The molecular structure of azidobenzene was first estimated on the basis of the well-known structures of benzene and CH_3N_3 determined by the electron diffraction experiment,[23] and finally taken by the standard bond order-bond length relation as shown in Fig. 1 (a).[24] The molecular structure of the benzenediazonium ion[25] shown in Fig. 1(b), was determined by the X-ray diffraction technique on the chloride crystal and was taken for calculation. The molecular structure of nitrenobenzene was taken by using the standard bond order-bond length relation as shown in Fig. 1(c). For the pyrene dirivatives, we adopted the results of the X-ray diffraction experiment of pyrene crystal[26] assuming all the angles to be 120° and the C–N and N–N bond lengths equal to those of the benzene derivatives.

The only out-of-plain (z axis) π-electron orbital on each atom taken in the calculation is shown in Figs. 1(a), (b), and (c) for azidobenzene, benzenediazonium ion, and nitrenobenzene, respectively. The ESR study[27,28] shows that the ground state of nitrenobenzene is the $n\pi$ type triplet in which one π-electron occupies the half filled orbital mostly localized on the nitrogen atom. Thus, the ground state of nitrenes under consideration may be regarded as odd π-electron systems.

The calculation was performed with a Facom 270—30 electronic computer at the Institute of Physical and Chemical Research.

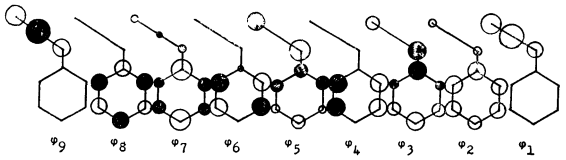
a) Axes x and y are taken as shown in Fig. 1.

b) This column shows coefficients of main electron configurations the contribution of which exceeds 9%. $(i\rightarrow j)$ indicates the electron configuration corresponding to the one electron excitation from the i-th MO (φ_i) to the j-th MO (φ_j). The MO's used in the CI calculation are schematically shown in the following diagram.



authors[1,2] new bands were newly observed at 49300 and 51700 cm^{-1}.

As is clearly seen in Table 1 in which the calculated transition energies and oscillator strengths are given together with the observed values, there is a good agreement between the calculated and observed ones. We show the nature of each transition by giving the coefficients of electron configurations mainly contributed to the corresponding excited state. The bands at 35000, 40200, 49300, and 51700 cm^{-1} can be interpreted as a shifted α band of benzene, an intramolecular charge-transfer (CT) band, a band with mixed characters of CT and local excitation (LE) corresponding to the α band of benzene, and a mixing band of the α and β bands of benzene, respectively. The shifted β bands of benzene may be expected to appear at higher frequencies than the observed wave number region. The present assignment of the absorption spectrum of azidobenzene is similar to that of dimethylaniline.[29] This means that the π-electrons of the azido group give an effect similar to those of the dimethylamino group to the absorption spectrum of benzene.

The π-electron densities and bond orders calculated for azidobenzene are listed in Table 2, which shows that the π-electron migrates from the azido group to the benzene ring by 0.05e. This means that the azido group is an electron donating one like the dimethylamino group.

Finally we found the $n\pi^*$ type transition at 30900 cm^{-1} ($\varepsilon\sim100$) for the concentrated solution of azidobenzene.

a) N_1, N_2, and N_3 are taken as shown in Fig. 1.

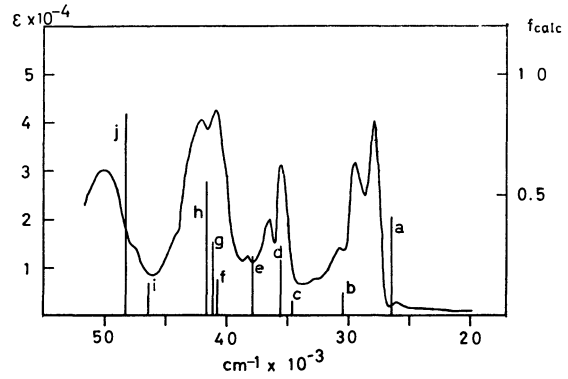

Fig. 3. The electronic absorption spectrum of 1-azidopyrene in ethanol at room temperature. The vertical lines represent the calculated transition energies and oscillator strengths (f_{calc}).

Electronic Spectrum of 1-Azidopyrene. Figure 3 shows the electronic absorption spectrum of 1-azidopyrene in the ethanol solution at room temperature. The calculated and observed peak wave numbers and oscillator strengths for various transitions with lower energies are given in Table 3. Although many transitions are expected in the region $(20\simeq50)\times10^3$ cm^{-1}, those with an oscillator strength greater than 0.05 are shown, except for the lowest energy transition at 26000 cm^{-1}. In the case of 1-azidopyrene, transitions cannot be characterized by three or four dominant electron configurations, except for the lowest two or three transitions. The characters of the transitions are therefore not shown in Table 3. The weak band at 26000 cm^{-1} may be regarded as a shifted α band of pyrene. Band a in Table 3 is assigned to LE (~50%)+CT (~50%), and bands b and d are characterized by CT. In spite of the existence of the CT bands, the spectral shape is similar to that of pyrene. This is because the absorption intensities of the main bands pertinent to the parent hydrocarbon are very strong and the CT bands are covered by them. Most of the observed peaks are attributed to the superposition of several transitions. The peak positions of the 1-azidopyrene spectrum are shifted toward longer wavelengths compared with those of the pyrene spectrum and are similar to those of the 1-aminopyrene spectrum.

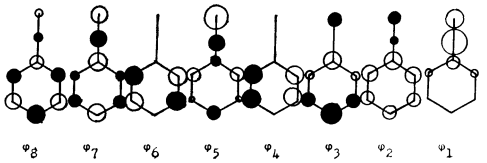
The MO's used in the CI calculation are schematically shown in the following diagram.



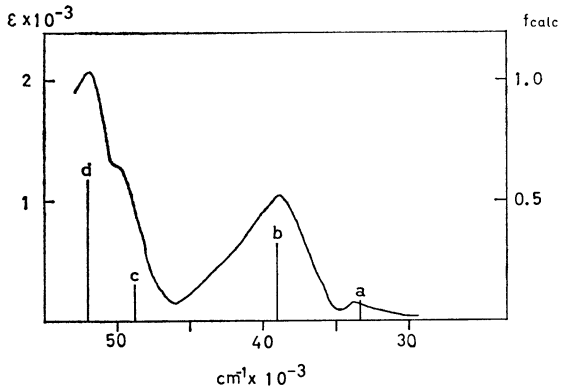


Fig. 4. The electronic absorption spectrum of benzenediazonium fluoroborate in ethanol at room temperature. The vertical lines represent the calculated transition energies and oscillator strengths (f_{calc}).

Figure 4 shows the electronic absorption spectrum of benzenediazonium fluoroborate in the ethanol solution. The bands below 40000 cm^{-1} are coincident in their positions and intensities with those given by Sukigara and Kikuchi.[7] The calculated transition energies and oscillator strengths are given in Table 4, together with the observed values. We can find a good agreement between the observed and calculated values both for the transition energies and for the oscillator strenghts. The nature of each transition is also shown in this table by giving the coefficient of the electron configuration mainly contributed to the corresponding excited state.

The observed absorption spectrum of the benzenediazonium ion is similar to that of azidobenzene. The characters of the bands are also similar to each other for both compounds. However, the directions of electron transfer between the substituent group and the benzene ring are reverse to each other for both compounds, *viz.*, in the case of the benzenediazonium ion, the substituent group acts as an electron acceptor. This is clear from the π-electron density given in Table 2.

The $n\pi^*$ type transition was observed at 30800 cm^{-1} ($\varepsilon \sim 120$) for the concentrated solution.

Electronic Spectrum of the 1-Pyrenediazonium Ion. Figure 5 shows the electronic absorption spectrum of

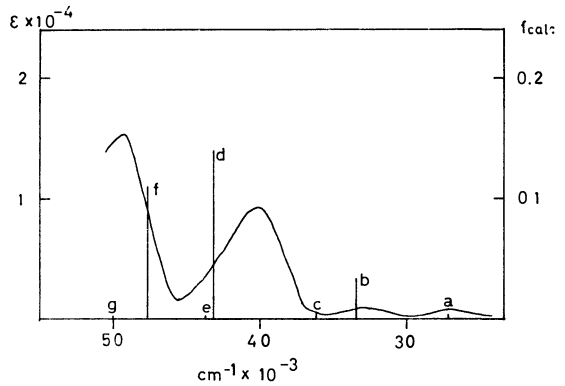

Fig. 6. The electronic absorption spectrum of nitrenobenzene in ethanol at 77°K. The vertical lines represent the calculated transition energies and oscillator strengths (f_{calc})

the 1-pyrenediazonium ion in the ethanol solution at room temperature. The transition energies and oscillator strengths are given in Table 5 for several transitions of lower energies and with oscillator strengths greater than 0.05. Band a in this table is assigned to LE (∼60%)+CT (∼40%), and band b to pure CT. Each of the observed peaks shown in Fig. 6 is the superposition of several bands.

Electronic Spectrum of Nitrenobenzene. Figure 6 shows the electronic absorption spectrum of nitrenobenzene in the ethanol solution. The bands at higher frequencies than 40000 cm^{-1} were newly found by the present authors. The observed transition energies and oscillator strengths are given in Fig. 6 together with the calculated values. There is a good agreement between the observed and calculated values both for transition energies and oscillator strengths. The nature of each transition is also shown in Table 6.

The electronic spectrum of nitrenobenzene resembles very much that of the benzyl, anilino, or phenoxyl radical. The two lower bands, a and b, can be assigned to the $\psi_0 \rightarrow \psi_+$ and $\psi_0 \rightarrow \psi_-$ transitions in the Dewar and Longuet-Higgins notation.[30] The strong bands

of d and f are represented by the superposition of CT and back CT components, which are also transitions characteristic of open-shell systems. The weak bands of c and e are covered by the strong bands, d and f.

Electronic Spectrum of 1-Nitrenopyrene. Curves (a) and (b) in Fig. 7 show the electronic absorption spectra of 1-nitrenopyrene in the benzene and ethanol solutions at 77 K, respectively. The calculated and observed results for the transitions with higher oscillator strengths than 0.05 are given in Table 7.

In this case, the two lower absorption bands at 23800 and 29000 cm^{-1} represented by a and b, respectively, are assigned to $\psi_0\rightarrow\psi_+$ and $\psi_0\rightarrow\psi_-$ transitions in the Dewar and Longuet-Higgins notation.[30] Band c is assigned to the LE transition of pyrene. Since other transitions cannot be characterized by three or four dominant electron configurations, we do not show the characters of transitions in Table 7.

We should like to express our sincere thanks to Dr. Kazuo Shibata and Dr. Teruo Ogawa, The Institute of Physical and Chemical Research, for their kindness in permitting us to use the Shimadzu MPS spectrophotometer for measuring the absorption spectrum of the opaque solution at liquid nitrogen temperature.

The Electronic States of Tetracyanoethylene and Its Anion Radical as Studied by Their Infrared Spectra

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received August 3, 1972)

The infrared spectra of tetracyanoethylene (TCNE) and its anion radical in the rock-salt region were examined in order to observe any appreciable frequency differences between their corresponding bands. The vibrational assignments were made, and the basic Urey-Bradley force field was determined for the TCNE anion radical. By comparing them with those of the neutral TCNE, we discussed the difference in the electronic states between the neutral TCNE and its anion radical. The half-occupied molecular orbital of the TCNE anion radical was found to belong to the B_{2g} irreducible representation.

The infrared spectrum of an ion radical is known to be appreciably different from that of its neutral molecule.[1-11] The spectrum difference may be attributed to the difference in their intramolecular force fields. In a previous paper,[8] we examined the infrared spectra (650—4000 cm^{-1}) of *p*-chloranil and its anion radical. In order to explain the appreciable frequency differences between their corresponding bands, the fundamental frequencies were assigned, and the simple Urey-Bradley force fields were determined for both the neutral and anion radical molecules. It was found that the difference in the infrared spectra between these two molecules could be understood on the basis of the difference in their electronic structures caused by an extra electron on the *p*-chloranil anion radical.

The tetracyanoethylene (TCNE) molecule is known to be a strong electron acceptor, and its anion radical is stable.[12] The infrared and Raman spectra of the neutral TCNE were measured by Takenaka and Hayashi.[13] In order to make vibrational assignments and determine the force constants for this molecule, they carried out normal coordinate treatments for the in-plane vibrations by using the basic Urey-Bradley force field. On the other hand, Stanley *et al.* examined the infrared spectra of the sodium and potassium salts of the TCNE anion radical by using thin polycrystalline films.[5] Although they reported that the spectrum of the TCNE anion radical differs appreciably from that of the neutral TCNE, they did not assign the fundamental frequencies quantitatively or determine the force constants for the TCNE anion radical. Therefore, in the present paper, the fundamental frequencies were assigned and the basic Urey-Bradley force field was determined for the TCNE anion radical. The purpose of the present paper is to compare these data with those of the neutral TCNE and to investigate the difference in the electronic states between the neutral TCNE and its anion radical.

Calculations

First, let us consider the experimental and theoretical results on the neutral TCNE reported by Takenaka and Hayashi.[13] The observed fundamental frequencies in the infrared and Raman spectra of the neutral TCNE are given in Table 1. In order to assign the vibrational spectra, they used the ***GF*** matrix method developed by Wilson.[14] It was assumed that the vibrational spectra could be treated under the molecular point group V_h. A representative of each type of internal coordinate is shown in Fig. 1. The equilibrium bond lengths adopted are those determined from X-ray analysis by Bekoe and Trueblood:[15] $R_0=1.317$ Å, $r_0=1.449$ Å, and $l_0=1.15$ Å. For the

bond angles, $\alpha_0=\beta_0=120°$ and $\theta_0=180°$ were assumed for the sake of simplicity. The normal vibrations of TCNE were reduced to the symmetry species:

$$\Gamma = 5A_g(R)+4B_{1g}(R)+4B_{2u}(IR)+4B_{3u}(IR) + 2A_u\,(\text{inactive})+2B_{1u}(IR)+2B_{2g}(R)+B_{3g}(R), \quad (1)$$

where the first four are the in-plane vibrations and the rest are the out-of-plane vibrations. (R) and (IR) indicate the Raman and infrared active modes respectively. In order to calculate the fundamental frequencies, the basic Urey-Bradley force field was used as the potential function for TCNE. For the in-plane vibrations, three bond-stretching (K(C=C), K(C-C), and K(C≡N)), three angle-bending (H(C–C–C), H(C–C=C), H(C–C≡N)), and four non-bonded repulsion force constants (F(C–C–C), F(C–C=C), F(C–C≡N), and C) were necessary. The constant, C, represents the repulsion between two carbon atoms in the *cis*-position.[16–18] Repetitions of the calculation with several sets of force constants were then carried out by the trial-and-error method by the use of the Jacobian matrix. For the in-plane vibrations, Takenaka and Hayashi obtained the final set of force constants shown in Table 2.[13] The fundamental frequencies calculated with these constants are compared in Table 1 with the observed values. The agreement is satisfactory except in the case of the 679 cm^{-1} frequency (ν_3) of the A_g species.

Table 2. The force constants estimated for the neutral TCNE and its anion radical (md/Å)[a]

Force constant	The neutral TCNE[b]	Its anion radical
K(C=C)	6.31	4.00

K(C≡N)	16.84	15.70
H(C-C-C)	0.05	
H(C-C=C)	0.16	
H(C-C≡N)	0.13	
F(C-C-C)	1.11	
F(C-C=C)	1.04	
F(C-C≡N)	0.08	
C	0.11	

a) $F' = -0.1F$, $C' = -0.1C$. b) Ref. 13.

Next, let us consider the vibrational spectrum of the TCNE anion radical. The fundamental frequencies in the infrared spectrum of the potassium salt of the TCNE anion radical measured by Stanley *et al.* are also given in Table 1.[5,12] Since the counter cation of the salt is a simple alkali metal cation, the observed spectrum of the salt in the rock-salt region must be due solely to that of the TCNE anion radical itself. Its spectroscopic features are found to be appreciably dissimilar to those of the neutral TCNE. The most interesting new features in the TCNE anion radical spectrum are: (1) the very intense band at 1371 cm^{-1}, (2) the appreciable red-shifts of the doublet 2208 and 2183 cm^{-1} bands in the cyanide-stretching region compared to the 2262 and 2230 cm^{-1} bands in the neutral TCNE, and (3) the marked absence of absorption in the 600—1300 cm^{-1} region, where the strongest TCNE fundamental absorptions occur.[5] The C–C modes, which absorb strongly at 1155 and 959 cm^{-1} in the neutral TCNE, can be designated as the source of the very weak bands at 1187 and 970 cm^{-1} in the TCNE anion radical.

In order to explain these appreciable frequency differences, let us analyze the vibrational spectrum of the TCNE anion radical. Since the molecular and crystal structures of the potassium salt of the TCNE anion radical have not yet been ascertained, it was assumed that the molecular structure of the anion radical was almost identical with that of the neutral TCNE. This assumption means that the $\boldsymbol{G}$ matrix calculated for the neutral TCNE was also used for the anion radical (see below). Since only the intramolecular vibrations are expected to appear in the rock-salt region, the vibrational spectra of the crystalline compound can be approximately treated under the molecular point group V_h. In general, the effects of crystal fields on vibrational frequencies are small. Therefore, to a first approximation, its contribution to the spectrum of the TCNE anion radical was ignored in our treatment. Hence, twenty-four normal modes of vibrations for the TCNE anion radical were also reduced to the same symmetry species as in Eq. (1) of the neutral TCNE. (We calculated only the in-plane vibrations, because no out-of-plane vibration is expected to appear in the region now under consideration.) We have designated the very weak bands at 1187 and 970 cm^{-1} as the C–C modes in the TCNE anion radical. Since no other infrared-active fundamental modes occur between 600 and 2000 cm^{-1}, there is no apparent source for the intense 1371 cm^{-1} band in the anion radical. The assignment of this band is important in estimating the force constants of the TCNE anion radical. If a strong charge-transfer interaction takes place between the neighbouring TCNE anion radical species,[19] the

18) D. E. Mann, L. Fano, J. H. Meal, and T. Shimanouchi, *ibid.*, **27**, 51 (1957).

19) The charge-transfer interaction between neighbouring ion radical molecules has been found with a number of crystalline ion radical salts. See, for example, Y. Iida and Y. Matsunaga, This Bulletin, **41**, 2615 (1968); Y. Iida, *ibid.*, **42**, 71, 637 (1969); Y. Iida, *ibid.*, **43**, 2772 (1970); Y. Iida, *ibid.*, **44**, 663, 1777 (1971); Y. Iida, *ibid.*, **45**, 105, 624 (1972).

Ferguson-Matsen theory of activation then applies and certain intense bands in the infrared spectrum can be assigned to totally symmetric modes.[20-22] By the use of this approach with the TCNE anion radical, the strong band at 1371 cm^{-1} can be assigned to the totally symmetric C=C stretching A_g mode,[5,10] which was observed at 1573 cm^{-1} in the Raman spectrum of the neutral TCNE.[13] The 202 cm^{-1} red shift seems to be consistent with the following discussion of the electronic states of TCNE and its anion radical (see below).

In order to calculate the fundamental frequencies, Wilson's ***GF*** matrix method was also applied to the TCNE anion radical; a representative of each type of internal coordinate for in-plane fundamental vibrations is given in Fig. 1. The basic Urey-Bradley force field was employed as the potential function. The notations for the three bond-stretching, three angle-bending, and four non-bonded repulsion force constants used are those for the neutral TCNE. At this time, it is assumed that the stretching force constants of the TCNE anion radical are different from those of the neutral TCNE, while the other force constants remain almost constant. Rigorously speaking, this treatment is not correct, but it is justified as long as the observed fundamental frequencies are mostly due to the bond stretching modes. Then, the trial force constant for the TCNE anion radical were taken by modifying the stretching force constants for the neutral TCNE determined by Takenaka and Hayashi.[13] Refinements of the force constants for the TCNE anion radical were then carried out by the trial-and-error method, making use of the Jacobian matrix. The final set of force constants thus obtained for the TCNE anion radical is given in Table 2, while in Table 1 the frequencies calculated with these constants are compared with the observed values. The calculated values of the fundamental vibrations were found to agree well with the observed values.

Discussion

Since a total of 10 force constants of the anion radical were evaluated from an experimental assignment of 5 frequencies, we suspect that these values of the force constants are not the best ones for the TCNE anion radical. However, the stretching force constants are still meaningful, because the observed fundamental frequencies are almost all due to the stretching modes. Therefore, below we will discuss only the difference in the stretching force constants between the neutral TCNE and its anion radical. As is shown in Table 2, K(C=C)=6.31 md/Å, K(C–C)=4.80, and K(C≡N)=16.84 for the neutral TCNE, while K(C=C)=4.00, K(C–C)=5.23, and K(C≡N)=15.70 for its anion radical. We can see that the extra electron on the TCNE anion radical causes the decrease in the K(C=C) and K(C≡N) values and the increase in the K(C–C) value.

It is well known that the stretching force constant, $K(12)$, of a bond (12) in a conjugated system is greatly affected by its bond order, $p(12)$. According to Coulson and Longuet-Higgins,[23] $K(12)$ can be expressed by:

$$K(12) = \{(1-p(12))K_s + p(12)K_d\} + \left\{\frac{K_s K_d(s-d)}{K_s(1-p(12)) + K_d p(12)}\right\}^2 \frac{\pi(1212)}{2}, \quad (2)$$

where K_s and K_d are the force constants associated with pure single and double bonds respectively, where π-(1212) is the self-polarizability of the bond (12), and where s and d are the bond lengths of pure single and double bonds respectively.

In a homopolar carbon-carbon bond, the second term involving the self-polarizability may be small.[24] In this case, the stretching force constant, $K(12)$, is predominantly determined by the bond order, $p(12)$. Therefore, the extra electron on the TCNE anion radical causes a decrease in the C=C bond order, p(C=C), and an increase in the C–C bond order, p(C–C), compared to those of the neutral TCNE. From the values of K(C=C) and K(C–C) in the infrared spectra, the decrease in p(C=C) was estimated to be 0.36, while the increase in p(C–C) was estimated to be 0.08, by using the empirical relationship between $K(12)$ and $p(12)$.[8]

On the other hand, in order to confirm these results, we further calculated the p(C=C) and p(C–C) values of the neutral TCNE and its anion radical by the use of the Hückel molecular orbital theory.[25] It was assumed that the extra electron on the TCNE anion radical enters in the lowest-vacant molecular orbital of the neutral TCNE. This orbital has the irreducible representation of B_{2g}, where the coefficients of the C_1, C_3, and N_7 atomic orbitals are given by 0.5305,

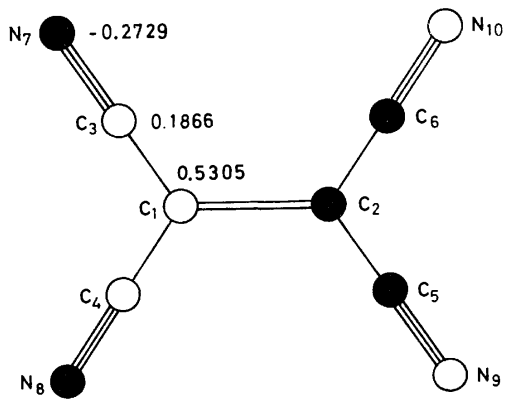

Fig. 2. Schematic representation of the half-occupied molecular orbital of the TCNE anion radical calculated from the Hückel molecular orbital method. The open and closed circles indicate that the coefficients of the atomic orbitals are positive and negative, respectively.

24) A. Streitwieser, Jr., "Molecular Orbital Theory", John Wiley & Sons, New York and London (1961).
25) In calculating the Hückel molecular orbitals for the neutral TCNE, the Coulomb integrals of the C and N atoms are taken as α and $\alpha+\beta$, respectively, while the resonance integrals of the C=C, C–C and C≡N bonds, as β, 0.9β and 2.0β, respectively.

0.1866, and −0.2729 respectively (see Fig. 2). Therefore, the extra electron causes a decrease in p(C=C) by 0.28, and an increase in p(C–C) by 0.10, compared to the values of the neutral TCNE. These molecular orbital results are found to agree well with those evaluated from the infrared spectra.

In the heteropolar C≡N bond, although the expression of K(C≡N) *versus* p(C≡N) of the neutral TCNE or its anion radical is not so simple, the extra electron on the TCNE anion radical causes a decrease in K(C≡N); this decrease will definitely lead to a decrease of p(C≡N). In accordance with this view, the Hückel molecular orbital theory shows a decrease in p(C≡N) by 0.05 when an extra electron enters into the lowest-vacant orbital of the neutral TCNE.

Concluding Remarks

The present investigation clearly shows that the difference in the vibrational spectra between the neutral TCNE and its anion radical can be understood on the basis of the difference in their electronic structures. By using these differences, the half-occupied molecular orbital of the TCNE anion radical was found to belong to the B_{2g} irreducible representation. On the other hand, the crystal-field effect may make some contribution to the frequency shifts in these vibrational spectra. In fact, Moore *et al.* observed that certain vibrational frequencies of the TCNE anion radical salts are influenced by the species of the counter cations.[10] However, in a first approximation, this contribution can be neglected in comparison with that of the intramolecular force field.

Rigorously speaking, the $\boldsymbol{G}$ matrix for the anion radical is not identical with that for the neutral TCNE, since the molecular structure of the anion radical is slightly different from that of the neutral TCNE. The difference in their $\boldsymbol{G}$ matrices may make some contribution to the frequency difference. However, this contribution is negligibly small for the bands due to the bond-stretching modes.

The set of force constants obtained for the TCNE anion radical cannot be regarded as a unique solution, since the observation of the fundamental frequencies is limited to the infrared spectra. In this sense, it is also quite desirable to measure the Raman spectrum of the TCNE anion radical. We consider, however, that the set of force constants presented here is reliable enough for studying the difference in the stretching force constants between the neutral TCNE and its anion radical.

In conclusion, the application of the infrared spectra of a neutral molecule and its ion radical can provide valuable knowledge on their electronic structures as well as on their molecular structures. It is interesting to see that their frequency differences give some information concerning the nature of the half-occupied orbital in the ion radical molecular orbitals.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 426—430 (1973)

Comparison of the Conductance Equations of Fuoss-Onsager, Fuoss-Hsia and Pitts with the Data of Bis(2,9-dimethyl-1,10-phenanthroline)Cu(I) Perchlorate

Katsuhiko MIYOSHI

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received August 14, 1972)

Conductance equations derived by Fuoss-Onsager (1965), Fuoss-Hsia (1967) and Pitts (1953) were compared using the conductance data of bis(2,9-dimethyl-1,10-phenanthroline)Cu(I) perchlorate in acetonitrile, nitrobenzene and nitromethane at 25°C, which have relatively high dielectric constant. The chelate salt was found to be completely dissociated in these solvents. Though the Pitts equation was found to reproduce the data more satisfactorily than the Fuoss-Onsager (F–O) and the Fuoss-Hsia (F–H) equations, the derived distance of the closest approach a from the Pitts equation was unrealistically small for the bulky complex salt. It was shown that the F–H equation is preferable for the analysis of conductance data for both associated and unassociated electrolytes.

Theoretical comparison of the conductance theories established by Fuoss and Onsager,[1,2] and Pitts[3] was made recently by Pitts *et al.*[4] They pointed out that though both theories were nominally based on the same model of "a charged sphere in a continuum" there were differences in formulation and procedure, and they criticised the boundary conditions used in the F–O theory. Fuoss and Onsager assumed that only the radial component of the vector velocity vanishes at contact and that the potential and field should be continuous when the distance between two ionic centers is equal to a. On the other hand, Pitts required the conditions that the asymmetric (perturbed) part of the potential must vanish at $r=a$ and the velocity vector vanish on the surface of the ion. They emphasized the superiority of the Pitts theory by comparing the extent of fitting of both theories to experimental data.

Stokes[5] was the first to compare these theories ex-

perimentally and reported that the F–O equation reproduced the conductance data of hydrochloric acid in water at 25°C only up to 0.004 N, whereas the Pitts equation could be applied to 0.02 N. Fernandez-Prini and Prue[6] also compared these equations using high precision data of inorganic salts composed of monoatomic ions in water, methanol and dimethyl formamide all of which are hydrogen-bonded solvents and solvate strongly to ions, especially small ions. They found that the Pitts equation accounts satisfactorily for the experimental data and the derived parameters are reasonable except in methanol, in which the distance of the closest approach calculated by the Pitts equation was found to be smaller than that by the F–O equation by about 1 Å. However, it is ambiguous whether the derived a-value corresponds to the contact or the solvent-separated contact distance of an ion pair, since both types of ion pairs may exist in the hydrogen-bonded solvents such as water and methanol. A reasonable value of a can therefore have some arbitrariness.

Thus, measurements with bulky electrolytes in some aprotic organic solvents which do not seem to solvate ions strongly are expected to clarify whether a-values obtained are reasonable or not, since a-values in this case will correspond to the contact distances. Bis(2,9-dimethyl-1,10-phenanthroline)Cu(I) perchlorate was chosen because of its stability in solution and symmetry, thus being suitable as a model electrolyte for conductance measurement. Since the chelate cation is surrounded by bulky aromatic groups, the association constants are expected to be smaller than those of the hydrodynamically corresponding tetrabutylammonium salt in which the positive charge is located predominantly on the nitrogen atom.[7]

Experimental

Materials. Bis(2,9-dimethyl-1,10-phenanthroline)Cu(I) perchlorate (Dojin Chemicals Ltd.) was recrystallized from acetone solution. Its purity was checked by analysis. The analytical data were as follows. Found: C, 58.05; H, 4.11; N, 9.67%. Calcd for $C_{28}H_{24}N_4O_4ClCu$: C, 58.03; H, 4.17; N, 9.67%. The stability of the chelate cation in each solvent was confirmed by the absorption spectrum in the visible region. Nitrobenzene was washed three times with conductivity water, kept over anhydrous calcium chloride for several days and filtered off. The filtrate was passed through a molecular sieve and fractionated under reduced pressure (below 10 mmHg). The product was still slightly yellow, its specific conductance being negligibly small. Reagent grade acetonitrile was kept over potassium hydroxide pellets for 24 hr and distilled over phosphorus pentoxide, followed by fractionation. Its specific conductance was 3.3×10^{-8} ohm^{-1}cm^{-1}. Reagent grade nitromethane was dried with anhydrous calcium chloride and distilled over drierite under reduced pressure. A middle fraction was collected. Its specific conductance was 6.0×10^{-8} ohm^{-1}cm^{-1}. Purity of the solvents was checked by measuring their densities. Observed values were 1.1986 and 0.7766 for $PhNO_2$ and CH_3CN, respectively, which were in good agreement with the values in literature, viz., 1.1977[8] and 0.7767,[9] respectively. The density of CH_3NO_2 was 1.1298, slightly lower than the value 1.1312 reported by Kay *et al.*[10] They purified CH_3NO_2 by distillation at reduced pressure followed by fractional crystallization, which, however, was found to increase the water content. Water content of the solvents used was examined by titration with the Karl Fischer reagent and found to be less than 0.01 wt% in CH_3NO_2 and CH_3CN and 0.001wt% in $PhNO_2$. Other physical properties of the solvents were taken from literature.[8,9,10]

Apparatus and Procedure. Conductance measurements were carried out with a conductometer, type MY-7 (Yanagimoto Mfg. Co., Ltd.) with a Wheatstone bridge (800 c/s). All the resistances were calibrated with a resistance box (Yokogawa Electric Works Ltd.) standardized by Shinkawa Electric Co. Pyrex conductance cells were of Erlenmeyer type with lightly platinized electrodes, containing about 200 ml of solution, and were standardized with aqueous KCl solutions, using the Lind, Zwolenik and Fuoss constants.[11] Potassium chloride was recrystallized three times from conductivity water and dried at 500°C. Cells were washed with nitric acid and steam before each run. Cell solutions were thermostated to 25±0.01°C in a double water bath with a mercury-in-glass thermoregulator. In order to attain temperature equilibrium rapidly and avoid the polarization effect during measurements, the solution in the cell was stirred by a magnetic stirrer. All solutions were prepared gravimetrically since the molecular weight of the complex salt is very high (579.522). For each run, a sample of 100—110 mg was directly added to the solvent of known conductivity in the cell. After a constant value of resistance was attained, 30 ml of solution was siphoned out and an equal volume of the solvent was added to the cell. The procedure was continued until an appropriate concentration was attained. Concentration range was $\kappa a<0.2$ within which the approximations used to establish the conductance equations are valid. CH_3CN and CH_3NO_2 are so volatile and hygroscopic that a drybox was used for preparation of the solutions.

Results and Discussion

The measured equivalent conductance Λ and the corresponding concentration C in equivalents per liter are given in Table 1. These data were analyzed by means of the following three equations for unassociated electrolytes.

Fuoss-Onsager equation (1965)[2]:

$$\Lambda = \Lambda_0 - SC^{1/2} + E'C\ln(6E_1'C) + LC \qquad (1)$$

$$S = \alpha\Lambda_0 + \beta_0,\quad E' = E_1'\Lambda_0 - E_2',$$

$$E_1' = 2.942\times10^{12}/(DT)^3,$$

$$E_2' = 0.4333\times10^8/\eta(DT)^2,\quad L = L_1 + L_2(b),$$

$$ab = \beta = e^2/DkT$$

$$L_1 = 3.202E_1'\Lambda_0 - 3.420\,E_2' + \alpha\beta_0$$

$$L_2(b) = 2E_1'\Lambda_0 h(b) + 44E_2'/3b - 2E'\ln b$$

$$h(b) = (2b^2+2b-1)/b^3$$

Fuoss-Hsia equation (1967)[12] modified by Fernandez-Prini (1969)[13]:

$$\Lambda = \Lambda_0 - SC^{1/2} + EC\log C + J_1C - J_2C^{3/2} \quad (2)$$

$$E = E_1\Lambda_0 - E_2,\ E_1 = 2.3026(\kappa^2a^2b^2/24C),$$

$$E_2 = 2.3026(\kappa ab\beta_0/16C^{1/2}),\ J_1 = \delta_1\Lambda_0 + \delta_2$$

$$J_2 = \delta_3\Lambda_0 + \delta_4$$

$$\delta_1 = [(\kappa ab)^2/24C][1.8147+2\ln(ka/C^{1/2}) + 2h(b)]$$

$$\delta_2 = \alpha\beta_0 + \beta_0(\kappa a/C^{1/2}) - \beta_0[(\kappa ab)/16C^{1/2}] \times[1.5337+(4/3b)+2\ln(\kappa a/C^{1/2})]$$

$$\delta_3 = [b^2(\kappa a)^3/24C^{3/2}][0.6094+(4.4748/b)+(3.8284/b^2)]$$

$$\delta_4 = [\beta_0(\kappa ab)^2/24C][2h(b)-1.9384]+\alpha\beta_0(\kappa a/C^{1/2}) + [\beta_0(\kappa a)^2/C] - [\beta_0 b(\kappa a)^2/16C][1.5405+(2.2761/b)] - (\beta_0^2\kappa ab/16\Lambda_0C^{1/2})[(4/3b)-2.2194]$$

Pitts equation (1953)[3] modified by Fernandez-Prini and Prue (1965)[6,14]:

$$\Lambda = \Lambda_0 - SC^{1/2} + EC\log C + J_1C - J_2C^{3/2} \quad (3)$$

$$\delta_1 = (\kappa ab)^2[\ln(\kappa a/C^{1/2}) + 2/b + 1.7718]/12C$$

$$\delta_2 = \beta_0\kappa a/C^{1/2} + \beta_0\kappa ab[0.01387-\ln(\kappa a/C^{1/2})]/8C^{1\,2}$$

$$\delta_3 = (\kappa ab)^3[1.2929/b^2 + 1.5732/b]/6C^{3/2}$$

$$\delta_4 = \beta_0(\kappa a)^2/C + 0.23484\beta_0 b(\kappa a)^2/3C$$

All calculations were performed on a TOSBAC 3400 digital computer using the least squares method proposed by Kay.[15] The following equation was used.

$$\Delta\Lambda = \Lambda(\text{obsd}) - \Lambda(\text{calcd}) = \Delta\Lambda_0 + (C\partial J_1/\partial a - C^{3/2}\partial J_2/\partial a)\Delta a$$

(In Fernandez-Prini and Prue's paper, equation (8) is misprinted.) In order to bring the data into conformity with Fernandez-Prini's treatment, the data weighted by concentration were also analysed. No viscosity correction was made. Parameters obtained

are given in Tables 2 and 3, where σ is a standard deviation. The complex salt was found to be completely dissociated in these solvents, since when the data were treated with a three-parameter equation involving the association constant K_A, a negative K_A with a larger standard deviation was derived. The magnitude of standard deviations in Tables 2 and 3 clearly indicates that the Pitts equation is preferable to the F–O and F–H equations.

As is suggested by Fernandez-Prini and Prue,[6] it is useful to introduce Λ_0' to examine the fitting,

$$\Lambda_0' = \Lambda(\text{obsd}) - \Lambda(\text{calcd}) + \Lambda_0$$

Λ_0' calculated from the observed conductance weighted by concentration is plotted against concentration in Figures 1, 2 and 3. We see that the Pitts equation

shows the best performance in every case. The plots of Λ_0' from the F–O equation have a curvature, meaning a deficiency of the concentration dependent terms in the equation. Similar results were obtained for hydrogen chloride in water and alkali metal halides in water, methanol and dimethyl formamide by Fernandez-Prini and Prue and for alkali metal halides in water by Pitts *et al.*[4] The plot from the F–H equation which contains $C^{3/2}$ term also seems to be curved, but the curvature is not so noticeable as that from the F–O equation. On the other hand, Tables 2 and 3 show that a-values obtained with the Pitts equation are considerably smaller than those with the F–O and F–H equations. This trend is also found by Fernandez-Prini and Prue.

Perchlorate ion is known to be one of the least solvated ions and it may be assumed that a large cation such as this chelate is not solvated, since the positive charge on the cation is screened by the bulky aromatic ligands. Thus a-values in this case will correspond to the contact distance between the cation and the anion.

It may thus be concluded that a-values from the Pitts equation are unrealistically small because the sum of the crystallographic radius of ClO_4^- and that of the chelate cation estimated from the bond lengths significantly exceeds 3.5 Å obtained with the Pitts equation. (The crystallographic radius of the chelate cation is not found in literature to the author's knowledge). It is also seen from Tables 2 and 3 that a-values derived with the F–O and F–H equations seem to be small for the bulky complex perchlorate. However, it should be noted that a-values generally show a considerable dependence upon the dielectric constant of the medium,[2,16] and that those obtained with tetraalkylammonium halides and picrates in CH_3NO_2, MeOH and CH_3CN are almost constant irrespective of a considerable variation in crystallographic radius and smaller than those expected from their ionic radii, viz., the derived a-values are 3.9± 0.3 Å,[10] 3.6±0.2 Å,[17] and 3.6±0.2 Å[9] for all the halides and picrates investigated in CH_3NO_2, MeOH and CH_3CN, respectively. Of course a viscosity correction affecting a-values to some extent[9] was made in

16) J. Lind and R. M. Fuoss, *J. Phys. Chem.*, **65**, 999, 1414 (1961), *ibid.*, **66**, 1727 (1962).
17) R. L. Kay, C. Zawoyski, and D. F. Evans, *ibid.*, **69**, 4208 (1965).

these cases. Evans and Gardam[18] found that when the F–H equation was applied to several tetraalkylammonium salts in alcohols, small but constant a-values were obtained which were independent of the dielectric constant. It is seen from Tables 2 and 3 that a-values from the F–H equation are slightly larger than those from the F–O equation. Though the continuum theory is adequate to describe the concentration dependence of the conductance, the size dependence in the F–O theory appears to need revision.[17]

The reason why the Pitts equation in general gives smaller values of a has been discussed by Fernandez-Prini and Prue[6,13] in outline and by Pitts[4] in detail. The main differences between these theories lie in the boundary conditions used to solve the equation of continuity. Pitts neglected the Brownian terms in the velocity of the ion from the viewpoint of the model his theory was based on. The Pitts equation does not allow for the kinetic (osmotic) term which contributes to the increase in the velocity of the ion in the F–O theory. Valleau[19] pointed out that this term should be regarded as completely unrealistic and should be dropped. Recently Carman[4,20] has stated from the consideration of the cancellation of terms in the F–O theory that the E value in the F–O theory should be $(E_1\Lambda_0-2E_2)$[21] but not $(E_1\Lambda_0-E_2)$. He emphasized that the F–O and Pitts theories are not mutually exclusive since they are based on the same model.

As Pitts *et al.*[4] pointed out, it is too complicated to discuss the two theories term by term and it is more useful to compare the resulting parameters. When the data of the complex salt in CH_3CN–CCl_4 and $PhNO_2$–CCl_4 mixtures with dielectric constants less than 15 were analyzed with the Pitts equation involving the association constant K_A term, no convergence was obtained whereas the F–O and the F–H equations gave reasonable parameters.[22]

From the present discussions, it is concluded that the F–H equation is recommended for the analysis of the conductance data of both unassociated and associated electrolytes also in these aprotic solvents.[13]

The author wishes to express his deep gratitude to Professor Yuroku Yamamoto, Hiroshima University, and to Mr. Toshihiro Tominaga for their valuable discussions and directions in the course of this study.

Anodic Oxidation of Benzoic Acid in Nitriles

Yoshiharu MATSUDA,* Kazuo KIMURA, Chiaki IWAKURA, and Hideo TAMURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received March 13, 1972)

The anodic oxidation of benzoic acid in acetonitrile and propionitrile was studied. Electrolysis was employed under a controlled potential or current. Benzoic acid was changed into an intermediate benzoyloxy radical through de-electronation in acetonitrile, and the resulting radical was reacted with acetonitrile to give *N*-acetylanthranilic acid in a 38% yield under constant potential electrolysis. In propionitrile, the anodic oxidation gave *N*-propionylanthranilic acid, *N*-propionylbenzamide, and dipropionylamine. No Kolbe-type reaction was observed.

Many works[1-3] have been reported on the anodic oxidation of aliphatic carboxylic acids, which is connected with the Kolbe reaction. On the other hand, the anodic oxidation of aromatic carboxylic acids has been investigated by only a few workers[4-8], and the mechanism has not yet been discussed. Therefore, it is of interest to investigate the anodic oxidation of aromatic carboxylic acids and discuss its mechanism. Fichter and Uhl[8] have reported that the anodic oxidation of benzoic acid in an aqueous solution gave hydroxybenzoic acid, hydroquinone, and catechol.

In an attempt at testing the solvent effect on the anodic oxidation of benzoic acid, we used acetonitrile and propionitrile instead of water. The electrolysis was employed under a controlled potential or current. Benzoic acid was changed into a benzoyloxy radical, the intermediate, through de-electronation in acetonitrile, and the resulting radical was reacted with the nitrile to give *N*-acetylanthranilic acid in a 38% yield under a constant potential electrolysis. In pro-

pionitrile, the anodic oxidation afforded *N*-propionylanthranilic acid, *N*-propionylbenzamide, and dipropionylamine. No Kolbe-type reaction was observed.

Experimental

Reagents. The benzoic acid, lithium perchlorate, acetonitrile, and propionitrile used were reagents guaranteed by JIS and the Wako Pure Chemical Ind. Co., Ltd. The nitriles were refluxed over phosphorus pentoxide and distilled.

Electrodes and Electrolytic Cells. A platinum wire sealed into a glass tube with the surface area of 0.289 cm^2 was used as the anode for the study of the mechanism. The volume of the H cell with a sintered glass disk diaphragm was 50 ml. In the electrolysis at a constant current or potential, a platinum plate with the effective surface area of 2×2 cm^2 was used as the anode, and the volume of the cell was 200 ml. The electrodes were polished with emery paper and then immersed in acetone for 10 min. Iron, nickel, lead, lead oxide, titanium, tantalum, and gold were also tested as anode materials. The base electrolyte solutions were nitriles containing lithium perchlorate, and benzoic acid was added to the anode compartment. The reference electrode was a saturated calomel electrode or a silver nitrate electrode (Ag/0.1 M $AgNO_3$ in CH_3CN), and a Luggin capillary and a salt bridge were used for the junction between a test electrode and a reference electrode. The cathode was a mercury-pool electrode. Triangular potential waves were generated by using a potentiostats and a function generator. The electrolysis was generally operated at a constant current or at a constant potential.

Measurement of Current-potential Curves. Argon gas was bubbled into the electrolyte for 10 min before the electrolysis. In the measurement by the stationary method, the anode potential was kept at each initial voltage in the range from 1.6 to 1.9 V (*vs.* SCE) for 5 min, and then the potential was anodically moved. In the case of single-sweep voltammetry, the anode potential was initially kept at 1.7 V (*vs.* Ag/0.1 N Ag^+) for 5 min, and then the potential was anodically swept at the rate of 16.2 mV/sec.

Anodic Oxidation of Benzoic Acid in Acetonitrile at a Constant Current. During the electrolysis, lithium perchlorate was sometimes added to the electrolyte to suppress the rise in the electric resistance of the electrolyte by the consumption of benzoic acid and lithium perchlorate. After the electrolysis, the solvent acetonitrile was removed from the anolyte by distillation and 100 ml of water was added to the residue. The aqueous solution was extracted with 100 ml of ether. After washing with 50 ml of water, the ether solution was dried over anhydrous sodium sulfate and concentrated. The residue (1.78 g) was chromatographed on Wakogel ($SiO_2 \cdot xH_2O$). Upon chromatography, the first fraction (eluent: n-hexane) gave 0.23 g of a yellow liquid (unidentified). The second fraction (eluent : benzene) afforded 0.37 g of benzoic acid. The third fraction gave 0.76 g of *N*-acetylanthranilic acid (mp 180—181°C (lit,[9] 186°C)); a mixed-mp determination with an authentic sample showed no depression. The structure was also identified by IR and mass spectra. The fourth fraction gave 0.40 g of a brown viscous liquid (unidentified). When the catholyte was treated by the same procedure, *N*-acetylanthranilic acid (0.13 g), benzoic acid (0.67 g), and an unidentified substance (0.95 g) were obtained.

9) A. Kaufmann, *Ber.*, **42**, 3480 (1909).

Anodic Oxidation of Benzoic Acid in Propionitrile at a Constant Current. After electrolysis, the anolyte and the catholyte were basified with aqueous sodium hydroxide and organic materials were extracted with 100 ml of ether, respectively. The organic layer was concentrated, and the residue (1.65 g) from the anolyte was chromatographed on Wakogel. The first fraction (eluent : hexane) gave 0.11 g of an unidentified liquid. The second fraction (eluent : benzene) afforded 0.48 g of *N*-propionylbenzamide (mp 97.0°C (lit,[10] 98°C)); the structure was identified as above. The third fraction (eluent : ether) afforded 0.39 g of dipropionylamine (mp 153—154°C (lit,[11] 153—154°C)); a mixed-mp determination with an authentic sample showed no depression; the structure was identified as above. The fourth fraction (eluent : ether and methanol) gave 0.63 g of a dark brown viscous liquid (unidentified). The aqueous layer was acidified with aqueous sulphuric acid, and then extracted with ether. After the removal of the ether, the residue (1.50 g) was similarly chlomatographed on Wakogel. The first fraction (eluent : hexane) gave 0.09 g of a brown viscous liquid (unidentified). The second fraction (eluent : benzene) gave 0.17 g of recovered benzoic acid, while the third fraction (eluent : benzene) gave 0.13 g of an unidentified yellow viscous liquid. The fourth fraction (eluent : ether) afforded 0.88 g of *N*-propionylanthranilic acid (mp 116—117°C (lit,[12] 117°C)); a mixed-mp determination with an authentic sample showed no depression; the structure was identified by means of the IR, mass, and NMR spectra. The fifth fraction (eluent : methanol) gave 0.21 g of a dark brown viscous liquid (unidentified). The catholyte was treated in the same way as above, giving *N*-propionylanthranilic acid (0.18 g), recovered benzoic acid (0.11 g), dipropionylamine (trace), and an unidentified substance (1.58 g).

Anodic Oxidation of Benzoic Acid in Acetonitrile at a Constant Potential. The anode potential was kept at 2.20 V against a silver nitrate electrode. The reaction products were treated in the same way as in the anodic oxidation of benzoic acid in acetonitrile at a constant current.

Results and Discussion

A typical potential-current curve of benzoic acid in acetonitrile obtained by the stationary method using a platinum-wire electrode is shown in Fig. 1. The anodic oxidation current was observed beyond 2.0 V against SCE. Similar potential-current curves were obtained in the anodic oxidation of benzoic acid in propionitrile. The single-sweep voltammetry was also applied. The shapes of the potential-current curves were similar to that obtained by the stationary method, and the oxidation current of benzoic acid was observed over 1.9 V against a Ag/0.1 N Ag^+ electrode.

By using single-sweep voltammetry, some materials were tested for the anode in acetonitrile containing lithium perchlorate in order to observe the effect of the base electrolyte. In the cases of platinum and gold electrodes, the current resulting from the anodic oxidation of the electrolyte was observed over approxi-

mately 2.3 V. Therefore, these electrodes were suitable for use as anodes in this study. In contrast, on the iron, nickel, lead, lead oxide, titanium, and tantalum anodes, the oxidation current of the electrolyte not containing benzoic acid appeared below 1.9 V. This result shows that these materials are not suitable as anodes.

The anodic oxidation of benzoic acid at a constant current gave mainly *N*-acetylanthranilic acid in a 20% yield,[13] together with unreacted benzoic acid and a small amount of unidentified products. The overall results of the electrolysis are shown in Table 1. The *N*-acetylanthranilic acid obtained in the catholyte must have migrated from the anolyte through the diaphragm.

During the electrolysis, a gas, which was confirmed by gas chromatography to be composed of nitrogen, oxygen, carbon dioxide, hydrogen, and methane, was evolved on both the anode and the cathode. The imbalance in the material balance in Table 1 must be due to the gas evolution.

Table 1. Results of anodic oxidation of benzoic acid in acetonitrile at a constant current

Anode: Pt, Cathode: Hg, Supporting electrolyte: 1.0 M $LiClO_4$, 30—36°C, 6 hr, Current: 0.4 A, Cell voltage: 18—45 V, Anode potential: 2.45—2.75 V *vs.* SCE, Initial content of benzoic acid: 4.00 g (32.8 mmol)

Product	*N*-Acetylanthranilic acid	Unidentified substance	Recovered benzoic acid
Anolyte	0.76 g (4.2 mmol)	0.63 g	0.37 g (3.0 mmol)
Catholyte	0.13 g (0.72 mmol)	0.95 g	0.67 g (5.5 mmol)

Evolved gas in anode compartment: $CO_2>H_2>CH_4$.

The anodic oxidation of benzoic acid in propionitrile at a constant current was done under conditions corresponding to those in acetonitrile. The overall experimental results are shown in Table 2. *N*-Propionylanthranilic acid, *N*-propionylbenzamide, and dipropionylamine were produced. During the electrolysis, the evolution of a gas composed of hydrogen, carbon dioxide, ethane, and ethylene was similarly observed.

The results of the anodic oxidation of benzoic acid at a constant potential are shown in Table 3. In this electrolysis, no gas evolution was observed, since the polarization on the anode was suppressed.

The comparison of the current efficiencies of the anodic oxidation of benzoic acid in acetonitrile between that at a constant current and that at a constant potential are shown in Table 4; we assumed that two electrons are consumed in the reaction process to produce *N*-acetylanthranilic acid. In the anodic oxidation at a constant potential, gas was not evolved and the side reactions was probably suppressed. Therefore, the material balance in Table 3 is explicable.

For the purpose of clearing the reaction mechanism, some electrochemical measurements were applied; the single-sweep voltammetry was introduced initially. A remarkable anodic oxidation current was measured over 2.0 V against the reference electrode. The Tafel relation was obtained in the potential range from 2.05 to 2.20 V, when the base current due to the anodic

At a constant current	20%	16%

a) The yield was calculated as the ratio of the numbers of the *N*-anthranilic acid produced and the benzoic acid reacted.

oxidation of the electrolyte not containing benzoic acid was deduced from each current value in order to estimate the net oxidation current of benzoic acid. These results are shown in Fig. 2. The linear relation between the logarithm of the concentration of benzoic acid and the current was obtained from the data shown in Fig. 3. Since the slope of the lines in Fig. 3 was 1, the reaction order for benzoic acid in the first electrochemical process should be first-order.

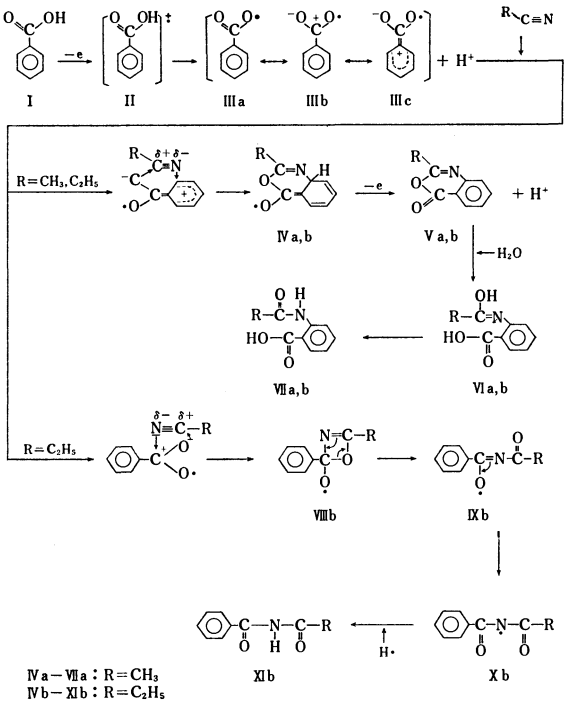
On the basis of the results mentioned above, the rate determining process for the anodic oxidation of benzoic acid could be suggested to be a charge-transfer reaction and its reaction would be first-order for benzoic acid.

At the initial stage, the de-electronation of benzoic acid would produce the radical cation, $[PhCOOH]^+$, on the anode. This radical cation would easily release a proton to yield a benzoyloxy radical, as is shown in Scheme 1.



Scheme 1.

In general, the benzoyloxy radical generated by the pyrolysis of benzoyl peroxide in acetonitrile dose not react with acetonitrile to give *N*-acetylanthranilic acid. As acetonitrile is presumed to be inactive in this system, a considerable part of the benzoyloxy radical is expected to be decarbonated. In addition, some part of the benzoyloxy radical abstracts hydrogen from acetonitrile to form benzoic acid and the cyanomethyl radical, which then dimerizes to yield 1,2-dicyanoethane.

However, in this study, the benzoyloxy radical (III in Scheme 1) on the anode does not abstract hydrogen but reacts with acetonitrile, which would be rather active on the anode, to give a new radical (IVa). This radical (IVa) would be immediately oxidized and deprotonated on the anode to give an unstable product, 2-methyl-6*H*-1,3-benzoxazin-6-one (Va). During working-up, this unstable product (Va) would then be hydrolyzed to give *N*-acetylanthranilic acid (VIIa). The reaction mechanism of the anodic oxidation of benzoic acid in acetonitrile is outlined in Scheme 1. A similar reaction is considered for the formation of *N*-propionylanthranilic acid (VIIb) by the anodic oxidation of benzoic acid in propionitrile. Accordingly, on the anodic oxidation of benzoic acid in acetonitrile or propionitrile, the hydrogen at the ortho-position of benzoic acid is displaced by the acetamide or propionamide group in the main process.

On the anodic oxidation of benzoic acid in propionitrile, *N*-propionylbenzamide (XIb) and dipropionylamine were obtained, besides *N*-propionylanthranilic acid (VIIb), though the origin of these different reactivities between the solvent acetonitrile and the propionitrile has not yet been clarified. *N*-Propionylbenzamide (XIb) would be formed according to Scheme 1. Dipropionylamine might be obtained through the coupling of propionitrile and the following hydrolysis, or through the coupling of the propionyl and the *N*-propionyl radicals which arise from the successive electrolysis of the compound (XIb).

In conclusion, the anodic oxidation of benzoic acid in acetonitrile gave *N*-acetylanthranilic acid through the formation of a benzoyloxy radical, its reaction with acetonitrile to form 2-methyl-6*H*-1,3-benzoxazin-6-one, and the following hydrolysis. The anodic oxidation of benzoic acid in propionitrile gave *N*-propionylanthranilic acid, *N*-propionylbenzamide, and dipropionylamine.

The authors wish to express their thanks to Dr. Yoshiki Ohshiro for his helpful discussion and encouragement throughout the course of this work.

(Received July 17, 1972)

It has already been found that the Birch reduction of 1,1,4aα-trimethyl-2α-hydroxy-8-methoxy-1,2,3,4,4a,9-hexahydrophenanthrene affords a tetrahydro derivative, contrary to expectations. The present paper will describe the details of the molecular structure of the unexpected reduction product, as revealed by an X-ray crystal analysis of its *p*-bromobenzoate (racemate). The crystals are triclinic, with two molecules in a unit cell of the dimensions: $a=11.155$, $b=18.123$, $c=5.912$ Å, $\alpha=94°39'$, $\beta=111°35'$, and $\gamma=90°42'$. The space group is $P\bar{1}$. The intensity measurement was made on an automatic four-circle diffractometer with Cu$K\alpha$ radiation. The structure was solved by the heavy-atom method, and was refined by the block-diagonal-matrix least-squares method, anisotropic thermal motions being assumed for all the non-hydrogen atoms. From a difference map, twenty-six of the thirty-one hydrogen atoms were also found. The final R factor was 6.5%. As a result of the present study, it has been found that the C ring of cyclohexene-type shows an unusual behavior. The length of the C–C single bond opposite to the double bond in this ring is found to be only about 1.34 Å. This remarkable shortening seems to be due to special vibrations of the two atoms concerned. The whole cyclohexene ring takes a considerably flattened, half-chair form.

It has recently been found that the reduction of I with *tert*-butyl alcohol and lithium in liquid ammonia produces a tetrahydro derivative, II (mp 162—164°C), and not the expected product, III or IV, and that the methoxyl group in the product obtained is much more reactive than those in usual allyl methyl ethers.[1] This enhanced reactivity of the methoxyl group seemed to be closely related with the conformation of the tricyclic system in the molecule. In order to obtain reliable information about the molecular conformation of II and to facilitate the understanding of the unusual chemical reactivity, an X-ray crystal analysis of its *p*-bromobenzoate (racemate) has been carried out.

Experimental

Colorless, single crystals of the racemic *p*-bromobenzoate, $C_{25}H_{31}O_3Br$, were obtained from an ether solution. Pre-

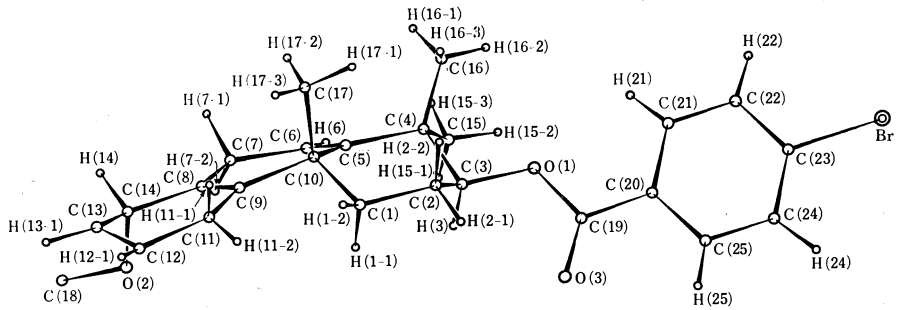

Fig. 1. The molecular framework and the numbering system of the atoms. The five hydrogen atoms which were not located in the difference map are not drawn. The absolute configuration in this picture is the inverse of those in Figs. 2, 3, and 4.

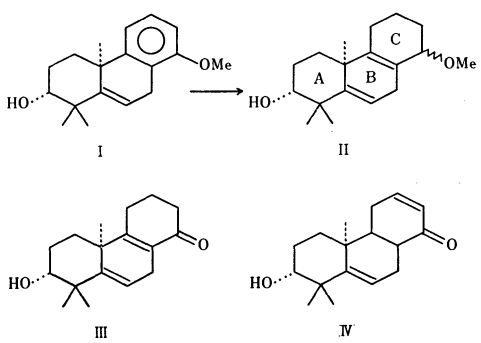

liminary photographic data and optical observations showed that the crystals were probably triclinic. The crystal data derived from diffractometer measurements are summarized in Table 1. A crystal with dimensions of about $0.1\times0.3\times0.5$ mm was sealed in a glass capillary tube and was used for the intensity measurement. The intensity data were collected with an automatic four-circle diffractometer at this University, using monochromatized Cu$K\alpha$ radiation. The intensities of the reflections with 2θ values up to 140° were measured by the ω–2θ scan technique; they were corrected for the Lorentz and polarization factors, but not for the absorption effect. In all, 3079 independent structure factors greater than $3\sigma(F)$ were obtained.

Table 1. The crystal data

Crystal system space group	Triclinic $P\bar{1}$
a	11.155±0.003 Å
b	18.123±0.003
c	5.912±0.002
α	94°39′±3′
β	111°35′±3′
γ	90°42′±3′
Z	2
D_x	1.378 g/cm³

Structure Determination

The space group was assumed to be $P\bar{1}$ throughout the present study. The position of the bromine atom was derived from a sharpened Patterson function. The first Fourier map, based on the heavy atom alone, yielded all the positions of the non-hydrogen atoms. The approximate coordinates thus obtained were first refined by the block-diagonal-matrix least-squares method, using isotropic temperature factors for all the atoms. Five cycles of the refinement reduced the value of the discrepancy factor, R, to 20.5%. Then, the least-squares refinement with anisotropic temperature factors for only the bromine atom was repeated. Consequently, it was found that the thermal parameters of the C(12) and C(13) atoms became very large (10.9 and 8.0 Å² respectively), although the R factor was decreased to 12.7%. In order to confirm the structure thus obtained, a difference synthesis was carried out, excluding five atoms: C(11), C(12), C(13), C(18), and O(2). The resulting map showed that the positions of the five atoms were all essentially correct, and that a single peak corresponded to each of these atoms. The structure thus confirmed was further refined by the least-squares method, anisotropic thermal motions being assumed for all the atoms; the R factor dropped to 8.7%. From a second difference Fourier map, twenty-six of the thirty-one hydrogen-atom positions were found. Further least-squares refinement including these hydrogen atoms reduced the R factor to 6.5%. The atomic parameters thus obtained are listed in Table 2.

All the calculations necessary for the present study were carried out on a FACOM 230—60 computer at the Computer Center of Hokkaido University.

Tables of the observed and calculated structure factors are preserved by the Chemical Society of Japan.

Results and Discussion

The molecular framework thus obtained and the torsion angles for the A, B, and C rings are shown in Figs. 1 and 2 respectively. As will be seen in these figures, the C ring takes a considerably flattened half-chair form, with the methoxyl group, O(2)–C(18)H_3, placed in the axial position and on the opposite side of the mean plane of the molecule to the C(17) atom, while the A ring has a distorted chair form, with the O(1) atom in the equatorial position. On the other hand, the B ring containing two endocyclic double bonds exists in the boat conformation. The bond distances and angles, along with their estimated standard deviations, are given in Tables 3 and 4 respectively. The correction for the thermal motion was made on the assumption of a riding motion by means of the Busing-Levy method.[2] Considering their standard deviations, these values are all reasonable except for the C(12)–C(13) bond. The unusual behavior of this bond will be described in detail later.

The chair form of the A ring is somewhat distorted, as has been described above. This may be mainly due to the fusion of the B ring, but it may be partly due to the repulsion between the two axial methyl groups, C(16)H_3 and C(17)H_3. As will be seen in Fig. 2, the A ring is less puckered than the normal chair-shaped ring of cyclohexane. From the average valence angle in the ring, 112.2°, the average torsion angle is estimated to be 52.6° by using Altona's equation.[3] This value is in good agreement with the average of the six observed torsion angles, 52.2°. The conformations of the three methyl groups in the A ring are shown in Fig. 3. In order to avoid a closer approach of the H(16–3) and H(17–1) atoms, neither the C(16)-H_3 nor C(17)H_3 methyl group takes the ideal staggered conformation; the deviations are about 13° and 10° respectively. Thus, the H(16–3) and H(17–1) atoms maintain a distance of about 2.05 Å. On the other hand, the conformation of the equatorial C(15)H_3 group around the C(15)–C(4) bond also deviates by

about 3° from the ideal staggered conformation. The distance of the H(15-3) atom from the H(6) atom is about 2.14 Å.

The B ring contains two non-conjugated double bonds, C(5)=C(6) and C(8)=C(9). The latter double bond is somewhat twisted, although the former holds a good planarity. The deviations of the atoms from the least-squares best plane through the C(7), C(8), C(9), C(10), C(11), and C(14) atoms are given in Table 5. The angle of twisting around the C(8)=C(9) bond is estimated to be about 3.7° by averaging the torsion angles, C(7)-C(8)-C(9)-C(10) and C(14)-C(8)-C(9)-C(11). The angle between the above best plane and the least-squares plane through the C(4), C(5), C(6), C(7), and C(10) atoms is about 15.1°.

The C ring is the most interesting part of the present molecule, since it seems to have a close relation to the high reactivity of the methoxyl group. The conformation and dimensions of this ring are shown in Fig. 4. This figure includes three remarkable features. The first is that the length of the C(12)-C(13) bond, 1.340±0.010 Å, is too short for a C-C single bond, and that the C-C-C valence angles at the C(12) and C(13) atoms, 119.7±0.6° and 117.5±0.7°, are too large for tetrahedral valence angles. Judging from these dimensions alone, the C(12)-C(13) bond must be a C=C double bond. However, both elemental analysis and NMR spectrum demonstrate that the C(12) and C(13) atoms form a single bond.[1] The second is that the C(12) and C(13) atoms vibrate vigorously in a direction almost perpendicular to the mean plane of the C ring. The root-mean-square deviations and direction cosines in the principal axes of the thermal ellipsoids are given in Table 6. The largest root-mean-square deviations for the C(12) and C(13) atoms are no less than about 0.55 and 0.52 Å respectively. Even though the C(12)-C(13) bond distance is corrected for these large thermal motions, the correction is only about 0.007 Å as long as the riding motion is assumed. However, if the highly-correlated antiparallel motion is assumed for the two atoms, the corrected distance amounts to about 1.73 Å. Accordingly, the shortening of the C(12)-C(13) single bond might be explained by such a thermal motion effect, but it

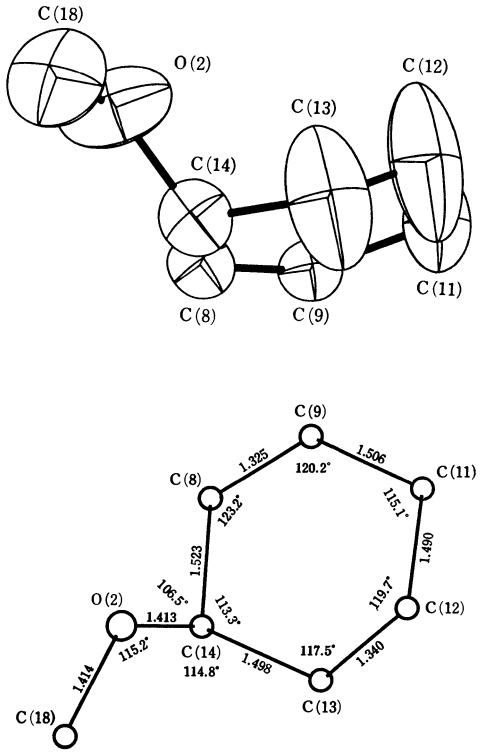

Fig. 4. The conformation and dimensions of the C ring. The thermal ellipsoids are scaled to enclose 50% probability.

seems to be difficult at the present stage to answer the question why these two atoms vibrate vigorously in a direction nearly antiparallel to each other. On the other hand, if this remarkable anisotropy of thermal motion were due to some disordering associated with the conformation of the C ring, the electron density distribution would afford double peaks for the C(12) and C(13) atoms, since the separation between two possible

Table 5. The deviations from the least-squares plane through the C(7), C(8), C(9), C(10), C(11), and C(14) atoms

C (10)	−0.049	C (6)	+0.348

positions is estimated to be about 0.76 Å from the observed distance for the C(12)–C(13) single bond. However, in fact, the difference map calculated excluding these atoms gave single peaks to them, as has been already mentioned in the section of Structure Determination. Hence, it seems to be unreasonable to think that the unusual behavior of the two atoms is to be explained by such a disordering. The third feature is that the methoxyl group is not in the equatorial position, but in the axial position, and that the half-chair form of the C ring is considerably more flattened than those in many other substances containing a cyclohexene ring.[4] The deviations from the least-squares best plane through the C(8), C(9), C(11), and C(14) atoms are no more than about 0.17 and 0.28 Å for the C(12) and C(13) atoms respectively; these values are considerably smaller than those found in cyclohexene, ±0.3673 Å.[5] One of the important factors which control the conformation of the C ring might be the H(1–2)···H(11–2) interaction, since the distance between the two hydrogen atoms, 2.17 Å, varies sensitively with the conformational change of the C ring. The methoxyl carbon atom, C(18), is placed at such a position that the O(2)–C(18) bond makes azimuthal angles of about 156.2° and 77.6° with the C(8)–C(14) and C(13)–C(14) bonds around the C(14)–O(2) bond respectively. It is interesting

I: x/a, y/b, z/c (given in Table 2). II: x/a, $1+y/b$, z/c. III: x/a, $-1+y/b$, z/c. IV: x/a, y/b, $1+z/c$. V: x/a, y/b, $-1+z/c$. VI: x/a, $1+y/b$, $-1+z/c$. VII: x/a, $-1+y/b$, $1+z/c$. VIII: $-x/a$, $1-y/b$, $1-z/c$. IX: $1-x/a$, $1-y/b$, $1-z/c$.

to note in Fig. 4 that the O(2) atom as well as the C(13) atom vibrates rotationally with the C(8)–C(14) bond as an axis of rotation. It has already been mentioned that the five hydrogen atoms could not be found in the difference Fourier map. Three of them are methoxyl hydrogen atoms, and the remaining two are axial ones at the C(12) and C(13) atoms. It seems at first sight strange that only the equatorial hydrogen atoms at the C(12) and C(13) atoms can be located, notwithstanding the large thermal motions of these two carbon atoms. This may be explained by taking it into consideration that, since, in the cyclohexene molecule, the equatorial hydrogen atoms at the C(12) and C(13) atoms deviate by only about 0.10 Å from the double-bond plane,[5] there are always equatorial hydrogen atoms in the neighborhood of the double-bond plane even if the α and β hydrogen atoms exchange the axial and equatorial positions with each other by a flipping of the ring.

The *p*-bromobenzoate group is not planar as a whole, but the carboxylate group is twisted at an angle of about 7.1° from the benzene-ring plane. The C(3) and O(3) atoms also deviate by about 3.2° from the eclipsed conformation around the O(1)–C(19) bond. On the other hand, the benzoyl group takes roughly the *cis* conformation with the H(3) atom around the O(1)–C(3) bond; the deviation from the ideal *cis* conformation is about 21°. Consequently, the O(3) atom is situated at a very small distance (about 2.36 Å) from the H(3) atom. This suggests that these two atoms exert a stronger attractive force on each other than the usual van der Waals interaction.

The molecular arrangement viewed along the *c* axis is shown in Fig. 5. The principal intermolecular distances are listed in Table 7. The molecules are connected mainly by the usual van der Waals interactions.

The authors would like to express their thanks to Dr. Yoichi Shiozaki of this University for his advice on the intensity measurements.

The Coordination Bonding and Stability of the 1 : 1 Complexes of Copper(II) with Various Bidentate Ligands in Aqueous-methanolic Solutions

Hiroshi Yokoi, Masaki Otagiri, and Taro Isobe

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai

(Received December 23, 1971)

ESR and spectrophotometric studies have been made of a number of 1 : 1 complexes of copper(II) with ethylenediamine, its analogues, and amino acids in aqueous-methanolic solutions. It has been shown that the complexes in the solutions are characteristic of copper(II) ions with a normal tetragonal environment and that their metal-ligand bondings are intermediate in the degree of covalency between those of hydrated cupric ions and the corresponding 1 : 2 complexes. The disproportionation constants and their temperature dependences, determined for the 1 : 1 complexes by the ESR and spectrophotometric methods, have been discussed, with particular empahsis on the fact that those values are in fair agreement with those derived from the step-by-step formation constants and the thermodynamic data obtained in aqueous solutions in the literature.

It is a very interesting problem in coordination chemistry to study the bonding character and stability of the 1 : 1 complexes of copper(II) with various bidentate ligands in aqueous solutions, sinec the 1 : 1 complexes can be regarded as intermediates in the formation of the 1 : 2 complexes. This problem is also of importance in estimating the reaction mechanisms of various metal-ion-catalyzed-reactions in organic, inorganic, and biological chemistries.[1-4] There have been almost no other works on the physical properties of the 1 : 1 complexes in solution but the one reported by Lewis *et al.*; they interpreted the ^{17}O NMR and ESR results of aqueous solutions of cupric salts and of 1 : 1 and 1 : 2 complexes of copper(II) with ethylenediamine in terms of molecular orbitals.[5]

The purpose of the present paper is to investigate the metal-ligand bondings of the 1 : 1 complexes of copper(II) with ethylenediamine, its analogues, and amino acids in aqueous-methanolic solutions, to compare them with those of cupric ions and the 1 : 2 complexes using the ESR and spectrophotometric methods, and furthermore, to discuss the stability of the 1 : 1 complexes in solution.

Experimental

Materials. The 1 : 1 complexes of copper(II) with bidentate ligands were produced according to equilibrium by mixing cupric ions and the 1 : 2 complexes in solution, as will be described in detail later. $Cu(ClO_4)_2 \cdot 6H_2O$ was used as the source of the cupric ions. The 1 : 2 complexes employed here, which had been prepared and purified in a previous work,[6] were $[Cu(en)_2] \cdot (ClO_4)_2$, $[Cu(dmen)_2] \cdot (ClO_4)_2$, $[Cu(deen)_2] \cdot (ClO_4)_2$, $[Cu(tn)_2] \cdot (ClO_4)_2$, $[Cu(L\text{-ala})_2]$, $[Cu(L\text{-ser})_2]$, and $[Cu(\beta\text{-ala})_2] \cdot 6H_2O$, where en, dmen, deen, tn, L-ala, L-ser, and β-ala are ethylenediamine, *N,N*-dimethylethylenediamine, *N,N*-diethylethylenediamine, trimethylenediamine, the anions of L-alanine, L-serine, and β-alanine respectively. The $(0.970 \pm 0.005) \times 10^{-2}$ mol/l solution of the cupric ions and the 1.000×10^{-2} mol/l solutions of the 1 : 2 complexes were prepared using an equivolume mixture of water and methanol as the solvent; the concentration of cupric ions was checked by a usual colorimetric determination, using sodium diethyldithiocarbamate.[7]

Measurements. The sample solutions used for the ESR and spectrophotometric measurements were mixtures of the above-mentioned solution of cupric ion and any of the above-described solutions of the 1 : 2 complexes at various volume ratios. The ESR spectra were measured at the temperature of liquid nitrogen with a Hitachi 771 X-band ESR spectrometer. The measurements of the visible absorption spectra were carried out at room temperature with a Hitachi EPS-3T spectrophotometer, using 1-cm quartz cells.

Results and Discussion

When a cupric salt and a stable 1 : 2 complex of copper(II) with a bidentate ligand, A, are dissolved in an aqueous solvent, the following equilibrium is generally established in the solution (with charge and hydrated water molecules omitted):

$$Cu + CuA_2 \rightleftharpoons 2CuA \quad (1)$$

$$K = \frac{[CuA]^2}{[Cu][CuA_2]} \quad (2)$$

where CuA represents a 1 : 1 complex. The relative amounts of the three species in the solution, therefore, vary according to the K value.

The X-band ESR spectra for the systems containing the 1 : 1 complexes of copper(II) with ethylenediamine and L-alanine are shown in Figs, 1 and 2 as typical ESR spectra in this work; the other systems showed almost the same spectral behavior. The ESR line shapes observed for the randomly-oriented and magnetically-diluted samples of copper(II) complexes have been investigated in some detail.[8] Accordingly,

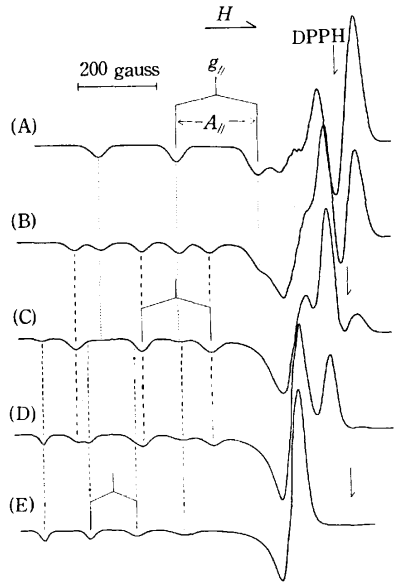

Fig. 1. The X-band ESR spectra of the mixtures of $Cu(ClO_4)_2 \cdot 6H_2O$ and $[Cu(en)_2] \cdot (ClO_4)_2$ in the following molar ratios (measured at 77K, total concentration of Cu(II) in each solution: 1×10^{-2} M, Solvent: an equivolume mixture of water and methanol).
(A) 0 : 1, (B) 1 : 3, (C) 1 : 1, (D) 3 : 1, (E) 1 : 0.

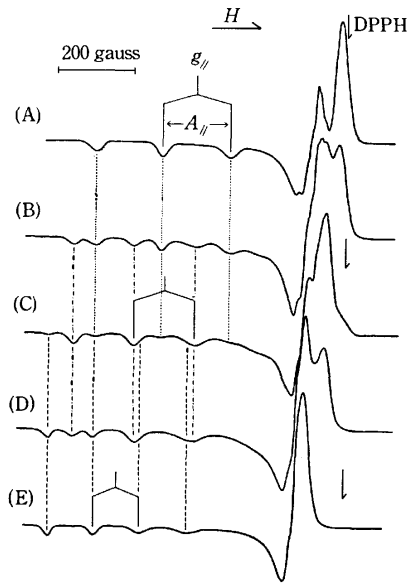

Fig. 2. The X-band ESR spectra of the mixtures of $Cu(ClO_4)_2 \cdot 6H_2O$ and $[Cu(L\text{-ala})_2]$ in the following molar ratios (measured at 77K, total concentration of Cu(II) in each solution: 1×10^{-2} M, Solvent: an equivolume mixture of water and methanol).
(A) 0 : 1, (B) 1 : 3, (C) 1 : 1, (D) 3 : 1, (E) 1 : 0.

it is clear that all the ESR spectra observed for the mixtures of the cupric salt solution and any of the 1 : 2 complex solutions are made up of the superposition of three different spectra, as Figs. 1 and 2 show. The several vertical dotted lines in these figures clearly point out that two of the three spectra are due to Cu and CuA_2, and the third spectrum, to CuA; there are not more than these three species in any sample solution, and the three species may coexist at equilibrium. It has also been shown that all the ESR spectra of the

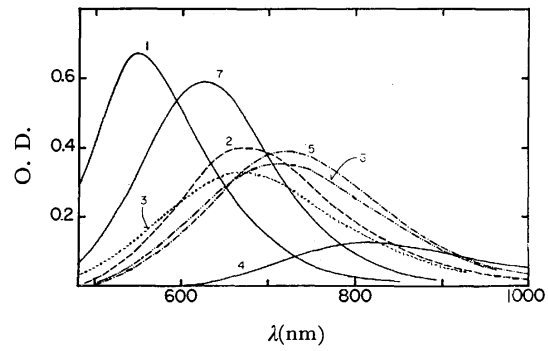

Fig. 3. The visible absorption spectra of the following complex species at room temperature (total concentration of Cu(II) in each solution: 1.00×10^{-2} M, Solvent: an equivolume mixture of water and methanol)
(1) $[Cu(en)_2] \cdot (ClO_4)_2$, (2) $[Cu(en)_2] \cdot (ClO_4)_2$, (2) $[Cu(en)_2] \cdot (ClO_4)_2 + Cu(ClO_4)_2$ (molar ratio of 1 : 1), (3) calculated spectrum of $[Cu(en)(OH_2)_2]^{2+}$, (4) $Cu(ClO_4)_2$, (5) $[Cu(L\text{-ala})_2] + Cu(ClO_4)_2$ (molar ratio of 1 : 1), (6) calculated spectrum of $[Cu(L\text{-ala})(OH_2)_2]^+$, (7) $[Cu(L\text{-ala})_2]$.

CuA_2 species employed in this work are of an axially-symmetrical type.[9,10] The computer simulation of ESR line shapes, furthermore, has revealed that any of the ESR spectra of Cu, CuA, and CuA_2 (A=en) in frozen aqueous solutions are characteristic of cupric ions with an axially-symmetric g tensor.[5] It can reasonably be concluded, from all the observed ESR line shapes in this work, that each of the CuA species also has a normal tetragonal copper(II) environment. The $g_{//}$ and $|A_{//}|$ values analyzed for all the species are listed in Table 1.

The visible absorption spectra of the same sample solutions as in Figs. 1 and 2 are shown in Fig. 3; they are typical of this work. The visible absorption spectrum of CuA can be obtained using the K value in Eq. (2) and the spectral data of Cu and CuA_2. A spectrophotometric method for determining the K value will be described later. Some of the analyzed data are listed in Table 1. It can be seen from this table the wavelength of the maximum absorption of CuA appears almost in the middle between those of Cu and CuA_2; this fact suggests that the ligand-field energies of CuA may be intermediate between those of Cu and CuA_2. Furthermore, concerning the dipole strength of the visible absorption transition, D, we found that CuA is intermediate in the D value between Cu and CuA_2. It has generally been accepted that the intensity of the visible absorption spectrum in a copper(II) complex always increases as the symmetry of its ligand field decreases.[11,12] Accordingly, it seems probable that CuA is not much lower in the symmetry of the ligand field than are Cu and CuA_2. From the fact of an axially-symmetric g tensor of CuA, and from

a) The samples represent the solutions of the complexes listed in this table, which are expressed with charge omitted, where an equivolume mixture of water and methanol was used as the solvent.
b) The pH at 25°C in a concentration of 0.01 M.
c) The values in parentheses are the data for the equimolar mixture of cupric ions and the 1 : 2 complexes in the above-mentioned solvent.
d) D represents the dipole strength of visible absorption transition;

$$D = 3.99 \times 10^{-20} \int \frac{\varepsilon_\sigma}{\sigma} d\sigma \quad (cm^2)$$

where σ expresses the wave number. The values in parentheses mean the same as given in the above footnote (b).
e) See the text.

the fact that CuA is intermediate in the values of D and of ligand field energies between Cu and CuA_2, it can be concluded that the ligand field of CuA is of an axial symmetry to almost the same degree as those of Cu and CuA_2. This conclusion, which is unexpected in view of the fact that the coordination symmetry of CuA is apparently less than tetragonal, agrees with the previously-reported suggestion that the symmetry of a ligand field is kept in as high a degree as possible for the copper(II) complexes in solution.[6]

The $g_{//}$ and $|A_{//}|$ values of CuA are intermediate between those of Cu and CuA_2, although CuA is somewhat closer to CuA_2 than to Cu in these values. The $g_{//}$ value is a good parameter for estimating the the degree of covalency of the metal-ligand bondings in planar copper(II) complexes; generally, the metal-ligand bondings become more covalent as the $g_{//}$ values increase.[13] The covalency of the metal-ligand bonding of CuA, therefore, is intermediate in degree between those of Cu and CuA_2. The same result can be derived from a consideration of the orbital reduction tion factors, one of which, $k_{//}^2$, is expressed in the following equation:

$$g_{//} - 2 = \frac{8\lambda_0 k_{//}^2}{\Delta E} \tag{3}$$

where λ_0 is the spin-orbit coupling constant for the free cupric ion and where $\Delta E = E_{x^2-y^2} - E_{xy}$. This $k_{//}^2$ value also has been considered to be an approximate parameter for expressing the degree of covalency of metal-ligand bondings for a series of square-planar copper(II) complexes structurally similar to each other.[14-16] The relative values of $k_{//}^2$ were calculated for all the copper(II) complexes dealt with here, using the energy value at the absorption peak as ΔE for convenience; they are listed in Table 1. It is clearly shown in this table that CuA is intermediate in the $k_{//}^2$ value between Cu and CuA_2. The findings that the metal-ligand bonding of CuA is intermediate in the degree of covalency between those of Cu and CuA_2, and that CuA is of a nearly tetragonal symmetry in the copper(II) ion environment, mean that the Cu-OH_2 bond in the molecular plane of CuA becomes stronger than that of Cu and the Cu–A bond of CuA, weaker than that of CuA_2, and, consequently, that, in CuA, the bond strength of in-plane Cu–OH_2 is almost equal to that of Cu–A.

When the step-by-step formation constants of K_1 and K_2 are expressed as follows (with charge and hydrated water molecules omitted):

$$Cu + A \rightleftarrows CuA \qquad K_1 = \frac{[CuA]}{[Cu][A]} \tag{4}$$

$$CuA + A \rightleftarrows CuA_2 \qquad K_2 = \frac{[CuA_2]}{[CuA][A]} \tag{5}$$

the following general equations can be set up, using K in Eq. (2):

$$\log K = \log K_1 - \log K_2 \tag{6}$$

a) The system means the mixtures of cupric ions and the 1 : 2 complexes (with charge and hydrated water molecules omitted). b) The pH at 25°C of the equivolume mixture of the 0.01 M aqueous-methanolic solutions of the two species in each system. c) An equivolume mixture of water and methanol. d) The values of log K in aqueous solution were calculated from Eq. (6) using the stepwise formation constants in the literature which determined in aqueous solution chiefly by the glass electrode method.[19,20] The values with errors express the means of two or more data. e) The value of ($\log K_{25}-\log K_0$) was used as a measure of the temperature dependence of log K in aqueous solution, where K_t represents K at t°C. The values with errors express the means of two or more data. f) Since the data for this system have not been reported, the values determined for the system Cu+Cu(L-thr)$_2$ were cited for reference, where L-thr represents the anion of L-threonine.

$$\log K = \frac{1}{2.30R}\left\{-\frac{(\Delta H_1-\Delta H_2)}{T}+(\Delta S_1-\Delta S_2)\right\} \quad (7)$$

where the symbols written in Eqs. (6) and (7) have their usual meanings. The values of log K were determined by the usual spectrophotometric method.[17]

When we represent the total concentrations of CuA_2 and Cu with xc and c respectively, and the concentration of CuA, with u, the equilibrium constant in Eq. (2) can be written by:

$$K = \frac{4u^2}{(xc-u)(c-u)} \quad (8)$$

On the other hand, the observed optical density, D', at a wavelength where the absorption of Cu is negligible is as follows:

$$D' = \varepsilon_p(xc-u) + 2\varepsilon_m u \quad (9)$$

where ε_p and ε_m mean the extinction coefficients of CuA_2 and CuA respectively. Furthermore, y and $\Delta\varepsilon$ were defined as follows:

$$y = \frac{D'-\varepsilon_p xc}{c} = (2\varepsilon_m-\varepsilon_p)\cdot\frac{c}{u} = \Delta\varepsilon\cdot\frac{u}{c} \quad (10)$$

From Eqs. (8) and (10), we obtain;

$$y^2 + P\cdot(1+x)\cdot y\cdot\Delta\varepsilon - P\cdot x\cdot\Delta\varepsilon^2 = 0 \quad (11)$$

where $P=K/(4-K)$. When two numerical sets of the x and y values at a certain wavelength are introduced into Eq. (11), we can find the values of $\Delta\varepsilon$ and P, from which the value of K can then be determined. The observed optical densities and the calculated values of y, $\Delta\varepsilon$, P, and K for the same systems as in Fig. 3 are listed in Tables 2 and 3. All the values of log K determined by this spectrophotometric method and by the previously-described ESR method[18] are listed in Table 4, together with the values of log K and their temperature dependences, which were calculated from Eqs. (6) and (7) using the step-by-step formation constants and the thermodynamic constants obtained in aqueous solutions by many investigators.[19,20]

It is clearly shown in Table 4 that the values of log K listed in the third, fourth, and fifth columns of the table are comparable to each other. All these values, moreover, are larger than the value of log K expected statistically, 0.60;[21] this means that there exist certain factors which promote the formation of the 1 : 1 complexes.[18,22-24] It seems likely that appreciably-accurate values of log K can be obtained by the ESR method, since all the magnetic parameters of CuA are intermediate in magnitude between those of Cu and CuA_2, since essential errors in estimating the concentrations of the three species are possibly cancelled out in Eq. (2).[18] However, the temperature at which the values of log K were determined by this ESR method is uncertain, although it is definitely a temperature between −50 and −100°C.[18] The temperature dependences of log K for all the systems in aqueous-methanolic solutions can be estimated by comparing the values of log K in the third and fourth columns of Table 4. In most systems, the temperature dependences in aqueous-methanolic solutions are in fair agreement with those in aqueous solutions. In System II, however, the temperature dependence of log K determined in this work is different

20) J. J. Christensen and R. M. Izatt, "Handbook of Metal Ligand Heats and Related Thermodynamic Quantities," Marcel Dekker, New York (1970).
21) The value of 0.60 can be formally explained on the following scheme, assuming that there are $4n$ particles of Cu and A respectively in solution and A is bonded to either Cu or CuA with the same probability.
[$4n$ Cu+$4n$ A]→[($2n$ Cu, $2n$ CuA)+$2n$ A]→[n Cu, $2n$ CuA, n CuA_2]
Accordingly, $\log K=\log[Cu][CuA_2]=\log n\times n=\log 4=0.60$.

in tendency from that obtained in aqueous solutions, although this result may not be accurate because of insufficient thermodynamic data on aqueous solutions for this system. The values of $\log K$ at 25°C listed in the third and fifth columns of Table 4 are somewhat different for the systems having relatively less stable 1 : 2 complexes. These differences may be due to the different solvent used, since the solvent effect on the complexes becomes more profound as they are less stable. Systems I—IV are those diamines, and Systems V—VII, those of amino acids. It is also shown in Table 4 that, in the former systems, the values of $\log K$ increase with a rise in the temperature, while in the latter systems the values decrease. The thermodynamic constants derived from these data are listed in Table 5. It is well known that, in complex formation, the nitrogen donors are softer than the oxygen donors and that both ΔH and ΔS are markedly lower for the formation of complexes by nitrogen than oxygen donors.[25] For both copper(II) complexes of ethylenediamine and L-alanine, the difference between ΔH_1 and ΔH_2 is quite small in magnitude, but the difference between ΔS_1 and ΔS_2 is markedly larger for the L-alanine complex than for the ethylenedimaine complexes; for the latter complex, $\Delta S_2=0$ and ΔS_1 is much smaller in magnitude than ΔS_1 and ΔS_2 for the former complex. Accordingly, the entropy term is more important in stabilizing the 1 : 1 complexes for amino acids than for diamines, as is clearly demonstrated in Table 5.

a) The solvent used is an equivolume mixture of water and methanol. The temperature at which the K values are determined by the ESR method was assumed to be −75°C. The values in parentheses in the table are the ones derived from the data in aqueous solution in the literature.[19,20]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 447—451 (1973)

ESR Studies of Dimer Formation by the β-Diketone Chelate Complexes of Copper(II) in Toluene[1)]

Hiroshi Yokoi and Taro Isobe

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai

(Received January 6, 1972)

A study of the ESR spectra of several β-diketone chelate complexes of copper(II) in the frozen solution of toluene has revealed that triplet-state dimers are formed at high concentrations in the solution and that these dimers are in equilibrium with only the monomers. The approximate equilibrium constants have been determined by a careful analysis of the ESR spectra observed in various concentrations. Structures for the dimers have been suggested from magnetic parameters properly determined using a point dipole model.

In recent years, many ESR studies of the triplet state of binuclear copper(II) complexes have been carried out with especial interest being taken in the mechanisms of the magnetic interactions between the two copper atoms.[2-11)] There have, however, been only a few ESR investigations of the triplet state obtained by the dimerization of mononuclear stable copper(II) complexes.[12-14)] The ESR experiments described in this paper will establish the new fact that dimeric and

monomeric species coexist at equilibrium in the toluene solutions of some copper(II) β-diketonates. The purpose of this paper is to propose structures for the dimers and to determine the equilibrium constants through an analysis of the observed ESR spectra.

Experimental

Materials. The β-diketone chelate complexes of copper(II) employed in this work are $Cu(acac)_2$, $Cu(bzac)_2$, $Cu(Etacest)_2$, and $Cu(Meacest)_2$, where acac, bzac, Etacest, and Meacest are the anions of acetylacetone, benzoylacetone, ethyl acetoacetate, and methyl acetoacetate respectively. They were prepared and purified according to the usual method.[15] Commercial toluene was purified by successive shaking with sulfuric acid and sodium hydroxide, followed by drying over sodium and, finally, fractional distillation.

ESR Measurements. The ESR spectra of the above-mentioned complexes in toluene in various concentrations were measured at the temperature of liquid nitrogen over the field range of 0 to 6,000 gauss, using a Hitachi 771 X-band ESR spectrometer. The toluene solutions were transferred into quartz tubes 4 mm in internal diameter and then solidified with liquid nitrogen as quickly as possible. These frozen solutions were the actual samples for ESR measurements used in this work.

Results and Discussion

The observed ESR spectra of $Cu(Etacest)_2$ and $Cu(acac)_2$ in toluene at the temperature of liquid nitrogen are shown in Figs. 1 and 2 respectively. $Cu(Meacest)_2$ and $Cu(bzac)_2$ were similar to $Cu(Etacest)_2$ and $Cu(acac)_2$ respectively in the ESR line shape. These spectra are complicated, and all of them showed weak absorptions at the low-field of about 1,500 gauss. The ESR spectra in these figures which are constructed by excluding sharp absorption lines are similar in line shape to the spectra observed for various binuclear copper(II)

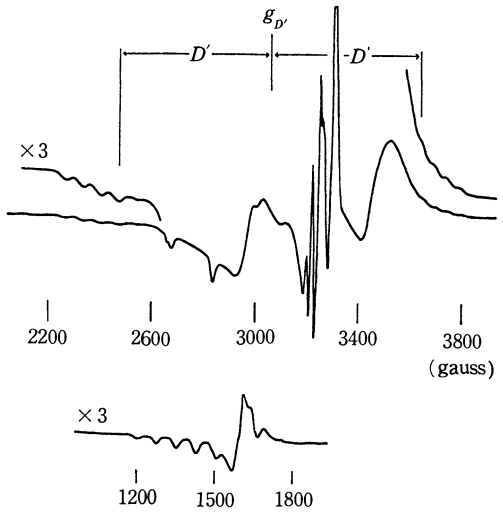

Fig. 1. The X-band first-derivative ESR spectrum of $Cu(Etacest)_2$ in toluene at 77K (c^0 : 1.03×10^{-2} M, the lower spectrum is the half-field spectrum of the $\Delta M=2$ transition).

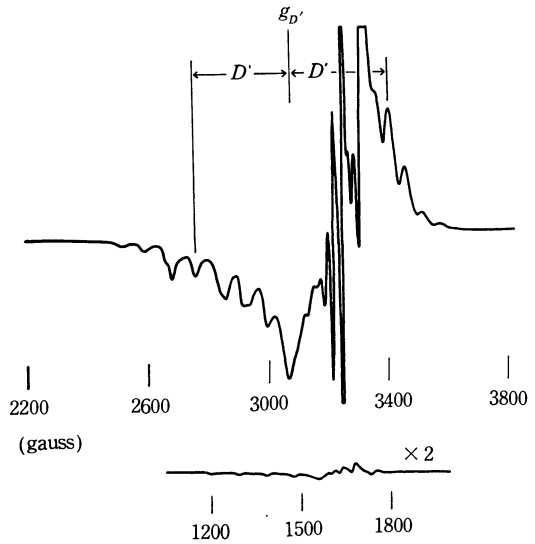

Fig. 2. The X-band first-derivative ESR spectrum of $Cu(acac)_2$ in toluene at 77K (c^0 : 2.22×10^{-3} M).

complexes with copper-copper spin interactions.[5-14] The ESR line shapes for randomly-oriented and magnetically-diluted copper(II) complexes have been studied in some detail by many investigators.[16] It can be clearly understood by a comparison of all these ESR line shapes that all the ESR spectra observed in this work are made up to the superposition of two types of spectra; one is due to triplet-state dimers, and the other, due to doublet-state monomers.

The spin Hamiltonian for triplet-state copper(II) dimers, on the assumption of axial symmetry, is written as follows:

$$H = \beta[g_{//}H_zS_z+g_\perp(H_xS_x+H_yS_y)] + D[S_z^2-S(S+1)/3] + A_{//}S_zI_z + A_\perp(S_xI_x+S_yI_y) \quad (1)$$

where all the symbols have their usual meanings. The zero-field splitting parameter, D, is composed of the following two terms:

$$D = D_{dd} + D_{pseudo} \quad (2)$$

In Eq. (2), D_{dd} expresses the magnetic dipole-dipole interaction term, and $D_{pseudo}=-J[(g_{//}-2)^2/4-(g_\perp-2)^2]/8$, where $-J$ is the energy separation between the singlet ground state and the first excited triplet state.[2] We wish now to estimate D_{dd}, from which the copper-copper atomic distance, R, can be estimated; then, the structures for the corresponding dimers can be proposed.[9,17] Since D only is a measurable value, D_{pseudo} must be estimated in order to determine D_{dd}. It has been considered that the structures for dimeric complexes in solution may be analogous to those in a crystal and that the $-J$ values in the two states may be almost the same.[14] The $-J$ value of $Cu(acac)_2$ in a crystal has been estimated to be less than 0.3 cm^{-1} from the value of θ in the

Curie-Weiss formula[18,19] and from the unification phenomenon of two separate ESR absorption lines with different g values due to a spin-exchange interaction.[20] The value of D_{pseudo} for $Cu(acac)_2$ in a crystal, which can be calculated from the above-described equation of D_{pseudo} using the above-estimated $-J$ value, is no more than a small percentage of the experimentally-determined D values (about 0.05 cm^{-1}) in this work. Furthermore, a change in the $-J$ value does not sensitively contribute to the calculated R value.[10] The assumption of $D=D_{dd}$, therefore, holds approximately good for all the dimers in this work. The copper-copper atomic distance, R, can be approximately estimated by means of the following equation, derived by the use of a point dipole model:

$$R = (0.650\, g_{//}^2/D_{dd})^{1/3} \quad (3)$$

where $g_{//}$ and D_{dd} are the parameters defined in Eqs. (1) and (2).[9,17] It has been demonstrated that the agreement between the experimentally-determined R value and the R value estimated from Eq. (3) is fairly good.[10] A closer examination of the ESR spectra observed in this work shows that the hyperfine coupling constants observed at the two edges of the triplet spectra for $\Delta M=1$ are appreciably different from each other. Chikira and Isobe have revealed, through the computer simulation of these types of triplet ESR line shapes, that the above-mentioned differences in the hyperfine structure are due to the discrepancy between the principal axes of the D and A tensors in orientation.[21] They have also reported that, generally, the approximate R value can be obtained directly by substituting $g_{D'}$ and D' for $g_{//}$ and D_{dd} respectively in Eq. (3), regardless of the $-J$ value over a considerable wide range, where $g_{D'}$, and D' are defined in Figs. 1 and 2.[21] The analyzed results for all the complexes are listed in Table 1.

The first two complexes in Table 1 are quite similar to each other in ESR behavior; such is also the case with the other two complexes in the table. The molecular configuration of $Cu(acac)_2$ in a crystal is schematically shown in Fig. 3(A), where the R value

Table 1. Magnetic parameters and R[a] values

	$g_{//}$	$g_{\perp}$	$\lvert A_{//}\rvert$ $\times 10^4$ cm^{-1}	$g_{D'}$[b]	D'[b] $\times 10^4$ cm^{-1}	R (Å)
$Cu(Etacest)_2$	2.282	2.05	176	2.174	590	3.73
$Cu(Meacest)_2$	2.275	2.06	174	2.167	581	3.75
$Cu(acac)_2$	2.255	2.05	191	2.161	326	4.53
$Cu(bzac)_2$	2.255	2.05	192	2.157	331	4.50

a) R represents the copper-copper distance (Å).
b) The parameters are defined in Figs. 1 and 2.

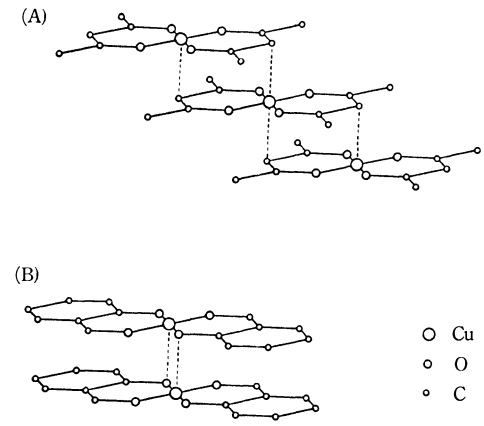

Fig. 3. The schematically represented crystal structures of (A): $Cu(acac)_2$ and (B): crystal form of bis-(salicylaldehydato)copper(II).

is 4.52 Å.[22] This R value surprisingly agrees with the R value calculated from D' value, as is shown in Table 1. Accordingly, it may be concluded that the dimeric structure of $Cu(acac)_2$ in toluene is the same as that in a crystal and that, furthermore, the dimers of $Cu(bzac)_2$ in toluene also have a similar structure. On the other hand, the crystal structure of Cu(Etacest)$_2$, whose R value is 4.53 Å,[23] is analogous to that of $Cu(acac)_2$; in their crystals, the carbon atoms of the –CH– groups of adjacent molecules occupy the apical positions of the copper atom. The R value calculated from D' for the dimers of Cu(Etacest)$_2$ in toluene is 3.75 Å, as is listed in Table 1. The large difference between the two R values for this complex clearly indicates that its dimeric structure in toluene is quite different from that in a crystal. Interestingly, (salicylaldehydato)copper(II), which is analogous in physical and chemical behavior to Cu(Etacest)$_2$,[26,27] has two different crystal structures[24,25]; one is similar to the crystal structure of $Cu(acac)_2$, and the other, to those of *N,N'*-disalicylidene ethylenediamine copper(II),[28] the γ-form of bis-(*N*-methyl-salicylaldiminato)copper(II),[29] and bis-(8-hydroxyquinolinato)copper(II).[30] The latter crystal structure is schematically shown in Fig. 3(B), where the directly-coordinating oxygen atoms of adjacent molecules occupy the apical positions of the copper atom. The R value is calculated to be 3.73 Å for this type of structure, assuming about 3.15 Å as a reasonable copper-apical oxygen distance. It seems likely, therefore, that the

dimers of Cu(Etacest)$_2$ in toluene have a structure analogous to the one shown in Fig. 3(B).

A large concentration dependece of the ESR spectra was observed for each of the complexes employed here, as is shown in Fig. 4. The Q value can now be defined as the intensity ratio of a certain absorption line of the dimers to a certain line of the monomers in a first-derivative ESR spectrum; for instance, $Q=H_D/H_M$ in the case of Fig. 4. It is clear that all the complexes in toluene regularly change in their Q values with their initial concentrations, as may be seen in Fig. 4. It seemed that it would be very interesting to see whether or not the following type of equilibrium is established in the solution:

$$2M \rightleftharpoons M_2 \tag{4}$$

$$K=\frac{[M_2]}{[M]^2} \tag{5}$$

where M and M_2 represent monomeric and dimeric molecules respectively. An attempt to establish the proof of the presence of such an equilibrium and to determine the K value will be described below.

When q is introduced as the proportional constant of the equation $Q=q\cdot([M_2]/[M])$, the following equation can be derived from Eq. (5):

$$2Q^2+qQ=Kq^2c^0 \tag{6}$$

where c^0 is the initial concentration of a complex in toluene. It was assumed that the $[M_2]/[M]$ ratio is equal to the ratio of one-half of the integrated intensity of the ESR spectral component due to the triplet-state dimers to the integrated intensity of the spectral component due to the monomers; the coefficient of one-half means that the transition of $\Delta M=1$ occurs twice within a whole-field sweep for each of the dimeric molecules, while it does so once for each of the monomeric molecules. The determination of the q value is troublesome and is responsible for the greatest error in evaluating the K value from Eq. (6). The q value was here determined by the following method.

There was a remarkable increase in the apparent intensity ratio of the ESR spectral component due to the monomers to the one due to the dimers as the c^0 value became smaller. For the monomers, accordingly, the approximate ratio of the totally-integrated spectral intensity to the height of a certain first-derivative ESR absorption line can be determined from an ESR spectrum observed in a very low concentration. Since the integrated intensity of the spectral component due to the monomers can be obtained for each of the observed ESR spectra using the above-determined ratio, the integrated intensity due to the dimers also can be determined by deducting the one due to the monomers from the totally-integrated intensity of the spectrum; the q value can then be straightforwardly evaluated from those intensity values.

The analyzed data for Cu(Etacest)$_2$, as an example, are listed in Table 2, where the q value was determined to be 0.14 ± 0.02 by using the absorption lines of H_D and H_M shown in Fig. 4. The plot of $2Q^2+qQ$ *vs.* c^0 for this complex is shown in Fig. 5. The data for

the other complexes are not listed here; only the plots are shown in Figs. 5 and 6. All these plots were clearly found to be linear; accordingly, the K values could be evaluated from the slopes of these linear plots. The K values thus obtained are listed in Table 3, together with the determined q values.

The fact that a plot of $2Q^2+qQ$ *vs.* c^0 gives a straight line for all the complexes in toluene indicates that both species of dimers and monomers are present in the equilibrium of Eq. (4) in the toluene solution of the complexes; the other species —for example, polymers— do not exist in the solution. The large K values determined for the first three complexes in Table 3 indicate that most molecules of the three complexes are dissolved into toluene as dimers. The linear plots above-described, furthermore, indicate that the reproducibility of this experimental method for estimating the equilibrium constants is not poor; the experimental method accompanying the solidification of the sample solutions in liquid nitrogen is applicable to various quantitative analyses, as in this case. The temperature at which the equilibrium constants are determined, however, is uncertain in this experiment, although it is undoubtedly near the freezing point of toluene (−95°C).[31,32] Such a dimer formation could not be observed in any of the various organic solvents ordinarily used other than toluene. Furthermore, bis-(dipivaloylmethanato)copper(II) and bis-(trifluoroacetylacetonato)copper(II), which are also β-diketone chelate complexes similar in various properties to $Cu(acac)_2$ and $Cu(Etacest)_2$ respectively, did not exhibit such a dimer formation in toluene; this experimental fact suggests the importance of the steric factors in the dimer formation. At any rate, the factors governing the dimer formation seem to be very complicated; a further investigation of this problem is now in progress.

Rocker-type DTA Apparatus for Fluid Samples

Satohiro TANAKA

National Chemical Laboratory for Industry, Hon-machi, Shibuya-ku, Tokyo

(Received February 15, 1972)

A Rocker-type DTA apparatus, with agitation by rocking, has been developed for use in the thermal analysis of various fluid mixture systems. The heater block, with its assembled cells, is continuously rocked at 20 r.p.m. with a rocking of 180° angle. The glass cell has a volume of about 8 ml and is sealed by means of a burner with a sample of about 5 ml. Distilled water is used as the inert reference in the reference holder. Two thermocouples are inserted in each cell, one to determine the temperature difference and the other for sample temperature measurements. The double thermocouple gives a constant transition temperature of the sample over a wide range of heating rates. The apparatus is applied to solid-liquid and starch-water systems. Variables affecting the DTA thermogram of the $K_2Cr_2O_7$–H_2O system are investigated, and a method is established to correlate the DTA curve with the solubility curve for the system.

It is sometimes necessary to perform the thermal analysis of heterogeneous fluid mixture systems such as solid-liquid and starch-water[1] systems. The most important conditions for the thermal analysis of such systems are to avoid the escape of the vapor of the samples and to avoid composition inhomogeneity in the sample cells. These conditions are usually obtained by the use of a sealed sample holder and by stirring the samples adequately.

Various stirring techniques are available; the final choice is dependent on the nature of the system to be investigated. Propellor-type stirrers driven by a shaft are sometimes used.[2,3] However they cease to operate when a fraction of the sample is solidified, and they allow the vapor of the sample to escape through the gland around the shaft of the stirrers and allow a considerable amount of heat to be conducted from or to the holder through the shaft. An alternative method is to use a sealed-in stirrer operated by means of a solenoid,[4] but in this case the stirrer stops when only a fraction of the sample is solidified and it is necessary to ensure that no electrical interference is produced in the temperature-measuring circuit in the solenoid. To ensure the adequate stirring of the sample inside a sealed holder, the rocking method[5–8] may be used. Here, the agitation of the sample continues until practically all the material has solidified, and at the same time the material is completely sealed in the holder. Gilpatrick *et al.*[8] have also described the use of a commercial rocker unit for phase studies of a molten salt system, NaF–KF–BF_3. In the apparatus to be described here, adequate stirring has also been obtained by applying the rocking method, and the DTA of solid-liquid and potato starch-water systems has been successfully performed.

Experimental

Apparatus. A whole diagram of the apparatus is shown schematically in Fig. 1. The center of gravity of the block assembly and the rack is adjusted to coincide with the shaft, the axle of rotation, so as to assure smooth rotation. The holder contents are then stirred by continuous rocking through an arc of 180° at a speed of 20 rpm achieved by means of a synchronous motor. The heater block is made of aluminum; a cross-section of heater block assembly is shown in Fig. 2. The holder used is made of glass; it is also shown in Fig. 2. The holder has a volume of about 8 ml and is sealed by means of a burner with a content of about 5 ml. The block is heated by a noninductively-wound nichrome wire insulated by a mica sheet against the surface of the block. The heater is controlled by a variable-voltage transformer to give the desired constant heating rates.

Chromel-Alumel thermocouples are used to measure the block, sample, and temperature differences. In the well of each holder, two junctions of the thermocouples are inserted to measure the temperature and temperature differences. This arrangement gives a constant transition temperature of sample over a wide range of heating rates. The electrical leads for the heater and thermocouples are hung in wide U-

turns to prevent the breaking of the leads by the repeated bending introduced by the rocking of the assembly. The differential thermocouple emf is preamplified by Okura Model AM-1001 D. C. amplifier and fed to the input of a Rikadenki Model B-341 three-pen recorder. The block and sample temperatures emf are similarly fed to the inputs of the recorder without preamplification.

Materials. Benzoic acid, a standard sample for combustion calorimetry obtained from the Resource Research Institute, Japan, and Tokyo Kasei zone-refined naphthalene were used to calibrate the temperature thermocouple through their melting points. Kokusan Chemical Works extra-pure potassium dichromate, potassium nitrate, cobalt sulfate, and Wakō Junyaku potato starch were used without further purification. Distilled water was used as the reference material and as one component of the sample binary mixtures.

Results and Discussion

Some Examples. Figure 3 shows the effect of the heating rate on the peak temperatures.

