concentration, and are expressed by the molar extinction coefficient, ε, and the molar ellipticity, $[\theta]$. As for the dependence of the concentration on the ellipticities, we refer to each figure.

Results and Discussion

Effect on Absorption Spectra. AO molecules aggregate in an aqueous solution. Thus, in the concentration range from 10^{-3} to 10^{-6} M of AO, as the concentration increases, the intensity of the monomer band at 492 nm (α-band) gradually decreases and the dimer band at about 470 nm (β-band) appears.[12]

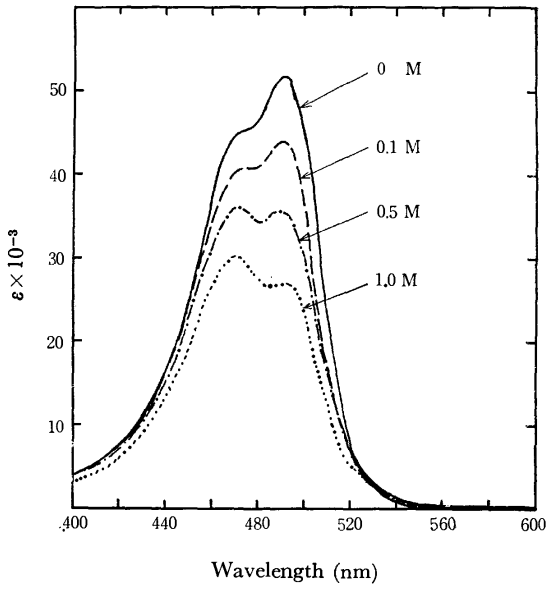

Fig. 1. Absorption spectra of AO at various KCl concentrations (pH=4.5, [AO]=2×10^{-5}M).

With a further increase in the concentration of AO, the β-band shifts toward a shorter wavelength (γ-band, about 450 nm); this corresponds to the formation of higher aggregates.

Figure 1 shows the change in the absorption spectrum of AO with a variation in the potassium chloride concentration. As the concentration of potassium chloride increases, the intensity of the monomer band becomes weak, while the dimer band increases in intensity. There is an isosbestic point at about 520 nm, indicating that only two molecular species, the AO monomer and the dimer, are present in the system. The AO dimer is probably held by dispersion force and/or hydrophobic interaction between the π-electron system, which overcomes the electrostatic repulsion force between the two AO cations. From Fig. 1, it is obvious that potassium chloride promotes the dimerization of AO. This may be due to the fact that the binding of the chloride anions to the AO cation reduces the electrostatic repulsion force between the cations of AO. The coulombic repulsion between the AO cations is minimized when the charged amino groups on both sides lie along opposite edges of the sandwich,[13] and the anions are attached laterally to the dye cation without affecting the internal coupling of AO. Therefore, it is reasonable that Fig. 1 shows the extent of the dimerization of the AO cations.

If the association is enhanced through an increase in the concentration of Cl^-, the following two equilibria can be considered for the association step of the AO cations in the presence of the anion:[14]

$$2D^+ + A^- \rightleftarrows (D_2A)^+ \quad (1)$$

$$2D^+ + 2A^- \rightleftarrows (D_2A_2) \quad (2)$$

where D^+ and A^- denote the dye cation and the anion respectively.

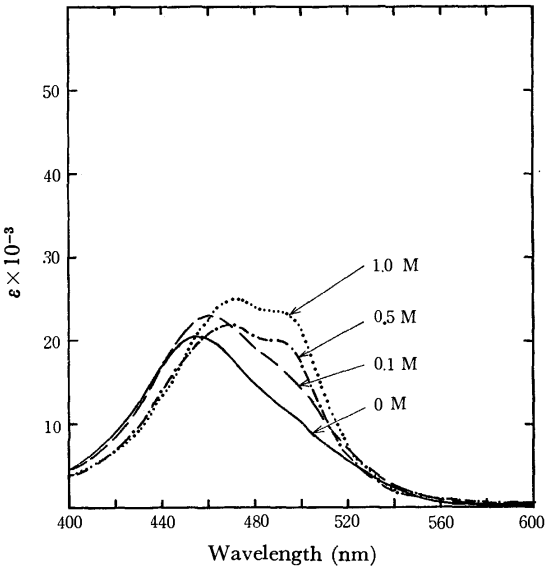

Fig. 2. Absorption spectra of PLGA–AO system at various KCl concentrations (R/D=10, pH=4.5, [AO]=2×10^{-5}M).

Figure 2 shows the change in the absorption spectrum of AO in an aqueous solution with various potassium chloride concentrations at pH=4.5 and R/D=10. The intensity of the γ-band is stronger than those of the α-band and the β-band; however, with an increase in the potassium chloride concentration the intensity of the β-band becomes rather strong. This spectral profile is scarcely influenced by the variation in R/D values. From these results, it can be concluded that the addition of potassium chloride to the AO system promotes the dimerization of the AO cation, even in the presence of PLGA.

Effect on the Helix-coil Transition of PLGA. Figure 3 shows the helix-coil transition of PLGA at various potassium chloride concentrations. The helix-coil transition of PLGA occurs in the pH range from 5.6 to 6.8. However, the transition range of pH was gradually lowered with an increase in the potassium chloride con-

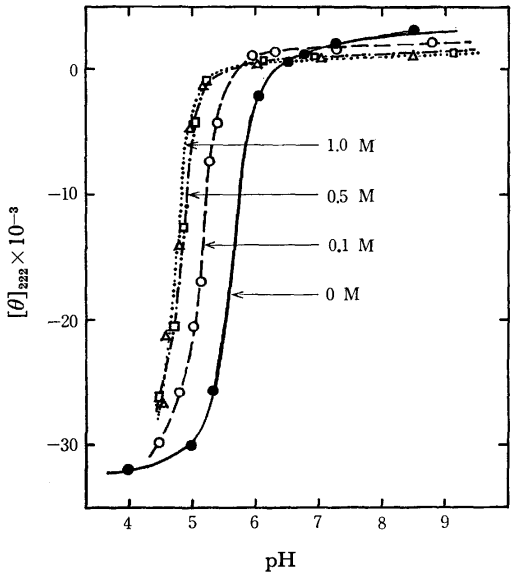

Fig. 3. Helix-coil transition of PLGA at various KCl concentrations.

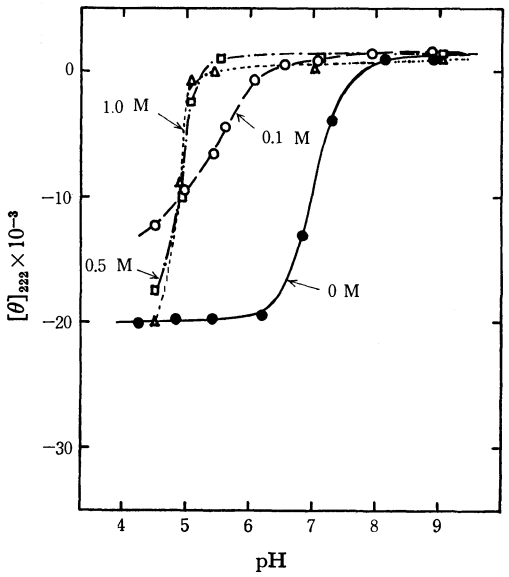

Fig. 4. Helix-coil transition of PLGA in PLGA–AO system at various KCl concentrations (R/D=6, [AO]=2×10^{-5}M).

centration. This indicated that the apparent pK_a value of PLGA was lowered by the electrostatic interaction between the carboxylate anions of side chains and the potassium cations.[15]

Figure 4 shows the effect of the addition of potassium chloride on the helix-coil transition of PLGA in the PLGA–AO system. At lower concentrations of potassium chloride, the transition range of pH remained unchanged, as dose the range in the case of the PLGA solution. When the R/D values are small, *e.g.*, smaller than about 10, the AO cations come to bind to the carboxylate anions of PLGA with an increase in the pH value in the absence of potassium chloride and stabilize the helical structure of PLGA.[9]

On the contrary, the results in Fig. 4 show that, at higher concentrations of potassium chloride, the stabilization of the helical structure of PLGA by AO molecules is lowered. In this case, this phenomenon may be elucidated by the fact that the neutral AO dimer is formed according to Eq. (2), thus reducing the binding of AO cations to PLGA.

At various concentrations of potassium chloride in the PLGA–AO system, the helix fraction (f_H) of PLGA was estimated in order to examine the influence of potassium chloride on the helix stability of PLGA (Fig. 5). It was found that f_H values tended to increase with a decrease in the R/D values when potassium chloride was added to the PLGA–AO system. This implies that the decrease in f_H value results from reducing the ionic coupling of the AO cation with the carboxylate anion. Therefore, the interaction of PLGA with AO is lowered and the stability of helical structure increases with a decrease in the R/D value and with an increase in the concentration of potassium chloride.

Relation between Dimer Formation and CD. The magnitude of CD is also dependent on the potassium chloride concentration, as may be seen in Fig. 6. While the magnitude of the positive CD band at about 435 nm and that of the negative CD band at about 465 nm decrease with an increase in the potassium chloride concentration, the magnitude of the positive CD band at about 520 nm increases with an increase in the concentration of potassium chloride. This spectral change is elucidated by the fact that, at higher concentrations of potassium chloride, the dyes aggregated in a helical fashion along the peptide chain decrease. The extent of the increase in the ellipticity of the CD band at 520 nm is larger when the potassium chloride concentration is lower. Since Eq. (1) is applicable in the case of lower concentrations of potassium chloride, where the cationic AO dimer is easily formed, AO dimer can be bound to the ionized carboxyl groups of PLGA. At higher concentrations, however, Eq. (2) seems to be more reasonable; if it holds, the binding of the AO dimer would be reduced. The change in the ellipticity of the CD band at 520 nm can be explained as follows. From the correlation between the positions of the absorption bands of the AO dimer, it can be demonstrated that the CD band at 520 nm is

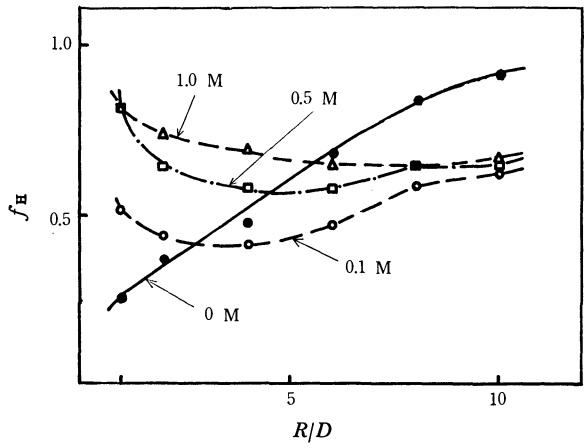

Fig. 5. R/D dependence of helix fraction (f_H) of PLGA in PLGA–AO system at various KCl concentrations (pH=4.5, [AO]=2×10^{-5}M).

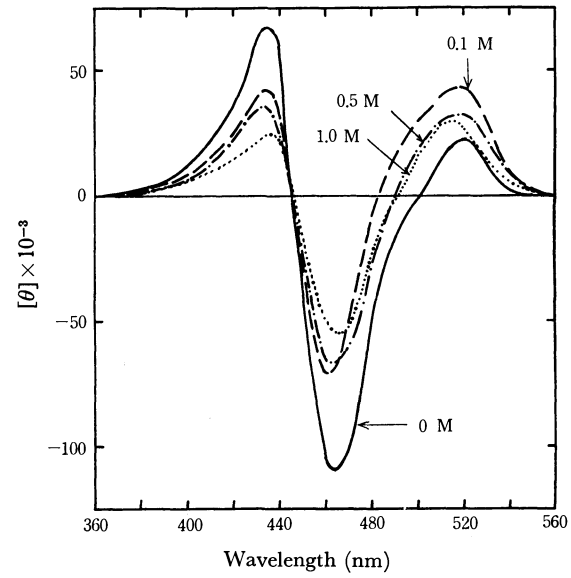

Fig. 6. CD spectra of PLGA–AO system at various KCl concentrations (R/D=10, pH=4.5, [AO]=2×10^{-5}M).

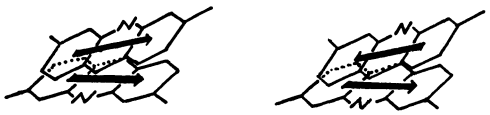
15) E. Iizuka and J. T. Yang, *Biochemistry*, **4**, 1249 (1965).

due to the binding of the dimeric AO molecule to the isolated site in an asymmetric environment of PLGA. Thus, the positive CD band at 520 nm can be ascribed to the Cotton effect originating from the AO dimer bound to PLGA. This assumption is consistent with the information obtained from the electronic spectrum of the AO dimer.[12,16,17]



(a) (b)

Fig. 7. AO dimer on PLGA–AO complex. The arrows are direction-pair of the monomer transition dipoles.

The dimer spectrum of the AO molecule has two peaks, a strong one at about 465 nm and a weak one at about 510 nm, which can be explained in terms of the simple exciton theory.[18] The stronger band at the shorter wavelength can be assigned to an allowed transition, and the weaker band at the longer wavelength, to a forbidden transition. When AO molecules in the dimer state are oriented at small angles to each other in binding to PLGA, an optical activity is induced and the CD band arising from the dimer on PLGA may split into two components, having signs opposite to each other.

In the staggered conformation for the dimeric AO, we can consider two modes for the direction-pair of the monomer transition dipoles: (a) the directions of the monomer transition dipoles are the same, and (b) the directions of the monomer transition dipoles are opposite to one another. In the case of (a), a negative CD band arises at a shorter wavelength, whereas a positive CD band arises at a longer wavelength in the case of (b). The weak negative dichroism, concealed under the larger negative CD band, can be expected at a shorter wavelength, besides a positive dichroism at 520 nm.

Yamaoka and Resnik[11] proposed that the induced Cotton effects could arise from the dye monomers bound near the asymmetric carbon atoms in polypeptide in the case of very large R/D values. Under these conditions, the Cotton effects may be induced mainly by an interaction between dyes in the monomeric state on PLGA, since the aggregation of dye on the polymer is not plausible. On the other hand, in the case of smaller R/D values the Cotton effects may be induced mainly by an exciton interaction between dye dimers bound to PLGA.

The Structure and Reactivity of Nickel Hydroxide

Masao SAKASHITA and Norio SATO

Electrochemistry Labolatory, Faculty of Engineering, Hokkaido University, Sapporo 060

(Received October 4, 1972)

This paper examines the correlation between the structure and the reactivity of nickel hydroxide, using X-ray diffraction, DTA, IR spectroscopy, and gravimetry during dehydration. The degree of crystallization of β-nickel hydroxide depends on the preparation conditions of the hydroxide. Highly-crystallized β-nickel hydroxide has "free" hydroxyl groups, as is to be expected from its brucite structure. Poorly-crystallized β-hydroxide, however, has "hydrogen-bonded" hydroxyl groups, this finding is in disagreement with a previous result that "hydrogen-bonded" hydroxyl groups were found to exist only in α-form nickel hydroxide. The dehydration of the hydroxide is shown to take place in first-order kinetics with an activation energy which increases as the crystallization extends.

Nickel hydroxide and nickel oxide are produced during the corrosion of nickel and constitute surface-oxide film.[1] Nickel hydroxide is also used as an active material for the positive electrode of a nickel-cadmium battery. Many attempts have been made to determine the structure of nickel hydroxide,[2-6] and it has been proposed that nickel hydroxide exists in the α-form and the β-form. The α-nickel hydroxide contains crystallized water with "hydrogen-bonded" hydroxyl groups, while the β-form hydroxide contains no excess water and has "free" hydroxyl groups with no hydrogen-bond. McEwen,[7] however, found, by using electron microscopy and diffraction, that the α-form nickel hydroxide proposed by Bode can not exist. In

spite of the many results reported, the structures and the reactivities have not been established exactly.

This paper will examine the correlation between the structures of nickel hydroxide prepared under several conditions and the dehydration kinetics by using the X-ray diffraction, DTA, IR, and gravimetry.

Experimental

Materials. Four types of nickel hydroxide powders were prepared from nickel nitrate and ammonia water under the conditions described below.

Sample *a* was a fresh hydroxide prepared by mixing 0.2 M $Ni(NO_3)_2$ with 0.2 M NH_3H_2O at room temperature; it was washed by water immediately after precipitation, Sample *b* was prepared under the same conditions except for the solution being 1.0 M NH_3H_2O and the temperature of preparation being 60~70 °C. Samples *c* and *d* were prepared by aging Sample *b* at 30 °C for 24 hr (Sample *c*) and 35 days (Sample *d*).

All of the precipitated nickel hydroxides were dried in a vacuum of 10^{-2} mmHg at 110 °C for 4 hr after having been dried in a desiccator over silica gel in 20 mmHg for 2 days. The sample was ground (200 to 300 mesh) and calcinated in a vacuum at 110 °C before measurements.

The specific surface area of each sample was determined by the BET method using N_2 gas adsorption; the values are listed in the first column of Table 1.

Table 1. Characteristics of nickel hydroxide samples

Sample	Specific surface area m^2/g	Mean particle diameter Å	Total weight loss % (w/w)	E_a [a] kcal/mol
a	59	150	20.2	20
b	45	420	19.5	30
c	31	650	19.0	33
d	30	700	19.2	49

a) Activation energy in dehydration reaction.

X-Ray Diffraction. The samples were examined by the powder method with Cu*Kα* radiation. As the diffractometer a Geigerflex 2030/P apparatus (Rigaku Denki Co., Ltd.) was used. The mean particle diameter was calculated approximately by the line-broadening method, referring to highly pure silicon as the standard.

Differential Thermal Analysis (DTA). The DTA of nickel hydroxide which had been preheated in 10^{-3} mmHg at 110 °C was carried out in air, using Al_2O_3 as the standard. A thermoflex 8001 apparatus (Rigaku Denki Co., Ltd.) was used, and the rate of heating was 10 °C/min.

IR Spectroscopy. Disks transparent to infrared radiation were prepared by pressing nickel hydroxide to about 10 ton/cm^2. Their thicknesses were between 0.03 and 0.05 mm. The disks were then placed in an IR cell with sodium chloride windows and could be connected with a conventional high-vacuum system. The spectra were taken at room temperature after treatment at the desired temperatures using a Hitachi grating spectrometer, IR-G2.

Dehydration of Nickel Hydroxide. The weight loss during the dehydration of the hydroxide, which had been dried in a vacuum at 110 °C for 1 hr, was measured gravimetrically by using a quartz spring balance placed in a quartz tube and a cathetometer (0.01 mm=0.0392 mg) under isothermal and isobaric conditions, with air provided, in 40 mmHg. The weight loss measured was then corrected by taking the buoyancy effect into account; its magnitude was separately measured with anhydrous nickel oxide. In order to reduce the pressure change caused by the water vapour produced during the dehydration, silica gel was placed in a drying tube connected to the spring balance system. The temperature was measured outside a quartz tube placed in a furnace and was controlled within an accuracy of ±1 °C. The total weight loss in the dehydration was checked in a vacuum at 400 °C.

Results and Discussion

Structure of Nickel Hydroxide. It has been reported in the literature[5,8] that the α-form nickel hydroxide can be prepared by precipitation in a mixture of nickel nitrate and diluted ammonia water at temperatures lower than 25 °C and that the β-form can be formed by mixing nickel nitrate with concentrated ammonia water at temperatures above 60 °C.

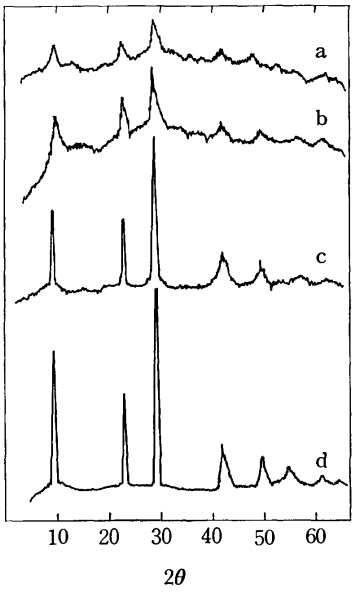

Fig. 1. X-Ray diffraction patterns of nickel hydroxide (sample *a* to *d*)

Since the α-form hydroxide proposed by Bode[3] is markedly different from the β-form, it is possible how to identify the crystal form. The conditions under which Sample *a* was prepared seem to coincide with the conditions of preparing the α-form given by the literature.[5,8] All the nickel hydroxide prepared in this work, however, shows the pattern of the β-form in the X-ray diffraction, as is shown in Fig. 1. It may also be seen in Fig. 1 that, as the crystallization extends, the X-ray diffraction pattern becomes sharp for the β-form from Samples *a* to *d*. The crystallization of nickel hydroxide is seen to increase as the concentration of ammonia in the solution for precipitation increases, as the temperature of precipitation rises, and as the aging of the hydroxide extends. The mean particle diameters of the four samples are listed in the second column of Table 1.

8) H. Bode, K. Dehmelt, and J. Witte, *Z. Anorg. Allg. Chem.*, **366**, 1 (1969).

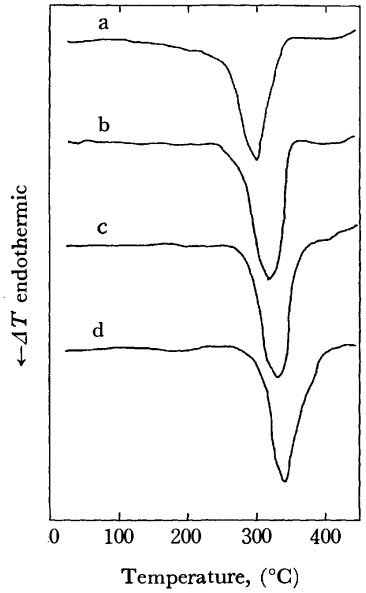

Fig. 2. DTA of nickel hydroxide dried in 10^{-2}mmHg at 110 °C for 4 hr.

