
10

The UV characteristics were also in accord with the values described in literature.[9] A plausible reaction mechanism for the formation of **10** is as follows:

Table 3. Analytical and spectral data of 4-aminopyrimidines: 
Compd.	R	Mp (°C)	Recrystn solvent	Yield (%)	Formula	Analysis (%) Calcd C	H	N	Found C	H	N
1a	H–	149—151[a]	—	32	$C_4H_5N_3$	50.51	5.30	44.19	50.53	5.30	43.79

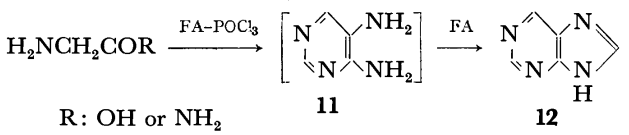
Glycinamide, when treated with FA–$POCl_3$, did not give 4,5-diaminopyrimidine (**11**); instead, purine (**12**) was obtained in 7% yield. From the above arguments it is clear that the reaction proceeded *via* intermediary formation of **11**.



Glycine itself also yielded purine when treated under the same conditions. Here again, the conversion of glycine to glycinamide could be the first step in this reaction, as in the case of the formation of 4-aminopyrimidine from acetic acid.

Further Aspects of This One-Step Synthesis. With the hope of ultimately employing the present reaction as a practical synthetic tool, we tried to synthesize a hitherto unknown diazaisolog (**16**) of the antidepressant drug, 5-(3-dimethylaminopropyl)-10,11-dihydro-5*H*-dibenz[*b*,*f*]azepine[10] (**17**), which is clinically used extensively. The results are shown in Chart 1. Interestingly, 5,6-dihydro-11*H*-dibenz[2,3]azepino[7,6-*d*]-pyrimidine (**15a**) and 9-chloro-5,6-dihydrobenz[2,3]-azepino[7,6-*d*]pyrimidine (**15b**) were obtained from homohydrocarbostyril (**13a**) and 8-chloro-homohydrocarbostyril (**13b**) in 29 and 42% yields, respectively. Similarly, **16a** and **16b** were obtained from **14a** and **14b** as shown in Chart 1.

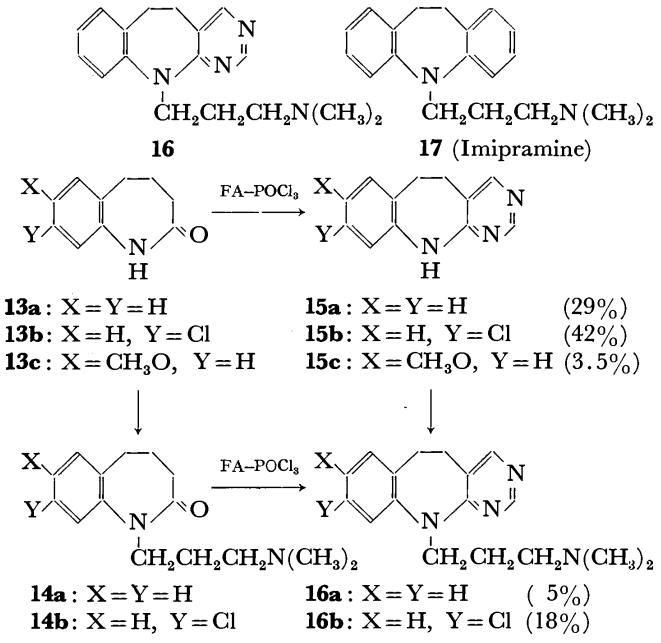


Chart 1

Both **16a** and **16b** showed weak antidepressant activities; the biological effects of these compounds will be described elsewhere.

Experimental

Mps were taken in open capillaries and are uncorrected. NMR spectra were recorded for solns in $CDCl_3$ or in d_6-DMSO (internal TMS standard), using a Varian A-60 spectrophotometer. Mass spectra (70 eV) were recorded on a Hitachi RMU-6D double focusing spectrometer and UV spectra on a Hitachi recording spectrophotometer.

Reactants. **13a**, **13b**, and **13c** were prepared by reported procedures.[11] All other reactants were obtained from commercial sources and purified by distillation or recrystallization where necessary.

General Procedure. To a mixture of carboxamides (0.01 mol) and FA (0.02 mol) in a stainless steel vessel (30 ml), $POCl_3$ (0.03 mol) was added under dry ice–acetone cooling. After being closed tightly, the vessel was heated at 120 °C for 12 hr. Then water (15 ml) was added to dissolve the reaction mixture. After neutralization with aqueous NaOH, the products were extracted with 3×5 ml EtOAc, dried over Na_2SO_4, filtered and evaporated. Column chromatography of the residue on silica gel using $CHCl_3$: acetone: EtOH (70: 30: 3) as solvent, yielded the products.

The following compounds were prepared by the general procedure unless otherwise stated.

4-Dimethylaminopyrimidine (2). *N,N*-Dimethylacetamide (0.87 g, 0.01 mol) yielded 0.21 g of **2**; mp *ca.* 40 °C (lit,[12] *ca.* 40 °C); NMR (δ) $CDCl_3$: 3.10 (s, 6H), 6.30 (broad d, 1H), 8.20 (broad s, 1H), 8.55 (broad s, 1H). Found: C, 58.35; H, 7.32; N, 34.01%.

4-Anilinopyrimidine (3). Acetanilide (1.35 g, 0.01 mol) gave 0.15 g of **3**; mp 139—142 °C (lit,[13] 142—143 °C); NMR (δ) $CDCl_3$: 6.75 (dd, J=3 and 10 Hz, 1H), 7.20—7.50 (m, 5H), 8.25 (d, J=10 Hz, 1H), 8.52 (broad s, 1H), 8.66 (s, 1H). Found: C, 70.21; H, 5.31; N, 24.29%.

5,6-Dihydro-7H-pyrrolo[2,3-d]pyrimidine (7). α-Pyrrolidone (0.85 g, 0.01 mol) yielded 0.11 g of **7**; mp 113—114 °C; NMR (δ) $CDCl_3$: 2.86—3.36 (m, 2H), 3.54—3.92 (m, 2H), 6.24 (broad s, 1H), 7.96 (s, 1H), 8.34 (s, 1H); UV (mμ) λ_{max} (ε) H_2O (pH 1): 266 (10700); H_2O (pH 11): 250 (7560), 284 (4180). Found: C, 59.32; H, 5.89; N, 34.51%. Calcd for $C_6H_7N_3$: C, 59.48; H, 5.82; N, 34.69%.

5,6,7,8-Tetrahydropyrido[2,3-d]pyrimidine (8). δ-Valerolactam (0.99 g, 0.01 mol) gave 0.19 g of **8**; mp 106—108 °C; NMR (δ) $CDCl_3$: 1.65—2.15 (m, 2H), 2.5—2.9 (m, 2H), 3.3—3.6 (m, 2H), 6.64 (broad s, 1H), 7.94 (s, 1H), 8.35 (s, 1H); UV (mμ) λ_{max} (ε) H_2O (pH 1): 262 (12100), H_2O (pH 11): 247 (9730), 286 (4750). Found: C, 62.38; H, 6.62; N, 30.92%. Calcd for $C_7H_9N_3$: C, 62.20; H, 6.71; N, 31.09%.

5,6,7,8-Tetrahydro-9H-pyrimido[4,5-b]azepine (9). ε-Caprolactam (1.13 g, 0.01 mol) gave 0.11 g of **9** after recrystallization from *n*-hexane; mp 99.5—101 °C; mol wt 149 (100%) (mass); NMR (δ) $CDCl_3$: 1.6—2.1 (m, 4H), 2.5—2.9 (m, 2H), 3.2—3.5 (m, 2H), 5.85 (braod s, 1H), 8.04 (s, 1H), 8.40 (s, 1H); UV (mμ) λ_{max} (ε) H_2O (pH 1): 274 (11500); H_2O (pH 11): 251 (7640), 282 (5210). Found: C, 64.16; H, 7.24; N, 28.10%. Calcd for $C_8H_{11}N_3$: C, 64.40; H, 7.43; N, 28.17%.

4-Amino-6,7-dihydro-5H-cyclopenta[d]pyrimidine (10). Adipamide (1.44 g, 0.01 mol) yielded 0.19 g of **10**; mp 231—234 °C (lit,[9] 235—238 °C); mol wt 135 (100%) (mass); NMR (δ) d_6-DMSO: 1.65—2.35 (m, 2H), 2.45—2.95 (m, 4H), 6.55 (broad s, 2H), 8.20 (s, 1H); UV (mμ) λ_{max} (ε) H_2O (pH 11): 238 (10800), 266 (5640) [lit,[9] H_2O (pH 13) 237 (8610), 266 (5370)]. Found: C, 61.94; H, 6.67; N, 30.98%.

Purine (12). Following the general procedure, 1.10 g of glycinamide hydrochloride (0.01 mol) was reacted with FA-$POCl_3$. Chromatography on Amberlite CG-120 and silica gel [MeOH: $CHCl_3$ (1: 1)] yielded 0.09 g of **12**. The IR spectra agreed well with that of an authentic sample.

5,6-Dihydro-11H-benz[2,3]azepino[7,6-d]pyrimidine (15a). 1,3,4,5-Tetrahydro-2*H*-1-benzazepin-2-one (**13a**, 1.61 g, 0.01 mol) gave 0.57 g of **15a**; mp 168—170.5 °C; NMR (δ) d_6-DMSO: 3.02 (s, 4H), 6.75—7.35 (m, 4H), 8.13 (broad s, 1H), 8.15 (s, 1H), 8.57 (s, 1H). Found: C, 72.67; H, 5.53; N, 21.15%. Calcd for $C_{12}H_{11}N_3$: C, 73.07; H, 5.62; N, 21.31%.

9-Chloro-5,6-dihydro-11H-benz[2,3]azepino[7,6-d]pyrimidine (15b). 8-Chloro-1,3,4,5-tetrahydro-2*H*-1-benzazepin-2-one (**13b**, 1.96 g, 0.01 mol) gave 0.97 g of **15b**, mp 177—178 °C; NMR (δ) $CDCl_3$: 3.00 (s, 4H), 6.8—7.2 (m, 3H), 8.15 (broad s, 1H), 8.21 (s, 1H), 8.61 (s, 1H). Found: C, 62.00; H, 4.35; N, 18.44; Cl, 15.47%. Calcd for $C_{12}H_{10}N_3Cl$: C, 62.21; H, 4.35; N, 18.14; Cl, 15.30%.

8-Methoxy-5,6-11H-benz[2,3]azepino[7,6-d]pyrimidine (15c). 7-Methoxy-1,3,4,5-tetrahydro-2*H*-1-benzazepin-2-one (**13c**, 1.91 g, 0.01 mol) yielded 0.08 g of **15c**; mp 145—146 °C; NMR (δ) $CDCl_3$: 2.99 (s, 4H), 3.79 (s, 3H), 6.6—6.9 (m, 2H), 6.85 (s, 1H), 8.05 (broad s, 1H), 8.15 (s, 1H), 8.53 (s, 1H). Found: C, 68.80; H, 5.56; N, 18.30%. Calcd for $C_{13}H_{13}ON_3$: C, 68.70; H, 5.77; N, 18.49%.

11-(3-Dimethylaminopropyl)-5,6-dihydro-11H-benz[2,3]azepino-[7,6-d]pyrimidine (16a). 1-(3-Dimethylaminopropyl)-1,3,4,5-tetrahydro-2*H*-1-benzazepin-2-one (**14a**, 2.46 g, 0.01 mol) gave a yellow powder of **16a** (0.14 g); NMR (δ) $CDCl_3$: 1.6—2.1 (m, 2H), 2.12 (s, 6H), 2.2—2.35 (m, 2H), 3.00 (s, 4H), 4.22 (t, J=11 Hz, 2H), 7.0—7.3 (m, 4H), 8.20 (s, 1H), 8.52 (s, 1H).

The dihydrochloride was prepared and recrystallized from EtOH-ether; mp 233—234 °C. Found: C, 57.49; H, 7.20; N, 16.06; Cl, 19.99%. Calcd for $C_{17}H_{22}N_4 \cdot 2HCl$: C, 57.47; H, 6.81; N, 15.77; Cl, 19.96%.

9-Chloro-11-(3-dimethylaminopropyl)-5,6-dihydro-11H-benz[2,3]-azepino[7,6-d]pyrimidine (16b). Method 1: Following the general procedure, 8-chloro-1-(3-dimethylaminopropyl)-1,3,4,5-tetrahydro-2*H*-1-benzazepin-2-one (**14b**, 2.81 g, 0.01 mol) gave 0.57 g of **16b**; mp 93—94 °C; NMR (δ) $CDCl_3$: 1.5—2.0 (m, 2H), 2.15 (s, 6H), 2.25—2.45 (m, 2H), 2.97 (s, 4H), 4.18 (t, J=12 Hz, 2H), 7.05—7.3 (m, 3H), 8.11 (s, 1H), 8.61 (s, 1H).

The dihydrochloride was prepared and recrystallized from EtOH-ether; mp 234—235 °C. Found: C, 51.92; H, 5.78; N, 14.41; Cl, 26.96%. Calcd for $C_{17}H_{21}N_4Cl \cdot 2HCl$: C, 52.39; H, 5.95; N, 14.37; Cl, 27.29%.

Method 2: To a solution of 9-chloro-5,6-dihydro-1H-benz-[2,3]azepino[7,6-*d*]pyrimidine (**15b**, 1.16 g, 0.005 mol) and 3-dimethylaminopropylchloride (1.83 g, 0.015 mol) in 4 ml of DMSO, 0.43 g of NaH (54% in mineral oil) in 6 ml of DMSO was added with stirring under nitrogen. After being stirred for 4 hr at room temperature, the reaction mixture was poured into 30 ml of water and extracted with 2×20 ml ether. The usual work up and chromatography on basic alumina using benzene: ethyl acetate (1: 1) as solvent yielded 0.62 g og **16b**.

The following compounds (**14a** and **14b**) were prepared by this method.

1-(3-Dimethylaminopropyl)-1,3,4,5-tetrahydro-2H-1-benzazepin-2-one (14a). 1,3,4,5-Tetrahydro-2*H*-1-benzazepin-2-one (**13a**, 16.1 g, 0.1 mol) gave a yellow oil of **14a** which did not crystallize (17.4 g); NMR (δ) $CDCl_3$: 1.5—2.0 (m, 2H), 2.14 (s, 6H), 2.15—2.35 (m, 4H), 2.35—2.45 (m, 2H), 2.6—2.9 (m, 2H), 3.90 (t, J=11 Hz, 2H), 7.1—7.3 (m, 4H). Found: C, 73.21; H, 9.18; N, 11.55%. Calcd for $C_{15}H_{22}ON_2$: C, 73.13; H, 9.00; N, 11.37%.

8-Chloro-1-(3-dimethylaminopropyl)-1,3,4,5-tetrahydro-2H-1-benzazepin-2-one (14b). 8-Chloro-1,3,4,5-tetrahydro-2*H*-1-benzazepin-2-one (**13b**, 45.0 g, 0.23 mol) gave a yellow oil of **14b** (44.3 g); NMR (δ) d_6-DMSO: 1.4—1.9 (m, 2H), 2.10 (s, 6H), 2.1—2.4 (m, 6H), 2.45—2.8 (m, 2H), 3.82 (t, J=12 Hz, 2H), 7.25 (d, 2H), 7.43 (broad s, 1H). Found: C, 63.73; H, 7.64; N, 9.46; Cl, 12.37%. Calcd for $C_{15}H_{21}ON_2Cl$: C, 64.16; H, 7.54; N, 9.98; Cl, 12.63%.

The hydrochloride was recrystallized from EtOH–ether; mp 160—161 °C. Found: C, 56.77; H, 7.15; N, 8.82; Cl, 22.12%. Calcd for $C_{15}H_{21}ON_2Cl \cdot HCl$: C, 56.80; H, 6.99; N, 8.83; Cl, 22.35%.

The author is grateful to Drs. S. Tatsuoka, E. Ohmura, K. Morita, and M. Ochiai of the same division for their discussion and encouragement throughout this work. Thanks are also given to Mr. H. Shimadzu for his assistance with the experimental work.

New Furanoeremophilane Derivatives from *Farfugium japonicum* Kitamura

Hajime NAGANO, Yoshiaki TANAHASHI, Yoshihiko MORIYAMA, and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received April 2, 1973)

Five new furanoeremophilane derivatives, I, II, III, IV, and V, have been isolated from *Farfugium japonicum* Kitamura, and their structures have been determined. Conformations of some furanoeremophilane derivatives are discussed.

In addition to the previously reported farfugin A and B,[1] five new furanoeremophilane derivatives, I, II, III, IV, and V, have been isolated from *Farfugium japonicum* Kitamura (=*Ligularia tussilaginea* Makino). In this paper we wish to describe the structure determination of these compounds.

	R_1	R_2
(I)	$-CO-C(CH_3)=CH-CH_3$	$-CO-C(CH_3)=CH-CH_3$
(II)	$-CO-C(CH_3)=CH-CH_3$	H
(VI)	H	H
	R_3	R_4
(IV)	$-CO-C(CH_3)=CH-CH_3$	β-OH
(V)	$-CO-C(CH_3)=CH-CH_3$	β-H
(XIV)	H	β-OH
(XV)	H	β-H

Compound I, a viscous oil, M^+ at *m/e* 414 ($C_{25}H_{34}O_5$), $[\alpha]_D$ +17° (in MeOH), was positive to the Ehrlich test. IR, UV, PMR, and mass spectra (*cf.* Experimental and Table 1) suggest the presence of a β-methyl substituted furan ring, a secondary and a tertiary methyl and also that of partial structures: $(CH_3)_2C{=}CHCOO-$ and $CH_3CH{=}C(CH_3)COO-$. The latter moiety was determined as angeloyloxyl group by benzene induced solvent shift[2] ($\delta^{CCl_4}-\delta^{C_6D_6}=0.56$) of the olefinic proton found to be *trans* to the ester group.

Reduction of I with lithium aluminum hydride in ether gave a diol (VI), mp 187 °C (decomp.), M^+ at *m/e* 250 ($C_{15}H_{22}O_3$), $[\alpha]_D$ −24° (in EtOH), which on oxidation with active manganese dioxide[3] in benzene afforded a diketone (VIIa), mp 210 °C, M^+ at *m/e* 246 ($C_{15}H_{18}O_3$), $[\alpha]_D$ +26° (in $CHCl_3$), λ_{max} 282 nm (ε 15600), and a hydroxy-ketone (VIIIa), mp 176.5 °C, M^+ at *m/e* 248 ($C_{15}H_{20}O_3$), $[\alpha]_D$ −31° (in MeOH). Compound VIIa was found to be identical with known 3,9-dioxo-furanoeremophilane (VIIa) derived from kablicin, a furanoeremophilane derivative isolated from *Petasites kablikianus*.[4] Thus, the diol (VI) must be 3,9-dihydroxy-furanoeremophilane. Compound I would be either 3-angeloyloxy-9-senecioyloxy- or 3-senecioyloxy-9-angeloyloxy-furanoeremophilane.

Dehydration of VI with *p*-toluenesulfonyl chloride in pyridine at 110 °C gave two products, IX [M^+ at *m/e* 232 ($C_{15}H_{20}O_2$)] and X [M^+ at *m/e* 214 ($C_{15}H_{18}O$)]. The structures IX and X are compatible with their other spectral data, respectively (*cf.* Experimental).

Catalytic hydrogenation of IX over 10% palladium-charcoal in ethanol gave a pair of epimers at C-10: XIa, an oil, M^+ at *m/e* 234 ($C_{15}H_{22}O_2$), $[\alpha]_D$ −22° (in MeOH), and XIb, mp 79—80 °C, M^+ at *m/e* 234 ($C_{15}H_{22}O_2$), $[\alpha]_D$ +67° (in MeOH). The latter proved to be identical with furanoligularanol (XIb) (3β-hydroxy-10αH-furanoeremophilane),[5] derived from furanoligularenone.[5] Therefore, the stereochemistry including absolute configuration of 3-hydroxyl group of the diol (VI) should be β(*S*).

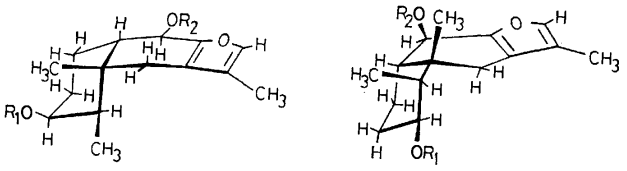
a) Coupling constants are expressed in Hz.
s: singlet, d: doublet, q: quartet, m: multiplet.

Compound II, an oil, M^+ at m/e 332 ($C_{20}H_{28}O_4$), $[\alpha]_D$ −11° (in MeOH), was related to I by partial hydrolysis of I with ethanolic potassium hydroxide at room temperature to give II. When I was absorped on silica gel and then eluted with solvent, II was formed.[6] Reduction of II with lithium aluminum hydride gave VI. Spectral data of II show the presence of a secondary hydroxyl and the absence of a senecioyl group. Thus, II is a desenecioyl derivative of I. In the PMR spectrum of II (Table 1), an allylic proton on hydroxy-bearing carbon resonates at δ^{CCl_4} 4.30, while the corresponding allylic proton signal of I appears at δ^{CCl_4} 5.43. These observations show that the hydroxyl group of II and the senecioyloxyl group of I are located on C-9. Therefore, I must be 3β-angeloyloxy-9-senecioyloxy-furanoeremophilane, and II should be 3β-angeloyloxy-9-hydroxy-furanoeremophilane.

Furanoeremophilane derivatives would exist in two interchangeable conformations such as **A** (steroidal) and **B** (non-steroidal conformation).[7] A number of furanoeremophilane derivatives have been isolated from the plants of Compositae. However, no description for the existence in non-steroidal conformation has yet been reported.



A **B**

In the PMR spectra of I, II, and VI, a broad signal (half-band width ~15 Hz) due to a proton at C-3α appears at δ^{CCl_4} 5.20, δ^{CCl_4} 5.16, and δ^{CDCl_3} 4.08, respectively, indicating an axial nature[8] for this proton. In the spectrum of II in benzene-d_6, the 3α(axial)-proton signal is observed as a quintet due to a large diaxial ($J_{2\beta.3\alpha}$=10 Hz) and two smaller axial-equatorial ($J_{2\alpha.3\alpha}=J_{3\alpha.4\alpha}$=5 Hz) vicinal couplings. An allylic proton at C-9 of I, II, and VI resonates as a singlet (half-band width ~3 Hz), suggesting a vicinal coupling ($J_{9.10}$) is small. These data can only be interpreted on the basis of the non-steroidal conformation (**B**) with the substituent at C-9 in β-configuration, in which the dihedral angle between $C_{(9\alpha)}$-H and $C_{(10\beta)}$-H is about 70—80° on Dreiding model. This dihedral angle

6) This suggests that II might be an artifact derived from I during isolation procedures involving silica gel chromatography. In the crude extract of the plant the absence of II was detected on tlc. Therefore, II is considered to be an artifact.

7) Z. Samek, J. Harmatha, L. Novotný, and F. Šorm, *Coll. Czech. Chem. Comm.*, **34**, 2792 (1969).

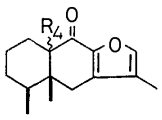
8) N. S. Bhacca and D. H. Williams, "Applications of NMR Spectroscopy in Organic Chemistry," Holden-Day, San Francisco (1964), pp. 77, 165.

would increase more than 80° resulting in reduction of vicinal coupling ($J_{9\alpha,10\beta}$), when a 1,3-diaxial interaction between the methyl group at C-5β and the substituent at C-9β becomes more important.

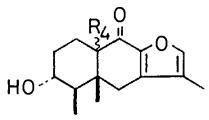
The structures including absolute configurations of I, II, and VI are thus determined as 3β-angeloyloxy-9β-senecioyloxyfuranoeremophilane (I), 3β-angeloyloxy-9β-hydroxyfuranoeremophilane (II) and 3β,9β-dihydroxy-furanoeremophilane (VI), respectively.

The hydroxy-ketone (VIIIa) exhibits an UV absorption at λ_{max} 281 nm (ε 17000), showing that the carbonyl group conjugated with furan ring is located on C-9.[9] The ORD data (*cf.* Experimental) of VIIIa is closely related to that of 9-oxo-furanoeremophilane (XIIa).[4] As VIIIa was formed by oxidation of VI, the hydroxyl group at C-3 of VIIIa must be β; this received support from the determination of absolute configuration at C-3 of VIIIa as *S* by the Horeau's method[10] (esterification 84%; optical yield (−) 25%). Therefore, the hydroxy-ketone (VIIIa) is (3*S*)-hydroxy-9-oxo-furanoeremophilane.

The same structure (VIIIa) has already been given by Rivett and Woolard for epieuryopsonol (mp 216—217 °C).[11] However, our hydroxy-ketone (VIIIa) (mp 176.5 °C) is different from epieuryopsonol. This discrepancy could be overcome when the structure of epieuryopsonol is revised from VIIIa to its 10αH-epimer, 3β-hydroxy-9-oxo-10αH-furanoeremophilane (VIIIb). This received support from an alkaline epimerization of the hydroxy-ketone (VIIIa) (mp 176.5 °C) to give its 10αH-epimer (VIIIb), mp 218—219 °C, whose PMR data are in accord with those[11] of epieuryopsonol. The structures of euryopsonol (XIIIa), dehydroeuryopsonol (VIIa), and of deoxydehydroeuryopsonol (XIIa)[11] are to be revised to XIIIb, VIIb, and XIIb, respectively. Expermiental data[11] of these euryopsonol derivatives can be best interpreted on the basis of 10αH-furanoeremophilane rather than furanoeremophilane skeleton, when compared with those of kablicin derivatives[4] (*cf.* Table 2). During isolation procedures of euryopsonol including treatment with alkali,[11] an epimerization at C-10 must have occurred to afford more stable 10αH-epimer (XIIIb).



(XIIa) R_4=β-H
(XIIb) R_4=α-H



(XIIIa) R_4=β-H
(XIIIb) R_4=α-H

Compound III, an oil, M^+ at *m/e* 316 ($C_{20}H_{28}O_3$), $[\alpha]_D$ −38° (in MeOH), was positive to the Ehrlich test. The PMR spectrum (Table 1) showed the presence of an angeloyl group. Reduction of III with lithium aluminum hydride in ether gave XIa, $[\alpha]_D$ −25° (in MeOH). Therefore, III is 3β-angeloyloxy-furanoeremophilane.[12]

Spectral data of compound IV, mp 82—84 °C, M^+ at *m/e* 332 ($C_{20}H_{28}O_4$), $[\alpha]_D$ −68° (in MeOH), suggest the presence of a hydroxyl and a senecioyl groups. On reduction with lithium aluminum hydride, IV yielded a diol, mp 126 °C (decomp.), $[\alpha]_D$ +50° (in MeOH), identical with 6β,10β-dihydroxy-furanoeremophilane (XIV) isolated from *Ligularia japonica* Less.[13] Thus, the structure of IV is represented by 6β-senecioyloxy-10β-hydroxy-furanoeremophilane (IV).

The presence of a senecioyl group is suggested for compound V, an oil, M^+ at *m/e* 316 ($C_{20}H_{28}O_3$), on the basis of spectral data. Reduction of V with lithium aluminum hydride gave known petasalbin (XV),[14] $[\alpha]_D$ −14° (in MeOH). Compound V must be 6β-senecioyloxy-furanoeremophilane (V).

In the PMR spectra of III and XIa, a broad multiplet (half-band width ~15 Hz) due to a proton at C-3α appears at δ^{CCl_4} 5.34 and 4.08 respectively. This shows an axial nature for this proton, suggesting that III and XIa are in a non-steroidal rather than a steroidal conformation.

The PMR spectrum of 3β,9α-dihydroxy-furanoeremophilane[15] (XVI), prepared from VIIIa by reduction with lithium aluminum hydride, shows a broad multiplet (half-band width ~15 Hz) at δ^{CDCl_3} 4.20 due to a proton at C-3α. A proton at C-9β resonates as a doublet ($J_{9\beta,10\beta}$=6 Hz) at δ^{CDCl_3} 4.80. These data are compatible with a non-steroidal conformation for XVI.

TABLE 2[a]

Furanoeremophilanes	3α-hydroxy-9-oxo-		3β-hydroxy-9-oxo-		3,9-dioxo-		9-oxo-	
Derivaitves of kablicin[4]	XIIIa (176 °C)	XIIIb (230 °C)			VIIa (210 °C)	VIIb (225 °C)	XIIa (112 °C)	XIIb (148—149 °C)
Derivatives of euryopsonol[11]		euryopsonol (230—231 °C)		epieuryopsonol (216—217 °C)		dehydro-euryopsonol (224—225 °C)		deoxydehydro-euryopsonol (145 °C)
This report			VIIIa (176.5 °C)	VIIIb (218—219 °C)	VIIa (210 °C)			

a) Mps are indicated in parentheses.

15) Oxidation of XVI with active manganese dioxide led to regeneration of VIIIa.

Compounds I, II, III, VI, XIa, and XVI were thus shown to be in the non-steroidal conformation[16] such as **B**. The 3β-acyloxyl or 3β-hydroxyl group of these compounds is in an equatorial conformation, which avoids the unfavorable 1,3-diaxial interaction between 3β-substituent and 5β-methyl group; this must be the driving force to bring these compounds in a non-steroidal conformation. A predominance of this driving force over the 1,3-diaxial interaction between 9β-substituent and 5β-methyl group was shown for I, II, and VI.

Experimental

IR, UV, and Mass spectra were measured using Hitachi EPI-G2, Hitachi EPS-3 and Hitachi RMU-6 spectrometers, respectively. PMR spectra were taken on JEOL JNM-PS-100 (100 MHz) and Hitachi R-20 (60 MHz) spectrometers. Chemical shifts are expressed in δ (TMS as an internal standard). Merck Kieselgel G and Kieselgel 60 PF_{254} were used for analytical and preparative tlc, respectively. For column chromatography Wakogel C 200 was used.

Isolation. The roots of *Farfugium japonicum* Kitamura (15 kg) were extracted with ether at room temperature. The extract was then filtered, dried over anhydrous sodium sulfate and evaporated to afford a viscous oil (80 g). The oil (30 g) was again dissolved in ether, washed with 5% aqueous sodium carbonate solution, dried with anhydrous sodium sulfate and evaporated. The residue (18 g) was immediately chromatographed on silica gel (400 g) with light petroleum-ether (10: 1) as eluent (each fraction 400 ml).

Fractions 1 and 2 gave a viscous oil (1.46 g), a half of which was repeatedly chromatographed on silica gel (eluent: light petroleum-ether (100: 1)) to give an oil (124 mg). The oil was further purified by preparative tlc to afford III (77 mg) and V (16 mg).

Fraction 3 afforded I, a viscous oil (4.92 g).

Fractions 4 and 5 afforded a pale yellow oil (2.96 g), containing IV, which was isolated by preparative tlc.

The extract residue (6 g) in light petroleum was absorped on silica gel. After one day, elution with light petroleum-ether (25: 1, 3 l) and then with light petroleum-ether (10: 1. 6 l) afforded an oil (917 mg). On repeated chromatography followed by preparative tlc of the oil, II (46 mg) was obtained.

3β-Angeloyloxy-9β-senecioyloxy-furanoeremophilane (I). Compound I was a viscous oil, $[\alpha]_D^{17}$ +17° (*c* 1.45, in MeOH). Its spot on tlc plate showed yellow green color to the Ehrlich test, and developed blue color when 2% ceric sulfate reagent was sprayed and then heated. Spectral data of I are as follows; UV: λ_{max}^{MeOH} 220 nm (ε 32000); IR: ν_{max}^{liquid} 1720, 1650, and 1560 cm^{-1}; PMR (Table 1); MS *m/e* 414 (relative intensity 1.5%, M^+ ($C_{25}H_{34}O_5$)), *m/e* 83 (54%, $[CH_3CH{=}C(CH_3)CO]^+$ and $[(CH_3)_2C{=}CHCO]^+$) and *m/e* 55 (100%, $[CH_3CH{=}CCH_3]^+$ and $[(CH_3)_2C{=}CH]^+$).

3β-Angeloyloxy-9β-hydroxy-furanoeremophilane (II). Compound II, an oil, $[\alpha]_D^{14}$ −11° (*c* 0.8, in MeOH), was positive to the Ehrlich test, and displayed blue coloring with 2% ceric sulfate reagent when heated on tlc plate. Characterization of II is as follows; UV λ_{max}^{EtOH} 219 nm(ε 14500); IR: ν_{max}^{liquid} 1700, 1640, and 1560 cm^{-1}; PMR (Table 1); MS: *m/e* 332 (4%, M^+ ($C_{20}H_{28}O_4$)), *m/e* 314 (5%, $[M-H_2O]^+$), *m/e* 124 (100%, *retro*-Diels-Alder fragment), *m/e* 83 (85%, $[CH_3CH{=}C(CH_3)CO]^+$), and *m/e* 55 (70%, $[CH_3CH{=}CCH_3]^+$).

Reduction of I with Lithium Aluminum Hydride. I (996 mg) in dry ether (50 ml) was refluxed with lithium aluminum hydride (200 mg) for 1.5 hr under nitrogen atmosphere. Then, the excess of lithium aluminum hydride was decomposed with water, and extracted with ether. The usual treatment gave a crystalline product, which was recrystallized from isopropyl ether to give VI (364 mg). The residue obtained from the mother liquid was chromatographed on silica gel (30 g) with light petroleum-ether (1:1) as eluent to give further VI (40 mg). 3β,9β-Dihydroxy-furanoeremophilane (VI), mp 187 °C (decomp.), $[\alpha]_D^{19}$ −24° (*c* 0.47, in EtOH); UV: λ_{max}^{EtOH} 222.5 nm (ε 7200); IR: ν_{max}^{Nujol} 3475, 3380, and 1565 cm^{-1}; PMR ($CDCl_3$): δ 1.00 (d, *J*=7 Hz, $C_{(4)}$-CH_3), 1.14 (s, $C_{(5)}$-CH_3), 1.90 (d, *J*=1.5 Hz, $C_{(11)}$-CH_3), 1.96 (d, *J*=(−) 17 Hz, $C_{(6)}$-H), 2.66 (d, *J*=(−) 17 Hz, $C_{(6)}$-H), 4.08 (m, $C_{(3)}$-H), 4.40 (s, $C_{(9)}$-H), and 7.12 (q, *J*=1.5 Hz, $C_{(12)}$-H); MS: *m/e* 250 (6%, M^+ ($C_{15}H_{22}O_3$)) and *m/e* 124 (100%, *retro*-Diels-Alder fragment). Found: C, 72.12; H, 8.70%. Calcd for $C_{15}H_{22}O_3$: C, 71.79; H, 8.86%.

Reduction of II with Lithium Aluminum Hydride. Treatment of II with lithium aluminum hydride by the same procedures described as above gave VI, mp 187 °C (decomp.), $[\alpha]_D^{15}$ −28° (*c* 1.0, in MeOH).

Hydrolysis of I. *A*: I (1.86 g) was chromatographed on silica gel (50 g) using light petroleum-ether (50: 1) as eluent. However, only 48 mg of I was recovered and from the fractions eluted with ether a yellowish oil (640 mg) was obtained. The oil was repeatedly chromatographed on silica gel (35 g) with light petroleum-ether (10: 1) to give II (96 mg).

B: A solution of potassium hydroxide (1 g) in ethanol (25 ml) was added to I (277 mg) and the mixture was allowed to stand overnight at room temperature, added water and extracted with ether. The extract was washed with water, dried with anhydrous sodium sulfate and evaporated under reduced pressure to give an oil (191 mg) containing II and VI. VI was not detected on tlc before the evaporation of the solvent. Therefore, this compound must be formed on heating during the above procedures.

C: The residue obtained by the procedures *A* and *B* were combined, dissolved in ethanolic potassium hydroxide and refluxed for 2.5 hr under nitrogen atmosphere. After usual treatment, the resulting residue was recrystallized from isopropyl ether to give VI. The aqueous layer was acidified with dil hydrochloric acid and extracted with ether. After the solvent was distilled off, the residue was allowed to stand for several days and tiglic acid (an isomerization product of angelic acid) was obtained as crystals.

Oxidation of VI with Active Manganese Dioxide. To a solution of VI (154 mg) in benzene (50 ml) was added active manganese dioxide[3] (1.5 g) and stirred for 22 hr under nitrogen atmosphere. After filtration, the solvent was removed to afford a residue, which was chromatographed on silica gel (7 g). Fractions eluted with light petroleum-ether (1: 1) gave VIIa (64 mg), and successive elution with ether gave VIIIa (70 mg).

3,9-Dioxo-furanoeremophilane (VIIa); mp 210 °C (recrystallized from ethanol), $[\alpha]_D^{19}$ +26° (*c* 0.71, in $CHCl_3$); UV: λ_{max}^{EtOH} 282 nm (ε 15600); IR: ν_{max}^{Nujol} 1715, 1657, and 1530 cm^{-1}; PMR ($CDCl_3$): δ 0.96 (d, *J*=7 Hz, $C_{(4)}$-CH_3), 1.11

16) The PMR spectra of furanopetasine[9] (2α-angeloyloxy-9α-hydroxy-furanoeremophilane; 2β-H at δ^{CDCl_3} 5.20, half-band width ~15 Hz) and furanopetasol[9] (2α,9α-dihydroxy-furanoeremophilane; 2β-H at δ^{CDCl_3} 4.06, half-band width~15 Hz), offered through courtesy of Dr. L. Novotný, showed that these compounds also existed in a non-steroidal conformation, in which the substituents at C-2α and C-9α were equatorial.

(s, $C_{(5)}$-CH_3), 2.01 (d, J=1.5 Hz, $C_{(11)}$-CH_3), and 7.42 (q, J=1.5 Hz, $C_{(12)}$-H); MS: *m/e* 246 (39%, M^+ ($C_{15}H_{18}O_3$)), *m/e* 175 (100%), and *m/e* 122 (5%). The PMR spectrum of VIIa in the presence of Eu(dpm)$_3$ (0.45 mol equivalent) as shift reagent revealed the presence of a partial structure -CO-CH(CH_3)-$\dot{C}$-; namely, signals due to $C_{(4)}$-CH_3 and $C_{(4)}$-H appeared at δ^{CDCl_3} 3.39 (d, J=6.5 Hz) and at δ^{CDCl_3} 6.35 (q, J=6.5 Hz), respectively. Diketone (VIIa)[17] was found to be identical (mp 210 °C) with 3,9-dioxo-furanoeremophilane.

3β-Hydroxy-9-oxo-furanoeremophilane (VIIIa); mp 176.5 °C (recrystallized from isopropyl ether), $[\alpha]_D^{20}$ −31° (*c* 0.97, in MeOH); UV: λ_{max}^{EtOH} 281 nm (ε 17000); ORD (*c* 0.14, in MeOH): $[\phi]_{280}$ −6800°, $[\phi]_{260}^{trough}$ −14000°, $[\phi]_{230}^{peak}$ −10000°, $[\phi]_{208}^{trough}$ −27000° and $[\phi]_{200}$ −6800°; IR: ν_{max}^{Nujol} 3500, 1650, and 1525 cm^{-1}; PMR ($CDCl_3$): δ 0.99 (d, J=7 Hz, $C_{(4)}$-CH_3), 1.10 (s, $C_{(5)}$-CH_3), 1.98 (d, J=1.5 Hz, $C_{(11)}$-CH_3), 4.17 (m, $C_{(3)}$-H), and 7.41 (q, J=1.5 Hz, $C_{(12)}$-H); MS: *m/e* 248 (5%, M^+ ($C_{15}H_{20}O_3$)), *m/e* 91 (46%), *m/e* 77 (32%), and *m/e* 66 (100%). Found: C, 72.83; H, 7.82%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

Application of the Horeau's Method[10] to VIIIa. VIIIa (18.6 mg, 0.075 mmol) in pyridine (3 ml) was allowed to stand with α-phenylbutyric anhydride (69.6 mg, 0.224 mmol) for 18 hr at room temperature. The reaction mixture was then heated with one drop of water. After benzene was added, the mixture was titrated with 0.1 M KOH in the presence of phenolphthalein. The aqueous layer was acidified with dil sulfuric acid and then extracted with benzene. After usual treatment of the extract, the solvent was evaporated to give α-phenylbutyric acid. The optical rotation value (α_D −0.025°) was observed for the benzene solution (5 ml) of the acid using a 0.5 dm cell.

Alkaline Epimerization of VIIIa. To a solution of VIIIa (45 mg) in ethanol (20 ml), 10% aqueous sodium hydroxide (5 ml) was added and the mixture was refluxed for 1 hr under nitrogen atmosphere. After the reaction mixture was treated as usual, the residue (41 mg) was chromatographed on silica gel (3 g) using light petroleum–ether (3: 1) as eluent to give the epimerized product VIIIb (12 mg). Successive elution with ether gave VIIIa (*ca.* 30 mg). Compound VIIIb; mp 218—219 °C (recrystallized from isopropyl ether); IR: ν_{max}^{Nujol} 3480 and 1650 cm^{-1}; PMR ($CDCl_3$): δ 1.02 (s, $C_{(5)}$-CH_3), 1.16 (d, J=7 Hz, $C_{(4)}$-CH_3), 1.97 (d, J=~1 Hz, $C_{(11)}$-CH_3), 3.88 (m, $C_{(3)}$-H), and 7.32 (q, J=~1 Hz, $C_{(12)}$-H).

Dehydration of VI with p-*Toluenesulfonyl Chloride in Pyridine.* To a solution of VI (398 mg) in pyridine (10 ml), *p*-toluenesulfonyl chloride (400 mg) was added and heated at 110 °C (oil bath temperature) for 20 min under nitrogen atmosphere. Evaporation of the solvent gave a reddish residue, which was immediately chromatographed on silica gel (30 g) using light petroleum–ether (20: 1) as eluent. (each fraction *ca.* 70 ml).

Fraction 2 gave a pale yellow oil, X (20 mg); UV: λ_{max}^{MeOH} 293 nm (ε ~10000); PMR (C_6D_6): δ 1.09 (s, $C_{(5)}$-CH_3), 1.60 (m, $C_{(4)}$-CH_3), 1.78 (d, J=1.5 Hz, $C_{(11)}$-CH_3), 5.35 (m, $C_{(3)}$-H), 6.13 (d, J=~1 Hz, $C_{(9)}$-H), and 6.93 (q, J=1.5 Hz, $C_{(12)}$-H); MS: *m/e* 214 (46%, M^+ ($C_{15}H_{18}O$)), and *m/e* 199 (100%, $[M-CH_3]^+$), which was sensitive to the air. This compound (X) on tlc plate developed a bright red color with 2% ceric sulfate reagent.

Fractions 7—16 gave a pale yellow oil, IX (140 mg); UV: λ_{max}^{MeOH} 292 nm (ε ~10000); IR: ν_{max}^{liquid} 3400 cm^{-1}; PMR (CCl_4): δ 1.05 (s, $C_{(5)}$-CH_3), 1.10 (d, J=6 Hz, $C_{(4)}$-CH_3), 1.90 (d, J=1.5 Hz, $C_{(11)}$-CH_3), 3.84 (m, $C_{(3)}$-H), 5.93 (d, J=2.5 Hz, $C_{(9)}$-H), and 6.86 (m, $C_{(12)}$-H); MS: *m/e* 232 (39%, M^+($C_{15}H_{20}O_2$)), *m/e* 199 (79%, $[M-CH_3-H_2O]^+$), *m/e* 159 (100%), and *m/e* 145 (44%), which was sensitive to the air. The compound (IX) on tlc plate developed a bright red color with 2% ceric sulfate reagent.

Hydrogenation of IX over Pd–C. Hydrogenation of IX (114 mg) in ethanol was effected over Pd–C (10%) (31 mg) with stirring for 3.5 hr. Filtration of the catalyst and evaporation of the solvent under reduced pressure gave an oil (95 mg). From the oil, XIa (20 mg) and XIb (40 mg) were separated by preparative tlc. Sublimation of the latter gave colorless crystals (XIb), mp 79—80 °C (recrystallized from light petroleum), $[\alpha]_D^{25}$ +67° (*c* 0.7, in MeOH); IR: ν_{max}^{Nujol} 3350, 1640, and 1560 cm^{-1}; PMR (CCl_4): δ 0.86 (s, $C_{(5)}$-CH_3), 1.10 (d, J=7 Hz, $C_{(4)}$-CH_3), 1.86 (d, J=~1 Hz, $C_{(11)}$-CH_3), 3.84 (m, $C_{(3)}$-H), and 7.00 (m, $C_{(12)}$-H); MS: *m/e* 234 (12%, M^+ ($C_{15}H_{22}O_2$)), and *m/e* 108 (100%, *retro*-Diels-Alder fragment), which was identical with furanoligularanol (XIb),[5] mp 79—80 °C, $[\alpha]_D^{24}$ +78° (*c* 0.8, in MeOH),[18] prepared from furanoligularenone.[5] Compound XIa was an oil, $[\alpha]_D^{24}$ −22° (*c* 1.0, in MeOH); IR: ν_{max}^{liquid} 3360, 1640, and 1560 cm^{-1}; PMR (CCl_4): δ 0.94 (d, J=7 Hz, $C_{(4)}$-CH_3), 0.94 (s, $C_{(5)}$-CH_3), 1.86 (d, J=1.5 Hz, $C_{(11)}$-CH_3), 4.12 (m, $C_{(3)}$-H), and 6.91 (m, $C_{(12)}$-H); MS: *m/e* 234 (10%, M^+ ($C_{15}H_{22}O_2$)), and *m/e* 108 (100%, *retro*-Diels-Alder fragment).

3β-Angeloyloxy-furanoeremophilane (III). Compound III, an oil, $[\alpha]_D^{14}$ −38° (*c* 1.3, in MeOH), was positive to the Ehrlich test (purple). Spectral data of III are as follows; IR: ν_{max}^{liquid} 1705, 1640, and 1560 cm^{-1}; PMR (Table 1); MS: *m/e* 316 (5%, M^+ ($C_{20}H_{28}O_3$)), 108 (100%, *retro*-Diels-Alder fragment), *m/e* 83 (40%, $[CH_3CH{=}C(CH_3)CO]^+$), and *m/e* 55 (30%, $[CH_3CH{=}CCH_3]^+$).

Reduction of III with Lithium Aluminum Hydride. To a suspension of lithium aluminum hydride (48 mg) in dry ether (2 ml), III (77 mg) in dry ether (4 ml) was added and stirred at room temperature under nitrogen atmosphere. After completion of the reaction, the mixture was treated as usual and the resulting residue was chromatographed on silica gel (4 g). Fractions eluted with light petroleum–ether (10: 1) gave a compound identical with XIa, M^+ at *m/e* 234 ($C_{15}H_{22}O_2$), $[\alpha]_D^{28}$ −25° (*c* 1.3, in MeOH). Identification was effected on $[\alpha]_D$, IR, PMR, MS, and tlc.

6β-Senecioyloxy-10β-hydroxy-furanoeremophilane (IV). Compound IV, mp 82—84 °C (recrystallized from light petroleum), $[\alpha]_D^{15}$ −68° (c, 0.84, in MeOH), was positive to the Ehrlich test (purple), and displayed intense blue coloring with 2% ceric sulfate reagent when heated on tlc plate. Characterization of IV is as follows; UV: λ_{max}^{EtOH} 218 nm (ε 21000); IR: $\nu_{max}^{CCl_4}$ 3513, 1715, and 1644 cm^{-1}; PMR (Table 1); MS: *m/e* 332 (1.4%, M^+($C_{20}H_{28}O_4$)), *m/e* 83 (100%, $[(CH_3)_2C{=}CHCO]^+$), and *m/e* 55 (23%, $[(CH_3)_2C{=}CH]^+$).

Reduction of IV with Lithium Aluminum Hydride. Reduction of IV (39 mg) with lithium aluminum hydride (39 mg) in ether (5 ml) gave a crystalline product (10 mg), mp 126° (decomp.), M^+ at *m/e* 250 ($C_{15}H_{22}O_3$), $[\alpha]_D^{20}$ +50° (*c* 0.17, in EtOH), which was identified with the authentic sample of 6β,10β-dihydroxyfuranoeremophilane (XIV)[13] by mp, $[\alpha]_D$, IR, PMR, MS, and tlc.

6β-Senecioyloxy-furanoeremophilane (V). Compound V,

17) In the PMR spectra of VIIa, a remarkable benzene-induced solvent shift ($\delta^{CDCl_3}-\delta^{C_6D_6}$=0.28) was observed for the signal due to a secondary methyl adjacent to carbonyl group. This shows an axial nature[8] for the 4β-methyl group suggesting that VIIa is in a non-steroidal conformation.

18) Pure furanoligularanol (XIb) has these physical constants. Mp 63°C and $[\alpha]_D$+53° (*c* 0.5, in $CHCl_3$) were given for the same compound in the literature.[5]

a viscous oil, was positive to the Ehrlich test. Characterization of V is as follows; IR: ν_{max}^{liquid} 1710, 1645, and 1563 cm^{-1}; PMR (Table 1); MS (indirect inlet system): *m/e* 316 (1%, $M^+(C_{20}H_{28}O_3)$), *m/e* 159 (77%), *m/e* 145 (29%), *m/e* 83 (100%, $[(CH_3)_2C{=}CHCO]^+$), and *m/e* 55 (23%, $[(CH_3)_2C{=}CH]^+$).

Reduction of V with Lithium Aluminum Hydride. Treatment of V with lithium aluminum hydride by the same procedures described above gave a compound, M^+ at *m/e* 234 ($C_{15}H_{22}O_2$), $[\alpha]_D^{18}$ −14° (*c* 0.7, in MeOH), identical with petasalbin (XV)[14] (IR, PMR, MS, and tlc).

Reduction of VIIIa with Lithium Aluminum Hydride. Reduction of VIIIa (33 mg) with lithium aluminum hydride (50 mg) in ether (30 ml) with stirring for 2 hr under nitrogen atmosphere, and then usual work-up gave XVI (29 mg), mp 81—83 °C (sublimation); IR: ν_{max}^{Nujol} 3330, 1660, and 1565 cm^{-1}; PMR ($CDCl_3$): δ 0.97 (s, $C_{(5)}$-CH_3), 1.00 (d, J=7 Hz, $C_{(4)}$-CH_3), 1.90 (d, J=1.5 Hz, $C_{(11)}$-CH_3), 4.20 (m, $C_{(3)}$-H), 4.80 (d, J=6 Hz, $C_{(9)}$-H), and 7.11 (q, J=1.5 Hz, $C_{(12)}$-H); MS: *m/e* 250 (6%, M^+ ($C_{15}H_{22}O_3$)) and *m/e* 124 (100%, *retro*-Diels-Alder fragment).

Oxidation of XVI with Active Manganese Dioxide. To a solution of XVI (20 mg) in benzene (4 ml) was added active manganese dioxide[3] (100 mg) and stirred for 4 hr under nitrogen atmosphere. After filtration, the solvent was removed to afford a crystalline product, which was recrystallized from isopropyl ether to give VIIIa (12 mg).

The authors wish to express their thanks to Dr. L. Novotný, Czechoslovak Academy of Science, for a generous gift of furanopetasine and furanopetasol.

Transylidations of Stable Sulfonium Ylids[1)]

Haruo MATSUYAMA, Hiroshi MINATO, and Michio KOBAYASHI
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

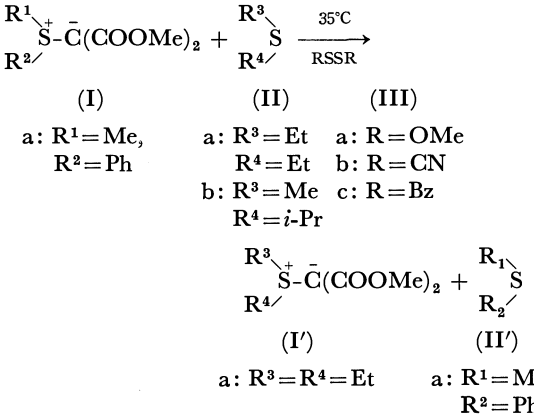
(Received April 3, 1973)

In the presence of a dialkoxy disulfide, sulfonium bis(methoxycarbonyl)methylids underwent transylidation with a dialkyl sulfide or pyridine at 35 °C. Thiocyanogen and benzoyl disulfide showed a similar catalytic effect. The kinetics of this reaction were investigated, and its mechanism was discussed.

A sulfur ylid containing two electron-withdrawing substituents on its negatively charged carbon atom is thermally stable, and the nucleophilicity of its negatively charged carbon atom is much less than that of an ylid containing only one electron-withdrawing substituent. While the mono-substituted ylids are used for various synthetic purposes by using their reactivity with carbonyl compounds and electron-deficient olefins,[2)] the di-substituted ylids show almost no reactivity with these electrophiles. Recently, reactions between dialkyl-sulfonium bis(methoxycarbonyl)methylids and several electrophiles have been reported on, but they require a fairly long time at high temperatures.[3)]

In the presence of a dialkoxy disulfide, dimethyl diazomalonate smoothly reacted with dialkyl sulfides at room temperature and the corresponding ylids were formed in good yields.[4)]

We have found that in the presence of a catalytic amount of dialkoxy disulfide (III), ylid (I) ($R^1R^2S^+C^-(COOMe)_2$) underwent transylidation with a dialkyl sulfide (II) very easily.



The only one example of transylidation in the literature is the case of methylarylsulfonium phenacylid in which the ylid dimerizes by dipolar attraction and then the dimer redissociates with the sulfide function scrambled.[5)]

The scope and mechanism of the transylidation between ylid I and dialkyl sulfides or pyridines are discussed in this paper.

Results and Discussion

In the absence of III, I is very stable and shows no transylidation when it is mixed with II at 35 °C.

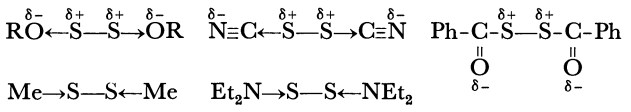
a) Reaction mixture consists of I (0.5—0.6 mmol), II (0.5—1.0 mmol), and III(0.2—0.4 mmol).

When Ia was heated with excess IIa (15 mol/mol Ia) in nitromethane at 86 °C for 25 hr, the mixture contained the original Ia (58%), Ia′ (34%), and IIa′ (42%). Thus, transylidation takes place upon heating, but very slowly.

However, when a catalytic amount of III is present, transylidation proceeds very easily. The results are summarized in Table 1. It is shown that dialkyl sulfides can attack all the ylids studied whereas methyl phenyl sulfide cannot carry out transylidation. It is also clear that alkyl phenyl ylids react with dialkyl sulfides rapidly but dialkyl ylids react with them rather slowly.



Various disulfides were examined as regards their catalytic activity in this transylidation. Neither dimethyl disulfide nor diethylamino disulfide[6)] was effective, but thiocyanogen and benzoyl disulfide possessed a catalytic activity similar to that of III (Tables 1 and 3). Thus the disulfides containing electron-withdrawing substituents catalyze the transylidation, the electron-deficiency on the –S–S–probably being responsible for the catalytic activity.

Since methylphenylsulfonium bis(methoxycarbonyl)-methylid easily reacts with dialkyl sulfides, the steric effect of alkyl groups of II on transylidation was examined by using this ylid. The results are shown in Table 2. It is evident that the sulfides with more bulky alkyl groups react more slowly; the order of reactivity is $Me_2S > (CH_2)_4S > MeSEt > Et_2S >$ MeSPr-*i*~MeSBu-*n* $\gg$ *t*-BuSBu-*t*.

	93	5.4	83	17	17
	1203	1.9	89	7	7

a) Mixture consists of Ia(0.5 mmol), II (0.6—0.8 mmol), and IIIb (0.07—0.12 mmol).

It was found that S-ylids can be converted into N-ylids when pyridine derivatives are used instead of dialkyl sulfides. Table 3 shows the results of such experiments with Ia and thiocyanogen (IIIb). The methyl groups at positions 3 and 4 of pyridine show very little effect on the rate, whereas the methyl group at position 2 reduces it considerably. A similar steric retardation of rate by the 2-methyl group of 2-methylpyridine was described in its S_N2 reaction with methyl iodide.[7,8)]

The slow reaction with quinoline can be ascribed to the steric effect exerted by the hydrogen atom at position 8. The reaction with isoquinoline is a little faster than that with quinoline, and considerably slower than that of pyridine. This small reactivity of isoquinoline cannot be explained easily. The slow reaction with 4-cyanopyridine can be ascribed to its smaller nucleophilicity due to the presence of the electron-withdrawing CN group.

The reaction between isopropyl methyl sulfide (IIb) and ylid Ia was slow enough to determine its rate. The effects of concentrations of reactants and catalyst IIIa were examined. The results are summarized in Table 4. The second-order rate constants calculated by assuming $-d[Ia]/dt=k[Ia][IIb]$ increased with the initial concentration of IIb; apparently the rate depends on [IIb] to a greater extent than that expressed by means of this equation. The rates increased also with the initial concentration of IIIa.

Similarly the effects of concentrations of reactants in the reaction among Ia, 4-methylpyridine (IVa), and IIIa were examined. The results are shown in Table 5. The second-order rate constants calculated decreased with the initial concentration of IVa; apparently the rate depends on [IVa] much less. When the first-order rate constants were calculated by assuming that $-d[Ia]/dt=k[Ia]$, they were found to be almost independent of the initial concentration of IVa. As regards the initial concentration of IIIa, the rates were found to increase with [IIIa].

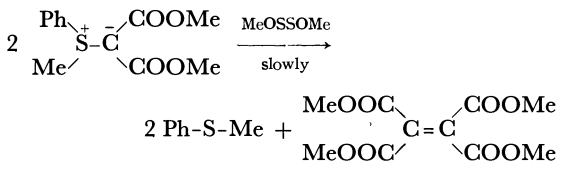
0.85	1.32	1.09	41.6	30.1

Table 6. Rates of decomposition of ylid Ia in the presence of IIIa

Reactants (mol/l) $PhMeS^+-C^-(COOMe)_2$ (Ia)	Reactants (mol/l) $(MeOS)_2$ (IIIa)	First-order rate constant calculated from $-d[Ia]/dt=k[Ia]$ $10^5\times k$ (sec^{-1})
0.85	1.36	0.8
0.85	2.27	2.7

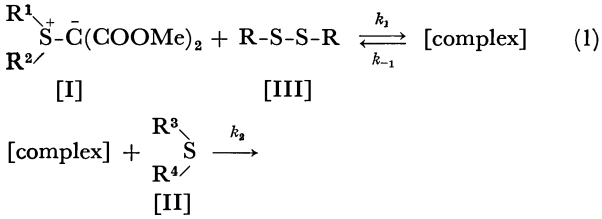
In the absence of dialkyl sulfides, ylid Ia remained unchanged but was found to decompose slowly at 35 °C when about the same amount of IIIa was present. The products were methyl phenyl sulfide and methyl ethylenetetracarboxylate.

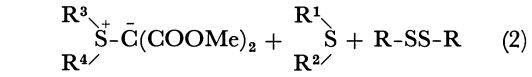


IIIa remained unchanged during the course of reaction. Table 6 shows the results of rate measurements. The first-order rate constants calculated by assuming $-d[Ia]/dt=k[Ia]$ increased with [IIIa]. The rate constants were much smaller than those obtained in the reactions among Ia, IIb, and IIIa or Ia, IVa, and IIIa. This means that almost no decomposition of Ia took place during transylidation between Ia and IIb or Ia and IVa.

The results obtained can be summarized as follows.
1) Transylidation does not take place unless an electron-deficient disulfide (MeOSSOMe, NC–SS–CN or Bz–SS–Bz) is present.
2) When I and III are mixed, I slowly decomposes. Thus, some interaction exists between I and III.
3) Substrates which can attack I possess electron-rich S or N atoms.
4) Transylidation is slower with bulky nucleophiles.
5) The rates of transylidation increase with the concentration of III.
6) During the transylidation, III does not decompose.

A plausible reaction scheme which is consistent with these results is as follows.



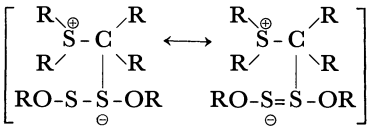


By assuming that concentration of the complex is very small and applying the steady state assumption, the rate of transylidation can be expressed as

$$-\frac{d[I]}{dt}=\frac{k_1k_2[I][II][III]}{k_{-1}+k_2[II]}$$

When 4-methylpyridine (IVa) was used in place of II, the rates appeared to be approximately of first-order in both [I] and [III], and not to depend upon [IVa]. This can be explained by assuming that in the case of 4-methylpyridine the second step proceeds very fast in comparison with the backward reaction of the first step, $k_2[IVa]\gg k_{-1}$.

Although attempts for obtaining supporting evidence by spectroscopic methods were not successful, the following structure is most plausible as the complex between I and III.



Effects of the substituents on the negatively charged carbon atom of ylid I were investigated. The results are shown in Table 7. Transylidation proceeds faster with the ylids containing COOMe and more slowly with those containing COMe. It is known that contribution of a betaine structure is greater in acetyl ylids than that in alkoxycarbonyl ylids.[9]

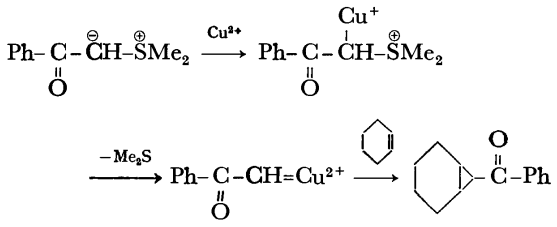
(Ib)	Ph	COMe	COOMe	Me_2S	460	39	36	61
(Ic)	Ph	COMe	COMe	Me_2S	770[b)]	47	32	40
(Id)	Me	COOMe	COOMe	Et_2S	313	55	33	45
(Ie)	Me	CN	CN	Et_2S	174[c)]	—	—	92
(If)	Me	H	COPh	—	57[c)]	—	—	95

a) Mixture consists of I (0.5 mmol), II(0.6—0.8 mmol), and IIIa (0.2—0.3 mmol), except in the case of Ic.
b) Mixture consists of Ic (0.5 mmol), II (6.5 mmol), and IIIa (0.3 mmol).
c) Catalytic decomposition of ylid proceeded rapidly.

It is reasonable that the greater the nucleophilicity of the ylid carbanion, the easier the formation of complex with III and the faster the transylidation process.

In the presence of III, dimethylsulfonium phenacylid (I_f) was found to decompose rapidly, producing dimethyl sulfide in a quantitative yield. This suggests that the ylid carbanion with strong nucleophilicity tends to form a complex with III very rapidly.

In a study on the thermolysis of dimethylsulfonium phenacylid in cyclohexene in the presence of $CuSO_4$ or ZnI_2, Trost[10] proposed the formation of a complex between electron-deficient Cu^{2+} or Zn^{2+} and electron-rich ylid carbanion. This complex is similar to the one we proposed as regards the reaction between an electron-deficient disulfide and electron-rich ylid carbanion.



Experimental

Materials. Sulfonium bis(methoxycarbonyl)methylids were prepared by copper-catalyzed decomposition of dimethyl diazomalonate in large excess sulfides.[11]

Dimethyl sulfide, tetrahydrothiophene, di-*t*-butyl sulfide, dimethyl disulfide, pyridine, methylpyridines, 4-cyanopyridine, quinoline, and isoquinoline were of reagent grade and used without further purification. Other sulfides were prepared from the corresponding sodium mercaptides and alkyl halides.[12]

Dimethoxy disulfide was synthesized by the method of Thompson.[13] Thiocyanogen[14] and benzoyl disulfide[15] were prepared by the methods described in the literature. Diethylamino disulfide was synthesized by adding sulfur monochloride (0.1 mol) to a dichloromethane solution of diethylamine (0.4 mol) at 0 °C; bp 115 °C/6 mmHg (lit,[16] bp 137 °C/29 mmHg).

General Procedure. A $CDCl_3$ solution of I, II, and III containing nitromethane (internal standard) was placed in an NMR tube at 35 °C, and the intensity changes of the signals of the original ylid(I), new ylid(I′) and new sulfide (II′) were determined. After the original ylid(I) completely disappeared, *n*-hexane was added to the reaction mixture. The ylid crystals which precipitated were filtered and recrystallized from methanol. The melting points, IR, and NMR spectra of the ylids obtained were identical with those reported in the literature.[17]

Synthesis and Substitution of 1,3,4,6-Tetra-substituted-3,6-dihalogeno-2,5-piperazinediones

Juji YOSHIMURA, Yuichi SUGIYAMA, and Hiroshi NAKAMURA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received April 25, 1973)

Addition of chlorine to 3,6-dimethylene- (**3**) and 3,6-dibenzylidene-1,4-dimethyl-2,5-piperazinediones gave isomers of the corresponding tetrachloride, and substitution of 1,3,4,6-tetramethyl-2,5-piperazinedione with bromine also gave tetrabromide (**2**) of the same type *via* successive elimination and addition reactions. Treatment of **2** with water and with methanolic sodium acetate gave the corresponding 3,6-dihydroxy and dimethoxy derivatives, respectively, while treatment with sodium iodide, sodium sulfide, sodium thiocyanate, or sodium thioacetate gave only **3** and sulfur in a good yield. Similar results were obtained in the case of octahydro-5*H*,10*H*-dipyrrolo[1,2-*a*: 1′,2′-*d*]pyrazine-5,10-dione. However, bromination of 6,13-dioxo-6a,7,13a,14-tetrahydro-6*H*,13*H*-pyrazino[1,2-*a*: 4,5-*a*′]diindole gave rise only to aromatization. Configurations of the isomers obtained and the reaction processes were discussed.

3,6-Epidithio-2,5-piperazinedione skeleton is a unique partial structure of a class of antibiotics such as gliotoxin,[1] sporidesmin,[2] and others.[3,4] A few homologues were synthesized by substitution of the halogeno group of 3,6-dihalogeno-2,5-piperazinediones, having no alkyl substituents at 3- and 6-positions, with the mercapto group followed by intramolecular disulfide-ring formation.[5-7] In order to clarify the limitation of this synthetic route, synthesis and reactivity of 3,6-dihalogeno-2,5-piperazinediones were examined.

Results and Discussion

Bromination of *meso* or *racemic* 1,3,4,6-tetramethyl-2,5-piperazinedione (**1a** and **1b**) in benzene, newly obtained by condensation of two moles of *N*-methylalanine,[8] gave one isomeric 3,6-dibromo-3,6-bis(bromomethyl)-1,4-dimethyl-2,5-piperazinedione (**2**) and HBr_3 adduct of **1** which gave **1** in water with liberation of bromine. Treatment of **2** with sodium iodide gave 3,6-dimethylene-1,4-dimethyl-2,5-piperazinedione (**3**) in a good yield, which was reversely converted into **2** by addition of bromine. Bromo functions at 3- and 6-positions in **2** were selectively converted into hydroxy (**4**) or methoxy (**5**) groups in aqueous ethanol or methanolic sodium acetate, whereas attempted substitution with acetylthio, methylthio, mercapto, or cyanothio groups gave only **3** and sulfur. Similarly, substitution of octahydro-5*H*,10*H*-dipyrrolo[1,2-*a*: 1′,2′-*d*]pyrazine-5,10-dione[9] with bromine in benzene gave 1,5a,6,10a-tetrabromo-octahydro-5*H*,10*H*-dipyrrolo[1,2-*a*: 1′,2′-*d*]-pyrazine-5,10-dione (**6**) and HBr_3 adduct of the starting material. Treatment of **6** with methanol or sodium acetate in acetic acid gave 1,6-dibromo-5a,10a-dimethoxy-octahydro-5*H*,10*H*-dipyrrolo[1,2-*a*: 1′,2′-*d*]-pyrazine-5,10-dione (**7**) and 1,6-dibromo-2,3,7,8-tetrahydro-5*H*,10*H*-dipyrrolo[1,2-*a*: 1′,2′-*d*]pyrazine-5,10-dione (**8**), respectively. However, treatment of **6** with potassium iodide gave a mixture of **8** and its mono and di-debrominated compounds. Furthermore, bromination of 6,13-dioxo-6a,7,13a,14-tetrahydro-6*H*,13*H*-pyrazino[1,2-*a*: 4,5-*a*′]diindole (**9**) in methanol, obtained from two moles of ethyl 2-indoline-carboxylate,[10] deposited selectively the corresponding 2,9-dibromo derivative (**10**) in 79% yield, the position of their bromo groups being determined from the splitting of magnetically equivalent H_4 and H_{11} (δ 7.96, J=8.5 Hz) appearing in the lowest magnetic field in the NMR spectrum and characteristic absorptions (825—835 cm^{-1}) in the IR spectrum. Further bromination of **10** in chloroform gave exclusively 2,9-dibromo-6,13-dioxo-6*H*,13*H*-pyrazino[1,2-*a*: 4,5-*a*′]diindole (**11**).

On the other hand, simple halogenation of 3,6-dibenzylidene-1,4-dimethyl-2,5-piperazinedione[11] or **3** with sulfur dichloride in the presence of zinc chloride or chlorine gave 3,6-bis(α-chlorobenzyl)- (**12**) and 3,6-bis(chloromethyl)-3,6-dichloro-1,4-dimethyl-2,5-piperazinedione (**13**), respectively. Although each compound from **2** to **10** consisted of only one isomer, four isomers (**12a**—**d**) among the theoretically possible four *racemic* and two *meso* forms were separated by fractional crystallization in the former case, but, not the approximate 1 to 1 mixture of *racemic* and *meso* isomers in the latter.

Table 1. Proton chemical shifts in isomeric 2,5-piperazinediones

Compounds	Chemical shift (δ) of main protons			
	N–Me or N–H	C–Me	C–H	S–Me
14 *meso*	2.06	—	4.86	3.10
racemic	2.38	—	4.60	3.09
15 *meso*	7.72	1.22	4.00	—
(D, D)	7.92	1.25	3.98	—
16 *meso*	7.83	1.21	4.13	—
(L, L)	7.93	1.27	4.07	—
1b *meso*	2.94	1.52	3.95	—
1a *racemic*	2.94	1.49	3.89	—
12a	1.53, 2.65	—	5.83, 6.47	—
b	3.29	—	5.61	—
c	2.35, 3.58	—	5.67, 5.82	—
d	3.39	—	5.74	—

Meso and *racemic* 3,6-disubstituted-2,5-piperazinediones were deduced by X-ray analysis[12] to have planar and skewed boat conformations, respectively. They do not seem to be distinguishable by NMR technique, but a comparison of NMR data of both isomers of 1,4-dimethyl-3,6-bis(methylthio)- (**14**),[6] 3,6-dimethyl- (**15**),[13] and 6-methyl-3-isobutyl-2,5-piperazinedione (**16**)[13] indicates that the chemical shift fo 3,6-hydrogens of *meso* form is usually greater (in δ) than that of the *racemic* or optically active form (Table 1). This was utilized to deduce the configuration of **1a** and **1b**, though such similarity is not observed in the C-methyl groups.

(A) (B)

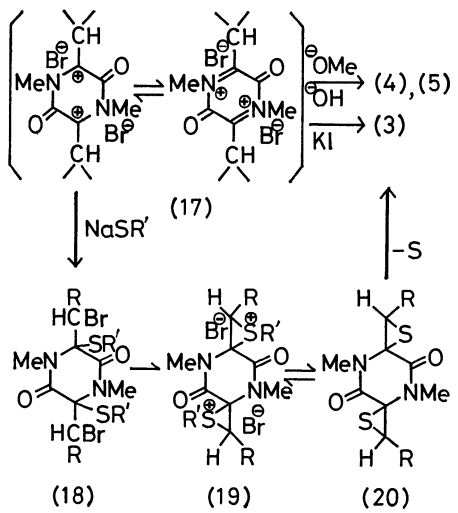
Fig. 1. Conformation of the five-membered rings in **6** and **7** (A), and in **9** and **10** (B).

NMR data of **12a**—**d** indicate that they are certainly isomers to each other, although their configurations could not be determined.

On the other hand, coupling constants of protons in the five-membered ring of **7** and **9** ascertained by simulation indicated that they exist in twist and flattened envelope conformation, as shown in Fig. 1(A) and (B), respectively. Conformation (A) suggests that **7** is the *meso* isomer with planar 2,5-piperazinedione skeleton. The five-membered ring in *N*-acyl-indoline derivatives exists in a planar conformation,[14] but conformation (B) in **9** might be attributed to the condensed planar benzene ring.

The fact that tetrabromides (**2** and **6**) were obtained by simple substitution with bromine and that the former was also produced by addition reaction indicates that the substitution of 3,6-dialkyl-2,5-piperazinediones with bromine is usually followed by elimination of hydrogen bromide and re-addition of bromine, even though bromine was used in a smaller amount than stoichiometric. Exceptional formation of the elimination product **11** from **10** would be attributed to the resonance stabilization of the indole moiety. In all successful syntheses of 3,6-epidithio-2,5-piperazinediones *via* the corresponding 3,6-dibromo derivatives,[5-7] the bromides included only 3,6-substituents having no hydrogen at α-position such as the phenyl group. Easy elimination of hydrogen bromide would be due to the polarized structure of 3,6-dibromo derivatives (**17**) stabilized by mesomeric resonance of immonium and carbonium ions[6] (Fig. 2).

The fact that attempted substitution of **2** with sulfur-containing nucleophiles gave sulfur and **3** would be



(18) (19) (20)

Fig. 2. Possible passways in substitution of **2**.

due to the character of sulfur atom and the presence of the vicinal bromine atom. Compounds (**18**) once substituted would easily shift to the spiro-type thiiranium ions (**19**). It is well-known that the sulfonium halides frequently decompose to thioether and other products depending on the conditions,[14] especially smoothly in alcohols,[15] and that ethylenesulfides having aromatic substituents such as diphenylene-dichloroethylenesulfide turned to the corresponding olefin and sulfur, even under cooling.[16] Thus, it could be concluded that **19** was smoothly transformed into **3** through the corresponding spiro-sulfide (**20**) with liberation of sulfur (Fig. 2).

Experimental

All the melting points are uncorrected. The solutions were evaporated under reduced pressure at a bath temperature not exceeding 60 °C. The infrared spectra were measured in KBr discs with a Hitachi EPI-G2 spectrometer. The NMR spectra were obtained at 100 MHz with a JNM-4H-100 spectrometer in deuteriochloroform unless otherwise stated, using TMS as an internal reference. Chemical shifts and coupling constants were recorded in δ and Hz units, and frequencies in cm^{-1}.

*1,3,4,6-Tetramethyl-2,5-piperazinedione (**1a** and **1b**).* A suspension of *N*-methylalanine (10 g, 59 mmol) in ethyleneglycol (10 g) was heated at 180—190 °C for 6 hr on an oil bath, poured into water (100 ml) and extracted with three portions of chloroform (100 ml). The combined extracts were dried over sodium sulfate and evaporated to give a sirup, which was fractionated on a silica gel column (WAKO-GEL C-200) by elution with chloroform–ligroin (3:1) to give **1a** (2.2 g, 44%) and **1b** (1.2 g, 24%) which were recrystallized from ether. Mp **1a**: 121—123 °C, **1b**: 135—136 °C. IR: **1a**: 1640 (NC=O), **1b**: 1630 (NC=O).

Found: C, 56.47; H, 8.24; N, 15.93%. Calcd for $C_8H_{14}N_2O_2$: C, 56.45; H, 8.29; N, 16.46%.

*3,6-Dibromo-3,6-bis(bromomethyl)-1,4-dimethyl-2,5-piperazinedione (**2**).* Bromine (0.7 ml, 13.3 mmol) was added to a solution of **1a** (1 g, 5.9 mmol) in dried benzene (50 ml) and kept at room temperature for 24 hr to give a yellow precipitate, which was filtered and washed with dried benzene. The precipitate was deduced to be a HBr_3 adduct of **1a** from analytical data (Found: C, 23.38; H, 3.80; N, 6.87; Br, 57.81%. Calcd for $C_8H_{15}N_2O_2Br_3$: C, 23.38; H, 3.68; N, 6.82; Br, 58.34%) and from the fact that treatment of the adduct with saturated sodium bicarbonate and sodium sulfite followed by extraction with chloroform gave **1a** in 66% recovery. Evaporation of the filtrate from the adduct gave a white precipitate of **2** (500 mg, 18%) which was washed with ethanol and recrystallized from chloroform. Mp 185—188 °C (decomp.); NMR: 3.22 ($N-CH_3$), 4.03 and 4.74 (CH_2: ABq, J=11.0). IR: 1700 (C=O).

Found: C, 19.97; H, 2.15; N, 5.80; Br, 65.62%. Calcd for $C_8H_{10}N_2O_2Br_4$: C, 19.78; H, 2.07; N, 5.77; Br, 65.77%.

*1,4-Dimethyl-3,6-dimethylene-2,5-piperazinedione (**3**).* A suspension of **2** (1 g, 2.1 mmol) and sodium iodide (2 g, 13 mmol) in ethanol (20 ml) was stirred at room temperature for 1 day and then evaporated. The residue was treated with chloroform (50 ml) and aqueous sulfite. The chloroform layer was washed with water and evaporated to give white needles which were recrystallized from ethanol. Yield, 320 mg (90%). Mp 230 °C (decomp.). NMR: 3.31 (N-Me), 4.98 and 5.87 (CH_2; ABq, J_{gem}=2.0). IR: 1600 (C=C), 1670 (NC=O).

Found: C, 58.23; H, 6.08; N, 17.09%. Calcd for $C_8H_{10}N_2O_2$: C, 57.82; H, 6.07; N, 16.86%.

*3,6-Bis(bromomethyl)-3,6-dihydroxy-1,4-dimethyl-2,5-piperazinedione (**4**).* A suspension of **2** (1 g, 2.1 mmol) in 50 ml of 50% ethanol was stirred at 70 °C for 2 days and then evaporated. The residue was triturated and recrystallized from methanol to give white crystals. Yield, 230 mg (35%); Mp 230 °C (decomp.); NMR (CF_3COOH): 3.15 (N-Me), 3.68 and 3.88 (CH_2; ABq, J_{gem}=11.5). IR: 1640 (NC=O), 3260 (OH).

Found: C, 26.61; H, 3.30; N, 7.68; Br, 43.95%. Calcd for $C_8H_{12}N_2O_4Br_2$: C, 26.68; H, 3.36; N, 7.78; Br, 44.40%.

*3,6-Bis(bromomethyl)-3,6-dimethoxy-1,4-dimethyl-2,5-piperazinedione (**5**).* A suspension of **2** (1 g, 2.1 mmol) and sodium acetate (1 g, 12 mmol) in methanol (50 ml) was stirred at room temperature for 10 hr and then evaporated. The residue was extracted with chloroform. Evaporation of the extracts gave crystals (700 mg, 86%) which were recrystallized from chloroform–ligroin. Mp 165 °C (decomp.); NMR: 3.00 (OMe), 3.20 (NMe), 3.52 and 4.10 (CH_2: ABq, J_{gem}=11.3). IR: 1670 (NC=O).

Found: C, 31.40; H, 3.91; N, 7.16%. Calcd for $C_{10}H_{16}N_2O_4Br_2$: C, 30.95; H, 4.16; N, 7.22%.

*1,5a,6,10a-Tetrabromo-octahydro-5H,10H-dipyrrolo[1,2-a: 1',2'-d]pyrazine-5,10-dione (**6**).* Bromine (0.7 ml, 13.3 mmol) was added to a dried benzene (50 ml) solution of L-proline anhydride (1 g, 5.1 mmol) and allowed to stand at room temperature for 1 day. Yellow precipitates which appeared were treated with saturated sodium bicarbonate and sodium sulfite to give insoluble white powder. A second crop was obtained from the first filtrate by evaporation and washing the residue with ethanol (5 ml). Total yield, 500 mg (19%). Unchanged starting material (700 mg) was recovered from the aqueous filtrate by extraction with chloroform (100 ml). Mp 183—185 °C (decomp.); IR: 1690 (NC=O).

Found: C, 23.18; H, 1.94; N, 5.29%. Calcd for $C_{10}H_{10}N_2O_2Br_4$: C, 23.56; H, 1.98; N, 5.49%.

*1,6-Dibromo-5a,10a-dimethoxy-octahydro-5H,10H-dipyrrolo[1,2-a: 1',2'-d]pyrazine-5,10-dione (**7**).* A solution of **6** (400 mg, 0.78 mmol) and sodium acetate (400 mg, 4.9 mmol) in methanol (50 ml) was refluxed for 8 hr, evaporated, and the residue was extracted with chloroform (50 ml). Evaporation of extracts gave a sirup which was crystallized from ethanol. Yield, 115 mg (36%); mp 267—268 °C; NMR: 2.28 (H_2 and H_7; oct), 2.71 ($H_{2'}$ and $H_{7'}$; nine peaks, $J_{2,2'}=J_{7,7'}=14.4$), 3.35 (OMe; s), 3.61 (H_3 and H_8; oct, $J_{2,3}=J_{7,8}=1.7$, $J_{2',3}=J_{7',8}=9.6$), 4.03 ($H_{3'}$ and $H_{8'}$; oct, $J_{2,3'}=J_{7,8'}=8.0$, $J_{2',3'}=J_{7',8'}=10.0$, $J_{3,3'}=J_{8,8'}=12.5$), 4.62 (H_1 and H_6; d, $J_{1,2'}=J_{6,7'}=4.6$). IR: 1660 (NC=O).

Found: C, 34.97; H, 3.79; N, 7.01; Br, 39.31%. Calcd for $C_{12}H_{16}N_2O_4Br_2$: C, 34.97; H, 3.91; N, 6.79; Br, 38.79%.

*1,6-Dibromo-2,3,7,8-tetrahydro-5H,10H-dipyrrolo[1,2-a: 1',2'-d]pyrazine-5,10-dione (**8**).* A solution of **6** (1 g, 2.1 mmol) and anhydrous sodium acetate (1 g, 12 mmol) in acetic acid (20 ml) was heated at 100 °C for 5 hr with stirring, evaporated, and the resulting residue was extracted with several portions of chloroform (50 ml). The extracts were mixed with ethanol

A suspension of **9** (90 mg, 0.31 mmol) and bromine (1.0 g, 19.5 mmol) in methanol (80 ml) was stirred for 1 hr to give a white powder (120 mg, 79%) which was recrystallized from chloroform–ligroin. Mp 309 °C. NMR: 7.40 (H_1; s), 7.37 (H_3; d), 8.40 (H_4; d, $J_{3,4}=8.5$). Other proton signals are almost the same as for **9**. IR: 1670, 1700 (NC=O).

Found: C, 48.07; H, 2.56; N, 6.26%. Calcd for $C_{18}H_{12}N_2O_2Br_2$: C, 48.24; H, 2.89; N, 6.25%.

*2,9-Dibromo-6,13-dioxo-6*H,*13*H-*pyrazino*[*1,2*-a: *4,5*-a′]*diindole* (**11**). Excess bromine was added to a solution of **10** (300 mg, 1.3 mmol) in chloroform (60 ml) and allowed to stand at room temperature for 1 day to give yellow precipitates (260 mg, 87%). These were recrystallized from a large amount of chloroform to give fine yellow needles. Mp 359 °C (sublime). IR: 1687 (C=O).

Found: C, 48.28; H, 1.56; N, 6.23%. Calcd for $C_{18}H_8N_2O_2Br_2$: C, 48.68; H, 1.82; N, 6.31%.

3,6-Dichloro-3,6-bis(α-chlorobenzyl)-1,4-dimethyl-2,5-piperazinedione (**12a—d**). A solution of 3,6-dibenzylidene-1,4-dimethyl-2,5-piperazinedione (12 g, 38 mmol), sulfur dichloride (40 ml) and a catalytic amount of zinc chloride in dioxane (40 ml) was allowed to stand at room temperature for 2 days, and then poured into a mixed solution of saturated sodium sulfite and chloroform. The chloroform layer was evaporated, and the residual powder was recrystallized from chloroform–ligroin to give fine crystals (**12**). **12a** (3.46 g, 20%), **12b** and **12c** (6.45 g, 37%) were separated by fractional crystallization from chloroform–ligroin. Mp **12a**; 227 °C (decomp.), **12b**; 203—205 °C (decomp.), **12c**; 186 °C. IR: **12a**; 1675, **12b**; 1670, **12c**; 1680 (NC=O).

Found: **12a**; C, 52.15; H, 3.65; N, 5.95%. **12b**; C, 52.35; H, 3.77; N, 5.77%. **12c**; C, 52.30; H, 3.93; N, 6.09%. Calcd for $C_{20}H_{18}N_2O_2Cl_4$: C, 52.20; H, 3.94; N, 6.08%.

The other isomer (**12d**) was obtained as follows. A solution of 3,6-dibenzylidene-1,4-dimethyl-2,5-piperazinedione (5.0 g, 16 mmol) in sulfur dichloride (50 ml) containing chlorine was treated as above. The white powder (2.1 g) obtained was fractionally recrystallized from chloroform–ligroin to give **12d** (0.6 g, 8%) and **12b** (1.02 g, 14%). Mp **12d**; 183 °C. IR: 1682 (NC=O).

Found: C, 51.94; H, 3.76; N, 6.09%. Calcd for $C_{20}H_{18}N_2O_2Cl_4$: C, 52.20; H, 3.94; N, 6.08%.

3,6-Dichloro-3,6-bis(chloromethyl)-2,5-piperazinedione (**13**). A solution of **3** (100 mg, 0.92 mmol) in chloroform (10 ml) saturated with chlorine was left to stand for 30 min, and then evaporated to give a crude product (175 mg), which was recrystallized from chloroform to give white crystals. Yield, 110 mg (39%). Mp 150—200 °C.

Found: C, 31.63; H, 3.43; N, 9.07%. Calcd for $C_8H_{10}N_2O_2Cl_4$: C, 31.20; H, 3.27; N, 9.10%.

NMR spectrum of this compound showed the two methylene and *N*-methyl signals with intensity ratio of nearly 1 to 1, indicating a mixture of *meso* and *racemic* isomers.

The authors are indebted to the members of the Laboratory of Organic Analysis for the microanalysis and to Mr. H. Matsumoto for NMR measurements.

Crystal and Molecular Structure of ω-Amino Acids, ω-Aminosulfonic Acids and Their Derivatives. VI. The Crystal and Molecular Structure of DL-γ-Amino-β-hydroxybutyric Acid (GABOB), A Nervous Inhibitory Chemical Transmitter

Ken-ichi TOMITA, Masahiro HARADA, and Takaji FUJIWARA

Faculty of Pharmaceutical Sciences, Osaka University, Toneyama, Toyonaka, Osaka 560

(Received May 1, 1973)

DL-γ-Amino-β-hydroxybutyric acid (GABOB), $C_4H_9O_3N$, forms monoclinic plate crystals of space group $P2_1/c$, with $a=7.43$, $b=8.29$, $c=9.34$ Å, $\beta=110.9°$, and four molecules in the unit cell. Intensity data were collected by a film method. The structure was solved by the direct method with the symbolic addition procedure, and refined by least-squares methods to $R=0.096$. GABOB molecule having the zwitterionic structure, NH_3^+-CH_2-CH(OH)-CH_2-COO^-, forms *trans-zigzag* skeletal conformation with an intramolecular OH···O hydrogen bond of 2.773 Å, and contacts with each other by three dimensional network of NH···O and OH···O hydrogen bonds.

Using chloroxypropylphthalimide as a starting material, γ-amino-β-hydroxybutyric acid (GABOB) has been originally synthesized by M. Tomita[1] in 1923, and the optical and stereo-isomers were isolated by treatment with brucin and by difference in solubility. In order to characterize these isomers, some physicochemical investigations have been carried out and the hypothetical structures, an intramolecular hydrogen bonded form and an extended one, were proposed.[2] However, the crystal structure has not yet been determined. The chemical structure of vitamin B_T, L-carnitine, which acts as a growth factor for some insects,[3] was identified as L-γ-trimethyl-β-hydroxybutyrobetaine,[4] a trimethyl-derivative of GABOB, and the crystal structure of its hydrochloride is now solved in our laboratory.[5] Moreover, it is of most interest that GABOB is also a potent inhibitory chemical transmitter[6] in central nervous system as well as γ-aminobutyric acid (GABA) of which crystal structure was recently elucidated.[7]

In a previous paper,[8] we reported briefly about some structural features of GABOB, and this paper deals with the detailed structure analysis of this compound and the comparison of its molecular structure with those of other related compounds.

Experimental

A sample of DL-γ-amino-β-hydroxybutyric acid (GABOB) was kindly supplied by Prof. A. Musashi, Kobe Women's College of Pharmacy, Kobe. GABOB crystallizes as transparent plates from *N,N*-dimethylformamide solution by slow evaporation at room temperature. Weissenberg and precession photographs indicated the crystal to be monoclinic.

Table 1. CRYSTAL DATA FOR GABOB

$C_4H_9O_3N$	F.W.=119.1
Monoclinic	Space group $P2_1/c$
$a=7.43(1)$ Å	$Z=4$
$b=8.29(1)$	$D_m=1.45$ g cm^{-3}
$c=9.34(2)$	$D_c=1.47$ g cm^{-3}
$\beta=110.9(2)°$	

Unit cell dimensions were determined from zero-layer Weissenberg photographs about the a and b axes which were calibrated with superimposed aluminum powder photographs. The systematic extinctions (*h0l*, $l=2n+1$; *0k0*, $k=2n+1$) indicated the space group to be $P2_1/c$. The density was measured by flotation in a mixture of benzene and carbon tetrachloride. The crystal data are given in Table 1. Intensity data by a crystal of approximate dimensions, $0.15\times0.03\times0.5$ mm, were obtained from multiple-film equi-inclination Weissenberg photographs taken around the a axis. Another additional data were collected on a Rigaku-Denki four-circle computer-controlled diffractometer, using Ni-filtered Cu$K\alpha$ radiation, which were only used for the scaling purpose of the former data. Altogether, 930 independent reflections were measured. Lorentz and polarization corrections were applied but absorption correction was neglected. The observed structure factors were adjusted to their absolute values by the usual procedure, then the normalized structure factors were calculated.

Structure Determination and Refinement

The structure of DL-GABOB was solved by the symbolic addition method using a computer program DPD. After three cycles of the symbolic addition procedure for 124 reflections with $|E|\geqq1.5$ and with probability greater than 97%, signs of 97 reflections were determined. Possible two E-maps were calculated, and one of which revealed clearly the correct peaks of GABOB molecule.

Refinement of the structure was carried out by a block-diagonal least-squares procedure, using a program BLLS with unit weight for non-zero reflections. Five cycles of refinement with the isotropic temperature factors for the non-hydrogen atoms reduced an *R* index ($R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$) to 0.18. After the

refinement with the anisotropic temperature factors for all the non-hydrogen atoms, a difference Fourier synthesis was calculated. The peaks of all nine hydrogen atoms, including three attached to the amino-nitrogen atom, were found at their proper positions. The further least-squares refinement including the hydrogen atoms with isotropic temperature factors was continued until all shifts in the atomic coordinates became less than 10% of the estimated standard deviation. The final R index was 0.096 (0.123 including $F_o=0$). The final positional and thermal parameters are listed in Table 2. A list of the observed and calculated structure factors is presented in Table 3.

All the numerical computations were done on an NEAC 2200—500 computer in the Computing Center of this University and an FACOM 230-60 in the Data Processing Center of Kyoto University, using the program written by Dr. T. Ashida and by the authors.

Results and Discussion

The bond lengths and angles of DL-GABOB are shown in Fig. 1. The bond lengths and angles of the main chain are essentially the same as the corresponding ones of γ-aminobutyric acid (GABA).[7] The C3-O3 bond length of β-hydroxyl group, 1.425 Å, corresponds

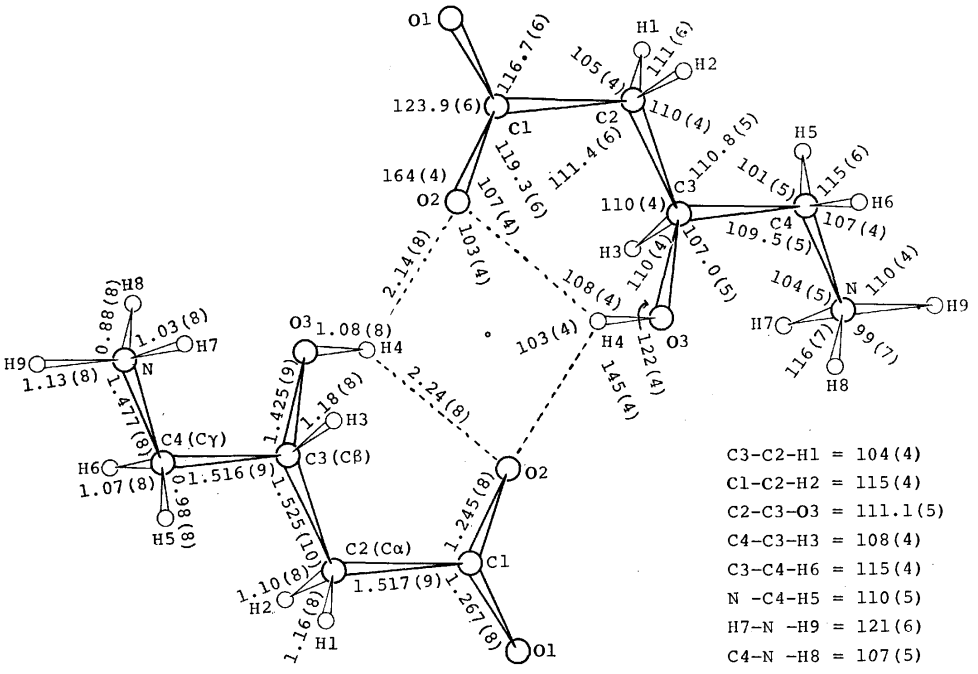

Fig. 1. Bond distances (Å) and bond angles (°). The estimated standard deviations are shown in parentheses. The broken lines indicate the hydrogen bonds.

TABLE 3. OBSERVED AND CALCULATED STRUCTURE FACTORS ($\times 10$)
Reflections marked * were omitted from the least-squares refinement.

to the normal C–O single bond length. DL-GABOB molecule has the ziwtterionic structure, NH_3^+–CH_2–CH(OH)–CH_2–COO^-, by the protonation to the γ-amino group. D and L molecules are related by a center of symmetry as shown in Fig. 1, and the hydrogen atom attached to the O3 atom takes part in the intra- and intermolecular bifurcated hydrogen bond to form DL dimer. GABOB molecule forms the expected *trans-zigzag* conformation in crystalline state. The Cα(C2), Cβ(C3), Cγ(C4) and N atoms which compose the skeletal structure of GABOB are in a plane (plane I), and the O1, O2, and C1 atoms of the carboxyl group including the Cα(C2) atom are in another plane (plane II). Deviations of the atoms from each plane are listed in Table 4. The dihedral angle of 11.5° between these two planes indicates that all the atoms in main chain are roughly in one plane. Deviations of each atom from the best plane including all the atoms except O3 are as follows; O1: −0.19, O2: 0.06, C1: −0.03, C2: 0.17, C3: 0.10, C4: 0.14, and N: −0.20 Å. Newman projections of atoms in respect to the C1–C2, C2–C3, and C3–C4 bonds with the torsion angles are shown in Figs. 2a and 2b for GABOB and GABA, respectively. The largest conformational difference between GABOB and GABA in crystalline state is found in their torsion angles in respect to the C2–C3 bond, which are *trans* (173.7°) in GABOB and *gauche* (73.6°) in GABA, respectively. The intramolecular hydrogen

bond between the O3 and the O2 atom in GABOB molecule is thought to play an important role in restricting the rotational freedom around the C2–C3 bond and keeping the extended *trans-zigzag* conformation of the molecule.

GABOB is well known as a potent inhibitory chemical transmitter in central nervous system as well as GABA, and it is of most interest that the skeletal conformation of GABOB is just the same as that of GABA hydrochloride,[9] but is different from that of GABA.[7] It is still obscure why these chemical transmitters may be released from the membrane of nerve ganglion into synapse and inhibit the transmitting of the stimulus to neighboring nerve cell, however, it may be postulated that GABA may be induced the change of its molecular conformation by binding to an ion (probably potassium or chlorine ion) due to the increase of ion concentration in presynaptic membrane by the stimulus and may be selectively released through the channel of membrane into synapse with the ion. On the other hand, the molecular conformation of GABOB is fixed as the extended *trans-zigzag* one due to the OH···O intramolecular hydrogen bond of 2.773 Å and probably released into synapse without any affection by ion concentration. GABA or GABOB in synapse may bind to the postsynaptic receptor site at neighboring nerve cell membrane in order to decrease the membrane resistance, chiefly attributable to an increase in Cl^- permeability. The nature of the interactions between the chemical transmitter and its receptor molecule is electrostatic, hydrogen bonding and van der Waals, and the resulting force between the molecules depends on the mutual orientation and conformation of the molecules. The zwitterionic form of GABA or GABOB may affect on the electrostatic interaction with the receptor and the amino group may participate in the hydrogen bonding with the receptor as a donor while the carboxyl group acts as an acceptor of hydrogen bond. In this case, the important intramolecular distances between the amino nitrogen atom and the carboxyl oxygen atoms are equal within the standard deviations; N–O1=6.052, 6.11 Å, N–O2=5.027, 5.15 Å for DL-GABOB and GABA hydrochloride, respectively. This important role of the extended *trans-zigzag* conformation for the inhibitory action may be also supported by the fact that muscimol, an isoxazole betaine isolated from *Amanita muscaria*, having a restricted similar backbone conformation, acts as a GABA-like depressant.[10] In addition, the O3 atom of GABOB is engaged in OH···O intramolecular hydrogen bond of 2.773 Å and this atom seems to interact with extra active sites of a receptor in nervous system than the GABA molecule does.

Distances and angles of the hydrogen bonds are listed in Table 5. The crystal structure of DL-GABOB is shown in Fig. 3. DL-GABOB molecules are connected by three-dimensional networks of NH···O and OH···O type hydrogen bonds, in which O3H···O2 hydrogen bond holds D-antipode of GABOB with its L-form related by a center of symmetry. There are

Restricted Rotation Involving the Tetrahedral Carbon. VII. Rotation About the Carbon-Group IV Single Bond[1]

Fumio SUZUKI, Michinori ŌKI,* and Hiroshi NAKANISHI**

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

***National Chemical Laboratory for Industry, Shibuya, Tokyo 151*

(Received May 25, 1973)

9-*t*-Butyl-, 9-trimethylsilyl-, 9-trimethylgermyl-, and 9-trimethylstannyl-1,2,3,4-tetrachloro-9,10-dihydro-9,10-ethenoanthracenes were prepared by the addition of tetrachlorobenzyne to 1-$(CH_3)_3$M-substituted naphthalene. The carbon compound showed very high barrier to rotation, whereas the coalescence phenomenon of three methyl signals was observed for silicon, germanium, and tin compounds. The barrier ($\Delta G^{\ddagger}$) to rotation at 298 K was obtained as 19.1 ± 0.5, 17.2 ± 1.2, and 11.7 ± 0.4 kcal/mol for Si, Ge, and Sn compounds, respectively. The decrease in the barrier on increasing the atomic size was attributed to the release of repulsive interaction to a greater extent, since the longer bond length should result in the larger displacement of the methyl group even though the bond angle deformation is the same.

It was revealed, in one of the recent papers from this laboratory, that the barrier to rotation about a C–C single bond in some Diels-Alder adducts derived from 9-substituted anthracenes was extremely high.[2] These results allured the present authors to examine the outcome by the change of one of the sp^3 hybridized carbon to an atom of other fourth group elements.

One of the points of interest is to see the effect of

the change in bond length. As to the conformational energies of cyclohexane derivatives, it is known that chlorine, bromine, and iodine show rather similar values[3] in spite of the fact that the van der Waals radius of iodine is much greater than that of chlorine. The phenomenon has been attributed to the bond length. Namely, although the iodine atom is bulkier than chlorine, the interaction of the atom in question with the 3-hydrogen in the axial conformation is counterbalanced because the distance between hydrogen and iodine is greater.

Molecular models of 9-trimethylsilyltriptycene and its analogs indicate that the increase in bond length leads to the increased interference with the benzo bridges, because the longer C–M bond places the methyl group more closely to the substituent of the benzo group. This is just the contrary to the expectation from the analogy of the cyclohexane derivatives. This increasing interference may result in the increase in the barrier to rotation. Therefore it becomes interesting to see the effect of changing the *t*-butyl group to trimethylsilyl, trimethylgermyl, and then to trimethylstannyl.

This paper deals with the rotational barrier in 9-$(CH_3)_3$M-substituted 1,2,3,4-tetrachloro-9,10-dihydro-9,10-ethenoanthracenes, where M is C, Si, Ge, or Sn. Although the selection of the compounds was made according to the ease of syntheses, the distinct effect of the change of the central atom was observed.

Experimental

Syntheses. The syntheses of the compounds were performed by treating 1-$(CH_3)_3$M-substituted naphthalene (**1**) with tetrachlorobenzyne.[4] 1-*t*-Butylnaphthalene,[5] 1-trimethylsilylnaphthalene,[6] and 1-trimethylstannylnaphthalene[7] were known compounds and were prepared by following the procedures of literatures. The reaction of the benzyne gave both 1,4-adduct (**2**) and 5,8-adduct (**3**). The desired adduct (**2**) was separated by chromatography.

*1-Trimethylgermylnaphthalene (**1c**).* A solution of 1-naphthylmagnesium bromide, prepared from 10.3 g (0.05 mol) of 1-bromonaphthalene and 1.2 g (0.05 mol) of magnesium in 100 ml of ether, was added to 0.07 mol (15.0 g) of tetrachlorogermane in 50 ml of ether at −10 °C over a period of 1 hr. The mixture was set aside for 2 hr at room temperature and then heated under reflux for 0.5 hr. Methylmagnesium iodide prepared from 42.5 g (0.3 mol) of methyl iodide, 7.2 g (0.3 mol) of magnesium and 200 ml of ether was added to the above solution with vigorous stirring and the whole was refluxed for 2 hr. The mixture was cooled and treated with water. The organic layer was dried over sodium sulfate and evaporated to give a yellow oil. This crude product was directly used for the next reaction.

*1,2,3,4-Tetrachloro-9-t-butyl-9,10-dihydro-9,10-ethenoanthracene (**2a**).* A solution of butyllithium, prepared from 4.6 g (0.05 mol) of butyl bromide, 0.7 g (0.1 mol) of lithium, and 100 ml of ether, was added to a suspension of 14.2 g (0.05 mol) of hexachlorobenzene in 600 ml of ether at −30 °C over a period of 1 hr. To this mixture, a solution of 9.2 g (0.05 mol) of 1-*t*-butylnaphthalene in 50 ml of ether was added. The whole was set aside at room temperature for 1 hr, heated under reflux for 1 hr, cooled and treated with water. The organic layer was separated, washed with water, dried over sodium sulfate, and evaporated. The residue was taken up in hexane and chromatographed on alumina. Elution of the mixture with hexane gave a mixture of 1,4-adduct (**2a**) and 5,8-adduct (**3a**) in 1:2 ratio. NMR data of **3a** in $CDCl_3$ (δ from internal TMS): 1.53 (9H, s), 5.56 (1H, t, J=3.6 Hz), 6.30 (1H, t, J=3.6 Hz), 6.85—7.40 (5H, m). The NMR data for **2a** are given in Table 1.

The mixture of **2a** and **3a** was dissolved in hexane and rechromatographed on silica gel impregnated with silver nitrate. Elution with hexane gave pure **2a**, mp 162—164 °C, as a first eluate in *ca.* 5% yield based upon the starting 1-*t*-butylnaphthalene. Found: C, 60.23; H, 4.07; Cl, 35.73%. Calcd for $C_{20}H_{16}Cl_4$: C, 60.36; H, 4.06; Cl, 35.58%.

*1,2,3,4-Tetrachloro-9-trimethylsilyl-9,10-dihydro-9,10-ethenoanthracene (**2b**),* mp 157—159 °C, was similarly obtained as a mixture with the 5,8-adduct (**3b**) [NMR, $CDCl_3$, δ from TMS: 0.45 (9H, s), 5.62 (1H, q, J=4.6 and 3.0 Hz), 5.90 (1H, q, J=4.6 and 3.0 Hz), 6.95—7.43 (5H, m)] in 1:2 ratio and purified by SiO_2–$AgNO_3$ chromatography. The yield of pure **2b** was *ca.* 5%. Found: C, 55.53; H, 3.98; Cl, 34.08%. Calcd for $C_{19}H_{16}Cl_4Si$: C, 55.25; H, 3.94; Cl, 34.25%.

*1,2,3,4-Tetrachloro-9-trimethylgermyl-9,10-dihydro-9,10-ethenoanthracene (**2c**),* mp >315 °C, was similarly obtained as a mixture with **3c** (1:1.5 ratio). Pure **2c** was isolated in *ca.* 5% yield. Found: C, 49.95; H, 3.37; Cl, 31.17%. Calcd for $C_{19}H_{16}Cl_4Ge$: C, 49.74; H, 3.55; Cl, 30.89%. Only the NMR data of the 5,8-adduct (**3c**) were recorded ($CDCl_3$, δ from TMS): 0.57 (9H, s), 5.59—5.90 (2H, m), 6.97—7.41 (5H, m).

*1,2,3,4-Tetrachloro-9-trimethylstannyl-9,10-dihydro-9,10-ethenoanthracene (**2d**),* mp 165—166.5 °C, was obtained in *ca.* 5% yield. Found: C, 45.40; H, 2.98; Cl, 28.07%. Calcd for $C_{19}H_{16}Cl_4Sn$: C, 45.21; H, 2.98; Cl, 28.09%. NMR data of the 5,8-adduct (**3d**) were as follows ($CDCl_3$, δ from TMS): 0.51 (9H, s), 5.58 (2H, m), 5.70—7.50 (5H, m).

Spectral Measurement and Calculation. The NMR spectra were recorded on a Hitachi R-20B spectrometer operating at 60 MHz. The samples were dissolved in an appropriate solvent to make up *ca.* 10% solution. The temperature was read by the difference in chemical shifts of methanol protons in the lower temperature region and by that of ethylene glycol in the higher temperature region. T_2 was measured from the line-width of an appropriate additive in the sample

solution: for mainly technical reasons, *t*-butylbenzene, tetrachloroethane, and dichloromethane were used for **2b**, **2c**, and **2d**, respectively.

Theoretical spectra were obtained by the use of EXNMR program.[1] The couplings of protons with ^{117}Sn and ^{119}Sn were neglected in the line-shape analysis because of the low natural abundance of the respective species. The agreement between the observed and the calculated spectra was excellent.

Results and Discussion

The NMR data of the adducts **2** in deuteriochloroform at 34 °C are summarized in Table 1. It is immediately noticed that the carbon, silicon, and germanium compounds show three kinds of methyl peaks, whereas the tin compound gives only one signal for the trimethylstannyl group. The rotation about the C_9–M bond must be slow on the NMR time scale for the compounds whose M is C, Si, or Ge, because, if the rotation in question is frozen, the three methyl groups must be in the different magnetic environment from each other (see **4**). The appearance of only one signal for the trimethylstannyl group in **2d** may be attributed to either a fortuitous coincidence of the chemical shifts of three methyl groups under the conditions or the fast exchange of the methyls on the NMR time scale. The latter was found to be the case because lowering the temperature caused the broadening of the signals and finally resulted in the appearance of three kinds of methyl signals. The chemical shifts at −58.5 °C from the internal TMS in CS_2 were 0.14, 0.51, and 0.85 ppm.

Temperature was raised to find the coalescence temperature and to observe the line shapes of compounds **2a**, **2b**, and **2c**. Spectra of **2b** and **2c** were temperature dependent and coalescence of the three signals was observed. However, the spectrum of **2a** was stout and did not show temperature dependence up to 200 °C. Even the broadening of the signal could not be observed.

From these results and the chemical shifts of the three methyl groups, the barrier to rotation about C_{Bu}–C_9 bond of **2a** is estimated to be at least 25 kcal/mol. The rate constants of rotation of other compounds were obtained by computer simulation of the curves. The activation energies were calculated by plotting the rate constants against the reciprocals of temperature. The ΔH^*, ΔS^*, and ΔG^* were obtained by putting these data to Eyring's equation. The results are shown in Table 2.

Although the use of the same solvent is desirable for the discussion, it was impossible to use a common solvent for the series of compounds. Hexachlorobutadiene is suitable for measurement at high temperatures but is too viscous to obtain a good spectra at *ca.* 50 °C. Likewise, tetrachloroethylene is good at *ca.* 50 °C but is not suitable for measurement at high and at very low temperatures. Fortunately, however, it is known that the solvent change does not affect the activation parameters of internal rotation to a great extent in the case of biphenyl derivatives.[8] This conclusion may reasonably be transferred to the present situation, since the internal rotation is the common subject in both cases. We believe the following discussion is valid, since only the nonpolar solvents are used in the present work and no strong solute-solvent interaction is anticipated.

Descending the fourth group element from carbon to the elements of the lower period gives monotonous decrease in ΔG^*'s and ΔH^*'s. This is rather unexpected from the results of examination of the molecular models, as mentioned before, and demands further consideration. Recently, Oullette and his co-workers carried out the force field calculation of various butane analogs $CH_3CH_2MH_2CH_3$ containing silicon, germanium, or tin.[9] The conclusion from that calculation is that the *gauche* conformation is strikingly stable over the *trans* conformation and the barrier to rotation is mainly controlled by the stability of the ground state where nonbonding H–H attractive interaction contributes strongly to the total energy. Thus in this series, the potential of the transition state of rotation is almost the same irrespective to the kind of element M (except carbon) and the increasing size of M decreases the

Table 2. Activation parameters for rotation (at 25 °C)

	T_c (°C)	E_a kcal/mol	ΔH^* kcal/mol	ΔS^* eu	ΔG^* kcal/mol	solvent
2a	>200				>25	hexachlorobutadiene

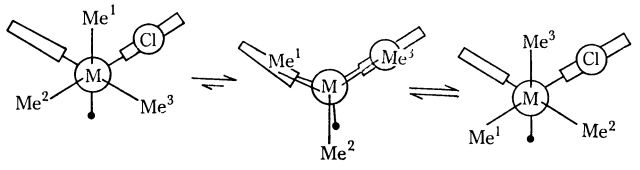
barrier to rotation.

The phenomena in the Diels-Alder adducts dealt with here might have been explained in a similar manner, if the steric conditions of the butane analogs were applicable to the compounds in question. However, although the compound **2** is the ethane type molecule, the situations are quite different from those of $CH_3CH_2MH_2$-CH_3. In the latter compound, it is known that the distance between the two methyl groups is larger than the sum of two van der Waals radii of the methyl. The attractive term is important even at the eclipsed conformation. On the other hand, the steric situation of compound **2** is overcrowded. Inspection of the model of the ground state (**4** and **4'**) indicates that the distance between chlorine at 1-position and a closest methyl group from that atom is within the sum of the van der Waals radii of the two substituents. Therefore, although the molecule will deform to some extent to minimize the van der Waals repulsion, the steric conditions are thought to be severe at the transition state (**5**). It seems, then, natural to seek the reason for the phenomenon in repulsive forces rather than the attractive.



4 **5** **4'**

Since the molecular model shows severe overlap of the groups at the transition state **5**, the bond length will be stretched and the bond angle distorted to help to decrease the energy of the transition state. The energy of stretching a bond and that of deforming a bond angle may be discussed in terms of force constants obtained from the infrared study. Thus the force constants of respective moieties are collected in Table 3 from the literature.[10]

Table 3. Force constants for bond stretching and angle deformation

	C	Si	Ge	Sn
Bond Stretching constant (C–M) mdyn/A	4.50	2.97	2.70	2.12
Angle bending constant (C–M–C) mdyn/rad	0.799	0.570	0.490	0.320

Although it may seem that the smaller force constants for stretching the C–M bond should play some part in lessening the barrier to rotation when M is the large atom, the molecular model is not in conformity with this idea. When M becomes large, both the C_9–M and C_{CH_3}–M bonds become longer and, as a consequence, the overlap of the chlorine and the methyl group at the transition state becomes worse. Therefore, relief of steric strain at the transition state by stretching the bond should be small in its extent, if any.

Another way of relieving the steric interference at the transition state is to deform the bond angles concerned with the $(CH_3)_3M$ group, because the other part of the molecule is very rigid. The force constants of angle bending also decreases as M becomes large. Therefore, the ease of angle deformation increases as we descend the periodic table from carbon to tin. The important point here seems to be that even the deformation of the same degree results in the different degree of release of the steric strain. When the C–M bond is longer, the actual placement of the methyl group can become more apart from the groups which contribute mainly to the strain at the transition state, even though the angle deformation is the same. Thus we believe that the longer bond distance is the main cause for decreasing the barrier to rotation, when M is the large atom, and the smaller force constants for the C–M–C angle deformation is an additional factor which helps to decrease the barrier height.

An Attempt at Simultaneous Observation by Polarizing Microscopy and by Differential Thermal Analysis*

Kazuko Sasaki Kunihisa

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received June 23, 1972)

An apparatus for differential thermal analysis using a polarizing microscope has been developed. With this device it is possible to observe the state of a sample under the heating or cooling conditions with a polarizing microscope and to obtain the DTA curve simultaneously. The transformations of several substances—potassium laurate, ammonium nitrate and tripalmitin— were observed. The results are in agreement with those obtained by X-ray diffraction. The relation between the appearance of Phase III of NH_4NO_3 and the water content of the sample was considered on the basis of the microscopic observations. In the case of tripalmitin, two types of transformations were observed under cooling conditions. The relation between the DTA curve of tripalmitin and the heating rate has also been studied. The apparatus may be useful for the study of liquid crystals.

Recently, various kinds of apparatus for thermal analysis have been developed. Particularly, the simultaneous measurement of two parameters, such as X-ray diffraction —differential thermal analysis or thermogravimetry— differential thermal analysis, has been established.

The apparatus has been devised to observe the state of the substance microscopically on heating or cooling and simultaneously to obtain the DTA curve. The device has been constructed by setting the furnace for DTA on the sample stage of a polarizing microscope.

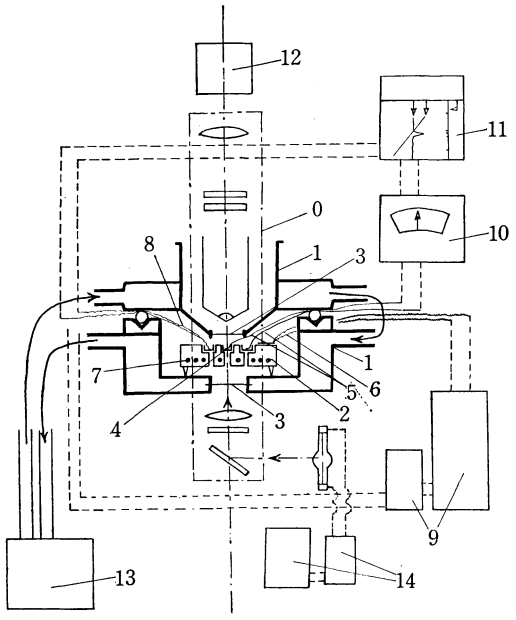

Fig. 1. The structure of DTA furnace and other parts.

* Presented in part at the 4th Conf. Therm. Anal. Japan (1968) and the 23th Conf. the Chem. Soc. Japan (1970).

Apparatus

Figure 1 shows a diagram of the apparatus and illustrates the structure of the furnace. Both the lid and the base of the furnace (1) have transparent parts (3) made of quartz at their centers, water can be circurated in them from the cooling system (13). A flat cyrindrical copper block (2) was made with an embedded sheath nichrome wire heater (7) (1 mmϕ, 33 ohm) and three hollows. Each hollow has a slit at the bottom to admit light. Disc-like sample holders (4) made of quartz are inserted into the hollows of the block. The inner size is 3 mm$\phi \times$ 1 mm. The thickness of the quartz is 0.5 mm. The lid and bottom of the sample holders are polished optically. Both the differential thermocouple (5) and the temperature thermocouple (8) are Al–Cr of the sheath type (0.5 mmϕ). The input of the heater embedded in the block is controlled by a temperature programmer (9) together with a sheet-like thermocouple (6) on the block.

Microscopic observations have been made through crossed nicols and a color-sensitive plate. The multiplicity is 100. The light source (14) is usually a Tungsten lamp (30 W) or Xenon lamp (150 W).

A microswitch was set up at the tip of the release of the camera in order to interlock the camera shutter

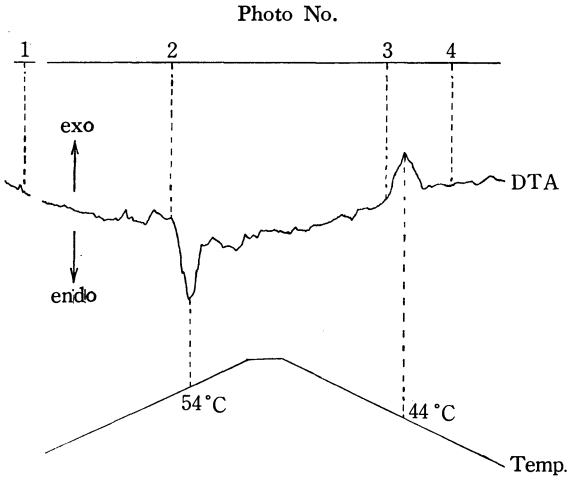

Fig. 2. DTA of potassium laurate at heating and cooling condition. Rate, 1.25 °C/min., Sensitivity, ±50 μV.

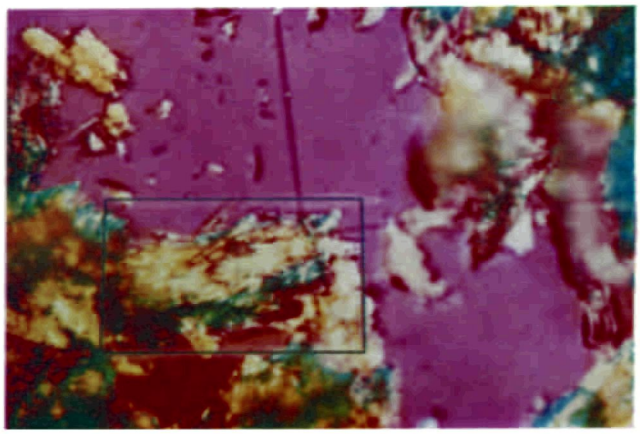
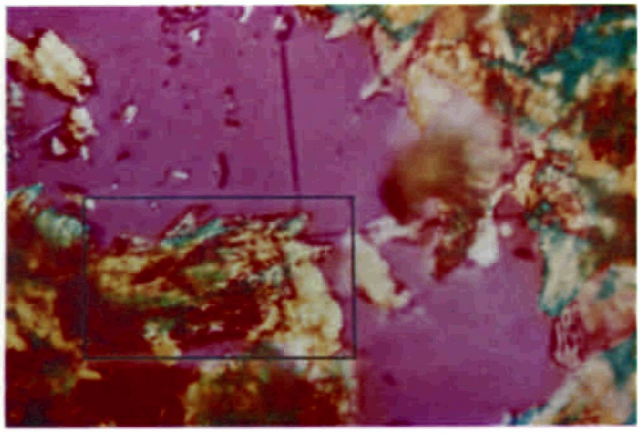
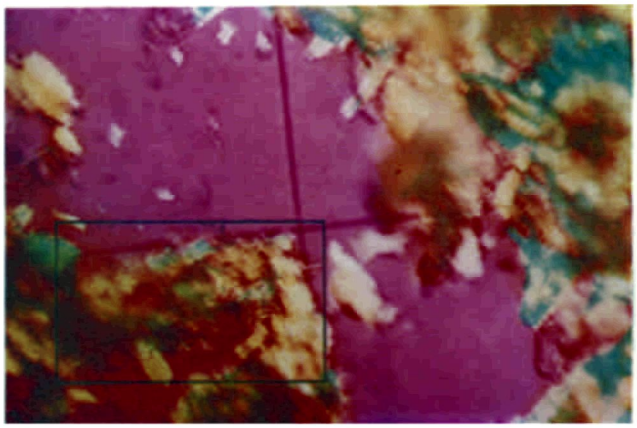
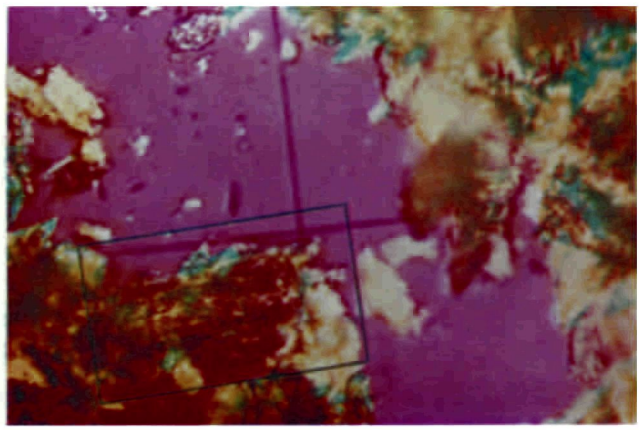
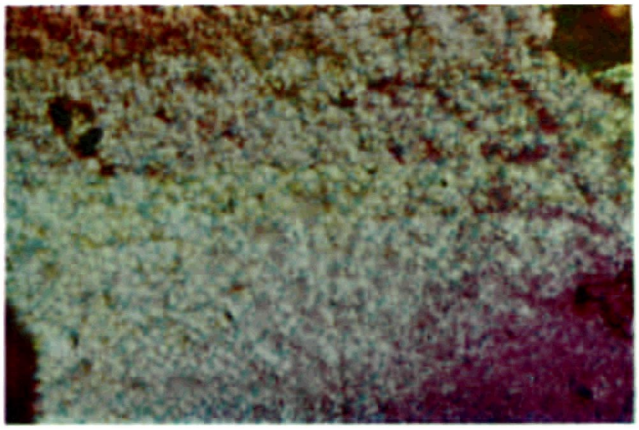
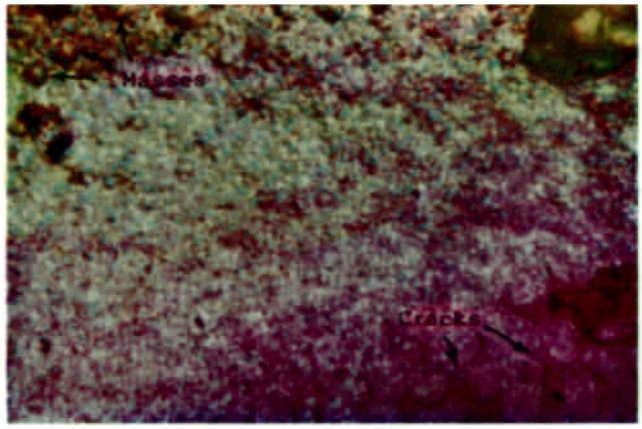




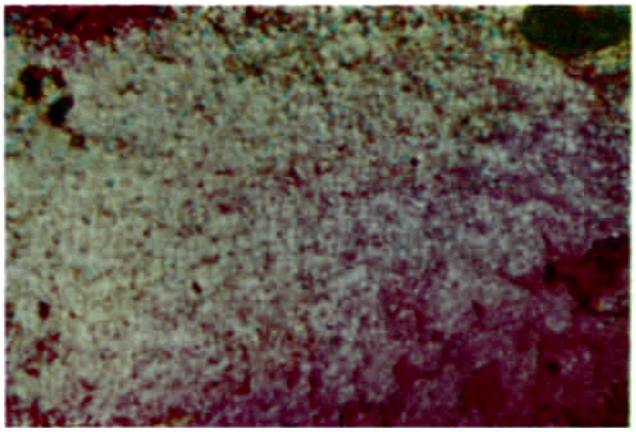


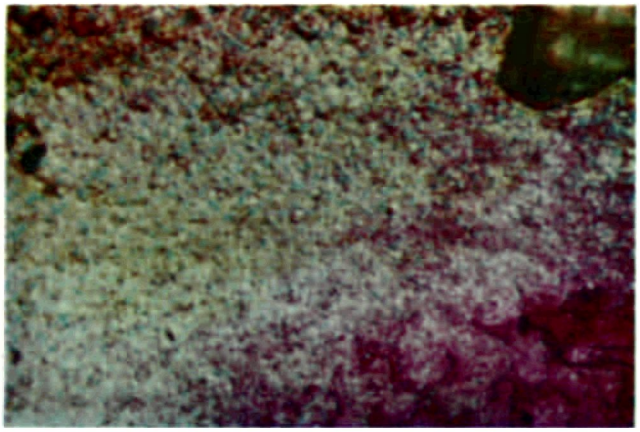






Masses
Cracks





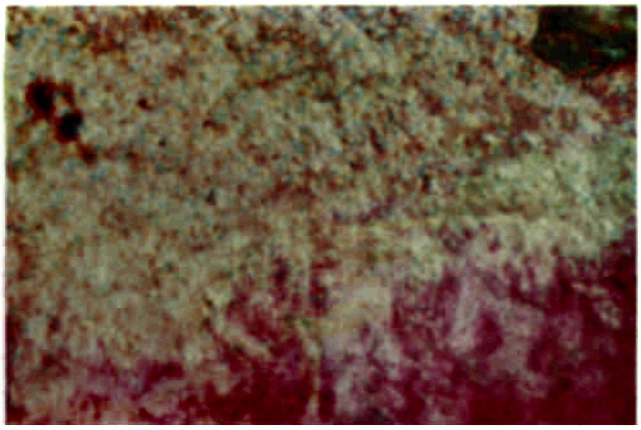


Figure 7-1 shows the thin layer of the α form made by the rapid cooling of the melt at 0 °C. Figure 7-2 shows the beginning of the transformation. The color of Fig. 7-2 is more similar to the back of the sample than that of Fig. 7-1. This means that the crystal layers are becoming transparent. At the same time, contraction occurs, as can be proved by the cracks in at the lower right in Fig. 7-2 and the several masses produced at the upper left in Fig. 7-2. Both the cracks and the masses are indicated by arrows.

At the peak of the endothermic state (Fig. 7-3), the sample becomes more transparent than at the beginning (Fig. 7-2). This means that the sample has turned more isotropic, like liquid.

Near the exothermic state, the crystalline state of the sample begins to recover. This can be deduced from the fact that Fig. 7-4 is less transparent than Fig. 7-3.

Figure 7-5 shows the sample at 58 °C. This photograph looks almost the same as Fig. 7-1 except for the cracks. Since the heating rate of this experiment is 2.5 °C/min, about 4 min elapse from Figs. 7-4 to 7-5. This means that the sample recovers a complete crystalline state after 4 min.

Figure 7-6 shows the beginning of the melting of the β form (66 °C). The photograph looks out of focus because of the movement of the crystal layer.

Upon cooling, two types of phase changes were observed. In this case, no temperature programming was carried out, as is shown in Fig. 8.

In the first case, the supercooled state was maintained from the melting point of the β form to the transition point, at which point crystallization suddenly began, accompanied by both heat absorption and evolution (Figs. 9-1 and 9-2). In the second case, crystallization took place as soon as the temperature arrived near the melting point of the β form (Figs. 11-1 and -2): afterwards, the crystal layer became transparent near the transition point (Fig. 11-3). In this case, no heat absorption was observed, but heat evolution was (Fig. 10).

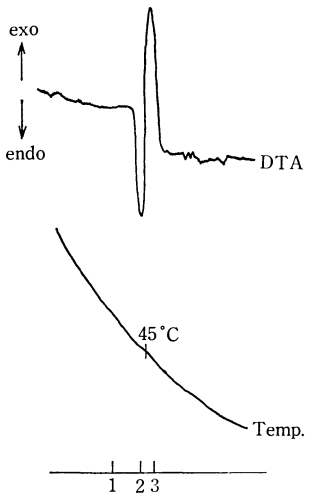

Fig. 8. DTA of tripalmitin at natural cooling. (1st case)

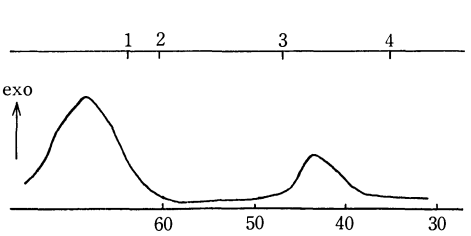

Fig. 10. DTA of tripalmitin at natural cooling. (2nd case)

Discussion

The results of the above experiments suggest that the apparatus is quite useful, even though the photographs are not very good. These results are in agreement with those obtained by X-ray diffraction.

Two transformations of ammonium nitrate made a particularly good contrast with each other. Brown and McLaren suggested that the IV—III transformation requires the presence of some moisture because of the severe structural change involved. They theorized that the transition took place by means of the dissolution and recrystallization of the solid. As proof, they cited the large increase in electrical conductance on the IV—III change. However, a large increase in electrical conductance is also observed upon the III—II change.

The transformations among IV, III, and II seem to take place with some regularities, according to the author's microscopic observations. That is, in the case of IV—III, a brightness appears longitudinally in the needle (a-axis) single crystal, but in the case of III—II, the brightness appears laterally in the crystal with expansion and contraction. If the IV—III modification takes place by means of dissolution and recrystallization, the sample should be more at random.

The III—II transition is far more drastic than that of IV—III as a phenomenon. Considering the similarities among I, II, IV, and V,[2] the presence of moisture seems to disturb the transformation of Phase IV to Phase II, on the other hand, it seems to make Phase IV turn into Phase III. Therefore, once the sample changes into Phase III, it may be forced to undergo the drastic III—II transformation (*cf.* Fig. 12).

In the case of tripalmitin, the heat absorption upon heating suggests the latent heat of melting of the α form. The successive heat evolution indicates the transformation from the α to β form, because the β form is more stable than the α form. The melting of the α form could not be observed microscopically. However, a transparency could be observed. On the other hand, at the beginning of the melting of the β form (Fig. 7-5), no transparency could be observed, even though the crystal layer started to move. Therefore, the transparency at the transformation may not indicate the melting state of the α form, but only an isotropic state during change to another form, β.

The heat absorption disappears with a decrease in the heating rate. In the case of a low heating rate it seems that the α form changes to the β form directly without actually passing through the melting state.

6) E. S. Lutton, *J. Amer. Chem. Soc.*, **67**, 524 (1945).

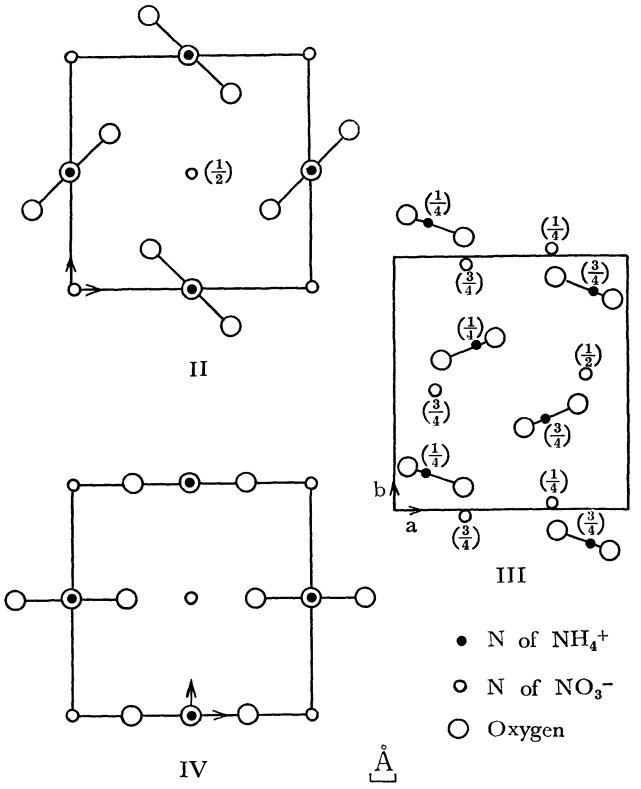

Fig. 12. Projections onto (001) of the structures of forms II, IV and III of ammonium nitrate.[2]

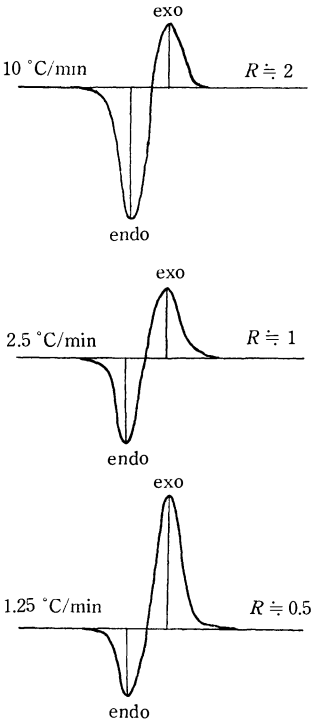

Fig. 13. The influence of heating rate on DTA curve of tripalmitin. R; ratio of endothermic peak to exothermic peak.

Figure 13 shows the relation between the heating rate and the DTA curve. The peak of the heat absorption becomes higher with increase in the heating rate, but that of the heat evolution becomes lower. These results support the theory that the α form melts directly when rapidly heated.[5] The peak of the heat absorption becomes lower with a lowering of the heating rate, but that of the heat evolution becomes higher. These results support the microscopic observation that the α form changes to the β form directly, with no melting, when slowly heated.

Upon cooling, it is reasonable to consider that the endothermic peak of the first case (Fig. 8) indicates the heat of the transformation of the β form to the α form and that the exothermic peak indicates the solidification of the α form. The second case (Fig. 10) can be interpreted as meaning that the melted sample does not cause a supercooled state; instead, the β form is deposited directly and is then transformed into the α form at the transition temperature. However, the β form does not usually change into the α form, because the β form is more stable than the α form. Considering the inhibition rule, it does not seem reasonable to assume that the first deposited phase corresponds to the β form. Since the solid state appeared over 60 °C, it did not seem to be the β′ form (mp 55.5 °C). It must be studied further in the future.

Conclusion

The above attempt at simultaneous microscopic and DTA observation has been achieved qualitatively, but not yet quantitatively. However, several useful results have been obtained by the use of this apparatus. They may contribute to the study of liquid crystals.

The present apparatus is limited to use from room temperature up to 350 °C because of the limits of the heat-resistivity of the sheet-like thermocouple and the other materials. Practically, all the experiments were done below 200 °C. Photography was restricted by the illumination of the light source.

The author wishes to thank Mrs. Midori Gotoh of this laboratory for offering the potassium laurate and tripalmitin, materials of her own study. She also kindly presented many references concerning them. The author also wishes to thank Mr. Satohiro Tanaka of this laboratory for his advice and encouragement.

Evaluation of Diffusion Coefficients of Myosins from Sedimentation Boundary Curve

Masao YOKOYAMA, Atsunobu OHMOTO, and Yuji MIYAZAWA
Department of Chemistry, Science University of Tokyo, Kagurazaka, Tokyo 162
(Received November 30, 1972)

Fujita[1,2] showed that the height-area ratios of schlieren patterns obtained during a sedimentation velocity experiment can be used for the evaluation of the diffusion coefficient of the solute component in solution. This indicates that sedimentation and diffusion coefficients can be obtained under the same conditions. Considering the labile and restrictive nature of purified biological active macromolecules available for physico-chemical measurements, the evaluation of molecular weight from sedimentation and diffusion coefficients is still valuable.

The reported molecular weights of skeletal myosin are 4.2×10^5—6.2×10^5. The discrepancies were discussed in terms of the presence of aggregates in the samples.[3,4] In the present study, the diffusion coefficients for myosins prepared from smooth and skeletal muscles are evaluated from sedimentation boundary curves using Fujita's method, and the molecular weights of these myosins are calculated from the sedimentation and diffusion coefficients extrapolated to infinite dilution.

Experimental

Preparation of Sample. Smooth muscle myosin (myosin-S) was prepared from parts of the smooth muscle of horse gullet by ammonium sulfate fractionation.[5,6] Skeletal muscle myosin (myosin-A) prepared from rabbit skeletal muscle by the ammonium sulfate fractionation method[7] was supplied by Prof. T. Sekine. These myosins were dissolved in 0.5 M KCl solution containing 1/150 M phosphate buffer (pH 7.5). All sedimentation measurements were performed within three days after the final purification to minimize the formation of aggregates in the sample solutions. Concentrations of the solutions were determined from the optical densities at 279 nm. The extinction coefficients used were 600 cm^2/g[6] for myosin-S and 560 cm^2/g[8] for myosin-A.

Ultracentrifugal Experiment. A Hitachi UCA-1 ultracentrifuge equipped with schlieren optics was used. The temperature of the rotor was kept at 5.0 ± 0.1 °C. A synthetic boundary cell of double sector type and a conventional cell were used. To avoid direct contact of the sample solution with a metallic surface, which sometimes causes denaturation of proteins, either a cell made of epoxy resin or an aluminum cell coated with Teflon was used. The speed of the rotor was 10490—60000 rpm.

Results and Discussion

Sedimentation Coefficient. Sedimentation coefficients were calculated from the rates of movement of the boundary peak at several rotor speeds. The following equation[9] was used to correct the sedimentation coefficients at higher rotor speeds for pressure effect:

$$\ln(r_*/r_a)/\omega^2 t = S^0(C_0)\{1+[k_sC_0-m(1+2k_sC_0)/2(1+k_sC_0)][(r_*/r_a)^2-1]\} \quad (1)$$

where r_* and r_a are the distances from the center of rotation to the peak and the solution meniscus, respectively, ω is angular velocity, t time, $S^0(C_0)$ the sedimentation coefficient at concentration C_0, which is the initial concentration of the solution, m a parameter, and k_s a positive parameter characteristic of a given system. For the data at rotor speeds lower than 32000 rpm, at which the peak sedimented slowly and the boundary diffused quickly, the following equation was used.[10]

$$-2S\omega^2 t = \ln\left\{1-\left(\int_{r_a}^{r_p}(r^2-r_a^2)(dc/dr)dr\right)\Big/C_0r_a^2\right\} \quad (2)$$

where r_p is the distance from the center of rotation to a point arbitrarily chosen in the plateau region. The values of S obtained by Eq. (2) were equated to $S^0(C_0)$. Values of t were corrected graphically by using the conditions where $\ln(r_*/r_a)$ vanishes at $t=0$. In all experiments, the coefficient for the term $[(r_*/r_a)^2-1]$ in Eq. (1) was very small, no significant dependence of sedimentation coefficient on angular velocity being found. The sedimentation coefficients were corrected for concentration dependence by

$$1/S^0(C_0) = (1/S_0)(1+k_sC_0) \quad (3)$$

Figure 1 shows the concentration dependence of the sedimentation coefficient for myosin-S, the data being expressed by $1/S^0(C_0)=0.247(\pm0.001)+0.0230(\pm0.0003)C_0$ where C_0 is given in units of mg/ml. Figure 2 shows the results for myosin-A, the data being expressed by $1/S^0(C_0)=0.252(\pm0.004)+0.0246(\pm0.0003)C_0$.

Diffusion Coefficient. Data for the height-area ratio H/A from a series of sedimentation boundary curves could be used for the evaluation of diffusion

coefficient D, when an adequate equation for H/A is available. Fujita[1,2] derived the following equation for this purpose.

$$G^{-1}(2r_a\omega^2S_0k_sC_0(H/A)t) = [r_a\omega^2k_sC_0S_0/2D^{1/2}][1-(S_0\omega^2t/2)(1-k_sC_0)]t^{1/2} \quad (4)$$

where G^{-1} is the inverse function of G. The value of D can then be determined from the slope of a plot of $[1-(1/2)(1-k_sC_0)\omega^2S_0t]t^{1/2}$ *vs.* $G^{-1}(2r_a\omega^2S_0k_sC_0(H/A)t)$. Figures 3 and 4 show the plots of $[1-(1/2)(1-k_sC_0)\omega^2S_0t]t^{1/2}$ *vs.* $G^{-1}(2r_a\omega^2S_0k_sC_0(H/A)t)$ for the smooth and skeletal muscle myosins, respectively. The zero-time corrections were made by plotting $(A/H)^2$ against time and extrapolating $(A/H)^2$ to zero. We see that the data points for each experiment lie on a straight line, most of the lines passing through the origin.

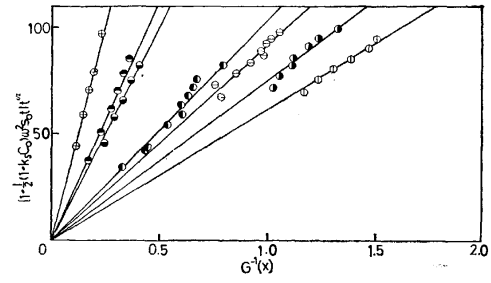

Fig. 3. Typical plots of $[1-(1/2)(1-k_sC_0)\omega^2S_0t]t^{1/2}$ against $G^{-1}(2r_a\omega^2k_sC_0S_0(H/A)t)$ for myosin-S. ⊕: $C_0=3.24$ mg/ml at 10490 rpm; ◒: 1.61 mg/ml at 21410 rpm; ◒: 0.98 mg/ml at 31820 rpm; ◐: 0.83 mg/ml; ⊖: 1.01 mg/ml; ◑: 1.25 mg/ml; ⦶: 1.95 mg/ml. The points not specified by the rotor speed were obtained at 43700 rpm.

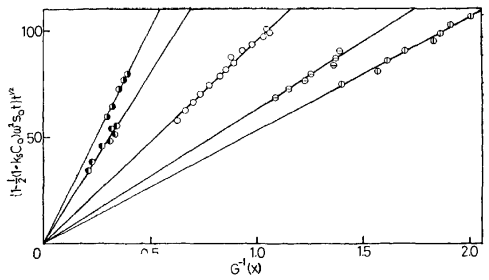

Fig. 4. Typical plots of $[1-(1/2)(1-k_sC_0)\omega^2S_0t]t^{1/2}$ against $G^{-1}(2r_a\omega^2k_sC_0S_0(H/A)t)$ for myosin-A. ◑: $C_0=2.01$ mg/ml at 21410 rpm; ◐: 0.76 mg/ml; ○: 1.13 mg/ml; ⊖: 1.85 mg/ml; ⦶: 2.46 mg/ml. The points not specified by the rotor speed were obtained at 43700 rpm.

Without zero-time corrections, however, the plots showed marked departure from the coordinate origin. According to the conditions used in deriving Eq. (4), the diffusion coefficient obtained from this equation may be taken as the one at $\bar{C}=C_0/2$.[2] The values of D for both myosins are plotted against C_0 in Fig. 5,

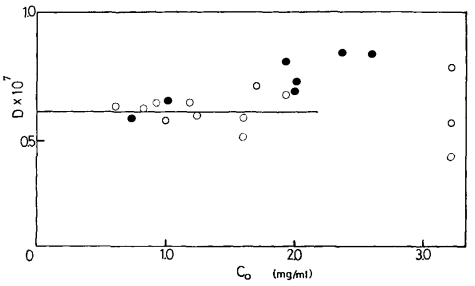

Fig. 5. Diffusion coefficients of myosins plotted against initial concentration, C_0. ○: myosin-S; ●: myosin-A.

which shows very small concentration dependence for either myosin, though the two sets of plotted points diverge considerably at higher concentrations. Considering the experimental error, the values for D at infinite dilution D_0 for both myosins may be taken as 0.64×10^{-7} cm²/sec. When this is reduced to 20 °C in water, we obtain 0.99×10^{-7} cm²/sec, which coincides with the values reported for myosin-A by other authors.[11-14] Substitution of the S_0 and D_0 values obtained into the Svedberg formula gives molecular weights of $5.2_7\times10^5$ for myosin-S and $5.1_0\times10^5$ for myosin-A. These values are slightly smaller than $5.8_7\times10^5$ for myosin-A reported by Harrington *et al.*[17] and $5.8_1\times10^5$ for myosin-S obtained from sedimantation equilibrium.[6] They are comparable with the values ranging between 5.0×10^5 and 5.5×10^5 obtained from sedimentation-diffusion measurements by others.[11-16]

Solubilization of TCNQ by Anionic Surfactants

Shinya MUTO, Yoshiaki AONO,* and Kenjiro MEGURO

Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received January 30, 1973)

In a previous paper,[1] we reported on the remarkable coloration due to a charge transfer interaction between 7,7,8,8-tetracyanoquinodimethane (TCNQ) and cationic surfactants when the former was solubilized into the latter. A similar phenomenon has been reported by Deguchi *et al.*[2] for the interaction between TCNQ and nonionic surfactants.

The present paper deals with the determination of the cmc of anionic surfactants by measuring the change in shape of the absorption spectrum of TCNQ due to its solubilization.

Experimental

Lithium dodecyl sulfate (LiDS), sodium dodecyl sulfate (SDS), potassium dodecyl sulfate (KDS) and triethanol ammonium dodecyl sulfate (TDS) were used as anionic surfactants. They were synthesized by the same method as described previously.[1] All products were extracted for about 200 hr with petroleum ether and recrystallized five times from water–isopropyl alcohol mixtures. No minima were observed in the diagram of surface tension against the concentration of anionic surfactants. 7,7,8,8-tetracyanoquinodimethane (TCNQ) was synthesized by the usual method[1] and recrystallized five times from acetonitrile. Sodium chloride of extra pure grade was subjected to ignition.

Water was purified by percolation of tap water through an ion-exchanger, followed by distillation from alkaline potassium permanganate in a pyrex still. The specific conductance of water was $(1\sim1.9)\times10^{-6}$ ohm^{-1} cm^{-1} at 25 °C.

Solubilization measurement: the procedure was essentially the same as that described previously.[1] TCNQ (3 mg) was added to anionic surfactant solutions (15 ml) in L-type tubes and shaken for about three days (72 hr) in a water thermostat at 40±0.1 °C. After shaking, excess TCNQ was filtered off through glass filters. The absorption spectra of the samples were measured in 10 mm cells with a spectrophotometer (Hitachi EPS-3T) at 40±0.1 °C. The measurement was carried out on the same day as filtration, usually within 3 hr of filtration because of slow fading of color of the TCNQ-surfactant micelle complex solution.

Surface tension: measured with a Wilhelmy-type surface tensiometer (Shimazu ST-1) at 40±0.1 °C, the value obtained with 10 min of dipping being defined as surface tension.

Conductance: specific conductance was measured with a conductometer (Toa Electronics Model CM-1DS) and conductivity cell (Toa Electronics Type CG-201PL) at 40± 0.1 °C.

Results and Discussion

Remarkable coloration took place when TCNQ was solubilized in anionic surfactant solutions above cmc. The coloration was observed one day after the start of shaking in a thermostat at 40±0.1 °C. It increased gradually and reached equilibrium after about 72 hr. At equilibrium the color of TCNQ solubilized in LiDS, SDS, KDS, and TDS solutions was blue-purple, being almost the same for them all when observed with the naked eye. The absorption spectra of TCNQ solubilized in SDS and TDS solutions are shown in Figs. 1 and 2, respectively. Almost the same absorption spectra were observed for the other two surfactants. TCNQ in the solubilized state has absorption maxima

Table 1. Critical micelle concentration of anionic surfactants by electroconductance, surface tension and solubilization of TCNQ at 40 °C

Surfactant	Electro-conductance (mmol/l)	Surface tension (mmol/l)	Solubilization of TCNQ (mmol/l)
LiDS	8.4	7.0	7.6
SDS	8.1	6.8	7.0
KDS	7.4	6.6	5.8
TDS	6.2	5.5	6.0
Salt solution of SDS (concentration of NaCl)			
10 mmol/l	5.5	4.4	4.6
20 mmol/l	3.6	3.0	3.3

at 400 and 550 mμ above cmc but below, no remarkable absorption was observed except for some slight absorption bands at 400 and 620 mμ. Their intensities were very weak and broad. The intensities of the bands at 400 and 550 mμ increased rapidly above cmc with concentration of the surfactant.

Figure 3 shows the plot of the optical density at 400 and 550 mμ against the logarithm of surfactant concentration, in which the inflection point coincides with the cmc value. The cmc values of anionic surfactants obtained by this method are summarized in Table 1. They agree with those obtained by surface tension and electroconductance methods.

The effect of addition of sodium chloride on the spectrum of TCNQ solubilized into aqueous solution of SDS is shown in Fig. 4. The shape of the absorption spectrum is almost the same as that shown in Fig. 1. However, it was found that the addition of salt increased the intensity of the band of solubilized TCNQ and decreased the cmc of SDS. The cmc values measured in the presence of salt are given in Table 1. Increase in the intensity of the band of solubilized TCNQ by addition of salt is of particular interest (Fig. 4).

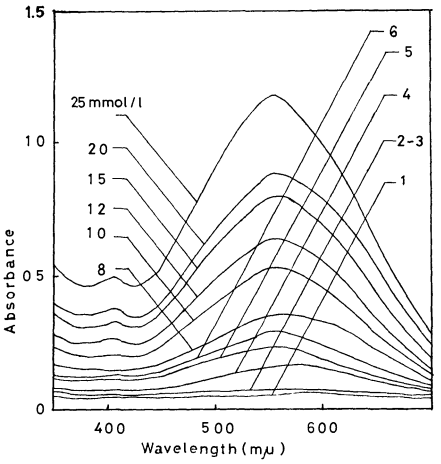

Fig. 4. The effect of addition of sodium chloride on the absorbance of spectrum of TCNQ solubilized into aqueous solution of SDS. Concentration of sodium chloride: 20 mmol/l. Figures show concentration of SDS solutions.

The Chlorine Nuclear Quadrupole Resonance of Several Oxygen-chlorine Bonds

Tsutomu OKUDA, Yoshihiro FURUKAWA, Koji YAMADA, and Hisao NEGITA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received February 8, 1973)

It seemed that it would be of interest to investigate the chlorine electronic structure in the O–Cl bond by means of the nuclear quadrupole resonance (NQR), since the oxygen atom is more electronegative than the chlorine atom and since various coordination states of the chlorine atom appear in the compounds with O–Cl bonds. Although many reports have been published on NQR studies of the chlorates in which the chlorine atom is bound by three oxygen atoms, there have been few reports on the other compounds with O–Cl bonds. Therefore, we have observed the ^{35}Cl NQR frequencies of the O–Cl bonds in the following compounds: *t*-butyl hypochlorite, *t*-amyl hypochlorite, sodium chlorite and its trihydrate, and silver chlorite. In these compounds, the two organic hypochlorites contain a chlorine atom bound by only one oxygen atom, whereas the chlorine atom in the chlorite is bound by two oxygen atoms. Furthermore, we have measured the NQR Zeeman effect using the single crystal of $NaClO_2 \cdot 3H_2O$.

Experimental

The sodium chlorite trihydrate was obtained by recrystallization from an aqueous solution of commercial $NaClO_2$. The single crystal was grown from its saturated aqueous solution at about 35 °C. The anhydrate salts were obtained by drying $NaClO_2 \cdot 3H_2O$ over KOH in a desiccator *in vacuo*. The silver chlorite was prepared by the reaction of $NaClO_2$ with $AgNO_3$. The alkyl hypochlorites were prepared by bubbling chlorine gas through an aqueous solution of the relevant alcohol and sodium hydroxide.

The NQR spectrometer was a self-quenching, superregenerative oscillator with frequency modulation; the ab-

$NaClO_2 \cdot 3H_3O$	53.502	51.121

a) Experimental error is within ±0.01 MHz.

sorption lines were displayed on an oscilloscope. A Zeeman magnetic field was applied by means of a Helmholtz coil.

Results and Discussion

Table 1 shows the resonance frequencies at the temperature of liquid nitrogen and at room temperature. It is noteworthy that all the resonance frequencies in Table 1 are quite high compared with those of the usual chlorine compounds.

If the asymmetry parameter of the field gradient at the chlorine atom in R–OCl is assumed to be negligible, referred to $\eta=0.04$ for gaseous CH_3OCl,[1] the quadrupole coupling constant of 110.22 MHz (average) is obtained for *t*-BuOCl, and that of 110.98 MHz, for *t*-AmOCl, at 77 K. These values are slightly higher than that of atomic chlorine. This is an expected tendency, taking into account the electronegativity difference between oxygen and chlorine. Assuming the s character of the O–Cl bond to be 0.12, as in the case of the N–Cl bond,[2] and no $d\pi$-$p\pi$ bonding, the partial charge on the chlorine atom is $+0.16\,e$. This is in accordance with the fact that R–OCl is used as a chlorinating reagent in organic syntheses.

The resonance frequencies of $NaClO_2$ and $AgClO_2$ have been reported by Ragle;[3] they are in good agreement with our results, listed in Table 1. We have newly observed the resonance frequencies of $NaClO_2 \cdot 3H_2O$ and measured the Zeeman effect on its single crystal. Only one zero-splitting pattern was observed, as is shown in Fig. 1. This is consistent with the triclinic lattice of this compound. The asymmetry parameter of the field gradient was derived from the

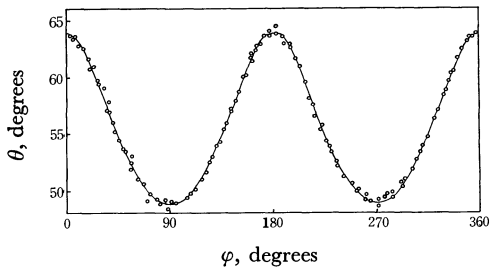

Fig. 1. Zeeman zero-splitting pattern of the chlorine atom in $NaClO_2 \cdot 3H_2O$ at room temperature.
$\sin^2\theta=2/(3-\eta\cos 2\varphi)$, $\eta=0.52$

2) R. M. Hart and M. A. Whitehead, *Trans. Faraday Soc.*, **67**, 1569 (1971).

3) J. L. Ragle, *J. Chem. Phys.*, **32**, 403 (1960).

usual equation, using the least-squares method, as 0.52 ± 0.02. From this value, the quadrupole coupling constant was calculated to be 94.348 MHz.

The bonding orbitals of the chlorine atom in the ClO_2^- ion may be presented as follows:[4]

$$\psi_1 = p_x,$$
$$\psi_2 = (\cot\theta)s - (1-\cot^2\theta)^{1/2}p_y,$$
$$\psi_3 = \sqrt{\frac{1}{2}}(1-\cot^2\theta)^{1/2}s + \sqrt{\frac{1}{2}}(\cot\theta)p_y + \sqrt{\frac{1}{2}}p_z,$$
$$\psi_4 = \sqrt{\frac{1}{2}}(1-\cot^2\theta)^{1/2}s + \sqrt{\frac{1}{2}}(\cot\theta)p_y - \sqrt{\frac{1}{2}}p_z, \quad (1)$$

where 2θ represents the $\angle$O–Cl–O bond angle. The x axis lies perpendicularly to the plane of the ClO_2^- ion and the y axis is directed along the twofold axis of the ion. We will express the electron population of the two bonding orbitals, ψ_3 and ψ_4, of the chlorine atom by A, and those of the orbitals occupied by the lone pair, ψ_1 and ψ_2, by B and 2 respectively. Using the Townes-Dailey theory, the electric-field gradients at the chlorine atom can be expressed as functions of θ, A, and B:

$$q_x/q_0(1+\varepsilon)^n = (1-\cot^2\theta)(A-2)/2 + B - A,$$
$$q_y/q_0(1+\varepsilon)^n = (1-\cot^2\theta)(2-A) + (A-B)/2,$$
$$q_z/q_0(1+\varepsilon)^n = (1-\cot^2\theta)(A-2)/2 + (A-B)/2, \quad (2)$$

where ε is 0.15 for the chlorine atom and where eq_0 is the field gradient of atomic chlorine. The symbol, n, represents the charge on the chlorine atom. The observed quadrupole coupling constant and asymmetry parameter are $|e^2Qq_i/h|$ and $(eq_k-eq_j)/eq_i$ when $|q_i|>|q_j|>|q_k|$.

The value of 2θ is in the range between 90° and 180°. If $B=2$, it can readily be found that q_x has the maximum absolute value of the field gradient when 2θ is between 90° and 109°28′. This is the case with the halogen bridge in the dimer molecule of the Group IIIb element or in the layer lattice as ScI_3, if the oxygen atom is replaced by the metal atom.[5] When 2θ is over 109°28′ and when $B=2$, the maximum field gradient becomes q_z.

The crystal structures of NH_4ClO_2 and $AgClO_2$ have been confirmed by means of X-ray diffraction.[6] The 2θ angles are found to be $110.5°\pm1.4°$ for NH_4ClO_2 and $111°\pm3°$ for $AgClO_2$. These angles are both larger than 109°28′. Also, the maximum field gradient at the chlorine atom in ClO_2 has been shown to be oriented along the axis of q_z.[7] Therefore, it seems reasonable to analyze the present data, by assuming that q_z is the maximum component of the field gradient.

As it is impossible to determine the three variables from the observed NQR parameters, we first assume the bond angle in this compound to be 111°. Substituting this value into Eq. (2), the following values

4) E. A. C. Lucken, "Nuclear Quadrupole Coupling Constants," Academic Press Inc., New York (1969).

5) See Ref. 4; P. A. Edwards and R. G. Barnes, *J. Chem. Phys.* **55**, 4664 (1971).

6) R. B. Gillespie, R. A. Sparks, and K. N. Trueblood, *Acta Crystallogr.*, **12**, 867 (1959); J. Cooper and R. E. Marsh, *ibid.*, **14**, 202 (1961).

7) R. F. Curl, *J. Chem. Phys.*, **37**, 779 (1962).

are obtained: $A=0.90$ and $B=1.73$. The decrease in B from 2 may be attributed to the presence of the $d\pi$-$p\pi$ bonding in the O–Cl bond. The value of A, 0.90, indicates that the charge of $0.60\,e$ is transferred to the oxygen atom from the chlorine atom in the σ bond of the O–Cl. The total charge on the chlorine atom is found to be $+1.47\,e$.

Taking 2θ to be larger than 111°, A becomes larger, whereas B becomes smaller. When $2\theta=123°$, $A=1.10$ and $B=2$, so the total charge on the chlorine atom is $+0.80\,e$. Actually, it may take an intermediate value between $+1.47\,e$ and $+0.80\,e$.

The temperature dependences were measured between 77 K and room temperature for $AgClO_2$, $NaClO_2$, and $NaClO_2\cdot 3H_2O$. All the frequency *vs.* temperature curves decrease steadily as the temperature is raised.

The ESR Spectra of Alkyl Radicals Formed in UV-irradiated Trialkyl Phosphate Glasses

Mitsuo SATO, Takashi KATSU, Yuzaburo FUJITA, and Takao KWAN
Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received February 16, 1973)

We have recently reported the results of ESR studies of the intermediate radicals formed in UV-irradiated glasses of alkylalcohols,[1] alkanethiols,[2] and alkyl dithiophosphates.[3] As part of our continuing study of the photochemical production of intermediate radicals, we have now made a similar investigation into a series of tri-*n*-alkyl phosphates. As a result, we have found that alkyl radicals are formed rather selectively during the UV-irradiation of trialkyl phosphates at 77 K. In the present note we wish to communicate briefly the results of this investigation, since the photo-production of alkyl radicals from trialkyl phosphates has not yet been reported.

Experimental

The trialkyl phosphates employed in this work were $(CH_3O)_3PO$, $(C_2H_5O)_3PO$, $(n\text{-}C_3H_7O)_3PO$, and $(n\text{-}C_4H_9O)_3PO$. They were all commercial reagents supplied by the Tokyo Kasei Kogyo Co., and all were used without further purification. Each of the trialkyl phosphates showed a weak absorption spectrum in the region of 220—280 nm,[4] with a steep absorption edge below 220 nm. Thus, the UV light of the 253.7 nm wavelength from a low-pressure mercury lamp (Ushio Electric Co., Ltd., UL-200W) housed with a Vycor glass filter was thought to be effective. The UV-irradiation and ESR measurements were carried out at 77 K. Each sample gave a cracked-free glass upon cooling, and a few minutes' irradiation gave rise to an intense signal with a good S/N ratio. The other experimental details were similar to those of the previous report.[3]

Results and Discussion

ESR Spectra of Intermediate Radicals. Typical ESR spectra of photoproduced radicals are shown in Figs. 1 and 2.

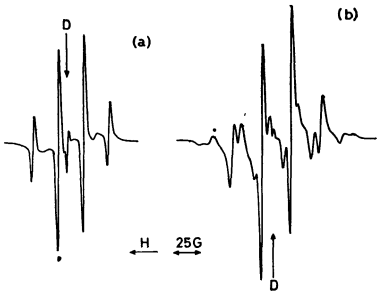

Fig. 1. ESR spectra of UV-irradiated trialkyl phosphates at 77 K.
(a) $(CH_3O)_3PO$, irradiation time 1.0 min;
(b) $(C_2H_5O)_3PO$, irradiation time 3.0 min;
D, defect signal (g=2.000) resulted from the quartz Dewar vessel.

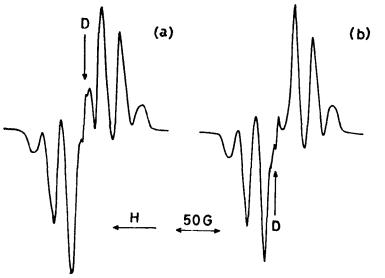

Fig. 2. ESR spectra of UV-irradiated trialkyl phosphates at 77 K.
(a) $(n\text{-}C_3H_7O)_3PO$, irradiation time 3.0 min;
(b) $(n\text{-}C_4H_9O)_3PO$, irradiation time 3.0 min.

The spectra obtained from trimethyl and triethyl phosphates were well-resolved and were assigned to methyl and ethyl radicals respectively (Fig. 1). The following hf coupling constants were in close agreement with those previously reported:[5]

1) K. Hatano, M. Yanagita, Y. Fujita, and T. Kwan, *Kogyo Kagaku Zasshi*, **72**, 123 (1969).

4) This band can tentatively be assigned to a (n–π^*) transition after M. Halman and I. Platzner (*J. Chem. Soc.*, **1965**, 1440).
5) R. W. Fessenden and R. H. Schuler, *J. Chem. Phys.*, **39**, 2147 (1963).

$\dot{C}H_3$ A^H = 23.0 Gauss

$CH_3\dot{C}H_2$ A_α^H = 21.9 Gauss, A_β^H = 27.0 Gauss

It follows from Fig. 1, however, that ethyl radicals give hf lines with an unequal linewidth; moreover, the intensity distribution differs from the theoretical one, while the quartet hf lines of methyl radicals are equal in linewidth and their relative intensities are very close to the theoretical ratio of 1 : 3 : 3 : 1. Such an unequal linewidth as observed in the spectrum of the ethyl radical has already been interpreted by Cochran *et al.*[6] as arising from the effect of the anisotropic hf interaction with the α-protons. It seems, therefore, probable that the motional character of the ethyl radical differs from that of the methyl radical; such a supposition is in accordance with the decay behavior of these radicals, as will be described below.

The spectra obtained from UV-irradiated tri-*n*-propyl phosphate and tri-*n*-butyl phosphate are shown in Fig. 2. The two spectra are very similar in appearance and both consist of six broad hf lines resolved only poorly, with a splitting of 22—23 Gauss. By analogy with the spectra of radicals with the general formula of $RCH_2\dot{C}H_2$, as interpreted by Ayscough and Thomson,[7] the two spectra can be assigned to $CH_3CH_2\dot{C}H_2$ and $CH_3CH_2CH_2\dot{C}H_2$ respectively. The six hf lines may be explained on the assumption that the hf coupling constant for one of the β-protons is almost twice as great as that of the other β-proton and that of the α-protons (A_α^H=22 Gauss, $A_\beta^{H_1}$=22 Gauss, $A_\beta^{H_2}$=44 Gauss). The unequivalence of the β-protons in contrast to the ethyl radical indicates that these radicals are rather strongly constrained in the matrices, without any averaging movements of the CH_2 group. Such an interpretation is consistent with that reported by Shimada *et al.*,[8] who studied the ESR of radicals of the $CH_3\dot{C}HCH_2$-~~~ trapped in γ-irradiated polyethylene.

In general, the signal intensities of alkyl radicals were found to increase almost linearly with an increase in the irradiation time. No signal other than alkyl radicals was detected within 15 min irradiation of triethyl phosphate, tri-*n*-propyl phosphate and tri-*n*-butyl phosphate or within 2 min irradiation of trimethyl phosphate.[9] It appears from these results that alkyl radicals are formed primarily.

Since the trialkyl phosphates employed in the present work showed UV-absorption bands in the region of 220—280 nm assignable to a (n-π^*) transition, it is tempting to suppose that the electronic excitation of trialkyl phosphate molecules is associated with the rupture of the C–O bond rather than that of the C–H or P–O bond. It should be noted here that such an effect of UV-irradiation has a close resemblance, as far as the ESR information is concerned, to that of the γ-irradiation recently reported by several workers.[10,11]

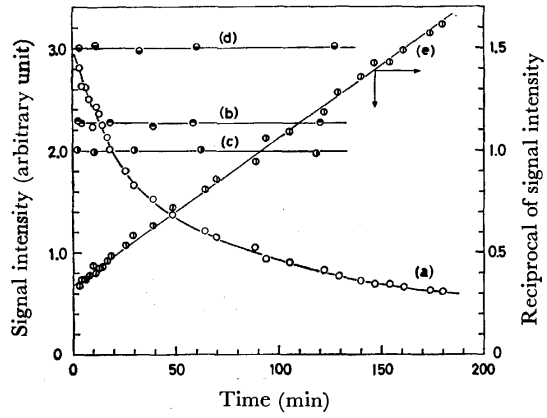

Fig. 3. Decay curves of alkyl radicals UV-produced and trapped in trialkyl phosphates at 77 K.
Signal intensity *vs.* time after UV-irradiation, (a) $\dot{C}H_3$, (b) $CH_3\dot{C}H_2$, (c) $CH_3CH_2\dot{C}H_2$, (d) $CH_3CH_2CH_2\dot{C}H_2$; Reciprocal of signal intensity *vs.* time after UV-irradiation, (e) $\dot{C}H_3$.

Stability of Alkyl Radicals. The signal intensities of the alkyl radicals trapped in the matrices were examined as a function of the time after the termination of the UV-irradiation. The results are shown in Fig. 3. It was found that ethyl, *n*-propyl, and *n*-butyl radicals did not decay at all within the period of observation, indicating that these radicals are stable in the matrices.

On the other hand, methyl radicals were found to decay, as is shown in Fig. 3, according to this equation: $-d[\dot{C}H_3]/dt = k[\dot{C}H_3]^2$. The second-order kinetics may imply that the radical recombination (1) takes place rather than the hydrogen-atom abstraction in the matrix (2).

$$\dot{C}H_3 + \dot{C}H_3 = C_2H_6 \quad (1)$$

$$\dot{C}H_3 + (CH_3O)_2P(=O)OCH_3 = CH_4 + (CH_3O)_2P(=O)O\dot{C}H_2 \quad (2)$$

However, the minor decay process due to the hydrogen-atom abstraction was proved by the appearance of a three-line spectrum (average splitting, 20 Gauss) ascribable to $(CH_3O)_2PO(O\dot{C}H_2)$ only after a considerable decay of the methyl radicals.

Reactions of ^{82}Br Activated by Isomeric Transition in CH_4: A Re-Evaluation*

Richard W. HELTON, David W. OATES, and Edward P. RACK
University of Nebraska, Lincoln, Nebraska 68508 U.S.A.

(Received September 18, 1972)

In the first experiments utilizing rare-gas moderators in reactions of ^{82}Br activated by isomeric transition, Nicholas and Rack[1] found that in the $^{82}Br+CH_4$ system, the total organic product yield, extrapolated to zero mole fraction moderator, was $7.4\pm0.5\%$. The organic yield data appeared to extrapolate to $3.7\pm0.5\%$ at zero mole fraction CH_4 for the various rare-gas moderators, suggesting that 7.4% minus 3.7% was formed by excess kinetic energy processes and that 3.7% of the organic ^{82}Br was formed by thermal (kinetic energy independent) processes.

Tachikawa[2,3] studied the effect of argon moderator on the individual product yields of (I.T.)-activated ^{82}Br in CH_4. The extrapolation to zero mole fraction argon ($6.1\pm0.7\%$) agreed well with that of Nicholas and Rack, considering the larger amount of Br_2 scavenger used by Tachikawa (0.11 mol fraction Br_2), compared to a constant 15 Torr Br_2 at 700 Torr total pressure used by Nicholas and Rack. However, Tachikawa found that extrapolation to zero mole fraction CH_4 gave a total organic yield of $1.6\pm0.4\%$. Since this difference is much too large for experimental error, and the value at this extrapolation is necessary for determining the relative importances of kinetic energy dependent and thermal reactions, it was decided that a re-evaluation of the system was in order, to determine the nature of this discrepancy.

A description of our sample making techniques, irradiation procedures, and extraction techniques can be found elsewhere.[4-7] At least six samples were made for each condition, each containing 5 Torr of Br_2, and varying amounts of CH_4 and argon, for a total system pressure of 700 Torr. Neutron irradiations were for 30 sec in the Omaha, Nebraska, V. A. Hospital reactor, employing the "in-reactor technique" described by Nicholas and Rack.[1] All relative product distributions were determined by radiogas chromatography[8] employing a modified flow-through proportional counter of the type described by Wolf *et al.*[9] Only two organic products were observed in each case, $CH_3{}^{82}Br$ and $CH_2Br^{82}Br$.

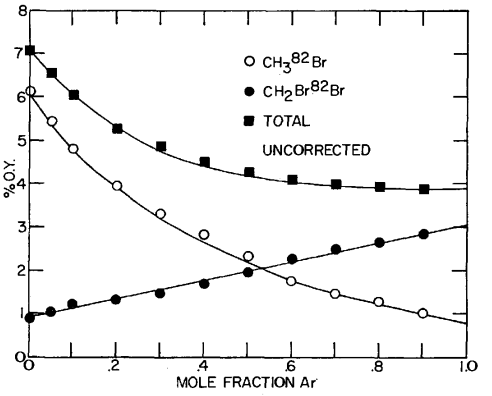

Fig. 1. Effect of Ar moderator on the product distribution in the reaction of (I.T.)-activated ^{82}Br with CH_4.

Depicted in Fig. 1 are the total organic product and individual organic product yields as a function of mole fraction argon. It can be seen that the extrapolations to zero mole fraction argon are in good agreement with both Nicholas and Rack, and Tachikawa. The $CH_3{}^{82}Br$ curve, also, strongly resembles that of Tachikawa. However, the $CH_2Br^{82}Br$ product increases linearly with increasing mole fraction argon, so that the total organic product yield resembles that of Nicholas and Rack, extrapolating to $3.8\pm0.4\%$ at zero mole fraction CH_4.

This linear dependence of organic yield upon concentration of moderator has been previously reported[10] and determined to be due to rare-gas sensitized radiation damage.

Figure 2 represents the total and individual organic product yields as a function of argon concentration, corrected for radiation damage.[10] Mixtures of CH_4

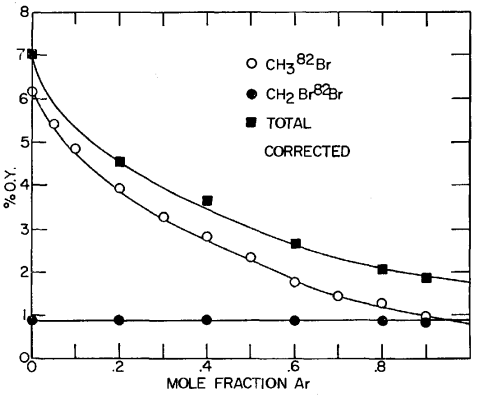

Fig. 2. Effect of Ar moderator on the reaction of (I.T.)-activated ^{82}Br with CH_4, corrected for radiation damage.

and argon containing 5 Torr of Br_2 and 0.1 Torr of ^{131}I labeled molecular I_2 were irradiated for 30 sec in the nuclear reactor. The percent of ^{131}I as total organic product yield was plotted as a function of argon concentration. Gas chromatographic analysis of the ^{131}I-labeled organic products was also performed. No $CH_3{}^{131}I$ product was detected at the various argon concentrations. Extrapolation of the corrected individual product yields to zero mole fraction CH_4 gives $0.9\pm0.2\%$ and $0.8\pm0.2\%$ for $CH_2Br^{82}Br$ and $CH_3{}^{82}Br$, respectively. This compares very well with the data of Tachikawa for the Br_2–CH_4–Ar system ($CH_2Br^{82}Br$, $1.1\pm0.2\%$ and $CH_3{}^{82}Br$, $0.5\pm0.2\%$), and, also, with other moderator studies.[11]

An important observation from inspection of Figs. 1 and 2 is that the only ^{82}Br labeled product affected by the argon-sensitized radiation damage is $CH_2Br^{82}Br$, which is formed exclusively by thermal (non-kinetic energy activated) ion-molecule reactions. No radiation damage is associated with the $CH_3{}^{82}Br$ product.

The apparent reason that this laboratory observes moderator-sensitized radiation damage while Tachikawa does not, is that we irradiated the premixed sample, containing all system components, and Tachikawa mixes the components after making the Br_2 radioactive.[3,11]

Nuclear Quadrupole Resonance of Nitrogen-14 in the Naphthalene-Tetracyanoethylene Complex

Shinzaburo ONDA, Ryuichi IKEDA, Daiyu NAKAMURA, and Masaji KUBO

Department of Chemistry, Nagoya University, Chikusa, Nagoya 464

(Received May 14, 1973)

Tetracyanoethylene (TCNE) is known to be a strong electron acceptor capable of forming various stable molecular complexes,[1] of which naphthalene-TCNE is an example. The present investigation has been undertaken on the nuclear quadrupole resonance of ^{14}N in the complex in order to compare the spectra with those of TCNE previously reported[2] and to discuss the nature of intermolecular interaction between naphthalene and TCNE.

The 1:1 molecular complex of naphthalene and TCNE was prepared by a method described by Merrifield and Phillips.[3] Red-brown needle crystals deposited on mixing equimolar warm concentrated solutions of the components in ethyl acetate followed by cooling. Although the crystals gradually turned wine red on cooling to liquid nitrogen temperature, the appearance of the crystals showed no changes indicative of the first-order phase transition taking place in the temperature range investigated. The nuclear quadrupole resonance of ^{14}N was observed by means of a modified Pound-Watkins type spectrometer already described.[4] Frequency modulation was used for the determination of resonance frequencies, while Zeeman modulation was employed for the assignment of resonance signals to ν^{I} and ν^{II}. Resonance frequencies were measured by use of a Model VP-43A frequency counter from Matsushita Communication Industry Co., Ltd.

Since ^{14}N has a nuclear spin equal to unity, one can usually observe two resonance frequencies, $\nu^{I}=eQq\cdot(3+\eta)/4$ and $\nu^{II}=eQq(3-\eta)/4$, for resonant nuclei having a nonvanishing asymmetry parameter, η. Naphthalene-TCNE yielded two sets of ν^{I} and ν^{II} frequencies at liquid nitrogen temperature ($\nu^{I}=3278.2\pm0.1$ and 3246.2 ± 0.1 kHz and $\nu^{II}=3145.2\pm0.3$ and 3082.3 ± 0.1 kHz). The appearance of the two sets indicates that there are two kinds of crystallographically non-equivalent nitrogen atoms in crystals. Williams and Wallwork[5] have carried out X-ray analysis of this complex, and found that it forms monoclinic crystals belonging to the space group C2/m with two units of the complex in a unit cell. Naphthalene and TCNE molecules are stacked alternately in infinite columns aligned parallel to the c axis. Centrosymmetric TCNE molecules are located at inversion centers, and C=C bonds are directed along twofold axes. Therefore, all cyano groups are equivalent in a crystal in contradiction to the results of the present study. However, the X-ray analysis carried out at room temperature showed that the thermal vibration of a naphthalene molecule about an axis perpendicular to the molecular plane is abnormally large and that the geometry of naphthalene molecules could hardly be determined exactly. Therefore, the disagreement may be attributable to a slight change in crystal structure possibly taking place between room and liquid nitrogen temperatures. Although sharp and fairly intense signals were observed at liquid nitrogen temperature

except for a very weak line of the second lowest frequency, no resonance could be detected at dry ice and room temperatures. This suggests that an order-disorder phase transition involving naphthalene molecules takes place between dry ice and liquid nitrogen temperatures.

Because two ν^{I} frequencies as well as two ν^{II} frequencies observed for naphthalene-TCNE are close to each other, one-to-one correspondence is infeasible between ν^{I} and ν^{II}. Therefore, averages were taken for the calculation of the quadurpole coupling constant and the asymmetry parameter. The results are shown in Table 1 along with those of some related compounds.

Table 1. Quadrupole coupling constants, eQq, and asymmetry parameters, η, of ^{14}N in naphthalene-TCNE and related compounds at liquid nitrogen temperature

Compound	eQq (kHz)	η (%)	Reference
Naphthalene-TCNE	4251	7.0	
TCNE	4221[a)]	4.4	2)
Acrylonitrile	3800	4.77	6)
Methacrylonitrile	3831	4.46	6)

a) eQq=4331 kHz in Table 1 of Reference 2 should read 4221 kHz.

As has been reported in a previous paper,[7] the quadrupole coupling constant and the asymmetry parameter of nitrogen in a cyano group having unequal π-electron populations, $1+i_{\pi\perp}$ and $1+i_{\pi//}$, can be expressed by

$$eQq = \left| s+i_{\sigma}-si_{\sigma}-\frac{1}{2}(i_{\pi\perp}+i_{\pi\parallel}) \right| \frac{eQq_{p}}{1+i\varepsilon} \quad (1)$$

$$\eta eQq = \frac{3}{2}\left| i_{\pi\perp}-i_{\pi\parallel} \right| \frac{eQq_{p}}{1+i\varepsilon} \quad (2)$$

Here it is assumed that the sp-hybridized σ-bond orbital and the lone pair orbital of nitrogen accommodate $1+i_{\sigma}$ and 2 electrons, respectively. The symbols, s, eQq_{p}, i, and ε denote the extent of s-character of the σ-orbital, the absolute value of the quadrupole coupling constant of an electron in a 2p-orbital of ^{14}N, the total ionicity of nitrogen, and the screening constant introduced by Townes and Schawlow,[8] respectively.

According to Eq. (2), relatively small asymmetry parameters observed for naphthalene-TCNE and TCNE indicate that the difference, $i_{\pi\perp}-i_{\pi//}$, in π-electron population is fairly small. This means that the π-electron systems of cyano groups in a TCNE molecule are not conjugated with the ethylenic double bond to a great extent. The same conclusion can be derived for acrylonitrile and methacrylonitrile. The quadrupole coupling constants of the complex and TCNE are considerably higher than those of acrylonitrile and its derivatives. This is rather difficult to interpret quantitatively because the theoretical equations involve several unknown parameters. However, Eq. (1) clearly shows that the quadrupole coupling constant decreases with increasing polarization of π-electrons in a cyano group. Accordingly, it is concluded that the π-bonds of cyano groups are less polarized in TCNE molecules than in acrylonitrile and its derivatives.

Since naphthalene-TCNE is a charge transfer complex, electron transfer is expected to take place from naphthalene to TCNE. In view of the stacking structure of the complex, such a transfer would result in an increase in the electronic population of π-orbitals directed at right angles to the molecular plane of TCNE. This leads to an increase in the asymmetry parameter and a decrease in the quadrupole coupling constant of nitrogen atoms in a TCNE molecule. In fact the observed asymmetry parameter of the complex is larger than that of TCNE. However, the difference between the observed asymmetry parameters of the two compounds is so small that it can be explained in terms of the effect of crystal field as well. Furthermore, the quadrupole coupling constant of the complex is slightly larger than that of TCNE in contradiction to the expectation. These facts suggest that the extent of charge transfer is fairly small and that the electronic state of nitrogen atoms in TCNE molecules remains essentially unaffected on forming a charge transfer complex with naphthalene.

Quite recently, Murgich and Pissanetzky[9] studied the nuclear quadrupole resonance of ^{14}N in potassium tetracyanoquinodimethanide, and found a small quadrupole coupling constant, 3.4 MHz (average), and a large asymmetry parameter, 52% (average). These results support the adequacy of the foregoing theoretical prediction.

Phase Transition in Organic Semiconductor. Entropy Change Due to Conduction Carriers

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 16, 1973)

There are a few organic semiconductors that are known to undergo phase transitions. The phase transitions of such materials are particularly interesting, because the anomalies in their electrical conductivities are associated with the phase transitions.[1-4] In a previous paper,[3] we studied the entropy for the system of conduction carriers (*i.e.*, electrons and holes) in an intrinsic semiconductor. By the use of a statistical theory, we examined to what extent this kind of entropy contributes to the total entropy change of the phase transition as determined from the heat-capacity measurements.

According to this theory, for an intrinsic semiconductor with very narrow band width, the magnitude of the entropy for the system of conduction carriers at temperature, T, is expressed by

$$S(\text{carrier}) = -4R\{f \ln f + (1-f) \ln (1-f)\}, \quad (1)$$

where $f \approx 1/\{\exp(E_g/2kT)+1\}$; E_g is the energy gap between the conduction band and the valence band. Consider the case when a first-order phase transition takes place in the intrinsic semiconductor at the T_c temperature in the solid state. The energy gaps for the low- and high-temperature phases are assumed to be E_g and E_g', respectively. At the transition temperature, the Fermi-Dirac distribution function, f, and the entropy due to the conduction carriers, S(carrier), in the low-temperature phase can be derived from the T_c and E_g values, while those in the high-temperature phase, f' and S'(carrier), from the T_c and E_g' values. Therefore, for the system of the conduction carriers, the entropy change, ΔS(carrier), associated with the phase transition is estimated to be

$$\Delta S(\text{carrier}) = S'(\text{carrier}) - S(\text{carrier}). \quad (2)$$

Let us consider two possible cases of the phase transitions. The first is of the phase transitions for intrinsic semiconductors where the E_g value in the low-temperature phase exceeds the E_g' value in the high-temperature phase. In this case, since the magnitude of S'(carrier) is larger than that of S(carrier) at $T=T_c$, a certain kind of order→disorder process with respect to the conduction carriers is involved in the phase transition, and the ΔS(carrier) value is positive in going from the low-temperature phase to the high-temperature phase. Therefore, if the phase transition of the semiconductor is endothermic, the ΔS(carrier) term plays a positive or additive contribution to the total entropy change of the phase transition, ΔS(total), as determined from heat-capacity measurements. The first-order phase transition of the semiconductive anion radical salt of $[(C_6H_5)_3PCH_3]^+ (TCNQ)_2^-$, where TCNQ is 7,7,8,8-tetracyanoquinodimethane, at $T_c=315.7$ K corresponds to one of these examples. According to the heat-capacity measurements by Kosaki *et al.*,[5] the enthalpy and the total entropy creation associated with this phase transition were experimentally determined to be 485.18 cal/mol and 1.7206 cal/K·mol, respectively. We have observed, at 315.7 K, a discontinuity in the temperature dependence of the electrical conductivity and a slight crystal volume decrease in the high-temperature phase.[1,4,6] By means of the temperature dependence of the conductivity, the E_g and E_g' values were experimentally determined to be 0.82 ± 0.04 eV and 0.60 ± 0.04 eV, respectively.[1,4] The crystal volume decrease perhaps gives rise to the fact that E_g exceeds E_g'. By the use of Eqs. (1) and (2), we have $\Delta S(\text{carrier})=1.5\times10^{-3}$ cal/K·mol for this phase transition. Therefore, we can evidently see that this positive ΔS(carrier) value contributes to the whole entropy creation of $\Delta S(\text{total})=1.7206$ cal/K·mol by 8.7×10^{-2}%.

The second case is of the phase transitions for intrinsic semiconductor where the E_g value is less than the E_g' value. This kind of phenomenon will be usually observed when a crystal volume increase is caused by the phase transition in the high-temperature phase. At this time, in going from the low-temperature phase to the high-temperature phase, a certain kind of disorder→order change with respect to the conduction carriers takes place at the phase transition, because the magnitude of S(carrier) is definitely larger than that of S'(carrier) at $T=T_c$. Therefore, for the endothermic phase transition of the semiconductor, although its over-all entropy is increased, the entropy for the system of the conduction carriers is decreased, and the ΔS(carrier) term plays a negative contribution to the total entropy change, ΔS(total), of the phase transition. We have to indicate the importance of this phenomenon. For example, the phase transition of crystalline hexamethylbenzene at $T_c=384.1$ K corresponds to this case. For this phase transtioin, the enthalpy change was experimentally determined to be 4.2×10^2 cal/mol, and the total entropy creation is estimated to be 1.1 cal/K·mol.[7,8] On the other hand, Kurematsu

et al. measured the electrical conductivity and the crystal volume of this compound and found, at the transition temperature, an anomaly in the temperature dependence of the conductivity and an abrupt crystal volume increase in the high-temperature phase.[2] They assumed that the hexamethylbenzene crystal belonged to an intrinsic semiconductor, and determined experimentally the energy gaps in the low- and high-temperature phases, E_g and E_g', to be 2.5 and 4.5 eV, respectively. For this compound, the crystal volume increase perhaps gives rise to the fact that E_g is less than E_g'. By putting the E_g, E_g', and T_c values into Eqs. (1) and (2), we have $\Delta S(\text{carrier}) = -1.18 \times 10^{-14}$ cal/K·mol. Therefore, this negative ΔS(carrier) value, although its magnitude is very small, is found to make a negative contribution to the total entropy creation for this phase transition.

For such organic semiconductors as a hexamethylbenzene crystal, where the energy gap is considerably larger than kT, the magnitude of the entropy for the system of the conduction carriers is negligibly small, because the distributions of the electrons in the conduction band and of the holes in the valence band are quite limited at the temperature T. However, for semiconductors in which the energy gap is comparable to kT, the carrier population and, thus, the magnitude of the entropy due to the conduction carriers are very much increased. Consider the case when these semiconductors undergo first-order endothermic phase transitions. If the E_g value in the low-temperature phase is less than the E_g' value in the high-temperature phase, an appreciable amount of negative ΔS(carrier) value due to disorder→order process of the conduction carriers should make a significant negative contribution to the mechanism of the phase transitions. An attempt is currently under way to find such materials.

Carbon-13 NMR Spectra of 1-Arylpropynes and 1-Arylpropenes. Transmission of the Electronic Effects of Substituents through Carbon-Carbon Triple and Double Bonds

Kunisuke IZAWA, Tadashi OKUYAMA, and Takayuki FUENO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received June 16, 1973)

It has been customary to use the Hammett $\rho\sigma$ relationship for the analysis of substituent effects on the side-chain reactions of benzene. The magnitude of reaction constant ρ usually diminishes with the increasing number of bonds intervening between the substituent and the reaction site.[1] This attenuation of the ρ value allows us to evaluate the efficiency of the intervening group in transmitting the electronic effect of substituents. A similar treatment is applicable to the ground-state properties; various spectral data have been analyzed on this basis.[2]

In the present work, we have investigated the effects of ring substituents on the ^{13}C chemical shifts of 1-phenylpropyne (**1**) and 1-phenylpropene (**2**) in order to compare the efficiencies of the C=C and C≡C bonds in transmitting the substituent effects. The C≡C bond has been found to be a less efficient transmitter.

Results

The ^{13}C NMR spectra of 1-phenylpropyne (**1**), *cis*- and *trans*-1-phenylpropenes (**2c** and **2t**) and their ring-substituted derivatives have been recorded in neat liquid. The chemical shifts were expressed in ppm *downfield* from tetramethylsilane as the standard.

The assignment of the α- and β-carbon signals of **1** was accomplished by the partial proton-decoupling technique. White and Levy[3] have recently reported the CMR spectral data of **1** and assigned the signals at 85.7 and 79.8 ppm to the α- and β-carbons, respectively, without any sound basis. On the other hand, Frei and Bernstein[4] observed the β-carbon signal at 86.8 ppm, using a ^{13}C-enriched sample. We have found that the signal at 86.4 ppm splits into quartet by partial proton-decoupling. The observed splitting must be due to the methyl protons. Although the spin coupling constants between ^{13}C and ^{1}H which are separated by more than one bond do not necessarily attenuate with an increase in the number of intervening bonds,[5] we have a good reason to say that $J_{C\text{-}C\text{-}H}$ is greater than $J_{C\text{-}C\text{-}C\text{-}H}$ in **1**. It is reported that the coupling constants between the methyl protons and the acetylenic carbons of propyne, $J_{C\text{-}C\text{-}H}$ and $J_{C\text{-}C\text{-}C\text{-}H}$, are 10.6 and 4.8 Hz, respectively.[6] Thus, the quartet signal can be assigned to the β-carbon, to which the methyl group is bonded. The assignment is compatible with the observation reported by Frei and Bernstein.[4]

6) J. N. Shoolery, *J. Mol. Spectrosc.*, **63**, 110 (1960).

The assignment of the α- and β-carbon signals of **2c** and **2t** was carried out with the aid of the additivity rule of Savitsky *et al.*[7] A methyl substitution of ethylene causes 12.9 ppm downfield and 7.4 ppm upfield shifts of the carbons α and β to the substitution, respectively.[7] In the same way, a phenyl substitution results in 13.0 ppm downfield and 10.5 ppm upfield shifts of the α- and β-carbons, respectively.[8] Using these shift values and the chemical shift of the ethylene carbon (122.8 ppm), we estimate the chemical shifts of the α- and β-carbons of **2** to be 128.4 and 125.2 ppm. Thus, the signals appearing at *ca.* 130 and 126 ppm of both **2c** and **2t** can be assigned to the α- and β-carbons, respectively.

Chemical shifts of sp and sp^3 carbons are substantially different from those of sp^2 carbons. Assignment of the signals of ring carbons was worked out, using both the partial proton-decoupling technique and the known additivity rule.[9]

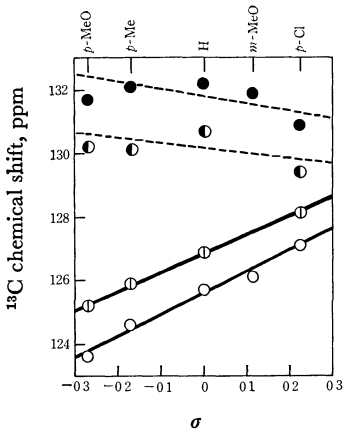

Fig. 2. Hammett plots of the ^{13}C chemical shifts of the α- and β-carbons of *cis*- and *trans*-1-phenylpropenes. **2c**; α(◐), β(◑), **2t**; α(●), β(○).

Listed in Table 1 are the ^{13}C chemical shift data obtained for the α- and β-carbons in the derivatives of **1**, **2c**, and **2t**. They are plotted against the Hammett σ constants in Figs. 1 and 2. In any case studied, the β-carbon shows a better linearity than does the α-carbon. The ρ values for the former carbon are given in Table 2, together with the related data.

Discussion

According to the present CMR data given in Table 2, the transmission efficiency of the unsaturated bond in either of **1** or **2c** is lower than that observed for **2t**. The low efficiency in **2c** may be due to the conformational effect arising from its nonplanar structure.[10] Since our specific aim here is to compare the electronic effects of the C=C and C≡C bonds in transmitting the substituent effect, the transmission efficiency of a C=C bond should be evaluated from the results for **2t**, which is coplanar and hence is free from the conformational problem. This leads to a conclusion that the efficiency of a C≡C bond is smaller than that of a C=C bond free from steric strain. The same trend is discernible in the comparison of the ρ values for the β-carbon shifts of phenylacetylene ($\rho=3.6$ ppm/σ[11]) and styrene ($\rho=4.73$ ppm/σ[8]).

It is known that ^{13}C chemical shifts well reflect the electron density (especially the π-electron density) of the carbon atom.[12] Savitsky *et al.*[7] have shown from CMR observations that the polarization of a C=C bond by an electron-donating group should effect an increase (upfield shift) in electron density at the β-carbon and a decrease (downfield shift) at the α-carbon. Most likely, the polarization effect of substituents will be the greater, the greater their electron donating or withdrawing property. The view is in line with our

finding that, in both **1** and **2**, the signs of the ρ values for the α- and β-carbons are opposite to each other (Figs. 1 and 2). The small ρ-values of the β-carbon in phenylacetylenes as compared with those in styrenes may then be taken as an indication that a C≡C bond is less sensitive than a C=C bond to a perturbation in bond-polarity due to the introduction of polarizing substituents. This low sensitivity of a C≡C bond seems to be ascribable to the opposite polarization of orthogonal π-electrons in the triple bond.

The chemical shifts themselves of the α- and β-carbons seem to deserve brief comment. The polarization argument leads to the result that the side-chain unsaturated bonds of **1** and **2** are polarized in opposite directions.

$$C_6H_5-\overset{\delta-}{C}\equiv\overset{\delta+}{C}-CH_3 \qquad C_6H_5-\overset{\delta+}{C}H=\overset{\delta-}{C}H-CH_3$$

That is, for the acetylenic bond, the phenyl group appears to be less electron-donating than the methyl group, while the former is more electron-donating than the latter in the olefinic bond. However, this difference in the direction of polarization has no bearing with the lower sensitivity of the triple bond to the electronic effect of ring substituents.

Experimental

Preparation of the ring-substituted 1-phenylpropenes and 1-phenylpropynes will be described elsewhere.[13]

The ^{13}C NMR spectra of a neat liquid in an 8 mm φ sample tube were recorded at 25 °C on a JEOL C-60HL spectrometer with a 15.09 MHz RF unit. The signal to noise ratio of the spectra was enhanced by the ^{13}C–H noise decoupling. The chemical shift measurements were performed with a nuclear-resonance single-side-band technique, their accuracies being within ±0.2 ppm. CS_2 was used as an external standard. The chemical shifts are given in ppm downfield from TMS by using the chemical shift of CS_2 of 193.7 ppm.

The authors wish to thank Mr. H. Okuda for recording CMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2883—2885 (1973)

The Photoconductivity of Poly(*N*-vinylcarbazole). IV.[1] The Photoconductivity of Copolymers of *N*-Vinylcarbazole with Styrene, Vinyl Acetate, and *N*-Vinylpyrrolidone[2]

Kenichi OKAMOTO,* Keishi KATO, Kenji MURAO, Shigekazu KUSABAYASHI,* and Hiroshi MIKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received March 21, 1972)

In a previous paper,[1] the present authors proposed a mechanism of carrier migration in a poly-*N*-vinylcarbazole (PVCz) film based mainly on the structure of the polymer. The carriers seem to move easily along the chain from a carbazyl group to another adjacent carbazyl group through the overlap of the π-electrons of the carbazyl rings in the same polymer chain. In this note we wish to report that this manner of carrier migration is also suggested by an examination of the photoconductivity of the copolymers of *N*-vinylcarbazole (VCz) with styrene, vinyl acetate, or *N*-vinylpyrrolidone, as well as the alternate one-to-one copolymer of VCz and fumaronitrile (FN).

Copolymers rich in VCz were prepared by radical polymerization. The polymerization was carried out in a vacuum sealed tube at 60 °C for 2.5 hr. Azobisisobutyronitrile was used as the catalyst (1 mol%), and benzene as the solvent (1 mol/l). The feed ratio of monomers (VCz/comonomer) was 9/1. The copolymers thus obtained were fractionated by benzene–xylene in order to remove the PVCz homopolymer and were then purified by repeated reprecipitations (benzene–acetone). The alternate VCz–FN copolymer was prepared as has been described elsewhere.[3] The VCz content in the copolymers was determined both by elementary analysis and by UV absorption measurements. (The following absorption coefficients were used; $\varepsilon_{345}=3500$, $\varepsilon_{331}=2950$ l/mol cm.) The preparation of a sandwich-type cell and the electrical measurements were carried out in the same manner as has been described previously.[1]

The absorption spectra (both the positions of the absorption peaks and the molar extinction coefficient per carbazole unit) of the copolymers are the same as that of PVCz in the wavelength region longer than 300 mμ, where the comonomer components have no absorption. The films used in the measurement were 15 μ thick and completely absorbed the incident light shorter than 357 mμ. The fluorescence spectra of the copolymer films were almost the same as that of a PVCz film except in the case of the alternate VCz–FN

PVCz doped with polystyrene (15 mol%)	56 (1/2)	540 (1/1.6)	20 (1/1.7)	160 (1/2)	800 (1/2.5)	35 (1/2.3)
Alternate 1:1 copolymer of VCz and FN	0	0	0	0	0	0

Values in parentheses represents the factors of decrease in the photocurrent as compared with the photocurrent of PVCz.

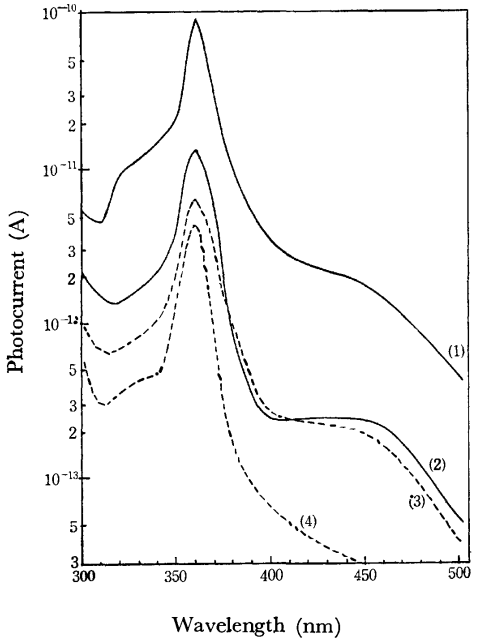

Fig. 1. Photocurrent of the copolymers of VCz with negative electrode illumination.
(1) PVCz, (2) VCz–styrene (15 mol%) copolymer, (3) VCz–vinyl acetate (17 mol%) copolymer, (4) VCz–*N*-vinylpyrrolidone (20 mol%) copolymer.

copolymer. In the film of the alternate copolymer, the excimer fluorescence was quenched almost completely and a weak emission due to the exciplex was observed.

The photocurrent was measured in a Nesa-Polymer-Gold sandwich-type cell (area of electrode: 1 cm^2) under 7000 V/cm in a high vacuum under the illumination of monochromatic light (2×10^{13} photons/cm^2 sec) at 20 °C. The copolymer films showed photoconductive properties similar to those observed in a PVCz film.[1] As is shown in Fig. 1 and Table 1, however, the photocurrent of the films of the copolymers (VCz content, 92—80 mol%), was smaller in magnitude by a factor of 5—50 than the photocurrent of the PVCz film. The photocurrent decreased in all spectral regions, irrespectively of the polarity of the illuminated electrode. The reduction of the photocurrent occurred in every copolymer, independently of the kind of comonomer. The alternate VCz–FN copolymer does not show any photoconductivity, although the FN component is thought to favor the formation of the cation of carbazole chromophore. The amount of decrease in the photocurrent depends mainly on the content of the comonomer.

On the other hand, the photocurrent in the PVCz film doped with polystyrene (dope amount, 15 mol%) decreased by only a factor of 1.5—2.5 as compared with the photocurrent in an undoped PVCz film. This decrease in the photocurrent is much smaller than that of the photocurrent in the VCz–styrene copolymer with the same content of the styrene component (15 mol%).

As has been reported in the previous paper,[1] the large photoconductivity of PVCz can be attributed both to the extrinsic carrier generation by the interaction of an exciton with some impurity and to the carrier migration through the overlap of π-electrons of the carbazyl groups in the same polymer chain. It has been found, from the study of the energy transfer,[4] that, in the films of the VCz-rich copolymers, the number of the carbazyl groups covered by an exciton during its lifetime is limited by the excimer-forming site in the copolymer chain in the same manner as in PVCz; it is evaluated to be almost the same (700) as in a PVCz film. Assuming that the conditions of the impurity (density and distribution) are almost the same in the copolymer films and in a PVCz film, the probability of an exciton interacting with any impurity will, therefore, be almost the same in both films. Consequently, the efficiency of the extrinsic carrier generation is not expected to decrease sufficiently to explain the observed results in the films of the copolymers rich in VCz. The comonomer components such as styrene may not be anticipated to act as trap centers or recombination

4) K. Okamoto, A. Yano, S. Kusabayashi, and H. Mikawa, Preprint of the 24th Anual Meeting of the Chemical Society of Japan, I-p. 142 (April, 1971). To be published in this Bulletin.

centers in view of the doping effect of some aromatic compounds on the photoconductivity of PVCz.[5] It seems, therefore, to be difficult to consider the significant decrease in the lifetime of the carrier due to trapping effect of the comonomer in the copolymer films.

Judging from the correlation between the crystallinity and the photocurrent in a PVCz film,[1] a small decrease in the crystallinity of the films does not seem to decrease the photocurrent significantly. As there was no significant difference in the crystallinity between the untreated films of the copolymers and of PVCz, the considerable decrease in the photocurrent in the films of the copolymers seems not to be due to any change in the crystallinity.

Therefore, the significant decrease in the photocurrent in the copolymers does not seem to be due to the lowering of the efficiency of the extrinsic carrier generation nor to the lowering of the crystallinity, but to the interruption effect of the comonomer components on the carrier migration. In the case of the copolymer of VCz with a comonomer such as styrene, with a small π-electron system, the sequence of the overlap of the adjacent carbazyl groups in the same polymer chain is frequently interrupted by the comonomer units introduced. As the lifetime of the carrier will be shorter than that of the exciton because of its higher energy state, it is supposed that during its lifetime a carrier covers a smaller number of the carbazyl groups than does an exciton. The excimer-forming site is hardly thought to limit the carrier migration, although it is able to act as a carrier trap. The carrier migration is, therefore, directly affected and reduced by the interruption of the overlap of the π-electrons of the carbazyl groups due to the comonomer component. This is the reason for the significant decrease in the photocurrent in the copolymers. This is also supported by the following three facts. First, as has been described previously, the decrease in the photocurrent of the copolymers does not depend on either the wavelength of the illuminated light, or the polarity of the illuminated electrode. Secondly, the decrease in the photocurrent in the PVCz film doped with polystyrene was not so large as in the film of the VCz–styrene copolymer. Thirdly, the alternate VCz–FN copolymer, where there is no sequence of carbazyl groups in the same polymer chain, has no primary photocurrent.

In conclusion, the photocurrent of the copolymers is reduced by a factor of 5—50. This might be due to the sum of the following three effects; the lowering of the efficiency of carrier generation, the reduction of the carrier life-time, and the disturbance of the carrier migration. The predominant effect seems to be the third effect, that is, the disturbance of carrier migration due to the interruption effect of the comonomer component on the overlap of the π-electrons of the carbazyl groups.

The Condensation of Orthophosphates with Acid Anhydrides

Makoto WATANABE, Hideaki USAMI, and Munehiro SUGASE

Department of Industrial Chemistry, Chubu Institute of Technology, Matsumoto-cho, Kasugai-shi, Aichi 487

(Received October 16, 1972)

Thilo *et al.* prepared potassium trimetaphosphate and sodium trimetaphosphate by treating monopotassium and monosodium orthophosphate respectively in a mixed solution of acetic acid and acetic anhydride.[1,2] Kasparek reported on the dehydration of various dihydrogen orthophosphates and pyrophosphates using the mixed solution mentioned above.[3,4] In a previous paper,[5] the present authors reported on the dehydration of mono-, di-, and trisodium orthophosphates in the same solution at 100 °C. In every case, the main product was the sodium trimetaphosphate. In the present work, the condensation reactions of mono- di-, and trisodium orthophosphates were carried out in mixed solutions of acetic acid and propionic, *n*-butyric, isobutyric, succinic, or maleic anhydride.

Experimental

Materials and Procedure. All the materials used were of a commercial grade. The water of the crystallization of orthophosphate was removed by heating it in an air bath at 120 °C. When propionic, *n*-butyric, or isobutyric anhydride was used as the dehydrating agent, 50 g of the anhydride was taken in a four-necked, round-bottomed, 200 ml flask; then 50 ml of acetic acid and 5 g of orthophosphate were added. The three samples of the mixture were heated, stirred, and refluxed at 100 °C for 10, 20, and 30 hr respectively. In the cases of succinic and maleic anhydrides, 25 g of the anhydride was placed in a four-necked, round-bottomed, 200 ml flask; then 100 ml of acetic acid and 5 g of orthophosphate were added, and the mixture was treated in the way described above. Each mixture was cooled after reaction periods of 10, 20, and 30 hr. The resulting precipitate was filtered off and washed with acetone. The composition of the phosphates con-

tained in the precipitate was determined by X-ray diffractometry and paper chromatography.

X-Ray Diffractometry. The samples were ground with an agate mortar until they could pass through a 150-mesh sieve, and their X-ray diffraction pattern was taken with a Toshiba Model ADG-102 X-ray diffractometer.

Paper Chromatography. The separation and determination of condensed phosphates were performed with the method described in the present authors' previous paper.[5]

Results and Discussion

Mono-, di-, and trisodium orthophosphates were dissolved completely in a mixed solution of acid anhydride and acetic acid at 100 °C. A white product was freshly precipitated; appeared as a condensed phosphate. The quantity of the precipitate increased with increasing in the reaction time in every case. As Tables 1, 2, 3, and 4 show, except for the NaH_2PO_4–$(CHCO)_2O$–CH_3COOH system, the main product is trimetaphosphate. When propionic, *n*-butyric, or isobutyric anhydride is used as dehydrating agent, the content of trimetaphosphate in the precipitate increases with an increase in the reaction time, while the orthophosphate content decreases. In the condensation of mono- or disodium orthophosphate, a small amount of condensed phosphates, which have a longer chain than that of tripolyphosphate, exists after a reaction period of 10 hr. Tripolyphosphate also exists after reaction periods of 10, 20, and 30 hr. On the other hand, in the reaction of trisodium orthophosphate, the longer-chain phosphates and tripolyphosphate do not exist after any reaction period except in the case of the Na_3PO_4–$(CH_3CH_2CO)_2O$–CH_3COOH system. In the condensation of monosodium orthophosphate with succinic or maleic anhydride, the content of trimetaphosphate is smaller than that of di- or trisodium orthophosphate. In the reactions of di- and trisodium orthophosphates with succinic and maleic anhydrides, the content of trimetaphosphate at a reaction time of 40 hr is more than 90% in all cases.

(S, M, Na1, Na2, and Na3 represent succinic anhydride, maleic anhydride, mono-, di-, and trisodium orthophosphate respectively.)

Griffith and Buxton[6] reported that, when sodium polyphosphate (with a longer chain than in tetra) was hydrolyzed, trimetaphosphate was formed, while in the hydrolysis of polyphosphate with cations other than the sodium ion, scarcely no trimetaphosphate was formed. They concluded from these facts that the sodium ion is related to the formation of the trimetaphosphate ring. The fact that, in the present work, the main product is trimetaphosphate, seems related to the above conclusion. The yield of the precipitate and the theoretical value of $(NaPO_3)_3$ to be obtained per 5.00 g of each of the orthophosphates are shown in Table 5. The theoretical values are calculated assuming that the orthophosphates are completely converted into $(NaPO_3)_3$ by means of the equations described in the previous paper.[5] The formation process of sodium trimetaphosphate has already been discussed by Kasparek,[3] the same process has also been considered for these condensation reactions.

Table 5. The yields of the deposits and the theoretical amounts of $(NaPO_3)_3$ per 5 g of orthophosphates

		Acid anhydride

Some Palladium Complexes Containing a Benzoyl Group

Keinosuke SUZUKI and Minoru NISHIDA

Inorganic Chemistry Laboratory, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received February 27, 1973)

The acyl complexes of transition metals are prepared by the reaction of acyl halides with low-oxidation transition metal complexes or by the insertion of CO into the metal-carbon bond of alkyl or aryl complexes. The formation of the complexes containing a benzoyl group have also been reported in several papers.[1-4] However, no palladium complex with a benzoyl group has yet been prepared. In this paper we will report on the formation and the infrared spectra of PdCl(COPh)$(PPh_3)_2$ (I) and other benzoyl complexes of palladium derived from (I) by ligand-exchange reactions.

Results and Discussion

The reaction of $Pd(PPh_3)_4$ with PhCOX gave PdX(COPh)$(PPh_3)_2$ (X=Cl, Br). The recrystallization of the chloride (I) from acetone gave (I′) containing one molecule of acetone. Two other complexes, PdCl(COPh)(P–P) (III) and PdCl(COPh)(phen) (IV) (P–P=$Ph_2PCH_2CH_2PPh_2$, phen=*o*-phenanthroline), were obtained by the ligand-exchange reaction of (I). In the solid state, all the complexes are stable enough to handle in air, but are unstable in solution. The reaction of (I) with dipyridyl did not give the expected compound, PdCl(COPh)(dipy). This failure might be due to the fact that the ligand exists in the *trans* form in the free state.

TABLE 1. IR DATA OF THE PALLADIUM COMPLEXES (cm^{-1})

	Complex	ν(C=O)	ν(Pd–Cl)
(I)	PdCl(COPh)$(PPh_3)_2$	1640	235
(I′)	PdCl(COPh)$(PPh_3)_2(CH_3)_2CO$	1702 1648	235
(II)	PdBr(COPh)$(PPh_3)_2$	1640	—
(III)	PdCl(COPh)(P–P)	1639	282
(IV)	PdCl(COPh)(phen)	1643	325

The infrared data of the complexes prepared are summarized in Table 1. As is clear from the table, all the complexes have a strong band due to ν(CO) *ca.* 1640 cm^{-1}, this is characteristic of a benzoyl group coordinated to a transition metal. The –C=O stretching frequency has been lowered *ca.* 80 cm^{-1} in comparison with the ν(CO) of the free benzoyl chloride. Green[5] suggested that the lowering may be due either to some double bonding of the metal with π-orbitals of the C=O group or to some direct interaction of the metal with the C=O group. In the ^{13}C NMR of $Fe(CO)_2(\pi\text{-}C_5H_5)(COPh)$,[6] the resonance of $^{13}COPh$ showed a large low-field shift which could be associated with the multiple bonding between the *d*-orbitals of the metal and the sp^2 carbon atom. Therefore, it was expected that the change in the donor atom *trans*

to the benzoyl group has some effect on the ν(CO) of the ligand. However, the ν(CO) values of the complexes studied here remained approximately constant. Although the results may be explained by assuming either that the difference in the π-acceptor property of the donor atom is small[7] or that the direct interaction between the metal and the CO group is important, further investigations seem to be necessary to examine the effect of π-interaction on the ν(CO) of the acyl group.

In (I'), the band due to the ν(CO) of acetone was observed at 1702 cm^{-1}. The band is shifted *ca.* 30 cm^{-1} to wave numbers lower than that of free acetone. However, this shift is smaller than the lowering of ν(CO) found for the acetone which coordinates to Rh through a lone pair on the oxygen.[8] Thus, it seems to be difficult to discuss the coordination of acetone for (I') on the basis of the ν(CO) data alone.

The far infrared spectrum of (I) showed three bands, at 317, 270, and 235 cm^{-1}. The two bands at 270 and 235 cm^{-1} disappeared in the corresponding bromide. Since the ν(Pd–Cl) of (III), where P is *trans* to Cl, appeared at 281 cm^{-1}, one possible explanation of the disappearance of the band at 270 cm^{-1} is to assume the presence of the *cis*-isomer. However, its existence is rather suspected when the steric hindrance of the two bulky groups (PPh_3) in the *cis*-position is considered. Thus, the assignment of the band at 270 cm^{-1} is uncertain at present. Probably ^{31}P NMR measurements would clarify the ambiguity.

Recently Dent *et al.*[9] reported that the assignment of ν(Pt–Cl) for $PtCl(COPh)(PPh_3)_2$ made by Baired and Wilkinson[1] was incorrect and that the ν(Pt–Cl) really appeared at 261 cm^{-1}, indicating a large *trans* influence of an acyl group. This is also true in iridium complexes.[4,10] The large *trans* influence of an acyl group seems to be a general tendency, and the band at 235 cm^{-1} of (I) is probably due to the ν(Pd–Cl), where Cl is *trans* to the benzoyl group.

Experimental

Measurements. The infrared spectra were recorded with JASCO-DS-402G and HITACHI EPI-L2 spectrometers (nujol or HCB mulls).

Materials. The $Pd(PPh_3)_4$ was prepared by the method described in the literature.[11] The benzoyl chloride and benzoyl bromide were distilled before use. All the solvents used were dried over sodium and distilled under nitrogen. All the reactions were carried out under nitrogen.

Chloro(benzoyl)bis(triphenylphosphine)palladium (I): Into 0.9 g of $Pd(PPh_3)_4$ in 100 ml of benzene, we stirred 0.5 ml of C_6H_5COCl in 50 ml of benzene. After the yellow solution had then been allowed to be stirred overnight, it was concentrated to about 30 ml and filtered off to remove the small amount of precipitates formed. The filtrate was subsequently treated with 150 ml of ether. The pale yellow precipitates were filtered, washed with ether, and dried *in vacuo*. Found: C, 66.4; H, 4.9; Pd, 13.6%. Calcd for $C_{43}H_{35}ClOP_2Pd$: C, 66.9; H, 4.6; Pd, 13.8%.

The recrystallization of (I) from acetone gave $PdCl(COPh)(PPh_3)_2(CH_3)_2CO$, (I'). Found: C, 66.7; H, 4.9; Pd, 12.8%. Calcd for $C_{46}H_{41}ClO_2P_2Pd$: C, 66.6; H, 5.0; Pd, 12.8%.

Similarly, $PdBr(COPh)(PPh_3)_2$ (II) was prepared by the reaction of $Pd(PPh_3)_4$ with benzoyl bromide. Found: C, 62.5; H, 4.2; Pd, 12.9%. Calcd for $C_{43}H_{35}BrOP_2Pd$: C, 63.3; H, 4.3; Pd, 13.0%.

Chloro(benzoyl)1,2-bis(diphenylphosphino)ethanepalladium (III): To 1 g of $PdCl(COPh)(PPh_3)_2$ in 100 ml of benzene, we added 0.5 g of $Ph_2PCH_2CH_2PPh_2$ in 10 ml of benzene. About ten minutes later, yellow crystals started to precipitate. After the mixture had been stirred for 1 hr, the crystals were filtered off, washed with ether, and dried *in vacuo*. Found: C, 61.7; H, 4.6; Pd, 15.9%. Calcd for $C_{33}H_{29}ClOP_2Pd$: C, 61.4; H, 4.5; Pd, 16.5%.

Chloro(benzoyl)(*o*-phenanthroline)palladium (IV) was prepared in a similar way. Found: C, 53.1; H, 3.1; Pd, 24.5; N, 6.7%. Calcd for $C_{19}H_{13}N_2ClOPd$: C, 53.4; H, 3.1; Pd, 24.9; N, 6.7%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2889—2890 (1973)

The Hydrolysis of Y^{3+}, La^{3+}, Gd^{3+}, and Er^{3+} Ions in Heavy Water[1)]

Toshihiko AMAYA,[2)] Hidetake KAKIHANA, and Masunobu MAEDA*

Research Laboratory of Nuclear Reactors, Tokyo Institute of Technology, O-okayama, Meguro, Tokyo 152

**Department of Electrochemistry, Tokyo Institute of Technology, O-okayama, Meguro, Tokyo 152*

(Received March 2, 1973)

In the preceding papers,[3-6)] we studied the hydrolysis reactions of Be^{2+}, UO_2^{2+}, and Cu^{2+} ions in heavy water, and found that the compositions of the hydrolysis species formed in heavy water are the same as those in light water, while the stability constants of the complexes in heavy water are smaller than those in light water.

In the present work, the hydrolysis reactions of Y^{3+}, La^{3+}, Gd^{3+}, and Er^{3+} ions in heavy water have been studied and the results have been compared with those previously obtained in light water.[7)]

Symbols

The symbols used are the same as those described in Refs. 3 and 7.

Experimental

Reagents and Apparatus. The reagents used were, unless otherwise stated, prepared and analyzed as has been described in Ref. 7. A rare-earth perchlorate solution of heavy water was prepared from its solution of light water by repeated evaporation under an infrared lamp, while adding heavy water.

All the apparatuses employed were the same as those used in Ref. 7.

Procedures. All the measurements were carried out in a paraffin-oil thermostat kept at 25.00±0.01 °C and placed in a room thermostated at 25±1 °C.

The hydrolysis of the rare-earth ions was investigated by measurements of the deuterium-ion concentration with a glass electrode. A hydrolyzed test solution prepared by the procedures described in the preceding paper[7)] was electrolyzed to generate D^+ ions by means of constant-current coulometry. The same cell assembly as that described in Refs. 3 and 7 was used for the emf measurements and the constant-current coulometry.

Results and Discussion

The $Z(\log d)_B$ data for Y^{3+}, La^{3+}, Gd^{3+}, and Er^{3+} ions are graphically represented in Fig. 1.

The experimental data were analyzed by the methods

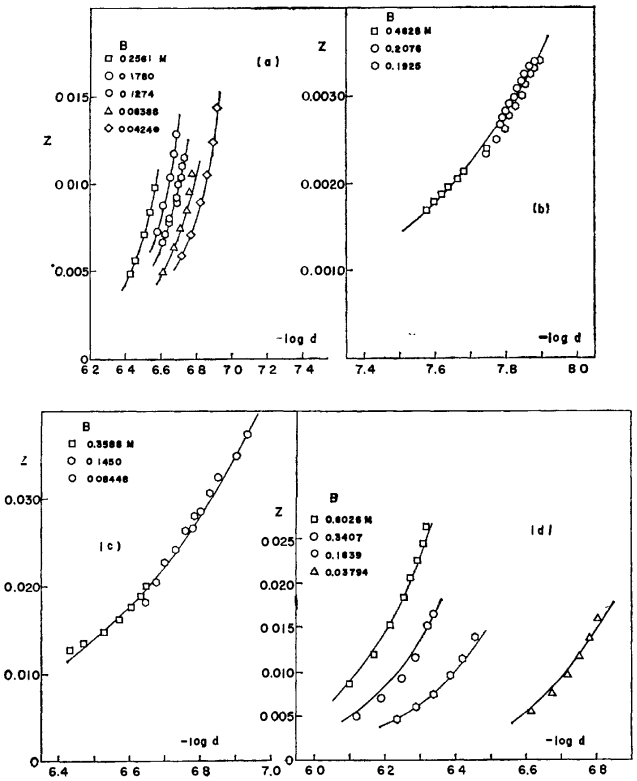

Fig. 1. Average number, Z, of OD bound per a) Y(III), b) La(III), c) Gd (III) and d) Er (III), as a function of $-\log d$. The drawn curves were calculated with the stability constants listed in Table 1.

described in Ref. 7.

The most probable values for the stability constants of the hydrolysis species, calculated by means of the generalized least-squares method with the aid of an electronic computer (HITAC 5020), are listed in Table 1; the results in light water previously reported[7] are also listed for the sake of comparison.

The conclusions which we derived in the preceding works were confirmed in the present study; that is, the compositions of the species formed in heavy water are the same as those in light water, while the values of the equilibrium constants are smaller in heavy water than in light water.

We plotted the difference in the $\log \beta_{2,2}$ values in light and heavy water, $\Delta\log \beta_{2,2}=\log \beta_{2,2}(\text{in } H_2O)-\log \beta_{2,2}(\text{in } D_2O)$ against $\log \beta_{2,2}(\text{in } H_2O)$ for the (2,2) hydrolysis species of Y^{3+} and Er^{3+} ions, as well as those of the $(CH_3)_2Sn^{2+}$,[8] UO_2^{2+}, and Cu^{2+} ions.[4-6] The plot is shown in Fig. 2. The figure shows that $\Delta\log \beta_{2,2}$ is practically independent of the change in $\log \beta_{2,2}$ (in H_2O) at about 0.7.

Many workers[9] have reported that ΔpK (the difference in the pK values of an acid in light and heavy water) increased with $pK(\text{in } H_2O)$. In contrast with these conclusions, Ohtaki and Maeda[10] have pointed out that ΔpK is independent of $pK(\text{in } H_2O)$ for many organic acids with a similar structure for which a linear free-energy relationship holds. It is interesting that the same tendency has been found for the hydrolysis of the metal ions; it can be regarded as a dissociation reaction of weak acids, although no simple relation like the LFER for organic acids has been found between the acidities and other physico-chemical properties of aquated metal ions.

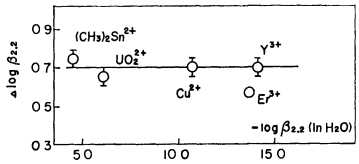

Fig. 2. $\Delta\log \beta_{2,2}=\log \beta_{2,2}$ (in H_2O) $-\log \beta_{2,2}$ (in D_2O) as a function of $-\log \beta_{2,2}$ (in H_2O).

The authors wish to thank Dr. Hitoshi Ohtaki for his valuable discussions.

The Anionic Polymerization of *n*-Butyraldehyde Azine

Mikiharu KAMACHI and Shunsuke MURAHASHI

Department of Polymer Science, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received November 7, 1972)

Little is known concerning the polymerization of compounds with C=N bonds except for carbodiimides[1] and isocyanates.[2-6] We have already reported on the anionic polymerization of acetaldazine and have reported that the polymer thus obtained was a viscous oligomer.[7,8] The failure to obtain a high polymer from acetaldazine may be due to the proton transfer of the active hydrogens of the α,ω-methyl groups in the monomer. Thus, we are led to the polymerization of *n*-butyraldehyde azine, which has less active α-hydrogen than acetaldazine, and to the comparison of the molecular weight of the obtained polymer with those of formaldazine and acetaldazine under similar conditions.

The results of the polymerization of *n*-butyraldehyde azine by BuLi under various conditions are shown in Table 1. The oligomer was prepared in a good yield and was separated into a methanol-insoluble part (Oligomer 1) and a methanol-soluble part (Oligomer

2). In order to make it clear whether or not the addition polymerization occurs, the polymer thus obtained was characterized first.

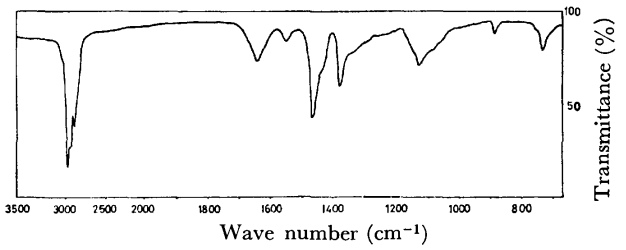

Fig. 1. The IR spectrum of oligomer 1 (KBr).

The IR spectrum of Oligomer 1 is shown in Fig. 1. It shows absorption bands at 1645 cm^{-1} ($\nu_{C=N}$) and 1555 cm^{-1} ($\nu_{N=N}$). The IR spectrum of Oligomer 2 is identical to that of Oligomer 1 except for its intensity. The UV spectrum of Oligomer 1 was measured in the range from 220 to 700 nm in a hexane solution; it showed an absorption maximum at 235 nm, a shoulder at 296 nm, and a weak absorption at 378 nm showing the -N=N- group.[12] The absorptions at 235 and 296 nm may be assigned to the n-π^* transition of the -C=N bond.[8] The NMR spectrum of Oligomer 1 is shown in Fig. 2. Each peak was assigned as is shown in Fig. 2, taking into account the conventionally available data. These assignments were consistent with the results of the IR spectra and the qualitative chemical tests. The product obtained from the treatment of the Oligomer, 1 or 2, with dilute aqueous hydrochloric acid was distilled into another ampoule containing an alcoholic solution of 2,4-dinitrophenylhydrazine by using a high-vacuum technique. An orange-yellow solid was thus formed (mp 118—122 °C). The product was identified as n-butyraldehyde hydrazone by a mixed-melting-point test with the authentic product, thus indicating the existence of pendant $-N=CH-CH_2-CH_2-CH_3$ groups.