Blank-run DTA curves of distilled water in both holders are shown in Fig. 4 and 5. The regular variation in the base line synchronous with the rocking cycle is increased with the increase in the sample temperature and the heating rate. The blank run in Fig. 4 is performed under a high heating rate in order to observe the irregularity of base line, while general runs with actual samples are performed under a mod-

erate heating rate, nearly equal to or less than about 1°C/min., and have more smooth base lines than the run in Fig. 4.

DTA curves of various solid-liquid mixture systems of known compositions are shown in Figs. 6 to 8. A shift in the position of the base line to a new level is observed in Figs. 6 and 7. The temperature at which the shift occurs is nearly in agreement with the dissolution temperature in the literature.[9] The dissolution temperature, at which the solid phases in a mixture of the prepared compositions dissolve completely, are 50°C for $K_2Cr_2O_7/H_2O=0.354$ and 62°C for $CoSO_4/H_2O=1.13$,[9] while the shifts are found at about 50—63°C respectively. The two peaks at 53°C and 59°C are considered to be due to the dehydration reactions of $CoSO_4 \cdot 7H_2O$, but the peak temperatures cannot be identified with any one of the dehydration temperatures in the literature.[9]

The base-line shift is also found for the potato starch-water system, as is shown in Fig. 9. The shift temperature of about 60—62°C is in agreement with the gelatinization temperature of the starch in water.[10] The direction of the shift is from a lower heat capacity at a lower temperature to a higher capacity at a higher temperature. This display is graphically analogous to that shown in the DTA thermogram of a glass transition in a high polymer.

DTA curves of a Solid-liquid System. The thermal analysis of a solid-liquid mixture system with this apparatus has been studied in some detail by investigating the thermal behavior of the $K_2Cr_2O_7$-H_2O system and the variables affecting the appearance of the DTA curve of the system. The requirements to achieve a reproducible DTA curve and a sharp shift (see Fig. 6) in the neighborhood of the dissolution temperature are as follows:

(1) the solid phase should be fine powder;
(2) the sample holder should be in good thermal contact with the wall of the DTA block and
(3) the proper heating rate should be chosen so as to give a precise solubility temperature from the shift of the DTA curve.

(1) and (3) are necessary to maintain the system under thermochemical equilibrium as much as possible during the course of the thermal analysis, while (2) is required to obtain a sharp shift of the curve.

The shift temperatures were selected from various portions of the DTA shift curve, as is illustrated in Fig. 10. Point A is the intersection of the extrapolated straight-line portion of the side of the shift with the base line at a lower temperature, while C is the extrapolated intersection with the base line at a higher temperature. Point B is the middle point of the AC line. The effect of the heating rate on the shift tem-

○: Experimental, ——: Literature.[11]

peratures at which the various points occurred during the dissolution process of the system is shown in Fig. 11. Temperature T_A, estimated at Point A, approaches the dissolution temperature[11] of the system in the prepared composition as the heating rate decreases and is approximately equal to the dissolution temperature at 1°C per minute. Since the best measure from T_A at 1°C per minute was thus obtained, this temperature was selected for other compositions of the systems. The temperatures, T_A, for the various compositions thus obtained are shown in Fig. 12; a comparison with the solubility curve from the literature[11] shows a satisfactory agreement between them.

Discussion of the DTA Shift Curve. In the DTA apparatus described here, adequate and continuous stirring is achieved by rocking; one can, therefore, assume a uniform temperature inside the holders and can set down equations describing the heat flow into the sample and reference holders as follows;

$$C_s \frac{dT_s}{dt} = h_s(T_b - T_s) + \frac{dQ}{dt} \quad (1)$$

$$C_r \frac{dT_r}{dt} = h_r(T_b - T_r). \quad (2)$$

Notations:
C=heat capacity of the holder
h= coefficient of heat transfer between the holder and the wall of the metal block
T=temperature
t=time
Q=heat evolved or absorbed in the sample holder
s, r, b=subscripts denote the quantity of the sample holder, the reference holder, and the metal block respectively

By subtracting (2) from (1), by rearranging, and by using the $y=T_s-T_r$ relation, one obtains;

$$C_s \frac{dy}{dt} + (C_s - C_r)\frac{dT_r}{dt} = -h_s y + (h_s - h_r)(T_b - T_r) + \frac{dQ}{dt}. \quad (3)$$

When the system under consideration is in a steady state, $dQ/dt=0$, the above equation becomes;

$$(C_s - C_r)\frac{dT_r}{dt} = -h_s y_0 + (h_s - h_r)(T_b - T_r), \quad (4)$$

where the subscript 0 denotes the quantity in the steady state. From (2) and (4), one obtains;

$$y_0 = \left(\frac{C_r}{h_r} - \frac{C_s}{h_s}\right)\frac{dT_r}{dt}. \quad (5)$$

The $y_0=(T_s-T_r)_0$ quantity is the height of the base line of the DTA curve in a steady state, and dT_r/dt is the heating or cooling rate of the system.

Let us consider the DTA curve shown in Fig. 10, which is a typical curve in the DTA of a solid-liquid system. Equation (5) becomes;

$$\left(\frac{C_r}{h_r} - \frac{C_{s,\,I}}{h_s}\right)\frac{dT_r}{dt} = y_{0,\,I} \quad (6)$$

for the lower temperature part of the XX' base line, and;

$$\left(\frac{C_r}{h_r} - \frac{C_{s,\,II}}{h_s}\right)\frac{dT_r}{dt} = y_{0,\,II} \quad (7)$$

for the higher temperature part of the Y'Y base line. Considering the relation:

$$y_{0,\,II} > y_{0,\,I} \quad (8)$$

$$dT_r/dt > 0 \quad (8')$$

for the curve, we obtain the following inequality relation from (6) and (7);

$$C_{s,\,I} > C_{s,\,II}. \quad (9)$$

Now let us consider a solid-liquid system in a closed vessel. We suppose that there are a pure solid state, a completely mixed liquid solution, and a negligible space of the vapor phase, and that the system is under a thermochemical equilibrium.

M=weight of the liquid phase
m=weight of the solid phase
C_{SL}=heat capacity per weight of the solid-liquid system in a closed vessel
C_L=heat capacity per weight of the liquid phase
C_S=heat capacity per weight of the solid phase
H_S=heat of solution per weight of the solid
$x=m/(M+m)$
T=temperature

During the heating of the system, the small quantity of heat input, dQ, has three components: two specific-heat components, $MC_L dT$ and $mC_S dT$, which raise the temperature of the system by dT, and heat-of-solution component, $H_S(-dm)$, where dm is the weight of the solid which dissolves when the temperature is raised by dT. Therefore, we obtain:

$$dQ = MC_L dT + mC_S dT + H_S(-dm),$$

and;

$$C_{SL} = \frac{1}{M+m}\frac{dQ}{dT} = C_L + x(C_S - C_L) - H_S\frac{dx}{dT} \quad (10)$$

for the heat capacity of the solid-liquid system.

Now we will confine our discussion to the $K_2Cr_2O_7$-H_2O system at the temperature range of about 10°C involving the dissolution temperature. As the temperature of the system rises, the C_{SL} quantity is approximately constant or varies linearly with T as may be

11) The Chemical Society of Japan (ed.), "Kagaku-Benran," Maruzen, Tokyo (1958), p. 634.

seen from a consideration of the variation of the three terms on the right-hand side of (10) in this system. At the dissolution temperature at which the solid phase completely dissolves into the liquid phase ($x=0$), the specific heat capacity becomes equal to C_L, and we have a discontinuous variation of the specific heat:

$$(C_{SL}-C_L)_{x=0} = -H_S \frac{dx}{dT}. \quad (11)$$

Since there are these experimental facts:

$H_S>0$ (the heat of solution is endothermic)

$dx/dT<0$ (the solid phase dissolves as the temperature rises)

for the $K_2Cr_2O_7$-H_2O system, we obtain this inequality relation;

$$C_{SL,\,x=0} > C_{L,\,x=0}. \quad (12)$$

(12) may be compared with (9). Since, in (9), the heat capacity, $C_{S,I}$, at lower temperature is that of the solid-liquid-mixture phase, and since $C_{S,II}$ at higher temperature is that of the liquid-solution phase, the relation (12) deduced from thermochemical consideration is in agreement with that (9) deduced from the analysis of the DTA shift curve.

The author wishes to acknowledge the contrbutions of Dr. Shigeru Tomita and Mr. Kazuki Terashima of this Institute for their suggestions and discussions, and of Mr. Eitaro Kitamura and Mr. Seiji Awano of this Institute toward the construction of the apparatus.

Kinetics of the Aquation of Iron(III) Monophenolate Complexes; Absence of the Acid-dependent Path

Koichi NAKAMURA, Toshihiko TSUCHIDA,* Akihiko YAMAGISHI, and Masatoshi FUJIMOTO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received May 4, 1972)

The complex formation between Fe(III) and 10 kinds of phenols was investigated using a stopped-flow apparatus. It was confirmed that the reaction rate is acid-independent in the acid region 0.01—1.0 M. A mechanism for the aquation of the iron(III)-phenol complex is proposed in which a proton transfers intramolecularly from a co-ordinated water molecule to a phenolate ion, *viz.*, $Fe(OH_2)_5A^{2+} \rightarrow Fe(OH_2)_4(OH)\cdot AH^{2+}$. From the observed isotope effects it was concluded that the state of a proton of HA in $Fe(OH_2)_4(OH)\cdot AH^{2+}$ differs from that in a free phenol.

Extensive work has been made on the kinetics of the ligand substitutions of tervalent iron in aqueous solution.[1] Recently Cavasino and Di Dio obtained the substitution rate of Fe(III) for various monophenols using the temperature-jump method.[2] They concluded that in the acid region 0.01—0.09 M $HClO_4$, the complexes is formed through the reaction between $Fe(OH)^{2+}$ and a phenol molecule and that the rate of formation, 1.5×10^3 $M^{-1}sec^{-1}$, is almost independent of the kind of entering phenol.

The rate constants they obtained for the reaction of $Fe(OH)^{2+}$ and phenols are of the same order of magnitude as for the other ligands and in line with the proposal that the rate-determining step is the release of a co-ordinated water molecule from $Fe(OH)^{2+}$. However, the absence of the reaction path involving $Fe(OH_2)_6^{3+}$ and a phenol molecule means that the rate-determining step is no longer the release of a water molecule from $Fe(OH_2)_6^{3+}$. In other words, it is impossible to form the complex from the outer-sphere complex between $[Fe(OH_2)_6]^{3+}$ and a phenol molecule. This is an interesting result. However, the acid concentration chosen by Cavasino and Di Dio is not sufficiently high to conclude that there is no reaction path between $Fe(OH_2)_6^{3+}$ and a phenol molecule. We therefore performed the kinetic investigation of the reaction by pH-jump method at a higher acidity region (0.1—1.0 M $HClO_4$). It was confirmed that the reaction between $Fe(OH_2)_6^{3+}$ and a phenol does not lead to the complex in the acidity region studied. We conclude that during the course of the aquation reaction, proton transfer occurs intramolecularly from a co-ordinated water molecule to a phenolate ion. The isotope effect was also studied and discussed on the basis of the mechanism.

Experimental

Materials. Iron(III) perchlorate was prepared by heating the chloride with a small excess of perchloric acid and recrystallized *in vacuo*. The concentration of iron(III) was determined titrimetrically with EDTA. The perchloric acid content was determined by passing an aliquot of the solution through a column of cation-exchange resin in the hydrogen-form, and titrating the effluent with sodium hydroxide. The ionic strength was adjusted with the purified reagent grade sodium perchlorate.[3]

Phenols were purified according to Milburn.[4] The purity was confirmed by melting point and thin-layer chromatography.

Measurements. The optical densities were measured with a Hitachi recording spectrophotometer Model EPS-3T. pH was measured with a Radiometer equipped with G 200B glass electrode and K 100 reference calomel electrode. pD of the deuterium oxide solution was evaluated as 0.4 plus the pH-meter reading.[5] Kinetic measurements were performed using a Yanagimoto stopped-flow spectrophotometer Model SPS-1.

In the acid region, the equilibrium of the complex formation is written as

$$Fe^{3+} + HA \rightleftharpoons FeA^{2+} + H^+,$$

where HA denotes a phenol molecule. Since the equilibrium constant is in the order of 10^{-2} for monophenols, the concentration of the complex is greatly reduced in such a high acid region as 0.1—1.0 M. It is therefore difficult to obtain the rate constant at a high proton concentration by the ordinary mixing method. To overcome this difficulty, we rapidly mixed a solution of the complex in low acidic media with a solution containing a large amount of proton. The rapid pH-jump shifts the equilibrium towards dissociation. Since the proton transfer of aquo-iron(III) is generally much faster than the complex formation,[6] the observed decrease in the optical density corresponds to the aquation process of the complex in a high acid medium.

For the measurement of kinetic isotope effect a temperature-jump apparatus (Messanlagen Studiengesellschaft, Göttingen) was used.

Results

Static Measurements. Although the stability constants of complexes between iron(III) and various kinds of phenol were obtained by Milburn,[4] no consideration was given on the possibility of protolysis of a coordinated water in the complexes. We therefore tried to estimate the degree of the protolysis of the complex, spectrophotometrically, following scheme I.

$$\begin{array}{ccc} & (1) & (3) \\ & & \\ Fe^{3+} + HA & \overset{K_1}{\rightleftharpoons} & FeA^{2+} + H^+ \\ K_h \Big\| & & \Big\| K_G \\ H^+ + Fe(OH)^{2+} + HA & \overset{K_2}{\rightleftharpoons} & Fe(OH)A^+ + 2H^+ \\ & (2) & (4) \end{array}$$

Scheme I.

Under the conditions of $[Fe(III)]_t \ll [HA]_t$ ($[\ ]_t$ denotes the total concentration), the following relationship is derived from A, the optical density due to the complex, a, the total concentration of the phenol, and b, the total concentration of Fe(III).

$$\frac{1}{A} = \frac{1}{\varepsilon b}\left(1 + \frac{[H^+]+K_h}{aK}\right) \qquad (1)$$

where ε and K are defined as

$$\varepsilon = (\varepsilon_1 + \varepsilon_2 K_G/[H^+])/(1 + K_G/[H^+])$$

and

$$K = K_1(1 + K_G/[H^+]) .$$

ε_1 and ε_2 denote the extinction coefficients of FeA^{2+} and $Fe(OH)A^+$, respectively, and $K_G = K_2K_h/K_1$.

Figure 1 shows the plots of A^{-1} *vs.* a^{-1} for *p*-nitrophenol; the phenol forms a stable complex with Fe(III). The ratio $([H^+]+K_h)/(\text{slope})$ was found to be almost constant; they are 5.2×10^{-2} ($[H^+]=1.7\times10^{-2}$ M), 5.8×10^{-2} (8.8×10^{-3} M), 6.1×10^{-2} (5.6×10^{-3} M) and 5.7×10^{-2} (2.4×10^{-3} M). Since the ratio is equal to $\varepsilon_1 bK_1(1+\varepsilon_2/\varepsilon_1 \cdot K_G/[H^+])$, this result indicates that the value of $\varepsilon_2/\varepsilon_1 \cdot K_G/[H^+]$ is so small as to be within experimental error. The upper limit of K_G is estimated to be 10^{-4} M, assuming that $\varepsilon_2/\varepsilon_1$ is in the order of unity. The contribution of $Fe(OH)A^+$ to the optical density can also be neglected under the experimental conditions. In discussing the kinetic data, we used the stability constants obtained by Milburn.[4]

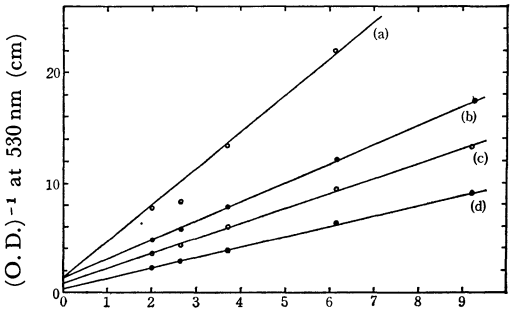

Fig. 1. Plots of equation (1) for *p*-nitrophenol.
$[Fe^{3+}]=1.03\times10^{-3}$ M, $[H^+]=$(a) $1.70)\times10^{-2}$ M, (b) 8.77×10^{-3} M, (c) 5.55×10^{-3} M, (d) 2.36×10^{-3} M, at 25.0°C.

Kinetics. The decrease in the optical density on the pH-jump measurements corresponds to the aquation of $Fe(OH_2)_5A^{2+}$ as elucidated above. Following a derivation similar to that of Cavasino and Di Dio,[2] the first-order rate constant is expressed in terms of the rate constants of individual paths in the above scheme as

$$k_{obs} = \frac{k_{13}[H^+]}{K_cK_H} + \frac{k_{24}K_h}{K_cK_H}, \qquad (2)$$

where k_{13} and k_{24} are the forward rate constants for the reaction between Fe^{3+} and HA, and between $Fe(OH)^{2+}$ and HA, respectively. The proton concentration at which the first term becomes predominant is expected to be above 0.3 M, since $K_h=3\times10^{-3}$ M and k_{13}/k_{24} is in the order of 10^{-2} for the reaction of Fe(III) with analogous ligands.[1] The proton concentration is higher than that chosen by Cavasino and Di Dio by one order of magnitude. For this very reason we performed the pH-jump experiment in such a high acidity region as 0.1—1 M.

Figure 2 shows the values of the first-order rate constant k_{obs} obtained for *p*-nitrophenol in the proton concentration range 0.01—0.9 M. The plots were found to be independent of proton concentration at

Ionic strength is (△) 0.10 M, (●) 0.65 M, (○) 1.00 M.

each temperature. The upper limit of k_{13} is estimated to be 1 M^{-1} sec^{-1}. The value is smaller than the rate constants obtained in the analogous reactions of $Fe(OH_2)_6^{3+}$ ($10-10^2$ M^{-1} sec^{-1}) by one or two order of magnitude. Figure 2 also shows that the rate of aquation is independent of the ionic strength.

Similar results were obtained for other phenols. In Table 1 are summarized the rate constants of the complex formation and aquation at an ionic strength 0.1 (M) and at 25.0°C together with the activation parameters from the data between 15 and 30°C.

Isotope effect on the rate constants was measured by the temperature-jump method. The rate, pH and optical densities were all measured at 95, 53 and 0% D_2O. The values were extrapolated to 100% D_2O by parabola. The results are given in Table 2 together with the isotope effects of the equilibrium constants of the protolysis of $Fe(OH_2)_6^{3+}$ and of the acid dissociation of *p*-nitrophenol.

Discussion

The results demonstrate that the rate constant is independent of the acid concentration. According to Eq. (2), this means that even in the acid concentrations 0.1—1.0 M, no reaction path is involved between Fe^{3+} and a phenol molecule in contrast to other ligands.[1] We attribute this anomalous fact to the proton transfer from an entering phenol molecule to OH^- in $Fe(OH)^{2+}$ in the course of the complex formation between $Fe(OH)^{2+}$ and AH, *viz.*,

$$Fe(OH_2)_4(OH)AH^{2+} \underset{K_1}{\rightleftharpoons} Fe(OH_2)_5A^{2+}, \qquad (3)$$

where K_1 is the equilibrium constant of the reaction. In the case of the reaction between $Fe(OH_2)_6^{3+}$ and a phenol molecule, the complex is not formed *via* a transient complex $Fe(OH_2)_5AH^{3+}$ as in (3), because $Fe(OH_2)_5AH^{3+}$ has no proton acceptor like OH^- in its ligands. Even 2,4-dinitrophenol, with an acid dissociation constant higher than that of acetic acid, follows this mechanism. The neutral species of acetic acid, CH_3COOH, reacts with $Fe(OH_2)_6^{3+}$ with the rate constant of 4.8 M^{-1} sec^{-1}.[7] Thus, the absence of the reaction path between $Fe(OH_2)_6^{3+}$ and a phenol molecule cannot be attributed only to the strong bonding of a proton to a phenolate ion. At the present stage it is not clear what factor in phenols brings about such an anomaly.

7) F. Accascina, F. P. Cavasino, and E, Di Dio, *Trans. Faraday Soc.* **65**, 489 (1969).

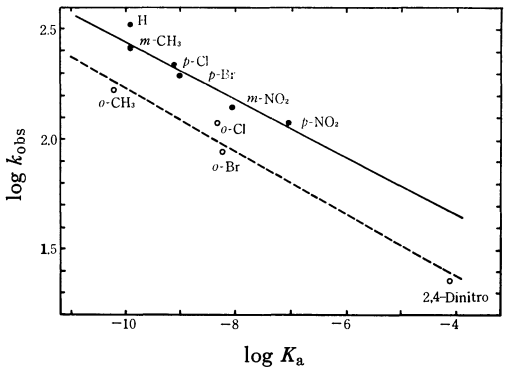

Fig. 3. Dependence of the first-order rate constants on the acid dissociation constants for substituted phenols.

In Fig. 3 is shown the dependence of the aquation rate on K_a of each phenol. Meta- and para-substituted phenols are on a straight line with a slope of 0.11. Ortho-substituted phenols are roughly on a line with a slope of the same magnitude but about 0.2 below the above groups. The linear dependence means that the stronger the bonding of a proton to a pnenolate ion, the lower the aquation rate. It is interpreted that K_i increases with decrease in K_a. The small slope, however, indicates that the change in K_a has a relatively small influence on K_i. This suggests that the proton of AH in $Fe(OH_2)_4(OH)$-AH^{2+} is in a different state from that in a free phenol molecule.

The isotope effects of kinetics and equilibrium lead us to a similar conclusion concerning the state of the proton in AH of $Fe(OH_2)_4(OH)AH^{2+}$. As shown in Table 2, the equilibrium constant of the following intermolecular proton transfer in D_2O, K_D is greater than that in H_2O, K_H,

$$Fe(OH_2)_5(OH)^{2+} + AH \underset{K_H}{\rightleftharpoons} Fe(OH_2)_6^{3+} + A^- \qquad (4)$$

Since a proton transfers from AH to OH coordinated to Fe^{3+} in both equilibria (3) and (4), we can expect the same isotope effect in equilibrium (3). Supposing that the isotope effect in the aquation reaction lies mainly in (3), we expect that the aquation rate is higher in D_2O than in H_2O. However, the observed aquation rate in H_2O is 2.37 times greater than in D_2O. The isotope effect was interpreted in terms of zero-point energy of the vibration of a proton.[8] Comparing the zero-point energy of the vibration of a proton of AH on the left-hand with that of OH_2 on the right-hand side of Eqs. (3) and (4), the observed isotope effects are expressed as

$$\frac{1}{2}h\nu_{OH} - \frac{1}{2}h\nu_{OD} > \frac{1}{2}h\nu_{AH} - \frac{1}{2}h\nu_{AD} \text{ in (3)}$$

and $$\frac{1}{2}h\nu'_{OH} - \frac{1}{2}h\nu'_{OD} < \frac{1}{2}h\nu'_{AH} - \frac{1}{2}h\nu'_{AD} \text{ in (4)}$$

where ν_{OH} and ν_{AH} are the frequencies of vibration of proton of OH_2 in $Fe(OH_2)_5A^{2+}$ and of AH in $Fe(OH_2)_4(OH)AH$, respectively, and ν'_{OH} and ν'_{AH} in $Fe(OH_2)_6^{3+}$ and in a free HA, respectively. If the proton in H_2O is not much affected in complexation,[9] or $\nu_{OH}=\nu'_{OH}$, we get

$$\frac{1}{2}h\nu_{AH} - \frac{1}{2}h\nu_{AD} < \frac{1}{2}h\nu'_{AH} - \frac{1}{2}h\nu'_{AD} \text{ or}$$

$$\nu_{AH} < \nu'_{AH}.$$

It then follows that a proton of AH in $Fe(OH_2)_4(OH)$-AH is more loosely bound to a phenolate than a proton of a free AH, and that this causes the depedence of an aquation rate on K_a to be small.

Another interesting feature is the composition of iron(III)-phenol complex. It is known that iron(III) forms only a 1 : 1 complex with phenols even in 500 time excess of phenol.[10] The above scheme predicts that 1 : 2 complexes would be formed *via* the reaction between $Fe(OH_2)_4(OH)A^+$ and HA. However, the hydrolysis is greatly depressed by the complexation. Thus, from the kinetic point of view, 1 : 2 complexes between iron(III) and a phenol molecule is very unlikely because of the above mechanism and the low hydrolysis of 1 : 1 complexes.

Polarographic Studies of the Anodic Oxidation of Mercury. II. The Anodic Adsorption Wave of Ethylamine in *N,N*-Dimethylformamide

Yoshihisa MATSUI and Yoshio DATE

Department of Agricultural Chemistry, Shimane University, Nishikawazu, Matsue

(Received June 3, 1972)

Ethylamine at concentrations lower than 0.5 mM in N,N-dimethylformamide gives a diffusion-controlled anodic wave due to the reversible oxidation of the mercury to a 1 : 2 complex of mercury(II) with the amine. At higher concentrations, another anodic wave appears at a potential less positive than the main wave; this has been attributed to the adsorption of the oxidation product on the mercury electrode. The adsorption prewave was analyzed on the basis of Brdička's theory, in which the Langmurian adsorption was assumed. It was shown that the nature of the prewave can be well interpreted on the additional assumption that the adsorption coefficient of the adsorbed complex decreases exponentially as the electrode potential becomes more positive.

In a previous paper,[1] it was shown that ammonia, methylamine, and dimethylamine anodically depolarize the dropping mercury electrode in N,N-dimethylformamide (DMF) to form 1 : 2 complexes of mercury (II) with the amines. Furthermore, it was suggested that the complexes are adsorbed on the electrode surface to cause the flowing of the extra anodic current. However, the nature of the anodic adsorption current has not yet been examined in detail.

The present study was undertaken not only in order to extend the previous study to ethylamine, but also in order to examine the characteristics of the anodic adsorption current in detail.

Experimental

The solvent, DMF, and the supporting electrolyte, tetraethylammonium perchlorate, were purified as had been described previously.[1] Ethylamine, which had been separated from a commercial 70% aqueous solution by the addition of a saturated NaOH solution, was dried and distilled over granular NaOH. The concentration of the amine in DMF was determined by titration against an aqueous hydrochloric acid. A solution of mercury(II) perchlorate in DMF was prepared as has been described elsewhere.[2]

Polarograms were obtained in a manner similar to that described before.[1] All the potentials reported in the present paper refer to an aqueous, saturated calomel electrode connected with a cell solution by means of a DMF-agar salt bridge.[3]

Results and Discussion

The polarographic behavior of ethylamine was examined with a dropping mercury electrode over a wide concentration range from 0.1 to 100 mM in DMF. The amine gave a single well-defined anodic wave at concentrations lower than 0.5 mM. At higher concentrations, another anodic wave appeared at a potential less positive than the main wave. The polarographic characteristics of these waves are summarized in Tables 1 and 2. The total limiting current (i_d) was virtually proportional to the bulk concentration of the amine, and also to the square root of the effective pressure (h_{corr}) on the mercury drop; these findings indicate that the total limiting current is diffusion-controlled. On the other hand, the limiting current (i_p) of the prewave was virtually independent of the bulk concentration of the amine when it was lower than 20 mM. It was also shown that the value of i_p increases in proportion to h_{corr}. These results indicate that the prewave has the nature of an adsorption current. At concentrations higher than 20 mM, the value of i_p gradually increased with an increase in the concentration. This may be at-

tributed to the formation of additional superimposed layers of the adsorbate on the mercury surface, for the curve obtained by plotting i_p against the amine concentration resembles the B. E. T. isotherm (Fig. 1). The half-wave potential of the total anodic wave at high amine concentrations shifted toward the positive value as the concentration increased. The film of the adsorbate may inhibit the electrode process, thus causing the positive shift.

Figure 2 shows the effect of the temperature on the heights of the total wave and the prewave, which linearly increased with the temperature. The average rates of increase were 1.38% and 0.89% per degree respectively. These values also indicate that the former is controlled by diffusion, and the latter, by adsorption. The fact that the adsorption wave appeared at potentials less positive than the main wave suggests that the adsorbate is the oxidation product rather than the depolarizer.[4]

Figure 3 shows the effect of ethylamine on the electrocapillary curve in DMF containing 0.10 M tetraethylammonium perchlorate. A significant decrease in the surface tension of the mercury drop was

caused by the addition of a small amount of the amine. The decrease began at *ca.* 0.00 V *vs.* SCE, where the anodic prewave appeared, and finished at *ca.* +0.20 V *vs.* SCE, where the main wave just approached its plateau. It is obvious that the adsorption of the oxidation product on the electrode surface is responsible for the appearance of the prewave. It can also be presumed that the desorption of the product facilitates the electrolytic process.

Figure 4 shows the results of the amperometric titration of mercury(II) perchlorate against ethylamine. The limiting current of the mercury(II) ion decreased with the addition of ethylamine. At the same time, a second cathodic wave appeared at a more negative potential. The wave height increased in proportion to the ratio of the concentration of ethylamine to that of the mercury(II) ion, until the ratio exceeded 2.0. Thereafter, the wave of the mercury(II) ion disappeared, the height of the second cathodic wave reached a virtually constant value, and an anodic limiting current appeared and increased in proportion to the

III: Wave height of $EtNH_2$.

excess amount of the amine. These results are similar to those for methylamine reported in a previous paper;[1] it can likewise be thought that the mercury(II) ion reacts with ethylamine to form the 1 : 2 complex, $Hg(EtNH_2)_2^{2+}$, which then gives the second cathodic wave. It can also be considered that the anodic wave of the amine is due to the polarographically reversible oxidation of mercury to $Hg(EtNH_2)_2^{2+}$:

$$Hg + 2EtNH_2 \rightleftharpoons Hg(EtNH_2)_2^{2+} + 2e \quad (1)$$

Provided that the electrode process is simply expressed in terms of Eq. (1), the equation for the current-potential curve should be given by:[1]

$$E = E_0 - (RT/2F)\ln\beta_2 + (RT/2F)\ln k_0^2/k_2 + (RT/2F)\ln i/(i_d-i)^2 \quad (2)$$

In this equation, E_0 represents the ordinary standard potential of the mercury-mercury(II) half-cell; β_2, the overall stability constant of the complex of $Hg(EtNH_2)_2^{2+}$, and k_0 and k_2, the Ilkovič equation constants for the amine and the complex, respectively. The plot of log $i/(i_d-i)^2$ *vs.* E for the wave of 0.46 mM ethylamine is shown in Fig. 5. A straight line with the reciprocal slope of about 0.030 V was obtained at the more positive potentials of the wave, whereas the plot deviated from the line at the less positive potentials of the wave. In analogy with the case of methylamine,[1] the deviation may be due to the adsorption of the oxidation product, $Hg(EtNH_2)_2^{2+}$, on the electrode surface. On the assumption that Eq. (2) holds for the more positive potentials of the wave, the value of β_2 was estimated to be $10^{16.5}$. In this calculation, E_0 was taken to be 0.557 V *vs.* SCE.[2]

The Analysis of the Adsorption Prewave. When the amine concentration was high enough, the adsorption prewave could be well resolved from the main wave. Furthermore, it seems, on the basis of the results shown in Fig. 1, that the adsorption obeys the Langmuir isotherm at amine concentrations lower than 20 mM. Therefore, we undertook to analyze the prewave on the basis of Brdička's theory of the adsorption wave. On assuming that the oxidation product, $Hg(EtNH_2)_2^{2+}$, is the only adsorbate, and that the adsorption obeys the Langmuir isotherm, the anodic current (i) can be related to the concentrations of the amine and the complex (a and x_2 respectively) on the electrode surface by the following equations:[5]

$$i_d - i = k_0 a \quad (3)$$

$$i = k_2 x_2 + (i_p w x_2/(1+wx_2)) \quad (4)$$

In this equation, w, is the adsorption coefficient of $Hg(EtNH_2)_2^{2+}$. The height of the prewave, i_p, is correlated with the maximum amount of substance adsorbed per unit area of the electrode (Z) by the following equation:

$$i_p = knFm^{2/3}t^{-1/3}Z \quad (5)$$

where

$$k = 0.85\ cm^2g^{-2/3} \text{ at } 25°C$$

and where n is the number of the electrons participating in the electrode process; m, the mass of mercury flowing out of the capillary per unit time, and t, the drop time. The value of Z for $Hg(EtNH_2)_2^{2+}$ at amine concentrations lower than 10 mM was calculated from this equation to be 1.17×10^{-9} mol/cm^2; this is slightly less than that for $Hg(MeNH_2)_2^{2+}$ (1.41×10^{-9} mol/cm^2 [1]).

When it is assumed that, at the potentials corresponding to the prewave, the amount of the oxidation product diffusing into the solution is negligibly small compared with that adsorbed on the electrode surface, Eq. (4) can be simplified as follows:

$$i = i_p w x_2/(1+wx_2) \quad (6)$$

Thus, a and x_2 are given by:

$$a = (i_d-i)/k_0 \quad (7)$$

$$x_2 = i/w(i_p-i) \quad (8)$$

On the other hand, the electrode potential is expressed by the equation:

$$E = E_0 - (RT/2F)\ln\beta_2 + (RT/2F)\ln x_2/a^2 \quad (9)$$

By introducing Eqs. (7) and (8) into Eq. (9), we obtain:

$$E = E_0 - (RT/2F)\ln\beta_2 + (RT/F)\ln k_0 - (RT/2F)\ln w + (RT/2F)\ln i/(i_p-i)(i_d-i)^2 \quad (10)$$

If the adsorption coefficient of $Hg(EtNH_2)_2^{2+}$ does not change with the potential, the first four terms on the right-hand side of Eq. (10) are constant. Then, the plot of log $i/(i_p-i)(i_d-i)^2$ *vs.* E should give a straight line with a reciprocal slope of 0.030 V at 25°C. The results for the prewaves given by 2.8—43.5 mM ethylamine are shown in Fig. 6. The plot gave a good straight line. However, the reciprocal slope (0.047 V) was significantly larger than the theoretical value. It might be considered that the increase in the reciprocal slope is due to the irreversibility of the electrode process. However, this can be ruled out in the present case, for the fact that the reciprocal slope of the log-plot was equal to 0.030 V for the wave

5) R. Brdička, *Z. Elektrochem.*, **48**, 278 (1942).

of the amine at a low concentration, and the fact that the half-wave potential of the oxidation wave of the amine was approximately equal to that of the reduction wave of $Hg(EtNH_2)_2^{2+}$ obtained in the amperometric titration, show that the electrode process is reversible. According to Guidelli,[4] it is possible that the increase in the slope of the adsorption wave is caused by the change in the adsorption coefficient with the potential. Since the adsorbed complex, $Hg(EtNH_2)_2^{2+}$, has a positive charge, it seems natural to consider that the adsorption energy (φ) of the complex may be lowered, as the electrode potential becomes more positive, by an increase in the electronic repulsion between the adsorbed complex and the electrode. In fact, it was found that the polarographic behavior of the prewave can be well explained on the basis of the assumption that the energy of the electronic repulsion between the divalent positive ion and the electrode is in proportion to $2FE$. Then, φ may be written as:

$$\varphi_0 - \varphi = 2F\gamma E \tag{11}$$

where φ_0 is the adsorption energy at 0.00 V *vs.* SCE, and γ, the proportionality constant. On the other hand, w is generally proportional to exp (φ/RT),[5] so that:

$$w = w_0 \exp(-2F\gamma E/RT) \tag{12}$$

In this equation, w_0 corresponds to the adsorption coefficient at 0.00 V *vs.* SCE. By combining Eqs. (10) and (12), we obtain:

$$(1-\gamma)E = E_0 - (RT/2F)\ln\beta_2 + (RT/F)\ln k_0 - (RT/2F)\ln w_0 + (RT/2F)\ln i/(i_p-i)(i_d-i)^2 \tag{13}$$

This equation indicates that the reciprocal slope of the plot of log $i/(i_p-i)(i_d-i)^2$ *vs.* E is equal to $0.030/(1-\gamma)$ V at 25°C. By taking γ as 0.36, we obtain the slope of 0.047 V, which agrees with the observed value. From Eq. (13), Eq. (14) is readily derived:

$$E_{p,1/2} = C - (1/(1-\gamma))(RT/F)\ln(i_d-i_p/2) \tag{14}$$

where $E_{p,1/2}$ is the half-wave potential of the prewave, and C, the constant. This equation shows that $E_{p,1/2}$ should shift toward a more negative potential with an increase in the amine concentration. The relation between $E_{p,1/2}$ and log $(i_d-i_p/2)$ observed was virtually linear, with a slope of −0.092 V (Fig. 7); this is fairly well in agreement with the value, −0.094 V, calculated on the basis of Eq. (15), which γ is taken as 0.36. This is one evidence in support of the validity of Eq. (13). Since the numerical values of the constants and the variables in Eq. (13) are all either known or experimentally estimated except for w_0, it is possible to calculate the value of w_0. Thus, we obtained the value of w_0 as 4.6×10^6 l/mol for $Hg(EtNH_2)_2^{2+}$. This value is so large that it is consistent with the above assumption that the amount of the oxidation product diffusing into the solution is negligibly small compared with that adsorbed on the electrode surface at the potentials corresponding to the prewave of ethylamine.

Thus, it is obvious that the present method of treatment of an adsorption wave is plausible in this case. However, it is still uncertain whether or not it can generally be applied to the prewaves due to the adsorption of ionic compounds. This will be studied further in succeeding papers.

Polarographic Studies of the Anodic Oxidation of Mercury. III. The Adsorption of the Mercury(II) Complexes of Ammonia and Alkylamines on the Mercury Electrode Surface

Yoshihisa MATSUI, Hitoshi TAKAYA, and Yoshio DATE

Department of Agricultural Chemistry, Shimane University, Nishikawazu, Matsue

(Received June 3, 1972)

A solution of ammonia, methylamine, *n*-propylamine, isopropylamine, or *n*-butylamine in *N,N*-dimethylformamide gives an anodic prewave due to the adsorption of the oxidation product, $Hg(amine)_2^{2+}$, on the dropping mercury electrode. The shape of the prewave of each amine can be well interpreted by an equation derived on the basis of the assumptions that the adsorption follows the Langmuir isotherm and that the adsorption coefficient of the adsorbate complex decreases exponentially as the electrode potential becomes more positive. Some physicochemical properties of the mercury(II) complexes, such as the overall stability constants and the adsorption coefficients at 0.0 V *vs.* SCE, were determined by analyses of the polarographic waves.

In a previous paper,[1] it was shown that the shape of the anodic adsorption prewave given by ethylamine in *N,N*-dimethylformamide (DMF) can be well interpreted by an equation which is derived on the basis of the assumptions that the adsorption of the oxidation product, $Hg(EtNH_2)_2^{2+}$, follows the Langmuir isotherm and that the adsorption coefficient of the product decreases exponentially as the electrode potential becomes more positive. The change in the adsorption coefficient was attributed to the change in the energy of the electrostatic repulsion between the ionic adsorbate and the positively-charged electrode with a potential. However, it is still uncertain whether or not the treatment can be generally applied to the prewaves due to the adsorption of ionic species. The present study was undertaken in order to extend the previous study to the prewaves of ammonia and alkylamines other than ethylamine, *i.e.*, methyl-, *n*-propyl-, isopropyl-, and *n*-butylamine.

Experimental

The solvent (DMF) and the supporting electrolyte (tetraethylammonium perchlorate) were purified as had been described previously.[2] The *n*-propylamine, isopropylamine, and *n*-butylamine were commercially-obtained and were used after distillation. Aqueous solutions of ammonia and methylamine obtained commercially (28 and 30% respectively) were used for polarography without removing the water.

The DC polarography was carried out with a Yanagimoto polarograph, model P8-DP. A cadmium-cadmium chloride electrode proposed by Marple[3] was used as the reference electrode instead of the bridged saturated calomel electrode which had been used in the previous studies.[1,2] The cadmium electrode was connected with a cell solution by a DMF-methylcellulose bridge containing 0.5 M tetraethylammonium perchlorate. The reference electrode gave a stable and reproducible potential of −0.667 V *vs.* SEC. All the measurements were carried out at 25°C.

Results and Discussion

Electrode Reaction Mechanism. The polarographic behavior of *n*-propylamine, isopropylamine, and *n*-butylamine was examined over the wide concentration range from 0.1 to 100 mM. Similarly, the behavior of ammonia and methylamine, which had been examined previously,[2] was reinvestigated, since none of them had been examined at concentrations higher than 5 mM. The results for these depolarizers were very similar to one another and to that for ethylamine.[1] Thus, a dilute solution of each amine (below 0.5 mM) gave a single anodic wave. At concentrations higher than 1.0 mM, another anodic wave appeared in each amine, except ammonia, at a potential less positive than that of the main wave. In the case of ammonia, no prewave appeared until the concentration exceeded 5.0 mM. In every case, however, the prewave had the nature of an adsorption, whereas the total anodic wave was diffusion-controlled; this conclusion was confirmed by an examination of the dependence of the limiting currents on the amine concentrations and on the effective mercury pressure.

When mercury(II) perchlorate was added to each of the amine solutions, the polarographic wave of the resulting solution became partly cathodic. However, the half-wave potential of the total wave was scarcely influenced by the addition of the mercury(II) ion. When the concentration of the mercury(II) ion added becomes equal to half that of the amine, the total wave became completely cathodic. These results are similar to those for methyl- and ethylamine reported previously,[1,2] and it can likewise be considered that the anodic wave given by each amine in the present study is also due to the polarographically reversible oxidation of mercury to the 1 : 2 complex of mercury(II) with the amine (Eq. (1)):

$$Hg + 2am \rightleftharpoons Hg(am)_2^{2+} + 2e \qquad (1)$$

Figure 1 shows the results of log-plots ($\log i/(i_d - i)^2$ *vs.* potential) for the anodic waves given by dilute solutions of *n*-propylamine, isopropylamine, and *n*-butylamine. Similar plots have been reported in a previous paper[2] for the cases of ammonia and methylamine. A straight line with a reciprocal slope of 0.030 V was obtained at the more positive potentials of the wave in each amine, as had been expected from the current-potential equation derived from Eq. (1).[2] The deviation of the plot from the straight line at the less positive potentials of each wave may be caused by the adsorption of the oxidation product, $Hg(am)_2^{2+}$,

on the electrode surface.

Analyses of the Adsorption Prewaves. According to a previous paper,[1] if the adsorption of the oxidation product, $Hg(am)_2^{2+}$, follows the Langmuir isotherm, and if the adsorption coefficient of the complex exponentially decreases as the electrode potential becomes more positive, the plot of $\log i/(i_p-i)(i_d-i)^2$ *vs.* the potential for the adsorption prewave of each amine should give a straight line with a reciprocal slope of $0.030/(1-\gamma)$ V at 25°C, where γ is a proportionality constant in the equation relating the adsorption energy of the mercury(II) complex to the electrode potential,[1] and where i_p is the height of the prewave. Likewise, the plot of the half-wave potential ($E_{p,1/2}$) of the prewave *vs.* $\log[i_d-(i_p/2)]$ should be linear, with a slope of $-0.060/(1-\gamma)$ V at 25°C. These plots for ammonia, *n*-propylamine, and *n*-butylamine are shown in Figs. 2 and 3. In fact, the plot of $\log i/(i_p-i)(i_d-i)^2$ *vs.* the potential was virtually linear at any concentration of any amine. The plot of $E_{p,1/2}$ *vs.* $\log[i_d-(i_p/2)]$ was also virtually linear for each amine. Similar results were also obtained for methylamine and isopropylamine.

It is interesting that, in each amine, the absolute value of the slope in the plot of $E_{p,1/2}$ *vs.* $\log(i_d-(i_p/2))$ is virtually equal to double that of the reciprocal slope in the plot of $\log i/(i_p-i)(i_d-i)^2$ *vs.* the potential. This result agrees exactly with that expected theoretically. The values of γ evaluated from the slopes are listed in Table 1. Except for ammonia, all of them are virtually equal to one another. In ammonia, the value of γ is significantly smaller than those for alkylamines. This indicates that the mercury(II) complex of ammonia is more easily desorbed than those of alkylamines from the electrode surface as the electrode potential becomes more positive. In the adsorption of the mercury(II) complexes on the electrode, the electric repulsion between the positively-charged mercury (II) and the positively-charged electrode may be lowered by the shielding of the ligands present between them. In the complex of ammonia, however, the shielding effect may be small, probably because of the small size of the ligand. Therefore, the complex of ammonia may be more subject to the effect of the change in electric field in the vicinity of the electrode than the complexes of alkylamines. We will discuss this problem further later. In any event, all the results shown above clearly indicate that the present method of the analysis of an adsorption prewave is

applicable at least to the prewaves given by any alkylamines.

Some Physicochemical Properties of Alkylamines and Their Mercury(II) Complexes in DMF. Table 2 shows the diffusion coefficients (D_a) of several amines in DMF. They were evaluated from the total height of the anodič wave of each amine on the basis of the Ilkovič equation. The value of D_a decreases with an increase in the molecular weight of the amine. According to Kolthoff and Lingane,[4] the diffusion coefficient of uncharged substances is inversely proportional to the cube root of the molecular weight (M) of the substances. In fact, the plot of log D_a *vs.* log M for the amines studied was roughly linear, with a slope of −0.33 (Fig. 4). This shows that no alkylamines are essentially subject to solvation in DMF.

Table 3 shows the diffusion coefficients (D_c) of the mercury(II) complexes of ammonia and several alkylamines, as well as that of the mercury(II) ion. They were also evaluated from the height of the reduction wave of each mercury(II) complex or the mercury (II) ion on the basis of the Ilkovič equation. It is interesting that no values of D_c are so different from one another as the values of D_a are. It even seems that

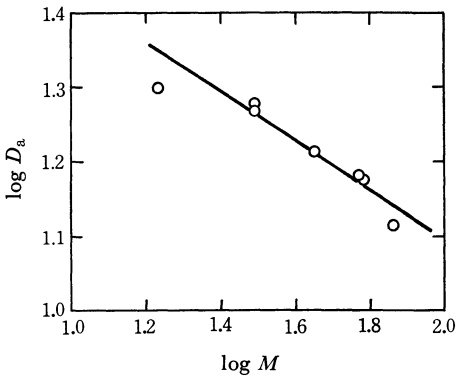

Fig. 4. Plot of log D_a *vs.* log M. Slope: −0.33

the values of D_c are virtually equal to one another. Since the mercury(II) ion usually forms a complex in which four ligands coordinate in the tetrahedral configuration, the "simple" mercury(II) ion may actually be coordinated by four molecules of the solvent, DMF. This idea is supported by the fact that the value of D_c is too small for the "simple" mercury (II) ion to be really simple. When the solvated mercury(II) ion forms a complex with ammonia or alkylamine, two of the four molecules of DMF coordinating to the mercury(II) ion are replaced by two molecules of the ammonia or the amine. In this case, however, it seems that the molecular weight or the size of the mercury(II) complex does not significantly change with the change in the kind of ligand. This may be the reason why the value of D_c is virtually invariant, irrespective of the kind of ligand in the mercury(II) complex.

Table 4 shows the overall stability constants (β_2) of the $Hg(am)_2^{2+}$ complex. They were evaluated from the results of the log-plots given in Fig. 1 in a manner which has been described previously.[2] All the values obtained are approximately equal to one another. There is no apparent tendency for the value of β_2 to increase or decrease with an increase in the size of the alkyl groups of the amines. According to Bjerrum,[5] the value of β_2 in an aqueous solution increases with an increase in the basic strength of

amine. However, no such relation was observed in the present case. It is notable that the mercury(II) complexes of diamines are more stable than those of monoamines by a factor of about 10^7. This may be due to the chelate formation in the former complexes.

Table 5 shows the adsorption characteristics for the mercury(II) complexes of ammonia and alkylamines on the mercury electrode. The maximal amount of the adsorbate per unit of area (Z) and the area (a) of the electrode surface occupied by one adsorbate molecule were evaluated from the heights of the prewaves of ammonia and alkylamines by the use of an equation described previously.[2] The adsorption coefficients (w_0) of the adsorbates at 0.0 V *vs.* SCE were evaluated from the results of the log-plots in Fig. 2 in a manner which has previously been reported.[1] The values of a thus obtained are reasonable for the size of the mercury(II) complexes. They increase with an increase in the size of the alkyl groups of the amines. It is uncertain whether the alkyl groups in the mercury(II) complexes are oriented horizontally or vertically to the electrode surface. However, the values of a are large enough to suggest that the alkyl groups are horizontally oriented to the electrode surface.

An interesting result was obtained with regard to the value of w_0. Thus, the value for the complex of ammonia was the smallest of all, whereas that for the complex of ethylamine was the largest. With a further increase in the size of the alkyl groups of amines, the value of w_0 decreased. It seems that the value of w_0 is a measure of the adsorptivity of the mercury(II) complexes on the electrode surface. The larger the value of w_0, the stronger is the adsorptivity, and *vice versa*. In the adsorption of the mercury(II) complex on the mercury electrode immersed in a DMF solution, the hydrophobic interaction between the alkyl groups of the adsorbate complexes and the electrode may play no important role because of the high solubility of the aliphatic groups in the solution, although such an interaction is very important for the adsorption in an aqueous solution.[6] The interaction between the amino groups of the ligands and the electrode may also be negligible, for no alkylamines are significantly adsorbed on the electrode. Therefore, the adsorption of the mercury(II) complexes on the electrode may be caused by the attractive interaction between the mercury(II) ion and the electrode mercury. If so, the attractive force may decrease with an increase in the size of the ligand alkylamines present between the mercury(II) ion and the electrode. This may be responsible for the fact that the value of w_0 decreases in the order of the mercury(II) complexes of ethylamine, n-propylamine, isopropylamine, and n-butylamine. On the other hand, the w_0 values of the mercury(II) complexes of ammonia and methylamine are smaller than that of the ethylamine complex. In these cases, the ligands are so small that the mercury(II) ion in the complexes may be subject to the strong force of electrostatic repulsion from the electrode which is positively charged at 0.0 V *vs.* SCE. This presumption is in agreement with that derived above on the basis of the values of γ. Thus, the adsorptivity of each complex of mercury(II) with alkylamine may eventually be determined by the relative values of the two kinds of force, *i.e.*, the chemical attractive force and the electrostatic repulsive force of the electrode mercury acting on the mercury(II) ion.

In the present study, only ammonia and primary alkylamines have been examined. However, secondary alkylamines also give an anodic adsorption prewave, as has been reported previously.[2] This will be dealt with in a succeeding paper.

NMR Study of Amino Acids and Their Derivatives. V. Structures and Formation Constants of Zinc–L-Aspartic Acid Complexes in Aqueous Solution

Hidehiro ISHIZUKA, Takeo YAMAMOTO, Yoji ARATA and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received June 29, 1972)

NMR spectra of L-aspartic acid coordinated with Zn ions were measured in aqueous solution at various pH values. Three species of zinc–L-aspartic acid complexes were identified *i.e.*, 1 : 1 zinc–L-aspartic acid(zwitter ionic form) complex (MAH), and 1 : 1 and 1 : 2 zinc-aspartic acid(anionic form) complexes (designated as MA and MA_2, respectively). It is shown that, in MAH, the amino acid coordinates with Zn as a monodentate ligand, whereas in MA and MA_2, approximately 65% of the molecules of amino acid coordinate as a tridentate ligand. From the chemical shift data, the equilibrium constants for these complexes are determined as follows: pK_a-(MAH)$=5.3\pm0.2$ and $\log K_2=4.5\pm0.2$ where $K_a(MAH)=[MA][H^+]/[MAH]$ and $K_2=[MA_2]/[MA][A]$.

Nuclear magnetic resonance (NMR) has been successfully used in investigating the structure of amino acids in aqueous solution.[1] We have previously investigated the structure of L-cysteine,[2] L-phenylalanine[3] and L-serine[4]. The present paper reports an NMR study of L-aspartic acid–zinc ion system at various pH values. Structures of Zn–L-aspartic acid complexes which possibly exist in solution are presented together with their equilibrium constants.

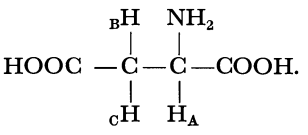
Experimental

Reagent grade L-aspartic acid, zinc nitrate, tetramethylammonium chloride and sodium hydroxide were used to prepare solutions of zinc-free L-aspartic acid, 1 : 1 and 1 : 2 zinc-L-aspartic acid in water. The concentration of aspartic acid in each solution is 0.10 M. Five mM of tetramethylammonium chloride is added to each solution as an internal reference.

The pH of the solution was controlled by adding concentrated sodium hydroxide solution and measured with a Toa Dempa pH meter, Model HM-5A. NMR spectra were recorded with a JNM 4H-100 spectrometer operating at 100 MHz.

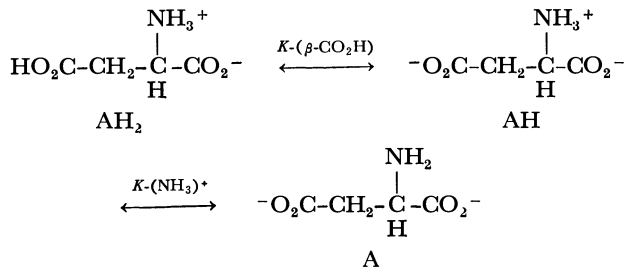
Results and Discussion

The α- and β-protons of L-aspartic acid are designated as follows:



NMR spectra of this ABC three spin system were analyzed as described previously.[4]

Chemical Shift. Zinc-free Aspartic Acid Solution: Chemical shifts for zinc-free aspartic acid solutions are shown in Fig. 1, where stepwise shifts are observed in the pH range 4—5 and 9—11. These shifts are attributed to the dissociation of the β-COOH and NH_3^+ groups, respectively.[5] The three species and dissociation constants involved are designated as follows:



Chemical shifts of the three protons ν_A, ν_B and ν_C for AH and A forms are listed in Table 1. The $pK(NH_3^+)$ value estimated from the pH dependence of ν_A is in good agreement with values determined by the potentiometric titration method[6–8] (Table 2). The present result obtained above pH 7 agree well with those reported by Pachler[9] and Taddei and Pratt.[10]

Zn(II)–L-Aspartic Acid Solution: Figure 1 shows the chemical shift of the three protons in the 1 : 1 and 1 : 2 solutions, for the 1 : 1 solution the average values of ν_B and ν_C are obtained by analyzing the

○ Zn(II) free solution
The average values of ν_B and ν_C are plotted for the 1 : 1 solution, and pH≥8.3 for the 1 : 2 solution.

system as an AB_2 spin system and plotted, since $\Delta\nu_{BC}$, the difference between ν_B and ν_C, is too small (≲4 Hz) for the spectra to be analyzed as an ABC spin system.

In the titration curve for the A proton, high field shift due to dissociation of the NH_3^+ group occurs at a pH much lower than in the zinc-free aspartic acid solution, suggesting that the following complex formation takes place:

$$-NH_3^+ \rightarrow -NH_2\text{-}Zn^{2+}.$$

Figure 1 shows that the coordination of the amino group is complete at pH 6.7 and at pH 8.6 for the 1 : 1 and the 1 : 2 solutions, respectively.[11)] It should also be noted that the A-proton chemical shifts for these systems (columns 4 and 5, Table 1) are lower than that of zinc-free aspartic acid in A form. This low field shift may be due to participation of the amino group in the complex formation with zinc ion.

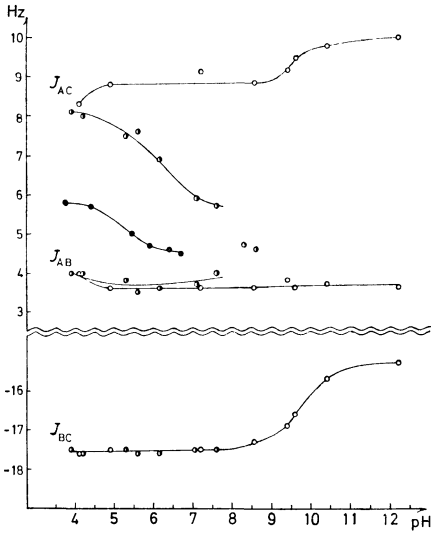

Fig. 2. The pH dependence of the spin coupling constant between CH protons of L-aspartic acid.
● Zn(II)—Asp 1 : 1 solution
◑ Zn(II)—Asp 1 : 2 solution
○ Zn(II) free solution
The average values of J_{AB} and J_{AC} are plotted for the 1 : 1 solution, and at pH≥8.3 for the 1 : 2 solution.

The difference $\Delta\nu_{BC}$ at pH 3.7—4.9 decreases in the following order: zinc-free, 1 : 2, 1 : 1 solutions. This suggests that at least one zinc–L-aspartic acid complex with a smaller $\Delta\nu_{BC}$ value exists in the pH range.[12)] It is assumed that the observed chemical shifts are the average of contributions from zinc-free and coordinated (1 : 1 and 1 : 2 complexes) aspartic acid as follows:

$$\Delta\nu_{BC(obs)} = f\Delta\nu_{BC(free)} + (c_1+c_2)\Delta\nu_{BC(coord)} \quad (1)$$

where

$$f + c_1 + c_2 = 1 \quad (2)$$

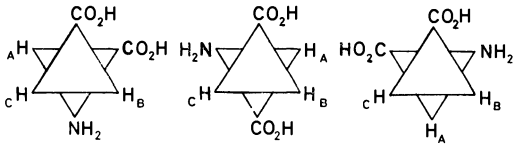
Here, f, c_1 and c_2 are the fractional population of zinc-free and coordinated (1 : 1 and 1 : 2 complexes) aspartic acid, respectively. The values of $\Delta\nu_{BC(free)}$ and $\Delta\nu_{BC(coord)}$ were obtained by the data for the zinc-free and 1 : 1 solutions respectively, as follows: $\Delta\nu_{BC(free)}$=11.4(pH 4.1)~13.4 Hz(pH 4.9) and $\Delta\nu_{BC(coord)}$≲4 Hz. Comparison of these values with $\Delta\nu_{BC(obs)}$ for the 1 : 2 and 1 : 1 solutions indicates that c_2 is negligibly small, $f \fallingdotseq c_1 \fallingdotseq 0.5$, $c_2 \fallingdotseq 0$ for the 1 : 2 solution and $f \fallingdotseq c_2 \fallingdotseq 0$, $c_1 \fallingdotseq 1$ for 1 : 1 solution (*cf.* Fig. 1). Thus, it may be concluded that a 1 : 1 complex (designated as MAH) is dominant in the pH range examined.

Spin Coupling Constant. The spin coupling constants for the 1 : 1, 1 : 2 and zinc-free aspartic acid solutions are shown in Fig. 2, where the average of J_{AB} and J_{AC} was plotted for the 1 : 1 solution throughout the pH range examined, and for the 1 : 2 solution at pH≳8.3.

The vicinal coupling constants, J_{AB} and J_{AC} obtained can be used to discuss possible conformations of L-

11) NMR spectra could not be measured at pH>6.7 and at pH>8.6 for the 1 : 1 and the 1 : 2 solutions, respectively, because of limited solubility of the samples.

12) $\Delta\nu_{BC(obs)}$ does not change by adding sodium nitrate to the zinc-free solution, indicating that $\Delta\nu_{BC}$ is independent of the ionic strength.



I II III

Fig. 3. The three rotational isomers of L-aspartic acid.

aspartic acid in the present systems. It is assumed that J_{AB} and J_{AC} are the statistical average of contributions from three rotational isomers I, II and III of staggered form, as shown in Fig. 3.

Thus

$$J_{AB} = p_I J_t + p_{II} J_g + p_{III} J_g \quad (3)$$

$$J_{AC} = p_I J_g + p_{II} J_t + p_{III} J_g, \quad (4)$$

where

$$p_I + p_{II} + p_{III} = 1. \quad (5)$$

Here, p_I, p_{II} and p_{III} are the fractional populations of the three rotational isomers, and J_t and J_g are the spin coupling constants between *trans* and *gauche* proton pairs, respectively. It is further assumed that J_t and J_g do not change when aspartic acid coordinates to zinc ion. This assumption may be confirmed by the following experiment. In L-alanine the spin coupling constant between alpha and beta protons was constant, *i. e.*, J=7.2 Hz, both at pH 4.2 and 6.7 in 1 : 2 zinc–L-alanine solution and at pH 2.5 and 6.0 in the absence of zinc ion. This result suggests that, since $p_I=p_{II}=p_{III}$ in L-alanine, J_t and J_g are not influenced by the coordination of the amino acid to zinc ion.

In the present study, J_t=13.6 Hz and J_g=2.6 Hz were used to obtain the fractional populations p_I, p_{II} and p_{III}.[4] Figure 4 shows the results for the 1 : 1, 1 : 2 and zinc-free aspartic acid solutions.[13]

In the pH region where MAH dominates, isomer I with the two carboxyl anions *gauche* to each other makes only a minor contribution in the 1 : 2 solution. This strongly suggests that in this pH region aspartic acid coordinates as a monodentate ligand using either one of the two carboxyl anions; aspartic acid as a bidentate ligand, coordinating with the α- and β-carboxyl groups, would result in a large populations the rotational isomer I. As Fig. 4 shows, p_{II} increases with pH and becomes constant and equal to about 65% at pH 6.7 and at pH 8.6 in the 1 : 1 and 1 : 2 solution, respectively; isomer III becomes dominant in the pH region where aspartic acid can coordinate with zinc ion in the A form (See Fig. 1). This result suggests that in this pH range L-aspartic acid behaves as a tridentate ligand, coordinating with the amino, α- and β-carboxyl groups to zinc ion. Although isomer III is dominant in these systems, p_I and p_{II} are also not negligibly small, suggesting that

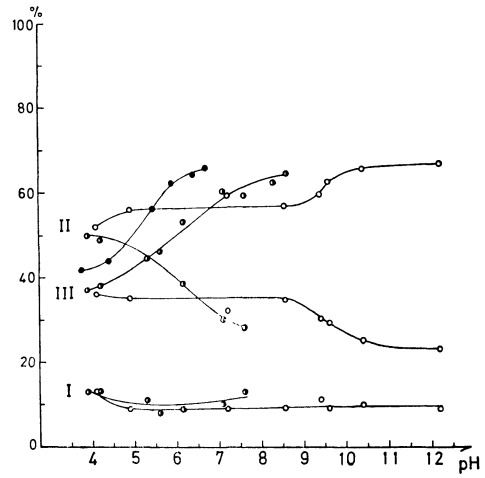


Fig. 4. pH dependence of the fractional populations of the fractional populations of the three rotational isomers.
● Zn(II)—Asp 1 : 1 solution
◑ Zn(II)—Asp 1 : 2 solution
○ Zn(II) free solution
Only the population of isomer III is plotted for the 1 : 1 solution and pH≥8.3 for the 1 : 2 solution.

bidentate species possibly exist as minor components; one of the possible species may be the isomer II coordinating with the amino and β-carboxyl groups, and another isomer I or II which coordinates with the amino and α-carboxyl groups.

In contrast to the above results, an x-ray diffraction study shows that only rotational isomer III is present in solid zinc aspartate trihydrate.[14] Martin and Mathur[15] suggested on the basis of their NMR study that in di(L-histidino)zinc complex a rotational isomer corresponding to the above mentioned isomer III is dominant in aqueous solutions. However, the pH of the solutions are not stated definitely, and the population of the rotational isomer is not given.

Equilibrium Constants among Zinc–L-Aspartic Acid Complexes. On the basis of the experimental results mentioned above, it is assumed that the following equilibria are dominant in the 1 : 1 and 1 : 2 zinc–aspartic acid solutions at pH≳4.5:

$$\mathrm{MAH} \overset{K(\mathrm{MAH})}{\longleftrightarrow} \mathrm{MA} + \mathrm{H^+}, \quad K(\mathrm{MAH}) = \frac{[\mathrm{MA}][\mathrm{H^+}]}{[\mathrm{MAH}]}, \quad (6)$$

$$\mathrm{MA} + \mathrm{AH} \overset{K(\mathrm{MA\text{-}AH})}{\longleftrightarrow} \mathrm{MA_2} + \mathrm{H^+},$$

$$K(\mathrm{MA\text{-}AH}) = \frac{[\mathrm{MA_2}][\mathrm{H^+}]}{[\mathrm{MA}][\mathrm{AH}]}. \quad (7)$$

Here, MAH denotes the 1 : 1 zinc–aspartic acid(AH form) complex, and MA and MA_2 the 1 : 1 and 1 : 2 zinc–aspartic acid(A form) complexes, respectively. The equilibrium constants were determined from the pH dependence of ν_A by curve fitting. It is assumed that ν_A of MAH is equal to that of AH. The pH dependence of ν_A for the 1 : 1 and 1 : 2 solutions cal-

13) The assignment of the curves to isomers I and II in Fig. 4 may be reversed. Considering steric hindrance, however, one would expect isomer II with two carboxyl anions *trans* to each other to be more stable than isomer I.

14) T. Doyne, R. Pepinsky, and T. Watanabe, *Acta Crystallogr.*, **10**, 438 (1957).

15) R. B. Martin and R. Mathur, *J. Amer. Chem. Soc.*, **87**, 1065, (1965).

culated using $pK(MAH)=5.3$ and $pK(MA\text{–}AH)=5.3$ is plotted in Fig. 1. These curves are in good agreement with the experimental data. The following stability constant for the 1 : 2 complex can be determined by using the values of $pK(MA\text{–}AH)$ and $pK(NH_3^+)$:

$$K_2 = \frac{[MA][A]}{[MA_2]}$$

The values of $pK(MAH)$ and $\log K_2$ are given in the second and third row, respectively, of Table 2, together with the reported $\log K_2$ value determined by the potentiometric titration method.[8]

Conclusion

Three zinc–L-aspartic acid complexes, MAH, MA and MA_2, were identified in the zinc ion–aspartic acid systems. The dominant($\sim$65%) species for MA and MA_2 is a tridentate complex with the amino acid coordinating with the amino, α- and β-carboxyl groups. As minor components, bidentate species are suggested to exist, where the ligand coordinates with the amino and α- or β-carboxyl groups. The dominant species for MAH is a monodentate complex coordinating with one of the two carboxyl groups. The equilibrium constants of these complexes, $pK(MAH)$ and $\log K_2$ were determined (Table 2).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 471—474 (1973)

Mechanisms and Kinetics of the Decomposition of Trioxalatocobaltate(III) in Aqueous Sulfuric Acid

Masaru KIMURA and Toshiro SATO

Department of Applied Chemistry, Yamagata University, Yonezawa

(Received July 5, 1972)

The kinetics of the thermal decomposition of the trioxalatocobaltate(III) complex were studied in a sulfuric acid solution in the absence and in the presence of oxygen from 25 to 40°C. The decomposition of trioxalatocobaltate(III) was described by the equation: $-d[Co(C_2O_4)_3^{3-}]/dt=(k_1+k_2[H^+])[Co(C_2O_4)_3^{3-}]$. The values of k_1 and k_2 were 6×10^{-6} sec^{-1} and 1.8×10^{-5} M^{-1} sec^{-1} respectively at 25°C. The values of the activation enthalpy change, $\Delta H_1^{\neq}$ and $\Delta H_2^{\neq}$, were 29.7 and 30.0 kcal mol^{-1} respectively. The values of the activation entropy change, $\Delta S_1^{\neq}$ and $\Delta S_2^{\neq}$, were 17.4 and 20.9 eu respectively at 40°C. Although hydrogen peroxide was formed in the presence of oxygen, and although a white precipitate of the polymerized products of acrylonitrile was found in the presence of acrylonitrile, neither oxygen nor acrylonitrile affected the kinetics of the decomposition of trioxalatocobaltate(III). The decomposition of peroxodisulfate was induced by the decompossition of trioxalatocobaltate(III). However, the rate of the decomposition of trioxalatocobaltate(III) was not affected by peroxodisulfate. On the other hand, both copper(II) and iron(III) ions were accelerators of the decompsition of trioxalatocobaltate(III). An anion radical of CO_2^- was predicted as an intermediate. The reaction mechanisms will be presented to account for these facts.

It has been known for many years[1] that trioxalatocobaltate(III) decomposes photochemically and thermochemically with internal redox to produce cobalt(II), carbon dioxide and oxalate. Recently, Kolthoff *et al.*[2] have found that hydrogen peroxide is formed upon the decomposition of trioxalatocobaltate(III) in the presence of oxygen in an acidic medium. The initial reaction is:

$$Co(C_2O_4)_3^{3-} \rightarrow Co(C_2O_4)_n^{(2-2n)} + (2-n)\,C_2O_4^{2-} + CO_2 + CO_2^- \quad (1)$$

The anion radical in Reaction (1) may be either $C_2O_4^-$ or CO_2^-. However, the two forms do not appear to be distinguishable on the basis of kinetic or spectroscopic evidence.[3] Following the consensus of previous workers, we will write CO_2 in the present paper.

It would be interesting to know if the CO_2^- radical would not reduce $Co(C_2O_4)_3^{3-}$, but the two would combine with each other to produce $C_2O_4^{2-}$. With the purpose of interpreting the reaction mechanisms, the rate of the decomposition of trioxalatocobaltate(III) was measured in the presence of oxygen, acrylonitrile, copper(II) ion, iron(III) ion, or peroxodisulfate, all of which may be able to react rapidly with the CO_2^-.

Experimental

Chemicals. The potassium trioxalatocobaltate(III) complex was synthesized following the directions of Sörensen.[4] A guaranteed-reagent-grade potassium peroxodisulfate of the Kanto Kagaku Co., Inc., was recrystallized twice from redistilled water and dried at 40°C in a vacuum desiccator. Extra pure acrylonitrile of the Kanto Chemical Co., Inc., was used without further purification. Cupric sulfate, ferric ammonium sulfate, sulfuric acid, oxalic acid and cobaltous sulfate, all of a guaranteed reagent grade were used without further purification. The water was purified by distillation from an alkaline permanganate solution. Pure

nitrogen and oxygen were used for the experiments in the absence and in the presence of oxygen respectively.

Technique. A reaction was started by adding a given ammount of the trioxalatocobaltate(III) complex to the reaction mixture. The reaction mixture was saturated with either nitrogen or oxygen, which was bubbled through the reaction mixture. Aliquot samples were withdrawn at appropriate times and mixed with cold water to slow the decomposition of trioxalatocobaltate(III). The decomposition of trioxalatocobaltate(III) during under the analytical run at 20°C was practically negligible. The trioxalatocobaltate(III) concentration was measured at 600 nm in the visible spectrum in a solution of 0.05 M sulfuric acid at 20°C. The cobaltous(II) ion produced in the course of the decomposition of trioxalatocobaltate(III) does not interfere with the absorbance of trioxalatocobaltate(III) at 600 nm. In a few experiments in the presence of copper(II), the concentration of trioxalatocobaltate(III) was determined polarographically at +0.2 V *vs.* SCE. In an experiment in presence of peroxodisulfate, the sum of the concentrations of peroxodisulfate and trioxalatocobaltate(III) was determined by using the polarographic diffusion current at +0.2 V *vs.* SCE. Peroxodisulfate did not interfere with the visible spectrum of trioxalatocobaltate(III). The concentration of the cobaltous(II) ion was determined polarographically. The concentration of oxalic acid or the sum of oxalic acid and hydrogen peroxide was determined by titration with permanganate at 50°C.

Results and Discussion

Kinetics. As is shown in Figs. 1 and 2, the rate of the decomposition of trioxalatocobaltate(III) is of the first order with respect to trioxalatocobaltate-(III) in any given reaction mixture; i. e., the kinetics are described by the equation:

$$-\mathrm{d}[\mathrm{Co}(\mathrm{C_2O_4})_3{}^{3-}]/\mathrm{d}t = k_0[\mathrm{Co}(\mathrm{C_2O_4})_3{}^{3-}] \quad (2)$$

Figure 3 indicates that the overall rate constant (k_0) of the reaction is given by:

$$k_0 = k_1 + k_2[\mathrm{H^+}] \quad (3)$$

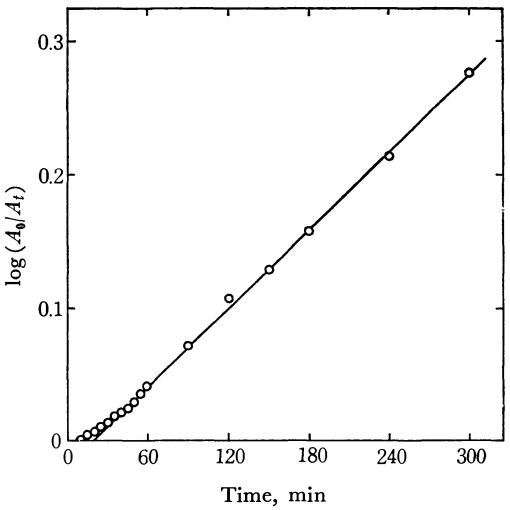

Fig. 1. First order plot for the decomposition of 4.0×10^{-3} M sulfuric acid at 25°C in dark and in nitrogen saturated.

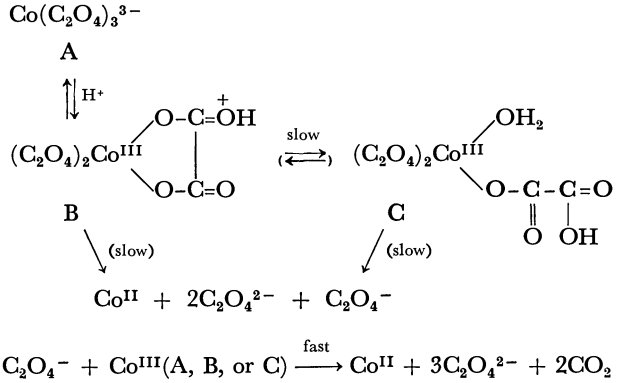
where k_1 and k_2 are the rate constants of Reactions (8) and (8′) respectively.

Figure 1 indicates that there is an induction period in the initial stage of the reaction. However, the induction period disappears completely at 40°C, as can be seen in Figure 2. Recently Kruszyna and Milburn[5] have found a similar induction period at 25°C in a 1 M sulfuric acid solution. It will be necessary here to present a brief review from their discussion.[5] The existence of the induction period requires that there are two or more consecutive slow steps in a reaction sequence leading to cobalt(II); they predicted the following reaction mechanisms:



Their major points are that, during the very early stages of reaction, A and B will compete with C in the quenching of $C_2O_4^-$ radical, but for the middle and later stages of reaction, no significant amounts of A and B will remain, and $C_2O_4^-$ (or CO_2^-) will be quenched by C only.

The above assumption that the C_2O_4 radical reduces Co^{III} oxalato complex rapidly, is entirely inconsistent with our results. However, it appears that the induction

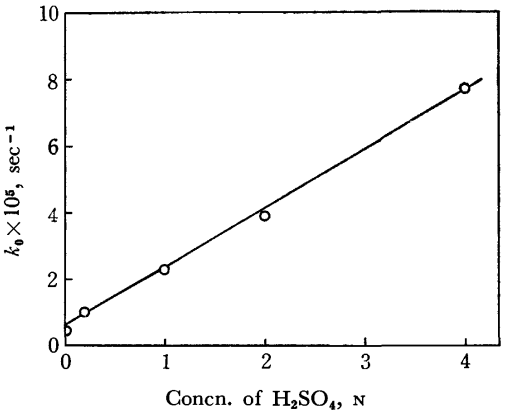

Fig. 3. Sulfuric acid dependence on the rate constant k_0. Condition: 4.0×10^{-3} M $K_3Co(C_2O_4)_3$; Dark; 25°C; N_2 sat. k_0 is the rate constant of the overall reaction (7).

period can be due to the slow steps, from A to C. Such slow steps would be accelerated by the elevated temperature, and the induction period must disappear under such conditions. This prediction is consistent with the fact that the induction period seems to disappear at 40°C.

Enthalpy and Entropy of Activation. The rate constants were determined at several temperatures. The logarithms of the rate constants were in a linear relation to $1/T$. The rate constants for the decomposition of trioxalatocobaltate(III) in 0.1 and 1.0 M sulfuric acid solutions, together with the enthalpy and entropy of activation, are given in Table 1.

Table 1. Temperature dependence on the rate of decomposition of trioxalatocobaltate(III). N_2 saturated; dark

Temp. °C	k_0 (sec^{-1}) in 0.1 M H_2SO_4	k_0 (sec^{-1}) in 1.0 M H_2SO_4	k_2 (sec^{-1} M^{-1})
25	1.0×10^{-5}	3.9×10^{-5}	1.8×10^{-5}
30	2.2×10^{-5}	8.8×10^{-5}	3.7×10^{-5}
35	5.2×10^{-5}	20.7×10^{-5}	9.6×10^{-5}
40	10.8×10^{-5}	46.5×10^{-5}	19.8×10^{-5}

$\Delta H_1^{\ddagger} = 29.7$ kcal; $\Delta H_2^{\ddagger} = 30.2$ kcal.

$\Delta S_1^{\ddagger} = 17.4$ eu; $\Delta S_2^{\ddagger} = 20.9$ eu at 40°C.

where $\Delta H_1^{\ddagger}$ and $\Delta S_2^{\ddagger}$ are the activation enthalpy and the entropy of Reaction (8), and where $\Delta H_2^{\ddagger}$ and $\Delta S_2^{\ddagger}$, those of Reaction (8′).

A number of workers[1,5-12] have proposed the monodentate oxalato species as an intermediate in the decomposition of the trioxalato metal complexes, $M(C_2O_4)_3^{3-}$; *e. g.*, in the case of trioxalatocobaltate(III), the following reactions are offered:

$$Co(C_2O_4)_3^{3-} + H_2O \rightarrow Co(C_2O_4)_2(OC_2O_3)(H_2O)^{3-} \quad (4)$$

$$Oo(C_2O_4)_3^{3-} + H_3O^+ \rightarrow Co(C_2O_4)_2(OC_2O_3H)(H_2O)^{2-} \quad (5)$$

In the present study, the enthalpy of the activation of the [H$^+$]-dependent reaction was almost equal to that of [H$^+$]-independent one. This may indicate that the decomposition of trioxalatocobaltate(III) occurs through two reactions (4) and (5). However, there have been many contradictory discussions: Kruszyna and Milburn[5] have emphasized that the protonated intermediate offers the major path for the decomposition and that the direct decomposition of $Co(C_2O_4)_3^{3-}$ occurs at a finite rate[13]. On the contrary, Aggett and Odell[9b] have suggested that the thermal decomposition of trioxalatocobaltate(III) proceeds through the unprotonated $Co(C_2O_4)_2(OC_2O_3)(H_2O)^{3-}$.

Partially-released monodentate oxalato intermediates may lead to a larger positive entropy change. This assumption is in agreement with the present results. Copestake and Uri[1a] have suggested that the hydrolysis reaction:

$$Co(C_2O_4)_3^{3-} + H_2O \rightarrow HCo(C_2O_4)_3^{2-} + OH^- \quad (6)$$

is improbable, since (a) solution of $K_3Co(C_2O_4)_3$ are neutral than alkaline, and (b) pH of a 10^{-2} M solution of $H_3Co(C_2O_4)_3$ is such that all the three hydrogen atoms are completely dissociated. That is, $H_3Co(C_2O_4)_3$ is a very strong acid. In view of these facts, the positive entropy change can hardly be expected to be due to the dehydration by the hydrogen ion.

Stoichiometry. To verify the stoichiometry of the reaction, 4.2×10^{-3} M trioxalatocobaltate(III) was kept in 0.1 M sulfuric acid solutions for 15 hr at 40°C. The solution was saturated with nitrogen or oxygen gas in a closed glass-stoppered vessel sealed with wax. Under these conditions, a green solution of trioxalatocobaltate(III) turns completely pink due to the formation of cobalt(II) ion. No trioxalatocobaltate(III) is left in the solution after 15 hours, and the cobalt(II) ion and oxalic acid are formed in the absence of oxygen as the decomposition products. Hydrogen peroxide is formed in the presence of oxygen. The amount of peroxide formed is equimolar to the amount of oxalic acid which disappears.[14] Therefore,

14) The details were reported previously (see Ref. 2).

the sum of oxalic acid and hydrogen peroxide should be equal to the amount of oxalic acid formed in the absence of oxygen. The reaction products were analyzed. The results are listed in Table 2. Table 2 indicates that one mol/l of trioxalatocobaltate(III) produces 2.5 mol/l of oxalic acid in the absence of oxygen, or 2.5 mol/l of a total of oxalic acid and hydrogen peroxide in the presence of oxygen.

That is, in the case of the absence of oxygen the overall reaction is:

$$Co(C_2O_4)_3^{3-} \xrightarrow{k_0} Co(C_2O_4)_n^{(2-2n)} + (2.5-n)C_2O_4^{2-} \quad (7)$$

where n is 0, 1, and/or 2.

The Influence of Other Substances on the Decomposition Rate. Various substances were added to the reaction mixture of 4×10^{-3} M $K_3Co(C_2O_4)_3$ and 0.1 M H_2SO_4.

TABLE 3. INFLUENCE OF OTHER SUBSTANCES ON THE DECOMPOSITION RATE. SOLUTIONS OF 4.0×10^{-3} M $Co(C_2O_4)_3$, 0.1 M H_2SO_4, AND THE GIVEN SUBSTANCES. N_2-SATURATED UNLESS OTHERWISE STATED; IN THE DARK UNLESS OTHERWISE STATED; AT 40°C

Substances added[a)]	Rate constant, $k_0\times10^4$, sec^{-1}
None	1.1
None	1.0 (in O_2 sat.)
None	1.3 (in light[b)])
0.5% Acrylonitrile	1.0
1.0% Acrylonitrile	1.0
0.004 M $K_2S_2O_8$	1.0
0.002 M Fe(III)	1.1
0.01 M Fe(III)	2.2
0.002 M Cu(II)	1.1
0.015 M Cu(II)	1.7
0.01 M Co(II)	1.1
0.01 M $H_2C_2O_4$	1.0

a) The sulfate salts of Fe(III), Cu(II), and Co(II) were used.
b) A 100-watt tungsten lamp was placed at a distance of 15 cm from the reaction mixture.

(*a*) The decomposition rate in the solution in the presence of oxygen was almost equal to that in the absence of oxygen. In the presence of oxygen, hydrogen peroxide was formed in the course of the decomposition of trioxalatocobaltate(III).

(*b*) Though photochemistry is outside the scope of the present investigation, the decomposition rate in light exposed by a tungsten lamp was compared to that in the dark. As can be seen in Table 3, light accelerates the decomposition of trioxalatocobaltate(III). This appears reasonable, since trioxalatocobaltate(III) has been known to be photochemically active and to be used as a chemical actinometer.[1a)]

(*c*) Acrylonitrile did not affect the decomposition rate of trioxalatocobaltate(III), although its polymerized products were found in the reacting solution.

(*d*) The decomposition rate of trioxalatocobaltate(III) was not affected by the presence of peroxodisulfate. However, the decomposition of peroxodisulfate was induced by the decomposition of trioxalatocobaltate(III). This fact indicates that the CO_2^- radical formed by the decomposition of trioxalatocobaltate(III) reacts with peroxodisulfate as follows:

$$Co(C_2O_4)_3^{3-} \rightarrow Co(C_2O_4)_n^{(2-2n)} + (2-n)C_2O_4^{2-} + CO_2 + CO_2^- \quad (8)$$

$$Co(C_2O_4)_3^{3-} + H^+ \rightarrow Co(C_2O_4)_n^{(2-2n)} + (2-n)C_2O_4^{2-} + CO_2 + CO_2^- + H^+ \quad (8')$$

$$S_2O_8^{2-} + CO_2^- \rightarrow SO_4^- + SO_4^{2-} + CO_2 \quad (9)$$

(*e*) Both iron(III) and copper(II) ions accelerated the decomposition rate of trioxalatocobaltate(III). This can be accounted for by following reactions (8) and (8').

$$Fe(III) \text{ or } Cu(II) + CO_2^- \rightarrow CO_2 + Fe(II) \text{ or } Cu(I) \quad (10)$$

$$Co(C_2O_4)_3^{3-} + Fe(II) \text{ or } Cu(I) \xrightarrow{fast} Fe(III) \text{ or } Cu(II) + Co(C_2O_4)_n^{(2-2n)} + (3-n)C_2O_4^{2-} \quad (11)$$

Reactions (10) and (11) constitute a chain reaction.

Mechanisms. The radicals of CO_2^- and HO_2 are apt to be considered to be oxidized by trioxalatocobaltate(III), since both radicals are generally reductants; *e. g.*, in the present study, iron(III), copper (II), and peroxodisulfate were reduced by the radicals. However, none of our results supported the reaction between trioxalatocobaltate(III) and CO_2^- or HO_2 radical; rather, they supported the combination reaction of CO_2^- or HO_2 with each other to make the $C_2O_4^{2-}$ ion, or H_2O_2, respectively. Consequently, the following reaction mechanisms of the thermochemical decomposition of trioxalatocobaltate(III) are presented to account for these results:

$$Co(C_2O_4)_3^{3-} \xrightarrow{k_1} Co(C_2O_4)_n^{(2-2n)} + (2-n)C_2O_4^{2-} + CO_2^- + CO_2 \quad (8)$$

$$Co(C_2O_4)_3^{3-} + H^+ \xrightarrow{k_2} Co(C_2O_4)_n^{(2-2n)} + (2-n)C_2O_4^{2-} + CO_2 + CO_2^- + H^+ \quad (8')$$

$$2CO_2^- \xrightarrow{fast} C_2O_4^{2-} \text{ (in the absence of oxygen)} \quad (12)$$

$$CO_2^- + O_2 \xrightarrow{fast} O_2CO_2^- \text{ (in the presence of oxygen)} \quad (13)$$

$$O_2CO_2^- + H^+ \rightarrow HO_2 + CO_2 \quad (14)$$

$$2HO_2 \xrightarrow{fast} H_2O_2 + O_2 \quad (15)$$

The overall reaction corresponds to Reaction (7) and is consistent with the results of stoichiometry listed in Table 2.

Preparation and Characterization of Cobalt(III) Complexes with *N*-Carboxylate Derivatives of L-Prolinate

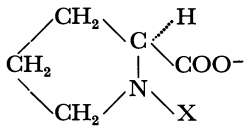
Ken-ichi OKAMOTO, Jinsai HIDAKA, and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received July 3, 1972)

Four cobalt(III) complex anions, bis(L-prolinate-*N*-monopropionato)-, (L-prolinate-*N*-monoacetato)(iminodiacetato)-, (L-prolinate-*N*-monopropionato)(iminodiacetato)- and (L-prolinate-*N*-monoacetato)(L-prolinate-*N*-monopropionato)cobaltate(III) were synthesized. They were isolated as sodium or potassium salts by ion-exchange column chromatography. These complexes were characterized on the basis of their absorption and circular dichroism spectra in the visible and near ultraviolet regions. All the complexes obtained in solid state have *trans(N)*-RR or *trans(N)*-R configuration. Two geometrical isomers were obtained for (L-prolinate-*N*-monopropionato)triamminecobalt(III) complexes.

L-prolinate is a unique aminocarboxylate bidentate ligand, since the secondary amine nitrogen of pyrrolidine ring coordinates stereospecifically to a metal ion with only S configuration. This has been recognized from circular dichroism (CD) studies[1] or X-ray crystal structure analyses[2,3] of several L-prolinato metal complexes. In the course of our study on stereochemistry of six isomers of bis(L-alaninate-*N*-monoacetato)cobaltate(III),[4] we found that an *N*-carboxylate derivative of L-prolinate, L-prolinate-*N*-monoacetate gave only two isomers of the bis(O,N,O-tridentato)cobalt(III) complex. This was explained from the viewpoint that the chiral nitrogen center of the coordinated L-prolinate-*N*-monoacetate takes only R configuration, and the ligand only a *facial* coordination. In the present paper, the stereochemistry of some cobalt(III) complexes of another L-prolinate derivative, L-prolinate-*N*-monopropionate is reported.



X=H : L-prolinate
X=CH_2COO^- : L-prolinate-*N*-monoacetate (abbreviated to L-proma^{2-})
X=$CH_2CH_2COO^-$: L-prolinate-*N*-monopropionate (abbreviated to L-promp^{2-})

The difference between L-proma^{2-} and L-promp^{2-} is that the former forms two five-membered chelate rings by coordination, whereas the latter forms a five- and a six-membered chelate ring by an α-aminocarboxylate part and an *N*-propionate foot, respectively.

Experimental

Preparation of Ligands. *(1)* *L-Proline-N-monoacetic Acid*: The preparation was reported previously.[4]

(2) *L-Proline-N-monopropionic Acid*: A solution of 25 g of L-proline in 54 ml of 4 N sodium hydroxide was mixed with a solution of 23.5 g of 3-chloropropionic acid in 54 ml of 2 N sodium hydroxide, and 80 ml of 4 N sodium hydroxide was added drop by drop to the mixture with vigorous stirring at 80—85°C on an oil bath. The pH of mixture was maintained in a 8—9 range during the reaction. After the sodium hydroxide solution had been added, the reaction mixture was heated at 85°C for about 20 min. This was cooled to 40°C and 36 ml of concentrated hydrochloric acid was added. The solution was concentrated in a vacuum evaporator at 40°C until white crystals appeared. The product was filtered off and the filtrate was concentrated again. After the operation was repeated six times (about 38 g of white crystals were obtained in total), a large amount of ethanol was added to the final filtrate. The white crystals separated were collected by filtration (26 g). The combined white crystals were contaminated with a small amount of sodium chloride. This was recrystallized from a warm (hydrochloric acid)-water (1 : 100) solution. The pure crystals were washed with ethanol and dried in a vacuum desiccator. $[\alpha]_D^{20}=-55.5°$ (c. 8.7, water). Found: C, 51.22; H, 6.98; N, 7.55%. Calcd for L-prompH$_2$=$C_8H_{13}NO_4$: C, 51.33; H, 7.00; N, 7.48%.

Preparation and Separation of Complexes. *(3)* trans(N)-*K*[*Co*(L-*proma*)$_2$]·3H_2O: The preparation of this complex was already reported.[4] One corresponding *cis(N)* isomer was obtained concurrently in solution, but it was not obtained in solid state because of poor stability.

(4) trans(N)-*Na*[*Co*(L-*promp*)$_2$]·3H_2O: A solution of 10 g (0.042 mol) of $CoCl_2\cdot 6H_2O$ in 10 ml of water was added to a solution of L-proline-*N*-monopropionic acid (0.084 mol) which was neutralized in advance by the addition of sodium hydroxide. To this was gradually added 10 g of lead dioxide and the resulting mixture was constantly stirred at about 50°C for an hr, whereupon the color of the solution turned from dark red to violet. After having been kept for 30 min at room temperature, the mixture was filtered to remove an excess of lead dioxide. A large amount of ethanol-acetone (1 : 1) mixture was added to the filtrate and a small amount of the resulting sodium chloride was filtered off. The filtrate was concentrated in a vacuum evaporator at about 30°C and poured into a column (25 mm×1500 mm) containing strong-base anion exchange resin (Dowex 1X8 200—400 mesh, chloride form). After the column had been swept with water, the adsorbed band was eluted with 0.075 N aqueous solution of sodium chloride at a rate of 2.5 ml per min. Only one violet band was eluted. The sodium chloride in the eluate was fractionally separated by adding an appropriate amount of ethanol to the concentrated solution. The desired complex was obtained by concentrating the filtrate almost to dryness. The product was washed with ethanol

and then dried in a vacuum desiccator.

(5) trans(N)-*K*[*Co*(L-*proma*)(*ida*)]·2.5H_2O: A solution of 0.042 mol of iminodiacetic acid neutralized by sodium hydroxide was mixed with a neutralized solution of 0.042 mol of L-proline-*N*-monoacetic acid. To this was added gradually a solution of 10 g (0.042 mol) of $CoCl_2 \cdot 6H_2O$ in 10 ml of water and then 10 g of lead dioxide. After the mixture was constantly stirred at about 50°C for an hr, its pH was adjusted to 6.5 with 6 N hydrochloric acid. This was stirred again for an hr to complete the reaction. The solution turned violet. An excess of lead dioxide was filtered off. When a large amount of ethanol was added to the filtrate, a bluish violet deposit was obtained, which was filtered. It was confirmed from column chromatography and absorption measurements that the bluish violet deposit consisted of *trans(N)*- and *cis(N)*-Na[Co(ida)$_2$]. The concentrated filtrate was poured into a column (35 mm × 500 mm) containing the same resin as used in (4). Five colored bands *viz.*, a brownish red one (i) in a small amount, two red ones (ii) and (iii) and two violet ones (iv) and (v) in small amounts, were eluted in this order with 0.07 N aqueous solution of potassium chloride. The first spin-allowed d-d absorption band of each eluate showed that the first three, (i), (ii) and (iii), are of *trans(N)* type and the latter two (iv) and (v) of *cis(N)*. Of the three *trans(N)* eluates, (i) was confirmed to be *trans(N)*-[Co(ida)$_2$]$^-$[5] and (iii) *trans(N)*-[Co(L-proma)$_2$]$^-$[4]. Eluate (ii) was then concentrated in a vacuum evaporator. The coexisting potassium chloride was fractionally precipitated by adding ethanol to the concentrated solution and filtered off. Finally, a saturated solution of silver acetate was added drop by drop to the concentrated filtrate and the resulting silver chloride was filtered off. The desired complex was obtained by adding a large amount of ethanol to the filtrate and recrystallized from a small amount of water by adding ethanol. The pure complex was washed with ethanol and dried in a vacuum desiccator. Eluates (iv) and (v) were so unstable that they were not obtained in solid state.

(6) trans(N)-*K*[*Co*(L-*promp*)(*ida*)]·2H_2O: This complex was prepared and separated by a similar procedure to that for *trans(N)*-K[Co(L-proma)(ida)]. Four colored bands, a violet one (i), a reddish violet one (ii), a brownish red one (iii) in a small amount, and another violet one (iv) were eluted in this order. The absorption measurements of the eluates indicated that (i) contained *trans(N)*-[Co(L-promp)$_2$]$^-$, (iii) *trans(N)*-[Co(ida)$_2$]$^-$ and (iv) *cis(N)*-[Co(ida)$_2$]$^-$. Eluate (ii) was concentrated to dryness in a vacuum evaporator. The complex was extracted with a large amount of absolute ethanol and solidified by adding ether to the extract. After the resulting suspension was centrifuged, the complex was filtered and dried in a vacuum desiccator. The isolated potassium salt was hygroscopic.

(7) trans(N)-*K*[*Co*(L-*proma*)(L-*promp*)]·3H_2O: A solution of 10 g (0.042 mol) of $CoCl_2 \cdot 6H_2O$ in 10 ml of water was added to a neutralized equimolar mixture (0.042 mol) of L-proline-*N*-monoacetic acid and L-proline-*N*-monopropionic acid. To this was added 10 g of lead dioxide and the resulting mixture was mechanically stirred at about 40°C for an hr. The color of the solution turned from dark red to reddish purple. An excess of lead dioxide was filtered off and the filtrate was treated with a column as described in (4) and (5). Three colored bands, a violet one (i), a purple one (ii), and a red one (iii), were eluted in this order. It was confirmed from the absorption measurements that (i) contained *trans(N)*[Co(L-promp)$_2$]$^-$ and (iii) *trans(N)*-[Co(L-proma)$_2$]$^-$. Eluate (ii) was concentrated to dryness in a vacuum evaporator. Solidification was carried out by a similar procedure to that for *trans(N)*-K[Co(L-promp)(ida)]. The complex was obtained as hygroscopic potassium salt.

(8) trans(O)-[*Co*(L-*promp*)(NH_3)$_3$]ClO_4 *and* cis(O)-[*Co*(L-*promp*)(NH_3)$_3$]$ClO_4 \cdot 1/2H_2O \cdot 1/4C_2H_5OH$: A solution of 9 g (0.17 mol) of ammonium chloride and 10 ml of 28% aqueous ammonia (0.15 mol) in 15 ml of water was mixed with a neutral solution of 0.042 mol of L-proline-*N*-monopropionic acid. To this were added a solution of 10 g (0.042 mol) of $CoCl_2 \cdot 6H_2O$ in 10 ml of water and 10 g of lead dioxide. The reaction mixture was constantly stirred at about 40°C for an hr. The color of the solution turned from dark red to reddish yellow and finally to red. After having been allowed to stand at room temperature for 30 min, the mixture was filtered to remove an excess of lead dioxide, and the filtrate was kept in a refrigerator. A small amount of yellow depoint, $[Co(NH_3)_6]Cl_3$, was filtered off. The filtrate was poured into a column (35 mm × 500 mm) containing strong-acid cation exchange resin (Dowex 50WX8 200—400 mesh, sodium form). After the column had been swept with water, the adsorbed band was eluted with 0.1 N aqueous solution of sodium perchlorate at a rate of 2.5 ml per min. Two red bands, (i) in a small amount and (ii) in a large amount were eluted in this order. When eluate (i) was concentrated in a vacuum evaporator, red crystals appeared. Eluate (ii) was also concentrated in a vacuum evaporator; the desired complex was obtained in this case by adding a large amount of ethanol to the concentrated solution. This was recrystallized from a small amount of water by adding ethanol. Both the complexes were washed with ethanol and dried in a vacuum desiccator. On the basis of absorption measurements, isomers (i) and (ii) were confirmed to be *trans(O)* and *cis(O)* ones, respectively; the absorption maxima of isomer (i) are at 18.5 and 27.0×10^3 cm^{-1} with a shoulder at about 21.0×10^3 cm^{-1}, and of isomer (ii) 19.3 and 27.3×10^3 cm^{-1}.

The analytical results for the six new cobalt(III) complexes are given in Table 1.

Measurements. The electronic absorption spectra were measured by a Beckman DU spectrophotometer and Shimadzu spectrophotometer UV-200. The CD spectra were recorded with a Roussel-Jouan dichrograph. All the measurements were carried out in aqueous solutions at room temperature.

Results and Discussion

The *trans(N)* and *cis(N)* isomers of a [$Co^{III}(O)_4(N)_2$] type complex can be identified by the splitting pattern of their first spin-allowed d-d absorption bands.[6,7] All the [$Co^{III}(O)_4(N)_2$] type complexes show well-separated splitting components in their first absorption bands (Figs. 1 and 2, and Table 2); these are therefore assigned to the *trans(N)* structure. The corresponding *cis(N)* isomers are expected to be unstable because of a rather short contact (from molecular model considerations) of the pyrrolidine ring to another ligand coordinated.[4] No *cis(N)* isomers were detected in column chromatographic

experiments of [Co(L-proma)(L-promp)]$^-$ and [Co(L-promp)$_2$]$^-$. Some indication of *cis*(*N*) isomers was obtained in the column chromatography of the ida-mixed complexes, but they were too unstable to isolate, except for the case of *cis*(*N*)-[Co(ida)$_2$]$^-$.

As is seen in Fig. 3, two isomers are possible for the *trans*(*N*) complex with two O,N,O-tridentate ligands. It is recognized[4,5,8] that the tridentate ligand such as ida^{2-} or L-proma^{2-} is hardly coordinated meridionally in Co(III) complexes, except for the case of *trans*(*O*)-[Co(ida)(dien)]$^{+}$[8]. L-promp^{2-} here employed forms a five- and a six-membered chelate ring by coordination. A molecular model examination reveals that the *N*-propionate moiety of L-promp^{2-} spans in a less strained circumstance than the *N*-acetate one of L-proma^{2-}. Thus it seems that a *meridional* coordination (Fig. 3a) is less improbable for L-promp^{2-} than for L-proma^{2-}. The preparation of [Co(L-promp)(NH$_3$)$_3$]$^+$ revealed the formation of the meridionally coordinated isomer, though the yield was very low. It was confirmed from the ion-exchange column chromatography and absorption measurements in the visible region that a major portion of the obtained triammine complex consists of the *cis*(*O*) isomer with *facial* coordination of L-promp^{2-} and that the *trans*(*O*) one with *meridional* coordination is formed in only a trace amount. Thus, it is assumed that the stable *trans*(*N*) complexes obtained in good yield take the

facial coodinations (Fig. 3b) of L-promp^{2-}, L-proma^{2-} and ida^{2-} ligands.

The nitrogen atom of L-proma^{2-} or L-promp^{2-} is a chiral center in the present complexes. It can be considered that three isomers, RR, RS, and SS, with respect to the two coordinated nitrogen atoms, are possible for each bis(O,N,O-tridentato) complex. But it is well-established[1-4] that L-prolinate and its *N*-carboxylate derivatives cannot take configurations R and S, respectively, of the coordinated nitrogen atom. Consequently, only the RR type is possible for each of the *facial trans(N)* complexes. In fact, only one *trans(N)* isomer was obtained for each of the [Co(L-proma)$_2$]$^-$, [Co(L-proma)(L-promp)]$^-$ and [Co(L-promp)$_2$]$^-$ complexes. A quite similar consideration can be applied the mixed complexes with an ida^{2-} ligand, [Co(L-proma)(ida)]$^-$ and [Co(L-promp)(ida)]$^-$; thus each of them is assigned to *facial trans(N)*-R configuration.

Absorption and CD spectra. The five *facial trans(N)* complexes show reasonable correlation among their absorption spectra. The first and second spin-allowed d-d absorption bands of the bis type complexes are shifted to lower energy and intensified, in the order ida^{2-}→L-proma^{2-}→L-promp^{2-} (Figs. 1 and 2, and Table 2). A mixed complex, R-[Co(L-promp)(ida)]$^-$, shows its first band in a middle position between the first bands of parent complexes, RR-[Co(L-promp)$_2$]$^-$ and [Co(ida)$_2$]$^-$. Similar relationships are also substantiated for the other mixed complexes, R-[Co(L-proma)(ida)]$^-$ and RR-[Co(L-proma)(L-promp)]$^-$.

In contrast to these absorption behaviors, their CD spectra in the corresponding region differ significantly from each other (Figs. 1 and 2, and Table 3). In the first absorption band region, the lower energy CD bands commonly have a positive sign, though it seems that R-[Co(L-proma)(ida)]$^-$ lacks this CD band. Another common feature in the CD spectra of five *facial trans(N)*-R or -RR complexes is observed in the second absorption band region; namely all of them have negative CD. In contrast, the CD pattern in the region 17—22$\times 10^3$ cm^{-1} changes remarkably with substitution of ligands. That is, RR-[Co(L-proma)$_2$]$^-$ shows an intense negative CD band and RR-[Co(L-(promp)$_2$]$^-$ an intense positive one (Fig. 1 and Table 3). In the corresponding region, the mixed complex, RR-[Co(L-proma)(L-promp)]$^-$, shows two CD components, a positive one at 18.4$\times 10^3$ cm^{-1} and a negative one at about 27.1$\times 10^3$ cm^{-1}. R-[Co(L-proma)(ida)]$^-$ shows a negative major CD band which corresponds well to the major one of bis(L-proma) com-

plex, while R-[Co(L-promp)(ida)]$^-$ shows two CD bands in the region 17—22 $\times 10^3$ cm^{-1} (Fig. 2 and Table 3). It seems that the sign reversal of the major CD band between RR-[Co(L-promp)$_2$]$^-$ and RR-[Co(L-proma)$_2$]$^-$ arises from the difference in the *N*-carboxylate moieties, since both the L-promp^{2-} and L-proma^{2-} ligands take the *facial* R(*N*) form by coordination and the resulting complexes take quite a similar configuration to each other. A similar sign reversal was reported[9] for the major CD bands in the visible region between copper(II) complexes of L-prolinate and its *N*-methyl derivative. Thus one should be surprised at the poor additivity of CD curves in the present complexes, rather than at the sign reversal between L-proma^{2-} and L-promp^{2-} complexes. The sum of CD curves of *trans(N)*-R-[Co(L-proma)-(ida)]$^-$ and -[Co(L-promp)(ida)]$^-$ poorly reproduces the observed curve of *trans(N)*-RR-[Co(L-proma)-(L-promp)]$^-$. A similar treatment for the CD curves of *trans(N)*-RR-[Co(L-proma)$_2$]$^-$ and -[Co(L-promp)$_2$]$^-$ also cannot reproduce the curve for the mixed complex *trans(N)*-RR-[Co(L-proma)(L-promp)]$^-$. These facts present a strange contrast to almost perfect additivity observed for several cobalt(III) complexes with some simple α-aminocarboxylates or their derivatives; for instance Koine *et al.*[10] showed that the CD curve of *trans(N)*-(L-alaninate-*N*,*N*-diacetato)(L-prolinato)-cobaltate(III) was clearly reproduced by summing up those of *trans(N)*-(L-alaninate-*N*,*N*-diacetato)(glycinato)cobaltate(III) and *trans(N)*-(ammoniatriacetato)(L-prolinato)cobaltate(III). Poor additivity of the present complexes would be related to less rigid conformations of the L-prolinate derivative tridentate ligands in a complicated sector spaces, which were produced by a rather low symmetry of the complexes, and which should have different space distributions of sector signs from one complex to another.

Kinetics and Mechanism of Formation of Monothiocyanato and Mononitrilotriacetato Complexes of Iron(III)

Shigenobu FUNAHASHI, Shoji ADACHI,* and Motoharu TANAKA**

Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received July 6, 1972)

Kinetics of the formation of monothiocyanato and mononitrilotriacetato complexes of iron(III) in aqueous solution have been studied by using a stopped-flow technique:

$$Fe^{3+} + SCN^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} FeNCS^{2+}$$

$$FeOH^{2+} + SCN^- \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} FeNCS^{2+} + OH^-$$

$$FeOH^{2+} + H_2nta^- \xrightarrow{k} Fe(nta) + H^+$$

Rate constants at 25°C and $\mu=0.5$ ($NaClO_4$) are as follows: $k_1=90\ M^{-1}\ sec^{-1}$, $k_{-1}=1.6\ sec^{-1}$, $k_2=5.1\times10^3\ M^{-1}\ sec^{-1}$, $k_{-2}=10\times10^{13}\ M^{-1}\ sec^{-1}$, $k=1.0\times10^5\ M^{-1}\ sec^{-1}$. Some discussions are made on the effect of hydroxide ion on the complex formation reactions.

The complex formation reactions of iron(III) have been extensively studied for various ligands: F^-[1], Cl^-[2-4], Br^-[4,5], azide[6-8], SCN^-[3,9], aliphatic acids[10-12], SO_4^{2-}[3,13,14], substituted phenols[15], acetylacetone[16], oxalic acid[17], substituted malonic acids[18], salicylic acid[19], sulfosalicylic acid[19], 8-hydroxyquinoline[19], salicylaldehyde[19].

According to the earlier kinetic studies, the reaction

rate constants for all the $Fe^{3+}+L$ reactions lie in the range $1—10^2\ M^{-1}\,sec^{-1}$, and those for the $FeOH^{2+}+L$ reactions in the range $10^2—10^5 M^{-1}sec^{-1}$ at 25°C. These results indicate that the substitution of a water molecule in the inner coordination sphere of the metal ion is the rate-determining process of the complex formation reaction.[20]

Since there is very little information on the kinetics of complex formation of iron(III) ion with multidentate ligands, we have studied the kinetics of iron(III) ion with nitrilotriacetate (tetradentate) to compare the results with the kinetic properties of monodentate ligands. Our primary intention was to determine whether the rate of the complex formation of iron(III) is controlled by the release of a water molecule in the inner coordination sphere or by the chelate ring closure (sterically controlled substitution) as found for some complexes,[21-23] and to elucidate the effect of hydroxide ion on the complex formation reactions.

Experimental

Reagents. *Iron(III) Perchlorate*: The reagent grade iron(III) chloride was dissolved in perchloric acid and chloride was expelled by evaporation. The absence of chloride ion was checked by silver nitrate. The iron(III) perchlorate was recrystallized twice from 60% perchloric acid solution. Its concentration was determined by a standard EDTA solution with Variamine Blue B as an indicator.[24]

Sodium Thiocyanate: The reagent grade sodium thiocyanate was recrystallized twice from distilled water. The thiocyanate solution was standardized by the method of Volhard.

Nitrilotriacetic Acid: The acid form of NTA obtained from Dojindo Co., Ltd., was recrystallized twice from distilled water. The purified NTA was dissolved in 1 equivalent of sodium hydroxide.

Methods of preparation of sodium perchlorate and sodium hydroxide have been described previously.[25]

Measurements. Supplementary spectra were taken on a JASCO Model ORD/UV-5 optical rotatory dispersion recorder and a Hitachi Perkin-Elmer 139 UV-VIS spectrophotometer.

Hydrogen ion concentration was determined by a Radiometer PHM-4d (Copenhagen) with a Type G202 B glass electrode and a Type K 401 calomel. A 1.00×10^{-2} M perchloric acid at an ionic strength of 0.5 M ($[HClO_4]+[NaClO_4]=0.5$ M) was used as a standard solution. The liquid junction potential was taken into consideration.

The acidities of solutions were adjusted by addition of a solution of sodium hydroxide prepared by electrolysis of a sodium perchlorate solution. Ionic strengths were adjusted by addition of sodium perchlorate.

The kinetics of formation of complexes of iron(III) was studied spectrophotometrically by means of a stopped-flow technique using a Rapid Scan Spectrophotometer Type RSP-2 (Hitachi, Ltd., Tokyo). The reactant syringes thermostated at 25±0.1°C were connected to the two-stage mixing chamber with eight jets, with which was aligned a quartz observation tube 10-mm long and 2-mm in diameter. The runs of reactions at a fixed wavelength (460 nm for $FeNCS^{2+}$ and 262.5 nm for Fe(nta)) in the absorption spectrum of the complex were memorized on an oscilloscope (Hitachi V-OL-Memoriscope). The screen of the oscilloscope was photographed. The traces of absorbance against reaction time were analyzed.

Results

Kinetics of Formation of the Monothiocyanato Complex of Iron(III).[26] The kinetic data are consistent with the assumption that the formation of $FeNCS^{2+}$ proceeds *via* two paths, one involving the reaction of Fe^{3+} with SCN^- and the other involving the reaction of $FeOH^{2+}$ with SCN^-, and that the equilibrium between Fe^{3+} and $FeOH^{2+}$ ($Fe^{3+}+H_2O\rightleftharpoons FeOH^{2+}+H^+$) is established throughout the course of the reaction. The rate of formation of $FeNCS^{2+}$ is then given by

$$\frac{d[FeNCS^{2+}]}{dt} = k_1[Fe^{3+}][SCN^-] + k_2[FeOH^{2+}][SCN^-] - k_{-1}[FeNCS^{2+}] - k_{-2}[FeNCS^{2+}][OH^-] \quad (1)$$

where the rate constants are defined by the following:

$$Fe^{3+} + SCN^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} FeNCS^{2+} \quad (2)$$

$$FeOH^{2+} + SCN^- \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} FeNCS^{2+} + OH^- \quad (3)$$

Since $C_{Fe} \gg C_{SCN}$, it follows that

$$[Fe^{3+}] = \frac{C_{Fe}}{1 + \frac{K^{-H}_{FeOH}}{[H^+]}}$$

where C_{Fe} is the total concentration of iron(III) and $K^{-H}_{FeOH}=[FeOH^{2+}][H^+]/[Fe^{3+}]=10^{-2.73}$.[14,27] Moreover, under the conditions used in this investigation $K^{-H}_{FeOH}/[H^+] \ll 1$.