The DTA curves of four samples are shown in Fig. 2. For all samples, one endothermic peak due to the dehydration is observed between 200 and 400 °C. This indicates that the nickel hydroxide, in which physically-adsorbed water is dehydrated in a vacuum at 110 °C, contains only one kind of water species to be dehydrated. The rate of the dehydration of highly-crystallized nickel hydroxide is expected to be small, because the temperature of the peak is shifted to a higher temperature in the order from Samples *a* to *d*, that is, in the order of crystallization.

The dehydration phenomenon shown in the DTA curves in Fig. 2 is coincident with the weight loss of Samples *a* and *c* during the nonisothermal dehydration shown in Fig. 3, in which the weight loss was measured as the temperature rose at the rate of 5 °C/min in air at 40 mmHg. In Fig. 3, α represents the dehydration ratio referred to the total weight loss. Since the total weight loss in reference to the initial weight shown in the third column of Table 1 is 19~20% (w/w) and is nearly equal to 1 mol% of water for all samples, it seems that the excess water or bound water previously

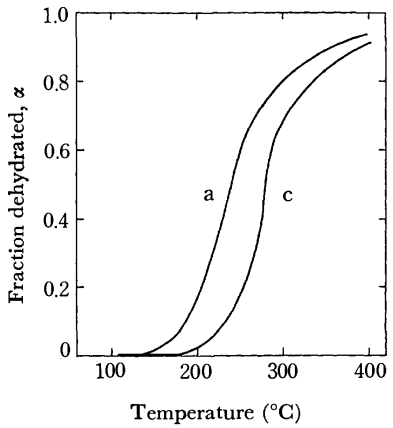

Fig. 3. Weight loss with dehydration of nickel hydroxide (sample a and c)

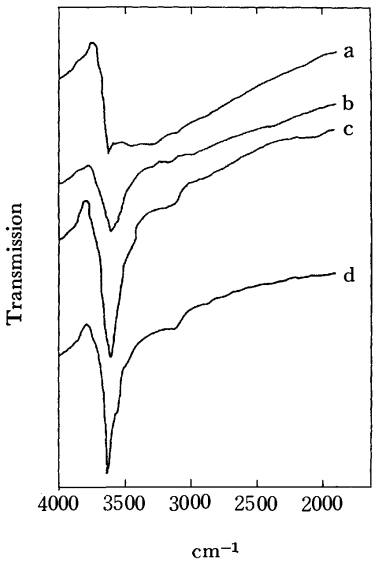

Fig. 4. IR spectra of nickel hydroxide dried in 10^{-5}mmHg at 25 °C.

observed in ferric oxide[9] is not present in nickel hydroxide.

The IR spectra of four samples in the range between 4000 and 2000 cm^{-1} are shown in Fig. 4. The bands due to the antisymmetric stretching of the hydroxyl group broaden in the order from Samples *d* to *a*. This indicates that Sample *a* has a hydroxyl group "hydrogen-bonded," while Sample d has a nearly "free" hydroxyl group at 3620 cm^{-1}. Samples *b* and *c* have an intermediate hydroxyl group between Samples *a* and *d*.

The variations in the IR spectra of Samples *a* and *d* with the temperature of the heat treatment above 100 °C in 10^{-5} mmHg for 1 hr are shown in Figs. 5 and 6. It may be seen in Fig. 5 that the hydroxyl

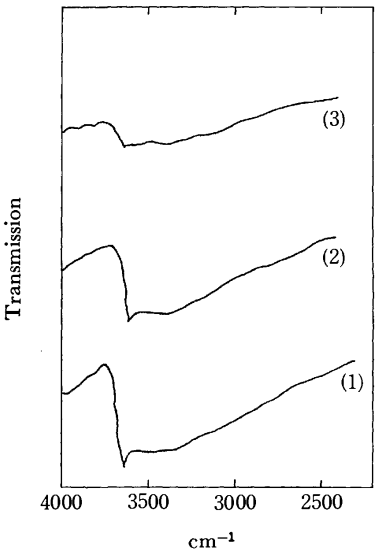

Fig. 5. Variations of IR spectrum of nickel hydroxide (sample a) with calcination in 10^{-5}mm Hg for 1 hr; (1) 110 °C, (2) 150 °C, (3) 200 °C.

9) R. Furuichi, N. Sato, and G. Okamoto, *Chimia*, **23**, 455 (1969).

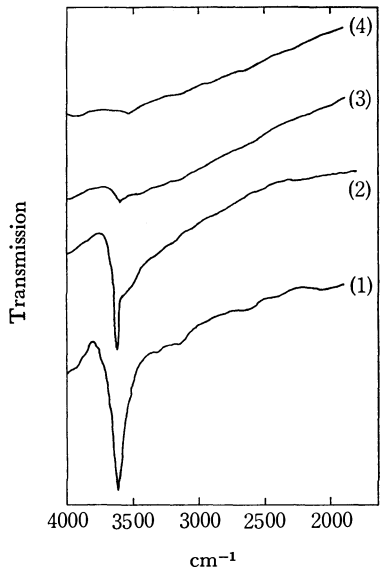

Fig. 6. Variations of IR spectrum of nickel hydroxide (sample d) with calcination in 10^{-5}mmHg for 1 hr; (1) 110 °C, (2) 200 °C, (3) 250 °C, (4) 300 °C.

group in Sample *a* is hydrogen-bonded not only in the initial state, but also in partially-dehydrated states. As Fig. 6 shows, Sample *d* has the "free" hydroxyl group in the partially-dehydrated states as well as in the initial state. As has already been discussed, the samples of nickel hydroxide used in this work were all of the β-form, as is indicated by the X-ray diffraction and by the fact that no excess water was present. In the brucite structure of β-form, it is structually impossible to form a hydrogen bond between hydroxyl groups. The hydrogen bond present in Sample *a* may, therefore, be attributed to the formation of a hydrogen bond between hydroxyl groups on the surface of crystallite.

At any rate, it is a fact that the hydrogen-bonded hydroxyl group exists in poorly-crystallized β-form nickel hydroxide; hence, a hydrogen bond is not always the characteristic of the α-form. It should also be noted that the bonding state of the hydroxyl group in each sample does not change during the dehydration, as is shown in Figs. 5 and 6.

Dehydration Kinetics. The overall dehydration reaction that was measured by the weight loss may be written by:

$$Ni(OH)_{2(solid)} \longrightarrow NiO_{(solid)} + H_2O_{(gas)} \quad (1)$$

and the normalized rate equation, by:

$$F(\alpha) = F(\alpha=0.5)t/t_{0.5}, \quad (2)$$

where α is the fraction of water dehydrated in time t and where $t_{0.5}$ is the time required for 50% dehydration. $F(\alpha)$ can be theoretically derived by assuming the reaction mechanism proposed by many workers for several solid-state reactions.[10-12]

As is shown in Fig. 7, all the dehydration data for the four types of nickel hydroxide conformed to the

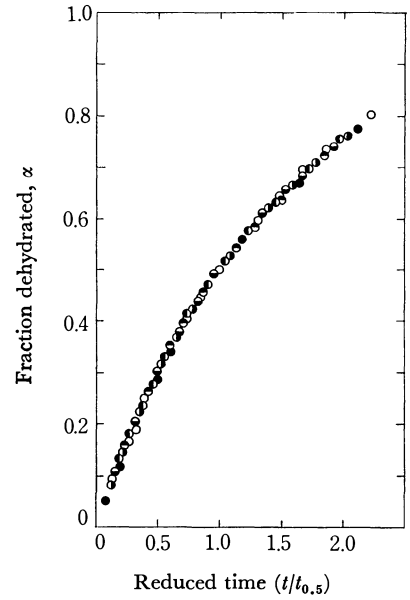

Fig. 7. Fraction dehydrated, α, *versus* reaction time, $t/t_{0.5}$, in reference to the time for 50% dehydration of nickel hydroxide in 40 mmHg air at 225 °C (●) for a sample a, at 242 °C (○) for sample b, at 245 °C (◐) and 268 °C (◑) for sample c, at 243 °C (◒) and 250 °C (◓) for sample d.

same curve of α *vs.* $t/t_{0.5}$. This indicates that the same reaction mechanism operates in all the samples examined.

If the reaction is controlled by a diffusion in the solid, one obtain this equation: $D_1(\alpha)=\alpha^2=0.25\times t/t_{0.5}$, for one-dimensional diffusion and this equation: $D_3(\alpha)=[1-(1-\alpha)^{1/3}]^2=0.0426\times t/t_{0.5}$, for three-dimensional diffusion. In the case of phase-boundary controlled reactions, one has this equation: $R_2(\alpha)=1-(1-\alpha)^{1/2}=0.293\times t/t_{0.5}$, for a two-dimensional reaction and this equation: $R_3(\alpha)=1-(1-\alpha)^{1/3}=0.206\times t/t_{0.5}$, for a three-dimensional reaction. If the dehydration process occurring in the particle is the limiting step, the de-

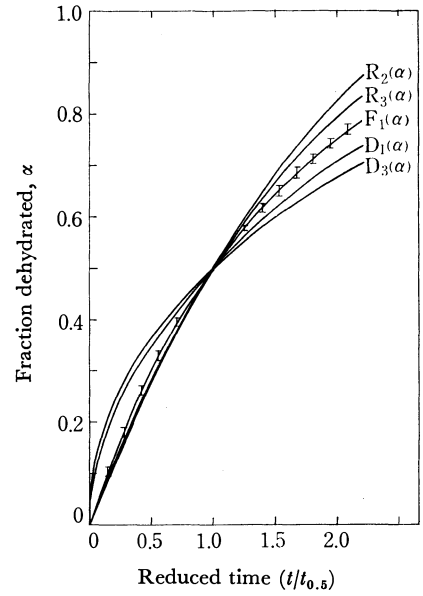

Fig. 8. Comparison of observed values, indicated by vertical line segment, with calculated α versus $t/t_{0.5}$ relation for various dehydration mechanisms.

10) R. E. Carter, *J. Chem. Phys.*, **34**, 2010 (1961).
11) E. A. Giess, *J. Amer. Ceram. Soc.*, **46**, 374 (1963).
12) J. H. Sharp, G. W. Brindley, and B. N. N. Achar, *ibid.*, **49**, 379 (1966).

hydration is of the first-order kinetics represented by this equation: $F_1(\alpha)=\ln(1-\alpha)=-0.693\times t/t_{0.5}$. The α and $t/t_{0.5}$ for each mechanism calculated are compared with the experimental results in Figs. 7 and 8. All the experimental data are seen to be in good agreement with $F_1(\alpha)$. Accordingly, the first-order reaction mechanism is operative.

Another mechanism has been proposed by Hazell *et al.*,[13] who examined the thermal decomposition of iron(II), cobalt(II), and nickel(II) hydroxides and assumed a phase-boundary reaction mechanism in the range of α less than 0.6. The first-order kinetics, however, is valid not only in the $\alpha<0.6$ range, but also in the $\alpha>0.6$ range.

The first-order kinetics assuming that the dehydration extends in the bulk of crystals is also supported by the electronmicrographical finding[14] which shows the hexagonal crystal form of the original nickel hydroxide to remain in the partially-dehydrated state. If the diffusion mechanism operated, there would be some diffusing water or hydrated hydroxyl groups in the bulk of the crystals and, hence, the IR spectrum would show a broadening peak in the partially-dehydrated state. Since the IR spectrum of Sample *d* shown in Fig. 6, however, has a sharp peak of the "free" hydroxyl groups in the partially-dehydrated state, it seems that the diffusion is unlikely to limit the reaction rate.

The Arrhenius activation energies for the four types of nickel hydroxide are listed in the fourth column in Table 1.

The table indicates that the activation energy also increases with the degree of crystallization. All the activation energies are seen to be larger than the heat of dehydration of nickel hydroxide, $\Delta H^\circ=12.4$ kcal/mol, a finding which is in agreement with the usual conception.

Conclusion

Nickel hydroxide samples prepared from nickel nitrate and ammonia water in the range of concentration from 0.2 to 1.0 M at temperatures between 20 and 60 °C are all β-form, in disagreement with the work of Bode. The more extended crystallization results from the more concentrated ammonia solution, the higher temperature of precipitation, and the more extended time of the aging of the precipitates.

The β-nickel hydroxide contains, in addition to the physically-adsorbed water, only one kind of water which exists in the form of hydroxyl groups corresponding to an endothermic peak in DTA between 200 and 400 °C. The endothermic peak shifts to higher temperatures as the degree of the crystallization rises.

The hydroxyl group of β-nickel hydroxide is "free" in the highly-crystallized particle, but "hydrogen-bonded" in the poorly-crystallized particle.

The dehydration reaction of nickel hydroxide is represented by a first-order reaction mechanism, with an activation energy which increases with the extent of crystallization.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1987—1990 (1973)

Crystal Structure of the Potassium Salt of Chloranil

Michiko KONNO, Hayao KOBAYASHI, Fumiyuki MARUMO, and Yoshihiko SAITO
The Institute for Solid State Physics, The University of Tokyo, Roppongi 7, Minatoku, Tokyo 106
(Received October 23, 1972)

The crystal structures of K^+(chloranil)$^-$ have been studied by X-ray diffraction. Several polymorphs were recognized, two of which (α- and β-forms) grew into comparatively good crystals. The α-form is orthorhombic, space group $P2_12_12_1$ with unit cell dimensions: $a=13.49$, $b=17.02$, $c=4.03$ Å. The β-form is orthorhombic, space group $P22_12$ with unit cell dimensions: $a=14.13$, $b=17.35$, $c=3.71$ Å. The structure of the α-form was deduced from the Patterson synthesis and refined by the block-diagonal least-squares method. The final R value was 0.13 for 146 observed reflections. Chloranil anions are stacked with equal intervals in the crystal, forming columns parallel to the c axis, the interplanar spacing being 3.47 Å. The electrostatic energy calculated by Evjen's method was about -148 kcal/mol, indicating that the structure is essentially ionic.

The magnetic, optical and electronic properties of chloranil anion radical (CA^-) salts of alkali metals[1-5] have been extensively studied in an effort to obtain information on the electronic structures of these radical salts. It is of interest that the absorption spectra of Li^+CA^- and Na^+CA^- greatly differ from those of K^+CA^- and Rb^+CA^-. The two former salts show a strong intermolecular charge-transfer band in the near infrared region and a blue shifted band originating from the monomer band in the visible region, whereas the latter salts show a weak charge-transfer band in the

near infrared region and a band quite similar to the anion radical monomer band. This seems to indicate stronger charge-transfer interaction between the anion radicals in lithium and sodium salts than in potassium and rubidium salts. A knowledge of the crystal structure is highly desirable for understanding the difference between the electronic structures of these radical salts. The crystal of K^+CA^- has been subjected to X-ray crystal analysis as a part of our systematic studies on the radical salts.

Experimental

Dark green crystals of K^+CA^- were grown from an acetone solution by the diffusion method according to Torrey and Hunter.[6] The shape of the crystals depends on the conditions of growing. Sometimes they are needle-like and sometimes platy. Several polymorphs were recognized from X-ray diffraction patterns, two of which (referred to as α- and β-forms) were orthorhombic and had comparatively good crystallinity. The structure of the α-form was determined in the present study. The cell dimensions and possible space groups were obtained from oscillation and Weissenberg photographs. Since the c axis is very short in both modifications, it is impossible to decide whether the systematic absences observed for $00l$ reflections were due to the space group symmetries of crystals or merely due to an accidental extinction. Important crystallographic data are given in Table 1. A crystal with the dimensions $0.04\times0.38\times0.15$ mm^3 was used for the intensity measurements of the α-form. Equi-inclination Weissenberg photographs were taken around the b axis (0th to 7th layer) and around the c axis (0th and 1st layer), utilizing the multiple film technique with Cu$K\alpha$ radiation. The intensities were estimated visually with a calibrated intensity scale. Accuracy of the measurements was bad, the diffraction spots being markedly diffuse owing to poor crystallinity of the specimen. In total, intensities of only 146 independent reflections could be collected. The usual Lorentz, polarization and spot shape corrections were applied, but no corrections were made for absorption.

TABLE 1. CRYSTALLOGRAPHIC DATA OF α- AND β-MODIFICATION OF K^+CA^- CRYSTALS

Chemical formula Crystal system	α $KC_6O_2Cl_4$ Orthorhombic	β $KC_6O_2Cl_4$ Orthorhombic

D_c	2.04 g·cm^{-3}	2.08 g·cm^{-3}

Structure Determination of the α-Form

Three-dimensional Patterson maps were synthesized. The space groups $P2_12_12_1$ and $P2_12_12$ can be distinguished by examining the peak distribution in the Patterson maps. The space group $P2_12_12_1$ was found to be the true space group of this crystal. The positions of chlorine atoms were derived from the Patterson maps with the aid of the known molecular structure of chloranil.[7] All the remaining atoms were located from successive Fourier and difference Fourier syntheses. The structure was refined by a block-diagonal least-squares program HBLS-IV due to Dr. Ashida, assigning anisotropic temperature factors to Cl and K atoms and isotropic temperature factors to all the remaining atoms. The weighting scheme used was $w=1.0$ for $F_0\geq20.0$ and $w=0.5$ otherwise. The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[8] The final R-value was 0.13 for 146 observed reflections. The final atomic parameters are given in Table 2 with their standard deviations. The observed and calculated structure factors are compared in Table 3.

Description of Structure and Discussion

The structure viewed along the b and c axes is presented in Figs. 1(a) and (b), respectively. Chloranil anions are planar and stacked with equal intervals,

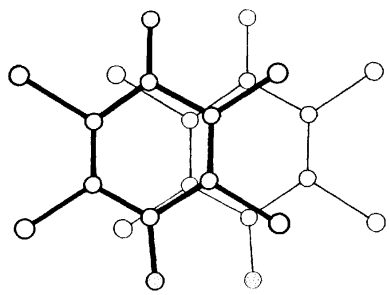

Fig. 2. Nearest-neighbor packing within the column of CA^- anions. Direction of view is perpendicular to the molecular plane.

forming columns parallel to the c axis. These columns are held together through K^+ ions. Since chloranil anions are inclined at an angle of 30° with respect to (001), an anion does not fall exactly upon the adjacent one in the same column when the structure is viewed perpendicularly to the molecular plane (Fig. 2). The least-squares plane through the atoms of anion is

$$0.468x + 0.190y + 0.863z = 4.35$$

where x, y, and z are coordinates in Å units referred to the crystal axes a, b, and c, respectively. The interplanar spacing is 3.47 Å. Intermolecular atomic distances are given in Fig. 1(a). Bond distances and angles within an anion are shown in Fig. 3. Since the number of observable reflections is small, the

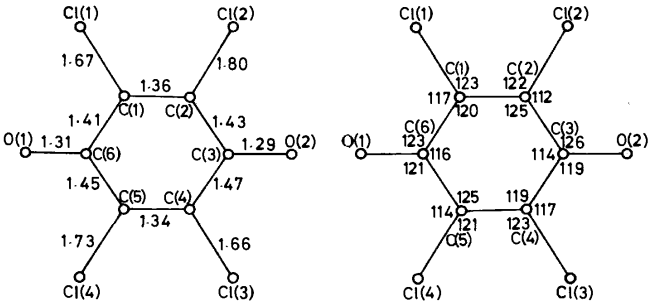

Fig. 3. Bond lengths(Å) and bond angles(degrees) within CA^- anion.

estimated standard deviations are extremely large: 0.22 Å for C–C, 0.19 Å for C–O, 0.16 Å for C–Cl. Thus it may not be practicable to discuss the interatomic distances and bond angles in detail. The average distances of chemically equivalent bonds are 1.35 Å for C=C, 1.44 Å for C–C, and 1.30 Å for C–O. Bond distances of C=C, C–C, and C–O in a chloranil anion were deduced by Iida[9] from infrared absorption spectra to be 1.37, 1.45, and 1.31 Å, respectively. The observed values of C=C, C–C, and C–O are in good accordance with these values. The K^+ ion lies at the center of a rectangle formed by two O(1) and two O(2) atoms related by c translation, respectively. The K–O distances are in the range 2.58—2.68 Å (Fig. 1(b)).

The structure does not contain dimeric CA^- anions, and the overlap between two adjacent CA^- anions in the column is rather small as shown in Fig. 2. This is in line with the spectroscopic study of this anion radical salt in crystals.