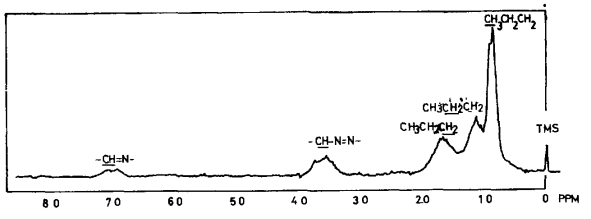

Fig. 2. The NMR spectrum of Oligomer 1 (CCl_4 5% solution).

In order to establish the existence of the $-\underset{\underset{R}{|}}{CH}-N=$ $N-\underset{\underset{R}{|}}{CH}-$ group, which is likely to cleave thermally at the C–N bonds and which evolves nitrogen molecule, the mild pyrolysis of Oligomer 1 at 200 °C was carried out under a high vacuum and the gaseous product thus obtained was collected into a vial for mass spectrometry. High-resolution mass spectrometry showed that the gas product was a nitrogen molecule (m/e 28.02).

These results suggest the following structure for the Oligomer 1:

$$C_5H_9-(\underset{\underset{N=CHC_3H_7}{|}}{CH}-N)_x-(CH-N=N-CH)_y-H$$
(C_3H_7 on each CH)

It was proved by the results of the IR spectra that Oligomer 1 is similar to Oligomer 2 except in its molecular weight.

The structure of the oligomer was consistent with that of the acetaldazine. Evidence for the hydrazone rearrangement, which was pointed out in the case of acetaldazine,[8] was found in the IR spectrum of Oligomer 2, which was allowed to stand, but not in Oligomer 1. This indicates that the rearrangement of Oligomer 1 is more difficult than that of Oligomer 2.

Table 2. Comparison of the molecular weights of the polymer obtained from various azines

Substance	State	Molecular weight (Degree of polym.)
Formaldazine[a]	Solid	$\eta_{sp/c}=0.25$[b]
Formaldazine[c,d]	Solid	Insoluble polymer
n-Butyrazine[c]		
Oligomer 1	Solid	2990 (21)
Oligomer 2	Tacky solid	1440 (10)
Acetaldazine[c]	Tacky solid	900 (10)

a) Formaldazine was polymerized by a trace of water at 0 °C.
b) H_2O Solution at 30 °C.
c) Monomer=0.89 mol/l, BuLi=30 mmol/l. Solvent, THF. Polym. temp. 0 °C.
d) Molar concentration of formaldazine was calculated by assuming that its density is the same as that of acetaldazine, because that of formaldazine was not determined.

The degree of polymerization of the oligomer of n-butyraldehyde azine was a little larger than that of the acetaldazine which was obtained under similar conditions, as is shown in Table 2, in spite of the increase in the bulkiness of the substituent group. This might be due to the decrease in the number of active hydrogens in α,ω-alkyl groups of n-butyraldehyde azine. In order to make this point clear, formaldazine, which has no active hydrogen, was polymerized to a solid polymer by a trace of water at room temperature and then explosively by butyllithium at −78 °C.[9] The intrinsic viscosity of the former was found to be 0.25 in an aqueous solution, but the latter polymer was insoluble in water as well as in common organic solvents. The degree of polymerization of the formaldazine polymer may be much larger than that of n-butyraldehyde azine. Thus, it is shown that high polymers can be anionically obtained from the C=N–N=C bond as well as from the diene bond.

These facts suggest that a cause of oligomerization in α,ω-disubstituted azine might be a proton transfer of active hydrogen.

9) M. Kamachi and S. Murahashi, to be published.

Experimental

Reagents. The *n*-butyraldehyde azine was prepared from hydrazine hydrate and *n*-butyraldehyde according to the procedure of Curtius;[10] it was purified by reduced-pressure distillation through a Widmer column under nitrogen. The tetrahydrofuran was refluxed over metallic sodium and distilled into an ampoule on a high-vacuum system. The *n*-butyllithium was prepared in *n*-heptane by the method of Ziegler, and the concentration was determined by double titration.[11]

Polymerization. A 10 ml polymerization ampoule equipped with a nitrogen inlet with a stopcock was connected to a high-vacuum system, evacuated, and flushed with nitrogen by opening the stopcock. The ampoule was then removed under nitrogen flushing, after which a solution of butyllithium in heptane was injected by means of a hypodermic syringe into the ampoule under nitrogen. The ampoule was again connected to a high-vacuum system, the heptane was evaporated, and then the solvent and the monomer, which has previously been dried and degassed, were distilled into it. After being sealed off, the ampoule was placed in a thermostat at a given temperature. The polymerization system gradually turned orange-red in bulk polymerization, but immediately colored in a tetrahydrofuran solution.

The polymerization system became a red gel in the bulk polymerization and a red viscous solution in the solution polymerization. The reaction system was added to an excess of methanol to separate a methanol-insoluble polymer (Oligomer 1) and a methanol-soluble polymer (Oligomer 2). Oligomer 1 was filtered, washed with methanol, and dried. Oligomer 1 was a pale yellow solid, softening at 82—92 °C, which was soluble in petroleum benzine, benzene, toluene, and tetrahydrofuran.

Found: C, 69.18; H, 11.16; N, 19.83%. Calcd for $C_8H_{16}N_2$: C, 68.57; H, 11.43; N, 20.00%.

Oligomer 2 was isolated by evaporating the filtrate, and it was freed from inorganic salt by washing its ether solution with a small amount of distilled water. Oligomer 2 was a pale yellow to yellow viscous liquid (or tacky solid), soluble in aliphatic hydrocarbon, acetone, benzene, methanol, and tetrahydrofuran.

Found: C, 69.84; H, 10.99; N, 18.83%. Calcd for $C_8H_{16}N_2$: C, 68.57; H, 11.43; N, 20.00%.

The number-average molecular weights of these oligomers were determined by means of a vapour-presure osmometer (Mechro lab. 301A) in benzene.

The structure of the polymer was determined by studying its IR spectrum and NMR spectrum (Varian A 60) and by qualitative chemical tests for functional groups. The mass spectrum of the gas product obtained from the mild pyrolysis of the polymer was determined by means of a Hitachi model-10Z mass spectrometer.

The authors are grateful to Professor Shunichi Nozakura for several comments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2892—2893 (1973)

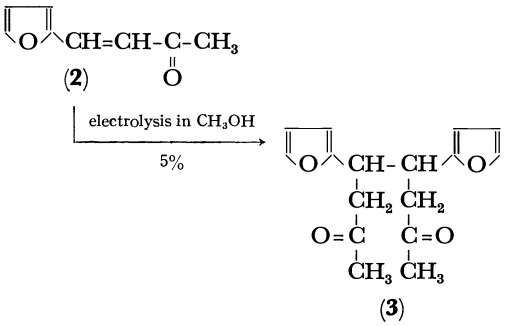
The Synthesis of (4,5-Di(2-furyl)-2,7-octanedione) by the Electrolysis of (4-(2-Furyl)-3-buten-2-one)

Hajime SATONAKA, Zei SAITO, and Toshio SHIMURA

Industrial Research Institute of Kanagawa Prefecture, Showa-machi, Kanazawa-ku, Yokohama 236

(Received December 1, 1972)

4-(2-Furyl)-3-buten-2-one (**2**), which resembles methyl 3-(2-furyl)acrylate (**1**), was electrolyzed in methyl alcohol containing sulfuric acid as a supporting electrolyte. While **1** was oxidized to methyl 3-(2,5-dimethoxy-2,5-dihydrofuryl)acrylate[1-4] and 5,5'-bis[2-(methoxycarbonyl)vinyl]-2,2'-bifuryl,[5] **2** was reduced to 4,5-di(2-furyl)-2,7-octanedione (**3**) under similar conditions.



The IR spectrum of the dimer (**3**) showed a carbonyl band at 1708 cm^{-1} and bands of the furan ring at 3125, 1511, 1020, 886, and 758 cm^{-1}.[6] The UV spectrum in methyl alcohol showed a maximum peak at 220 mμ with a molar extinction coefficient of 11000. The NMR spectrum showed signals of furan-ring protons at τ 2.68 (2H, multiplet), 3.78 (2H, multiplet), and 3.91 (2H, multiplet), of methin protons at 6.40 (2H, multiplet), of methylene protons at 7.35 (4H, multiplet), and of methyl protons at 8.07 (6H, singlet). The mass spectrum exhibited its intense peaks

at *m/e* 274 (M^+), 217 ($M^+-CH_2COCH_3$), 137 ($M^+/2$), and 43 ($^+COCH_3$). The elementary analysis agreed with the formula of $C_{16}H_{18}O_4$. On the basis of these results, the product was determined to be 4,5-di(2-furyl)-2,7-octanedione (**3**).

Table 1. Yields of 4,5-difuryl-2,7-octadione by the electrolyses in the various solvents (%)[a]

Solvent	Yield	Solvent	Yield
CH_3OH	5	DMF	5
C_2H_5OH	2	Pyridine	3
$(CH_3)_2CO$	7	Dioxane	Trace
THF	1		

a) Averages of the three times experiments.

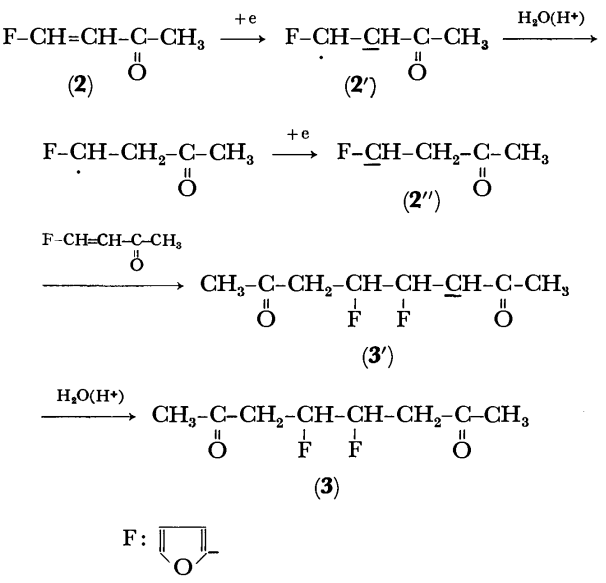
Similar electrolyses were repeated for ethyl alcohol, acetone, tetrahydrofuran (THF), *N,N*-dimethylformamide (DMF), pyridine, and dioxane in the same way as was used for in methyl alcohol. The yields of the product are given in Table 1. The results when water was mixed in methyl alcohol, acetone, and DMF in various proportions, and when the reactions were carried out in these mixed solvents, are given in Table 2. It was found that the yields increased with the addition of water and came to a maximum at the point where the volume of water amounted to about 50—70%.

Table 2. Yields of 4,5-difuryl-2,7-octadione in the various water-mixed solvents (%)[a]

Solvent	H_2O (%)			
	10	25	35	50
CH_3OH	6	24	15	4
$(CH_3)_2CO$	45	52	46	34
DMF	24	30	40	15

a) Average of the three times experiments

Assuming that these reactions proceed by means of a mechanism similar to that in the hydrodimerization of acrylonitrile,[7-11] furfurylideneacetone (**2**) can be said to undergo an over-all two-electron uptake at the cathode. This probably occurs in two one-electron stages. The radical anion (**2'**) may react with water (or the proton) before the second electron is taken up. The carbanion (**2''**) may attack highly-polarized molecules of the monomer attracted to the cathode. The interaction of the dione anion (**3'**) with water (or the proton) might terminate the reactions and yield 4,5-di(2-furyl)-2,7-octanedione (**3**).



Experimental

4-(2-Furyl)-3-buten-2-one (2). This material was prepared by the condensation of furfural with acetone by the method of G. J. Leuck *et al.*[12] Yellow crystals; mp 37—39 °C.

4,5-Di(2-furyl)-2,7-octanedione (3). To a solution of 10 g of 4-(2-furyl)-3-buten-2-one in 200 ml of methyl alcohol, 1 ml of conc. sulfuric acid was added; the mixture was then electrolysed in a Clauson-Kaas electrolyser[13] for 4 hr with 15 V, 1—2 A at −40——50 °C. A product was obtained by the subsequent filtration of the electrolyzed solution. Recrystallization from methyl alcohol gave colorless needles with a melting point of 123 °C; 0.5 g (5%). The experiments using other solvents and the water-mixed solvents were carried out under similar conditions.

Found: C, 70.25; H, 6.51%. Calcd for $C_{16}H_{18}O_4$: C, 70.06; H, 6.61%.

IR (cm^{-1}, KBr): 3125 ($\nu_{=C-H}$), 1708 ($\nu_{-C=O}$), 1511, 1020, 886, 758 (furan nucleus).

Formation of Trithiocarbonate by the Reaction of 2,2-Diphenylethylenesulfonamide and Carbon Disulfide

Kiyoshi HASEGAWA, Tadashi SASAKI,* and Syuzi HIROOKA

Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Takaoka-shi 933

**Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464*

(Received December 6, 1972)

We have reported[1-3] on the syntheses and intramolecular Michael cycloaddition of $RCH{=}CHSO_2N{=}CX{-}S^-M^+$ ($R{=}H$, $R^1C_6H_4$; $X{=}SR^2$, OR^2, NHR^2, $N(R^2)_2$, S^-M^+). The reaction of 2,2-diphenylethylenesulfonamide **1** with carbon disulfide and alkyl halides afforded unexpected trithiocarbonates. This paper describes the mechanism of these new reactions studied by the use of the carbon disulfide-^{35}S tracer technique.

Results and Discussion

The reaction of **1** with carbon disulfide and alkyl halides in the presence of base in DMF or DMSO gave alkyl 2,2-diphenylvinyl trithiocarbonates **2** as yellow crystals, **1** being recovered by acidifying the alkaline filtrate. The results are summarized in Table 1. The

$$\underset{\mathbf{1}}{(C_6H_5)_2C{=}CHSO_2NH_2} \xrightarrow[CS_2,\ RX]{:B} \underset{\mathbf{2}}{(C_6H_5)_2C{=}CH{-}S{-}\overset{\overset{S}{\|}}{C}{-}SR}$$

IR spectrum of **2a** displayed the strongest band at 1065 cm^{-1} due to the C=S bond,[4] but no absorption due to the SO_2 group. The NMR spectrum of **2a** exhibited a peak of the methine proton at δ 7.71. The mass spectrum showed a molecular ion peak at *m/e* 302.0270 assignable to a molecular formula $C_{16}H_{14}S_3$. Final structural elucidation of **2** was accomplished by the following degradation. Treatment of **2** with excess hydrazine afforded thiocarbohydrazid **3**, mp 167—168 °C (lit,[5] 168 °C), alkanethiol **4**, and *N,N'*-bis(2,2-diphenylvinyl)hydrazine **5** which was

$$\mathbf{2} \xrightarrow[N_2H_4]{} \underset{\mathbf{3}}{H_2NHN\overset{\overset{S}{\|}}{C}NHNH_2} + \underset{\mathbf{4}}{RSH} + ((C_6H_5)_2C{=}CHSH) \xrightarrow{N_2H_4} \underset{\mathbf{5}}{(C_6H_5)_2C{=}CHNHNHCH{=}C(C_6H_5)_2}$$

formed from 2 mol of 2,2-diphenylvinylthiol and 1 mol of hydrazine.

The yield of **2** increased with the amount of carbon disulfide and base added, but no further increase was observed when more than two equiv. of carbon disulfide and base were used. The reaction of **1** and carbon disulfide was quite rapid and a considerable yield (40%) of **2a** was obtained in a minute. The origin of three sulfur atoms in **2** were sought with carbon disulfide-^{35}S. Carbon disulfide-^{35}S was converted in to *N,N,N',N'*-tetramethylthiuram disulfide-^{35}S **6** by the usual method.[6] The specific activities of **6** and **2a** were found to be 25.84×10^5 dpm/mmol and 19.79×10^5 dpm/mmol, respectively. The fact that the relative ^{35}S atom ratio of **6** to **2a** was 4.00: 3.07 supports the mechanism that all the three sulfur atoms of **2** come from two moles of carbon disulfide. The trithiocarbonate formation was specific to the sulfonamide **1**. Neither *N,N*-dimethylsulfonamide nor 2-phenyl-2-methylethylenesulfonamide took part in it. The IR absorption peak at 2080 cm^{-1} due to the N=C=S bond was recognized in the reaction mixture of **1** and carbon disulfide. The following intramolecular rearrangement mechanism is proposed: (1) electrophilic attack of CS_2 on the N atom to form reactive **7**, (2) intramolecular S_N attack of thiolate anion on the 1-carbon atom with a loss of sulfinate anion, (3) cleavage of the C–S bond, (4) attack of CS_2 on the thiolate anion, and (5) alkylation.

The resonance stabilization of the diphenylmethylcarbanion **8** provides an important driving force which causes the thiolate anion attack on the 1-carbon atom. When DMF was removed *in vacuo* from the basic reaction mixture before alkylation, yellow hygroscopic crystals **12** ($\nu_{C=S}$ 1040, and 990 cm^{-1}) and a viscous oil ($\nu_{N=C=S}$ 2080 cm^{-1}) were obtained. This seems to be mainly composed of **11**, though it could not be

purified. Even when **1** and carbon disulfide were allowed to react for a minute followed by alkylation, **2** was the only product. This supports the view that conversion of **7** into **12** may proceed faster than the formation of **7**. The present rearrangement reaction seems to be a new case in which Smiles-type rearrangement can occur at a methine carbon atom[7] conjugated with two phenyl groups.

Experimental

All melting points are uncorrected. Specific activities of the labelled compounds were counted with a TEN-GSL-163 liquid scintillation counter using a mixture of POPOP and PPO (0.005 g and 0.4 g in 100 ml of toluene) as a scintillator.

Specific Activity of Carbon Disulfide-^{35}S Stock Solution. Radioactive carbon disulfide (2.7 mCi of ^{35}S in 15 mg) was transferred into unlabelled carbon disulfide (10 ml) by means of a vacuum line. Approximately 0.5 ml of this solution was diluted with unlabelled carbon disulfide (10 ml) to provide the stock solution used in reactions leading to labelled products. *N,N,N',N'*-Tetramethylthiuram disulfide-^{35}S was prepared from the carbon disulfide-^{35}S stock solution by the usual method[6] and its specific activity was measured.

Liquid Scintillation Counting. The radioactivity of each sample in count per minute (cpm) was measured three times with different weighing, disintegration value per minute (dpm) being obtained in reference to the quenching calibration curve.

2,2-Diphenylethylenesulfonamide ***1***. In an analogous manner to that described by B. M. Culbortson[8] for the synthesis of 2-phenylethylenesulfonamide, 1,1-diphenylethylene (48.0 g, 0.266 mol) was treated with sulfuryl chloride (60 g, 0.445 mol) in DMF (60 ml) to give 13.5 g (17%) of 2,2-diphenylethylenesulfonyl chloride. The sulfonamide was prepared in 79% yield from crude sulfonyl chloride in benzene and 28% aqueous ammonia. Recrystallization from water gave colorless crystals, mp 136—137 °C. IR (KBr): 3340 and 3240 (NH_2), 3030 (=CH), 1585 (C=C), 1310 and 1130 (SO_2) cm^{-1}. NMR (DMSO-d_6): δ 6.92 (s, 1H, =CH), 6.96 (s, 2H, NH_2), and 7.34±0.10 (m, 10H, diphenyl). Mass spectrum (75 eV) *m/e* (rel. intensity): 89 (33, $C_6H_5C^+$), 93 (8, $C^+HSO_2NH_2$), 102 (10, $C_6H_5C{=}C^+H$), 152 (20, $2C_6H_4^+$), 165 (14) and 167 (15, $(C_6H_5)_2C^+\pm H$), 178 (100, $(C_6H_5)_2C{=}C^+$), 179 (70, $(C_6H_5)_2C{=}CH^+$), 195 (23, M^+-SO_2), and 259 (53, M^+).

Found: C, 64.71; H, 4.92; N, 5.34; S, 12.38%. Calcd for $C_{14}H_{13}NO_2S$: C, 64.86; H, 5.05; N, 5.40; S, 12.35%.

Labelled Trithiocarbonate from ***1****, Carbon Disulfide-^{35}S and Methyl Iodide.* To a stirred solution of **1** (0.78 g, 3.0 mmol) in DMF (8.0 ml) were added carefully sodium hydroxide (0.24 g, 6.0 ml) in water (0.5 ml) and then a carbon disulfide-^{35}S stock solution (0.57 g, 7.5 mmol) at room temperature. The orange-yellow reaction mixture was stirred for 2 hr. Methyl iodide (0.51 g, 3.6 mmol) was then added drop by drop at 20—30 °C. The yellow reaction mixture was stirred for 2 hr at 20—30 °C, and poured into ice water (100 ml), and the resulting alkaline solution was left to stand overnight. The yellow crystals were collected and thoroughly washed twice with 20 ml portions of 1M sodium hydroxide solution to give 0.50 g (55%) of **2a**. Recrystallization from methanol gave yellow crystals. The alkaline filtrate was acidified with concentrated hydrochloric acid to recover 0.27 g (35%) of **1**. The IR, NMR, and mass spectra of unlabelled trithiocarbonate are given below. IR (KBr): 3020 (=CH), 1595 (C=C), 1065 (C=S), 815, 755 and 690 cm^{-1}. NMR ($CDCl_3$): δ 2.80 (s, 3H, CH_3), 7.34 (m, 10H, diphenyl), and 7.71 (s, 1H, =CH). Mass spectrum (75 eV) *m/e* (rel. intensity): 91 (100, C^+SSCH_3), 152 (7, $2C_6H_4^+$), 165 (15) and 167 (7, $(C_6H_5)_2C^+\pm H$), 178 (28, $(C_6H_5)_2C{=}C^+$), 179 (11, $(C_6H_5)_2C{=}CH^+$), 210 (21, $(C_6H_5)_2C{=}CS^+$), 211 (31, $(C_6H_5)_2C{=}CHS^+$), 226 (15, M^+-CS_2), 255 (4, M^+-SCH_3), and 302.0270 (43, calcd molecular weight, 302.0257).

Reaction of ***2*** *with Hydrazine.* Methanethiol was evolved when a solution of **2a** (1.46 g, 4.8 mmol) and 80% hydrazine hydrate (0.75 g, 15 mmol) in ethanol (50 ml) was refluxed for 3.5 hr. The reaction mixture was cooled overnight. Light pink precipitates (0.33 g, 65%) of **3** were obtained. Evaporation of the ethanol from the basic filtrate *in vacuo* left a yellow oily product which was acidified with sulfuric acid under cooling to afford a soft solid. It was triturated with ether to yield colorless crystals. Recrystallization from benzene-petroleum ether gave 0.64 g (69%) of **5**, mp 156—157 °C. IR (KBr): 3400 (weak, NH), 3020 (=CH), 1630 (NH), 1590 (C=C), 1490, 1450, 750, 740, and 690 cm^{-1}. NMR ($CDCl_3$): δ 5.02 (d, 2H, 2=CH), 8.25 (d, 2H, 2NH, J_{CHNH}=7.5 Hz), and 7.27 (m, 20H, phenyl). Mass spectrum (75 eV) *m/e*: 388 (M^+).

Found: C, 86.56; H, 6.06; N, 7.45%. Calcd for $C_{28}H_{24}N_2$: C, 86.56; H, 6.23; N, 7.21%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2896—2897 (1973)

A Copper(II) Complex of 1,1′-Diacetylferrocene Bis(thiosemicarbazone)

Yoshimori OMOTE, Ryuichiro KOBAYASHI, and Noboru SUGIYAMA
Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo 112

(Received December 14, 1972)

During the course of an investigation of the intramolecular interaction between substituents in 1,1′-disubstituted ferrocenes, we examined the possibility of the intramolecular bridging in complexation of 1,1-diacetylferrocene derivatives. Among many reports on complexes of substituted ferrocenes with inorganic acceptors, there have been a few examples about complexes of 1,1′-disubstituted ferrocenes.[1-4] Hauser and Cain[1] reported a copper(II) complex of 1,1′-dibenzoylacetylferrocene in which cupric ion played a role of an electron acceptor and β-dicarbonyl group played a role of an electron donor. Pavlik and Handlir[2] reported that in the complex of 1,1′-diacetylferrocene with aluminum chloride both carbonyl groups were bound to the monomeric aluminum chloride.

These examples are characteristic to have C=O bonding in donor group. Now we want to report the synthesis and structure of copper complex of 1,1′-diacetylferrocene bis-thiosemicarbazone in which C=N bonding is expected to play a role of a donor.

Acetylferrocene thiosemicarbazone (I) and 1,1′-diacetylferrocene bis-thiosemicarbazone (II) were prepared by treatment with thiosemicarbazide. The structure of thiosemicarbazones I and II is in accordance with elemental analyses and the infrared spectra, especially absorptions by N–H stretching vibrations at 3445 to 3150 cm^{-1} and absorptions by C=N group at 1606 cm^{-1} being observed.

The copper(II) complex of acetylferrocene thiosemicarbazone (III) was prepared by treating with cupric acetate. The elemental analysis supports the structure III. In the infrared spectrum of III the intensity of the C=N band at about 1600 cm^{-1} has increased in comparison with that of the corresponding thiosemicarbazone. On the basis of this evidence, it is reasonable to suggest the structure III for the compound.

The copper(II) complex of 1,1′-diacetylferrocene bis-thiosemicarbazone (IV) was prepared in the similar manner as above. From the similarity of the infrared spectrum of this complex IV to that of III, it can be assumed that the structure around cupric ion of this compound is similar to that of III. In order to ascertain this suggestion, the changes of the absorption spectrum of I and II in ethanol by addition of cupric acetate were examined. As shown in Fig. 1, with a decrease in molar ratio of I to cupric acetate, the intensity of the band at 308 nm decreased, while that of the band at 328 nm increased. The absorption spectrum of an equimolar mixture of the thiosemicarbazone and cupric acetate gives a spectrum almost identical with that of III, indicating the formation of the complex III. There is an isosbestic point at 326 nm indicating that only two species, I and III, are present.

The absorption spectra in a series of molar ratio of II to cupric acetate are shown in Fig. 1. The change of absorption spectra with the decrease in molar ratio are very similar to the former case. The absorption spectrum of IV cannot be measured because of its slight solubility, but the absorption spectrum in molar ratio of 1 : 2, in which the formation of the complex appears to be completed, is very close to that of III. These facts also support the structure III and IV.

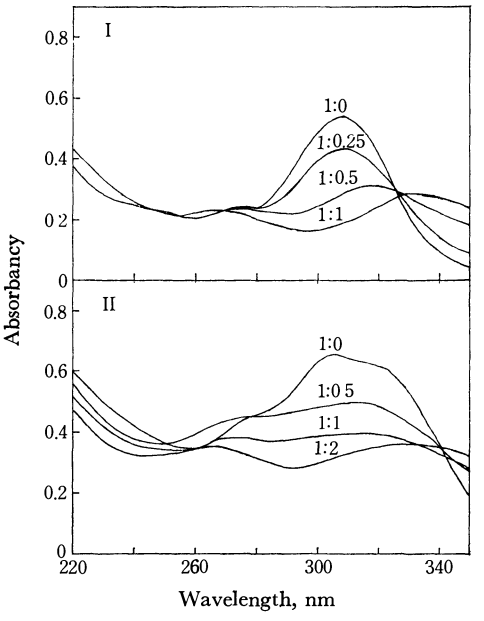

Fig. 1. The changes of the absorption spectra of acetylferrocene thiosemicarbazone(I) and 1,1′-diacetylferrocene thiosemicarbazone(II) upon the addition of cupric acetate. The figures give the molar ratio of thiosemicarbazones (2×10^{-5} mol/l) to cupric acetate.

Experimental

Acetylferrocene Thiosemicarbazone (I). The method for the preparation of copper(II) complex of formylferrocene

1) C. R. Hauser and C. E. Cain, *J. Org. Chem.*, **23**, 1142 (1958).
2) I. Pavlik and K. Handlir, *Collect. Czech. Chem. Comm.*, **31**, 1958 (1966).
3) I. Pavlik, J. Klikorka, and K. Handlir, *Z. Chem.*, **8**, 390 (1968).
4) E. B. Moynaham, F. D. Popp, and M. F. Werneke, *J. Organometal. Chem.*, **19**, 229 (1969).

thiosemicarbazone[5] was modified and used. Acetylferrocene (5 mmol) in ethanol (20 ml) was added dropwise to a solution of thiosemicarbazide (5 mmol) in water (30 ml). Glacial acetic acid (1 ml) was then added and the resulting mixture was heated in a steam bath for 1.5 hr. After the mixture was cooled the precipitate was collected, washed with aqueous ethanol, dried, and recrystallized repeatedly from ethanol, red crystals, mp 176.5—177.5 °C; yield 43%.

Found: C, 51.73; H, 4.97; N, 14.20%. Calcd for $C_{13}H_{15}FeN_3S$: C, 51.90; H, 5.00; N, 14.00%. IR (KBr) cm^{-1}: 3420, 3285, 3180, 1606, 1591. UV: λ_{max}^{EtOH} nm(ε) 239 (12600), 273 (12400), 308 (27100), 455 (960). NMR (DMSO-d_6): τ 0.10 (s, 1H), 2.00 (bs, 1H), 2.40 (bs, 1H), 5.23 (t, 2H), 5.65 (t, 2H), 5.83 (s, 5H), 7.80 (s, 3H).

1,1′-Diacetylferrocene Bis-thiosemicarbazone (II). In a similar manner as described above, the title compound was prepared and recrystallized repeatedly from ethanol, red crystals, mp 163—164.5 °C; yield 60%.

Found: C, 44.63; H, 5.26; N, 19.27%. Calcd for $C_{16}H_{20}FeN_6S_2$–H_2O: C, 44.25; H, 5.11; N, 19.35%. IR (KBr) cm^{-1}: 3445, 3250, 3150, 1606, 1593. UV: λ_{max}^{EtOH} nm(ε) 280 (22700), 305 (33000), 318 (31300), 458 (1570). NMR (DMSO)-d_6): τ 0.11 (s, 2H), 1.97 (m, 2H), 2.37 (m, 2H), 5.22 (t, 4H), 5.65 (t, 4H), 7.88 (s, 6H).

Copper(II) Complex of Acetylferrocene Thiosemicarbazone (III). Cupric acetate (2.5 mmol) in 25 ml of ethanol was added to a warm solution of acetylferrocene thiosemicarbazone (5 mmol) in 25 ml of ethanol. The resulting mixture was warmed at 70 °C for 1 hr. The precipitate, which formed after cooling, was removed by filtration, washed with aqueous hydrochloric acid solution, water, and cold ethanol, and dried, black powder, mp 160—161 °C; yield 59%.

Found: C, 46.84; H, 4.65; N, 12.05%. Calcd for $C_{26}H_{28}CuFe_2N_6S_2$: C, 47.00; H, 4.20; N, 12.60%. IR (KBr) cm^{-1}: 3465, 3425, 3325, 3200, 3095, 1611, 1598. UV: λ_{max}^{EtOH} nm(ε) 261 (10800), 328 (12000), 431 (1970).

Copper(II) Complex of 1,1′-Diacetylferrocene Bis-thiosemicarbazone (IV). In a similar manner as described above, the copper complex of 1,1′-diacetylferrocene bis-thiosemicarbazone was prepared, brown powder, mp>300 °C; yield 80%. The purification by recrystallization of this copper complex was very difficult because of its slight solubility in most solvents.

Found: C, 39.22; H, 4.02; N, 16.06%. Calcd for $(C_{16}H_{18}CuFeN_6S_2)_n$: C, 40.20; H, 3.77; N, 17.60%. IR (KBr) cm^{-1}: 3440, 3340, 3170, 1614, 1588.

UV Spectra of Copper(II) Complexes of Acetylferrocene Thiosemicarbazone and 1,1′-Diacetylferrocene Bis-thiosemicarbazone. The UV absorption spectra were measured in ethanol. The molar ratio of acetylferrocene thiosemicarbazone and cupric acetate were 1:0, 1:0.25, 1:0.5, and 1:1, while those of 1,1′-diacetylferrocene bis-thiosemicarbazone and cupric acetate were 1:0, 1:0.5, 1:1, and 1:2.

Reactions of Diazoacetophenones in the Presence of Metal Chelates. V. Reaction of *o*-Methoxy-α-diazoacetophenone

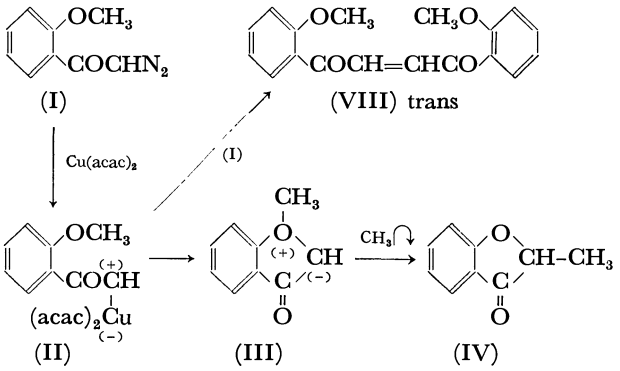
Toshikazu IBATA, Kozaburo UEDA,* and Matsuji TAKEBAYASHI**

Department of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received December 25, 1972)

The predominant formation of carbonyl ylides takes place by the intramolecular attack of carbenoid on a carbonyl group in the copper chelate-catalyzed decomposition of *o*-alkoxycarbonyl-α-diazoacetophenones.[1] A similar facilitation might be expected in the formation of oxonium ylide by the intramolecular attack of carbenoid-carbon on ether oxygen at *ortho* position. The copper chelate-catalyzed decomposition of *o*-methoxy-α-diazoacetophenone was carried out, and formation of the oxonium ylide was confirmed.

Decomposition of *o*-methoxy-α-diazoacetophenone (I) was carried out in benzene solution containing a catalytic amount of bis(acetylacetonate)copper. Column chromatography of the reaction mixture on silica gel gave 2-methylcoumaranone (IV, 52%), bis-(*o*-methoxybenzoyl)ethylene (VIII, 7%) and a carbene-oligomer (30%).[2] Dibenzoylethylene (VIII), the formal dimer of the carbene intermediate, is considered to be obtained by the reaction of the carbene (II)



Scheme 1.

2) The oligomer showed a similar IR spectrum to that described before (M. Takebayashi, T. Ibata, and K. Ueda, This Bulletin, **43**, 1500 (1970)).

with starting diazo compound (I)[3] competing with the formation of IV. Formation of IV might be explained by assuming the intermediacy of an oxonium ylide (III) produced by the intramolecular electrophilic attack of the carbenoid carbon on the ether oxygen atom, followed by methyl migration (Scheme 1).

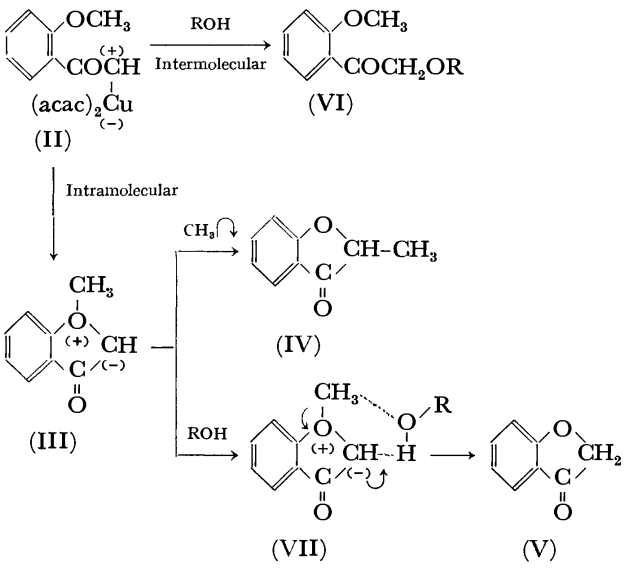
Since the copper chelate-catalyzed decomposition of diazoketones in alcohols gives the corresponding keto-ethers,[4] facility of the oxonium ylide formation was investigated utilizing the competitive reaction between intramolecular formation of the oxonium ylide and the intermolecular reaction with alcohols. The copper-catalyzed decomposition of I was carried out in a mixed solvent of alcohol and benzene in various proportions at 80 °C for 30 min. A soluble part of the reaction mixture in *n*-heptane was analyzed by gas chromatography. Coumaranone (V), 2-methylcoumaranone (IV) and keto-ether (VI) were characterized and determined quantitatively by comparing their retention times with those of authentic samples. Molar ratios of the products are listed in Table 1.

Table 1. Decomposition of I in alcohol-benzene solution

Alcohol	wt% of Alc.	Products				
		IV	V	VI	V/IV	VI/IV+V
EtOH	50	10.8	10.9	78.3	1.01	3.61
	10	13.9	12.2	73.9	0.88	3.83
	5	14.7	12.9	72.4	0.88	2.62
	2	18.0	14.1	67.9	0.78	2.12
	1	20.8	16.9	62.3	0.81	1.65
t-BuOH	30	26.4	7.0	66.6	0.24	1.99
	10	36.4	6.9	56.7	0.19	1.31
	2	42.1	5.6	52.2	0.12	1.09
	1	49.3	2.4	48.3	0.05	0.93

With the decrease of alcohol concentration in ethyl alcohol–benzene solution, the yields of VI decreased and those of both VI and V increased. This suggests that the formation of keto-ether (VI) depends upon the concentration of alcohol and competes with the formation of IV and V. Although coumaranone (V) is produced in the acid catalysis[5] of I, a control experiment showed that I did not give V under refluxing in an alcohol–benzene solution in the absence of $Cu(acac)_2$ catalyst. Contribution of alcohol to the formation of V was supported by the fact that V was not obtained in a benzene solution in the presence of $Cu(acac)_2$ without alcohol. Decrease in the value of V/IV with the decrease in alcohol concentration is consistent with the above assumption.

Thus the formation of V might be explained in terms of the intermediacy of oxonium ylide (III) which reacts with alcohols affording coumaranone (V) *via* VII (Scheme 2).



Scheme 2.

Keto-ether (VI) can be obtained by the intermolecular reaction of carbenoid (II) with alcohol competing with the intramolecular formation of the oxonium ylide (III) which gives IV and V by successive reactions. The ratio V/(IV+V) (Table 1) which decreases with decrease in alcohol concentration supports the mechanism shown in Scheme 2.

In the case of *t*-butyl alcohol, similar results were obtained except for the yields of V, which decrease with decrease in alcohol concentration. The ratio VI/IV is one third of that in ethyl alcohol reflecting the reactivity of alcohols toward copper-carbenoid (II).[4]

On the other hand, a product which could be formed through the corresponding oxonium ylide generated by the intermolecular carbenoid reaction was not recognized in a catalytic decomposition of α-diazoacetophenone in anisole in spite of careful inspection of the products.

Experimental

Material. *o*-Methoxy-α-diazoacetophenone (I) was prepared by slow addition of an ethereal solution of *o*-methoxybenzoyl chloride[6] to a large excess (about 3 molar equivalents) of cold ethereal diazomethane.[7] The oily product obtained by the evaporation of ether after drying over $MgSO_4$ was used for the reaction without further purification. IR (neat): 2200 (C=N=N), 1605 (C=O of diazoketone), 1250 (C-O-C), and 755 cm^{-1} (Ph). The elemental analysis of I was satisfactory.

Catalytic Decomposition of I in Benzene. In a flask fitted with a dropping funnel and a reflux condenser connected to a gas burette was placed 0.05 g (0.19 mmol) of $Cu(acac)_2$ dissolved in 50 ml of benzene. To the solution was added dropwise a solution of I (5.8 mmol) in 30 ml of benzene. The evolution of nitrogen was almost quantitative. When it was over, the reaction mixture was separated by silica gel

chromatography. 2-Methylcoumaranone (IV, 0.439 g, 52%) accompanied by bis(*o*-methoxybenzoyl)ethylene (VIII, 0.059 g, 7%) and an oligomer of *o*-methoxybenzoylcarbene (0.253 g, 30%)[2] was obtained. IR (neat) of IV: 1720 (C=O), 1245 (C–O–C), and 755 cm^{-1} (Ph). NMR ($CDCl_3$) of IV: 2.2—3.2 (m, 4H, aromatic proton), 5.65 (q, 1H, methine-H), and 8.61 τ (t, 3H, CH_3). Found: C, 73.12; H, 5.40%. Calcd for $C_9H_8O_2$: C, 72.96; H, 5.44%.

Competitive Reaction of I in Alcohol–Benzene Solution. A solution of I (5.7 mmol) in a mixed solvent (30 ml) of alcohol–benzene was added dropwise to 50 ml of mixed solvent of same composition containing $Cu(acac)_2$ (0.05 g, 0.19 mmol) at 80 °C. After evaporation of solvent under reduced pressure, the reaction mixture was treated with *n*-heptane, and the soluble part in *n*-heptane was analyzed quantitatively by gas chromatography. The product ratios obtained are given in Table 1. Coumaranone (V) was isolated by preparative gas chromatography (and silica gel column chromatography) of the reaction mixture. IR (KBr) of V: 1720 (C=O), 1460 (CH_2), 1190 (C–O–C), and 764 cm^{-1} (Ph). NMR ($CDCl_3$) of V: 2.2—3.1 (m, 4H, aromatic proton) and 5.40 τ (s, 2H, CH_2).

Syntheses and Reactions of Metal Organics. VIII. The Formation of 2,5-Piperazinediones from Metal Alkoxides and α-Amino Acids

Norio Yoshino and Takeshi Yoshino

Department of Industrial Chemistry, Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received January 18, 1973)

In preliminary studies of the yellowing of wool by ultraviolet light[1] it was observed that the pretreatment of wool with an alkyl titanate, for example, tetra-*n*-butyl titanate, protects wool from yellowing. It has been proved that this protection is not due to the screening of wool from ultraviolet light by the titanate. Other observations have suggested that the titanates may react with proteins, peptides, and amino acids. Many reactions of metal (IV) alkoxides and metal (IV) chlorides with amines, amides, and carboxylic acids have been studied,[2] but few with amino acids have been studied. The present investigation is concerned with the reactions of titanium isopropoxide, *n*-butoxide, and zirconium isopropoxide with glycine and DL-α-alanine.

On heating α-amino acids, two moles of them condense to 2,5-piperazinediones, but the products are colorized by partial thermal decomposition. On the addition of metal alkoxides, they acted as dehydrating agents on α-amino acids in the presence of alcohols, but did not do so in hydrocarbon solvents.

The reactions proceeded as follows:

$$2H_2NCHRCOOH + 2M(OR')_4 \longrightarrow [RCHCONH]_2 + 2M(OR')_2O + 4R'OH$$

(R=H or Me, R'=^{i}Pr or ^{n}Bu, M=Zr or Ti)

Experimental

Reaction of Zirconium Isopropoxide with Glycine. A mixture of glycine (2.0 g, 27 mmol) and zirconium isopropoxide (13.1 g, 40 mmol) in 50 ml of ethyl alcohol was heated to boiling while being stirred. The glycine dissolved completely within 2 hr. On heating at the boiling point of the clear solution for 1.5 hr, some precipitates began to appear. Heating was continued for 20 hr in order to complete the precipitation. The white precipitates obtained were washed with cold ethyl alcohol and dried under a vacuum; yield, 1.1 g; mp 309 °C (decomp.). The product was identified with 2,5-piperazinedione by means of its melting point (lit,[3] mp 311—312 °C) and its IR spectrum.

Reaction of Zirconium Isopropoxide with DL-α-*Alanine.* The isolation of 3,6-dimethyl-2,5-piperazinedione (0.7 g) from DL-α-alanine (2.0 g, 22 mmol) and zirconium isopropoxide (11.0 g, 33 mmol) was accomplished in the same way as has been described for the preceding experiment; mp 268—269 °C (lit,[4] mp 271 °C). The IR spectrum of this product was identical with that of an authenic specimen.

Reactions of Titanium Alkoxides with Glycine. A mixture of glycine (2.0 g, 27 mmol) and titanium isopropoxide (11.3 g, 40 mmol) in 50 ml of isopropyl alcohol was heated to boiling with stirring. The glycine did not dissolve completely, but a light brown powder (1.5 g) was obtained after 20 hrs' heating; mp 307.5—308.5 °C (decomp.).

From the reaction of titanium *n*-butoxide (13.6 g, 40 mmol) and glycine (2.0 g, 27 mmol) in ethyl or isopropyl alcohol, a light brown powder (1.1—1.5 g) was also obtained. These products were identified with 2,5-piperazinedione.

Reaction of Titanium n-*Butoxide with* DL-α-*Alanine.* From the reaction of titanium *n*-butoxide (11.2 g, 33 mmol) and DL-α-alanine (2.0 g, 22 mmol) in 50 ml of methyl, ethyl, or isopropyl alcohol, colorless needles (0.7—0.8 g) were formed. All the products melted at 267 °C and were identified with 3,6-dimethyl-2,5-piperazinedione.

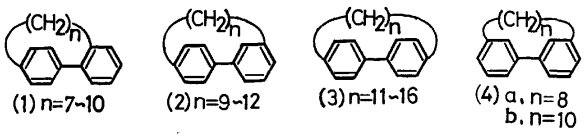
Syntheses and Properties of *m,m'*-Polymethylenebiphenyls

Koji YAMAMOTO, Yosihiko NAITO, Yukiyasu TANAKA, and Masao NAKAZAKI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received January 26, 1973)

Reports were given on the preparation of three systems of compounds (**1**), (**2**), and (**3**), with varying lengths of polymethylene bridge spanning *o,p'*-, *m,p'*-, and *p,p'*-positions of biphenyl, respectively.[1-3]



The present communication describes the syntheses and properties of biphenyls (**4**) with *m,m'*-polymethylene bridge.[4]

Preparation of (**4**) was carried out according to the sequence of reactions illustrated in Chart 1. The usual sequence involving malonic ester synthesis and LAH reduction is extended to the side chains of dibromide (**5a**), *via* (**5b**), and (**5c**), to give the homologous dibromide (**5d**). The malonic ester synthesis applied to the resulting dibromide (**5d**) afforded diester (**5g**), mp 48—49 °C, which was cyclized to acyloin (**6**) by the Prelog-Stoll acyloin condensation. The Clemmensen reduction of (**6**) gave *m,m'*-decamethylenebiphenyl (**4b**), mp 58—59 °C.

Because of severe steric strain in the lower homolog *m,m'*-octamethylenebiphenyl (**4a**), its synthesis was effected only by making a detour through the more flexible intermediates (**7**), (**8**), and (**9**) with saturated biphenyl moiety.

Hydrolysis followed by esterification of dinitrile (**5e**) secured from dibromide (**5d**), afforded diester (**5f**). Catalytic hydrogenation (1 atm, room temperature) over Adams' catalyst of ester (**5f**) in acetic acid gave saturated ester (**7**), which was cyclized by acyloin condensation to yield saturated acyloin (**8**). The Clemmensen reduction of (**8**) afforded saturated hydrocarbon (**9**).

The final step of the synthesis was dehydrogenation of (**9**) by heating with 10% Pd/C catalyst at 260—300 °C for 3 hr yielding *m,m'*-octamethylenebiphenyl (**4a**), mp 73—74 °C. Dehydrogenation under more drastic conditions (360—390 °C for 3 hr) converted (**9**) into perylene (**10**) apparently *via* biphenyl derivative (**4a**).

The electronic spectrum of *m,m'*-polymethylenebiphenyls (**4**) (**4a**: λ_{max} 253 nm, log ε 4.22; **4b**: λ_{max} 253 nm, log ε 4.21 in *n*-hexane) shifts towards longer wavelength with higher intensity compared to the reference compound (3,3'-dimethylbiphenyl: λ_{max} 250 nm, log ε 4.20 in *n*-hexane).

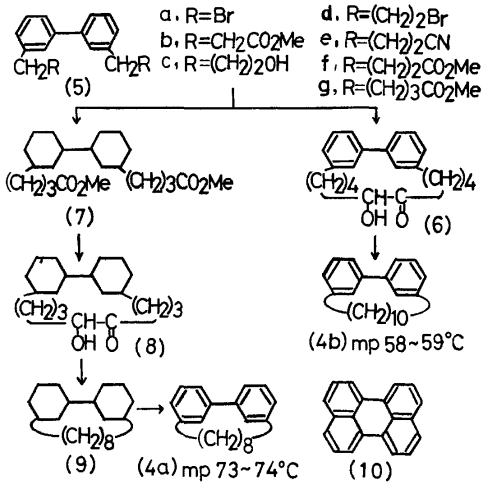


Chart 1

The NMR data of the *m,m'*-polymethylenebiphenyls are shown in Table 1. Absorptions due to the hydrogens of polymethylene bridges appear at lower field than those of the polymethylene in *o,p'*-, *m,p'*-, and *p,p'*-polymethylene bridged biphenyls. Among the *m,m'*-polymethylenebiphenyl derivatives (**4**), the methylene hydrogens of the lower homolog (**4a**) (8.45 τ) absorb at lower field than the higher homolog (**4b**) (8.67 τ).

TABLE 1. NMR SPECTRAL DATA IN CARBON TETRACHLORIDE

Compound	Aromatic protons, τ	Aliphatic protons, τ		
4a	2.62—3.15 (8H)	7.31 (4H)	8.33 (4H)	8.67 (12H)
4b	2.49—3.15 (8H)	7.26 (4H)	8.30 (4H)	8.45 (8H)

The results can be rationalized by assuming that the *m,m'*-polymethylene bridges in the biphenyl derivatives (**4**) are coplanar with the molecular planes as shown by molecular models, and that they are deshielded by the biphenyl moieties, the deshielding being apparently more effective in the shorter bridged compound (**4a**) than in (**4b**).

Experimental

m,m'-*Bis-(3-carbomethoxypropyl)-bicyclohexyl* (**7**). Six grams of diester (**5f**) was hydrogenated with 0.6 g of platinum oxide in 45 ml of acetic acid at 40 °C under 1 atmosphere. The reaction stopped after 70 hr when 90% of the theoretical amount of hydrogen had been absorbed. The catalyst was removed by filtration, the solvent was evaporated in a vacuum, and the product was distilled to yield a colorless liquid, bp 142—144 °C/0.05 mmHg, 5.4 g (87%).

4) R. V. M. Campbell, L. Crombie, B. Tuck, and D. A. Whiting, *Chem. Commun.*, 1206 (1970).

4-Hydroxy-5-oxo-m,m′-*octamethylenebicyclohexyl (8)*. A solution of 2.7 g of the saturated diester (**7**) in 150 ml of xylene was added to a suspension of 1.2 g of sodium in 400 ml of xylene over 48 hr under nitrogen atmosphere. The usual work-up[5] of the reaction mixture then gave crude acyloin (**8**), 1.2 g (53%).

m,m′-*Octamethylenebicyclohexyl (9)*. Amalgamated zinc was prepared by swirling 33 g of zinc with a solution of 1 g of $HgCl_2$ and 1 ml of concd HCl in 100 ml of water. A solution of 1.2 g of acyloin (**8**) in 30 ml of toluene was added to the amalgamated zinc with 100 ml each of concd HCl and acetic acid. The mixture was heated under reflux for 48 hr, during which time four 20 ml-portions of concd HCl were added. After the usual treatment, the crude reaction product was distilled to yield a colorless liquid, bp 116—118 °C/0.1 mmHg, 0.5 g (46%).

Found: C, 86.23; H, 13.19%. Calcd for $C_{20}H_{36}$: C, 86.88; H, 13.12%.

m,m′-*Octamethylenebiphenyl (4a)*. Dehydrogenation of 0.5 g of saturated hydrocarbon (**9**) was accomplished by heating with 0.04 g of 10% palladium-on-charcoal at 260—300 °C for 3 hr. The theoretical amount of hydrogen was evolved, the reaction product was taken up in *n*-hexane, filtered free of catalyst and crystallized from ethanol to give 0.3 g (63%) of (**4a**), needles, mp 73—74 °C.

Found: C, 90.71; H, 9.32%. Calcd for $C_{20}H_{24}$: C, 90.80; H, 9.26%.

5-Hydroxy-6-oxo-m,m′-*decamethylenebiphenyl (6)*. The acyloin reaction was carried out in a manner similar to that described for (**8**). From 11 g of diester (**5g**) was obtained 4.2 g (51%) of the crude acyloin (**6**).

m,m′-*Decamethylenebiphenyl (4b)*. Four grams of acyloin (**6**) was converted into hydrocarbon with zinc and acid as described for (**9**). The product was isolated in the usual way and recrystallization from ethanol gave 0.8 g (21%) of (**4b**), needles, mp 58—59 °C.

Found: C, 90.11; H, 10.03%. Calcd for $C_{22}H_{28}$: C, 90.23; H, 9.88%.

Electrocatalytic Chemistry of the Transition Metal Complexes. III. Dehydrogenation of Cyclohexadienes Catalyzed by the Electro-reduced Cobalt Complex of $\alpha,\beta,\gamma,\delta$-Tetraphenylporphine

Hironori KAGEYAMA, Masanobu HIDAI, and Yasuzo UCHIDA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received February 14, 1973)

Although there are some reports on the disproportionation of 1,3- and 1,4-cyclohexadiene (CHD) to produce benzene and cyclohexene,[1] only a few reports have appeared in which 1,3- and 1,4-CHD were dehydrogenated to produce benzene by using the homogeneous transition metal complexes such as the metal complexes of $\alpha,\beta,\gamma,\delta$-tetraphenylporphine (M(TPP)),[2] and dichloropalladium(II).[3]

In the previous papers,[4,5] the authors reported that the electro-reduced Co(TPP) had the catalytic activity of dehydrogenating cyclohexene to 1,3- and 1,4-CHD, and benzene (Bz). In this paper, the dehydrogenation reaction of 1,3- and 1,4-CHD by using the same catalyst will be described.

Experimental

Tetra-*n*-butylammonium perchlorate (TBAP),[6] Co(TPP),[7] 1,4-CHD,[8] and 1,3-CHD[9] were prepared according to the published methods. The conditions of electrolysis were: the concentration of Co(TPP), 1.0×10^{-3} mol/l; the concentration of TBAP, 2.0×10^{-1} mol/l; solvent, 10.0 ml; an anode, a platinum wire; a cathode, a platinum plate (the electrode area, 3.0 cm^2); a reference electrode, a silver wire; potential, -2.0 V; temperature, room temperature; reaction time, 24 hr; atmosphere, nitrogen; a electrolyzer, a Yanagimoto Controlled Potential Electrolyzer Model VE-3S; and an electrolytic cell, an H-type cell with a side arm to enable the insertion of an Ag wire reference electrode. The quantitative analysis of the products was performed by glc. The visible spectra of the reaction solution after electrolysis were measured using a Shimadzu Model MPS-50L Spectrophotometer.

Results and Discussion

Dehydrogenation of 1,3- and 1,4-CHD. The current efficiency for formation of benzene was defined as

Table 1. Dehydrogenation of 1,3- and 1,4-cyclohexadiene catalyzed by the electro-reduced Co(TPP) in various solvents

Solvent	CHD	CHD/Co molar ratio	Composition of the products (%)					η'_{Bz} (%)[c]
			cC_6[a]	cC_6'[b]	1,3-CHD	1,4-CHD	Bz	
DMF	1,3	159	0	0	100	0	0	0
	1,4	128	0	6.1	15.5	68.9	6.0	104
HMPT	1,3	154	0	0	100	0	0	0
	1,4	131	0	0	0	93.0	7.0	81.2
PhCN	1,3	147	0	0	87.0	7.0	6.0	126
	1,4	121	4.5	0	0	75.7	19.8	408

Conditions: an anode, a Pt wire; a cathode, a Pt plate; a reference electrode, an Ag wire; the concentration of Co(TPP), 1.0×10^{-2} mol/l, the concentration of TBAP, 2.0×10^{-1} mol/l, potential, -2.0 V; solvent, 10.0 ml; temperature, r.t.; reaction time, 24 hr.
a) cyclohexane b) cyclohexene c) current efficiency for formation of benzene.

follows:

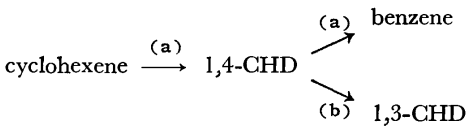
$$\eta'_{Bz}\,(\%) = (\text{Amount of Bz(mole)})\times 200/\text{Current passage (Faraday)}$$

The results are shown in Table 1. In the electrolysis of 1,4-CHD with the use of dimethylformamide (DMF), hexamethylphosphoric triamide (HMPT), and benzonitrile (PhCN) as the solvent, the current efficiencies were higher than 100%, indicating that the dehydrogenation reaction is catalytic. The current efficiencies in the electrolysis of 1,3-CHD were much lower than those in the electrolysis of 1,4-CHD. Furthermore, the current efficiency in the case of PhCN used as the solvent was much higher than the current efficiencies in that of DMF and HMPT used.

In the 1,4-CHD–DMF system, 1,4-CHD was isomerized to produce 1,3-CHD. Cyclohexene and benzene were also produced in the same system, which are considered to be derived from the disproportionation of 1,4-CHD, since the amount of benzene was about equal to that of cyclohexene.[1] In the 1,4-CHD–HMPT system, 1,4-CHD was dehydrogenated to afford benzene, but 1,3-CHD was not observed in the reaction system.

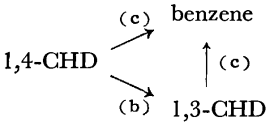
In the 1,3-CHD–PhCN system, 1,3-CHD was isomerized to give 1,4-CHD, and was also dehydrogenated to produce benzene. However, in the 1,4-CHD–PhCN system, 1,4-CHD was not isomerized, but was dehydrogenated to produce benzene, and a little amount of cyclohexane was formed.

The reaction schemes in the case of the above three solvents used are summarized as follows:
in the case of DMF used as the solvent;



in the case of HMPT used as the solvent;

in the case of PhCN used as the solvent;



(a) disproportionation, (b) isomerization, (c) dehydrogenation

Effect of Addition of Methanol. The current efficiencies decreased with the addition of dry methanol to the reaction solution as shown in Table 2. The similar results have been reported in the dehydrogenation of cyclohexene catalyzed by the electro-reduced Co(TPP).[5] It may be reasonable to assume that added alcohol reacts with the conjugated ring of the catalytically active electro-reduced Co(TPP) to cleave or weaken the conjugated ring.

The Visible Spectra of the Reaction Solution after Electrolysis. In the visible spectrum of the HMPT solution containing 1,4-CHD after electrolysis, the new bands appeared at 620 and 417 nm, which were assigned to the Q-band and Soret-band, respectively, of the cobalt complex of $\alpha,\beta,\gamma,\delta$-tetraphenylchlorin (Co(TPC)) in which two hydrogen atoms are attached to a pyrrole

Table 2. Effect of addition of methanol

Solvent	CHD	CHD/Co molar ratio	MeOH/Co molar ratio	Composition of the products (%)					η'_{Bz} (%)
				cC_6	cC_6'	1,3-CHD	1,4-CHD	Bz	
DMF	1,3	102	138	0	0	100	0	0	0
	1,4	80	135	0	0.6	7.3	73.8	18.3	59.3
HMPT	1,3	101	131	0	0	100	0	0	0
	1,4	102	132	0	1.5	2.4	93.3	2.8	31.0
PhCN	1,3	99	137	0.1	0	56.9	0	43.0	72.6
	1,4	106	132	0	0	0	53.2	46.8	174

fragment of porphyrin skeleton.[10]

In a previous paper,[5] the authors reported that the active species for the dehydrogenation of cyclohexene could be the species electro-reduced at −2.0 V *vs.* Ag wire, *viz.*, $[Co^{I}(TPP)^{\cdot-}]^{-}$, and the formation of Co(TPC) was observed in the electrolysis of cyclohexene by using dioxane as the solvent.

From the above results, therefore, it may be reasonable to assume that the active species for the dehydrogenation of 1,3- and 1,4-CHD was analogous to that for the dehydrogenation of cyclohexene.

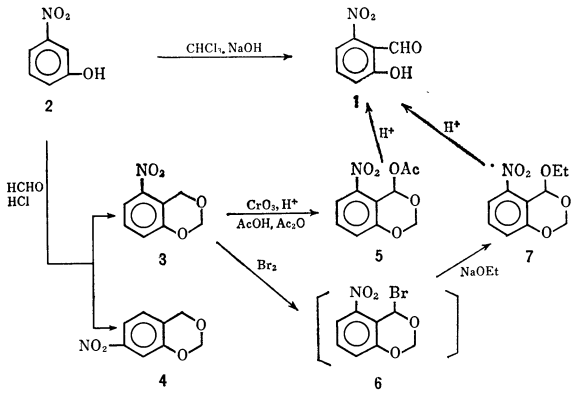
Catalytic Activities of Salicylaldehyde Derivatives. III. An Improved Synthesis of 6-Nitrosalicylaldehyde

Makoto ANDO and Sakae EMOTO

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received February 19, 1973)

In connection with our studies of the catalytic activities of salicylaldehyde derivatives,[1] it was necessary to synthesize 6-nitrosalicylaldehyde (**1**). Although **1** had been prepared from *m*-nitrophenol (**2**) by the Reimer-Tiemann reaction in a 3—4% yield,[2,3] our reinvestigation showed that the yield was still poor and variable. The methyl ether of **1** has been obtained in a 19% yield from 3-nitro-*o*-cresol,[4] which, in turn, is prepared from 2,6-dinitrotoluene, but this method is unsuitable for preparing a large quantity of **1**. In this paper, we wish to describe an improved synthesis of **1** *via* 5-nitro-1,3-benzodioxane (**3**); it is shown in the scheme.



Mehta and Ayyar has previously synthesized **3** in a 13% yield,[3a] by refluxing a mixture of **2**, formaldehyde (1.5 mol equivalents), and hydrochloric acid for 2—3 hr. The yield of **3** could be increased up to 30% when we used 2 mol equivalents of formaldehyde and prolonged the reaction time to 5—6 hr (a longer reaction time decreased the yield), and after the reaction mixture had been treated according to the Mehta method, a non-crystalline residue was purified by the use of a silica gel column. A small amount of 7-nitro-1,3-benzodioxane (**4**), which had been prepared from **2**, formaldehyde, and sulfuric acid at 40 °C in a poor yield,[5] was also obtained from the non-crystalline residue. 6-Nitrosalicylic acid had previously been prepared by the oxidation of **3** with chromic anhydride and sulfuric acid in acetic acid,[3a] but when we attempted the oxidation in a mixture of acetic acid and acetic anhydride, a product (**5**), into which one acetoxy group was introduced was obtained. Because, by the acidic hydrolysis of **5**, **1** was synthesized, **5** was confirmed to be 4-acetoxy-5-nitro-1,3-benzodioxane. In carbon tetrachloride, **3** was brominated with 1 mol of bromine under the light of a tungsten lamp to give a monobrominated product (**6**); this product was very unstable and decomposed in air, so, after the bromination had been completed, a solution of **6** in carbon tetrachloride was used immediately in the next step. The solution of **6** in carbon tetrachloride was added to a solution of an excessive amount of sodium ethoxide in ethanol to convert the bromo compound into an ethoxy one (**7**), which was then hydrolyzed to **1** by acid. Consequentlyl **6** and **7** were confirmed to be 4-bromo- and 4-ethoxy-5-nitro-1,3-benzodioxanes respectively. The total yield of **1** by this route was 24% based on **2**; as compared with the synthesis by means of the Reimer-Tiemann reaction, the total yield was very much increased, and so **1** can be prepared in a large quantity.

Experimental

All the mps and bp are uncorrected.

5-Nitro-1,3-benzodioxane (3). A mixture of **2** (250 g), a 37% formaldehyde aqueous solution (375 ml), and concd hydrochloric acid (750 ml) was boiled under reflux with vigorous stirring for 5 hr. After being cooled, a clear supernatant was poured off and the residue was stirred with a

hot 3 M sodium hydroxide aqueous solution (1 l). After this mixture had then been cooled, the insoluble material was separated by filtration and extraction (1 M sodium hydroxide, 1 l) was repeated twice. After the residue had been dried, it was dissolved in hot ethanol (2 l); an insoluble, oily product was filtered off with charcoal, and then the solution was allowed to stand overnight at room temperature. The resultant turbid solution was treated again with charcoal, after which the solvent was removed under diminished pressure until the solid **3** deposited, whereupon the **3** was separated by filtration. The separation of **3** was repeated until an oily product resulted. The solvent of the oily product was removed *in vacuo*; the residue was dissolved in benzene and then purified by silica gel-column chromatography (*ca.* 50 fold in weight). At first **3** was eluted by benzene; elution was then continued by the use of a mixture of benzene and ethyl acetate, and then ethyl acetate. The second fraction was collected and was confirmed to be 7-nitro-1,3-benzodioxane (**4**) by studies of the mp and by elemental analyses. Mp 91—92 °C (lit,[5] 90.5 °C); yield, 5.3 g (1.6%). The total yield of **3** was 98.5 g (30%). Mp 73—74 °C (lit,[3a] 78 °C). It was recrystallized from ethanol (mp 75 °C), but crude **3** was used in the next step.

4-Acetoxy-5-nitro-1,3-benzodioxane (5). Into a solution of **3** (65 g) in acetic acid (650 ml) and acetic anhydride (650 ml), sulfuric acid (50 ml) was stirred below 10 °C. Solid chromic anhydride (50 g) was then added to the solution in small portions at 0—5 °C; about 30 min was required for the addition. Stirring was continued for another 90 min after the chromic anhydride had been added at the same temperature; the reaction mixture was then poured into ice water and allowed to stand for several hours. A precipitate was then collected on a filter and recrystallized from methanol. Mp 98 °C; yield, 46.0 g (54%); IR (KBr) 1760 cm^{-1} (C=O).

Found: C, 50.24; H, 3.79; N, 5.94%. Calcd for $C_{10}H_9O_6N$: C, 50.21; H, 3.79; N, 5.86%.

6-Nitrosalicylaldehyde (1) from 5. A mixture of **5** (14.3 g), ethanol (75 ml), water (75 ml), and concd sulfuric acid (15 ml) was boiled for 3 hr with stirring. The cooled mixture was then diluted with water and extracted with benzene. The benzene layer was dried over anhydrous magnesium sulfate, and the solvents were removed under reduced pressure. The residue was dissolved in benzene and extracted with a dil sodium hydroxide aqueous solution. The aqueous solution was then acidified with hydrochloric acid and extracted with benzene. The solution was dried over anhydrous magnesium sulfate and concentrated under diminished pressure. Crude **1** was purified by reprecipitation with alkali-acid. Mp 51—52 °C (lit, 54—55 °C,[2] 50—51 °C[3a]); yield, 8.3 g (83%). IR of **1**, prepared from **5**, agreed with that of the authentic sample.

4-Ethoxy-5-nitro-1,3-benzodioxane (7). Under the light of a tungsten lamp, a solution of bromine (22.4 g) in carbon tetrachloride (25 ml) was added to a boiling solution of **3** (25.4 g) in carbon tetrachloride (250 ml) over a period of 1 hr, after which boiling was continued for 3 hr. After the mixture had been cooled, an insoluble product was filtered off with celite. A clear solution which contained some fuming hydrogen bromide was stirred, drop by drop, into a solution of sodium ethoxide in ethanol (prepared from 4.4 g of sodium and 90 ml of ethanol; 1.3 mol equivalents) at 10—15 °C. This required 15 min; stirring was then continued for 3 hr at room temperature. A precipitate was dissolved by the addition of water, and the carbon tetrachloride layer was separated. The aqueous solution was extracted with carbon tetrachloride, and the combined carbon tetrachloride solution was washed well with water and then dried over anhydrous magnesium sulfate. The solvent was removed under reduced pressure, and the residue was distilled in a vacuum. Bp 123—127 °C/4 mmHg; yield, 29.3 g (93%).

Found: C, 53.51; H, 4.98; N, 6.18%. Calcd for $C_{10}H_{11}O_5N$: C, 53.33; H, 4.92; N, 6.22%.

6-Nitrosalicylaldehyde (1) from 7. A mixture of **7** (10 g), ethanol (100 ml), water (100 ml), and concd sulfuric acid (20 ml) was reacted as has been described in the hydrolysis of **5**. Mp 52 °C; yield, 6.6 g (89%).

In conclusion, the authors wish to express their thanks to Dr. Haruo Homma and his staff of this Institute for elemental analyses. This work was financially supported in part by a research grant for studies of life sciences by this Institute, which help the authors acknowledge gratefully.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2905—2906 (1973)

Phenolysis of *exo*- and *endo*-2-Norbornyl *p*-Toluenesulfonates. Rates and Product Distributions

Kunio OKAMOTO, Tomomi KINOSHITA, and Yuji ITO

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received February 23, 1973)

Although norbornyl arenesulfonate solvolysis has been extensively studied with regard to the non-classical nature of the norbornyl cation,[1,2] the system has never been subjected to solvolytic study with the use of a phenolic solvent, which is suitable for S_N1-solvolysis.[3]

This study was carried out in order to compare the results of 2-norbornyl tosylate (ROTs) phenolysis with those of the previous studies[1b] in common solvolytic solvents with regard to the *exo*/*endo* rate ratio and epimeric nature of the products, and to examine the distribution of the O- and C-norbornylated phenols for information on the non-classical nature of the solvolysis intermediates from *exo*- and *endo*-ROTs in the phenolic solvent.

Titrimetric first-order rate constants (k_1) for the two epimeric ROTs's in a phenol–benzene (1: 1 by wt.) solvent are given in Table 1. The *exo*/*endo* rate ratios for the phenolysis are 591 at 25 °C and 622 at 50 °C, being comparable with the acetolysis rate ratio of 185 at 50 °C,[1a] and also with the ethanolysis rate ratio of 171 at 50 °C.[2]

Phenolysis of 2-norbornyl tosylates gives the phenyl ether (ROC_6H_5), and *o*- and *p*-norbornylated phenols (*o*- and *p*-RC_6H_4OH), and a mixture of nortricyclene and norbornene. The results for representative runs are given in Table 2. Using capillary gas chromatography, we have examined the *exo*/*endo* epimer ratio of the substitution products. Control experiments showed 0.1% *endo*-epimer in ROC_6H_5 and 0.02% *endo*-epimer in both *o*- and *p*-RC_6H_4OH to be detectable. However, neither *endo*-ROC_6H_5 nor *endo*-RC_6H_4OH were observed in the phenolysis products from *exo*- and *endo*-ROTs, the *endo*-epimer content being definitely <0.1% for ROC_6H_5 and <0.02% for *o*- and *p*-RC_6H_4OH.

Table 1. Titrimetric phenolysis rates of 2-norbornyl tosylates[a]

	Tosylate M	NaOPh M	Temp. °C	k_1 sec^{-1}	*exo*/*endo*

			50.0	5.55×10^{-2}[b]	622
endo			25.0	6.40×10^{-6}[b]	
	0.1009	0.1041	50.0	8.92×10^{-5}	
	0.1009	0.1041	75.0	8.65×10^{-4}	

a) Solvent: PhOH–Benzene (1:1 by wt.). b) Extrapolated from data at other temperatures.

Product distributions for the phenolysis of epimeric tosylates in the presence of sodium phenoxide (0.007—0.095 M) were determined in the phenoxide/substrate concentration ratios 7.6—9.5 at 50.0 °C. The distribution of products resulting from the reaction of phenol molecule with phenolysis intermediate can be estimated by the graphic extrapolation of the distribution curve to the zero phenoxide concentration, as in the case for 1-adamantyl,[3a] 2-octyl,[3b] and tetrahydrolinalyl systems;[3b] the distribution of products resulting from the reaction of phenoxide ion with phenolysis intermediate has been calculated by the method previously reported.[3] The results are given in Table 3.

The calculated product distributions for the *exo*-

3) a) K. Okamoto, K. Matsubara, and T. Kinoshita, This Bulletin, **45**, 1191 (1972). b) K. Okamoto and T. Kinoshita, *ibid.*, **45**, 2802 (1972).

and *endo*-tosylates are in line with each other within experimental error in both phenol molecule and phenoxide ion reactions. The *endo*-tosylate initially produces the classical norbornyl ion and subsequently most the classical ion becomes non-classical before it is captured by the nucleophile.[1] The distribution character for the phenolysis products probably indicates that the life of the classical ion is relatively short in the phenolysis medium, and consequently most of the products from *endo*-ROTs stem from the non-classical norbornyl cation.

Experimental[4]

Materials. *exo*-2-Norbornanol[2] and *endo*-2-norbornanol (the *exo*-epimer content 8.1% by glc)[5-8] were prepared by known methods. *exo*- and *endo*-2-Norbornyl *p*-toluenesulfonates[1a] and nortricyclene[9] were obtained in the usual manner. Sodium phenoxide was prepared by the reported method.[3a] The other organic reagents employed were of analytical reagent grade and were fractionated just prior to use.

Syntheses of exo- *and* endo-*2-Norbornyl Phenyl Ethers.* A mixture of a potassium salt of *exo*-2-norbornanol (prepared from the alcohol and potassium in benzene) and bromobenzene in hexamethylphosphoric triamide was heated at 150 °C for 32 hr. The usual work up gave *exo*-2-norbornyl phenyl ether (bp 100—103 °C/1.8 mmHg, lit,[9] bp 98 °C/1 mmHg; the *exo*-epimer content >99.9% by glc). *endo*-2-Norbornyl phenyl ether was prepared from *endo*-2-norbornanol in a similar manner; bp 102—105 °C/2 mmHg; the *endo*/*exo* ratio 35.5/64.5 by glc. Found: C, 83.13; H, 8.82%. Calcd for $C_{13}H_{16}O$: C, 83.03; H, 8.52%.

Syntheses of exo- *and* endo-*2-Norbornylphenols.* *o*- and *p*-*endo*-2-Norbornylphenols were synthesized according to the method of Kheifits and Gol'dovskii;[10] the *o*-isomer, bp 124—126 °C/1.8 mmHg (lit,[10] bp 119—123 °C/0.3 mmHg); the *p*-isomer, bp 174—177 °C/4.0 mmHg (lit,[10] bp 125—129 °C/0.3 mmHg). *o*- and *p*-*exo*-2-Norbornylphenols were obtained by *exo*-2-norbornyl tosylate phenolyses; the *o*-isomer, mp 47.3—48.5 °C (corr.) (lit,[11] mp 49—50 °C); the *p*-isomer, mp 128.6—129.4 °C (corr.) (lit,[12] mp 133—135.5 °C).

Isolation of the Phenolysis Product. A flask containing the reaction mixture was placed in a constant-temperature bath for at least ten half-lives. After the work up[3] products were separated by column chromatography or by thin-layer chromatography (silica gel).

Kinetic Measurement. This was carried out by the usual sealed-ampoule and pipetting out technique.[3] In each case, smooth first-order rate plots were obtained over 70—80% reaction.

Product Analysis by Gas Chromatography. The product distribution was analysed by glc using a 2 m × 3 mm column with Apiezon Grease on Neopak 1A at 230 °C. The epimer analysis of each product was performed by glc using a Hitachi Golay column R-45 at 83 °C for 2-norbornanol (retention time: *exo*-epimer, 51.3 min; *endo*-epimer, 56.6 min) and a Hitachi Golay column Q-45 at 230 °C for 2-norbornyl phenyl ether (retention time: *exo*-epimer, 105.1 min; *endo*-epimer, 106.9 min). Norbornylphenols were converted into norbornylanisols by the use of dimethyl sulfate[13] prior to glc analysis, carried out using the column Q-45 at 230 °C: *o*-(2-norbornyl)anisol[10] (retention time: *exo*-epimer, 116 min; *endo*-epimer, 114 min); *p*-(2-norbornyl)anisol[10] (retention time: *exo*-epimer, 79 min; *endo*-epimer, 77 min).

4) A Hitachi Model 023-6003 gas chromatographic instrument, with a flame ionization detector, a Hitachi Model 215 IR spectrophotometer, and a Hitachi Model R-24 60 MHz NMR instrument were used for the analytical work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2907—2908 (1973)

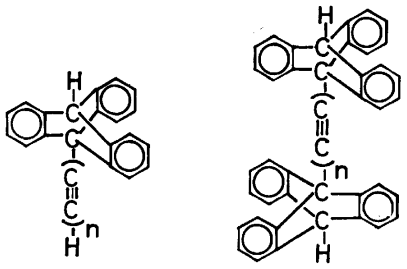
Preparation of 9-Butadiynyltriptycene and 9,9′-Ditriptycyltetraacetylene

Shuzo AKIYAMA, Fumio OGURA, and Masazumi NAKAGAWA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka, 560

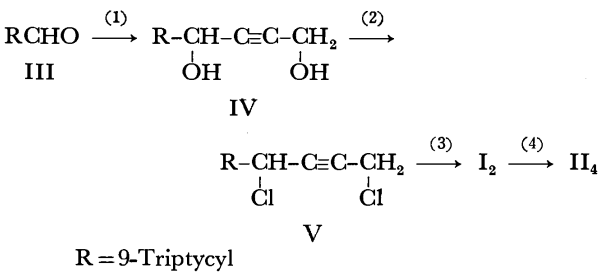
(Received March 7, 1973)

The preparation of 9-ethynyltriptycene (I_1) and 9,9′-ditriptycyldiacetylene (II_2) was given in a previous paper.[1] The present paper deals with the preparation of their higher analogues, 9-butadiynyltriptycene (I_2) and 9,9′-ditriptycyltetraacetylene (II_4), which was performed according to the following scheme.



I_n II_n

n = 1, 2 n = 2, 4



R = 9-Triptycyl

(1): $BrMgC{\equiv}C\text{-}CH_2OMgBr$; (2): $SOCl_2$-pyridine;
(3): $NaNH_2$ in liq. NH_3; (4): $Cu(OAc)_2$-pyridine

Scheme

9-Butadiynyltriptycene (I_2) was found to be highly stable in sharp contrast to the instability of other butadiynyl compounds such as phenanthryldiacetylene[2] and pyrenyldiacetylene.[3] The oxidative coupling of I_2 by Eglinton's method afforded highly stable and scarcely soluble II_4 in a quantitative yield. Theilacker and co-workers have pointed out that the introduction of an electron-attractive group at 9-position of triptycene nucleus causes an appreciable hypochromism of long wavelength absorption.[4] As shown in the Table, I_2 exhibits more enhanced hypochromism in a long wavelength region than I_1.[1]

The unusually high stability of I_1,[1] I_2, II_2,[1] and II_4, which can be attributed to the rigid and bulky cage structure of the triptycyl group, indicates the possibility of preparing much higher members of this class of polyacetylene. However, this seemed impracticable in view of the extremely poor solubility of II_4.

TABLE 1. HYPOCHROMISM OF 9-SUBSTITUTED TRIPTYCENES
(λ in nm in ethanol)

Triptycene		I_1		I_2	
λ	ε	λ	ε	λ	ε
197	62900	198	59000	198	62200
211	64200	210.5	63800	211	65200
270	3600	269.5	2800	270	2500
278	4900	277	3600	277.5	3200

Experimental

All the melting points were uncorrected. The IR and NMR spectra were measured with Hitachi EPI-2 and Varian A-60 spectrometers, respectively. The UV spectra were obtained on Hitachi EPS-3T and Zeiss PMQII,M4QIII spectrometers.

1-(9-Triptycyl)-2-butyne-1,4-diol (IV). To an ice-cooled solution of bis-Grignard derivative of propargyl alcohol [prepared from magnesium, 2.30 g; ethyl bromide, 10.5 g; propargyl alcohol, 2.69 g and tetrahydrofuran, 70 ml] was added over 20 min period a solution of 9-formyltriptycene[5] (III, 4.51 g, 0.061 mol) in the same solvent (150 ml). The cooling bath was then removed and the mixture was stirred overnight at room temperature. A saturated solution of ammonium chloride was added to the reaction mixture and the aqueous layer was extracted with benzene. The residue obtained by evaporating the combined organic layer *in vacuo* was mixed with benzene (30 ml) to give IV as colorless crystalline powder in a quantitative yield. A solution of IV thus obtained in tetrahydrofuran was passed through a thin layer of alumina. A small amount of benzene was added to the concentrated filtrate to yield pure IV, colorless tiny cubes, mp 284—285 °C, IR (KBr-disk): 3560—3050 (O-H), 1063, 1023 (C-O) cm^{-1}.

Found: C, 85.16; H, 5.56%. Calcd for $C_{24}H_{18}O_2$: C, 85.18; H, 5.36%.

9-Butadiynyltriptycene (I_2). A solution of thionyl chloride (3.57 g, 0.03 mol) in tetrahydrofuran (5 ml) was added over a 20 min period to an ice-cooled solution of IV (3.38 g, 0.01 mol) in a mixture of pyridine (2.37 g, 0.03 mol) and tetrahydrofuran (40 ml). After the mixture had been stirred for 2 hr at 55 °C, cracked ice was added and extraction was carried out with benzene (150 ml). The extract, after being washed and dried, was concentrated under reduced pressure. A solution of the residue (crude V) in tetrahydrofuran (5 ml) was added to a solution of sodium amide [prepared from sodium, 3.0 g, 0.13 g-atom] in liquid ammonia (150 ml) at

−70 °C. After being stirred for 2 hr, the ammonia was allowed to evaporate. The residue was mixed with a saturated solution of ammonium chloride and the organic solvent was removed under reduced pressure. Insoluble material was collected by filtration, washed with water and dried. The material was crystallized from benzene–cyclohexane to give faint brown crystalline powder, 1.52 g (50%). A solution of crude I_2 in carbon tetrachloride was percolated through a thin layer of alumina. Concentration of the filtrate afforded colorless cubes which were recrystallized from benzine to give pure I_2, mp 189—191 °C, IR (KBr-disk): 3285 (≡C–H), 2245 (C≡C) cm^{-1}, NMR ($CDCl_3$): τ 2.25—3.08 (m, 12H, aromatic H), 4.65 (s, 1H, bridgehead H), 7.67 (s, 1H, –C≡C–H).

Found: C, 95.65; H, 4.59%. Calcd for $C_{24}H_{14}$: C, 95.33; H, 4.67%.

9,9′-Ditriptycyltetraacetylene (II_4). Treatment of analytically pure I_2 with cupric acetate monohydrate in pyridine afforded colorless tiny cubes in a quantitative yield, mp >300 °C, IR (KBr-disk): 2230 (C≡C) cm^{-1}. The crystals were digested with dilute hydrochloric acid and washed with water to remove a trace of inorganic material. Recrystallization of II_4 was found to be unfeasible on account of extremely poor solubility.

Found: C, 95.22; H, 4.38%. Calcd for $C_{48}H_{26}$: C, 95.65; H, 4.35%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2908—2909 (1973)

Formation and Reduction of 2-Acyl-1-tetralones

Masaaki IWATA and Sakae EMOTO

The Institute of Physical and Chemical Research, Hirosawa, Wako-shi, Saitama 351

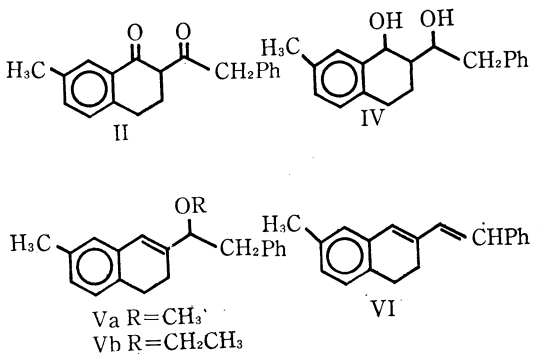
(Received March 8, 1973)

Following the synthesis of co-enzyme model compounds, we have attempted to synthesize the substituted polycyclenes from 7-methyl-1-tetralone (I), an important intermediate in the preparation of natural products. In the present pa er we deal with the formation and reduction of 2-acyl-1-tetralone from I.

In the presence of sodium methoxide in methanol under nitrogen atmosphere, I could not be acylated with methyl acetate or phenyl acetate under any conditions and only afforded 7-methyl-1-naphthol, while sodium hydride in dimethyl sulfoxide (DMSO) gave 7-methyl-2-phenylacetyl-1-tetralone (II) in good yield besides the formation of methyl 2,4-diphenylacetoacetate (III), a self-condensation product of the ester. II and III were enolized in $CDCl_3$ and CCl_4 in 73 and 55% yield, respectively. They were determined by integral ratio of enolic hydroxyl and methine protons in the NMR spectra.

In the preparation of β-diols from β-diketones metallic sodium often gives unsatisfactory results particularly in β-diketones containing aroyl groups as the functional group.[1] Catalytic hydrogenation of aliphatic β-diketones in the presence of Raney nickel afforded β-diols in excellent yield, but this method requires high temperature and high pressure.[2] Thus it is desirable to find a mild reduction method of β-diketones to β-diols. Recent works[3] on reduction with the use of $LiAlH_4$ are valuable as regards the accomplishment of mild reduction. We attempted the reduction of II with $NaBH_4$ and found an interesting solvent effect in subsequent dehydration of β-diols (IV).

Reduction of II with $NaBH_4$ in ethanol followed by



treatment with hydrochloric acid afforded 2-(1-hydroxy-2-phenylethyl)-7-methyl-1,2,3,4-tetrahydro-1-naphthol (IV) (53%), 3-(1-ethoxy-2-phenylethyl)-6-methyl-1,2-dihydronaphthalene (Vb) (6%), and 3-styryl-6-methyl-1,2-dihydronaphthalene (VI) (5%). Since Vb and VI were expected from IV in the work up, treatment of IV with acid was investigated. On being treated with 9M H_2SO_4 in benzene–methanol, IV was converted into 3-(1-methoxy-2-phenylethyl)-6-methyl-1,2-dihydronaphthalene (Va) (78%) and VI (22%). When IV was treated with the same acid in 2-propanol (more bulky alcohol), only VI was obtained quantitatively. VI gave neither Va nor Vb. These results suggest that Va and Vb were formed from IV by the S_N2 acid-catalyzed substitution of hydroxyl group on the side chain after the completion of dehydration of hydroxyl group on the ring and that both V were irreversibly dealkoxylated to VI.

Experimental

Instruments for spectral measurements were Shimadzu IR 27 (IR), Hitachi 124 spectrophotometer (UV), Japan Electron Optics Model C-60 (NMR) and JMS-OISG (MS). Merck Art. 7734 was used for separation of products on a silica gel

column by elution chromatography and Wakogel B-5 UA for thin layer chromatography (tlc).

Materials. 7-Methyl-1-tetralone (I) was synthesized in three steps from toluene and succinic anhydride, mp 31.5—32.5 °C (lit,[4] 33 °C).

7-Methyl-2-phenylacetyl-1-tetralone (II). I (0.04 mol) was treated with methyl phenylacetate (0.08 mol) and sodium hydride (0.08 mol) in DMSO (20 ml). After completion of the reaction, the mixture was poured into ice water (200 ml) containing 15 ml of concd. HCl and extracted with ether. The etheral extract was added dropwise to 200 ml of a hot aqueous cupric acetate solution (10%), and the mixture was stirred overnight. The precipitate was collected by filtration and washed with water, methanol and ether successively. For analytical use, a part of the precipitate was recrystallized from benzene–methanol as dark green crystals, mp 232—235 °C (decomp.). Found: Cu, 10.24%. Calcd for $C_{38}H_{34}O_4Cu$: Cu, 10.35%. UV: $\lambda_{max}(\varepsilon)$ (in methanol) 211 (40800), 253.6 (37700), 260 (35400), 334 (10200), 338.5 (3100), and 410 (2500) nm.

The copper chelate was treated with 10% sulfuric acid (60 ml) and the organic layer was extracted with benzene. After evaporation of the solvent, the residue was chromatographed on a silica gel column with benzene to give II (65%) and III (24%).

II was obtained as dark red plates, mp 56.5—58 °C. Found: C, 81.86; H, 6.71%. Calcd for $C_{19}H_{18}O_2$: C, 81.98; H, 6.52%. UV: $\lambda_{max}(\varepsilon)$ (in methanol) 236 (11000), 245s (9200), 258 (6900), 310 (10700), and 347 (18400) nm. NMR ($CDCl_3$): 2.32 (3H, singlet, $-CH_3$), 7.28 (5H, s, phenyl protons), 7.72 (1H, broad s, isolated aromatic proton in tetralone ring), 7.10 (2H, multiplet, two neighboring aromatic protons in tetralone ring), 2.66 (centered) (4H, m, two methylene protons in tetralone ring), 3.80 (2H, s, benzyl protons in the chain), 3.97 (0.2667H, s, CO–CH–CO), and 16.50 (0.7333H, s, enol proton) ppm.

III was obtained as light yellow needles, mp 60—62.5 °C. Found: C, 76.19; H, 6.07%. Calcd for $C_{17}H_{16}O_3$: C, 76.10; H, 6.01%. MS (75 eV): parent peak at *m/e* 268 and base peak at *m/e* 91 ($C_7H_7^+$). UV: $\lambda_{max}(\varepsilon)$ (in methanol) 210 (13600), 254 (3700), and 264s (3370) nm. IR (KBr disk): ν_{max} 1770 (–COOMe) and 1740 (–CO–) cm^{-1}. NMR (CCl_4): 3.59 (3H, s, $-OCH_3$), 3.61 (2H, s, $-CH_2-$), 4.62 (0.455H, s, –CH–), and 13.05 (0.545H, s, enol proton) ppm.

Reduction of II with Sodium Borohydride. In Ethanol: Sodium borohydride was added at room temperature to I (6.13 mmol) in 60 ml of ethanol at once. The color of the orange-red solution gradually vanished. The reaction was accomplished after 8 hr. The solution was acidified with 6M hydrochloric acid and the solvent was removed under reduced pressure by repeated addition of methanol. The residue was chromatographed on a silica gel column with benzene to give IV (53.2%), Vb (6%), and VI (5%).

A part of IV crystallized during the course of chromatographic separation; fine white needles, mp 164—174.5 °C. Found: C, 80.76; H, 8.12%. Calcd for $C_{19}H_{22}O_2$: C, 80.81; H, 7.85%. Exact mass measurement: For parent peak, Found: 282.16121, Calcd for $C_{19}H_{22}O_2$: 282.16198. UV: $\lambda_{max}(\varepsilon)$ (in methanol) 262s (600), 264 (650), 269 (780), and 278.5 (760) nm. NMR ($CDCl_3$): 2.30 (3H, s, $-CH_3$) and 7.23 (5H, s, phenyl protons) ppm.

Vb was obtained as colorless oily liquid showing fluorescence. Found: C, 86.17; H, 8.03%. Calcd for $C_{21}H_{24}O$: C, 86.25; H, 8.27%. Exact mass measurement: For parent peak, Found: 292.17921, Calcd for $C_{21}H_{24}O$: 292.18272. IR (NaCl plates): ν_{max} 1085 (C–O–C) and 700 (–Ph) cm^{-1}. NMR ($CDCl_3$): 1.14 (3H, triplet, $J=12.0$ Hz, $-OCH_2\underline{CH_3}$), 2.27 (3H, s, Ar–CH_3), 3.33 (2H, quartet, $J=12.0$ Hz, $-OC\underline{H_2}-CH_3$), 4.00 (1H, t, $J=11.0$ Hz, –CH–O–), 6.21 (1H, s, –C–CH–), 6.95 (2H, broad s, two adjacent aromatic protons), and 7.22 (5H, s, phenyl protons) ppm.

VI was obtained as light yellow amorphous solid, mp 118—126 °C. Found: C, 91.71; H, 6.94%. Calcd for $C_{19}H_{18}$: C, 92.36; H, 7.37%. Exact mass measurement: For parent peak, Found: 246.13723, Calcd for $C_{19}H_{18}$: 246.14085. IR (KBr disk): ν_{max} 960 (C=CH) cm^{-1}. UV: $\lambda_{max}(\varepsilon)$ (in methanol) 213 (16500), 230 (11000), 237s (9900), 245 (9800), 252s (7900), 261 (6600), 309s (18000), 325 (31000), 340 (40000), and 358 (29700) nm. NMR ($CDCl_3$): 2.29 (3H, s, Ar–CH_3) and 2.65 (centered) (4H, AA′BB′, $-CH_2CH_2-$) ppm, (aliphatic protons): (olefinic and aromatic protons) = 7: 11.

In Methanol: IV was vigorously stirred in benzene–methanol (3: 2 v/v) with sulfuric acid (9M) until no IV was detected on tlc. The mixture was extracted with benzene after neutralization with sodium bicarbonate on a silica gel column with benzene to give Va (78%) and VI (22%).

Va was obtained as colorless oily liquid showing fluorescence. Found: C, 86.28; H, 7.95%. Calcd for $C_{20}H_{22}O$: C, 86.28; H, 7.97%. IR (NaCl plates): ν_{max} 1095 (C–O–C) and 700 (–Ph) cm^{-1}. UV: $\lambda_{max}(\varepsilon)$ (in methanol) 266 (12000), 274 (11000), and 303 (1700) nm. NMR ($CDCl_3$): 2.26 (3H, s, Ar–CH_3), 3.23 (3H, s, $-OCH_3$), 3.90 (1H, t, $J=11.5$ Hz, –CH–O–), 6.23 (1H, s, C=CH), 6.81 (1H, s, isolated aromatic protons), 6.96 (2H, s, two adjacent aromatic protons), and 7.22 (5H, s, –Ph) ppm.

In Benzene: IV was vigorously stirred in benzene with 9M sulfuric acid until no IV was detected on tlc. The same work up as in methanol gave VI quantitatively.

In 2-Propanol: As the same operation as in methanol was carried out in 2-propanol. VI was quantitatively obtained after the work up. No alkoxylated product was detected.

Reaction of Va with Acid. To Va in methanol was added a small amount of concd. sulfuric acid and the mixture was allowed to stand at room temperature for 24 hr. From the solution VI crystallized quantitatively. Even when the solution containing only VI was allowed to stand further, no detectable amount of Va was found on tlc, indicating that formation of VI from Va was irreversible.

This study was supported in part by a Grant for Life Science from this Institute.

Aromatic Substitution of Olefins. XX. Reactions of Triphenylamine, -phosphine, -arsine, -stibine, and -bismuth with Styrene in the Presence of Palladium(II) Salts

Ryuzo Asano, Ichiro Moritani, Yuzo Fujiwara, and Shiichiro Teranishi
Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received March 13, 1973)

We reported[1-3] that direct substitution of benzene derivatives with olefins can take place in the presence of palladium(II) salts, and that nonbenzenoid aromatic compounds such as ferrocene, furan and thiophene can also react with olefins to give alkenyl-derivatives. In continuation of these studies we wish to determine the reactivity of triphenylphosphine, which has both aromatic ring and donor P atom, toward olefins. Extensive studies on reactions of triphenylphosphine with transition metals have been carried out. It is well known that phosphine metal halide complexes form an internal metal-carbon bond.[4] However, little is known about the reaction of triphenylphosphine in the presence of transition metal compounds involving the cleavage of the phosphorus-carbon bond.[5] In this paper we report a study of the reaction of styrene with triphenylamine, -phosphine, -arsine, -stibine, or -bismuth.

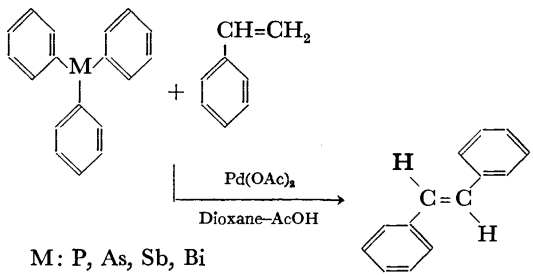
Table 1. Reaction of styrene with group V triphenyl-compounds by palladium (II) acetate[a]

Triphenyl-compound	Product and yield, %[b]	
NPh_3	*trans*-*p*-Diphenylaminostilbene	41
PPh_3	*trans*-Stilbene	64
	Methyldiphenylphosphine oxide	22
$AsPh_3$	*trans*-Stilbene	99
	Biphenyl	14
$SbPh_3$	*trans*-Stilbene	67
	Biphenyl	108
$BiPh_3$	*trans*-Stilbene	7
	Biphenyl	108
	trans, *trans*-1,4-Diphenylbutadiene	11
$BiPh_3$[c]	Biphenyl	3
	Benzene	
$P(p\text{-}CH_3C_6H_4)_3$	*trans*-*p*-Methylstilbene	41
	p,*p*′-Dimethylbiphenyl	3
	Methyldi-*p*-tolylphosphine oxide	10
$PdCl_2(PPh_3)_2$[d]	*trans*-Stilbene	3

a) Equimolar amounts of the triphenyl-compound, styrene, and palladium (II) acetate were used. All the reactions were carried out under reflux for 6 hr. b) Yields are based on palladium (II) acetate. c) The reaction was carried out in the absence of palladium (II) acetate. d) Dichlorobis (triphenylphosphine) palladium (II) was used in place of triphenylphosphine and palladium (II) acetate.

Results and Discussion

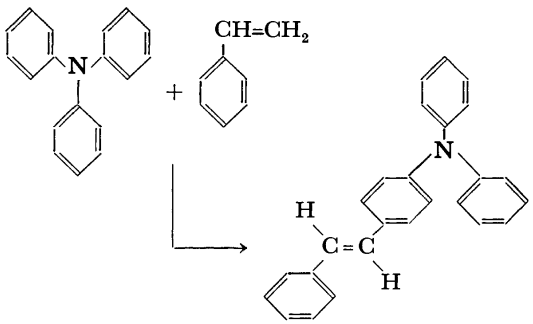
A solution of styrene, triphenylphosphine (1 mol equiv.), palladium(II) acetate (1 mol equiv.) in acetic acid and dioxane was stirred under relux for 6 hr, to give *trans*-stilbene (64%) with methyldiphenylphosphine oxide and metallic palladium. Reactions with other group V triphenyl-compounds such as triphenylamine, -arsine, -stibine, and -bismuth were carried out under similar reaction conditions. The results are given in Table 1. It is evident that these triphenyl-compounds can easily react with styrene to give *trans*-stilbene involving the cleavage of the M–C bond except for the case of triphenylamine (Eq. (1)).



(1)

M: P, As, Sb, Bi

In the reaction of triphenylamine with styrene, the product is not *trans*-stilbene but *trans*-*p*-diphenylaminostilbene which is the normal substitution product (Eq. (2)). This may be due to the higher energy of the N–C bond.



(2)

With respect to the formation of *trans*-stilbene, the reactivity is in the order triphenylarsine>triphenylstibine≃triphenylphosphine>triphenylbismuth>triphenylamine. The donor ability decreases in the order $NPh_3>PPh_3>AsPh_3>SbPh_3\gg BiPh_3$,[6] and the M–C bond energy increased in the same order M=Bi<Sb<As<P<N.[7] The yields of *trans*-stilbene for the tri-

Electrochemistry of Organic Sulfur Compounds. IV.[1] Anodic Sulfonium Formation from Alkyl Phenyl Sulfides

Sigeru TORII, Yuziro MATSUYAMA, Koji KAWASAKI, and Kenji UNEYAMA

Department of Industrial Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700

(Received March 19, 1973)

In recent years, various sulfonium salts and sulfonium ylides have been utilized as key intermediates for organic syntheses.[2] We have examined the electrochemical preparation of useful sulfonium salts which would provide sulfonium ylides. In a previous paper,[1] we described a novel anodic synthesis of a sulfonium salt from diphenyl sulfide and proposed a mechanism for the anodic process; sulfides (Ph–S–R) are oxidized in the anodic process to provide primarily a radical cation $[Ph–S–R]^{+\cdot}$, which undergoes either S–R bond cleavage to give thiyl radical and cation R^+, or electrophilic attack by water and/or sulfide to provide sulfoxide and/or sulfonium salt. The S–R cleavage is promoted by a substituent R such as benzyl and triphenylmethyl groups due to the stability of the cation R^+. Selection of the reaction pathway, either sulfoxidation or sulfonium salt formation, probably depends on the stability of the cation radical **2** and the presence of water in the reaction media.[3] This paper shows that anodic oxidation of alkyl phenyl sulfides **1** in general gives sulfonium salts **3** in anhydrous media and some chemical properties of **3**.

Alkyl phenyl sulfides **1** (2.5 mmol) dissolved in acetonitrile containing lithium perchlorate were electrolyzed at room temperature using platinum foils as electrodes without separation of the anodic compartment. Thus, 1.2 equivalent of constant current (200 mA) was applied with the terminal voltage kept at about 5.5 V. Products were separated by column chromatography on silica gel. The results are listed in Table 1.

TABLE 1. PRODUCTS OF ANODIC OXIDATION OF **1** IN ACETONITRILE

1 R	**3** (%)[a]	Sulfoxide (%)[a]	Recovered **1** (%)[b]
Methyl (**1a**)	60 (**3a**)	trace	19

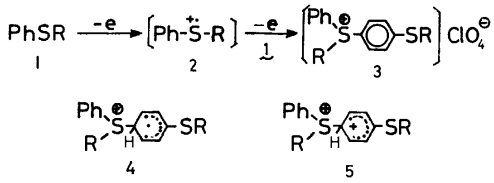
Cyclohexyl (**1c**)	57 (**3c**)	trace	20
Phenyl[1]	71	trace	19

a) The yield is calculated on the basis of **1**. b) *m*-Chlorothioanisole, diphenyl sulfide, and phenyl benzyl sulfide were employed for internal standards for glpc.

Alkyl phenyl sulfides **1** afforded the corresponding sulfonium perchlorates **3** in *ca.* 60—70% yields on the basis of **1**. This suggests that in the absence of water anodic oxidation of **1** takes place predominantly leading to the formation of the salts **3** in contrast to the results obtained with water–acetonitrile[3] or water–hydrogen chloride giving sulfoxides.[4]

Formation of **3b** from **1b** reveals that the divalent sulfide would be more reactive as compared with the double bond[5] of **1b**, since the phenyl group of **1** should undergo electrophilic attack by the cation radical of **2** rather than intramolecular attack of the double bond. No evidence of the S–R bond cleavage of **1** was observed during the course of electrolysis since no diphenyl disulfide was detected in glpc.[3]

Accordingly, the cation radical **2** would attack the *para*-position of the phenyl ring to give a cyclohexadienyl radical intermediate **4**, which would be readily oxidized to **5** followed by deprotonation to give **3**. Or, a dication formed incipiently from further oxidation of **2** would couple with the sulfide **1** leading to **5**.



The sulfonium salt **3a**, pale brownish crystals, could be purified by recrystallization from dichloromethane–ether. Its IR spectrum had a characteristic strong band at 1095 cm^{-1} due to the sulfonium group and its NMR spectrum showed a singlet (3H) at δ 3.62 corresponding to the methyl group attached to the trivalent sulfur atom of **3a**. Treatment of **3a** with *n*-butyllithium followed by benzaldehyde in tetrahydrofuran at −78 °C gave the epoxide **6** (50%) and the sulfide **7** (50%).[6] Reduction of **3a** with lithium aluminum hydride gave **7** (60%).[7]

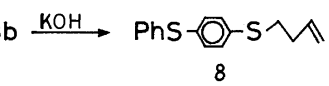
Trippett, *J. Chem. Soc.*, **1961**, 4263.

The structure of the sulfonium salt **3b**,[8] a brown oil, was characterized by its IR and NMR spectra. Treatment of **3b** with potassium hydroxide in ethylene glycol at 80 °C provided **8** and butadiene, the latter being trapped in a bromine–carbon tetrachloride solution.



8

Structural assignment of the salt **3c**,[8] a slightly brownish amorphous solid, was carried out by comparison of its IR and NMR spectral data with those of the homologous compounds **3a** and **3b**.

Experimental

Preparation of Sulfides. Sulfides **1a** and **1c** were prepared from sodium thiophenoxide and the corresponding alkyl halides.[9] Sulfide **1b** was prepared as follows. Thiophenol (22.0 g) in 25 ml of dioxane was refluxed with 1,4-dibromobutane (50 g) and pyridine (18.0 g) with stirring for 12.5 hr. The mixture was poured onto ice and extracted with $CHCl_3$. Distillation of the extracts gave phenyl δ-bromobutyl sulfide (31%): bp 151—157 °C/8.0 mmHg. Refluxing of the sulfide with an equimolar amount of potassium *t*-butoxide in dry *t*-butanol for 1 hr provided sulfide **1b** (60%): bp 95—98 °C/6.0 mmHg; IR (Neat) 1640 (m, C=C), 1580 (m, Ph-S), 915, 740, 690 cm^{-1}; NMR ($CDCl_3$) δ 7.00—7.40 (m, 5H, Ph), 5.40—6.20 (m, 1H, -CH=C), 4.80—5.30 (m, 2H, C=CH_2), 2.80—3.10 (m, 2H, CH_2-C=C), 2.40 (t, 2H, J= 8 Hz, CH_2-S); Mass (*m/e*) 164 (M^+). Found: C, 73.00; H, 7.25%. Calcd for $C_{10}H_{12}S$: C, 73.13; H, 7.37%.

Electrolysis. Electrolysis of **1a** was carried out as follows: A solution of **1a** (310 mg) and $LiClO_4$ (500 mg) in 10 ml of dry CH_3CN in a 20 ml tall beaker was electrolyzed under N_2 at *ca.* 20 °C using two 3 cm^2 platinum foils without separation of the compartment. Constant current (200 mA, 1.2 equiv) was applied while the terminal voltage was about 5.5 V. Electrolyses of **1b** and **1c** were carried out in a similar manner to that for **1a**.

*Phenyl Methyl-*p*-methylthiophenyl-sulfonium Perchlorate (3a).* The reaction mixture combined with *m*-chlorothioanisole (79 mg, 0.5 mmol) as an internal standard for glpc was concentrated. The residue was taken up in $CHCl_3$, washed with water, dried (Na_2SO_4) and concentrated. The residue was developed on silica gel column with $CHCl_3$ and then acetone. The $CHCl_3$ eluent was subjected to glpc analysis (Diasolid L, 10% polyneopentyl glycol succinate (PNGS) coated column, 1 m long, 150 °C). The amount of recovered **1a** was calculated by comparison of the peak area with that of the internal standard. The acetone eluent was crude sulfonium salt **3a** (261 mg), which was solidified in a vacuum. Crystallization of the salt from CH_2Cl_2-ether (1:2) gave slightly brownish white crystals: mp 132.0—132.5 °C; IR (Nujol) 1580 (m), 1120—1070 (vs, sulfonium), 820, 760, 695 cm^{-1}; NMR ($CDCl_3$) δ 7.30—8.00 (m, 9H, Ph), 3.62 (s, 3H, $=S^+-CH_3$), 2.43 (s, 3H, S-CH_3). Found: C, 48.30; H, 4.28%. Calcd for $C_{14}H_{15}ClO_4S_2$: C, 48.48; H, 4.35%.

Reaction of 3a with n*-Butyllithium.* To a mixture of **3a** (347 mg) in 5 ml of dry THF under N_2 at −78 °C was added dropwise with stirring 0.9 ml of *n*-butyllithium in ether (1.64 M). The yellow solution was stirred for 45 min and to this was added 0.1 ml (*ca.* 1 mmol) of benzaldehyde in 3 ml of THF. The mixture was stirred for 1 hr at −78 °C, then the bath was removed. After tetralin (66 mg, 0.5 mmol) and phenyl benzyl sulfide (100 mg) had been added as internal standards for glpc, the reaction mixture was poured onto ice and extracted with ether. The extracts were washed, dried (Na_2SO_4), and distilled. The fraction, bp below 123 °C/13 mmHg, was analyzed by glpc (Diasolid L, 10% PNGS coated column, 2 m long, 100 °C) giving benzaldehyde (53 mg) and **6** (60 mg); their retention times in glpc were consistent with those of authentic samples, their spectral data supporting their structures. Continued distillation of the pot residue gave a fraction, bp below 120 °C/0.08 mmHg, which was analyzed by glpc (Diasolid L, 10% Silicone SE-30, 2 m long, 180—210 °C) giving **7** (147 mg) as a colorless oil: IR (neat) 1580 (m), 1480 (m), 810, 740, 690 cm^{-1}; NMR ($CDCl_3$) δ 7.10—7.40 (9H, Ph), 2.45 (s, 3H, S-CH_3); Mass (*m/e*) 232 (M^+), 217, 185, 108. Found: C, 67.21; H, 5.30%. Calcd for $C_{13}H_{12}S_2$: C, 67.19; H, 5.21%.

*Phenyl-3-butenyl-*p*-(3-butenylthio)phenyl-sulfonium Perchlorate (3b).* Crude sulfonium salt **3b** was purified by passing through a short silica gel column with $CHCl_3$-acetone (1:1), followed by tlc on silica gel with ethyl acetate to afford a brown oily **3b**:[8] IR (neat) 1650, 1580, 1120—1070 (s), 930, 820, 750, 680 cm^{-1}; NMR ($CDCl_3$) δ 7.20—8.10 (m, 9H, Ph), 5.50—6.20 (m, 2H, -CH=C), 4.90—5.30 (m, 4H, -C=CH_2), 4.22 (t, 2H, J=8 Hz, $=S^+-CH_2$), 3.03 (t, 2H, J=7 Hz, S-CH_2), 2.30—2.80 (m, 4H, CH_2-C=C).

*Phenyl Cyclohexyl-*p*-cyclohexylthiophenyl-sulfonium Perchlorate (3c).* Isolation was carried out in a similar manner to that for **3a**. The sulfonium salt **3c**, a slightly brownish amorphous solid:[8] IR (Nujol) 1580, 1070—1110 (s), 820, 750, 685 cm^{-1}; NMR ($CDCl_3$) δ 7.20—8.40 (m, 9H, Ph), 4.50—5.20 (m, 1H, $=S^+-CH$), 2.90—3.60 (m, 1H, S-CH), 1.00—2.30 (m, 20H, CH_2).

Reduction of 3a by Lithium Aluminum Hydride. To a mixture of **3a** (347 mg) in 4 ml of dry THF under N_2 was added at once 57 mg of $LiAlH_4$. This was stirred at 5 °C for 1 hr and quenched by addition of 5 ml of saturated aqueous ammonium chloride. After phenyl benzyl sulfide (100 mg) had been added as an internal standard for glpc, the mixture was extracted with ether, washed and dried (Na_2SO_4). The residue was analyzed by glpc (Diasolid L, 10% Silicone SE-30, 2 m long, 180—210 °C) giving **7** (139 mg). The retention time of **7** in glpc and its spectral data support the structure.

Reaction of 3b with Potassium Hydroxide. A mixture of **3b** (580 mg) and KOH (120 mg) in 4 ml of ethylene glycol was heated at 80 °C for 1 hr in a 10 ml tall beaker equipped with N_2 bubbler. The N_2 gas was passed through a trap containing 5 ml solution of CCl_4 with bromine. The mixture was extracted with ether, washed and dried (Na_2SO_4). Separation of the concentrated extracts by tlc on silica gel with CH_2Cl_2 gave **8** (133 mg) as a major product: IR (neat) 1650, 1580, 920, 740, 690 cm^{-1}; NMR ($CDCl_3$) δ 7.10—7.40 (broad s, 9H, Ph), 5.50—6.20 (m, 1H, -CH=C), 4.80—5.20 (m, 2H, C=CH_2), 2.70—3.10 (m, 2H, S-CH_2), 2.10—2.60 (m, 2H, -CH_2-C=C); Mass (*m/e*) 272 (M^+), 231, 218, 197. Found: C, 70.67; H, 6.03%. Calcd for $C_{16}H_{16}S_2$: C, 70.54; H, 5.96%.

From the CCl_4 solution white crystals were obtained and assigned to be 1,2,3,4-tetrabromobutane in comparison with its spectral data with that of authentic sample.

8) Difficulties were encountered in the microanalyses of **1b** and **1c** because of their hygroscopic nature.

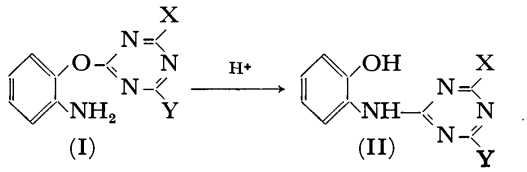
The Catalytic Effect of Acid on the *O*→*N* Migration of the *s*-Triazinyl Group of *O*-(*s*-Triazinyl)-2-aminophenols

Takeo SHIOJIMA, Yōji HASHIDA, and Kohji MATSUI

Department of Synthetic Chemistry, Faculty of Engineering, Gunma University, Tenjincho, Kiryu, Gunma 376

(Recieved March 20, 1973)

In a previous paper[1] we have reported that *O*-(*s*-triazinyl)-2-aminophenols (I) rearrange readily in the presence of acid to give *N*-(*s*-triazinyl)-2-aminophenols. However, the details of the rearrangement in the presence of acid have not yet been given. This paper will report the quantitative results on the influence of acid on the rearrangement of *O*-(*s*-triazinyl)-2-aminophenols.



(I) (II)

a: X=OCH_3 Y=$N(CH_3)_2$
b: X=Y=$N(CH_3)_2$

Experimental

Materials. The *O*-(*s*-triazinyl)-2-aminophenols were synthesized by the method described in a previous paper.[2] The *O*-(2,4-dinitrophenyl)-2-aminophenol (III) was prepared by the method of Roberts.[3]

Kinetic Measurements. The kinetic measurements were carried out in a manner similar to that described in a previous paper[2] in buffer solutions of a constant ionic strength of 0.1 at 25 °C; the apparent first-order rate constants were calculated using Eq. (1);

$$k' = -2.303/t \log \{D_\infty - (D_t)/(D_\infty) - D_0\} \quad (1)$$

where D_0, D_∞, and D_t denote the optical densities of a solution at an appropriate wavelength observed at initial and infinite times, and at time t. The measurements were carried out in aqueous solutions in the cases of the compounds (I) and in a 50% (vol) methanolic solution in the case of compound (III).

Results and Discussion

The effect of the pH of the solution on the apparent rate constants (k') for the rearrangement of Ia, Ib, and III were investigated; compound (III) was used in order to elucidate the function of the *s*-triazine nucleus by means of a comparison of the results of I and III. The results are shown in Fig. 1.

In the case of III, the apparent rate constant decreased with an increase in the acidity of the solution; the result is considered to be due to a decrease in the concentration of III by protonation at the amino group.

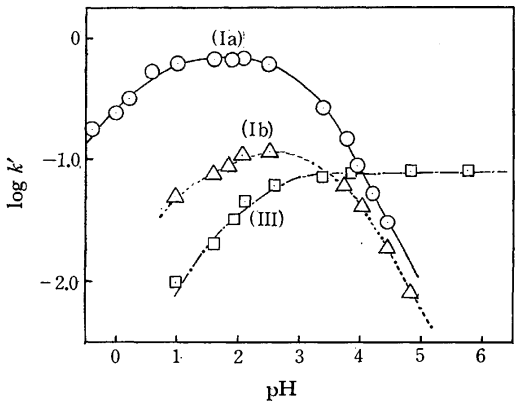


Fig. 1. pH dependence of the apparent rate constants for the rearrangement reactions of compounds (Ia, Ib, and III). (unit of k' is min^{-1})

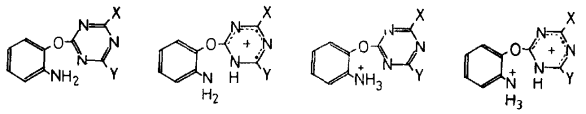
On the contrary, in the case of Ia or Ib, no simple relation between log k' and pH value was observed. With an increase in the acidity of the solution, the apparent rate constant increased in the pH region above 3; however, it decreased in the pH region below 2. In these cases, the presence of two kinds of basic groups, *i.e.*, the amino and *s*-triazinyl groups, is considered to be the reason for the complexity. Under the present experimental conditions, the four species indicated by (A)—(D) may be assumed to be present in the solutions:



(A) (B) (C) (D)

Among these, B is expected to be the most reactive species, for in this case an intramolecular nucleophilic attack by the amino group is considered to take place most readily by lowering the electron density of the ring-carbon atoms of the *s*-triazine nucleus. In the pH region above 3, the fact that the rate constant increased with an increase in the acidity of the medium can be explained by assuming that the concentration of B increases with the increase in the acidity by a preferential protonation at the ring-nitrogen atom of the *s*-triazine nucleus.[4,5] On the other hand, in the pH region below 2, it is assumed that the apparent rate constant decreased because of a decrease in the concentration of B as a result of further protonation at the amino group to give D.

If we assume that the protonation (expressed by Eq.

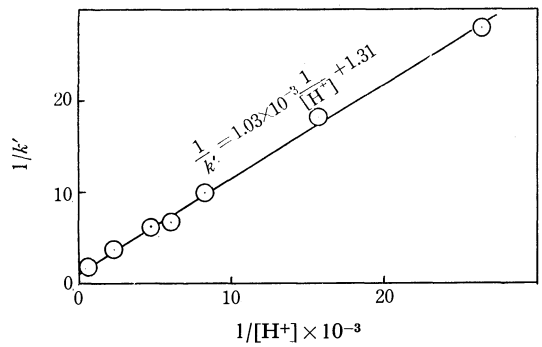

Fig. 2. Plots of $1/k'$ against $1/[H^+]$ for the rearrangement of compound (Ia) in the pH range of 4.42 to 2.50.

(2)) proceeds much faster than the rearrangement (Eq. (3)), and that B is the only reactive species, the apparent rate constant may be expressed by Eq. (4):[6]

$$(A) + H^+ \overset{K_a}{\rightleftarrows} (B) \quad (2)$$

$$(B) \overset{k}{\longrightarrow} (II) \quad (3)$$

$$1/k' = 1/k + 1/kK[H^+] \quad (4)$$

K_a: equilibrium constant

6) From Eq. (2) and (3), the rate of the rearrangement of B is expressed by Eq. (5):

$$v = k[B] = kK[A] \times [H^+] \quad (5)$$

Since the apparent rate constant was calculated in the manner described in the Experimental section, the rate of the rearrangement in the presence of acid can be written by Eq. (6):

$$v = k'([A]+[B]) = k'[A](1+K[H^+]) \quad (6)$$

From the assumption presented above, Eq. (4) is obtained by putting Eqs. (5) and (6) as equal.

Table 1. Rate constants and dissociation constants (pK_a)

Compound	$pK_a(TH^+)$[a]	pK_a (NH_3^+)	k (min^{-1})
Ia	3.11	0.33	7.63×10^{-1}
Ib	3.64	0.886	1.32×10^{-1}
III		1.99	7.50×10^{-2}

a) TH^+ denote the species (B).

From Eq. (4), the plots of $1/k'$ against $1/[H^+]$ may be expected to give a straight line. Indeed, a linear relation was observed, as is shown in Fig. 2 in the case of (Ia).

From the intercepts and slopes of the lines, the rate constants of the reactive species (B) and the equilibrium constants were calculated; they are listed in Table 1. From the data obtained in the pH region below 2, the equilibrium constants attributable to the amino group were also obtained. Using these values, the relations between $\log k'$ and pH values can be calculated; they are shown in Fig. 1 by full, dotted, and dashed lines. It can be seen that the corresponding experimental results (expressed by circles, squares, and triangles respectively) lie close to the calculated lines. This finding supports the assumptions that the basicity of the *s*-triazine nucleus is stronger than that of the amino group and that the reactive species in the presence of acid is the protonated product at the ring nitrogen of the *s*-triazine nucleus (B), which rearranges faster by a factor of 4 orders or more than the neutral molecule.[2]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2915—2917 (1973)

The Reaction of 2-Chlorotropone with Methyl Methacrylate

Hitoshi TAKESHITA,* Masatoshi SHIMA, and Shô ITÔ

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received March 22, 1973)

The Diels-Alder reaction of troponoids with cyclic dienophiles including maleic anhydride is known to give only respective *endo*-adducts[1] with exception for tropolones[2-4] which yielded two stereoisomers. Our recent study[5] has disclosed even in the last case that the *endo*-adduct was initially formed but it underwent an acyloin rearrangement to the *exo*-isomer at the later stage. Contrary to the reactions with cyclic dienophiles, troponoids formed four regio- and stereoisomeric adducts in concerted fashion when an acyclic dienophile, acrylonitrile, was used.[6] We have extended our study to the reaction using 2-chlorotropone with methyl methacrylate, another acyclic dienophile for the generalization of the reaction.

adducts, III (19), IV (23), V (2), and VI (2.3%), were produced. The structures of these adducts were deduced by spectroscopic analyses. Thus, all the compounds have α,β-unsaturated carbonyl chromophore in IR and UV spectra showing them to be normal ${}_{\pi}4+{}_{\pi}2$ adducts, bicyclo[3.2.2]nona-3,6-dien-2-one derivatives. The presence of the absorption maximum around 260 nm for III and IV revealed them to be 3-chloro-derivatives,[7] and the absence of this particular absorption in the other two (V and VI) is therefore discernible as 1-chloro-derivatives. The methylene proton signals, in NMR spectra of all the four (III—VI) appears as AB patterns of ABX systems. Therefore, the methyl and methoxycarbonyl groups in V and VI can be located at C-8 position (Otherwise the signal should appear primarily as AB type). In order to confirm the poistion of these groups in III and IV the corresponding deuterio-derivatives were prepared using 2-chlorotropone-3,5,7-d_3 (I-d_3) and the major products, III-d_3 and IV-d_3, were isolated. The NMR signals of the methylene protons appeared as the AB type both in III-d_3 and IV-d_3, establishing the position of the substituents at C-9. The orientation of the substituents in III and IV was again deduced from the differences in chemical shifts of the methylene protons, which should suffer the magnetic anisotropy from the adjacent carbonyl group of the substituent. The *exo*-protons, having smaller coupling constants with bridge head protons and long-range couplings with one of olefinic protons in III and VI appeared in considerably higher field than those in IV and V, revealing the formers (III and VI) to have *exo*-methyl and *endo*-methoxycarbonyl groups and the latters (IV and V) the opposite orientations.

All of the adducts are the primary products of the reaction of I and II because each adduct was quantitatively recovered after being heated in the presence of II at 140 °C for 48 hr.

Table 2. Relative yield of Diels-Alder adducts of 2-chlorotropone

Dienophiles	Sites of the reaction[a]					
	[4,7]		[5,2]		[7,4]	
	exo	*endo*	*exo*	*endo*	*exo*	*endo*
II			4.3	5.0	49.7	41.0
Acrylonitrile	8.6	11.1	39.5			40.8

a) [*m*,*n*] denotes the positions of I which formed a bond between β- and α-positions of dienophiles, respectively.

Thus, the dienophile reacted rather regiospecifically but nonstereospecifically. As summarized in Table 2, this is quite a contrast with the reaction of I and acrylonitrile[6] which afforded the adducts with stereospecificity but without regiospecificity. In the present reaction, the polar effect due to electron-releasing chlorine atom and electron-withdrawal ester group appears to be reinforced with steric repulsion between chlorine and the substituents at α-carbon atom of II to exhibit the high regiospecificity. The lack of stereospecificity may come from the stabilization of transition state by the methyl group as well as the methoxycarbonyl group.[8,9]

Experimental

Reaction of 2-Chlorotropone (I) and Methyl Methacrylate (II). I (2 g) and II (9 ml) were heated at 135—140 °C for 48 hr in a sealed glass tubing. After the removal of the excess of II, the residual oil was distilled under reduced pressure to give faintly yellow liquid (1.95 g) which was chromatographed through silica gel (40 g) with chloroform-pet. ether (4: 1). From the least polar fractions, the adduct III was separated out as colorless crystals whose recrystallization from cyclohexane yielded colorless prisms, mp 98—99 °C (320 mg).

Found: C, 60.27; H, 5.59%. Calcd for $C_{12}H_{13}O_3Cl$: C, 59.88; H, 5.44%. λ_{max}^{MeOH} 241 (ε=6020), 262 (sh), 320 nm (ε=100). ν^{KBr}: 1738, 1685 cm^{-1} (C=O), 1632, 1598 cm^{-1} (C=C, strong). Following fractions yielded the adduct IV which was distilled on a cold finger to give colorless liquid, bp 130 °C/1.5 mmHg (bath temp.) (190 mg) with a distinct single spot on thin layer chromatograms. Found: C, 60.12;

8) Y. Kobuke, T. Fueno, and J. Furukawa, *J. Amer. Chem. Soc.*, **92**, 6548 (1970).

9) However, there is an experiment which shows a contravention to this explanation. *cf.* K. N. Houk and L. J. Luskus, *ibid.*, **93**, 4606 (1971).

H, 5.63%. λ_{max}^{MeOH} 240.5 (ε=6000), 262 (sh), 323 nm (ε=100). ν^{liq}: 1735, 1685 cm^{-1} (C=O), 1631, 1598 cm^{-1} (C=C, strong). Subsequent fractions contained the adduct V and a few mg of recovered I which was removed by brief extraction with concd hydrochloric acid. Analytical specimen of V was obtained by cold finger distillation to give 76 mg of colorless liquid, bp 130 °C/1.5 mmHg (bath temp.). Found: C, 59.79; H, 5.75%. λ_{max}^{MeOH} 225 (ε=8050), 330 nm (ε=200), ν^{liq}: 1736, 1680 cm^{-1} (C=O), 1630, 1600 cm^{-1} (C=C, weak). The most polar fraction afforded the adduct VI (80 mg) as colorless plates, mp 110.5—112 °C (fr. cyclohexane). Found: C, 60.12; H, 5.74%. λ_{max}^{MeOH} 225 (ε=8000), 330 nm (ε=180). ν^{KBr}: 1735, 1680 cm^{-1} (C=O), 1630, 1598 cm^{-1} (C=C, weak). Repeated chromatography of intermediary fractions further afforded some amounts of the adducts, III to VI, but the absence of their isomer was confirmed by NMR spectral analysis of every fraction of the chromatography. Final yields of the products were estimated by NMR analysis as 19 (III), 23 (IV), 2 (V), and 2.3% (VI), respectively.

Reaction of 2-Chlorotropone-3,5,7-d_3(I-d_3) and II. I-d_3 (200 mg) and II (1 g) were heated in a sealed glass tubing at 135—145 °C for 60 hr. A similar work up with the above afforded III-d_3, mp 98—99 °C (20 mg) and IV-d_3, colorless liquid (30 mg). The other two compounds were not isolated.

Heating of the Adducts (III, IV, V, and VI) with II. Each adduct (10—20 mg) was mixed with II (1—2 ml) in a sealed tube and heated at 140±5 °C for 48 hr. After the evaporation of II, whole residue was analyzed by NMR spectral determination. Only the starting compound was shown to be presented in each reaction.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2917—2918 (1973)

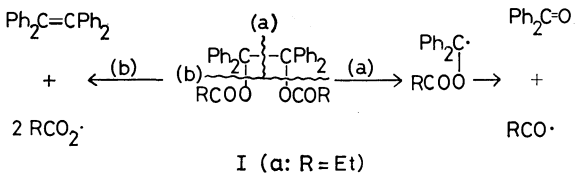
The Oxidation of Alkylbenzenes and Acylcarbinols by Means of Benzopinacol Diesters

Katuzi KITATANI, Tamio SHIRAFUJI, and Hitosi NOZAKI

Department of Industrial Chemistry, Kyōto University, Yoshida, Sakyō-ku, Kyōto 606

(Received March 30, 1973)

The thermal decomposition of benzopinacol diesters (I) in benzene at 150—160 °C results in the (a) cleavage of the central carbon-carbon bond of I, followed by the acyl radical-release or hydrogen-abstraction of the resulting acyloxydiphenylmethyl radical, thus affording benzophenone (II) and benzhydryl esters (III). The trace amount of tetraphenylethylene (IV) (<5%) thus obtained was ascribed to the (b) cleavage.[1,2]



I (a: R=Et)

We have found that benzopinacol dipropionate (Ia) serves as a catalyst in the autoxidation of ethylbenzene, cumene, and tetralin. Table 1 summarizes the yields of the resulting ketones, acetophenone and α-tetralone, and of the products (II and IV) arising from Ia. No trace of III has been observed. Each mol of Ia accounted for *ca.* 20 mol of acetophenone or α-tetralone.

We found also that benzoin and an acyloin were oxidized to the corresponding α-diketones by Ia. The heating of a 0.1 M anisole solution of benzoin and Ia in a mol ratio of 2: 1 at 130 °C under a nitrogen atmosphere gave a quantitative yield of benzil, the Ia being converted to II (43) and IV (26%). The reaction of 2-hydroxycyclododecanone with Ia under the same conditions gave cyclododecane-1,2-dione in a 50% yield, besides II (34) and IV (31%). The yields are based on the amount of each component consumed, either the substrate or Ia. In order to examine the possible autoxidation, a mixture of benzoin and Ia in a mol ratio of 4: 1 was heated under an oxygen atmosphere. About 50% of benzoin was oxidized to afford the corresponding yield of benzil. 2-Hydroxycyclododecanone also behaved similarly, or it was not autoxidized at all under such conditions.

The exact nature of this stoichiometric oxidation is still not known, but the oxidation of benzylic methylene is apparently catalyzed by radicals generated from Ia. It should be added that the reaction of *N,N*-dimethylaniline as a solvent with Ia and Cu(II)Cl_2 (in a mol ratio of 1: 2) afforded an acylated product, *N*-methyl-

TABLE 1. AUTOXIDATION OF ALKYLBENZENES IN THE PRESENCE OF BENZOPINACOL DIPROPIONATE

Substrate	Reaction[a] temp °C	hr	Product (%)[b]	Ph_2CO[c]	$Ph_2C=CPh_2$[c]
Ethylbenzene	150	48	Acetophenone 47 (30)	67	33
Cumene	150	48	Acetophenone 36 (84)	60	12
Tetralin	120	17	α-Tetralone 45 (50)	32	25

a) A mixture of Ia and the alkylbenzene in a mol ratio of *ca.* 1: 200 was heated in oxygen atmosphere.
b) The yields of products are based on the consumed amount of the hydrocarbon. Data in the parentheses show the conversion (%) of hydrocarbons.
c) The yields are based on the added amount of Ia.

1) T. Shirafuji, Y. Yamamoto, and H. Nozaki, This Bulletin, **45**, 2574 (1972).

2) Copper (II) carboxylates in aqueous DMF catalyze the decomposition of diphenyldiazomethane to afford benzopinacol diesters. This reaction constitutes the only available approach to the novel class of I esters. See T. Shirafuji, Y. Yamamoto, and H. Nozaki, *Tetrahedron*, **27**, 5353 (1971).

propionanilide (V), in a 44% yield (based on both propionyl groups of Ia). In the absence of Cu(II), the formation of V was not detected. This can be explained by assuming that the intermediary propionyl radical, after having been generated *via* the cleavage (a), is oxidized by Cu(II) to the acyl cation.[3] The ion is trapped by *N,N*-dimethylaniline to afford the intermediate, $(Me_2N(Ph)–COEt)^+$, which loses its methyl cation to provide V.

The acyloxy and alkyl radicals assumed to be generated *via* the (b) cleavage have not yet been characterized, but we cannot exclude the possibility of their being due, partly at least, to the oxidations mentioned above. The reasons are that consistently higher yields of IV have been obtained in these cases and IV can not be ascribed to diphenylcarbene,[4] but instead possibly results from the acyloxydiphenylmethyl radical in the (a) cleavage.

Experimental

All the melting and boiling points are uncorrected. The glc analyses and separations were performed with columns (1 m) packed with HVSG (30%) on Celite 545 or SE 30 (5%) on Chromosorb. Unless otherwise stated, the yields were estimated by glc analyses.

The Oxidation of Ethylbenzene by Means of the Oxygen-Benzopinacol Dipropionate (Ia) System. A mixture of ethylbenzene (0.95 g, 9.0 mmol) and Ia (25 mg, 0.050 mmol) was heated under stirring and refluxing (140—150 °C) in an oxygen atmosphere for 48 hr. The reaction mixture was first heated at 60 °C for 30 min with 2 N aqueous NaOH (1 ml), neutralized with aqueous sulfuric acid, and then extracted with ether. The extract was washed with an aqueous solution (1%) of $FeSO_4$, dried (Na_2SO_4), and concentrated *in vacuo*. Glc separation (HVSG 30%, 1 m; 150 °C) gave acetophenone (0.15 g, 47%), benzophenone (15 mg, 67%), tetraphenylethylene (6.0 mg, 33%), and the recovered ethylbenzene (0.66 g, 70%).

The Oxidation of Benzoin by Ia. An anisole solution (5 ml) of a mixture of benzoin (0.21 g, 1.0 mmol) and Ia (0.24 g, 0.50 mmol) was heated at 130 °C for 24 hr under a nitrogen atmosphere. The concentration of the reaction mixture *in vacuo*, followed by glc separation (SE 30 30%, 1 m; 180 °C), gave benzil (0.20 g, 95%), benzophenone (80 mg, 43%), and tetraphenylethylene (40 mg, 26%).

The Reaction of N,N-*Dimethylaniline with Ia in the Presence of Cupric Chloride.* A mixture of *N,N*-dimethylaniline (1 ml), Ia (0.10 g, 0.20 mmol), and $CuCl_2 \cdot 2H_2O$ (70 mg, 0.40 mmol) was heated at 150—160 °C for 17 hr under stirring in a nitrogen atmosphere. Heating was continued until the solution turned blue. The reaction mixture was then washed with aqueous $NaHCO_3$ and extracted with benzene. The extract was concentrated and subjected to glc (SE 30 30%, 1 m; 150 °C) to afford *N*-methylpropionanilide (30 mg, 44%), benzophenone (40 mg, 60%), and tetraphenylethylene (15 mg, 22%). The *N*-methylpropionanilide (mp 56 °C (lit,[5] 56—58 °C)) was identical with an authentic sample[5] (IR, NMR, MS, and glc retention time).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2918—2919 (1973)

Synthesis of Dihydrofarfugin B

Hidekazu SHIRASAKI, Hideo KOMATSU, Hajime NAGANO, Yoshihiko MORIYAMA, Yoshiaki TANAHASHI, and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received April 2, 1973)

Farfugin A (I) and farfugin B (II) have been isolated from the benzene extract of *Farfugium japonicum* Kitamura (=*Ligularia tussilaginea* Makino). Spectral data of the latter and its derivatives led to two alternative structures, II and III for farfugin B. The structure of farfugin B was finally deduced to be 3,5-dimethyl-6-(*trans-n*-3-pentenyl)benzofuran (II) on the basis of NOE (Nuclear Overhauser Effect) experiments.[1,2]

We report here the synthesis of dihydrofarfugin B (IV); this confirms the structure of II for farfugin B.

Grignard reagent prepared from 1-methyl-2-bromo-4-methoxybenzene (V)[3] was treated with *n*-pentanal to give an alcohol (VI). Dehydration of VI with iodine[4] gave the dehydrated product (VII), which was subjected to hydrogenation over Pd–C to afford VIII. Demethylation of VIII with hydrobromic acid in acetic acid gave a phenol (IX).

Finally the furan moiety was introduced as follows. Phenoxyacetone (X), prepared from the reaction of the phenol (IX) with chloroacetone, was cyclized with polyphosphoric acid on heating. This cyclization occurred toward two directions to give two isomeric benzofuran derivatives, (IV) and (XI), in the ratio of 5: 2. The PMR spectrum of the minor component showed a signal of AB type quartet (δ_A=6.91 and δ_B=7.03 ppm; J=9 Hz) due to the aromatic *ortho*-

protons. This led to the structure of 3,5-dimethyl-4-*n*-pentylbenzofuran (XI) for the minor component. The major one was consequently assigned to be 3,5-dimethyl-6-*n*-pentylbenzofuran (IV), which was found to be identical with dihydrofarfugin B in all respects (IR, PMR, UV, and mass spectra). The presence of *trans*-*n*-3-pentenyl side chain was already shown for farfugin B.[1] Thus, the structure of farfugin B was confirmed to be 3,5-dimethyl-6-(*trans*-*n*-3-pentenyl) benzofuran (II).

Experimental

IR spectra were taken in neat film, and PMR spectra were measured in $CDCl_3$ containing TMS as internal standard.

*1-(1-Hydroxy-*n*-pentyl)-2-methyl-5-methoxybenzene (VI).* To the Grignard reagent prepared from 1-methyl-2-bromo-4-methoxybenzene (V)[3] (12.1 g, 58 mmol) in dry tetrahydrofuran (50 ml) and magnesium ribbon (1.75 g, 72 mmol), a solution of *n*-pentanal (6.02 g, 70 mmol) in dry tetrahydrofuran (20 ml) was added dropwise and stirred for 1 hr at room temperature. The reaction material was poured on a mixture of crashed ice (100 g) and concentrated hydrochloric acid (10 ml). This was extracted with ether three times (each 100 ml). After usual work-up, the extract gave a residue (14.0 g) containing VI, a part of which was purified by chromatography on silica gel with benzene as eluent to give pure VI, an oil, IR: ν_{max} 3380 cm^{-1} (OH); PMR: δ 0.90 (m, terminal C$\underline{H}_3$ on a side chain), 2.24 (s, aromatic C$\underline{H}_3$), 3.79 (s, OC$\underline{H}_3$), 4.88 (t, J=6 Hz, -C$\underline{H}$-OH), and 6.50—7.10 (aromatic protons); MS: *m/e* 208 (M^+; $C_{13}H_{20}O_2$). Found: C, 74.91; H, 9.72%. Calcd for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68%.

*1-(*n*-1-Pentenyl)-2-methyl-5-methoxybenzene (VII).* The above residue (3.51 g) was heated with iodine (170 mg)[4] at 100 °C for 3 hr. The reaction mixture was chromatographed on silica gel (150 g) with benzene as eluent to afford VII (2.23 g; yield 78% from V), an oil, PMR: δ 0.95 (m, terminal C$\underline{H}_3$), 2.18 (m, 2H, allylic protons), 2.24 (s, aromatic C$\underline{H}_3$), 3.78 (s, OC$\underline{H}_3$), and 6.10—7.30 (aromatic and olefinic protons); MS: *m/e* 190 (M^+; $C_{13}H_{18}O$). Found: C, 81.88; H, 9.68%. Calcd for $C_{13}H_{18}O$: C, 82.06; H, 9.54%.

*1-*n*-Pentyl-2-methyl-5-methoxybenzene (VIII).* Hydrogenation of VII (1.16 g, 6.1 mmol) was effected in ethanol over 10% palladium-charcoal. After usual treatment, VIII (926 mg; yield 79%), an oil, was obtained. Characterization of VIII is as follows; PMR: δ 0.89 (m, terminal C$\underline{H}_3$), 2.21 (s, aromatic C$\underline{H}_3$), 2.54 (m, 2H, benzyl protons), 3.74 (s, OC$\underline{H}_3$), and 6.50—7.20 (aromatic protons); MS: *m/e* 192 (M^+; $C_{13}H_{20}O$). Found: C, 81.28; H, 10.68%. Calcd for $C_{13}H_{20}O$: C, 81.20; H, 10.48%.

*1-*n*-Pentyl-2-methyl-5-hydroxybenzene (IX).* To a solution of VIII (0.79 g, 4.1 mmol) in acetic acid (5 ml), 48% hydrobromic acid (5 ml) was added and the mixture was heated under reflux for 20 hr. Acetic acid was removed under reduced pressure and ether (100 ml) was added to the residue. The ether solution was washed with saturated aqueous solution of sodium bicarbonate and then treated as usual. The residue was chromatographed on silica gel (50 g) with benzene as eluent to give IX (285 mg; yield 39%), an oil, IR: ν_{max} 3380 cm^{-1} (OH); PMR: δ 0.88 (m, terminal C$\underline{H}_3$), 2.19 (s, aromatic C$\underline{H}_3$), 2.49 (m, 2H, benzyl protons), 5.57 (s, O$\underline{H}$), and 6.45—7.10 (aromatic protons); MS: *m/e* 178 (M^+; $C_{12}H_{18}O$). Found: C, 80.87; H, 10.48%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%.

*1-*n*-Pentyl-2-methyl-5-acetonyloxybenzene (X).* A solution of IX (266 mg, 1.5 mmol) in dry acetone (10 ml) was heated under reflux with chloroacetone (299 mg) and potassium iodide (130 mg) for 20 hr. The solvent was distilled off and ether (100 ml) was added to the residue, and the ether solution was treated as usual. The residue was chromatographed on silica gel (30 g) with benzene as eluent to afford X (252 mg; yield 72%), an oil, IR: ν_{max} 1720 cm^{-1} (CO); PMR: δ 0.90 (m, terminal C$\underline{H}_3$), 2.16 (s, 6H, aromatic C$\underline{H}_3$ and -COC$\underline{H}_3$), 2.51 (m, 2H, benzyl protons), 4.35 (s, -OC$\underline{H}_2$CO-) and 6.40—7.02 (aromatic protons); MS: *m/e* 234 (M^+; $C_{15}H_{22}O_2$). Found: C, 76.64; H, 9.48%. Calcd for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%.

*3,5-Dimethyl-6-*n*-pentylbenzofuran (IV) and 3,5-Dimethyl-4-*n*-pentylbenzofuran (XI).* Acetonyloxy derivative (X) (200 mg, 0.86 mmol) was heated with polyphosphoric acid (4 g) at 100 °C for 10 min under a nitrogen atmosphere. After cooling, the reaction material was poured on a mixture of crashed ice (50 g) and concentrated hydrochloric acid (5 g) to decompose the excess polyphosphoric acid. This was extracted with ether and the ethereal solution was washed with saturated aqueous solution of sodium bicarbonate (100 ml) and then treated as usual. The residue obtained was chromatographed on silica gel to give a mixture (45.4 mg; yield 25%) of IV and XI. The mixture was further chromatographed using 20% $AgNO_3$-impregnated silica gel with petroleum ether as eluent and IV (17.7 mg) and XI (7.5 mg) were obtained. Spectral data of IV, an oil, are as follows; IR: ν_{max} 1625, 1580, 800, 780 cm^{-1}; PMR: δ 0.90 (m, terminal C$\underline{H}_3$), 2.20 (d, J=2 Hz, C$\underline{H}_3$ on a furan ring), 2.38 (s, aromatic C$\underline{H}_3$), 2.66 (m, 2H, benzyl protons), and 7.05—7.20 (protons on a furan and a benzene ring); UV: λ_{max}^{EtOH} 251.5 nm (ε 11300); MS: *m/e* 216 (M^+; $C_{15}H_{20}O$). The compound IV was found to be identical with dihydrofarfugin B (IR, PMR, UV, and mass spectra).

Characterization of XI, an oil, is as follows; IR: ν_{max} 1580, 780 cm^{-1}; PMR: δ 0.93 (m, terminal C$\underline{H}_3$), 2.36 (two methyl groups on a furan and a benzene ring), 2.87 (m, 2H, benzyl protons), 6.97 (an AB quartet, δ_A=6.91, δ_B=7.03, J=9 Hz), and 7.16 (d, J=2 Hz, a proton on a furan ring); UV: λ_{max}^{EtOH} 254.3 nm (ε 12400); MS: *m/e* 216 (M^+; $C_{15}H_{20}O$). Found: C, 83.06; H, 9.55%. Calcd for $C_{15}H_{20}O$: C, 83.28; H, 9.32%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2920—2921 (1973)

Stereostructure of Zonarene

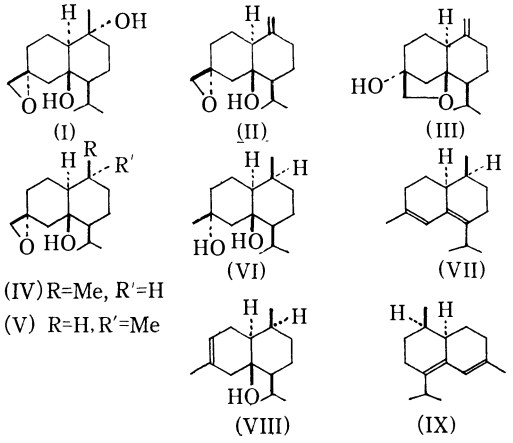
Masanobu IGUCHI, Masatake NIWA, and Shosuke YAMAMURA*

Faculty of Pharmacy, Meijo University, Showa-ku, Nagoya 468

(Received May 1, 1973)

Zonarene, a cadinane-type sesquiterpene, has been isolated from the brown seaweed (*Dictyopteris zonarioides*), and the structure of this hydrocarbon also been established by Fenical and his co-workers except for its stereostructure.[1] In the present paper, we wish to describe the stereostructure of zonarene including the absolute configuration by means of chemical transformation from preisocalamendiol, which has been synthesized from *l*-santonin,[2] to (+)-zonarene.

As described in the previous papers,[3,4] the epoxy-diol (I) was obtained from isocalamendiol, an acid-catalyzed cyclization product of preisocalamendiol, the absolute configuration of which had been already established. Further treatment of I with $POCl_3$–pyridine afforded the known dehydration product (II)[4] and a hydroxy-olefin (III)[5] in 40 and 27% yields, respectively. The structure of the latter was confirmed by its spectral data, in particular by the NMR signal at δ 3.46 ppm (2H, s) assigned to two protons attached to the carbon atom bearing the ether-oxygen atom. Catalytic hydrogenation of II on PtO_2 in AcOEt (room temp., 1.5 hr) afforded a mixture of two dihydro-compounds [IV (mp 69—70 °C) and V (mp 77—80 °C) in 82 and 6% yields, respectively]. On the basis of the comparison of the NMR spectra between IV and V, the newly formed secondary methyl group in the main product (IV) must be in an axial configuration (δ 1.05 ppm), whereas the corresponding methyl group in the latter is in an equatorial configuration (δ 0.85 or 0.87 ppm).[6] When treated with $LiAlH_4$ in ether (room temp., 2 hr), IV was converted into the corresponding diol (VI, mp 104—105 °C) in 92% yield. Finally, action of $POCl_3$–pyridine (room temp., overnight, and then 40 °C, 2 hr) on VI converted it to a mixture of two dehydration products (VII and VIII in 30 and 38% yields, respectively). The former was completely identical with an authentic sample of zonarene (glc and IR spectrum) except for the sign of the optical rotation cited in the literature.[1] The structure of the latter was characterized by its physical data [ν_{max}(film) 3550 cm^{-1}; $\delta(CCl_4)$ 1.63 (3H, br.s) and 5.48 ppm (1H, br.s)]. In conclusion, the stereostructure of zonarene including the absolute configuration should be represented by IX. Recently, the same result has also been obtained by Andersen and his co-workers.[7]



Experimental

All the melting-points are uncorrected. The IR spectra were recorded on a Hitachi-215 spectrophotometer. The NMR spectra were taken on Varian A-60 and Nihondenshi JNM-60H (60 MHz) spectrometers, using $CDCl_3$ as the solvent, unless otherwise stated. Only prominent peaks are cited. The chemical shifts are given in ppm relative to the internal TMS. The coupling constants are given in Hz (s: singlet; d: doublet; t: triplet; q: quartet; m: multiplet). The mass spectra were obtained on a Hitachi RMU-6D mass spectrometer operating with an ionization energy of 70 eV. Optical rotation was measured on a JASCO ORD/UV-5 spectrometer using MeOH as a solvent.

Dehydration of the Epoxy-diol (I). According to essentially the same condition as previously reported,[4] dehydration of the epoxy-diol (560 mg) in pyridine (10 ml) with $POCl_3$ (2 ml) in pyridine (4 ml) was carried out to give a pale brown oil (500 mg), which was chromatographed on alumina (Katayama Co. Ltd., 150—250 mesh; 10 g) and eluted with *n*-hexane–ether (1 : 1) to give the known colorless liquid (208 mg) of II[4] as the first fraction. After elution of II, a colorless liquid (140 mg) of III was isolated; ν_{max}^{film} 3460 br., 3080, 1645, 900, and 885 cm^{-1}; δ 0.91 (3H, d, J=7.0 Hz), 0.94 (3H, d, J=7.0 Hz), 3.46 (2H, s), 4.80 (1H, br.s), and 4.98 ppm (1H, br.s). Found: *m/e* 236.1785. Calcd for $C_{15}H_{24}O_2$: *m/e* 236.1776.

Catalytic Hydrogenation of the Epoxy-olefin (II). Catalytic hydrogenation of the epoxy-olefin (220 mg) in AcOEt (5 ml) over PtO_2 (5 mg) was carried out at room temp. for 1.5 hr, and then filtered to remove the catalyst. The filtrate was concentrated under reduced pressure to give a colorless liquid (220 mg), from which two reduction products were separated by preparative tlc (neutral alumina (E. Merck,

A. G., Germany)) using *n*-hexane–benzene (1: 1). The upper fraction gave white crystals (181 mg) of IV; mp 69—70 °C (from *n*-hexane); ν_{max}^{KBr} 3570 cm^{-1}; δ (CCl_4) 0.87 (3H, d, J=6.9 Hz), 0.90 (3H, d, J=6.9 Hz), 1.05 (3H, d, J=7.0 Hz), and 2.46 ppm (2H, s). Found: *m/e* 238.1940. Calcd for $C_{15}H_{26}O_2$: *m/e* 238.1933. From the lower fraction, a colorless liquid (31 mg) was obtained, which was further purified by preparative tlc (Kieselgel GF_{254}) using *n*-hexane–ether (2: 1) to give white crystals (14 mg) of V; mp 77—80 °C (from *n*-hexane); ν_{max}^{film} 3570 cm^{-1}; δ (CCl_4) 0.85 and 0.87 (9H, each br.d, $J\simeq$6.3 Hz), and 2.48 ppm (2H, s). Found: *m/e* 238.1901. Calcd for $C_{15}H_{26}O_2$: *m/e* 238.1933.

Reduction of Dihydro-epoxide (IV) with $LiAlH_4$. $LiAlH_4$ (10 mg) was added to a solution of IV (130 mg) in anhyd. ether (10 ml), and then the mixture was stirred at room temp. for 2 hr. After the decomposition of the excess reagent with three drops of water, the reaction solution was filtered. The filtrate was concentrated under reduced pressure to give white crystals, which was purified by preparative tlc (Wakogel B5-F) using *n*-hexane–ether (2: 1) to give white crystals (120 mg) of the diol (VI); mp 104—105 °C; ν_{max}^{KBr} 3340 br. cm^{-1}; δ 0.93 (6H, d, J=7.0 Hz), 1.05 (3H, d, J=7.0 Hz), 1.20 (3H, s), and 2.85 ppm (2H, s, OH); *m/e* 240 (M^+). Found: C, 74.70; H, 12.01%. Calcd for $C_{15}H_{28}O_2$: C, 74.95; H, 11.74%.

Dehydration of the Diol (VI). Into a solution of the diol (110 mg) in anhyd. pyridine (10 ml) was slowly stirred a solution of $POCl_3$ (2 ml) in anhyd. pyridine (2 ml) at −15 °C. The reaction solution was further stirred at room temp. overnight, and then at 40 °C for 2 hr. The reaction solution was then poured into large amounts of ice and extracted with ether. The ether extract was washed successively with 5% hydrochloric acid and with water, and then dried over anhydrous Na_2SO_4. The subsequent removal of the solvent gave a pale yellow oil (100 mg), from which two dehydration products were obtained by preparative tlc (Wakogel B5-F) using *n*-hexane–benzene (2: 1). The upper fraction afforded a colorless oil (33 mg), which was further purified by preparative tlc (10% $AgNO_3$-Wakogel B5-F) using *n*-hexane–benzene (2: 1) to give a colorless liquid (28 mg) of (+)-zonarene (VII, $[\alpha]_D^{25}$ +322°) (glc, tlc, and IR spectrum). On the other hand, the lower fraction afforded a colorless oil (42 mg), which was also purified by preparative tlc (Wakogel B5-F) using *n*-hexane–benzene (1: 1) to give a colorless liquid (39 mg) of VIII; ν_{max}^{film} 3550 cm^{-1}; δ (CCl_4) 0.94 (6H, d, J=6.4 Hz), 1.04 (3H, d, J=6.0 Hz), 1.63 (3H, br.s), and 5.48 ppm (1H, br.s). Found: *m/e* 222.1975. Calcd for $C_{15}H_{26}O$: *m/e* 222.1984).

The authors wish to thank Dr. W. Fenical (University of California, U.S.A.) for an authentic sample of zonarene. They are also indebted to Professor Akira Tatematsu and Mr. Hiroshi Sakurai (Meijo University) for measurements of high resolution mass spectra.

Reaction of Sydnones with Phosphorus Pentasulfide

Kosaku SUGIMOTO and Masaki OHTA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received June 11, 1973)

The reaction of 3-phenylsydnone(Ia) with phosphorus pentasulfide has been reported by Baker[1] in which the reactants were heated in toluene under reflux for six hours and 1,4-diphenyl-1,2,4,5-tetrazine (II) was obtained. Other example of the reaction of sydnone with phosphorus pentasulfide has not been reported in the literature.

In this note, reactions of 3,4-diphenylsydnone (Ib), 3-benzylsydnone (Ic), and 3-isopropyl-4-phenylsydnone (Id) with phosphorus pentasulfide are described.

We now found that the reaction of Ia with phosphorus pentasulfide in methylene chloride proceeded even at room temperature yielding II. When this reaction was carried out in the presence of dimethyl acetylenedicarboxylate or acrylonitrile, II was obtained suggesting that the formation of 1,3-dipolar intermediate from sydnone could be excluded. Reaction of Ib with phosphorus pentasulfide in a mixture of methylene chloride and carbon disulfide at room temperature afforded *N*-phenyl-*N*-thiobenzoylhydrazine (IIIa). When this reaction was carried out in benzene under reflux, IIIa was obtained and tetrazine derivative was not formed.

Reaction of Ic with phosphorus pentasulfide in a mixture of methylene chloride and carbon disulfide at room temperature afforded *N*-benzyl-*N*-thioformylhydrazine (IIIb). The reaction of Id with phosphorus pentasulfide under the same condition resulted in the recovery of the starting material, while in benzene under reflux afforded *N*-isopropyl-*N*-thiobenzoylhydrazine (IIIc) was obtained.

It seems probable that the present reaction proceeds through 1,3-addition of P=S double bond to sydnone under elimination of carbon dioxide, but the formation of *N*-substituted-*N*-thioacylhydrazine instead of tetrazine derivative cannot be explained satisfactorily.

Experimental

Reaction of Ia with P_4S_{10}. To a solution of Ia (2.5 g) in 50 ml of methylene chloride was added 2.0 g of P_4S_{10} and the mixture was stirred for 5 days at room temperature and filtered. The filtrate was evaporated *in vacuo* and the residue was crystallized from methylene chloride to give 0.5 g of II, mp 196—197 °C (lit,[1] mp 193 °C).

Found: C, 71.01; H, 5.29; N, 23.50%. Calcd for $C_{14}H_{12}N_4$: C, 71.19; H, 5.08; N, 23.73%.

Reaction of Ib with P_4S_{10}. To a solution of Ib (2.0 g) in 30 ml of methylene chloride was added a suspension of P_4S_{10} (1.1 g) in 40 ml of carbon disulfide and the mixture was stirred at room temperature for 7 days under nitrogen atmosphere. The solvent was removed *in vacuo* and the residue was subjected to column chromatography using silica gel and 0.6 g of IIIa was obtained. Recrystallization from methylene chloride–hexane afforded crystals of IIIa, mp 116—117 °C.

Found: C, 68.45; H, 5.32; N, 12.45; S, 13.91%. Calcd for $C_{13}H_{12}N_2S$: C, 68.42; H, 5.22; N, 12.28; S, 14.08%. IR (KBr): 3230, 3170 cm^{-1}. NMR ($CDCl_3$): 2.8 (s, 10H), 3.9 (s, 2H) (exchangeable by D_2O).

Reaction of Ic with P_4S_{10}. Three grams of Ic and 0.8 g of P_4S_{10} were reacted in a similar manner as described above and the product was isolated by column chromatography (0.4 g) and recrystallized from benzene–hexane, mp 111—112 °C.

Found: C, 58.11; H, 6.12; N, 16.81; S, 19.07%. Calcd for $C_8H_{10}N_2S$: C, 57.82; H, 6.06; N, 16.85; S, 19.29%. IR (KBr): 3240, 3170 cm^{-1}. NMR ($CDCl_3$): 0.7 (s, 1H), 2.5 (s, 5H), 5.1 (s, 2H) (exchangeable by D_2O).

Reaction of Id with P_4S_{10}. A mixture of Id (3.0 g), P_4S_{10} (0.8 g) and 40 ml of benzene was refluxed for 3 hr. After removal of the solvent, the residue was subjected to column chromatography and 0.9 g of IIIc was obtained which was recrystallized from benzene–cyclohexane, mp 68—69 °C.

Found: C, 62.02; H, 7.14; N, 14.24; S, 16.26%. Calcd for $C_{10}H_{14}N_2S$: C, 61.86; H, 7.22; N, 14.43; S, 16.49%. IR (KBr): 3240, 3130 cm^{-1}.

Diels-Alder Reaction of "Anhydrochloral-urethane" with 1,3-Dienes[1]

Takeshi IMAGAWA, Keiiti SISIDO, and Mituyosi KAWANISI
Department of Industrial Chemistry, Kyoto University, Kyoto 606

(Received January 24, 1973)

"Anhydrochloral-urethane" *N*-(2,2,2-trichloroethylidene)alkoxycarbonylamine (I), known since 1891,[2] was not actually synthesized until 1968 by Ulrich and his coworkers.[3] They gave good evidences of the reactivity of the C=N double bond in imine I toward the addition of nucleophiles.

The strongly electrophilic C=N double bond in some imines is successfully applied to the Diels-Alder reaction.[4] The enhanced electrophilicity and the simplicity of substituents prompted us to subject imine I ($R=C_2H_5$) to the Diels-Alder reaction as a dienophile affording the 2-ethoxycarbonyl-3-trichloromethyl-2-azabicyclo[2.2.1]heptenes (IIa, b) or 1-ethoxycarbonyl-2-tri-chloromethyl-1,2,3,6-tetrahydropyridines (III).

Reaction of I with cyclopentadiene in refluxing benzene for 3 hr gave two isomeric adducts in the ratio 2:1 (90% combined yield). The 1:1 nature of these adducts was evidenced by elemental analyses and MS spectroscopy which gave a peak corresponding to the $M^+ - CCl_3$ fragment ion as the base peak originated from the fragmentation β to the nitrogen atom, accompanied by a very weak molecular ion peak. The predominant crystalline adduct (IIa) was shown to possess an *exo* trichloromethyl group and the minor oily product (IIb) an *endo* trichloromethyl function, by NMR and IR spectroscopy. Especially noteworthy was the coupling constant between the proton α to the trichloromethyl group and the bridgehead proton. The value for IIa was 3.0 Hz, whereas that for IIb was nearly 0 Hz (Table 1). This difference is recognized in the elucidation of the sterochemistry of bicyclo[2.2.1]heptane ring systems.[5] It is further endorsed by the chemical shifts of the bridge methylene protons. Although both the methylene protons of IIb were degenerated at δ 1.66, the signals of those of IIa appeared at δ 1.45 and 2.74, indicating the anisotropic effect of the *exo* trichloromethyl on the nearer *syn* proton. The assignment of the configuration is also supported by IR spectra in CCl_4 solution, showing the carbonyl frequency of the urethane moiety of IIa at a higher wave number than that of IIb resulting from the decrease of overlap between the electrons of the carbonyl group and the lone-pair electrons of the nitrogen atom of IIa by a steric hindrance.

Kresze and Albrecht reported on the reaction of *N*-trichloroethylidene-*p*-toluenesulfonamide (IV) with

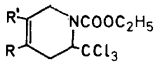
a) δ values in CCl_4 (60 MHz). b) s, singlet, b, broad; d, doublet; m, multiplet; cm, complex multiplet; t, triplet; q, quartet; AB, AB quartet composed of broad lines (Only the central position is shown in δ values).

cyclopentadiene to give an adduct of mp 134 °C in 93% yield,[6] but no mention seems to have been made about its stereochemistry. On reexamining the reaction we confirmed that the configuration of the adduct IIc is in the same situation as that of our predominant adduct IIa by comparison of their NMR spectra. Both showed similar patterns of the protons in the azabicyclo[2.2.1]heptene rings.

$CCl_3CH{=}NCOOR$

I

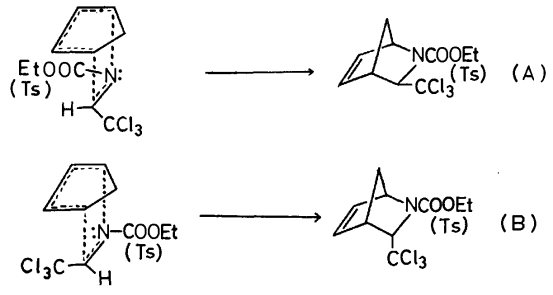


IIa: $R=CCl_3$, $R'=H$, $R''=COOC_2H_5$
b: $R=H$, $R'=CCl_3$, $R''=COOC_2H_5$
c: $R=CCl_3$, $R'=H$, $R''=SO_2C_6H_4CH_3$-*p*

IIIa: $R=R'=H$
b: $R=CH_3$, $R=H'$
c: $R=R'=CH_3$

Formula.

At first glance, the *exo* orientation of the trichloromethyl group in the exclusive or major adduct seems inconsistent with the so-called *endo* addition rule.[7] However, the results are well explained on the basis of the rule of maximum accumulation of double bonds as follows (Scheme 1). When dienophiles I and IV are assumed to have *anti* configuration[8] at the transition state of the reaction, course A is more favorable than B, since not the trichloromethyl group but the conjugated ethoxycarbonyl or *p*-toluenesulfonyl group should play a dominant role in the maximum overlapping of unsaturation. Consequently, the major or exclusive product has the trichloromethyl group in the *exo* arrangement. The reason for IV exclusively giving the *exo* adduct but I the *exo*- as well as *endo*-adduct may be ascribed to the stronger directive effect of the sulfonyl group, since the Diels-Alder reaction of *trans*-1-benzoyl-2-benzenesulfonylethylene and cyclopentadiene has been reported[9] to give the *endo* benzenesulfonyl adduct and the *endo* benzoyl adduct in the ratio 3: 1.



Scheme 1.

Heating benzene solutions of I and butadiene, isoprene, and 2,3-dimethylbutadiene in a pressure bottle at 100—120 °C gave 1-ethoxycarbonyl-2-trichloromethyl-1,2,3,6-tetrahydropyridines (IIIa—c) in 55, 75, and 78% yield, respectively. The adduct of isoprene was a single compound and tentatively assigned to IIIb, because the chemical shift of the protons of C_3 was nearer that of IIIc than IIIa; this assignment and the regiospecificity are consistent with the result in an analogous reaction.[10]

Experimental[11]

Reaction of I with Cyclopentadiene. Refluxing a benzene (25 ml) solution of freshly prepared I (5.00 g) and cyclopentadiene (2.5 g) for 3 hr gave an oily mixture after evaporation. This was chromatographed over 80 g of alumina with benzene as an eluent.

The faster moving zone gave, after removal of the solvent, 3.85 g (59%) of oily IIa; bp 136—138 °C/4 mmHg, $n_D^{23.5°}$

The Novel Synthesis of Two Diastereomers of γ-Hydroxyproline[1)]

Yong Kyun LEE* and Takeo KANEKO**

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received May 1, 1973)

L-γ-Hydroxyproline is known as a component amino acid of limited proteins such as gelatine or collagen. Although several synthetic routes had been studied by many researchers, no satisfactory methods have been developed yet in view of the yield of the product and of the separation of two diastereomers formed. As far as literatures were concerned, γ-hydroxyproline had been synthesized through either 2-amino-5-halogeno-4-valerolactone[2-8)] or 2-halogeno-5-amino-4-valerolactone[9)] starting from epichlorohydrin. Alternatively, it had been also synthesized through 2,5-dichloro-4-valerolactone from either epichlorohydrin or alkyl halide.[10,11)] In every case, comparable amounts of racemic diastereomers, *i.e.*, DL- and DL-*allo*-γ-hydroxyproline have been formed. When these mixtures were attempted to be separated each other through their copper complexes, the purification of the more soluble DL-*allo* complex met often difficulty, though the less soluble DL-complex has been obtained in relatively pure state.

The authors found now a new synthetic method to lead to γ-hydroxyproline from 2-amino-5-bromo-4-valerolactone hydrobromide which was obtained as a diastereomeric mixture in good yield by heating 2,3-dibromopropylacetamidomalonate with hydrobromic acid. This mixture was readily separable from aqueous solution due to the difference in solubilities. This improvement in the synthetic route established a new way through which DL- and DL-*allo*-γ-hydroxyproline are available both in pure states.

Thus, diethyl acetamidomalonate (I) was condensed with equimolar allyl bromide (II) using sodium

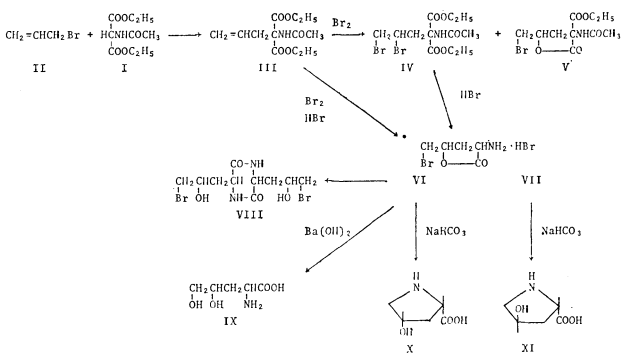

Fig. 1. Synthetic route for γ-hydroxyproline.

alkoxide in absolute ethanol according to the method of Albertson.[12] To the resulting allylacetamidomalonate (III), bromine was added in absolute ether to afford crystals of dibromo compound (IV). When the mother liquor thus obtained was kept for long time, 5-bromo-4-valerolactone derivative (V) was crystallized out slowly. The bromination in chloroform or carbon tetrachloride resulted in an improved yield of V but not that of IV. When the dibromo compound IV was hydrolyzed with hydrobromic acid, a mixture of two racemic diastereomers of 2-amino-5-bromo-4-valerolactone hydrobromide was obtained in good yield. This mixture was separated successfully into a less soluble isomer (VI) and a more soluble isomer (VII) from aqueous solution. The mixture of VI and VII could be also obtained in satisfactory yield even when the bromination product was hydrolyzed directly without separation of IV. The amount ratio of VI and VII in any mixtures thus obtained was always close to 1:1.

The treatment of the less soluble salt VI with pyridine gave the dioxopiperazine (VIII) composing of two molecules of 5-bromo-4-hydroxy-2-aminovaleric acid, the structure of which was confirmed by elemental analyses and IR spectrum: ν_{max}, 3210 and 3050 cm^{-1} (NH), 1637 cm^{-1} (NHCO).

Table 1. Formation of DL-allohydroxyproline and DL-γ-hydroxyproline from 2-amino-5-bromo-4-valerolactone (VI, VII)

Basic reagent	Reaction		Yield (%)	
	Temp. (°C)	Time (hr)	DL-*allo* (from VI)	DL (from VII)
28% Aqueous ammonia	100	5	30	20
Ammonia (Saturated in abs. CH_3OH)	40	5	72	42
$NaHCO_3$(10% aq. sol.)	90	1	80	46
$Ba(OH)_2$ (0.2N sol)	100	2	54	30—35

For conversion of the aminobromolactone hydrobromide (VI or VII) into γ-hydroxyproline, various basic reagents, were examined as shown in Table 1. Among these reagents, sodium hydrogen carbonate gave best result giving 55% overall yield of hydroxyproline from I. When barium hydroxide was used in the above reaction, a compound giving deep purple color with ninhydrin and a positive test with periodic acid, was obtained. The structure of this compound was deduced to 2-amino-4,5-dihydroxyvaleric acid (IX) from its elemental analysis in addition to the properties mentioned above. From the less soluble salt (VI), very pure DL-*allo*-hydroxyproline was obtained solely, while the more soluble salt (VII) gave DL-hydroxyproline after purification of its crude material through copper complex.

According to the conventional method for separation of the final synthetic product, γ-hydroxyproline, through copper complex, it was difficult to secure the pure *allo* compound. The present method has advantage of ease of separation of DL-*allo*-γ-hydroxyproline in very pure form and also of DL-γ-hydroxyproline due to the less solubility of its copper complex. The stereochemistries of the lactone VI and VII were unambiguously deduced from those of hydroxyproline that was derived from each compound. Thus orientation of amino and bromomethyl groups must be *cis* in VI and *trans* in VII.

Experimental

All melting points are uncorrected.

Ethyl 2-Acetamido-4,5-dibromo-2-ethoxycarbonylvalerate (IV). To a solution of 5 g of diethyl allylacetamidomalonate[12] (III) in 40 ml of absolute ether, 3.5 g of bromine was added dropwise at −10—−15 °C for 1 hr. The reaction mixture was stirred at −10 °C for another 2 hr and then at 0 °C for 2 hr. Ether was removed under reduced pressure. The residue was triturated with a small amount of water to give crystals of IV. These were filtered and recrystallized from 90% aqueous ethanol, yield 5.4 g (67%), mp 83—84 °C.

Found: C, 34.63; H, 4.42; N, 3.32; Br, 38.44%. Calcd for $C_{12}H_{19}O_5NBr_2$: C, 34.55; H, 4.59; N, 3.36; Br, 38.32%.

2-Acetamido-5-bromo-2-ethoxycarbonyl-4-valerolactone (V). When the mother liquor from IV was kept for two weeks, crystals of V appeared. The crystals were filtered and recrystallized twice from 50% aqueous ethanol, mp 141—142 °C.

Found: C, 39.29; H, 4.48; N, 4.41; Br, 27.53%. Calcd for $C_{10}H_{14}O_5NBr$: C, 38.98; H, 4.58; N, 4.55; Br, 25.94%.

2-Amino-5-bromo-4-valerolactone Hydrobromide (VI and VII). *Method A*: The compound IV (30 g) was refluxed with 48% hydrobromic acid for 4 hr. Hydrobromic acid was removed by evaporation under reduced pressure. After the residue was kept in a refrigerator overnight, a solid mixture of VI and VII was filtered, yield 19 g (95%). It was dissolved in 5 ml of hot water and kept in a refrigerator overnight. The crystals of VI were separated out. These were filtered and washed with little acetone, yield 8 g. A solution of these crystals in 60 ml of methanol was treated with charcoal, and then concentrated to about 15 ml. Crystals formed were filtered and recrystallized from methanol, mp 244 °C (decomp.).

Found: C, 21.68; H, 3.30; N, 5.04; Br, 57.98%. Calcd for $C_5H_9O_2NBr_2$: C, 21.84; H, 3.30; N, 5.09; Br, 58.13%.

The mother liquor from VI was concentrated under reduced pressure. After addition of acetone, the solution was set aside for a few days to recover further crops of VI. However, easy soluble salt VII could not be obtained in crystalline state from the filtrate by this procedure.

Method B: To a solution of 20 g of III in 40 ml of chloroform, a solution of 15 g of bromine in 15 ml of chloroform was added at 20 °C with stirring for 1 hr. The stirring was continued for another 2 hr. Chloroform was removed under reduced pressure. To the syrupy residue obtained, 150 g of 48% hydrobromic acid was added. After refluxing for 3 hr, the solution was evaporated under reduced pressure and then cooled. The resulting crystals were filtered off to afford 19.6 g (92%) of a mixture of VI and VII hydrobromides. Through the treatment of the mixture as in the method A, 9.4 g of the less soluble salt VI in crystalline state, mp 222 °C (decomp.) and 9 g of the more soluble salt VII as syrup were obtained.

2,4-Bis(3-bromo-2-hydroxypropyl)-3,6-dioxopiperazine (VIII). Into a solution of 500 mg of VI in a small amount of water, 0.2 g of pyridine was added and the reaction mixture was allowed to stand at room temperature overnight. A crys-

talline product was separated out, mp 183 °C (decomp.). After recrystallization from water, the melting point raised up to 186 °C (decomp.).

Found: C, 31.06; H, 4.20; N, 7.02; Br, 40.45%. Calcd for $C_{10}H_{16}O_4N_2Br_2$: C, 30.95; H, 4.16; N, 7.22; Br, 41.19%.

Hydrolysis of VI and VII. *a) By Aqueous Ammonia*: A mixture of 5 g of the less soluble salt VI and 110 ml of 28% aqueous ammonia was heated at 90—100 °C in a pressure bottle for 5 hr and then kept at room temperature for 24 hr. The ammonia and water were removed under reduced pressure and 30 ml of concentrated hydrochloric acid was added into the residue. The solution was heated at 80—90 °C for 1.5 hr and then evaporated under reduced pressure to obtain a syrupy residue. A solution of the residue in a small amount of water was made alkaline to phenolphthalein with 1M sodium hydroxide and then heated for about 10 min. After cooling, the solution was acidified with 1M hydrochloric acid and evaporated under reduced pressure. The inorganic materials were removed by treating several times with ethanol and finally with silver carbonate. The syrupy residue was crystallized from water and ethanol to give DL-*allo*-γ-hydroxyproline (X), yield 0.7 g, mp 238 °C (decomp.). Found: C, 45.99: H, 6.65; N, 10.44%. Calcd for $C_5H_9O_3N$: C, 45.79; H, 6.92; N, 10.68%.

The more soluble salt VII (5 g) was treated like as mentioned above. The resulting syrupy residue was dissolved in 50 ml of water and heated with cupric carbonate for 1 hr giving sky-blue copper complex, yield 1.5 g. A suspension of the copper complex in water was treated with hydrogen sulfide. The filtrate from copper sulfide was evaporated to the residue which was crystallized from water and ethanol giving pure DL-γ-hydroxyproline (XI), yield 0.5 g (20%), mp 246 °C (decomp.). Found: C, 45.80; H, 6.87; N, 10.69%

2-Amino-4,5-dihydroxyvaleric Acid (IX) A solution of 5 g of VI in 200 ml of 0.2N barium hydroxide was heated in a boiling water bath for 2 hr. From the hydrolyzate X was separated by usual way. The mother liquor from X was treated with cupric carbonate and the precipitate was recrystallized from water and ethanol to give a sky-blue copper complex. This copper compound was treated with hydrogen sulfide and filtered. The filtrate was evaporated and the residue was crystallized from water and ethanol giving IX, yield 0.7 g. This was recrystallized from 50% aqueous ethanol twice, mp 105 °C (decomp. at 175 °C).

Found: C, 36.10; H, 7.53; N, 8.19; H_2O, 9.15%. Calcd for $C_5H_{11}O_4N \cdot H_2O$: C, 35.92; H, 7.84; N, 8.38; H_2O, 10.78%.

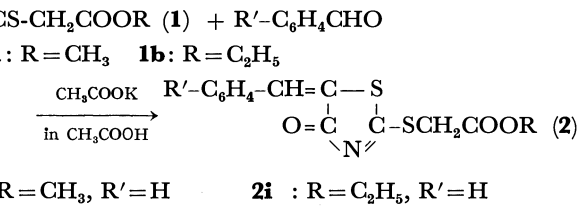
Thiocyanoacetate. V. Reaction of Thiocyanoacetic Esters with Aromatic Aldehydes in the Presence of Potassium Acetate[1]

Satoshi KAMBE*

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received October 21, 1972)

In the course of studies on the reaction of thiocyanoacetic ester (**1**) with aldehydes, it was found that the base as a catalyst might have some distinct effect on the nature of the reaction.[1,2] For the confirmation the author has investigated the effects of potassium acetate–acetic acid system on the reaction course.

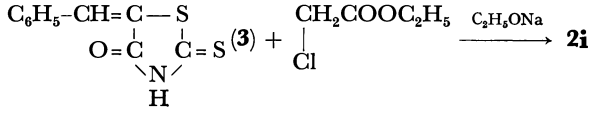


Scheme 1.

The reaction of **1** with aromatic aldehydes was carried out in an acetic acid containing potassium acetate, direct synthesis of 1,3-oxathiolan-2-one derivatives being expected.

However, an unexpected acid-unstable crystalline product was obtained upon the treatment of **1b** with benzaldehyde in acetic acid containing potassium acetate. The structure of 5-benzylidene-2-ethoxycarbonylmethylthio-1,3-thiazolin-4-one (**2i**) was indicated by elemental analysis, IR, NMR, and mass spectra. **2i** was identical with an authentic sample prepared from 5-benzylidene-1,3-thiazolidine-2-thione-4-one (**3**) and ethyl chloroacetate with sodium ethoxide in ethanol.

On the other hand, **2i** is readily hydrolyzed with hydrochloric acid to yield 5-benzylidene-1,3-thiazolidine-2,4-dione (**4**).[3] Furthermore, **1b** reacted easily with ethyl thioglycollate (**5**) in acetic acid containing potassium acetate to give 2-ethoxycarbonylmethylthio-1,3-thiazolin-4-one (**6**), which gave **2i** in the reaction



Scheme 2.

with benzaldehyde in acetic acid containing potassium acetate.

1,3-Thiazolin-4-one derivatives (**2**) could be obtained by the reaction of **1** with other aldehydes. The results are summarized in Table 1. **1** might be led to mercaptoacetate (**5**) in the presence of potassium acetate, since thiocyanates are converted into mercaptanes when treated with basic reagents.[4] The reaction of **1b** with benzaldehyde in acetic acid without using potassium acetate gave only product **4** in poor yield. Heintz[5] and Klason[6] reported that 1,3-thiazolidine-2,4-dione was obtained when **1** was treated with acid.

$$HSCH_2COOC_2H_5\ (\mathbf{5}) + \mathbf{1b} \xrightarrow[\text{in } CH_3COOH]{CH_3COOK} \underset{\mathbf{(6)}}{O{=}C(N)C{-}S{-}CH_2COOC_2H_5}$$

$$\mathbf{6} + C_6H_5CHO \xrightarrow[\text{in } CH_3COOH]{CH_3COOK} \mathbf{2i}$$

Scheme 3.

Accordingly, it seems that **1b** was hydrolyzed with acetic acid, yielding the 1,3-thiazolidine-2,4-dione which is then condensed with benzaldehyde to give **4**.

A reaction pathway is postulated in Scheme 4.

$$\mathbf{1} \xrightarrow{CH_3COOK} \mathbf{5} \xrightarrow{(1)} \mathbf{6} \xrightarrow{R'\text{-}C_6H_4CHO} \mathbf{2}$$

Scheme 4.

Experimental

All the melting points are uncorrected. IR spectra were measured with a Shimadzu IR-27G spectrophotometer in KBr pellets. NMR spectra were determined in DMSO-d_6 with a JEOLCO JNM-C-60 high-resolution NMR spectrometer (60 MHz), using tetramethylsilane as an internal standard. Mass spectra were measured with a JMS-O1S instrument operating at 75 eV.

*Reaction of Thiocyanoacetate Ester (**1**) with Aromatic Aldehyde. Procedure.* A mixture of **1** (0.04 mol), aromatic aldehyde (0.02 mol) and potassium acetate (2 g) in acetic acid (15 ml) was stirred at 90—100 °C,[7] and then poured into crushed ice with vigorous stirring. The resulting precipitates were collected, washed with ether and recrystallized from ethanol. The yield and properties are summarized in Table 1. NMR (δ): **2a**; 4.00 (OCH_3), 4.50 (SCH_2), 7.55 (C_6H_5), and 8.30

4) J. W. Dienske, *Rec. Trav. Chim. Pays-Bas*, **50**, 21 (1931).
5) W. Heintz, *Ann.*, **136**, 232 (1865).
6) P. Klason, *Ber.*, **10**, 1350 (1877).
7) Reaction times in each case are indicated in Table 1.

(=CH). **2i**; 1.40 (CH_3), 4.50 (OCH_2), 4.60 (SCH_2), 6.50 (C_6H_5), and 8.45 (=CH). MS spectrum: **2i** (relative abundance); *m/e* 307 (87), 262 (24), 234 (11), 188 (8), 161 (39), 133 (100), and 101 (30). NMR and MS data of other compounds are deleted.

Reaction of 5-Benzylidene-1,3-thiazolidine-2-thione-4-one (3) with Ethyl Chloroacetate. To a solution of **3** (0.01 mol) in absolute ethanol (30 ml) containing metallic sodium (0.3 g) was added ethyl chloroacetate (0.01 mol), and the solution was stirred for 15 hr under gentle reflux. The sodium chloride thus precipitated was then filtered out. After the filtrate had been left to stand overnight, crystalline matter was separated which was collected and washed with water. Recrystallization from ethanol gave **2i**; yield 23%, mp 138—139 °C. Unreacted **3** was recovered from the filtrate of **2i**.

Reaction of Ethyl Thiocyanoacetate (1b) with Ethyl Thioglycollate (5). To a mixture of **1b** (0.02 mol) and potassium acetate (0.02 mol) in acetic acid (15 ml) was added dropwise **5** (0.02 mol) with stirring. The raection temperature was maintained at 25—30 °C. After completion of addition, stirring was continued for 10 hr. The reaction mixture was poured into water with vigorous stirring. The resulting precipitate was filtered and washed with ether. Recrystallization from CCl_4 gave **6**; yield 60%; mp 78—79 °C. IR (cm^{-1}): 1750 (O–C=O) and 1700 (C=O). NMR (δ): 1.35 (CH_3), 4.40 (OCH_2), 4.45 (ring CH_2), and 4.60 (SCH_2). Found: C, 38.11; H, 4.06; N, 6.39; S, 29.20%. Calcd for $C_7H_9O_3S_2N$: C, 38.36; H, 4.14; N, 6.39; S, 29.20%.

Reaction of 2-Ethoxycarbonylmethylthio-1,3-thiazolin-4-one (6) with Benzaldehyde. A solution of **6** (5 mmol) and benzaldehyde (5 mmol) in acetic acid (10 ml) containing potassium acetate (5 mmol) was refluxed for 2 hr. After cooling, the solution was poured into water and allowed to stand for several hours. The solid product (**2i**) precipitated was recrystallized from ethanol; yield 48%, mp 138—139 °C.

Hydrolysis of **2i**. To ethanol (5 ml) containing concd. hydrochloric acid (15 ml) was added **2i** (5 mmol). The mixture was refluxed for 2 hr and then cooled to room temperature. Deposited solid product (**4**) was recrystallized from ethanol; yield 32%; mp 239—240 °C (lit,[3] 239—240 °C).

Reaction of Ethyl Thiocyanoacetate (1b) with Benzaldehyde in Acetic Acid. A solution of **1b** and benzaldehyde in acetic acid (10 ml) was refluxed for 15 hr. The reaction mixture, on cooling, was poured onto cracked ice. The crystalline matter thus formed was collected and washed with ether. Recrystallization from ethanol gave **4**; yield 0.5%; mp 239—240 °C.

The author wishes to express his thanks to Dr. Hiroshi Midorikawa, Dr. Heinosuke Yasuda, and Mr. Toshio Hayashi for their helpful discussions and encouragement. Thanks are also due to Dr. Haruo Homma and his staff for the microanalyses.

The ESR Study of the Interaction of O_2 with Ag Dispersed on Silica Gel

Natsuko SHIMIZU, Kazuo SHIMOKOSHI, and Iwao YASUMORI

Department of Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received January 31, 1973)

The state of adsorbed oxygen on metallic silver dispersed on silica gel has been studied by ESR. The spectra observed by the interaction of oxygen and the surface were found to be composed of spectra due to two different species. One of the species, which was formed separately by the contact with oxygen at −110 °C, was identified with O_2^- chemisorbed on metallic silver by a comparison of the observed g values and the other features with those previously reported. The other species has a doublet at $g=2.036$. This spectrum was reproduced by the interaction of N_2O with the silver surface. Further, the γ-irradiation of the silver samples in the presence of O_2 and N_2O markedly enhanced the intensity of this spectrum, showing a low-field hump. On the basis of the g values and the splitting of the high-field doublet, assuming that the doublet is due to the hyperfine interaction of an unpaired electron with the silver nucleus, the species was assigned to Ag^{2+} in the present system. It is postulated that this species is possibly formed by the dissociative and/or charge-transfer chemisorption of O_2 and N_2O, suggesting the presence of non-paramagnetic oxygen species, such as O^{2-}, as a counter ion of Ag^{2+}.

It is of importance to investigate the nature of adsorbed oxygen on silver because of its interesting behavior in the catalytic oxidation of ethylene. Recently Clarkson and Cilliro[1] have reported the ESR observation of O_2^- chemisorbed on a metallic silver surface supported by Vycor glass, together with the reactivity of the O_2^- with CO. However, the nature of the adsorbed states of oxygen has not yet been satisfactorily elucidated, since various forms of adsorbed oxygen have been suggested to be present on the silver surface.[2-5] The work of the present paper was initiated to investigate the catalytic activity of metallic silver in the oxidation of olefins by means of electron spin resonance spectroscopy (ESR).

In the present study we found ESR evidence for the presence of two kinds of oxygen species adsorbed on metallic silver dispersed on silica gel; we then incorporated our results with those of experiments with the γ-irradiation of the silica gel samples.

On the other hand, the ESR spectra of γ-irradiated silica gel and the effects of some additives have been reported previously.[6-9] However, no ESR study of the effects of metallic adsorbates on the irradiation has yet been reported despite the relevance to radiation chemistry.[10,11] In the present paper we will also report on the effects of γ-irradiation on the ESR spectra.

Experimental

Silica gel was prepared by the hydrolysis of ethyl orthosilicate, followed by drying at 110 °C and heating at 450 °C in air. Ethyl orthosilicate was distilled several times before the hydrolysis. Silver was impregnated on silica gel from the solution of silver nitrate, followed by drying and heating as above. The concentrations of silver were in the range of 0.5—6.0 wt%. The samples were reduced with hydrogen of 40 Torr at 100 °C and then at 300 °C for 2 hours in each case. High-purity gases of H_2, O_2 and N_2O from the Takachiho Chemical Co. were used without further purification.

γ-Irradiation was carried out by exposure to ^{60}Co at room temperature. The dose was 1—2 Mrads. The ESR measurements were made by means of a JEOL JES-3BS-X spectrometer with 100 kHz modulation. All the spectra were recorded at −110 °C.

Results and Discussion

Figure 1 (a) shows the spectrum (A) ($g=1.98$, $\Delta H=175\pm5$G) observed in the sample of the dispersed silver (2 wt%) on the silica gel after reduction. The intensity of this signal increased with the amount of silver. As has been suggested by Nicolau *et al.*,[12] who observed the spectra in the systems of Pt and Pd supported on charcoal, this signal (A) may be attributed to the unpaired electron produced by the strong interaction of the silver with the silica gel surface.

When the silver samples were exposed to oxygen of 5 Torr at 26 °C, new spectra were observed, as is shown in Fig. 1 (b). By heating the samples to 200 °C, the spectra were changed; particularly, the lower-field shoulder increased and became distinct (Fig. 1 (c)). Therefore, the signal is possibly composed of spectra due to two different species. This was further confirmed by the following experiments. When oxygen came into contact with the silver samples at −110 °C and the spectra were recorded at the same temperature, only the B signal was observed as a new signal (Fig. 2 (a)). The lower-field pattern in Fig. 1 (c) was reproduced when the silver samples were exposed to N_2O (110 Torr) at room temperature for about 60 hours, as is shown in Fig. 2 (b).

From these results, it was concluded that the spectra in Figs. 1 (b) and (c) consist of three signals, A, B, and

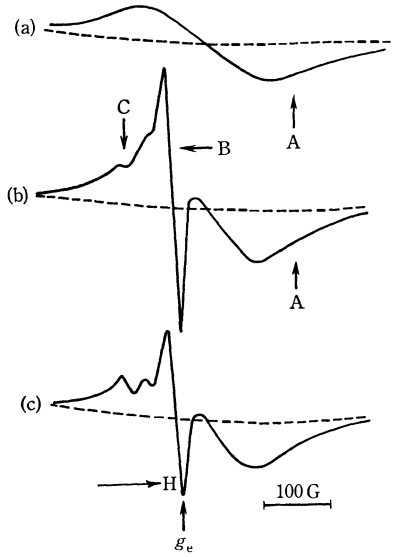

Fig. 1. Electron spin resonance spectra obtained after a) reduction of Ag dispersed silica gel, b) exposure of the Ag–SiO_2 to oxygen (5 Torr) at 26 °C, and c) heating at 200 °C in the presence of oxygen. All spectra were recorded at −110 °C. The broken line shows the signal from silica gel treated under the same conditions as the Ag–SiO_2 samples. g_e indicates the resonance field of free electron.

C. By evacuation at room temperature, the B signal decreased in its intensity, but after heating at 200 °C in the presence of oxygen the B signal became independent of the evacuation. The contact of O_2 and N_2O with the silica gel did not give any spectra of the surface species under the same conditions as those described for the silver samples.

The g tensors for oxygen species adsorbed on various surfaces have been reported.[13-14] According to the recent report by Clarkson and Cilliro,[1] the spectrum observed in the system of O_2–Ag supported on Vycor glass has been identified with that of O_2^-. The g values estimated from the B spectrum, which was obtained by subtracting the A and C signals from the observed spectra, were $g_{xx}=2.002\pm0.001$, $g_{yy}=2.010\pm0.001$, and $g_{zz}=2.040\pm0.005$. These g values, though they have some experimental error, are only reasonable for O_2^- as the oxygen species, and they are comparable to those reported by Setaka and Kwan.[14] Therefore, the B spectrum can be identified with that of O_2^-.

In order to obtain a definite assignment of these spectra, the γ-irradiations of silica gel and the silver samples were carried out. In the irradiations of the silver samples, the signals due to the paramagnetic centers formed by the irradiation, as is shown in Fig. 3, were observed in addition to the broad signal, A. The spectra were composed of a sharp and intense single line near $g=2.001$ and a number of lines due to other centers.

These spectra were essentially the same as those reported by Kazanskii *et al.*,[7] though the resolution and the relative intensity of each component were different. As may clearly be seen in Fig. 3, the spectra obtained by reducing the field modulation showed a number of lines which could not simply be identified, as has been done by Kazanskii *et al.*, with the center that couples with four equivalent protons on the surface. In the irradiation of silica gel itself, unlike the case with silver samples, the lines due to the surface centers were relatively intense compared to the sharp line. It has been suggested[7] that the sharp line can be assigned to the spectrum of the trapped electron in the bulk. Therefore, the fact that the relative intensity of the sharp line to the surface centers was larger in the irradiated silver samples than in the irradiated silica gel may suggest that the formation of the surface centers by the irradiation is hindered by the surface silver metal.

When the silver samples were irradiated in the presence of O_2 (5 Torr), in addition to the signals in Fig. 3 the B and C signals were observed with an increased intensity compared with those observed before the

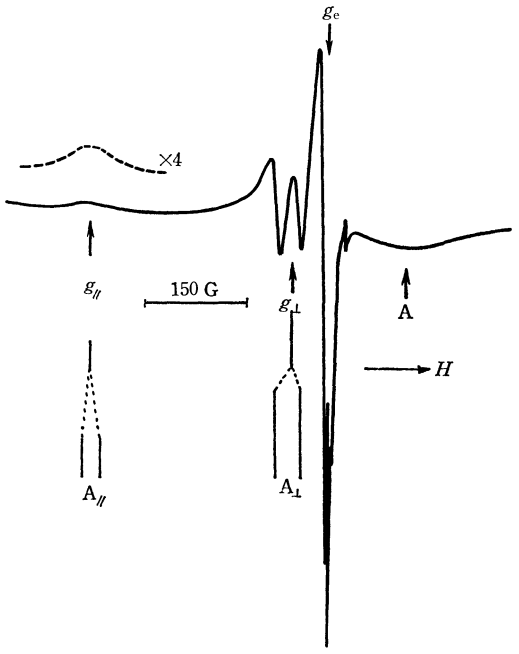

Fig. 4. Electron spin resonance spectrum obtained after γ-irradiation of the Ag–SiO_2 sample at 26 °C in the presence of O_2. The stick diagram indicates our assignment for the g and A of Ag^{2+}. The broken line at extremity corresponds to a signal amplification of 4.0. $g_\perp$ and $g_{//}$ corresponds to the resonance fields of the perpendicular and parallel components. $A_\perp$ and $A_{//}$ are the hfs of silver nucleus in perpendicular and parallel components. The value from reference (16) is used for $A_{//}$.

irradiation. The intensity of the sharp signal decreased in the presence of O_2. This is, possibly, a result of the interaction between the electron trapped in the center and oxygen, this interaction forming O_2^-.[7] The spectra are given in Fig. 4. The γ-irradiation of

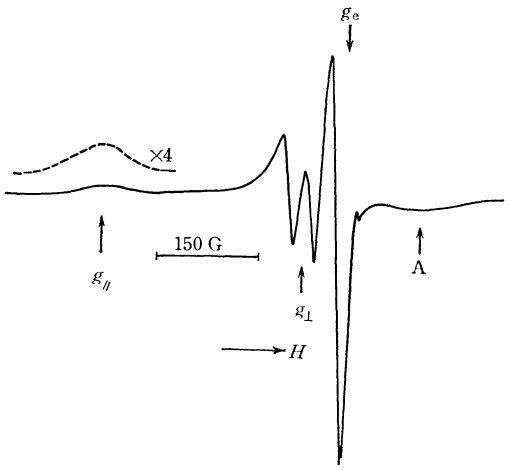

Fig. 5. Electron spin resonance spectrum obtained after γ-irradiation of the Ag–SiO_2 in the presence of nitrous oxide at 26 °C, and recorded at −110 °C.

the silver samples in the presence of N_2O (300 Torr) provided spectra almost identical with those obtained in the presence of O_2, as is shown in Fig. 5, though the intensity of B relative to C was slightly different.

The irradiation of the silica gel in the presence of O_2 and N_2O was also examined. A signal with a broad linewidth was observed upon the irradiation in the presence of O_2. The signal was similar to the B signal and has been assigned to the surface peroxide on silica gel[7] by Kazanskii. The irradiation of the silica gel with N_2O did not give the broad line, unlike the results of the irradiation of the silver samples. Further, it was found that the intensity of the surface peroxide was decreased to about 55% by warming the samples from −110 °C to 25 °C, while that of the B signal was decreased to about 35%. Therefore, the spectra obtained in the irradiation of the silver samples with O_2 and N_2O are not likely to be the surface peroxide on the silica gel, though the simultaneous formation of the surface peroxide can not be excluded in the irradiation of the silver sample with O_2. Consequently, the formation of O_2^- on the surface of the silver samples is the result of the interaction of O_2 not with silica gel, but with the metallic silver dispersed on silica gel.

In the identification of the C signal, assuming that the low-field hump, which becomes distinct by γ-irradiation, shows the parallel component of C, and that the doublet at g=2.036 is due to the hyperfine splitting, the magnetic parameters of this signal were

Table 1. ESR parameters for Ag^{2+}

a) The values were obtained from the spectra of Ag^{2+} formed in frozen acid solution at 77 K.

estimated to be as listed in Table 1. This was further confirmed by the fact that the intensity ratios of the high-field doublet to the low-field hump were constant in different experimental run with a variety of dosages. Since these values are almost equivalent with those of Ag^{2+} which have been reported by McMillan and Smaller,[15] the C signal can be identified with that of Ag^{2+} in the present system, though the poor resolution of the spectrum made it difficult to measure the splitting in the parallel component. More recently, Starkie and Symons[16] have reported their observation of Ag^{2+} trapped on silica gel formed by the γ-irradiation of the silica gel samples, which were integrated with an alcoholic solution of silver nitrate. The spectra of Ag^{2+} were only obtained in samples which had been dried for a long time *in vacuo*, while the irradiation of the wet samples provided the spectra of atomic silver. The magnetic parameters reported are also listed in Table 1.

The observation of Ag^{2+} in the present system suggests that there is a particular state of adsorbed oxygen which stabilizes Ag^{2+} by abstracting electrons from Ag. In the case of N_2O adsorption without the irradiation, though Ag^{2+} was obtained, the spectrum of O_2^- was not observed. Therefore, Ag^{2+} may be formed by the interaction with the electron-accepting species such as O_2 and N_2O, forming non-paramagnetic oxygen species such as O^{2-} as a counter ion of Ag^{2+}.

The observation of the O_2^- spectrum in the irradiation of the N_2O-silver sample can be explained if one takes into consideration the possibility that the molecular oxygen is produced by the catalytic[17] or radiolytic decomposition of N_2O by the irradiation on the silver surface.

In addition, the reactivity with ethylene of these oxygen species adsorbed on the silver surface was examined. The results obtained preliminarily showed that, when ethylene (5 Torr) was added to the silver samples, showing the B and C spectra, at 200 °C for 4 hours, the C spectrum was gradually decreased and the B spectrum disappeared. From the present results, it is not sufficient to conclude the participation of those oxygen species in the epoxidation reaction of ethylene. However, it is evident that the species identified with O_2^-, and Ag^{2+}, which was possibly formed accompanied by non-paramagnetic oxygen species, can react with ethylene.

In the present experiments we have for the first time observed Ag^{2+}, which may be formed by the interaction of metallic silver with such electron-accepting species as O_2 and N_2O. As a counter ion of Ag^{2+}, we postulated the presence of non-paramagnetic species such as O^{2-} [2] which may be formed by the dissociative adsorption of O_2 and N_2O. The presence of O_2^- on the surface of metallic silver was confirmed.

ESR Studies of the Cation Radicals Produced by $SbCl_5$ Oxidation of Some Biphenyls with *ortho-* and *para*-Dialkyl Substituents

Kazuhiko Ishizu, Muneki Ohuchi, Fujito Nemoto, and Masao Suga

**Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790*

(Received February 8, 1973)

The cation radicals of some alkylbiphenyls such as 4,4′-bitolyl, 4,4′-di-*t*-butylbiphenyl, and 2,2′, 4,4′, 6,6′-bimesityl, were generated by $SbCl_5$ oxidation in CH_2Cl_2. The ESR observation was carried out, and the Q values of the methyl and *t*-butyl were estimated based on either the theoretical spin density or the experimentally-determined spin density from the ^{13}C-hyperfine splitting. The Q value of the methyl in the cation radical was found to be 1.5 times that for the anion radical. The *t*-butyl groups of the cation radical also showed a much larger Q value than that for the anion radical. The perturbation of the spin density due to the steric hindrance was investigated with reference to the prediction of the McLachlan's MO calculations carried out for the hindered biphenyl. The experimentally-determined spin density derived from the Q value established for the *para*-derivative can be adequately interpreted on the assumption that the planar character of the biphenyl would be much reduced, contrary to the tendency found for the anion radicals. This effect suggests that a different delocalization of the unpaired electron may be expected between the cation and the anion radical: that is, the unpaired electron brings about a fair bonding on the central 1–1′ bond in the anion radical, but an antibonding for the cation radical, because the odd π-orbital of the cation has its node between the central 1–1′ bond.

The oxidation of aromatic hydrocarbons with $SbCl_5$ in CH_2Cl_2 is now one of the standard methods for preparation of the cation radicals in solution.[1] There have been numerous ESR studies of the aromatic cation radicals, which have often provided a useful test of molecular orbital theories. In the previous papers, we have reported several studies of the alkyl biphenyl anion radicals;[2-5] we hoped to compare the alkyl proton splitting with that of the cation radicals in order

to demonstrate the importance of the hyperconjugation mechanism in these derivatives. The ESR studies of the *ortho*-derivatives would be attractive, because the conformational change in the biphenyl ring can be elucidated by an investigation of the steric hindrance observed for the cation radical and the anion radical.

In the present paper, we wish to report the results of ESR studies of the cation radicals generated by the usual $SbCl_5$ oxidation of some alkyl biphenyls, such as 4,4′-bitolyl, 4,4′-di-*t*-butylbiphenyl, and 2,2′, 4,4′,6,6′-bimesityl. The alkyl proton splitting was determined and the splitting parameters, Q^R, of the methyl and *t*-butyl groups were calculated on the basis of McLachlan's spin density for the ring carbon atoms. The twisting angle between the two phenyls was estimated with reference to the theoretical spin density of the hindered biphenyl. The experimentally-determined spin density for the cation radical was compared with that for the anion radical, and we will present new experimental evidence that the presence of the unpaired electron in the frontier orbital actually plays an important role in causing a large modification of the conformation of biphenyl.

Experimental

Materials and ESR Samples. 4,4′-bitolyl, (mp 121—122 °C), 4,4′-di-*t*-butylbiphenyl, (mp 198—199 °C), and 2,2′, 4,4′, 6,6′-bimesityl (mp 102—103 °C) were synthesized by Ullman reactions in the manner described bofore.[4] Commercial-grade dichloromethane was dried over P_2O_5 and fractionally distilled. Antimony pentachloride purchased from Nakarai Chemicals Ltd was used without further purification. About a 10% solution of $SbCl_5$ was prepared using CH_2Cl_2 as the solvent and it was stocked in a refrigerator. The materials (*ca.* 2 mg) were placed in a reaction tube (I) and 1 ml of the 10% $SbCl_5$ solution was mixed with 5 ml of CH_2Cl_2 in the side arm tube (II), shown in Fig. 1. The inside of the reaction tube was evacuated, and the reaction tube (I) was placed in liquid N_2; then $SbCl_5$ and CH_2Cl_2 were distilled into the reaction tube (I), which was placed in an aceton-dry ice bath after the removal of the oxidizing agent. As the frozen reaction mixture was melted in an aceton-dry ice bath, the oxidation of the materials proceeded smoothly and the reaction mixture began change in color from deep-blue to blue-green for the *para*-derivatives and to yellow for the *ortho*-derivatives.

The radical solution thus prepared was inserted in a pre-cooled ESR cell, and the ESR spectra were recarded at −40—70 °C. The ESR apparatus employed here was JEOL ME-3X spectrometer operating with a 100 kHz magnetic-field modulation. The magnetic field was calibrated by means of the ring proton hyperfine coupling constant of the perylene cation radical prepared in concentrated sulfuric acid.

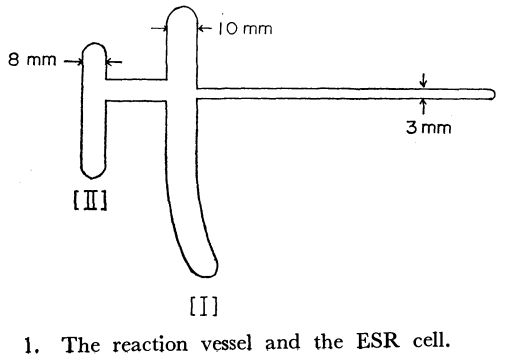

Fig. 1. The reaction vessel and the ESR cell.

Results and Discussion

4,4′-Bitolyl. The spectrum of the 4,4′-bitolyl cation radical observed at −50 °C is shown in Fig. 2. The ESR signal intensity was rapidly depressed when the observing temperature was brought to −30 °C. The largest septet splitting (8.79 Gauss) was easily assigned to those of methyl protons (a_4^H), and the quintet splitting (2.64 Gauss) was ascribed to the *ortho*-ring protons (a_2^H) taking into account McLachlan's MO calculation of the spin density. The *meta*-proton splitting could not be detected in the observed spectrum. The hyperfine coupling constants of each proton thus determined are; $a_4^{CH_3}=8.79$, $a_2^H=2.64$, and $a_3^H<0.03$ Gauss.[6] These values are nearly comparable with those of the cation radical generated by the XeF_2 oxidation of toluene.[7] Besides the proton hyperfine structure, three kinds of ^{13}C-hyperfine splitting were recorded, as is shown in Fig. 3. We found that the absolute values of these hyperfine coupling constants are much like those of the *ortho* (a_2^C)-, the *meta* (a_3^C)-, and the *para* (a_4^C)-ring carbon atoms of the 3,3′,5,5′-tetra-*t*-butylbiphenyl anion radical, as has already been reported,[8] but the splitting of a_1^C, was not resolved in the present case. The ^{13}C hyperfine splittings were assumed to be as follows; $a_2^C=1.83$, $a_3^C=-3.59$, and $a_4^C=8.47$ Gauss.

4,4′-Di-t-butyl Biphenyl. The ESR spectrum of 4,4′-di-t-butylbiphenyl, shown in Fig. 4, was observed in the temperature range of −70 °C to −60 °C. Besides the *ortho*-proton splitting of 2.67 Gauss, one may see the t-butyl proton splitting (0.38 Gauss), which is three times larger than that of the anion radical.[9] The proton hyperfine coupling constants thus estimated are $a_2^H=2.67$ and $a_4^{t\text{-}But}=0.38$ Gauss.

Bimesityl. The ESR spectrum of the cation radical, given in Fig. 5-a, was recorded at −55 °C.

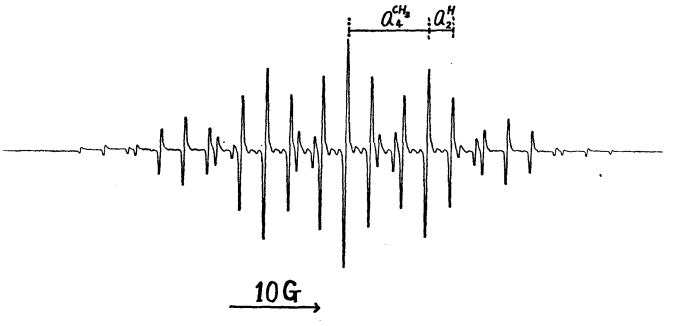

Fig. 2. The ESR spectrum of 4,4′-bitolyl cation radical observed at −50 °C.

b) The computer simulated spectrum.

Table 1. The observed hyperfine coupling constants of the alkyl biphenyl anion and cation radicals (Gauss)

		$a_2^H, a_2^{CH_3}$	a_3^H	a_4^R
4,4'-Bitolyl	Anion	2.66	0.51	5.63
	Cation	2.64		8.79
4,4'-Di-*t*-butyl Biphenyl	Anion	2.64	0.60	0.10[9]
	Cation	2.67		0.38
2,2', 4,4', 6,6'-Bimesityl	Cation	2.19	0.13	8.79

The bimesityl cation radical is fairly stable for a continuous observation of the ESR spectrum for about 4 hr, but the cation radicals of the other *ortho*-methyl biphenyls, such as 2,2'-bitolyl and 2,2',6,6'-bixylyl, were not successfully generated. The hyperfine structures of the observed spectrum can be well analyzed in terms of the septet splitting of the *para*-methyl protons (8.79 Gauss) and of the *ortho*-methyl proton splitting (2.19 Gauss). The computer-calculated spectrum, shown in Fig. 5-b, is in good agreement with the observed spectrum. Under the higher resolving conditions, the ring proton splitting of the *meta*-position, a_3^H was measured to be 0.13 Gauss. The hyperfine coupling constants thus determined are $a_2^{CH_3}=2.19$, $a_3^H=0.13$ and $a_4^{CH_3}=8.79$ Gauss.

Biphenyl and the Other Alkylbiphenyl. Biphenyl was dissolved in CH_2Cl_2 and treated with $SbCl_5$ in the same manner. The resulting blue solution showed a strong ESR absorption split into eleven equally-spaced hyperfine lines (2.12 Gauss). The hyperfine structure of the spectrum was, however, identical with that for the 4,4'-dichlorobiphenyl cation radical previously reported.[7] The 4-chlorobiphenyl also gave the same ESR spectrum of dichlorobiphenyl. The 3,3',5,5'-tetra-methylbiphenyl and the 3,3',5,5'-tetra-*t*-butylbiphenyl afforded poorly-resolved ESR spectrum, but we failed to detect the ESR absorptions of the alkylbiphenyls, such as 4,4'-diethylbiphenyl and 4,4'-di-isopropylbiphenyl.

Hyperconjugation of the Alkyl Group. McLachlan's MO calculations of the spin density were carried out for 4,4'-bitolyl using two different models, the inductive and the hyperconjugative models. In the inductive model, the Coulomb integral of the ring-carbon atoms

a) $Q^{CH_3}=-27$ Gauss was used. b) Estimated from the a_3^C and a_4^C values, based on the Karplus and Fraenkels formula.

neighboring the methyl group, α_{CH_3}, was estimated to be $\alpha_{CH_3}=\alpha-0.2\beta$. The Coulson-Crawford parameters were used for the hyperconjugation model of the methyl groups ($>C_1-C_2\equiv H_3$) as follows; $\alpha_2=\alpha-0.1\beta$, $\alpha_{H_3}=\alpha-0.5\beta$, $\beta_{C-C}=0.7\beta$, $\beta_{C-H_3}=2.5\beta$.[10] McLachlan's parameter was taken as $\lambda=1.1$ everywhere. Based on the observed values of the ring-proton splitting (a_i^H), the experimental values of the spin density (ρ_i^π) were calculated based on the Colpa-Bolton's formula, expressed as follows;

$$a_i^H = Q_{CH}^H\rho_i^\pi \pm K_{CH}^H[\rho_i^\pi]^2$$

where the negative sign is applicable to the cation, and the positive sign, to the anion radicals, and where the parameters were taken as $Q_{CH}^H=-27$ Gauss and $K_{CH}^H=-12$ Gauss. Both the experimental and theoretical values of the spin density (ρ_i^π) are summarized in Table 2,

It has been well known that the methyl protons of the cation radical usually give a much larger splitting than those of the anion radical, and this effect has been accepted as being straightfoward evidence supporting the importance of the hyperconjugation mechanism in the methyl group.[12] The methyl proton splitting of the 4,4′-bitolyl cation radical is indeed 1.5 times larger than that for the anion radical, as may be seen in Table 1.

In the case of the cation radical, however, the ρ_4^π can not be derived from the methyl proton splitting, because the Q^{CH_3} value has not been widely established. In the present works, the experimental values of ρ_3^π and ρ_4^π were estimated from the ^{13}C-hyperfine splitting constant, a_3^C, a_4^C using the Karplus-Fraenkel formula:[13]

$$a_i^C = (S^C-\sum_{i=1}^{3}Q_{C_iX_i}^C)\rho_i^\pi - \sum_{i=1}^{3}Q_{X_kC_i}^C\rho_k^\pi$$

where $S^C=-12.7$ Gauss, the contribution from the 1s electron of C_i; where $Q_{C_iX_k}^C$ ($Q_{C_iH}^C=19.5$, $Q_{C_iC_k}^C=14.4$ Gauss), the $\sigma-\pi$ interaction parameter produced by the ρ_i^π on the C_i atom bonded to sp^2-hybridized ring carbon atoms, and where $Q_{C_kC_i}^C=-13.9$ Gauss represents a polarization from the neighboring sp^2-carbon atom. The parameters ($Q_{CC'}^C=30.0$, $Q_{C'C}^C=-20.9$ Gauss) for a sp^2-hybridized carbon bonded to the sp^3-carbon of the methyl group (C′) are referred to the value calculated by Strauss and Fraenkel.[14]

By substituting these parameters into the equation, the following equations were derived, neglecting the spin density on the methyl carbon at the *para*-position:

$$a_3^C = 35.5\rho_3^\pi - 14.4(\rho_2^\pi+\rho_3^\pi)$$

$$a_4^C = 46.1\rho_4^\pi - 28.8\rho_3^\pi$$

Using the experimental value of ρ_2^π obtained from the ring-proton splitting, ρ_3^π and ρ_4^π were thus calculated to be $\rho_3^\pi=0.0172$ and $\rho_4^\pi=0.1945$, which showed an excellent agreement with the theoretically-calculated values shown in Table 2.

The methyl-proton splitting parameter, Q^{CH_3}, was calculated to be 43.5 Gauss on the basis of the calculated value, assuming an inductive model of hyperconjugation. It can also be estimated to be 45.2 Gauss on basis of the experimental spin density, ρ_4^π, as determined from the ^{13}C-hyperfine splitting.

Of interest is the comparison of the *t*-butyl proton splitting, $Q^{t\text{-But}}$, which is tentatively estimated using the theoretical spin density calculated by the inductive model for the methyl group.

The $Q^{t\text{-But}}$ value for the cation radical (1.88) is about four times that for the anion radical (0.50).

Steric Hindrance of the Biphenyl Cation Radical. Molecular orbital calculations of the spin density were carried out for hindered models of the 2,2′,4,4′, 6,6′-bimesityl cation radical, assuming that the value of the resonance integral between the central 1-1′ bond varies with the function of the twisting angle, θ, of the two phenyls; that is, $\beta_{11'}=\beta\cos\theta$.

In Fig. 6, we show the dependence of the twisting angle, θ, on the theoretical spin density at the ring carbon atoms. The calculation results of both the inductive and hyperconjugative models suggested that the steric hindrance may cause a large depression in the spin density at the *ortho*-position (ρ_2^π), but may have scarcely any effect on the *para*-position (ρ_4^π). Therefore, either the degree of the depression in ρ_2^π or the increment in ρ_4^π/ρ_2^π would also be a good measure for estimating the degree of the steric hindrance, as has been described before.[3,4] According to the MO calculation, there is a possibility that the negative

spin densities at the *meta*-position, ρ_3^π, change to positive sign with an increase in the steric effect.

We have, however, disregarded the effect on the *meta*-position, because the observed *meta*-proton splitting is too small for us to qualify the steric effect on the basis of the present ESR observations. The experimental spin densities of the ρ_2^π and ρ_4^π/ρ_2^π values were calculated using the Q^{CH_3} value estimated for the p,p'-bitolyl cation radical; that is, $\rho_2^\pi=0.050$, $\rho_4^\pi=0.2021$, and $\rho_4^\pi/\rho_2^\pi=4.40$. Unfortunately, the ESR observation of the 2,2′,4,4′,6,6′-bimesityl anion radical has never been successfully achieved. However, for the 2,2′,6,6′-bixylyl anion radical, these values were already known to be $\rho_2^\pi=0.082$ and $\rho_4^\pi/\rho_2^\pi=2.30$.[4] Furthermore, the ρ_2^π of the anion radicals of the *ortho*-alkyl derivatives hitherto studied have been coincidently close to this value, and the ratios of ρ_4^π/ρ_2^π lay together in the range from 2.30 to 2.50.[2,4,5]

A large discrepancy in the ρ_2^π and ρ_4^π/ρ_2^π values can be seen between the cation and the anion radical. This suggests that the more stronger steric hindrance may work on the cation radical rather than on the anion radical.

According to the MO calculation, the twisting angle of the two phenyls would be around 70° in this cation radical, rather close to the values for the neutral molecules,[15], while it is assumed to be 45°∼50° for the anion radicals of hindered alkylbiphenyls. In order to explain the different planar characters of the biphenyl observed for the cation and the anion radical, the bonding character between the central 1–1′ bond may be considered in terms of the partial bond order in the frontier molecular orbital of each ion radical.

In the case of the anion radical, the conjugation between the two phenyl rings may be enhanced by the presence of the unpaired electron, which has a positive bond order between the central 1–1′ bond in the π_{n+1} molecular orbital. The similar enhanced planar character of biphenyl reported for the excited triplet state of *ortho*-methyl derivatives[16,17] has also been interpreted in terms of the delocalization of the unpaired electron across the two phenyl rings.

On the contrary, the unpaired electron occupies the molecular orbital in the case of cation radicals, and the conjugation of the two phenyls may be strongly reduced, just as in the neutral molecules, because the wave function has the node and there is a negative bond order between the 1–1′ bonds in these molecules.

The numerical calculations were carried out on the FACOM 230—60 at the Data Processing Center, Kyoto University.

The Kinetics of Oxygen Exchange between Arsenate Ions and Solvent Water

Akiko OKUMURA and Nobukazu OKAZAKI

Department of Chemistry, Nara Women's University, Nara 630

(Received February 12, 1973)

The rates of oxygen exchange between arsenate ions and water have been measured at 14.5 °C and 30 °C over the pH range of 6.5—12.5. The rate, R, may be expressed by the rate law:

$$R = k_1[H_2AsO_4^-] + k_2[HAsO_4^{2-}] + k_3[AsO_4^{3-}] + k_4[H_2AsO_4^-]^2 + k_5[H_2AsO_4^-][HAsO_4^{2-}] + k_6[HAsO_4^{2-}]^2.$$

The exchange rates at 30 °C and $I=0.55$ have been analyzed in terms of this rate law to obtain the values of the rate constants, k_1—k_6. The activation energy of the over-all exchange reaction is 13.2±0.2 kcal/mol at pH 7.51 and 22.14±0.02 kcal/mol at pH 9.79. The reaction shows a negative salt effect in the region of pH 7.5, and a positive salt effect at pH 9.3.

The oxygen exchange of arsenate ions in an aqueous solution has been studied, except for the earlier qualitative studies,[1] mainly from the biochemical point of view.[2] In order to explore the possibility of the use of ^{18}O-labelled arsenate in biochemical tracer work, Kouba and Varner[3] have measured the exchange half-times at several pH's between 2 and 10 at 32 °C; they estimated a very low activation energy of 3.7 kcal/mol for the exchange reaction at pH 8.0. We have studied the kinetics of this reaction in more detail in order to elucidate its mechanisms.

Experimental

Materials. Disodium hydrogen arsenate heptahydrate (Special grade, JIS) was recrystallized from water. Water enriched in oxygen-18 (*ca.* 2 atom%) and guanidine hydrochloride were treated as has been described in a previous paper.[4] Lithium perchlorate was obtained by neutralizing lithium carbonate (Special grade, JIS) with perchloric acid (Special grade, JIS), and was repeatedly recrystallized. The other chemicals were of an analytical reagent grade, and were used without further purification.

Procedure. The procedures were almost the same as those used in the previous work.[4] The exchange reaction was started by diluting an isotopically-equilibrated solution of disodium hydrogen arsenate in oxygen-18 water with a relatively large amount of isotopically normal water. The pH value of the solution was controlled by adding a small amount of hydrochloric acid or of a sodium hydroxide solution. The ionic strength was adjusted by the addition of sodium chloride. The reactions were carried out in an ice-water bath or in a constant temperature bath. At appropriate intervals a portion of the solution was removed, and the arsenate ions were precipitated by adding a barium chloride solution. The compositions of the precipitates from the solutions at pH 5.6 and 8.9 were shown by chemical analysis to be $BaHAsO_4 \cdot H_2O$. The precipitate was separated by means of a centrifuge, washed three times with absolute ethanol, dried in an oven at 110 °C, and converted into carbon dioxide by the guanidine hydrochloride method.[5] The isotopic analysis of the carbon dioxide was made on a Hitachi RMS-I-type mass spectrometer.

The rate of oxygen exchange in g atom per 1 in unit of time was calculated by means of the formulas:

$$R = \frac{4[\mathrm{As(V)}][H_2O]}{4[\mathrm{As(V)}]+[H_2O]} \cdot k_{ex},$$

and

$$k_{ex} = -\frac{1}{t} \cdot \ln\left\{1 - \frac{O_0 - O_t}{O_0 - O_\infty}\right\}, \quad \text{(I)}$$

where O_0, O_t, and O_∞ are the oxygen-18 contents of the arsenate oxygen at the times 0, t, and infinity respectively, and where [As(V)] and $[H_2O]$ are the molar concentrations of the arsenate and water respectively. The McKay plots were satisfactorily linear over two half-lives except for the runs at pH>11.

Induced Exchange. It has been found in the preliminary work that oxygen exchange between arsenate ions and water is induced on the precipitation of arsenates by metallic ions. The extent of the induced exchange varies with the nature of the metallic ions; it is found to be larger for the ions of transition metals and for the cations with higher charges. With the barium ion as precipitant, which induces the oxygen exchange least of all the metal ions tried, the induced exchange amounts to *ca.* 20% of the total exchange at pH 9.0 and 30 °C. The extent increases with an increase in the acidity. Prestwood and Wahl[6] have discussed the effect of induced exchange on the kinetics of Tl(I)–Tl(III) exchange reaction. They have shown that, when the separation-induced exchange and the incomplete separation effects are reproducible, the equation of the form of (I), with the values of specific activities measured after separation, gives the real rate that occurs in solution. Their argument, with necessary changes, applies to the present case. The presence of the crystal water in the precipitate of barium arsenate may be treated as a case of incomplete separation in the sense of these authors. Since the precipitate has a definite composition, and since the oxygen-18 content of the crystal water is approximately equal to that of the normal water, we may make use of Eq. (I) in calculating the exchange rate in solution.

To check the above arguments experimentally, we have carried out the following two experiments. 1) In a kinetic run (pH 7.40, 30 °C), the precipitate of barium hydrogen arsenate monohydrate was divided into two portions. One portion was dried at 110 °C for an hour and then analysed as has been described above. Barium hydrogen arsenate monohydrate loses its water of crystallisation above 120 °C.[7]

7) R. H. Vallance, "A Text-book of Inorganic Chemistry," ed. by J. N. Friends, Vol. VI, Part IV, (1938), Charles Griffin Co., London, p. 194.

The other portion was dehydrated at 170 °C for two hours to the anhydrous salt and then analysed for its oxygen-18 content. The two methods gave approximately equal ^{18}O-concentrations, the difference being not more than 5 per cent. This fact shows that the scrambling of oxygen atoms occurs between arsenate ions and crystal water in the course of the dehydration of barium hydrogen arsenate monohydrate. Similar phenomena have been observed with disodium hydrogen and sodium dihydrogen arsenates at room temperature.[8] The first-order rate constants of ^{18}O-exchange, k_{ex}, obtained by the two methods are 0.233 ± 0.001 hr^{-1} and 0.234 ± 0.002 hr^{-1} for the drying temperatures of 110 °C and 170 °C respectively. 2) An oxygen-exchange reaction of arsenate ions (pH 8.89, 30 °C, [As(V)]=1.2 M) was followed by two different methods of ^{18}O-analysis, one by analysing the arsenate oxygen by the method described above, and the other by measuring the increase in the ^{18}O-content of the solvent water. The solvent water was separated by the freeze-dry method and was analysed by the guanidine hydrochloride method. The values of k_{ex} obtained are 0.0880 ± 0.0002 hr^{-1} and 0.0928 ± 0.0007 hr^{-1} for the arsenate analysis and the water analysis respectively. Taking into consideration the difference in the analytical methods, the agreement between the two values of k_{ex} may be considered to be satisfactory. These results show that the induced exchange does not affect the kinetics of the oxygen-exchange reaction of arsenate ions.

Determination of the Dissociation Constants of Arsenic Acid. For the analysis of the exchange rate, it is desirable to obtain the pK_2 and pK_3 values of arsenic acid under the conditions of the kinetic runs. These have been determined by potentiometric titrations with a glass electrode. Solutions of potassium dihydrogen arsenate containing an amount of potassium chloride necessary to maintain the desired ionic strength were titrated with a solution of carbonate-free potassium hydroxide. The concentrations of the solutions were so chosen as to give the desired ionic strength at the half-neutralisation point. The values obtained are given in the following table.

Table 1. The values of pK_2 and pK_3 of arsenic acid[a]

	Temp. °C	Ionic strength 0.13	0.30	0.55
pK_2	0	$6.83_7\pm0.00_5$	—	$6.59_6\pm0.01_5$
	14.5	$6.77_7\pm0.00_4$	—	$6.56_1\pm0.00_6$
	30.0	$6.75_0\pm0.00_3$	—	$6.53_1\pm0.01_4$
pK_3	14.5	—	$11.30_6\pm0.02_6$	$11.19_2\pm0.01_0$
	30.0	—	$11.21_5\pm0.01_3$	$11.01_5\pm0.01_0$

a) Here the dissociation constant is defined by $K=a_{H^+}\cdot[A^-]/[HA]$, where a_{H^+} is the activity of the hydrogen ion and where [HA] and [A$^-$] are the molar concentrations of an acid and its conjugate base. The values of the pK's were obtained from two series of titrations, each with ten titrations. The errors indicated are the probable errors.