Therefore

$$\frac{d[FeNCS^{2+}]}{dt} = \left(k_1 + \frac{k_2 K^{-H}_{FeOH}}{[H^+]}\right) C_{Fe}[SCN^-] - (k_{-1} + k_{-2}[OH^-])[FeNCS^{2+}] \quad (4)$$

Integrating Eq. (4) we get

$$\ln\left(1 - \frac{[FeNCS^{2+}]}{[FeNCS^{2+}]_{eq}}\right) = -\left(k_1 + k_{-1} + \frac{k_2 K^{-H}_{FeOH}}{[H^+]} + k_{-2}[OH^-]\right)t \quad (5)$$

where $[FeNCS^{2+}]_{eq}$ is the concentration of $FeNCS^{2+}$

26) The iron(III) complex with thiocyanate appears to be $FeNCS^{2+}$ (monoisothiocyanatoiron(III)) as suggested by the following authors: S. Fronaeous and R. Larsson (*Acta Chem. Scand.*, **16**, 1447 (1962)), and A. Haim and N. Sutin (*J. Amer. Chem. Soc.*, **87**, 4210 (1965)).
27) L. G. Sillén and A. E. Martell, "Stability Constants of Metal Ion Complexes," Special Publication No. 17. The Chemical Society, London, 1964.

under equilibrium conditions. Then

$$\ln\left(1+\frac{A_t}{A_{eq}}\right) = -k_0 t \tag{6}$$

$$k_0 = k_1 C_{Fe} + k_{-1} + \frac{k_2 K_{FeOH}^{-H} C_{Fe}}{[H^+]} + \frac{k_{-2} K_w}{[H^+]} \tag{7}$$

where A_t and A_{eq} are the absorbances of the reaction system at t seconds after the start of the reaction and at equilibrium, respectively, k_0 a conditional rate constant obtained by experiments, and $K_w=[H^+][OH^-]$.

Some conditional rate constants under various experimental conditions are given in Table 1. These data indicate clearly a linear relationship between k_0 and the reciprocal concentration of hydrogen ion with a nonzero intercept (Fig. 1). Thus the conditional rate constant k_0 is expressed by

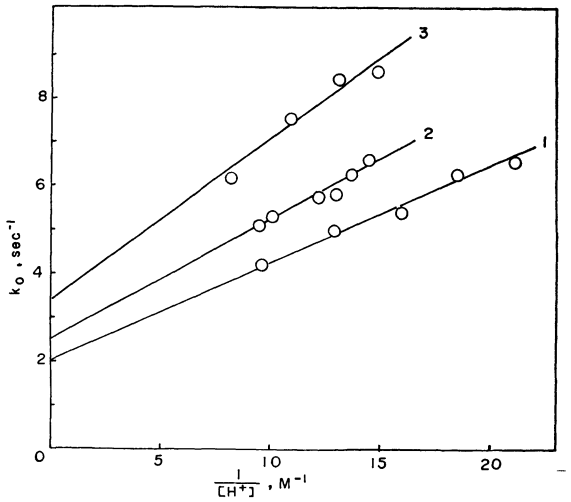

Fig. 1. k_0 as a function of the reciprocal concentration of hydrogen ion. $C_{SCN}=2.00\times10^{-4}$ M, 25°C, $\mu=0.5$ M ($NaClO_4$), 1: $C_{Fe}=3.98\times10^{-3}$ M; 2: $C_{Fe}=9.97\times10^{-3}$ M; 3: $C_{Fe}=2.00\times10^{-2}$ M.

$$k_0 = k_{0(1)} + k_{0(2)} \frac{1}{[H^+]} \tag{8}$$

Moreover, the values of intercepts ($k_{0(1)}$) are found proportional to the concentration of ferric ion (Fig. 2a). The values of slopes ($k_{0(2)}$) are also linearly related to the concentration of ferric ion (Fig. 2b). These results are consistent with the proposed reaction mechanism, *i.e.*,

$$k_{0(1)} = k_1 C_{Fe} + k_{-1} \tag{9}$$

$$k_{0(2)} = k_2 K_{FeOH}^{-H} C_{Fe} + k_{-2} K_w \tag{10}$$

The values of rate constants k_1, k_{-1}, $k_2K_{FeOH}^{-H}$, and $k_{-2}K_w$ were determined from the intercepts and the slopes of plots by the method of least squares: $k_1=90\pm5$ $M^{-1}sec^{-1}$, $k_{-1}=1.6\pm0.2$ sec^{-1}, $k_2K_{FeOH}^{-H}=9.5$ $M^{-2}sec^{-1}$, $k_{-2}K_w=0.19$ $M^{-1}sec^{-1}$. Using the values $K_{FeOH}^{-H}=1.87\times10^{-3}$ [14,27] and $\log K_w=-13.73$[28] at 25°C and $\mu=0.5$ M, we obtain $k_2=5.1\pm0.5\times10^3 M^{-1}sec^{-1}$ and $k_{-2}=1.0\pm0.1\times10^{13}$ $M^{-1}sec^{-1}$.

Kinetics of Formation of the Mononitrilotriacetato Complex of Iron(III). Under the present experimental conditions, the formation reaction of the mononitrilotriacetato complex of iron(III) is expressed as follows:

$$Fe' + nta' \xrightarrow{k_{0(H)}} Fe(nta) \tag{11}$$

where Fe′ and nta′ denote all the species of iron(III) not combined with NTA and those of NTA not combined with iron(III), respectively. The Fe(III)–NTA complex exists as Fe(nta).[29] The rate equation of the formation of the Fe(III)–NTA complex is given by[30]

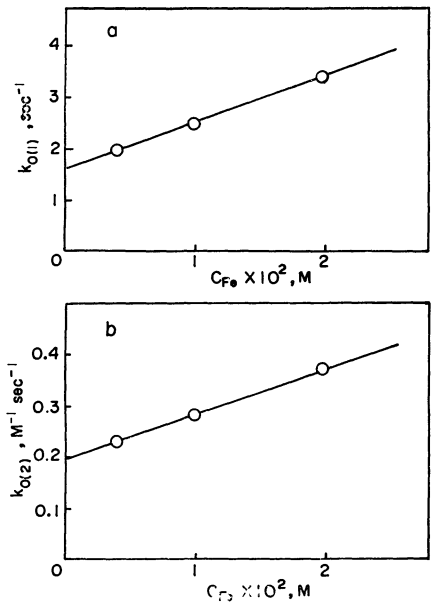

Fig. 2. Rate constants as a function of the total concentration of iron(III) ion.

30) The protolytic reactions are sufficiently rapid for these steps to be assumed to be in equilibrium at all times.

$$\frac{d[Fe(nta)]}{dt} = k_{0(H)}[Fe'][nta'] \quad (12)$$

The linearity of the second-order plot for Eq. (12) is excellent. Thus we can estimate the conditional rate constant $k_{0(H)}$ from the slope of the second-order plot. Some conditional rate constants are given in Table 2.

The rate equation seems to be expressed as follows:

$$\frac{d[Fe(nta)]}{dt} = k_1[Fe^{3+}][H_2nta^-] + k_2[Fe^{3+}][H_3nta] + k_3[FeOH^{2+}][H_2nta^-] + k_4[FeOH^{2+}][H_3nta]$$
$$= \frac{\frac{k_1}{K_{H_3nta}[H^+]} + k_2 + \frac{k_3K^{-H}_{FeOH}}{K_{H_3nta}[H^+]^2} + \frac{k_4K^{-H}_{FeOH}}{[H^+]}}{\left(1+\frac{K^{-H}_{FeOH}}{[H^+]}\right)\left(1+\frac{1}{K_{H_3nta}[H^+]}\right)}[Fe'][nta'] \quad (13)$$

where

$$[Fe'] = [Fe^{3+}] + [FeOH^{2+}] = [Fe^{3+}]\left(1+\frac{K^{-H}_{FeOH}}{[H^+]}\right)$$

$$[nta'] = [H_3nta] + [H_2nta^-] = [H_3nta]\left(1+\frac{1}{K_{H_3nta}[H^+]}\right)$$

with $K_{H_3nta}=[H_3nta]/[H_2nta^-][H^+]=10^{1.9}$.[31] Therefore the conditional second-order rate constant $k_{0(H)}$ has the following relationship.

$$k_{0(H)}\left(1+\frac{K^{-H}_{FeOH}}{[H^+]}\right)\left(1+\frac{1}{K_{H_3nta}[H^+]}\right) = k_2 + \left(\frac{k_1}{K_{H_3nta}} + k_4K^{-H}_{FeOH}\right)\frac{1}{[H^+]} + \frac{k_3K^{-H}_{FeOH}}{K_{H_3nta}}\frac{1}{[H^+]^2} \quad (14)$$

Logarithm of the value of the left side of Eq. (14) is plotted against $-\log [H^+]$ in Fig. 3. The plot gives a straight line with a slope of two. This means that under the present experimental conditions the formation of the Fe(III)–NTA complex proceeds through the reaction of $FeOH^{2+}$ and H_2nta^-. We estimated the value of k_3 from the intercept of the straight line: $k_3=1.0\pm0.2\times10^5$ $M^{-1}sec^{-1}$ at 25°C and 0.5 M ionic strength.

Discussion

The kinetic behavior of the reactions in the present study is compared with the behavior predicted by the current general mechanism for metal-ligand complex formation as formulated by Eigen (Eigen mechanism),[32,33] which accounts for most kinetic data on the formation of complexes.

Values of k_1 and k_2 are given in Table 3 together with the corresponding values reported by other authors. The rate constants are in reasonable agreement with some previous kinetic results, the difference in conditions being taken into consideration.

The straight line represents the theoretical straight line with a slope of two.

According to the Eigen mechanism, the complex formation reaction involves the fast formation of an outer-sphere complex followed by the substitution of a water molecule coordinated to the metal ion. Therefore the iron(III) complex formation can be depicted as follows:

$$Fe(H_2O)_6^{3+} + X^- \overset{K_{os}}{\rightleftharpoons} Fe(H_2O)_6^{3+}\cdots X^- \overset{k_w}{\longrightarrow} FeX(H_2O)_5^{2+} + H_2O \quad (15)$$

TABLE 3. VALUES OF RATE CONSTANTS AT 25°C FOR THE REACTIONS OF Fe^{3+} AND $Fe(OH)^{2+}$ WITH SCN^-

k_1, $M^{-1}sec^{-1}$	k_2, $M^{-1}sec^{-1}$	Reference
127±10	$1.0\pm0.1\times10^4$	Ref. 9[a]
150±50		Ref. 3
90± 5	$5.1\pm0.5\times10^3$	This work

a) $\mu=0.4$ M

$$FeOH(H_2O)_5^{2+} + X^- \overset{K_{OS(OH)}}{\rightleftharpoons} FeOH(H_2O)_5^{2+}\cdots X^- \overset{k_{w(OH)}}{\longrightarrow} FeX(H_2O)_5^{2+} + OH^- \quad (16)$$

where K_{OS} is the equilibrium constant for outer-sphere association and k_w is the first-order rate constant for the rate-determining water substitution. According to the above mechanism, the second-order rate constant obtained is equal to $K_{OS}k_w$. The rate for the reaction of $FeOH(H_2O)_5^{2+}$ is higher than that of $Fe(H_2O)_6^{3+}$. As pointed out in the formation of nickel(II) complexes,[34] it is understandable that the electron donation from hydroxide ion makes the dissociation of coordinated water molecules from $FeOH(H_2O)_5^{2+}$ faster than from the aquo ferric ion.

The combination of H^+ and OH^- is the fastest reaction possible in aqueous solution. The rate constant has been measured as 1.4×10^{11} $M^{-1}sec^{-1}$ at 25°C, a value corresponding to the theoretical limit for the rate of a chemical reaction (diffusion-controlled processes).[35] The value of the rate constant k_{-2} of the reaction of $FeNCS^{2+}$ with OH^- is 1.0×10^{13} $M^{-1}sec^{-1}$ which is greater by more than one order of magnitude than the rate constants for diffusion-controlled reactions.[36] This seems to suggest that the reaction proceeds through the mixed-ligand complex $Fe(OH)(NCS)^+$ involving OH^- and SCN^-, that is,

$$FeNCS(H_2O)_5^{2+} + H_2O \overset{K^{-H}_{Fe(OH)(NCS)}}{\longleftrightarrow} Fe(OH)(NCS)(H_2O)_4^+ + H_3O^+ \quad (17)$$

$$Fe(OH)(NCS)(H_2O)_4^+ \overset{k'_{-2}}{\longrightarrow} FeOH(H_2O)_5^{2+} + SCN^- \quad (18)$$

Thus we have the relationship

$$k_{-2} = K^{-H}_{Fe(OH)(NCS)}k'_{-2}/K_w \quad (19)$$

The hydrolysis constant of $FeNCS^{2+}$ was measured by Lister and Rivington: $[Fe(OH)(NCS)^+][H^+]/[FeNCS^{2+}]=6.5\pm1\times10^{-5}$ at 25°C and $\mu=1.2$.[37] Assuming that the value of $K^{-H}_{Fe(OH)(NCS)}$ is $10^{-4.2}$, we have estimated $k'_{-2}=10^{3.5}$, which is about 1000 times larger than the value of the rate constant k_{-1} for the dissociation of $FeNCS^{2+}$. The dissociation of SCN^- from $Fe(OH)(NCS)(H_2O)_4^+$ seems to be facilitated by the electron donation from OH^- to a greater extent than that from H_2O in $FeNCS(H_2O)_5^{2+}$. This is understood in the same way as in the complex formation where k_2 is greater than k_1.

From the results of the iron(III) complex formation (Eigen mechanism), it is expected that the rate constant for the reaction of $FeOH^{2+}$ with SCN^- is the same as for the reaction of $FeOH^{2+}$ with H_2nta^-, as the charge of reacting ligands is the same. In effect the value of the rate constant for H_2nta^- is 20 times greater than that for SCN^- which is approximately equal to the theoretical value expected from the Eigen mechanism. The enhanced rate for H_2nta^- can be accounted for in terms of the internal conjugate base mechanism proposed by Rorabacher.[38] To account for abnormality of the reaction of nickel ion with polyamines, he proposed a modification of the Eigen mechanism wherein a basic donor atom of a reacting multidentate ligand forms a hydrogen-bond to a coordinated water molecule, thereby stabilizing the outer-sphere complex and labilizing subsequent water loss.

Hydroxo group of $FeOH^{2+}$ is basic and H_2nta^- is acid. Thus the hydrogen-bond would be formed between $FeOH^{2+}$ and H_2nta^- thereby stabilizing more effectively the $FeOH^{2+}\cdots H_2nta^-$ outer-sphere complex than the $FeOH^{2+}\cdots SCN^-$ outer-sphere complex.

A similar enhancement of rate constants for the formation of iron(III) complexes has been observed in the formation of iron(III) complexes with some substituted malonic acids (HL). The rate constants for the reaction ($FeOH^{2+}+HL^-$) are 1.3×10^5, 1.2×10^5, 1.0×10^5, 1.0×10^5, 1.1×10^5 $M^{-1}sec^{-1}$ at 25°C and $\mu=0.5$ M for malonic, methylmalonic, *n*-butylmalonic, benzylmalonic, and cyclobutane-1,1-dicarboxylic acids, respectively.[18] It is understandable that larger values of rate constants in these reactions are due to the formation of hydrogen-bond between $FeOH^{2+}$ and HL^-.

Nickel(II), Cobalt(II), Palladium(II) and Beryllium(II) Chelates of 2,4,6-Heptanetrione[1]

Fumio SAGARA,* Hiroshi KOBAYASHI, and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received July 6, 1972)

Divalent metal chelates of heptane-2,4,6-trione (H_2daa) were synthesized and their structures were discussed. Nickel(II), cobalt(II) and palladium(II) ions gave Ni(Hdaa)$_2\cdot 2H_2O$, Ni_2(daa)$_2\cdot 4H_2O$, Ni_2(daa)$_2\cdot$4Py, Co(Hdaa)$_2\cdot 2H_2O$, Co_2(daa)$_2\cdot 4H_2O$, Co_2(daa)$_2\cdot$4Py, Pd(Hdaa)$_2$ and Pd(Hdaa)$_2\cdot 2H_2O$ respectively, while beryllium(II) ion unexpectedly gave bis(2-amino-2-heptene-4,6-dionato)beryllium(II) which resulted from an amino-derivative of the original ligand. Spectroscopic results suggested that the coordination structure of nickel(II) and cobalt(II) ions was octahedral hexacoordinate, that of palladium(II) ion square planar tetracoordinate and that of beryllium(II) ion tetrahedral tetracoordinate. NMR study of the palladium(II) chelate suggested partial enolization of an uncoordinated carbonyl group. It was also found that nickel, cobalt and platinum ions promoted catalytically the bimolecular-condensation of heptane-2,4,6-trione.

In previous papers we have reported on the syntheses and keto-enol tautomerism of heptane-2,4,6-trione (H_2daa) and its methylated derivatives,[2] and also on the properties and structures of their copper(II) chelates.[3] The characteristic feature of this particular β,δ-triketone is that the planar ligand behaves as either monobasic bidentate ligand or dibasic terdentate ligand depending upon the conditions of reaction as well as the kind of metal ion involved. Thus it is of interest to see how heptane-2,4,6-trione reacts with divalent metal ions of various coordination structures. This paper reports on the syntheses, and on the structures of palladium(II), nickel(II), cobalt(II) and beryllium (II) chelates of heptane-2,4,6-trione.

Experimental

Apparatus and Procedure. All the melting points were not corrected. NMR spectra were recorded on a Varian A-60, using tetramethylsilane as an internal reference. Spectral measurements in infrared and visible regions, and thermogravimetric analyses were carried out as described previously.[3]

Synthesis of the Chelates. a) Palladium Chelates. Bis(heptane-2,4,6-trionato)palladium(II). [*Pd(Hdaa)$_2$*]: In 50 ml of methanol were dissolved 0.30 g (0.0017 mol) of palladium(II) chloride and 3.0 g (0.021 mol) of heptane-2,4,6-trione, and the mixture was kept standing overnight at room temperature. The resulting yellow powdery precipitates were collected by filtration, and the product was purified through a silica gel column (Wakogel *Q*-23) in the form of a chloroform solution. Yield 0.12 g (18% from palladium chloride).

Found: C, 42.81; H, 4.76%. Calcd for $C_{14}H_{18}O_6Pd$: C, 43.26; H, 4.67%.

Bis(heptane-2,4,6-trionato)palladium(II) Dihydrate. [*Pd(Hdaa)$_2\cdot 2H_2O$*]. To 300 ml of tetrahydrofuran was added 0.30 g (0.0017 mol) of palladium chloride and the mixture was stirred at room temperature for 3 days to give a clear solution. To this was added 3.0 g(0.021 mol) of heptane-2,4,6-trione, and the pH of the solution was adjusted to 4 (on pH indicator paper) with aqueous ammonia. After being refluxed for 4—5 hr, the solution was kept standing overnight at room temperature to give yellow powdery precipitates. The product was recrystallized from tetrahydrofuran. Yield 0.30 g (42% from palladium chloride).

Found: C, 40.08; H, 5.15%. Calcd for $C_{14}H_{18}O_6Pd\cdot 2H_2O$: C, 39.59; H, 5.22%.

b) Nickel Chelates. Bis(heptane-2,4,6-trionato)nickel(II) Dihydrate. [*Ni(Hdaa)$_2\cdot 2H_2O$*]. *Procedure A*: To 30 ml of an ether solution containing 2.80 g(0.0197 mol) of heptane-2,4,6-trione was added 0.30 g (0.0011 mol) of anhydrous bis(acetylacetonato)nickel(II), and the clear solution was left for 1 hr at room temperature to give blue powdery precipitates. The product was collected by filtration, washed with ether and air-dried. Yield 0.17 g (39% from the nickel acetylacetonate).

Found: C, 44.60; H, 6.01; Ni, 15.57%. Calcd for $C_{14}H_{18}O_6Ni\cdot 2H_2O$: C, 44.60; H, 5.88; Ni, 15.57%. $\bar{\nu}_{max}$ in 95% methanol (ε): 15.8 (6.3), 13.6 (shoulder) (2.9), and 9.3 kK (5.7). $\bar{\nu}_{min}$: 19.2 (0.9) and 12.2 kK (1.4).

Procedure B: A mixture of 0.98 g (0.0021 mol) of bis-(heptane-2,4,6-trionato)dinickel(II) tetrahydrate and 3.0 g (0.021 mol) of heptane-2,4,6-trione was carefully warmed at 55—60°C (slightly above the melting point of the ligand, mp 42.5—43.5°C). The green molten paste was kept at this temperature for 90 min with occasional stirring. After the reaction, 100 ml of ether was added portionwise to this reaction mixture to precipitate the pale green nickel chelate. Excess ligand was removed by filtration. The product was finally washed with ether and air-dried and was identified by IR spectral comparison with the nickel chelate obtained by procedure A. Yield 0.68 g (43% from the 2 : 2 nickel chelate)

Bis(heptane-2,4,6-trionato)dinickel(II) Tetrahydrate. [*Ni$_2$(daa)$_2\cdot 4H_2O$*]. *Procedure A*: To 50 ml of methanol was added 1.0 g (0.007 mol) of heptane-2,4,6-trione and 2.0 g (0.0069 mol) of nickel(II) nitrate hexahydrate, and pH of the solution was adjusted to about 7 with aqueous methanolic ammonia (1 : 1 by volume) to give bright green powdery precipitates. The product was collected by filtration, washed with water and dried under reduced pressure. Yield 1.5 g (93%).

The sample thus obtained is fairly soluble in various organic solvents such as methanol, chloroform and tetrahydrofuran. Recrystallization from methanol gave green crystallites. Thermogravimetric analysis on the recrystallized chelate showed 16% of weight decrease in the region between 100 and 160°C, which corresponded to the loss of four molecules of water (Calcd as a tetrahydrate: 15.3%).

Found: C, 35.10; H, 5.22; Ni, 25.03%. Calcd for C_{14}-

3) F. Sagara, H. Kobayashi, and K. Ueno, *ibid.*, **45**, 794 (1972).

$H_{16}O_6Ni_2 \cdot 4H_2O$: C, 35.80; H, 5.15; Ni, 25.00%.

$\bar{\nu}_{max}$ in 95% methanol (ε): 24.1 (shoulder) (530), 16.8 (16), 13.7 (shoulder) (11) and 10.0 kK (15). $\bar{\nu}_{min}(\varepsilon)$: 17.7 (13) and 12.2 kK (8.8).

Procedure B: A methanol solution (3 ml) containing 1.0 g (0.0027 mol) of bis(heptane-2,4,6-trionato)nickel(II) dihydrate was heated at 50°C for 30 min, to give blue powdery precipitates. The product was collected by filtration, washed with ether and air-dried. Yield 0.42 g (66%). The nickel chelate was found to be identical with the sample obtained by procedure A by infrared spectral comparison.

Pyridine Adduct of Bis(heptane-2,4,6-trionato)dinickel(II). [$Ni_2(daa)_2 \cdot 4Py$]. *Procedure A*: A mixture of 2.0 g (0.0043 mol) of bis-(heptane-2,4,6-trionato)dinickel(II) tetrahydrate and 50 ml of pyridine was stirred for several hours, and the resulting blue powdery precipitates were collected by filtration and air-dried. Yield 1.0 g (33%).

The pyridine adduct is fairly soluble in various organic solvents and can be recrystallized from methanol. Thermogravimetric analysis showed 44% weight decrease in the range 90—140°C, which indicated the loss of four pyridine molecules (Calcd: 44.2%).

Found: C, 57.12; H, 5.04; N, 8.16; Ni, 16.44%. Calcd for $C_{14}H_{16}O_6Ni_2 \cdot 4(C_5H_5N)$: C, 57.19; H, 5.08; N, 7.85; Ni, 16.44%.

Procedure B: To a hot solution of 490 mg (0.001mol) of bis(heptane-2,4,6-trionato)dinickel(II) tetrahydrate in 100 ml of methanol was added 100 ml of pyridine at 60°C. The green solution was kept at this temperature for 2 hr, when a small amount of glittering flaky precipitate was obtained. The solution was allowed to cool to room temperature for 3 hr. The resulting precipitate was collected by filtration and washed with a small amount of chilled methanol and air-dried. Yield 390 mg (52%). IR spectral comparison showed that the flaky product was identical with the powdery pyridine adduct from procedure A.

c) Cobalt Chelates. Bis(heptane-2,4,6-trionato)cobalt(II) Dihydrate. [$Co(Hdaa)_2 \cdot 2H_2O$]: A mixture of 0.67 g (0.0014 mol) of bis(heptane-2,4,6-trionato)dicobalt(II) tetrahydrate and 2.0 g (0.014 mol) of heptane-2,4,6-trione was treated at 52—54°C for an hour in a similar manner to that in procedure B for preparation of the 1 : 2 nickel chelate. The product was light pink powder. Yield 0.62 g (58% from the 2 : 2 cobalt chelate).

Found: C, 44.52; H, 6.09%. Cacld for $C_{14}H_{18}O_6Co \cdot 2H_2O$: C, 44.57; H, 5.88%.

When the dihydrate was dried at room temperature in a vacuum (0.3—0.4 mmHg) for a few hours, it turned from light pink to pink, affording a dehydrated product whose composition was found to be $C_{14}H_{18}O_6Co \cdot 1/4H_2O$ by elemental analysis.

Bis(heptane-2,4,6-trionato)dicobalt(II) Tetrahydrate. [$Co_2(daa)_2 \cdot 4H_2O$]. The 2 : 2 chelate was synthesized according to procedures essentially similar to those described for the 2 : 2 nickel chelate, either procedure A or B.

The 2 : 2 cobalt(II) chelate was obtained as brown powder from 2.5 g (0.018 mol) of heptane-2,4,6-trione and 5.13 g (0.018 mol) of cobalt(II) nitrate hexahydrate in methanol-water at 55—60°C with the final pH values 6—8. Yield 2.9 g (70%).

Thermogravimetric analysis on the tetrahydrate chelate revealed that a gradual weight loss due to four moles dehydration took place from room temperature to 180°C, leaving an anhydrous chelate $Co_2(daa)_2$ which decomposed spontaneously at 235°C.

Found: C, 35.94; H, 5.09; Co, 25.2%. Calcd for $C_{14}H_{16}O_6Co_2 \cdot 4H_2O$: C, 35.76; H, 5.15; Co, 25.07%.

The same 2 : 2 chelate was obtained by refluxing a methanol solution of bis(heptane-2,4,6-trionato)cobalt(II) dihydrate.

Pyridine Adduct of Bis(heptane-2,4,6-trionato)dicobalt(II). [$Co_2(daa)_2 \cdot 4Py$]. One gram of 2 : 2 cobalt chelate (tetrahydrate) was dissolved in a methanol-pyridine mixture, and the clear solution was concentrated by evaporation to give yellow brown crystalline precipitates. The product was collected by filtration and dried over phosphorus pentoxide and activated charcoal at room temperature under reduced pressure. Yield 1.2 g (80%).

Found: C, 56.46; H, 5.05; N, 7.76%. Calcd for $C_{14}H_{16}O_6Co_2 \cdot 4(C_5H_5N)$: C, 57.19; H, 5.08; N, 7.84%.

d) Beryllium Chelate. Bis(2-amino-2-heptene-4,6-dionato)beryllium(II). [$Be(aho)_2$]: Beryllium nitrate trihydrate (1.5 g, 0.008 mol) dissolved in ethanol (10 ml) was added to an ethanol solution (20 ml) of heptane-2,4,6-trione (2.31 g, 0.0163 mol) at 40°C. To the resulting pale pink solution was added 12 ml of a mixture of ethanol–aqueous ammonia (1 : 1 by volume) at 30—40°C and the solution was stirred for 10 min. After being left standing for an additional 40 min, the resulting pale yellow crystalline precipitates were collected by filtration and recrystallized from acetonitrile. Yield 1.73 g(75%). The product was found to be a 1 : 2 beryllium chelate of 2-amino-2-heptene-4,6-dione which resulted from the amination of terminal carbonyl oxygen of heptane-2,4,6-trione.

Found: C, 58.13; H, 6.97; N, 9.54%. Calcd for $C_{14}H_{20}O_4N_2Be$: C, 58.12; H, 6.97; N, 9.68%.

Results and Discussion

Synthetic Conditions of the Chelates. The 2 : 2 chelates of nickel(II) and cobalt(II) can be synthesized by procedures similar to those employed in the synthesis of bis(heptane-2,4,6-trionato)dicopper(II), either by subjecting the corresponding metal ion to the reaction with an equimolar amount of heptane-2,4,6-trione in methanol at pH about 7, or by heating a methanol solution of the corresponding 1 : 2 chelate.[3] The nickel(II) and cobalt(II) chelates were obtained as tetrahydrates.

On the other hand, the 2 : 2 chelate of palladium (II) could not be obtained despite our efforts to employ various reaction conditions including those mentioned above. The chelate obtained from the reaction mixtures was always 1 : 2 palladium(II) chelate, anhydrous or dihydrate, depending upon the reaction conditions. The main reason for the difficulty of forming a 2 : 2 palladium(II) chelate could be understood to be due to the larger ionic size of palladium(II) ion than that of copper(II), nickel(II) or cobalt(II) ion. Palladium(II) ion can hardly be accomodated in the binuclear centers of the 2 : 2 chelate.

It is interesting to note that the 1 : 2 palladium(II) chelate can be obtained in a dihydrate form as well as in an anhydrous form, while the chelates of copper(II), nickel(II) and cobalt(II) are obtained only in a dihydrate form. The dehydration of the latter chelates, even at reduced pressure and at lower temperature, always resulted in rearrangement into the corresponding 2 : 2 chelates. The relative stability of 1 : 2 palladium(II) chelate in an anhydrous form might be con-

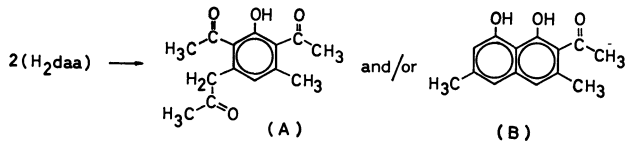
a) Products A and B melted at 113 and 182°C, respectively. They were identified with the reported compounds by their melting points and elemental analyses. A. J. Birch, D. W. Cameron, and R. W. Rickards, *J. Chem. Soc.*, **1960**, 4395.

nected with the difficulty of forming 2 : 2 chelate as discussed above.

In the case of beryllium chelate, the use of ammonia to adjust the pH of reaction medium resulted in the amination of terminal carbonyl group in heptane-2,4,6-trione, so that only 1 : 2 chelate of the amino derivative was obtained. Attempts to obtain a 2 : 2 beryllium(II) chelate using various reaction conditions were unsuccessful.

In contrast to the relative easiness of obtaining 2 : 2 chelates with nickel(II) and cobalt(II), the corresponding 1 : 2 chelates could not be obtained by the standard procedures which were employed in the synthesis of 1 : 2 copper(II) chelate. During the course of an investigation on the synthesis of 1 : 2 chelates of nickel (II) and cobalt(II), it was found that the bimolecular condensation of heptane-2,4,6-trione was accelerated in the presence of 2 : 2 nickel or cobalt chelate according to the following reaction scheme.



Scheme 1.

A similar effect was also observed with platinum(II) salt, but neither copper(II) ion nor copper(II) chelate was effective for promoting such condensation reactions. When pure heptane-2,4,6-trione was heated above its melting point, no cyclized condensation product has obtained. However, when an excess of the ligand was brought into contact with such metal chelates, especially at an elevated temperature, the cyclized product A or B was obtained in the reaction mixture depending upon the condition of reaction. Table 1 summarizes the result.

Thus, when nickel(II) or cobalt(II) ion was allowed to react with excess heptane-2,4,6-trione with the purpose of obtaining a 1 : 2 chelate, the reaction products were always a 2 : 2 chelate and cyclized by-products but no 1 : 2 chelate. Accordingly, the 1 : 2 chelates had to be prepared by the ligand exchange reaction between a bis(acetylacetonato)-metal chelate and heptane-2,4,6-trione in anhydrous ether, or by the reaction between 2 : 2 metal chelates and molten heptane-2,4,6-trione at a temperature slightly above its melting point.

Structures of Nickel(II)- and Cobalt(II) Chelates. The infrared spectra of 1 : 2 chelates of nickel(II) and cobalt(II), [$Ni(Hdaa)_2.2H_2O$ and $Co(Hdaa)_2.2H_2O$], show characteristic bands in 3000—3400 cm^{-1} and 1500—1700 cm^{-1} regions. A broad band with a maximum at 3280 cm^{-1} for the nickel- and 3400 cm^{-1} for the cobalt chelates can be assigned to the hydrated water. This makes a sharp contrast with those observed in the 1 : 2 copper(II)- and palladium(II) dihydrate chelates, where a sharp band at 3530 cm^{-1} and a multiplet weak band with maxima at about 3420, 3350 and 3260 cm^{-1} appear. The broad band of 1 : 2 nickel(II)- and cobalt(II) chelates suggests a rather strong coordination of water molecules to the central metal ion along the z axis, while the ligand molecules coordinate along the x—y plane. On the other hand, a multiplet band with fine structure of 1 : 2 copper(II) and palladium(II) chelates indicates the weaker interaction of hydrated water molecules with metal ion.

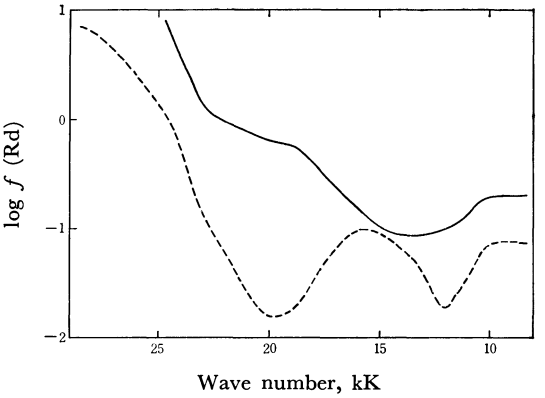


Fig. 1. Diffuse reflectance spectra of $Ni(Hdaa)_2 \cdot 2H_2O$ (-----) and $Co(Hdaa)_2 \cdot 2H_2O$ (——).

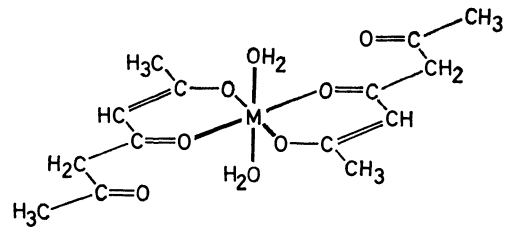
In the 1500—1700 cm^{-1} region, there are observed a sharp band at 1720 cm^{-1} for the nickel(II)- and 1695 cm^{-1} for the cobalt(II) chelates and a strong band with several shoulders at 1500—1600 cm^{-1} for the both chelates. These bands can be assigned to an uncoordinated carbonyl group and a coordinated carbonyl group in conjugated chelate ring system respectively as in the case of 1 : 2 copper(II) chelate.

The power reflectance spectra of the 1 : 2 chelates of nickel(II) and cobalt(II) are shown in Fig. 1. In the case of $Ni(Hdaa)_2.2H_2O$, two broad bands at 9300 and 15800 cm^{-1} with a shoulder at 25000 cm^{-1} were observed, and in the case of $Co(Hdaa)_2.2H_2O$, a band at 19000 cm^{-1} and a broad band at 9000—9500 cm^{-1} were observed. These spectra are found to be very much similar to those of bis(acetylacetonato)nickel-

(II) dihydrate[4] or -cobalt(II) dihydrate[5] respectively. These results strongly suggest the octahedral coordination structure around the central metal ion for both 1 : 2 chelates as proposed in structure I.



Structure I. M=Ni(II) or Co(II).

As to the 2 : 2 chelates of nickel(II) and cobalt(II), [$Ni_2(daa)_2.4H_2O$ and $Co_2(daa)_2.4H_2O$], infrared spectra were characterized with a broad band at 3200—3400 cm^{-1} and a band with shoulders at 1500—1600 cm^{-1}, which could be assigned to hydrated water and coordinated carbonyl groups in the conjugated chelate ring system, respectively. Absence of a band due to the uncoordinated carbonyl groups indicates that all carbonyl groups are involved in the coordination to the metal ions.

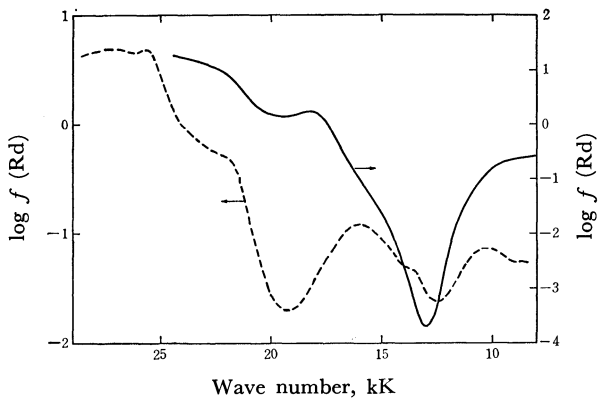


Fig. 2. Diffuse reflectance spectra of $Ni_2(daa)_2 \cdot 4H_2O$ (----) and $Co_2(daa)_2 \cdot 4H_2O$ (——).

The solid reflectance spectra of these hydrated chelates in visible region are shown in Fig. 2. They show two bands at 10400 and 16000 cm^{-1} with shoulders at 13500 and 22000 cm^{-1} for nickel(II) chelate, and a single band at 18200 cm^{-1} with shoulders at 9000 and 23000 cm^{-1} for cobalt(II) chelate. The results suggest that the coordination structure around nickel(II) or cobalt(II) ion is also octahedral.

The molecular weight of anhydrous 2 : 2 nickel(II) chelate in methanol, determined by the vapor pressure osmometer, was found to be 410 which is close to the calculated value of 397.7 for $Ni_2(daa)_2$. Consideation of these observations leads to the conclusion that the structures of $Ni_2(daa)_2.4H_2O$ and $Co_2(daa)_2.4H_2O$ can be assigned to structure II, in which four molecules of hydrated water coordinate to the central metal ions along the z axis.

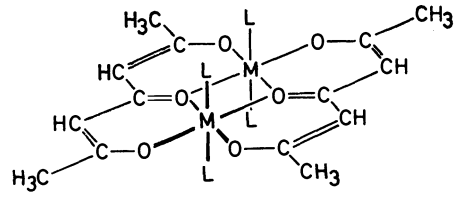
5) F. A. Cotton and R. H. Soderberg, *Inorg. Chem.*, **3**, 1 (1964).



Structure II. M=Ni(II) or Co(II), L=H_2O or Pyridine.

Pyridine Adducts of 2 : 2 Chelates. Coordinated water in 2 : 2 nickel- and cobalt(II) chelates can easily be replaced by pyridine, affording the pyridine adducts having the formula $M_2(daa)_2.4Py$, where M denotes Ni(II) or Co(II).

The absence of infrared absorption band due to free carbonyl group at around 1700 cm^{-1} indicates that the coordination structure of heptane-2,4,6-trione remained intact and the addition of pyridine merely caused the replacement of coordinated water with pyridine.

The solid reflectance spectra of pyridine adducts in visible region shown in Fig. 3 are characterized by two

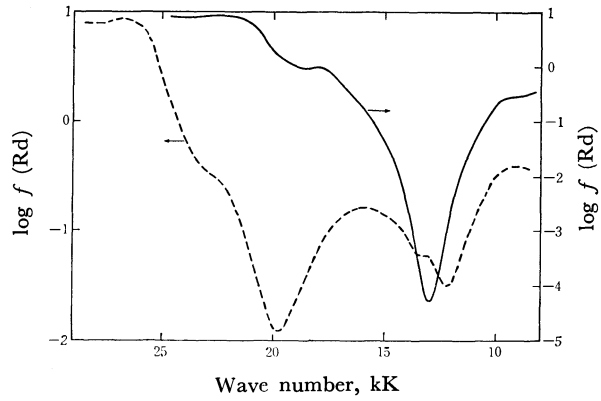


Fig. 3. Diffuse reflectance spectra of $Ni_2(daa)_2 \cdot 4Py$ (----) and $Co_2(daa)_2 \cdot 4Py$ (——).

broad bands at 9200 and 16000 cm^{-1} and shoulders at 13000 and 22500 cm^{-1} for nickel(II) chelate and at 9000, 18200 and 22000 cm^{-1} for cobalt(II) chelate, indicating the octahedral hexacoordinate structure around nickel(II) or cobalt(II) ion as shown in structure II.

Thermogravimetric analysis of the pyridine adducts as well as hydrates of 2 : 2 chelates revealed that pyridine or water dissociated above 90°C, leaving anhydrous 2 : 2 chelates.

Structure of Palladium(II) Chelate. The 1 : 2 palladium(II) chelate could be obtained either as dihydrate or anhydrous form. Infrared absorption spectrum of the anhydrous sample was characterized with a weak multiplet band at 3400 cm^{-1} region, a sharp strong band at 1730 cm^{-1} due to uncoordinated carbonyl groups, and complex bands in 1500—1600 cm^{-1} region due to coordinated carbonyl groups conjugated with olefinic chelate ring.

The NMR spectrum of the anhydrous chelate in $CDCl_3$ (1.0 M solution) is shown in Fig. 4. Peaks at δ=2.12, 2.24, 3.42 and 5.47 ppm can be assigned to methyl(a), methyl(b), methylene(c) and methine(d)

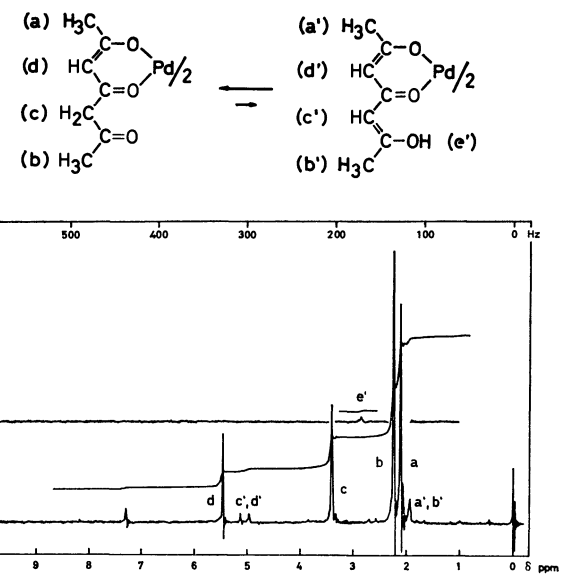

Fig. 4. NMR spectrum of the 1 : 2 palladium chelate and its tautomers. Assignments of the NMR peaks correspond to the protons indicated by alphabetical letters in the above structural formulae.

protons, respectively. However, weak peaks are also observed at $\delta=1.93$, 4.97, 5.13 and 11.85 ppm. If we consider the partial enolization of uncoordinated carbonyl groups, these weak peaks can be reasonably assigned to the protons of enolized chelate as indicated in Fig. 4.

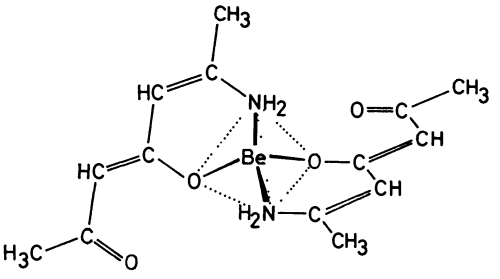
Thus the weak multiplet infrared absorption band at 3400 cm^{-1} region can also be assigned to the enol hydroxyl group. The relatively weak intensity of the signals due to the enolic isomer, in the infrared and NMR spectra, indicates that the extent of enolization in the 1 : 2 palladium(II) chelate is rather small.

Thus, the anhydrous 1 : 2 palladium(II) chelate $Pd(Hdaa)_2$ can be assigned to structure I, but with no water. As to dihydrate chelate $Pd(Hdaa)_2 \cdot 2H_2O$, the most probable structure is I, with water molecules weakly coordinated to palladium(II) ion along z axis.

Structure of Beryllium(II) Chelate. Despite our effort to obtain a 1 : 2 beryllium(II) chelate of heptane-2,4,6-trione by the reaction of beryllium(II) ion with free ligand in an ethanol–ammonia medium, a 1 : 2 beryllium chelate of 2-amino-2-heptene-4,6-dione was obtained unexpectedly.

The result of elemental analysis indicates that it is a 1 : 2 chelate of monoamino derivative of heptane-2,4,6-trione. Two sharp infrared absorption bands at 3390 and 3300 cm^{-1}, which appeared at a relatively lower frequency region than usual primary amines, suggest that the primary amino group may coordinate to beryllium(II) ion.[6] Other characteristic bands at 1635 and 1525 cm^{-1} may be assigned to uncoordinated and coordinated carbonyl groups, respectively, though the frequency of the former band is slightly lower than that expected for α,β : γ,δ-unsaturated ketones.

Although there is no positive evidence, structure III is most likely to be assigned to bis(2-amino-2-heptene-4,6-dionato)beryllium(II) based on the following observations.



Structure III.

When acetylacetone was brought into reaction with beryllium(II) ion in the presence of ammonia, only bis(acetylacetonato)beryllium(II) was obtained. When 2-methoxy-2-heptene-4,6-dione[3] was brought into reaction with beryllium(II) ion in the presence of ammonia, the product was bis(2-methoxy-2-heptene-4,6-dionato)beryllium(II). Thus, the amination seems to be characteristic to β,δ-triketones. It does not proceed on β-diketones nor β,δ-triketones in which the terminal carbonyl group is fixed in the form of an enol ether. Thus, it is reasonable to assume that the chelation occurs between heptane-2,4,6-trione and beryllium(II) ion to give bis(heptane-2,4,6-trionato)-beryllium(II) as an intermediate product, which in turn reacts with ammonia to afford 2-amino-2-heptene-4,6-dionato chelate. When heptane-2,4,6-trione reacts with ammonia in the absence of metal ion, it is known that amination occurs on the terminal carbonyl group, affording 2,6-dimethyl-4-pyridone as a cyclization product.[7] Thus, it is likely that amination occurs on the chelated ligand but not on the free ligand, and that the position of amination may be on the terminal carbonyl group. As regards whether the 1 : 2 beryllium chelate is an O,O-coordinated structure with the amino group uncoordinated, or the rearrangement occurs after amination resulting in an O,N-coordinated structure with the carbonyl group uncoordinated, the latter seems probable. This is supported by the fact that 2-amino-2-heptene-4,6-dione is stable only in the form of beryllium chelate, and attempts to recover the free aminated ligand from the beryllium(II) chelate were unsuccessful, only giving the original heptane-2,4,6-trione. Therefore, the amino group might be protected by the coordination to the metal ion.

The authors are grateful to the Ministry of Education for financial support. They also thank Messrs. Isao Yoshida, Toshiaki Kozaki and Shizuhiko Honkawa for their assistance.

Calmagite:[1] The Formation Constants of Zinc(II) Chelates and Its Use as a Metal Indicator

Genkichi NAKAGAWA, Hiroko WADA, and Yoshio FUJITA

Nagoya Institute of Technology, Showa-ku, Nagoya

(Received July 12, 1972)

The acid dissociation constants of Calmagite [1-(2-hydroxy-5-methylphenylazo)-2-naphthol-4-sulfonic acid] and the formation constants of zinc(II) chelates have been determined spectrophotometrically at 25°C and at the ionic strengths of 0.1 and 1.0. In an ammoniacal medium zinc forms mixed-ligand complexes with Calmagite (I^{3-}) and ammonia (X); $ZnIX_n^-$. The formation constants of the zinc(II)-Calmagite chelates are $\log K_{ZnI}=11.75$, $\log K_{ZnI_2}=7.82$, $\log K^{X}_{ZnIX}=2.09$, and $\log K^{X}_{ZnIX_2}=1.70$ ($\mu=1.0$). Calmagite is recommended as an indicator for the titration of zinc(II) with EDTA. The color transition of Calmagite is clearer and sharper, and the aqueous solution of the indicator is more stable, than in the case of Eriochrome Black T.

Eriochrome Black T has been exclusively used as a metal indicator in the complexometric titration of magnesium, zinc, cadmium, lead, etc. Lindstrom and Diehl recommended Calmagite as the metal indicator for magnesium,[2] because the aqueous solution of Calmagite is more stable than that of Eriochrome Black T. However, Calmagite has not been so much used for a metal indicator as Eriochrome Black T. Kodama and Miyamoto[3] determined the stability constants of Calmagite chelates of copper(II), nickel(II), cobalt(II), zinc(II), cadmium(II), and lead(II) by the exchange reaction of Calmagite with the metalnitrilotriacetic acid chelates and proposed the use of Calmagite as an indicator for zinc, cadmium, and lead. Their value of the stability constant of zinc-Calmagite seems, however, to be too high in comparison with that of the zinc-Eriochrome Black T chelate.

The present paper will deal with the formation of mixed-ligand complexes of zinc-Calmagite chelates in an ammoniacal medium and with the behavior of Calmagite as a metal indicator for zinc in detail.

Experimental

Reagents. *Zinc Chloride*: Zinc metal (99.999%) was dissolved in hydrochloric acid to prepare a zinc chloride solution.

Calmagite: Calmagite from the Dōjindō Co., Ltd., was purified by a procedure described by Lindstrom and Diehl.[2] The Calmagite stock solution was prepared every week and was standardized with a copper standard solution by photometric titration.

EDTA: Reagent-grade EDTA·2Na obtained from the Dōjindō Co., Ltd., was dissolved in distilled water and standardized complexometrically against a standard zinc solution.

Ammonia Solution: A reagent-grade ammonia solution was distilled, and pure ammonia was collected in distilled water. The concentration of ammonia was determined with a standard hydrochloric acid solution.

Potassium Acetate and Potassium Nitrate: Reagent-grade chemicals were purified by recrystallization.

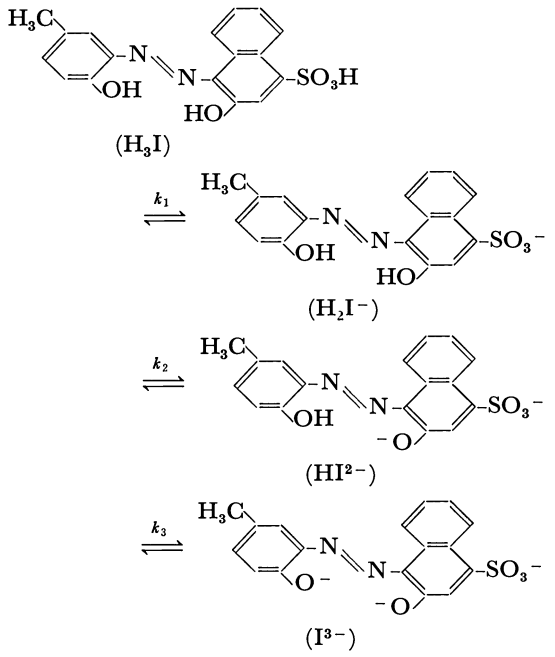
Acetic Acid, Boric Acid and Postassium Hydroxide: Reagent-grade chemicals were used without further purification.

Apparatus. A Hitachi Model 124 Double-beam Spectrophotometer, a Hitachi Model 356 Two-wavelength Double-beam Spectrophotometer, a Hitachi-Horiba pH Meter type F-5 equipped with Horiba glass and calomel electrodes, and a Hirama Automatic Recording Titrator were used.

Experimental Procedure. The ionic strength was maintained at 0.1 or 1.0 with potassium nitrate. The pH was adjusted by adding buffer solutions of potassium acetate-acetic acid, potassium hydroxide-boric acid, or ammonia-ammonium chloride. The absorbance of the solution was measured by the use of a silica cell with a light path of 1.0 cm. After measuring the absorbance, the accurate pH value was measured with a pH meter which had been calibrated with two standard buffer solutions. All the experiments were carried out at 25±1°C.

Results

The Acid Dissociation Constants of Calmagite. The dissociation of the free acid of Calmagite may be represented as follows:



The predominant species of Calmagite in the solutions of pH 2—6, pH 9—10, and pH>13 are H_2I^-, HI^{2-}, and I^{3-} respectively. The acid dissociation constants (pk_2 and pk_3) were determined by the spectrophotometric method at an ionic strength of 0.1 or 1.0. Since

1) 1-(2-Hydroxy-5-methylphenylazo)-2-naphthol-4-sulfonic acid
2) F Lindstrom and H. Diehl, *Anal. Chem.*, **32**, 1123 (1960).
3) M. Kodama and K. Miyamoto, This Bulletin, **42**, 835 (1969).

the sulfonic acid group is a strong acid, the pk_1 could not be measured. The values of pk_2 and pk_3 given in Table 2 agree well with those of Lindstrom and Diehl.

The Formation Constants of Zinc(II)-Calmagite Chelates. Calmagite forms a 1 : 1 chelate with zinc when the concentration of zinc is in a sufficient excess compared with that of Calmagite. In the vicinity of pH 6, the predominant species of the free ligand being H_2I^-, the formation of ZnI^- is expressed as follows, and the equilibrium constant is given by Eq. (1) (The charge will be omitted in the equations for the sake of simplicity):

$$Zn^{2+} + H_2I^- \overset{K}{\rightleftharpoons} ZnI^- + 2H^+$$

$$K = \frac{[ZnI][H]^2}{[Zn][H_2I]} \quad (1)$$

The absorbance of the solutions containing Calmagite and about a hundredfold excess of zinc(II) were measured at 550 nm, where the difference in absorbance between ZnI^- and H_2I^- is sufficiently large. The variation in the absorbance with the pH is shown in Table 1. From these data, the value of the equilibrium constant, K, was evaluated by means of Hildebrand-Reilley's method[4] and the formation constant, K_{ZnI}, was calculated from K and the acid dissociation constants of Calmagite, k_2 and k_3:

$$K_{ZnI} = \frac{[ZnI]}{[Zn][I]} = \frac{K}{k_2 \times k_3} \quad (2)$$

Table 1. Absorbance of 1 : 1 zinc-calmagite chelate in solutions of various pH's[a)]

pH	Absorbance at 550 nm	pH	Absorbance at 550 nm
5.89	0.670	5.22	0.594
5.59	0.652	5.09	0.579
5.46	0.627	4.89	0.555
5.35	0.609		

a) $C_{Zn} = 2.00 \times 10^{-3}$ mol/l, $C_I = 2.86 \times 10^{-5}$ mol/l, Acetate buffer, $\mu = 1.0$ (KNO_3), 25°C, Cell length 1 cm.

Zinc(II) forms a 1 : 2 chelate with Calmagite at high pH values (pH>9) in the presence of a large excess of the ligand. The absorption spectra of the solutions containing 1.00×10^{-5} mol/l of zinc and 4.00×10^{-5} mol/l of Calmagite in the pH range from 9 to 10.5 (buffered with potassium hydroxide and boric acid) are shown in Fig. 1. Curves 1 and 5 are the absorption spectra of HI^{2-} and ZnI_2^{4-} respectively. From the absorbance at 640 nm, where the difference in absorbance between the ligand and the zinc chelate is large, the total concentration of the ligand combined with the zinc can be evaluated. The absorption spectra presented by Curves 2—4 show the successive formation of ZnI^- and ZnI_2^{4-} chelates. Under these experimental conditions, the concentration of the free zinc ion is negligible and the following stoichiometric relationships hold:

$$C_{Zn} = [ZnI] + [ZnI_2] \quad (3)$$

$$C_I = [ZnI] + 2[ZnI_2] + [HI] \quad (4)$$

where C_{Zn} and C_I are the analytical concentrations of zinc and Calmagite respectively and where [HI] is the total concentration of Calmagite not combined with the zinc ion.

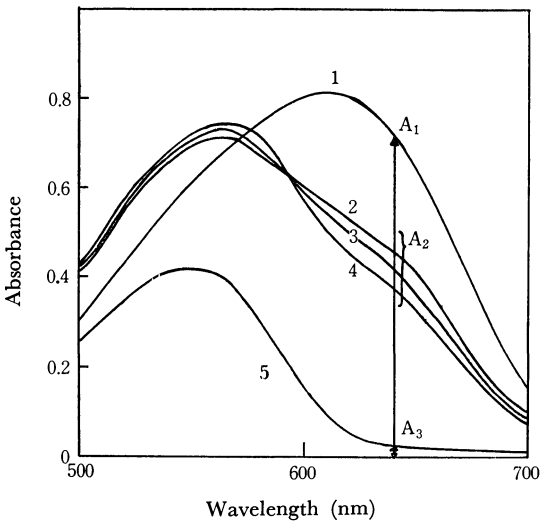


Fig. 1. Absorption spectra of zinc-Calmagite chelates.
$C_I = 4.01 \times 10^{-5}$ mol/l, $C_{Zn} = 1.00 \times 10^{-5}$ mol/l
1: Calmagite only, pH 10.10, 2: pH 9.42, 3: pH 10.02, 4: pH 10.64, 5: ZnI_2 (against reagent blank)

The [HI] values under the given conditions were calculated from the absorbances, A_1, A_2, and A_3, shown in Fig. 1. By representing the molar absorptivity of the ligand, HI^{2-}, and the chelates, ZnI^- and ZnI_2^{4-}, as ε_{HI}, ε_{ZnI}, and ε_{ZnI_2} respectively, we obtain:

$$A_1 = \varepsilon_{HI} C_I \quad (5)$$

$$A_2 = \varepsilon_{HI}[HI] + \varepsilon_{ZnI}[ZnI] + \varepsilon_{ZnI_2}[ZnI_2] \quad (6)$$

$$A_3 = \varepsilon_{ZnI_2} C_{Zn} \quad (7)$$

The absorption spectrum of the ZnI_2^{4-} chelate has same shape as that of the ZnI^- chelate, but the molar absorptivity of ZnI_2^{4-} is twice as much as that of ZnI^-:

$$2\varepsilon_{ZnI} = \varepsilon_{ZnI_2} \quad (8)$$

By combining Eqs. (4)—(8), and by disignating C_I/C_{Zn} as a, the total concentration of the free ligand is given by Eq. (9):

$$[HI] = \frac{(2A_2 - aA_3)C_I}{2A_1 - aA_3} \quad (9)$$

By substituting [HI] into Eqs. (3) and (4), we can obtain $[ZnI_2]$ and [ZnI] under the given conditions.

The successive formation constant of ZnI_2^{4-} is defined by Eq. (10):

$$K_{ZnI_2} = \frac{[ZnI_2]}{[ZnI][I]} \quad (10)$$

[I] can be calculated by means of Eq. (11):

$$[I] = [HI]k_3/[H] \quad (11)$$

A plot of $\log [ZnI_2]/[ZnI]$ *vs.* pI gave a straight line with a slope of -1, $\log K_{ZnI_2}$ was evaluated from the x-intercept.

4) G. P. Hildebrand and C. N. Reilley, *Anal. Chem.*, **29**, 258 (1957).

TABLE 2. ACID DISSOCIATION CONSTANTS AND COMPLEX FORMATION CONSTANTS OF ZINC-CALMAGITE AT 25°C

Acid dissociation constants		
pk_2	pk_3	Ionic strength
7.92	12.50	0.1 (KNO_3)
7.84	12.08	1.0 (KCl)

Complex formation constants				
$\log K_{ZnI}$	$\log K_{ZnI_2}$	$\log K^X_{ZnIX}$	$\log K^X_{ZnIX_2}$	Ionic strength
12.52	7.71			0.1 (KNO_3)
11.75	7.82			1.0 (KNO_3)
11.57		2.09	1.70	1.0 (KNO_3)

The successive formation constants, K_{ZnI} and K_{ZnI_2}, thus obtained are listed in Table 2.

The Formation of Mixed Ligand Complexes. The absorption spectra of 1 : 1 zinc-Calmagite chelates shift to longer wavelengths in an ammoniacal medium. Therefore, it is supposed that zinc may form the mixed ligand complexes, $ZnIX_n^-$, with Calmagite, I^{3-}, and with ammonia, X.

If the mixed ligand complexes are formed, the over-all formation constant of mixed ligand complexes can be defined by Eq. (12):

$$\beta_{ZnIX_n} = \frac{[ZnIX_n]}{[ZnI][X]^n} \tag{12}$$

and the total concentration of the zinc-Calmagite chelates [(ZnI)'] is given by Eq. (13):

$$[(ZnI)'] = [ZnI] + [ZnIX] + [ZnIX_2] + \cdots + [ZnIX_n] = [ZnI]\alpha_{ZnI(X)} \tag{13}$$

where:

$$\alpha_{ZnI(X)} = 1 + \sum_{n=1}^{n} \beta_{ZnIX_n}[X]^n \tag{14}$$

Since zinc ion forms ammine complexes in an ammoniacal medium, the total concentration of zinc not combined with Calmagite, [Zn'] is represented by Eq. (15):

$$[Zn'] = [Zn] + [ZnX] + [ZnX_2] + \cdots + [ZnX_m] = [Zn]\alpha_{Zn(X)} \tag{15}$$

$$\alpha_{Zn(X)} = 1 + \sum_{m=1}^{m} \beta_m[X]^m \tag{16}$$

where β_m is the over-all formation constant of zinc ammine complexes. Taking into account the protonation of Calmagite,

$$[I'] = [I]\alpha_{I(H)} \tag{17}$$

and:

$$\alpha_{I(H)} = 1 + \frac{[H]}{k_3} + \frac{[H]^2}{k_2k_3} \tag{18}$$

The conditional formation constant of the zinc-Calmagite chelate is given by Eq. (19)

$$K_{Zn'I'(ZnI)'} = \frac{[(ZnI)']}{[Zn'][I']} \tag{19}$$

The experiments were carried out under the conditions where $C_I=3.6\times10^{-5}$ mol/l, $C_{Zn}=6.5\times10^{-5}$ mol/l, $C_X=0.1$—1.0 mol/l in the pH range from 7 to 9, and $\mu=1.0$. Some typical absorption spectra are shown in Fig. 2. The absorbances, A_1, A_2, and A_3, in Fig. 2 are expressed as follows:

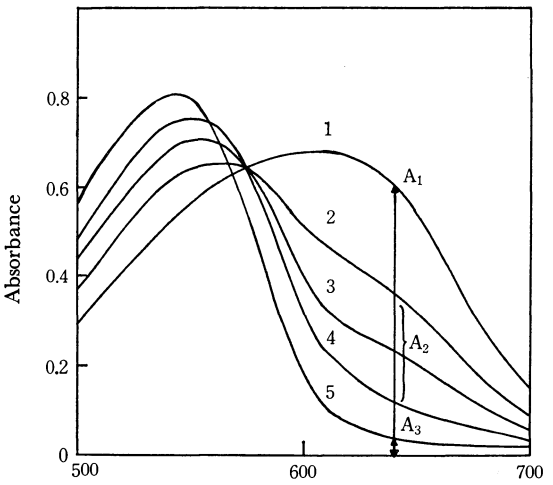

Fig. 2. Absorption spectra of mixed ligand complexes.
$C_I=3.59\times10^{-5}$ mol/l, $C_{Zn}=6.50\times10^{-5}$ mol/l
1: Calmagite only, pH 9.00, 2: pH 8.98, $[NH_3]=5.02\times10^{-1}$ mol/l, 3: pH 9.00, $[NH_3]=2.96\times10^{-1}$ mol/l, 4: pH 8.99, $[NH_3]=1.46\times10^{-1}$ mol/l, 5: pH 9.00, $[NH_3]=0$

$$A_1 = \varepsilon_I C_I \tag{20}$$

$$A_2 = \varepsilon_I[I'] + \varepsilon_{ZnI}[ZnI] + \sum_{n=1}^{n} \varepsilon_{ZnIX_n}[ZnIX_n] \tag{21}$$

$$A_3 = \varepsilon_{ZnI}C_I \tag{22}$$

where ε_I, ε_{ZnI}, and ε_{ZnIX_n} are the molar absorptivities of the free ligand, ZnI^-, and the mixed ligand complex, $ZnIX_n^-$, respectively. From the absorption spectra of ZnI^- and $ZnIX_n^-$, at 640 nm, ε_{ZnI} is found to be almost equal to ε_{ZnIX_n}. Therefore, [I'] can be calculated from the absorbances at 640 nm in a manner analogous to that used in the previous section:

$$[I'] = \frac{(A_2-A_3)C_I}{A_1-A_3} \tag{23}$$

Also, [(ZnI)'] and [Zn'] are given by Eqs. (24) and (25):

$$[(ZnI)'] = C_I - [I'] \tag{24}$$

$$[Zn'] = C_{Zn} - [(ZnI)'] \tag{25}$$

If we obtain the [I'] values from experiments, the conditional formation constant, $K_{Zn'I'(ZnI)'}$, under the given conditions can be calculated by means of Eqs. (19), (24) and (25).

By substituting Eqs. (13), (15), and (17) into Eq. (19), the conditional formation constant of mixed ligand complexes can be rewritten as follows:

$$K_{Zn'I'(ZnI)'} = \frac{K_{ZnI}\alpha_{ZnI(X)}}{\alpha_{Zn(X)}\alpha_{I(H)}} \tag{26}$$

Since [X] can be calculated from the total concentration of ammonia ($C_X=[NH_3]+[NH_4^+]$) and the pH value[5], $\alpha_{Zn(X)}$ in each experiment can be calculated by means of Eq. (16)[6] and $\alpha_{I(H)}$ can be obtained from the pHs of the solutions by means of Eq. (18). Using Eq. (26), $K_{ZnI}\alpha_{ZnI(X)}$ can be evaluated from $K_{Zn'I'(ZnI)'}$.

The relation of log $K_{ZnI}\alpha_{ZnI(X)}$ and pX[7] is shown in Fig. 3. log $K_{ZnI}\alpha_{ZnI(X)}$ is a function of pX and the curve approaches a straight line with a slope of 2 in the vicinity of pX=0. From these results, it is clear that zinc forms mixed ligand complexes with Calmagite and ammonia. $K_{ZnI}\alpha_{ZnI(X)}$ can be written as Eq. (27):

$$K_{ZnI}\alpha_{ZnI(X)} = K_{ZnI}(1+K^{X}_{ZnIX}[X] + K^{X}_{ZnXI}K^{X}_{ZnIX_2}[X]^2) \quad (27)$$

where:

$$K^{X}_{ZnIX} = \frac{[ZnIX]}{[ZnI][X]}, \quad K^{X}_{ZnIX_2} = \frac{[ZnIX_2]}{[ZnIX][X]}$$

From the data plotted in Fig. 3, the successive formation constants of the mixed ligand complexes were calculated by means of a HIPAC 103 computer using the least squares method; the following values were thus obtained: log K_{ZnI}=11.57, log K^{X}_{ZnIX}=2.09, and log $K^{X}_{ZnIX_2}$=1.70.

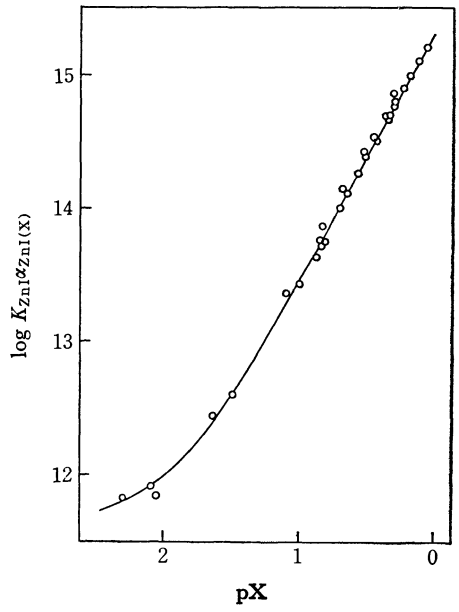

Fig. 3. log $K_{ZnI}\alpha_{ZnI(X)}$ *vs.* pX.

Use as a Metal Indicator for Zinc. In the chelatometric titration of metals, a sharp color change of the indicator is obtained at the equivalence point when the following relationships hold:[8]

$$pM_{\phi=0.5} - pM_{a=0} \gtrsim 3$$

$$pM_{a=2} - pM_{\phi=0.5} \gtrsim 3$$

where $pM_{a=0}$, $pM_{a=2}$, and $pM_{\phi=0.5}$ are pM's before titration, when titrated in a 100% excess and at a 50% color transition respectively.

$pM_{a=0}$, $pM_{a=2}$, and $pM_{\phi=0.5}$ were calculated under various conditions and plotted against the pH (Fig. 4). The optimum conditions for the titration of zinc with EDTA using Calmagite as an indicator can be predicted from the plots of pM *vs.* pH. Zinc forms hydroxide

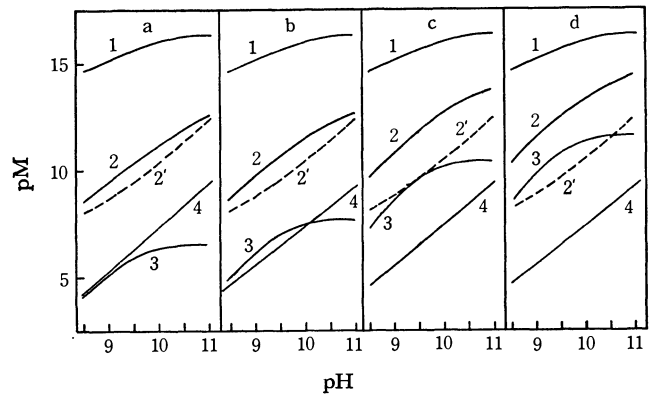

Fig. 4. Optimum conditions for titration of zinc.
$[NH_3]+[NH_4^+]$ (mol/l), a: 0.05, b: 0.1, c: 0.5, d: 1.0

in the range of pH>8.5 when the total concentration of ammonia ($[NH_3]+[NH_4^+]$) is less than 0.1 mol/l. If the total concentration of ammonia is between 0.1 and 0.5 mol/l, it is expected that a sharp color transition of Calmagite can be observed at the equivalence point in the pH range from 8.5 to 10.5. When the concentration of ammonia is 1 mol/l or more, the indicator is considerably discolored before the equivalence point and the color transition after the equivalence point is sluggish.

These considerations were verified by photometric titration. In Fig. 5 the photometric titration curves are shown. The results of photometric titration are in close agreement with the theoretical results.

Discussion

In a previous paper[9] we reported that indium(III) forms mixed ligand complexes with 2-(2-pyridylazo)-4-methylphenol (PAC) and the acetate ion. It is of much interest now to have found that zinc(II) forms mixed ligand complexes with Calmagite and ammonia.

When the concetration of ammonia is less than 1 mol/l, it has been shown experimentally that less than two moles of ammonia coordinate with the zinc-Calmagite chelate. Since zinc may form octahedral complexes, three moles of ammonia might combine with the zinc-Calmagite chelate at an ammonia concentration of more than 1 mol/l. The successive formation constants of the mixed ligand complexes are smaller than those of corresponding zinc ammine complexes (log $K_{ZnX}=2.59$, log $K_{ZnX_2}=2.32$).

It has been recognized that the formation of mixed ligand complexes plays an important role in the complexometric titration of zinc. If zinc did not form mixed ligand Complexes with calmagite, the total concentration of ammonia should be kept near 0.1 mol/l. However, the titration can be carried out even in a solution containing a total of 0.5 mol/l of ammonia. The formation of the mixed ligand complexes makes the ammonia concentration in the solutions not critical. In the case of Eriochrome Black T, zinc also forms mixed ligand complexes with ammonia.

Calmagite has some advantageous properties as a metal indicator for the titration of zinc; *i. e.*, the aqueous solution of Calmagite is more stable and the color transition is clearer and sharper than in the case of Eriochrome Black T.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 493—495 (1973)

Polarographic Reductions of Alkaline Earth Metal Ions in Hexamethylphosphoramide. Effect of Cation of the Supporting Electrolyte*

Kosuke IZUTSU,** Sachiko SAKURA, and Taitiro FUJINAGA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received July 17, 1972)

Polarographic reductions of barium, strontium and calcium ions in hexamethylphosphoramide (HMPA) have been investigated in the supporting electrolytes of various perchlorates. The reduction of these alkaline earth metal ions are strongly influenced by the cation of the supporting electrolyte. When the size of the cation of the supporting electrolyte is small and easily adsorbed on the negatively charged electrode surface as in the cases of Me_4N^+ and Et_4N^+ ions, the reduction of the metal ions does not occur until that of the supporting electrolyte. The reduction becomes easier with the increase of cationic size. Thus, in Hex_4NClO_4 or $LiClO_4$, these metal ions are reduced almost reversibly. These effects of the cation of the supporting electrolyte can be explained as electrode surface phenomena as in the reduction of alkali metal ions.

In a previous paper,[1] we reported on the polarographic reduction of alkali metal ions in hexamethylphosphoramide (HMPA). We observed a significant influence of the cation of the supporting electrolyte on reduction: Sodium ion in 0.05 M Et_4NClO_4, for example, is not reduced until the reduction of the supporting electrolyte takes place. In 0.05 M Pr_4NClO_4 and 0.05 M Bu_4NClO_4 solutions, however, it gives a small reduction wave, the limiting current of which is controlled by the rate of the preceding process. With 0.05 M $LiClO_4$ as a supporting electrolyte, a reversible, diffusion-controlled sodium wave is obtained at −2.47 V *vs.* Ag/0.1 M $AgClO_4$ (HMPA). We attributed these effects to the change of the double-layer properties with the species of the cation of the supporting electrolyte.

We have investigated the polarographic behavior of the calcium, strontium and barium ions in HMPA by use of various perchlorates as supporting electrolytes. A significant effect of the cation of the supporting electrolyte was also observed as in the reduction of alkali metal ions. The reduction of magnesium ion was not studied, because in the solution of magnesium perchlorate an unexpected wave was observed which might be due to some decomposition product of HMPA.

Apparatus and Reagents

Apparatus. The AC polarograms were recorded with a Yanagimoto polarograph, Type P8-AC. The dropping mercury electrode had the following characteristics in 0.05 M Et_4NClO_4-HMPA and at $h=62$ cm: $m=1.88$ mg/sec with the circuit open and $t=1.39$ sec at −2.6 V *vs.* Ag/0.1 M $AgClO_4$ (HMPA) electrode. Other apparatus were the same as described previously.[1]. All experiments were carried out at 25±0.1°C.

Reagents. Tetra-*n*-hexylammonium perchlorate (Hex_4NClO_4) was prepared from $AgClO_4$ and Hex_4NI (product of the Eastman Kodak Co.) in ethanol, and recrystallized three times from ethanol. It was air dried. Other tetraalkylammonium perchlorates and lithium perchlorate were prepared and dried following the previous procedures.[1] The calcium and strontium perchlorates were prepared by neutralizing the reagent grade calcium and strontium hydroxides, respectively, with perchloric acid. The barium perchlorate was obtained commercially. These alkaline earth perchlorates were dried in a vacuum at 200°C. HMPA was purified following the method in the previous report.[1]

Experimental

The polarographic behavior of the calcium, strontium and barium ions in HMPA was examined by use of Me_4NClO_4, Et_4NClO_4, Pr_4NClO_4, Bu_4NClO_4, Hex_4NClO_4, and

a) The concentration of the supporting electrolyte is 0.05 M in each case.
$E_{1/2}$: half-wave potential in V *vs.* Ag/0.1 M $AgClO_4$, i_l: limiting current in μA, i_p: AC peak height in μmho, C: concentration of the depolarizer in mM, and τ: drop time at the peak potential in sec.
b) Kinetic controlled, irreversible wave.
c) Diffusion controlled, reversible wave, but with a polarographic maximum.

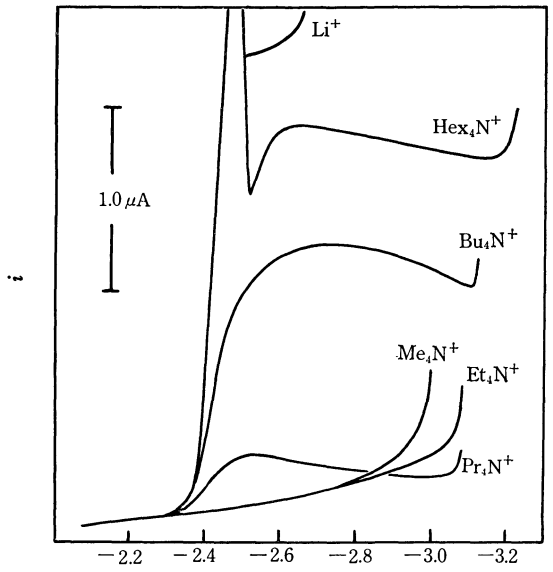

Fig. 1. Polarograms of 1.05 mM $Ba(ClO_4)_2$ in HMPA.
0.05 M solutions of various perchlorates are used as the supporting electrolytes. Cation of the supporting electrolyte is shown on each curve.

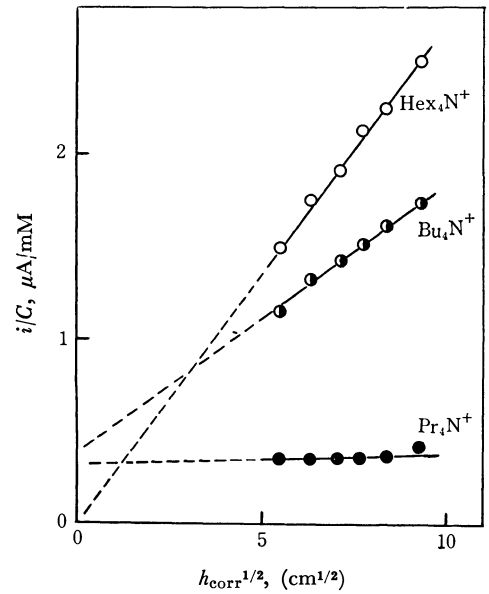

Fig. 2. Effect of the height of the mercury column on the limiting current of barium wave in HMPA.
Cations of the supporting electrolytes of 0.05 M perchlorates are shown on the curves.

$LiClO_4$ as supporting electrolytes. The results are summarized in Figs. 1, 4, and 5 and in Table 1.

Barium Ion. The barium ion in HMPA is irreducible when 0.05 M Me_4NClO_4 or 0.05 M Et_4NClO_4 is used as the supporting electrolyte (Fig. 1). In 0.05 M Pr_4NClO_4, however, a small wave appears at around −2.4 V and the limiting current is controlled by the rate of a preceding process, as judged from its dependence on the square root of the height of the mercury column (Fig. 2). In 0.05 M Br_4NClO_4, the barium wave is fairly well-defined but the i_l–$h^{1/2}$ relation in Fig. 2 shows that the limiting current is still not entirely diffusion-controlled. With 0.05 M Hex_4NClO_4 as the supporting electrolyte, a big maximum of the first kind is observed in the DC wave, but from the i_l–$h^{1/2}$ relation (Fig. 2) and from the high AC wave (Table 1) the reduction seems to be reversible and diffusion-controlled. The big limiting current observed in 0.05 M $LiClO_4$ is probably due to the maximum of the second kind.[1)]

Figure 3 shows the effect of Et_4NClO_4 on the barium wave in 0.05 M Hex_4NClO_4. It is noted that the addition of a very small amount of Et_4NClO_4 completely interferes with the reduction of the barium ion.

Strontium Ion. The strontium ion is irreducible in 0.05 M Me_4NClO_4, 0.05 M Et_4NClO_4, 0.05 M Pr_4NClO_4 (Fig. 4). With 0.05 M Bu_4NClO_4 as a supporting electrolyte, an irreversible wave is observed and the limiting current is controlled partly by diffusion and partly by the rate of a preceding process. In 0.05 M Hex_4NClO_4, a diffusion-controlled wave is obtained with the half-wave potential at about −2.61V, though the value is somewhat inaccurate due to the maximum of the first kind. The reduction in this supporting electrolyte seems to be reversible judging from the height of the AC polarographic wave (Table 1).

Calcium Ion. The calcium ion is irreducible in 0.05 M Me_4NClO_4, 0.05 M Et_4NClO_4, and 0.05 M Pr_4NClO_4 solutions (Fig. 5). In 0.05 M Bu_4NClO_4, an irreversible wave is observed, but the reduction is also controlled by the rate of a precedig process and then wave height is only half that of the diffusion wave. In 0.05 M Hex_4NClO_4 solution, the reduction of calcium ion preceeds reversibly, though an abnormal small maximum (or decrease of the base current) appears about 0.2V in advance to the main wave at $E_{1/2}=-2.76$ V, which also is accompanied by a small maximum (Fig. 5).

The calcium perchlorate salt is hygroscopic and the small amount of water from the salt makes the height of both

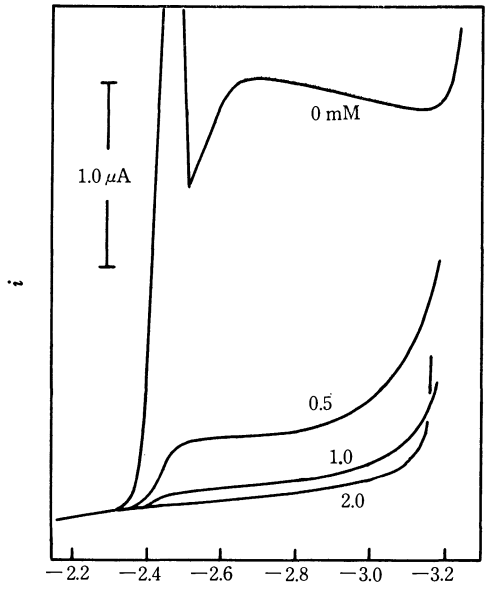

Fig. 3. Effect of the addition of the Et_4N^+ ion on the reduction wave of 1.07 mM barium ion in 0.05 M Hex_4NClO_4-HMPA.
Concentration of Et_4N^+ ion in mM is shown on each curve.

Cation of the supporting electrolyte is shown on each curve.

maxima increase. However, the reason for the appearance of the abnormal maximum, change of height and the shift of the potential of the abnormal maximum by the addition of water has not been elucidated yet.

Discussion

As in the case of alkali metal ions,[1] the reduction of alkaline earth metal ions in HMPA is strongly influenced by the cation of the supporting electrolyte. The effect is closely related to the size of the solvated cation of the supporting electrolyte. If the size of the solvated cation of the supporting electrolyte is small as in the cases of Et_4NClO_4 and Me_4NClO_4, the reduction

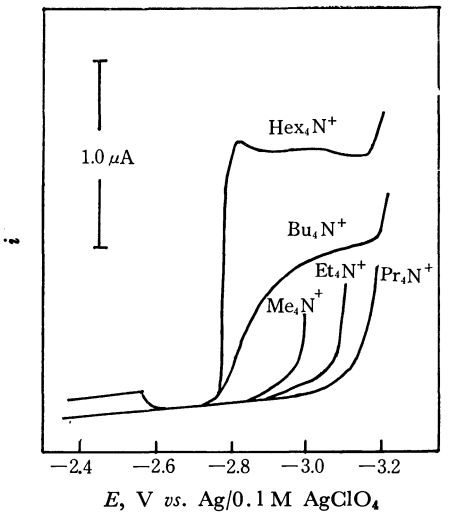

Fig. 5. Polarograms of 0.81 mM $Ca(ClO_4)_2$ in HMPA.
Cation of the supporting electrolyte is shown on each curve.

of all alkaline earth metal ions is made irreducible. The reduction becomes easier with the increase in size. In Hex_4NClO_4 solutions, the reduction of all alkaline earth metal ions proceeds reversibly and is diffusion-controlled. When the size is in between these two extremes, reduction is irreversible and the limiting current is kinetically controlled.

The adsorption of monovalent cation on the charged electrode surface at highly negative potential becomes easier with the decrease of the size of the solvated cation and, in the presence of two kinds of monovalent cations, a preferential adsorption of the smaller cation takes place.[1]

In the supporting electrolyte with small cation, the approach of heavily solvated alkali metal ions to the electrode surface is difficult and a preceding process is necessary in advance to the reduction of these ions. We considered this preceding process to be either a (partial) desolvation of the depolarizing cation or the penetration of the depolarizing ion through the adsorbed layer of the cation of the supporting electrolyte.

In HMPA, alkaline earth metal ions are heavily solvated and the Stokes law radii of the solvated ions 5.8—6.0Å for barium, strontium and calcium ions.[2] These values are much larger than 2.7Å for Et_4N^+, 3.2Å for MeN^+ and 3.7Å for Pr_4N^+, somewhat larger than 4.3Å for Bu_4N^+ and 4.9Å for Li^+, and approximately the same as 5.7Å for Hex_4N^+. Similar to the case of alkali metal ions, the reduction of alkaline earth metal ions in the supporting electrolyte with relatively small cation also seems to be difficult.

Gutmann *et al.*[3] reported that alkaline earth metal ions in dimethylacetoamide (DMA) are irreducible unless a small amount of water is introduced into the electrolytic solutions. They used Et_4NClO_4 as the supporting electrolyte. Alkaline earth metal ions in DMA also become reducible by using supporting electrolytes with larger cations.

Selective Activation of Methylene or Methine Groups in Coordinated Dipeptide Schiff Bases

Osamu UYAMA, Yasuo NAKAO, and Akitsugu NAKAHARA

Department of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received July 18, 1972)

Nickel(II) and cobalt(III) chelates of the Schiff bases derived from salicylaldehyde and dipeptides such as glycylglycine, glycylalanine and alanylglycine have newly been prepared. The reactivity of methylene or methine groups in the dipeptide moieties of those Schiff base chelates has been investigated on the basis of their PMR spectra in D_2O. It has been confirmed that the methylene or methine protons of the *N*-terminal amino acid residue are more easily activated than those of the *C*-terminal amino acid residue.

It was demonstrated by Williams and Busch[1] that the methylene or methine protons of α-amino acids are activated on chelation with metal ions. Fore this, threonine had been synthesized from bis(glycinato)copper(II) and acetaldehyde in the presence of sodium carbonate.[2] It was reasoned that the amino group would be protected by coordination, and sufficient activation of the methylene group would result from the polarizing effect of the metal ion.[2-4]

Similar investigations have recently been extended to the case of coordinated dipeptides. For example, Noda *et al.*[5] reported that the main product out of the reaction between glycylglycine and formadehyde in the presence of copper(II) is serylglycine, not accompanied by glycylserine or serylserine at all. This suggests that the methylene group in the *N*-terminal amino acid residue is selectively activated on chelation with metal ion. On the other hand, Gillard *et al.*[6] reported that the methylene protons of the *C*-terminal amino acid residue in the cobalt(III) dipeptide chelates are replaced easily in alkaline solution by the deuterons of heavy water, but not those of the *N*-terminal amino acid residue.

In order to clarifying the two conflicting results, we have investigated the selective activation of methylene or methine groups in coordinated dipeptide Schiff bases.

This paper deals with the preparation of nickel(II) and cobalt(III) chelates of the Schiff bases derived from salicylaldehyde and dipeptides containing glycine and/or α-alanine, and the results of PMR study of those chelates in view of the selective activation of methylene or methine groups in coordinated dipeptide moieties. On the basis of our findings, the conclusions of Noda *et al.* and Gillard *et al.* have consistently been explained.

Experimental

Glycyl-α-alanine and *α-alanylglycine* were prepared according to the method of Hanson and Smith[7] and Miller *et al.*[8], respectively.

Na[Ni(Sal=Gly·Gly)]·H_2O was obtained in a similar way to that described in the preceding paper[9] employing 1 N sodium hydroxide solution. Found: C, 38.97; H, 3.29; N, 8.17%. Calcd for $Na[Ni(C_{11}H_9N_2O_4)]\cdot H_2O$: C, 39.67; H, 3.31; N, 8.42%.

K[Ni(Sal=L-Ala·Gly)]·H_2O: 1.5 g of L-alanylglycine and 3 g of bis(salicylaldehydato)nickel(II) were dissolved in 15 ml of water. The mixture was adjusted to pH 9—10 with 1 N potassium hydroxide solution, stirred at 25°C for an hour and filtered. To the filtrate was added 600 ml of a mixture of ether and ethanol (1 : 1 by volume) with constant stirring, orange crystals being deposited. These were dissolved in a small quantity of water, and then recrystallized by dropwise addition of a mixture of ethanol and ether (1 : 1 by volume). Found: C, 39.16; H, 3.22; N, 7.63%. Calcd for $K[Ni(C_{12}H_{11}N_2O_4)]\cdot H_2O$: C, 39.67; H, 3.58; N, 7.72%.

K[Ni(Sal=Gly-L-Ala)]·2H_2O was prepared by the same method as described above. Found: C, 37.73; H, 3.65; N, 7.42%. Calcd for $K[Ni(C_{12}H_{11}N_2O_4)]\cdot 2H_2O$: C, 37.82; H, 3.94; N, 7.35%.

Ba[Co(NO_2)$_2$(Sal=Gly·Gly)]·2H_2O: To a mixture of 4 g of $Na_3[Co(NO_2)_6]$ and 20 ml of water was added a solution of glycylglycine (1.3 g) and salicylaldehyde (1.2 g). The resulting mixture was adjusted to pH 9 with 2 N sodium hydroxide solution. After it had been stirred at 60°C for two hours, the reaction mixture was filtered. A hot saturated aqueous solution of $BaCl_2\cdot 2H_2O$(10 g) was then added to the filtrate. Upon cooling the solution, crystals were obtained and recrystallized from hot water. Found: C, 23.86; H, 2.36; N, 10.20%. Calcd for $Ba[Co(NO_2)_2(C_{11}H_9N_2O_4)]\cdot 2H_2O$: C, 23.68; H, 2.33; N, 10.05%.

Ba[Co(NO_2)$_2$(Sal=DL-Ala·Gly)]·3H_2O was obtained in the same way. Found: C, 24.22; H, 2.99; N, 9.69%. Calcd for $Ba[Co(NO_2)_2(C_{12}H_{11}N_2O_4)]\cdot 3H_2O$: C, 24.44; H, 2.89; N, 9.50%.

Ba[Co(NO_2)$_2$(Sal=Gly-L-Ala)]·2H_2O was obtained also in the same way. Found: C, 25.03; H, 2.65; N, 9.76%. Calcd for $Ba[Co(NO_2)_2(C_{12}H_{11}N_2O_4)]\cdot 2H_2O$: C, 25.21; H, 2.65; N, 9.80%.

PMR Measurement. The spectra were obtained by the use of a JEOL C-60HL Spectrometer for deuterium oxide solution containing about 200 mg of complex/0.8 ml D_2O. The chemical shift was measured relative to the sodium salt of trimethylsilylpropane sulfonic acid taken as an internal standard. The barium salts of the cobalt(III) complexes

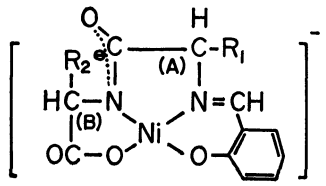
were converted into lithium salts using lithium sulfate, with which the barium ion was precipitated as $BaSO_4$. The pD-adjustment was performed by the addition of 2 N NaOD-heady water solution. A Yanagimoto pH-66A pH meter equipped with a MGR-11A combined electrode was used after standardization with a Nakarai standard buffer solution (pH 6.86 and 9.18 at 25°C).

Results and Discussion

Proton NMR spectroscopy is a convenient method for studying the behavior of hydrogen atoms in metal Schiff base complexes. We prepared a series of diamagnetic nickel(II) and cobalt(III) complexes of the Schiff bases derived from salicylaldehyde and dipeptides (glycylglycine, glycyl-α-alanine and α-alanylglycine) and investigated their PMR spectra at various pD-values.

Nickel(II) Complexes. The structures of nickel(II) complexes are given in Fig. 1, in which the methylene or methine group of the *N*-terminal amino acid residue is denoted by (A), and that of the *C*-terminal amino acid residue by (B).



R_1, R_2=H or CH_3

Fig. 1. General structure of nickel(II)-dipeptide-Schiff base complexes.

The PMR spectra for $[Ni(Sal{=}Gly{\cdot}Gly)]^-$ are illustrated in Fig. 2; (a) is the spectrum recorded comparatively soon after the solution was prepared at room temperature and at pD 11.6. The resonance signals at 2.8 and 3.4 ppm are considered to be due to the methylene protons of (A) and (B), and those at 6.5—8 ppm the phenyl and the azomethine protons. Apparently the spectrum indicates that both the methylene protons of (A) and (B) are not replaced by deuterons. On the other hand, the spectrum shown in Fig. 2-(b), which was recorded after allowing the same solution to stand at 40°C for 27 days indicates that the signal at 3.4 ppm has decreased but not that at 2.8 ppm. This suggests that the only one methylene protons of either (A) or (B) are replaced by deuterons, but not those of the others. We see from Fig. 2-(c) that both the signals at 3.4 and 2.8 ppm decrease on allowing the solution to stand at 40°C and at pD 13.1 for 23 days. Under this condition the above trend is so remarkable as regards the signal at 3.4 ppm that even the mark of signal cannot be observed. It is considered that at this high pD-value both kinds of methylene protons are eventually activated, but the one is more easily activated than the other.

Figure 3 shows the spectra of $[Ni(Sal{=}L\text{-}Ala{\cdot}Gly)]^-$ under various conditions. Spectrum (a) recorded

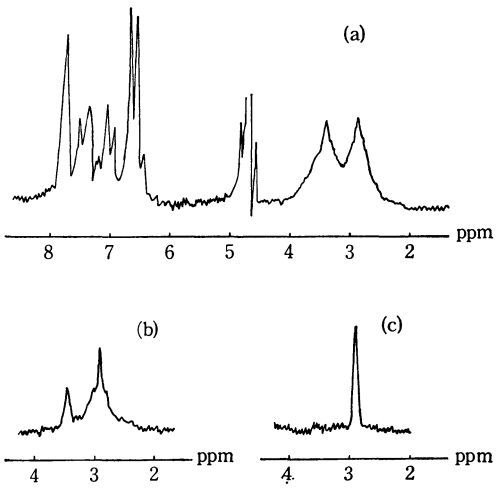


Fig. 2. PMR spectra of $[Ni(Sal{=}Gly{\cdot}Gly)]^-$: (a) pD 11.6, room temp., after 2 hr; (b) pD 11.6, 40°C, after 27 days; (c) pD 13.1, 40°C, after 23 days.

comparatively soon after preparing the solution (room temperature, pD 10.2) indicates that neither the protons of the methylene group (B)(R_2=H) or of the methine group (A)(R_1=CH_3) are replaced by deuterons. The resonance signal of a doublet at 1.2 ppm arises from the methyl protons, that at 2.8 ppm from the methylene protons of (B) and that of a quartet at 3.4 ppm from the methine proton of (A). As is seen in Fig. 3-(b), the methyl doublet at 1.2 ppm partly collapses on allowing the solution to stand at 40°C and at pD 11, producing a singlet on account of the deuterization of the methine proton of (A), but the signal at 2.8 ppm due to the methylene protons of (B) does not decrease.

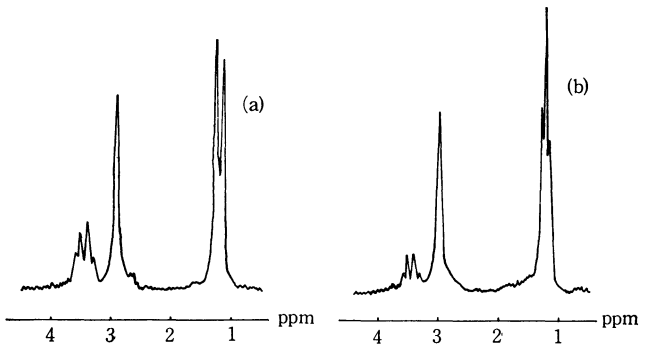

Fig. 3. PMR spectra of $[Ni(Sal{=}L\text{-}Ala{\cdot}Gly)]^-$: (a) pD 10.2, room temp, after 2 hr; (b) pD 11, 40°C, after 27 days.

The spectra of $[Ni(Sal{=}Gly{-}L\text{-}Ala)]^-$ under various conditions are illustrated in Fig. 4. (a) is the spectrum obtained comparatively soon after preparing the solution (room temperature, pD 10.6), indicating that the protons of both the methylene group (A) (R_1=H) and the methine group (B)(R_2=CH_3) are not replaced by deuterons. The resonance signal of a doublet[10] at 1.3 ppm arises from the methyl protons

10) Careful inspection of the signal shows that it is composed of a couple of doublets. This may be because of the coexistence of two isomers relative to the different conformation of the methyl group, namely, pseudo-equatorial and pseudo-axial.

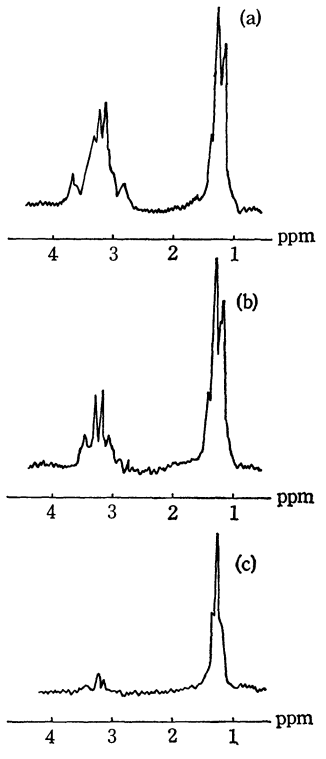

Fig. 4. PMR spectra of [Ni(Sal=Gly-L-Ala)]$^-$: (a) pD 10.6, room temp., after 2 hr; (b) pD 11, 40°C, after 27 days; (c) pD 14, 40°C, after 27 days.

(R_2=CH_3). The signals at 3—3.5 ppm arise from the methylene and the methine protons of (A) and (B), respectively. On allowing the solution to stand at 40°C and at pD 11 for 27 days, the signals at 3—3.5 ppm turn out to be a quartet on account of the deuterization of the *N*-terminal methylene protons, whereas the doublet at 1.3 ppm remains unchanged (Fig. 4-(b)). However, at pD 14 the signal at 3—3.5 ppm completely disappears and even the doublet at 1.3 ppm completely collapses to give a singlet on allowing the solution to stand at 40°C for 27 days. This indicates that i) only the *N*-terminal methylene or methine group is activated at around pD 11, and ii) the protons of both (A)- and (B)-methylene or methine group are activated at around pD 13—14, the former being activated more easily.

The preferential activation of the methylene or methine group at the *N*-terminal amino acid residue appears to be different from the conclusion of Gillard *et al.*[6] In order to clarify whether this arises from the formation of chelates of dipeptide Schiff bases instead of simple dipeptide chelates or from the difference in the kind of central metal ion, we have further investigated the pmr spectra of cobalt(III) complexes of similar dipeptide Schiff bases.

Cobalt(III) Complexes. Three new dinitro-cobalt(III) complexes of the Schiff bases derived from salicylaldehyde and dipeptides (glycylglycine, α-alanylglycine and glycyl-α-alanine) were synthesized. It was concluded that their structures are *trans* form, since their infrared spectra are quite similar to the corresponding planar nickel(II)-dipeptide-Schiff base complexes. The general structural formula of these complexes is shown in Fig. 5, in which the cobalt(III) chelate ring containing the *N*-terminal amino acid residue is denoted by (C) and that containing *C*-terminal amino acid residue by (D).

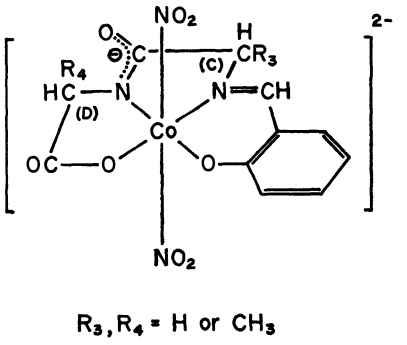

Fig. 5. General structure of cobalt(III)-dipeptide-Schiff base complexes.

The PMR spectra of $[Co(NO_2)_2(Sal{=}Gly{\cdot}Gly)]^{2-}$ in D_2O under various conditions are illustrated in Fig. 6. Spectrum (a), which was recorded comparatively soon after the preparation of the solution, shows that no protons of the methylene groups of (C) and (D) (R_3=R_4=H) are replaced by deuterons. The resonance signals at 4.1 and 4.5 ppm are due to the methylene protons of (C) and (D), and those at 6.5—8 ppm to the phenyl and the azomethine protons. After 3 days at 40°C (pD 10.6), the signal at 4.5 ppm decreased, but not that at 4.1 ppm (Fig. 6-(b)). This suggests that only one methylene group is activated at pD 10.6. Decomposition of the complex was observed in a stronger basic solution.

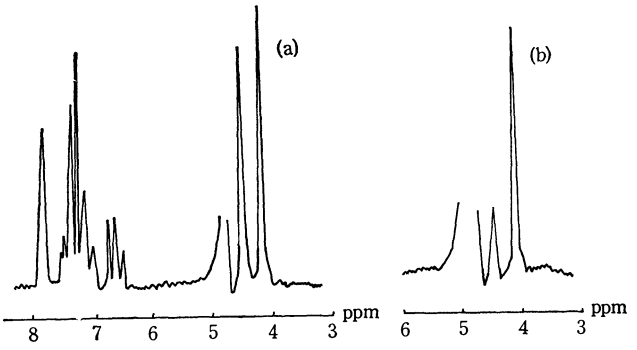

Fig. 6. PMR spectra of $[Co(NO_2)_2(Sal{=}Gly{\cdot}Gly)]^{2-}$: (a) pD 6.8, room temp., after 2 hr; (b) pD 10.6, 40°C, after 3 days.

Figure 7 shows the spectrum of $[Co(NO_2)_2(Sal{=}$DL-Ala·Gly$)]^{2-}$. It is obvious that the protons of methylene or methine groups are not replaced by deuterons within two hours at room temperature and at pD 7. The signal at 1.4 ppm arises from the methyl protons (R_3=CH_3), that at 4.2 ppm from the methylene protons (D) (R_4=H), and that of a quartet at 4.4 ppm from the methine proton (C). On allowing the solution to stand at 40°C and at pD 10.6 for a day, the doublet signal for the methyl group at 1.4 ppm slightly collapses to give a singlet on account of the deuterization of the methine proton (C), the signal

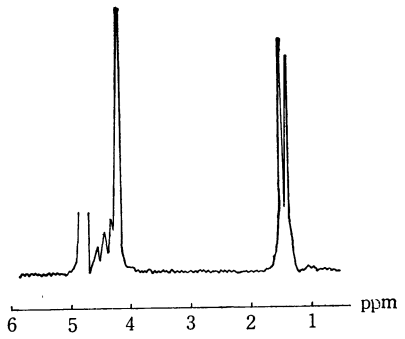

Fig. 7. PMR spectrum of $[Co(NO_2)_2(Sal=DL\text{-}Ala\cdot Gly)]^{2-}$: pD 7, room temp., after 2 hr.

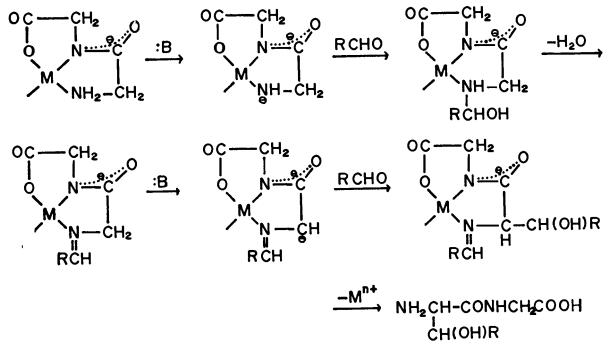
for the methylene protons (D) remaining unchanged. Further deuterization expected to occur in the methylene group of (D) was not successfully observed on account of gradual decomposition of the complex. It can be said also for the cobalt(III)-dipeptide-Schiff base chelates that the methylene or methine group of (C) is activated more easily than that of (D). In other words, there is no essential difference between the nickel(II)- and cobalt(III)-chelates as far as the selective activation of the methylene or methine group in coordinated dipeptide Schiff bases is concerned.

Thus the confliction with the results of Gillard *et al.*,[6] who concluded the preferential activation of the methylene or methine group of (D), appears to arise from the difference in the structure of the terminal amino group (dipeptide Schiff base or simple dipeptide).

Reactions of Coordinated Dipeptide Schiff Bases with Formaldehyde. A preliminary experiment on the reactions of the above nickel(II) or cobalt(III) complexes with formaldehyde was carried out. In the case of the reaction of *N*-salicylideneglycylglycinatonickelate(II) in a slightly basic solution at 100°C the main products were serylglycine and α-hydroxymethylserylglycine. Apparently the result is consistent with the conclusion of the above described PMR-study and at the same time with the result reported by Noda *et al.*[5] Though the peptide they used was glycylglycine and not *N*-salicylideneglycylglycine, it might be considered that glycylglycine in the presence of copper(II) reacted with formaldehyde to form the Schiff base. If this is true, the selective activation of the methylene group at the *N*-terminal glycine moiety is understandable in the light of the above PMR-study. In the structure of the coordinated dipeptide Schiff bases, the electron-withdrawing effect of the metal ion can reach the α-carbon atom through azomethine nitrogen atom, whose electronic structure should differ entirely from that of the simple amino nitrogen in glycylglycine. This will probably enhance the reactivity of the *N*-terminal methylene group in glycylglycine moiety.

Thus, we proposed a reaction mechanism as illustrated in Scheme 1 for the reaction of Noda *et al.* The



Scheme 1.

mechanism may explain why the main products of the reaction were serylglycine and α-hydroxymethylserylglycine. Further it is also consistent with the mechanism presented by Ichikawa *et al.*[11] for the reaction of the bis(glycinato)- or pyruvylideneglycinatocopper(II) with formaldehyde. It does not contradict the conclusion on the selective activation of the methylene or methine group at the *C*-terminal amino acid moiety only in simple dipeptide chelates.[6]

The authors are grateful to Mr. H. Okuda for PMR measurements. Expenses for this work were defrayed in part by a grant from the Ministry of Education.

Spectrophotometric Study on the Extraction of the Ternary Complex Composed of Vanadium(V), 8-Hydroxyquinoline-5-sulfonic Acid and Zephiramine

Tomihito KAMBARA and Masao SUGAWARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received July 28, 1972)

The ternary complex composed of vanadium(V),8-hydroxyquinoline-5-sulphonic acid (H_2QS), and zephiramine (Z^+Cl^-) was extracted into chloroform. The absorption maxima of the ternary complex in the organic layer were 375 and 580 nm at pH 2.8 and 375 nm at pH 4.8. The optimum pH range for the extraction was 4.5—5.4. Beer's law held for 1.29—35.6 μg of vanadium(V). The molar absorptivity of the complex was 0.99×10^4 cm^{-1} mol^{-1} l. The composition of the ternary complex was estimated to be $[VO_2^+Z^+(QS^{2-}Z^+)_2]_o$ and the extraction equilibrium was given by

$$VO_2^+ + 2[(HQS^-Z^+)]_o + Z^+ + 2OH^- \rightleftharpoons [VO_2^+Z^+(QS^{2-}Z^+)_2]_o + 2H_2O \quad (1)$$

The logarithm of the equilibrium constant K of this equation was found to be 32.57 ± 0.49.

Oxine, *N*-benzoylphenylhydroxylamine, hydrogen peroxide, and phosphotungstic acid have been used mainly for the determination of trace amounts of vanadium(V). 8-Hydroxyquinoline-5-sulphonic acid (H_2QS), a water-soluble oxine derivative, was also suggested as a chelating agent for vanadium(V).[1] However, details of analytical conditions are lacking. We have extracted ionic association complex of vanadium(V)-H_2QS chelate anion with zephiramine (tetradecyl-dimethyl-benzyl-ammonium chloride) into chloroform. Yellow coloration of the extract obtained from a weakly acidic medium was very stable and the intensity was proportional to the concentration of vanadium(V) in the aqueous layer. A dark green coloration was also obtained by extraction from an acidic medium. However, because of the low sensitivity and instability of coloration, the extraction from a weakly acidic medium is preferable for determination of vanadium(V).

Experimental

Reagent. *Vanadium(V) Standard Solution*: 0.1770 g of guaranteed ammonium metavanadate NH_4VO_3 (Kanto Chemicals Co.) was dissolved in 25 ml of 2 M H_2SO_4 and diluted to 1 liter with water. The solution was standardized by EDTA-titration using a Cu-PAN indicator. The solution was diluted as required.

H_2QS Solution: 1.00×10^{-3} M solution was prepared by dissolving H_2QS (Wako Chemicals Co.) into water.

Zephiramine Solution: 5.00×10^{-3} M solution was prepared by dissolving Dotite zephiramine in water.

Buffer Solutions: A sulphuric acid-acetate buffer solution was prepared by mixing 0.5 M solutions of sulphuric acid and sodium acetate. A borate buffer solution was prepared by mixing 0.1 M solutions of hydrochloric acid and borax.

Chloroform was purified by washing with sulphuric acid, diluted sodium hydroxide and water, followed by distillation.

The other reagents used were all of analytical reagent grade. Resin-deionized water was used.

Apparatus. A Shimadzu QV-50 spectrophotometer with 10-mm cells was used for measurements of absorbance. A Hatachi-Horiba, Model F-5, glass electrode pH meter was used for pH measurements. An Iwaki KM shaker was used.

Procedure. Vanadium(V) (25.5 μg) was dissolved with 6 ml H_2QS solution and 2.5 ml zephiramine solution in a 100 ml separatory funnel. The pH adjustment was performed with 15 ml of the sulphuric acid-acetate buffer solution in the range 4.7—4.9 and then filled up to 50 ml with water. The mixtures with 10 ml of chloroform were shaken for 10 min and left for 5 min to let the layers separate. The chloroform layer was transfered to a beaker containing anhydrous Na_2SO_4 and offered to a optical measurement. The absorbance of the extract at 375 nm was measured against the reagent blank obtained in the same way.

Results and Discussion

Absorption Spectra. Absorption spectra of the aqueous layer are presented in Fig. 1. The vanadium (V)-H_2QS chelate anion in water has an absorption maximum at 365 nm. The ternary complex formed by addition of zephiramine has different absorption maximum depending on pH value, *viz.*, 375 nm at pH 4.8, 395 and 580 nm at pH 2.8. The ionic association complex extracted into chloroform has a yellow coloration at pH 4.8 and dark green coloration at pH 2.8. The absorption maximum of the yellow extract is 375 nm and those of the dark green extract are 375 and 580 nm as shown in Fig. 2. The yellow

TABLE 1. COMPARISON OF SENSITIVITY OF SOME COMMON SPECTROPHOTOMETRIC METHODS FOR VANADIUM(V)

Reagent	Chemical formula	Molar absorptivity (cm^{-1} mol^{-1} l)	Wavelength (nm)	Reference
Oxine	$VO(OH)Ox_2$	3220 ($CHCl_3$)	540	
		6200 ($CHCl_3$)	365	2
	$C_4H_9NH_3VO_2Ox_2$	7000 (benzene)	380	
N-Benzoylphenyl-hydroxylamine	$VO(OH)(BPA)_2$	4500 (benzene)	530	3
		4650 ($CHCl_3$)	510	4
4-(2-Pyridylazo)-resorcin and zephiramine		43000 ($CHCl_3$)	560	5
8-Hydroxyquinoline-5-sulphonic acid and zephiramine	VO_2+Z($QS^{2-}Z^+$)$_2$	9900 ($CHCl_3$)	375	

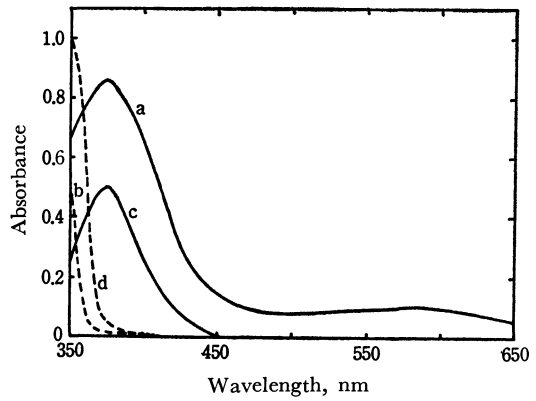

Fig. 2. Absorption spectra of the ternary complex V(V)-QS-Z in chloroform layer.
Curve (a) $[V(V)]_w = 2.0 \times 10^{-5}$ M, $[QS]_w = 2.4 \times 10^{-4}$ M, $[Z]_w = 5.0 \times 10^{-4}$ M, pH 2.8, *vs.* reagent blank, (b) reagent blank *vs.* $CHCl_3$, Curve (c) $[V(V)]_w = 1.0 \times 10^{-5}$ M, $[QS]_w = 1.2 \times 10^{-4}$ M, $[Z]_w = 5.0 \times 10^{-4}$ M, pH 4.8, *vs.* reagent blank, (d) reagent blank *vs.* $CHCl_3$, Volume of aqueous layer $V_w = 50$ ml, Volume of organic layer $V_o = 10$ ml.

extract was very stable and the absorbance at 375 nm was found to remain unchanged after being left standing for 6 hours, but that at 580 nm decreased in the dark green extract.