Electrostatic interactions seem to play the most important role in this anion radical salt. For the sake of confirmation, the electrostatic energy was calculated by Evjen's procedure.[10] The structure was divided into electrically neutral shells in the form of a rhombus as indicated in Fig. 4, which shows the structure of the α-form viewed along the a axis. Centers of CA^- anions drawn with solid lines are at the same level as K^+ ions with solid circles, while those drawn with broken lines are shifted by $a/2$ with respect to those drawn with solid lines. The charge of CA^- anion was assumed to be located equally at the two oxygen atoms. This assumption was supported by the theoretical calculation by Giacometti.[11] The electrostatic energy of K^+ ions and anions in each shell was calculated in the usual way. The summation of the energy converged quickly, giving a value of −148 kcal/mol. This amounts to 3/4 of the electrostatic energy of NaCl crystal and is much greater than the contributions of the van der Waals energy, charge-transfer energy, *etc.* The arrangement of K and O atoms appears to be determined mainly by electrostatic energy. When positions of two O atoms in a CA^- anion are fixed in the structure, freedom of rotation remains around the line joining the two O atoms for the anion molecule. The optimum orientation of the anion molecule was estimated for the α-form by adopting the following form for the potential energy V due to the van der Waals and repulsive forces.

$$V = \sum_i \sum_j \left(\frac{a_{ij} \exp(-b_{ij} r_{ij})}{r_{ij}^{d_{ij}}} - \frac{c_{ij}}{r_{ij}^6} \right)$$

where r_{ij} is the distance between the i-th atom in a CA^- molecule and the j-th atom in the neighboring molecules, and a_{ij}, b_{ij}, c_{ij}, and d_{ij} are the constants depending on atomic species, the values tabulated by De Santis *et al.*[12] being given. The summation for i is taken over all atoms in the CA^- molecule under consideration and that for j is taken over atoms in all the 16 neighboring molecules. During the calculation, the shape of the molecule and the symmetry of the crystal were conserved. The structure was calculated to be most stable when the molecular plane makes an angle of 34° with the (001) plane as illustrated in Fig. 5. This is in good agreement with the experimental value of 30°.

(Received October 24, 1972)

The radical pair system of a stable free radical, di-*p*-anisyl-nitric-oxide (DANO), has been observed in the magnetically-diluted crystal of 4,4-dimethoxy-benzophenone. The existence of the radical pair has been ascertained by the characteristic ESR absorptions, which give rise to the zero-field splitting and half-field resonance, of the powdered sample as well as by a comparison of the magnitude of the hyperfine coupling constant of the isolated radical with that of the pair system. The precise ESR measurements were performed using a single crystal containing 7.5% DANO radicals oriented well in the diamagnetic matrix. The fine structure parameters, $|D|$ and $|E|$, have been determined to be 186 Gauss and 2 Gauss respectively, from which the distance between the two radical molecules in the pair system is estimated to be 5.4 Å. In order to deduce the structures of the radical pair, the *g*-value and the hyperfine coupling constant of the isolated radical have also been determined.

Paramagnetic entities diluted in the crystals have been fruitfully investigated by electron spin resonance (ESR) techniques in order to gather information on the structures and magnetic properties of solids. Many of these works are concerned with the color center or with the radiation damage in diamagnetic matrix crystals, and some authors have studied the stable radicals in the matrix.[1–3] One of the present authors (Y.D.) has reported on the ESR measurement of the organic stable radical, diphenyl-nitric-oxide (DPNO), in a diamagnetic matrix crystal of benzophenone.[1] Analyzing the dependence of the line shape on the radical concentration, he elucidated the property of an exchange interaction between neighboring radicals and discussed the effects of exchange narrowing in the concentrated radical solid. He has also found that, in the very diluted radical crystal, the exchange interaction is so weak that the ESR line-width broadening is attributable dominantly to the dipolar interaction between two radicals. Griffith *et al.* established experimentally an exact and approximate method for determining the $\tilde{g}$- and hyperfine-tensors of the nitroxide free radical, di-*tert*-butyl-nitric-oxide.[2]

On the other hand, the triplet states of radical pairs in the irradiated organic crystals and polymers have been found by many authors.[4,5] By determining the $\tilde{g}$-tensors and the fine and hyperfine splitting tensors of the radical pair in the X-ray-irradiated single crystal of dimethyl-glyoxime at the temperature of liq. N_2, Kurita has elucidated the position of the radiation damage in the molecule and clarified the tructures of the radical pairs formed between the two neighboring molecules.[4]

The ESR of the triplet state has been utilized for the analysis of the magnetic properties of solids after the work of Bleany and Bowers.[6] One such study has been of the triplet state in the crystal of anion radical salt of 7,7,8,8-tetra-cyanoquinodimethane (TCNQ) reported by Chesnut *et al.*, who have observed the mobile triplet exciton.[7] From the analysis of the temperature dependence of the signal intensity, they have also determined the magnitude of a singlet-triplet energy separation, which is in fairly good agreement with the results of some other magnetic measurements.

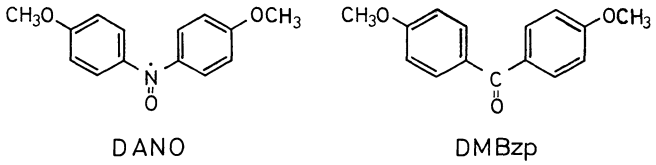

Fig. 1. Molecular structures of the radical and diamagnetic matrix.

In the present work we observed the "radical pair" of a stable free radical DANO diluted in a diamagnetic matrix crystal in order to discuss the structures and properties of DANO radical pairs. The diamagnetic matrix carefully chosen was 4,4-dimethoxy-benzophenone (DMBzp), in which the radical molecules are considered to be uniformly oriented. From the angular dependence of the ESR spectra of the radical pairs and the isolated radicals, the magnitude of the dipolar interaction is estimated and the structure of the radical pair in the diamagnetic matrix is clarified. We will discuss only the sample with a 7.5% radical concentration, the concentration dependence of the ESR spectrum will also be discussed in the last part of this paper.

Experimental

The DANO radical was synthesized by the method of Meyer *et al.*[8] After the recrystallization from ether, the

radical and DMBzp were dissolved together in an acetone–ethanol mixed solvent. The sample crystals were obtained by recrystallization from a slow evaporation of the solvent. The radical concentration was determined by a precise ultimate analysis of the amount of nitrogen in the sample. The appearance of the mixed crystal was greatly dependent on the radical concentration. In the concentrated region, the single crystal could not be grown well; it formed only a thin, plate-like feather.[9] In the low-concentration region (especially less than 10% concentration) well crystallized samples like needles or oblique prisms were obtained. The simplicity of the ESR spectra obtained from these crystals indicate that the radical molecules are almost uniformly mixed with the matrix molecules.

The DMBzp single crystal containing 7.5% DANO radicals was grown in the form of a mono- or triclinic prism. As the crystallographic study has not yet been done, a rectangular coordinate system, a, b, and c, was defined for convenience from its shape. The c axis was selected parallel to the long edge, and the a axis, normal to the well-developed face. One of the single crystals is shown in Fig. 2, with a, b, and c axis.

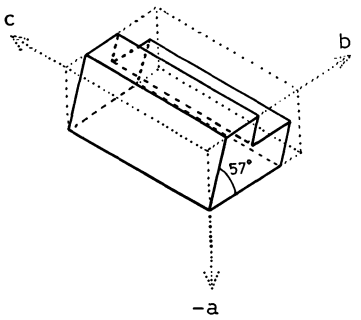

Fig. 2. A sketch of a single crystal of DMBzp containing 7.5% DANO radical. a, b, and c indicate a rectangular coordinate system adopted in the present paper.

The ESR measurements were carried out using a X-band spectrometer ME3X of JEOLCO at room temperature. The angular dependence of the ESR spectra was obtained by rotating the crystal around the a, b, or c axis, which is set perpendicular to the magnetic-field direction. The magnetic field was calibrated by the hyperfine splittings of Mn^{2+} doped in MgO and of the peroxylamine-disulfonate ion,[10] as well as by the signal of DPPH (g=2.0036).

Results

ESR Spectrum of Powdered Sample. The ESR spectrum in the g=2 region (near 3300 Gauss) is shown in Fig. 3a). In addition to a sharp absorption due to isolated radicals in the matrix, there exist a pair of broad peaks separated by about 185 Gauss and some other feeble and broad absorptions in both the higher and lower external fields. The side peaks are regarded as the triplet absorptions due to radical pairs, and so the zero-field splitting parameters, $|D|$ and $|E|$, are evaluated as 185 and 0 Gauss respectively by the method of Wasserman *et al.*[11]

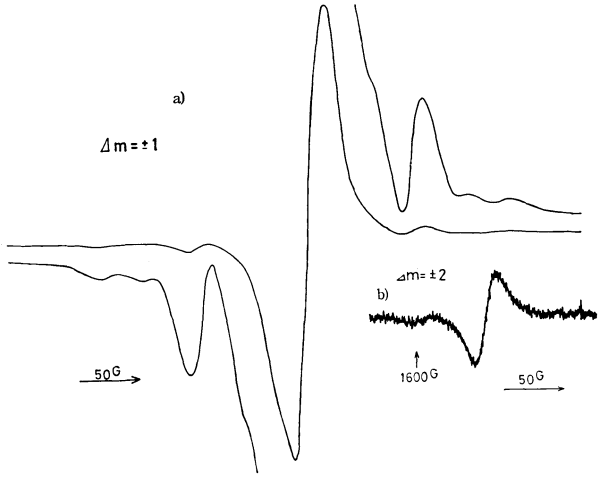

Fig. 3. a) ESR spectrum of the powdered sample of diluted DANO radical, b) $\Delta m_s = \pm 2$ transition spectrum of powdered sample.

The absorption near g=4 (1650 Gauss) shown in Fig. 3b) is the characteristic triplet absorption due to the $\Delta m_s = \pm 2$ transition. This forbidden transition was observed under the conditions of about a 100-times higher ESR spectrometer gain than that for the allowed triplet absorption, $\Delta m_s = \pm 1$ in Fig. 3a).

ESR Spectra from Single Crystal. Some of the typical ESR spectra of the single crystal are shown in Fig. 4. In (a) a pair of absorptions can be seen, one on each side of the central peak. Some other pairs of absorptions which are hidden in (a) appear in (b). When the hyperfine (hf) splitting of the central peak becomes large in some field directions, the absorptions at both sides split further into several peaks, as

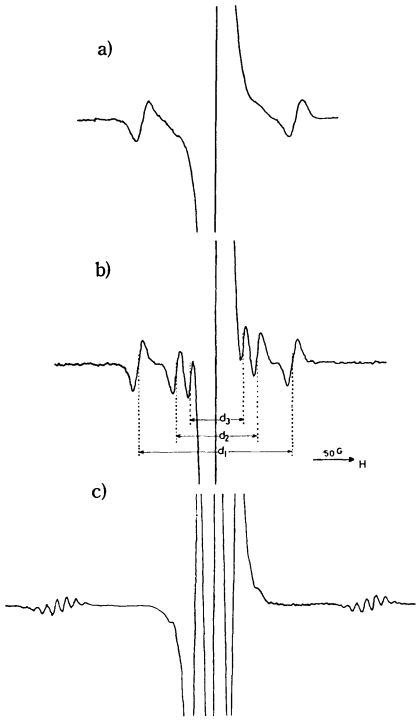

Fig. 4. Some of the ESR spectra of a single crystal of diluted DANO radical. The spectra are explained in the text. a) a//***H***, b) b//***H***, c) c//***H***.

is sohwn in (c). These can be attributed to the hf structure of two nitrogen nuclei in triplet-state radical pairs. This explanation is also supported by the fact that the splitting width of the side peaks is about half as wide as that of the central peak. The observed splittings due to the zero-field interaction are denoted by d_1, d_2, and d_3 in Fig. 4b).

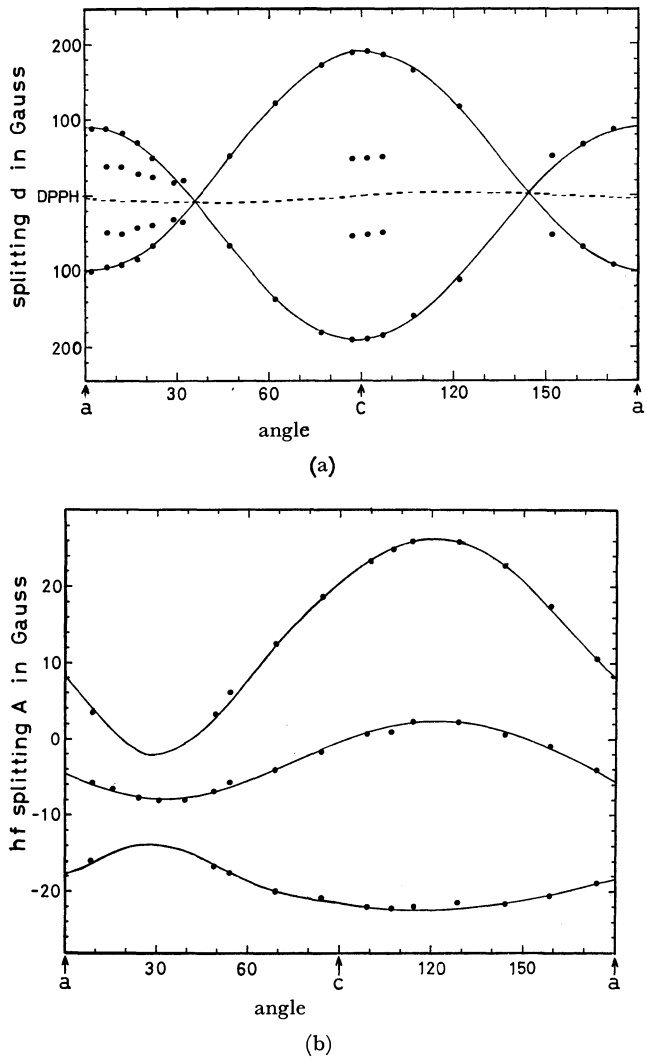

Fig. 5. Angular variation of the spectral line position in the ca plane. The position are measured from the absorption of DPPH.
a) Doublet splittings due to radical pair.
b) Nitrogen hf splittings of isolated radical.

The angular dependences of d_1 and d_2, as measured with the external magnetic field, H, in the ac plane, are shown in Fig. 5a). The nitrogen hf splitting and the g-value (denoted as g_{isol}) of the isolated radicals in the matrix, measured on the same plane, are also shown in Fig. 5b). The well-separated structures of the central peak and the simple angular variation in the hf structure parameter and g_{isol} indicate that the $\tilde{\boldsymbol{g}}$- or $\tilde{\boldsymbol{A}}_N$-tensor has the same principal axes and principal values for all radicals in the matrix.

The d_1 of the triplet-state absorption as well as the g_{isol} and hf parameters of the isolated radicals are also discussed.

Discussion

Two-spin System. In order to analyze the zero-field splittings observed, we can introduce the spin Hamiltonian of the triplet state of the radical pair, assuming that the principal axes of the $\tilde{\boldsymbol{g}}$-tensors of the two radicals are common;

$$\boldsymbol{H} = \beta \boldsymbol{H}\cdot\tilde{\boldsymbol{g}}\cdot\boldsymbol{S} + \boldsymbol{S}\cdot\tilde{\boldsymbol{D}}\cdot\boldsymbol{S} \quad (1)$$

where $\boldsymbol{S}=\boldsymbol{S}^{1}+\boldsymbol{S}^{11}$ and where the subscripts 1 and 11 indicate the radicals which form the radical-pair system. The energy levels and the separation, d, of the dipole-dipole doublet splitting at an arbitrary crystal orientation relative to the magnetic field are analyzed by Kurita[4] in the case of the axially-symmetric $\tilde{\boldsymbol{D}}$-tensor; this method is well suited for triplet species of the radical pair in the irradiated single crystal. For the nonaxial $\tilde{\boldsymbol{D}}$-tensor, if the principal axis can be set parallel or perpendicular to the external field, $\boldsymbol{H}$, the method of analysis without approximation has been reported by many authors.[12,13] In this paper the approximate method using the perturbation theory given by Itoh[14] will be used, for it needs no supposition about its crystal structure and principal-axis direction. In this method, the following assumptions are made: 1) the g-anisotropy is small, and 2) $g\beta\boldsymbol{H} \gg |D|, |E|$. Both of these assumptions are considered to be valid in the present case of the organic radical.

The method may be summarized as follows: the second term of Eq. (1) is treated as a perturbing Hamiltonian, and then the $\tilde{\boldsymbol{D}}$-tensor is represented as D_{ij} (i, j=a, b, c) on the basis of the rectangular coordinate axes, a, b, and c, which are fixed in the crystal. When the crystal is rotated around the c axis and when the external field, $\boldsymbol{H}$, makes an angle, θ, with the a axis, the resonance-field separation of the two absroptions is given, after second-order perturbation calculations, by:

$$d = 3(g_e/g_{zz})(D_{aa}\cos^2\theta + 2D_{ab}\sin\theta\cdot\cos\theta + D_{bb}\sin^2\theta) \quad (2)$$

where g_e is the g-factor of the free electron, g_{zz} is the zz-component of the $\tilde{\boldsymbol{g}}$-tensor, and z refers to the external-field direction. The tensor components with respect to the experimental coordinate system were determined by the least-squares method. Then, the $\tilde{\boldsymbol{D}}$-tensor was diagonalized to obtain the principal values.

We will not discuss the hfs of the radical-pair system in detail, but when $\boldsymbol{A}^{1}=\boldsymbol{A}^{11}$ the hfs Hamiltonian can be expressed[4] as:

$$\boldsymbol{H}_{hfs} = (1/2)\boldsymbol{I}\cdot\tilde{\boldsymbol{A}}\cdot\boldsymbol{S} \quad (3)$$

This equation suggests that a hf coupling of the pair system will be observed with a half of that of the isolated radicals, as may be seen in Fig. 4c).

One-spin System. An organic radical oriented in

14) K. Itoh, "Jikken Kagaku Koza," ed. by the Chemical Society of Japan, Maruzen, Tokyo (1967), Vol. 13, p. 153.

the diamagnetic crystal can be described by the following Hamiltonian:

$$\boldsymbol{H} = \beta \boldsymbol{S}\cdot\tilde{\boldsymbol{g}}\cdot\boldsymbol{H} + \boldsymbol{I}\cdot\tilde{\boldsymbol{A}}\cdot\boldsymbol{S} \quad (4)$$

The results of the calculation when $I=1$, and especially in nitroxide radicals, have been reported by Griffith *et al.*[2] In the present paper, as the crystal structure is not known, the method described in the textbook of Carrington and McLachlan[15] is used. The principal values of $\tilde{\boldsymbol{g}}$- and hf-tensors and their directions can be obtained by the next equations:

$$(g_{obs})^2 = g_{aa}^2\cos^2\theta + 2g_{ab}^2\sin\theta\cdot\cos\theta + g_{bb}^2\sin^2\theta \quad (5a)$$

$$(A_{obs})^2 = A_{aa}^2\cos^2\theta + 2A_{ab}^2\sin\theta\cdot\cos\theta + A_{bb}^2\sin^2\theta \quad (5b)$$

where θ and the a, b, and c indices are defined as in the discussion of the two-spin system and where g^2_{ij} and A^2_{ij} are defined as the ij components of the $\boldsymbol{g}^2=({}^t\tilde{\boldsymbol{g}}\cdot\tilde{\boldsymbol{g}})$ and $\boldsymbol{A}^2=({}^t\tilde{\boldsymbol{A}}\cdot\tilde{\boldsymbol{A}})$ tensors respectively. The treatment of Eq. (5) is the same as that of Eq. (2).

Table 1. Experimental parameters for DANO radical in DMBzp

	Principal value	Angle with a	b	c	Parameters

A_3	24.6±0.2	122	90	32	

Structure of the Two-spin System in the Matrix. The $\tilde{\boldsymbol{D}}$-tensor is analyzed for the side peak, d_1, which is clearly observed in all the external-field directions. The principal values and principal axes of the $\tilde{\boldsymbol{D}}$-, $\tilde{\boldsymbol{g}}$-, and hf-tensors are shown in Table 1. The D value is consistent with the data estimated from the powdered sample in Fig. 3a). By applying the measured D and E values to the equation of the resonance field of the $\Delta m_s=\pm2$ transition, $g\beta H_{dq}=\sqrt{(1/4)(h\nu)-(1/3)(D^2+3E^2)}$, one can obtain $H_{dq}=1620$ Gauss, which also agrees well with our measurement of the powdered sample (Fig. 3b).

The radical pairs in the organic crystal produced by irradiation have been reported to be $E=0$ or $E/D\neq0$: this is considered to be due to the localization of the unpaired electron in the molecule.[16] This holds also in the present case for the DANO stable radical pair. Comparing with a transition-metal complex or a TCNQ salt, in which the E/D value is not small (~0.1), the unpaired electron of the DANO radical, which has a spin density of more than 70% on the N=O bond, may be considered as a point dipole. By applying the equation: $|D|=3g^2\beta^2/2r^3$, where r is the distance between the two radicals, one can obtain $r=5.4$ Å. From the principal axes of $\tilde{\boldsymbol{D}}$, one can also determine the direction of the radical-pair axis to be parallel to the c axis.

Since one-site spectra are obtained for the isolated radical in any crystalline orientation, all the DANO radicals are considered to be oriented with the N=O bond aligned along the unique direction in the matrix even if there is more than one site in a unit cell. Consequently, one can assume that the $\tilde{\boldsymbol{g}}$-tensor orientation of radicals forming a radical pair is the same as that of the isolated radicals.

Kikuchi has calculated the g-values of several nitric-oxide radicals using the CNDO/2 molecular orbital calculation method.[17] The calculated principal g-values in the case of H_2NO and a conjugated radical, diphenyl-nitric-oxide (DPNO), are cited in Table 2, along with the principal axes from his paper. The principal values are in fairly good agreement with those of our results shown in Table 1.