Results and Discussion

pH *Dependence of the Exchange Rate.* The dependence of the exchange rate on the pH is shown in Fig. 1. In the neighbourhood of pH=pK_2, the logarithm of the rate varies linearly with the pH, and the rate is approximately first-order in the hydrogen-ion concentration. At pH≃9, the dissociation of $H_2AsO_4^-$ is almost complete and the dissociation of $HAsO_4^{2-}$ begins. In this pH region, the variation in the exchange rate with the pH slows down, and at 30 °C the rate is nearly independent of the pH. At pH>10, the rate falls off again with the increase in the dissociation of $HAsO_4^{2-}$.

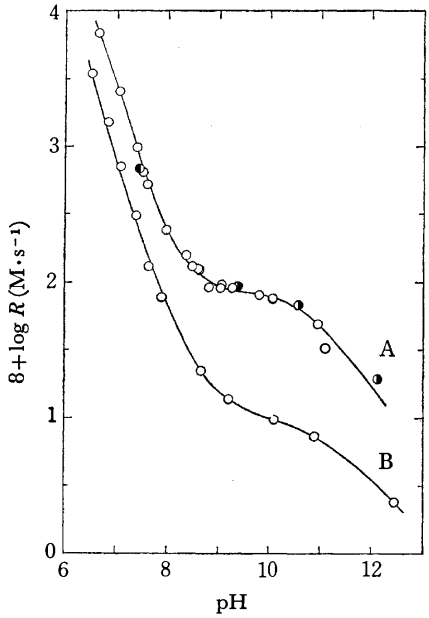

Fig. 1. pH-Rate profiles of the oxygen exchange between arsenate ions and water at 30°(A) and 14.5 °C(B). I= 0.55 M (○: NaCl, ◐: $NaClO_4$, ◑: $LiClO_4$). [As(V)] ≃6.8×10^{-2} M. The curves at 30 °C were calculated by the use of the rate constants obtained.

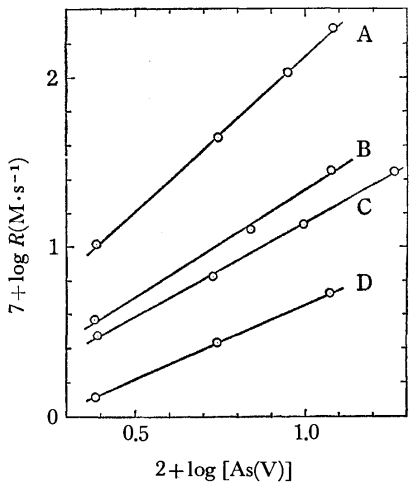

Fig. 2. Dependence of the exchange rate on [As(V)]. 30 °C. I=0.55 M. A: pH 7.51, B: pH 8.47, C: pH 9.27, D: pH 11.1.

Dependence on the Total Arsenate Concentration, [As(V)]. This was studied at four pH's, 7.51, 8.47, 9.27, and 11.1, at 30 °C and I=0.55 M (Fig. 2). Plots of log R against log [As(V)] yield straight lines with slopes of 1.83 ± 0.02, 1.26 ± 0.03, 1.11 ± 0.01, and 0.89 ± 0.01 for the pH values of 7.51, 8.47, 9.27, and 11.1 respectively.

8) A. Okumura and N. Okazaki, This Bulletin, **46**, 2981 (1973).

Mechanisms of the Oxygen Exchange. At pH≃7.5 and at 30 °C, the rate of oxygen exchange may be expressed as $R=k[H^+][As(V)]^{1.8}$. In this region, bimolecular mechanisms between arsenate ions predominate:

$$H_2AsO_4^- + H_2AsO_4^- \overset{k_4}{\rightleftharpoons} H_2As_2O_7^{2-} + H_2O, \quad (4)$$

$$H_2AsO_4^- + HAsO_4^{2-} \overset{k_5}{\rightleftharpoons} HAs_2O_7^{3-} + H_2O, \quad (5)$$

$$HAsO_4^{2-} + HAsO_4^{2-} \overset{k_6}{\rightleftharpoons} As_2O_7^{4-} + H_2O. \quad (6)$$

The role of the hydrogen ion is to shift the pre-equilibrium:

$$H_2AsO_4^- \rightleftharpoons HAsO_4^{2-} + H^+,$$

from right to left in favour of the more reactive arsenate species, $H_2AsO_4^-$. It has been believed that the diarsenate ion hydrolyzes very rapidly and therefore cannot exist in aqueous solutions.[9] However, the present result shows that, in an aqueous solution, the condensation of the arsenate ions occurs as well as the hydrolysis of the diarsenate ion. The order with respect to the [As(V)] of 1.8 suggests the occurrence of some first-order paths of the oxygen exchange. These are probably:

$$H_2AsO_3O^{*-} + H_2O \overset{k_1}{\rightleftharpoons} H_2AsO_4^- + H_2O^*, \quad (1)$$

and

$$HAsO_3O^{*2-} + H_2O \overset{k_2}{\rightleftharpoons} HAsO_4^{2-} + H_2O^*. \quad (2)$$

In the region of pH≃9 at 30 °C, where the dissociation of $H_2AsO_4^-$ is almost complete and where $HAsO_4^{2-}$ begins to dissociate, the observed rate law is $R\simeq k'[H^+]^0[As(V)]^{1.1}$. Since, in this region, $[HAsO_4^-]$ is nearly independent of pH, a zero-order dependence on $[H^+]$ may be expected. The observed [As(V)] dependence of 1.1 suggests that, above pH 9, the first-order path (2) controls the total exchange rate. At pH 11.1, the contribution of the bimolecular path (6) becomes negligible. In addition to the above five paths, a pseudo-first-order path:

$$AsO_3O^{*3-} + H_2O \overset{k_3}{\rightleftharpoons} AsO_4^{3-} + H_2O^*, \quad (3)$$

may be expected to make a contribution, if slight, to the total rate.

The rate law of oxygen exchange of arsenate ions may be written as:

$$\begin{aligned} R &= R_1 + R_2 + R_3 + R_4 + R_5 + R_6 \\ &= k_1[H_2AsO_4^-] + k_2[HAsO_4^{2-}] + k_3[AsO_4^{3-}] \\ &\quad + k_4[H_2AsO_4^-]^2 + k_5[H_2AsO_4^-][HAsO_4^{2-}] \\ &\quad + k_6[HAsO_4^{2-}]^2. \end{aligned} \quad (7)$$

Temperature Dependence of the Exchange Rate. This has been studied at pH 7.51 (0 °C, 20 °C, and 30 °C) and at pH 9.79 (30 °C, 40 °C, and 50 °C). Plots of log R against $1/T$ are shown in Fig. 3. From the slopes of the plots, the values of the activation energy are calculated to be 13.2±0.2 kcal/mol at pH 7.51 and 22.14±0.02 kcal/mol at pH 9.79. At 30 °C and pH 9.79, it can be estimated that nearly 95% of the oxygen exchange occurs through Path (2). The value of 22 kcal/mol gives the approximate value of the activation energy of this path. At 30 °C and pH 7.51, the contributions of the second-order rate terms, R_4 and R_5, to the total rate are estimated to be 44 and 38% respectively. The value of 13 kcal/mol gives an upper limit for the activation energies of these bimolecular paths between arsenate ions.

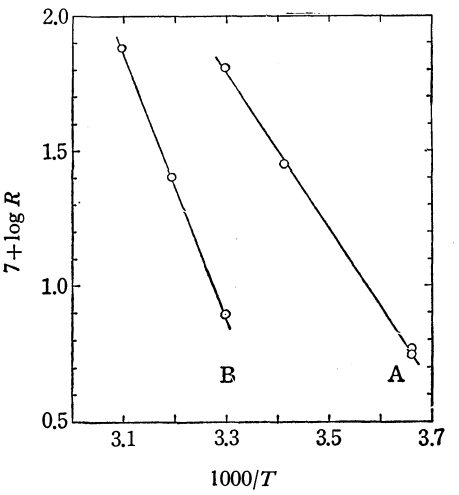

Fig. 3. Temperature dependence of the exchange rate at pH 7.51(A) and 9.79(B). [As(V)]=0.068 M, I=0.55 M.

Salt Effect. On the rate-pH profile at 30 °C (Fig. 1), the plots at pH 7.45, 9.37, 10.58, and 12.12 were obtained with solutions whose ionic strengths had been adjusted with sodium or lithium perchlorate instead of sodium chloride. These plots fall on a curve with the other plots within the range of experimental error. This fact shows the absence of any specific effects of the chloride and perchlorate ions.

The effect of the ionic strength on the exchange rate has been studied at 30 °C at pH 7.72 and 9.29. At a fixed total concentration of the arsenate, the ionic strength was varied by the addition of sodium chloride. The values of the exchange rate thus obtained are listed in the following table:

Table 2. The effect of the ionic strength on the exchange rate ($R\times10^6$) at 30°C

pH	Ionic strengths.			
	0.2	0.55	0.7	1.0
7.72	5.64	—	5.07	3.83
9.29	0.854	0.906	—	0.926

The salt effect is negative at pH 7.72 and positive at pH 9.29. The exchange paths (4), (5), and (6), which predominate in the region of pH 7.72 are expected to exhibit a positive salt effect. Thus, the negative salt effect observed must be due to an equilibrium salt effect which overcomes the kinetic salt effect. An increase in the ionic strength decreases the concentration of the more active species, $H_2AsO_4^-$, by increasing the dissociation constant of $H_2AsO_4^-$. In the region of pH 9, where the extent of the dissociation of

9) "Gmelins Handbuch der Anorganischen Chemie," 8-te Aufl. Syst. -Nr. 17, (1952), Verlag Chemie, Weinheim/Bergstrasse. S. 358.

$HAsO_4^{2-}$ is small, the change in the dissociation constant of $HAsO_4^{2-}$ is without appreciable effect on the concentration of $HAsO_4^{2-}$, and so the kinetic salt effect predominates.

Analysis of the Exchange Rate at 30 °C. The exchange rates observed can be analyzed by the use of the rate law (7). The concentrations of the ionic species were calculated by the relations:

$$[As(V)] = [H_2AsO_4^-] + [HAsO_4^{2-}] + [AsO_4^{3-}], \quad (8)$$

$$K_2 = a_{H^+} \cdot [HAsO_4^{2-}]/[H_2AsO_4^-], \quad (9)$$

$$K_3 = a_{H^+} \cdot [AsO_4^{3-}]/[HAsO_4^{2-}]. \quad (10)$$

Over the range of pH<9, the k_3-term in the rate law may be neglected, and by using the (8), (9), and (10) relations, Eq. (7) can be rewritten in the form:

$$\frac{R}{[H_2AsO_4^-]} = \left(k_1 + k_2\frac{K_2}{a_{H^+}}\right) + [As(V)] \times \left\{\frac{k_4}{1+(K_2/a_{H^+})+(K_2K_3/a_{H^+}^2)} + \frac{k_5}{1+(a_{H^+}/K_2)+(K_3/a_{H^+})} + \frac{k_6}{(a_{H^+}/K_2)\{1+(a_{H^+}/K_2)+(K_3/a_{H^+})\}}\right\}. \quad (11)$$

In Fig. 4, the data of Fig. 2 are replotted according to

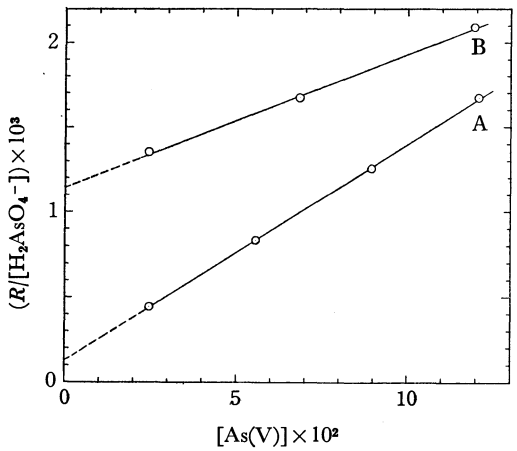

Fig. 4. $R/[H_2AsO_4^-]$ as a function of [As(V)] at pH 7.51(A) and 8.47(B) at 30 °C.

Eq. (11). The least-squares treatment of the plots yields:

$$k_1 + 9.48k_2 = (0.124 \pm 0.006) \times 10^{-3}, \quad (12)$$

$$0.954k_4 + 0.905k_5 + 8.58k_6 = (0.128\pm0.001)\times10^{-1}, \text{ at pH } 7.51, \quad (13)$$

and:

$$k_1 + 87.7k_2 = (1.15\pm0.02) \times 10^{-3}, \quad (14)$$

$$0.0112k_4 + 0.986k_5 + 86.5k_6 = (0.0784\pm0.002)\times10^{-1}, \text{ at pH } 8.48. \quad (15)$$

In the region of pH>9, by neglecting the k_1- and k_4-terms, Eq. (7) can be transformed into:

$$\frac{R}{[HAsO_4^{2-}]} = \left(k_2 + k_3\frac{K_3}{a_{H^+}}\right) + [As(V)]\left\{\frac{k_5}{1+(K_2/a_{H^+})+(K_2K_3/a_{H^+}^2)} + \frac{k_6}{1+(a_{H^+}/K_2)+(K_3/a_{H^+})}\right\}. \quad (16)$$

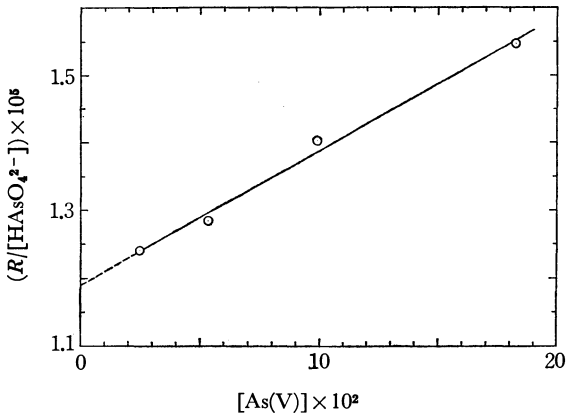

Fig. 5. $R/[HAsO_4^{2-}]$ as a function of [As(V)] at pH 9.27 and 30 °C.

Fig. 5 shows a plot of $R/[HAsO_4^{2-}]$ against [As(V)] at pH 9.27 and I=0.55 M, the data used being the same as those of Fig. 2C. From the intercept and the slope of a line passing through the plots, we obtain:

$$k_2 + 0.0179k_3 = (1.19\pm0.01) \times 10^{-5}, \quad (17)$$

and

$$0.00180k_5 + 0.981k_6 = (0.0198\pm0.0008) \times 10^{-3}. \quad (18)$$

Since k_2 may be reasonably assumed to be larger than k_3, the value of k_2 may be fixed from (17), with an uncertainty of 2% at most to be:

$$k_2 = (1.19\pm0.01) \times 10^{-5}\,s^{-1}.$$

Eqs. (13), (15), and (18) can be solved simultaneously for k_4, k_5, and k_6. The results are:

$$k_4 = 0.74 \times 10^{-1}\,M^{-1}s^{-1},$$

$$k_5 = 0.64 \times 10^{-2}\,M^{-1}s^{-1},$$

and

$$k_6 = 0.85 \times 10^{-5}\,M^{-1}s^{-1}.$$

The value of k_1 is subject to some uncertainty. By using the value of k_2 obtained above, k_1 is evaluated from (12) to be 1.1×10^{-4} and from (14) to be 1.1×10^{-5}. The former value may be better, because the k_1-path plays a more important role at pH 7.51 than at pH 8.48.

The value of k_3 is also attended with uncertainty, because the k_3-path plays an important role only in the most alkaline region of this study, where experimental troubles make the exact determination of the exchange rate difficult. At pH>9.5, where the contribution of the k_5-path to the total rate is negligible, the rate law (7) becomes:

$$R = k_2[HAsO_4^{2-}] + k_3[AsO_4^{3-}] + k_6[HAsO_4^{2-}]^2,$$

which can be transformed into:

$$R - k_6[HAsO_4^{2-}]^2 = k_2[As(V)] + (k_3-k_2)[AsO_4^{3-}].$$

In this pH region, the contribution of the k_6-term is small, being *ca.* 5% of the total rate at pH 9.79. Fig. 6 shows a plot of $R-k_6[HAsO_4^{2-}]^2$ against $[AsO_4^{3-}]$ at a constant value of [As(V)], the value of k_6 obtained above being used. The observed rates were normalized to $[As(V)]=6.8\times10^{-2}$ M by assuming $R\propto[As(V)]$. The least-squares treatment of the plots yields the value: $k_2[As(V)]=(0.080\pm0.003)\times10^{-5}$, and $k_3-k_2=-(0.010\pm0.001)\times10^{-3}$, whence we ob-

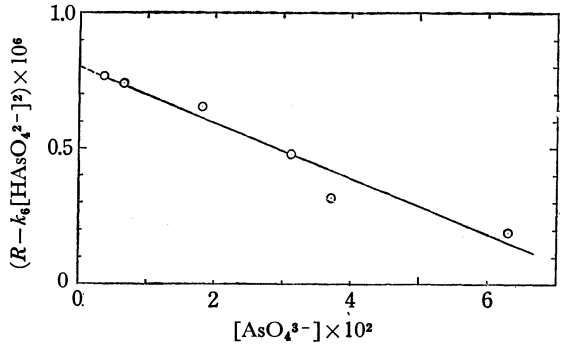

Fig. 6. A plot of $R-k_6[HAsO_4^{2-}]^2$ against $[AsO_4^{3-}]$. 30 °C. [As(V)]=0.068 M. I=0.55 M.

tain:

$$k_2 = 1.18 \times 10^{-5}\ s^{-1},$$

and

$$k_3 = 0.15 \times 10^{-5}\ s^{-1}.$$

The values of the rate constants obtained are summarized in the following table. Other methods of evaluating the rate constants yielded values which are in satisfactory agreement with those above. The rate-pH profile at 30 °C in Fig. 1 was calculated by using these rate constants; it shows a satisfactory agreement with the plots obtained by the experiments except for the most alkaline region.

The rate constant, k_1', of the oxygen exchange of dihydrogen phosphate ions:

$$H_2PO_4^- + H_2O^* \rightleftharpoons H_2PO_3O^{*-} + H_2O,$$

has been found to be $4\times10^{-6}\ s^{-1}$ at 100 °C.[10] If the activation energy of this process is assumed to be about the same as that of the hydrolysis of the monoanion of methyl dihydrogen phosphate (30 kcal/mol),[10] k_1' has a value of 4×10^{-10} at 30 °C, which is smaller by a factor of 10^6 than the corresponding rate constant, k_1, of the dihydrogen arsenate ion.

Table 3. Rate constants of the oxygen exchange between arsenate ions and water at 30 °C (I=0.55 M)

Exchange path	Rate constants
$H_2AsO_4^- + H_2O \rightleftharpoons$	k_1: $1\times10^{-4}\ s^{-1}$
$HAsO_4^{2-} + H_2O \rightleftharpoons$	k_2: $1.2\times10^{-5}\ s^{-1}$
$AsO_4^{3-} + H_2O \rightleftharpoons$	k_3: $1.5\times10^{-6}\ s^{-1}$
$H_2AsO_4^- + H_2AsO_4^- \rightleftharpoons H_2As_2O_7^{2-} + H_2O$	k_4: $7.4\times10^{-2}\ M^{-1}\ s^{-1}$
$H_2AsO_4^- + HAsO_4^{2-} \rightleftharpoons HAs_2O_7^{3-} + H_2O$	k_5: $6.4\times10^{-3}\ M^{-1}\ s^{-1}$
$HAsO_4^{2-} + HAsO_4^{2-} \rightleftharpoons As_2O_7^{4-} + H_2O$	k_6: $8.5\times10^{-6}\ M^{-1}\ s^{-1}$

A hydrogen-bonded cyclic intermediate between a dihydrogen phosphate ion and a water molecule has been postulated for the oxygen exchange of dihydrogen phosphate ions.[11] Such a special reactivity of the monoanion was not observed in the oxygen exchange of arsenate ions, the rate constant, k_1, being only an order of magnitude larger than k_2, which in turn is also an order of magnitude larger than k_3. The exchange paths, (1)—(3), involve probably the nucleophilic attack of a water molecule on the arsenic atom of arsenate ions.

From the values of the constant, k_2, and the activation energy of Path (2) (22 kcal/mol), the entropy of activation of this path is calculated to be $\Delta S^{\ddagger}_2 = -11$ cal K^{-1} mol^{-1} (30 °C). This value is consistent with a mechanism which involves a bimolecular substitution process between an arsenate ion and a water molecule as the rate-limiting step.

The authors wish to thank Professor Shinichi Kawaguchi of Osaka City University for his helpful discussions.

An MO-simulation of Elementary Reactions in Hydrocarbon Oxidation. I. A Bimolecular Coupling Reaction of the Methyl Radical and Molecular Oxygen

Katsutoshi OHKUBO and Futoshi KITAGAWA

Department of Synthetic Chemistry, Kumamoto University, Kurokami, Kumamoto 860

(Received February 24, 1973)

An MO-simulation of the geometrical change in the bimolecular methane oxidation, $CH_3+O_2\rightarrow CH_3O_2$, was performed using the CNDO/2 approximation. The geometry of CH_3O_2 was predicted to take $r_{OO}=1.19$ Å and $\angle COO=111°$ with fixed distances of $r_{CO}=1.44$ Å and $r_{CH}=1.09$ Å. The coupling reaction proceeds smoothly, without any appreciable activation energy, with the geometric transformation of the momentarily-living CH_3--O_2, with $r_{CO}=2.36\sim1.44$ Å, $r_{OO}=1.132\sim1.19$ Å, and $\angle COO=90\sim111°$. The magnitude of the electron migration between CH_3 and O_2 throughout the reaction was estimated.

Recent shock-tube[1,2] or ignition-delay[3,4] investigations have been concerned with methane oxidation involving the elementary bimolecular reaction of CH_3 and O_2, from the kinetic point of view.[5] Clark *et al.*[2] have reported the rate constant for the CH_3 and O_2 coupling reaction to be 1.987×10^7 M^{-1} s^{-1}, while Basco *et al.*[6] have evaluated the rate constant to be 2.7×10^8 M^{-1} s^{-1}; the coupling reaction may thus proceed very rapidly and easily. In this respect, the activation energy for the reaction has been estimated to be 18.0 kcal/mol by the ignition-delay investigation of Skinner *et al.*[4]

No theoretical investigation has, however, been concerned with the process of the coupling reaction of CH_3 and O_2 from the energetic and electronic points of view. Therefore, it is necessary to perform the MO-simulation for the $CH_3+O_2\rightarrow CH_3O_2$ reaction.

The goal of the present investigation using the CNDO/2 theory[7] was to get a reliable prediction of the geometrical changes (and those of the electronic structures) of CH_3 and CH_3O_2 generated in the course of methane oxidation and to shed some light on the elementary bimolecular reaction of CH_3 and the $^3\Sigma_g^-$ state of O_2.

Method of Calculation

In this work, the following three systems were investigated: (a) the methyl radical, CH_3, (b) the methylperoxyl radical, CH_3O_2, and (c) the bimolecular coupling reaction of CH_3 and the $^3\Sigma_g^-$ O_2.

The geometric parameters are shown in the proper figures, but the interatomic distrances of C–H and C–O were fixed at 1.09 Å and 1.44 Å respectively for the sake of simplicity.

The method of calculation was CNDO/2, using the integrals and parametrization in Ref. 7.

Results and Discussion

Methyl Radical and Triplet Molecular Oxygen. The geometry of neutral CH_3 has long been known to take the "planar C_{3v}" (*viz.* D_{3h}) $^2A_2''$ state as the energetically most stable species. The vacuum UV spectroscopic study of Herzberg[8] gave the planar D_{3h} structure with the optimized bond length of C–H (r_{CH}), 1.079 Å, while some semiempirical[9] and nonempirical[10–12] treatments of CH_3 have favored a planar or nearly planar C_{3v} configuration.

The present CNDO/2 calculations on CH_3 at the angle of 70°32′∼90° between a C–H bond and a threefold axis suggest that the planar D_{3h} structure is most likely, as had been expected. Here, the predicted CH_3 geometry resulting from the semiempirical and *ab initio* calculations is summarized in Table 1 for the sake of comparison.

On the other hand, the equilibrium bond length of O–O in the $^3\Sigma_g^-$ O_2 has now been established to be 1.132 Å[7] (CNDO/2 calculation) or 1.207 Å[13] (experiment). The former value was used for the present MO-simulations.

The frontier orbitals of the singly-occupied (SO), nonbonding carbon 2p-orbital of the D_{3h} CH_3 (−13.188 eV) and of the doubly-degenerate SO $1\pi_g$-orbitals of O_2 (−14.856 eV) play a predominant role in the bimolecular coupling reaction of both species. The coupling reaction may be initially made possible by the maximum overlapping of the frontier orbitals mentioned above at the right angle of C–O–O (see below).

Methylperoxyl Radical. Neither the semiempirical nor the *ab initio* treatment has hitherto been concerned with the CH_3O_2 geometry, except in the case of an

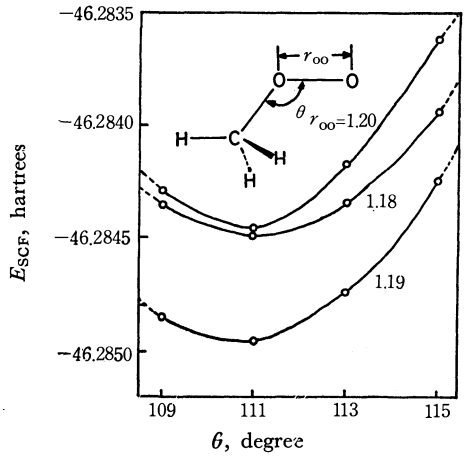

Fig. 1. SCF total energies E_{SCF} of CH_3O_2 as a function of two geometric parameters (r_{OO} and θ).

iterative extended Hückel MO treatment.[14] The CNDO/2 investigation is carried out on CH_3O_2 with the O–O bondlength (r_{OO}) of 1.15∼1.45 Å and the bond angle of C-O-O (θ) of 103∼115° under the fixed angle of HCH, 109°28′. Fig. 1 presents the SCF total energies, E_{SCF}, of CH_3O_2 as a function of two geometric parameters, r_{OO} and θ. As can be seen from Fig. 1, CH_3O_2 with r_{OO}=1.19 Å and θ=111° is shown to be the energetically most stable species. The predicted angle of 111° differs by only 3° from that of HO_2 (108°) obtained from the vibration spectrum study of Paukert and Johnston,[15] but it differs considerably from the HO_2 angle of 104.6°[16] predicted using the *ab initio* SCF–CI calculation.

On the other hand, our predicted O–O bond distance, 1.19 Å, is much closer to that of diatomic O_2 (1.207 Å[13]) than that of H_2O_2 (1.475 Å[17]) or HO_2 (1.458 Å[16]).

Some remarks will be now made concerning the electronic property of CH_3O_2 on the basis of the computed results listed in Table 2. The estimated ionization potential of 13.83 eV is slightly less than that of 14.66 eV[18] found in HO_2. This may be in harmony with the opinion that the larger the alkyl group, R, in the RO_2 radical becomes, the more the ionization potential is lowered.[14] Moreover, the g value (2.003) computed by the Stone equation[21] is somewhat less than that of the experiment (2.015).[14]

Here, it may be worthy of emphasis that the expansion of the radical spin orbital is perpendicular to the cross-section of the C–O–O (xy-plane in Table 2).

a) The geometry of CH_3-O_2 is the same to that in Table 2.
b) The nonbonding carbon p-orbital of CH_3.

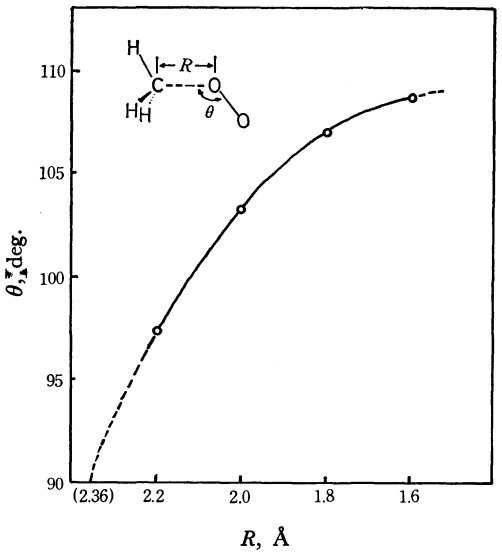

Fig. 2. Bond angle of C-O-O (θ) as a function of C-O distance (R) along the minimum potential barrier.

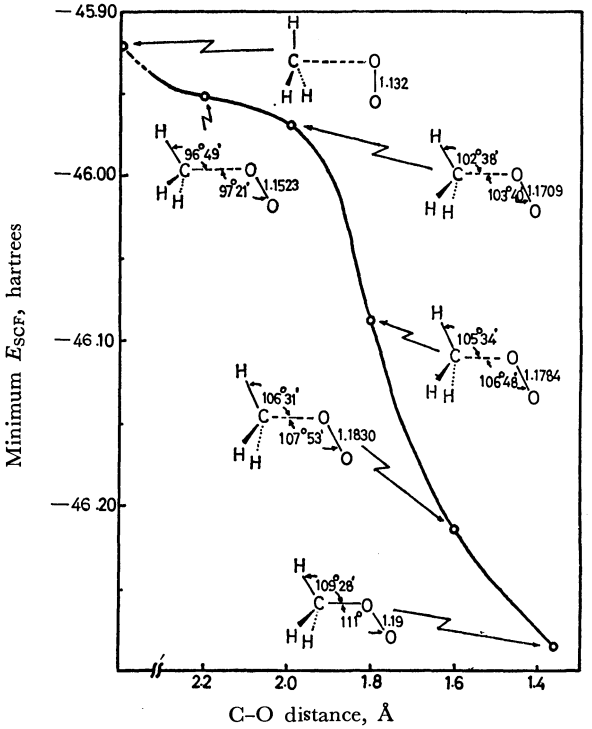

Fig. 3. Changes in minimum SCF total energies and configurations of CH_3--O_2 along the reaction path, $CH_3+O_2 \rightarrow CH_3$--$O_2$.

E_{SCF} value: this is an inevitable consequence from the basic quantum principle. The process of the coupling reaction of CH_3 and O_2 will, then, be estimated by gradually curtailing the C–O distance, giving attention to the minimum energy surface and the geometric transformation of the momentarily-living CH_3–O_2. The curve of the minimum E_{SCF} value as a function of the C–O distance is shown in Fig. 2, together with the configuration of CH_3–O_2. As Fig. 2 indicates, the coupling reaction proceeds smoothly, without any appreciable peak of the electronic energy path.

It is of interest to predict the C–O distance at the start of the reaction between CH_3 and O_2 before discussing the geometric transformation of CH_3–O_2. Bearing in mind the initial mode of the interaction between CH_3 and O_2 (*viz.*, $\angle COO=90°$), the abovementioned C–O distance surely corresponds to the R value (C–O distance) at $\angle COO=90°$ under a minimum energy surface. Judging from the correlation between R and θ (angle of C–O–O) under such a minimum energy surface (see Fig. 2), the coupling reaction of CH_3 and O_2 should start at $R=2.36$ Å ($\theta=90°$).

With regard to the geometric transformation of CH_3—O_2 through the reaction progress, the following aspects are noticeable: slack expandings of $\angle HCO$ and $\angle COO$ with a gradual stretching of the O–O follows the hasty widening of both the angles with the lengthening of the O–O under $R<2.0$ Å (see Fig. 2).

Mention should also be made here of the electron migration between CH_3 and O_2 through the reaction. Taking into consideration the electron densities of

the s and p orbitals on the carbon or oxygen atom (see Table 3), the predominant electron-migration can be depicted by the following representations.

The electron once transferred from the nonbonding half-occupied carbon p_y'-orbital to the O_α p_y-orbital through a $p\sigma$-type overlapping migrates further to the O_β p_y-orbital through $p\pi$-delocalization:

$$p_y'^{(C)} \xrightarrow{\text{through } p\sigma \text{ of C-O}\alpha} p_y^{(O\alpha)} \xrightarrow{\text{through } p_y\pi \text{ of } O_2} p_y^{(O\beta)}$$

There exists a back-donation from the O_β p_z-orbital to the O_α p_z-orbital through the $p\pi$-conjugation:

$$p_z^{(O\beta)} \xrightarrow{\text{through } p_z\pi \text{ of } O_2} p_z^{(O\alpha)}$$

However, further back-donation from the O_β p_z-orbital to the C p_z-orbital through the pseudo π orbital of the C–O_α bond cannot be expected, as may be seen from Table 3.

The calculations were carried out on a FACOM 230—60 computer at the Data Processing Center of Kyushu University.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2945—2949 (1973)

The Crystal Structure of an *N*-Methylphenothiazine–7,7,8,8-Tetracyanoquinodimethane Complex, *N*-MePZT–TCNQ

Hayao KOBAYASHI

Department of Chemistry, Faculty of Science, Toho University, Narashino, Chiba 275

(Received March 2, 1973)

Crystals of the 1 : 1 charge-transfer complex of *N*-MePZT-TCNQ are monoclinic with those lattice constants: $a=10.904$, $b=13.321$, $c=7.086$ Å, and $\beta=91.06°$, and with the space group C2/m. X-ray structure analysis showed that the mixed-stacks of *N*-MePZT and TCNQ exist along the c axis. *N*-MePZT is disordered, and its apparent molecular symmetry is C_{2h}, taking four possible conformations. The molecular geometry of TCNQ indicates that the amount of the charge transferred from *N*-MePZT is very small ($<0.2e$).

7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ) is a powerful electron acceptor and forms a number of charge-transfer complexes. *N*-methylphenothiazine (*N*-MePZT) is an electron donor. A neutral *N*-MePZT molecule has a folded structure,[1] while the PZT skeleton is planar in crystals of trinitrobenzene-PZT.[2] As was pointed out by Fritchie,[2] the van der Waals packing requirement of an alternating donor-acceptor stack might suggest that PZT is essentially planar in a 1 : 1 complex. Crystals of *N*-MePZT-TCNQ were subjected to X-ray structure analysis in order to examine the molecular structure of the component molecules.

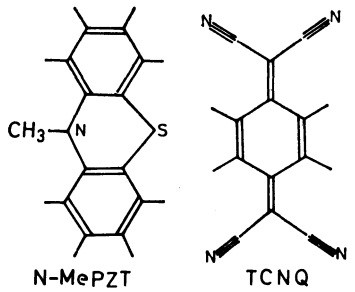

Fig. 1. The molecular structures of *N*-MePZT and TCNQ.

Experimental

Black crystals of *N*-MePZT-TCNQ were obtained by the slow evaporation of an equimolar acetone solution of the components. Oscillation and Weissenberg photographs showed the crystal to be monoclinic. The systematic absence for *hkl* with $h+k=2n+1$ indicated that the space group is C2/m, Cm, or C2. The unit-cell dimensions, as determined by means of a diffractometer with Mo$K\alpha$ radiation, are $a=10.904\pm0.002$, $b=13.321\pm0.002$, $c=7.086\pm0.001$ Å, and $\beta=91.06\pm0.04°$. The density measured by the flotation method was 1.32 g/cm^3, whereas the calculated density on the assumption of $Z=2$ is 1.347 g/cm^3. The intensity data were collected on a Rigaku automated four-circle diffractometer by employing a ω–2θ scan technique. A crystal with dimensions of $0.25\times0.13\times0.18$ mm was used. Of the 1274 accessible reflections with $2\theta\leqq55°$, significant counts were recorded for 576 reflections. Measurements of two reference reflections, (2,0,0) and (0,0,2), were repeated every fifty reflections.

Structure and Determination

The trial structure was easily deduced from packing considerations. The space group C2/m was assumed; this was verified at a latter stage. Refinements were performed by means of Fourier synthesis, followed by the block-diagonal least-squares method. Three hydrogen atoms (H1, H2, and H3 in Table 1) were found on the three-dimensional-difference Fourier maps and were refined isotropically. No hydrogen atoms of the methyl group came out. Because of the requirements of the space group, the orientation of *N*-MePZT must be disordered and the apparent molecular symmetry is C_{2h}, which seems to be consistent with the fact that diffuse scattering appears around strong Bragg reflections. Possible models of the disordered structure of *N*-MePZT were easily deduced. The model shown in Fig. 2 is the most plausible one because the difference Fourier synthesis shows nitrogen and sulfur atoms

a) Isotropic temperature factor *B*.

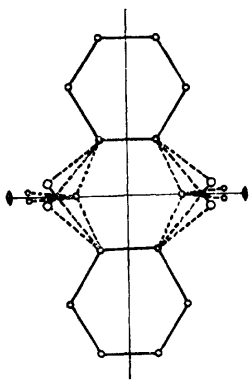

Fig. 2. The model of the disordered structure of *N*-MePZT.

separately. The nitrogen atom lies on the twofold axis, while the sulfur atom is in general position. Anisotropic refinement gave an *R*-value of 0.096. Other models were also considered, but they did not give good *R*-values. The final positional and thermal parameters are given in Table 1. The observed and calculated structure factors are compared in Table 2.

Results and Discussion

The structure is shown in Fig. 3. It consists of mixed stacking columns of alternating donor (*N*-MePZT) and acceptor (TCNQ) molecules. The mode of overlapping is shown in Fig. 4. The average intermolecular distance is 3.44 Å; the least-squares planes of both the molecules are given in Table 3.

The crystal structure analyses of neutral phenothiazine (PZT) and *N*-MePZT have revealed that these molecules have a non-planar structure folded along the N–S direction. A PZT molecule in a crystal of a PZT-3,5-dinitrobenzene complex has a folded structure with a dihedral angle of 156°,[3] and it is planar in a PZT-TNB (trinitrobenzene) complex.[2] Fritchie suggested that a PZT molecule in PZT-TNB is actively folding at room temperature, taking two possible conformations with dihedral angles of about 165—172°.

a) The atoms C4, S, and N1 were not used for the the calculation of least-squares plane.

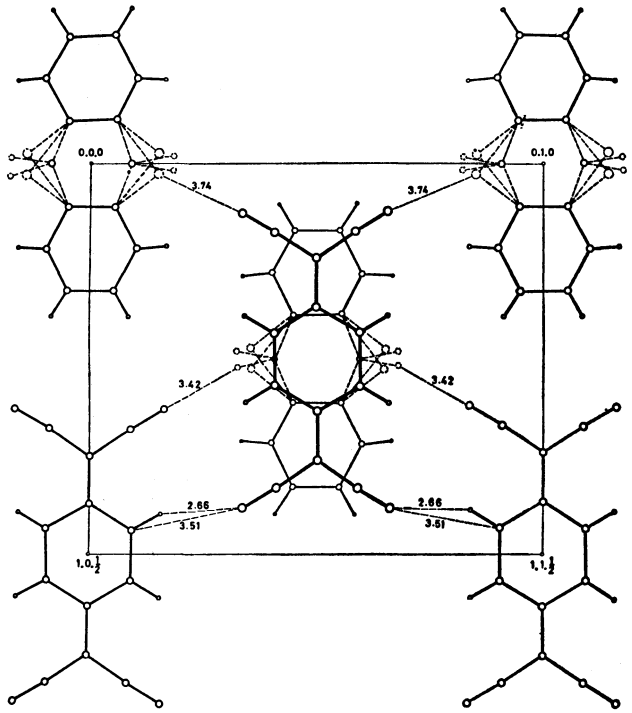

Fig. 3. The molecular arrangement and the short contacts in the plane (102), viewed along the *c* axis.

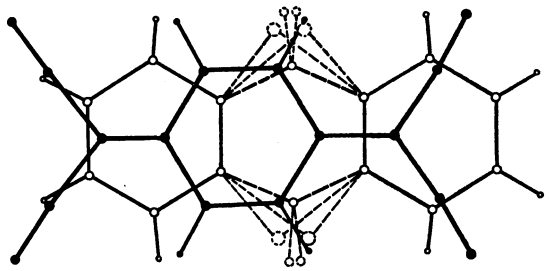

Fig. 4. The molecular overlap as viewed in the direction perpendicular to the mean molecular planes.

In view of the fact that the molecular symmetry of *N*-MePZT is C_{2h} and that the sulfur atom deviates about 0.4 Å from the molecular plane (Table 3), it may be reasonable to conclude that *N*-MePZT is disordered, taking four conformations with dihedral angles of about 160—170 °C with equal probability as is shown in Fig. 5. In addition, the nitrogen atom is

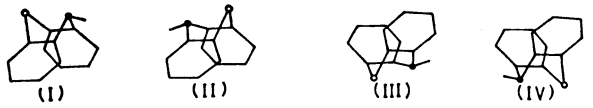

Fig. 5. The accessible structures and orientations of *N*-MePZT.

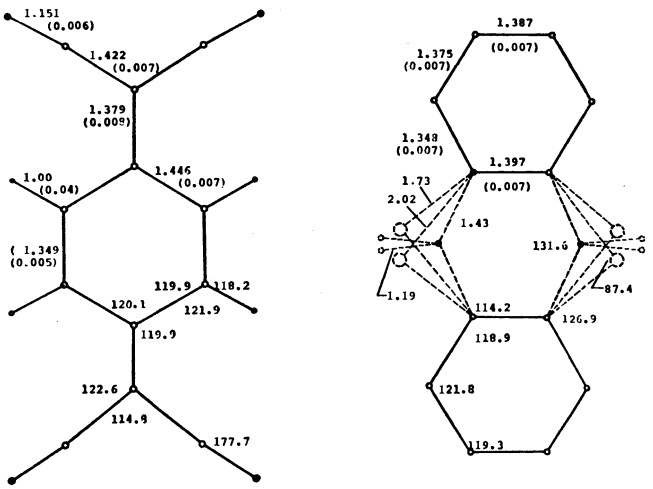

Fig. 6. Bond lengths(Å) and angles(°).
The estimated standard deviations of bond lengths are shown in parentheses. Those of bond angles are about 0.50° for all the angles spanned by non-hydrogen atoms except carbon atom of methyl group and about 4.0° for the angles involving the hydrogen atoms and carbon atom of methyl group.

on the twofold axis, that is, on the molecular plane; this is consistent with the small deviation of the nitrogen atom from the molecular plane in neutral *N*-MePZT and PZT[1,4] (0.07, 0.03 Å).

The bond lengths and angles are shown in Fig. 6. The two C–S bonds are 1.73 and 2.02 Å, giving a mean value of 1.87 Å (Fig. 6), and N–C is 1.43 Å. These values are consistent with those of neutral *N*-MePZT, (1.82, 1.43 Å). The C–C bonds parallel to the twofold axis of the molecule are longer than the others, and the N–C (methyl) bond is very short. These facts are undoubtedly due to the disorder of *N*-MePZT.

The molecular structure of TCNQ is normal. The

bond lengths shown in Fig. 6 are uncorrected for thermal libration. Some rigid-body parameters for TCNQ are given in Table 4 and Fig. 7. The translational motion nearly isotropic while the libration is quite anisotropic. The r.m.s. amplitude of 5.7° about the long axis is the largest.

Recent studies of TCNQ anion radical salts have revealed a dependence of the molecular geometry on its formal charge ($TCNQ^0$, $TCNQ^{-1/2}$, $TCNQ^-$).[5,6] In a charge-transfer complex, TCNQ may be charged to some extent according to the magnitude of the charge-transfer interaction. If the bond lengths obtained are sufficiently accurate, they will show values intermediate between those of $TCNQ^0$ and $TCNQ^-$. The bond lengths of TCNQ in the charge-transfer complexes so far reported are summarized in Fig. 8. The standard bond lengths of $TCNQ^0$, $TCNQ^{-1/2}$, and $TCNQ^-$ are taken mainly from Refs. 5 and 6. This

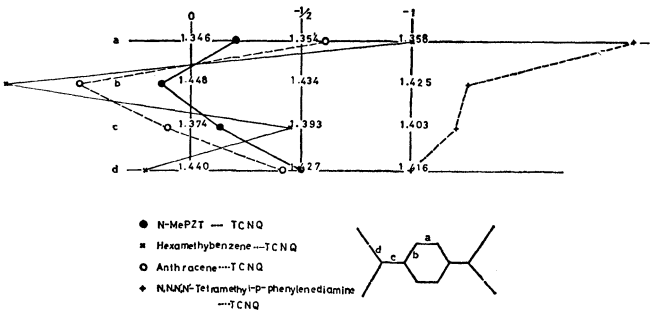

Fig. 8. The bond lengths of TCNQ.
The values are corrected for thermal vibration.

figure can be regarded as a diagram which relates bond length to the amount of transferred charge, δ ($TCNQ^{-\delta}$). The "a" bond lengths of $TCNQ^0$ (neutral molecule), $TCNQ^{-1/2}$, and $TCNQ^-$ are 1.346, 1.354, and 1.358 Å respectively. The "a" bond elongates with an increase in the charge transferred from a donor to TCNQ. Thus, the bond lengths seem to be a rough measure of the amount of charge-transfer. For example, the "a" bond seems to show the formal charge, δ, of TCNQ ($TCNQ^{-\delta}$) of about 0.25 in an *N*-MePZT-TCNQ complex. The dots corresponding to the observed bond length are scattered, probably because of the inaccuracy of the experiments. Despite the inaccuracy, the diagram seems to indicate that the average bond lengths of TCNQ in *N*-MePZT, anthracene-TCNQ,[7] and hexamethylbenzene-TCNQ[8] correspond to those of molecules with a small formal charge ($\delta<0.2$). In the case of *N*-MePZT-TCNQ, the amount of transferred electrons seems to be about 0.15e. The ESR, IR, and electronic spectra indicate that an *N*-MePZT-TCNQ complex is not an ionic type but almost neutral,[9] and they support the above conclusion. In tetramethyl-*p*-phenylenediamine (TMPD)-TCNQ,[10] the distribution of the bond lengths differs from the distributions of those of the other non-ionic complexes. The electron transferred from TMPD to TCNQ seems to be more than one, which is a rather unexpected situation.

The crystal structure of *N*-MePZT-TCNQ is similar to that of the average structure of PZT-TCNQ.[11] The main difference between the two complexes is that the former has the orientational disorder of *N*-MePZT, while the latter is a sinusoidally modulated structure. In the crystal of PZT-TCNQ, PZT are held by hydrogen bonds of N–H=N type. On the other hand, in *N*-MePZT-TCNQ, *N*-MePZT are packed loosely by van der Waals forces. Thus, the orientation of *N*-MePZT is likely to be easily disordered.

The author would like to express his thanks to Professor Yoshihiko Saito for his keen interest. He also wishes to thank Professor Minoru Kinoshita and Dr. N. S. Bhat for valuable discussions and information.

The Effects of Doubly-excited Configurations in the P-P-P-CI Calculation

Hiroyuki SHINODA, Hidenobu TATEMATSU, and Tomoo MIYAZAKI

Department of Applied Chemistry, Faculty of Science and Engineering, Waseda University, Nishi-Ohkubo, Shinjuku-ku, Tokyo 160

(Received March 7, 1973)

The effects of doubly-excited configurations, especially of the χ_{kl}^{mn} type, on the results of P-P-P-CI calculations of unsaturated compounds have been discussed by comparing the results obtained by three different types of CI treatment. The calculations of the pi-electronic total energies of ground states, the electronic transition energies, the oscillator strengths, and the pi-electronic densities of sixteen molecules were performed. The core resonance integrals and electronic repulsion integrals were readjusted so that the transition energies, obtained by CI calculations considering all the singly- and doubly-excited configurations, might coincided with the experimental results. From the results of these calculations, it is found that χ_{kl}^{mn}-type configurations play an important role in CI calculation.

Although the configuration interaction (CI) treatment considering singly-excited configurations has been investigated in detail in connection with molecular orbital (MO) calculations, few studies of the CI treatment considering doubly-excited configurations have been done.[1-6] Evleth[1] calculated transition energies by means of the P-P-P method,[7-9] the LCAO-SCF-MO method in the Pariser-Parr-Pople scheme, followed by CI treatment considering doubly-excited configurations (DEC's) under the restriction of considering only the highest two occupied levels of MO. He concluded that the DEC's are important to the calculation for transition energies which are also affected by the parameters used in the SCF-MO calculation. Allinger and Stuart[2] investigated the contribution of higher excited configurations in the CI calculations of transition energies for several unsaturated hydrocarbons. They concluded that it is not necessary to include all of the doubly-excited configurations, but it is necessary to include some triply-excited configurations, and that the higher excited configurations may be cut off at 20 eV over the ground configuration. Kashiwagi[3] calculated several electronic properties of non-alternant hydrocarbons by the P-P-P-CI method, taking account of a cut-off treatment such as has been described above. He found that the oscillator strengths and pi-electronic densities of excited states are sensitive to the introduction of DEC to the CI calculation, while transition energy to low excited states are rather insensitive, and that the introduction of DEC gives satisfactory results in the calculation of oscillator strengths. The appropriate condition of the cut-off treatment determined in his work was 13 eV. Hirota and Nagakura[4] discussed the effects of parameters and DEC's on several electronic properties calculated by the P-P-P-CI method for the molecules containing hetero-atoms. They found that the CI treatment including DEC's reduced the effect of one-center core integrals upon the calculated energy levels, and that the oscillator strengths for electronic transitions and the separations between the lowest and the second-lowest excited states were improved by this CI treatment.

The present investigation was undertaken in order to clarify the effects of DEC, especially of the χ_{kl}^{mn} type, which includes four orbitals k, l, m, and n, each containing a single electron, on the pi-electronic properties as calculated by the P-P-P-CI method for the ground and excited singlet states of unsaturated molecules. In the P-P-P-CI calculation the values of parameters, which were included in the core resonance integrals and electronic repulsion integrals, were determined so that the transition energies to some excited states might coincide with the experimental results.

Methods of Calculation

In the molecular orbital calculation of the P–P–P scheme used in this work, the core resonance integral, $\beta_{\mu\nu}$, and the two-center electronic repulsion integral, $\gamma_{\mu\nu}$, were approximated as follows:

$$\beta_{\mu\nu} = \frac{1}{2}\kappa(\beta_\mu^\circ + \beta_\nu^\circ)S_{\mu\nu} \quad (1)$$

$$\gamma_{\mu\nu} = b_{AB}/(R_{\mu\nu} + a_{AB}) \quad (2)$$

Equation (1) is the formula used in the modified CNDO method proposed by Bene and Jaffé.[10,11] Equation (2) is similar to the Mataga-Nishimoto's formula.[12] For one-center core integrals and one-center electronic repulsion integrals, the values of Table 1 in Ref. 13 were used. The parameters in these equations for carbon were readjusted so that the three transition energies of benzene (B_{2u}, B_{1u}, and E_{1u}) might coincide with the experimental values, the CI treatment in this calculation including all singly- and doubly-excited configurations. The appropriate values of these parameters were 0.645, 3.32 Å, and 35.10 Å eV for κ, a_{AB}, and b_{AB} respectively, provided that the unit of $R_{\mu\nu}$ in Eq. (2) is Å. Then, these parameter values were adopted for the calculations of all the molecules treated in this work. This value of the parameter, κ, was larger than that adjusted by the calculation including the CI treatment with singly-

a) See text.

excited configurations alone; this fact has been pointed out by other investigators as well.[5] The values of a_{AB} and b_{AB} for other pairs of atoms (C, N, and O) were determined so that the calculated values might agree very well with the observed transition energies of reference molecules. These parameter values are listed in Table 1. Before the calculation according to the parameters determined in this work were applied to several molecules, the variations in the transition energies of benzene with the change in the value of κ were discussed, the $\gamma_{\mu\nu}$ in this calculation being estimated by the Pariser-Parr approximation. Also, these transition energies obtained by calculations using the $\gamma_{\mu\nu}$ from Eq. (2) were compared with those calculated by the use of the parameters estimated by Bene and Jaffé.[10]

The configurations in CI treatments may be classified into seven basic types: χ_0, χ_k^m, χ_{kk}^{mm}, χ_{kk}^{mn}, χ_{kl}^{mm}, χ_{kl}^{mn} (1), and χ_{kl}^{mn} (2), in accordance with the Murrell and McEwen's notation.[6] χ_{kl}^{mn} (1) and χ_{kl}^{mn} (2) indicate the doubly-excited configurations which include four orbitals, k, l, m, and n, each containing a single electron; the number in parentheses is the symbol classifying the two wave functions which are eigenfunctions of the spin operator, $\mathbf{S}^2$. In order to investigate the effect of DEC on the calculated pi-electronic properties, three types of calculations were performed. They are different from each other in the point of the number of configurations included in the CI calculation. Method I includes all singly-excited configurations, while Method II includes singly- and doubly-excited configurations except for the χ_{kl}^{mn} type, and Method III, all singly- and doubly-excited configurations.

The ground-state energies, transition energies, oscillator strengths, and pi-electronic densities obtained by these three type of calculations were compared with each other for sixteen compounds. The geometries of molecules followed the data listed in Ref. 14.

Results and Discussion

Figure 1 shows the variation in the transition energies

c) observed values.

of benzene with the change in the value of κ. The transition energies increase linearly with the increased value of κ. However, the energy difference between excited states is not affected by the value of κ. In Fig. 2, the transition energies of benzene calculated by the use of the parameters estimated by Bene and Jaffé[10] are compared with the results obtained from the parameters estimated in this work. It may be seen that the energy difference between excited states of molecule is remarkably affected by the value of $\gamma_{\mu\nu}$.

In Method I, it is a matter of course that the energy of the ground state is not affected by the CI treatment considering singly-excited configurations alone. However, the ground states are stabilized by CI treatments considering singly- and doubly-excited configurations in Methods II and III, because the CI matrix elements between the ground configuration and DEC are not equal to zero. The magnitude of this stabilization

energy and the contribution of the ground configuration for the ground state are listed in Table 2. From the table, it may be seen that the ground states are stabilized by from 0.20 to 0.47 eV in Method II, and by from 0.42 to 0.78 eV in Method III, and that the contributions of the ground configuration for the ground state are about 98% and 96% in Methods II and III respectively. These results show that the degree of effects of χ_{kl}^{mn}-type configurations on the results of CI calculation for the ground state is the same as that of other DEC's. The calculated transition energies and oscillator strengths are listed in Table 3, in which the experimental values are also included. In the results of Methods II and III, the transition energies are seen to depend upon the stabilization of the ground states; the energy scheme is given in Fig. 3. From Table 3 it may be found that the transition energies to low excited states calculated by Method III are in good agreement with the experimental results, and that the differences between the results from Methods I and II and between those from Methods II and III are generally less than 0.2 eV, though there are some exceptions. From these results, it is found that the degree of the effect of χ_{kl}^{mn}-type configurations on the calculated transition energies is the same as that of other DEC's. Furthermore, it is noteworthy that the energy differences between the lowest and the second-lowest excited states are improved by Method III, considering χ_{kl}^{mn}-type configurations, and that there are inversions in the order of excited levels for some molecules, as is indicated in Fig. 3-b.

The oscillator strengths calculated by Method I for the electronic transition are larger than the experimental results, but they are very much improved by Methods II and III, which consider the DEC's. From the fact that the differences between the results from Methods I and II are almost the same as those from Methods II and III, it is found that the effect of χ_{kl}^{mn}-type configurations on the oscillator strength is comparable with that of the other DEC's.

When the transition energies of molecules involving degenerate levels, such as benzene and *s*-triazine, are calculated, it should be noted that there is a defect in Method II, which considers DEC's without χ_{kl}^{mn}-type configurations, for the levels of excited states, which must be degenerate, are obtained as split levels, although the degree of splitting is very small (about 0.01 eV).

The pi-electronic densities of atomic sites in molecules varies slightly with each method of calculation. Generally, these variations in electronic densities for excited states are larger than those for the ground states of molecules. Table 4 indicates the electronic densities of fulvene and pyridazine as calculated by Methods I, II, and III. The variations between the electronic densities of these molecules calculated by the different methods are larger than those of the other molecules considered in this work. For ground states, the electron distributions in molecules were averaged by Method III as compared with other methods; the order of the magnitudes of electronic densities of the atomic sites in a molecule, except in the case of fulvene, was not affected by the method of calculation. For excited states, the calculated electron distribution did not always show the tendencies described above (see Table 4). The electronic densities of atomic sites in molecules calculated by Method III may be inferred to be reliable from the fact that the oscillator strengths are improved by this method.

Conclusion

In the P-P-P-CI calculation considering the doubly-excited configurations, the effects of the κ parameter, referring to the resonance integral, β, and of the two-center electronic repulsion integral, $\gamma_{\mu\nu}$, on the transition energies of benzene were discussed. Also these parameters were readjusted so that the transition energies might coincide with the experimental results. The energy difference between the excited states of a molecule was affected remarkably by the value of $\gamma_{\mu\nu}$. By comparing the results from the three different types of calculations, which are different from each other in the point of the number of configuration included in the CI calculation, it is found that the introduction of the doubly-excited configurations to the CI treatment is effective in calculating the pi-electronic properties and that the effects of χ_{kl}^{mn}-type configurations on the results are the same as those of other doubly-excited configurations.

The Electronic States of *p*-Bromanil and Its Anion Radical as Studied by Means of Their Infrared Spectra

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 14, 1973)

The infrared spectra (400—4000 cm^{-1}) were measured with neutral *p*-bromanil and its anion radical. Appreciable frequency differences between their corresponding bands were observed. The fundamental frequencies were assigned, and the simple Urey-Bradley force fields were determined for both the neutral *p*-bromanil and its anion radical. The differences in the molecular and electronic structures between these two molecules were discussed on the basis of these results. The half-occupied molecular orbital of the *p*-bromanil anion radical was found to belong to the b_{3g} irreducible representation.

The infrared spectrum of an ion radical is known to be appreciably different from that of its neutral molecule.[1-12] The spectrum difference may be attributed to the difference in their intramolecular force fields. Up to now, however, attempts have scarcely been made to study such differences quantitatively.[8,12] In a previous paper,[8] we examined the infrared spectra (650—4000 cm^{-1}) of *p*-chloranil and its anion radical (see Fig. 1). In order to explain the appreciable frequency differences between their corresponding bands, the fundamental frequencies were assigned, and the simple Urey-Bradley force fields (UBFF's) were determined for both the neutral and anion radical molecules. It was found that the difference in the infrared spectra between these two molecules could be understood in terms of the difference in their electronic structures caused by the extra electron on the *p*-chloranil anion radical.[8,9]

In the present paper, the infrared spectra (400—4000 cm^{-1}) were measured with *p*-bromanil and its anion radical (see Fig. 1). In order to make vibrational assignments and to determine the force constants for these molecules, the normal coordinate treatments were carried out for the in-plane vibrations by using the simple UBFF's. The electronic states of the neutral *p*-bromanil and its anion radical were discussed on the basis of these experimental and theoretical investigations. We shall examine how the extra electron on the anion radical causes the difference in the molecular and electronic structures between the neutral *p*-bromanil and its anion radical. On the other hand, the substituent effects upon the molecular and electronic structures of the halogen-substituted *p*-benzoquinones and their anion radicals are interesting in comparison with the results previously reported for *p*-chloranil and its anion radical.[8]

Experimental

Materials. Commercially-available *p*-bromanil (Tokyo Kasei Kogyo Co., Ltd., GR grade) was used without further purification. Its anion radical salt with the potassium cation (K^+ *p*-Bromanil$^-$) was synthesized according to the method of Torrey and Hunter.[13]

Measurements. The infrared spectra of these solid compounds were measured as Nujol mulls in the range from 400 to 4000 cm^{-1} using a Japan Spectroscopic Co., Ltd. IR-G infrared spectrometer. The infrared spectra in the regions where the absorption due to Nujol appears were measured using hexachlorobutadiene mulls. The spectra obtained for these compounds are reproduced in Fig. 2.

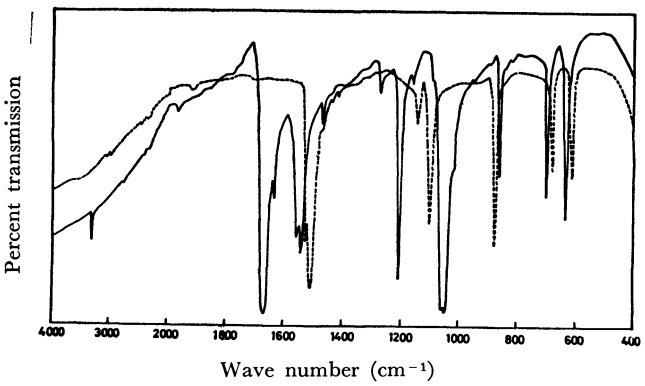

Fig. 2. The infrared spectra of *p*-bromanil and its anion radical salt with potassium cation.
———: *p*-Bromanil, ·····: K^+ *p*-Bromanil$^-$

Since the counter cation of the salt is a simple alkali metal cation, the observed spectrum of K^+ *p*-Bromanil$^-$ in the region under investigation should be due to that of the *p*-bromanil anion radical itself. The values of the absorption peaks observed for the neutral *p*-bromanil and its anion radical are listed in Table 1.

Normal Coordinate Treatment for In-plane Vibrations

In the infrared spectra of neutral *p*-bromanil and its anion radical, we observed appreciable frequency differences between their corresponding bands. For example, the C=O stretching mode of 1672 cm^{-1} in the neutral *p*-bromanil was found to be considerably red-shifted to 1515 cm^{-1} in the anion radical. Since only the intramolecular vibrations are expected to appear in the region from 400 to 4000 cm^{-1}, we attributed the spectrum difference between the neutral *p*-bromanil and its anion radical to the difference in their intramolecular force fields. The effect of crystal fields upon the vibrational frequencies is small in comparison with that of the intramolecular force fields. Therefore, to a first approximation, the contribution of the crystal fields to the spectra of *p*-bromanil and its anion radical was ignored in the present investigation.

The vibrational spectra of *p*-bromanil and its anion radical were then treated under the molecular point group, D_{2h}, and were analyzed by using a normal coordinate treatment. The molecular and crystal structures of the neutral *p*-bromanil have not yet been ascertained, although those of *p*-chloranil were determined by Chu, Jeffrey, and Sakurai.[14] It was assumed that the *p*-bromanil molecule was planar. By referring to the molecular structure of *p*-chloranil, the equilibrium bond lengths of *p*-bromanil were taken as l(C=O)=1.195 Å, l(C=C)=1.342, l(C–C)=1.477, and l(C–Br)=1.89, while the bond angles were taken as $\angle$(O=C–C)=121°22′, $\angle$(C–C–Br)=116°15′, and $\angle$(C=C–Br)=122°23′ (see Fig. 1). Since the structure of K^+ *p*-Bromanil$^-$ has not yet been determined, it was assumed that the molecular structure of the anion radical was almost identical with that of the neutral *p*-bromanil. This assumption means that the ***G*** matrix calculated for *p*-bromanil was also used for its anion radical (see below). Hence, thirty normal modes of vibrations for *p*-bromanil or its anion radical were reduced to the symmetry species:

$$\Gamma = 6A_g(R) + 5B_{1g}(R) + 5B_{2u}(IR) + 5B_{3u}(IR) + 1B_{2g}(R) + 3B_{3g}(R) + 2A_u(\text{inactive}) + 3B_{1u}(IR), \quad (1)$$

where the first four are the in-plane vibrations, and the rest, the out-of-plane vibrations. The signs of (R) and (IR) indicate the Raman and infrared active modes respectively. We calculated only the in-plane vibrations, because no out-of-plane vibration is expected to appear in the region now under consideration.

Wilson's ***GF*** matrix method was used in this work.[15] A representative example of each type of internal coordinate for the in-plane vibrations is given in Fig. 3. A simple UBFF was employed as the potential function. Then, four bond-stretching (K(C=O), K(C=C), K(C–C) and K(C–Br)), five angle-bending (H(O=C–C), H(C–C–Br), H(C=C–Br), H(C–C–C) and H(C=

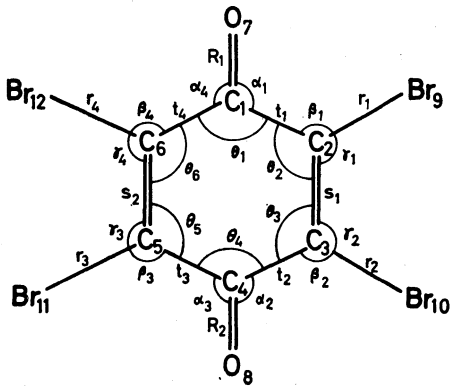

Fig. 3. The internal coordinates for the in-plane fundamental vibrations of *p*-bromanil or its anion radical.

C–C)), and five non-bonded repulsion force constants (F(O=C–C), F(C–C–Br), F(C=C–Br), F(C–C–C), F(C=C–C)) were necessary. At this time, it was assumed that the stretching force constants of *p*-bromanil were different from those of its anion radical, while the other force constants remained almost constant. Within the framework of this approximation, we could well explain the difference in the observed fundamental frequencies between *p*-bromanil and its anion radical. The trial force constants for *p*-bromanil were taken by referring to the values for benzene, halogen-substituted benzenes, *p*-benzoquinone, and *p*-chloranil,[8,16–18] while those for the *p*-bromanil anion radical were taken by modifying the force constants for the neutral *p*-bromanil. Refinements of the force constants were then carried out by the trial-and-error method, making use of the Jacobian matrix. The final sets of force constants thus obtained for the neutral *p*-bromanil and its anion radical are given in Table 2, while the frequencies calculated with these constants are compared in Table 1 with the observed values. In both of these molecules, the calculated values of the fundamental vibrations were found to agree well with the observed values, except for the following two points, which remain to be elucidated:

(1) Two absorption peaks were observed, at 705 cm^{-1} and 650 for the neutral *p*-bromanil or at 684 cm^{-1} and 618 for its anion radical, while only one fundamental vibration was expected to appear around this region.[19] It seems improbable to assign one of them to an out-of-plane vibration, because such a vibration would not appear around this region.

(2) The calculated 1256 cm^{-1} band in the anion radical cannot be assigned to any of the observed bands, presumably because of its weak intensity.

Table 2. The force constants estimated for the neutral *p*-bromanil and its anion radical (md/Å)[a]

Force constant	The neutral *p*-bromanil	Its anion radical

Discussion

The Electronic States of p-*Bromanil and Its Anion Radical.* Since a total of 14 force constants of *p*-bromanil or its anion radical were evaluated from an experimental assignment of 6 frequencies, we suspect that these values of the force constants are not the best ones for these compounds. However, the stretching force constants are still meaningful, because the observed fundamental frequencies are almost all due to the bond-stretching modes. Therefore, below, we will discuss only the difference in the stretching force constants between the neutral *p*-bromanil and its anion radical. As is shown in Table 2, K(C=O)=9.62 md/Å, K(C=C)=6.67, K(C–C)=2.96, and K(C–Br)=2.63 for the neutral *p*-bromanil, while K(C=O)=7.10 md/Å, K(C=C)=6.26, K(C–C)=3.33, and K(C–Br)=2.17 for its anion radical. We can see that an extra electron on the *p*-bromanil anion radical markedly causes a decrease in the K(C=O), K(C=C) and K(C–Br) values and an increase in the K(C–C) value.

It is well known that the stretching force constant, $K(12)$, of a bond (12) in a conjugated system is greatly affected by its bond order, $p(12)$. According to Coulson and Longuet-Higgins,[20] $K(12)$ can be expressed by

$$K(12) = \{(1-p(12))K_s + p(12)K_d\} + \left\{\frac{K_sK_d(s-d)}{K_s(1-p(12))+K_dp(12)}\right\}^2 \frac{\pi(1212)}{2}, \quad (2)$$

where K_s and K_d are the force constants associated with pure single and double bonds respectively; $\pi(1212)$ is the self-polarizability of the bond (12); s and d are the bond lengths of pure single and double bonds respectively.

In a homopolar carbon-carbon bond, the second

19) In *p*-chloranil, the corresponding bands were observed at 752 cm^{-1} and 715, and in its anion radical, at 725 cm^{-1} and 694. It appears that the bands at 752 cm^{-1} and 725 in *p*-chloranil and its anion radical shift to 650 cm^{-1} and 618 in *p*-bromanil and its anion radical, respectively, but it is not adequate to consider such band shifts in the cases of the other bands. Therefore, the bands at 650 cm^{-1} and 618 in *p*-bromanil and its anion radical were assigned to the fundamental vibrations of the C–Br stretching mode. See Ref. 8.

20) C. A. Coulson and H. C. Longuet-Higgins, *Proc. Roy. Soc. Ser. A*, **193**, 456 (1948).

term involving the self-polarizability may be small.[21] In this case, the stretching force constant, $K(12)$, is predominantly determined by the bond order, $p(12)$. By the use of the empirical relationship between $K(12)$ and $p(12)$ given in a previous paper,[8] we can evaluate the bond orders of the C=C and C–C bonds in *p*-bromanil and its anion radical. From the values of K(C=C) and K(C–C) in the infrared spectra, the p(C=C) and p(C–C) values for the neutral *p*-bromanil were estimated to be 0.88 and 0.27 respectively, while those for its anion radical were estimated to be 0.82 and 0.36 respectively. Therefore, we can see that the extra electron on the *p*-bromanil anion radical causes a decrease in p(C=C) by 0.06 and an increase in p(C–C) by 0.09. On the other hand, in order to confirm these results, we further calculated the p(C=C) and p(C–C) values of the neutral *p*-bromanil and its anion radical by the use of the molecular orbitals. For the sake of simplicity, the SCF molecular orbitals of the neutral *p*-benzoquinone calculated by Kunii and Kuroda (see Fig. 4) were used,[22] because the electronic state of the π-conjugated system in *p*-bromanil can be regarded as very similar to that in *p*-benzoquinone. It was also assumed that the extra electron of the anion radical enters into the lowest vacant molecular orbital of the neutral *p*-benzoquinone. As is shown in Fig. 4, this orbital has the irreducible representation of the symmetry, b_{3g}, where the coefficients of the C_1, C_2, and O_7 atomic orbitals were given by +0.35887, +0.31428, and −0.41674 respectively.[22] From the molecular orbital method, the p(C=C) and p(C–C) values for the neutral *p*-bromanil were estimated to be 0.91 and 0.30 respectively, while those for its anion radical were estimated to be 0.81 and 0.41 respectively. Therefore, the extra electron causes a decrease in p(C=C) by 0.10 and an increase in p(C–C) by 0.11 compared to the values of the neutral *p*-bromanil. These molecular orbital results are found to agree well with those evaluated from the infrared spectra.

Next, let us examine the heteropolar C=O bond. If we take, in Eq. (2), the values of K_s=5.0 md/Å and K_d=10.7 proposed by Bratoz and Besnainou,[23] and

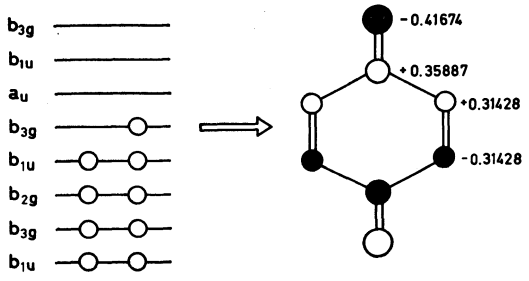

Fig. 4. Schematic representation of the molecular orbitals of the *p*-benzoquinone anion radical molecule. For the half-occupied molecular orbital with the b_{3g} irreducible representation, the open and closed circles indicate that the coefficients of the atomic orbitals are positive and negative, respectively. See text.

if we neglect the contribution of the self-polarizability to K(C=O), those C=O stretching force constants for *p*-bromanil and its anion radical give the values of p(C=O) of 0.81 and 0.37 respectively. These values should be compared with those of 0.85 and 0.70 respectively calculated from their molecular orbitals. In the neutral *p*-bromanil, the agreement is rather satisfactory. Although the extra electron definitely decreases the C=O bond order, no quantitative agreement is obtained in the anion radical. One reason for this might be the neglect of the self-polarizability.

As for the C–Br bond, although the description of K(C–Br) *versus* p(C–Br) for the neutral *p*-bromanil and its anion radical is not simple, the extra electron on the *p*-bromanil anion radical causes a decrease in K(C–Br); this decrease will definitely lead to a decrease in p(C–Br). However, the estimation of p(C–Br) by the molecular-orbital method is rather complicated, because we have some difficulties in finding appropriate parameters for the Br atomic orbitals.

Some Information on the Molecular Structures of p-*Bromanil and Its Anion Radical.* There is a well-known relation between the bond order, $p(12)$, and the bond length, $l(12)$, of a carbon-carbon bond (12); this was first derived by Coulson.[21,24] By using this relationship, the p(C=C) and p(C–C) values estimated from the infrared spectra give l(C=C) and l(C–C) respectively. The l(C=C) and l(C–C) values for the neutral *p*-bromanil were thus estimated to be 1.35_6 Å and 1.47_5 respectively, while those for its anion radical were estimated to be 1.36_8 Å and 1.45_6 respectively. The values of the neutral *p*-bromanil are in good agreement with those of l(C=C)=1.342 Å and l(C–C)=1.477 respectively, which were employed in the previous calculation. We can further see that the extra electron on the anion radical may cause an increase of 0.01 Å in l(C=C) and a decrease of 0.02 Å in l(C–C) compared to the values of *p*-bromanil. However, no observation of the molecular structure has yet been made for the anion radical.

As for the relation between the stretching force constant and the bond length of a C=O bond, Badger proposed the following equation:[25]

$$K(\text{C=O}) = 1.86/\{l(\text{C=O}) - 0.68\}^3, \qquad (3)$$

where K and l are in md/Å and Å units respectively. For *p*-bromanil and its anion radical, the values of l(C=O) derived from their force constants by Eq. (3) are 1.26 Å and 1.32 respectively. The former value is rather larger than the observed value of 1.195 Å. We may expect that the C=O bond length of the *p*-bromanil anion radical is longer than that of its neutral molecule by 0.06 Å; however, no experimental result is available at present.

Although we have no information on the relation between the stretching force constant and the bond length of the C–Br bond, the extra electron on the *p*-bromanil anion radical probably causes the difference in l(C–Br)

between *p*-bromanil and its anion radical.

Comparison with the Results of p-*Chloranil and Its Anion Radical.* In a previous paper,[8] the values of the stretching force constants for the neutral *p*-chloranil were reported to be $K(C{=}O)=9.7$ md/Å, $K(C{=}C)=6.6$, $K(C{-}C)=3.0$, and $K(C{-}Cl)=2.67$, while those for its anion radical were reported to be $K(C{=}O)=7.3$ md/Å, $K(C{=}C)=6.1$, $K(C{-}C)=3.5$, and $K(C{-}Cl)=2.67$. In comparison with those of the neutral *p*-bromanil and its anion radical, we can see that, in either the neutral molecule or its anion radical, the stretching force constants of the benzoquinone system are scarcely affected by replacing the chlorine substituents by the bromine substituents. This means that the molecular and electronic structures of the benzoquinone systems of *p*-bromanil and its anion radical are very similar to those of *p*-chloranil and its anion radical respectively. Although the previous paper described that the extra electron on the *p*-chloranil anion radical did not decrease the $K(C{-}Cl)$ value,[8] this description is no longer adequate. More accurate assignments of the fundamental frequencies of *p*-chloranil and its anion radical will show the decrease in the $K(C{-}Cl)$ value in the anion radical; this situation seems to be analogous to that of *p*-bromanil and its anion radical.

Concluding Remarks

The present investigation clearly shows that the predominant factor in the difference in the vibrational spectra between the neutral *p*-bromanil and its anion radical can be understood in terms of the differences in their electronic structures. By using these differences, the half-occupied molecular orbital of the *p*-bromanil anion radical was found to belong to the b_{3g} irreducible representation. However, we noticed some disagreements between the C=O bond orders obtained from the infrared spectra and those obtained from the molecular orbitals. We consider that these disagreements may be caused not only by the neglect of the self-polarizability, but also by the frequency shifts due to the crystal-field effect. Although the crystal-field effect may be more important for the anion radical salt than for the neutral molecular crystal, this contribution to the frequency shifts of *p*-bromanil and its anion radical may be small in comparison with the difference in their intramolecular force fields.

Rigorously speaking, the $\boldsymbol{G}$ matrix for the anion radical is no longer identical with that for the neutral *p*-bromanil, since the molecular structure of the anion radical was found to be slightly different from that of the neutral *p*-bromanil. Although the difference in their $\boldsymbol{G}$ matrices may make some contribution to the frequency differences, this contribution can be disregarded for the bands due to the bond-stretching modes.

The set of force constants presented in Table 2 cannot be regarded as a unique solution, since the observations of the fundamental frequencies are limited to the infrared spectra. In this sense, it is quite desirable to measure the Raman spectra of *p*-bromanil and its anion radical. We consider, however, that the set of force constants presented here is reliable enough for studying the difference in the stretching force constants between the neutral *p*-bromanil and its anion radical.

In conclusion, the application of the infrared spectra of a neutral molecule and its ion radical can provide valuable knowledge on their electronic structures as well as on their molecular structures. It is interesting to see that their frequency differences give some information concerning the nature of the half-occupied orbital in the ion-radical molecular orbitals.

The Crystal Structure of Trimellitic Acid for the Pseudo-cell

Fusao TAKUSAGAWA, Ken HIROTSU, and Akira SHIMADA

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received March 19, 1973)

The crystal structure of trimellitic acid(benzene-1,2,4-tricarboxylic acid) for the pseudo-cell was determined by the method of X-ray diffraction. The crystal is monoclinic, with the space group of I2/c and with a=15.91, b=61.35, c=8.99 Å, and β=95.4°. The appearence of diffraction patterns strongly indicated the existence of the pseudo-cell with $b/5$ and with the space group of I2/c. The structure of the pseudo-cell was determined by the symbolic addition method. The final R value is 13.6%. There is no intramolecular hydrogen bond between the adjacent carboxyl groups, and one of these carboxyl groups twists greatly out of the plane of a benzene ring so that the repulsion between the oxygen atoms is reduced. Each molecule is joined, through three kinds of hydrogen bonds, with three neighboring molecules. These hydrogen bonds are formed between the carboxyl groups related by the center of symmetry and the two-fold axis. The molecular dimensions and packing obtained by the refinement for the pseudo-cell do not seem to contain unacceptable results.

In a series of benzene derivatives which are substituted with one to six carboxyl groups, the crystal structures of several members have already been studied by means of X-ray studies to obtain valuable information in the field of crystal chemistry: benzoic acid,[1] phthalic acid,[2,3] isophthalic acid,[4] terephthalic acid,[5] trimesic acid,[6] hemimellitic acid,[7] pyromellitic acid,[8,9] and mellitic acid.[10] Since the trimellitic acid has a pair of adjacent carboxyl groups, just like phthalic acid, hemimellitic acid, pyromellitic acid, and mellitic acid, it is of interest to elucidate the steric hindrance of these carboxyl groups. There has been no intramolecular hydrogen bond between the adjacent carboxyl groups in these crystals. Hence, it is also of interest to examine the hydrogen bond formation in this crystal and also to compare the molecular dimensions of this compound with those of other similar carboxylic acids.

Experimental

The crystal was obtained in the form of a colorless plate by recrystallization from an aqueous solution. The cell dimensions were measured from zero-layer Weissenberg photographs, which were calibrated with superimposed Al powder lines. They are given with other crystal data in Table 1. The density was determined by the flotation method in a mixture of tetrachloromethane and benzene.

The diffraction patterns strongly suggest the existence of a pseudo-cell with the parameters shown in Table 1. The intensity data were collected for the 0—8 layers around the a and b(pseudo-cell) axes by the use of the multiple-film equi-inclination Weissenberg technique with Cu$K\alpha$ radiation. The intensities of the diffraction spots were estimated visually by comparison with a calibrated intensity standard. The characteristics of the intensity data were as follows:

$k=5n$, Strong reflections

$k=5n\pm2$, Weak reflections

$k=5n\pm1$, Absent

The intensity distribution in $0kl$ is shown in Fig. 1. There were 1424 independent reflections for the pseudo-cell ($k=5n$), while about 3500 reflections were measured for the real cell. The data were corrected for spot shape and for Lorentz and polarization factors. No absorption correction was

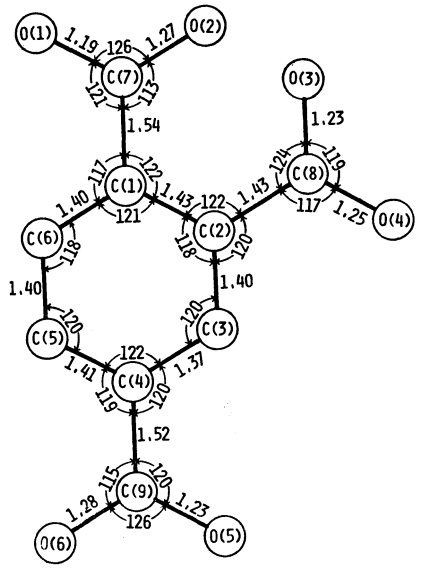

Fig. 2. Molecular dimensions of trimellitic acid. The estimated standard deviations are as follows:
C–C=0.02 Å, C–O=0.01~0.02 Å, C–C–C=0.8~1.0°, C–C–O=0.6~0.9°, O–C–O=0.5~1.0°

applied. They were then corrected and reduced to the structure factors by means of the procedure described by Hamilton, Rollet, and Sparks.[11]

Both cells, real and pseudo, were found to be monoclinic, with a space group of I2/c or Ic. The former was tentatively assumed on the basis of the statistical averages and distributions of normalized structure amplitudes in the pseudo-cell.

Phase Determination

Since the phase determination procedure for this crystal was applied only to the pseudo-cell, the indices were transformed to refer to this cell; *i.e.*, only those data with $k=5n$ were used, and the k index was divided by five. The absolute scale and approximate temperature factors were determined by means of Wilson's statistics.[12] The normalized structure amplitudes, $|E|$, were computed from these values. The symbolic addition procedure was used to determine the phases.[13] The origin was specified by assigning the signs to two linearly independent reflections.[14] Three additional E's were assigned arbitrary symbols.

Table 3. Assignment of the two origin specifying reflections and three other reflections as a starting set

h	k	l	$\|E\|$	Sign	N.I.P.[a]
4	1	3	3.34	+	88
1	10	1	3.06	−	72
9	2	5	3.40	A	50
−4	1	1	3.18	B	161
7	3	6	3.01	C	43

a) N. I. P.=Number of interaction pairs.

The starting set of phases is listed in Table 3. 114 signs for $|E|>1.5$ were determined by the application of the Σ_2 relations. From the accumulated information about the signs of the 114 reflections, it was obvious that the sign of A was +, while that of B was + and that of C was −. An E-map computed on the basis of these 114 terms revealed most of atomic positions. The peak values for all the atoms were higher than 127, the average value was 244. The maximum value of the ghost peaks was 197. A Fourier map was calculated on the basis of the structure amplitudes phased on the contributions of eight peaks(higher than 200) in order to rule out wrong peaks in the E-map.

The refinement of the positional parameters, the thermal parameters, and one scale factor was carried out by means of the block-diagonal least-squares method, with a modified version of the HBLS-IV program.[15] Four cycles of refinement with isotropic thermal parameters lowered the R value to 23.3%. At this stage of refinement, anisotropic thermal parameters were introduced; four subsequent cycles of

refinement dropped the R value to 13.6%, excluding unobserved reflections. The observed and calculated structure factors are listed in Table 2.

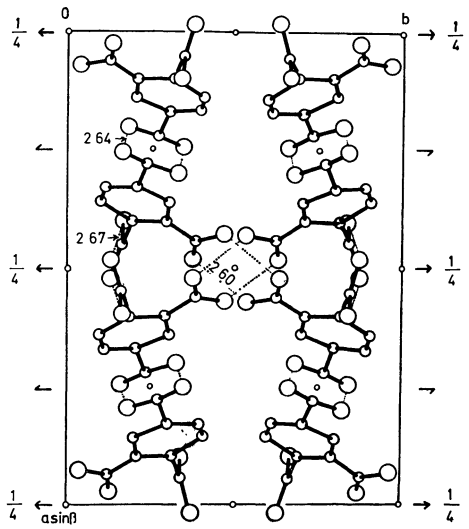

Fig. 6. A view of the crystal structure down the c axis. Hydrogen bonds are shown by broken lines.

Results and Discussion

The final positional and anisotropic thermal parameters are listed, along with their estimated standard deviations, in Table 4. Figures 3 and 4 show the electron density map along the c axis, calculated at the end of the refinement, and the thermal ellipsoids, which are scaled to include a 20% probability, respectively. The bond lengths and angles are given in Fig. 2. The equation of the least-squares plane of a benzene ring is given, along with the deviations of all the atoms from this plane, in Table 5.

A benzene ring is planar with the maximum deviation of 0.04 Å. The average values of the C(ring)–C(ring) and C(ring)–C(carboxyl) bond lengths are

1.40 and 1.49 Å, respectively. All the C–C–C bond angles lie within the range of 120±3°. In the carboxyl groups at the 1- and 4-positions, the C–O(H) and C–O bond lengths differ significantly from each other, while those of the carboxyl group at the 2-position are approximately equal. There is no intramolecular hydrogen bond between the adjacent carboxyl groups, and these groups twist by 88° (C(7)-O(1)O(2)) and 9°(C(8)O(3)O(4)) out of the plane of a benzene ring, so that the repulsion between the oxygen atoms is reduced, as is shown in Fig. 4.

The crystal structure is shown in Figs. 5 and 6. Each molecule is joined, through three kinds of hydrogen bonds (2.60, 2.64 and 2.67 Å), with three neighboring molecules. These hydrogen bonds are formed between the carboxyl groups related by the center of symmetry and the two-fold axis, as is usual in carboxylic acids.

The molecular dimensions and packing obtained by the refinement for the pseudo-cell do not seem to contain unacceptable results in comparison with other carboxylic acids[1-10] with a benzene ring. A crystal structure analysis based on the real cell is now in progress.

Hydrates of Organic Compounds. I. Solid-Liquid Phase Equilibria in the Water+1,4-Dioxane System and Some Properties of 1,4-Dioxane Hydrate

Haruo NAKAYAMA and Masao TAHARA

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Ooka-machi, Minami-ku, Yokohama 233

(Received March 22, 1973)

The solid-liquid phase diagram for the water +1,4-dioxane system has been determined by the ordinary cooling curve method and with the aid of a differential scanning calorimeter (DSC). The diagram shows the existence of a hydrate which is stable in rather narrow ranges of temperature (−15.8∼−13.5 °C) and of composition (37.0∼46.5 wt% dioxane). From the phase relations and an analysis of the calorimetric data, the composition and the heat of formation (from the liquid states of both components) of the hydrate have been estimated to be $C_4H_8O_2 \cdot mH_2O$ with $m=36\sim39$ and $\Delta H_1=-51.3$ (for $m=36$)∼−55.6 (for $m=39$) kcal/mol respectively. This hydrate seems to be the same as that recently reported by Rosso *et al.*, though the compositions and the temperature ranges are very different.

In our previous papers,[1-3] from the thermodynamic measurements (heat of mixing, vapour pressure, volume change on mixing, and so forth) for aqueous solutions of various ethers, the dissolution states of ether molecules in water have been discussed. The main conclusion from these results is that the most important factor which characterizes the properties of these solutions is the structural modifications of water around the solute. In the present paper, an attempt will be made to examine some properties of the crystalline hydrates of cyclic ethers. It is conceivable that, in an aqueous solution, the local order of the water molecule induced around the solute is very similar to the state of a hydrogen-bonded water which surrounds a guest molecule in a clathrate. The propriety of such an analogy has been pointed out by a number of investigators.[4]

By various experimental techniques (such as X-ray diffraction,[5-7] phase diagram,[8,9] and dielectric absorption,[10,11]) it is now apparent that the crystalline hydrates of several cyclic ethers (such as propylene oxide, trimethylene oxide, and tetrahydrofuran) are clathrate hydrates. However, the phase diagrams[9,12,13] for the binary system of water and 1,4-dioxane, a typical cyclic ether, show no indication of a hydrate; furthermore, it has been pointed out that this rather abnormal behavior is closely associated with the unusual behavior of dilute aqueous solutions of 1,4-dioxane.[9] Very recently, nevertheless, from the phase diagram studies as well, Rosso and others[14] have reported a hitherto unknown 1,4-dioxane hydrate which contains

34 moles of water to one mole of dioxane. The temperature and composition ranges in which it can exist are −12.3 °C(peritectic)∼−14.2 °C(eutectic) and 31.5∼33.5 wt% dioxane. However, there are two notable features in their results. First, their phase diagram is appreciably different from those hitherto reported[6,12,13] over almost the entire range of composition. Secondly, as has been mentioned above, the estimated composition of the hydrate is expressed as $C_4H_8O_2 \cdot 34H_2O$; this is very different from the characteristic composition of the cubic Structure II hydrate (Structure II clathrate has 17 moles of water to one mole of the guest species). All the experimental data at present available show that the hydrates of low molecular-weight cyclic ethers, except ethylene oxide, are normal Type II hydrates.

In order to clarify these ambiguous points, the present work has first been undertaken in order to re-examine the solid-liquid phase equilibria in this binary system. Furthermore, from the phase diagram obtained and from the heat changes observed at peritectic and eutectic temperatures, the composition of a hydrate and the heat reaction accompanying its formation from liquid water and liquid dioxane have been estimated.

Experimental

Reagent-grade 1,4-dioxane was further purified by both crystallization and fractional distillation from sodium. The freezing points were always determined from the cooling curves. The apparatus to measure the freezing points was, for the most part, conventional. It consisted of a Pyrex tube (2.5×15 cm) sealed inside an outer jacket connected to a vacuum. The thermocouple, coated with Teflon, was inserted directly into the freezing tube, and its out-put was connected to a 1 mV recorder. Stirring was established with either a motor-driven glass stirrer or a Teflon disk-vibrator that moved vertically at high periods. A flexible Teflon sleeve was used to seal the opening between the cap and the stirring mechanism. A dry ice+acetone mixture was used as a coolant.

In order to measure the amount of heat absorbed when a hydrate melted and/or was decomposed, a differential scanning calorimeter (DSC) was employed (Shimadzu Seisakusho, SC-20). A small amount (10—20 mg) of the 1,4-dioxane+water mixture of a known composition, sealed in an aluminium pan, was cooled to about −40 °C. After being annealed at this temperature for about two hours, the sample was slowly heated at the rate of 0.5 °C/min. Pure water was used as the reference sample. The correction for the temperature and for the amount of heat was established by comparing, under the same experimental conditions, the melting point and the heat of fusion of pure water (1.436 kcal/mol[15] at 0 °C). The determination of a peritectic temperature was carried out from temperature reading on a DSC chart since, in the cooling-curve method, the change in the curve at such a temperature is somewhat ambiguous.

Results and Discussion

The Existence of a 1,4-Dioxane Hydrate. The solid-liquid phase diagram for the 1,4-dioxane+water system is shown in Fig. 1, in which most of the peritectic temperatures are obtained from DSC measurements. This phase diagram obviously shows the existence of a 1,4-dioxane hydrate in the temperature range of −13.5°C (peritectic temperature)——15.8 °C (eutectic temperature) and in the composition range of 37.0—46.5 wt% dioxane. This phase diagram is in fair agreement with the other data[6,12,13] over the major part of the composition, yet all the data except ours overlook the existence of a hydrate in a rather narrow composition range. As has been mentioned above, the measurements of Rosso and Carbonnel[14] deviate appreciably from all the data, including ours, though their report was the first to point out the existence of a hydrate. The compositions and temperatures of characteristic points in the phase diagram for this binary system are summarized in Table 1, together with the values available in the literature.

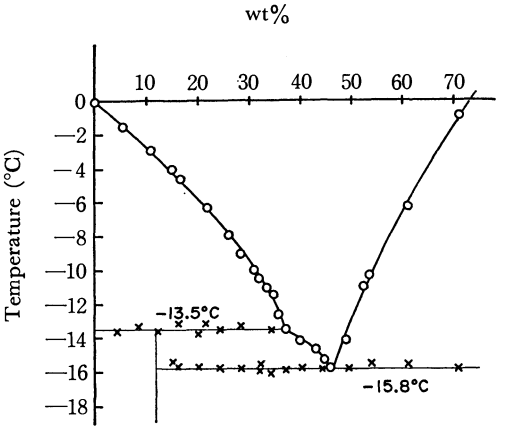

Fig. 1. The solid-liquid phase diagram for the 1,4-dioxane+water system.

Table 1. Characteristic points in the phase diagram of 1,4-dioxane+water system

Points	This work	Other work
Peritectic point		
composition(X_p)[a]	0.107	0.086[14]
temperature(T_p)[b]	−13.5	−12.3[14]
Eutectic point		
composition(X_e)	0.151	0.146,[12] 0.148,[13] 0.093[14]
temperature(T_e)	−15.8	−15.1,[9] −14.9,[12] −15.6,[13] −14.2[14]

a) X is the mole fraction of dioxane. b) in °C.

The composition of the hydrate cannot be clearly determined solely from the phase diagram since it exhibits a peritectic decomposition at −13.5 °C and since, unfortunately, the concentration dependence of the peritectic-halt length in cooling curves is quite uncertain. Thus, the composition of the hydrate was estimated by analyzing the heat change observed in the DSC measurements (Section (2)).

Typical results of the DSC measurements are illustrated in Fig. 2 as a function of the dioxane content. As may be seen from this figure, two characteristic peaks are observed around −13 °C and −16 °C.

15) D. Eisenberg and W. Kauzmann, "The Structure and Properties of Water", Oxford University Press, London, (1969).

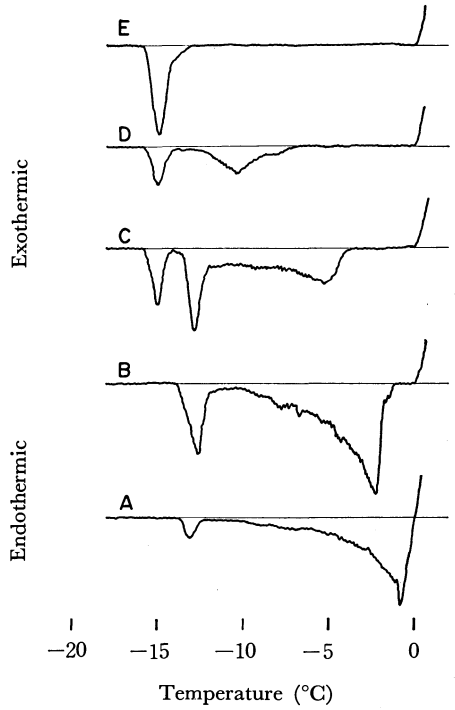

Fig. 2. Representative DSC charts for the 1,4-dioxane+water system as a function of weight per cent of 1,4-dioxane. A: X=0.009 (4%), B: X=0.027 (12%), C: X=0.061 (24%), D: X=0.088 (32%), E: X=0.143 (45%).

It is reasonable to ascribe the endothermic peak near −13 °C to the peritectic decomposition of a hydrate, thus presenting further support for the existence of a 1,4-dioxane hydrate. The other peak, near −16 °C, is unquestionably due to the melting of solids (hydrate and/or solid dioxane) at the eutectic temperature. The remarkably exothermic peak near 0 °C is due to the melting of pure water sealed in a reference pan.

Estimation of the Composition and of the Heat of Formation of the 1,4-*Dioxane Hydrate.* It is obvious that the hydrate has a hydration number greater than 17, which is the typical composition of the Type II clathrate hydrate, since, in the above phase-diagram experiments (Figs 1 and 2), the eutectic halt (at −15.8 °C) has been clearly observed at mole fractions lower than 1/18. In order to determine the probable composition of the hydrate and, at the same time, the heat of reaction, ΔH_1, accompanying its formation from liquid water and liquid dioxane, *i.e.*,

$$\text{1,4-dioxane}(l) + m\text{H}_2\text{O}(l) \rightarrow \text{1,4-dioxane}\cdot m\text{H}_2\text{O}(s), \quad (1)$$

the heat changes observed in the DSC measurements were analyzed as follows.

We assume that the composition of the hydrate can always be expressed as a stoichiometric compound, $C_4H_8O_2\cdot m H_2O$, in which m is a constant. The observed heat changes can be classified into the following four groups. The notations X_p, X_e, T_p, and T_e have the same meanings as in Table 1.

(a) The Heat Change, ΔH_p, at T_p and in the Composition Range between 0 and X_i. X_i denotes the mole fraction of dioxane in the solid hydrate, *i.e.*, $X_i=1/(m+1)$. The ΔH_p corresponds to the enthalpy change when, on heating, all the hydrate decomposes into a mixture of ordinary ice and a solution whose concentration is X_p. Thus, ΔH_p can be given by the following relation:

$$\frac{\Delta H_p}{n_2} = -\Delta H_i + \left(\frac{1}{X_p} - m - 1\right)\cdot\Delta H_{f,w} + \frac{\Delta H_M}{X_p} \quad (2)$$

where n_2 is the total number of moles of dioxane contained in the sample, $\Delta H_{f,w}$ is the heat of fusion of ordinary ice at T_p, and ΔH_M is the hypothetical heat of mixing (per mole of mixture) of liquid dioxane with water at T_p and X_p. If m is a constant, as is supposed above, the right-hand side of Eq. (2) should be constant. In Fig. 3 the observed values of $\Delta H_p/n_2$ are plotted against the mole fraction of dioxane (X). At first, it increases with an increase in X; then it reaches an almost constant value of 10.1 kcal/mol near X=0.02, after which it decreases drastically above $X>0.027$. The concentration dependence at a low mole fraction ($X<0.02$) reflects the situation that there is a minimum concentration necessary to make the hydrate stable. The marked decrease above $X>0.027$ presumably shows that Eq. (2) can not hold over X=0.027; *i.e.*, X_i is close to 0.027.

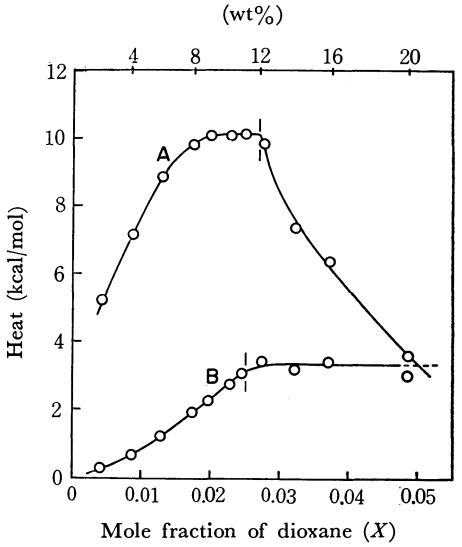

Fig. 3. The concentration dependence of the value of the left-hand side of Eq. (2) (curve A), and of Eq. (3) (curve B).

(b) The Heat Change, $\Delta H_p'$, at T_p and in the Composition Range between X_i and X_p. The $\Delta H_p'$ corresponds to the enthalpy change when the hydrate, after having been in equilibrium with an aqueous solution of dioxane, decomposes into a mixture of ordinary ice and an X_p solution. Simple calculation leads to the following equation:

$$\frac{\Delta H_p'}{(n_1+n_2)X_p - n_2} = -\frac{\Delta H_i}{mX_p-(1-X_p)} - \frac{1}{X_p}\cdot\Delta H_{f,w} + \left\{\frac{m+1}{mX_p-(1-X_p)} - \frac{1}{X_p}\right\}\cdot\Delta H_M \quad (3)$$

where n_1 is the number of moles of water in the sample. From the DSC measurements, unfortunately, only approximate values of $\Delta H_p'$ can be obtained (especially in the concentration range above X=0.05 (about 20 wt%)), because great difficulty is experienced in separating the peak corresponding to $\Delta H_p'$ from that due to the heat change at T_e and also from those of

subsequent reactions occurring in the temperature range between T_e and T_p. In Fig. 3, the observed values of $\Delta H_p'/\{(n_1+n_2)X_p-n_2\}$ are also plotted against X. At first it increases with an increase in X and reaches an almost constant value (about 3 kcal/mol) above $X=0.025$. It seems reasonable to consider that the inconstancy of the values of $\Delta H_p'/\{(n_1+n_2)X_p-n_2\}$ at low mole fractions ($X<0.025$) is due to the fact that Eq. (3) cannot hold in this region; *i.e.*, X_i is approximately equal to 0.025.

Therefore, from the concentration dependences of Eqs. (2) and (3), we arrive at the conclusion that $X_I=0.025-0.027$; that is, $m=36$—39. The change in m from 36 to 39 corresponds to a variation in dioxane content of less than one per cent (11.1∼12.0 wt%).

(c) The Heat Change, ΔH_e, at T_e and in the Composition Range between X_i and X_e. This enthalpy change corresponds to the melting of solid dioxane and of a part of the hydrate, and to the establishment of an equilibrium between the rest of the hydrate and an X_e solution. The ΔH_e must satisfy the following equation:

$$\frac{\Delta H_e}{n_2-n_1/m} = -\frac{1-X_e}{(m+1)X_e-1}\cdot\Delta H_I + \Delta H_{f,d} + \frac{m}{X_e(m+1)-1}\cdot\Delta H_M' \qquad (4)$$

is which $\Delta H_{f,d}$ is the heat of fusion of pure dioxane at T_e and $\Delta H_M'$ is the hypothetical heat of mixing (per mole of mixture) of dioxane with water at T_e and X_e. The temperature dependence of the ΔH_I is neglected. The average value of the left-hand side of Eq. (4) over six solutions of different compositions is found to be 11.6 kcal/mol.

(d) The Heat Change, $\Delta H_e'$, at T_e and in the Composition Range between X_e and $X=1$. This $\Delta H_e'$ is an enthalpy change when all of the hydrate and a part of a solid dioxane melt and when the rest of the solid dioxane comes to be in equilibrium with an aqueous solution of X_e. Thus, $\Delta H_e'$ is expressed as:

$$\frac{\Delta H_e'}{n_1} = -\frac{\Delta H_I}{m} + \left(\frac{X_e}{1-X_e}-\frac{1}{m}\right)\cdot\Delta H_{f,d} + \frac{\Delta H_M'}{1-X_e} \qquad (5)$$

in which all the notations are the same as above. The average value of the experimental data for $\Delta H_e'/n_1$ is 1.74 kcal/mol.

In order to calculate the most probable pair of values of m (as has been concluded above, $m=36$—39) and ΔH_I from these experimental results, the following numerical values are employed: $X_p=0.107$ (Table 1), $X_e=0.151$ (Table 1), $\Delta H_{f,w}=1.436$ kcal/mol,[16] $\Delta H_{f,d}=3.632$ kcal/mol,[17] $\Delta H_M=-0.150$ kcal/mol,[18] and $\Delta H_M'=-0.165$ kcal/mol.[18] As a result of calculation, it has been found that the most plausible pairs of m and ΔH_I, which meet above four equations simultaneously, are $m=36$ and $\Delta H_I=-51.3$ kcal/mol, $m=37$ and $\Delta H_I=-52.7$ kcal/mol, $m=38$ and $\Delta H_I=-54.1$ kcal/mol, and $m=39$ and $\Delta H_I=-55.6$ kcal/mol. Tentatively, if we insert $m=37$ and $\Delta H_I=-52.7$ kcal/mol into Eqs. (2)—(5), the following values are obtained: Eq. (2)=10.1 kcal/mol, Eq. (3)=3.3 kcal/mol, Eq. (4)=11.8 kcal/mol, and Eq. (5)=1.78 kcal/mol. These values are in good agreement with the experimental results presented above.

From these results, the following two features are worth noting: (a) The determined composition of the 1,4-dioxane hydrate ($C_4H_8O_2\cdot(36$—$39)H_2O$) differs greatly from that characteristic of the Structure II hydrate. This suggests, therefore, that the 1,4-dioxane hydrate has a structure either new or one of those described by Jeffrey and his co-workers.[19] (b) The estimated values of ΔH_I happen to be very close to $-\Delta H_{f,w}\cdot m$, irrespective of the choice of m (the differences between the two are 0.4—0.5 kcal/mol). The reason for this can be considered to be as follows. The reaction of Eq. (1) can be divided into the following three hypothetical processes: $m_2HO(l)\rightarrow mH_2O(s,\alpha)\rightarrow mH_2O(s,\beta)$ and a dissolution of liquid dioxane into the vacant $H_2O(s,\beta)$ lattice. The $H_2O(s,\alpha)$ means an ordinary ice I, and $H_2O(s,\beta)$ means the metastable clathrate lattice (the β-modification of water). The heat change in the first process is simply equal to $-\Delta H_{f,w}\cdot m$, *i.e.*, $-1.436\cdot m$ kcal/mol, if the temperature dependence of the heat of fusion of ice is neglected. The heat change in the second process can be approximately taken as zero (Eucken's assumption), as has been verified for several gas hydrates.[20,21] Finally, if, in the hydrate, there is no specific interaction, such as hydrogen bonding, between the dioxane molecule and the water host lattice, the heat change in the third process may also be slight, because this heat change[22] can be approximately expressed as $\Delta H_{vap}-\sqrt{\Delta H_{vap}\cdot\Delta H_{ice}}$, in which ΔH_{vap} is the heat of vaporization of liquid dioxane and ΔH_{ice} is the heat of sublimation of ice, and because the numerical value of ΔH_{ice} (8.0 kcal/mol[20]) is very close to the ΔH_{vap}. Thus, we may expect that the heat change in Eq. (1), that is, ΔH_I, will be close to $-1.436\cdot m$ kcal/mol provided the above assumptions are appropriate. In conclusion, we may expect that there are no specific interactions, such as hydrogen bonding, between dioxane (guest molecule) and water (host lattice).

16) This value is the heat of fusion of water at 0 °C (Ref. 15). Temperature correction is not made because of the experimental accuracy in DSC measurements.

17) C. J. Jacobs and G. S. Parks, *J. Amer. Chem. Soc.*, **56**, 1513 (1934). The value 3.632 kcal/mol is the sum of the heat of fusion at its melting point (3.070 kcal/mol) and the heat of transition at −0.3 °C (0.562 kcal/mol). In this case also temperature correction is not made.

18) These values are obtained from a long extrapolation of the experimental data (K. W. Morcom and R. W. Smith, *Trans. Faraday Soc.*, **66**, 1073 (1970)) for the temperature dependence of the heat of mixing of the 1,4-dioxane+water system.

19) P. T. Beurskens and G. A. Jeffrey, *J. Chem. Phys.*, **40**, 906 (1964), and earlier papers.

20) R. M. Barrer and W. I. Stuart, *Proc. Roy. Soc. Ser. A*, **243**, 172 (1957).

21) J. C. Platteeuw and J. H. van der Waals, *Mol. Phys.*, **1**, 91 (1958).

22) This heat change is a sum of two types of heat; heat of vaporization of liquid dioxane (ΔH_{vap}) and cohesive energy between gaseous dioxane and vacant $H_2O(s,\beta)$ lattice. The latter heat (exothermic) can be expressed, as a first approximation, as a geometrical mean of cohesive energies of both components, *i.e.*, $-\sqrt{\Delta H_{vap}\cdot\Delta H_{ice}}$, provided that there are no specific interactions between dioxane and H_2O lattice.

The Microwave Spectrum of Methyl Iodide in Excited Vibrational States. Fermi and Coriolis Interactions among v_3+v_6, v_5, and v_2 Vibrations

Yoshiyuki KAWASHIMA and Chiaki HIROSE

Laboratory of Molecular Spectroscopy, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received April 4, 1973)

The J=2←1 transitions of methyl iodide in the v_3, v_6, $2v_3$, v_2, v_3+v_6, and v_5 vibrationally-excited states are observed. In v_3+v_6, the central component, ν_{36}^0, of the J=2←1, K=1←1 transition is observed at 14.6 MHz, higher than the ν_{36}^+ of the *l*-type doubling. This is interpreted by the fact that the E state with $K=-l=\pm1$ is affected more strongly by the Fermi resonance through k_{356} than is the A state with $K=l=\pm1$. The Fermi resonance through k_{356} causes the Coriolis coupling between v_2 and v_5 through $\zeta_{25}^{(y)}$ to be transferred to v_3+v_6. As a result, the *l*-type doubling constant, q_6, is determined to be −5.8 MHz. The Stark effect in the presence of the *l*-type doubling and nuclear quadrupole splitting is formulated and used in the analysis.

The vibration-rotation bands of CH_3I were studied by Jones and Thompson, who determined the vibration-rotation constants, α_v^B, for several vibrational modes.[1] Further studies by Morino *et al.* by infrared[2] and microwave spectroscopy[3] made clear that the Fermi resonance was present through k_{356} between the v_3+v_6 and v_5 states. According to a recent study of the vibration-rotation spectra by Matsuura *et al.*,[4] the Coriolis interactions through $\zeta_{25}^{(y)}$ and a higher-order term $\xi_{356}^{(y)}$ should also be taken into account to make the infrared and microwave spectra consistent with each other. With their results at hand, the J=2←1 microwave transitions have been observed in the present study, and the effect of the Fermi resonance on the *l*-type doubling has been analyzed.

Buckingham and Stephens analyzed the Stark effect of CH_3I by taking into account cross-product terms between the molecular Stark effect, H_E, and the electric quadrupole coupling, H_Q, of the iodine atom as H_EH_Q and $H_E{}^2H_Q$ in order to get a more accurate dipole moment.[5] Their formulation has been extended in the present study to include the effect of the *l*-type doubling used in the assignment of the spectra.

Experimental

The sample of CH_3I was distilled before use. The microwave spectrometer used was of a conventional 100-kHz Stark-modulation type. The absorption cell was made of an X-band waveguide 3 m long. In order to increase the intensities for higher vibrational levels, the absorption cell was heated to about 60—80 °C. The J=2←1 transitions were observed with an Oki 30V10 klystron.

Assignment of the Spectra

The Stark effect of the J=2←1 and K=1←1 transitions is of the first order, whereas that of the J=2←1 and K=0←0 transitions is of the second order. The K=1←1 transitions were observed at the relatively low Stark field of about 15 V/cm.

The observed transition frequencies of the lines for v_3, v_6, $2v_3$, and v_2 coincided with those predicted from the constants obtained from the measurement of the J=1←0 transitions.[3] The satellite lines which appeared equally spaced at the upper- and lower-frequency sides of the v_6 spectra, ν_6^0, were identified as the ν_6^+ and ν_6^- components of the *l*-type doubling. The ν_v^+ and ν_v^- notations refer, respectively, to the transitions between the upper and lower levels of the *l*-type doubling, *i.e.*, the transitions between the levels with $K=l=\pm1$, the A symmetry, and ν_v^0 corresponds to the transition between the levels with $K=-l=\pm1$, the E symmetry.

The spectra for v_5 and v_3+v_6 were assigned by the use of their Stark effects. The Stark effects of the ν_v^+ and ν_v^- lines are different from that of the ν_v^0 line because a nonvanishing matrix element of the Stark effect is present between the *l*-type doublets. The Stark effect in the presence of both nuclear quadrupole coupling and *l*-type doubling has been formulated; it will be described in the Appendix. The calculated Stark effects for the F=7/2←5/2, J=2←1, and K=1←1 transitions are shown in Figs. 1a and 2a. The observed Stark effects of the candidate lines, which were not resolved into M_F components, are shown in Figs. 3 and 4. To make a better comparison between the observed and calculated Stark patterns, the line shape of the merged spectrum was calculated on the assumption of the Lorentzian line shapes, with the half-width at the half-height of $\Delta\nu$=0.5 MHz. The peak frequencies of the resultant curves at various strengths of the Stark field are plotted in Figs. 1b and 2b for the transitions in v_6 and v_3+v_6 respectively. The value of 0.5 MHz for $\Delta\nu$ was estimated from the zero-field line width of the square-wave modulated spectra. From Figs. 1b and 3, ν_6^-, ν_6^0, and ν_6^+ were assigned to the lines appearing from the lower to higher frequencies. A similar comparison of Figs. 2b and 4 established that ν_{36}^0 was observed at a frequency higher than ν_{36}^+. The ν_5^0 was not observed for some unknown reason, but ν_5^+ and ν_5^- were assigned on similar grounds.

The observed frequencies for v_3, $2v_3$, and v_2 are summarized in Table 1. The deviations were calculated by means of the rotational constant and eQq, which were derived from the least-squares fitting of the ob-

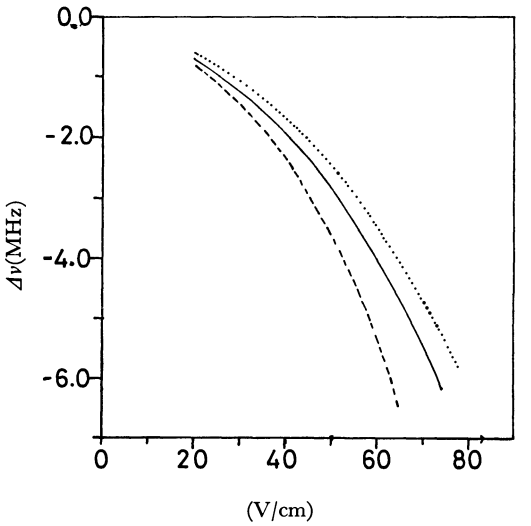

Fig. 2b. Calculated peak frequency *vs.* Stark field.

served frequencies of the J=2←1 and K=±1,0 transitions for v_3, $2v_3$, and v_2. The second-order correction on eQq was made by the procedure Gordy *et al.*[6] used in their analysis of the rotational spectra of the ground vibrational state of CH_3I. Table 2 lists the vibration-rotation constants, defined as $\alpha_v = B_0 - B_v$, and eQq.

The transitions, ν_v^+, ν_v^-, or ν_v^0, listed in Table 3 were analyzed in terms of the effective rotational constants, B_v^+, B_v^-, and B_v^0, and in terms of eQq separately from the other set; the differences in the effective rotational constants, $B_v^+ - B_v^-$, were taken as $|q_v|$. They are listed in Table 4.

Kuczkowski showed that, for CD_3I[7], the effects of asymmetry in eQq, which is induced by the degenerate vibrations on transition frequencies, were not more than 0.7 MHz. Therefore, these effects were neglected in the present study.

Discussion

Table II shows that the values of α_v^B are in good agreement with those obtained from the J=1←0 transitions[3] and infrared spectroscopy.[1,4,8] From this it is clear that there is no significant perturbation working on these vibrational states. However, v_2 is perturbed by the $\zeta_{25}^{(y)}$ Coriolis coupling, as will be discussed below.

l-Type Doubling Affected by Coriolis Coupling. As has been pointed out by Morino and Hirose, who studied CH_3Br and CD_3Br,[9] the rotational levels in v_5 are remarkably affected by the Coriolis coupling with v_2, while the effective rotational constants for v_2 are essentially unchanged.

The application of their formula to CH_3I indicates that the Coriolis coupling between v_2 and v_5 should be taken into account, but the higher-order interaction through $\xi^{(y)}_{356}$, which was reported by Matsuura *et al.*, was found to be negligible in the present case. Thus, the present problem is to solve the Fermi resonance through k_{356} and the Coriolis coupling through $\zeta^{(y)}_{25}$ as principal perturbers of the rotational levels in v_3+v_6, v_5, and v_2.

l-Type Doubling Affected by Fermi Resonance. The degenerate Coriolis coupling constant, $\zeta^{(z)}_5$, has a negative value, whereas $\zeta^{(z)}_6$, which should apply to

$-4A_v K l_v \zeta_v^{(z)}$; one of the levels with $K=l_v=\pm 1$, which has the A symmetry, is further split by the l-type doubling. A schematic diagram is shown in Fig. 5. If we take Δ as the vibrational separation of the unperturbed levels, v_3+v_6 and v_5, the separation between the E levels ($K=\pm 1$) is smaller than Δ by $-2\times(A_5^0\zeta_5^{(z)}-A_{36}^0\zeta_6^{(z)})+(A_5^0-A_{36}^0)$, while that between the A levels ($K=\pm 1$) is larger by the same amount. Substituting the values of $A_5^0=5.127$ cm^{-1}, $A_{36}^0=5.2116$ cm^{-1},

10) Y. Morino and J. Nakamura, This Bulletin **38**, 443 (1965).

$\zeta_5^{(z)}=-0.2444$, and $\zeta_6^{(z)}=0.2019$,[4] we get 4.611 cm^{-1} for $-2({}^0_5A\zeta_5^{(z)}-A_{36}^0\zeta_6^{(z)})+(A_5^0-A_{36}^0)$, which is as much as 20% of the vibrational difference, Δ, of about 24.0 cm^{-1}.

The basic formulas to be applied to the Fermi resonance in the present case were given in a preceding paper.[3] When the corrections for the above-mentioned term are included, we get the following equations for the effective (perturbed) rotational constants:

$$B_5(K=0) = \{(1+\Delta/[\Delta^2+4W^2]^{1/2})B_5^0 + (1-\Delta/[\Delta^2+4W^2]^{1/2})B_{36}^0\}/2, \quad (1)$$

$$B_{36}(K=0) = \{(1-\Delta/[\Delta^2+4W^2]^{1/2})B_5^0 + (1+\Delta/[\Delta^2+4W^2]^{1/2})B_{36}^0\}/2, \quad (2)$$

$$B_5(K=1, E) = [\{1+(\Delta-\delta)/[(\Delta-\delta)^2+4W^2]^{1/2}\}B_5^0 + \{1-(\Delta-\delta)/[(\Delta-\delta)^2+4W^2]^{1/2}\}B_{36}^0]/2, \quad (3)$$

$$B_{36}(K=1, E) = [\{1-(\Delta-\delta)/[(\Delta-\delta)^2+4W^2]^{1/2}\}B_5^0 + \{1+(\Delta-\delta)/[(\Delta-\delta)^2+4W^2]^{1/2}\}B_{36}^0]/2, \quad (4)$$

$$B_5^{\pm}(K=1, A) = [\{1+(\Delta+\delta)/[(\Delta+\delta)^2+4W^2]^{1/2}\}(B_5^0\pm q_5/2) + \{1-(\Delta+\delta)/[(\Delta+\delta)^2+4W^2]^{1/2}\} \times (B_{36}^0\pm q_6/2)]/2, \quad (5)$$

and

$$B_{36}^{\pm}(K=1, A) = [\{1-(\Delta+\delta)/[(\Delta+\delta)^2+4W^2]^{1/2}\} + (B_5^0\pm q_5/2) + \{1+(\Delta+\delta)/[(\Delta+\delta)^2+4W^2]^{1/2}\} \times (B_{36}^0\pm q_6/2)]/2, \quad (6)$$

where:

$$\Delta = v_5^0 - v_{36}^0 + A_5^0(\zeta_5^{(z)})^2 - A_{36}^0(\zeta_6^{(z)})^2, \quad (7)$$

$$W = k_{356}/2\sqrt{2}, \quad (8)$$

$$\delta = -2(A_5^0\zeta_5^{(z)}-A_{36}^0\zeta_6^{(z)}) + (A_5^0-A_{36}^0), \quad (9)$$

where A_5^0, A_3^0, B_5^0, and B_{36}^0 denote the rotational constants for the unperturbed v_5 and v_3+v_6 states respectively, and where q_5 and q_6 are the l-type doubling constants. The constants, $\zeta_{36}^{(z)}$ and q_{36}, are set equal to $\zeta_6^{(z)}$ and q_6 respectively in the above equations. Equations (1) and (2) are identical with Eqs. (2) and (3) of Ref. 3. Thus, the J=2←1 and K=0←0 transitions can be predicted from the results given in Ref. 3.

Using the results reported in Refs. 3 and 4, we get the values listed in Table 5. The results show that the central line, $\nu_{36}{}^0$, which gives B_{36}(K=1,E), is shifted up by 12.6 MHz from the K=0 line, in agreement with the predicted value. The $\nu_{36}{}^0$ frequency can exceed that of the $\nu_{36}{}^+$ line; the assignment we have given indicates that this is the case for CH_3I.

The analysis of the spectra in v_6 has given $|q_6|=5.8$ MHz (Table 4),[11] and q_5 can not be very different from the calculated value of 13.4 MHz.[12] Furthermore, the substitution of the above-mentioned values of q_6 and q_5 into Eq. (6) gives $B^+{}_{36}-B^-{}_{36}=3.9\pm0.2$ MHz, significantly different from the observed value, 3.1 ± 0.2 MHz. This difference can be accounted for by taking account of both the Fermi resonance and the Coriolis coupling, as will be discussed below.

Table 5. Effective rotational constants and energy differences[a]

B_5(K=0)[a]	7498.10 MHz	B_5(K=1, E)[a]	7495.01 MHz
B_{36}(K=0)[a]	7433.88 MHz	B_{36}(K=1, E)[a]	7436.96 MHz

δ[c]	4.522 cm^{-1}		

a) Rotational constants perturbed by the Fermi resonance through k_{356}. b) Ref. 4. c) $\delta=-2(A_5^0\zeta_5^{(z)}-A_{36}^0\zeta_6^{(z)})+(A_5^0-A_{36}^0)$. d) Ref. 3.

l-Types Doubling Affected by Both Fermi and Coriolis Interactions. The Fermi resonance causes the rotational levels in v_5 and v_3+v_6 to be mixed up considerably. Since the Coriolis coupling through $\zeta_{25}^{(y)}$ is expected to be significant, the two perturbations should be solved simultaneously in order to make a more complete analysis of the spectra.

One of the two levels of the (K=1,A) state, designated as (−) in Ref. 9, is not coupled by the Coriolis interaction to any rotational level of v_2, while the (+) state is coupled to the (J,K=0) level of v_2 through $\zeta_{25}^{(y)}$ (see case I(a) of Ref. 9). The present case can be reduced to two problems. One is for the (−) state, where only the Fermi resonance is present, and the secular equation is expressed by:

$$\begin{vmatrix} E_1-\lambda & W \\ W & E_2-\lambda \end{vmatrix} = 0 \quad (10)$$

where

$$E_1 = v_3^0 + v_6^0 + B_{36}^0J(J+1) + A_{36}^0 - B_{36}^0 - 2A_{36}^0\zeta_6^{(z)} - q_6J(J+1)/2 + A_{36}^0(\zeta_6^{(z)})^2,$$

$$E_2 = v_5^0 + B_5^0J(J+1) + A_5^0 - B_5^0 - 2A_5^0\zeta_5^{(z)} - q_5{}^*J(J+1)/2 + A_5^0(\zeta_5^{(z)})^2,$$

$$W = k_{356}/2\sqrt{2}$$

and $q_5{}^*$ is the unperturbed l-type doubling constant for the v_5 state, −0.66 MHz.[4] The other is for the (+) state, (K=1,E), and K=0, where the Fermi resonance between v_5 and v_3+v_6 and the Coriolis coupling between v_5 and v_2 have to be taken into account simultaneously; the secular equation to be solved is expressed by Eq. (11)[13]:

$$\begin{vmatrix} E_1-\lambda & W & 0 \\ W & E_2-\lambda & C \\ 0 & C & E_3-\lambda \end{vmatrix} = 0. \quad (11)$$

The expressions for the E_i and C elements are for the K=0 level:

11) Evidence for a negative sign of q_6 is given in the Discussion part.

12) The harmonic term of the l-type doubling constant q_5 for CD_3I, CH_3Br, and CD_3Br are calculated to be 15.5, 26.0 and 32.0 MHz, respectively, while the corresponding observed values are 15.2, 26.3 and 32.2 MHz.

13) Equations (10) and (11) do not apply to the K=±1 levels of v_2, since they are further connected to the K=±2 levels of v_5 through $\zeta_{25}^{(y)}$. Thus the solution of Eq. (11) obtained from Eq. (12) is not exact for λ_3.

$$E_1 = v_3^0 + v_6^0 + B_{36}^0 J(J+1) + A_{36}^0(\zeta_6^{(z)})^2,$$
$$E_2 = v_5^0 + B_5^0 J(J+1) + A_5^0(\zeta_5^{(z)})^2,$$
$$E_3 = v_2^0 + B_2^0 J(J+1) + A_2^0 - B_2^0, \quad (12)$$
$$C = \{(v_2^0/v_5^0)^{1/2} + (v_5^0/v_2^0)^{1/2}\}[J(J+1)/2]^{1/2} B_e \zeta_{25}^{(y)},$$

for the (K=1,E) level:

$$E_1 = v_3^0 + v_6^0 + B_{36}^0 J(J+1) + A_{36}^0 - B_{36}^0 + 2A_{36}^0\zeta_6^{(z)} + A_{36}^0(\zeta_6^{(z)})^2,$$
$$E_2 = v_5^0 + B_5^0 J(J+1) + A_5^0 - B_5^0 + 2A_5^0\zeta_5^{(z)} + A_5^0(\zeta_5^{(3)})^2,$$
$$E_3 = v_2^0 + B_2^0 J(J+1) + 4(A_2^0 - B_2^0), \quad (13)$$
$$C = \{(v_2^0/v_5^0)^{1/2} + (v_5^0/v_2^0)^{1/2}\}[(J-1)(J+2)/2]^{1/2} B_e \zeta_{25}^{(y)},$$

and for the (+) level:

$$E_1 = v_3^0 + v_6^0 + B_{36}^0 J(J+1) + A_{36}^0 - B_{36}^0 - 2A_{36}^0\zeta_6^{(z)} + q_6 J(J+1)/2 + A_{36}^0(\zeta_6^{(z)})^2,$$
$$E_2 = v_5^0 + B_5^0 J(J+1) + A_5^0 - B_5^0 - 2A_5^0\zeta_5^{(z)} + q_5^* J(J+1)/2 + A_5^0(\zeta_6^{(z)})^2,$$
$$E_3 = v_2^0 + B_2^0 J(J+1), \quad (14)$$
$$C = \{(v_2^0/v_5^0)^{1/2} + (v_5^0/v_2^0)^{1/2}\}[J(J+1)]^{1/2} B_e \zeta_{25}^{(y)},$$

where the equilibrium rotational constant, B_e, is set equal to the ground-state rotational constant, B_0, 7501.25 MHz.[3]

A computer calculation was performed by using the values reported in Refs. 3 and 4; the results are listed in Table VI. The Coriolis interaction through $\zeta_{25}^{(y)}$ was corrected for the B_5^0 listed in Table V; 7500.16 MHz was used in the calculation. The agreement with the observed values confirms the reported values.

a) 2.5 times variance.

Determination of the Sign of q_6. The combined effect of the Fermi and Coriolis interactions enables us to determine the sign of the l-type doubling constant, q_6, by microwave spectroscopy. The effect on B_{36}^+ is different from that on B_{36}^-; the difference between B_{36}^+ and B_{36}^- is 1.7 MHz, even when we assume q_6=0.0 MHz. This difference can be interpreted as indications that the $\zeta_{25}^{(y)}$ term, which is dominant in the l-type doubling of v_5, is transferred to v_3+v_6 through the Fermi resonance. We have to add the normal l-type doubling in v_3+v_6, which is supposedly the same as in v_6, to make the resultant B_{36}^+ and B_{36}^- values agree with the observed values. The dotted lines and broken lines in Fig. 6 show the predicted rotational constants *vs.* the absolute value of q_6 for the cases of $q_6>0$ and $q_6<0$, respectively, while the solid lines are the observed rotational constants. For the $|q_6|$=5.8 MHz value, the broken lines are closer to the observed values than the dotted lines, the latter

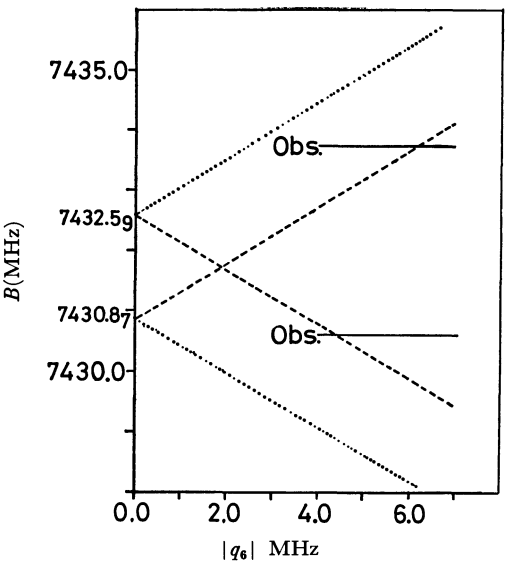

Fig. 6. Predicted rotational constants of the l-type doubling in v_3+v_6, v_{36}^+ and v_{36}^-, *vs.* $|q_6|$. Dotted and broken lines correspond to the prediction for $q_6>0$ and for $q_6<0$, respectively, and the solid lines indicate the observed rotational constants.

difference being too large to be accounted for the higher-order terms ignored in the present analysis. Therefore, the negative sign of q_6, that is, q_6=−5.8 MHz, is preferred. This is in agreement with the conclusion of Matsuura *et al.*[4]

Appendix

Stark effect in the degenerate vibrational states of CH_3I.

The effective Hamiltonian which has to be solved is expressed as:

$$H = H_{rot} + H_Q + H_l + H_E, \quad (A1)$$

where H_{rot}, H_Q, H_l, and H_E are the Hamiltonian operators for the rotation, the nuclear quadrupole coupling caused by the iodine nucleus, the l-type doubling, and the Stark effect respectively.

Since the differences in energy for different J values (more than 15 GHz) are much larger than those among the splittings caused by H_Q or H_l, only the terms which are diagonal in J need to be considered for the present purpose; the off-diagonal terms can be treated as second-order perturbations. Furthermore, an appropriate representation for the present case of a weak-field case is $|v_t,l_t\rangle|F,M_F,J,K,M_J\rangle$. We set another restriction: The degenerate vibration is singly excited, *i.e.* v_t=1, $l_t=\pm1$. However, combination tones of the v_3+v_6 type are not excluded from the present considerations, since the degenerate vibration is still singly-excited.

The nonvanishing matrix elements of H_Q and H_E for the $|F,M_F,J,K,M_J\rangle$ wave function have been given in textbooks[14,15] or papers.[16,17] We still have to consider H_l. Since H_l is of no significance when K=0, $|K|\geqq2$, or K=

17) F. Coester, *ibid.*, **77**, 454 (1950).

$-l_t=\pm1$,[18] the Stark effect is essentially equal to that in the ground-vibrational state. The effect of H_l is significant only when $K=l_t=\pm1$, where the proper representations are expressed as:

$$|v_t, l, F, M_F, J, l, M_J; + \rangle = \{|v_t, l, F, M_F, J, l, M_J\rangle + |v_t, -1, F, M_F, J, -1, M_J\rangle\}/\sqrt{2} \quad \text{(A2)}$$

and:

$$|v_t, l, F, M_F, J, l, M_J; - \rangle = \{|v_t, l, F, M_F, J, l, M_J\rangle - |v_t, -1, F, M_F, J, -1, M_J\rangle\}/\sqrt{2}. \quad \text{(A3)}$$

The functions expressed in Eqs. (A2) and (A3) diagonalize both H_{rot} and H_l. The nonvanishing matrix elements of H_Q and H_E in the above representations are:

$$\langle v_t, l, F, M_F, J, l, M_J; + |H_Q| v_t, l, F, M_F, J, l, M_J; + \rangle = \langle v_t, l, F, M_F, J, l, M_J; - |H_Q| v_t, l, F, M_F, J, l, M_J; - \rangle = \langle F, M_F, J, K=1, M_J|H_Q|F, M_F, J, K=1, M_J\rangle = (eQq/2)\{3K^2-J(J+1)\}\{3C(C+1)/4-I(I+1)J(J+1)\}/\{I(2I-1)J(2J-1)(J+1)(2J+3)\}, \quad \text{(A4)}$$

where:

$$C = F(F+1) - I(I+1) - J(J+1),$$

$$\langle v_t, l, F, M_F, J, l, M_J; + |H_E|v_t, l, F, M_F, J, l, M_J; - \rangle = \langle F, M_F, I, K=1, M_J|H_E|F, M_F, J, K=1, M_J\rangle = -\mu E\, M_F\{J(J+1)+F(F+1)-I(I+1)\}/\{2J(J+1)F(F+1)\}, \quad \text{(A5)}$$

and where:

$$\langle v_t, l, F, M_F, J, l, M_J; + |H_E|v_t, l, F+1, M_F, J, l, M_J; - \rangle = \langle v_t, l, F+1, M_F, J, l, M_J; + |H_E|v_t, l, F, M_F, J, l, M_J; - \rangle = \langle F, M_F, J, K=1, M_J|H_E|F+1, M_F, J, K=1, M_J\rangle = \langle F+1, M_F, J, K=1, M_J|H_E|F, M_F, J, K=1, M_J\rangle = -\mu E[\{(F+1)^2-M_F^2\}\{(F+1)^2-(I-J)^2\} \times \{(I+J+1)^2-(F+1)^2\}]^{1/2}/[2J(J+1)(F+1)\{(2F+1)(2F+3)\}^{1/2}], \quad \text{(A6)}$$

where eQq is the electric quadrupole coupling constant of the iodine atom, μ is the electric dipole moment, and E is the applied electric field.

Since H_E is nonvanishing only between the (+) and (−) levels which are split by the l-type doubling, the secular equation to be solved is twice as large as that in the case of $K=-l_t=\pm1$. These off-diagonal elements, in combination with the relatively small splitting caused by H_l (about a few tens of MHz in contrast to about a hundred MHz of splittings among different F levels), can complicate the Stark effect. Especially, the F levels lying in between the other F levels can be severely perturbed.

In the actual analysis, a computer was used in both cases, and the shifts in transition frequencies due to the Stark field were derived for the $J=2\leftarrow1$, $F=7/2\leftarrow5/2$, and $K=1\leftarrow1$ transitions of the v_6 and v_3+v_6 vibrational states in order to compare them with the observations.

The authors are very grateful to Professor Kunio Kozima for his encouragement during the course of this work. We are much indebted to Professor Kozo Kuchitsu for his assistance in preparing the manuscript. Thanks are also due to Professor Emeritus Yonezo Morino for his critical reading of this paper and Dr. Hiroatsu Matsuura for his helpful discussion.

18) The energy levels for $K\geqq2$, which consists of four levels, are not in strict degeneracy; for $|K-l_t|=3n\pm1$ ($n=0,1,2,\cdots$), they are split into two doubly degenerate levels, and for $|K-l_t|=3n$ ($n=0,1,2,\cdots$), there are three levels with A_1, A_2, and E symmetries. Since the splittings among the levels interrelated by H_E are negligible for CH_3I, we can treat them as though the levels were degenerate. It should be noted, however, that H_E has an off-diagonal element between A_1 and A_2 levels in contrast to the diagonal element for the E levels.

The Electronic Structure of Nickelocene by Means of the Configurational Interaction Method

Shunsuke KOBINATA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received Auguest 1, 1972)

The electronic structures of nickelocene have been investigated by means of the configurational interaction method. The locally-excited configurations of the central metal ion and the charge-transfer configurations corresponding to an electron transfer from the ligand system to the central metal ion have been taken into account. A correspondence with the crystal-field treatment has been obtained using the partitioning technique of solving the secular equation. The energies of the charge-transfer configurations, the resonance integrals, and the Racah parameters were determined so as to obtain the best fit with the observed d-d transition energies.

The nature of the bonding in the sandwich complexes has been the subject of extensive experimental and theoretical investigations. Many calculations based on the MO theory or the crystal-field (CF) theory have been made, but they had led to rather scattered results.[1-7] With regard to the spectral assignment of the low-lying absorption bands (d-d transitions), the CF treatment seems more reliable than the MO treatment for the present.

Recently, a detailed study of the electronic state of nickelocene has been successfully made by I. Pavlik *et al.* using the CF treatment.[8] This method is based on an electrostatic model. On the other hand, many experiments, for example, NMR[9,10] and ESR,[11,12] clearly show the presence of a considerable covalency between nickel and cyclopentadienyl rings.

In this respect it is interesting to inquire into the origin of the validity of the CF treatment and the physical contents of the CF parameters (D_s and D_t) of nickelocene. Previously we have dealt with Cu(II) complexes by means of the configurational interaction (CI) method and have shown that the CF and CI methods give approximately equivalent results with regard to the d-d transition energies. The comparison of the CF parameters with the CI parameters gives useful information about the nature of bonding of Cu(II) complexes.[13]

In this study the electronic structures of nickelocene were treated by means of the CI method, and the physical content of the CF parameters and the nature of bonding in nickelocene were investigated.

Method

In the treatment of the CI method[14,15] nickelocene is considered to be a composite of two component groups: nickel ion and a ligand system composed of two cyclopentadienyl (cp) rings. The total electronic state is described as a superposition of various configurational wave functions: the ionic configurations (locally-excited configurations of the central metal ion or the ligand system) and the charge-transfer (CT) configurations, which correspond to an electron transfer from the ligand system, and *vice versa* if necessary. The ionic configurations are defined as those configurations in which the nickel ion has eight valence electrons (Ni^{2+}).

With regard to the ionic configurations, we took into account only the locally-excited configurations of the central metal ion, which arise from the rearrangement of d electrons within the d-shells, because we are interested primarily in the d-d transitions. In the ionic configurations the fivefold degenerate d AO's of the central metal ion are split into three levels:[16]

$$\left.\begin{aligned} \langle d_0|V_c|d_0\rangle &= 2D_s^{ion} - 6D_t^{ion} \\ \langle d_{\pm1}|V_c|d_{\pm1}\rangle &= D_s^{ion} + 4D_t^{ion} \\ \langle d_{\pm2}|V_c|d_{\pm2}\rangle &= -2D_s^{ion} - D_t^{ion} \end{aligned}\right\} \quad (1)$$

as a result of the electrostatic potential (V_c) from the ligands, where D_s^{ion} and D_t^{ion} are the CF parameters. They are usually determined so as to obtain the best coincidence between the calculated and the observed d-d transition energies. Here, they are considered to be the quantities which contain only the contribution of the electrostatic potential from the ligands. The energies of various terms of Ni^{2+} (d^8 configuration; ^3F, ^3P, ^1D, ^1G, ^1S) under the influence of V_c are shown in Ref. 8. The basic wave functions used in the CF method, $\Phi_M^{ion}(S, M_S, L, M_L)$, should be replaced by:

$$\Phi_M^{ion}(S,M_S,L,M_L) = A\Phi_L^0\Phi_M^{ion}(S,M_S,L,M_L) \quad (2)$$

in the CI treatment, where Φ_L^0 is the wave function of two cp anions in their ground state. A is the antisymmetrizer for the exchange of the electrons between

the nickel ion and the ligand system. S, M_S and L, M_L are the quantum numbers of the spin and the orbital angular momentum.

As to the CT configurations, those which are formed by an electron transfer to 3d AO of the central metal ion from the filled ligand π MO were considered first (3d-CT). The filled π MO's which belong to the same irreducible representation as the d AO under the D_{5d} molecular symmetry group are given as:[17]

$$\left.\begin{array}{ll}(d_0); & \phi(a_{1g}) = 1/\sqrt{2}\,(\phi_a(a_2) + \phi_b(a_2)) \\ (d_{\pm1}); & \phi(e_{1g}\pm) = 1/\sqrt{2}\,(\phi_a(e_1\pm) + \phi_b(e_1\pm))\end{array}\right\} \quad (3)$$

where the suffixes a and b indicate the two cp rings. $\phi(a_2)$ and $\phi(e_1)$ are the π MO's of a cp ring, corresponding to the lowest and highest occupied π MO of the cp anion respectively.

$$\left.\begin{array}{l}\phi(a_2) = 1/\sqrt{5}\,(x_1+x_2+x_3+x_4+x_5) \\ \phi(e_1\pm) = 1/\sqrt{5}\,(x_1+\sigma^{\pm1}x_2+\sigma^{\pm2}x_3+\sigma^{\pm3}x_4+\sigma^{\pm4}x_5)\end{array}\right\} \quad (4)$$

where x_t is the $2p\pi$ AO of the carbon atom. $\sigma=\exp(2\pi i/5)$.

The energies of 3d-CT configurations were represented as $E_0^{CT}(a_{1g})$ or $E_1^{CT}(e_{1g})$, depending on whether an electron was transferred from $\varphi(a_{1g})$ or $\varphi(e_{1g})$. The wave functions of the CT configurations are written as:

$$\Phi_\alpha^{CT}(S,M_S,L,M_L) = \sum A\Phi_L^{CT}(S',M_S'',M_L')\Phi_M^{CT}(S'',M_S'',L'',M_L'') \\ <S',M_S',S'',M_S''|S,M_S><M_L',M_L''|M_L> \quad (5)$$

where summation is taken over S',M_S',S'',M_S'',M'_L and M_L''. $<S,'M_S',S,''M_S''|S,M_S>$ and $<M_L',M_L''|M_L>$ are the vector coupling coefficients for the spin angular momentum and the irreducible representation of the molecular symmetry group, D_{5d}.[18] $\Phi_M^{CT}(S, M_S, L, M_L)$, and $\Phi_L^{CT}(S, M_S, M_L)$ are the wave functions of the central metal ion (d^9 configuration) and the ligand system in a 3d-CT configuration (11π electrons). α is used to distinguish the independent Φ^{CT}'s belonging to the same irreducible representation. They are tabulated in Table 1. For the triplet state (S=1), we considered exclusively the state with the spin magnetic quantum number $M_S=1$.

The resonance interactions between the ionic configurations and CT configurations are calculated by the method of Longuett-Higgins and Murrell,[19] which lead to the group resonance integrals (β_0 and β_1) between the 3d AO of the central metal ion and the $2p\pi$ MO of cp rings,

$$\left.\begin{array}{l}\beta_0 = <d_0|\mathcal{H}|\phi(a_{1g})> \\ \beta_1 = <d_{\pm1}|\mathcal{H}|\phi(e_{1g}\pm)>\end{array}\right\} \quad (6)$$

The diagonal and off-diagonal matrix elements of the secular equations are tabulated in Table 2, in which the Φ^{ion} (S=1, L=3) state, corresponding to the lowest state of the Ni^{2+} ion, *i.e.*, ^3F, is chosen as the standard of energy. B and C are the Racah parameters.

The CT configurations, formed by an electron transfer from a filled π-MO of the ligand system to the 4s or 4p AO of the central metal ion (4s-CT or 4p-CT), can easily be constructed using the vector coupling coefficients, in a manner similar to that used to construct the 3d-CT configurations. It is apparent that the effect of the 4s and 4p-CT configurations on the low-lying d^8 configurations is a uniform stabilization of these energies. Hence, these configurations do not affect the d AO splittings in a higher approximation.[14] The CT configurations corresponding to an electron transfer from the ligand σ orbital to the central metal ion can also be neglected in a higher approximation, because ESR[11] and NMR[20] experiments have shown that, in nickelocene, the electron delocalization between the cp rings and the nickel ion takes place mainly through the π orbitals of the cp rings.

To see the relation between the cf and CI treatments, it is necessary first to transform the basis of the CI method (ionic and CT configurations) to the ionic configurations which appear in the CF treatment.

By means of the partitioning technique,[21,22] the secular equation in the CI treatment (Table 2) is transformed to:

$$\sum_{j=1}^{N_1}\left\{<\Phi_i^{ion}|\mathcal{H}|\Phi_j^{ion}> - \sum_{p=N_1+1}^{N_1+N_{CT}}\frac{<\Phi_i^{ion}|\mathcal{H}|\Phi_p^{CT}><\Phi_p^{CT}|\mathcal{H}|\Phi_i^{ion}>}{<\Phi_p^{CT}|\mathcal{H}|\Phi_p^{CT}>-E}\right\}c_i^{ion} = Ec_i^{ion} \quad (7)$$

Table 1. The wave functions of CT configurations

$$\begin{aligned}
\Phi^{CT}(^3A_{2g}) &= (1/\sqrt{2})(L(1/2,E_1^+)M(1/2,E_1^-) \\
&\quad -L(1/2,E_1^-)M(1/2,E_1^+)) \\
\Phi_1^{CT}(^3E_{1g}) &= L(1/2,E_1^-)M(1/2,E_2^+) \\
\Phi_2^{CT}(^3E_{1g}) &= L(1/2,E_1^+)M(1/2,A_1) \\
\Phi_3^{CT}(^3E_{1g}) &= L(1/2,A_1)M(1/2,E_1^+) \\
\Phi_1^{CT}(^3E_{2g}) &= L(1/2,E_1^+)M(1/2,E_1^+) \\
\Phi_2^{CT}(^3E_{2g}) &= L(1/2,E_1^-)M(1/2,E_2^-) \\
\Phi_3^{CT}(^3E_{2g}) &= L(1/2,A_1)M(1/2,E_2^+) \\
\Phi_1^{CT}(^1A_{1g}) &= (1/2)(L(1/2,E_1^+)M(-1/2,E_1^-) \\
&\quad -L(-1/2,E_1^+)M(1/2,E_1^-) \\
&\quad +L(1/2,E_1^-)M(-1/2,E_1^+) \\
&\quad -L(-1/2,E_1^-)M(1/2,E_1^+)) \\
\Phi_2^{CT}(^1A_{1g}) &= 1/\sqrt{2})(L(1/2,A_1)M(-1/2,A_1) \\
&\quad -L(-1/2,A_1)M(1/2,A_1)) \\
\Phi_1^{CT}(^1E_{1g}) &= (1/\sqrt{2})(L(1/2,E_1^+)M(-1/2,A_1) \\
&\quad -L(-1/2,E_1^+)M(1/2,A_1)) \\
\Phi_2^{CT}(^1E_{1g}) &= (1/\sqrt{2})(L(1/2,E_1^-)M(-1/2,E_2^+) \\
&\quad -L(-1/2,E_1^-)M(1/2,E_2)) \\
\Phi_3^{CT}(^1E_{1g}) &= (1/\sqrt{2})(L(1/2,A_1)M(-1/2,E_1^+) \\
&\quad -L(-1/2,A_1)M(1/2,E_1^+)) \\
\Phi_1^{CT}(^1E_{2g}) &= (1/\sqrt{2})(L(1/2,E_1^+)M(-1/2,E_1^+) \\
&\quad -L(-1/2,E_1^+)M(1/2,E_1^+)) \\
\Phi_2^{CT}(^1E_{2g}) &= (1/\sqrt{2})(L(1/2,E_1^-)M(-1/2,E_2^-) \\
&\quad -L(-1/2,E_1^-)M(1/2;E_2^-)) \\
\Phi_3^{CT}(^1E_{2g}) &= (1/\sqrt{2})(L(1/2,A_1)M(-1/2,E_2^+) \\
&\quad -L(-1/2,A_1)M(1/2,E_2^+))
\end{aligned}$$

$L(1/2,E_1^+)$ and $M(-1/2,E_1^-)$ indicate $\Phi_L^{CT}(S=1/2,M_S=1/2, M_L=1)$ and $\Phi_M^{CT}(S=1/2,M_S=-1/2,M_L=-1)$, respectively. (Eq. (5)).

where N_I and N_{CT} are the numbers of bases of the ionic and CT configurations respectively. c_i^{ion} and c_p^{CT} are the CI coefficients acting on Φ_i^{ion} and Φ_p^{CT} respectively. E is the eigenvalue. The secular equation obtained above is different from those ordinarily obtained, because E is present in the denominator. An eigenvalue, E, is composed of the uniform stabilization energies produced by the 4s-CT and 4p-CT configurations, ΔE(4s-CT) and ΔE(4p-CT), and of the stabilization energy produced by 3d-CT (Fig. 1). Writing the average stabilization energy by 3d-CT as ΔE(3d-CT), a constant

$$\Delta E = \Delta E(3d-CT) + \Delta E(4s-CT) + \Delta E(4p-CT) \quad (7)$$

may be added to E without any influence on the splitting of 3d levels. If the E in the denominator is replaced by an average energy, $\bar{E}$, after the above procedure, the secular equation (7) is reduced to an ordinary one, the basis of which is the same as that of the CF treatment. Each matrix element depends only on 3d-CT, not on 4s-CT and 4p-CT. The above replacement would be a good approximation for

low-lying d-d transition energies if $E_1^{CT}-\bar{E}$ is much larger than the breadth of the eigenvalues corresponding to the locally-excited configurations of the central metal ion, *i.e.*, the d-d transition energies. As will be shown in the next section, the quite large value of $E_1^{CT}-\bar{E}$ estimated by means of the CI treatment confirms that this is the case. Furthermore, the success of the CF treatment itself implies that this replacement is a good approximation. Therefore, using these definitions:

$$\left.\begin{aligned}\sigma_1 &= \beta_1^2/(E_1^{CT}-\bar{E})\\ \sigma_0 &= \beta_0^2/(E_0^{CT}-\bar{E})\end{aligned}\right\} \quad (8)$$

the average stabilization energy by 3d-CT can be represented, so as to satisfy the center of gravity rule, as:

$$\Delta E(3d-CT) = (4/5)\sigma_1 + (2/5)\sigma_0 \quad (9)$$

We obtain exactly the same form of the secular equations as those obtained by means of the CF treatment by defining as follows:

$$D_s = D_s^{ion} + D_s^{cov}$$
$$D_t = D_t^{ion} + D_t^{cov}$$

where:

$$\left.\begin{aligned}D_s^{cov} &= (5/35)\sigma_1 + (5/35)\sigma_0\\ D_t^{cov} &= (4/35)\sigma_1 - (3/35)\sigma_0\end{aligned}\right\} \quad (10)$$

The only differences are the replacement of the D_s^{ion} and D_t^{ion} of the CF treatment by the D_s and D_t in Eq. 10. These differences lose all meaning when the D_s^{ion} and D_t^{ion} are considered as parameters which should be determined so as to obtain the best fit with the observed d-d transition energies, as is usually done in the CF calculations. This implies that the CF parameter treatment is approximately equivalent to the CI treatment with respect to the d-d transition energies. Hence, the CF treatment is valid even in the presence of considerable covalency.

Results and Discussion

CI Parameters. In order to calculate the d-d transition energies theoretically by means of the CI method, it is necessary to estimate the eight quantities, D_s^{ion}, D_t^{ion}, E_1^{CT}, E_0^{CT}, B, C, β_1 and β_0, shown in Table 2. At present, it is difficult to estimate these quantities theoretically with sufficient confidence. Therefore, it seems justifiable to use an alternative method of estimating these quantities empirically, considering them as CI parameters which should be determined so as to obtain the best fit with the observed d-d transition energies.

In order to reduce the number of unknown parameters, the following approximations were made. In the first place, the D_s^{ion}, and D_t^{ion} in Table 2 were assumed to be negligible, because it is known that the effect of the electrostatic terms on the d-orbital splitting is generally rather small.[24] The validity of this approximation was confirmed by the consistency of the results obtained under this approximation. E_0^{CT} was estimated to be equal to E_1^{CT} plus the difference between the second and the first ionization potentials of the cp anion. This difference was calculated by the method of Pariser-Parr-Pople,[25,26] and using Koopmans' theorem, as 5.145 eV. Hence, we obtained:

$$E_0^{CT} = E_1^{CT} + 5.145\ \text{eV}$$

We carried out two types of calculation, Calcn. 1 and Calcn. 2. In Calcn. 1, $C/B=4.0$ was assumed, as is usually done in a CF treatment.[23] In Calcn. 2, B and C were considered to be independent parameters. With these assumptions, the number of independent CI parameters to be determined is reduced to four in Calcn. 1 (β_1, β_0, E_1^{CT} and B) and to five in Calcn. 2 (β_1, β_0, E_1^{CT}, B and C). Because five d-d bands have been observed for nickelocene, we can determine these CI parameters uniquely so as to obtain the best coincidence with the observed d-d transition energies. The results are shown in Table 3. The average deviation is about 1 kK for Calcn. 1 and 0.2 kK for Calcn. 2. This small deviation must result from the neglect of the two-electron charge-transfer configurations and the locally-excited configurations of the ligand system. Calcn. 2 gives the $B/C=6.85$ ratio, which is rather large compared with the value of the free ion. It is very near to that of $C/B=6.87$ obtained in the CF treatment of nickelocene by Pavlik *et al.*[8] The ratio of B to the free ion value B_{ion}, the nephelauxetic ratio, was obtained as $\beta=0.80$ by means of Calcn. 2, using $B_{ion}=1030\ \text{cm}^{-1}$. In the CF treatment, $\beta=0.56$ has been obtained.[8] Calc. 1 gives the unreasonable value of $\beta=1.0$. This probably results from the unreasonable

assumption that the C/B ratio is independent of the complex formation, that is, $C/B=4.0$.[27] It is known that the nephelauxetic ratio consists of two factors, the central-field covalency and the symmetry-restricted covalency.[24] Because, in the CI treatment, the latter effect is taken into account to some extent, it seems reasonable that the nephelauxetic ratio in the CI treatment is larger than in the CF method.

As to the resonance integral the value of $\beta_1=-6.40$ eV and $\beta_0=-3.712$ eV were obtained. At first sight these values seem too large compared with the corresponding values of ferrocene, which is known to be more covalent than nickelocene, for which $\beta_1=-3.3468$ eV and $\beta_0=0$ have been used in the MO calculation.[28] In the Wolfsberg-Helmholz approximation, the resonance integral, β_{ij}, is estimated to be:

$$\beta_{ij} = -F(I_i+I_j)G_{ij}/2 \qquad (11)$$

where G_{ij} is the group overlap integral and where F is a constant, for which a value of about 2 has usually been used. I_i and I_j are the valence-state ionization potentials of the relevant AO's. I_i and I_j depend strongly on the electronic charge and the electronic configuration of the relevant atom. The β_{ij} in the MO calculation is related to the value for the self-consistent charge distribution and electron configuration, whereas the β_{ij} in the CI treatment would be more closely related to the value for the "zeroth-order" charge distribution and the electron configuration. In nickelocene the β_1 and β_0 of the CI treatment may be estimated as:

$$\left.\begin{aligned}\beta_1 &= -(1/2)F(I(\mathrm{Ni^{2+}}) + I(\mathrm{C^{-1/5}}))\langle \mathrm{d}_1|\psi(\mathrm{e_{1g}}^+)\rangle \\ \beta_0 &= -(1/2)F(I(\mathrm{Ni^{2+}}) + I(\mathrm{C^{-1/5}}))\langle \mathrm{d}_0|\psi(\mathrm{a_{1g}})\rangle\end{aligned}\right\} \qquad (12)$$

where $I(\mathrm{Ni^{2+}})$ and $I(\mathrm{C^{-1/5}})$ are the ionization potentials of $\mathrm{Ni^{2+}}$ and $I(\mathrm{C^{-1/5}})$, which were estimated to be 35.17 eV and 9.10 eV respectively.[30] The group overlap integrals, $\langle \mathrm{d}_1/\psi(\mathrm{e_{1g}}^+)\rangle$ and $\langle \mathrm{d}_0/\psi(\mathrm{a_{1g}})\rangle$, were calculated, on the basis of the radial 3d functions tabulated by Richardson *et al.*, to be 0.139 and 0.059 respectively.[31] This calculation made use of the geometry reported by Ronova and Alekseev.[32] With these values and taking $F=2$, the values of $\beta_1=-6.16$ eV and $\beta_0=-2.64$ eV are obtained from Eq. (12). These values coincide fairly well with the values obtained empirically by the CI method (Table 3). Hence, the values of the resonance integrals obtained from the CI treatment seem not to be unreasonable.

As to the energy of CT configuration, the value of $E_1^{CT}=9.53$ eV was obtained. The electronic absorption band at about 32700 $\mathrm{cm^{-1}}$ of nickelocene has been assigned to an intramolecular CT band by Scott and Becker.[33] Therefore, the above value of E_1^{CT}

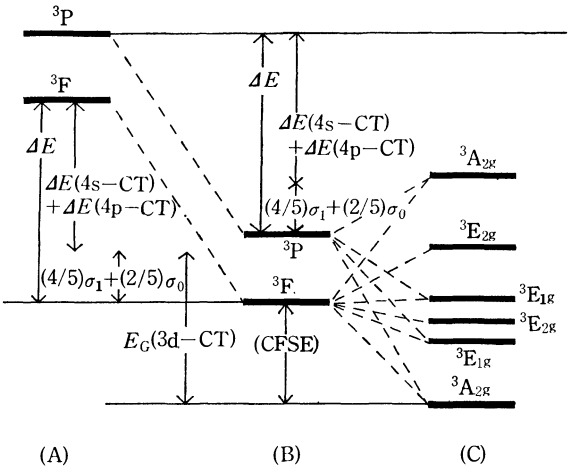

Fig. 1. Schematic illustration of the relation between the quantities ΔE, ΔE(4s-CT)+ΔE(4p-CT), $(4/5)\sigma_1+(2/5)\sigma_0$, E_G(3d-CT) and CFSE.
(A) represents the position of energy level of the ionic configurations. (B) represents the energy level after the uniform shift of Eq. 7. (C) is the final energy level.

implies that the CT state is the state of the strong mixing of the CT and the appropriate locally-excited configurations. A more detailed study of the resonance integrals in the CI and MO treatments and an analysis of the CT states will be undertaken in the future.

The E_G (3d-CT) value of −5.28 eV was obtained for the ground-state stabilization energy due to the 3d-CT, which is considerably larger than the value of Cu(en)$_2$(NCS)$_2$, E_G(3d-CT)$=-2.35$ eV. As can be seen from Fig. 1, E_G(3d-CT) is equal to the sum of the ground-state stabilization energy measured from the center of gravity of the ^{3}F term and the average stabilization energy due to 3d-CT, ΔE(3d-CT) of Eq. (9). The former should be equal to the crystal-field stabilization energy (CFSE) of the CF treatment, CFSE$=-2.89$ eV. From the values of $D_s=3290$ $\mathrm{cm^{-1}}$ and $D_t=1696$ $\mathrm{cm^{-1}}$ obtained in the CF treatment, we can estimate

$$\sigma_1 = 18.38\,\mathrm{kK}: \qquad \sigma_0 = 4.66\,\mathrm{kK}$$

following to Eqs. (8) and (10), neglecting D_s^{ion} and D_t^{ion}. Thus, we obtain:

$$E_G(3d-CT) = \mathrm{CFSE} - (4/5)\sigma_1 - (2/5)\sigma_0 = -4.94\,\mathrm{eV}$$

which agrees reasonably well with the value obtained from the CI calculation, E_G(3d-CT)$=-5.28$ eV. Hence, the large value of E_G(3d-CT) of nickelocene seems reasonable.

Although, the physical meaning of the average energy of Eq. (8) is complicated, it is expected, for the theory to be self-consistent as a whole, that the $\bar{E}$ derived from σ_1 and σ_0 are equal. Substituting the values of β_1, β_0, E_1^{CT}, and E_1^{CT} tabulated in Table 3 into the right-hand side of Eq. 8, the average energy, $\bar{E}$, is determined to be:

Calcn. 1 $\bar{E}=-7.32$ eV from σ_1
$\bar{E}=-9.35$ eV from σ_0
average $\bar{E}=-8.34\pm1.0$ eV

Calcn. 2 $\left.\begin{array}{l}\overline{E} = -8.43\,\text{eV from } \sigma_1 \\ \overline{E} = -9.03\,\text{eV from } \sigma_0\end{array}\right\}$

average $\overline{E} = -8.76 \pm 0.3\,\text{eV}$

In Calcn. 2 a much smaller deviation of $\overline{E}$ was obtained, similarly to the case of the d-d transition energies. The good agreement between the $\overline{E}$'s obtained above implies that the values of β_1, β_0, E_1^{CT} and E_0^{CT} obtained in the CI treatment are "self-consistent."

Oxygen Exchange between Arsenate Ions and Water of Crystallization in the Course of Hydration and Dehydration of Disodium Hydrogen Arsenate and Sodium Dihydrogen Arsenate

Akiko Okumura and Nobukazu Okazaki

Department of Chemistry, Nara Women's University, Nara 630

(Received October 23, 1972)

Oxygen exchange between arsenate ions and crystal water in the course of hydration of anhydrous salt with water vapor and subsequent dehydration of the resulting hydrate has been studied with disodium hydrogen arsenate and with sodium dihydrogen arsenate. There is a remarkable difference in the exchange behavior between the anhydrous salt prepared by dehydration *in vacuo* at room temperature and that prepared at higher temperatures. In the former, the degree of exchange increases with increasing molar ratio of the reactants(arsenate to water), while in the latter, it is independent of the molar ratio. In the exchange reactions of the anhydrous salt prepared at higher temperatures, the number of exchangeable oxygen atoms of an arsenate ion is found to be 0.5 (that is, one atom for two arsenate ions) for disodium hydrogen arsenate, and 4 for sodium dihydrogen arsenate.

In previous publications,[1-3] we reported on the studies of deuterium and oxygen-18 exchange reactions between crystal water and anhydrous salt(or lower hydrate) in the course of hydration of anhydrous salt with water vapor and subsequent dehydration of the resulting hydrate. The characteristics of these reactions are: 1) With crystalline anhydrous salt prepared by dehydration at higher temperatures(*ca.* 100 °C), the amount of anhydrous salt which takes part in the exchange reaction is always equivalent to the amount of water used for hydration. On the other hand, with highly dispersed anhydrous salt prepared by dehydration *in vacuo* at room temperature, the amount of anhydrous salt which takes part in the exchange reaction increases, for a given amount of water, with increasing amount of anhydrous salt used. 2) In the exchange reactions of oxalic acid,[1] copper sulfate monohydrate,[2] sodium dihydrogen phosphate and racemic acid,[3] all the hydrogen atoms which are easily replaced by the hydrogen atoms of water in aqueous solutions are exchangeable for those of crystal water. The oxygen-18 exchange of copper sulfate monohydrate has shown that scrambling of the "fifth" water molecule of copper sulfate pentahydrate with the remaining four molecules of crystal water occurs in the process of hydration and dehydration.[2] In these exchange reactions, exchange equilibrium is reached during the process of hydration and dehydration. Thus, with regard to the exchangeability of hydrogen or oxygen atom, the exchange reactions of anhydrous salt with crystal water seem to be analogous to the exchange reactions in solution. The present paper describes the oxygen exchange reactions of arsenate ions with crystal water in the course of hydration and dehydration, in one of which the exchangeability of arsenate oxygen has been found to differ greatly from that of arsenate oxygen in aqueous solutions.

Experimental

Materials. Disodium hydrogen arsenate heptahydrate(Special grade, JIS) was used without further purification. Sodium dihydrogen arsenate monohydrate was prepared as follows. Arsenic acid(60%, chemically pure) was neutralized to its first neutralization point with a sodium hydroxide solution(Special grade, JIS). The salt obtained on concentrating the solution was recrystallized twice from water. Oxygen-18 water(excess density *ca.* 800γ) was obtained by the fractionation of water. Its deuterium content was normalized by repeated exchange with ammonium chloride. It was refluxed with alkaline permanganate and distilled twice.

Preparation of Anhydrous Salts. Two kinds of anhydrous salts were studied both for disodium hydrogen arsenate and for sodium dihydrogen arsenate. One, probably in a highly dispersed state, was prepared by dehydration *in vacuo* at 30 °C. The other, crystalline, was prepared by dehydration to a constant weight at higher temperatures under the atmospheric pressure. In practice, the hydrates were partially dehydrated *in vacuo* at room temperature and then dehydrated and annealed at higher temperatures(95 °C for disodium hydrogen arsenate, 70 °C for sodium dihydrogen arsenate). To check the composition of the arsenates obtained, a portion of the anhydrous salt was heated to yield

pyro- or meta-arsenate, and the water released was collected and weighed. The amount of the water was in satisfactory agreement with the stoichiometric amount.

Procedure. The procedure was the same as that used earlier.[1] A weighed amount of anhydrous salt was hydrated in a vacuum system at a constant temperature with heavy water vapor. After the completion of hydration, which took about 10 hours, the hydrate was dehydrated by condensing the water vapor in a trap cooled with a dry ice-ethanol bath. The water obtained was purified thoroughly, and its excess density was measured by the flotation method. The excess density of oxygen-18 water is, to a good approximation, proportional to its oxygen-18 atom fraction in excess of the natural.

Results and Discussion

The reaction can be formulated as follows:

$$(Na,\ H)_3AsO_4 + H_2{}^{18}O \rightleftarrows \text{Hydrate} + \text{Anhydrous salt} \rightleftarrows (Na,\ H)_3AsO_3{}^{18}O + H_2O.$$

The balance of oxygen-18 atoms in this reaction is,

$$M_wD_i = M_wD_f + n_OM_s'k_OD_f, \quad (1)$$

where D_i and D_f: the excess oxygen-18 atom fractions of water before hydration and after dehydration respectively,

M_w: the number of moles of water used for the hydration,

M_s': the number of moles of the arsenate taking part in the exchange reaction,

n_O: the number of exchangeable oxygen atoms in an arsenate ion,

k_O: the oxygen-18 partition coefficient between the arsenate and the hydrate water ($k_O \simeq 1$).

Eq. (1) can be rewritten as:

$$(D_i - D_f)/D_fk_O = \Delta D/D_fk_O = n_O(M_s'/M_w). \quad (2)$$

As the anhydrous salt was always used in excess, a part of it is left unhydrated even after the completion of hydration. If, of the M_s moles of the anhydrous salt used, M_s' moles take part in the exchange reaction, Eq. (2) can be written as:

$$\Delta D/D_fk_O = n_O(M_s'/M_s)(M_s/M_w). \quad (3)$$

Accordingly, if we plot the result of the exchange reaction, taking $\Delta D/D_fk_O$ as ordinate and M_s/M_w as abscissa, the slope of a line drawn through the plotted point and the origin gives the value of $n_O(M_s'/M_s)$, and hence of (M_s'/M_s).

As a special case, when the anhydrous salt and the hydrate water take part in the exchange reaction in the equivalent proportion corresponding to the formula $(Na,H)_3AsO_4 \cdot mH_2O$, $mM_s' = M_w$. Eq. (2) then becomes:

$$\Delta D/D_fk_O = n_O/m. \quad (4)$$

In this case the value of $\Delta D/D_fk_O$ becomes independent of M_s/M_w. This situation is realized when the exchange reaction occurs exclusively in the reaction zone and the hydrate lattice.[1]

Disodium Hydrogen Arsenate. The results obtained with disodium hydrogen arsenate are shown in Fig. 1. Hydration was carried out at 20 °C with water vapor of *ca* 10 mmHg, and dehydration at 30 °C *in vacuo*. It will be seen that there is a qualitative difference in exchange behavior between the anhydrous salt prepared *in vacuo* at room temperature and that prepared at 95 °C. In the former case, the degree of oxygen exchange, $\Delta D/D_fk_O$, increases with increasing excess of the anhydrous salt. The line passing through the plotted points and the origin gives a slope $(=n_O(M_s'/M_s))$ of 1.71. If the value of n_O is taken to be 4, which is the case with the oxygen exchange of arsenate ions in aqueous solution, $M_s'/M_s = 0.43$. That is, 43% of the anhydrous salt used takes part in the exchange reaction irrespective of the value of the molar ratio M_s/M_w. This fact suggests that the enhanced exchangeability of the anhydrous salt prepared at room temperature is the property of the anhydrous salt itself. In this case, the exchange reaction probably occurs mainly on the surface of the highly dispersed solid, M_s'/M_s being a measure of surface-to-bulk ratio of the anhydrous salt.

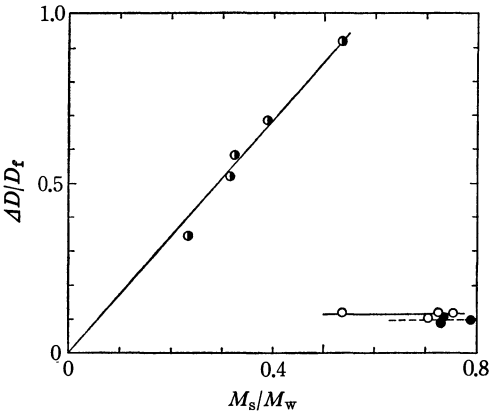

Fig. 1. Degree of exchange $\Delta D/D_f$ as a function of the ratio of moles of anhydrous disodium hydrogen arsenate to moles of water, M_s/M_w. ◑, Oxygen exchange of the anhydrous salt prepared by dehydration *in vacuo* at 30 °C. ○: Oxygen exchange of the anhydrous salt prepared at 95 °C, ●: Deuterium exchange of the anhydrous salt prepared at 95 °C.

On the other hand, with the anhydrous salt prepared at 95 °C, the value of the degree of oxygen exchange, $\Delta D/D_fk_O$, is 0.1, independent of the values of M_s/M_w. The anhydrous salt and the hydrate water react with each other in a fixed proportion. From (4) we get:

$$n_O/m = 0.1, \quad (5)$$

where m is the number of crystal water of the hydrate formed on hydration of the anhydrous salt.

By using the deuterium exchange reaction in the process of hydration and dehydration, we can estimate the value of m.[3] For the deuterium exchange, an appropriate equation corresponding to (2) is

$$\Delta D/D_fk_D = M_s'/2M_w, \quad (6)$$

where k_D is the deuterium partition coefficient between the arsenate and crystal water in the hydrate. The deuterium exchange of the anhydrous salt prepared at 95 °C was studied under the same conditions as those of the oxygen-18 exchange (Fig. 1). It will be seen that the values of $\Delta D/D_f$ are independent of M_s/M_w. The anhydrous salt and the hydrate water take part in the exchange reaction in the stoichiometric

proportion determined by the formula, $Na_2HAsO_4 \cdot mH_2O$. By using the relation, $mM_s' = M_w$, and the mean value of $\Delta D/D_f = 0.095$, Eq. (6) can be written as:

$$m = k_D/0.19. \quad (7)$$

The value of k_D was determined as follows. Disodium hydrogen arsenate labelled with deuterium was prepared by crystallization from HDO solution. The salt was dehydrated *in vacuo* at 25 °C to remove the crystal water. The anhydrous salt obtained was then heated to 200 °C to yield pyroarsenate. The excess density of the water obtained in each step was measured by the flotation method. The value of k_D is given by the ratio of the excess density of water obtained in the second step to that in the first step. Four determinations yielded a value $k_D = 0.78 \pm 0.01$.

The value of m is calculated to be 4.1 from Eq. (7). Tetrahydrate of disodium hydrogen arsenate has not been reported. Pentahydrate is the nearest to it in composition among the known hydrates of disodium hydrogen arsenate.[4] Thus, the deuterium and the oxygen-18 exchange reactions under the given conditions proceed by way of the formation of penta- or tetra-hydrate. From Eq. (5) we obtain $n_O = 0.5$ or 0.4, that is, in the oxygen-18 exchange reaction in question, the number of exchangeable oxygen atoms is 0.5 per arsenate ion, or an atom for two arsenate ions.

It may be suspected that the exchange reaction does not attain the exchange equilibrium during the process of hydration and dehydration. To check this point, the anhydrous arsenate, after being hydrated partially with heavy water vapor, was kept at a constant temperature for a definite time before dehydration. The conditions for the hydration and dehydration were the same as those shown in Fig. 1. Deuterium exchange as well as oxygen exchange was studied, the results being shown in Fig. 2. The exchange reaction does not proceed appreciably in the partially hydrated arsenate at 20 °C, but does so at 30 °C and 40 °C. The data at 30 °C were obtained by using the doubly labelled water $HD^{18}O$. In this case, both the deuterium and oxygen-18 exchange reactions can be studied in a single process of hydration and dehydration. After the dehydration, the deuterium and the oxygen-18 contents of the water were measured separately.

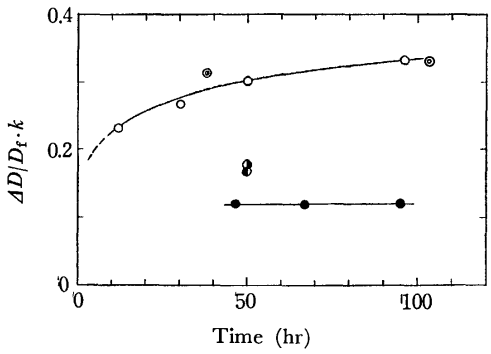

Fig. 2. Oxygen and deuterium exchange reactions in the partially hydrated disodium hydrogen arsenate. ●: Oxygen exchange; 20 °C, ◑: Oxygen exchange; 30 °C, ◐: Deuterium exchange; 30 °C, ○: Oxygen exchange; 40 °C, ◎: Deuterium exchange; 40 °C.

For the deuterium exchange it has been shown[1-3] that, during the process of hydration and dehydration, exchange equilibrium is established between the hydrate water and that part of the anhydrous salt which has taken part in the exchange reaction, and that the progress of the exchange reaction in the partially hydrated arsenate is due to the participation of fresh anhydrous arsenate which has not taken part in the exchange reaction. Fig. 2 shows that the progress of the oxygen-18 exchange keeps pace with that of the deuterium exchange. This suggests that also for the oxygen-18 exchange reaction exchange equilibrium is established during the process of hydration and dehydration, and that the progress of the exchange in partially hydrated arsenate is due to the participation of the fresh part of the anhydrous arsenate.

The number of exchangeable oxygen atoms in an arsenate ion, n_O, can also be calculated without the knowledge of the value of m. By dividing Eq. (2) by Eq. (6), we obtain:

$$k_D(\Delta D/D_f)_O/k_O(\Delta D/D_f)_D = 2n_O, \quad (8)$$

where the suffixes O and D refer to the oxygen and the deuterium exchange reactions, respectively. Here it has been assumed that $(M_s'/M_w)_D = (M_s'/M_w)_O$. The parallel progress of the oxygen and deuterium exchange reactions (Fig. 2) suggests the assumption to be probable. It is valid with doubly labelled water, since the oxygen and the deuterium exchange reactions are studied in a single process of hydration and dehydration. Fig. 2 shows that $(\Delta D/D_f)_O/k_O \simeq (\Delta D/D_f)_D/k_D$ for the experiments at 40 °C and 30 °C with doubly labelled water. Hence, $2n_O \simeq 1$, or $n_O \simeq 0.5$, in agreement with the result obtained above.

In the exchange reactions of the anhydrous salt prepared at room temperature, it has been shown that, assuming all four oxygen atoms of arsenate ion to be exchangeable, 43% of the anhydrous arsenate used takes part in the exchange reaction. If two of the four oxygen atoms are assumed to be exchangeable, 86% of the anhydrous arsenate should participate. However, the number of exchangeable oxygen atoms should not be smaller than 2, for then more than 100% of the anhydrous arsenate used should have taken part in the exchange reaction. Thus there is a remarkable difference in the number of exchangeable oxygen atoms between the crystalline and the highly dispersed anhydrous arsenate. In the latter, the ions would be rather loosely bound with each other, and the exchange reaction with adsorbed water or with hydrate water may be considered to be more or less analogous to the exchange reaction in solution. On the other hand, with the crystalline anhydrous arsenate, the exchange reaction would be controlled by the geometry of the crystal lattice of the anhydrous arsenate, and it is possible that the number of exchangeable oxygen atoms is also limited by the crystal structure of the anhydrous arsenate. In the absence of information on the crystal structures of the anhydrous and the

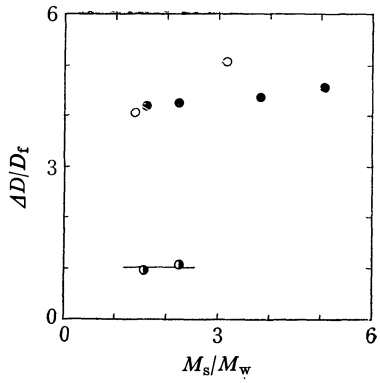

Fig. 3. Degree of exchange $\Delta D/D_f$ as a function of the ratio of moles of anhydrous sodium dihydrogen arsenate to moles of water, M_s/M_w. ○: Oxygen exchange of the anhydrous salt prepared *in vacuo* at 22 °C, ●: Oxygen exchange of the anhydrous salt prepared at 70 °C, ◑: Deuterium exchange of the anhydrous salt prepared at 70 °C.

hydrated forms of the arsenate, we cannot give a picture of hydration and dehydration, or an explanation of the number of exchangeable oxygen atoms.

Sodium Dihydrogen Arsenate. The results obtained with sodium dihydrogen arsenate are given in Fig. 3. For the anhydrous salt prepared *in vacuo* at 30 °C, hydration was carried out at 30 °C with water vapor of *ca* 16 mm, and dehydration at 30 °C *in vacuo*. For the anhydrous salt prepared at 70 °C, hydration was carried out at 22 °C with water vapor of *ca* 13 mm, and dehydration at 22 °C *in vacuo*. The characteristics of the exchange reaction of the crystal water may be seen, but the difference in behavior between the two kinds of anhydrous arsenate is not so well marked as in the case of disodium hydrogen arsenate. The values of $\Delta D/D_f$ for the anhydrous arsenate prepared at 70 °C increase with increasing M_s/M_w. From the results of deuterium exchange of the anhydrous arsenate prepared at 70 °C, the number of crystal water of the hydrate formed on hydration of the anhydrous salt, m, can be calculated by the relation:

$$m = k_D/(\Delta D/D_f)_D. \quad (9)$$

where k_D is the deuterium partition coefficient between the dihydrogen arsenate ion and crystal water in the hydrate of sodium dihydrogen arsenate. This was determined as follows. $NaHDAsO_4 \cdot HDO$ was prepared by crystallization from HDO solution. The salt obtained was dehydrated *in vacuo* at 30 °C to separate the crystal water, and then the resulting anhydrous salt was heated at 350 °C to yield metaarsenate. k_D is given by the ratio of the deuterium atom fraction of the arsenate hydrogen, that is, that of the water obtained in the second step, to that of the crystal water. Three determinations yielded a value $k_D = 0.845 \pm 0.002$. By using this value and that of $\Delta D/D_f$ for the deuterium exchange (Fig. 3), m is calculated to be 0.85 from Eq. (9). The exchange reaction between the crystal water and the arsenate ion in sodium dihydrogen arsenate proceeds through the formation of monohydrate under the condition of the experiments.

By substituting the value of m obtained and the value of $\Delta D/D_f$ of the oxygen exchange (Fig. 3) in Eq. (4), the number of exchangeable oxygen atoms of sodium dihydrogen arsenate, n_O, is calculated to be 4.3 ± 0.1. In the exchange reaction of sodium dihydrogen arsenate, all four atoms of the arsenate oxygen are exchangeable. This is in strong contrast to the exchange reaction of disodium hydrogen arsenate, where one atom for two arsenate ions is found to be exchangeable.

The authors wish to thank Professor Shinichi Kawaguchi of Osaka City University for his helpful discussions and Mrs. Kazuko Ando for her assistance.

Acidic properties of Binary Metal Oxides

(Received February 3, 1973)

Eighteen binary metal oxides consisting of TiO_2–M_mO_n, ZnO–M_mO_n and Al_2O_3–M_mO_n (M_mO_n: metal oxide) were prepared by the usual co-precipitation method, their acid amounts and strengths being determined by *n*-butylamine titration using various acid-base indicators. The acid strengths of fourteen of the tested binary oxides of molar ratio 1 : 1 were found to be remarkably higher than those of the component single oxides. High acid strengths were as follows: $H_0 \leqq -8.2$ for TiO_2–SiO_2, $H_0 \leqq -5.6$ for TiO_2–Al_2O_3 and Al_2O_3–ZrO_2 and $H_0 \leqq -3$ for TiO_2–CdO, TiO_2–SnO_2 and ZnO–SiO_2. The acid amounts of sixteen binary oxides were larger than those of the component oxides. The effect of the composition of binary oxides on acidity was examined for TiO_2–Al_2O_3, ZnO–Al_2O_3 and Al_2O_3–ZrO_2. The acidity maxima appearing for TiO_2–Al_2O_3 and ZnO–Al_2O_3 were found to be of molar ratio $\simeq 9 : 1$ and for Al_2O_3–$ZrO_2 \simeq 3 : 2$. A fairly good correlation has been demonstrated between the observed highest acid strengths and the average electronegativities of metal ions of binary oxides.

Some binary metal oxides such as SiO_2–Al_2O_3, SiO_2–ZrO_2, SiO_2–MgO and Al_2O_3–Bi_2O_3 are known to show acidic property and have long been used as solid acid catalysts.[1] These combinations of oxides contain either SiO_2 or Al_2O_3, both essential constituents of clay minerals. However, combinations such as TiO_2–ZnO, TiO_2–ZrO_2 and ZnO–Bi_2O_3 containing no clay mineral component were recently found to exhibit remarkable acidic property[2-6] and catalytic activity.[2,4] Since many other combinations are also expected to exhibit acidic property and it is considered important for theoretical development and practical use of mixed oxides to find combinations of oxides giving acidic property and to correlate it with the physico-chemical properties of metal oxides, we prepared various binary oxides and examined their acid amounts and sterngths. The binary oxides are restricted to colorless materials to which an acidity measurement by the amine titration method using indicators can be applied. The observed acid strengths are correlated with the electronegativities of metal ions of binary oxides. The effect of the composition of some binary oxides on acidic property was also examined.

Experimental

Preparation of Metal Oxides. Binary metal oxides were prepared by the thermal decomposition of their hydroxides at 500 °C for 3 hr. in air. The hydroxides were co-precipitated by adding 28% of ammonia water to the mixed aqueous solution of water soluble metal salts (Table 1). The precipitates were washed thoroughly to remove adhering anions such as chloride ion. Each single oxide was prepared similarly as above. Binary oxides containing silica were prepared by kneading the wetted hydroxides of silicon and other metal and calcining at 500 °C for 3 hr after drying at 70—80 °C. The silicon hydroxide was prepared from aqueous sodium silicate by adding aqueous hydrochloric acid and drying at 70—80 °C for 3 hr. The amount of oxide in the binary oxides containing silica was determined by gravimetric analysis of the oxide obtained by calcining the hydroxide.

TABLE 1. STARTING MATERIALS OF OXIDES

Oxides	Starting materials	Oxides	Starting materials
TiO_2	$TiCl_4$	Bi_2O_3	$BiCl_3$
ZnO	$ZnCl_2$	SiO_2	Na_2SiO_3
Sb_2O_5	$SbCl_5$	PbO	$Pb(NO_3)_2$
ZrO_2	$ZrOCl_2$	CdO	$CdCl_2$
Al_2O_3	$AlCl_3$	SnO_2	$SnCl_2$
MgO	$MgCl_2$		

Measurement of Specific Surface Area and Acidity. Specific surface area was obtained by applying the BET method to the adsorption isotherm of nitrogen at −196 °C. Surface acidity was measured by *n*-butylamine titration using the following indicators: methyl red ($pK_a = +4.8$), phenylazonaphthylamine (+4.0), *p*-dimethylaminoazobenzene (+3.3), benzeneazodiphenylamine (+1.5), dicinnamalacetone (−3.0), benzalacetophenone (−5.6) and anthraquinone (−8.2).

X-Ray Diffraction. X-Ray powder diffraction diagrams were recorded with an X-ray diffractometer (Rigakudenki, Geigerflex SG-7). Nickel filtered CuK_α was used as X-ray radiation source.

Results and Discussion

Single Oxides and Binary Oxides Containing Titanium Oxide. The acidity distribution of single oxides which are component oxides of binary oxides are shown in Table 2, together with the surface areas. SiO_2 gave no X-ray diffraction lines indicating its amorphous form. Al_2O_3 gave only weak diffraction lines indicating its partial crystal and TiO_2, ZrO_2, CdO, SnO_2, ZnO, Sb_2O_5 and PbO gave strong diffraction lines indicating each crystal. We see that the acid strengths of the single oxides are generally weak ($H_0 > +1.5$), TiO_2 and ZnO weaker than those observed previously.[2] This is considered to be due to the difference in the mode of preparation.

a) Color of the indicator (pK_a = +6.8) changed.

The acid amounts and strengths of the binary oxides containing TiO_2 (molar ratio=1) are shown in Table 3. The X-ray diffraction diagrams of TiO_2–SiO_2 and TiO_2–ZrO_2 showed only diffused or weak diffraction lines and were assumed to be amorphous. TiO_2–Al_2O_3 gave only the diffraction lines of TiO_2. Thediffraction lines of TiO_2–MgO, TiO_2–Bi_2O_3, TiO_2–CdO and TiO_2–SnO_2 were those of the component oxides. The results indicate the binary oxides are not mechanically mixed oxides. The acid strengths of TiO_2–SiO_2 and TiO_2–ZrO_2, found to be surprisingly high, were $H_0 \leqq -8.2$ and those of TiO_2–Al_2O_3 and TiO_2–CdO, also high, −5.6 and −3, respectively. Since SiO_2–ZrO_2 is known to have very high acid strength ($H_0 \leqq -8.2$),[7] it can be said that the combinations of oxides of metals (Si, Ti and Zr) which belong to the same fourth group in the periodic table show the highest acid strength. All the binary oxides containing TiO_2 showed higher acid strength than each component oxide. The acid amount at a certain acid strength per unit surface area of any binary oxide was larger than the sum of the acid amounts divided by the sum of the surface areas of the component oxides. The results indicate that the new acidic sites which differ from those of single oxides are created on the surface of binary oxides.

The acidity change with variation of composition was examined in the case of TiO_2–Al_2O_3. As shown in Fig. 1, the acidity maximum was observed when the molar ratio of TiO_2–Al_2O_3 is about 1 : 9. It is interesting to note that the acidity maximum of SiO_2–Al_2O_3 appears when the molar ratio is about 8 : 2,[8] despite the fact that both TiO_2 and SiO_2 are oxides

of metals of the same fourth group in the periodic table and that the acidity maximum of TiO_2–ZnO[2] appears when the molar ratio is 1 : 9 as in the case of TiO_2–Al_2O_3. Recently, TiO_2–Al_2O_3 was reported to show high catalytic activity for the synthesis of aniline from phenol and ammonia.[9] The high activity can be now understood to be due to its high acid strength. SiO_2–TiO_2 shows higher activity than SiO_2–Al_2O_3 for the aniline synthesis.[10]

Binary Oxides Containing Zinc Oxide or Alumina and Other Binary Oxides. The acidity distribution of the binary oxides containing ZnO or Al_2O_3 and other binary oxides (molar ratio=1) is shown in Table 3. According to X-ray diffraction, ZnO–SiO_2 and Al_2O_3–ZrO_2 were amorphous and ZnO–MgO gave only the diffraction lines of ZnO. ZnO–Al_2O_3, ZnO–ZrO_2, ZnO–Sb_2O_5 and ZnO–PbO gave diffraction lines differing from those of the component oxides. The results indicate that these binary oxides are not mechanically mixed oxides. The binary oxides which showed high acid strength were ZnO–SiO_2, Al_2O_3–ZrO_2 and ZrO_2–CdO. The acid strengths of binary oxides containing ZnO are relatively weak. The acidity changes of ZnO–Al_2O_3 and Al_2O_3–ZrO_2 with composition are shown in Figs. 2 and 3, where the acidity maxima are found when the molar ratios are

9) R. S. Parker, Japanese Pat. Sho 42-23571.
10) K. Tanabe, M. Ito, and M. Sato, *Chem. Commun.*, in press.

approximately 1 : 9 and 3 : 2, respectively. Many binary oxides show higher acid amount and strength than each component oxide (Table 3). The acid strengths of ZnO–MgO and Al_2O_3–Sb_2O_5 were the same as those of one of the component oxides, whereas their acid amounts per unit surface area were smaller. In the case of ZnO–Sb_2O_5 and ZnO–PbO, both acid strength and amount were lower than those of the component oxides. It was reported that both SiO_2 and ZnO are almost inactive for the isomerization of butenes, although the combination of both oxides is active.[11] The activity is considered to be due to the action of strong acid sites generated on the surface of SiO_2–ZnO.

Correlation between Acid Strengths of Binary Oxides and Electronegativities of Metal Ions of Metal Oxides. The observed highest acid strengths of binary oxides (molar ratio=1) are plotted against the algebraically averaged electronegativities of metal ions in Fig. 4, where the data indicated by open circles were cited from the literature (Ref. 2 for TiO_2–ZnO; Ref. 7 for SiO_2–ZrO_2; Ref. 12 for SiO_2–Al_2O_3, SiO_2–Y_2O_3, SiO_2–La_2O_3). The electronegativity values of various metal ions were cited from the work of Tanaka and Ozaki.[13] The highest acid strengths were found to increase with the increase of the algebraically averaged electronegativities. The correlation between the acid strengths and the geometrically averaged values of electronegativities was slightly worse than but almost the same as that shown in Fig. 4. Since the electronegativity of metal ion (Me^{+n}) is related to its acid strength (pK_a) as shown in $Me^{+n}+H_2O \rightleftarrows [Me(OH)]^{+(n-1)}+H^+$, the relation given in Fig. 4 seems to be reasonable. However, the reason why the algebraically or geometrically *averaged* values of electronegativities are correlated with the acid strengths is not yet clear. Nevertheless, the correlation in Fig. 4 is useful for predicting the acid strengths of unknown binary oxides.

Solvent Effect under High Pressure. Participation of Solvent in the Activated Complex in the Menschutkin Reaction

Katsuhiro TAMURA, Yoshiaki OGO, and Tatsuya IMOTO

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received February 8, 1973)

Rates of the reaction between 3,5-lutidine with ethyl iodide have been measured at 50 °C over the pressure range 1—1,940 kg/cm² in benzene-nitrobenzene mixtures. The solvation number and average pressure within the solvation-shell of activated complex have been estimated from the rates and the compression of solvent. The solvation number was almost independent of solvent composition, but not the average pressure within the solvation-shell. Estimation of the structural term of the activation volume $\Delta_1 V^{\neq}$ in the reaction has been discussed. The logarithms of the rate constants showed a linear relation with the E_T-values under atmospheric pressure.

The fundamental equation for the effect of pressure on the rate constant of a chemical reaction is

$$\left(\frac{\partial \ln k}{\partial P}\right)_T = -\frac{\Delta V^{\neq}}{RT} \quad (1)$$

where $\Delta V^{\neq}$ is the activation volume of the reaction, *i.e.* the difference of the partial molar volumes of the reactants in the transition state and the initial state. The activation volume gives important information on the structure and properties of the transition state. The activation volume is of use for the mechanistic interpretation of chemical reactions since there is no method for investigating the detailed shape of activated complexes.

The reaction of alkylhalides with tertiary amines, known as the Menschutkin reaction, is a well-known heterolytic reaction under high pressure. The importance associated with the "ionic-solvation" component of $\Delta V^{\neq}$ implies that the magnitude of activation volume should depend on the nature o solvent. There are experimental evidences that $\Delta V^{\neq}$ is solvent-dependent. An extensive study of the influence of the solvent on the Menschutkin reaction under high pressure was made by Gonikberg and his collaborators.[1] The solvation number and the average pressure within the solvation-shell in the transition state for the Menschutkin reaction was estimated by Kondo *et al.*[2] Their investigation deals with the average values of various solvents. Actually, the values would change because of the variation of the influence of solvent on the activated complex if the nature of solvent

(solvent polarity) is altered.

Some attempts have been made to correlate the rate constants for the Menschutkin reactions with the polarity parameters of solvents representing various aspects of solvation. A solvent dielectric constant has been widely used as a measure of solvent polarity. However, it represents only a single macroscopic characteristic of solvent and cannot express adequately all the interactions between solute and solvent molecules. Thus empirical parameters of solvent polarity have been proposed for understanding the complexities of molecular interactions in solution. E_T-values are known as a solvent polarity scale which covers a greater range of solvents. The scale was obtained by determining the molar transition energy E_T for the solvatochromic band in the spectrum of a pyridinium *N*-phenolbetaine in various solvents.

This work deals with the scale as regards the reaction of 3,5-lutidine with ethyl iodide. The solvation number and average pressure within the solvation-shell in transition state for benzene-nitrobenzene mixtures were obtained by means of the compression of solvents. The relationships between the polarity of the solvent and the reaction rate were studied by the use of the E_T-value as an empirical parameter of solvent polarity.

Experimental

Materials. Commerical 3,5-lutidine was dried overnight with sodium hydroxide and distilled twice at reduced pressure; bp 59 °C/14 mmHg, n_D^{25} 1.5030. Commerical ethyl iodide of special grade was washed with dilute potassium hydroxide solution and water, dried with calcium chloride and filtered. After addition of sodium metal to the filtered substance, the solution was distilled at atmospheric pressure; bp 71.3 °C, n_D^{20} 1.5131.

Commercial benzene and nitrobenzene of special grade were purified according to method given in literature;[3] n_D^{20} (benzene) 1.5013, n_D^{20} (nitrobenzene) 1.5526.

N-(4-Hydroxy-3,5-diphenyl-phenyl)-2,4,6-triphenylpyridinium betaine, a color change indicator used for the measurement of the E_T-value, was synthesized as follows. 2,6-Diphenyl-4-aminophenol was prepared from dibenzyl ketone and sodium nitromalonaldehyde monohydrate synthesized from mucobromic acid. Betaine was obtained from the reaction between this substance and 2,4,6-triphenylpyrylium perchlorate synthesized from acetophenone and benzaldehyde.[4] The betaine was recrystallized in a methanol-water mixture (1 : 1); mp 207—280 °C. Found; C, 83.58; H, 5.26; N, 2.61%. Calcd for $C_{41}H_{33}O_3N$: C, 83.79; H, 5.66; N, 2.38%.

The E_T-values were determined for the solvatochromic band in the spectrum of a pyridinium betaine by using the following equation.

$$E_T = h\nu = 2.859 \times 10^5/\lambda_{max} \text{ (in Å)} \qquad \text{(kcal/mol)}$$

Procedures. Solutions of equimolar concentration (0.25 M) of 3,5-lutidine and ethyl iodide were introduced into a 5-ml reaction cell, and placed in a high pressure apparatus held at 50±0.12 °C during the reaction and quickly pressurized. After decompression the reaction cell was emptied into a flask containing 15-ml water. The reaction product was extracted by vigorous shaking with water. A portion of the aqueous layer was analyzed by titration with a silver nitrate solution.

E_T-values were measured with a Hitachi 139-type UV-VIS spectrophotometer.

Measurement of Compression. The compression, $K = (V_0 - V_p)/V_0$, was determined by the measurement of the solvent volumes at atmospheric pressure V_0 and at P atom pressure V_p. The experiments for the benzene-nitrobenzene mixtures were carried out at 50 °C by means of Adams' method using a piezometer of about 11-ml capacity.[5] The pressure was measured by a Heise Bourdon-type gauge, the accuracy being checked with a pressure balance (free-piston pressure gauge). The rates of compression were in the order of 100 atm/min. The volume changes of Pyrex glass and mercury at high pressure was corrected with the values in literature.[6]

Results and Discussion

The rate constants of the reaction of 3,5-lutidine with ethyl iodide in benzene–nitrobenzene mixtures at 50 °C over the pressure range 1—1940 kg/cm² are summarized in Table 1. All the reaction rates followed second-order equation. The rate constants increased with an increase in pressure and concentration of nitrobenzene. The unexpected large rate constant at 0.8 mole fraction nitrobenzene and 1940 kg/cm² pressure suggests an unusual high concentration of reactants resulting from the freezing of solvent. The freezing temperatures of benzene and nitrobenzene under 2000 kg/cm² have been reported to be 58.0 and 49.5 °C, respectively.[7]

Estimation of Activation Volume. In order to evaluate ΔV^* it is necessary to confirm the functional dependence of rate constant upon pressure. Derivation of an analytical expression for the dependence has been discussed by various workers. Golinkin *et al.*[8] concluded that the quadratic function (3) provided the best representation of the dependence of logarithm of rate constant on pressure for some organic reactions. We checked the following three functions by the least-mean-squares method. It was concluded that a second-order polynomial (3) gives the best description of this system.

$$\ln k = A + BP \tag{2}$$

$$\ln k = A + BP + CP^2 \tag{3}$$

$$\ln (k/k_o)/P = A + BP^{0.523} \tag{4}$$

It is assumed in Eq. (2) that the dependence of the logaithm of the rate constant on pressure is linear. Eq. (4) is the Benson-Berson equation modified by means of the Tait equation.

a) $n=2$, $\Delta_1 V^{\ddagger} = -18$ cm^3/mol

The functional constants of Eq. (3) and the standard deviation are given in Table 2.

Substituting Eq. (3) into Eq. (1) we obtain the following equation for the evaluation of $\Delta V^{\ddagger}$.

$$\Delta V^{\ddagger} = -RT(B+2CP) \quad (5)$$

The activation volumes at atmospheric pressure calculated by this equation are listed in Table 3.

$\Delta V^{\ddagger}$ denotes the change of partial molar volumes which occurs when the transition state is formed from the initial species as given by Eq. (6). $\Delta V^{\ddagger}$ may be also expressed by Eq. (7) by considering the solvation term of the activated complex with partial electric charge. Eq. (8) is given in terms of compression.

$$\Delta V^{\ddagger} = \overline{V}^{\ddagger} - (\overline{V}_L + \overline{V}_E) \quad (6)$$

$$= [V^{\ddagger} - (\overline{V}_L + \overline{V}_E)] - n(V_0 - V) \quad (7)$$

$$= [V^{\ddagger} - (\overline{V}_L + \overline{V}_E)] - nKV_0 \quad (8)$$

The bar represents a partial molar volume, L and E refer to 3,5-lutidine and ethyl iodide, respectively, n the number of solvent molecules incorporated into transition state (solvation number), V_0 molar volume of solvent, V molar volume of compressed solvent due to solvation, and K compression of the solvent.

By measurement of the partial molar volume of 3,5-lutidine and ethyl iodide, the partial molar volumes of both reagents were almost independent of solvent composition and were obtained as 116 and 84.3 cm^3 at 50 °C, respectively. Thus the partial molar volumes of the reactants seem to be equal to their molar volumes.

The $\Delta V^{\ddagger}$ value is the sum of $\Delta_1 V^{\ddagger}$ and $\Delta_2 V^{\ddagger}$, the former being the volume change of reacting particles themselves when they form the activated complex (structural effect), and the latter the corresponding volume change in the solvent (solvation effect). The value $\Delta_1 V^{\ddagger}$ corresponds to the first term and $\Delta_2 V^{\ddagger}$ to the second term on the right-hand side of Eqs. (7) and (8). Thus, the magnitude of K in Eq. (8) denotes the volume change due to the interaction of the surrounding solvent molecules with the activated complex, *i.e.* the compression of the solvent due to solvation. If Gonikberg's value[9] −18 cm^3/mol obtained from the reaction of pyridine with ethyl iodide can be used as the value $[V^{\ddagger} - (\overline{V}_L + \overline{V}_E)]$ in Eq. (8), the product of the solvation number and the compression, (nK), can be estimated from the observed values $\Delta V^{\ddagger}$ and V_0. Since the solvation number n can be evaluated we can estimate the average pressure within the solvation-shell of activated complex ΔP from the corresponding compression-pressure curve.

Estimation of Solvation Number and Average Pressure within Solvation-shell of Activated Complex. Eq. (9) is given by differentiation of Eq. (7) with respect to V_0 assuming that n and V are independent of external

9) M. G. Gonikberg and B. S. El'yanov, *Izv. Akad. Nauk SSSR, Otd. Khim. Nauk*, **1960**, 629.

pressure over the pressure range studied.

$$\frac{\partial \Delta V^{\neq}}{\partial V_0} = \frac{\partial}{\partial P}[V^{\neq}-(V_L+V_E)]\frac{\partial P}{\partial V_0} - n \qquad (9)$$

$$= -(\beta+n)$$

$$\beta = -\frac{\partial}{\partial P}[V^{\neq}-(V_L+V_E)]\frac{\partial P}{\partial V_0}$$

A similar equation was introduced by Gonikberg and El'yanov.[9]

If we assume that $\beta=0$, then we obtain the following expression for solvation number.

$$n = -\frac{\partial \Delta V^{\neq}}{\partial V_0} \qquad (10)$$

There is no evidence that β is zero. However, the partial molar volumes of 3,5-lutidine and ethyl iodide are nearly equal to their molar volumes. Therefore $[V^{\neq}-(V_L+V_E)]$ gives the structural effect of the activation volume $\Delta_1 V^{\neq}$. In a free-radical chain reaction without the participation of solvent, the activation volume is independent of the pressure over small pressure range. This suggests that the influence of β is negligible.

Figure 1 shows a plot of $\Delta V^{\neq}$ against V_0 under various pressures in nitrobenzene. We see that good linearity holds. The solvation number is evaluated to be 2 from the slope. Similar values have been estimated by the same plot for the other mixtures and benzene. The value K in Eq. (8) can be calculated by the use of these values. The results are listed in Table 3. Figure 2 shows the experimental results on the compression of the solvent at various pressures. The average pressures within the solvation-shell of activated complex ΔP were estimated from this graph (Table 3). The values of ΔP are not independent of solvent composition and show higher values for the solvents rich in benzene.

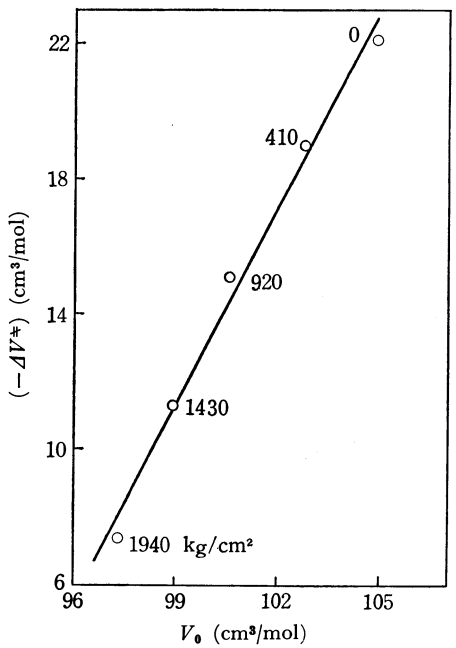

Fig. 1. Plots of activation volumes *vs.* molar volumes of solvent for the reaction of 3,5-lutidine with ethyl iodide at 50 °C in nitrobenzene.

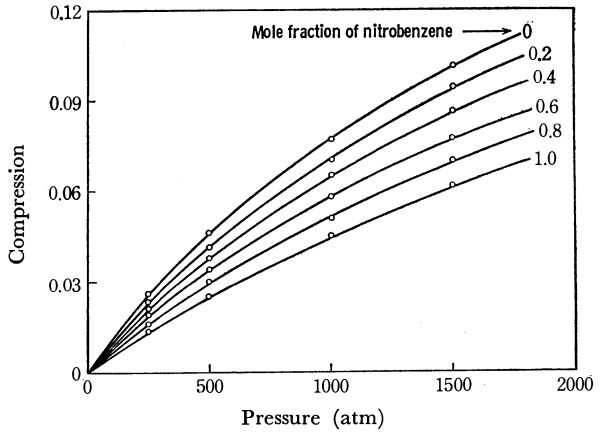

Fig. 2. Variation of the compression of solvent with pressure.

Gonikberg and El'yanov[9] tried to calculate $\Delta_1 V^{\neq}$ in the reaction of pyridine with ethyl iodide. They proposed three values of activation volume, −14, −18, and −22.5 cm³/mol, which were obtained by different analytical procedures. It seems reasonable to assume that −22.5 cm³/mol is too small since the over-all activation volume in nitrobenzene was observed to be −22.1 cm³/mol. The value −14 cm³/mol is also unfavorable since ΔP in benzene was calculated to be 2800 kg/cm², being extremely higher than the freezing pressure of benzene at 50 °C. It was concluded that the value −18 cm³/mol is reasonable. The data in Table 3 were calculated from $\Delta_1 V^{\neq}=-18$ cm³/mol. The ΔP of benzene was slightly higher than the value of freezing pressure. This was estimated by extrapolating the compression-pressure curve to freezing pressure. The unfavorable result might be due to the fact that inaccuracy of the starting data on the estimation of $\Delta V^{\neq}$ is large since the reaction in benzene takes place very slowly as compared with that in other solvents. Consequently, the value of ΔP of benzene is of low reliability.

The value ΔP can be evaluated also as follows. Isothermal compressibility is defined by $\kappa=-1/V(\partial V/$

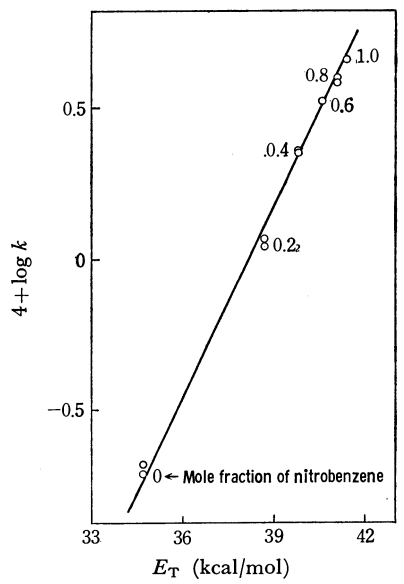

Fig. 3. Relation of $\log k$ *vs.* E_T-values.

$\partial P)_T$. We can write $\kappa'=(V_0-V_p)/V_0\cdot 1/\Delta P=K/\Delta P$ at certain pressure interval ΔP, and obtain an equation analogous to (8).

$$\Delta V^{\neq} = [V^{\neq}-(V_L+V_E)] - n\kappa' V_o \Delta P \qquad (11)$$

However, κ' at pressure interval of ΔP cnanot be obtained experimentally, and κ at atmospheric pressure is generally used as κ' for the estimation of the ΔP in Eq. (11). Thus the procedure by means of the direct measurement of K is more accurate than that with the use of Eq. (11).

E_T-value. The E_T-values and the λ_{max} of benzene–nitrobenzene mixtures at 25 °C are shown in Table 4. Figure 3 gives a plot of the E_T-values against logarithms of the rate constants under atmospheric pressure. It seems that the E_T-value is an available empirical parameter of the solvent polarity for the present reaction because of the linearity. Gonikberg and El'yanov[10] reported that the volume contraction due to solvation in the transition state is 1/6—1/14 of that in the final state in the Menschutkin reaction. It is suggested that the E_T-values are useful parameters in this type of reaction. The activation volumes and E_T-values at atmospheric pressure became greater with an increase in the quantity of nitrobenzene, but no particular correlation has yet been established between them. In order to correlate the E_T-values to the activation volumes, it is necessary to observe the pressure dependence of the E_T-values, since the pressure dependence of the rate constant is required for the calculation of activation volume.

TABLE 4. λ_{max} AND E_T-VALUES FOR BENZENE–NITROBENZENE MIXTURES AT 25°C

	Mole fraction of nitrobenzene					
	0	0.2	0.4	0.6	0.8	1.0

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2992—2997 (1973)

Kinetic Studies of Fast Reactions in Aqueous Solutions of Amylamine by Means of Ultrasonic Absorption

Sadakatsu NISHIKAWA, Tatsuya YASUNAGA, and Kojiro TAKAHASHI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received March 22, 1973)

The ultrasonic absorptions in aqueous solutions of amylamine were measured in the frequency range of 3.5—220 MHz and in the concentration range of 0.01—3.06 M. Two kinds of relaxations were observed. One was attributed to the 5A—A_5 reaction of non-ionized molecules of amylamine, and the rate constants were determined from the concentration dependence of the relaxation time at various temperatures. The thermodynamic parameters were determined from the temperature dependence of the rate and equilibrium constants. The other was attributed to hydrolysis, which is a diffusion-controlled reaction. In order to clarify the relation between the stability of the aggregate and the length of the hydrophobic group, the ultrasonic absorptions in aqueous solutions of propylamine were also measured. The excess absorption due to the association-dissociation reaction was not observed; only that due to hydrolysis was observed. It was deduced from this investigation that the aggregate formed by the hydrophobic bonding exists in the aqueous solutions of normal amines, the carbon numbers of which are more than 4.

The method of ultrasonic absorption has been successfully applied to the investigation of reaction kinetics which occur rapidly, since the relaxation time and excess absorption determined from the absorption data are related to the kinetic parameters. It is well known that a number of binary mixtures exhibit a maximum in their excess absorptions at an intermediate concentration.[1] It has been previously reported by the present authors[2,3] that there are two kinds of relaxation processes in aqueous solutions of butylamine. One, associated with the maximum excess absorption phenomena, was attributed to the association-dissociation reaction of the non-ionized molecules, and the other, to hydrolysis. Accordingly, the same phenomena may be expected to be observed in aqueous solutions of other amines.

Andreae and his co-workers[1] have explained the excess absorption of ultrasonic waves in aqueous solutions of amylamine as a solute-solvent interaction. However, this analysis employs a rather unusually defined equilibrium constant, and some of the stoichiometries reported appear to be implausible. Moreover, the data reported are insufficient for a reasonable analysis of the excess absorption mechanism.

The purpose of the present investigation is to clarify in detail the excess absorption mechanism of ultrasonic

waves in aqueous solutions of amylamine on the basis of that in the aqueous solution of butylamine[2] and to reveal the characteristic properties of the aqueous solutions of amines. This type of information is particularly desirable for an understanding of the more complex biochemical reactions.

Experimental

The amylamine and propylamine were of a guaranteed reagent grade, and KOH was added to them to remove the water because the relatively concentrated solutions were made at the required concentrations by weight. They were distilled after the filtration of KOH. The purities were verified by gas chromatography to be higher than 99.9%. Deionized and distilled water was used as the solvent. The relatively dilute solutions (less than 0.5 M) were prepared by the dilution of the stock solution. The other chemicals used were all of a guaranteed reagent grade. The measurements of the ultrasonic absorption were carried out at the odd harmonic frequencies of 0.5, 5, and 20 MHz X-cut quartz transducers by means of the pulse technique.[4] The frequency range of the measurement was 3.5—220 MHz. Since the aqueous solutions of amines are highly basic, the cell was designed to be air-tight and dry nitrogen gas was passed over the solutions to prevent the contamination of the specimens by oxidation with air. The sing-around method was employed at 1.92 MHz to measure the sound velocity. The densities were measured by means of a standard pycnometer. The pH values of the solutions were measured by means of a Hitachi Horiba type F-5 pH meter. All the measurements for the aqueous solutions of amylamine were made at 15, 20, 25, and 30 °C, and for those of propylamine, at 20 °C.

Results

In Fig. 1 the plots of α/f^2 *vs.* the concentration for the aqueous solutions of amylamine at 20 °C are shown, where α is the sound absorption coefficient, and f, the frequency. As may be seen in this figure, the absorption and the peak sound absorption concentration (P.S.A.C) depend on the frequency. This behavior leads us to predict the existence of the relaxation phenomena. In general, the sound absorption caused by the several relaxation processes can be described by the following equation:

$$\alpha/f^2 = \sum_i \frac{A_i}{1+(f/f_{ri})^2} + B \qquad (1)$$

where f_{ri} is the relaxation frequency for the i-th process and where A_i and B are constants. Figure 2 shows the representative ultrasonic absorption spectra of the aqueous solutions of amylamine at 20 °C. The spectra in the concentration range of more than 1 M and less than 0.4 M show the characteristic behavior due to the single relaxation process, which is expressed by the case of $i=1$ in Eq. (1). On the other hand, the spectra in the concentration range between 1.0 and 0.4 M can be represented by the double relaxation process, which correspond to the case of $i=2$ in Eq. (1). These facts indicate that there are two kinds of relaxation processes in the aqueous solution of amylamine. The relaxation parameters, A_i, B, and f_{ri}, were determined so as to obtain the best fit of the

data to Eq. (1). However, the spectrum at 0.490 M could not be analyzed because the absorption coefficients at low frequencies could not be observed. The excess absorptions, A_1, which were observed in the concentration range of more than 0.5 M in the lower frequency range are shown in Fig. 3. As may be seen in this figure, the positions of the P.S.A.C are independent of the temperature. The sound velocity also shows the peak at an intermediate concentration, as may be seen in Fig. 4. The concentration at which the sound velocity shows its maximum is lower than that of the excess absorption.

The ultrasonic absorptions in aqueous solutions of propylamine were also measured; same representative spectra are shown in Fig. 5. As may be seen in this figure, no double relaxation processes were observed, but only a single one was observed; no characteristic excess absorption such as is observed in the relatively concentrated solutions of butylamine and amylamine was found. In Table 1, the ultrasonic parameters and sound velocity obtained for the aqueous solutions of

amylamine and propylamine are listed, together with the density, the pH, and the activity coefficient of the ions, the last of which was calculated by means of Davies equation:[5] $-\log\gamma=0.5[\{\sqrt{I}/(1+\sqrt{I})\}-0.3I]$, where γ is the activity coefficient, and I, the ionic strength.

Interpretation of Results

First, for the excess absorption observed in the lower frequency range in the aqueous solution of amylamine, the following reaction is considered.

$$nA \underset{k_b}{\overset{k_f}{\rightleftharpoons}} A_n \qquad (2)$$

where A is the monomer, A_n, the aggregate, n, the aggregation number, and k_f and k_b, the forward and backward rate constants respectively. If one denotes the molar concentrations of the A and A_n components by C_1 and C_2, the relaxation time, τ_1, and the maximum excess absorption per wavelength, μ_{max_1}, can be written as follows:

$$2\pi f_{r_1} = \tau_1^{-1} = \overline{k_f} n^2 (\overline{C_1})^{n-1} + \overline{k_b} \qquad (3)$$

$$\mu_{max_1} = \frac{1}{2} A_1 f_{r_1} c = \frac{\pi\rho c^2}{2} \cdot \frac{(\Delta V_1^\circ)^2}{RT} \overline{k_f} \cdot (\overline{C_1})^n \cdot \tau_1 \qquad (4)$$

where ρ is the density, c, the velocity of sound, ΔV_1°, the standard volume change, R, the gas constant, and T, the absolute temperature. The equilibrium values of the rate constants and the concentrations are indicated by a bar over each symbol. The detailed derivatives of Eqs. (3) and (4) were reported in a previous paper.[2] In aqueous solutions of amines, there also exists the following equilibrium:

$$R\text{-}NH_3^+ + OH^- \underset{k_2}{\overset{k_1}{\rightleftharpoons}} R\text{-}NH_2 + H_2O \qquad (5)$$

where k_1 and k_2 are the forward and backward rate constants respectively. The dissociation constant, K_b, is defined by:

$$K_b = \frac{\overline{k_2}}{\overline{k_1}} = \frac{\gamma^2[OH^-]^2}{[R-NH_2]} \qquad (6)$$

where γ is the mean activity coefficient of the ion. If the non-ionized molecules are associated with the aggregation, Eqs. (3) and (4) can be expressed in terms of K_b and $\gamma[OH^-]$ as follows:

$$2\pi f_{r_1} = \tau_1^{-1} = \overline{k_f} n^2 \left(\frac{\gamma^2[OH^-]^2}{K_b}\right)^{n-1} + \overline{k_b} \qquad (7)$$

$$\mu_{max_1} = \frac{\pi\rho c^2}{2} \cdot \frac{(\Delta V_1^\circ)^2}{RT} \cdot \overline{k_f} \left(\frac{\gamma^2[OH^-]^2}{K_b}\right)^n \cdot \tau_1 \qquad (8)$$

The aggregation number was determined from the slope of the plots of $\log(\mu_{max_1}/\rho c^2\tau_1)$ *vs.* $\log(\gamma^2[OH^-]^2)$; the result was $n=5$. Figure 6 shows the plots of f_{r_1} *vs.* $(\gamma^2[OH^-]^2)^4$ for the aqueous solution of amylamine at 20 °C. If the dissociation constant, K_b, is known, the rate constants, $\overline{k_f}$ and $\overline{k_b}$, may be determined from the slope and intercept respectively. However, no dissociation constant has been reported except

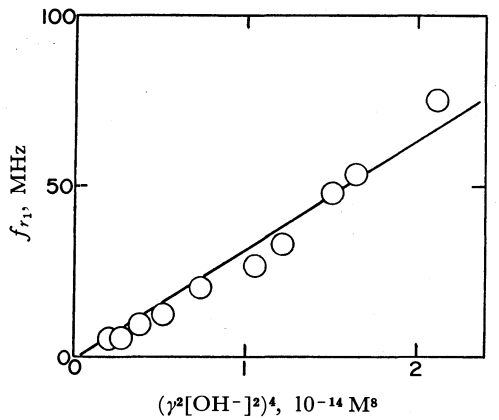

Fig. 6. The plots of f_{r_1} *vs.* $(\gamma^2[OH^-]^2)^4$ for aqueous solutions of amylamine at 20 °C.

for one at 25 °C,[6] and the intercept of these plots in Fig. 6 is close to zero. Therefore, the rate constants were determined in the following manner. Equation (7) can be rewritten as:

$$2\pi f_{r_1} = \tau_1^{-1} = n\overline{k_b} K_b \cdot \frac{C_0}{\gamma^2[OH^-]^2} - (n-1)\overline{k_b} \qquad (9)$$

where $C_0=[R-NH_2]+n[(R-NH_2)_n]$. Then, one can determine the values of $\overline{k_b}$ and $\overline{K_b}$ from the intercept and the slope of the plots of f_{r_1} *vs.* $C_0/\gamma^2[OH^-]^2$, which are shown in Fig. 7. The value of $\overline{k_f}$ was obtained using the slope of the plots of f_{r_1} *vs.* $(\gamma^2[OH^-]^2)^4$ in Fig. 6. The standard volume change was calculated by means of Eq. (4). In Table 2, the rate constants, the dissociation constant, and the standard volume change obtained are listed, together with the free energy, ΔF, which was calculated by means of: $K=\overline{k_b}/\overline{k_f}=\exp(-\Delta F/RT)$. The dissociation constant, K_b, was also determined from the $K_b=\gamma^2[OH^-]^2/(C_0'-[OH^-])$ relation in the concentration range of less than 0.25 M, in which it is expected that only the equilibrium expressed by Eq. (5) exists, where $C_0'=[R-NH_2]+[R-NH_3^+]$. These dissociation constants are indicated by K_b' in Table 2.

Secondly, for the sake of explaining the excess absorption observed in the aqueous solution of propylamine and the other one observed in the aqueous solution of amylamine, let us consider the hydrolysis which is expressed by Eq. (5). The relation between the relaxation time, τ_2, and the concentration can be

expressed as follows:

$$2\pi f_{r_2} = \tau_2^{-1} = 2\bar{k}_1\gamma^2[OH^-] + \bar{k}_2 \quad (10)$$

The excess absorption per wavelength can be written as:

$$\mu_{max_2} = \frac{1}{2}A_2 f_{r_2} c = \frac{1}{2}\pi\rho c^2 \frac{(\Delta V_2^\circ)^2}{RT}\Gamma_c \quad (11)$$

where $\Gamma_c = (1/[OH^-] + 1/[R{-}NH_3^+] + 1/[R{-}NH_2])^{-1}$. Figure 8 shows the plots of f_{r_2} *vs.* γ^2[OH$^-$] for the aqueous solutions of amylamine and propylamine. The forward and backward rate constants were determined from the slope and intercept respectively. The standard volume change associated with the hydrolysis was calculated by means of Eq. (11). In Table 3, the rate constants and standard volume change obtained in the present investigation are listed, together with the results for other monoamines.

Discussion

First, the excess absorption mechanism observed in an aqueous solution of amylamine in the lower frequency range will be discussed. For the mechanism associated with the peak sound absorption, several models have been proposed, such as AA+BB→2AB[7] and A+nB→AB$_n$,[1] where A is the solute, and B, the solvent molecules. All these models are due to the solute-solvent interaction. However, they are not acceptable in the case of the aqueous solutions of amines, as has been discussed in a previous paper.[2] In addition, if the cause of this excess absorption is associated with this solute-solvent interaction, the same absorption should be observed in any aqueous solution of amines. The fact that no excess absorption due to this mechanism was observed in the aqueous solution of propylamine also rules out these models. As is shown in Figs. 6 and 7, the linearities of the plots of f_{r_1} *vs.* $(\gamma^2[OH^-]^2)^4$ and f_{r_1} *vs.* $C_0/\gamma^2[OH^-]^2$ and the reasonable values of the dissociation constants, K_b, lead to the conclusion that the cause of the excess absorption is the association-dissociation reaction of amine. The theoretical maximum excess absorption per wavelength, which was calculated by Eq. (4) using the obtained values of $\bar{k}_f$ and ΔV_1°, are shown in Fig. 9, together with the experimental results. The agreement between the observed and calculated values also confirms the present model. In order to ascertain the natures of the aggregate, the ultrasonic absorptions were measured in aqueous solutions of butylamine hydrochloride and amylamine hydrochloride and in cyclohexane solutions of butylamine and amylamine. However, no excess absorptions were observed, as may be seen in Fig. 10. These facts lead us to the conclusions that the aggregate considered here consists of non-ionized amine molecules and that the water molecules participate in the aggregation of amines. In general, the molecules which consist of hydrophilic and hydrophobic groups have a tendency to aggregate in an aqueous solution. This aggregate is formed

by hydrophobic bonding, by which the ice berg structures of water which are formed around the nonpolar group of the molecule are broken and change to the normal structures of water. Since the standard volume change associated with the association-dissociation reaction of amines is comparatively large, this may be due to the change in the structure of the solvent water. The relaxation time[8] associated with this structural change in water is so small that the contribution of this relaxation to the association-dissociation reaction of amines may be neglected.

The thermodynamic parameters can be determined from the temperature dependence of the rate constants and the equilibrium constant obtained for the association-dissociation reaction of amylamine. According to the rate theory of reaction, the rate constant, k_i, is expressed by:

$$k_i = PT\exp\left(-\frac{\Delta F_i^{\neq}}{RT}\right) = PT\exp\left(-\frac{\Delta H_i^{\neq} - T\Delta S_i^{\neq}}{RT}\right) \quad (12)$$

where $\Delta H_i^{\neq}$ is the activation enthaply, $\Delta S_i^{\neq}$, the activation entropy, and P, the constant. The activation enthalpy is determined from the slope of the plots of $\ln(k_i/T)$ *vs.* $1/T$; the results are $\Delta H_f^{\neq}=8.7$ kcal/mol and $\Delta H_b^{\neq}=0$ kcal/mol. The enthalpy change was found to be -9.0 kcal/mol from the plots of $\ln K$ *vs.* $1/T$. Furthermore, through $\Delta F=\Delta H-T\Delta S$ the entropy change was calculated to be $\Delta S=-14$ e.u. It is well known that surface-active agents form a micelle by hydrophobic bonding in an aqueous solution with more than critical micelle concentration.[9] The thermodynamic parameters for micelle formation show the same temperature dependence as those of the association of amylamine, though the enthalpy change that in the latter is comparatively large. This confirms the aggregate of amylamine is formed by hydrophobic bonding. Compared with the case of the aqueous solution of butylamine,[2] the aggregation number increases with an increase in the chain length of the hydrophobic group and the dissociation rate constant of the aggregate for amylamine is smaller than that of butylamine. These facts mean that the aggregate is stabilized with an increase in the chain length of the hydrophobic group. It is also noteworthy that the aqueous solution of octylamine forms a mesomorphic phase, which consists of highly associated molecules. The ultrasonic investigation for this phase has previously been done by the present authors.[10]

Next, let us discuss the excess absorption mechanism in the aqueous solution of propylamine and the other one in the aqueous solution of amylamine. It has been reported by many authors[11-14] that there exists an excess absorption associated with hydrolysis in aqueous solutions of amines. As may be seen in Fig. 8, the linearities of the plots of f_{r_2} *vs.* $\gamma^2[OH^-]$ show that the cause of the excess absorption mechanism is attributed to the perturbation of the equilibrium expressed by Eq. (5). The obtained values of the rate constant, k_1, are pertinent for the proton transfer reaction. As may be seen in Table 3, the rate constants for the proton transfer reaction for normal amines are not appreciably dependent on the hydrophobic chain length, though the long chain length may affect the rate of the reaction.[13]

Finally, since there exist two types of equilibria in the solution of amylamine, it may be necessary to consider precisely the following two step mechanism, that is, the reaction which is coupled by Eqs. (2) and (5):

$$A^+ + B^- \rightleftharpoons A \rightleftharpoons \frac{1}{n}A_n \quad (13)$$

However, as has been described in the previous paper,[2] it has been verified that the contribution of the faster process, which is associated with hydrolysis, to the slower one, which is associated with the association-dissociation reaction, is so small that two different relaxation processes can be interpreted independently.