Effect of pH. The aqueous layer adjusted to various pH values was treated by the above procedure. It was found that optimum pH range for the extraction was 4.5—5.4; 2.4—2.8 for the dark green extract. In borate buffer solution, no stable and constant absorbance was obtained.

Effect of H_2QS and Zephiramine Concentrations. Concentrations of H_2QS and zephiramine were varied. Absorbance of the extract was found to be constant with concentration range higher than 10-fold of H_2QS and 20—40-fold of zephiramine to vanadium(V).

Effect of Shaking Time. Shaking time was varied from 3 min to 20 min in the above procedure. It was found that the quantitative extraction of vanadium(V) was attained for shaking longer than 5 minutes.

Extractability and Molar Absorptivity. A 50-ml portion of the aqueous layer containing 25.5 μg of vanadium(V) was shaken with 10 ml of chloroform, and the absorbance of the extract was measrued. 25 ml of the separated aqueous layer was then re-extracted with 5 ml of chloroform. Extractability was calculated from the sum of absorbances of the extracts and that of the first extract. It was found that 99.9% of vanadium(V) was extracted by a single extraction, the molar absorptivity of the ternary complex being 0.99×10^4 cm^{-1} mol^{-1} l. The molar absorptivity is larger than that of the corresponding oxine complex as shown in Table 1.

Calibration Curve. Extraction of varying amounts of vanadium(V) was carried out. Beer's law held in the concentration range 1.29—35.6 μg of vanadium(V). Sandell's sensitivity for the absorbance of 0.001 was 0.0051 μg cm^{-2}. The relative standard deviation obtained by 7 measurements was 0.74% for 25.5 μg of vanadium(V).

Composition of Vanadium(V)-H_2QS Complexes. A continuous variation method applied at pH 4.0 indicated that mole ratio of H_2QS to vanadium(V) was 2 : 1. The same result was obtained also by the mole ratio method.

Composition of the Ternary Complex. A continuous variation method of the three-component system[6-9] was applied to the determination of the composition of the ternary complex. The sum of concentrations of vanadium(V), H_2QS, and zephiramine in the aqueous layer was kept to 7.00×10^{-5} M and the extraction was carried out at pH 4.8. As shown in Fig. 3, maximum absorbance was obtained at the concentration ratio of vanadium(V): H_2QS: zephiramine = 1.2 : 2.5 : 3.5, namely 1 : 2 : 3. The above result was confirmed by using Affsprung's method.[10] It is known that the group V–OH in 8-hydroxyquinolate is acidic and reacts with amines.[11]

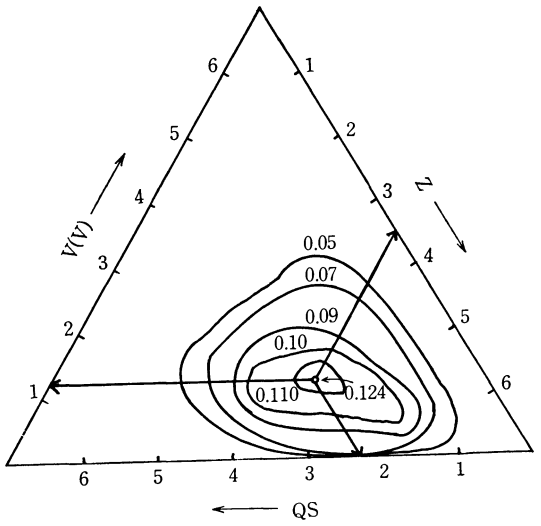

Fig. 3. Continuous variation method applied to three-component system of V(V)-QS-Z complex in organic layer. $V_w=50$ ml, $V_o=10$ ml, $[V(V)]_w+[QS]_w+[Z]_w=7.00\times10^{-5}$ M, pH 4.8, Wavelength: 375 nm, *vs.* $CHCl_3$.

The composition of the ternary complex was therefore estimated to be $[VO_2{}^+Z^+(QS^{2-}Z^+)_2]_o$.

Equilibrium Constant. Extraction of the ternary complex can be given by

$$VO_2{}^+ + 2[(HQS^-Z^+)]_o + Z^+ + 2OH^- \rightleftharpoons [VO_2{}^+Z^+(QS^{2-}Z^+)_2]_o + 2H_2O \quad (1)$$

with the equilibrium constant K

$$K=\frac{[VO_2{}^+Z^+(QS^{2-}Z^+)_2]_o}{[VO_2{}^+][(HQS^-Z^+)]_o{}^2[Z^+][OH^-]^2} \quad (2)$$

where subscript o denotes the organic layer. 50 ml of the aqueous layer, containig $*C$ mole of vanadium-(V), $2*C$ mole of H_2QS and $3*C$ mole of zephiramine was equilibrated with 10 ml of chloroform. By measurements of absorbance of the extract, concentration of the ternary complex C_T was calculated from the molar absorptivity. Equation (2) is then given by

$$K=\frac{[C_T]}{\left[*C-\frac{10}{50}C_T\right]\left[\frac{50}{10}\times2*C-2C_T\right]^2[*C][OH^-]^2} \quad (3)$$

The results obtained with various values of concentration of $*C$ are shown in Table 2. The logarithm of the equilibrium constant is 32.57 ± 0.49.

Kinetic Studies of the Nickel Maleate Complex Formation in Solution by the Pressure-jump Method

Shoji HARADA and Tatsuya YASUNAGA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received August 7, 1972)

Nickel maleate complex formation reaction in an aqueous solution, $Ni^{2+}+Mal^{2-} \underset{k_d}{\overset{k_f}{\rightleftharpoons}} NiMal$, where Mal^{2-} represents the maleate ion, was studied by the pressure-jump method. The rate constants and the stability constant were obtained; $k_f=8.4\times10^5\ M^{-1}\ s^{-1}$, $k_d=2.1\times10^3\ s^{-1}$, and $K=4\times10^2\ M^{-1}$ at 25°C and at $\mu\rightarrow0$. The thermodynamic parameters of this reaction were obtained from studies at various temperatures between 10 and 30°C. The results indicate that the nickel maleate is stable as a monodentated complex rather than as a chelate complex. Moreover, the nickel dicarboxylate complex formation reactions and the rate equations were discussed.

Static measurements of the stabilities of the chelate complexes[1-3] have revealed that the stabilities depend greatly on the carbon number or the structure of the ligands; *e. g.*, the five-membered ring complex is more stable than the six membered one. In the nickel dicarboxylate, the oxalate ion makes a more stable complex than that of the malonate.[4] The same ligand effects can also be observed in the kinetic measurements;[5,6] the difference in the stabilities has been attributed to that of the ligand-dissociation rate constants.

The nickel dicarboxylate complex formation reaction, which involves the replacement of the two coordinated water molecules, has usually been interpreted

by the step-by-step mechanism proposed by Eigen *et. al.*[7] For the assignment of the relaxation effects, however, two different theories have been proposed. According to the first theory,[5,6,8,9] the rate-determining step is supposed to be the formation of the first bond between the metal ion and the ligand, whereas in the second theory[10,11] the ring closure of the chelate is assumed.

One of the two purposes of the present work is to discuss these two theories; the other was to ascertain the ligand effects on the stability constants, the rate constants, the reaction mechanisms, and the thermodynamic parameters of the nickel dicarboxylate complex formation reactions.

Experimental

All of the chemicals used were of a reagent grade. A stock solution of the nickel maleate was prepared by mixing a stoichiometric amount of $NiSO_4$ with maleic acid, and the sulfate ion was precipitated out as the insoluble $BaSO_4$. The solid $BaSO_4$ was removed by filtration. The concentration of the nickel maleate of the stock solution was determined by dimethylglyoxime titration. Each solution studied was prepared by diluting the stock solution to the desired concentration. The pH's of the solutions were 7.1—7.2, with most of the ligands in the dissociated form. No buffering or supporting electrolytes were added, and so the ionic strength of the solution was varied arbitrarily.

The pressure-jump apparatus used has been described in considerable detail elsewhere.[8] The only significant change made was that a single cell is now employed, rather than a double cell; *i. e.*, a valuable resistor was used in place of the reference cell. This improvement has resulted not only in making the experiments more easy, but also in increasing the signal-to-noise ratio. The time constant of the apparatus was 100 μs. The solution of either the nickel ion or the maleate ion in the absence of the other showed no relaxation effect in the present time range. This proved that the relaxation effect is due to the nickel maleate complex formation reaction.

The measurements were carried out at 10, 15, 20, 25, and 30°C in the concentration range from 5.06×10^{-4} to 5.06×10^{-2} M of the nickel maleate. The relaxation times quoted are the mean values of several runs.

Results

The experimental conditions and the observed relaxation times at 25°C are shown in Table 1. The concentration dependence of the relaxation time can be explained on the basis of this simple mechanism:

$$M^{2+} + L^{2-} \underset{k_d}{\overset{k_f}{\rightleftharpoons}} ML. \qquad (1)$$

where M^{2+} is the metal ion, L^{2-} is the ligand, and ML is the complex. For such a mechanism, $1/\tau$ is given by the expression:

$$1/\tau = k_f\gamma_\pm^2(C_M+C_L) + k_d \qquad (2)$$

where k_f, k_d are the rate constants of the complex formation and the dissociation at zero ionic strength respectively, where $\gamma_\pm$ is the mean activity coefficient of the free ions at a finite ionic strength, and where C_M, C_L are the concentrations of the metal and the ligand ions respectively.

a) C_o refers to the total stoichiometric concentrations of the nickel maleate.

For the evaluation of the rate constants, $1/\tau$ is normally plotted against $\gamma_\pm^2(C_M+C_L)$. The intercept, corresponding to $\gamma_\pm^2(C_M+C_L)=0$, yields k_d, while k_f can be obtained from the slope. Such a plot requires a knowledge of the stability constant, K, in order to calculate the concentrations of the free ions. An appropriate literature value was not, however, available, and so the values were evaluated as follows. As the first approximation, a value of K which was roughly estimated from that of the succinate complex[9] was used to calculated the ionic concentrations. The mean activity coefficients were evaluated from the ionic strengths, which had themselves been calculated from the ionic concentration, using the Kielland equation.[12] Then, the $1/\tau$ values were plotted against $\gamma_\pm^2(C_M+C_L)$. The stability constant, which should coincide with the first estimated K value, was obtained from the ratio between k_f and k_d. Successive approximations were performed until a constant K value was obtained. The final results are shown in Fig. 1. The rate and the stability constants at various temperatures are given in Table 2.

The Arrhenius energies of activation, ΔE_f^* and ΔE_d^*, were obtained from the plot of $\log k_f$ and $\log k_d$ respectively against $1/T$, as is shown in Fig. 2. The other thermodynamic parameters of the complex formation, *i. e.*, the entropy of activation, ΔS_f^*, the enthalpy of activation, ΔH_f^*, and the free energy of activation, ΔG_f^*, were calculated from the following

equations; they are listed in Table 3:

$$\log A = \log\frac{eRT}{Nh} + \frac{\Delta S_f^{\neq}}{2.3R} \tag{3}$$

$$\Delta H_f^{\neq} = \Delta E_f^{\neq} - RT \tag{4}$$

$$\Delta G_{f\neq} = \Delta H_f^{\neq} - T\Delta S_f^{\neq} \tag{5}$$

where A is the frequency factor.

Discussion

The complex formation reactions between a metal ion and a bidentate ligand have been usually represented by the following mechanism:

$$\underset{(I)}{M^{2+} + L^{2-}} \underset{k_{-0}}{\overset{k_0}{\rightleftharpoons}} \underset{(II)}{MO\overset{H}{\underset{H}{}}L} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{(III)}{M-L} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \underset{(IV)}{ML}. \tag{6}$$

where (I) is the free ion, (II) is the outer-sphere complex, (III) is the monodentated complex, and (IV) is the bidentated chelate complex.

In the case of the nickel maleate, however, Eq. (6) cannot be applied directly. The stability constants of the nickel dicarboxylate in Table 4 show that the oxalate is a very stable five-membered chelate complex and that the malonate is a less stable six-membered chelate complex. The maleate and the succinate are much less stable, and their stability constants are nearly equivalent to that of the adipate. Moreover, the rate constants of the complex formation and the dissociation of the maleate and the succinate are quite similar to those of the adipate, as is shown in Table 4. Taking into account the fact that the adipate ion does not form a chelate complex,[13] these facts suggest that the maleate and the succinate ions do not form a chelate complex, either. Assuming that the concentration of the chelate complex is negligibly small in comparison with those of the other species, Eq. (6) can be simplified as follows:

$$\underset{(I)}{Ni^{2+} + Mal^{2-}} \underset{k_{-0}}{\overset{k_0}{\rightleftharpoons}} \underset{(II)}{NiO\overset{H}{\underset{H}{}}Mal} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{(III)}{Ni-Mal.} \tag{7}$$

In this reaction, the formation of the outer-sphere complex seems to be very fast, so the relaxation time of the rate-determining step of Eq. (7) is given by the equation:

$$1/\tau = \frac{k_1K_0\gamma_{\pm}^2(C_M+C_L)}{1+K_0\gamma_{\pm}^2(C_M+C_L)} + k_{-1} \tag{8}$$

where K_0 ($=k_0/k_{-0}$) is the outer-sphere complex formation constant. In the present experiments, $K_0\gamma_{\pm}^2(C_M+C_L)$ is much smaller than unity; therefore Eq. (8) can be simplified to:

$$1/\tau = k_1K_0\gamma_{\pm}^2(C_M+C_L) + k_{-1}. \tag{9}$$

Since the concentration of the outer-sphere complex is small, the overall stability constant is given as follows:

$$K = K_0\frac{k_1}{k_{-1}} = \frac{k_f}{k_d}. \tag{10}$$

a) The reported rate constant at 20°C was converted to the value at 25°C.

By comparing Eq. (9) with Eq. (2), the following equations were obtained:

$$k_f = k_1K_0 \tag{11}$$

$$k_d = k_{-1}. \tag{12}$$

The outer-sphere complex formation constant was calculated to be $K_0=25\ M^{-1}$ by the Fuoss equation.[14] Then, k_1 was calculated from k_f and Eq. (11) to be $3.4\times10^4\ s^{-1}$ at 25°C. The value is very close to the water-exchange rate constant on the nickel ion,[15] $k^*=2.7\times10^4\ s^{-1}$. This fact suggests that the rate-determining step of the nickel maleate complex formation is the loss of the water molecule from the inner coordination sphere of the nickel ion. Moreover, the value of k_d is in good agreement with the dissociation rate constant of the nickel maleate, $k_{-1}=2\times10^3\ s^{-1}$, reported by Hoffmann *et al.*[10,16] These coincidences of the data lead to the conclusion that the above procedures are valid.

The kinetic data of the nickel maleate complex formation in Table 3 can be compared with those of other complexes.[5,6,9] $\Delta E_f^{\neq}$, $\Delta H_f^{\neq}$, and $\Delta S_f^{\neq}$ are relatively larger than those of other, analogous nickel dicarboxylate complexes. These differences may be attributed to differences in the stabilities of the outer-sphere complexes. The stability constant can be referred to the literature value at $\mu=0.1$.[17] By dividing the value by $\gamma_\pm^2=0.154$, the stability constant at zero ionic strength was estimated to be $650\ M^{-1}$, which was almost the same, within the limits of experimental error, as our result.

The relaxation effects in the nickel dicarboxylate solution have been discussed by two different theories. In one theory,[5,6,8] the monodentated complex formation step, (II)⇌(III) in Eq. (6), is considered to be the rate-determining step. On the assumption that C_{II}, $C_{III}\ll C_I, C_{IV}$ and that $k_{-1}\ll k_2$, the rate constants in Eq. (2) were related to the parameters in Eq. (6) as follows:

$$k_f = K_0k_1\left(\frac{k_2}{k_2+k_{-1}}\right) \tag{13}$$

$$\simeq K_0k_1. \tag{14}$$

$$k_d = k_{-1}\left(\frac{k_{-2}}{k_2+k_{-1}}\right) \tag{15}$$

$$\simeq k_{-1}/K_2. \tag{16}$$

where $K_2=k_2/k_{-2}$. The values of k_1 obtained for many kinds of complexes by means of Eq. (14) are of the order of $\sim10^4\ s^{-1}$, which is very close to the water-exchange rate on the nickel ion;[15] hence, the loss of the water molecule from the inner-coordination sphere of the nickel ion may be considered to be the rate-determining step. The fact that the value of k_d reflects the stabilities of the chelate complexes can be interpreted in terms of Eq. (16), where K_2 shows the stabilities of the chelate. This theory may also be applied to the nickel dicarboxylate complex whose k_f is relatively large ($\gg10^5\ M^{-1}\ s^{-1}$), while at the same time, its k_d is very small. By this theory, Bear *et al.*[9] have assumed that the nickel succinate is a stable chelate complex, *i. e.*, $K_2\gg1$, and have obtained a large value for k_d. It can be seen from Eq. (16), however, that if $K_2\gg1$, k_{-1} will also become very large. The fact is in disagreement with the postulated condition, $k_{-1}\ll k_2$. If $K_2\simeq1$ is assumed, the rate equations become more complicated[18] than Eqs. (1) and (2). In the nickel succinate solution, the relaxation effect has been expressed by a single relaxation and the concentration dependency of τ can be expressed by Eq. (2). This means that the same interpretations should be applied to the succinate as to the maleate system. Moreover, the agreement of k_d with the dissociation rate constant of the succinate,[10,16] $k_{-1}\simeq3\times10^3\ s^{-1}$, indicates that Eq. (12) should be used rather

18) G. H. Czerlinski, "Chemical Relaxation," Marcel Dekker Inc., New York, (1966).

than Eq. (16).

On the other hand, Hoffmann *et al.*[10,11] have considered that the rate-determining step of the complex formation is the chelate-ring closure, *i. e.*, (III)$\rightleftharpoons$(IV) in Eq. (6). They assumed that K_0k_1 is constant (8.5×10^5 M^{-1} s^{-1}) for all the nickel dicarboxylates and that the small difference in k_f can be attributed to the $k_2/(k_2+k_{-1})$ term. As can be seen from Eq. (15), however, when k_d becomes relatively large, the k_{-2}/k_2 term increases and C_{III} cannot be neglected in comparison with C_{IV}. This fact disagrees with the assumptions used in deriving Eqs. (13) and (15). Therefore, this procedure can be appropriately applied to a system where $k_f \ll 8.5\times 10^5$ M^{-1} s^{-1} and where at the same time, k_d is small.

In summary, when k_d becomes large, $k_d \gtrsim 10^3$ s^{-1}, C_{III} cannot be neglected and Eqs. (13) and (15) need to be re-evaluated. In some cases where C_{III} is much larger than C_{IV}, Eqs. (7) to (12) should be applied.

Study on Oxazolopyrimidines. VI. Formation of 3-Substituted Xanthines *via* 7(6*H*)-Iminooxazolopyrimidines

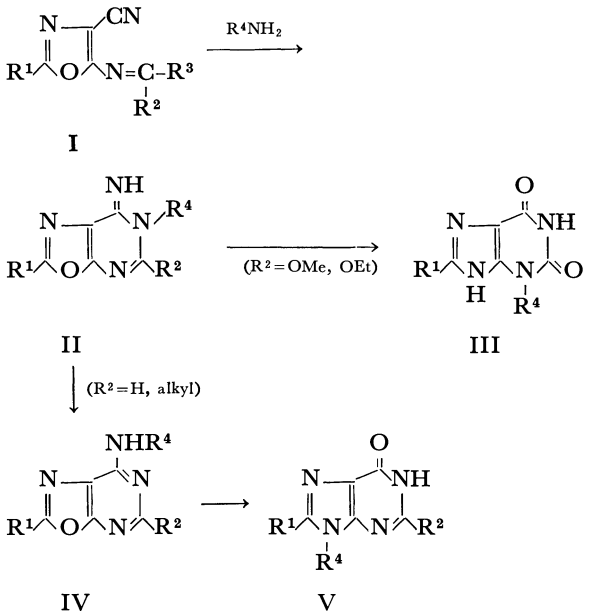
Yozo Ohtsuka

Sagami Chemical Research Center, Onuma, Sagamihara, Kanagawa

(Received August 8, 1972)

The condensation of several primary amines with 4-cyano-5-dialkoxymethylenaminooxazole gave 6-substituted 5-alkoxy-7(6*H*)-iminooxazolo[5,4-*d*]pyrimidines. These compounds were converted into 3-substituted xanthines by treatment with aqueous alkali or by heating in formamide. The present reaction was compared with an analogous reaction, formation of 9-substituted hypoxantines *via* 7-aminooxazolo[5,4-*d*]pyridimine derivatives, and the difference in the reaction course was discussed in terms of the effect of substituents on the stability of oxazolopyrimidine intermediates.

The reaction of 4-cyano-5-ethoxymethylenaminooxazole (I, R^2=H or alkyl, R^3=OEt) with amines giving 9-substituted hypoxanthines(V) *via* 7-alkyl-(aryl)aminooxazolopyrimidines(IV) has been reported previously.[1] This paper describes another mode of reaction in which the influence of the substituent in oxazolopyrimidine intermediates (II, R^2=alkoxy) leads to the formation of 3-substituted xanthines(III) under similar reaction conditions.



3-Substituted xanthines, important because of their biological properties[2] and of their usefulness as intermediates,[3] have been prepared previously from substituted ureas through pyrimidine derivatives.[3b,4-6] The present method provides a new route for the preparation of 3-substituted xanthines.

4-Cyano-5-diethoxymethylenaminooxazole(Ia, R^1=H, R^2=R^3=OEt) reacted with normal-alkylamines to give 6-alkyl-5-ethoxy-7(6*H*)-iminooxazolo[5,4-*d*]pyrimidines(IIa-e) as colorless crystals(Table 1). With several amines, such as isopropylamine, *t*-butylamine, aniline and benzylamine, isolation of products corresponding to compounds II has failed. The dimethoxymethylenamino compound(Ib, R^1=H, R^2=R^3=OMe), however, reacted with benzylamine to give the methoxy compound(IIf in Table 1). These products were relatively unstable and decomposed gradually on standing in moist air. The decomposition was greatly accelerated by the presence of a trace of alkali. The structure of these compounds was

a) Determined in dimethylsulfoxide(DMSO)-d_6 solution except with IId ($CDCl_3$).

identified on the basis of their spectral properties (Table 2) and elementary analysis. It was supported by the structure of the products of the subsequent reaction (see later). The compound II and 7-alkylamino compound(IV) were distinguished by comparison of the following properties: i) The compound II's were generally less stable than the compound IV's especially when they were heated in polar solvents.[7] ii) The most intense IR band in the 1600 cm^{-1} region of II appears at a higher frequency region by about 40 cm^{-1} than that of IV. iii) In NMR spectra of IV, NH and α-CH of N-alkyl group were observed as broad peaks, whereas the spectra of II showed no distinct NH absorption and α-CH of N-alkyl group was observed as sharp lines, probably due to the rapid exchange of imino-proton with solvent.[8]

The oxazole-imidazole conversion in 7-aminooxazolopyrimidines[1,9] was applied to the compound II. Thus, by treatment with aqueous alkali(Method A) or by heating in formamide(Method B), compounds IIa–f were found to give 3-substituted xanthines(IIIa–f) as shown in Table 3. The structures of III's were confirmed by comparison with authentic samples or with the samples prepared from pyrimidine derivatives. Table 3 also showed an example of comparison between two methods of preparation. Better results were generally obtained with Method B, although all of II's gave III's by Method A. The formation of 9-sub-

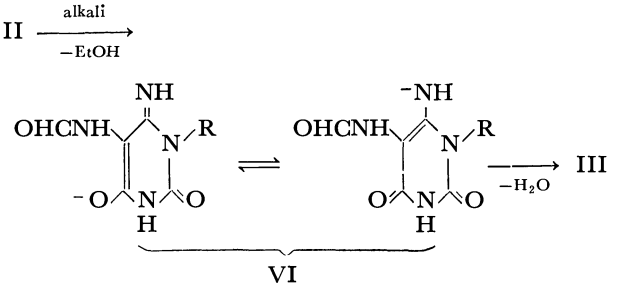
stituted xanthines or other rearranged products was not detected.

In previous studies on the conversion reaction of I into V, imino-intermediate(II) was not isolated. Careful re-examination of the reaction of 4-cyano-5-ethoxymethylenaminooxazole(Ic, $R^1=R^2=H$, $R^3=OEt$) and aqueous methylamine showed that the analogous imino-intermediate(IIg, $R^1=R^2=H$, $R^4=CH_3$) could be obtained in crude state (as shown by its IR and NMR spectrum), but further purification induced the Dimroth rearrangement into IVa($R^1=R^2=H$, $R^4=CH_3$). The rate of the rearrangement is known to decrease with an increase in electron density on the pyrimidine ring.[10] Therefore, in the present reaction, the electron-donating effect of the 5-alkoxy group may stabilize the structure II.

The preference of ring fission either at the oxazole or the pyrimidine ring of imino-intermediate(II) seemed to be determined by two factors. One is the electronic effect of the 5-substituent, and the other is the stability of the uracil-type intermediate, which is suggested by the following result. Under similar conditions to those in the change of II into III, 7-amino-5-ethoxyoxazolopyrimidine(IVb, $R^1=R^4=H$, $R^2=OEt$)[9] gave only 2-ethoxyhypoxanthine(Va, $R^1=R^4=H$, $R^2=OEt$). This compound, Va, was stable to hot aqueous alkali and hydrolysis to xanthine was only accomplished by refluxing in concentrated acid. Acid conditions are generally used for hydrolysis of an alkoxy group of pyrimidines or purines, and alkali seems to be effective only with compounds in which the alkoxy group is activated.[11] Thus, the easy conversion of II into III under alkaline condition seems to be assisted by the stability of the uracil-type intermediates(VI).



The easy hydrolysis of an ethoxy group probably initiates the reaction, but no experiment has been done to confirm the mechanism.

Degradation of purine derivatives generally occurs at the pyrimidine ring. With 7(6*H*)-iminooxazolopyrimidines, the two constituent rings have similar reactivity and the direction of ring rupture is determined by the character of the substituent. Other synthetic applications of the interesting properties of oxazolopyrimidine derivatives are being explored.

Experimental

Melting points were measured on a hot-stage apparatus and uncorrected. The IR, NMR, and MS spectra were determined with a Perkin-Elmer 337, a Hitachi-Perkin-Elmer R-20B (60 MHz) and a Hitachi RMU-6E (70 eV) spectrometer, respectively.

Preparation of Starting Materials (I). Preparation of 4-cyano-5-diethoxymethylenaminooxazole (Ia) was described in a previous paper.[12] 4-Cyano-5-dimethoxymethylenaminooxazole (Ib) was prepared by the method analogous to that used for Ia. Thus, 5-amino-4-cyanooxazole (3.0 g), tetramethyl orthocarbonate (15 ml) and acetic anhydride (15 ml) were refluxed for 7 hr. The reaction mixture was distilled *in vacuo* and a fraction, bp 113—115°C/0.28 mmHg, was collected, which solidified on cooling. The product was recrystallized from methylcyclohexane to give colorless solid, mp 65.0—65.5°C (Yield; 47.8%). ν_{max}^{KBr}: 2208 cm^{-1} (C≡N). NMR ($CDCl_3$) δ: 7.52 (s, 1H, C_2-proton), 4.03 (s, 6H, methyl protons).

Found: C, 46.40; H, 3.68; N, 23.03%. Calcd for $C_7H_7N_3O_3$: C, 46.41; H, 3.68; N, 23.20%.

Preparation of Oxazolopyrimidine Derivatives (II). 5-Ethoxy-6-methyl-7(6H)-iminooxazolo[5,4-d]pyrimidine (IIa): To an ice-cooled aqueous solution of methylamine (30%, 1 ml), 4-cyano-5-diethoxymethylenaminooxazole (Ia, 2.0 g) was added in one portion. The mixture was stirred at room temperature until a solid was separated. On warming gradually to 40—50°C, the solid was melted and then a second solid started to precipitate. After 1 hr, the reaction mixture was cooled and resulting crystals (1.1 g) were collected by filtration. The compound IIb and IIc were prepared by this method.

5-Ethoxy-6-n-butyl-7(6H)-iminooxazolo[5,4-d]pyrimidine (IIId). An ethanol solution of *n*-butylamine (1.4 g in 15 ml) was mixed with Ia (1.5 g) under cooling. After stirring at room temperature for 15 min, the residual amine and ethanol were evaporated from the mixture under reduced pressure. Resulting crystals were dried *in vacuo* for 30 min and then refluxed in ethanol (20 ml) for 6 hr. Concentration of the mixture gave a light tan solid (1.0 g). This product was purified for analysis by re-precipitation from 4 N aqueous NaOH–HCl followed by recrystallization from water. The compound IIe was prepared by this method.

5-Methoxy-6-benzyl-7(6H)-iminooxazolo[5,4-d]pyrimidine (IIf). To a cold mixture of benzylamine (1.2 g) and Ib (2.0 g), a few drops of water added. Resuting semisolid was stirred at room temperature for 1 hr and then 50°C for 30 min. After cooling, the solid was collected and washed with water. Resulting crystals were dried *in vacuo* for 30 min and then refluxed in ethanol. The hot reaction mixture was filtered and the filtrate was concentrated to give a solid which was recrystallized from water-ethanol.

Reaction of 4-Cyano-5-ethoxymethylenaminooxazole (Ic) with methylamine. To an ice-cooled aqueous solution of methylamine (30%, 1 ml), Ic (1.65 g) was added in one portion. A solid started to precipitate immediately from solution, but on continued stirring it dissolved. After several minutes, a second solid precipitated. Immediate filtration and washing with a small quantity of cold water gave a crystalline solid (1.2 g). The second solid was identified as 5-ethoxy-7(6*H*)-imino-6-methyloxazolo[5,4-*d*]pyrimidine (IIg) from its IR (absence of nitrle group) and NMR spectrum (a broad NH-absorption at about 8.4 ppm and a

singlet at a about 7.9 ppm), but recrystallization from water or ethanol gave 7-methylaminooxazolo-pyrimidine (IVa).[1]

Preparation of 3-Substituted Xanthines from Oxazolopyrimidine Derivatives. Method A: A mixture of the compound II and a aqueous NaOH was warmed on a water bath until it became a homologous solution (5—30 min). After cooling, acidification of the reaction mixture by acetic acid gave the product.

Method B: The compound II was heated in formamide at 180°C for 5—15 min. Formamide was distilled off *in vacuo* and the residue was crystallized from water.

The structures of products were identified as 3-substituted xanthines from their elementary analysis and from the coinsidence of their spectroscopic properties (IR and NMR spectra) with those of authentic samples (IIIa and IIIf)[5,2b] or with those of samples prepared from pyrimidine derivatives by the method described below (IIIb—IIIe).

3-Phenethylxanthine (IIIe). This compound was obtained from IIe by Method B. Recrystallization from aqueous ethanol gave colorless needles, mp 315—316°C. ν_{max}^{KBr} cm^{-1}: 3122, 2820, 1700, 1561, 1427, 1218, 981, 830, 707. NMR (DMSO-d_6) δ: 8.00 (s, 1H, C_2-proton), 7.22 (s, 5H, phenyl protons), 4.20 and 2.96 (t, 2H, methylene protons, respectively).

Found: C, 60.68; H, 4.60; N, 22.08%. Calcd for $C_{13}H_{12}N_4O_2$: C, 60.93; H, 4.72; N, 21.87%.

Preparation of 3-Substituted Xanthines from Pyrimidine Derivatives. Cyanoacetylureas, $RNHCONHCOCH_2CN$, were prepared from substituted ureas and cyanoacetic acid by method of Traube.[13] These compounds were converted into isonitroso derivatives, RNHCONHCOC (=NOH)CN,[14] followed by reduction with zinc and formic acid to formylamine derivatives, RNHCONHCOCH(CN)NHCHO.[5] These compounds were treated with alkali[5] to give formylaminopyrimidines. Without further purification, these materials were heated under reflux in formic acid for 5 hr. 3-Substituted xanthines, thus obtained, were confirmed to be identical with the samples prepared from II's from their spectroscopic properties. Analytical data of these compounds were shown in Table 4.

The author wishes to thank Prof. S. Simamura for discussions and Mr. K. Sugimoto and Mr. T. Miyazaki for their technical assistance.

The Reaction of Propargyl Compounds with Carbon Monoxide and Water in the Presence of Iron Carbonyl Catalyst

Fumio WADA and Tsutomu MATSUDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka-shi

(Received February 26, 1972)

The reaction of propargyl alcohol as well as its acetate and methyl ether with carbon monoxide and water in the presence of ironpentacarbonyl-amine catalyst under oxymethylation conditions proved to proceed at a much faster rate than that of 1-butyn-4-ol, 1-pentyn-5-ol and alkylacetylenes accompanied by elimination of the functional groups at C-3 to give dimethyl methylsuccinate. 3-Methyl-1-butyn-3-ol and 1-ethynylcyclohexanol reacted in a similar manner, but gave mixtures of unsaturated monoesters and diesters, saturated and unsaturated. The faster rate of reaction and the product obtained were interpreted by a scheme involving a concerted attack of hydroirontetracarbonyl anion, $HFe(CO)_4^-$, at the terminal position to split off the group at C-3. The mononuclear hydrido anion was assumed to be an active catalytic species in the reaction on the basis of both the infrared spectra of the catalyst system under the reaction conditions and the efficiency of potassium hydroxide as a base component.

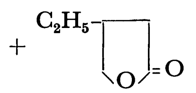
In a series of investigations[1)] on the oxymethylation of unsaturated compounds by carbon monoxide and water (or hydrogen) in the presence of ironpentacarbonyl and a base, we found that this type of catalyst could bring about three kinds of reactions, oxymethylation, hydrogenation and carboxylation and that the principal course of the reaction depends on the structure of reactants as shown in the following reactions.

$$R\text{-}CH_2\text{-}CH{=}CH_2 \rightarrow R\text{-}CH_2\text{-}CH_2\text{-}CH_2(CH_2OH) + R\text{-}CH_2\text{-}CH(CH_2OH)\text{-}CH_3 \qquad (1)$$

$$\left.\begin{array}{l} CH_2{=}CH\text{-}CO_2CH_3 \rightarrow CH_3\text{-}CH_2\text{-}CO_2CH_3 \\ CH_2{=}CH\text{-}CH_2OH \rightarrow CH_3\text{-}CH_2\text{-}CH_2OH \end{array}\right\} \qquad (2)$$

$$CH_2{=}CH\text{-}(CH_2)_2\text{-}CO_2CH_3 \rightarrow CH_2(CH_2OH)\text{-}(CH_2)_3\text{-}CO_2CH_3 \text{ and isomers} + CH_3\text{-}(CH_2)_3\text{-}CO_2CH_3 \qquad (3)$$

$$C_2H_5\text{-}C{\equiv}CH \rightarrow C_2H_5\text{-}CH_2CH_2(CO_2CH_3) + C_2H_5\text{-}CH(CO_2CH_3)\text{-}CH_2(CO_2CH_3)$$



(4)

Simple olefins gave a mixture of oxymethylated products at 175°C, while α,β-unsaturated esters, nitriles and allylic alcohols were hydrogenated exclusively to the corresponding saturated compounds at a somewhat lower temperature. However, oxymethylation of the substituted compounds was found to occur when the double bond was separated from ester or hydroxyl group by more than one methylene group (Eq. (3)).[1d)] A similar effect of a neighboring double bond was observed by examining the time dependence of the products in the oxymethylation of isomeric hexadienes.[1b)] This paper deals with an extention of the neighboring substituent effect to acetylenic compounds, and presents both unusual behaviours of propargyl alcohol and its derivatives (I) and a probable structure of an active catalytic species in the reaction.

Results and Discussion

Products and their yields under vairous reaction conditions are summarized in Table 1. The reaction of propargyl alcohol proceeded rapidly at 175°C under concurrent formation of an unidentified by-product even in a short reaction time such as 40 min. The main product (II) formed as the sole product at 125°C was confirmed to be dimethyl methylsuccinate. Propargyl acetate and 3-methoxy-1-propyne showed similar reactivities and both afforded II in comparable yields. Formation of II from these compounds regardless of their functional groups can be explained by the route in which addition of methoxycarbonyl groups proceeded under elimination of the groups at C–3 *i. e.*, OH, OAc or OCH_3. Elimination accompanied by carboxylation also occurred in the reaction of the substituted propargyl alcohols, 3-methyl-1-butyn-3-ol (Id) and 1-ethynylcyclohexanol (Ie). However, these compounds afforded complex mixtures consisting of an unsaturated monoester and both saturated and unsaturated diesters. The structural features of these products suggest a reaction scheme in which the first carboxylation occurred exclusively at the terminal position and the subsequent step involving either the second carboxylation or hydrogenation led to the final products. The latter step seems to be considerably slower than the former for compounds which are sterically hindered by substitution at C–3. On the other hand, the reaction of 1-butyn-4-ol was found to proceed at a much slower rate as shown in Fig. 1.

b) Potassium hydroxide (0.10 mol) was used in place of triethylamine.

c) The reaction was carried out under the initial carbon monoxide pressure, 3 kg/cm².

Formation of the product identified as α-methyl-γ-butyrolactone and α-methylcrotonolactone can be explained by a different pathway in which the addition of a methoxycarbonyl occurrs at β-carbon and then the hydroxyl group at C-3 takes part in the cyclization to give lactones. This means that the mechanism of formation of these lactones differs from that of the γ-lactones obtained from the reaction of alkylacetylenes (Eq. (4)). Although several compounds are left unidentified, the products from 1-pentyn-5-ol seem to be those which retained the original hydroxyl moiety. Thus, it is concluded that the elimination process plays an important role in the reaction of propargyl compounds, and gives rise to both the increased reaction rate and the characteristic feature of the products. A similar carbonylation under elimination of a functional group has been reported by Nogi and Tsuji[2] in the palladium catalyzed reactions of propargyl compounds in alcoholic solvents.

When we proceed to formulate a reaction course which includes the elimination of the electronegative group from the propargyl position, the formation of an intermediate of allenic structure would have to be considered as a possible pathway. However, the

reaction of allene under the same conditions proved to be more sluggish than that of propargyl alcohol and led to a complex mixture in which neither methylsuccinate nor the corresponding unsaturated compounds was detected.

The reaction of propargyl alcohol utilizing potassium hydroxide in place of triethylamine was found to proceed in a similar way but at an increased rate, and provided an interesting difference from the oxymethylation of olefins, where potassium hydroxide proved to be a nearly ineffective base. Although the result suggests that the active species in the reaction of propargyl compounds is mononuclear hydroirontetracarbonyl anion, $HFe(CO)_4^-$, it is not clear why both triethylamine and potassium hydroxide act as an equally effective base, if we take into consideration the fact that the nature of the base is responsible for the formation of different kind of hydrido ironcarbonyls[3] according to the following reactions.

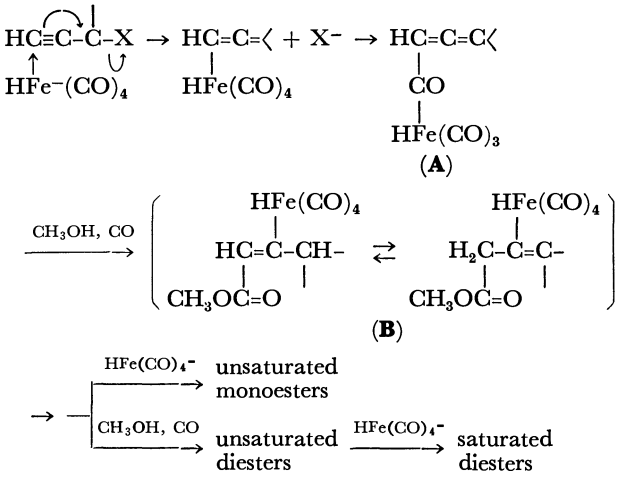
$$Fe(CO)_5 + 3KOH \rightarrow K^+HFe(CO)_4^- + K_2CO_3 + H_2O \quad (5)$$

$$3Fe(CO)_5 + NR_3 + 2H_2O \rightarrow HFe_3(CO)_{11}^{-}H\overset{+}{N}R_3 + 2CO_2 + 2CO + H_2 \quad (6)$$

A qualitative examination of these catalyst systems by infrared spectra revealed that the hydrido species formed under the present experimental conditions was not trinuclear but mononuclear anion, irrespective of the base utilized as shown in Fig. 2. This would imply that not only the nature of the base but also the presence of carbon monoxide under pressure is an important factor in determining the structure of hydrido ironcarbonyl species in solution. It is of interest that the absorption at 1880 cm^{-1} attributable to the mononuclear anion in methanol persisted unchanged for 6.5 hr at 150°C in the presence of triethylamine (Fig. 2a), but when potassium hydroxide was used, the anion initially formed in a larger quantity decreased rapidly and completely collapsed to ironpentacarbonyl after being heated for 3 hr at the same temperature (Fig. 2b), possibly by the consumption of potassium hydroxide due to repetition of reaction (5) and the following.

$$K^+HFe(CO)_4^- + H_2O \xrightarrow{CO} Fe(CO)_5 + H_2 + K_2CO_3 \quad (7)$$

We thus propose the scheme for the reactions of propargyl compounds as follows.



The essential step would be the concerted attack of mononuclear hydrido ironcarbonyl anion at the terminal carbon to split off the anion X^-, the following insertion of carbon monixide giving an acyl iron intermediate (**A**). Although the subsequent step leaves considerable ambiguity in the present stage of experiment, the reaction of methanol to **A** probably

3) R. B. King and F. C. A. Stone, "Inorganic Syntheses", Vol. VII, p. 193 (1963), W. McFarlane and G. Wilkinson, *ibid.*, Vol. VIII, p. 181 (1966).

affords another iron containing intermediate (**B**), which reacts in two ways: 1) hydrogenation by the hydrido anion to give unsaturated monoesters and 2) second carboxylation to unsaturated diesters. The facile formation of the hydrido anion from ironpentacarbonyl in the presence of potassium hydroxide would be resposible for the observation that pressure drop in experiment 5 started at a lower temperature (125°C) than 150°C (Fig. 1, curve B). However, potassium hydroxide essential for the regeneration of the hydrido anion from ironpentacarbonyl is consumed irreversibly to form potassium carbonate under the reaction conditions according to reactions (5) and and (7). The process constitutes a side reaction which inactivates the catalysis system and is presumably a principal factor distinguishing the function of potassium hydroxide from that of tertiary amines, and accounts for the formation of unsaturated diesters in experiment 5 as compared to nearly none in experiment 4 and also for the previous result[1a] where the catalysis system containing potassium hydroxide was nearly ineffective in the oxymethylation of olefins which required longer reaction time(20—30 hr) and higher reaction temperature (170—175°C).

Experimental

Materials. Commercial propargyl alcohol was purified by distillation. Propargyl acetate was prepared by acetylation propargyl alcohol. 3-Methoxy-1-propyne was obtained by debromination of 2,3-dibromo-1-methoxypropane.[4] 3-Methyl-1-butyn-3-ol, 1-ethynylcyclohexanol and 1-butyn-4-ol were synthesized by the reaction of sodium acetylide with acetone, cyclohexanone and ethylene oxide in liquid ammonia, respectively.[5] 1-Pentyn-5-ol was obtained by treatment of tetrahydrofurfuryl chloride with sodium amide in liquid ammonia.[6]

General reaction procedure. Acetylenic compound (0.25 mol), triethylamine (0.25 mol), water (0.40 mol), ironpentacarbonyl (0.05 mol) and 70 ml of methanol were placed in a 300 ml autoclave. After air was displaced with carbon monoxide, carbon monoxide was introduced until pressure became 90—100 kg/cm^2. The mixture was heated under stirring to the desired temperature ranging from 70 to 175°C in about one hour and held at the reaction temperature until the pressure drop substantially ceased. To a dark green reaction mixture was added 100—150 ml of saturated sodium chloride solution and the organic component was taken up by ether. After neutralizing the remaining amine, the ethereal solution was dried and concentrated. The product collected by distillation of the residue was analyzed by gas chromatography and the yeilds of each component were calculated by assuming a proportionality between peak area and weight. The main components of the product were separated by gas chromatography and determined by infrared spectra, NMR and elementary analysis.

Product Identification. The principal product (II) obtained from Ia, Ib and Ic was confirmed as dimethyl methylsuccinate by its infrared spectrum, NMR and elementary analysis (Found: C, 57.72%; H, 7.74%) and further substantiated by comparison with an authentic sample. The other three components found in the reaction of propargyl alcohol using potassium hydroxide as a base were separated analytically by gas chromatography. They gave the following results.

III: dimethyl methylmaleate, NMR: 2.25 (d, 3H), 3.72 (s, 3H), 3.73 (s, 3H) and 6.67 (quar, 1H). Found: C, 53.40; H, 6.53%. Calcd for $C_7H_{10}O_4$: C, 53.16; H, 6.37%.

IVa: dimethyl itaconate, NMR: 3.24 (d, 2H), 3.64 (s, 3H), 3.73 (s, 3H), 5.65 (m, 1H) and 6.22 (m, 1H).

IVb: dimethyl methylfumarate, NMR: 2.2 (d, 3H), 3.67 (s, 3H), 3.73 (s, 3H) and 5.75 (quar, 1H). Found: C, 53.20; H, 6.53%. Calcd for $C_7H_{10}O_4$: C, 53.16; H, 6.37%.

Their structure were further confirmed by hydrogenation to form dimethyl methylsuccinate.

Distillation of the reaction product from 3-methyl-1-butyn-3-ol gave two fractions. Two components V and VI in the lower fraction (64.0/85 —91.0°C/65 mmHg) and five components VII–XI in the higher fraction (105—147°C/4 mmHg were separated by gas chromatography and analyzed. No alcoholic component could be detected.

V: methyl β-isopropylacrylate (*cis* and *trans* mixture), NMR: 1.05 (d, 6H), 1.85—2.64 (m, 1H), 3.60 (s, 3H), 5.55 (quar, 1H) and 6.71 (quar, 1H). Found: C, 64.76; H, 9.16%. Calcd for $C_7H_{12}O_2$: C, 65.59; H, 9.44%.

VI: methyl 4-methyl-3-pentenoate, NMR: 1.59 (s, 3H), 1.70 (d, 3H), 2.87 (d, 2H), 3.55 (s, 3H) and 5.17 (m, 1H). Found: C, 65.89; H, 9.64%.

VII: dimethyl isopropylsuccinate, NMR: 0.91 (s, 6H), 1.90—2.75 (m, 4H), 3.56 (s, 3H) and 3.58 (s, 3H). Found: C, 57.48; H, 8.59%. Calcd for $C_9H_{16}O_4$: C, 57.43; H, 8.57%.

VIII: dimethyl isopropylmaleate or fumarate, NMR: 1.10(d, 6H), 2.50 (m, 1H), 3.50(s, 3H), 3.57 (s, 3H) and 5.58 (d, 1H). Found: C, 58.37; H, 7.76%. Calcd for $C_9H_{14}O_4$: C, 58.05; H, 7.85%.

IX: 3-isopropyl-γ-butyrolactone, $\nu_{C=O}$; 1780 cm^{-1}, NMR: 0.93 (d, 3H), 0.96 (d, 3H), 1.45 (m, 1H), 1.80—2.60 (m, 3H) and 3.50—4.40 (m, 2H). Found: C, 65.60; H, 9.24%. Calcd for $C_7H_{12}O_2$: C, 65.59; H, 9.44%

X: dimethyl isopropylidenesuccinate, NMR: 1.80 (s, 3H), 2.10 (s, 3H), 3.25 (s, 2H), 3.60 (s, 3H) and 3,65 (s, 3H). Found: C, 59.02; H, 7.77%.

XI: 4,4-dimethyl-3-methoxycarbonyl-γ-butyrolactone, $\nu_{C=O}$; 1780, 1740 cm^{-1}. NMR: 1.25 (s, 3H), 1.58 (s, 3H), 2.4—3.32 (m, 3H) and 3.73 (s, 3H). Found: C, 55.85; H, 7.26%. Calcd for $C_8H_{12}O_4$: C, 55.80; H, 7.03%.

Four compounds separated in a similar manner from the product of 1-ethynylcyclohexanol were identified as follows.

XII: methyl 3-cyclohexylidenepropionate, NMR: 1.53 (m, 6H), 2.10 (m, 4H), 2.94 (d, 2H), 3.62 (s, 3H) and 5.21 (t, 1H).

XIII: methyl trans-β-cyclohexylacrylate, NMR: 1.50 (m, 11H), 3.68 (s, 3H), 5.69 (quar, 1H) and 6.85 (quar, 1H).

XIV: dimethyl cyclohexylsuccinate, NMR: 1.61 (m, 6H), 1.95 (m, 4H), 2.48 (m, 4H), 3.62 (s, 3H) and 3.64 (s, 3H).

XV: dimethyl cyclohexylidenesuccinate, NMR: 1.63 (m, 6H), 2.22 (m, 2H), 2.65 (m, 2H), 3.28 (s, 2H), 3.62 (s, 3H) and 3.68 (s, 3H).

The gas chromatogram of the product from 1-butyn-4-ol indicated the presence of two principal components XVI and XVII, but no alcoholic component such as *n*-butanol and 3- or 2-butenol-1. Assignment of their lactone structures

6) E. R. H. Jones, G. Eglinton, and M. C. Whiting, "Organic Syntheses", Coll. Vol. IV, p. 755 (1963).

based on the higher carbonyl absorptions and the absence of methoxycarbonyl group were characterized by the NMR peak in 3.50 to 3.75 ppm region. The saturated lactone could be differentiated from an authentic β-methyl isomer by their γ-proton signals in the 3.5—4.5 ppm region.

XVI: α-methyl-γ-butyrolactone, $\nu_{C=O}$; 1770 cm^{-1}. NMR 1.22 (d, 3H), 1.67—2.17 (m, 1H), 2.17—2.82 (m, 2H) and 4.0—4.33 (m, 2H). Found: C, 59.94; H, 8.27%. Calcd for $C_5H_8O_2$: C, 59.98; H, 8.05%.

XVII: α-methyl-γ-crotonolactone, $\nu_{C=O}$; 1760 cm^{-1}, $\nu_{C=C}$; 1660 cm^{-1}. NMR: 1.9 (quar, 3H), 4.72 (m, 2H) and 7.18 (quar, 1H). Found: C, 60.50; H, 6.29%. Calcd for $C_5H_6O_2$: C, 61.21; H, 6.17%.

Distillation of the product from 1-pentyn-5-ol gave two fractions. Owing to the complex nature and less volatility, attempted separation of the components in the higher fraction by gas chromatography afforded no pure samples. The three principal components in the lower fraction were separated by gas chromatography, two of them being confirmed as 1-pentene-5-ol and the strating material by comparison of their infrared spectra and in accordance with the retention times. The other component was proved to be methyl tetrahydrofuryl acetate by comparison with an authentic compound.

XX: methyl tetrahydrofuryl acetate, $\nu_{C=O}$; 1742 cm^{-1}. Found: C, 57.89; H, 8.71%. Calcd for $C_7H_{12}O_3$: C, 58.31; H, 8.39%.

Infrared Examination of the Catalysis System. A catalyst mixture in methanol containing ironpentacarbonyl (or $HFe_3(CO)_{11}^-HN^+Et_3$), a base and water in the same ratio as that used in the above reactions under the initial carbon monoxide pressure of 100 kg/cm^2 was heated to 150°C under stirring. A small aliquot was withdrawn from the vessel to a glass pressure sampler at a suitable interval starting from the instant 150°C was reached (or from 125°C in the presence of potassium hydroxide). The change of the ironcarbonyl species was followed by infrared spectra immediately taken after sampling, using the absorptions at 1995 cm^{-1} for ironpentacarbonyl and 1880 cm^{-1} for mononuclear hydroirontetracarbonyl anion. Light brownish yellow color of each aliquot at the time of sampling was indicative of the absence (or disappearance) of trinuclear hydrido species, which is readily discernible by its strong deep red color with a quantity less than 0.1%. The color of the samples, however, gradually turned pink due to slow conversion of the mononuclear anion to trinuclear species under atmospheric pressure.

Asymmetric Hydrogenation of C=O Double Bond with Modified Raney Nickel Catalyst. XXV. Contributions of pH-Adjusting Reagents in the Asymmetric Hydrogenation

Tadashi TANABE*, Kazuo OKUDA, and Yoshiharu IZUMI

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Suita, Osaka

(Received March 9, 1972)

In the asymmetric hydrogenation of methyl acetoacetate with modified Raney nickel catalysts, the effects of pH-adjusting reagents were studied using D-tartaric acid, L-2-hydroxyisovaleric acid, L-glutamic acid, and L-aspartic acid as the modifying reagents. The effects of various metal ions and ammonium ions were investigated at pH 5.0. The asymmetric activity of the catalyst modified with the 2-hydroxy monocarboxylic acid or 2-amino dicarboxylic acid was not affected by the pH-adjusting reagents. However, 2-hydroxy dicarboxylic acid was markedly influenced by the reagents. The univalent metal ion was more effective than divalent or ammonium ions. Sodium hydroxide was the best pH-adjusting reagent. The adsorption state of the modifying reagent was discussed on the basis of the effects of the pH-adjusting reagent.

In the asymmetric hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate, the pH of a modifying solution has been found to affect the asymmetric activity of the catalyst.[1,2] All the modifying reagents which have been tested, except neutral amino acids,[3] can be classified into two groups according to the effects of the modifying pH, as is shown in Fig. 1.

Group A: The hydroxy dicarboxylic acids. The asymmetric activity of catalyst modified with an acid of this group is at its maximum at about pH 5 and decreases on both the acidic and alkaline sides.

Group B: The hydroxy monocarboxylic acids and most monoamino dicarboxylic acids. The asymmetric activity of a catalyst treated with this group of acids is not influenced by the modifying pH on the acidic side and decreases with an increase in the modifying pH.

It was suggested by Tatsumi[4] that the pH-dependency of the asymmetric activity of the catalyst modified with the 2-hydroxy carboxylic acid might be brought about by the neutralization of the carboxyl groups. However, the case of the pH-dependency and the factors producing the two different kinds of effects of the modifying pH was not clear. The in-

fluences of the various pH-adjusting ions were studied, and the adsorption state of the modifying reagent and the pH-dependency of the asymmetric activity are discussed.

Experimental

L-2-Hydroxyisovaleric Acid (HIV). The HIV was prepared by the method of Winitz *et al.*[5]

Divalent Metel D-Tartarates. Divalent metal D-tartarates were prepared from the metal chlorides and sodium tartarate.[6]

Preparation of Raney Nickel Catalyst. Raney nickel alloy (40% of nickel, 1.5 g) was developed with a 20% aqueous sodium hydroxide solution (20 ml) and the suspension was allowed to stand for 1 hr at 100°C. Then the catalyst was washed with total 500 ml of deionized water.

Preparation of the Modifying Solution and the Modification of the Catalyst. The pH of a 1—2% aqueous solution (100—200 ml) of a modifying reagent was adjusted to 5.0 with a diluted aqueous solution of the metal hydroxide or a solid metal oxide, except for the study of the effect of the divalent metal ion on the asymmetric activity of the catalyst modified with D-tartaric acid. As, with the divalent transition metal oxide or the hydroxide, the pH-adjustment of a D-tartaric acid solution was difficult, metal D-tartarate prepared from the corresponding metal chloride and sodium D-tartarate was saturated in 0.2—1 l of water and the resulting solution was adjusted to pH 5.0 with D-tartaric acid. The modifying solution thus prepared was brought to the specified temperature and poured onto the catalyst; the suspension was then kept, with occasional shaking, at the specified temperature for 1.5 hr. After the removal of the modifying solution by decantation, the catalyst was washed once with water and three times with methanol.

Hydrogenation of Methyl Acetoacetate and Measurement of the Optical Rotation of the Product. Methyl acetoacetate (17.5 ml) was hydrogenated with a modified catalyst obtained by the procedure described in the previous section, under an initial pressure of 90 kg/cm² at 60°C in a shaking autoclave. The catalyst was then removed by filtration and the filtrate was distilled under reduced pressure (bp 61—62°C/12 mmHg). The optical rotation of the methyl 3-hydroxybutyrate thus produced was measured without dilution in a 1-dm tube.

Results and Discussion

The Influence of the Remaining Developing Reagent. Though the Raney nickel catalyst was washed with a sufficient amount of water (500 ml of water/600 mg of catalyst) after development with a 20% sodium hydroxide solution, a small smount of the remaining sodium ion could interchange with the metal ions used for the pH-adjustment and influence the asymmetric activity of the catalyst. For the study of the effect of the metal ions remaining in the catalysts, the two kinds of catalysts, those developed with sodium hydroxide and with potassium hydroxide, were modified with D-tartaric acid, and the their asymmetric activities were compared each other. The results are shown in Table 1.

Table 1. Effect of residual developing reagent in Raney nickel catalyst

Mod. reagent	Develop. reagent	pH-Adjusting reageat	Optical rotation of product α_D^{40}
D-Tartaric acid	NaOH	NaOH	−7.73
D-Tartaric acid	KOH	NaOH	−7.32
D-Tartaric acid	NaOH	KOH	−3.70

The asymmetric activity of the catalyst developed with sodium hydroxide and modified with potassium tartarate is considerably lower than that of the catalyst modified with sodium tartarate. However, the asymmetric activity of the catalyst developed with potassium hydroxide and modified with sodium tartarate hardly differed from that of the catalyst developed with sodium hydroxide and modified with sodium tartarate. Accordingly, the exchange of the ions used for the pH-adjustment with the sodium ion remaining on the catalyst surface seems to be negligible, judging from the above results.

The Effect of the pH-Adjusting Reagents on the Asym-

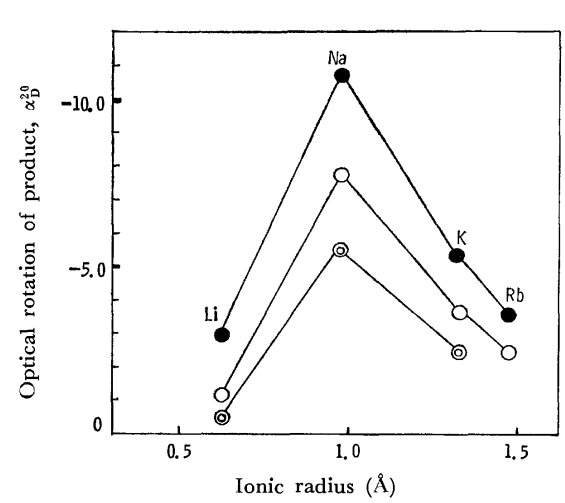

Fig. 2. Effect of pH-adjusting reagent. Catalysts were modified with D-tartaric acid, and D-malic acid at pH 5.0, 0°C and 100°C.

metric Activity of the Catalyst Modified with the Hydroxy Dicarboxylic Acid. The Effect of the Univalent Alkaline Ion: On the modification with the acid belonging to Group A, the asymmetric activity of the catalyst increased with the elevation of the modifying pH in the acidic region and reached a maximum between pH 5 and 8. In the alkaline region, the asymmetric activity of the catalyst gently decreased with the elevation of the modifying pH. In the present investigation, the modifying solutions of D-tartaric acid and D-malic acid were adjusted to pH 5.0, and the effect the univalent metal ion was studied. The results are shown in Fig. 2.

An intimate relation between the asymmetric activities of the catalyst and the bulk of the ions used for the pH-adjustment of the modifying solutions was found in the cases of modifications with D-malic acid and D-tartaric acid at 0°C and 100°C. That is, bulkier or smaller ions than sodium decreased the asymmetric activity; an optimum value was observed with sodium. The facts suggest that metal ions contribute to the enantiotopic selection of the substrate and that at least one carboxyl group of the hydroxy dicarboxylic acid forms salt with the metal ion on the catalyst surface.

The Effect of the Mixed Univalent Ions: The modifying pH was adjusted with equal amounts of two kinds of cations and the asymmetric activities were compared with the calculated values, which were given as a mean of the values obtained with the catalysts treated with the solutions adjusted with the cations separately. As is shown in Table 2, the observed activities were not proportional to the concentrations of ions, and stronger bases predominantly controlled the asymmetric activity.

The Effect of the Divalent Metal Ions: The effect of the divalent metal ion was examined using divalent metal D-tartarate; the results are shown in Table 3. The calcium ion gave the catalyst a slightly higher symmetric activity than the zinc, cupric, ferrous, nickel, and cobaltous ions. These divalent ions gave much lower asymmetric activities than the monovalent ions. These facts suggest that the divalent cations, which can form intermolecular or intramolecular salts with the dicarboxylic acids, contribute to the adsorption of a modifying reagent in a different manner from the univalent cations.

The Effect of the Amines: The influence of the bulk of the alkyl substituent of ammonia was also studied; the results are shown in Table 4. The asymmetric activity of a catalyst was lower when modified with a solution adjusted with the amines than when modified with a solution adjusted with the sodium ion. No effect of the bulk of the alkyl substituents was observed.

The Effect of the Metal Ions on the Asymmetric Activity of the Catalyst Modified with Hydroxy Monocarboxylic Acid: As has already been reported in a previous paper,[7] the 2-hydroxy monocarboxylic acid differed

from the 2-hydroxy dicarboxylic acid in that it gave the catalyst a constant asymmetric activity independently of the modifying pH in the acidic region.

The effects of univalent metal ions and ammonium ions were studied using a catalyst modified with L-2-hydroxyisovaleric acid (HIV). The results are shown in Table 5. The asymmetric activities of the catalysts modified with HIV were not affected by the pH-adjusting reagent and had values similar to that of the catalyst modified with a pH-adjusted solution containing the sodium ion. These results are quite different from the results obtained in the case of tartaric acid and show that the cation used for pH-adjustment does not take part in the adsorption of the hydroxy mono-carboxylic acid.

The Effect of Metal Ions and Ammonium Ions on the Asymmetric Activity of the Catalyst Modified with the Amino Acid: Most amino acids, except for α-alkyl substituted amino acids, are classified in Group A on the basis of their pH-dependency, and the asymmetric activities of the catalyst treated with those amino acids were not affected by the modifying pH in the acidic region.

The effects of metal and ammonium ions on the asymmetric activities of the catalysts treated with L-aspartic acid and L-glutamic acid were also studied; the results are shown in Tables 6 and 7.

The bulk of the univalent metal ions and ammonium ions, all except ethylenediamine and pyridine, did not affect the asymmetric activities; this is different from the results with D-malic acid and D-tartaric acid. Ethylenediamine and pyridine decreased the asymmetric activities of the catalysts. The divalent metal ions and the ammonium ions did not so decrease the asymmetric activities of the catalysts as was found on the modification with HIV, and the asymmetric activities of the catalysts were nearly the same when the pH of the modifying solution was adjusted, either with the amines or with the univalent cation, to that of the one modified with the solution pH-adjusted with the univalent cation.

Judging from these facts, the amino dicarboxylic acid seems to be adsorbed on the catalyst surface in a state which is not influenced by the ion used for the pH-adjustment, unlike the case of hydroxy dicarboxylic acid. That is, both the two carboxyl groups of the amino dicarboxylic acid may be used for the adsorption on the catalyst surface and may not form an ionic bond with the cation used for the pH-adjustment. Ethylenediamine and pyridine, which have a strong affinity for nickel, seem to be adsorbed competitively well onto the catalyst and inhibit the adsorption of the amino acid, thus decreasing the asymmetric activity of the catalyst.

The Adsorption State of the Modifying Reagent. It can be concluded, from the effects of the cations used for the pH-adjustment on the asymmetric activities of the catalysts modified with the hydroxy mono- and dicarboxylic acids at pH 5, that the α-carboxyl group of the hydroxy carboxylic acid contributes to the adsorption onto the catalyst surface and that the remaining ω-carboxyl group of the hydroxy dicarboxylic acid forms an ionic bond with the cation used for the pH-adjustment. The cation bound to the ω-carboxyl group takes part in the enantiotopic selection of the substrate as a substituent of the modifying reagent.

The α- and ω-carboxyl groups of an amino dicarboxylic acid chemically bind with the nickel catalyst, and the cations and amines used for the pH-adjustment of the modifying solution do not affect the asymmetric activities of the catalysts modified with amino acids. These facts are also supported by the findings by Ninomiya of our research group[8] that the absorption spectrum of the glutamic acid on the evaporated nickel film on quartz very similar to that of nickel chelate.

Aldol Condensations of Aldehydes over Disodium Phthalocyanine[1,2]

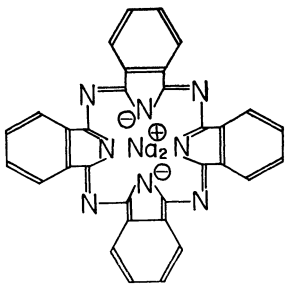
Hiroo INOUE, Kenzo KUNIKAWA, and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka

(Received April 3, 1972)

Disodium phthalocyanine (Pc-Na_2) acts as a base for the aldol condensations of aldehydes, although it shows no effect upon those of ketones. In the aldol condensation of isobutyl aldehyde by Pc-Na_2 in *n*-hexane, 2,6-diisopropyl-5,5-dimethyl-1,3-dioxane-4-ol (III) is produced through two processes with different rates; the reaction proceeds first by the slower rate, and then by a more rapid rate after a certain reaction period. The process is different from that of the catalysis by sodium ethoxide. During the reaction, Pc-Na_2 is converted to sodium-free phthalocyanine (Pc-H_2) *via* an intermediate. The formation of the intermediate results in the retardation of the aldol condensation with the product and phthalocyanine anions. Furthermore, the adsorption of water on Pc-Na_2 brings about the retardation of the reaction.

In acid-base catalyses of organic compounds, the formation of a complex between catalyst and substrate brings about a rate enhancement and a specificity toward the catalyzed reaction. These catalyzed reactions are found in processes in frozen solutions,[3] in inclusion compounds,[4] in micellar solutions,[5] and in polymeric compounds[6] which have been studied as models for enzymic catalysis. Now we will attempt to study the dimerization of two substrates over a plate-like organic molecule with a character of an acid or a base. The present investigation will deal with the heterogeneous base-catalysis of Pc-Na_2 on the aldol condensations of aldehydes and ketones. The Pc-Na_2 contains ion pairs as an active site in a planar-macrocyclic π-system, and might have an affinity for aldehydes and ketones. Our purpose in this paper is to investigate the specific action of Pc-Na_2 as a base for the aldol condensation, and to find the correlation between the reactivity and the features of the chemical structure of Pc-Na_2.



Pc-Na_2

Experimental

Materials. All of the aldehydes and ketones were purchased from commercial sources. These materials were distilled through a Vigreux column before use. The solvents were dried by the usual methods and were distilled twice before use. The Pc-Na_2 was prepared by heating sodium and *o*-phthalonitrile in *n*-amyl alcohol at 130—140°C according to the method reported by Barrett, Dent, and Linstead.[7] The purification was carried out by the following method: 10 g of Pc-Na_2 was dispersed in 20 ml of hot *n*-amyl alcohol, filtered off, washed several times with 20 ml of anhydrous ether, and dried over calcium chloride under the reduced pressure of 1 mmHg at 100°C for 3 hr, unless stated otherwise. The sodium content of the Pc-Na_2 used here was 7.99% (Calcd for Pc-Na_2: 8.24%). The IR spectrum of Pc-Na_2 had absorptions characteristic of the structure of the phthalocyanine dianion at 1640, 1040, and 790—770 cm^{-1}. On the other hand, the IR spectrum of Pc-H_2 agreed with that of α- and/or β-phthalocyanine, described in the literature.[8] The visible spectrum of Pc-Na_2 observed by means of a KBr plate showed broad absorptions at 620 (sh) and 720 mμ, while that of Pc-H_2 showed them at 650 and 740 (sh)mμ.

Procedures for Reactions. Similar procedures were used for all the reactions. In a typical experiment, a solution of 8.0 g of isobutyl aldehyde in 10 ml of *n*-hexane was placed in a 100-ml flask containing a Teflon stirring bar, and the flask was placed in a thermostat bath at 25±1°C. Immediately after nitrogen gas had passed into the system for 3 min, 0.1 g of Pc-Na_2 was added to the solution, the flask was capped with a stopper, and the solution was stirred vigorously by means of a magnetic stirrer. After a reaction period, 80 ml of *n*-hexane was added to the system to stop the reaction, the resulting solution was filtered off, and the precipitate was washed repeatedly with *n*-hexane. The combined *n*-hexane layer was then washed with a small amount of a 5—10 wt% hydrochloric acid solution and then water. *n*-Hexane and the volatile components were completely removed under reduced pressure. In the reaction time of 20 hr, 6.0 g of a residual oil was obtained; this oil was then submitted to an analysis of its product. On the other hand, the distillation of the oil (bp 90—91°C/2 mmHg) yielded 5.6 g (70%) of a mixture of 2,6-diisopropyl-5,5-dimethyl-1,3-dioxane-4-ol (III)[9] and the monoisobutyrate of 2,2,4-trimethyl-1,3-pentanediol (IV), which could be

separated by glc.

Analyses of Products. All of the products were identified by a comparison of their IR and NMR-spectra, the results of elementary analyses of their 2,4-dinitrophenylhydrazone, their retention times in glc, and their molecular weights with those of authentic specimens prepared by the methods described in the literature.[10] The identification of IV was based on the observation that the molecular weight was 218 (calcd for monoester, 216), and the alkaline hydrolysis of the ester gave, quantitatively, 2,2,4-trimethyl-1,3-pentanediol and isobutyric acid. However, IV was regarded as a mixture of two monoisobutyrates with an isobutyroyl group at the 1- or 3-hydroxyl group. The red-brown polymeric material (Va) prepared from acetaldehyde was converted to the 2,4-dinitrophenylhydrazone. Anal. Found: C, 57.46; H, 5.90; N, 11.06%. The avarage molecular weight of Va was 320. The IR spectrum of Va exhibited bands at 3400, 2950-2800, 1710, 1680, 1440, 1370, and 1100 cm^{-1}. The UV spectrum of Va in ethanol had absorptions at 233, 285, 324, and 360 mμ.

The amounts of all the products except for III and IV were determined by means of distillation. The amounts of III and IV were determined by the following method: after completely removing the reaction solvent, 0.1 g of the residue, containing III and IV, was dissolved in 2 ml of methanol, and then into the solution there was added a solution of 0.4 g of 2,4-dinitrophenylhydrazine in 100 ml of a 2 N hydrochloric acid solution. The resulting solution was kept standing overnight. The precipitate was then filtered off, dried over calcium chloride, and weighed. From the weight of the precipitate, the amount of III was determined within an error of ±3%. Furthermore, it was confirmed by glc that the mixture consists of only III and IV. The amount of IV was determined by substracting the amount of III from 0.1 g of the mixture. The value thus obtained agreed with that determined by the glc analysis within an error of ±2—3%.

Analysis of the Sodium Cation. A weighed amount (0.1—0.2 g) of a sample in a crucible was burned cautiously with a small flame, and then it was heated strongly for 3—5 hr to change it completely to ash. The ash was dissolved in 20 ml of distilled water and was then titrated with 1/10 N hydrochloric acid, using methyl orange as the indicator. The sodium content could be measured within an error of ±2% by this method.

Results and Discussion

Action of Pc–Na_2 as a Base. When Pc–Na_2 was dispersed in acetonitrile or ethyl acetate, no product was obtained, but the Pc–Na_2 was recovered unchanged. However, a dispersion of Pc–Na_2 in aldehydes resulted in the corresponding condensation products, such as I, II, III, IV, and V. The yields of these products changed depending on the structure of the starting aldehydes, as Table 1 shows. In the aldol condensation of acetaldehyde, the red-brown polymeric material (Va) was obtained in a 70% yield. The values of *m* and *n* of Va were 3—4 and 2—3 respectively. The IR spectrum of Va was similar to that of

$RCH_2CH(OH)CHRCHO$

I a: $R=CH_3$
b: $R=CH_3CH_2$

$RCH_2CH{=}CRCHO$

II a: $R=CH_3$

V a: $R=H$
b: $R=CH_3$
c: $R=CH_3CH_2$

the polymer produced by using $(CH_3)_3N$[11] and Na–Hg[12] as the catalyst. The aldol condensation of propionaldehyde or *n*-butyraldehyde by Pc–Na_2 gave the corresponding aldols (Ia or Ib) and α,β-unsaturated aldehydes (IIa or IIb). Isobutyl aldehyde was converted to 2,6-diisopropyl-5,5-dimethyl-1,3-dioxane-4-ol (III) and the monoisobutyrate of 2,2,4-trimethyl-1,3-pentanediol (IV) in 21 and 50% yields respectively through a secondary reaction of the intermediate aldol. The sodium-cation content of the recovered phthalocyanine in all cases was in the range of 4.60—5.90%, which changed with the reaction conditions. The IR spectrum of the recovered phthalocyanine had the characteristic absorpions due to the phthalocyanine anion at 1642, 1040, and 790—770 cm^{-1}, and that due to the sodium-free phthalocyanine at 1000 cm^{-1}.

CH_3	CH_3	III, IV	21, 50

a) The amount of Pc–Na_2 dispersed: 3.3 mol% in aldehydes. The reaction was carried out under a nitrogen atmosphere at room temperature for 20 hr.
b) The yields of I, II, III, and IV were based on aldehydes.
c) This was calculated by weight of polymer/weight of aldehyde × 100.

Ketones, such as acetone, methyl ethyl ketone, and acetophenone, could not undergo self-condensation by Pc–Na_2, not even at 100°C, although the sodium ethoxide-catalyzed condensation of acetone gave the polymeric material and phorone in 10 and 11% yields respectively. However, Pc–Na_2 acted as a base for the mixed condensation of isobutyl aldehyde and either acetone or methyl ethyl ketone (the molar ratio of isobutyl aldehyde to ketone; 2.4 or 2) under the same conditions as have been described above as giving

39% yield in the case of acetone, based on the starting amount of isobutyl aldehyde. Thus, it was found that Pc–Na_2 acts as a base for aldehydes and ketones, and that the action is specific for the aldol condensations of aldehydes.

Aldol Condensation of Isobutyl Aldehyde Catalyzed by Sodium Ethoxide. Sodium ethoxide was dispersed or dissolved in *n*-hexane, ethanol, and dimethyl sulfoxide, all containing isobutyl aldehyde. Sodium ethoxide, dispersed in *n*-hexane, changed from a solid to an emulsion state as the reaction proceeded, and III and IV were obtained as the products. In the case of the ethanol solvent, however, IV was converted further to 2,2,4-trimethyl-1,3-pentanediol and ethyl isobutyrate by the ester-exchange reaction. As Table 2 shows, it was observed in all cases that III is formed predominantly without an induction period. As the reaction time increased, however, the yield of III decreased and that of IV increased. The trends for the consecutive formation of IV were observed distinctly in the cases of the ethanol and dimethyl sulfoxide solvents. On the other hand, the heterogeneous catalysis in the *n*-hexane solvent tended to give a high yield of III, even in a prolonged reaction time. However, the increase in the amount of sodium ethoxide resulted in a rise in the yield of IV. IV would be produced by the intramolecular Cannizzaro reaction of the anion of III, derived from III with a base. Therefore, the effective concentration of the base must be of importance in the formation of IV.

The Condensation by Pc–Na_2. In *n*-hexane and acetonitrile solvents, III was first produced predominantly in the slow rate, as is shown in Fig. 1. After

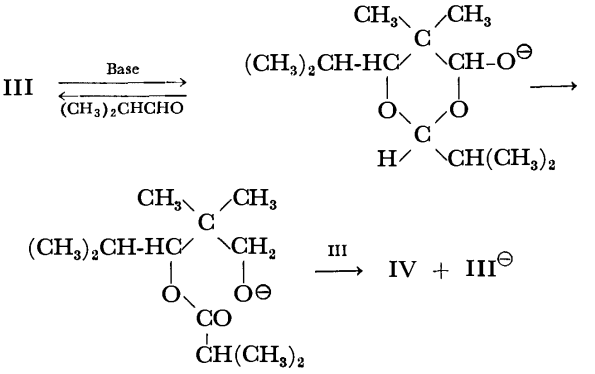
b) The brackets indicated the yield of diol.



6 hr, the rate of the formation of III increased rapidly. When the yield of III reached about 60%, it was observed that III began to be converted to IV, as Table 3 shows. The fractional yield of IV in a longer reaction time became higher than in the case of sodium ethoxide. In the ethanol solvent, III and IV were first produced without the slow step; IV was converted further to 2,2,4-trimethyl-1,3-pentanediol and ethyl isobutyrate as the reaction time increased. These facts indicate that the dianion of Pc–Na_2 is transferred to ethanol, thus leading to the homogeneous catalysis by the ethoxide anion. Furthermore, the adsorption of two moles of water per mole of Pc–Na_2 resulted in a retardation of the condensation of isobutyl aldehyde by Pc–Na_2; that is, the yield of III in *n*-hexane was 30—40% after the reaction time of 9 hr. However, the presence of water resulted in the formation of III predominantly.

b) The brackets indicated the yield of diol.

Removal of the Sodium Cation from Pc–Na_2. After the aldol condensation of isobutyl aldehyde by the 100°C-dried Pc–Na_2 in *n*-hexane had been carried out for a reaction period under the conditions described above, the precipitate was collected by filtration and subsequently dried. The sodium content and the IR and visible spectra of the precipitate were measured. As is shown in Fig. 1, the curve of the change in the sodium content consisted of two steps. The flexion of the curve almost coincided with that of the formation curve of III. Furthermore, the formation of III was nearly parallel with the removal of the sodium cation during the period of the slow formation of III, the amount of III produced being 1.5—2 larger than that of the sodium cation removed.

On the other hand, the IR spectrum of the precipitate changed as the reaction proceeded. The ab-

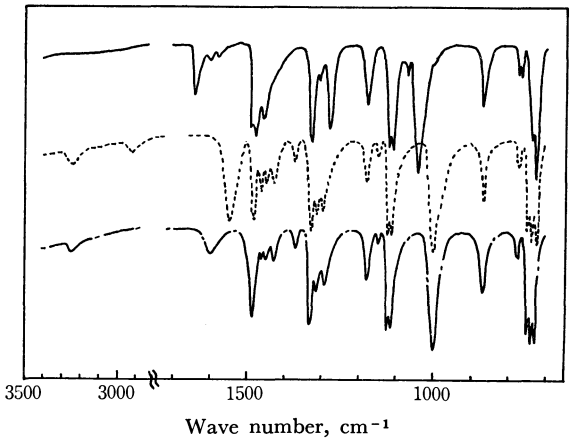

Fig. 2. The IR spectra of Pc-Na_2 (——), Pc-H_2 (— — —) and the intermediate (- - - -).

sorption peaks of the phthalocyanine anion and dianion at 1640 and 1040 cm^{-1} decreased, while that of the sodium-free phthalocyanine at 1000 cm^{-1} increased. In addition, a new band appeared at 1550 cm^{-1} (Fig. 2). The new band increased rapidly as the reaction proceeded, and then decreased. In Fig. 1, the ratio (R) of the intensity of the new band to that of a band at 870 or 1120 cm^{-1}, the intensity of which did not differ from Pc-Na_2 to Pc-H_2, is plotted against an interval of the reaction time. The maximum of the intensity ratio was observed in the reaction time of 3 hr,

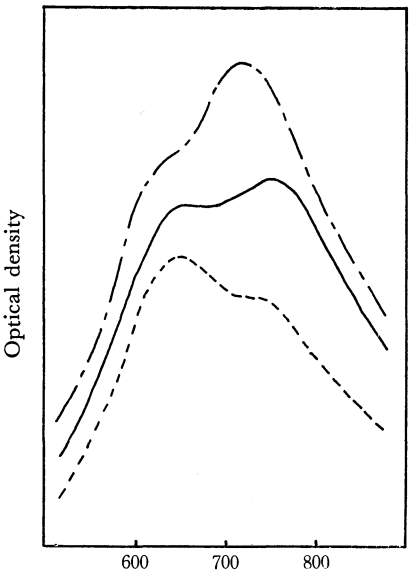

Fig. 3. The visible absorption spectra of Pc-Na_2 (— — —), Pc-H_2 (- - - -) and the intermediate (——) by KBr plate.

which lay in the slow step. When the reaction was carried out in 1/10 less Pc-Na_2 than that shown in Fig. 1, the intensity ratio was observed to reach a maximum sharply with a higher value in a shorter reaction time; then it decreased at a slower rate. These facts indicate that a stable intermediate exists in the reaction process. The sodium content of the intermediate with the maximum value of R at 1550 cm^{-1} was 3.86%. This value means that the intermediate is a monosodium phthalocyanine derivative. Its visible absorption spectrum, as observed by means of a KBr plate, showed two absorptions, at 650 and 750 mμ, although that of Pc-H_2 had absorptions at 650 and 740 (sh) mμ, as is shown in Fig. 3. The new band at 1550 cm^{-1} did not change even when the intermediate was heated at 100°C under a reduced pressure of 1 mmHg for 2 hr, but it disappeared when it was dispersed in ethanol, and the resulting IR spectrum agreed with that of Pc-H_2. Thus, the intermediate was a monosodium derivative with IR and visible spectra which differed from those of Pc-Na_2, Pc-NaH, and Pc-H_2, and with the departing sodium cation with a slow rate. However, the structure of the intermediate is not yet clear. When the intermediate was converted to Pc-H_2, the reaction proceeded rapidly by means of a catalysis similar to that in the case of sodium ethoxide. However, the consecutive formation of IV occurred more easily in the presence of the phthalocyanine molecule than in the case of sodium ethoxide. This may be caused by the fact that the product anion is concentrated over the phthalocyanine molecule.

The Reactions of Stannic Halides with Some Triphenylphosphine, -arsine and -stibine-substituted Iron Carbonyls

Tetsuo TAKANO

Department of Chemisjry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received April 6, 1972)

The reactions of stannic chloride and bromide with triphenylphosphine, -arsine and -stibine tetracarbonyl iron(0) undergo oxidative-elimination reactions to afford new binuclear organometallic compounds in good yields; $Fe(CO)_4EPh_3+SnX_4 \rightarrow Fe(CO)_3EPh_3SnX_4+CO$ (E=P, As, Sb; X=Cl, Br; Ph=C_6H_5), where one molecule of carbon monoxide is discharged. The complexes are characterized by elemental analysis, by infrared and Mössbauer spectroscopies, and by conductivity measurements; these data are used to predict their possible formulation as nonionic, hexa-co-ordinate iron derivatives of the $Fe(CO)_3(X)(EPh_3)(SnX_3)$ type containing a tin-to-iron metal-metal bond.

A number of Lewis acid-base adducts containing hetero metal-metal bonds have previously been prepared by treating zerovalent transition-metal carbonyl complexes with main-group metal halides.[1),2)] These reaction may, for convenience, be devided into two classes: (a) oxidative-addition reactions and (b) oxidative-elimination reactions, according to whether or not the elimination of carbon monoxide occurs during the reaction.[3)] Examples of Reaction (a) are found among numerous mercury-to-transition-metal-bonded compounds.[4-6)] By Reaction (b) Graham and Kummer have synthesized a series of tin-molybdenum- and tin-tungsten-bonded compounds.[7)] It is also hoped that, with a good choice of ligands, iron carbonyl derivatives will undergo a reaction of either the (a) or (b) type with appropriate main-group halides to yield new hetero binuclear compounds.

In this paper syntheses of tin-iron-bonded compounds will be described, and the structure and the nature of the isolated products will be discussed on the basis of the spectroscopic data.

Experimental

All the preparative procedures were carried out under nitrogen, and the solvents available were purified by distillation prior to use. The stannic chloride and stannic bromide were commercially obtained. The substituted-iron carbonyls were prepared according to the methods in the literature, and their purities were checked by both elemental analysis and by studying their infrared spectra.[8-10)]

Preparation of $Fe(CO)_3PPh_3SnCl_4$. A solution of stannic chloride (10 mM) dissolved in 50 ml of dichloromethane was stirred, by drop, into triphenylphosphine tetracarbonyliron (10 mM) in the same solvent. As the reaction proceeded, the solution gradually changed from yellow into red; at the same time a vigorous evolution of carbon monoxide was observed. After the solution had been stirred for an hour, the solvent was removed under reduced pressure. The red residue was then extracted in 20 ml of nitromethane; the solution was subsequently allowed to stand in a refrigerator until yellow crystals separated.

Procedures similar to this were used to prepare other tin-iron-bonded compounds.

The molecular weights were measured osmometrically in methyl ethyl ketone. The magnetic susceptibilities were determined by the Gouy method at room temperature. The electric conductivities in nitromethane solutions were determined at 25°C using a Radiometer type CDM 2d-Conductivitymeter. The infrared spectra were obtained as Nujol mull on a Hitachi EPI-G2 Grating Spectrometer. The Mössbauer spectra were recorded with a Hitachi 505 Mössbauer Spectrometer equipped with a cryostat maintaining a γ-ray emitter (^{57}Co diffused onto platinum foil) and an absorber at the temperature of liquid nitrogen.

Results and Discussion

Results of the elemental analyses and the physical properties for the isolated Sn-Fe complexes are summarized in Tables 1 and 2 respectively. These products can be described by the general formula $Fe(CO)_3EPh_3SnX_4$, where E is P, As, or Sb, where X is Cl or Br, and where Ph is C_6H_5. They are diamagnetic, yellow-to-orange crystals and are sufficiently stable in air for various physicochemical experiments. They are readily soluble in chloroform, benzene, nitromethane, alcohols, and many other polar organic solvents. The obtained molecular weights correspond to a monomer structure. The electric conductivities in nitromethane and the infrared frequencies in the carbonyl stretching region are given in Table 3. The conductivities of the products suggest their essentially nonionic character, in spite of the observed small conductance, which is presumably due to partial dissociation in nitromethane. The observed low molecular weights in methyl ethyl ketone reflect it.

Each complex exhibits three carbonyl stretching bands. It is interesting to note that the averaged stretching frequencies of each product undergo a high shift of about 100 cm^{-1} compared to the starting iron carbonyl complexes, $Fe(CO)_4EPh_3$.

Figure 1 shows the ^{57}Fe Mössbauer spectra of $Fe(CO)_4PPh_3$ and $Fe(CO)_3PPh_3SnCl_4$. The isomer shift and the quadrupole splitting values of the products are presented in Table 4, along with the values of the related iron carbonyl complexes. In triphenylarsine

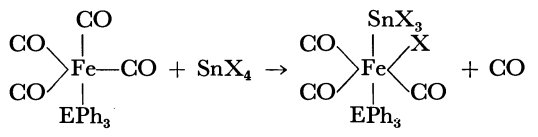
Q. S. Quadrupole splitting (mm/sec).

quadrupole splitting smaller than the starting iron carbonyl complex. The small quadrupole splitting suggests that the products have a more symmetrical environment around the iron atom, probably a hexa-co-ordinate octahedral structure containing a tin-iron metal-metal bond. The determination of the precise structure of $Fe(CO)_3AsSnBr_4$ by single-crystal X-ray analysis is currently in progress in this laboratory.

It can be concluded that the iron derivatives obtained here should be formulated as $Fe(CO)_3(X)EPh_3(SnX_3)$ and that an ionic formulation such as $[Fe(CO_3)EPh_3\text{-}SnX_3]X$ or $[Fe(CO)_3EPh_3X]SnX_3$ should be ruled out. The above reactions may proceed as follows:



(1)

The elimination of one molecule of carbon monoxide was confirmed by gas-burette measurements. Thus, the reaction may reasonably be classified as an oxidative-elimination reaction and the products may be regarded as Lewis acid-base adducts.

Under the same preparative conditions as in the above experiments, no reaction occurred between iron carbonyl derivatives, $Fe(CO)_4EPh_3$, $Fe(CO)_3\text{-}(EPh_3)_2$, and tetramethyltin, trimethyltin chloride, dimethyltin dibromide, and tin tetraiodide. Probably these failures are due to the low Lewis acidity of the metal-halide reactants.

The Cobalt Carbonyl-catalyzed Hydroesterification of Butadiene with Carbon Monoxide and Methanol

Akio MATSUDA

National Chemical Laboratory for Industry (Tokyo Kogyo Shikensho), Mita, Meguro-ku, Tokyo

(Received April 12, 1972)

The cobalt carbonyl-catalyzed hydromethoxycarbonylation of butadiene is studied. The reaction proceeds in the presence of a pyridine base to give methyl 3-pentenoate. Isoquinoline is found to be a better solvent for the production of methyl 3-pentenoate than pyridine, not only because the yield of the ester is somewhat higher in the presence of isoquinoline than in the presence of pyridine, but also because it is far less volatile than pyridine, so that the product can be easily separated from the solvent and the catalyst by distillation. Also, the hydromethoxycarbonylation of methyl 3-pentenoate under somewhat different conditions is found to give a good yield of dimethyl adipate. The hydroformylation of methyl 3-pentenoate is studied as well. The effect of such a solvent as THF, benzene, and acetonitrile in increasing the selectivity to methyl 5-formylpentanoate is found to increase in this order: acetonitrile < benzene < THF.

In the first paper of this series it was reported that the initial rate of the cobalt carbonyl-catalyzed hydroesterification of propylene was remarkably promoted by the presence of a small amount of hydrogen and an excess of pyridine.[1] In a following paper concerning the hydroesterification of acrylonitrile, the reaction mechanism was discussed on the bases of the kinetic results and the IR study of the reaction intermediates.[2]

The present investigation will deal with the hydroesterification of butadiene. The results varied in some respects from those of previous studies which dealt only with mono-olefins.[1,2] For example, in the hydroesterification of mono-olefins, hydrogen added in the synthesis gas played a significant role in accelerating the reaction.[1,2] However, in the present hydroesterification of butadiene, hydrogen exerted essentially no effect on the reaction rate. On the other hand, the effect of pyridine on the hydroesterification of butadiene was remarkable in that both the reaction rate and the selectivity to methyl 3-pentenoate steadily increased with an increase in the concentration of pyridine. The inhibition by a large excess of pyridine which is usually observed in the case of mono-olefins[1,2] did not appear at all in this experiment. The reaction proceeded in pyridine at a relatively low temperature (100—140°C), and methyl 3-pentenoate was selectively produced.

It has already been found by Imyanitov et al. that the hydrocarboxylation of butadiene also proceeded in the presence of pyridine to give 3-pentenoic acid.[3] They also reported the results of their hydroesterification of butadiene in the presence of pyridine;[4] they carried out the reaction at a higher temperature (210 °C), and obtained a mixture of unsaturated and saturated mono esters and saturated diesters. On the other hand, in the present investigation a better method for the selective production of methyl 3-pentenoate by the hydroesterification of butadiene was explored. As a result, it was found that isoquinoline was a better solvent than pyridine for this purpose, not only because the yield of methyl 3-pentenoate was somewhat improved when the reaction was carried out in the presence of isoquinoline instead of pyridine, but also because isoquinoline (bp 240°C) is less volatile than pyridine (bp 115°C), so methyl 3-pentenoate can be easily removed from the reaction mixture by vacuum distillation at a low temperature, the catalyst and isoquinoline being left as a residue.

The hydroesterification and the hydroformylation of the resulting methyl 3-pentenoate to give the corresponding diesters and formyl esters were also examined.

Experimental

Such reagents as butadiene, carbon monoxide, methanol, and pyridine were obtained commercially. The butadiene was 99% pure. The carbon monoxide was 99.5% pure, containing 0.018% hydrogen. The amount of butadiene remaining in the gas phase after the reaction was analyzed by passing the gas through methanol cooled by dry ice, followed by the gas-chromatographical analysis of the methanol solution. The amount of the dissolved butadiene and that of each product in the liquid product were also gas-chromatographically analyzed. The gas-chromatographical analyses were performed with a 9-m column of propyleneglycol-adipic acid polyester at the column temperature of 150°C (2-ethylhexyl acetate was added as an internal standard when necessary). Standard samples for the gas-chromatographical analyses were prepared as follows. Dimethyl adipate, methyl *n*-pentanoate, and methyl 4-pentenoate were prepared by the esterification of commercially-obtained adipic acid, *n*-pentanoic acid, and 4-pentenoic acid with methanol. The others were prepared by the distillation of the reaction products with a rectifier of the spinning-band type, followed by separation with a preparative gas-chromatograph (Perkin-Elmer F-21). These samples were identified by means of their IR and NMR spectra.

Methyl 3-Pentenoate: IR spectrum: C=O (ester) 1744 cm^{-1}, NMR spectrum: CH_3 τ 8.33, CH_2 τ 7.05, OCH_3 τ 6.40 (singlet), CH τ 4.50 (the NMR spectrum was complex because the sample was a mixture of *cis*- and *trans*-forms)

Methyl 2-Pentenoate: IR spectrum: C=O (ester) 1730 cm^{-1}, C=C (conjugated with C=O) 1662 cm^{-1}. NMR spectrum: CH_3 τ 8.88 (triplet), CH_2 τ 7.76 (quintet), OCH_3 τ 6.34 (singlet), $CH(-COOCH_3)$ τ 4.27 (sextet), $CH(-CH_2)$ τ 3.07 (sextet)

Dimethyl α-Methylglutarate: IR spectrum: C=O (ester) 1742 cm^{-1}. NMR spectrum: CH_3 τ 8.83 (doublet), CH_2-(-CH) τ 8.19 (quintet), CH_2 (-$COOCH_3$) τ 7.73 (triplet), CH τ 7.45—7.8 (multiplet), OCH_3 τ 6.38, 6.40.

Dimethyl Ethylsuccinate: IR spectrum: C=O (ester) 1740 cm^{-1}. NMR spectrum: CH_3 τ 9.06 (triplet), CH_2(-CH_3) τ 8.39 (quintet), CH(-$COOCH_3$) τ 7.35—7.75 (multiplet), CH_2(-$COOCH_3$) τ 7.35 (doublet), OCH_3 τ 6.36, 6.38.

Methyl 5-Formylpentanoate: IR spectrum: C=O (ester and aldehyde) 1720—1740 cm^{-1}. NMR spectrum: CH_2CH_2 (-CH_2COOCH_3) τ 8.2—8.4 (overlapped multiplet), CH_2-(-$COOCH_3$), CH_2(-CHO) τ 7.4—7.8 (overlapped multiplet), OCH_3 τ 6.37 (singlet), CHO τ 0.23 (triplet). The structure of this compound was further confirmed by its oxidation with air, followed by esterification with methanol into dimethyl adipate.

Methyl 4-Formylpentanoate: IR spectrum: C=O (ester and aldehyde) 1740, 1710 cm^{-1}. NMR spectrum: CH_3(-CH-CHO) τ 8.88 (doublet), CH_2(-CH_2COOCH_3) τ 7.9—8.5 (multiplet), CH_2(-$COOCH_3$) τ 7.67 (triplet), CH(-CHO) τ 7.5—7.9 (overlapped multiplet), OCH_3 τ 6.39 (singlet), CHO τ 0.39 (doublet). The structure of this compound was further confirmed by its oxidation with air and by its subsequent esterification with methanol into dimethyl α-methylglutarate.

Methyl 3-Formylpentanoate: IR spectrum: C=O (ester and aldehyde) 1740, 1710 cm^{-1}. NMR spectrum: CH_3(-CH_2) τ 9.02 (triplet), CH_2(-CH_3) τ 8.1—8.6 (multiplet), $CHCH_2$-(-$COOCH_3$) τ 7.2—7.8 (multiplet), OCH_3 τ 6.40 (singlet). CHO τ 0.35. The structure of this compound was further confirmed by its oxidation with air and by its subsequent esterification with methanol into dimethyl ethylsuccinate.

The reactions were carried out with a 300-ml (or a 100-ml) stainless steel autoclave. The catalyst, $Co_2(CO)_8$, was put into a small Teflon cup and placed on a wing of the stirrer so that the reaction would not start until the stirring (an up-and-down motion) began. For the measurement of the initial rate, a small portion of the reaction mixture was withdrawn a short, definite time after the stirring began; this portion was gas chromatographically analyzed with the aid of an internal standard (methyl benzoate or benzonitrile) which had been added to the reaction mixture before the reaction.[5]

The effect of bases was examined by carrying out the reaction in the presence of various bases. In control experiments carried out in the absence of a base (in toluene or acetonitrile), the reaction products were confirmed, by the measurement of the IR spectra, not to contain any carbonylated product (there was an absence of absorption at 1700—1800 cm^{-1}). The effect of the pyridine concentration was examined by varying the concentration of pyridine in a solvent mixture (acetonitrile plus pyridine) from zero to 100%.

The methyl 3-pentenoate for the hydroesterification and hydroformylation experiments was continuously produced by the hydroesterification of butadiene, using isoquinoline as the solvent. A solution consisting of 5.4 g of $Co_2(CO)_8$, 8.6 g of methanol, and 34 g of isoquinoline was pumped into a 100 ml stainless steel autoclave, and the autoclave brought to the condition of 130°C and 300 kg/cm^2 by heating and by introducing carbon monoxide from a pressure reservoir; the stirrer was started, and then butadiene was continuously fed from the bottom of the autoclave at a rate of 0.05 mol/hr, the carbon monoxide being supplied from the pressure reservoir to keep the pressure constant. Three hours after the start of the reaction, the reaction was interrupted and reaction mixture was totally withdrawn from the bottom of the autoclave through a cooling tube. The volatile components including methyl 3-pentenoate were then separated from the reaction mixture by vacuum distillation at a low temperature (below 50°C), while an isoquinoline solution of cobalt carbonyl was recovered as a residue. This recovered isoquinoline solution of cobalt carbonyl was catalytically active, and was used again in the next run. The effect of recycling the catalyst solution is illustrated in Table 1.

5) The use of 2-ethylhexyl acetate as an internal standard was avoided, since it can undergo transesterification with methanol under the reaction condition. The effect of the addition of a small amount of methylbenzoate (or benzonitrile) on the results of the reaction was negligible.

Results

The Addition of Bases. The effectiveness of bases in increasing the yield of methyl 3-pentenoate decreased in this order: γ-picoline>isoquinoline>pyridine>3,4-lutidine>β-picoline>4-vinylpyridine>α-picoline, quinoline, 4-cyanopyridine>triethylamine (Table 2). Triethylamine was almost ineffective. In the absence of pyridine bases, methyl 3-pentenoate was not produced, while only the conversion of bu-

tadiene increased. This increase in the conversion is due to the polymerization, not to the hydroesterification of butadiene (cf. Experimental section).

The Effect of the Pyridine Conecntration. The initial rate increased with the increase in the concentration of pyridine (Fig. 1). The conversion of butadiene, and the yield of, and the selectivity, to methyl 3-pentenoate all increased with the increase in the concentration of pyridine; however, they reached a maximum at the concentration of 5 mol/l and remained essentially unchanged thereafter.

The Effect of the Carbon Monoxide Partial Pressure. The effect of the pressure was examined at two different temperatures (100 and 140°C). The results are shown in Tables 3 and 4. The initial rate at 100°C increased with the increase in the pressure; it reached a maximum at 200 kg/cm² and leveled off thereafter. The conversion of butadiene and the selectivity to methyl 3-pentenoate both increased with the increase in the pressure, reached a maximum at 200 kg/cm², and declined thereafter. The selectivity to 4-vinyl 1-cyclohexene decreased as the pressure was increased. from 100 to 150 kg/cm², reached a minimum at 150—200 kg/cm², and then increased.

At 140°C, on the other hand, the conversion of butadiene and the selectivity to methyl 3-pentenoate both increased, while the selectivity to 4-vinyl 1-cyclohexene decreased with the increase in the pressure in the range from 150 to 600 kg/cm².

The Effect of the Hydrogen Partial Pressure. Two hydroesterification runs of butadiene were carried out, with and without hydrogen, and the results were compared. Of the two experiments (listed in Table 5), one was carried out in the absence of hydrogen, while the other one was carried out with an initial hydrogen pressure of 137 kg/cm² under identical conditions; these experiments were carried out with the same carbon monoxide partial pressure, the initial pressure in the former experiment being 380 kg/cm², while that in the latter experiment was 517 kg/cm² (380+137). In the presence of hydrogen, the resulting methyl 3-pentenoate was partly hydrogenated into methyl *n*-pentanoate. Also, the dimerization of butadiene into 4-vinyl 1-cyclohexene and the polymerization of butadiene into unidentified polymers were accelerated and the selectivity to methyl 3-pentenoate decreased. Clearly hydrogen has no accelerating effect on the hydroesterification of butadiene, since the yield of methyl 3-pentenoate plus its hydrogenation product, methyl *n*-pentanoate, did not increase with the presence of hydrogen.

a) *cf.* Table 6.

3-pentenoate proceeded at 160—200°C in the presence of pyridine and such a solvent as benzene, toluene, or *n*-heptane; dimethyl adipate was produced in a good yield, while dimethyl α-methylglutarate and dimethyl ethylsuccinate were produced in minor amounts. The results are summarized in Table 6. Methyl 3-pentenoate was partly hydrogenated to methyl *n*-pentanoate in spite of the fact that the reaction was carried out in the absence of hydrogen. Hydrogen can be formed from methanol and carbon monoxide in the presence of cobalt carbonyl.[6] In fact, it was confirmed that hydrogen was produced from methanol and carbon monoxide under the conditions of Table 6, and that carbon dioxide and methyl acetate were produced, together with hydrogen, without the formation of dimethylether:

$$2CH_3OH+2CO \longrightarrow CH_3COOCH_3+CO_2+H_2$$

In the presence of a small excess of pyridine(Py/$Co_2(CO_8)$=8), the reaction proceeded at 160°C. In the presence of a large excess of pyridine (Py/$Co_2(CO)_8$=127), however, a higher temperature (180—200°C) and the use of such a solvent as has been mentioned above were necessary for the reaction to proceed. In the absence of pyridine, on the other hand, only the isomerization of methyl 3-pentenoate into methyl 2-pentenoate and methyl 4-pentenoate took place, with the hydroesterification occurring very sparingly.

The Direct Synthesis of Dimethyl Adipate from Butadiene, Carbon Monoxide, and Methanol. It has been found that the hydroesterification of butadiene proceeded in the presence of pyridine at 100—140°C to give methyl 3-pentenoate, but the further hydroesterification of methyl 3-pentenoate did not occur at these temperatures. On the other hand, in the experiments cited in Table 6, it has also been found that the hydroesterification of methyl 3-pentenoate proceeded in the presence of pyridine at 160—200°C to give diesters. Therefore, it should be possible, by the combination of the above two results, to synthesize diesters directly from butadiene, i. e., by merely carrying out the reaction in two steps, at two different temperatures. For example, the hydroesterification of butadiene was carried out at 110—130°C as the first-stage reaction, and then the temperature was raised to 200°C to carry out the reaction of the second stage(Table 7). The selectivity to each diester increased as the temperature of the first stage decreased; this is probably because

d) Carried out in the presence of 200 mmol of pyridine.

the selectivity to methyl 3-pentenoate in the first stage increased as the temperature of that stage decreased.

The addition of a small amount of water (up to 10 mmol) had almost no effect on a similar reaction carried out in two stages (1st stage, 140°C, 600 kg/cm²: 2nd stage, 200°C, 600—610 kg/cm²), although the yield of dimethyl adipate decreased somewhat in the presence of 20 mmol of water.

The Hydroformylation of Methyl 3-Pentenoate. The hydroformylation of methyl 3-pentenoate was carried out in the presence of $Co_2(CO)_8$ at 140—200°C, under the synthesis gas ($Co/H_2=1$) pressure of 100—250 kg/cm². The effect of the solvent and such a ligand as pyridine or triphenylphosphine is shown in Table 8. In the presence of 2 mmol of $Co_2(CO)_8$, the reaction proceeded at 140°C (100 kg/cm²) and formylesters were produced, but the selectivity to formylesters was only 38 per cent, presumably because the formylesters easily polymerized under such a high concentration of $Co_2(CO)_8$.

When the amount of $Co_2(CO)_8$ was reduced to to 0.02 mmol, the reaction did not occur at 140°C; however, it proceeded at 200°C(250 kg/cm²) and the selectivity to formylesters increased to 59 per cent (No. 2). The addition of triphenylphosphine had almost no effect on the reaction(No. 3). The addition of pyridine increased the selectivity to formylesters to 74—77 per cent(No. 4,5); however, the selectivity to methyl 5-formylpentanoate did not increase so much(40—41%), as it worked to decrease the 5F/(4F+3F) ratio. On the other hand, when acetonitrile was used as a solvent(No. 6), the total selectivity to formylesters increased to 67 per cent while the 5F/(4F+3F) ratio decreased remarkably(0.69). When tetrahydrofuran(THF) was used as the solvent(No. 7,8), on the other hand, the selectivity to the total formylester increased(77—81%), together with the 5F/(4F+3F) ratio (1.5—1.7). When pyridine was added to the THF solvent(No. 9), the 5F/(4F+3F) ratio decreased to 1.3, the selectivity to methyl 5-formyl-pentanoate declining to 40 per cent as a result.

TABLE 9. THE EFFECT OF SOLVENTS ON THE INITIAL RATE OF THE ISOMERIZATION OF METHYL 3-PENTENOATE

Solvent	Initial rate of formation (mmol/min)	
	Methyl 2-pentenoate	Methyl 4-pentenoate
Benzene	2.0	0.42
Acetonitrile	1.4	0.07
THF	2.4	0.49

The fact that the selectivity to total formylesters increased by the use of such a solvent as THF, dioxane, methyl acetate, and acetonitrile instead of benzene, or by the addition of pyridine to the benzene solvent, suggests that the polymerization of formylester slows down in the presence of those above-mentioned solvents or pyridine. The fact that the 5F/(4F+3F) ratio increased in the order of acetonitrile<methyl acetate<benzene, dioxane<THF may have a bearing upon the ease of the isomerization of methyl 3-pentenoate in these solvents.

The Initial Rate of the Isomerization of Methyl 3-Pentenoate. For the measurement of the initial rate of the isomerization of methyl 3-pentenoate, the reactions were carried out in a 100-ml autoclave with 0.02 mol of methyl 3-pentenoate diluted with a solvent to 50 ml(room temp.) and with 0.2 mmol of $Co_2(CO)_8$, at 140°C under a constant pressure (70 kg/cm²) of carbon monoxide containing 2% hydrogen; under these conditions (a very low hydrogen partial pressure), only the isomerization of methyl 3-pentenoate occurred measurably without the hydroformylation. A small portion of the reaction mixture was withdrawn from the autoclave 10 minutes after the stirring began; this portion was analyzed. The results are summarized in Table 9. Clearly, the isomerization of methyl

3-pentenoate into methyl 2-pentenoate and methyl 4-pentenoate proceeds more rapidly in THF than in benzene, and this isomerization proceeds most slowly in acetonitrile.

Discussion

The cobalt carbonyl-catalyzed oxo reaction of butadiene is known to yield a mixture of mono aldehydes and ketones, without any formation of dialdehydes. It is believed that butadiene is hydrogenated by $HCo(CO)_4$ into butenes, which then undergo hydroformylation to give monoaldehydes.[7]

In the case of the present hydroesterification of butadiene, however, the reaction was carried out with carbon monoxide containing almost no hydrogen, and it was observed that the reaction started in the presence of $Co_2(CO)_8$ without any induction time, and that the reaction rate did not increase upon the addition of hydrogen (Table 5). Presumably, $HCo(CO)_4$, the active intermediate of the oxo reaction, does not take part in the present reaction. As a matter of fact, the inhibition by pyridine observed in the usual oxo reaction (as a result of salt formation between $HCo(CO)_4$ and pyridine)[8] was not observed here, and the reaction was successfully carried out in pyridine. Dicobalt octacarbonyl undergoes disproportionation in the presence of pyridine (Eq. (1)), as has been stated by Wender *et al.*[9]; that this also occurs during the reaction is evident form the fact that the strong absorption of $Co(CO)_4^-$ at 1890 cm^{-1} and the weak bands at 1960—2100 cm^{-1} (probably the absorption of $Co^+(CO)_4Py$) appeared on the IR spectrum of the pyridine solution of $Co_2(CO)_8$ when it was treated under the present reaction conditions.

$$Co_2(CO)_8 + Py \longrightarrow Co^+(CO)_4Py(+Co(CO)_4^-) \quad (1)$$

Therefore, the present reaction probably involves the ion-pair, $Co^+(CO)_4Py(+Co(CO)_4^-)$, as the active intermediate; however, the mechanism is still not clear, nor will it be until more detailed studies of the reaction intermediate are performed.

The hydroesterification of methyl 3-penteonate, on the other hand, evidently involves $HCo(CO)_4$ as the active intermediate, since the reaction was retarded by a high concentration of pyridine and since the hydrogenation took place simultaneously(Table 6). The isomerization of olefins can proceed by the cycle of the addition and elimination of $HCo(CO)_4$.[10] Thus, four types of alkylcobalt tetracarbonyls can be produced from methyl 3-pentenoate in the following equilibrium:

$$CH_3CH_2CH{=}CHCOOCH_3 + HCo(CO)_4 \rightleftharpoons CH_3CH_2CH_2CH(Co(CO)_4)COOCH_3 \quad (\alpha)$$

$$CH_3CH{=}CHCH_2COOCH_3 + HCo(CO)_4 \rightleftharpoons CH_3CH_2CH(Co(CO)_4)CH_2COOCH_3 \quad (\beta)$$

$$CH_2{=}CHCH_2CH_2COOCH_3 + HCo(CO)_4 \rightleftharpoons CH_3CH(Co(CO)_4)CH_2CH_2COOCH_3 \quad (\gamma)$$

$$CH_2CH_2CH_2CH_2COOCH_3 \quad | \quad Co(CO)_4 \quad (\delta)$$

The mechanism of the formation of ester in the presence of pyridine *via* an alkylcobalt tetracarbonyl intermediate have already been discussed in a previous paper;[2] dimethyl adipate should result *via* δ, dimethyl α-methylglutarate from γ, dimethyl ethylsuccinate from β, and dimethyl propylmalonate from α. The facts that the selectivity to esters decreased in the order of dimethyl adipate>dimethyl α-methylglutarate>dimethyl ethylsuccinate, and that dimethyl propylmalonate was not detected in the products, suggest that the hydroesterification rates *via* these intermediates decrease in the order of $\delta>\gamma>\beta$, and that the α-intermediate is extraordinarily unreactive in this reaction.