Table 2. Calculated g-values for some nitric-oxide radicals[17]

	$H_2N\dot{O}$	DPNO	Axis
g_x	2.0062	2.0046	g_y	2.0091	2.0086	
g_z	2.0023	2.0023	
g_{av}	2.0059	2.0051	

Assuming the same principal axis system, one can estimate the orientation of the paired DANO molecules in the matrix crystal. Figure 6 shows a model of the two-spin system obtained from the relative orientation of the $\tilde{\boldsymbol{D}}$- and $\tilde{\boldsymbol{g}}$-tensors. Although the crystal structure of the matrix crystal is not known, the distance of the two radical molecules, r, and their alignment in the matrix determined experimentally may be compared with the crystal structure of DANO[9] cited in Fig. 7. The crystal structure of the DANO radical in Fig. 7 is orthorhombic, with four sites per unit cell; all the N=O bonds of molecules, however,

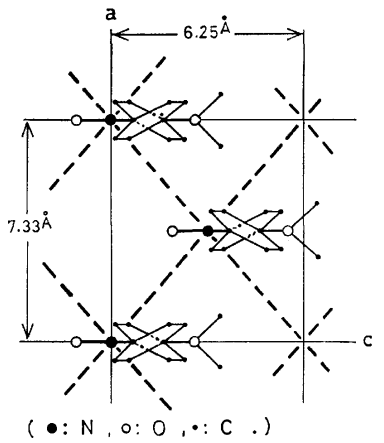

Fig. 7. Crystal structure of DANO reported by Hanson,[9] as viewed on a (010) projection
------: the nearest neighbor direction (4.81 Å)

are aligned along the c axis direction of the crystal. The distance of the nearest neighbor molecule of DANO is 4.81 Å, which is of the same order of experimental value, 5.4 Å, for DANO in DMBzp. Unlike the DANO crystal with the two distinct directions of the nearest-neighbor molecules, there is only one nearest-neighbor direction in DMBzp. This may mean a lower symmetry of the DMBzp crystal than that of the DANO crystal.

Our model for the radical pairs diluted in DMBzp is appropriate considering the alignment and the packing structure of the molecules in the matrix crystal.

Effect of the Radical Concentration. The radical concentration has great effects on both the line shape and the triplet absorption intensity. In the crystal with more than 30% DANO, the triplet absorption was not clearly observed because of the exchange narrowing effect. In a very diluted system, on the other hand, it was observed with a very weak intensity. For the 7.5% sample, the main subject of the present paper, the integrated absorption intensity ratio of the side peaks to the main peak was estimated to be 1900/11000~0.17. Assuming a one-dimensional lattice containing the radical molecule with the fractional concentration, c, the probabilities of making the radical pair and the isolated radical are approximately $2c^2$ and $c-2c^2$ respectively in the small c region. By this simple model with $c=0.075$, one can enumerate the ratio, $2c^2/(c-2c^2)$, as 0.18, which is consistent with the experimental intensity ratio.

The other peaks in Fig. 4b), whose intensities are nearly equal to each other, are considered to be due to the next-nearest neighbor molecules in the matrix. The other weak absorptions in Fig. 3a) suggest the possibility of another radical pair or a three-spin system. No more detailed discussions of these ESR absorptions can be done at present because the crystal structure of a matrix crystal is not known.

Conclusion

The existence of the stable radical triplet state is confirmed from: (1) the ESR line shape of the powdered sample; (2) the D and E values of the triplet state obtained from measurements of powdered and single-crystal samples, (3) a comparison of the hf coupling in the pair system with that in the isolated radical; (4) the forbidden transition of $\Delta m_s=\pm 2$, and (5) the ESR intensity compared with the estimation of the chance of making the two-spin system in the small radical-concentration region. The magnetic properties of this triplet radical pair and isolated radicals have been discussed. The structure of the radical pair in the diamagnetic matrix has been proposed on the basis of an analysis of the ESR spectra.

The authors are much obliged to Professor Hideo Takaki for his continuous encouragement throughout this work, and also to Dr. Mamoru Mekata and other members of his laboratory for their helpful discussions.

The Chlorination of Benzene with a Sodium Chloride-Ferric Chloride Melt

Yasukatsu TAMAI and Yasuo OHTSUKA

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received October 24, 1972)

The chlorination of C_6H_6 with a NaCl–$FeCl_3$ (52: 48 in mol) melt was studied in a batch reactor at 250 °C and at a constant pressure. The main chlorinated products were monochlorobenzene (MCB) and dichlorobenzene (DCB). The isomers in DCB were *ortho* and *para*, and did not include the *meta* form. The rate of chlorination was nearly proportional to the benzene pressure in the range from 0.5 to 2.0 atm. When O_2 was introduced into the reaction system, both the rate of chlorination and the selectivity of MCB increased with the increase in the partial pressure of O_2. These facts suggest that chlorination proceeds by the electrophilic substitution on the melt surface. It was indicated by an X-ray diffraction examination of the powder of the salts used, which lost the activity for chlorination after a prolonged experiment in the presence of O_2, that the source of Cl was $FeCl_3$ and not NaCl in this reaction.

Molten salts have relatively high thermal conductivities and heat capacities. These thermal characteristics are favorable to reaction-temperature control when the salts are used as chemical-reaction media, especially in highly exothermic reactions. Furthermore, the higher mobility of ions in fused salts seems to give an interesting difference from solid salts where the ion plays an important role as a component of the expected reaction. In view of these facts, studies have recently been done on the use of molten salts as organic reaction media, mainly as catalysts.[1] Only a few studies have, however, been made on the use of molten salts as reagents;[2] especially, little work has been reported on the reaction of aromatic hydrocarbons with molten chlorides. Therefore, we studied the chlorination of C_6H_6 with a NaCl–$FeCl_3$ melt, and examined the effect of O_2 on it; this effect is of interest in connection with oxychlorination.

Experimental

Scope of Experiment. The choice of the NaCl–$FeCl_3$ melt as a chlorinating agent was based on the following considerations. The chlorination of C_6H_6 with molten chlorides took place when their metallic cations, of a polyvalent type, were used in the form of a higher valence state.[3] NaCl–$FeCl_3$ (52: 48 in mol) melt has a low melting point (*ca.* 160 °C), and the vapor pressure is very small below 500 °C.[4] C_6H_6 was selected because the product distribution, especially the isomer distribution of DCB, suggests whether the reaction mechanism is radical or ionic. The benzene pressure was varied to see where the chlorination occurred—that is, in the gas phase, at the interface, or in the bulk molten phase. To examine the effect of O_2 on the chlorination, chlorination was done at various partial pressures of O_2—that is, at different ratios of O_2 to C_6H_6. Many runs were made repeatedly with the same melt charge. The purpose is to investigate the influence of the aging of the melt on the chlorination. The contact time was varied to see whether chlorination proceeded successively or simultaneously by examining the subsequent change in the ratio of MCB to DCB.

Materials. The anhydrous $FeCl_3$ was 98.5% pure, and the NaCl and C_6H_6 were guaranteed reagents from Wako Pure Chemicals Industries, Ltd. The oxygen was 99.8% pure and was obtained from the Miyagi Sanso Co. These materials were used without further purification.

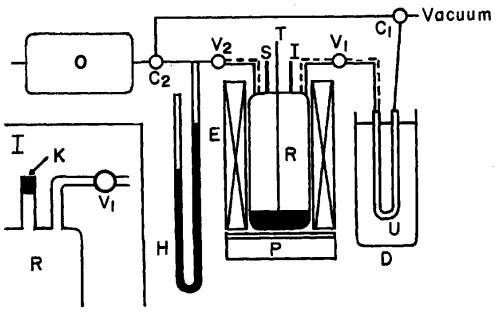

Fig. 1. Apparatus.
C: glass cock, D: dry-ice methanol trap, E: electric furnace, H: Hg-manometer, I: injection mouth of benzene, K: silicone rubber, O: oxygen reservoir, P: plate heater, R: reactor, S: charging mouth of salts, T: thermocouple, U: U-tube, V: teflon needle valve, – – –: electrically tracing.

Apparatus. The apparatus is illustrated in Fig. 1. The reactor (R) consisted of a Pyrex vessel 60 mm in diameter and 130 mm long. It was equipped with two open stems: one (S) was to charge salts, and the other (I), to introduce C_6H_6. As is shown in the detailed figure, at the top of (I) a plug of silicone rubber (K) was attached, through which C_6H_6 was injected. (R) was heated by a surrounding electric furnace (E) and by a plate heater (P) at the bottom. The reaction temperature was measured with a chromel-alumel thermocouple (T) located in a well embedded in the melt, and was controlled within ±5 °C. (R) was connected to the oxygen reservoir (O) and a U-tube (U) in a dry-ice methanol trap (D; *ca.* −75 °C) through two separate Pyrex tubings. Each tubing had a Teflon needle valve (V), by which the influence of grease contamination was avoided, to close or open the line. The Pyrex lines were electrically heated to prevent chlorination products from condensing.

Procedure. The salts were ground separately and mixed together by weight (15.2 g of NaCl and 38.9 g of $FeCl_3$) in a dry box of flowing nitrogen. The mixed salts were charged quickly through (S) into (R) in laboratory air. After charging, (S) was sealed off. Then, the salts were heated to melt and then further continuously up to the reaction temperature under a vacuum produced by a rotary pump. After 30–60 mins' preheating under a vacuum, (V_1) and (V_2) were closed, and a given amount of C_6H_6 was injected through (I) into (R) with a syringe. In the following discussion, this time of injection was taken as the time of initiation of the reaction.

In this reactor, the gas volume above the melt was 250 cm^3, and the contact area was 23.7 cm^2.

After a definite contact time, (V_1) was opened to introduce the products into (U), which was then evacuated with special care so as to condense the products perfectly. To make sure that all the contents of (R) were taken out, (V_2) was opened to measure the residual pressure by means of a Hg-manometer (H). When the condensation was finished, (V_1) was closed and (U), containing the condensed materials, was removed into a Dewar vessel for storage.

The next run was usually conducted immediately after the foregoing run without changing the melt used. The procedure was repeated in the exactly same way and the melt was under a vacuum all the time between the runs.

To study the effect of O_2, the following procedures were employed. At first, the melt was preheated under a vacuum in the way described above, and then (V_1) was closed and the three-way cock (C_2) was opened to let the oxygen gas in (O) flow into the reactor until the scheduled pressure was reached (this pressure could be read with (H)). After this introduction of O_2, (V_2) was closed and a calculated amount of C_6H_6 was injected so that the total pressure could reach the atmospheric level.

Conditions of Chlorination. *General Conditions*: Unless otherwise stated, the chlorination was studied under the following conditions; amount of salts, 15.2 g of NaCl and 38.9 g of $FeCl_3$; reaction temperature, 250 °C; contact time, 50 min; total pressure, 1.0 atm. The melt was newly-prepared prior to every run in all the examinations, except when the effect of the aging of the melt was studied. The variables were as follows.

Partial Pressure of O_2: 0–0.33 atm at a constant total pressure of 1.0 atm.

Benzene Pressure: 0.5–2.0 atm in the absence of O_2.

Number of Runs: 6–9 runs with the same melt charge at constant partial pressures of O_2, 0–0.33 atm.

Contact Time: 20–120 min at a constant partial pressure of O_2, 0.33 atm.

Analytical Method. *Benzene Derivatives*: The liquid products, collected in a dry-ice methanol trap, were analyzed by the gas-chromatography method with 5% Bentone 34 and 5% DIDP on 60–80 mesh Celite 545 as the partitioning agent.[5]

Cl_2 and HCl: The Cl_2 evolved from the melt in the absence of C_6H_6 was detected by iodometry. The HCl formed by chlorination was identified by the use of an aqueous solution of ammonia.

Salts Used: To analyze the salts used, the following special experiment was conducted. That is, the chlorination of C_6H_6 in the presence of O_2 was run as follows; many runs were made with an unchanged melt charge of a rather small amount, that is, 3.0 g of NaCl and 7.8 g of $FeCl_3$ (52: 48 in mol), using the same procedure as has been described before, until the melt did not react with C_6H_6. At that time the reaction conditions were slightly modified; temperatures, 250–450 °C; contact time, 50 min; partial pressure of O_2, 0.33 atm; total pressure, 1.0 atm. Then, the melt was solidified in the vessel under a vacuum and taken out to be ground. The ground powder was analyzed by means of a standard X-ray diffraction unit, cobalt $K\alpha$ radiation being used.

Results and Discussion

The main chlorinated products were monochlorobenzene (MCB) and dichlorobenzene (DCB). A small amount of trichlorobenzene (TCB) was also formed. HCl was evolved as a by-product. The isomers in DCB were *ortho* and *para*, and did not include the *meta* form. Most of the TCB was the 1,2,4-isomer. These results were common findings throughout the experiments whether O_2 existed in the reaction system or not. In addition, the chlorination of MCB under the same conditions as in this work gave the same isomer distributions of DCB and TCB as do the present results on C_6H_6.[6]

It has been reported that, in the gas-phase chlorination of C_6H_6 with Cl_2 in the absence of the catalyst above 400 °C, the orientation is reversed and the products containing *m*-DCB and 1,3,5-TCB are obtained.[7] With the chlorination of MCB at 275 to 500 °C, all three DCBs are formed, with the *meta*-isomer predominating.[8] These gas-phase chlorinations in the absence of the catalyst proceed by the radical substitution, the initiation of which is the formation of a Cl radical by the thermal activation.

The present isomer distributions of DCB and TCB differ markedly from these, suggesting that the chlorination of C_6H_6 with the NaCl–$FeCl_3$ melt proceeds by the electrophilic substitution.

The chlorination of C_6H_6 in the presence of O_2 gave the same isomer distributions of DCB and TCB as in the absence of O_2. The formation of phenol as an oxidation product was expected, but not found. Carbon, CO, CO_2, and H_2O, all of which may be formed by the combustion of C_6H_6, were not identified. A very small amount of a liquid material was obtained; it was immiscible with C_6H_6 and chlorinated benzenes and was soluble in acetone and H_2O. This material may be H_2O. Furthermore, a carbon-like material was observed on the reactor wall. This material was insoluble in hot water and hydrochloric acid. These materials may be combustion products. Their amounts, however, are negligible, because, according to the observed mass balance, the charged benzene is almost completely converted to chlorinated benzenes. The formation of a compound like H_2O may also suggest the chlorination of C_6H_6 by the HCl formed and O_2 introduced, that is, oxychlorination. To elucidate its process, a quantitative analysis of HCl and H_2O should be made.

◎: unreacted C_6H_6, △: *p*/*o*, ●: MCB, ○: DCB.

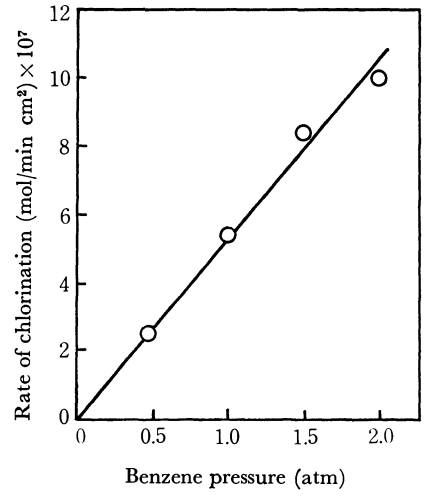

Fig. 5. Dependence of rate of chlorination on benzene pressure.

The effect of the O_2 introduced into the reaction system on the chlorination is shown in Figs. 2 and 3. Figure 2 shows that the conversion of C_6H_6 increases with the increase in the partial pressure of O_2, that is, the decrease in the partial pressure of C_6H_6. It is shown in Fig. 3 that the O_2 introduced raises both the rate of chlorination, which is expressed as moles of chlorinated benzenes formed per unit of contact time per unit of contact area, and the selectivity of MCB. In other words, O_2 promotes the chlorination and favors the formation of MCB.

The fact that the O_2 introduced raises the rate of chlorination seems to support the above suggestion of the electrophilic substitution, for, the O_2 molecule generally behaves as an inhibitor in the radical reaction because of its easy bonding to a radical. Therefore, if the radical mechanism were predominant in this chlorination, the effect of O_2 described above would not be observed.

The influence of the benzene pressure on the chlorination is shown in Figs. 4 and 5. Figure 4 shows that the products distribution is independent of the benzene pressure. The rate of chlorination is nearly proportional to the benzene pressure in the range from 0.5 to 2.0 atm, as is shown in Fig. 5. A very small amount of free Cl_2 was evolved from the melt in the absence of C_6H_6. The pressure of Cl_2 on the NaCl–$FeCl_3$ (54: 46 in mol) melt at 250 °C was estimated to be about 10^{-5} mmHg. This estimation was made by using the pressure of the $FeCl_3$ vapor, which existed almost entirely in the form of Fe_2Cl_6 at 250 °C, about 10^{-4} mmHg,[4] and the equilibrium constant between Cl_2 and Fe_2Cl_6.[9] The gas-phase chlorination by free Cl_2, however, is not considerable, because it proceeds by the radical mechanism, which gives isomer distributions of DCB and TCB different from the present results.

It is considered that the chlorination in the bulk of the melt is not appreciable because of the poor solubility of organic compounds in molten salts.[1a] By the way, the solubility of Cl_2 in molten chlorides, which is larger than those of other inorganic gases, is 3.65×10^{-7}

9) L. E. Wilson and N. W. Gregory, *J. Phys. Chem.*, **62**, 433 (1958).

mol per cm^3 of the NaCl–KCl (50: 50 in mol) melt at 750 °C.[10]

These discussions suggest that the chlorination of C_6H_6 with the NaCl–$FeCl_3$ melt takes place mainly on the melt surface. Accordingly, the rate of chlorination may be represented as the product of the rate constant, the concentration of the adsorbed benzene on the melt surface, and that of the active species. Therefore, the fact that the rate of chlorination is nearly proportional to the benzene pressure suggests that the adsorption of C_6H_6 is of a Henry-type in the pressure range from 0.5 to 2.0 atm.

The effect of the aging of the melt on the chlorination is shown in Figs. 6 and 7. The decrease in reactivity is not observed within the conducted runs whether O_2 exists in the reaction system or not, as is shown in these figures. These results may throw some doubt on the above suggestion that chlorination occurs mainly on the melt surface, for, as the numbers of runs increase, that is, as the reaction time gets longer, the composition of the melt surface should change because of the consumption of Cl. Therefore, the reactivity should decrease if the surface reaction is predominant. However, the fact that the reactivity does not decrease does not necessarily conflict with the surface-composition change resulting from the consumption of Cl. The color of the surface layer of the solidified salts used turned dark-green after many runs in the absence of O_2 and red-brown in the presence of O_2. Such changes suggest the formation of $FeCl_2$ and Fe_2O_3 respectively; Fe_2O_3 was identified by X-ray diffraction, as will be shown later. However, in the working state, the $FeCl_2$ and Fe_2O_3 formed do not stay on the melt surface as a solid, but dissolve or are suspended in the bulk of the melt. In other words, the active species of chlorination easily diffuses from the bulk to the interface. To elucidate further the suggestion that chlorination takes place predominantly on the melt surface, the effect of changes in the contact area on the chlorination, the determination of the surface tension of the melt during chlorination, and so on should be studied in the future.

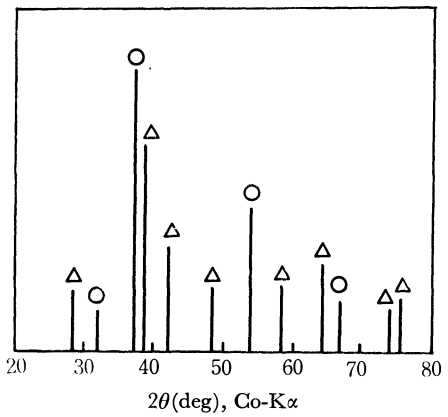

Fig. 10. X-ray diffraction pattern of used salts.
○: NaCl △: α-Fe_2O_3

The dependence of the chlorination on the contact time is shown in Figs. 8 and 9. It is shown in Fig. 9 that the selectivities of poly-substituted DCB and TCB get higher as the conversion of C_6H_6 higher. This tendency was observed whether O_2 existed in the reaction system or not. It suggests the possibility that chlorination proceeds consecutively; to confirm this mechanism, runs at shorter or longer contact times should be examined.

Figure 10 shows the X-ray diffraction pattern of the salts used, which became inactive to chlorination in the presence of O_2. The observed peaks were assigned to NaCl and α-Fe_2O_3. These results indicate that the source of Cl was $FeCl_3$ and not NaCl in this reaction. This indication gives the impression that only $FeCl_3$ participated in the chlorination. The following result, however, suggests that NaCl also participates in the chlorination. That is, when KCl was used in place of NaCl and when the chlorination of C_6H_6 with the KCl–$FeCl_3$ (52: 48 in mol; mp *ca.* 230 °C) was conducted under the same conditions as in this work, the reactivity decreased.[6] Cook *et al.* showed the existence of $NaFeCl_4$ by examinations of the vapor pressure above the NaCl–$FeCl_3$ melts and by the X-ray diffraction of their powder,[4] and Gruen *et al.* indicated the existence of $FeCl_4^-$ by studying the absorption spectra of $FeCl_3$ in a LiCl–KCl eutectic.[11] These reports also suggest that NaCl participates in this reaction.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2000—2003 (1973)

Water Content on Metal Oxides. I. Water Content on Silica Gel, Magnesium Oxide, Zinc Oxide, and Titanium Dioxide

Tetsuo MORIMOTO and Hiromitu NAONO*

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received October 30, 1972)

The surface water content has been determined on silica gel, magnesium oxide, zinc oxide, and titanium dioxide by means of active hydrogen analysis and by the successive-ignition-loss method. Except for magnesium oxide pretreated at 100 °C, it has been found that the water contents obtained from the two methods on every oxide tested are in good agreement with each other. The successive-ignition-loss method gives an extraordinarily high value of water content on magnesium oxide pretreated at 100 °C, probably because of the retention of inner hydroxyl groups. The present results indicate that the two methods are equally reliable for the quantitative determination of the water content on metal oxides. Moreover, the simultaneous application of both methods make it possible to estimate each amount of surface hydroxyl groups and physisorbed water molecules.