The Crystal Structure of Hemimellitic Acid Dihydrate

Fusao TAKUSAGAWA and Akira SHIMADA

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received March 27, 1973)

The crystal structure of hemimellitic acid dihydrate (benzene-1,2,3-tricarboxylic acid dihydrate) has been determined by the X-ray diffraction method. The crystals are triclinic, with a space group of $P\bar{1}$ and with cell dimensions of $a=11.02$, $b=9.12$, $c=8.72$ Å, $\alpha=106.2°$, $\beta=140.2°$, and $\gamma=84.2°$. The structure was determined by an inspection of a sharpened Patterson map. The final R value was 9.25% for 1532 observed reflections. The hemimellitic acid molecule has the approximate C_s symmetry. Three carboxyl groups twist by 4.5°, 86.8°, and 10.3° out of the plane of a benzene ring. The hemimellitic acid and water molecules are joined by seven independent O-H···O hydrogen bonds to form a three-dimensional network. The water molecules are hydrogen-bonded to each other around a center of symmetry to form a unique four-membered ring. The hydrogen bonds observed are classified by means of the combination of donor and acceptor groups in five types. These types of hydrogen bonds are discussed in the comparison with several carboxylic acid hydrates.

This work is a part of series of hydrogen-bonding studies by means of X-ray crystal structure analyses of several compounds which have the adjacent carboxyl groups substituted on a benzene ring. These kinds of compounds, which have already been analyzed by the X-ray diffraction method, are phthalic acid,[1] trimellitic acid,[2] pyromellitic acid,[3] and mellitic acid.[4] No intramolecular hydrogen bond has been found between the adjacent carboxyl groups in these crystal structures, but the vicinal carboxyl groups are twisted out of the plane of a benzene ring so that the repulsions were reduced between the oxygen atoms in these groups. Since the present compound has three adjacent carboxyl groups, it seemed that it would be of interest to elucidate the mutual relations of the steric hindrance by adjacent carboxyl groups. Moreover, all the hydrogen bonds in the crystal structures of benzene-carboxylic acids,[1-8] except for pyromellitic acid dihydrate are found to exist between the carboxyl groups related by a center of symmetry or a two-fold axis. On the other hand, there is no such type of hydrogen bond in the crystal of pyromellitic acid dihydrate; however, the observed types were similar to those of oxalic acid dihydrate. In view of the fact that the present compound contains water molecules, it seemed that it would also be of interest to examine the way of hydrogen bonding system in the crystal.

Experimental

The crystals were obtained in the form of colorless plates by recrystallization from a H_3PO_4 aqueous solution. Weissenberg photographs showed the crystal to be triclinic, with a space group of $P1$ or $P\bar{1}$. The unit-cell dimensions were measured from zero-layer Weissenberg photographs which had been calibrated with superimposed Al powder lines. The crystal data are given in Table 1. The crystals were shaped to cylinders with an average diameter of 0.4 mm for the a and c axes specimens. The intensity data were collected for the 0—10 layers around the a axis and for the 0—1 layers around the c axis by the use of the multiple-film equi-inclination Weissenberg technique with CuKα radiation. The intensities were estimated visually by comparison with an intensity scale. Of the possible 2425 reflections within the CuKα sphere, 1975 independent reflections were measured; 443 were too weak to be observed.

No absorption and extinction corrections were applied. The space group was identified as $P\bar{1}$ on the basis of the statistical average for normalized structure factors.

Structure Determination and Refinement

The crystal structure was solved by an inspection of a sharpened Patterson map which had been resolved sufficiently enough to give the orientation and location of a hemimellitic acid molecule in the unit cell. The first postulated structure gave an R value of 59%; this decreased to 49% in three cycles of least-squares refinements with individual isotropic thermal parameters. A difference Fourier map showed the positions of the water oxygen atoms.

Anisotropic thermal parameters were introduced and the block-diagonal least-squares refinement was continued in order to reduce the R value to 11.5%. At this stage of refinement, a difference Fourier synthesis was computed, and from this the positions of ten hydrogen atoms were located (Fig. 1). There are

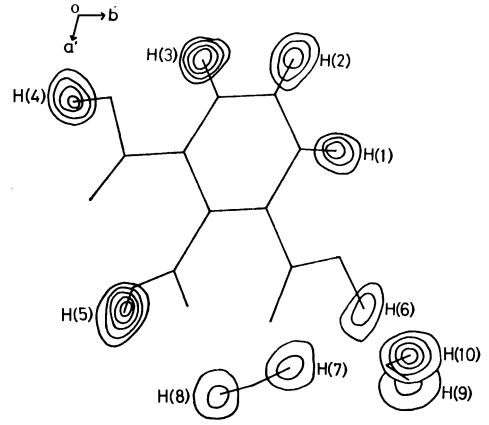

Fig. 1. A composite drawing of the electron density associated with the hydrogen atoms. The contours at intervals of 0.1 e·Å^{-3}, beginning with 0.2 e·Å^{-3} contour.

several spurious peaks on this map besides those due to hydrogen atoms. With anisotropic thermal parameters for non-hydrogen atoms and with isotropic thermal parameters for hydrogen atoms, the final R value was 9.25%, excluding unobserved reflections. The $\Sigma w(F_o-F_c)^2$ function was minimized, where:

$$w = 0.5 \text{ for } |F_o| \leqq 0.5,$$
$$w = 1.0 \text{ for } 0.5 < |F_o| < 5.0 \text{ and}$$
$$w = 5.0/|F_o| \text{ for } 5.0 \leqq |F_o|.$$

The atomic scattering factors used were those listed in the International Table for X-ray Crystallography for C, N, and O atoms and the spherical scattering factors proposed by Stewart, Davidson, and Simpson[9] for the H atom. The observed and calculated structure factors are listed in Table 2.[10] The fractional coordinates and thermal parameters are listed in Table 3.

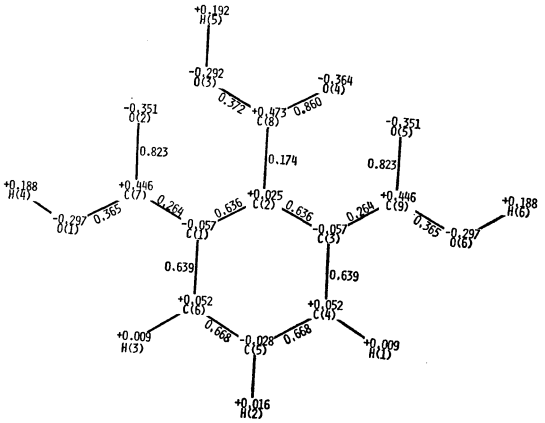

Fig. 4. The π-bond orders and net charges calculated by the CNDO/2 method. The hemimellitic acid molecule is assumed to have the C_s symmetry.

nine carbon atoms are:

$$-0.9843X - 0.1725Y + 0.0382Z = -4.8629 \text{ and}$$

$$-0.9854X - 0.9854Y + 0.0452Z = -4.8202,$$

where X, Y, and Z are coordinates in Å referred to an orthogonal set, where the X and Z axes are parallel to the a and b* axes and where Y lies on the ab plane. This coordinate system is used throughout this paper. The maximum deviation of ring atoms from the least-squares plane of a benzene ring is 0.007 Å. The benzene ring is essentially planar. The displacements of all the atoms from two planes are listed in Table 4. A molecule is approximately planar except for the O(3), O(4), and H(5) atoms of one carboxyl group.

The maximum differences among the C–C bond lengths and among the C–C–C bond angles in the benzene ring, 0.030(7) Å and 1.6(5)°, are significant from their estimated standard deviations (the values in parentheses denote the e.s.d.'s in the last digits). In two halves of the benzene ring divided through the line from C(2) to C(5) atoms, the differences between the corresponding bond lengths and angles are 0.003(7) Å (C(2)—C(3) and C(2)—C(1)), 0.002(7) Å (C(3)—C(4) and C(1)—C(6)), 0.004(7) Å (C(4)—C(5) and C(6)—C(5)), 0.2(5)° (C(2)—C(3)–C(4) and C(2)–C(1)–C(6)) and 0.0(5)° (C(3)–C(4)–C(5) and C(1)–C(6)–C(5)). These values show that the benzene ring in this molecule has the approximate C_{2v} symmetry. The significant differences in the C–C bond lengths and C–C–C bond angles in the benzene ring are due to the substitution of the carboxyl groups. This fact is supported by the π-bond orders calculated by the use of the CNDO/2 method, as is shown in Fig. 4. In this calculation, the molecule is assumed to have the C_s symmetry. The bond orders of the C(4)–C(5) and C(5)–C(6) bonds are the largest, those of the C(3)–C(4) and C(1)–C(6) bonds are second, and those of the C(1)–C(2) and C(2)–C(3) bonds are the smallest.

In these C–C bonds joining the carboxyl groups to a benzene ring, the slight differences between the C(2)–C(8) and C(1)–C(7) bond lengths, and between the C(2)–C(8) and C(3)–C(9) bond lengths, 0.009(7) and 0.015(7) Å, lie within the limits of their estimated standard deviations. However, the significance in these differences may be supported by the fact that the observed bond lengths are correlated well with their calculated bond orders, as is shown in Fig. 4. The differences between the C(7)–C(1)–C(6) and C(7)–C(1)–C(2) bond angles, between the C(8)–C(2)–C(1) and C(8)–C(2)–C(3) bond angles, and between the C(9)–C(3)–C(2) and C(9)–C(3)–C(4) bond angles are 0.7(5)°, 0.4(5),° and 1.5(5)°. These values have no significance and show that the repulsions between the carboxyl groups are reduced not by the changes in the C–C–C bond angles, but by the twists of the C–C bonds, as will be seen below.

The dimensions of three carboxyl groups agree with each other within the limits of experimental error. Two C–O bond lengths in each carboxyl group are clearly different from each other. The bonds between the carbon and carbonyl oxygen atoms, C(7)–O(2), C(8)–O(4), and C(9)–O(5), are shorter than those between the carbon and hydroxyl oxygen atoms, C(7)–O(1), C(8)–O(3), and C(9)–O(6) by an average value of 0.100(7) Å. This supports the fact that the carboxyl hydrogen atoms of hemimellitic acid are definitely associated with hydroxyl oxygen atoms. The carboxyl groups at the 1- and 3-positions twist slightly

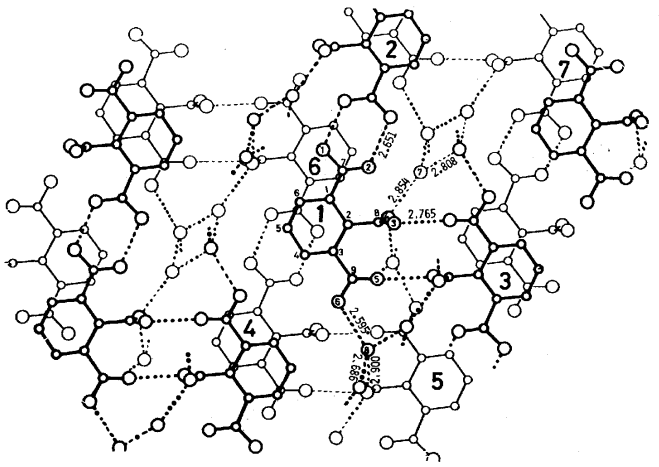

Fig. 7. A view of the erystal structure perpendicular to the (3 1 $\bar{2}$) plane, showing the relative orientation of the plane.

by 4.5° and 10.3° out of the plane of a benzene ring, while the carboxyl group at the 2-position twists greatly, by 86.8° so that the repulsions are reduced among the O(2), O(3), O(4), and O(5) atoms. Hence, the hemimellitic acid molecule has the approximate C_s symmetry in solids.

Molecular Arrangement and Hydrogen-bond System. The crystal structure is shown in Figs. 5, 6, and 7. The distances and angles of the hydrogen bonds are listed in Table 5. The hemimellitic acid molecule and one water molecule are arranged in layers closely parallel to the (3 1 $\bar{2}$) plane, with a spacing of 3.514 Å, except for the O(3), O(4), and H(5) atoms of one carboxyl group, and the O(7), H(7), H(8), H(9), and H(10) atoms of water molecules. The least-squares plane through the non-hydrogen atoms of a hemimellitic acid molecule and a water oxygen atom O(8), except for the O(3) and O(4) atoms, is:

$$-0.9836X-0.1792Y+0.0206Z=-4.8973.$$

The dihedral angle which this plane makes with the (3 1 $\bar{2}$) plane is 6.5°. Figures 6 and 7 show the views parallel to and perpendicular to the (3 1 $\bar{2}$) plane respectively; they illustrate the relative orientation of the molecules in two neighboring layers. In Figs. 5, 6 and 7, the same numerals designate the same molecules. The symmetry codes corresponding to these numbers are shown in Table 5.

Each hemimellitic acid molecule on the same plane is joined through two kinds of hydrogen bonds, with distances of 2.651(6) and 2.765(6) Å, around the center of symmetry with two neighboring molecules and forms a zig-zag chain along the [1 1 2] direction. In the O(3)-H(5)···O(5) hydrogen bond, the C(9)-O(5)···

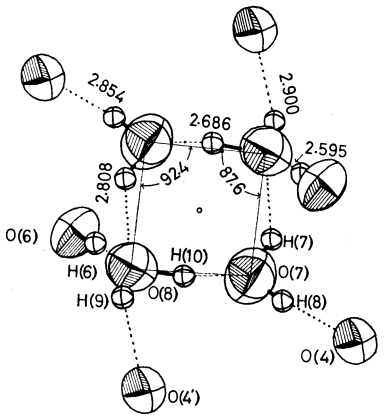

Fig. 8. Perspective view showing the environment of four-membered ring of water molecules. The hydrogen bonds are shown by broken lines.

H(5) and C(9)–O(5)···O(3) hydrogen bonding angles are 169(2)° and 169.7(4)° respectively. These values indicate that the bisector of lone pairs in the carbonyl oxygen atom O(5) is directed toward a hydrogen-bond donor group. Although the hydrogen atom in most of the O–H···O hydrogen bonds interacts with one lone pair of the acceptor oxygen atom, the H(5) atom in this hydrogen bond does so with two lone pairs of the O(5) atom.

The water molecules which lie among these chains are hydrogen-bonded around the center of symmetry to form the four-membered ring. This is a unique example of the four-membered ring being formed only by the use of water oxygen atoms, as is shown in Fig. 8. In this ring, the angles of O···O···O are 87.4° and 92.3°, and the O···O distances are 2.686(7) and 2.808(7) Å. These values show that this ring conformation is an approximate square.

The zig-zag chains of hemimellitic acid molecules are linked to each other by three kinds of hydrogen bonds with the distances of 2.595(6), 2.854(7), and 2.900(6) Å, through the medium of the four-membered ring of water molecules, thus forming the three-dimensional network.

It may be noted that the structure of hemimellitic acid dihydrate contains all the types of O–H···O hydrogen bonds among the water molecules and carboxyl groups. The observed seven hydrogen bonds can be classified by means of the combination of the donor and acceptor groups in five types, as is shown in Fig. 9. The (a) type is the most popular hydrogen bond in carboxylic acids. However, this type was not found in hydrate compounds, such as pyromellitic acid dihydrate and oxalic acid dihydrate. The observed distance, 2.651 (6) Å, is quite normal and is shorter than that of the (b) type, 2.765 Å. Types (b), (c) and (d) are found in pyromellitic acid dihydrate, which is the only hydrate compound in the crystal structures of benzene-carboxylic acids determined hitherto. The agreements between the hydrogen bonding distances, and between the hydrogen bonding angles of hemimellitic acid dihydrate and those of pyromellitic acid dihydrate, are quite good; these values are listed

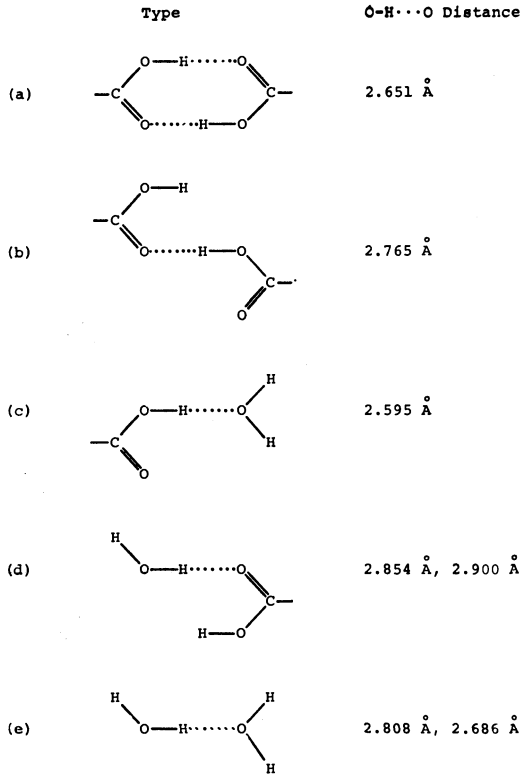

Fig. 9. The types of hydrogen bonds among the carboxyl groups and water molecules.

with those of α-oxalic acid dihydrate[12] in Table 6. In the (b) type, the hydrogen bonding angle, C=O···O, is significantly larger than 120°. Those angles in hemimellitic acid dihydrate, pyromellitic acid dihydrate, and dipicolinic acid monohydrate[13] are 169.7°, 152.2°, and 170.6°. Both (c) and (d) types are often found in carboxylic-acid hydrates. The hydrogen-bond distances of these two types are distinctly

13) F. Takusagawa, K. Hirotsu and A. Shimada, This Bulletin, **46**, 2020 (1973).

different from each other. Most of the water oxygen atoms in the (c) type act as one acceptor of a short hydrogen bond. However, in the present compound, the water oxygen atom acts as an acceptor from two donors. This fact may cause the differences in the hydrogen bonding distances and angles in comparison with pyromellitic acid dihydrate. The carboxyl oxygen atom in the (d) type participates in two long hydrogen bonds with waters as donor groups; these bonds have the approximately equal distances. Types (c) and (d) reveal the remarkable feature of a hydrogen bond between the water molecule and carboxyl group.

Computer Programs. All the calculations were performed on a FACOM 270-30 computer at the Computer Center of Osaka City University by the use of the following programs: RSLC-3 (cell constant),[14] RSSFR-3 (Fourier synthesis),[15] HBLS-IV (block-diagonal least-squares refinement),[16] DAPH (bond length, bond angle, and least-squares plane),[17] SCALE (film factor, Lp and layer scaling),[18] TE-I (thermal ellipsoid),[19] and CNINDO (CNDO and INDO calculations).[10]

The authors wish to express their thanks to Dr. Kichisuke Nishimoto of this faculty for his useful advice on the CNDO calculation. The authors are also indebted to Mr. Ken Hirotsu for his useful advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3004—3007 (1973)

The Ultrasonic Velocity and the Absorption of Aqueous *t*-Butyl Alcohol Solutions in Relation to the Structures of Water and Solutions

Harumi ENDO and Otohiko NOMOTO

Department of Applied Physics, Defense Academy, Yokosuka 239

(Received March 30, 1973)

The adiabatic compressibility *vs.* concentration curves in aqueous solutions of *t*-butyl alcohol (*t*-Bu) over a certain temperature range have a common intersection at a fixed concentration (μ_c^β). The sound absorptions of solutions are nearly constant and are independent of the concentration up to a concentration (μ_1^α) nearly the same as the μ_c^β. On the basis of the value of $\mu_c^\beta(\cong\mu_1^\alpha)$, the properties and the dissolved state of *t*-Bu in liquid water discussed in terms of the liquid clathrate hydrate model. At this concentration, the liquid clathrate hydrate of *t*-Bu consists of 18-hedron, containing 32 water molecules for each *t*-Bu molecule. For higher concentrations than μ_c^β, the breakdown of the liquid clathrate hydrate by the addition of excess *t*-Bu occurs, accompanied by an increase in the number of clusters.

In previous papers,[1,2] the sound velocity (V), the density (ρ), and the adiabatic compressibility (β) in aqueous solutions of nonelectrolytes have been investigated as functions of the concentration (μ: mole fraction). For each aqueous solution, it has been found that the V-μ curves and β-μ curves have common intersections at the fixed concentrations of μ_c and μ_c^β respectively, the sound velocity (V_c) and the compressibility (β_c) at these concentrations being independent of the temperature over a certain range (ΔT_c^V and ΔT_c^β) respectively.

From the temperature dependency of the β-μ curves in these systems, it can be concluded that the structural unit termed "liquid clathrate hydrate" with a composition of μ_c^β or r_c^β=(water/solute) does exist for various aqueous systems.

A number of papers have been published on the ultrasonic absorption (α) in aqueous solutions of nonelectrolytes—alcohol homologs,[3-6] substituted alcohols,[7,8] urea and its derivatives,[9] acetone,[3] dioxane,[3,10,11] dioxolane,[12] amines,[13,14] *etc.*; the main interest is, however, the behavior of an absorption peak in the α-μ curve. Blandamer *et al.* have pointed out that the sound absorption for some aqueous systems—alcohols,[4,5] substituted alcohols,[7] dioxolane,[12] amine[13]—in a lower concentration range is

relatively insensitive to the compositions of the solutions (see also Thamsen[8]). Above this concentration, the value of α increases rapidly, reaches a maximum, and then gradually decreases to a lower value of α. According to Blandamer *et al.*,[4,5,7,12,13] this behavior of the α-μ curve in the lower concentration range is attributable to the formation of a clathrate in a solution. In one group of theories, the absorption peaks are explained in terms of a chemical relaxation process (*cf.* Andrea *et al.*[15]) involving the formation and decomposition of associated complexes, but the behavior of the α-μ curve in the lower concentration range can not be interpreted in terms of this mechanism.

In the present work, the acoustical properties of an aqueous solution of *t*-Bu have been studied both for the sound velocity and the absorption. It was found that the concentration (μ_1^{α}) at the sudden increase of the α-μ curve corresponds to μ_c^{β}. On the basis of this result, we will report that the low-concentration absorption-behavior of a *t*-Bu solution can also be explained on the basis of the liquid clathrate hydrate model used for the explanation of the behavior of β.

Experimental

Materials. Water was purified by two distillations. In order to purify the *t*-Bu, the reagent-grade product was refluxed with calcium oxide and then distilled.

Ultrasonic Apparatus. The ultrasonic pulse method was used for the absorption measurement. The absorption coefficients were determined at 60 MHz, and the mean value of 5~9 measurements was used. A crystal-controlled ultrasonic interferometer operating at a frequency of 5 MHz was used for the velocity measurements. The experimental error for the absorption data was about ±2%, and the overall accuracy of the sound velocity data was within ±0.2 m/s.

Measurements of Viscosity and Density. The viscosity coefficient (η) was measured for aqueous solutions by means of a modified Ostwald capillary viscometer. The density measurement was made by means of an Ostwald-type pycnometer. All the measurements were carried out between 20° and 50 °C at 5.0±0.1 °C intervals.

Classical Absorption Coefficient (α_η). The α_η at frequency (f) was calculated by the relation:

$$\alpha_\eta/f^2 = \frac{8\pi^2\eta}{3\rho V^3}$$

Results

Ultrasonic Velocity. In Fig. 1, the sound velocity is plotted against the mole fraction for aqueous solutions of *t*-Bu. The intersection point of V-μ curves for various temperatures converges to one point (μ_c^V= 0.032), at which V_c is constant (=1601 m/s) in this temperature range (20—35 °C). The parameters, V_c, μ_c^V, v_c^V, r_c^V, and ΔT_c^V, were obtained from Fig. 1; they are summarized in the left-hand half of Table 1. Here the notations used were the same as those used in Refs. 1 and 2.

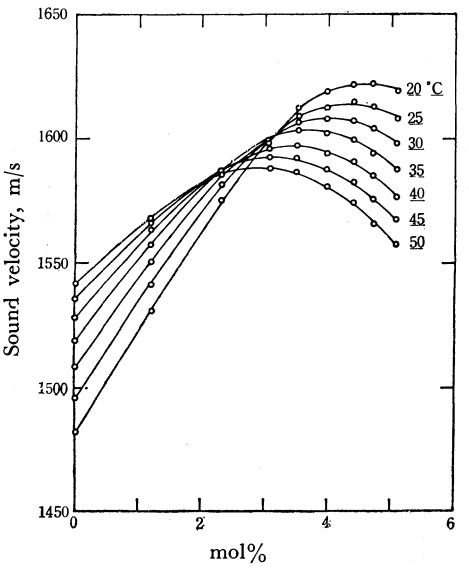

Fig. 1. Concentration dependence of sound velocity.

Table 1. Data concerning V-μ curve and β-μ curve of aqueous *t*-Bu solutions

	Sound velocity		Adiabatic compressibility
V_c	1601 m/s	β_c	40.0×10^{-12} cm²/dyn
μ_c^V	3.2 mol%	μ_c^β	3.0 mol%
v_c^V	14.7 vol.%	v_c^β	13.9 vol.%
r_c^V	30	r_c^β	32
ΔT_c^V	20—35 °C	ΔT_c^β	20—35 °C

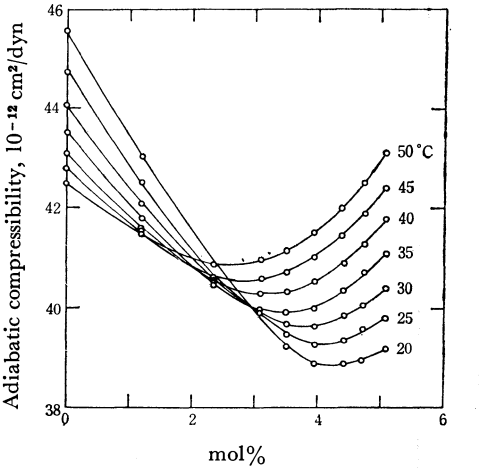

Fig. 2. Concentration dependence of adiabatic compressibility.

Adiabatic Compressibility. In Fig. 2, the adiabatic compressibility is plotted against the mole fraction for aqueous solutions of *t*-Bu. It is found that the β-μ curves at various temperatures intersect at one common point (μ_c^β=0.030), at which β_c is constant ($=40.0\times10^{-12}$ cm²/dyn). The values of β_c, μ_c^β, r_c^β, v_c^β, and ΔT_c^β are shown in the right-hand half of Table 1. The behavior of the V-μ and β-μ curves for various temperatures is similar to that of other nonelectrolytes.[1,2]

Viscosity and Classical Absorption Coefficients. The

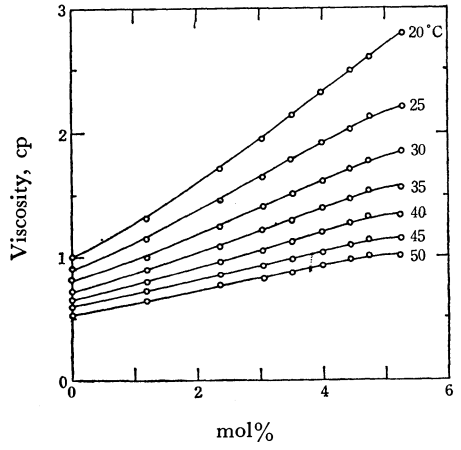

Fig. 3. Concentration dependence of viscosity.

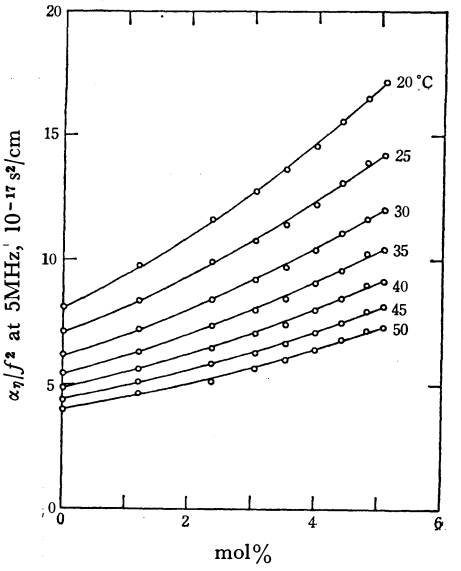

Fig. 4. Concentration dependence of classical absorption.

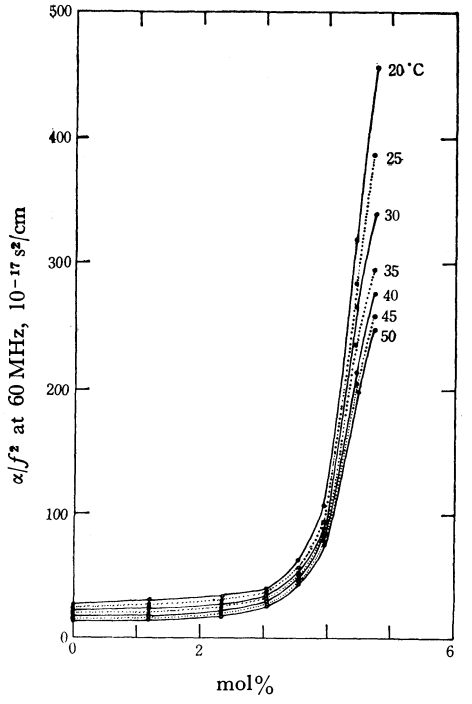

Fig. 5. Concentration dependence of sound absorption.

η-μ curves are shown in Fig. 3. The values of η at various temperatures increased monotonously with an increase in the concentration. The classical absorption coefficients (α_η/f^2) are shown in Fig. 4. The behavior of the α_η/f^2-μ curves at various temperatures is almost like that of the η-μ curves.

Ultrasonic Absorption Coefficients. The α/f^2-μ curves are given in Fig. 5. It is seen that α/f^2 was relatively insensitive to the change in μ in a low concentration range, and that it increased suddenly at a definite concentration. This limiting concentration is denoted by μ_1^a. It is seen that $\mu_1^a \cong 0.03$ mole fraction for the 20—35 °C temperature range, and that it decreases slightly in the higher temperature range ($\mu \cong 0.02$ for 40—50 °C). In the 20—35 °C temperature range, the value of μ_1^a for the α/f^2-μ curves coincides with that of μ_c^β for the β-μ curves. The behavior of the excess absorption ($\Delta\alpha/f^2=\alpha/f^2-\alpha_\eta/f^2$) is not significantly different from that of α/f^2 alone.

Discussion

The experimental results shown above can be interpreted in terms of the same model of aqueous non-electrolyte solutions as was employed in previous papers.[1,2] In our model, μ_c^β corresponds to the concentration where $d\beta_{st}/dT$ (β_{st}=structural compressibility) becomes zero. Solute molecules are accommodated in water clusters without changing their size and ice-1 structure up to this concentration. Therefore, the β_{st} of the solution decreases with an increase in the concentration up to this point, thus keeping the water-cluster structure intact. On the other hand, the β_∞(instantaneous compressibility) is constant and $d\beta_\infty/dT=0$ up to this concentration in order to keep the number of water cluster constant. We have seen[1,2] that the ratio r_c^β(=water/solute) at this concentration, μ_c^β, corresponds to the specific molecular ratios for some clathrate-making substances, and we assumed that the "liquid clathrate hydrate" exists at this composition. Here, the β_{st} of the "water-solute-cluster" at the composition of r_c^β is small, but this value is not zero since the size of this "water-solute-cluster" is significantly larger than that of this structure unit. Beyond this concentration, the number of clusters increases, resulting in a decrease in their mean size. This increase in the number of clusters takes place slowly, accompanying a decrease in β_{st} up to the concentration of $d\beta/d\mu=0$, at which the "water-solute-cluster" is destroyed separately. This is also accompanied by an increase in the β_∞($d\beta_\infty/dT>0$).

Now that the r_c^β for *t*-Bu—water system becomes 32, as was observed for tetra-ethyl ammonium chloride, the shape of the clathrate was assumed to be 18-hedron. (The solid clathrate hydrate of this composition of the *t*-Bu—water system is not known, but a "double hydrate" with help gas (H_2S) of the $16X8Y136H_2O$ (X=H_2S and Y=*t*-Bu) composition is known).

The above finding, that the ultrasonic absorption remains nearly constant, that it is not very different from that of water in the lower concentration range, and that it increases rather rapidly from a certain

concentration $\mu_1^{\alpha}(\cong\mu_c^{\beta})$, is of prime importance in elucidating the mechanism of the ultrasonic absorption in aqueous nonelectrolyte systems. This behavior is not explicable on the basis of the reaction-type theory[14,15] between a solute and solvent molecules. It can, however, be explained easily, at least qualitatively, on the basis of the "entropy of mixing"-type diffusion-theory[16,17] of sound absorption in aqueous systems if we employ the same model of the aqueous systems as was employed previously[1,2] in explaining the behavior of the sound velocity and the adiabatic compressibility. According to this theory,[16,17] the excess sound absorption in aqueous nonelectrolytes arises from the irreversible entropy production caused by the diffusion of solutes into the groups of water molecules produced by the collapse of water-clusters under sound pressure. If we assume that the solute molecules are all incorporated in water-clusters up to the concentration of μ_c^{β} as has been assumed previously,[1,2] almost no diffusion can be expected when some of the clusters are collapsed under the sound pressure, because the collapse of clusters does not accompany a local concentration change. This explains the initial concentration-independent part of the absorption curves. The increase in ultrasonic absorption beyond $\mu_c^{\beta}(\cong\mu_1^{\alpha})$ is to be expected, because free solute molecules or smaller clusters of different compositions are present at higher concentrations, as has been assumed previously.[1,2]

17) O. Nomoto, *ibid.*, **12**, 300 (1957).

We[1,2] ourselves have also previously pointed out that when V_c and β_c are plotted as functions of v_c^V and v_c^{β} respectively, the various solutes can be classified into three groups according to the shapes of the curves. Here, v_c^V and v_c^{β} indicate the volume fractions corresponding to μ_c^V and μ_c^{β} at 20 °C respectively.

The first group (I) consists of the urea-homolog series, hexamethylenetetramine, and glycerine. The molecules of the solutes belonging to this group collaborate in making the framework of water constituent part of liquid water. The sound velocity, V_c, and v_c^V and the adiabatic compressibility, β_c, at v_c^{β} for this series of solutes are represented by:

$$V_c = 403\,v_c^V + 1547 \text{ (m/s)}$$

$$\beta_c = (45.6-42.7\,v_c^{\beta})\times 10^{-12} \text{ (cm}^2\text{/dyn)}$$

respectively.

The second group (II) consists of formamide, acetamide, and the alcohol homolog series except for the lowest-molecular-weight substances in each homolog. These solutes only fill up the cavity of the liquid water structure. The V_c *vs.* v_c^V and β_c *vs.* v_c^{β} relations for this group are represented, respectively, by:

$$V_c = 1143\,v_c^V + 1390 \text{ (m/s)}$$

$$\beta_c = (77.5-236.7\,v_c^{\beta})\times 10^{-12} \text{ (cm}^2\text{/dyn)}$$

The third group (III) consists of the lowest-molecular-weight substances in each homolog series. This group will presumably have intermediate properties between Groups (I) and (II).

Notice that *t*-Bu, although of the alcohol homolog series, belongs to Group (I).

ESR Evidence for the Destruction of the Four-membered Chelate Structure of Bis(*O,O'*-diethyldithiophosphato)oxovanadium(IV) by Pyridine Bases

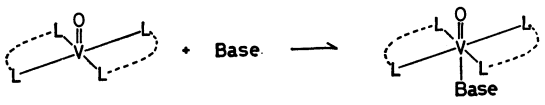
Mitsuo SATO, Yuzaburo FUJITA, and Takao KWAN

Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received March 31, 1973)

The interaction of bis(*O,O'*-diethyldithiophosphato)oxovanadium(IV), $VOdtp_2$, with pyridine bases has been studied in toluene by ESR. It has been found that the four-membered chelate structure of $VOdtp_2$ is disrupted by pyridine bases to form the complex species identified as $VOdtp_2 \cdot Py$ and $VOdtp_2 \cdot Py_2$ by their characteristic ESR spectra. The coordination structures of the newly-formed complexes are discussed in association with the substitution equilibria involved.

It is well known that square pyramidal oxovanadium(IV) complexes coordinated with bidentate ligands form 1 : 1 adducts in solutions with a variety of bases according to this expression:[1]



For example, the base adducts of bisacetylacetonato oxovanadium(IV) have been worked out[2] and the effects of adduct formation on the optical absorption and ESR spectra have also been reported.[3]

We have made an ESR investigation of the reaction of bis(*O,O'*-diethyldithiophosphato)oxovanadium(IV),

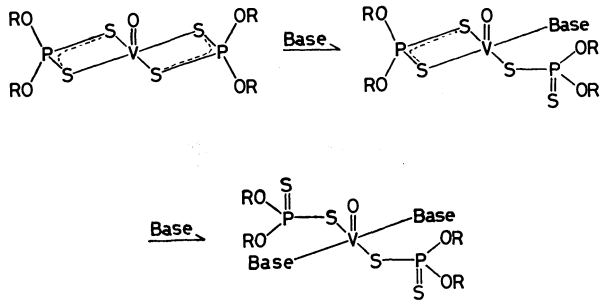
$VOdtp_2$, with pyridine bases. As a result, we found that pyridine bases displace equatorial sulfur ligands, leading to the partial destruction of the four-membered chelate rings, as is indicated below:



In the present report, we wish to describe the evidence for the destruction of the chelate structure, together with the characteristics of this reaction, since no such type of reaction has yet been reported for oxovanadium complexes.

Experimental

Materials. *O,O'*-Diethyldithiophosphoric acid (dtpH) was prepared as has been described previously.[4] Vanadyl sulfate hydrate ($VOSO_4 \cdot nH_2O$) was obtained from the Kishida Kagaku Co. Toluene and pyridine (G.R. Grade, Wako Junyaku Kogyo Co.) were purified by distillation from calcium hydride and potassium hydroxide respectively. All the other reagents used were of a G.R. grade and were also obtained commercially.

Preparation of Bis(O,O'-diethyldithiophosphato)oxovanadium(IV), $VOdtp_2$. Vanadyl sulfate hydrate was treated with sodium carbonate, and the precipitate was filtered and washed with distilled water until free of sodium sulfate. The precipitate was immediately added to an isopentane solution of dtpH under a flow of dry nitrogen. The suspended mixture was then stirred at room temperature until the precipitate almost dissolved. The resulting purple solution was filtered; the filtrate was then cooled by the rapid evaporation of isopentane with a vigorous flow of nitrogen to separate out a crystalline solid. The repeated recrystallization of the solid from isopentane under an atmosphere of nitrogen gave blue-purple, needle-like crystal. (Anal. Calcd. for $VO[S_2P(OC_2H_5)_2]_2$: C, 21.97; H, 4.61; V, 11.64%. Found: C, 22.12; H, 4.69; V, 11.90%.).

Measurements of the ESR Spectra. Since toluene and pyridine solutions of $VOdtp_2$ were unstable to air, all the measurements were carried out on sample solution carefully prepared in an atmosphere of nitrogen or *in vacuo*. The ESR spectra were recorded both at room temperature and at 77 K with JEOL spectrometers, Model P-10 and ME-1X (X-band), using 100 KHz field modulation. The magnetic field was calibrated with an ESR marker, MgO : Mn^{2+} powder, supplied by JEOL. Powdered DPPH was used as the reference in the determination of the *g*-values.

Results and Discussion

Interpretation of ESR Spectra and Structures of Oxovanadium Complexes in Solutions. Toluene solutions containing $VOdtp_2$ and pyridine bases in various mole ratios, as well as toluene and pyridine solutions of $VOdtp_2$, were subjected to ESR measurements both at room temperature and at 77 K. Typical ESR spectra thus obtained are illustrated in Figs. 1 and 2, while the ESR parameters calculated by the method of Kivelson and Lee[5] are presented in Table 1.

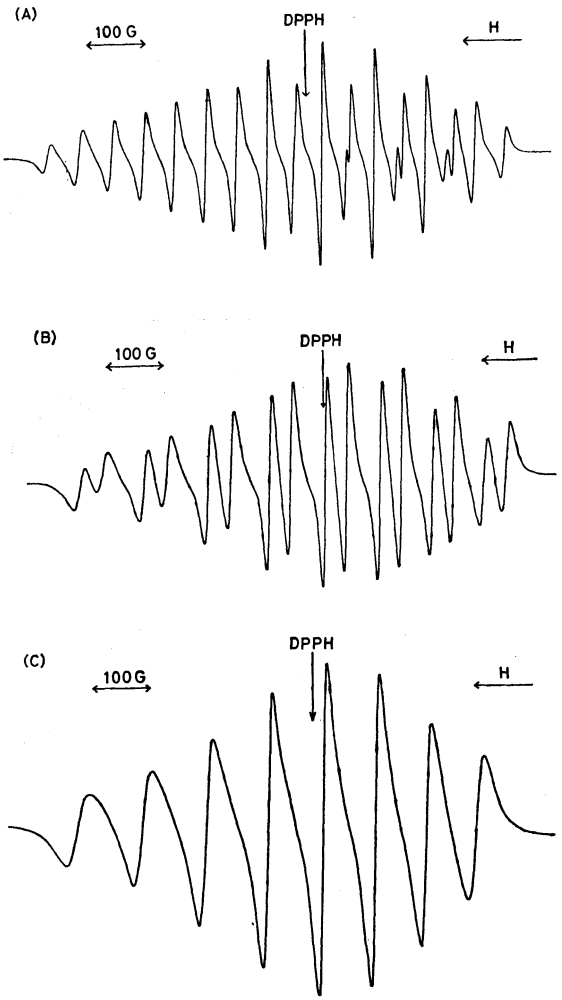


Fig. 1. ESR spectra of toluene-pyridine solutions of $VOdtp_2$ at room temperature.
(A) $VOdtp_2$ in toluene, $[VOdtp_2]=0.012$ M;
(B) $VOdtp_2$-pyridine in toluene, $[VOdtp_2]=0.018$ M, [pyridine] = 0.36 M;
(C) $VOdtp_2$ in pyridine, $[VOdtp_2]=0.024$ M.

$VOdtp_2$ in Toluene Solution: As is illustrated in Figs. 1–A and 2–A, a toluene solution of $VOdtp_2$ gave spectra quite similar to those previously reported[6,7] for $VOdtp_2$ in non-coordinating solvents. It can be seen from Figs. 1–A and 2–A that eight hf lines characteristic of the

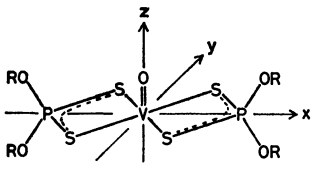
vanadium nucleus ($I=7/2$) are further split into three components with the intensity ratio of 1 : 2 : 1, probably by means of the shf interaction with the two equivalent phosphorus nuclei ($I=1/2$). The ESR parameters (Table 1) are in good agreement with those obtained by previous workers.[6,7]

On the other hand, it has already been suggested[6,7] that $VOdtp_2$ has a tetragonal pyramidal structure which can be depicted as:



[I] $VOdtp_2$

Such a structural model seems to be quite reasonable, since this is the basic type of coordination known for many oxovanadium(IV) complexes[8] and since dithiophosphate ligands have, in general, a great tendency to form a four-membered chelate structure with metal ions.

Furthermore, the suggested structure [I], which possesses a local symmetry of C_{2v},[9] can well satisfy the ESR parameters shown in Table 1. The g-values and vanadium hf constants are in good agreement with the theory that assumes a single unpaired electron located in an A_1 orbital mainly consisting of the vanadium $3d_{x^2-y^2}$ orbital.[5,10] The isotropic phosphorus constant ($a^P=51$ Gauss) can also be interpreted in terms of a direct vanadium($3d_{x^2-y^2}$)– phosphorus(3S) interaction.[7] It is important for us to note that the vanadium $3d_{x^2-y^2}$ orbital possesses the correct symmetry so as to interact directly with the two equivalent phosphorus 3s orbitals.

Our interpretation of the ESR spectra of $VOdtp_2$ in toluene is, in fact, in good agreement with those given by the previous workers and can be taken to furnish further support for the proposed structure [I]. We have, however, noted that such a structure is valid only when $VOdtp_2$ is present in non-coordinating solvents.[11]

$VOdtp_2$-Pyridine Bases in Toluene Solutions: When a certain amount of pyridine bases, such as pyridine, 4-methylpyridine, and 4-cyanopyridine, was added to a toluene solution of $VOdtp_2$, the spectra shown in Figs. 1–A and 2–A were replaced by the spectra characterized by 16 resonance lines. Typical examples are illustrated in Figs. 1–B and 2–B. It seems to us that such spectra are quite a new type of spectra. However, these spectra can easily be explained if the shf interaction due to one phosphorus nucleus split each of the eight vanadium hf lines into two components equal in intensity. In accordance with this assumption, the liquid solution spectrum (Fig. 1–B) consists of 16 resonance lines, while the frozen solution spectrum (Fig. 2–B) consists of two sets of 16 resonance lines, corresponding to the parallel and perpendicular directions ($g_\parallel$ and $g_\perp$).

The intensity of the 16-line spectrum was examined at room temperature as a function of the concentrations of the pyridine bases. The intensities of the 16-line spectrum relative to the 24-line spectrum[12] were found to be strongly dependent upon the mole ratios of the pyridine bases to $VOdtp_2$ in solutions. For example, the gradual addition of pyridine to a toluene solution of $VOdtp_2$ brought about a progressive decrease in the intensity of the 24-line spectrum, accompanied by a simultaneous appearance of the 16-line spectrum; the superimposed spectra of the 16- and 24-line spectra with comparable intensities were observ-

8) R. J. Clark, "The Chemistry of Titanium and Vanadium," Elsevier Publishing Co., New York (1968), p. 202.

9) The ligand field can be considered as a strong C_{4v} component with a perturbation lowering the symmetry to C_{2v}.

10) B. R. McGarvey, *Transition Metal Chemistry*, **3**, 89 (1966).

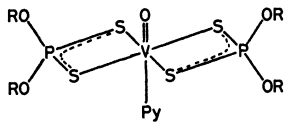
11) We have been unable to observe such spectra as are shown in Figs. 1-A and 2-A for $VOdtp_2$ dissolved in coordinating solvents, such as methyl alcohol, ethyl alcohol, diethylether, and tetrahydrofuran. This indicates that $VOdtp_2$ is highly reactive toward the coordinating solvents to be converted into another complex species. Further study along this line is now in progress.

12) The spectrum shown in Fig. 1–A is conveniently denoted as the "24-line spectrum," although fewer than the 24 expected lines are resolved because of line overlappings.

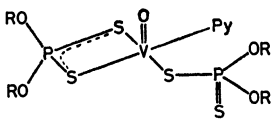
ed when the mole ratio of [pyridine]/[$VOdtp_2$] was around 2; the 24-line spectrum completely disappeared to give such a typical 16-line spectrum as is shown in Fig. 1–B when the [pyridine]/[$VOdtp_2$] ratio reached more than 10. A further increase in the [pyridine]/[$VOdtp_2$] ratio beyond 100, however, caused a decrease in the intensity of the 16-line spectrum, with an appearance of the 8-line spectrum, as will be described below.

On the other hand, Job's method of continuous variations, as applied to the $VOdtp_2$–pyridine base system at room temperature, showed that the intensity of the 16-line spectrum reached a maximum at about 50 mol% of the pyridine base. It is thus evident that one mole of $VOdtp_2$ reacts with one mole of the pyridine base to form a complex species, which then gives rise to the 16-line spectrum. It seems, therefore, probable that the complex species may result either from the addition of the pyridine base to the open coordination position of $VOdtp_2$ or from the displacement of the sulfur ligand by the pyridine base, and that the complex species may have a stoichiometry of $VOdtp_2$·Py, where Py denotes the pyridine base.

On the basis of the above considerations, we can now discuss the following structural models:



[II] $VOdtp_2$·Py



[III] $VOdtp_2$·Py

where it is assumed that the pyridine base in [II] is weakly coordinated as the sixth ligand, while the pyridine base in [III] is rather strongly coordinated as an equatorial ligand and the sulfur ligand displaced by the pyridine base is free or weakly coordinated to the axial site *trans* to the oxygen atom.

Both of the presumed models are compatible with the *g*-values and vanadium hf constants obtained (Table 1), if these structures are taken to have an approximate symmetry of C_{2v} with the electronic ground state of $^2A_1$, having an unpaired electron mainly in the vanadium $3d_{x^2-y^2}$ orbital, as in the case of $VOdtp_2$[I].

However, the observed shf splitting due to one phosphorus nucleus is in accord with the [III] structure rather than the [II] structure, because it can be expected from [II] that the two phosphorus nuclei take part in the shf interaction equivalently. On the other hand, one can reasonably expect from [III] that only the phosphorus nucleus located in the direction of the lobes of the vanadium $3d_{x^2-y^2}$ orbital contributes to the shf splitting, while the other phosphorus nucleus does not give rise to the resolved shf splitting because of its situation removed from interaction with the vanadium $3d_{x^2-y^2}$ orbital.

It is interesting to note that the isotropic shf constant (a^P=37 Gauss) for $VOdtp_2$·Py[III] is decreased considerably as compared with that (a^P=51 Gauss) found for $VOdtp_2$ [I]. This implies that the extent of the delocalization of the unpaired electron over the phosphorus 3s orbital is reduced from 1.4% for $VOdtp_2$ to 1.0% for $VOdtp_2$·Py.[13] Such a reduction may be explained on the assumption that either the lowering of the structural symmetry or the weakening of the four-membered chelate structure caused by the introduction of the pyridine base in the square plane results in the reduction of a direct vanadium($3d_{x^2-y^2}$)-phosphorus(3s) interaction.

TABLE 1. ESR PARAMETERS FOR $VOdtp_2$ DISSOLVED IN TOLUENE–PYRIDINE SOLUTIONS[a]

Solvents	Toluene	Toluene–Pyridine[b]	Pyridine
Typical spectra assignment	Figs. 1-A, 2-A	Figs. 1-B, 2-B	Figs. 1-C, 2-C
	$VOdtp_2$[I]	$VOdtp_2$·Py[III]	$VOdtp_2$·Py_2[IV]
Isotropic values			
g_0	1.981	1.976	1.974
$\|a^V\|$ Gauss	95.5	95.5	96.0
$\|a^P\|$ Gauss	51.0(2P)[c]	37.0(1P)[c]	—[d]
Anisotropic values			
$g_\parallel$	1.967	1.958	1.955
$g_\perp$	1.987	1.982	1.980
$\|A_\parallel^V\|$ Gauss	168	170	171
$\|A_\perp^V\|$ Gauss	59	59	59
$\|A_\parallel^P\|$ Gauss	52(2P)	37(1P)	—
$\|A_\perp^P\|$ Gauss	50(2P)	38(1P)	—

a) Isotropic and anisotropic values, obtained from the liquid solution spectra (Fig. 1) and the frozen solution spectra (Fig. 2) respectively, are presented. It is noted that all the experimental values thus obtained fit closely to the relations of $g_0=(g_\parallel+2g_\perp)/3$, $a^V=(A_\parallel^V+2A_\perp^V)/3$, and $a^P=(A_\parallel^P+2A_\perp^P)/3$. Uncertainty in the values is as follows: $g_0(\pm0.003)$; $g_\perp(\pm0.004)$; $g_\parallel(\pm0.008)$; a^V,a^P (±1.0); $A_\perp^V$, $A_\parallel^P$, $A_\perp^P(\pm2.0)$; $A_\parallel^V(\pm4.0)$.

b) No significant difference was found in ESR parameters between the spectra derived from the addition of pyridine, 4-methylpyridine, and 4-cyanopyridine.

c) Shf coupling constants due to the two equivalent phosphorus nuclei (2P) and due to one phosphorus nucleus (1P).

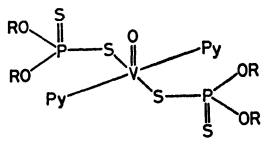
d) Shf splitting was not observed.

VOdtp$_2$ in Pyridine Solution: The spectra observed in a pyridine solution of $VOdtp_2$ are shown in Figs. 1–C and 2–C. It can be seen that the spectra consist of eight vanadium hf lines, without any phosphorus shf splitting. Quite similar spectra were also observed in toluene solutions of $VOdtp_2$ containing a large excess of pyridine bases.

The absence of phosphorus shf splitting is taken to indicate clearly that the complex species in pyridine does not carry the coordination unit consisting of the four-membered chelate structure with the phosphorus atom located diagonally to the vanadium atom. It seems likely that pyridine causes the complete destruc-

13) The spin densities of the phosphorus 3s orbital were calculated by using a hf interaction for unit occupancy of a phosphorus 3s orbital as 3640 Gauss (P. W. Atkins and M. C. R. Symons, "The Structure of Inorganic Radicals," Elsevier, Amsterdam (1967)).

tion of the chelate structure as a result of the displacement of equatorial sulfur ligands. Thus, one can tentatively presume that the complex species in pyridine has a stoichiometry of $VOdtp_2 \cdot Py_2$ and such a coordination model:



[IV] $VOdtp_2 \cdot Py_2$

The *g*-values and vanadium hf constants (Table 1) are also interpretable on the basis of this structural model which places the unpaired electron in the vanadium $3d_{x^2-y^2}$ orbital in the first approximation, as in the cases of $VOdtp_2$[I] and $VOdtp_2 \cdot Py$[III]. On the other hand, one might expect from the [IV] structure that the nitrogen instead of the phosphorus shf splitting is resolved. However, one may recall that oxovanadium complexes coordinated with nitrogen ligands seldom exhibit a resolved shf splitting.[5,14]

Reaction Scheme between $VOdtp_2$ and Pyridine Bases. The most important ESR information presented above is that the four-membered chelate structure of $VOdtp_2$[I] is destroyed by pyridine bases to form $VOdtp_2 \cdot Py_2$[III] or $VOdtp_2 \cdot Py_2$[IV], depending upon the concentrations of the pyridine bases in solutions. Accordingly, we can summarize the reactions of $VOdtp_2$ with pyridine bases as follows:

$$\underset{[I]}{VOdtp_2} + Py = \underset{[III]}{VOdtp_2 \cdot Py} \quad (1)$$

$$\underset{[III]}{VOdtp_2 \cdot Py} + Py = \underset{[IV]}{VOdtp_2 \cdot Py_2} \quad (2)$$

When pyridine concentrations are lower, $VOdtp_2$ reacts with the pyridine bases according to Reaction (1) to form the 1 : 1 complex, $VOdtp_2 \cdot Py$. It should be noted that Reaction (1) is not a simple process in which pyridine bases add to the open coordination position *trans* to the oxygen atom to form six-coordinate adducts. However, it seems quite possible that $VOdtp_2 \cdot Py$[III] is formed *via* an associative pathway[15] in which pyridine bases add first to the open coordination site, producing intermediate six-coordinate adducts with the [II] structure. The fact that the presence of the intermediate adduct [II] was not evidenced by ESR and optical absorption spectra probably implies that such a coordination structure is unstable and is rapidly converted into the [III] structure.

On the contrary, Reaction (2) takes place when $VOdtp_2 \cdot Py$ interacts with a large excess of pyridine bases. Thus, on the dissolution of $VOdtp_2$ in pyridine, both of the four-membered chelate rings are disrupted as a result of Reactions (1) and (2) to give $VOdtp_2 \cdot Py_2$ with the [IV] structure. The pyridine solution of $VOdtp_2 \cdot Py_2$ was found to be rather unstable and to liberate slowly a blue precipitate on standing *in vacuo*.

The reaction schemes, (1) and (2), disclosed here is of particular interest because the Reaction (1) affords a marked contrast to the well-established scheme of the formation of 1 : 1 adducts of $VO(acac)_2$ with a variety of bases,[2,3] where the addition of bases occurs to the sixth position of the otherwise unaltered complex. Such a difference in the scheme of base addition arises partly from the different nature of equatorial ligands in oxovanadium complexes.

This work was supported in part by a grant of the Ministry of Education, to which the authors' grateful acknowledgements are made.

Photolysis of Ethylene at 1634 Å and 1849 Å

Hiroshi HARA and Ikuzo TANAKA

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received April 2, 1973)

The photolysis of ethylene was carried out at room temperature at 1634 Å and 1849 Å. Products at both wavelengths were hydrogen, acetylene, ethane, *n*-butane and 1-butene. Product analysis and the radical scavenger technique indicate the primary processes to be as follows.

$$C_2H_4 + h\nu \longrightarrow \begin{cases} C_2H_2 + H_2 \\ C_2H_2 + 2H \\ C_2H_3 + H \end{cases}$$

The molecular elimination process in the primary processes varied with wavelengths, and was determined to be 47% and 53% at 1634 Å and 1849 Å, respectively. With reference to the percentage reported at other wavelengths, it is pointed out that molecular elimination is suppressed with the increase in excitation energy.

The photochemistry of ethylene has long been studied[1-6] and the reaction mechanism is proposed from the results of investigations at 1236 Å and 1470 Å,[1-3]

$$C_2H_4 + h\nu \longrightarrow \begin{cases} C_2H_2 + H_2 & \Phi_1 \\ C_2H_2 + 2H & \Phi_2 \end{cases}$$

where Φ_1 and Φ_2 stand for the quantum yields of the respective reactions. These are followed by the secondary processes,

$$H + C_2H_4 \longrightarrow C_2H_5$$

$$C_2H_5 + C_2H_5 \longrightarrow \begin{cases} C_2H_4 + C_2H_6 \\ n\text{-}C_4H_{10} \end{cases}$$

The quantum yield Φ_1 relative to Φ_2 decreases as the excitation energy increases. Since some molecules such as ethane show a wavelength dependence of the quantum yield of molecular elimination, it seems interesting to study the wavelength dependence of Φ_1 relative to Φ_2 over a wider range.

Ethylene was studied at longer wavelengths. For quantitative treatment, the percentage of the molecular mechanism is expressed by $\Phi_1/(\Phi_1+\Phi_2+\Phi_3)$, where Φ_3 is the quantum yield of the vinyl radical formation process

$$C_2H_4 + h\nu \longrightarrow C_2H_3 + H$$

which was recently found in the photolysis of ethylene at 1470—1931 Å by Potzinger *et al.*[7] In the present study, the primary process of the vinyl radical formation is discussed in detail.

Ethyl radicals were formed in the secondary process of the photolysis of ethylene, and underwent disproportionation reaction or recombination reaction. A number of investigators have determined the ratio of the constants of these two reactions, generating ethyl radicals from different source. The reported ratios show a spread but most values lie in the range 0.10—0.17. The ratio in the photolysis of ethylene is discussed in the present study.

The V–N system beginning near 2650 Å consists of a long progression of broad diffuse bands, starting at 2150 Å and rising rapidly in intensity with decreasing wavelength. At 1744 Å, the V–N bands disappear under the intense bands of the first Rydberg transition, but the V–N system obviously continues, and finally reaches a broad flat maximum at about 1620 Å. At still shorter wavelengths the absorption decreases fairly steadily, down to the next strong Rydberg transition which begins at 1393 Å.[11]

Thus the absorption at 1236 Å corresponds to the second R–N transition, and that at 1470 Å to the mixture of the R–N and V–N transitions. On the other hand, the absorptions at both 1634 Å and 1849 Å in this study correspond to V–N transition.

Experimental

The light source of 1634 Å was an electrodeless discharge bromine lamp, construction of which was reported elsewhere,[12,13] and that of 1849 Å was a conventional low-pressure mercury lamp. The reaction system was a quartz cylinder with quartz windows and a glass-made circulator.

Nitrogen gas was allowed to flow between the lamp and the cell during the photolysis to avoid the absorption of oxygen at 1634 Å.

Ethylene was obtained from Takachiho Chem. Ind. Co. Gas chromatographic analysis showed the presence of impurity, 0.1% ethane. After purification by gas chromatography using an active carbon column, the impurity level was below 0.01%. Nitric oxide was also obtained from

Takachiho Chem. Ind. Co. and was used without further purification. The reaction was followed by freezing out the unreacted ethylene and any condensable products with liquid nitrogen to a sample collection tube. The condensables were analyzed with a Hitachi Model KGL-2A gas chromatograph equipped with a flame ionization detector using a 2 m long column of silica gel-squalane, and with a Hitachi Model 063 gas chromatograph, equipped with a flame ionization detector for hydrocarbon products using a 9 m long column of squalane on Chromosorb P support. For hydrogen, a 1 m long column of active carbon and a thermal conductivity detector were used, a copper oxide furnace being provided between the column and the detector to convert hydrogen into water for higher sensitivity. In order to determine the ratio of hydrogen to ethylene, the reaction system was attached to the Toepler pump system to collect the entire amount of products and the unreacted into the sample collection tube. All experiments were carried out at room temperature.

Results

Photolysis at 1634 Å. The products of photolysis with radiation at 1634 Å were hydrogen, acetylene, ethane, *n*-butane and 1-butene. They are the same as in the photolysis at 1236 Å and 1470 Å except that only traces of 1-butene and hexane were detected and no C-4 compounds other than *n*-butane were observed.[2,3]

In order to see the effect of the secondary photolysis which should be negligibly small, the yields of acetylene, ethane and *n*-butane, were determined for different irradiation times. The relative yields are plotted as a function of irradiation time in Fig. 1. This result provided a linear function of time so that complications due to the secondary photolysis was not significant within one percent of conversion. The following photolysis was conducted within this limit.

Photolysis in the presence of nitric oxide was performed with a constant pressure of ethylene and a fixed time of irradiation. No appreciable decrease in the yield of acetylene was observed in these experiments.

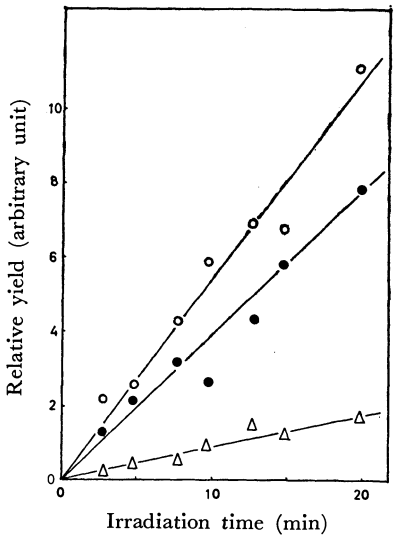

Fig. 1. Relative yields of products *vs.* irradiation time. C_2H_2 (○), *n*-C_4H_{10} (●), and C_2H_6 (△).

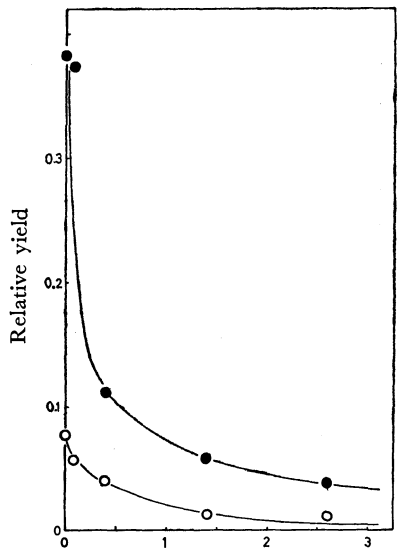

Fig. 2. Relative yields of *n*-C_4H_{10} and C_2H_6 to C_2H_2 *vs.* added NO pressure (C_2H_4; 20 Torr). *n*-C_4H_{10} (●) and C_2H_6 (○).

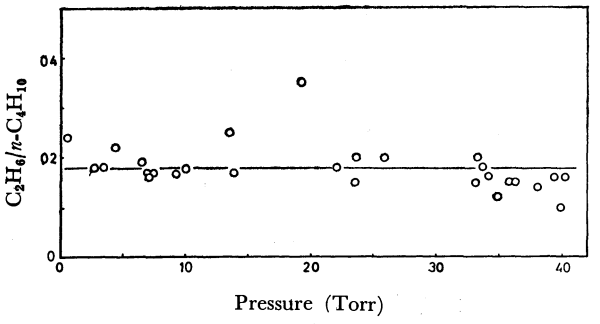

Fig. 3. C_2H_6 to *n*-C_4H_{10} ratio *vs.* C_2H_4 pressure at 1634 Å.

As shown in Fig. 2, ethane and *n*-butane decreased remarkably with increasing concentration of nitric oxide which was an effective free-radical scavenger. These results support the view that acetylene, at least the majority of it, was formed in the primary processes, and that ethane and *n*-butane were formed in the radical reaction.

The ratio of ethane to *n*-butane is plotted as a function of ethylene pressure in the range 0.6—40 Torr in Fig. 3. The ratio calculated to be 0.18±0.04 is independent of ethylene pressure.

The ratio of 1-butene to *n*-butane as products is almost constant, 0.045±0.008 in the pressure range 5—40 Torr.

Photolysis at 1849 Å. The products of the photolysis with light of 1849 Å were hydrogen, acetylene, ethane, *n*-butane and 1-butene as in the case of the photolysis at 1634 Å.

The ratio of ethane to *n*-butane was measured at various pressures of ethylene as shown in Fig. 4. It is independent of ethylene pressure and gives the average value of 0.30±0.06.

The ratio of 1-butene to *n*-butane was determined to be 0.19±0.04, pressure independent in the range 5—35 Torr.

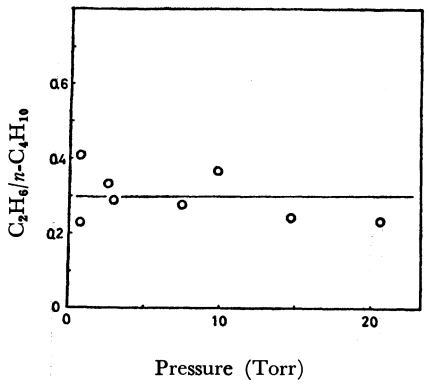

Fig. 4. C_2H_6 to n-C_4H_{10} ratio *vs.* C_2H_4 pressure at 1849 Å.

Discussion

Reaction Mechanism. The formation of a considerable amount of 1-butene at 1634 Å and 1849 Å affords the following processes which account for the products of the present work as well as those of the previous work using shorter wavelengths.

$$C_2H_4 + h\nu \xrightarrow{\Phi_1} C_2H_2 + H_2 \quad (1)$$

$$\xrightarrow{\Phi_2} C_2H_2 + 2H \quad (2)$$

$$\xrightarrow{\Phi_3} C_2H_3 + H \quad (3)$$

$$H + C_2H_4 \xrightarrow{k_4} C_2H_5 \quad (4)$$

$$C_2H_5 + C_2H_5 \xrightarrow{k_5} C_2H_4 + C_2H_6 \quad (5)$$

$$\xrightarrow{k_6} n\text{-}C_4H_{10} \quad (6)$$

$$C_2H_3 + C_2H_5 \xrightarrow{k_7} 2C_2H_4 \quad (7)$$

$$\xrightarrow{k_8} C_2H_2 + C_2H_6 \quad (8)$$

$$\xrightarrow{k_9} 1\text{-}C_4H_8 \quad (9)$$

Steady state treatment led to the relationship

$$\frac{R(C_2H_6) + R(n\text{-}C_4H_{10})}{R(C_2H_2)} = \frac{\Phi_2 + \Phi_3 \cdot \dfrac{k_8}{k_7+k_8+k_9}}{\Phi_1 + \Phi_2 + \Phi_3 \cdot \dfrac{k_8}{k_7+k_8+k_9}} \equiv \alpha \quad (10)$$

$$1 - \frac{R(H_2)}{R(C_2H_2)} = \frac{\Phi_2 + \Phi_3 \cdot \dfrac{k_8}{k_7+k_8+k_9}}{\Phi_1 + \Phi_2 + \Phi_3 \cdot \dfrac{k_8}{k_7+k_8+k_9}} \equiv \beta \quad (11)$$

$$\frac{R(C_2H_6)}{R(n\text{-}C_4H_{10})} = \frac{k_5}{k_6} + \frac{\Phi_3}{\Phi_2} \cdot \frac{k_5+k_6}{k_6} \cdot \frac{k_8}{k_7+k_8+k_9} \equiv \gamma \quad (12)$$

$$\frac{R(1\text{-}C_4H_8)}{R(n\text{-}C_4H_{10})} = \frac{\Phi_3}{\Phi_2} \cdot \frac{k_5+k_6}{k_6} \cdot \frac{k_9}{k_7+k_8+k_9} \equiv \delta \quad (13)$$

where α, β, γ, and δ are the experimentally available values of the product ratios, and R(M) is the formation rate of M.

Reaction (8) is an important process which explains the difference in the ratio of ethane to n-butane at 1634 Å and at 1849 Å. According to a recent work. k_8 is not negligibly small compared with k_7 and k_9, namely $k_7 : k_8 : k_9 = 1.00 : 0.43 : 0.89$.[14] Potzinger *et al.* did not include Reaction (8) on the basis that the addition of oxygen to ethylene had no effect on the quantum yield for acetylene.[7] It might be because the contribution of Reaction (8) at the formation of acetylene was not important. In the present study, however, the Reaction (8) must not be ruled out.

TABLE 1. k_5/k_6 IN THE PHOTOLYSES OF ETHYLENE AT DIFFERENT WAVELENGTHS

Excitation wavelength	k_5/k_6	Ref.
1236 Å[a)]	0.18	(3)
1470 Å	0.15	(2)
	0.19	(14)
1634 Å	0.16±0.04	this work
1849 Å	0.21±0.06	this work

a) CH_2CD_2

Disproportionation and Recombination of Ethyl Radicals. Ethyl radical is formed in the photolysis of ethylene. If ethane and n-butane are formed only through ethyl radical reactions, the ratio of the formed amount of ethane to that of n-butane directly leads to k_5/k_6. The photolyses at 1236 Å and 1470 Å are such cases. In the present study, the ratios of ethane to n-butane are 0.18 at 1634 Å and 0.30 at 1849 Å, suggesting the additional amount of ethane from Reaction (8). Thus from Eqs. (12) and (13), we obtain the relation.

$$\frac{k_5}{k_6} = \gamma - \frac{k_8}{k_9} \cdot \delta$$

From our experimental values of γ, δ and reported value of k_8/k_9, 0.48,[14] the value of k_5/k_6 should be obtained.

At 1634 Å, γ is 0.18±0.04 and δ is 0.045±0.008, then k_5/k_6 is 0.16±0.04. At 1849 Å, γ and δ are 0.30±0.06 and 0.19±0.04, respectively, so k_5/k_6 is 0.21±0.06. Comparison of this ratio at different wavelengths is made in Table 1. In consideration of this ratio 0.13+0.02,[8-10] obtained previously from different sources of ethyl radicals, these values in the photolysis of ethylene agree well within the error limit.

Molecular Mechanism of the Primary Processes at 1634 Å *and* 1849 Å. Substitution of our values of k_5/k_6 and the reported relative values, $k_7 : k_8 : k_9 = 1.00 : 0.43 : 0.89$,[14] into Eqs. (12) and (13) gives the following.

$$\frac{R(C_2H_6) + R(n\text{-}C_4H_{10})}{R(C_2H_2)} = \frac{\Phi_2 + 0.19\Phi_3}{\Phi_1 + \Phi_2 + 0.19\Phi_3} \equiv \alpha \quad (15)$$

$$1 - \frac{R(H_2)}{R(C_2H_2)} = \frac{\Phi_2 + 0.19\Phi_3}{\Phi_1 + \Phi_2 + 0.19\Phi_3} \equiv \beta \quad (16)$$

$$\frac{R(C_2H_6)}{R(n\text{-}C_4H_{10})} = 0.16 + 0.22\frac{\Phi_3}{\Phi_2} \equiv \gamma \text{ (for 1634 Å)} \quad (17\text{-}8)$$

$$= 0.21 + 0.22\frac{\Phi_3}{\Phi_2} \equiv \gamma \text{ (for 1849 Å)} \quad (17\text{-}2)$$

$$\frac{R(1\text{-}C_4H_8)}{R(n\text{-}C_4H_{10})} = 0.44\frac{\Phi_3}{\Phi_2} \equiv \delta \text{ (for 1634 Å)} \quad (18\text{-}1)$$

$$= 0.46\frac{\Phi_3}{\Phi_2} \equiv \delta \text{ (for 1849 Å)} \quad (18\text{-}2)$$

Relative quantum yields of the primary processes can

14) T. Ibuki and Y. Takezaki, private communication.

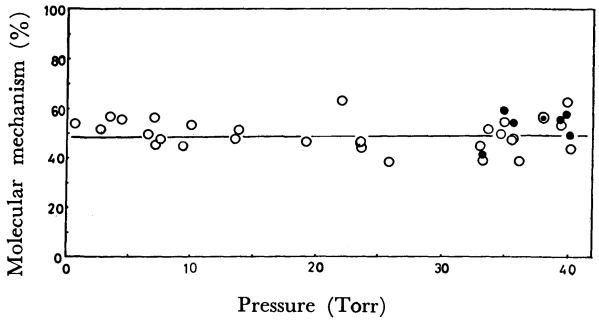

Fig. 5. Molecular mechanism (%) *vs.* C_2H_4 pressure at 1634 Å.
(○) from Eqs. (15) and (17—1); (●) from Eqs. (16) and (17—1).

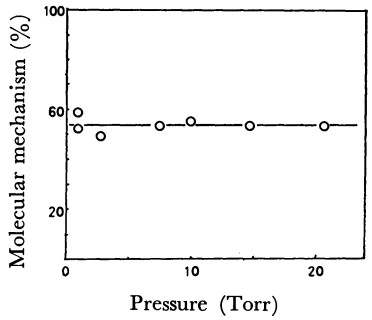

Fig. 6. Molecular mechanism (%) *vs.* C_2H_4 pressure at 1849 Å.

be obtained using Eqs. (15)—(18) with the values of α, β, γ, and δ.

In most experiments, α and γ values were used to obtain the percentage of the molecular elimination process, which is shown in Fig. 5 as a function of ethylene pressure at 1634 Å and in Fig. 6 at 1849 Å. It is pressure independent at both wavelengths. The average values of molecular mechanism, Φ_1, are 47% at 1634 Å and 53% at 1849 Å.

Φ_1 at 1634 Å calculated from β and γ values is also shown in Fig. 5, giving the average value 51%.

The value of δ from the ratio of 1-butene and *n*-butane is 0.045 at 1634 Å and 0.19 at 1849 Å. The relative quantum yields of the primary processes also can be calculated at 1634 Å and 1849 Å using δ values instead

Table 2. Relative quantum yield at 1634 Å and 1849 Å

		Relative quantum yield from			
		(15) and (17)	(16) and (17)	(15) and (18)	(16) and (18)

of γ values. They are summarized in Table II, and are in good agreement within experimental error.

Formation of vinyl radical in the primary process, proposed in the flash photolysis study of ethylene[5] and 1470—1931 Å photolysis of ethylene,[7] explains the presence of 1-butene as a product which should be formed by the recombination reaction of vinyl and ethyl radicals.

Another fact supporting the formation of vinyl radical is the good agreement between the ratio of Φ_3 to Φ_2 from γ and that from δ. At 1634 Å, the ratio of Φ_3 to Φ_2 is 0.091 from γ and 0.10 from δ. At 1849 Å it is 0.41 from γ and 0.41 from δ. Agreement of the ratios indicates the formation of vinyl radical in the primary process.

The precursors proposed by Potzinger *et al.*, leading to the three different primary processes, are of great interest. In this study, however, the quantum yields determined are relative and cannot support or deny their proposed mechanism. Our data can be compared with their data extrapolated to zero pressure in their mechanism.

The relative quantum yields obtained in this investigation are shown in Fig. 7 as a function of the excess energy together with the reported results[2,3,7,15,16]. The excess energy is defined by

$$E(\text{excess energy}) = E(h\nu) - \Delta H \quad (18)$$

where $E(h\nu)$ is the photon energy of the excitation light, and ΔH is heat of reaction:

$$C_2H_4 = C_2H_2 + H_2 \quad \Delta H = 41.7\,\text{kcal/mol} = 1.8\,\text{eV} \quad (19)$$

Figure 7 would permit the interpretation that the internal energy of an excited ethylene molecule increases as the irradiation photon energy increases, so that molecular mechanism of the primary process could take place less easily than atomic mechanism at shorter wavelengths.

It is concluded that ethylene shows a similar wavelength dependence of the primary processes to that of ethane, where the experimental data of some simple molecules, such as ethylene, ethane ammonia and water, have been qualitatively interpreted by a simple theoretical treatment of the RRKM theory.[17]

Molecular Interactions of *p*-(*N*,*N*-Dimethylamino)-Benzonitrile. Electrostatic Self-Complex and Hetero-Complex Formation in the Ground and Excited States

Nobuaki NAKASHIMA and Noboru MATAGA[1)]

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received May 24, 1973)

Electrostatic self-complex formation of *p*-(*N*,*N*-dimethylamino)-benzonitrile and its hetero-complex formation with benzonitrile in cyclohexane matrix were studied in detail. The possibilities of ground state complex and excimer formation in various liquid solvents were examined thoroughly.

p-(*N*,*N*-Dimethylamino)-benzonitrile(DMABN) exhibits dual fluorescence bands in polar solvents, F_a at longer wavelength side (*ca.* 400—500 nm) and F_b at shorter wavelength side (*ca.* 360 nm). In nonpolar solvents and rigid matrix at low temperatures only the F_b band can be observed. Lippert *et al.*[2)] ascribed this phenomenon to two emitting electronic states, a strongly polar one (^1L_a) and a less polar one (^1L_b).

On the other hand, Rotkiewicz *et al.* assigned the emissions to the existence of two isomers α and β differing in polarity and in the orientation of the dimethylamino group.[3)] In the case of α form which is strongly polar and emits the F_a fluorescence, the lone pair of amino nitrogen is assumed parallel to the plane of benzene ring. In the case of less polar β form emitting the F_b fluorescence, the lone pair is considered to be perpendicular to the benzene ring.

Recently, we have measured time-resolved fluorescence spectra and fluorescence rise and decay curves of DMABN in MTHF (methyltetrahydrofuran) and have demonstrated clearly the relaxation process due to the interaction between the solvent and the strongly polar state of the solute, leading to the dual fluorescence.[4)] Either of the above two interpretations by Lippert *et al.* and Rotkiewicz *et al.* may be consistent with our result of time-resolved fluorescence studies if we assume that α isomer is formed from the β isomer in the excited state. In the course of this study, we have found that the ground state DMABN forms self-complexes and also complexes with benzonitrile in cyclohexane matrix.[4)] We have made more detailed investigations on these aggregation phenomena in cyclohexane matrix and, moreover, examined the possibilities of the ground state aggregates as well as excimer formations in various liquid solvents. We have found no definite ground state complex formation in the liquid solution.

On the other hand, McGlynn and co-workers have recently reported absorption and luminescence spectra which they ascribed to the dimer of DMABN.[5)] Moreover, they claimed that the F_a band is an excimer emission. According to our present study, their dimer band is due to some unknown impurity and their claim of excimer fluorescence is erroneous.

Experimental

DMABN (K and K) was recrystallized several times from *n*-hexane (Wako, spectrograde). Diethyl ether (Merck, spectrograde), toluene (Merck, spectrograde), acetonitrile (Merck, spectrograde), tetrahydrofuran (THF) (Wako, spectrograde) and methylcyclohexane (Wako, spectrograde) were used without purification. Methanol, propylene glycol, benzonitrile and ethanol were all Wako analytical grade reagents and used without further purification.

The absorption spectra were measured by a Cary 15 and a Shimadzu MPS-50L spectrometer. Cells with optical paths of 1 mm, 400 μ, 25 μ and 2 μ were made by inserting thin packings between quartz plates. Fluorescence spectra were measured by an Aminco-Bowman spectrophotofluorometer. The detector for luminescence was photomultiplier of type RCA 1P28. The temperature of a solution for the measurement was controlled by a constant flow of cold nitrogen gas in a metal Dewar vessel with quartz windows or a cuvette was immersed in ethanol in a quartz Dewar vessel and the temperature of ethanol was controlled by drop ping liquid nitrogen. Solutions for the measurement were not deaerated but some of them were flushed with nitrogen.

Results and Discussion

The extinction coefficient of the absorption band at 330—360 nm in propylene glycol solution decreased to about one-third or one-half of the initial value, respectively, when DMABN was recrystallized once from *n*-hexane or water. We observed that the extinction coefficient around 250 nm also decreased by recrystallization. After being recrystallized five times from *n*-hexane, DMABN did not show practically any absorption band at 330—360 nm region. Thus, it seems to be clear that the absorption band at 330—360 nm ascribed by McGlynn *et al.* to the dimer of DMABN is due to some unknown impurity. This impurity appears to show absorption band not only at 330—360 nm but also at about 250 nm. The impurity absorption band seems to become strong in such hydroxylic solvents as water and alcohols. However, it is quite weak in various non-hydroxylic solvents such as aliphatic as well as aromatic hydrocarbons, ethers and nitriles, even when a crude sample is used. Therefore, the intensity of the impurity band does not depend on the solvent polarity but seems to be affected by hydrogen bonding interaction.

If there occurs the ground state dimerization of DMABN, its absorption spectra should show a concentration dependence. We have examined the concentration effect upon the absorption and fluorescence spectra of DMABN in propylene glycol by changing its concentration within the range 1×10^{-5} up to 5×10^{-3} M. We found no change in the spectra. This result is contrary to that of McGlynn *et al.*, and the fluorescence band assigned by them to the ground state dimer is clearly due to the unknown impurity.

We can observe true spectral change due to the ground state aggregation of DMABN in cyclohexane matrix at low temperatures as described in detail in section B. In the case of highly concentrated solutions (0.1—2 M), we can recognize a little change in the fluorescence spectra. We have confirmed, however, that this spectral change is not due to the excimer formation claimed by McGlynn *et al.*

A. On the Possibility of Excimer Formation in Highly Concentrated Solutions of DMABN. If F_a and F_b bands are an excimer and monomer emission of DMABN, respectively, as claimed by McGlynn *et al.*, the intensity ratio $I(F_a)/I(F_b)$ should increase as the concentration is increased. However, the ratio does not show any concentration dependence within the range 1×10^{-5} M up to 1×10^{-2} M in all solvents we have examined. Therefore, the excimer formation cannot be responsible for the F_a fluorescence. In toluene and ether solutions, the ratio increases and F_a band shows a red shift at very high concentration as indicated in Fig. 1 and Table 1. However, in such polar solvents as methanol and acetonitrile, the intensity ratio decreases and F_a band shows a little blue shift at a very high concentration as one can see from Fig. 2 and Table 1.

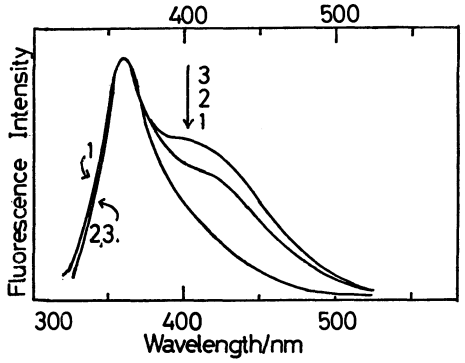

Fig. 1. Concentration effect of the fluorescence spectra of of DMABN in diethylether. [DMABN], 1: 5×10^{-5} M, 2: 1×10^{-1} M, 3: 2.5×10^{-1} M. The spectra were corrected for the response of the entire analyzing system.

	(20)	2	b)	465±2

a) Dielectric constant of the solvent. Taken from J. A. Riddick and W. B. Bunger, "Techniques of Chemistry," 2. Organic Solvents., Third ed., John Wiley and Sons, New York (1970), p. 563. b) The intensity was too weak to determine the wavelength of the band maximum. c) Because of the overlapping of the F_b band which is much stronger than F_a band, the determination of the peak wavelength was not possible.

In highly concentrated solutions, DMABN seems to play not only the role of the solute but also that of the polar solvent molecule. Presumably, DMABN molecule may be more polar than toluene and ethers. Therefore, in the case of the highly concentrated solutions in these solvents, the electrostatic dipolar interactions between the strongly polar excited state and ground state DMABN molecules may facilitate the appearance and red shift of the F_a band. Contrary to this, dielectric constant of "DMABN solvent" may be smaller than those of methanol and acetonitrile, leading to the decrease of the intensity ratio and the blue shift of the F_a band at a very high concentration in these solvents.

The above electrostatic interactions, however, appear to involve not only the long range one determined by the bulk dielectric constant but also short range interactions which may be deemed 1 : 1 or 1 : *n* electrostatic loose "self-complex" formation. For the increase of the F_a band intensity in toluene and ethers starts already at 5×10^{-2} M where the increase of the bulk dielectric constant due to the added DMABN may certainly be neglected. The self-complex in the present case does not mean the formation of such a definite stoichiometric complex by a specific short range interaction as the typical exciplex, but loose association of excited DMABN with ground state DMABN molecules by means of dipole-dipole interactions.

The electrostatic self-complex formation may be rather difficult in strongly polar solvents such as methanol and acetonitrile, since the interaction between the polar solvent molecules and the excited DMABN may be quite strong. Therefore, the bulk electrostatic effect may be rather important in this case.

We have confirmed in the case of highly concen-

The spectra were corrected.

trated solutions that the fluorescence excitation spectra measured at F_a band coincides with those measured at F_b band. Accordingly, the increase of the F_a band intensity at high concentration does not seem to be ascribed to the ground state complex formation. Moreover, it has been confirmed that the absorption spectra of highly concentrated solutions in methanol and ethanol are the same as those of 2×10^{-5} M solutions. Therefore, the electrostatic interactions leading to the fluorescence spectral changes are occurring in the excited state.

The excited DMABN molecule will make the electrostatic complex not only with the same kind of molecules but also with different kind of polar molecules. We have examined its interaction with benzonitrile in methylcyclohexane. As shown in Fig. 3, one can recognize a considerable change of the fluorescence spectra at 5×10^{-2} M of added benzonitrile. The spectra show an apparent red shift and intensity increase at the long wavelength side of the band by temperature lowering, which may be ascribed to the appearance of the F_a band caused by electrostatic "hetero-complexes" formation with benzonitrile molecules. In this case too, we have confirmed that the absorption spectra of DMABN do not show any change by the addition of 5×10^{-2} M benzonitrile. Therefore, the interaction with benzonitrile molecules leading to the appearance of F_a band is occurring in the excited state. The present hetero-complex also is not a definite complex but loose aggregation of excited DMABN with benzonitrile by means of dipole-dipole interactions, since one cannot recognize a definite isoemissive point in the emission spectra. Electrostatic loose complex formation of an excited polar solute molecule with polar solvent molecules has been assumed, for example, in the case of indole or tryptophan in alcohol or aqueous solution[6,7] as well as DMABN-propionitrile-methylcyclohexane system.[8]

E_d: excitation spectra of F_d band.

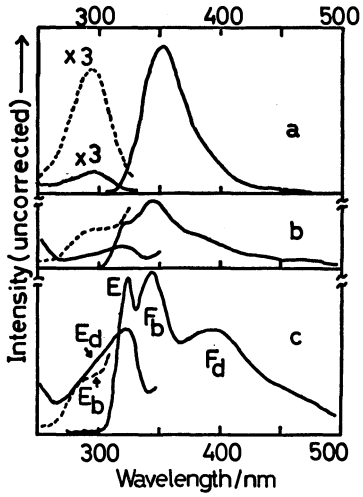

Fig. 5. Temperature effect on the fluorescence and excitation spectra of DMABN in cyclohexane matrix.
[DMABN] $=5\times10^{-4}$ M.
a. 20 ± 3 °C, b. -24 ± 3 °C, c. -45 ± 3 °C.
The meanings of E, E_b and E_d are the same as those in Fig. 4.

At any rate, the above results in nonpolar and slightly polar solvents may be well understood as due to the loose 1 : 1 or 1 : n electrostatic self-complex or hetero-complex formation and the results in strongly polar solvents may be ascribed mainly to an electrostatic bulk effect. Change of the fluorescence spectra due to the complex formation of DMABN occurs also in cyclohexane matrix at low temperatures as we have briefly reported previously. In the case of cyclohexane matrix, however, the complex is formed already in the ground state. The studies in cyclohexane matrix may be quite useful for the elucidation of the aggregation phenomena of DMABN. We have made a de-

tailed investigation along this line.

B. Aggregation in Cyclohexane Matrix. The effects of DMABN concentration as well as temperature upon the luminescence and excitation spectra have been investigated as shown in Figs. 4 and 5. When temperature is kept constant at -45 ± 3 °C and concentration is increased, the intensity of the band at 390 nm (F_d band) increases and its peak wavelength does not depend on the concentration as one can see from Fig. 4. When the temperature is lowered keeping the concentration at 5×10^{-4} M, the F_d band intensity increases as indicated in Fig. 5. In both of Figs. 4 and 5, we can observe the F_b band at *ca.* 340 nm together with the F_d band. The excitation spectrum of F_b band is observed at *ca.* 290 nm, the wavelength of the absorption band of DMABN. However, that of the F_d band is observed at about 320 nm which is different from the absorption peak of DMABN monomer. Since the excitation spectra at shorter wavelengths than 250 nm were not accurate, they are not shown here.

In view of its concentration and temperature dependences and its excitation spectra different from those of the monomer, the F_d band may be ascribed to an aggregated state of DMABN. In order to confirm the change of absorption spectra in cyclohexane matrix, we have measured directly the absorption spectra at several temperatures as shown in Fig. 6. Temperature lowering causes the intensity increase of the bands at 320 ± 10 nm and at 240 ± 5 nm. The absorption peak at 320 nm is in good agreement with the peak of the excitation spectra of F_d band. One can see also in Fig. 6 that the temperature lowering causes the intensity decrease of the 285 nm band. Presumably, the absorption bands at 320 and 240 nm may be assigned to the dimer of DMABN and the F_d band to its fluorescence. The F_d band may be mainly due to the F_a band appeared as a result of the electrostatic interaction between the halves in the dimer. However, the wavelength of the F_d band is a little shorter than that of the F_a band in highly concentrated toluene solution or diethyl ether solution. This result may be ascribed to the fact that the ground state of the aggregate is stabilized considerably and there is no reorientation stabilization due to the surrounding solvent dipoles in the case of the cyclohexane matrix. Moreover higher aggregate may be formed in the excited state of highly concentrated liquid solution, leading to the larger red shift of the F_a band.

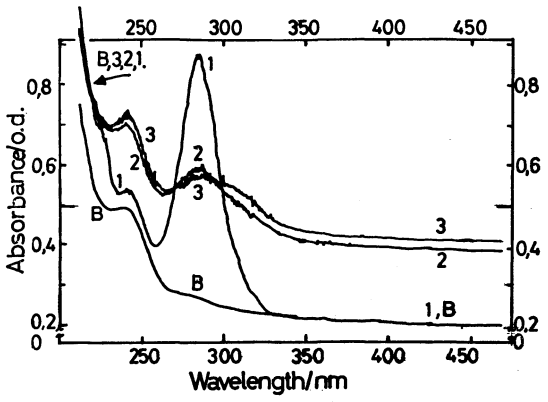

Fig. 6. Absorption spectra of DMABN in cyclohexane matrix.
Optical path ~400 μ. B. Base line (absorbance of the Dewar vessel and cell containing cyclohexane only).
[DMABN] = 5×10^{-4} M.
1. −20 °C, 2. -30 ± 2 °C, 3. -46 ± 1°C,
Because of the increase of scattering of light by the crystallization of cyclohexane, the base line is elevated at lower temperatures. However, it is elevated almost uniformly at all observed wavelengths.

Since the absorption bands of the aggregate as well as the F_d band do not show any shift caused by the temperature lowering and the concentration increase, higher aggregates do not appear to be formed in the ground state as well as in the excited state. In the case of the most concentrated solution in Fig. 4(c), we can recognize a fluorescence band at 460 nm in addition to the 390 nm band. In the previous report we also assigned this band to the dimer. However, we have confirmed that the excitation spectra of 460 nm band appears at longer wavelength (~360 nm) than 320 nm and there occurs a considerable decrease in the intensity of 460 nm band after repeated recrystallization of DMABN from *n*-hexane. Moreover, this band was not detectable in a concentrated liquid solution. Therefore, we conclude here that this fluorescence band is due to an aggregate of unknown impurity in DMABN.

If the dimer takes the sandwich configuration where the dimethylamino group lies over the cyano group, the simplified exciton resonance model predicts that the transition between the higher energy exciton state and the ground state is allowed. However, we cannot observe the intensification of the absorption at shorter wavelength side of the monomer band, but we can see only the appearance of the 320 nm band in Fig. 6. The 240 nm band is too much blue shifted from the 285 nm band to be assigned to the higher energy excited state, if we assume the 320 nm band is the lower energy one. The appearance of the 320 and 240 nm bands can be well understood as due to the electrostatic interaction between the excited and non-excited halves in the dimer causing the red shift of the monomer bands at 285 nm and at shorter wavelength than 235 nm, respectively. Of course, we cannot reject entirely the exciton type interaction mechanism

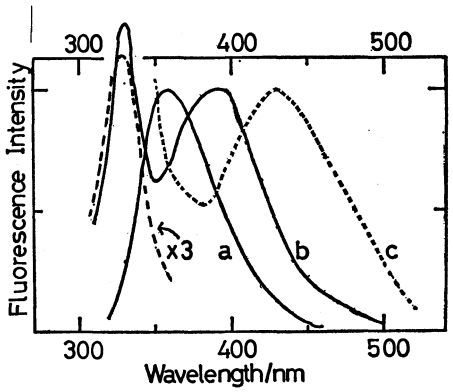

Fig. 7. Fluorescence spectra of DMABN-benzonitrile system in cyclohexane matrix.
[DMABN] = 2×10^{-5} M, [benzonitrile] = 4.9×10^{-2} M.

The spectra were corrected.

on the basis of the above experimental results. There might be more or less contribution of the exciton type interaction to the excited state of the dimer, leading to a little longer fluorescence lifetime of the dimer than that of the monomer.[4] However, it may not be important for the shift of the spectra.

We have examined also the interaction of DMABN with benzonitrile in cyclohexane matrix as shown in Fig. 7. We reported similar spectra in the previous report,[4] where the concentration of DMABN was 5×10^{-4} M. At this concentration, self-complex formation in addition to the formation of hetero-complexes with benzonitrile might be possible. Therefore, we have studied the interaction with benzonitrile, keeping the concentration of DMABN at 2×10^{-5} M, where the self-complex formation can be neglected.

One can see from Fig. 7 that the fluorescence spectra show a remarkable red shift by temperature lowering. As shown in Table 2, not only the fluorescence band but also the excitation spectra show a considerable red shift by the temperature lowering. Whether this hetero-complex is 1 : 1 or 1 : n ($n\geqq2$) aggregate is not very clear at the present stage of the investigation.

We should note here that, we can see only one fluorescence band at 20 °C in Fig. 7. However, we observe two bands at 0 °C as well as at −17 °C, of which the longer wavelength band may be assigned to the complex as discussed above. In the previous report, we have assigned tentatively the short wavelength band to the uncomplexed DMABN. However, this assignment is not well-founded. We cannot make final conclusion at present about the nature of this band.

TABLE 2. TEMPERATURE EFFECT ON THE FLUORESCENCE AND EXCITATION SPECTRA OF DMABN-BENZONITRILE-CYCLOHEXANE SYSTEM

[Benzonitrile] (M)	Temperature (°C)	λ^{f}_{max} (nm)	λ^{e}_{max} (nm)
0	20±1	350±3	284±2
5×10^{-2}	20±1	360±3	288±2
5×10^{-2}	0±1	390±3	292±2
5×10^{-2}	−17±1	430±3	297±2

λ^{f}_{max}: fluorescence band maximum (corrected).
λ^{e}_{max}: maximum of excitation spectra (uncorrected).

At any rate, we have proved that DMABN forms (classical) electrostatic complexes with polar molecules, including the self-complex formation and that the complexation is facilitated in cyclohexane matrix.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3020—3031 (1973)

Calorimetric Study of the Glassy State. VIII. Heat Capacity and Relaxational Phenomena of Isopropylbenzene

Koji KISHIMOTO, Hiroshi SUGA, and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received June 25, 1973)

The heat capacities of isopropylbenzene were measured with an adiabatic calorimeter for the crystal from 14 to 177.13 K (T_m), for the glassy state from 14 to around 126 K (glass transition temperature: T_g) and for the liquid from T_g to 313 K, with a sample of 99.93% purity. The heat and entropy of fusion were found to be 7326 J mol^{-1} and 41.36 J K^{-1} mol^{-1}, respectively. Based on these data, a set of thermodynamic functions are tabulated at rounded temperatures. In addition to the primary glass transition phenomenon, a secondary enthalpy relaxation as well as a step-like heat capacity anomaly was observed at around 70 K. These facts were discussed in correlation with the β-relaxation already observed by dielectric measurement. Configurational entropies of the supercooled liquid and of the glassy state were calculated to investigate a relation with relaxational properties. The agreement is found between the temperatures where catastrophe occurs in viscosity (T_0), and where the configurational entropy vanishes (T_2). Finally, a kind of heat capacity break observed in the liquid state is discussed against the view that this behavior is compatible with a third-order thermodynamic transition.

Recently a considerable number of papers on the glassy state have been accumulated and the concept of "*glassy state*" as a kind of state of matter is getting familiar to the wider circle of investigators. Nevertheless, rather scanty are quantitative treatments to describe this state from the thermodynamic point of view and further to clarify a relationship between dynamical and static properties. One of the purposes of this study is to elucidate a correlation between such dynamical properties as viscosity and relaxation time, and the static ones such as heat capacity, *etc.* In answer to this subject, Adam and Gibbs[1] proposed a description of the relaxation time, τ, in terms of the configurational entropy, S_c. The relation proposed by them is as follows:

$$\tau = A \exp(C/TS_c), \quad (1)$$

where A and C are constants. It was reported that this equation conformed well to the experimental results.[2,3]

As is well known, relaxations found below the glass transition temperature, T_g, are usually designated as

1) G. Adam and J. H. Gibbs, *J. Chem. Phys.*, **43**, 139 (1965).

2) S. S. Chang and A. B. Bestul, *ibid.*, **56**, 503 (1972).

3) J. Greet and D. Turnbull, *ibid.*, **47**, 2185 (1967).

β-relaxation, γ-relaxation, *etc.* in their order of appearance with decreasing temperature. β-relaxation phenomena are frequently observed by mechanical,[4] dielectric and/or nuclear magnetic resonance[5] methods not only for polymers but also for low molecular weight compounds. It is widely believed that heat capacity is not seriously affected by the molecular motions giving rise to these mechanical or dielectric relaxations. We have examined the possible observation by precise calorimetry in the present investigation. On the other hand, several workers have suggested a possible existence of a phase change in a liquid state. In 1953 Moore *et al.*[6] found the discontinuities in the several physical properties such as heat capacity, vapor pressure, density, compressibility, and viscosity in the liquid alkanes. Davies *et al.*[7] pointed out that the discontinuities in viscosity in the liquid states should correspond to thermodynamic transitions of the third order in the sense of Ehrenfest. The verification of the validity of their discussions on the nature of the transition is another principal object of the present investigation.

Experimental

Material. About 40 cm^3 of isopropylbenzene (Tokyo Kagaku Seiki Co. Ltd., claimed purity better than 99.9%) was first purified by molecular sieve (Linde 4A) under vacuum to remove low molecular weight impurities, and subjected to vacuum distillation. The purified sample of 24.997 g of the middle fraction of the distillate was introduced into a container for the heat capacity measurements by vacuum distillation. Helium exchange gas to aid heat transfer in the container was not used. But, no difficulty in establishments of thermal equilibrium was encountered except for the glass transition and the melting temperature ranges. The analysis of the fractional melting process of the sample, as will be described later, indicated the impurity content of 0.07 mol%.

Apparatus. The measurement of heat capacity of isopropylbenzene was carried out by using an adiabatic calorimeter which had been constructed already in this laboratory.[8] A capsule-type platinum resistance thermometer used for the measurement was already calibrated in our laboratory by comparison with the laboratory standard thermometer which had been calibrated at the US National Bureau of Standards according to the International Practical Temperature Scale (1948) above 90 K and the provisional NBS scale below 90 K.

Results

DTA. As a preliminary study of the thermal properties of this material, the differential thermal analysis (DTA) was performed. The results are shown in Fig. 1. Run-1 is for a cooling with a rate of about −0.7 K/min. In Run-1 a sharp exothermic peak was observed at 102 K following after a slight and gradual shift in the base line around 130 K. This

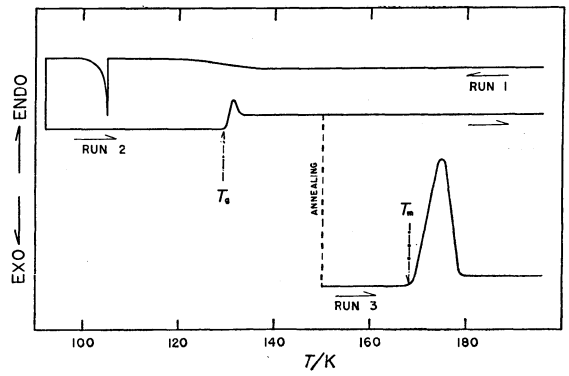

Fig. 1. DTA curves of isopropylbenzene.

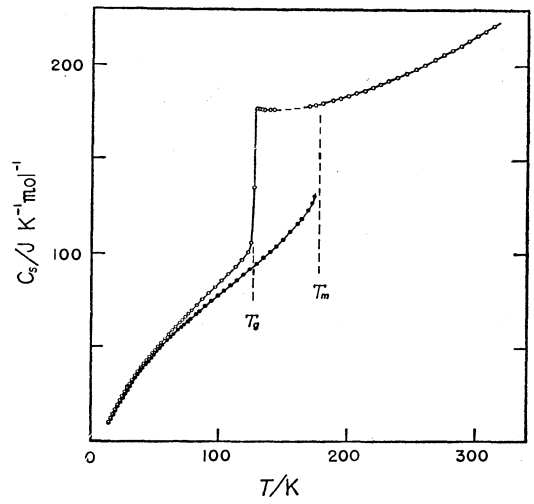

Fig. 2. Heat capacities of isopropylbenzene.
●: Crystalline phase,
○: Glassy, supercooled liquid and liquid phases.

sharp exothermic peak is attributed to the formation of cracks in the sample when the sample vitrifies. The evolution of heat is accompanied with sounding and flashing of visible light. The details of this phenomenon will be published elsewhere.[9] Run-2 is the subsequent heating (heating rate: 1.8 K/min). Only a peak due to the glass transition was observed at 130 K. Run-3 shows the heating curve of the sample which is subjected to annealing at 150 K for over two hours. The endothermic peak at 176 K was attributed to the fusion of the crystalline phase.

Heat Capacity Measurements. The heat capacity data for isopropylbenzene are listed in Table 1 and are depicted in Fig. 2. These series are numbered chronologically so that the thermal history may be followed. Estimation of the vaporization correction was performed by use of the equation given by Hoge.[10] With the aid of the data on the vapor pressure[11] and the specific volume,[12] the correction on the heat capacities

was assessed to be less than 0.004% at the highest temperature of the measurements. This figure is within an experimental error of our apparatus. As a consequence, the measured heat capacities are regarded as ones under saturated pressure, C_s. The curvature correction is not taken into consideration.

The glassy state of the specimen was established by cooling the supercooled liquid sample to the liquid nitrogen temperature with a rate of −0.7 K/min in the glass transition region. In order to measure the heat capacities of the supercooled liquid just below the melting point and also just above T_g, we have prepared the sample by two different ways. The supercooled liquid obtained by raising temperature just above T_g was observed to crystallize around 145 K. The measurement on the supercooled liquid in the range from T_g to 141 K was performed in this manner. The measurement from 169 K to the melting point was made for the liquid cooled down to the temperatures not below 165 K to avoid the crystallization during measurements.

The crystalline phase was obtained from the supercooled liquid which had been prepared by heating the glassy state above T_g. The crystal was usually annealed at around 165 K to ensure the completion of the crystallization. No evidence for the existence of a metastable crystalline phase was found from the pursuit of spontaneous temperature rise of the sample during the crystallization process.

Determination of the Purity. To determine the melting point and the purity of the present material, a fractional melting experiment was carried out. In Fig. 3 the reciprocal of the fraction of the sample melted, $1/f$, is plotted against the equilibrium final temperature, T_f, of each energy input. As ample time was required for the establishment of thermal equilibrium during the melting process, the extrapolated value of the temperature to the time being infinite at each input was used as T_f. These values are given in Table 2. It is apparent that T_f *versus* $1/f$ plot does not yield a straight line. Therefore, White-

The melting point of pure isopropylbenzene=177.13 K
Mol% of impurity=0.07%

Taylor-Rossini's method[13,14] which treats impurities as solid-insoluble and liquid-soluble is not applicable. Then, we adopted Mastrangelo-Dornte's method[15] in which they derive a solid solutions treatment for calorimetric melting point data. The equation derived by them is as follows:

$$T_f = T^* - \frac{R(T^*)^2}{\Delta H_F} \frac{X_2}{\frac{K}{1-K}+f}, \qquad (2)$$

where T^* is the triple point of a hypothetical 100% pure material whose heat of fusion is ΔH_F, R the gas constant and X_2 a mole fraction of the impurity whose distribution between the solid and liquid phases is expressed by K. For the determination of K, T^* and X_2 the method of least squares was applied. From this treatment X_2 and T^* are determined to be 0.7×10^{-3} and 177.13 K, respectively. The solid curve in Fig. 3 is the theoretical curve of Eq. (2) with the value of 0.2128 for K. As is seen, data fit this theoretical curve fairly well.

The heat of fusion was measured twice and the values of the molar heat of fusion are given in Table 3.

Estimation of the Heat Capacity for the Supercooled Liquid. Since the heat capacity of the supercooled liquid between 142 and 169 K could not be measured as a result of interference from the crystallization, it was estimated by graphical interpolation of the measured heat capacity data of the supercooled liquid below T_m and just above T_g. A dashed curve in Fig. 2 represents the interpolated heat capacity. The errors arising from arbitrariness in this interpolation are at most 0.2% of C_s of the supercooled liquid. Adequacy of the interpolation as well as the absence of crystal or crystallite in the actual specimen in the glassy state obtained was confirmed by comparing the enthalpy of the supercooled liquid at 142.74 K obtained from the direct measurement with that calculated by use of the interpolated heat capacity. The former is 13.33 kJ mol^{-1} and the latter is 13.34 kJ mol^{-1}. Reference 16 illustrates the procedure of the direct measurement.

Residual Entropy of Glassy State. The entropy of the crystal at 0 K was concluded to obey the third law of thermodynamics by comparison of the gaseous entropy determined from thermal data with that computed from the calculated data, as described later. Based on this result the residual entropy of the glassy phase was calculated by a well-defined method which is given in Table 4. Contributions from entropy below 14 K for the crystalline and the glassy phases were determined by adopting the method of effective frequency distribution[17] with some modification. The necessary preset-parameters in this modified method include the two Debye and the Einstein cut-off frequencies. After the conversion of the measured heat capacity C_p into C_v with the aid of the Nernst-Lindemann[18] equation, the effective frequency distributions were determined for several sets of these preset-parameters by using about 20 values for C_v between 14 and 50 K. Fig. 4(A) shows the frequency distributions which reproduce best the heat capacity for the crystalline state of isopropylbenzene and Fig. 4 (B) for the glassy state. The values of entropy below 14 K used in order to assess the residual entropy and to derive the thermodynamic functions of the glassy, crystalline and

liquid phases were obtained by averaging the values of entropy which were calculated based on each lattice frequency spectrum shown in Fig. 4. The residual entropy of the glassy state turns out to be 12.0± 0.5 J K^{-1} mol^{-1}.

Thermodynamic Functions. Thermodynamic functions for the crystalline, glassy and liquid states were derived from the smoothed heat capacity data based on the values listed in Tables 3 and 4, and were all tabulated in Table 5. In the derivation of these values, the crystalline phase at 0 K was taken as a reference state.

Verification of the Third Law for the Crystalline Phase. The calorimetric entropy of isopropylbenzene as an ideal gas at 298.15 K was determined and given in Table 6, together with the values for the heat of vaporization,[19] the critical temperature and pressure.[20] The values of the spectroscopic entropy calculated by Taylor *et al.*[21] for isopropylbenzene, *n*-propylbenzene and *n*-butylbenzene in their ideal gas states

are compared with the calorimetric ones in Table where δ means $[S(\text{calorimetric})-S(\text{calculated})]/S(\text{calorimetric})\times 100$. The calculated values for these benzene derivatives show systematically positive deviations from the calorimetric ones. These discrepancies seem to exceed the estimated inaccuracies of respective experiments. In view of the approximate method adopted in calculating the spectroscopic entropies, however, it seems plausible to conclude that the third law of thermodynamics is applicable to the crystalline phase of isopropylbenzene rather than to assume a possible existence of randomness at zero Kelvin.

β-Relaxational Phenomenon. In the preceding series[22] of papers we concerned ourselves exclusively with the relaxational effect of primary glass transition phenomena. Glassy state or glassy-crystalline state is a non-equilibrium state and tends to be stabilized by releasing its excess enthalpy toward an equilibrium state. The practical observation of the enthalpy relaxation phenomena is usually limited within a temperature interval of 10—30 K below T_g, owing to the elongation of relaxation time.

During the course of heat capacity measurement in the glassy state, we encountered unusual temperature drifts and a step-like heat capacity increment at around 70 K, far below the primary glass transition temperature. Figure 5 shows the change of the temperature drifts in series 6. Slight exothermic drifts revealed themselves at around 50 K and gradually increased up to about 70 K. On the contrary, above 70 K endothermic drifts were observed and disappeared gradually at higher temperatures. This variation of the temperature drifts is quite similar to that observed in the usual glass transition region. The magnitude of the drifts

in this case is far smaller than that around T_g, but larger than that due to a heat leak to or from the calorimetric cell arising from the incompleteness of adiabatic conditions.

Heat capacity measurements for the glassy state in this region were performed several times under different conditions. The C_s values of the glassy state subtracted by those of the crystalline phase were depicted in Fig. 6 for each run and tabulated in Table 8. One can find the abrupt increase in the heat capacity at around 80 K which has a resemblance to that at an ordinary glass transition point. For each series, the specimen was cooled from temperatures far above the melting point down to the liquid nitrogen temperature and then cooled further to around 50 K except for series 6 by use of liquid hydrogen or solid nitrogen as a refrigerant. The thermal history for each series is listed in Table 9. In series 6, the specimen in the glassy state was allowed to stand at the liquid nitrogen temperature for one night prior to being cooled down to 14 K. The thermal drifts were already mentioned for this series (Fig. 5). In the case of series 15, exothermic drifts change into endothermic ones at around 72 K. In series 17, the changeover of the drifts occurs at 78 K. In series 18 the specimen was annealed for 15 days at the liquid nitrogen temperature. In this case only endothermic drifts appeared in the temperature range from 55 to 80 K. The temperature drifts in series 19 were almost the same as in series 18. As is shown in this figure, the hystereses in the heat capacity due to the different thermal histories were perceptible, which reminds us of glass transition phenomena.

The temperature drifts similar to those in the primary glass transition region and the abrupt increase in C_s seem to support the view that a β-transition exists around 70—80 K.

Discussion

β-Relaxation. Johari *et al.*[23] found the β-relaxation for isopropylbenzene by means of dielectric measurements and showed that the Arrhenius plot of the frequency of maximum loss f_{max} against $1/T$ gives a straight line with an activation energy of 8 kcal/mol. Using their data, we extrapolated this Arrhenius plot and determined the temperature at which f_{max} becomes equal to 10^{-3} Hz to be 76 K.

The calorimetric β-transition temperature, T_β, of

23) G. P. Johari and M. Goldstein, *J. Chem. Phys.*, **53**, 2372 (1970).

about 80 K, is in agreement with that inferred from the dielectric measurement. However, the behavior of the thermal drifts in the β-transition region was not interpreted in terms of cooling rates around T_g, and T_β, respectively.

This failure in explanation may be attributed to the small magnitude of the observable temperature drifts which are apt to be significantly influenced by the incomplete adiabatic conditions. The other explanation may be that we could not quench the specimen instantly from the temperature above T_g to far below T_β because at least a few hours were compelled to be consumed under our experimental conditions. As a result the cooling rate could not be varied definitely from run to run. This makes a possible correlation between the cooling rates around both T_g and T_β and the behavior of the temperature drifts difficult to be clarified.

Goldstein[24] proposed that β-relaxation is intrinsic to the glassy state and arising from such degrees of freedom whose freezing out is responsible for the main glass transition. To explain β-relaxation on the basis of the earlier description given by Orowan[25] for viscous flow as an activated process, he put an additional hypothesis to Orowan's picture. The hypothesis is that the packing of molecules in an amorphous state is always such as to give rise to a distribution of barrier height against molecular motions responsible for viscous flow. The existence of lower barriers makes some molecular motions possible to be excited even at temperatures where viscous flow can no longer occur at a detectable rate. When these modes of motion become frozen-in, the β-relaxation would be observed.

However, this hypothesis alone can not account for a question why a maximum of dielectric loss or an abrupt change in heat capacity does appear. The existence of β-relaxation will lead to a hump or a shoulder in relaxation spectra in a shorter time-region than that responsible for the main glass transition, though the broadening out of relaxation spectra can be interpreted by cooperative molecular motions as well as by the distribution of potential barrier heights. If a hump or a shoulder does not exist in the spectra, a maximum of dielectric loss or an abrupt increase in heat capacity below T_g will not be expected and only a continuous loss will appear. In Goldstein's picture there is no reason for the existence of a hump (*i.e.*, the existence of many barriers with the same heights in a particular range). However, by taking into account molecular rearrangements involving defects or holes as a hypothesis in addition to Goldstein's description, the above question can be explained. Around holes less cooperative molecular motions should occur in a shorter time than those in other normal parts. Such molecular motions are expected to be responsible for a hump in the spectra and consequently related to β-relaxation.

Relation between Relaxation Time and Configurational Entropy. The validity of the Adam-Gibbs equation (Eq. (1)) was examined along the following line. Viscosity, η, in a supercooled liquid region is given by the Fulcher-Tammann-Hesse equation

$$\ln \eta = A' + B'/(T - T_0), \tag{2}$$

where A', B' and T_0 are constants. η is also related to τ by the equation

$$\eta = G_\infty \tau, \tag{3}$$

where G_∞ is the limiting high frequency shear modulus. If Eq. (1) holds, combination of Eqs. (1) and (3) yields

$$\ln \eta = \ln G_\infty + \ln A + \frac{C}{TS_c}. \tag{4}$$

The temperature dependence of G_∞ is given by the following equation[26]

$$G_\infty = G_0 + \frac{B''}{T - T_0'},$$

where G_0 is the rigidity modulus at the temperature T_0', and B'' a constant. On the other hand, τ and η usually vary exponentially with temperature. Therefore, the temperature dependence of G_∞ may be neglected compared with those of τ and η, and comparing Eq. (2) with Eq. (4), one is led to a conclusion that the quantity TS_c is proportional to $T - T_0$ and S_c must vanish at T_0 as far as the approximation adopted above is correct. The temperature at which the configurational entropy vanishes is designated as T_2. Experimentally, T_2 temperature is determined from the intersection of the extrapolated entropy curve of a supercooled liquid (curve *c–d* in Fig. 7) and the entropy curve (*a–g*) which is obtained by subtracting the residual entropy (segment *e–a* of the ordinate) from the entropy curve for the glassy state (*e–f*). Curve *a–g* is corresponding to the entropy curve of a hypothetical phonon system in the glassy state. However, estimation of the entropy of the hypothetical phonon system of this ideal glass by the method described above is not accurate. If the temperature of supercooled liquid is lowered along the equilibrium curve *d–c*, volume contraction takes place mainly by virtue of the change in the configura-

tion. This volume contraction will change the frequency distribution spectra and in turn affects the entropy of the phonon system[27] in a decreasing direction. Accordingly, T_2 thus obtained is an upper limit of the temperature at which the configurational entropy vanishes. On the other hand, the temperature at which the entropy curve of crystal (a–b) intersects curve c–d is considered as a lower limit.

For comparison, T_2 temperature along with the values of T_0 obtained from the viscosity data based on the Fulcher-Tammann-Hesse equation (Eq. (2).) are listed in Table 10 for two compounds. The second

Table 10. Comparison between T_2 and T_0

	Calorimetric T_2	Viscosity T_0
Isopropylbenzene	109.5—103.5K	93.8K
o-Terphenyl	207 —204K	200K

column shows the upper and the lower limits for T_2. Consistency between the values of T_2 obtained by the static method of calorimetry and T_0 by the dynamical method of viscosity measurements is fairly good. This agreement supports the Adam-Gibbs equation. Figure 8 depicts TS_c plotted against temperature for isopropylbenzene. Although estimation of S_c includes an unavoidable ambiguity due to the extrapolation of curve a–g (Fig. 7) up to about 160 K, a fairly well linear relationship was observed between them. For propan-1-ol[28] small deviation is seen in the plot of TS_c *vs.* T. For the supercooled liquid phases of o-terphenyl[2] and 2-methylpentane[38] as well as for the supercooled plastic crystalline phase of 2,3-dimethylbutane,[16] this relationship was found to hold also fairly well. In such a way, we can propose a rough method to interpret the relaxation time in terms of the configurational entropy by using the Adam-Gibbs equation for an equilibrium supercooled liquid phase and/or for a supercooled plastic crystalline phase.

It may be added that the relation $TS_c \propto T-T_2$ has to lead the following thermodynamic functions:

$$C_{conf} \propto \frac{1}{T}\theta(T-T_0)$$

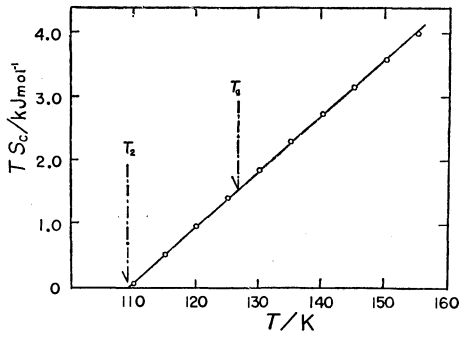

Fig. 8. Temperature dependence of the configurational entropy multiplied by temperature for isopropylbenzene.

and

$$H_c \propto \ln\frac{T}{T_2}\theta(T-T_0) ,$$

where C_{conf} is configurational heat capacity and θ the step function.

Anomalous Behavior of the Heat Capacity in the Liquid State. Recently there have been suggested the possible existence of a phase change in a liquid state by several workers. In 1953 Moore *et al.*[6] found the discontinuities in the several physical properties such as heat capacity, vapor pressure, density, compressibility, and viscosity of liquid alkanes. For example, they found that the change of the heat capacity of *n*-heptane with temperature can be well represented by two straight lines with a more or less gradual transition from one to the other over a rather narrow temperature range. They attributed these discontinuities to the onset of specific molecular motions (*i.e.*, translation↔libration↔free rotation). Davies *et al.*[7] pointed out that the discontinuity in viscositity of liquid should correspond to a thermodynamic transition which is due to the restriction of the rotation of molecules (translation↔one axis rotation↔two axes rotation equivalent to free rotation). They referred to the analysis of the heat capacity data by Moore *et al.*, mentioned above, and they concluded that the transition should correspond to the third order in the sense of Ehrenfest.

As is well known, the viscosity, η, of liquids at temperatures fairly above their melting points is well described by the Arrhenius equation

$$\ln\eta = A+E/RT, \qquad (5)$$

where A is a constant, R the gas constant, and E the activation energy for viscous flow. However, this equation is not usually applicable to liquids of high viscosity or to supercooled liquids. Fulcher[29] and Tammann & Hesse[30] found an empirical equation for these liquids

$$\ln\eta = A'+B'/(T-T_0) , \qquad (2)$$

where A', B' and T_0 are constants. For some liquids it became apparent[31] that the viscosity could not be

●: from Ref. 12. ○: from Ref. 19.

described by a single equation (Eq. (2)) over the whole temperature range except for the high temperature Arrhenius region. Thus, two sets of constants in Eq. (2) are required in two separate temperature regions. The temperature at which Arrhenius type temperature dependence changes into non-Arrhenius one is designated as Arrhenius temperature T_A. The temperature at which transformation of one type of non-Arrhenius behavior occurs into another type of non-Arrhenius behavior is designated as intersection temperature T_K. It is interesting to know how heat capacity behaves at T_A and T_K, and also to investigate the order of transitions if they exist.

The heat capacity data of isopropylbenzene over the temperature range in question are reproduced in Fig. 9 in an enlarged scale. Above *ca.* 285 K the heat capacity is well represented by a straight line, while below that it fails. The change of the heat capacity with temperature below T_A is not described by a straight line as was suggested by Moore *et al.* in the case of *n*-heptane. This is true of many compounds described later we examined for which the heat capacity data are available in the literature. The lowest temperature below which the heat capacity deviates from the straight line can not be determined within the temperature range of some 5 K because of the restriction of the precision in our heat capacity measurement. But it agrees with the Arrhenius temperature, T_A, of

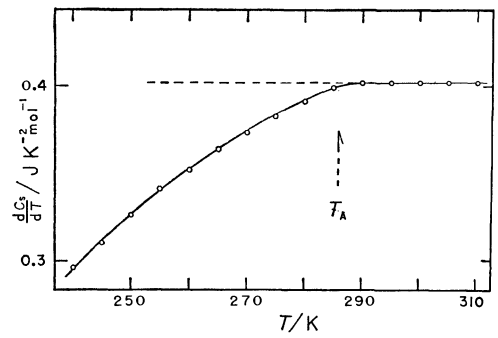

Fig. 12. Temperature derivative of heat capacity for isopropylbenzene in the liquid state.

283 K.[7] The encraty, C_s/T, of isopropylbenzene is plotted against $1/T$ in Fig. 10, which will be compared with the plots of $\ln\eta$ *vs.* $1/T$ of the same substance given in Fig. 11. These figures show that above *ca.* 285 K both C_s/T and $\ln\eta$ vary linearly with $1/T$.

At the third-order transition point the third derivative of the Gibbs free energy with respect to temperature $(\partial^3 G/\partial T^3)_p = -\partial(C_p/T)/\partial T$ is discontinuous, which should lead to a jump in dC_p/dT. dC_s/dT of isopropylbenzene determined from the smoothed curve of C_s is plotted in Fig. 12. By the way, in the case of isopropylbenzene $(C_p - C_s)/C_p$ at 313 K amounts to 0.63×10^{-4} which is within an experimental error, so we can regard C_s as C_p over the whole temperature range of our observation. No jump in dC_p/dT or d^2C_p/dT^2 is found, as is seen in Fig. 12. If dC_p/dT *vs.* T curve is concave upward up to T_A and then horizontal, the anomalous behavior of the heat capacity at T_A is compatible with the fourth-order transition because a jump appears in d^2C_p/dT^2 *vs.* T curve in this case. Actually, however, the dC_p/dT *vs.* T curve is convex upward, so this anomalous behavior is a transition, if any, of higher order than fourth. This fact is quite the same for *n*-butylbenzene,[32] *n*-propylbenzene[32] and ethylbenzene[33], *etc.* In order to discuss the nature of the anomalous behavior of this kind, more detailed heat capacity measurements with higher precision and resolution would be required.

Liquids composed of spherical molecules such as neopentane[19,34] and carbon tetrachloride[35-37] show Arrhenius behavior of the viscosity and the linear temperature dependence of the heat capacity, C_s, over the whole temperature range investigated. These are just the behavior of isopropylbenzene and analogous compounds in the limiting higher temperature region above T_A. These facts suggest a similarity of

rotational modes in a period of successive translational jump for non-spherical molecules above T_A to those modes for spherical molecules.

In passing, we should call attention to the way of compilation of heat capacity data of liquids. Usually the temperature dependence of the heat capacity of liquid is expressed as a following equation over a whole temperature range.

$$C_p = a + bT + cT^2 + dT^3,$$

where a,b,c and d are constants. However, based on our results we propose to divide the temperature range of liquid at least into two parts for more appropriate method of the compilation, *i.e.*, above and below T_A.

Summary

(1) The heat capacities of isopropylbenzene were measured for the crystal from 14 to T_m (177.13 K), for the glassy state from 14 to T_g (around 126 K) and for the liquid from T_g to 313 K, on a sample with purity of 99.93%. The heat and entropy of fusion were found to be 7326 J mol^{-1} and 41.36 J K^{-1} mol^{-1}, respectively. Gibbs energy function, enthalpy function and entropy in the solid and liquid states were calculated at selected temperatures from 15 to 310 K.

(2) The calorimetric entropy in the ideal gas state at 298.15 K, 386.53 J K^{-1} mol^{-1}, was compared with the calculated one given by Taylor *et al.* It was concluded that the crystal follows the third law of thermodynamics. Based on this result, the residual entropy for the glassy state was determined to be 12.0$\pm$0.5 J K^{-1} mol^{-1}.

(3) Aside from the primary glass transition phenomenon, a secondary relaxation was found in temperature drifts of the calorimetric cell in the temperature region centered at around 70 K and a step-like heat capacity anomaly was observed at around 75 K. This phenomenon was discussed with relation to the β-relaxation already observed by dielectric measurement.

(4) Temperature dependence of the configurational entropy of the supercooled liquid was investigated to see whether the Adam-Gibbs equation holds or not. And also, the agreement was found between the temperature at which catastrophe occurs in viscosity and the temperature at which the configurational entropy vanishes.

(5) A kind of heat capacity break was observed in the liquid state, which was discussed against the view that this behavior was compatible with the third-order thermodynamic transition. The temperature *ca.* 285 K at which anomalous behavior of heat capacity occurred was in agreement with that where a discontinuity in the temperature dependence of the viscosity was found.

Brillouin Scattering and Elastic Constants of Potassium Bromide

Hiroatsu MATSUURA and Tatsuo MIYAZAWA

Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received July 12, 1973)

The Brillouin scattering of KBr crystals was measured by using a helium-neon laser and a pressure-scanned Fabry-Perot interferometer. The Brillouin shifts were measured for various crystal orientations with the scattering vector in the [110] plane. In addition to the strong Brillouin peaks due to the longitudinal acoustic mode, relatively weak Brillouin peaks due to the transverse mode with admixture of the longitudinal mode were clearly resolved for a certain range of crystal orientations. From these Brillouin shifts, the frequencies and velocities of thermally excited sound waves of the wavelength 286.9 nm were obtained, and the three independent elastic constants of the KBr crystal for sound waves of microwave frequencies 6—12 GHz were determined as $C_{11}=3.37\times10^{11}$, $C_{12}=0.61\times10^{11}$ and $C_{44}=0.51\times10^{11}$ dyn/cm^2. The elastic constants determined in the present study were close to the ultrasonic values, indicating little dispersion of the sound velocities for the regions between 10 MHz and 10 GHz.

Brillouin spectroscopy has become a valuable technique for studying thermal and transport properties of matter, with the introduction of lasers as intense monochromatic sources, combined with high-resolution interferometers. One of the important applications is the measurement of velocities of thermal sound-waves in crystals in the microwave region. The sound-wave velocity obtained from Brillouin scattering is used to determine the elastic constants, without any external acoustic excitation. The Brillouin scattering technique has been employed for determining the elastic constants of some alkali halide crystals. The elastic constants determined accurately for KCl, RbCl and KI crystals[1] agreed very well with the results of ultrasonic measurements, indicating that there was no dispersion of sound-wave velocities for the regions between 10 MHz and 10 GHz.

In the present study, the Brillouin scattering of KBr crystals was measured by using a helium-neon laser and a pressure-scanned Fabry-Perot interferometer. The elastic constants determined are compared with ultrasonic values and the sound velocity dispersion is discussed. The present results are also compared with previous results of a Brillouin scattering study on KBr.[2]

a) Averaged experimental errors for the frequency and the velocity are ± 0.07 GHz and ± 20 m/sec, respectively.

Experimental

The experimental arrangement for the observation of Brillouin scattering spectra used in the present study is shown schematically in Fig. 1. The light source was a helium-neon gas laser (Nippon Electric Co., Model GLG 108), which was operated in the fundamental transverse mode at 632.8 nm with an output of about 50 mW. The laser beam passed through the sample which was rotated in such a way that any direction in a [110] plane could be set parallel to the scattering vector. The light scattered at 90° away from the direction of the incident beam was led to a pressure-scanned Fabry-Perot interferometer of Mizojiri Kogaku Kogyo Co. The ring pattern was centered on an aperture of a 1 mm diameter and the intensity of the emerging light was detected by an S20 photomultiplier (Hamamatsu Corp., R374), whose output was measured by an electronic picoammeter and recorded on an X–Y recorder. The electric vector of the incident laser light was set perpendicular to the scattering plane. The spacer between the interferometer etalons had a thickness of 6 mm, giving a free spectral range of 25 GHz. The exact thickness was measured by a micrometer to within 4 μm. The interferometer was scanned by evacuating the optical chamber and then allowing air leakage slowly.

In the measurements of the Brillouin scattering, the crystal

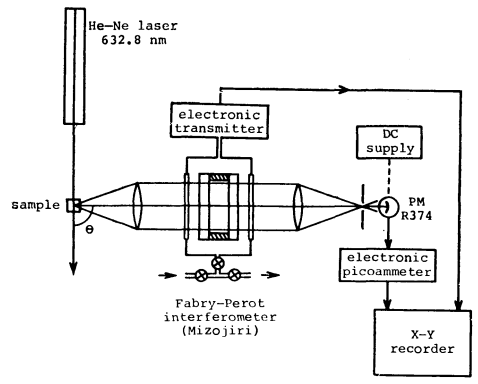

Fig. 1. Experimental arrangement for Brillouin scattering measurements.

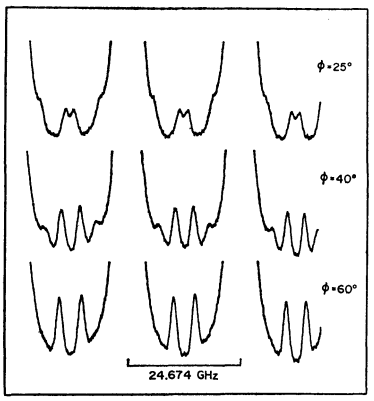

Fig. 2. Brillouin spectra of KBr for $\phi = 25°$, 40° and 60°.

sample of KBr, a cube with 5 mm on an edge, was immersed in anethole ($CH_3CH{=}CHC_6H_4OCH_3$). This liquid had nearly the same index of refraction as KBr, and surface scattering from KBr crystal was largely eliminated. The sample was supported by a rotatable holder so that the scattering vector was kept in the [110] plane of the crystal. The Brillouin spectra were measured as a function of the angle ϕ (24°—90°) between the scattering vector and the [001] direction. For $\phi<25°$, the Stokes Brillouin line overlapped the anti-Stokes line (and *vice versa*) of the adjacent spectral order. The spectra were scanned as slowly as about ten minutes over one free spectral range of 25 GHz, so as to resolve relatively weak Brillouin lines due to the transverse mode with admixture of the longitudinal mode. The scattering measurements were made at 20±1 °C at least six times for each orientation of the crystal.

Typical examples of the observed spectra for $\phi=25°$, 40° and 60° are shown in Fig. 2, and the observed frequency shifts and sound velocities are listed in Table 1.

Brillouin Scattering and Elastic Constants

Brillouin scattering shifts are proportional to the velocity of thermally excited sound waves whose wavelengths are of the same order as the wavelength of light. The sound velocity, V, in the medium is related to the frequency shift, Ω, due to the Doppler effect on the light from reflection by the sound wave:[1,3]

$$\Omega/\omega = \pm 2(V/c)n\sin(\theta/2), \tag{1}$$

where ω is the frequency of the incident light wave, c is the velocity of light in vacuum, n is index of refraction of the medium and θ is the angle of scattering. The frequency shift, Ω, is equal to the frequency of the sound wave responsible for the light scattering.

In a crystal, there are in general three modes of elastic waves, one longitudinal and two transverse modes, propagating with different velocities. Thus, V in Eq. (1) can take three values and accordingly one should observe generally three pairs of Brillouin components with different frequency shifts in the scattering by any crystal.[4] Also, in the crystal, one may obtain from the Brillouin spectra the frequencies and velocities of sound waves as a function of crystal orientation. This observation can be made by bringing different crystal directions parallel to the scattering vector. For a cubic crystal, each of the three acoustic waves which propagate in the direction of principal symmetry, namely the [001], [111] or [110] direction, is a pure longitudinal or transverse wave, and the two transverse modes are degenerate for the [001] and [111] directions. In general for the cubic crystal, the sound waves which propagate in the [110] plane have the following polarizations; the first acoustic wave (T) is purely transverse for any crystal direction, the second wave (M) is largely transverse with admixture of the longitudinal mode, and the third wave (L) is almost entirely longitudinal.

The elastic constants are closely related to the sound velocities of the three waves in the acoustic branches. The sound velocities, V, are given as roots of the following equation[5]

$$\begin{vmatrix} \lambda_{11}-\rho V^2 & \lambda_{12} & \lambda_{13} \\ \lambda_{12} & \lambda_{22}-\rho V^2 & \lambda_{23} \\ \lambda_{13} & \lambda_{23} & \lambda_{33}-\rho V^2 \end{vmatrix} = 0, \tag{2}$$

where ρ is the mass density, and λ_{ab} is given by

$$\lambda_{ab} = l^2C_{1a1b} + m^2C_{2a2b} + n^2C_{3a3b} + mn(C_{2a3b}+C_{3a2b}) + nl(C_{3a1b}+C_{1a3b}) + lm(C_{1a2b}+C_{2a1b}), \tag{3}$$

where l, m and n are the direction cosines of the propagation direction of the sound wave and the suffixes to the elastic constants are written in full. However, the elastic constants C_{iajb} in Eq. (3) may be converted into C_{pq} in the more usual notation by changing the suffixes ia and jb to p and q, respectively, in manner that 11→1, 22→2, 33→3, 23→4, 31→5 and 12→6. The general expression in Eq. (2) is specialized for the case of a cubic crystal as a function of the propagation direction, ϕ, in the [110] plane, where ϕ is the angle between the [001] direction and the propagation direction of the sound wave,

$$\begin{vmatrix} \frac{1}{2}[(C_{44}+C_{11}) + (C_{44}-C_{11})\cos^2\phi] - \rho V^2 & -\frac{1}{2}(C_{44}+C_{12})\sin^2\phi & -\frac{1}{\sqrt{2}}(C_{44}+C_{12})\sin\phi\cos\phi \\ -\frac{1}{2}(C_{44}+C_{12})\sin^2\phi & \frac{1}{2}[(C_{44}+C_{11}) + (C_{44}-C_{11})\cos^2\phi] - \rho V^2 & \frac{1}{\sqrt{2}}(C_{44}+C_{12})\sin\phi\cos\phi \\ -\frac{1}{\sqrt{2}}(C_{44}+C_{12})\sin\phi\cos\phi & \frac{1}{\sqrt{2}}(C_{44}+C_{12})\sin\phi\cos\phi & C_{44}-(C_{44}-C_{11})\cos^2\phi - \rho V^2 \end{vmatrix} = 0. \tag{4}$$

Equation (4) may be rewritten into a more convenient form by transforming the coordinates a, b and c into $(1/\sqrt{2})(a+b)$, $(1/\sqrt{2})(a-b)$ and c. Of these new coordinates, the first one is perpendicular to the [110] plane and corresponds to the pure transverse mode (T), and the hybridization of the second and third, both in the [110] plane, gives the longitudinal mode (L) and mixed mode (M). The transformed equation is given by

$$\begin{vmatrix} \frac{1}{2}[(C_{11}-C_{12}) + (2C_{44}+C_{12}-C_{11})\cos^2\phi] - \rho V^2 & 0 & 0 \\ 0 & \frac{1}{2}[(2C_{44}+C_{11}+C_{12}) - (C_{11}+C_{12})\cos^2\phi] - \rho V^2 & -(C_{44}+C_{12})\sin\phi\cos\phi \\ 0 & -(C_{44}+C_{12})\sin\phi\cos\phi & C_{44} - (C_{44}-C_{11})\cos^2\phi - \rho V^2 \end{vmatrix} = 0. \tag{5}$$

3) R. S. Krishnan, "The Raman Effect," ed. by A. Anderson, Marcel Dekker, New York (1971), p. 343.

4) If the birefringence is taken into consideration, there should in general be twelve pairs of Brillouin components.[3]

5) M. J. P. Musgrave, *Proc. Roy. Soc. London*, **A226**, 339 (1954).

Accordingly, the velocities of the three sound waves, V_T, V_L and V_M, are obtained as

$$\rho[V_T(\phi)]^2 = \frac{1}{2}[(C_{11}-C_{12}) + (2C_{44}+C_{12}-C_{11})\cos^2\phi], \tag{6}$$

$$\rho[V_L(\phi)]^2 = \frac{1}{4}[(4C_{44}+C_{11}+C_{12}) - (2C_{44}+C_{12}-C_{11})\cos^2\phi + \{(C_{11}+C_{12})^2 + (2C_{44}+C_{12}-C_{11}) \times [(8C_{44}+14C_{12}+6C_{11})\cos^2\phi - (6C_{44}+15C_{12}+9C_{11})\cos^4\phi]\}^{1/2}], \tag{7}$$

and

$$\rho[V_M(\phi)]^2 = \frac{1}{4}[(4C_{44}+C_{11}+C_{12}) - (2C_{44}+C_{12}-C_{11})\cos^2\phi - \{(C_{11}+C_{12})^2 + (2C_{44}+C_{12}-C_{11}) \times [(8C_{44}+14C_{12}+6C_{11})\cos^2\phi - (6C_{44}+15C_{12}+9C_{11})\cos^4\phi]\}^{1/2}]. \tag{8}$$

For the directions of principal symmetry [001], [111] and [110], corresponding to $\phi=0°$, 54.7° and 90°, respectively, Eqs. (6), (7) and (8) are reduced to the following simplified forms; for the [001] direction, $\rho V_L^2=C_{11}$ and $\rho V_M^2=\rho V_T^2=C_{44}$; for the [111] direction, $\rho V_L^2=[2(2C_{44}+C_{12})+C_{11}]/3$ and $\rho V_M^2=\rho V_T^2=(C_{44}+C_{11}-C_{12})/3$; and for the [110] direction, $\rho V_L^2=(2C_{44}+C_{12}+C_{11})/2$, $\rho V_M^2=C_{44}$ and $\rho V_T^2=(C_{11}-C_{12})/2$.

The intensity of the Brillouin scattering in a crystal is determined by the polarization directions of the incident and scattered light waves and of the sound wave, the propagation direction of the sound wave, and the magnitude of the elasto-optical constants.[6] The formulas for the Brillouin intensity have been derived for a cubic crystal as a function of the angle ϕ.[1] The formulas indicate that the Brillouin intensity of the longitudinal mode (L) in the entire ϕ region and of the mixed mode (M) in a certain ϕ region is strong enough, but the intensity of the purely transverse mode (T) is much weaker than the former two modes. Therefore, the Brillouin component due to the transverse mode is not expected to be observable in the spectra.

Results

In the present study, the Brillouin scattering measurements were made for the scattering angle $\theta=90°$, and the wavelength of the scattering sound wave λ_s is given from Eq. (1) by

$$\lambda_s = \lambda_0/(\sqrt{2}n), \tag{9}$$

where λ_0 is the wavelength of the incident light in vacuum. By substituting $\lambda_0=632.8$ nm for a helium–neon laser and $n=1.5594$ for KBr,[7] $\lambda_s=286.9$ nm is obtained, which is common to all orientations of the crystal.

The observed spectra in Fig. 2 exhibit two kinds of Brillouin components, a stronger one with a larger frequency shift and a weaker one with a smaller frequency shift. The former is assigned to the longitudinal mode (L) and the latter to the mixed mode (M) (a largely transverse mode with admixture of the longitudinal mode), as suggested from the theoretical relative intensities. The Brillouin component due to the mixed mode was resolved clearly for $\phi=30°$—44°. The intensity of this mode was previously expected to be strong enough only for this ϕ region.[1,2] Also, if ϕ is smaller than 30°, the velocity of the mixed mode is so low that the mixed-mode peak apparently merges into the strong central peak. Variation of the relative intensity of the longitudinal mode with the angle ϕ is also noted in Fig. 2. The intensity increases progressively as ϕ is increased up to 60°, and reaches maximum and finally decreases slightly as ϕ is further increased to 90°. This pattern is in agreement with the intensity variation previously calculated for KBr by Kaplan *et al.*[2]

The sound velocities listed in Table 1 were obtained from the observed frequency shifts by Eq. (1). In Fig. 3, the observed sound velocities V_L and V_M for the longitudinal and mixed modes are plotted against the angle ϕ. From the observed sound velocities, the three independent elastic constants C_{11}, C_{12} and C_{44} were determined from Eqs. (7) and (8) by the method of least squares. The mass density[8] of $\rho=2.744$ g/cm^3 was used for the calculation. The values of the elastic constants are listed in Table 2, and the sound velocities V_L, V_M and V_T calculated from these

elastic constants are shown in Fig. 3.

Discussion

In the present study, the elastic constants C_{11}, C_{12} and C_{44} of KBr were determined for sound waves of microwave frequencies 6—12 GHz by the Brillouin scattering technique. The elastic constants thus determined may be compared with the values for the ultrasonic region (10 MHz region) as measured by externally generated sound waves. In Table 2, previous results of ultrasonic measurements are also listed for comparison with the Brillouin results. Although there are some discrepancies among the ultrasonic results by different workers, the present hypersonic values by Brillouin scattering and the ultrasonic values are close to each other, indicating little dispersion of the sound-wave velocity for the regions between 10 MHz and 10 GHz corresponding to the frequency change of three orders of magnitude. Kaplan *et al.*[2] have also measured Brillouin scattering spectra of KBr and have obtained the elastic constants. However, their C_{12} value is appreciably smaller than ours (see Table 2). Comparison of Fig. 3 in this paper and Fig. 1b in Ref. 2 indicates that the sound velocity measured by Kaplan *et al.* is slightly smaller than the present result for the longitudinal mode but larger for the mixed mode; these differences make their C_{12} value smaller. The previous Brillouin study[1] on other alkali halides of KCl, RbCl and KI indicated the absence of dispersion of the sound-wave velocity for the hypersonic and ultrasonic regions. Accordingly, the little dispersion found for KBr in the present study seems to be reasonable.

The elastic constants of KBr have also been obtained by the technique of thermal diffuse scattering of X-rays,[9] in which measurements were made of the intensity of weak diffuse X-rays reflected from crystals. The elastic constants determined by this method are also listed in Table 2. However, the accuracy of this method is not high enough for discussing the dispersion of the sound velocity for the visible and X-ray regions.

In the present measurements of Brillouin scattering of KBr, the Brillouin component due to the mixed mode was observed for $\phi=25°$—$50°$, but the frequency-shift data for $\phi=30°$—$44°$ were used for the calculation of the elastic constants. The observation of the mixed mode is necessary for determining C_{12} and C_{44} separately; the velocity of the longitudinal mode depends largely on $(2C_{44}+C_{12})$ and C_{11}, as seen from Eq. (7), but the velocity of the mixed mode is sensitive to C_{44}. Our observation of the mixed mode for $\phi=30°$—$44°$ and the longitudinal mode for $\phi=24°$—$90°$ was good enough for the determination of the three elastic constants.

Numerical calculations in the present study were carried out with a NEAC 2200—700 computer at the Computer Center of Osaka University.

The Photoelectron Spectra of Alcohols, Mercaptans and Amines

Hitoshi OGATA, Hatsuki ONIZUKA, Yoshimasa NIHEI, and Hitoshi KAMADA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received December 19, 1972)

The HeI photoelectron spectra of aliphatic amines, alcohols and mercaptans were measured. These spectra, especially those of methylsubstituted compounds, were interpreted in terms of the orbital energies and corresponding eigenvectors calculated by the CNDO/2 and the INDO type self-consistent field molecular orbital techniques. Modification of CNDO/2 was also performed and the results are briefly discussed.

Photoelectron spectroscopy (pes) has become a powerful tool for the interpretation of the electronic structure of molecules and the corresponding ions, and widely used for studies of various molecular systems. The present paper is meant to make a contribution to the interpretation of the photoelectron (pe) spectra of some aliphatic alcohols, ROH, mercaptans, RSH, and amines, RNH_2. The CNDO/2[1] and the INDO[2] calculations have been performed on these molecules in order to interpret the pe spectra. We assume throughout the validity of Koopmans' theorem.[3] Since the calculations have been performed in the ground state geometries, the calculated ionization potentials will be compared with the experimental vertical values throughout.

Experimental

A Jasco Model PE-1 Photoelectron Spectrometer was used for measurements. The resonance line of He(584 Å) was emitted by means of DC glow discharge. A hemispherical electrostatic condenser with 100 mm diameter was used for electron energy analysis, a channel electron multiplier for detection and a pulse counting method for signal processing system. As low energy electrons are largely affected by terrestrial magnetic field and fluctuating magnetic field around the apparatus, they were eliminated by μ-metal shielding. In order to obtain ionization potentials from spectra, xenon gas is mixed into the sample gas as internal standards of ionization potential. We have measured the spectra of aliphatic amines, RNH_2, alcohols, ROH and mercaptans, RSH, where R=CH_3, C_2H_5, *n*-C_3H_7, *iso*-C_3H_7, *n*-C_4H_9, *iso*-C_4H_9, *sec*-C_4H_9 and *tert*-C_4H_9. The spectra were obtained in gas phase at room temperature. The compounds were obtained commercially, and further purification was not performed. Theoretical calculations were based on the CNDO/2 and the INDO method.

Results and Discussion

Alcohols. Figure 1 shows the pe spectra of eight aliphatic alcohols.[4] Each spectrum contains a relatively sharp and symmetrical peak in the lowest ionization potential (i.p.) region (termed as the first band) and a series of broad peaks in the higher i.p. region.

The first band of methanol shows fine structure ascribable to the vibration of the ion in the ground electronic state. It consists of at least three peaks, and the spacing is about 960 cm^{-1}. The intense band in the infrared absorption spectra of methanol located in 990 to 1050 cm^{-1} is complicated and may be related to CO stretching, OH bending and CH bending (CH rocking) modes. Fine structure observed in the pe spectra of methanol may be due to these vibrational modes of methanol ion.

Refaey and Chupka measured the photoionization total cross section of methanol and found six sharp peaks in the region of photon energy from 10.5 to 12.0 eV.[5] They concluded that these peaks might be due to vibration of methanol ion in the electronic ground state. They also stated that to ascertain this assignment it would be necessary to measure the pe spectra of CH_3OH.

Brehm *et al.* measured the pe spectra of methanol using Lyα line (12.08 eV) and He resonance line as light sources.[6] Their results show that both first

bands of methanol obtained by Lyα and He resonance line give similar fine structure, *i.e.*, there are only three peaks due to vibration of CH_3OH^+. Of the six peaks in the derivative curve of the total ionization cross section presented by Chupka, the envelope of three peaks located in the region from 10.8 to 11.2 eV bears a striking resemblance to that of the first band of the pe spectra. On the other hand, the remaining three peaks in the derivative curve which are in 11.3 to 11.6 eV cannot be found in the pe spectra. Accordingly, three of six peaks located in higher energy region reported by Chupka may be due to some other process than the direct ionization, presumably due to auto-ionization process.

It is interesting while the 0–0 peak is the most intense in the first pe band of water,[7] the 0–1 peak is the most intense in the case of methanol. This fact, perhaps, indicates that the character of the highest occupied molecular orbital (HOMO) of methanol is considerably different from that of water. In fact, this is ascertained by the calculated HOMO's: the HOMO of water is wholly composed of an oxygen 2p atomic orbital, but, as for methanol, only 62% of the HOMO is composed of an oxygen 2p atomic orbital.

Fig. 2 shows the models of methanol and methyl mercaptan used in theoretical calculations. Results for methanol obtained by the CNDO/2 and the INDO method are summarized in Table 1. In Table 1 1OZ, for example, indicates the $2p_z$ atomic orbital of an oxygen atom. Wave functions are approximated as a linear combination of atomic orbitals and the coefficients, C_{ht}, are given in Table 1. The calculated orbital energies are compared with observed vertical i.p.'s. The first band of the pe spectrum of methanol is thought to be due to the ionization from a "lone pair" orbital localized on an oxygen atom. This is ascertained by the fact that the first band of the pe spectrum is considerably sharp. But this "lone pair" orbital is not completely atomic: only 62% of this orbital is composed of an oxygen $2p_y$ atomic orbital. Relationship between band shapes of the photoelectron spectra which can be assigned to "lone pair" orbitals and the wave functions obtained from theoretical calculations has been considered in detail elsewhere.[8]

As for methanol, ethanol, 2-propanol, *sec*-butanol and *tert*-butanol, the well-defined second i.p.'s can be determined. But as for alcohols with straight chain alkyl group, the second band overlaps with higher ionization potential bands and the second i.p.'s cannot be determined. Figure 1 shows that the more the alkyl group is branched, the second ionization band is the more clearly isolated.

Table 1 shows that the nature of the 5a′ orbital of methanol is rather indistinct. This orbital consists of contribution of CH and OH bonding character. It is interesting that the second occupied orbitals of alcohols that have strongly electron-releasing branched alkyl groups, *i.e.*, *iso*-propanol, *tert*-butanol, have con-

8) H. Ogata, H. Onizuka, Y. Nihei, and H. Kamada, *Chem. Lett.*, **1972**, 895.

siderable CO bonding character. Though third i.p.'s cannot be given from pe spectra except for methanol and ethanol, calculations show that the third occupied orbitals consist of mainly CO bonding orbitals. In the case of methanol the fourth pe band is thought to be the ionization from CH_3 group.

Mercaptans. The pe spectra of eight aliphatic mercaptans are shown in Fig. 3. Calculated ionization potentials and the corresponding eigenvectors are given in Table 2. The first to the third vertical i.p.'s can be readily obtained from spectra and they are summarized in Table 3. Since an oxygen and a sulfur atoms belong to the same column of the periodic table, pe spectra of mercaptans might be expected to contain some of the characteristic features of the spectra of alcohols, *i.e.*, they would contain a sharp intense peak ascribable to a 3p "lone pair" electrons localized on the sulfur atom in the lowest i.p. region, and a series of broader bands in higher i.p. region. The i.p.'s of the "lone pair" electrons may be expected to be lower in mercaptans than in alcohols because a sulfur atom has 3p "lone pair" electrons. Comparison of Fig. 3 with Fig. 1 shows the validity of these predictions.

Mercaptans give pe spectra composed of a sharp intense peak at the lowest i.p. region and a series of broader but well-resolved bands in higher i.p. region.

Table 2 shows that the largest contribution to the HOMO is given by 1SY, and amounts to more than 80%. The first band of each mercaptan is assigned to the ionization from the "lone pair" orbital localized on a sulfur atom on the ground that this band is composed of single sharp peak and that calculations show the HOMO is non-bonding. That the first bands of mercaptans are sharp compared with those of alcohols and that though the first band of methanol contains vibrational fine structure, mercaptan shows no vibrational structure, are consistent with the difference between the degree of contribution of 1OY and 1SY to the HOMO.

When the comparison is made between methyl- and *tert*-butyl-substituted compounds, the contribution of 1NX and 1OY to the highest occupied orbital reduces from 51% to 32% for amines and from 62% to 36% for alcohols. On the contrary, the contribution of 1SY to it only reduces from 85% to 82%. This property is the marked characteristic of the "lone pair" orbital of aliphatic mercaptan. Of the eight alkyl-substituted amines, alcohols and mercaptans, methyl-substituted compounds have the highest i.p.'s and *tert*-butyl-substituted compounds have the lowest i.p.'s. Difference of ionization potentials of methyl and *tert*-butyl-substituted compounds is 0.40 eV for amine, 0.77 eV for alcohol and 0.41 eV for mercaptan. The first i.p.'s of amines, alcohols and mercaptans are given graphically in Fig. 4.

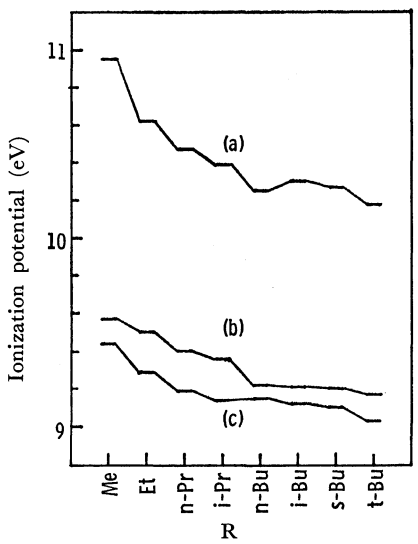

Fig. 4. The first adiabatic i.p.'s of (a) alcohols, (b) amines and (c) mercaptans.

Unlike alcohols, the second bands of mercaptans are all separated from the higher i.p. bands. The second occupied molecular orbital of methyl mercaptan is indistinct in character but has the feature that the electronic population is relatively high on the SH functional group of this molecule. The third vertical ionization potentials can be determined from spectra and calculations indicate that the third occupied molecular orbital of methyl mercaptan is rich in SC bonding

character. As in the case of methanol, the fourth ionization band of methyl mercaptan is largely contributed to by CH_3 group.

Amines. The first i.p.'s of the aliphaticamines have been measured by photoionization[9] and by low resolution pes.[10] Recently, the i.p.'s of methylamine determined by the high resolution pe spectra and those predicted by the INDO type MO calculations have been reported by McDowell *et al.*[11]

The pe spectra of aliphatic amines are shown in Fig. 5. Since the lowest i.p. bands of amines are very broad and show no vibrational fine structure, it is difficult to determine the first adiabatic i.p.'s. But if the onsets of these bands are taken for the adiabatic i.p.'s, our values are in good agreement with those reported by Watanabe *et al.*[9] The first pe bands of amines can be assigned to the ionization from the so-called "lone pair" orbitals. That these bands are very broad compared with those of the first i.p. bands of alcohols and mercaptans is the characteristic feature of amines.[8] As in the case of alcohols, the second i.p.'s can be determined only for amines which have the strong electron-releasing alkyl group, *i.e.* *iso*-C_3H_7 and *tert*-C_4H_9. Calculated results for ethylamine are summarized in Table 4.

Although one center exchange integrals are neglected in CNDO/2, they are taken into account in the INDO method. It is supposed that the inclusion of one center exchange integrals most affects the energy level of an orbital which is localized. Tables

MO Sym.	a′	a″	a′	a′

1, 2 and 4 show that the first i.p.'s calculated by INDO are, in all cases, lower than those calculated by CNDO/2 and the remaining i.p.'s obtained by INDO are somewhat lower but the two methods give essentially the same results.

Modification of the CNDO/2 method. Making a comparison between the observed i.p.'s and the calculated orbital energies by the use of Koopmans' theorem, the calculated values are too large as can be seen from Tables 1 and 2. In order to improve calculated orbital energies, some changes of approximations were introduced to the CNDO/2 method.

From the preliminary calculations, it became clear that the change in the coulombic repulsion integrals causes the parallel translation of the orbital energies and that the bonding parameters have relationship to the intervals of the orbital energies. Taking these facts into consideration, it is necessary first to investigate the parametrization of the electron repulsion integrals, γ_{AB}. These integrals calculated by using the Slater orbitals in the original CNDO/2 method are much larger compared with those semiempirically evaluated.[12] In the present modification, therefore, these integrals are calculated by Klopman's equation.[12] The next modification relates to bonding parameters. In the CNDO/2 approximation, β_A^0 is treated as a parameter characteristic of atom A. In our modification, the following approximations were introduced:

$$\beta^0_{AB} = (1/2)K(z_A' + z_B')$$

where z_A' is the effective nuclear charge of atom A, and K is a constant determined for each row.

Figure 6 shows the variation of orbital energies of

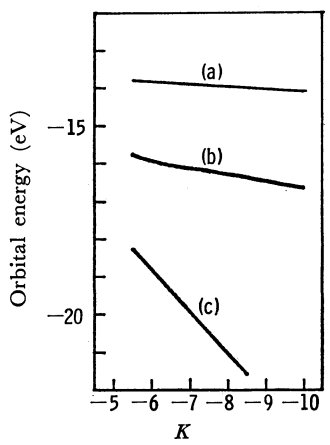

Fig. 6. Orbital energies of water *vs.* parameter *K*. (a) $1b_1$, (b) $3a_1$ and (c) $1b_2$ orbitals.

H_2O. The observed difference between the first and the second i.p.'s is 2.1 eV and that between the second and the third ionization potential is 3.7 eV. The value of -6.5 was adopted for K so as to fill these conditions. The same procedure has been performed for the determination of K of the third-row atoms and the value of -2.3 was obtained citing H_2S as instance.

Results for methanol, methyl mercaptan and ethylamine are given in Tables 1, 2 and 4, respectively. Ionization potentials obtained by these modifications are still larger compared with the observed values but considerable improvement was obtained. It should be noted that the CNDO/2, INDO and the modified CNDO/2 calculations lead to the same ordering of the molecular orbital energy levels.

The authors wish to thank Mr. H. Matsumoto for his continuous help in the measurements of the photoelectron spectra.

The electrification of iron oxides pretreated at various temperatures from 600 to 1200 °C has been investigated in water by measuring the ζ-potential as a function of the pH. From the surface-chemical point of view, iron oxides pretreated at temperatures lower than 800 °C behave differently from those pretreated at higher temperatures; the isoelectric point of the former samples reaches an equilibrium value in a few hours, while that of the latter samples increases slowly to an equilibrium value with an increase in the surface hydration. On the other hand, the equilibrium isoelectric point of iron oxide decreases sharply upon heat treatment at 800—1000 °C, corresponding to the change in the chemical composition of iron oxide from Fe_2O_3 to Fe_3O_4.

Metal oxide surfaces are usually hydrated in water to produce surface hydroxyl groups, which should have extensive effects on the surface properties of metal oxides.[1-4] The electrification of metal oxide surfaces has also been explained in terms of the dissociation of surface hydroxyl groups and the adsorption of H^+ on them:[5,6]

$$MO^-(s) + 2H^+ \rightleftharpoons MOH_2^+(s) \quad (1)$$

The sign of the charge, positive or negative, carried on the surface may be considered to depend on the nature of the metal oxides and the surface properties. With regard to the former effect, Parks[6] has found the empirical rule that the larger the ionic valency, and the smaller the ionic radius of the metal ion, the smaller the isoelectric point of metal oxide. On the other hand, the effects of the crystal structure and of the surface state (especially the surface hydration) on the surface charge have not been investigated in detail. Here, on iron oxide carefully prepared, the effect of the surface hydration on the surface charge is examined, and the dependence of the electrification on the pretreatment temperature is discussed.

Experimental

Materials. Three kinds of iron oxides were prepared in this work. The addition of an excess amount of 3 mol/l ammonia water to a 1 mol/l $Fe(NO_3)_3$ solution yielded a precipitate of iron hydroxide gel. The precipitate was washed fully with distilled water through a glass filter and then dried at 100 °C for 24 hr. Dried iron hydroxide was decomposed in air at 600 °C into iron oxide and washed with distilled water. Furthermore, iron oxide was heated in air at various temperatures between 600 °C and 1400 °C for 3 hr. Finally, the samples were thoroughly washed with distilled water until the conductivity of the filtrate became nearly that of pure water (FI). Since soluble impurities were detected in the filtrate after the recalicination of the FI samples, calcination and washing were repeated more than ten times in order to purify the samples further. This procedure improved the purity of samples so much that we were not able to detect soluble impurities in the final filtrate (FII). Pure iron (99.99%) was oxidized in air at 1400 °C for 3 hr to produce Fe_3O_4. This sample was then crushed in an agate mortar and heated in air at various temperatures between 200 °C and 1400 °C (FIII).

The nitrogen adsorption was measured at the temperature of liquid nitrogen on the FII samples, and the specific surface areas obtained were 6.57 and 1.50 m^2/g for samples treated at 600 and 800 °C (FII-600 and FII-800) respectively. For the samples treated at temperatures higher than 1000 °C, the specific surface area was found to be less than 0.1 m^2/g.

X-Ray diffraction analysis proved that iron oxides calcined below 1200 °C exhibit the rhombohedral α-Fe_2O_3 structure, while in the sample calcined at 1400 °C two types of structures coexist: a large part of Fe_3O_4 and a very small part of α-Fe_2O_3.

Determination of the Isoelectric Point. The isoelectric points of iron oxide were determined by the measurement of the ζ-potential in solutions with various pH values at 25 °C by means of the streaming potential method.[7] The potential values were calculated by using the Helmholtz-Smoluchowski equation. The pH value of the solutions was controlled with HCl and NaOH, and NaCl was used to adjust the ionic strength of the solutions (10^{-3} mol/l). The solid reagents used were recrystallized once from guaranteed-grade reagents. The water which was used for preparing the iron hydroxide and electrolyte solutions and for washing the samples was redistilled one. The second distillation was performed from an alkaline permanganate solution. Before preparing the electrolyte solution, purified water was bubbled with N_2 in order to exclude any dissolved CO_2.

Measurements of Hydration.[8] FII samples calcined at 600 and 1200 °C were immersed into water for various time intervals in order to obtain differently-hydrated samples. After degassing the hydrated samples in a vacuum of 10^{-5} Torr at 25 °C for 10 hr, by which almost all the physisorbed water molecules were removed. The samples were calcined at 1000 °C and the water vapor released was condensed into a dry-ice trap. The condensed water was vaporized and determined volumetrically at 25.0 °C.

Results and Discussion

Immediately after the calcination of the FII samples at various temperatures, they were mounted in the cell of the streaming potential apparatus; then the potential was measured at intervals. During the time between successive measurements, the solution was forced to stream through the diaphragm by applying pressure with N_2 (100 mmHg); the streaming velocity was 4.1 and 110 ml/hr in the cases of FII-600 and FII-1200 respectively. In Fig. 1, the ζ-potential values of FII samples in solutions of different pH values are plotted against the time elapsed after the contact of the solid surface with a solution. Figure 1 shows that the ζ-potential value increases steeply in the

first stage and then slowly; in some cases, the sign of the surface charge changes from negative to positive. The ζ-potential value of FII–600 and FII–800 could attain an equilibrium in a few hours, but it took a long time in the cases of FII–1000 and FII–1200 (about 200 hr). From the data given in Fig. 1 the isoelectric point can be determined to be changed with the immersion time (Fig. 2). It may be understood from Fig. 2 that the isoelectric point of iron oxides calcined at lower temperatures rapidly approaches higher equilibrium values, while those calcined at higher temperatures attain lower equilibrium values very slowly.

In Fig. 3, the water content of the FII–600 and FII–1200 surfaces is plotted as a function of the immersion time. This is expressed as the number of OH groups per 1 g of the sample left on the surface after long outgassing at 25 °C. It has been made clear that the water content thus obtained is mostly composed of chemisorbed water.[9] It can be seen from Fig. 3 that the surface of FII–600 can hydrate very rapidly in water to attain a saturated water content, while the hydration of FII–1200 proceeds very slowly. Taking into account the specific surface area, the water content of FII–600 can be expressed as about 13 OH's per 100 Å^2, irrespective of the hydration time. On the other hand, the specific surface area of FII–1200 is so small that it could not be determined exactly and that it was impossible to estimate the density of the surface water content, but it is evident that the density increases with the hydration time. The difference in hydration properties between the FII–600 and FII–1200 surfaces may be considered to correspond to the difference in the surface structure. Figure 4 shows the isoelectric point and the water content of FII–600 and FII-1200 as a function of the hydration time, where a good parallelism can be seen between the two quantities in each iron oxide.

It has been proposed that surface hydration may affect the surface charge of metal oxide.[6,10–12] However, no experimental evidence for this proposition has been reported. Therefore, the present results of direct measurements of the isoelectric point and of the surface hydration give the first verification of the proposition (Fig. 4). An increase in the water content of the FII surface must be due to the increase in chemisorbed water, as has been described above.

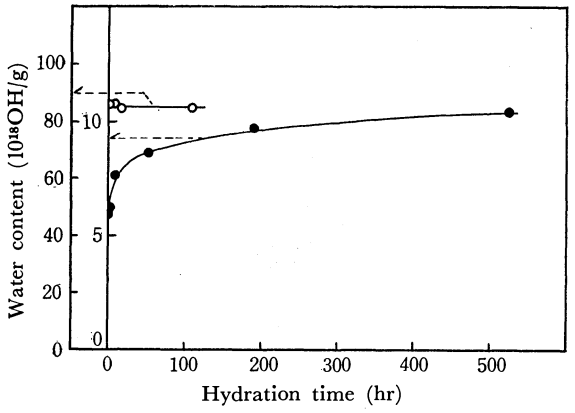

Fig. 3. Water content of FII against hydration time. Pretreatment temperature, ○: 600 °C, ●: 1200 °C.

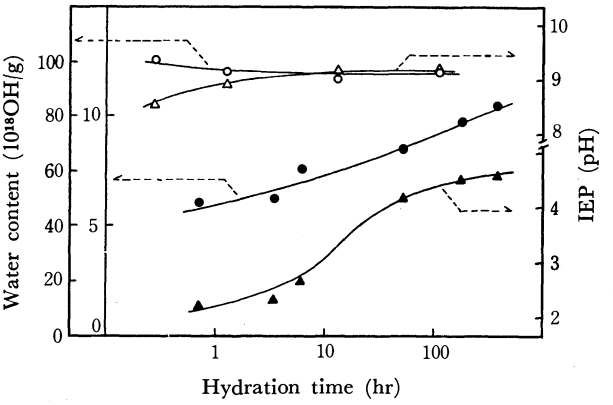

Fig. 4. Water content and IEP of FII against hydration time. ○: Water content, △: IEP. Open symbol, 600 °C; filled symbol, 1200 °C.

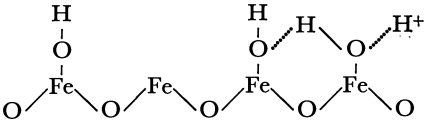
As is shown in Fig. 4, the progress of hydration gives rise to an enhanced density of the surface water content of iron oxide, which may itself possibly result in the mutual interaction of neighboring hydroxyl groups through hydrogen bonding:



The hydrogen-bond formation will make the oxygen atom less free and, at the same time, slightly richer in electron density compared with that in an isolated hydroxyl group, facilitating the attraction of another proton to it from the solution. Thus, it is reasonable that the isoelectric point of iron oxide is raised by the progress of hydration.

In Fig. 5, the equilibrium value of the isoelectric points of iron oxides is plotted against the calcination temperature. Generally, it can be seen from Fig. 5

that the isoelectric point of iron oxides (FI, FII) calcined below 800 °C shows an almost constant value (9.3—9.5), irrespective of the pretreatment temperature, while it falls sharply when pretreated at temperatures higher than 800 °C. The isoelectric point of FI falls sharply upon treatment at a temperature higher than in the case of FII, but an additional test showed that prolonged heating for more than 6 hr made the isoelectric point of FI similar to that of FII. The FIII samples which were prepared by the crushing and subsequent calcination of iron oxide in air at various temperatures represent the isoelectric points approximate to those of FI and FII; the variation in the isoelectric point between 800 and 1000 °C is similar to that of FI and FII.

Isoelectric points of the samples treated at lower temperatures (FI, FII, and FIII) are 8.1—9.5, approximate to the values of 8.2—9.1[13,14] reported for Fe_2O_3 samples, while the values (4.0—5.7) obtained with the samples treated at higher temperatures are close to that for Fe_3O_4 (6.5).[15] X-Ray diffraction analysis demonstrated that the crystal structure of FI and FII changes from Fe_2O_3 to Fe_3O_4 upon treatment at 1400 °C. Furthermore, the crystal structure of FIII calcined below 1200 °C was found to be α-Fe_2O_3, like those of the other two samples, though the FIII sample exhibits the Fe_3O_4 structure just after preparation by oxidizing pure iron. These facts suggest that iron oxides calcined below 800 °C have the higher isoelectric points characteristic of the Fe_2O_3 crystal structure, whereas those calcined above 1000 °C have the lower isoelectric points characteristic of the Fe_3O_4 structure, which might be produced on the surface even at temperatures (1000—1200 °C) lower than the decomposition temperature (1390 °C)[16] of Fe_2O_3 to Fe_3O_4.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3043—3048 (1973)

The Effect of the Temperature on the Mass Spectra of Aliphatic Primary Alcohols and 1-Alkenes. I.

Hiroko HOSHINO, Susumu TAJIMA, and Toshikazu TSUCHIYA
National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received April 23, 1973)

The decomposition of the $(M-18)^+$ ion of aliphatic alcohols and that of the M^+ ion of 1-alkenes are studied. The temperature effect of the ion source of a mass spectrometer on the ratios of the intensities of these ions, those of the ions produced from them by C_2H_4 elimination, and those of the metastable ions for the corresponding fragmentation was measured and was compared with the results to be expected from a simple QET consideration. A discrepancy between the result expected and the experimental result was found for 1-alkenes. In order to clarify the cause of the discrepancy, the photoelectron spectrum was measured for 1-hexanol and for 1-hexene and was assumed to represent the internal energy distribution function, $P(E)$, for each of these substances. Taking the shape of the $P(E)$ into account, the result for 1-alkenes was explained.

It is well known that there is so striking a similarity between the mass spectra of aliphatic primary alcohols and those of 1-alkenes that a group of peaks in the mass spectra of alcohols is called as "olefin peaks," this has prompted studies of the fragmentation mechanism of these alcohols. By study of the appearance potentials of the ion corresponding to the "olefin molecule" or by study of the time variation in the intensity of the "olefin peaks" in the mass spectra of alcohols, it has been shown that no olefin molecule is actually formed by, for instance, any surface reaction, in the ionization chamber before ionization takes place.[1] The mass spectra of primary alcohols, particularly the intensities of the $(M-18)^+$ ion peak and the peaks related to the ion, are known to be strongly dependent on the conditions of measurement, such as the temperature or the materials of the sample manifold of the instrument used.[2] However, the details of these phenomena have not yet been clarified.

It is of primary importance to obtain reproducible mass spectra in the various applications of mass spectrometry to organic chemistry. As a first step to finding the conditions under which we can obtain reproducible results, it is desirable that the mechanism of fragmentation resulting in the poorly reproducible peaks be clarified. In the present work, the effect of the temperature of the ion source of a mass spectrometer on a few peaks, mentioned above, in the mass spectra of primary alcohols and those of 1-alkenes was investigated.

Experimental

A CEC21-103C mass spectrometer was used to obtain the mass spectra of aliphatic primary alcohols and the corresponding 1-alkenes. The number of carbon atoms of the alcohols and the 1-alkenes investigated ranged from 5 to 12 and from 6 to 10, respectively. For alcohols, ions in the following decompositions were investigated, because the $(\text{alcohol}-H_2O)^+$ ion is known to be sensitive to the temperature of the ion source:

$$\begin{aligned} C_nH_{2n+1}OH &\rightarrow (C_nH_{2n+1}OH)^+ \\ &\rightarrow (C_nH_{2n})^+ + H_2O \\ &\quad {}^{*'}\big\downarrow \\ &\quad\longrightarrow (C_nH_{2n}-28)^+ + C_2H_4 \end{aligned} \tag{1}$$

In the decomposition, the intensities of the $(C_nH_{2n})^+$ and $(C_nH_{2n}-28)^+$ ions and that of the metastable ion, $*'$, are denoted as M', F', and m' respectively. For 1-alkenes, the following decomposition was studied:

$$C_nH_{2n} \rightarrow C_nH_{2n}^+ \xrightarrow{*} (C_nH_{2n}-28)^+ + C_2H_4 \tag{2}$$

In the decomposition, the intensities of the $(C_nH_{2n})^+$, and $(C_nH_{2n}-28)^+$ ions and that of the metastable ion, $*$, are denoted as M, F and m respectively. The height of the metastable peak was taken as the m or m′ intensity. When the metastable peak was partly masked by an adjacent peak, the height of the metastable peak was determined after it had been resolved with a Du Pont 310 Curve Resolver.

F'/M', m'/M', and m'/F' for alcohols, and F/M, m/M, and m/F for 1-alkenes were measured under various temperatures, and the relation between the values of these intensity ratios and the temperature of the ion source was investigated from the standpoint of QET. The temperature range covered was between 120 and 250 °C.

The appearance potentials, A, of the $C_nH_{2n}^+$ ions from hexanol and 1-hexene, $A(M')$ and $A(M)$ respectively, and that of the $(C_nH_{2n}-28)^+$ ion from the hexene, $A(F)$, were measured at the ion-source temperature of 250 °C using the EDD technique.[3] The constant, b, in the EDD calculation was taken as 0.67. In the measurement, the influence of the filament-shielding voltage of the ion source on the appearance potential obtained was taken into account.[4] Xenon was used for the correction of the energy axis. The results obtained were $A(M)=9.33$ eV and $A(M)-A(F)=0.12$ eV. The photoelectron spectra of hexanol and 1-hexene were measured with a photoelectron spectrometer, PE-1, made by the Japan Spectroscopic Co., Ltd., using He I. The temperature of the sample in the measurement was less than 100 °C. Xenon was used for calibrating the energy axis again.

The alcohols were obtained from the Tokyo Kasei Co., Ltd., and were used after distillation. The olefins were API Standard Samples, the purity of which was guaranteed to be more than 99.7%. All the reagents were mass-spectroscopically confirmed to be pure.

Results and Discussion

The relations between the temperature of the ion source and the m'/M', m'/F', F'/M', m/M, m/F, and F/M ratios are shown in Figs. 1—6 respectively. As may be seen from the figures, the tangents of the curves for the m/M, m'/M', F/M, F'/M' and m/F ratios *versus* the temperature are positive, whereas the tangent of the curve for the m'/F' ratio is negative. Though Figs. 1—6 were obtained with an electron-accelerating voltage, V_e, of 70 eV, the tangent for each curve was found to keep the same sign when V_e was lowered until $V_e=10.0$ eV.

According to QET in its simplest form,[5] the rate constant, k, for the unimolecular fragmentation with a metastable ion, m:

$$A^+ \longrightarrow B^+ \tag{3}$$

is written as:

$$k = \nu\left(1 - \frac{\varepsilon}{E}\right)^{n-1} \tag{4}$$

where ν is the frequency factor, ε is the activation energy, E is the internal energy of the A^+ ion, and n is the effective number of harmonic oscillators of which the A^+ molecule is assumed to be composed. In Reaction (3), it is assumed that B^+ does not decompose further.

Before applying QET to the results shown in Figs. 1—6, the effect of the potential successive decompositions from F'^+ or F^+ and that of the potential competitive decompositions from M'^+ or M^+ on the results shown in Figs. 1—6 have to be investigated in order to examine whether the rate constant in the form of Eq. (4) can be used for Reactions (1) and (2).

When bombarded by electrons of $V_e=70$ eV, the $(M'-28)^+$ ions from alcohols and the $(M-28)^+$ ions from 1-alkenes are shown to decompose further into the $(M'-43)^+$, and $(M'-45)^+$ ions, and into the $(M-43)^+$, $(M-45)^+$ ions, respectively, by the appearance of the corresponding metastable peaks. However, in the spectra obtained at electron-acceleration voltages lower than $V_e=12$ eV, the intensities of the ions produced by the successive fragmentations were found to be nearly zero. Because the signs of the tangent of the curves shown in Figs. 1—6 remain the same down to $V_e=10.0$ eV, it is reasonable to assume that the rate constant in the form of Eq. (4) can be used to discuss qualitatively the temperature effect on the intensity of the ions in Reactions(1) and (2) without taking the influence of the successive fragmentations into account.

At low electron-acceleration voltages, two reactions, (5) and (6), competing with Reactions (1) and (2) respectively, were observed:

$$M'^+ \longrightarrow (M'-29)^+ \tag{5}$$

$$M^+ \longrightarrow (M-29)^+ \tag{6}$$

The appearance potentials for these ions, A, were measured for 1-alkenes, such as 1-hexene and 1-octene, and were found to be $A(M-28)<A(M-29)$, as was to be expected for the reasons to be given below. As for the appearance potentials of the corresponding ions for alcohols, $A(M'-28)^+$ is inferred to be smaller than $A(M'-29)^+$, because the $(M'-28)^+$ ion is considered to be produced by rearrangement, and the $(M'-29)^+$

Figs. 1—6 show the relation of intensity ratios of ions in Reaction (1) or (2) *versus* the temperature of the ion source. The mark for each curve stands for the carbon number of the compound as indicated below.
⊖ 5; △ 6; ○ 7; ● 8; □ 9; ◐ 10; ▲ 11; ⊙ 12.

ion, to be a simple cleavage of a bond from the $M^{\cdot+}$ ion[6,7]. Actually, the values of the $(M'-29)^+/(M'-28)^{\cdot+}$ and $(M-29)^+/(M-28)^{\cdot+}$ intensity ratios, which were 1—0.5 at $V_e=70$ eV, were found to decrease as the electron energy was lowered. The implication of these results is that the competitive reactions, (5) and (6), have no serious effect upon the general behavior of the curves shown in Figs. 1—6, at least not in the low-electron energy range, the sign of the tangent of the curves can, therefore, be investigated without taking the influences of these reactions into account as long as the qualitative considerations are concerned, although the influences of Reactions (5) and (6) on the intensities of $M'^{\cdot+}$ or $M^{\cdot+}$ respectively can not be neglected in any quantitative consideration. Such being the circumstances, the results of Figs. 1—6 were investigated as follows. In the investigation, the $M'^{\cdot+}$ ion, produced by water elimination from alcohol, is considered to be the parent ion for Reaction (2), since the $F'^{\cdot+}$ ion is shown to be produced from the $M'^{\cdot+}$ ion by the presence of the metastable ion.

et al.[10] and Williams *et al.*[6,11] have investigated quantitatively the effects of n[8,9], ε[10], E[11] and ν[6] in Eq. (4) on the fragmentation patterns of an appropriate series of compounds or of appropriate combinations of compounds.

In the present investigation, the A^+ ion in the unimolecular decomposition reaction, (3), is assumed to have an internal energy distribution function of $P(E)$. The times spent by an ion in various parts of the mass spectrometer were assumed to be as follows. The mean time spent by a newly-formed ion in the ionization chamber is t_1. After being accelerated, the ions dissociated between the times t_2 and t_3 are observed as a metastable peak, and the A^+ ions which do not dissociate until t_4, are observed as the parent ion, A^+. Then, of the total ions produced, the fractions of the ions, A, B, and m, are given by:[12]

$$[A] = \int_0^{\varepsilon} P(E)dE + \int_{\varepsilon}^{\infty} P(E)\exp\{-k(E)t_4\}dE \quad (7)$$

$$[B] = \int_{\varepsilon}^{\infty} P(E)[1-\exp\{-k(E)t_1\}]dE \quad (8)$$

$$[m] = \int_{\varepsilon}^{\infty} P(E)[\exp\{-k(E)t_2\}-\exp\{-k(E)t_3\}]dE \quad (9)$$

Ehrhardt *et al.*[13] have given an expression for $P(E)$, based on statistical mechanics, as follows:

$$P(E) = F(E)G(T)\exp(-E/kT)$$

For the sake of simlicity, the following expression for $P(E)$ was assumed in the present investigation:

$$P(\mathrm{E}) = \frac{E}{(kT)^2}\exp(-E/kT) \quad (10)$$

where k is the Boltzmann constant and where T is the temperature of the molecule. Figure 7 shows schematically the behavior of $P(E)$ for two different temperatures. As the temperature rises, the maximum value of $P(E)$ decreases and the mean value of E increases. This tendency is in accordance with the results previously reported.[13-15]

Assuming Eq. (10) for $P(E)$, the $R\equiv$[B]/[A], $R'\equiv$[m]/[B], and $R^*\equiv$[m]/[A] ratios were calculated using Eqs. (7)—(9). In the calculation, it was assumed that the $m/e=100$ ion is focused at the ion-acceleration voltage of 1000 V and that $t_1=t_2=3$ μs, $t_3=4$ μs, and $t_4=12$ μs. The results are shown in Fig. 8. From the figure, it may be seen that, under these assumptions, as the temperature of the molecules increases and as, consequently, the mean internal energy and the rate constant increase, both R and R^* increase and R′ decreases in the range of $kT < 1.5$ eV.

The results shown in Fig. 8 can be applied to Reactions (1) and (2), and the ratios, F/M, m/M, *etc*, given in Figs. 1—6 can be expected to behave qualitatively,

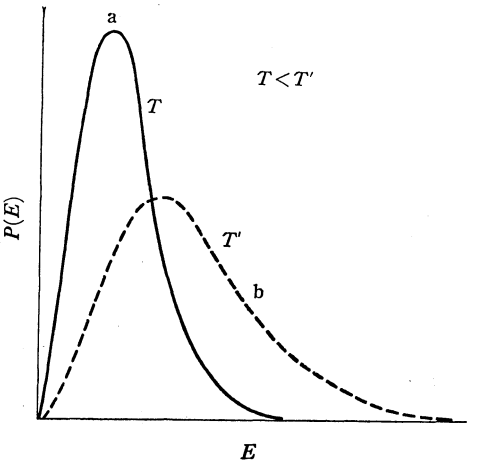

Fig. 7. Illustration of typical behavior expected for a simple internal energy distribution function.
a : lower temperature.
b : higher temperature.

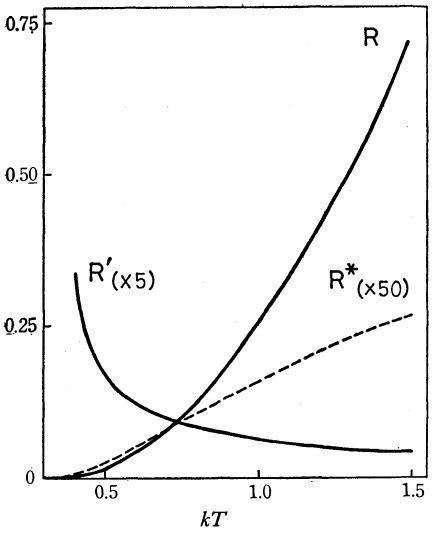

Fig. 8. Intensity ratios of ions calculated from Eqs. (7)—(9) *versus* internal energy E.

in accord with the curves shown in Fig. 8 under the assumption cited.

A comparison of Figs. 1—6 with each of the corresponding curves in Fig. 8 reveals that the expectation is met in all with the exception of Fig. 5; *i.e.*, the signs of the tangents of the curves in Figs. 1—4 and Fig. 6 are in accord with those of the corresponding curves in Fig. 8. On the contrary, the sign of the tangent for the curve in Fig. 5 is positive, whereas that for the curve, R', in Fig. 8 is negative.

In order to explain this discrepancy, the shape of the internal energy distribution function, $P(E)$, was investigated as follows. McLafferty *et al.*,[14] in their study of substituent effects in unimolecular decompositions of diphenylethane derivatives, have taken the effect of the shape of $P(E)$ curves into account in explaining the temperature dependence of the ratio of the intensity of the metastable ion to the parent ion, R^* in the present study, for their sample substances. They synthesized the photoelectron spectrum for a substance from the known spectrum for each moiety

compound of which the substance was composed, and used the synthesized photoelectron spectrum as $P(E)$ for the substance. Using the structure of the synthesized $P(E)$ curve and the value of internal energy corresponding to the range of the abscissa called the "metastable window," which is considered to mainly contribute to the production of the metastable ion observed, they explained the temperature effect on metastable ions.

There have been various investigations[16-19] of possible methods for the evaluation of the internal energy distribution functions resulting in ions from the impact of energetic electrons; their shortcomings have been analysed by Meisels *et al.*[20] According to them, the photoelectron spectrum gives a resonable representation of the actual functions for molecules where multiple ionization and autoionization occur to only a relatively minor extent. On the other hand, another report notes[21] that it is too crude an approximation to use photoelectron spectra as a representation of the internal energy distribution function for some compounds in interpreting their mass spectra. It seems difficult to reach a decisive conclusion concerning the problem for the time being.

Under these circumstances, the photoelectron spectra were used as an approximate representation of the internal energy distribution function in the present study, and the temperature effects shown in Figs. 1—6, especially the effect shown in Fig. 5, were investigated following McLafferty *et al.*[14]

In the present report, *n*-hexanol and 1-hexene were taken as examples, and the photoelectron spectrum of each of these compounds was measured. Figures 9 and 10 show the spectra for *n*-hexanol and 1-hexene respectively. The ionization potentials of $^2P_{1/2}$ and $^2P_{3/2}$

*, "Metastable Window."

for xenon, 13.44 eV and 12.14 eV respectively, were used for energy calibration. The vertical ionization potential and the adiabatic ionization potential[22] for 1-hexene were found to be 9.61 eV and 9.31 eV respectively. The ionization potential of 1-hexene, measured by the photoionization method, has been reported to be 9.45±0.02 eV[17] and 9.46±0.02 eV.[23] The appearance potentials of M^+ and F^+ for 1-hexene, $A(M)$ and $A(F)$, respectively, as measured by electron impact in the present study, are shown by arrows in Fig. 10. The $A(M)$ value thus obtained, 9.33 eV, coincides with the result obtained from the photoelectron spectrum mentioned above, but it is lower than the literature value. Though the reason for the disagreement is not clear, it is noticeable that the mean value, 9.46 eV, of the vertical and the adiabatic ionization potentials obtained from the photoelectron spectrum is consistent with the literature value.

In order to obtain the internal energy value corresponding to the "metastable window," as is shown in the report of McLafferty *et al.*,[14] $\log k(E)$ was calculated for 1-hexene by Eq. (4) as a function of E. In the calculation, ε was taken as 0.12 eV and n was assumed to be $n=(3N-6)/3$, where N is the number of atoms in the molecule. Figure 11 shows the results. Generally, the ν value for a fragmentation with a rearrangement, such as the McLafferty rearrangement, is smaller than that for a simple cleavage of a bond[5,6]. Yeo *et al.*[7] used $\nu=3\times10^6$ for fragmentations with the rearrangement of a hydrogen atom or an oxygen atom and thus obtained results which are close to those obtained in their experiments. Both the log $k(E)$ *versus* E curves for $\nu=10^7$ and $\nu=10^6$ were calculated; they are shown in Fig. 11. The real value for ν was assumed to be in the range between these two values. It may be seen from the figure that the

internal energy corresponding to the "metastable window" in this case is in a small range centered about $E=1$ eV, as is shown by an asterisk in Fig. 10. As the temperature is increased, the curve in Fig. 10 takes a flatter form as a whole, like the broken curve in Fig. 7, and the fraction of the area under the curve, which covers the energy region marked by an asterisk in Fig. 10, gets larger, resulting in an increase in the metastable-ion intensity. On the other hand, because the fractional change in the area under the curve corresponding to the fragment ion F^+, as the temperature is increased, is relatively small, as may be seen from Fig. 3 cited above,[14] the behavior of the curves shown in Fig. 5 is explained. The results given in Figs. 4 and 6 can be understood as has been discussed before.

The signs of the tangents of all the curves, shown in Figs. 1—3, for 1-hexanol, are as would be expected from the simple consideration, in which no particular structure is assumed for the internal energy distribution function for the precursor ion, M'^+, which itself, in this case, is produced from the molecular ion. This suggests that the internal energy distribution function for M'^+ is of a simple form, as is the curve given in Fig. 7, which has no structure, in contrast to the photoelectron spectrum of 1-hexene (Fig. 10). This implies that no 1-hexene molecule is actually produced in the ion source of the mass spectrometer; this is consistent with an observation cited before.[1]

Danby *et al.*[24] report that the sum of the coincident electron spectra corresponding to the parent ion and the fragment ion from methylene chloride agrees with the photoelectron spectra for all the electrons. If this result is also valid for 1-hexanol, it follows from the inference described above that the internal energy distribution function for the fraction of the molecular ion, which is observed as the parent ion in the mass spectrum of 1-hexanol, may be of a simple form without any marked structure, at least in the vicinity of the "metastable window," because the photoelectron spectrum of 1-hexanol is of a simple form without any marked structure, as may be seen in Fig. 10.

The authors are indebted to Mr. Hiroshi Matsumoto and Mr. Tadashi Miyazaki for carrying out the photoelectron spectrometry experiments, to Mr. Mikitake Nakayama for purifying the alcohols, and to Miss Fusako Isogai for preparing the manuscript.

Molecular Structure of Acetamide as Studied by Gas Electron Diffraction

Mitsuo KITANO and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received May 4, 1973)

The bond distances (r_g) and angles (r_a) in acetamide CH_3CONH_2 have been determined by gas electron diffraction as follows: C–C=1.519±0.006 Å, C–N=1.380±0.004 Å, C=O=1.220±0.003 Å, C–H (average)=1.124±0.010 Å, N–H (average)=1.022±0.011 Å, ∠N–C=O=122.0±0.6°, ∠C–C–H (average)=109.8±2°, and ∠C–C–N=115.1±1.6° (or 112.2±1.6°). In comparison with the molecular structure in the crystal, the C–N bond is about 0.05 Å longer, whereas the C=O bond is about 0.04 Å shorter. The C–N and C=O bonds appear to be slightly shorter than the corresponding bonds in *N*-methylacetamide.

The present paper is a part of the systematic analyses of simple amide structures by gas electron diffraction, following the study of *N*-methylacetamide reported in a previous paper.[1] The gas-phase structure of acetamide was first determined by Kimura and Aoki[2] by the visual method of electron diffraction, and the molecular structures in the trigonal and orthorhombic crystals were studied by Senti and Harker[3] and by Hamilton,[4] respectively. The purpose of the present study is to improve the accuracy by an order of magnitude by the sector-microphotometer method of elec-

tron diffraction.

Experimental

A commercial sample was heated to about 160 °C by a high-temperature nozzle,[5] and diffraction photographs were taken with 40 kV electrons at camera distances of 112.30 mm (short) and 246.86 mm (long). The scale factors of the diffraction patterns were calibrated to within 0.10% with reference to the r_a(C=O) distance of carbon dioxide (1.1646 Å).[6] The densities of four plates taken at each camera distance were measured by a digital microphotometer.[7] Other experimental conditions are described elsewhere.[6,8]

Molecular intensities in the ranges $s=2.2$—15.7 and 9.4—37.7 Å^{-1} were obtained from the long and short distance data, respectively.[9] Since they agreed with each other in the overlapping region within experimental error (about 0.03 in the absolute $sM(s)$ scale), they were joined at $s=11.6$ Å^{-1} (Fig. 1). Most of the calculations were carried out on a HITAC-5020E in the Computer Centre of the University of Tokyo.

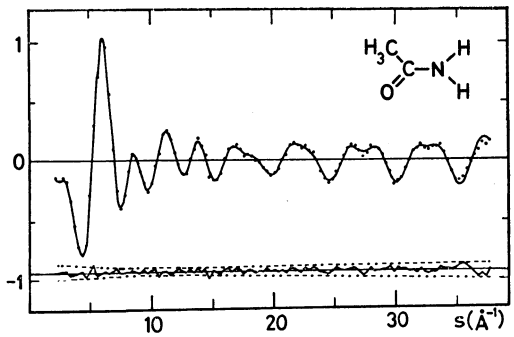

Fig. 1. Experimental and theoretical molecular intensities for acetamide. Typical observed $sM(s)$ values are shown in dots, and the best-fit theoretical is shown in the solid curve. The indices of resolution for long and short camera distances are 0.935 and 0.985, respectively. The lower solid and broken curves represent the residuals and the error limits in the $sM(s)$ to a fractional error of 1×10^{-3} of the original photocurrent,[7] respectively.

Analysis

The molecular intensity was analyzed under the following assumptions:

1) All the atoms except for the two hydrogen atoms of the methyl group are coplanar.

2) One of the hydrogen atoms of the methyl group eclipses the C=O bond.[10] The threefold potential barrier of the methyl torsion is 1 kcal/mol.[10]

3) The methyl group has local C_{3v} symmetry with the tilt angle equal to zero.

4) Two N–H distances (r_g) are equal to each other.

5) The C–N–H_1 and C–N–H_2 angles (r_α), which are *trans* and *cis* to the C=O bond, are equal to the corresponding r_s angles in formamide,[11] 120.0° and 118.5°, respectively.

The mean amplitudes of vibration and the vibrational corrections for the shrinkage effect (r_a-r_α)[12,13] were calculated from a set of modified Urey-Bradley force constants reported by Suzuki[1] and a number of force constants for out-of-plane displacements reported by Itoh[15] for *N*-methylacetamide, both determined from frequencies observed in the liquid phase. The results are given in Table 1. The contributions to the vibrational corrections from the methyl and C–N torsions were estimated in the way described in a previous paper.[1] The asymmetry parameters κ for the bonded C–H and N–H distances were assumed to be 1.8×10^{-5} Å^3, and the rest of the κ parameters were ignored.[16]

The r_g distances and r_α angles derived from least-squares analyses[17] are listed in Table 2 with limits of error estimated from the internal consistency and reproducibility of the parameters, with additional account for systematic errors.[17–19] The mean amplitudes for the C=O, C–N, and C–C bonds were varied and were

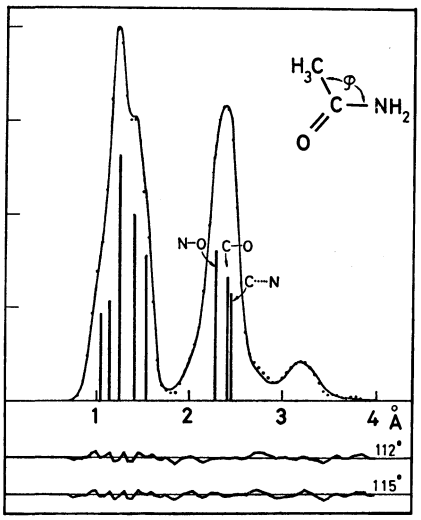

Fig. 2. Experimental (dots) and theoretical radial distribution curves. The lower curves represent residuals based on the models with the C-C-N angle (φ) assumed to be 112° and 115°. Vertical bars represent principal atom pairs based on the 115° model. A damping factor, exp $(-0.0016s^2)$, is used.

X_1=C-C′, X_2=C′-N, X_3=N-H (average), X_4=C′=O, X_5=C-H (average), X_6=∠C-C′-N, X_7=∠N-C′=O, X_8=∠C′-C-H (average), $l_1=l$(C′=O), $l_2=l$(C-N), $l_3=l$(C-C′), k_1=index for long and k_2=index for short. Units ($\times 10^{-4}$) for the distances and mean amplitudes are Å, those for the angles are rad, and those for the indices are dimensionless.

found to be 0.043±0.005, 0.049±0.005, and 0.055± 0.007 Å, respectively. In comparison with the corresponding calculated values in Table 1 (0.040, 0.043, and 0.052 Å), a slight discrepancy is observed in the C–N amplitude. This difference is possibly due to that in the C–N stretching force constants in the gas and liquid phases (See Discussion for the C-N bond lengths in the gas and condensed phases). The rest of the mean amplitudes were fixed to the calculated values listed in Table 2. The error matrix is given in Table 3. The theoretical molecular intensity and radial distribution curves based on this structure are compared in Figs. 1 and 2, respectively, with the corresponding observed curves.

The least-squares analyses resulted in two alternative choices for the C–C–N and C–C=O angles. The C–C–N angle converged to about 115° and 112° when its initial estimates were larger and smaller, respectively, than 114°. The double minimum character of the weighted sum of squared residuals arises from the alternative assignments of the nonbonded C–O and C–N distances to 2.40 and 2.44 Å. All the rest of the parameters, including the O=C–N angle, are not essentially influenced by this ambiguity. As illustrated in Fig. 2, the radial distribution curves based on these alternative sets are almost equally acceptable, and therefore, no definite conclusion can be reached by electron diffraction alone. Since the 115° model is closer to the structure of *N*-methylacetamide,[1] it seems to be more plausible than the 112° model.

As for the torsional motion of the methyl group, the present experimental data are insensitive to the minimum position and the barrier of the potential. A least-squares analysis based on the model that the methyl group is staggered with the C=O bond gave a set of structural parameters essentially equal to those given in Table 3.

Discussion

The structure of acetamide determined in the present study is compared in Table 2 with those in the gas and crystal phases reported in the past and with the structure of *N*-methylacetamide. The most remarkable differences in the gas and crystal structures are found in the C–N and C=O bond distances, which are about 0.05 Å longer and 0.04 Å shorter, respectively, in the gas phase than in the crystal phase. This trend, which is also observed in *N*-methylacetamide, may be interpreted as due to the effect of intermolecular hydrogen bonds in the crystal.[1] Acetamide and *N*-methylacetamide have nearly equal C–C bond distance and O=C–N angles, whereas the former molecule has slightly shorter C–N and C=O bonds than the latter.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3051—3055 (1973)

Intermediates and Mechanism of Photo-Oxygenation Reaction of Triethylamine

Hiroshi TSUBOMURA, Teruo YAGISHITA*, and Hiroo TOI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received June 4, 1973)

The electronic absorption spectrum caused by the charge transfer interaction between oxygen and triethylamine was studied quantitatively. It is concluded that there is no particular stabilization between them due to the charge transfer interactions. The intermediate radicals produced by the excitation of triethylamine-O_2 in the region of the charge transfer band were studied by the ESR method at various temperatures from 77 to 300 K. The chemical analysis of the irradiation products of the same system was also carried out. The radicals observed are methyl, ethyl, and possibly, $(C_2H_5)_2\dot{N}CHCH_3$, $\dot{O}OH$ and $(C_2H_5)_2NO\cdot$. The products identified are acetaldehyde and diethylamine. Based on these results, the various reactions taking place in the overall photochemical process were speculated.

It is well known that oxygen gives rise to charge transfer(CT) absorption spectra with various organic substances.[1] The upper states for the absorption processes are theoretically predicted to be almost pure ionic pairs, $D^+\cdots O_2^-$, where D is an electron donor. In the case of aniline derivatives, we have found that an ion-pair formation occurs from this excited CT state followed by electron recombination leading mostly to the ground state of aniline.[2] In the case of aliphatic compounds, on the other hand, oxidation reactions seem to ensue generally.

Systematic studies of the photo-chemical reactions of such oxygen CT complexes seem to be very important, because, by doing so, we might be able to get a general information on the chemical driving forces for the CT complexes which are related with such biological processes as photosynthesis. The photo-oxygenation process is also very important as one taking part in the auto-oxidation. In spite of these importances, there seems to have been rather scanty work on direct photo-oxygenation reactions so far, aside from numerous works concerning photo-sensitized oxygenation reactions.[3] In the case of ethyl ether, Stenberg *et al.*[4]

found that the excitation of the O_2-ether system in the region of its CT absorption leads mainly to the formation of ethyl acetate. For aliphatic amines, Stratford[5] studied the direct photo-oxidation of trialkylamines in detail. He found that, in the case of tri-*n*-butylamine, dibutylamine, butyric acid and tributylamine *N*-oxide are among the products.

Experimental

Materials. Reagent grade triethylamine was dried overnight with potassium hydroxide, and fractionally distilled with a Widmer column. *n*-Heptane and most other hydrocarbons were treated with concentrated sulfuric acid, washed, dried with calcium chloride and then with sodium wire, and fractionally distilled. Acetonitrile was dried with calcium chloride and refluxed with phosphorus pentoxide and fractionally distilled. Commercially available pure oxygen was dried by liquefaction with liquid nitrogen.

Measurements of the CT Absorption Spectra. Pure triethylamine (TEA) or the *n*-heptane solution of TEA was placed in an ampoule with a magnetic rotor inside and a side arm connected to a quartz cell for the spectral measurements. The ampoule was connected through a ground glass joint to a vacuum line, and the TEA or the solution was degassed by means of the freeze-pump-thaw technique. After the absorption spectrum was measured at room temperature, oxygen was introduced into the line at *ca.* 1 atm pressure, the line being closed and the pressure being read quickly with a mercury manometer. Then, the liquid was vigorously stirred by the magnetic stirrer for a few minutes and the pressure drop was read. By this procedure, the concentration of the oxygen in the solution could be determined. The solution was transferred to the quartz cell and its ultraviolet absorption spectrum was measured by use of a Cary 15 spectrophotometer.

ESR Measurements. The ESR measurements were made using a JES-3BX or a JES-ME-2X spectrometer of Japan Electron-Optics Laboratory Co. at the X band. The magnetic field was measured by use of the proton magnetic resonance signal. The *g*-values of short-life species were determined by inclusion of a Mn^{2+} reference sample.

The solution containing TEA was put into a pyrex ampoule connected to a quartz ESR capillary cell. After dried oxygen gas was bubbled in, the solution was transferred into the ESR cell, which was then placed into a Dewar vessel and cooled with liquid nitrogen. The cell was irradiated with a Ushio 500 W high pressure mercury lamp through a Toshiba UV-D2 glass filter which transmits the light in the region of the CT band (300—400 nm).

The Analysis of the Photo-Oxygenation Products. TEA in a reaction vessel (a cylinder, 24 mm in diameter) made of sodium glass, transparent beyond 310 nm, was irradiated with the 500 W high pressure mercury lamp 25 cm apart from the reaction vessel with oxygen bubbling in through a glass capillary tube. The reaction products were analyzed by the gas chromatographic, chemical and IR techniques.

Results

UV Absorption Spectra. In Fig. 1, the absorption spectra of *n*-heptane solutions of TEA dissolving oxygen are shown, the absorption of the deoxygenated solution being subtracted for each curve. From the absorbances and the amount of dissolved oxygen determined by the manometric method, the Benesi-Hildebrand plot[6] was made, which leads to molar extinction coefficients of 640 at 310 nm, 970 at 300 nm, and 1550 at 290 nm. The equilibrium constants obtained ranged from 0.05 to 0.08, showing that the binding between oxygen and TEA is very weak or practically nil. In Fig. 2, the Benesi-Hildebrand plot for λ=290 nm is shown as an example.

ESR Studies. The excitations of TEA in *n*-heptane in the range of the CT band at 77 K for about 10 min gave an ESR spectrum as shown by curve A in Fig. 3. The spectrum is symmetric with respect to the magnetic field, the *g* value being 2.0025. The intensity increased with irradiation till about 2 hr, after which it began to be saturated. At 77 K, the

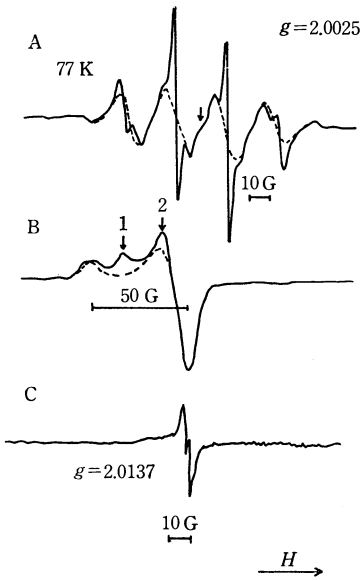

Fig. 3. The ESR spectra of the species produced by the UV-irradiation of triethylamine(1) : *n*-heptane(5)–O_2 at 77 K (A), followed by warming in the dark (B and C).

spectrum stayed unchanged after the light was turned off. The intensity was proportional to the concentration of oxygen. It was confirmed that *n*-heptane and methylcyclohexane dissolving oxygen did not show any ESR signal when irradiated.

The spectrum has a prominent quartet, with an intensity ratio of approximately 1 : 3 : 3 : 1 and a hyperfine coupling constant of 26 G. These features show that methyl radical is present in the solution. It has been confirmed that similar spectra were obtained when TEA in acetonitrile or a 1 : 1 mixture of *n*-propyl and isopropyl alcohols was UV-irradiated at 77 K.

When the component of the spectrum due to the methyl radical is subtracted from the spectrum of Fig. 3A, the curve shown by the broken line is obtained. This appears to be a symmetric quartet, but might more probably be a sextet which is due to a five proton system (see later sections). From the present situation, the species most relevant to this spectrum is the ethyl radical.

In the case of the decalin solution, an ESR spectrum was obtained as shown in Fig. 4. A similar spectrum was obtained for the methylcyclohexane solution. Here, the structure due to the methyl radical is much weaker, and the sextet is prominent. This result can be understood by assuming that the methyl radical is more mobile in these solvents at 77 K than in the other solvents and is unable to survive at 77 K, while the larger radical relevant to the sextet is less mobile

Table 1. The *g*-factors of peroxy radicals

	g_1	g_2	g_3
In isopentane matrix at 77 K	2.0034	2.0034	2.0369
In *n*-heptane matrix at elevated temp	2.0029	2.0029	2.0353
OOH[7]	2.0044	2.0044	2.0393

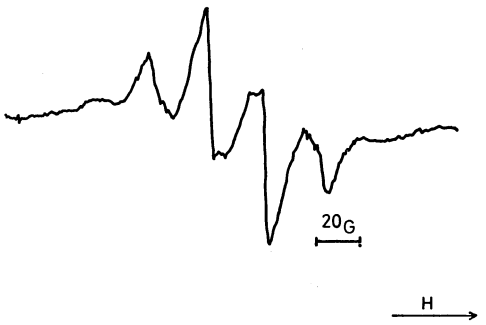

Fig. 4. The ESR spectrum of UV-irradiated triethylamine(1): decalin(1)-O_2 at 77 K.

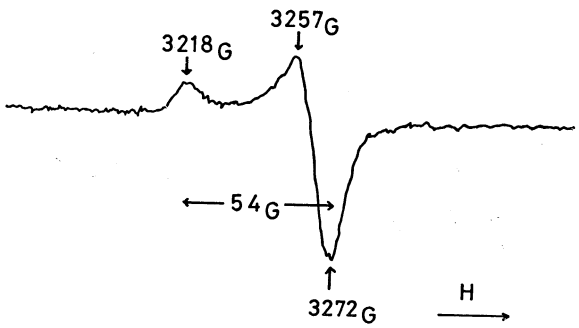

Fig. 5. The ESR spectrm of UV-irradiated triethylamine(1): isopentane(5)–O_2 at 77 K.

and more stable at the same temperature.

For the case of the isopentane solution, a spectrum was obtained showing large anisotropic *g*-factors (Fig. 5 and Table 1). The *g*-factors are a little different from those of OOH and the species for the spectrum may be assigned to an organic peroxy radical. It is often recognized that the isopentane matrix at 77 K is softer than other matrices, so that oxygen can move through the matrix at 77 K, making encounter with a radical and reacting with it even at that temperature.

When the liquid nitrogen in the Dewar vessel was removed and the irradiated solution of TEA was allowed to warm up, the ESR spectrum changed as shown in Fig. 3 for the case of *n*-heptane solution. The analysis of curve B as assigned to a peroxy radical reveals that the peak indicated by an arrow (1) is no doubt due to a different species and the peak indicated by an arrow (2) shows that a small amount of methyl radical still survives in that spectrum. What remains is very much similar to the spectrum of the isopentane solution (Fig. 5 and Table 1) and undoubtedly represents that the same species are present in the two cases. At intermediate temperatures between those for curve A and B, the methyl quartet gets weaker while at the same time the peroxy signal gets stronger. These results indicate that as the matrix begins to soften, the methyl and ethyl radicals transform into diamagnetic species and the oxygen molecules begin to move through the matrix and react with a carbon radical to form the peroxide.

7) F. J. Adrian, E. L. Cochran, and V. A. Bowers, *J. Chem. Phys.*, **47**, 5441 (1967).

At the still higher temperature, the ESR signal almost disappears once, and then reappears taking the form shown by curve C in Fig. 3. This is a slightly split singlet with the g-value of 2.016, which is not accurate because of the fast scanning. The spectrum fades out quickly at higher temperature. The average g-value for the peroxy spectrum of curve B is 2.0137, fairly close to the above-mentioned value and therefore the spectrum C is attributable to the same peroxy radical as that for curve B rapidly rotating in the warm matrix. The disappearance of the signal at the intermediate temperature then indicates a dimerization reaction as shown below,

$$\mathrm{ROO\cdot} + \mathrm{ROO\cdot} \longrightarrow \mathrm{ROOOOR},$$

taking place when the radicals gets fairly mobile. The dimer then dissociates into the monomer radicals at higher temperature, giving spectrum C. Such a dimerization-redissociation phenomenon was observed before.[8]

By irradiating continuously a n-heptane solution of TEA at room temperature, an ESR spectrum was obtained as shown in Fig. 6. The spectrum was very weak and the intensity was proportional to the oxygen pressure. It disappeared immediately when the light is extinguished. The spectrum shows the characteristics of the nitrogen hyperfine structure, with $g=2.0036$ and the nitrogen coupling constant $a_N=15$ G. From the stability of this species, it is most probably an N-oxyl radical. The a_N value of diethylamine-N-oxyl radical observed is 16.7 G.[9] Also, g and a_N of di-t-butylamine-N-oxyl are 2.00595 and 15.36 G, respectively.[10] These values nearly agree with those obtained for the observed spectrum, and from the present situation, it seems most probable that the species obtained is diethylamine-N-oxyl (Et_2NO).

The Analyses of the Photo-Oxygenation Reaction Products. When TEA bubbled with oxygen was irradiated at room temperature in the region of the CT band for a few minutes as described in Experimental section, the amine became turbid, and then began to color yellow. By further irradiation, the yellow color deepened and brown viscous liquid gradually accumulated at the bottom. These processes took about one hour. In the case where the oxygen gas, together with some volatile reaction products, was passed into a cold trap, containing a dilute sulfuric acid solution of 2,4-dinitrophenylhydrazine, a yellow precipitate was immediately formed. The precipitate was purified by recrystallization and identified as the phenylhydrazone of acetaldehyde by elementary analysis and by comparison of its IR spectrum with that of the authentic sample. The yellow-colored sample was also found to contain diethylamine, by treating the sample with p-toluenesulfonyl chloride under Hinsberg's method.

The gas-chromatographic analyses of the amine solutions were carried out also at various stages of the irradiation. At the stage where the amine became first turbid, a peak whose retention time agreed with that of acetaldehyde appeared, together with an unidentified one and the large peak of TEA. By further irradiation, another peak was found. Then, from a sample taken at the stage of yellow coloration, a peak was obtained which is assigned to diethylamine by its retention time, together with at least two small peaks at the longer retention time. The last one agreed in the retention time with that of a product obtained from a reaction mixture of acetaldehyde and diethylamine. The amounts of acetaldehyde and diethylamine obtained are estimated to be about 1 mol% of TEA. The gas-chromatogram of the brown, viscous, bottom layer was very broad and no component was clearly identified.

The infrared spectra of the irradiated sample at various stages were measured as shown in Fig. 7. By the irradiation, absorptions appear at the regions

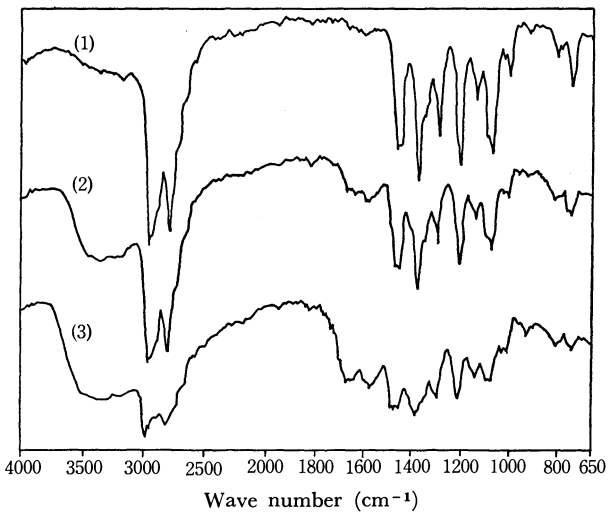

Fig. 7. The infrared absorption spectra of the UV-irradiated triethylamine.

(2) The upper layer of the yellow-colored sample.
(3) The lower layer of the same sample.

of 3300 and 1600 cm^{-1}, which suggest the appearance of an amino group or a hydrogen-bonded OH species and carbonyl groups, respectively.

Discussion

Under the present experimental conditions, it is obvious that the first step of the photo-oxygenation reaction of TEA is the formation of the charge transfer state.

$$Et_3N\cdots O_2 \xrightarrow{h\nu} Et_3N^+\cdots O_2^- \qquad (1)$$

At 77 K, the following two processes can be considered.

1. The proton transfer process from the charge transfer state.

$$Et_2N^+\text{-}CH(H)\text{-}CH_3 \longrightarrow Et_2N\text{-}\dot{C}H\text{-}CH_3 \qquad (2)$$
$$O\text{-}O^- \qquad\qquad \cdot O\text{-}OH$$

(named R· hereafter)

The calculation of the enthalpy change for this process by use of known thermochemical data leads to the conclusion that the above process is almost isothermal or slightly endothermic.

2. Re-excitation from the charge transfer singlet state. Though there is no data for the lifetime of the CT state, it might be possible that the CT triplet state which is first attained by photo-excitation degrades to a more stable CT singlet state having a spin different from that of the ground state or to the amine's triplet state, then reabsorbs another photon, and is excited to a higher state. From such higher states, the dissociation of the C–H, C–C, or C–N bond might be probable.

$$^3[Et_3N^+\cdots O_2^-] \longrightarrow \underbrace{^1[Et_3N^+\cdots O_2^-] \text{ or } ^3[Et_3N]\cdots O_2}_{\downarrow h\nu'} \qquad (3)$$
$$\dot{C}H_3,\ \dot{C}_2H_5,\ \dot{E}t_2N,\ R\cdot,\ etc.$$

This second process probably accounts for the methyl and ethyl signals of our ESR measurements at 77 K. It might be possible also that the radical produced by the first process(designated by R·) and the HOO· radical form a pair with $S=0$, or 1. This might be the reason why the signals for R· and HOO· were too weak to be observed in our experiments.

By warming up the matrix, our results tell that the signals for the methyl and ethyl radicals become weaker, and simultaneously, the signal for the peroxy radical increases. These changes can easily be attributed to the softening of the matrix, making the alkyl radicals unstable and the oxygen molecules to diffuse through the matrix till they encounter and react with the larger radicals, for instance, R·, to form the peroxy radical ROO·.

$$R\cdot + O_2 \longrightarrow ROO\cdot$$

The peroxy signal observed, with a slight splitting by a proton, seems to support its assignment to the above-mentioned species, ROO·. The presence of *N*-oxyl radical found from the ESR measurements by continued irradiation at room temperature and that of acetaldehyde from chemical analysis suggest the following process from this ROO·.

$$Et_2N\text{-}CH\text{-}CH_3 \longrightarrow Et_2NO\cdot + CH_3CHO$$
$$\cdot O\text{-}O$$

(ROO·)

The origin of the diethylamine isolated from the photolysis product is not clear, but at least part of the material might have been formed from diethylamino radical obtained in process 2.

The overall processes leading to the yellow viscous material seem to be extremely complex. One possible route is the condensation reaction between acetaldehyde and diethylamine *via* the formation of an enamine.

$$CH_3CHO + Et_2NH \longrightarrow CH_2{=}CH\text{-}NEt_2 + H_2O$$
$$\downarrow$$
$$\lesssim$$
$$\downarrow$$

More condensation reactions

The *N*-oxyl radical, some peroxides and other radicals formed photo-chemically may take part in the further reactions.

Molecular Association and Electronic Spectra of Naphthoic Acids: Formation of an Excimer-like Complex in 1-Naphthoic Acid in Rigid-Glass Matrix

Michio KITAMURA and Hiroaki BABA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received June 16, 1973)

Absorption and fluorescence spectra of 1- and 2-naphthoic acid (1- and 2-NA) have been studied in a hydrocarbon rigid-glass matrix at 77 K and in the crystal. Each of these acids is associated to form a hydrogen-bonded dimer. On increasing the concentration of 1- or 2-NA, the dimer is further associated to give a higher-order complex that may be assumed to be a tetramer. The fluorescence spectra of the monomer and dimer are in mirror-image relation to their respective absorption spectra in both 1- and 2-NA. When the tetramer of 1-NA is photo-excited, a broad structureless fluorescence emission appears, with the maximum at *ca.* 7000 cm^{-1} to the red from the 0–0 band of the dimer fluorescence. The structureless fluorescence spectrum, which has no mirror-image relation to the absorption spectrum of the tetramer, is supposed to originate from an "excimer-like tetramer" of 1-NA. Photo-excitation of the 2-NA tetramer results in a structured fluorescence emission which is considered to come from the simple excited state of the tetramer. The fluorescence lifetimes, quantum yields, and fluorescence-polarization spectra were measured for various molecular species of 1- and 2-NA. The natural fluorescence lifetime of the excimer-like tetramer of 1-NA is evaluated to be 320 nsec, which is 51 times as long as that of the dimer, and the fluorescence from the excimer-like tetramer is polarized mainly along the short molecular axis of the naphthalene nucleus. It is concluded from these observations that the excimer-like tetramer has a symmetrical configuration, with the planes of the constituent dimer molecules parallel to each other, and its fluorescence process is essentially symmetry forbidden.

In a previous paper,[1] we reported the emission spectra of benzoic acid in a hydrocarbon matrix at 77 K with particular regard to effects of dimer formation. As in the case of benzoic acid, 1-naphthoic acid (1-NA) and 2-naphthoic acid (2-NA) are each associated easily to form a dimer containing two O–H··· O hydrogen bonds. The monomer of benzoic acid gives no fluorescence and only its dimer fluoresces, whereas both the monomer and dimer of the naphthoic acids are known to fluoresce.[2]

In the present study, absorption and fluorescence spectra of 1- and 2-NA have been examined in detail from the viewpoint of molecular association. It was found that, as the concentration of 1- or 2-NA in a hydrocarbon rigid-glass matrix is increased, the hydrogen-bonded dimer is associated further to form a tetramer. In 1-NA, the fluorescence was found to originate from an "excimer-like tetramer." The fluorescence spectra of crystal samples of the naphthoic acids were also obtained for the sake of comparison.

Experimental

1-Naphthoic acid (1-NA), G. R. grade, obtained from Wako Pure Chemical Industries, and 2-naphthoic acid (2-NA), G. R. grade, from Tokyo Kasei Industries were recrystallized from 95% ethyl alcohol and sublimed *in vacuo*. Isopentane, methylcyclohexane, and ethyl ether were purified by the same methods as described in the previous paper.[1] A mixture of isopentane and methylcyclohexane (6 : 1 by volume) was used as solvent, which is referred to as PM in this paper.

Absorption spectra were obtained at 77 K or at room temperature with a Hitachi EPS-3 spectrophotometer, and emission and excitation spectra with a Hitachi MPF-2A spectrophotometer or with an apparatus constructed in our laboratory.[3] Absorption measurements at 77 K were carried out on rigid-glass samples in a quartz cell of 10 mm or 1 mm path length placed in a glass Dewar vessel with quartz windows. Emission measurements at 77 K were made using a 10 mm square quartz cell and a quartz tube cell, 4 mm in diameter. The correction of emission and excitation spectra was made by the relative methods.[1]

Fluorescence decays were observed using 8-nsec exciting light pulses generated by electric discharges through the atmosphere, and the fluorescence lifetimes were obtained by the deconvolution method. Fluorescence quantum yields were determined according to the same procedure as described in Ref. 1.

The measurements of fluorescence polarization were made by the photoselection method.[3,4] The degree of polarization, P is defined as $P=(I_{\parallel}-I_{\perp})/(I_{\parallel}+I_{\perp})$, where $I_{\parallel}$ and $I_{\perp}$ are the intensities of the emitted light polarized, respectively, parallel and perpendicular to the exciting light, which is polarized with the electric vector perpendicular to the plane formed by the excitation and emission beams. The P values were corrected in the usual manner for instrumental and other factors.[3]

Absorption spectra of crystals were measured at room temperature and 77 K using crystal films prepared by evaporation. The crystal fluorescence and excitation spectra were obtained by the front-surface viewing method using crystal powder and crystal films.

The fluorescence spectrum of 1-NA in PM at 4.2 K was observed by immersing the sample cell (a 4-mm quartz tube) directly in liquid helium in a quartz Dewar vessel.

Results and Discussion

The naphthoic acids have large association constants in a hydrocarbon solvent. The monomer–dimer equilibrium constants, K, in PM at room temperature were determined through the procedure of Hosoya *et al.*[5] Since the solubilities of the acids

are very poor in PM, the concentrations of the acids were of the order of 10^{-4} to 10^{-7} mol/l. The results are as follows:

1-naphthoic acid, $K=7.6\times10^4$ l/mol

2-naphthoic acid, $K=3.4\times10^4$ l/mol

Absorption Spectra. The absorption spectra at 77 K of 1- and 2-NA in PM are shown in Figs. 1(a) and 2. The K values obtained at room temperature, together with the large binding energies (~10 kcal/mol)[6] estimated for the formation of the dimer, indicate that virtually no monomeric species exists in PM at 77 K with the concentrations adopted in this study. As was reported,[1] the benzoic acid monomer exists in PM even at 77 K. It was confirmed that the naphthoic acids do not show such an unusual phenomenon. In Figs. 1(a) and 2, the absorption spectra in PM containing 5% ethyl ether by volume are regarded as representing approximately the spectra of the monomers.

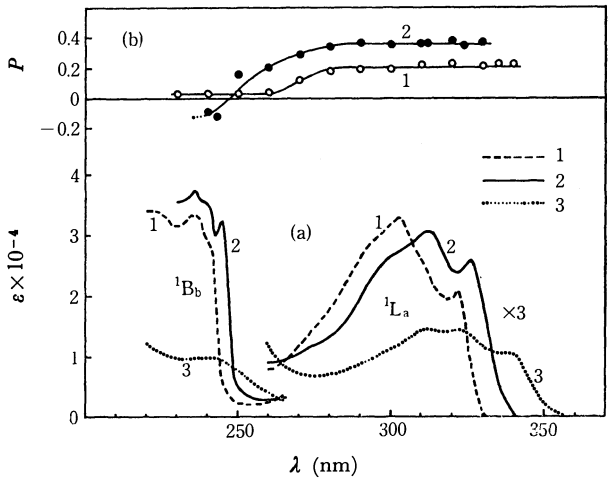

Fig. 1. (a) Absorption spectra of 1-naphthoic acid in PM at 77 K. (1) monomer (see text); (2) dimer (solute concentration, 1.0×10^{-5} mol/l); (3) a mixture of dimer and tetramer (1.0×10^{-4} mol/l).
(b) Excitation-polarization spectra of 1-naphthoic acid at 4.0×10^{-5} mol/l, obtained by monitoring the fluorescence at two wavelengths: (1) 440 nm (excimer-like tetramer fluorescence region); (2) 353 nm (dimer fluorescence region).

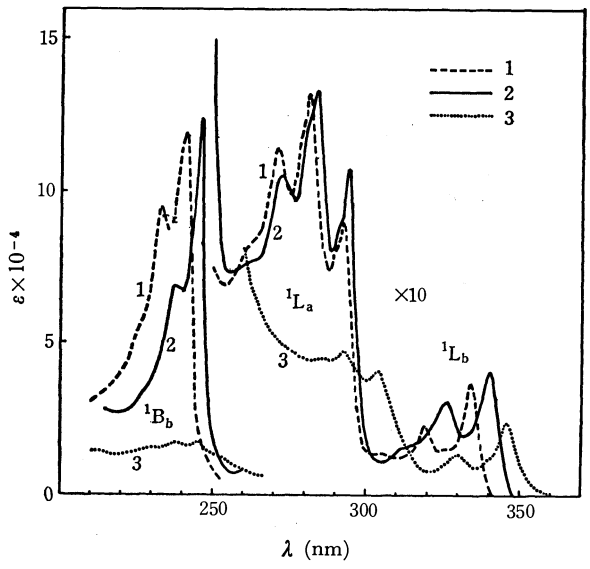

Fig. 2. Absorption spectra of 2-naphthoic acid in PM at 77 K. (1) monomer (see text); (2) dimer (solute concentration, 1.0×10^{-5} mol/l); (3) tetramer (1.0×10^{-4} mol/l).