The hydroformylation of methyl 3-pentenoate may also proceed *via* these intermediates, *i. e.*, by the formation of acylcobalt tricarbonyls from these intermediates, followed by its hydrogenation to give formylesters according to the mechanism proposed by Heck;[11] 5-formyl-(5F), 4-formyl-(4F), 3-formyl-(3F), and 2-formyl-(2F) esters should result from the δ, γ, β, and α intermediates respectively. The fact that the effectiveness of solvents in increasing the 5F/(4F+3F) ratio decreased in the order of THF>benzene, dioxane>methyl acetate>acetonitrile may be explained in connection with the fact that the effect of solvents in increasing the rate of the isomerization of methyl 3-pentenoate decreased in a similar order; THF>benzene>acetonitrile (Table 8), since the 5F/(4F+3F) ratio will increase as the rate of the isomerization of γ into the δ intermediate increases. However, another possibility exists that the equilibrium toward the straight-chain acylcobalt carbonyl may be particularly favored in THF, as has been mentioned by Takegami *et al.*,[12] who studied the isomerization of acyl-

cobalt carbonyls in various solvents. In a previous paper concerning the intramolecular hydroesterification of allylalcohol,[13] it has already been mentioned that the double-bond isomerization of allylalcohol is reduced by the use of acetonitrile as a solvent.

In conclusion, it can be said that THF is effective in increasing the ratio of the straight-chain formylester, because it accelerates the isomerization of γ- into the δ-intermediate, or because the equilibrium toward the straight-chain acylcobalt carbonyl is particularly favored in THF, or because of a combination of the above two factors. Also, it may be said that acetonitrile decreases the ratio of the straight-chain formylester because it retards the isomerization of γ- into the δ-intermediate.

The Reaction of β-Amino α,β-Unsaturated Esters with Amines

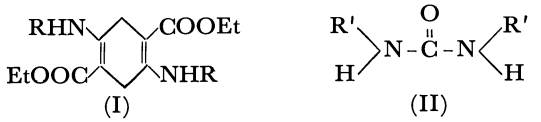
Yasukazu YOKOYAMA and Akira TAI

Research Center of Tekkosha Co., Ltd., Yahata-cho, Musashino-shi, Tokyo

(Received April 13, 1972)

The reactions between amines and 1,4-bis(ethoxycarbonyl)-2,5-bis(alkyl- or arylamino)-1,4-cyclohexadiene(I) and its analogs are studied. The main products are *N,N'*-disubstituted urea(II) and 1,4-bis(alkyl- or arylamino)-1,4-cyclohexadiene(V) instead of the expected carboxamide. The presence of small amounts of ethyl *N*-substituted carbamate (III) in the products leads to the conclusion that the reaction proceeds through two successive steps: the nucleophilic attack by an amine upon a carbonyl carbon atom of the ethoxycarbonyl group, with a cleavage of a carbon-carbon bond to give III and V, and the amidation of III *in situ*, giving II. The rate of the second step is much faster than that of the first step. The formation of II occurs in the compounds with a β-amino α,β-unsaturated carbonyl group.

The treatment of carboxylic esters with amines is known to be a convenient method for the preparation of carboxamides. However, the reactions between 1,4-bis(ethoxycarbonyl)-2,5-bis(alkyl- or arylamino)-1,4-cyclohexadiene(I) and amines give *N,N'*-disubstituted urea(II), but none of the expected carbxamide.



(I) (II)

a: R=R'=$CH_3(CH_2)_4$-
b: R=R'=C_6H_5-

Similar results have been reported by Roberts and Edwards[1] in the reaction of ethyl β-anilinocrotonate (VI) with aniline. While this type of the reaction is expected to occur generally in compounds with a β-amino α,β-unsaturated carbonyl group, no details of the reaction mechanism have been reported. In this paper, the reaction pathway will be elucidated and the reaction mechanism will be explained.

Results and Discussion

When Ia was heated with pentylamine at temperatures above 230°C in toluene, the reaction proceeded to a certain extent, thus giving *N,N'*-dipentylurea(IIa). The same reaction product was obtained in a good yield by the treatment of Ib with pentylamine. The absence of *N*-pentyl-*N'*-phenylurea and/or *N,N'*-diphenylurea in the products of the latter case excluded the possibility of the transfer of the RNH- group in I to the product during the reaction.

The formation of II might result from the transfer of the carbonyl group from I to the amine used in the reaction. There are two possible pathways, depending on whether the cleavage of the C–C or that of the C–O bond takes place first, as is represented in Scheme 1.

Roberts and Edwards[1] assumed that the cleavage of ethyl β-anilinocrotonate(VI) with aniline took place through the route shown in (1B), but the presence of an intermediate (IV) has not yet been confirmed. The analyses of the reaction products obtained by keeping a mixture of Ib and aniline for 1 hr at 230°C in toluene revealed the presence of small amounts of ethyl *N*-phenylcarbamate(III), but an absence of the carboxamide(VI). The same analytical results were obtained for the reaction products of VI with aniline. In both reactions, the formation of decarboxylated products was detected. The formation of IIb by the treatment of III with aniline was also confirmed. The reactions, therefore, must proceed along the route shown in (1A).

The overall rate of this reaction was mostly controlled at the steps from I to III, since the yield of II from III was four times that from I under the same reaction conditions.

a) Reaction conditions: A solution of 1.00×10^{-2} mol of amine and 2.46×10^{-3} mol of Ib in 10 ml of toluene was heated at 230±1°C for 1 hr.

b) Taken from: S. Patai, "The chemistry of the amino group", Interscience Publishers, New York, N. Y. (1968), p. 174, 182.

c) Calculated from an integrated form of bimolecular rate equation as below;

$$k_2 = 1/[C_0t(M-2)]\times\ln(M-2Y)/M(1-Y)$$

Y: Yield of II in a period of first 1 hr, M: Initial molar ratio of reactants; [amine]/[(I)], C_0: Initial molar concentration of I, t: reaction time; 3.6×10^3 sec.

The effects of the pK_a values of amines on the reaction rate were investigated in the reactions of Ib with various amines. The yields and rate constants roughly evaluated by fitting the integrated form of the bimolecular rate equation to the yields are listed in Table 1. The reactivity of the amines examined increased with the increase in their basicity, and the logarithm of the rate constants fell near a line when plotted against the pK_a values of the corresponding amines (Fig. 1). The reaction appeared to be a nucleophilic substitution at the carbonyl carbon atom involving slow C–N bond formation, followed by a relatively fast C–C bond fission proceeding through a tetrahedral intermediate.

The rate of the reaction was also affected by the nature of the substituent(R) on the nitrogen atom of I. The yields of IIb in reactions between aniline and various *N*-substituted I are shown in Table 2. The yields increased in the order of: R=alkyl, H, aryl; this order was the reverse of that of the basicity of amines, RNH_2. The electron density on the carbonyl carbon atom in I increases with the increase in the electron-donating effect of the RNH– group exerted through the double bond, inhibiting the nucleophilic attack of $R'NH_2$.

To gain insight into the factors which govern the

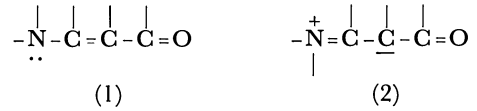
a) Reaction conditions: A solution of 8.0×10^{-2} mol of aniline and 1.0×10^{-2} mol of I in 40 ml of toluene was heated at 230±2°C for 1 hr.
b) Taken from: S. Patai, "The chemistry of the amino group", Interscience Publishers, New York, N. Y. (1968), pp. 174, 182.

facile C–C bond cleavage, various types of β-anilino α,β-unsaturated carbonyl compounds were subjected to reactions with aniline. The results are summarized in Table 3. The C–C bond cleavage occurred not only in β-anilino α,β-unsaturated carboxylic esters, but also in the β-anilino α,β-unsaturated ketone. On the other hand, the compounds in which the α,β-double bond is incorporated with an aromatic system gave neither II nor amide.

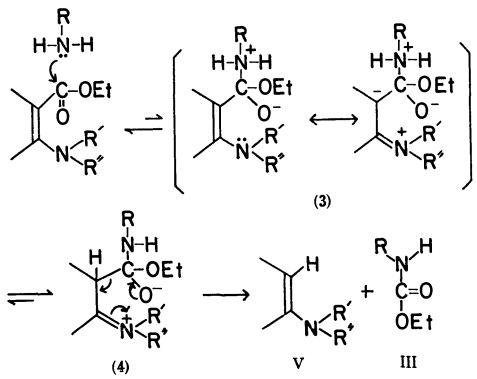
Aliphatic β-amino α,β-unsasurated carbonyl compounds exist exclusively in the enamine form[2] and are capable of reaction with an electrophile on nitrogen or on an α-carbon atom, as is shown by the mesomeric forms, (1) and (2):



(1) (2)

The electron-donating sites in enamines may take part in the proton-transfer step in the reaction pathway, directing the reaction to the fission of the C–C bond instead of the C–O bond.

The proposed reaction mechanism is shown in Scheme 2.



Scheme 2.

The ammonium hydrogen in (3) transfers either to the carbon atom or to the nitrogen atom, instead of to the ethoxyl oxygen atom, as is the case with an ordinary amidation.

TABLE 3. REACTIONS BETWEEN ANILINE AND β-ANILINO α,β-UNSATURATED CARBONYL COMPOUNDS

In the case of enamines, protonation takes place rapidly on nitrogen and is followed by a transfer of the proton to the carbon.[3] Therefore, the final product of the proton-transfer step is presumably a C-protonated step (4), which gives III and V through the C–C bond cleavage. The resulting III was then considerably quickly converted to II by the reaction with the excess amine presented.

Experimental

The infrared spectra were recorded on a Hitachi EPI-G3 spectrometer. The analyses of the volatile substances were carried out by means of a Hitachi Model 063 gas chromatograph equipped with a thermal conductivity cell. A 100× 0.5 cm packed column of Apiezon L (25%) on Chromosorb-W was used at a flow rate of 40 ml/min of He gas. For thin-layer chromotagraphy (tlc), a plate of Silica-gel HF (E. Merk Co.) was used. Plates were developed with Solvent 1 (ether/hexane=20/30) or Solvent 2 (benzene/tetrahydrofuran/acetic acid=25/25/1). For column chromatography, a column of 20×1.8 cm was prepared by slurrying silica gel (Wako Gel C-200, Wako Chemical Co.) in benzene for packing. The melting points and boiling points were not corrected.

Materials. All the reagents except those listed below were obtained from commercial sources and were used without further purification. The aniline, pentylamine, and toluene were dried over synthetic zeorite (Zeorum A-4, Tekkosha Co.) and distilled before use. The solid amines listed in Table 1 were purified by recrystallization. The ethyl *o*-anilinobenzoate(XI) was purified by silica gel column chromatography before use. The 1,4-bis(ethoxycarbonyl)-2,5-bis(alkyl- or arylamino)-1,4-cyclohexadiene(Ia: mp 76—77°C, Ib: mp 164—165°C, Ic: mp 218—220°C, Id: mp 240—243°C, Ie: mp 187—188°C, If: mp 117—119°C)[4], the ethyl β-anilinocrotonate(VI)[1] (bp 116—122°C/3×10^{-2} mmHg), the ethyl β-(*N*-methylanilino)-crotonate(VII)[5] (bp 110—120°C/4×10^{-3} mmHg), the ethyl α-ethyl β-anilinocrotonate(VIII)[1] (bp 105—107°C/5×10^{-3} mmHg), the 4-anilino-3-penten-2-one(IX)[6] (mp 47—48°C), the diethyl 2,5-dianilinoterephthalate(X)[7] (mp 142—143°C), and the 1,4-cyclohexanedione[8] (mp 71—73°C) were prepared by published procedures.

Reactions. *a) Ia with Pentylamine*: In a glass ampoule, 1.0 g (2.5 mmol) of Ia, 0.78 g (10 mmol) of pentylamine, and 10 ml of toluene were placed. The free space was filled up with nitrogen before the ampoule was sealed. The ampoule was then heated at 230°C for 1 hr in an oil bath. The contents of the ampoule were subsequently transferred to a flask and were concentrated to half of their original volume. The crystals which appeared were collected by filtration, washed with cold ethanol, and dried in a vacuum to give 0.017 g of IIa, which was confirmed by a comparison of its IR spectrum with that of an authentic sample prepared from urea and pentylamine.[9] Recrystallization from ethanol gave an analytically pure sample: mp 98—100°C, Found: C, 66.01; H, 12.07; N, 13.92%. IR(cm^{-1}): 3345(–NH–), 2960(–CH_3), 2925(–CH_2–), 1625, 1580, and 1276 (amide).

b) Ib with Pentylamine: From 1.00 g (2.46 mmol) of Ib, 0.87 g (10 mmol) of pentylamine, and 10 ml of toluene, 0.226 g of white crystals was obtained by the procedure described in *a)*. The product was determined to be IIa by a mixed-melting-point determination with an authentic sample.

c) Ib with Aniline. A mixture of 1.00 g (2.46 mmol) of Ib, 0.93 g (10.0 mmol) of aniline, and 10 ml of toluene was heated at 230°C in a way similar to that described in *a)*. A white precipitate which separated when the reaction mixture was brought to room temperature was collected by filtration, washed with 10 ml of cold toluene, and dried in a vacuum to give 0.09 g of IIb, which was confirmed by a comparison of its IR spectrum with that of an authentic sample. Recrystallization from toluene gave an analytical sample: mp 242°C, Found: C, 73.64; H, 5.75; N, 13.12%. IR (cm^{-1}): 3325 and 3280(–NH–), 1652, 1557, and 1319 (amide), 755 and 695(phenyl).

A small portion of the filtrate was freed from aniline and toluene under reduced pressure. The residue was dissolved in 1 ml of benzene and was then placed at the top of the column. Elution was achieved with 100 ml portions of each of the following series of solvents: benzene, benzene/ether=80/20, benzene/ether=50/50, ether, and methanol. About 90 fractions of 5 g each were collected. The constituents of each fraction was determined by tlc. Fractions 1—4 gave nothing. Fractions 5—8 gave a mixture of two substances, which appeared at the R_f value of 0.61 (Compound A) and 0.58 (Compound B) in tlc (Solvent 1). The isolation of each compound was achieved by preparative tlc. Compound A (red crystals, mp 141—142°C) was found to be completely identical with X by IR spectroscopic analysis and by a mixed-melting-point determination with an authentic sample. Compound B [brown oil, IR(cm^{-1}): 3390 and 3350(–NH–), 1690, 1256, and 1216(ester), 1602 and 1500(C=C, aromatics), 1317(C–N), 745 and 700(phenyl)] was assumed to be ethyl 2,5-dianilinobenzoate(XII) on the basis of its IR spectrum, which was almost the same as that of *N,N'*-diphenyl-*p*-phenylenediamine(XIII) except for additional absorptions suggesting the presence of an ester group in the molecule. Fractions 9—14 showed a single spot on tlc (Solvent 1). The removal of the solvent from it gave a light yellow oil. The compound changed spontaneously to brown solids upon contact with air. Recrystallization from benzene gave pale gray crystals: mp 146—150°C. IR(cm^{-1}): 3390(–NH–), 1602 and 1500(C=C, aromatics), 1317(C–N), 822(*p*-disubstituted benzene), 745 and 700(phenyl). Its IR spectrum and the R_f value of tlc completely matched those of an authentic sample of *N,N'*-diphenyl-*p*-phenylenediamine. Since compounds with a cyclohexadiene ring are easily converted to aromatic compounds when they are brought into contact with air in the presence of the solvent, X, XII, and XIII were supposed to have been derived from Ib, 1-ethoxycarbonyl-2,5-dianilino-1,4-cyclohexadiene(XIV), and 1,4-dianilino-1,4-cyclohexadiene(Va) respectively, all of which existed in the original reaction products. The formation of XIII by the treatment of air with the Schiff's base obtained from 1,4-cyclohexanedione and aniline was confirmed by a separate experiment. Thus, the decarboxylation of Ib resulting in a Schiff's base (Va) was indirectly confirmed. Fractions 15—26 gave practically nothing. Fractions 27—32 showed a single spot on tlc (Solvent 1). The removal of the solvent from any one of them gave a thick oil which solidified on standing in a refrigerator. Recrystallization from ethanol gave white crystals: mp 51—53°C, IR(cm^{-1}):

3315(-NH-), 3050(aromatics), 2975(aliphatics), 1722, 1240, and 1060(ester), 1705, 1540, and 1320(amid), 750 and 695 (phenyl). With respect to the IR spectrum, the R_f value of tlc, and the mixed-melting-point determination, the compound was identical with an authentic sample of ethyl *N*-phenylcarbamate(III). Fractions 33—36 gave a mixture of aniline, III, and IIb. Fractions 37—39 gave IIb. Fractions 40—62 gave nothing. Fractions 63—70 gave deep red crystals, which were identical with ethyl hydrogen 2,5-dianilinoterephthalate in IR spectrum and in the R_f value of tlc. This compound was expected to have been converted X, which existed in Ib as an impurity. The details of the reaction products between aniline and X are described in *j*). Fractions 71—90 gave practically nothing.

d) Ib with Various Amines. The amounts of reagents in each run were adjusted to 2.46 mmol of Ib, 10 mmol of amines, and 10 ml of toluene. The reaction were carried out at 230°C for 1 hr. The resulting *N,N'*-disubstituted urea was isolated from the reaction products by the process described in *a*). The yields and products of each run are listed in Table 1.

e) Various I Substances with Aniline. The reactions were carried out in the way described in *a*). The yield of IIb in each run is listed in Table 2.

f) VI with Aniline. A mixture of 1.9 g of VI, 4.0 g of aniline, and 10 ml of toluene was heated in a way similar to that described in *a*). IIb(0.53 g) was separated from the reaction products. The distillation of the filtrate gave three fractions; bp 35—40°C/50 mmHg(toluene), bp 78—82°C/13 mmHg, and nonvolatile substances. The gas chromatogram(at 150°C) of the fraction at bp 78—82°C/13 mmHg showed two peaks, at R_t=2.2 min and 4.1 min. The former peak was identical with that of aniline, while the latter peak was matched that of the anil of acetone prepared by the method of Kuhn and Schretzmann.[10] The tlc(Solvent 1) of the nonvolatile substance showed a big spot at R_f=0.55. The isolation of this substance by preparative tlc gave light yellow crystals. The IR spectrum, mp, and R_f value of this compound were identical with those of an authentic sample of III.

g) Other β-Anilino α,β-unsaturated Carboxylic Acid Esters with Aniline. In a way similar to that described in *a*), VII and VIII were subjected to a reaction with aniline. The results are listed in Table 3.

h) IX with Aniline. The reaction was carried out in a manner similar to that in the case of I. The tlc(Solvent 1) of the products showed a big spot (R_f=0.04). The compound corresponding to this spot was isolated by preparative tlc and was determined to be acetanilide by an IR spectroscopic analysis and by a mixed-melting-point determination with an authentic sample. From one-twentieth of the product, 10.7 mg of acetanilide were obtained as crystals; mp 112—114°C.

i) III with Aniline. A mixture of 1.0 g of III, 2.2 g of aniline, and 10 ml of toluene was subjected to a reaction under the same conditions as in *a*). IIb was thus obtained in a yield of 0.50 g. (39%).

j) X with Aniline. Since the reaction between X and aniline in the presence of the solvent (toluene) was slow, the reaction was carried out in the absence of the solvent. Thus, a mixture of 1.0 g of X and 19 ml of aniline was heated for 2.0 hr at 220°C in a sealed tube. The product was then roughly divided into a nonvolatile solid and a volatile liquid by vacuum distillation. The solid was composed of three substances, which appeared at R_f values of 0.66 (Compound A), 0.46 (Compound B), and 0.37 (Compound C) in tlc(Solvent 2). Each compound was isolated by preparative tlc and its structure was determined by IR spectroscopic and elemental analysis to be as follows: Compound A: unchanged X; Compound B: ethyl hydrogen 2,5-dianilinoterephthalate, Found: C, 68.67; H, 5.43; N, 7.39%. Calcd for $C_{22}H_{20}N_2O_4$: C, 70.20; H, 5.36; N, 7.44%. IR(cm^{-1}), 3360(-NH-), 1698, 1264, and 1160 (ester), 1668 and 1540 (-COOH), 750 and 694(phenyl); Compound C: 2,5-dianilinoterephthalic acid, Found: C, 66.01; H, 4.72; N, 7.63%. The IR spectrum of this compound was identical with that of a saponification product of X. The gas chromatogram of the volatile liquid obtained at 120°C showed two peaks, corresponding to aniline (R_t=1.5 min) and *N*-ethylaniline (R_t=2.7 min) respectively.[11] The structure of the latter compound was confirmed by a study of its IR spectrum.

k) XI with Aniline. Acid-freed XI (1.0 g) and aniline (10 m*l*) were heated for 2 hr at 230°C in a sealed tube. The tlc (Solvent 2) of the product showed two prominent spots, at R_f 0.62 (aniline) and 0.78(XI), and one weak spot, at R_f 0.64(2-anilinobenzoic acid). No further treatment of the product was undertaken.

10) R. Kuhn and H. Schretzmann, *Chem. Ber.*, **90**, 557 (1957).

11) It has been reported that alkyl-oxygen fission in the hydrolysis of esters might occur if the carbonium ion to be formed is sufficiently stable[12] or if the rate of the $B_{AC}2$ reaction of the ester is remarkably diminished by steric hindrance.[13] In this reaction, it may be considered that the nucleophilic attack of aniline molecules occurred hardly at all at the carbonyl carbon atom, but more at the alkyl carbon atom. Therefore, alkyl-oxygen fission occurred to form acid and *N*-ethylaniline. The further details of this reaction will be reported separately.

Reaction of *O,O*-Dialkyl Dithiophosphoric Acid. III.[1] Reductive Cleavage Reactions of Nitrogen-Nitrogen Bond by *O,O*-Diethyl Dithiophosphoric Acid

Shigeru Oae, Nobuko Tsujimoto,[2] and Akira Nakanishi

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

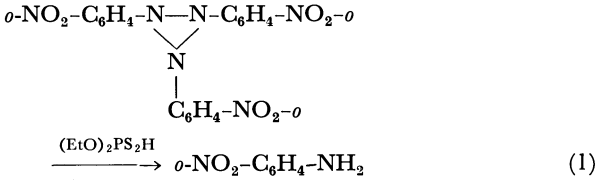
(Received May, 6, 1972)

o-Nitroaniline was obtained when tri(*o*-nitrophenyl) triaziridine(I) was allowed to react with excess *O,O*-diethyl dithiophosphoric acid. It was found that azobenzene derivatives(IIa-e) are converted into the corresponding reduction products aniline derivatives(IVa-e) in the reaction with excess *O,O*-diethyl dithiophosphoric acid. Similarly, arylhydrazines (IIIa-c) were converted into the corresponding aniline derivatives (IVa,d,e) by the action of *O,O*-diethyl dithiophosphoric acid.

In a previous paper,[1] we reported on the reactions between *O,O*-dialkyl dithiophosphoric acid and various compounds having a semipolar linkage. Meanwhile, we have found that compounds having a less polarized nitrogen-nitrogen linkage or none at all, such as tri-(*o*-nitrophenyl)triaziridine(I), azobenzene(IIa—e), and arylhydrazine(IIIa—c), also readily react with *O,O*-diethyl dithiophosphoric acid to afford the corresponding reduction products. The reduction of tri(*o*-nitrophenyl)triaziridine(I) to *o*-nitroaniline, and the formation of *o*-nitroaniline from I appear to support the structure of I to be of triaziridine ring. The reduction of IIa—e to anilines and benzidine in the reaction with *O,O*-diethyl dithiophosphoric acid is also interesting, since there has been no report that azobenzene is reduced by organic reducing agents. Meanwhile in the N–N bond cleavage reaction of IIIa—c with *O,O*-diethyl dithiophosphoric acid, nucleophilic substitution on the nitrogen atom (Chart 3) appears to take place to afford anilines (IVa,d,e). This is one of only a few known examples of nucleophilic substitution on the nitrogen atom. This paper gives a detailed account of the N–N bond cleavage reaction with an acidic mercaptan, *O,O*-diethyl dithiophosphoric acid ($pK_a=1.62$[3]).

Results and Discussion

Reaction of Tri(o-nitrophenyl)triaziridine(I) with $(EtO)_2PS_2H$. Recently, tri(*o*-nitrophenyl)triaziridine(I), a remarkably stable derivative of the triaziridine ring system,[4,5] has been prepared by the thermolysis of *o*-nitrophenyliminopyridinium betaine.[6] However, catalytic hydrogenation of I over PtO_2 or the reduction of I with Zn/AcOH afforded *o*-phenylenediamine,[6] *viz.*, both the nitro group and triaziridine ring were similtaneously reduced. The reaction of I with a large excess of $(EtO)_2PS_2H$ at 80°C for 24 hr[7] gave *o*-nitroaniline in a 12% yield and unreacted I (70%) as shown by Eq. (1). Thus $(EtO)_2PS_2H$ is the first selective reducing agent which cleaves the N–N bond of aziridine ring without reducing *o*-nitro group. This strongly suggests the structure of I to be of a three-membered triaziridine ring. Although we could neither detect nor isolate any such intermediate as



(1)

2,2′-dinitroazobenzene, the reduction pathway undoubtedly involves the cleavage of azo (–N=N–) and/or hydrazo (–NH–NH–) linkages. We therefore allowed azobenzene derivatives to react with $(EtO)_2PS_2H$ and found the reaction to proceed more easily than I. The conversion of I into *o*-nitroaniline is considered to follow the scheme shown in Chart 1. The initial step of the reaction between I and $(EtO)_2PS_2H$

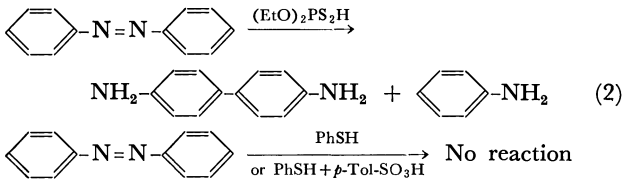
7) I did not react with conc. H_2SO_4 or thiophenol and was then recovered.

would be the formation of an intermediate(i), which reacts further with another mole of $(EtO)_2PS_2H$ to afford an intermediate(ii) and *o*-nitroaniline. (ii) then immediately changes to azobenzene(iii) and bis-[*O,O*-diethyl thiophosphoryl]disulfide(iv). (iii) is readily reduced to *o*-nitroaniline by $(EtO)_2PS_2H$ under the reaction conditions.

Reaction of Azobenzene(IIa—e) with $(EtO)_2PS_2H$. As anticipated 2,2′-dinitroazobenzene(iii) can be reduced smoothly with $(EtO)_2PS_2H$ to *o*-nitroaniline. It is well-known that azobenzene is reduced to the corresponding reduction product by treatment with such inorganic reducing agents as $Na_2S_2O_4$,[8] NH_2-$NH_2 \cdot H_2O$/Cu,[9] or HCl/Zn.[10] However, it is not known that azobenzene is reduced to aniline in the reaction with any organic reducing agent, such as acidic mercaptans. Actually the reaction between azobenzene(IIa) (1 mol) and $(EtO)_2PS_2H$ (10 mol) at 70°C for 24 hr gave benzidine and aniline (IVa) in the yields of 27% and 40%, respectively [Eq. (2)]. Since no reaction takes place when azobenzene is treated with a large excess of thiophenol either in the presence or absence of *p*-Tol-SO_3H, the reduction of azobenzene with $(EtO)_2PS_2H$ is caused by the inherently-built-in high acidity and nucleophilicity of the dithiophosphoric acid.



(2)

The reaction with $(EtO)_2PS_2H$ was successfully applied to the reduction of a few substituted azobenzene derivatives (IIb—e) [Eq. (3)]. The results are listed in Table 1. In an attempt to trap an intermediate of this reaction an equimolar mixture of IIa and *O,O*-diethyl dithiophosphoric acid was kept at 0°C for 24 hr, and then 10% benzidine and 38% recovered IIa were obtained. Thus, neither intermediate nor aniline (IVa), a reduction product of azobenzene, could be obtained. However, benzidine and IVa are presumed to be formed *via* an initial formation of hydrazobenzene(Va) or its derivative. We therefore allowed Va to react with *O,O*-diethyl dithiophosphoric acid. The results are summarized in Table 2.

IIb: R=H, R′=Cl
c: R=Me, R′=Cl
d: R=R′=Me
e: R=R′=Cl

(3)

IVb: R=H, R′=Cl
c: R=Me, R′=Cl
d: R=R′=Me
e: R=R′=Cl

A mixture of hydrazobenzene(Va) (1 mol) and excess *O,O*-diethyl dithiophosphoric acid was heated at 70°C for 24 hr. As in the case of IIa, benzidine and IVa were obtained in the 50% and 32% yields, respectively. IIa was obtained when less than two moles of $(EtO)_2PS_2H$ was used. In order to understand the process of formation of IIa, 4,4′-dichlorohydrazobenzene(Vb) (1 mol) was treated with $(EtO)_2PS_2H$ (1 mol); 4,4′-dichloroazobenzene(IIe) (50%) and 4-chloroaniline(IVe) (50%) were obtained. When $(EtO)_2PS_2H$ was used as an acid catalyst, the same reaction occurred (Table 3). This is in line with the observation[10] that in acid catalysis one molecule of hydrazo compound becomes oxidized to the azo compound, while another is reduced to two molecules of amine.

As regards the reaction mechanism for the conversion of IIa into benzidine and IVa, the sequence of reactions shown in Chart 2 is conceivable. The initial step of the reaction between II and *O,O*-diethyl dithiophosphoric acid would be the formation of an intermediate(v) similar to that[11] between azobenzene and an arenesulfinic acid which has also a similar pK_a

TABLE 1. YIELD OF ANILINE DERIVATIVES (IVb-e) BY TREATMENT OF AZOBENZENE DERIVATIVES (IIb-e) WITH EXCESS *O,O*-DIETHYL DITHIOPHOSPHORIC ACID AT 70°C

Table 3. Reaction of 4,4'-dichlorohydrazobenzene(Vb) with *O,O*-diethyl dithiophosphosphoric acid at room temperature[a)]

$(EtO)_2PS_2H$ (mol)	(Vb) (mol)	Reaction time	Yield (%) of product (IIe)	(IVe)
1	1	24 hr	50	50
0.2	1	7 day	50	50

a) An equimolar mixture of 4-chloro-4'-methylhydrazobenzene(Vc) and *O,O*-diethyl dithiophosphoric acid gave IIc(50%), IVc(25%), and IVe(25%). There was no cross-over of amine group between 4-chloroaniline and 4-methylaniline during the course of reaction.

value 1—1.5.[12)] Then the intermediate(v), upon reaction with another mole of $(EtO)_2PS_2H$, gives benzidine or hydrazobenzene derivatives(vi), which, however, could not be isolated. Hydrazobenzene (vi) would either be reduced with $(EtO)_2PS_2H$ to aniline or rearrange to benzidine or undergo acid catalyzed disproportionation[10)] to give II and IV.

Reaction of Arylhydrazine (IIIa—c) with $(EtO)_2PS_2H$. Since hydrazobenzene was found to be cleaved readily by $(EtO)_2PS_2H$, we applied this procedure for the N–N bond cleavage of arylhydrazine(IIIa—c). When a mixture of phenylhydrazine(IIIa) (1 mol) and $(EtO)_2PS_2H$ (10 mol) was heated at 70°C for 24 hr, aniline (IVa) was obtained in a 51% yield. In an alternative procedure to prepare IVa, an equimolar mixture of IIIa and $(EtO)_2PS_2H$ in ether was kept at room temperature to give hygroscopic phenylhydrazinium *O,O*-diethyl dithiophosphate (viia). The structure of viia was identified by NMR and IR spectra (Tables 5,6). The salt (VIIa) was then heated under refluxing in benzene to yield IVa. Similarly, other arylhydrazines (IIIb, c) were also reduced to the corresponding aniline derivatives (IVd, e), as listed in Table 4. These reactions are assumed to proceed *via* the formation of an intermediate salt (vii) prior to the formation of the

reduction product VI and *S*-amino-*O,O*-diethyl dithiophosphate (VIII). Compound (VIII) is so unstable that, upon being kept standing, it is converted into bis[*O,O*-diethyl thiophosphoryl]disulfide (VI).[1)]

These reduction reactions of azobenzenes (IIa—e) and arylhydrazines (IIIa—c) with *O,O*-diethyl dithiophosphoric acid are interesting examples of nucleophilic substitution on the nitrogen atom.

Reaction of Tri(o-nitrophenyl)triaziridine with $(EtO_2)PS_2H$. Tri(*o*-nitrophenyl)triaziridine(500 mg) was reacted with 5 g of $(EtO)_2PS_2H$ at 80°C. After 24 hr aqueous Na_2CO_3 was added to this reaction mixture of remove excess $(EtO)_2PS_2H$. The reaction products were extracted with $CHCl_3$ from *aq.* Na_2CO_3 solution, and then chromatographed(silica gel column) with benzene-hexane(1 : 1) to give bis[*O,O*-diethyl thiophosphoryl] disulfide, 90 mg of *o*-nitroaniline(12%), and 560 mg of recovered tri(*o*-nitrophenyl)triaziridine(70%).

Reaction of Azobenzene(IIa) with Excess $(EtO)_2PS_2H$. A mixture of IIa(1.82 g, 0.01 mol) and $(EtO)_2PS_2H$(18.6 g, 0.1 mol) was heated at 70°C for 24 hr. Excess Na_2CO_3 was added to the reaction mixture and the product was extracted with benzene. After removal of benzene at atmospheric pressure, the residue was chromatographed through a silica gel column with $CHCl_3$ as an eluent to give benzidine, 0.40 g, 27%, mp 113—115°C (lit,[23] mp 115—120°C) and aniline(IVa), 0.74 g, 40%. These compounds were identified by comparing their IR spectra and melting points with those of the corresponding authentic samples. In this reaction small amounts of three other unidentified liquids were also obtained.

Reaction of Azobenzene Derivatives(IIb-c) with excess $(EtO)_2PS_2H$. A mixture of IIb-e(0.01 mol) and $(EtO)_2PS_2H$-(0.1 mol) was heated at 70°C until the reaction mixture changed in to a clear solution. The mixture was treated with excess Na_2CO_3 and extracted with benzene. The benzene solution was extracted with 10% aqueous HCl and the aqueous layer was concentrated under reduced pressure to obtain HCl salts of aniline derivatives (IVb-e). A small amount of water was added to the crude salts of IVb-e and neutralized with Na_2CO_3 and then extracted with benzene. The benzene layer was dried over $MgSO_4$ and concentrated under atmospheric pressure to give aniline derivatives(IVb-e), which were found to be identical with the authentic samples in melting points and IR spectra. The amounts of IVb and IVc were estimated by comparison with the mixture of authentic samples. The yields are summarized in Table 1.

Reaction of an Equimolar Mixture of Azobenzene(IIa) and $(EtO)_2PS_2H$. To a solution of IIa(1.82 g, 0.01 mol) in ether(5 ml) was added dropwise a solution of $(EtO)_2PS_2H$ (1.86 g, 0.01 mol). The mixture was allowed to stand at 0°C overnight. The white precipitates were collected and washed thoroughly with ether to give crude *O,O*-diethyl dithiophosphate of benzidine. The crude salt of benzidine was neutralized with aqueous Na_2CO_3 and then extracted with benzene. The benzene solution was dried over $MgSO_4$ and upon removal of the benzene benzidine, 0.19 g, 10%, mp 113—116°C(lit,[23] mp 115—120°C), was obtained. The ether filtrate was concentrated to give orange crystals, which were recrystallized from ethanol to give recovered azobenzene, 0.7 g, 38%, mp 64—66°C(lit,[14] mp 66—67.5°C).

Reaction of Hydrazobenzene(Va) with Excess $(EtO)_2PS_2H$. A mixture of Va(1.84 g, 0.01 mol) and $(EtO_2)PS_2H$(18.6 g, 0.1 mol) was heated at 70°C for 24 hr. Excess Na_2CO_3 was added to the reaction mixture and the mixture was extracted with benzene. After removal of the benzene at atmospheric pressure, the residue was chromatographed through a silica gel column with $CHCl_3$ as an eluent to give benzidine, 0.92 g, 50%, mp 113—116°C(lit,[23] mp 115—120°C) and aniline(IVa)(0.60 g, 31%), which were found to be identical with the corresponding compounds.

Reaction of an Equimolar Mixture of Hydrazobenzene (Va) and $(EtO)_2PS_2H$ at 70°C. To a solution of Va(1.84 g, 0.01 mol) in ether (5 ml) was added dropwise a solution of $(EtO)_2PS_2H$ (1.86 g, 0.01 mol). The mixture was heated at 70°C overnight. The white mass was collected and washed thoroughly with ether to give crude *O,O*-diethyl dithiophosphate of benzidine. The crude salt of benzidine was neutralized with aqueous Na_2CO_3 and then extracted with benzene. The benzene solution was dried with $MgSO_4$ and the benzene was removed to give benzidine, 0.32 g, 17%, mp 112—116°C(lit,[23] 115—120°C). The ether filtrate was concentrated to give an orange residue. The residue was chromatographed through a silica gel column with $CHCl_3$ as an eluent to give aniline(0.19 g, 10%) and azobenzene (IIa), 0.55 g, 30%, mp 65°C(lit,[14] mp 66—67.5°C).

Reaction of an Equimolar mixture of Hydrazobenzene(Va) and $(EtO)_2PS_2H$ at 0°C. To a solution of Va(1.84 g, 0.01 mole) in ether (5 ml) was added dropwise a solution of $(EtO)_2PS_2H$ (1.86 g, 0.01 mol). The mixture was allowed to stand at 0°C overnight. Treatment of the reaction mixture in a manner similar to that described above gave benzidine (0.18 g, 10%), mp 112—116°C(lit,[23] mp 115—120°C),

aniline(IVa) (0.18 g, 9%), and azobenzene(IIa), 0.67 g, 37%, mp 65°C(lit.[14] mp 66—67.5°C) while recovering hydrazobenzene(Va), 0.13 g, 7%, mp 123—126°C(lit,[19] mp 126°C).

Reaction of an Equilimolar Mixture of 4,4'-Dichlorohydrazobenzene (Vb) and $(EtO)_2PS_2H$. To a solution of Vb (2.52 g, 0.01 mole) in ether (10 ml) was added dropwise a solution of $(EtO)_2PS_2H$(1.86 g, 0.01 mol). The mixture was allowed to stand at room temperature for 24 hr, and the ether was removed to give crystals which were then washed with ethanol to give 4,4'-dichloroazobenzene(IIe), 1.25 g, 50% mp 176—177.5°C (lit,[18] mp 177—178°C). The ethanol filtrate was condensed and neutralized with aqueous Na_2CO_3 and then extracted with benzene. After removal of the benzene at atmospheric pressure, the residue was recrystallized from ether to give 4-chloroaniline(IVe), 1.27 g, 50%, 71—72°C (lit,[24] mp 72.5°C).

Reaction of 4,4'-Dichlorohydrazobenzene(Vb) with $(EtO)_2PS_2H$ as Acid Catalysis. To a solution of Vb(2.52 g, 0.01 mol) in ether(10 ml) was added dropwise a solution of $(EtO)_2PS_2H$(0.37 g, 0.002 mol). The reaction mixture was allowed to stand at room temperature for 7 days. Treatment of the reaction mixture in a manner similar to that described above gave 4,4'-dichloroazobenzene(IIe) (1.25 g, 50%) and 4-chloroaniline(IVe) (1.27 g, 50%), which were identical with the corresponding authentic samples.

Equimolar Reactions between 4-Chloro-4'-methylhydrazobenzene (Vc) and $(EtO)_2PS_2H$. To a solution of Vc (2.32 g, 0.01 mol) in ether(10 ml) was added dropwise an etheral solution of $(EtO)_2PS_2H$(1.86 g, 0.01 mol). The mixture was allowed to stand at room temperature for 24 hr. Ether was removed to give orange crystals. The crystals were washed with ethanol to give 4-chloro-4'-methylazobenzene (IIc) (1.15 g, 50%), mp 152—153°C(lit,[17] mp 153°C). There is no crossover of aniline group between 4-chloroaniline and 4-methylaniline during the course of reaction. The ethanol filtrate was condensed and neutralized with aquoeus Na_2CO_3 and then extracted with benzene. After removal of the benzene at atmospheric pressure, the residue containing 4-chloroaniline and 4-methylaniline was determined spectrometrically.

TABLE 6. IR SPECTRA OF ARYLHYDRAZINIUM O,O-DIETHYL DITHIOPHOSPHATE

Comp.	ν_{max}^{KBr} (cm^{-1})					
IIIa	3250,	1025,	1010,	940,	920,	680
IIIb	3220,	1030,	1015,	940,	680,	660
IIIc	3250,	1020,	1005,	940,	900,	660

General Procedure for the Reaction of Arylhydrazine(IIIa-c) with Excess $(EtO)_2PS_2H$. A mixture of IIIa–c(0.01 mol) and $(EtO)_2PS_2H$(0.01 mol) was heated at 70°C until the reaction mixture changed into a clear solution. The mixture was treated with excess Na_2CO_3 and extracted with benzene. The benzene solution was extracted with 10% aqueous HCl and dried over $MgSO_4$ and then condensed to give a colorless oil(1.5—2.0 g), which was identical with the authentic sample, bis[O,O-diethyl thiophosphory]disulfide.[25] Aqueous HCl solution (10%) was concentrated under reduced pressure to give HCl salt of aniline derivatives (IVa, d, e). A small amount of water was added to the crude salts of IVa,d,e and neutralized with Na_2CO_3 and then extracted with benzene. The benzene solution was dried over $MgSO_4$. Removal of benzene gave aniline derivatives (IVa,d,e). The yields of IVa,d,e are given in Table 4.

Reaction of an Equimolar of Arylhydrazine(IIIa–c) and $(EtO)_2PS_2H$. To a solution of IIIa–c(0.01 mol) in ether(10—50 ml) was added dropwise an ether solution of $(EtO)_2PS_2H$(0.01 mol). The mixture was allowed to stand at room temperature for several hours. The precipitates were collected and recrystallized from ether to give arylhydrazinium O,O-diethyl dithiophosphate quantitatively. These products were hygroscopic white needles and identified by their NMR and IR spectra listed in Table 5 and 6. A solution of arylhydrazinium O,O-diethyl dithiophosphates in benzene was heated under refluxing for 1—2 days. After removal of the benzene at atmospheric pressure, the residue was distilled or recrystallized to give aniline derivatives (IVa,d,e) (50—70% yield).

Chemistry of Cyanoacetylenes. Part XIV.[1] One-step Synthesis of Some Ethynyl Heterocycles and Their Reactions with Diazomethane

Tadashi SASAKI, Shoji EGUCHI, and Michio SUGIMOTO

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464

(Received May 9, 1972)

The Ritter reaction of cyano- and chlorocyanoacetylene with appropriate substrates provided a facile one step synthesis of 4,4-dimethyl-2-ethynyloxazoline (**5**), 4,4,6-trimethyl-2-ethynyl (**7**) and -2-chloroethynyl-5,6-dihydro-1,3-oxazine (**8**), 5,5-dimethyl-3-isopropylidene-2-ethynyl- (**10**) and -2-chloroethynyl-1-pyrroline (**11**). On treatment with diazomethane, **7** gave 4,4,6-trimethyl-2-(4-1*H*-pyrazolyl)- (**13**) and -2-(3-1*H*-pyrazolyl)-5,6-dihydro-1,3-oxazine (**14**) in 42 and 40% yields respectively, while **8** afforded only 4,4,6-trimethyl-2-[3-(4-chloro-1-methyl)-pyrazolyl]-5,6-dihydro-1,3-oxazine (**15**) in 52% yield. On the other hand, **10** gave 5,5-dimethyl-3-isopropylidene-2-(3-1*H*-pyrazolyl)-1-pyrroline (**16**) in 64% yield and **11**, 5,5-dimethyl-3-isopropylidene-2-[3-(4-chloro-1-methyl)-pyrazolyl]-1-pyrroline (**17**) in 16% yield.

We reported that cyano- and chlorocyanoacetylene undergo the Ritter reaction with some olefins and alcohols to give the corresponding propiolamide derivatives.[2,3] As an extension of this study, we have applied the Ritter reaction[4] of the cyanoacetylenes to the synthesis of some ethynylheterocycles by using appropriate substrates.

We employed 2-methylallyl alcohol (**4**), hexylene glycol (**6**) and 2,5-dimethyl-2,5-hexanediol (**9**) with the hope of synthesizing 2-ethynyl- and 2-chloroethynyl derivatives of 4,4-dimethyloxazoline, 4,4,6-trimethyl-5,6-dihydro-1,3-oxazine, and 5,5-dimethyl-3-isopropylidene-1-pyrroline from our interest in their pharmacological activity[5] and utility as synthetic intermediates.[6]

Results and Discussion

The Ritter Reactions. The reaction of 2-methylallyl alcohol (**4**) with cyanoacetylene in sulfuric acid (95%) at 0°C for 1 hr afforded a complex mixture of products, from which an oily basic product **5** was obtained in 4.9% yield by distillation under reduced pressure. The structure of **5** was determined as 4,4-dimethyl-2-ethynyloxazoline from analytical and spectral data. The IR absorptions at 3300, 2160, and 1620 cm^{-1} demonstrated the presence of C≡CH and C=N functions, and NMR ($CDCl_3$) spectrum manifested signals at τ 6.05 (s, 2H, $C\underline{H}_2$), 7.05 (s, 1H, C≡C$\underline{H}$) and 8.70 (s, 6H, $C(C\underline{H}_3)_2$), supporting the above assignment. The Ritter reaction of 2-methylallylchloride (**1**) with cyanoacetylene is known to afford *N*-(chloro-*t*-butyl)propiolamide **2** in a good yield,[2] and the cyclization of **2** with ethanolic potassium hydroxide gives the corresponding 2-vinyloxazoline derivatives **3**.[2] We examined the direct cyclization of **2** with potassium hydroxide in tetrahydrofuran and proved that **2** gave also 2-ethynyloxazoline **5** in 24% yield (Scheme 1). Attempts to improve the yield of **5** in the Ritter reaction of **4** with cyanoacetylene were unsuccessful because of the formation of large amounts of intractable polymeric materials, and therefore, the cyclization method of **2** was concluded to be superior to the Ritter reaction of **4** in this case.

Treatment of hexylene glycol **6** with an equimolar amount of cyanoacetylene in sulfuric acid afforded the desired 2-ethynyl-5,6-dihydro-1,3-oxazine derivative **7** (Scheme 2). The best yield of **7** was 26.5% which

was obtained under drastic conditions at 50°C. Only a trace amount of **7** was produced under milder conditions at room temperature. The structural elucidation of the product was based on the analytical and spectral data: **7** showed a molecular ion peak at *m/e* 151 (M^+) in the mass spectrum, and strong IR (KBr) absorptions at 3200 and 2130 (C≡CH) and 1625 (C=N) cm^{-1}. The NMR ($CDCl_3$) signals at τ 5.5—6.1 (broad m, 1H, 6-H), 7.38 (s, 1H, C≡CH), 8.0—8.5 (m of AB portion of an ABX pattern, 2H, CH_2), 8.65 (d, J=6.1 Hz, 3H, 6-CH_3) and 8.78 (s, 6H, 4,4-$(CH_3)_2$) were in line with the assigned structure.

Scheme 2.

The Ritter reaction of **6** with chlorocyanoacetylene under the same conditions at 50°C gave 2-chloroethynyl-4,6,6-trimethyl-5,6-dihydro-1,3-oxazine (**8**) in 21.6% yield. The assigned structure was evidenced by analytical and spectral data.

The reaction of 2,5-dimethyl-2,5-hexanediol (**9**) with cyanoacetylene afforded 2-ethynyl-5,5-dimethyl-3-isopropylidene-1-pyrroline (**10**) as a colorless oil. A molecular formula $C_{11}H_{15}N$ was evidenced by analysis and mass spectral molecular weight, *m/e* 161 (M^+). The assigned structure was compatible with the NMR spectrum which revealed signals at τ 6.83 (s, 1H, C≡CH), 7.63 (q, J=2.3 Hz, 2H, CH_2), 7.78 (t, J=2.3 Hz, 3H, C^aH_3), 8.22 (s, 3H, C^bH_3) and 8.75 (s, 6H, 5,5-$(CH_3)_2$). The yield of **10** varied 46—60% depending on the addition method (see Experimental) (Scheme 3).

11 **12**

Scheme 3.

The same reaction of **9** with chlorocyanoacetylene gave 2-chloroethynyl-5,5-dimethyl-3-isopropylidene-1-pyrroline (**11**), purification of which was difficult because of facile decomposition; **11** was characterized by the spectral data: *m/e* 196 (M^+) and 198 (M+2) in 3 : 1 ratio; ν_{max}^{film} 2260, 1655, and 1540 cm^{-1}; τ (CD-Cl_3) 7.65 (q, J=2.3 Hz, 2H, CH_2), 7.83 (t, J=2.3 Hz, 3H, C^aH_3), 8.25 (s, 3H, C^bH_3), and 8.79 (s, 6H, 5,5-$(CH_3)_2$). The assigned structure of **11** was also supported by the reaction with diazomethane as described below. On distillation of crude **11** under reduced pressure, a crystalline product **12** was obtained in a low yield, which gave *m/e* 232 (M^+) and 234 (M+2) with a ratio of 3 : 2; ν_{max}^{KBr} 1650, 1620, 1565, and 750 cm^{-1}; τ ($CDCl_3$) 3.38 (s, 1H, C=CH), 7.60 (q, J=2.3 Hz, 2H, CH_2), 8.05 (t, J=2.3 Hz, 3H, C^aH_3), and 8.71 (s, 6H, 5,5-$(CH_3)_2$). The structure of **12** was assigned as 2-β,β-dichlorovinyl-5,5-dimethyl 3-isopropylidene-1-pyrroline. The formation of **12** is rationalyzed by the Markownikov addition[7,8] of hydrogen chloride to **11** (Scheme 3). It is uncertain whether the origin of hydrogen chloride is **11** itself or some other chloroethynyl side-products in the Ritter reaction.

Reaction of **7**,**8**,**10**, *and* **11** *with Diazomethane.* The formation of pyrazole derivatives by 1,3-dipolar cycloaddition reactions of diazomethane to acetylenic bonds is well-known.[9] However, only a few studies have been made on unsymmetrically substituted acetylenes with a bulky heterocyclic rings.[10,11]

On treatment with a large excess of diazomethane in ether at room temperature, **7** afforded two crystalline products **13** and **14** in 42 and 40% yields, respectively. Both products were 1 : 1 adducts on the basis of their mass spectra, *m/e* 193. Compound **13** was assigned as 4,4,6-trimethyl-2-(4-1*H*-pyrazolyl)-5,6-dihydro-1,3-oxazine by appearance of a singlet signal at τ 2.15 for two protons, and **14** as 4,4,6-trimethyl-2-(3-1*H*-pyrazolyl)-5,6-dihydro-1,3-oxazine by the NMR signals at τ 2.48 and 3.38 (both d, J=1.9 Hz, each 1H) (Scheme 4). On the other hand, the reaction of **8** with diazomethane afforded only one product **15** in 52% yield, which was characterized as 4,4,6-trimethyl-2-[3-(4-chloro-1-methyl)pyrazolyl]-5,6-dihydro-1,3-oxazine by analysis and spectral data: *m/e* 241 (M^+) and 243 (M+2) with a 3 : 1 ratio; τ ($CDCl_3$) 2.68 (s, 1H, 5-H of the pyrazole), 5.70 (m, 1H, 6-H), 6.01 (s, 3H, NCH_3), 8.10 (m, 2H, CH_2), 8.62 (d, J=6.0 Hz, 3H, 6-CH_3) and 8.70 (s, 6H, 4,4-$(CH_3)_2$). The fact that

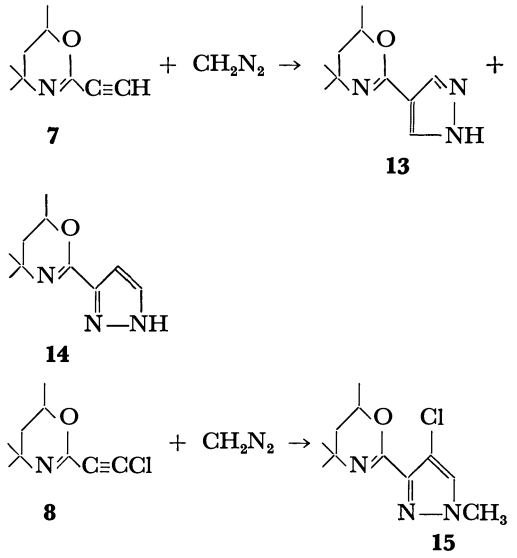
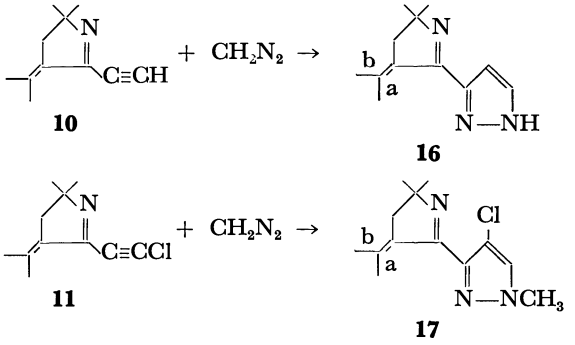
11) For 1,3-dipolar cycloaddition reactions of 5-nitro-2-furyldiazomethane, see T. Sasaki, S. Eguchi, and A. Kojima, *J. Heterocyclic Chem.*, **5**, 243 (1968).

7 affords an isomeric mixture of **13** and **14** in *ca.* 1 : 1 ratio and that **8** gave only **15** suggests that the orientation of the cycloaddition was controlled by the electronic factor rather than the steric one.[12]



Scheme 4.

The reaction of **10** and **11** with diazomethane afforded only one adduct each **16** and **17** in 64 and 16 (from **11**)% yields, respectively (Scheme 5). The structural assignments were based on analytical and spectral data: **16** showed characteristic vinyl proton signals at τ 2.52 (d, J=1.9 Hz, 1H, 5-H of the pyrazole), and 3.55 (d, J=1.9 Hz, 1H, 4-H of the pyrazole). **17** showed one vinyl proton signal at τ 2.63 (s) and *N*-methyl protons signal at τ 6.12 (s), supporting the assigned structures.



Scheme 5.

The formation of each single product in the above reactions indicates that 1-pyrroline ring in **10** and **11** is more electron-withdrawing than 1,3-oxazine ring in **7** and **8**. Simultaneous *N*-methylation of the pyrazole rings from the chloroethynyl derivatives is apparently ascribable to lower basicity of the pyrazole ring by the presence of an electronegative chloro-substituent.[13]

Experimental

All mp and bp are uncorrected. NMR spectra were recorded on a JEOL-C-60HL spectrometer at 60 MHz with TMS as the internal standard, and mass spectra on a JEOL-OISG mass spectrometer at 75 eV. IR spectra were obtained with a JASCO IR-S spectrometer. Microanalyses were carried out with a Perkin-Elmer 240 Elemental Analyzer.

*Reaction of Cyanoacetylene with 2-Methylallyl Alcohol (**4**).* To a stirred sulfuric acid (95%, 15 ml) was added slowly a mixture of **4** (3.60 g, 0.050 mol) and cyanoacetylene[14] (2.55 g, 0.050 mol) under ice-cooling over a period of 10 min. After stirring was continued for further 1 hr, the mixture was poured onto ice-water (ca. 300 ml) and washed with chloroform (30 ml×5). The water layer was basified with 20% aqueous sodium hydroxide under ice-cooling and extracted with chloroform (30 ml×5). The dried (Na_2SO_4) extracts were evaporated to give 2.4 g of crude basic products. Flask distillation at 0.11 mmHg gave a distillate trapped at liquid nitrogen temperature, which was further purified by passing through a neutral alumina column using benzene as an eluent to give 0.301 g (4.9%) of analytically pure *2-ethynyl-4,4-dimethyloxazoline* **5**: n_D^{18} 1.4905; *m/e* 123 (M^+); λ_{max}^{MeOH} 219 nm (ε 4000).

Found: C, 68.53; H, 7.32; N, 11.27%. Calcd for C_7H_9NO: C, 68.27; H, 7.37; N, 11.37%.

*Cyclization of N-(Chloro-t-butyl)propiolamide **2** to **5**.* A mixture of **2** (0.22 g, 1.4 mmol) and potassium hydroxide (0.13 g) in dry THF (10 ml) was refluxed under nitrogen atmosphere for 4 hr. The cooled mixture was treated with water and extracted with chloroform (10 ml×5). The work-up afforded **5** in 23.8% yield.

*Reaction of Cyanoacetylene with Hexylene Glycol (**6**).* A mixture of cyanoacetylene (1.3 g, 0.025 mol) and **6** (2.95 g, 0.025 mol) was added to stirred sulfuric acid (20 ml) over a period of ca. 10 min at room temperature; the temperature was raised up to *ca.* 50°C and stirring was continued for 1 day at room temperature. The mixture was poured onto ice-water and extracted with chloroform (80 ml×5) after being basified with 20% aqueous sodium hydroxide. The combined extracts were dried (Na_2SO_4) and evaporated to give a dark brownish residue which was distilled to afford *2-ethynyl-4,4,6-trimethylethyl-5,6-dihydro-1,3-oxazine* **7**) (1.0 g, 26.5%); an analytical sample was obtained after recrystallization of the solidified distillate from *n*-hexane: bp 54—56°C (0.6 mmHg); mp 75—77°C; λ_{max}^{EtOH} 208 nm (ε 9250).

Found: C, 71.25; H, 8.80; N, 9.37%. Calcd for $C_9H_{13}NO$: C, 71.49; H, 8.67; N, 9.26%.

*Reaction of Chlorocyanoacetylene with **6**.* The reaction of chlorocyanoacetylene[15] with **6** under similar conditions to those described above gave *2-chloroethynyl-4,4,6-trimethyl-5,6-dihydro-1,3-oxazine* (**8**) (21.6%): bp 67—68°C (0.4 mmHg); n_D^{20} 1.5035; ν_{max}^{film} 2260 and 1638 cm^{-1}; λ_{max}^{EtOH} 222 nm (ε 10000); τ ($CDCl_3$) 5.80 (m, 1H, 6-H), 8.20 (m, 2H, CH_2), 8.68 (d, J=6.1 Hz, 3H, 6-CH_3), 8.78 (s, 6H, 4,4-$(CH_3)_2$); *m/e* 185 (M^+) and 187 (M+2) in 3 : 1 ratio.

Found: C, 58.01; H, 6.84; N, 7.31%. Calcd for $C_9H_{12}NOCl$: C, 58.21; H, 6.51; N, 7.54%.

*Reaction of Cyanoacetylene with 2,5-Dimethyl-2,5-hexanediol (**9**).* To a stirred sulfuric acid (20 ml) was added **9** (3.65 g, 0.025 mol) slowly below 5°C over a 1-hour period,

14) S. Murahashi, T. Takisawa, S. Kuroda, and S. Maikawa, *Nippon Kagaku Zasshi*, **77**, 1689 (1956); *Chem. Abstr.*, **53**, 5163f (1959).

15) E. Kloster-Jensen, *Acta Chem. Scand.*, **18**, 1629 (1964).

followed by addition of cyanoacetylene (1.3 g, 0.025 mol) over a period of 20 min under ice-cooling. After stirring was continued for 1 day at room temperature, the work-up and distillation afforded *2-ethynyl-5,5-dimethyl-3-isopropylidene-1-pyrroline* (**10**) (2.42 g, 60%) as an oil: bp 61—62°C (0.5 mmHg); n_D^{18} 1.5231; ν_{max}^{film} 3300, 3200, 2140, 1655, and 1640 cm^{-1}; λ_{max}^{MeOH} 267 nm (ε 11000), 223 (6900), and 208 (6100).

Found: C, 81.84; H, 9.65; N, 8.51%. Calcd for $C_{11}H_{15}N$: C, 81.93; H, 9.38; N, 8.69%.

Addition of cyanoacetylene to sulfuric acid, followed by that of **9** lowered the yield of **10** to 46%.

Reaction of Chlorocyanoacetylene with ***9***. A similar reaction of chlorocyanoacetylene (2.2 g, 0.025 mol) with **9** (3.65 g, 0.025 mol) afforded crude *2-chloroethynyl-5,5-dimethyl-3-isopropylidene-1-pyrroline* (**11**) (5.0 g, quantitative) as a brownish oil which was characterized by spectral data (see Text) but it decomposed gradually on standing. Distillation under reduced pressure gave *2-(β,β-dichlorovinyl)-5,5-dimethyl-3-isopropylidene-1-pyrroline* (**12**) (7% from **9**) as an oil which solidified on standing. Recrystallization from *n*-hexane gave an analytically pure sample of **12**: bp 72—75°C (0.5 mmHg); mp 53—55°C; λ_{max}^{MeOH} 252 nm (ε 9000), infl. 231 and 223 nm.

Found: C, 57.12; H, 6.47; N, 5.85%. Calcd for $C_{11}H_{15}NCl_2$: C, 56.91; H, 6.51; N, 6.03%.

Reaction of ***7*** *with Diazomethane.* Treatment of **7** (151 mg, 1.00 mmol) with a large excess of ethereal diazomethane at room temperature for 1 day, followed by removal of excess diazomethane and the solvent afforded a solid residue (153 mg) which was recrystallized from *n*-hexane–dichloromethane to give *4,4,6-trimethyl-2-(4-*H*-pyrazolyl)-2,6-dihydro-1,3-oxazine* (***13***) (81 mg, 42%) as colorless crystals: mp 169—172°C; ν_{max}^{KBr} 3160, 1660, 1640, and 1580 cm^{-1}; λ_{max}^{EtOH} 220 (ε 13200); τ ($CDCl_3$) −1.75 (s, 1H, NH), 2.15 (s, 2H, 3′-H and 5′-H in the pyrazole ring), 5.75 (m, 1H, 6-H), 8.05 (m, 2H, CH_2), 8.65 (d, J=6.0 Hz, 3H, 6-CH_3), and 8.72 (s, 6H, 4,4-$(CH_3)_2$); *m/e* 193 (M^+).

Found: C, 62.32; H, 7.85; N, 21.88%. Calcd for $C_{10}H_{15}N_3C$: C, 62.15; H, 7.82; N, 21.75%.

Purification of the mother liquor on a silica gel column eluting with $CHCl_3$–MeOH afforded *4,4,6-trimethyl-2-(3-*1H*-pyrazolyl)-5,6-dihydro-1,3-oxazine* (***14***) (72 mg, 40%) as a semi-solid material: ν_{max}^{film} 3160, 1660, 1640, and 1560 cm^{-1}; λ_{max}^{MeOH} 224 nm (ε 12000); τ ($CDCl_3$) −0.92 (s, 1H, NH), 2.48 and 3.38 (each d, J=1.9 Hz, each 1H, CH=CH), 5.70 (m, 1H, 6-H), 8.05 (m, 2H, CH_2), 8.57 (d, J=6.01 Hz, 3H, 6-CH_3), and 8.67 (s, 6H, 4,4-$(CH_3)_2$); *m/e* 193 (M^+).

Found: C, 62.26; H, 7.63; N, 21.83%. Calcd for $C_{10}H_{15}N_3O$: C, 62.15; H, 7.82; N, 21.75%.

Reaction of ***8*** *with Diazomethane.* Treatment of **8** (186 mg, 1.00 mmol) with excess diazomethane in ether at room temperature for 1 day gave a solid product after removal of the solvent, which on recrystallization from *n*-hexane–dichloromethane afforded *4,4,6-trimethyl-2-[3-(4-chloro-1-methyl)pyrazolyl]-5,6-dihydro-1,3-oxazine* (***15***) (126 mg, 52.1 %) as colorless crystals: mp 78—80°C; ν_{max}^{KBr} 1660 and 1650 cm^{-1}; λ_{max}^{EtOH} 224 nm (ε 10200).

Found: C, 55.10; H, 6.79; N, 17.09%. Calcd for $C_{11}H_{16}N_3OCl$: C, 54.65; H, 6.67; N, 17.38%.

Reaction of 10 *with Diazomethane.* A similar treatment of **10** (161 mg, 1.00 mmol) with excess diazomethane for 1 day afforded *5,5-dimethyl-2-(3-1*H*-pyrazolyl)-3-isopropylidene-1-pyrroline* (***16***) (130 mg, 63.9%) as crystals after recrystallization from ether–*n*-hexane: mp 133—135°C; ν_{max}^{KBr} 3160, 1655, 1585, and 1545 cm^{-1}; λ_{max}^{MeOH} 252 nm (ε 10000); τ ($CDCl_3$) 0.02 (s, 1H, NH), 2.52 and 3.55 (each d, J=1.9 Hz, each 1H, CH=CH), 7.45 (q, J=1.65 Hz, 2H, CH_2), 8.28 (s, 3H, C^bH_3), 8.32 (t, J=1.65 Hz, 3H, C^aH_3), and 8.68 (s, 6H, 5,5-$(CH_3)_2$(; *m/e* 203 (M^+).

Found: C, 70.96; H, 8.38; N, 20.67%. Calcd for $C_{12}H_{17}N_3$: C, 70.90; H, 8.43; N, 20.67%.

Reaction of ***11*** *with Diazomethane.* A similar treatment of crude **11** with excess diazomethane in ether followed by purification on a neutral alumina column eluting with $CHCl_3$–MeOH afforded *5,5-dimethyl-2-[3-(4-chloro-1-methyl)pyrazolyl]-3-isopropylidene-1-pyrroline* (***17***) (16% from **9**) as a semi-solid: ν_{max}^{film} 1650, 1590, and 1540 cm^{-1}; λ_{max}^{MeOH} 250 nm (ε 6800); τ ($CDCl_3$) 2.63 (s, 1H, C=CH), 6.12 (s, 3H, NCH_3), 7.45 (q, J=1.7 Hz, 2H, CH_2), 8.19 (s, 3H, C^bH_3), 8.45 (t, J=1.7 Hz, 3H, C^aH_3), and 8.65 (s, 6H, 5,5-$(CH_3)_2$); *m/e* 252 (M^+) and 254 (M+2) in 3 : 1 ratio.

Found: C, 62.32; H, 6.92; N, 16.68%. Calcd for $C_{13}H_{18}N_3Cl$: C, 62.02; H, 6.92; N, 16.68%.

Substituent Effects on Dissociation Constants of 4- and 6-Styryl-2-aminotropones

Kimiaki IMAFUKU and Hisashi MATSUMURA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto

(Received May 18, 1972)

The dissociation constants of two series of 4- and 6-styryl-2-aminotropones were measured spectrophotometrically in 50% aqueous methanol at 20°C. It was found that Hammett's free energy relationship is applied to the analysis of substituent effects, with $\rho=0.59$ and 0.40, respectively, and that there is a difference between the electronic effects of the two isomers.

The transmission of electronic effects from one aromatic ring to another through the linkage between them has recently aroused considerable interest. For stilbenes which have an ethylene linkage between two benzene rings, the dissociation constants of various 4-aminostilbenes[1] and 4-hydroxystilbenes[2] and the chemical shifts of 4-fluorostilbenes[3] were measured. It was found that the electronic effect of the substituent in one ring is transmitted through the ethylene linkage to the *p*-substituent in another ring and is correlated by the Hammett equation.

One of the authors (H. M.) investigated the reactions of 4-styryltropolone and its derivatives, which have a similar ethylene linkage, with various nucleophilic reagents.[4] In order to examine the reactivities quantitatively, we measured the dissociation constants of some 4-[5] and 5-styryltropolones[6] (Fig. 1). We found that the electronic effects of substituents in the benzene ring are transmitted through the ethylene linkage to tropolone nucleus, though the effects are small as in the case of stilbenes.[1,2]

In 4-styryltropolone, there are two tautomeric forms, *viz.*, 2-hydroxy-4-styryltropone and 2-hydroxy-6-styryltropone. The dissociation constants of 4-styryltropolones are, therefore, a combination of two non-equivalent tautomeric forms evidenced by the different ultraviolet absorption spectra of 4- and 6-styryl-2-hydroxytropones[7] and the substituent effects in these two forms should differ.

In order to determine the difference of substituent effects between the 4- and 6-(substituted styryl)tropones, the dissociation constants of 4- and 6-styryl-2-aminotropones (Fig. 1) were measured spectrophotometrically. It was shown that a difference in the electronic effect between the two forms actually exists.

(B) 4- and 6-Styryl-2-aminotropones.

Results and Discussion

Dissociation Constants. The dissociation constants of two series of 2-aminotropones, *viz.*, 2-amino-4-styryltropones and 2-amino-6-styryltropones with substituent in the benzene ring, were determined spectrophotometrically in 50% aqueous methanol at 20°. The results expressed in terms of pK_a values are summarized in Table 1. Since activity coefficients were not introduced into the calculations, the dissociation constants do not represent thermodynamic terms, giving only a relative measure of base strength.

Table 1. Dissociation constants of 2-amino-4- and 6-styryltropones

No.	R	pK_a	
		4-Styryl	6-Styryl
1	*p*-OCH_3	2.71	2.69
2	*p*-CH_3	2.64	2.65
3	H	2.54	2.57
4	*p*-Cl	2.39	2.51
5	*p*-Br	2.34	2.50
6	*m*-Cl	2.33	2.42
7	*m*-NO_2	2.14	—
8	*p*-NO_2	2.08	—

Numbering of substituents refers to that given in Figs. 2 and 3.

The dissociation constants are comparable to the pK_a value (2.17) of 2-aminotropone.[8] Further, the 4- and 6-styryl-2-aminotropones show the pK_a values between 2.08 [4-(*p*-nitrostyryl)] and 2.71 [4-(*p*-methoxystyryl)], and are less basic than *p*-(substituted styryl)-anilines (*i.e.* 3'- and 4'-substituted 4-aminostilbenes [pK_a 3.43 (*p*-nitro) to 3.86 (*p*-methoxy)]).[1] This is attributed to the electron-withdrawing effect of the carbonyl group adjacent to the amino group in tropone nucleus.

Substituent Effects. When the pK_a values of 2-amino-4-styryltropones are plotted against the Hammett

substituent constants, σ,[9] of the substituent in the benzene ring, the plot gives the line shown in Fig. 2, and the following equation is obtained by the least square method.

$$pK_a = 2.53 - 0.59\sigma \quad (r=0.993)$$

For the 2-amino-6-styryltropones, a similar Hammett plot is given (Fig. 3) and the following equation is obtained.

$$pK_a = 2.58 - 0.40\sigma \quad (r=0.992)$$

Thus, it was found that the electronic effects of the substituents in the benzene ring are transmitted through the ethylene linkage to the amino group in the tropone nucleus and are correlated by the Hammett equation. However, the effects are small and considered to be

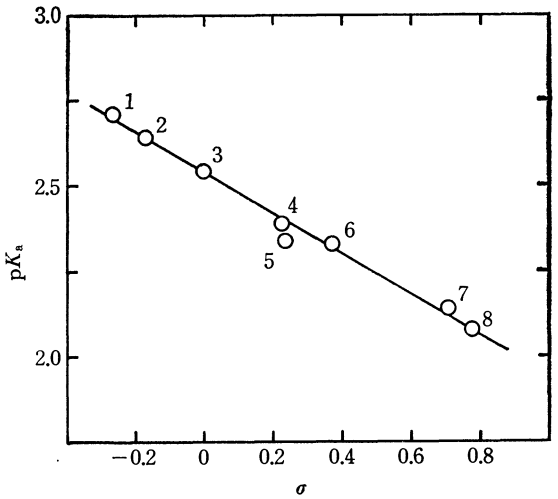

Fig. 2. The Hammett plot of pK_a's of 2-amino-4-styryltropones.

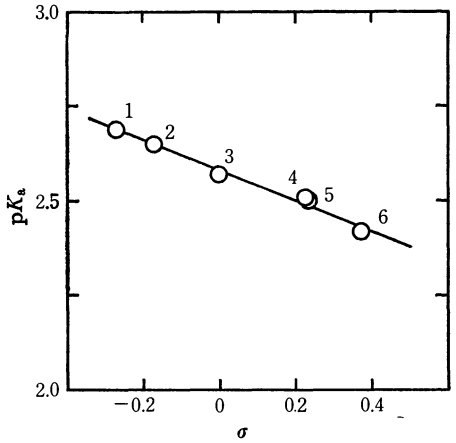

Fig. 3. The Hammett plot of pK_a's of 2-amino-6-styryltropones.

inductive, since the styryl group in these 4- and 6-styryl-2-aminotropones is located at such a position that the resonance interaction between the styryl group and the reaction centre of tropone nucleus is inhibited.

When the 4-styryl and 6-styryl derivatives are compared with each other, the reaction constant (0.59) of 4-styryl isomers is larger than that of 6-styryl isomers (0.40) because of the difference in distance between the styryl group and the amino group. However, both of them are comparable to the ρ value of the dissociation of 4-aminostilbenes (0.42 in 50% aqueous ethanol at 20°).[1]

Experimental

Materials. The 2-amino-4-styryltropones and 2-amino-6-styryltropones were prepared by the method des-

cribed elsewhere.[12]

4-Styryltropones[13] were treated with an excess of diazomethane in chloroform to give two isomers, *viz.*, 2-methoxy-4-styryltropones and 2-methoxy-6-styryltropones. The two isomers were separated by preparative thin layer chromatography.

Each methyl ether was ammonolyzed with ammonia in absolute ethanol in a sealed tube to give the desired 2-amino-4-styryltropones or 2-amino-6-styryltropones. They were purified by recrystallization from ethanol or benzene.

Their melting points and analytical data are listed in Table 2.

Measurements of the Dissociation Constants. The dissociation constants of the 2-amino-4-styryltropones and 2-amino-6-styryltropones were measured spectrophotometrically in 50% aqueous methnol at 20° by the method of Flexer *et al.*[14]

These constants were obtained by using the equation

$$pK_a = pH - \log \frac{\varepsilon_{BH^+} - \varepsilon}{\varepsilon - \varepsilon_B}$$

where ε_B and ε_{BH^+} are the molar extinction coefficients of the base and conjugate acid, respectively. As an example, the spectral change of 2-amino-4-styryltropone upon pH change of medium is shown in Fig. 4.

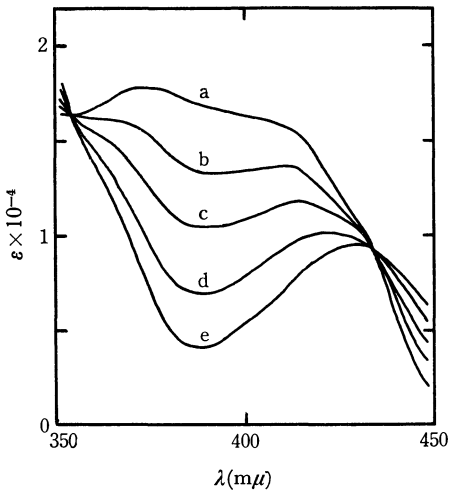

Fig. 4. Electronic Spectra of 2-Amino-4-styryltropone in 50% aqueous methanol.
a: pH 1.03 (conjugate acid), b: pH 2.15, c: pH 2.52, d: pH 3.09, e: pH 6.34 (free base)

The absorption spectra were taken on a Hitachi EPS-3T spectrophotometer, and the pH values were measured by a Hitachi-Horiba F-5 pH meter.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 546—550 (1973)

Solvent Effect on the Free Radical Phenylation with Phenylazotriphenylmethane

Michio KOBAYASHI, Hiroshi MINATO, and Nobuko WATANABE

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo

(Received June 1, 1972)

The effect of solvent on free radical phenylation of arenes was studied by using phenylazotriphenylmethane as the source of phenyl radical. Mixtures of two arenes were phenylated in a solvent (CCl_4, CH_3CN, DMSO, or cyclohexane), and isomer distributions of diaryls produced were determined. The effect of salts ($NaNO_2$, KNO_2, $NaClO_4$) was also studied in DMSO. Both the solvent effect and salt effect suggest the contribution of polar structure in the transition states for the formation of phenylcyclohexadienyl radicals.

Decomposition of phenylazotriphenylmethane (PAT) yields phenyl radical and triphenylmethyl radical.[1] An investigation on the effect of solvents on the rate of the homolysis of PAT showed that the solvent effect is not too great, and an isokinetic relationship holds.[2] The isomer distributions and partial rate factors in phenylations of arenes with PAT were reported in a previous paper.[3]

Although phenylations of arenes have been investigated with various phenyl radical sources (benzoyl peroxide, *N*-nitrosoacetanilide, the Gomberg reaction, *etc.*),[4] their experimental conditions vary considerably and little evidence has been given which warrants the arguments based on the comparison of these data. It has recently been established that free radical phenylation with phenylazo *p*-tolyl sulfone is very little affected by changes in temperature.[5] The effect of solvents on free radical phenylation has not been reported in the literature. Although solvent effects on free radical reactions are believed to be small, a considerable solvent effect was reported on photo-chlorination of

substituted toluenes by Russell and Williamson, Jr.[6]

When isomer distributions and partial rate factors in phenylation of arenes are determined, usually a phenyl-radical generator is dissolved in an equimolar mixture of benzene and an arene, and thermally or photochemically decomposed; the amounts of diaryls produced are determined by use of glc, IR, or the isotope dilution method. In these methods, the reacting substrates themselves are the solvents. Thus, what is really determined is the results of reactions of different substrates in different media (solvents). These methods are based on an assumption that solvent effect is negligible in these free radical reactions. However, no one can say *a priori* that the stability of a substituted cyclohexadienyl radical in nitrobenzene is the same as that in anisole. For accurate comparison, aromatic substrates should be phenylated in a large amount of a common inert solvent.

PAT is an effective phenyl radical generator, and its rate of decomposition is very little affected by solvent. In order to investigate the effect of solvent on the free radical phenylation of arenes, arenes have been phenylated with PAT in a large amount of a solvent (CCl_4, CH_3CN, DMSO, or cyclohexane). The effect of added salts ($NaNO_2$, KNO_2, or $NaClO_4$) has also been investigated in DMSO. Results of these investigations are given in this paper.

Experimental

Materials. Solvents and aromatic substrates were purified according to the methods described in "Organic Solvents."[7]

Analyses of Phenylation Products. *(a) In DMSO*: Nitrogen was bubbled through a mixture of PAT (5 mmol), two arenes (0.125 mol each) and DMSO (0.50 mol) for one hr for removal of oxygen, and then the mixture was heated at 60°C till evolution of nitrogen ceased. After an internal standard for glc determination was added, the mixture was washed with water in order to remove DMSO, and concentrated under reduced pressure. The residual oil was analyzed by glc (10% Apiezon L-Chromosorb column, 2 m or 5 m; a Hitachi K53 Gas Chromatograph).

(b) In CH_3CN: A mixture of PAT (5 mmol), two arenes (0.125 mmol each) and CH_3CN (1.0 mol) was treated in a manner similar to that described above for the experiment with DMSO.

(c) In CCl_4: A mixture of PAT (5 mmol), two arenes (0.125 mol each) and CCl_4 (1.0 mol) was also similarly treated. Because of the occurrence of reactions with CCl_4, yields of diphenyls were less, and much 1,1,1-triphenyl-2,2,2-trichloroethane and some benzophenone were found.

(d) In Cyclohexane: Because of smaller solubility of PAT in this solvent, 5 mmol of PAT was dissolved in 1.25 mol of cyclohexane and 0.125 mol each of two arenes. In this solvent, much cyclohexylation of arenes by cyclohexyl radical took place, and glc determination of diaryls and cyclohexylarenes was possible only in a few cases. Thus, the data in cyclohexane should be evaluated with some reservation.

Calculation of Partial Rate Factors. Partial rate factors for PhCN, PhCl, and PhEt were obtained from the isomer distributions of diaryls produced by the decomposition of PAT in mixtures of benzene, an arene and a solvent. In the experiments with PhOMe and $PhNO_2$, removal of these high-boiling arenes requires high temperature, and some nonsubstituted diphenyl is lost during concentration. The partial rate factors for PhOMe and $PhNO_2$ were therefore calculated from the partial rate factors of chlorobenzene and the isomer distributions of diaryls produced by the decomposition of PAT in mixtures of chlorobenzene, an arene, and a solvent.

Rates of Decomposition of PAT. Rates of decomposition of PAT were determined by measureing the rates of evolution of nitrogen.

Results and Discussion

The rates of decomposition of PAT were found to be of first order. As shown in Table 1, the rate constants vary to some extent in different media, but not too greatly.

Table 1. First order rate constants of decomposition of PAT in various media at 60°C[a]

Phenylation of several arenes was carried out in various media using PAT as the phenyl radical source. Atkinson, Perkins, and Ward recently reported that when PAT was decomposed in chlorobenzene the *ortho*-phenylated cyclohexadienyl radical was trapped by trityl radical, and 2-chloro-1,4-dihydro-4-tritylbiphenyl was formed.[8] In our experiments, the residual oil obtained by concentration of the reaction mixture was fed directly to the injection port of the gas chromatograph, and any coupling products formed must have been thermolyzed to diaryl and triphenylmethane; therefore the normal diaryl distribution was observed.

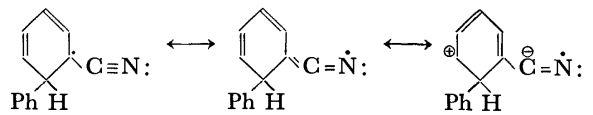
a) The value 1.32 should replace the value 2.6 given in our previous paper by mistake.[3] The correct ρ value for the left half of the V-shaped line for phenylation in aromatic solvents is, therefore, −0.460 instead of −1.51.

8) D. J. Atkinson, M. J. Perkins, and P. Ward, *J. Chem. Soc. C*, **1971**, 3240.

Isomer distributions and partial rate factors are shown in Tables 1 and 3. It is clear that variations in isomer distribution and partial rate factors are greater than experimental error. The variations in isomer distributions in particular are fairly great. In general, when the amount of an *o*-isomer increases, the amount of the corresponding *p*-isomer decreases.

When the logarithms of *meta* and *para* partial rate factors are plotted against σ values, *meta* partial rate factors do not vary much with σ values, whereas the plots for *para* partial rate factors usually form V-shaped lines. The ρ value in the right half region is +1.06 in acetonitrile and +0.93 in DMSO; these values differ from the corresponding value for benzoyl peroxide in aromatic solvents (+1.15), that for *N*-nitrosoacetanilide in aromatic solvents (+1.27), and that for phenylazo *p*-tolyl sulfone in aromatic solvents (1.38). The data indicate that the reactivities of arenes with phenyl radical depend on the type of phenyl radical source and also of the solvents used.

The partial rate factors for anisole and benzonitrile are greater in the solvents of greater polarity. This can be rationalized in terms of the stabilization of the transition states by solvation with polar solvents; there must be contribution of a polar structure to the transition states for formation of cyclohexadienyl radicals (a substituted cyclohexadienyl radical form is shown below for the sake of convenience).



When anisole is used as a substrate, the partial rate factors in anisole alone are greater than those in CCl_4 or cyclohexane. This can be ascribed to the fact that anisole itself is a polar solvent.

With ethylbenzene the partial rate factors in polar solvents are smaller than those in CCl_4. This is probably because the contribution of polar structure to transition state is very little when an ethyl group is a substituent.

Since the partial rate factors are the ratios of the reactivities of arenes with that of benzene (or chlorobenzene), the solvent effects observed on partial rate factors should be understood as the difference between the solvent effects on the reactivities of arenes and those on benzene (or chlorobenzene). The solvent effects on the partial rate factor for the *ortho* position of chlorobenzene are very small as shown in Table 3, and we can assume that the solvent effects on partial rate factors represent the solvent effects on the reactivities of arenes. In fact, when phenylation of an equimolar mixture of anisole and benzene was compared with that of an equimolar mixture of anisole and chlorobenzene, the results were the same within experimental error.

The solvent effects on the partial rate factors of nitrobenzene are fairly large, but it is difficult to give an adequate explanation. It might have something to do with the fact that nitrobenzene itself is a polar solvent.

Effect of Temperature on Partial Rate Factors and Isomer

Distribuitons. The partial rate factors in phenylation of arenes with phenylazo *p*-tolyl sulfone change very little with temperature.[5)] Table 4 compares the isomer distributions and the partial rate factors in phenylation with PAT at 60 and 80°C. It is clear that they change very little with temperature in this case too. Since partial rate factors are always smaller at higher temperatures, the activation energy for phenylation of benzene must be a little greater than those for phenylation of substituted benzenes.

Effect of Salts on Partial Rate Factors and Isomer Distributions. If the solvent effect is due to the contribution of polar structures to transition state, addition of salts to the medium is expected to result in change

in partial rate factors and isomer distributions. Arenes were phenylated in the media containing sodium perchlorate and sodium nitrite. The results are summarized in Tables 5 and 6. The effect of added salts is fairly great in chlorobenzene and nitrobenzene; in both cases the amount of the *ortho* isomer decreases and that of the *para* isomer increases upon addition of salt. In the case of nitrobenzene, the presence of $NaClO_4$ and $NaNO_2$ in about the same concentration results in different isomer distributions. Thus, not only the ionic strength but also the kind of anion probably influence the stabilization of transition state. Since DMSO solvates cations strongly but solvates anions very little, the anions added are more free than the counter cations, thus directly contributing to the stabilization of transition state.

Decrease in the amount of *ortho* isomers and increase in that of *para* isomers could arise either from the decrease of *ortho* partial rate factors or from the increase of *para* partial rate factors. Table 6 shows that, in general, partial rate factors increase upon addition of salts and the increase of *para* partial rate factors are especially great. Only one exception is the case of nitrobenzene, in which the *ortho* partial rate factor decreased upon addition of salts. Thus both the solvent effect and the salt effect are irregular in the case of nitrobenzene.

Although more detailed investigations are required for understanding the salt effect in phenylation, the fact that all the partial rate factors (except for that of the *ortho* position of nitrobenzene) increase upon addition of salts suggests that the contribution of polar structure in the transition state is greater for the addition of phenyl radical to substituted benzenes than that of phenyl radical to benzene itself; increase in ionic strength should stabilize the transition state for the addition of phenyl radical to substituted benzenes.

In conclusion, both the solvent effect and salt effect suggest the contribution of polar structure in the transition state for the addition of phenyl radical to arenes.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 550—553 (1973)

Synthetic Studies by the Use of Carbonates. II.[1] An Easy Method of Preparing Cyclic Carbonates of Polyhydroxy Compounds by Transesterification with Ethylene Carbonate

Hajime KOMURA, Teruo YOSHINO, and Yoshiharu ISHIDO

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo

(Received June 14, 1972)

Transesterification reactions of polyhydroxy compounds, such as 1-*O*-*p*-nitrobenzoyl-, 1-*O*-benzylglycerols, 1,2;3,4-di-*O*-, 3,4-*O*-isopropylidene-D-mannitols, 1,2-*O*-isopropylidene-α-D-glucofuranose, uridine, 1,2;5,6-di-*O*-isopropylidene-D-mannitol, and D-mannitol, by ethylene carbonate were attempted; the corresponding products were obtained in good yields except in the case of uridine, which gave 2,2′-anhydro-1-β-D-arabinofuranosyluracil.

Since the synthesis of α-D-glucofuranose 1,2;5,6-dicarbonate from D-glucose and phosgene, although in a considerably low yield, was reported,[2] a number of sugar carbonates have been prepared for the purpose of investigating the partial blocking of hydroxy groups of carbohydrates by the use of phosgene, alkyl or aryl chloroformates, diphenyl carbonate under basic conditions, by the use of carbonyl diimidazole, or by changing the *O*-methylene group into carbonate through oxidation with permanganate.[3] In contrast with such blocking groups as alkylidene and arylidene groups, the carbonate group can easily be removed under basic conditions, and it has been widely used in the field of carbohydrate chemistry with due regard to its properties.

Results and Discussion

In view of the glycidol[4] and glycerol 1,2-carbonate[5] syntheses involving the reaction of ethylene carbonate (**1**) with glycerol, the present authors investigated the preparation of cyclic carbonates of polyhydroxy compounds, taking the stability and wieldiness of **1** into consideration. The starting materials were selected on the basis of the following categories: i) 1-*O*-*p*-nitrobenzoyl-(**2**), 1-*O*-benzylglycerols(**3**), 1,2;3,4-di-*O*-(**4**), 3,4-*O*-isopropylidene-D-mannitols(**5**), and 1,2-*O*-isopro-

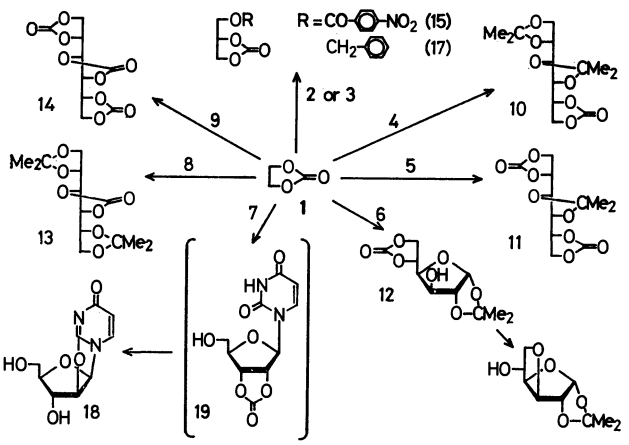
Table 1. Preparations of carbonates by transesterification reaction with ethylene carbonate (**1**)

Starting Material	Reaction Conditions		Product	
			Yield	IR Absorption[a]
1-*O*-*p*-Nitrobenzoylglycerol (**2**)	130—140°C/20—30 mmHg	2 hr	30%[b]	1785 cm^{-1}
1-*O*-Benzylglycerol (**3**)	150/15	1[c]	80	1790
1,2;3,4-Di-*O*-isopropylidene-D-mannitol (**4**)	160/40	1	90	1790
3,4-*O*-Isopropylidene-D-mannitol (**5**)	150—160/30	1	65	1785, 1800
1,2-*O*-Isopropylidene-α-D-glucofuranose (**6**)	140—145/40	1	71	1785, 1800
Uridine (**7**)	140—145/15	1.5	71[d]	—
1,2;5,6-Di-*O*-isopropylidene-D-mannitol (**8**)	160/40	1	76	1785
D-Mannitol (**9**)	150/20	6	65	1790, 1820

a) The absorption bands stand for those of five-membered cyclic carbonate. b) In this reaction, ethylene glycol di-*O*-*p*-nitrobenzoate(**16**) was obtained in 16% yield as a by-product. c) A catalytic amount of sodium bicarbonate was applied in this case. d) This product was identified with 2,2′-anhydro-1-β-D-arabinofuranosyluracil(**18**).

pylidene-α-D-glucofuranose(**6**) as involving vicinal primary and secondary hydroxyl groups, and ii) uridine (**7**) and 1,2;5,6-di-*O*-isopropylidene-D-mannitol(**8**) as involving vicinal secondary hydroxyl groups. iii) D-Mannitol was, in addition, used because it involved both types of vicinal hydroxyl groups. These compounds were heated with 3—4 mol of **1** under reduced pressure to remove the ethylene glycol co-produced in the course of the reactions. Moreover, the reactions were carried out in a Pyrex-glass flask to avoid the decomposition of the carbonate once formed, in view of the results reported by Reist *et al.*,[6] and by Hall and Hough.[7] The results are demonstrated in Table 1. In the cases of **4**, **5**, **6**, **8**, and **9**, the corresponding cyclic carbonates, *i.e.*, 1,2;3,4-di-*O*-isopropylidene-D-mannitol 5,6-carbonate(**10**), 3,4-*O*-isopropylidene-D-mannitol 1,2;5,6-dicarbonate(**11**), 1,2-*O*-isopropylidene-α-D-glucofuranose 5,6-carbonate(**12**),[8] 1,2;5,6-di-*O*-isopropylidene-D-mannitol 3,4-carbonate(**13**), and D-mannitol 1,2;3,4;5,6-tricarbonate(**14**), were obtained in 90, 65, 71, 76, and 65% yields respectively. On the other hand, different results were obtained in the cases of **2**, **3**, and **7**. The reaction with **2** gave a mixture of the corresponding 1,2-carbonate(**15**) and di-*p*-nitrobenzoate of ethylene glycol(**16**) in 30 and 16% yields respectively. These results may be explained in terms of the susceptibility of the carbonyl carbon of the *p*-nitrobenzoyl group to the nucleophilic attack of the hydroxyl group of ethylene glycol. Since the reaction with **3** was confirmed by means of tlc to leave a small amount of **3** in the reaction mixture, even after 2 hr, the reaction was carried out in the presence of sodium bicarbonate as a catalyst to afford 1-*O*-benzylglycerol



Scheme II.

2,3-carbonate(**17**) in an 80% yield. Moreover, contrary to expectations, **7** afforded 2,2′-anhydro-1-β-D-arabinofuranosyluracil(**18**) selectively. **18** was considered to be produced *via* the 2′,3′-carbonate of **7** (**19**); *i.e.*, the 2′-carbon of **19** was subjected to the intramolecular nucleophilic substitution reaction by the carbonyl group of the 2-position to produce **18**; this result may be ascribed to the nucleophilicity of the carbonyl group being larger than that of the hydroxyl group of ethylene glycol. The structures of the products obtained here were confirmed by elemental analyses, and by a study of the IR, NMR, and UV spectra.

On the basis of these results, it can be concluded that **1** can also be used in the preparation of the five-membered cyclic carbonate of polyhydroxy compounds.

Experimental

All the melting points are uncorrected. The IR spectra were taken with a Hitachi EPI-2S apparatus. The UV spectrum was measured on a Hitachi EPS-3T in distilled water. The NMR spectra were taken with a Varian XL-100 apparatus.

1-O-p-Nitrobenzoylglycerol (2). According to the method of Hennis,[9] glycerol α-monochlorohydrin (11 g,

8) W. N. Haworth and C. R. Porter, *ibid.*, **1929**, 2796 [Mp 223—224°C (dec.), $[\alpha]_{5780}^{20}$ −36°]; A preparation of this compound by the same procedure was recently reported in a paper (P. A. Gent, R. Gigg, and R. Conant, *J. Chem. Soc. Perkin Trans. I.*, **1972**, 248) as a part of an investigation on phenyloxazoline derivative of amino-sugars.

9) H. E. Hennis, J. P. Easterly, Jr., L. R. Collins, and L. R. Thompson, *Ind. Eng. Chem.*, **6**, 193 (1967); H. E. Hennis, L. R. Thompson, and J. P. Long, *ibid.*, **7**, 96 (1968).

100 mmol) and sodium *p*-nitrobenzoate (19 g, 100 mmol) were suspended in dimethylformamide (150 ml), together with tetraethylammonium iodide (TEAI) (13 g, 50 mmol); the mixture was then heated at 130—140°C for 2 hr with stirring. After cooling, acetone (100 ml) was added to the resultant mixture, and the solvents were evaporated *in vacuo* to give a sirup after the filtration of the unchanged TEAI. After the sirup had been dissolved in hot ethyl acetate (50 ml) and left to stand overnight in a refrigerator, pale yellow crystals of **2** (12.7 g, 52.7%) were obtained. Mp 107—107.5°C. IR(KBr): 1720 cm^{-1} (ester C=O). Found: C, 49.31; H, 4.72; N, 5.72%. Calcd for $C_{10}H_{11}O_6N$: C, 49.79; H, 4.60; N, 5.81%.

3-O-p-Nitrobenzoylglycerol 1,2-Carbonate (15). *1-O-p-*Nitrobenzoylglycerol (**2**) (7.2 g, 30 mmol) was heated, together with ethylene carbonate (**1**) (9.0 g, 105 mmol), at 130—140°C/20—30 mmHg for 2 hr, and finally again at 140°C/10 mmHg, until the distillation of **1** stopped. The residue was chromatographed on a column (diameter: 5 cm) of silica gel (100 g), with chloroform–ethyl acetate (99:1) used for the elution, after which the effluent was fractionated into a volume of 10 ml. The concentration of Fractions No. 41—75 *in vacuo*, followed by recrystallization from ethyl acetate, gave ethylene glycol di-*p*-nitrobenzoate (**16**) (1.7 g, 16%). Mp 142—143.5°C. Found: C, 53.08; H, 3.08; N, 7.89%. Calcd for $C_{16}H_{12}O_8N_2$: C, 53.34; H, 3.36; N, 7.78%. The concentration of Fractions No. 88—214 *in vacuo*, followed by recrystallization from ethyl acetate, gave **15** (2.4 g, 30%). Mp 149.5—150°C. Found: C, 49.30; H, 3.16; N, 5.31%. Calcd for $C_{11}H_9O_7N$: C, 49.44; H, 3.40; N, 5.24%. IR(KBr): 1785 (five-membered cyclic carbonate), 1720 (ester C=O), 1270, 1170 (ester C–O–C), 1520, and 1345 (NO_2) cm^{-1}.

1-O-Benzylglycerol 2,3-Carbonate (17). The transesterification reaction was carried out by the same procedure as above, using 1-*O*-benzylglycerol (**3**) (5.4 g, 30 mmol) and **1** (9.0 g, 105 mmol) together with a catalytic amount of sodium bicarbonate (0.1 g), at 150°C/15 mmHg for 1 hr. After the filtration of the precipitated crystals and the washing of the crystals with ethyl acetate (5 ml), the filtrate and washings were combined; the mixture was then concentrated *in vacuo* to give a heavy liquid. The residue was distilled to give **17** (5.6 g, 80%) boiling at 146—147°C/0.17 mmHg (Found: C, 63.53; H, 5.53%).[10] IR(NaCl): 1790 cm^{-1} (five-membered cyclic carbonate). Without sodium bicarbonate, it was necessary to prolong the reaction to 2.5 hr in order to afford an almost equal yield of the product.

1,2-O-Isopropylidene-α-D-glucofuranose 5,6-Carbonate (12). 1,2-*O*-Isopropylidene-α-D-glucofuranose (**6**)[11] (22 g, 100-mmol) and **1** (30 g, 350 mmol) were fused at 140—145°C/40 mmHg for 1 hr, and the **1** was finally removed by reducing the pressure to 17 mmHg. The residual crystals were recrystallized from ethanol to give **12** (17 g, 71%).[6,7,8] Mp 219—220°C (dec.); 223—224°C (measured in a capillary tube of Hario-glass: decomposed after fusion without coloration). $[\alpha]_D^{22}$ −29° (*c* 1.0, Me_2CO). IR(KBr): 1785 and 1800 cm^{-1} (five-membered cyclic carbonate). NMR (acetone-d_6, TMS): δ 5.94 (H-1, d, $J_{1,2}$=3.3 Hz), 4.50 (H-2, d, $J_{2,3}$=0 Hz), 4.29 (H-3, q, $J_{3,4}$=3.5 Hz), 4.46 (H-4, sex., $J_{4,5}$=3.2 Hz), 5.05 (H-5, octet, $J_{5,6}$=8.7 Hz and $J_{5,6'}$=6.4 Hz), 4.46 (H-6, t, $J_{6,6'}$=8.7 Hz), 4.53 (H-6', q), 4.71 (HO-3, q, $J_{3,OH}$=4.5 Hz and $J_{4,OH}$=1.0 Hz), 1.25 and 1.40 (Me, two s, unassignable). On the use of a usual commercial flask in the above reaction, 3,6-anhydro-1,2-*O*-isopropylidene-α-D-glucofuranose was obtained in an 80% yield by treating the resultant reaction mixture with distilled water (300 ml), by the subsequent extraction of the aqueous solution with ether (200 ml ×4), followed by washing with water (200 ml), by the evaporation of the solvent *in vacuo* to a semicrystalline sirup after drying with anhydrous sodium sulfate, and by the recrystallization of the residue from light petroleum ether. Mp 44—46°C.[6,7,12,13]

2,2'-Anhydro-1-β-D-arabinofuranosyluracil (18). A transesterification reaction was similarly carried out in this case by treating uridine (**7**) (2.5 g, 10 mmol) and **1** (3.0 g, 35 mmol) at 140—145°C/15 mmHg for 1.5 hr. After about 1 hr, the crystallization of the product occurred; the crystals were, after cooling, treated with methanol (5 ml). They were filtered and recrystallized from 25% aqueous methanol to give **18** (1.6 g, 71%). Mp 238—244°C (dec.). $[\alpha]_D^{22}$ −22.2° (*c* 1.0, H_2O). $\lambda_{max}^{H_2O}$ 224 (ε 7860) and 251 nm (ε 7600). $\lambda_{min}^{H_2O}$ 236 nm (ε 5940). A slight shoulder was observed at about 270 nm.[14]

1,2;3,4-Di-O-isopropylidene-D-mannitol 5,6-Carbonate (10). The transesterification was carried out by treating 1,2;3,4-di-*O*-isopropylidne-D-mannitol (**4**)[15] (1.3 g, 5 mmol) and **1** (1.5 g, 17.5 mmol) at 160°C/40 mmHg for 1 hr; the residual crystals were then recrystallized from ethanol to give colorless crystals of **10** (1.3 g, 90%). Mp 111—112°C. $[\alpha]_D^{22}$ −50° (*c* 0.97, Me_2CO). IR (KBr): 1790 cm^{-1} (five-membered cyclic carbonate). Found: C, 54.08; H, 6.88%. Calcd for $C_{13}H_{20}O_7$: C, 54.16; H, 6.99%. Without recrystallization, the product was already analytically pure enough.

3,4-O-Isopropylidene-D-mannitol 1,2;5,6-Dicarbonate (11). 3,4-*O*-Isopropylidene-D-mannitol (**5**)[15] (1.1 g, 5 mmol) and **1** (1.5 g, 17.5 mmol) were heated together at 150—160°C/30 mmHg for 1 hr, and the residue was, after cooling, dissolved in ethanol (*ca.* 10 ml). After the solution had then been allowed to stand at room temperature, colorless needles of **11** (0.9 g, 65%) were obtained. This product was analytically pure enough without recrystallization (Found: C, 48.15; H, 5.19%). Mp 205—207°C. $[\alpha]_D^{22}$ −16.3° (*c* 1.0, Me_2CO).[16]

1,2;5,6-Di-O-isopropylidene-D-mannitol 3,4-Carbonate (13). 1,2;5,6-Di-*O*-isopropylidene-D-mannitol (**8**)[17] (1.3 g, 5 mmol) and **1** (1.5 g, 17.5 mmol) were heated at 160°C/40 mmHg for 1 hr. The raw crystals, obtained in the same manner as above, were recrystallized from ethanol to give colorless crystals of **13** (1.1 g, 76%). Mp 144—145°C.[18] $[\alpha]_D^{22}$ −111° (*c* 0.97, Me_2CO). IR (KBr): 1785 cm^{-1} with a shoulder at

Synthetic Studies by the Use of Carbonates. III.[1] The Condensation Reactions of Ethylene Carbonate with a Variety of Phenols Catalyzed by Lithium Hydride or Tetraethylammonium Halides

Teruo Yoshino, Shigeru Inaba, and Yoshiharu Ishido

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo

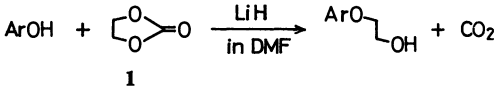
(Received June 14, 1972)

The condensation reactions of ethylene carbonate with a variety of phenols in the presence of tetraethylammonium halides were examined; they were found to give the corresponding aryl β-hydroxyethyl ethers in good yields. The reactions in the presence of lithium hydride in place of the tetraethylammonium halides were also examined for the sake of comparison, and these results were discussed.

The first paper of this series[2] described the condensation reactions of ethylene carbonate(**1**) with hydrohalides of various amines, which resulted in the formation of β-hydroxyethylated ammonium salts in good yields. Although the condensation reaction of **1** with phenols in the presence of potassium carbonate or sodium hydride had previously been reported,[3] the present authors investigated the reaction in the presence of lithium hydride or tetraethylammonium halides in place of the above inorganic salt or hydride because of their greater wieldiness; we also investigated the possibility that the reaction might be carried out under completely neutral conditions by the use of the ammonium halides.

Results and Discussion

Reactions Catalyzed by Lithium Hydride. Phenols were subjected to a condensation reaction with an equimolar amount of **1** in the presence of the corresponding phenoxide ion, which had been generated by treating the phenols with a catalytic amount of lithium hydride, as is shown in Scheme 1; the results are shown in Table 1. Phenol, *p*-nitrophenol, salicylanilide, and



1

Scheme I.

Table 1. Reactions of ethylene carbonate (**1**) with some phenols catalyzed by lithium hydride[a]

Phenols	Reaction conditions		Products	
	Temp, °C	Period, hr	Mp (Bp), °C	Yield, %
Phenol	145—150	7	(89—92/0.4 mmHg)	88.5
p-Nitrophenol	150	6	83—85	90
2,4-Dinitrophenol	150—160	3	—	—[b]
Salicylanilide	145	2.5	109—112	86
β-Naphthol	145	2	72—74	74

a) All the reactions were carried out by the use of 10 mmol of **1** and 11 mmol of phenols in dimethylformamide (5 ml) and a catalytic amount of lithium hydride was applied as catalyst.
b) This phenol was quantitatively recovered.

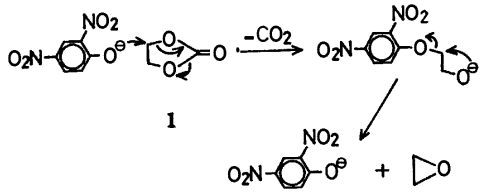
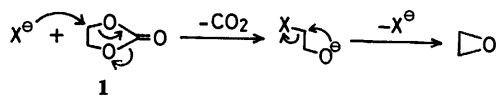
β-naphthol gave the corresponding aryl β-hydroxyethyl ethers in 88.5, 90, 86, and 74% yields respectively. However, 2,4-dinitrophenol gave none of the expected ether and was recovered quantitatively in spite of the almost quantitative evolution of carbon dioxide gas. Even the use of an equimolar amount of sodium hydride resulted in a quantitative recovery of 2,4-dinitrophenol. The difference observed between the case of the phenol and those of the other phenols can be explained by supposing that the β-2,4-dinitrophenoxyethoxide ion formed in the course of the reaction might be subject to a subsequent intramolecular substitution reaction to give ethylene oxide and the 2,4-dinitrophenoxide ion because of the lowered electron density on the β-methylene carbon arising from the strong electron-withdrawing effect of the 2,4-dinitrophenyl group (Scheme II).



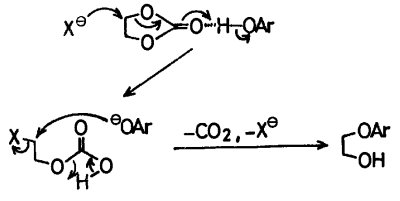
Scheme II.

Reactions Catalyzed by Tetraethylammonium Halides. The decomposition reaction of **1** in the presence of metal halides[4] or tetraalkylammonium halides[5] has been shown to give ethylene oxide *via* the β-haloethoxide ion, accompanied by the evolution of carbon dioxide gas. In view of the reaction mechanism (Scheme III),



Scheme III.

the addition of phenols to the reaction system was assumed to bring about the formation of the corresponding aryl β-hydroxyethyl ethers, as is depicted in Scheme IV; *i.e.*, the resultant β-haloethoxide ion may



Scheme IV

abstract a proton from the phenols to afford ethylene halohydrin and the phenoxide ion, and the halohydrin may then be subject to the nucleophilic attack by the anion to afford the corresponding aryl β-hydroxyethyl ethers. On the basis of this assumption, a variety of phenols were heated with **1** at 140°C in the presence of tetraethylammonium halides as the catalyst until the evolution of carbon dioxide gas ceased. The series of phenols shown in Table 2 gave the corresponding aryl β-hydroxyethyl ethers in high yields. In contrast with the above case, in which lithium hydride was used as the catalyst, 2,4-dinitrophenol gave the corresponding ether in a 73% yield.

The reaction may be explained as proceeding *via* a concerted mechanism (Scheme IV)[6] in view of the facts that the reaction of **1** with tetraethylammonium halides giving ethylene oxide requires a reaction temperature above 160°C at least,[2] that no reaction of **1** with phenols takes place even at 180°C, and that the reactions described here can easily take place even at 130—140°C, *i.e.*, the reaction may be induced by the nucleophilic attack of the halide ion as well as by the electron-withdrawing effect of the carbonyl group of **1** enhanced by the hydrogen bonding with phenols. The reaction is apparently different from that catalyzed by lithium hydride, since no basic species are involved in the final reaction mixture.

The procedure is, furthermore, characterized by the following points: 1) Aryl β-hydroxyethyl ethers are obtainable in high yields under completely neutral conditions. 2) The end-point of the reaction can be noticed by measuring the volume of carbon dioxide

Table 2. Reactions of ethylene carbonate (**1**) with a variety of phenols catalyzed by tetraethylammonium halides[a]

Phenols	Reaction conditions		Products	
	Temp, °C	Period, hr	Mp (Bp), °C	Yield, %
Phenol[b]	140	4.0	(116/12.5 mmHg)	95
p-Nitrophenol[b]	150	4.0	83—85	91

gas evolved. 3) The easy separation of the catalysts from the resultant reaction mixture is possible by distributing them between the organic solvent and water, and the catalysts can be recovered in almost quantitative yields by the concentration of the aqueous layer.

Experimental

All the melting points are uncorrected. The IR spectra were taken with a Hitachi EPI-2S apparatus, while the NMR spectra were measured with a Varian T-60 spectrometer, using tetramethylsilane (TMS) or sodium 2,2-dimethylsilapentanesulfonate (DSS) as the internal standard.

Preparation of Aryl β-Hydroxyethyl Ethers by the Use of Lithium Hydride as a Catalyst. *β-Hydroxyethyl Phenyl Ether*: A solution of phenol (2.8 g, 30 mmol) in dimethylformamide (DMF, 5 ml) was treated with lithium hydride (10 mg) at 100°C until no evolution of hydrogen gas was noticed. Ethylene carbonate (**1**) (2.8 g, 33 mmol) was then added to the solution, and the mixture was heated at 145—155°C until the evolution of carbon dioxide gas ceased (about 7 hr). The DMF was then evaporated *in vacuo*, the resultant sirup was extracted with chloroform (100 ml), and the extract was washed with water (30 ml×2). The organic layer was concentrated and distilled. Yield, 2.4 g; 89%. Bp 89—92°C/0.04 mmHg (lit.[3] 118°C/10 mmHg). IR (NaCl): 3355, 1080 (OH), and 1246 (Ph–O–C) cm^{-1}. NMR ($CDCl_3$, TMS): δ 3.97 (m, –C**H**$_2$–).