The surface hydroxyl groups on metal oxide play an important role in the adsorption of molecules. Several methods have thus far been examined in estimating the surface hydroxyl groups.[1-13] Morimoto *et al.* have studied the metal oxide surface by measuring the water content by means of the successive-ignition-loss method.[14-16] On the other hand, Fripiat *et al.* adopted Zerewitinoff's method to determine active

hydrogen in the analysis of the water content on silica gel.[7]

In order to obtain reliable data on the water content, it is desirable to compare the water content as determined by different methods and to investigate the characteristic features of each method. The water content on silica gel has been examined by various methods,[12] but for the other metal oxides few works have been reported and different methods have not been compared. In connection with this problem, the active hydrogen analysis and the successive-ignition-loss method have been used for measuring the water content on several metal oxides pretreated at different temperatures. This paper will report the finding that both methods give, except in special cases, consistent data on the water content of silica gel, magnesium oxide, zinc oxide, and titanium dioxide.

Experimental

Materials. The metal oxides used in this work were silica gel, magnesium oxide, zinc oxide, and titanium dioxied. The silica gel was prepared by the hydrolysis of ethyl orthosilicate, which had been purified by redistillation.[17] Zinc oxide furnished by the Sakai Chemical Co. was the sample which was prepared by burning zinc metal in air. Titanium dioxide furnished by the Teikoku Kako Co. was prepared by the hydrolysis of titanium sulfate; it was purified further by washing it with dilute ammonia water, nitric acid, and then thoroughly with distilled water. The magnesium oxide was synthesized *via* methylate. Twenty grams of magnesium metal (99.9% purity) were allowed to react with 300 g of purified methyl alcohol at 50—60 °C for 4 hr. The methyl alcohol solution of magnesium methylate thus obtained was kept at *ca.* 5 °C for one night. The crystals of magnesium methylate thus deposited were then further recrystallized from methyl alcohol. The magnesium hydroxide was made by hydrolyzing 30 g of magnesium methylate in 1000 g of distilled water at 60 °C for 7 hr. The excess water and methyl alcohol evolved by the hydrolysis were evaporated out. The magnesium oxide was obtained by calcining magnesium hydroxide at 800 °C for 3 hr in the atmosphere.

The methyl magnesium iodide used for active hydrogen analysis was synthesized by reacting 50 g of methyl iodide with 9 g of magnesium metal in 150 g of dried *n*-butyl ether at 60—70 °C for 4 hr. After the sedimentation of the excess magnesium metal, the supernatant solution was used for active hydrogen analysis.

Specific Surface Areas of the Oxides. The nitrogen adsorption isotherms were measured on the powdered samples at the temperature of liquid nitrogen. Assuming that the nitrogen molecular area was 16.2 Å^2, the surface areas of the powder were calculated by using the BET equation. The specific surface areas of silica gel, magnesium oxide, zinc oxide, and titanium dioxide pretreated *in vacuo* for 4 hr are given in Table 1.

Table 1. Specific surface area of metal oxides

Pretreatment temperature (°C)	Metal oxides (m^2/g)			
	SiO_2	MgO	ZnO	TiO_2
100	423	67	6.4	9.7
200			5.5	
300	422	71	5.6	9.9
500	431	65	4.4	9.3
800	396	77		
1000	333

Water-content Measurement by Means of Active Hydrogen Analysis. The measuring apparatus for active hydrogen on metal oxide is shown in Fig. 1; it was constructed by modifying the apparatus used for the determination of the active hydrogen of organic compounds by Krynitsky *et al.*[18] The oxide powder used at one time was 0.3—2.0 g; it was pretreated *in vacuo* for 4 hr in a thin-walled glass bulb. The degree of vacuum attained in the pretreatment was 10^{-5} Torr at 100, 200, and 300 °C, and 10^{-3} Torr at 500, 800, and 1000 °C. After the pretreatment had finished, the neck of the bulb was sealed off and connected to a glass rod by fusion. The bulb was then transferred into reaction vessel containing 80 ml of a methylmagnesium iodide solution, and then it was broken in the solution by pushing in a glass rod. Since the reaction between methylmagnesium iodide and active hydrogen on metal oxide generates methane gas, the gas volume was measured by means of a gas burette at appropriate intervals. Prior to the measurements, the apparatus was calibrated by using pure benzoic acid; the volume of methane evolved from the reaction of benzoic acid with methyl magnesium iodide was confirmed to coincide with the calculated value.

Water-content Measurement by Means of the Successive-Ignition-Loss Method. The water content in metal oxides was determined by a procedure described previously.[14] By this method, water molecules can be removed from the surface through the condensation dehydration of surface hydroxyl groups; moreover, the physisorbed water, if present, can be desorbed.

Results and Discussion

Methane gas is evolved by the reaction of methylmagnesium iodide with the surface hydroxyl groups or with the physisorbed water molecules:[7]

$$CH_3MgI + HO\text{-(oxide surface)} \longrightarrow CH_4 + MgIO\text{-(oxide surface)}$$

$$CH_3MgI + H_2O \longrightarrow CH_4 + MgI(OH)$$

17) T. Morimoto and H. Naono, This Bulletin., **45**, 700 (1972).

18) J. A. Krynitsky, J. E. Johnson, and H. W. Carhart, *J. Amer. Chem. Soc.*, **70**, 486 (1948).

The volume of methane gas, V(ml(STP)/g oxide), is given by this equation:

$$V = \left\{V_1 - \left(V_2 - \frac{W}{\rho}\right)\right\} \cdot \frac{1}{W} \cdot \frac{273}{273+t}$$

where V_1 is the volume as measured by means of a gas burette, V_2 is the volume of a glass bulb, W and ρ are the weight and density of the oxide powder, and t is the measuring temperature (23—27 °C). In Figs. 2 and 3, V is plotted against the reaction time at various pretreatment temperatures for silica gel, magnesium oxide, zinc oxide, and titanium dioxide. It can be seen from these figures that the evolution of methane gas ceases within 30—50 min.

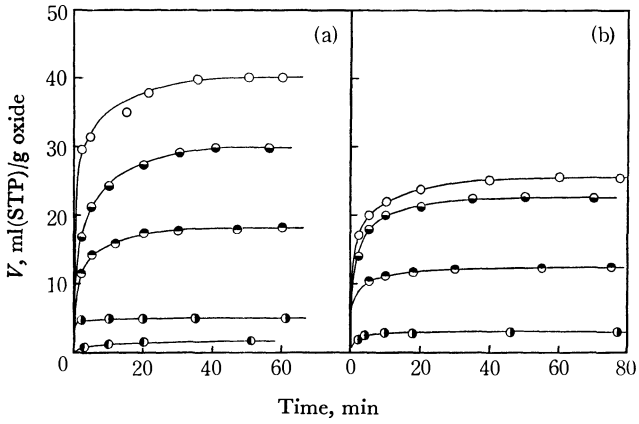

Fig. 2. Reaction of methylmagnesium iodide with active hydrogen on silica gel (a) and magnesium oxide (b). Pretreatment temperatures, ○: 100 °C, ◒: 300 °C, ◓: 500 °C, ◑: 800 °C, ◐: 1000 °C.

In all the cases of oxides, the volume of the methane gas decreases with an increase in the pretreatment temperature; that is, the active hydrogen is removed from the oxide surface by pretreating oxides at elevated temperatures *in vacuo*. On the basis of the reaction of methylmagnesium iodide with the solid surface, we can calculate the water content on metal oxides from the amount of methane gas evolved. Taking into account the specific surface areas listed in Table 1, the water content can be expressed in the number of

hydroxyl groups on an area of 100 Å², as is shown in Figs. 4—6. In these figures, the values of the water content, as determined by the active hydrogen analysis, are illustrated, together with those obtained by the successive-ignition-loss method.

Silica Gel. As can be seen from Figs. 2 and 3, the evolution of methane gas from silica gel occurs as rapidly as that from the other oxides, though the specific surface area of silica gel is much larger than those of the others. Furthermore, as may be seen from Fig. 4, the water contents on silica gel, as determined by the two methods, are in good agreement with each other. Therefore, it may be considered from these results that methylmagnesium iodide molecules react readily with all the active hydrogen atoms on silica gel.

Generally, on metal oxides pretreated at lower temperatures the surface may possibly retain physisorbed water molecules, together with chemisorbed water as surface hydroxyl groups, though only the latter exist on surfaces pretreated at higher temperatures. Here, it will be very interesting to analyze the water content into the surface hydroxyl groups and the physisorbed water. As has been stated above, one water molecule can be estimated to contain one hydroxyl group by the methylmagnesium iodide method, and two hydroxyl groups by the successive-ignition-loss method. Accordingly, when an appreciable amount of the physisorbed water exists on the metal surface, the water content obtained by the latter method should be larger than that obtained by the former one, as will be reported with regard to the water content on alumina pretreated at 100 °C *in vacuo*.[19] Since the water contents obtained on silica gel by the two methods accord well with each other, it may be concluded that only the surface hydroxyl groups exist on silica gel pretreated above 100 °C *in vacuo*.

Magnesium Oxide. Figure 5 shows that the water contents obtained on magnesium oxide by the active hydrogen analysis agrees fairly well those obtained by the successive-ignition-loss method, except for the sample pretreated at 100 °C. On 100 °C-treated sample, however, the two methods give very different values as to the water content; it is found to be 9.6 OH/100 Å^2 by the former, and 23.4 OH/100 Å^2 by the latter method. As has been described above, if physisorbed water exists on magnesium oxide, the latter method will give a larger value for the water content. Now, assuming that the difference between the values of the water content obtained by the two methods is due to the presence of the physisorbed water, we can calculate each of the surface hydroxyl groups and the physisorbed water. The calculation results in a negative value (−4.2 OH/100 Å^2) as the density of the surface hydroxyl groups. Thus, the large difference between the data obtained by the two methods cannot be explained only by the existence of physisorbed water.

With the successive-ignition-loss method it is possible to detect the hydroxyl groups in the inner layer of the solid besides those on the surface, because the oxide powder is ignited at elevated temperatures. On the contrary, in the active hydrogen analysis, only the surface hydroxyl groups can be determined, because methylmagnesium iodide molecules can react only the surface of the solid. The extraordinarily high value obtained by the successive-ignition-loss method stated above makes it possible to infer that the hydroxyl groups exist not only on the surface, but also in the inner layer of magnesium oxide crystals.

Assuming that a hydroxyl group is formed on a surface magnesium atom, the surface hydroxyl groups on the (100) face of magnesium oxide can be calculated crystallographically to be 11.3 OH/100 Å^2. The calculated water content approximates the value obtained by the active hydrogen analysis, being about twice as large as the value obtained by the successive-ignition-loss method. Thus, the water content obtained by the successive-ignition-loss method on the 100 °C-treated magnesium oxide corresponds to the two-layer coverage of hydroxyl groups. It is known that magnesium oxide is gradually changed into magnesium hydroxide by the reaction with water. Therefore, the value of 23.4 OH/100 Å^2 obtained on 100 °C-treated magnesium oxide may reasonably be said to originate from the chemisorption of water vapor from the atmosphere during preservation. On the samples treated above 300 °C, the two methods give similar results for the water content below the monolayer coverage, which shows that only the surface hydroxyl groups exist on magnesium oxide.

So far, methylmagnesium iodide has been mainly used for the determination of the hydroxyl groups on silica, which is known as a weakly acidic surface. On the contrary, magnesium oxide is well known as a basic solid; its basicity was intestigated by Tanabe and Yamaguchi by using bromo-thymol-blue as an indicator.[20] It is very interesting to note that the hydroxyl groups on such a basic solid as magnesium oxide react quantitatively with methylmagnesium iodide. In conclusion, all the hydroxyl groups on the acidic and basic surfaces can be measured quantitatively by means of the present active hydrogen analysis.

Zinc Oxide and Titanium Dioxide. The water content on zinc oxide and titanium dioxide is shown in Fig. 6 as a function of the pretreatment temperature. As can be seen from Fig. 6, the data obtained by different methods are, as a whole, in agreement with each other and the water content decreases remarkably with the increase in the pretreatment temperature. In these cases, an appreciable fluctuation of the data is observed in the active hydrogen analysis, probably because of the small quantities of methane gas evolved. A trend can be seen that the successive-ignition-loss method gives a slightly higher value in the water content on the 100 °C-treated zinc oxide than does the other method; this greater value may be attributed to the existence of the physisorbed water.

The above results lead to the conclusion that the surface hydroxyl groups can reasonably be measured quantitatively by both active hydrogen analysis and the successive-ignition-loss method. Furthermore, it is possible to estimate the values of both physisorbed water and surface hydroxyl groups by the simultaneous application of the two methods.

The authors wish to express their thanks to Miss Toshie Takeshita for her experimental assistance.

Energy Transfer in the Radiolysis of Neopentane-Alkane Mixture in the Solid Phase at 77 K

Masaki KATO, Yoshiyuki SAITAKE, Tetsuo MIYAZAKI,* and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received November 2, 1972)

When neopentane containing a small amount of cyclohexane is γ-irradiated at 77 K, the cyclohexyl radical is mainly formed by the energy transfer from neopentane to cyclohexane. The addition of CCl_4, which is an electron scavenger and an excitation acceptor, to the mixture suppresses the formation of the cyclohexyl radical. This fact indicates that the energy transfer is not due to an ion-molecule reaction. When CO_2, which can capture an electron in the neopentane matrix to form CO_2^-, is added to the neopentane–cyclohexane mixture, scarcely any CO_2^- is formed by the irradiation. When ethyl chloride or nitrous oxide is added to the neopentane–cyclohexane mixture, the formation of the cyclohexyl radical is not suppressed, although these additives capture electrons effectively in the solid neopentane. The addition of tetramethylethylene (TME) to the neopentane–cyclohexane–carbon dioxide mixture does not affect the formation of the cyclohexyl radical, although an appreciable amount of TME^+ is formed. These results show that the energy transfer is not due to the ionic process, but to a non-ionic process. The energy transfer is explained by two possible mechanisms, a selective abstraction reaction by the hydrogen atom and an excitation transfer *via* a highly-excited state.

We have previously studied the radiolysis in the solid state in order to elucidate the primary process of radiolysis in the solid state and in order to obtain information about reaction kinetics in the solid state. The quite peculiar phenomena[1-6] we then found could not be explained by applying the mechanism of the radiolysis in the gas and liquid phases to the solid phase.

Therefore, we have indicated that two important problems must be solved in order to elucidate the cause of the peculiar phenomena in the radiolysis of solid hydrocarbons. One problem is the energy transfer in the primary process; the other is how the state of the solid matrix, such as its phase or defects, affects the reaction in the solid phase.

When neopentane containing a small amount of another alkane is γ-irradiated in the solid phase at 77 K, the solute radical is mainly formed by the energy transfer from the γ-irradiated neopentane to the solute.[6] Even if the ionization potential and the energy of the first singlet excited state of the solute are higher than those of neopentane, the solute radical is effectively formed. It was suggested, from the point of view of energetics, that the energy transfer may occur *via* a non-ionic process.[6]

We have here obtained clearer results demonstrating the mechanism of the non-ionic energy transfer in the radiolysis of neopentane containing cyclohexane in the solid phase.

Experimental

The neopentane and cyclopentane supplied by the Tokyo Kagaku Seiki Co. were more than 99.9% pure. Spectrograde cyclohexane and toluene were passed through a 1 m column packed with silica gel and then distilled on a vacuum line before use. The tetramethylethylene supplied by the Tokyo Kagaku Seiki Co. was more than 99.0% pure. The ethane and carbon dioxide supplied by the Takachiho-Shoji Co. were of a high purity and were used without further purification. The carbon tetrachloride was used after distillation on a vacuum line.

Samples were irradiated with γ-rays from a ^{60}Co source at 77 K and at a dose rate of 7.8×10^5 rad/hr. The total dose was 2.0×10^5 rad. The ESR spectra of irradiated samples were measured at 77 K on a JES-3BX ESR spectrometer.

Results and Discussion

Radiolysis of Neopentane Containing Cyclohexane in the Solid Phase at 77 K. When neopentane containing a small amount of cyclohexane is γ-irradiated at 77 K, the cyclohexyl radical is mainly formed, while the formation of the solvent radical is suppressed. The ESR spectra of the irradiated samples were shown in a previous paper.[6] The yields of the cyclohexyl radical are shown in Fig. 1 as a function of the concentration of cyclohexane. Cyclohexane at a concentration of over 0.2% accepts energy efficiently from the irradiated neopentane. When neopentane containing other alkanes, such as ethane, propane, and cyclopentane, is γ-irradiated at 77 K, the energy transfer from neopentane to the solute also occurs efficiently.[6] Since the ionization potential and the first excited state of these alkanes are higher than those of neopentane, a charge transfer from the neopentane cation in a ground state and/or an excitation transfer from neopentane in the first excited state to the solute are impossible. Therefore, we will discuss here whether the energy

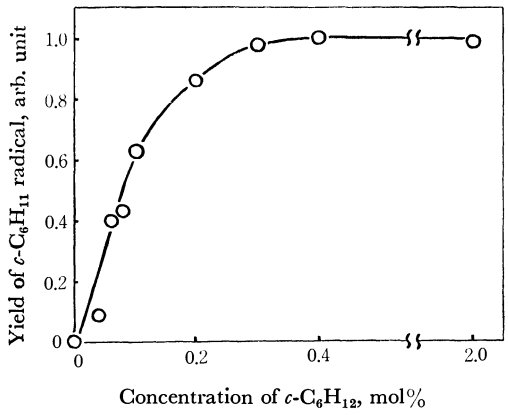

Fig. 1. Formation of cyclohexyl radical as a function of the concentration of cyclohexane in the radiolysis of solid neopentane at 77 K.

transfer is due to an ionic process, such as an ion-molecule reaction and a positive charge transfer *via* an excited ion, or to a non-ionic process.

Ion-Molecule Reaction. Willard *et al.* proposed that the solvent radical may be formed by the ion-molecule reaction in the radiolysis of 3-methylpentane in the solid phase.[7] According to this mechanism, the formation of the solute radical in the radiolysis of neopentane containing alkane may be represented as follows:

$$\text{neo-}C_5H_{12} \rightsquigarrow C_5H_{12}^+ + e^- \quad (1)$$

$$C_5H_{12}^+ + \text{neo-}C_5H_{12} \longrightarrow C_5H_{13}^+ + C_5H_{11}\cdot \quad (2)$$

$$C_5H_{12}^+ + RH \longrightarrow C_5H_{13}^+ + R\cdot \quad (3)$$

$$C_5H_{13}^+ + e^- \longrightarrow C_5H_{12} + H \quad (4)$$

$$H + H \longrightarrow H_2 \quad (5)$$

where RH represents some alkane as a solute. In the previous paper,[6] it was suggested that, for the following reasons, these reactions seem unlikely.

First, when neopentane containing cyclopentane is γ-irradiated at 77 K, the cyclopentyl radical is mainly formed. If the formation of the cyclopentyl radical is due to Reaction (3), neither the amounts of the $C_5H_{13}^+$ ion nor the yields of hydrogen (Reactions (4) and (5)) change upon the addition of cyclopentane. The experimental results, however, show that the yields of hydrogen increase sharply upon the addition of cyclopentane.

Second, the ion-molecule reaction between a neopentane parent ion and an ethane molecule (Reaction (3)) is expected to be endothermic.

Third, though the proton-transfer reaction of polar molecules has been found by means of the mass spectrometer, the reaction cannot be detected in any alkane systems except for methane and ethane. The reaction seems to become more difficult as the molecular weight of alkane increases.[8] It has been reported, from a study of the high-pressure mass spectrometry of propane, that the protonated alkane ion was not detected at all, but only a clustered parent ion.[9]

In the present study we have obtained clear results which support the previous suggestion. Carbon tetrachloride, which is an electron scavenger and an excitation acceptor,[1,10] was added to the neopentane-cyclohexane mixture. If Reactions (1)—(3) occur in the solid phase, CCl_4 will capture the electron (Reaction (6)) and prolong the lifetime of the cation:

$$e^- + CCl_4 \longrightarrow Cl^- + CCl_3\cdot \quad (6)$$

Therefore, the ion-molecule reaction (3) should be promoted by the addition of CCl_4, as has been observed in the radiolysis of liquid neopentane.[11] The effect of CCl_4 on the formation of the cyclohexyl radical is shown in Fig. 2. The formation of the cyclohexyl radical, however, is suppressed by the addition of CCl_4. The formation of solute radicals in the radiolysis of neopentane containing ethane or cyclopentane is also suppressed by the addition of CCl_4. Since carbon tetrachloride does not react with the neopentane cation in the liquid phase,[12,13] it may be a source of difficulty that carbon tetrachloride disturbs the ion-molecule reaction (3). Therefore, Reactions (1)—(3) are not responsible for the formation of solute radicals in the radiolysis of neopentane containing alkane.

of the solute radical in the radiolysis of neopentane containing cyclohexane may be represented as follows:

$$\text{neo-}C_5H_{12} \rightsquigarrow C_5H_{12}^{+*} + e^- \quad (7)$$

$$C_5H_{12}^{+*} + \text{cyclo-}C_6H_{12} \longrightarrow C_5H_{12} + C_6H_{12}^{+} \quad (8)$$

$$C_6H_{12}^{+} + e^- \longrightarrow C_6H_{11}\cdot + H \quad (9)$$

where $C_5H_{12}^{+*}$ represents an excited cation. Though the information on the excited ion is very scanty at present, we will point out some drawbacks to this mechanism.