When the concentration of 1- or 2-NA is 10^{-5} mol/l, only the spectrum of the dimer is obtained at 77 K. As the concentration is increased from 10^{-5} mol/l to 10^{-4} mol/l, new absorption grows up at somewhat longer wavelengths. The absorption spectra corresponding to different concentrations of the acid give an isosbestic point, indicating the existence of an equilibrium between the dimer and a new molecular complex. The new complex is assumed here to be a tetramer of 1- or 2-NA. In Fig. 1(a) or 2, the absorption spectrum represented by the dotted line is considered to be due to the tetramer, but in Fig. 1(a) the spectrum is attributed in part to the dimer. It is further assumed that the tetramer consists of two dimer molecules with their molecular planes parallel to each other; here the hydrogen-bonded dimer is regarded as planar. From the absorption-spectral data, the dimer–tetramer equilibrium constant was estimated to be *ca.* 2.5×10^4 l/mol for 1-NA. This value involves some uncertainty, because the amount of the tetramer produced varies according to the rate of cooling the solution.

In Figs. 1(a) and 2, the values for the molar extinction coefficients, ε, for the dimer and tetramer are defined as the values per monomer. It is evident that the ε values for the dimer defined in this way are comparable to those for the monomer, which fact shows that the π-electronic interaction between the unit monomer molecules is relatively weak in the dimer. This is consistent with the fact that the dimer is formed through the hydrogen bonds and is essentially planar as a whole.[7,8]

The ε values for the tetramer are considerably different from those for the monomer and dimer. This shows a strong π-electronic interaction to occur between the unit dimer molecules in the tetramer, and supports the preceding assumption concerning the configuration of the tetramer. However, inspection of the absorption spectra in Figs. 1(a) and 2 will lead to the following broad assignments of the electronic absorption bands, irrespective of the form of absorbing species (*i.e.*, monomer, dimer or tetramer). In 1-NA, the first absorption band is assigned to the $^1A\rightarrow{}^1L_a$ transition in the Platt notation, with the weak $^1A\rightarrow{}^1L_b$ transition being assumed to be hidden under the $^1A\rightarrow{}^1L_a$ (*vide infra*), and the second band is assigned to the $^1A\rightarrow{}^1B_b$ transition. In 2-NA, the first, second, and third absorption bands are assigned respectively to the $^1A\rightarrow{}^1L_b$, $\rightarrow{}^1L_a$, and $\rightarrow{}^1B_b$ transitions.

In Fig. 3 are shown the absorption spectra of crystal films of the naphthoic acids. These spectra are very broad and clearly different from the absorption spectra

of the tetramers in solution (Figs. 1(a) and 2).

Fluorescence and Excitation Spectra. Figures 4(a) and 5(a) show the fluorescence spectra of 1- and 2-NA in PM solution and in the crystal at 77 K. The fluorescence spectra in PM containing 5% ethyl ether are attributed to the monomer as in the case of the absorption spectra.

The fluorescence spectrum at the solute concentration of 10^{-5} mol/l is due to the dimer. The fluorescence spectra of the monomer and dimer are in mirror-image relation to their respective absorption spectra. For 1-NA, on increasing the concentration, the intensity of the structured dimer fluorescence decreases and, at the same time, a new broad structureless fluorescence emission appears, its maximum being shifted to the red by about 7000 cm^{-1} from the 0-0 band of the dimer fluorescence. The new fluorescence spectrum has no mirror-image relation to the absorption spectrum of the tetramer. Only the broad spectrum with its maximum at 440 nm is observed upon excitation

at 340 nm, where the tetramer alone is considered to be excited (*cf.* Fig. 1(a)). For 2-NA, the increase of the concentration results in a structured fluorescence which is red shifted by only 1700 cm^{-1} from the 0-0 band of the dimer fluorescence.

The new broad structureless fluorescence of 1-NA is considered to originate from an "excimer-like tetramer" in which the interplanar distance between the dimer molecules constituting the tetramer is definitely shortened as a result of the excitation of the tetramer. It should be noted that 1-NA dimer is here regarded as corresponding to the monomer in the ordinary excimer.[9-12] On the other hand, the new structured fluorescence of 2-NA is assigned to the simple tetramer.

In each of the monomer, dimer, and tetramer of the naphthoic acids, the corrected excitation spectrum related to the fluorescence was found to be in good agreement with the corresponding absorption spectrum.

The corrected excitation spectrum of the excimer-like tetramer of 1-NA is shown in Fig. 6 by a broken line. The excitation spectrum is similar to but somewhat different from the absorption spectrum for the 10^{-4} mol/l solution of 1-NA. Since in this solution the tetramer is considered to be largely responsible for the latter spectrum, it must be reasonable to assume that, actually, the excitation spectrum fully agrees with the absorption spectrum of the tetramer alone. The discrepancy between the excitation and absorption spectra for the 10^{-4} mol/l solution can then be at-

Table 1. Fluorescence lifetimes and quantum yields for 1- and 2-naphthoic acids at 77 K

Compound		τ_f(nsec)	Φ_f	τ_f^0(nsec)	k_f(sec^{-1})
1-Naphthoic acid	Dimer	1.9	0.30	6.3	1.6×10^8
	Excimer-like tetramer	83.7	0.26	320	3.1×10^6
	Crystal	69.7			
2-Naphthoic acid	Dimer	23	0.54	43	2.3×10^7
	Tetramer	25	0.53	47	2.1×10^7
	Crystal	18			

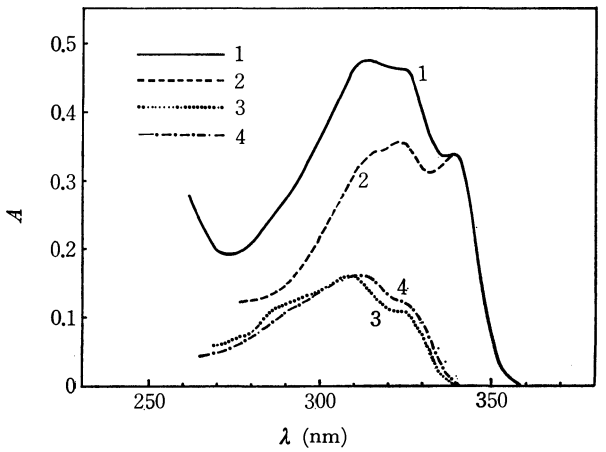

Fig. 6. Excitation spectrum related to the fluorescence from excimer-like tetramer and absorption spectra of 1-naphthoic acid. (1) absorption spectrum of a mixture of dimer and tetramer (solute concentration, 1.0×10^{-4} mol/l); (2) excitation spectrum of excimer-like tetramer; (3) subtracted spectrum (see text for the derivation of this spectral curve); (4) absorption spectrum of dimer (1.0×10^{-5} mol/l).

tributed to the fact that the absorption spectrum involves to some extent the contribution of the dimer. On the basis of the finding that the absorption band at 340 nm (Fig. 1(a)) is due to the tetramer alone, the excitation and absorption spectra are so drawn in Fig. 6 that the both spectra may have the same intensity at that wavelength. Under these conditions, subtraction of the excitation spectrum from the absorption spectrum for the 10^{-4} mol/l solution will yield the absorption spectrum for the dimer. This proves to be true, as is seen in Fig. 6. These considerations clearly indicate that the excimer-like tetramer of 1-NA is formed when the tetramer which exists already in the ground state is photo-excited.

The fluorescence spectra for the crystals of 1-NA and 2-NA are similar to those for the excimer-like tetramer of 1-NA and the simple tetramer of 2-NA, respectively, but the crystal spectra are slightly shifted to the blue (see Figs. 4(a) and 5(a)). The corrected excitation spectra associated with the crystal fluorescence emissions agree well with the crystal absorption spectra in both 1- and 2-NA (see Figs. 3(a) and 3(b)). It may be noted that the structureless excimeric fluorescence spectra of 1-NA in the crystal as well as in the rigid-glass matrix disappeared when a phosphoroscope (50 rps) was used.

Formation of the Excimer-like Tetramer. We are now in a position to examine in detail the excimer-like tetramer of 1-NA in comparison with the simple tetramer of 2-NA. To inquire into the mechanism of the formation of the excimer-like tetramer, it is desirable to know the nature of the excited states of the dimer. For this purpose we shall first consider the fluorescence lifetimes.

Table 1 shows observed fluorescence lifetimes, τ_f, and quantum yields, Φ_f, for 1- and 2-NA at 77 K. The τ_f value for the 1-NA dimer is 1.9 nsec, while that for the 2-NA dimer is 23 nsec. The natural lifetimes, τ_f^0, obtained by the use of the quantum yields are also shown in the table. The τ_f^0 values for the dimers of 1- and 2-NA are 6.3 and 43 nsec, respectively. This suggests that the lowest excited singlet state (fluorescent state), S_1, of the 1-NA dimer is the ^1L_a state and S_1 of the 2-NA dimer is the ^1L_b state. In fact, these values of τ_f^0 agree well with the ones calculated from the Strickler-Berg equation[13] on the basis of the above state assignments; the calculated values are 6.2 and 29.2 nsec, respectively, for the 1- and 2-NA dimers. In the 1-NA dimer the ^1L_a and ^1L_b absorption bands cannot be separated from each other, so that it is tentatively assumed here that the intensity of the ^1L_a absorption band is 80% of the whole absorption intensity in the region from 270 nm to 340 nm (see Fig. 1(a)). This assumption is based on the expectation that the ratio between the intensities of the ^1L_a and ^1L_b bands in the 1-NA dimer is not appreciably different from the corresponding ratios in other simpler naphthalene derivatives.[14-16]

In the 2-NA dimer, it follows from the absorption spectrum given in Fig. 2 that the ^1L_a state, which is the second excited singlet state, is located at an energy about 4600 cm^{-1} above the ^1L_b (S_1) state. It is generally known that the ^1L_a state is responsible for the formation of an excimer,[17,18] and that if the ^1L_a level is much higher than the ^1L_b, the excimer formation is hardly possible.[19] Thus, the difference in the tendency to form an excimer-like tetramer between 1- and 2-NA dimers seems to come from the difference in their electronic structure.

The potential curves illustrating the interaction of the two dimer molecules are shown schematically in Fig. 7. In 1-NA, the attractive force leading to the excimer-like tetramer may result from the inter-

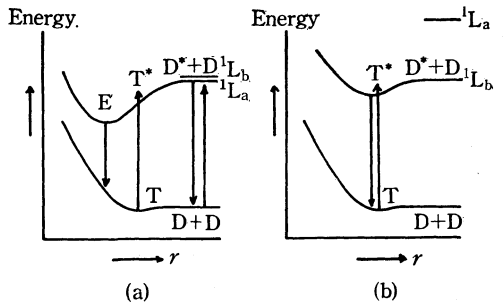

Fig. 7. Schematic potential energy curves showing the formation of excimer-like tetramer of 1-naphthoic acid (a) and tetramer of 2-naphthoic acid (b). r represents the interplanar distance.

action of the ^1L_a state and charge resonance states.[17] The excimer-like tetramer is thus formed along the potential curve for the excited state in Fig. 7(a).

As may be inferred from Fig. 7(b), the situation is different in the case of 2-NA, where the fluorescence is emitted from the simple excited state of the tetramer.

A broad structureless fluorescence emission to be assigned to the excimer-like tetramer was also observed at 4.2 K for 1-NA in PM. In this case, the fluorescence band maximum shows a slight blue shift of *ca.* 140 cm^{-1} compared with the fluorescence at 77 K. The probable increase of the matrix rigidity accompanying the temperature decrease will prevent the excimer-like tetramer from reaching its equilibrium state during its lifetime. This may result in the blue shift mentioned above.

Crystals of 1- and 2-NA are known to consist of nearly planar centrosymmetrical dimer molecules that are formed by the two O–H···O hydrogen bonds,[7,8] and the adjacent dimer molecules have their molecular planes parallel to each other. The difference in spectral behavior between the fluorescence emissions of the 1- and 2-NA crystals (Figs. 4(a) and 5(a)) may be interpreted, as before, in terms of the difference in the relative positions of the ^1L_a and ^1L_b levels. Furthermore, in 1-NA the crystal structure is more favorable for the strong π-electronic interaction to occur.[7,8]

Geometrical Configuration and Electronic Structure of the Excimer-like Tetramer. The geometrical configuration of excimers has been studied by means of intramolecular excimer fluorescence and excimer fluorescence in the crystal.[20,21] The results seem to indicate that a symmetrically overlapping configuration is favorable for the excimer formation. For such a configuration, theoretical considerations predict that the electronic transition associated with the excimer fluorescence should be symmetry forbidden.[11] However, the fact that most of the observed lifetimes of excimers in solution are relatively short is inconsistent with the above prediction.[9]

The lifetimes and quantum yields of the naphthoic acids are given in Table 1. It is seen that in 1-NA the excimer-like tetramer has a much longer natural lifetime τ_f^0 than does the dimer. The radiative rate constants $k_f(=1/\tau_f^0)$ for the dimer, excimer-like tetramer, and tetramer will be denoted by k_f^D, k_f^E, and k_f^T, respectively. Then, from the data in Table 1 the following are obtained:

$$\text{1-naphthoic acid,}\quad k_f^D/k_f^E = 51$$

$$\text{2-naphthoic acid,}\quad k_f^D/k_f^T = 1.1$$

The results suggest that the fluorescence transition in the excimer-like tetramer is electronically forbidden.

The electronic structure of the excimer of naphthalene has attracted much attention.[12,18,22] McGlynn *et al.* showed that in a naphthalene excimer of relatively high symmetry, the transition between its fluorescent and ground states is forbidden.[12] In a similar manner it may be concluded that the excimer-like tetramer of 1-NA has a symmetrical configuration, with the planes of the constituent dimer molecules parallel to each other, and that its fluorescence process is essentially symmetry forbidden. Mataga *et al.* measured the fluorescence lifetimes of excimers of anthracene, perylene, and other aromatic hydrocarbons in cyclohexane matrix at 77 K,[23] and found that the lifetimes are of the order of 10^2 nsec and are longer than the fluorescence lifetimes of the corresponding monomers. Thus, with respect to the configuration and fluorescent state of the excimers, they reached a conclusion similar to the one we have just derived.

The question may then be raised why the "forbidden" fluorescence transition from the excimer-like tetramer of 1-NA has a relatively small but non-zero value of radiative rate constant ($k_f^E = 3.1 \times 10^6$ sec^{-1}). In general, an electronically-forbidden transition in a molecule may become allowed through vibronic interaction. Thus, for instance, in aromatic hydrocarbons like naphthalene, $k_f(^1L_a)/k_f(^1L_b)$ is of the order of 10 to 10^2,[11] where $k_f(^1L_a)$ and $k_f(^1L_b)$ are the radiative rate constants for the $^1L_a \rightarrow {}^1A$ and $^1L_b \rightarrow {}^1A$ transitions, respectively; the former transition is allowed, while the latter is essentially forbidden. As has been shown, $k_f^D/k_f^E = 51$, so that it would be reasonable to consider that the "forbidden" fluorescence transition in the excimer-like tetramer steals a transition probability from other allowed transitions. Alternatively, we may suppose that the excimer-like tetramer deviates slightly from the symmetrical configuration, resulting in the non-zero value of the rate constant k_f^E.

Only a few studies have hitherto been made on the polarization of the excimer fluorescence because of experimental difficulties.[24–26] The excimer fluorescence has been observed not only in fluid solutions, but also in rigid matrices.[27,28] However, most of these matrices are opaque ones, *e.g.*, frozen cyclohexane and *n*-hexane, and are not suitable for the polarization measurement.

We observed the fluorescence- and excitation-polarization spectra for the dimer and excimer-like tetramer of 1-NA in the transparent rigid-glass PM solution, together with the fluorescence-polarization spectra of the dimer and tetramer of 2-NA in the same solution. Figures 1(b) and 4(b) show respectively the excitation- and fluorescence-polarization spectra of 1-NA. Figure 4(b) is concerned with the fluorescence-polarization spectrum of 1–NA at the concentration of 4×10^{-5} mol/l, where both dimer and tetramer exist in the ground state. In the region of the excimer-like tetramer fluorescence (between 410 and 500 nm), the P values are 0.20 with respect to excitation at 310 nm (line 1), and 0.04 with respect to excitation at 240 nm (line 2). It may be noted that excitation at 340 nm, where only the tetramer is excited, leads to the same P values as excitation at 310 nm. In the region of the dimer fluorescence (between 335 and 380 nm), the P values are 0.36 for excitation at 310 nm (line 1) and -0.10 for excitation at 240 nm (line 3). The same results were also obtained at the 1-NA concentration of 10^{-5} mol/l, where only the dimer exists.

The fluorescence-polarization spectra of 2-NA are shown in Fig. 5(b). The polarization spectrum of the dimer was obtained at the 2-NA concentration of 1.0×10^{-5} mol/l, and that of the tetramer at 1.0×10^{-4} mol/l. The P values are 0.28 for the dimer (line 1) and 0.18 for the tetramer (line 2) with respect to the excitation in the region of the longest-wavelength absorption band.

In 1-NA, the $^1A\rightarrow{}^1L_a$ and $^1A\rightarrow{}^1B_b$ transitions are considered to be polarized largely along the short and long axes of the naphthalene nucleus, respectively.[29] Then, the polarization data for the 1-NA dimer (Figs. 1(b) and 4(b)) are reasonably explained by assuming that the dimer fluorescence has a transition moment parallel to the short axis. The fluorescence spectra of the dimer and tetramer of 2-NA are positively polarized with respect to the excitation into the ^1L_b state (Fig. 5(b)), so that the fluorescent state is regarded as the ^1L_b in either case. However, the P value is somewhat smaller for the tetramer, showing that the increase in the degree of molecular association is accompanied by a factor which leads to depolarization.

A comparison of the polarization data for the excimer-like tetramer of 1-NA with the corresponding data for the dimer (Figs. 1(b) and 4(b)) shows that depolarization occurs obviously in the fluorescence emission in passing from the dimer to the excimer-like tetramer. However, referring to the situation in 2-NA, one may say that the fluorescence emitted from the excimer-like tetramer is polarized essentially along the short axis, as in the case of the dimer fluorescence.

As has been mentioned, the "forbidden" transition associated with the fluorescence of the excimer-like tetramer may become partially allowed either by vibronic interaction or by deviation from the symmetrical configuration. Among the lower excited states of the excimer-like tetramer, there should exist an electronic state from which the transition to the ground state is symmetry allowed. The energy of this allowed transition must be higher than that of the forbidden transition, since the latter transition is related to the lowest excited state. According to the proposed mechanism of the formation of the excimer-like tetramer (*cf.* Fig. 7), the transition moment of the allowed transition in question should be parallel to the moment of the $^1A\rightarrow{}^1L_a$ transition in the dimer or simple tetramer of 1-NA. As regards the vibronic interaction, the forbidden transition will steal the transition probability efficiently from the allowed transition, because the energy difference between the two transitions concerned would not be large. On the other hand, the deviation from the symmetrical configuration, if it occurs at all, will result in a mixing of the allowed transition metioned above with the forbidden transition. These considerations account for the observed polarization of the fluorescence from the excimer-like tetramer.

We wish to express our thanks to Professor S. P. McGlynn for his criticism and discussion, and to Mr. Masahisa Fujita for his help in carrying out the lifetime measurement.

Electron-donating Strengths of Some Ketimines Intermolecular Charge Transfer Studies

R. ABU-EITTAH and M. M. HAMED

Department of Chemistry, Faculty of Science, University of Cairo, Giza, Egypt

(Received March 6, 1972)

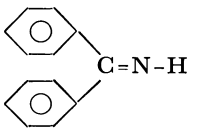
The electron-donating strengths of some ketimines have been investigated *via* the formation of charge transfer complexes with iodine as electron-acceptor. Two types of ketimines were chosen as electron-donors, namely, the =N– unsubstituted as well as the =N– substituted ketimines. With the first type of donors the "n" charge transfer complex was obtained whereas with the second type the "π" charge transfer complexes were obtained. The equilibrium constants were computed for the different types of complexes. An attempt is made to estimate the ionization potentials of the donors from the position of the charge transfer band characteristic of the specific complex.

The electron-donating properties of a Lewis-base can very well be investigated through its ability of forming an intermolecular charge transfer complex with a Lewis-acid. The more stable the complex formed, the stronger is the Lewis base. A wide variety of such complexes has been studied. Different types of electron donors are known, organic as well as inorganic molecules.[1] The donors are usually classified as either "n" or "π" donors depending on the type of their molecular orbital that overlaps with the empty molecular orbital of the acceptor.[2–6] Also, a number of electron acceptors have been used but mainly iodine, chloranil, tetracyanoethylene and maleic anhydride are well known.[7] It has been confirmed that the "n" complexes are much more stronger than the "π" ones. Literature is very rich with intermolecular charge transfer studies and many reviews are available.[8,9] Also, Drago[10–13] and his co-workers, Tamres[14–16] and his co-workers have extensively investigated a wide variety of the charge transfer complexes.

The donor properties of many, nitrogen containing, organic molecules have been investigated.[4,6,13,17] However the electron-donating properties of "Ketimines" have not yet been studied. The "Ketimine" molecule contains a C=N– group which may be called an electron sink. Hence it will be interesting to investigate the donating properties of such a group of compounds. The donating properties will essentially depend on some steric factors as well as on the planarity of the molecule.

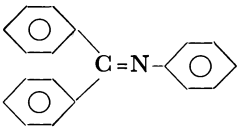
Experimental

Materials. *1,1-Diphenylmethylenimine*:



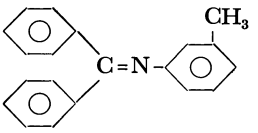
It was prepared from Grignard reaction between freshly distilled bromobenzene and phenyl cyanide. Decomposition of the complex was carried out by absolute methanol.[18] The product was purified by vaccum distillation. Refractive index of the prepared sample is the same as that reported in the literature (n_D^{19} 1.6191).[18]

N-*(Diphenylmethylene)aniline*:



It was prepared by condensation of benzophenone and aniline till the calculated volume of water is collected.[19] The sample was purified by several recrystallization. Melting point is 112—113 °C as compared with 113—114 °C found in literature.[19]

N-*(Diphenylmethylene)*m-*toluidine*.



It was prepared by the same procedure used for the *N*-phenyl derivative. Melting point is 81—82 °C as compared with 82.5 found in the literature.[20]

was purified by vigorously stirring with fuming sulphuric acid for eight hours. It was washed with water, saturated sodium carbonate and finally with water. The solvent was dried by keeping over anhydrous magnesium sulphate for 24 hr. The solvent was distilled and then used for scanning the spectra.

Apparatus. Beckman DK spectrophotometer was used. The cells were fused silica of 1.0 cm thickness.

Results and Discussion

1,1-Diphenylmethylenimine-Iodine System. Equilibrium Studies: When solutions of the ketimine (D), and iodine, in cyclohexane, are mixed the following equilibrium exists assuming that only a 1 : 1 complex is formed.

$$D + I_2 \rightleftharpoons D \cdot I_2 \quad (1)$$

The equilibrium constant K is given by:

$$K = [C_c]/[C_D - C_c][C_{I_2} - C_c] \quad (2)$$

where, C_C is the molar concentration of the charge transfer complex, C_D is the initial concentration of the ketimine and C_{I_2} is the initial concentration of iodine. If the absorbance "A" is due to complexed as well as noncomplexed iodine and A_0 corresponds to the absorbance of the initial iodine solution then, assuming Beer's law is obeyed, Eq. (2) will read, after rearrangement:[21]

$$K^{-1} = \frac{A - A_0}{\varepsilon_c - \varepsilon_{I_2}} - C_{I_2} - C_D + \frac{C_D C_{I_2}(\varepsilon_c - \varepsilon_{I_2})}{A - A_0} \quad (3)$$

This equation will be used to calculate the equilibrium constant for some "Ketimine-iodine" system from the variation of the absorbance of the iodine 520 nm band on mixing with the donor.

If at a given wavelength, the absorbance is only due to the charge transfer complex, then A_0 and ε_{I_2} are zero and Eq. (3) becomes:

$$K^{-1} = \frac{A}{\varepsilon_c} - C_{I_2} - C_D + \frac{C_D C_{I_2}}{A}\varepsilon_c \quad (4)$$

When both C_D and C_{I_2} are both small and each is much more than C_C, then Eq. (4) can be rearranged to read:

$$\frac{C_{I_2} C_D}{A} = \frac{1}{K\varepsilon_c} + \frac{C_{I_2} + C_D}{\varepsilon_c} - \frac{K C_{I_2} C_D}{\varepsilon_c} \quad (5)$$

If C_D is equal to or of the order of C_{I_2} (and both are small), the last term of (5) can be neglected and a plot of $C_{I_2} \cdot C_D/A$ *versus* $(C_{I_2} + C_D)$ will give a straight line. According to Scott,[22] the best straight line is drawn through the experimental points. From the slope and intercept ε_C and K are computed.

Figure 1 show the absorption spectra of mixtures of the ketimine and iodine solutions in the 465—330 nm region. Cyclohexane is used as the solvent and as the blank. The best experimental conditions for studying this CT system were found to use equal concentrations of both the donor and the acceptor. In the 465—330 nm region neither iodine nor the ketimine has an absorption band and their absorbance in this region is quite negligible. However, the spectra of the "iodine-ketimine" mixtures show a discrete and well defined band with λ_{max} at 398 nm. This band is assigned to a charge transfer transition characteristic of the charge transfer complex $(C_6H_5)_2C{=}NH \cdot I_2$ obtained on mixing the ketimine with iodine. The spectra of a number of "donor-acceptor" mixtures were scanned. Equation (5) is used to compute ε_C and K. Figure 2 shows a

plot of $C_{I_2} \cdot C_D/A$ (at λ=398 nm) *versus* $(C_{I_2}+C_D)$. A quite satisfactory straight line relationship is obtained. Data needed to plot Fig. 2 are given in Table 1 and are obtained from Fig. 1. Several plots, as shown in Fig. 2, were drawn at different wavelengths. Results are highly reproducible as shown in Table 2. Variation of K with wavelength has been attributed to the formation of I_3^-.[23]

Table 2. Numerical values of K and ε for the 1,1-diphenylmethylenimine-iodine charge transfer complex at room temperature (18 °C)

λ, nm	K	$1/\varepsilon K$	ε
410	83.49	4.90×10^{-6}	2445
404	83.50	4.85×10^{-6}	2469
398	83.33	4.80×10^{-6}	2500
392	85.37	4.80×10^{-6}	2440
386	84.08	4.90×10^{-6}	2427

The numerical value of the equilibrium constant K of the charge transfer complex of the 1,1-diphenylmethylenimineiodine system is of the order of 84. Reproducibility of the results is quite satisfactory. The relatively high value of "K" suggests strongly that one is dealing with an "n" charge transfer complex. The π charge transfer complexes are much weaker than the n ones. The equilibrium constants for π charge transfer complexes vary between 0.15 and 1.35 for benzene or alkyl benzenes-iodine systems.[25,26]

Position of the Charge Transfer Band and Ionization Potential of 1,1-Diphenylmethylenimine. Figure 3

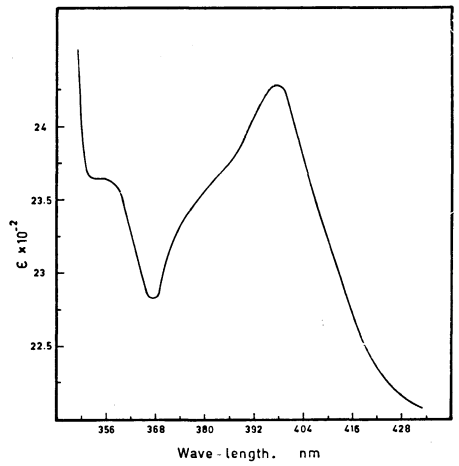

Fig. 3. Charge transfer band of "iodine-1,1-diphenylmethylenimine" System.

shows the charge transfer band of 1,1-diphenylmethylenimine-iodine complex. There are some semiempirical relations which predict the position of the charge transfer band if the ionization potential of the donor is known and others which predict the ionization potential of the donor knownig the position of the charge transfer band. Ionization potentials are determined by a number of methods but most of them cannot differentiate between n and π ionization potentials. On the other hand, ionization potentials obtained from charge transfer studies can be identified as either n or π ionization potentials.

Briegleb[9] *Equation.*

$$E_{CT} = I_D - 5.2 + 1.5/(I_D - 5.2)$$

gives the relation between the energy of the charge transfer band (E_{CT}) and the ionization potential of the donor (I_D) when iodine is the acceptor. Using 3.115 eV for E_{CT} for the 1,1-diphenylmethylenimine-iodine system the n ionization potential of 1,1-diphenylmethylenimine is found to be 7.72 eV.

N-*(Diphenylmethylene)aniline-iodine System. Equilibrium Studies*: Figures 4a and b show the absorption spectra of the pure ketimine, pure iodine and mixtures of both in the 650—350 nm region. Cyclohexane is the solvent and the blank and spectra were scanned at room temperature. Iodine concentration (in the free solution and in the mixtures) was kept constant at 8.5038×10^{-4} M whereas that of the ketimine varied between 1.8153×10^{-2} and 4.8410×10^{-2}. The spectra in Fig. 4 show only the perturbed visible iodine band. That is, no new characteristic band was obtained for the charge transfer transition. On mixing iodine solution with that of the ketimine, the 520 nm band of iodine was blue shifted and the absorbance decreased as the concentration of the ketimine increased. Figure 4a shows one clear and definite isosbestic point. These experimental observations are characteristics of a charge transfer complex. However, since the perturbation of the iodine band is slight and no characteristic charge transfer band was obtained (Fig. 4a) we conclude that we are dealing with a weak charge transfer complex,

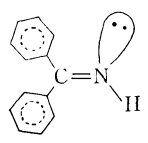
Average (calculated for the 95% probability limite)	7.4731 ± 0.3875	619

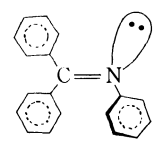
a) Excluded values

most probably a "π" one. The explicit Eq. (3) was used to calculate "K", results are given in Table 3.

Results given in Table 3 are quite reproducible. Figure 4a led to the conclusion that we are dealing with a weak complex. Table 3 confirms this conclusion. Most probably we are dealing with a π complex since K is of the order of 7 whereas that for the 1,1-diphenylmethylenimine-iodine complex K is of the order of 84. It is known that the π complexes are much weaker than those of the n ones. It is worthy to rationalize why, when 1,1-diphenylmethylenimine (a) was the donor an n charge transfer complex is obtained whereas



(a)



(b)

when *N*-(diphenylmethylene)aniline (b) was the donor a π complex was obtained. Assuming sp^2 hybridization for nitrogen atom, the lone pair of electrons occupies one of the sp^2 hybrid orbitals which is perpendicular to the π atomic orbitals of the rest of the molecule. Hence, overlap of this n orbital with the σ^* molecular orbital of iodine is not sterically hindered and a quite stable n charge transfer complex is obtained. On the other hand, in case of the *N*-(diphenylmethylene)aniline, the phenyl group attached to the -*N* atom is not coplanar with the rest of the molecule. As a result the n orbital is conjugated with the π system of the phenyl group attached to the –N atom. Hence, we have no free n orbital to overlap with the σ^* molecular orbital of iodine and only a π charge transfer complex is botained. The π charge transfer complexes are much weaker than the n ones and usually, donot show an absorption band of their own.[25,26] Overlap of transitions is commonly encountered with π complexes.

The above discussion is confirmed when we consider the electronic absorption spectra of the two donors: 1,1-diphenylmethylenimine (a) and *N*-(diphenylmethylene)aniline (b) as shown in Fig. 5. The spectra of

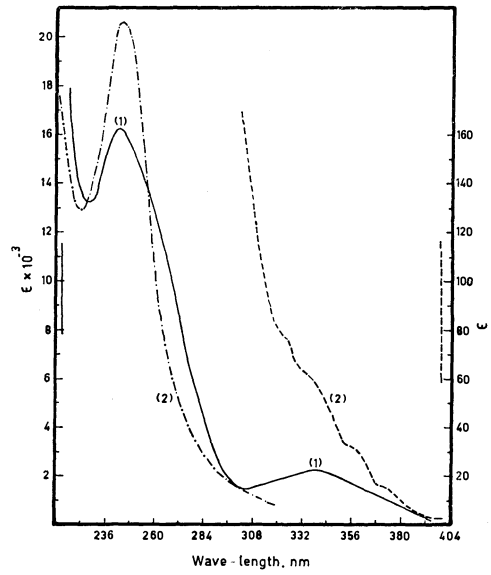


Fig. 5. Electronic absorption spectra of 1,1-(diphenylmethylenimine) (2) and *N*-(diphenylmethylene) aniline (1) in cyclohexane.

the two compounds are very much similar and each show two $\pi\rightarrow\pi^*$ electronic transitions in the ultraviolet region (discussion of the spectra of some ketimines will be subjected in a separate comunication). If conjugation extended over the whole molecule in (b) (molecule is completely planar), then its spectrum would have been significantly different from that of (a). This means that in (b), the benzene ring attached to the nitrogen atom does not lie in the plane of the molecule but may be perpendicular to it. Consequently the n orbital of the nitrogen atom is conjugated with its π cloud and is not free to form an n charge transfer complex when mixed with iodine. This is also confirmed by the fact that the spectrum of 1,1-diphenylmethylenimine shows a separate band for the $n\rightarrow\pi^*$

transition whereas the spectrum of *N*-(diphenylmethylene)aniline does not show this band (Fig. 5). Deviation from coplanarity was also indicated when the spectra of benzylidine aniline were investigated.[24] However, numerical values of the equilibrium constant of "*N*-(diphenylmethylene)aniline-iodine" charge transfer complex indicate that the lone pair of electrons on the nitrogen atom contributes substantially to the relative stability of such a complex. On the other hand, steric factors (in addition to conjugation of n electrons with the π system) inhibit strong interaction with iodine.

Position of the Charge Transfer Band and Ionization Potential of the Donor. When the spectra of pure iodine (3.4270×10^{-5} M), pure *N*-(diphenylmethylene)-aniline (2.4018×10^{-4} M) and their mixtures were scanned in the visible-near ultraviolet region 400—300 nm

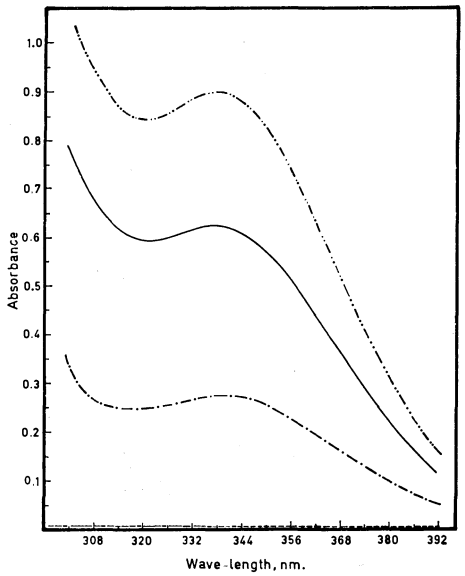

Fig. 6. Electronic absorption spectra of iodine, *N*-(diphenylmethylene) aniline and their charge transfer complex in cyclohexane.
----- Iodine [3.4270×10^{-5} M]
— · — Charg transfer complex
—— Ketimine [2.4018×10^{-4} M]
—··— Mixture of I_2 and ketimine

the absorbance of the mixture is significantly greater than the sum of the absorbances of the free ketimine (Fig. 6) and free iodine. The difference is the absorbance of the charge transfer complex. Thus, in this system, the charge transfer transition and the first $\pi\rightarrow\pi^*$ transition of the donor are overlapping. The energy of the charge transfer band, E_{CT}, is 3.67 eV ($\lambda_{max}=338$ nm) is substituted in Briegleb's equation to yield 8.40 eV as the first ionization potential of *N*-(diphenylmethylene)aniline. Results of Fig. 6 indicate clearly that the electronic transition of the donor with λ_{max} at 338 is $\pi\rightarrow\pi^*$ one ($\varepsilon=2160$). However this transition may be overlapping on the $n\rightarrow\pi^*$ one.

N-*(Diphenylmethylene)*-m-*Toluidine-iodine Systems.* To confirm the above results we used *N*-(diphenylmethylene)-*m*-toluidine as the donor and iodine as the acceptor. The same procedure used with *N*-(diphenylmethylene)aniline was followed. The results obtained with the two donors were very much similar. On mixing iodine solution with that of *N*-(diphenylmethylene) *m*-toluidine the 520 nm iodine band was slightly perturbed, a clear isosbestic point is obtained and no new charge transfer band was obtained. Equation (3) was used to calculate the equilibrium constant. Results are given in Table 4.

Table 4. Numerical values of the equilibrium constant *K* and the molar extinction coefficient ε of the *N*-(diphenylmethylene)-*m*-toluidine-iodine charge transfer complex at room temperature (25 °C)

Mixtures	*K*	ε_c
1,2	5.6895	656
1,3	5.6401	654
1,4	6.2227	676
2,3	5.5481	650
2,4	6.3645	683
3,4	6.7114	695
Average (calculated for the 95% probability limit)	6.0294 ± 0.4949	669

Results of Table 4 are quite reproducible. Also the values of *K* agree fairly well with these obtained for the *N*-(diphenylmethylene)aniline-iodine charge transfer complex. This what one expects when the two donors forms the same type of complex with iodine. The relatively small values of "*K*" as well as the slight perturbation of the iodine band on complexation suggest that we have a weak charge transfer complex.

ESR Line Width and Exchange Narrowing in Powder Samples

B. N. MISRA and S. K. GUPTA
Department of Physics, Allahabad University, Allahabad, India
(Received November 4, 1972)

Electron Spin Resonance Spectra of 1-1 Diphenyl-2-Picryl Hydrazyl (DPPH) recrystallized from some aliphatic and aromatic solvents have been studied at room temperature in the X-band region. Measurements of lineshape, linewidth and *g* value were carried out, all the samples being subjected to microchemical analyses with determination of density and melting point. A theoretical study of ESR linewidths has been carried out by means of the Kubo-Tomita theory of ESR linewidth. A quantitative estimation of dipolar width, exchange frequency, exchange integral and asymptotic Curie temperature for each sample was made. A reduction of exchange narrowing has been suggested to be the main cause of broadening.

Earlier ESR studies[1-7] showed that broader ESR lines with a notable change in shape and *g* value are obtained when free radicals are recrystallized from different solvents. In order to make a detailed theoretical study of various interactions, we used powder samples of 1-1 Diphenyl-2-Picryl-Hydrazyl recrystallized from various organic solvents. The changes obtained in ESR parameters have been quantitatively interpreted with the help of the Kubo-Tomita theory of ESR linewidth. The decrease in exchange coupling has been suggested as the main cause of broadening in the lines. The resulting broadening of the lines has been interpreted in terms of the nature and structure of the solvent used for recrystallization.

Experimental Technique and Method of Measurement

A Bruker X-Band BER 402 Reflection type ESR Spectrometer was used. An Alpha NMR Gaussmeter was used for field measurement, and a Hewlett-Packard frequency counter (hp-525-A) and converter (hp-524-B) for frequency measurement.

The powder free radical DPPH (Purum grade, M/s Fluka, Switzerland) was used. This was prepared from the corresponding hydrazine by oxidation in chloroform solution with lead dioxide. The recrystallized samples were prepared by using analytical grade solvents by slow evaporation technique. The density and melting point of each sample was measured. The linewidth, lineshape and *g*-values were determined by the usual method.[3]

Microchemical analysis of the samples was carried out by direct titration of their solutions in pyridine against chlorauric acid (solution of gold chloride in water) using gallocyanine (in glacial acetic acid) solution as an indicator. The colour changes sharply from bluish green to brownish pink at end point. It was observed that the reaction between chlorauric acid and DPPH takes place in the ratio of 1: 1, confirmed by potentiometric titration.

Results and Discussion

The results of microchemical analysis, density, melting point and ESR parameters such as linewidth and *g* value are given in Table 1.

Line Shape. The shape of ESR lines depends on crystal structure, magnetic dilution and on exchange coupling. The Lorentzian lineshape of the recrystallized samples suggests that the samples are a case of large exchange effect.[9,10] Samples obtained by recrystallization from other solvents have also been reported to show Lorentzian shape of the ESR lines over a wide range of magnetic dilution, frequency and temperature.[11-14]

Line Width. The data in Table 1 indicate that the linewidth of recrystallized powder samples have increased as compared to that of the parent free radical DPPH. This simply suggests that the factors responsible for narrowing the ESR lines have sufficiently reduced after recrystallization of the free radical. It is known that the linewidth from the single crystal of DPPH are highly anisotropic[15,16] changing by as much as a factor of 2. In the polycrystalline sample, a linewidth is averaged out over all orientations of the crystallites with the result that a broader line should be observed. The linewidth of 1.9 Gauss (K-band) for a single crystal of DPPH changes to 3.7 Gauss in powder.[3]

In free radicals, apart from the anisotropy effect, the main causes of linewidth are dipole-dipole and exchange interactions, the latter playing the main role in narrowing the lines. Hence, it can be assumed that the broadening of the lines of the recrystallized sample excluding the anisotropy effect may be due to the change in exchange coupling. A quantitative estimation of the parameters, dipolar broadening and exchange frequency have been made.

The theory of linewidth has been developed on the basis of these interactions by van Vleck,[9] Anderson and Weiss[10] and Kubo and Tomita.[17] The expressions given by Chirkov and Kokin[18] from the Kubo-Tomita theory have been used for computation:

The half width between half power points

$$\Delta\omega = 4.18\omega_{10}^2/\omega_{20} \text{ radian s}^{-1} \quad (1)$$

ω_{10}^2, the dipolar width $= 3.79\, g^4\beta^4\hbar^{-2}d^{-6}$ radian^2 s^{-2} (2)

ω_{20}, the exchange frequency $= 3.65|J|/\hbar$ radian s^{-1} (3)

and the exchange integral $J = k\theta/12$

where k is the Boltzmann constant, θ is the asymptotic Curie temperature and all other symbols have their usual meanings. Since the crystal structure and hence d^{-6} is not known for all the samples, we assumed as a very rough approximation that the system has a simple cubic structure. Thus

$$\sum_k r_{jk}^{-6} = 8.4d^{-6}$$

where d is the lattice constant for the crystal, and

$$r_{jk}^{-3} = N\rho/M$$

where N is Avogadro's number, ρ is density and M the molecular weight. This gives an average distance of 7.98 Å between the spins in DPPH powder which is comparable with the value obtained from crystal structure data. Data of microchemical analysis and density (Table 1) have been used to evaluate the value of mean spin distance.

The values of dipolar width ω_{10}^2, exchange frequency ω_{20} and half width between half powder points for DPPH have been computed by taking Curie temperature[1,18] $\theta = -10$ K:

$$\omega_{10}^2 = 15.76\times10^{17} \text{ radian}^2 \text{ s}^{-2}$$
$$\omega_{20} = 3.89\times10^{11} \text{ radian s}^{-1}$$
$$\Delta\omega = 16.54\times10^{6} \text{ radian s}^{-1}$$

The full width $\Delta H_{1/2} = 2\Delta\omega/r = 1.88$ Oersteds

The dipolar broadening ω_{10}^2 was computed by means of (2). The values of ω_{20} was obtained by means of (1) by utilizing the computed values of ω_{10}^2 and measured values of $\Delta\omega$. With these values, exchange integral J and asymptotic Curie temperature θ were calculated for all samples including DPPH. The results are given in Table 2. The lower values of ω_{20} of DPPH powder indicate that the linewidth has been averaged out due

to the polycrystalline nature of the free radical. The computed values of dipolar width decrease in all the recrystallized samples. The simultaneous decrease in exchange narrowing ω_{20} is sufficiently large. This is also the case in exchange integral J. Thus it can be said that the exchange is more effective in controlling the linewidth. The difference in decrease of exchange coupling for the same magnetic dilution of two different samples is probably controlled by the nature of solvent. The dilution may be due to the permanent inclusion of solvent molecules in the free radical unit cell[19] or a solvent molecule may have associated with the free radical molecule and a molecular addition complex may have formed.[4-6] It can be concluded from the data of microchemical analysis that a greater affinity of complex formation or association was found for the compounds having benzene ring attached with the amino group and chlorine (solvents 2—4). The samples recrystallized from these solvents show a maximum decrease in the exchange coupling. The amino group was found to be more effective in lowering the value of exchange coupling even without benzene ring *viz.* isobutylamine. These form the first category of solvents used here. The second category of solvents include benzyl alcohol and chlorobenzene. The results of their microanalysis do not indicate much dilution but the change in linewidth is comparable with the samples of the first category of solvents. The unexpected broadening present in their ESR lines may be due to the presence of lone pair of electrons on their oxygen and chlorine atoms. The other solvents (Table 1) form the third catagory where the changes in linewidth and exchange coupling parameters are not abnormal and are in agreement with the data on microchemical analysis.

g *Value.* A different value of g has been obtained for different samples. In general, the g value of a substance depends upon many factors such as nuclear and molecular magnetic fields, crystal orientation and applied magnetic field. Crystal orientation has been found to be very effective in DPPH, with the result that a quite measurable anisotropy in the g value of a single crystal of DPPH[3,20] is observed. In polycrystalline sample one gets g factor averaged out over all possible orientations of the polycrystallites present. Hence the changes in g value contain an unknown contribution of g anisotropy and no definite conclusion can be drawn from the change in g value. The change in structure of the free radical responsible for the change in g values does occur[19] after recrystallization of free radical.

Conclusion. The broadening in ESR lines and resulting decrease in exchange coupling depends upon the nature and affinity of the solvents to form complex with the free radical molecule. The changes thus produced in exchange coupling and structure of the free radical due to addition complex formation have not been effective in changing the shape of ESR lines.

Intramolecular Rotations in 1,2-Dialkoxyethanes in the Liquid State

Arati DAS, Alpana GHATAK, Abul HASAN, and S. B. ROY
Department of Optics, Indian Association for the Cultivation of Science, Calcutta-32, India
(Received April 2, 1973)

Dielectric measurements have been made in 1,2-dimethoxy- and 1,2-diethoxyethane in the liquid state in 1.62, 3.17, and 3.49 cm microwave region. Both the molecules are found to relax mostly by methoxy/ethoxy group rotations.

The methoxy group rotation has been reported in anisole both in pure liquid[1,2] and in dilute solutions[3,4] in non polar solvents. It was observed that while the weight factor C_2 for methoxy group rotation in anisole in dilute solution is about 0.8,[3,4] it is only about 0.2[2] in the pure liquid state. The decrease in the value of C_2 from dilute solution to the pure liquid was explained by Garg and Smyth[2] to be due to some restraint in the C–O bond resulting the methoxy group rotation not completely free but hindered.

Similar rotation of the methoxy group has not been reported in aliphatic molecules. In order to study how the methoxy or ethoxy group behave to dipolar relaxation in aliphatic molecules, dielectric studies have been made in the case of 1,2-dimethoxy- and 1,2-diethoxyethane in pure liquid state in 1.62, 3.17, and 3.49 cm microwave region. The results are presented and discussed in the paper.

Experimental

Pure samples of 1,2-dimethoxy- and 1,2-diethoxyethane procured from Schuchardt (Germany) were first dried and fractionated. The proper fraction was distilled under reduced pressure before use in the investigations. The experimental arrangements for measuring the complex dielectric permittivity (ε' and ε''), static dielectric constant ε_0 refractive index n_D and viscosity η were the same as described earlier.[5] The temperature of the experiment was kept constant within ± 1 °C by means of a thermostat. The accuracy in the measurements of ε' and ε'' are about 3 and 5% respectively.

Results

The experimental values of ε', ε'', ε_0, n_D^2 and η are given in Table 1. Cole-Cole arc plots (Fig. 1) were

drawn with the dielectric data at each temperature. The values of the distribution parameter α were obtained from the arc plots and the most probable relaxation times were calculated by the usual method. The activation energy for dielectric relaxation $\Delta H\tau$ was obtained from the straight line plots of $\log \tau T$ *vs.* $1/T$ (Fig. 2) and the activation energy for viscous flow $\Delta H\eta$ was obtained from the plots of $\log \eta$ *vs.* $1/T$. The values of α, τ, $\Delta H\tau$, and $\Delta H\eta$ are given in Table 2.

Discussion

It can be seen from Table 2 that the distribution parameter in both the liquids are appreciable. So attempts were made to analyse the data in terms of two relaxation processes but were not successful. In order to understand whether the τ-values in the Table 2 belong to orientation of molecules or the groups, the following consideration will help us to clarify the mechanism of the relaxation processes involved in the present case.

The molecule of 1,2-dibromoethane is smaller in size than the molecule of 1,2-dimethoxyethane (since CH_3 group is of the same size as the Br-atom). But the τ-value in the former is 8.6 ps[5] at 30 °C which is much larger than the value of 3.0 ps at 30 °C obtained for the latter molecule. Evidently, the τ-value of 3.0 ps can not correspond to the relaxation time due to molecular orientation in 1,2-dimethoxyethane. Moreover, this τ-value of 3.0 ps at 30 °C in this molecule compares very well with the τ-value of 3.2 ps at 20 °C for the methoxy group rotation in anisole[2] in the liquid state. So it is reasonably concluded that the τ-value of 3.0 ps is due to the methoxy group rotation in 1,2-dimethoxyethane. That the dielectric data could not be resolved into group and molecular relaxation may be due to the fact that the relaxation in this molecule is mostly from methoxy group rotation. In this respect the behaviour of molecules of 1,2-dimethoxyethane differs markedly from that of anisole in the liquid state where contribution from methoxy group rotation is only 0.2.[2] The difference in the weight factor for group rotation in anisole and in 1,2-dimethoxyethane can be understood from consideration of the respective values of dipolar activation energy $\Delta H\tau$. The activation energy for group rotation ($\Delta H\tau_2$) in the former molecule is 1.5 kcal[2] while in the latter it is only 0.53 kcal/mol. This shows that the methoxy group is more flexible in 1,2-dimethoxyethane than in anisole in the liquid state. The high flexibility of the methoxy group makes it possible for 1,2-dimethoxyethane molecule to have four rotational isomers as is reported from spectroscopic studies.[6]

From similar considerations, it is seen that the value of 5.5 ps at 30 °C for τ-value in 1,2-diethoxyethane compares fairly well with the value of about 4 ps at 20 °C in the ethoxy group rotation in phenetole[7] in the liquid state. So in the case of 1,2-diethoxyethane also the relaxation is mainly due to orientation of the ethoxy group. The activation energy of dielectric relaxation in this molecule as can be seen from Table 2 is about 0.25 kcal/mol, which is even smaller than that in 1,2-dimethoxyethane. This means that the ethoxy group in 1,2-dimethoxyethane is more flexible than the methoxy group in 1,2-dimethoxyethane. A larger number of rotamers reported to be present in 1,2-diethoxyethane[6] lends support to this. It is to be noted here that the τ-value of methoxy group rotation at any temperature is less than that of the τ-value of the ethoxy group rotation at the same temperature, which is consistent with the sizes of the groups.

The authors are thankful to Professor G. S. Kastha for his interest in the work.

Polarographic Study of the Substitution Reactions between Nickel(II) Ions and Copper(II) Chelates of Triethylenetetraminehexaacetic Acid

Md. Shamsul HAQUE and Miloslav KOPANICA*

Department of Chemistry, Bangladesh Agricultural University, Mymensingh, Bangladesh

**J. Heyrovsky Polarographic Institute, Czechoslovak Academy of Sciences, Prague, Czechoslovakia*

(Received September, 30, 1972)

The mechanism of substitution reaction between nickel ion and Cu-TTHA chelate was studied by polarographic technique. During the study of the substitution reaction the existence of mixed binuclear chelate $CuXNi^{2-}$ was verified and the value of the stability constant was calculated on the basis of polarographic data. Formation of the mixed binuclear chelate was further verified by the amperometric titration of the equimolar mixture of both metal ions with TTHA. Finally the existence of mixed binuclear chelate $CuXNi^{2-}$ was verified by potentiometric titration method. When nickel is present in large excess the replacement of Cu^{2+} ions from Cu_2X^{2-} occurred directly without formation of intermediate mixed binuclear chelate. The stability constant of Cu_2X^{2-} was calculated from equilibrium study.

The practical utility of EDTA as a titrant for metal ions and in some other fields has encouraged the researchers for ligands with a greater affinity and selectivity for metal ions. One fruitful approach has been the study of higher homologs of EDTA, such as DTPA and TTHA. Their acid dissociation constants were determined by Frost[1] while Grimes *et al.*[2] reported the formation constants of alkaline earth metal chelates with TTHA. The analytical application of TTHA has been studied by Pribil and Vesely[3] mainly in complexometric titration. The interaction between TTHA and various metal ions in aqueous solution was studied by many authors who used mostly potentiometric method[4-8] and in some cases they employed polarographic measurement[9-11] and the stability constants of the metal chelates of TTHA are reported.

During last decade a great interest has been given to study the nature and the mechanism of the electrophilic substitution reaction involving metal ion 'M' and metal chelate M–EDTA by polarographic method[12-15] and by spectrophotometric method.[16-17] It has been found that during the substitution reaction between the metal ion M' and M–EDTA chelate a mixed binuclear intermediate chelate of the type M–EDTA–M' was formed.[17-18] Kopanica[19] has suggested that the substitution reaction between calcium ion and Zn–TTHA chelate proceed through a mixed binuclear chelate which is comparitively stable.

From the review of the literature it appeared that the nature and the mechanism of the substitution reaction of metal chelates of TTHA was not studied intensively. The present work was undertaken with a view to study the mechanism and kinetics of the substitutions reactions of metal chelate of TTHA. In course of the study special attention has been given to verify the existence of the reaction intermediates and also to determine their stability constants. It has been found that under given conditions the attack of the metal ion M' on the chelate molecule M–TTHA results in the formation of relatively stable mixed binuclear chelate M–TTHA–M'.

Experimental

Reagents. Triethylenetetraminehexaacetic acid (TTHA) is sparingly soluble in water. A 0.01 M stock solution was prepared by dissolving 2.484 g of TTHA in 13 ml of 1 M NaOH and by diluting to 500 ml with redistilled water.[10] The solution was standardized against standard zinc solution amperometrically and also by complexometric titration using Eriochrome Black T as an indicator. Solutions of 0.01 M Cu(II) and 0.01 M Ni(II) were prepared from the respective sulphate salt and were standardised against standard Na_2-EDTA solution by amperometric titration[20-21] and also by complexometric titration against standard Na_2EDTA solution using murexide indicator.[22] A 0.2 M acetate buffer (pH 3.55—5.76) and 0.2 M $NaClO_4$ solution (pH 5.0—5.55) were prepared according to the known method.[23-24]

Apparatus. *Polarographic Arrangement*: The current–voltage curves were measured with a pen-recording polarograph model LP-60. This polarograph was designed and produced by the Czechoslovak National Enterprise Laboratorni Pristroje (Laboratory Instrument) in Prague and exported through the foreign trade company KOVO of Czechoslovakia. A saturated calomel electrode of large surface area was prepared in one compartment of the Kalousek cell and used as reference electrode. The other compartment was used for electrolysis of the solution under investigation. Dropping mercury electrode (DME) was used as indicating electrode. The capillary characteristics, measured in 0.2 M KNO_3 solution at a mercury height of 60.0 cm at temperature 20 °C and at a potential −0.60 V, were $m=2.34$ mg/s and $t=3.675$ s.

Procedure. The polarographic current–voltage curves were recorded with a pen-recording polarograph as described before. Polarographic measurements were carried out in 0.2 M acetate buffer of pH 4.7 and in 0.2 M $NaClO_4$ solution of pH 5.15 at 20 °C unless it is mentioned otherwise. Gelatin was added as a maximum suppressor by 0.003% in concentration. The corrected height of the mercury reservior was kept constant at 60.0 cm. The dissolved oxygen from the sample solutions was removed by bubbling pure nitrogen gas through the solutions prior measurement.

Copper(II) and nickel(II) form Cu_2X^{2-} and Ni_2X^{2-} with TTHA (H_6X=TTHA) when copper(II) ions and nickel(II) ions react separately with TTHA. Amperometric titration of equimolar mixture of copper(II) ions and nickel(II) ions with TTHA was carried out in 0.2 M acetate buffer and 0.2 M $NaClO_4$ solution to ascertain the joint behaviour and it was observed that both copper wave and nickel wave diminished simulatneously and became zero when the molar ratio Cu: Ni: TTHA=1: 1: 1.

Exactly equimolar amounts of copper and TTHA solutions were mixed in a number of flasks containing 0.2 M $NaClO_4$ solution and then exactly equimolar amount of nickel solution was added. The ionic strength was adjusted to $\mu=0.2$ with requisite amount of concentrated $NaClO_4$ solution and the volumes of all the samples were made equal by the supporting electrolyte. Polarograms were recorded after 20 min, 24 and 72 hr and it was found that all the nickel ions added have entered into the Cu–TTHA chelate and no copper was released from the chelate. Both the above experiments indicate the formation of a stable mixed binulcear $CuXNi^{2-}$ chelate.

The effect of excess of Ni^{2+} ions on $CuXNi^{2-}$ chelate was investigated in acetate buffer and in $NaClO_4$ solution as follows. Solutions $CuXNi^{2-}$ were prepared in 12 measuring flasks and varying amount of nickel solution was added. The ionic strength was adjusted by adding concentrated $NaClO_4$ solution and the volumes of all the samples were made equal by the supporting electrolyte. The samples were kept in a thermostat at 20 °C for 72 hr and polarograms were recorded. The concentrations of released copper and unreacted nickel were measured directly from the polarograms with the help of calibration curves for copper and nickel. The effect of excess of Ni^{2+} ions on Cu_2X^{2-} was studied as above. In all cases limiting currents of free metal ions were corrected for residual current.

Potentiometric Measurement. The interaction of hexabasic TTHA acid with metal ions was studied potentiometrically. A Radiometer pH meter model PHM 4 with pH scale 0 to 14 and reproducibility of ±0.001 pH unit was calibrated so as to determine the hydrogen ion concentration directly and this was done by direct titration of standard dil. HCl with standard NaOH solution in a medium of constant ionic strength ($\mu=0.2$) maintained by KNO_3 solution. A stream of pure nitrogen gas was passed through the titration vessel and the solution was stirred with a magnetic stirrer before each measurement. The hexabasic TTHA acid was first titrated with standard NaOH solution. Since TTHA is a decadentate ligand, both 1: 1 and 2: 1 metal chelates were expected to be formed and therefore mixtures of metal and ligand of the above ratios were investigated. To ascertain the formation of mixed binuclear metal chelates Cu–X–Ni type, mixtures of Cu^{2+} ions, Ni^{2+} ions and TTHA of ratios 1: 1: 1 were titrated against standard NaOH solution.

Results

Polarographic Investigation of the Reaction between Copper(II), Nickel(II) and TTHA. Amperometric titration of Cu(II) ions and Ni(II) ions with TTHA separately showed that Cu_2X^{2-} chelate and Ni_2X^{2-} chelate were formed. An equimolar mixture of Cu(II) ions and Ni(II) ions was titrated amperometrically with TTHA in 0.2 M acetate buffer and also in 0.2 M $NaClO_4$ solution. The titration polarograms, recorded 20 hr after addition of TTHA, consist of three waves; first one due to the reduction of free copper ions, second one due to the reduction of copper from the chelate and third one due to the reduction of free nickel ions. No wave for the reduction of nickel chelate is appeared. The limiting currents of Cu(II) ions, chelate and Ni(II) ions were measured at −0.20, −0.80, and −1.25 V *vs.* SCE respectively. The height of the limiting currents of Cu(II) ions and Ni(II) ions decreased simultaneously with the addition of TTHA and the height of the chelate wave increased. The height of the waves of Cu(II) ions and Ni(II) ions became zero at the molar ratio 1: 1: 1 of Cu^{2+}, Ni^{2+}, and TTHA and only the wave of the chelate appeared (Fig. 1). The titration curves indicate that most probably a mixed binuclear $CuXNi^{2-}$ chelate is formed which is quite stable and polarographically active. An increase of concentration of TTHA beyond the above ratio shifted the half-wave potential of the chelate wave towards negative potential.

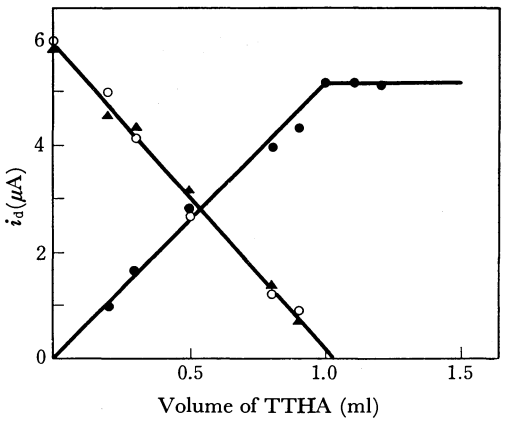

Fig. 1. Amperometric titration of a mixture of Cu(II) ions and Ni(II) ions (1: 1) with TTHA in acetate buffer of pH 4.7. Recorded 20 hr after addition. ○: wave of free copper ions, ●: wave of chelate, ▲: wave of free nickel ions.

Polarographic Behaviour of $CuXNi^{2-}$ Chelate. Polarogram recorded from solution containing Cu^{2+}, TTHA and Ni^{2+} in the molar ratio 1:1:1 in 0.2 M acetate buffer shows that only a single well-defined wave appears due to the reduction of copper from the chelate $CuXNi^{2-}$. The half-wave potential of the wave is −0.248 V *vs.* SCE. The polarographic behaviour such as the effect of (a) pressure, (b) excess TTHA, (c) temperature and (d) gelatin on the reduction wave of $CuXNi^{2-}$ chelate is similar to the corresponding behaviour of Cu_2X^{2-} chelate wave. The effect of pH on the reduction wave of $CuXNi^{2-}$ is different from its effect on the reduction wave of Cu_2X^{2-} when all other conditions are maintained constant. In case of $CuXNi^{2-}$, the second wave does not appear at higher pH as it appears in case of Cu_2X^{2-} chelate. The height of the limiting current of $CuXNi^{2-}$ remains unchanged with pH of the buffer but the half-wave potential of $CuXNi^{2-}$ wave shifted towards negative with the increase of pH. The above observations supported the proposal of the formation of a mixed binuclear $CuXNi^{2-}$ chelate.

Potentiometric Titration Studies. Potentiometric titration curves of TTHA acid in absence of metal ions and in presence of one and two moles of metal ions per mole of TTHA are presented in Fig. 2. The

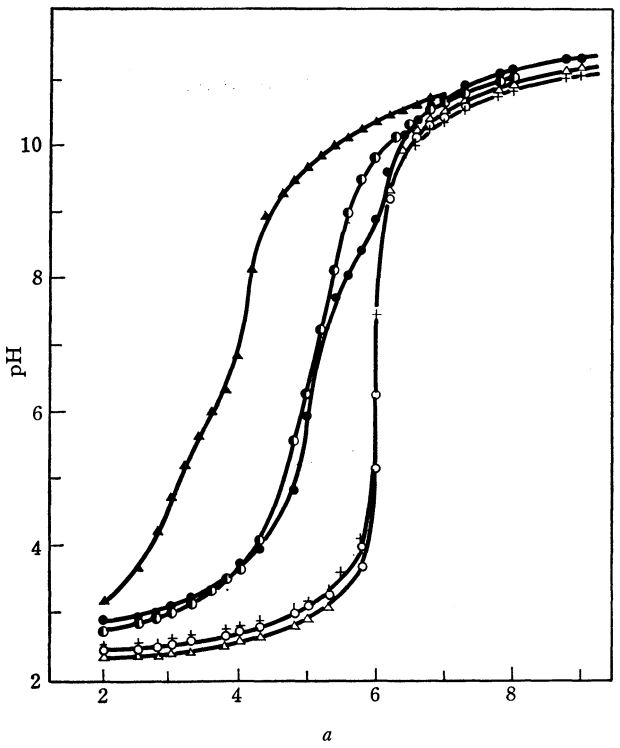

Fig. 2. Potentiometric titration of Cu(II) & Ni(II) chelates of TTHA at 20 °C in 0.20 M KNO_3 with the following molar ratios of metal ions to TTHA.
1) TTHA alone, 2) Cu: TTHA (1:1), 3) Ni: TTHA (1:1), 4) Cu: TTHA (2:1), 5) Cu: Ni: TTHA (1:1:1), 6) Ni: TTHA (2:1). '*a*'=mol of base added per mol of ligand. $C_{TTHA}=8.3\times10^{-4}$ M.

pH is plotted against '*a*', the number of moles of hydroxide ion added per mole of TTHA. The neutralization of the free TTHA occurs in three steps, which has a weak inflection at $a=3$ and a strong inflection at $a=4$. The first step is the reaction of the neutral form of the ligand to form a trinegative anion. The next step occurs at an '*a*' value 4 and results in the formation of tetranegative anion. The neutralization of 5th and 6th protons occurs between an '*a*' value 4 and 6 in overlapping dissociation steps.

The titration curve of 1:1 Cu: TTHA consists of two inflections at an '*a*' value of 5 and 6 indicating the formation of a protonated metal chelate which dissociates at relatively higher pH value to form a normal chelate (Fig. 2). In case of 1:1 Ni: TTHA system the subsequent dissociation step is not as sharp as in the case of Cu: TTHA system. The reaction in case of Cu(II): TTHA system can be represented as follows:

$$H_6X + Cu^{2+} + 5OH^- \longrightarrow CuHX^{3-} + 5H_2O,\ 5OH^-/TTHA \quad (1)$$

where H_6X represents TTHA. Since $CuHX^{3-}$ is a relatively weak acid, the second reaction step involves the neutralization of the remaining proton to form a normal chelate CuX^{4-}.

$$CuX^{3-} + OH^- \longrightarrow CuX^{4-} + H_2O,\ OH^-/TTHA \quad (2)$$

The reactions of Ni(II) occur similarly.

The titration curve of 2:1 Cu: TTHA indicates that the 6 protons of the ligand are neutralized in a single step at an '*a*' value of 6 and a binuclear Cu_2X^{2-} chelate is formed.

$$H_6X + 2Cu^{2+} + 6OH^- \longrightarrow Cu_2X^{2-} + 6H_2O,\ 6OH^-/TTHA \quad (3)$$

Similar titration curve is obtained when 2:1 Ni: TTHA is titrated. No indication of the formation of hydroxo chelate is observed at higher pH.

The titration curve of a mixture of Cu^{2+} ions, Ni^{2+} ions and TTHA of molar ratio 1:1:1 has a single inflection at an '*a*' value of 6 indicating the formation of stable mixed binuclear chelate $CuXNi^{2-}$. The reaction is represented as follows:

$$Cu^{2+} + Ni^{2+} + H_6X + 6OH^- \longrightarrow CuXNi^{2-} + 6H_2O,\ 6OH^-/TTHA \quad (4)$$

There is no subsequent hydrolysis step at higher pH and this indicates that the mixed binuclear chelate $CuXNi^{2-}$ is quite stable.

Polarographic Investigation of the Reaction between $CuXNi^{2-}$ Chelate and Nickel(II) Ions. Amperometric titration of an equimolar mixture of Cu(II) ions and Ni(II) ions with TTHA, and potentiometric titration of 1:1:1 molar ratio of Cu(II) ions, Ni(II) ions and TTHA bear the evidence of formation of a mixed binuclear $CuXNi^{2-}$ chelate over the pH range 4.7—5.15. Polarogram of $CuXNi^{2-}$ chelate is a well-defined wave ($E_{1/2}=-0.248$ V *vs.* SCE) due to the reduction of copper from the chelate. Addition of further amount of Ni(II) ions to the solution of $CuXNi^{2-}$ shows that copper is replaced by nickel from $CuXNi^{2-}$ to form binuclear Ni_2X^{2-} chelate. The exchange reaction is represented as follows:

$$CuXNi^{2-} + Ni^{2+} \rightleftharpoons Ni_2X^{2-} + Cu^{2+} \quad (5)$$

First set: in 0.2M acetate buffer of pH 4.70
Second set: in 0.2M $NaClO_4$ solution of pH 5.15
X=TTHA

The kinetic study of the Eq. (5) showed that the equilibrium reached within 48 hr, still to ensure completion of the reaction, the equilibrium concentrations were studied after 72 hr. The equilibrium constant K_{eq} of the reaction (5) can be defined as

$$K_{eq} = \frac{[Ni_2X^{2-}]\times[Cu^{2+}]}{[CuXNi^{2-}]\times[Ni^{2+}]} \quad (6)$$

$$= \frac{[Ni_2X^{2-}]}{[NiX^{4-}]\times[Ni^{2+}]} \times \frac{[Cu^{2+}]\times[NiX^{4-}]}{[CuXNi^{2-}]}$$

$$= K^{Ni}_{Ni_2X}\cdot K^{Cu}_{CuXNi} \quad (6a)$$

where

$$NiX^{4-} + Ni^{2+} = Ni_2X^{2-},$$

$$K^{Ni}_{Ni_2X} = \frac{[Ni_2X^{2-}]}{[NiX^{4-}]\times[Ni^{2+}]} \quad (7)$$

and

$$CuXNi^{2-} = Cu^{2+} + NiX^{4-},$$

$$K^{Cu}_{CuXNi} = \frac{[Cu^{2+}]\times[NiX^{4-}]}{[CuXNi^{2-}]} \quad (8)$$

The determination of the equilibrium constant K_{eq} leads directly to the determination of the stability (formation) constant of $CuXNi^{2-}$ which is related to K_{eq} by Eq. (6a). The Eq. (7) represents formation constant of Ni_2X^{2-} and Eq. (8) represents the dissociation constant of $CuXNi^{2-}$ and its reciprocal is the stability (formation) constant K^{Cu}_{CuXNi} of $CuXNi^{2-}$chelate.

In equilibrium state, the concentrations of released copper ions and unreacted nickel ions are measured from the polarograms by means of calibration curves. As the metal ions and the metal chelates are not hydrolysed at the pH used, the concentrations of other species in the equilibrium state were calculated according to the method of M. Kopanica[19] and can be given by

$$[CuXNi^{2-}] = C_{Cu} - [Cu^{2+}] \quad (9)$$

$$[Ni_2X^{2-}] = C_X - [CuXNi^{2-}] = C_X - C_{Cu} + [Cu^{2+}] \quad (10)$$

where C_{Cu}, C_X represent the total concentration of copper and the ligand respectively. Substituting the value of $[Cu^{2+}]$, $[Ni^{2+}]$, $[CuXNi^{2-}]$, and $[Ni_2X^{2-}]$ into Eq. (6) gives the Eq. (11)

$$K_{eq} = \frac{[Cu^{2+}]^2}{\{C_{Cu}-[Cu^{2+}]\}[Ni^{2+}]} \quad (11)$$

The equilibrium constant K_{eq} is calculated with the help of Eq. (11). When K_{eq} is substituted into Eq. (6a) and the reciprocal of dissociation constant is taken as stability constant of $CuXNi^{2-}$, then the Eq. (6a) is reduced to Eq. (12).

$$K^{Cu}_{CuXNi} = \frac{K^{Ni}_{Ni_2X}}{K_{eq}} \quad (12)$$

The formation constant $K^{Ni}_{Ni_2X}$ is known[25] and hence K^{Cu}_{CuXNi} is calculated from Eq. (12) and the values of log K^{Cu}_{CuXNi} are presented in Table 1.

Reaction between Cu_2X^{2-} Chelate and Ni(II) Ions. Amperometric titration and potentiometric titration results showed that Cu_2X^{2-} chelate is formed in acetate buffer and $NaClO_4$ solution when copper ions and TTHA are present in the molar ratio 2: 1. When excess of Ni(II) ions are added to the solution of Cu_2X^{2-}, copper is released from the chelate and Ni_2X^{2-} is formed. At higher concentration of Ni^{2+}, the exchange reaction takes place directly without the formation of mixed intermediate binuclear chelate. The exchange reaction is expressed as follows:

$$Cu_2X^{2-} + 2Ni^{2+} \rightleftharpoons Ni_2X^{2-} + 2Cu^{2+} \quad (13)$$

The equilibrium constant K_{eq} of the reaction (13) is represented by

$$K_{eq} = \frac{[Ni_2X^{2-}]\times[Cu^{2+}]^2}{[Ni^{2+}]^2\times[Cu_2X^{2-}]} \quad (14)$$

$$= \frac{[Ni_2X^{2-}]}{[Ni^{2+}]^2\times[X^{6-}]} \times \frac{[Cu^{2+}]^2\times[X^{6-}]}{[Cu_2X^{2-}]} = \frac{K_{Ni_2X}}{K_{Cu_2X}} \quad (14a)$$

where K_{Ni_2X} and K_{Cu_2X} are the formation constants of Ni_2X^{2-} and Cu_2X^{2-} respectively. The Eq. (13) is studied in 0.2 M $NaClO_4$ of pH 5.15 and the equi-

librium concentrations of released copper ions and unreacted nickel ions are measured polarographically 72 hr after mixing. The total concentrations of Cu^{2+}, Ni^{2+} and TTHA are known, the concentrations of Cu_2X^{2-} and Ni_2X^{2-} are calculated and hence the value of K_{eq} is calculated from Eq. (14). The formation constant K_{Ni_2X} is known[25] and hence the formation (stability) constant K_{Cu_2X} of Cu_2X^{2-} is calculated from Eq. (14a) and the values of $\log K_{Cu_2X}$ are presented in Table 2.

Discussion

During the study of the substitution reactions between Cu–TTHA chelate and nickel ions, the existence of the mixed binuclear chelate $CuXNi^{2-}$ is established. This has been done by amperometric titration of equimolar mixture of Cu^{2+} ions and Ni^{2+} ions with TTHA. Figure 1 shows the simultaneous decrease of free Cu^{2+} ions and free Ni^{2+} ions waves during the addition of TTHA while new wave appeared which is not the wave of Cu_2X^{2-} chelate ($E_{1/2Cu_XNi}=-0.248$ V, $E_{1/2Cu_2X}=-0.240$ V *vs.* SCE). Section of polarographic behaviour of $CuXNi^{2-}$ chelate is a summary of proofs that the new wave observed does not correspond to the wave of Cu_2X^{2-} chelate. Further evidence of the existence of the mixed binuclear chelate $CuXNi^{2-}$ is the quantitative treatment of the system containing Cu^{2+} ions, Ni^{2+} ions and TTHA ligand. The polarographic measurement enables to collect the data of the concentrations of free Cu^{2+} ions and Ni^{2+} ions which are used for the calculation of the formation constant K^{Cu}_{CuXNi}, the log value of which is 15.30. This constant value calculated under different concentration conditions (Table 1) verifies the proposal of mixed binuclear chelate formation. Further verification of the system of calculation and the accuracy of the experimental data is done by the determination of the stability constant of Cu_2X^{2-} chelate based on the substitution reaction between Cu_2X^{2-} chelate and Ni^{2+} ions (Table 2). The agreement of the obtained value of the stability constant K_{Cu_2X} with the literature value[25] is satisfactory.

Finally the existence of the mixed binuclear chelate $CuXNi^{2-}$ is verified by potentiometric study of neutralization of the mixture of Cu^{2+} ions, Ni^{2+} ions and TTHA ligand (Fig. 2).

Comparison of the results obtained by the polarographic study of the substitution reaction of Cu-chelate with Ni^{2+} ions led to the following conclusion. In the reaction between CuY^{2-} (H_4Y=EDTA) and Ni^{2+} ions the mixed binuclear chelate CuYNi exists only as an intermediate state. During the polarographic examination of the substitution reaction $CuY^{2-}+Ni^{2+}$ (1 : 1) it has been found that in equilibrium state, which comes after 24 hr of mixing, the concentration of free Ni^{2+} ions is equal to the concentration of CuY^{2-} chelate. At the beginning of the reaction the concentration of CuY^{2-} chelate is higher than that of free Ni^{2+} ions. This indicates that at the beginning of the reaction Ni^{2+} ions enter into the CuY^{2-} chelate to form the intermediate CuYNi chelate of sufficient concentration which gradually dissociates to Cu^{2+} and NiY^{2-} chelate. When the substitution reaction of DTPA chelate is studied the formation of mixed binuclear chelate $CuZNi^{-}$ (H_5Z=DTPA) is established and the stability constant of this chelate is determined.[26] In the case of substitution reaction of TTHA chelate the formation of the mixed binuclear chelate is again established. From the above results it is evident that the stability of the mixed binuclear chelate increases with the increase of the number of the donor groups in the ligand molecule.

A UV Study of the Magnesium Haematoporphyrin Complex

V. D. ANAND* and W. R. CARPER

Garvey Research Center, Department of Chemistry, Wichita State University, Wichita, Kansas, 67208 USA

(Received April 10, 1973)

The interaction between magnesium and haematoporphyrin has been studied spectrophotometricaly as a function of concentration, pH and temperature and the existence of a strong 1 : 1 complex has been established. The Benesi-Hildebrand equation was used to determine K_c's at various wavelengths and temperatures, at pH's of 7.4, 8.2, and 9.0. The enthalpy of complex formation is seen to change from +9.78 kcal/mol to −9.50 kcal/mol as the pH changes from 8.2 to 9.0. This change may be a reflection of the change in the various ligands which coordinate to the magnesium ion in addition to the porphyrin ring.

The porphyrins are a group of compounds that play an extremely important role in the metabolism of plants and animals. A large number of porphyrin derivatives have been isolated, all of which contain the basic prophyrin nucleus.[1-6] One of the first porphyrins to be isolated was haematoporphyrin, about which this report is concerned.

In the present study, addition of magnesium acetate to haematoporphyrin produced marked changes in the difference spectra and these changes were analyzed as a function of pH, concentration and temperature. Equilibrium constants and ΔH's for a 1 : 1 complex have been determined at the pH's of 7.4, 8.2, and 9.0 for the following equilibrium:

$$PH_2 + Mg^{2+} \rightleftharpoons \{MgPH_2\}^{2+} \quad (1)$$

As is indicated in the text, the above equilibrium is far stronger than a displacement equilibrium of the type studied by Brisbin and Balahura.[7] They have measured the equilibrium constants for copper(II) and zinc(II) complexes with haematoporphyrin which result in the following proton displacements:

$$Zn^{2+} + PH_2 \rightleftharpoons ZnP + 2H^+ \quad (2)$$

$$Cu^{2+} + PH_4^{2+} \rightleftharpoons CuP + 4H^+ \quad (3)$$

In their analysis, the 500—600 mμ region was used, and K_C for Eq. (2) was 1.3×10^{-7} at a pH of 7.0.

Experimental

Reagent grade chemicals were used throughout the investigation. Haematoporphyrin dihydrochloride was obtained initially from Calbiochem and finally in recrystallized form from Mann Laboratories. Tris buffer solutions at 0.05 M were used at all pH's.

It should be emphasized that unless the commercial haematoporphyrin is recrystallized, it will be found to contain numerous impurities. However, it can be easily separated from its impurities by the use of Sephadex G-25 in a borate buffer of pH 8.6. This separation has been extensively studied by Momenteau, Ropars and Rougee[8] and Rimington and Belcher.[9]

Survey spectra were recorded with a Beckman DK-2 and a Beckman DU was used to record the actual absorbances. Each spectrophotometer was thermostatted to within 0.1 °C of the desired temperature. The wavelengths used for the analysis were 425, 430, 435, 440, and 445 mμ. The solutions were made up such that the metal concentration was at least 100 times greater than the heamatoporphyrin concentration over a ten-fold range. At least ten points were used at each of the five wavelengths, and the resulting formation constants are an average of the results at each of these wavelengths. As is required in the analysis, Beer's law was obeyed by al of the data used.

Results and Discussion

Some typical difference spectra are given in Fig. 1. Here magnesium acetate was added to haematoporphyrin in a tris buffer of pH 9.0. The haematoporphyrin absorbance was subtracted out and yielded

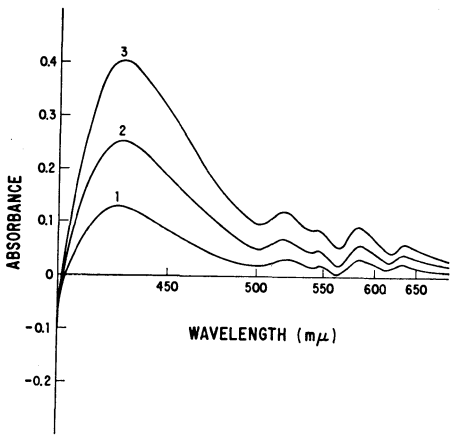

Fig. 1. Recorded difference spectra of the complex as a function of concentration at 25 °C in a tris buffer, pH 9.0. In all cases the haematoporphyrin concentration is 10^{-4} M. The concentrations of magnesium acetate are 10^{-2} M in 1, 4×10^{-2} M in 2 and 0.1 M in 3.

the resulting curves. It was routinely possible to vary the absorbance reversibly with respect to temperature.

A Job's plot made at 430 mμ of a pH 9.0 solution is given in Fig. 2 and establishes the presence of a 1 : 1

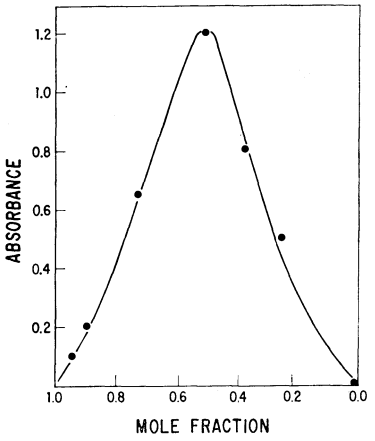

Fig. 2. Job's plot of magnesium-haematoporphyrin complex in a pH 9.0 buffer at 430 mμ at 28 °C.

magnesium-haematoporphyrin complex. Having defined the stoichiometry of the complex, it was possible to analyze the difference spectra of the complex, using the Benesi-Hildebrand (BH) method.[10] In this approach, the relationship

$$1/\log [I_0/I] = 1/K_c\varepsilon_c[M][H] + 1/\varepsilon_c[H] \quad (4)$$

is valid, providing that [M] ⋙ [H], where ε_C is the absorbance coefficient of the complex and [M] and [H] are the molar concentrations of the magnesium ion and haematoporphyrin, respectively.

A plot of $[H]/\log [I_0/I]$ *vs.* 1/[M] gives a slope of $1/K_C\varepsilon_C$, a y intercept of $1/\varepsilon_C$ and a x intercept of $-K_C$. It should be pointed out that if K_C is small, or if Beer's law is not obeyed, then the BH method can no longer be used.

Tables 1 and 2 contain the results of the UV analysis at the pH 's 7.4, 8.2 and 9.0. It should be emphasized that at a pH of 7.4, one is approaching the limits of solubility with respect to haematoporphyrin. As can be readily seen, the formation constants roughly decrease with increasing pH in the vicinity of 37 °C and the enthalpy of complex formation goes from endothermic to exothermic between a pH of 8.2 and 9.0.

In order to explain the drastic change in enthalpy with pH, one may invoke either of the following models or a combination thereof. The initial model (I) is concerned with the changing species that are coordinated to the magnesium ion in addition to the porphyrin nucleus. This effect may be due solely to

a more exothermic bond between the metal and hydroxyl ion than that between the metal ion and a water molecule or a tris anion. However, there is also the possibility of a polymerization effect where the ionized propionic sidechains from one porphyrin complex coordinate to the magnesium of another complex. This was suggested by Loach and Calvin for the manganese haematoporphyrin complex.[11] As porphyrins and metalloporphyrins are known to dimerize, this is not an unreasonable idea, particularly at high pH's.

Model (II) would concern itself with the effect of pH upon the pyrrole hydrogen atoms and the subsequent or simultaneous complex formation between the dianion and the magnesium ion. Unfortunately, the neutral species is stable even in concentrated sodium hydroxide[6] and it would appear that this event is unlikely.

In conclusion, it seems that the environmental changes around the magnesium ion drasticly affect its thermodynamic properties with respect to the complex. As a result, the function of the complex as an efficient electron acceptor may be considerably altered by a pH variation of less than one unit.

Some Reversible and Irreversible Electrode Processes at DME. A Study on Uranyl and Zinc Complexes of L-Hydroxyproline in Aqueous and Aqueous-Methanolic Solutions

P. C. RAWAT and C. M. GUPTA*

Department of Chemistry, M.R. Engineering College, Jaipur, India

**Chemical Laboratories, University of Rajasthan, Jaipur, India*

(Received October 23, 1972)

Complexes of zinc and uranyl ions with L-hydroxyproline (LHP) have been investigated by polarographic method of analysis at 25±1 and 35±1 °C. At pH 4.5, formation of uranyl-LHP complex was observed with metal to ligand ratio of 1: 1 in aqueous and aqueous-methanolic solutions. The stability constant for the complex species is log K_c=1.50, 1.30, 1.61, 1.87 in aqueous (25 °C), aqueous (35 °C), aqueous-methanolic (10% v/v) and aqueous-methanolic (50% v/v) media respectively. Between pH 3.0—12.0, zinc–LHP complex has been observed to be reduced irreversibly at DME. Detailed investigations have been reported on the system at 25±1 °C and 35±1 °C at pH 10.0 in varying concentrations of the ligand. Kinetic parameters—the formal rate constant $K^\circ_{f,h}$ and transfer coefficient α have been calculated.

Owing to their numerous advantages and interesting properties, amino-acids are finding an increasingly wider applications in chemical technology, biochemistry and various fields of analytical chemistry. Moreover, this class of compounds is characterstically provided with two or more functional groups, the donor atoms from which are capable of combining with a metal atom and, so situated in the molecule, that they permit the formation of a chelate ring with the metal atom as the closing member. L-hydroxyproline (LHP) is one such compound and there are scanty references[1-4] as to the chelate forming capabilities of this acid. The paper is a continuation of our earlier insestigations on the complex forming abilities of L-hydroxyproline with different metal ions. The properties of Cd(II) and Pb(II) complexes have been previously investigated in aqueous and aquo-nonaqueous media.[5] There is however, no reference in literature to the study of uranyl–LHP and zinc–LHP system, and hence the present work has been initiated. The present communication describes the nature of the complexes formed between uranyl ion or zinc ion with LHP by polarographic technique of analysis.

Experimental

L-Hydroxyproline (W. Germany) and AnalaR(BDH) potassium nitrate, potassium chloride, zinc sulphate and uranyl nitrate were used. All solutions were prepared in air free conductivity water. Gelatin at a concentration of 0.004% in final solutions was found satisfactory as maxima suppresor in uranyl–LHP system. No maxima supressor was used in zinc–LHP Studies.

Polarographic waves were recorded with a manual polarograph using a H-cell in conjunction with saturated calomel electrode as reference electrode. The DME had the characterstics: −2.768 mg/s and t=2.8 s (in μ=0.5 M KNO_3 or KCl at −1.15 V *vs.* SCE).

The experiments were performed with 0.5 mM uranyl or zinc in varying concentrations of LHP (0.0 to 0.035 M). Ionic strength was kept constant at μ=0.5 M by adding requisite amounts of KNO_3 (Zinc–LHP system) and KCl (Uranyl–LHP system). Dilute solutions of HCl or NaOH (0.01 M) were used for adjusting pH of the solutions on a Cambridge bench pattern (null-deflection type) pH meter.

Studies on the systems were performed at two temperatures 25±1 °C and 35±1 °C in order to calculate thermodynamic parameters.

Our earlier investigations[5-9] on the behaviours of complexation processes in aqueous-aquo-nonaqueous mixtures furnished significant polarographic data pertaining to stability and composition of the complex species. In sequence to these studies, uranyl–LHP system was further investigated under identical conditions in aqueous-methanolic solutions (10—50% v/v).

Uranyl–LHP system has been throughout studied in weakly acid media (pH=4.5) at μ=0.5 M KCl, in order to obtain diffusion controlled, reversible and one electron reduction of U(VI) to U(V) at DME.[10]

Results and Discussion

Uranyl–LHP System. Reduction: Uranyl ion in LHP gives a one electron reduction at DME which is diffusion controlled and reversible, as revealed by constant values of $i_d/h^{1/2}_{eff}$, the temperature coefficient (1.1—1.5%) and slope of the conventional log i/i_d–i plots (60±3) mV. The wave nature remained the same in all the experimental conditions studied.

Effect of Ligand Concentration: A cathodic shift in $E_{1/2}$, coupled with decrease in diffusion current with increasing concentration of the ligand (0.0—0.035 M) indicates complexation. The plot of $E_{1/2}$ *vs.* $-\log C_X$ results in a straight line (Fig. 1). It is therefore reasonable to conclude the complex being reduced is composed of only one species. The number of ligand/uranyl ion as estimated by expression[11]

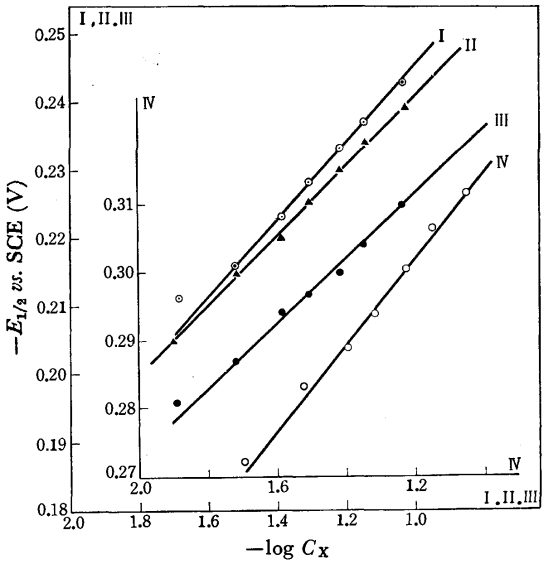

Fig. 1. Plots of $E_{1/2}$ *vs.* $-\log C_x$ for UO_2^{2+}-LHP system at 25 °C (▲), 35 °C (●), 10% methanolic (⊙), and 50% methanolic (○) media.

$$p = -\frac{d(E_{1/2})_c}{d\log C_x} \Big/ \frac{RT}{0.4343nF}$$

is found to be unity. The overall formation constant $\log K_C$ as derived from expression.[11]

$$\Delta E_{1/2} = (E_{1/2})_c - (E_{1/2})_s = \frac{RT}{0.4343nF}\log \beta_p + \mathrm{P}\cdot\frac{RT}{0.4343nF}\log C_x$$

and other polarographic data for different temperature and media are summarised in Table 1.

Effect of Non-aqueous Media: The stability constant $\log K_C$ is found to increase with increasing non-aqueous concentration (methanol) in the media. This suggests stronger metal to ligand binding in the media. This is quite significant and in conformity with our earlier studies on different systems[5-9] and also with similar studies by other workers.[12-14]

Effect of Temperature: Stability constants $\log K_C$ value shows a decrease at increased temperature. This establishes exothermic nature of the interaction between U(VI) and LHP. The thermodynamic constants ΔG, ΔH, and ΔS as calculated from standard equations[15] are summarized in Table 2.

35±1	1.30	−1.83	−8.4	−21.3

L-Hydroxyproline is an amino-acid with pK_1=9.58 and pK_{12}=1.93.[16] Therefore at pH (4.5) on which the system has been investigated, the predominant ligand species must be a dipole molecule rather than the L-hydroxyprolinate ion. In the light of this discussion the complex species and electrode reaction can be possibly formul ated as under.

$$UO_2^{2+} + HL \text{ (dipole molecule)} \rightleftharpoons [UO_2(HL)]^{2+}$$

UO_2^{2+} and $[UO_2(HL)]^{2+}$ co-exist and undergo electrode reaction

$$UO_2^{2+} + [UO_2(HL)]^{2+} + H^+ + 2e \rightleftharpoons 2UO_2^+ + (HL\text{-}H)^+$$

Zinc-LHP System. Reduction: Zinc in LHP (Zn=0.5 mM, μ=0.5 M KNO_3, LHP=0.125 M) was initially investigated in a wide range of pH of the solutions (3.0 to 12.0) at 25±1 °C. The metal ion was observed to give a well defined, diffusion controlled wave in all the solutions. The conventional log plots were linear, but the resulting slopes were not found to be in agreement with the theoretical values, thus indicating the irreversible nature of the electrode reaction. However, the H.W.E.T. shifted towards more negative values with increase in pH suggesting formation of a stable, soluble Zn-LHP complex. Further, studies on the system were preferred at pH=10.0.

	(b)	1.290	49	3.040	1.11	2.14	1.55×10^{-22}

Effect of Concentration of the Ligand: The zinc–LHP reduction wave, however remained irreversible and diffusion controlled in all the concentrations of the ligand (0.0 to 0.035 M) corresponding to 0.5 mM zinc at μ=0.5 M (KNO_3) and pH=10.0. The wave nature did not change at higher temperature 35±1 °C as well.

Kinetic Parameters: From Koutecky's[17] treatment of irreversible waves as modified by Meites and Israel[18] it follows that for a cathodic wave (at 25 °C) with $E_{1/2}$ more then −1.0 V *vs.* SCE

$$E_{DME} + 0.2412 = \frac{0.05915}{\alpha n}\log\frac{1.349K^{\circ}_{f,h}}{D_0^{1/2}} - \frac{0.0542}{\alpha n}(\log i/(i_d-i) - 0.546\log t) \quad (1)$$

and

$$E^{\circ}_{1/2} = -0.2412 + \frac{0.05915}{\alpha n}\log\frac{1.349K^{\circ}_{f,h}}{D_0^{1/2}} \quad (2)$$

17) J. Koutecky, *Coll. Czech. Chem. Commun.*, **18**, 597 (1953).
18) L. Meites and Y. Israel, *J. Amer. Chem. Soc.*, **83**, 4903 (1961).

The kinetic parameters have thus been calculated by employing Eqs. (1) and (2). The αn was obtained by equating the slope of the straight line plot E_{DME} *vs.* $(\log i/(i_d-i) - 0.546\log t)$ with $0.0542/\alpha n$. The same plot gives the intercept where the quantity being plotted along the abscissa is zero, which is equal to the parameter $E_{1/2}$ defined by the Eq. (2), which was then used to calculate $K^{o}_{f,h}$. The values of $K^{o}_{f,h}$ and αn at 25±1 °C and 35±1 °C (using analogous equations valid at this temperature) in various concentrations of the ligand are summarized in Table 3. From the perusal of the results, it is obvious that the electrode reaction is highly irreversible and increased concentration of the ligand further adds to the irreversibility of the reaction. There is no significant change in this character even at higher temperature.

Liquid-Liquid Extraction of Zinc with Thiothenoyltrifluoroacetone Direct Photometric Determination in the Organic Phase

K. R. SOLANKE and S. M. KHOPKAR

Department of Chemistry, Indian Institute of Technology, Bombay, 400076 India

(Received January 5, 1973)

The thioderivative of 2-thenoyltrifluoroacetone [1,1,1-trifluoro-4-(2-thienyl)-4-mercaptobut-3-en-2-one (STTA)] is used for the simultaneous extraction and direct photometric determination of zinc. About 68 μg of zinc was quantitatively extracted at pH 7—7.5 with 10 ml of 0.001 M STTA in carbon tetrachloride as yellow green colored complex. It was measured spectrophotometrically at 450 nm. The system conformed to Beer's law over the concentration range of 0.4 to 30 μg of zinc per ml. The color of the complex was stable for more than 96 hr. Zinc was extracted quantitatively and was determined in the presence of large excess of (1: 300) ions which are associated with it. The method was made selective by using sequestering agents like ascorbic, oxalic, citric acids or alkali cyanide to form unextractable negatively charged complexes. The selective extraction with mesityl oxide was used to eliminate the interferences due to iron and chromium. The procedure was found to be applicable for the analysis of zinc in gun metal and brass. The proposed method is comparable with the standard methods for the extraction of zinc.

Thiothenoyltrifluoroacetone (1,1,1-Trifluoro-4-(2-thienyl)-4-mercaptobut-3-en-2-one (STTA) has been used as the extracting and colorimetric reagent for the number of transition elements.[1] It was observed that zinc can be quantitatively extracted at pH 7.0—7.5 with 0.001 M STTA in carbon tetrachloride. The yellow green complex can be measured spectrophotometrically at 450 nm.

The method proposed in this paper with thiothenoyltrifluoroacetone as the extracting and colorimetric reagent is simple, rapid and selective. It is possible to accomplish clean cut separation of zinc at micro gram concentrations. It was found to be applicable to analysis of zinc in alloys such as gun metal and brass.

Experimental

Apparatus and Reagents. Type SF-4 quartz spectrophotometer with 10 mm matched cells. Type FEK-57 photoelectric filter photometer with 10 mm Corex glass cells. Cambridge pH meter with glass electrode; wrist action flask shaker.

Thiothenoyltrifluoroacetone (1,1,1-trifluoro-4-(2-thienyl)-4-mercaptobut-3-en-2-one (STTA) was synthesised from 2-thenoyltrifluoroacetone (Koch-light England) as per the method indicated in earlier paper[2] with all the necessary precautions to get the best yield as described by Kiba.[3] About 0.001 M reagent in carbon tetrachloride was used. The reagent was always preserved in the refrigerator.

A stock solution of zinc was prepared by dissolving about 1.2 gm of zinc sulphate hexahydrate in 100 ml of distilled water containing 0.001% of sulphuric acid. The solution was standardized complexometrically[4] with EDTA, and was found to contain 2.7 mg of zinc per ml. The dilute solution containing 67.5 μg per ml of zinc was prepared by appropriate dilution.

General Procedure. An aliquot of solution containing about 67.5 μg of zinc was taken. After addition of 10 ml of water, the pH of the solution was adjusted to 7—7.5 with 0.01 M sulphuric acid or ammonium hydroxide. The solution was diluted to 25 ml with water. It was then transferred into a 250 ml separating funnel. Then 10 ml of 0.001 M STTA in carbon tetrachloride was added. The solution was then extracted on the wrist action flask shaker for about ten minutes. The solution was allowed to settle and separate. The yellow green colored organic phase was withdrawn in a ten ml volumetric flask. It was then measured spectrophotometrically at 450 nm against the reagent blank prepared similarly. The amount of zinc was then calculated from the calibration curve.

For interference studies the solution containing desired ion was added before the pH adjustment.

Results and Discussion

Absorption Spectra. The absorption spectra of Zn–STTA complex (Zn=9.333×10^{-3} M) extracted at pH 7 against the reagent blank (A) and that of complex against carbon tetrachloride (B) is shown in Fig. 1. The spectrum of reagent blank against carbon tetrachloride (C) is also shown. The yellow green Zn–STTA chelate solution showed the maximum absorption at 450 nm. The cruve steadily fell until absorbance became negligible beyond 500 nm. The reagent blank had strong absorbance at 410 nm. This became insignificant compared to chelate solution from 450 nm onwards. Therefore, all the absorbance measurements were taken at 450 nm. The molar absorptivity was 6.697×10^{3} calculated on the basis of zinc contents (9.3×10^{-3} M) with the absorbance of 0.300 at 450 nm when 1 cm cells were used. The sensitivity (as per Sandell's definition) is 0.0022 μg/cm^2.

Extraction as the Function of pH. The solvent extraction behaviour of Zn–STTA system was studied over the pH region of 0.5—10.0 (Fig. 2). It was observed that there is no extraction in the pH region of 0—3.5. The extraction commenced at pH 4.0 and half of the zinc was extracted at pH 6. The extraction was quantitative at pH 7.0—7.5. Beyond this pH region the extraction had decreased. It became insignificant at pH 9.0. Therefore the optimum pH of extraction is 7.0—7.5.

Adherence to Beer's Law. The varying amounts of zinc ranging from 4.25 to 303.75 μg per ml were taken. They were extracted at pH 7.0 with 0.001 M STTA in carbon tetrachloride as described earlier. To observe the adherence of the system to Beer's law, their absorbances were measured at three different wave lengths namely 440, 450, 460 nm (Table 1). The yellow green zinc–STTA system conformed to Beer's law at 450 nm over the concentration range of 0.4 to 30.3 μg/ml of zinc.

Table 1. Applicability of Beer's law
pH=7, 0.001 M STTA in carbon tetrachloride

Zinc taken μg	Absorbance		
	440 nm	450 nm	460 nm
4.25	0.015	0.030	0.020
8.5	0.025	0.060	0.035
17.0	0.040	0.100	0.070
33.75	0.080	0.180	0.160

Stability of Colour of the Complex. The absorbance of the colored complex was measured at elapsed interval of 0.5, 8, 16, 24, 48, 96, and 120 hr. The value of the absorbance was found to be constant *viz.* 0.300 until 96 hr. The absorbance after 120 hr was about 0.280. This showed that the complex was stable for at least 96 hr.

Period of Equilibration. With all other factors constant the period of shaking was varied from 3—30 min, on wrist action flask shaker. It was seen that the extraction was quantitative if period of equilibration was 7.5 min. Hence in all measurements, extraction was carried out for at least 10 min.

Effect of Reagent Concentration. The concentration of the reagent was varied from 1×10^{-4} M to 2×10^{-3} M. Similarly the volume of 1.0×10^{-3} M reagent was varied from 2.5 to 20 ml. It was seen (Table 2) that the extraction was quantitative with the reagent concentration of 1×10^{-3} M. It was incomplete with low concentration of the reagent. The extractions did not improve substantially at the higher reagent concen-

Table 2. Effect of reagent concentration
Zn=67.5 μg pH=7.00

STTA concetration (M) × 10^{-3}	STTA added	Absorbance at 450 nm
0.10	10	0.240
0.25	10	0.290
0.50	10	0.300

tration. The variation in volume of the reagent showed that the extraction was quantitative with 10 ml of 1.0×10^{-3} M of the reagent in carbon tetrachloride.

Effect of the Salting-out Agents. Various salting-out agents such as sulfates of sodium, lithium, potassium, ammonium, magnesium and calcium were tried as the salting-out agents. The extraction of zinc was carried out in the presence of the salting-out agents, with 0.001 M STTA in carbon tetrachloride. It was observed from values of absorbance that the extraction remained constant with the use of 0.2—2 M of lithium, sodium, potassium and ammonium sulfates (Table 3). There was insignificant decrease in the extractability of zinc with 2 M calcium or magnesium sulfate. There was some enhancement in extraction if 1—3 M ammonium sulfate was used as the salting-out agent. On the whole the results revealed that the salting-out agents did not materially enhance the extraction.

Table 3. Effect of salting-out agent
Zn=67.5 μg pH=7.0 0.001 M STTA-CCl_4

Salting-out agent	Molarity (M)	Absorbance at 460 nm
Li_2SO_4	0.5—3.0	0.300

	2.0	0.270

Effect of Diverse Ions. The effect of presence of several ions on the extraction behaviour of zinc was studied (Table 4). The tolerance limit was set as the amount required to cause ±2% error in zinc recovery.

It was observed that complexing anions like oxalate, citrate, tartrate are tolerated in the ratio 1 : 300. While thalium, alkali and alkaline earths and anions such as molybdate, selenite, phosphate, thiosulfate *etc.* are tolerated in the ratio of 1 : 150. Other ions were

tolerated in the ratios exceeding 1 : 15. Some ions such as lead, silver, cadmium, tin formed characteristic colored complex with reagent and showed strong interference. The interference of some of the ions could be removed by complexing with sequestering agents. As a matter of fact sequestering agents are tolerated in larger amounts (*viz.* 20000 μg) and hence can be used for masking number of metals. Further some of the ions which might hydrolyse at very high concentrations can be successfully complexed with sequestering agents to prevent hydrolytic precipitation. Thus sequestering agents play two fold role to eliminate interference and mitigate hydrolysis of certain ions. Hence antimony was complexed with oxalic acid; aluminium, cerium and zirconium with citric acid and silver, copper and gold were complexed with alkali cyanide. The process of selective extraction (2) with mesityl oxide (4-methyl-3-pentane-2-one) was also used to eliminate the interferences due to iron(III) and chromium(III).

Separation of Zinc from Gun Metal. About one gm of gun metal was dissolved in concentrated nitric acid. Tin was removed as metastannic acid and was determined gravimetrically. The filtrate was evaporated to dryness. The residue was dissolved in water, and made up to 1 litre. One ml of the diluted solution was taken. It was adjusted to pH 2.5 to extract copper with 0.1 M acetylacetone in benzene as described in earlier[2] paper. The aqueous solution was taken. To this solution 3 M hydrochloric acid and 2 M lithium chloride was added. It was extracted with a 10 ml of tributyl phosphate in MIBK to quantitatively remove lead.[6] The aqueous phase containing zinc was taken. Its pH was adjusted to 7.0. Then zinc was extracted with 10 ml of 0.001 M STTA in carbon tetrachloride. The yellow green colored complex was measured spectrophotometrically at 450 nm. Another aliquot of solution containing zinc after removal of copper and lead as described earlier was taken. The acidity was adjusted to 3 M with hydrochloric acid. Then it was extracted twice with 10 ml of 8% tribenzoylamine.[7] Zinc from the combined organic phase was stripped with 10 ml of 0.1 M hydrochloric acid and was determined as usual.[8] It was found that the percentage of zinc found by STTA method was 4.6, 4.9, 4.8 while percentage of zinc by TBA method was 4.5, 4.4, 4.3 as against 4.5% actually present.

Separation of Zinc from Brass. About 0.885 gm of brass sample was dissolved in concentrated nitric acid. Tin was which was present in traces was removed as insoluble residue of metastannic acid. The filtrate was evaporated to dryness and extracted with water. The solution was made up to 1 litre. Then 2 ml of diluted solution was taken and copper from it was removed by extraction as described earlier.[2] The aqueous phase was then taken. The pH was adjusted to 7.0. Then it was extracted with 10 ml of 0.001 M STTA in carbon tetrachloride. The yellow green colored complex was measured at 450 nm. The percentage of zinc was found to be 35.9, 35.4, 36.2 as against 36%. Another aliquot of solution containing zinc after removing tin and copper was taken. It was then extracted with 8% tribenzylamine[7] from 3 M hydrochloric acid. It was stripped to the aqueous phase with 0.1 M hydrochloric acid and was determined as usual.[8] The percentage of zinc was found to be 35.8, 35.2, 36.0 as against 36%. This shows the method proposed by us for the extractive separation and colorimetric determination of zinc compares favourably well with standard method.[7]

Comparison with Other Methods. Four sets of five samples containing varying amounts of zinc were taken. Then zinc from each sample was determined by extraction with thiothenoyltrifluoroacetone (STTA); tribenzoylamine (TBA);[7] triisooctylamine (TIOA)[9] and dithizone[10] methods (Table 5). It was interesting to

Table 5. Comparison with other methods

Zinc taken μg	Zinc found (%) by			
	STTA method	TBA method (7)	TIOA method (9)	Dithizone method (10)
6.35	6.30	6.0	6.4	6.4
12.75	12.5	12.2	12.70	12.5
48.0	48.0	47.9	48.4	48.2
101.25	102.0	100.00	101.3	103.0
202.5	200.5	198.7	202.6	204.0

observe that the amount of zinc found by STTA method compares favourably well with other methods for the extraction of zinc. This further shows that the proposed method is rapid, simple, selective as well as sensitive. Total operation of each run requires only 30 min. It is possible to accomplish clean-cut separation of zinc from cadmium, mercury, copper, silver, gold, aluminium and iron with which it is usually associated.

(Received December 21, 1972)

To define the properties of molybdenum-containing species which appear in the acidification of neutral molybdate solution with mineral acid, the reverse process, *i.e.* the titration of molybdic acid of acidified molybdate solution with sodium hydroxide, was examined and the titration curves were obtained thermometrically as well as potentiometrically. In the thermometric titration curves there are inflections not found on the pH-titration curves of the same systems. Titration curves of both methods change with molybdenum concentration, the reaction process being found to be responsible for the change. Polymolybdate anions were identified with the aid of the ultraviolet spectrophotometry of Punger *et al.* A neutral salt such as sodium perchlorate or lithium perchlorate was found to affect the shape of the thermometric titration curve, since in the presence of such salt octamolybdate ion was readily converted into heptamolybdate ion.

In a previous paper we reported on the formation of molybdenum-containing polyanions in the process of acidification of neutral molybdate solution,[1] the investigation being carried out by means of thermometric titration. The inflections on the titration curves gave useful information. The reverse reaction, *i.e.* neutralization of molybdic acid or acidified molybdate solution with alkali hydroxide, seems to be of interest in connection with the above process. We carried out the thermometric titration with a titrator of a new type.[2]

The reaction between molybdic acid and alkali hydroxide has been investigated mainly by pH-titration and conductometric titration. Cannon[3] reported two inflections at P-values 0.5 and 2.0 the alkali/Mo equivalent ratio, on the pH-titration curve of 0.310 M molybdic acid solution prepared by Auger's method.[4] He also reported that in the presence of 3 M sodium chloride the first inflection shifted to a larger P-value while the second remained unchanged. The shift was accounted for by the variation of the activity coefficient of hydrogen ion in the solution containing sodium chloride. Richardson[5] tried pH- and conductometric titrations with 2.2×10^{-1}—3.4×10^{-4} M molybdic acid prepared by an ion-exchange technique, and reported two inflections on the titration curves at P-values 0.5 and 2.0. The form of titration curve changes with the concentration of molybdic acid solution. Jain and Jain[6] carried out pH-titration with 0.018 M molybdic acid prepared by ion-exchange and also found two inflections on the titration curve at 0.5 and 2.0; in the presence of 4 M sodium chloride, the first shifted to 0.85 while the second remained constant. From the results they concluded that octamolybdate ($Mo_8O_{26}^{4-}$) exists in the initial molybdic acid solution and can be transformed into heptamolybdate($Mo_7O_{24}^{6-}$) in a medium with high ionic strength.

We observed four distinct inflections on the thermometric titration curve when acidified molybdate solution in the concentration range of molybdenum 2.29×10^{-1}—1.07×10^{-1} M was titrated with sodium hydroxide solution. The heat of the reaction of the four steps was estimated from each titration curve.[1] Richardson[5] and Heitner-Wirguin and Cohen[7] concluded that a similar equilibrium could be applied to an acidifed molybdate solution and a molybdic acid solution as a result of pH- and conductometric titrations[5] and ion-exchange technique.[7] We have examined the ionic equilibria by means of thermometric titration of acidified molybdate solution and molybdic acid solution in wide concentration ranges. The titration curves were compared with each other and also with the curve obtained by potentiometric titration. The effect of a neutral salt such as sodium perchlorate or lithium perchlorate on shape of the titration curve was also examined.

Experimental

Reagents. *Molybdic acid solution*[8]: Twenty grams of sodium molybdate dihydrate of reagent grade was dissolved in 200 ml of distilled water, and the solution was passed through a column of polystyrene cation-exchange resin(Amberlite IR-120, mesh 32—100). In order to remove sodium ion completely, the effluent was poured on the other column of the same cation-exchanger. The process was repeated till no sodium ion could be found in the effluent. 0.2 M molybdic acid solution was prepared by adjusting the volume of the solution to a definite volume. Standardization of the molybdenum content was made gravimetrically after precipitating molybdenum as 8-hydroxyquinolinate.[11]

8) Sasaki and Sillén[9] prepared 1 M molybdic acid solution by the use of cation exchanger (Dowex 50 X-8). The solution was found to show a strong Tyndall effect. After being left to stand for a few days a white precipitate appeared. However, the 0.2 M molybdic acid solution we prepared was very stable, the Tyndall effect being observed eventually after ten days and no precipitate appearing after one month. We prepared a fresh solution of molybdic acid every three days and the octamer was defined as the predominant species in the solution by the differential spectrophotometric method of Pungor and Halasz.[10]

Preparation of Ion-exchanger Column: The cation exchanger should be free from reducing substance. 100 ml of powdered resin was suspended in acetone for about three hours to remove acetone-soluble substance. The resin was then poured into distilled water to let the resin particles settle, followed by repeated washing with water and decantation. The resin particles were put into 0.2% potassium dichromate solution and allowed to stand for a day. A slurry of the resin was poured into a glass tube 1.5×60 cm for chromatographic use, fitted with a sintered glass filter at one end. 500 ml of 3 M hydrochloric acid and 200 ml of 2 M sodium chloride solution were passed successively through the column. 200 ml of 3 M hydrochloric acid was then passed to make the hydrogen form of resin. Finally the column was washed with distilled water to remove chloride ion.

Acidified Molybdate Solution: A sodium molybdate solution was made acidic by adding perchloric acid of 2.00 times the molarity of the molybdate. The concentration of molybdenum was determined gravimetrically in a similar manner to that described above.[11]

All the other reagents were of guaranteed reagent grade (Wako Chemicals Co.) unless otherwise stated, and used without further purification.

Apparatus. *Thermometric titrator*: A thermometric titrator (TOA Electric Co.) was used. Construction has been described in detail.[2]

All pH measurements were made using a Metrohm potentiograph E 336 with a glass-calomel electrode system calibrated with buffer solutions complying with accepted standards.

All spectrophotometric measurements were carried out with an automatic Shimadzu ultraviolet spectrophotometer. Silica microcuvettes of path lengths 1.0—0.02 mm were used.

Procedure. The procedure was just the same as before.[1,2] Titration was carried out for molybdic acid in the concentration range 0.2—0.004 M. Following Richardson's prescription, the molybdic acid solution was left to stand for about twelve hours after preparation to attain homogeneity.[5] Titration with sodium hydroxide was performed under conditions where the volume of the titrant to be required was not to exceed 10% of the total volume of the final solution in the titration cell.

The spectra of the solutions examined were measured against distilled water and neutral monomeric molybdate solution according to the method by Pungor and Halasz.[10] All experiments were conducted at 25 °C.

Results and Discussion

Thermometric Titration Curves of Molybdic Acid and Acidified Molybdate Solution with Sodium Hydroxide. The titration curves of molybdic acid in 2.29×10^{-1} M and 4.58×10^{-3} M are shown in Figs. 1 and 2, respectively. We see four inflections in the former and two in the latter. The P-values are listed in Table 1. In consequence of the titration of acidified molybdate solution in 2.14×10^{-1} to 5.35×10^{-3} M with sodium hydroxide solution, similar titration curves to those as in the case of molybdic acid were obtained. The P-values of each titration curve are listed in Table 2. It is evident that the shape of the titration curve depends upon the initial concentration of molybdenum. A variation of the P-value could be observed in a wide range of concentration of molybdic acid rather than in that of acidified molybdate. This may be

a) The ratio of acid added to molybdate in an acidified molybdate solution is 2.00.

attributed to the variation of ionic strength during the titration of molybdic acid solution, since in the latter case sodium ion is initially present in the solution and the change of ionic strength is relatively small. Thus, the shape of the titration curve seems to be determined not only by the concentration of molybdic acid taken initially but by the variation of the ionic strength in the solution during titration.

pH-Titration Curves of Molybdic Acid and Acidified Molybdate Solution with Sodium Hydroxide. The pH-titration curves of molybdic acid in the range 2.10×10^{-1}—4.20×10^{-3} M are shown in Fig. 3. Two inflections can be seen in all of them. The P-values of the inflections estimated by secondary differentiation

1.07×10^{-2}	0.52	2.0
8.56×10^{-3}	0.52	2.0
5.35×10^{-3}	0.51	2.0

of the curve are shown in Table 3. In the pH-titration of acidified molybdate solution in the range 2.14×10^{-1}—5.35×10^{-3} M with sodium hydroxide, similar titration curves were obtained. The P-values of the inflections are listed in Table 4.

We see that the P-value of the second inflection was held constant at about 2.0, while that of the first inflection was 0.6 in higher and 0.5 in lower concentration of molybdic acid. Previous investigations[3] showed that the first inflection does not depend on the concentration of molybdic acid, its P-value being held constant at 0.5, potentiometrically and conductometrically. However, Heitner-Wirguin and Cohen reported variations of the P-values of both the first and second inflections with the concentration of molybdic acid from their results on the pH-titration of molybdic acid with sodium hydroxide solution.[7] This discrepancy is difficult to interpret because of the lack of understanding of the chemical species existing in the solution or appearing during the course of titration.

Richardson[5] pointed out that the variety of titration curves might result to some extent from the hydrolysis of the salt formed in a dilute solution. He assumed the hydrolysis from the results of his conductometric titration of molybdic acid with sodium hydroxide solution, in which a variation of titration curves was found in every case. We proposed a different assumption from his, since the variation of titration

curves, either potentiometric and thermometric, depends upon the initial concentration of molybdic acid or acidified molybdate. The variation should show a difference in the reaction process in each case. The chemical species existing in the solution before titration was identified by spectrophotometry as octamolybdate ion and that after titration monomeric molybate ion.[9]

From Tables 1—4 and spectrophotometric measurements, we conclude that the titration of about 2×10^{-1} M molybdic acid or acidified molybdate solution with sodium hydroxide solution might proceed through the following four reaction process:

$$H_4Mo_8O_{26} + 3OH^- = HMo_8O_{26}^{3-} + 3H_2O \quad (P=0-0.375) \quad (1)$$

$$7HMo_8O_{26}^{3-} + 11OH^- = 8H_2Mo_7O_{24}^{4-} + H_2O \quad (P=0.375-0.571) \quad (2)$$

$$H_2Mo_7O_{24}^{4-} + 2OH^- = Mo_7O_{24}^{6-} + 2H_2O \quad (P=0.571-0.857) \quad (3)$$

$$Mo_7O_{24}^{6-} + 8OH^- = 7MoO_4^{2-} + 4H_2O \quad (P=0.857-2.00) \quad (4)$$

On the other hand, in the titration of *ca.* 5×10^{-3} M molybdic acid or acidified molybdate solution, P-values of the inflections seem to prove the existence of two reaction processes:

$$H_4Mo_8O_{26} + 4OH^- = Mo_8O_{26}^{4-} + 4H_2O \quad (P=0-0.500) \quad (5)$$

$$Mo_8O_{26}^{4-} + 12OH^- = 8MoO_4^{2-} + 6H_2O \quad (P=0.500-2.00) \quad (6)$$

It is supposed that in the range above 4×10^{-2} M reactions (1)—(4) are predominant and (5) and (6) subdominant, while below that concentration reactions (5) and (6) become predominant and (1)—(4) subdominant.

Titration of Molybdic Acid with Sodium Hydroxide Solution in the Presence of Sodium Perchlorate or Lithium Perchlorate. Molybdic acid of concentrations 2.00×10^{-1}—2.00×10^{-2} M in 4 M sodium perchlorate solution was titrated with sodium hydroxide solution and thermometric titration curves were obtained; the curve of 2.00×10^{-1} molybdic acid is shown in Fig. 4 and that of 2.00×10^{-2} M molybdic acid in Fig. 5. P-values of the inflections of titration curves for molybdic acid in various concentrations are given in Table 5. Three inflections were observed in the case of 2.00×10^{-1} M molybdic acid. In the case of 2.00×10^{-2} M, the P-value of the first inflection was 0.856, but 0.542 in absence of sodium perchlorate. The pH-titration curves were also obtained under the same conditions for 2.00×10^{-1}—2.00×10^{-2} M molybdic acid in 4 M sodium perchlorate solution. Each titration curve was similar to the corresponding one of the pH-titration curves (Fig. 3). The P-values of the inflections of the curves are given in Table 6. The influence of sodium perchlorate on the P-values of the first inflections seems to be important in various concentrations of molybdic acid.

We examined exclusively the first inflections of the thermometric titration curves for 2.00×10^{-2} M molybdic acid in the presence of the perchlorate in varying concentrations. The results are shown in Table 7. The second inflection remained constant at the P-value of 2.00 in all runs. We see that the amount of neutral salt necessary to change the P-value of the first inflection from 0.542 to 0.856 differs for sodium and lithium salts, *i.e.*, above 3.0 M of sodium

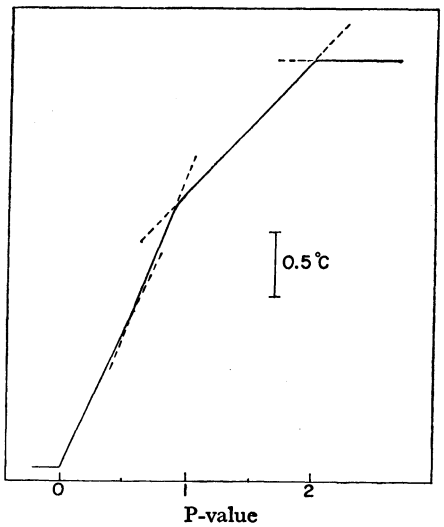

Fig. 4. Thermometric titration of 2.00×10^{-1} M molybdic acid with sodium hydroxide in the presence of 4.0 M sodium perchlorate.

perchlorate and above 4.4 M of lithium perchlorate. The difference of salt concentration between sodium perchlorate and lithium perchlorate required to display the salt effect sufficiently seems therefore to be in conflict with Cannon's interpretation of the salt effect, for which discussion was given only from the data in the presence of sodium chloride. The difference might be caused by the extent of protonation of molybdate owing to the difference in hydration of cations and anions of the salt added.[7] We have obtained the spectrum with only a well defined maximum at 258 mμ in the absorption of 2.00×10^{-2} M molybdic acid in 4 M sodium perchlorate solution against sodium monomeric molybdate in the region 210—330 mμ.[11] The molybdenum-containing species in this solution was revealed as being heptamolybdate ion and not octamolybdate ion. This shows the validity of the assumption on salt effect described by Jain and Jain.[6] Thus, we concluded that the reactions proceeding in the titration of 2.00×10^{-2} M molybdic acid in 3 M sodium perchlorate or in 4.4 M lithium perchlorate with

sodium hydroxide solution might consist of the following two steps:

$$H_6Mo_7O_{24} + 6OH^- = Mo_7O_{24}^{6-} + 6H_2O \quad (P=0-0.857)$$

$$Mo_7O_{24}^{6-} + 8OH^- = 7MoO_4^{2-} + 4H_2O \quad (P=0.857-2.00)$$

The Thermal Properties of Gallium-bearing Allophane

Mitsuhiro KASAI, Yoshiyuki KUDO, and Shuichi HAMADA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received February 8, 1973)

The DTA patterns of synthesized coprecipitated gels, SiO_2–Al_2O_3–Ga_2O_3–H_2O system, resembled that of allophane, and the exothermic peak temperature in the DTA was lowered continuously from 980 to 810 °C with an increase in the gallium content, while that on mixed gels scarcely lowered. The apparent activation energy for this exothermic reaction on the coprecipitated gels decreased with an increase in the gallium content, while that on the mixed gels hardly changed. The crystallization process during the heat treatment of the gels depended on the content and on the coexistence state of the gallium. A unit cell volume of a mullite crystallized at 1200 °C in the coprecipitated gels was enlarged by forming a solid solution with the gallium ion, in contrast to the small change in that formed in the mixed gels. Further, the exothermic peak in the DTA was considered to originate not only from the formation of the mullite, but also from that of the silico-alumina spinel in the gallium-bearing gels; the exothermic reaction products seem to depend on the composition or the coexistence state of gallium in the gels.

The lower crystalline minerals of the SiO_2–Al_2O_3–H_2O system, found in nature as allophane, frequently contain iron. In a previous paper,[1] a synthesized iron-coprecipitated gel was recognized to be an iron-bearing allophane. Gallium occurs widely, but in trace amounts, and it is considered to coexist as a solid solution in aluminum minerals, as in nature. Mixed systems of aluminum and gallium have been studied in connection with those of the Al_2O_3–Ga_2O_3–H_2O system,[2] (Al, Ga)$_2O_3$,[3,4] $2SiO_2 \cdot 3$(Al, Ga)$_2O_3$,[5] and gallium-bearing feldspar.[6]

In this work, the properties of the synthesized gallium-coprecipitated gels of the SiO_2–Al_2O_3–Ga_2O_3–H_2O system were studied in order to examine the coexistence state of gallium in them.

Experimental

Materials. The gallium-coprecipitated samples were prepared in the following manner:[1,7] coprecipitated gels were obtained by boiling mixed solutions of aluminum sulfate, sodium silicate, and gallium sulfate at pH 5.9—6.4, a pH value obtained by adding hexamethylenetetramine. The $Ga_2O_3/(Al_2O_3+Ga_2O_3)$ molar ratio in the mixed solutions was varied from zero to 1.0 at a constant molar ratio of 2.0 as $SiO_2/(Al_2O_3+Ga_2O_3)$. The gels thus coprecipitated were washed by decantation and then air-dried for three weeks. The gallium-mixed samples were prepared by mixing a synthesized allophane, free from gallium, and a hydrated gallium(III) oxide in order to compare the properties of the coprecipitated samples. The amorphous hydrated gallium(III) oxide was prepared by precipitation with ammonia water at pH 4.0 and by subsequent air-drying, like the coprecipitated samples, as one of the components in the mixed samples. The air-dried hydrated gallium(III) oxide gel obtained at pH 4.0 was identified as amorphous from its X-ray powder diffraction pattern, and its chemical composition was estimated to be $Ga_2O_3 \cdot 4.1H_2O$ (corresponding to $Ga(OH)_3 \cdot 0.5H_2O$) from the ignition loss, though the air-dried gels obtained at pH 5.3 and 7.7 were found to contain a crystalline GaOOH[8] and their chemical compositions were $Ga_2O_3 \cdot 2.0H_2O$ and $Ga_2O_3 \cdot 1.2H_2O$ (corresponding to $Ga(OH)_3 \cdot$GaOOH and $Ga(OH)_3 \cdot 9$GaOOH) respectively.

Procedure. The chemical compositions of the samples were estimated gravimetrically for SiO_2, Al_2O_3, and H_2O (±),[9] and colorimetrically for Ga_2O_3.[10]

The differential thermal analysis was carried out in the temperature range from room temperature to 1000 °C and at the heating rate of 10 °C/min with a Rigaku Denki Thermoflex model 8002 differential thermal analyzer.

The X-ray powder diffractogram of the sample was taken with an X-ray diffractometer, model JDX-5P, of the Japan Electron Optics Laboratory Co. The diffraction angles were calibrated by using those of silicon. The sample, in a quartz tube, was heated at 800, 900, 1000, 1100, and 1200 °C for 5 hr in an electric furnace. The firing products were identified and their relative amounts were estimated by using the diffraction peaks at (120) and (210) of the mullite, that at (101) of the cristobalite, those at (200) and (004) of the β-gallia, and those at (220) and (311) of the silico-alumina spinel. The unit-cell dimensions of the mullite, one of the firing products at 1200 °C, were calculated by using the diffraction peaks at (400), (041), (331), and (002) of the mullite.

Results

The chemical compositions of the gallium-bearing samples are shown in Table 1. The $SiO_2/(Al_2O_3+Ga_2O_3)$ and the $H_2O(\pm)/(Al_2O_3+Ga_2O_3)$ molar ratios in the coprecipitated samples decreased with an increase in the gallium content, while the $H_2O(\pm)/(Al_2O_3+Ga_2O_3)$ ratio in the mixed samples did not vary in spite of the change in the gallium content.

The Differential Thermal Analysis of the Samples. All the samples were amorphous or lower crystalline materials, for there were few sharp X-ray powder diffraction peaks. The Ga-0 sample, free from gallium, showed a broad endothermic peak and a sharp exothermic peak at 100 and 980 °C respectively in the

a) $Al_2O_3+Ga_2O_3$. b) Allophane, free from gallium. c) The postscripts "C" and "M" denote the coprecipitated and mixed samples, respectively. d) Calculated.

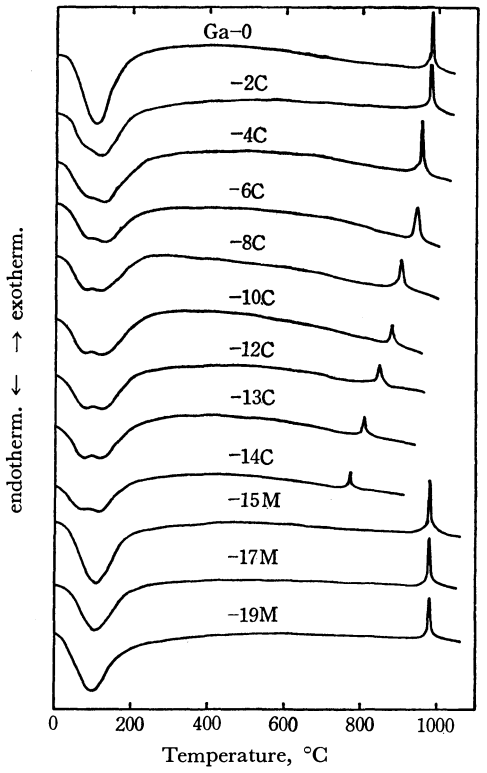

Fig. 1. DTA curves of gallium-bearing samples.

DTA which were assigned to the allophane. The patterns of the DTA of the samples were also similar to that of the allophane, though the endothermic peak split into two peaks with an increase in the gallium content, as is shown in Fig. 1. The exothermic peak temperature in the DTA on the coprecipitated samples

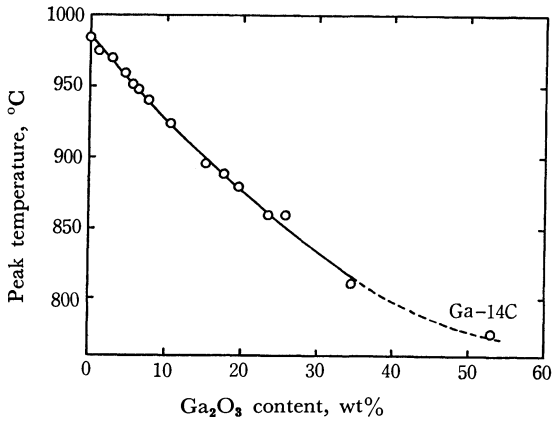

Fig. 2. Plot of exothermic-peak temperature in DTA of coprecipitated samples against gallium content.

was lowered from 980 to 810 °C with an increase in the gallium content, in contrast to the small shift of the exothermic peak temperature of the mixed samples, as is shown in Fig. 2. The peak temperature of the Ga-14C sample, free from aluminum, was 775 °C.

The Variation in the Firing Products in the Samples during Heat Treatment. The crystalline phases formed in the heat-treated samples at 800, 900, 1000, 1100, and 1200 °C for 5 hr were identified as the mullite, the silico-alumina spinel,[11] the β-gallia, and the cristobalite by means of X-ray powder diffractometry. The firing products at each temperature are shown in Table 2. The crystallization process of the coprecipitated samples was found to vary, depending on the con-

A: amorphous, M: mullite, Sp: silico-alumina spinel, G: β-gallia, C: cristobalite.

dition of the original samples, as is shown in Table 2. The crystallization of the mullite tended to become difficult with an increase in the gallium content of the samples; thus, the mullite was not observed as a firing product in the samples with more than 25.83 wt% of Ga_2O_3.

On the contrary, the crystallization process of the mixed samples was analogous with each other in spite of the variation in the gallium content without forming the silico-alumina spinel. Therefore, the coexistence state of gallium in the coprecipitated samples were considered to be different from that of the mixed samples, judging from the dissimilarity between the crystallization processes of the coprecipitated and of the mixed samples.

In order to examine the cause of the exothermic peak around 900 °C in the DTA, the Ga-1C, -3C, -8C, -11C, -13C, -14C, and -16M samples were preheated up to temperatures just below and above their peak temperatures at the rate of 10 °C/min in the DTA equipment. The phases of these preheated samples were identified by X-ray diffractometry to be as is shown in Table 3. When these samples were again examined by the DTA, the sharp exothermic peak was observed only in the samples which retained the amorphous state after preheating just below the peak temperatures, except for the Ga-16M sample. As is shown in Table 3, the exothermic change in the coprecipitated samples was found to lead to the formation of the mullite or the silico-alumina spinel from the amorphous state.

The apparent activation energy, E_a, for the exothermic change was estimated by the following Kissinger equation:[12]

$$d(\ln \theta/T_m^2)/d(1/T_m) = -E_a/R$$

where θ is the heating rate (3, 5, 10, 15, and 20 °C/min); T_m, the peak temperature in the DTA, and R, the gas constant.

Table 3. Phases of preheated samples

Sample	Peak temp. of original state, °C	Phase after heat treatment	
		below peak temp.	above peak temp.
Ga-1C	975	A (960 °C)	M (990 °C)
Ga-3C	959	A (930 °C)	M (985 °C)
Ga-8C	895	A (872 °C)	Sp (910 °C)
Ga-11C	859	A (848 °C)	Sp (875 °C)
Ga-13C	810	A (798 °C)	Sp (834 °C)
Ga-14C	775	A (762 °C)	Sp (787 °C)
Ga-16M	980	G (970 °C)	M, G (995 °C)

A: amorphous, M: mullite, Sp: silico-alumina spinel, G: β-gallia.

The E_a values of the exothermic change in the coprecipitated samples decreased with an increase in the gallium content, while those in the mixed samples were nearly equal to that of the Ga-0 sample and scarcely changed at all in spite of the variation in the gallium content, as is shown in Table 4.

Table 4. Apparent activation energy for exothermic change around 900 °C

Sample	E_a, kcal/mol
Ga-0	243
Ga-7C	215
Ga-11C	209
Ga-14C	196
Ga-17M	227
Ga-19M	239

The Unit Cell Dimensions of the Mullite Formed in the Heat-treated Samples. The relationship between the unit cell volume, V, of the mullite heat-treated at 1200 °C for 5 hr and the gallium content in the original samples is shown in Fig. 3. The V of the mullite formed in the coprecipitated samples increased with an increase in the gallium content up to 15.25 wt% as Ga_2O_3, and then decreased above 17.72wt%, while those in the mixed samples scarcely changed at all in spite of variation in the gallium content in all except the Ga-18M sample.

The relationship between the unit cell length along the c axis, c_0, and the V of the mullite formed in the coprecipitated samples was approximately linear, as is shown in Fig. 4, in contrast to the case in the heat-treated mixed samples. Although the c_0 and V values of gallium-free mullite varied with the silica/alumina ratio,[13] the variation in the c_0 and the V of

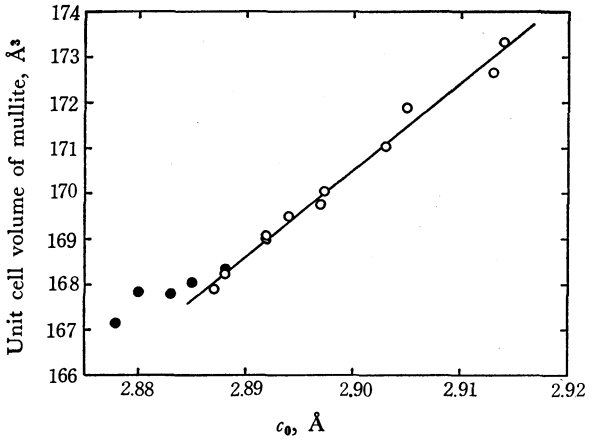

Fig. 4. Plot of unit cell volume against c_0 of mullite formed at 1200°C.
○; coprecipitated samples, ●; mixed samples

the mullite formed in the coprecipitated samples remarkably exceeded those caused by a change in the silica/alumina ratio.

Therefore, much of the gallium in the coprecipitated samples was considered to be included in the mullite by forming a solid solution, although a limit of the amount of gallium included in the mullite was obscure.

The maximum value of the V (173.3 Å^3, the Ga–8C sample) was larger than the reported value of the gallium-bearing mullite (170.1 Å^3).[5] However, it is difficult to compare them directly, since the substantial amount of gallium in the mullite formed in the Ga–8C sample can not be estimated.

Discussion

Because the exothermic peak around 900 °C in the DTA on the coprecipitated gels shifted continuously toward lower temperatures as the gallium content increased, the causes of all the exothermic peak must have the same pattern. The exothermic peak around 900 °C on the silica-alumina gel has been explanied as originating from the formation of mullite[14,15] or γ-alumina.[16] In the case of the coprecipitated gels with less gallium (*e.g.*, the Ga–1C and –3C samples), the results shown in Table 3 favor the conclusion that the formation of the mullite was responsible for this peak. On the contrary, the exothermic reaction product from the coprecipitated gels with more gallium (*e.g.*, the Ga–8C, –11C, and –13C samples) was found to be the silico-alumina spinel, similar to that of the Ga–14C sample, free from aluminum.

If the exothermic peak originates from the formation of the mullite, the inconsistency between a reduction in the apparent activation energy for the exothermic reaction and a rising trend of the crystallization temperature of the mullite with an increase in the gallium content can not be explained. A direct examination of the preheated samples indicated that the exothermic peak in the DTA resulted not only from the formation of the specified mineral, *i.e.*, mullite, but also from that of the silico-alumina spinel, which was a metastable phase. Furthermore, this exothermic peak is considered to originate in a structural change in the silica-alumina based gels, a change which arises from the formation of the mullite or the silico-alumina spinel, although its details are obscure; the kind of exothermic reaction products will depend on the composition, the coexistence state of gallium in the gels, and the crystallographic geometry.

The β-gallia formed was found to include aluminum ions as a solid solution, since the spacings of the β-gallia, one of the firing products in the gallium-rich coprecipitated samples and the aluminum-free one, decreased with the decrease in the gallium content. For example, the spacing for the (311) of the β-gallia[17] crystallized at 1200 °C in the Ga–11C, –12C, and –14C samples were 1.518, 1.529, and 1.545 Å respectively, while those in the two mixed samples, Ga–17M and –19M, were 1.542 and 1.545 Å respectively.

Judging from the chemical compositions and the results of the DTA and of the X-ray powder diffractometry of the heat-treated samples, the coprecipitated samples, the SiO_2–Al_2O_3–Ga_2O_3–H_2O system, prepared in this work are considered to be an allophane-like material, *i.e.*, a gallium-bearing allophane.

An MO-theoretical Interpretation of the Reductive Cleavage of Organic Halides by Pentacyanocobaltate(II)

Katsutoshi OHKUBO, Hirokazu KANAEDA, and Kohji TSUCHIHASHI

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received February 14, 1973)

The mechanism of the reductive cleavage of organic halides (RX) by pentacyanocobaltate(II) $Co(CN)_5^{3-}$ was investigated by means of the extended Hückel MO theory. First, the molecular structure of $Co(CN)_5^{3-}$ was considered to be the square-pyramidal C_{4v} configuration, without H_2O as its sixth ligand. Secondly, the order of the observed rate constants for the $Co(CN)_5^{3-}+RX \rightarrow Co(CN)_5X^{3-}+R\cdot$ reaction was found to be in satisfactory accordance with that of the calculated binding energies of the R–X bond. Thirdly, the reductive cleavage of RX by $Co(CN)_5^{3-}$ proceeds by the aid of the predominant electron-migration from the highest-occupied, lone-pair halogen-orbital to the singly-occupied d_{z^2} Co-orbital and from the highest-occupied d_{xz} (or d_{yz}) Co-orbital to the lowest-unoccupied, antibonding $p\sigma^*$ orbital of the R–X bond. Finally, the mode of the interaction between $Co(CN)_5^{3-}$ and RX was precisely discussed in terms of the homolytic cleavage of the R–X bond.

It has been well established that organocobalt compounds can be easily formed by the reductive cleavage of organic halides with pentacyanocobaltate(II)[1-6]:

$$2Co(CN)_5^{3-} + RX \rightarrow Co(CN)_5R^{3-} + Co(CN)_5X^{3-} \quad (1)$$

The mechanism of such a reaction has been interpreted mainly, by the kinetic and other studies of Halpern *et al.*,[2,3,6] in terms of the free-radical reaction according to:

$$Co(CN)_5^{3-} + RX \rightarrow Co(CN)_5X^{3-} + R\cdot \quad \text{(rate-determining)} \quad (2)$$

$$Co(CN)_5^{3-} + R\cdot \rightarrow Co(CN)_5R^{3-} \quad (3)$$

Since any precise discussion referred to the above reactions, however, depends in the early stages on a molecular level, molecular orbital study seems significant.

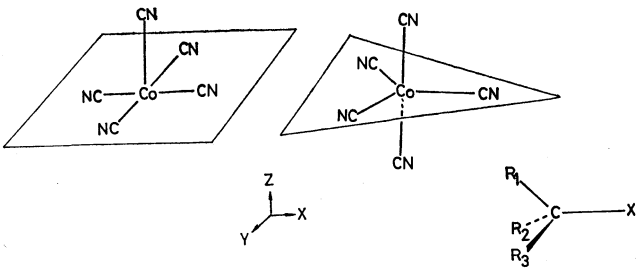
The present study was undertaken in order to elucidate the mechanism of the reductive cleavage of RX by $Co(CN)_5^{3-}$, using throughout the extended Hückel MO method, with particular reference to the plausible model of the interaction between the two compounds.

Method of Calculation

An extended Hückel MO (EHMO) method[7] involving metal d-orbitals was used for the calculations on the following three systems:

(a) pentacyanocobaltate(II) : square-pyramidal C_{4v} and trigonal-bipyramidal D_{3h} $Co(CN)_5^{3-}$, (b) organic halides: RI (R=CH_3, C_2H_5, *i*-C_3H_7, and *t*-C_4H_9), $XCH_2CO_2CH_3$ and XCH_2CONH_2 (X=Cl, Br, and I), and (c) an interacting system of $Co(CN)_5^{3-}$ and RX (CH_3I was tentatively taken).

The orbital exponents and ionization energies for the s and p orbitals of the C, N, O, and halogen atoms were supplied by Clementi[8] and by Jaffé[9] respectively. The ionization energies for the s, p, and d orbitals of the Co atom were, respectively, taken to be 10.0 eV,[10] 8.0 eV,[10] and 11.0 eV.[10]



Co-C=2.30−1.50 Å
C-N=1.30 Å
C-Cl=1.767 Å
C-Br=1.939 Å
C-I=2.139 Å

Fig. 1. Geometries of pentacyanocobaltate(II) and organic halides used for the calculation.

The geometries used for the calculations are illustrated in Fig. 1; the interatomic distance and the valence angles for $XCH_2CO_2CH_3$ and XCH_2CONH_2 were determined uniformly from those[12] of $CH_3CO_2CH_3$ and CH_3CONH_2, with the fixed angle of C–C–X (109°28′), for the sake of simplicity.

Results and Discussion

Molecular Structure of $Co(CN)_5^{3-}$. The molecular structure of $Co(CN)_5^{3-}$ in solution has not yet been strictly established; the square-pyramidal C_{4v} $Co(CN)_5^{3-}$ has been predominantly discussed as compared with the trigonal-bipyramidal D_{3h} one.

C_{4v} $E_{EH} = -1009.116$ eV

D_{3h} $E_{EH} = -1009.770$ eV

Fig. 2. Electronic structures of C_{4v} and D_{3h} $Co(CN)_5^{3-}$.

We will first discuss which structure, the C_{4v} or the D_{3h}, is more likely for $Co(CN)_5^{3-}$. Fig. 2 shows the formal charges (Q_A), the bond populations (M_{A-B}), and the total electronic energies (E_{EH}) of C_{4v} and D_{3h} $Co(CN)_5^{3-}$ at a fixed Co–C distance of 1.81 Å.[13] As Fig. 2 indicates, the electronic structures of the C_{4v} and the D_{3h} $Co(CN)_5^{3-}$ resemble each other, since they have almost the same values of Q_A, M_{A-B}, and E_{EH}.

According to the E_{EH} values of the C_{4v} and D_{3h} $Co(CN)_5^{3-}$ at the Co–C distances of 1.5~2.3 Å (Table 1), the latter cobaltate seems to be slightly more stable than the former. The energy difference between the two cobaltates is, however, quite small; that is, it is difficult to conclude the stability of the trigonal-pyramidal D_{3h} structure for $Co(CN)_5^{3-}$ from the total energy, neglecting the electron-electron and nuclear-nuclear repulsions.

On the other hand, the 10 Dq value estimated from the energy difference between the lowest-unoccupied (LU) and the singly-occupied (SO) orbitals[14] of the Co atom offers some information about the molecular structure of $Co(CN)_5^{3-}$. The 10 Dq value for the C_{4v} $Co(CN)_5^{3-}$, 32.09 kK, at the Co–C distance of 1.81 Å was found to be in good agreement with that of 33 kK obtained experimentally by Caulton.[15]

Since the C_{4v} structure was demonstrated by Alexander and Gray[16] in their ESR and UV spectroscopic investigations of $Co(CN)_5^{3-}$, and since the theoretical values of 10 Dq agree with those in the experiments, the square-pyramidal C_{4v} $Co(CN)_5^{3-}$ seems to be more likely than the trigonal-pyramidal D_{3h} one, and the Co–C distance seems to be about 1.81 Å.

a) Co-CN bond on x-axis.

On the other hand, there have been some discussions[17] referred to $Co(CN)_5^{3-}$ coordinated by H_2O as its sixth ligand in aqueous solutions. According to the calculated results of the C_{4v} $Co(CN)^{3-}$, H_2O, and octahedral $Co(CN)_5OH_2^{3-}$ (Co–O was taken to be 1.93 Å,[18] the isolated systems of $Co(CN)_5^{3-}$ and H_2O (the sum of their E_{EH} values = −1169.72 eV) can be said to be energetically more stable than $Co(CN)_5OH_2^{3-}$ ($E_{EH} = -1167.96$ eV). It may be deduced, therefore, that H_2O does not coordinate directly to $Co(CN)_5^{3-}$.

Here, the bond nature of the C_{4v} $Co(CN)_5^{3-}$ will be discussed briefly. Table 2 lists the AO bond populations (N_{A-B}) of the Co–C and C–N bonds. The d Co-orbitals contribute mainly to the dp-π-type bond

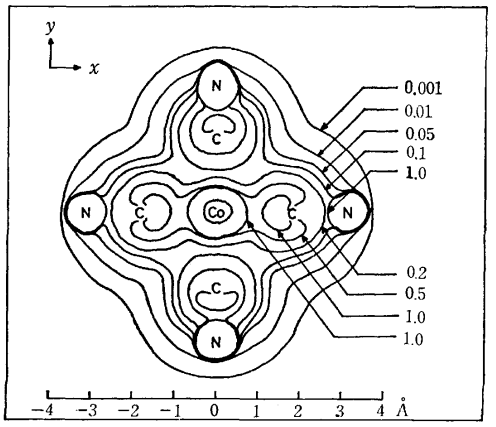

Fig. 3. Charge density contour of C_{4v} $Co(CN)_5^{3-}$. (The representation is in xy cross section.)

13) Lipscomb *et al.*[10] emphasized the Co–CN distance of 1.81 Å by their study on $Co(CN)_5H^{3-}$.

14) The LUMO and the SOMO are, respectively, $d_{x^2-y^2}$ and d_{z^2} orbitals for the C_{4v} $Co(CN)_5^{3-}$ and are, respectively, d_{z^2} and d_{xy} orbitals for the D_{3h} $Co(CN)_5^{3-}$.

15) K. G. Caulton, *Inorg. Chem.*, **7**, 392 (1968).

16) J. J. Alexander and H. B. Gray, *J. Amer. Chem. Soc.*, **89**, 3356 (1967).

17) For instance, see J. M. Pratt, and R. J. P. Williams, *J. Chem. Soc., Ser.* A, **1967**, 1291.

18) The purely covalent bond-distance was used because the usual bond-distances of metal-oxygen in aquo-complexes are purely covalent (see Ref. 12).

d) Interacting system between CH_3I and $Co(CN)_5^{3-}$, and the geometries were shown in Table 4.

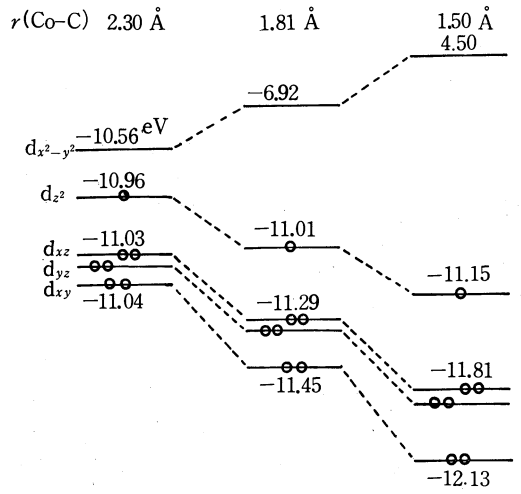

Fig. 4. d-Orbital separation of C_{4v} $Co(CN)_5^{3-}$ as a function of Co–C distance.

formation of the Co–C bond, and the $d_{x^2-y^2}$ Co-orbital takes part in the ds-σ-type bond formation of the Co–C in some measure. The net charge-density contour for the C_{4v} $Co(CN)_5^{3-}$ is illustrated in Fig. 3 to facilitate an understanding of the bond nature discussed above and the electron distribution of the compound.

Frontier Orbitals of $Co(CN)_5^{3-}$ and RX. The d-orbital separation on the Co atom of the C_{4v} $Co(CN)_5^{3-}$ is shown in Fig. 4; the cobaltate is characterized by the SO d_{z^2} and the doubly-degenerate, highest occupied (HO) d_{xz} and d_{yz} Co-orbitals. On the other hand, the frontier orbitals of RX are the doubly-degenerate, HO lone-pair p_z and p_y orbitals on X and the antibonding, LU $p\sigma^*$ orbital on the C–X axis. It seems certain that the above-mentioned orbitals corresponding to the frontier MOs play an important role in the reductive cleavage of RX by $Co(CN)_5^{3-}$: The SOMO (and/or the HOMO) of $Co(CN)_5^{3-}$ interacts predominantly with the LUMO, the HOMO, or both the MOs of RX respectively in the nucleophilic, electrophilic, or radical attack of the former on the latter.

Correlation between the Electronic States of RX and the Reaction Rates for $Co(CN)_5^{3-}+RX \rightarrow Co(CN)_5X^{3-}+R\cdot$. In this section, we will discuss the correlation between the bond nature of RX and the observed rate constants, k_{obsd}, for Eq. (2) (see Introduction). As can be seen from Table 3, the order of k_{obsd} values is satisfactorily reflected in that of the dissociation energies, D_{298} (in other words, binding energies or M_{C-X} values). On the other hand, no parallelism between the order of the AO-bond population of the $p\sigma$-orbitals on the C–X axis (N_{p_σ}) or of the lone-pair p_z-orbital on X ($N_{lone-pair}$) and that of the k_{obsd} values can be consistently realized between the two series of RI and $XCH_2CO_2CH_3$ and/or XCH_2CONH_2; that is, the order of the k_{obsd} values cannot be explained by only that of the N_{p_σ} or $N_{lone-pair}$ values. It can be deduced, therefore, that both the $p\sigma^*$ C–X orbital and the lone-pair X-orbital take part directly in the interaction with $Co(CN)_5^{3-}$.

Interacting System of $Co(CN)_5^{3-}$ and RX. We will here determine the most plausible mode of the interaction between $Co(CN)_5^{3-}$ and RX in terms of the homolytic cleavage of the R–X bond. The EH-MO calculations were performed on the two modes of interaction between $Co(CN)_5^{3-}$ and RX (CH_3I was tentatively used), *i.e.*, Type-A and Type-B, both illustrated in Table 4.

It may be found from Table 4 that the C–I bond of CH_3I is most weakened by the Type-B interaction at $\theta=45°$ in view of the fact that the M_{C-I} values of such interaction are the smallest throught the reaction progress. The Type-B interaction at $\theta=45°$ seems to be the most appropriate interacting form in which plausible overlappings between the frontier orbitals of both compounds can be established (see Fig. 5).

With regard to the electron migrations between $Co(CN)_5^{3-}$ and RX, the migrations depicted by Eqs. (4)~(7) can be considered on the basis of the changes in the electron densities of the s and p X-orbitals and the d Co-orbitals, as is indicated in Table 5:

$$p_z^{(X)}\ \text{(lone-pair)} \xrightarrow{\text{through } d_{z^2}{}^{(Co)}-p_z{}^{(X)}} d_{z^2}{}^{(Co)}\ \text{(predominant)} \quad (4)$$

$$p_y{}^{(X)}\ \text{(lone-pair)} \xrightarrow{\text{through } d_{yz}{}^{(Co)}-p_y{}^{(X)}} d_{yz}{}^{(Co)} \quad (5)$$

$$\xrightarrow{\text{through } d_{xy}{}^{(Co)}-p_y{}^{(X)}} d_{xy}{}^{(Co)} \quad (6)$$

$$d_{xz}{}^{(Co)} \xrightarrow{\text{through } d_{xz}{}^{(Co)}-p_x{}^{(X)}} p_x{}^{(X)}\ \text{(predominant)} \quad (7)$$

The predominant electron-migrations depicted by Eqs. (4) and (7) bring about, respectively, the decrease in the bonding character of the R–X and the increase in the antibonding character of the same bond, as may be seen from the energy-change in the frontier orbital levels of RX (*viz.* CH_3I) in Fig. 5.

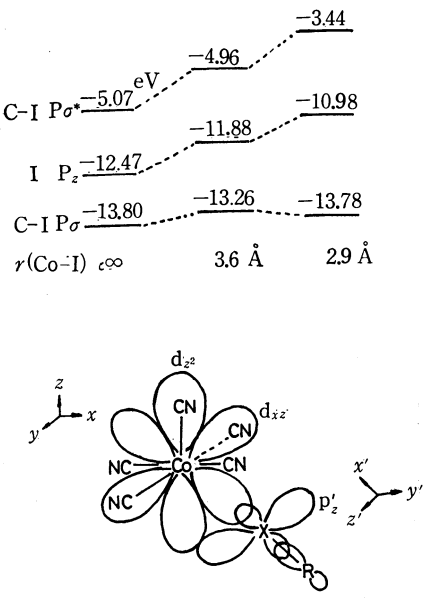

Fig. 5. MO-energy changes in frontier orbitals of RX by optimized interaction of $Co(CN)_5^{3-}$.

The present calculations were carried out on a FACOM 230-60 computer at the Data Processing Center of Kyushu University.

The Solubility of Sulfur in Na_2O-SiO_2 Melts under Various Oxygen Partial Pressures at 1100 °C, 1250 °C, and 1300 °C

Shigeru NAGASHIMA and Takashi KATSURA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 17, 1973)

The solubility of sulfur in Na_2O–SiO_2 melts with the Na_2O/SiO_2 molar ratios of 1/3, 1/2, and 1/1 was investigated by varying the oxygen partial pressure at 1100, 1250, and 1300 °C. The results at 1100 °C are complicated, for the equilibrium state within the gas phase is not established. From the experiments at 1250 and 1300 °C, the following conclusions are reached: (1) When the temperature and the Na_2O/SiO_2 ratio in the melt are constant, the solubility of sulfur increases with an increase of the total amount of sulfur in the gas phase. (2) When the temperature, the Na_2O/SiO_2 ratio, and the total amount of sulfur in the gas phase are constant, the solubility of sulfur shows its minimum at a specific oxygen partial pressure; at higher oxygen partial pressures, the sulfur dissolves in the melts mostly as sulfate, while at lower oxygen partial pressures, the sulfur dissolves mostly as sulfide. (3) When the temperature and the total amount of sulfur in the gas phase are constant, the solubility rises greatly with an increase in the Na_2O/SiO_2 ratio in the melt. (4) When the Na_2O/SiO_2 ratio in the melt and the total amount of sulfur in the gas phase are constant, the minimum point of the solubility shifts in the direction of higher oxygen partial pressures as the temperature increases. This corresponds to the shifts of the equilibrated gas composition as the temperature increases.

The solubility of sulfur in melts at high temperatures is important not only for geochemistry but also for metallurgy and ceramics. Fincham and Richardson[1] investigated the effect of the oxygen partial pressure on the solubility of sulfur in silicate and alumino silicate melts by equilibrating the melts with gas mixtures (SO_2–CO_2–H_2) at 1350—1650 °C. On the basis of thermodynamic calculations at 1425—1650 °C, they concluded that sulfur dissolves in the CaO–Al_2O_3–SiO_2 melts as sulfate at oxygen partial pressures higher than about 10^{-3} atm, and that sulfur dissolves as sulfide at oxygen partial pressures lower than about 10^{-5} atm. Similar results were obtained later by other investigators[2-3] using different kinds of melts. However, no study has been published on the alkali silicate systems.

The present objectives are to: (1) obtain fundamental thermodynamic information about the solubility of sulfur in the Na_2O–SiO_2 melts and (2) actually prove the dissolving state of sulfur in silicate melts by chemical analysis. The solubility of sulfur was studied at very high oxygen partial pressures by Holmquist,[4] but no study has ever been made over wider range of oxygen partial pressures.

Experimental

Furnace, Temperature Control, and Procedure. These were almost the same as those adopted by Iwasaki and Katsura.[5]

Gas Mixture. Commercial gases (SO_2, CO_2, and H_2) were purified with phosphorus pentoxide and were mixed in the required ratio by a capillary technique. The rate of gas flow was fixed at 0.66 cm/s throughout the present experiments. Preliminary experiments at about 0.3 cm/s proved that the gas-flow rate does not have any significant effect on the results.

Materials. Sodium silicate glasses with the required compositions (the Na_2O/SiO_2 molar ratios of 1/1, 1/2, and 1/3) were prepared by melting mixtures of sodium carbonate and silica of an analytical grade in platinum crucibles. The sodium contents of these glasses were chemically analyzed in the form of Na_2SO_4 after dissolving the glasses with HF and H_2SO_4; the results agreed well with the calculated values within an error of 0.5%. The sulfur content of these glasses was less than 0.001%. Samples with a known amount of sulfur were also prepared by melting mixtures of sodium carbonate, sodium sulfate, and silica.

Chemical Analysis of Total Sulfur. The total sulfur in the quenched samples was determined by the following two methods, according to the sulfur content: (1) for high concentrations of sulfur (>0.5%), the sulfur was determined by the method of Kiba *et al.*[6] with some modifications; (2) for low concentrations of sulfur (0.001—0.5%), the sulfur was determined as in a previous paper.[7] In order to check the reliability of the methods, the sample with a known amount of sulfur mentioned above was analyzed by the methods, (1) and (2). Some results for the samples with the Na_2O/SiO_2 ratio of 1/2 were as follows: (Added: 4.0% S, Found: 3.9, 4.0, 3.7% S; Added: 0.34% S, Found: 0.32, 0.34, 0.33% S).

Chemical Analysis of Sulfide- and Sulfate-Sulfur. The sulfide- and sulfate-sulfur in the samples was determined with tin(II)-strong phosphoric acid and strong phosphoric acid in the same way as has been reported previously.[7]

Results and Discussion

Establishment of Equilibration. (1) Equilibrium Composition of the Gas Phases: The equilibrium composition of the gas phase at 1100, 1250, and 1300 °C was obtained by means of a digital computer using the linear programing method of White *et al.*[8] and using the thermodynamic data on the chemaical species (H_2, CO_2, CO, H_2O, O_2, SO_3, SO_2, SO, S_2, HS, H_2S,

COS, CS, CS_2); the values of the standard free energy of the formation of each gas species were taken from "JANAF" Thermochemical Tables.[9] A HITAC-8500 was used for the computations.

Since it is not feasible to confirm whether the actually-established partial pressure of each gaseous species coincides with the thermodynamically-calculated value, the actual oxygen partial pressure was measured for each gas mixture by using a solid electrolyte composed of $(ZrO_2)_{0.85}(CaO)_{0.15}$,[10,11] and the establishment of equilibration was judged through a comparison of the measured value with the calculated one.

A comparison of the measured oxygen partial pressure, P_{O_2}(obsd), with the calculated one, P_{O_2}(calcd) is given in Fig. 1(1) and -(2). As Fig. 1(1) shows, at 1100 °C the measured oxygen partial pressures deviate greatly from the values calculated by the thermodynamic data; this suggests a significant deviation from the equilibrium state within the gas phase. On the other hand, as is shown in Fig. 1(2), at 1250 °C the measured values are in fairly good agreement with the calculated ones, although they deviate slightly with a decrease in the oxygen partial pressure and with an increase in the $(SO_2)_i$ concentration. The results at 1300 °C were almost the same as those at 1250 °C. Therefore, at 1250 and 1300 °C the gas phase is considered to be approximately in equilibrium. The present study was mainly carried out at relatively high oxygen partial pressures above 10^{-12} atm P_{O_2} at 1250 and 1300 °C. The calculated P_{O_2} was adopted except for that at 1100 °C.

(2) Equilibration between Melts and the Gas Phase: The equilibrium amount of total sulfur in the melt was determined by varying the reaction time and by using various starting samples with the same Na_2O/SiO_2 ratio but containing different amounts of sulfur. Examples of the results are given in Fig. 2. The Na content of each sample after heating was analyzed to prove it to be unchanged in the bulk composition throughout the reaction.

Experiments at 1100 °C. Preliminary experiments were performed at 1100 °C, although, as was mentioned above, the gas phase was not equilibrated at this temperature. The solubility of gaseous species in silicate and phosphate melts has been studied by several investigators.[4,12-13] Of these, Pearce[12] studied the solubility of CO_2 in Na_2O–SiO_2 melts and observed that the solubility of CO_2 increases with an increase in the Na_2O/SiO_2 ratio. He explained that the solubility of CO_2 depends on the oxygen-ion activity ($a_{O^{2-}}$) in the melts.

In the present study, the solubility of sulfur decreases rapidly with a decrease in the oxygen partial pressures, ranging from 10^{-5} to 10^{-10} atm P_{O_2}, when the Na_2O/SiO_2 ratio is constant, while the solubility

remains substantially constant though the P_{O_2} value decreases from 10^{-10} to 10^{-15} atm except for the case of $Na_2O/SiO_2=1$. These results are very different from those by Fincham and Richardson.[1] The difference can not be well explained, since the gas phase deviated far from the equilibrium state.

Experiments at 1250 °C. (1) The Solubility of Sulfur Affected by the Oxygen Partial Pressure: Fig. 3 shows the relationship between the solubility of sulfur in sodium silicate melts and the oxygen partial pressure at 1250 °C. The solubility increases greatly with an increase in the Na_2O/SiO_2 ratio, in the same way as was seen at 1100 °C, when the $(SO_2)_I$ concentration is constant. The solubility increases with an increase in the $(SO_2)_I$, as shown in Fig. 3, when the Na_2O/SiO_2 value is 1/2. When both the Na_2O/SiO_2 ratio in the melts and the $(SO_2)_I$ concentration are constant, the solubility shows its minimum at a specific oxygen partial pressure. Fincham and Richardson[1] also obtained the minimum solubility of sulfur in the CaO–Al_2O_3–SiO_2 systems and presumed the following two equilibria:

$$\frac{1}{2}S_2 + \frac{3}{2}O_2 + (O^{2-})_{melt} = (SO_4^{2-})_{melt} \quad (1)$$

$$K_1 = \frac{a_{SO_4^{2-}}}{P_{S_2}^{1/2} P_{O_2}^{3/2} a_{O^{2-}}}$$

$$\frac{1}{2}S_2 + (O^{2-})_{melt} = (S^{2-})_{melt} + \frac{1}{2}O_2 \quad (2)$$

$$K_2 = \frac{P_{O_2}^{1/2} a_{S^{2-}}}{P_{S_2}^{1/2} a_{O^{2-}}}$$

If the oxygen ion activity of the melts, $(a_{O^{2-}})$, is constant in the constant melt composition and at a given temperature, and if, in addition, the activities of SO_4^{2-} and S^{2-} in the melt are proportional to the total sulfur concentrations, $(\%\ S)_{melt}$, the equilibrium constants, K_1 and K_2, may be written as K_1' and K_2' respectively:

$$K_1' = \frac{(\%S)_{melt}}{P_{S_2}^{1/2} P_{O_2}^{3/2}} \quad (1)'$$

$$K_2' = \frac{P_{O_2}^{1/2} (\%S)_{melt}}{P_{S_2}^{1/2}} \quad (2)'$$

Figure 4 illustrates the relationship between the apparent equilibrium constants, K_1' and K_2', and the oxygen partial pressure on the basis of the present experiments. The results show that $\log K_1'$ is almost constant at high oxygen partial pressures, and that $\log K_2'$ is almost constant at low oxygen partial pressures, although the constant, K_1', varies somewhat in the case of melts with the Na_2O/SiO_2 ratio of 1/1 at high oxygen partial pressures. This suggests that the sulfur dissolves as sulfate at high oxygen partial pressures and as sulfide at low oxygen partial pressures.

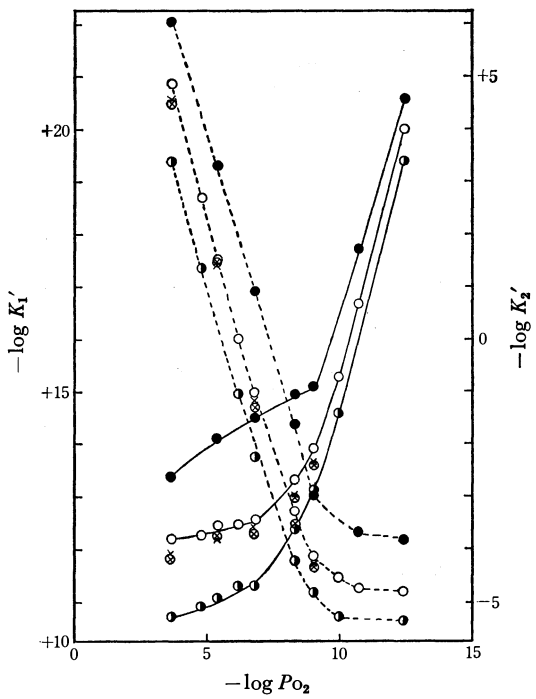

Fig. 4. Sulfate (K_1')(——) and sulfide (K_2')(——) equilibrium constants as a function of oxygen partial pressure for Na_2O–SiO_2 melts at 1250 °C.

(2) Relationship between the Solubility of Total Sulfur and the Partial Pressures of the Sulfur Compounds: The relationship between the solubility of sulfur in the melts and the calculated partial pressures of various sulfur compounds in the gas phase was examined. Figs. 5-(1) and -(2) show the relationship between the total sulfur content of the melts, and P_{SO_3} and P_{H_2S}, respectively. The number in parentheses placed close to each individual point indicates the value of $-\log P_{O_2}$. However, in order to avoid illegibility, the values are omitted at some points in the figures.

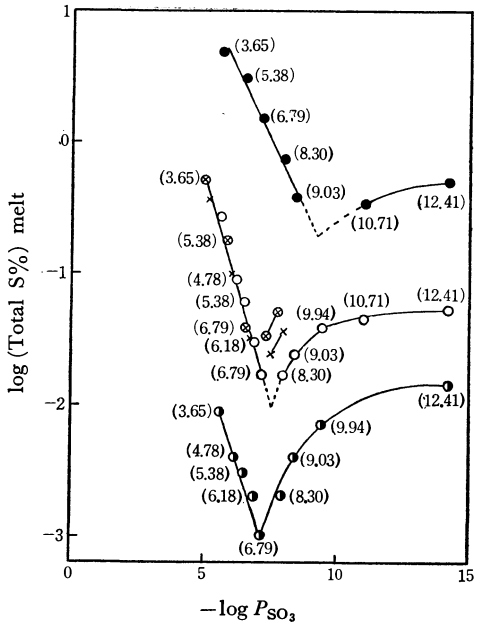

Fig. 5(1). Variation of sulfur content of Na_2O–SiO_2 melts with P_{SO_3} at 1250 °C.

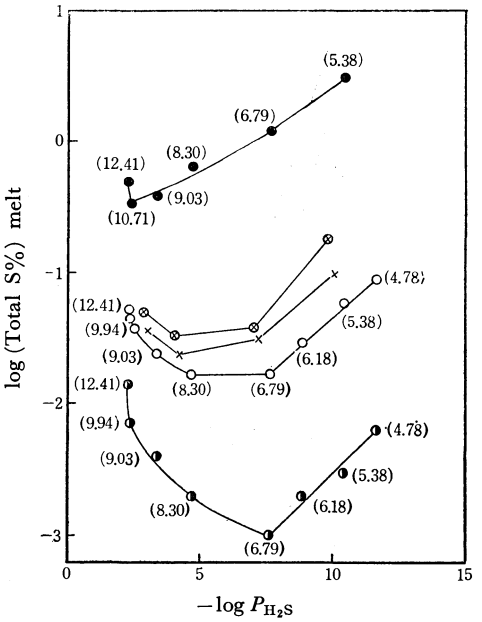

Fig. 5(2). Variation of sulfur content of Na_2O–SiO_2 melts with P_{H_2S} at 1250 °C.

As may be seen in Fig. 5-(1), the total sulfur content of a melt increases with an increase in P_{SO_3} at relatively high oxygen partial pressures; this relation may be expressed as a linear equation as follows:

$$\log (\%\ S)_{melt} = k_1 + (0.7 \sim 0.75) \times \log P_{SO_3} \qquad (3),$$

where k_1 is constant and where Equation (3) is applicable in the range above 10^{-9} atm P_{O_2} when the Na_2O/SiO_2 ratio is 1/1 and in the range above $10^{-6.8}$ atm P_{O_2} when the Na_2O/SiO_2 ratios are 1/2 and 1/3. These results support the idea that the sulfur dissolves mainly as sulfate at high oxygen partial pressures. On the other hand, as is shown in Fig. 5-(2), the total sulfur content of a melt increases with an increase in P_{H_2S} at relatively low oxygen partial pressures, though we can not obtain a simple equation such as has just been obtained at relatively high oxygen partial pressures. However, this trend may also support the idea that the total sulfur may dissolve mainly as sulfide at low oxygen partial pressures.

The relationships between the solubility of sulfur and the sulfur compounds in the gas phase other than SO_3 and H_2S were also examined, but the relationships showed significant discrepancies in all cases from the general rules expected thermodynamically.

(3) Determination of Sulfide- and Sulfate-Sulfur in Melts: One of the most direct and definite methods to distinguish the state of dissolved sulfur in a melt is to chemically analyze the sulfide- and sulfate-sulfur separately. The method of determining sulfide and sulfate has been established, as has been mentioned before.[7] Here, in Table 1 we show some analytical results in the case of the $Na_2O/SiO_2=1/2$.

As may clearly be seen in Table 1, the total sulfur is mostly in the form of sulfate at higher oxygen partial pressures (above $10^{-6.8}$ atm P_{O_2}). On the other hand, at lower oxygen partial pressures (below 10^{-9} atm P_{O_2}), the total sulfur is mostly in the form of sulfide.

TABLE 1. SULFIDE- AND SULFATE-SULFUR CONTENT OF Na_2O–SiO_2 (1:2) MELTS AT 1250°C

$(SO_2)_I$: 0.5% (0.03 cc/sec)					
$(CO_2)_I$ (cc/s)	$(H_2)_I$	$-\log P_{O_2}$ (calcd.)	Total-S	Sulfide-S	Sulfate-S
6	0	3.65	0.27	<0.001	0.27
	0.02	5.38	0.060	<0.001	0.060
	0.1	6.79	0.017	0.001	0.016
5.5	0.5	8.30	0.017	0.008	0.009
5	1	9.03	0.024	0.021	0.003
3	3	10.71	0.044	0.042	0.002
1	5	12.41	0.053	0.052	0.001

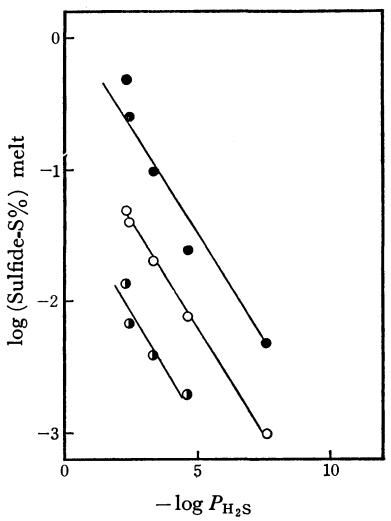

Fig. 6. Variation of sulfide-sulfur content of Na_2O-SiO_2 melts with P_{H_2S} at 1250 °C.

Fig. 6 shows the relationship between the analyzed sulfide-sulfur content in the melts and P_{H_2S}. As may be seen in Fig. 6, the sulfide-sulfur content increases almost linearly with an increase in P_{H_2S}, leading to the

following equation:

$$\log (\%\ S)_{melt} = k_2 + 0.3 \times \log P_{H_2S},$$

where k_2 is constant.

This fact proves the thermodynamic prediction that sulfur should dissolve in the form of sulfide when the melt was at relatively low oxygen partial pressures.

Effect of the Temperature on the Solubility of Sulfur. Figure 7 shows the relationship between the sulfur content of the sodium silicate melts and the oxygen partial pressure at 0.5% of $(SO_2)_I$ and at 1250 and 1300 °C. As may be seen in Fig. 7, the minimum point of the solubility moves in the direction of higher oxygen partial pressures as the temperature increases. Fig. 7 indicates that the increase in the solubility of the total sulfur does not necessarily correspond to the temperature change. This is because the partial pressure of each sulfur compound varies according to the temperature change. The experimental results at 1100 °C were complicated, since the gas phase was not in the chemical equilibrium state. However, in some experiments at 1100 °C, *i.e.*, under the conditions of $(CO_2)_I$: 6 cc/s and $(SO_2)_I$: 0.03 cc/s, the measured oxygen partial pressure showed a good agreement with the calculated value [P_{O_2}(obsd) $= 10^{-4.33}$ atm, P_{O_2}(calcd) $= 10^{-4.35}$ atm], and the results corresponded reasonably to the experiments at 1250 and 1300 °C, *i.e.*, under the conditions of $(CO_2)_I$: 6 cc/s and (SO_2): 0.03 cc/s. At these three temperatures, P_{SO_2} and P_{SO_3} were nearly the same and were calculated to be $10^{-2.3}$ atm and $10^{-5.6}$ atm respectively. In Fig. 8, the sulfate content in each melt is plotted against $1/T$, where T is the absolute temperature. This shows that the solubility of the sulfate decreases with an increase in the temperature. Moreover, from Fig. 8, the following empirical equations were obtained:

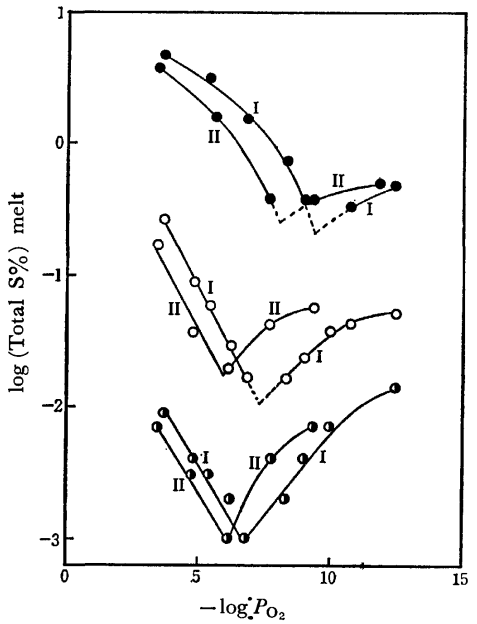

Fig. 7. Variation of sulfur content of Na_2O-SiO_2 melts with partial pressure of oxygen at 1250 °C and 1300 °C and at 0.5% of $(SO_2)_I$. I at 1250 °C, II at 1300 °C.

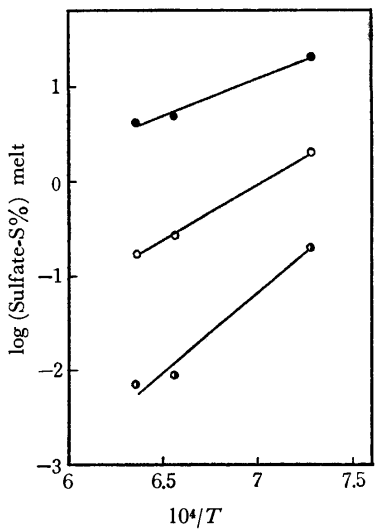

Fig. 8. Change of sulfate-solubility with temperature. [$(CO_2)_I$: 6 cc/sec, $(SO_2)_I$: 0.03 cc/s]

$$\log (\%S)_{melt} = 0.76 \times \frac{10^4}{T} - 4.2$$

for Na_2O-SiO_2 (1:1) melt

$$\log (\%S)_{melt} = 1.16 \times \frac{10^4}{T} - 8.1$$

for Na_2O-SiO_2 (1:2) melt

$$\log (\%S)_{melt} = 1.74 \times \frac{10^4}{T} - 13.4$$

for Na_2O-SiO_2 (1:3) melt

The change in solubility with the temperature can be written as in following equation[14]: $R \ln a = \bar{L}/T +$ constant, where R is the gas constant, a is the activity of solute, and $\bar{L}$ is the relative partial molal enthalpy of a solution. When this equation is compared with the above three ones, it is found that the relative partial molal enthalpies have positive values. However, the change in the solubility of sulfur in the form of sulfide with the temperature is complicated, and it was impossible to obtain a simple relation similar to that obtained above for the sulfate solubility.

The authors wish to thank Dr. Hisajiro Osada of the Tokyo Institute of Technology for his help in calculating the partial pressures of gaseous species. The authors also wish to thank Dr. Takejiro Ozawa and Mr. Kenzo Kitayama of the Tokyo Institute of Technology for their encouragement and many discussions during this study.

Stereoselectivity in Mixed Tris-type Complexes of Cobalt(III) with L-Proline and L- or D-Aspartic Acid[1]

Toshitsugu MATSUDA and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received March 22, 1973)

Mixed complexes with L-proline and L- or D-aspartic acid, $[Co(L\text{-pro})_{3-n}(L\text{-(or D-)asp})_n]^{n-}$ (n=1,2), have been prepared and separated into a number of stereoisomers by means of ion-exchange chromatography. The structures of the isomers have been characterized by various spectral data. As to the $[Co(L\text{-pro})(D\text{-asp})_2]^{2-}$ and $[Co(L\text{-pro})_2(D\text{-asp})]^{-}$ complexes, all of three possible *mer*-isomers have been isolated in their Δ-forms. The formation ratios among the isomeric species in the reaction system have been estimated spectrophotometrically. Marked differences in stereoselectivity have been found between the L-aspartato complexes and the corresponding D-aspartato complexes. These selectivities have been qualitatively explained in terms of the interaction between the dangling β-carboxylate group in a chelated aspartate ion and the adjacent ligand.

Through several experiments on the stereoselectivity in mixed-ligand complexes of cobalt(III) containing L-aspartic acid as a bidentate ligand, we have isolated a number of complexes and ascertained their stereoselective formations in various degrees.[2-5] In comparison with these aspartato complexes, the mixed complexes containing L-glutamic acid have also been investigated.[6] On the other hand, Denning and Piper[7] have obtained three of the four possible isomers of tris(L-prolinato)cobalt(III) in different yields; they have said that the absence of one isomer (*i.e.*, *mer*-Λ) is predictable on steric grounds. Yasui *et al.*[8] have obtained only one isomer (*i. e.*, *fac*-Λ), consistent with the consideration of the molecular models.

Thus, in the present work L- or D-aspartic acid and L-proline were chosen as the ligands. That is, two series of complexes, $[Co(L\text{-pro})_{3-n}(L\text{-asp})_n]^{n-}$ and $[Co(L\text{-pro})_{3-n}(D\text{-asp})_n]^{n-}$ (n=1,2), have been prepared, and their diastereoisomers have been isolated. These isomers have been characterized on the basis of the spectral data; the degree of the stereoselectivity has also been evaluated spectrometrically.

Experimental

Preparations. Freshly prepared (7.2 g, 0.02 mol) sodium tricarbonatocobaltate(III) trihydrate[9] and 4.6 g (0.04 mol) of L-proline were dissolved in 50 ml of water; the mixture was then stirred at 60 °C for 2 hr, whereupon the solution became blue-violet in color. Then, 4.0 g (0.03 mol) of L-aspartic acid was added to the above solution. After activated charcoal (1.0 g) had then been added, the reaction mixture was stirred for an additional 3 hr at 60 °C; the solution turned red-violet, and a small amount of a water-insoluble material was precipitated. After the removal of the precipitates and charcoal by filtration, the filtrate was passed through a column containing a cation-exchange resin in hydrogen form (Dowex 50W-X8, 100—200 mesh). By this treatment, the coexisting $[CoCO_3(L\text{-pro})_2]^{-}$ species was converted to a cationic species, which was adsorbed on the column. The effluent was adjusted to pH ~8.5 with an aqueous solution of sodium hydroxide. The resulting solution was charged on an anion-exchange resin column containing 100—200 mesh Dowex 1-X8 in chloride form (column diameter, 7.0 cm; resin height, 45 cm). The same experiment was then carried out using D-aspartic acid instead of L-aspartic acid.

When water was passed through the column, a non-charged tris(L-prolinato)cobalt(III) complex flowed out. Then, chromatographic separation was carried out with a $CaCl_2$ solution (prepared initially in 0.03 M and finally in 0.05 M) at the rate of *ca.* 0.5 ml/min. Through the prolonged elutions, five bands for the L-aspartato-L-prolinato series complexes and ten bands for the D-aspartato-L-prolinato series complexes were separated. These eluted bands were collected in fractions and labeled from L-1 to L-5 for the L-aspartato complexes and from D-1 to D-10 for the D-aspartato complexes, according to the elution order. The four fractions of L-1, L-3, D-5 and D-10 were colored red, and the other fractions, violet. Except the L-2, L-5 and D-4 fractions, each of the other fraction was concentrated to a small volume under reduced pressure at a temperature below 35 °C. Ethanol was added to the concentrate to precipitate calcium salt of the desired isomer. This crude salt was dissolved in a small amount of water, and then the solution was passed through a column containing Dowex 50W-X8 resin in hydrogen form. By this chromatographic procedure, each salt obtained from the L-3 and D-3 fractions was separated into two bands, alternately colored violet and red. These were again labeled as L-3′ and L-3″, and as D-3′ and D-3″. All the effluents thus obtained were evaporated to dryness at 35 °C, and the following procedures were employed. Each residue of the D-2, D-3′, D-5, D-7, and D-8 fractions was dissolved in a minimum amount of water, and acetone was added. After that, the solution was kept in an ice-box for several days to crystallize a hydrogen compound of each isomer. On the other hand, each residue of the L-1, L-3″, D-1, D-3″, D-6, D-9, and D-10 fractions was dissolved in an aqueous solution slightly alkalined with a Na_2CO_3 solution; the solution was then acidified with aqueous hydrochloric acid to precipitate the desired isomer as the hydrogen compound. Each residue obtained from the L-3′ and L-4 fractions was dissolved in a minimum amount of water, after which the solution was passed again through a Dowex 50W-X8 column in hydrogen form. The effluent was evaporated

a) Measured in 60% perchloric acid. b) ( ): calcd. c) Because of the poor yield, no elemental analyses were carried out.

to dryness at 30 °C. A violet, glassy material was thus obtained.

To the L–2 and D–4 fractions, acetone was added to precipitate calcium salts of the complexes. Attempts to isolate these isomers as hydrogen compounds were unsuccessful. The remaining fraction, L–5, was once concentrated to precipitate crude calcium salt, and the crude material was dissolved in 60% perchloric acid. When an aqueous NaOH solution was added to the solution drop by drop, the hydrogen compound of the complex began to precipitate.

The recrystallizations were repeated with all the compounds except those obtained from the L-3′ and L–4 fractions until their main CD peaks showed constant intensities. The results of the elemental analyses are summarized in Table 1.

Formation Ratios. From the spectral data of the fractions, the formation ratios among the bands separated chromatographically were evaluated. For some isomers not isolated as crystals, we assumed their ε values from the known ε values of the corresponding isomers (that is, 100 for the D–1 and 120 for the D–5).

Measurements. The absorption spectra were measured with a Hitachi Perkin-Elmer Model 139 UV-VIS spectrophotometer. The circular dichroism spectra were recorded on a JASCO Model ORD/UV-5 spectropolarimeter. The proton magnetic resonance spectra were recorded on a JEOL Model C–60H spectrometer at about 25 °C, using deuterium oxide containing an equivalent mole of Na_2CO_3 as the solvent. The values of the chemical shifts were referred to internal sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS).

Results and Discussion

Characterization of the Isomers. From the results of the elemental analyses and the elution order, it was apparent that the compounds obtained from the L–1 and L–2 fractions were the isomers of the bis(L-prolinato)L-aspartatocobaltate(III) complex, while the compounds obtained from the L–3′, L–3″, L–4, and L–5 fractions were the isomers of the L-prolinatobis(L-aspartato)cobaltate(III) complex. Likewise, for the D-aspartato complexes, it was apparent that the compounds obtained from the D–1∼D–5 fractions were the isomers of the bis(L-prolinato)D-aspartatocobaltate(III) complex, and that the compounds from the D–6∼D–10 fractions were the isomers of L-prolinatobis(D-aspartato)cobaltate(III), although for the compounds from the D–1 and D–5 fractions we have no results of elemental analyses because of their extremely poor yields. The geometrical form (*mer* or *fac*) of each compound could easily be identified on the basis

of its absorption spectrum; the violet compounds could be identified as *mer* forms, and the red ones, as *fac* forms. The absorption spectral data in 60% perchloric acid are given in Table 1. The absolute configurations of the isomers were determined from the signs of the main CD peaks in the first absorption band region. The CD spectra of the isolated compounds

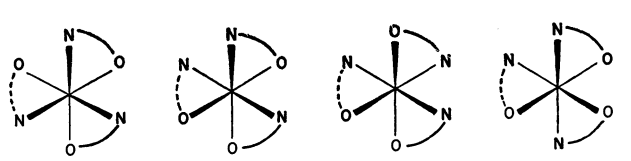
are shown in Figs. 1—3.

Through the experiments, an interesting fact has been found with regard to the elution order; for the D-aspartato complexes, the *mer* isomers were eluted earlier than the corresponding *fac* ones. This was a general trend in geometrical isomers of a complex. However, for the L-aspartato complexes, the *fac* isomers were eluted earlier than the corresponding *mer* ones.

Structure of mer *Isomers.* In a tris-chelated complex with two kinds of α-aminoacidato ligands, three geometrical isomers are possible for the *mer* form (Fig. 4). In our previous works,[3,6] at least two isomers among the three have been found. In the present work, three isomers were separated for the *mer*-*Δ*-[Co(L-pro)(D-asp)$_2$]$^{2-}$ species. For the sake of convenience, these will be labeled *mer*-1-*Δ*, *mer*-2-*Δ*, and *mer*-3-*Δ*, according to the elution order. The absorption spectra of these isomers are shown in Fig. 5. These spectra, as well as the CD spectra (Fig. 2), exhibit different shapes among the three isomers.

With the *mer*-[Co(L-pro)(L-asp)$_2$]$^{2-}$ complex, only one isomer of the *Δ* form was isolated (see Table 2), and no other two isomers of the same form were detected. The molecular models for the three possible isomers of this *Δ* form indicate that a certain steric interaction exists between a pyrrolidine ring of the chelated L-prolinate ion and a side-chain of a chelated L-aspartate in the geometry of each *cis*(N)*cis*(O) and *trans*(N)*cis*(O), while no such interaction exists in the geometry of *cis*(N)*trans*(O). From these facts, it may



fac *cis*(N)*cis*(O) *cis*(N)*trans*(O) *trans*(N)*cis*(O)
mer

be considered that formations of the isomers of both *cis*(N)*cis*(O) and *trans*(N)*cis*(O) will be less favored than that of the isomer of *cis*(N)*trans*(O). This consideration leads to the conclusion that the *mer*-*Λ*-[Co(L-pro)-(L-aspH)$_2$] complex, in which only one *Λ*-isomer is isolated, has the *cis*(N)*trans*(O) structure.

The PMR spectra concerning the methylene proton signals due to the coordinated aspartate ions in the bis(aspartato) complexes are shown in Fig. 6. Each spectrum is characteristic of each isomer. For the CH_2 signal of an aspartate ion, the AB portion of a ABX pattern is expected, and the separation width of the appeared doublet is represented by the expression of $(J_{AX}+J_{BX})/2$.[10] Moreover, since the vicinal coupling constant depends on the dihedral angle,[11] it is considered that the width of the doublet reflects the orientation of the side-chain of the coordinated aspartate. From this point of view, it is considered that two side-chains of the aspartate ions in the *mer*-1-*Δ* isomer are oriented differently, for considerably different widths are observed (Fig. 6(a)). Separately, measurements with the *fac*-[Co(L-asp)$_3$]$^{3-}$ complexes gave different spectra between the *Δ* and *Λ* isomers

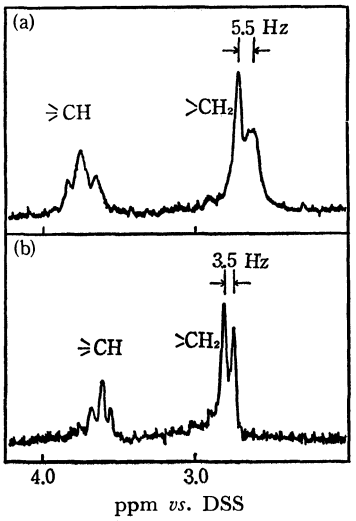

Fig. 7. PMR spectra of *fac*-[Co(L-asp)$_3$]$^{3-}$ in D_2O (pD ~8)
(a) *fac*-*Λ* isomer (b) *fac*-*Δ* isomer

(Fig. 7); the *Λ* isomer exhibits a more separated doublet than the *Δ* isomer. This fact means that the orientations of the aspartate side-chain will be affected by the interactions of the *β*-carboxylate groups with adjacent ligands. Thus, it is considered on the basis of a comparison of the spectra (c) and (d) in Fig. 6 that the *mer*-3-*Δ* isomer of the bis(D-aspartato) complex and the *mer*-*Λ* isomer of the bis(L-aspartato) complex have the same geometry, *cis*(N)*trans*(O). In this geometry, both *β*-carboxylate groups in an isomer are able to interact equally with the adjacent NH_2 groups, while in the other geometries one *β*-carboxylate interacts with the NH_2 group and the other *β*-carboxylate, with adjacent carboxylate group. The structural assignments of the other *mer*-1-*Δ* and *mer*-2-*Δ* complexes are difficult at present. For the [Co(L-pro)$_2$(D-asp)]$^-$ complex, three *mer*-*Δ* isomers have been isolated, but their geometrical assignments are also difficult.

Absorption and CD Spectra. Figure 8 shows the absorption spectra of the *fac*-*Δ*-[Co(L-pro)$_{3-n}$(L-aspH)$_n$]

a) No analyses.

(n=1,2,3) and *fac*-Λ-$[Co(L\text{-pro})(D\text{-aspH})_2]$ complexes. In the L-aspartato complex species, both the first and second absorption bands show bathochromic shifts with an increase in the number of the chelated proline, as is to be expected from a weaker ligand field of a secondary amine group than that of primary amine. Moreover, the differences in the absorption and CD spectral data (Table 1) among the three *mer*-Δ isomers of the $[Co(L\text{-pro})(D\text{-aspH})_2]$ complex seem to be attributable mainly to a weaker ligand field of secondary amine group of proline. It is interesting that the absorption maxima of the *fac*-Λ-$[Co(L\text{-pro})(D\text{-aspH})_2]$ (D–10) complex are observed at a lower energy than the maxima of the *fac*-Δ-$[Co(L\text{-pro})(L\text{-aspH})_2]$ (L–3'') complex. The former complex differs from the latter merely in the orientation of the pyrrolidine ring of the chelated proline, since the mirror image of the *fac*-Λ-$[Co(L\text{-pro})(D\text{-asp})_2]^{2-}$ is the *fac*-Δ-$[Co(D\text{-pro})(L\text{-asp})_2]^{2-}$.

Stereoselectivity. Each fraction separated chromatographically showed distinctly a plus or a minus CD sign in the first absorption-band region. With each fraction, the ratio of the observed intensity of the main CD peak to the absorbance at the Band I maximum was estimated. On the other hand, the ratio of the $\Delta\varepsilon_{max}$ to the ε_{max} of Band I was estimated with each complex isolated. When the former ratio was divided by the latter, the quotient was within 0.8~1 in all the fractions. Since this fact indicated that only one isomer predominated in each fraction, the minor species were ignored in evaluating the formation ratios. The results are given in Table 2.

In the bis(L-aspartato) complex species, the selective formation of the Δ isomer is found for the *fac* form, while the selective formation of the Λ isomer is found for the *mer* form. In the bis(D-aspartato) complex species, the Λ isomer for the *fac* form and the Δ isomer for the *mer* are found preferentially. The *fac*/*mer* ratios have been estimated as *ca.* 1/2 and 1/4.6 for the bis(L-aspartato) and the bis(D-aspartato) complex species respectively.

In the bis(L-prolinato) species, remarkable differences in selectivity occur depending upon the optical form of the chelated aspartate ion (*i.e.*, L or D). The L-aspartato complex species exhibit preferential formations of Δ isomers for both the *fac* and *mer* forms. The *fac*/*mer* ratio is estimated as 1/3.5. On the other hand, the D-aspartato complex species exhibit a preferential formation of the Δ isomer for the *mer* form, while no preferential formation is observed in the *fac* form, and the formation amounts themselves are very poor; the *fac*/*mer* ratio is estimated to be *ca.* 1/35, indicating serious inter-ligand interactions.

Until now, the selectivity in the mixed L-aspartato complexes with other amino acids[2,3] or diamines[4,5] has been interpreted in terms of hydrogen-bonding between the β-carboxylate group of the chelated L-aspartate ion and the amino group in the adjacent ligand. The stereoselectivity observed in this study can also be interpreted in this way. The interactions between the side-chain of an aspartate ion and the adjacent ligand can now be classified into the following four types from the stereo models: (A) a favorable interaction through a hydrogen bond, in which the apical position (a) in Fig. 9 is occupied by an amino group; (B) an electrostatic repulsive interaction between the β-carboxylate group and the chelated oxygen atom occupying the apical position (a); (C) some interactions of the side-chain with the pyrrolidine ring of the chelated proline, in which hydrogen-bonding is not favorable because of the existence of the pyrrolidine ring; (D) a marked steric crowding

TABLE 3. INTERACTION OF THE SIDE-CHAIN OF COORDINATED ASPARTATE

Complex \ Isomer	Config.	*fac*	*mer*		
			cis(N)*cis*(O)	*cis*(N)*trans*(O)	*trans*(N)*cis*(O)
$Co(L\text{-pro})_2(L\text{-asp})^-$	Δ	A	B	B	A
	Λ	B	D	B(X)	D
$Co(L\text{-pro})(L\text{-asp})_2^{2-}$	Δ	A A	A B	A B	B B
	Λ	B B	B D	A A	B D
$Co(L\text{-pro})_2(D\text{-asp})^-$	Δ	B	A	B	A
	Λ	C	B	B(X)	C
$Co(L\text{-pro})(D\text{-asp})_2^{2-}$	Δ	B B	A B	A A	A B
	Λ	A C	A B	B C	B B

A: polar interaction with the amino group in the adjacent ligand. B: polar interaction with the carboxylate group in the adjacent ligand. C: some interaction with the pyrrolidine ring. D: steric interaction with the pyrrolidine ring. X: steric interaction between two pyrrolidine rings.

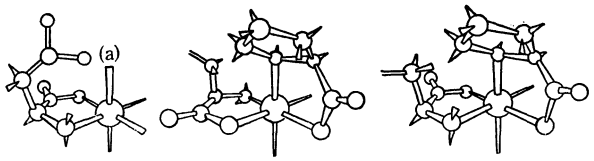

Fig. 9. Interactions of coordinated aspartate.

between the pyrrolidine ring and the side-chain of the chelated aspartate ion. These four types are drawn in Fig. 9. The relation between the types and the geometrical arrangements are given in Table 3. In this table, the symbol X expresses the existence of a steric hindrance between the two pyrrolidine rings.

Thus, the preferential formations of the Δ isomer in the *fac*-[Co(L-pro)(L-asp)$_2$]$^{2-}$ and of the Λ isomer in the *fac*-[Co(L-pro)(D-asp)$_2$]$^{2-}$ can be explained by the favorable interaction of Type A. The preference of the Δ isomers in the *mer*-[Co(L-pro)$_2$(D-asp)]$^-$ can also be explained in this way. The preferential formation of the Λ isomers in the *mer*-[Co(L-pro)$_2$(L-asp)]$^-$ can be explained by considering there to be less stability in the opposed Λ isomers containing the interactions of Types D and X. Moreover, the poorer formation of the *fac* isomers of the [Co(L-pro)$_2$(D-asp)]$^-$ complex than of the *mer* ones can be interpreted in terms of the lack of a favorable interaction of Type A.

Molecular Complexes of Arenetricarbonylchromium

Hiroshi KOBAYASHI, Mitaka KOBAYASHI, and Youkoh KAIZU

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 11, 1973)

Arenetricarbonylchromium forms a charge-transfer molecular complex with electron acceptors such as 1,3,5-trinitrobenzene and tetracyanoethylene but not with electron donors such as *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine. The ionization potentials of arenetricarbonylchromium complexes were determined from the charge-transfer transition energies in the molecular complexes. The molecular complexes are formed by a charge-transfer interaction of electron acceptor toward the π-coordinating benzene ring of arenetricarbonylchromium in the case of 1,3,5-trinitrobenzene, and by a charge-transfer toward the central chromium in the case of tetracyanoethylene.

Effects of the tricarbonylchromium group on the chemical properties of the π-coordinating benzene ring in arenetricarbonylchromium are more likely those of an electron-withdrawing group such as a para-nitro substituent. In fact, pK_a of phenylacetic acid coordinating to tricarbonylchromium is as high as that of *p*-nitrophenylacetic acid. Benzoic acid-tricarbonylchromium is an acid stronger than benzoic acid and anilinetricarbonylchromium is a base weaker than aniline.[1,2] Furthermore arenetricarbonylchromium complexes show a higher susceptibility to nucleophilic substitutions such as[1,3]

$$C_6H_5ClCr(CO)_3 \xrightarrow{NaOCH_3} C_6H_5OCH_3Cr(CO)_3$$

whereas the complexes are less susceptible to electrophilic substitutions such as Friedel-Crafts acylation.[4] This indicates an electron-withdrawing effect of tricarbonylchromium group. Larger dipole moments of arenetricarbonylchromium complexes might indicate a large charge-migration toward tricarbonylchromium.[5-7]

In the present work, arenetricarbonylchromium complexes were found to behave as electron donor rather than electron acceptor in charge-transfer molecular complex formation. Arenetricarbonylchromium forms molecular complexes with 1,3,5-trinitrobenzene (1,3,5-TNB) and tetracyanoethylene (TCNE) but not with *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD). Bis-π-benzenechromium, however, forms a 1 : 1 salt-like molecular complex with TCNE described as $[\pi\text{-}(C_6H_6)_2Cr]^+TCNE^-$.[8] Arenetricarbonylchromium is not so readily oxidized as bis-π-benzenechromium but a charge-transfer molecular complex formation of arenetricarbonylchromium with 1,3,5-TNB has been reported.[9-10] An X-ray crystallography study has revealed a geometry of "face to face" contact of the counterpart benzene rings in a molecular complex of anisoletricarbonylchromium and 1,3,5-TNB.[11] We have obtained the ionization potentials of arenetricarbonylchromium complexes from the charge-transfer transition energies in the molecular complexes of

arenetricarbonylchromium with TCNE or 1,3,5-TNB.

Experimental

Materials. Arenetricarbonylchromium complexes were prepared according to the methods in the literature[1] by refluxing hexacarbonylchromium (High Pressure Chem. Co. Penn. U.S.A.) with the corresponding benzene derivatives under dry nitrogen atmosphere. For the arenes of low boiling point such as fluorobenzene, chlorobenzene, benzene, toluene, and acetophenone, diglyme was used as solvent. Solid benzoic acid was also dissolved in diglyme. The refluxed mixture was filtered, the filtrate being then condensed by vacuum distillation. The residue thus obtained was recrystallized from petroleum ether. The complexes were identified by elemental analysis (Table 1). Diglyme, petroleum ether and benzene derivatives used for the preparation of arenetricarbonylchromium complexes were dried and distilled by the usual methods.[12]

N,N,N',N'-Tetramethyl-*p*-phenylenediamine (TMPD) dihydrochloride (Tokyo Kasei Co.) was neutralized with NaOH and the free amine thus obtained was purified by vacuum distillation. 1,3,5-Trinitrobenzene (1,3,5-TNB, Tokyo Kasei Co.) was recrystallized from dil HNO_3 and then from ethanol. Tetracyanoethylene (TCNE, Tokyo Kasei Co.) was recrystallized from chlorobenzene.

Preparation of Molecular Complexes with 1,3,5-*Trinitrobenzene.* 150 mg of toluenetricarbonylchromium (tolueneCr$(CO)_3$) in 5 ml *n*-heptane and 70 mg of 1,3,5-TNB in 5 ml *n*-heptane were separately heated up to 80 °C and then mixed. When the solution was cooled, red crystals of a 1 : 1 molecular complex of tolueneCr$(CO)_3$ and 1,3,5-TNB were precipitated. The complex was repeatedly recrystallized from *n*-heptane. mp 85.5—86.0 °C (mp of tolueneCr$(CO)_3$: 80.0—81.0 °C; mp of 1,3,5-TNB: 123.0—123.5 °C).

Found: C, 43.0; H, 2.3; N, 10.1; Cr, 11.8%. Calcd for $C_{16}H_{11}N_3O_9Cr$: C, 43.5; H, 2.5; N, 9.5; Cr, 11.8%. Chromium was determined by colorimetry after carbonate fusion.

The 1 : 1 1,3,5-TNB molecular complexes of *o*-xyleneCr$(CO)_3$, *N,N*-dimethylanilineCr$(CO)_3$ and anisoleCr$(CO)_3$ were prepared by similar methods: *o*-xyleneCr$(CO)_3$–1,3,5-TNB mp 86.0—87.0 °C (mp of *o*-xyleneCr$(CO)_3$: 90.0—90.5 °C).

Found: C, 44.9; H, 2.8; N, 9.3; Cr, 11.7%. Calcd for $C_{17}H_{13}N_3O_9Cr$: C, 44.9; H, 2.9; N, 9.2; Cr, 11.4%. *N,N*-dimethylanilineCr$(CO)_3$·1,3,5-TNB mp 102.0—102.5 °C (mp of *N,N*-dimethylanilineCr$(CO)_3$: 143.5—144.0 °C).

Found: C, 43.5; H, 2.8; N, 12.3; Cr, 11.2%. Calcd for $C_{17}H_{14}N_4O_9Cr$: C, 43.4; H, 3.0; N, 11.9; Cr, 11.1%. AnisoleCr$(CO)_3$·1,3,5-TNB mp 93.0—93.5 °C (mp of anisoleCr$(CO)_3$: 84.5—85.0 °C).

Found: C, 42.1; H, 2.2; N, 9.4; Cr, 11.3%. Calcd for $C_{16}H_{11}N_3O_{10}Cr$: C, 42.0; H, 2.4; N, 9.2; Cr, 11.4%.

Measurements of Absorption Spectra and Determination of the Complex Formation Constants. Absorption spectra were recorded on a Shimadzu automatic recording spectrophotometer Model MPS-50. The cell compartment was thermostatted at a constant temperature (25 °C).

The solvent 1,2-dichloroethane (Wako Pure Chem. Co.) was dried and purified by the usual procedure.[12]

The equilibrium constant K of a 1 : 1 molecular complex formation between electron donor D and electron acceptor A is given by

$$K = \frac{[D\cdot A]}{([D]_0-[D\cdot A])([A]_0-[D\cdot A])},$$

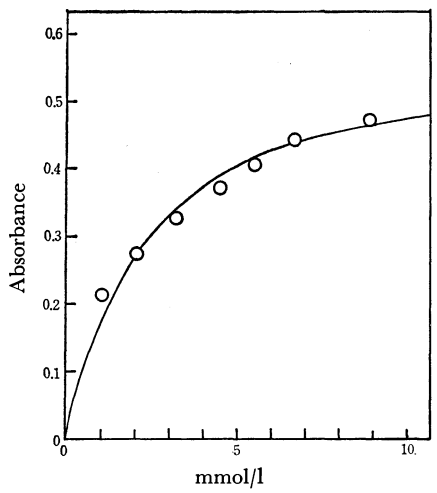

Fig. 1. Change of the absorbance at 13800 cm^{-1} in the charge-transfer band of 1:1 molecular complex of tolueneCr$(CO)_3$ and TCNE as a function of the initial concentration of tolueneCr$(CO)_3$ at 25°C.
$[TCNE]_0 = 1.06\times10^{-3}$ $mol\cdot l^{-1}$.

12) D. D. Perrin, W. L. F. Armarego, and D. R. Perrin, "Purification of Laboratory Chemicals," Pergamon Press, Oxford (1966).

where $[\ ]_0$ denotes the initial concentrations, and [D·A], the concentration of molecular complex D·A. Measurements were carried out at a wave number in the charge-transfer band of the molecular complex where molar absorption coefficients ε_D and ε_A are negligibly small. Assuming Beer's law, [D·A] is rewritten in terms of the observed absorbance $E=\varepsilon_C\cdot[D\cdot A]\cdot l$, where ε_C is the molar absorption coefficient of molecular complex formed in solution, and l, the optical path length. Thus it follows that

$$[D]_0[A]_0\, l/E = \{[D]_0+[A]_0-E/\varepsilon_C\cdot l\}\cdot 1/\varepsilon_C+1/K\varepsilon_C\,.$$

Measurements were carried out at 25 °C for various initial concentrations of D and A. K and ε_C were then evaluated according to the methods described by Rose and Drago,[13] and Lang.[14] In Fig. 1, the absorbance measured at 13800 cm^{-1} is shown as a function of the initial concentration o toluene$Cr(CO)_3$ in the presence of constant initial concentration of TCNE (1.06×10^{-3} mol·l^{-1}). Plots of $[D]_0[A]_0l/E$ *versus* $\{[D]_0+[A]_0-E/\varepsilon_C\cdot l\}$ give a straight line (Fig. 2) for a self-consistent value of ε_C obtained by iterative calculations.

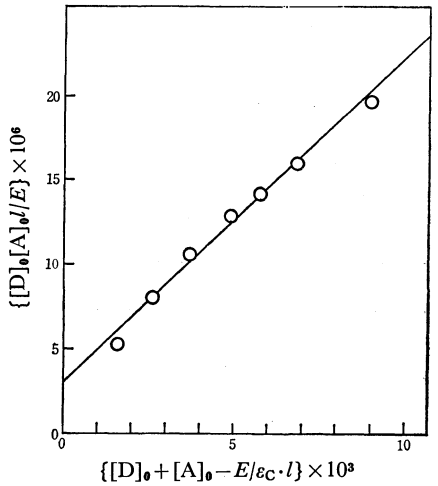

Fig. 2. Plots of $[D]_0[A]_0\cdot l/E$ *versus* $\{[D]_0+[A]_0-E/\varepsilon_C\cdot l\}$ for a self-consistent of ε_C at 25 °C. $[D]_0\equiv$[toluene-$Cr(CO)_3$]$_0$; $[A]_0\equiv[TCNE]_0=1.06\times10^{-3}$ mol·l^{-1}; $\varepsilon_C=520$.

Infrared Absorption Spectra. Infrared absorption spectra of arenetricarbonylchromium complexes and their molecular complexes with 1,3,5-TNB were taken on a Hitachi spectrophotometer Model EPI-G3.

NMR and ESR Spectra. NMR spectra in 1,2-dichloroethane were recorded on a 60 MHz Varian spectrometer Model T-60. Tetramethylsilane was used as an internal standard. ESR spectra in 1,2-dichloroethane were measured with a Japan Electron Optics Laboratory Co. spectrometer Model JES-3BX.

Results and Discussion

No molecular complex formation of arenetricarbonylchromium with electron-donating TMPD was detected in the absorption measurements. We have not succeeded so far in the isolation of a molecular complex of arenetricarbonylchromium with TMPD, but some 1 : 1 molecular complexes with 1,3,5-TNB could be isolated in a pure state. A charge-transfer band at 20200 cm^{-1} (Fig. 3) implies a molecular complex formation between toluene$Cr(CO)_3$ and 1,3,5-TNB in 1,2-dichloroethane. Molar absorption coefficient of the molecular complex and the equilibrium constant of complex formation were determined to be $\varepsilon_C=55$ l·mol^{-1}·cm^{-1} and $K=70$ l·mol^{-1} at 25 °C from the measurements for various initial concentrations of toluene$Cr(CO)_3$ and 1,3,5-TNB. Since TCNE is a stronger acceptor than 1,3,5-TNB and thus the charge-transfer band in the molecular complex with TCNE shows a remarkable shift toward lower wave number, a good resolution of the charge-transfer band is ob-

tained as shown in Fig. 4. Molar absorption coefficients and complex formation constants of 1 : 1 molecular complexes of arenetricarbonylchromium with 1,3,5-TNB or TCNE are given in Table 2.

Although an ESR signal has been reported for bis-π-benzenechromium with TCNE,[8] no signal was found for the molecular complexes of arenetricarbonylchromium with 1,3,5-TNB or TCNE formed in 1,2-dichloroethane. Thus their ground state should be a singlet. In fact, proton NMR spectra were observed in the usual region even when most part of the arenetricarbonylchromium complex present in solution forms a molecular complex with acceptor. Since no appreciable shift was observed in molecular complex formation, no further information has been obtained from the NMR spectra.

The charge-transfer transition energies of the molecular complexes with a common acceptor are given by a linear function of the ionization potential I_p of the donor

$$h\nu_{CT} = \{I_p - C_1\} + C_2/\{I_p - C_1\},$$

where C_1 and C_2 are constants determined only by the acceptor. The values given for 1,3,5-TNB are $C_1 = 5.00$ and $C_2 = 0.70$,[15] and for TCNE, $C_1 = 6.10$ and $C_2 = 0.54$.[16] The ionization potential of toluene$Cr(CO)_3$ was estimated to be 7.18 eV from the charge-transfer excitation energy in a molecular complex with 1,3,5-TNB, and 7.40 eV from the one with TCNE.

1) Ref. 19. 2) Ref. 20. 3) Ref. 18; evaluated from the charge-transfer excitation energies in the molecular complexes with TCNE. 4) determined in the present work. 5) Plots shown in Fig. 5 predict I_p=9.42 eV from the observed carbonyl stretching frequency in $C_6H_5COCH_3Cr(CO)_3$ 1979 cm^{-1}. The charge-transfer band in the molecular complex with TCNE is not well resolved from the (n, π^*) transition of $C_6H_5COCH_3$ and thus the ionization potential is not determined directly by method 3).

The ionization potential of toluene in the molecular complex with 1,3,5-TNB is 8.91 eV,[17] while that in the complex with TCNE is 8.90 eV.[18] The ionization potential of toluene$Cr(CO)_3$ is lower than that of free toluene by 1.73 eV in the complex with 1,3,5-TNB and 1.5 eV in that with TCNE. The ionization potentials of some arenes and their coresponding arenetricarbonylchromium complexes, evaluated from the charge-transfer excitation energies in the molecular complexes with 1,3,5-TNB and TCNE, are given in Table 3. The empirical linear functions used to estimate the ionization potentials of arenetricarbonylchromium complexes originally fitted naphthalene.[15,16] The functions, however, can well reproduce the ionization potentials of various aromatic hydrocarbons and show a difference of less than 0.1 eV of the ionization potentials obtained for molecular complexes with 1,3,5-TNB and TCNE. It should be noted that the ionization potentials of arenes evaluated from the charge-transfer excitation energies agree in the 1,3,5-TNB and TCNE systems, whereas those of arenetricarbonylchromium complexes differ in the two systems beyond experimental error. The ionization potentials of arenetricarbonylchromium complexes in the TCNE system obtained are given in Table 4, together with the carbonyl stretching frequencies of arenetricarbonylchromium in 1,2-dichloroethane measured in the present work and those in cyclohexane taken from literature.[19,20] A shift of the infrared peak toward higher frequency was observed in the order

$$C_6H_5COOH > C_6H_5COCH_3 > C_6H_5F > C_6H_5Cl > C_6H_6 > C_6H_5CH_3 > C_6H_5OCH_3 > o\text{-}C_6H_4(CH_3)_2 \geqq m\text{-}C_6H_4(CH_3)_2 > p\text{-}C_6H_4(CH_3)_2 > 1,3,5\text{-}C_6H_3(CH_3)_3 > C_6H_5N(CH_3)_2 .$$

Arenes: 0, C_6H_5COOH; 1, $C_6H_5COCH_3$; 2, C_6H_5F; 3, C_6H_5Cl; 4, C_6H_6; 5, $C_6H_5CH_3$; 6, $C_6H_5OCH_3$; 7, *o*-$C_6H_4(CH_3)_2$; 8, *m*-$C_6H_4(CH_3)_2$; 9, *p*-$C_6H_4(CH_3)_2$; 10, 1,3,5-$C_6H_3(CH_3)_3$; 11, $C_6H_5N(CH_3)_2$.

When the antibonding orbital of carbonyl is given a certain charge by chromium-carbonyl back-donation, the carbonyl stretching frequency is shifted toward lower frequency. The above order was in good agreement with that observed in the ionization potentials of arenes (Fig. 5). The stronger donating arene gives rise to more back-donation from chromium to carbonyl groups in arenetricarbonylchromium complex. Plots of the ionization potentials of arenetricarbonylchromium in the molecular complexes with 1,3,5-TNB against the carbonyl frequencies give a straight line except the point of dimethylanilineCr(CO)$_3$, where the ionization potential is much reduced (Fig. 6).

However, it is evident that the ionization potential of arenetricarbonylchromium in the 1,3,5-TNB molecular complex decreases with a decrease in the ionization potential of coordinating arene. Since the coordinating arene enhances the charge density on carbonyl groups, the acceptor 1,3,5-TNB might exert a charge-transfer interaction toward the carbonyl groups other than the coordinating arene. Apparently no shift was observed in the carbonyl stretching frequencies upon molecular complex formation in solution. The molecular complexes even in the solid state showed no appreciable shift of the IR peaks except dimethylanilineCr$(CO)_3$ (Table 5). DimethylanilineCr$(CO)_3$ shows an appreciable shift of the carbonyl frequency in KBr disk, arising from an intermolecular interaction between dimethylanilineCr$(CO)_3$ in the solid state. Thus the remarkable difference of carbonyl stretching frequencies in the KBr disk of dimethylanilineCr$(CO)_3$ and its 1,3,5-TNB complex does not necessarily imply a reduction in the bond order of the carbonyl groups by a direct charge-transfer interaction of 1,3,5-TNB toward the carbonyl groups. In fact, the carbonyl stretching frequency makes no sizable shift in 1,2-dichloroethane solution, even when the concentrations of dimethylanilineCr$(CO)_3$ and 1,3,5-TNB were so chosen as to obtain an almost complete complex formation. An X-ray crystallography study of a molecular complex anisoleCr$(CO)_3$·1,3,5-TNB has revealed that the acceptor 1,3,5-TNB makes a charge-transfer interaction with coordinating arene rather than carbonyl groups.[11] The absorption spectra of the KBr disk of anisoleCr$(CO)_3$·1,3,5-TNB and dimethylanilineCr-

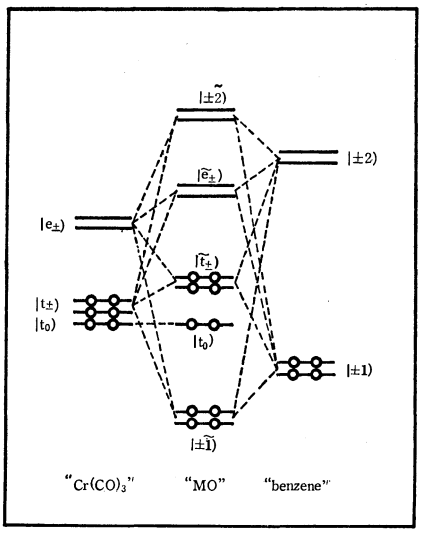

Fig. 8. Molecular orbital levels in arenetricarbonylchromium (schematic). "$Cr(CO)_3$" implies molecular orbitals mainly localized on zero-valent chromium d orbitals which are split by σ ligand field and π back-donation in tricarbonyl chromium, and "benzene" implies the highest occupied and the lowest vacant orbitals of benzene. Chromium d orbitals are given by

$$|e_+) = \sqrt{\frac{2}{3}}|+1) - \sqrt{\frac{1}{3}}|-2)$$

$$|e_-) = \sqrt{\frac{2}{3}}|-1) + \sqrt{\frac{1}{3}}|+2)$$

$$|t_+) = \sqrt{\frac{1}{3}}|+1) + \sqrt{\frac{2}{3}}|-2)$$

$$|t_-) = \sqrt{\frac{1}{3}}|-1) - \sqrt{\frac{2}{3}}|+2)$$

$$|t_0) = |0)$$

The MO's formed are denoted by ~with the name of a component orbital in the highest contribution.

$(CO)_3 \cdot$1,3,5-TNB were measured. The solid state spectra thus obtained were in good agreement with the solution spectra. This implies that the molecular complex formed in solution should have a similar geometry to the structure formed in the solid state. In the case of the TCNE complexes, however, the ionization potential increases with a decrease in the ionization potential of coordinating arene (Fig. 6). As Fig. 7 shows, the stability of molecular complexes with TCNE increases with a decrease in the ionization potential of arenetricarbonylchromium in the TCNE molecular complex and also a decrease in the charge-density of the carbonyl groups. No shift was observed in the carbonyl stretching frequencies upon molecular complex formation with TCNE. Thus it should be concluded that the acceptor TCNE makes a direct interaction with the central chromium.

Schematic molecular orbital levels of the outer electrons in arenetricarbonylchromium are shown in Fig. 8. An interaction of the highest filled benzene orbitals $|\pm1)$ and vacant chromium $d\sigma$ orbitals $|e_\pm)$ gives rise to a charge-migration from π-coordinating benzene to chromium. In the contrast, an interaction of the filled chromium orbitals $|t_\pm)$, participating in the back-donation in Cr–CO, and the lowest vacant benzene orbitals $|\pm2)$ gives a charge-migration from chromium $d\pi$ orbitals to coordinating benzene. A semi-empirical molecular orbital calculation predicted that the resulting charge-migration occurs from π-coordinating benzene to carbonyl groups.[21] Regardless of the charge-migration, the highest filled orbitals $|\pm1)$ are stabilized by interaction with the chromium $d\sigma$ orbitals $|e_\pm)$, leading to increase of the ionization potentials of coordinating arene. The ionization potential of arenetricarbonylchromium is a work to be done for detachment of an electron in the molecular orbital $|\tilde{t}_\pm)$ or $|t_0)$. The orbital $|t_0)$ is delocalized over the chromium and the carbonyls but has no population on the π-coordinating arene, whereas the orbitals $|\tilde{t}_\pm)$ have populations not only on the carbonyls but also on the π-coordinating arene.

When a molecular complex is formed by a charge-transfer interaction involving the orbital $|t_0)$, the acceptor accepts electronic charge from the carbonyl groups in an outer-sphere mechanism or directly from the central chromium in an inner-sphere mechanism. In fact, a protonation of arenetricarbonylchromium results in the formation of a hydrido complex,[22,23] in which a proton forms a direct binding with the central chromium. However, a bulky acceptor such as 1,3,5-TNB can not make an appreciable interaction with the chromium-localized $|t_0)$ orbital for steric hindrance, the molecular complex being formed by a charge-transfer interaction involving the molecular orbital $|\tilde{t}_\pm)$ delocalized over the π-coordinating benzene and carbonyl groups. Direct interaction between 1,3,5-TNB and carbonyl groups could be eliminated because of the small overlapping between the acceptor and carbonyl orbitals despite the high population of chromium $d\pi$ electron on the carbonyl groups.

In the case of TCNE, an enhancement in the charge-populations in π-coordinating arene and carbonyl groups of the donor reduces the stability of the molecular complex. Thus the acceptor TCNE makes direct interaction with the orbital $|t_0)$ localized on the central chromium by an inner-sphere mechanism, although TCNE is not so small. The stability of the molecular complex increases with a decrease in the ionization potential of the orbital $|t_0)$. With the decrease of ionization potential of arene the back-donation in Cr–CO is enhanced. By a charge-migration from the top filled orbitals $|\pm1)$ of arene, orbital $|t_0)$ is stabilized by an enhancement of the back-donation in Cr–CO, whereas orbital $|\tilde{t}_\pm)$ is rather destabilized. As is shown in Fig. 6, the ionization potential of arenetricarbonylchromium in the molecular complex with TCNE is the ionization potential of $|t_0)$, which increases with a decrease in the ionization potential of arene, while the ionization potential of arenetricarbonylchromium in the molecular complex with 1,3,5-TNB is the ionization potential of $|\tilde{t}_\pm)$, which decreases with a decrease in the ionization potential of arene.

Since orbital $|\pm1)$ of the π-coordinating arene is stabilized by interaction with orbital $|t_\pm)$, which makes

21) D. G. Carroll and S. P. McGlynn, *Inorg. Chem.*, **7**, 1285 (1968).

a charge-transfer from arene to chromium-carbonyl orbitals, the substitution reactions in the π-coordinating benzene ring are more likely those of the benzene ring with electron-withdrawing substituents. However, the chromium-localized orbitals $|t_0)$ and $|\tilde{t}_\pm)$ play important roles in the charge-transfer molecular complex formation, and thus arenetricarbonylchromium acts as an electron donor rather than an electron acceptor as shown in the nucleophilic substitutions in π-coordinating benzene ring of arenetricarbonylchromium. The acceptor TCNE can accept electronic charge by an inner-sphere interaction with orbital $|t_0)$ on the π-coordinating arene.

The authors wish to express their thanks to Professor Seinosuke Otsuka, Osaka University, for valuable discussions on the interaction of TCNE.

Circular Dichroism of Copper(II) Complexes with Optically Active Tetradentate Ligands in Aqueous Solutions

Tasuku MURAKAMI and Masahiro HATANO

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai 980

(Received April 17, 1973)

The circular dichroism(CD) spectra of copper(II) complexes containing the asymmetric tetradentate ligands, such as ethylenediamine-*N,N'*-di-L-α-propionate, ethylenediamine-*N,N'*-di-L-α-isovalerate, and ethylenediamine-*N,N'*-di-L-α-hydrocinnamate, were measured in an aqueous solution. Each of the CD curves can be resolved into four components in the d–d region by Gaussian analysis; these components are related to the four possible d–d transitions of the copper(II) ion. The visible CD spectrum profile of the complexes varies with the variation in ligands; this implies that the conformation of the complexes is affected appreciably by the bulkiness of the side chain in the ligand.

In the analyses of the absolute configurations of many metal complexes by means of CD measurements, the empirical rule, that the conformations of complexes containing similar ligands may be identical with each other when the CD spectra observed for these complexes resemble each other in shape and sign, has been very often employed. It has been reported that the copper(II) complexes containing a series of L-α-amino acids exhibit similar CD curves in an aqueous solution. Therefore, the conformations of these complexes seem to be identical with each other in an aqueous solution.[1-3]

In this study, we wish to report that the observed CD spectra of three copper(II) complexes containing optically active tetradentate ligands, prepared by joining the amino groups of identical amino acid with one ethylene group, are very different from each other, and that these complexes may adopt different conformations in an aqueous solution.