β-Hydroxyethyl p-*Nitrophenyl Ether*: The reaction of *p*-nitrophenol (7.0 g, 50 mmol) with **1** (4.4 g, 50 mmol) catalyzed by lithium hydride (10 mg) in DMF (5 ml) was carried out at 150°C for 6 hr; raw crystals similarly obtained were recrystallized from ethanol to give the product. Yield, 6.4 g; 90%. Mp 83—85°C. IR (KBr): 3230, 1076 (OH), 1273 (Ar–O–C), 1508, and 1344 (NO_2) cm^{-1}. NMR ($CDCl_3$, TMS): δ 4.00 (2H, A_2B_2 type J=4 Hz, –C**H**$_2$OH) and 4.20 (2H, Ar–O–C**H**$_2$–).

Found: C, 52.39; H, 5.01; N, 7.70%. Calcd for $C_8H_9O_4N$: C, 52.40; H, 4.95; N, 7.65%.

β-Hydroxyethyl o-*Phenylcarbamoylphenoxy Ether*: The reaction of salicylanilide (2.1 g, 10 mmol) with **1** (1.0 g, 11 mmol) in DMF (10 ml) catalyzed by lithium hydride (5 mg) was carried out at 145°C for 2.5 hr. Yield, 2.2 g; 86%. Mp 109—112°C (from methanol). IR (KBr): 3310, 1075 (OH), 1240 (Ar–O–C), and 1642 (–CO–NH–) cm^{-1}. NMR (DMSO-d_6, DSS): δ 4.20 (2H, A_2B_2 type J=5 Hz, –C**H**$_2$–OH) and 4.60 (2H, Ar–O–C**H**$_2$).

Found: C, 70.24; H, 5.70; N, 5.36%. Calcd for $C_{15}H_{15}O_3N$: C, 70.02; H, 5.88; N, 5.44%.

β-Hydroxyethyl β-Naphthyl Ether: The reaction of β-naphthol (2.9 g, 20 mmol) with **1** (2.0 g, 22 mmol) in DMF (5 ml) catalyzed by lithium hydride (5 mg) was carried out at 145°C for 2 hr. Mp 72—74°C {from benzene–petroleum ether (1: 1); lit.[3] 76.7°C}. IR (KBr): 3325, 1085 (OH), and 1253 (Ar–O–C) cm^{-1}. NMR ($CDCl_3$, TMS): δ 4.02 (2H, A_2B_2 type J=4 Hz, –C**H**$_2$OH) and 4.20 (2H, Ar–O–C**H**$_2$–).

Reaction of 1 with 2,4-Dinitrophenol. a) The reaction of **1** (2.7 g, 30 mmol) with 2,4-dinitrophenol (5.4 g, 30 mmol) was carried out at 150°C by the use of lithium hydride (10 mg). The evolution of gases ceased after about 3 hr. The resultant mixture was dissolved in chloroform (100 ml), and the extract was successively washed with 1M aqueous hydrochloric acid (40 ml) and water (40 ml×2). The concentration of the organic layer *in vacuo* after drying with anhydrous calcium chloride recovered 2,4-dinitrophenol (5.0 g, 93%). b) When sodium hydride (50% in oil) (0.5 g, 10 mmol) was used in place of lithium hydride in the above reaction, 2,4-dinitrophenol (5.1 g, 94%) was recovered. c) When sodium hydride (50% in oil) (1.4 g, 30 mmol) was used in the above reaction, the phenol (5.0 g, 93%) was also recovered.

Preparation of Aryl β-Hydroxyethyl Ethers Catalyzed by Tetraethylammonium Halides. *β-Hydroxyethyl Phenyl Ether*: A mixture of phenol (1.88 g, 22 mmol), **1** (1.94 g, 22 mmol), and tetraethylammonium iodide (1.0 g, 0.36 mmol) was heated at 145°C. The evolution of carbon dioxide gas ceased after about 4 hr. The resultant mixture was dissolved in chloroform (100 ml) and then washed with water (20 ml). The concentration of the organic layer after drying with anhydrous calcium chloride and subsequent distillation gave the product (2.62 g, 95%). Bp 116°C/12.5 mmHg.

β-Hydroxyethyl p-*Nitrophenyl Ether*: A mixture of *p*-nitrophenol (2.8 g, 20 mmol), **1** (2.0 g, 22 mmol), and tetraethylammonium iodide (1.0 g, 0.36 mmol) was heated at 150°C for 4 hr. The resultant mixture was dissolved in benzene (50 ml), and then the precipitated tetraethylammonium iodide was removed by filtration. The filtrate was evaporated *in vacuo* to dryness to give crude, pale yellow crystals, which were subsequently recrystallized from ethanol. Yield, 3.26 g; 91%. Mp 83—85°C.

β-Hydroxyethyl o-*Nitrophenyl Ether*: A mixture of *o*-nitrophenol (2.8 g, 20 mmol), **1** (1.94 g, 22 mmol), and tetraethylammonium iodide (1.0 g, 0.36 mmol) was heated at 130°C for 1 hr; the resultant mixture was treated in the same way as above and then distilled. Yield, 2.85 g; 78%. Bp 170—180°C/10—15 mmHg. IR (KBr): 3425, 1090 (OH), 1250 (Ar–O–C), 1522, and 1360 (NO_2) cm^{-1}. NMR ($CDCl_3$, TMS): δ 3.97 (2H, A_2B_2 type J=5 Hz, –C**H**$_2$OH) and 4.25 (2H, Ar–O–C**H**$_2$–).

Found: C, 52.50; H, 5.01; N, 7.56%. Calcd for $C_{15}H_{15}O_3N$: C, 52.46; H, 4.95; N, 7.65%.

β-Hydroxyethyl m-*Nitrophenyl Ether*: The reaction of *m*-nitrophenol (1.40 g, 10 mmol) with **1** (0.88 g, 10 mmol) was carried out in the presence of tetraethylammonium bromide (2.1 g, 10 mmol) in DMF (5 ml) at 170°C for 30 min. Raw crystals obtained in the same manner as above were recrystallized from methanol. Yield, 1.70 g; 93%. IR (KBr): 3250, 1050 (OH), 1240 (Ar–O–C), 1520, and 1345 (NO_2) cm^{-1}. NMR ($CDCl_3$, TMS): δ 4.03 (2H, A_2B_2 type J=4 Hz, –C**H**$_2$OH) and 4.71 (2H, Ar–O–C**H**$_2$–).

Found: C, 52.22; H, 5.16; N, 7.56%. Calcd for $C_{15}H_{15}O_3N$: C, 52.46; H, 4.95; N, 7.65%.

β-Hydroxyethyl 2,4-Dinitrophenyl Ether: A mixture of 2,4-dinitrophenol (2.68 g, 20 mmol), **1** (1.94 g, 22 mmol), and tetraethylammonium iodide (1.78 g, 5 mmol) was heated at 140°C for 2.25 hr; the resultant mixture was treated in the same way as above to give raw crystals, which were then recrystallized from ethanol. Yield, 3.30 g; 73%. Mp 110.5—111°C. IR (KBr): 3200, 1070 (OH), 1280 (Ar–O–C), 1520, and 1350 (NO_2) cm^{-1}. NMR ($CDCl_3$, TMS): δ 3.85 (2H, A_2B_2 type J=5 Hz, –C**H**$_2$OH), and 4.46 (2H, Ar–O–C**H**$_2$–).

Found: C, 42.29; H, 3.77; N, 12.56%. Calcd for $C_{15}H_{14}O_5N_2$: C, 42.11; H, 3.53; N, 12.28%.

β-Hydroxyethyl p-*Methoxyphenyl Ether*: A mixture of *p*-methoxyphenol (3.7 g, 30 mmol) and **1** (2.7 g, 33 mmol) was heated together with tetraethylammonium bromide (2.1 g, 10 mmol) at 155—160°C for 2.5 hr; raw crystals obtained in the same way as above were then recrystallized from ethanol. Yield, 3.34 g; 88%. Mp 63—65°C. IR (KBr): 3300, 1070 (OH), and 1230 (Ar–O–C) cm^{-1}.

Found: C, 64.23; H, 7.19%. Calcd for $C_9H_{12}O_3$: C, 64.27; H, 7.19%.

β-Hydroxyethyl p-*Methylphenyl Ether*: A mixture of *p*-cresol (1.08 g, 10 mmol) and **1** (0.88 g, 10 mmol) in DMF (5 ml) was heated together with tetraethylammonium bromide (2.10 g, 10 mmol) at 170°C for 1.3 hr, and the resultant mixture was treated as above. The raw liquid thus obtained was distilled. Yield, 1.22 g; 80%. Bp 84—95°C/0.4 mmHg. IR (NaCl): 3300, 1070 (OH), and 1240 (Ar–O–C) cm^{-1}. NMR ($CDCl_3$, TMS): δ 3.90 (4H, Ar–O–C**H**$_2$–C**H**$_2$–OH).

Found: C, 71.24; H, 7.94%. Calcd for $C_9H_{12}O_2$: C, 71.01; H, 7.95%.

β-Hydroxyethyl β-Naphthyl Ether: The reaction of β-naphthol (2.88 g, 20 mmol) with **1** (1.94 g, 22 mmol) catalyzed by tetraethylammonium iodide (1.0 g, 0.36 mmol) was carried out at 130°C for 4 hr; the resultant mixture was treated as above to give raw crystals, which were then recrystallized from ethanol. Yield, 3.71 g; 98%. Mp 72—73°C.

2,2-Di-[p-*(β-hydroxyethyloxy)-phenyl*]-*propane.* A mixture of 2,2-di-(*p*-hydroxyphenyl)propane (2.3 g, 20 mmol) and **1** (1.94 g, 22 mmol) was heated together with tetraethylammonium iodide (1.28 g, 5 mmol) at 130°C for 6 hr; raw crystals obtained in the same way as above were then recrystallized from ethanol. Yield, 2.38 g; 77%. Mp 109—111°C (lit.[7] 110.5°C). IR (KBr): 3460, 1090 (OH), and 1250 (Ar–O–C) cm^{-1}. NMR ($CDCl_3$, TMS): δ 3.93 (2H, A_2B_2 type J=6 Hz, –C**H**$_2$OH), and 4.03 (2H, Ar–O–C**H**$_2$–).

The authors are grateful to the Ministry of Education, Japanese Government, for a Scientific Research Grant-in-Aid, and to the members of the Laboratory of Organic Elemental Analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 556—561 (1973)

On the Mechanism of the Acid Catalysis and New Activating Agents in the Fusion Reaction of an Acylated Sugar with a Purine Derivative*

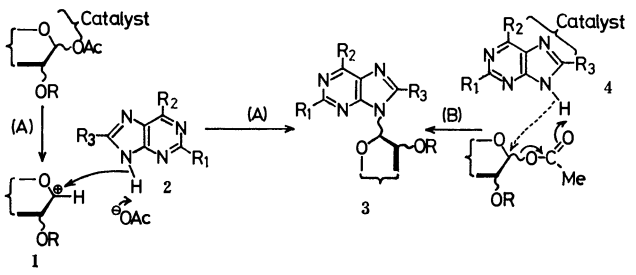
Masao SEKIYA, Teruo YOSHINO, Hisayuki TANAKA, and Yoshiharu ISHIDO

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo

(Received June 19, 1972)

An examination of the site where the acidic catalysts might strongly interact in the fusion reaction of a purine derivative with a fully-acylated sugar led to the conclusion that a purine derivative was activated by the interaction with the catalysts, and, moreover, resulted in the discovery of a new type of activating agent other than the acidic catalysts which had previously been known in the fusion method. In the presence of an excess amount of activating agents, *e.g.*, *p*-nitrophenol, the condensation reaction of theophylline with 1,2,3,4,6-penta-*O*-acetyl-*β*-D-glucopyranose proceeded, even in the absence of *p*-toluenesulfonic acid, to give the corresponding nucleoside. Some of the activating agents were found to form molecular compounds with theophylline, and a few of the latter to afford the corresponding nucleoside similarly. A possible mechanism for the activation process of theophylline by the above agents was discussed.

In a previous paper[1] concerned with the fusion reaction of a purine derivative with an acylated sugar, an assumption concerning such a mechanism of acid catalysis was made involving two possibilities (Scheme I): A) The acidic catalyst might interact with an acylated sugar molecule to afford the C-1 carbonium ion (**1**), and **1** might then successivly be subject to the attack of a purine (**2**) to give the corresponding nucleoside (**3**). B) Alternatively, the catalyst might interact with an electron-sufficient nitrogen atom in the purine nucleus to form an activated complex (**4**), and **4** might then be subject to the reaction with an acylated sugar, accompanied by the elimination of acetic acid, thus affording **3**. In order to solve this problem, a competitive reaction of a purine derivative with a phenol for condensation with a fully-acetylated sugar in the presence of an acidic catalyst was examined; the results thus obtained will be described in the present article.



Scheme I.

Results and Discussion

To confirm the above proposed mechanism of the acid catalysis, a condensation reaction of 1,2,3,4,6-penta-*O*-acetyl-*β*-D-glucopyranose (**5a**) with theophyl-

* A part of this paper was presented at the Symposium on the Charge Transfer Complexes, June 10, 1969 (Nagoya).

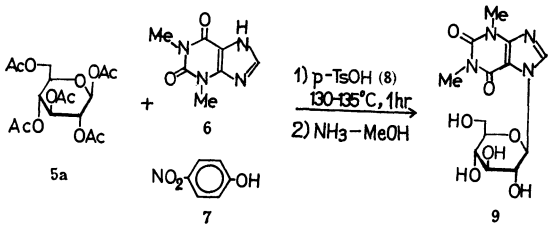
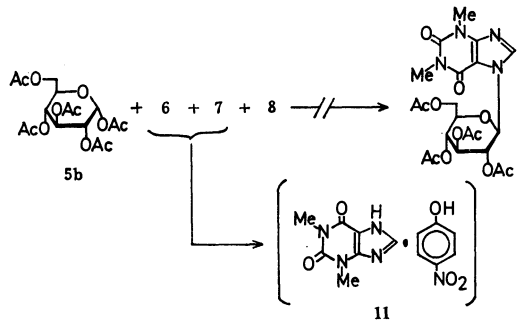


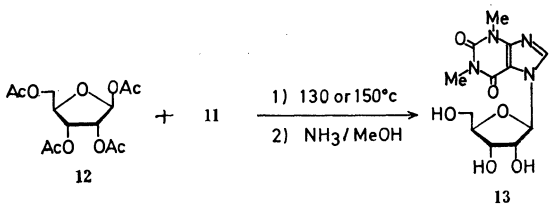
Scheme II.

line (**6**) in competition with *p*-nitrophenol (**7**), in the presence of *p*-toluenesulfonic acid (**8**) as a catalyst, was carried out as a model experiment (Scheme II). After the addition of **5a** (10 mmol) to a homogeneously prefused mixture of **6** (10 mmol), **7** (30 mmol), and **8** (0.05 mmol), the mixture was stirred at 130—135°C under atmospheric pressure and then treated as usual. 7-β-D-Glucopyranosyltheophylline (**9**) was selectively obtained in a 67% yield after the deacetylation of the corresponding tetra-*O*-acetate. This result is of much interest in view of the molar ratio of **6** to **7** and the considerably lowered reaction temperature in comparison with that (160°C) applied in an equimolar fusion reaction of **5a** with **6**.[2] No by-product other than a small amount of *p*-nitrophenyl acetate was observed by tlc or by a column chromatographic separation test on the mixture prior to the deacetylation. The reaction which proceeds *via* the mechanism A may be expected to give a mixture of acetates of *p*-nitrophenyl D-glucopyranosides (**10**) and **9**. On the other hand, the reaction *via* the mechanism B may be expected to give **9** selectively, since **8** should strongly interact with the most basic **6**. Moreover, tetra-*O*-acetate of the β-anomer of **10** (**10a**) was examined by using it in the reaction in place of **5a** in the same way as above, based on the assumption of a possible course of the formation of **9** *via* **10**; however, this examination resulted in the quantitative recovery of **10a**. Accordingly, it was concluded that the acid catalysis takes place *via* the mechanism B.



Scheme III.

The application of 1,2,3,4,6-penta-*O*-acetyl-α-D-glucopyranose (**5b**) (the α-anomer of **5a**) to the above competitive reaction, on the other hand, resulted in the formation of a molecular compound (**11**), composed of equimolar **6** and **7**, in a quantitative yield, and **5b** was recovered almost quantitatively (Scheme III). The recovery of **5b** in this case may be explained by considering that the difference in the stability of the 1-*O*-acetyl group between **5a** and **5b** arises from the anomeric effect.[3] The formation of **11** was remarkably interesting in view of the nature of the molecular compounds, whose components are generally accepted to be linked with each other by an intermolecular interaction such as polarization bonding;[4] hence, its properties were examined. Since **11** separated out on the dissolution of the resultant reaction mixture in benzene, the preparation of **11** from **6** and **7** was attempted by dissolving them in hot chloroform, benzene, and toluene respectively; the solution gave **11** in a fairly good yield in each case after having been allowed to cool at room temperature. However, the use of water, ethanol, or nitromethane as a solvent furnished no molecular compound. Moreover, considerable differences were observed in the IR spectral comparison of **11** with each component, as may be seen in Fig. 1. These differences suggest that a certain intermolecular interaction might exist between **6** and **7**, and that **6** might be activated by an intermolecular interaction such as polarization bonding. On the basis of this assumption, an equimolar fusion reaction of 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose (**12**) (mp 82°C) with **11** (mp 148—150°C) was attempted at 130 and at 150°C respectively for 3 hr without the acidic catalyst, followed by deacetylation; this gave 7-β-D-ribofuranosyltheophylline (**13**) in 30 and 59% yields respectively (Scheme IV). The activation of **6** by **7** was thus con-



Scheme IV.

firmed, and the corresponding fusion reaction of **5a** with **6** in the presence of an excess amount of **7** was carried out. The acetate of **9** was also obtained in a good yield, although this reaction required a longer period than that in the presence of **8**. These results are of much interest in view of the fact that **7** exerts no catalytic effect on the fusion reaction when a catalytic amount is used, although it is acidic ($pKa=7.14$). Thus, the possibility of the activation of a purine by a compound other than the acidic catalysts, which have been known to be active in the fusion method,[1] was established.

In view of the above results, an extensive search for compounds which might behave as activating agents for a purine in the fusion reaction with a fully-acylated sugar was carried out by means of the reaction of **5a**

2) T. Shimadate, *ibid.*, **83**, 212 (1962): According to this paper, the equimolar fusion reaction of **5a** with **6** takes place at 160°C in the presence of **8** or zinc chloride, respectively, and gave the equimolar compound of **9** with **6** in 7% and 3% yield, respectively.

with **6** in the absence of **8**. In the light of the properties of **7**, the potential activating agents were chosen as below:

I) Compounds with a nitro group as an electron-attracting group,
nitrobenzene, *p*-chloronitrobenzene, and methyl *p*-nitrophenyl ether (*p*-nitroanisole).

II) Phenols,
a) *o*-, *m*-nitrophenols (**14**), 2,4-dinitrophenol, and 2,4,6-trinitrophenol (picric acid)
b) phenol, *o*-, *m*-, *p*-chlorophenols, and *p*-methoxyphenol.

III) Carboxylic acids and their derivatives,
a) aromatic carboxylic acids,
benzoic acid, *o*- (**15**), *m*-nitrobenzoic acid (**16**), *o*-, *m*-chlorobenzoic acids, and salicylic acid (**17**)
b) aliphatic carboxylic acids,
acetic acid, propionic acid, and maleic acid
c) acid anhydrides and esters,
succinic anhydride, phthalic anhydride, and methyl *o*-, *m*-nitrobenzoates.

IV) Acceptor in EDA complexes,
p-benzoquinone.

V) Amides,
a) aromatic sulfonamides,
p-toluenesulfonamide (**18**), *N*-methyl- (**19**), *N*,*N*-dimethyl-*p*-toluenesulfonamides (**20**), *p*-chlorobenzenesulfonamide (**21**), *N*-acetyl- (**22**), and *N*-phenyl-*p*-toluenesulfonamides (*p*-toluenesulfonanilide) (**23**).
b) carboxyamides,
benzamide, benzanilide, and salicylamide.

Using the order of these categories, we made a general survey of the factors affecting the activation process of **6** in the condensation reaction. No activating agent was found among the compounds in Category I; this fact suggested that acidic as well as electron-attracting substituents might be required for the activation of **6**. To confirm this view, the compounds in Categories II and III were examined; the results supported the theory, although only **14**, **15**, **16**, and **17** were found to be effective. This fact, moreover, suggested that the activation process of **6** might be delicately connected with the correlation in the mutual

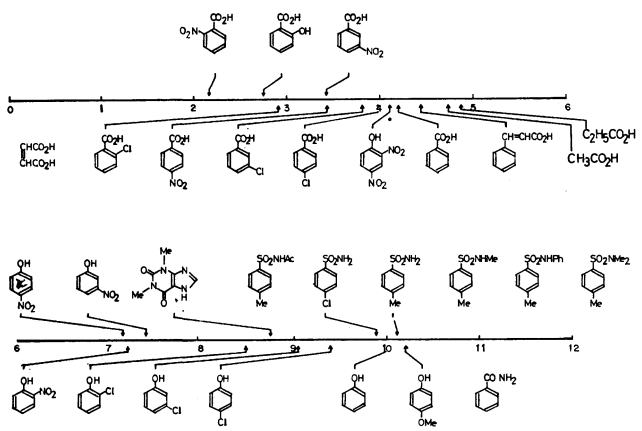

Fig. 2.

position of substituents on the aromatic nuclei, and that aromatic nuclei might be required, at least for the activation. Subsequently, an examination of *p*-benzoquinone (Category IV), which is well known as a typical acceptor in the field of electron-donor-acceptor (EDA) complexes,[4] was carried out; it was found to be ineffective. Moreover, all the sulfonamides in Category Va (**18**—**23**) were found to be effective, in contrast with the carboxyamides in Category Vb. In view of these results, a consideration was made of the factors affecting the activation of **6**: (1) The activation process is conceivably independent from the homogeneity of the reaction system, since all the attempted reactions were carried out in a completely homogeneous state. (2) The possibility of the participation of such a potential active intermediate as **10** was also denied for such compounds as 2,3,4,6-tetra-*O*-acetyl-1-*O*-*o*-nitrobenzoyl-*β*-D-glucopyranose gave no nucleoside even when treated with **6** in the presence of *o*-nitrobenzoic acid in the same way as has been described in the examination reaction of **10a** with **6**, although the formation of a transesterification product had been confirmed in the fusion reaction of **5a** with various carboxylic acids.[5] (3) In considering the possibility that the activation effect of these compounds in Categories II—V might depend on their acidity, they were arranged in the order of their p*Ka* values, as is shown in Fig. 2, and the effective and ineffective ones were placed above and under the line graduating in p*Ka* value. It was thus proved that the effectiveness of the activating agents is independent of their acidity. (4) Consequently, the activation of **6** was deduced to be brought about by such a certain intermolecular interaction as was noticed between **6** and **7**. Incidentally, an intermolecular interaction of such species of heterocyclic compounds has recently been discussed by Shefter[6] in his X-ray crystal structure analysis of the molecular compounds of *p*-chlorosalicylic acid with caffeine[6a] and with theobromine.[6b]

The nature of the intermolecular interaction in these cases was described as the polarization bonding which was proposed by Wallwork.[4] Moreover, it has been shown that **6** and caffeine are both capable of forming EDA complexes with *p*-benzoquinone in water,[7] and that the rate of the alkaline hydrolysis of methyl *trans*-cinnamate is reduced by the addition of such imidazole homologues as **6** because of the formation of EDA complexes.[8] Although the preparations of molecular compounds of all the applied agents with **6** were attempted on the basis of the above facts by dissolving equimolar amounts of them in hot chloroform, no molecular compound such as **11** was isolated except in the cases of **14**, **15**, **16**, **17**, *m*-chlorobenzoic acid, and salicylamide. In addition, *p*-nitro- and 3,5-dinitrobenzoic acid, which can not be used in the reaction because of their high melting points, also gave the corresponding molecular compounds. These results are summarized in Table 2. The IR spectra of these molecular compounds were considerably different from those of each component; the difference was especially remarkable in the specific absorption band of the N–H stretching of **6**. The absorption band was significantly simplified or sharpened by forming the corresponding

Table 1. Condensation reaction of 1,2,3,4,6-penta-*O*-acetyl-*β*-D-glucopyranose (**5a**) with theophylline (**6**) in the presence of activating agents[a]

Activating agent	Reaction temp. (°C)	Period (hr)	Yield of 7-*β*-D-glucopyranosyltheophylline tetra-*O*-acetate (%)

a) All the preparations were carried out by the use of **6**(10 mmol) and countercomponents (11 mmol), respectively, in chloroform (30—50 ml) under reflux.
b) The condensation reaction of **5a** with **6** was not attempted on account of their high melting point.
c) The corresponding molecular compounds could not affect the reaction of **5a** with **6**.

molecular compounds. Moreover, the IR spectroscopic behavior of the phenolic hydroxyl group of **7** was easily detected by examining the spectrum of the molecular compound of **7** with caffeine, which is the $N_{(7)}$-methyl derivative of **6**, in a similar manner. The shift of the O–H stretching absorption band to a lower frequency from the original band of **7** was estimated to be about 180 cm^{-1}. Although various individual variations were observed, similar tendencies were recognized in the specific IR absorption bands of all the countercomponents other than **7**. The magnitude of the activation by such intermolecular interaction is considered to be delicately affected by the correlative position on the aromatic nuclei and by the chemical properties of each functional group in view of the facts that all the homologues are not necessarily effective for the reaction in each category, and that **16** is not effective for the reaction of **6** with **5a**, but is effective for that of **6** with 2,3,4,6-tetra-*O*-acetyl-1-*O*-trichloroacetyl-β-D-glucopyranose.[9] Moreover, there may be no correlation between the formation of a crystalline molecular compound and the activation of **6** in view of the facts that all the sulfonamides are effective for the reaction, although they gave no crystalline molecular compound, and that *m*-chlorobenzoic acid and salicylamide, which are ineffective for the reaction, afforded the corresponding molecular compounds. Furthermore, the intermolecular interaction observed among these molcular compounds was assumed to be not so strong on the basis of the facts that no formation of crystalline molecular compounds took place in such polar solvents as water, ethanol, and nitromethane, and that their UV absorption spectra could not be determined because of the dissociation into their components in the concentration of 10^{-4} mole per liter in chloroform. On the basis of these facts, **6** was deduced to be activated by the polarization bonding with the activating agents described above.

It may be concluded from these experiments that a new type of fusion method for the synthesis of purine nucleosides involving an intermolecular interaction between a purine and an activating agent was established.[10]

Experimental

All the melting points are uncorrected. The IR absorption spectra were taken with a Hitachi-225 in a pellet of potassium bromide, while the NMR spectra were taken with a Varian T-60 in deuteriochloroform ($CDCl_3$) by the use of tetramethylsilane (TMS) as the internal standard.

Competitive Reaction of Theophylline (6) with p-*Nitrophenol (7) for the Condensation with 1,2,3,4,6-Penta-*O*-acetyl-β-*D*-glucopyranose (5a).* Theophylline (**6**) (1.8 g, 10 mmol), *p*-nitrophenol (**7**) (4.2 g, 30 mmol), and *p*-toluenesulfonic acid (**8**) (100 mg, 0.5 mmol) were heated in an oil-bath (130—135°C) to fuse them homogeneously under stirring, and then 1,2,3,4,6-penta-*O*-acetyl-β-D-glucopyranose (**5a**) (3.9 g, 10 mmol)[11] was added to the prefused mixture. After the addition, the mixture was stirred for 1 hr at that temperature under atmospheric pressure, and then it was allowed to cool at room temperature. The resultant mixture was dissolved in benzene (300 ml), and the solution was successively washed with a 1M aqueous sodium hydroxide solution to remove the co-produced acetic acid, unchanged **6**, and **7**, and with water, and then dried over anhydrous calcium chloride. After removing the desiccant by filtration, the organic layer was concentrated *in vacuo* to a pale yellow half-glassy sirup. The sirup was dissolved in methanol (200 ml) and was mixed with methanolic ammonia (200 ml) which had been prepared by saturating methanol with ammonia gas at 0°C. After standing in a round-bottomed flask (500 ml) with a tight stopper at room temperature overnight, the mixture was cooled in an ice-bath and then concentrated *in vacuo* to about a quarter of the original volume. The crystals thus precipitated were filtered by suction and were dissolved in water (10 ml) by warming. The solution was mixed with acetone (100—150 ml) after decoloration with active charcoal. After the solution had been stored in a refrigerator overnight, the resultant crystals were filtered and dried over phosphorus

9) M. Sekiya, T. Yoshino, H. Tanaka, and Y. Ishido, unpublished data: The tetra-*O*-acetate of **9** was obtained in 55% yield.

10) The reaction is found to be also applicable to the other purine derivatives such as $N_{(6)}$-benzyladenine *etc.*, to which the usual fusion reaction has been inapplicable, and the results will be published elsewhere.

11) E. Fischer, *Ber.*, **49**, 584 (1916).

pentoxide at 110°C *in vacuo* to give 7-β-D-glucopyranosyltheophylline (**9**)[12] (2.3 g, 67% yield). Mp 265—267°C. $[\alpha]_{578}^{21}$ −3° (*c* 1.0, H_2O). $\lambda_{max}^{H_2O}$ 275 nm (ε 7200). The NMR spectra of the above sirup was taken prior to deacetylation; it was found to be almost as pure as 7-(2′,3′,4′,6′-tetra-*O*-acetyl-β-D-glucopyranosyl)theophylline: δ ($CDCl_3$) 1.92 (3H; AcO-2′), 2.04, 2.07 (9H; AcO-3′, 4′, and 6′), 3.43, 3.60 (6H; MeN-1 and 3), 3.95—4.30 (3H; H-5′, $6'_a$, and $6'_b$), 5.2—5.7 (3H; H-2′, 3′, and 4′), 6.21 (1H; H-1′, $J_{1',2'}=10$ Hz), and 7.90 (1H; H-8) ppm.

*The Molecular Compound of Theophylline (**6**) with* p-*Nitrophenol (**7**): Theophylline—*p-*Nitrophenol (**11**).* a) On the use of 1,2,3,4,6-penta-*O*-acetyl-α-D-glucopyranose (**5b**)[13] in the competitive reaction in place of **5a**, white scaly crystals were separated when the resultant reaction mixture was dissolved in benzene. The crystals were filtered and dried over phosphorus pentoxide at 110°C *in vacuo*, and a molecular compound composed of equimolar **6** and **7** (**11**) (3.1 g, 97% yield) was obtained. Mp 148—150°C. The IR spectrum of **11** is shown in Fig. 1. However, no new absorption band was found in either its UV or visible region spectrum. After the removal of the residual **7** as described in the previous experiment, the organic layer was concentrated *in vacuo* to give **5b** (3.5 g, 90% recovery). b) **11** was also obtained quantitatively by dissolving an equimolar amount of **6** (1.8 g, 10 mmol) and **7** (1.6 g, 11.4 mmol) in hot chloroform (30—50 ml), and by then allowing the solution to cool at room temperature.

*An Equimolar Fusion Reaction of the Molecular Compound (**11**) with 1,2,3,5-Tetra-*O*-acetyl-β-D-ribofuranose (**12**).* To 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose (**12**)[14] (3.2 g, 10 mmol) prefused at 130°C, was added finely-powdered **11** (3.2 g, 10 mmol), after which the mixture was stirred at 130°C for 3 hr under atmospheric pressure. The resultant reaction mixture was dissolved in chloroform (150—200 ml), successively washed with a 1M aqueous sodium hydroxide solution and water in the same way as has been described in the first example of this section, and dried over anhydrous calcium chloride. The solution was, after the desiccant had been removed by filtration, concentrated *in vacuo* to a sirup; the sirup was then dissolved in methanol (100 ml) and mixed with methanolic ammonia, as has been described above. After standing in a refrigerator overnight, the solution was evaporated *in vacuo* to dryness and the residue was triturated with ethanol (10 ml). The resultant crystals were filtered and recrystallized from ethanol (*ca.* 200 ml) with the use of active charcoal to give 7-β-D-ribofuranosyltheophylline (**13**) (1.2 g, 39% yield). Mp 189.5—191°C. $[\alpha]_D^{25}$ +27.1° (*c* 1.02, H_2O). $\lambda_{max}^{H_2O}$ 274 nm (ε 8400). This product was identified with an authentic specimen.[1] **13** was also obtained in a 59% yield by carrying out this reaction at 150°C for 3 hr.

*Examination for the Potential Activating Agents by Means of the Condensation Reaction of **6** with **5a**.* The reactions of the examination were carried out with each potential compound under the conditions summarized in Table 1 or by managing to make the reaction system homogeneous; the resultant reaction mixtures were treated in the same way as has been described in the first example of this section. On the basis of the properties of the potential agents applied, the procedures for their removal from the resultant mixtures were varied as below. a) Phenols, *p*-toluene-, and *p*-chlorobenzenesulfonamide: The washing procedure of the organic solution of each resultant mixture was carried out with a 1M aqueous sodium hydroxide solution. b) Carboxylic acids: The procedure was carried out with an aqueous sodium carbonate or bicarbonate solution. c) *p*-Chloro- and *p*-methoxynitrobenzene: These compounds were removed by steam distillation. d) The other amides and acid anhydrides: These were separated by the column chromatography of the resultant reaction mixtures; that is, the mixtures were treated on a short column (d: 3 cm) packed with Mallinckrodt silicic acid (100 mesh, 45 g); the column was first eluted with chloroform to give the potential activating agents as the first, and **5a** as the second fraction. Successive elution with benzene–methanol (9: 1) gave the tetra-*O*-acetate of **9** as the third fraction; unchanged **6** was obtained by the following elution with ethanol. The third fraction thus obtained was evaporated at 30—40°C, and then again at 100°C, finally to a half-glassy sirup, and weighed. The purity of each of the above products can be checked NMR spectroscopically by a comparison of the ratio of 2′-*O*-acetyl (δ 1.92 ppm) to other *O*-acetyl (*ca.* δ 2.06 ppm) signals in the integration curve. The yields demonstrated in Table 1 were calculated from the weight and this ratio in the NMR spectra of each product. To make sure of the composition of each product, the products were examined by tlc (eluting solvent: benzene–methanol=9: 1 v/v). In the case of *p*-nitrophenol (**7**), *p*-nitrophenyl acetate (*ca.* 100 mg) was obtained as a fraction before that of **7**.

Preparation of Molecular Compounds. As has been described in the second example of this section, the potential activating agents were each dissolved in hot chloroform together with an equimolar amount of **6**, after which the solution was allowed to cool at room temperature for crystallization. The precipitated crystals were subsequently filtered and dried at 110°C *in vacuo* over phosphorus pentoxide. The IR spectra of the molecular compounds of **6** with *m*-nitrophenol (**14**), with *o*-(**15**), *m*-nitrobenzoic acid (**16**), and with salicylic acid (**17**) showed the same tendency as has been described in the case of **11**. The experimental results are summarized in Table 2. No new absorption band was, on the other hand, observed in either the UV or the visible region spectrum similar to those of **11**. Almost the same results were obtained by the use of benzene, toluene, or xylene as the solvent for the preparation.

Preparation of the Molecular Compound of Caffeine with p-*Nitrophenol (**7**).* As has been described in the previous experiment, equimolar amounts of caffeine (1.95 g, 10 mmol) and **7** (1.60 g, 11 mmol) were dissolved in xylene (50 ml) under reflux, and the resultant solution was allowed to cool at room temperature for crystallization. The needles thus precipitated were filtered and dried at 110°C over phosphorus pentoxide *in vacuo* to give the molecular compound (3.20 g, 95% yield). Mp 154.5—156°C. Found: C, 50.36; H, 4.61; N, 20.64%. Calcd for $C_{14}H_{15}N_5O_5$: C, 50.45; H, 4.54; N, 21.00%. IR (KBr): 3170 cm^{-1} (phenolic OH).

The authors are grateful to the Ministry of Education, Japanese Government, for a Scientific Research Grant-in-Aid, and to the Kurata Foundation for a grant. They also wish to thank Professor Takeshi Nakajima, Tohoku University, for his valuable suggestion as to the structure of the molecular compounds, and Mr. Masaru Koezuka for his help with elemental analysis.

The Reversible Acylation of β-Diketone with Acyl Chloride in the Presence of Aluminum Chloride

Kiyotada MATSUI, Masatoshi MOTOI, and Tetsuro NOJIRI*

Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kodatsuno, Kanazawa

(Received June 21, 1972)

The treatment of acetylacetone (I) with *n*-butyryl chloride in the presence of aluminum chloride in nitrobenzene gave *n*-butyrylacetone and di-*n*-butyrylmethane at 45°C. The same products were obtained, along with *n*-butyric acid, when *n*-butyrylacetone or di-*n*-butyrylmethane was treated with acetyl chloride under analogous conditions. The reactions between I and benzoyl chloride and between benzoylacetone or dibenzoylmethane and acetyl chloride gave products consisting of I, benzoylacetone, dibenzoyl-, diacetylbenzoyl-, acetyldibenzoyl-, tribenzoyl-methane, and benzoic acid. These findings show that β-diketone can reversibly react with acyl chloride to form new β-diketones by way of the mixed triacylmethanes. The acylation mechanism is discussed.

In our previous papers[1] it was shown that the aluminum chloride-catalyzed acylation of ethyl acetoacetate with aroyl chloride, accompanied by deacylation, involves the following sequence of four-step equilibria among the substrate and products in the presence of aroyl and acetyl chlorides:

$$(CH_3CO)_2CHCOOC_2H_5 \rightleftarrows CH_3COCH_2COOC_2H_5 \rightleftarrows$$
$$CH_3\overset{\overset{ArCO}{|}}{C}HCOOC_2H_5 \rightleftarrows ArCOCH_2COOC_2H_5 \rightleftarrows$$
$$(ArCO)_2CHCOOC_2H_5$$

The similar acylation[2] of acetylacetone (I) with *n*-butyryl chloride was established to proceed by the coordination of the acyl chloride with the metal atom of the β-diketone complex. The purpose of this paper is to give more information on the reaction of β-diketones with acid chlorides other than the *n*-butyryl chloride.

As is shown in Table 1, the butyrylation of I with *n*-butyryl chloride and the acetylation of *n*-butyrylacetone or di-*n*-butyrylmethane with acetyl chloride in the presence of aluminum chloride in nitrobenzene all gave the same products—I, *n*-butyrylacetone, di-*n*-butyrylmethane, and *n*-butyric acid—at 45°C. The latter acid obviously results from the hydrolysis of the *n*-butyryl chloride derived from the starting butyrylated ketones except when *n*-butyryl chloride is used. The products resulting from either the benzoylation of I or the acetylation of benzoylacetone or dibenzoylmethane consisted of I, benzoylacetone, dibenzoylmethane, and benzoic acid; also, triacylmethanes and aluminum chelate of dibenzoylmethane, $[(C_6H_5CO)_2CH]_3Al$, were obtained under certain conditions. Tribenzoylmethane was isolated in every case, while acetyldibenzoyl- and diacetylbenzoyl-methane were not always isolated. The latter was obtained particularly, along with the former in small amounts, when I was benzoylated in a stream of dry nitrogen gas for a shorter reaction time in order to avoid the effect of the hydrogen chloride formed. Both mixed triacylmethanes were also obtained from aluminum trisacetylacetonate, which could undergo benzoylation without liberating a large amount of hydrogen chloride because of its enolate structure. From these facts, it appears that the mixed triacylmethanes tend to decompose more easily into β-diketones and acyl chlorides as the amount of hydrogen chloride formed is increased. The acid chlorides thus formed can react with any β-diketones present in the reacting mixture to yield the triacylmethanes. Among these, the mixed triacylmethanes act as intermediates for the formation of the new β-diketones. Apparently, there is the following equilibrium in the presence of the acyl chlorides and aluminum chloride:

$$CH_3COCH_2COR \rightleftarrows CH_3\overset{\overset{ArCO}{|}}{C}HCOR \rightleftarrows$$
$$RCOCH_2COAr \rightleftarrows \overset{\overset{COR}{|}}{C}H(COAr)_2$$
$$R = CH_3 \text{ or } Ar$$

Triacetylmethane, though not isolated, seems to take part in this equilibrium, because it is known to be synthesized by the aluminum chloride-catalyzed reaction of I with acetyl chloride.[3]

In the presence of various amounts of aluminum chloride, I was benzoylated with 2 equivalents of benzoyl chloride under comparable conditions. The use of a 0.3 equivalent of the condensing agent afforded the benzoylated ketones (including tribenzoylmethane) and the aluminum chelate of dibenzoylmethane in a relatively low and a high yield respectively, but the former were obtained in high yields at the expense of the latter on the increase of the condensing agent to a 0.5 or 0.7 equivalent. Accordingly, it seems that the increase in the condensing agent allows the benzoylation to proceed with a high yield by hindering the formation of the stable aluminum chelate. The control of the chelate-ring formation by aluminum chloride has also been visualized as spectral evidence for the action of aluminum chloride on I[2] or aluminum trisacetylacetonate.[4] The above variation in yield with the amount of aluminum chloride was also observed with the butyrylation reaction.[2] In this case,

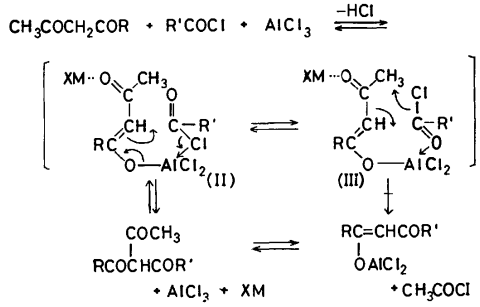
Solvent: $C_6H_5NO_2$ 10 ml, a) $(ClCH_2)_2$ 5 ml; reaction temp.: 45°C, b) 55°C; N_2: The reaction was carried out in a stream of nitrogen gas. ( ): The yield of recovered material. [ ]: The yield of Al chelate of β-diketone (included in the yield of β-diketone). c) less than 1% yield of acetyldibenzoylmethane. d) both 1.7%, yields of diacetylbenzoyl- and acetyldibenzoyl-methane; e) 2.2, 0.2%. f) 2.3, 0.7% yields respectively.

however, relatively large amounts of aluminum chloride were required to give the products in a maximum yield, but no aluminum chelate was obtained, even when a small amount of aluminum chloride was used. On the other hand, the fact that the yields of the benzoylated ketones were decreased on the use of more than 1.2 equivalents of aluminum chloride suggests that the liberation of aluminum chloride causes the condensation to proceed, and that an excess of aluminum chloride tends to coordinate with the acyl chloride resulting from the coordination complex between acyl chloride and dichloroaluminum β-diketonate complex as was pointed out in a previous paper.[2] Such a coordination complex is in the forms of II and III (Scheme 1), which should be in a rapid mobile equilibrium because of the abilities of chlorine and carbonyl oxygen in the acyl chloride to coordinate with the metal atom of enolate. Complex II must be more favorable for the intramolecular condensation to form triacylmethane, which is then deacylated easily to give β-diketone as shown in Scheme I.

However, there is no denying an acyl exchange through Complex III. Moreover, when an ester was used as the acylating agent, a coordination complex corresponding to III proved to lead directly to a new



MX=$AlCl_3$ or HCl; R=CH_3 or C_3H_7, where R'=C_3H_7; R=CH_3 or C_6H_5 where R'=C_6H_5

Scheme I.

β-diketonate. Such a transacylation will be reported in our next paper.[5]

In the reaction of benzoylacetone with benzoyl chloride or in that of dibenzoylmethane with acetyl chloride, the yields of dibenzoylmethane and especially of its aluminum chelate were far higher than those from the reaction of I with benzoyl chloride. The high yield of the aluminum chelate can be explained as being due mainly to high concentrations of dibenzoylmethane

5) K. Matsui and M. Motoi, This Bulletin, **46**, 565 (1973).

compared with those of aluminum chloride in the reacting mixture. However, in the reaction of I with *p*-nitrobenzoyl chloride the high yields of di-*p*-nitrobenzoylmethane and its aluminum chelate seem to be ascribable to the susceptibility of certain intermediates to acylation or deacetylation, as well as to the high stabilities of the final products.

From the standpoint of synthetic chemistry, this acylation of I is useful for preparing β-diketones, such as di-*p*-nitrobenzoylmethane and di-chloroacetylmethane, sensible to alkali. Their yields are shown in Table 1.

Experimental

Materials. The benzoylacetone[6] (mp 59°C) and the dibenzoylmethane[7] (mp 79—80°C) were prepared according to the literature. Commercial acetyl chloride was used after distillation; bp 51—52°C. The chloroacetyl[8] (bp 104—105°C), benzoyl[9] (bp 192°C) and *p*-nitrobenzoyl chlorides[9] (bp 160°C/26 mmHg), were prepared from the corresponding carboxylic acids, commercially obtained, according to the literature. The diacetylbenzoyl- and acetyldibenzoyl-methane were prepared by the benzoylation of acetyl- and benzoylacetone respectively, according to the Schotten-Baumann method; the former has mp of 30—31°C and bp of 107—108°C/2 mmHg, its copper chelate, mp 247—249°C (benzene), (lit,[10] mp 35°C, bp 167°C/22 mmHg, copper chelate mp 228°C), while the latter has mp of 106.5—107.5°C, (lit,[11] 99—101°C). The other materials were described previously.[2]

Acylation Method and Separation Procedure for Product. Both were the same as in the previous paper,[2] except for the following:

a) Butyrylated Product: For the estimation of *n*-butyric acid, the sodium bicarbonate extract was acidified with sulfuric acid and then extracted with ether. The ether extract was dried, evaporated carefully, and then analyzed, using acetophenone as the internal standard, by gas-liquid chromatography at 130°C.

b) Benzoylated Product: The reaction mixture, quenched with crushed ice and hydrochloric acid, was shaken with ether to separate it into 2 layers. The lower layer was extracted with ether 2 days later; then, after 5 or more days, the dibenzoylmethane which gradually crystallized out was collected by filtration. The upper layer, freed from aluminum chloride, was occasionally shaken with an aqueous sodium bicarbonate solution until the Beilstein test for benzoyl chloride became negligible. The partial distillation of the aqueous extract gave a distillate containing a slight amount of acetophenone (obtained as its 2,4-dinitrophenylhydrazone). The pot residue was acidified to give benzoic acid. The above organic layers were combined and separated successively into a crude copper chelate of each, diacetylbenzoylmethane, acetylacetone, acetyldibenzoylmethane, and benzoylacetone, according to our usual fractionation method,[12] which consists of fractional extraction (the step-by-step extraction of an acid with small, successive portions of alkali, followed by thin-layer chromatographic test of the acidified extracts) and subsequent treatment with a copper acetate solution. The remaining organic layer was steam-distilled *in vacuo* to remove the nitrobenzene. The residual solid was triturated with ether, and then an aluminum chelate of dibenzoylmethane was filtered off.[13] The ethereal filtrate was shaken with a copper acetate solution to give a copper chelate of dibenzoylmethane. This chelate is insoluble in ether after drying.

The copper chelates suspended in their ether solution, when consisting mainly of the copper chelates of the first three substances above, were freed from the chelate of acetylacetone by washing them with aqueous acetic acids (3%); then the ether was replaced with a small amount of benzene to crystallize a chelate of acetyldibenzoylmethane, which was collected by filtration. The solvent of the filtrate was replaced with a small amount of ether to crystallize the chelate of diacetylbenzoylmethane. The ethereal mother liquor gave a slight amount of the chelate of benzoylacetone on concentration. The above aqueous acetic acid washings and the copper acetate solution used for the chelate preparation were shaken with methylene chloride in order to obtain the chelate of acetylacetone.

Acetyldibenzoylmethane: Its copper chelate was shaken with ether and hydrochloric acid; the ether layer was then evaporated to leave colorless crystals; mp 106—107°C (ligroin).

Diacetylbenzoylmethane: Its copper chelate, slightly soluble in ether, was recrystallized from benzene to give cobalt-blue crystals (mp 246—248°C), which were decomposed as above to give an oil.

Tribenzoylmethane: This substance, present in both free and copper chelate forms, was present mainly in the crude copper chelates of benzoylacetone and of dibenzoylmethane. Each crude chelate (weighed) was decomposed as above to give a solid, which was dissolved in acetone–ethyl acetate; then, after 24 hr, the solvent was replaced with ether to give tribenzoylmethane in an ether-insoluble form (mp 235—237°C (acetone)). This tribenzoylmethane does not form its copper chelate directly.

Acetylacetone: Its copper chelate was decomposed to give a liquid. Its 2,4-dinitrophenylhydrazone has mp of 125—126°C (lit,[14] 122°C).

Benzoylacetone: The recrystallization of the copper chelate from methanol gave greenish-blue needles; mp 200—202°C (lit,[15] 195—196°C). This chelate was decomposed as above to give colorless needles; mp 60—61°C (petroleum ether).

Dibenzoylmethane: The decomposition of its copper or aluminum chelate gave light yellow needles; mp 80—81°C (methanol).

All the above substances were identified by the mixed-melting point method and/or by means of their similarity in thin-layer chromatographic behavior with authentic samples, except for impossible cases. Each yield other than that of tribenzoylmethane was calculated from the weight of the copper chelate.

c) p-Nitrobenzoylated Product: The reaction mixture quenched was shaken with a small amount of ether; then

it was separated into two layers with a centrifuge. From the organic layer a solid was filtered off and then washed with ether. The solid was dissolved in tetrahydrofuran and acidified with hydrochloric acid to give di-*p*-nitrobenzoylmethane; mp 248°C (tetrahydrofuran). The combined organic solution was freed from *p*-nitrobenzoic acid with a sodium bicarbonate solution; then it was steam-distilled *in vacuo*. The pot residue was triturated with ether, and then di-*p*-nitrobenzoylmethane was filtered off. The ethereal filtrate, after it had been shaken with a copper acetate solution, was evaporated to dryness and triturated with methanol; then a copper chelate was filtered off. This, when decomposed, gave *p*-nitrobenzoylacetone; mp 115—116°C (methanol). (lit,[16] 112—113.5°C), (Found: N, 7.1%). The concentration of the methanolic filtrate gave a small amount of *p*-nitroacetophenone; mp 80—81°C (ethanol). These substances were identified by the mixed-melting-point method with authentic samples.[13]

16) H. Burgess, *J. Chem. Soc.*, **1927**, 2017.

d) Dichloroacetylmethane: The reaction mixture, quenched, was shaken with ether. After washing with water, the ether layer was shaken with a copper acetate solution; then it was filtered and washed with ether to give a crystalline copper chelate. The upper layer of the filtrate was washed with dilute acetic acid and subsequently concentrated to give the same chelate as above. Dilute sulfuric acid (10%) was added in portions to the mixture of the copper chelates and fresh ether with stirring until the ether layer became colorless. The ether layer was then dried over sodium sulfate, concentrated, and cooled to give colorless needles; mp 41.5—42.5°C (ether–petroleum ether), (lit,[17] solid at 0°C). Found: C, 35.84; H, 3.56; Cl, 41.66%; mol wt (benzene), 168. Calcd for $C_5H_6Cl_2O_2$: C, 35.50; H, 3.55; Cl, 41.95%; mol wt, 169.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 565—569 (1973)

The Transacylation between β-Diketone and Ester in the Presence of Aluminum Chloride

Kiyotada MATSUI and Masatoshi MOTOI

Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kodatsuno, Kanazawa

(Received June 21, 1972)

The reaction of acetylacetone with an equivalent of phenyl benzoate in the presence of 2 equivalents of aluminum chloride in nitrobenzene afforded benzoylacetone (26% yield), dibenzoylmethane (4%), and phenyl acetate (37%), together with small amounts of phenolic ketones at 45°C. The total yield, based on the acyl groups introduced into the β-diketones, is similar to the yield of the ester newly formed. Such a similarity, suggestive of a transacylation, was also observed both on the use of *p*-nitrophenyl benzoate and on the treatment of benzoylacetone with phenyl benzoate or on that of dibenzoylmethane with *p*-nitrophenyl acetate. The non-formation of triacylmethanes is a strong evidence for the transacylation reaction, in which β-diketones and some esters exchange acyl groups directly. The analogous treatment of acetylacetone with α-naphthyl benzoate produced phenolic ketones, such as 2-acetyl- and 4-acetyl-1-naphthol, and the same benzoylated ketones as above in yields of 30 and 32% respectively. The considerably higher ratio of the 2-acetyl to the 4-acetyl isomer than that from the Fries rearrangement of α-naphthyl acetate indicates that another transacylation is accompanied by a rearrangement proceeding through complexes different from those in the Fries rearrangement.

In the course of studies[1] of the aluminum chloride-catalyzed acylation reaction of active methylene compounds with acid chlorides, the use of *p*-nitrophenyl benzoate, which is known to react only as an acylating agent for the Friedel-Crafts reaction,[2] was tried in the acylation of acetylacetone (I) in order to obtain insight into the mechanism of this acylation reaction. Thus, benzoylated ketones, such as benzoylacetone (II) and dibenzoylmethane (III), and *p*-nitrophenyl acetate were both obtained in about the same yields:

$$(CH_3CO)_2CH_2 + p\text{-}O_2NC_6H_4OOCC_6H_5 \longrightarrow CH_3CO\text{-}CH_2COC_6H_5 + (C_6H_5CO)_2CH_2 + p\text{-}O_2NC_6H_4OOCCH_3$$

This seems to imply that a transacylation between the reactants is involved in this unusual acylation reaction. The purpose of this paper is to report on such reactions between β-diketones and some esters.

The reaction of I with an equivalent of phenyl benzoate in the presence of an equivalent of aluminum chloride in nitrobenzene at 45°C for 3 hr gave II and phenyl acetate in low yields, as is shown in Table 1. The increase in the condensing agent to 2 equivalents afforded III in addition to the foregoing products, all in noticeably high yields, together with small amounts of phenolic ketones, such as *o*-hydroxy-, *p*-hydroxyacetophenone, and *p*-hydroxybenzophenone. The formation of III can be explained as being due to the benzoylation of the II formed, because the similar benzoylation of II gave III and phenyl acetate in about the same yields. The yields of the main prod-

$AlCl_3$: mol ratio 2, a) 1, a') 3; solvent: $C_6H_5NO_2$ 7 ml, b) $(ClCH_2)_2$ 7 ml; reaction temp.: 45°C, c) 55°C; d) The yields based on I, the others based on phenylbenzoate; ( ): the yields of recovered materials; e) 8 and 30% yields of diacetylbenzoylmethane and of phenol respectively; f) Identification of the phenolic ketones could not be effected because of small amounts.

ucts were not increased adequately by the increase either in the condensing agent to 3 equivalents or in the acylating agent to 2 equivalents. The rise in the reaction temperature to 55°C led to some increase in yields, and the extension of the reaction time to 20 hr, giving relatively higher yields of the benzoylated ketones, resulted in an increase in the phenolic ketones at the expense of both phenyl acetate and recovered benzoate. The other products isolated were phenol, benzoic acid (both in 1—8% yields), and the unchanged I and phenyl benzoate; no triacylmethane was isolated, in contrast with the results of a similar acylation with acid chlorides.[1c)] However, there is one common feature—the acylation with either the ester or the *n*-butyryl chloride[1a)] requires 2 equivalents of aluminum chloride in order to obtain a satisfactory yield. Such a requirement for the condensing agent was also observed, more markedly, in the reaction of I with *p*-nitrophenyl benzoate. On the other hand, the similarity of the total yield based on the benzoyl groups introduced into the β-diketones (*e.g.*, the yield of III obtained from I, noted in Table 1, should be doubled) to the yield of phenyl acetate is suggestive of a transacylation during the reaction.

TABLE 2. FRIES REARRANGEMENT OF ESTER AND REACTION BETWEEN PHENOL AND ACYL CHLORIDE AT 45°C

Reactant (10 mmol)	Product (%)				
	1-HO-2-Ac-C_6H_4	1-HO-4-Ac-C_6H_4	1-HO-4-Bz-C_6H_4	PhOAc	PhOBz
PhOAc	7	9		(75)

PhOBz			4		(89)
PhOH+BzCl			22		72

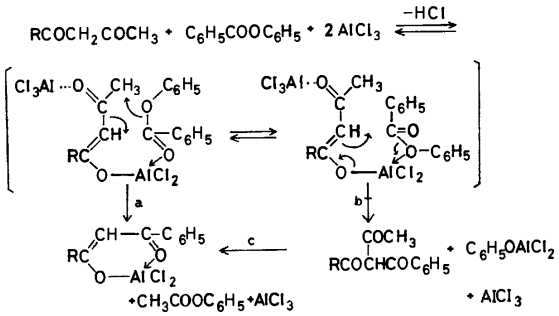
$AlCl_3$: 10 mmol; solvent: $C_6H_5NO_2$ 7 ml; reaction time: 3 hr; ( ): the yield of recovered material.

The esters present in the reacting mixture are subject to some extent to the rearrangement to yield phenolic ketones, but it is a question whether or not the formation of these products is due to acyl chlorides, which may be generated as intermediates because of the similarity of the conditions to those for the acylation with acyl chloride.[1c)] Therefore, the reaction of phenol

with acid chloride and the Fries rearrangement of the phenyl ester were carried out under conditions similar to those used for the present reaction. In consequence, in the reaction between I and phenyl benzoate, the slight yields of hydroxyacetophenones, contrasting with the moderate yield of the phenyl acetate, are due to the Fries rearrangement of the phenyl acetate formed, not to the reaction of phenol with acetyl chloride (Table 2). Similarly, as compared with the moderate yield of the benzoylated ketones or of the unaltered benzoic ester, the low yield of *p*-hydroxybenzophenone is ascribable to the Fries rearrangement of the phenyl benzoate used, not to the reaction of phenol with benzoyl chloride. Judging from these facts, not only the phenolic ketones, but also the acetic ester and β-ketones obtained, do not seem to be formed by the action of the acyl chlorides suspected of being intermediates.

With the benzoylation of aluminum trisacetylacetonate, the use of benzoyl chloride gave II, III, and tribenzoylmethane in considerably high yields, similar to those from the analogous benzoylation of I,[1c] whereas the use of phenyl benzoate gave only II in a 3% yield (Table 1). The use of *p*-nitrobenzoyl chloride for the acylation of I afforded di-*p*-nitrobenzoylmethane in a high yield, while a similar acylation with phenyl *p*-nitrobenzoate gave a less acylated product, *p*-nitrobenzoylacetone, in a low yield. The ester as acylating agent seems to follow a course differing substantially from that of acid chloride.

In the aluminum chloride-catalyzed reaction between synthesized diacetylbenzoylmethane and phenol (Scheme 1, Path c, R=CH_3), II and phenyl acetate were obtained in relatively high yields (Table 1), but the triacylmethane, which has not been isolated, was recovered and the phenol remained unchanged in a considerably higher yield than that from the present acylation reaction. This suggests that the triacylmethane capable of behaving as an acylating agent, if formed as an intermediate, can survive the reaction of I with phenyl benzoate. However, not even the isolation of stable tribenzoylmethane was accomplished. The above findings indicate that the present acylation, predominating over the Fries rearrangement, proceeds by transacylation between I (or II) and phenyl benzoate (Path a), without forming triacylmethane (Path b). The transacylation can be explained in terms of an intramolecular condensation of a complex which is generated by the ability of the carbonyl oxygen of the ester to coordinate with the metal atom of the dichloroaluminum β-diketonate complex proposed previously.[1a] The reaction mechanism is illustrated in Scheme 1.



R=CH_3 or C_6H_5

Scheme 1.

This mechanism is also supported by the idea that the acylation of I with an ester, giving higher yields of β-diketones in nitrobenzene than those in ethylene chloride, seems to proceed by some charge separation in the transition state.

The acylation of I with different benzoic esters showed that, except for ethyl benzoate which failed to react, the substituted phenyl benzoates gave decreasing yields of β-diketones in this order: *p*-nitrophenyl>phenyl>*p*-cresyl>*o*-cresyl benzoate. With acetic esters, phenyl acetate failed to react with III, whereas *p*-nitrophenyl acetate did react to give equimolar amounts of II and *p*-nitrophenyl benzoate.

Table 3. Reaction of acetylacetone with naphthyl benzoate, Fries rearrangement of naphthyl ester, and reaction of naphthol with acyl chloride at 45°C

$AlCl_3$: mol ratio 1, a) .2; solvent: $C_6H_5NO_2$ 7 ml; reaction time: 3 hr; ( ): the yield of recovered material.

These facts indicate that the transacylation is facilitated by electron-attracting groups in the phenol portion of the ester and rendered somewhat difficult by electron-donating groups. With substituted benzoic esters other than that described above, phenyl *p*- and *o*-toluate also gave slight amounts of copper complexes from the β-diketone fraction separated from the reaction mixture; therefore, further studies were not undertaken.

α-Naphthyl benzoate and its β-isomer, when used, were subjected to the Fries rearrangement to form relatively large amounts of 4-benzoyl-1- and 1-benzoyl-2-naphthol respectively, giving both the foregoing β-diketones. Simultaneously, the latter ester gave β-naphthyl acetate, whereas the former gave 2-acetyl- and 4-acetyl-1-naphthol, instead of the acetic ester (Table 3). Here again, the two yields of the benzoylated ketones and of acetyl-1-naphthols are similar to each other. The Fries rearrangement of α-naphthyl acetate and the acylation of α-naphthol with acetyl chloride, when carried out under conditions comparable to those of the present reaction, gave isomeric mixtures of acetyl-1-naphthols in the 2-acetyl/4-acetyl ratios of 1.2 and 0.8 respectively. The higher isomer ratio of 2.3 obtained from the reaction of I with α-naphthyl benzoate suggests that, independently of the intermediate α-naphthyl acetate as well as of acetyl chloride, the acetyl-1-naphthols form by way of complexes different from those in the Fries rearrangement.[3] It can be deduced that an acetylium ion to be formed from a coordination complex as is illustrated in Scheme 1, concurrent with the closure of the chelate ring of the new β-diketonate, can uniquely complex with a leaving α-naphthoxide ion without becoming free; then it can migrate more easily to the 2 position in the nucleus to give the isomeric mixture.

Experimental

Materials. The following benzoic esters were prepared from the corresponding phenols and benzoyl chloride according to the Schotten-Baumann method: phenyl (mp 70—71°C (lit,[4] 70°C)), α-naphthyl (mp 57.5—58.5°C (lit,[5] 56°C)), β-naphthyl (mp 109—109.5°C (lit,[6] 106°C)), and *o*-cresyl benzoate (bp 301°C (lit,[7] 307—308°C/728 mmHg)). *p*-Nitrophenyl (mp 147.5—148.5°C (lit,[8] 142.5°C)), *p*-cresyl benzoate (mp 73°C (lit,[9] 71.5°C)), phenyl *p*-nitrobenzoate (mp 131—132°C (lit,[10] 129°C)), and *p*-nitrophenyl acetate (mp 77.5—78°C (lit,[11] 81—82°C)) were prepared from the corresponding phenols and acid chlorides. α-Naphthyl and β-naphthyl acetate were prepared from the corresponding naphthols and acetic anhydride in the presence of a catalytic amount of concentrated sulfuric acid, which melted at 45.5—46°C (lit,[12] 46°C) and 70—70.5°C (lit,[13] 70°C) respectively.

Reaction Method and Separation Procedure. Both were the same as in our previous paper[1c] except for the use of esters as acylating agents and the following points.

a) Product from the Reaction with Phenyl Benzoate: The reaction mixture, quenched, was shaken with cold hydrochloric acid and ether, and then separated into two layers. The upper layer was freed from benzoic acid with a sodium bicarbonate solution, dried over sodium sulfate, concentrated, and then distilled under reduced pressures (16—20 mmHg). At a later stage of the distillation, a small amount of nitrobenzene was supplied in order to remove the volatile substances completely. From the distillate phenol, phenyl acetate and *o*-hydroxyacetophenone (sometimes a slight amount of acetophenone also) were determined by glpc analysis on a column (0.3×200 cm) packed with polyethylene succinate (30%) on celite (hydrogen flow, 40 ml/min), using dimethyl azelate as the internal standard at 200°C. From the remaining distillate, acetyl- and benzoyl-acetone were obtained as their respective copper chelates according to our fractionation method.[1c,14] This method was also applied to the pot residue to obtain three extracts. The first extract, in ether, was shaken with a copper acetate solution; then the solvent was replaced with a small amount of ether–petroleum ether (1:2) to crystallize a copper chelate of benzoylacetone. The mother liquor was evaporated to leave a crude *p*-hydroxyacetophenone. The same treatment of the second extract gave the same chelate, along with a crude *p*-hydroxybenzophenone. The third extract and extracted residue were combined, evaporated, and then steam distilled *in vacuo* to remove the nitrobenzene. The trituration of the residue with ether gave an ether-insoluble aluminum chelate[1c] of dibenzoylmethane. The resulting ether solution was freed from dibenzoylmethane with a copper acetate solution; it was then evaporated to give phenyl benzoate, which was recrystallized from ethanol. The crude *p*-hydroxy-acetophenone and -benzophenone were treated individually with a dilute sodium hydroxide solution to remove slight amounts of the copper chelates; then they were purified according to the fractional extraction method described in a previous paper.[14] The former melts at 110—111°C, the latter, at 135—136°C. Both melting points were undepressed on admixture with authentic samples.

b) Product from the Reaction with p-*Nitrophenyl Benzoate*: The separation procedure was the same as above except for the following. From the pot residue, much of the *p*-nitrophenyl acetate was removed by crystallizing it from benzene–petroleum ether. The mother liquor was concentrated and then chromatographed on a column packed with silica gel. The eluents used, benzene–petroleum ether (1:1), the same (2:3), benzene, and benzene–ether (3:1), eluted successively dibenzoylmethane, *p*-nitrophenyl benzoate, a mixture, and *p*-nitrophenol respectively. The mixture (weighed) in ether was extracted with successive, small portions of a 0.1N sodium hydroxide solution to obtain benzoylacetone; then it was concentrated to crystallize *p*-nitrophenyl acetate; mp 78—79°C, undepressed on admixture with an authentic sample.

c) Product from the Reaction with o- *or* p-*Cresyl Benzoate*: The mixture distilled with nitrobenzene, after glpc analysis for determining cresyl acetates and cresols, was separated into acetyl– and benzoyl–acetone according to the fractionation method. The pot residue was treated with benzene–

petroleum ether (1: 3) to crystallize *p*-cresyl benzoate. The mother liquor was concentrated and chromatographed using benzene–petroleum ether (1: 1) and benzene–ether (1: 1), which gave *p*-cresyl benzoate and benzoylacetone respectively. *o*-Cresyl benzoate, when used, was determined by a glpc analysis of the pot residue. From the remainder, benzoylacetone was separated by alkaline extraction.

d) Product from the Reaction with α-Naphthyl Benzoate: The pot residue was chromatographed similarly using benzene–petroleum ether (2: 3), the same (1: 1), and benzene–ether (1: 1), which gave three effluents successively. The evaporation of the first effluent gave α-naphthyl benzoate, which was then recrystallized from ether–petroleum ether; mp 58—59°C. The solvent of the second effluent was replaced with ether, freed from dibenzoylmethane as described above, and then extracted fractionally with the 0.1N sodium hydroxide solution to separate 2-acetyl-1-naphthol, which was then recrystallized from petroleum ether–ether; mp 100—101°C (lit,[15] 100—101°C). The concentration of the remaining ether solution gave α-naphthyl benzoate; mp 57—58°C. The third effluent was made up to about 100 ml by the addition of ether; then it was treated as above with the 0.1N sodium hydroxide solution to separate 4-acetyl-1-naphthol, which was subsequently recrystallized from benzene–ethanol; mp 204—206°C (lit,[15] 200—201°C). The solvent of the remaining solution was replaced with benzene to crystallize 4-benzoyl-1-naphthol; mp 165—166°C, (lit,[15] 163—164°C). The mother liquor was separated into 4-acetyl-, 4-benzoyl-1-naphthol, and benzoylacetone according to the fractional extraction method. The melting points of the three acylated naphthols were undepressed on admixture with authentic samples.

e) Product from the Reaction with β-Naphthyl Benzoate: The pot residue was chromatographed using as eluents benzene–petroleum ether (1: 1), the same (3: 1), benzene, and ether; this gave β-naphthyl benzoate, a mixture, β-naphthol, and benzoylacetone respectively. The ether solution of the mixture was freed from dibenzoylmethane as above and then evaporated to leave a solid. This solid in a small amount of benzene was chromatographed using benzene–petroleum ether (3: 2); this gave β-naphthyl acetate (mp 69.5—70°C (ether–petroleum ether)) and 1-benzoyl-2-naphthol (mp 144—145°C (benzene), (lit,[15] 140—141°C)). Both were undepressed on admixture with authentic samples.

f) Product from the Reaction with Phenyl p-*Nitrobenzoate*: The separation procedures were the same as in the case of *a*). The alkaline extract from the ether solution of the pot residue and the ether extract from the aqueous solution containing aluminum chloride both gave *p*-nitrobenzoylacetone. This was then recrystallized from methanol; it melts at 113—114°C, undepressed on admixture with an authentic sample.

g) Product from the Reaction between Diacetylbenzoylmethane and Phenol: The mixture distilled with nitrobenzene, the ethereal extract from the aqueous layer containing aluminum chloride, and the pot residue were separated individually by the usual fractionation method into copper chelates of diacetylbenzoylmethane and of benzoylacetone. However, the former chelate from the pot residue was contaminated with *p*-hydroxyacetophenone, which was isolated by alkaline extraction.

Acylation of Phenol with Acid Chlorides and the Fries Rearrangement of Esters. For the former reaction, phenol was dissolved in a solution of aluminum chloride in nitrobenzene; then acid chloride was added. For the Fries rearrangement, the ester was added to the nitrobenzene solution of aluminum chloride. Each product obtained was treated according to the appropriate separation procedure described above.

Putranjic Acid. Synthesis and Stereostructure

Reiko AOYAGI, Yoshihiko MORIYAMA, Takahiko TSUYUKI, and Takeyoshi TAKAHASHI
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo
(Received July 6, 1972)

Putranjic acid, isolated from *Putranjiva roxburghii* has been synthesized from friedelane-2,3-dione and has been shown to be (2S)-2-hydroxy-3,4-seco-friedelan-3-oic acid.

Several friedelin derivatives have been isolated from stem-bark, leaves and seeds of *Putranjiva roxburghii* (Euphorbiacea).[1-10] From the acidic fraction of the stem-bark of the plant, Garg and Mitra[1,5] and Seshadri *et al.*[6,8] independently isolated putranjic acid[11] and putric acid, respectively, which were found to be the same triterpene monohydroxy-acid, 2-hydroxy-3,4-seco-friedelan-3-oic acid (I).

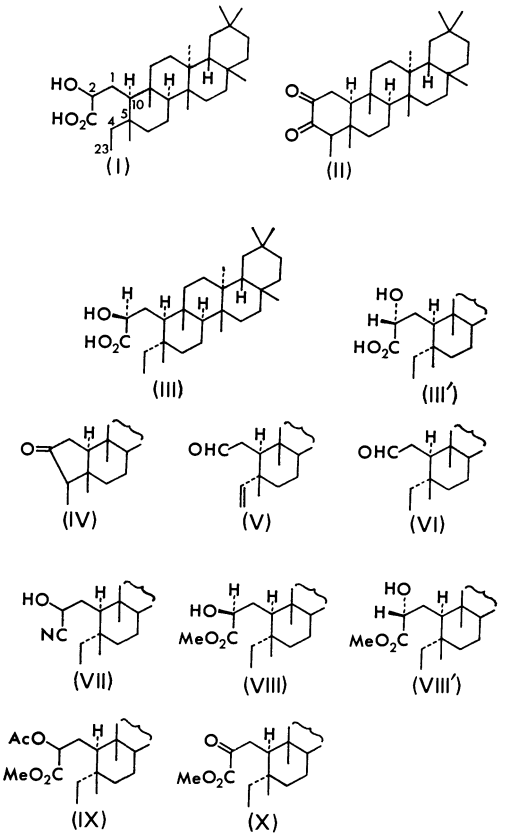
11) In this paper, we use the name putranjic acid, which was first given by Garg and Mitra to the acid.

The structure of putranjic acid[5,8] has been deduced from spectral and chemical data, although no direct comparison with friedelin derivatives has been made. Thus, the configuration of any asymmetric center in this acid has been left undetermined. In a preliminary communication,[12] we have reported the synthesis of putranjic acid from friedelane-2,3-dione (II). The complete stereostructure of putranjic acid has been shown to be (2S)-2-hydroxy-3,4-seco-friedelan-3-oic acid (III). Detailed experimental data are given below.[13]



Friedelane-2,3-dione (II)[14] was subjected to benzylic acid rearrangement by refluxing with potassium hydroxide in diethylene glycol. The resulting hydroxy-acid was treated with lead tetraacetate in acetic acid to give norfriedelin (IV),[15] which was shown to contain its epimer by glc examination. On treatment with base, the mixture afforded pure norfriedelin (IV). Thus the alkaline unstable component would probably be 4α-methyl epimer of IV.

Norfriedelin (IV) was irradiated with a high pressure mercury lamp in *n*-hexane and converted into 5α-vinyl-10β-formylmethyl-des-A-friedelane (V),[16] which on catalytic hydrogenation gave 5α-ethyl-10β-formylmethyl-des-A-friedelane (VI).[8] The saturated aldehyde (VI) was identical with a product which had been obtained by photoreaction of friedelin.[17]

The saturated seco-aldehyde (VI) was converted into its cyanohydrin derivative (VII), which was further hydrolyzed with hydrochloric acid and acetic acid. On treatment with diazomethane, the reaction products gave two hydroxy-esters (VIII and VIII') and an acetoxy-ester (IX). The hydroxy-esters (VIII and VIII') were separated by silica gel column chromatography into VIII [mp 176.5—177.0°C, $[\alpha]_D^{25}$ −2.0° ($CHCl_3$)] and VIII' [mp 133—134°C, $[\alpha]_D^{25}$ +2.5° ($CHCl_3$)]. The hydroxy-ester (VIII) was identical with methyl putrate (methyl putranjate,[1] mp 176°C, $[\alpha]_D$ −23.5°; methyl putrate,[8] mp 175—176°C, $[\alpha]_D$ −8.3°) with respect to mp, IR, NMR, MS, and tlc. There are some discrepancies between our optical rotation values and those reported by two Indian groups. The disagreements depend on the purity of the samples and on the accuracy of measurement.

The acetoxy-ester (IX) was hydrolyzed with potassium hydroxide and treated with diazomethane to give a mixture of VIII and VIII'. This shows that the acetoxy-ester (IX) consists of an epimeric mixture. The total yields of VIII and VIII' were 23.9 and 21.0%, respectively, from the saturated seco-aldehyde (VI).

Oxidation of VIII and VIII' with the Jones reagent gave the same keto-ester (X) [mp 153°C]; the spectral data were identical with those of methyl oxoputranjate[5] (methyl oxoputrate[8]).

The hydroxy-esters (VIII and VIII') were hydrolyzed with potassium hydroxide in ethanol to give hydroxy-acids, (III) [mp 227.0—227.5°C, $[\alpha]_D^{35}$ +19° ($CHCl_3$)] and (III') [mp 240.0—241.5°C, $[\alpha]_D^{35}$ −1.0° ($CHCl_3$)], respectively. The hydroxy-acid (III) was identical

Table

Acid		$[\alpha]_{Acid}$	$[\alpha]_{Me\text{-}ester}$	$[\alpha]_{Acid} - [\alpha]_{Me\text{-}ester}$
Lactic[18]	S	+ 3.82°	− 8.25°	+12.07°
	R	− 2.26°	+ 7.46°	− 9.72°
Leucic[19,20]	S	+19.4°	−12.5°	+31.9°

13) Sengupta *et al.* recently established the configurations of all asymmetric centers in putranjivic acid (3,4-seco-friedel-4(23)-en-3-oic acid) by synthesis of methyl putranjivate from friedel-3-ene through a lengthy pathway [P. Sengupta and A. K. Dey, *Tetrahedron*, **28**, 1307 (1972)]. The synthesis indicates the establishment of configurations of putranjic acid except C-2 position. The configuration at C-2 of putranjic acid was determined as S by CD measurement of its xanthate; This result is in line with our conclusion.

with natural putranjic acid with respect to mp, IR and optical rotation (putranjic acid,[1] mp 218—220°C, $[\alpha]_D$ +1°; putric acid,[8] mp 220—222°C, $[\alpha]_D$ +21.3°). The mixture with an authentic sample showed no melting point depression. While the optical rotation values of these two natural products did not coincide, our value was almost the same as that of Seshadri's group.

Optical rotations of some α-hydroxy carboxylic acids bearing methylene group in β-position and those of their methyl esters are listed in the Table. As a rule, the differences ($\Delta=[\alpha]_{Acid}-[\alpha]_{Me\text{-}ester}$) are positive in *S*-configuration and negative in *R*-configuration. The configuration at C-2 of putranjic acid should therefore be of *S*-configuration. Consequently putranjic acid is shown to be (2*S*)-2-hydroxy-3,4-seco-friedelan-3-oic acid; that is 10β-[(2*S*)-2-carboxy-2-hydroxy]ethyl-5α-ethyl-des-A-friedelane (III).

Experimental[21]

Isolation of Friedelane-2,3-dione (II). The "cork smoker wash solid"[22] was washed with acetone to remove the dark colored impurities and extracted with benzene below 15°C. Evaporation of the benzene gave a dark brown solid, to which hot acetone was added and heated for a while under reflux. The hot suspension was filtered. On cooling the filtrate gave a crude crystal, a 1:1 mixture of friedelin and friedelane-2,3-dione, which was dissolved in benzene and passed through a column of alumina. Friedelane-2,3-dione (II),[14] eluted with ethyl acetate, was crystallized from the same solvent, and showed mp 271—272°C. The content of II was about 30% based on the starting material.

Norfriedelin (IV) from II. A suspension of II (10 g) in diethylene glycol (250 ml) was heated under reflux with potassium hydroxide (10 g) for 4.5 hr under a nitrogen atmosphere. After cooling, water (1 l) was added. Precipitates were collected on a filter paper and washed with water. The dried precipitates were dissolved in acetic acid (1.5 l) and lead tetraacetate (24 g) was added to the solution, which was stirred for two days at room temperature. After destroying the excess lead tetraacetate with ethylene glycol (20 ml), the acetic acid was evaporated to give crude norfriedelin. The product gave one spot on tlc, but was shown to contain a small amount of its C-4 methyl epimer by glc examination (column; Diasolid H-523, 250°C, retention time 31.4 and 28.8 min, respectively). The epimeric mixture was treated with alkali to afford pure norfriedelin with a longer retention time. Recrystallization from acetone gave 6.0 g of norfriedelin (IV),[15] mp 240.5—241.5°C, ν_{max} (Nujol) 1735 cm^{-1}, M^+ 412.

5α-Vinyl-10β-formylmethyl-des-A-friedelane (V) from IV. Norfriedelin (IV, 997 mg) was irradiated with a high pressure mercury lamp in *n*-hexane (700 ml) for 45 hr under an argon atmosphere at room temperature. The reaction products were separated by silica gel column chromatography and an aldehyde fraction was collected and crystallized from acetone to afford 236 mg of 5α-vinyl-10β-formylmethyl-des-A-friedelane (V),[16] mp 162.5—163.5°C, ν_{max} (Nujol) 2700, 1713, 1660, 1000, and 903 cm^{-1}, M^+ 412, NMR ($CDCl_3$) δ 9.70 (t, J=2—3 Hz, -CHO).

5α-Ethyl-10β-formylmethyl-des-A-friedelane (VI) from V. The unsaturated seco-aldehyde (V, 600 mg) was dissolved in ethanol (60 ml) and hydrogenated in the presence of 10% Pd-C (14 mg) for 1 hr at room temperature. The usual treatment and recrystallization from ether gave 5α-ethyl-10β-formylmethyl-des-A-friedelane (VI,[8] 57.4 mg) as needles, mp 181.0—181.5°C, ν_{max} (Nujol) 2720 and 1708 cm^{-1}, no absorption of double bond, M^+ 414, NMR ($CDCl_3$) δ 9.70 (t, J=2—3 Hz, -CHO).

Methyl Putranjate (VIII) and Its Epimer (VIII') from VI. Saturated aldehyde (VI, 50 mg) was dissolved in ethanol (50 ml) and acetic acid (5 ml), and a solution of potassium cyanide (300 mg) in water (1 ml) was added dropwise under stirring at room temperature. The reaction mixture was further stirred for 12 hr and extracted with ether, and the ethereal extract was washed with water. Cyanohydrin (VII) was separated from the starting material (VI) by silica gel column chromatography. Without further purification, it was dissolved in a mixture of acetic acid (30 ml) and concentrated hydrochloric acid (3 ml). This was heated under reflux for 1 hr and after the usual work-up the reaction product was treated with diazomethane in ether and chromatographed on silica gel (50 g) to give three compounds. Fractions, first eluted with benzene, gave 13.6 mg of *O*-acetyl-ester (IX), ν_{max} (Nujol) 1750, 1225, 1078, and 1058 cm^{-1}, M^+ 516, NMR (CCl_4) δ 3.76 (s, $-COOCH_3$), 2.11 (s, $-OCOCH_3$). This fraction gave one spot on tlc.

A second product was collected by further elution of the same solvent. On recrystallization from methanol–water, 3.3 mg of VIII' was obtained, mp 133—134°C, $[\alpha]_D^{25}$ +2.5° (*c* 1.0, $CHCl_3$), ν_{max} (Nujol) 3520, 1708, 1065, and 1025 cm^{-1}, Found: C, 78.16; H, 11.22%. Calcd for $C_{31}H_{54}O_3$: C, 78.42; H, 11.47%. M^+ 474 (the fragmentation pattern was the same as that of VIII), NMR (CCl_4) δ 3.78 (s, $-COOCH_3$).

Further elution with the same solvent gave methyl putranjate (VIII). Recrystallization from methanol–water gave 6.0 mg of VIII, mp 176.5—177.0°C, $[\alpha]_D^{25}$ −2.0° (*c* 0.80, $CHCl_3$), ν_{max} (Nujol) 3530, 1730, and 1100 cm^{-1}, Found: C, 78.21; H, 11.48%. Calcd for $C_{31}H_{54}O_3$: C, 78.42; H, 11.47%. M^+ 474, NMR (CCl_4) δ 3.78 (s, $-COOCH_3$), 3.95 (t, J=5.5 Hz, -CHOH).

Acetoxy-ester (IX, 13.6 mg) was hydrolyzed with potassium hydroxide (20 mg) in ethanol (30 ml) at 40°C for 4 hr. The hydrolysate was treated with diazomethane in ether and separated by silica gel chromatography to give VIII (5.9 mg) and VIII' (7.2 mg) after recrystallization. Thus, the total yields of methyl putranjate (11.9 mg) and its epimer (10.9 mg) were 23.9 and 21.1%, respectively, based on the saturated aldehyde (VI).

Putranjic Acid (III) and Its Epimer (III') from VIII and VIII'. Methyl putranjate (VIII, 50 mg) and potassium hydroxide (10 mg) in ethanol (30 ml) were warmed at 40°C for 4 hr. The acid, after being acidified with hydrochloric acid, was extracted with ether and recrystallized from methanol–water, giving 47.5 mg of putranjic acid (III), mp 227.0—227.5°C, $[\alpha]_D^{35}$ +19° (*c* 0.38, $CHCl_3$) ν_{max} (Nujol) 3520 and 1720 cm^{-1}.

The epimeric acid (III', 35 mg) was obtained from VIII' (40 mg) by the same procedure, mp 240.0—241.5°C, $[\alpha]_D^{35}$ −1.0° (*c* 0.38, $CHCl_3$), ν_{max} (Nujol) 3430 and 1703 cm^{-1}.

Methyl Putranjate (VIII) from Putranjic Acid (III). To putranjic acid (18 mg) in ether (10 ml) was added diazomethane in ether. After evaporation the residue was chromatographed and recrystallized from methanol–water to

21) All melting points were determined on a hot block and uncorrected. IR and mass spectra were measured using Hitachi EPI-G2 and Hitachi RMU-6 spectrometers. NMR spectra were taken on a Hitachi Model R-24 NMR spectrometer at 60 MHz, using TMS as an internal standard. Tlc was carried out on silica gel G (E. Merck).

22) R. Stevenson, *J. Org. Chem.*, **26**, 2142 (1961).

yield methyl putranjate (VIII, 16 mg). Mp, IR, and tlc were identical with those of the authentic sample.

By the same procedure the epimeric acid (III′) was converted into the ester (VIII′).

Methyl Oxoputranjate (X) from VIII and VIII′. Methyl putranjate (VIII, 11.0 mg) was dissolved in acetone at 0—5°C and the Jones reagent (7 ml) was added dropwise with stirring for 1.5 hr. The reaction mixture was extracted with ether and the ethereal extract was washed with water. Distillation of the solvent and recrystallization from methanol gave methyl oxoputranjate (X, 10.0 mg) as white needles, mp 153°C, ν_{max} (Nujol) 1750, 1730, and 1083 cm^{-1}, Found: C, 78.52; H, 10.83%. Calcd for $C_{31}H_{52}O_3$: C, 78.76; H, 11.09%. NMR (CCl_4) δ 3.80 (s, $-COOCH_3$), 2.65 (q, $-CO-CH_2-$), 1.88 (t, J=6 Hz, C-10 H).[23]

The epimeric hydroxy-ester (VIII′) gave the same oxidation product (X) by the same reaction procedure.

The authors wish to thank Professor T. R. Seshadri for the generous gift of the authentic sample of methyl putrate, and Professor C. R. Mitra for the authentic sample of putranjic acid. The authors are also grateful to the Ministry of Education for a grant-in-aid.

23) Lit. methyl oxoputranjate,[5] mp 148—149°C, NMR δ 1.9 (t, J=5.5 Hz, 1H), 2.75 (q, J=5.5 and 4.5 Hz, 2H: methyl oxoputrate, mp 152—154°C, $[\alpha]_D$ +24.0°, ν_{max} (KBr) 1760 cm^{-1}, NMR (CCl_4) δ 3.82, 2·67 (q), 1.9 (t, J=5 Hz).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 572—576 (1973)

Syntheses of New Arginine Derivatives as a Substrate for Trypsin or Papain[1]

Norio NISHI and Junzo NOGUCHI

Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo

(Received July 13, 1972)

Two new enzymic substrates, tosyl-L(D or DL)-arginine-*p*-nitroanilide (L-TAPA, D-TAPA, and DL-TAPA) and acetyl-L(D or DL)-arginine-*p*-nitroanilide (L-AAPA, D-AAPA, and DL-AAPA) were synthesized by the route for benzoyl-L-arginine-*p*-nitroanilide (L-BAPA) reported previously. The previous method for synthesis of L-BAPA was then improved by the direct benzoylation of L-arginine-*p*-nitroanilide dihydrochloride (L-APA), into which N^{α}-benzyloxycarbonyl-N^{ω}-nitro-L-arginine-*p*-nitroanilide was converted by the simultaneous removal of benzyloxycarbonyl and nitro groups with hydrogen fluoride. This route has the advantages of shorter reaction steps and a better over-all yield than in the case of the previous method. The method is also applicable to the synthesis of L(D or DL)-AAPA, but it is hard to prepare L(D or DL)-TAPA by the method.

L-Arginine derivatives of amide,[2-5] the methyl or ethyl ester[6-10] and α- or β-naphthylamide[11,12] have been useful as substrates for trypsin or papain. However, it has been very difficult to synthesize the derivatives of L-arginine-*p*-nitroanilide because of the racemization during the synthetic process, although these materials seem to be useful in measuring photometrically the accurate activity of enzyme.[13] Recently, we prepared benzoyl-L-arginine-*p*-nitroanilide (L-BAPA) without any racemization.[14] Using L- and D-BAPA against papain, it was revealed that D-antipode acts as a competitive inhibitor against L-antipode. These materials were also utilized to study the reaction rate using DL-BAPA as a substrate.[15] In this paper, an improved method for the preparation of L-BAPA and the preparation of tosyl-L (D or DL)-arginine-*p*-nitroanilide hydrochloride (L-TAPA, D-TAPA, and DL-TAPA), acetyl-L (D or DL)-arginine-*p*-nitroanilide hydrochloride (L-AAPA, D-AAPA, and DL-AAPA), L-arginine-*p*-nitroanilide dihydrochloride (L-APA), and benzoyl-D-arginine-*p*-nitroanilide hydrochloride (D-BAPA)[13] will be described. These derivatives will be useful in giving some interesting information about the variation in the reaction mechanism of the enzyme according to the effect of the *N*-protecting groups and the inhibition by D-antipode.

Experimental

The ultraviolet and visible absorption spectra were measured with a Hitachi 124 spectrophotometer. The optical rotations

were measured with a Yanagimoto Direct-reading Polarimeter, Model OR-10, and an Automatic Recording Polarimeter, Model OR-1. The elemental analysis was carried out by means of a Yanagimoto C.H.N. Corder, Model MT-2, and a Coleman Nitrogen Analyser, Model 29. The melting points for the samples over 220°C were determined with a Mitamura hot-stage apparatus.

N^{α}-Benzyloxycarbonyl-N^{ω}-nitro-L-arginine-p-nitroanilide (I). This was prepared by a method previously described.[14]

N^{α}-Benzyloxycarbonyl-N^{ω}-nitro-DL-arginine-p-nitroanilide (DL-I). This was prepared from N^{α}-benzyloxycarbonyl-N^{ω}-nitro-DL-arginine (50.0 g, 142 mmol) and *p*-nitrophenyl isocyanate (47.0 g, 286 mmol) by the same method as I. Yield, 44 g (65.7%); mp 191°C. Found: C, 50.7; H, 4.78; N, 20.7%. Calcd for $C_{20}H_{23}N_7O_7$: C, 50.7; H, 4.90; N, 20.7%.

N^{α}-Benzyloxycarbonyl-N^{ω}-nitro-D-arginine-p-nitroanilide (D-I). This was prepared from N^{α}-benzyloxycarbonyl-N^{ω}-nitro-D-arginine[16] (3.0 g, 8.4 mmol) and *p*-nitrophenyl isocyanate (2.8 g, 17.0 mmol) by the same method as I. Yield, 3.1 g (77.5%); mp 178°C; $[\alpha]_D^{29}$ −53.0° (*c* 1.05, HMPA[17]).

N^{ω}-Nitro-L-arginine-p-nitroanilide Hydrobromide (II). This was prepared by the method previously described.[14]

N^{ω}-Nitro-DL-arginine-p-nitroanilide Hydrobromide (DL-II). This was prepared by the same method as II from N^{α}-benzyloxycarbonyl-N^{ω}-nitro-DL-arginine-*p*-nitroanilide (DL-I) (40.0 g, 84.5 mmol), using hydrogen bromide. Yield, 32.0 g (90.1%); mp 155°C. Found: C, 34.5; H, 4.58; N, 22.9; Br, 18.8%. Calcd for $C_{12}H_{18}N_7O_5Br$: C, 34.3; H, 4.32; N, 23.3; Br, 19.0%.

N^{ω}-Nitro-D-arginine-p-nitroanilide Hydrobromide (D-II). This was prepared by the same method as (II) from N^{α}-benzyloxycarbonyl-N^{ω}-nitro-D-arginine-*p*-nitroanilide (D-I) (6.6 g, 13.9 mmol), using hydrogen bromide. Yield, 4.2 g (71.7%); mp 175°C; $[\alpha]_D^{25}$ −43.1° (*c* 1.0, DMF[18]). Found: C, 34.9; H, 4.41; N, 23.0; Br, 18.7%. Calcd for $C_{12}H_{18}N_7O_5Br$: C, 34.3; H, 4.32; N, 23.3; Br, 19.0%.

L-Arginine-p-nitroanilide Dihydrochloride (L-APA. III). N^{α}-Benzyloxycarbonyl-N^{ω}-nitro-L-arginine-*p*-nitroanilide (I, 15.0 g, 31.7 mmol) was treated with hydrogen fluoride at 0°C for 3 hr to remove the nitro and the benzyloxycarbonyl groups; the procedure was the same as that used for N^{α}-tosyl-N^{ω}-nitro-L-arginine-*p*-nitroanilide (V). After the evaporation of hydrogen fluoride, the residue was dissolved in 400 ml of water, then, the solution was extracted with ether to remove the anisole. To the aqueous solution, treated with charcoal, 12M hydrochloric acid (5.2 ml, 62.4 mmol) was added; the solution was then evaporated to dryness in order to convert the hydrofluoride into the hydrochloride. In order to replace the hydrofluoride completely with hydrochloride, the residue was dissolved again in 1M hydrochloric acid (60 ml, 60 mmol) and the solution was evaporated to dryness. The crystalline hydrochloride was collected with ethanol and then dried. 9.7 g (83.3%); mp 242°C. It was recrystallized from water and ethanol. Yield, 9.4 g (80.8%); mp 245°C; $[\alpha]_D^{23}$ +81.7° (*c* 1, water). Found: C, 39.5; H, 5.72; N, 22.7; Cl, 19.1%. Calcd for $C_{12}H_{20}N_6O_3Cl_2$: C, 39.2; H, 5.49; N, 22.9; Cl, 19.3%.

N^{α}-Tosyl-N^{ω}-nitro-L-arginine-p-nitroanilide (V). N^{ω}-Nitro-L-arginine-*p*-nitroanilide hydrobromide (II, 5.0 g, 11.9 mmol) was dissolved in a mixture of tetrahydrofuran and water (9:1, 50 ml) and then cooled to −3°C. After the addition of triethylamine (3.8 ml, 27.4 mmol) to the solution, tosyl chloride (2.95 g, 15.5 mmol) in 9 ml of tetrahydrofuran was dropped with stirring over 5 min. After reaction for 2 hr, it was kept for another 3 hr at room temperature. Then the solution was evaporated to dryness at room temperature. The residue was crystallized by washing it with ether, water, 1M hydrochloric acid, water, and 5% sodium bicarbonate successively. The crystals were collected by filtration, washed with water and ether, and then dried. Yield, 5.8 g (98.8%); mp 155°C. It was recrystallized from tetrahydrofuran and water. Yield, 5.3 g (90.3%); mp 161°C; $[\alpha]_D^{20}$ −3.6° (*c* 1.0, HMPA). Found: C, 46.2; H, 4.67; N, 19.6%. Calcd for $C_{19}H_{23}N_7O_7S$: C, 46.2; H, 4.70; N, 19.9%.

N^{α}-Tosyl-N^{ω}-nitro-DL-agrinine-p-nitroanilide (DL-V). This was prepared by a method similar to that used for V from N^{ω}-nitro-DL-arginine-*p*-nitroanilide hydrobromide (DL-II) (5.0 g, 11.9 mmol) and tosyl chloride (2.94 g, 15.4 mmol). Yield, 5.2 g (88.6%); mp 214°C. Found: C, 46.1; H, 4.82; N, 19.6%. Calcd for $C_{19}H_{23}N_7O_7S$: C, 46.2; H, 4.70; N, 19.9%.

N^{α}-Tosyl-N^{ω}-nitro-D-arginine-p-nitroanilide (D-V). This was prepared from N^{ω}-nitro-D-arginine-*p*-nitroanilide hydrobromide (D-II) (1.0 g, 2.38 mmol) and tosyl chloride (0.59 g, 3.10 mmol) by the same method as was used for V. Yield, 1.0 g (85.2%); mp 161°C; $[\alpha]_D^{20}$ +3.6° (*c* 1.0, HMPA).

N^{α}-Tosyl-L-arginine-p-nitroanilide Hydrochloride (L-TAPA, VIII). N^{α}-Tosyl-N^{ω}-nitro-L-arginine-*p*-nitroanilide (V, 5 g, 10.1 mmol) was mixed with anisole (5 ml, 46.2 mmol) in a HF-reaction cylinder. Forty milliliters of hydrogen fluoride dried with CoF_3 were collected in the cylinder under cooling with liquid nitrogen; the mixture was then allowed to react at 0°C for 40 min with stirring. The excess HF was removed under reduced pressure, and the residue was kept *in vacuo* for another 2 hr. The residue was crystallized by trituration with ether. The crystallized hydrofluoride was suspended in 200 ml of 3M hydrochloric acid and then stirred for one hour at room temperature to convert it into the hydrochloride. After cooling, the crystalline hydrochloride was filtered, washed with 3M hydrochloric acid and a small amount of ice cold water, and then dried. In order to complete the replacement of hydrochloride, a 75 ml portion of 3M hydrochloric acid was added to the hydrofluoride salt in glacial acetic acid and the solution was evaporated *in vacuo* to dryness at room temperature. The residue was again dissolved in a mixed solvent of acetic and hydrochloric acid, and the solvent was removed, repeatedly; then it was recrystallized from ethanol. Yield, 3.7 g (75.3%); mp 245°C; $[\alpha]_D^{23}$ −32.0° (*c* 1.0, DMF). Found: C, 47.2; H, 5.13; N, 17.0; Cl, 7.10%. Calcd for $C_{19}H_{25}N_6O_5ClS$: C, 47.1; H, 5.20; N, 17.3; Cl, 7.31%.

N^{α}-Tosyl-L-arginine-p-nitroanilide p-Toluenesulfonate (L-TAPA·CH_3·C_6H_4·SO_3H, X). L-Arginine-*p*-nitroanilide dihydrochloride (III, 1.4 g, 3.81 mmol) was dissolved in water (56 ml), and then the mixture was cooled to 0°C. After adding an ether solution (56 ml) of tosyl chloride (0.94 g, 4.95 mmol), an aqueous solution (5 ml) of sodium hydroxide (0.50 g, 12.5 mmol) was dropped in over a thirty-minute period with vigorous stirring. The reaction was continued for one hour at 0°C and for 2 hr at room temperature. Carbon dioxide was bubbled into it for a few minutes to precipitate crystals. This material was dissolved in a mixture of 1M hydrochloric acid and glacial acetic acid, and then the solution was evaporated to dryness. The product was collected with water and recrystallized from water. Yield, 0.30 g (12.7%); mp 206°C. Found: C, 50.0; H, 5.16; N, 13.4%. Calcd for $C_{26}H_{32}N_6O_8S_2$: C, 50.3; H, 5.20; N, 13.5%.

N^{α}-Tosyl-DL-arginine-p-nitroanilide Hydrochloride (DL-TAPA, DL-VIII). This was prepared by the same method as

16) H. Yajima and K. Kubo, *J. Amer. Chem. Soc.*, **87**, 2039 (1965).
17) HMPA: hexamethylphosphoramide.
18) DMF: dimethylformamide.

was used for VIII from N^{α}-tosyl-N^{ω}-nitro-DL-arginine-*p*-nitroanilide (DL-V) (4.0 g, 8.11 mmol), using hydrogen fluoride. Yield, 3.1 g (78.9%); mp 224°C. Found: C, 46.7; H, 5.11; N, 17.3; Cl, 7.20%. Calcd for $C_{19}H_{25}N_6O_5ClS$: C, 47.1; H, 5.20; N, 17.3; Cl, 7.31%.

N^{α}-*Tosyl-*D*-arginine-*p*-nitroanilide Hydrochloride (*D*-TAPA. *D*-VIII).* This was prepared by the same method as was used for VIII from N^{α}-tosyl-N^{ω}-nitro-D-arginine-*p*-nitroanilide (D-V) (0.9 g, 1.83 mmol), using hydrogen fluoride. Yield, 0.7 g (79.1%); mp 245°C; $[\alpha]_D^{23}$ +32.3° (*c* 1.0, DMF). Found: C, 47.2; H, 47.2; H, 5.18; N, 17.1; Cl, 7.10%. Calcd for $C_{19}H_{25}N_6O_5ClS$: C, 47.1; H, 5.20; N, 17.3; Cl, 7.31%.

N^{α}-*Acetyl-*N^{ω}*-nitro-*L*-arginine-*p*-nitroanilide (VI).* N^{α}-Nitro-L-arginine-*p*-nitroanilide hydrobromide (II, 10 g, 23.8 mmol) was dissolved in a mixture of tetrahydrofuran and water (9: 1, 100 ml), and then the mixture was cooled to −3°C. After the addition of triethylamine (7.7 ml, 55.6 mmol) to the solution, acetic anhydride (3.2 ml, 31.7 mmol) was dropped into it with stirring in 5 min. After 4 hr, the pH was adjusted to 4 by the addition of 1M hydrochloric acid, and then the solution was evaporated to dryness at room temperature. The residue was crystallized by treatment with 1M hydrochloric acid, filtered, washed with water, and then dried. Yield, 7.8 g (86.0%); mp 185°C. It was then recrystallized from DMF and water. Yield, 7.5 g (82.7%); mp 193°C; $[\alpha]_D^{29}$ +61.7° (*c* 1.0, HMPA). Found: C, 44.5; H, 4.70; N, 25.4%. Calcd for $C_{14}H_{19}N_7O_6$: C, 44.1; H, 5.02; N, 25.7%.

N^{α}-*Acetyl-*N^{ω}*-nitro-*DL*-arginine-*p*-nitroanilide (DL-VI).* This was prepared by the same method as was used for VI from N^{ω}-nitro-DL-arginine-*p*-nitroanilide hydrobromide (DL-II) (5.0 g, 11.9 mmol) and acetic anhydride (1.8 ml, 17.8 mmol). Yield, 3.5 g (77.2%); mp 215°C. Found: C, 44.2; H, 4.93; N, 25.4%. Calcd for $C_{14}H_{19}N_7O_6$: C, 44.1; H, 5.02; N, 25.7%.

N^{α}-*Acetyl-*N^{ω}*-nitro-*D*-arginine-*p*-nitroanilide (D-VI).* This was prepared by the same method as was used for VI from N^{ω}-nitro-D-arginine-*p*-nitroanilide hydrobromide (D-II) (1.0 g, 2.38 mmol) and acetic anhydride (0.36 ml, 3.56 mmol). Yield, 0.6 g (66.2%); mp 193°C, $[\alpha]_D^{29}$ −61.9° (*c* 1.0, HMPA).

N^{α}-*Acetyl-*L*-arginine-*p*-nitroanilide Hydrochloride (*L*-AAPA. IX).* (Method A). N^{α}-Acetyl-N^{ω}-nitro-L-arginine-*p*-nitroanilide (VI, 5.0 g, 13.1 mmol) was treated with hydrogen fluoride to remove the nitro group by the same procedure as was used for N^{α}-tosyl-N^{ω}-nitro-L-arginine-*p*-nitroanilide (V). After treatment with ether, the dried residue of hydrofluoride was dissolved in a mixture of 1M hydrochloric acid (70 ml) and glacial acetic acid (30 ml): then the solution was evaporated to dryness *in vacuo* at room temperature to convert it into its hydrochloride. The residue was crystallized with acetone, filtered, washed with acetone, and then dried. Yield, 4.6 g (85.5%); mp 135—136°C. This crude material was then dissolved in a small amount of 1M hydrochloric acid, and acetone was added to the mixture until the solution was faintly clouded. N^{α}-Acetyl-L-arginine-*p*-nitroanilide hydrochloride was crystallized out on standing at 0°C with trituration by repeating the gradual addition of acetone and cooling. The crystals were filtered out, washed with acetone, and then dried. Yield, 3.9 g (72.8%); mp 139°C; $[\alpha]_D^{20}$ −19.0° (*c* 1.0, water). Found: C, 41.0; H, 6.00; N, 20.4; Cl, 9.00%. Calcd for $C_{14}H_{21}O_4N_6Cl \cdot 2H_2O$: C, 41.1; H, 6.16; N, 20.6; Cl, 8.67%.

(Method B). L-Arginine-*p*-nitroanilide dihydrochloride (III, 0.3 g, 0.82 mmol) was dissolved in water (12 ml), the solution was cooled to 0°C after ether (12 ml) had then been added. Acetic anhydride (0.09 ml) and then an aqueous solution (1.4 ml) of sodium carbonate (0.14 g, 1.27 mmol) were added into it with vigorous stirring. The reaction mixture was kept for 1 hr at 0°C and then for another hour at room temperature. The solution was evaporated to dryness after being acidified to pH 3 with concentrated hydrochloric acid. The residue was dissolved in a mixture of 1M hydrochloric acid and glacial acetic acid (1:1 v/v, 20 ml) and the solution was evaporated to dryness. After this procedure had been repeated once more, the residue was dissolved in ethanol to remove the sodium chloride and the solution was evaporated. The crude product was recrystallized from 1M hydrochloric acid and acetone by the same procedure as that of Method A. Yield, 0.25 g (74.8%); mp 139°C; $[\alpha]_D^{20}$ −19.0° (*c* 1.0, water).

N^{α}-*Acetyl-*DL*-arginine-*p*-nitroanilide Hydrochloride (*DL*-AAPA, DL-IX).* This was prepared by the same method as was used for IX from N^{α}-acetyl-N^{ω}-nitro-DL-arginine-*p*-nitroanilide (DL-VI) (3.0 g, 7.87 mmol), using hydrogen fluoride. Yield, 2.8 g (91.1%); mp 230°C. Found: C, 42.9; H, 5.60; N, 21.2; Cl, 9.00%. Calcd for $C_{14}H_{21}O_4N_6Cl \cdot H_2O$: C, 43.0; H, 5.93; N, 21.5; Cl, 9.07%.

N^{α}-*Acetyl-*D*-arginine-*p*-nitroanilide Hydrochloride (*D*-AAPA, D-IX).* This was prepared by the same method as was used for IX from N^{α}-acetyl-N^{ω}-nitro-D-arginine-*p*-nitroanilide (D-VI) (0.5 g, 1.31 mmol), using hydrogen fluoride. Yield, 0.3 g (56.0%); mp 139°C; $[\alpha]_D^{20}$ +19.0° (*c* 1.0, water). This product was lyophilized and stored in a dark place. Found: C, 41.3; H, 5.93; N, 20.1; Cl, 9.0%. Calcd for $C_{14}H_{21}O_4N_6Cl \cdot 2H_2O$: C, 41.1; H, 6.16; N, 20.6; Cl, 8.67%.

N^{α}-*Benzoyl-*L*-arginine-*p*-nitroanilide Hydrochloride (*L*-BAPA, VII).* (Method A). L-Arginine-*p*-nitroanilide dihydrochloride (III, 5.0 g, 13.6 mmol) was dissolved in water (200 ml) and then cooled to 0°C. After the addition of benzoyl chloride (1.75 ml, 15.2 mmol) and ether (200 ml) to the solution, an aqueous solution (23 ml) of sodium carbonate (2.25 g, 21.2 mmol) was dropped into it with vigorous stirring in 15 min. The reaction mixture was kept for 1 hr at 0°C and for 3 hr at 20°C. The precipitate was then collected by filtration and washed with a small amount of water. To a hot solution of this material in 50% acetic acid (100 ml), 1M hydrochloric acid (50 ml) was added and nitrogen was bubbled in for a few minutes. After it had then been cooled to room temperature, the solution was evaporated to dryness and the residue was treated with ethanol and evaporated repeatedly to remove the acetic acid completely. It was then recrystallized from ethanol. Yield, 4.6 g (77.7%); mp 225°C; $[\alpha]_D^{25}$ +14.2° (*c* 1.0, water). Found: C, 52.2; H, 5.35; N, 19.2; Cl, 8.00%. Calcd for $C_{19}H_{23}N_6O_4Cl$: C, 52.2; H, 5.33; N, 19.3; Cl, 8.15%.

(Method B). N^{α}-Benzyloxycarbonyl-N^{ω}-nitro-L-arginine-*p*-nitroanilide (I, 5 g, 10.5 mmol) was treated with hydrogen fluoride as has been described in the case of L-arginine-*p*-nitroanilide dihydrochloride (L-APA, III). After the evaporation of the hydrogen fluoride, the residue was dissolved in water (150 ml) and the solution was extracted with ether to remove the anisole. The aqueous solution was then cooled to 0°C, and the pH was adjusted to 9 by the addition of sodium carbonate. Benzoyl chloride (1.25 ml, 10.8 mmol) and ether (10 ml) were vigorously stirred into it, and the reaction was continued for 2 hr. The precipitate in a syrup was crystallized by acidification to pH 1—2 with concentrated hydrochloric acid and then kept overnight in an ice box. The crystalline product was filtered, washed successively with dilute hydrochloric acid, a small amount of ice water, and ether, and then dried. It was subsequently recrystallized from ethanol. Yield, 2.5 g (53.8%); mp 224°C. The product was dissolved in hot water (50 ml) and treated with charcoal; the solution was concentrated to about 15 ml and then crystallized with

trituration. To the mixture, 1M hydrochloric acid (15 ml) was added, after which the mixture was cooled for one hour at 0°C. The crystalline N^{α}-benzoyl-L-arginine-*p*-nitroanilide hydrochloride was filtered, washed with a small amount of water, and then dried. Yield, 2.4 g (52.3%); mp 225°C; $[\alpha]_D^{25}$ +14.2° (*c* 1.0, water). Found: C, 52.7; H, 5.47; N, 19.4; Cl, 8.1%. Calcd for $C_{19}H_{23}N_6O_4Cl$: C, 52.5; H, 5.33; N, 19.3; Cl, 8.15%.

N^{α}-*Benzoyl*-N^{ω}-*nitro*-D-*arginine*-p-*nitroanilide (*D-*IV)*. This was prepared by the same method as was used for IV[14] from N^{ω}-nitro-D-arginine-*p*-nitroanilide hydrobromide (D-II) (1.0 g, 2.38 mmol) and benzoyl chloride (0.31 ml, 2.62 mmol). Yield, 0.7 g (66.4%); mp 246°C; $[\alpha]_D^{26}$ −61.0° (*c* 1.12, HMPA).

N^{α}-*Benzoyl*-D-*arginine*-p-*nitroanilide Hydrochloride (*D-*BAPA,* D-*VII)*. This compound was prepared by the same method as was used for VII[14] from N^{α}-benzoyl-N^{ω}-nitro-D-arginine-*p*-nitroanilide (D-IV) (0.65 g, 1.47 mmol), using hydrogen fluoride. It has no crystalline water and is sparingly soluble in water. Yield, 0.4 g (62.7%); mp 225°C; $[\alpha]_D^{25}$ −14.2° (*c* 1.0, water). Found: C, 52.7; H, 5.47; N, 19.0; Cl, 8.0%. Calcd for $C_{19}H_{23}N_6O_4Cl$: C, 52.5: H, 5.33; N, 19.3; Cl, 8.15%.

To make it easily soluble in water, it was redissolved in water and lyophilized. The crystals contain crystalline water and were stored in a brown sample bottle. Found: C, 47.9; H, 5.94; N, 17.5; Cl, 7.20%. Calcd for $C_{19}H_{23}N_6O_4Cl \cdot 2.5H_2O$: C, 47.6; H, 5.88; N, 17.5; Cl, 7.39%, mp 100—150° (broad).