First, carbon dioxide captures an electron in the solid phase to form CO_2^- (Reaction (10)), and its formation can be easily detected by ESR spectroscopy:

$$e^- + CO_2 \longrightarrow CO_2^- \quad (10)$$

If Reaction (7) occurred in the radiolysis of neopentane, CO_2^- should be formed upon the addition of CO_2. Since cyclohexane traps the mobile excited cation in Reaction (8), it is expected that the electron may be more easily captured by CO_2 in the presence of cyclohexane, as has been discussed in connection with the radiolysis of 3-methylpentane.[14,15] The yields of CO_2^- in the radiolysis of neopentane–cyclohexane–CO_2 (2%) mixture are shown in Fig. 3. The yields of CO_2^- are quite small, contrary to the expectation based on Reactions (7), (8), (9), and (10). The G-values of CO_2^- are only 0.04—0.01, although the yields of the cyclohexyl radical amount to 2 G-units in the radiolysis of the neopentane–cyclohexane(3%)–CO_2(2%) mixture and cyclohexane captures a large amount of active species. There is a possibility that CO_2 is not dissolved into the neopentane matrix and that it cannot capture an electron in this matrix. This possibility is, however, obviated by the following experimental results. When tetramethylethylene is added to the neopentane–CO_2 (2%) mixture, an appreciable amount of CO_2^- is formed (Fig. 3).

Second, since the efficiency of electron capture by carbon dioxide is relatively small, we have used more efficient electron scavengers, such as ethyl chloride and nitrous oxide. Figure 4 shows the effects of ethyl chloride and nitrous oxide on the formation of the cyclohexyl radical in the radiolysis of the neopentane–cyclohexane (2%) mixture at 77 K. When ethyl chloride captures an electron, it produces the ethyl radical by dissociative electron attachment. The yields of the ethyl radical, which represent the amounts of electrons captured by ethyl chloride, are also shown in the figure. The yields of the cyclohexyl radical decrease gradually upon the addition of ethyl chloride, while the yields of the ethyl radical increase sharply upon the addition of a small amount of ethyl chloride. The decreases in the yields of the cyclohexyl radical are much smaller than the yields of the ethyl radical at the concentrations of 0.5 and 2% ethyl chloride. It has been reported that nitrous oxide can efficiently capture an electron in the radiolysis of solid neopentane at 77 K.[16] According to the product analysis, the $G(N_2)$ in the radiolysis of neopentane containing nitrous oxide (4%) at 77 K was about 0.5, suggesting that nitrous oxide captures an electron in the solid neopentane at 77 K. The yields of the cyclohexyl radical do not decrease at all upon the addition of nitrous oxide. Therefore, the neutralization reaction does not participate in the formation of the cyclohexyl radical in the radiolysis of neopentane containing cyclohexane at 77 K.

Third, Fig. 5 shows the effect of tetramethylethylene (TME) on the formation of the cyclohexyl radical in the radiolysis of the neopentane–cyclohexane(1%)–CO_2 (2%) mixture at 77 K. Though an appreciable amount of TME^+ is formed upon the addition of TME, and though $G(TME^+)$ amounts approximately to 1—1.5 at 2% of TME, the yields of cyclohexyl radical do not decrease at all. Therefore, the charge transfer reaction does not participate in the formation of cyclohexyl radical.

●: yield of cyclohexyl radical.
○: yields of TME^+.

Fourth, since the neopentane parent ion is quite unstable and decomposes in the period of one vibration in the gas[17] and liquid phases,[13,18,19] the excited ion may decompose before charge transfer.

From the present discussions, it seems to be difficult to explain the energy transfer in the radiolysis of solid neopentane by the ionic processes. In the present poor state of knowledge of the radiolysis in the solid phase, we cannot decide the true mechanism of the energy transfer. We will try, however, to explain the energy transfer by two possible non-ionic processes as a basis for further study.

Selective Abstraction Reaction by the Hydrogen Atom. The formation of the solute radical in the radiolysis of neopentane may be explained by the selective abstraction reactions:

$$\text{neo-}C_5H_{12} \rightsquigarrow C_5H_{12}^* \quad (11)$$

$$C_5H_{12}^* \longrightarrow C_5H_{11}\cdot + H \quad (12)$$

$$H + H \text{ or } R\cdot \longrightarrow H_2 \text{ or } RH \quad (13)$$

$$H + C_5H_{12} \longrightarrow C_5H_{11}\cdot + H_2 \quad (14)$$

$$H + C_2H_6 \longrightarrow C_2H_5\cdot + H_2 \quad (15)$$

where $C_5H_{12}^*$ and R· represent an excited neopentane molecule and some radical respectively. If the H atom in these reactions is a hot hydrogen atom, the rate constant of Reaction (14) is a little larger than that of Reaction (15) in the gas phase.[20] Therefore, it cannot be expected that the ethyl radical is formed selectively in the radiolysis of neopentane containing a small amount of ethane. If the H atom is a thermal hydrogen atom, Reaction (15) cannot occur at 77 K because of its high activation energy. Therefore, we must assume that the reaction of the hydrogen atom in the crystalline neopentane is quite different from that in the gas and liquid phases, and that the H-atom reacts selectively with ethane with a low activation energy at 77 K.

It has been reported recently that H-atom abstraction reaction by a thermal methyl radical occurs with low activation energy in the solid phase.[21] Recently we have found that the hot hydrogen atom produced by the photolysis of hydrogen iodide reacts selectively with solute alkane in the neopentane matrix at 77 K.[22] The result, which cannot be explained by this mechanism, is that the yields of solvent radicals in the radiolysis of neopentane or isobutane decrease below 50% of the initial yields upon the addition of an additive.

Excitation Transfer via a Highly-excited State. According to the mechanism of the excitation transfer, the reaction scheme may be represented as follows:

$$\text{neo-}C_5H_{12} \rightsquigarrow C_5H_{12}^* \quad (11)$$

$$C_5H_{12}^* \longrightarrow C_5H_{11}\cdot + H \quad (12)$$

$$\searrow\ C_4H_9\cdot + CH_3\cdot \quad (16)$$

$$C_5H_{12}^* + RH \longrightarrow C_5H_{12} + RH^* \quad (17)$$

$$RH^* \longrightarrow R\cdot + H \quad (18)$$

Reaction (17) is the excitation transfer to other alkane. Since an appreciable quantity of solute radicals is formed by the addition of ethane, propane, and cyclopentane, whose first excited states are higher than that of neopentane, the excitation transfer may occur *via* the highly-excited state.

The excitation transfer has also been proposed in the radiolysis of isobutane[1] and polyethylene[23] in the solid phase. From the calculation, it was suggested that the excitation transfer is possible in the alkane.[24]

The authors wish to express their appreciation to Professor John E. Willard of the University of Wisconsin for his kind discussion.

Radioactive Iodine Exchange and the Dushman Reaction

Ryusaburo FURUICHI* and Herman A. LIEBHAFSKY

Department of Chemistry, Texas A & M University, College Station, Texas 77843, U.S.A.

(Received November 7, 1972)

Critical studies were made on the Dushman reaction, $6H^+ + 5I^- + IO_3^- = 3I_2 + 3H_2O$. Rate measurements of radioactive iodine exchange away from chemical equilibrium gave results which made the rate law for the Dushman reaction doubtful. Measurements of $d(H^+)/dt$ confirmed the rate law. The contrary interpretation resulted because existing chemical information was not considered. This situation holds in many radioactive iodine exchange experiments done on the Dushman reaction.

The reaction between iodate and iodide ions in acid solution was first studied systematically by Dushman.[1] Its rate law in simplified form was found to be[2,3]

$$-\frac{[IO_3^-]}{dt} = [IO_3^-][H^+]^2\{2.4\times10^4[I^-] + 7.6\times10^{10}[I^-]^2 + 5.5\times10^{10}[I^-][I_3^-]\} \quad \text{at } 25°C \qquad (1)^4$$

The $[I^-]$ and $[I^-]^2$ terms contribute equally to the rate when $[I^-]$ is near 10^{-7}. The $[I_3^-]$ term is negligible when $[I^-]$ greatly exceeds $[I_3^-]$, which is the case when IO_3^- and I^- are the only iodine species initially mixed.

Measurements of the rate of radioactive iodine isotope exchange have placed Eq. (1) in doubt. Measurements at chemical equilibrium[5-7] led to different formulations of the $[I^-]$ term. Measurements away from equilibrium in nearly neutral solution by Myers and Kennedy[6] showed no exchange under conditions where it was expected that the rate of exchange *via* the $[I^-]^2$ term could easily be measured.

A survey of literature on the relevant exchange measurements away from chemical equilibrium[6,8-15] shows a marked discrepancy (Table 1).

The Dushman reaction participates in the oscillatory decomposition[16] of H_2O_2. In particular, $[I^-]$ during the $[I^-]$ pulses changes about 10-fold at concentrations where the $[I^-]^2$ term of Eq. (1) contributes significantly to the rate, indicating that the contribution changes by almost 100-fold during a single pulse (see Ref. 16, Fig. 1). Such fluctuations could trigger oscillations. There is no hope of understanding the oscillatory

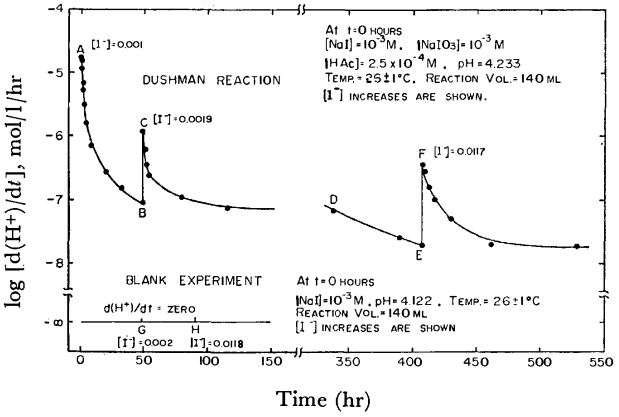

Fig. 1. Decrease of $d(H^+)/dt$ with time in the reaction mixtures of the figure.
Note the breaks in the coordinate axes.

decomposition so long as the present confusion about the Dushman reaction continues.

Experimental

Abel and Stadler[3] carried out their work on the $[I^-]^2$ term in acid solution. Myers and Kennedy[6] used a reaction mixture which they considered nearly neutral. The difference in $[H^+]$ seemed to be responsible for any conflict between the two investigations.

The Dushman reaction may be written as

$$6H^+ + 5I^- + IO_3^- = 3I_2 + 3H_2O \qquad (2)$$

Hydrogen ion is rapidly consumed as the reaction proceeds. If the $[H^+]^2$ term in Eq. (1) is correct, the rate of reaction will decrease rapidly as $[H^+]$ decreases. Working near $(H^+)=10^{-7}$ will be difficult because formation of even a small amount of I_2 (or I_3^-) will cause large relative change in (H^+) and thus in the rate. Hence it is desirable to follow the rate by measuring $d(H^+)/dt$.

Preliminary experiments with $HClO_4$ confirmed the above. Good measurements of $d(H^+)/dt$ could not be made because the rate decreased too rapidly. Measurements in buffered solutions were also difficult. Consequently, acetic acid (HAc) was chosen as a medium between strong acid and buffered solution as regards $d(H^+)/dt$. It can give rates in reaction mixtures with $[I^-]$ and $[IO_3^-]$ large enough to be considered constant during the experiment.

The reaction mixtures were prepared by mixing NaI, $NaIO_3$, and HAc (J. T. Baker Chemical Co.) solutions. The initial composition is given in Fig. 1. The reaction mixture was contained in a stoppered flask kept in the dark at room temperature except during the pH measurements, which were carried out with a glass electrode (Orion Type 801 Digital Ionalyser). The solution became yellowish as the reaction proceeded. Values of $d(H^+)/dt$ for the logarithmic ordinate of Fig. 1 were obtained by graphical differentiation of the curves of pH against time. Addition of NaI is indicated by points B and E.

A blank experiment was carried out because the oxygen from air can sometimes oxidize I^- to form I_2 and I_3^- with the consumption of H^+. The result was satisfactory.

Discussion of the Results of New Rate Measurements

Figure 1 is qualitatively in accord with Eq. (1): the decreases in rate beyond points A, C, and F point to an $(H^+)^2$ term in the rate law. The perpendicular increases along BC and EF seem in accord with an $(I^-)^2$ term. For a quantitative comparison, one must remember that the progress of reaction is measured by $d\sum(H^+)/dt$, and that

$$\sum(H^+) = (H^+) + (HAc) \qquad (3)$$

$$[HAc] = (HAc) + (Ac^-) = 2.5\times10^{-4}\ \text{mol/l} \qquad (4)$$

and

$$\frac{(H^+)(Ac^-)}{(HAc)} = 1.8\times10^{-5} \quad \text{at } 25°C \qquad (5)$$

from which it follows that

$$\frac{d\sum(H^+)}{dt} = \frac{d(H^+)}{dt} + \frac{d(HAc)}{dt} = \frac{d(H^+)}{dt}\left[1+\frac{4.5\times10^{-9}}{\{(H^+)+1.8\times10^{-5}\}^2}\right] \qquad (7)$$

The $d\sum(H^+)/dt$ calculated by means of Eq. (7) from the measured $d(H^+)/dt$ and (H^+) should be equal to the rate calculated from the rate equation found by Abel and Stadler[3] for HAc solutions.

Agreement is satisfactory (Table 2) considering the difficulties and the fact that Abel and Stadler measured the rate in a different way (iodimetric determination of $-d(IO_3^-)/dt$). We thus conclude that Table 1 contains no evidence that the Dushman reaction does not proceed as expected. It seems clear that all chemical information available should be considered in designing and interpreting radioisotope exchange experiments on this reaction and others.

General Discussion of the Dushman Reaction

Chemical Information. The following three equilibria should be considered.

$$6H^+ + 5I^- + IO_3^- \rightleftharpoons 3I_2 + 3H_2O$$
$$K_8 = 1.6\times10^{47} \quad \text{at } 25°C[6,17] \qquad (8)$$

$$I_2 + H_2O \rightleftharpoons H^+ + HIO + I^-$$
$$K_9 = 5.4\times10^{-13} \quad \text{at } 25°C[18] \qquad (9)$$

$$I_3^- \rightleftharpoons I_2 + I^-$$
$$K_{10} = 1.4\times10^{-3} \quad \text{at } 25°C[19] \qquad (10)$$

In (8), the forward rate is fast in acid solution as Eq. (1) indicates, the reverse rate being slow. For (9) and (10), forward and reverse rates are fast.[20] I_2 does not react directly with IO_3^-.

Isotope exchange between I_2 and IO_3^- cannot occur directly. Exchange between I^- and IO_3^- is possible *via* the Dushman reaction. Equilibria (9) and (10) make an accompanying indirect exchange between I_2 and IO_3^- possible.

Radioactive Iodine Exchange at Chemical Equilibrium. There is no confusion of experimental results for radioactive iodine exchange between I_2 and IO_3^- at chemical

Calculated rate (mol/l/min)[3]	7.0×10^{-5}	1.7×10^{-5}	8.4×10^{-6}	3.3×10^{-6}	3.1×10^{-6}	2.4×10^{-6}	5.7×10^{-5}

a) Measured $d(H^+)/dt$ from Fig. 1.
b) To be compared with calculated rate.

equilibrium.[5-7] The rate of exchange is[6,21]

$$R=\frac{2\{I_2\}\{IO_3^-\}}{2\{I_2\}+\{IO_3^-\}}\times\frac{\ln 2}{T_{1/2}} \qquad (11)$$

where $T_{1/2}$ is the half time for the exchange and R the constant rate, since the system is in chemical equilibrium. For Eq. (11) to be valid, either of the two iodine species added should be initially inactive, and exchange should proceed along a single path which in this case is that of the Dushman reaction. The braces in the equation enclose gram-formula weight of the iodine species.

The measured rates of radioisotope exchange agree fairly well with rates calculated from Eq. (1) for the equilibrium concentrations.[7] Only the $[I^-]$ term is significant in this calculation.

Radioactive Iodine Exchange Away from Chemical Equilibrium. The rate of exchange is determined by Eq. (1), in which the $[I^-]^2$ term has been confirmed. Only the most important case will be discussed.

When radioactive I^- is mixed with excess nonradioactive IO_3^- in acid solution at concentrations such that no solid I_2 is formed, the Dushman reaction will proceed at a rate given by Eq. (1). I_2 and I_3^-, both radioactive, will be produced. As the reaction proceeds, (H^+), (IO_3^-), and (I^-) will decrease, as will the rate of reaction (Fig. 1). As (I^-) decreases, the order of reaction with respect to $[I^-]$ will change as Eq. (1) requires. (I_3^-) will decrease along with (I^-) in conformity with Equilibrium (10). Radioactive IO_3^- will begin to form when steps in the reverse Dushman reaction begin to proceed at an appreciable rate. In equilibrium, forward and reverse rates will be equal, and Eq. (11) will hold.

Experiment 127 of Myers and Kennedy. Myers and Kennedy[6] reported that in an extention of their equilibrium exchange measurements to higher iodide concentrations, Experiment 127 was performed with $[NaI]=5\times10^{-3}$ and $[NaIO_3]=0.1$ in nearly neutral solution at 50 °C. No measurable exchange was found in any of the five samples of solution taken over a period of 1600 hr. They concluded that $T_{1/2}$ in Eq. (11) exceeded 5×10^5 hr at 50 °C.

By use of Eq. (11), they calculated the expected $T_{1/2}$ of 2.8×10^4 hr at 25 °C for the experiment. The calculation is not acceptable because their system was not in equilibrium. They used a value of R calculated from the $[I^-]^2$ term of Eq. (1) with $(H^+)=10^{-7}$. As (H^+) is drastically reduced during the approach to chemical equilibrium, the rate at equilibrium should be far less than their value of R to obtain $T_{1/2}=2.8\times10^4$ hr.

It is possible to calculate the expected equilibrium rate for Experiment 127. Here H_2O plays somewhat the same role as HAc in Fig. 1, and OH^- is analogous to Ac^-. Here the Dushman reaction is

$$3H_2O + 5I^- + IO_3^- = 3I_2 + 6OH^- \qquad (12)$$

Further, Equilibrium (10) requires that 3.6 mol of I_3^- form at 25 °C for each mole of I_2, which means that 2×4.6 mol OH^- will be formed for each mole of I_2 produced in Reaction (12). Thus

$$(OH^-)_{eq} = 10^{-7} + 9.2\times(I_2)_{eq} \qquad (13)$$

for an initially neutral reaction mixture that has gone to equilibrium. Obviously,

$$(H^+)_{eq}=\frac{10^{-14}}{10^{-7}+9.2\times(I_2)_{eq}} \quad \text{at 25°C} \qquad (14)$$

For known $[I^-]$ and $[IO_3^-]$, Equilibrium (8) gives the relation of $(H^+)_{eq}$ to $(I_2)_{eq}$ because

$$K_8=\frac{(I_2)^3}{(H^+)^6(I^-)^5(IO_3^-)}=1.6\times10^{47} \quad \text{at 25°C} \qquad (15)$$

The last two equations give the rounded values $(I_2)_{eq}=7.6\times10^{-7}$ and $(H^+)_{eq}=1.4\times10^{-9}$ for Experiment 127. The expected value of $T_{1/2}$ is

$$T_{1/2}=2.8\times10^4\left\{\frac{10^{-7}}{1.4\times10^{-9}}\right\}^2=1.4\times10^8 \text{ hr} \quad \text{at 25°C} \qquad (16)$$

The expected half time $T_{1/2}$ at 50 °C will be lower, perhaps 10-fold lower, than the value in Eq. (16). This lower half time still exceeds 5×10^5 hr. Therefore, our calculated value is in accord with the results of Experiment 127.

There is thus no conflict between the results of Experiment 127 and the $[I^-]^2$ term in Eq. (1). Considerations about mechanism[6,22] that assumed such a conflict are invalid. To verify the $[I^-]^2$ term by measuring the rate of isotope exchange, one ought to make the measurements on reaction mixtures at chemical equilibrium.

In order to clarify the discrepancies in Table 1, each conclusion therein should be examined as in Experiment 127, and all available chemical information be given due consideration.

We thank Professor Emile Schweikert for helpful discussions and the Robert A. Welch Foundation for support of the work.

The Crystal Structure of Orotic Acid Monohydrate (Vitamin B_{13})

Fusao TAKUSAGAWA and Akira SHIMADA

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received November 17, 1972)

The crystal structure of orotic acid monohydrate (Vitamin B_{13}) has been determined by the method of X-ray diffraction. The crystals are triclinic with the space group of $P\bar{1}$ and with cell dimensions of $a=9.561$, $b=7.261$, $c=5.895$ Å, $\alpha=117.6°$, $\beta=107.6°$, and $\gamma=90.4°$. The structure was determined by an inspection of the sharpened Patterson map. The final R value was 5.75% for 1345 observed reflections. The uracil group of orotic acid resembles uracil itself in its molecular dimensions. The molecules are arranged in layers closely parallel to the $(\bar{2}\ 1\ 1)$ plane. The orotic acid molecules are linked through two kinds of N–H···O hydrogen bonds in zig-zag chains extending in the [1 1 1] direction. Each chain is joined, by three kinds of O–H···O hydrogen bonds through the medium of a water molecule, with two neighboring chains, and each forms a sheet parallel to the $(\bar{2}\ 1\ 1)$ plane. The hydrogen bond of the water molecule as an acceptor is of the F type, in which the bisector of lone pairs in the oxygen atom is directed toward a donor group.