Experimental

The asymmetric tetradentate ligands used in this study are ethylenediamine-*N,N'*-di-L-α-propionic acid(abbreviated to $EDDPH_2$), ethylenediamine-*N,N'*-di-L-α-isovaleric acid ($EDDVH_2$), and ethylenediamine-*N,N'*-di-L-α-hydrocinnamic acid($EDDCH_2$), prepared from L-alanine, L-valine, and L-phenylalanine respectively by a method similar to that described in the literature.[4]

Each of the complex solutions for the spectral observation was prepared by mixing equimolar aliquots of an aqueous stock solution of copper(II) nitrate with the tetradentate acids. An equivalent quantity of a base (sodium hydroxide) was always added to assure the virtually complete formation of the complexes. The copper(II) solution was standardized by EDTA titration, using murexide as the metal-ion indicator.[5] The CD curves were obtained by means of a JASCO J-20A spectropolarimeter in the region from 200 to 1000 nm. The absorption measurements were made by means of a Hitachi EPS-3T spectrophotometer at room temperature.

Results and Discussion

The CD spectra of [Cu(EDDP)], [Cu(EDDV)], and [Cu(EDDC)] in an aqueous solution are shown in Fig. 1. The visible CD spectra are very different from each other. Especially, the main CD components of the two complexes, [Cu(EDDP)] and [Cu(EDDV)], are opposite in sign. Applying the "empirical rule" described above to the present case, it seems reasonable to expect that these complexes include different extents of some types of conformers in an aqueous solution.

By an examination of the molecular models, two conformations can be constructed for these complexes, as is illustrated in Fig. 2. In the (I) conformation the orientation of the ring substituent groups is equatorial,

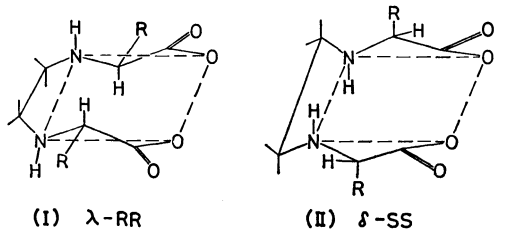

Fig. 2. The two possible conformers. The symbols δ and λ represent the conformations of the central en-type chelate ring, and R and S the configurations of the asymmetric donor nitrogen.

whereas in the (II) conformation the orientation is axial. In general, it is accepted that the equatorial orientation is more stable than the axial orientation in most chelate complexes. However, the energy difference between the two types of orientations of the substituent groups in the amino acid chelate portions of the present tetradentate ligands is much smaller than that in the en-type chelate ring, since, in the en-type chelate ring, the *gauche* structure discriminates greatly between the two orientations, whereas in the amino acid chelate ring this is not the case because of its planarity.[6] Furthermore, the energy difference between the two orientations in square-planar complexes can be expected to be much smaller than that in octahedral complexes. In square-planar complexes, the interaction of the axially-oriented substituent group with the molecules occupying the apical positions may be small.[7] Therefore, the energy difference between the two conformers, (I) and (II), in Fig. 2 seems to be not so large that an equilibrium may exist between the two conformers in an aqueous solution. The equilibrium distribution between the two conformers should vary with the bulkiness of the substituents; hence, these three complexes are speculated to have different equilibrium constants in (I)⇌(II). Thus, we seem to be able to account convincingly for the spectral results observed here in terms of the equilibrium.

If there is such an equilibrium in the complexes, an appreciable change in the CD curves of these complexes would be expected with a variation in the temperature because of the temperature dependence of the equilibrium. In practice, the CD curves observed for these complexes change considerably with a variation in the temperature, despite the limited temperature range. For example, the temperature dependence of the CD curve in the EDDV complex is shown in Fig. 3.

As the origins of the temperature dependence of the CD spectra, vibronic effects or an equilibrium between some conformers may be expected. Since it has been suggested that the magnitudes of the CD bands of metal complexes are only weakly influenced by the vibronic effects,[8] the temperature dependence may be mainly due to the existence of an equilibrium. Furthermore, the presence of an isosbestic point in Fig. 3 indicates the binary equilibrium. Thus, the temperature dependence observed here may be attributed to the equilibrium between the two conformers, (I) and (II), in Fig. 2.

It is clear that the visible CD spectra in Fig. 1 are composed of some d-d transition components. The observed shapes of the CD curves depend essentially on the relative magnitudes of these components, which should subsequently change with the variation in the equilibrium distribution described above. Therefore, it seemed that it would be worthwhile to resolve each of the CD spectra into their transition components.

Each of the visible CD spectra in Fig. 1 can be apparently resolved into four CD bands, although these four bands may not correspond exactly to the four com-

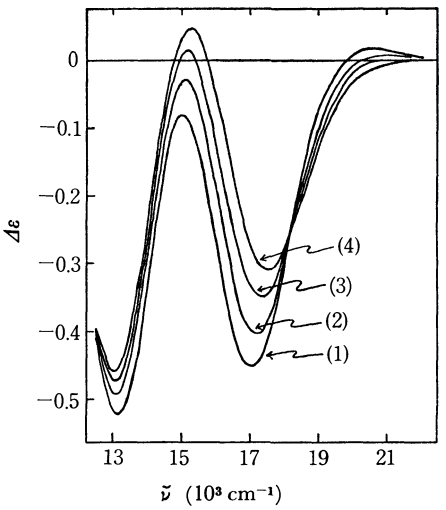

Fig. 3. CD variation with the temperature in the EDDV complex; (1) 3°±1 °C, (2) 27.5°±0.2 °C, (3) 51.2°±0.2 °C, (4) 72.0°±0.3 °C

6) Equatorial and axial orientations in these tetradentate ligands are somewhat different from the so-called 'quasi'-equatorial and 'quasi'-axial orientations in amino acid chelates. By the examination of the molecular models, the *gauche* structure of the N-C-C-N skeleton may be responsible for the orientation of the substituents, and the energy difference between the two orientations seems to be larger than that in the amino acid chelates.

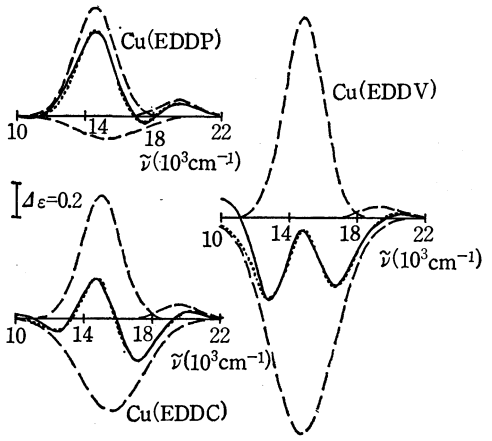

Fig. 4. Gaussian analyses of the CD spectra observed at room temperature: The solid curves are measured spectra; the dashed curves are the Gaussian components; the dotted curves represent the Gaussian summations.

ponents of the d-d transitions. From a comparison of the CD shapes in the 12000—18000 cm^{-1} region, it can be anticipated that each of the CD curves in this region is composed of two components, each of which has one peak near 15000 cm^{-1} with an opposite sign. In the CD spectrum of the EDDV complex at room temperature, the positive one of the two components is not observed in any appreciable amount (Fig. 1). However, the positive component emerges at the higher temperature, as is shown in Fig. 3. Moreover, small positive CD bands appear at about 10000 and 20000 cm^{-1}, and finally these CD curves could be composed of four components.

In order to support the view that these CD curves are composed of four components, we attempted to resolve the CD spectra by Gaussian analysis.[9] A set of Gaussian analyses is presented in Fig. 4. The analyses led to only the three bands at the higher wavenumber side, for we failed to observe the whole of the CD band at the lowest wave number. The slight discrepancies between the summed curves and the measured curves are within the limits of experimental error. Thus, it is almost certain that the curves in the visible region are composed of four components, which are related to the four possible d-d transitions.[10] The corresponding resolved components in the three spectra are situated at almost the same wave numbers, but with different magnitudes. Since the relative magnitudes of the respective components change with the variation in the equilibrium distribution between the two conformers, different CD spectra might be observed for the present three complexes. On the basis of the curve resolutions for the obtained CD curves, the assignments of the four components in the visible region of these complexes will be reported in the next paper.

9) The analyses of the band envelopes were accomplished by trial and error, assuming a symmetrical and purely Gaussian shape for every component band, and assuming that the corresponding resolved components in the respective curves may be the same d-d origin and hence have the same band widths.

10) Wilson and Martin reported that four ligand field bands are identified in the solution circular dichroism of the bis type complex of *N*-methyl-L-alanine with copper(II). E. W. Wilson, Jr., and R. B. Martin, *Inorg. Chem.*, **10**, 1197 (1971).

Derivatographic Studies on Transition Metal Complexes. XI.[1] Thermal Ligand-exchange Reaction of *cis*- and *trans*-[CoXY(N$_4$)]SCN·*n*H$_2$O Type Complexes[2]

Ryokichi Tsuchiya, Tatsuo Murakami,* and Eishin Kyuno

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received April 20, 1973)

The thermal ligand-exchange reaction was investigated by derivatographic and isothermal methods for the following complex thiocyanates: *cis*-[CoCl$_2$en$_2$]SCN, *cis*-[CoClBren$_2$]SCN·H$_2$O, *cis*-[CoBr$_2$en$_2$]SCN·H$_2$O and the corresponding *trans*-complexes, and several corresponding triethylenetetramine complexes *cis*-α-[CoXYtrien]-SCN·H$_2$O, where X and Y represent Cl$^-$ and Br$^-$ ion, respectively. *cis*-Complexes, except for *cis*-[CoCl$_2$en$_2$]SCN were found to exhibit obviously the ligand-exchange reaction in which Cl$^-$ or Br$^-$ is substituted by SCN$^-$ just after the liberation of lattice water takes place. On the other hand, *cis*-[CoCl$_2$en$_2$]SCN showed only partial ligand-exchange reaction accompanied by immediate thermal decomposition even at higher temperature than in the other monohydrates. In contrast, all the anhydrated *trans*-complexes *trans*-[CoCl$_2$en$_2$]SCN, *trans*-[CoClBren$_2$]-SCN and *trans*-[CoBr$_2$en$_2$]SCN did not give such a reaction upon heating. The activation energies of *cis*-[CoClBren$_2$]SCN·H$_2$O were found to be $E_a=26\pm2$ kcal/mol for dehydration and $E_a=54\pm2$ kcal/mol for ligand-exchange. The thermal ligand-exchange reaction proceeded in *cis*-type complexes without change in the geometrical configuration of the original complexes. No racemization or inversion could be observed in the optically active complex.

Of several types of thermal reactions on transition metal complexes in a solid phase, the isomerization reactions for *trans*-[CoCl$_2$(NH$_3$)$_4$]IO$_3$·2H$_2$O,[3] *cis,trans*-[CoCl$_2$(NH$_3$)$_2$en]ClO$_4$[4] and *trans*-[CoCl$_2$pn$_2$](H$_5$O$_2$)·Cl$_2$,[5,6] and the racemization reactions for *d-cis*-[CrCl$_2$en$_2$]Cl,[7] *d*-[Coen$_3$]I$_3$·H$_2$O,[7] and *l*-K$_3$[Co(C$_2$O$_4$)$_3$]·*n*H$_2$O[8,9] have been reported. In most cases, solid phase reactions occurred without exchange of the ligand by counter ions. However, few studies have been carried out on the ligand-exchange reaction between anionic ligand coordinated and the counter ion in outer coordination sphere.

Radioactive chloride exchange reaction takes place when *trans*-[Co*Cl$_2$pn$_2$](H$_5$O$_2$)·Cl$_2$ or *trans*-[CoCl$_2$pn$_2$](H$_5$O$_2$)·*Cl is heated.[6] In this reaction, the complete chloride scrambling might occur during the course of dehydration or dehydrochlorination. This suggests that the aquation-anation mechanism is acceptable.

Another type of thermal exchange reaction was found[10] in *cis,trans*-[CoCl$_2$(NH$_3$)$_2$en]SCN·H$_2$O. It contains not only stereochemical change in the coordination sphere but also ligand-exchange with the counter ion: *i.e.*, the reaction of this complex proceeds in two steps as follows.

(1) *cis, trans*-[CoCl$_2$(NH$_3$)$_2$en]SCN·H$_2$O → *cis, trans*-[CoCl$_2$(NH$_3$)$_2$en]SCN + H$_2$O

(2) *cis, trans*-[CoCl$_2$(NH$_3$)$_2$en]SCN → *cis, cis*-[CoCl(NCS)(NH$_3$)$_2$en]Cl

In (2) the stereochemical change and ligand-exchange occur simultaneously, water of crystallization playing no important role. For thermal reaction in this complex, an associative mechanism with seven coordinated reaction intermediates was proposed.[10]

Thermal reaction in a solid phase is affected by several factors, one of which is the steric effect of a chelate ring. Thus, it is of interest to investigate the effect of chelation of neutral ligands in *cis*- and *trans*-[CoXY(N$_4$)]SCN·*n*H$_2$O, as compared with *cis,trans*-[CoCl$_2$(NH$_3$)$_2$en]SCN·H$_2$O. Coordinated halogen ions will also affect the thermal reaction.

We have also attempted to survey the role of lattice water on the ligand-exchange reaction and examine the influence of isomeric configurations of starting complexes; *viz.*, the effect brought about by the difference in coordination site of two halogen ions.

We have prepared *cis*- and *trans*-[CoXY(N$_4$)]SCN·*n*H$_2$O type complexes and investigated their thermal ligand-exchange reactions in detail.

Experimental

Preparation of Complex Thiocyanates. Complexes *cis*-[CoCl$_2$en$_2$]Cl, *cis*-[CoClBren$_2$]Br and *cis*-[CoBr$_2$en$_2$]Br and the corresponding trans complexes were prepared by the methods in literature.[11,12] Their thiocyanates were obtained by adding an excess amount of potassium thiocyanate to the cold saturated solution of the corresponding chloride or bromide. Recrystallization was carried out from a dilute solution of potassium thiocyanate. The crystals were filtered and washed with small amounts of water, ethanol and ether

$(-)_D$-*cis*-α-[$CoBr_2$trien]SCN·H_2O	19.36	19.06	4.70	4.58	16.36	15.88

and then air-dried.

The triethylenetetramine complexes *cis*-α-[$CoCl_2$trien]Cl,[13] *cis*-α-[CoClBrtrien]Br[14] and *cis*-α-[$CoBr_2$trien]Br[15] were obtained by the known methods. The thiocyanates were obtained by a similar method to that for the corresponding ethylenediamine complexes. The optically active complex $(-)_D$-*cis*-[$CoBr_2$trien]SCN·H_2O was obtained by the reaction of $(-)_D$-*cis*-α-[$CoBr_2$trien]Br with potassium thiocyanate in an aqueous solution.

The complexes obtained were identified by elemental analysis and spectral measurement. The results are given in Table 1.

Derivatographic Measurement. The apparatus and technique for derivatography were the same as described previously.[5]

Isothermal Measurement. A Shimadzu TM-1A Thermanobalance and an Abderhalden apparatus were used for isothermal measurement. The procedures of measurement and analysis were also the same as given previously.[16]

Spectral Measurement. The electronic, infrared and circular dichroism spectra were measured with a Hitachi ERS spectrophotometer, JASCO Model IR-E, IR-F spectrophotometer, and JASCO Model ORD/UV-5 spectrophotometer, respectively.

Results and Discussion

Structure of Reaction Products. When freshly prepared *cis*-type complexes except for *cis*-[$CoCl_2en_2$]SCN were heated, the original violet color turned brick-red, showing that the counter ion may coordinate in place of halogen ligand after dehydration. The IR spectra of *cis*-[$CoClBren_2$]SCN·H_2O and the reaction product are shown in Fig. 1.

We see that C≡N stretching band is shifted from 2040 cm^{-1} to 2100 cm^{-1} upon heating. It is well-known[17] that there is a characteristic difference between the infrared spectra of the complexes containing SCN^- of different

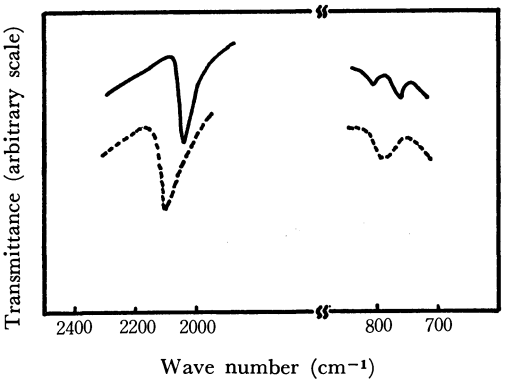

Fig. 1. IR spectra of *cis*-[$CoClBren_2$]SCN·H_2O (——) and its reaction product (----).

coordination modes and those of the complexes having SCN^- as counter ion, *viz.*, the infrared absorption band assigned to C≡N stretching vibration in the thiocyanate ion attached to a metal ion appears in the higher wavenumber region than that in the inorganic thiocyanate anion. The shift from 2040 cm^{-1} to 2100 cm^{-1} may be attributed to a cobalt(III)-thiocyanate bonding formation, and the thiocyanate ion in outer sphere probably coordinates to the central metal after dehydration.

The linkage isomerism of N-bonded or S-bonded thiocyanate ion in the coordination is distinct from the presence of a C–S stretching vibration band in the frequency region 690—860 cm^{-1} and NCS bending in the region 400—490 cm^{-1}. It is known[17] that the C–S stretching band appears in 780—860 cm^{-1} for M–NCS and 690—720 cm^{-1} for M–SCN and NCS bending band, in 450—490 cm^{-1} for M–NCS and 400—440 cm^{-1} for M–SCN.

After the exchange reaction is over, the C–S stretching band shifts towards the higher wave number region from 760 cm^{-1} which is given by SCN^- counter ion, partly overlapping the NH_2 deformation band. Although there is no obvious evidence for the change of frequency in NCS bending, it may be concluded that the thiocyanate ion participates in bonding through nitrogen atom to central cobalt(III) ion.

The IR spectra of *cis*-[$CoBr_2en_2$]SCN·H_2O and its reaction product are very similar to those of *cis*-[$CoClBren_2$]SCN·H_2O.

TABLE 2. ABSORPTION MAXIMA OF STARTING COMPLEXES AND REACTION PRODUCTS

	Starting complex	Reaction product
cis-$[CoCl_2en_2]SCN$	540 (2.11)	a)
cis-$[CoClBren_2]SCN \cdot H_2O$	549 (2.03)	505 (2.21)
cis-$[CoBr_2en_2]SCN \cdot H_2O$	554 (2.05)	510 (2.25)
cis-α-$[CoCl_2trien]SCN \cdot H_2O$	539 (2.08)	506 (2.32)
cis-α-$[CoClBrtrien]SCN \cdot H_2O$	546 (2.11)	506 (2.34)
cis-α-$[CoBr_2trien]SCN \cdot H_2O$	552 (2.10)	508 (2.40)

Values in parentheses are absorption coefficients.

a) *cis*-$[CoCl_2en_2]SCN$ could not be completely converted into *cis*-$[CoCl(NCS)en_2]Cl$.

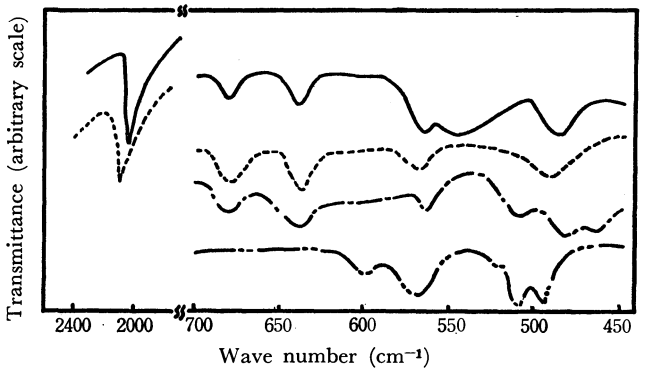

Fig. 2. IR spectra of *cis*-α-$[CoCl_2trien]SCN \cdot H_2O$ (——), its reaction product (·····), *cis*-α-$[CoCl_2trien]Cl$ (– – –) and *cis*-β-$[CoCl_2trien]Cl$ (— — —).

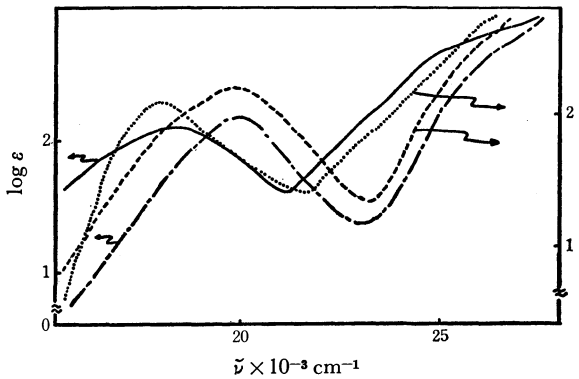

Fig. 3. Absorption spectra of *cis*-$[CoClBren_2]SCN \cdot H_2O$ (——), its reaction product (– – –), *cis*-$[CoCl(NCS)en_2]Cl$ (– – –) and *trans*-$[CoCl(NCS)en_2]Br$ (·····).

The corresponding trien complexes give a similar pattern to the bis-en complexes in IR spectra before and after the thermal reaction. The IR spectra of *cis*-α-$[CoCl_2trien]SCN \cdot H_2O$, the reaction product, and the related complexes are shown in Fig. 2.

In the far-infrared region, the pattern of the absorption bands originating from the skeletal vibration in each complex does not change much after thermal reaction. There are three geometrical isomers, *cis*-α, cis-β and trans ones, in the octahedral complex involving the trien chelate. The skeletal vibration is more useful in distinguishing these isomers. The configuration of the reaction product of *cis*-α-$[CoCl_2trien]SCN \cdot H_2O$ is considered to be the same as that of the starting complex (Fig. 2). Thus, the ligand-exchange reaction does not involve the stereochemical change, the isomerization from *cis*-α to *cis*-β or *trans*-form.

When two halogen ions in the preheating complex are the same, the chromophore of the reaction product is easily seen. For example, when *cis*-$[CoBr_2en_2]SCN \cdot H_2O$ is heated the product obtained is obviously $[CoBr(NCS)en_2]Br$, but it can not be deduced from only IR data whether Cl^- or Br^- ion is substituted by SCN^- ion upon heating the *cis*-chloro-bromo complex. UV spectra can be used to assign the geometrical isomers and the chromophore of cobalt(III) complexes.[18,19] Numerical values of the absorption maxima of the complexes and their reaction products are shown in Table 2. All the reaction products have absorption maxima at *ca.* 505 nm, and no shoulders at *ca.* 550 nm.

In the chromophore of $[CoX(NCS)(N_4)]$, the first absorption band of *cis*-compound, in general, appears in rather higher frequency than that of *trans*-one. *cis*-$[CoCl(NCS)en_2]Cl$ and *trans*-$[CoCl(NCS)en_2]Br$ were found to exhibit the first absorption maxima at 505 nm and 555 nm, respectively.[20] The absorption spectra of *cis*-$[CoClBren_2]SCN \cdot H_2O$, its reaction product, and the related complexes are given in Fig. 3.

The spectral feature of the reaction product of *cis*-$[CoClBren_2]SCN \cdot H_2O$ is in good agreement with that of *cis*-$[CoCl(NCS)en_2]Cl$. It is therefore concluded that the reaction product from *cis*-$[CoClBren_2]SCN \cdot H_2O$ is *cis*-$[CoCl(NCS)en_2]Br$. Thus, the thiocyanate ion in outer sphere is considered to substitute the coordinated bromide ion but not chloride ion, the *cis*-structure in thermal ligand-exchange reaction being retained. The reaction product from *cis*-$[CoBr_2en_2]SCN \cdot H_2O$, the chromophore of which is $[CoBr(NCS)en_2]$, has a first absorption maxima at 510 nm, and is considered to be *cis*-$[CoBr(NCS)en_2]Br$. This is due to the fact that the ligand field of Cl^- ion is stronger than that of Br^- ion.

Three trien complexes give a similar spectral behavior to that in the bis-en complexes (Table 2). It is concluded that the ligand-exchange reaction proceeds retaining *cis*-form.

Optically active $(-)_D$-*cis*-α-$[CoBr_2trien]SCN \cdot H_2O$ was also used. Apparent difference in activity of the complex was observed before and after the reaction. Their CD and UV spectra are given in Fig. 4.

19) R. A. O. Wentworth and T. S. Piper, *Inorg. Chem.*, **4**, 709 (1965).

20) H. Kuroya and R. Tsuchida, This Bulletin, **15**, 427 (1940).

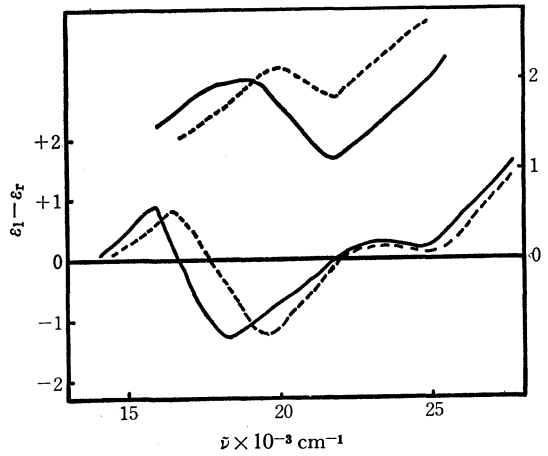

Fig. 4. CD and absorption spectra of $(-)_D$-*cis*-α-[$CoBr_2$trien]-SCN·H_2O (----) and its reaction product (----).

Although the CD spectrum of the reaction product shifts slightly towards the higher frequency side due to the substitution of Br^- by SCN^-, its pattern remains almost unchanged with the same sign even after the reaction. $(+)_D$-*cis*-$[CoCl_2en_2]^+$ and $(+)_{5461}$-*cis*-[Co(NCS)en_2]$^+$ have similar CD curves with the same sign, and their absolute configurations are found to be the same, namely, *Λ*.[21] Complex $(-)_D$-*cis*-α-[$CoBr_2$trien]SCN·H_2O and its reaction product $(-)_D$-*cis*-α-[CoBr(NCS)trien]Br were found to have the same absolute configuration, since the ring chirality of the trien complex is almost equal to that of bis-en complex. The thermal reaction in the optically active complex is found to accompany neither racemization nor inversion reactions.

It is thus concluded that the thermal ligand-exchange reaction for *cis*-[CoXY(N_4)]SCN·H_2O type complexes proceeds retaining both geometrical and optical configurations giving the formula *cis*-[CoX(NCS)-(N_4)]Y.

Derivatographic Studies. The derivatograms for the complexes examined are given in Figs. 5, 6 and 7. *cis*-[$CoClBren_2$]SCN·H_2O and *cis*-[$CoBr_2en_2$]SCN·H_2O each exhibit a small exothermic peak at *ca.* 125 °C after the appearance of the endothermic peak due to the dehydration in DTA curve (Fig. 5). The exothermic peak corresponds to the ligand-exchange reaction between Br^- ion in the coordination and SCN^- ion in outer sphere as for *cis,trans*-[$CoCl_2(NH_3)_2$en]SCN·H_2O[10] in which the exchange between the chloride ion and the thiocyanate ion takes place with an exothermic peak.

cis-[$CoCl_2en_2$]SCN with no lattice water shows no peak in this temperature range, but an exothermic peak overlapping with complicated decomposition peaks at higher temperature. Even upon isothermal heating, it decomposes as soon as the color change begins to appear. At this stage, the C≡N stretching band splits into two peaks at 2040 cm^{-1} and 2100 cm^{-1}. The ligand-exchange reaction does not proceed stoichiometrically for *cis*-[$CoCl_2en_2$]SCN unlike that for *cis*-[$CoClBren_2$]SCN·H_2O.

21) T. E. MacDermott, A. M. Sargeson, *Austr. J. Chem.*, **16**, 334 (1963).

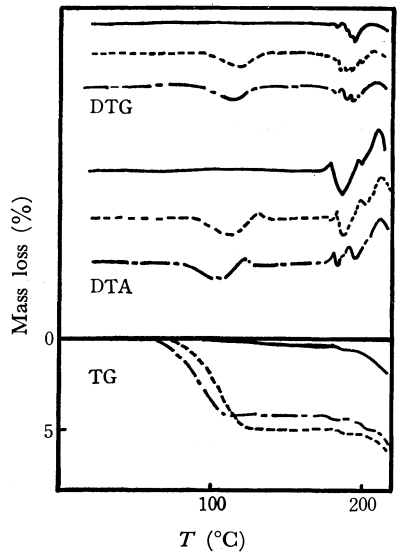

Fig. 5. Derivatograms of *cis*-[$CoCl_2en_2$]SCN (——), *cis*-[$CoClBren_2$]SCN·H_2O (----) and *cis*-[$CoBr_2en_2$]SCN·H_2O (——).

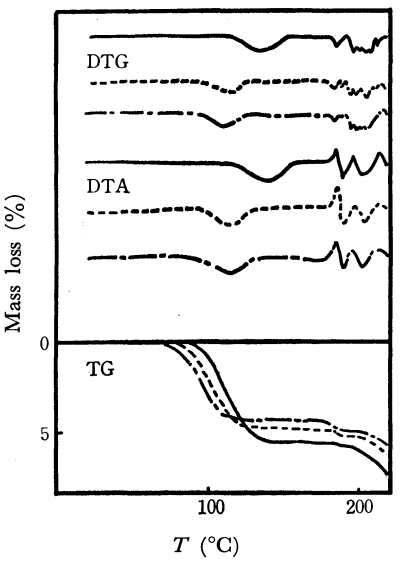

Fig. 6. Derivatograms of *cis*-α-[$CoCl_2$trien]SCN·H_2O (——), *cis*-α-[CoClBrtrien]SCN·H_2O (----) and *cis*-α-[$CoBr_2$trien]-SCN·H_2O (——).

Each derivatogram of the three trien complexes exhibits only one peak attributable to the liberation of lattice water (Fog. 6). The color of the sample changed from violet to brick red after appearance of the endothermic peak, the C≡N stretching band being shifted to 2100 cm^{-1}. The ligand-exchange reaction for the trien complexes might take place in the temperature range of thermal dehydration, since the peak is considered to overlap that of dehydration.

cis-α-[$CoBr_2$trien]SCN·H_2O readily loses a certain amount of lattice water with no color change on being kept in a vacuum desiccator at room temperature. The derivatogram of this complex exhibits a small exothermic peak at 100 °C due to the lack of a large endothermic peak. This peak appearing with color change could be attributed to the ligand-exchange reaction occurring on heating.

Table 3. Thermochemical functions

Complex	ΔH_d kcal/mol[a)]	E_a^d kcal/mol[b)]	ΔH_e kcal/mol[c)]	E_a^e kcal/mol[d)]
cis-$[CoClBren_2]SCN \cdot H_2O$	10.8±2.0	26±3	−1.2±1.0	50±5
cis-α-$[CoCl_2trien]SCN \cdot H_2O$	8.6±2.0	33±3		
cis-α-$[CoClBrtrien]SCN \cdot H_2O$	7.8±2.0	31±3		
cis-α-$[CoBr_2trien]SCN \cdot H_2O$	7.2±2.0	30±3		

a) and c) are enthalpy changes of dehydration and ligand-exchange reaction, respectively. b) and d) are activation energies of dehydration and ligand-exchange reaction, respectively.

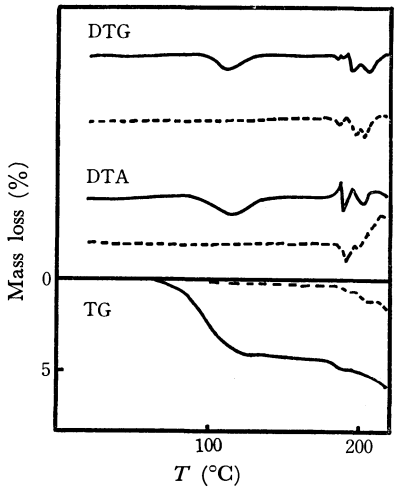

Fig. 7. Derivatograms of $(-)_D$-*cis*-α-$[CoBr_2trien]SCN \cdot H_2O$ (——) and *trans*-$[CoClBren_2]SCN$ (——).

The deviatogram of optically active $(-)_D$-*cis*-α-$[CoBr_2trien]SCN \cdot H_2O$ given in Fig. 7 is similar to that of the corresponding racemic complex. Since all the reaction products indicate the same spectral behavior, it can be concluded that the thermal ligand-exchange reaction occurs just after thermal dehydration.

The following reaction sequence for the *cis*-type complexes is proposed.

(1) *cis*-$[CoXY(N_4)]SCN \cdot H_2O$
$\rightarrow$ *cis*-$[CoXY(N_4)]SCN + H_2O$

(2) *cis*-$[CoXY(N_4)]SCN$
$\rightarrow$ *cis*-$[CoX(NCS)(N_4)]Y$.

In the case of coexistence of Cl^- and Br^- ions in the coordination sphere, the ligand-exchange of Br^- by SCN^- will be more predominant than Cl^-.

On the other hand, the green *trans*-complexes *trans*-$[CoCl_2en_2]SCN$, *trans*-$[CoClBren_2]SCN$ and *trans*-$[CoBr_2en_2]SCN$ have no lattice water, and exhibit no color change on heating. The derivatogram of *trans*-$[CoClBren_2]SCN$ is given in Fig. 7 as an example. In the DTA, DTG and TG curves of this derivatogram, neither the peak for dehydration nor that for the ligand-exchange reaction appears below 185 °C when the complicated thermal decomposition is initiated.

It is understood that the ligand-exchange reaction does not take place in the three dehydrated *trans*-complexes, whereas in the anhydrated *cis*-$[CoCl_2en_2]SCN$ the partial ligand-exchange reaction occurs just before thermal decomposition takes place. This indicates that the configuration of trans isomers should prevent the occurrence of the thermal ligand-exchange reaction.

The thermochemical functions calculated from DTA and DTG curves of the derivatograms are given in Table 3. Because of the incomplete separation of the peaks in DTA curves, no genuine enthalpy changes corresponding to each process of dehydration and ligand-exchange reaction could be calculated separately for *cis*-$[CoClBren_2]SCN \cdot H_2O$, and no DTG and DTA curves of the derivatogram of *cis*-$[CoBr_2en_2]SCN \cdot H_2O$ could be analyzed.

Isothermal Studies. In the isothermal study of *cis*-$[CoClBren_2]SCN \cdot H_2O$, the rate constants of dehydration and ligand-exchange reaction were determined at various temperatures.

Since *cis*-$[CoClBren_2]SCN \cdot H_2O$ and its reaction product *cis*-$[CoCl(NCS)en_2]Br$ have the absorption coefficients 64.9 and 161.8 at 505 nm and 108.5 and 132 at 549 nm in DMSO, respectively, with a 1.0 cm cell, the ratios of the concentration of chloro-bromo/chloro-isothiocyanato complex in the reaction products at a given heating time can be determined spectrophotometrically by means of the equations

$$64.9X + 161.8Y = D_{505}$$
$$108.5X + 132Y = D_{549},$$

where X and Y are the concentrations (in mol^{-1}) of the chloro-bromo and chloro-isothiocyanato complexes, respectively, and D_{505} and D_{549} the absorbances at 505 nm and 549 nm, respectively. The rate constants of the ligand-exchange reaction were calculated from the conversion ratios of the two isomers in each product X/Y. The rate of dehydration was estimated from the weight change of sample with a thermobalance.

The rate constants k_d for dehydration and the rate constants k_e for the ligand-exchange reaction are given in Table 4. The Arrhenius plots of the rate constants are shown in Fig. 8.

The activation energies are (26±1) kcal/mol and (54±2) kcal/mol for dehydration and ligand-exchange reaction, respectively. The values agree with those obtained by analysis of the derivatogram.

Table 4. Rate constants of dehydrvtion and ligand-exchange reaction for *cis*-$[CoClBren_2]SCN \cdot H_2O$

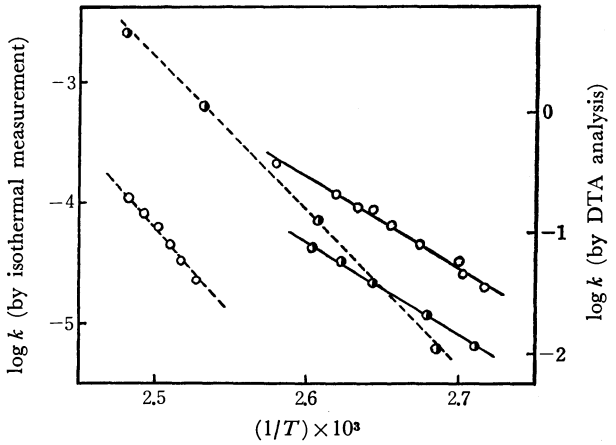

Fig. 8. Arrhenius plots for *cis*-[CoClBren$_2$]SCN·H_2O in the dehydration (——) and ligand-exchange reaction (----) by DTA analysis (○) and isothermal measurement (◑).

If the thermal reaction in a solid phase proceeds through the aquation-anation pathway, the activation energy of the thermal reaction will be nearly equal to that of dehydration, and if the reaction proceeds by intramolecular mechanism, the activation energy would be comparatively higher than that by aquation-anation mechanism.

In the study of *cis*-[CoClBren$_2$]SCN·H_2O, the two Arrhenius plots for dehydration and the ligand-exchange reaction were not parallel with each other (Fig. 8), and the activation energy of the ligand-exchange reaction was considerably higher than that of dehydration. It is assumed that the lattice water plays no important role in the ligand-exchange reaction.

The ligand-exchange reaction occurs after dehydration and thus proceeds *via* the intramolecular mechanism. All the reaction products of *cis*-[CoXY(N$_4$)]-SCN·H_2O type complexes were of *cis*-structure with respect to a halogen ion originally coordinated and an isothiocyanate ion entering the coordination sphere.

When *cis*-[CoClBren$_2$]SCN·H_2O and $CuSO_4 \cdot 5H_2O$ separately placed in a sealed tube were heated, the reaction product of the former differed from that obtained in an open system, *viz.*, it was a mixture of *cis*- and *trans*-[CoCl(NCS)en$_2$]Br. In such a closed system, the gaseous water molecule evolving from the sample and $CuSO_4 \cdot 5H_2O$ can not escape from the reaction system, and may aquate the complex catalytically at the solid surface. The thermal reaction might proceed through the aquation-anation pathway accompanied by the stereochemical change, isomerization from *cis* to *trans*-form.

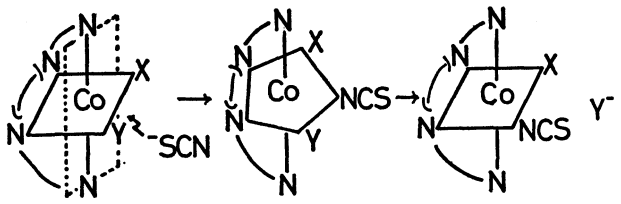

Fig. 9. Probable reaction mechanism.

The following reaction mechanism for the ligand-exchange reaction of *cis*-[CoXY(N$_4$)]SCN·H_2O type complex in the solid phase is postulated (Fig. 9).

The thiocyanate ion would attack at a position *cis* to the two halogen ions coordinated to form the seven coordinated reaction intermediates and then one of the halogen ions would be removed to outer coordination sphere. In the case of the coexistence of Cl^- and Br^- ions in the coordination, the Co–Br bond breaking takes place after making the seven coordinated intermediate, since the Co–Br bond energy is considered to be smaller than the Co–Cl one.

The thermal reaction products through this pathway should be of *cis*-structure without any stereochemical change such as racemization or an inversion in the optically active complex. The exchange reaction and isomerization from *cis,trans*-[CoCl$_2$(NH$_3$)$_2$en]SCN·H_2O to *cis,cis*-[CoCl(NCS)(NH$_3$)$_2$en]Cl occurred simultaneously, where the thiocyanate ion in outer sphere attacked at a position trans to the two halogen ions. In the case of *cis*-[CoXY(N$_4$)]SCN·H_2O, however, the chelate ring of ethylenediamine or triethylenetetramine might prevent the thiocyanate ion from attacking the trans site and make the *cis*-attack more easily. After the liberation of water molecule from the crystal lattice upon heating, packing may somewhat loosen as in an amorphous substance.

The looseness would affect the acceleration of the mobility of the thiocyanate ion in the solid phase. The assumption seems plausible, since the monohydrated *cis*-complexes exhibit a perfect ligand-exchange after dehydration, while the other anhydrous *cis*-[CoCl$_2$en$_2$]SCN showed only partial ligand-exchange just before thermal decomposition.

Kinetic Studies of the Nickel Lactate Complex Formation in Solution by the Pressure-jump Method

Shoji HARADA, Hideyuki TANABE, and Tatsuya YASUNAGA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

(Received April 23, 1973)

The nickel lactate complex formation reaction in an aqueous solution was studied by the pressure-jump method and the overall rate constants, the stability constants, and the activation parameters were determined. The results were interpreted by the use of the step-by-step complex formation mechanism, and it was revealed that the rate-determining step is the chelate-ring formation process. The ligand effect on the rate of the complex formation was also considered.

With the help of the relaxation techniques,[1,2] fast metal complex formation reactions in solution have been studied. In many cases, the relaxation effects have been interpreted by the step-by-step mechanism,[3] and it has been revealed that the rate-determining step is the dissociation of a water molecule from the inner-coordination sphere of the metal ion. For the complex formation with the bidentate ligand, one more step of chelation should be added to the unidentate-complex-formation mechanism. Kinetic studies of some of the nickel dicarboxylate-complex-formation reactions have been performed[4–7] by the use of the above mechanism. For the assignment of the relaxation effect, however, two different theories have been proposed. In one theory,[4,5] the rate-determining step was considered to be the first-bond formation between the nickel ion and the ligand. In the other,[6,7] it was ascribed to the chelation process. The present authors have studied the nickel dicarboxylate-complex-formation reactions[8–10] and discussed if one of the two theories can be properly applied. In the present studies, the same attempts have also been made in the case of the univalent-bidentate-ligand complex of the nickel ion. The results obtained will be compared to the kinetic data of other bidentate-ligand complexes.

Experimental

All of the chemicals used were of a reagent grade. A stock solution of the nickel lactate was prepared by mixing a stoichiometric amount of $NiSO_4$ and lactic acid where the sulfate ion was precipitated out as $BaSO_4$ by $Ba(OH)_2$ titration. The concentration of the nickel lactate was determined by dimethylglyoxime titration. The solutions studied were prepared by the dilution of the stock solution to the desired concentration. The pH's of the solutions were 5.5—5.8, where most of the ligand was in the dissociated form.

The pressure-jump apparatus used has been described in considerable detail elsewhere.[8] To ensure that the observed relaxation is due to the complex formation reaction of the nickel lactate, blank experiments were carried out with solutions containing only nickel nitrate or sodium lactate under the same conditions. In no case was a relaxation effect observed. The measurements were carried out at 10, 15, 20, 25 and 30 °C in the concentration range from 1.01×10^{-3} to 5.04×10^{-2} M of nickel lactate. The relaxation times quoted are the mean values of at least four runs.

Results and Discussion

The experimental conditions and the reciprocal relaxation times observed at 25 °C are shown in Table 1. The concentration dependence of the relaxation time can be interpreted in terms of the following simple mechanism:

$$M^{2+} + L^- \underset{k_d}{\overset{k_f}{\rightleftharpoons}} ML^+ \qquad (1)$$

where M^{2+} is the metal ion, L^- is the ligand ion, ML^+ is the complex, and k_f and k_d are the formation and the dissociation rate constants respectively. Taking into account the small stability constant and the experimental conditions of the low concentration of the nickel lactate, the concentrations of ML_2 or higher-order complexes are assumed to be negligible. For the mechanism (1), the relaxation time, τ, is related to the rate constants as follows:

$$1/\tau = k_f\gamma_M\gamma_L(C_M+C_L) + k_d\gamma_{ML} \qquad (2)$$

where γ is the activity coefficient, C is the equilibrium concentration, and the subscript indicates the corresponding ionic species. Assuming that $\gamma_{ML}=\gamma_L$, Eq. (2) is rearranged to:

$$1/(\tau\cdot\gamma_{ML}) = k_f\gamma_M(C_M+C_L) + k_d. \qquad (3)$$

When the stability constant is given, the concentrations of each ionic species can be calculated. The activity coefficients are calculated by the following Davies[11] equation.

$$\log\gamma_i = -\left(\frac{1}{2}\right)\cdot Z_i^2\left(\frac{\mu^{1/2}}{1+\mu^{1/2}} - 0.3\,\mu\right) \qquad (4)$$

where Z_i is the charge of the i-th ion and where μ is the ionic strength of the solution. If the suggested

a) C_0 refers to the total stoichiometric concentrations of the nickel lactate.

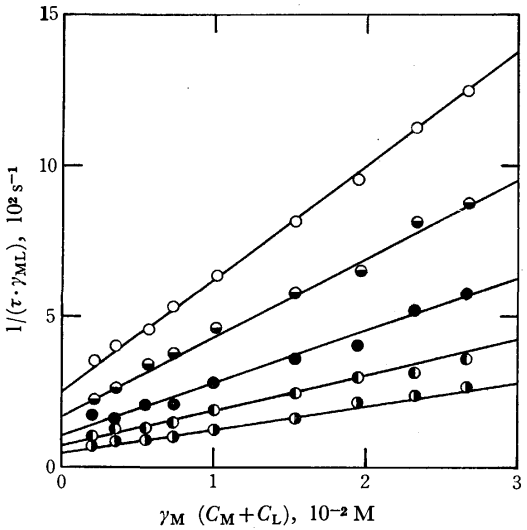

Fig. 1. $1/(\tau\cdot\gamma_{ML})$ *vs.* $\gamma_M(C_M+C_L)$ plot at 10 °C (◑), 15 °C (◐), 20 °C (●), 25 °C (◒), and 30 °C (○).

mechanism is correct, the plot of $1/(\tau\cdot\gamma_{ML})$ *vs.* $\gamma_M(C_M+C_L)$ should be linear; then, k_f and k_d are obtained from the slope and the intercept of the straight line respectively. The stability constant $K(=k_f/k_d)$, which should coincide with the first assumed value, was obtained from the ratio between k_f and k_d. Successive approximations were performed until a constant K was obtained. The final plots at various temperatures are shown in Fig. 1. The lines are the best fit ones based on a least-squares treatment. The rate and the stability constants are summarized in Table 2.

The Arrhenius energies of activation, $\Delta E_f^{\neq}$ and $\Delta E_d^{\neq}$, were obtained from the plot of $\log k_f$ and $\log k_d$ against $1/T$ respectively. Other thermodynamic parameters of the complex formation, *i.e.*, the entropy of activation, $\Delta S_f^{\neq}$; the enthalpy of activation, $\Delta H_f^{\neq}$, and the free energy of activation, $\Delta G_f^{\neq}$, were calculated from the following equations; they are listed in Table 3:

$$\log A = \log\frac{eRT}{Nh} + \frac{\Delta S_f^{\neq}}{2.3R} \quad (5)$$

$$\Delta H_f^{\neq} = \Delta E_f^{\neq} - RT \quad (6)$$

$$\Delta G_f^{\neq} = \Delta H_f^{\neq} - T\Delta S_f^{\neq} \quad (7)$$

where A is the frequency factor.

TABLE 2. THE FORMATION AND THE DISSOCIATION RATE CONSTANTS AND THE STABILITY CONSTANTS OF THE NICKEL LACTATE ($\mu\rightarrow 0$)

t, °C	k_f (10^3 M^{-1} s^{-1})	k_d (s^{-1})	K (10^2 M^{-1})
10	7.7±1.0	48±8	1.6±0.4
15	11.5±1.2	72±10	1.6±0.4
20	17.3±1.3	108±22	1.6±0.4
25	26.0±3.1	170±38	1.5±0.4

TABLE 3. KINETIC DATA OF THE NICKEL LACTATE COMPLEX FORMATION AT 25°C ($\mu\rightarrow 0$)

K, M^{-1}	$1.5(\pm 0.4)\times 10^2$
k_f, M^{-1} s^{-1}	$2.60(\pm 0.31)\times 10^4$
k_d, s^{-1}	$1.70(\pm 0.38)\times 10^2$
$\Delta E_f^{\neq}$, kcal·mol^{-1}	13.5±2.3
$\Delta E_d^{\neq}$, kcal·mol^{-1}	14.1±3.0
$\Delta G_f^{\neq}$, kcal·mol^{-1}	11.4±2.3
$\Delta H_f^{\neq}$, kcal·mol^{-1}	12.9±2.3
$\Delta S_f^{\neq}$, cal·K^{-1}·mol^{-1}	5±8

The kinetic data obtained for the nickel lactate are compared with the other literature values. The stability constant is very close to the value obtained by Evans *et al.*[12] by the use of conductivity method. The value is also close to the stability constant of the nickel glycollate.[13] At the same time, k_f and k_d are also very close to those of the nickel glycollate.[14] Considering the structural resembrance of the two ligands, the above coincidences of the data can be easily understood. The activation parameters are very close to those of the oxalate[4] and the malonate complexes[5]: *i.e.*, $\Delta E_f^{\neq}$=14—16 kcal·mol^{-1}, $\Delta H_f^{\neq}$=13—15 kcal·mol^{-1}, $\Delta S_f^{\neq}$=5—16 cal·mol^{-1}·K^{-1}, and $\Delta G_f^{\neq}$=10—11 kcal·mol^{-1}. These coincidences imply that the relaxations observed result from similar reactions.

The lactate ligand makes a chelate complex where the carboxyl group and the hydroxyl group are coordinated to the nickel ion. Therefore, the complex

a) The rate constant of the individual steps were calculated from the original data in the same way as that carried out in the nickel lactate system.

formation reaction (1) must be composed of the following step-by-step mechanism:

$$Ni^{2+}+L^- \overset{K_0}{\rightleftharpoons} Ni^{2+}O\overset{H}{\underset{H}{\diagup\diagdown}}L^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ni^+-L \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Ni^+ = L \quad (8)$$

(I) (II) (III) (IV)

where (I) is the free ions, (II) is the outer-sphere complex, (III) is the unidentated complex (probably coordinated by the carboxyl group), (IV) is the chelate complex, and K_0 is the outer-sphere stability constant. The observed relaxation phenomena can be characterized by a single relaxation time; therefore, it may be ascribed to one of the steps in the above mechanism. On the assumption that the intermediate species, (II) and (III), are in the steady state, the rate constants in Eq. (8) are related to the overall formation and the dissociation rate constants, k_f and k_d, in Eq. (1) by the following equations:

$$k_f = K_0k_1\left(\frac{k_2}{k_2+k_{-1}}\right) \quad (9)$$

$$k_d = k_{-1}\left(\frac{k_{-2}}{k_2+k_{-1}}\right). \quad (10)$$

It has usually been admitted[1,3] that k_1 is equal to the water-substitution rate constant of the nickel ion,[15] $2.7\times10^4\ s^{-1}$. Moreover, K_0 can be calculated to be $5.4\ M^{-1}$ for the 2—1 electrolyte by means of this equation:[16,17]

$$K_0 = (4\pi Na^3/3000)\cdot e^{-U(a)/kT} \quad (11)$$

where N is Avogadro's number, $U(a)$ is the Coulomb energy, and a is the distance of the closest approach of ion-pair partners, which was assumed to be 5 Å. Therefore, $K_0k_1=1.5\times10^5\ M^{-1}s^{-1}$. The same value of K_0k_1 is also obtained from the kinetic studies of the nickel acetate. The fact that k_f in Table 2 is about an order of magnitude smaller than K_0k_1 means that the value in the parentheses in Eq. (9) is much smaller than unity, *i.e.*, $k_2 \ll k_{-1}$, and that the rate-determining step of the complex formation is not the first-bond formation, but the chelate-ring formation step. If the value of k_{-1} is given, k_2 and k_{-2} can be calculated from Eqs. (9) and (10) by the use of k_f and k_d. Hoffmann *et al.*[7,14] have reported that log k_{-1} bears a linear relationship to the basicity of the ligand. Applying this relationship to the lactate complex, k_{-1} was estimated to be $9\times10^3\ s^{-1}$. By the use of these values, k_2 and k_{-2} were calculated; they are listed in Table 4. The data in Table 4 show that the rate-determining step of the complex formation is the chelation step of the OH group and that of the complex dissociation process is the chelate-ring rupture.

The rate constants of all the steps of the lactate complex formation are very close to those of the glycollate. This means that the rate constants and the stability constants are not affected by the small difference in structure between the two ligands. In comparison with the six-membered dicarboxylate complex, *i.e.*, the oxalate, the lactate is two orders less stable; this may be ascribed not only to the stabilities of the ion-pair formation, but also, and mainly, to the stabilities of the chelate or the rate of the chelate-ring rupture.

Application of the Zone Melting Technique to Metal Chelate Systems. VII. Computer-assisted Consideration on the Solute Distribution Profiles in Zone Melting Process

Shigeru MAEDA, Hiroshi KOBAYASHI, and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received Feburary 1, 1973)

A new equation is derived which gives the solute distribution along a column after a zone melting chromatography (ZMC) process, where the initial charge of a sample mixture of $k<1$ is placed on the upper end of the column, one zone length high. The solute distribution differs significantly from that obtained by Pfann's equation on an infinite ingot, in the neighborhood of the upper end as expected from the difference in the initial conditions. The solute distribution is calculated numerically for the case in which the initial charge is placed by several zone lengths on the column top. The present multiple zone charge method shows little difference in solute distribution from the conventional single zone charge method, having the advantage of increasing the sample amount to be fractionated. Numerical calculation is performed to find the zone length with which the greatest amount of the solute of $k<1$ is concentrated into the bottom fraction of a certain length of a given column after each zone pass. A series of resulting zone lengths, showing a stepwise shortening, pass after pass, provides the optimum mode of decrease in the zone length.

We successfully applied the zone melting method to systems containing metal chelates.[1-6] The basic theory of zone melting was thoroughly covered by Pfann.[7] We have extended the theory by presenting mathematical expressions which give the solute distribution profile in specific methods of zone melting operation for a higher separation efficiency. Discussion is given on the theoretical basis for the experimental work. Since the equations are not given in simple analytical forms, the solute distribution profiles were computed numerically by use of FACOM 230—60 of the Computer Center of Kyushu University.

Solute Distribution on a Semi-infinite Column in Zone Melting Chromatography (ZMC)

The basic equation determining the solute distribution along the solid column after n-th zone pass was described in the form of difference differential equation on the basis of mass balance as follows.[8]

$$dC_n(x)/dx = k\{C_{n-1}(x+l) - C_n(x)\}/l \qquad (1)$$

where l is the length of a molten zone, x denotes the position of the freezing interface of the zone which travels in the positive x direction, $C_n(x)$ is the solute concentration at x after the n-th zone pass, and k, the distribution coefficient, is defined as a ratio of solute concentration (weight/volume) in the frozen solid to that in the molten liquid.

Analytical solutions of Eq. (1) were derived by Reiss and Helfand[8] for various types of ZMC methods on the following assumptions for simplification:

1) a constant distribution coefficient k, regardless of the concentration of the solute or freezing conditions,
2) no diffusion in the solid,
3) infinitely rapid mixing in the melt,
4) a negligibly small change in density upon freezing,
5) a constant zone length, l,
6) flat solid-melt interfaces perpendicular to the column axis,
7) a uniform cross section of the column.

When the initial charge of a sample is placed at midpoint on an infinitely long column of a uniform unit cross section (Fig. 1), distribution of the solute is given by an analytical expression,[8] which is further simplified by Pfann[9] as

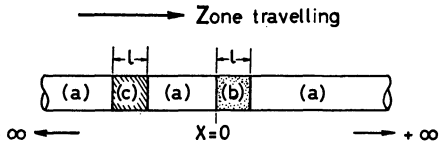

Fig. 1. ZMC on an infinitely long column
(a): Pure solid solvent
(b): Initial charge of sample mixture
(c): Molten zone

$$C_n(x) = C_i k[k\{(x/l)+m\}]^m \exp[-k\{(x/l)+m\}]/m! \qquad (2)$$

where $m=n-1$, $-\infty<x<+\infty$, and C_i is the concentration of a solute in the initial charge.[10]

Practically it is much easier to place the initial charge of a solute mixture on either end than at the midpoint of a pure solid solvent column.

* Contribution No. 287 from the Department of Organic Synthesis, Kyushu University. Presented in part before the International Congress on Analytical Chemistry, April 7, 1972 in Kyoto. Part VI by the same authors, Ref. 6.

9) W. G. Pfann, *Anal. Chem.*, **36**, p. 2231 (1964).

10) According to Pfann. [Ref. 7, pp. 10, 30 and 59 and *J. Appl. Phys.*, **35**, 258 (1964)], Eq. (2) is valid without the third and fourth assumptions, if concentration is expressed in weight fraction or mole fraction, l defined as the length of solid that is melted to form the zone and k is an effective value consistent with the freezing conditions.

Solutes with k less than unity move in the direction of zone travelling, and no ZMC column is required which extends in the opposite direction to that of the zone travelling from the position of the initial charge.

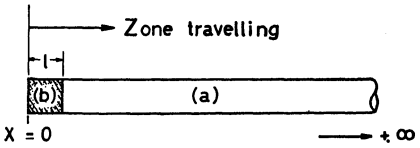

Fig. 2. ZMC on a semi-infintely long column
(a): Pure solid solvent
(b): Initial charge of sample mixture and molten zone.

Assuming that the initial charge is placed one zone length high on the upper end of a semi-infinite column extending from $x=0$ to $x=+\infty$, and that the zone travels downwards, Eq. (1) can be solved using iterative methods for each succeeding pass. After the first zone pass, it can be rewritten as

$$(l/k)\{dC_1(x)/dx\} + C_1(x) = C_0(x+l) \quad (3)$$

where $C_0(x+l)=0$ regardless of x in the region $x>0$. Thus

$$dC_1(x)/C_1(x) = (-k/l)dx \quad (4)$$

A solution of this equation is

$$C_1(x) = C_1(0)\exp(-kx/l) \quad (5)$$

where $C_1(0)=kC_i$

After the second zone pass, the basic differential equation is written as

$$(l/k)\{dC_2(x)/dx\} + C_2(x) = C_1(x+l) \quad (6)$$

The right hand side of this equation is given by Eq. (5), and we have

$$dC_2(x)/dx + (k/l)C_2(x) = (k/l)C_1(0)\exp\{-k(x+l)/l\} \quad (7)$$

A solution of this equation is analytically derived as

$$C_2(x) = \exp(-k/l)\{C_2(0) + (kx/l)C_1(0)\exp(-k)\} \quad (8)$$

where

$$C_2(0) = (k/l)\int_0^l C_1(x)dx \quad (9)$$

Repeating similar treatments, after the n-th zone pass we have the following solution.

$$C_n(x) = \exp(-kx/l)\{\sum_{r=0}^{n-1}(k/l)^r C_{n-r}(0) \times \exp(-rk)x(x+rl)^{r-1}/r!\} \quad (10)$$

where

$$C_n(0) = (k/l)\int_0^l C_{n-1}(x)dx$$
$$= \{1-\exp(-k)\}C_{n-1}(0) + \sum_{r=1}^{n-2} C_{n-1-r}(0)\exp(-rk) \times \left[\{1-\exp(-k)\} + (k/l)^r \sum_{p=0}^{r-1} \frac{lp(rl)^{r-p-1} - l(p+1)\exp(-k)\{(r+1)l\}^{r-p-1}}{(k/l)^p(r-p)!}\right] \quad (11)$$

Equation (10) can be readily proved to be one of the analytical solutions of Eq. (1) by the method of mathematical induction (Appendix).

Equations (10) and (11) are highly iterative and can be calculated only by a digital computer for relatively large n-values, the results being illustrated in Fig. 3 along with those of Eq. (2) for comparison. Solute distribution by Eq. (10) differs from that by Eq. (2) with respect to the fact that the solute does not distribute in the region of negative x, namely

$$\int_0^{+\infty} C_n(x)dx = 1$$

for Eq. (10) in contrast to

$$\int_{-\infty}^{+\infty} C_n(x)dx = 1$$

for Eq. (2).

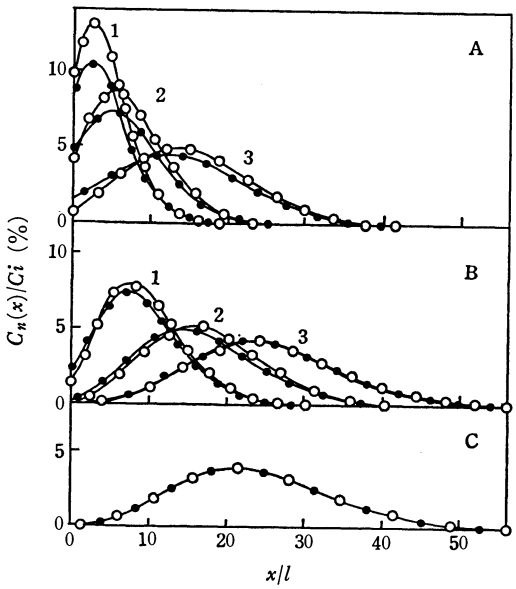

Fig. 3. Comparisons of the distribution profiles between Reiss-Helfand's and the present equations.
○—○ the present equation (10)
●—● Reiss-Helfand's equation (2)
A: $k=0.80$, 1; $n=10$, 2; $n=20$, 3, $n=50$
B: $k=0.56$, 1; $n=10$, 2; $n=20$, 3; $n=30$
C: $k=0.30$, $n=10$.

A comparison of curves from both equations indicates that the distribution curves of Eq. (10) shift to the direction of positive x slightly greater than those of Eq. (2), obviously owing to the effect of a semi-infinite column as mentioned above. This tendency is especially marked when the solute distribution peak is in the neighborhood of the column top. Otherwise, the distribution curves from Eq. (10) are almost superimposable on those from Eq. (2).

If we refer to Eq. (2), the peak position x_{max} increases linearly with n, as is given by

$$x_{max}/l = (n-1)(1-k)/k \quad (12)$$

On the other hand, if we refer to Eq. (10), it is difficult to obtain such a relationship mathematically. Numerical calculation affords the relationship between x_{max}/l and n, which is slightly deviated from linearity in the range of small n-values (Fig. 4), x_{max}/l being generalized dimensionless expression of the peak position.

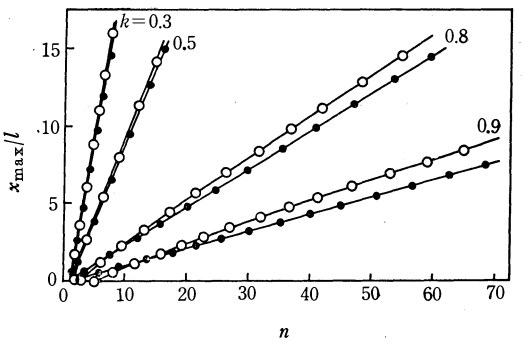

Fig. 4. The peak position *versus* number of zone passes.

ZMC Distribution Curve on a Multiple Zone Charge Method

The theory of ZMC fractionation tells us that the separation between two components having different k-values becomes more effective with increasing number of zone passes n, as shown by Eq. (12),[9] the shorter zone length being required for attaining the more efficient separation on the column of a limited length, L. However, such shortened zone length would decrease the amount of the sample to be fractionated, as long as the sample mixture was placed initially one zone length high. Thus the question arises of how the separation is affected when the initial charge of a sample mixture is placed by more than single zone length on the column top.

Assuming that the sample mixture of k less than unity is charged by T-folds of a unit zone length l on the upper end of a column from which a zone starts to travel downwards (Fig. 5), the solute distribution after a ZMC process can be calculated as follows.

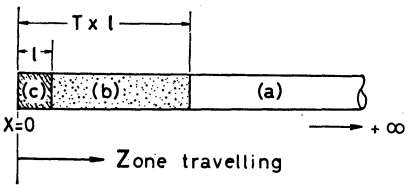

Fig. 5. Multiple zone charge method.
(a): Pure solid solvent
(b): Initial charge of sample mixture
(c): Molten zone

At the first zone pass, in so far as the freezing interface of a molten zone moves in the region $0<x<(T-1)l$, the solute is distributed by an ordinary zone melting process according to the equation,[7]

$$C_1(x)/C_i = 1 - (1-k)\exp(-kx/l) \quad (13)$$

where $0<x<(T-1)l$.

When the freezing interface arrives at $x=(T-1)l$, the solute concentration in the solid just frozen at this point is given by

$$C_1(x)/C_i = 1 - (1-k)\exp\{-k(T-1)\} \quad (14)$$

The solute concentration in the molten zone is therefore given by

$$C_i' = C_i[1-(1-k)\exp\{-k(T-1)\}]/k \quad (15)$$

From this point, ZMC process begins with C_i' as the initial concentration according to an equation analogous to Eq. (5):

$$C_1\{x-(T-1)l\} = kC_i'\exp[-k\{x-(T-1)l\}/l] \quad (16)$$

After the second zone pass, the solute is redistributed according to Eq. (1) from the solute distribution profile developed on the preceding zone pass. The analytical method for determining the solute distribution profile is generally too complicated, and a numerical computation provides much easier solution.

Computation was carried out by the Runge-Kutta-Gill method for Eq. (1), taking the zone length l and the initial concentration C_i both as unity, the grid spacing being one twentieth of the zone length.[11] The solute concentration at the upper end of the column on each pass $C_n(0)$ is given by

$$C_n(0) = k\int_0^1 C_{n-1}(x)\mathrm{d}x \quad (17)$$

which was also computed by use of Simpson's numerical integration method with an integration step equal to the grid spacing.

Numerically computed concentration profile after each pass was counter-checked by Simpson's integration of a solute amount over the whole range of solute distribution in a similar procedure to that described above. The integrated magnitude of the solute amount remained constant from pass to pass, being equal to that in the initial charge TlC_i.

A few examples of solute distribution profiles after 20 zone passes are shown in Fig. 6. Each curve is normalized for comparison, which suggests that are very little differences between the distribution curves where T-values are less than 5, especially in the case of small k-values. The situation is further clarified by Figs. 7 and 8 showing the peak position and the half peak width plotted against n for a certain range of T-values, respectively, which were also numerically computed. If one compares the peak position of the multiple zone charge method with that of the ordinary single zone charge method ($T=1$) in the case of $k=0.3$ after 40 zone passes, the peak position by the former method shifts towards positive x only 1.3% of that by the latter method. Even in the case of $k=0.8$, the relative distance of the shift is within 8%. Fig. 8 indicates that the difference in the half peak widths between the two methods is also insignificant; the relative differences are within only 0.4 and 3.5% for

A: $k=0.3$, B: $k=0.8$

$k=0.3$ and 0.8 after 40 zone passes, respectively, the difference decreasing considerably with increase in number of zone passes. As far as the efficacy as a separating method is concerned, we could find no disadvantages in the present multiple zone charge method as compared with the ordinary single zone charge method.

This method should be useful working with a large quantity of sample or solutes, solubilities of which in a solid solvent are relatively small. With use of the single zone charge method, even if the length of the initial charge is not rigorously equal to a unit zone length, no significant difference would result as regards the solute distribution profile.

An Optimum Mode of Stepwise Decreasing Zone Length for Improving the Concentrating Efficiency by Zone Melting Method

Regarding the efficiency of the zone melting method as a separating technique, normal freezing was the most effective at the first zone pass and the shorter zone length was the more effective after an indefinitely large number of zone passes,[12] and the solute concentration profile is expected to approach very rapidly the ultimate distribution by adjusting the zone length in the following manner; at the first zone pass, $l=L$, namely normal freezing process, and after the second pass, zone length decreases stepwise pass after pass. Such a method would be useful from the viewpoint of saving time.

Eckschlager and co-workers calculated the efficiency as a refining method for the cases where zone length decreased in seemingly arbitrary manner with increase in zone passes.[13] We have also investigated the technique, and calculated the optimum mode of stepwise decrease of zone length, which gave the maximum concentration in the bottom portion of a given length S after each zone pass.

Optimization of zone length is carried out in the following procedure for a set of specified k- and S values:
1) At the first zone pass ($n=1$), zone length is equal to the total column length L, the solute distribution being therefore determined by the normal freezing process, which has been given analytically[14] as

$$C_1(x) = kC_0(1-x/L)^{k-1} \tag{18}$$

where x denotes the position of the freezing interface as $x=0$ at the column top, and C_0 the initial concentration of a solute of k less than unity in the ingot.
2) At the second pass ($n=2$), based upon the distribution profile developed by the normal freezing process, distribution profiles are numerically calculated for 200 different zone lengths l_j with an increment of $0.005L$ unit from $0.005L$ to $1.0L$.

$$l_j = 0.005\,Lj \qquad j = 1, \cdots\cdots, 200 \tag{19}$$

Computation for the region of the zone melting process was programmed by the Runge-Kutta-Gill method for Eq. (1)[11], where $n=2$ and $l=l_j$ ($j=1, \cdots\cdots, 200$), taking $L=100$ and $C_0=1$, and grid spacing defined as $L/2000$. Normal freezing on the last zone length of the column is calculated numerically for the points in the region in $L-l_j<x<L$ with an increment of $L/2000$, which is equal in magnitude to the grid spacing, according to the analytical equation

$$C_{nj}(x) = kC'_j\{(L-x)/l_j\}^{k-1} \tag{20}$$

where

$$C'_j = C_{nj}(L-l_j)/k \tag{21}$$

$n=2$ and $L-l_j<x<L$.

Solute concentration at the column top, $C_{2j}(0)$, is given by

$$C_{2j}(0) = k\int_0^{l_j} C_1(x)\mathrm{d}x \tag{22}$$

This was computed by Simpson's numerical method with an integration step equal to the grid spacing defined in the Runge-Kutta-Gill calculation.

Solute amount in the bottom portion of a specified length S is given by

12) a) L. Burris, Jr., C. H. Stockman, and I. G. Dillon, *Trans. AIME*, **203**, 1017 (1955). b) W. G. Pfann, Ref. 7, pp. 31 and 42—45.
13) K. Eckschlager, V. Ettel, P. Stopka, and Z. Kodejs, *Coll. Czech. Chem. Commun.*, **36**, 3900 (1971).
14) W. G. Pfann, Ref. 7, p 11.

$$M_{nSj} = C_0L - \int_0^{L-S} C_{nj}(x)\mathrm{d}x \qquad (23)$$

where $n=2$, assuming a unit cross section of the column. The second term for each distribution profile was computed also by Simpson's method in a similar manner to that described above.

The distribution profile giving the highest value of M_{2Sj} with different j is then stored into the memory for calculation of zone lengths in the 3rd pass, and the zone length bringing the highest M_{2Sj}-value is defined as the optimum zone length in the 2nd pass.

3) At the n-th pass after the third pass, the optimum zone length is determined in a similar manner to that described above, from the distribution profile which is brought by the optimized $(n-1)$-th zone pass. The distribution profile which is formed by the zone length optimized for the n-th pass, is then stored for computation of the zone lengths in the $(n+1)$-th pass.

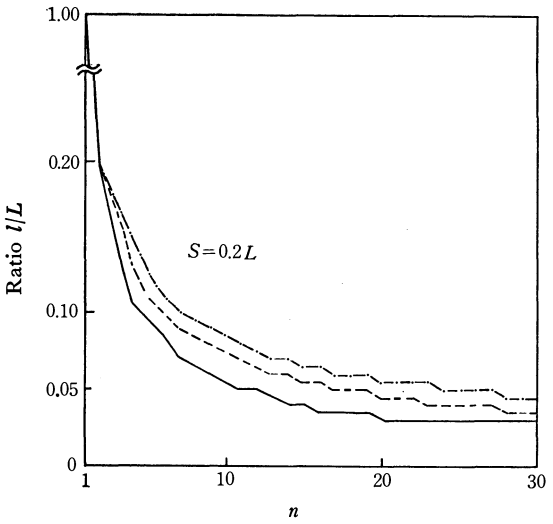

Fig. 9—1. Optimum zone length in ratio to L on each zone pass.

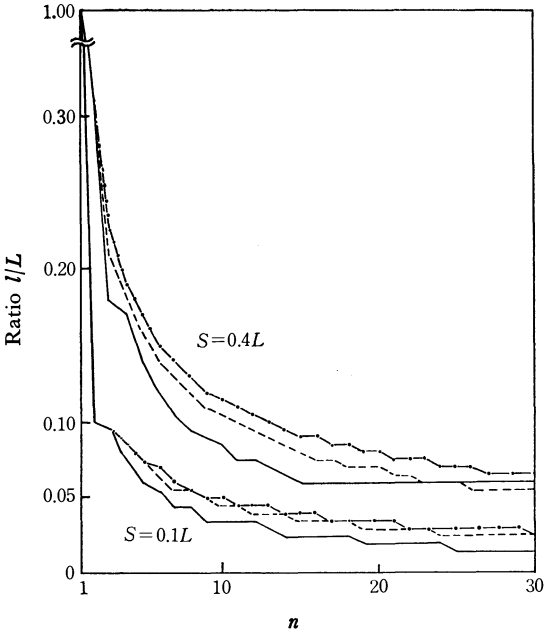

Fig. 9—2. Optimum zone length in ratio to L on each zone pass.
—·—· $k=0.8$, ——— $k=0.5$, —— $k=0.2$

Fig. 9 shows a few examples of the optimized mode of stepwise decrease of zone length for various k and S-values.

The superior efficacy of the present decreasing zone length (DZ) method is shown in Fig. 10 and Tables 1 and 2, in comparison with the conventional constant zone length (CZ) method.

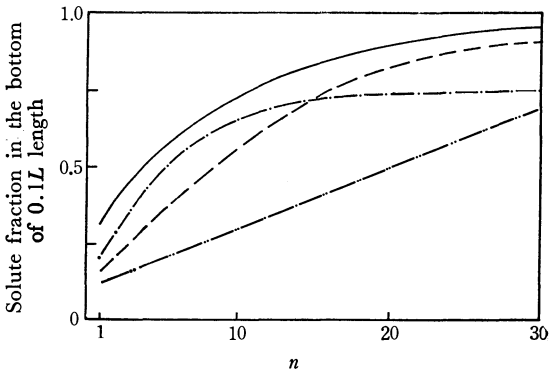

Fig. 10. Solute fraction concentrated into the bottom portion of $0.1L$ length after n-th zone pass, $k=0.5$.
—— DZ method, ——— CZ method, $l=0.05L$, —·—· CZ method, $l=0.10L$, —··— CZ method, $l=0.02L$

In Fig. 10 the solute fraction, which is concentrated in the bottom portion of $S=0.1\ L$, is plotted against number of zone passes upon applying the DZ- and CZ methods to a system of $k=0.5$. It is apparent that, though the solute is concentrated in various ways to the bottom portion, efficiency in concentrating a solute by the DZ method is always superior to the CZ method, when compared at the same number of zone passes.

Table 1. Fraction concentrated into a portion of $0.1\ L$ at the bottom after the 30 th zone pass

k	DZ method	CZ method		
		$l=0.1L$	$l=0.05L$	$l=0.02L$
0.1	1.0000	0.9899	0.9997	1.0000
0.2	1.0000	0.9599	0.9970	1.0000
0.3	0.9997	0.9099	0.9883	0.9906
0.4	0.9955	0.8399	0.9663	0.8915
0.5	0.9600	0.7491	0.9077	0.6883
0.6	0.8435	0.6337	0.7716	0.4977

0.8	0.4081	0.3355	0.3584	0.2445
0.9	0.2195	0.1976	0.2000	0.1614

Table 1 gives a comparison of the two methods as regards concentrating techniques. Values indicate the fraction of the solute concentrated into the bottom portion of 0.1 L after 30 zone passes.

Table 2 gives a comparison from a viewpoint of refining efficiency. Values indicate the length (% to L) of the portion which is purified to the average concentration level indicated on each heading. After 30 zone passes of the DZ method, for example, within 79.7% of the column length from the top, averaged

TABLE 2. LENGTH OF PURIFIED PORTION IN % OF A WHOLE LENGTH FROM THE COLUMN TOP AFTER THE 30 TH ZONE PASS

	DZ method		CZ method					
			$l=0.1L$		$l=0.05L$		$l=0.02L$	
C_{av}/C_0	1/100	1/1000	1/100	1/1000	1/100	1/1000	1/100	1/1000
$k=0.1$	97.9	96.5	89.7	82.3	94.9	91.2	97.9	96.5
0.2	96.8	95.1	83.6	74.6	91.9	87.6	96.8	95.0
0.3	95.7	93.1	77.9	65.9	89.3	83.5	89.4	62.7
0.4	91.8	81.7	70.5	54.6	85.3	72.3	49.5	29.9
0.5	79.7	48.7	59.3	32.3	62.7	24.2	25.1	9.6
0.6	43.4	2.2	31.2	0	20.2	0	8.1	0
0.7	0	0	0	0	0	0	0	0
0.8	0	0	0	0	0	0	0	0
0.9	0	0	0	0	0	0	0	0

concentration C_{av} of an impurity of $k=0.5$ is less than 1/100 of the initial concentration C_0, and within 48.7 % of the column length, the impurity level is less than 1/1000, while by the CZ method of $l=0.02\,L$, the corresponding length is 25.1 and 9.6% for the respective impurity levels.

It should be mentioned that, since a series of the optimum zone lengths is determined by a specified set of k- and S values of a system under consideration, and since the mode of stepwise decrease of zone length differs considerably with k- and S values, difficulties remain in the instrumentation of the present DZ method.

Appendix

Proof that Eq. (10) is a solution of Eq. (1).

If $K_n(x)$ is defined by

$$K_n(x) = \exp(\beta x)C_n(x) \tag{24}$$

where $\beta=k/l$, then Eqs. (1) and (10) can be rewritten respecitively as

$$dK_n(x)/dx = \beta\exp(-k)K_{n-1}(x+l) \tag{25}$$

$$K_n(x) = \sum_{r=0}^{n-1}\beta^r C_{n-r}(0)\exp(-rk)x(x+rl)^{r-1}/r! \tag{26}$$

Equation (10) can be verified to be a solution of Eq. (1) by showing that Eq. (26) is a solution of Eq. (25).

First, we verify that Eq. (26) is a solution of Eq. (25) when $n=1$.

From Eq. (26), $K_1(x)$ is given by

$$K_1(x) = C_1(0) \tag{27}$$

By substituting Eq. (5) into Eq. (24) where $n=1$, Eq. (27) can be found to hold under the present initial conditions.

Assuming that Eq. (26) is the right solution at $n=N$, we verify that it also holds for $n=N+1$.

Equation (25) is written for $n=N+1$ as

$$dK_{N+1}(x)/dx = \beta\exp(-k)K_N(x+l) \tag{28}$$

By integrating the equation over the region from 0 to x, we have

$$\int_0^x dK_{N+1}(x) = \beta\exp(-k)\int_0^x K_N(x+l)dx \tag{29}$$

or

$$K_{N+1}(x) - K_{N+1}(0) = \beta\exp(-k)\int_0^x K_N(x+l)dx \tag{30}$$

By substituting Eq. (26) into Eq. (30), the right-hand side is written as

$$\beta\exp(-k)\int_0^x K_N(x+l)dx = \beta\exp(-k)\sum_{r=0}^{N-1}[\{\beta^r C_{N-r}(0)\exp(-rk)/r!\} \times \int_0^x (x+l)\{x+(r+1)l\}^{r-1}dx] \tag{31}$$

The last integration can be readily performed to give

$$\int_0^x (x+l)(x+(r+1)l\}^{r-1}dx = x\{x+(r+1)l\}^r/(r+1)$$

Substituting this relation into Eq. (31), we obtain

$$\beta\exp(-k)\int_0^x K_N(x+l)dx = \beta\exp(-k)\sum_{r=0}^{N-1}\beta^r C_{N-r}(0) \times \exp(-rk)x\{x+(r+1)l\}^r/r!(r+1) = \sum_{r=0}^{N-1}\beta^{(r+1)}C_{N-r}(0) \times \exp\{-(r+1)k\}x\{x+(r+1)l\}^r/(r+1)! \tag{32}$$

Substituting this relation into Eq. (30), and considering the identity

$$K_{N+1}(0) = C_{N+1}(0) \tag{33}$$

which is readily derived from Eq. (24), we have

$$K_{N+1}(x) = C_{N+1}(0) + \sum_{r=0}^{N-1}\beta^{(r+1)}C_{N-r}(0) \times \exp\{-(r+1)k\}x\{x+(r+1)l\}^r/(r+1)! = \sum_{s=0}^{N}\beta^s C_{N+1-s}(0)\exp(-sk)x(x+sl)^{s-1}/s! \tag{34}$$

where $s=r+1$.

This can readily be seen to be equivalent to Eq. (26), where $n=N+1$. Equation (26) is proved by mathematical induction to be a solution of Eq. (25) for all n, n being any positive integer. Thus by introducing Eq. (26) into Eq. (24), we obtain Eq. (10).

The authors are grateful to Dr. S. Gondo, Department of Chemical Engineering, and Mr. T. Tsuneyuki, Department of Organic Synthesis, Kyushu University, for their helpful advice in FORTRAN programming.

Circular Dichroism and Absolute Configuration of Triammine(sarcosinate-*N*-monopropionato)cobalt(III) Chloride and Several Analogues

Ken-ichi OKAMOTO, Jinsai HIDAKA, and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received June 13, 1973)

cis(O)- and *trans(O)*-Triammine(sarcosinate-*N*-monopropionato)cobalt(III) salts, which have an asymmetrically coordinated nitrogen atom, were prepared and the *cis(O)* isomer was optically resolved through its diastereomeric salt with $(+)_{546}$-(ethylenediaminetetraacetato)cobaltate(III) anion. The less soluble diastereomeric salt produced $(+)_{546}$-*cis(O)* isomer of the triammine cation, and its absolute configuration (*R*) was established from circular dichroism spectrum, referring to the stereochemistry of the several analogous triammine complexes stereospecifically formed, which contain L-alaninate- and L-prolinate-*N*-monocarboxylate ligands, where the carboxylate stands for acetate or propionate. Two diastereomeric isomers, *R*(N)-L(C) and *S*(N)-L(C), were synthesized for the *cis(O)*-(L-alaninate-*N*-monopropionato)triamminecobalt(III) perchlorate salt.

In previous papers,[1,2] the stereochemistry was studied for cobalt(III) complexes with several *O,N,O*-tridentate ligands such as L-alaninate-*N*-monoacetate (L-alama^{2-})[1] and L-prolinate-*N*-monopropionate (L-promp^{2-}).[2] Most of these *O,N,O*-tridentate ligands contain an asymmetric carbon atom, and the cobalt(III) complexes formed have two or more kinds of chiral centers, namely each one of asymmetric carbon (L) and nitrogen (*R* or *S*) atoms per one ligand, and in some cases a configurational chirality (*Δ* or *Λ*). The additivity of the two or more kinds of circular dichroism (CD) contributions was discussed, but the lack of an appropriate model complex which contains only one asymmetric nitrogen atoms prevented us from thorough elucidation. The present paper deals with such a model complex newly synthesized, triammine(sarcosinate-*N*-monopropionato)cobalt(III) cation. The ligand sarcosinate-*N*-monopropionate (sarmp^{2-}) forms a five- and a six-membered chelate rings by coordination of an α-aminocarboxylate foot and an *N*-propionate one, respectively. This allowed the existence of two geometrical isomers, *cis(O)* and *trans(O)*, of the triammine complex.

The optical resolution of the *cis(O)* isomer was made successfully and the absolute configuration was established from the consideration of the CD spectrum, referring to the stereochemistry and CD spectra of analogous triammine complexes with L-alama^{2-}, L-alamp^{2-} (L-alaninate-*N*-monopropionate), L-proma^{2-} (L-prolinate-*N*-monoacetate), and L-promp^{2-}. The conclusion coincides with that obtained by an X-ray crystal structure study of the diastereomer, $(+)_{546}$-*cis(O)*-[Co(sarmp)$(NH_3)_3$]·$(+)_{546}$-[Co(edta)]·H_2O, of which a preliminary report has been presented recently.[3]

Experimental

Preparation of Ligands. (1). L-alanine-*N*-monoacetic, L-proline-*N*-monoacetic and L-proline-*N*-monopropionic acids were described in the previous papers.[1,2]

(2) L-Alanine-N-monopropionic Acid. A solution of 41 g (0.46 mol) of L-alanine in 92 ml of 5 M potassium hydroxide was mixed with the solution of 50 g (0.46 mol) of 3-chloropropionic acid in 92 ml of 2.5 M potassium hydroxide, and 92 ml of 7.5 M potassium hydroxide was added drop by drop to the mixture with vigorous stirring at 80—85 °C on an oil bath. The mixture was maintained in the pH range 8—9 during the reaction. The reaction mixture was further stirred for about 15 min, cooled to 40 °C, and 119 ml (1.44 mol) of 70% perchloric acid was added to it. The potassium perchlorate resulted was filtered off. The filtrate was concentrated in a vacuum evaporator at 40 °C. The solution concentrated was neutralized with 18 g (0.45 mol) of sodium hydroxide in 20 ml of water. The white deposit was filtered, and recrystallized from warm water. The crystals were washed with ethanol and ether, and then dried in a vacuum desiccator. Yield 33 g. $[\alpha]_D^{20}=+3.2°$ (*c.* 2.47, water). Found: C, 43.93; H, 6.89; N, 8.54%. Calcd for L-alampH$_2$=$C_6H_{11}NO_4$: C, 44.72; H, 6.88; N, 8.69%.

(3). Sarcosine-*N*-monopropionic acid was prepared by the procedure similar to that in (2), and more soluble in water than the other acids. Found: C, 43.49; H, 6.82; N, 8.43%. Calcd for sarmpH$_2$·1/4H_2O=$C_6H_{11}NO_4$·1/4-H_2O: C, 43.50; H, 7.00; N, 8.46%.

Preparation and Separation of Complexes. A solution of 8.9 g (0.17 mol) of ammonium chloride and 9.9 ml (0.15 mol) of 28% aqueous ammonia in 40 ml of water was mixed with a solution of the *O,N,O*-tridentate acid (0.042 mol) neutralized by sodium hydroxide in 20 ml of water. To this was added a solution of 10 g (0.042 mol) of cobalt(II) chloride hexahydrate in 10 ml of water. The molar ratio among Co^{2+}, *O,N,O*-tridentate ligand, NH_3, and NH_4^+ takes 1 : 1 : 3.5 : 4. Ten grams of lead dioxide was added to the mixture, and this was stirred at about 40—50 °C for an hr. The color of the solution turned from dark red to reddish violet. After having been allowed to stand at room temperature for 30 min, the reaction mixture was filtered to remove an excess of lead dioxide, and the filtrate was kept in a refrigerator. A small amount of yellow deposit, [Co$(NH_3)_6$]Cl_3, was filtered off. The filtrate was poured into a column (35 mm × 500 mm) containing strong-acid cation exchange resin (Dowex 50WX8 200—400 mesh, sodium form). After the column had been swept with water, the adsorbed band was eluted with 0.1 M aqueous solution of sodium perchlorate at a rate of 2.5 ml per min.

(4) trans(O)- *and* cis(O)-[*Co*(L-*promp*)$(NH_3)_3$]ClO_4. The complexes were already reported.[2] A great portion of the complex obtained consisted of the *cis(O)* isomer, and the *trans(O)* one occurred in a trace amount.

(5) trans(O)-[*Co(sarmp)*$(NH_3)_3$]ClO_4 *and* cis(O)-[*Co-(sarmp)*-$(NH_3)_3$]*Cl*. Two colored bands, violet one (i)

in a small amount and red one (ii) in a large amount, were eluted in this order. These eluates were separately concentrated in a vacuum evaporator and a large amount of ethanol was added to the concentrated solution. The desired complex was collected by filtration and recrystallized from a small amount of water by adding ethanol. It was confirmed by absorption measurements that the eluate (i) contained *trans(O)*-[Co(sarmp)$(NH_3)_3]^+$ and the eluate (ii) *cis(O)* one. The pure complexes were obtained as perchlorate salts. The *cis(O)* perchlorate was dissolved in a small amount of water and the solution was poured into a column containing strong-base anion exchange resin (Dowex 1-X8, 200—400 mesh, chloride form). The column was eluted with water and an appropriate amount of acetone was added to the eluate. In this procedure, the *cis(O)* perchlorate was converted into the chloride salt and washed with acetone and then dried in a vacuum desiccator.

(6) cis(O)-[*Co(ida)*$(NH_3)_3]ClO_4$. Two colored bands, a reddish violet one (i) in a small amount and a red one (ii) in a large amount, were eluted in this order. It was identified by absorption measurements and analytical results that the eluate (i) was a by-product containing two iminodiacetate ligands and the eluate (ii) was *cis(O)*-[Co(ida)$(NH_3)_3]^+$. The eluate (ii) was treated as in (5) and the desired complex was obtained as perchlorate salt.

(7) cis(O)-[*Co(*L-*proma)*$(NH_3)_3]ClO_4$. Two colored bands, violet one (i) in a small amount and red one (ii) in a large amount, were eluted in this order. From the absorption measurements, the eluate (i) was confirmed to be a by-product as in (6) and the eluate (ii) *cis(O)*-[Co(L-proma)$(NH_3)_3]^+$. The eluate (ii) was treated as in (5).

(8) cis(O)-[*Co(*L-*alama)*$(NH_3)_3]ClO_4$. Only one red band was eluted and the desired complex was obtained by adding a large amount of ethanol to the concentrated eluate and recrystallized from a small amount of water by adding ethanol. Two kinds of crystals were obtained and it was confirmed that one was *cis(O)*-[Co(L-alama)$(NH_3)_3]ClO_4 \cdot 1/2H_2O \cdot 1/4C_2H_5OH$ and the other *cis(O)*-[Co(L-alama)$(NH_3)_3]ClO_4 \cdot 3/4H_2O$, from their absorption and NMR spectra and by elemental analysis (see Table 1).

(9) trans(O)-[*Co(*L-*alamp)*$(NH_3)_3]ClO_4$, R- *and* S-cis(O)-[*Co(*L-*alamp)*$(NH_3)_3]ClO_4$. By elution, a reddish purple band (i) in a large amount and two adjacent red bands (ii) and (iii) in small amounts were obtained. By absorption measurements, it was confirmed that the eluate (i) contained *trans(O)*-[Co(L-alamp)$(NH_3)_3]^+$ and the eluates (ii) and (iii) *cis(O)*-[Co(L-alamp)$(NH_3)_3]^+$. These eluates were separately concentrated in a vacuum evaporator. The perchlorate of *trans(O)* isomer was precipitated by concentrating the eluate (i) and recrystallized from a small amount of water by adding ethanol. The perchlorates of *cis(O)* isomers ii (*R*) and iii (*S*) were obtained by adding a large amount of ethanol to the concentrated eluates (ii) and (iii), respectively. The isomer iii was recrystallized from ethanol and obtained as hygroscopic crystals. These pure complexes were washed with ethanol and dried in a vacuum desiccator.

Optical Resolution of Complex.

(10) $(+)_{546}$-cis(O)-[*Co(sarmp)*$(NH_3)_3]Cl$. Silver acetate (0.30 g) was added to a solution of 0.54 g of racemic *cis(O)*-[Co(sarmp)$(NH_3)_3]$Cl in a minimum amount of water and the silver chloride resulted was filtered off. A solution of 0.375 g of $(+)_{546}$-K[Co(edta)]$\cdot 2H_2O$[4] in a minimum amount of water was added to the filtrate. The mixture was concentrated by stream of air at room temperature and then kept in a refrigerator overnight. The violet crystals deposited as the less soluble diastereomer were collected by filtration (yield: 95 mg) and recrystallized from a small amount of water by adding ethanol. The pure diastereomer was washed with ethanol and dried in a vacuum desiccator. An aqueous solution of the diastereomer was poured into a column containing strong-base anion exchange resin (Dowex 1-X8, 200—400 mesh, chloride form) and the column was washed with water. An appropriate amount of acetone was added to the eluate to obtain the desired complex. The optically active $(+)_{546}$-*cis(O)*-[Co(sarmp)-$(NH_3)_3]$Cl was washed with acetone and dried in a vacuum desiccator. $\Delta\varepsilon_{546} = +0.35$.

The analytical results for the cobalt(III) complexes obtained are shown in Table 1.

Measurements. The electronic absorption spectra were measured by a Beckman DU spectrophotometer and Shimadzu spectrophotometer UV-200. The CD spectra were recorded with a JASCO Model J-10 or J-20 spectropolarimeter with a CD attachment or by Roussel-Jouan Dichrograph. A Yanagimoto spectropolarimeter, Model 185, was used to examine the eluates from the chromatographic column. All the measurements were made in aqueous solution at room temperature.

The infrared spectra were measured with a JASCO DS-402G spectrophotometer with NaCl prism using KBr disk samples. The proton nuclear magnetic resonance spectra of the complexes were recorded with a Japan Electron Optics JNM-4H 100 spectrometer operating at 100 MHz, in D_2O solutions. Measurements were carried out using *t*-butanol as an internal standard. All the signals lie at a lower field than that of the standard. The chemical shifts are referred to NaTMS (sodium trimethylsilylpropanesulfonate) as zero; *t*-butanol resonate at 1.234 ppm down field of NaTMS.

Results and Discussion

Visible Absorption Spectra. The present triammine complexes which belong to a $[Co^{III}(O)_2(N)_4]$ type are divided into two groups on the characteristics of splitting of their first d–d absorption bands. The first group has a shoulder at higher energy side of the major peak which is located at $18.3—19.0 \times 10^3$ cm^{-1}, and the second group a vague shoulder at lower energy side of the major peak, $19.3—19.9 \times 10^3$ cm^{-1} (Fig. 1 and Table 2). By referring to a general theory of the splitting pattern of first absorption bands of cobalt(III) complexes,[5,6] it is concluded that the first group (including L-alamp, L-promp, and sarmp complexes) has *trans(O)* structure with a meridionally coordinated *O,N,O*-tridentate ligand and the second (including ida, L-alama, and L-proma complexes and another set of L-alamp, L-promp, and sarmp ones) has *cis(O)* structure with a facially coordinated *O,N,O*-tridentate ligand. The ligands ida, L-alama, and L-proma form two five-membered chelate rings by coordination and the ligands L-alamp, L-promp, and sarmp form each one of five- and six-membered chelate ring with an α-aminocarboxylate part and an *N*-propionate foot, respectively. Thus the inclusion of the six-membered

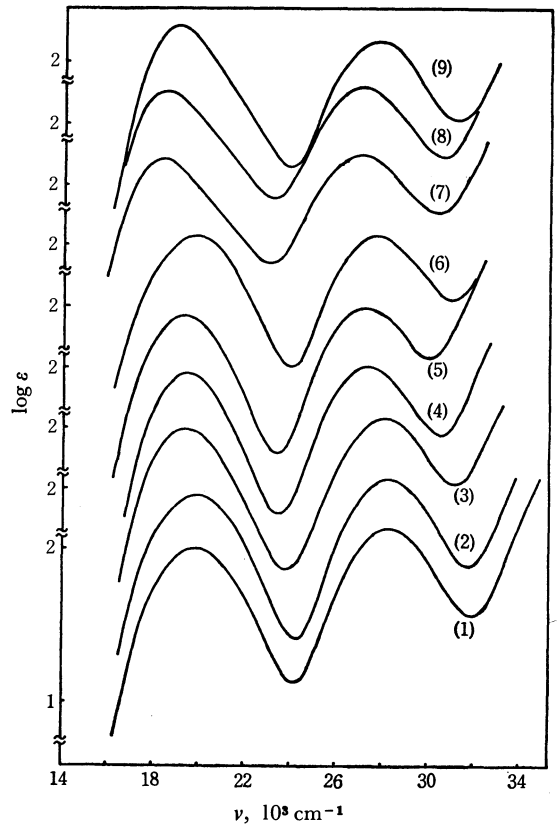

Fig. 1. Absorption curves of $[Co(O,N,O\text{-tridentato})(NH_3)_3]^+$ complexes: (1) ida *cis(O)*, (2) L-alama *cis(O)*, (3) L-proma *cis(O)*, (4) sarmp *cis(O)*, (5) L-promp *cis(O)*, (6) L-alamp *cis(O)-R*, (7) sarmp *trans(O)*, (8) L-promp *trans(O)*, and (9) L-alamp *trans(O)*.

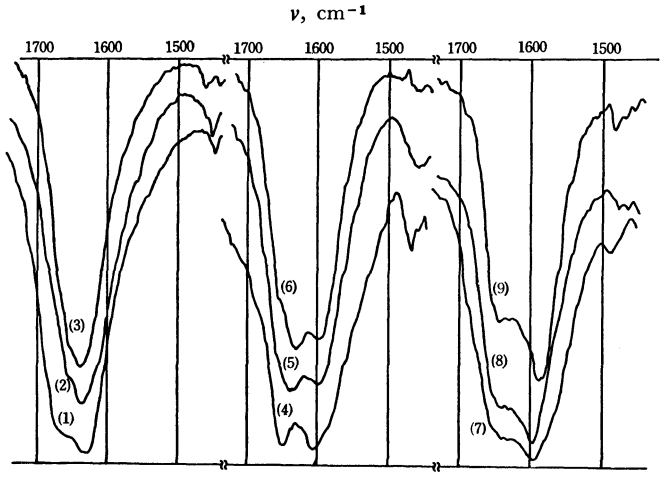

Fig. 2. Infrared curves in antisymmetric C=O stretching band region: (1) ida *cis(O)*, (2) L-alama *cis(O)*, (3) L-proma *cis(O)*, (4) sarmp *cis(O)*, (5) L-alamp *cis(O)-R*, (6) L-promp *cis(O)*, (7) sarmp *trans(O)*, (8) L-alamp *trans(O)*, and (9) L-promp *trans(O)*.

chelate ring is probably a reason for the stable existence of the meridionally coordinated form of the L-alamp, L-promp, and sarmp ligands. It may be worthwhile to note that the maximum intensities of the longer wavelength components of the first absorption bands for the *trans(O)* isomers are unusually large, and this fact is a reason for the apparently weak splitting of the first absorption bands of the *trans(O)* complexes.

Infrared Spectra. The IR spectra in the 1500—1800 cm^{-1} region are illustrated in Fig. 2. The *cis(O)* complexes with ida, L-alama, and L-proma show a strong band at 1630—1640 cm^{-1} and the *cis(O)* complexes with L-alamp, L-promp, and sarmp two strong bands at 1590—1610 cm^{-1} and 1630—1650 cm^{-1}, while the *trans(O)* complexes with L-alamp, L-promp, and sarmp show a strong band at 1585—1600 cm^{-1} with a shoulder at about 1635 cm^{-1}. The bands at 1620—1650 cm^{-1} region are assigned to the antisymmetric C=O stretching of the five-membered chelate ring.[7] The bands at 1585—1610 cm^{-1} region can be assigned to the corresponding carboxylate stretching of the six-membered chelate ring as in the case of $[Co(aspartato)_2]^-$[8] and [Co(ethylenediaminedisuccinato)]$^-$[9].

Stereospecific Formation of Isomers. Since the coordinated nitrogen atom of the *O,N,O*-tridentate complexes is asymmetric except for the ida complex, two isomers *R* and *S* with respect to the nitrogen atom are possible for each of the complexes. Experimentally, only one *cis(O)* isomer was obtained for $[Co(L\text{-proma})(NH_3)_3]^+$, while each one of *cis(O)* and *trans(O)*

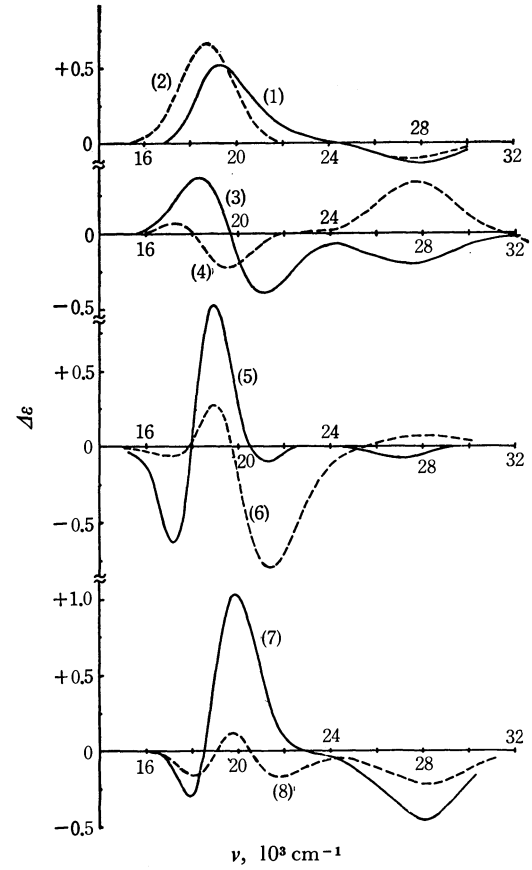

Fig. 3. CD curves of $[Co(O,N,O\text{-tridentato})(NH_3)_3]^+$ complexes: (1) sarmp *cis(O)-R*, (2) L-promp *cis(O)-R*, (3) L-alamp *cis(O)-R*, (4) L-alamp *cis(O)-S*, (5) L-promp *trans(O)-R*, (6) L-alamp *trans(O)-R*, (7) L-proma *cis(O)-R*, and (8) L-alama *cis(O)-R*.

isomer for [Co(L-promp)$(NH_3)_3$]$^+$. It has been well established that the configuration of the nitrogen atom of L-prolinate-*N*-monocarboxylate is restricted to *R* by coordination.[1,2] Accordingly, the three complexes are resonably assigned to *R* configuration. As shown in Fig. 3 and Table 3, CD behavior of *cis(O)*-R-[Co(L-promp)$(NH_3)_3$]$^+$ is similar to that of *cis(O)*-R-[Co(sarmp)$(NH_3)_3$]$^+$, of which the absolute configuration has been determined by an X-ray study.[3]

One *trans(O)* and two *cis(O)* isomers were isolated for the [Co(L-alamp)$(NH_3)_3$]$^+$ complex. Of the two *cis(O)* isomers the latter eluent (isomer iii) was obtained in an extremely low yield. Molecular model constructions indicate that a repulsion between the methyl group of *N*-alaninate chelate ring and the ethylenic portion of the *N*-propionate ring exists so far as the nitrogen atom takes *S* configuration, while no repulsion arises for *R* configuration. This suggests that the isomer ii takes *R* configuration and the isomer iii *S* one, and the NMR data of the two *cis(O)* isomers lead us to the same conclusion. One methyl doublet appears at 1.57 and 1.56 ppm for the isomer ii and iii, respectively. According to a theory of C–O interchelate ring magnetic anisotropic deshielding,[11] the methyl protons in the *S* configuration should resonate up field from that of the *R* one. Accordingly, the isomer ii is assigned to *R* and the isomer iii to *S*. The stereospecific dominancy for *R* configuration of L-alamp is also substantiated for the *trans(O)* isomer, because the CD pattern of this isomer (−, +, and − longer wavelength side) isomer similar to that of *trans*-*(O)*-*R*-[Co(L-promp)$(NH_3)_3$]$^+$ in the first absorption band region (Fig. 3).

Contrary to the L-alamp complex, only one *cis(O)* isomer is obtained for the L-alama one. The NMR spectrum points out that the isomer obtained is not a mixture of *R* and *S* isomers. In a former work,[1] two isomers (*RR* and *RS*) of three possible ones (*RR*, *RS*, and *SS*) were obtained for *trans(N)*-[Co(L-alama)$_2$]$^-$ and the non-existence of *SS* isomer and the lower yield of *RS* isomer were explained from the repulsion between the *N*-alaninate methyl group and the protons of acetate of an *S* ligand. The same situation can be supposed for the present triammine complex, *cis(O)*-[Co(L-alama)$(NH_3)_3$]$^+$. It is thus concluded that the *cis(O)* L-alama isomer obtained takes *R* configuration.

CD and Absolute Configuration. The CD spectra are shown in Fig. 3 and Table 3. The diastereomeric pair of isomers of L-alamp *cis(O)* complex, *R*(N)–L(C) and *S*(N)–L(C), provides a tool to evaluate three vicinal CD contributions *R*(N), *S*(N), and L(C) by adoption of additivity rule[1,11,12]; *i.e.*, the curves (9) *R*(N), (10) *S*(N), and (11) L(C) in Fig. 4 were obtained.

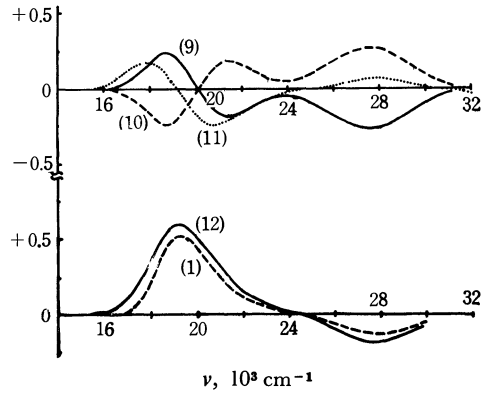

Fig. 4. Curve analyses of *cis(O)*-[Co(*O*,*N*,*O*-tridentato)-$(NH_3)_3$]$^+$ complexes: (9) *R* vicinal curve in L-alamp complex, $1/2\times\{(3)-(4)\}$, (10) *S* vicinal curve in L-alamp complex, $1/2\times\{(4)-(3)\}$, (11) L vicinal curve in L-alamp complex, $1/2\times\{(3)+(4)\}$, (12) *R* vicinal curve in L-promp complex, (2)—(11), compared with the observed R vicinal curve (1) of sarmp *cis(O)*-*R* complex.

Substraction of the curve (11) from the curve (2) in Fig. 3 produces a vicinal curve (12) for the *R*(N) contribution of L-promp *cis(O)* complex, and this coincides well with the observed CD curve (1) for the $(+)_{546}$-*cis(O)*-[Co(sarmp)$(NH_3)_3$]$^+$ complex, which has only one vicinal contribution of the asymmetric nitrogen center. This fact establishes the absolute configuration *R* of the sarmp $(+)_{546}$-*cis(O)* complex in accordance with the result from the X-ray study employing the Bijvoet method.[3] It is noteworthy that the *R*(N) vicinal curve (12) or (1) disagrees with the curve (9), but this may be acceptable since the former is for a tertiary amine nitrogen atom, while the latter for secondary amine nitrogen. Maricondi, Jordan, and Douglas[13,14] showed that a drastic change of the CD intensity of vicinal contribution occurred between the two kinds of coordinated nitrogen centers in some cobalt(III) complexes of edta and its derivatives.

In the first absorption band region, three CD components (−, +, and − from longer wavelength side) are observed for the L-promp *trans(O)*-*R* complex and this pattern corresponds well with that of the L-alamp *trans(O)*-*R* one, though there are some differences in intensities (Fig. 3 and Table 3). A similar correlation in CD components is also observed for the L-proma *cis(O)*-*R* and L-alama *cis(O)*-*R* complexes. In the last two pairs of complexes, it is not possible to evaluate the individual vicinal contributions of *R*(N) and L(C), because the sarmp *trans(O)* complex was not resolved (due to its lower yield) and the diastereomeric pair of *R*(N)–L(C) and *S*(N)–L(C) of L-alama complex was also not obtained.

The Tautomeric Equilibria of 4-(Dialkylamino)azobenzene Derivatives. II.[1] 2- and/or 2′-Methyl-4-(dimethylamino)azobenzene Derivatives

Shunzo YAMAMOTO

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received November 16, 1972)

The tautomeric equilibrium constants, K_t=[ammonium ion]/[azonium ion], of the first conjugate acids of 2- and/or 2′-methyl-4-dimethylaminoazobenzene derivatives were estimated by the spectrophotometric method. The effects of the 2- and 2′-methyl groups on the basicity of the amino and the azo nitrogens were examined in order to explain the effects on the tautomeric equilibrium. The effects of the 2- and 2′-methyl groups on the basicity of the amino nitrogen is an inductive one only, while the effects on the basicity of the azo nitrogens are both electronic and steric. The latter effect of the 2′-methyl group is very large, but that of the 2-methyl group is not significant. The order of K_t in a series of compounds is almost the same as that of the basicity of the azo nitrogens. That is to say, the magnitude of K_t is mainly governed by the basicity of the azo nitrogens.

The tautomeric equilibrium constants between the ammonium and the azonium ions of 4-dimethylaminoazobenzene derivatives have been reported by several workers.[2-6] Jaffé *et al.*[4] reported that the constants for 4′-substituted-4-dimethylaminoazobenzenes follow the Hammett equation.

In a previous paper,[7] we studied the effects of *N*-alkyl groups on the tautomeric equilibria for 4-dialkylaminoazobenzene derivatives and found that the base strength of the azo and the amino nitrogens is mainly governed by the degree of resonance interaction between the amino group and the rest of the molecule.

Recently, Haselbach[8] measured the pK_a values of a number of *p*- and *o*-substituted azobenzenes and showed that the *o*-methyl group exhibits both electronic and steric effects. For 2- and/or 2′-methyl-4-dimethylaminoazobenzene derivatives, the basicity of the azo nitrogens may be similarly influenced by the 2- and 2′-methyl groups, but the basicity of the amino nitrogen may be not so much influenced. Therefore, it can be expected that the tautomeric equilibrium is greatly affected by the 2- and 2′-methyl groups. As far as we know, there has been no systematic study of the effects of 2- and/or 2′-methyl groups on the tautomeric equilibrium. The purpose of the present paper is to examine to what extent the tautomeric equilibrium of the first conjugate acids of 4-dimethylaminoazobenzene derivatives is influenced by the introduction of the methyl groups into the *ortho* positions.

Experimental

Compounds. The 4-dimethylaminoazobenzene derivatives were prepared and purified by procedures described in previous papers.[7,9]

2-Methyl-4-dimethylaminoazobenzene: mp 67—67.5 °C (lit, 68—68.5 °C)

2′-Methyl-4-dimethylaminoazobenzene: mp 73.5 °C (lit, 73.5—74 °C)

2,4′-Dimethyl-4-dimethylaminoazobenzene: mp 126 °C (lit, 121 °C)

2′,4′-Dimethyl-4-dimethylaminoazobenzene: mp 137 °C (Found: C, 75.48; H, 7.70; N, 16.32%. Calcd: C, 75.85; H, 7.56; N, 16.59%).

2-Methyl-4′-chloro-4-dimethylaminoazobenzene: mp 96 °C (Found: C, 65.61; H, 6.31; N, 15.67%. Calcd: C, 65.81; H, 5.89; N, 15.35%).

2′-Methyl-4′-chloro-4-dimethylaminoazobenzene: mp 117 °C (Found: C, 65.41; H, 6.13; N, 15.09%. Calcd: C, 65.81; H, 5.89; N, 15.35%).

Measurements. The absorption spectra of the azo compounds and their conjugate acids, and the pH values of the solutions, were measured in *ca.* 50% aqueous ethanol at 25±0.5 °C by the methods described in a previous paper.[7] The dissociation constants, pK_a, were calculated by a standard method.[10] The average deviations for all the compounds were within ±0.05 pH units.

Results and Discussion

Table 1 shows the absorption bands of 4-dimethylaminoazobenzene derivatives and their conjugate acids (the B band is the conjugation band of the base, and the A and C bands are the conjugation bands of the ammonium and the azonium ions respectively). The $\varepsilon_a/\varepsilon_c$ ratio gives a measure of the tautomeric equilibrium, where ε_a is the apparent molar extinction coefficient at the peak of the A band, and where ε_c is that at the peak of the C band. As is shown in Table 1, the tautomeric equilibrium is sensitive to 2- and 2′-methyl groups. Especially for 2-methyl derivatives, the equilibrium greatly shifts to the azonium form, while for 2′-methyl derivatives the equilibrium shifts to the ammonium form.

According to Eq. (2) in Ref. (7), the tautomeric equilibrium constant, K_t, may be expressed as:

$$K_t = \frac{[\text{ammonium ion}]}{[\text{azonium ion}]} = \frac{\varepsilon_c^{III}}{\varepsilon_a^{II}} \cdot \frac{\varepsilon_a}{\varepsilon_c} - \frac{\varepsilon_a^{III}}{\varepsilon_a^{II}} \qquad (1)$$

where ε_a^{II} and ε_a^{III} are the molar extinction coefficients of the ammonium and azonium ion at the wavelength

maximum of the A band, and where ε_c^{III} is that of the azonium ion at the wavelength maximum of the C band. As has been described in the previous paper, when ε_a is sufficiently large ($\varepsilon_a > 10000$), as in the cases of dimethylaminoazobenzene and the like, the contribution of the second term on the right-hand side of Eq. (1) can be neglected. For 2-methyl derivatives, however, the second term can not be neglected. This can be estimated in the following way. According to Jaffé and Yeh,[4] the molar extinction coefficient (ε_a^{III}) of the azonium ion at about 320 nm is about 2000. On the other hand, ε_a^{II} is more than 20000.[7] Therefore, the $\varepsilon_a^{III}/\varepsilon_a^{II}$ value is about 0.1. The $\varepsilon_c^{III}/\varepsilon_a^{II}$ values were estimated in the manner described in a previous paper;[7] they are listed in Table 2. The K_t values calculated are listed in Table 2.

The tautomeric equilibrium constant is a measure of the difference between the basicity of the amino nitrogen (pK_1) and that of the azo nitrogen (pK_2). Hence, an examination of the effects of 2- and 2′-methyl groups on both pK_1 and pK_2 is necessary in order to interpret the effects on K_t. The pK_1 and pK_2 values were calculated according to the method described in a previous paper;[7] they are given in Table 2.

For all three groups in Table 2, the pK_1 increases in this order: unsubstituted < 2′-methyl < 2-methyl < 2,2′-dimethyl derivatives. The resonance effects of the 2-methyl group might not be significant, since this group is in the *meta* position to the amino group. As for the 2′-methyl group, this effect also does not seem to be important. Further, the steric effect of these groups on the pK_1 is not significant, since these groups are apart from the amino group. Therefore, of the effects of the 2- and 2′-methyl groups the inductive effect may be predominant.

The ΔpK_1 and ΔpK_2 values, which show the differences in pK_1 and pK_2 between 2- and/or 2′-methylated and the corresponding unmethylated compounds, are shown in Table 3 (a) and (b). An inspection of the ΔpK_1 values in Table 3 (a) shows that the introduction of an extra methyl group on the 2-position always results in a definite increase in pK_1. The same thing holds for the 2′-methyl group as well (see Table 3 (b)). This can easily be understood by remembering that the effects of the 2- and 2′-methyl groups on the pK_1 are only inductive.

As is shown in Table 2, the introduction of a methyl group into the 2-position increases the pK_2, while that into the 2′-position decreases the pK_2. These findings

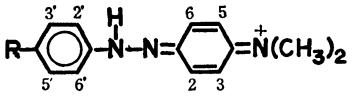
show that the 2′-methyl group sterically hinders the addition of a proton and decreases the pK_2, while the 2-methyl group does not hinder the addition, but, rather, increases the pK_2 through its electronic effect.[9] This supports the idea that the azonium ion of 4-dimethylaminoazobenzene derivatives is of the following resonance-stabilized type:[11]



As is shown in Table 3 (a) and (b), the constancy of the ΔpK_2 values shows the additivity of the effects of 2- and 2′-methyl groups on the basicity of the azo nitrogens. The values of 0.88 and −0.89 for the ΔpK_2 values of the 2- and 2′-methyl groups roughly agree with the corresponding values obtained by Haselbach[8] for 4-methoxyazobenzene derivatives.

The effects of the 2- and 2′-methyl groups on pK_1 are only inductive; therefore, the order of pK_1 is simple (unsubstituted < 2′-methyl < 2-methyl < 2,2′-dimethyl derivatives). On the other hand, the effects on pK_2 may be both electronic and steric, and the order of pK_2 is more complicated (2′-methyl < 2,2′-dimethyl ≈ unsubstituted < 2-methyl derivatives). The order of K_t is almost the same as that of pK_2. This shows that the magnitude of K_t is mainly governed by the basicity of the azo nitrogens.

The author would like to thank Professor Shigeo Hasegawa and Dr. Norio Nishimura for their kind guidance.

Liquid Crystalline Properties of Substituted Azo- and Azoxy-benzenes. I[1]

Kei MURASE and Haruaki WATANABE

Ibaraki Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Tokai, Ibaraki 319—11

(Received November 27, 1972)

In order to obtain low-temperature mesomorphic materials, thirty-two *p*-alkyl-*p'*-alkoxy-azo- and -azoxy-benzenes have been synthesized. The former have been made by the condensation of *p*-*n*-alkylnitrosobenzenes and *p*-*n*-alkoxyanilines, and the latter, by the oxidation of the former. Twenty-nine of the compounds show nematic behavior. In the majority of cases, the nematic temperature range of the azoxy compounds, which have been considered to consist of two isomers synthesized simultaneously, is appreciably wide.

In order to use a new electro-optic effect of nematic liquid crystals[2] to display elements, the present authors are studying the preparation of new mesomorphic materials[3,4] which, it is hoped, will exhibit nematic behavior at a low and wide temperature range, and will respond at high speeds and with high contrast ratios to an applied electric field.

Many compounds of *p,p'*-di-*n*-alkoxy-benzylideneanilines, -azobenzenes, and -azoxybenzenes are well known to show mesomorphism.[5] Recently, almost all the compounds of *p*-*n*-alkoxybenzylidene-*p'*-*n*-alkylanilines have been found to be mesomorphic.[3,6,7] Because their less polar alkyl substituents make the molecular interactions weak, they show mesomorphic transitions at much lower temperatures than the corresponding *p,p'*-dialkoxybenzylideneanilines.

For the same reason, it was presumed that *p*-*n*-alkyl-*p'*-*n*-alkoxy-azo- or -azoxy-benzenes would be mesomorphic in a low temperature range. This work was carried out to ascertain the validity of this assumption. Thirty-two new compounds have been synthesized in this work; some of them have recently been studied by a method different from ours, and the same results have been shown.[8,9,10]

Experimental

The transition temperatures were determined with a Mitamura Riken micro hot stage. The NMR spectra were measured on a JEOL C-60 HL apparatus, using CCl_4 as the solvent.

Raw Materials. *p*-Nitrotoluene and *p*-ethylnitrobenzene were purchased from commercial sources and were not distilled further. *p*-*n*-Propylnitrobenzene (bp 96—100 °C/2 mmHg) and *p*-*n*-butylnitrobenzene were prepared by the nitration of the corresponding *n*-alkylbenzenes. *p*-Anisidine and *p*-phenetidine were purchased from commercial sources and were not refined. *p*-*n*-Propoxyaniline (bp 74—75 °C/1.5 mmHg), *p*-*n*-butoxyaniline (bp 103—104 °C/1.5 mmHg), and *p*-*n*-hexyloxyaniline (bp 155—158 °C/5 mmHg) were prepared by the reduction of corresponding *p*-*n*-alkoxynitrobenzenes.[11]

Preparation of p-*Alkylnitrosobenzenes. General Procedure*: A solution of *p*-*n*-alkylnitrobenzene (14—18 g) in 60 ml of ethanol and an aqueous solution of ammonium chloride (5.4 g) were mixed and then kept at 60—65 °C. Zinc dust (15 g) was added to the mixture under vigorous stirring for two or three minutes. Then the zinc oxide was removed and the filtrate was cooled at dry ice-methanol temperature. The resulting solid was filtered and washed with benzene. After vacuum drying white *p*-alkylphenylhydroxylamine was obtained in a 10—20% yield.

Then, a solution of the hydroxylamine (3 g) in 100 ml of ethanol was poured into an ice-cooled aqueous solution of $FeCl_3 \cdot 6H_2O$ (10.8 g). By extraction with ether, the green *p*-*n*-alkylnitrosobenzene was separated. The yield was about 90%.

Preparation of p-*Alkyl*-p'-*alkoxyazobenzenes. General Procedure*: A solution of *p*-*n*-alkylnitrosobenzene (3 g) in 25 ml of ethanol and a solution of an equimolar quantity of the appropriate *p*-*n*-alkoxyaniline in 10 ml of acetic acid were cooled with ice-water and then mixed. After the cooling had been continued for about an hour, an orange-red crystalline product was given by filtration in a 70—90% yield. The product was recrystallized twice from a methanol solution. IR(KBr): 1580 (N=N), 1255 (C-O-C) and 835 (*p*-subst. benzene-ring) cm^{-1}. NMR(CCl_4): τ 2.20 and 2.28 (double d, J=9 Hz, inner aromatic 4H), 2.87 and 3.20 (double d, J=8 Hz, outer aromatic 4H).

Preparation of p-*Alkyl*-p'-*alkoxyazoxybenzenes. General Procedure*: The azobenzene (6 g) was dissolved in acetic acid (90 ml) and then warmed to 60—70 °C. While the solution was being stirred continuously, a 90-ml portion of aqueous hydrogen peroxide (30%) was added. After the color of the solution became yellow, cold water (100 ml) was added. Then the product was extracted with *n*-hexane (300 ml). The yield was 55—85%. The additional recrystallization of the product was done twice. IR (Nujol): 1565—70 and 1280 (N=N→O), 1255 (C-O-C) and 835 (*p*-subst. benzene-ring) cm^{-1}. NMR (CCL_4): τ 1.80 (m, inner aromatic 4H), 2.81 and 3.20 (double d, J=8 Hz, outer aromatic 4H).

Results and Discussion

Sixteen compounds of *p*-*n*-alkyl-*p'*-*n*-alkoxyazoxybenzenes were synthesized, and all were converted into the corresponding azoxybenzenes (strictly speaking, each of the compounds seems to be a mixture of Compounds I and II[10]) by oxidation.

(II)

The structures of the obtained compounds were confirmed by means of their IR and NMR spectra. Although *p,p'*-dialkyl and *p,p'*-dialkoxy compounds were expected to have also been produced by exchange reaction,[12] it can be concluded from the characterization of the NMR spectra of the aliphatic protons that the obtained compounds do not contain those mentioned above.

Contrary to Steinsträsser's result,[10] the difference in NMR spectra between Compounds I and II was not apparent in ours. Therefore, the isomer compositions of the azoxybenzenes are ambiguous.

The elemental compositions of the obtained compounds were also confirmed. The analyzed C, H, and N contents are in fair agreement with the calculated values.

The transition temperatures of the obtained compounds are shown in Tables 1 and 2. It is apparent from these results that the majority of the compounds show nematic behavior in the relatively low temperature range, which is appreciably wide, especially in the azoxybenzenes. The wide nematic range of the azoxy compounds gives evidence that each of them consists of two isomers synthesized simultaneously.

The deviations in the transition temperatures of some of the obtained compounds from those of the

analogous compounds which have two *n*-alkoxy groups as the *para* substituents[13] are shown in Table 3. As expected, all the transition temperatures of the obtained compounds are much lower than those of the comparable analogues.

Consequently, the materials obtained in this study may be used in the practical display so far as the transition temperature is concerned. Further study of the electro-optic effect of these materials is now in progress; the results will be presented in a subsequent paper.

The authors wish to thank Mr. Toshikuni Kaino and Mr. Tetsuo Wachi for their helpful cooperation in the measurements.

The Reaction of Nucleophilic Reagents at the β-Position of 3-Bromo-4-nitropyridine *N*-Oxide

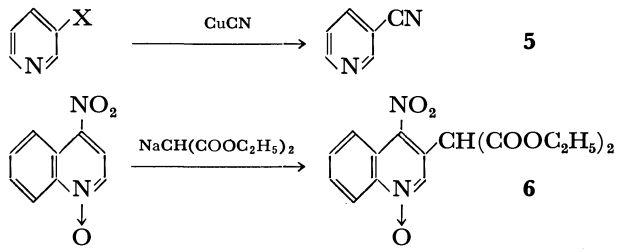
Eizo MATSUMURA and Masahiro ARIGA

Department of Chemistry, Osaka Kyoiku University, Tennoji-ku, Osaka 543

(Received January 9, 1973)

Some nucleophilic substitutions on the β-position of the pyridine nucleus were carried out. The reactions of 3-bromo-4-nitropyridine *N*-oxide(**1**) with diethyl sodiomalonate, ethyl sodiocyanoacetate, and ethyl sodioacetoacetate in diethyl carbonate or pyridine afforded 3-bis-(ethoxycarbonyl)methyl-4-nitropyridine *N*-oxide (**2**), 3-cyano(ethoxycarbonyl)methyl-4-nitropyridine *N*-oxide (**3**), and 3-acetyl(ethoxycarbonyl)methyl-4-nitropyridine *N*-oxide (**4**) respectively, and ethyl sodioacetoacetate, when treated at a higher temperature, gave 3-ethoxycarbonyl-2-methyl-furo(3,2-*c*)pyridine *N*-oxide (**5**). A probable mechanism of the reaction was presented.

The nucleophilic substitution reaction of pyridine homologues and their *N*-oxides have been widely investigated for a long time, and there are several reviews on the subject.[1-3] Most of such substitutions of the pyridine ring take place at the α or γ-position, especially with the carbanions. In this connection, several carbanion sources, such as active methylenes, enamines, Grignard reagents, alkyl metals, and metal cyanides, have been developed,[4] but only a few examples of the introduction of carbanions to the β-position of the pyridine ring have been reported, among which are the followings.[5,6]

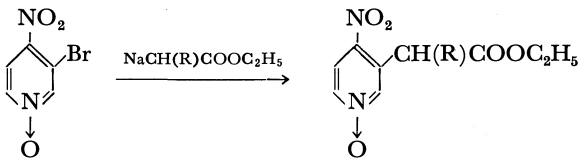


In the present investigation, since the authors' interests focussed on the carbanion introduction to the β-position of the pyridine ring, the reactions of 3-bromo-4-nitropyridine *N*-oxide with several active methylene compounds were worked out. The choice of the substrate was based on the following considerations; in the case of a nucleophilic attack, a bromide anion is a better leaving group than a hydride anion, and the β-carbon occupied by the bromine is activated by the inductive and tautomeric effects of the neighbouring nitro group.[7]

Results and Discussion

Diethyl malonate, ethyl cyanoacetate, and ethyl acetoacetate were employed as nucleophilic reagents.

The Reaction of 3-Bromo-4-nitropyridine N-*Oxide (1) with Diethyl Sodiomalonate.* On the treatment of **1** with diethyl sodiomalonate in diethyl carbonate at 50 °C, pale yellow needles (**2**) were obtained in a satisfactory yield after purification through a silica gel column. The NMR spectrum of Compound **2** showed four different kinds of hydrogens; a triplet at δ 1.28 and a quartet at 4.27 (CH_3CH_2OCO), a singlet at 5.31($CHPy(COOEt)_2$), and several peaks between 7.93—8.25 (aromatic hydrogens) in an area ratio of 6 : 4 : 1 : 3. The infrared spectrum of **2** indicated the presence of ester carbonyl, nitro, and *N*-oxide groups. The treatment of **2** with 20% sulfuric acid at 130 °C for 3 hours gave 3-(1-oxido-4-nitro)pyridylacetic acid. On the basis of these data, **2** was proved to be 3-bis(ethoxycarbonyl)methyl-4-nitropyridine *N*-oxide (**2**), showing that the malonate anion was introduced into the β-position of the pyridine nucleus.



(**1**)

(**2**, **3**, and **4**)
2: R=$COOC_2H_5$
3: R=CN
4: R=$COCH_3$

The Reaction of 1 with Ethyl Sodiocyanoacetate. When **1** was treated with ethyl sodiocyanoacetate, the reaction proceeded similarly, and 3-cyano(ethoxycarbonyl)methyl-4-nitropyridine *N*-oxide (**3**) was obtained. The NMR spectrum of **3** was analogous to that of **2** with the exception of the fact that the methine proton at δ 5.58 was exchangeable with deuterium. The acidity of **3** was also shown by the capacity to form a deeply-coloured quaternary ammonium salt, even with aqueous ammonia.

The Reaction of 1 with Ethyl Sodioacetoacetate. The treatment of **1** with ethyl sodioacetoacetate had results different from those of the two preceding reactions.

At a lower temperature (30—35 °C), the reaction proceeded much as in the above two reactions to give 3-acetyl(ethoxycarbonyl)methyl-4-nitropyridine *N*-oxide

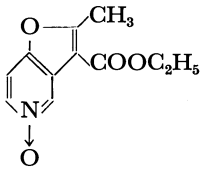
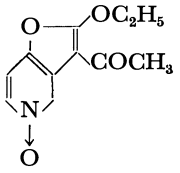
(**4**). However, the NMR spectrum of **4** showed a different aspect from the two preceding products (**2** and **3**). The singlet due to the methine proton was weakened to a negligible intensity, and a new D_2O-exchageable singlet corresponding to one proton appeared at δ 13.07, indicating that **4** exists as an enol, but the O–H absorption band was not observed in the IR spectrum. The fact that the methylene signal, which should originally be a quartet, splits into twelve peaks suggests that **4** exists in more than two enol forms. It seems also that the reactivity of the methine proton might act as a driving force to further the reaction.

When the reaction was followed by further treatment at a higher temperature (80—90 °C), colourless crystals (**5**) were obtained which had the empirical formulas of $C_{11}H_{12}NO_{4.5}$ and $C_{11}H_{11}NO_4$ after drying over phosphorus pentoxide. The IR spectrum of **5** indicated the subsistence of the carbonyl group and the *N*-oxide group and the lack of a nitro group. The NMR spectrum of **5** showed 6 different kinds of hydrogens. From the above data, **5** was assumed to be either **5a**, or **5b**.



(**5a**)

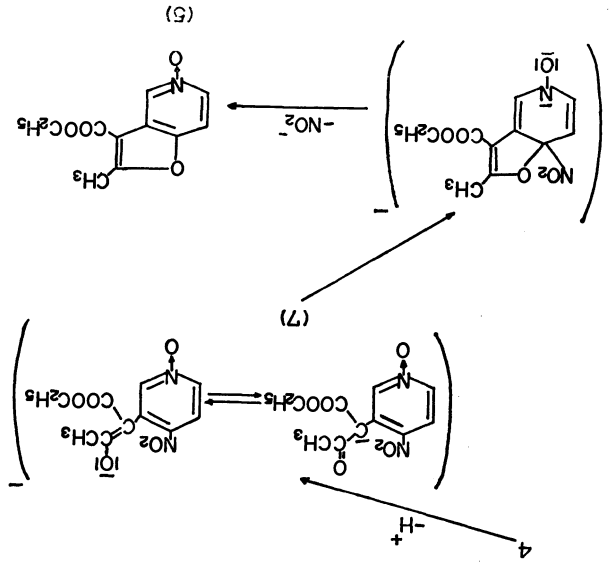


(**5b**)

The reaction of **1** with diethyl sodiomalonate and ethyl sodiocyanoacetate did not produce a compound corresponding to **5**, even at a higher temperature. This fact suggests that the acetyl carbonyl group rather than the ester carbonyl group takes part in the reaction and that **5** might be **5a** rather than **5b**. This inference was supported by the fact that the treatment of **5** with 10% hydrochloric acid gave a colourless carboxylic acid (**6**), $C_9H_7NO_4$. Thus, **5** was proved to be **5a**, 3-ethoxycarbonyl-2-methylfuro(3,2-*c*)pyridine *N*-oxide, and **6** was proved to be 2-methyl-5-oxidofuro-(3,2-*c*)pyridine-3-carboxylic acid.

The above results prove that ethyl sodioacetoacetate behaved, at a higher temperature, differently from the other reagents and gave a fused heterocyclic compound; this was because of the outstanding activity of the methine proton and the acetyl carbonyl group of **4** as has been mentioned above. The judgment that **5** was formed *via* **4** was supported by the facts that **4** was obtained at a lower temperature, that **5** was a preferential product at a higher temperature, and the fact that a deep red-purple in colour of the reaction mixture as was common to all the reactions yielding **2**, **3**, and **4**, faded in the case of **5** with a rise in the temperature. A probable course of the formation of **5** was proporsed as in the following scheme.

A methine proton of the preliminary product, **4**, is extracted by the excess base to give an anion, **7**, which is shown as a resonance of two canonical formula. The *O*-anion internally attacks the 4–*C*, which is activated by the nitro and *N*-oxide group; this is followed by the departure of the nitrate anion to give **5**.



Scheme

Consequently, the introduction of carbanion to the β-position of the pyridine ring was successfully achieved by the displacement of the bromide anion activated by the *ortho*-nitro group. The results were of great value not only in the point of the accomplishment of the introduction of the *C*-anion into the β-position of the pyridine nucleus with ease, but also in the point of the use of the product (**2**, **3**, and **4**) as synthetic intermediates, because the 4-nitro group of the products was still active in response to the nucleophilic attack. Further work is in progress on this point.

Experimental

All the melting points are uncorrected. The IR spectra were obtained on a Hitachi Infrared Spectrophotometer, EPI-S2, as Nujol mulls. The NMR spectra were recorded on a Hitachi High Resolution NMR Spectrometer, 20B, with TMS as the internal standard.

3-Bromo-4-nitropyridine N-*oxide* (**1**). 3-bromopyridine[8] was treated with 5 equivalent amounts of 30% hydrogen peroxide and 100 equivalent amounts of glacial acetic acid at 70—80 °C for 20 hr to give 3-bromopyridine *N*-oxide in a 92.3% yield as hydrochloride. 3-Bromo-4-nitropyridine *N*-oxide (**1**) (mp 152—152.5 °C) was obtained in a 57.5% yield from 3-bromopyridine *N*-oxide by the method of Jujo.[9]

The Reaction of **1**. *(a) With Diethyl Sodiomalonate*: Into a solution of 1.0 g of 3-bromo-4-nitropyridine *N*-oxide (**1**) in 50 ml of diethyl carbonate, a solution of diethyl sodiomalonate, which had been formed from 0.3 g of sodium and 2.2 g of diethyl malonate in 50 ml of diethyl carbonate, was stirred from a dropping funnel at 15—20 °C over a period of an hour; then the mixture was heated at 50—60 °C for 5 hr. The resulting mixture was neutralized with dil hydrochloric acid to pH 3. The organic layer was separated, and the water layer was extracted with chloroform. After drying over anhydrous sodium sulfate, the combined organic layers were evaporated; the residue was dissolved in 10 ml of chloroform and refined through a silica gel (Wakogel C-300) column. After the elution of diethyl malonate with chloro-

form, the evaporation of the ethereal elute gave 1.25 g (91.9%) of 3-bis(ethoxycarbonyl)methyl-4-nitropyridine *N*-oxide (**2**) as pale yellow needles; mp 97—98 °C (recrystallized from acetone-isopropyl ether). Found: C, 48.08; H, 4.51; N, 9.19%; Calcd for $C_{12}H_{14}N_2O_7$: C, 48.33; H, 4.73; N, 9.39%. IR: 1750 cm^{-1} (C=O), 1520 and 1350 (NO_2), and 1245 (N→O). NMR($CDCl_3$): δ 1.28 (6H, t), 4.27 (4H, q), 5.31 (1H, s), and 7.93—8.25 (3H, m).

(b) With Ethyl Sodiocyanoacetate: A similar treatment of **1** with ethyl sodiocyanoacetate formed from 0.3 g of sodium and 2.0 g of ethyl cyanoacetate in pyridine at 0 °C, but with the solvent being evaporated before the neutralization, gave 0.92 g (80.3%) of 3-cyano(ethoxycarbonyl)-methyl-4-nitropyridine *N*-oxide (**3**) as pale yellow needles; mp 147 °C (recrystallized from methyl alcohol). Found: C, 47.75; H, 3.65; N, 16.57%; Calcd for $C_{10}H_9N_3O_5$: C, 47.81; H, 3.59; N, 16.73%. IR: 2225 cm^{-1} (CN), 1745 (C=O), 1520 and 1340 (NO_2), and 1240 (N→O). NMR($CDCl_3$): δ 1.34 (3H, t), 4.34 (2H, q), 5.58 (1H, s), and 8.06—8.45 (3H, m).

(c) With Ethyl Sodioacetoacetate at a Lower Temperature: A solution of 1.0 g of **1** and ethyl sodioacetoacetate from 0.3 g of sodium and 2.1 g of ethyl acetoacetate in 100 ml of diethyl carbonate was kept at 30—35 °C for 12 hr; then the reaction mixture was treated as above to give 0.8 g (65.4%) of 3-acetyl(ethoxycarbonyl)methyl-4-nitropyridine *N*-oxide (**4**) as yellow leaflets; mp 95—96 °C (recrystallized from ethyl ether). Found: C, 49.46; H, 4.48; N, 10.26%; Calcd for $C_{11}H_{12}N_2O_6$: C, 49.25; H, 4.48; N, 10.26%. IR: 1645 cm^{-1} (C=O), 1620 (C=C), 1510 and 1350 (NO_2), and 1260 (N→O). NMR($CDCl_3$): δ 1.13 (3H, t), 1.96 (3H, s), 4.24 (2H, m), 7.90—8.27 (3H, m), and 13.07 (1H, s).

(d) With Ethyl Sodioacetoacetate at a Higher Temperature: The reaction mixture of the above reaction was further heated at 80—90 °C for an additional 5 hr. The resulting mixture was treated by the same procedure, and from the alcoholic elute, 0.82 g (78.2%) of 3-ethoxycarbonyl-2-methylfuro(3,2-*c*)pyridine *N*-oxide (**5**) semihydrate was obtained as colourless prisms; mp 150 °C (recrystallized from acetone). Found: C, 57.31; H, 5.23; N, 5.92%; Calcd for $C_{11}H_{11}NO_4 \cdot 1/2\ H_2O$: C, 57.39; H, 5.22; N, 6.09%, after drying over phosphorus pentoxide, Found: C, 59.64; H, 4.88; N, 6.08%; Calcd for $C_{11}H_{11}NO_4$: C, 59.28; H, 4.96; N, 6.33%. IR: 1695 cm^{-1}(C=O) and 1245 (N→O). NMR($CDCl_3$): δ 1.42 (3H, t), 2.78 (3H, s), 4.40 (2H, q), 7.31 (1H, d), 8.10 (1H, dd), and 8.82 (1H, d).

Hydrolysis of ***5***. A mixture of **5** and 10 ml of 10% hydrochloric acid was refluxed for 5 hr, and then cooled. The crystalline precipitates were collected and recrystallized from 0.1% hydrochloric acid to give 0.15 g (89.4%) of 2-methyl-5-oxidofuro(3,2-*c*)pyridine-3-carboxylic acid (**6**) as colourless needles; mp 254 °C (decomp.). Found: C, 55.69; H, 3.46; N, 7.06%; Calcd for $C_9H_9NO_4$: C, 55.96; H, 3.65; N, 7.25%. IR: 1690 cm^{-1}(broad)(COOH), 1245 (N→O). NMR(CD_3COOD): δ 2.83(3H, s), 7.71 (1H, d), 8.55 (1H, dd), and 9.10 (1H, d).

Hydrolysis of ***2***. A mixture of 1.0 g of **2** and 10 g of 30% sulfuric acid was heated at 130 °C for 3 hr; the reaction mixture was then neutralized with sodium carbonate to pH 2. The precipitates were collected by filtration and recrystallized from methyl alcohol to give 0.5 g (81.0%) of 3-(1-oxide-4-nitro)pyridylacetic acid as colourless needles; mp 161—162 °C. Found: C, 42.65; H, 2.56; N, 14.21%; Calcd for $C_7H_4N_2O_5$: C, 42.68; H, 2.58; N, 14.08%. IR: 1530 and 1350 cm^{-1}(NO_2), 1710 (C=O), and 1260 (N→O).

Ammonium Salt of ***3***. A tenth gram of **3** was dissolved in 10 ml of concd. ammonium hydroxide; then the mixture was evapolated to dryness, and recrystallized from acetone-isopropyl ether to give 0.09 g of ammonium salt of **3** as dark violet needles; mp 160—161 °C. Found: C, 44.75; H, 4.42; N, 20.57%. Calcd for $C_{10}H_{12}N_4O_5$: C, 44.77; H, 4.48; N, 20.89%.

The Catalytic Effect of Bases on the O→N Migration of the s-Triazinyl Group in *O*-(*s*-Triazinyl)-2-aminophenols

Takeo SHIOJIMA, Yōji HASHIDA, and Kohji MATSUI

Department of Chemistry, Faculty of Engineering, Gunma University, Tenjincho, Kiryu, Gunma 376

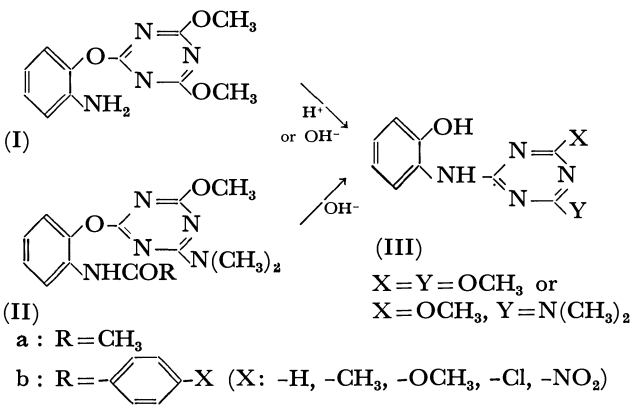
(Received March 20, 1973)

The catalytic effect of bases on the O→N migration of the *s*-triazinyl group in *O*-(*s*-triazinyl)-2-aminophenols has been studied kinetically. In the rearrangement of *N*-(acyl)-*O*-(*s*-triazinyl)-2-aminophenols (II) in alkaline aqueous methanol, the reactive species was found to be an ion formed by the ionization of the acylamino group. In the case of *O*-(*s*-triazinyl)-2-aminophenols (I), the rearrangement was subjected to a general base catalysis, although the extent was small.

Many examples of Smiles rearrangement have been known to be catalysed by an acid or a base.[1] In the course of our studies of the Smiles rearrangement of *s*-triazine derivatives, we reported[2-4] that *O*-(*s*-triazinyl)-2-aminophenols and N^1,N^1-bis(*s*-triazinyl)-*o*-phenylenediamines rearrange readily in protic solvents, especially in the presence of an acid or a base, to give *N*-(*s*-triazinyl)-2-aminophenols and N^1,N^2-bis(*s*-triazinyl)-*o*-phenylenediamines respectively. A similar O→N migration of the *s*-triazinyl group was also observed in the reaction of *N*-(acyl)- or *N*-(*s*-triazinyl)-*O*-(s-triazinyl)-2-aminophenol in the presence of a base.[2] However, these studies have been limited to qualitative discussions, and details of the effects of acids and bases on the rearrangement have not been sufficiently elucidated. This paper will report quantitative results on the influences of bases on the rearrangement.

Results and Discussion

O-(*s*-Triazinyl)-2-aminophenol (I) was prepared by a known method,[5] while *N*-acyl-*O*-(*s*-triazinyl)-2-aminophenols (IIa—b) were synthesized by acylating *O*-(4-dimethylamino-6-methoxy-*s*-triazin-2-yl)-2-aminophenol with acetic anhydride or 4-substituted benzoyl chlorides.[2] The new compounds thus obtained are listed in Table 1.



Effect of a Base on the Rearrangement of N-*(Acyl)*-O-*(s-triazinyl)-2-aminophenols (II).* The compounds (II) are stable in neutral and acidic solutions, but give rearranged products (III)[5] under the hydrolytic cleavage conditions of the acyl group when dissolved in an alkaline solution. Since the molar extinction coefficients of the original compounds at the absorption maxima (280—310 nm) are much smaller than those of the rearranged products, the apparent rate constants of the rearrangement were obtained spectrophotometrically from Eq. (1):

$$k' = -\frac{2.303}{t}\log\frac{D_\infty - D_t}{D_\infty - D_0} \quad (1)$$

where D_0, D_∞, and D_t denote the optical densities of a solution observed at initial and infinite times and at time t respectively. In every case, a plot of $\log D_\infty - D_t / D_\infty - D_0$ against the reaction time (t) gave a straight line.

The apparent rate constants (k') for the rearrangement of *N*-acetyl (IIa) and *N*-benzoyl (IIb) derivatives measured at various pH values are listed in Table 2. Fig. 1 shows the pH —rate profile in the case of (IIa).

As is shown in Fig. 1, the dependence of $\log k'$ on pH was linear with a unit slope. A similar relation was observed in the cases of *N*-benzoyl derivatives (IIb); however, no increase in the rate constant was

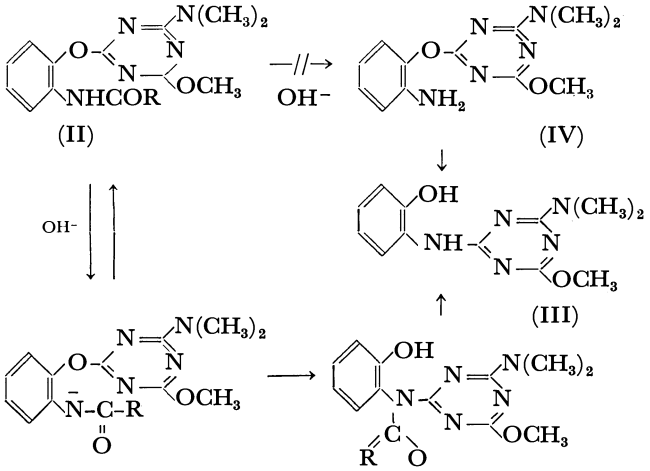
observed in the presence of a base such as pyridine at a constant pH value, suggesting that the rate-determining step of the reaction does not involve an abstraction of a proton from the NH– acyl group. Therefore, two reaction sequences can be considered:



One is a process involving a preferential hydrolytic cleavage of the acyl group to give (IV), followed by the O→N migration of the *s*-triazinyl group. However, under similar reaction conditions, no hydrolytic fission of an acyl group was observed in *N*-acyl arylamines. In addition, the rearrangement of (II) proceeded much more rapidly than that of (I) in the presence of alkali. Therefore, another path, one involving the rate-determining formation of the *N*-acyl-*N*-*s*-triazinyl derivative by the O→N rearrangement, followed by a hydrolytic cleavage of the acyl group, is considered to be reasonable. Although an intermediary *N*-acyl-*N*-triazinyl derivative was not obtained in every case, this reaction sequence may be supported by the consideration that generally, since the nucleophilic reactivity of a Ar–NH–acyl group is known to be lower than that of the parent amino group, the rearrangement of *N*-(acyl)-*O*-(2,4-dinitrophenyl)-2-aminophenols is slower than that of the parent aminoether.[6] Therefore, it seems unreasonable to consider that the reaction of (II) in the presence of alkali proceeds by a direct nucleophilic attack of the NH–acyl group; the reactive species may be assumed to be an anion formed by the dissociation of the NH–acyl group and the rate may be expressed by Eq. (2):

$$v = k\ (\text{Anion}) \qquad (2)$$

This assumption is verified by the fact that the dependence of $\log k'$ on pH was linear with a unit slope; the result may be understood by assuming that the concentration of the anion increases by a factor of ten per pH unit under a given set of reaction conditions. Since these compounds rearrange readily in alkaline solutions, the measurement of their pK_a values is impossible experimentally; the concentration of the anion remains unknown, and the real value of the rate constant could not be determined.

Recently, it has been suggested[7] that the rearrangement of *O*-*s*-triazinyl-*N*-acyl derivatives of 1-amino-8-hydroxynaphthalene-3,6-disulfonic acid to *N*-*s*-triazinyl-*N*-acyl derivatives proceeds by means of a direct nucleophilic attack on the acylamino group. However, further examinations will be necessary before this postulation can be accepted.

The effect of a substituent in the benzoyl group of *N*-(benzoyl)-*O*-(*s*-triazinyl)-2-aminophenol (IIb) was also studied at a constant pH value. The results are

a) Figures in the upper column indicate the concentrations of pyridine derivatives. b) Figures in the lower column indicate the rate constants.

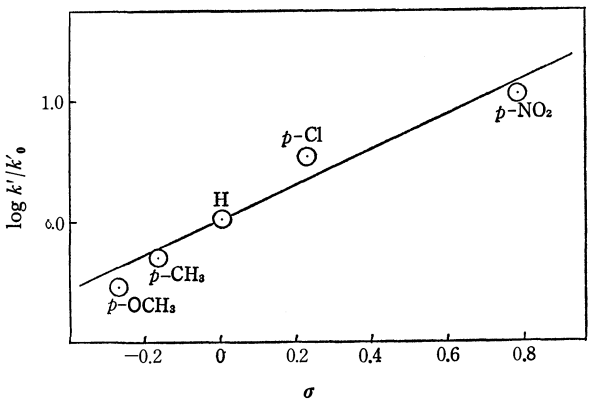

Fig. 2. Plot of the rate constants for the rearrangement of *N*-(4-substituted benzoyl)-*O*-(4-dimethylamino-6-methoxy-*s*-triazin-2-yl)-2-aminophenols (IIb) against the substituent constants.

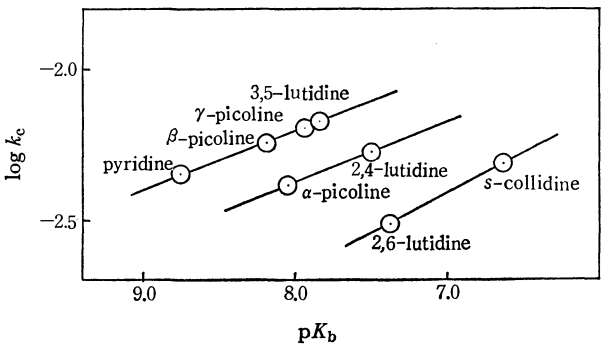

Fig. 3. Brönsted plot for the base-catalytic rearrangement of *O*-(4,6-dimethoxy-*s*-triazin-2-yl)-2-aminophenol (I).

given in Table 3, while a plot of log k'/k'_0 (where k' and k'_0 denote the apparent rate constants of substituted and unsubstituted benzoyl derivatives respectively) against the σ-value of the substituent is shown in Fig. 2. The substituent effect may be considered from two points of view. One is the effect upon the pK_a value of the benzamido group, namely, the effect on the concentration of the reactive anion, and the other is the effect upon the nucleophilic reactivity of the attacking anion. In the former, an electron-attracting substituent favors the rearrangement by increasing the concentration of the anion, while an electron-releasing substituent favors the latter.

As is shown in Fig. 2, it can be seen that the effect on the concentration of the anion dominates the rate change.

Effects of Bases on the Rearrangement of O-*(s-Triazinyl)-2-aminophenols (I).* In Table 4 are listed the rate constants for the rearrangement of (I) at various pH values. It is obvious from Table 4, that the rate constant (k) increases slightly with an increase in pH value in the pH range above 11.5. In this case, however, it is unlikely that an abstraction of the proton from the amino group occurs prior to the rearrangement, because an increase in the rate constant was not proportional to an increase in the pH value.

As is shown in Table 5, the rearrangement was also accelerated by such organic bases as pyridine and its methyl derivatives. Under the present reaction conditions, the rates were proportional to the concentration of bases. Therefore, the rate constant in the presence of a base can be expressed by Eq. (3):

$$k = k_0 + k_c\ (\text{Base}) \qquad (3)$$

where k, k_0, and k_c represent the rate constant observed, the rate constant in pure methanol, and the catalytic

constant by the base respectively. The catalytic constants obtained are summarized in Table 5, while Fig. 3 shows the relations between the log k_c and pK_b values of pyridine derivatives, which are given in three parallel lines.

Pyridine derivatives containing no methyl group in the α-position belong to Type 1, while those containing one methyl group in the α-position belong to Type 2 and those containing two methyl groups in the α,α'-positions belong to Type 3; among the pyridine derivatives of the same series, the Brönsted rule was found to hold. These facts indicate that the steric hindrance plays an important role in the catalytic efficiency of pyridine derivatives.

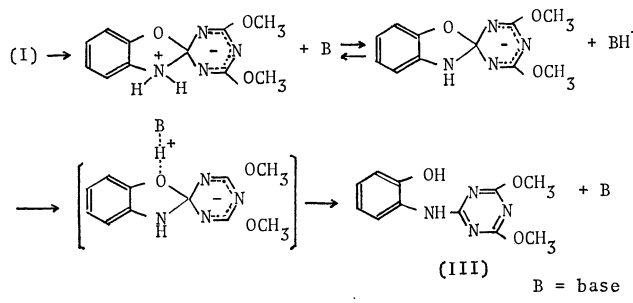
An acceleration of rearrangement was also observed in triethylamine; the catalytic constant in this case was found to be $k_c=6.58\times10^{-3}$.

Furthermore, a similar catalytic effect by triethylamine was observed in the rearrangement of *O*-(2,4-dinitrophenyl)-2-aminophenol in methanol at 25 °C ($k=2.88\times10^{-2}$), indicating that the base catalysis is not limited to the case of the *s*-triazine derivative.

Ordinary nucleophilic substitution reactions of activated aromatic halogen or aryloxy compounds with nucleophiles are considered to proceed by means of an addition-elimination process involving the intermediary formation of the σ-complex.[8,9] When an amine is used as a nucleophile, the catalytic effect by a base has been observed.[9,10] In the reaction of 2,4-dinitrophenyl phenyl ether with piperidine, the catalytic functions of bases have been interpreted in terms of the reaction mechanism involving the reversible transformation of the intermediate complex into its conjugate base, followed by the general acid-catalyzed detachment of the leaving group.[11,12]

Generally, Smiles rearrangements including the reaction of compound (I) can be considered to proceed in a manner similar to that of the ordinary nucleophilic aromatic substitution involving the formation of an intermediate complex;[13] this assumption may be supported by the facts observed in the rearrangement of 4- and 2-nitro-2'-hydroxydiphenyl sulfones,[14] in which the reactions are accompanied by a striking color change from deep-red to pale yellow, suggesting the formation of a Meisenheimer-type intermediate.

From these facts and considerations, it may be reasonable to consider that, in the rearrangement of *O*-(*s*-triazinyl)-2-aminophenol (I), a base participates in the proton transfer and detachment of the leaving group in the intermediate complex, as is shown below:



Experimental

All the melting points are uncorrected. The ultraviolet spectra were recorded on a Hitachi-124 UV-VIS spectrophotometer. The elemental analyses were performed at the Microanalytical Center of Gunma University.

Materials. N-*(4-Substituted benzoyl)*-O-*(s-triazinyl)-2-aminophenols*: A typical preparation is shown below in the case of *N*-(4-chlorobenzoyl)-*O*-(4-dimethylamino-6-methoxy-*s*-triazin-2-yl)-2-aminophenol. Into a mixture of 2.6 g (0.01 mol) of *O*-(4-dimethylamino-6-methoxy-*s*-triazin-2-yl)-2-aminophenol and 0.8 g (0.01 mol) of sodium bicarbonate in 10 ml of water in 50 ml of acetone, was added 1.7 g (0.01 mol) of *p*-chlorobenzoyl chloride in 30 ml of acetone dropwise with stirring at room temperature. After having been stirred for 6 hr at room temperature, the reaction mixture was poured into 500 ml of ice-water; the precipitate thus obtained was filtered and dried.

Kinetic Measurements. The kinetic measurements were carried out in buffered solutions at a constant ionic strength.

(Received March 22, 1973)

The kinetics of the substitution reactions of CyDTA with zinc(II)-IDA, -HIDA, and -NTA complexes and those with cobalt(II)-IDA, -HIDA, -NTA, -EtEN, and Dien complexes were studied by using the polarographic technique. All the substitution reactions studied in this paper were found to have a common reaction mechanism. They were first-order with respect to the CyDTA anion, and they were also first-order with respect to the metal(II) complex with a 1 : 1 composition; their reaction mechanism could be formulated as:

$$MX_2^{(2-2m)+} \rightleftharpoons MX^{(2-m)+} + X^{m-} \quad \text{in a rapid equilibrium}$$

$$MX^{(2-m)+} + \begin{cases} HY^{3-} \rightleftharpoons MY^{2-} + HX^{(1-m)+} \\ Y^{4-} \rightleftharpoons MY^{2-} + X^{m-} \end{cases} \quad \text{rate determining steps}$$

From a comparison of the observed rate constants with those estimated on the basis of the proposed reaction intermediate, the detailed reaction mechanism and structures of the reaction intermediates were discussed. The steric effect of the cyclohexane ring on the rate of the substitution reaction was also discussed.

We have studied a series of substitution reactions involving metal(II) aminopolycarboxylate complexes and have determined their detailed reaction mechanism.[2] Usually, the nucleophilic substitution reactions involving zinc(II) complexes proceed so rapidly that one can not determine their reaction rates accurately by employing a conventional technique. However, the substitution reaction of CyDTA with the zinc(II) aminopolycarboxylate complex proceeds at a measurable rate under the usual experimental conditions. In this paper, we will deal with the kinetics of the substitution reactions of CyDTA with zinc(II)-IDA, -HIDA, and -NTA complexes, and will discuss the detailed reaction mechanism and the steric effect of the cyclohexane ring on their reaction rates. To describe more precisely the reaction mechanism and the above steric effect, the substitution reactions of CyDTA with the cobalt(II) complexes of IDA, HIDA, NTA, EtEN, and Dien will also be studied.

Experimental

Reagents. The preparation and the standardization of zinc(II) and cobalt(II) solutions were described previously.[3,2a] Reagent-grade IDA, HIDA, NTA, and CyDTA were recrystallized from their aqueous solutions by adding pure hydrochloric acid and ethanol. The Dien and EtEN used in this study were purified by distilling them under reduced pressure. The other chemicals used were of an analytical reagent grade and were used without further purification.

Apparatus and Experimental Procedures. The apparatus and the experimental procedures were the same as those described previously.[2c] In this study, all the measurements were conducted in solutions of an ionic strength of 0.30 ($NaClO_4$ for the IDA, HIDA, and NTA systems; KNO_3 for the EtEN and Dien systems). No buffer reagent was used in this study, because free IDA, HIDA, NTA, EtEN, and Dien have enough buffer capacity to maintain the pH values of sample solutions constant over the entire pH range covered. The sample solutions used in the kinetic study of the substitution reactions of CyDTA with the cobalt(II)-IDA, -HIDA, and -NTA complexes always contained large excesses of complexed and uncomplexed IDA, HIDA, and NTA over CyDTA, while those in the reactions of CyDTA with zinc(II)-IDA, -HIDA, and -NTA complexes and with the cobalt(II)-EtEN and -Dien complexes contained large excesses of CyDTA and uncomplexed IDA, HIDA, NTA, EtEN, and Dien over the metal(II) complex. Therefore, all the substitution reactions studied in this paper could be treated as pseudo first-order reactions. The rates of the substitution reactions of CyDTA with the zinc(II) complexes and those of the reactions with the cobalt(II)-polyamine complexes were followed by measuring the change in the reduction wave-height of the zinc(II) complex and the oxidation wave-height of the cobalt(II) complex respectively. On the other hand, the rates of the substitution reactions with the cobalt(II)-IDA, -HIDA, and -NTA complexes were followed by determining the change in the dissolution wave-height due to the uncomplexed CyDTA.

Results and Discussion

Although not all the results will be shown here, the following facts were found in preliminary experiments. Provided that the other experimental conditions are kept constant, the forward pseudo first-order rate constant, k^+_{ap}, obtained from the slope of the linear relation between $\log(i_0/i_t)$ and t, was (1) inversely proportional to the concentration of the uncomplexed

IDA, HIDA, NTA, EtEN, and Dien, $[X]_f$, (2) exactly proportional to the concentration of the metal(II) complex (the cobalt(II)-IDA, -HIDA, and -NTA systems), [Me(II)], or the CyDTA concentration (the cobalt(II)-EtEN and -Dien systems and the zinc(II)-IDA, -HIDA, and -NTA systems), $[Y]_f$, and (3) independent of the initial concentration of CyDTA (the cobalt(II)-IDA, -HIDA, and -NTA systems) or that of the metal(II) complex (the cobalt(II)-EtEN and -Dien systems and the zinc(II)-IDA, -HIDA, and -NTA systems). Furthermore, as is shown by the results obtained in the reactions with zinc(II)-HIDA, cobalt-(II)-Dien and cobalt(II)-HIDA complexes (Figs. 1, 2, and 3), the k^+_{ap} multiplied by $K_2\cdot[X]_f\cdot(\alpha_H)_Y/(\alpha_H)_X[Ex]$

is a linear function of the concentration of the hydrogen ion, $[H^+]$, and is given by:

$$\frac{k^+_{ap}K_2[X]_f\cdot(\alpha_H)_Y}{(\alpha_H)_X[Ex]} = k_\alpha + k_\beta\cdot[H^+] \qquad (1_a)$$

where [Ex] denotes $[Y]_f$ or [Me(II)], and where $(\alpha_H)_Y$ and $(\alpha_H)_X$ are the (α_H) values of CyDTA and IDA, HIDA, NTA, EtEN, or Dien respectively, and where the other symbols used in the equation (1) have their usual meanings.[4,5,6] Considering that, under the present experimental conditions (8.90<pH<9.80 in the IDA system, 8.30<pH<9.80 in the HIDA system, 9.00<pH<9.60 in the NTA system, 9.70<pH<10.70 in the EtEN system, and 9.50<pH<11.0 in the Dien system), all the metal ions are considered to exist in the form of $MX_2^{(2-2m)+}$, the above experimental facts suggest that all the substitution reactions have the following common reaction mechanism:

$$MX_2^{(2-2m)+} \rightleftharpoons MX^{(2-m)+} + X^{m-} \quad \text{in a rapid equilibrium}$$

$$MX^{(2-m)+} + \begin{cases} HY^{3-} \overset{k_H}{\rightleftharpoons} MY^{2-} + HX^{(1-m)+} \\ Y^{4-} \overset{k_o}{\rightleftharpoons} MY^{2-} + X^{m-} \end{cases} \quad \text{rds}$$

For the above reaction mechanism, Eq. (1_a) can be rewritten as:

$$\frac{k^+_{ap}\cdot K_2\cdot[X]_f\cdot(\alpha_H)_Y}{(\alpha_H)_X[Ex]} = k_o + k_H\cdot\frac{[H^+]}{|K_4} \qquad (1_b)$$

where $|K_4$ is the fourth dissociation constant of CyDTA. From the slopes and the intercepts of the linear relations between $k^+_{ap}\cdot K_2\cdot[X]_f\cdot(\alpha_H)_Y/(\alpha_H)_X\cdot[Ex]$ and $[H^+]$, the k_H and k_0 values were determined; they are listed in Tables 1, 2, and 3. As is clear from the data in Table 1, the rates of the substitution reactions of CyDTA with zinc(II) complexes are much larger than

their corresponding dissociation rates.[7] This can be explained in terms of the formation of the mixed-ligand-complex reaction intermediates involving the CyDTA anion. As was attempted in the substitution reaction of EDTA or EDTAOH with the nickel(II) ethylenediaminemonoacetate (EDMA) complex,[8] we tried to estimate the structure of the reaction intermediate in the substitution reaction by comparing the relative rate constant observed with that calculated on the basis of the proposed reaction intermediate. The substitution reactions of CyDTA with the zinc(II)-HIDA and -NTA complexes proceed at measurable rates, but the corresponding EDTA reactions proceed so rapidly that one can not determine their rates by employing a conventional method. Usually, this can be ascribed to the steric effect of the cyclohexane ring on the substitution reaction. Generally speaking, it is reasonable to believe that the steric hindrance which will be encountered in the substitution reaction of CyDTA with the zinc(II)-HIDA complex is quite similar to that in the reaction with the zinc(II)-NTA complex. If the above assumption is correct, one can determine the structure of the reaction intermediate by comparing the relative rate constants for the zinc(II)-HIDA and -NTA complexes with those estimated on the basis of the proposed reaction intermediates. In the polarographic study of zinc(II)-HIDA and -NTA complexes in an acetate buffer solution, we found that these complexes dissociate through the glycinate reaction intermediate, where the leaving group is bonded to the zinc(II) ion through the glycinate chelate ring.[7] Therefore, it is natural to consider that the HIDA and NTA anions in the reaction intermediates in the substitution reactions of CyDTA are also bonded to the zinc(II) ion through the glycinate chelate ring. As is shown by the data in Table 1, the relative rate constants calculated with the aid of this well-known relation: $k=k_{rds}\cdot K_L\cdot K_A\cdot K_{st}\cdot K_{elec}/K_{MX}$,[5] on the basis of reaction intermediates given in Fig. 4 agree well with those observed. The relative

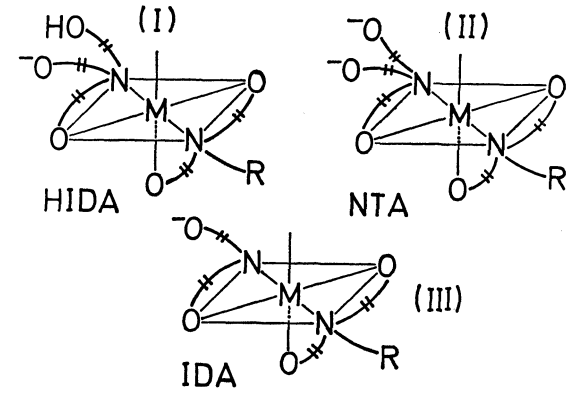

Fig. 4. Reaction intermediates.

rate constants calculated on the basis of the reaction intermediates other than those shown in Fig. 4 showed no satisfactory agreement with the observed ones. Since it is reasonable to consider that the steric effect brought about by the cyclohexane ring in the CyDTA reaction of the zinc(II)-NTA complex is not different from that of the zinc(II)-HIDA complex, the above agreement can be said to be an indication that the CyDTA anion in the reaction intermediate coordinates to the zinc(II) ion through the iminodiacetate group. In the calculation of the relative rate constants, the formation constants determined at 20 °C were used. Previously,[4] we ascribed the sluggishness of the substitution reaction of CyDTA with the nickel(II)-HIDA complex to the steric interaction of the cyclohexane ring with the hydroxyethyl group of the HIDA anion. However, the Fisher-Hirschfelder-Taylor molecular model shows that the steric interaction of the

7) M. Kodama, K. Namekawa, and T. Horiuchi, This Bulletin, to be published.

8) M. Kodama, M. Hashimoto, and T. Watanabe, *ibid.*, **45**, 2761 (1972).

cyclohexane ring with the hydroxyethyl group of the HIDA anion in the reaction intermediate is negligibly small. Furthermore, the fact that the rates of the reactions with zinc(II)- and cobalt(II)-IDA complexes can also be understood by assuming the reaction intermediates III (Tables 1 and 2) shows that the sluggishness of the CyDTA reaction with the metal(II)-HIDA complex can not be ascribed solely to the above steric interaction. For the successful formation of I and II in Fig. 4, the approach of the CyDTA anion to the coordination sphere and the formation of the zinc(II)-CyDTA bond should not be hindered by the steric interaction between the glycinate chelate ring, through which the leaving group is bonded to the zinc(II) ion, and the free iminodiacetate group of the CyDTA anion. The above steric requirement will be satisfied completely only when the rotation of the uncoordinated IDA group of CyDTA around the C–N bond is not hindered. However, as is shown by the molecular model, the cyclohexane ring in the CyDTA anion provides a greater barrier to the rotation of its uncoordinated IDA group. Therefore, the I and II structures can be formed, but only with some difficulty. Thus, the slow substitution reaction of CyDTA can be ascribed mainly to the above difficulty encountered in the reaction-intermediate formation. Undoubtedly, if the above steric effect of the cyclohexane ring on the rate of the substitution reaction can be neglected, the rate constant ratio between the dissociation of the zinc(II)-HIDA complex and its substitution reaction with CyDTA should be $10^{7.58}$. The observed ratio was $10^{3.42}$. Although the dissociation and substitution rates were determined at different temperatures (25 and 0 °C respectively), the above discrepancy can be accounted for by the steric effect of the CyDTA anion on the substitution reaction. Previously,[5] we mentioned in our kinetic study of the substitution reactions of Calmagite with the cobalt(II) and nickel(II) aminopolycarboxylate complexes that the reaction of the cobalt(II) complex proceeds through a reaction intermediate with the same structure as that in the reaction of the nickel(II) complex. Therefore, the finding that the reaction intermediate in the substitution reaction involving the zinc(II) aminopolycarboxylate complex has the same structure as that of the reaction involving thenickel(II) complex[4] suggests that the substitution reactions of CyDTA with the cobalt(II)-aminopolycarboxylate complexes proceed through the same reaction intermediate as that of the zinc(II) complex. In Table 2, the relative rate constant calculated on the basis of the reaction intermediates in Fig. 4, using the numerical data listed there also are compared with those observed. The calculated values agreed well with the observed ones. As in the case of the substitution reaction of CyDTA with the nickel(II) aminopolycarboxylate complex, the k_H value is much smaller than the k_0 value. Since the protonation of the CyDTA anion bonded to the metal(II) ion will reduce the electrostatic repulsion between the uncoordinated carboxylate groups and will stabilize the reaction intermediate, the fact that the k_H value is smaller than the k_0 value suggests the importance of the deprotonation of the attacking group in the formation of the reaction intermediate. The molecular model also shows that the protonation of the nitrogen atom in the uncoordinated IDA group in the CyDTA anion will provide a greater barrier to the formation of the reaction intermediate. Thus, the small k_H value can be understood in terms of the above barrier to the formation of the reaction intermediate. In this investigation, we also dealt with the substitution reactions of CyDTA with the cobalt(II)-EtEN and -Dien complexes. The rate constants for the two elementary reaction pathways are listed in Table 3. Previously,[8] we reported that the substitution reaction of EDTA with the nickel(II)-Dien complex proceeds through the outer-sphere complex, where the leaving Dien is bonded to the nickel(II) ion through the ethylenediamine chelate ring. The rates of the substitution reactions of CyDTA with the cobalt(II)-EtEN and -Dien complexes can also be understood by assuming an outer-sphere complex formation between the cobalt(II) complex ion and CyDTA anion. The rate constant ratio between the Dien and EtEN systems, calculated on the basis of the outer-sphere complex in which the leaving group is bonded to the cobalt(II) ion through the ethylenediamine chelate ring, agrees fairly well with the observed one. The k_H values for the cobalt(II)-polyamine systems are about ten times smaller than the k_0 values. This factor is clearly consistent with the relative electrostatic attraction of the ions concerned. Although the substitution reaction involving the cobalt(II)-EtEN complex was studied at 0 °C, the k_0 value is nearly identical to the characteristic rate constant for the water-loss from the cobalt(II) aquo ion at 25 °C. In considering the fact that the rate constant for the water loss at 0 °C must be smaller than that at 25 °C, and the fact that the equilibrium constant for the outer-sphere association between the cobalt(II) complex and the CyDTA anion is larger than unity,[9] the above agreement can also be taken as evidence for the water-loss mechanism proposed for the reactions of CyDTA with the cobalt(II)-polyamine complexes.

A-Substituted 5β-Steroids. V.[1] Syntheses and Some Reactions of 1-Oxygenated 5β-Cholestanes

J. Yasuo SATOH, Katsumi MISAWA, T. Tomoyoshi TAKAHASHI, Masakatsu HIROSE, C. Akira HORIUCHI, Shin-ichiro TSUJII*, and Akira HAGITANI

Department of Chemistry, St. Paul's (Rikkyo) University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171
** Rock Paint Co., Ltd., Himejima, Nishi-Yodogawa-ku, Osaka 555*

(Received March 22, 1973)

1-Oxygenated 5β-cholestanes were synthesized in good yield from 3-oxygenated 5β-cholestane through 5β-cholest-1-en-3-one. The reaction of 1β,2β-epoxy-5β-cholestan-3-one with hydrogen halide occurs with a normal ring cleavage resulting in the formation of 2-halo-5β-cholest-1-en-3-one. The reaction of 1β-hydroxy-5β-cholest-2-ene with chromium trioxide gave the allylic rearrangement product, 5β-cholest-1-en-3-one. The oxidative acetylation and bromination of 5β-cholestan-1-one is described.

Although studies have been made on the syntheses of 1-oxygenated 5α-steroids,[2] only very little information can be found on 5β-steroids concerning the reactions of introducing oxygenated groups at the C_1 position.[3]

In a previous paper, we reported on the synthesis of 5β-cholest-1-en-3-one as a key intermediate for the synthetic pathway of 1-oxygenated 5β-cholestanes.[4] In the present paper, the synthesis of 1-oxygenated 5β-cholestanes is given in detail together with reactions of some of them.

Djerassi *et al.*[5] reported that 1-oxygenated 5α-cholestanes were synthesized from 5α-cholest-1-en-3-one derived from 3-oxygenated 5α-cholestane. Since the bromination of 3-oxo-5α-steroid gives a 2-brominated product, the 1-en-3-oxo derivative could easily be derived from the product by dehydrobromination. However, this procedure can be applied to 5β-steroid because the bromination of the 3-oxo derivative does not occur at C_2. Williamson and Johnson reported the synthesis of 4α-bromo-5α-cholestan-3-one, a compound that can be produced only with difficulty by the direct bromination of 5α-cholestan-3-one, or by the reductive monodebromination of the 2α,4α-dibromo-3-oxo derivative with chromous acetate.[6] We attempted the preparation of 2-bromo-5β-cholestan-3-one by the application of this method to 2β,4β-dibromo-5β-cholestan-3-one (**1**),[7] and achieved good results. The syntheses of 1-oxygenated 5β-cholestanes from 5β-cholest-1-en-3-one (**3**) were then carried out following the procedure of Djerassi *et al.*[5] for the synthesis of 1-oxygenated 5α-cholestanes. Some reactions have been examined for the 1-oxygenated derivatives thus obtained.

Results and Discussion

The α-bromoketone derived from 2β,4β-dibromo-5β-cholestan-3-one (**1**) by reductive monodebromination with chromous acetate was determined as 2β-bromo-5β-cholestan-3-one (**2**) from its NMR spectrum. The bromine susceptible to reductive elimination was found to be at C_4 rather than that at C_2 in the 5β-series, but at C_2 in the 5α-series.[6] By treating the product with calcium carbonate/dimethylformamide, 5β-cholest-1-en-3-one (**3**) was formed in good yield. Thus it seems that this pathway improves the insertion of the 1-en-3-oxo function in 5β-steroid.

The epoxy ketone derived from the 1-en-3-oxo derivative (**3**) with alkaline hydrogen peroxide was identified as 1β,2β-epoxy-5β-cholestan-3-one (**4**) from the fact that it shows a negative Cotton curve in its ORD spectrum.[8] The structure is also supported by the ring opening reaction of the epoxy ketone with hydrogen halide. If the epoxy ring has a β-orientation, it will be transformed into 2-halo-5β-cholest-1-en-3-one (**5**) in this reaction. In the present instance, the chemical shift of the C_1-vinyl proton in the presumed structure was calculated from the equation proposed by Matter *et al.*,[9] and the values (**5a**, τ 2.74; **5b**, 3.01) agreed very closely with the ones observed (τ 2.75 and 3.01, respectively) for the compound obtained. These results show that in the epoxydation of derivative (**3**) the attack of the reagent took place at the β-side of the molecule. The attack is the reverse of that in the epoxydation of 5α-cholest-1-en-3-one.[5] This is attritable to the environmental complexity of the α-side of 5β-steroids.

Reductive elimination of the 1β,2β-epoxy-3-oxo derivative (**4**) with 100% hydrazine hydrate gave an allylic alcohol (**6**). Catalytic hydrogenation of (**6**) followed by its acetylation gave 1β-acetoxy-5β-cholestane (**7b**). This shows that the hydrazine reduction product has a β-oriented hydroxy group at C_1. Oxidation of the catalytic hydrogenation product (**7a**) gave 5β-cholestan-1-one (**8**), which shows a negative Cotton curve having a shoulder near 310 nm similar to 5β-cholestan-2-one[10] in the ORD spectrum.

In the synthetic pathway of 5β-cholestan-1-one from 5β-cholest-1-en-3-one (**3**), the synthesis from **3** to **7a** without purification of each product, followed by chromatographic separation of the oxidation product of **7a** in the last step, gave the 1-oxo derivative (**8**) in 55% yield based on the 1-en-3-oxo derivative.

Catalytic reduction of derivative (**8**) proceeds stereospecifically to give an equatorial hydroxy group. The configuration of the product (**9a**) was determined from the NMR spectrum of its acetate (**9b**). C_1-H of the acetate appeared in a higher field than that of the 1β-acetoxy epimer (**7b**), showing a triplet. This stereospecificity is attributable to preferential attack from the β-side rather than the α-side, which has a stereochemical complexity similar to the epoxy ketone (**4**). This catalytic reduction of the 1-oxo derivative is identical with that of Schlegel and Tamm on the catalytic reduction of methyl 1-oxo-etianate.[3a]

Oxidation of 2-en-1β-ol (**6**) with chromium trioxide gave predominantly 5β-cholest-1-en-3-one (**3**) along with a minor component, 5β-cholest-2-en-1-one (**10**). This may be attributed to the small interaction involved with respect to the 19-methyl group in the case of the reaction pathway through a six-membered transition state (A) between the 1β-chromic ester formed and the allylic position, as compared with that in the case of the pathway through a cyclic transition state (B) between the 1β-chromic ester and $C_{1\alpha}$-H (Fig. 1). We see that the properties of 1β-hydroxy-5β-cholest-2-ene (**6**) are similar to those of 1β-halo-5β-cholestan-2-one, which gave a 3-substituted product through various reactions.[11]

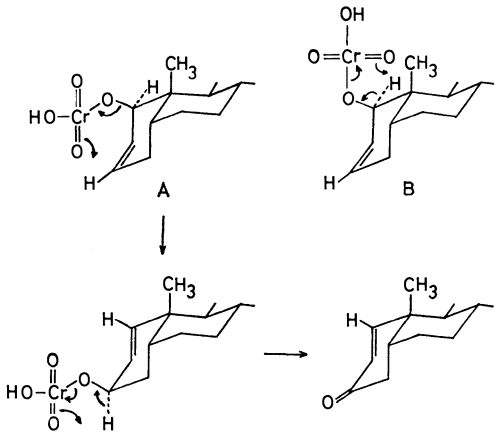

Fig. 1.

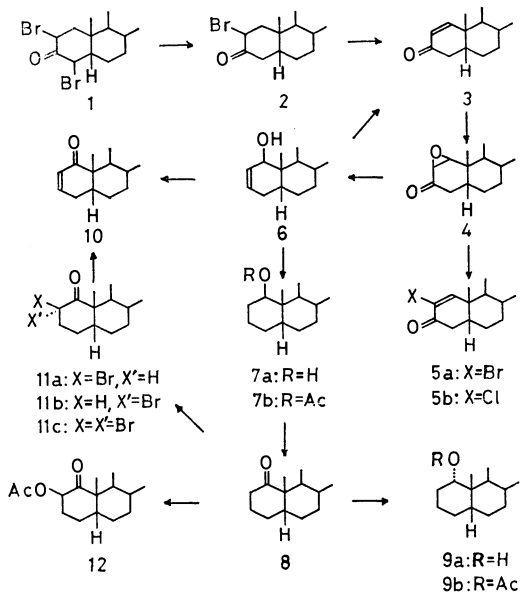
The reaction of 5β-cholestan-1-one (**8**) with bromine in acetic acid gave mainly a compound melting at 118—119 °C with two minor products: "A", mp 69—70.5 °C and "B", mp 141.5—143.5 °C. The main product was determined to be 2β-bromo-5β-cholestan-1-one (**11a**) from the fact that the ORD curve showed a negative Cotton effect and its λ_1 had a blue shift of 5 nm from that of the parent ketone (**8**), and from the coupling constant in the NMR spectrum. Dehydrobromination of bromoketone (**11a**) with Ca-



CO_3/DMF gave an α,β-unsaturated ketone, identical with 5β-cholest-2-en-1-one (**10**) obtained from 1β-hydroxy-5β-cholest-2-ene (**6**) with chromium trioxide. The minor product "A" was determined to be the 2α-bromo epimer (**11b**) from the small half-height width of the peak at τ 5.69 in its NMR spectrum, as compared with that of the 2β-epimer (**11a**), and from the ORD curve showing a red shift of 28 nm from that of the parent ketone (**8**). The product could easily be converted into the 2β-epimer (**11a**) with HBr/AcOH. The NMR spectrum of the other product "B" did not reveal any peaks due to –CH(Br)–. Hence the product was concluded to be a 2,2-dibromo-1-oxo derivative (**11c**).

Oxidative acetylation of 5β-cholestan-1-one (**8**) with lead tetraacetate gave 2β-acetoxy-5β-cholestan-1-one (**12**). It was found from the NMR spectrum that the acetate was not deformed, as was the case with the other α-acyloxy-keto-5β-steroids having an equatorial acyloxy group in ring A.[12]

Experimental

All melting points are uncorrected. The IR spectra were measured on a Shimadzu model IR-27B infrared spectrometer, ORD spectra on a JASCO model ORD/UV-5 spectrometer, and NMR spectra on Hitachi-Perkin Elmer R-20A and JEOL model JNM-4H-100 instruments using TMS as an internal standard.

2β-Bromo-5β-cholestan-3-one (2). To a solution of **1** (31.7 g) in acetic acid (600 ml) and chloroform (240 ml) was added chromous acetate prepared from chromic chloride according to the method of Williamson and Johnson.[6] The end point of the reaction was confirmed by tlc. Ether extracts from the reaction mixture were neutralized, washed and evaporated. Crystallization of the residue from ethanol gave needles (22.2 g), mp 138—140 °C, IR (KBr): 1727 cm^{-1}; ORD (*c* 0.216, dioxane) at 16 °C: $[\alpha]_{311}$ −296° (trough) and $[\alpha]_{267}$ +494°; NMR (CCl_4) τ: 5.42 (dd, $J_{1\alpha,2}$=5 and

*5β-Cholest-1-en-3-one (**3**).* A mixture of **2** (19.4 g), calcium carbonate (20 g), and DMF (300 ml) was refluxed for 2 hr. After the usual work-up, the resultant residue, on crystallization from ethanol, gave needles (12.8 g), mp 108—109 °C (lit,[3c] 105—106 °C).

*Synthesis of 5β-Cholestan-1-one (**8**) from 5β-Cholest-1-en-3-one (**3**).* The synthesis was carried out following the procedure of Djerassi *et al.*[5] for the synthesis of 5α-cholestan-1-one from 5α-cholest-1-en-3-one. Details are therefore omitted. Reaction of **3** (10 g) with 1 M sodium hydroxide solution (100 ml), dioxane (510 ml), and 30% hydrogen peroxide (35 ml) at room temperature for 15 hr gave **4** (7.4 g), mp 107—108.5 °C (lit,[3c] 107—109 °C), from ethanol. When the temperature was raised to 34—40 °C, the reaction was completed in 5 hr. By refluxing **4** (2.42 g) with 100% hydrazine hydrate (14.7 ml) for 15 min, **6** was obtained as a colorless amorphous substance (1.26 g), mp 95—96 °C (lit,[3c] 98—99 °C), from acetone. Hydrogenation of **6** (9.8 g) was carried out with 10% Pd-C (7 g) in cyclohexane (35 ml). Since crystallization of **7a** could not be accomplished from the residue (9.8 g, IR: 3330 cm^{-1}), the following procedure was used. A solution of **7a** (10 g) in acetic acid (605 ml) was treated with chromium trioxide (2.6 g) in acetic acid (242 ml) and water (12 ml) at room temperature. After being stirred for 5 hr, the reaction mixture was treated in the usual manner. The residue was chromatographed on silica gel. Elution with benzene–petroleum ether (1 : 1) gave needles of **8** (4.9 g), mp 101—102 °C (lit,[3c] 101—102 °C), from ethanol (Found: C, 83.79; H, 12.02%).

*Epoxy Ring Opening Reaction of 1β,2β-Epoxy-5β-cholestan-3-one (**4**).* A solution of **4** (200 mg) in chloroform (20 ml) was treated with 48% hydrobromic acid (2 ml) at room temperature for 24 hr. The reaction mixture was poured into water and the chloroform layer was worked up in the usual manner. Crystallization of the resulting oil from ethanol gave **5a** (156 mg), mp 137—139 °C; λ_{max}^{EtOH} 257 nm (ε 12500); IR (KBr): 1696 and 1600 cm^{-1}; ORD (*c* 0.611, dioxane) at 18.5 °C: $[\alpha]_{375.5}$ +200° (sh), $[\alpha]_{360}$ +237° (peak), $[\alpha]_{350}$ +193° (trough), $[\alpha]_{345.5}$ +198° (peak), $[\alpha]_{334}$ +148° (trough), $[\alpha]_{331}$ +149° (peak), $[\alpha]_{323}$ +136° (trough), and $[\alpha]_{300}$ +265°; NMR (CCl_4) τ: 2.75 (s, 1H) and 8.77 (s, 3H).

Found: C, 69.76; H, 9.43%. Calcd for $C_{27}H_{43}OBr$: C, 69.96; H, 9.36%.

When the epoxide was treated with 35% hydrochloric acid under the same conditions, **5b** (137 mg) mp 130—132.5 °C, was obtained from ethanol. λ_{max}^{EtOH} 249 nm (ε 10500); IR (KBr): 1703 and 1606 cm^{-1}; ORD (*c* 0.434, dioxane) at 18.5 °C: $[\alpha]_{373}$ +761° (sh), $[\alpha]_{359.5}$ +885° (peak), $[\alpha]_{350}$ +747° (trough), $[\alpha]_{344}$ +789° (peak), $[\alpha]_{334}$ +630° (trough), $[\alpha]_{328}$ +685° (peak), $[\alpha]_{323}$ +643° (trough), and $[\alpha]_{300}$ +1266°; NMR (CCl_4) τ: 3.01 (s, 1H), and 8.79 (s, 3H).

Found: C, 77.17; H, 10.27%. Calcd for $C_{27}H_{43}OCl$: C, 77.38; H, 10.34%.

*1β-Acetoxy-5β-cholestane (**7b**).* **7a** (2.3 g) was treated with acetic anhydride (55 ml) and pyridine (55 ml) for 10 hr at room temperature. After the usual work-up, the residue was chromatographed on silica gel. Benzene elution, on crystallization from ethanol, gave needles (1.48 g), mp 104—105.5 °C (lit,[3c] 100—101 °C).

*1α-Acetoxy-5β-cholestane(**9b**).* Sodium borohydride (500 mg) was gradually added to a solution consisting of **8** (1 g), ether (75 ml) and methanol (25 ml). After the usual work-up, an oily product (1.1 g; IR; 3400 cm^{-1}) was obtained. Attempts to crystallize it with several solvents were unsuccessful, and it was acetylated in the usual manner. **9b** was obtained as needles (783 mg) from ethanol. Mp 40—42 °C, IR (KBr): 1735 and 1242 cm^{-1}; NMR (CCl_4) τ: 5.57 (t, $J_{1.2}=7.5$ Hz, 1H) and 8.06 (s, 3H).

Found: C, 80.59; H, 11.72%. Calcd for $C_{29}H_{50}O_2$: C, 80.87; H, 11.71%.

*Oxidation of 5β-Cholest-2-en-1β-ol (**6**).* A solution of **6** (900 mg) in acetone (7 ml) was treated with chromium trioxide (560 mg) and 40% H_2SO_4 solution (0.8 ml) at 10—15 °C. After 30 min, a small amount of methanol was added to the reaction mixture. The ether extracts from the solution were washed with sodium hydrogen carbonate solution and water, dried and evaporated. The residue was chromatographed on silica gel. From the first elution with benzene–petroleum ether (1 : 1), **10** (36 mg) was obtained from ethanol as needles, mp 100—101.5 °C (lit,[3c] 99—100 °C); IR (KBr): 1672 and 1631 cm^{-1}; λ_{max}^{EtOH} 223 nm (ε 7000); ORD (*c* 0.196, dioxane) at 23.5 °C: $[\alpha]_{400}$ −143°, $[\alpha]_{384}$ −250° (trough), $[\alpha]_{373}$ −89° (peak), $[\alpha]_{366}$ −189° (trough), $[\alpha]_{356}$ +92° (peak), $[\alpha]_{349}$ −59° (trough), $[\alpha]_{342}$ +120° (peak), $[\alpha]_{334}$ +20° (trough), $[\alpha]_{327}$ +112° (peak), $[\alpha]_{322}$ +94° (trough), and $[\alpha]_{280}$ +339°; NMR (CCl_4) τ: 3.40 (dq, $J_{3.4\alpha}=2.1$, $J_{3.4\beta}=5.0$ and $J_{2,3}=10.2$ Hz, 1H) and 4.32 (dd, $J_{2.4\beta}=1.7$ and $J_{2.3}=10.2$ Hz, 1H).

Found: C, 84.02; H, 11.46%. Calcd for $C_{27}H_{44}O$: C, 84.31; H, 11.53%.

The next fraction eluted with the same solvent, on crystallization from ethanol, gave needles of **3** (640 mg), mp 108—109 °C.

*Bromination of 5β-Cholestan-1-one (**8**).* To a solution of **8** (2.89 g) in acetic acid (200 ml) was added bromine (1.2 g) in acetic acid (50 ml). After being stirred for 30 min at room temperature, the reaction mixture was treated in the usual manner. The resulting oil (3.7 g) was chromatographed on silica gel. From the first elution with benzene–petroleum ether (1 : 9), **11c** was obtained as needles (184 mg), mp 141.5—143°C, IR (KBr): 1714 cm^{-1}; ORD (*c* 0.22, dioxane) at 21 °C: $[\alpha]_{350}$ +854° (peak) and $[\alpha]_{294}$ −1240° (trough); NMR ($CDCl_3$) τ: 8.70 (s, 3H).

Found: C, 59.65; H, 8.19%. Calcd for $C_{27}H_{44}OBr_2$: C, 59.56; H, 8.15%.

The second fraction, eluted with benzene–petroleum ether (2 : 8), on crystallization from ethanol gave plates of **11b** (494 mg), mp 69—70.5 °C, IR (KBr): 1699 cm^{-1}; ORD (*c* 0.66, dioxane) at 20 °C: $[\alpha]_{350}$ +555° (peak), $[\alpha]_{324}$ +350° (sh), and $[\alpha]_{304}$ −400° (trough); NMR ($CDCl_3$) τ: 5.67 m, $W_{h/2}=6.5$ Hz, 1H) and 8.85 (s, 3H).

Found: C, 69.76; H, 9.84%. Calcd for $C_{27}H_{45}OBr$: C, 69.66; H, 9.74%.

The third fraction, eluted with the same solvent, on crystallization from ethanol, gave needles (1.22 g) of **11a**, mp 118—119 °C, IR (KBr): 1711 cm^{-1}; ORD (*c* 0.46, dioxane) at 30 °C: $[\alpha]_{317}$ −1150° (trough), $[\alpha]_{308}$ −1020° (sh), and $[\alpha]_{272}$ +1080° (peak); NMR ($CDCl_3$) τ: 5.04 (dd, $J_{2,3\alpha}=6$ and $J_{2,3\beta}=12.5$ Hz, 1H) and 8.76 (s, 3H).

Found: C, 69.58; H, 9.96%. Calcd for $C_{27}H_{45}OBr$: C, 69.66; H, 9.74%.

Epimerization of **11b** with hydrogen bromide in acetic acid gave **11a**.

A solution of the 2β-bromo derivative (**11b**) (1.5 g) in DMF (25 ml) was refluxed with calcium carbonate (1.5 g). After 3 hr, the reaction mixture was treated in the usual manner. Crystallization of the product from ethanol gave needles (1.1 g), mp 99—101 °C. The compound was identical with 5β-cholest-2-en-1-one (**10**) in the IR and NMR spectra.

*2β-Acetoxy-5β-cholestan-1-one (**12**).* A mixture consisting of **8** (1 g), lead tetraacetate (1.2 g), boron trifluoride etherate (1.9 ml), and benzene (30 ml) was stirred at 30 °C in a nitrogen atmosphere. After 20 hr, the reaction mixture was poured into water and the benzene layer was taken up in ether. The ethereal solution was washed with water, dried and evaporated. Crystallization of the residue from ethanol gave needles (320 mg), mp 88—90 °C, IR (KBr): 1747 and 1711 cm^{-1}; ORD (*c* 0.23, dioxane) at 20 °C: $[\alpha]_{312}$ −1662° (trough), $[\alpha]_{304}$ −1386° (sh), and $[\alpha]_{264}$ +1586° (peak); NMR ($CDCl_3$) τ: 4.60 (dd, $J_{2,3\alpha}=5.8$ and $J_{2,3\beta}=12.7$ Hz, 1H) and 7.88 (s, 3H).

Found: C, 78.11; H, 11.02%. Calcd for $C_{29}H_{48}O_3$: C, 78.33; H, 10.88%.

Catalytic Decomposition of Stable Sulfur Ylids[1]

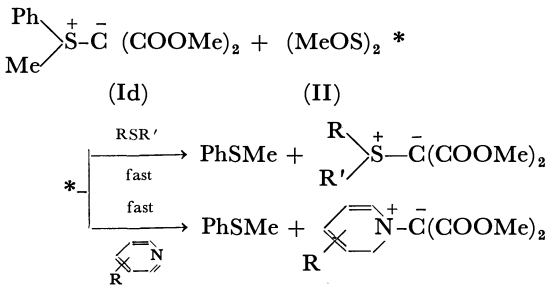
Haruo MATSUYAMA, Hiroshi MINATO, and Michio KOBAYASHI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

(Received April 26, 1973)

In the presence of dimethoxy disulfide, such stable sulfur ylids as Me_2S^+–$C^-(COOMe)_2$, Me_2S^+–$C^-(CN)_2$, and Me_2S^+–C^-HCOPh were found to decompose at 35 °C, forming methyl sulfide and an olefin or a cyclopropane. Thiocyanogen and trifluoromethyl disulfide were found to possess similar catalytic activity. The scope and mechanism of these reactions are discussed.

Sulfur ylids possessing two electron-withdrawing substituents on the negatively-charged carbon atom are thermally stable, and their nucleophilicity is much less than that of mono-substituted sulfur ylids. Recently, we have reported that methylphenylsulfonium bis(methoxycarbonyl)methylid (Id) undergoes transylidation with alkyl sulfides and pyridines at 35 °C when dimethoxy disulfide (II) is present.[2]



It has been found that, when an alkyl sulfide or a pyridine is absent and II is present, Id slowly decomposes, yielding methyl phenyl sulfide and methyl ethylenetetracarboxylate almost quantitatively.

$$[Id] + [II] \xrightarrow{slow} PhSMe + (MeOOC)_2C{=}C(COOMe)_2$$

The decompositions of ylids under acidic conditions[3] or at higher temperatures[4] have been reported, but the decomposition of thermally stable ylids under such mild conditions have never been reported yet. In order to clarify the mechanism of this reaction, the effects of catalysts and ylid substituents on the decomposition have now been studied; the results will be described in this paper.

Results and Discussion

In the absence of dimethoxy disulfide [II], the ylids [I] listed in Table 1 are stable for a long time at 35 °C and show no change. However, when equimolar amounts of I and II are mixed in, the decomposition of I takes place slowly.

Ic is a mono-substituted ylid; it decomposes much faster than di-substituted ylides, producing methyl sulfide and *trans*-1,2,3-tribenzoylcyclopropane. Di-substituted ylids (Ia, Ib, and Id) decompose slowly and give the corresponding sulfide and olefin. Two ylids containing acetyl groups (Ie: Me_2S^+—C^-(COOMe)(COMe), If: Me_2S^+—$C^-(COMe)_2$) do not decompose under the same conditions.

Thiocyanogen $(SC{\equiv}N)_2$ and bistrifluoromethyl disulfide showed catalytic activity similar to that of II. The common feature in these sulfides is that the electron density on the –S–S– group is much lowered by the electron-withdrawing substituents:

$$\overset{\delta-}{MeO}\leftarrow\overset{\delta+}{S}—\overset{\delta+}{S}\rightarrow\overset{\delta-}{OMe} \qquad \overset{\delta-}{N}{\equiv}C\leftarrow\overset{\delta+}{S}—\overset{\delta+}{S}\rightarrow C{\equiv}\overset{\delta-}{N}$$

$$\overset{\delta-}{F_3C}\leftarrow\overset{\delta+}{S}—\overset{\delta+}{S}\rightarrow\overset{\delta-}{CF_3}$$

Trost reported that, when an ylid was heated with copper(II) sulfate, it quantitatively decomposed.[5] In order to explain this reaction, he proposed that the copper(II)-ylid complex is formed.

In order to compare the disulfide-catalyzed decomposition with the Cu(II)-catalyzed decomposition, Ia and Ib were heated under the conditions used by Trost. In the presence of Cu(II), Ia decomposed and formed the corresponding sulfide and olefin, but Ib did not decompose appreciably. Id slowly decomposed

0.46	2.73	6.0	19.0

a) Calculated from $-d[Ia]/dt = k[Ia]$.

even in the absence of $CuSO_4$. The results are shown in Table 2.

When Tables 1 and 2 are compared, it is clear that the disulfide-catalyzed decomposition proceeds much faster under milder conditions than the Cu(II)-catalyzed decomposition.

Then, the effect of the concentration of IIa on the rate of the decomposition of Ia was examined; the results are shown in Table 3. The first-order rate constants for the decomposition of Ia were greater when the concentration of IIa was greater.

The results of the investigations of the disulfide-catalyzed transylidation and decomposition of ylids can be summarized as follows:

1) Disulfides containing electron-withdrawing substituents catalyze both the transylidation and decomposition.

2) The rates of both reactions increase with the concentration of catalytic disulfide.

3) The catalytic disulfide does not decompose during the reaction.

4) The order of reactivity for transylidation[2] is:

$$R_2S^+—C^-(COOMe)_2 > R_2S^+—C^-(COOMe)(COMe) \gg R_2S^+—C^-(COMe)_2$$

and that for decomposition is:

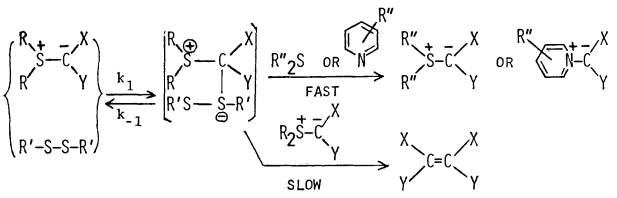
$$R_2S^+—C^-HCOPh > R_2S^+—C^-(COOMe)_2 \approx R_2S^+—C^-(CN)_2 \gg R_2S^+—C^-(COOMe)(COMe)$$

and $R_2S^+—C^-(COMe)_2$

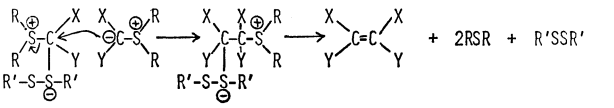
These orders are similar to the order of the nucleophilicity of the negatively-charged carbon atom of ylids.

The transylidation and ylid decomposition may be

expressed by the following scheme, involving a disulfide-ylid adduct:



When an alkyl sulfide or pyridine is present, their nucleophilic attack on the adduct takes place rapidly, and the corresponding new ylid is formed. When such a powerful nucleophile is absent, the ylid itself functions as a nucleophile, the nucleophilic attack of the negatively-charged carbon atom of the ylid on the adduct results in the C–C bond formation, and the corresponding olefin is obtained. This process may be represented as follows:



As Table 1 shows, Ic decomposed very rapidly. This is reasonable, because the mono-substituted ylid with great nucleophilicity must form the adduct readily; furthermore, the nucleophilic attack of Ic on the adduct must be faster than that of di-substituted ylids. Since Ic is known to undergo a Michael addition with dibenzoylethylene,[5] the olefin formed by the decomposition-dimerization of Ic reacts with another molecule of Ic faster than the adduct, and *trans*-1,2,3-tribenzoylcyclopropane is the final product.

The nucleophilicity of Ia and Ib is much smaller, and the olefins formed do not receive any further nucleophiclic attack of ylids. Two ylids, Ie and If, which did not decompose under the reaction conditions, underwent transylidation extremely slowly. The nucleophilicity of these ylids is very small, the adduct is formed to a very small extent, and both the transylidation and ylid decomposition take place very slowly.

Experimental

Materials. The ylids (Ia, Ib,[6] Ic,[5] Id,[4] Ie, and If[7]), dimethoxy disulfide,[8] and thiocyanogen[9] were synthesized according to the procedures described in the literature. Bistrifluoromethyl disulfide was synthesized by the reaction between trichloromethanesulfenyl chloride and sodium fluoride in sulfolane.[10]

Decomposition of Ib in the presence of Thiocyanogen. A chloroform solution (50 ml) of Ib (1.15 g, 9.14 mmol) was mixed with thiocyanogen (3.0 g, 0.66 mmol; dissolved in CCl_4) in a 50-ml, egg-shaped flask at 35 °C. The disappearance of Ib (Me_2S^+—, δ, 2.80 ppm) and the formation of Me_2S (δ, 2.10 ppm) were followed by use of NMR spectroscopy. When the Me_2S^+— signal completely disappeared, the reaction mixture was concentrated with a rotatory evaporator. The residue was chromatographed (Wakogel Q-22, 200 mesh), and with a benzene–ether (1 : 1) mixture 0.66 g of tetracyanoethylene (5.2 mmol, 57%) was obtained. Sublimation gave 0.49 g (3.8 mmol, 42%), melting at 197—199 °C (lit,[11] 200 °C) and possessing the same infrared spectrum as that of an authentic sample.[12]

The Decomposition of Id in the Presence of II. A mixture of Id (0.85 g, 3.33 mmol), nitromethane (20 ml), and II (0.54 g, 4.32 mmol) in a 50-ml, egg-shaped flask was placed in a constant-temperature bath at 35 °C. The decrease in Id (PhMeS$^+$–, δ, 3.26 ppm) and the increase in PhSMe (δ, 2.50 ppm) were followed by NMR spectroscopy, using 1,1,2,2-tetrachloroethane as the internal standard. The chromatographic separation of the residue gave 0.40 g (3.08 mmol, 92%) of methyl ethylenetetracarboxylate. Its identity was established by a comparison of its infrared absorptions ($\nu_{C=O}$, 1740 cm^{-1}), mp (121—122 °C) and gas-chromatographic retention time (Carbowax 20 M, 10%, 2 m, 200 °C) with those of an authentic sample synthesized by the copper-catalyzed decomposition of methyl diazomalonate.

The Decomposition of Ic in the Presence of II. The reaction in a mixture of Ic (0.54 g, 3.0 mmol), nitromethane (20 ml), and II (0.63 g, 5.0 mmol) at 35 °C was followed by NMR spectroscopy, with 1,1,2,2-tetrachloroethane as the internal standard. After evaporation and chromatography, *trans*-1,2,3-tribenzoylcyclopropane was obtained; Yield, 0.32 g (0.27 mmol, 90%); mp 214—216 °C (lit,[13] 215 °C); IR ($\nu_{C=O}$ 1670 cm^{-1}); NMR, identical with that reported in the literature.[14]

The $CuSO_4$-Catalyzed Decomposition of Ia. A mixture of Ia (1.74 g, 9.04 mmol), chloroform (20 ml), and anhydrous $CuSO_4$ (3.42 g, 21.4 mmol) was refluxed for 48 hr. When the $CuSO_4$ was filtered and the solvent was evaporated, white solids remained. Their IR absorptions indicated the presence of methyl ethylenetetracarboxylate ($\nu_{C=O}$, 1740 cm^{-1}) and Ia ($\nu_{C=O}$, 1620—1660 cm^{-1}). The amount of Ia was determined by NMR, using nitromethane as the internal standard. Methyl ethylenetetracarboxylate was separated by column chromatography and determined by gas chromatography (5.42 mmol, 60%).

The Thermal Decomposition of Id in the Absence of a Catalyst. A mixture of Id (0.20 g, 0.77 mmol) and nitromethane (10 ml) in a 50-ml flask was heated at 86 °C for 48 hr. After the mixture had been concentrated, the amounts of methyl phenyl sulfide (0.14 mmol, 18%) and the remaining Id (0.62 mmol, 80%) were determined by NMR spectroscopy, using 1,1,2,2-tetrachloroethane as the internal standard.

The Determination of the Rate of Decomposition of Ia. A $CDCl_3$ solution of Ia (0.320 mmol) and a suitable amount of dimethoxy disulfide were mixed in an NMR tube. After nitromethane (0.79 mmol; δ, 4.33 ppm) had been added as the internal standard, more $CDCl_3$ was added with a microsyringe so that the total volume became 700 μl. The disappearance of Ia was followed by observing the decrease in Me_2S^+– (δ, 2.89 ppm).

The Synthesis of Azulene Derivatives Condensed with Several Heterocycles[1)]

Tetsuo NOZOE,* Toyonobu ASAO,** and Masao KOBAYASHI***

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Aoba, Sendai 980

(Received May 28, 1973)

The reactions of ethyl 1,2-diaminoazulene-3-carboxylate with formic acid, nitrous acid, glyoxal sodium bisulfite, diacetyl, and benzil afforded the corresponding azulene derivatives condensed at the 1,2-position with nitrogen-containing heterocycles, namely, imidazole, triazole, and pyrazine rings. 2-Amino-1-formylazulene reacted with guanidine or thiourea to give 2-aminoazuleno[2,1-*d*]pyrimidine. The ultraviolet and visible absorption spectra of these azulenes are presented.

Azulene derivatives condensed with furans,[2,3)] pyrroles,[4)] thiophenes,[5)] pyridines,[6,7)] pyrazines,[8)] thiapyran,[9)] and azepine[9)] have already been synthesized.

During the course of an investigation of the reactions of 1,2-diaminoazulene derivatives and 2-amino-1-formylazulene, the present authors have synthesized azuleno[1,2-*d*]imidazole, azuleno[1,2-*d*]triazole, azuleno[2,1-*b*]pyrazine and azuleno[2,1-*d*]pyrimidine derivatives; the results will be reported in this paper.

The heating of 1,2-diacetamidoazulene (I)[10)] in acetic anhydride or acetic acid in anticipation of the formation of an azulenoimidazole derivative led to the complete recovery of the starting material, and the treatment of I in hydrochloric acid at the boiling point resulted in the formation of a resinous product besides the starting compound.

The reaction of the hydrochloride of ethyl 1,2-diaminoazulene-3-carboxylate (II)[10)] and 40% aqueous formic acid yielded yellow crystals (III) in a good yield. The results of the elemental analyses ($C_{14}H_{14}O_3N_2$) and the infrared spectrum (3420 and 3300 cm^{-1} (NH_2)) indicate that Compound (III) is not the expected azulenoimidazole, but ethyl 2-amino-1-formamidoazulene-3-carboxylate. An alternative structure for III, ethyl 1-amino-2-formamidoazulene-3-carboxylate, may be excluded because an amino group at the 1-position is less sterically hindered and must be more basic than one at the 2-position.[10)]

The acetylation of III afforded the 2-acetamido derivative (IV), whose ultraviolet spectrum shows a curve very similar to that of ethyl 1,2-diacetamidoazulene-3-carboxylate.[10)]

The reaction of II with anhydrous formic acid yielded light purple crystals, the elemental analyses ($C_{14}H_{12}O_2N_2$) and the infrared spectrum of which show one sharp carbonyl band at 1680 cm^{-1}; the compound may, therefore, be assumed to be ethyl azuleno[1,2-*d*]-imidazole-9-carboxylate (V).

The treatment of the solution of II in hydrochloric acid with sodium nitrite afforded orange crystals (VI) in a fairly good yield. From the analyses ($C_{13}H_{11}O_2N_3$) and the similarity of the ultraviolet spectrum (Fig. 1) to that of Compound (V), Compound (VI) is considered to be ethyl azuleno[1,2-*d*]triazole-9-carboxylate.

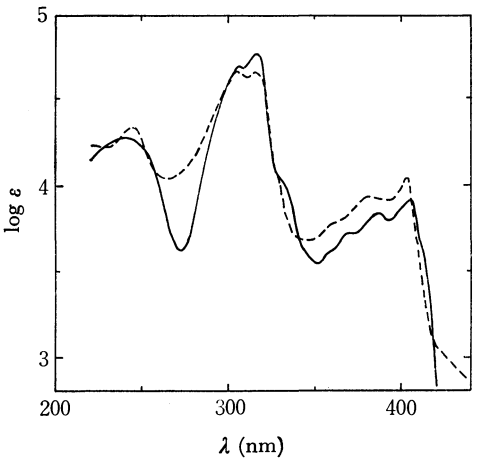

Fig. 1. UV absorption spectra of V (——) and VI (------) in methanol.

The attempted derivation of V and VI to azuleno-[1,2-*d*]imidazole and azuleno[1,2-*d*]triazole respectively by alkaline hydrolysis, followed by thermal decarboxylation, resulted in the formation of a resinous substance; no objective compounds could be obtained.

The reactions of II and an aqueous solution of glyoxal or glyoxal sodium bisulfite under various conditions yielded resinous products; no pure products could be isolated. However, when unstable ethyl 1,2-diaminoazulene-3-carboxylate (IIa), obtained by passing a methanolic solution of II through an ion-exchange resin (Amberlite IRA-410), was reacted with glyoxal sodium bisulfite, ethyl azuleno[2,1-*b*]pyrazine-10-car-

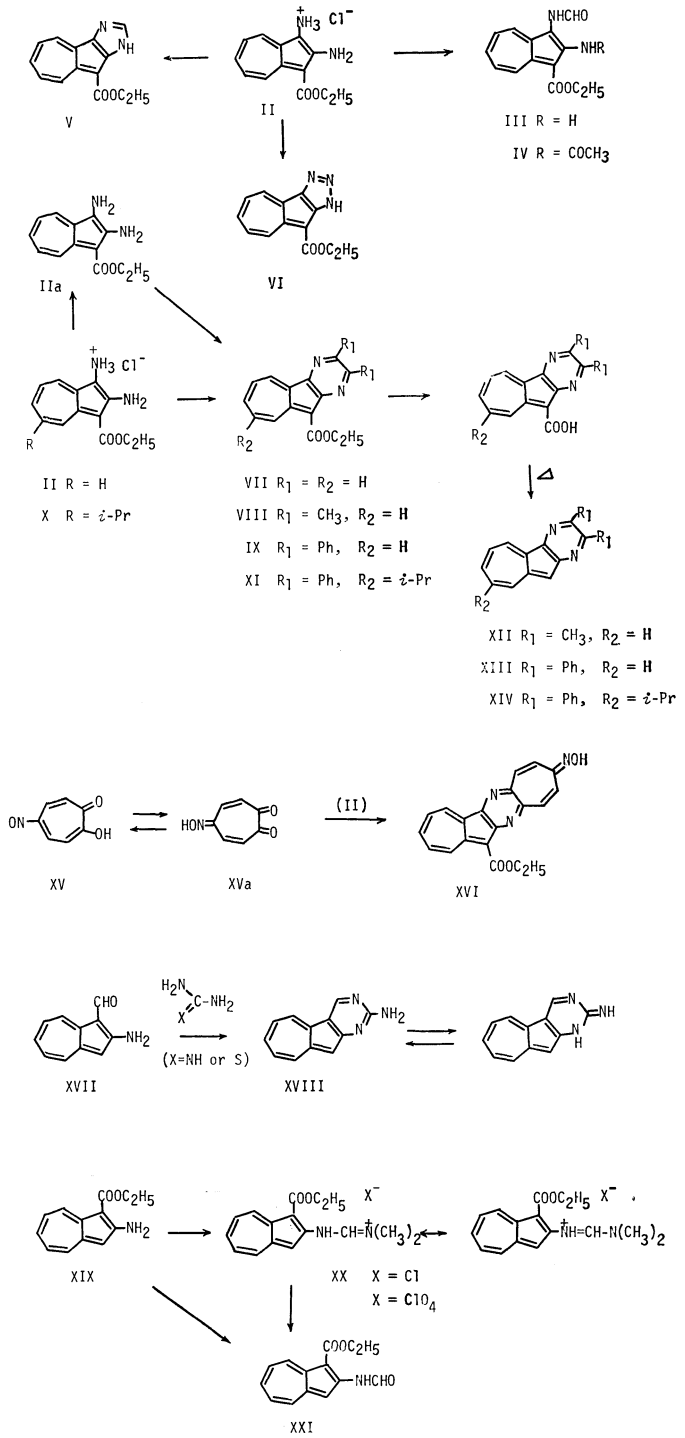
boxylate (VII) was obtained as greenish brown crystals in a low yield.

The reaction of II with diacetyl and benzil proceeded smoothly to give the corresponding products, 2,3-dimethyl and 2,3-diphenyl derivatives (VIII and IX respectively).

The hydrochloride of ethyl 1,2-diamino-5-isopropylazulene-3-carboxylate (X)[10] afforded the 8-isopropyl derivative (XI) by means of a reaction with benzil.

The hydrolysis of Compounds VIII, IX, and XI with ethanolic alkali gave the corresponding carboxylic acids, and the thermal decarboxylation yielded 2,3-dimethyl-, 2,3-diphenyl-, and 2,3-diphenyl-8-isopropylazuleno[2,1-*b*]pyrazine (XII, XIII, and XIV respectively).



It has been shown that 5-nitrosotropolone (XV) reacted with *o*-diamine derivatives *via* its tautometic *o*-diketone form (XVa) to give troponoids fused with pyrazine or quinoxaline rings.[11,12]

The reaction of II with XV gave yellowish-green crystals (XVI) as an insoluble precipitate. The infrared spectrum of XVI shows an OH band at 3400 cm^{-1}, and the permanganate oxidation of XVI, followed by methylation with diazomethane, afforded tetramethyl pyrazinetetracarboxylate;[12] therefore, Compound XVI must has the structure shown in the scheme.

2-Amino-1-formylazulene (XVII)[6] reacted with guanidine, and orange needles (XVIII) were obtained. The analyses of the compound accord with the $C_{12}H_9N_3$ formula, and the infrared spectrum displays bands at 3300 and 3100 cm^{-1} similar to those of 2-aminopyrimidine;[13] thus, the compound may be considered to be 2-aminoazuleno[2,1-*d*]pyrimidine.

A similar reaction of XVII with thiourea gave the same compound (XVIII); this fact shows that the aza-nitrogen at the 1-position of XVIII came from an amino group at the 2-position of XVII in the reaction with thiourea.

The reactions of XVII with formamide and of 2-chloro-1-formylazulene with guanidine resulted in the recovery of the starting compounds in both cases.

The attempted formylation of ethyl 2-acetamidoazulene-1-carboxylate by the Vilsmeier method resulted in the complete recovery of the starting azulene. However, the similar formylation of ethyl 2-aminoazulene-1-carboxylate (XIX) afforded crystalline chloride (XX: X=Cl), which was easily converted to perchlorate (XX: X=ClO_4). The mild treatment of the chloride with sodium hydrogen carbonate yielded ethyl 2-formamidoazulene-1-carboxylate (XXI), which was also obtained by the direct formylation of XIX with formic acid. Therefore, Compound (XX) may be considered to have the structure shown in the scheme.

The unreactivity of the azulene attached by the ethoxycarbonyl group at the 1-position to the Vilsmeier reaction must be attributable to the electron-withdrawing effect of the ethoxycarbonyl group, as is observed in the diazo-coupling reaction of the same compound.[10]

Experimental[14]

Ethyl 2-Amino-1-formamidoazulene-3-carboxylate (III). A solution of II (134 mg) in 40% formic acid (2 ml) was heated on a water bath for 30 min. After cooling, the crystals which separated out were filtered to yield 135 mg of yellowish-brown crystals; mp 200 °C. The crystals were chromatographed on alumina, using acetone as the solvent, and then recrystallized from ethyl acetate to give III as orange-yellow

micro needles; mp 203—204 °C.

Found: C, 64.82; H, 5.45; N, 11.04%. Calcd for $C_{14}H_{14}O_3N_2$: C, 65.10; H, 5.46; N, 10.85%.

λ_{max}^{MeOH} nm (log ε); 242 (3.94), 315.5 (4.46), and 355 (3.62).

Ethyl 2-Acetamido-1-formamidoazulene-3-carboxylate (IV). A solution of III (100 mg) in acetic anhydride (0.5 ml) was heated on a water bath for 50 min. The solvent was then removed to leave a violet residue, which was dissolved in chloroform, and passed through an alumina column; 70 mg of violet needles were thus obtained. Recrystallization from ethanol afforded IV as violet micro needles; mp 220—222 °C.

Found: C, 63.88; H, 5.64; N, 9.28%. Calcd for $C_{16}H_{16}O_4N_2$: C, 63.99; H, 5.37; N, 9.33%.

λ_{max}^{MeOH} nm (log ε); 225^{sh} (4.32), 248 (4.35), 314 (4.73), 360 (3.84) 375^{sh} (3.70) and 535 (2.67).

Ethyl Azuleno[1,2-d]imidazole-9-carboxylate (V). A solution of II (196 mg) in anhydrous formic acid (1.5 ml) was heated on a water bath for 1 hr. To the solution we then added water (10 ml), after which the solution was neutralized with sodium hydrogen carbonate and extracted with chloroform. When the extract was dried and passed through an alumina column, violet crystals were obtained, recrystallization from benzene afforded light brownish-purple crystals (V); mp 202 °C.

Found: C, 70.13; H, 5.30; N, 10.93%. Calcd for $C_{14}H_{12}O_2N_2$: C, 69.99; H, 5.03; N, 11.66%.

λ_{max}^{MeOH} nm (log ε): 243.5 (4.28), 305 (4.70), 317 (4.72), 332^{sh} (4. 1), 370 (3.73), 386 (3.84), 405 (3.92), 475^{sh} (2.27), 515 (2.36) and 550^{sh} (2.32).

Ethyl Azuleno[1,2-d]triazole-9-carboxylate (VI). To a solution of II (134 mg) in acetic acid (60 mg), water (7 ml), and dioxane (2 ml), a solution of sodium nitrite (38 mg) in water (2 ml) was added under cooling. After the addition, the solution was stirred for 15 min at 60 °C and then for 2 hr at room temperature. After cooling with ice, an 80 mg portion of a brown product was obtained; it was recrystallized from benzene to give orange needles (VI); mp 178 °C (decomp.).

Found: C, 64.46; H, 4.72; N, 17.30%. Calcd for $C_{13}H_{11}O_2N_3$: C, 64.72; H, 4.60; N, 17.42%.

λ_{max}^{MeOH} nm (log ε); 244 (4.35), 302 (4.68), 316 (4.71), 360^{sh} (3.78), 380 (3.95), 402 (4.06), and 480 (2.50).

Ethyl Azuleno[2,1-b]pyrazine-10-carboxylate (VII). To a stirred solution of 200 mg of II in methanol (30 ml), ion-exchange resin (Amberlite IRA-410) was added in small portions to almost the neutral point, after which the resin was filtered off. To the solution, a solution of glyoxal sodium bisulfite (260 mg) in water (40 ml) was added drop by drop, after which the solution was kept at room temperature overnight. The methanol was removed under reduced pressure, and the residue was extracted with chloroform and dried. The evaporation of the solvent gave a greenish brown residue; when this residue was dissolved in benzene and passed through an alumina column, yellowish green crystals were obtained. Recrystallization from ethanol–petroleum ether gave VII as pale greenish crystals; mp 112—115 °C.

Found: C, 71.43; H, 4.46; N, 10.73%. Calcd for $C_{15}H_{12}O_2N_2$: C, 71.41; H, 4.80; N, 11.11%.

λ_{max}^{MeOH} nm (log ε): 224 (4.32), 251 (4.36); 318 (4.63), 330 (4.64), 369 (3.79), 391 (3.96), 417 (4.03), 468 (2.39), 505 (2.46) 540 (2.47), and 585 (2.33).

Ethyl 2,3-Dimethylazuleno[2,1-b]pyrazine-10-carboxylate (VIII). A solution of II (300 mg) and diacetyl (200 mg) in ethanol (40 ml) was stirred for 3 hr at room temperature. Water (500 ml) was then added, and the solution was extracted with chloroform. After drying, the extract was passed through an alumina column; yellowish green crystals were thus obtained. Recrystallization from benzene–cyclohexane yielded 210 mg of VIII as greenish needles; mp 138—139 °C.

Found: C, 72.72; H, 5.46; N, 9.76%. Calcd for $C_{17}H_{16}O_2N_2$: C, 72.84; H, 5.75; N, 9.99%.

λ_{max}^{MeOH} nm (log ε): 227 (4.34), 255 (4.39), 325 (4.68), 338 (4.74), 373 (3.85), 395 (3.89), 416 (3.89), 520 (2.38), 554 (2.41), 600^{sh} (2.29), and 660^{sh} (1.75).

2,3-Dimethylazuleno[2,1-b]pyrazine (XII). A solution of VIII (120 mg) in ethanol (6 ml) and a 1M sodium hydroxide solution (4 ml) was refluxed for 6 hr. The ethanol was removed, water was added, the solution was acidified with hydrochloric acid, and then the solution was extracted with chloroform. The dark brown product obtained by removing the solvent was heated under reduced pressure to afford a dark greenish product. Recrystallization from cyclohexane gave XII as violet prisms; mp 143 °C.

Found: C, 80.94; H, 5.70; N, 13.15%. Calcd for $C_{14}H_{12}N_2$: C, 80.74; H, 5.81; N, 13.45%.

λ_{max}^{MeOH} nm (log ε): 470 (2.00), 505 (2.11), 550 (2.24), 595 (2.28), and 650 (2.16).

Ethyl 2,3-Diphenylazuleno[2,1-b]pyrazine-10-carboxylate (IX). When a solution of II (60 mg) and benzil (50 mg) in ethanol (7 ml) was heated on a water bath for 10 min, greenish needles were precipitated out. After cooling, 70 mg of crystals were obtained; recrystallization from ethanol then gave IX as yellowish green silky needles; mp 209—210 °C.

Found: C, 80.10; H, 5.00; N, 6.93%. Calcd for $C_{27}H_{20}O_2N_2$: C, 80.18; H, 4.98; N, 6.92%.

λ_{max}^{MeOH} nm (log ε): 235 (4.41), 287 (4.50), 361 (4.71), 410^{sh} (5.07), 520^{sh} (2.51), 560 (2.58), and 604 (2.50).

2,3-Diphenylazuleno[2,1-b]pyrazine (XIII). A solution of IX (304 mg) in ethanol (50 ml) and a 1M sodium hydroxide solution (8 ml) was refluxed for 5 hr. The ethanol was then removed, water (30 ml) was added, the solution was acidified with hydrochloric acid, and the dark greenish crystals thus precipitated out were filtered and dried. The crystals were submitted to decarboxylation by heating under reduced pressure to afford greenish crystals, which were dissolved in chloroform, passed through an alumina column, and recrystallized from benzene–cyclohexane to give XIII as greenish crystals (75 mg); mp 180—181 °C.

Found: C, 86.90; H, 4.85; N, 8.33%. Calcd for $C_{24}H_{16}N_2$: C, 86.72; H, 4.85; N, 8.43%.

λ_{max}^{MeOH} nm (log ε): 290.5 (4.37), 354 (4.63), 410^{sh} (3.95), 510 (2.29), 555 (2.36), 605 (2.38), 660 (2.24), and 738 (1.88).