The Ultraviolet and Visible Absorption Spectra of L-*TAPA,* L-*AAPA, and* L-*APA*. The ultraviolet and visible absorption spectra of L-TAPA, L-AAPA, and L-APA in an aqueous sodium chloride solution are shown in Fig. 1. The absorption spectra of L-BAPA[14] and *p*-nitroaniline[13] are also shown in Fig. 1. The values of the molar extinction coefficients, ε, at the optimum absorptions are as follows:

L-TAPA: 317 mμ, $\varepsilon = 1.10 \times 10^4$
L-AAPA: 316 mμ, $\varepsilon = 1.14 \times 10^4$
L-APA: 304 mμ, $\varepsilon = 1.14 \times 10^4$

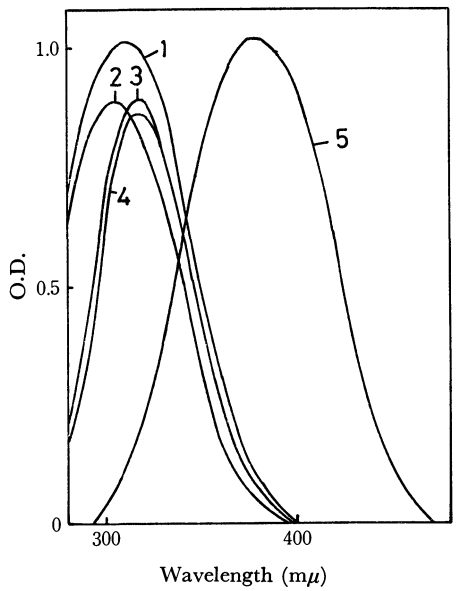

Fig. 1. Absorption spectra of L-AAPA, L-TAPA, and L-APA, all at concentration of 7.8×10^{-5}M in 0.05M NaCl solution, pH 6.2 and 22°C. 1: L-BAPA[12,1)], 2: L-APA, 3: L-AAPA, 4: L-TAPA, 5: *p*-nitroaniline.[12)]

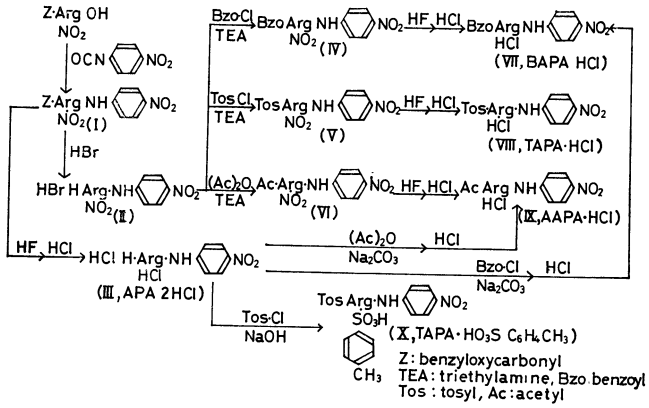
Results and Discussion

The synthetic routes shown in this paper are summarized in Scheme 1.



Scheme 1.

The Syntheses of L(D *or* DL)-*TAPA,* L(D *or* DL)-*AAPA, and* D-*BAPA*. The synthetic route of optically active L-BAPA described previously[14] was followed in order to avoid the racemization through the formation of oxazolone in the reaction. N^{α}-Benzyloxycarbonyl-N^{ω}-nitro-L-agrinine-*p*-nitroanilide was prepared by a reaction between N^{α}-benzyloxycarbonyl-N^{ω}-nitro-L-arginine and *p*-nitrophenyl isocyanate, because the α-carboxyl group of N^{α}-benzyloxycarbonyl-N^{ω}-nitro-arginine can easily be cyclized into its δ-lactam, also, the amino group of *p*-nitroaniline is too inactive to form an amide bond in the ordinary way. The benzyloxycarbonyl group was removed with hydrogen bromide, and then the product was benzoylated by benzoyl chloride; finally, the nitro group was removed with hydrogen fluoride[19] into L-BAPA. This route was also applicable to the synthesis of L-AAPA (IX) and L-TAPA (VIII) by acetylation or tosylation. The nitro group with hydrogen fluoride could be sufficiently removed in 40 min at 0°C, as was L-BAPA. The hydrofluoride of L-TAPA formed by denitration with hydrogen fluoride is convertible into its hydrochloride up to about 90% by stirring the suspension of the salt in 3M hydrochloric acid for 1 hr at room temperature. Then, the product was dissolved in a mixture of glacial acetic acid and 3M hydrochloric acid (1: 1 v/v) at room temperature and the solvent was evaporated *in vacuo*. Since L-AAPA is soluble in hydrochloric acid, L-AAPA hydrofluoride can be converted into its hydrochloride by the repeated concentration of the solution in a mixture of glacial acetic acid and 1M hydrochloric acid (1: 1 v/v) at room temperature. The calcium nitrate test of hydrogen fluoride showed negative in the L-TAPA hydrochloride and L-AAPA hydrochloride produced. DL-TAPA, and DL-AAPA, and D-TAPA, D-AAPA, and D-BAPA, were also prepared from DL-arginine hydrochloride and D-arginine hydro-

19) S. Sakakibara, Y. Shimonishi, Y. Kishida, M. Okada, and H. Sugihara, This Bulletin, **40**, 2164 (1967); S. Sakakibara, Y. Kishida, R. Nishizawa, and Y. Shimonishi, *ibid.*, **41**, 438 (1968); S. Sakakibara, N. Nakamizo, Y. Kishida, and S. Yoshimura, *ibid.*, **41**, 1477 (1968).

chloride respectively by the same method. These properties are summarized below:

Compound	Mp (°C)	$[\alpha]_D$ (°)	ε at optimum absorption
L-TAPA·HCl	245	−32.0 (*c* 1.0, DMF)	1.10×10^4 (317 mμ)
D-TAPA·HCl	245	+32.3 (*c* 1.0, DMF)	
DL-TAPA·HCl	224	0	
L-AAPA·HCl·$2H_2O$	139	−19.0 (*c* 1.0, water)	1.14×10^4 (316 mμ)
D-AAPA·HCl·$2H_2O$	139	+19.0 (*c* 1.0, water)	
DL-AAPA·HCl·H_2O	230	0	
L-APA·2HCl	245	+81.7 (*c* 1.0, water)	1.14×10^4 (304 mμ)
D-BAPA·HCl	225	−14.2 (*c* 1.0, water)	

The Improved Synthetic Method of L-*BAPA and* L-*AAPA.* The method of synthesizing L-BAPA through the (I)—L-APA(III)—L-BAPA(VII) route had shorter reaction steps and a better overall yield than the previous method.[14] L-Arginine-*p*-nitroanilide dihydrochloride (L-APA, III) was derived from N^{α}-benzyloxycarbonyl-N^{ω}-nitro-L-arginine-*p*-nitroanilide (I) by the simultaneous removal of the benzyloxycarbonyl group and the nitro group with hydrogen fluoride, after which the hydrofluoride was converted into its hydrochloride by a method similar to that described above. In this case, the protecting groups were removed with hydrogen fluoride for 3 hr at 0°C, because the complete reaction had hardly proceeded at all in 40 min at 0°C. L-BAPA(VII) was obtainable from L-APA (III) by the benzoylation of the α-amino group with sodium carbonate as a base. The reaction was carried out homogeneously in emulsion by vigorous stirring in a mixture of water and ether (1: 1 v/v). By this route, L-BAPA can be prepared in one step from I without isolating L-APA. The yield of L-BAPA in the method is 52—63%. Moreover, the experimental treatment was simplified exceedingly. L-AAPA was also prepared by the same method, but the expected results were not obtained in the preparation of L-TAPA by the direct tosylation of L-APA. L-APA does not react with tosyl chloride in sodium carbonate, but forms *p*-toluenesulfonate of L-TAPA in sodium hydroxide; the yield was very low and it was very difficult to convert it into its hydrochloride. Therefore, this method seems to be unsuitable for the preparation of L-TAPA.

The Attempts at the Preparations of D-*TAPA and* D-*AAPA by Enzymic Digestion.* Erlanger *et al.* prepared D-BAPA by the enzymic digestion of DL-BAPA.[13] We have now used the method in the preparation of D-TAPA and D-AAPA from DL-TAPA and DL-AAPA, but we found it to be almost entirely unsuitable in both cases. In DL-TAPA, the reaction proceeds very slowly and, a large amount of enzymes and a long reaction time were necessary to complete the reaction; moreover, it was necessary to use a lot of solution for the reaction, because DL-TAPA was more sparingly soluble in water than DL-BAPA. In the case of DL-AAPA, the self-decomposition of DL-AAPA was assumed in a phosphate buffer and the D-AAPA produced was easily soluble in water and was very difficult to separate from the sub-products, such as acetyl-L-arginine or *p*-nitroaniline, and enzymes. Although D-BAPA was prepared from DL-BAPA by the biochemical method, the direct synthesis seems to be more easier than the enzymic preparation. The absorption spectra of TAPA, AAPA, and APA have their bases at about 400 mμ much like BAPA, and the enzymic activity can be measured by means of the amount of *p*-nitroaniline formed at 410 mμ, the same as with BAPA. When TAPA is used as a substrate, DMF or DMSO should be used to increase the solubility in water. AAPA and APA are easily soluble in water and may be used as substrate or inhibitor, although AAPA tends to self-decompose into the deacetylation or cleavage of the amide bond in a phosphate buffer. When L(D)-BAPA was stocked in a crystalline form, a part of it sometimes became sparingly soluble in water, although no changes were assumed in the chromatography or absorption spectrum. The lyophilized crystal contains crystalline water and is more easily soluble in water than the crystal without water. Therefore, it is desirable to use the lyophilize method in the preparation of L(D)-BAPA as a substrate. The details of the substrates will be published elsewhere.

The authors are very much indebted to Dr. Seiichi Tokura for the measurement of the enzymic activity.

New Syntheses of Maculosidine and Pteleine

Tetsuya SEKIBA

Faculty of Chemical Engineering, Toyama Technical College, Hongo, Toyama

(Received July 14, 1972)

2,3-Dihydromaculosidine and 2,3-dihydropteleine were obtained from 2,4-dimethoxy- and 4-methoxy-aniline by condensation with diethyl β-benzyloxyethylmalonate, followed by methylation and subsequent cyclodebenzylation with polyphosphoric acid. The dehydrogenation of the dihydro compounds with 2,3-dichloro-5,6-dicyanobenzoquinone gave maculosidine (4,6,8-trimethoxyfuro[2,3-*b*]quinoline) and pteleine (4,6-dimethoxyfuro[2,3-*b*]quinoline) in relatively high yields. Similarly, evolitrine (4,7-dimethoxyfuro[2,3-*b*]quinoline) and γ-fagarine (4,8-dimethoxyfuro[2,3-*b*]quinoline) were also prepared.

Maculosidine, together with kokusaginine, was isolated from the leaves of *Flindersia maculosa* Lindl.[1] Its structure can be represented as 4,6,8-trimethoxyfuro[2,3-*b*]quinoline (Ia), as has been shown by spectral and degradative studies.[2] Pteleine (4,6-dimethoxyfuro[2,3-*b*]quinoline (Ib)) was found in the roots of *Platydesma campanulata* Mann[3] and *Ptelea trifoliata* L.[4] The syntheses of Ia[5] and Ib[6] from 2,4-dimethoxyaniline (IIa) and 4-methoxyaniline (IIb) were reported by Govindachari and his co-workers, and by Pai *et al.*, according to the method of Tuppy and Böhm.[7] This procedure, however, was troublesome and did not give satisfactory results.

This paper will describe convenient syntheses of Ia, b from IIa, b by a modification of Ohta and Mori's method.[8] In a similar manner, improved syntheses of evolitrine (Ic, 4,7-dimethoxyfuro[2,3-*b*]quinoline) and γ-fagarine (Id, 4,8-dimethoxyfuro[2,3-*b*]quinoline) can also be realized.

With the removal of ethanol (two moles), the condensation of aniline derivatives (IIa—d) and diethyl β-benzyloxyethylmalonate in diphenyl ether gave the 4-hydroxy-2-quinolone derivatives (IIIa—d), which were then easily methylated with diazomethane into the 4-methoxy compounds (IVa—d). While the IR spectra of IVa—d indicated the absence of the hydroxyl group, which was present in those of IIIa—d (*ca.* 3200—3500 cm^{-1}) (Table 1), the NMR spectra[9] of

a) Nujol b) KBr

IVa—d exhibited signals for three protons (δ *ca.* 3.93s ppm) (Table 2) of the methoxy group. IVa—d gave positive color reactions with ferric chloride in ethanol (*e.g.*, IVa (reddish brown)), suggesting the presence of a keto-enol tautomerism of the amide group. The cyclodebenzylation of IVa—d with polyphosphoric acid yielded 2,3-dihydrofuro[2,3-*b*]quinoline derivatives (Va—d). The structures of Va—d were assigned on the basis of the NMR spectra, which showed signals at δ *ca.* 3.5t and 4.5t attributable to two methylene protons of a dihydrofuran ring system (Table 3). Difficulty had been experienced in the dehydrogenation of the dihydro derivatives of furoquinoline alkaloids (*e.g.*, dihydroacronycidine[10] and dihydrokokusaginine[11,12]) by treatment with *N*-bromosuccinimide, followed by dehydrobromination. The dehydrogenation of Va—d with 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ), however, gave furo[2,3-*b*]quinoline derivatives (maculosidine (Ia),[1] pteleine (Ib),[3,4] evolitrine (Ic),[13]

off. The solution was then poured into 300 ml of petroleum benzine, and the mixture was allowed to stand overnight. The solvent was decanted, and the residual oily precipitate was dissolved in chloroform. The chloroform solution was extracted with five 100 ml portions of a 5% sodium hydroxide solution. Washed with chloroform, the alkaline solution was acidified with an aqueous acetic acid solution (1: 1). The acidic solution was extracted with chloroform. After the solvent had been evaporated, the residue was triturated with ether and recrystallized to give IIIa—d (Tables 1, 4).

3-(2-Benzyloxyethyl)-4-methoxy-2-quinolones (IVa—d). A solution of IIIa—d (5.0 g) in chloroform (70 ml) was treated with an ethereal diazomethane solution, and then the mixture was allowed to stand overnight. After a usual work-up, the product was recrystallized to give IVa—d (Tables 1,2,5), which gave a light brown or a reddish brown color with ferric chloride in ethanol.

2,3-Dihydrofuro[2,3-b]quinolines (Va—d). A mixture of IVa—d (0.7 g) and polyphosphoric acid (13 g) was heated at 120—130°C for 1.5—3 hr. The cooled mixture was poured into water, and the insoluble materials were filtered off. The aqueous solution was neutralized with diluted aqueous ammonia. The precipitate was collected, washed with water, and recrystallized to give Va—d (Tables 1,3,6).

Furo[2,3-b]quinolines (Ia—d). To a solution of Va—d (1.0 g) in dry benzene (150 ml), DDQ (1.0 g) was added, the mixture was then stirred under reflux for 8 hr in an atmosphere of nitrogen. The reaction mixture was filtered, and the solvent was evaporated *in vacuo*. The residue was dis-

solved in chloroform, and the solution was extracted with dilute hydrochloric acid. After the aqueous solution had been neutralized with dilute aqueous ammonia, the resulting precipitate was collected and recrystallized to give Ia—d (Tables 1,3,7). The product was purified by means of chromatography on alumina (300 mesh, chloroform–2% ethanol).

The author wishes to express his deep gratitude to Professor Kenji Fukui, Hiroshima University, for his encouragement through the course of this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 580—583 (1973)

The Reaction of Methyl 2-Dimethoxymethyl-3-methoxypropionate with Amidines[1,2]

Takenori NISHINO, Yoshiyuki MIICHI, and Kanji TOKUYAMA
Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553

(Received July 21, 1972)

The reaction of methyl 2-dialkoxymethyl-3-methoxypropionate with acetamidine has been reported to afford 2-methyl-4-hydroxy-5-methoxymethylpyrimidine (**13a**) by a different mode than the reaction of 2-dimethoxymethyl-3-methoxypropionitrile (**1**), which affords dihydropyrimidopyrimidine (**4**). As the presence of this difference seemed to be somewhat curious from the viewpoint of the reaction mechanism, the reaction of methyl 2-dimethoxymethyl-3-methoxypropionate (**7**) with acetamidine was reinvestigated. The reaction products were **13a** and acetamidinomethylpyrimidine (**17a**). Similar results were obtained by the reaction of **7** with benzamidine. As the compound **17** corresponds to **4**, the reaction of **7** was concluded to proceed in a manner similar to that of **1**; that is, no essential difference exists between the reactions of **1** and **7** with amidines.

In previous papers,[2-5] we have presented the pathway of the reaction of 2-dimethoxymethyl-3-methoxypropionitrile (**1**) with amidines. The reaction proceeds mainly *via* the pathway of **1** → 2-dimethoxymethylacrylonitrile (**2**) → dihydropyrimidines (**3**) → dihydropyrimidopyrimidines (**4**). The existence of the minor pathway of **1** → 2-methoxymethylene-3-methoxy-

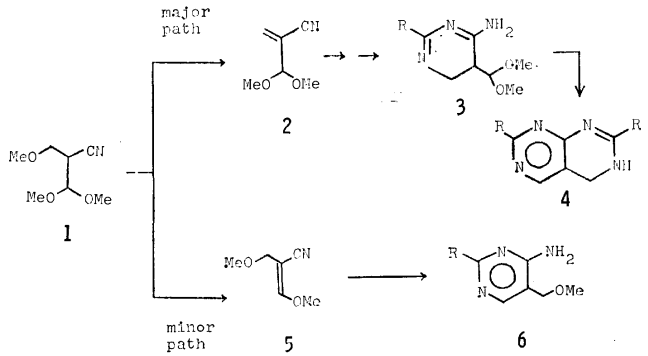

Chart 1.

propionitrile (**5**) → 5-methoxymethylpyrimidines (**6**) was also established.

Similar results can naturally be expected in the reaction of the ester analog of **1**. However, the reaction of the ester analog with acetamidine did not yield products corresponding to **3** and **4**, but only the product corresponding to **6**.[6] Although an explanation of this remarkable difference between the two reactions had been proposed, it seems to be somewhat in conflict with the revised mechanism of the reaction of **1** with acetamidine. Therefore, we attempted to reinvestigate the reaction of the ester analog.

Methyl 2-dimethoxymethyl-3-methoxypropionate (**7**), 2-dimethoxymethylacrylate (**9**), and 2-methoxymethylene-3-methoxypropionate (**10**) were prepared by the usual methods[6] and were used as the starting materials. Their structures were identified by a comparison of their spectra with the spectra of the corresponding propionitriles.[6-8]

At the outset, the possibility of the conversion of **7** into **9** was examined. When a mixture of **7** and sodium methoxide was left at room temperature overnight, the spot of **7** disappeared in the tlc. Without purification, the product was treated with acetamidine to give a pyrimidine (**12**), $C_{14}H_{22}N_2O_6$, which showed the bands due to ester and acetal groups in the IR spectrum and a behavior similar to that of 2-methyl-4-hydroxy-5-methoxymethylpyrimidine (**13a**)[9] in the UV. Therefore, its structure was identified as 2-methyl-4-hydroxy-5-(2′-carbomethoxy-2′-dimethoxymethyl-3′-methoxy)-propylpyrimidine. The NMR spectrum also supported this structure.

By analogy with the base-catalyzed reaction of **1**,[3] a dimeric substance of **7** (**11**) should exist in the product. The possible intermediate, **11**, suggested the presence of the equilibrium, **7** ⇌ the anion of **7** (**8**) ⇌ **9** under basic conditions, since **11** would be formed by the reaction of **8** with **9**, as shown in Chart 2. Consequently, the formation of the reaction products with **9**, corresponding to the product from the major pathway

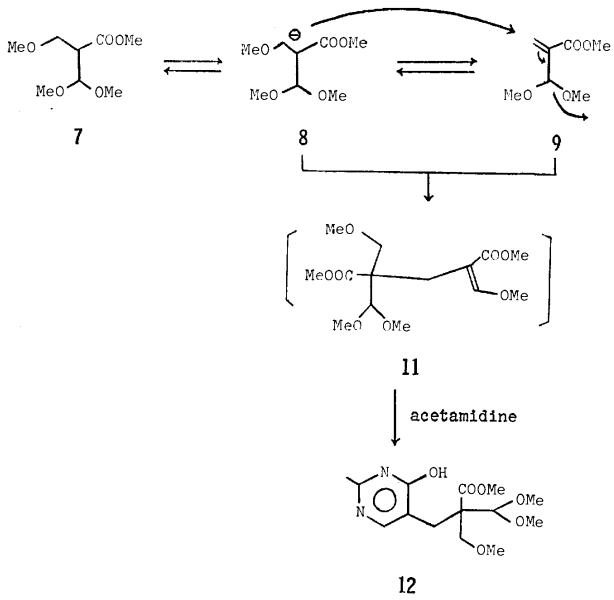

Chart 2.

of the reaction of **1**, was anticipated in the reaction of **7** with acetamidine.

When a mixture of **7** and acetamidine was refluxed in methanol, **13a** and another product (**17a**) were obtained as expected. The structure of **17a** was identified as 2-methyl-4-hydroxy-5-acetamidinomethylpyrimidine by a comparison of the spectral data with those of an authentic sample.[4] The relative ratio of the yields of **13a** and **17a** was about 3: 2, as determined by NMR spectroscopy.

It is quite natural to consider that **17a** was formed *via* a pathway corresponding to that of the reaction of **1**. Chart 3 shows a possible pathway *via* **9** and a dihydropyrimidine (**14**) as key intermediates.

The step **14**→**17a** was proved in a previous paper.[4] The treatment of **9** with acetamidine in 1,2-dimethoxy-

ethane at a low temperature did not afford **13a**, but **14a** as the major product, along with a limited amount of **17a**. On the other hand, that of **10** in 1,2-dimethoxyethane instantly yielded only **13a** in a high yield. These results support the above pathway.

Similar results were obtained in the reaction of **7** with benzamidine. When a mixture of **7** and benzamidine was refluxed in methanol for a long time, crystals appeared which had a correct analysis for $C_{18}H_{16}N_4O$. Therefore, the structure of the crystals was identified as that of the phenyl analog of **17a** (**17b**). The structure was also confirmed by the spectral data. From the mother liquor, the phenyl analog of **13a** (**13b**) was isolated, its structure was confirmed from the combined data of elemental and spectral analyses.

The above results support the idea that the reaction with benzamidine proceeded in a manner similar to that with acetamidine. The relative ratio of the yields of **13b** and **17b** was about 2: 1.

As has been described above, the pathway of the reaction of **1** with amidines can be applied to the reaction of **7**. It can be concluded that there is no essential difference between the two reactions.

Experimental

All the melting points were recorded on a Kofler block and have not been corrected. The NMR spectra were taken with a Varian A-60-A spectrometer, using tetramethylsilane as the internal reference, and the chemical shifts were expressed in δ values (s: singlet, d: doublet, t: triplet, q: quartet, m: multiplet, bs: broad singlet). The UV spectra were observed in methanol and are reported in nm. The molecular weights were determined by means of a vapor-pressure osmometer in benzene. The solvents used were removed under reduced pressure.

Methyl 2-Dimethoxymethyl-3-methoxypropionate (**7**) was prepared by the usual method.[6] Bp 62°C/2 mmHg. $N_D^{26.2}$ 1.4211. IR_{film} 1744 cm^{-1} (ester), 1100, 1070 (acetal). NMR (CCl_4) 3.42—3.58 (m, 2H, H_3, AB part), 2.86 (m, 1H, H_2, M part; J_{AM} 4.5 Hz, $J_{BM}=J_{MX}$ 8 Hz), 4.43 (d, 1H, C<u>H</u>$(OMe)_2$, X part), 3.65 (s, 3H, COOMe), 3.23 (s, 3H), 3.25 (s, 3H, CH$(O\underline{Me})_2$), 3.28 (s, 3H, 3-MeO). Found: C, 50.06; H, 8.42%; mol wt, 200. Calcd for $C_8H_{16}O_5$: C, 49.99; H,8.39%; mol wt, 192.

Methyl 2-Dimethoxymethylacrylate (**9**) *and Methyl 2-Methoxymethylene-3-methoxypropionate* (**10**) were prepared by the usual methods.[6] **9**: Bp 42—44°C/3.5 mmHg. $N_D^{26.2}$ 1.4295. IR_{film} 1730 cm^{-1} (ester), 1630 (C=C), 1100, 1075, 1055 (acetal, C–O–C). NMR (CCl_4) 6.23 (d, 1H, H_3, $J_{3,3'}$ 2 Hz), 5.90 (q, 1H, $H_{3'}$, $J_{3',A}$ 1 Hz), 5.10 (d, 1H, H_A, C<u>H</u>$(OMe)_2$), 3.27 (s, 6H, CH$(O\underline{Me})_2$), 3.72 (s, 3H, COOMe). Found: C, 52.49; H, 7.70%; mol wt, 191. Calcd for $C_7H_{12}O_4$: C, 52.94; H, 7.55%; mol wt, 160. **10**: purified by gas chromatography (Column, PEG 20 M 20%, 176±2°; flow rate, helium 25.0 ml/min). $N_D^{26.5}$ 1.4644. IR_{film} 1712 (ester), 1642 cm^{-1} (C=C). UV 237 (ε 15200). NMR (CCl_4), 3.98 (s, 2H, H_3), 7.33 (s, 1H, =C<u>H</u>OMe), 3.18 (s, 3H, 3-MeO), 3.85 (s, 3H, =CHO<u>Me</u>), 3.65 (s, 3H, COOMe). Found: C, 52.69; H, 7.73%, mol wt, 162. Calcd for $C_7H_{12}O_4$: C, 52.49; H, 7.55%; mol wt 160.

Reaction of Methyl 2-Dimethoxymethyl-3-methoxypropionate (**7**) *with Sodium Methoxide.* A mixture of **7** (2 g) and sodium methoxide (265 mg) was left at room temperature overnight. The spot due to **7** disappeared in the tlc. A solution of acetamidine, which has been prepared from acetamidine hydrochloride (1.32 g), sodium (200 mg), and methanol (13 ml), was then added to the mixture. The solution was refluxed for 5 hr, and then the solvent was removed. The residue was extracted with ether. The ether-extracted syrup was fractionated by column chromatography (alumina, 40 g,; benzene 7: methanol 1: ethyl acetate 2, v/v). From the initial fractions, crystals were obtained. The recrystallization of the crystals from ethyl acetate gave acetamide. From the mother liquor, needles of **12** were obtained; this substance was then recrystalized from ether. The yield was 30 mg. Mp 132.4—133°C. IR_{KBr} 1740 cm^{-1} (ester), 1650 (C=N), 1100 (C–O–C). UV 278 (ε 6000), +HCl 265. +NaOH 276. MS 314 (M^+). NMR (CD_3OD) 7.73 (s, 1H, H_6), 4.58 (s, 1H, C<u>H</u>$(OMe)_2$), 3.58 (s, 2H, –C<u>H</u>$_2$–OMe), 3.65 (s, 3H, COOMe), 3.47 (s, 6H, CH$(O\underline{Me})_2$), 3.20 (s, 3H, $CH_2O\underline{Me}$), 2.88 (s, 2H, C_5-CH_2), 2.33 (s, 3H, C_2-Me). Found: C, 53.69; H, 7.15; N, 9.07%. Calcd for $C_{14}H_{22}N_2O_6$: C, 53.49; H, 7.05; N, 8.91%.

Reaction of Methyl 2-Dimethoxymethyl-3-methoxypropionate (**7**) *with Amidines.* *(1) Reaction with Acetamidine*: (i) Acetamidine hydrochloride (2.25 g) was dissolved in a solution of sodium (0.505 g) in methanol (15 ml) and then the sodium chloride thus precipitated was filtered out. To the filtrate, **7** (2 g) was added, after which the solution (18.65 g) was refluxed for 6 hr. One gram of the solution was used for the determination of the relative ratio of **13a** and **17a** by NMR spectroscopy, using methanol-d_4 as the solvent. Singlets due to the methylene group of **13a** at 4.30 δ and that of **17a** at 4.20 δ were integrated. The ratio (**13a** : **17a**) was 3: 2. The remainder of the solution was evaporated to dryness, and the residue was fractionated by column chromatography [silica gel (40 g), ethanol]. From the initial fractions, **13a** (720 mg, 45%) was obtained.[9] (ii) Five grams of **7** were treated in methanol (20 ml) with acetamidine hydrochloride (5.4 g), and sodium (1.2 g). The solvent was then removed, and the residue was washed with dioxane (100 ml) and subsequently recrystallized from ethanol. Plates of **17a** (132 mg) were obtained; they were purified as the dihydrochlorides [mp 237—240°C (dec)].[4]

(2) Reaction with Benzamidine: A solution of **7** (1.5 g) and benzamidine (2.1 g) in methanol (10 ml) was refluxed for 15 hr. After cooling, there appeared crystals (**17b**, 345 mg) which were collected by filtration. The filtrate was evaporated to dryness and then washed with petroleum ether. The petroleum ether contained **7**. The residue was chromatographed over silica gel (30 g). The first fraction, eluted with ether (150 ml) afforded a mixture of **13b** and **17b** (37 mg). The second fraction, eluted with a mixture (150 ml) of ether (10 parts) and ethanol (1 parts) and the third one, eluted with a mixture (120 ml) of ether (1 part) and ethanol (1 part) gave needles of **13b** (565 mg). **13b**: mp 188.5—191.2°C (dec), (recryst. from ethanol). UV 242 (ε 15200), 296 (ε 1100), +HCl 242, 281, +NaOH 237, 282, 295. IR_{KBr} 1663 cm^{-1} (C=C, C=N). NMR ($CDCl_3$) 8.18 (bs, 1H, H_6), 4.44 (d, 2H, –CH_2–, J=1 Hz), 3.32 (s, 3H, MeO–). Found: C, 66.62; H, 5.48; N, 12.88%. Calcd for $C_{12}H_{12}N_2O_2$: C, 66.65; H, 5.59; N, 12.96%. **17b**: leaflets, mp 255.5—257°C (dec) (recryst. from methanol). UV 235 (ε 28300), 295 (ε 10000), +HCl 235, 285, +NaOH 234, 285, 294. IR_{KBr} 1695, 1625 cm^{-1} (C=C, C=N). MS 304 (M^+), 287 (M^+–NH_3), 200 (M^+–C(=NH)–Ph), 185 (M^+–HN–C(=NH)–Ph). Found: C, 71.27; H, 5.28; N, 18.59%. Calcd for $C_{18}H_{16}N_4O$: C, 71.03; H, 5.30; N, 18.41%.

Reaction of Methyl 2-Dimethoxymethylacrylate (**9**) *with Aceta-*

midine. Acetamidine hydrochloride (5.3 g) was added to a methanolic sodium methoxide, prepared from methanol (20 ml) and sodium (1.2 g), after which the solution was filtered to remove precipitates. The filtrate was evaporated to dryness, and to the residue 1,2-dimethoxyethane (7 ml) was added. Under stirring, a solution of **9** (3 g) in 1,2-dimethoxyethane (7 ml) was added to the solution in portions at below 5°C. The solution was left in a refrigerator for 2 days and then neutralized with methanolic hydrogen chloride. The crystals of the dihydrochloride of **17a** (2.3 g)[4] were collected by filtration.

*Reaction of Methyl 2-Methoxymethylene-3-methoxypropionate (**10**) with Acetamidine.* Acetamidine hydrochloride (1.2 g) was added to methanolic sodium methoxide, which had been prepared from methanol (6 ml) and sodium (302 mg). The solution was filtered from precipitated sodium chloride and then evaporated to dryness. A solution of **10** (700 mg) in 1,2-dimethoxyethane (2 ml) was added to a mixture of the residue and 1,2-dimethoxyethane (3 ml). Crystals appeared instantly; they were collected by filtration and then extracted with chloroform. The evaporation of the chloroform gave **13a** (635 mg).[9]

The authors express their deep gratitude to Professor Toshihiko Okamoto, the University of Tokyo, for his discussion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 583—586 (1973)

The Structure of Shikokianidin, a Minor Component of *Isodon shikokianus* Hara

Takahiko Isobe, Tadao Kamikawa, Isao Kubo, and Takashi Kubota
Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received July 24, 1972)

Shikokianidin from *Isodon shikokianus* Hara is formulated as structure (**3**) on the basis of chemical and spectroscopic evidence.

The isolation of two bitter principles, oridonin (**1**) and shikokianin (**2**) from the extract of *Isodon shikokianus* Hara has already been reported.[1] From the less polar fractions of the extract we have obtained a new, non-bitter diterpene, designated shikokianidin (**3**), $C_{26}H_{34}O_9$, mp 218—219°C, $[\alpha]_D$ −109°. Shikokianidin showed hydroxylic, acetoxy and 6-membered ketonic absorptions in the infrared spectrum (ν_{max} 3450, 1745, 1725, 1260, and 1230 cm^{-1}). Its NMR spectrum (Fig. 1) showed signals attributable to two tertiary C-methyl groups (δ 1.10 and 1.41), three acetyl groups (δ 1.95, 2.02, and 2.12), and a hydroxyl group (δ 4.33, s, exchangeable with D_2O). These spectroscopic data account for eight oxygen atoms out of nine of those of shikokianidin. In addition, there is a three-proton multiplet at *ca.* δ 4.9 which could be assigned to three –CH(OAc)–protons. The lack of a signal for –CH(OH)– in the NMR spectrum confirmed the tertiary nature of the free hydroxyl group. Other significant features of the NMR spectrum of (**3**) include signals arising from ≡C–CH_2–O– (δ 4.23, dd, J=2 and 10 Hz; δ 4.84, dd, J=1.5 and 10 Hz) and a terminal methylene group (δ 5.07, dd, J=1.5 and 3 Hz; δ 5.43, t, J=3 Hz). From analogy with congeners the former group probably constitutes a hemiacetal system and the latter is involved in the D ring.

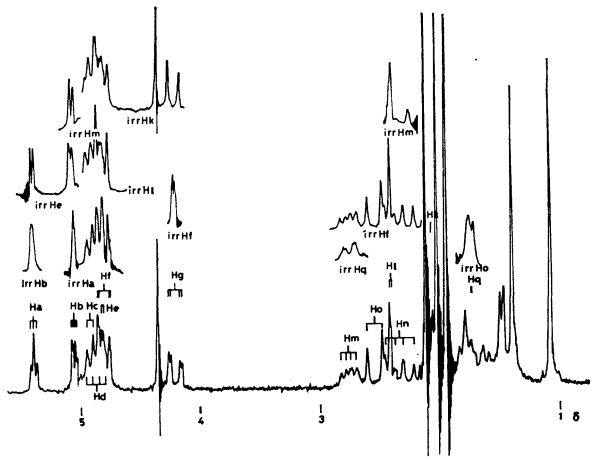

Fig. 1. The NMR spectrum of shikokianidin (**3**).

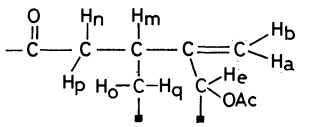
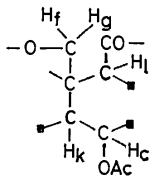


(4)

Spin decoupling (NMDR) experiments performed on shikokianidin demonstrated the presence of structural unit (**4**). On irradiation of the H_e proton located at δ 4.85 (d, J=1.5 Hz), the triplet at δ 5.43 (H_a) collapsed to a doublet (J=3 Hz), showing the removal of allylic coupling and the retention of geminal coupling (J_{gem}=3 Hz). When the H_a proton was irradiated the H_e proton appeared as a singlet with a small splitting (J<1 Hz), indicative of a neighbouring quaternary centre, and the H_b proton (δ 5.07) collapsed to a doublet ($J\simeq$1 Hz). On the other hand, when the H_m proton located at δ 2.77 (q, J=5 and 9 Hz) was irradiated, the H_b proton collapsed to a sharp doublet ($J_{a,b}$=3 Hz) and the H_n proton at δ 2.36 (q, J=9 and 16 Hz) to a doublet ($J_{n,p}$=16 Hz). Conversely,

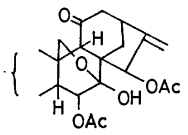
1) T. Kubota and I. Kubo, This Bulletin, **42**, 1778 (1969).

irradiation at δ 1.75 (H_q) resulted in the collapse of the H_m proton signal to a broad double doublet ($J_{m,n}$= 9, $J_{b,m}$=2 Hz), and irradiation of the H_o proton at δ 2.56 (d, $J_{o,q}$=13 Hz) resulted in the collapse of the multiplet at δ 1.75 to a doublet ($J_{m,q}$=5 Hz). The results suggest that the H_m proton is coupled to H_b, H_n, and H_q and the latter two protons to H_p and H_o, respectively, and the dihedral angles between H_m and H_p, H_m and H_o are both close to 90°. The magnitude of the geminal coupling constant between H_n and H_p (J=16 Hz) suggests that these two protons are adjacent to a carbonyl group.[2] Furthermore, NMDR experiments of **3** afforded evidence for the presence of structural unit (**5**).



(5)

On irradiation of the H_l proton at δ 2.42 (d, J= 1.5 Hz), the double doublet pattern for H_f proton (δ 4.84, J=1.5 and 10 Hz) was reduced to a doublet (J=10 Hz) showing the removal of long-range coupling through a W-configuration and the retention of geminal coupling. Irradiation at the centre of the double doublet for H_f proton resulted in the collapse of the H_l proton signal to a singlet and the H_g proton signal to a doublet (J=2 Hz). The chemical shift of the H_l proton is indicative of the presence of a neighbouring carbonyl group.[3] On irradiation at δ 2.06 (H_k proton), the double doublet pattern for H_g proton (δ 4.23, J=2 and 10 Hz) was reduced to a doublet (J=10 Hz) and the double doublet pattern for H_c proton (δ 4.93, J=5 Hz) was reduced to a singlet, showing the removal of both long-range coupling through a W-configuration and vicinal coupling. Thus expansion of the part structures **4** and **5** to **6** would be admissible if we assume that shikokianidin has ent-kaurane skeleton with a hemiacetal ring. Further evidence to support this part structure was provided by acid treatment of shikokianidin.



(6)

Treatment of **3** with 2N hydrochloric acid gave a seco-aldehyde **7**, $C_{24}H_{32}O_8$. The NMR spectrum of the seco-aldehyde showed the presence of two tertiary C-methyl groups (δ 1.07 and 1.33), two acetyl groups (δ 1.90 and 2.09), a hydroxyl group (δ 4.56, exchangeable with D_2O), two olefinic protons conjugated with an aldehyde (δ 6.00, s; δ 6.33, d, J=1.5 Hz) and an aldehyde proton (δ 9.51, s). (see Fig. 2, where the lower part of the spectrum is omitted).

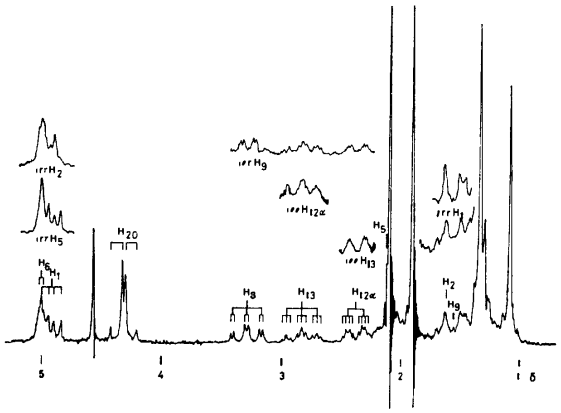


Fig. 2. The NMR spectrum of seco-aldehyde (**7**).

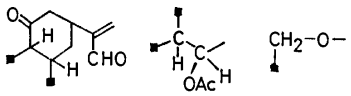
NMDR experiments demonstrated the presence of the part structure (**8**).



(8)

The results lead to assignment of structure **7** to the seco-aldehyde except for the position of one secondary acetoxy group in ring **A**. From biogenetic grounds, it is most reasonable to place this acetoxy group at position C_1 or C_3. The NMR spectrum of **7** showed a one proton quartet at δ 4.91 (J=6 and 10 Hz) and a one proton doublet at δ 4.99 (J=4 Hz), the latter being assigned to H_7 (on irradiation at δ 2.14 this collapsed to a singlet), and the former to $H_{1\beta}$ or $H_{3\beta}$ (on irradiation at δ 1.63 this collapsed to a doublet J=10 Hz). The axial nature of this proton was evident from the large axial-axial coupling (J=10 Hz) and small axial-equatorial coupling (J=6 Hz). The splitting pattern of this proton is quite similar to that of the C_1 proton of shikokianin (**2**).[4] A possible mechanism for this transformation would be a hydrolysis of the allylic acetate with concomitant opening of the hemiacetal as demonstrated in trichokaurin,[5] followed by reverse aldol reaction and re-cyclization to hemiacetal.

Catalytic reduction of shikokianidin gave dihydro-

3) S. Forsen and T. Norin, *ibid.*, **1964**, 2845.
4) The original assignment of the NMR spectrum of **2** was incomplete and some conflicting results were reported.[1] The correct assignment is as follows; two tertiary *C*-methyl protons (δ 1.16 and 1.18), two acetyl protons (δ 1.91 and 2.11), two hydroxyl protons (δ *ca.* 4.7, C_7-**OH** and δ 5.93, d, J=12 Hz, C_6-OH; both exchangeable with D_2O), $H_{12\beta}$ (δ 2.82, q, J=4 and 15 Hz), $H_{12\alpha}$ (δ 2.40, q, J=9 and 15 Hz), $H_{14\alpha}$ (δ 2.84, d, J=13 Hz), H_{13} (δ 3.07, q, J=4 and 9 Hz), H_6 (δ 4.01, q, J=10 and 12 Hz), ≡C-CH_2-O- (δ 4.11, d, J=10 Hz with small splitting; δ 4.44, q, J=2 and 10 Hz), H_1 (δ 4.74, q, J=5 and 10 Hz), H_{11} (δ 4.86, t, J=4 Hz) and two olefinic protons (δ 5.50 and 6.00).
5) E. Fujita, T. Fujita, M. Shibuya, and T. Shingu, *Tetrahedron*, **25**, 2517 (1969).

shikokianidin (**9**), $C_{26}H_{36}O_9$. The NMR spectrum of **9** showed the presence of a secondary methyl group (δ 0.71, d, J=7 Hz) and a –CH(OAc)– proton (δ 4.86, d, J=10 Hz). NMDR experiments demonstrated that the proton attached to the secondary methyl group and the proton of the type –CH(OAc)– are vicinal (on irradiation at δ 2.51, both the secondary methyl and the –CH(OAc)– proton signals collapsed to singlets). Since the hydrogenation of the C_{15} double bond is assumed to occur from the less hindered side of the molecule, the newly introduced secondary methyl is presumably β. The dihedral angle between the protons H_{15} and H_{16} is assumed to be 0° from the coupling constant (J=10 Hz). Thus the acetoxy group at C_{15} can be assigned as β.

Treatment of **9** with methanolic ammonia gave trisdeacetyldihydroshikokianidin (**10**), $C_{20}H_{30}O_6$, with an IR frequency (1710 cm^{-1}) compatible with a cyclohexanone. The NMR spectrum (in $CDCl_3$–C_5D_5N) showed signals for one secondary (δ 0.96, d, J=7 Hz) and two tertiary (δ 1.07 and 1.11) *C*-methyl groups, three –CH(OH)– protons (δ 3.90, q, J=7 and 9 Hz, H_1; δ 4.57, d, J=11 Hz, H_{15}; δ 4.78, q, J=3 and 8 Hz, H_6) and ≡C–CH_2–O– protons (δ 4.60, q, J= 1 and 12 Hz; δ 5.95, d, J=12 Hz).

From analogy with the congeners a tentative assignment of stereochemistry as shown in **3** can now be extended to shikokianidin. On examination of a molecular model, the proton H_5 and the proton H_9 are in close proximity (both axial). When the proton at C_5 was irradiated, NOE enhancement was observed in the integrated area of H_9 signal (15%). Another relative stereochemistry may now be deduced from a consideration on the NMR data of shikokianidin. As already discussed, the acetoxy groups at C_1 and C_{15} can be assigned as α and β, respectively. The C_6 proton gives rise to a doublet (J=4 Hz). This suggests an equatorial disposition with coupling to an adjacent axial C_5 proton (the ring B takes a boat conformation). The C_{13} proton showed a spectrum assumed to be the X part of an ABX system ($J_{12\alpha,13}$= 9 Hz, $J_{14\beta,13}$=5 Hz, with small allylic coupling). This suggests that the C_{13} proton is equatorial and the dihedral angles between H_{13} and $H_{12\beta}$, and H_{13} and $H_{14\alpha}$ are both 90°. The stereochemistry of the seco-aldehyde produced by an acid-treatment of **3** can now be formulated as **7**. It is anticipated that ring C takes a strain-free chair form and that the ring junctures take the most stable *trans-anti-trans* configuration. The C_8 proton (δ 3.28) showed a six-line spectrum with coupling constants $J_{8,9}=J_{8,14\beta}$=12 Hz, $J_{8,14\alpha}$=3 Hz. The low-field shift of this signal is attributable to the proximity of the hemiacetal oxygen atom.[6] The C_{13} proton (δ 2.82) showed a nine-line spectrum with coupling constants $J_{12\beta,13}=J_{13,14\beta}$=13 Hz, $J_{12\alpha,13}=J_{13,14\alpha}$= 4 Hz.

Shikokianidin shows a positive CD. However, no similar compounds are available for a comparative study.

Finally, we have confirmed the proposed structure by relating **3** to shikokianin (**2**), which in turn relates to nodosin.[7] Lithium aluminum hydride reduction of **3** gave a mixture of three reduction products. One of the reduction products was deacetylshikokianidin. The other two products were isomeric pentaols (**11**) and (**12**). On the other hand, the reduction of shikokianin (**2**) with lithium aluminum hydride gave pentaol (**11**), the latter proving to be identical with one of the pentaols derived from **3**. Thus the structure of shikokianidin including the absolute configuration has been established.

Experimental

NMR spectra were determined on a JEOL PS-100 (100 MHz) spectrometer in deuterochloroform solutions, unless otherwise stated. IR spectra were recorded on Nujol mull with a Japan Spectroscopic IR-S spectrophotometer. CD data were obtained in chloroform solution with a Jasco ORD/UV-5 (equipped with CD attachment). Column chromatography was performed with Mallinckrodt silicic acid.

Isolation. The dried leaves of *Isodon shikokianus* Hara were extracted with ether. The crude extract was treated with activated charcoal, concentrated and chromatographed in ether over silicic acid. Elution with the same solvent gave shikokianidin, shikokianin, and oridonin in this order. The less polar fractions were collected and recrystallised from ethanol to give pure shikokianidin (**3**), mp 218—219°C, $[\alpha]_D$ −109° (pyridine). Found: C, 63.79; H, 7.14%. Calcd for $C_{26}H_{34}O_9$: C, 63.66; H, 6.99%, ν_{max} 3450, 1745, 1725, 1260 and 1230 cm^{-1}, λ_{max}^{EtOH} 301 nm (ε 77).

Acid-treatment of Shikokianidin (3). Shikokianidin (320 mg) was heated in refluxing methanol (15 ml) containing 2N hydrochloric acid (15 ml) for 3 hr. On cooling, crystals were separated and recrystallised from ethanol to give the seco-aldehyde (**7**), mp 268—269°C. Found: C, 64.24; H, 7.31%. Calcd for $C_{24}H_{32}O_8$: C, 63.98; H, 7.61%, ν_{max} 3400, 1730, 1700 and 1240 cm^{-1}.

Dihydroshikokianidin (9). Shikokianidin was hydrogenated in ethanol over 10% palladium-charcoal. The crude product was recrystallised from dilute ethanol to give dihydroshikokianidin (**9**) as colorless prisms, mp 178—180°C, Found: C, 63.33; H, 7.43%. Calcd for $C_{26}H_{36}O_9$: C, 63.40; H, 7.37%, ν_{max} 3480, 1730, 1260, and 1230 cm^{-1}, δ 0.71 (3H, d, J=7 Hz, *sec* CMe), 1.09 and 1.39 (each 3H, *tert* CMe), 1.98, 2.00, and 2.14 (each 3H, OAc), 2.34 (1H, d, J=1 Hz, H_9), 4.22 (1H, dd, J=2 and 10 Hz, H_{20}), 4.34 (1H, s, OH), 4.83 (1H, dd, J=1 and 10 Hz, H_{20}), 4.87 (1H, d, J=10 Hz, H_{15}), *ca.* 4.9 (1H, m, H_1).

Trisdeacetyldihydroshikokianidin (10). Dihydroshikokianidin (100 mg) was dissolved in ammonia saturated methanol (20 ml). After the mixture had been left standing for 23 days at room temperature, it was concentrated to dryness under reduced pressure. The residue was chromatographed over preparative plates to give trisdeacetyldihydroshikokianidin (**10**), (29 mg), mp 268—271°C (dec) (from acetone–light petroleum). Found: C, 65.50; H, 8.30%. Calcd for $C_{20}H_{30}O_6$: C, 65.55; H, 8.25%, ν_{max} 3360, 1710, and 1180 cm^{-1}, δ ($CDCl_3$-C_5D_5N) 0.96 (3H, d, J=7 Hz, *sec* CMe), 1.07 and 1.11 (each 3H, *tert* CMe), 2.25 (1H, s, H_9), 2.72 (1H, dd, J=1 and 6.5 Hz, H_5), 3.90 (1H, q, J=7 and 9 Hz), 4.57 (1H, d, J=11 Hz, H_{15}), 4.60 (1H, dd, J=1 and 12 Hz, H_{20}), 4.78 (1H, dd, J=3 and 8 Hz, H_6), 5.47 (broad OH), 5.95 (1H, d, J=12 Hz, H_{20}).

Reduction of Shikokianidin with LAH. Shikokianidin (50 mg) was refluxed with lithium aluminum hydride (100 mg) in ether (20 ml) for 3 hr. The excess of the reagent was decomposed with ethyl acetate and the resulting emulsion was washed with dilute hydrochloric acid and then with water. Drying and evaporation of the solution gave a residue which was purified by tlc ($CHCl_3$–MeOH, 9:1) to yield deacetylshikokianidin and the mixture of pentaols (A) and (B). Pentaol (A) was identified as ent-5β,20-epoxykaur-16-ene-1β,6α,7α,11β,15α-pentaol (**11**) by tlc (solvent system: $CHCl_3$–MeOH, 9: 1; AcOEt–CH_2Cl_2, 7: 3; CH_2Cl_2–Me_2CO, 1: 1).

Reduction of Shikokianin with LAH. Similarly, shikokianin (300 mg) was reduced with lithium aluminum hydride to give pentaol (**11**), mp 253—255°C (dec) (from methanol–chloroform), Found: C, 64.18; H, 8.28%. Calcd for $C_{20}H_{30}O_6 \cdot 1/2H_2O$: C, 63.98; H, 8.32%, ν_{max} 3300, 1650, and 1565 cm^{-1}.

We are grateful to Dr. K. Kuriyama, Shionogi Research Laboratory, for the CD measurements.

The Jacobsen Reaction of Iodopseudocumenes and Related Compounds. Orientation in the Iodination of Halopseudocumenes[1]

Hitomi SUZUKI and Takashi SUGIYAMA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

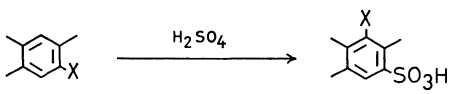
**Institute for Chemical Research, Kyoto University, Gokasho, Uji, Kyoto*

(Received July 18, 1972)

The Jacobsen reaction of iodopseudocumenes and related compounds was investigated. Both 3- and 5-iodopseudocumenes gave essentially the same product which consisted of 3,5-diiodopseudocumene (VI, 53%), 3,6-diiodopseudocumene (VII, 44%) and 5,6-diiodopseudocumene (VIII, 3%). The unexpected result was interpreted in terms of a mechanism involving a prior interconversion of the 3- and 5-iodo isomers followed by the ordinary process of aromatic disproportionation. 6-Iodopseudocumene gave VII as the major product. By prolonged contact with concentrated sulfuric acid, VI and VIII were found to undergo partial isomerization to give VII. Early structural assignment by Smith and Moyle for two diiodopseudocumenes was revised. Reactions of 4- and 5-iodohemimellitenes with sulfuric acid gave 4,6-diiodohemimellitene (XII) as the major product. A diiodohemimellitene melting at 114°C was found to be a mixture of XII and 4,5-diiodohemimellitene (XI), the former being predominant. Isomeric chloro-, bromo-, and iodopseudocumenes were iodinated with iodine-periodic acid dihydrate and the orientation in the products was determined.

5-Chloropseudocumene (I, X=Cl) reacts with concentrated sulfuric acid to give 3-chloropseudocumene-5-sulfonic acid (II, X=Cl).[4] 5-Bromopseudocumene (I, X=Br) behaves similarly, giving 3-bromopseudocumene-5-sulfonic acid (II, X=Br) along with small amounts of 3,5,6-tribromopseudocumene.[5] The reaction is known as the Jacobsen reaction.

5-Iodopseudocumene (III) was reported to afford



I II

two diiodopseudocumenes and two sulfonic acids derived from an iodopseudocumene and pseudocumene, respectively.[6] Although Kürzel did not designate specific structures for these products, Smith and Moyle formulated them as 3,6-diiodopseudocumene (VII), 5,6-diiodopseudocumene (VIII), 3-iodopseudocumene-5-sulfonic acid (II, X=I), and pseudocumene-5-sulfonic

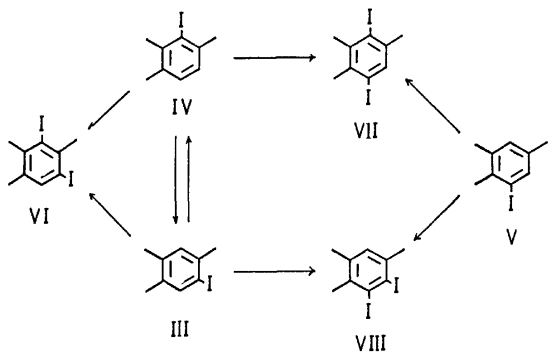
acid (II, X=H), respectively.[2] The assignment has since been cited.[7] However, the 3,6-orientation of iodine atoms in the disproportionation product of III is rather unexpected because the Jacobsen reaction of aromatic iodo compounds is usually known to proceed like a progressive iodination of the starting compound.[8] Thus the reaction of III and related compounds with sulfuric acid was re-examined in some detail.

Kürzel reported that III dissolved in sulfuric acid and left to stand at room temperature gave an oily mass which, by vacuum distillation and subsequent cooling, could be separated into colorless plates melting at 73°C and an oily substance freezing below 0°C.[6] We repeated the experiment and examined the oily product by gas chromatography as well as by direct comparison with the infrared and ^{1}H-NMR spectra of authentic specimens. The product was found to be a mixture of all three isomeric diiodopseudocumenes consisting of 3,5-diiodopseudocumene (VI; mp 8—9°C; bp 202—204°C/21 mmHg; 53%), VII (mp 75—76°C; 44%), and VIII (mp 51—52°C; bp 197—199°C/18 mmHg; 3%).[9] Some 3,5,6-triiodopseudocumene (mp 193—195°C) was also formed, whose amount steadily increased on prolonged treatment with sulfuric acid. It was therefore concluded that the Kürzel diiodopseudocumenes were most likely to be VI and VII, the former being possibly accompanied by some other isomers.

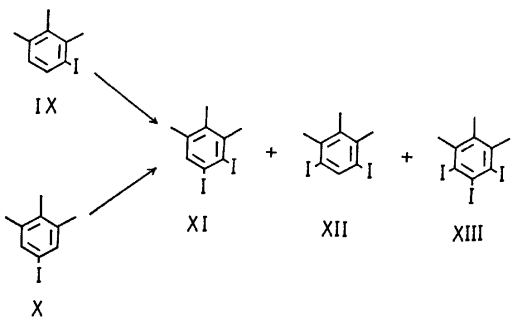
The idea that the unusual 3,6-orientation of iodine atoms in the product might arise from a rearrangement of the initially formed VI and VIII does not seem likely, since diiodopseudocumenes were found to be quite slow to isomerize under the same conditions. Thus the only other possibility is that III in contact with sulfuric acid partly isomerized to 3-iodopseudocumene (IV), which was then iodinated to give VI and VII. In order to confirm this, IV and 6-iodopseudocumene (V) were prepared and treated in a similar manner. The 3-iodo isomer gave essentially the same product as that obtained from III, whereas the 6-iodo isomer gave VII along with a very small amount of VIII.



When a dilute solution of III or IV in dichloromethane was stirred with a small amount of sulfuric acid at room temperature, both isomers were found to undergo mutual interconversion, giving a mixture of III (87—92%) and IV (8—13%). In contrast, V showed little tendency to isomerize but underwent slow disproportionation.

The composition and constitution of sulfonated products were not further investigated, but the only major sulfonic acid obtained from either one of the reaction mixtures was identified as pseudocumene-5-sulfonic acid (II, X=H). An iodopseudocumenesulfonic acid (amide; mp 193—194°C) isolated in small amounts from the reaction mixture of V was probably 6-iodopseudocumene-3-sulfonic acid.

The other isomeric iodotrimethylbenzenes similarly underwent facile disproportionation. Both 4- and 5-iodohemimellitene (IX and X) reacted with sulfuric acid to give 4,6-diiodohemimellitene (XII) as the major product which was usually accompanied by an appreciable amount of 4,5-diiodohemimellitene (XI) and some 4,5,6-triiodohemimellitene (XIII). A diiodohemimellitene melting at 114°C, obtained from the Jacobsen reaction of 5-iodohemimellitene,[3] was found to be an intimate mixture of XI and XII, the latter being predominant. Iodomesitylene gave either diiodomesitylene or triiodomesitylene depending on the conditions employed.[10]



So far no quantitative data have been found in literature on the electrophilic reaction of halopseudocumenes. Accordingly, it seemed of interest to extend our work to the ordinary iodination of various isomeric halopseudocumenes, in order to see how they behave towards electrophilic iodine under the condition in which no migration of substituent groups was allowed. The iodination with iodine-periodic acid dihydrate was clean and smooth, and the products were determined by means of gas chromatography and ^{1}H-NMR spectroscopy. The results are summarized in Table 1. Combined directing effects of substituent groups agreed fairly well with the ones predicted from the additivity principle. For 3-chloropseudocumene some discrepancy was observed, which probably arose from the underestimation by the additivity principle of the rate of substitution at the position *para* to chlorine atom.

In sharp contrast to the product from the Jacobsen reaction, the above iodination products from III and V contained a substantial amount of VIII. Although

Table 1. Products from the iodination of halopseudocumenes with iodine-periodic acid dihydrate

Halopseudocumene		Product composition (%)[a]	
3-Halo series		5-Iodo	6-Iodo
	X=Cl	40.5	59.5
	=Br	57.8	42.2
	=I	69.3	30.7
5-Halo series		3-Iodo	6-Iodo
	X=Cl	61.8	38.2
	=Br	74.6	25.4
	=I	79.9	20.1
6-Halo series		3-Iodo	5-Iodo
	X=Br	62.8	37.2
	=I	63.3	36.7

a) Determined gas chromatographically. Dihalopseudocumenes appeared in the order; 3,6- >3,5- >5,6-.

VI and VIII could be partly converted into VII on prolonged contact with sulfuric acid, such isomerization was not so rapid and complete as to rationalize the marked difference in the composition. The result can be reasonably explained in terms of a mechanism involving partial isomerization of III to IV which, even in a small concentration, would undergo preferential iodination due to favorable electronic and steric reasons. The predominance of VII in the product mixture probably resulted from its greater stability towards the deiodination-reiodination process.

The present result represents the second clearly observed deviation from the established rule for the Jacobsen reaction of aromatic iodo compounds. The first example was observed in the reaction of 2-iodo-*m*-xylene, which underwent rapid isomerization into the 4-iodo isomer followed by disproportionation, giving 4,6-diiodo-*m*-xylene as the final product.[11]

Experimental

All melting and boiling points are uncorrected. Infrared spectra were measured on Nujol mulls with a Jasco DS-402 G spectrophotometer. ^{1}H-NMR spectra were obtained for carbon tetrachloride solutions on a JEOL PS-100 spectrometer using TMS as an internal reference. Gas chromatographic data were obtained on a Hitachi Model F6-D gas chromatograph using a capillary column (0.5 ϕ, 45 m) coated with Apiezon Grease L at column temperature of 165°C.

5-Iodopseudocumene (*III*; mp 36—37°C[6]; bp 135—136°C/21 mmHg) was prepared from a commercial pseudocumidine (2,4,5-trimethylaniline). IR: 868, 946, and 1145 cm^{-1}; NMR; 7.90 (2 Me), 7.72 (Me), 3.14 (aromatic H), and 2.55 τ (aromatic H).

3-Iodopseudocumene (IV). 2,3,6-Trimethylphenylmagnesium bromide was prepared in the usual manner from 3-bromopseudocumene (bp 112—114°C/18 mmHg; 15 g)[12], magnesium (1.9 g), and dried tetrahydrofuran (70 ml). Iodine (*ca.* 20 g) was slowly added to the Grignard solution. The mixture was heated under gentle reflux for 30 min and hydrolyzed with excess dilute hydrochloric acid. The organic layer was separated, dried and concentrated, and the residue was distilled to give product (16.2 g, 87%) boiling at 140—141°C/25 mmHg. IR: 778, 802, 984, 1131, and 1169 cm^{-1}; NMR: 7.75 (Me), 7.64 (2 Me), and 3.18 τ (2 aromatic H).

Found: C, 44.21; H, 4.49%. Calcd for $C_9H_{11}I$: C, 43.92; H, 4.51%.

6-Iodopseudocumene (*V*; bp 138—139°C/24 mmHg) was prepared from 6-bromopseudocumene (bp 120—121°C/22 mmHg)[5] in a similar manner. IR: 785, 848, 1005, 1124, and 1256 cm^{-1}; NMR: 7.84 (Me), 7.77 (Me), 7.71 (Me), 3.22 and 2.60 τ (aromatic H).

Found: C, 44.19; H, 4.52%. Calcd for $C_9H_{11}I$: C, 43.92; H, 4.51%.

4-Iodohemimellitene (*IX*; bp 144—145°C/22 mmHg) and *5-iodohemimellitene* (*X*; mp 34—36°C)[13] were prepared from the corresponding trimethylanilines.[14,15] Synthesis of diiodo and triiodo derivatives of pseudocumene and hemimellitene used as authentic specimens will be described in the accompanying paper.[16]

General Procedure for the Jacobsen Reaction. i) A solution of iodotrimethylbenzene (4.9 g, 0.02 mol) in dichloromethane (20 ml) was stirred vigorously with concentrated sulfuric acid (4.9 g, 0.05 mol) at room temperature. After 15 hr the reaction was quenched by the addition of water, and the organic layer was separated, washed with dilute aqueous sodium sulfite and dried over anhydrous magnesium sulfate. The oily substance (3.3—3.8 g) obtained after removal of the solvent was directly examined by infrared and ^{1}H-NMR spectroscopy as well as by thin-layer and gas-chromatography.

ii) Iodotrimethylbenzene (4.9 g, 0.02 mol) was stirred with concentrated sulfuric acid (15 g, 0.15 mol) overnight at room temperature. The dark mixture was poured on crushed ice and a pasty solid was extracted with a mixture of dichloromethane and light petroluem. The extract was washed with dilute aqueous sodium sulfite and then passed over a short alumina column to remove some polymeric substance formed during the course of reaction. The eluate was evaporated and the residual oil or semi-solid (1.5—2.0 g) were directly subjected to gas chromatographic and spectral inspection.

Procedure for the Iodination of Halopseudocumenes.[17] A mixture of halopseudocumene (0.05 mol), iodine (5.1 g), periodic acid dihydrate (2.28 g), and 80% acetic acid (40 ml) containing catalytic amount of sulfuric acid was heated with stirring at 70—75°C for several hours until the color of iodine disappeared. After cooling, water was added and an oily precipitate or a semisolid mass was extracted with ether; the ethereal extract was dried over calcium chloride and distilled. A mixture of iodinated halopseudocumenes (90—97%) was obtained mostly distilling over in the range shown below;

Iodinated chloropseudocumenes, bp 167—170°C/16 mmHg
Iodinated bromopseudocumenes, bp 173—177°C/16 mmHg
Diiodopseudocumenes, bp 197—200°C/20 mmHg

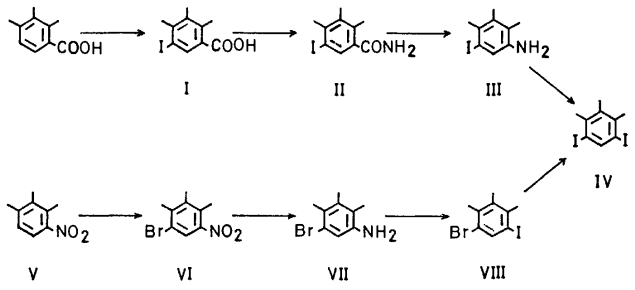
(Received July 18, 1972)

A complete set of diiodo and triiodo derivatives of 1,2,3-trimethylbenzene and 1,2,4-trimethylbenzene has been prepared and their physical properties are recorded. Use of polyiodo derivatives as a means for characterizing polyalkylbenzenes and their derivatives has been proposed.

In a reinvestigation of the Jacobsen reaction of 5-iodo-1,2,4-trimethylbenzene,[2] some diiodo and triiodotrimethylbenzenes were required as reference compounds. A survey of literature revealed that only one[3] of the six diiodotrimethylbenzenes and one triiodotrimethylbenzene[3] have so far been characterized. The present paper describes the synthesis of a complete set of diiodo and triiodo derivatives of the trimethylbenzenes given in the title.

Diiodotrimethylbenzenes. In a previous paper,[5] the Jacobsen reaction of 5-iodo-1,2,3-trimethylbenzene was reported to give diiodo-1,2,3-trimethylbenzene melting at 114°C. Reinvestigation of the product revealed that it was in fact an intimate mixture of two diiodo-1,2,3-trimethylbenzenes. The major component was identified as 4,6-diiodo-1,2,3-trimethylbenzene (IV; mp 129—130°C) through the synthesis *via* two routes from 1,2,3-trimethylbenzene (Scheme 1). The minor component was identical with the authentic 4,5-diiodo-1,2,3-trimethylbenzene (mp 67—69°C) obtained from the iodination of 5-iodo-1,2,3-trimethylbenzene.

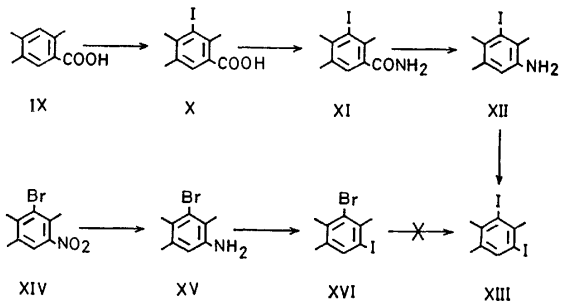
Direct iodination of 1,2,3-trimethylbenzene with two equivalent amounts of iodinating agent (iodine–periodic acid dihydrate)[6] gave a mixture of the 4,5- and 4,6-diiodo isomers in the ratio 1 : 1.95. Less soluble IV



Scheme 1.

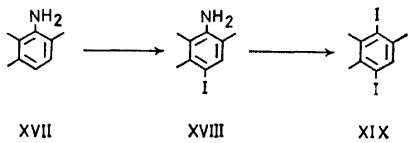
was readily obtained as beautiful needles, but a small amount of isomeric impurity tenaciously clinging to the product was difficult to remove.

Two diiodo-1,2,4-trimethylbenzenes of unidentified structures were reported to be formed from the Jacobsen reaction of 5-iodo-1,2,4-trimethylbenzene.[7] Direct iodination of 1,2,4-trimethylbenzene with two equivalents of the iodinating agent was found to give 3,5-diiodo-1,2,4-trimethylbenzene (XIII) as the major product (*ca.* 80%).[8] However, separation of this product from the accompanying isomers was difficult due to a slight difference in boiling point. Pure XIII was obtained from 2,4,5-trimethylbenzoic acid (IX; durylic acid) according to the sequence shown in Scheme 2.



Scheme 2.

Fractional distillation of the product from nitration of 1,2,4-trimethylbenzene gave the 3-nitro compound as an early distillate, which was reduced to 2,3,6-trimethylaniline (XVII) and treated with iodine under alkaline conditions to give 4-iodo-2,3,6-trimethylaniline (XVIII). Diazotization and the subsequent treatment with aqueous potassium iodide gave 3,6-diiodo-1,2,4-trimethylbenzene (XIX).

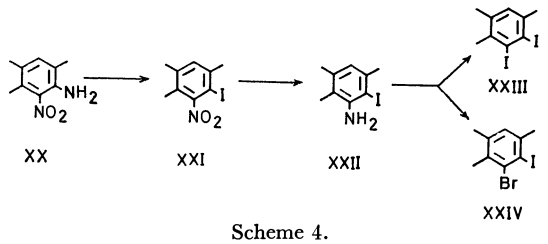


Scheme 3.

1) The Reaction of Polysubstituted Aromatics. XXXI. Part XXX: This Bulletin, **46**, 586 (1973).
2) H. Suzuki and T. Sugiyama, *ibid.*, **46**, 586 (1973).
3) 2,4-Diiodo-1,3,5-trimethylbenzene and 2,4,6-triiodo-1,3,5-trimethylbenzene; both were first obtained by the Jacobsen reaction of 2-iodo-1,3,5-trimethylbenzene.[4]
4) A. Töhl and R. Eckel, *Ber.*, **26**, 1099 (1893).
5) H. Suzuki and R. Goto, This Bulletin, **36**, 389 (1963).
6) H. Suzuki, K. Nakamura, and R. Goto, *ibid.*, **39**, 128 (1966); H. Suzuki, "Organic Syntheses," Vol. 51, p. 94 (1971).
7) C. Kürzel, *Ber.*, **22**, 1586 (1889).
8) The product was found to be a mixture of 3,5-diiodo-1,2,4-trimethylbenzene (79%), 5,6-diiodo-1,2,4-trimethylbenzene (17%), and 3,6-diiodo-1,2,4-trimethylbenzene (4%).

5,6-Diiodo-1,2,4-trimethylbenzene (XXIII) required a lengthy synthetic route. Attempts to introduce an iodine atom directly at the 6-position of 2,4,5-trimethylaniline failed due to the inevitable formation of tarry substance. *N*-Acetyl derivative could be iodinated at the 6-position but removal of the acetyl group was not possible under alkaline conditions. Under forced acidic conditions, elementary iodine was liberated instead.

Triiodotrimethylbenzenes. Literature contains only 2,4,6-triiodo-1,3,5-trimethylbenzene (triiodomesitylene).[4] Iodine-periodic acid as iodinating agent readily converted 1,2,3- and 1,2,4-trimethylbenzenes into the corresponding triiodo derivatives, both of which were high-melting crystals poorly soluble in cold organic solvents. On storage under diffused light, 4,5,6-triiodo-1,2,3-trimethylbenzene gradually turned yellow.



Scheme 4.

Use of Polyiodo Derivatives for Characterization Purpose. Iodine–periodic acid as an iodinating agent provides a simple direct route to polyiodopolyalkylbenzenes. Ease

a) Numerals in parentheses refer to the number of methyl groups.

of access makes polyiodo derivatives useful for the characterization of polyalkylbenzenes and their derivatives. They are especially so when the given sample is a liquid available only in a small amount, since the introduction of iodine atoms multiplies molecular weight and converts a liquid hydrocarbon into a well-crystallized solid with moderate melting range. Polyiodo derivatives are preferred to polynitro and polybromo derivatives, because the latters are often accompanied by side-chain substituted products and their mixture melting test is sometimes deceptive due to a slight depression of melting point. Physical properties of some polyiodo and mixed haloiodo derivatives of polyalkylbenzenes, most of which are new, are summarized in Table 1.

Experimental

All melting and boiling points are uncorrected. Infrared spectra were recorded in Nujol on a Jasco DS-402G spectrophotometer. ^1H NMR spectra were measured in carbon tetrachloride solutions on a JEOL PS-100 spectrometer against internal TMS.

5-Iodo-2,3,4-trimethylbenzamide (II). A mixture of 5-iodo-2,3,4-trimethylbenzoic acid (I, 14.0 g)[9] and thionyl chloride (10 g) was warmed until there was no more evolution of gaseous product. After removal of excess thionyl chloride under reduced pressure, the residual solid was dissolved in benzene, and dry ammonia gas was bubbled through the solution. The precipitate was filtered off and recrystallized from hot dioxane to give amide as white needles (13.1 g, 94%), mp 275—276°C. IR: 687, 716, 765, 884, 1041, 1113, 1187, 1542, 1624, 1649, 3160, and 3330 cm^{-1}.

Found: C, 41.60; H, 4.21%. Calcd for $C_{10}H_{12}NIO$: C, 41.54; H, 4.19%.

3-Iodo-2,4,5-trimethylbenzamide (*XI*; mp 236—237°C) was prepared in a similar manner from 3-iodo-2,4,5-trimethylbenzoic acid (X).[9] IR: 702, 827, 889, 990, 1125, 1405, 1624, 1649, 3150, and 3320 cm^{-1}.

Found: C, 41.52; H, 4.07%. Calcd for $C_{10}H_{12}NIO$: C, 41.54; H, 4.19%.

5-Iodo-2,3,4-trimethylaniline (III). A solution of potassium hydroxide (11.2 g) and bromine (12 g) in water (100 ml) was poured on II (9.6 g) suspended in ethanol (100 ml). The mixture was stirred at room temperature for 5 hr and then a solution of potassium hydroxide (15 g) in water (50 ml) was added. The temperature was maintained at 50—60°C for 3 hr and then at 60—70°C for 3 hr. Finally the reaction mixture was steam-distilled to give amine as white solid, which was recrystallized from light petroleum to yield pure product (1.6 g, 18%), mp 79—80°C. IR: 754, 844, 866, 947, 1115, 1206, 1273, 1288, 1573, 1618, 3320, and 3410 cm^{-1}; NMR; 8.03 (Me), 7.81 (Me), 7.70 (Me), 6.75 (NH_2), and 3.04 τ (aromatic H).

Found: C, 41.53; H, 4.74%. Calcd for $C_9H_{12}NI$: C, 41.40; H, 4.63%.

3-Iodo-2,4,5-trimethylaniline (*XII*; mp 57—58°C) was obtained in a similar manner from XI. IR: 784, 855, 979, 1231, 1275, 1285, 1548, 1598, 1630, 3190, 3290, and 3380 cm^{-1}; NMR: 7.80 (Me), 7.73 (Me), 7.70 (Me), 6.65 (NH_2), and 3.70 τ (aromatic H).

Found: C, 41.67; H, 4.72%. Calcd for $C_9H_{12}NI$: C, 41.40; H, 4.63%.

4-Iodo-2,3,6-trimethylaniline (XVIII). To a suspension of sodium hydrogen carbonate (17 g) in water (150 ml), 2,3,6-trimethylaniline (XVII; bp 125—127°C/18 mmHg; 9.0 g) dissolved in ether (80 ml) was added. Stirring was continued for an hour, after which the solvent was removed and a black residual solid was steam-distilled. The amine separated as white needles in the distillate was collected by filtration and recrystallized from light petroleum, mp 100—101°C. Yield, 8.2 g (47%). IR: 754, 839, 854, 869, 972, 1080, 1167, 1311, 1560, 1621, 3270, and 3360 cm^{-1}; NMR: 7.96 (Me), 7.86 (Me), 7.71 (Me), 6.08 (NH_2), and 3.58 τ (aromatic H).

Found: C, 41.58; H, 4.56%. Calcd for $C_9H_{12}NI$: C, 41.40; H, 4.63%.

6-Bromo-4-nitro-1,2,3-trimethylbenzene (VI). A mixture of 4-nitro-1,2,3-trimethylbenzene (V; bp 147—149°C/18 mmHg; 7.0 g) and bromine (10 g) was allowed to stand overnight at room temperature. Hydrogen bromide evolved gently and a solid product was obtained, which was crystallized from hot ethanol to give pale yellow needles (9.1 g, 88%), mp 82—83°C. IR: 664, 711, 755, 819, 868, 943, 1038, 1188, 1353, and 1520 cm^{-1}; NMR: 7.69 (Me), 7.67 (Me), 7.55 (Me), and 2.22 τ (aromatic H).

Found: C, 44.46; H, 4.37%. Calcd for $C_9H_{10}NBrO_2$: C, 44.28; H, 4.13%.

5-Nitro-1,2,4-trimethylbenzene (mp 70—71°C; bp 127—129°C/22 mmHg) treated with bromine in a similar manner to that above gave *3-bromo-5-nitro-1,2,4-trimethylbenzene* (*XIV*; mp 89—90°C). NMR: 7.61 (Me), 7.56 (Me), 7.48 (Me), and 2.52 τ (aromatic H).

Found: C, 44.37; H, 2.48%. Calcd for $C_9H_{10}NBrO_2$: C, 44.28; H, 4.13%.

5-Iodo-6-nitro-1,2,4-trimethylbenzene (XXI). To a solution of 6-nitro-2,4,5-trimethylaniline (XX, 9 g)[10] in sulfuric acid (20 ml) was added finely powdered sodium nitrite (3.6 g) with stirring. The mixture was stirred for 30 min and then poured onto crushed ice. The resulting solution of diazonium salt was filtered and the filtrate was added to a solution of potassium iodide (10 g) in a small amount of water. After the mixture was left to stand overnight, the precipitated tan solid was filtered off and passed over a short alumina column with a mixture of benzene and ligroin. From the eluate the iodo compound was obtained as prisms (11.2 g, 77%), mp 130—131°C. IR: 759, 871, 905, 969, 1152, 1255, and 1523 cm^{-1}; NMR: 7.84 (Me), 7.73 (Me), 7.55 (Me), and 2.88τ (aromatic H).

Found: C, 37.29; H, 3.44%. Calcd for $C_9H_{10}NIO_2$: C, 37.13; H, 3.46%.

4-Bromo-6-iodo-1,2,3-trimethylbenzene (VIII), 3-bromo-5-iodo-1,2,4-trimethylbenzene (XVI), and 6-bromo-5-iodo-1,2,4-trimethylbenzene (XXIV) were prepared from the corresponding bromoanilines by a similar procedure. The products were purified through distillation followed by recrystallization from light petroleum.

VIII: mp 97—99°C. IR: 844, 856, 906, 1007, and 1155 cm^{-1}; NMR: 7.69 (Me), 7.68 (Me), 7.62 (Me), and 2.13 τ (aromatic H).

Found: C, 33.22; H, 3.05%. Calcd for $C_9H_{10}BrI$: C, 33.26; H, 3.10%.

XVI: bp 174—177°C/16 mmHg. IR: 734, 805, 866, 948, 993, 1151, and 1350 cm^{-1}; NMR: 7.80 (Me), 7.74 (Me), 7.40 (Me), and 2.48 τ (aromatic H).

Found: C, 33.80; H, 3.11%. Calcd for $C_9H_{10}BrI$: C, 33.26; H, 3.10%.

XXIV: mp 45—46°C; bp 173—176°C/14 mmHg. IR: 758, 804, 864, 961, 993, 1013, 1032, 1138, and 1355 cm^{-1};

9) H. Suzuki, This Bulletin, **44**, 2871 (1971).

10) M. H. Huender, *Rec. Trav. Chim. Pays-Bas*, **34**, 1 (1913).

NMR: 7.79 (Me), 7.59 (Me), and 3.09 τ (aromatic H).

Found: C, 33.26; H, 3.16%. Calcd for $C_9H_{10}BrI$: C, 33.26; H, 3.10%.

6-Iodo-2,3,5-trimethylaniline (XXII). Stannous chloride dihydrate (30 g) was dissolved in a mixture of hydrochloric acid (d=1.18, 35 ml) and ethanol (35 ml). To this solution was added XXI (9.7 g) with stirring. After the end of reaction, sodium hydroxide solution was added until the precipitated stannic hydroxide redissolved, and the solution was steam-distilled. Amine was separated from the distillate by ether-extraction and recrystallized from light petroleum. Colorless needles (6.5 g, 75%), mp 81—82°C. IR: 838, 973, 1017, 1106, 1282, 1318, 1552, 1622, 3290, and 3370 cm^{-1}; NMR: 7.95 (Me), 7.85 (Me), 7.71 (Me), 6.03 (NH_2), and 3.57 τ (aromatic H).

Found: C, 41.40; H, 4.58%. Calcd for $C_9H_{12}NI$: C, 41.40; H, 4.63%.

5-Bromo-2,3,4-trimethylaniline (VII; mp 86—87°C) and *3-bromo-2,4,5-trimethylaniline (XV*; mp 57—59°C) were prepared in a similar manner from VI and XIV, respectively.

VII: IR: 766, 845, 874, 954, 1116, 1206, 1217, 1279, 1295, 1586, 1619, 3340, and 3430 cm^{-1}; NMR: 8.05 (Me), 7.85 (Me), 7.77 (Me), 6.73 (NH_2), and 3.36 τ (aromatic H).

Found: C, 50.59; H, 5.72%. Calcd for $C_9H_{12}NBr$: C, 50.48; H, 5.65%.

XV: IR: 800, 857, 986, 1232, 1278, 1290, 1554, 1607, 1635, 3190, 3290, and 3390 cm^{-1}; NMR: 7.83 (Me), 7.81 (Me), 7.76 (Me), 6.66 (NH_2), and 3.72 τ (aromatic H).

Found: C, 50.42; H, 5.91%. Calcd for $C_9H_{12}NBr$: C, 50.48; H, 5.65%.

4,6-Diiodo-1,2,3-trimethylbenzene (IV). Method 1: Sodium nitrite (0.5 g) was added below 10°C to a solution of III (1.4 g) in sulfuric acid (8 ml). After stirring for 30 min, the mixture was poured onto crushed ice, and the resulting solution was filtered and added to a solution of potassium iodide (1.5 g) in a small amount of water. The mixture was allowed to stand overnight, and the black precipitate was collected by filtration and passed over a short alumina column with light petroleum. From the eluate IV was obtained as colorless plates (0.8 g, 40%), mp 129—130°C. IR: 834, 856, 899, 999, and 1148 cm^{-1}; NMR: 7.68 (Me), 7.62 (2 Me), and 1.88 τ (aromatic H).

Found: C, 29.20; H, 2.78%. Calcd for $C_9H_{10}I_2$: C, 29.06; H, 2.71%.

Other diiodotrimethylbenzenes were prepared in a similar manner from the corresponding iodotrimethylanilines.

3,6-Diiodo-1,2,4-trimethylbenzene (XIX): mp 75—76°C. IR: 739, 852, 992, 1129, and 1248 cm^{-1}; NMR: 7.67 (Me), 7.53 (Me), 7.47 (Me), and 2.47 τ (aromatic H).

Found: C, 29.13; H, 2.66%. Calcd for $C_9H_{10}I_2$: C, 29.06; H, 2.71%.

3,5-Diiodo-1,2,4-trimethylbenzene (XIII): Mp 8—9°C; bp 202—204°C/21 mmHg. IR: 732, 791, 866, 942, 983, 1142, and 1342 cm^{-1}; NMR: 7.76 (Me), 7.66 (Me), 7.27 (Me), and 2.46 τ (aromatic H).

Found: C, 29.21; H, 2.62%. Calcd for $C_9H_{10}I_2$: C, 29.06; H, 2.71%.

5,6-Diiodo-1,2,4-trimethylbenzene (XXIII): Mp 51—52°C; bp 197—199°C/18 mmHg. IR: 746, 788, 865, 955, 990, 1013, 1031, 1131, and 1351 cm^{-1}; NMR: 7.76 (Me), 7.52 (Me), 7.47 (Me), and 3.07 τ (aromatic H).

Found: C, 29.19; H, 2.68%. Calcd for $C_9H_{10}I_2$: C, 29.06; H, 2.71%.

Method 2: The Grignard reagent was prepared in the usual manner from VIII (5.2 g), magnesium (0.4 g), and tetrahydrofuran (40 ml). To the reagent was added at one time dried magnesium iodide (4.5 g) and an additional amount of magnesium (0.6 g), and the mixture was stirred overnight under reflux. After being cooled the mixture was rapidly stirred and iodine (*ca.* 11—12 g) was added in small portions until the brown color began to persist. Excess dilute hydrochloric acid was added, and the organic layer was separated, dried, and evaporated to leave a light brown solid. It was fractionally distilled under reduced pressure and the fraction boiling at 190—200°C/17 mmHg was collected and crystallized from light petroleum. Colorless plates (0.8 g, 14%), mp 124—128°C, were spectroscopically identical with the compound obtained by method 1.

The above procedure applied to 3-bromo-5-iodo-1,2,4-trimethylbenzene (XVI) gave unsatisfactory results, since the bromine atom at the 3-position was found to be slow to react.

4,5-Diiodo-1,2,3-trimethylbenzene and triiodo derivatives of 1,2,3- and 1,2,4-trimethylbenzenes were prepared by the direct iodination of 5-iodo-1,2,3-trimethylbenzene and two corresponding hydrocarbons, respectively, with iodine–periodic acid dihydrare.[6]

4,5-Diiodo-1,2,3-trimethylbenzene: Mp 67—69°C. IR: 835, 858, 902, 997, and 1193 cm^{-1}; NMR: 7.86 (Me), 7.82 (Me), 7.42 (Me), and 2.47 τ (aromatic H).

4,5,6-Triiodo-1,2,3-trimethylbenzene: Mp 232—235°C. IR: 916, 999, 1198, and 1328 cm^{-1}; NMR: 7.65 (Me), and 7.31 τ (2 Me).

Found: C, 21.62; H, 1.70%. Calcd for $C_9H_9I_3$: C, 21.71; H, 1.82%.

3,5,6-Triiodo-1,2,4-trimethylbenzene: Mp 193—195°C. IR: 751, 814, 946, 984, 1128, 1225, and 1325 cm^{-1}; NMR: 7.46 (Me), 7.27 (Me), and 6.93 τ (Me).

Found: C, 21.58; H, 1.76%. Calcd for $C_9H_9I_3$: C, 21.71; H, 1.82%.

General Procedure for the Preparation of Polyiodo Derivatives from Polyalkylbenzenes. A polyalkylbenzene (*ca.* 0.1—0.3 g) dissolved in 80% acetic acid (5 ml) containing a catalytic amount of sulfuric acid was rapidly stirred and heated with iodine (1.0 g) and periodic acid dihydrate (0.45 g) at 70—80°C for 30 min—1 hr. The mixture was then poured into aqueous sodium hydrogen sulfite to remove excess reagent. The white precipitate was collected by filtration and crystallized from ethanol.

Studies on Amino-hexoses. XVII. Identification of the Deamination Products from D-Glucosaminitol

Tomoyuki BANDO and Yoshio MATSUSHIMA

Department of Chemistry, Osaka University College of Science, Toyonaka

(Received July 26, 1972)

The nitrous deamination products of D-glucosaminitol were fractionated with a Dowex-1 free base column after the reaction mixture had been reduced with sodium borohydride. The chromatography gave discrete five peaks, four of which were identified as 2-deoxy-D-*arabino*-hexitol, 2-deoxy-D-*ribo*-hexitol, 2-hydroxymethyl-2-deoxy-D-*arabino*(or *ribo*)-pentitol and D-mannitol in a total yield over 90%. The nitrous deamination products fractionated with a Dowex-1 borate column were identified as 2-deoxy-D-*arabino*-hexose, 2-deoxy-D-*erythro*-3-hexulose, 2-hydroxymethyl-2-deoxy-D-*arabino*(or *ribo*)-pentose and D-mannitol. The formation of products other than D-mannitol was interpreted in terms of intramolecular rearrangement accompanying nitrous deamination.

The nitrous deamination reaction of amino-sugars was once of an unclarified nature in sugar chemistry.[1] However, owing to the progress in the theory of reactivity and molecular conformation,[2] it is now well understood that glucosamine and galactosamine give 2,5-anhydro-mannose and 2,5-anhydro-talose respectively by nitrous deamination, while mannosamine gives glucose, all of these amino-sugars having more or less rigid molecular conformation due to the ring structure.

One of the present authors demonstrated that nitrous deamination of glucosaminitol, which can take various conformations due to the chain structure, gave 2-deoxy-*arabino*-hexose(2-deoxy-glucose) in about 30% yield.[1] The remainder of the reaction products was not identified because of difficulty of analysis. In the present paper are described the results obtained using various chromatographic techniques in the analysis of the reaction products which, as expected, comprise various compounds. These compounds were identified in the following way: A mixture of nitrous deamination products which was highly reducing to Park-Johnson reagent[8] was reduced with sodium borohydride, the reducing groups of the products thus being converted into alcoholic groups. The mixture of the polyhydric alcohols obtained was then fractionated with a column of Dowex-1 free base[3-6] and each fraction was compared with the authentic samples by means of mixed melting point measurement, gas-liquid chromatography, or periodate oxidation.[7,8] On the other hand, the nitrous deamination mixture was directly fractionated with a Dowex-1 borate column,[9] each fraction separated being reduced with sodium borohydride, and the products were compared with the authentic samples by means of gas-liquid chromatography. A probable mechanism of the deamination reactions and the pro-

cedure of the analyses are summarized in Scheme 1.

Experimental

Deamination Reaction. To a solution of 2.0 g of D-glucosaminitol free base (mp 132—134°C)[1] in 40 ml of water was added 1.5 g sodium nitrite, and to this mixture was added dropwise 2.0 ml of acetic acid under mechanical stirring at room temperature. After being left to stand overnight, the reaction mixture showed strong reducing action to Park-Johnson reagent[10], ninhydrin reaction becoming negative.

Reduction of the Deamination Products. The pH of the deamination mixture was adjusted to 7—8 by adding potassium borate and to this solution was added 1.5 g of sodium borohydride. The whole mixture was allowed to stand overnight at 4°C. Excess borohydride was decomposed by treating with Dowex-50 free acid, and the filtrate from the resin was evaporated *in vacuo*. The residue was co-distilled three times with methanol to remove boric acid, and was used for the following column chromatography.

Separation of the Reduced Products. The reduced products corresponding to 2.0 g of glucosaminitol were dissolved in a small amount of water, and the solution was placed on a Dowex-1X4 (OH^- form, 100—200 mesh, 3×110 cm) column. Elution was carried out at the velocity of 1 ml per minute using water free from carbon dioxide as an eluent, each 10 ml fraction being collected. The chromatographic pattern as detected by a color reaction of formaldehyde[11] which had been produced by periodate oxidation of the substances is shown in Fig. 1.

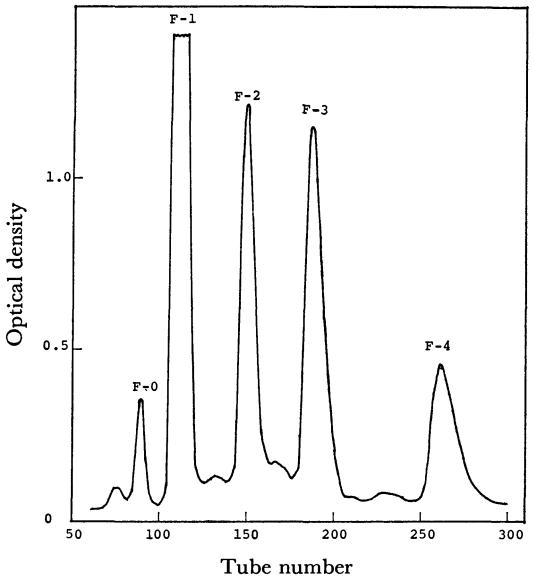

Fig. 1. Dowex-1X4 free base column chromatography of the reduced deamination products.

The results of gas-liquid chromatography of each fraction are shown in Table 1. We see that the fraction F-0 in the Dowex-1 chromatography seemed to be heterogenous and the yield was too low for further study. Crystallization occurred upon evaporation of the solvent *in vacuo* except for the cases of F-0 and F-3.

The yield of each fraction is given in Table 1. Physical constants, elemental analyses, and molecular formulae of each fraction are summarized in Table 2.

11) T. Nash, *Biochem. J.*, **55**, 416 (1953).

Table 1. Recovery, theoretical yield, and retention ratio (R_s) to the internal standard (pentaerythritol) in gas-liquid chromatography

The retention time of the internal standard is 5.6 min. The conditions of gas-liquid chromatography are identical with those described under Fig. 3.

Fraction	Recovery (mg)	Yield (%)	R_s of each fraction	R of authentic samples
F-0	25	1.67	0.535 1.83 2.0	—
F-1	827	55.14	3.22	3.23
F-2	213	14.21	3.34	3.36
F-3	249	16.60	2.74	—
F-4	73	4.44	5.11	5.12

Table 2. Melting point, specific rotation, elemental analysis, and molecular formula according to elemental analysis of the fractions F-1—4

	Mp (°C)	$[\alpha]_D^{20}$ in H_2O	Elemental analysis C%	Elemental analysis H%	Molecular formula
F-1	105—108	+16.2	43.09	8.45	$C_6H_{14}O_5$
F-2	88— 90	−13.1	42.79	8.41	$C_6H_{14}O_5$
F-3	sirup	−3.2	42.89	8.88	$C_6H_{14}O_5$
F-4	165—167.5	0	39.53	7.77	$C_6H_{14}O_6$

Calcd for $C_6H_{14}O_5$: C, 43.36%; H, 8.49%.
Calcd for $C_6H_{14}O_6$; C, 39.56%; H, 7.75%.

Periodate Oxidation of F-1—4. The oxidation products were reduced with sodium borohydride and analyzed by gas-liquid chromatography. The results are summarized in Table 3. As judged from the various evidence mentioned above, the fractions F-1—4 should be 2-deoxy-D-*arabino*-hexitol, 2-deoxy-D-*ribo*-hexitol, 2-hydroxymethyl-2-deoxy-D-*arabino* (or *ribo*)-pentitol, and D-mannitol respectively, the structural formulae of which are shown in Scheme 1.

Table 3. The periodate oxidation products of the fractions F-1—4 successively reduced with sodium borohydride

	HIO_4[7] (mol)	HCHO[11] (mol)	HCOOH[8] (mol)	Product
F-1	2.95	1.05	2.26	1,3-Propanediol
F-2	2.70	1.04	2.18	1,3-Propanediol
F-3	1.85	1.00	1.29	Tris(hydroxymethyl)methane
F-4	4.95	2.00	4.00	—

Direct Separation of the Deamination Products. The chromatographic pattern of the separation of the deamination products using a Dowex-1 borate column is shown in Fig. 2. Of the four peaks observed the peak F-4′ showed no reducing power. The patterns of gas-liquid chromatography of F-1′—4′ are shown in Fig. 3 (a—d). The yield of each fraction was calculated on the basis of the gas-liquid chromatogram of the deamination mixture shown in Fig. 4, and the data are summarized in Table 4. The borohydride-reduced fractions F-1′—3′ were also analyzed by gas-liquid chromatography, and the results are shown in Fig. 3(a—c) as broken lines. F-1′ gave 2-deoxy-D-*arabino*-hexitol, F-2′ 2-hydroxymethyl-2-deoxy-D-*arabino*(or *ribo*)-pentitol, and F-3′ 2-deoxy-D-*ribo*- and *arabino*-hexitol, F-4′ was a non-reducing substance which

was identified as D-mannitol. In conclusion, D-glucosaminitol gave the following four compounds by nitrous deamination, the structural formulae of which are also shown in Scheme 1: 2-deoxy-D-*arabino*-hexose, 2-hydroxymethyl-2-deoxy-D-*arabino*-(or *ribo*)-pentose, 2-deoxy-D-*erythro*-3-hexulose, and D-mannitol. A very small amount (0.6%) of a substance which showed retention time identical with 2,5-anhydro-D-mannitol[12] was observed in gas-liquid chromatography. However, the substance was not studied in detail due to the lack of material.

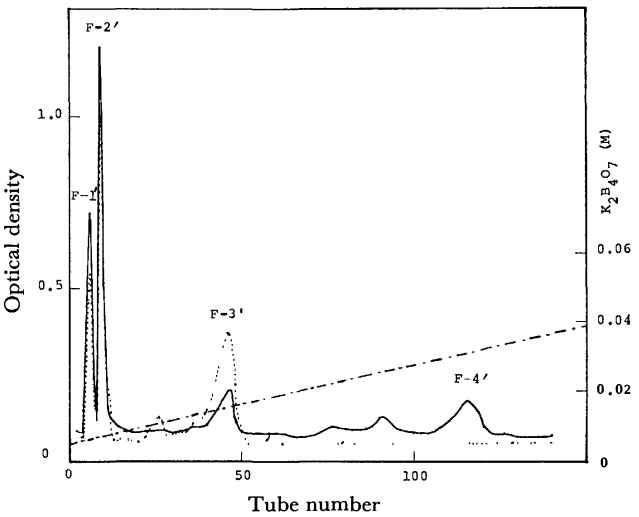

Fig. 2. Dowex-1X10 borate column (200—400 mesh, 0.9×17 cm) chromatography of the deamination mixture.
---- Concentration of potassium borate (eluent).
—— Formaldehyde determined by acetylacetone method[11] after the specimen had been oxidized with periodate.
—— Reducing power determined by Park-Johnson method.[10]

Table 4. Yields of the deamination products determined by means of gas-liquid chromatography

	Yield (%)
F-1′	45.8
F-2′	17.2
F-3′	22.8
F-4′	4.6

Preparation of the Reference Compounds. (a) 2-Deoxy-D-*arabino*-hexitol was prepared by reducing 250 mg of commercial 2-deoxy-D-*arabino*-hexose with sodium borohydride. Crystals appeared in ethanol solution giving 125 mg of the specimen which melted at 105—108.5°C, and had $[\alpha]_D^{20}$ +18.2 (*c*, 4.06 in H_2O). Found: C, 43.70; H, 8.50%. Calcd for $C_6H_{14}O_5$: C, 43.36; H, 8.49%. Bergmann *et al.*[13] gave mp 104—106°C, and $[\alpha]_D$ +17.5 (*c*, 10.0 in H_2O). (b) 2-Deoxy D-*ribo*-hexitol was prepared by reducing 2-deoxy-D-*ribo*-hexose which was synthesized by the known procedures.[14-17] Two hundred and ninety milligrams of the hexose was reduced

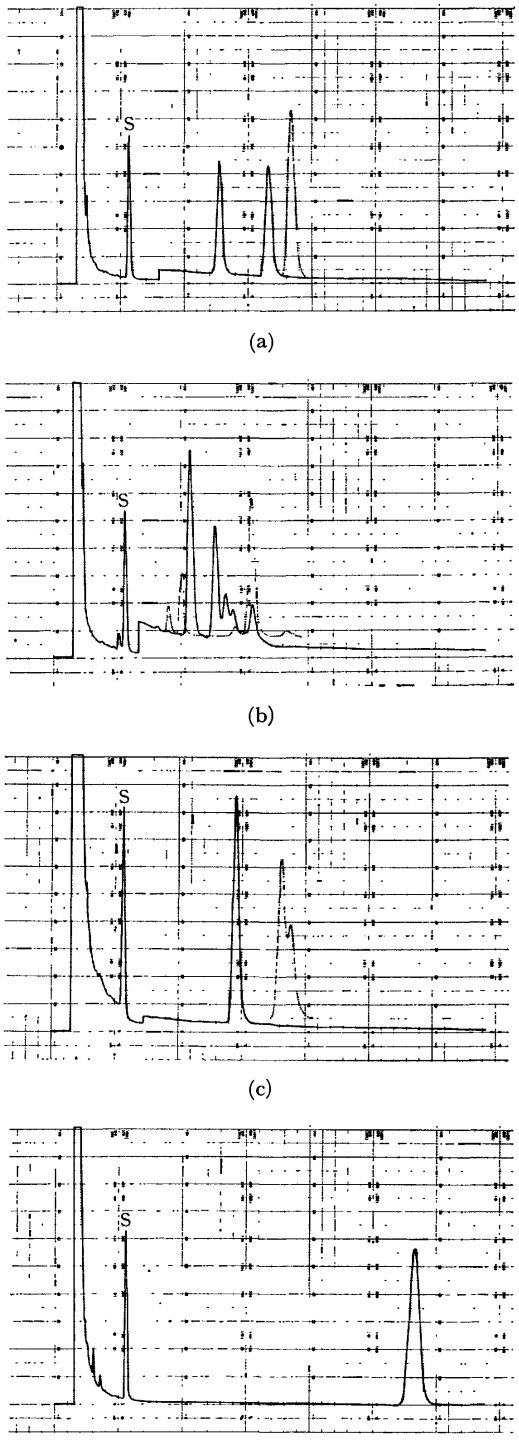

Fig. 3(a—d). Gas-liquid chromatography of the fractions F-1′—4′. A glass column (0.3×300 cm) was packed with 3% SE 52 on 90—100 mesh Chromosorb W which had been treated with dimethyldichlorosilane. The flow rate of the carrier nitrogen was 22 ml per minute, and the column temperature was 180°C. The internal standard(S) was pentaerythritol. Fig. 3(a) shows the anomers of 2-deoxy-D-*arabino*-hexose, the reduction product of which shows retention time identical with 2-deoxy-D-*arabino*-hexitol (broken line). Fig. 3(b) shows heterogeneity of the fraction F-2′. However, the main peak of the reduced F-2′ had retention time identical with that of F-3. The fraction F-3′[Fig. 3(c)] gave upon reduction two hexitols, 2-deoxy-D-*arabino*- and *ribo*-hexitols. Fig. 3(d) shows D-mannitol.

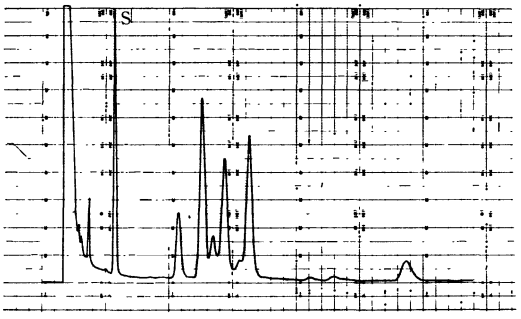

Fig. 4. Gas-liquid chromatography of the deamination mixture before fractionation. All the conditions of the chromatography were identical with those described under Fig. 3.

with sodium borohydride, giving 225 mg of the hexitol which crystallized from ethanol–ether mixture. mp 89—91°C, $[\alpha]_D^{20}$ −9.8° (*c* 7.1, H_2O); Found: C, 43.15; H, 8.48%. Calcd for $C_6H_{14}O_5$: C, 43.36; H, 8.49%. (c) 2.5-Anhydro-D-mannitol was prepared by the known method. mp 100—102°C, $[\alpha]_D^{20}$ +53 (*c* 1.17, H_2O). Bera *et al.*[18] gave mp 100—101°C, $[\alpha]_D^{20}$ +58.2. Found: C, 44.00; H, 7.34%. Calcd for $C_6H_{12}O_5$: C, 43.90; H, 7.37%. (d) D-Mannitol was prepared by reducing commercial D-mannose with sodium borohydride. mp 167—168°C. Braham[19] gave mp 166—168°C. Found: C, 39.46; H, 7.73%. Calcd for $C_6H_{14}O_6$: C, 39.56; H, 7.75%. (e) Tris(hydroxymethyl)methane was prepared by lithium aluminum hydride reduction of the reaction mixture of ethyl malonate and formaldehyde[20]. To 16 ml of ethyl malonate was added 1.0 g of potassium bicarbonate, and to this mixture was added dropwise 7.0 ml of commercial formaldehyde solution under stirring. The mixture was extracted with ether after 2 hours, and the extract was washed with saturated ammonium sulfate and then with water. The ether solution was dried over anhydrous magnesium sulfate. Eight grams of lithium aluminum hydride was added to about 100 ml of the ether solution, and the solution was refluxed overnight. Excess lithium aluminum hydride was decomposed by treatment with ethyl acetate, and the reaction mixture was evaporated *in vacuo*. The residue was acetylated with acetic anhydride–sodium acetate, and the reaction mixture was extracted with chloroform. The chloroform extract was evaporated *in vacuo* and the residue was treated with sodium methoxide in methanol. The mixture of polyhydric alcohols thus obtained was analyzed first by gas-liquid chromatography using the standard trimethylsilylation method. The chromatogram showed three distinct peaks, two of which were identified as propanediol-1,3 and pentaerythritol. The remaining peak was expected to be tris(hydroxymethyl)methane. A preparative chromatography using Dowex-1 free base[4-6] was successful in fractionating three substances, one of which was identified as tris(hydroxymethyl)methane by elemental analyses of itself and its tri-3,5-dinitrobenzoyl derivative. mp 87—89°C. Found: C, 46.47; H, 9.70%. Calcd for $C_4H_{10}O_3$: C, 45.27; H, 9.50%. Tri-3,5-dinitrobenzoyl derivative gave mp 155.5—156°C. Found: C, 43.54; H, 2.60; N, 11.89%. Calcd for $C_{25}H_{16}O_{18}N_6$: C, 43.62; H, 2.34; N, 12.21%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 596—599 (1973)

The Photo-induced Addition of Acetic Acid to Cyclohexene Derivatives[1)]

Ta-Yan LEONG, Takeshi IMAGAWA, Koichi KIMOTO, and Mituyosi KAWANISI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received August 1, 1972)

The irradiation of methyl 3-cyclohexene-1-carboxylate in acetic acid in the presence of benzene as a sensitizer yields methyl *trans*-4-acetoxycyclohexanecarboxylate predominantly, together with a small amount of methyl *trans*-3-acetoxycyclohexane-1-carboxylate; the corresponding *cis*-isomers are not detected. Under the same conditions, on the irradiation of dimethyl esters of *cis*- and *trans*-4-cyclohexene-1,2-dicarboxylic acids, the two possible isomers of acetic-acid adducts with respect to each starting substance are obtained. The irradiation of *trans*-8-oxabicyclo[4.3.0]non-3-ene gives the two possible acetic-acid adducts, whereas in the case of the irradiation of the *cis*-isomer, only two equatorially-substituted acetic-acid adducts are obtained. The structural elucidation and the mechanism of the formation of these compounds are discussed.

The incorporation of protic solvents in excited cycloalkenes by sensitization has proved a fertile field for mechanistic as well as synthetic olefin photochemistry.[2-8)] We have been engaged in studies aimed at

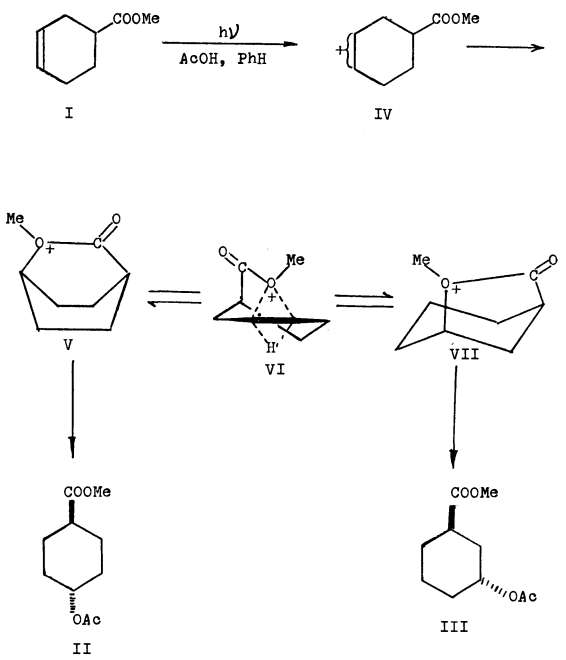
the application of this reaction;[9] we have found that cyclohexenes and cycloheptenes containing an acyloxy group at the allylic and homoallylic positions gave products resulting from the regiospecific addition of polar solvents,[9b] and have assumed the participation of the oxygen functions in the orientation of the reaction pathways.[9d,e] As an extension of this research, as well as a comparison with the results obtained previously, we have now studied the stereochemistry of the polar addition of acetic acid to methyl 3-cyclohexene-1-carboxylate (I) together with cyclohexenes with two substituents, VIII and XI, and bicyclic compounds, XIV and XVII.

Results and Discussion

When methyl 3-cyclohexene-1-carboxylate (I) was irradiated in acetic acid in the presence of benzene as a sensitizer, methyl *trans*-4-acetoxycyclohexane-1-carboxylate (II) was obtained predominantly, together with a small amount of methyl *trans*-3-acetoxycyclohexane-1-carboxylate (III) in a 60% yield (II: III= 97: 3). Authentic specimens of II and III were obtained by using the previously-reported method.[10] The identity of the photoproducts with the authentic specimens was satisfactory. We had already observed that, in the case of cyclohex-3-en-1-yl acetate under similar conditions, only a *cis-trans* mixture (*ca.* 1: 1) of 1,4-diacetoxycyclohexane was obtained regiospecifically; here the contribution of the oxygen functions to the transition state and/or to the intermediate at the protonation stage had been assumed.[9d] In the present case, a possible mechanism for the formation of II and III is depicted in Scheme 1, which indicates that the formation of II and III is due to the intermediacy of oxonium ions. The protonation of photo-excited six-membered cyclic olefin in protic media giving carbonium-ion species appears to be established.[2,3] Therefore, the formation of a carbonium ion (IV) is not exceptional; this in turn collapses into oxonium ions (V) and (VII). The incorporation of the 1,4- or 1,3-bridged ions, such as (V) or (VII), was advanced by Noyce in speaking of the reaction of methoxycyclohexanecarboxylic acids with acetic anhydride.[11] If we assume an equilibrium between these oxonium ions (V) and (VII), in which the doubly-bridged ion (VI) represents the transition state, the exclusive formation of *trans*-products (1,4- and 1,3-) can be understood. It should be noted that this mechanism can also explain the predominant formation of the thermodynamically more stable 1,4-isomer (II). Thus, in the present case, the participation of the oxygen function presumably plays an important role in directing the reaction pathways as well. We will return to the discussion of the mechanistic aspects of the protonation stage after more experimental facts are known.



Scheme 1.

When dimethyl 4-cyclohexene-*cis*-1,2-dicarboxylate (VIII) was irradiated in acetic acid under the same conditions, dimethyl *c*-4-acetoxycyclohexane-*r*-1,*c*-2-dicarboxylate (IX) and dimethyl *t*-4-acetoxycyclohexane-*r*-1,*c*-2-dicarboxylate (X)[12] were obtained in a 25% yield (IX: X=71: 29).

The photoreaction of dimethyl 4-cyclohexene-*trans*-1,2-dicarboxylate (XI) was effected similarly; dimethyl *c*-4-acetoxycyclohexane-*r*-1,*t*-2-dicarboxylate (XII) and dimethyl *t*-4-acetoxycyclohexane-*r*-1,*t*-2-dicarboxylate (XIII) were obtained in a 25% yield (XII: XIII= 34: 66). The structures of IX, X, XII, and XIII were deduced from the respective IR and NMR spectra and were further elucidated by comparison with the authentic specimens prepared by the acetylation of the corresponding known alcohols.[13,14]

Judging from the products of these photoreactions, it can be deduced that, in the cases of VIII and XI, the role of the participation of the oxygen functions is unimportant.