This work is a part of a series of X-ray studies of aromatic carboxylic acids. The series has already covered pyromellitic acid dihydrate,[1] trimellitic acid,[2] hemimellitic acid dihydrate,[3] dipicolinic acid monohydrate,[4] dinicotinic acid,[4] quinolinic acid,[4] and cinchomeronic acid.[4] These investigations have given several interesting results, and it is of interest to elucidate the molecular structure of the carboxylic acid based on the pyrimidine ring and the mode of hydrogen-bond formation. Moreover, the orotic acid is vitamin B_{13} and is a biologically-important substance, as are uracil, thymine, and other compounds with a uracil group. In view of the fact that the crystal structures of many uracil derivatives have been determined by the X-ray method, it is also of interest to compare uracil itself with its derivatives in molecular dimensions and in the hydrogen-bond system of the uracil group.

Experimental

A sample of orotic acid was supplied by the Sigma Chemical Co.; crystallization from water yielded crystals of a suitable size. The unit cell dimensions were measured from zero-layer Weissenberg photographs, which were calibrated with superimposed Al powder lines. The crystal data are given in Table 1. Using a spherically-shaped crystal with an average diameter of 0.3 mm, the intensity data were collected for the 0—6 layers around the c axis and the 0—2 layers around the b axis by the use of the multiple-film equi-inclination integrating Weissenberg technique, with Cu$K\alpha$ radiation. The intensities were estimated visually by comparison with a calibration-intensity standard. Of the 1562 possible reflections within the Cu$K\alpha$ sphere, 1488 independent reflections were measured; 143 were too weak to be observed. No absorption correction was applied. The space group $P\bar{1}$ was assigned on the basis of the statistical average for normalized structure factors.

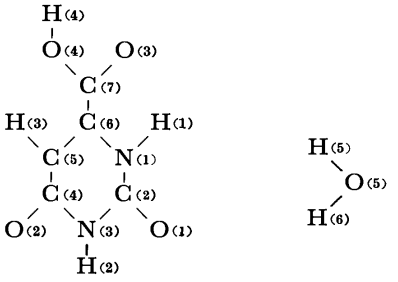
Molecular weight	174.06
Crystal system	Triclinic
Space group	$P\bar{1}$
Cell dimensions;	
a	9.561±0.006Å
b	7.261±0.006
c	5.895±0.006
α	117.6±0.09°
β	107.6±0.08
γ	90.4±0.09
V	340.7±0.4Å^3
Z	2
Density (calculated)	1.697 g/cm^3
Density (by flotation)	1.68
Linear absorption coefficient for Cu$K\alpha$	15.4 cm^{-1}
The atom numbering	



Structure Determination and Refinement

The crystal structure was determined by the inspection of a sharpened Patterson map, which was resolved sufficiently enough to give the orientation and location of the orotic acid molecule in the unit cell. The first postulated structure gave an R value of 63%, which decreased to 35% in three cycles of least-squares refinement with individual isotropic thermal parameters. A difference Fourier map clearly showed the position of water oxygen atom. Since the $\bar{2}\ 1\ 1$ reflection seemed to have a strong extinction effect, it was removed from the later refinements.

Anisotropic thermal parameters were introduced, and

1) F. Takusagawa, K. Hirotsu, and A. Shimada, This Bulletin, **44**, 1274 (1971).

2) F. Takusagawa, K. Hirotsu, and A. Shimada, to be published.

3) F. Takusagawa, K. Hirotsu, and A. Shimada, to be published.

TABLE. 2. THE OBSERVED AND CALCULATED STRUCTURE FACTORS. F_O, F_C, and DF have been multiplied by 10. The unobserved reflections are indicated by an asterisk. The reflections with $|F_O-F_C|/|F_O|$ larger than 0.3 are indicated by a plus sign.

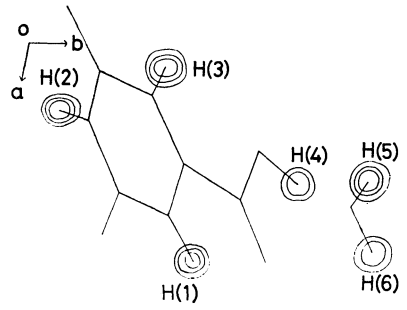

Fig. 1. A composite drawing of the electron density associated with the hydrogen atoms. The contours are at intervals of 0.2 e Å^{-3}, beginning with the 0.2 e Å^{-3} contour.

the block-diagonal least-squares refinement was continued, reducing the R value to 8.1%. At this stage, a difference Fourier map was computed, from which the positions of six hydrogen atoms were then found (Fig. 1). There was no unexplainable peak on this map except those due to hydrogen atoms. With anisotropic thermal parameters for non-hydrogen atoms and isotropic thermal parameters for hydrogen atoms, the final R value was found to be 5.75%, excluding unobserved reflections. The $\sum w(F_o-F_c)^2$ function was minimized, where;

$$w = 0.5 \text{ for } |F_o| \leqq 0.5,$$
$$w = 1.0 \text{ for } 0.5 < |F_o| < 5.0 \text{ and}$$
$$w = 5.0/|F_o| \text{ for } 5.0 \leqq |F_o|.$$

The atomic scattering factors used were those listed in the International Table for X-ray Crystallography for C, N, and O atoms and the spherical scattering factors proposed by Stewart, Davidson, and Simpson[5] for the H atom. The observed and calculated structure factors are listed in Table 2, while the fractional coordinates and thermal parameters are listed in Table 3.

Results and Discussion

Molecular Structure of Orotic Acid. The bond lengths and angles are listed, along their estimated standard deviations, in Table 4 and are shown in Fig.

TABLE 3. THE FINAL PARAMETERS AND THEIR ESTIMATED STANDARD DEVIATIONS (IN PARENTHESES)
The coordinates of the non-hydrogen atoms have been multiplied by 10^4; those of the hydrogen atoms, by 10^3. The anisotropic thermal parameters of non-hydrogen atoms are of the form $\exp[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)]$, and have been multiplied by 10^5. For the hydrogen atoms the values listed are isotropic thermal parameters B(Å^2).

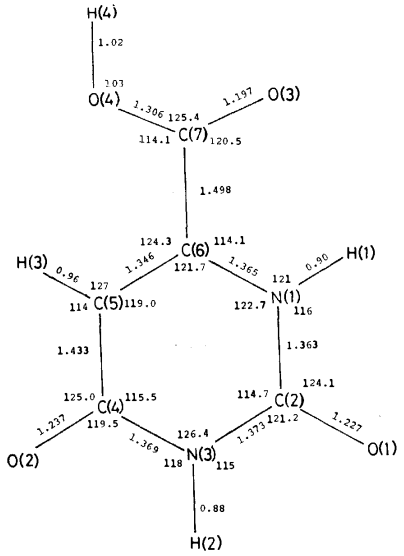

Fig. 2. Dimensions of the orotic acid molecule.

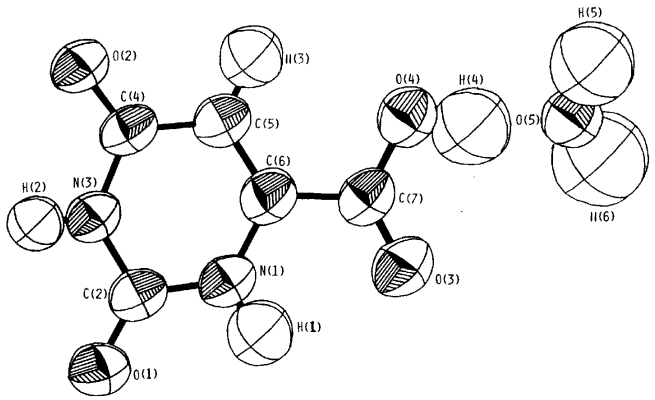

Fig. 3. The anisotropic thermal ellipsoids of non-hydrogen atoms and the isotropic thermal ellipsoids of hydrogen atoms. Ellipsoids are scaled to include the 74% probability.

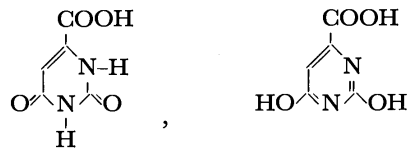
2. Figure 3 shows the anisotropic thermal ellipsoids of non-hydrogen atoms and the isotropic thermal ellipsoids of hydrogen atoms. Ellipsoids are scaled to include the 74% probability.

The orotic acid molecule may be a mixture of tautomers, such as;



However, according to the present study, the molecule clearly takes the keto form in the crystal. This is quite evident from the assignment of hydrogen atoms in the difference Fourier map. It is also confirmed by the C(2)–O(1) and C(4)–O(2) bond lengths, 1.227(3) and 1.237(3) Å, and the C(2)–N(3)–C(4) and C(2)–N(1)–C(6) bond angles, 122.7(2)° and 126.4(2)° respectively

					H(3)	+0.082
					H(4)	+0.186

a) The bond lengths are calculated by the following equations,
$D_{C-C}=1.512-0.180P$
$D_{C-N}=1.436-0.180P$
$D_{C-O}=1.370-0.180P$
K. Nishimoto and L. S. Forster, *Theor. Chim. Acta* (Berl.), **4**,155 (1966).

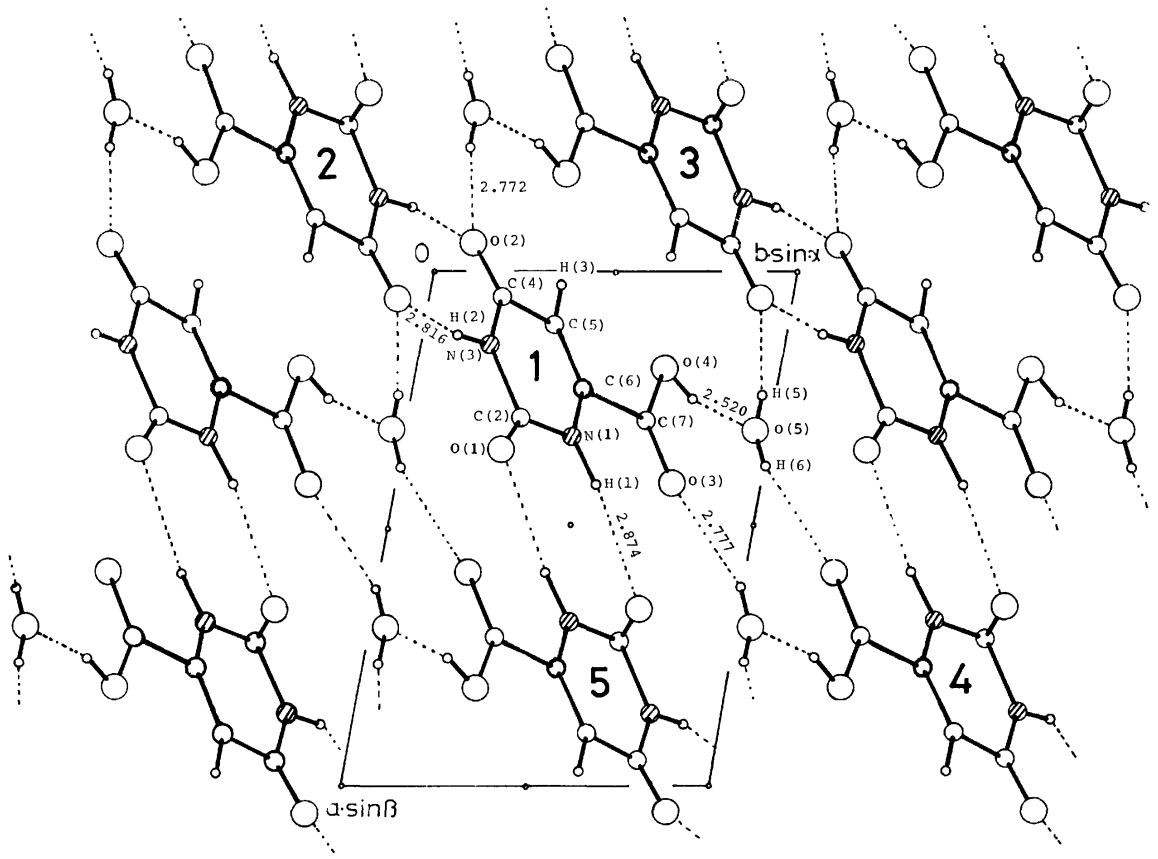

Fig. 4. A view of the crystal structure down the *c* axis. The hydrogen bonds are shown by broken lines.

(the values in parentheses denote the e.s.d.'s in the last digits, here and throughout this paper).

The pyrimidine ring is planar. The equation of the least-squares plane through six atoms of the pyrimidine ring is:

$$-0.6557X + 0.4402Y + 0.6134Z = 0.0078$$

where X, Y, and Z are coordinates in Å referred to an orthogonal set of axes, where X and Z are parallel to the a and c^* axes, and where Y lies in the ab plane; this coordinate system is used throughout this paper. The maximum deviation of a ring atom from this plane is 0.019 Å. The displacements of all the atoms from the plane are listed in Table 5.

The comparisons between the corresponding bond lengths and bond angles of orotic acid, and uracil,[6] thymine,[7] methylthymine,[8] thymidine,[9] methylthymidine,[10] and deoxyuridine[11] are given in Table 6. Those of uracil are in good agreement with those found in orotic acid, except for the C(2)–O(1) bond length and the N(3)–C(2)–O(1) bond angle. This means that the substitution of the carboxyl group does not appreciably change the bond lengths and angles of the uracil group. The C(2)–N(3)–C(4) bond angle is 3.7(2)° larger than the C(2)–N(1)–C(6) bond angle. Many other compounds which have the uracil group show a similar tendency. The net charges on each atom have been calculated by the CNDO method;[12] they are listed, along the π-bond orders, in Table 8. The C(2) atom has the most positive charge (0.522), and the C(4) atom has the second (0.437) in the uracil group. Therefore, the C(2)–N(3)–C(4) bond angle might be larger than the C(2)–N(1)–C(6) bond angle, since the repulsion between the C(2) and C(4) atoms is clearly stronger than that between the C(2) and C(6) atoms. There is a significant difference between the two bond angles, N(1)–C(6)–C(7) (114.1(2)°) and C(5)–C(6)–C(7) (124.3(2)°). A similar difference between the two angles is also observed in uracil. There is a difference of 0.010(3) Å between the C(2)–O(1) and C(4)–O(2) bond lengths. Although this difference

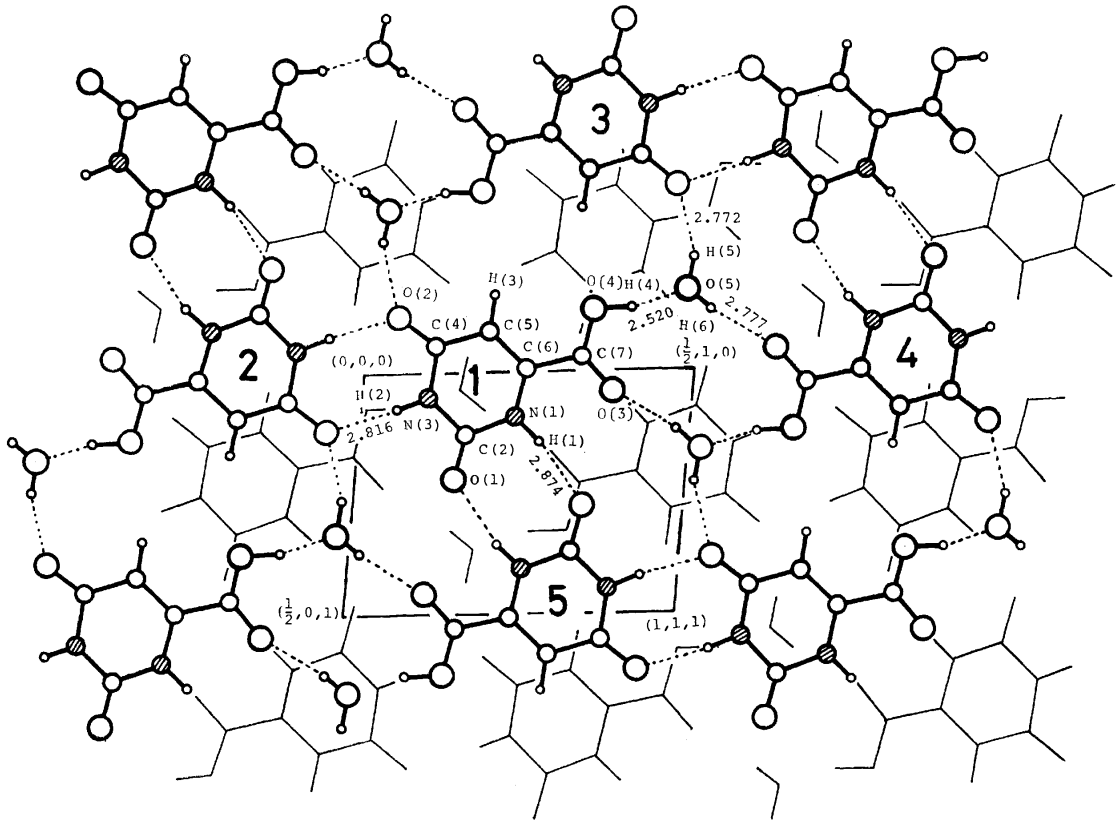

Fig. 6. A view of the crystal structure perpendicular to the ($\bar{2}$ 1 1) plane, showing the relative orientation of the molecules in two adjacent layers parallel to the ($\bar{2}$ 1 1) plane.

may be on the borderline of experimental error, similar differences between the two C=O bond lengths are also observed in thymidine,[9] methyluridine,[10] deoxyuridine,[11] methylthymine,[8] and uracil.[6] The π-bond orders of the C(2)–O(1) and C(4)–O(2) bonds are 0.793 and 0.821 respectively. These values are contrary to the observed lengths, as is shown in Table 8. The difference between the N(3)–C(2)–O(1) and N(3)–C(4)–O(2) bond angles is 1.7(2)°. Similar differences are also observed in uracil, thymine, methylthymine, thymidine, and methyluridine. In a carboxyl group, the C(7)–O(3) bond length is 0.109(3) Å shorter than the C(7)–O(4) bond length. Hence, the carboxyl group clearly consists of carbonyl and hydroxyl groups. The carboxyl group is twisted by 2.2° out of the plane of the pyrimidine ring.

Molecular Arrangement and Hydrogen-bond System.

The crystal structure is shown in Figs. 4, 5, and 6, while the distances and angles of hydrogen bonds are listed in Table 7. The molecules are arranged in layers closely parallel to the ($\bar{2}$ 1 1) plane. This plane has a spacing of 3.102 Å. The best plane, calculated by a least-squares analysis, through the carbon, nitrogen and oxygen atoms of two molecules, 1 and 2, is:

$$-0.6514X + 0.4183Y + 0.6289Z = 0.0000 \quad \text{(i)}$$

The best planes through the molecules, 1 and 3, and the molecules, 1 and 4, are found by the same procedure to be:

$$-0.6573X + 0.4183Y + 0.6289Z = -0.0630 \quad \text{(ii)}$$

$$-0.6580X + 0.4216Y + 0.6239Z = -0.0558 \quad \text{(iii)}$$

respectively. The dihedral angles which these best planes make with the ($\bar{2}$ 1 1) plane are 0.4° (i), 0.6° (ii), and 0.7° (iii). Figures 5 and 6 show the views parallel and perpendicular to the ($\bar{2}$ 1 1) plane respectively, illustrating the relative orientation of the molecules in two neighboring layers. The upper layer in Fig. 6, containing the molecules drawn with heavy lines, passes through the point of origin (0, 0, 0). In Figs. 4, 5, and 6, the same numerals designate the same molecules. The symmetry codes corresponding to these numbers are shown in Table 7.

In crystals of uracil and thymine, one of the oxygen atoms is hydrogen-bonded to the nitrogen atoms, N(1) and N(3), of two different molecules, while the other is not hydrogen-bonded to any nitrogen atom. However, in the case of the orotic acid monohydrate, each oxygen atom of the uracil group is hydrogen-bonded to one nitrogen atom of each of two different molecules. In uracil and thymine, the distances of the two N–H···O hydrogen bonds are equal within the limits of experimental error. There is, however, a significant difference between the two N–H···O hydrogen bond distances, 2.874(3) and 2.816(3) Å, in this crystal. The O(2) atom participates in two kinds of hydrogen bonds (O···H–N; 2.816(3) Å, O···H–O; 2.772(3) Å), while the O(1) atom participates in only one hydrogen bond (O···H–N; 2.874(3) Å).

Each molecule is joined, through two kinds of N–H···O hydrogen bonds around the center of symmetry, with two neighboring molecules and forms a zig-zag chain along the [1 1 1] direction. Each chain

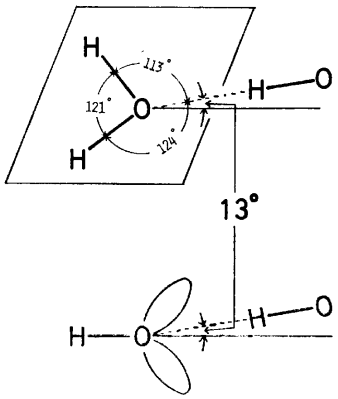

Fig. 7. Diagrammatic view of the water molecule in orotic acid. The value 13° indicates the angle between the O···H vector and the plane of the water molecule.

is joined, by three kinds of O–H···O hydrogen bonds through the medium of the water molecule, with two neighboring chains and forms a sheet parallel to the ($\bar{2}$ 1 1) plane. These three hydrogen-bond distances are 2.772(3) and 2.777(3) Å for O···HOH, which are equal within the limits of experimental error, and 2.520(3) Å for H_2O···HO, which seems to be a nearly symmetrical hydrogen bond.