Ethyl 2,3-Diphenyl-8-isopropylazuleno[2,1-b]pyrazine-10-carboxylate (XI). A solution of ethyl 2-amino-5-isopropyl-1-(*p*-tolylazo)azulene-3-carboxylate in ethyl acetate was submitted to catalytic hydrogenation in the presence of 5% Pd-C. After two molar equivalents of hydrogen had been absorbed, the catalyst was removed, to the filtrate was added a solution of benzil (250 mg) in ethanol (5 ml), and the resulted solution was kept at room temperature overnight. The solvent was then removed, and the residue was dissolved in chloroform and passed through an alumina column. The product obtained from greenish effluents was recrystallized from cyclohexane and then from ethanol to give XI (100 mg) as yellowish green needles; mp 211 °C.

Found: C, 80.98; H, 5.73; N, 6.21%. Calcd for $C_{30}H_{26}O_2N_2$: C, 80.69; H, 5.87; N, 6.27%.

λ_{max}^{MeOH} nm (log ε): 237 (4.41), 291 (4.51), 364 (4.72), 410^{sh} (4.15), 430^{sh} (3.91), 565 (2.63), and 620 (2.55).

2,3-Diphenyl-8-isopropylazuleno[2,1-b]pyrazine (XIV). A solution of XI (140 mg) in ethanol (16 ml) and a 1M sodium hydroxide solution (4 ml) was refluxed for 5 hr. The ethanol was then removed, water was added, and the solution was acidified to give a dark brown solid. The solid was dried

and decarboxylated by heating under reduced pressure, thus yielding a yellowish solid, which was subsequently purified by chromatography and repeated sublimation to afford yellowish green crystals, mp 61 °C.

Found: N, 7.64%. Calcd for $C_{27}H_{22}N_2$: N, 7.48%.

λ_{max}^{MeOH} nm (log ε): 281 (4.30), 355 (4.51), 410^{sh} (3.80), 440^{sh} (3.39), 510^{sh} (1.96), 560 (2.07), 605 (2.09), 660 (1.98), and 740^{sh} (1.54).

The Reaction of II and 5-Nitrosotropolone (XV). To a solution of 150 mg of II in methanol (20 ml), a solution of XV (100 mg) in methanol (10 ml) was added, and the resulting solution was stirred at room temperature from 2 hr. After cooling, the precipitate (90 mg) was filtered and then recrystallized from diluted pyridine to give yellowish green micro crystals (XVI): the mp blackens from around 290 °C.

Found: C, 68.49; H, 4.02; N, 11.44%. Calcd for $C_{20}H_{15}O_3N_3$: C, 69.55; H, 4.38; N, 12.17%.

λ_{max}^{MeOH} nm (log ε): 229 (3.41), 245 (4.35), 314 (4.55), 397 (4.58), 590 (2.80), 630 (2.79), and 690^{sh} (2.56).

Oxidation of XVI. Into a solution of XVI (300 mg) in a 10% potassium hydroxide solution (40 ml), a solution of potassium permanganate (3.6 g) in water (110 ml) was added drop by drop at 70—80 °C. After 2 hr, a small amount of methanol was added, manganese dioxide was filtered out and washed with a dilute pottassium hydroxide solution, and the combined filtrate and washing were concentrated to about 20 ml. The solution was then acidified with hydrochloric acid and extracted with ether; 30 mg of pale yellow crystals (mp 191 °C) were thus obtained. The crystals were methylated with diazomethane, and the product was purified by chromatography to give colorless crystals (mp 181 °C), whose infrared absorption spectrum was superimposable upon that of authentic tetramethyl pyrazinetetracarboxylate.

2-Aminoazuleno[2,1-d]pyrimidine (XVIII). a) To a solution of guanidine hydrochloride (168 mg) in ethanol (3 ml) containing sodium ethoxide prepared from 42.8 mg of sodium, 2-amino-1-formylazulene (XVII) (250 mg) was added, and the resulting solution was refluxed for 15 hr. After cooling, the precipitate was filtered and washed with water to give 90 mg of crystals. Recrystallization from ethanol gave XVIII as brown needles; mp 283 °C (decomp.).

Found: C, 73.59; H, 4.36; N, 21.22%. Calcd for $C_{12}H_9N_3$: C, 73.83; H, 4.65; N, 21.53%.

λ_{max}^{MeOH} nm (log ε): 250 (4.09), 324 (4.82), 336 (4.78), 391 (3.50), 418 (3.16), 514 (3.62), 550 (2.43), and 610 (2.06).

b) A solution of 2-amino-1-formylazulene (300 mg) and thiourea (160 mg) in ethanol (10 ml) containing sodium ethoxide prepared from 50 mg of sodium was refluxed for 12 hr. The solvent was then removed, and the residue was washed with water. Crystallization from ethanol gave 80 mg of brown crystals, and the starting azulene (150 mg) was recovered from the filtrate. The recrystallization of the former crystals from ethanol gave brown needles (mp 282 °C (decomp.)), whose infrared spectrum was superimposable upon that of the XVIII obtained by means of Method a).

Vilsmeier Reaction of Ethyl 2-Aminoazulene-1-carboxylate (XIX). Into a solution of XIX (1 g) in dimethylformamide (20 ml), a solution of phosphorus oxychloride (2 g) in dimethylformamide (6 ml) was stirred under cooling with ice. After standing at room temperature overnight, the precipitate was filtered and washed with chloroform to give 1.19 g of crystals. Recrystallization from ethanol afforded orange crystals (XX: X=Cl); mp 205—206 °C (decomp.). Perchlorate (XX: X=ClO_4); pink crystals (from ethanol); mp over 280 °C.

Found: C, 51.98; H, 4.78; N, 7.11%. Calcd for $C_{16}H_{19}O_6N_2Cl$: C, 51.83; H, 5.17; N, 7.56%.

Ethyl 2-Formamidoazulene-1-carboxylate (XXI). a) A solution of chloride (XX) (100 mg) in water was made slightly alkaline by adding sodium carbonate solution, and then it was extracted with chloroform. The extract was dried, passed through an alumina column, and recrystallized from benzene to afford 50 mg of XXI as orange needles; mp 81—83 °C.

Found: C, 67.28; H, 5.31; N, 5.63%. Calcd for $C_{14}H_{13}O_3N \cdot 1/2H_2O$: C, 66.65; H, 5.59; N, 5.56%.

b) A solution of ethyl 2-aminoazulene-1-carboxylate (XIX) (100 mg) in formic acid (1 ml) and pyridine (0.5 ml) was allowed to stand at room temperature for 2 days. The precipitate which separated out was filtered; 108 mg of reddish brown crystals (mp 83 °C) were thus obtained. The infrared spectrum of the crystals was superimposable upon that of XXI obtained by means of Method a).

Synthesis of "Reversed" Nucleosides of Some Purine and Pyrimidine Bases

Shunzo FUKATSU,* Yoshiro TAKEDA,** and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 222

(Received Feburary 3, 1973)

The title compounds have been synthesized by condensation of terminal iodo-sugars with purine bases and pyrimidine bases in dimethylformamide in the presence of sodium hydride or lithiu ı hydride.

As part of investigations of the synthesis of new nucleosides and analogues,[1-3] the synthesis of "reversed" nucleosides[4] (ribose derivatives of adenine bonded at C-5 of the sugar moiety) and their analogues seemed to be of interest, the compounds being useful as synthetic intermediates as in the synthesis[5] of eritadenine (lentynasine). Some reversed nucleosides were synthesized by Leonard *et al.*[4] and Hildesheim *et al.*[6] as compounds related to kinetin, a cell division factor.

The reversed nucleosides were synthesized by use of C-5 sulfonate derivatives of 2-deoxy-D-ribose and D-ribose.[4,5] Martinez and Lee[7] prepared 1-(2',2'-diethoxyethyl)uracil by the reaction of uracil with 2-bromo-1,1-diethoxyethane in dimethylformamide in the presence of sodium hydride. This was the first direct *N*-monoalkylation of uracil. We have extended the reaction to the preparation of reversed nucleosides by an alternative method using terminal iodo derivatives of sugars.

In the conventional synthesis of nucleosides using glycosyl halides, the mercuri-method[8] and fusion method[9] are known to be convenient, but attempts to apply these condensation methods to the present synthesis were unsuccessful.

Methyl 5-deoxy-5-iodo-2,3-*O*-isopropylidene-D-ribofuranoside (**1**) was synthesized from the corresponding 5-*O*-methyl derivative by the procedure of Kissman and Baker.[10] The iodo compound (**1**) reacted smoothly with 6-benzamidopurine (**2**) in dimethylformamide in the presence of lithium hydride to afford, after removal of the protecting groups, methyl 5-(6-aminopurin-9-yl)-5-deoxy-α- and β-D-ribofuranoside (**3** and **4**) in a total yield of 24% (Scheme 1). The methyl riboside of this

Scheme 1

β-compound was previously synthesized by Kawazu *et al.*[5] by an alternative procedure. An analogous reaction of **1** with uracil (**5**) or 4-*N*-acetylcytosine (**6**) gave a masked condensation product (**7** or **8**), which afforded, after removal of the protecting groups, methyl 5-deoxy-5-(uracil-1-yl)-α- and β-D-ribofuranoside (**9** and **10**) or methyl 5-(cytosin-1-yl)-5-deoxy-α- and β-D-ribofuranoside (**11** and **12**) (Table 1).

On the other hand, methyl 2,3,4-tri-*O*-acetyl-6-deoxy-6-iodo-α-D-glucoside (**13**) was prepared by treatment of methyl 2,3,4-tri-*O*-acetyl-6-tosyloxy-α-D-glucoside[11] with sodium iodide in acetic anhydride in a good yield. Condensation of **13** with **2** in dimethylformamide in the presence of sodium hydride afforded the masked condensation product (**15**), in a 35% yield, which gave, after removal of the protecting groups, methyl 6-(6-aminopurin-9-yl)-6-deoxy-α-D-glucoside (**17**) in a 60% yield. A similar condensation of 2,6-benzamidopurine (**14**), uracil (**5**) or 4-*N*-acetylcytosine (**6**) with **13** afforded the masked condensation products (**16**, **19**, or **20**), which gave, after removal of protecting groups, methyl 6-(2,6-diaminopurin-9-yl)-6-deoxy-α-D-glucoside (**18**), methyl 6-deoxy-6-(uracil-1-yl)-α-D-glucoside (**21**), and methyl 6-(cytosin-1-yl)-6-deoxy-α-D-glucoside (**22**) (Scheme 2).

9-Substitution on the purine bases and 1-substitution

Since the aminopurines alkylated on the nitrogen atoms **7** or **9** have rarely been obtained by direct alkylation of the aminopurines,[12] the above-mentioned results are interesting.

Experimental

*Methyl 5-(6-Aminopurin-9-yl)-5-deoxy-α- and β-D-Ribofuranoside (**3** and **4**).* To a solution of 6-benzamidopurine (1.42 g, 6.0 mmol) in 60 ml of anhydrous dimethylformamide was added lithium hydride (48 mg, 6.0 mmol) with stirring. To this was added a solution of methyl 5-iodo-5-deoxy-2,3-*O*-isopropylidene-D-riboside (1.85 g, 6.0 mmol) in 10 ml of anhydrous dimethylformamide. The mixture was heated at 130—135 °C for 12 hr. After cooling to room temperature, the dimethylformamide solution was evaporated to dryness *in vacuo*. The residue was extracted with two 45 ml portions of chloroform, filtered and washed with two 30 ml portions of water. The chloroform solution was dried over anhydrous sodium sulfate, filtered and evaporated to dryness *in vacuo*. The residue (3.13 g) was dissolved in 30 ml of methanol and filtered. Alumina (8 g, Merck) was added, and the resulting suspension was evaporated to dryness. The residue was placed on the top of a column of 60 g (2×29 cm) of alumina packed with benzene and eluted successively with benzene, benzene–ethyl acetate (1: 1), ethyl acetate, and ethyl acetate–methanol (3: 1). Evaporation of the last eluate afforded 0.84 g of colorless solid, which was dissolved in 28 ml of anhydrous methanol. The solution was saturated with ammonia at 0 °C, sealed, and allowed to stand at 10 °C for 18 hr. The solution was evaporated to dryness *in vacuo*. The residue was dissolved in 11 ml of methanol and the mixture was refluxed for 4 hr after addition of 5 ml of 0.4N sulfuric acid. The solution was cooled and barium carbonate was added until the pH was neutral. The precipitate was removed by filtration and washed with warm 50% methanol solution. The combined filtrate and washings were evaporated *in vacuo* to give a sirup. The residue was dissolved in water (10 ml) and chromatographed on a Dowex 1×2 (OH form) column (1×38 cm) and eluted with water. Fractions monitored by their ultraviolet absorption were separated into two portions. The first portion was evaporated to dryness to yield **3**, 0.07 g (0.25 mmol, 4%), α-anomer.

12) See, for example, G. A. Howard, "Purines and Related Ring Systems," Chapt. XX in "Chemistry of Carbon Compounds," Vol. IV, E. H. Rodd, Ed., Elsevier Publishing Co. (1960), p. 1691; J. H. Lister, "Physicochemical Aspects of Purines" in "Advances in Heterocyclic Chemistry," Vol. 6, A. R. Katritzky, Ed., Academic Press (1966), p. 40.

The solid was found homogenous by tlc, but could not be crystallized. The second portion was evaporated to dryness to yield **4**, 0.33 g (1.2 mmol, 20%) as colorless needles, β-anomer.

Methyl 5-(Uracil-1-yl)-5-deoxy-α- and β-D-Ribofuranoside (9 and 10). To a mixture of uracil (0.57 g, 5.2 mmol) and lithium hydride (41.5 mg, 5.2 mmol) in 10 ml of anhydrous dimethylformamide was added a solution of **1** (1.7 g, 5.2 mmol) in anhydrous dimethylformamide with stirring. The solution was heated at 130—132 °C for 12 hr. It was then evaporated *in vacuo* to give a sirup, which was dissolved in 16 ml of chloroform. The resulting solution was washed two 28 ml portions of water, dried over sodium sulfate and filtered. The filtrate was evaporated to dryness *in vacuo*. The residue (1.6 g) was recrystallized from ethanol to yield 0.54 g (1.6 mmol, 31%) of methyl 5-deoxy-2,3-*O*-isopropylidene-5-(uracil-1-yl)-D-riboside (**7**) as needles, mp 189—190 °C, $[\alpha]_D^{17}$ +78.7° (*c* 0.5, chloroform), λ_{max}^{MeOH} 266 mμ (ε 9940), ν_{max}^{KBr} (cm^{-1}), 3000 (NH, OH), 1715, 1680 (uracil), 1098 (C–O–C). Found: C, 52.63; H, 6.03; N, 9.01%. Calcd for $C_{13}H_{18}N_2O_6$: C, 52.34; H, 6.08; N, 9.39%; mol wt, 298.

A sample of **7** (0.54 g, 1.6 mmol) was dissolved in a solution of methanol, the solution being refluxed for 2 hr after addition of 0.8N sulfuric acid (3 ml). It was then neutralized with barium carbonate and filtered. The filtrate was passed through a column of 20 ml (0.8×2.6 cm) of CG-400 (OH form), and eluted with 0.1% ammonia solution. Fractions monitored by their ultraviolet absorption were separated into two portions. The first portion was evaporated to dryness to yield **9**, α-anomer, 0.13 g (0.51 mmol), and the second to yield **10**, β-anomer, 0.26 g (1.02 mmol). The total yield including α- and β-anomers was 30%.

NMR (DMSO-d_6), α-anomer: δ 11.05 (1H, s, pyrimidine C_4–OH), 7.49 and 5.53 (1H, each d, J=8.0 Hz, pyrimidine H_5 and H_6), 4.64 (1H, s, $H_{1'}$), 3.25 (3H, s, CH_3O–); β-anomer: δ 4.82 (1H, d, J=3 Hz, $H_{1'}$).

Methyl 5-(Cytosin-1-yl)-5-deoxy-α- and β-D-Ribofuranoside (11 and 12). *N*-Acetylcytosine (1.54 g, 1.0 mmol) was made to react with lithium hydride (90 mg, 1.1 mmol) and **1** (3.4 g, 1.04 mmol) in 55 ml of anhydrous dimethylformamide. The solution was evaporated to give a sirup, which was dissolved in 120 ml of chloroform. The solution was washed with two 50 ml portions of water, dried over sodium sulfate, and filtered. The filtrate was evaporated *in vacuo* to give a gum, which was chromatographed on a column (2×36 cm) of alumina (100 g, acid washed, Merck), and eluted successively with benzene, benzene–ethyl acetate (1:1), ethyl acetate and ethyl acetate–methanol (1:1). Fractions as determined by their ultraviolet absorption were combined and evaporated to dryness *in vacuo*. The residue was recrystallized from ethanol to give methyl 5-(*N*-acetylcytosin-1-yl)-5-deoxy-2,3-*O*-isopropylidene-D-riboside (**8**) (1.37 g, 41%) as needles, mp 209—211 °C, $[\alpha]_D^{13}$ +75.4° (*c* 0.5, chloroform), λ_{max}^{MeOH} 248 mμ (ε 13200), 301 mμ (ε 6650), ν_{max}^{KBr} (cm^{-1}), 3290 (NH, OH), 1700 (*N*-acetyl), 1670, 1625 (pyrimidine), 1098 (C–O–C).

A 1.0 g portion of **8** was dissolved in 30 ml of methanolic ammonia (saturated at 0 °C) and kept at 0 °C for 16 hr. The solution was evaporated *in vacuo* to dryness. The residue was dissolved in a solution of 0.8N sulfuric acid (6.5 ml) and methanol (15 ml) and the solution was heated under reflux for 1 hr. The solution was neutralized to about pH 7 (test paper) with barium carbonate powder and filtered. The filtrate was passed through a column (1.5×30 cm) of CG-400 (OH form, 40 ml) and eluted with water. Fractions monitored by their ultraviolet absorption were separated into two portions, the first being evaporated to dryness to yield 0.1 g (4%) of **11**, α-anomer, and the second to yield 0.26 g (11%) of **12**, β-anomer.

Methyl 2,3,4-Tri-O-acetyl-6-deoxy-6-iodo-α-D-glucopyranoside (13). A solution of methyl 2,3,4-tri-*O*-acetyl-6-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside[10] (41.9 g, 0.088 mol) in 450 ml of acetic anhydride was refluxed with dry sodium iodide (25 g, 0.17 mol) for 1 hr. The mixture was cooled and poured with stirring into 1.2 l of ice water. The suspension was allowed to stand at about 10 °C in the refrigerator for 18 hr. The solid acetate was then filtered, washed with water, and dried *in vacuo* to yield 16.9 g (45%) of **13**, wihch was recrystallized from ethanol, mp 149—150 °C (lit,[10] mp 150—151 °C).

Methyl 6-(6-Aminopurin-9-yl)-6-deoxy-α-D-glucoside (17). 6-Benzamidopurine (**2**) (2.10 g, 8.8 mmol) was made to react with sodium hydride (250 mg, 10.4 mmol) and methyl 2,3,4-tri-*O*-acetyl-6-deoxy-6-iodo-α-D-glucoside (**13**) (3.50 g, 8.2 mmol) in 80 ml of dimethylformamide. The solution was evaporated *in vacuo* to give a sirup, which was extracted with two 75 ml portions of chloroform. The filtered chloroform extract was washed with two 75 ml portions of water, dried with sodium sulfate, filtered, and evaporated to dryness. The residue (4.96 g) was dissolved in 40 ml of methanol, the insoluble matter being removed by filtration. To the filtrate, was added alumina (10 g, acid washed, Merck) and the mixture was evaporated to dryness. The residue was placed on a column of alumina (80 g) and eluted with ethyl acetate–chloroform (6:4), ethyl acetate–methanol (1:1) and methanol, successively. Fractions monitored by their ultraviolet absorption (λ_{max}^{MeOH} 280 mμ) were combined and evaporated to dryness *in vacuo* to give a crude solid of **15**, 2.71 g, λ_{max}^{MeOH} 280 mμ.

A 1.7 g portion of the crude solid of **15** was dissolved in 600 ml of anhydrous methanol at room temperature, and the solution was saturated with dry ammonia at 0 °C. After storage in a refrigerator for 18 hr, the solution was evaporated to dryness *in vacuo*. The residue was dissolved in 30 ml of water, the solution was placed on a column of 120 ml of Dowex 1×2 (OH form, 200—400 Mesh) and the column was eluted with water. The fractions having ultraviolet absorption at 260 mμ were combined and evaporated to dryness *in vacuo*. The residue was crystallized from hot water to yield 0.57 g of **17**, colorless needles (20.7%, based on the iodo sugar), ν_{max}^{KBr} (cm^{-1}), 3380, 3340, 3210 (NH, OH), 1646, 1613, 1583 (purinyl), 1053, 1006 (C–O–C); NMR (DMSO-d_6), δ 8.12 and 8.22 (1H, each s, purine H_2 and H_8), 7.23 (2H, s, $-NH_2$), 4.55 (1H, d, J=3 Hz, $H_{1'}$), 3.90 (3H, s, CH_3O–).

Methyl 6-(2,6-Diaminopurin-9-yl)-6-deoxy-α-D-glucoside (18). 2,6-Benzamidopurine (**14**) was made to react with sodium hydride (50 mg, 2.0 mmol) and **13** (0.5 g, 1.2 mmol) in 16 ml of dimethylformamide and treated under the same conditions as for **15**. Chromatography of the residue (0.59 g) on a column of alumina (20 g) gave **16** as a colorless glass, 0.169 g (28.6%); λ_{max}^{MeOH} 248 mμ (ε 19150), 304 mμ (ε 8700), 345 mμ (ε 11600), ν_{max}^{KBr} (cm^{-1}), 1757 (ester), 1640, 1600, 1570 (purinyl). Found: N, 12.57%. Calcd for $C_{32}H_{32}N_6O_{10}$: N, 12.72%.

A 0.169 g portion of **16** was treated with methanolic ammonia followed by chromatography as the hydrolysis of **15** to **17** to give needles of **18**, 66 mg (16.7%).

Methyl 6-Deoxy-6-(uracil-1-yl)-α-D-glucoside (21). Uracil (6.0 g, 53.5 mmol) was made to react with sodium hydride (1.28 g, 53.5 mmol) and **13** (21.3 g, 49.5 mmol) to give a gum (25.1 g), which was chromatographed on a column of alumina (500 g, acid washed, Merck), being eluted succes-

sively with benzene, benzene–ethyl acetate (1: 1), ethyl acetate, ethyl acetate–methanol (5: 1) and methanol. Fractions containing the product of ultraviolet absorption (λ_{max}^{MeOH} 260 mμ) were combined and evaporated to dryness *in vacuo*. The residue was crystallized from ethanol to give needles of **19**, 2.46 g (12%), mp 195 °C $[\alpha]_D^{13}$ +133.6° (*c* 0.5, chloroform), λ_{max}^{MeOH} 260 mμ (ε 10300) NMR (DMSO-d_6) δ 5.53 and 7.52 (1H, each d, J=8 Hz, pyrimidine H_5 and H_6), 11.25 (1H, s, pyrimidine C_4–OH), 4.89 (2H, s, $-CH_2-$), 3.19 (3H, s, CH_3O-), 1.99 (6H, s, CH_3CO-), 1.93 (3H, s, CH_3CO-). Found: C, 49.46; H, 5.46; N, 6.65%. Calcd for $C_{17}H_{22}N_2O_{10}$: C, 49.28; H, 5.35; N, 6.76%; mol wt, 414.

A 0.53 g (1.3 mmol) portion of **19** was treated with methanolic ammonia as in the hydrolysis of **15** to **17** and then chromatographed on a column of Dowex 1×2 (OH form). Elution was effected with water and 0.3N ammonia, elution with 0.1N hydrochloric acid (40 ml). Fractions as determined by their ultraviolet absorption (266 mμ) were combined, and evaporated to dryness *in vacuo*. The residue was crystallized from ethanol–water to give needles of **21**, 0.2 g (46.5%). NMR (DMSO-d_6): δ 5.60 and 7.62 (1H, each d, pyrimidine H_5 and H_6), 4.60 (1H, d, J=3 Hz, $H_{1'}$), 3.16 (3H, s, CH_3O-).

*Methyl 6-(Cytosin-1-yl)-6-deoxy-α-D-glucoside (**22**).* *N*-Acetylcytosine (**6**) (2.8 g, 18.5 mmol) was made to react with sodium hydride (450 mg, 18.5 mmol) and **13** (7.4 g, 17.2 mmol) in 170 ml of anhydrous dimethylformamide to give a residue, which was dissolved in 253 ml of chloroform, washed with two 105 ml portions of water, dried with sodium sulfate, filtered, and evaporated to dryness. The residue was crystallized from ethanol to give needles, 2.73 g (35%) of methyl 6-(*N*-acetylcytosin-1-yl)-2,3,4,6-tetradeoxy-2,3,4-tri-*O*-acetyl-α-D-glucoside (**20**), mp 242—243 °C, $[\alpha]_D^{16}$ +260° (*c* 0.5, chloroform), λ_{max}^{EtOH} 243 mμ (ε 15600), 301 mμ (ε 7240), ν_{max}^{KBr} (cm^{-1}), 1760 (ester), NMR ($CDCl_3$), δ 7.68 and 7.37 (1H, each d, J=7.5 Hz, pyrimidine H_5 and H_6), 4.91 (2H, s, $-CH_2-$), 3.16 (3H, s, CH_3O-), 2.28 (3H, s, $-N-COCH_3$), 2.08, 2.04 and 1.99 (3H, each s, $-O-COCH_3$). Found: C, 49.73; H, 5.59; N, 8.96%. Calcd for $C_{19}H_{25}N_3O_{10}$: C, 50.22; H, 5.32; N, 9.25%; mol wt, 455.

A 2.0 g (4.4 mmol) portion of **20** was treated with methanolic ammonia followed by chromatography as in the hydrolysis of **15** to **17**. The fractions containing ultraviolet absorbing material were combined and evaporated to dryness. The residue was crystallized from ethanol–water (10: 1) to give 1.13 g (27%) of needles of **22**.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3168—3173 (1973)

Formation and Reaction of Cyclohexanone Oxime Hydrogen Sulfate[1)]

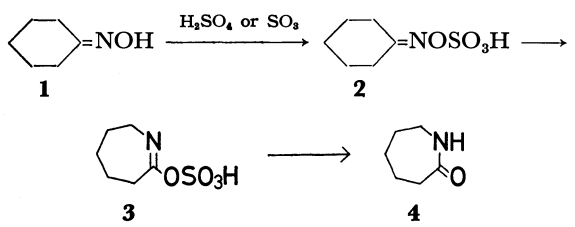
Kiyoshi FUKUI, Masaru UCHIDA, and Mitsuo MASAKI

Polymer Research Laboratory, Ube Industries, Ltd., Goi, Minamikaigan, Ichihara, Chiba 290

(Received May 11, 1973)

Cyclohexanone oxime hydrogen sulfate, prepared by the reaction of cyclohexanone oxime with sulfur trioxide–1,4-dioxane complex under mild conditions, was isolated as stable salts with various Lewis bases. It was found that a Beckmann rearrangement of the oxime hydrogen sulfate to 3,4,5,6-tetrahydro-2*H*-azepin-7-ol hydrogen sulfate was retarded by the weak Lewis base 1,4-dioxane and prevented by a stronger Lewis base aniline. The rearrangement of the oxime hydrogen sulfate was also found to be promoted by Lewis acids such as sulfur trioxide, tin tetrachloride or zinc chloride. Hydrogen chloride retarded the rearrangement. Alcoholysis of the oxime hydrogen sulfate gave cyclohexanone oxime and monoalkyl sulfate quantitatively, while hydrolysis of the oxime hydrogen sulfate gave cyclohexanone, cyclohexanone oxime and ε-caprolactam.

It has been suggested that the Beckmann rearrangement of cyclohexanone oxime (**1**) by sulfuric acid and/or sulfur trioxide involves cyclohexanone oxime hydrogen sulfate (**2**) and 3,4,5,6-tetrahydro-2*H*-azepin-7-ol hydrogen sulfate (**3**) as intermediates.[2,3)] Ogata *et al.*[3)] obtained **2** as an unstable solid in the reaction of **1** with chlorosulfonic acid. Csuros *et al.*[4)] reported that the reaction of cyclohexanone with hydroxylamine-*O*-sulfonic acid in the presence of potassium bicarbonate led to the formation of potassium salt of **2** (**5a**), which was hydrolyzed to ε-caprolactam (**4**) in aqueous acidic or basic solution. **3** was isolated in the reaction of **1** with the sulfur trioxide–1,4-dioxane complex by Turbak,[5)] who postulated that **2** was an intermediate in the reaction. However, very little is known about the reactivity of these intermediates. This paper deals with the formation and reactions of **2**.



Formation of **2** by the reaction of **1** with sulfur trioxide has not been reported, presumably because the reactivity of free sulfur trioxide is too great to permit

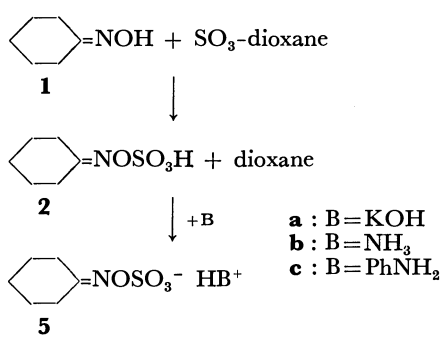
a) Recrystallized from methanol–ether.
b) Attempts to determine the melting point of the salt were unsuccessful as the salt was extremely hygroscopic.
c) Recrystallized from ethanol.
d) Recrystallized from methanol–acetone.

a controlled reaction. Recently, Kelly and Matthews[6] reported the reaction of **1** with the complexes of sulfur trioxide with various Lewis bases, which resulted in the formation of **2**. Independently of this, we found that the reaction of **1** with the sulfur trioxide–1,4-dioxane complex afforded **2** under mild conditions.[1]

When the complex was treated with **1** in ethylene dichloride below 20 °C, **2** was formed as a crystalline precipitate. Since it is extremely hygroscopic and decomposes explosively, **2** was confirmed by treatment of the reaction mixture with ammonia or aniline under cooling, giving the corresponding ammonium (**5b**) or anilinium salt (**5c**). In a similar way salts with various organic bases such as diethylamine, triethylamine, *n*-propylamine, isopropylamine, *t*-butylamine, cyclohexylamine or imidazole were obtained.



Attempts to rearrange **5c** were unsuccessful. When **5c** suspended in ethylene dichloride was heated at refluxing temperature for 20 min, the statring material was recovered in a high yield. Treatment of **5b** with potassium hydroxide and **5c** with potassium bicarbonate in aqueous solution led to the formation of **5a**, which was identical with the specimen prepared according to the method described by Csuros.[4] When **5c** was treated with 2,4-dinitrophenylhydrazine under acidic conditions, 2,4-dinitrophenylhydrazone of cyclohexanone was formed.

When **2** was heated at 50 °C for about 15 min in the presence of 1/2 equiv. of 1,4-dioxane in ethylene dichloride, it was exothermically transformed into **3**, which was confirmed by treatment of the reaction mixture with aniline, giving anilinium phenylsulfamate and **4**.[7] In the presence of 1 equiv. of 1,4-dioxane, however, the exothermic rearrangement of **2** to **3** occurred after heating for 20—30 min at the same temperature. Apparently 1,4-dioxane retarded the rearrangement of **2** to **3**, which is probably due to the formation of the salt-like compound between 1,4-dioxane and **2**. The retarding effect by 1,4-dioxane as a Lewis base is also supported by the fact that the rearrangement of the salt of **2** with a stronger base,

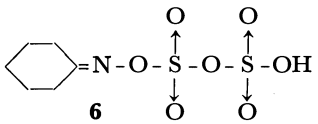
6) K. K. Kelly and J. S. Matthews, *J. Org. Chem.*, **36**, 2159 (1971).

7) It was found that the reaction of 3,4,5,6-tetrahydro-2*H*-azepin-7-ol hydrogen sulfate with 2 equiv. of aniline in refluxing ethylene dichloride led to exclusive formation of anilinium phenylsulfamate and ε-caprolactam: M. Masaki, M. Uchida and K. Fukui, This Bulletin, **46**, 3174 (1973).

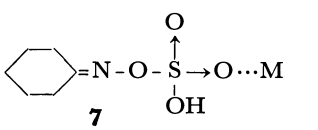
5c, did not occur even when it was heated at 82 °C for 20 min under anhydrous conditions. The retarding effect of bases for the rearrangement suggests that **2** would be formed if sulfur trioxide was gradually added to **1** under mild conditions, since **2** formed initially would be stabilized by the unreacted oxime, a Lewis base.

As expected, cyclohexanone oxime hydrogen sulfate (**2**) was obtained as a colorless crystalline precipitate by the gradual addition of sulfur trioxide to **1** in ethylene dichloride below −6 °C. The suspension of **2** in ethylene dichloride was then heated in order to examine the rearrangement of **2** in the absence of the Lewis base. As soon as the temperature of the suspension reached 44 °C, a vigorous exothermic reaction occurred, **2** being transformed into **3**. The conditions under which **2** began to rearrange were apparently milder than those needed in the presence of 1,4-dioxane. However, when the addition of sulfur trioxide was attempted at room temperature, the reaction accompanied decomposition.[8]

On the other hand, an inverse addition method did not lead to the formation of **2**. When **1** was added to sulfur trioxide in ethylene dichloride below −2 °C, a vigorous exothermic reaction occurred, no formation of **2** being observed. However, after hydrolysis of the reaction product **4** was obtained in 85% yield. This indicates that sulfur trioxide promotes the rearrangement of **2**. The rearrangement of **2** took place even below −3 °C, when sulfur trioxide was added to a suspension of **2** in ethylene dichloride. Kuhara and Todo[9] demonstrated that the rates of rearrangement of a series of ester of benzophenone oxime were proportional to the acid strength of the esterifying acid. The rate-determining step in a Beckmann rearrangement is known to be the partial ionization of the nitrogen-oxygen bond of the oxime.[10] The promoting effect by sulfur trioxide might be explained by a formation of cyclohexanone oxime hydrogen pyrosulfate (**6**), or by a simple coordination (**7**) of sulfur trioxide to the oxygen atom of **2**.



6

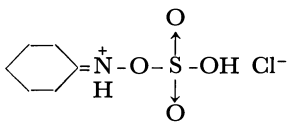


7

M: SO_3, $SnCl_4$, $ZnCl_2$

Thus, we examined whether other Lewis acids promote the rearrangement of **2**. When tin tetrachloride was added to the suspension of **2** in ethylene dichloride, the exothermic rearrangement began to occur below 15 °C, as expected. An analogous effect was observed by using zinc chloride.

The effect of hydrogen chloride on rearrangement of **2** was also studied, a retarding effect being observed. Treatment of cyclohexanone oxime monohydrochloride with sulfur trioxide below −2 °C, and heating of the reaction mixture at 50 °C for 30 min followed by hydrolysis of the product yielded only 52% of **4**. This might be rationalized by the fact that hydrogen chloride protonated on the nitrogen atom[11] of **2** to give **8**, contrary to the case of a Lewis acid, and the nitrogen-oxygen bond became difficult to be cleaved.



8

Hydrolysis of **2** under refluxing conditions gave **4** in 64% yield and a mixture of cyclohexanone and **1** in 17% yield. In a similar way, the hydrolysis of **2** in the presence of Lewis bases such as 1,4-dioxane, **4** and aniline yielded three products. These results are in contrast to those of Kelly and Matthews,[6] who reported the hydrolysis of **2** in the presence of 1,4-dioxane or **4** resulting exclusively in the formation of **4**.

In contrast, methanolysis of **2** gave rise to the formation of **1** and monomethyl sulfate, which was confirmed by treatment of the reaction mixture with aniline, giving the corresponding anilinium salt in 96% yield. Analogous alcoholysis of **2** with *n*-butanol gave **1** in 81% and mono-*n*-butyl sulfate in 76% yield.

Experimental

Concentration and evaporation were carried out under reduced pressure with a rotary evaporator. All melting points were determined in a liquid bath and are uncorrected.

Reaction of Cyclohexanone Oxime (1) with Sulfur Trioxide–1,4-Dioxane Complex. A solution of 1,4-dioxane (2.3 g, 26 mmol) in ethylene dichloride (10 ml) was added dropwise below 10 °C, with stirring, to a solution of sulfur trioxide (2 ml, 48 mmol) in ethylene dichloride (40 ml). To the resulting suspension of sulfur trioxide–1,4-dioxane complex was added dropwise a solution of **1** (5.43 g, 48 mmol) in ethylene dichloride (30 ml) with stirring below 20 °C. The complex dissolved and then colorless crystals separated gradually. The crystals was confirmed to be cyclohexanone oxime hydrogen sulfate (**2**).

Oxime hydrogen sulfate (**2**) is hygroscopic and becomes like honey when allowed to stand in an atmosphere after filtration. When dried over phosphorus pentoxide in a vacuum desiccator it decomposed within a few hour.

Aniline Salt of Cyclohexanone Oxime Hydrogen Sulfate (5c). To a suspension of **2** prepared from sulfur trioxide (5 ml, 120 mmol), 1,4-dioxane (10.5 g, 120 mmol) and **1** (13.6 g, 120 mmol) in ethylene dichloride (150 ml) was added dropwise aniline (33.5 g, 360 mmol) with stirring below 10 °C. The resulting mixture was stirred at room temperature for 1 hr. A crystalline substance, aniline salt of cyclohexanone

8) It has been shown that when cyclohexanone oxime hydrogen sulfate was heated in the presence of cyclohexanone oxime or ε-caprolactam, the oxime hydrogen sulfate decomposed to give an intractable substance: M. Masaki, K. Fukui, M. Uchida, K. Yamamoto, and I. Uchida, This Bulletin, **46**, 3179 (1973).

oxime hydrogen sulfate (**5c**), was collected by filtration (35.2 g). Recrystallization from ethanol gave colorless needles. Yield 31.5 g. Mp and analytical results are shown in Table 1.

A solution of **5c** (0.5 g, 0.17 mmol) in water (40 ml) and methanol (40 ml) was treated with a solution of 2,4-dinitrophenylhydrazine[12] to give 2,4-dinitrophenylhydrazone of cyclohexanone (0.48 g, 99%). Recrystallization from ethanol gave orange leaves, mp 159 °C (lit,[13] 160 °C).

A suspension of **5c** (13.13 g, 46 mmol) in ethylene dichloride (100 ml) was heated under reflux for 20 min and then stirred at room temperature for 41 hr. The crystalline substance collected by filtration was identified as the starting material. Yield 10.6 g (81%).

*Ammonia Salt of Cyclohexanone Oxime Hydrogen Sulfate (**5b**).* To a suspension of **2** prepared from sulfur trioxide (5 ml, 120 mmol), 1,4-dioxane (10.5 g, 120 mmol) and **1** (13.6 g, 120 mmol) in ethylene dichloride (150 ml) was added gaseous ammonia below 0 °C. The resulting mixture was stirred at room temperature for 1 hr and allowed to stand overnight. A crystalline substance, ammonia salt of cyclohexanone oxime hydrogen sulfate (**5b**), was collected by filtration. Yield 22.8 g (91%). Mp 140—145 °C decomp.

*Diethylamine Salt of Cyclohexanone Oxime Hydrogen Sulfate (**5d**).* A suspension of **2** (48 mmol) in ethylene dichloride prepared in a similar way to that for **5b** was treated with a solution of diethylamine (3.5 g, 49 mmol) in ethylene dichloride (10 ml) with stirring below 0 °C. The resulting mixture was stirred at room temperature for 1 hr and concentrated, the residue being treated with ether. A crystalline substance, diethylamine salt of cyclohexanone oxime hydrogen sulfate (**5d**) was collected by filtration. Yield 11.7 g. Mp and analytical results are given in Table 1.

*Triethylamine, n-Propylamine, Isopropylamine, and t-Butylamine Salts of Cyclohexanone Oxime Hydrogen Sulfate (**5e**, **5f**, **5g**, and **5h**).* These ammonium salts were prepared by treating **2** with the corresponding amines in a similar way to that for **5d**. The results are given in Table 1.

*Cyclohexylamine and Imidazole Salts of Cyclohexanone Oxime Hydrogen Sulfate (**5i** and **5j**).* These salts were prepared by treating **2** with cyclohexylamine and imidazole, respectively, in a similar way to that for **5c**. The results are shown in Table 1.

*Potassium Salt of Cyclohexanone Oxime Hydrogen Sulfate (**5a**).* *a) From Aniline Salt of Cyclohexanone Oxime Hydrogen Sulfate (**5c**):* A saturated aqueous solution of potassium bicarbonate was added to an aqueous solution of **5c** (2.86 g, 10 mmol) until gas evolution ceased. The resulting mixture was washed with benzene and concentrated. The residue was treated with an aqueous ethanol. The crystalline precipitate was collected by filtration and identified with authentic potassium salt of cyclohexanone oxime hydrogen sulfate (**5a**)[4] by infrared spectrum. Yield 1.6 g (69%). Extraction with ethanol by means of Soxhlet extractor gave colorless needles as an extract, mp 172—180 °C (lit,[4] 155—180 °C decomp.).

*b) From Ammonia Salt of Cyclohexanone Oxime Hydrogen Sulfate (**5b**):* An aqueous solution of potassium hydroxide (0.56 g, 10 mmol) was added under ice cooling to an aqueous solution of **5b** (2.1 g, 10 mmol). The resulting solution was concentrated. Treatment of the residue with an aqueous ethanol afforded the potassium salt of cyclohexanone oxime hydrogen sulfate (**5a**), the infrared spectrum of which was superimposable on that of the authentic sample.[4] Yield 1.3 g (56%).

*Addition of Sulfur Trioxide to Cyclohexanone Oxime (**1**).* *a) Addition under Ice-Salt Cooling:* A solution of sulfur trioxide (2 ml, 48 mmol) in ethylene dichloride (40 ml) was added dropwise with stirring below −6.5 °C to a solution of **1** (5.4 g, 48 mmol) in ethylene dichloride (40 ml). The resulting solution was stirred under ice-salt cooling for 1 hr and then treated with a solution of aniline (4.46 g, 48 mmol) in ethylene dichloride (20 ml) below −5 °C. The mixture was stirred at room temperature for 3 hr and filtered to give aniline salt of cyclohexanone oxime hydrogen sulfate (**5c**) as a crystalline substance. Yield 11.23 g (82%).

b) Addition at Room Temperature: A solution of sulfur trioxide (5 ml, 120 mmol) in ethylene dichloride (40 ml) was added dropwise at room temperature to a solution of **1** (13.5 g, 120 mmol) in ethylene dichloride (60 ml). The temperature of the mixture rose to a refluxing temperature. The reaction mixture was treated under ice-salt cooling with water (20 ml) and aqueous ammonium hydroxide (20 ml of a 28% solution) and concentrated. The residue was dissolved in water (40 ml) and extracted with chloroform (40 ml×4). Evaporation of chloroform from the combined extracts afforded a brown crystalline residue, the solution of which in benzene (50 ml) was extracted with water (50 ml×4). The combined aqueous layers were concentrated to about 40 ml and extracted with chloroform (40 ml×4). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give **4**. Yield 6.4 g (47%).

*Addition of Cyclohexanone Oxime (**1**) to Sulfur Trioxide.* A solution of **1** (5.4 g, 48 mmol) in ethylene dichloride (60 ml) was gradually added dropwise below −2 °C, with stirring, to a solution of sulfur trioxide (2 ml, 48 mmol) in ethylene dichloride (40 ml). The mixture was stirred under cooling for 1 hr and at room temperature for 3 hr, treated under ice-salt cooling with water (20 ml) and aqueous ammonium hydroxide (20 ml of a 28% solution) and concentrated. The residue was dissolved in water (40 ml) and extracted with chloroform (40 ml×4). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give **4**. Yield 4.6 g (85%).

Reaction of Cyclohexanone Oxime Monohydrochloride with Sulfur Trioxide. A solution of sulfur trioxide (2 ml, 48 mmol) in ethylene dichloride (40 ml) was added dropwise, with stirring, below −2.5 °C to a solution of cyclohexanone oxime monohydrochloride (7.2 g, 48 mmol), prepared according to the method of Saito,[11b] in ethylene dichloride (60 ml). The resulting mixture was heated at 50 °C for 30 min, stirred at room temperature for 1.5 hr, treated with water (20 ml) and aqueous ammonium hydroxide (20 ml of a 28% solution) under ice-salt cooling, and concentrated. The residue was dissolved in water (40 ml) and extracted with chloroform (40 ml×4). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give a mixture of **1** and **4** (4 g), which was confirmed by vapor-phase chromatographic analysis. The mixture (0.5 g) was treated with a solution of 2,4-dinitrophenylhydrazine[12] to afford 2,4-dinitrophenylhydrazone of cyclohexanone (0.38 g), the amount of **1** being 1.2 g and that of **4** 2.8 g (52%).

*Rearrangement of Cyclohexanone Oxime Hydrogen Sulfate (**2**).* *a)* A solution of sulfur trioxide (2 ml, 48 mmol) in ethylene dichloride (40 ml) was added dropwise, with stirring, below −1.5 °C to a solution of **1** (5.4 g, 48 mmol) in ethylene dichloride (60 ml). When the resulting suspension of **2** was heated to 44 °C, the suspended **2** disappeared and the temperature of the mixture rose to 49.5 °C. The resulting solu-

12) The solution of 2,4-dinitrophenylhydrazine used was prepared from 2,4-dinitrophenylhydrazine (3 g), conc. sulfuric acid (15 ml), methanol (70 ml), and water (20 ml): R. L. Shriner, R. C. Fuson, and D. Y. Curtin, "The Systematic Identification of Organic Compound," Wiley, New York (1956), p. 111.

13) C. F. H. Allen, *J. Amer. Chem. Soc.*, **52**, 2955 (1930).

tion was stirred at room temperature, treated with water (20 ml) and aqueous ammonium hydroxide (20 ml of a 28% solution) under ice-salt cooling, and then concentrated. The residue was dissolved in water (40 ml) and extracted with chloroform (40 ml×5). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give **4**. Yield 4.3 g (80%).

b) In the Presence of 1/2 Equiv. of 1,4-Dioxane: To a suspension of sulfur trioxide–1,4-dioxane complex, prepared from sulfur trioxide (2 ml, 48 mmol) and 1,4-dioxane (2.3 g, 26 mmol) in ethylene dichloride (50 ml) was added dropwise a solution of **1** (5.42 g, 48 mmol) in ethylene dichloride (30 ml) below −5 °C with stirring. When the resulting suspension was heated at 50 °C for 15 min, the suspended **2** disappeared and the temperature of the mixture rose rapidly to 58 °C. The resulting solution was stirred at room temperature for 3 hr and then treated with a solution of aniline (8.93 g, 96 mmol) in ethylene dichloride (20 ml) under ice-salt cooling. The mixture was stirred at room temperature for 20 min, heated at refluxing temperature for 1 hr, and then allowed to stand at room temperature overnight. The crystalline substance, anilinium phenylsulfamate, was collected by filtration. Yield 11.15 g (87%). Mp 185—195 °C. Found: C, 54.01; H, 5.26; N, 10.85; S, 12.24%. Calcd for $C_{12}H_{14}N_2O_3S$: C, 54.12; H, 5.30; N, 10.52; S, 12.04%.

The filtrate was concentrated. The residue was dissolved in water (30 ml) and aqueous hydrochloric acid (10 ml of 1 N solution) and extracted with chloroform (40 ml×4). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give **4**. Yield 4.59 g (85%).

c) In the Presence of 1 Equiv. of 1,4-Dioxane: When a suspension of **2** in the presence of 1 equiv. of 1,4-dioxane, prepared from sulfur trioxide (2 ml, 48 mmol), 1,4-dioxane (4.4 g, 50 mmol) and **1** (5.4 g, 48 mmol) in ethylene dichloride (100 ml) was heated at 50 °C for 26 min, the suspended **2** disappeared and the temperature of the mixture rose rapidly to 60 °C. The mixture was treated with water (20 ml) and aqueous ammonium hydroxide (20 ml of a 28% solution) under ice-salt cooling and concentrated. The residue was dissolved in water (40 ml) and extracted with chloroform (40 ml×4). The combined extracts were evaporated to give **4**. Yield 4.7 g (87%).

d) In the Presence of Sulfur Trioxide: To a suspension of **2** prepared by the addition of sulfur trioxide (2 ml, 48 mmol) in ethylene dichloride (40 ml) to **1** (5.4 g, 48 mmol) in ethylene dichloride (60 ml) was added a solution of sulfur trioxide (12 mmol) in ethylene dichloride (10 ml) dropwise below −5 °C with stirring. The suspension turned solution, the temperature of the mixture rising to 10 °C. The mixture was stirred at room temperature for 1.5 hr and heated at 50 °C for 30 min, no exothermic phenomenon being observed. The mixture was then treated with water (20 ml) and aqueous ammonium hydroxide (20 ml of a 28% solution) under ice-salt cooling and concentrated. The residue was dissolved in water (40 ml) and extracted with chloroform (40 ml×4). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give **4**. Yield 4.7 g (87%).

e) In the Presence of Tin Tetrachloride: To a suspension of **2**, prepared from sulfur trioxide (2 ml, 48 mmol) and **1** (5.4 g, 48 mmol) in ethylene dichloride (80 ml) was added a solution of tin tetrachloride (6.25 g, 24 mmol) in ethylene dichloride (20 ml) dropwise below −4 °C. The resulting solution was gradually warmed with stirring. After reaching 15 °C, the temperature of the mixture rose exothermically to 36.5 °C and colorless crystals separated. The suspension was stirred at room temperature for 2.5 hr, treated with water (20 ml) and aqueous ammonium hydroxide (20 ml of a 28% solution) under ice-salt cooling, and concentrated. The residue was treated with water (40 ml) and the precipitate was removed by filtration. The filtrate was extracted with chloroform (40 ml×4). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give **4**. Yield 4.7 g (87%).

f) In the Presence of Zinc Chloride: A solution of sulfur trioxide (2 ml, 48 mmol) in ethylene dichloride (40 ml) was added dropwise, with stirring, below −8 °C to a solution of cyclohexanone oxime–zinc chloride complex (8.7 g, 24 mmol) in ethylene dichloride (60 ml). The resulting mixture of **2** and zinc chloride was stirred at room temperature for 2 hr. The temperature of the mixture rose exothermically to 32 °C. The mixture was then treated with water (20 ml) and aqueous ammonium hydroxide (20 ml of a 28% solution) under ice-salt cooling and concentrated. The residue was dissolved in water (40 ml) and extracted with chloroform (40 ml×5). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give **4**. Yield 4.73 g (87%).

Cyclohexanone Oxime–Zinc Chloride Complex. A solution of zinc chloride (21 g, 150 mmol) in acetone (50 ml) was added dropwise with stirring at room temperature to a solution of **1** (34 g, 300 mmol) in ethyl acetate (50 ml). The mixture was stirred at room temperature for 3 hr and concentrated. The residue was treated with isopropyl ether and the crystalline cyclohexanone oxime–zinc chloride complex was collected by filtration. Yield 31 g (57%). Recrystallization from isopropyl ether gave colorless crystals, mp 90—91 °C. Found: C, 39.87; H, 6.40; Cl, 19.38%. Calcd for $C_{12}H_{22}Cl_2N_2O_2Zn$: C, 39.75; H, 6.12; Cl, 19.55%.

Hydrolysis of Cyclohexanone Oxime Hydrogen Sulfate (2). To a suspension of **2**, prepared from sulfur trioxide (2 ml, 48 mmol) and **1** (5.42 g, 48 mmol) in ethylene dichloride (80 ml), was added water (20 ml) under ice-salt cooling. The mixture was then heated under refluxing for 1 hr, and neutralized with aqueous potassium hydroxide under ice-salt cooling. The precipitate, potassium sulfate (2.95 g), was removed by filtration, and the filtrate was divided into an organic layer and an aqueous layer.

The organic layer was dried over anhydrous sodium sulfate, and evaporated to give a mixture (3.34 g) of cyclohexanone, **1** and **4**, which were identified by vapor-phase chromatographic analysis. One gram of the mixture was dissolved in aqueous methanol (100 ml of a 50% solution) and treated with 2,4-dinitrophenylhydrazine to give 2,4-dinitrophenylhydrazone of cyclohexanone (0.64 g). Thus, the amount of cyclohexanone and **1** in the mixture was 7.69 mmol (16%) and that of **4** was calculated to be 2.47 g (46%).

The aqueous layer was extracted with chloroform (60 ml×3). The combined extracts were evaporated to give a mixture (1.03 g) of cyclohexanone and **1** (0.467 mmol, 1%), and **4** (0.98 g, 18%), the amounts of which were determined by a treatment of the mixture with 2,4-dinitrophenylhydrazine.

Hydrolysis of Cyclohexanone Oxime Hydrogen Sulfate (2) in the Presence of Lewis Base. a) In the Presence of 1,4-Dioxane: A suspension of **2**, prepared from sulfur trioxide (2 ml, 48 mmol), 1,4-dioxane (4.4 g, 50 mmol) and **1** (5.42 g, 48 mmol) in ethylene dichloride (100 ml), was treated with water (20 ml) under ice-salt cooling. The mixture was heated under refluxing for 1 hr, and neutralized with aqueous potassium hydroxide under ice-salt cooling. A precipitate, potassium sulfate (4.01 g), was removed by filtration, and the filtrate was treated in a similar way to that described above.

The organic layer was confirmed to involve cyclohexanone

and **1** (11.38 mmol, 24%) and **4** (2.15 g, 40%).

The aqueous layer included cyclohexanone and **1** (0.647 mmol, 1.3%) and **4** (0.75 g, 14%).

b) In the Presence of ε-Caprolactam (4): To a suspension of **2**, prepared from sulfur trioxide (2 ml, 48 mmol) and **1** (5.42 g, 48 mmol) in ethylene dichloride (70 ml), was added a solution of **4** (5.42 g, 48 mmol) in ethylene dichloride (30 ml) under ice-salt cooling. The resulting solution was treated with water (20 ml) under ice-salt cooling, heated under refluxing for 1 hr, and neutralized with aqueous potassium hydroxide under ice-salt cooling. A precipitate, potassium sulfate (3.88 g), was removed by filtration, and the filtrate was treated as above.

The organic layer was confirmed to involve cyclohexanone and **1** (14.8 mmol, 31%) and **4** (60 mmol).

The aqueous layer included cyclohexanone and **1** (0.647 mmol, 1.3%) and **4** (18.5 mmol).

Hydrolysis of Aniline Salt of Cyclohexanone Oxime Hydrogen Sulfate (5c). A solution of **5c** (4.43 g, 15 mmol) in water (50 ml) was heated under reflux for 1 hr and extracted with chloroform (50 ml×4). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give a mixture of cyclohexanone, **1** and **4**. Yield 1.42 g. The mixture was dissolved in aqueous methanol (100 ml of a 50% solution) and treated with a solution of 2,4-dinitrophenylhydrazine to give 2,4-dinitrophenylhydrazone of cyclohexanone (0.33 g, 1.19 mmol, 8%). Thus, the amount of **4** in the mixture was calculated to be 1.29 g (75%).

Methanolysis of Cyclohexanone Oxime Hydrogen Sulfate (2). To a suspension of **2**, prepared from sulfur trioxide (2 ml, 48 mmol), 1,4-dioxane (4.4 g, 50 mmol) and **1** (5.42 g, 48 mmol) in ethylene dichloride (90 ml), was added a solution of methanol (2 g, 63 mmol) in ethylene dichloride (10 ml) dropwise with stirring below −11.5 °C. The mixture was stirred at room temperature for 18.5 hr and treated with a solution of aniline (4.47 g, 48 mmol) in ethylene dichloride (20 ml) with stirring below −3 °C. The mixture was stirred at room temperature for 3 hr and aniline salt of monomethyl sulfate precipitated was collected by filtration. Yield 9.17 g (93%). Recrystallization from acetonitrile gave colorless needles, mp 160 °C. Found: C, 40.98; H, 5.20; N, 7.06; S, 15.45%. Calcd for $C_7H_{11}NO_4S$: C, 40.98; H, 5.37; N, 6.83; S, 15.61%.

The filtrate was concentrated and the residue was treated with benzene (100 ml) to give 0.29 g of crystals, whose infrared spectrum was identical with that of the crystals obtained above. Total yield 96%.

The filtrate was washed with water (50 ml×3), dried over anhydrous sodium sulfate and evaporated to give **1** (4.62 g, 85%). The combined washings were concentrated to about 50 ml and extracted with chloroform (50 ml×4). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give further **1** (0.22 g, 4%).

n-Butanolysis of Cyclohexanone Oxime Hydrogen Sulfate (2). To a suspension of **2**, prepared from sulfur trioxide (2 ml, 48 mmol), 1,4-dioxane (4.2 g, 48 mmol), and **1** (5.4 g, 48 mmol) in ethylene dichloride (70 ml) was added a solution of *n*-butanol (3.6 g, 49 mmol) in ethylene dichloride (15 ml) dropwise with stirring at −5—0 °C. The mixture was stirred for 1 hr and then treated with a solution of aniline (4.47 g, 48 mmol) in ethylene dichloride (15 ml) under ice-salt cooling. The resulting suspension was stirred at room temperature for 2 hr and then concentrated. The residue was treated with cyclohexane (60 ml), and aniline salt of mono-*n*-butyl sulfate precipitated was collected by filtration. Yield 10 g (84%). Recrystallization from ethyl acetate gave colorless needles, mp 110—115 °C. The infrared spectrum was superimposable on that of an authentic sample (mp 111.5—112 °C).[14]

The filtrate was washed with water, dried over anhydrous sodium sulfate, and evaporated to give **1** (4.1 g, 76%).

Reaction of 3,4,5,6-Tetrahydro-2*H*-azepin-7-ol Hydrogen Sulfate with Nucleophilic Reagents

Mitsuo MASAKI, Masaru UCHIDA, and Kiyoshi FUKUI

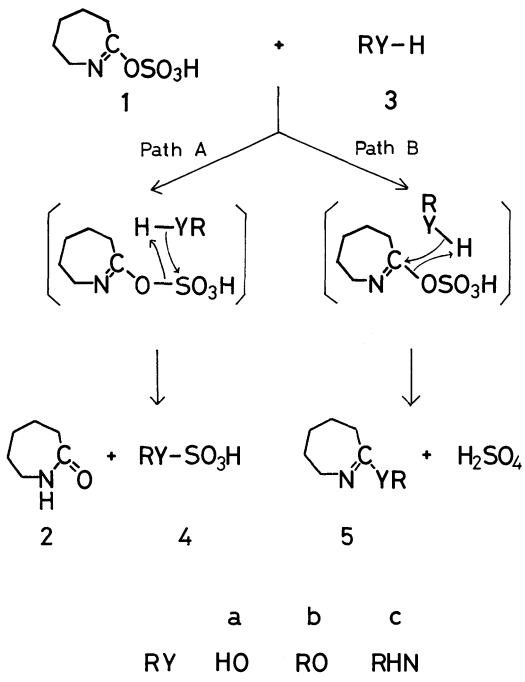
Polymer Research Laboratory, Ube Industries, Ltd., Goi, Minamikaigan, Ichihara, Chiba 290

(Received May 11, 1973)

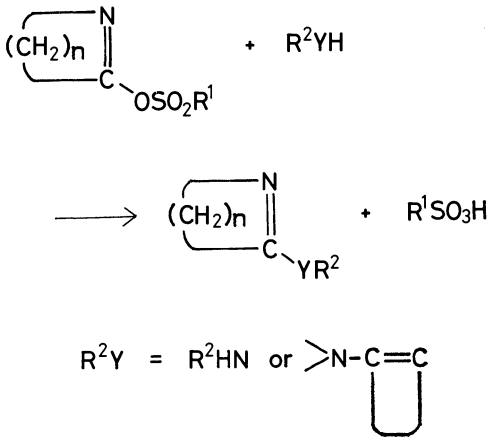
The reaction of 3,4,5,6-tetrahydro-2*H*-azepin-7-ol hydrogen sulfate with nucleophilic reagents was studied. The tetrahydroazepin-7-ol hydrogen sulfate reacted with alcohols and oximes to give respectively ε-caprolactam and the corresponding hydrogen sulfate of the reagents in good yields. Treatment with cyclohexylamine or benzylamine afforded ε-caprolactam, the amine salt of the corresponding sulfamic acid, and the corresponding amine salt of the tetrahydroazepin-7-ol hydrogen sulfate, while anilinium phenylsulfamate was formed exclusively in the reaction with aniline. From these results, the tetrahydroazepin-7-ol hydrogen sulfate was confirmed to undergo exclusively a cleavage of the oxygen-sulfur bond by an attack of nucleophiles on the sulfur atom.

3,4,5,6-Tetrahydro-2*H*-azepin-7-ol hydrogen sulfate (**1**) is known as an isolatable intermediate in a Beckmann rearrangement of cyclohexanone oxime to ε-caprolactam (**2**), when sulfuric acid and/or sulfur trioxide is used as the rearranging agent.[1,2] However, the reactivity of **1** has not been studied except for hydrolysis,[2] which gave ε-caprolactam (**2**) and sulfuric acid. The hydrolytic reaction can be envisaged to take place through two pathways (Scheme 1); A which involves a nucleophilic attack by water (**3a**) on the sulfur atom of **1**, resulting in the tetrahydroazepinyl substituted oxygen-sulfur bond fission, and B which involves a nucleophilic attack by water (**3a**) on the carbon atom, resulting in the carbon-oxygen bond fission. No report has referred to the mechanism of the hydrolysis, presumably because both pathways give rise to identical products.

When nucleophilic reagents other than water such as alcohol or amine are used with **1**, a reaction along path A would give ε-caprolactam (**2**) and the corresponding sulfonated derivatives of reagent (**4**), while path B would give rise to the formation of sulfuric acid and 7-substituted 3,4,5,6-tetrahydro-2*H*-azepine derivatives (**5**), such as 7-alkoxy (**5b**) or 7-amino compound (**5c**). Reactions of 2-aza-1-cycloalkenyl benzenesulfonates with amine[3,4] or enamine[5] have been reported to yield α-substituted cyclic imino compounds resulting from the cleavage of the carbon-oxygen bond (Scheme 2). Thermal rearrangement of cycloalkanone oxime benzenesulfonates in the presence of alcohols or amines is also known to give α-substituted cyclic imino compounds.[6] The reaction of the oxime benzenesulfonates with acetic acid or methanol afforded lactam as a main product.[7]



Scheme 1.



Scheme 2.

We have found that nucleophilic reagents caused an exclusive cleavage of the oxygen-sulfur bond of tetrahydroazepin-7-ol hydrogen sulfate (**1**, path A). This paper describes the reaction of **1** with alcohols, amines, and oximes.

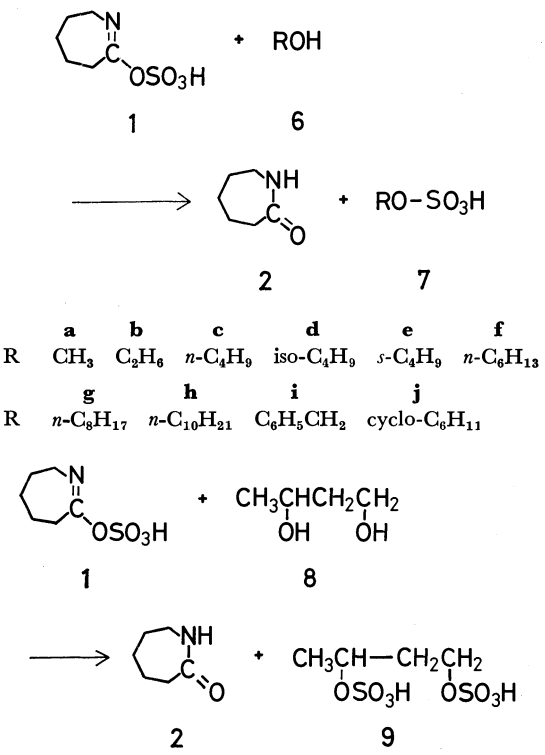
Results and Discussion

Reaction of 3,4,5,6-Tetrahydro-2H-azepin-7-ol Hydrogen Sulfate (1) with Alcohols. When **1** was treated with methanol (**6a**) in ethylene dichloride at 50 °C, ε-caprolactam (**2**) and monomethyl sulfate (**7a**) were obtained in 99 and 85% yields, respectively. The latter was isolated as a sodium salt. A similar treatment of **1**



with a half equiv. of 1,3-butanediol (**8**) yielded ε-caprolactam and 1,3-butanediol bis(hydrogen sulfate) (**9**) in 96 and 90% yields, respectively. **9** was isolated as a barium salt. Similarly, reactions of **1** with various alcohols (**6**) gave ε-caprolactam and the corresponding monoalkyl sulfates (**7**) in good yields. Monoalkyl sulfates (**7**) were isolated as stable salts with *S*-benzylthioformamidine. The results are summarized in Tables 1 and 2.

Table 1. Reaction of 3,4,5,6-tetrahydro-2*H*-azepin-7-ol hydrogen sulfate (**1**) with alcohols

	Alcohol	Products, yields %	
		Lactam	Monoalkyl sulfate
6a	Methanol	99	85[a]
6b	Ethyl alcohol	90	51[b]
6c	Butyl alcohol	98	95[b]
6d	Isobutyl alcohol	97	89[b]
6e	*sec*-Butyl alcohol	94	86[b]
6f	Hexyl alcohol	77	78[b]

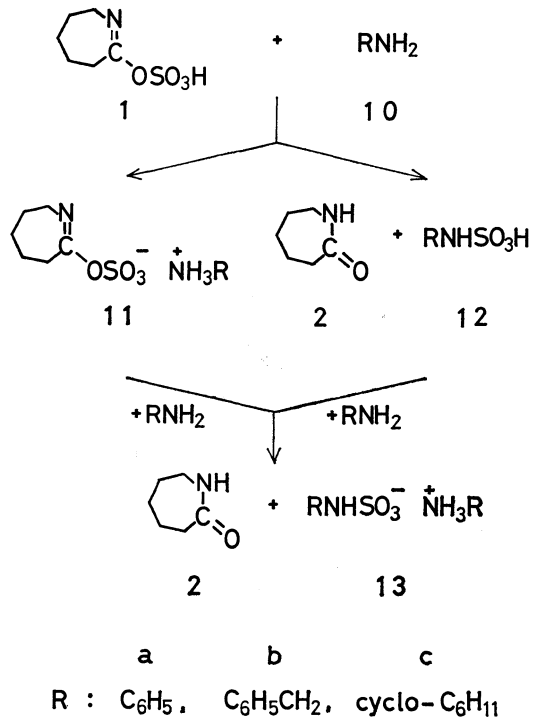
In these reactions, formation of 7-alkoxy-3,4,5,6-tetrahydro-2*H*-azepine (**5b**, path B) was not detected. In a reaction of **1** with *tert*-butyl alcohol, ε-caprolactam (**2**) and sulfuric acid were isolated. Formation of sulfuric acid could be explained by the decomposition[8] of mono-*tert*-butyl sulfate formed initially, along path A.

Reaction of 3,4,5,6-Tetrahydro-2H-azepin-7-ol Hydrogen Sulfate (1) with Amines. Treatment of **1** with 2 equiv. of aniline (**10a**) in ethylene dichloride at refluxing temperature afforded **2** and anilinium phenylsulfamate (**13a**) in 93 and 87% yields, respectively. However, reaction of **1** with 2 equiv. of benzylamine (**10b**) afforded not only **2** and benzylammonium benzylsulfamate (**13b**), but also benzylamine salt of **1** (**11b**). A considerable amount of the latter was obtained even when the reaction was carried out at 80 °C for 7 hr. Similarly, reaction of **1** with 2 equiv. of cyclohexylamine (**10c**) afforded **2**, cyclohexylammonium cyclohexanesulfamate (**13c**), and cyclohexylamine salt of **1**

8) C. M. Suter and J. D. Malkemus, *ibid.*, **63**, 978 (1941).



(**11c**) in 22, 27, and 69% yields, respectively.

Thus, the reaction of **1** with an amine could be explained to consist of two competitive reactions, a simple salt formation between **1** and the amine, and a nucleophilic attack of the amine on sulfur atom of **1** to give **2** and the corresponding sulfamic acid (**12**) which afforded the corresponding ammonium salt (**13**). Exclusive formation of **13a** in the reaction with aniline was rationalized by the fact that **11a** could undergo a further nucleophilic attack by another molecule of aniline to give **2** and **13a**.

When **1** was treated with 1 equiv. of aniline below −8 °C, aniline salt of **1** (**11a**) was produced in 75% yield. A reaction of **11a** with aniline at 80 °C resulted in the formation of **13a** in 67% yield. The cyclohexylamine salt (**11c**) was obtained by a treatment of **1** with 1 equiv. of cyclohexylamine (**10c**) in 76% yield. Reaction of **11c** with aniline was carried out at 80 °C for 1 hr, the starting materials being recovered.

The difference in reactivity of **11a** and **11c** could be ascribed to the basicity of the parent amines (**10**). The anionic character of sulfate moiety of the salt (**11**) would increase with increasing basicity of **10**. The electron density on the sulfur atom of sulfate (**11c**) would be larger than that of sulfate (**11a**), and it would become difficult for the former to undergo a nucleophilic attack by an amine on the sulfur atom as compared with the case of aniline salt (**11a**). Analogous phenomena have been observed in the Beckmann rearrangement of cyclohexanone oxime hydrogen sulfate (**15a**), its rearrangement being retarded by the Lewis base.[9] Salt formation with the base would increase the electron density on the sulfur atom of **15a** and make the heterolytic fission of nitrogen-oxygen bond more difficult, which is a rate-determining step in the rearrangement.[10]

Table 3. Reaction of 3,4,5,6-tetrahydro-2*H*-azepin-7-ol hydrogen sulfate (**1**) with oximes

	Oxime	Products, yield %	
		Lactam	Oxime hydrogen sulfate
14a	Cyclohexanone oxime	82	90[a]
14b	Acetoxime	100	85[b]
14c	Acetophenone oxime	66	50[b]
14d	Cyclopentanone oxime	96	63[b]
14e	Cyclododecanone oxime	100	68[b]

a) Based on conversion into the anilinium salt.
b) Based on conversion into the imidazolium salt.

Table 4. Imidazolium salts of oxime hydrogen sulfates (**15**)

good yields. Formation of **15a** was confirmed by treatment of the reaction mixture with aniline, giving aniline salt of cyclohexanone oxime hydrogen sulfate in 90% yield. Similar reactions of **1** with acetoxime (**14b**), acetophenone oxime (**14c**), cyclopentanone oxime (**14d**), and cyclododecanone oxime (**14e**) resulted in the formation of the corresponding oxime hydrogen sulfate (**15**) and **2** in good yields. Most of the oxime hydrogen sulfate (**15**) were isolated as stable salts with imidazole. The results are summarized in Tables 3 and 4.

Experimental

Concentration and evaporation were performed with a rotary evaporator under reduced pressure. Melting points were determined in a liquid bath and are uncorrected. Reagents and organic solvents for reactions were used as anhydrous states.

3,4,5,6-Tetrahydro-2H-azepin-7-ol Hydrogen Sulfate (1). A solution of **1** in ethylene dichloride was prepared by two methods. *a*) A modification of the method of Giuffre *et al*:[1] A solution of sulfur trioxide (2 ml, 48 mmol) in ethylene dichloride (40 ml) was added dropwise to a solution of ε-caprolactam (5.42 g, 48 mmol) in an appropriate amount of ethylene dichloride with stirring under ice cooling; *b*) A modification of the method of Turbak:[2] A suspension of cyclohexanone oxime hydrogen sulfate was heated to 40—50 °C until exothermic rearrangement took place.

Reaction of 1 with Methanol. Methanol (3.8 g, 120 mmol) was added dropwise with stirring at room temperature to a solution of **1** (120 mmol) in ethylene dichloride (250 ml). The mixture was then stirred at room temperature for 30 min, heated to 50 °C and further stirred for 30 min. The reaction mixture was concentrated. The syrup-like residue was dissolved in ice water (50 ml) and treated with a solution of sodium hydroxide (4.8 g, 120 mmol) under cooling. The solution was then extracted with chloroform (50 ml×4). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give **2.** Yield 13.5 g (99%).

The aqueous solution remaining after chloroform extraction was concentrated to 10 ml, and ethyl alcohol (50 ml) was added to the concentrate. The crystalline precipitate was collected by filtration and found to be identical with authentic sodium monomethyl sulfate monohydrate by infrared spectrum. Yield 15.5 g (85%).

Reaction of 1 with 1,3-Butanediol. A solution of 1,3-butanediol (5.4 g, 60 mmol) in ethylene dichloride (20 ml) was added dropwise to a solution of **1** (120 mmol) in ethylene dichloride (250 ml) with stirring at room temperature. The mixture was thereafter stirred for 30 min at room temperature, heated to 50 °C and stirred for 30 min. The reaction mixture was concentrated. The syrup-like residue was dissolved in ice water (50 ml) and neutralized with an aqueous barium hydroxide. The aqueous solution was extracted with chloroform (50 ml×4). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give **2.** Yield 13 g (96%).

The aqueous solution remaining after chloroform extraction was treated with activated carbon and concentrated to 20 ml. Ethyl alcohol was added to the concentrate to cause precipitation of barium 1,3-butanediol bis(hydrogen sulfate) dihydrate, which was collected by filtration and confirmed by an infrared spectroscopic comparison with that of an authentic sample. Yield 19.2 g (90%).

Reaction of 1 with Ethyl Alcohol. To a solution of **1** (48 mmol) in ethylene dichloride (85 ml) was added dropwise at room temperature a solution of ethyl alcohol (2.2 g, 48 mmol) in ethylene dichloride (15 ml). The mixture was stirred for 1 hr at room temperature, heated to 50 °C, and further stirred for 30 min. The reaction mixture was concentrated. The syrup-like residue was dissolved in water (25 ml) and neutralized with sodium bicarbonate. The aqueous solution was then extracted with chloroform (30 ml× 5). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give **2.** Yield 4.85 g (89%).

The aqueous solution remaining after chloroform extraction was treated with activated carbon. A solution of *S*-benzylthioformamidine hydrochloride (9.72 g, 48 mmol) in water (15 ml) was then added to the aqueous solution. The resulting solution was concentrated and ethyl alcohol was added to the residue. An insoluble matter was removed by filtration and the filtrate was treated with water (30 ml) to give *S*-benzylthioformamidinium monoethyl sulfate as pale yellow needles. Yield 1.05 g (7%). The mp and analytical results are shown in Table 2.

The filtrate was concentrated and the residue was treated with methanol (90 ml) to afford more *S*-benzylthioformamidinium monoethyl sulfate. Yield 5.8 g (41%).

Reaction of 1 with Butyl Alcohol, Isobutyl Alcohol, sec-*Butyl Alcohol, Hexyl Alcohol, Octyl Alcohol, Decyl Alcohol, Benzyl Alcohol, or Cyclohexanol.* In a similar way to that for the reaction of **1** with ethyl alcohol, a solution of **1** (48 mmol) in ethylene dichloride (85 ml) was treated with a solution of the alcohol (48 mmol) in ethylene dichloride (15 ml). The results are summarized in Tables 1 and 2.

Reaction of 1 with tert-*Butyl Alcohol.* To a solution of **1** (48 mmol) in ethylene dichloride (70 ml) was added dropwise with stirring below 0 °C a solution of *tert*-butyl alcohol (3.6 g, 48 mmol) in ethylene dichloride (10 ml). The mixture was stirred at room temperature for 2 hr and at 40 °C for 1 hr, and then treated with aniline (4.5 g, 48 mmol) under 0 °C. The resulting mixture was allowed to stand overnight. The crystalline substance collected by filtration was confirmed as anilinium sulfate by comparison of its infrared spectrum with that of the authentic sample. Yield 6.76 g (48% based upon **1**). The filtrate was concentrated to half, and treated with aniline (4.5 g, 48 mmol) under ice cooling to afford more anilinium sulfate. Yield 5.56 g (39%).

The ethylene dichloride solution separated from the above crystalline substance by filtration was concentrated. The residue was dissolved in water (40 ml) and hydrochloric aicd (1N, 10 ml) and extracted with chloroform (50 ml×4). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give **2.** Yield 4.93 g (91%).

Reaction of 1 with Two Equiv. of Aniline. To a solution of **1** (48 mmol) in ethylene dichloride (80 ml) was added dropwise below −5 °C with stirring a solution of aniline (8.93 g, 96 mmol) in ethylene dichloride (20 ml). Stirring was continued for 30 min. The mixture was heated under reflux for 1 hr, and then allowed to stand at room temperature to cool down. The precipitated crystals were collected by filtration and identified as anilinium phenylsulfamate (**13a**) by comparison of its infrared spectrum with that of the authentic sample.[9]

The mother liquor separated from the crystals was concentrated. Water (50 ml) was added to the residue, and the aqueous solution was washed with ether (50 ml) and extracted with chloroform (50 ml×5). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give **2.** Yield 5 g (93%).

Reaction of 1 with One Equiv. of Aniline. A solution of aniline (4.47 g, 48 mmol) in ethylene dichloride (30 ml) was added dropwise to a solution of **1** (48 mmol) in ethylene dichloride (100 ml) with stirring below −8 °C, taking about 15 min. Stirring was continued for 2 hr below −5 °C and overnight at room temperature. The mixture was filtered to give 11.94 g of colorless powder, which was identified by elemental analysis and infrared spectrum as a homogeneous mixture of aniline salt of 3,4,5,6-tetrahydro-2*H*-azepin-7-ol hydrogen sulfate and anilinium hydrogen sulfate (4:1 in molar ratio). Mp 124—146 °C. Found: C, 48.43; H, 6.06; N, 9.43; S, 12.24%. Calcd for $(C_{12}H_{18}N_2O_4S)_4 \cdot C_6H_9NO_4S$: C, 48.53; H, 6.07; N, 9.44; S, 11.99%. The infrared spectrum exhibited characteristic absorption bands at 1650 cm^{-1} (C=N), and 1270 and 1200 cm^{-1} (SO_2). The yield of **11a** was 10.23 g (75%).

The filtrate was concentrated, and the residue was dissolved in water (12 ml) and extracted with chloroform (20 ml×5). The combined extracts were dried over anhydrous sodium sulfate and concentrated to dryness, yielding 1.13 g (21%) of **2**.

Reaction of Aniline Salt of 1 (11a) with Aniline. A solution of aniline (2.81 g, 30 mmol) in ethylene dichloride (20 ml) was added with stirring below 0 °C to a suspension of a mixture of **11a** (6.5 g, 22.8 mmol) and anilinium hydrogen sulfate (1.1 g, 5.7 mmol) in ethylene dichloride (40 ml). The mixture was stirred at room temperature for 1 hr and then at the refluxing temperature for 1 hr. Filtration afforded 7 g of colorless powder which was identified by infrared spectrum as a mixture consisting of anilinium phenylsulfamate (**13a**) and a small amount of anilinium sulfate.

Reaction of 1 with Two Equiv. of Benzylamine. To a solution of **1** (48 mmol) in ethylene dichloride (80 ml) was added dropwise at room temperature with stirring a solution of benzylamine (10.27 g, 96 mmol) in ethylene dichloride (20 ml) over 17 min period. When the reaction temperature reached 40 °C at the highest, crystals were precipitated. It was then heated under reflux for 7 hr and cooled. The crystalline precipitate was collected by filtration. 7.09 g of benzylammonium benzylsulfamate (**13b**) was obtained, which was identified by comparison of its infrared spectrum with that of the sample synthesized by a reaction of sulfur trioxide–1,4-dioxane complex with 2 equiv. of benzylamine. Yield 50%.

The filtrate separated from **13b** was concentrated and the residue was treated with benzene (50 ml). The crystalline substance collected by filtration was identified by infrared spectrum as a mixture (4.33 g) of **13b** and benzylamine salt of **1** (**11b**), which exhibited characteristic absorption bands at 1630 cm^{-1} (C=N), and 1260 and 1210 cm^{-1} (SO_2). The mixture was dissolved in water (50 ml), and the resulting solution was heated under reflux for 1 hr and extracted with chloroform (50 ml×4). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give **2**. Yield 1.39 g (26%). The yield of **11b** was 3.74 g (26%) and that of **13b** 0.59 g (4%).

The filtrate was concentrated, and the residue was dissolved in aqueous sulfuric acid (0.5N, 40 ml) and extracted with chloroform (40 ml×5). Concentration of the combined extracts afforded a yellow oily substance (7.16 g), which was extracted with hot hexane (50 ml×4). Evaporation of hexane from the combined extracts afforded **2** as colorless crystals. Yield 2.99 g (55%).

Reaction of 1 with Two Equiv. of Cyclohexylamine. To a solution of **1** (48 mmol) in ethylene dichloride (80 ml) was added dropwise with stirring below −2 °C a solution of cyclohexylamine (9.5 g, 96 mmol) in ethylene dichloride (20 ml). The mixture was stirred at room temperature for 1.5 hr, heated under reflux for 1 hr, and allowed to stand at room temperature to cool down. The crystalline substance collected by filtration was identified by infrared spectrum as cyclohexylammonium cyclohexanesulfamate (**13c**). Yield 4.06 g (27%).

The filtrate separated from **13c** was concentrated and the residue was treated with benzene (100 ml). The crystalline precipitate was collected by filtration and identified by infrared spectrum as cyclohexylamine salt of **1** (**11c**), which exhibited characteristic absorption bands at 1630 cm^{-1} (C=N), and 1260 and 1210 cm^{-1} (SO_2). Yield 9.72 g (69%).

The filtrate was concentrated, and the residue was dissolved in water (35 ml) and extracted with chloroform (40 ml×4). Concentration of the combined extracts afforded an oily substance (2.77 g), which was extracted with hot hexane (60 ml×4). Evaporation of hexane from the combined extracts afforded **2** as colorless crystals. Yield 1.22 g (22%).

Reaction of 1 with One Equiv. of Cyclohexylamine. A solution of cyclohexylamine (4.75 g, 48 mmol) in ethylene dichloride (20 ml) was added dropwise to a solution of **1** (48 mmol) in ethylene dichloride (80 ml) with stirring below −7 °C. Stirring was continued for 30 min below −9 °C and overnight at room temperature. The mixture was filtered to give 7.42 g of colorless powder, which was identified by infrared spectrum as cyclohexylamine salt of **1** (**11c**). Yield 53%.

The filtrate separated from **11c** was evaporated and the residue was treated with benzene (100 ml) to give more **11c** as an insoluble matter. Yield 3.19 g (23%).

Reaction of Cyclohexylamine Salt of 1 (11c) with Aniline. A solution of aniline (2.79 g, 30 mmol) in ethylene dichloride (10 ml) was added with stirring at room temperature to a suspension of **11c** (8.76 g, 30 mmol) in ethylene dichloride (50 ml). The mixture was heated under reflux for 1 hr and stirred at room temperature for 2 hr. The mixture was concentrated and the residue was treated with benzene (50 ml). The crystalline substance collected by filtration was identified as the starting material, amine salt (**11c**). Yield 7.36 g (84%).

Benzylammonium Benzylsulfamate (13b). A solution of 1,4-dioxane (4.4 g, 50 mmol) in ethylene dichloride (20 ml) was added dropwise to a solution of sulfur trioxide (2 ml, 48 mmol) in ethylene dichloride (40 ml) with stirring below 4 °C. To the resulting suspension of sulfur trioxide–1,4-dioxane complex was added dropwise with stirring below −1 °C a solution of benzylamine (10.3 g, 96 mmol) in ethylene dichloride (30 ml). The mixture was stirred at room temperature for 4 hr, and the crystalline substance, benzylammonium benzylsulfamate (**13b**), was collected by filtration. Yield 11.45 g (81%). Recrystallization from methanol gave colorless needles, mp 174—176 °C. Found: C, 57.04; H, 6.40; N, 9.71%. Calcd for $C_{14}H_{18}N_2O_3S$: C, 57.14; H, 6.12; N, 9.52%.

Cyclohexylammonium Cyclohexanesulfamate (13c). A suspension of sulfur trioxide–1,4-dioxane complex (1:1 in molar ratio, 48 mmol) in ethylene dichloride (60 ml) was treated with a solution of cyclohexylamine (9.5 g, 96 mmol) in ethylene dichloride (30 ml) in a similar way to that for **13b**. The mixture was stirred at room temperature and filtered to give 9.48 g of cyclohexylammonium cyclohexanesulfamate (**13c**). Yield 71%. Recrystallization from methanol–ether gave colorless crystals, mp 191 °C (lit,[11] 198—200 °C). Found: N, 10.18; S, 11.37%. Calcd for $C_{12}H_{26}$-

11) L. F. Audrieth and M. Sveda, *J. Org. Chem.*, **9**, 89 (1944).

N_2O_3S: N, 10.07; S, 11.51%.

Reaction of ***1*** *with Cyclohexanone Oxime.* A solution of cyclohexanone oxime (13.6 g, 120 mmol) in ethylene dichloride (50 ml) was added dropwise to a solution of **1** (120 mmol) in ethylene dichloride (170 ml) with stirring below 3 °C. Stirring was continued further for 30 min under cooling and for 1 hr at room temperature. The mixture was then treated with a solution of aniline (11.2 g, 120 mmol) in ethylene dichloride (30 ml) below 0 °C and stirred at room temperature for 1 hr. The crystalline precipitate was collected by filtration and identified by comparison of its infrared spectrum with that of authentic aniline salt of cyclohexanone oxime hydrogen sulfate.[9] Yield 31.3 g (90%).

Concentration of the filtrate afforded an oily substance which was dissolved in water (50 ml), washed with benzene (10 ml) and extracted with chloroform (50 ml×4). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give **2**. Yield 11.2 g (82%).

Reaction of ***1*** *with Acetoxime.* To a solution of **1** (48 mmol) in ethylene dichloride (90 ml) was added dropwise with stirring below −2 °C a solution of acetoxime (3.5 g, 48 mmol) in ethylene dichloride (20 ml). The mixture was stirred for 1 hr at room temperature, and then cooled down to −5 °C or below. A solution of imidazole (3.3 g, 48 mmol) in ethylene dichloride (50 ml) was then added dropwise to the mixture. A colorless precipitate was formed at once. Stirring was continued for further 30 min under cooling. The precipitated imidazole salt of acetoxime hydrogen sulfate was collected by filtration. Yield 8.9 g (84%). Recrystallization from methanol–acetone gave colorless prisms, mp 102—105 °C. Found: N, 18.84; S, 14.37%. Calcd for $C_6H_{11}N_3O_4S$: N, 18.99; S, 14.49%.

Concentration of the filtrate afforded a syrup-like residue which was extracted with benzene (30 ml), the extract being evaporated to give **2**. Yield 5.3 g (98%).

Reaction of ***1*** *with Acetophenone Oxime, Cyclopentanone Oxime, and Cyclododecanone Oxime.* In a similar way to that for the reaction of **1** with acetoxime, a solution of **1** (48 mmol) in ethylene dichloride (80 ml) was treated with a solution of acetophenone oxime (6.5 g, 48 mmol), cyclopentanone oxime (4.7 g, 48 mmol), or cyclododecanone oxime (9.5 g, 48 mmol) in an appropriate amount of ethylene dichloride. The reaction mixture was then treated with a solution of imidazole (3.8 g, 48 mmol) in chloroform (30 ml). The results are summarized in Tables 3 and 4.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3179—3183 (1973)

Reaction of 3,4,5,6,-Tetrahydro-2*H*-azepin-7-ol Hydrogen Sulfate with Cyclohexanone Oxime–Tin Tetrachloride Complex

Mitsuo MASAKI, Kiyoshi FUKUI, Masaru UCHIDA, Koichi YAMAMOTO, and Izuhiko UCHIDA

Polymer Research Laboratory, Ube Industries, Ltd., Goi, Minamikaigan, Ichihara, Chiba 290

(Received May 11, 1973)

Cyclohexanone oxime hydrogen sulfate was found to undergo facile rearrangement to 3,4,5,6-tetrahydro-2*H*-azepin-7-ol hydrogen sulfate in the presence of ε-caprolactam–tin tetrachloride complex, while the oxime hydrogen sulfate decomposed in the presence of ε-caprolactam. Other metal halides were studied to see if the oxime hydrogen sulfate undergoes rearrangement in the presence of the lactam. Cyclohexanone oxime–tin tetrachloride complex was synthesized. Its reaction with the tetrahydroazepin-7-ol hydrogen sulfate was found to give the lactam–tin tetrachloride complex and the oxime hydrogen sulfate which regenerated the tetrahydroazepin-7-ol hydrogen sulfate in the reaction system. Tin tetrachloride complex was prepared with several oximes.

Tetrahydroazepin-7-ol hydrogen sulfate undergoes an oxygen-sulfur bond fission exclusively on treatment with nucleophilic reagents.[1] The reaction of 3,4,5,6-tetrahydro-2*H*-azepin-7-ol hydrogen sulfate (**1**) with cyclohexanone oxime (**2**) afforded ε-caprolactam (**3**) and cyclohexanone oxime hydrogen sulfate (**4**) in good yields. The reaction indicates a possible regeneration of **1** in the reaction system, since the compound has been known to be produced by a thermal rearrangement of **4**.[2] It is of interest to examine the possibility, because a Beckmann rearrangement using sulfuric acid and/or sulfur trioxide as a rearranging agent has been known to require at least one equiv. of the agent.[3] Preliminary experiments revealed, however, that **4** decomposed in the presence of **3** and did not undergo rearrangement. Though the decomposition products

2) K. Fukui, M. Uchida, and M. Masaki, *ibid.*, **46**, 3168 (1973).

3) a) L. G. Donaruma and W. Z. Heldt, "Organic Reactions," Vol. 11, ed. by A. C. Cope *et al.*, John Wiley & Sons, Inc., New York, N. Y., (1960) p. 57; b) N. Tokura, R. Asami, and R. Tada, *Sci. Repts. Research Inst., Tohoku Univ., Ser.* **A8**, 151 (1956).

and mechanism are not clear,[4] the decomposition seems to be ascribable to an interaction between the oxime hydrogen sulfate (strong acid) and the lactam function (weak base). Thus **4** might be expected to undergo rearrangement normally, when the lactam function is protected by converting the lactam into a complex with Lewis acid.

This paper describes a Beckmann rearrangement of oxime hydrogen sulfate (**4**) in the presence of lactam–Lewis acid complex and a conversion of cyclohexanone oxime–tin tetrachloride complex into ε-caprolactam-tin tetrachloride complex by means of a circulatory use of sulfur trioxide moiety in **4** or tetrahydroazepin-7-ol hydrogen sulfate (**1**).

Results and Discussion

When a mixture of cyclohexanone oxime hydrogen sulfate (**4**) and 1 equiv. of ε-caprolactam–zinc chloride complex (2: 1 in molar ratio, **5a**) in ethylene dichloride was heated to 64 °C, no exothermic phenomenon nor any remarkable coloration of the reaction mixture was observed, in contrast to the fact that **4** decomposes with a remarkable coloration of the mixture in the presence of ε-caprolactam (**3**) under similar conditions, and when alone, undergoes rearrangement exothermally under milder conditions.[2] After hydrolysis and neutralization of the reaction product, **3** was obtained in 152% yield based upon the lactam complex (**5a**). The results showed that more than 52% of **4** underwent rearrangement to **1** and less than 48% decomposed, competitively. The partial decomposition might be due to a partial dissociation of **5a** into **3** and zinc chloride.

When a mixture of **4** and 1 equiv. of ε-caprolactam–tin tetrachloride complex (2: 1 in molar ratio, **5b**) in ethylene dichloride was gradually heated to 48 °C, exothermic rearrangement of **4** occurred to afford **3** in 190% yield, after hydrolysis and neutralization. It is apparent that at least 90% of **4** rearranged in the presence of **5b**.

Various metal halides were similarly examined to see whether **4** underwent rearrangement in their presence with ε-caprolactam (**5**). The results are summarized in Table 1. Tin tetrachloride was found to be most effective among the metal halides examined.

It might be concluded that a regeneration of **1** in the reaction system is possible, when tin tetrachloride is added subsequently to the formation of **4** and **3** in the reaction of **1** with **2**. It might be expected that a reaction of **1** with cyclohexanone oxime–tin tetrachloride complex (**6**) affords **5b** and **1**.

Treatment of **2** with 1/2 equiv. of tin tetrachloride in ethylene dichloride gave cyclohexanone oxime–tin tetrachloride complex (2: 1 in molar ratio, **6**), which was confirmed by elemental analysis and infrared spectrum. Since this was the first example of complexes of oximes with tin tetrachloride, several other oximes were treated in a similar way with tin tetrachloride. The results are summarized in Table 2. All complexes (**7**—**11**) synthesized consist of two oximes and one tin tetrachloride in molar ratio.

When **6** was treated with 1 equiv. of 3,4,5,6-tetrahydro-2*H*-azepin-7-ol hydrogen sulfate (**1**) in ethylene dichloride at room temperature, a slight exothermic reaction occurred, **5b** being obtained as a crystalline

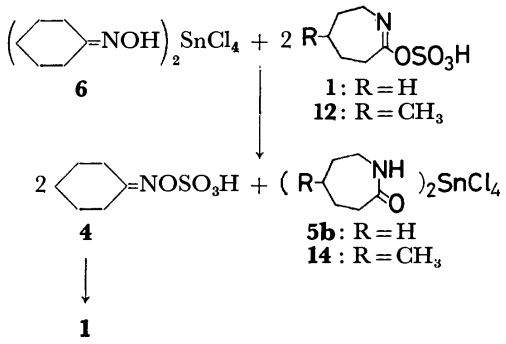
4) The oxime hydrogen sulfate decomposed when heated in the presence of 1 equiv. of ε-caprolactam, giving an intractable mixture consisting of more than at least three components. A similar decomposition also took place when substances having amide function were used in place of ε-caprolactam.



Scheme 1

precipitate in 65% yield. Hydrolysis and neutralization of products in the solution afforded **3** in 113% yield based on **1**, showing the presence of more than 13% yield of **5b** in the solution. The reaction can be summarized as in Scheme 1.

Although oximes are known to be transformed into amides or lactams by means of Lewis acid,[5] such a rearrangement requires more drastic conditions. Control experiments showed that the starting material was recovered when the oxime complex was heated under reflux in ethylene dichloride alone or in the presence of excess tin tetrachloride. We were able to isolate a reaction intermediate, the oxime hydrogen sulfate derived from the oxime complex.

When a reaction of 4-methyl-3,4,5,6-tetrahydro-2*H*-azepin-7-ol hydrogen sulfate (**12**) with cyclohexanone oxime-tin tetrachloride complex (**6**) in ethylene dichloride below 5 °C was followed by treatment with imidazole, 4-methyl-ε-caprolactam (**13**) and imidazole salt of cyclohexanone oxime hydrogen sulfate were obtained in 87 and 62% yields, respectively.

When the reaction mixture resulting from the reaction of **1** and 1 equiv. of **6** (Scheme 1) was further treated with 1 equiv. of **6**, a slight exothermic reaction occurred and **5a** was obtained as a crystalline precipitate in 85% yield based upon **6**. The regeneration of **1** in the reaction mixture was thus confirmed.

Experimental

Concentration and evaporation were carried out with a rotary evaporator under reduced pressure. All melting points were determined in a liquid bath, and are uncorrected unless otherwise stated. Solvents were used after drying and distillation.

Materials. Complexes of ε-caprolactam with zinc chloride (**5a**),[6] tin tetrachloride (**5b**),[6] boron trifluoride (**5c**),[7] cadmium chloride (**5d**),[8] mercuric chloride (**5e**),[8] ferric chloride (**5f**),[8] and zirconium tetrachloride (**5g**)[8] were prepared by known methods. The suspension of cyclohexanone oxime hydrogen sulfate (**4**) in ethylene dichloride was prepared by a reaction of cyclohexanone oxime with sulfur trioxide–1,4-dioxane complex.[2] The solution of 3,4,5,6-tetrahydro-2*H*-azepin-7-ol hydrogen sulfate (**1**) in ethylene dichloride was prepared by two methods.[1]

ε-Caprolactam–Antimony Pentachloride Complex. The reaction of **3** with antimony pentachloride in methylene chloride has been reported by Rothe *et al.*[7a] to give ε-caprolactam–antimony pentachloride complex (3:2 in molar ratio). However, we obtained two complexes (2:1 and 1:1).

Complex (1: 1, 5h): A solution of **3** (2.71 g, 24 mmol) in ethylene dichloride (30 ml) was added dropwise to a solution of antimony pentachloride (7.18 g, 24 mmol) in ethylene dichloride (20 ml) with stirring below 0 °C. Crystals formed were collected by filtration. Yield 2.81 g (28%). Mp 135—145 °C (on a hot plate). Found: Cl, 42.72%. Calcd for $C_6H_{11}NO \cdot SbCl_5$: Cl, 43.01%.

The filtrate was concentrated and the residue was treated with benzene to give 4.2 g of crystals, whose infrared spectrum was identical with that of crystals obtained above. Total yield 70%.

Complex (2: 1, 5i): A solution of antimony pentachloride (7.17 g, 24 mmol) in ethylene dichloride (20 ml) was added to a solution of **3** (5.42 g, 48 mmol) in ethylene dichloride with stirring below −5 °C. The mixture was stirred at room temperature for 1 hr and filtered to give crystals. Yield 5.69 g (45%). Found: C, 27.33; H, 4.25; N, 5.21; Cl, 33.96%. Calcd for $C_{12}H_{22}N_2O_2 \cdot SbCl_5$: C, 27.43; H, 4.23; N, 5.33; Cl, 33.74%.

The filtrate was concentrated and the residue was treated with ethyl acetate to give 5.43 g of crystals, whose infrared spectrum was identical with that of crystals obtained above. Total yield 87%.

ε-Caprolactam–Tin Tetrabromide Complex (5j). A solution of tin tetrabromide (65.7 g, 0.15 mol) in ethylene dichloride (70 ml) was added dropwise to a solution of **3** (34 g, 0.3 mol) in ethylene dichloride with stirring under ice cooling. The mixture was stirred for 2 hr at room temperature and filtered to afford crystals. Yield 80.8 g (81%). Mp 145—146.5 °C. Found: C, 21.51; H, 3.16; N, 4.09; Br, 48.07%. Calcd for $C_{12}H_{22}N_2O_2 \cdot SnBr_4$: C, 21.67; H, 3.31; N, 4.21; Br, 48.11%.

Rearrangement of Cyclohexanone Oxime Hydrogen Sulfate (4).

a) In the Presence of ε-Caprolactam–Zinc Chloride Complex (5a): A solution of **5a** (8.7 g, 24 mmol) in ethylene dichloride (20 ml) was added dropwise to a suspension of **4** (48 mmol) in ethylene dichloride (70 ml) with stirring below −5.5 °C. The mixture was stirred at room temperature until dissolution, and then heated gradually to 64 °C. Stirring was continued for 1 hr, during which the temperature fell gradually to room temperature. The mixture was treated with water (20 ml) and then with aqueous ammonia (28%, 20 ml) under ice cooling, and concentrated. The residue was dissolved in water (50 ml) and extracted with chloroform (50 ml × 5). The combined extracts were dried over anhydrous sodium sulfate and concentrated to dryness, giving 8.24 g of **3**. The yield was 152% based upon the lactam complex.

b) In the Presence of ε-Caprolactam–Tin Tetrachloride Complex (5b): The complex (**5b**, 11.7 g, 24 mmol) was added to a suspension of **4** (48 mmol) in ethylene dichloride (80 ml) at room temperature. When the mixture was gradually heated to 48 °C, the temperature of the mixture rose to 65 °C. The resulting mixture was stirred at room temperature overnight, and then filtered to give colorless crystals which were identified by infrared spectrum as **5b**. Yield 7.15 g (61%). The filtrate was concentrated and the residue

9) L. Giuffre, G. Sioli, and E. Losio, *Chim. Ind.* (Milan), **50**, 983 (1968).

10) A.F. Turbak, *Ind. Eng., Chem. Prod. Res. Develop.*, **7**, 190 (1968).

was treated with water (50 ml), neutralized with aqueous ammonia under ice cooling, and evaporated to about half in volume. Tetrahydrofuran (50 ml) was added to the residual mixture and the gelatinous precipitate was removed by filtration and washed with tetrahydrofuran. The combined filtrate and washing were concentrated and the residue was dissolved in water (40 ml) and extracted with chloroform (40 ml×5). The combined extracts were dried over anhydrous sodium sulfate and concentrated to dryness, giving 7 g of **3**. Yield 129%. Total yield of **3** was 190% based upon **5b**.

c) In the Presence of Complexes of ε-Caprolactam with Boron Trifluoride, Cadmium Chloride, Mercuric Chloride, Ferric Chloride, Zirconium Tetrachloride, Antimony Pentachloride, or Tin Tetrabromide (5c—h, or 5j): Twenty four mmol of **5c**, **5d**, **5e**, **5f**, **5g** or **5j**, or 48 mmol of **5h** as crystals or a solution in ethylene dichloride was added with stirring to a suspension of **4** (48 mmol) in ethylene dichloride (80 ml) below −10 °C. The mixture was stirred for 20—60 min, during which time the temperature returned gradually to room temperature. The mixture was then slowly heated to the temperature given in Table 1, when an exothermic phenomenon was observed, the temperature of the reaction mixture being raised by degrees. After stirring for 2 hr at room temperature, the mixture was concentrated and the residue was treated with water (50 ml), neutralized with aqueous ammonia and treated with methanol (50 ml). The gelatinous precipitate was filtered and washed with methanol. The combined filtrate and washing were concentrated and the residue was dissolved in water (40 ml) and extracted with chloroform (50 ml×5). The combined extracts were dried over anhydrous sodium sulfate and concentrated to give **3**. A ratio of conversion of **4** into **1** was calculated by subtraction of the theoretical yield 5.42 g of **3** based on **5c—h**, or **5j** from the yield of **3** obtained from the extraction. The results are summarized in Table 1.

Cyclohexanone Oxime–Tin Tetrachloride Complex (6). To a solution of cyclohexanone oxime (**2**) (11.3 g, 100 mmol) in ethylene dichloride (50 ml) was added dropwise a solution of tin tetrachloride (13.0 g, 50 mmol) in ethylene dichloride (20 ml) with stirring below 10 °C. A colorless precipitate was soon formed. After being left to stand overnight, the mixture was filtered to give 23.7 g of colorless crystals. The results are given in Table 2.

Cyclopentanone Oxime–Tin Tetrachloride Complex (7). To a solution of cyclopentanone oxime (9.9 g, 100 mmol) in ethylene dichloride (50 ml) was added dropwise a solution of tin tetrachloride (13.0 g, 50 mmol) in ethylene dichloride (20 ml) with stirring below 10 °C. The mixture was stirred for 2 hr at room temperature and concentrated. Ethyl acetate (50 ml) was added to the sirupy residue and the resulting solution was allowed to stand at room temperature to give 20.1 g of colorless crystals. The results are given in Table 2.

Tin Tetrachloride Complex with Acetoxime (8), Acetophenone Oxime (9), and 4-Methylcyclohexanone Oxime (10). The complexes were synthesized as in the case of **6** (Table 2).

Cyclododecanone Oxime–Tin Tetrachloride Complex (11). This was synthesized as in the case of **7** (Table 2).

Reaction of 3,4,5,6-Tetrahydro-2H-azepin-7-ol Hydrogen Sulfate (1) with 1 Equiv. of Cyclohexanone Oxime–Tin Tetrachloride Complex (6). **6** (11.7 g, 24 mmol) was added to a solution of **1** (48 mmol) in ethylene dichloride (80 ml) with stirring at room temperature. The temperature of the mixture rose above *ca.* 2—3 °C, a homogeneous solution being formed within 20 min. Stirring was continued for approximately 90 min after the addition of the complex, when the temperature began to fall, the solution becoming turbid, and a precipitate formed gradually. After being allowed to stand at room temperature overnight, the mixture was filtered to give 7.6 g of colorless crystals, which were identified by infrared spectrum as ε-caprolactam–tin tetrachloride complex (**5b**). The yield based on the used oxime complex (**6**) was 65%. The filtrate was concentrated and the residue was dissolved in water, neutralized with ammonia, and extracted with chloroform to afford 6.5 g of **3**.

Reaction of 3,4,5,6-Tetrahydro-2H-azepin-7-ol Hydrogen Sulfate (1) with 2 Equiv. of Cyclohexanone Oxime–Tin Tetrachloride Complex (6). **6** (11.7 g, 24 mmol) was added to a solution of **1** (48 mmol) in ethylene dichloride (100 ml) with stirring at room temperature. The mixture rose by 2—3 °C, and became homogeneous within *ca.* 20 min. 90 min after addition of the complex, the temperature began to fall. **6** (11.7 g, 24 mmol) was again added to the mixture and stirring was continued. The reaction mixture rose 2—3 °C above room temperature. It was stirred overnight at room temperature, and then filtered to give 20.0 g of colorless crystals, which were identified by infrared spectrum as lactam complex (**5b**). The yield based upon the added oxime complex was 85%. The filtrate was treated as in the case of the reaction described above, 5.8 g of **3** being obtained.

Reaction of 4-Methyl-3,4,5,6-tetrahydro-2H-azepin-7-ol Hydrogen Sulfate (12) with Cyclohexanone Oxime–Tin Tetrachloride Complex (6): **6** (11.7 g, 24 mmol) was added with stirring at −10 °C to a solution of **12** (48 mmol) in ethylene dichloride (80 ml), prepared by the reaction of 4-methyl-ε-caprolactam (6.10 g, 48 mmol) and sulfur trioxide (2 ml, 48 mmol). The temperature of the mixture rose to −3 °C. The resulting suspension was stirred at 5 °C for approximately 1.5 hr, when it became a clear solution. This was cooled to −10 °C, and a solution of imidazole (6.5 g, 96 mmol) in chloroform (50 ml) was added dropwise. Stirring was continued, and the mixture was allowed to gradually return to room temperature. The colorless solid formed after the imidazole addition turned into an oily matter with temperature rise. After stirring at room temperature for 30 min the mixture was concentrated to remove ethylene dichloride and chloroform. To the oily residue was added tetrahydrofuran (100 ml) and the precipitated colorless solid was collected by filtration. The precipitate was hygroscopic. It was confirmed by infrared spectrum to be a mixture of imidazole salt of **1** and imidazole–tin tetrachloride complex. The mixture was added to acetonitrile (60 ml) and stirred at room temperature, in order to dissolve the imidazole salt of **1**. The insoluble imidazole–tin tetrachloride complex was separated by filtration. The filtrated cake weighed 5.8 g. The acetonitrile filtrate was concentrated to afford 7.8 g of imidazole salt of **1**, whose infrared spectrum was identical with that of the authentic specimen.[2] The yield based upon the added oxime complex (**6**) was 62%.

The tetrahydrofuran filtrate separated from the above colorless solid was concentrated, and the residue was treated with water (50 ml) and neutralized with aqueous ammonia under ice cooling. After a gelatinous precipitate was removed by filtration and washed with tetrahydrofuran, the combined filtrate and washing were concentrated. The residue was dissolved in 50 ml of water and extracted with chloroform (50 ml×5). The combined extracts were dried and concentrated to give 5.3 g of 4-methyl-ε-caprolactam. The yield based upon the employed 4-methyl-3,4,5,6-tetrahydro-2*H*-azepin-7-ol hydrogen sulfate (**12**) was 87%.

Attempted Thermal Rearrangement of Cyclohexanone Oxime–Tin Tetrachloride Complex (6). *a)* A suspension of **6** (2 g, 4.1 mmol) in ethylene dichloride (40 ml) was heated at

reflux temperature for 1.5 hr. The starting material **6** (1.9 g) was recovered in 95% yield.

b) To a suspension of **6** (10 g, 20.5 mmol) in ethylene dichloride (100 ml) was added tin tetrachloride (5.35 g, 20.5 mmol) and the mixture was heated at reflux temperature for 7.5 hr. After the mixture returned to room temperature the precipitate was collected by filtration. 8.6 g of **6** was recovered.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3183—3187 (1973)

The Synthesis and the Absolute Configurations of Lilac Alcohols, New Naturally Occurring Odorous Ingredients of Lilac Flower

Seiji WAKAYAMA, Satoshi NAMBA, Kazuo HOSOI,* and Masaji OHNO*

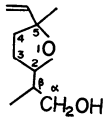
Chemical Laboratory, Hokkaido University of Education, Sapporo 060

**Basic Research Laboratories, Toray Industries, Inc., Kamakura 248*

(Received July 18, 1972)

The conversion of racemic linalyl acetate to racemic lilac alcohols has been completed in 5 steps and four diastereoisomers of β,5-dimethyl-5-vinyl-2-tetrahydrofuranethanol were obtained. *d*-Lilac alcohols were also synthesized from *d*-linalyl acetate and confirmed to be identical with natural ones. The absolute configurations of lilac alcohol-a, -b, -c, and -d were respectively shown to be (β*S*, 2*S*, 5*S*), (β*R*, 2*S*, 5*S*), (β*R*, 2*R*, 5*S*), and (β*S*, 2*R*, 5*S*) by the chemical and physical evidences.

In previous papers,[1,2] it has been reported that four new terpene alcohols with exquisite floral fragrance have been isolated from the flower of lilac, *Syringa vulgaris* L. They have been named lilac alcohol-a, -b, -c, and -d according to decreasing order of the relative abundance and the diastereomers of β,5-dimethyl-5-vinyl-2-tetrahydrofuranethanol (I) were assigned as the structures of lilac alcohol-a and -b. It was soon confirmed by spectroscopic evidence that lilac alcohol-c and -d are also diastereomers of (I). (*cf.* Table 1).



I

TABLE 1. CHARACTERIZATION OF LILAC ALCOHOLS

Lilac alcohol	a	b	c	d
Relative abundance	9.7	3.5	2.5	1
R_t[a] (min)	17.8	13.4	20.8	14.8
$[\alpha]_D^{21}$(natural)	+12.2	−6.6	−1.4	+4.3
$[\alpha]_D^{25}$(from *d*-II)	+ 6.7	−1.4	−0.5	+1.4
$[\alpha]_D^{25}$(from *l*-II)	−11.6	+3.0	+2.5	−2.9

a) Gas chromatographic analyses were carried out at 120 °C with a 3mm×3m column packed with 20% DEGS on Chromosorb W using JEOL GC-750.

Therefore, the lilac flower oil contains interestingly all diastereomers expected from the structure (I), but their extremely low yield from natural flower oil (-c and -d) made it difficult to investigate their stereochemical relationships. In this paper we wish to report the synthesis of lilac alcohols from linalyl acetate and their absolute configurations.[3]

Synthesis of Lilac Alcohols and the Absolute Configurations at C-2 and C-5. Four diastereomers of β,5-dimethyl-5-vinyl-2-tetrahydrofuranethanol (I) were obtained from racemic linalyl acetate in the following manner (Chart 1).

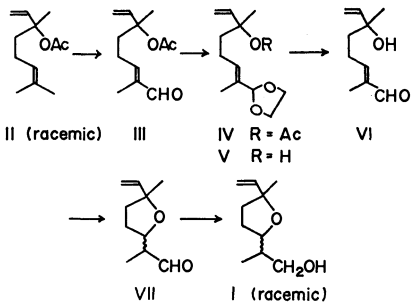


Chart 1.

Racemic linalyl acetate (II) was treated with selenium dioxide to afford α,β-unsaturated aldehyde (III) in 40% yield. Treatment of (III) with ethylene glycol in the presence of *p*-toluenesulfonic acid in benzene gave ethylene acetal (IV) which was hydrolysed with a 5% solution of sodium hydroxide to afford V. When the elution chromatography of V was carried out through a silica gel column, the ethylene acetal group underwent easy hydrolysis to afford VI (77% overall yield from III).[4] The direct hydrolysis of III afforded VI in only 6% yield along with VII. The intramolecular Michael addition of the tertiary alcohol to the α,β-

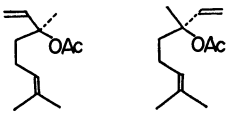
2) S. Wakayama, S. Namba, and M. Ohno, This Bulletin, **43**, 3319 (1970).

3) S. Wakayama, S. Namba, K. Hosoi, and M. Ohno, *ibid.*, **44**, 875 (1971).

4) During the course of our synthetic work on lilac alcohols from linalyl acetate, Naegeli and Weber published the use of the aldehyde III as an intermediate to davanone synthesis. P. Naegeli and G. Weber, *Tetrahedron Lett.*, **1970**, 959.

unsaturated aldehyde was effected with triethylamine to give a tetrahydrofuran derivative VII in 43% yield. Reduction of VII with $LiAlH_4$ afforded a mixture of four diastereomers of racemic lilac alcohol in 75% yield. From the mixture, each diastereomer was cleanly separated and purified by vapor phase chromatography. The relative concentration of the synthetic lilac alcohol-a, -b, -c, and -d was 2.0, 3.0, 2.5, and 1.0, respectively. The identity of the synthetic lilac alcohols with natural ones was confirmed by IR, NMR, and R_t (vpc) except for the optical activity.

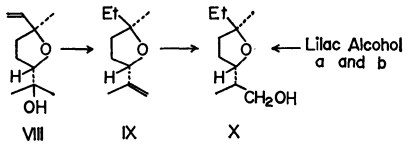
In order to establish the absolute configuration of natural lilac alcohols, *d*-linalyl acetate[5] (*d*-II, $[\alpha]_D^{25}$ +2.9) and *l*-linalyl acetate (*l*-II, $[\alpha]_D^{25}$ −5.0) were separately converted into the corresponding lilac alcohols in the manner described above for the racemic case. Although these starting materials were not optically pure, they proved to be pure enough for the diagnostic purpose of the absolute configuration.



d-II l-II

Thus, the physical properties of *d*-lilac alcohol-a, -b, -c, and -d derived from *d*-II were found to be consistent with the data obtained from the natural alcohols, as shown in Table 1.

Stereochemistry of the Tetrahydrofuran Ring. In a previous paper[2] lilac alcohol-a and -b and racemic *trans*-linalool oxide[6-8] (VIII) were converted into the same derivative (X).



VIII IX X

Therefore, the stereochemitry of lilac alcohol-a and -b was clearly shown to be *trans* as for the tetrahydrofuran ring, and also concluding that the stereochemistry of lilac alcohol-c and -d must be *cis* as for the tetrahydrofuran ring.

Furthermore, since the absolute configuration of *d*-linalool[9] is known, it follows from the above results that the absolute configurations at C-2 and C-5 of lilac alcohol-a, -b, -c, and -d are (2*S*, 5*S*), (2*S*, 5*S*), (2*R*, 5*S*), and (2*R*, 5*S*), respectively.

Configurations at C-2 and C-β. The NMR spectra

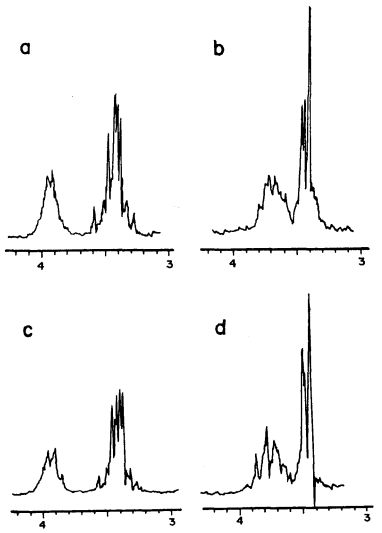


Fig. 1. The signal patterns of $-CH_2OH$ group.

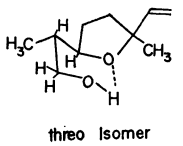
of lilac alcohols are very similar to one another except for the signal of the carbinol methylene shown in Fig. 1.

Lilac alcohol-a and -c show common patterns (ABX type) regarding the methylene signal of the CH_2OH group, while lilac alcohol-b and -d show another common signal for the same group. This fact suggests that the former pair and the latter pair have respectively the same configurations at C-2 and C-β, and it was considered that such configurational problem might be solved by the study of intramolecular hydrogen bonding between the hydroxyl group and the ether oxygen, as seen in the formula of *threo* isomer, for example.



threo Isomer

Therefore, we determined the relative extent of hydrogen bonding[10,12,13] in the diastereomeric lilac alcohol-a, -b, -c, and -d by (1) measuring the hydroxyl absorption of their IR spectra in high dilution and (2) observing the dilution shift of the hydroxyl proton in the NMR spectrum of each isomer. In addition, we examined in detail the coupling constants (half-height width), $J_{2,\beta}$, since the magnitude of the vicinal proton coupling constant $J_{2,\beta}$ is a measure of the relative population of the various conformations.[10] Consideration of non-bonded interactions and intramolecular hydrogen bonding between the hydroxyl group and the ether oxygen in the rotational isomers of *threo* lilac alcohols[11] suggests that conformer A would be more stable than B or C (Chart 2). Similar consideration suggests that conformer E and F of the *erythro* isomer would be more stable than D.

5) *d*-Linalyl acetate was synthesized from *d*-linalool (coriabder oil). The oil and *l*-linalyl acetate were supplied by Takasago Perfumery Co., Ltd., Japan.

6) This compound is a mixture of equal amount of (2*R*, 5*R*)- and (2*S*, 5*S*)-configuration.

10) K. D. Carlson, D. Weisleder, and M. E. Daxenbichler, *J. Amer. Chem. Soc.*, **92**, 6232 (1970), and references contained therein.

11) In the case of lilac alcohol, the ether oxygen and the hydroxy methylene group, and the ring methylene and methyl group are taken as the like groups, respectively.

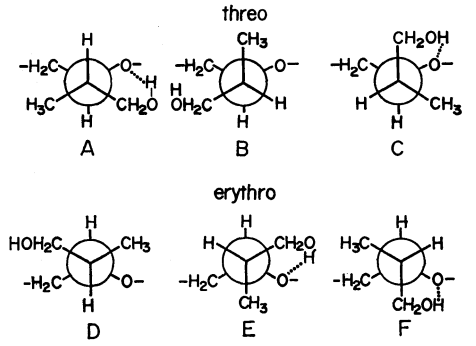

Chart 2. Staggered rotational isomers of the diastereoisomeric lilac alcohols*
(*Only one enantiomer is shown in each case.)

Infrared Study: Hydroxyl bands in the 3600 cm^{-1} region in the IR spectra of lilac alcohols were examined in carbon tetrachloride (0.005—0.025 M). At concentrations lower than 0.025 M, each alcohol shows two OH bands independent of concentration, which are assigned to free (3634—3640 cm^{-1}) and intramolecularly bonded (3520—3525 cm^{-1}) hydroxyl groups, showing that intermolecular hydrogen bonding is negligible in these concentrations. Table 2 shows

Table 2. Infrared data for lilac alcohols

Lilac alcohol	ν OH (free, cm^{-1})	ν OH (bonded, cm^{-1})	$\Delta\nu$ (cm^{-1})	Ratio of integrated band intensity (bonded/free)
a	3638	3525	113	5
b	3640	3520	120	12
c	3634	3522	112	4
d	3640	3520	120	14

that lilac alcohol-b and -d exhibit a longer frequency shift, $\Delta\nu$, than lilac alcohol-a and -c, and the former isomers have most significantly a clearly larger ratio of the integrated band intensity of bonded and free hydroxyl bands than that of the latter isomers. Therefore, lilac alcohol-b and -d should have a much more populous hydrogen bonded conformation than lilac alcohol-a and -c. From this evidence, it was assumed that lilac alcohol-b and -d have the *threo* configuration and -a and -c have the *erythro* configuration. In the latter case, conformers E and F may be composed to the similar order as acyclic analog, 3-methoxypropanol[12] $CH_3OCH_2CH_2CH_2OH$, and in the former case conformer A may be most stable owing to not only the nonbonded interaction but also the intramolecular hydrogen bonding.

NMR Studies: NMR spectra (100 MHz) of the alcohols were obtained in carbon tetrachloride. In Fig. 2, the chemical shift of each hydroxyl proton (tetramethylsilane as an internal standard) is plotted as a function of concentration of lilac alcohols. The smaller limiting slope of the lilac alcohol-b and -d compared with lilac alcohol-a and -c is consistent with stronger bonding[13,14] as confirmed by our IR studies.

12) A. B. Foster, A. H. Haines, and N. Stacey, *Tetrahedron*, **16**, 177 (1961).

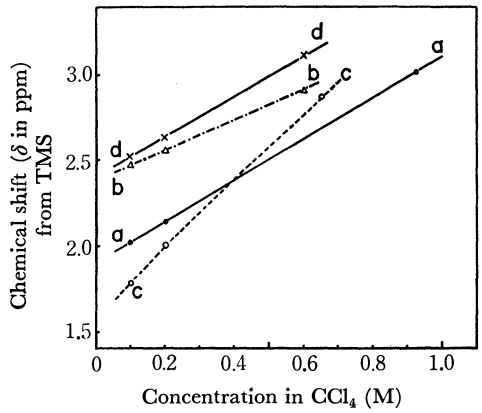

Fig. 2. Hydroxy proton chemical shift dependence on concentration of Lilac alcohols in CCl_4.

The -b and -d isomers have the larger limiting chemical shift for the hydroxyl proton. Thus, it was tentatively proposed to assign the *erythro* configuration to lilac alcohol-a and -c, and the *threo* configuration to lilac alcohol-b and -d.

If this conclusion is reasonable, *threo* isomers should have a larger vicinal coupling constant ($J_{2,\beta}$) than *erythro* isomers, because the coupling of the hydrogen at C-2 of *threo* and *erythro* isomers to the neighboring methylene group in the ring is considered to be the same order, but the coupling to the hydrogen at C-β should be stronger in *threo* configuration (anti conformation). In the *erythro* configuration, the contribution of conformer E and F seems to be larger than D to decrease the proton dihedral angle ($\phi_{2,\beta}$) of the averaged conformers (*gauche* conformation) or causing a smaller coupling constant than that of conformer A. The magnitudes of the vicinal coupling constants, $J_{2,\beta}$, are obtained as half-height width (Table 3), clearly showing as expected that lilac alcohol-b and -d have the larger coupling constants than those of lilac alcohol-a and -c.

Table 3. Half-height width of the vicinal coupling constants ($J_{2,\beta}$)

Lilac alcohol	Half-height width of >CH–O– (Hz)
a	13
b	22
c	15
d	22

All of the spectroscopic evidences obtained above consistently support the view that lilac alcohol-a and -c have *erythro* configuration and lilac alcohol-b and -d have *threo* configuration.

Both chemical and physical evidences indicate that the absolute configurations of lilac alcohol-a, -b, -c, and -d are (βS, 2*S*, 5*S*), (βR, 2*S*, 5*S*), (βR, 2*R*, 5*S*), and (βS, 2*R*, 5*S*), respectively.

Experimental

General Methods. The IR spectra were measured with a Hitachi EPI S-2 IR spectrophotometer and hydroxyl absorption bands in the 3600 cm^{-1} region in the IR spectra of lilac alcohols were examined in carbon tetrachloride (0.005—0.025 M), using Perkin-Elmer Model 125 infrared grating spectrophotometer. A 5.0 cm sodium chloride cell was used for the carbon tetrachloride solutions and the temperature of the measurements was about 25 °C. Spectrograde carbon tetrachloride was used directly after passing a molecular sieve column.

The NMR spectra were recorded on a Varian Associates HA-100 instrument and chemical shifts (δ) are given relative to internal tetramethylsilane standard.

The optical rotations were mersured on a Carl Zeiss photoelectric polarimeter in chloroform.

2,6-Dimethyl-6-acetoxy-2,7-octadienal (III): Linalyl acetate (II, 39.2 g, 0.2 mol) and selenium dioxide (22.2 g, 0.2 mol) were dissolved in 100 ml of 90% dioxane and the solution was heated at 80 °C for 5 hr. After removal of selenium deposited by filtration, the solvent was removed under a reduced pressure. The residue was treated with 100 ml of a mixed solvent of ether and petroleum ether (1: 1). The organic layer was separated by decantation. The solvent was removed and the residue was subjected to vacuum distillation (bp 113—115 °C/1.3 mmHg), affording 16 g (38% yield) of 2,6-dimethyl-6-acetoxy-2,7-octadienal (III).

Vpc: R_t 15.5 min (PEG 20 M, 180 °C, 3 mm×2 m, He 30 ml/min)

IR: ν_{max} 2720, 1735, 1685, 1640, 1365, 1245, 1170, 1105, 1020, 930 cm^{-1}.

NMR: 1.57 (*t*-Me, s), 1.73 (CH_3-C=C, d J=0.7 Hz), 1.98 (CH_3COO, s), 5.12, 5.16, 5.96 (-HC=CH_2), 6.49 (-HC=C-), 9.38 δ (CHO).

Found: C, 68.53; H, 8.58%. Calcd for $C_{12}H_{18}O_3$: C, 68.54; H, 8.63%.

6-Hydroxy-2,6-dimethyl-2,7-octadienal (VI): 2,6-Dimethyl-6-acetoxy-2,7-octadienal (III, 6.3 g, 0.03 mol), ethylene glycol (2.1 g, 0.033 mol), and *p*-toluenesulfonic acid (0.05 g) were dissolved in 100 ml of dry benzene, and the solution was refluxed for about 3 hr until 0.9 ml of water was removed, using a moisture collector. The solvent was removed under a reduced pressure and the residue was treated with 40 ml of 5% sodium hydroxide solution in aqueous methanol (75%) for 1 hr at room temperature. After removal of methanol, the residue was extracted with ether, and the ethereal solution was dried over anhydrous sodium sulfate. The solvent was removed and the residue was subjected to silica gel chromatography, using chloroform as an eluent. 6-Hydroxy-2,6-dimethyl-2,7-octadienal (VI) (3.9 g, 77% yield) was obtained, showing that the ethylene acetal group was hydrolysed during the chromatography.

Vpc: R_t, 12.1 min (PEG 20 M, 180 °C, 3 mm×2 m, He 30 ml/min)

IR: ν_{max} 3420 (OH), 2720 (CHO), 1680 (CHO), 1640 (C=C)cm^{-1}.

NMR: ($CDCl_3$) 1.32 (*t*-Me, s); 1.73 (CH_3-C=C); 5.01, 5.25, 5.93 (-CH=CH_2); 6.50 (-C=C-H), 9.31 δ (CHO).

Found: C, 71.21; H, 9.63%. Calcd for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59%.

2-(1-Formylethyl)-5-methyl-5-vinyltetrahydrofuran (VII): The hydroxyaldehyde (VI, 1.0 g) dissolved in 10 ml of methanol was treated with a catalytic amount of triethylamine under nitrogen atmosphere at 50 °C for 5 hr.

After removal of the solvent, the residue was subjected to silica gel chromatography. The fractions eluted with a mixed eluent of petroleum ether and ether (20: 1) afforded 0.23 g of VII and 0.7 g of the starting hydroxyaldehyde (VI) was recovered from the fractions eluted with methylene chloride–ether (10: 1). The recovered material was subjected to the same procedure for the intramolecular Michael reaction, giving 0.20 g of VII. The total yield was 43%.

Vpc: R_t 2.65 and 2.90 min (2: 1).

IR: ν_{max} 2720, 1720 (CHO), 1640 (C=C), 1040 (-O-) cm^{-1}.

NMR: ($CDCl_3$) 1.26 (*t*-Me, s); 4.07, 5.00, 5.76 (-CH=CH_2); 9.70 δ (CHO).

The analytical sample was purified by vacuum distillation, bp 99—101 °C/23 mmHg.

Found: C, 71.53; H, 9.48%. Calcd for $C_{10}H_{16}O_2$: C, 71.53; H, 9.59%.

Lilac Alcohols (I): The cyclic aldehyde (VII, 1.17 g) was dissolved in 20 ml of dry ether and 0.4 g of lithium aluminum hydride was added in small portions. After stirring at room temperature for 30 min followed by decomposition of the excess lithium aluminum hydride with water, the reaction mixture was acidified with 1M sulfuric acid and extracted with a mixed solvent of methylene chloride and ether. The organic layer was dried over sodium sulfate. After removal of the solvent, the residue was subjected to chromatography on alumina. Elution with ether gave 0.88 g (75%) of lilac alcohols, which were shown to be a mixture of four diastereomers and separated by vapor phase chromatography to afford each alcohol in pure state. The relative concentration of the synthetic lilac alcohol-a, -b, -c, and -d was 2.0, 3.0, 2.5, and 1.0, respectively. The identity of the synthetic lilac alcohols with natural ones was confirmed by IR, NMR and R_t (vpc).

Vpc: R_t; 12.3 (b), 13.75 (d), 15.8 (a), 19.1 (c) min. (PEG 20 M, 120 °C, 3 mm×2 m, He 30 ml/min)

IR: ν_{max} 3420 (OH), 1640 (C=C), 1100, 1025 (-O-) cm^{-1}.

NMR: see Fig. 1 and Table 4.

a) The signals of alcohols appear at 2.96—2.60 δ, depending on the concentration, and typical signals of vinyl group are observed with $J_{1,2}$=1.6Hz, $J_{1,3}$=8.0Hz and $J_{2,3}$=18 Hz.

The analytical sample was prepared by vacuum distillation, bp 110—112 °C/18 mmHg.

Found: C, 70.50; H, 10.69%. Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%.

d-Lilac alcohols were synthesized from *d*-linalyl acetate with $[\alpha]_D^{25}$ +2.9 (*c* 3.2) according to the same manner as described above and cleanly separated by vpc. The optical rotation was measured in chloroform, showing +6.7 (*c* 2.7), −1.4 (*c* 2.9), −0.5 (*c* 1.6), and +1.4 (*c* 2.8) for *d*-lilac alcohol-a, -b, -c, and -d, respectively.

l-Lilac alcohols were synthesized from *l*-linalyl acetate with $[\alpha]_D^{25}$ −5.0 (*c* 0.8) according to the same manner as described above, and cleanly separated by vpc. The optical rotations were measured in chloroform, showing −11.6 (*c* 1.1), +3.0 (*c* 1.0), +2.5 (*c* 0.8), and −2.9 (*c* 1.0) for *l*-lilac alcohol-a, -b, -c, and -d, respectively. The optical rotations of natural lilac alcohols listed in Table 1 were measured in chloroform, showing +12.2 (*c* 4.1), −6.6 (*c* 3.6), −1.4 (*c* 1.8), and +4.3 (*c* 1.7) for the alcohol-a, -b, -c, and -d, respectively.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3187—3193 (1973)

Synthetic Studies of Bacitracin. VIII.[1] Synthesis of Cyclohexapeptide Moiety[2]

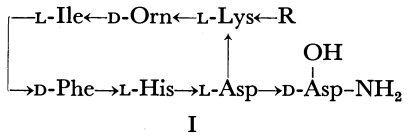
Eisuke MUNEKATA,* Yoshihiro MASUI,* Tetsuo SHIBA, and Takeo KANEKO**
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received May 1, 1973)

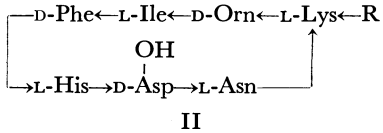
For the purpose of synthesis of antibiotic bacitracin of six amino acids-membered ring formula, the following intermediate peptides, *i.e.*, cyclo-(N^{α}-benzyloxycarbonyl-L-lysyl-N^{δ}-cyclopentyloxycarbonyl-D-ornithyl-L-isoleucyl-D-phenylalanyl-L-histidyl-α-methyl-L-aspartyl) (III) and N^{α}-benzyloxycarbonyl-N^{ε}-*t*-butyloxycarbonyl-L-lysyl-N^{δ}-cyclopentyloxycarbonyl-D-ornithyl-L-isoleucyl-D-phenylalanyl-N^{im}-benzyl-L-histidyl-L-aspartyl-D-isoasparagine benzyl ester (IV) were prepared. In this synthesis, cyclopentyloxycarbonyl group was introduced to protect δ-amino group of ornithine residue and cleavability of this protecting group for hydrogen fluoride was investigated.

Bacitracin A is an antibiotic peptide produced by *Bacillus licheniformis*.[3] The investigations on the chemical structure of bacitracins were performed by several groups since twenty five years ago.[4,5] Craig and his collaborators had suggested a chemical structure I of six amino acids-membered ring for bacitracin A as the most probable one in 1961.[5] However, Ressler *et al.* later proposed another formula II of seven amino acids-membered ring for the antibiotic.[6] A decisive judgment for a correct structure must be awaited after completion of the total synthesis of this antibiotic peptide unless it is conclusively determined by unobjectionable method like X-ray analysis. In connection with the situation, we attempted to synthesize both of the proposed structures in order to identify with the natural antibiotic.

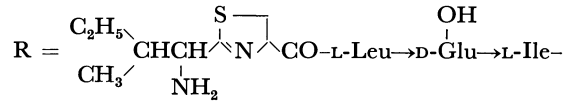
In our previous papers,[7,8] we prepared a peptide



I



II



analogue possessing a cysteinyl residue in the place of a thiazoline ring in bacitracin A of Craig's formula I, and demonstrated that it was unable to lead to the compound I through thiazoline ring cyclization from the cysteinyl peptide by the treatment with strong acid such as concentrated hydrochloric acid.[9] Therefore, the ring closure of the cysteine peptide in the final step of a synthetic program must be avoided. On the contrary, it seems most promising to accomplish the synthesis by the condensation of thiazoline moiety corresponding to *N*-terminal peptide with a remaining peptide fragment containing a macrocyclic structure at an appropriate synthetic stage followed by an exhaustive deprotection. We already developed the synthetic method of thiazoline peptides through the coupling of iminoether derivative of *N*-protected amino acids with cysteine ester or cysteinyl peptide.[1,10] This synthetic

strategy may also be applied to a synthesis of bacitracin F which is known to be a peptide transformed from bacitracin A *via* oxidative deamination under mild alkaline or neutral condition and possess a keto-thiazole moiety instead of amino-thiazoline in *N*-terminal part of the molecule of bacitracin A.

In this paper, we synthesized hexa- and heptapeptide derivatives corresponding to the ring peptide moiety of the structure I proposed by Craig *et al.*[5] in order to investigate a possibility to elongate these intermediate peptides to the whole structure of bacitracins. However, prior to this synthesis, we must overcome the difficult problem concerned with the selection of protective groups in building up these peptide chains. Particularly, the protection of δ-amino group of D-ornithine residue is in problem, since this protective group must remain throughout the whole synthetic pathway including cyclization of macro-ring as far as the final condensation step on the one hand, and, for the removal of this protection, reaction conditions such as in catalytic hydrogenation, reduction with sodium in liquid ammonia, and saponification, cannot be applied in view of instability of thiazoline or thiazole ring on the other hand. Furthermore, this protective group is also required to be resistant enough for catalytic hydrogenation, hydrazinolysis as well as mild acidolysis, those conditions being needed on a way of making up the cyclic peptide containing ornithine residue. The fact that both thiazoline and thiazole ring are stable under acidic condition, suggests a possible use of anhydrous hydrogen fluoride as reagent for removal of the all protective groups at the final step of the synthesis. These considerations lead us to utilize *s*-alkyloxycarbonyl group for protection of δ-amino group of ornithine residue, since this special protection may resist to the reaction condition mentioned above with the exception of facile cleavability with hydrogen fluoride.

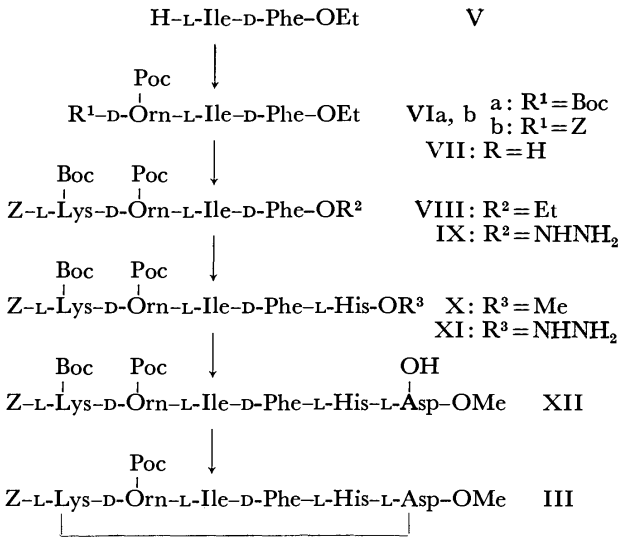
In preliminary tests, *s*-alkyloxycarbonyl groups such as isopropyloxycarbonyl, *s*-butyloxycarbonyl, 1-ethylpropyloxycarbonyl, cyclopentyloxycarbonyl, and cyclohexyloxycarbonyl were introduced into δ-amino group of L-ornithine. The derivatives thus prepared were treated with anhydrous hydrogen fluoride respectively. From the results obtained in the experiments as shown in Table 1, it was demonstrated that cyclopentyloxycarbonyl group was the most suitable for our purpose. Although this protective group had been introduced by McKay and Albertson who used hydrogen bromide in glacial acetic acid as removing agent,[11] its behavior for hydrogen fluoride has not been reported yet.

Table 1. Cleavability of N^{δ}-*s*-alkyloxycarbonyl group of L-ornithine in treatment with hydrogen fluoride

	0 °C 30 min	0 °C 60 min	20 °C 60 min
Isopropyloxycarbonyl		−	−
s-Butyloxycarbonyl		−	−
1-Ethylpropyloxycarbonyl	−	±	+
Cyclopentyloxycarbonyl	±	+	
Cyclohexyloxycarbonyl	−	±	+

+: cleavable −: stable

Using such a special protective group, the hexa- and heptapeptides, *i.e.*, cyclo-(N^{α}-Z-L-lysyl-L-N^{δ}-Poc-D-ornithyl-L-isoleucyl-D-phenylalanyl-L-histidyl-α-methyl-L-aspartyl) (III)[12] and N^{α}-Z-N^{ε}-Boc-L-lysyl-N^{δ}-Poc-D-ornithyl-L-isoleucyl-D-phenylalanyl-N^{im}-benzyl-L-histidyl-L-aspartyl-D-isoasparagine benzyl ester (IV)[12] were prepared.



Poc: cyclopentyloxycarbonyl, Boc: *t*-butyloxycarbonyl, Z: benzyloxycarbonyl

Scheme 1.

Thus the synthesis of these peptides was started with the coupling reaction of Z-L-isoleucine with ethyl D-phenylalaninate through the active ester method as shown in Scheme 1. The resulting acyl dipeptide ester was treated with hydrogen bromide in glacial acetic acid to afford V hydrobromide.[7] This compound was coupled with N^{α}-Boc-N^{δ}-Poc-D-ornithine or N^{α}-Z-N^{δ}-Poc-D-ornithine either by the active ester method or by the mixed anhydride method to give two corresponding acyl tripeptide derivatives VIa and VIb respectively. The Boc group was removed from VIa by exposing to hydrogen chloride in ethyl acetate and the Z group of VIb was removed by catalytic hydrogenation in the presence of hydrogen chloride.

The same tripeptide ester VII hydrochloride thus obtained was coupled with N^{α}-Z-N^{ε}-Boc-L-lysine *via* the active ester method to give VIII. This acyl tetrapeptide ester VIII was converted to a corresponding hydrazide IX. The protected tetrapeptide azide prepared from IX was coupled with methyl L-histidinate dihydrochloride to afford acyl pentapeptide ester X. The ester X was converted to the hydrazide XI which was then used for azide coupling reaction with aspartic acid moiety. Thus, removal of Z group from α-methyl Z-L-aspartate was carried out by heating with trifluoroacetic acid applying Weygand's technique[13]

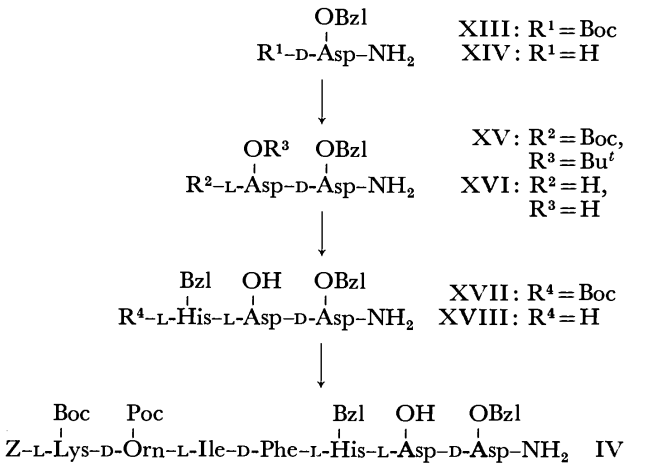
11) F. C. McKay and N. F. Albertson, *J. Amer. Chem. Soc.*, **79**, 4686 (1957).

12) Abbreviations: Z, benzyloxycarbonyl; Poc, cyclopentyloxycarbonyl; Boc, *t*-butyloxycarbonyl.

13) F. Weygand and W. Steglich, *Z. Naturforsch.*, **14b**, 472 (1959).

to give α-methyl L-aspartate trifluoroacetate. This compound was condensed with the azide prepared from the protected pentapeptide hydrazide XI mentioned above in the presence of triethylamine to afford a linear hexapeptide derivative XII. Attempts to obtain the same peptide by stepwise elongation method starting from *C*-terminal side failed, because of difficulty in purification of intermediate tri- or tetrapeptides due to their hygroscopic natures or troublesome tendencies to form gelatinous solid.

After removal of N^{ε}-Boc group of lysine residue in hexapeptide derivative XII obtained above, cyclization between ε-amino group of lysine residue and β-carboxyl group of aspartic acid residue was attempted in high dilution by *p*-nitrophenyl ester method, 1-succinimidyl ester method or carbodiimide method. However no satisfactory results were obtained in all cases. Only when cyanomethyl ester of the hexapeptide XII was tried to be cyclized, expected cyclohexapeptide III was obtained but in an extremely low yield. This cyclic peptide corresponds to macrocyclic part of Craig's formula. However, this cyclohexapeptide methyl ester III was resistant to conversion into a hydrazide which is a necessary intermediate to be coupled with *C*-terminal isoasparagine residue by the azide method. Therefore, we could not extend this synthetic route to reach to the heptapeptide (6—12) of the Craig's formula, and turned our efforts to an alternative way through coupling of the tetrapeptide fragment IX with *C*-terminal tripeptide derivative as shown in Scheme 2.



Bzl: benzyl, Z: benzyloxycarbonyl, Boc: *t*-butyloxycarbonyl, Poc: cyclopentyloxycarbonyl, Bu^t: *t*-butyl

Scheme 2.

Thus, β-benzyl Boc-D-aspartate was converted to benzyl Boc-D-isoasparaginate (XIII) by the active ester method. Boc group in XIII was removed by trifluoroacetic acid and the resulting deblocked product XIV was coupled with β-*t*-butyl Boc-L-aspartate by the 1-succinimidyl ester method to give acyl dipeptide ester XV. This compound XV thus obtained was treated with trifluoroacetic acid to afford L-aspartyl-D-isoasparagine benzyl ester (XVI) which was then acylated with N^{α}-Boc-N^{im}-benzyl-L-histidine-2,4,5-trichlorophenyl ester. In this case, we used benzyl group for protection of imidazole nitrogen in histidine residue in order to prevent the side reaction at cyclization reaction by the cyanomethyl ester method and to facilitate a purification of the product by silica gel column chromatography. The resulting tripeptide derivative XVII was exposed to trifluoroacetic acid to give deblocked ester XVIII. This compound XVIII was coupled with the tetrapeptide azide derived from the hydrazide IX prepared before to afford a linear heptapeptide derivative IV. All attempts to cyclize this compound, after removal of N^{ε}-Boc group on lysine residue, either by dicyclohexylcarbodiimide method, 1-succinimidyl ester method or cyanomethyl ester method did not give satisfactory results at the stage of this investigation.

Therefore, the presented results indicate that synthetic approaches from the intermediate hexa- and heptapeptides mentioned above to the whole structure of bacitracins of six amino acids-membered ring formula must be reinvestigated.

Experimental

All melting points are uncorrected. Silica gel G according to Stahl, Merck was used for thin-layer chromatography. Paper electrophoresis was carried out using Toyo filter paper No. 51 in a Toyo paper electrophoresis C apparatus at a potential gradient of 13 V/cm for 1—2 hr. The buffer used was pyridine–acetic acid–water (30: 4: 966, v/v/v, pH 6.4) unless otherwise stated. For silica gel column chromatography, Kieselgel 0.05—0.2 mm, Merck 70—325 mesh ASTM, was used.

N$^{\delta}$-s-*Alkyloxycarbonylornithines*. These compounds were prepared by the reaction of copper complex of ornithine with corresponding *s*-alkyloxycarbonyl chlorides through usual Schotten-Baumann type acylation. The complexes of the N^{δ}-acylornithines thus obtained were operated with hydrogen sulfide and the products were recrystallized from water. Reaction yields, melting points, elemental analyses, and optical properties of those compounds are shown in Table 2.

Treatment of N$^{\delta}$-*Alkyloxycarbonyl-L-ornithine with Hydrogen Fluoride*. N^{δ}-*s*-Alkyloxycarbonyl-L-ornithines were treated with hydrogen fluoride under the following three reaction conditions, *i.e.*, i) at 0 °C, for 30 min, ii) at 0 °C, for 60 min, iii) at 20 °C, for 60 min, respectively. After the given reaction period, excess hydrogen fluoride was removed *in vacuo* and the reaction vessel was dried over sodium hydroxide under reduced pressure. The residue was dissolved in water and the solution was extracted with ether. An aqueous layer was concentrated by lyophilization. The degree of deprotection was checked by thin-layer chromatography and paper electrophoresis. The quantitative results are shown in Table 1.

N$^{\delta}$-*Cyclopentyloxycarbonyl-D-ornithine*. This compound was prepared using cyclopentyloxycarbonyl chloride[11] by the same procedure described above for N^{δ}-*s*-alkyloxycarbonylornithines; yield, 64%; mp 251—253 °C; $[\alpha]_D^{20}$ −17.6° (*c* 1, 3 M HCl).

Found: C, 54.05; H, 8.29; N, 11.51%. Calcd for $C_{11}H_{20}O_4N_2$: C, 54.08; H, 8.25; N, 11.47%.

N$^{\alpha}$-t-*Butyloxycarbonyl*-N$^{\delta}$-*cyclopentyloxycarbonyl-D-ornithine*. This compound was prepared by acylation of N^{δ}-Poc-D-ornithine (22.3 g, 0.09 mol) with *t*-butyl azidoformate (15 g, 0.1 mol) and sodium carbonate (12 g) in dioxane–water (1: 1, v/v 800 ml). The reaction mixture was operated in the usual manner and the product was recrystallized from

Found: C, 55.63; H, 8.11; N, 7.83%. Calcd for $C_{16}H_{28}O_6N_2$: C, 55.80; H, 8.20; N, 8.13%.

Dicyclohexylammonium salt: (recrystallized from ethanol); mp 170—172 °C; $[\alpha]_D^{19}$ −9.3° (*c* 1, ethanol).

Found: C, 64.08; H, 9.83; N, 8.06%. Calcd for $C_{16}H_{28}O_6N_2 \cdot C_{12}H_{23}N$: C, 63.97; H, 9.78; N, 7.99%.

N^{α}-t-*Butyloxycarbonyl*-N^{δ}-*cyclopentyloxycarbonyl*-D-*ornithine* p-*Nitrophenyl Ester*. *N,N'*-Dicyclohexylcarbodiimide (6.6 g, 32 mmol) was added to an ice-cold solution of N^{α}-Boc-N^{δ}-Poc-D-ornithine (10.3 g, 30 mmol) and *p*-nitrophenol (4.2 g, 30 mmol) in ethyl acetate (200 ml) with stirring. The mixture was stirred at 0—3 °C for 1 hr and then at room temperature for 4 hr. Dicyclohexylurea formed was filtered off, washed with ethyl acetate and the combined filtrate was concentrated under reduced pressure. The residue was recrystallized from ethanol; yield, 8.0 g (57%); mp 146—147 °C; $[\alpha]_D^{19}$ +27.9° (*c* 1, dimethylformamide).

Found: C, 56.77; H, 6.77; N, 8.93%. Calcd for $C_{22}H_{31}O_8N_3$: C, 56.76; H, 6.71; N, 9.03%.

N^{α}-t-*Butyloxycarbonyl*-N^{δ}-*cyclopentyloxycarbonyl*-D-*ornithine 1-Succinimidyl Ester*. *N,N'*-Dicyclohexylcarbodiimide (3.1 g, 15 mmol) was added to an ice-cold solution of N^{α}-Boc-N^{δ}-Poc-D-ornithine (5.2 g, 15 mmol) and *N*-hydroxysuccinimide (1.8 g, 16 mmol) in tetrahydrofuran (150 ml) with stirring. The stirring was continued at 0—3 °C for 30 min and then at room temperature for 5 hr. Dicyclohexylurea formed was filtered off and washed with tetrahydrofuran. The combined filtrate was concentrated *in vacuo*. The residual syrup was crystallized from 2-propanol–isopropyl ether; yield, 5.2 g, (79%); mp 152—155 °C; $[\alpha]_D^{18}$ +21.1° (*c* 1, dimethylformamide).

Found: C, 54.48; H, 7.04; N, 9.42%. Calcd for $C_{20}H_{31}O_8N_3$: C, 54.41; H, 7.08; N, 9.52%.

N^{α}-t-*Butyloxycarbonyl*-N^{δ}-*cyclopentyloxycarbonyl*-D-*ornithyl*-L-*isoleucyl*-D-*phenylalanine Ethyl Ester (VIa)*. *(i) By 1-Succinimidyl Ester Procedure*: A solution of N^{α}-Boc-N^{δ}-Poc-D-ornithine 1-succinimidyl ester (5.7 g, 13 mmol) in dimethylformamide (60 ml) was added to an ice-cold solution of V hydrobromide[7] (5.0 g, 13 mmol) in dimethylformamide (150 ml) containing triethylamine (1.9 ml). The mixture was stirred in an ice bath for 1 hr and then at room temperature for 30 hr. The solution was concentrated under reduced pressure. Precipitate formed upon addition of water to the residue was filtered, washed with water and recrystallized from methanol; yield, 6.6 g, (80%); mp 188—190 °C; $[\alpha]_D^{19}$ +18.7° (*c* 1, dimethylformamide).

Found: C, 62.59; H, 8.30; N, 8.91%. Calcd for $C_{33}H_{52}O_8N_4$: C, 62.63; H, 8.28; N, 8.85%.

(ii) By p-*Nitrophenyl Ester Procedure*: The same compound VIa was prepared by coupling of N^{α}-*t*-Boc-N^{δ}-Poc-D-ornithine *p*-nitrophenyl ester (5.1 g, 11 mmol) and V hydrobromide[7] (4.3 g, 11 mmol) according to the usual procedure; yield, 5.3 g, (76%); mp 188—190 °C; $[\alpha]_D^{20}$ +18.9° (*c* 1, dimethylformamide).

Found: C, 62.60; H, 8.25; N, 8.86%.

(iii) By Mixed Anhydride Procedure: The same compound VIa was also prepared from a mixed anhydride of N^{α}-Boc-N^{δ}-D-ornithine (26.5 g, 77 mmol) with ethyl chloroformate (8.4 g, 77 mmol), and V hydrobromide[7] (29.8 g, 77 mmol) by the usual procedure; yield, 42 g, (86%); mp 187—190 °C; $[\alpha]_D^{20}$ +18.9° (*c* 1, dimethylformamide).

Found: C, 62.43; H, 8.41; N, 8.69%.

N^{α}-*Benzyloxycarbonyl*-N^{δ}-*cyclopentyloxycarbonyl*-D-*ornithine*. This compound was prepared by acylation of N^{δ}-Poc-D-ornithine (10 g, 40 mmol) with benzyloxycarbonyl chloride (8.5 g, 50 mmol) and aqueous 1M sodium hydroxide by the usual procedure. The oily product (14.3 g, 95%) thus obtained was used directly to the following esterification.

N^{α}-*Benzyloxycarbonyl*-N^{δ}-*cyclopentyloxycarbonyl*-D-*ornithine* p-*Nitrophenyl Ester*. *N,N'*-Dicyclohexylcarbodiimide (6.8 g, 33 mmol) was added to the chilled solution of N^{α}-Z-N^{δ}-Poc-D-ornithine (12.5 g, 33 mmol) and *p*-nitrophenol (4.6 g, 33 mmol) in ethyl acetate (50 ml). The mixture was stirred in an ice-bath for 1 hr and at room temperature for 3 hr. Dicyclohexylurea precipitated was filtered off and the residue was washed with ethyl acetate. The combined filtrate was concentrated and residual oil was kept under petroleum ether. The solidified material was collected by filtration and recrystallized from ethanol; yield, 12.9 g (78%); mp 118—120 °C; $[\alpha]_D^{21}$ +22.4° (*c* 1, dimethylformamide).

Found: C, 60.28; H, 5.85; N, 8.42%. Calcd for $C_{25}H_{29}O_8N_3$: C, 60.11; H, 5.85; N, 8.41%.

N^{α}-*Benzyloxycarbonyl*-N^{δ}-*cyclopentyloxycarbonyl*-D-*ornithyl*-L-*isoleucyl*-D-*phenylalanine Ethyl Ester (VIb)*. N^{α}-Z-N^{δ}-Poc-D-ornithine *p*-nitrophenyl ester (5.0 g, 10 mmol) in dimethylformamide (30 ml) was added to a solution of V hydrobromide[7] (4.0 g, 10 mmol) in dimethylformamide (100 ml) containing triethylamine (1.4 ml) with stirring in an ice-bath. The stirring was continued on ice cooling for 30 min and at room temperature for 20 hr. The solvent was removed *in vacuo* and residue was triturated with water. The precipitate was collected, washed with 5% sodium carbonate, water, 1M hydrochloric acid and water successively. The product was reprecipitated from ethanol; yield, 5.7 g (85%); mp 231—233 °C, $[\alpha]_D^{20}$ +9.6° (*c* 1, dimethylformamide).

Found: C, 64.94; H, 7.57; N, 8.40%. Calcd for $C_{36}H_{50}$-

O_8N_4: C, 64.84; H, 7.56; N, 8.40%.

N^{δ}-*Cyclopentyloxycarbonyl*-D-*ornithyl*-L-*isoleucyl*-D-*phenylalanine Ethyl Ester (VII) Hydrochloride.* *(i) From VIa*: The tripeptide derivative VIa (6.6 g, 10.4 mmol) was suspended in ethyl acetate (300 ml) and treated with hydrogen chloride in ethyl acetate (about 6.4 M, 150 ml). As vigorous stirring was continued, a clear solution was obtained and then the deposition of crystals was observed. The reaction mixture was kept at room temperature for 40 min. Upon addition of petroleum ether (800 ml), crystalline hydrochloride was deposited. It was filtered, washed with petroleum ether and dried over potassium hydroxide *in vacuo*. The crude product was combined with a second crop secured from the mother liquor, and recrystallized from methanol-ethyl ether; yield, 5.4 g, (92%); mp 197—200 °C (decomp.); $[\alpha]_D^{19}$ +1.4° (*c* 1.5, dimethylformamide).

Found: C, 58.93; H, 8.05; N, 9.78; Cl, 6.32%. Calcd for $C_{28}H_{44}O_6N_4 \cdot HCl$: C, 59.09; H, 7.97; N, 9.85; Cl, 6.23%.

(ii) From VIb: The tripeptide derivative VIb (10 g, 15 mmol) was dissolved in ethanol (200 ml) containing concentrated hydrochloric acid (2 ml). Palladium black was added to the solution and hydrogen gas was bubbled through the solution at room temperature for 10 hr. The catalyst was filtered off with the aid of celite and the filtrate was concentrated *in vacuo*. The precipitated solid was collected and recrystallized from methanol-ether; yield, 7.7 g, (91%); mp 198—199 °C (decomp.); $[\alpha]_D^{20}$ +1.2° (*c* 1.5, dimethylformamide).

Found: C, 59.17; H, 8.25; N, 9.61; Cl, 6.27%.

N^{α}-*Benzyloxycarbonyl*-N^{ε}-t-*butyloxycarbonyl*-L-*lysyl*-N^{δ}-*cyclopentyloxycarbonyl*-D-*ornithyl*-L-*isoleucyl*-D-*phenylalanine Ethyl Ester (VIII).* *(i) By 1-Succinimidyl Ester Procedure*: N^{α}-Z-N^{ε}-Boc-L-lysine 1-succinimidyl ester[14] (13.5 g, 28 mmol) in dimethylformamide (100 ml) was added to an ice-cold solution of the tripeptide ester VII hydrochloride (16 g, 28 mmol) and triethylamine (4 ml) in dimethylformamide (400 ml). The mixture was stirred at 0—3 °C for 30 min and then at room temperature for 30 hr. After most of the solvent had been removed under reduced pressure, the residue was diluted with water to yield a precipitate. It was collected by filtration, washed with 5% aqueous sodium carbonate, water, 5% aqueous citric acid and water successively. The product was reprecipitated from dimethylformamide-water and then dried *in vacuo* at 30 °C over phosphorus pentoxide; yield, 23.7 g, (94%); mp 218—221 °C (decomp.); $[\alpha]_D^{19}$ −10.8° (*c* 1, dimethylformamide).

Found: C, 63.09; H, 8.01; N, 9.35%. Calcd for $C_{47}H_{70}O_{11}N_6$: C, 63.06; H, 7.88; N, 9.39%.

Amino acid analysis: Lys+Orn, 2.10; Ile, 1.00; Phe, 0.97.

(ii) By p-*Nitrophenyl Ester Procedure*: The same tetrapeptide derivative VIII was obtained from N^{α}-Z-N^{ε}-Boc-L-lysine *p*-nitrophenyl ester[15] (3.2 g, 6.4 mmol) and the tripeptide ester VII hydrochloride (3.6 g, 6.3 mmol) by the usual method; yield, 4.4 g, (79%); mp 216—219 °C (decomp.); $[\alpha]_D^{19}$ −11.1° (*c* 1, dimethylformamide).

Found: C, 62.75; H, 7.96; N, 9.33%.

N^{α}-*Benzyloxycarbonyl*-N^{ε}-t-*butyloxycarbonyl*-L-*lysyl*-N^{δ}-*cyclopentyloxycarbonyl*-D-*ornithyl*-L-*isoleucyl*-D-*phenylalanine Hydrazide (IX) Hemihydrate.* Hydrazine hydrate (15 ml) was added to a solution of the tetrapeptide derivative VIII (7.3 g, 8.2 mmol) in dimethylformamide (150 ml) and the mixture was kept at room temperature for 48 hr. The solvent was removed *in vacuo* and the residue was solidified by addition of water. The resulting gelatinous mass was collected, washed with water, and dried *in vacuo*; yield, 6.8 g (93%); mp 187—190 °C (decomp.); $[\alpha]_D^{20}$ +8.9° (*c* 1, dimethylformamide).

Found: C, 60.56; H, 7.80; N, 12.46%. Calcd for $C_{45}H_{68}O_{10}N_8 \cdot 1/2\,H_2O$: C, 60.72; H, 7.81; N, 12.59%.

N^{α}-*Benzyloxycarbonyl*-N^{ε}-t-*butyloxycarbonyl*-L-*lysyl*-N^{δ}-*cyclopentyloxycarbonyl*-D-*ornithyl*-L-*isoleucyl*-D-*phenylalanyl*-L-*histidine Methyl Ester (X) Dihydrate.* A solution of sodium nitrite (1 g) in water (5 ml) was added to an ice-cold solution of the tetrapeptide hydrazide IX hemihydrate (8.9 g, 10 mmol) in a mixture of 60% acetic acid (200 ml) and 1M hydrochloric acid (20 ml) at −3—0 °C with vigorous stirring. After 10 min, excess cold water was added to the mixture. The resulting precipitate was filtered and washed thoroughly with water. The acyl tetrapeptide azide thus obtained was dissolved in dimethylformamide (200 ml) and cooled to 2—3 °C. This solution was added to an ice-cold solution of methyl L-histidinate dihydrochloride (5 g, 21 mmol) in dimethylformamide (100 ml) containing triethylamine (4 ml) with stirring. The mixture was stirred at 0—2 °C for 18 hr and then at room temperature for 24 hr. The mixture was concentrated *in vacuo* and the residue was triturated with water. The amorphous solid precipitated was collected and washed thoroughly with water. The product was reprecipitated from dimethylformamide-water, and dried over phosphorus pentoxide at 30—35 °C; yield, 8.4 g, (80%); mp 186—190 °C; $[\alpha]_D^{19}$ +6.0° (*c* 1, dimethylformamide).

Found: C, 59.53; H, 7.58; N, 11.90%. Calcd for $C_{52}H_{75}O_{12}N_9 \cdot 2H_2O$: C, 59.24; H, 7.55; N, 11.96%.

Amino acid analysis: Lys+Orn, 1.95; Ile, 1.00; Phe, 1.05; His, 0.96.

N^{α}-*Benzyloxycarbonyl*-N^{ε}-t-*butyloxycarbonyl*-L-*lysyl*-N^{δ}-*cyclopentyloxycarbonyl*-D-*ornithyl*-L-*isoleucyl*-D-*phenylalanyl*-L-*histidine Hydrazide (XI) Hydrate.* Hydrazine hydrate (10 ml) was added to a solution of the pentapeptide ester X dihydrate (5.5 g, 5.2 mmol) in dimethylformamide (150 ml). After the mixture had been kept at room temperature for 48 hr, the solvent was evaporated *in vacuo* and the residue obtained was diluted with water. The amorphous solid precipitated was filtered and washed with water. The product was reprecipitated from dimethylformamide-water and dried *in vacuo* over phosphorus pentoxide at 35 °C; yield, 5.1 g, (94%); mp 206—208 °C (decomp.); $[\alpha]_D^{17}$ +6.3° (*c* 1, dimethylformamide).

Found: C, 59.07; H, 7.46; N, 14.74%. Calcd for $C_{51}H_{75}O_{11}N_{11} \cdot H_2O$: C, 59.11; H, 7.49; N, 14.87%.

α-*Methyl* L-*Aspartate Trifluoroacetate.* α-Methyl Z-L-aspartate[16] (11.3 g, 40 mmol) prepared from the corresponding dicyclohexylammonium salt was dissolved in trifluoroacetic acid (40 ml) and the solution was heated under refluxing for 30 min. Excess acid was removed *in vacuo* and the residue was triturated with ethyl ether. The precipitate formed was collected by filtration and recrystallized from methanol-ethyl ether; yield, 9.4 g, (90%); mp 117—119 °C; $[\alpha]_D^{15}$ +13.0° (*c* 1, methanol).

Found: C, 32.31; H, 3.95; N, 5.36%. Calcd for $C_5H_9O_4N \cdot CF_3COOH$: C, 32.19; H, 3.86; N, 5.36%.

N^{α}-*Benzyloxycarbonyl*-N^{ε}-t-*butyloxycarbonyl*-L-*lysyl*-N^{δ}-*cyclopentyloxycarbonyl*-D-*ornithyl*-L-*isoleucyl*-D-*phenylalanyl*-L-*histidyl*-L-*aspartic Acid* α-*Methyl Ester (XII).* The pentapeptide hydrazide XI hydrate (4.0 g, 3.9 mmol) was dissolved in aqueous acetic acid (CH_3COOH 40 ml, H_2O 16 ml). Sodium nitrite (400 mg) in water (1 ml) was added to the soltuion at 0 °C and the reaction mixture was vigorously stirred at the

same temperature for 10 min. Saturated sodium chloride solution (250 ml) was added to the solution on ice cooling and the precipitated material was collected and washed thoroughly with ice-cold water. The solid thus obtained was dissolved in cold dimethylformamide (200 ml). This preparation was added to the cooled solution of α-methyl L-aspartate trifluoroacetate (1.6 g, 6.1 mmol) in dimethylformamide (100 ml) containing triethylamine (2 ml). The mixture was stirred at 0 °C for 12 hr and at room temperature for 24 hr. The solvent was removed *in vacuo* and excess water was added to the residue. The precipitate formed was collected, washed with water and reprecipitated from dimethylformamide–water; yield, 4.1 g, (93%); mp 167—175 °C; $[\alpha]_D^{19}$ +9.1° (*c* 1, dimethylformamide).

Found: C, 59.77; H, 7.60; N, 11.49%. Calcd for $C_{56}H_{80}O_{15}N_{10}$: C, 59.35; H, 7.12; N, 12.36%.

Cyclo-(N$^{\alpha}$-benzyloxycarbonyl-L-lysyl-N$^{\delta}$-cyclopentyloxycarbonyl-D-ornithyl-L-isoleucyl-D-phenylalanyl-L-histidyl-α-methyl-L-aspartyl) (III) Hydrate. To a solution of the hexapeptide derivative XII (6.0 g, 5.3 mmol) in dimethylformamide (50 ml), there were added chloroacetonitrile (3 ml) and triethylamine (6 ml). The reaction mixture was stirred at room temperature for 48 hr. The solvent was evaporated *in vacuo* and water was added to the residue. Solid formed was filtered and dried over phosphorus pentoxide *in vacuo*. The product (5.8 g) was treated with trifluoroacetic acid (60 ml) at room temperature for 30 min with stirring. Excess trifluoroacetic acid was removed *in vacuo*, and the residue was triturated with ethyl ether. The deblocked product thus obtained was dissolved in a mixture of dimethylformamide (20 ml) and acetic acid (5 ml). The solution was dropped into large excess pyridine (5 l) for 6 hr and the reaction mixture was stirred at 40—45 °C for 48 hr. The reaction mixture gave a spot showing positive Pauly and negative ninhydrin reaction at R_f 0.71, besides the original spot of deblocked linear peptide at R_f 0.1—0.2, and a minor spot of positive iodine test but negative both to Pauly[17] and ninhydrin reaction at R_f 0.91 on thin-layer chromatography using methanol–chloroform (2 : 8, v/v) as developing solvent. The solvent was evaporated *in vacuo* and the residue was purified by silica gel column chromatography (elution solvent: chloroform–methanol, 1:19—1:9 v/v) to obtain the cyclization product of R_f 0.71 on thin-layer chromatogram; yield, 53 mg (0.97%); mp 160—165 °C (decomp.); $[\alpha]_D^{18}$ +11.4° (*c* 1, dimethylformamide).

Found: C, 59.04; H, 7.03; N, 13.78%. Calcd for $C_{51}H_{70}O_{12}N_{10}\cdot H_2O$: C, 59.29; H, 7.03; N, 13.56%.

Benzyl t-Butyloxycarbonyl-D-isoasparaginate (XIII). Concentrated aqueous ammonia (5 ml) in tetrahydrofuran (50 ml) was added to a cooled solution of Boc-D-aspartic acid β-benzyl α-1-succinimidyl ester (21.0 g, 50 mmol) in tetrahydrofuran (200 ml). The mixture was stirred at room temperature for 3 hr. The solution was concentrated and the residual solid was recrystallized from methanol–ethyl ether; yield, 12.3 g, (76%); mp 159—160.5 °C (decomp.); $[\alpha]_D^{15}$ −1.3° (*c* 1, methanol).

Found: C, 59.54; H, 6.89; N, 8.69%. Calcd for $C_{16}H_{22}O_5N_2$: C, 59.61; H, 6.83; N, 8.69%.

Benzyl D-Isoasparaginate (XIV) Trifluoroacetate. The compound XIII (4.8 g, 15 mmol) was dissolved in trifluoroacetic acid (30 ml). The solution was stirred at room temperature for 20 min. Excess trifluoroacetic acid was evaporated and the residue obtained was triturated with anhydrous ethyl ether. The precipitate was recrystallized from methanol–ethyl ether; yield, 4.5 g, (90%); mp 185—186.5 °C (decomp.); $[\alpha]_D^{15}$ −1.1° (*c* 1, methanol).

Found: C, 46.32; H, 4.52; N, 8.33%. Calcd for $C_{11}H_{14}O_3N_2\cdot CF_3COOH$: C, 46.43; H, 4.50; N, 8.33%.

t-Butyloxycarbonyl-L-aspartic Acid β-t-Butyl α-1-Succinimidyl Ester. *N*-Hydroxysuccinimide (11.5 g, 0.1 mol) and β-*t*-butyl Boc-L-aspartate obtained from its dicyclohexylammonium salt (47.1 g, 0.1 mol) by desalting with citric acid were dissolved in tetrahydrofuran (300 ml) and cooled on an ice-bath. *N,N'*-Dicyclohexylcarbodiimide (20.6 g, 0.1 mol) was added to the solution and the reaction mixture was stirred on ice cooling for 2 hr and then at room temperature for 3 hr. The precipitate was filtered off and the combined filtrate was concentrated *in vacuo*. The residual solid was collected by filtration with the aid of petroleum ether and recrystallized from ethyl acetate–petroleum ether; yield, 27.5 g, (71%); mp 105—105.5 °C; $[\alpha]_D^{15}$ −15.2° (*c* 1, ethyl acetate).

Found: C, 52.97; H, 6.82; N, 7.21%. Calcd for $C_{17}H_{26}O_8N_2$: C, 52.84; H, 6.78; N, 7.25%.

t-Butyloxycarbonyl-β-t-butyl-L-aspartyl-D-isoasparagine Benzyl Ester (XV). A solution of Boc-L-aspartic acid β-*t*-butyl α-1-succinimidyl ester (9.7 g, 25 mmol) in chloroform (100 ml) was added to an ice-cold solution of benzyl D-isoasparaginate (XIV) trifluoroacetate (8.4 g, 25 mmol) in chloroform (200 ml) containing triethylamine (4 ml). The mixture was stirred on an ice-bath for 1 hr and at room temperature for 12 hr. The solvent was removed *in vacuo* and the residue was dissolved in ethyl acetate (200 ml). The ethyl acetate solution was washed with water and dried over anhydrous sodium sulfate. The solvent was removed *in vacuo* and the residue was kept under petroleum ether. The precipitate was collected and recrystallized from methanol–petroleum ether; yield, 11.0 g (89%); mp 120—121 °C; $[\alpha]_D^{14}$ −3.2° (*c* 1, methanol).

Found: C, 58.35; H, 7.12; N, 8.52%. Calcd for $C_{24}H_{35}O_8N_3$: C, 58.40; H, 7.15; N, 8.51%.

L-Aspartyl-D-isoasparagine Benzyl Ester (XVI) Hemihydrate. The dipeptide diester XV (4.0 g, 8.1 mmol) was dissolved in trifluoroacetic acid (15 ml). The mixture was stirred at room temperature for 30 min. Excess trifluoroacetic acid was evaporated *in vacuo*. The residue was kept under ethyl ether and the resulting solid was recrystallized from methanol–ethyl ether. During recrystallization, trifluoroacetic acid in salt form of the product was eliminated from the deblocked peptide derivative; yield, 2.6 g, (93%); mp 160—165 °C; $[\alpha]_D^{15}$ +6.7° (*c* 1, acetic acid).

Found: C, 52.26; H, 5.53; N, 12.05%. Calcd for $C_{15}H_{19}O_6N_3\cdot 1/2H_2O$: C, 52.02; H, 5.82; N, 12.13%.

t-Butyloxycarbonyl-N^{im}-benzyl-L-histidyl-L-aspartyl-D-isoasparagine Benzyl Ester (XVII) Hydrate. Boc-N^{im}-benzyl-L-histidine 2,4,5-trichlorophenyl ester[18] (7.9 g, 15 mmol) in dimethylformamide (30 ml) was added to a chilled solution of the compound XVI hemihydrate (5.2 g, 15 mmol) in dimethylformamide (70 ml) containing triethylamine (4.2 ml). The mixture was stirred at 0 °C for 1 hr and at room temperature for 12 hr. The solvent was removed *in vacuo* and the residual oil was diluted with water. The precipitate formed was collected by filtration. The product was purified by silica gel column chromatography (elution solvent: chloroform–methanol 9 : 1—7 : 3 v/v); yield, 3.2 g, (31%); mp 125—128 °C; $[\alpha]_D^{15}$ +6.5° (*c* 1, methanol).

Found: C, 58.48; H, 6.22; N, 12.20%. Calcd for $C_{33}H_{40}$-

17) Faint yellow: This spot is assumed to be N^{im}-cyanomethylated cyclohexapeptide.

$O_9N_6 \cdot H_2O$: C, 58.05; H, 6.20; N, 12.31%.

Amino acid analysis: N^{im}-Bzl-His, 1.08; Asp, 2.00; N^{im}-benzylhistidine was eluted with citrate buffer of pH 6.80 from the short column of amino acid analyzer.

N^{im}-Benzyl-L-histidyl-L-aspartyl-D-isoasparagine Benzyl Ester (XVIII) Bistrifluoroacetate. The compound XVII hydrate obtained above (683 mg, 1 mmol) was dissolved in trifluoroacetic acid (5 ml). The solution was stirred at room temperature for 30 min and excess acid was evaporated *in vacuo*. The residue was triturated with ethyl ether. The precipitate formed was collected by filtration. This product was homogeneous on paper electrophoresis at pH 4.8; yield, 713 mg (90%); mp 104—118 °C (decomp.); $[\alpha]_D^{15}$ +4.4° (*c* 1, methanol).

Found: C, 48.51; H, 4.42; N, 10.50%. Calcd for $C_{28}H_{32}O_7N_6 \cdot 2CF_3COOH$: C, 48.49; H, 4.32; N, 10.60%.

N^{α}-Benzyloxycarbonyl-N^{ε}-t-butyloxycarbonyl-L-lysyl-N^{δ}-cyclopentyloxycarbonyl-D-ornithyl-L-isoleucyl-D-phenylalanyl-N^{im}-benzyl-L-histidyl-L-aspartyl-D-isoasparagine Benzyl Ester (IV) Hydrate. The tetrapeptide hydrazide IX hemihydrate (291 mg, 0.33 mmol) was dissolved in a mixture of acetic acid (4 ml) and 1M hydrochloric acid (1.7 ml). A solution of sodium nitrite (40 mg) in water (0.5 ml) was added to the cooled solution mentioned above and the mixture was stirred at 0 °C for 30 min. Ice-cold saturated aqueous sodium chloride (50 ml) was added to the above solution. The deposit was collected by filtration and washed with cold water thoroughly. The product was dissolved in dimethylformamide (30 ml) and added to a solution of the tripeptide derivative XVIII bistrifluoroacetate (270 mg, 0.34 mmol) in dimethylformamide (20 ml) containing triethylamine (0.1 ml) at 0 °C. The solution was stirred at 5 °C for 48 hr and then at room temperature for 24 hr. The solvent was removed *in vacuo* and the residual oil was triturated with water. The precipitate was collected by filtration. The crude product was purified by silica gel column chromatography (elution solvent: chloroform–methanol 9:1—8:2; v/v); yield, 330 mg (70%); mp 185—195 °C; $[\alpha]_D^{15}$ +15.0° (*c* 1, dimethylformamide).

Found: C, 60.80; H, 7.04; N, 11.74%. Calcd for $C_{73}H_{96}O_{17}N_{12} \cdot H_2O$: C, 61.24; H, 6.90; N, 11.74%.

The authors are grateful to Peptide Center, Institute for Protein Research of Osaka University for carrying out the amino acid analyses and also deeply indebted to Ajinomoto Co., Ltd. and Commercial Solvent Corporation, U.S.A. for their kind offers of amino acids.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3193—3197 (1973)

Telomerization of Ethylene with Carbon Tetrachloride Initiated by *N*-Chloroalkylamines

Teruzo ASAHARA, Manabu SENŌ, and Noritaka OHTANI

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received May 18, 1973)

By using various *N*-chloroalkylamines, the telomerization of ethylene with carbon tetrachloride was carried out in a stainless steel autoclave at 130 °C. It was found that the yields and the compositions of telomers varied widely according to the kinds and the structures of *N*-chloroalkylamines. When *N*-chloromonoalkylamines or *N*-chlorodialkylamines were used, the total yield of telomers was high compared with the case using *N,N*-dichloroalkylamines. In the presence of both *N*-chloromonoalkylamines and *N*-chlorodialkylamines, the total yield of telomers became higher and the greater part of the telomers was 1:1 adduct ($n=1$ telomer $CCl_3CH_2CH_2Cl$) of ethylene with carbon tetrachloride.

The telomerization of ethylene with carbon tetrachloride by using various initiators, has been examined by many investigators. *N*-Chloroamine, which is known to have a small value of bond energy and a large value of chain transfer constant, adds easily to olefins by a free radical mechanism.[1] As an initiator of polymerization or telomerization, however, *N*-chloroalkylamine was not noticed except for some studies.[2-3] The previous report from our laboratory illustrated that telomerization of ethylene with carbon tetrachloride occurred by use of systems of *N,N*-dichloro-*n*-butylamine and amines to give the $n=1$ telomer, $CCl_3CH_2CH_2Cl$, as a main product.[4]

On the other hand, we found that *N,N*-dichloroalkylamines reacted with primary or secondary amines to produce *N*-chloromonoalkylamines and *N*-chlorodialkylamines as shown by the following equation.[5]

$$RNCl_2 + R'R''NH \longrightarrow RNHCl + R'R''NCl$$

R, R′=alkyl, R″=alkyl or H

These findings lead us to the attempt of telomerizations initiated by various *N*-chloroalkylamines. Furthermore, the systems of *N,N*-dichloroalkylamines and

amines were studied in detail and the result was compared with that for the cases of *N*-chloromonoalkylamines and *N*-chlorodialkylamines.

Experimental

Materials. Ethylene (purity 99.8%), carbon tetrachloride, and amines of commercial special grade were used without purification. *N,N*-Dichloroalkylamines[6] and *N*-chlorodialkylamines were prepared by bubbling chlorine gas into the aqueous solution of amines and sodium bicarbonate and were purified by distillation. *N,N*-Dichloro-*n*-butylamine, bp 55°C/28 mmHg, *N,N*-dichloro-*t*-butylamine, bp 42 °C/19.5 mmHg, *N,N*-dichloro-*s*-butylamine, bp 45.5 °C/20 mmHg, *N,N*-dichloroisobutylamine, bp 39 °C/25 mmHg, *N*-chlorodi-*n*-butylamine, bp 33 °C/2.5 mmHg, *N*-chloropiperidine, bp 29 °C/10 mmHg.

N-Chloromonoalkylamines[7] were prepared by mixing slowly the solution of corresponding amine hydrochloride with the aqueous solution of sodium hypochlorite in the presence of carbon tetrachloride. The resulting carbon tetrachloride solution was dried over sodium sulfate and the concentration was determined by the iodometric analysis.

Apparatus and Method. Telomerization was carried out in a 200 ml stainless steel (SUS 7) autoclave with a magnetic stirrer. In the autoclave, 1 mol of carbon tetrachloride and prescribed amounts of *N*-chloroamines were placed. After the autoclave was sealed, the air inside was replaced several times by ethylene. Ethylene was then charged to show a definite pressure. The autoclave was heated up to 130 °C and kept for a desired time. After the reaction, the autoclave was chilled to room temperature and the reaction mixture was washed by an aqueous potassium iodide solution and then an aqueous sodium thiosulfate solution. The product was fractionated by distillation into $n=1$ and $n=2$ telomers, which were identified by boiling point and NMR spectra.

Results and Discussion

Reactions of N,N-*Dichloroalkylamines with Primary or Secondary Amines.* It was made clear from the observations described later that primary and secondary amines react with *N,N*-dichloroalkylamines to form *N*-chloromonoalkylamine and *N*-chlorodialkylamine, respectively.

The reaction of *N,N*-dichloro-*n*-butylamine with *n*-butylamine in isooctane at 40 °C was examined by means of UV spectrometer. The absorption at 309 nm by *N,N*-dichloro-*n*-butylamine diminished in strength instead of the increase in strength of the absorption at 264 nm, which was identified to be owing to *N*-chloromono-*n*-butylamine. The ^{1}H NMR measurement of this reaction in carbon tetrachloride showed that the triplet absorption at δ 3.60 diminished and at the same time the triplet at δ 3.03 appeared and became greater. The former is owing to α-methylene protons of *N,N*-dichloro-*n*-butylamine and the latter was ascribed to that of *N*-chloromono-*n*-butylamine.

The reaction of *N,N*-dichloro-*n*-butylamine with di-*n*-butylamine was examined in the same way. The absorption at about 270 nm in the UV spectra and the triplets at δ 2.84 and δ 2.99 in the NMR spectra appeared and increased in strength as the reaction proceeded. The absorption around 270 nm can be explained as a combined peak of two absorptions, *i.e.*, that of *N*-chlorodi-*n*-butylamine at 274 nm and that of *N*-chloromono-*n*-butylamine at 264 nm, which have the similar molar absorption coefficient of about 400 $l \cdot cm^{-1} \cdot mol^{-1}$. The peak at δ 2.84 in the NMR spectra is owing to the α-methylene protons of *N*-chlorodi-*n*-butylamine and the peak at δ 2.99 to that of *N*-chloromono-*n*-butylamine. In these reactions, the concentration of the positive chlorine of *N*-chloroamines decreased by only 5—10%, when the conversion of *N,N*-dichloroamine was 50%. The similar results were obtained in the other systems of *N,N*-dichloroalkylamines and amines. The rate of reaction was low for amines with the bulky alkyl groups. In the case of dicyclohexylamine, the replacement reaction did not take place and dicyclohexylamine hydrochloride was obtained. The details will be reported in a separate paper.

Telomerization of Ethylene with Carbon Tetrachloride using N-*Chloroalkylamines.* The results of telomerizations using *N,N*-dichloroalkylamines, *N*-chloromonoalkylamines, and *N*-chlorodialkylamines are shown in Tables 1, 2, and 3, respectively.[8] When *N,N*-dichloroalkylamines were used, the yield of telomers was generally low. In the case of *N,N*-dichloro-*t*-butylamine, the yield of telomers is particularly low. The composition ratio of $n=1$ telomer was, however, very high compared with that of other cases using di-*t*-butyl peroxide (DTBP) and di-*n*-butylamine.

N-Chloromonoalkylamines were more reactive for initiation of telomerization than *N,N*-dichloroalkylamines and the following order with higher yields of telomers was observed: *t*-Bu<*s*-Bu and *n*-Bu<*i*-Bu. The same order was observed in the case of *N,N*-dichlorobutylamines. In addition, it was noticed that the yield of telomers increased and the composition ratio of $n=1$ telomer decreased when the alkyl group of *N*-chloromonoalkylamine was more bulky. The similar result was obtained in the case of *N*-chlorodialkylamines.

Table 1. Telomerization of ethylene with carbon tetrachloride using *N,N*-dichloroalkylamines[a]

a) Telomerization conditions: *N*-chlorodialkylamine, 0.02 mol; initial ethylene pressure, 20 kg/cm²; carbon tetrachloride, 1 mol; reaction temperature, 130 °C; reaction time, 1.5 hr.
b) Reaction time; 2.0 hr.

Telomerization of Ethylene with Carbon Tetrachloride using N,N-*Dichloroalkylamine–Amine Systems.* The effect of the composition ratio of *N,N*-dichloro-*n*-butylamine to *n*-butylamine is listed in Table 4. The yield of telomers decreases, but the composition ratio of $n=1$ telomer increases with the increase of the ratio of *N,N*-dichloroamine. The decrease in the yield of total telomers can be explained from the fact that the replacement reaction above-mentioned takes place as the amine interacts stronger with *N,N*-dichloroamine than carbon tetrachloride.

Table 4. Telomerization of ethylene with carbon tetrachloride using the system of *N,N*-dichloro-*n*-butylamine and *n*-butylamine[a)]

n-BuNCl$_2$ $\times10^{-2}$ mol	n-BuNH$_2$ $\times10^{-2}$ mol	Total yield of telomers g	Composition of telomers mol%		
			$n=1$	$n=2$	$n\geqq3$
0	2.0	46	57	35	8
0.5	1.5	37	57	33	10
1.0	1.0	17	73	17	10
1.5	0.5	11	72	19	9
2.0	0	4	—	—	—

a) Telomerization conditions: initial ethylene pressure, 20 kg/cm²; carbon tetrachloride, 1 mol; reaction temperature, 130 °C; reaction time, 1.5 hr.

As is shown in Table 5, both the yield of telomers and the composition ratio of $n=1$ telomer increase by adding di-*n*-butylamine to *N,N*-dichloroalkylamine. This binary system is more reactive than the single system of *N,N*-dichloroalkylamine, *N*-chloromonoalkylamine, or *N*-chlorodialkylamine. The reactivity of this system was dependent upon the alkyl group of *N,N*-dichlorobutylamines and the order of reactivity was the same to that of *N*-chloromonobutylamines and *N,N*-dichlorobutylamines.

Table 5. Telomerization of ethylene with carbon tetrachloride using the system of *N,N*-dichloroalkylamine and di-*n*-butylamine[a)]

Dichloroamine	Total yield of telomers g	Composition of telomers mol%		
		$n=1$	$n=2$	$n\geqq3$
n-BuNCl$_2$	60	86	12	3
i-BuNCl$_2$	91	87	12	1
s-BuNCl$_2$	70	88	9	3
t-BuNCl$_2$	23	77	18	5

a) Telomerization conditions: *N,N*-dichloroalkylamine, di-*n*-butylamine, 0.02 mol; initial ethylene pressure, 20 kg/cm²; carbon tetrachloride, 1 mol; reaction temperature, 130 °C; reaction time, 1.5 hr.

Table 6. Comparison of the system of *N*-chloromono-*n*-butylamine and *N*-chlorodi-*n*-butylamine with the system of *N,N*-dichloro-*n*-butyl amine and di-*n*-butylamine[a)]

Initiator system	Total yield of telomers g	Composition of telomers mol%		
		$n=1$	$n=2$	$n\geqq3$
n-BuNCl$_2$/$(n\text{-Bu})_2$NH	51	85	11	4
n-BuNHCl/$(n\text{-Bu})_2$NCl	52	82	14	4

a) Telomerization conditions: *N*-chloroamine, amine, 0.01 mol; initial ethylene pressure, 20 kg/cm²; carbon tetrachloride, 1 mol; reaction temperature, 130 °C; reaction time, 1.5 hr.

Table 6 shows the comparison of the result for the system of *N,N*-dichloro-*n*-butylamine and di-*n*-butylamine with that for the system of *N*-chloromono-*n*-butylamine and *N*-chlorodi-*n*-butylamine. The latter system is to be formed from the reaction in the former one. For the both systems, essentially the same results were obtained as expected. It was supposed that the reaction of *N,N*-dichloro-*n*-butylamine with di-*n*-butylamine at room temperature takes place rapidly to be almost completed within 30 min which is necessary to heat up the autoclave to the reaction temperature of 130 °C. The result for the 1 : 1 system of *N,N*-dichloro-*n*-butylamine–*n*-butylamine in Table 4 does not coincide with that for the *N*-chloromono-*n*-butylamine system in Table 2. This would show that the rate of the reaction of primary amines is slower than secondary amines.

Effects of Metal or Its Salts on the Telomerization Using N-*Chloroalkylamines.* The effect of iron, copper and their chlorides on the telomerization of ethylene with carbon tetrachloride using *N*-chloroalkylamines is

shown in Table 7. Remarkable decreases of the yield of telomers were observed when copper, its salts, and ferric chloride are added except the case of *N,N*-dichloro-*n*-butylamine. The addition of iron did not affect the reactivity of *N*-chloroalkylamines. The effect of ferrous chloride varied with the kind of *N*-chloroalkylamines. Particularly, the system of ferrous chloride and *N*-chlorodi-*n*-butylamine showed a marked increase in the yield of telomers and the ethylene

charged into the autoclave was completely consumed within 25 min.

These results are to be compared with those for the systems of di-*n*-butylamine and metal or its salts. As is shown in Table 8, the high yields of telomers were obtained for all systems and the inhibition effect of copper salts or ferric chloride was not found.

Mechanism of Initiation. It is supposed that the telomerization would be initiated by *N*-chloroalkylamine through following reactions (1—3).

$$\mathrm{R\text{-}N(X)(Cl)} \xrightarrow{\Delta} \mathrm{R\text{-}N\cdot(X)} + \mathrm{Cl\cdot} \quad (1)$$

(I)

$$\mathrm{R\text{-}N(X)(Cl)} + \mathrm{HCl} \longrightarrow \mathrm{R\text{-}\overset{+}{N}(X)(Cl)(H)\ Cl^-}$$

(II)

$$\xrightarrow{\Delta} \mathrm{R\text{-}\overset{+}{N}(X)(Cl)\ Cl^-} + \mathrm{Cl\cdot} \quad (2)$$

(III)

$$\mathrm{R\text{-}N(X)(Cl)} + \mathrm{CCl_4} \longrightarrow \mathrm{R\text{-}\overset{+}{N}(X)(H)\ Cl^-} + \mathrm{\cdot CCl_3} \quad (3)$$

(III′)

X=R, H, or Cl

In Reaction 1, amino radical (I) is formed through a thermal scission of nitrogen-chlorine bond. *N,N*-dichloro-*n*-butylamine was utilized for the chlorination of polybutadiene by Kagiya *et al.*[9] This decomposition is probably the main process of radical formation in the case of *N*-chloro-*t*-alkylamines having no hydrogen bonded to α-carbon and *N,N*-dichloroalkylamines.

N-Chlorodialkylamine and *N*-chloromonoalkylamine having α-hydrogen easily undergo thermal decomposition at high temperatures to release hydrogen chloride. In the same manner as Hofmann-Loeffler reaction of *N*-chloroalkylamine in sulfuric acid,[10] hydrogen chloride maybe forms a salt (II) with *N*-chloroalkylamine and II decomposes to form aminium radical (III) and chlorine atom. Practically, II was formed stably at −60 °C and decomposed at room temperature in methanol. The decomposition products from II were amine hydrochloride and chlorine gas.

One-electron transfer from *N*-chloroalkylamine to carbon tetrachloride results in the formation of aminium radical (III′) and trichloromethyl radical (Reaction 3). It was reported that amines, such as triethylamine, and carbon tetrachloride form an *n*-σ complex which shows a charge-transfer spectrum.[11] But the basicity of *N*-chloroalkylamines is weaker than that of amines and, therefore, an electron donation is not feasible. Then, the radical formation by Reaction 3 might be excluded.

The telomerization of octene-1 instead of ethylene with carbon tetrachloride was carried out in a 20 ml glass ampule and the result was compared with that of

9) H. Okamoto, S. Hagiwara, and T. Kagiya, *Kogyo Kagaku Zasshi*, **74**, 1466 (1971).
10) M. E. Wolff, *Chem. Rev.*, **63**, 55 (1963).
11) D. P. Stevenson and G. M. Coppinger, *J. Amer. Chem. Soc.*, **84**, 149 (1962).

the same reaction in the 200 ml stainless steel autoclave under the same reaction conditions. The yield of telomers in the ampule was less than one fifth of that in the autoclave. This suggests that the metal surface or the trace amount of metal resolved has a large effect on the initiation of *N*-chloroalkylamine as does the case for the system of triethanolamine–carbon tetrachloride[12] or the system of cellulose–water–carbon tetrachloride.[13] The telomers in the ampule was probably produced *via* the initiations indicated by Eqs. (1)—(2). On the other hand, most part of the telomers in the autoclave was likely formed *via* the following reactions.

$$2\,R\text{–}\underset{Cl}{\overset{X}{N}} + Fe \longrightarrow 2\,R\text{–}\overset{X}{N}\cdot + Fe^{2+} + 2\,Cl^- \quad (4)$$

$$n\,R\text{–}\underset{Cl}{\overset{X}{N}} + Fe^{2+} \longrightarrow \underset{(IV)}{[(RNXCl)_nFe^{2+}]} \quad (5)$$

$$R\text{–}\underset{Cl}{\overset{X}{N}} + Fe^{2+} \longrightarrow R\text{–}\overset{X}{N}\cdot + Fe^{3+} + Cl^- \quad (6)$$

$$IV + CCl_4 \longrightarrow \left[\begin{matrix}(RNXCl)_nFeCl^{2+}\\ \cdot CCl_3\end{matrix}\right]_{(V)} \quad (7)$$

Amino radical and ferrous ion are formed by the action of iron to *N*-chloroalkylamine, as suggested from studies by Otsu *et al.*[3] Although a part of ferrous ions is oxidized by *N*-chloroalkylamine to form ferric ion (Eq. (6)), most part of ferrous ions forms a complex (IV) with *N*-chloroalkylamine (Eq. (5)). This complex reacts with carbon tetrachloride to form trichloromethyl radical (Eq. (7)). The trichloromethyl radical thus formed seems to coordinate to iron–*N*-chloroalkylamine complex or to be trapped within the cage of this complex and carbon tetrachloride as in the system of triethyl phosphite–iron salts–carbon tetrachloride.[14]

Parts of amino radicals, aminium radicals, and chlorine atoms formed through Reactions 1, 2, 4, and 6 act as free radical initiators and give the telomers with the composition similar to that by usual radical initiators such as DTBP (Eqs. (8)—(9)).

$$I\cdot + n\,C_2H_4 \longrightarrow I(C_2H_4)_n\cdot \xrightarrow{CCl_4} I(C_2H_4)_nCl + \cdot CCl_3 \quad (8)$$

$$\cdot CCl_3 + n\,C_2H_4 \longrightarrow CCl_3(C_2H_4)_n\cdot \xrightarrow{CCl_4} CCl_3(C_2H_4)_nCl + \cdot CCl_3 \quad (9)$$

On the other hand, coordinated radicals (V) react with ethylene to produce $n=1$ telomer almost selectively.[14]

$$V + C_2H_4 \longrightarrow IV + CCl_3C_2H_4Cl \quad (10)$$

The telomerization of ethylene with chloroform using the system of *N*-chlorodi-*n*-butylamine and *N*-chloromono-*n*-butylamine afforded the product, a greater part of which was of chlorine abstracted type, *i.e.*, $CHCl_2(C_2H_4)_nCl$. To a contrary, the product of telomerization by DTBP or di-*n*-butylamine was of hydrogen abstracted type, $CCl_3(C_2H_4)_nH$. This result seems to support the above suggestion.

The authors would like to express their thanks to Mr. T. Suzuki for the assistance in the experiments.

Photoinduced Reactions. LXXIII. Solvent Dependence in the Photochemical Reaction of α-Nitroepoxides[1]

Isao SAITO, Masaaki TAKAMI, Toshiro KONOIKE, and Teruo MATSUURA
Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received June 21, 1973)

The photochemical reaction of α-nitroepoxides showed marked solvent dependence. The photolysis of (1,2-epoxy-2-nitropropyl)benzene (I) in 2-propanol led to the formation of three products 1-phenyl-1-isopropoxy-2-propanone (IIb), 1-phenyl-1,2-propanedione oxime (III) and 1-hydroxy-1-phenyl-2-propanone oxime (IV), whereas on irradiation in ether I gave exclusively IV. However, in *t*-butyl alcohol, benzene, acetone, acetonitrile or *n*-hexane, I was not susceptible to photolysis. The photolysis of α,α'-epoxy-α-nitrobibenzyl (V) in ether gave benzoin oxime (VII) in addition to benzaldehyde and benzoic acid, whereas in methanol it gave benzoin methyl ether (VI) in the dark. These reactions are interpreted in terms of effects of the acidity and hydrogen-donating property of solvents on the excited α-nitroepoxides. The pyrolysis of I and V were also examined.

The photochemical reaction of carbonyl compounds attached to a small ring has been extensively investigated.[2,3] Among these compounds, α,β-epoxyketones are known to give β-diketones and α-hydroxyketones[4-6] *via* mechanisms involving the initial n-π^* excitation followed by opening the epoxy ring.[5,6] In view of the similarity between photochemical behaviors of isoelectronic carbonyl and nitro groups,[7] such as photoreduction and α-cleavage, the photochemical behavior of α-nitroepoxides drew our attention. It also encouraged us that the solution photochemistry of aliphatic nitro compound has yet been little investigated.[8] The present paper deals with results obtained with certain α-nitro epoxides which undergo solvent-depending photochemical reactions.

Results and Discussion

Photolysis of (E)-(1,2-Epoxy-2-nitropropyl)benzene (I). In methanol, I[9] was found to be slowly converted into a methoxyketone IIa[10] with the participation of the solvent even in the dark, whereas I was stable to 2-propanol and ether in the absence of light. Irradiation of I in 2-propanol, ether and mixutres of them was carried out with light through Pyrex under bubbling nitrogen at room temperature. The ratio of photoproducts IIb,[10] III,[11] and IV[9] was solvent-dependent (Table 1). The photochemical conversions appear to occur in protic or hydrogen-donating solvents or ones having both properties since I was unsusceptible to photolysis in benzene, acetone, acetonitrile, and *n*-hexane, but was converted very slowly into III in *t*-butyl alcohol.

TABLE 1. PHOTOLYSIS OF I IN VARIOUS SOLVENTS

Solvent	Yields of products(%)[a]			
	II	III	IV	I
MeOH	85	—	—	12
i-PrOH	31	41	11	17
i-PrOH–Et_2O 9:1	20	25	15	39
i-PrOH–Et_2O 1:1	8	—	31	57
i-PrOH–Et_2O 1:9	—	—	30	67
Et_2O	—	—	20	80

a) The yields were determined by NMR analyses.

The conversion of I in methanol into IIa was accelerated by irradiation. The protic nature of solvents could be responsible for the formation of II. The decrease of the yield of II in the order, methanol > 2-propanol ≫ *t*-butyl alcohol, is probably due to steric hindrance of the solvents. The hydrogen-donating ability of solvents could be responsible for the formation of IV, since irradiation of I in ether gave exclusively IV. On the other hand, the formation of III should be ascribed to both protic and hydrogen-donating properties of solvents.

TABLE 2. QUENCHING EXPERIMENTS OF I WITH 1,3-PENTADIENE

Quencher concentration (mol/mol of I)	Yields of products (%)[a]					
	In 2-propanol				In ether	
	II	III	IV	I	IV	I
0	24	40	14	22	45	0
1.0	13	7	27	53	—	—
1.5	14	6	11	69	—	—
2.0	6	2	6	86	22	57
3.0	5	1	5	89	—	—
5.0	—	—	—	—	5	93

a) The yields were determined by NMR analyses.

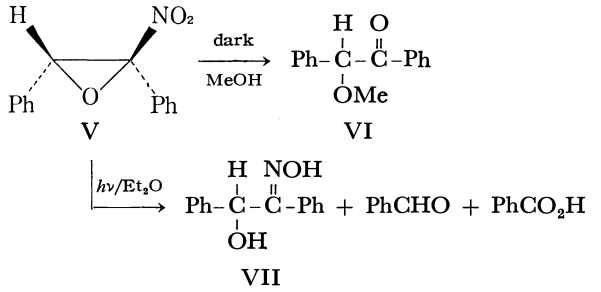
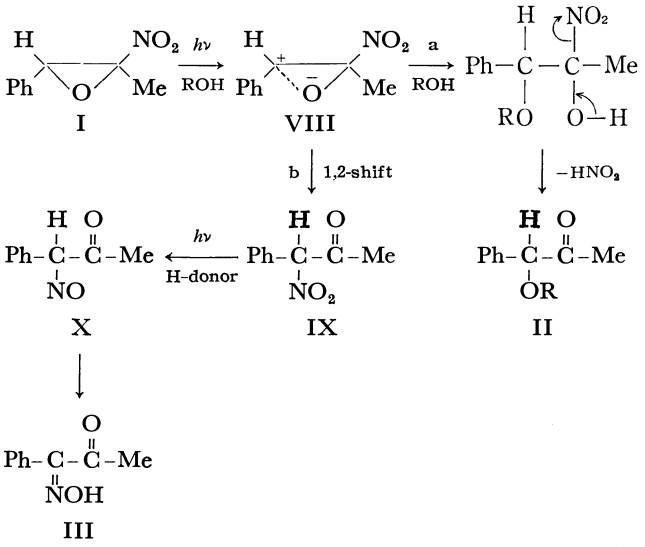
Photolysis of (E)-α,α'-Epoxy-α-nitrobibenzyl (V). Analogously to the dark reaction of I in methanol, V[9] reacted readily with methanol in the absence of light resulting in the formation of benzoin methyl ether (VI).[12] Irradiation of V in ether under similar conditions gave a complex mixture of products, from which benzoin oxime (35%) corresponding to IV, benzaldehyde (15%) and benzoic acid (11%) were isolated. The photolysis of V in 2-propanol was more complex and the isolation of pure products was unsuccessful, whereas V did not undergo photochemical change in *t*-butyl alcohol, benzene, and *n*-hexane under similar conditions.

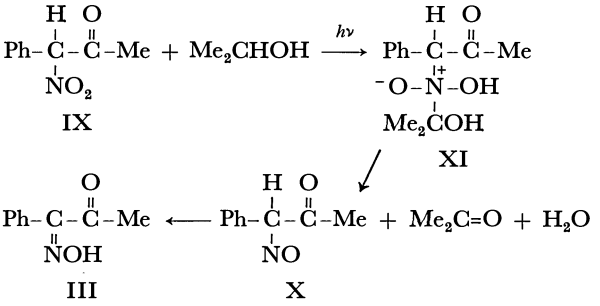


Mechanistic Consideration. As already pointed out, the presence of an aprotic solvent is requisite for the formation of II and III during the photolysis of I. This may be interpreted by considering on 1,3-dipolar intermediate VIII which is derived from the excited state of I, probably with the assistance of a solvent proton. The intermediate VIII may undergo two competitive processes, path a and path b shown in Scheme 1. In path a, VIII reacts with an alcohol to form II with the elimination of nitrous acid. Nitrogen oxides resulted from nitrous acid were experimentally detected. The photochemical addition of alcohols to simple epoxides has been reported,[13-15] although the reaction suffers auto-catalysis by a trace amount of acidic matter formed during the photolysis.[13,14] In methanol, which is more nucleophilic and has a more acidic proton than 2-propanol, the solvent can attack even in the ground state of I to the β-C–O bond having a considerably polar character attributable to the nitro group.



Scheme 1.

In path b, the 1,3-dipolar intermediate VIII undergoes a 1,2-shift of the nitro group to form an α-nitro ketone IX in competition with the attack of an alcohol to the cationic β-carbon. An analogous rearrangement of I to IX is known to occur by acid catalysis with boron trifluoride.[9] The α-nitroketone IX may be photochemically reduced in a hydrogen-donating solvent to III possibly *via* an α-nitrosoketone X. Supporting this scheme, IX was found to be rapidly reduced upon irradiation in 2-propanol to give III in good yield. To the best of our knowledge, the photoreduction of an aliphatic nitro compound to an oxime is the first example. The photoreduction of IX to III may be rationalized by a mechanism involving the intermediary formation of a coupling product XI between IX and 2-propanol (Scheme 2). Similar intermediates have been proposed by Reid and co-workers.[8]



Scheme 2.

For the formation of III, an alternative pathway should be considered, which involves photochemical deoxygenation of the epoxy ring of I followed by rearrangement of a nitroolefin XII to form III (Scheme 3). In fact, the photochemical rearrangement of XII into III has been reported by Chapman and co-workers.[16] We found that *cis*-α-nitrostilbene (XIII) underwent the same rearrangement to benzil oxime (XIV) in addition to the known isomerization to

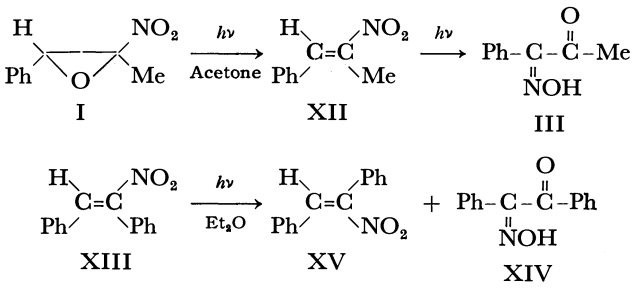
trans-α-nitrostilbene (XV).[17] Considering the fact that neither XIV nor XV was obtained by the photolysis of V, which is expected to form XIII according to Scheme 3, the pathway involving the initial deoxygenation is less probable than Scheme 1.



Scheme 3.

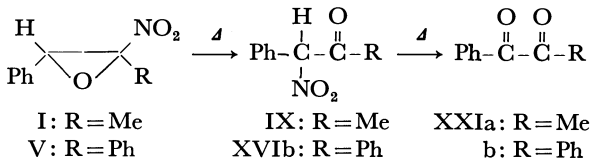
Four possible pathways were considered for the formation of α-hydroxyimino alcohols IV and VII by the photolysis in a hydrogen-donating solvent of I and V respectively (Scheme 4). Path a involves rearrangement to an α-nitroketone XVI analogous to the photorearrangement of α,β-epoxyketones to β-diketones,[4] followed by photoreduction leading to IV or VII. This pathway was eliminated by the finding that XVIb was unsusceptible to photolysis in ether. Path b involves reduction to an α-nitro alcohol XVII followed by further photoreduction leading to IV or VII. Path b was also excluded by the finding that neither XVIIa[9] or XVIIb[18] was susceptible to photolysis in ether.

Path c and path d involve photoreduction of the nitro group leading to a hydroxylamine XVIII and a nitrosoepoxide XIX respectively. The former will be tautomerized and the latter photoreduced to IV or VII. Attempts to synthesize these possible intermediates were unsuccessful. Available evidences at present cannot distinguish between path c and path d.

In order to obtain informations on the nature of the excited state of α-nitroepoxides, quenching experiments were carried out with I in 2-propanol and ether. Piperylene was found to quench both the disappearance of I and the formation of II, III, and IV in 2-propanol and of IV in ether. A triplet state of I may be responsible for the first step of the over-all reactions.

In conclusion, the photochemistry of α-nitroepoxides distinctly differs from that of α,β-epoxyketones, an isoelectronic analog. It may be reasonable to assume that the difference is due to a more polar character of nitro group which alters the electronic situation of the epoxy ring as already seen from the reactivity to methanol in the ground state.

Pyrolysis of α-Nitroepoxides I and V. When I was heated at 120—130 °C at atmospheric pressure, three products, IX (33%), XXIa[9] (21%) and benzaldehyde (6%) were obtained. Pyrolysis of I at 150 °C at 20 mmHg gave exclusively XXIa. A similar temperature dependence was observed in the pyrolysis of V. Thus XVIb was exclusively obtained on pyrolysis at 100 °C, while benzil (XXIb) (80%), benzaldehyde (15%) and benzoic acid (5%) were obtained at 150 °C.



It is evident that α-nitroketones IX and XVIb are an intermediate in the formation of XXI, since pyrolysis of IX at 150 °C and XVIb at 200 °C was found to give XXIa and XXIb respectively. The initial step

of these pyrolysis reactions may be a homolytic cleavage of the C–NO_2 bond as seen in the pyrolysis of nitromethane.[19]

Experimental

All mps are uncorrected. IR spectra were obtained by a Japan Spectroscopic Co., Model IRS spectrometer. NMR spectra were obtained on a Varian T-60 NMR spectrometer with TMS as an internal standard. Elemental analyses were performed at Elemental Analysis Center of Kyoto University.

Dark Reaction of (E)-(1,2-Epoxy-2-nitropropyl)benzene (I) with Methanol. A solution of I[9] (20 mg) in 20 ml of anhydrous methanol in a Pyrex tube was let to stand for 21 hr at room temperature under nitrogen atmosphere. After evaporating under reduced pressure, the residue showed two spots on tlc. Analysis of the residue by NMR indicated that it consisted of unreacted I (59%) and IIa (41%). After purifying by glpc (DC-550 Silicone on Celite column at 160 °C), IIa was obtained as a colorless oil, which was identified by a comparison of its IR spectrum with that of an authentic sample.[10] ν_{max} (neat) 1720 cm^{-1}; NMR ($CDCl_3$): δ 2.13 (s, 1H), 3.60 (s, 3H), 6.67 (s, 1H), and 7.40 (s, 5H).

Irradiation of (E)-(1,2-Epoxy-2-nitropropyl)benzene (I).

A) In Methanol: A solution of I [λ_{max}^{EtOH}: 290 nm (ε 450) and 230 nm (ε 4500)] (0.23 g) in 100 ml of purified methanol was irradiated with a 100 W high-pressure mercury lamp (Pyrex filter) under bubbling nitrogen for 5 hr. The gas outlet tube was connected to a trap containing a solution of sulfanilic acid (5 g) and *N,N*-dimethylnaphthylamine (5 g) in 200 ml of acetic acid. The trap solution was turned to red, indicating the liberation of nitrogen oxides.[20] The reaction mixture was evaporated to give a residue, the NMR spectrum of which showed the same spectral pattern as that of the dark reaction products. After purifying by glpc (DC-550 Silicone on Celite column at 160 °C), IIa was obtained as a colorless oil, which was identical with an authentic sample (IR).[10] The yields were determined by NMR analysis; IIa in 69% and I in 31%.

B) In 2-Propanol: A solution of I (0.50 g) in 5 ml of 2-propanol in a Pyrex tube was externally irradiated for 40 hr under nitrogen atmosphere with a 100 W high-pressure mercury lamp at room temperature. The reaction mixture was evaporated and the residue was chromatographed on neutralized alumina (15 g). Elution with benzene afforded 0.1 g of recovered I. Further elution with benzene yielded 0.15 g of IIb as a slightly yellow oil, which was identical with an authentic sample (IR).[10] Elution with chloroform gave a brown mass. After recrystallization from ethyl acetate colorless crystals were obtained (0.2 g), mp 160—161 °C, which were identified to be III by a comparison of its IR spectrum with that of an authentic sample.[11] ν_{max} (nujol) 3300 and 1670 cm^{-1}; NMR ($(CD_3)_2CO$): δ 2.47 (s, 3H), 7.36 (s, 5H), and 11.50 (s, 1H). Further elution with chloroform gave a brown mass. After recrystallization from ethyl acetate IV was obtained as colorless crystals (0.05 g), mp 111—112 °C, which were identical with an authentic sample (IR),[9] NMR ($(CD_3)_2CO$): δ 1.68 (s, 3H), 4.72 (s, 1H), 5.31 (s, 1H), 7.39 (s, 5H), and 11.40 (s, 1H).

C) In Ether: A solution of I (0.5 g) in 5 ml of anhydrous ether in a Pyrex tube was irradiated for 40 hr as above. The reaction mixture was evaporated and the resulting brown oil was chromatographed on neutralized alumina (15 g). Elution with chloroform gave colorless crystals. Recrystallization from ethyl acetate gave IV (0.15 g), mp 111—112 °C, which was identical with an authentic sample (IR).[9]

D) In Mixtures of 2-Propanol and Ether of Different Ratios: Solutions of I (50 mg) in each 20 ml of three solvent systems (2-propanol and ether; 9:1, 1:1, and 1:9) in Pyrex tubes under nitrogen atmosphere were irradiated for 40 hr with a 100 W high-pressure mercury lamp using a merry-go-round apparatus at room temperature. After evaporating, the yields of II, III, and IV were determined by NMR analysis. These results are shown in Table 1.

E) In Other Solvents (t-Butyl Alcohol, Benzene, Acetone, Acetonitrile, and n-Hexane): Solutions of I (50 mg) in each 20 ml of the solvents were externally irradiated under the same conditions as described in D). The reaction mixtures were monitored by tlc. After evaporating, the residues were analyzed by NMR indicating that I was recovered completely in benzene, acetone, acetonitrile, and *n*-hexane. Analyses of the product mixture obtained in *t*-butyl alcohol by tlc and NMR showed the existence of a small amount of III.

Dark Reaction of (E)-α,α'-Epoxy-α-nitrobibenzyl (V) in Methanol. A solution of V[9] (0.35 g) in 4 ml of anhydrous methanol in a Pyrex tube was let stand for 1 day at room temperature under nitrogen atmosphere. After evaporating, the residue showed a single spot on tlc and a single peak on glpc (DC-550 Silicone on Celite column at 160 °C). After purifying by glpc, the product VI was obtained as an oil, which was identical with an authentic sample (IR).[12] ν_{max} (neat) 1670 cm^{-1}; NMR ($CDCl_3$): δ 3.45 (s, 3H), 5.53 (s, 1H), and 8.20—7.20 (m, 10H).

Irradiation of (E)-α,α'-Epoxy-α-nitrobibenzyl (V). *A) In Methanol*: A solution of V [λ_{max}^{EtOH}: 290 (ε 800) and 232 nm (ε 6000)] (0.35 g) in 4 ml of anhydrous methanol was externally irradiated with a 100 W high-pressure mercury lamp for 40 hr under nitrogen atmosphere. After evaporating, glpc, tlc, and NMR analyses of the residue showed that it consisted of only IV.

B) In Ether: A solution of V (1.8 g) in 50 ml of dry ether was irradiated with a 100 W high-pressure mercury lamp under bubbling nitrogen at room temperature. After 11 hr V was completely consumed, which was monitored by tlc. The reaction mixture was evaporated and the residue was chromatographed on silica gel column (50 g). Elution with 90 ml of benzene afforded an oil (0.09 g), identified as benzaldehyde (IR). Elution with 800 ml of a mixture of benzene and chloroform (*ca.* 1:1) gave colorless crystals (0.28 g), identified as benzoic acid (IR). Elution with 100 ml of chloroform gave VII (0.63 g) as colorless crystals, mp 150—153 °C, which were identical with an authentic commercial sample (IR). NMR (DMSO-d_6): δ 5.60 (s, 1H), 7.27 (s, 10H), and 10.87 (s, 1H).

C) In 2-Propanol: A solution of V (0.1 g) in 20 ml of 2-propanol was externally irradiated with a 400 W high-pressure mercury lamp for 20 hr under nitrogen atmosphere at room temperature. After evaporating, the residue showed nine spots on tlc (silica gel with chloroform). The isolation of pure products was unsuccessful.

Irradiation of 2-Nitro-1-phenyl-1-propanol (XVIIa). A solution of XVIIa[9] (0.18 g) in 20 ml of ether in a Pyrex tube was externally irradiated with a 400 W high-pressure mercury lamp under nitrogen atmosphere for 50 hr at room temperature. After evaporating, the residue was analyzed by tlc and NMR showing that it consisted of only recovered XVIIa.

Irradiation of 1,2-Diphenyl-2-nitroethanol (XVIIb). A

19) a) C. G. Crawforth and D. J. Waddington, *Trans. Faraday Soc.*, **65**, 1334 (1969). b) K. Glänzer and J. Troe, *Helv. Chim. Acta*, **55**, 2884 (1972).

20) F. G. Germuth, *Ind. Eng. Chem., Anal. Ed.*, **1**, 28 (1929).

solution of XVIIb[18] (0.464 g) in 70 ml of ether was irradiated with a 100 W high-pressure mercury lamp (Pyrex filter) under bubbling nitrogen at room temperature for 20 hr. Analyses of the photolyzate by tlc, glpc, and NMR indicated no consumption of XVIIb.

Irradiation of 1-Nitro-1-phenyl-2-propanone (IX). A solution of IX[9] (50 mg) in 20 ml of 2-propanol in a Pyrex tube was externally irradiated for 22 hr with a 400 W high-pressure mercury lamp under nitrogen atmosphere at room temperature. After removal of 2-propanol under reduced pressure, a crystalline mass was obtained. Recrystallization from ethyl acetate gave III as colorless crystals (13 mg), mp 160—161 °C, which were identical with an authentic sample (IR and NMR).[11]

Preparation of 2-Nitro-2-phenylacetophenone (XVIb). To a solution of 1,2-diphenyl-2-nitroethanol (XVIIb;[18] 5 g) in 50 ml of acetone was added dropwise (30 min) under stirring a solution of chromium trioxide (13 g) in a mixture of 40 ml of water and 10 ml of conc. sulfuric acid at room temperature. After the addition of chromium trioxide, the reaction mixture was stirring for about 3 hr. The mixture was diluted with 150 ml of acetone and 150 ml of water, then extracted with ether. The ethereal layer was washed with water and dried over anhydrous sodium sulfate. After the removal of ether, a crystalline mass was obtained, which was recrystallized from a mixture of benzene and *n*-hexane gave 2 g of XVIb, mp 75 °C; ν_{max} (nujol) 1680, 1560, and 1350 cm^{-1}; NMR ($CDCl_3$): δ 7.3—8.0 (m).

Found: C, 69.51; H, 4.52; N, 5.83%. Calcd for $C_{14}H_{11}NO_2$: C, 69.70; H, 4.59; N, 5.80%.

Irradiation of 2-Nitro-2-phenylacetophenone (XVIb). A solution of XVIb (0.5 g) in 40 ml of ether in a Pyrex tube was externally irradiated with a 400 W high-pressure mercury lamp for 20 hr under nitrogen atmosphere at room temperature. After the removal of ether, analysis of the residue by tlc and NMR indicated no consumption of XVIb.

Quenching Experiments. *A) I with 1,3-Pentadiene in 2-Propanol*: 1,3-Pentadiene was distilled prior to use. Five solutions of I[9] (50 mg; 0.28×10^{-3} mol) in 20 ml of 2-propanol were prepared in Pyrex tubes. To each solution given amounts of 1,3-pentadiene, 0 μl, 30 μl (0.28×10^{-3} mol), 45 μl (0.42×10^{-3} mol), 60 μl (0.56×10^{-3} mol), and 90 μl (0.84×10^{-3} mol) were added. These five tubes were irradiated with a 400 W high-pressure mercury lamp using a merry-go-round apparatus for 13 hr under nitrogen atmosphere at room temperature. After evaporating, the residues were analyzed by NMR. The yields of recovered I and products were determined by NMR analysis. The results were summarized in Table 2.

B) I with 1,3-Pentadiene in Ether: Three solutions containing I (50 mg; 0.28×10^{-3} mol) and a given amount of 1,3-pentadiene (0 μl, 60 μl (0.56×10^{-3} mol) and 150 μl (1.40×10^{-3} mol), in 20 ml of ether were prepared in Pyrex tubes. These three tubes were irradiated for 18.5 hr as above. After evaporating each solution, the yields of recovered I and product IV were determined by NMR analysis. The results were summarized in Table 2.

Pyrolysis of (E)-(1,2-Epoxy-2-nitropropyl)benzene (I). *A) At 150 °C*: The pyrolysis of 20 mg of I[9] was done at 150 °C for 5 min under 20 mmHg. Analysis of the resulting yellow oil by NMR showed complete consumption of I and the yellow oil showed two peaks on glpc (DC-550 Silicone on Celite column at 150 °C). Glpc separation (DC-550 Silicone at 150 °C) gave XXIa as a yellow oil (13 mg), which was identical with an authentic sample.[9] ν_{max} (neat) 1710 and 1680 cm^{-1}; NMR (CCl_4): δ 2.13 (s, 3H) and 7.25—8.20 (m, 5H).

B) At 120—130 °C: A glass tube containing I[9] (25 mg) was heated at 120—130 °C for 10 min. Analysis of the resulting yellow oil by NMR showed that it consisted of recovered I (8%), XXIa (21%), benzaldehyde (6%), IX (33%), and an unknown product (30%). Among XXIa,[9] benzaldehyde, and the unknown product separated by glpc, the former two were identified by a comparison of the NMR and IR spectra with those of authentic samples. The methine proton peak of IX in the NMR spectrum of the product mixture was in accord with that of an authentic sample.[9] When an authentic sample of IX was heated at 150 °C for 5 min, XXIa was obtained quantitatively, which was monitored by NMR.

Pyrolysis of (E)-α,α'-Epoxy-α-nitrobibenzyl (V). *A) At 160 °C*: The pyrolysis of V[9] (24 mg) was done at 160 °C for 1 hr. Analysis of the resulting yellow oil by NMR showed complete consumption of V. Three products were isolated by glpc separation (DC-550 Silicone on Celite column at 160 °C), benzaldehyde (15%), benzoic acid (5%) and benzil (XXIb) (80%), which were identical with authentic samples (IR). The yields were determined by NMR analysis.

B) At 100 °C: The pyrolysis of V[9] (50 mg) was done at 100 °C for 2 hr under 20 mmHg. The reaction mixture solidified to give slightly yellow crystals, which were recrystallized from a mixture of benzene and *n*-hexane to give 25 mg of XVIb as colorless crystals, mp 75 °C, which were identical with an authentic sample (IR and NMR). Pyrolysis of XVIb at 200 °C in a glpc column gave a peak of XXIb.

Branched-chain Sugars. III. Addition of Vinylmagnesium Bromide to 5,6-Dideoxy-1,2-*O*-isopropylidene-6-*C*-nitro-3-*O*-substituted-α-D-*xylo*-hex-5-enofuranoses[1]

Takao IIDA, Masuo FUNABASHI, and Juji YOSHIMURA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 20, 1973)

Addition of vinylmagnesium bromide to 3-*O*-acetyl (**1**) and 3-*O*-benzyl (**3**) derivatives of 5,6-dideoxy-1,2-*O*-isopropylidene-6-*C*-nitro-α-D-*xylo*-hex-5-enofuranose gave the corresponding 5-deoxy-5-*C*-vinyl derivatives of L-*ido*-type, of which the configurations were proved by intramolecular cyclization into the corresponding nitrocyclitols. Conformations of **1** and **3** and that of the transition state in the addition reaction were discussed on the basis of their NMR parameters.

In order to find out a synthetic passway of 5,6-dideoxy-5-*C*-formyl-6-*C*-nitro-D-glucose as a key intermediate for synthesis of tetrodotoxin from D-glucose,[2] addition of vinylmagnesium bromide to 5,6-dideoxy-1,2-*O*-isopropylidene-6-*C*-nitro-3-*O*-substituted-α-D-*xylo*-hex-5-enofuranoses was examined and the configuration of products were determined to be of L-*ido*-type by intramolecular cyclization into the corresponding branched-chain nitrocyclitols.

Results and Discussion

A few papers on addition of the Grignard reagents to nitroolefins have been published,[3-6] however, no report on the similar reaction of sugar derivatives has been appeared in literatures. Baer and Rank synthesized 3-*O*-acetyl-6-deoxy-1,2-*O*-isopropylidene-6-*C*-nitro-α-D-*xylo*-hex-5-enofuranose (**1**) from 1,2-*O*-isopropylidene-α-D-glucofuranose by periodate oxidation, nitromethane condensation, 3,5-di-*O*-acetylation and elimination.[7] By the similar way, the corresponding 3-*O*-benzyl derivative (**3**) was obtained from 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-glucofuranose,[8] in which 5-*O*-acetyl-3-*O*-benzyl-1,2-*O*-isopropylidene-β-L-idofuranose (**2**) was obtained as crystals. The configuration of **2** was determined by comparison of its optical rotation ($[\alpha]_D$ −58.2°) with that of the corresponding 3-*O*-acetyl derivatives (D-*gluco* type, $[\alpha]_D$ +18.8°; L-*ido* type, $[\alpha]_D$ −30.1°).[9]

Reaction of **1** and **3** with four equivalents of vinylmagnesium bromide in tetrahydrofuran at 0 °C gave 3-*O*-acetyl (**4**) and 3-*O*-benzyl (**5**) derivatives of 5,6-dideoxy-1,2-*O*-isopropylidene-6-*C*-nitro-5-*C*-vinyl-β-L-idofuranose in 28 and 41% yield, respectively. The epimeric D-*gluco*-type isomer could not be detected by NMR spectra. Reaction of **1** with other Grignard reagents such as methyl, allyl, β-styryl, and phenylmagnesium bromide gave only intractable sirups, and the original nitro group could not be detected in IR spectra of the products, when large excess amount of reagents were used. Vinyllithium reaction of **3** gave **5** in much lower yield than that of the Grignard reaction. Hydrogenation of **5** in the presence of palladium-charcoal gave quantitatively the corresponding 5-*C*-ethyl derivative (**6**).

In order to prove the configuration at *C*-5, both **4** and **5** were respectively de-*O*-isopropylidenated in 70% acetic acid at 80—85 °C for 7—8 hr under monitoring with tlc, and then the hydrolyzed products were intramolecularly cyclized into the corresponding nitro cyclitols, without separation in a pure state. In the case of **5**, cyclization in ethanol at pH 8—9 for 2 days and successive acid-catalyzed acetylation gave 2,4-di-*O*-acetyl-3-*O*-benzyl-1-*O*-ethyl-(1,3,5/2,4,6)-6-nitro-5-vinylcyclohexanetetrol (**7**)[10] in 83% yield. When the cyclization was performed in methanol–water in the presence of equimolar amount of sodium bicarbonate, 3-*O*-benzyl-(3,5/1,2,4,6)-6-nitro-5-vinylcyclohexanetetrol (**8**)[10] was obtained in 52% yield, which was then converted into the corresponding 1,2,4-tri-*O*-acetate (**9**). Acetylation of the sirup obtained from the mother liquor of **8** gave the *C*-1 epimer of **9** (**10**). The ratio of **10** to **9** was 1 : 1.54. In the case of **4**, a similar cyclization and *O*-acetylation gave 1,2,3,4-tetra-*O*-acetyl-(1,3,5/2,4,6)-6-nitro-5-vinylcyclohexanetetrol (**11**)[10] as crystals in 11.4% yield. Hydrogenation of **8** in ethanol–acetic acid in the presence of platinum-charcoal gave 3-*O*-benzyl-(3,5/1,2,4,6)-6-amino-5-ethylcyclohexanetetrol (**12**)[10] as an acetate.

First-order analysis of NMR spectra of nitrocyclitols (**7**—**11**) by double resonance technique clarified their configurations (Table 1). The hydrogen signals at the branched point were distinguished by its multi-splittings and higher resonating magnetic field than others. Other ring-protons appeared in a lower field in the order of alkoxy, nitro, and acetoxy position. They have com-

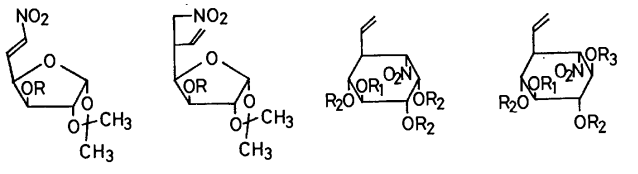
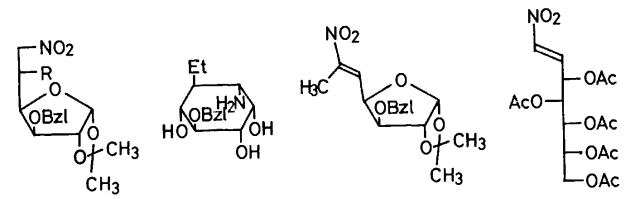
TABLE 1. NMR PARAMETERS OF *O*-ACETYLATED NITROCYCLITOLS

Compound	H_1	H_2	H_3	H_4	H_5	H_6	Other protons
7	3.95(t) $J_{1.2}=10.0$	5.27(t) $J_{2.3}=10.0$	3.64(t) $J_{3.4}=10.0$	5.04(t) $J_{4.5}=10.0$	2.72 $J_{5.6}=12.5$	4.47(dd) $J_{1.6}=10.0$	7.30 (Ph; m), 5.60 (H; m, $J_{5.7}=7.5$), 5.20—5.00 (H_{8a}, H_{8b}; m), 4.62 ($PhCH_2O$; s), 3.54 (OCH_2; q, $J_{CH_3.CH_2}=6.5$), 1.07 (CH_3; q), 2.00 and 1.93 (OAc; s).
9	5.95(t) $J_{1.2}=2.5$	5.00(dd) $J_{2.3}=10.0$	3.92(t) $J_{3.4}=10.0$	5.07(dd) $J_{4.5}=10.5$	3.25 $J_{5.6}=12.5$	4.65(dd) $J_{1.6}=2.5$	7.30 (Ph; m), 5.80—5.10 (H_7, H_{8a} and H_{8b}; m), 4.67 ($PhCH_2O$; s), 2.18, 2.00 and 1.98 (OAc).
10	5.60(t) $J_{1.2}=10.0$	5.20(t) $J_{2.3}=10.0$	3.75(t) $J_{3.4}=10.0$	5.08(dd) $J_{4.5}=12.5$	2.80 $J_{5.6}=12.5$	4.62(dd) $J_{1.6}=10.0$	7.29 (Ph; m), 5.60 (H_7; m), 5.2—5.0 (H_{8a}, H_{8b}; m), 4.62 ($PhCH_2O$; s), 2.08, 1.98 and 1.93 (OAc).
11	4.9—5.9 (H_1-H_4)				2.92 $J_{5.6}=10.5$	4.12 $J_{1.6}=12.5$	4.9—5.9 (H_7, H_{8a} and H_{8b}; $J_{5.7}=8.5$), 1.98 (4×OAc).

monly large *trans*-diaxial coupling constants except H_1 of **9**. Thus, the configuration of **4** and **5** was proved to be of L-*ido* type.



(**1**) R=Ac (**4**) R=Ac (**8**) R_1=Bzl, R_2=H (**7**) R_1=Bzl, R_2=Ac, R_3=Et
(**3**) R=Bzl (**5**) R=Bzl (**9**) R_1=Bzl, R_2=Ac (**10**) R_1=Bzl, R_2=R_3=Ac
(**11**) R_1=R_2=R_3=Ac



(**2**) R=OAc (**12**) (**13**) (**14**)
(**6**) R=Et

In order to deduce the conformation of nitroolefin function of **1** and **3**, 6-*C*-methyl derivative of **3** (**13**) was synthesized by a similar method to that of **3**, and also D-*gluco*-3,4,5,6,7-pentaacetoxy-1-nitro-1-heptene (**14**) from the corresponding 1-*C*-nitro-1-deoxyalditol[11] by the usual procedure.

NMR parameters of nitroolefin function of these compounds and 1-nitro-1-pentene (**15**)[12] (Table 2) showed that α-proton signals of **1** and **3** appear in the lower magnetic field than that of **14** and **15**, and $J_{\beta,\gamma}$ values in **1** and **3** are smaller than that of others. These facts indicate that the dihedral angle between H_4 and H_5 in **1** and **3** equals nearly 72° [13] in a conformation with a hydrogen-bonding between H_6 and the lactol oxygen, as shown in Fig. 1(A). While that of **13** means the angle should be larger than 140°, indicating the both protons are oriented to an almost true-*trans* as shown in (B).

TABLE 2. NMR PARAMETERS IN NITRO OLEFIN FUNCTIONS

Compound	(H_γ) (H_4)	(H_β) (H_5)	(H_α) (H_6)
1	5.05(t) $J_{4.5}=2.5$	7.10(dd) $J_{5.6}=13.0$	7.29(d)

(A) (B) (C)

Fig. 1. Conformation of nitro olefin functions.

If conformation (A) is maintained in the transition state of the Grignard reaction, vinyl group will approach to C_5 from the less-hindered down-side to give D-*gluco* type product, however, the configuration of products were L-*ido* type. Therefore, it will be concluded that the conformation in the transition state

11) J. Yoshimura and H. Ando, *Nippon Kagaku Zasshi*, **85**, 138 (1964).
12) A. I. Meyers and J. C. Sircar, *J. Org. Chem.*, **32**, 4134 (1967).
13) E. W. Garbish, *J. Amer. Chem. Soc.*, **86**, 5561 (1964).

was changed from (A) to (B) by coordination of the Grignard reagent to the nitro-oxygen, and the vinyl group attacked from less-hindered lactol-oxygen site, as shown in (C).

Experimental

All melting points are uncorrected. The solutions were evaporated under diminished pressure at a bath temperature not exceeding 45 °C. Specific rotations were measured in a 0.5-dm tube, with a Carl Zeiss photoelectric polarimeter. The IR spectra were recorded with a Hitachi Model EPI-GS spectrophotometer. The NMR spectra were taken in deuteriochloroform with a JMN-4H-100 MHz Spectrometer using tetramethylsilane as an internal standard. Chemical shifts and coupling constants were recorded in δ and Hz units, and frequencies in cm^{-1}.

5-O-Acetyl-3-O-benzyl-6-deoxy-1,2-O-isopropylidene-6-C-nitro-β-L-idofuranose (2). To a solution of 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-glucofuranose (60 g, 0.193 mol)[8] in benzene (500 ml) was added lead tetraacetate (80 g, 0.20 mol) portionwise under refluxing, filtered after cooling, and evaporated. The residual sirup was extracted with chloroform, and the extract was washed with water, dried, and evaporated to give the corresponding 5-aldehyde derivative (56 g) as a sirup. A solution of the sirup and nitromethane (40 ml, 0.65 mol) in ethanol (100 ml) was adjusted to pH 7.8—8.0 with 2M-sodium hydroxide, stood at room temperature for 5 hr, neutralized with acetic acid, and evaporated. The residual sirup was extracted with chloroform, and the extract was washed twice with water, dried, and evaporated to give sirupy mixture of 6-deoxy-6-*C*-nitro derivatives (52 g). A solution of this sirup and *p*-toluenesulfonic acid (0.5 g) in acetic anhydride (50 ml) was kept at room temperature for 3.5 hr, poured into ice-water to give semi-crystalline product in 75.1% (55 g) total yield.

Recrystallization from ethanol gave a pure isomer in 47.2% (33.2 g) yield. Mp 96—97 °C, $[\alpha]_D^{23}$ −58.2° (*c* 0.97, chloroform); IR: 1740 (ester), 1550 and 1368 (NO_2); NMR: 7.36 (Ph; s), 5.92 (H_1; d, $J_{1.2}$=3.5), 5.73 (H_5; m), 4.92 and 4.68 (H_{6a} and H_{6b}; ABq, J_{ab}=14.0, $J_{5.6a}$=3.5, $J_{5.6b}$=7.5), 4.69 and 4.51 (-CH_2-; ABq, J_{ab}=11.5), 4.62 (H_2; d), 4.40 (H_4; dd, $J_{3.4}$=3.0, $J_{4.5}$=5.0), 4.07 (H_3; d), 2.03 (OAc), 1.51 and 1.36 (2×C-CH_3).

Found: C, 56.78; H, 5.98; N, 3.48%. Calcd for $C_{18}H_{23}NO_8$: C, 56.68; H, 6.08; N, 3.67%.

3-O-Benzyl-5,6-dideoxy-1,2-O-isopropylidene-6-C-nitro-α-D-xylo-hex-5-enofuranose (3). A solution of **2** (2.0 g, 5.25 mmol) in benzene (70 ml) was refluxed in the presence of potassium carbonate (4.0 g, 28.6 mmol), filtered, and evaporated to give a sirup (1.8 g). Fractionation of the sirup on a Kieselgel column with benzene as an effluent gave the pure product as a sirup (1.14 g, 71.3%). $[\alpha]_D^{23}$ −29.1° (*c* 0.96, chloroform); IR: 1650 (C=C), 1510 and 1340 (conjugated NO_2), 735 and 691 (Ph); NMR: 7.35 (Ph; m), 7.30 (H_6; d, $J_{5.6}$=15.5), 7.13 (H_5; dd, $J_{4.5}$=2.5), 6.01 (H_1; d, $J_{1.2}$=3.5), 4.91 (H_4; t, $J_{3.4}$=2.5), 4.68 (H_2; d), 4.68 and 4.46 (CH_2; ABq, $J_{a.b}$=11.5), 4.06 (H_3; d), 1.52 and 1.37 (2×C-CH_3).

Found: C, 60.07; H, 6.08; N, 4.58%. Calcd for $C_{16}H_{19}NO_6$: C, 59.80; H, 5.96; N, 4.36%.

3-O-Benzyl-5,6-dideoxy-1,2-O-isopropylidene-6-C-nitro-5-C-vinyl-β-L-idofuranose (5). To a solution of a sirupy **3** [3.5 g, obtained from 5 g (13.1 mmol) of **2**] in THF (30 ml) was added dropwise a solution of vinyl magnesium bromide[14] in THF (30 ml) prepared from magnesium (1.25 g, 52.4 mmol) and excess amount of vinyl bromide under ice-cooling. After stirring for 1 hr at room temperature, the reaction mixture was neutralized with acetic acid (6 ml) under cooling, and extracted with chloroform. Evaporation of the extract gave a sirup (3.5 g) which was crystallized from ethanol. Yield, 41% (1.86 g); mp 103 °C; $[\alpha]_D^{23}$ −71.4° (*c* 1.23, chloroform); IR: 1640 (C=C), 1540 and 1373 (NO_2). NMR: 7.34 (Ph; s), 5.88 (H_1; d, $J_{1.2}$=3.8), 5.65 (H_7; octet, $J_{5.7}$=8.5, $J_{7.8a}$=17.5, $J_{7.8b}$=10.0), 5.18 and 5.14 ($J_{8a.8b}$=2.5), 4.66 and 4.39 (CH_2; ABq, $J_{a.b}$=10.3), 4.58 (H_2; d), 4.39 (H_6; d, $J_{5.6}$=6.0), 4.14 (H_4; dd, $J_{4.5}$=6.8), 3.84 (H_3; d, $J_{3.4}$=3.0), 3.45 (H_5; m), 1.29 and 1.46 (2×C-CH_3).

Found: C, 62.08; H, 6.79; N, 3.98%. Calcd for $C_{18}H_{23}NO_6$: C, 61.88; H, 6.64; N, 4.01%.

3-O-Acetyl-5,6-dideoxy-1,2-O-isopropylidene-6-C-nitro-5-C-vinyl-β-L-idofuranose (4). In the same manner as **5**, **1** (2.68 g, 9.85 mmol) was treated with 4 equimolar amount of vinylmagnesium bromide in THF. Fractionation of the product on a Kiesel Gel 60 column gave 0.87 g (28%) of **4** as a sirup. $[\alpha]_D^{23}$ −35.6° (*c* 0.96, chloroform); IR: 1745 (ester), 1635 (C=C), 1544 and 1381 (NO_2).

Found: C, 52.25; H, 6.49; N, 4.64%. Calcd for $C_{13}H_{19}NO_7$: C, 51.82; H, 6.36; N, 4.65%.

3-O-Benzyl-5,6-dideoxy-5-C-ethyl-1,2-O-isopropylidene-6-C-nitro-β-L-idofuranose (6). Hydrogenation of **5** (150 mg) in ethanol in the presence of palladium-charcoal (5%, 70 mg) at a room temperature showed the absorption of calculated amount of hydrogen (10.2 ml) within 6 min. Evaporation of the filtrate of the reaction mixture gave a sirup which was crystallized from petroleum ether. Mp 78—79 °C; $[\alpha]_D^{23}$ −50.5° (*c* 0.78, chloroform); IR: 1540 and 1374 (NO_2); NMR: 7.36 (Ph; s), 5.93 (H_1; d, $J_{1.2}$=4.0), 4.70 and 4.44 (CH_2; ABq, $J_{a.b}$=11.5), 4.66 (H_2; d), 4.47 and 4.23 (H_{6a} and H_{6b}; each q, $J_{6a.6b}$=12.5, $J_{5.6a}$=3.0, $J_{5.6b}$=6.0), 4.18 (H_4; q, $J_{3.4}$=3.0, $J_{4.5}$=8.0), 3.93 (H_3; d), 2.67 (H_5; m), 1.70—1.20 (H_7; m), 1.51 and 1.34 (2×C-CH_3), 0.97 (H_8; t, $J_{7.8}$=6.5).

Found: C, 61.57; H, 7.30; N, 3.79%. Calcd for $C_{18}H_{25}NO_6$: C, 61.52; H, 7.17; N, 3.99%.

2,4-Di-O-acetyl-3-O-benzyl-1-O-ethyl-(1,3,5/2,4,6)-6-nitro-5-vinylcyclohexanetetrol (7). A solution of **5** (0.35 g, 1 mmol) in 70% acetic acid (10 ml) was heated at 80—85 °C for 7.5 hr, evaporated to give a sirup. A solution of the sirup in ethanol (20 ml) adjusted to pH 8—9 with 2M potassium hydroxide was kept at room temperature for 2 days, neutralized with Amberlite IR-120, evaporated to give sirupy nitrocyclitol (0.28 g, 83%). Acid-catalyzed acetylation of the sirup gave the corresponding di-*O*-acetate in a quantitative yield, which was recrystallized from ethanol. Mp 146—147 °C; $[\alpha]_D^{23}$ −14.0° (*c* 0.96, chloroform). IR: 1743 and 1732 (ester), 1540 and 1368 (NO_2).

Found: C, 59.66; H, 6.40; N, 3.18%. Calcd for $C_{21}H_{27}NO_8$: C, 59.85; H, 6.46; N, 3.32%.

Intramolecular Cyclization of 3-O-Benzyl-5,6-dideoxy-6-C-nitro-5-C-vinyl-β-L-idofuranose in the Presence of Sodium Bicarbonate. A solution of a sirup obtained by de-isopropylidenation of **5** (1.91 g, 5.47 mmol), and sodium bicarbonate (60 mg) in methanol-water (each 30 ml) was kept at a room temperature for 11 hr, neutralized with Amberlite IR-120, and concentrated to give a semi-crystalline sirup which gave 3-*O*-benzyl-(3,5/1,2,4,6)-6-nitro-5-vinylcyclohexanetetrol (**8**) as crystals from ethanol. Yield, 0.88 g (52%); mp 168—169 °C; $[\alpha]_D^{23}$ −46.5° (*c* 0.99, methanol); IR: 3430, 3330, and 3190 (OH), 1548 and 1362 (NO_2), 734 and 700 (Ph).

Found: C, 58.27; H, 6.33; N, 4.38%. Calcd for $C_{15}H_{19}$-

14) D. Seyferth, "Organic Syntheses", Coll. Vol. IV, p. 258, (1963).

NO_6: C, 58.24; H, 6.19; N, 4.53%.

Acid-catalyzed acetylation of **8** (110 mg) gave quantitatively the corresponding tri-*O*-acetate (**9**) (160 mg) as a sirup which crystallized by standing for 1 month. Mp 95—96 °C; $[\alpha]_D^{23}$ −33.1° (*c* 1.01, chloroform); IR: 1740 (ester), 1550 and 1360 (NO_2).

Found: C, 58.35; H, 5.97; N, 3.09%. Calcd for $C_{21}H_{25}NO_9$: C, 57.92; H, 5.79; N, 3.22%.

On the other hand, evaporation of the mother liquor from **8** gave a sirup (0.52 g) which on acid-catalyzed acetylation gave 1,2,4-tri-*O*-acetyl-3-*O*-benzyl-(1,3,5/2,4,6)-6-nitro-5-vinylcyclohexanetetrol (**10**) as crystals which was recrystallized from ethanol. Yield, 0.7 g (34.2%); mp 165.5—166.5 °C; $[\alpha]_D^{23}$ −14.5° (*c* 1.83, chloroform); IR: 1740 (ester), 1545 and 1360 (NO_2).

Found: C, 57.66; H, 6.05; N, 3.10%. Calcd for $C_{21}H_{25}NO_9$: C, 57.92; H, 5.79; N, 3.22%.

1,2,3,4-Tetra-O-*acetyl-(1,3,5/2,4,6)-6-nitro-5-vinylcyclohexanetetrol (**11**).* De-isopropylidenation of **4** (0.34 g, 11.6 mmol) with 70% acetic acid gave a sirup (0.29 g). A solution of the sirup, and sodium bicarbonate (300 mg) in 50% methanol (20 ml) was kept at a room temperature for 1 day, neutralized with Amberlite IR-120, decolorized with charcoal, and evaporated to give a sirup (0.19 g). Acetylation of the sirup by the usual manner gave sirupy **11** (250 mg) which was crystallized from ether, and recrystallized from ethanol. Yield, 50 mg (11.4%); mp 169—170 °C; $[\alpha]_D^{23}$ −14.9° (*c* 0.74, chloroform).

Found: C, 49.57; H, 5.47; N, 3.69%. Calcd for $C_{16}H_{21}NO_{10}$: C, 49.26; H, 5.47; N, 3.62%.

*3-O-Benzyl-(3,5/1,2,4,6)-6-amino-5-ethylcyclohexanetetrol (**12**).* Hydrogenation of **8** (0.21 g) in ethanol in the presence of palladium-charcoal (110 mg, 5%) and a small amount of acetic acid for 1 day, and evaporation of the filtrate of the reaction mixture gave **12** as an acetate. Mp 203—204 °C; $[\alpha]_D^{32}$ −29.3° (*c* 1.27, methanol); IR: 3400 (OH), 3200 (NH_2) and 1680 (COOH).

Found: C, 59.80; H, 7.92; N, 4.02%. Calcd for $C_{17}H_{27}NO_6$: C, 59.81; H, 7.97; N, 4.10%.

*3-O-Benzyl-5,6,7-trideoxy-1,2-O-isopropylidene-6-C-nitro-α-D-xylo-hept-5-enofuranose (**13**).* A solution of 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-*xylo*-pentodialdose-(1,4), prepared from 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-glucofuranose (5.0 g, 16.1 mmol) by lead tetraacetate (8 g) oxidation, and nitroethane (10 ml) in ethanol (10 ml) was adjusted to pH 9.0 with 2M potassium hydroxide, kept at a room temperature for 17 hr, neutralized with acetic acid, and then evaporated. The residual sirup was extracted with chloroform, and the extract was washed twice with water, and evaporated to give sirupy nitro alcohol (3.7 g). Acetylation of the sirup by the usual manner gave the corresponding nitro acetate (4.5 g) as a sirup. A solution of the nitro acetate (2.1 g) in benzene was refluxed for 2.5 hr in the presence of anhydrous potassium carbonate (2.8 g), and evaporation of the filtrate of the reaction mixture gave a sirup (2.0 g). Fractionation of the sirup (1.07 g) on a Kiesel Gel 60 column (20 g) with benzene–ethyl acetate (100: 3) as an effluent gave **13** (0.69 g) as a sirup. $[\alpha]_D^{23}$ −49.4° (*c* 0.93, chloroform); IR: 1520 and 1340 (conjugated NO_2). NMR: 7.31 (Ph; s), 7.18 (H_5; d, $J_{4,5}$=7.5), 6.01 (H_1; d, $J_{1,2}$=4.0), 4.82 (H_4; dd, $J_{3,4}$=3.5), 4.67 (H_2; d), 4.68 and 4.42 (CH_2; ABq, $J_{a,b}$=12.5), 3.46 (H_3; d), 2.07 (H_7; s), 1.50 and 1.33 (2× C–CH_3).

Found: C, 60.51; H, 6.31; N, 4.46%. Calcd for $C_{17}H_{21}NO_6$: C, 60.88; H, 6.31; N, 4.18%.

D-gluco-*3,4,5,6,7-Pentaacetoxy-1-nitro-1-heptene (**14**).* Acetylation of 1-*C*-nitro-1-deoxy-D-*glycero*-D-*gulo*-heptitol[11] (0.92 g, 3.8 mmol) by the usual manner gave the corresponding hexaacetate (1.88 g) as a sirup. The benzene solution of the sirup was refluxed in the presence of anhydrous potassium carbonate for 1.5 hr, filtered, and the filtrate was evaporated to give a sirup which was crystallized from ethanol. Yield, 1.10 g (77%), mp 105—106 °C; $[\alpha]_D^{23}$ +20.1° (*c* 1.16, chloroform); IR: 3090 (olefinic C–H), 1740 (ester), 1650 (C=C), 1520 and 1357 (conjugated NO_2); NMR: 7.22 (H_2; dd, $J_{1,2}$=13.0, $J_{2,3}$=5.0), 6.97 (H_1; d), 5.62 (H_3; m), 5.45—5.20 (H_4 and H_5; m), 5.03 (H_6; m), 4.23 and 4.04 (H_{7a} and H_{7b}; $J_{a,b}$=12.5, $J_{6,7a}$=3.0, $J_{6,7b}$=5.0), 2.125, 2.08, 2.05, and 2.025 (5×OAc).

Found: C, 47.26; H, 5.33; N, 3.39%. Calcd for $C_{17}H_{23}NO_{12}$: C, 47.11; H, 5.35; N, 3.23%.

The authors are indebted to Mr. H. Matsumoto for NMR measurements, and members of Laboratory of Organic Analysis for microanalysis.

Branched-chain Sugars. IV. Synthesis of 5,6-Dideoxy-5-*C*-hydroxymethyl-1,2-*O*-isopropylidene-6-*C*-nitro-3-*O*-substituted-α-D-glucose Derivatives[1]

Juji YOSHIMURA, Takao IIDA, Hiroo WAKAI, and Masuo FUNABASHI

(Received June 22, 1973)

Addition of nitryl iodide to 5-deoxy-1,2,*O*-isopropylidene-3-*O*-methyl-5-*C*-methylene-6-*O*-substituted-α-D-*xylo*-hexofuranoses (**3** and **4**), and subsequent hydrogenation with sodium borohydride gave a mixture of the corresponding 5,6-dideoxy-5-*C*-hydroxymethyl-6-*C*-nitro derivatives of D-*gluco* and L-*ido* forms. The configuration of both isomers were determined by intramolecular cyclization into the corresponding nitrocyclohexanetetrols. The ratios of D-*gluco* to L-*ido* product were 1:2 in the case of 6-*O*-trityl derivative (**3**) and 4:5 in the case of 6-*O*-benzyl derivative (**4**), respectively.

In the previous paper,[1] addition of vinylmagnesium bromide to 5,6-dideoxy-1,2-*O*-isopropylidene-6-*C*-nitro-3-*O*-substituted-α-D-*xylo*-hex-5-enofuranoses gave exclusively the corresponding L-*ido*-type product. In order to synthesize a 5,6-dideoxy-6-*C*-nitro-5-*C*-hydroxymethyl derivative of D-*gluco* configuration, another pathway including addition of nitryl iodide[2] to 5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-5-*C*-methylene-6-*O*-substituted-α-D-*xylo*-hexofuranoses (**3** and **4**) and hydrogenation with sodium borohydride was examined, and the configuration of the product was determined to be a mixture of D-*gluco* and L-*ido* forms by intramolecular cyclization into the corresponding nitrocyclitol.

Results and Discussion

As the starting materials, 6-*O*-trityl (**1**) and 6-*O*-benzyl derivatives (**2**) of 1,2-*O*-isopropylidene-3-*O*-methyl-α-D-*xylo*-hexofuranos-5-ulose were synthesized by dimethyl sulfoxide oxidation of the corresponding 5-hydroxy derivatives,[3,4] respectively. Treatment of **1** and **2** with triphenylphosphonium methylide gave the corresponding 5-*C*-methylene derivatives (**3** and **4**) in 50 and 85% yield, respectively. Addition of nitryl iodide, prepared from silver nitrite and iodine, to **3** and **4** in ether in the dark place gave the corresponding addition product as crystals (**5**) and a sirup (**6**) in good yields, respectively. The homogeneity of **5** was deduced from the presence of the single methoxy signal in the NMR spectrum, however, the configuration at C_5-position could not be determined because of its instability. **6** was deduced to be a mixture of C_5-epimers and a small amount of unchanged **4**, and was used without further purification. Attempted elimination of **5** and **6** into the corresponding nitro olefin by use of potassium carbonate or 1,5-diazabicyclo-[5.4.0]undec-5-ene were unsuccessful. Hydrogenation of **5** and **6** in ethanol–tetrahydrofuran with sodium borohydride at 0 °C gave the corresponding 5,6-dideoxy-5-*C*-hydroxymethyl-6-*C*-nitro derivatives (**7** and **8**) in 55 and 79% yield, respectively. Both the compounds showed two kinds of methoxy proton signals in NMR spectra, indicating they are a mixture of C_5-epimers in the ratios of 1 to 2 and of 2 to 3, respectively. For resolution and assignment of both the epimers, **7** and **8** were de-*O*-isopropylidenated by treatment with 70% acetic acid at 90 °C for 10 hr under monitering with tlc, and cyclized intramolecularly without further purification. In the case of **8**, cyclization in ethanol at pH 9 for 40 hr at 30 °C, neutralization with Amberlite IR-120, and purification of the product on silica-gel column with benzene–ethyl acetate (2:3) gave the corresponding nitrocyclitols in 30% yield, which on acetylation gave 1-*O*-ethyl-3-*O*-methyl-(3,6/1,2,4,5)-5-benzyloxymethyl-6-nitrocyclohexanetetrol (**9**)[5] as crystals. When the cyclization was accomplished in 50% aqueous methanol in the presence of sodium bicarbonate at 30 °C for 3 days and the reaction mixture was then treated as above, two kinds of sirupy nitrocyclohexanetetrol were obtained in 31 and 21% yield, which upon acetylation gave 1,2,4-tri-*O*-acetyl-3-*O*-methyl-(3,6/1,2,4,5)-5-benzyloxymethyl-6-nitrocyclohexanetetrol (**10**)[5] and its (1,3,5/2,4,6)-diastereoisomer (**11**) as crystals. The ratio of the both

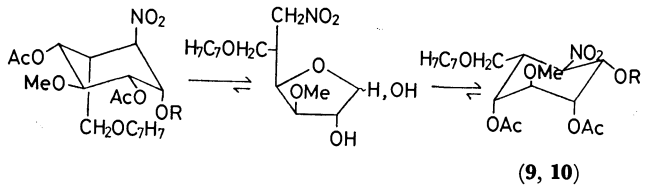
10	5.59(dd) $J_{1,2}=3.5$	5.50 $J_{2,3}=3.5$	3.7—3.3 $J_{3,4}=3.0$	5.27(m) $J_{4,5}=3.0$	2.92(m) $J_{5,6}=11.5$	4.45(t) $J_{1,6}=11.5$	7.27 (Ph), 4.47 and 4.27 ($PhCH_2O$; ABq, $J=12.0$), 3.48 (OMe), 3.7—3.3 ($C-CH_2O$; m), 2.02, 1.93 and 1.88 (OAc)
11	5.54(dd) $J_{1,2}=10.0$	5.05(dd) $J_{2,3}=9.5$	3.55 $J_{3,4}=9.0$	5.19(dd) $J_{4,5}=11.0$	2.39(tm) $J_{5,6}=10.5$	4.89(t) $J_{1,6}=10.5$	7.28 (Ph), 4.38 ($PhCH_2O$; s), 3.40 (OMe), 3.55—3.07 ($C-CH_2O$; m), 2.02 and 1.95 (OAc)
13	5.55(t) $J_{1,2}=10.0$	5.06(dd) $J_{2,3}=9.0$	3.46(t) $J_{3,4}=9.0$	5.09(t) $J_{4,5}=9.0$	2.55(tm) $J_{5,6}=11.5$	4.28(dd) $J_{1,6}=10.0$	4.22 and 3.72 ($C-CH_2O$; each q, $J_{5'a,5'b}=12.5$, $J_{5'a,5}=3.5$, $J_{5'b,5}=2.5$), 3.43(OMe), 2.10, 2.05 and 1.98(OAc)

epimers in the original crude nitrocyclitol was again estimated to be 4: 5 from the intensities of H_5 proton signals (δ 2.92 and 2.39) of the corresponding acetate. The main product **11** indicates that the L-*ido* form was predominant in **8**. In the case of **7**, a similar cyclization gave 3-*O*-methyl-(1,3,5/2,4,6)-5-hydroxymethyl-6-nitrocyclohexanetetrol (**12**)[5] as crystals in 37% yield, which on acetylation gave the corresponding tetra-*O*-acetate (**13**). The ratio of the expectable isomers in the crude nitrocyclitol estimated by the similar way as above (δ 2.92 and 2.55) was 1: 2, indicating again L-*ido* form was predominant in **7**, but the minor isomer could not be isolated in a pure state.

Configurations of **9**, **10**, **11**, and **13** predicted above were determined from the NMR parameters shown in Table 1, which were analyzed by double resonance technique. The proton signals at the branched point were distinguished by its multi-splittings and higher resonating magnetic field than others. Other ring protons appeared in a lower field in the order of alkoxy, nitro and acetoxy positions. The large *trans*-diaxial coupling constants in **11** and **13** indicate that the all substituents are in equatorial conformation, while small *gauche* coupling in H_2–H_4 of **9** and **10** indicate that substituents at these position are in axial conformation. As shown in Fig. 1, this conformation would be caused by the preferential adoption of the nitro group[6] and benzyloxymethyl group into an equatorial orientation.



(**9**, **10**)

Fig. 1. Conformation of (3,6/1,2,4,5)-type isomers

Experimental

All melting points are uncorrected. The solutions were evaporated under diminished pressure at a bath temperature not exceeding 45 °C. Specific rotations were measured in a 0.5-dm tube, with a Carl Zeiss photoelectric polarimeter. The IR spectra were recorded with a Hitachi Model EPI-GS spectrophotometer. The NMR spectra were taken in deuteriochloroform with a JMN-4H-100 MHz Spectrometer using tetramethylsilane as an internal standard. Chemical shifts and coupling constants were recorded in δ and Hz units, and frequencies in cm^{-1}.

1,2-O-Isopropylidene-3-O-methyl-6-O-trityl-α-D-xylo-hexofuranos-5-ulose (1). A solution of 1,2-*O*-isopropylidene-3-*O*-methyl-6-*O*-trityl-α-D-glucofuranose (41.5 g) in dimethyl sulfoxide (200 ml) and acetic anhydride (70 ml) was stood at room temperature for 21 hr, poured into ice-water (5 l) with stirring. The gummy precipitate was separated from the water layer by decantation, and dissolved in benzene. The benzene solution was washed with saturated sodium bicarbonate solution and water, and evaporated to give crystals which were recrystallized from ligroin. Yield, 17.5 g (45%), mp 146—147 °C, $[\alpha]_D^{23}$ −41° (*c* 0.5, $CHCl_3$). IR: 1740 (C=O), NMR: 7.5—7.1 (Ph_3C-; m), 5.87 (H_1; d, $J_{1,2}=3.5$), 4.85 (H_4; d, $J_{3,4}=3.5$), 4.47 (H_2; d), 4.09 (H_3; d), 4.01 (H_6; s), 3.18 (OCH_3), 1.46 and 1.28 ($2\times C-CH_3$).

6-O-Benzyl-1,2-O-isopropylidene-3-O-methyl-α-D-xylo-hexofuranos-5-ulose (2). A solution of 6-*O*-benzyl-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-glucofuranose (3.0 g, 9.35 mmol) in dimethyl sulfoxide (50 ml) and acetic anhydride (10 ml) was kept at room temperature for 1 day, poured into ice-water (500 ml), and extracted with chloroform. The extract was washed with saturated sodium bicarbonate solution and water, evaporated, and the sirup obtained was fractionated on a silicagel (Wakogel C-200) column with benzene–methanol (50: 1) to give a pure sirup (1.5 g, 50%). $[\alpha]_D^{23}$ −73° (*c* 0.5, $CHCl_3$). IR: 1728 (C=O); NMR: 7.32 (Ph; m), 5.96 (H_1; d, $J_{1,2}=3.0$), 4.71 (H_4; d, $J_{3,4}=3.5$), 4.55 (H_6; s), 4.51 (H_2; d), 4.35 ($-CH_2-$; s), 4.06 (H_3; d), 3.28 (OCH_3), 1.42 and 1.28 ($2\times C-CH_3$).

Found: C, 62.53; H, 6.72%. Calcd for $C_{17}H_{22}O_6$: C, 63.34; H, 6.88%.

5-Deoxy-1,2-O-isopropylidene-3-O-methyl-5-C-methylene-6-O-trityl-α-D-xylo-hexofuranose (3). To a suspended solution of triphenylmethylphosphonium bromide (28.2 g, 77.6 mmol) in tetrahydrofuran (400 ml) was added dropwise *n*-butyllithium in *n*-hexane (41.4 ml of 15% solution, 97 mmol) with stirring at 0 °C, and after 10 min was further added a solution of **1** (18.4 g, 38.8 mmol) in tetrahydrofuran (60 ml). The resulted solution was stirred for 1 hr, filtered, and evaporated. The resulted sirup was extracted with *n*-hexane, and

*6-O-Benzyl-5-deoxy-1,2-O-isopropylidene-3-O-methyl-5-C-methylene-α-*D-xylo-*hexofuranose (4).* Compound **3** (3.45 g, 10.7 mmol) was treated with triphenylmethylphosphonium bromide (7.6 g, 21.4 mmol) and *n*-butyllithium (26.7 mmol) as above to give a sirupy product in 85% (3 g) yield. $[\alpha]_D^{23}$ −57° (*c* 0.5, $CHCl_3$). IR: 1640 (C=C).

Found: C, 67.05; H, 7.95%. Calcd for $C_{18}H_{24}O_5$: C, 67.48; H, 7.55%.

*5,6-Dideoxy-5-iodo-1,2-O-isopropylidene-3-O-methyl-6-C-nitro-5-C-trityloxymethyl-α-*D-xylo-*hexofuranose (5).* To a suspended solution of iodine (5.30 g, 21.0 mmol) and silver nitrite (2.66 g, 17.2 mmol) in ether (500 ml) under stirring at 0 °C in the dark state, was added a solution of **3** (0.7 g, 14.8 mmol) in ether, and after stirring 1 day at room temperature the reaction mixture was filtered and evaporated. The resulted sirup was extracted with chloroform, and the extract was washed with sodium thiosulfate solution and water, dried, and evaporated to give a sirup (6.7 g, 70%) which was crystallized from benzene–*n*-hexane. Mp 171—172 °C, $[\alpha]_D^{23}$ −8° (*c* 0.5, $CHCl_3$). IR: 1540 and 1370 (NO_2); NMR: 7.63—7.20 (Ph_3C), 5.83 (H_1; d, $J_{1,2}$=3.5), 4.95 and 4.81 (H_{6a} and H_{6b}; ABq, $J_{a,b}$=13.0), 4.88 (H_4; d, $J_{3,4}$=3.0), 4.37 (H_2; d), 3.97 and 3.27 ($H_{5'a}$ and $H_{5'b}$; ABq, $J_{a,b}$=10.0), 3.47 (H_3; d), 2.81 (OCH_3), 1.55 and 1.30 (2×C-CH_3).

Found: C, 55.90; H, 5.02; N, 2.26%. Calcd for $C_{30}H_{32}NO_7I$: C, 55.82; H, 5.00; N, 2.17%.

*5,6-Dideoxy-1,2-O-isopropylidene-3-O-methyl-6-C-nitro-5-C-trityloxymethyl-α-*D-gluco- *and β-*L-ido-*furanose (7).* To a solution of **5** (6.0 g, 9.1 mmol) in tetrahydrofuran (90 ml) and ethanol (800 ml) was added portionwise sodium borohydride (2.46 g) at 0 °C, and after stirring for 1 day a small amount of water was added to decompose the hydride. The reaction mixture was then evaporated, the resulted residue was extracted with chloroform, and the extract was washed with water, dried, and evaporated to give a sirup which was crystallized from benzene–ethanol. Yield, 2.4 g (55%), mp 152—153 °C, $[\alpha]_D^{23}$ −46° (*c* 0.5, $CHCl_3$). IR: 1540 and 1365 (NO_2).

Found: C, 69.53; H, 6.46; N, 2.76%. Calcd for $C_{30}H_{33}NO_7$: C, 69.35; H, 6.39; N, 2.70%.

NMR spectrum of this crystal showed still two methyl proton signals (δ 3.17 and 2.99) in the intensity ratio 1:2.

*5-C-Benzyloxymethyl-5,6-dideoxy-1,2-O-isopropylidene-3-O-methyl-6-C-nitro-α-*D-gluco- *and β-*L-ido-*furanose (8).* Compound **4** (2.67 g, 0.34 mmol) was treated with nitryl iodide prepared from iodine (2.93 g, 11.5 mmol) and silver nitrite (1.49 g, 9.6 mmol) by a similar manner as in the case of **5**. NMR spectrum of the sirupy product (3.36 g, 85%) showed three kinds of methoxy proton signals (δ 3.14, 3.23, and 3.43), indicating the presence of C_5-epimers and a small amount of **4**. This sirup (3.3 g, 6.8 mmol) was hydrogenated with sodium borohydride (7 equimolar amount) to give a sirupy product which was purified with silica-gel column. Yield, 2.0 g, (79%), $[\alpha]_D^{23}$ −50° (*c* 0.5, $CHCl_3$). IR: 1540 and 1370 (NO_2).

Found: C, 59.86; H, 7.27; N, 3.50%. Calcd for $C_{18}H_{25}NO_7$: C, 58.84; H, 6.86; N, 3.81%.

NMR spectrum of this product showed two kinds of methoxy proton signals (δ 3.25 and 3.28) in the intensity ratio of 2:3, indicating the presence of C_5-epimers.

2,4-Di-O-acetyl-1-O-ethyl-3-O-methyl-(3,6/1,2,4,5)-5-benzyloxymethyl-6-nitrocyclohexanetetrol (9). A solution of **8** (300 mg, 0.82 mmol) in acetic acid (70%, 20 ml) was heated at 90 °C for 10 hr, and evaporated to give the de-*O*-isopropylidenated product as a sirup (260 mg). The pH of a solution of this sirup in ethanol (20 ml) was adjusted to 8.5—9 with 2M potassium hydroxide, stood for 40 hr at 30 °C, neutralized with Amberlite IR-120, evaporated to give a sirup which was fractionated on a silica-gel column (Wakogel C-200), using benzene–ethyl acetate as effluent. The purified sirupy nitrocyclitol (90 mg, 35%) was acetylated with acetic anhydride in the presence of *p*-toluenesulfonic acid as a catalyst to give **9** (70 mg, 70%). Mp 123—124 °C, $[\alpha]_D^{23}$ +45° (*c* 0.5, $CHCl_3$). IR: 1740 and 1720 (ester), 1540 and 1370 (NO_2).

11; mp 155—156 °C, $[\alpha]_D^{23}$ +29° (*c* 0.5, $CHCl_3$). IR: 1730 (ester), 1550 and 1360 (NO_2).

Found: C, 55.82; H, 5.98; N, 3.19%. Calcd for $C_{21}H_{27}NO_{10}$: C, 55.62; H, 6.00; N, 3.09%.

3-O-Methyl-(1,3,5/2,4,6)-5-hydroxymethyl-6-nitrocyclohexanetriol (12) and Its Tetra-O-acetate (13). A solution of *7* (1.0 g, 1.92 mmol) in 70% acetic acid (40 ml) was heated at 90 °C for 10 hr, evaporated, and the sirup obtained was redissolved in water and extracted three times with benzene. Evaporation of the water layer gave the hydrolyzed product (450 mg) as a sirup. A solution of this sirup (300 mg, 1.27 mmol) and sodium bicarbonate (106 mg, 1.26 mmol) in aqueous methanol (50%, 12 ml) was kept at 30 °C for 3 days, neutralized with Amberlite IR-120, and evaporated to give a sirup. Fractionation of this sirup on a silica-gel column with benzene–ethyl acetate gave crystalline **12**, which was recrystallized from ethanol. Yield, 110 mg (37%), mp 119—120 °C, $[\alpha]_D^{23}$ −17° (*c* 0.2, water). IR: 3540 and 3350 (OH), 1530 and 1365 (NO_2).

Found: C, 38.35; H, 6.42; N, 5.57%. Calcd for $C_8H_{15}NO_7 \cdot 1/2\ H_2O$: C, 39.02; H, 6.55; N, 5.69%.

Acid-catalyzed acetylation of **12** gave the corresponding tetra-*O*-acetate in 40% yield. Mp 166—167 °C, $[\alpha]_D^{23}$ −4° (*c* 0.5, $CHCl_3$). IR: 1730 (ester), 1544 and 1360 (NO_2).

Found: C, 47.54; H, 5.84; N, 3.36%. Calcd for $C_{16}H_{23}NO_{11}$: C, 47.41; H, 5.72; N, 3.46%.

The authors arei ndebted to Mr. H. Matsumoto for NMR measurements, and members of Laboratory of Organic Analysis for microanalyses.

Studies on Aminosugars. XXXVI. Syntheses of 3′,4′-Dideoxy- and 3′,4′,5″-Trideoxyribostamycin[1]

Daishiro IKEDA,* Toshihisa SUZUKI,* Tsutomu TSUCHIYA,* Sumio UMEZAWA,* and Hamao UMEZAWA**

(Received July 9, 1973)

3′,4′-Dideoxyribostamycin and 3′,4′,5″-trideoxyribostamycin have been prepared from ribostamycin *via* 3′,4′-unsaturation and 5″-iodo-3′,4′-unsaturation intermediates, respectively.

As described in previous papers, the 3′-deoxy[2,3] and 3′,4′-dideoxy[4,5] derivatives of kanamycins and neamine have been found to exhibit strong antibiotic activity against resistant bacteria carrying R factor and *Pseudomonas aeruginsoa*. The syntheses of these deoxy compounds were designed on the basis of mechanism of resistance[6] in resistant bacteria and as an extension of these works, we have now synthesized deoxyderivatives of another aminoglycoside antibiotic, ribostamycin,[7] which undergoes 3′-phosphorylation by the same enzymes,[8] kanamycin phosphotransferases I and II of resistant bacteria.

In order to protect the four amino groups, ribostamycin were treated with benzyl chloroformate in aqueous methanol in the presence of sodium carbonate to give tetra-*N*-benzyloxycarbonylribostamycin (**1**). The compound **1** was allowed to react with 1,1-dimethoxycyclohexane in dimethyl formamide (DMF) in the presence of catalytic amount of *p*-toluenesulfonic acid at 50 °C under diminished pressure. As described by Bissett, Evans, and Parrish,[9] the reaction under diminished pressure effectively removed the methanol which was liberated and the reaction was completed within 2 hr to give a tricyclohexylidene derivative (**2**), in a yield of 60%, in which one of the cyclohexylidene groups presented in a 1-methoxycyclohexyl form. The presence of the hemiketal group was confirmed by the observation of methoxyl group at τ 6.83 in the NMR spectrum. Acetylation of **2** gave the 6-*O*-acetyl derivative (**3**). Selective removal of the 5″-*O*-protecting group was achieved by treatment with acetone–40% acetic acid (4: 1) at room temperature to give a di-*O*-cyclohexylidene derivative (**4**) in a yield of 82%. Further acetylation gave the 5″,6-di-*O*-acetyl derivative (**5**). The cyclohexylidene group attached to the *trans* hydroxyl groups at 3′ and 4′ was selectively removed

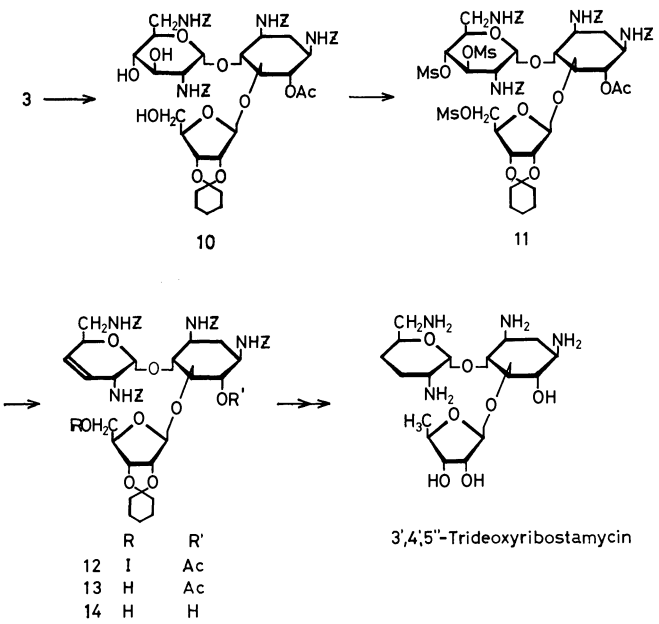
by treatment with hot acetone–60% acetic acid (1:1) to give the di-*O*-acetyl-mono-*O*-cyclohexylidene derivative (**6**) in a yield of 94%. Mesylation of **6** gave the 3′,4′-di-*O*-mesyl derivative (**7**). Subsequent 3′,4′-unsaturation was carried out by sodium iodide-zinc dust method reported by Tipson and Cohen[10] and Horton *et al.*[11] to give the 3′-eno derivative (**8**), which was obtained in a fairly good yield as expected from our works[12] on 3,4-unsaturated sugars. Treatment of **8** with methanolic ammonia gave the deacetylated derivative (**9**), which was then catalytically hydrogenated and decyclohexylidenated to give 3′,4′-dideoxyribostamycin in a yield of 54% from **8**.

On the other hand, the above-mentioned compound **3** was led to 3′,4′,5″-trideoxyribostamycin. Treatment of **3** with hot acetone–aqueous acetic acid gave the mono-*O*-cyclohexylidene derivative (**10**), which was then mesylated to give 3′,4′,5″-tri-*O*-mesyl derivative (**11**). Treatment of **11** with sodium iodide and zinc dust in DMF afforded the unsaturated iodo derivative **12**, namely, 6-*O*-acetyl-tetra-*N*-benzyloxycarbonyl-2″, 3″-*O*-cyclohexylidene-3′,4′-dideoxy-3′-eno-5″-iodoribostamycin (**12**) in a yield of 73%. Reduction of the iodo compound with Raney nickel and hydrogen in the presence of triethylamine gave the unsaturated 5″-deoxy derivative (**13**). Removal of the acetyl group by treatment with methanolic ammonia gave **14**, which was then catalytically hydrogenated with palladium black and hydrolyzed with acid to give the final product, 3′,4′,5″-trideoxyribostamycin.

The semisynthetic 3′,4′-dideoxyribostamycin showed[1] antibacterial activity similar to the parent ribostamycin against most of bacteria and, moreover, activity against *E. coli* carrying R factor of kanamycin phosphotransferase II and *Pseudomonas aeruginosa* resistant to ribostamycin. On the other hand, 3′,4′,5″-trideoxyribostamycin was found[1] to be less active than the parent antibiotic, indicating the involvement of the 5″-hydroxyl in antibacterial activity.



Experimental

Thin layer chromatography (tlc) was carried out on silica gel and the spots were visualized with sulfuric acid. Paper chromatography was performed on Toyo-Roshi paper No. 50 and the spots were detected with 0.5% ninhydrin in pyridine.

1,2′,3,6′-Tetra-N-*benzyloxycarbonylribostamycin (1).* To a mixture of ribostamycin sulfate (10 g, as ribostamycin·1.3 H_2SO_4) and anhydrous sodium carbonate (9 g) in 75% aqueous methanol (300 ml), benzyl chloroformate (15 g) was added under stirring at 5 °C and stirring was continued for 1 hr at that temperature. On tlc with benzene–methanol (4: 1), a spot (R_f 0.48) appeared. The reaction mixture was evaporated to dryness. The residue was extracted with hot acetone (100 ml × 3). Evaporation of the solution gave a solid, 15.3 g.

Found: C, 58.29; H, 5.80; N, 5.37%. Calcd for $C_{44}H_{58}N_4O_{18}\cdot H_2O$: C, 58.33; H, 5.99; N, 5.55%.

1,2′,3,6′-Tetra-N-*benzyloxycarbonyl-3′,4′;2″,3″-di*-O-*cyclohexylidene-5″*-O-*(1-methoxycyclohexyl)ribostamycin (2).* To a solution of **1** (2.76 g) and anhydrous *p*-toluenesulfonic acid (100 mg) in dry DMF (40 ml), 1,1-dimethoxycyclohexane (5.5 ml) was added and the solution was heated at 50 °C for 2 hr under reduced pressure (30—35 Torr). On tlc with benzene–diisopropyl ether (5: 1) a spot (**2**, R_f 0.49) accompanied by spots of R_f 0.90 and 0.59, appeared, but the spot for the starting material (R_f 0) was still strong. Therefore another 1,1-dimethoxycyclohexane (6 ml) and anhydrous *p*-toluenesulfonic acid (15 mg) were added and the solution was again heated at 50 °C under the reduced pressure for 2 hr. After addition of sodium hydrogen carbonate solution, the mixture was evaporated to dryness and the residue was extracted with acetone. Evaporation of the acetone solution gave a solid, which was chromatographed on a column of silica gel (240 g) with benzene–ethyl acetate (7: 2) containing triethylamine (0.5%). The portion containing **2** was evaporated to give a residue, which was reprecipitated from benzene–*n*-hexane yielding 1.93 g (60%), mp 92—94 °C, $[\alpha]_D^{17}$ +16.2° (*c* 2, $CHCl_3$).

Found: C, 64.39; H, 6.80; N, 4.58%. Calcd for $C_{68}H_{86}N_4O_{19}$: C, 64.65; H, 6.86; N, 4.43%.

NMR (in $CDCl_3$): τ 8.8—8.1 (30H broadened signals, cyclohexylidene protons), 6.83 (3H, s, $OC\underline{H}_3$), 2.65 (20H, $CO_2CH_2C_6\underline{H}_5$).

6-O-Acetyl-1,2′,3,6′-tetra-N-*benzyloxycarbonyl-3′,4′;2″,3″-di*-O-*cyclohexylidene-5″*-O-*(1-methoxycyclohexyl)ribostamycin (3).* To a solution of **2** (1.65 g) in dry pyridine (33 ml), acetic anhydride (1.96 g) was added and the solution was allowed to stand overnight at 37 °C. On tlc with benzene–ethyl acetate (7: 2) a spot (R_f 0.42) appeared. After addition of a small amount of methanol followed by standing for 1 hr, the solution was evaporated and the residue was dissolved in chloroform. The solution was washed with saturated sodium hydrogen carbonate solution and water, dried over sodium sulfate and evaporated to give a colorless solid. Reprecipitation from benzene–*n*-hexane yielded 1.60 g (95%), mp 95—97 °C, $[\alpha]_D^{17}$ +8.3° (*c* 1, $CHCl_3$).

Found: C, 64.39; H, 6.86; N, 4.43%. Calcd for $C_{70}H_{88}N_4O_{20}$: C, 64.40; H, 6.80; N, 4.29%.

NMR (in $CDCl_3$): τ 8.8—8.2 (30H broadened signals), 7.94 (3H, s, OAc), 6.85 (3H, s, $OC\underline{H}_3$), 2.65 and 2.63 (20H in total, $CO_2CH_2C_6\underline{H}_5$).

6-O-Acetyl-1,2',3,6'-tetra-N-benzyloxycarbonyl-3',4';2'',3''-di-O-cyclohexylideneribostamycin (4). A solution of **3** (450 mg) in acetone–40% acetic acid (4:1, 5 ml) was allowed to stand at room temperature for 3 hr. On tlc with benzene–ethyl acetate (5:2) a spot (**4**, R_f 0.22) accompanied by a minor spot (**10**, R_f 0) appeared. The solution was poured into a mixture of chloroform and saturated sodium hydrogen carbonate solution under stirring. The chloroform solution separated was washed with water, dried over sodium sulfate and evaporated. The syrup (430 mg) was chromatographed on a column of silica gel (22 g) with the same solvent system. The portion containing **4** was evaporated to give a solid (330 mg, 82%), mp 109—111 °C, $[\alpha]_D^{17}$ +18° (*c* 2, $CHCl_3$).

Found: C, 63.62; H, 6.32; N, 4.88%. Calcd for $C_{63}H_{76}N_4O_{18}$: C, 63.41; H, 6.42; N, 4.70%.

NMR (in $CDCl_3$): τ 8.8—8.2 (20H broadened signals, cyclohexylidene protons), 7.97 (3H, s, OAc), 2.72 and 2.68 (5H and 15H, s, respectively, $CO_2CH_2C_6\underline{H}_5$).

5'',6-Di-O-acetyl-1,2',3,6'-tetra-N-benzyloxycarbonyl-3',4';2'',3''-di-O-cyclohexylideneribostamycin (5). To a solution of **4** (200 mg) in pyridine (4 ml), acetic anhydride (27.4 mg) was added and the solution was allowed to stand at room temperature overnight. On tlc with benzene–ethyl acetate (5:2) a spot (R_f 0.37) appeared. The solution was poured into ice water with stirring. The resulting precipitate was filtered, washed with water and dried to give a solid, 200 mg (97%), which was reprecipitated from benzene–*n*-hexane, mp 95—98 °C, $[\alpha]_D^{17}$ +22° (*c* 0.67, $CHCl_3$).

Found: C, 63.06; H, 6.16; N, 4.64%. Calcd for $C_{65}H_{78}N_4O_{20}$: C, 63.19; H, 6.37; N, 4.54%.

NMR (in $CDCl_3$): τ 8.8—8.2 (20H broadened signals) 7.99 and 7.97 (both 3H, s, OAc), 2.69 and 2.66 (5H and 15H, s, respectively, $CO_2CH_2C_6\underline{H}_5$).

5'',6-Di-O-acetyl-1,2',3,6'-tetra-N-benzyloxycarbonyl-2'',3''-O-cyclohexylideneribostamycin (6). A solution of **5** (200 mg) in acetone–60% acetic acid (1:1, 7 ml) was heated at 50 °C for 1 hr. A single product (R_f 0.14 on tlc with benzene–ethyl acetate (3:2)) appeared. The solution was evaporated with toluene to give a solid, which was dissolved in chloroform. The solution was washed with saturated sodium hydrogen carbonate solution and water, dried over sodium sulfate and evaporated to give a solid. Reprecipitation from benzene–*n*-hexane yielded 175 mg (94%), mp 102—105 °C, $[\alpha]_D^{17}$ +7.7° (*c* 1.8, $CHCl_3$).

Found: C, 61.22; H, 5.95; N, 4.89%. Calcd for $C_{59}H_{70}N_4O_{20}$: C, 61.34; H, 6.11; N, 4.85%.

NMR (in $CDCl_3$): τ 8.9—8.2 (10H broadened signals, cyclohexylidene protons), 8.00 (6H, s, OAc), 2.73 and 2.70 (5H and 15H, s, respectively, $CO_2CH_2C_6\underline{H}_5$).

5'',6-Di-O-acetyl-1,2',3,6'-tetra-N-benzyloxycarbonyl-2'',3''-O-cyclohexylidene-3',4'-di-O-mesylribostamycin (7). To a solution of **6** (280 mg) in pyridine (5 ml), methanesulfonyl chloride (110 mg) was added and the solution was allowed to stand at room temperature overnight. After addition of a small amount of water, the solution was evaporated and the residue was dissolved in chloroform. The solution was washed successively with saturated potassium hydrogen sulfate solution, saturated sodium hydrogen carbonate solution and water, dried over sodium sulfate and evaporated to give a glassy solid, which was reprecipitated from benzene–*n*-hexane to give a solid, 279 mg (88%), mp 109—114 °C, $[\alpha]_D^{17}$ −4.7° (*c* 1.1, $CHCl_3$).

Found: C, 56.16; H, 5.61; N, 4.35; S, 4.58%. Calcd for $C_{61}H_{74}N_4O_{24}S_2$: C, 55.86; H, 5.69; N, 4.27; S, 4.89%.

NMR (in $CDCl_3$): τ 8.8—8.2 (10H), 7.93 (6H, s, OAc), 7.18 and 6.92 (both 3H, s, SO_2CH_3), 2.65, 2.62 and 2.59 (5H, 5H and 10H, s, respectively, $CO_2CH_2C_6\underline{H}_5$).

5'',6-Di-O-acetyl-1,2',3,6'-tetra-N-benzyloxycarbonyl-2'',3''-O-cyclohexylidene-3',4'-dideoxy-3'-eno-ribostamycin (8). To a solution of **7** (270 mg) in dry DMF (6 ml), anhydrous sodium iodide (3.0 g) and zinc dust (1.5 g) were added and the mixture was heated in an oil bath (91 °C) for 1 hr under vigorous stirring. Chloroform (30 ml) was added and the reaction mixture was filtered to remove the insoluble matters, which were washed with chloroform. The filtrate and the washings combined were washed successively with saturated sodium chloride solution, sodium thiosulfate solution and with water, dried over sodium sulfate and evaporated to give a yellow syrup (214 mg). On tlc with benzene–ethyl acetate (5:2), the syrup showed two spots of R_f 0.34 (**8**) and 0 (minor). The syrup was chromatographed on a column of silica gel (6 g) with benzene–ethyl acetate (5:2). The eulate containing **8** was evaporated to give a colorless solid, 156 mg (70%), mp 82—85 °C, $[\alpha]_D^{20}$ −30° (*c* 2, $CHCl_3$).

Found: C, 63.44; H, 6.02; N, 4.83%. Calcd for $C_{59}H_{68}N_4O_{18}$: C, 63.20; H, 6.11; N, 5.00%.

NMR (in $CDCl_3$): τ 8.8—8.2 (10H), 8.00 (6H, s, OAc), 4.42 (2H slightly broadened singlet, H-3',4'), 2.75, 2.71, 2.69, and 2.67 (each 5H, s, $CO_2CH_2C_6\underline{H}_5$).

1,2',3,6'-Tetra-N-benzyloxycarbonyl-2'',3''-O-cyclohexylidene-3',4'-dideoxy-3'-eno-ribostamycin (9). A solution of **8** (130 mg) in 10% ammonia in methanol (3 ml) was allowed to stand at room temperature overnight. The solution was evaporated and the residue was dissolved in benzene-ethyl acetate (1:1). The solution was passed through a short column of silica gel and the eluate containing **8** was evaporated to give a solid, 118 mg (98%), mp 89—93 °C, $[\alpha]_D^{21}$ −10° (*c* 2, $CHCl_3$).

Found: C, 64.05; H, 6.31; N, 5.24%. Calcd for $C_{55}H_{64}N_4O_{16}$: C, 63.69; H, 6.22; N, 5.40%.

NMR (in $CDCl_3$): τ 8.8—8.2 (10H), 4.45 (2H, slightly broadened singlet, H-3',4'), 2.75 and 2.72 (5H and 15H, s, respectively, $CO_2CH_2C_6\underline{H}_5$).

3',4'-Dideoxyribostamycin. A solution of **9** (50 mg) in aqueous dioxane (1:1, 2 ml) was hydrogenated with palladium black and hydrogen (50 psi) at 40 °C for 18 hr. The reaction mixture was filtered and the filtrate was evaporated to dryness. The residue was dissolved in 1M hydrochloric acid (0.5 ml) and the solution was heated at 60 °C for 1 hr. Addition of acetone gave a solid. The solid was charged on a column of CM Sephadex C-25 (NH_4^+) and, after washing the column with water (80 ml), it was developed with 0.01—0.4M ammonia with gradual increase in concentration. The product was eluted at the concentration of 0.3M ammonia. The portion was evaporated to give a solid, 11 mg (52%), mp 155—156 °C (decomp.), $[\alpha]_D^{20}$ +35° (*c* 1, H_2O). On paper chromatography with *n*-butanol–pyridine–water–acetic acid (6:4:3:1), it gave $R_{f\ \text{ribostamycin}}$ 1.50.

Found: C, 46.10; H, 8.38; N, 12.53%. Calcd for $C_{17}H_{34}N_4O_8\cdot H_2O$: C, 46.35; H, 8.24; N, 12.72%.

NMR (in D_2O): τ 9.0—7.7 (6H, m, H-2,3',4'), 4.65 (1H slightly broadened doublet, $J\sim1$ Hz, H-1''), 4.52 (1H, m, H-1').

On hydrolysis with 1M hydrochloric acid at 60 °C overnight, the product (R_f 0.40) gave 3',4'-dideoxyneamine[5] (R_f 0.56 on tlc with chloroform–methanol–17% ammonia (1:4:3)).

6-O-Acetyl-1,2',3,6'-tetra-N-benzyloxycarbonyl-2'',3''-O-cyclohexylideneribostamycin (10). Compound **3** (966 mg) was treated in a similar manner as described in the preparation of **6** from **5**. The solid obtained was reprecipitated from benzene–*n*-hexane yielding 808 mg (98%), mp 104—107 °C, $[\alpha]_D^{14}$ +1.3° (*c* 0.78, $CHCl_3$).

Found: C, 61.34; H, 5.80; N, 5.18%. Calcd for $C_{57}H_{68}N_4O_{19}$: C, 61.50; H, 6.16; N, 5.03%.

NMR (in $CDCl_3$): τ 8.9—8.2 (10H), 8.00 (3H, s, OAc), 2.73, 2.70 and 2.69 (5H, 10H and 5H, s, respectively, $CO_2CH_2C_6\underline{H}_5$).

6-O-Acetyl-1,2′,3,6′-tetra-N-benzyloxycarbonyl-2″,3″-O-cyclohexylidene-3′,4′,5″-tri-O-methanesulfonylribostamycin (11). Compound **10** (737 mg) was treated with methanesulfonyl chloride (465 mg) in pyridine (15 ml) in a similar manner as described in the preparation of **7** from **6**. The solid obtained was chromatographed on a short column of silica gel with benzene–ethyl acetate (2: 1). The eluate containing **11** was evaporated to give a solid, 840 mg (95%), mp 112—114 °C, $[\alpha]_D^{17}$ −8.8° (*c* 2.6, $CHCl_3$).

Found: C, 53.74; H, 5.60; N, 4.29; S, 7.31%. Calcd for $C_{60}H_{74}N_4O_{25}S_3$: C, 53.48; H, 5.54; N, 4.16; S, 7.14%.

NMR (in $CDCl_3$): τ 8.8—8.2 (10H), 7.97 (3H, s, OAc), 7.18, 6.98 and 6.96 (3H, s, each, $SO_2C\underline{H}_3$), 2.71, 2.70, 2.67 and 2.66 (5H, s, each, $CO_2CH_2C_6\underline{H}_5$).

6-O-Acetyl-1,2′,3,6′-tetra-N-benzyloxycarbonyl-2″,3″-O-cyclohexylidene-3′,4′,5″-trideoxy-3′-eno-5″-iodoribostamycin (12). To a solution of **11** (544 mg) in dry DMF (11 ml), anhydrous sodium iodide (5.45 g) and zinc dust (2.73 g) were added and the mixture was heated in an oil bath (90 °C) for 1 hr under vigorous stirring. Chloroform (50 ml) was added and the reaction mixture was filtered from the precipitates, which were washed with chloroform. The filtrate and washings combined were washed successively with saturated sodium chloride solution, sodium thiosulfate solution and with water, dried over sodium sulfate and evaporated. On tlc with benzene–ethyl acetate (5: 2), the slightly yellowish syrup showed two spots of R_f 0.61 (**12**) and 0.47 (**11**, minor). The syrup (500 mg) was chromatographed on a column of silica gel (25 g) with benzene–ethyl acetate (3: 1). The eluate containing **12** was evaporated to give a colorless solid, 350 mg (73%), mp 88—90 °C, $[\alpha]_D^{16}$ −30° (*c* 2, $CHCl_3$).

Found: C, 57.47; H, 5.38; N, 4.73; I, 11.08%. Calcd for $C_{57}H_{65}N_4O_{16}I$: C, 57.57; H, 5.51; N, 4.71; I, 10.68%.

NMR (in $CDCl_3$): τ 8.8—8.2 (10H), 8.00 (3H, s, OAc), 4.35 (2H slightly broadened singlet, H-3′,4′), 2.71, 2.68, 2.67 and 2.63 (each 5H, s, $CO_2CH_2C_6\underline{H}_5$).

6-O-Acetyl-1,2′,3,6′-tetra-N-benzyloxycarbonyl-2″,3″-O-cyclohexylidene-3′,4′,5″-trideoxy-3′-eno-ribostamycin (13). A solution of **12** (240 mg) in dioxane (3 ml) was hydrogenated with Raney nickel and hydrogen (50 psi) in the presence of triethylamine (0.1 ml) for 15 hr at 40 °C. On tlc with benzene–ethyl acetate (5: 2), the reaction mixture showed three spots of R_f 0.44 (**13**), 0.25 (de-OAc derivative) and 0.61 (**12**). After filtration, the solution was treated again with a fresh Raney nickel and hydrogen in the presence of triethylamine for 15 hr at 40 °C. The reaction mixture was filtered and the filtrate was evaporated to give a brown solid (171 mg). The solid was chromatographed on a column of silica gel (10 g) with benzene–ethyl acetate (3: 1). From the earlier eluate, **13** was obtained as a colorless solid, which was reprecipitated from benzene–*n*-hexane, yielding 91 mg (43%), mp 90—93 °C, $[\alpha]_D^{14}$ −29.8° (*c* 1.3, $CHCl_3$).

Found: C, 64.67; H, 6.17; N, 5.22%. Calcd for $C_{57}H_{66}N_4O_{16}$: C, 64.39; H, 6.26; N, 5.27%.

NMR (in $CDCl_3$): τ 8.82 (3H, d, J=6.5 Hz, $C\underline{H}_3$–CH(4″)), 8.8—8.2 (10H), 7.98 (3H, s, OAc), 4.38 (2H, s, H-3′,4′), 2.70, 2.66, 2.64 and 2.61 (each 5H, s, $CO_2CH_2C_6\underline{H}_5$).

From the late eluate, the de-*O*-acetylated product (**14**) was obtained in a yield of 57 mg (28%).

1,2′,3,6′-Tetra-N-benzyloxycarbonyl-2″,3″-O-cyclohexylidene-3′,4′,5″-trideoxy-3′-eno-ribostamycin (14). Compound **13** was treated similarly as described in the preparation of **9** from **8**. Yield 89%, mp 87—90 °C, $[\alpha]_D^{14}$ −26.6° (*c* 1.2, $CHCl_3$).

Found: C, 64.79; H, 6.14; N, 5.57%. Calcd for $C_{55}H_{64}N_4O_{15}$: C, 64.69; H, 6.32; N, 5.49%.

NMR (in $CDCl_3$): τ 8.78 (3H, d, J=6.5 Hz, CH_3–C(4″)), 8.8—8.2 (10H), 4.41 (2H, s, H-3′,4′), 2.71 and 2.67 (5H and 15H, s, respectively, $CO_2CH_2C_6\underline{H}_5$).

3′,4′,5″-Trideoxyribostamycin. A solution of **14** (120 mg) in aqueous dioxane (1: 1, 4 ml) was hydrogenated with palladium black and hydrogen (50 psi) at 35—40 °C for 15 hr. When water was added, the reaction mixture became turbid indicating that the hydrogenation was incomplete. The reaction mixture was filtered and the filtrate was evaporated to dryness. The residue was again treated as above with a fresh palladium black and hydrogen for 20 hr. The reaction mixture was filtered and the filtrate was evaporated to give a solid, which was dissolved in 1M hydrochloric acid (1 ml) and the solution was heated at 50 °C for 1 hr. After cooling, acetone was added to give a solid. The solid was charged on a column of Amberlite CG-50 (NH_4^+) and, after washing the column with water, it was developed with 0.1—0.4M ammonia with gradual increase in concentration. The product was emerged at the concentration of 0.3M ammonia. The eluate was evaporated to give a solid, 20 mg (40%), $[\alpha]_D^{14}$ +56° (*c* 0.7, H_2O). On paper chromatography with *n*-butanol–pyridine–water acetic acid (6:4:3:1), it gave $R_{f\ \text{ribostamycin}}$ 1.6.

Found: C, 48.32; H, 8.48; N, 13.11%. Calcd for $C_{17}H_{34}N_4O_7 \cdot H_2O$: C, 48.10; H, 8.55; N, 13.21%.

NMR (in D_2O): τ 9.0—7.7 (6H, m), 8.65 (3H, d, J= 6.5 Hz, $CH_3C\underline{H}$), 4.75 (1H slightly broadened singlet, H-1″), 4.62 (1H, m, H-1′).

The authors wish to thank Mr. Saburo Nakada for the elemental analysis and to Mr. Hiroshi Miyamoto for the technical assistance.

Kinetic Studies on the Cationic Ring-Opening Polymerization of Tetrahydrofuran Initiated by Superacid Esters[1)]

Shiro KOBAYASHI, Hidenori DANDA, and Takeo SAEGUSA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received July 13, 1973)

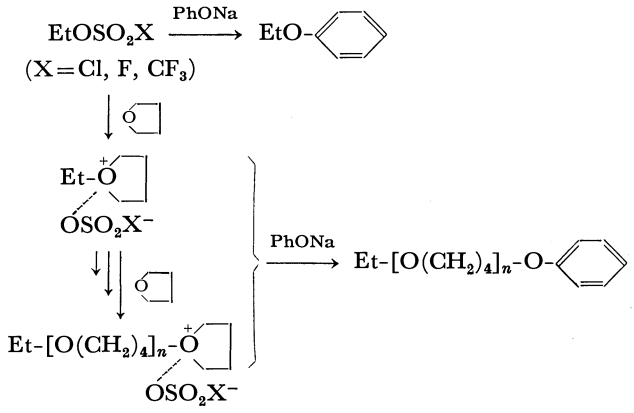
The present paper descibes kinetic studies on the cationic ring-opening polymerization of tetrahydrofuran (THF) initiated by superacid esters such as ethyl fluorosulfate ($EtOSO_2F$), chlorosulfate ($EtOSO_2Cl$), and trifluoromethanesulfonate ($EtOSO_2CF_3$). The phenoxyl end-capping method was found to de applicable to kinetic analyses of the THF polymerization initiated by superacid esters. Also, the rate constants of propagation (k_p) and of initiation (k_i) were determined directly by NMR spectroscopic method. Rate constants determined by these two methods were in good agreement within experimental error. As a polymerization mechanism it was established that the propagation proceeds *via* cyclic oxonium species. The k_p values of superacid esters varied depending upon the nature of the counter anion, OSO_2X^-, *e.g.*, k_p at 0 °C in CH_2Cl_2: 0.66×10^{-3} (X=F), 1.4×10^{-3} (X=Cl), and 1.7×10^{-3} ($X=CF_3$) l/mol·sec, respectively. These magnitudes, however, were at least lower than one half of those of typical Lewis acid initiators. Initiation by superacid ester is a dipole-diple reaction, and k_i values were about 1/10—1/20 of the corresponding value of triethyloxonium tetrafluoroborate ($Et_3O^+BF_4^-$). Activation parameters were calculated for both the propagation and initiation reactions. In order to compare the present systems with those of superacid initiators, model reactions were examined by NMR spectroscopy.

In the last decade chemistry of superacid systems has widely been developed especially in the field of cationic reactions.[2)] Thus, it has become possible to observe directly a variety of cationic species in such superacid media.[2a,b)] Superacids are, according to Gillespie[2c)] more acidic than 100% sulfuric acid, the most frequently used strong acid solvent. With this respect fluorosulfuric, chlorosulfuric and trifluoromethanesulfonic acids are the well-known among superacids.

It has been reported preliminarily in our recent presentation[3)] that ester derivatives of fluorosulfuric and chlorosulfuric acids are very effective initiators for the cationic ring-opening polymerization of tetrahydrofuran (THF), oxetane, β-propiolactone, 2-oxazoline, epichlorohydrin, and propylene oxide. At almost the same time with our presentation,[3)] Simith and Hubin[4)] have reported semi-quantitative studies of the THF polymerization initiated by superacid derivatives including methyl trifluoromethanesulfonate. In the present paper we wish to report kinetic studies on the ring-opening polymerization of THF initiated with superacid esters. The superacid esters employed were ethyl fluorosulfate ($EtOSO_2F$), chlorosulfate ($EtOSO_2Cl$), and trifluoromethanesulfonate ($EtOSO_2CF_3$). The kinetic analyses were made on the basis of our "phenoxyl end-capping" method[5,6)] which enabled the determination of the concentration of the propagating species [P*]. Furthermore, the kinetic analyses were also performed by NMR spectroscopy. Thus, rate constants were determined, for the first time, directly by NMR spectroscopic method.

Results and Discussion

Determination of [P*]. In the ring-opening polymerization of THF by superacid ester initiators the phenoxyl end-capping procedure is shown in Scheme 1. For the determination of [P*], the modification of the original procedure was made; *i.e.*, phenetole produced directly from the initiator was successfully separated from the polymer phenyl ether by vacuum distillation with the aid of Decalin as the distillation entrainer.[7)]



Scheme 1.

In Scheme 1, the reaction of sodium phenoxide with the propagating species and with the unreacted initiator should be quantitative in producing the polymer phenyl ether and phenetole, respectively. It has already been established that the propagating cyclic oxonium could be quantitatively converted into the polymer phenyl ether.[5)] In the present study, the reactions of sodium phenoxide with superacid esters were examined. $EtOSO_2F$ and $EtOSO_2Cl$

X=F, Cl

were allowed to react with sodium phenoxide in THF at room temperature, and the reaction mixture was treated in a similar manner as that for the polymerization system. The amount of phenetole produced was determined by UV spectroscopy. Reaction (1) has been regarded as quantitative (in Table 1). Thus, the phenoxyl end-capping method has been shown valid for the kinetic analysis of the THF polymerization initiated by superacid esters as in the case of the $Et_3O^+BF_4^-$ initiator system.[7]

Polymerization by Superacid Esters. Figure 1 shows the [P*]-time (Curve A) and conversion-time (Curve B) relationships in the THF polymerization initiated by $EtOSO_2F$. Throughout the polymerization, [P*] continued to increase. After 20 hr, [P*] reached to 63% of the initial concentration of the initiator. The induction period was observed in the conversion-time relationship and then, monomer was consumed monotonously. These observations indicate a slow initiation followed by a fast propagation.

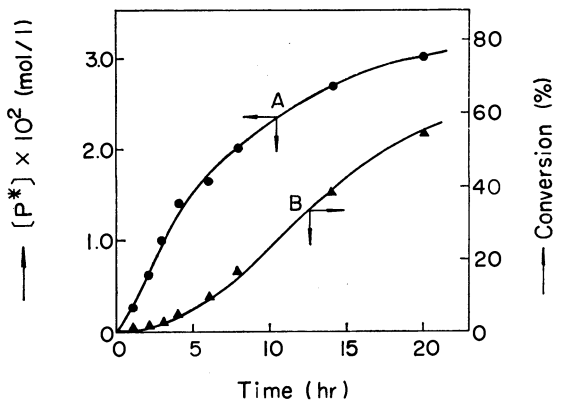

Fig. 1. Polymerization of THF by $EtOSO_2F$ at 0 °C. [P*]-time (Curve A) and monomer conversion-time (Curve B) relationships: $[I]=4.8\times10^{-2}$ mol/l, $[M]_0=9.80$ mol/l in CH_2Cl_2 solution.

It has been already established that in the cationic polymerization of THF the propagation reaction can be expressed by

$$\sim\sim\overset{+}{O}\langle\rangle + O\langle\rangle \overset{k_p}{\rightleftharpoons} \sim\sim O(CH_2)_4\text{-}\overset{+}{O}\langle\rangle \quad (2)$$

(A⁻ counterion)

On the basis of S_N2 mechanism the rate equation of propagation is given by

$$-\frac{d[M]}{dt} = k_p[P^*]\{[M]-[M]_e\} \quad (3)$$

where [M] and $[M]_e$ represent the instantaneous and equilibrium monomer concentrations, respectively, and k_p is the rate constant of propagation. Integration of Eq. (3) with respect to time gives

$$\ln\frac{[M]_{t_1}-[M]_e}{[M]_{t_2}-[M]_e} = k_p\int_{t_1}^{t_2}[P^*]dt \quad (4)$$

where $[M]_{t_1}$ and $[M]_{t_2}$ represent the monomer concentrations at time t_1 and t_2, respectively.

Based on the data in Fig. 1, the plot of Eq. (4) was made (Fig. 2). The slope of the straight line gave a k_p value of 0.66×10^{-3} l/mol·sec at 0 °C.

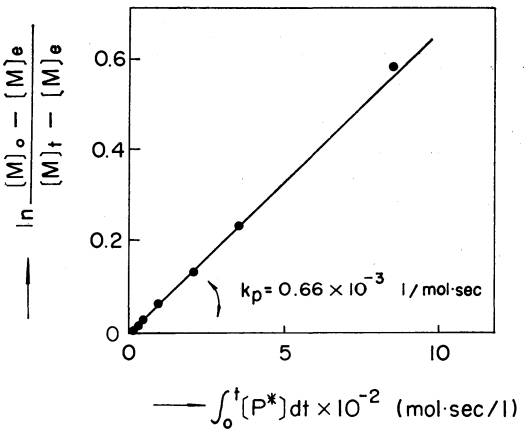

Fig. 2. Polymerization of THF by $EtOSO_2F$ at 0 °C: $[I]_0=4.8\times10^{-2}$ mol/l, $[M]_0=9.80$ mol/l in CH_2Cl_2 solution. $[M]_e=1.7$ mol/l.[8]

The initiation reaction can be formulated as

$$EtOSO_2X + O\langle\rangle \overset{k_i}{\rightleftharpoons} Et\text{-}\overset{+}{O}\langle\rangle \quad (5)$$

(OSO_2X^- counterion)

According to a bimolecular mechanism the rate equation of initiation is given by

$$-\frac{d[I]}{dt} = k_i[I][M] \quad (6)$$

Integration of Eq. (6) gave

$$\ln\frac{[I]_{t_1}}{[I]_{t_2}} = k_i\int_{t_2}^{t_1}[M]dt \quad (7)$$

where k_i is the rate constant of initiation and $[I]_{t_1}$ and $[I]_{t_2}$ are the instantaneous concentrations of the unreacted initiator at time t_1 and t_2, respectively.

Figure 3 shows the plot of Eq. (7) on the reasonable assumption that the amount of the reacted initiator corresponds to [P*] of Curve A in Fig. 1. The slope of the straight line of Fig. 3 gave the initiation rate constant, 0.33×10^{-5} l/mol·sec at 0 °C.

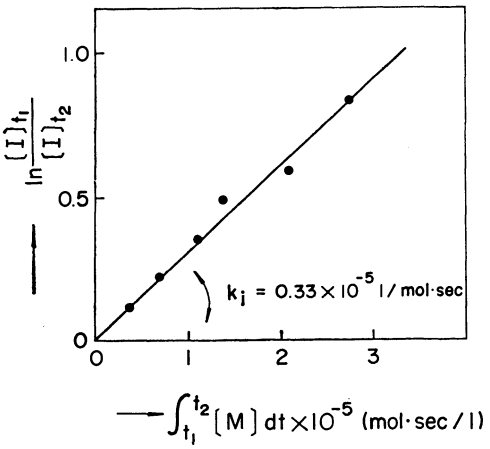

Fig. 3. Plots of Eq. (7) in the THF polymerization by $EtOSO_2F$ in CH_2Cl_2 at 0 °C. t_1=1.0 hr.

In a similar manner k_p and k_i values were determined at other temperatures. Furthermore, kinetic analyses were carried out on the THF polymerizations initiated by $EtOSO_2Cl$ and $EtOSO_2CF_3$. These results are summarized in Table 2.

TABLE 2. RATE CONSTANTS OF PROPAGATION (k_p) AND INITIATION (k_i) OF THE THF POLYMERIZATION[a]

Initiator	Temp (°C)	$10^3\cdot k_p$ (l/mol·sec)	$10^5\cdot k_i$ (l/mol·sec)
$EtOSO_2F$	8.4	1.4	0.67
	0	0.66	0.33
	−8.0	0.32	0.13
$EtOSO_2Cl$	6.5	2.2	0.50
	0	1.4	0.38
	−4.5	0.89	0.19
	−11.9	0.45	0.09
$EtOSO_2CF_3$	9.5	3.0	1.6
	0	1.7	0.80
	−7.8	0.76	0.45

a) Solution polymerization in CH_2Cl_2. $[M]_0$=9.80 mol/l, $[I]_0$=0.048 mol/l.

In all cases Arrhenius plots were linear, and the activation parameters were calculated (Table 3). For the purpose of comparison the k_p and k_i values at 0 °C are listed again, and the data with triethyloxonium tetrafluoroborate ($Et_3O^+BF_4^-$) initiator are also given in Table 3. The k_p value of $EtOSO_2F$ initiator is extremely small, *e.g.*, about 1/6 of that of $Et_3O^+BF_4^-$ initiator. The k_p values of $EtOSO_2Cl$ and $EtOSO_2CF_3$ initiators are between those of $EtOSO_2F$ and $Et_3O^+BF_4^-$. In the THF polymerization initiated by various Lewis acids such as BF_3, $SnCl_4$, $EtAlCl_2$, and Et_3Al–H_2O systems, the k_p values were determined by us using the phenoxyl end-capping methods.[11] The k_p values are in a narrow range between 3.7 and 9.9×10^{-3} l/mol·sec at 0 °C in CH_2Cl_2. Therefore, the k_p values by superacid esters of the present study are 1/15—1/2.2 for those of Lewis acid initiators. Since the activation parameters ($\Delta H_p^{\ddagger}$ and $\Delta S_p^{\ddagger}$) of $EtOSO_2X$ are very close to those of $Et_3O^+BF_4^-$, it is evident that the propagation of the polymerizations by superacid esters proceeds *via* an oxonium mechanism as shown in Eq. (2). Significant difference in k_p values between superacid esters and Lewis acids initiators may reasonably be attributed to the difference in the nature of the counter anions, A^- of Eq. (2). A recent report has revealed that the THF polymerization by $Et_3O^+BF_4^-$ proceeds *via* two species, *e.g.*, the free-ion and the ion-pair.[12] It may be likely that the effect of the counter anion on k_p is attributed partly to the different contribution of above two species toward k_p. Elucidation of this point must await further studies.

The initiation is a dipole-dipole reaction producing an oxonium ion (Eq. (5)). With this respect the initiation is similar to Menschutkin reaction in which an ammonium ion is formed from amine and alkyl halide (Eq. (8)). The initiation rate constant, k_i is at

$$R_3N + R'Y \longrightarrow R_3\overset{+}{R'}N\,Y^- \qquad (8)$$

least 2×10^2 times smaller than k_p in superacid ester systems. The k_i values of superacid esters are 1/20—1/10 of k_i of $Et_3O^+BF_4^-$. The activation parameters of the initiation exhibited relatively low $\Delta H_i^{\ddagger}$ and

NMR Studies. It has already been presented that the kinetics of the THF polymerization by superacid esters could be studied by means of NMR spectroscopy as well as the phenoxyl end-capping method.[15] In order to compare the kinetic data obtained by two different methods, the THF polymerization by superacid esters was examined also by NMR spectroscopy. A mixture of THF–$EtOSO_2CF_3$ (5: 1 molar ratio) in CH_2Cl_2 solution was introduced into an NMR sample tube at −78 °C. The tube was sealed and then the course of the reaction was followed by the change of NMR spectrum of the system. Figure 4 shows an

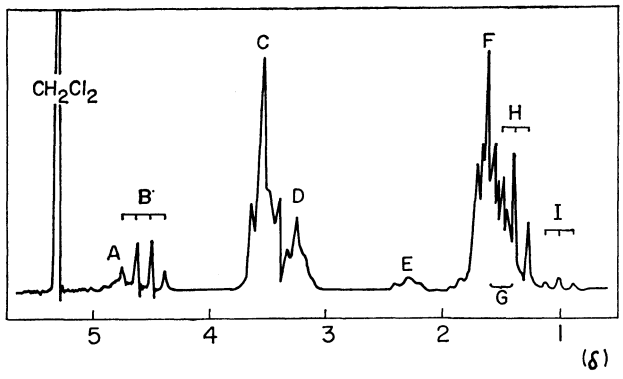

Fig. 4. NMR spectrum of the THF polymerization mixture by $EtOSO_2CF_3$ in CH_2Cl_2 after 20 min at 0 °C.

example NMR spectrum of the reaction system which was taken after 20 min at 0 °C. Signals C and D are due to α-methylene protons of THF monomer and of linear polymer, respectively. Peak F is due to β-methylene protons of THF monomer, while signal G due to β-methylene protons of polymer is overlapping with peaks F and H. A sharp quartet (B) and triplet (H) are due to methylene and methyl protons, respectively, of the initiator. Signals A (δ 4.72) and E (δ 2.32) are reasonably assigned to α- (six protons) and β- (four protons) methylene protons of cyclic oxonium of the propagating species. This assignment coinsides with that of our previous work[10] in which the formation of cyclic oxonium ions was clearly shown by NMR in the reaction of $Et_3O^+BF_4^-$ with cyclic ethers. Finally, a triplet (peak I) can be assigned to methyl protons of ethoxy group at polymer end. A

quartet due to methylene protons of the ethoxy group is overlapping with peak D. Table 4 summarizes the chemical shift assignments.

The concentrations of monomer, the initiator consumed and P* were determined by integration of signals C, I, and E, respectively. Thus, the kinetic analysis could be made in a similar way to that of the phenoxyl end-capping method. Figure 5 shows the variations of [P*]-time (Curve A) and of monomer conversion-time (Curve B), respectively. The molar concentration of cyclic oxonium species (obtained from the signal E) was equal to that of ethoxy group at the polymer end (obtained from the signal I) throughout the polymerization, *i.e.*, the system was of living character without termination. Therefore, the concentration of P* could be determined by either the

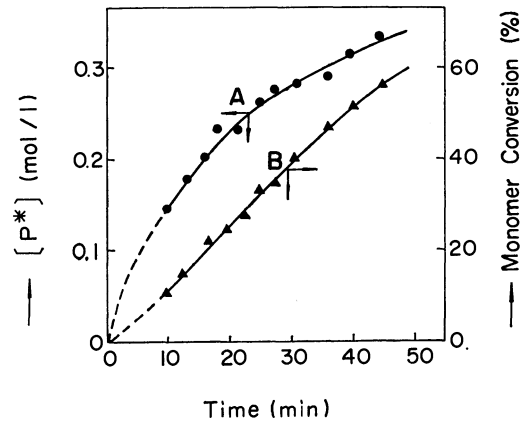

Fig. 5. Polymerization of THF with $EtOSO_2CF_3$ monitored by NMR spectroscopy. Solution polymerization at 0 °C. [P*]-time (Curve A) and monomer conversion-time (Curve B) relationships: $[I]_0$=1.27 mol/l, $[M]_0$=7.70 mol/l.

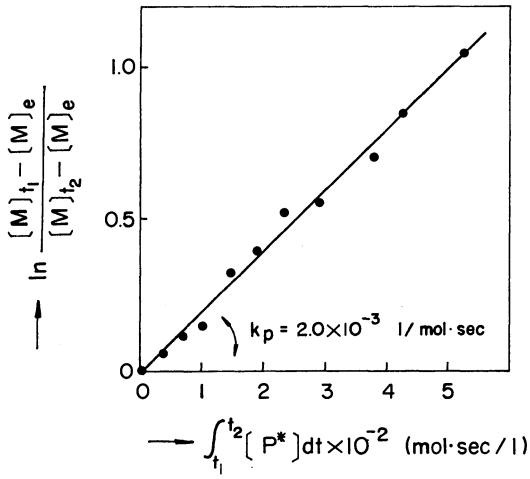

Fig. 6. Polymerization of THF by $EtOSO_2CF_3$ in CH_2Cl_2 at 0 °C: $[I]_0=1.27$ mol/l, $[M]_0=7.70$ mol/l, $[M]_e=1.7$ mol/l[18], $t_1=10$ min.

signal E or I.

Based on the data in Fig. 5 the plots of Eq. (4) gave a straight line. From the slope a k_p value was obtained as 2.0×10^{-3} l/mol·sec at 0 °C (Fig. 6). On the basis of the relationship that the concentration of the propagating species is equal to that of the initiator consumed, the [P*]-time relationship in Fig. 5 was plotted according to Eq. (7) as shown in Fig. 7. Then, a k_i value was obtained as 0.85×10^{-5} l/mol·sec at 0 °C from the slope of the straight line.

In an analogous manner k_p and k_i values were determined by NMR spectroscopy for the systems of $EtOSO_2F$ and $EtOSO_2Cl$ initiators (in Table 5). It can be seen that the rate constant values by NMR spectroscopy and by phenoxyl end-capping method

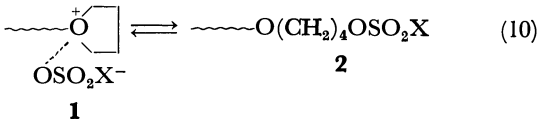
Table 5. Rate constants of propagation (k_p) and initiation (k_i) of the THF polymerization determined by NMR spectroscopy in CH_2Cl_2 solution at 0 °C[a]

Initiator	$10^3\cdot k_p$ (l/mol·sec)	$10_5\cdot k_i$ (l/mol·sec)
$EtOSO_2F$	0.8	0.5
$EtOSO_2Cl$	1.5	0.6
$EtOSO_2CF_3$	2.0	0.85

a) $[M]_0=7.70$mol/l, $[I]_0=1.27$ mol/l.

(Tables 5 and 2) are in good agreement within experimental error.

In all systems of three initiators, the polymerization proceeded *via* oxonium propagating species in accordance with the mechanism of Scheme 1. An equilibrium of oxonium-ester species (Eq. (10)) may come into play during the polymerization.

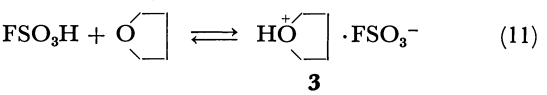


(10)

If the ester type species **2** were involved in the system, a peak should have appeared which is a characteristic signal of the α-methylene protons of an ester type ~~~~CH_2OSO_2X. However, any peak was not detected in the region of τ 4.25 throughout the THF polymerization initiated by a series of superacid esters under NMR measurement conditions. This indicates that the contribution of **2** to the propagation is, if any, very small during the THF polymerization where monomer is present in large excess, although the molar reaction of superacid ester and tetrahydropyran (Eq. (9)) has been proved to be an equilibrium system.[14]

Very recently, Pruckmayr and Wu have reported NMR studies on the THF polymerization initiated by superacids such as FSO_3H.[16] However, they did not determine the rate constants of such polymerization systems, in which "acidic" proton was present in a significant amount. Consequently, such proton made the polymerization systems complicated, bringing about termination, chain-transfer, the breaking of the polyether chain, the proton-proton exchange and so forth. Unlike these systems, the present reaction of superacid ester initiator is quite clean, since no "acidic" proton is involved. Therefore, NMR spectra were simple in all cases as shown in Fig. 4. So far as we know the present study is the first case that the initiation and propagation rate constants in the THF ploymerization were determined directly by means of high resolution NMR spectroscopy.

As to NMR spectral assignments Pruckmayr and Wu[16] ascribed a peak at δ 4.25 to α-methylene protons of cyclic trialkyloxonium in benzene. For a peak at δ 4.65 they assigned it to α-methylene protons of cyclic dialkyloxonium ion. Their assignment of cyclic trialkyloxonium ion, however, is not compatible with that of the present work. It is unlikely that cyclic dialkyloxonium ion (the protonated THF, **3**) was observed as a long-lived species at their NMR measurement conditions, since proton exchange reaction (Eq. (11)) is very fast. We attempted to observe **3** directly by NMR spectroscopy.



(11)

However, the direct observation of **3** as a long-lived species was unsuccessful in FSO_3H–benzene at 0 °C or in FSO_3H–CH_2Cl_2 solution even at lower temperature of −50 °C. Rapid proton exchange still took place at

16) G. Pruckmayr and T. K. Wu, *Macromolecules*, **6**, 33 (1973).

−50 °C. This rapid proton exchange is suggested from their observations[16] that the signal of α-methylene protons of monomer THF was shifted downfield to δ 3.75 in the presence of "acidic" protons[16] from δ 3.52 of free THF in the absence of such protons (Table 4) whereas the peak of α-methylene protons of polymer chain were less affected.

On the basis of above findings we think that a peak at δ 4.65 is due to α-methylene protons of cyclic trialkyloxonium ion (propagating species) and that a peak at δ 4.25 must be due to another species. For such species we propose here a polymer alkyl ester species of superacid as given by **2**. To support this,

$$\sim\!\sim\!\sim CH_2OSO_2X$$

2 (X=F)

a model compound (**4**) was prepared from 4-ethoxy-1-butanol and sulfuryl chloride according to Eq. (12). **4** is recognized as a 1:1 adduct of $EtOSO_2Cl$ and

$$CH_3CH_2O(CH_2)_4OH + SO_2Cl_2 \xrightarrow{\text{in } CH_2Cl_2} CH_3CH_2O(CH_2)_4OSO_2Cl + HCl \quad (12)$$

4

THF. The reaction of alcohol and sulfuryl chloride is probably the best one to prepare alkyl chlorosulfate.[17] Figure 8 shows NMR spectra of the reaction mixture of Eq. (12). At 30 min after the addition of sulfuryl chloride to the above ether alcohol a peak (A) due to α-methylene protons of OSO_2Cl group appeared at δ 4.25 (spectrum I in Fig. 8). After the reaction mixture was concentrated under reduced pressure with bubbling of dry nitrogen at 0 °C a spectrum of II (Fig. 8) was obtained. Additionally two peaks appeared at δ 4.70 (B) and δ 2.35 (C). They are assigned to α-(B) and β-(C) methylene protons of cyclic trialkyloxonium ion (**5**). This indicate that 30% of **4** (from integration) underwent an intramolecular cyclization to produce **5**. It should be added here that the chemical shifts are not changed by the nature of X (X= F, Cl, or CF_3) of OSO_2X in **4** or **5**.[18]

$$CH_3CH_2\ddot{O}(CH_2-CH_2)_2\,\delta^-OSO_2Cl \rightleftharpoons CH_3CH_2-\overset{+}{O}\!\left(\begin{matrix}CH_2-CH_2\\ \diagdown\ \diagup\\ O\end{matrix}\right)\,OSO_2Cl^- \quad (13)$$

4 **5**

All of these findings are taken to substantiate our assignments, *i.e.*, peaks at δ 4.65 and δ 4.25 are respectively due to α-methylene protons of cyclic trialkyloxonium ion (propagating species, **1**) and to α-methylene protons of superacid ester (**2**, X=F) of polymer chain. By the same reason, β-methylene protons of **1** corresponds to a peak at δ 2.40, which was assigned to β-methylene protons of **3**.[16] As to our assignment, the production of **2** is explained reasonably. For example, the initiator reacts with hydroxyl group at the polymer end to produce a polymer alkyl ester of fluorosulfuric acid as shown by Eq. (14). This kind of reaction, *i.e.*, a reaction of alcohol and superacid, provides a

$$FSO_3H + \sim\!\sim\!\sim CH_2OH \longrightarrow \sim\!\sim\!\sim CH_2OSO_2F + H_2O \quad (14)$$

2

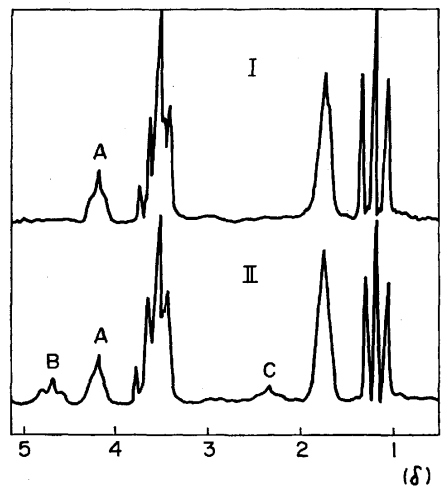


Fig. 8. NMR spectra of the reaction mixture of 4-ethoxy-1-butanol and sulfuryl chloride in CH_2Cl_2: (I) At 30 min after the addition of sulfuryl chloride at **0** °C; (II) After concentration at reduced pressure with bubbling of dry nitrogen at **0** °C.

good synthetic method of superacid ester.[19] Another possibility of the production of **2** is a reaction of the propagating species given by Eq. (10), in which the counter anion, OSO_2X^-, attacks nucleophilically the α-carbon atom of cyclic oxonium ion **1**. This type of reaction (Eq. (10)) may be facilitated in the presence of "acidic" protons. Thus, propagating cyclic trialkyloxonium ion **1** will eventually convert into species **2** according to Eq. (10). This agrees with the observation that peaks at δ 4.65 and 2.40 disappeared and instead a peak at δ 4.25 appeared at a long reaction time.[16]

Experimental

Materials. THF and solvents were purified as previously reported.[5,6] The THF solution of sodium phenoxide was prepared in a similar manner as reported.[5] Fluorosulfuric acid was prepared from hydrogen fluoride and fuming sulfuric acid, bp 69 °C/50 mmHg (lit,[20] 163 °C). $EtOSO_2F$ and $EtOSO_2CF_3$ were prepared by the reaction of diethyl sulfate with FSO_3H and with CF_3SO_3H, bp the former 88 °C/390 mmHg (lit,[19] 113 °C/752 mmHg) and the latter 55—58 °C/100 mmHg (lit,[20] 115 °C). $EtOSO_2Cl$ was prepared by the usual procedure[17] from sulfuryl chloride and ethanol, bp 58 °C/25 mmHg (lit,[17] 43 °C/10 mmHg). 4-Ethoxy-1-butanol was prepared from 1,4-butanediol, ethyl iodide and sodium, bp 70—72 °C/9 mmHg (lit,[21] 72 °C (8 mmHg)).

Polymerization Procedure. Polymerization was carried out under nitrogen. At a polymerization temperature 1.0 ml CH_2Cl_2 solution of the initiator (0.24 mmol) was added to 50 mmol of THF monomer, which resulted in the initial

monomer and catalyst concentrations of 9.80 mol/l and 0.048 mol/l, respectively. After a desired reaction time 1.5 ml THF solution of sodium phenoxide (0.5 mol/l) was added to stop the polymerization. The reaction mixture was stirred further for 30 min at room temperature. Then, it was treated with a large excess of 1M aqueous sodium hydroxide solution. The reaction mixture was extracted three times with 5 ml of CH_2Cl_2. The extracts were combined and dried over K_2CO_3 and centrifuged. The CH_2Cl_2 solution was diluted to 25 ml and the total amount of phenyl ether was determined by UV spectroscopy. A 1.0 ml portion of this CH_2Cl_2 solution was mixed with 4 ml of Decalin and the mixture was subjected to distillation at room temperature under reduced pressure (below 0.3 mmHg). The residue was dissolved in CH_2Cl_2 to the total volume of 20 ml. Then, the amount of phenyl ether at the polymer end was determined by UV analysis. Conversion percent was determined from the amount of the product polymer.

UV Measurements. All UV spectra were taken on Shimadzu UV-200 spectrometer in CH_2Cl_2 solution at room temperature.

NMR Measurements. Into 14.6 mmol of THF 2.4 mmol of $EtOSO_2CF_3$ in 0.40 ml CH_2Cl_2 was added slowly at −78 °C. After mixing a portion of the reaction mixture was transfered into an NMR sample tube, and then the tube was sealed at the same temperature. The extent of the reaction was negligible at −78 °C. The tube was then placed in the NMR probe insert which was kept constant at 0 °C. The time of the insertion was assumed to be the start of the reaction. Then, the reaction was followed. The instrument used was a Hitachi R-20B NMR spectrometer. The reaction temperature was kept constant within ±1 °C and the experimental error of the integration was within ±2%.

Kinetic Study on the Ring-Opening Polymerization of Tetrahydrofuran by Pyrosulfuryl Chloride Initiator[1]

Shiro KOBAYASHI, Takeo SAEGUSA, and Yoshiaki TANAKA[2]

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received July 13, 1973)

This paper deals with a kinetic study of the ring-opening polymerization of tetrahydrofuran (THF) initiated by pyrosulfuryl chloride (PSC). The kinetic analysis was based on the determination of the concentration of propagating species, [P*], by the phenoxyl end-capping method. The rate constants of the three elementary processes, propagation (k_p), initiation (k_i), and termination (k_t), were determined. Activation parameters for the propagation were; $\Delta E_p^{\neq}=12$ kcal/mol, and $A_p=7.6\times10^6$ l/mol·sec. From the k_p values and the NMR study of the THF–PSC reaction, it is concluded that the propagation proceeds *via* the bis-oxonium species **5b**. The ester type species **5a** may be involved at a very early stage of polymerization. However, its contribution was quite small throughout the polymerization. The THF polymerization initiated by PSC was characterized by the fast initiation. The mechanism of termination was also examined. The THF polymerization by trifluoromethanesulfonic anhydride was also studied kinetically, which was characterized by a living propagation by bis-oxonium species.

Relatively few studies have been reported on the reaction of pyrosulfuryl halides in the organic chemistry. Very recently, however, attention has been paid on the reactions of pyrosulfuryl fluoride.[3] We have recently reported a kinetic study of the polymerization of tetrahydrofuran (THF) by using superacid esters such as ethyl chlorosulfate, fluorosulfate, and trifluoromethanesulfonate.[4] As an extension of our previous study we report in the present study the kinetics of the THF polymerization initiated by pyrosulfuryl chloride, $Cl\text{-}SO_2\text{-}O\text{-}SO_2Cl$, (PSC). PSC is a derivative of superacid, *i.e.*, an anhydride of chlorosulfuric acid. Furthermore, it could be a bifunctional initiator for the cyclic ether polymerization.

Results and Discussion

Determination of [P] by the Phenoxyl End-Capping Method.* The phenoxyl end-capping method has originally been developed by Saegusa and Matsumoto[5] for the determination of [P*] in THF polymerization. Since then, this method has successfully been employed in kinetic analyses of polymerizations of various cyclic ethers including mono and bicyclic monomers.[6] This

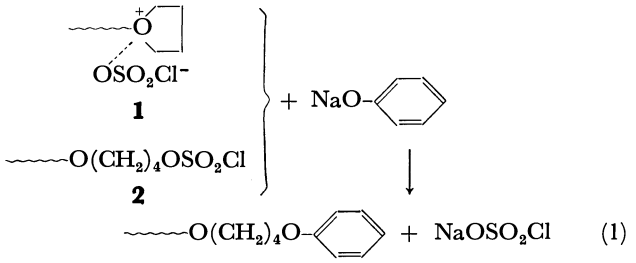
method was used also in the present study. It has been established in the polymerization of THF that the conversion of the propagating species into the phenyl ether group is quantitative under the phenoxyl end-capping reaction conditions regardless of the nature of the propagating species, *e.g.*, oxonium type (**1**) or ester type (**2**).[7] The concentration of the phenyl ether



(1)

group formed by the reaction of **1** or **2** with sodium phenoxide (Eq. (1)) was analyzed by its UV absorption at 272 mμ. The molar extinction coefficient value of the phenyl ether was obtained to be 1.93×10^3 l/mol·cm in the THF polymerization.[5,8]

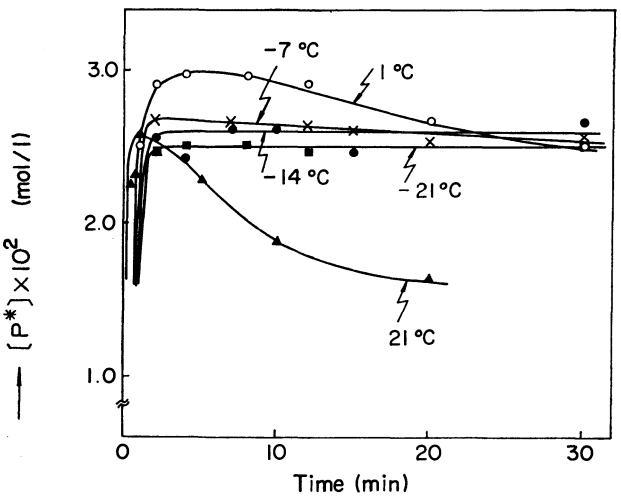


Fig. 1. [P*]-time plots in the polymerization of THF by PSC initiator in CH_2Cl_2: $[M]_0$, 9.9 mol/l; $[PSC]_0$, 0.0203 mol/l.

Polymerization of THF. The THF polymerization was carried out at five temperatures between −21 and 21 °C. The [P*] change during the THF polymerization was examined by means of the phenoxyl end-capping method. The time-[P*] relationships of the PSC-initiated polymerization are shown in Fig. 1. At −21 and −14 °C, P* was produced at an early stage of the polymerization, *i.e.*, within 3 min, and it remained constant thereafter. This indicates a rapid initiation and no occurrence of a termination at these temperatures. At higher temperatures [P*] reached to the maximum within few minutes, and then diminished slowly at 1 °C and fairly rapidly at 21 °C. The maximum concentration of P* during the polymerization is about 75% of the charged initiator concentration,

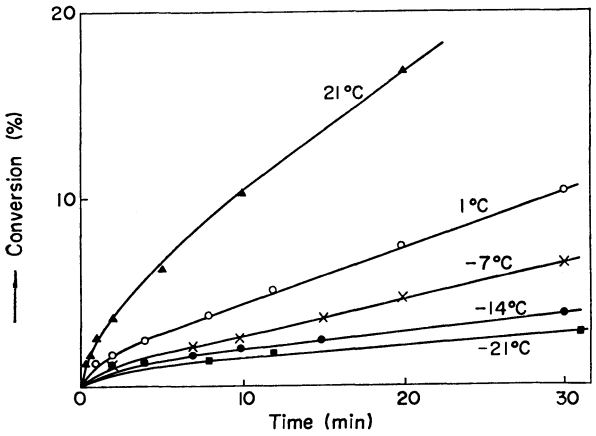

Fig. 2. Time-conversion curves in the THF polymerization by PSC initiator in CH_2Cl_2 at various temperatures: $[M]_0$, 9.9 mol/l; $[PSC]_0$, 0.0203 mol/l.

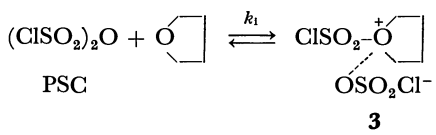
based on the assumption that PSC is a bifunctional initiator.

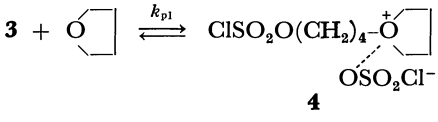
The time-conversion curves at five temperatures are shown in Fig. 2. From the time-[P*] and time-conversion relationships the propagation rate constant, k_p, was determined on the basis of the following procedure.

The initiation of THF by PSC must be expressed as Eq. (2)



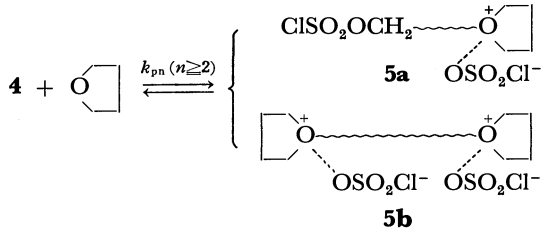
(2)

producing the oxonium species **3**. Then, the first propagation step takes place by the nucleophilic attack of THF monomer on **3**, by which the oxonium-ester type intermediate (**4**) may probably be produced



(3)

where k_{p1} represents the first propagation rate constant. In the later propagation stage, therefore, the growing chain end can be formulated as a bifunctional oxonium-ester (**5a**) and/or a bifunctional oxonium-oxonium type (**5b**) as shown in Eq. (4). As a matter of fact the formation of **5b** involves the conversion of ester into oxonium species.



(4)

It has been already established that the propagation of the THF polymerization proceeds *via* a bimolecular reaction between the propagating species and monomer, and hence obeys a following kinetic equation

7) T. Saegusa and S. Kobayashi, presented at the 21st Annual Meeting of the Society of Polymer Science, Japan, May, 1972.

8) T. Saegusa and S. Matsumoto, *J. Polym. Sci., Part A-1*, **6**, 1559 (1968).

$$-\frac{d[M]}{dt} = k_p[P^*]\{[M]-[M]_e\} \quad (5)$$

where [M] and $[M]_e$ denote the instantaneous and equilibrium monomer concentrations, respectively.[5] Integration of Eq. (5) with respect to time gives

$$\ln\frac{[M]_{t_1}-[M]_e}{[M]_{t_2}-[M]_e} = k_p\int_{t_1}^{t_2}[P^*]dt \quad (6)$$

where $[M]_{t1}$ and $[M]_{t2}$ are the monomer concentrations at time t_1 and t_2, respectively.

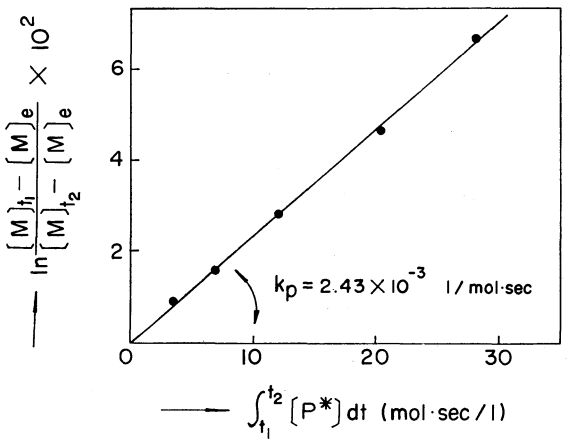


Fig. 3. Plots of Eq. (6) in the THF polymerization by PSC initiator at 1 °C: $[M]_0$, 1.7 mol/l; t_1, 8 min.

A linear plot of Eq. (6) gave a straight line passing through the origin as shown in Fig. 3, from which k_p at 1 °C was calculated. Similarly, k_p values at other temperatures were obtained and are summarized in Table 1.

Table 1. Rate constants and activation parameters of the THF polymerization by PSC[a]

°C	$10^3\times k_p$ (l/mol·sec)	$10^3\times k_i$ (l/mol·sec)	$10^4\times k_t$ (sec^{-1})
−21	0.42	—	—
−14	0.81	—	—
− 7	1.55	—	—
1	2.43	2.4	1.3
21	10.9(6.5)[b]	10(∼15)[b]	5.3
ΔE_p^* (kcal/mol)	12		
A_p (l/mol·sec)	7.6×10^6		

a) Polymerization conditions: $[M]_0$, 9.9 mol/l in CH_2Cl_2; $[PSC]_0$, 0.0203 mol/l.
b) Trifluoromethanesulfonic anhydride initiator at 21°C. Polymerization conditions were the same as those of PSC initiator.

The rate of initiation was estimated from the rate of the P* production. The rate equation is given by Eq. (7) according to the initiation reaction Eq. (2)

$$-\frac{d[PSC]}{dt} = k_i[PSC][M] \quad (7)$$

Thus, the initiation rate constant k_i was obtained from the slope of the linear plot of the integrated equation.

$$\ln\frac{[PSC]_0}{[PSC]_t} = k_i\int_0^t[M]dt \quad (8)$$

where $[PSC]_t$ was obtained on the assumption that $[PSC]_t=[PSC]_0-[P^*]$. From the [P*]-time relationship in Fig. 1 k_i was roughly calculated and given in Table 1.

A kinetic analysis of termination was also made on the basis of the [P*]-time curve. The termination of the THF polymerization has been assumed to be a unimolecular reaction.[9] Therefore, the following equation is derived

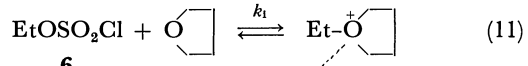
$$-\frac{d[P^*]}{dt} = k_t[P^*] - R_i \quad (9)$$

where R_i is the production rate of P* and k_t is the rate constant of termination. After the [P*] reaches to the maximum in few minitutes the production of P* ceases, *i.e.*, $R_i=0$. Hence, Eq. (9) becomes Eq. (10)

$$-\frac{d[P^*]}{dt} = k_t[P^*]$$
$$\therefore\quad -d(\ln[P^*])/dt = k_t \quad (10)$$

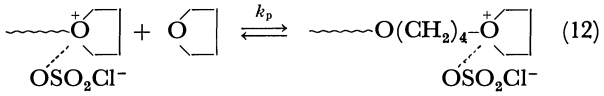
The plot of ln[P*] *vs.* time became a straight line after the [P*] maximum at 1 and 21 °C. These slopes gave k_t values, which are listed also in Table 1.

The k_p value initiated by PSC can reasonably be taken to represent the propagation *via* bis-oxonium species **5b** of Eq. (4) according to the following observations. Recently we have found that ethyl chlorosulfate (**6**) causes the THF polymerization *via* an oxonium ion (**7**) of Eq. (12).[4]



(11)

6



(12)

7

The k_p value obtained in the above system was 1.4×10^{-3} l/mol·sec at 0 °C in CH_2Cl_2.[4] In the PSC-initiated polymerization the conversion of ester (**5a**) into oxonium (**5b**) is not impossible because the ester **6** is able to induce the THF polymerization. However, the rate of oxonium formation, k_i of Eq. (11), 3.8×10^{-6} l/mol·sec at 0 °C, is very slow compared with k_p of Eq. (12), 1.4×10^{-3} l/mol·sec at 0 °C, *i.e.*, k_i is about 3.7×10^2 times smaller than k_p. Since ester species of **5a** has longer alkyl chain group than ethyl group of **6**, it may be less reactive than **6** as usually seen in the similar type S_N2 reactions.[10] Therefore, ester species in **5a** is at least 3.7×10^2 times less reactive than oxonium species in **5a** or **5b**. In this respect **5a** behaves like a monofunctional species of the oxonium type although ester species of **5a** is inherently not a dead species. The [P*] obtained by the phenoxyl end-capping methods represents both the oxonium (**1**) and ester (**2**) type propagating species. If the propagation proceeds *via* **5a** the fraction of the oxonium

9) H. Meerwein, D. Delfs, and H. Morshel, *Angew. Chem.*, **72**, 927 (1960).
10) C. K. Ingold, "Structure and Mechanism in Organic Chemistry," 2nd ed., Cornell University Press, (1969), Chapter VII.

concentration is one half of the observed [P*]. Then, the k_p values should be twice as large as those in Table 1 since the propagation rate of the ester type is negligible small. The k_p value, for example, at 1 °C results in 4.86×10^{-3} l/mol·sec which is too large compared with the observed k_p value of 1.4×10^{-3} l/mol·sec at 0 °C initiated by ethyl chlorosulfate **6** (Eq. (12)). The k_p values should be equal in principle when the same counter anion is involved in the propagation. Both PSC and ethyl chlorosulfate **6** initiators provide a same counter anion, OSO_2Cl^-. Even so, the k_p value of 2.43×10^{-3} l/mol·sec is still fairly larger than that of Eq. (12). All these findings indicate most likely that the PSC-initiated polymerization proceeds *via* bis-oxonium type **5b**. The contribution of **5a** is, if any, very small throughout the propagation of THF polymerization.

The k_p values obtained in the present study are interestingly compared with those initiated by typical Lewis acids.[6] For example, the k_p value at 0 °C by BF_3-epichlorohydrin initiator is reported to be 4.5×10^{-3} l/mol·sec,[5] the magnitude of which is about twice as large as that of the PSC-initiated polymerization.

Activation parameters of the propagation were also calculated. Arrhenius plot of k_p values gave a well-correlated straight line whose slope gave an activation energy ΔE_p^* of 12 kcal/mol. The same magnitude of ΔE_p^* was obtained in the BF_3-epichlorohydrin initiated polymerization.[11] This is again taken to support the bis-oxonium process **5b**.

For comparison, kinetics of the THF polymerization was carried out also by trifluoromethanesulfonic anhydride (**8**) initiator. The results are shown in Fig. 4. [P*] reached to the maximum within 2 min and kept constant thereafter. The maximum of [P*] was 85% of the charged initiator on the assumption that **8** is a bifunctional initiator. It should be noted that in the polymerization by **8** no termination took place even at a higher temperature, *e.g.*, **21** °C. From the relationships in Fig. 4 k_p values were calculated (Table 1).

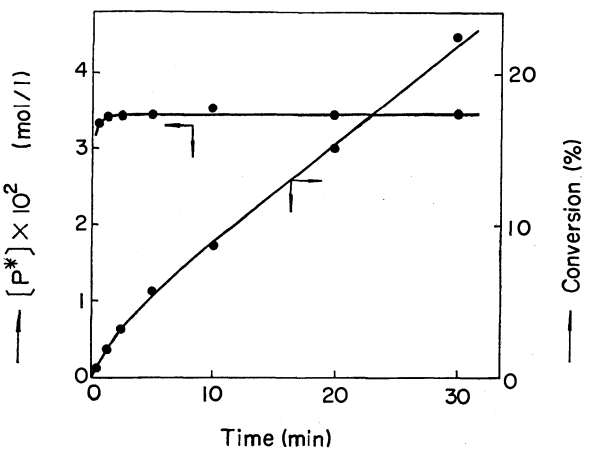


Fig. 4. Time-[P*], and time-conversion relationships in the THF polymerization initiated by trifluoromethanesulfonic anhydride at 21 °C in CH_2Cl_2: $[M]_0$, 9.9 mol/l; $[(CF_3SO_2)_2O]_0$, 0.0203 mol/l.

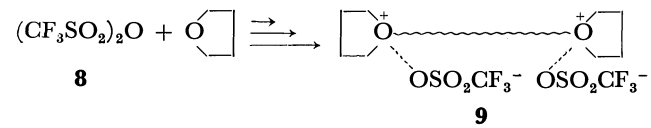
11) T. Saegusa, S. Matsumoto, M. Motoi, and H. Fujii, *Macromolecules*, **5**, 236 (1972).

The k_p of **8** is smaller than that of PSC initiator. It is likely that the polymerization initiated by **8** proceeds *via* bis-oxonium type **9** as suggested previously by Smith and Hubin.[12]



8 **9**

The PSC-initiated polymerization is characterized by a rapid initiation reaction as given in Table 1. The rate of the initiation is as fast as that of the propagation. Comparing k_i values between PSC and **6** of Eq. (11) PSC reacts with THF about 5.8×10^2 times faster than **6** at 1 °C. In addition the k_i value of PSC is also more than 10 times larger than that of triethyloxonium tetrafluoroborate in the THF polymerization.[13] The initiation rate of **8** is even faster than PSC. Therefore, the system initiated by **8** is recognized as that of a fast initiation but a slow propagation. This may account that polymer of very narrow molecular weight distribution ($M_W/M_N=1.08$) was obtained by **8** initiator.[12]

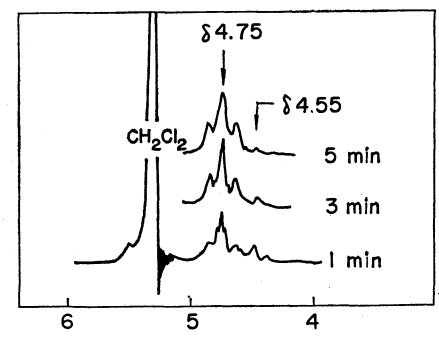


Fig. 5. NMR spectra of the reaction mixture of PSC with THF at 0 °C in CH_2Cl_2.
The molar ratio of PSC to THF was 1/5.

NMR Spectroscopy. To elucidate whether the ester type is involved or not, the reaction of THF with PSC in CH_2Cl_2 was examined by means of NMR spectroscopy. The THF to PSC molar ratio was 5/1. The reaction was carried out at 0 °C in an NMR sample tube under nitrogen. NMR spectra of the reaction system are shown in Fig. 5. After 1 min at 0 °C complex peaks appeared. Among them a triplet-like signal centered at δ 4.55 is reasonably assigned to α-methylene proton signal of the ester type **10** since that of an authentic tetramethylene bischlorosulfonate

~~~~CH_2OSO_2Cl $ClSO_2OCH_2CH_2CH_2CH_2OSO_2Cl$

10 **11**

11 appears at δ 4.60 in CH_2Cl_2 at 35 °C. Peaks centered at δ 4.75 is due to the α-methylene signal of oxonium type **12** whose assignment has already been established.[4,7,14] After 3 min at 0 °C, however, the

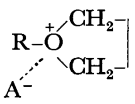
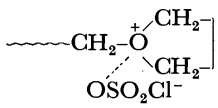
~~~~



12



13

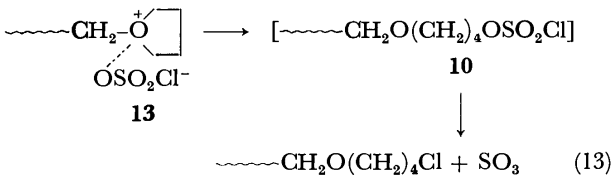
signal at δ 4.55 almost disappeared whereas the signal at δ 4.75 increased very much. It should be noted that the pattern of the signal at δ 4.75 changed from that of the reaction time of 1 min into a typical triplet-like one. The same triplet-like signal has been observed for the oxonium **13** at the same chemical shift.[4,14] After 5 min at 0 °C the ester signal has completely disappeared and only the oxonium signal was observed.

These findings indicate that the ester type species **10** converted into the oxonium species **13** at a very early stage to produce bis-oxonium species **5b**. This means that the contribution of ester type species **5a** is very small throughout the propagation stage which is in accordance with the kinetic results. It is interesting to note that in the PSC-initiated polymerization the reactivity of the ester involved at a very early stage is much enhanced probably due to the neighboring oxonium group.

Termination Mechanism. As seen in Fig. 1 considerable termination takes place at 21 °C in the PSC-initiated polymerization. Therefore, a reference reaction was carried out to examine the termination mechanism. At −78 °C THF was added to PSC in CH_2Cl_2 at a molar ratio of THF to PSC of 3: 1. The reaction system was allowed to warm up gradually to 25 °C and kept for 20 hr at this temperature. Then, the reaction mixture was treated with sodium phenoxide under the phenoxyl end-capping reaction conditions. White waxy polymer was obtained after work-up. The polymer was analyzed by elemental analysis, molecular weight measurement, iodometry, IR and NMR spectroscopy.

The results of elemental analysis was as follows: C, 66.56; H, 8.82 and Cl, 10.6%, respectively. The iodine value was null, *i.e.*, the polymer has no olefinic group. The molecular weight measurement by vapor pressure osmometry gave 309. From these data the polymer composition was proposed as $(C_6H_5)_{1.07}(OC_4H_8)_{2.68}Cl_{0.95}$ for the polymer. In addition, the NMR measurement of the polymer gave a polymer composition of $(C_6H_5)_{1.01}(OC_4H_8)_{2.6}$ from an integral ratio of phenyl protons *vs.* aliphatic protons. The IR spectrum of the polymer showed an absorption band at 650 cm^{-1} due to C–Cl stretching indicative of the presence of alkyl chloride.

Based on the above findings the termination mechanism is reasonably formulated as Eq. (13) which involves the nucleophilic attack of chloride anion of the counterion on the α-carbon of oxonium **13** with the liberation of SO_3. In this process it is not clear if the ester type intermediate **10** is involved or not. The termination of the PSC-initiated polymerization is in



13 10

$$\sim\sim\sim\sim CH_2O(CH_2)_4Cl + SO_3 \qquad (13)$$

sharp constrast to that of the trifluoromethanesulfonic anhydride **8** initiated one where no termination was observed even at a higher temperature of 21 °C. This is obviously due to the stability difference between the counter anions, OSO_2Cl^- and $OSO_2CF_3^-$.

Experimental

Materials. The THF monomer and methylene dichloride solvent were commercial reagents and were purified in the same manner as described previously.[5,8] PSC was prepared by the reaction of sulfur trioxide with carbon tetrachloride according to the literature procedure,[15] bp 147 °C (lit,[15] 147—148 °C). Trifluoromethanesulfonic anhydride **8** was prepared by the dehydration of trifluoromethanesulfonic acid with excess phosphorus pentoxide,[16] bp 84 °C (lit,[12] 84 °C).

Tetramethylene bischlorosulfate **11** was prepared by the following procedure. To 0.1 mol of 1,4-butanediol in 10 ml of CH_2Cl_2 0.26 mol of sulfuryl chloride in 30 ml of CH_2Cl_2 was added dropwise at −20 °C. During the addition nitrogen gas was bubbled into the reaction mixture to remove sulfur dioxide and hydrogen chloride in the system. The addition took 20 min. Then, the reaction mixture was gradually warmed up to 0 °C, and kept for 4 hr at 0 °C and for 12 hr at −78 °C. A white solid precipitated. The solid was isolated and recrystallized from CH_2Cl_2, mp 49—50 °C. The NMR spectrum in CH_2Cl_2 showed two triplet-like signals centered at δ 4.60 (4H) and at δ 2.06 (4H).

Polymerization Procedure and Determination of [P].* Polymerization was carried out in CH_2Cl_2 solution under nitrogen. The reaction was initiated with the addition, at polymerization temperature, of a CH_2Cl_2 solution of PSC to a monomer solution. After a desired time of reaction, the polymerization system was short stopped by the addition of a 0.5 mol/l THF solution of sodium phenoxide. The procedure for the determination of [P*] was the same as that of the reported previously.[4,7]

The analogous procedures were taken in the polymerization of trifluoromethanesulfonic anhydride initiator.

NMR Measurement. To 0.03 mol of THF monomer in 2 ml of CH_2Cl_2 0.006 mol of PSC in 1 ml of CH_2Cl_2 was added with vigorous stirring at −78 °C under nitrogen. A portion of the reaction mixture was transferred into an NMR sample tube by using a hypodermic syringe at −78 °C. Then, the NMR spectrum was recorded at 0 °C on Hitachi R-20B NMR spectrometer.

Molecular Weight Determination. The molecular weight of the polymer was measured by a vapor pressure osmometer (Hitachi Perkin-Elmer model 115) in benzene at 35 °C.

Polycondensation of Malononitrile and Methylenedimalononitrile with Bis(chloromethyl)Aromatic Compounds Using Triethylamine as Acid Acceptor

Nariyoshi KAWABATA,* Kenichi MATSUBARA, and Shinzo YAMASHITA
Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606
(Received November 16, 1972)

Malononitrile was found to undergo condensation reaction with benzyl chloride to give dibenzylmalononitrile in a quantitative yield under mild conditions when an organic base such as triethylamine was used as acid acceptor in dimethyl sulfoxide. The reaction was applied to the polycondensation of malononitrile and methylenedimalononitrile with *p*-xylylene dichloride and *p,p'*-bis(chloromethyl)diphenyl ether, polymers with intrinsic viscosity 0.14—0.22 dl/g being obtained in quantitative yields.

A number of research works have been carried out on the polycondensation of monomers which contain active hydrogen attached to oxygen, nitrogen or sulfur, *e.g.*, glycols, dibasic acids, diamines and dithiols. However, few works are found in the literature on the polycondensation of CH-acidic monomers.

It is well-known that active methylene compounds undergo condensation with alkyl halide to give mono- and/or dialkyl derivatives with the use of sodium hydride, sodium alkoxide, potassium alkoxide or other inorganic bases as acid acceptor. As example, the condensation of malononitrile with benzyl chloride using potassium hydroxide as base gives a mixture of mono- and dibenzylmalononitrile in 17.3 and 29.3% yields, respectively.[1] The same reaction with a combination of sodium hydride as base and dimethyl sulfoxide as solvent gives dibenzylmalononitrile in 75% yield.[2] The reaction was applied to polycondensation.[3] These reactions proceed *via* the formation of sodium or potassium salt of the active methylene compound as an intermediate, and eliminate alkali metal halides. They are thus condensations of salt of active methylene compound with organic halide. We have investigated the possibility of polycondensation of active methylene and methine compounds with bis(halomethyl)aromatic compounds without the use of an inorganic base as acid acceptor.

Results and Discussion

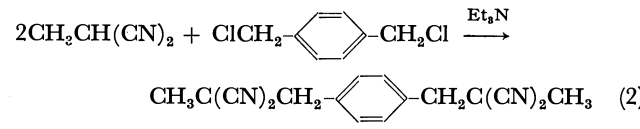
Model Reactions. Before carrying out the investigation, we first studied the condensation of malononitrile with benzyl chloride and related condensations as model reactions, and found that it proceeds smoothly at room temperature to give dibenzylmalononitrile (I) in a quantitative yield when an organic base such as triethylamine was used as acid acceptor in dimethyl sulfoxide under nitrogen atmosphere.

$$CH_2(CN)_2 + 2C_6H_5CH_2Cl \xrightarrow{Et_3N} C_6H_5CH_2C(CN)_2CH_2C_6H_5 \quad (1)$$

I

The reaction needs equimolar amount of triethylamine and eliminates triethylamine hydrochloride, while classical condensation with the use of an inorganic base as acid acceptor eliminates alkali metal halide. The infrared spectrum of the product was identical to that of the authentic sample. Dimethyl sulfoxide seems to be necessary for the condensation reaction. The yield of I was much lower in other solvents, *e.g.*, tetrahydrofuran.

Under similar reaction conditions, *p*-xylylene dichloride was found to undergo condensation reaction with monomethylmalononitrile to give *p*-xylylenebis(methylmalononitrile) (II) in 92% yield.



$$2CH_3CH(CN)_2 + ClCH_2\text{-}C_6H_4\text{-}CH_2Cl \xrightarrow{Et_3N} CH_3C(CN)_2CH_2\text{-}C_6H_4\text{-}CH_2C(CN)_2CH_3 \quad (2)$$

II

The structure of II was determined by elemental and spectral analyses.

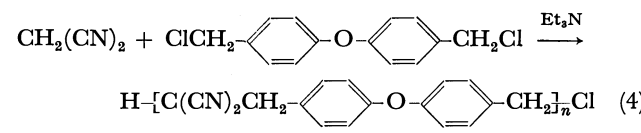
Condensation of methylenedimalononitrile with benzyl chloride under similar conditions was found to afford methylenebis(benzylmalononitrile) (III) in 88% yield.

$$CH(CN)_2CH_2CH(CN)_2 + 2C_6H_5CH_2Cl \xrightarrow{Et_3N} C_6H_5CH_2C(CN)_2CH_2C(CN)_2CH_2C_6H_5 \quad (3)$$

III

The structure of III was also determined by elemental and spectral analyses.

Polycondensation Reactions. Polycondensation of malononitrile with *p,p'*-bis(chloromethyl)diphenyl ether using triethylamine as an acid acceptor in dimethyl sulfoxide was carried out at room temperature in a similar manner to that for model reactions.



$$CH_2(CN)_2 + ClCH_2\text{-}C_6H_4\text{-}O\text{-}C_6H_4\text{-}CH_2Cl \xrightarrow{Et_3N} H\text{-}[C(CN)_2CH_2\text{-}C_6H_4\text{-}O\text{-}C_6H_4\text{-}CH_2]_n\text{-}Cl \quad (4)$$

IV

Polymer IV was obtained as a white powder in a quantitative yield and soluble in dimethylformamide, dimethyl sulfoxide and chloroform. Its structure was determined by elemental and spectral analyses, intrinsic viscosity in dimethyl sulfoxide at 30 °C being 0.15 dl/g.

* To whom inquiries should be directed.

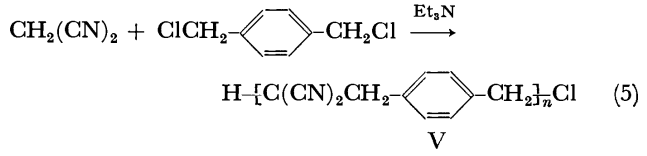
1) H. Normant and T. Cuvigny, *Bull. Soc. Chim. Fr.*, **1965**, 1881.

2) J. J. Bloomfield, *J. Org. Chem.*, **26**, 4112 (1961).

3) a) D. Brown, M. E. B. Jones, and W. R. Maltman, *J. Polym. Sci., Part B*, **6**, 635 (1968); b) Imperial Chemical Industries Ltd., Fr. 1 547 098 (1968); *Chem. Abstr.*, **71**, 40389f (1969).

The number average molecular weight of the polymer determined by vapor pressure osmometry in chloroform was 3200, *i.e.*, the number average degree of polymerization was about 12. Polycondensation of malononitrile with *p,p'*-bis(chloromethyl)diphenyl ether using sodium hydride as acid acceptor gave IV with a molecular weight of 5100.[3]

Polycondensation of malononitrile with *p*-xylylene dichloride under similar conditions gave polymer V in a quantitative yield.

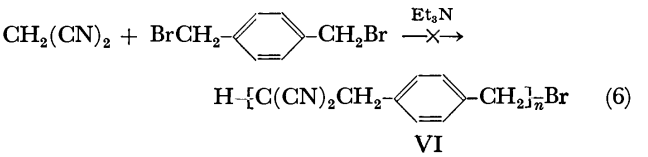


V

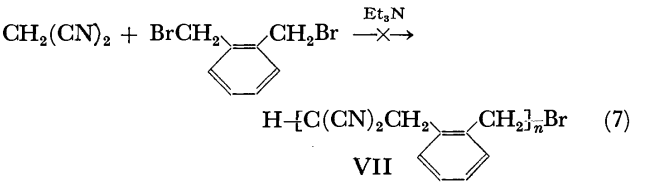
The polymer was soluble in sulfuric acid, but insoluble in most organic solvents. Its structure was determined by elemental and spectral analyses, intrinsic viscosity in sulfuric acid at 25 °C being 0.22 dl/g. Chemical analysis showed the presence of 0.96% of chlorine in the polymer. The result suggests that the number average degree of polymerization is about 22. Thermogravimetric analysis showed that the polymer was stable up to 330 °C under nitrogen atmosphere.

Efforts were made to increase the molecular weight of polymer V. Polycondensation (5) proceeded best in dimethyl sulfoxide. Polymer was obtained in neither diethyl ether nor chloroform. In tetrahydrofuran, low molecular weight oligomer was obtained only in 10% yield. In dimethylformamide, polymer was obtained in 60% yield, but its molecular weight was lower than that of the polymer obtained in dimethyl sulfoxide. The strong basicity of dimethyl sulfoxide seems to be essentially necessary for the polycondensation.

Polycondensation of malononitrile with *o*- and *p*-xylylene dibromides in a similar manner gave no polymeric material.

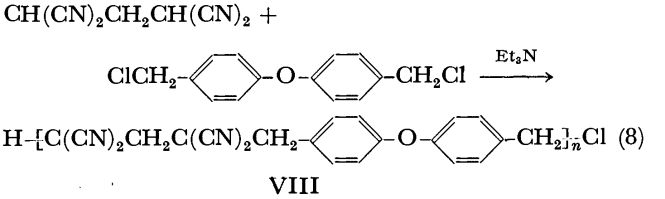


VI



VII

Polycondensation of methylenedimalononitrile with *p,p'*-bis(chloromethyl)diphenyl ether under similar conditions was also found to proceed smoothly to give polymer VIII in a quantitative yield.



VIII

The polymer was soluble in dimethyl sulfoxide but not in most organic solvents, its intrinsic viscosity in dimethyl sulfoxide at 30 °C being 0.14 dl/g and number average degree of polymerization estimated from the chlorine content about 9.

A similar polycondensation of methylenedimalononitrile with *p*-xylylene dichloride gave polymer IX in a quantitative yield.

IX

The polymer was insoluble in most organic solvents, the number average degree of polymerization estimated from the chlorine content being about 8.

Reactions of bis(chloromethyl)aromatic compounds with diethyl malonate, methyl cyanoacetate, acetylacetone and fluorene under similar reaction conditions gave no polymeric products.

Experimental

Materials. Malononitrile was purified by distillation. Methylenedimalononitrile (1,1,3,3-tetracyanopropane) was prepared from malononitrile and formaldehyde in the presence of piperidine,[4] mp 134—135 °C (lit,[4] 136—137 °C). NMR (in a 2:1 (volume ratio) mixture of CD_3CN and CCl_4, τ): 5.63 (2H, t, J=7.3 Hz), 7.23 (2H, t, J=7.3 Hz). Monomethylmalononitrile was prepared by the dehydration of monomethylmalonamide[5] with phosphorus pentoxide. Commercial *p*-xylylene dichloride and *o*- and *p*-xylylene dibromide were used without further purification. Benzyl chloride was purified by distillation. *p,p'*-Bis(chloromethyl)-diphenyl ether was prepared by the conventional method.[6] Triethylamine was purified by distillation in the presence of phenyl isocyanate. Dimethyl sulfoxide was refluxed over calcium hydride and distilled under reduced pressure. Tetrahydrofuran and diethyl ether were refluxed in the presence of benzophenone sodium ketyl and distilled. Chloroform was dried over calcium chloride and distilled. Dimethylformamide and dimethylacetamide were purified by distillation under reduced pressure. Nitrogen was purified by passing through a tube containing copper turnings in a furnace at 170 °C followed by drying with silica gel and molecular sieves.

General Procedure. Model reactions and polycondensations were carried out under a nitrogen atmosphere in Pyrex test tubes with magnetic stirring at room temperature. Organic halide and malononitrile or methylenedimalononitrile were dissolved in dimethyl sulfoxide. Triethylamine was added dropwise to the solution. Products were recovered by pouring into a large excess of water or methanol. Products of model reactions were purified by recrystallization from ethanol. Polymers IV and VIII were purified by reprecipitation from dimethyl sulfoxide with methanol followed by drying *in vacuo* over phosphorus pentoxide for prolonged periods at 120 and 90 °C, respectively. Polymers

V and IX were purified by drying *in vacuo* over phosphorus pentoxide at 190 and 150 °C, respectively, for prolonged periods of time.

Elemental analyses were performed at the Elemental Analyses Center of Kyoto University. Infrared spectra were recorded on a Japan Spectroscopic Co. Model 402G spectrometer. Proton magnetic resonance spectra were obtained with a Japan Electron Optics Lab. Model 4H-100 spectrometer using tetramethylsilane as an external standard. Viscosity measurements of polymer solutions were carried out in dimethyl sulfoxide at 30 °C or in sulfuric acid at 25 °C with an Ubbelohde-type dilution viscometer. The number average molecular weight of polymer was determined by vapor pressure osmometry in chloroform using a Hitachi-Perkin-Elmer Model 115 Molecular Weight Apparatus. Thermogravimetric analysis was performed with a thermobalance (wire-torsion balance) under nitrogen atmosphere.

Dibenzylmalononitrile (I). Condensation of malononitrile (20 mmol, 1.3 ml) with benzyl chloride (40 mmol, 4.6 ml) using triethylamine (42 mmol, 5.9 ml) as an acid acceptor in 5.0 ml of dimethyl sulfoxide for 18 hr gave I in a quantitative yield, mp 131.5 °C (lit,[2] 131.8—132.5 °C). The IR and NMR spectra were identical to those of an authentic sample.[2]

p-*Xylylenebis(methylmalononitrile) (II).* Reaction of monomethylmalononitrile (20 mmol, 1.60 g), *p*-xylylene dichloride (10 mmol, 1.75 g) and triethylamine (20 mmol, 2.8 ml) in dimethyl sulfoxide (10.0 ml) for 24 hr afforded II in 92% yield, mp 206 °C. Found: C, 73.53; H, 5.27; N, 21.51%. Calcd for $C_{16}H_{14}N_4$: C, 73.26; H, 5.38; N, 21.36%. NMR (CD_3COCD_3, τ): 3.18 (4H, s), 7.30 (4H, s), 8.80 (6H, s). IR (KBr disk): $\nu_{C\equiv N}$, 2250 cm^{-1}.

Methylenebis(benzylmalononitrile) (III). Reaction of methylenedimalononitrile (10 mmol, 1.44 g), benzyl chloride (20 mmol, 2.3 ml) and triethylamine (20 mmol, 2.8 ml) in 4.9 ml of dimethyl sulfoxide for 18 hr afforded III in 88% yield, mp 207 °C. Found: C, 77.85; H, 4.94; N, 17.23%. Calcd for $C_{21}H_{16}N_4$: C, 77.76; H, 4.97; N, 17.27%. NMR (CD_3COCD_3, τ): 3.10 (10H, s), 7.03 (4H, s), 7.59 (2H, s). IR (KBr disk): $\nu_{C\equiv N}$, 2250 cm^{-1}.

Polymer IV. Reaction of malononitrile (10 mmol, 0.66 g), *p,p'*-bis(chloromethyl)diphenyl ether (10 mmol, 2.67 g) and triethylamine (20 mmol, 2.8 ml) in 5.0 ml of dimethyl sulfoxide for 18 hr afforded polymer IV as a white powder in a quantitative yield. Found: C, 77.42, 77.43; H, 4.70, 4.75; N, 10.40; Cl, 0.73%. Calcd for $H(C_{17}H_{12}N_2O)_{12}Cl$: C, 77.54; H, 4.63; N, 10.64; Cl, 1.12%. NMR ($CDCl_3$, τ): 2.78 (8H, A_2B_2), 6.78 (4H, s). IR (KBr disk): $\nu_{C\equiv N}$, 2250 cm^{-1}.

Polymer V. Reaction of malononitrile (20 mmol, 1.32 g), *p*-xylylene dichloride (20 mmol, 3.50 g) and triethylamine (40 mmol, 5.6 ml) in 20.0 ml of dimethyl sulfoxide for 18 hr afforded polymer V in a quantitative yield. Found: C, 77.69; H, 4.49; N, 16.16; Cl, 0.96%. Calcd for $H(C_{11}H_8N_2)_{22}Cl$: C, 77.78; H, 4.77; N, 16.49; Cl, 0.95%. IR (KBr disk): $\nu_{C\equiv N}$, 2250 cm^{-1}. The IR spectrum showed a characteristic absorption of *p*-disubstituted benzene in the region 5—6 μ.

Polymer VIII. Reaction of methylenedimalononitrile (5 mmol, 0.72 g), *p,p'*-bis(chloromethyl)diphenyl ether (5 mmol, 1.34 g) and triethylamine (10 mmol, 1.4 ml) in 10.0 ml of dimethyl sulfoxide for 18 hr afforded polymer VIII in a quantitative yield. Found: C, 73.86; H, 4.22; N, 16.54; Cl, 1.21%. Calcd for $H(C_{21}H_{14}N_4O)_9Cl$: C, 73.66; H, 4.15; N, 16.36; Cl, 1.15%. NMR (CD_3SOCD_3, τ): 2.86 (8H, A_2B_2), 6.55 (4H, s), 7.06 (2H, s). IR (KBr disk): $\nu_{C\equiv N}$, 2250 cm^{-1}.

Polymer IX. Reaction of methylenedimalononitrile (10 mmol, 1.44 g) *p*-xylylene dichloride (10 mmol, 1.75 g) and triethylamine (20 mmol, 2.8 ml) in 20.0 ml of dimethyl sulfoxide for 24 hr afforded polymer IX in a quantitative yield. Found: C, 71.68, 71.73; H, 4.17, 4.33; N, 20.70, 21.09; Cl, 1.77, 1.80%. Calcd for $H(C_{15}H_{10}N_4)_8Cl$: C, 71.83; H, 4.07; N, 22.34; Cl, 1.77%. IR (KBr disk): $\nu_{C\equiv N}$, 2250 cm^{-1}. The IR spectrum showed a characteristic absorption of *p*-disubstituted benzene in the region 5—6 μ.

Compounds Relating to Dibenzoyladenine Riboside. The Choice between the N^6,1-Dibenzoyl and N^6,N^6-Dibenzoyl Structures

Kentaro ANZAI and Masanao MATSUI

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received January 29, 1973)

It was clarified, by NMR analysis and on the grounds of synthetic work, that dibenzoyladenine riboside and its analogues have the N^6,N^6-dibenzoyl structure rather than the N^6,1-dibenzoyl structure, which has customarily been used to describe the benzoyl derivatives of adenosine.

5′-*O*-Trityl-tetrabenzoyladenosine and its detritylated product were tentatively identified by Khorana and his colleagues[1] as N^6,1,2′-*O*,3′-*O*-tetrabenzoates (I and II), but without strictly excluding another possible assignment, N^6,N^6,2′-*O*-3′-*O*-tetrabenzoates (III and IV). Polybenzoylated adenosine residues in protected oligonucleotides have also been described in the N^6,1-dibenzoyl structure.[2] The perbenzoylated product of 2′,3′-*O*-ethoxymethylideneadenosine was registered by Sŏrm and his colleagues[3] as N^6,1,5′-*O*-tribenzoyl-2′,3′-*O*-ethoxymethylideneadenosine (V). The reaction product with benzoyl chloride of 6-benzamido-9-(5-deoxy-2, 3-*O*-isopropylidene-β-D-*erythro*-pent-4-enofuranosyl)purine was described by Moffatt and his colleagues[4] as the N^6,1-dibenzoate (VI).

We also met a similar situation when we synthesized derivatives of tubercidin[5] (7-deazaadenosine),[6] where two benzoyl groups were introduced into the pyrrolo-[2,3-*d*]pyrimidine moiety.[7–10] The perbenzoylated product of 2′,3′-*O*-isopropylidenetubercidin has been ambiguously described as *N*,*N*,5′-*O*-benzoyl-2′,3′-*O*-isopropylidenetubercidin.[11]

Thus, compounds relating to dibenzoyladenine riboside have been described as having the N^6,1-dibenzoyl structure, but without any reliable grounds. It is the purpose of this paper to present proof that they are actually N^6,N^6-dibenzoyl compounds.

The tetrabenzoyl derivatives of adenosine (III[1] and IV[1]) and the tribenzoyl derivatives of tubercidin (VII and VIII) show complex NMR patterns in the aromatic region; these patterns do not give any good information about the position of benzoylation. In the case of a dibenzoylated derivative (IX)[8] of adenosine and those of tubercidin (X,[8] XI,[7] and XII[7]) signals of four *ortho* protons of benzoyl groups have been observed to separate well from the signals of the other aromatic protons, and these four protons have been shown to be equivalent; IX δ 7.84 J_{ortho}=7 Hz, X δ 7.82 J_{ortho}=7 Hz, XI δ 7.84 J_{ortho}=8 Hz, XII δ 7.83 J_{ortho}=7 Hz.

To obtain more certain information about the position of benzoylation, we prepared several toluyl derivatives of adenosine and observed the signals of the methyl protons. The results are shown in Table 1. In every case the signals corresponding to two methyls of toluyl groups, which are introduced in the adenine moiety, are found never to split, exhibiting a sharp singlet. Moreover, the NMR spectrum of the ditoluyl compound (XVI) (Fig. 1) exhibits a pair of doublets (δ 7.13 and 7.74, J_{ortho}=8 Hz) assignable to aromatic protons of toluyl groups; this also supports the N^6,N^6-ditoluyl structure. In the case of a tubercidin derivative the NMR spectrum of the tritoluyl compound (XVIII) exhibited a sharp singlet at δ 2.34 corresponding to two methyls of toluyl groups introduced in the pyrrolo-[2,3-*d*]pyrimidine moiety. The spectrum of XIII was taken at lower temperatures (Fig. 2), for we expected that a signal at δ 2.28 corresponding to two methyls might split by the restricted rotation of the bond between N^6 and C-6. However, only a broadening of the signal was observed, so we devised another proof for the N^6,N^6-diacyl structure.

9-Methyladenine (XIX) was converted to its benzoyl *p*-toluyl derivative *via* two routes; thus, the benzoylated product of 9-methyl-N^6-*p*-toluyladenine and the toluylated product of N^6-benzoyl-9-methyladenine were prepared, and these two products were compared exhaustively. If they are the same compound, both acyl groups should be bound at N^6.

The reaction of 9-methyladenine (XIX) with excess *p*-toluyl chloride afforded N^6,N^6-di-*p*-toluyl-9-methyl-

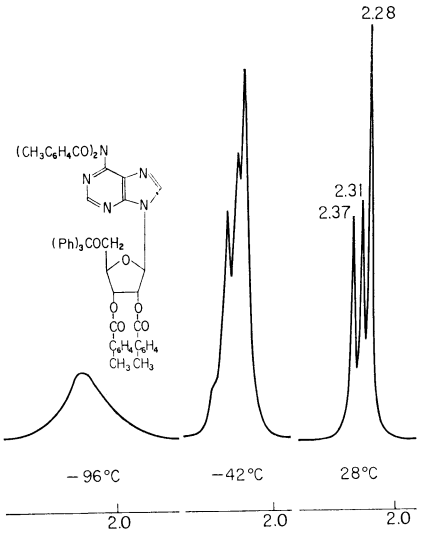

Fig. 2. NMR spectrum of N^6,N^6,2′-*O*, 3′-*O*-tetra-*p*-toluyl-5′-*O*-trityladenosine (XIII) at 28, −42, and −96 °C. (100 MHz, CS_2).

adenine (XX). The NMR spectrum of XX shows a sharp singlet at δ 2.31 corresponding to two methyls of *p*-toluyl groups. Similarly, N^6,N^6-di-*o*-toluyl-9-methyladenine (XXI) was prepared. The spectrum of XXI exhibits a six-proton singlet at δ 2.53. Attempts to prepare the monotoluyl compound (XXII), on the hydrolysis of XX, failed. In aqueous acetic acid, in a solution of sodium bicarbonate, or even in ethanol the only product obtained was XIX under the conditions where XX was partially hydrolysed. When XIX was treated with an equimolar amount of *p*-toluyl chloride, half of the starting material was converted to XX.

Compound XX was treated with lithium aluminum hydride in refluxing tetrahydrofuran to give 9-methyl-N^6-*p*-methylbenzyladenine (XXIII). However, when this reaction was carried out at room temperature, 9-methyl-N^6-*p*-toluyladenine (XXII) was obtained in a moderate yield. The benzoylation of XXII afforded N^6-benzoyl-9-methyl-N^6-*p*-toluyladenine (XXIV). Similarly, N^6,N^6-dibenzoyl-9-methyladenine (XXV) was treated with lithium aluminum hydride, and the product, N^6-benzoyl-9-methyladenine (XXVI), was treated with *p*-toluyl chloride. Thus, two samples of the benzoyl *p*-toluyl compound were prepared, and their NMR, IR (Fig. 3), UV, and Mass spectra were compared. It was shown that all of the spectral data were identical, strongly supporting the idea that dibenzoyladenine riboside and its derivatives should be described as having the N^6,N^6-dibenzoyl structure.

Preparation. The benzylidene benzoate (VIII) was prepared by the treatment of 2′,3′-*O*-benzylidenetubercidin (XXVII) with excess benzoyl chloride. The tetra-*p*-toluyl trityl ether (XIII) was prepared by the treatment of 5′-*O*-trityladenosine with excess *p*-toluyl chloride. The treatment of XIII in hot aqueous acetic acid for a short period afforded the detritylated compound (XIV). On the prolonged heating of XIII, the glycosidic bond was cloven and the isolated products were N^6,N^6-di-*p*-toluyladenine (XXVIII), N^6-*p*-toluyladenine (XXIX), and 2′,3′-*O*-di-*p*-toluylribose (XXX). The isopropylidene tri-*p*-toluyl compound (XV) was

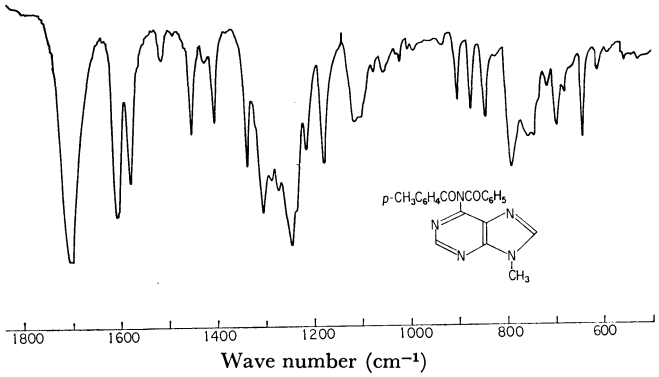

Fig. 3. IR spectrum of N^6-benzoyl-9-methyl-N^6-*p*-toluyladenine (XXIV). (KBr).

prepared by the treatment of 2′,3′-*O*-isopropylideneadenosine (XXXI) with excess *p*-toluyl chloride. Similarly, XVIII was prepared from 2′,3′-*O*-isopropylidenetubercidin (XXXII).[11] Compound XXXI was treated with ethyl vinyl ether in the presence of trifluoroacetic acid to give the acetal (XXXIII), which was then converted to the di-*p*-toluyl compound (XVII).

The treatment of XXXII with acetyl chloride afforded N^6,5′-*O*-diacetyl-2′,3′-*O*-isopropylidenetubercidin (XXXIV), and a triacetate corresponding to VII and XVIII was not obtained.

Experimental

2′,3′-O-Isopropylidenetubercidin (XXXII). The reported method[11] was improved to result in an increase in the yield. Tubercidin (5 g) was treated with tosyl chloride (37.5 g) in a mixture of acetone (250 ml) and acetone dimethyl acetal (25 ml) with stirring at room temperature. Within 2 hr the tubercidin was dissolved completely. The reaction mixture was poured into a cold solution of sodium bicarbonate (0.5 M, 1 liter), and the acetone was evaporated under reduced pressure. After the product had been extracted with chloroform, the organic layer was repeatedly washed with water and concentrated to dryness to afford a syrup (5.24 g, 92%), which was used without furthur purification for the succeeding processes. When acetone dimethyl acetal was excluded from this system, as has been reported previously,[11] the yield was 80%.

2′,3′-O-Benzylidenetubercidin (XXVII). A mixture of tubercidin (500 mg), zinc chloride (500 mg), and benzaldehyde (10 ml) was stirred at room temperature overnight and then poured into ice water. The product was extracted with chloroform, and the organic layer was washed with a cold solution of sodium bicarbonate and then with water. The chloroform was then evaporated, and petroleum ether was added to the residue. A syrupy sample of XXVII was separated by decantation and repeated precipitation from chloroform and petroleum ether; yield, 600 mg. An analytical sample was obtained by chromatography on silica gel (Kieselgel 0.05—0.2 mm, Merck), the developing being done with a mixture of ethyl acetate and methanol (9: 1); λ_{max}^{MeOH} mμ(ε) 270 (12000).

Found: C, 61.21; H, 5.27; N, 15.74%. Calcd for $C_{18}H_{18}O_4N_4$: C, 61.01; H, 5.12; N, 15.81%.

N⁶,N⁶,5′-O-Tribenzoyl-2′,3′-O-benzylidenetubercidin (VIII). Into a stirred solution of XXVII (5.1 g) in pyridine (50 ml), benzoyl chloride (10 g) was added dropwise keeping the temperature at −10 °C. The solution was then left at 0 °C for additional 4 hr and was then poured into an ice-cooled solution of sodium bicarbonate. The product was extracted with chloroform, and the solvent was evaporated to dryness. The residue was crystallized from ethyl acetate; yield, 6.9 g; mp 203 °C; $[\alpha]_D^{23}$ −87.5° (*c* 2.69, DMSO); λ_{max}^{MeOH} mμ(ε) 280 (sh, 12000), 224 (47000).

Found: C, 70.20; H, 4.55; N, 8.40%. Calcd for $C_{39}H_{30}O_7N_4$: C, 70.26; H, 4.54; N, 8.40%.

N⁶,N⁶,2′-O,3′-O-Tetra-p-toluyl-5′-O-trityladenosine (XIII). 5′-*O*-Trityladenosine[1] (2.6 g) was suspended in pyridine (20 ml), and then *p*-toluyl chloride (5 ml) was added at once. After stirring at room temperature for 18 hr, a clear solution was obtained. The reaction mixture was poured into an ice-cooled solution of sodium bicarbonate, and the product was extracted with chloroform. The solution was concentrated to dryness, and the residue was chromatographed on silica gel; development with a mixture of benzene and ethyl acetate (9: 1) resulted in the separation of XIII from triphenyl carbinol, the latter being eluted earlier. A crystalline mass melting at 132—138 °C was obtained from benzene and ligroin; yield, 5.1 g; $[\alpha]_D^{25}$ −71.7° (*c* 1.51, $CHCl_3$).

Found: C, 75.00; H, 5.43; N, 7.13%. Calcd for $C_{61}H_{51}O_8N_5$: C, 74.60; H, 5.24; N, 7.13%.

N⁶,N⁶,2′-O,3′-O-Tetra-p-toluyladenosine (XIV). A solution of XIII (1 g) in 70% aqueous acetic acid (50 ml) was heated on a water bath for 10 min. Several products were detected on tlc; among them one was found to be predominant; $R_{f\ major\ product}$: 1.3, 1.0, 0.3, 0 (benzene and ethyl acetate 4: 1). The major product was separated by chromatography on silica gel, developing with a mixture of benzene and ethyl acetate (4: 1) and increasing the content of the latter gradually; yield, 270 mg (36%). An analytical sample was obtained as crystals from benzene and ligroin; mp 173—174 °C; $[\alpha]_D^{25}$ −236° (*c* 1.73, $CHCl_3$).

Found: C, 68.23; H, 5.16; N, 9.35%. Calcd for $C_{42}H_{37}O_8N_5$: C, 68.19; H, 5.04; N, 9.47%.

Glycosidic Bond Cleavage of XIII. A solution of XIII (1 g) in 70% aqueous acetic acid (50 ml) was heated on a water bath for 2 hr. The formation of three products was shown on tlc (benzene and ethyl acetate 1: 1), and they

were separated by chromatography on silica gel. The least polar one was eluted with a mixture of benzene and ethyl acetate (1: 1) and was obtained as a syrup from benzene and petroleum ether; yield, 340 mg. It was identified as 2′,3′-*O*-di-*p*-toluylribose (XXX), $[\alpha]_D^{25}$ +14.8° (*c* 1.03, $CHCl_3$); λ_{max}^{MeOH} mμ(ε) 236 (21300); NMR (100 MHz, $CDCl_3$): δ 2.34 and 2.39 (6H, two singlets, $2C\underline{H}_3C_6H_4CO$); M^+ 386.

Found: C, 65.50; H, 5.70%. Calcd for $C_{21}H_{22}O_7$: C, 65.27; H, 5.74%.

After the column had been washed with ethyl acetate, a mixture of ethyl acetate and methanol (9: 1) was used for elution. Two products were obtained. The less polar one, which was identified as N^6,N^6-ditoluyladenine (XXVIII), was crystallized from chloroform and benzene; yield, 83 mg; mp 231 °C; λ_{max}^{MeOH} mμ(ε) 290 (sh, 6500), 240 (33400); NMR (100 MHz, DMSO-*d*): δ 2.32 (6H, s, $2C\underline{H}_3C_6H_4CO$), 7.24 and 7.84 (8H, two doublets, J=8 Hz, $2CH_3C_6\underline{H}_4CO$).

Found: C, 64.70; H, 5.23; N, 18.11%. Calcd for $C_{21}H_{17}N_5O_2\cdot H_2O$: C, 64.77; H, 4.92; N, 17.99%.

The most polar compound, N^6-toluyladenine (XXIX), was crystallized from chloroform and benzene; yield, 110 mg; mp 224—225 °C; λ_{max}^{MeOH} mμ(ε) 287 (23400), 252 (16200); NMR (100 MHz, DMSO-*d*): δ 2.40 (3H, s, $C\underline{H}_3C_6H_4CO$), 7.35 and 8.04 (4H, two doublets, J=8 Hz, $CH_3C_6\underline{H}_4CO$); M^+ 253.

Found: C, 61.45; H, 4.31; N, 27.95%. Calcd for $C_{13}H_{11}ON_5$: C, 61.65; H, 4.38; N, 27.66%.

N^6,N^6,*5′*-O-p-*Toluyl-2′,3′*-O-*isopropylideneadenosine (XV)*. To a solution of XXXI (614 mg) in pyridine (50 ml), *p*-toluyl chloride (1.6 g) was added, drop by drop, at −10 °C. The solution was then kept in a refrigerator overnight and subsequently poured into an ice-cooled solution of sodium bicarbonate. The product was extracted with chloroform, and the chloroform layer was concentrated to dryness. Tlc showed the presence of two UV-positive compounds, which were separated by silica gel chromatography, developing with a mixture of benzene and ethyl acetate (8: 1), the content of the latter being gradually increased. The less polar one was identified as *p*-toluic anhydride. The more polar compound, identified as XV, was crystallized from benzene and ligroin; yield, 550 mg; mp 170 °C, $[\alpha]_D^{25}$ −11.0° (*c* 1.69, $CHCl_3$).

Found: C, 67.15; H, 5.32; N, 10.55%. Calcd for $C_{37}H_{35}O_7N_5$: C, 67.16; H, 5.33; N, 10.59%.

5′-O-*(1-Ethoxyethyl)-2′,3′*-O-*isopropylideneadenosine (XXXIII)*. To a solution of XXXI (1 g) and ethyl vinyl ether (3 ml) in dimethylformamide (50 ml) cooled at −15——20 °C, trifluoroacetic acid (3 ml) was added. After 3 hr the reaction mixture was poured into a cold solution of sodium bicarbonate (0.5 M, 500 ml). The desired product was extracted with chloroform and was separated by silica gel chromatography, being eluted with a mixture of ethyl acetate and methanol (95: 5), the content of the latter being gradually increased. The eluate was concentrated to dryness, affording a syrup; yield, 785 mg; $[\alpha]_D^{25}$ −35.7° (*c* 0.32, $CHCl_3$); λ_{max}^{MeOH} mμ(ε) 260 (13000); Mass *m/e*: 379 (M^+), 364 (M^+-CH_3), 350 ($M^+-C_2H_5$), 334 ($M^+-C_2H_5O$).

Found: C, 54.32; H, 6.77; N, 18.07%. Calcd for $C_{17}H_{25}O_5N_5$: C, 53.81; H, 6.64; N, 18.46%.

N^6,N^6-*Di*-p-*toluyl-5′*-O-*(1-ethoxyethyl)-2′,3′*-O-*isopropylideneadenosine (XVII)*. To an ice-cooled and stirred solution of XXXIII (758 mg) in pyridine (5 ml), *p*-toluyl chloride (1 g) was added; it was then kept standing in a refrigerator overnight. The reaction mixture was poured onto a cold solution of sodium bicarbonate, and the product was extracted with chloroform. Silica gel chromatography, on developing with a mixture of benzene and ethyl acetate (4: 1), afforded 580 mg of a syrup; this was repeatedly precipitated from carbon tetrachloride and *n*-hexane; $[\alpha]_D^{25}$ −52.6° (*c* 0.79, $CHCl_3$).

Found: C, 64.11; H, 5.92; N, 10.91%. Calcd for $C_{33}H_{37}O_7N_5$: C, 64.37; H, 6.06; N, 11.38%.

N^6, N^6, *5′* - O - *Tri* - p - *toluyl* - *2′*, *3′* - O - *isopropylidenetubercidin (XVIII)*. To an ice-cooled and stirred soltion of XXXII (306 mg) in pyridine (30 ml), *p*-toluyl chloride (800 mg) was added drop by drop. After it had then been

kept standing in a refrigerator overnight, the reaction mixture was poured into a cold solution of sodium bicarbonate and the product was extracted with chloroform. The solution was concentrated to dryness, and the residue was crystallized from ethyl acetate and ligroin; yield, 460 mg (70%); mp 204—207 °C; $[\alpha]_D^{25}$ −47.5° (*c* 2.51, $CHCl_3$); λ_{max}^{MeOH} mμ(ε) 240 (47500); NMR (100 MHz, $CDCl_3$): δ 1.39 and 1.64 (6H, two singlets, isopropylidene methyls), 2.34 (6H, s, $(C\underline{H}_3C_6H_4CO)_2N$), 2.39 (3H, s, $C\underline{H}_3C_6H_4COO$).

Found: C, 68.55; H, 5.54; N, 8.34%. Calcd for $C_{38}H_{36}O_7N_4$: C, 69.08; H, 5.49; N, 8.48%.

N⁶,N⁶-*Di*-p-*toluyl-9-methyladenine (XX).* 9-Methyladenine (826 mg) was suspended in pyridine (50 ml), and then *p*-toluyl chloride (3 ml) was added at once. After the solution had been stirred at room temperature overnight, it was poured into a cold solution of sodium bicarbonate and the product was extracted with chloroform. *p*-Toluic anhydride formed was separated by silica gel chromatography, developing with a mixture of benzene and ethyl acetate (2: 1); thus, 1.37 g of XX were isolated. It was crystallized from benzene and *n*-hexane; mp 216—218 °C; λ_{max}^{MeOH} mμ(ε) 262 (30000); NMR (100 MHz, $CDCl_3$): δ 2.31 (6H, s, $(C\underline{H}_3C_6H_4CO)_2N$), 3.82 (3H, s, $CH_3N\langle$), 7.12 and 7.76 (8H, two doublets, J=8 Hz, $(CH_3C_6\underline{H}_4CO)_2N$), 8.20 (1H, s, H-8), 8.64 (1H, s, H-3).

Found: C, 68.49; H, 4.99; N, 18.17%. Calcd for $C_{22}H_{19}O_2N_5$: C, 68.56; H, 4.97; N, 18.17%.

N⁶,N⁶-*Di*-o-*toluyl-9-methyladenine (XXI).* 9-Methyladenine (92 mg) was treated with *o*-toluyl chloride (300 mg), as has been described in the preceeding section. The isolated product, XXI, was crystallized from carbon tetrachloride; yield, 160 mg; mp 184—185 °C; λ_{max}^{MeOH} mμ(ε) 270 (18400), 252 (20000); NMR (60 MHz, $CDCl_3$): δ 2.53 (6H, s, $2C\underline{H}_3C_6H_4CO$), 3.97 (3H, s, $CH_3N\langle$).

Found: C, 67.26; H, 4.90; N, 17.87%. Calcd for $C_{22}H_{19}O_2N_5\cdot 1/2H_2O$: C, 67.00; H, 5.11; N, 17.76%.

N⁶,N⁶-*Dibenzoyl-9-methyladenine (XXV).* 9-Methyladenine (1 g) was treated with benzoyl chloride (3 ml), as has been described in the preceeding section. Crystals of XXV were obtained from ethyl acetate and carbon tetrachloride; yield, 1.07 g; mp 182—184 °C; λ_{max}^{MeOH} mμ(ε) 270 (sh, 20000); 249 (26000).

Found: C, 65.96; H, 4.18; N, 19.42%. Calcd for $C_{20}H_{15}O_2N_5\cdot 1/2H_2O$: C, 65.56; H, 4.40; N, 19.12%.

9-Methyl-N⁶-p-*methylbenzyladenine (XXIII).* Compound XX (165 mg) was treated with lithium aluminum hydride (95 mg) in refluxing tetrahydrofuran (70 mg) for 17 hr. After the excess lithium aluminum hydride had been destroyed with water, the product, which was shown to be homogeneous on tlc, was extracted with chloroform. The solvent was evaporated, and the residue was crystallized from carbon tetrachloride; yield, 120 mg; mp 154 °C; λ_{max}^{MeOH} mμ(ε) 270 (18200); NMR (100 MHz, $CDCl_3$): δ 2.34 (3H, s, $C\underline{H}_3C_6H_4CH_2$), 3.82 (3H, s, $CH_3N\langle$), 3.90 (2H, broad d, J=4 Hz, $CH_3C_6H_4C\underline{H}_2$).

Found: C, 65.74; H, 5.94; N, 27.86%. Calcd for $C_{14}H_{15}N_5$: C, 65.38; H, 5.97; N, 27.65%.

9-Methyl-N⁶-p-*toluyladenine (XXII).* Compound XX (180 mg) was treated with lithium aluminum hydride (68 mg) in tetrahydrofuran (100 ml) at room temperature for 4 days. After the excess reagent had been destroyed with water, the products were extracted with chloroform. Tlc exhibited several UV-positive spots; among them, two major products were isolated by silica gel chromatography, developing with a mixture of ethyl acetate and methanol (9: 1), the content of the latter being gradually increased. The less polar one was identified as XXIII; yield, 15 mg. The more polar one, identified as XXII, was crystallized from ethyl acetate; yield 75 mg; mp 176—177 °C; λ_{max}^{MeOH} mμ(ε) 282 (15400); NMR (100 MHz, $CDCl_3$): δ 2.42 (3H, s, $C\underline{H}_3C_6H_4CO$), 3.90 (3H, s, $CH_3N\langle$).

Found: C, 60.82; H, 5.02; N, 25.73%. Calcd for $C_{14}H_{13}ON_5\cdot 1/2H_2O$: C, 60.85; H, 5.11; N, 25.35%.

N⁶-*Benzoyl-9-methyladenine (XXVI).* Compound XXV (730 mg) was treated with lithium aluminum hydride (250 mg) in tetrahydrofuran (100 ml) at room temperature for 6 days. After the excess reagent had then been destroyed with water, the products were extracted with chloroform and chromatographed on silica gel, developing with a mixture of ethyl acetate and methanol (9: 1), the content of the latter being gradually increased. The less polar one (yield, 107 mg) was found to be N^6-benzyl-9-methyladenine, as had already been reported by some workers.[12] The more polar one, which was identified as XXVI, was crystallized from ethyl acetate; yield, 133 mg; mp 189—191 °C; λ_{max}^{MeOH} mμ(ε) 280 (18300), 230 (sh, 14500).

Found: C, 61.65; H, 4.38; N, 27.96%. Calcd for $C_{13}H_{11}ON_5$: C, 61.47; H, 4.37; N, 28.38%.

N⁶-*Benzoyl-9-methyl*-N⁶-p-*toluyladenine (XXIV).* Compound XXII (125 mg) was treated with benzoyl chloride (108 mg) in pyridine (5 ml) at 0 °C for 1 hr; then the reaction mixture was poured into a cold solution of sodium bicarbonate. The product was extracted with chloroform and chromatographed on silica gel developing with ethyl acetate. From carbon tetrachloride, 34 mg of a glassy substance, which was shown to be homogeneous on tlc, were obtained. The analytical data showed that the solvent was difficult to exclude even on prolonged heating *in vacuo*; *e.g.*, after heating at 56 °C for 4 hr, a 2/3 equivalent of carbon tetrachloride was found to remain, and a 1/3 equivalent still remained after it had been treated at 80 °C for 8 hr. The same compound was prepared from XXVI (85 mg) and *p*-toluyl chloride (150 mg); yield, 40 mg; λ_{max}^{MeOH} mμ(ε) 270 (sh, 18700), 255 (20000); NMR (60 MHz, $CDCl_3$): δ 2.20 (3H, s, $C\underline{H}_3C_6H_4CO$), 4.00 (3H, s, $CH_3N\langle$); Mass *m/e*: 370 (M^+), 342 (M^+-CO), 266 ($M^+-C_6H_5CO+H$), 252 ($M^+-CH_3C_6H_4CO+H$).

N⁶,*5'*-O-*Diacetyl-2',3'*-O-*isopropylidenetubercidin (XXXIV).* To an ice-cooled solution of XXXII (306 mg, 1 mml) in pyridine, acetyl chloride (800 mg, 10 mml) was added drop by drop. After 2 hr, the reaction mixture was poured into a cold solution of sodium bicarbonate. The product was extracted with chloroform and chromatographed on silica gel, developing with a mixture of benzene and ethyl acetate (2: 1), the content of the latter being gradually increased. Precipitation from ethyl acetate and ligroin afforded 183 mg of a syrup; $[\alpha]_D^{25}$ −20.0° (*c* 2.04, $CHCl_3$); λ_{max}^{MeOH} mμ(ε) 287 (7800).

Found: C, 55.69; H, 5.57; N, 14.04%. Calcd for $C_{18}H_{22}O_6N_4$: C, 55.55; H, 5.59; N, 14.35%.

The Metalation of Fluorene by Means of the Diethylmagnesium-Hexamethylphosphoramide System

Masao TOMOI and Hiroshi KAKIUCHI

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Yokohama 233

(Received January 31, 1973)

The metalation of fluorene by means of the Et_2Mg–HMPA system was investigated. The reaction scarcely occurred at all when the mole ratio of HMPA: Et_2Mg fell below 1: 1, but it proceeded easily when the ratio was over 1: 1, and a solvent-separated ion pair of magnesium fluorenide was formed. When the ratio was 2: 1, the order of reaction was unity in both fluorene and Et_2Mg. It was demonstrated by the kinetic and NMR studies that the active species of metalation in such a case was not Et_2Mg but the Et_2Mg–HMPA complex, in which two molecules of HMPA are coordinated to Et_2Mg.

In recent years dipolar solvents, especially dipolar aprotic solvents, have frequently been used as media or reactants for organic reactions. Previously we[1] ourselves reported that Grignard's reagent (RMgX) could not polymerize styrene in toluene, but that high-molecular polystyrene could be obtained when hexamethylphosphoramide (HMPA) existed in over twice the molar quantity of RMgX. It was demonstrated that RMgX was changed to an ionic form, *i.e.*, carbanion, by the coordination of HMPA, and that the initiation reaction proceeded by means of the addition of the carbanion to the styrene monomer. In this paper, the metalation of fluorene by means of the diethylmagnesium–HMPA system will be investigated in order to make clear the role of HMPA in organomagnesium compound–HMPA systems. Normant[2] has already reported the metalation of fluorene by isopropylmagnesium chloride in HMPA, but the mechanism of the reaction has not yet been studied.

Experimental

Reagents. Fluorene (FL) was purified by recrystallization from ethanol. A solution of diethylmagnesium (Et_2Mg) was prepared by adding dioxane to an ether solution of ethylmagnesium bromide. The concentration of the solution of Et_2Mg was determined by acid-base titration.[3] HMPA was refluxed and distilled over calcium hydride *in vacuo*.

Metalation Reaction. The reaction of FL with Et_2Mg was done in 0.2 cm optical cells under an atmosphere of nitrogen. Et_2Mg in ether was added to a toluene solution of FL, and at last HMPA in toluene was introduced into the reaction system. Within two min of the mixing of the reagents, the cell was placed in a Hitachi EPS-3T recording spectrophotometer and the optical density at 373 nm was monitored as a function of the time. The absorption at this wavelength is due to the product, fluorenyl carbanion.

Measurement of the NMR Spectrum. The NMR spectrum of the Et_2Mg–HMPA system in ether was taken with a JNM C-60H spectrometer at room temperature, using teramethylsilane as the internal standard.

Results and Discussion

Electronic Spectrum of the Reaction Product. In the absence of HMPA, scarecely no reaction of FL and Et_2Mg in toluene or tetrahydrofuran (THF) occurred. However, the reaction easily proceeded in the presence of HMPA, and fluorenyl carbanion (FL^-) was formed. Figure 1 shows the spectra of the reaction product and fluorenyllithium in THF. The absorption spectrum of magnesium fluorenide has a peak at 373 nm. This peak has been assigned by Hogen-Esch and Smid[4] to the solvent-separated ion pair of alkali fluorenides in ethereal solvents. The spectrum of magnesium fluorenide in the visible region was similar to that of the solvent-separated ion pair of fluorenyllithium. These results indicate that the magnesium fluorenide produced in the presence of HMPA exists as a solvent-separated ion pair.

The NMR spectrum[5] of magnesium fluorenide produced by the reaction of FL with equimolar quantities of Et_2Mg at $[HMPA]/[Et_2Mg]=3$ indicated that the

product consisted of equimolar amounts of fluorenyl and ethyl groups. The fluorenyl part of the NMR spectrum of the product was similar to that of fluorenyllithium in THF.[6] Moreover, the chemical shift of methylene protons, δ_{CH_2}, in the product was −1.1, while the value of δ_{CH_2} in Et_2Mg was −0.88 at [HMPA]/[Et_2Mg]=3 (see below). This fact indicates that the diamagnetic anisotropy induced by the aromatic ring strongly shields the ethyl protons. Consequently, the metalation seems to proceed as is shown in Reaction (1), and ethylfluorenylmagnesium (FL^-Mg^+Et) is formed:

$$FL + Et_2Mg \longrightarrow FL^-Mg^+Et + EtH \quad (1)$$

$$2FL^-Mg^+Et \rightleftarrows (FL^-)_2Mg^{2+} + Et_2Mg \quad (2)$$

The mixed reagent (FL^-Mg^+Et) may coexist at equilibrium, as is shown in Reaction (2). The NMR data, however, indicate that the structure of the magnesium fluorenide produced is a mixed reagent rather than a mixture of difluorenylmagnesium ($(FL^-)_2Mg^{2+}$) and Et_2Mg. It has been reported by House *et al.*[7] that a similar mixed reagent was formed when dicyclopentadienylmagnesium and diethylmagnesium were mixed in ether. Since a large excess of Et_2Mg over FL was used in the kinetic experiment, the equilibrium could be considered to lie far to the left.

We allowed a reaction system to come to the steady state and then diluted it with various quantities of toluene, measuring the optical density of the solution at each stage. This showed that Beer's law was accurately obeyed; the extinction coefficient of magnesium fluorenide was $\varepsilon_{373}=9900$.

Kinetic Studies. In a previous paper,[1] we reported that the molar ratio of HMPA to a organomagnesium compound was a significant factor in the polymerization of styrene by the RMgX–HMPA. In this paper, the molar ratio, α, is defined as follows:

$$\alpha = \frac{[\text{HMPA}]}{[\text{Organomagnesium compound}]} \quad (3)$$

Figure 2 shows the variation in the optical density of the reaction system with the time at $\alpha=2$. The optical density increased with the time and became a constant value after about 20 hr. In the absence of HMPA ($\alpha=0$), the optical density remained zero, even after about 22 hr. Since a large excess of Et_2Mg over FL was used in this experiment, the order of the reaction in the latter reagent could be obtained from an analysis of the optical density-time curve.[8] In this manner, we found the order of the reaction in FL to be 1.0. Thus, we may write:

$$\text{Rate of production of } FL^- = dFL^-/dt = k[FL] \quad (4)$$

where k is the first-order rate constant.

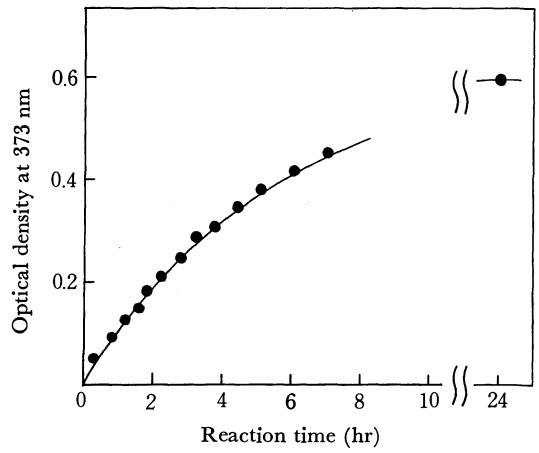

Fig. 2. A typical reaction rate plot.
$[FL]_0=3.04\times10^{-4}$ M, $[Et_2Mg]_0=2.37\times10^{-2}$ M, $[HMPA]_0=4.75\times10^{-2}$ M, Temp.: 19.0 °C.

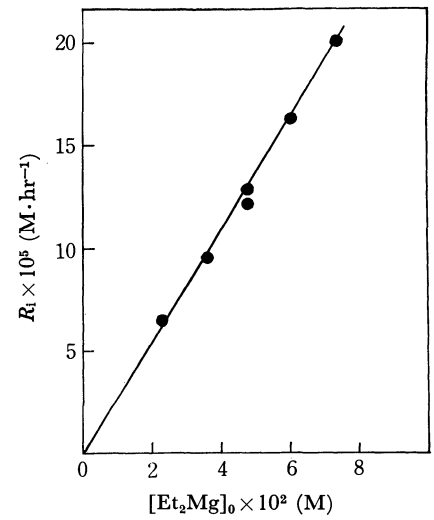

Fig. 3. Dependence of initial rate on initial diethylmagnesium concentration.
$[FL]_0=3.40\times10^{-4}$ M, $[HMPA]_0/[Et_2Mg]_0=2.0$, Temp.: 19.0 °C.

Figure 3 shows the dependence of the initial rate (R_i) on the initial diethylmagnesium concentration $[Et_2Mg]_0$ at $\alpha=2$. This finding indicates the order of the reaction in Et_2Mg to be 1.0. Consequently, the rate of the production of FL^- at $\alpha=2$ may be written as follows:

$$dFL^-/dt = k'[Et_2Mg][FL] \quad (5)$$

where k' is the second-order rate constant.

Effect of the Molar Ratio of HMPA to Et_2Mg (α). Figure 4 shows the dependence of the initial rate (R_i) on the molar ratio of HMPA to Et_2Mg (α) at a constant Et_2Mg concentration. When α is less than about unity, the rate of metalation is zero, while the reaction is significantly promoted when α is more than about unity. The relationship between R_i and α is indicated by the two straight lines, the slopes of which are dependent on the range of α. One is the range in α from about unity to about two, while the other is in the α range over about two. The increment of the rate was larger in the former range than in the latter.

The dependence of R_i on $[Et_2Mg]_0$ at a constant concentration of HMPA is shown in Fig. 5. When α was less than about two, the rate decreased greatly in spite of the increase in the concentration of Et_2Mg.

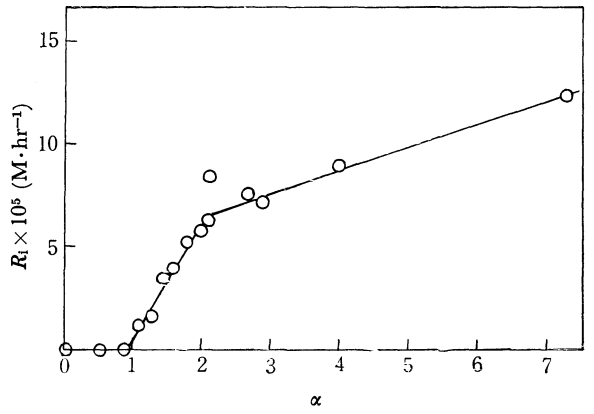

Fig. 4. Dependence of initial rate on α at a constant diethylmagnesium concentration.
$[FL]_0=2.80\times10^{-4}$ M, $[Et_2Mg]_0=3.95\times10^{-2}$ M, Temp.: 15.0 °C.

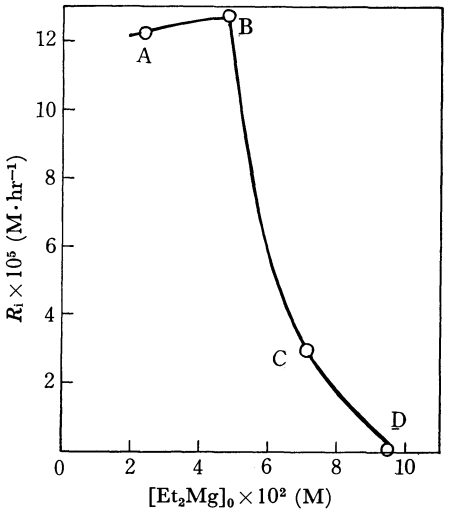

Fig. 5. Dependence of initial rate on initial diethylmagnesium concentration at a constant HMPA concentration.
$[FL]_0=3.40\times10^{-4}$ M, $[HMPA]_0=9.50\times10^{-2}$ M, Temp.: 19.0 °C.
The values of α are as follows;
A: 4.0, B: 2.0, C: 1.33, D: 1.0.

This fact indicates that, in the course of the reaction the important factor is not the Et_2Mg concentration, but the molar ratio of HMPA to Et_2Mg, this is, α.

NMR Spectrum of the Et_2Mg–HMPA System. The chemical shift of the methyl protons in Et_2Mg, δ_{CH_3}, was 1.17 in ether, while that of the methylene protons, δ_{CH_2}, was −0.65. The value of δ_{CH_2} was dependent on α. However, δ_{CH_3} scarcely changed in the presence of HMPA. Figure 6 shows the dependence of δ_{CH_2} on α. The change in δ_{CH_2} was small when α was less than about unity. The δ_{CH_2}, however, shifted upfield with an increase in α when α was between about unity and about two. When α was over about two, the magnitude of the decrease in δ_{CH_2} was small.

It is known that an approximately linear relationship exists between the internal chemical shift in ethyl compounds and the electronegativity of the substituent or the metal atom.[9] We could study the change in the

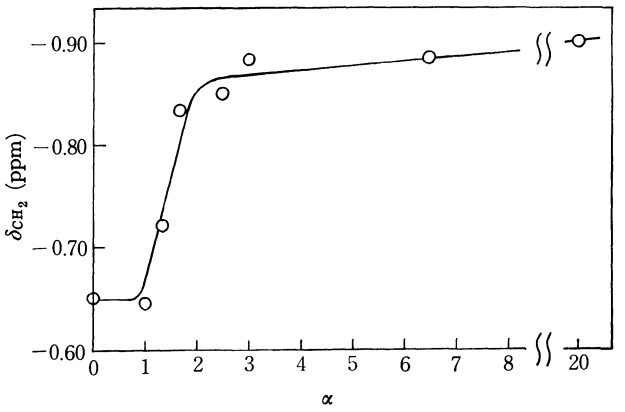

Fig. 6. Variation of δ_{CH_2} in Et_2Mg with α.
Solvent: ether, $[Et_2Mg]=0.50$—0.88 M.

electronegativity of magnesium metal in diethylmagnesium upon coordination with HMPA by using the relationship proposed by Narasimhan and Rogers:[10]

$$\text{Electronegativity} = 0.62(\delta_{CH_2}-\delta_{CH_3}) + 2.07 \quad (6)$$

where $\delta_{CH_2}-\delta_{CH_3}$ is the internal chemical shift in ethyl compounds. The electronegativity of magnesium in Et_2Mg was 0.94 (δ_{CH_2}, −0.65; δ_{CH_3} 1.17) in the absence of HMPA in ether. When α was equal to 3, the electronegativity of magnesium changed to 0.79 (δ_{CH_2}, −0.88; δ_{CH_3}, 1.17). In the presence of THF ([THF]/[Et_2Mg]=3), it was 0.89 (δ_{CH_2}, −0.74; δ_{CH_3}, 1.17).[5] This result indicates that the electronegativity of magnesium in Et_2Mg decreases upon coordination with HMPA or THF, and that HMPA coordinates to magnesium more strongly than THF, as is to be expected from the donicities of these solvents.[11] Our result is in agreement with that recently reported by Ducom,[12] who investigated the same system in benzene. Similar conclusions have been obtained in triethylalminium–donor[13,14] and diethylzinc–donor[14] systems.

Interaction of HMPA with Et_2Mg, and the Mechanism of the Metalation Reaction. It has been reported by Walker and Ashby[15] that Et_2Mg is predominantly monomeric in ether (degree of association=∼1.3 at [Et_2Mg]=∼1M). The dietherate species (I), therefore, must have changed to Species (II)—(IV) on the addition of HMPA to this system:

$$\underset{\text{(I)}}{Et_2Mg(Et_2O)_2} + HMPA \overset{K_1}{\rightleftharpoons} \underset{\text{(II)}}{Et_2Mg(Et_2O)(HMPA)} + Et_2O \quad (8)$$

$$\text{(II)} + HMPA \overset{K_2}{\rightleftharpoons} \underset{\text{(III)}}{Et_2Mg(HMPA)_2} + Et_2O \quad (9)$$

$$\text{(III)} + m\text{HMPA} \overset{K_3}{\rightleftharpoons} \underset{\text{(IV)}}{Et^-Mg^+Et(2+m)\text{HMPA}} \quad (10)$$

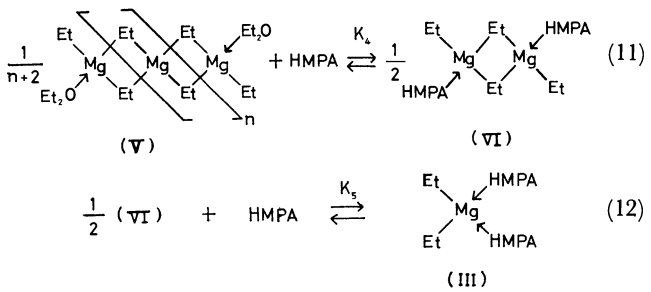
where K_1, K_2, and K_3 are the equilibrium constants in the three reactions.

The fact that the chemical shift, δ_{CH_2}, changed continuously suggests that the exchanges of these species are rapid at room temperature. If $K_1 > K_2 \gg 1$ and $K_3 \ll 1$ in these equilibria, Species (I) and Species (II), which is coordinated by one HMPA and one ether, coexist at equilibrium when α is less than unity. When α is between about unity and about two, Species (III), which is coordinated by two HMPA molecules, coexists with Species (II). The monomeric species (III) seems to change to an ionic form (IV) with the additional coordination of HMPA when $\alpha > 2$. As the δ_{CH_2} is considered to shift more upfield with an increase in the number of HMPA molecules coordinated to Mg, it is reasonable that the δ_{CH_2} of these species decreases in this order:

$$\delta_{CH_2}(I) > \delta_{CH_2}(II) > \delta_{CH_2}(III) > \delta_{CH_2}(IV).$$

A similar order has been suggested by Parris and Ashby in the case of dimethylmagnesium in THF.[16] The fact that the δ_{CH_2} shifted upfield with the increase in α at $1 < \alpha < 2$ is considered to be due to the increase in the concentration of Species (III). It can be explained that, because of the low concentration of Species (IV) formed in Reaction (10), the δ_{CH_2} decreased gradually at $\alpha > 2$.

The metalation reaction was done in a mixture of solvents of toluene and a small amount of ether. It could be assumed that Et_2Mg is present as aggregated forms (V) in a toluene–ether mixture rather than as a monomeric form. These aggregates must have been dissociated into less aggregated or monomeric forms on the addition of HMPA:



where K_4 and K_5 are the equilibrium constants in Reactions (11) and (12). The dimeric species (VI), which is coordinated by one HMPA molecule per Mg atom, seems to be present in this system. However, the monomeric form (II) shown in Reaction (8) may also coexist with Species (VI). The species which are coordinated by one HMPA per Mg must, in any event, have been changed to Species (III) coordinated with two HMPA molecules (Reactions (9) and (12)). Furthermore, Species (III) seems to change to the ionic species (IV), as is shown in Reaction (10).

If $K_4 > K_2 \approx K_5 \gg 1$ and $K_3 \ll 1$ in these reactions, the concentration of the monomeric species (III) at $\alpha \leq 2$ can be given as follows:

$$[Et_2Mg \cdot 2HMPA] \simeq 0 \text{ when } \alpha \leq 1$$
$$[Et_2Mg \cdot 2HMPA] = [HMPA] - [Et_2Mg] = [Et_2Mg](\alpha - 1) \text{ when } 1 < \alpha < 2 \quad (13)$$

where [HMPA] and $[Et_2Mg]$ are the total concentrations of HMPA and Et_2Mg respectively in the reaction system. The rate of the production of FL^- at $\alpha \leq 2$ can be given as in Eq. (14) by assuming that only Species (III) can react with FL:

$$FL + Et_2Mg \cdot 2HMPA \longrightarrow FL^-Mg^+Et \cdot 2HMPA + EtH$$
$$dFL^-/dt = k_1[Et_2Mg \cdot 2HMPA][FL] \quad (14)$$

where k_1 is the second-order rate constant. From Eqs. (13) and (14), we obtain Eqs. (15):

$$dFL^-/dt \simeq 0 \text{ when } \alpha \leq 1 \quad (15\text{-A})$$
$$dFL^-/dt = k_1(\alpha - 1)[Et_2Mg][FL] \text{ when } 1 < \alpha < 2 \quad (15\text{-B})$$
$$dFL^-/dt = k_1[Et_2Mg][FL] \text{ when } \alpha = 2 \quad (15\text{-C})$$

The dependence of the rate on α at $\alpha < 2$ (Fig. 4) could be explained in terms of Eqs. (15-A) and (15-B). The order of reaction at $\alpha = 2$ is in agreement with the experimental results shown in Eq. (5). These facts support the idea that the reactive species in the metalation reaction is the monomeric species (III) when $\alpha < 2$.

When α is more than two, the ionic species (IV) seems also to react with FL. The concentration of Species (IV) is given as follows:

$$[IV] = K_3[III][HMPA_f]^m \quad (16)$$

where $HMPA_f$ is the concentration of free HMPA and is given by the following equation:

$$[HMPA_f] = [HMPA] - 2[Et_2Mg] = (\alpha - 2)[Et_2Mg] \quad (17)$$

As the concentration of Species (IV) is considered to be low, the concentration of Species (III) is given as follows:

$$[III] = [Et_2Mg] - [IV] \simeq [Et_2Mg]. \quad (18)$$

From Eqs. (16), (17), and (18), we can obtain Eq. (19):

$$[IV] = K_3[Et_2Mg]\{(\alpha - 2)[Et_2Mg]\}^m = K_3(\alpha - 2)^m[Et_2Mg]^{1+m}. \quad (19)$$

Consequently, the rate at $\alpha < 2$ is given as follows:

$$dFL^-/dt = k_1[Et_2Mg][FL] + K_3 \cdot k_2(\alpha - 2)^m[Et_2Mg]^{1+m}[FL] \quad (20)$$

where k_2 is the rate constant in the reaction of Species (IV) with FL. The fact that a linear relationship exists between R_i and α when $\alpha \geq 2$ can be explained by assuming that m in Eq. (20) is equal to unity. That is to say, Et_2Mg probably changes to the ionic species with the coordination of three HMPA molecules. However, the formation of the ionic species from the organomagnesium compound (R_2Mg, RMgX) is considered to be dependent on the structure of the organic moiety in the compound. The relationship between the ease of carbanion formation from RMgX and the structure of the organic group, R, is now under investigation.

The Carbonylation of Alcohols Catalyzed by Cu(I) Carbonyl

Yoshie SOUMA and Hiroshi SANO

Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda, Osaka 563

(Received March 1, 1973)

In conc. H_2SO_4 containing the Cu(I) compound, alcohols react with carbon monoxide at room temperature and atmospheric pressure to produce *tert*-carboxylic acids in high yields. Primary carboxylic acid is not formed. It is assumed that the unstable Cu(I) tricarbonyl ion, $Cu(CO)_3^+$, is transiently formed in conc. H_2SO_4. An amount of the Cu(I) compound as small as 0.2 mol/l is sufficient. The catalyst is effective at H_2SO_4 concentrations above 80%. The reaction rate decreases with a decrease in the H_2SO_4 concentration. At H_2SO_4 concentrations of less than 80%, no carboxylic acids are obtained.

Many attempts to obtain carboxylic acid from alcohol and carbon monoxide have been made. Reppe *et al.*[1] reported the carbonylation of alcohols with the nickel carbonyl catalyst to give mixtures of straight-chain carboxylic acids and branched carboxylic acids. Adkins and Rosenthal[2] suggested that a possible course of the reaction was the dehydration of the alcohol to an olefin. These reactions proceed at high temperatures and under high pressures. Eidus *et al.*[3] reported the carbonylation of alcohols using an acid catalyst such as H_2SO_4 or H_3PO_4. Even in this reaction, however, an elevated pressure of carbon monoxide is necessary. Koch and Haff[4] reported the synthesis of branched carboxylic acids from alcohols using formic acid in conc. H_2SO_4.

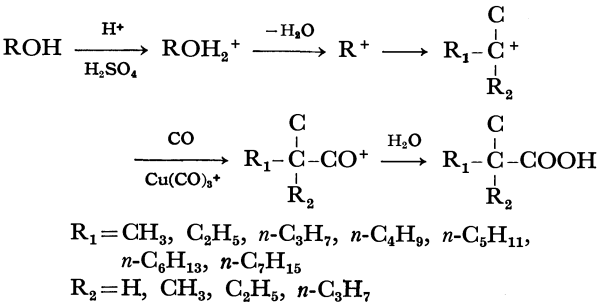
To carry out the carbonylation reaction under mild conditions, the present authors previously attempted the use of the Cu(I) carbonyl catalyst, prepared from Cu(I) compounds and carbon monoxide in conc. H_2SO_4.[5] The unstable Cu(I) tricarbonyl ion, $Cu(CO)_3^+$, acts as a catalyst for this carbonylation reaction. The carbonylation of olefin using the Cu(I) catalyst was reported; *tert*-carboxylic acids were thus obtained in high yields.[6]

In this report, the carbonylation of alcohol using the Cu(I) carbonyl catalyst was studied at room temperature and atmospheric pressure. Reactions using the Cu(I) carbonyl catalyst will prove of wide-ranging synthetic utility for carbonylation reactions.

Results and Discussion

The results of the carbonylation of alcohols using the Cu(I) carbonyl catalyst are shown in Table 1. Various alcohols (normal, secondary, and tertiary alcohols) are converted to *tert*-carboxylic acids in high yields. Alcohol is protonated and dehydrated to the carbonium ion, which rearranges to the stable tertiary carbonium ion prior to the carbonylation. Hence, no primary carboxylic acid is obtained.

The structures of the products were determined by



R_1=CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, n-C_5H_{11}, n-C_6H_{13}, n-C_7H_{15}

R_2=H, CH_3, C_2H_5, n-C_3H_7

a study of their NMR, IR, and mass spectra as well as by elemental analysis. In most cases, the products were mixtures of the isomers. When the mixtures were easily separable by glpc, each isomer was isolated by preparative glpc and was subjected to structure analysis. When the separation was not easy by glpc, the mixture was analyzed by means of ^{13}C NMR.

IV: Cu_2O 4 mmol

Cuprous oxide was used as the Cu(I) compound. The effect of the amount of cuprous oxide is illustrated in Fig. 1. Without cuprous oxide, the rate of the reaction was very slow, and the yield of carboxylic acid was less than 10% after 3 hr. When cuprous oxide was added in conc. H_2SO_4, the rate of the reaction increased rapidly, and *tert*-carboxylic acid was obtained in a high yield.

a) In most cases, 20 mmol of alcohol, 4 mmol of Cu(I) oxide, and 21 ml of 98% H_2SO_4 were used, and the reaction temperature was approximately 30°, while the reaction time varied from 1 to 2 hr. The pressure of carbon monoxide was 1 atm.
b) 10 mmol of alcohol was used.

Cuprous oxide absorbs carbon monoxide in conc. H_2SO_4 and forms an equilibrium mixture of Cu(I) carbonyl ions, $Cu(CO)^+$ and $Cu(CO)_3^+$:[5)]

$$Cu_2O + CO \overset{H^+}{\rightleftharpoons} Cu(CO)^+ + Cu(CO)_3^+$$

Only $Cu(CO)_3^+$ acts as a catalyst in the carbonylation reaction. With the absorption of carbon monoxide, the reddish color of cuprous oxide gradually changes to white. Every Cu^+ ion changes to a $Cu(CO)_3^+$ ion in conc. H_2SO_4 at -10 °C, under 7 atm of carbon monoxide. However, $Cu(CO)_3^+$ is unstable, and it exists as an equilibrium mixture with $Cu(CO)^+$ at the atmospheric pressure of carbon monoxide and at room temperature:

$$Cu(CO)_3^+ \rightleftharpoons Cu(CO)^+ + 2CO$$

In the presence of CO acceptors such as carbonium ions, CO is liberated from $Cu(CO)_3^+$ and reacts with the carbonium ion immediately. Carbon monoxide is continuously absorbed by the $Cu(CO)^+$ in the solution from the gas phase, and a constant amount of $Cu(CO)_3^+$, which acts as a catalyst, exists in conc. H_2SO_4. In the reaction system, Cu^+ acts as a "CO carrier" from the gas phase to the reaction species in the solution.

a) In most cases, 10.5 ml of H_2SO_4, 0.286 g of Cu_2O, and 1.25 ml of alcohol were used. The reaction temperature was 30°C, and the reaction time was 3 hr.

The influence of the H_2SO_4 concentration upon the carbonylation was also examined. The results are shown in Table 2. With the increase in the concentration above 80%, the reaction rate and the yield increased. No carboxylic acid was obtained at concentrations below 80%.

As to Cu(I) carbonyl, only $Cu(CO)^+$ exists in H_2SO_4 concentrations below 80%. It is known that $Cu(CO)_3^+/Cu(CO)^+$ gradually increases with an increase in the H_2SO_4 concentration above 80%.[5)] The effect of the H_2SO_4 concentration upon the carbonylation is parallel with the effect upon the formation of the unstable $Cu(CO)_3^+$ in the system.

Alcohol was added slowly to the Cu(I) carbonyl suspension. The absorption of carbon monoxide by the alcohol was then measured. The results are shown in Fig. 2. Among normal, secondary, and tertiary alcohols, the rates of CO absorption are different at every H_2SO_4 concentration (100, 91.5, and 84.4%). The rate increases in the following order; normal$<$secondary$<$tertiary. In normal alcohol, dehydration is difficult compared with that in secondary or tertiary alcohols. In 91.5% H_2SO_4 and 84.4% H_2SO_4, the rate of CO absorption became slower. This shows that dehydration and isomerization become more difficult with the decrease in the H_2SO_4 concentration. Roebuck and Evering studied the relation between the isomerization of the alkyl cation and the H_2SO_4 concentration,

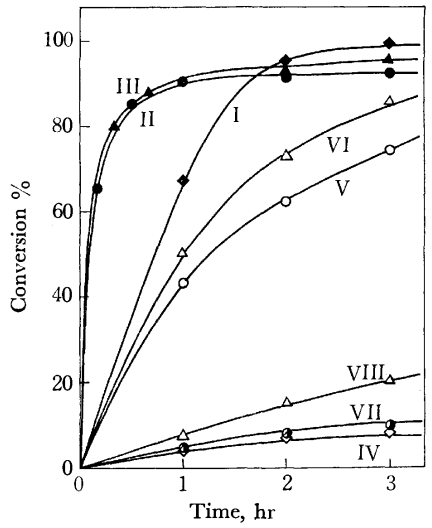

Fig. 2. The rate of CO absorption by alcohols (*n*, *sec*, *tert*). Alcohols (10 mmol) and H_2SO_4 (10 ml) were used at 30°. I: 1-hexanol in 100% H_2SO_4, II: 2-hexanol in 100% H_2SO_4, III: 3-methyl-3-pentanol in 100% H_2SO_4, IV: 1-hexanol in 91.5% H_2SO_4, V: 2-hexanol in 91.5% H_2SO_4, VI: 3-methyl-3-pentanol in 91.5% H_2SO_4, VII: 2-hexanol in 84.4% H_2SO_4, VIII: 3-methyl-3-pentanol in 84.4% H_2SO_4.

and reported that increasing the initial acid concentration from 95.5 to 99.8% increased the rate of isomerization as much as 64 fold.[7]

In the carbonylation of 3-methyl-3-pentanol, considerable amounts of 2,2-dimethylbutanoic acid and 2,2-dimethylpropionic acid are obtained as by-products. Möller[8] and Yoneda *et al.*[9] reported the same type of reactions. They explained the reaction as the disproportionation of the dimerized alkyl group in strong acid. On the other hand, Olah and Lukas[10] reported the formation of a very stable *tert*-butyl cation from C_5—C_{16} alkanes in a very strong acid medium at room temperature.

The effect of the amount of alcohol on the yield of *tert*-carboxylic acid was studied in the presence of constant amounts of 98% H_2SO_4 and Cu_2O. The results are shown in Table 3. When the amount of alcohol increases, the rate of reaction becomes very slow, and the yield of carboxylic acid decreases.

Table 3. The effect of the amount of alcohol on the yield of *tert*-carboxylic acid[a]

1-Hexanol	98% H_2SO_4	Mole ratio 1-hexanol/H_2SO_4	Yield of *tert*-C_7 acid
1.24 ml(10 mmol)	10.5 ml(200 mmol)	0.05	85%
2.24 (18 mmol)		0.09	79
5.24 (42 mmol)		0.21	53
7.24 (58 mmol)		0.29	41

a) The reaction temperature was 30°C, and 0.286 g of Cu_2O was used.

Experimental

The infrared spectra were taken as neat samples on a Hitachi EPI-S2 apparatus. The ^1H NMR spectra were taken on a JEOL PS-100 apparatus at 100 MHz in the CCl_4 solvent. The chemical shifts are given in δ units (ppm) downfield from the internal TMS. The mass spectra were measured on the Shimadzu-LKB-9000 gaschromatograph-mass spectrometer with a 70 eV ionizing current. The glpc analyses were performed using a 3 m FFAP column (10% on Chromosorb WAW). The elemental analyses were done on a Yanagimoto CHN MT-2 apparatus.

All the alcohols used in the experiment were commercial reagents and were purified by distillation. The Cu_2O, H_2SO_4, and carbon monoxide were all commercial reagents and were used without further purification.

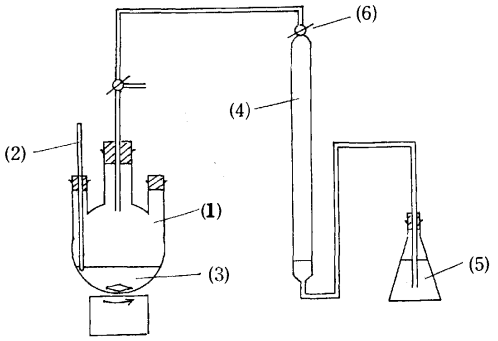

Fig. 3. The reaction apparatus of carbonylation. (1): 300 ml three-necked flask, (2): Thermometer, (3): Cu_2O +98% H_2SO_4, (4): Gas buret, (5): Leveling bottle, (6): Gas cock.

Preparation of Cu(I) Carbonyl. The apparatus is shown in Fig. 3. In a 300 ml, three-necked flask equipped with a thermometer and carbon monoxide gas buret, we placed 572 mg of Cu_2O and 21.0 ml of 98% H_2SO_4. The apparatus was evacuated by means of a diffusion pump to remove the air; then carbon monoxide was introduced from the gas buret. The mixture of Cu_2O and H_2SO_4 was then stirred vigorously. The carbon monoxide was absorbed by the Cu^+ in about 40 min. The CO/Cu^+ ratio reached 1.35 at 30°, CO 1 atm.

Carbonylation of Alcohol. By a syringe, 20 mmol of alcohol was added, drop by drop, to a Cu(I)-carbonyl suspension over a 20 min. The CO absorption by alcohol finished in from 1 to 3hr. The amount of CO absorption was measured using a CO gas buret. The amount of the conversion of alcohol to acid is equal to that of the CO absorption. The reaction mixture was then poured over ice-water. The products were extracted by benzene, and excess alkali was added to the benzene extract. The aqueous phase was acidified by H_2SO_4. The carboxylic acid was then again extracted by the use of benzene. In order to determine the yield of *tert*-carboxylic acid, a 1/10 volume of the benzene extract was titrated with a 1/10M NaOH ethanol solution. The yield of the carboxylic acid was also determined by gas chromatography by adding a known amount of the internal standard.

1,4-Dimethylcyclohexanecarboxylic Acid. This was obtained by the carbonylation of 2,5-dimethylcyclohexanol. The *cis* and *trans* isomers were separated by preparative glpc, the *trans* isomer as a white solid and the *cis* isomer as a liquid component. (lit,[4,11]) Bp 135—137°C/16—20 mmHg;

Solid Phase Peptide Synthesis by Oxidation-Reduction Condensation. Synthesis of LH-RH by Fragment Condensation on Solid Support

Rei MATSUEDA, Hiroshi MARUYAMA, Eiichi KITAZAWA, Hidekuni TAKAHAGI, and Teruaki MUKAIYAMA*

Product Development Laboratories, Sankyo Co. Ltd., Hiromachi, Shinagawa-ku, Tokyo 140
**Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152*

(Received March 22, 1973)

Solid phase peptide synthesis by oxidation-reduction condensation was investigated. The fragment condensation on solid support was examined by employing two types of chain elongation, that from *C*-terminal amino acid to *N*-terminal amino acid (A type elongation) and that from *N*-terminal amino acid to *C*-terminal amino acid (B type elongation). The feasibility of these two approaches A and B was demonstrated in two syntheses of LH-RH (luteinizing hormone-releasing hormone). The LH-RH prepared from the two different chain elongations showed identical mobilities on tlc, exhibiting full activities of natural LH-RH (AVS 77-33 # 215-269).

Solid phase peptide synthesis has provided a rapid method for preparation of many biologically active peptides[1] in which peptide chains have been lengthened from *C*-terminal amino acid to *N*-terminal amino acid (A type elongation). However, only a few investigations[2] have been reported on the preparation of oligopeptides by solid phase synthesis in which the peptide chain elongation was carried out from *N*-terminal amino acid to *C*-terminal amino acid (B type elongation). As regards type A, many modifications[3] have been attempted by fragment condensation to minimize the contaminants which bear similar properties to those of the desired product. On the other hand, no development was attained as regards type B because of the danger of racemization both in the deprotection and in the coupling steps. Recently, a modification[4] of this method was attempted by the use of azide coupling, but it was found not to be a general procedure because of low yields and of restrictions on reaction solvents. In the present experiment, application of the oxidation-reduction process with triphenylphosphine (Ph_3P) and 2,2′-dipyridyl disulfide ($(PyS)_2$) to solid phase peptide synthesis was investigated, taking into consideration the fact that development of both types of chain elongations would be achieved by fragment condensation with oxidation-reduction process possessing the advantages of minimizing side reactions and the racemization of a carboxyl component.[5] This paper describes successful syntheses of porcine luteinizing hormone-releasing hormone (LH-RH)[6] with a sequence of <Glu–His–Trp–Ser–Tyr–Gly–Leu–Arg–Pro–Gly–NH_2 by em-

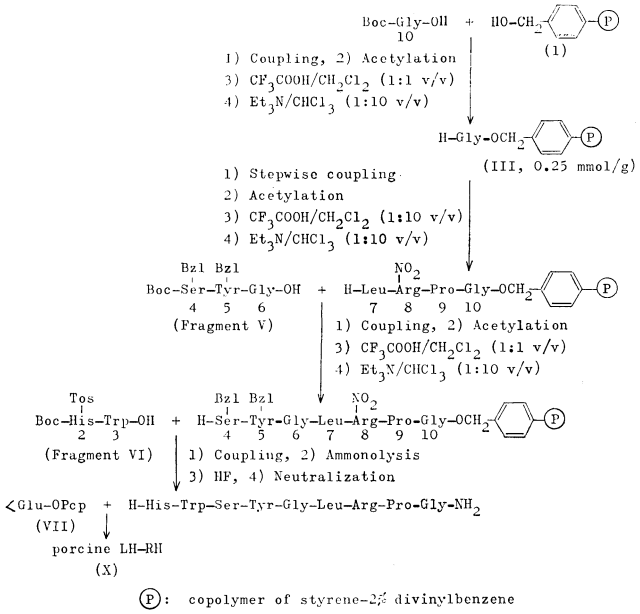

Fig. 1. Scheme for the synthesis of LH-RH by A type elongation.

ploying both A and B types of chain elongation.[7]

I. Chain Elongation from C-Terminal Amino Acid to N-Terminal Amino Acid (Type A). Attachment of the first amino acids or peptide fragments to the hydroxymethyl resin and the peptide chain elongation by fragment condensation have recently been achieved[8] by oxidation-reduction condensation. Synthesis of nonapeptide (2—10 sequence) of LH-RH was attempted by solid phase method as shown in Fig. 1. The chain elongation on solid support was designed to prepare nonapeptide since the tosyl group of the side chain of histidine was found to be partially cleaved by treatment with trifluoroacetic acid used for the removal of Boc-group. The syntheses of peptide fragments achieved by oxidation-reduction condensation in solution are outlined in Fig. 2 and physical properties of these intermediates are listed in Table 1. In the

Table 1. Physical properties of peptide fragments

Peptide fragment	Mp	$[\alpha]_D^t$° (*c*,solvent)
Fragment V	134°C	$[\alpha]_D^{20}$—6.2° (*c* 1, MeOH)
Fragment VI	148—150°C	$[\alpha]_D^{20}$ 15.2° (*c* 1, DMF)
XV	172—175°C	$[\alpha]_D^{20}$—9.6° (*c* 1, DMF)
XIX	168—171°C(decomp.)	$[\alpha]_D^{20}$—43.2° (*c* 2, DMF)

first step, esterification of a 2% crosslinked hydroxymethyl resin which was synthesized from usual chloromethyl resin (Schwarz-Mann, New York, Cl content: 2.0 mmol/g) with the first Boc-glycine was undertaken by using 3 fold excess each of Boc-glycine, Ph_3P and $(PyS)_2$ in CH_2Cl_2. The remaining free hydroxyl groups were covered by acetylation[9] in DMF.[10] The Boc-

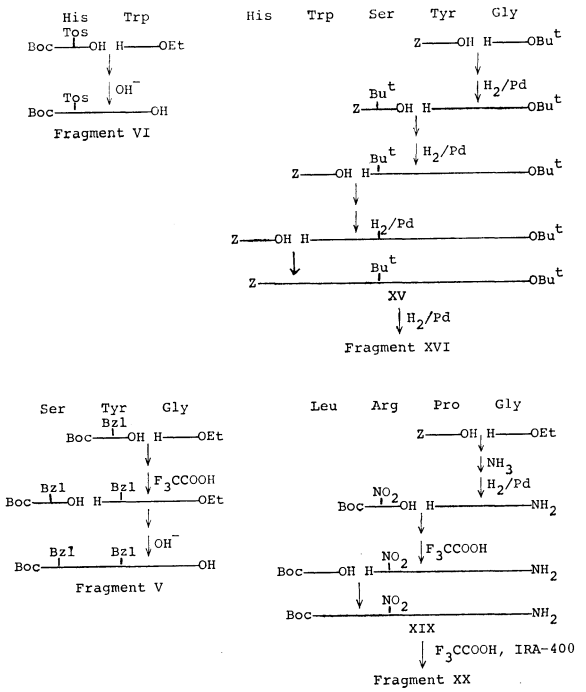

Fig. 2. Syntheses of peptide fragments.

glycine resin (III, 0.25 mmol/g) thus obtained was chain-lengthened to a tetrapeptide stage by stepwise elongation by oxidation-reduction condensation according to a similar procedure to that of the attachment of glycine to the resin. Removal of the Boc-group was performed by treatment with trifluoroacetic acid in CH_2Cl_2 (1:1 v/v) for 30 min, neutralization being carried out with triethylamine in $CHCl_3$ (1:10 v/v) for 10 min. The first coupling of tetrapeptide-resin with fragment V was achieved by treating the deprotected tetrapeptide-resin with a 1.5 fold excess of fragment V and 3 fold excess each of Ph_3P and $(PyS)_2$ in CH_2Cl_2 for 24 hr. The second coupling of heptapeptide-resin with fragment VI was also achieved by treating the deprotected heptapeptide-resin with 3 fold excess each of fragment VI, Ph_3P and $(PyS)_2$ in CH_2Cl_2 for 24 hr. A portion of this resulting resin was hydrolyzed in 3 M *p*-toluenesulfonic acid in the presence of 3-(2-aminoethyl)indole[11] after being treated with HF,[12] the amino acid analysis giving: His, 0.95; Trp, 0.84; Ser, 0.96; Tyr, 0.95; Gly, 2.12; Leu, 1; Arg, 0.93; Pro, 0.97.

Since triphenylphosphine oxide and 2-mercaptopyridine, coproducts produced in the above condensation, are very soluble in various organic solvents, they are washed away thoroughly in the washing steps. It is an important advantage over *N,N'*-dicyclohexylcarbodiimide-mediated coupling in which insoluble dicyclohexylurea are formed.

Removal of the completely protected peptide chain from the resin was undertaken by ammonolysis in absolute ethanol. The protected nonapeptide amide was purified by Avicel column in BuOH: AcOH: H_2O

7) The results were reported at the 10th Japanese Peptide Symposium held at Sapporo, 26, 27 September, 1972.

(4: 1: 1 v/v) and Sephadex LH-20 in DMF. The pure protected nonapeptide amide Boc-His(Tos)-Trp-Ser(Bzl)-Tyr(Bzl)-Gly-Leu-Arg(NO_2)-Pro-Gly-NH_2·H_2O (IX) was obtained as a white amorphous powder, weight 373 mg (48% yield based on the amount of glycine originally esterified to the resin), mp 197—201 °C (decomp.), $[\alpha]_D^{25}$ −27.6° (*c* 1, DMF). In order to check the racemization during fragment condensation, the nonapeptide amide was digested at 37 °C for 48 hr with aminopeptidase M after HF treatment and amino acid analysis of the digest gave: His, 1.06; Trp, 1.03; Ser, 1.02; Tyr, 1.02; Leu, 1; Gly, 1.04; Arg, and Pro were not observed. This shows that the fragment condensation by oxidation-reduction condensation was achieved with L-configuration being kept.

The nonapeptide amide was deprotected with HF in the presence of anisole and 2-mercaptopyridine[13] to avoid the decomposition of tryptophan residue. Conversion into LH-RH was attempted by coupling with <Glu-OPcp according to the procedure in the synthesis of thyrotropin-releasing hormone.[14] Since excess molar ratio of pyroglutamyl residue was observed to be incorporated to nonapeptide amide when 1.5 eq of <Glu-OPcp was used, the coupling was carried out in DMF by using 0.85 eq of <Glu-OPcp to nonapeptide amide after neutralization with Amberlite IRA-400 in MeOH. The product was applied to IRP-64 column in MeOH and eluted with 1% AcOH in MeOH. The peptide was purified on CM-Sephadex C-25[15c] column after gel filtration on Sephadex G-25 in 1 M AcOH. The decapeptide amide eluted with 0.15 M ammonium acetate was desalted by lyophilization three times and gel filtration on Sephadex G-25 in 1 M AcOH. Forty nine milligrams of pure LH-RH was obtained from 161 mg of the protected nonapeptide amide (IX) after precipitation from MeOH-Et_2O and drying at 40 °C *in vacuo* over P_2O_5. $[\alpha]_D^{20}$ −54.2° (*c* 1, 1% AcOH) lit, $[\alpha]_D^{28}$ −50.5±2° (*c* 1, 1% AcOH),[15a] $[\alpha]_D^{20}$ −52.9° (*c* 0.3, 1% AcOH),[15b] and $[\alpha]_D^{25}$ −48.2° (*c* 0.5, H_2O).[15c] This decapeptide amide was characterized as diacetate and trihydrate after further drying at 80 °C for 5 hr *in vacuo* over P_2O_5. The peptide was homogeneous on various tlc detected by Pauly, Ehrlich, Sakaguchi and Cl-tolidine reactions and gave the same R_f values as those reported.[15a] LH-RH activity of the purified decapeptide amide (amino acid content: 76%) was compared at 2 dose levels with that of natural LH-RH (AVS 77-33 # 215-269, amino acid content 67.5%) in ovariectomized, estrogen-progesterone treated rats. Serum LH levels were estimated by radioimmunoassay according to Niswender *et al.*[16] The synthetic LH-RH exhibited full activity[17] of the natural LH-RH.

II. Chain Elongation from N-*Terminal Amino Acid to* C-*Terminal Amino Acid (Type B).* Since Letsinger and Kornet[2] proposed the B type elongation of peptide chain, no successful developments have been reported in this type of chain elongation. Recently, a modification[4] of this method was attempted by the use of azide coupling. However, it was shown that this was not a general procedure because of low yields and restrictions on reaction solvents. Since the direction of B type chain elongation is similar to that in biosynthesis, it seemed attractive as an approach to biosynthesis by chemical means.

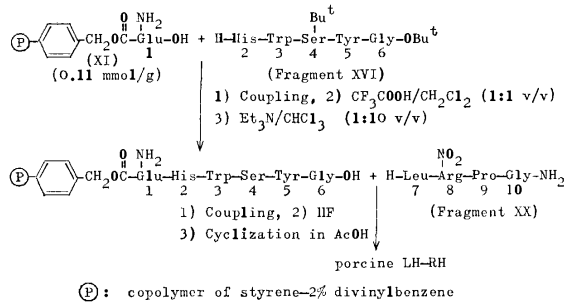

Fig. 3. Scheme for the synthesis of LH-RH by B type elongation.

The synthetic scheme for the B type elongation is shown in Fig. 3. In this approach, carboxyl protection was performed as *t*-butyl ester which is easily deprotected by trifluoroacetic acid. The building of decapeptide was designed to couple 3 fragments of 1,2—6 and 7—10 sequence in order to eliminate the trouble of preparing *t*-butyl ester of an acid-sensitive tryptophan and of racemization in fragment condensation with the use of glycine as a carboxyl component.

In the first step, an attachment of amino group of *t*-butyl glutaminate to a methylchloroformylated copolymer of styrene-2% divinylbenzene (Cl content: 1.4 mmol/g) was carried out in chloroform in the presence of triethylamine. The remaining chloroformyl group was covered by the reaction with diethylamine.[4] A resin-glutamine *t*-butyl ester containing 0.11 mmol/g was obtained. The first coupling of 2 g of resin-glutamine with fragment XVI was achieved by treating the deportected resin-glutamine with 3 fold excess each of fragment XVI, Ph_3P and $(PyS)_2$ in DMF and CH_2Cl_2 at room temperature for 10 hr and for an additional 24 hr after addition of 3 fold excess each of Ph_3P and $(PyS)_2$. The second coupling with fragment