Each water molecule is hydrogen-bonded to three oxygen atoms. The coordination of a water molecule is approximately trigonal planar. The hydrogen-bonding angles are H(4)–O(5)–H(5)=113(2)°, H(4)–O(5)–H(6)=124(3)°, and H(5)–O(5)–H(6)=121(3)°. The angle which the O(5)···H(4) vector of the hydrogen bond makes with the plane of the water molecule is 13° (Fig. 7). Therefore, the water molecule in this crystal is of the F type, according to the classification of Chidambaram, Sequeira, and Sikka;[13] that is, the bisector of lone pairs of the water oxygen atom is directed toward a hydrogen-bond donor group. In the hydrogen bond O(5)–H(6)···O(3), the C(7)–O(3)···H(6) hydrogen-bonding angle is 163(1)°. This value also indicates that the bisector of lone pairs in the carbonyl oxygen atom O(3) is directed toward a hydrogen-bond donor group.

Computer Programs. All the calculations were performed on a FACOM 270-30 computer at the Computer Center of Osaka City University, using these modified programs: RSLC-3 (cell constant),[14] RSSFR-3 (Fourier synthesis),[15] HBLS-IV (block-diagonal least-squares refinement),[16] DAPH (bond length, bond angle, least-squares plane),[17] SCALE (film factor, Lp, and layer scaling),[18] TE-I (thermal ellipsoid),[19] and CNINDO (CNDO and INDO calculations).[12]

The authors wish to express their thanks to Dr. K. Nishimoto of this faculty for his useful advice on the CNDO calculations.

The Crystal Structure of Dipicolinic Acid Monohydrate

Fusao TAKUSAGAWA, Ken HIROTSU, and Akira SHIMADA

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received December 4, 1972)

The crystal structure of the dipicolinic acid monohydrate has been determined by the method of X-ray diffraction. The crystal is orthorhombic, with a space group of $P2_12_12_1$ and with cell dimensions of $a=12.233$, $b=9.399$, and $c=6.817$ Å. The crystal structure was solved by an inspection of the Patterson map. The final R value was 5.67% for 964 observed reflections. The pyridine ring has the C_{2v} symmetry within the limits of experimental error. The protonation does not occur on the nitrogen atom of the pyridine ring, and two carboxyl groups consist of carbonyl and hydroxyl groups. There is a simple relation between the C–O bond length and the C–C–O bond angle. The molecules are arranged in layers closely parallel to the (0 0 1) plane. Each molecule on the same plane is hydrogen-bonded to form an endless chain along the b axis. These two chains on the planes at $z=1/8$ and 3/8 are linked together by the O–H···N hydrogen bond between the water and pyridine ring to form a double chain along the b axis. In this case, the angle between the N···H(7) vector of the hydrogen bond and the plane of the pyridine ring is 28°. This situation can be explained by the fact that two adjacent and bulky carboxyl groups wrap up the nitrogen atom as an acceptor of the hydrogen bond. The double chains are packed only by the van der Waals forces. The thermal diffuse scattering observed on Weissenberg photographs can be explained by this hydrogen-bond system.

This work is a part of series of X-ray diffraction studies on the O–H···N hydrogen bonding system in pyridine-dicarboxylic acids, which also cover dinicotinic acid,[1] quinolinic acid,[1] and cinchomeronic acid.[1] In connection with this work, the crystal structures of nicotinic acid[2] and benzoic acid[3] have also been established; they all have similar frameworks and isoelectronic structures. However, these two structures were found to be quite different from each other in the way of hydrogen-bond formation. The most remarkable feature is that the hydroxyl group in nicotinic acid is hydrogen-bonded not to the oxygen atom but to the nitrogen atom, although the hydrogen bond is plausible between two carboxyl groups, as in benzoic acid. This was explained by Wright and King[2] on the basis of the packing mode of the moelcules, which does not permit the O–H···O hydrogen bond in this case. Hence, it is of interest to elucidate the effect of the nitrogen atom in the pyridine ring on the hydrogen-bond formation in solids. The crystal structures of calcium dipicolinate trihydrate,[4] strontium dipicolinate tetrahydrate,[5] and some coordination compounds[6-8] containing dipicolinate were also determined by the X-ray method. It is also of interest to compare the molecular dimensions of dipicolinic acid itself with those of its salts and coordination compounds.

Experimental

The crystals were obtained in the form of colorless prisms by recrystallization from an aqueous solution. Weissenberg photographs showed the crystals to be orthorhombic, with the space group of $P2_12_12_1$. The unit cell dimensions were measured from zero-layer Weissenberg photographs taken with Cu$K\alpha$ radiation ($\lambda=1.5418$ Å); these photographs were calibrated with the superimposed Al powder lines ($a=4.0494$ Å). They are given, along other crystal data, in Table 1. There are four molecules in the unit cell, corresponding to the density of 1.56 g/cm³ observed by the flotation method. One crystal was in the shape of a sphere with the average diameter of 0.4 mm. The intensity data were collected for the 0—10 layers around the a axis and the 0—6 layers around the c axis by the use of the multiple-film equi-inclination integrating Weissenberg technique, with Cu$K\alpha$ radiation. The intensities of the diffraction spots

were estimated visually by comparison with an intensity standard. Of the 1071 possible reflections within the Cu$K\alpha$ sphere, 1026 independent reflections were measured; 62 were too weak to be observed. No absorption correction was applied. The appreciable thermal diffuse scattering along the a^* and c^* axes was observed on Weissenberg photographs.

Structure Determination and Refinement

At first, the crystal structure determination was attempted by the symbolic addition method. However, the statistical average for normalized structure factors showed an abnormal distribution as if this crystal had a centro-symmetric structure. Therefore, the phase refinement by the use of the tangent formula did not lead to the determination of the crystal structure. An effort was then made to solve the structure by the Patterson method. The sharpened Patterson map was resolved sufficiently to give the orientation and location of the molecule in the unit cell. The first postulated structure gave an R value of 52%, which decreased to 31% in three cycles of least-squares refinement with individual isotropic thermal factors. A difference Fourier map which was calculated by the use of these parameters clearly showed the position of the water oxygen atom. Since the 0 0 4 reflection seemed to have a strong extinction effect, this reflection was removed from the later refinements.

The coordinates and anisotropic thermal factors were refined in a block-diagonal least-squares procedure, minimizing the function $\sum w(F_o-F_c)^2$, where:

$$w = 0.5 \text{ for } |F_o| \leqq 0.5,$$
$$w = 1.0 \text{ for } 0.5 < |F_o| < 7.0 \text{ and}$$
$$w = 7.0/|F_o| \text{ for } 7.0 \leqq |F_o|.$$

The atomic scattering factors used were those listed in the International Table for X-ray Crystallography for C, N, and O atoms, and the spherical scattering factors proposed by Stewart, Davidson, and Simpson[9] for the H atom. At the stage of $R=7.9\%$, a difference Fourier map was computed, from which the positions of the seven hydrogen atoms were found (Fig. 1). With anisotropic thermal parameters for non-hydrogen atoms and isotropic thermal parameters for hydrogen atoms, the final R value was 5.67%, excluding unobserved reflections. The observed and calculated structure factors are listed in Table 2. The fractional coordinates and thermal parameters are listed in Table 3.

9) R. F. Stewart, E. R. Davidson, and W. T. Simpson, *J. Chem. Phys.*, **42**, 3175 (1965).

TABLE 3. THE FINAL PARAMETERS AND THEIR ESTIMATED STANDARD DEVIATIONS (IN PARENTHESES)

The coordinates of the non-hydrogen atoms have been multiplied by 10^4; those of the hydrogen atoms, by 10^3. The anisotropic thermal parameters of non-hydrogen atoms are of the form $\exp[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)]$, and have been multiplied by 10^5. For the hydrogen atoms, the values listed are isotropic thermal parameters B(Å^2).

Results and Discussion

Molecular Structure. The bond lengths and bond angles are listed, along their estimated standard deviations, in Table 4 and are shown in Fig. 2. Figure 1 shows a difference Fourier map along the c axis. There are three peaks around the water oxygen atom. Two of them correspond to the hydrogen atoms of the water molecule, while one may be a ghost peak or a peak due to disordered hydrogen atoms. There is no other

unexplainable peak in this difference Fourier map. Figure 3 shows the anisotropic thermal ellipsoids of non-hydrogen atoms and the isotropic thermal ellipsoids of hydrogen atoms. Ellipsoids are scaled to include 74% probability.

The pyridine ring is planar, and the maximum deviation of a ring atom from the least-squares plane is 0.007 Å. The equation of the least-squares plane through the six non-hydrogen atoms of the pyridine ring is;

$$0.0622X + 0.0208Y + 0.9979Z = 1.2303$$

where X, Y, and Z are coordinates in Å referred to an orthogonal set of axes and parallel to the a, b, and c axes. The displacements of all the atoms from the plane are listed in Table 5.

The comparisons between the corresponding bond lengths and bond angles of dipicolinic acid and calcium dipicolinate,[4] strontium dipicolinate[5] and pyridine[10] are given in Table 6. The pyridine ring has the C_{2v} symmetry within the limits of experimental error. The dimensions of the pyridine ring are in good agreement with those of pyridine itself, except for the C(2)–C(3) and C(3)–C(4) bond lengths. The net charges and π-bond orders calculated by the "complete neglect of the differential overlap (CNDO)" method[11] are shown in Fig. 4. The bond orders of the C(2)–C(3), C(3)–C(4), C(1)–C(2), and C(4)–C(5) bonds are 0.674, 0.659, 0.637, and 0.651 respectively. The first two bond orders are larger than the two others. These are in good correlation with the bond lengths obtained experimentally. The pyridine ring of dipicolinic acid

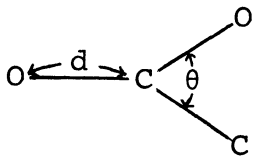
also agrees considerably well in dimensions with those of the salts of calcium and strontium.

The C(1)–N–C(5) bond angel is 116.8°; this means that the protonation did not occur on the nitrogen atom of the pyridine ring. The lengths of two C–C bonds joining the ring to the carboxyl groups are equal within the limits of experimental error; the average value is 1.509 Å, which is quite normal. The two C–O bond lengths in each carboxyl group are clearly different from each other. The bonds between the carbon and carbonyl oxygen atoms, C(6)–O(1) and C(7)–O(3), are shorter than those between the carbon and hydroxyl oxygen atoms, C(6)–O(2) and C(7)–O(4), by an average value of 0.108 Å. This finding also supports the fact that the hydrogen atoms of dipicolinic acid are definitely associated with the hydroxyl oxygen atoms. In both carboxyl groups, the C–C–O angles associated with the shorter C–O bonds are larger than those associated with longer C–O bonds, as is usually observed in carboxylic acids. There is a very simple relation between the C–O bond length and the C–C–O bond angle. This relation is $1/d=e\cdot\sin\theta+f$, where d is the C–O bond length, where θ is the C–C–O bond angle shown as follows;



and where e and f are constants. This relation is shown in Fig. 5. In spite of the simplicity of this equation, there is a good correlation between the experimental values.

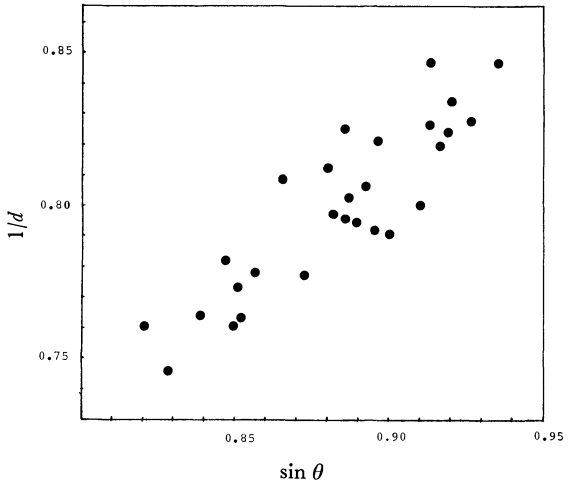


Fig. 5. The relation between the C–O bond lengths and C–C–O bond angles in carboxyl groups. The plotted compounds are dipicolinic acid, dinicotinic acid, quinolinic acid, cinchomeronic acid, calcium dipicolinate, strontium dipicolinate and oxalic acid.

The differences between the N–C(1)–C(6) and N–C(5)–C(7) bond angles, and between the C(2)–C(1)–C(6) and C(4)–C(5)–C(7) bond angles, are 3.1° and −3.2° respectively. These differences are significant, judging from their estimated standard deviations, and were not observed in calcium dipicolinate[4] and strontium dipicolinate.[5] This means that such differences depend on the orientation of the carboxyl groups and on the formation of hydrogen bonds. One carboxyl group (C(6)O(1)O(2)H(4)) is twisted by 0.8° out of the plane of the pyridine ring, while the other (C(7)O(3)O(4)H(5)) is twisted by 0.5° in the directions shown in Fig. 3.

Molecular Arrangement and Hydrogen-bond System. The crystal structure is shown in Figs. 6, 7, and 8. The distances and angles of hydrogen bonds are listed in Table 7. The dipicolinic acid and water molecules are arranged in layers closely parallel to the (0 0 1) plane, except the one hydrogen atom of the water molecule, and lie on the planes at $z=1/8$, 3/8, 5/8, and 7/8. These planes have a spacing of 1.704 Å. The best plane through the non-hydrogen atoms of a dipicolinic acid and a water molecule is calculated by the least-squares analysis to be:

$$0.0343X + 0.0171Y + 0.9993Z = 1.1129.$$

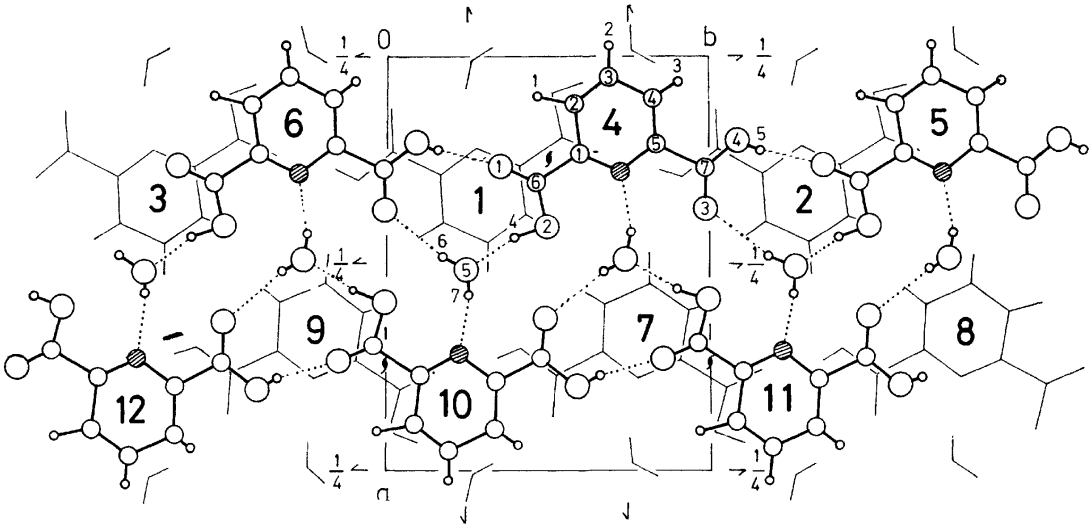

Fig. 6. A view of the crystal structure along the *c* axis, showing the relative orientation of the molecules in two adjacent layers parallel to the (0 0 1) plane. The hydrogen bonds are shown by broken lines.

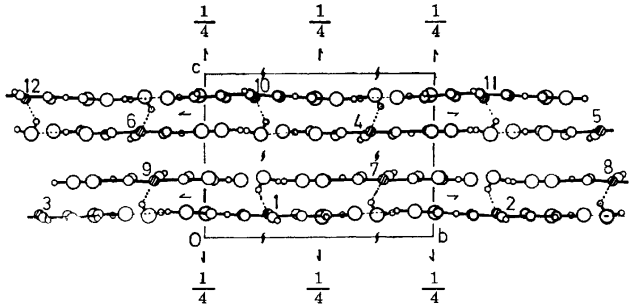

Fig. 7. A view of the crystal structure down the *a* axis. The hydrogen bonds are shown by broken lines.

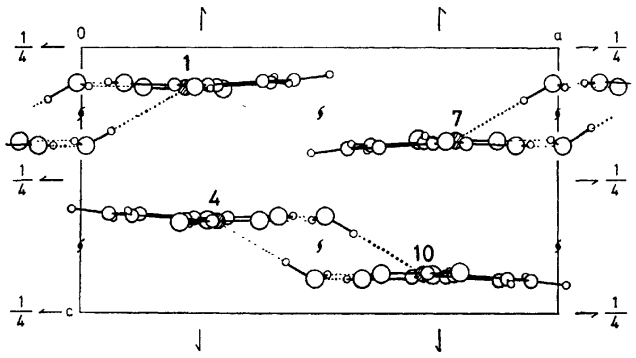

Fig. 8. A view of the crystal structure down the *b* axis. The hydrogen bonds are shown by broken lines.

The dihedral angle which it makes with the (0 0 1) plane is 2.1°. Figures 7 and 8 show the view parallel to the (0 0 1) plane, while Fig. 6 shows a view normal to the (0 0 1) plane, which illustrates the relative orientations of the molecules in two neighboring layers. The upper layer of the molecules drawn with heavy lines in this figure involves the molecules on the planes at $z=5/8$ and 7/8. In Figs. 6, 7, and 8, the same numerals designate the same molecules. The symmetry codes involving molecules which have these numbers are shown in Table 6.

Each molecule on the same plane is joined, through three hydrogen bonds, O(4)–H(5)···O(1), O(2)–H(4)···O(5), and O(5)–H(6)···O(3), with two neighboring molecules, and each forms an infinite chain along the *b* axis. In the O(4)–H(5)···O(1) hydrogen bond,

the C(6)–O(1)···H(5) and C(6)–O(1)···O(4) hydrogen bonding angles are 166° and 170.6° respectively. These values indicate that the bisector of the lone pairs in the carbonyl oxygen atom O(1) is directed toward a hydrogen-bond donor group. On the other hand, the C(7)–O(3)···H(6) and C(7)–O(3)···O(5) hydrogen bonding angles are 136° and 132.5° in the O(5)–H(6)···O(3) hydrogen bond. In this case, one of the lone pairs in the carbonyl oxygen atom O(3) is directed toward a hydrogen-bond donor group, as is usually observed in hydrogen bonds.

These two chains on the planes at $z=1/8$ and 3/8 are linked together by the O–H···N hydrogen bond between the water and the pyridine ring, and form a double chain along the b axis. The angle between the N···H(7) vector of the hydrogen bond and the plane of the pyridine ring is 28°, and the distances between N and H(7) and between N and O(5) are 2.07 and 2.941 Å respectively. Since the two carboxyl groups in α-positions prevent the formation of the O–H···N hydrogen bond which is parallel to the pyridine plane, the donor group of the hydrogen bond may deviate from the pyridine plane. In spite of such a steric hindrance and the presence of some other acceptors of the hydrogen bond, the O–H···N hydrogen bond is formed in this crystal. This suggests that the O–H···N hydrogen bond is more energetically favored than the O–H···O hydrogen bond in solids. The hydrogen-bonding system is also the same in the two chains on planes at $z=5/8$ and 7/8. These double chains are not joined by the hydrogen bond, but only by the van der Waals forces. Thus, the hydrogen-bond system in dipicolinic acid monohydrate plays an important role in connecting the molecules along the b axis.

The relation between the thermal diffuse scattering and the crystal structure can be explained on the basis of this hydrogen-bond system. There is an anisotropy of the bonding forces joining the molecules in the crystal. The molecules are linked by a strong hydrogen bond along the double chains (along the b axis in the crystal), but only the weak van der Waals forces act between chains (that is, perpendicular to the b axis). The nature of the bonding forces suggests that the vibrations are almost out-of-phase among different chains (almost an independent motion of one chain with respect to the others), but there should be a strong interaction in the motion of the molecules along the same chain. Therefore, the continuous thermal diffuse scattering appears along the directions of the a^* and c^* axes. Similar patterns were also observed in the crystals with molecules joined in the chain by hydrogen bonds.[12]

It will be of interest to compare the crystal structure of the present compound with that of isophthalic acid,[13] since they have similar frameworks and isoelectronic structures. The crystals of isophthalic acid which were recrystallized from the aqueous solution are not hydrates, and the molecules of isophthalic acid are linked together by hydrogen bonds between carboxyl groups. The reason for this difference between the crystal structures of these two compounds is the presence of a nitrogen atom in dipicolinic acid and the O–H···N hydrogen-bond formation with the aid of a water molecule.

Computer Programs. All the calculations were performed on a FACOM 270-30 computer at the Computer Center of Osaka City University using the following programs: RSLC-3 (cell constant),[14] RSSFR-3 (Fourier synthesis),[15] HBLS-IV (block-diagonal least-squares refinement),[16] DAPH (bond length, bond angle, and least-squares plane,[17] SCALE (film factor, Lp, and layer scaling),[18] TE-I (thermal ellipsoid),[19] PHASE-I, II, III (symbolic addition),[20] and CNINDO (CNDO and INDO calculations).[11]

The authors wish to express their thanks to Dr. K. Nishimoto of this faculty for his useful advice on the CNDO calculations.