The irradiation of *trans*-8-oxabicyclo[4.3.0]non-3-ene (XIV) yielded the two possible acetic-acid adducts, *t*-3-acetoxy-*r*-1-*trans*-8-oxabicyclo[4.3.0]nonane (XV) and *c*-3-acetoxy-*r*-1-*trans*-8-oxabicyclo[4.3.0]nonane (XVI), in a ratio of XV: XVI=80: 20 (yield=6%). The NMR spectra of XV and XVI showed half-band widths, W_H, of 14 and 8 Hz respectively for the –C**H**–OAc protons; thus, the structures of XV and XVI were unambiguously proved to have the structures shown in Scheme 2, since the fused systems have a *trans*-configuration and an inversion of the structure

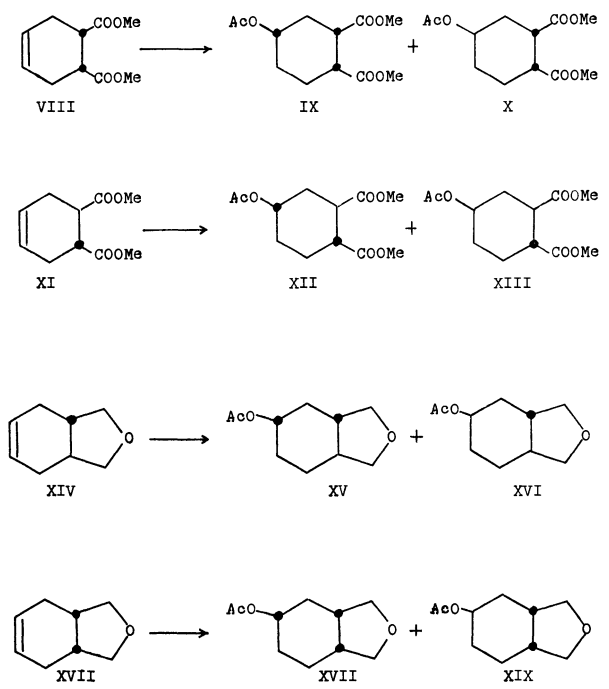

Scheme 2.

is impossible. An independent synthesis of XV and XVI was possible by means of the hydroboration of XIV, followed by alkaline oxidation and acetylation.[14]

On the other hand, when the photochemical reaction of *cis*-8-oxabicyclo[4.3.0]non-3-ene (XVII) was effected under the same conditions, two isomeric adducts were obtained, *t*-3-acetoxy-*r*-1-*cis*-8-oxabicyclo[4.3.0]nonane (XVIII) and *c*-3-acetoxy-*r*-1-*cis*-8-oxabicyclo[4.3.0]-nonane (XIX) in a ratio of 67: 33 (yield=5%); both had broad signals of W_H=14—17 Hz for the methine protons of –C**H**–OAc in their NMR spectra, indicating that the protons are situated axially. The adducts were assumed to have the structures indicated as XVIII and XIX, with equatorial acetoxy groups, which are thermodynamically more stable. A detailed description of the conformations of the alcoholic analogs of XVIII and XIX will appear in a separate paper.[15]

The small yield in the reaction of these bicyclic olefins can be ascribed to the inefficiency of the conversion into the distorted transoid olefins[2,3] *via* their triplet state because of the rigidity of the ring system. Bicyclic olefins such as bicyclo[3.3.1]non-3-ene were found to be fairly reactive toward the photoreaction in protic media, presumably because their structure has some flexibility.[9a]

Although Mundy succeeded in demonstrating the possibility of the long-range nonbonded electronic participation of the oxygen atom in XVII in ground-state chemistry,[16,17] the small yield in the present case restrains us from further discussion of the possible existence of such interaction in excited-state chemistry.

Experimental

All the temperature are uncorrected. Microanalyses were performed by Mrs. Kiyoko Fujimoto of our laboratory. The IR spectra were obtained in neat liquid film on a Shimadzu IR-27-G spectrophotometer. The NMR spectra were taken in 10% CCl_4 solutions on a JEOL C-60-H spectrometer, and the chemical shifts (δ) are reported relative to TMS as an internal standard. The glc analysis and separations were performed with a Shimadzu GC-4APT using a 3 m×3 mm column with 15% polyethylene glycol on 60/80 Chromosorb W operating at 180°C with a He flow rate of 40 ml/min. The MS spectra were taken using a Hitachi RMS-4 mass-spectrometer operated at 70 eV.

Starting Materials. Compounds I, VIII, and XI were prepared in the manner described in the literature.[14] The method of preparing XIV followed the one proposed by Eliel and Pillar;[18] XVII was obtained in asimilar manner and had properties identical with those reported by Christol *et al.*[19]

Photoreaction of Methyl 3-Cyclohexene-1-carboxylate (I) in Acetic Acid. A solution of I (3.27 g; 0.023 mol) and benzene (3 ml) in acetic acid (80 ml) was irradiated for 48 hr by means of a medium-pressure mercury arc in a quartz vessel. The photolysate was diluted with water (100 ml), neutralized (Na_2CO_3), extracted (ether), washed (water), and dried (Na_2SO_4). The adducts, II and III, were separated from the unreacted I by column chromatography (Al_2O_3) and isolated by preparative glc. II and III were obtained in a 60% yield in a ratio of 97: 3. They were identical in all respects with the authentic samples synthesized by the reported methods.[14]

*Photoreaction of Dimethyl 4-Cyclohexene-*cis*-1,2-dicarboxylate (VIII).* A mixture of VIII (5 g; 0.025 mol), benzene (3 ml), and acetic acid (85 ml) was irradiated for 48 hr and then treated in the manner described above. The adducts were obtained as a mixture by column chromatography and were purified by distillation. The mixture of IX and X (IX: X=71: 29) boiled at 114°C/4 mmHg (Yield: 25%). Found: C, 55.70; H, 6.52%. Calcd for $C_{12}H_{18}O_6$: C, 55.80; H, 7.03%. IX and X were separated by glc. The structure of IX was characterized by the following spectral data: IR: 2943(s), 1765(s), 1755(s), 1255(s), 1210(s), 1135(m), 1115(w), 1091(m), 1055(s), 1032(m), 1015(m), 923(w), 902(w), 855(w), 830(w), and 774(w) cm^{-1}. NMR: δ 4.91—4.41(m, 1H), 3.67(s, 6H), 3.08—2.31(m, 2H), 1.95(s, 3H), 2.31—1.30(m, 6H). MS: *m/e* 258(M^+ small), 227(M^+ −31, 4%), 198(M^+ −60, 20%), 185(43%), 166(80%), 138(100%). The structure of X was characterized similarly: IR: 2950(s), 1755(s), 1740(s), 1250(s), 1202(s), 1120(m), 1072(m), 1041(m), 1035(m), 999(m), 958-(w), 832(w), 776(w), cm^{-1}. NMR: δ 5.06—4.73(m, 1H), 3.65(s, 6H), 3.03—2.09(m, 2H), 1.98(s, 3H), 2.27—1.35(m, 6H). MS: *m/e* 258(M^+ samll), 227(M^+ −31, 32%), 198(M^+ −60, 21%), 166(79%), 138(80%), 79(100%).

Dimethyl *c*-4-acetoxycyclohexane-*r*-1,*c*-2-dicarboxylate (IX) was synthesized by the acetylation of the dimethyl *c*-4-hydroxycyclohexane-*r*-1,*c*-2-dicarboxylate obtained by the reduction of dimethyl 4-oxocyclohexane-*cis*-1,2-dicarboxylate as has been described by Klein *et al.*[14] Dimethyl *t*-4-acetoxycyclohexane-*r*-1,*c*-2-dicarboxylate (X) was obtained independently by the acetylation of the dimethyl *t*-4-hydroxycyclohexane-*r*-1,*c*-2-dicarboxylate prepared by the hydro-

boration of dimethyl 4-cyclohexene-*cis*-1,2-dicarboxylate.[13] The IR and NMR of IX and X synthesized in the above manner were identical in all respects with those of the photochemical products.

Photoreaction of Dimethyl 4-Cyclohexene-trans-*1,2-dicarboxylate (XI).* The irradiation of XI was similarly carried out using 6 g (0.03 mol) of XI in 100 ml of acetic acid, with 3.6 ml of benzene as a sensitizer. The isomeric mixture (bp 114°C/4 mmHg) of the photoproducts, XII and XIII in a ratio of 34: 66, was obtained in a 25% yield. Found: C, 55.70; H, 7.07%. Calcd for $C_{12}H_{18}O_6$: C, 55.80; H, 7.03%. The adducts, XII and XIII, were isolated in the manner described before. The structure of XII was assigned according to the following data: IR: 2950(m), 1742(s), 1244(s), 1072(w), 1040(s), 1018(s), 978(w), 941(w), 901(w), 853(w), 754(w) cm^{-1}. NMR: δ 4.91—4.19(m, 1H), 3.66(s, 6H), 2.89—1.81(m, 8H), 1.98(s, 3H). MS: *m/e* 258(M^+ small), 227(M^+ −31, 4%), 198(M^+ −60, 12%), 185(20%), 166(100%), 138(88%).

The structure of XIII was deduced similarly from the following spectral data: IR: 2970(m), 1741(s), 1240(s), 1039(s), 1019(s), 990(m), 958(w), 895(w), 857(w), 761(w) cm^{-1}. NMR: δ 5.15—4.96(m, 1H), 3.64(s, 6H), 2.85—1.30(m, 8H), 2.02(s, 3H). MS: *m/e* 258(M^+ small), 227(M^+ −31, 9%), 198(M^+ −60, 16%), 185(36%), 167(45%), 166(96%), 138(100%).

XII and XIII were independently obtained by the acetylation of the mixture of dimethyl *c*-4- and *t*-4-hydroxycyclohexane-*r*-1,*t*-2-dicarboxylates prepared from the hydroboration of XI, as has been previously reported.[14] The products synthesized in this manner were identical with the photochemical products.

Photoreaction of trans-*8-Oxabicyclo[4.3.0]non-3-ene (XIV).* A mixture of XIV (1.245 g; 0.1 mol), benzene (2 ml), and acetic acid (50 ml) was irradiated in the way previously described. A mixture of the photoproducts, *t*-3-acetoxy-*r*-1-*trans*-8-oxabicyclo[4.3.0]nonane (XV) and *c*-3-acetoxy-*r*-1-*trans*-8-oxabicyclo[4.3.0]nonane (XVI), was obtained in a 6% yield (XV: XVI=80: 20). The adducts were separated by glc. The structures of XV and XVI were supported by the following data. For XV: IR: 2932(s), 2890(s), 1736(s), 1242(s), 1090(w), 1060(w), 1018(s), 980(w), 955(w), 890(m) cm^{-1}. NMR: δ 5.11—4.40(m, 1H, W_H=14 Hz), 4.06—3.5(m, 2H), 3.51—2.81(m, 2H), 1.96(s, 3H), 2.31—1.01(m, 8H). MS: *m/e* 184(M^+ small), 141(M^+ −43, 13%), 124(M^+ −60, 66%), 79(100%). For XVI: IR: 2960(s), 2890(s), 1748(s), 1218(m), 1121(w), 1018(s), 974(w), 895(m) cm^{-1}. NMR: δ 5.30—5.03(m, 1H, W_H=8 Hz), 4.11—3.65(m, 2H), 3.48—2.98(m, 2H), 1.99(s, 3H), 2.35—1.24(m, 8H). MS: *m/e* 184(M^+ 3%), 141(M^+ −43, 40%), 124(M^+ −60, 14%), 43(100%).

Microanalyses were performed on the respective alcohols obtained by the LAH reduction of XV and XVI. For the alcohol from XV: Found: C, 67.57; H, 9.93%. For the alcohol from XVI: Found: C, 67.36; H, 10.19%. Calcd for $C_8H_{14}O_2$: C, 67.57; H, 9.93%.

Independent Synthesis of XV and XVI. A solution of XIV (1 g) in 5 ml of tetrahydrofuran was subjected to hydroboration, followed by alkaline oxidation, as has been described by Klein *et al.*[14] The alcohols thus obtained were converted into the corresponding acetates with a mixture of acetic anhydride and boron trifluoride etherate. The acetates obtained in this way were shown to have an isomeric ratio of XV: XVI=54: 46. The mixture of the acetates was separated into XV and XVI by glc; they were shown to be identical in all respects with those obtained photochemically.

Photoreaction of cis-*8-Oxabicyclo[4.3.0]non-3-ene (XVII).* The procedure was essentially the same as that for XIV; the adducts obtained in a 5% yield. Found: C, 65.01; H, 8.76%. Calcd for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75%. This mixture was separated into *t*-3-acetoxy-*r*-1-*cis*-8-oxabicyclo-[4.3.0]nonane (XVIII) and *c*-3-acetoxy-*r*-1-*cis*-8-oxabicyclo-[4.3.0]nonane (XIX) by preparative glc (XVIII: XIX=67: 33); the isomers had the following properties. For XVIII: IR: 2950(s), 2900(s), 1742(s), 1460(w), 1370(m), 1255(s), 1236(s), 1083(s), 1050(s), 1034(s), 1016(s), 995(w), 960(w), 900(m), 720(w) cm^{-1}. NMR: δ 5.01—4.52(m, 1H, W_H=17 Hz), 3.91—3.40(m, 4H), 2.51—1.09(m, 11H). MS: *m/e* 184(M^+ 2%), 141(M^+ −43, 24%), 124(M^+ −60, 28%), 43(100%). For XIX: IR: 2950(s), 2900(s), 1741(s), 1370(m), 1240(s), 1060(w), 1020(s), 895 cm^{-1}. NMR: δ 5.12—4.66(m, 1H, W_H=14 Hz), 4.04—3.33(m, 4H), 2.64—1.14(m, 11H). MS: *m/e* 184(M^+ 2%), 141(M^+ −43, 30%), 124(M^+ −60, 30%), 43(100%).

The elemental analysis of each isomer was performed upon the corresponding alcohol derived from the LAH reduction of XVIII and XIX. For the alcohol from XVIII; Found: C, 67.57; H, 10.17%. For the alcohol from XIX; Found: C, 67.35; H, 9.65%. Calcd for $C_8H_{15}O_2$: C, 67.57; H, 9.93%.

Professor Hitosi Nozaki is thanked for his interest in this work.

Dimerization of Isoprene by Palladium-Diphosphine Complex Catalyst

Kuniyuki TAKAHASHI,* Go HATA, and Akihisa MIYAKE

Basic Research Laboratories, Toray Industries, Inc., Tebiro, Kamakura

(Received August 7, 1972)

Oligomerization of isoprene catalyzed by the $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$–PhONa catalyst was studied. The catalyst activity was greatly enhanced by the addition of phenol. Five linear dimers were identified. Distribution of the isomeric dimers was remarkably affected by the molar ratio of phenol to isoprene. The reaction in the presence of a small amount of phenol (phenol/isoprene=1/30) gave 2,7-dimethyl-1,*trans*-3,7-octatriene derived from a tail-to-tail dimerization almost selectively, while the addition of a large amount of phenol (phenol/isoprene=1/1.5) afforded head-to-head dimers (2-vinyl-5-methyl-1,6-heptadiene and 3,6-dimethyl-1,*cis*-3,7-octatriene) as main dimers (more than 40% of all the dimers). In a 1:3 ratio of phenol to isoprene the dimers consisted of mainly 2,6-dimethyl-1,*trans*-3,7-octatriene derived from a head-to-tail dimerization.

It is well-known that oligomerization of 1,3-butadiene to cyclic or linear products is catalyzed by some transition metal complexes. A new type of linear dimerization of 1,3-butadiene catalyzed by transition metal compounds of group VIII of the periodic table, completed by addition of a compound having at least one active hydrogen atom to give 2,7-octadienyl derivatives as main products, has recently been found.[1-6] In this reaction palladium complexes, especially palladium-triphenylphosphine complexes, are the most effective.

In connection with the above reaction, we have found[7] that the reaction of 1,3-butadiene with active methylene compounds or amines catalyzed by palladium-diphosphine complexes gives 1:1 adducts of 1,3-butadiene to the active methylene compounds or the amines. This type of reaction was not applicable to other active hydrogen compounds such as phenol, alcohols and carboxylic acids, but the reaction in phenol was found to give a linear dimer 1,3,7-octatriene in a good yield. Further research has led us to find that a palladium-diphosphine complex catalyst shows a high catalytic activity in the linear dimerization of 1,3-butadiene and isoprene by addition of a catalytic amount of phenol.

The present paper deals with the dimerization of isoprene in the presence of $PdBr_2$ $(Ph_2PCH_2CH_2PPh_2)_2$, PhONa and PhOH as a catalyst system. Some catalysts containing chromium,[8] titanium,[9] hafnium,[10] and zirconium[11] have been reported to give linear dimers along with other oligomers. Zerovalent palladium-triphenylphosphine complexes have been also reported[12] to catalyze the reaction in 2-propanol to afford 2,7-dimethyl-1,3,7-octatriene almost selectively.

The reaction of isoprene catalyzed by a combination of $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$, PhONa and a small amount of phenol also gave 2,7-dimethyl-1,3,7-octatriene almost selectively, but it was found that by adding a large amount of phenol the reaction afforded 2,6-dimethyl-1,3,7-octatriene as the main product and other linear isomers as minor products.

The results given below deal with our work to determine the structure of the isomeric dimers of isoprene and to investigate the effect of phenol on the distribution of the isomers.

Experimental

Reagent. Isoprene was dried on calcium chloride and distilled under an argon atmosphere. Phenols were purified by distillation. Dibromobis(ethylenebisdiphenylphosphine) palladium (II) was prepared according to the procedure given by Chatt *et al.*[13]

Analysis. Gas-chromatography was used for identification and quantitative analysis. A squalane-on-Celite column and a Silicone DC 550 capillary column (a length: 90 feet, a diameter: 0.02 inch) were used. 4-Vinyl-cyclohexene was used as an internal standard. A preparative gas-chromatography apparatus equipped with a squalane-on-Celite column was used to isolate the products. IR, NMR, UV and mass spectra were also used to identify the products. Samples for the measurement of mass spectra were introduced directly to the mass spectrophotometer from gas-chromatography apparatus equipped with a capirally column.

General Procedure for the Dimerization of Isoprene. To a 100 ml stainless steel autoclave, $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$, PhONa, PhOH, isoprene and benzene were charged under an argon atmosphere. The autoclave was heated at 150°C with stirring.

Results and Discussion

The dimerization of isoprene catalyzed by a combination of $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$, PhONa and a small amount of PhOH gave a linear dimer almost

selectively. On the other hand, the reaction in the presence of a large amount of PhOH afforded various linear dimers. It was also found that the distribution of linear dimers was remarkably affected by the amount of phenol added. The gas chromatography of the dimers carried out with a 90 feet Silicone DC 550 capirally column is shown in Fig. 1.

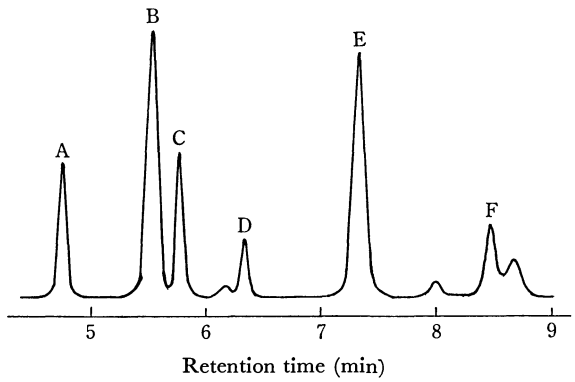

Fig. 1. Gas-chromatograph of isoprene dimers
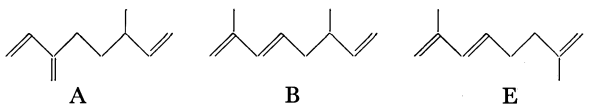
column: Silicone DC 550 (90 ft, 0.02 in)
temperature: 110°C

Products A, B, and E (Fig. 1) were isolated purely and identified by spectroscopic methods. The spectroscopic data are shown in Tables 1 and 2. Products A, B, and E were apparently derived from head-to-head, head-to-tail, and tail-to-tail dimerization of isoprene, respectively.



A B E

Product C was separated as a mixture with product D. Hydrogenation of the mixture gave only one product, 3,6-dimethyloctane, which was confirmed by the vpc equipped with a capillary column. The NMR spectrum of the mixture showed characteristic signals at τ 3.30 and 3.70 (two quartets, 1H), and τ 8.19 and 8.30 (two singlets, 3H). The intensity ratio of the lower chemical shift to the higher in each pair coincided with the weight ratio of C to D involved in the sample for the measurement of the NMR spectrum. This indicates that the signals at τ 3.30 and 8.19 are due to C and other signals to D. The chemical shifts due to

Table 2. Mass spectral data (relative intensities)

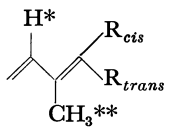
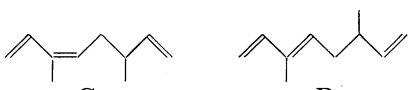
136	2	3	3	4	3

H* and H** of *cis* form in the following general fomula are lower (H*: 20—40 Hz,[14] H**: 0.07 Hz[15]) than those of the *trans* form. On the other hand, the mass spectra of C and D were equal (Table 2). Thus, the



structures of C and D were presumed as 3,6-dimethyl-1, *cis*-3,7-octatriene and 3,6-dimethyl-1, *trans*-3,6-octratriene, respectively.



C D

Product F was identified as a mixture of 1-methyl-4-(2-propenyl)cyclohexene and 1-methyl-3-(2-propenyl)-cyclohexene, which were derived from the Diels-Alder reaction of isoprene by spectroscopic measurements. Other products were not identified.

The effect of phenol on the distribution of the isomeric dimers was investigated and the results are summarized in Table 3. The reaction in the absence

a) Reaction conditions: $PdBr_2(Ph_2PCH_2CH_2PPh_2)_2$ 0.25 mmol, PhONa 2.5 mmol, benzene 15 ml, isoprene 0.3 mol, substituted phenol 0.1 mol, 150°C, 1 hr.
For b), c), d), and e), refer to Table 3

of phenol gave only a small amount of dimers.[16] However, by adding phenol the catalytic activity was greatly enhanced and linear dimers were afforded in a fairly good yield. With the increase of the amount of phenol, the yield of the dimers decreased while that of the trimers, whose structure was not investigated, increased. It is interesting that the distribution of 2,6-dimethyl-1, *trans*-3,7-octatriene (B), which was derived from the head-to-tail dimerization of isoprene, went up to 60% when 0.1 mol of phenol (to 0.3 mol of isoprene) was added. Further increase of the amount of phenol yielded a considerable amount of the head-to-head dimers (A) and (C) as main products (about 40% in dimers) although the head-to-head addition seems difficult to occur because of repulsion between methyl groups or for some such steric reason. The tail-to-tail isomer 2,7-dimethyl-1, *trans*-3,7-octatriene (E) was given almost selectively in the presence of only a small amount of phenol, but the yield decreased considerably with the increase of phenol. It was confirmed that the variation of the distribution of the isomeric dimers was influenced mostly by the molar ratio of phenol to isoprene.

The results of the investigation on the effect of substituted phenol are shown in Table 4. It is obvious that the effect of substituted groups on the distribution of isomeric dimers and the yield of the dimers is very large. The reaction in the presence of 2,4-xylenol gave linear dimers, mainly 2,7-dimethyl-1, *trans*-3,7-octatriene in a 82% yield. On the other hand, the reaction in *p*-chlorophenol yielded only a small amount of linear dimers, mainly 3,6-dimethyl-1, *cis*-3,7-octatriene, in a 14% yield, the reactivity being much smaller than that in 2,4-xylenol.

16) The diphosphine complex $PdBr_2(Ph_2CH_2CH_2PPh_2)_2$ had no catalytic activity. A zero-valent complex $Pd(Ph_2CH_2CH_2PPh_2)_2$ showed low catalytic activity. The catalytic activity of Pd(0) complexes, which is presumed to be similar to that of Pd(II) complexes,[7] was not studied in detail.

The Syntheses of Trimethyl *dl*-3-(Methoxycarbonylmethyl)-1,2,4-cyclopentanetricarboxylates[1]

Shosuke Ito and Yoshimasa Hirata

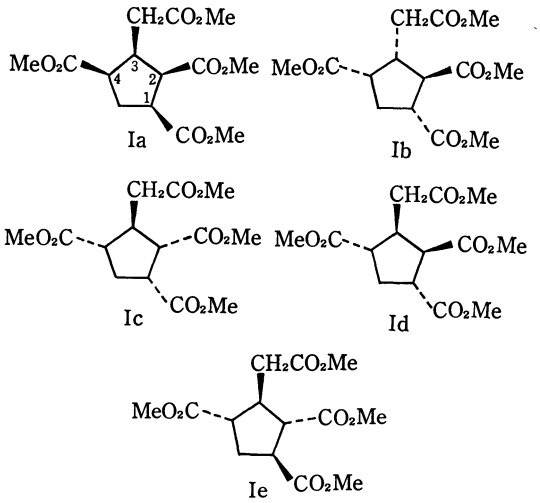
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received August 21, 1972)

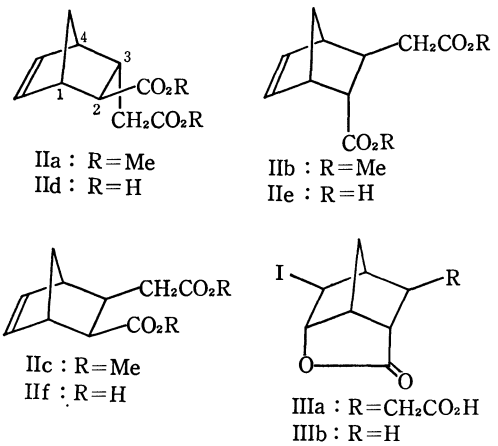
The five trimethyl *dl*-3-methoxycarbonylmethyl-1,2,4-cyclopentanetricarboxylates have been synthesized and their configurations determined. A comparison of their spectral properties with those of the corresponding ester obtained from ikarugamycin indicates that the latter has a *cis*, *trans*, *trans* configuration.

In the course of structural studies of a new antibiotic, ikarugamycin, a monocyclic tetramethyl ester, I ($C_{14}H_{20}O_8$) was obtained as one of the chromic acid oxidation products of ikarugamycin and has played an important role in the determination of the structure and the stereochemistry of ikarugamycin.[2]

The structure of I was assumed to be trimethyl 3-methoxycarbonylmethyl-1,2,4-cyclopentanetricarboxylate on the basis of the concomitant formations of tetramethyl 1,2,3,4-butanetetracarboxylate and tetramethyl 1,2,3,4-cyclopentanetetracarboxylate[2a] and of the following spectral data: δ 2.1—3.4 (8H, m), 3.58 (3H, s), 3.60 (6H, s), 3.63 (3H, s); *m/e* 316.1160. In order to determine the structure and stereochemistry of I, five stereoisomers of trimethyl *dl*-3-methoxycarbonylmethyl-1,2,4-cyclopentanetricarboxylates (Ia—Ie) were synthesized and their stereochemistry was unambiguously established.



The syntheses of two the stereoisomers, Ia[3] and Id,[4] had already been reported. The *cis*, *cis*, *cis*-isomer (Ia) had been prepared by the oxidation of *endo*-dicyclopentadiene with ozone and then with performic acid. Three stereoisomers (the *trans*, *trans*, *cis*-isomer (Ib), the *cis*, *trans*, *trans*-isomer (Ic), and the *trans*, *cis*, *trans*-isomer (Id)) were obtained by the oxidative fission of the double bond of each of three stereoisomeric 2-methoxycarbonyl-3-methoxycarbonylmethylbicyclo[2.2.1]hept-5-enes (IIa, IIb, and IIc respectively). The two *trans*-dimethyl esters (IIa and IIb) were prepared by the Diels-Alder reaction of cyclopentadiene with dimethyl *trans*-glutaconate and were separated by preparative glc. The stereochemistry of those stereoisomers was determined as follows. The dimethyl ester (IIb) was hydrolysed to the corresponding dicarboxylic acid (IIe), which was then easily converted into an iodolactone, IIIa, when treated with iodine and potassium iodide in the presence of sodium bicarbonate.[5] The IR spectrum of IIIa shows two absorption bands for a γ-lactone (1805 cm^{-1}) and a carboxylic acid (1739 cm^{-1}). The NMR spectrum of IIIa exhibits close similarities with that of IIIb[6] with respect to the chemical shifts and the coupling constants of three protons (H-1, 5-*endo*, and 6-*exo*). In addition, the iodolactone (IIIa) was reconverted into the carboxylic acid (IIe) when treated with zinc in acetic acid.[5] The above facts indicate that the iodolactone has the structure IIIa. Accordingly, the configuration of IIb was established. The *exo*, *cis*-dimethyl ester (IIc) was prepared, although in a low yield, by the Arndt-Eistert reaction of the half methyl ester derived from *exo*, *cis*-bicyclo[2.2.1]hept-5-ene-2,3-dicarboxylic anhydride.[7] By heating under reflux with methanolic sodium methoxide, the dimethyl ester, Ia, was completely isomerized to the fifth isomer (Ie) as the main product, together with Ic as a minor product.



1) A part of this work was preliminarily reported in Ref. 2b.

3) M. I. Fremery and E. K. Frieds, *J. Org. Chem.*, **28**, 2537 (1963).

4) R. H. Sullivan, Ger. 1078120 (1960).

5) For example, J. Meinwald, S. S. Labana, and M. S. Chadha, *J. Amer. Chem. Soc.*, **85**, 582 (1963).

6) R. M. Moriarty, H. Gopal, H. G. Walsh, K. C. Ramey, and D. C. Lini, *Tetrahedron Lett.*, **1966**, 4555.

7) D. Craig, *J. Amer. Chem. Soc.*, **73**, 4889 (1951).

The IR and NMR spectra and the behavior upon glc of the naturally derived ester (I) were identical with those of the synthetic *cis, trans, trans*-ester (Ic). On the other hand, the other isomers (Ia, Ib, Id, and Ie) were different from I in many respects.

Experimental

All melting points were uncorrected. The IR spectra were recorded on a JASCO IR-S spectrometer. The NMR spectra were recorded on a Nihondenshi JNM-C60H spectrometer, using CCl_4 as the solvent, unless otherwise stated. The chemical shifts are given in ppm relative to the internal TMS, and the coupling constants are given in Hz. The mass spectra were obtained on a Hitachi RMU-6D mass spectrometer operating with an ionization energy of 70 eV. The glc were carried out on a Varian Aerograph 1828-4 instrument. All the microanalytical samples of oily materials were obtained by the preparative glc.

Trimethyl cis, cis, cis-*3-Methoxycarbonylmethyl-1,2,4-cyclopentanetricarboxylate (Ia).* A solution of *endo*-dicyclopentadiene (300 mg) in methanol (60 ml) was ozonized at −70°C until the solution turned blue. The excess ozone was removed with a nitrogen stream, and then the solvent was evaporated under reduced pressure. After adding 98% formic acid (30 ml) and 53% hydrogen peroxide (4.5 ml), the mixture was stirred at 0°C for 1 hr and then at room temperature overnight. After the excess oxidizing reagents had been destroyed with sodium bisulfite, the mixture was concentrated under reduced pressure. The residue was digested in methanol and then filtered. The filtrates were concentrated under reduced pressure. The treatment of the residue with diazomethane gave a crude methyl ester (910 mg), which was chromatographed on silica gel (15 g) and eluted with *n*-hexane–ether (2: 1) to give 210 mg (29%) of Ia as a colorless oil; δ 2.0—3.3 (8H, m), 3.60 (6H, s), 3.62 (6H, s); *m/e* 316 (M^+). Found: C, 52.77; H, 6.85%. Calcd for $C_{14}H_{20}O_8$: C, 53.16; H, 6.37%.

trans-*2-Methoxycarbonyl-3-methoxycarbonylmethylbicyclo[2.2.1]-hept-5-enes (IIa and IIb).* A solution of dimethyl *trans*-glutaconate (2.88 g) and cyclopentadiene (6.6 g) in toluene (10 ml) was heated at 150°C for 22 hr. The subsequent distilation of the mixture gave 2.05 g (61%) of a mixture of IIa and IIb (bp 143—152°C/18 mmHg), which was then chromatographed on silica gel (70 g) and eluted with *n*-hexane–ether (6: 1) to give the following three fractions: Fraction 1 (1.20 g); IIa: IIb=4: 1, Fraction 2 (0.27 g); IIa: IIb= 1: 1, and Fraction 3 (0.45 g); IIa: IIb=1: 19. The pure samples of IIa and IIb were obtained by preparative glc (5% OV-17 column at 200°C) from Fractions 1 and 3 respectively. 2-*exo*-3-*endo*-isomer (IIa): δ 3.57 (3H, s), 3.62 (3H, s), 6.15 (2H, m); *m/e* 224 (M^+), 164, 159, 151, 66. 2-*endo*-3-*exo*-isomer (IIb): δ 3.55 (3H, s), 3.59 (3H, s), 5.96 (1H, dd, 5.6, 3.0), 6.19 (1H, dd, 5.6, 3.0); *m/e* 224 (M^+), 164, 159, 151, 66.

exo,cis-*2-Methoxycarbonyl-3-methoxycarbonylmethylbicyclo[2.2.1]-hept-5-ene (IIc).* A solution of[7] *exo,cis*-bicyclo[2.2.1]hept-5-ene-2,3-dicarboxylic anhydride[7] (2.5 g) in methanol (25 ml) was refluxed for 2 hr. The subsequent removal of the solvent under reduced pressure gave a half methyl ester ($\nu_{max}^{CHCl_3}$ 1741, 1711 cm^{-1}), which was then dissolved in benzene (20 ml). To the stirred solution, oxalyl chloride (4 ml) was added at 0°C; the mixture was kept at 0°C for 0.5 hr and then at room temperature for 2 hr. The solvent and the excess reagent were removed under reduced pressure to afford a crude acid chloride, which was then dissolved in benzene (10 ml). To a stirred, ethereal diazomethane (120 ml), the benzene solution was added, drop by drop at −10——5°C over a period of 0.5 hr; the mixture was then stirred at 0°C for 0.5 hr and subsequently at room temperature overnight. The removal of the solvent gave a crude diazoketone ($\nu_{max}^{CHCl_3}$ 2150, 1746, 1643 cm^{-1}), which was then dissolved in methanol (100 ml). A mixture of the methanol solution and silver oxide (freshly prepared from 1 g of silver nitrate) was refluxed for 2 hr with stirring. The mixture was then treated with charcoal, filtered through celite, and washed methanol. The filtrates were concentrated under reduced pressure to give a reddish oil (3.1 g), which was chromatographed on silica gel (35 g). Elution with *n*-hexane–ether (2: 1) afforded a mixture (0.63 g) containing IIc, which was purified by preparative glc (5% SE-30 column at 230°C) to give 0.21 g (7%) of IIc as a colorless oil; δ 3.64 (6H, s), 6.20 (2H, m); *m/e* 224 (M^+), 164, 159, 151, 66.

Alkaline Hydrolyses of IIa, IIb, and IIc. (a) 2-*endo*-3-*exo*-dicarboxylic acid (IIe): A solution of IIb (255 mg) in methanol (3 ml) and 10% aqueous potassium hydroxide (3 ml) was heated at 50°C for 2 hr. Working-up usual gave 155 mg (70%) of IIe as plates; mp 158—159°C (from chloroform). Found: C, 61.19; H, 6.08%. Calcd for $C_{10}H_{12}O_4$: C, 61.21; H, 6.17%. (b) 2-*exo*-3-*endo*-dicarboxylic acid (IId): The hydrolysis of IIa (21 mg) as described in (a) afforded 10 mg (55%) of IId as plates; mp 115—117°C (from benzene-*n*-hexane). Found: C, 61.29; H, 6.21%. Calcd for $C_{10}H_{12}O_4$: C, 61.21; H, 6.17%. (c) *exo,cis*-dicarboxylic acid (IIf): The hydrolysis of IIc (43 mg) as described in (a) afforded 32 mg (85%) of IIf as plates; mp 144—146°C (from benzene-*n*-hexane). Found: C, 61.63; H, 6.12%. Calcd for $C_{10}H_{12}O_4$: C, 61.21; H, 6.17%.

Trimethyl trans, trans, cis-*3-Methoxycarbonylmethyl-1,2,4-cyclopentanetricarboxylate (Ib).* Into a solution of IIa (102 mg) in methanol (20 ml), ozone was passed at −70°C until the solution turned blue. The excess ozone was removed with a nitrogen stream, and then the solvent was evaporated under reduced pressure. To the residue, 98% formic acid (10 ml) and 35% hydrogen peroxide (1 ml) were added; the solution was subsequently stirred at 0°C for 3 hr, and then at room temperature overnight. After destroying the excess oxidizing reagents with sodium bisulfite, the mixture was concentrated under reduced pressure to leave a residue, which was digested in methanol and then filtered. The filtrates were concentrated under reduced pressure to leave an oily residue. Further treatment with diazomethane gave a crude methyl ester, which was purified by preparative tlc with *n*-hexane–ether (1: 1) as a mobile phase to give 104 mg (73%) of Ib as a colorless oil; δ 2.1—3.4 (8H, m), 3.62 (6H, s), 3.68 (6H, s): *m/e* 316 (M^+). Found: C, 53.90; H, 6.67%. Calcd for $C_{14}H_{20}O_8$: C, 53.16; H, 6.37%.

Trimethyl cis, trans, trans-*3-Methoxycarbonylmethyl-1,2,4-cyclopentanetricarboxylate (Ic).* The dimethyl ester, IIb (101 mg), was oxidized as in the case of IIa to give 91 mg (64%) of Ic as a colorless oil; δ 2.1—3.5 (8H, m), 3.58 (3H, s), 3.60 (6H, s), 3.64 (3H, s); *m/e* 316 (M^+). Found: C, 53.36; H, 6.76%. Calcd for $C_{14}H_{20}O_8$: C, 53.16; H, 6.37%.

Trimethyl trans, cis, trans-*3-Methoxycarbonylmethyl-1,2,4-cyclopentanetricarboxylate (Id).* The dimethyl ester, IIc (32 mg), was oxidized as in the case of IIa to give 45 mg (100%) of Id as a colorless oil; δ 2.0—3.5 (8H, m), 3.61 (3H, s), 3.63 (3H, s), 3.67 (3H, s); *m/e* 316 (M^+). Found: C, 52.64; H, 6.46%. Calcd for $C_{14}H_{20}O_8$: C, 53.16; H, 6.37%.

Base-catalysed Equilibration of Ia: The Formation of Trimethyl trans, trans, trans-*3-Methoxycarbonylmethyl-1,2,4-cyclopentanetricarboxylate (Ie).* A solution of Ia (540 mg) and sodium methoxide in methanol (prepared from 200 mg of sodium and 10 ml of methanol) was refluxed for 1 hr. After having

been acidified with diluted hydrochloric acid, the reaction a mixture was concentrated under reduced pressure and then extracted with ether. The ethereal extracts were washed with water and a saturated sodium chloride solution, and then dried over anhydrous magnesium sulfate. The subsequent removal of the solvent gave a brown residue, which was chromatographed on silica gel (10 g) and eluted with *n*-hexane–ether (2:1) to give 345 mg (64%) of pure Ie as a colorless oil. Further elution with *n*-hexane–ether (1:1) gave a mixture (70 mg) of Ie and Ic. The latter was purified by preparative glc to give 15 mg of pure Ic. Ie: δ 1.9—3.5 (8H, m), 3.60 (3H, s), 3.64 (3H, s), 3.66 (6H, s); *m/e* 316 (M^+). Found: C, 52.90; H, 6.39%. Calcd for $C_{14}H_{20}O_8$: C, 53.16; H, 6.37%.

The Formation of Iodolactone IIIa. To a solution of the dicarboxylic acid, IIb (98 mg), and sodium bicarbonate (168 mg) in water (30 ml), a solution of iodine (254 mg) and potassium iodide (0.5 g) in water (1.5 ml) was added; the mixture was then stirred at room temperature for 20 hr in the dark. After extraction with ether, the aqueous layer was acidified with 6N hydrochloric acid, treated with sodium bisulfite until it became a clear, colorless solution, and then extracted with ether. The ethereal extracts were succesively washed with water and a saturated sodium chloride solution, and then dried over anhydrous magnesium sulfate. The evaporation of the solvent afforded crude crystals, which were recrystallized from chloroform to give 124 mg (76%) of IIIa as plates; mp 138—141°C; $\nu_{max}^{CHCl_3}$ 1800, 1786, 1725 (shoulder), 1716 cm^{-1}; ν_{max}^{THF} 1805, 1739 cm^{-1}; δ^{CDCl_3} 1.7—2.7 (7H, m), 3.18 (1H, m, H-1), 3.91 (1H, broad d, 2.4, H-5-*endo*), 5.11 (1H, broad d, 5.1, H-6-*exo*), 9.3 (1H, broad s, disappeared on addition of D_2O). Found: C, 37.29; H, 3.43%. Calcd for $C_{10}H_{11}O_4I$: C, 37.29; H, 3.44%.

Conversion of IIIa into IIb. A mixture of IIIa (31 mg) and zinc powder (100 mg) in acetic acid (10 ml) was stirred at room temperature for 0.5 hr, and then filtered through celite. The filtrate was concentrated to leave a residue, which was subsequently dissolved in diluted hydrochloric acid and extracted with ether. The extracts were washed with water and dried over anhydrous magnesium sulfate. The evaporation of the solvent afforded an oil, which was crystallized from chloroform to give 8 mg of plates; mp 155—157°C. The IR spectrum (KBr) of this material was completely identical with that of IIb.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 605—610 (1973)

Optically Active Triptycenes. V.* Synthesis, Optical Resolution and Absolute Configuration of 2,7-Disubstituted Triptycenes.

(Received June 29, 1972)

2,7-Dicarboxytriptycene retaining C_2-axis of symmetry was synthesized from 1,5-dichloroanthraquinone. Optical resolution of the triptycene afforded (+)- and (−)-enantiomers. The absolute configuration of (+)-2,7-dicarboxytriptycene was determined as 1R,6R by chemical correlation with (+)-2-methoxy-7-methoxycarbonyltriptycene which has 1R,6S configuration as confirmed by chemical transformation and X-ray structure analysis using the Bijvoet method. Starting from (+)-2,7-dicarboxytriptycene, a series of 2,7-disubstituted triptycenes having 1R,6R configuration has been prepared.

As pointed out in previous papers of this series,[1,2] optically active triptycenes can be regarded as most suitable compounds for the study of rotatory properties in view of their definite molecular geometry and the well-marked electronic transition of benzenoid chromophores.

It is desirable to synthesize simpler and well-defined dissymmetrical systems to facilitate theoretical approaches, since the X-ray analysis of (+)-2,5-dimethoxy-7-dimethylaminotriptycene hydrobromide (XVIII) by the Bijvoet method gave an antipodal absolute configuration[3] to that deduced by the rigorous analysis of CD spectra of this series of trisubstituted triptycenes.[4] If we take into account the effect of substitution on the direction of polarization of the transition of benzenoid chromophore,[5,6] C_2-symmetrical triptycenes having the same substituents at 2,7-positions seem to be favorable model compounds for the present purpose.

The present paper deals with the synthesis, optical resolution and determination of absolute configuration of 2,7-dicarboxytriptycene (VII) and the transformation of VII into various kinds of C_2-symmetrical 2,7-disubstituted triptycenes. The route of synthesis of VII is outlined in Scheme 1. 1,5-Dicarboxyanthraquinone (III) was prepared by acid hydrolysis of dicyano derivative (II) derived from 1,5-dichloroanthraquinone (I). III was reduced to 1,5-dicarboxyanthracene (IV).

Treatment of the sodium salt of IV with dimethyl sulfate afforded dimethyl ester (V). 2,7-Dimethoxycarbonyltriptycene (VI) was obtained by the addition of benzyne generated from diazotized anthranilic acid[7] with V.

Isomeric 5,7-dimethoxycarbonyltriptycene (VIII) having a plane of symmetry was prepared as a reference compound by a similar sequence of reaction starting from 1,8-dichloroanthraquinone[8] (Scheme 2).

Scheme 2.

After several experiments, the optical resolution of VII obtained from VI was attained with equimolar cinchonidine and cinchonine. Optically pure (+)-dicarboxylic acid (VII) was obtained from the cinchonidine salt by decomposition with acetic acid. On the other hand, the cinchonine salt afforded (−)-VII.

(+)-Dicarboxylic acid (VII) was converted into acid sodium salt by the action of equimolar methanolic sodium methoxide (Scheme 3). The reaction of excess dimethyl sulfate with the acid salt afforded (+)-half ester (IX). (+)-Half ester was converted into (+)-2-amino-7-carboxytriptycene (X) by the Curtius reaction *via* acid chloride, acid azide and isocyanate. The diazonium salt derived from (+)-amino derivative (X) was hydrolyzed to yield (+)-2-hydroxy-7-carboxy triptycene (XII). The reaction of dimethyl sulfate with (+)-XII afforded (+)-2-methoxy-7-methoxycarbonyltriptycene (XIV). The methoxy-methyl ester (XIV) was found to be identical with the authentic (+)-2-methoxy-7-methoxycarbonyltriptycene (XVI) prepared by a different route and proved to have 1R, 6R absolute configuration by chemical correlation with (+)-2,5-dimethoxy-7-substituted-triptycenes (XVIII and XVII).[2,9] (+)-XIV and (+)-XVI showed identical IR, NMR, UV, and CD spectra, and the mixed melting point showed no depression. Consequently, the absolute configuration of (+)-2,7-dicarboxytriptycene (VII) was demonstrated to be 1R,6R. The UV and CD spectra of (+)-XIV and (+)-XVI are given in Fig. 1.

The reaction sequence of transformation of (+)- or (−)-VII into C_2-symmetrical 2,7-disubstituted triptycenes is outlined in Scheme 4. (+)-Diaminotriptycene (XIX) was prepared from (+)-VII by the Curtius reaction *via* acid chloride, acid azide and isocyanate. Methylation of (+)-XII with trimethyl phosphate afforded (+)-dimethylamino derivative (XX). (−)-Dinitrotriptycene (XXI) could be prepared by the pertrifluoroacetic acid oxidation of (−)-diamine (XIX). The reaction of nitrosobenzene with (−)-XIX in acetic acid gave bis-phenylazo derivative (XXII). (+)-Difluoro derivative (XXIII) was prepared by the Schiemann reaction of (+)-XIX. Hydrolysis of diazonium salt derived from (+)-XIX yielded (+)-dihydroxytriptycene (XXIV) which was converted into (+)-diacetate (XXV) and (+)-dimethoxy derivative (XXVI). Diacid amide prepared from (+)-dicarboxylic acid (VII) was dehydrated with thionyl chloride in dimethylformamide to give (+)-dicyanotriptycene (XXVII). (+)-Dimethoxycarbonyltriptycene (VI) obtained from (+)-VII was reduced with lithium aluminum hydride to yield (+)-bis(hydroxymethyl)-triptycene (XXVIII) which could be oxidized to (+)-diformyl derivative (XXIX) with chromium trioxide-pyridine complex. The reaction of thionyl chloride with (+)-glycol (XXVIII) afforded bis-chloromethyl derivative which gave (+)-dimethyltriptycene

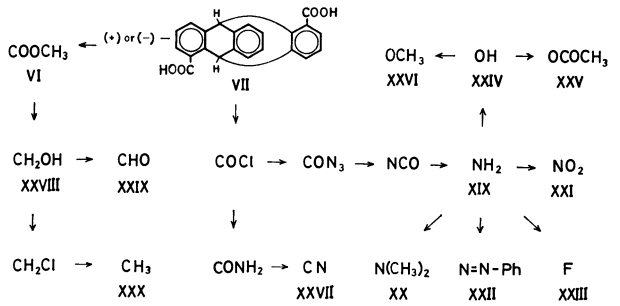

Scheme 4.

(XXX) on treatment with lithium aluminum hydride in boiling tetrahydrofuran.

In view of the method of preparation and the stable cage structure of triptycene skeleton, it is evident that (+)-series of 2,7-disubstituted triptycenes thus prepared has the same absolute configuration as (+)-VII (1R,6R) and (−)-series has an antipodal configuration.

Experimental

All the melting points are not corrected. Purified anhydrous solvents were used unless otherwise stated. Ligroin with bp 60—80°C was used. The IR spectra were measured with Hitachi EPI-2 and JASCO DS-301 spectrophotometers. The NMR spectra were obtained on a Varian A-60 spectrometer using TMS as an internal standard. Chemical shifts are recorded in τ unit. The UV spectra were measured with a Hitachi EPS-3T spectrophotometer. The optical rotations were measured with Rudolf 200S-80 and Yanagimoto ORD-185 spectropolarimeters at 15°C unless otherwise stated. The CD spectra were obtained on a Roussel-Jouan Dichrograph B, II-CD-185 and JASCO J-20 spectropolarimeter with CD attachments. The inflections and shoulders are indicated with an asterisk. The measurements of UV and CD spectra in an acidic medium were performed in methanol containing 10 vol% of 0.1M hydrochloric acid (abbreviated as MeOH–HCl). The experimental procedures referred to the optically active substances unless otherwise stated.

1,5-Dicyanoanthraquinone (II).[10] A mixture of I (50 g, 0.18 mol), cuprous cyanide (40 g, 0.45 mol) and phenylacetonitrile (460 ml) was refluxed for 70 min. The insoluble material was washed with benzene and digested with boiling 4M nitric acid to give II (44.5 g, 95.5%), mp >360°C, IR (Nujol mull): 2200 ($\nu_{C\equiv N}$) cm^{-1}.

1,5-Dicarboxyanthraquinone (III).[10] Water (200 ml) was added to a solution of II (86.0 g, 0.333 mol) in concentrated sulfuric acid (1000 ml) under ice-cooling. After being heated to 160°C for 1.5 hr, the mixture was poured onto water (1500 ml) to give dark brown crystals of III (80.5 g, 85.1%), mp >360°C, IR (Nujol mull): 1690 ($\nu_{C=O}$) cm^{-1}.

1,5-Dicarboxyanthracene (IV). A solution of III (27.16g, 0.0955 mol) in 15% aqueous ammonia (1200 ml) was treated with zinc dust (52 g) under stirring at 85—95°C. Stirring was continued for 5 hr at the same temperature under occasional addition of zinc dust and ammonia. The filtrate was treated with charcoal and acidified with 12M hydrochloric acid to afford IV as yellow crystals, mp >360°C, IR (Nujol mull): 1690 ($\nu_{C=O}$) cm^{-1}.

1,5-Dimethoxycarbonylanthracene (V). Thoroughly dried acid (IV, 99.8 g, 0.775 mol) was mixed with a methanolic sodium methoxide (from sodium, 23 g and methanol, 1400 ml) and the mixture was refluxed for 2 hr. Freshly distilled dimethyl sulfate (130 g, 1.031 mol) was added dropwise to the solution. After refluxing for 22 hr, the reaction mixture was concentrated under reduced pressure. Yellow crystals (107.1 g, 97.1%) obtained on addition of water (100 ml) to the concentrated mixture were recrystallized from methyl acetate and from benzene to yield pure V, yellow rods, mp 200—201°C, IR (KBr-disk): 1702 ($\nu_{C=O}$) cm^{-1}, NMR ($CDCl_3$): 0.28 (s, 2H, $C^{9,10}$-H), 1.58—2.58 (m, 6H, C^{2-4}-H and C^{6-8}-H), 5.91 (s, 6H, $-CO_2CH_3$), UV: $\lambda_{max}^{dioxane}$ (ε) 406 (8360), 385 (9820), 365 (7730), 348* (4060), 260.5 (12100), 224.4* (19400), 221.5 (19800) nm.

Found: C, 73.46; H, 4.80%. Calcd for $C_{18}H_{14}O_4$: C, 73.78; H, 4.80%.

When IV was treated with phosphorus pentachloride at 150—160°C and the product was mixed with methanol, V was obtained in a 35% yield along with 1,5-dimethoxycarbonyl-9-methoxyanthracene, greenish yellow rods, mp 135°C (8.5%).[11]

2,5-Dimethoxycarbonyltriptycene (VI) and the Adduct of Maleic Anhydride with 1,5-Dimethoxycarbonylanthracene (V). To a stirred solution of V (24.7 g, 0.084 mol) under gentle reflux was added dropwise a solution of anthranilic acid (12.4 g, 0.091 mol) in tetrahydrofuran (300 ml) over a period of 8 hr. Isoamyl nitrite (5.0 g, 0.038 mol) and anthranilic acid (5.0 g, 0.036 mol) were then added and the mixture was refluxed for further 2 hr. Brownish yellow solid (57.0 g) obtained by concentration of the reaction mixture was mixed with xylene (320 ml) and maleic anhydride (15.0 g) and refluxed for 1 hr. Water and dichloromethane (each 200 ml) were added to the reaction mixture and the organic layer was washed successively with 5% aqueous potassium hydroxide and water and dried. The brown residue obtained from the organic layer was dissolved in benzene and chromatographed on alumina. Crystalline solid (26.67 g, 85.8%) obtained from the benzene eluate was recrystallized from methanol and then sublimed *in vacuo* to afford pure VI, mp 209—209.5°C, IR (KBr-disk): 1717 ($\nu_{C=O}$) cm^{-1}, NMR (CCl_4): 2.21—3.11 (m, 12H, aromatic and bridgehead), 3.94 (s, 6H, $-CO_2CH_3$), UV: $\lambda_{max}^{dioxane}$ (ε) 298 (7270), 288* (6590), 222 (39200) nm.

Found: C, 77.61; H, 4.89%. Calcd for $C_{24}H_{18}O_4$: C, 77.82; H, 4.90%.

The adduct was isolated on acidification of the alkaline washings. The adduct, after recrystallization from acetone, was sublimed *in vacuo* to yield pure material, mp 258°C, IR (KBr-disk): 1862,1782($\nu_{C=O}$, anhydride), 1718($\nu_{C=O}$, $-CO_2CH_3$) cm^{-1}, UV: $\lambda_{max}^{dioxane}$ (ε) 222.5 (broad, 24000), 289 (4140) nm.

Found: C, 66.58; H, 4.08%. Calcd for $C_{22}H_{16}O_7$: C, 67.34; H, 4.11%.

2,7-Dicarboxytriptycene (VII). A solution of VI (18.09 g) in acetic acid (300 ml) containing 3M sulfuric acid (4 ml) was refluxed for 21 hr to precipitate fairly pure VII (16.6 g) in a quantitative yield. Recrystallization of VII from acetic acid yielded pure crystals containing 1 mol of acetic acid, mp 325°C (decomp.) (sublimed at 260°C).

Found: C, 71.71; H, 4.51%. Calcd for $C_{22}H_{14}O_4 \cdot C_2H_4O_2$: C, 71.63; H, 4.51%.

Crystals of VII free from acetic acid could be obtained on heating at 80°C for 6 hr *in vacuo*, mp 332—335°C (decomp.) (sublimed at 260°C), IR (KBr-disk): 1685 ($\nu_{C=O}$) cm^{-1}, NMR (DMSO-d_6): 2.23—3.18 (m, aromatic and bridgehead), UV: λ_{max}^{EtOH} (ε) 211 (44400), 287.5 (5600), 299 (6180) nn.

Found: C, 76.81; H, 4.21%. Calcd for $C_{22}H_{14}O_4$: 77.18; H, 4.12%.

Optical Resolution of dl-*2,7-Dicarboxytriptycene (VII).* To a hot solution of *dl*-VII (10.058 g, 0.0294 mol) in ethanol (350 ml) was added cinchonidine (8.649 g, 0.0294 mol) and the mixture was refluxed for 1 hr. Colorless solid (mp 188—195°C) obtained by concentration of the mixture was refluxed in methyl acetate (2350 ml) for 6.5 hr.[12] The mixture, on standing overnight in a refrigerator, gave crystals containing 1 mol of methyl acetate, mp 187—194°C, 8.305 g, $[\alpha]_{350}$ −261.0° (*c* 0.528, methanol). The salt was recrystallized 4 times from methyl acetate to give optically pure material, mp 186—189°C, $[\alpha]_{350}$ −146.3° (*c* 0.436, methanol).

Found: C, 74.62; H, 5.96; N, 4.19%. Calcd for $C_{41}H_{36}N_2O_5 \cdot C_3H_6O_2$: C, 74.35; H, 5.96; N, 3.94%.

Decomposition of the optically pure salt with acetic acid (150 ml) yielded (+)-VII (1.053 g) as colorless crystals, mp 342.5—350.0°C (decomp.) (sublimed at 260°C), ORD: $[\alpha]_{600}$ +33.33°, $[\alpha]_D$ +33.3°, $[\alpha]_{500}$ +54.81°, $[\alpha]_{400}$ +140.7°, $[\alpha]_{350}$ +328.1° (*c* 0.540, methanol), CD: λ_{max}^{MeOH} ($\Delta\varepsilon$) 304 (+1.6), 282 (+5.3), 259 (−1.7), 244 (−4.0), 233 (+6.0), 219 (−49.7) nm.

Found: C, 76.81; H, 4.21%. Calcd for $C_{22}H_{14}O_4$: C, 77.18; H, 4.12%.

The initial mother liquor was mixed with acetic acid to afford (−)-VII with a low optical purity, mp 321—328°C (decomp.) (sublimed at 275°C), $[\alpha]_{350}$ −129.4° (*c* 0.4325, methanol).

Starting from *dl*-VII (11.338 g, 0.033 mol), ethanol (350 ml) and cinchonine (9.749 g, 0.033 mol), crude cinchonine salt was prepared by an essentially similar procedure with (+)-enantiomer. A suspension of the salt in methyl acetate (2000 ml) was refluxed for 3 hr, and then concentrated to 800 ml. Crystals deposited on standing the solution in a refrigerator overnight were recrystallized 4 times from the same solvent to yield optically pure salt, $[\alpha]_{500}^{12}$ +112.1° (*c* 0.5925, methanol). The crystals obtained on treatment of the optically pure salt with acetic acid were recrystallized from acetic acid to afford pure (−)-VII, 1.227 g, mp 342—350°C (decomp.) (sublimed at 260°C), ORD: $[\alpha]_{600}$ −33.2°, $[\alpha]_D$ −33.9°, $[\alpha]_{500}$ −56.8°, $[\alpha]_{400}$ −141.9°, $[\alpha]_{350}$ −332.9° (*c* 0.5425, methanol).

Found: C, 77.04; H, 4.15%. Calcd for $C_{22}H_{14}O_4$: C, 77.18; H, 4.12%.

5,7-Dimethoxycarbonyltriptycene (VIII). According to the method used for VI, a solution of anthranilic acid (1.74 g, 0.0127 mol) in tetrahydrofuran was added dropwise to a mixture of 1,8-dimethoxycarbonylanthracene[8] (3.6 g, 0.012 mol), isoamyl nitrite (1.62 g, 0.0138 mol) and dichloromethane (58 ml). Crude crystals obtained after treatment of the reaction mixture with maleic anhydride were recrystallized from methanol to yield fairly pure VIII (2.84 g, 62.7%) which was recrystallized from the same solvent to give pure VIII, mp 176—177°C, IR (KBr-disk): 1720 ($\nu_{C=O}$) cm^{-1}, NMR (CCl_4): 2.04—3.13 (m, 11H, aromatic and C^6-H), 4.62 (s, 1H, C^1-H), 5.99 (s, 6H, $-CO_2CH_3$). The signal of the bridgehead proton at a proximate position to both ester groups (C^1-H) was shifted to the aromatic region by anisotropy of the ester carbonyl groups. UV: $\lambda_{max}^{dioxane}$ (ε) 222 (39600), 286 (5520), 298 (6010) nm.

Found: C, 77.58; H, 4.74%. Calcd for $C_{24}H_{18}O_4$: C, 77.82; H, 4.90%.

(+)-2-Carboxy-7-methoxycarbonyltriptycene (IX). (+)-VII (2.009 g, 5.868 mmol) was mixed with equimolar sodium methoxide in methanol (39 ml) prepared from sodium (0.35 g) and methanol (100 ml). The mixture, after being refluxed for 1 hr, was evaporated under reduced pressure to give monosodium salt. Thoroughly dried acid salt suspended in benzene (70 ml) was mixed with freshly distilled dimethyl sulfate (0.740 g, 5.868 mmol) and the mixture was refluxed. After 4.5 hr, an additional amount of dimethyl sulfate (0.740 g) in benzene (20 ml) was added and refluxing was continued for further 16.5 hr. The reaction mixture was worked up to give a mixture of (+)-VII and (+)-IX as crystalline solid. The mixture was extracted with benzene. (+)-IX (1.604 g, 76.7%) was obtained from the benzene extract and recrystallized from benzene–ligroin, mp 252°C (sublimed at 200°C), [racemate, mp 246—249°C (decomp.) (sublimed at 200°C)], NMR ($CDCl_3$): −0.80 (broad, s, 1H, -COOH), 2.10—3.03 (m, 12H, aromatic and bridgehead), 6.00 (s, 3H, $-CO_2CH_3$), UV: λ_{max}^{MeOH} (ε) 298 (6600), 287 (5900), 240* (10500), 207 (62900) nm, CD: λ_{max}^{MeOH} ($\Delta\varepsilon$) 306 (+1.64), 283 (+4.90), 258 (−1.04), 242 (−2.08), 234 (+2.0) nm.

Found: C, 77.58; H, 4.52%. Calcd for $C_{23}H_{16}O_4$: C, 77.51; H, 4.53%.

The benzene insoluble residue was recovered (+)-VII which was also obtained by acidification of the aqueous layer of the initial extraction (total 26.9% recovery).

(+)-2-Amino-7-carboxytriptycene (X). (+)-IX (4.00 g, 11.2 mmol) in tetrahydrofuran (60 ml) was refluxed with excess thionyl chloride (10 ml) for 2 hr, and the volatile material was removed under reduced pressure to give crude acid chloride [IR (Nujol mull): 1760 ($\nu_{C=O}$, -COCl), 1720 ($\nu_{C=O}$, $-CO_2CH_3$) cm^{-1}]. A solution of sodium azide (0.900 g in 10 ml of water) was added to an ice-cooled and stirred solution of acid chloride in tetrahydrofuran (40 ml), After being stirred for 3 hr at the same temperature, the reaction mixture was worked up to give acid azide [IR (Nujol moll): 2140 ($\nu_{N=\overset{+}{N}=\overset{-}{N}}$), 1720 ($\nu_{C=O}$, $-CO_2CH_3$), 1685 ($\nu_{C=O}$, $-CON_3$) cm^{-1}]. The azide gave isocyanate [IR (Nujol mull): 2250 ($\nu_{N=C=O}$), 1720 ($\nu_{C=O}$, $-CO_2CH_3$) cm^{-1}] upon heating to 135°C for 6 hr. A mixture of isocyanate, ethanol (150 ml), potassium hydroxide (20 g) and water (50 ml) was refluxed for 25 hr to give crude amino carboxylic acid (X, 2.109 g, 60.1%). Recrystallization of crude X from methyl acetate–petroleum ether (bp 35—45°C) yielded pure X containing 1 mol of methyl acetate. The crystals melted once at 170°C and immediately crystallized again and re-melted with decomposition at 234—235°C [racemate, mp 167—169°C(decomp.)], IR (KBr-disk): 3380 (ν_{N-H}), 1690 ($\nu_{C=O}$, $-CO_2CH_3$) cm^{-1}.

Found: C, 74.30; H, 5.42; N, 3.62%. Calcd for $C_{21}H_{15}NO_2 \cdot C_3H_6O_2$: C, 74.40; H, 5.46; N, 3.59%.

The methyl acetate could be removed by heating the crystals *in vacuo*.

(+)-2-Amino-7-methoxycarbonyltriptycene (XI). A mixture of X (0.500 g), methanol (10 ml) and concentrated sulfuric acid (1 ml) was refluxed to yield (+)-XI in a quantitative yield, mp 161—162°C (from methyl acetate–petroleum ether and then from ligroin) [racemate, mp 194—195°C (decomp.)], UV: λ_{max}^{MeOH} (ε) 293.5 (5760), 269 (3380), 240* (19000), 217 (36700), 207.5 (45200); $\lambda_{max}^{MeOH\text{-}HCl}$ (ε) 293 (3900), 276 (2980), 270* (2140), 240* (12600), 208.5 (52200) nm, CD: λ_{max}^{MeOH} ($\Delta\varepsilon$) 285 (+5.10), 265 (−3.23), 238 (+3.11); $\lambda_{max}^{MeOH\text{-}HCl}$ ($\Delta\varepsilon$) 302 (+0.19), 290 (−0.12), 273 (+3.48), 269 (+3.33), 252 (+0.75), 238 (−5.60), 226 (+2.90) nm.

Found: C, 80.89; H, 5.20; N, 4.23%. Calcd for $C_{22}H_{17}O_2N$: C, 80.71; H, 5.23; N, 4.28%.

(+)-2-Hydroxy-7-carboxytriptycene (XII). (+)-XI (1.736 g) in acetic acid (20.5 ml) was added to an ice-cooled and stirred solution of sodium nitrite (0.421 g) in concentrated sulfuric acid (3 ml). After 2 hr, the resulting solution of diazonium

12) This procedure is essential for effective resolution. Initially formed salt seems to rearrange in boiling methyl acetate to a stable form which has larger difference in solubility between the diastereomers.

salt was added dropwise to boiling 3M sulfuric acid (300 ml), yielding crude (+)-XII (1.135 g, 65.2%). Recrystallization of the crude material from methyl acetate–petroleum ether and from methyl acetate–benzene afforded pure (+)-XII, mp 269—271°C (decomp.) [racemate, mp 263—264°C (decomp.)].

Found: C, 78.69; H, 4.45%. Calcd for $C_{21}H_{14}O_3$: C, 80.24; H, 4.49%.

(+)-2-Hydroxy-7-methoxycarbonyltriptycene (XIII). Treatment of (+)-XII with methanol and sulfuric acid afforded (+)-XIII, mp 217—225°C (from ligroin) [racemate, mp 231—234°C], IR (KBr-disk): 3400 (ν_{O-H}), 1697 ($\nu_{C=O}$) cm^{-1}.

Found: C, 80.29; H, 5.02%. Calcd for $C_{22}H_{16}O_3$: C, 80.47; H, 4.91%.

(+)-2-Methoxy-7-methoxycarbonyltriptycene (XIV). A mixture of (+)-XIII (0.5188 g), dimethyl sulfate (0.66 g), anhydrous potassium carbonate (3 g) and acetone (70 ml) was refluxed for 8 hr under stirring to give crude (+)-XIII in a quantitative yield, mp 240—241°C (from methanol) [racemate, 219—222°C], IR (KBr-disk): 2850 (ν_{C-H}, $-OCH_3$), 1715 ($\nu_{C=O}$) cm^{-1}, NMR ($CDCl_3$): 2.33—3.17 (m, 11H, aromatic and C^6-H), 4.07 (s, 1H, C^1-H), 6.05 (s, 3H, $-CO_2CH_3$) 6.18 (s, 3H, $-OCH_3$), UV: $\lambda_{max}^{dioxane}$ (ε) 209.5 (53300), 215 (51100), 267 (3550), 283.5 (4130), 296 (3880); λ_{max}^{MeOH} (ε) 208.5 (67700), 215* (54300), 240* (13900), 266.5 (3430), 283 (4030), 296 (3750) nm, CD: $\lambda_{max}^{dioxane}$ ($\Delta\varepsilon$) 220 (−55.8), 232 (+12.7), 242* (+9.23), 265 (−2.31), 280 (+2.65), 325—290 (very broad peak, +0.41); λ_{max}^{MeOH} ($\Delta\varepsilon$) 232 (+12.6), 262 (−2.05), 276 (+2.51), 320—290 (very broad peak, +0.40) nm.

Found: C, 80.44; H, 5.24%. Calcd for $C_{23}H_{18}O_3$: C, 80.68; H, 5.30%.

The melting point showed no depression on admixture with an authentic specimen of (+)-XVI (mp 240—241°C).[9]

(+)-2-Methoxy-7-carboxytriptycene (XV). A mixture of (+)-XIV (0.200 g), acetic acid (20 ml) and 3M sulfuric acid (10 ml) was refluxed for 19 hr to yield (+)-XV, mp 267°C (decomp.) (from aqueous acetic acid) [racemate, mp 299—300°C (decomp.)], NMR (DMSO-d_6): 2.20—3.18 (m, 11H, aromatic and C^6-H), 3.93 (s, 1H, C^1-H), 6.13 (s, 3H, $-OCH_3$).

Found: C, 80.28; H, 4.91%. Calcd for $C_{22}H_{16}O_3$: C, 80.47; H, 4.91%.

(+)-2,7-Diaminotriptycene (XIX). (+)-Dicarboxytriptycene (VII, 432.5 mg) in tetrahydrofuran was refluxed for 2 hr with excess thionyl chloride, crude acid chloride (450.8 mg) being obtained by evaporating volatile material under reduced pressure. To an ice-cooled solution of the acid chloride in tetrahydrofuran was added a solution of sodium azide (155 mg) in water (2 ml). After 3 hr, the reaction mixture was poured onto water to give acid azide [386.8 mg, IR (Nujol mull): 2120 ($\nu_{N=\overset{+}{N}=\overset{-}{N}}$), 1685 ($\nu_{C=O}$) cm^{-1}]. A solution of thoroughly dried azide in benzene (100 ml) was refluxed for 4 hr. Isocyanate [388.2 mg, IR (Nujol mull): 2210 ($\nu_{C=O}$) cm^{-1}] obtained by evaporating the solvent *in vacuo* was mixed with water (10 ml), 99% ethanol (50 ml) and potassium hydroxide (4.0 g) and the mixture was refluxed for 6 hr. The reaction mixture was poured onto ice-water to yield crude (+)-XIX (319.6 mg) which was recrystallized from benzene and dried *in vacuo* at 110°C for 5 hr to give pure (+)-XIX, mp 266—267°C (sublimed at *ca.* 230°C) [racemate, mp 279—283°C (decomp.), sublimed at *ca.* 210°C], NMR ($CDCl_3$): 2.55—3.72 (m, 10H, aromatic), 4.62 (s, 2H, bridgehead), 6.45 (broad s, 4H, $-NH_2$), UV: λ_{max}^{MeOH} (ε) 194 (56900), 219.5 (56500), 240* (20900), 269 (4040), 275 (3320), 295 (3660); $\lambda_{max}^{MeOH\text{-}HCl}$ (ε) 212.5 (64400), 262* (1330), 269 (2230), 276.5 (2910) nm, CD: λ_{max}^{EtOH} ($\Delta\varepsilon$) 214 (−61.2), 227.5 (+55.3), 258* (−11.7), 268 (−17.1), 283* (+1.53), 297 (+6.37); $\lambda_{max}^{EtOH\text{-}HCl}$ ($\Delta\varepsilon$) 250.5 (+0.95), 262 (−2.22), 274 (−0.41), 277.5 (+0.31) nm.

Found: C, 84.45; H, 5.69; N, 9.90%. Calcd for $C_{20}H_{16}N_2$: C, 84.48; H, 5.67; N, 9.85%.

(+)-2,7-Bis(dimethylamino)triptycene (XX). After a mixture of (+)-XIX (197 mg) and trimethyl phosphate (200 mg) had been refluxed for 3 hr, a solution of sodium hydroxide (1.7 g) in water (2 ml) was added and the mixture was refluxed for 30 min. Water (30 ml) was added to the reaction mixture. Crude (+)-XX (0.226 g) deposited after being left to stand overnight was recrystallized from 99% ethanol and then sublimed *in vacuo* to give pure (+)-XX, mp 215—215.5°C (sublimed at 170°C) [racemate, mp 209—210°C, (sublimed at 160°C)], NMR ($CDCl_3$): 2.45—3.33 (m, 10H, aromatic), 4.07 (s, 2H, bridgehead), 7.22 (s, 12H, $N-CH_3$), UV: λ_{max}^{MeOH} (ε) 225 (42000), 240* (25200), 260* (15400), 275* (5000), 295* (1500) nm, CD: λ_{max}^{MeOH} ($\Delta\varepsilon$) 220 (−37.72), 236 (+24.33), 271 (−7.06), 292 (+1.11) nm.

Found: C, 84.86; H, 6.96; N, 8.26%. Calcd for $C_{24}H_{24}N_2$: C, 84.66; H, 7.11; N, 8.23%.

(−)-2,7-Dinitrotriptycene (XXI). To an ice-cooled and stirred mixture of dichloromethane (4.5 ml) and 90% hydrogen peroxide (0.24 ml) was added trifluoroacetic anhydride (1.5 ml). After 5 min, a solution of (−)-diamine (XIX, 297 mg) in the same solvent (10 ml) was added and the mixture was refluxed for 1 hr. After washing (aqueous sodium carbonate and water) and drying, the solvent was removed to yield yellow solid which was recrystallized from benzene–ligroin to afford pure (−)-XXI, mp 320—326°C (sublimed at 160°C) [racemate, mp 325—331°C (decomp.), (sublimed at 200°C)], UV: λ_{max}^{MeOH} (ε) 207* (61500), 254 (11200), 315 (4350) nm, CD: λ_{max}^{MeOH} ($\Delta\varepsilon$) 242 (+12.12), 282 (−2.15), 306 (+1.21), 328 (−0.91) nm.

Found: C, 69.31; H, 4.22; N, 7.08%. Calcd for $C_{20}H_{12}O_4N_2$: C, 69.76; H, 3.51; N, 8.14%.

(−)-2,7-Bis(phenylazo)triptycene (XXII). A mixture of (−)-diamine (XIX, 489.1 mg), nitrosobenzene (400 mg) and acetic acid (6 ml) was heated in a sealed tube at 200°C for 2 hr. The solvent was removed *in vacuo* and the residue dissolved in benzene was passed through a column of alumina (50 g). Crude crystals (600 mg) obtained from benzene eluate was recrystallized from benzene–ethanol to give pure (−)-XXII, mp 216—217°C [racemate, mp 272—273.1°C], NMR (CS_2): 1.82—3.02 (m, 20H, aromatic), 3.30 (s, 2H, bridgehead), UV: λ_{max}^{MeOH} (ε) 212 (53300), 232 (28000), 240* (23800), 242* (19000), 253* (12600), 258* (10800), 325 (33500), 440 (1600) nm, CD: λ_{max}^{MeOH} ($\Delta\varepsilon$) 216 (+11.3), 236 (+15.1), 248 (−6.40), 272 (−1.8), 320 (+9.56), 355 (−10.82), 438—432 (−1.38) nm.

Found: C, 82.69; H, 4.84; N, 11.88%. Calcd for $C_{32}H_{22}N_4$: C, 83.09; H, 4.79; N, 12.11%.

(+)-2,7-Difluorotriptycene (XXIII). A solution of (+)-XIX (500 mg) in hot concentrated hydrochloric acid (6 ml) was chilled to −15—−20°C and a solution of sodium nitrite (270 mg) in water (2 ml) was added under stirring. Sodium fluoroborate (500 mg) in a small amount of water was added to the mixture. After being stirred for 1 hr at the same temperature, diazonium fluoroborate deposited was filtered and washed successively with cold water, methanol and ether. Diazonium salt (550 mg) thus obtained was gradually heated to 150°C and maintained at the same temperature for 3 hr, resulting in a purple solid. The product dissolved in benzene was treated with active charcoal and recrystallized from aqueous ethanol to afford pure (+)-XXIII, mp 224—226°C [racemate, mp 236—139°C (decomp.)], NMR ($CDCl_3$): 2.30—3.20 (m, 10H, aromatic), 3.99 (s, 2H, bridgehead), UV: λ_{max}^{MeOH} (ε) 212.5 (60300), 235* (7920), 255* (2140), 260*

(2070), 268 (1700), 276 (1320) nm, CD: λ_{max}^{MeOH} ($\Delta\varepsilon$) 225 (+1.18), 255 (−2.40), 268 (+1.48), 278 (+2.83) nm.

Found: C, 82.68; H, 4.19%. Calcd for $C_{20}H_{12}F_2$: C, 82.74; H, 4.17%.

(+)-2,7-Dihydroxytriptycene (XXIV). To a solution of (+)-XIX (3.90 g) in acetic acid (80 ml) was added a solution of sodium nitrite (1.485 g) in water (4 ml) at 14—17°C. After being stirred for 3 hr at the same temperature, the mixture was added to boiling 3M sulfuric acid (240 ml) over a 30 min-period and boiling was continued for 1 hr. Brown solid (2.60 g) isolated from the reaction mixture was converted into acetate (XXV) and the purified (+)-XXV was reduced by lithium aluminum hydride to give pure (+)-XXIV, mp 280°C (from ethanol), UV: λ_{max}^{MeOH} (ε) 216.5 (51,800), 234 (12900), 240* (10000), 262* (3150), 267.5 (4070), 276.5 (3780), 286 (3510); $\lambda_{max}^{MeOH\text{-}NaOH}$ (ε) 217 (49,400), 245* (22500), 270 (4590), 277.5 (4530), 330 (5590) nm, CD: λ_{max}^{MeOH} ($\Delta\varepsilon$) 219 (+31.33), 232 (−5.53), 250 (−6.70), 264* (−4.75), 280 (+4.29), 285 (+4.58); $\lambda_{max}^{MeOH\text{-}NaOH}$ ($\Delta\varepsilon$) 215 (−38.8), 232 (+36.5), 268 (−11.6), 300 (+3.22), 303 (+3.24) nm.

Found: C, 83.59; H, 4.97%. Calcd for $C_{20}H_{14}O_2$: C, 83.90; H, 4.93%.

(+)-2,7-Diacetoxytriptycene (XXV). Crude crystals of (+)-XXV (1.05 g) obtained by heating a mixture of (+)-XXIV (800 mg), acetic anhydride (50 ml) and sodium acetate (2.0 g) at 100°C for 20 hr were dissolved in benzene and passed through a column of silica gel (30 g). Concentration of the filtrate afforded (+)-XXV, mp 209.8—213.7°C (from benzene–ligroin and from ethanol), NMR ($CDCl_3$): 2.45—3.23 (m, 10H, aromatic), 4.42 (s, 2H, bridgehead), 7.50 (s, 6H, CH_3CO_2-), UV: λ_{max}^{MeOH} (ε) 214 (59800), 240* (4200), 255* (1290), 262 (1220), 269 (1710), 276.5 (1990) nm, CD: λ_{max}^{MeOH} ($\Delta\varepsilon$) 235 (−0.38), 257 (−1.69), 269 (+0.75), 276 (+1.38) nm.

Found: C, 77.62; H, 4.90%. Calcd for $C_{24}H_{18}O_4$: C, 77.82; H, 4.90%.

(+)-2,7-Dimethoxytriptycene (XXVI). A mixture of (+)-2,7-dihydroxytriptycene (XXIV, 200 mg), dimethyl sulfate (300 mg) and acetone (50 ml) was refluxed for 19 hr in the presence of anhydrous potassium carbonate (3.0 g) to afford crude crystals of (+)-XXVI (200 mg). The crude material was recrystallized from ethanol–benzene to yield pure (+)-XXVI, mp 277.8°C, NMR ($CDCl_3$): 2.20—3.38 (m, 10H, aromatic), 4.00 (s, 2H, bridgehead), 6.08 (s, 6H, CH_3O-), UV: $\lambda_{max}^{dioxane}$ (ε) 218.5 (46800), 240* (9300), 263* (3380), 268 (4110), 276.5 (3560), 285 (3100) nm, CD: $\lambda_{max}^{dioxane}$ ($\Delta\varepsilon$) 225 (+44.16), 250 (−12.39), 271* (+2.09), 278 (+3.09), 284 (+2.93) nm.

Found: C, 84.33; H, 5.80%. Calcd for $C_{22}H_{18}O_2$: C, 84.05; H, 5.77%.

(+)-2,7-Dicyanotriptycene (XXVII). Thionyl chloride (1.27 g) was added to a solution of (+)-VII (300 mg) in tetrahydrofuran (30 ml) and the mixture was refluxed for 2 hr. Crude acid chloride (326.2 mg) was obtained by removing volatile material under reduced pressure. The reaction of 28% aqueous ammonia (7.5 ml) with acid chloride (288.9 mg) in tetrahydrofuran (15 ml) at room temperature afforded acid amide [292.7 mg, IR (Nujol mull): 3100 (ν_{N-H}), 1660 ($\nu_{C=O}$) cm^{-1}]. A mixture of acid amide (282.8 mg), dimethylformamide (40 ml) and thionyl chloride (4 ml) was heated to 70—80°C for 8 hr. The reaction mixture was filtered to remove sulfur deposited and the filtrate was passed through a short column of alumina (10 g). Colorless solid (108 mg) obtained from the eluate was recrystallized from methanol to yield pure (+)-XXVII, mp 261—262°C (sublimed at 210°C) [racemate, mp 247—250.5°C], IR (KBr-disk): 2230 ($\nu_{C\equiv N}$) cm^{-1}, NMR ($CDCl_3$): 2.18—2.92 (m, 10H, aromatic), 4.03 (s, 2H, bridgehead), UV: λ_{max}^{EtOH} (ε) 212* (37900), 222* (38600), 235* (20500), 280* (4750), 288.5 (6330), 298 (8090) nm, CD: λ_{max}^{EtOH} ($\Delta\varepsilon$) 220 (−28.6), 231 (+10.8), 240 (−2.86), 251 (+1.91), 280 (+6.34), 303 (+1.04) nm.

Found: C, 86.45; H, 4.12; N, 9.18%. Calcd for $C_{22}H_{12}N_2$: C, 86.82; H, 3.97; N, 9.21%.

(+)-2,7-Dimethoxycarbonyltriptycene (VI). (+)-Dicarboxylic acid (VII) was treated with methanol containing concentrated sulfuric acid to give (+)-VI, mp 170—171°C (from methanol), CD: $\lambda_{max}^{dioxane}$ ($\Delta\varepsilon$) 222 (−37.6), 235 (+6.71), 244 (−2.58), 257 (−0.97), 282 (+5.90), 305 (+1.83) nm.

Found: C, 77.56; H, 5.02%. Calcd for $C_{24}H_{18}O_4$: C, 77.82; H, 4.90%.

(+)-2,7-Bis(hydroxymethyl)triptycene (XXVIII). Reduction of (+)-VI with lithium aluminum hydride afforded (+)-XXVIII in a quantitative yield, mp 220—221°C (from carbon tetrachloride followed by vacuum sublimation) (sublimed at 190°C) [racemate, 203.5—205°C (sublimed at 170°C)], IR (KBr-disk): 3390 (ν_{O-H}) cm^{-1}, NMR ($CDCl_3$): 2.50—3.01 (m, 10H, aromatic), 4.01 (s, 2H, bridgehead), 5.17 (s, 4H, methylene), 8.03 (s, 2H, OH), UV: λ_{max}^{MeOH} (ε) 215 (60700), 240* (4800), 264* (1570), 272.5 (2640), 276.5* (2820), 280.5 (3720) nm, CD: λ_{max}^{MeOH} ($\Delta\varepsilon$) 238 (−1.54), 250(+0.62), 258 (−0.89), 270 (+2.16), 277 (+1.33), 282 (−0.89) nm.

Found: C, 84.02; H, 5.74%. Calcd for $C_{22}H_{18}O_2$: C, 84.05; H, 5.77%.

(+)-2,7-Diformyltriptycene (XXIX). A solution of (+)-XXVIII (180.4 mg) in pyridine (2 ml) was added to an ice-cooled and stirred suspension of chromium trioxide-pyridine complex (from the trioxide, 150 mg and pyridine, 2 ml) and the mixture was kept in a refrigerator overnight. Crude crystals (123.9 mg) were sublimed twice under reduced pressure to give pure (+)-XXIX, mp 244—247°C (decomp.) (sublimed at 175°C) [racemate, mp 249—253°C (decomp.) (sublimed at 195°C)], IR (KBr-disk): 1690 ($\nu_{C=O}$) cm^{-1}, NMR ($CDCl_3$): −0.18 (s, 2H, CHO), 2.30—3.05 (m, 12H, aromatic and bridgehead), UV: λ_{max}^{MeOH} (ε) 209 (54800), 215* (47300), 238* (18700), 251 (20500), 260* (16000), 278 (2290), 305* (4810), 318 (5470) nm, CD: λ_{max}^{MeOH} ($\Delta\varepsilon$) 228 (−23.3), 246 (+2.8), 260 (−4.7), 276 (+2.6), 296 (+3.2), 324 (+1.5) nm.

Found: C, 84.92; H, 4.57%. Calcd for $C_{22}H_{14}O_2$: C, 85.14; H, 4.55%.

(+)-2,7-Dimethyltriptycene (XXX). A solution of (+)-XVIII (239 mg) in benzene (25 ml) was refluxed with thionyl chloride (5 ml). Crude bis-chloromethyl derivative dissolved in tetrahydrofuran (15 ml) was added to a mixture of lithium aluminum hydride (772 mg) and the same solvent (75 ml). After being refluxed for 16 hr, a benzene solution of the product was passed through a column of alumina (20 g). The crystals obtained from the filtrate were recrystallized from aqueous methanol to give pure (+)-XXX, mp 133—137°C (decomp.) [racemate, mp 154.5—157°C (sublimed at 130°C)], NMR ($CDCl_3$): 2.53—3.18 (m, 10H, aromatic), 4.36 (s, 2H, bridgehead), 7.50 (s, 6H, CH_3), UV: λ_{max}^{MeOH} (ε) 198 (63900), 214* (70500), 217.5 (72300), 240* (5980), 257* (1400), 263 (1370), 270.5 (1910), 274.5* (1460), 278.5 (2340) nm, CD: λ_{max}^{MeOH} ($\Delta\varepsilon$) 259 (−3.5), 270.5 (+1.3), 278 (+1.8) nm.

Found: C, 93.06; H, 6.51%. Calcd for $C_{22}H_{18}$: C, 93.57; H, 6.43%.

Optically Active Triptycenes. IV.[1] Synthesis of Optically Active 2- or 5-Substituted 7-Carboxytriptycenes

Yoshiteru SAKATA, Fumio OGURA, and Masazumi NAKAGAWA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

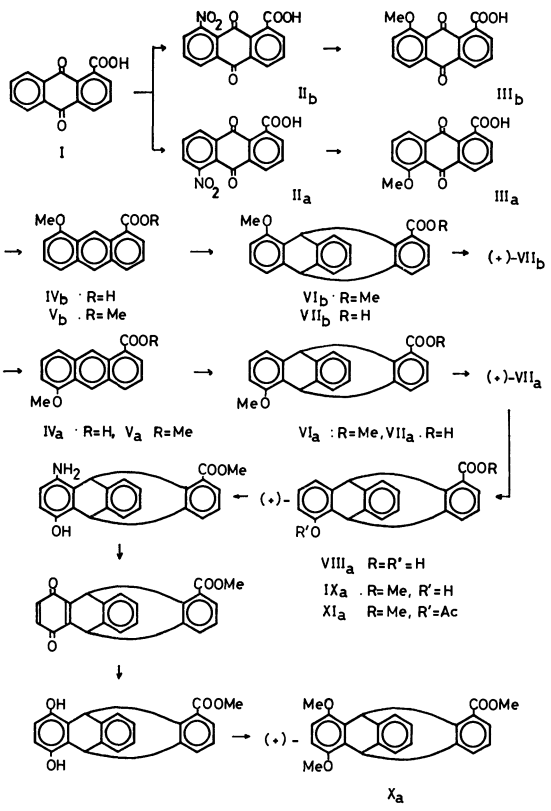
(Received August 11, 1972)

Starting from anthraquinone-1-carboxylic acid (I), 2-methoxy- and 5-methoxy-7-carboxytriptycenes (VIIa and VIIb) have been synthesized. Optical resolution of the triptycenecarboxylic acids with brucine afforded (+)-VIIa and (+)-VIIb. The absolute configuration of (+)-VIIa was determined to be 1R,6R by the chemical correlation with (+)-2,5-dimethoxy-7-methoxycarbonyltriptycene. From a comparison of the CD spectrum of (+)-5-methoxy-7-carboxytriptycene (VIIb) with that of (+)-2-acetoxy-5-methoxy-7-methoxycarbonyltriptycene (XIIIb), 1R,6R absolute configuration was assigned to (+)-VIIb. (+)-2-Hydroxy-5-phenylazo-7-carboxytriptycene (XIIa) was derived from (+)-VIIa. (+)-2-Chloro- and (+)-5-chloro-7-carboxytriptycenes (XVIIIa and XVIIIb) have been prepared from 5-chloro- and 8-chloro-1-carboxyanthraquinones (XIVa and XIVb). The absolute configuration of (+)-XVIIIa was determined to be 1R,6R by the chemical correlation with (−)-VIIa *via* (+)-2-chloro-5-methoxytriptycene (XIX).

The synthesis and optical resolution of 2,5,7-trisubstituted triptycenes have been reported in previous papers of this series,[2-4] and studies on C_2-symmetrical 2,7-disubstituted derivatives will be reported in the following paper.[5]

The present paper deals with the synthesis, optical resolution of 2- and 5-substituted 7-carboxytriptycenes and the determination of their absolute configuration by chemical correlation.

Anthraquinone-1-carboxylic acid (I) obtained by chromium trioxide oxidation of benzanthrone[6] was nitrated by the reported method[7] to yield 1-carboxy-5-nitro-anthraquinone (IIa) and 1-carboxy-8-nitro-anthraquinone (IIb). Treatment of the nitro compounds (IIa and IIb) with potassium hydroxide in methanol afforded methyl ether derivative (IIIa or IIIb). Carboxymethoxyanthracene (IVa or IVb) obtained by reduction of IIIa or IIIb with zinc dust and aqueous ammonia was converted into methyl ester (Va or Vb) by the usual method. Reaction of benzyne generated by the decomposition of benzenediazonium carboxylate[8] with Va or Vb gave 2-methoxy-7-methoxycarbonyl or 5-methoxy-7-methoxycarbonyltriptycene (VI or VIb). 2-Methoxy-7-carboxytriptycene (VIIa) obtained by the hydrolysis of VIa was treated with 0.5 equivalent of brucine dihydrate in ethanol. Recrystallization of the brucine salt from ethanol yielded (+)-VIIa with positive rotation in the visible region. The triptycene derivatives derived from (+)-VIIa will be referred to the (+)-series. The brucine salt of VIIb was recrystallized from acetone to afford (+)-VIIb. (+)-Hydroxycarboxylic acid (VIIIa) obtained on treatment of (+)-VIIa with a mixture of hydrobromic acid and hydriodic acids in acetic acid was converted into methyl ester (+)-IXa. Acetylation of (+)-IXa gave (+)-acetoxy methyl ester (+)-XIa, and coupling of benzenediazonium salt with (+)-VIIIa afforded (+)-azocarboxylic acid (+)-XIIa.



Scheme 1.

Coupling of diazotized sulfanilic acid with (+)-IXa followed by reduction afforded *p*-aminophenol derivative which was oxidized to yield *p*-benzoquinone derivative. Hydroquinone derivative obtained from the quinone was converted into dimethyl ether(+)-Xa. The dimethyl ether derivative (+)-Xa thus prepared was found to be identical with (+)-2,5-dimethoxy-7-meth-

oxycarbonyltriptycene (+)-X, derived from 1-methoxycarbonylanthracene and *p*-benzoquinone.[3] Since the absolute configuration of (+)-2,5-dimethoxy-7-dimethylaminotriptycene hydrobromide prepared from (+)-2,5-dimethoxy-7-methoxycarbonyltriptycene (+)-X has been proved to be 1R,6S using the Bijvoet method,[9] the absolute configuration of (+)-Xa now prepared can be determined as 1R,6S. Consequently, the 2,7-disubstituted triptycenes of (+)-series derived from (+)-VIIa should have the same 1R,6R absolute configuration.

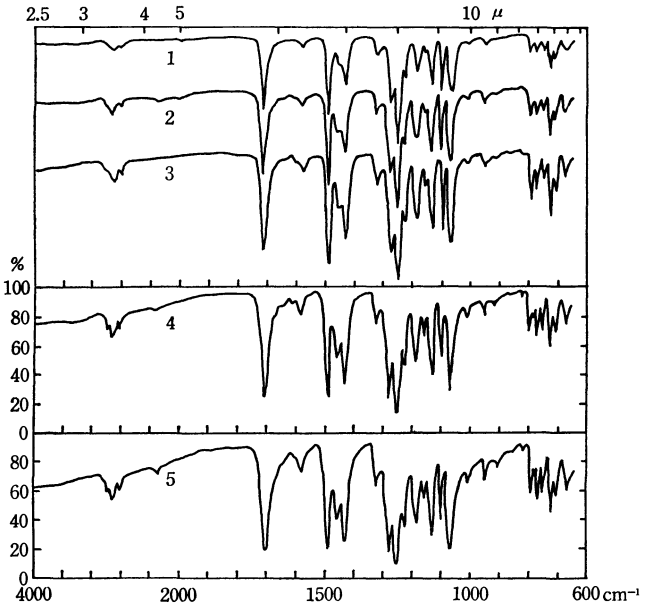

Fig. 1. IR spectra (KBr-disk) of (+)- and (—)-2,5-dimethoxy-7-methoxycarbonyltriptycene prepared by different process.
1: *dl*-Xa, 2: *dl*-Xb, 3:*dl*-X, 4: (+)-X, 5: (+)-Xa

dl-2-Methoxy-7-methoxycarbonyltriptycene (VIa) and *dl*-5-methoxy-7-methoxycarbonyltriptycene (VIb) could be transformed into *dl*-2,5-dimethoxy-7-methoxycarbonyltriptycene (*dl*-Xa and *dl*-Xb) according to the same reaction sequence used in the preparation of (+)-Xa from (+)-VIa. *dl*-2,5-Dimethoxy-7-methoxycarbonyltriptycene (*dl*-Xa, *dl*-Xb, and *dl*-X[3]) showed identical melting point (mp 227.0—228.5°C) and the mixed melting points showed no depression. As illustrated in Fig. 1, their IR spectra were found to be superimposable.

(+)-VIIb showed a negative Cotton effect in the longest wavelength region of the CD spectrum in contrast with the positive Cotton effect of (+)-VIIa in the same wavelength region. However, (+)-2-methoxy-5-acetoxy- and (+)-2-acetoxy-5-methoxy-7-methoxycarbonyltriptycenes (XIIIa and XIIIb) showed UV and CD spectra closely related with those of (+)-VIa and (+)-VIIb, respectively (Figs. 2 and 3). Since the absolute configuration of (+)-XIII has been established to be 1R,6S in relation to (+)-X,[4] 1R,6R absolute configuration may reasonably be assigned to

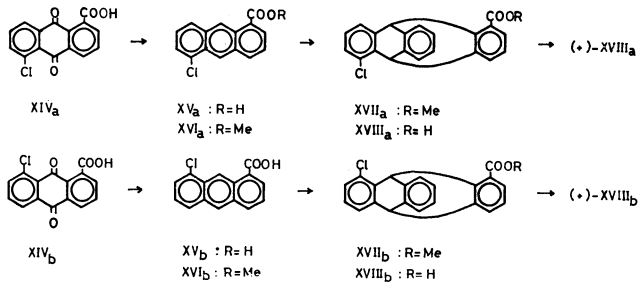
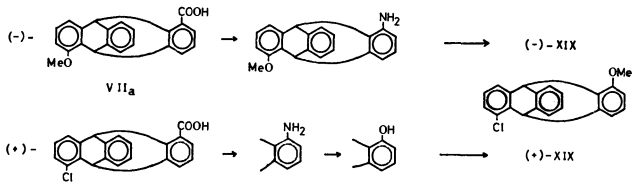


Scheme 2.

(+)-VIIb. The CD spectrum of (+)-XIa also showed a negative Cotton effect in the longest wavelength region.

In order to get information on the effect of magnitude of electric transition moment on the rotatory properties, replacement of the methoxyl group (spectroscopic moment 30)[10] in VIIa and VIIb with chlorine atom (spectroscopic moment 6)[10] was undertaken. 5-Chloroanthraquinone-1-carboxylic acid (XIVa) and 8-chloroanthraquinone-1-carboxylic acid (XIVb) prepared from anthraquinone-1-sulfonic acid by the reported method[11] were reduced to anthracene derivatives (XVa and XVb) by the procedure used in the preparation of IVa and IVb. The reaction of its methyl ester (XVIa or XVIb) with benzyne afforded chlorotriptycenecarboxylate (XVIIa or XVIIb). Chlorotriptycenecarboxylic acid (XVIIIa or XVIIIb) derived from XVIIa or XVIIb were resolved by means of brucine to yield optically pure (+)-5-chlorotriptycene-1-carboxylic acid, (+)-XVIIIa or 7-chlorotriptycene-1-carboxylic acid, (+)-XVIIIb.



Scheme 3.

(+)-2-Chloro-7-carboxytriptycene (XVIIIa) was converted by the Curtius reaction into 2-chloro-7-hydroxytriptycene *via* 2-chloro-7-amino derivative. Methylation of the phenolic derivative afforded (+)-2-chloro-5-methoxytriptycene (XIX). On the other hand, the Curtius reaction of (−)-2-methoxy-7-carboxytriptycene (VIIa) obtained from the mother liquor of the optical resolution of *dl*-VIIa by means of brucine in *ca.* 60% optical purity, yielded 2-methoxy-7-aminotriptycene which could be converted into (−)-2-chloro-5-methoxytriptycene (XIX) by the Sandmeyer reaction. The IR spectra of (+)-XIX and (−)-XIX thus prepared were found to be superimposable and their CD spectra showed antipodal curves. The absolute configuration of (−)-VIIa has been estimated to be 1S,6S on the bases of X-ray structure analysis by the

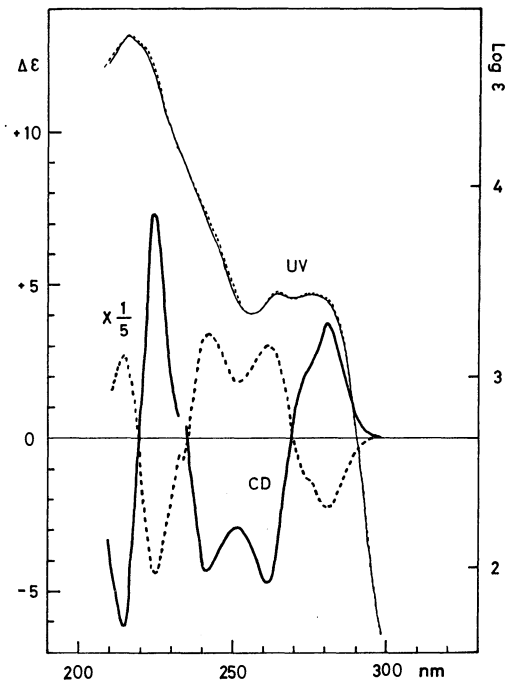


Fig. 4. UV and CD spectra of (+)-XIX (——) and (−)-XIX (····, optical purity 60%) in dioxane

Bijvoet method and the chemical correlation. Consequently, the absolute configuration of (+)-2-chloro-7-carboxytriptycene (XVIIIa) could be concluded to be 1R,6R on the same ground.

The bridgehead proton (C^1–H) proximate to carbomethoxy group and chlorine atom in XVIIb exhibited NMR signal at τ 2.57, whereas the signal of bridgehead proton (C^6–H) proximate to carbomethoxy group in XVIIa appeared at τ 3.00. The down-field shift of signal of the former compound could be attributed to magnetic anisotropy, van der Waals effect and electric field effect of the substituent groups.[12] The down-field shift of signal of bridgehead proton proximate to methoxycarbonyl group in VIb (τ 2.55) as compared with that of VIa (τ 3.00) indicates that the methoxyl group in VIb should occupy the 10-position. Consequently, the structure of IIb was firmly established to be 8-nitroanthraquinone-1-carboxylic acid.[13] The same effect of substituent groups on NMR spectrum was observed in the anthracene derivatives (Va and Vb) (see Experimental).

Experimental

All the melting points are not corrected. The IR (KBr-disk method) and UV spectra were measured with JASCO-402 and Hitachi EPS-3T spectrophotometers, respectively. The NMR spectra in deuteriochloroform were obtained on a Varian A-60 spectrometer using TMS as an internal standard. The CD spectra were measured with a Roussel-Jouan Dichrograph B and II CD-185.

5-Nitroanthraquinone-1-carboxylic Acid (IIa) and 8-Nitroanthra-

13) The position of nitro group in IIb was presumed to be the 8-position without firm experimental evidence.[7]

quinone-1-carboxylic Acid (IIb). Anthraquinone-1-carboxylic acid obtained from benzanthrone[5] was nitrated by the reported method.[12] IIa was obtained from the fraction less soluble in ethanol. The residue obtained on evaporating the ethanolic mother liquor was recrystallized from water to yield yellow crystals, mp 288—295°C. The IR spectrum of this substance showed absorptions characteristic of 1,8-disubstituted anthraquinone[14] at 810 and 755 cm^{-1}. The yellow crystals (IIb) were converted into methyl ester in the usual way, mp 147.0—148.4°C (from methanol), IR: 1723 ($\nu_{C=O}$, $-COOCH_3$), 1678 ($\nu_{C=O}$, quinone), 1540, 1328 ($C-NO_2$) 802, 743 (1,8-disubstituted anthraquinone) cm^{-1}.

Found: C, 62.53; H, 3.08; N, 4.26%. Calcd for $C_{16}H_9O_6N$: C, 61.74; H, 2.91; N, 4.50%.

5-Methoxyanthraquinone-1-carboxylic Acid (IIIa) and the Methyl Ester. A mixture of crude IIa (10 g), sodium hydroxide (15 g) and methanol (300 ml) was refluxed for 8 hr. The residue obtained by concentration of the dark red reaction mixture was mixed with water (300 ml). The insoluble material was removed by filtration. The filtrate was acidified with concentrated hydrochloric acid to yield crude IIIa as yellow solid, mp 270—280°C (decomp), 9.2 g (97%). Treatment of crude IIIa with methanol containing sulfuric acid afforded methyl ester, yellow needles, mp 184.5—186.0°C (from methanol), IR (KBr-disk): 2840 (ν_{C-H}, $-OCH_3$), 1727 ($\nu_{C=O}$, $-COOCH_3$), 1664 ($\nu_{C=O}$, quinone), 815, 707 (1,5-disubstituted anthraquinone) cm^{-1}.

Found: C, 68.60; H, 4.06%. Calcd for $C_{17}H_{12}O_5$: C, 68.91; H, 4.08%.

8-Methoxyanthraquinone-1-carboxylic Acid (IIIb) and the Methyl Ester. According to the procedure used for IIIa, crude IIb (69.4 g) was converted into crude IIIb (49.6 g, 75.3%) which was recrystallized from acetic acid, mp 270—285°C (decomp). Methyl ester, yellow needles, mp 228.5—229.5°C (from methanol) was obtained by the usual method, IR: 2840 (ν_{C-H}, $-OCH_3$), 1720, 1664 ($\nu_{C=O}$, $-COOCH_3$, quinone), 800, 745 (1,8-disubstituted anthraquinone) cm^{-1}.

Found: C, 69.05; H, 3.85%. Calcd for $C_{17}H_{12}O_5$: C, 68.91; H, 4.08%.

5-Methoxyanthracene-1-carboxylic Acid (IVa). A mixture of crude IIIa (33 g), 15% aqueous ammonia (1.1 liter) and zinc dust (55 g) was heated with stirring on a boiling water-bath for 8 hr. At 2 hr intervals, zinc dust (4 g) and concentrated aqueous ammonia (30 ml) were added to the reaction mixture. Excess zinc dust was removed by filtration and washed with aquous ammonia. The combined filtrate and washings were treated twice with active charcoal. The hot filtrate was made acid to Congo red with concentrated hydrochloric acid, yielding crude IVa as yellow precipitate, 26.0 g (88.1%), mp *ca.* 215°C (decomp.).

5-Methoxy-1-methoxycarbonylanthracene (Va). A mixture of crude IVa (25.0 g), anhydrous methanol (880 ml) and concentrated sulfuric acid (14 ml) was refluxed for 8 hr. After the solvent had been removed, the residue was mixed with water and extracted with benzene. The concentrated extract was subjected to a chromatography on alumina (700 g). Elution with benzene afforded crude methyl ester (Va, 17.9 g, 67.8%). The crude material was recrystallized from methanol to yield pure Va, yellow needles, mp 130.5—131.5°C, IR: 2830 (ν_{C-H}, $-OCH_3$), 1700 ($\nu_{C=O}$, $-COOCH_3$) cm^{-1}, NMR: τ 0.48 (C^9-H), 1.15 (C^{10}-H), 5.97 ($-COOCH_3$ and $-OCH_3$).

Found: C, 76.65; H, 5.22%. Calcd for $C_{17}H_{14}O_3$: C, 76.67; H, 5.30%.

8-Methoxyanthracene-1-carboxylic Acid (IVb). Reduction of crude IIIb (49.0 g) by the method used for IVa afforded crude IVb (39.3 g, 81.7%), mp *ca.* 180°C (decomp.). The crude material was used in the following reaction.

8-Methoxy-1-methoxycarbonylanthracene (Vb). Esterification of crude IVb (38 g) according to the method used for IVa followed by chromatography on alumina afforded crude Vb (17.0 g, 42.5%). The crude material was recrystallized from methanol to yield pure Vb, yellow leaflets, mp 132—132.5°C, IR: 2835 (ν_{C-H}, $-OCH_3$) 1705 ($\nu_{C=O}$, $-COOCH_3$), cm^{-1}. NMR: τ 0.05 (C^9-H), 1.63 (C^{10}-H), 5.93 ($-COOCH_3$ and $-OCH_3$).

Found: C, 76.76; H, 5.33%. Calcd for $C_{17}H_{14}O_3$: C, 76.67; H, 5.30%.

2-Methoxy-7-methoxycarbonyltriptycene (VIa). To a mixture of Va (3.0 g, 11 mmol), isoamyl nitrite (2 ml, 15 mmol) and 1,2-dimethoxyethane (20 ml), stirred under gentle reflux, was added over 20 min period a solution of anthranilic acid (2.6 g, 19 mmol) in the same solvent (10 ml), and then an additional amount of isoamyl nitrite (2 ml). A solution of anthranilic acid (2.6 g) in the same solvent (10 ml) was again added to the mixture over a period of 20 min. The mixture was stirred for further 10 min under reflux. Crystals deposited on cooling the mixture on an ice-salt bath were collected by filtration and washed 4 times with cold methanol–water (4: 1, 10 ml), yielding crystalline material (1.6 g). The material in xylene (20 ml) was refluxed for 5 min with maleic anhydride (1.0 g, 10 mmol) to remove the unreacted anthracene derivative. After the solvent had been removed under reduced pressure, the residue was dissolved in benzene and chromatographed on alumina (100 g) to afford VIa as colorless crystals, mp 232—232.5°C, IR: 2836 (ν_{C-H}, $-OCH_3$), 1713 ($\nu_{C=O}$, $-COOCH_3$) cm^{-1}, UV: $\lambda_{max}^{dioxane}$ (ε) 209.5 (53400), 215 (51000), 267 (3550), 283.5 (4100), 296 (3810) nm, NMR: τ 2.33—3.17 (m, 11H, aromatic and C^1-H), 4.07 (s, 1H, C^6-H), 6.05 (s, 3H, $-COOCH_3$).

Found: C, 80.72; H, 5.33%. Calcd for $C_{23}H_{18}O_3$: C, 80.68; H, 5.30%.

5-Methoxy-7-methoxycarbonyltriptycene (VIb). To a solution of Vb (4.286 g, 16.1 mmol) and isoamyl nitrite (1.9 g, 16 mmol) in dichloromethane (20 ml), stirred under reflux, was added a solution of anthranilic acid (2.3 g, 16.8 mmol) in tetrahydrofuran (60 ml) over a period of 5 hr. Pale yellow residue obtained on evaporation of the solvent was mixed with xylene (50 ml) and maleic anhydride (3.5 g, 36 mmol). After refluxing for 1 hr, water (70 ml) and dichloromethane (70 ml) were added to the reaction mixture. The organic layer was washed successively with cold 5% aqueous potassium hydroxide (20 ml × 5) and water, and dried (sodium sulfate). The residue obtained on evaporating the solvent was dissolved in benzene and chromatographed on alumina (120 g), yielding VIb (1.843 g, 33.4%) which was recrystallized from ethyl acetate to give pure VIb, colorless crystals, mp 220—221.5°C, IR: 2835 (ν_{C-H}, $-OCH_3$), 1708 ($\nu_{C=O}$, $-COOCH_3$) cm^{-1}, UV: $\lambda_{max}^{dioxane}$ (ε) 220 (44600), 268 (3740), 285 (4680), 295 (4260) nm, NMR: τ 2.55 (C^1-H), 4.55 (C^6-H), 6.00 ($-COOCH_3$).

Found: C, 80.52; H, 4.72%. Calcd for $C_{23}H_{18}O_3$: C, 80.68; H, 5.30%.

2-Methoxy-7-carboxytriptycene (VIIa). A mixture of VIa (1.231 g), acetic acid (30 ml) and 10% aqueous sulfuric acid (45 ml) was refluxed for 25 hr. VIIa (1.067 g) was obtained on cooling the reaction mixture. The filtrate gave a second crop of VIIa (94 mg) (total yield, quantitative). Pure VIIa, mp 299.0—300°C was obtained on recrystallization from acetic acid, IR: 2830 (ν_{C-H}, $-OCH_3$), 1677 ($\nu_{C=O}$, $-COOH$) cm^{-1}, UV: $\lambda_{max}^{dioxane}$ (ε) 298 (3810), 285 (4010), 269 (3460), 224 (31100) nm.

Found: C, 80.27; H, 4.83%. Calcd for $C_{22}H_{16}O_3$: C,

14) N. Oi, *Chem. Pharm. Bull.* (Tokyo), **5**, 153 (1957).

80.47; H, 4.91%.

5-Methoxy-7-carboxytriptycene (VIIb). Hydrolysis of VIb (790 mg) according to the above method afforded VIIb (660 mg, 95%) which was recrystallized from aqueous acetic acid, yielding pure VIIb, mp 305—308°C, IR: 2830 (ν_{C-H}, -OCH_3), 1680 ($\nu_{C=O}$, -COOH) cm^{-1}.

Found: C, 80.20; H, 4.61%. Calcd for $C_{22}H_{16}O_3$: C, 80.47; H, 4.91%.

Optical Resolution of 2-Methoxy-7-carboxytriptycene (VIIa).

To a hot solution of VIIa (4.70 g, 14.3 mmol) in 99% ethanol (270 ml) was added brucine dihydrate (3.08 g, 7.80 mmol) in one portion. After refluxing for 15 min, the mixture was allowed to stand overnight to deposit brucine salt (5.1 g). The salt was recrystallized twice from 99% ethanol to yield pure material, mp 196.0—198.0°C, IR: 3510 (ν_{N-H}), 1655 ($\nu_{C=O}$, -COO^-) cm^{-1}, $[\alpha]_{350}^{20}$ −268° (*c* 0.117, dioxane).

The pure salt (1.125 g) was dissolved in acetic acid (10 ml) on warming up to 90—95°C for 5 min. White precipitate (478 mg) obtained on addition of water (30 ml) to the acetic acid solution was recrystallized from acetic acid to give pure (+)-VIIa mp 267°C (decomp.), IR: 2830 (ν_{C-H}, -OCH_3), 1673 ($\nu_{C=O}$, -COOH) cm^{-1}, $[\alpha]_D^{20}$ +15.4°, $[\alpha]_{405}^{20}$ −74.4° (*c* 0.187, dioxane).

Found: C, 80.26; H, 4.76%. Calcd for $C_{22}H_{16}O_3$: C, 80.47; H, 4.91%.

(+)-2-Methoxy-7-methoxycarbonyltriptycene (VIa). A mixture of (+)-VIIa (35 mg), methanol (5 ml) and concentrated sulfuric acid (0.2 ml) was refluxed for 5 hr. Crystals (33 mg) deposited on cooling the reaction mixture were washed with a small amount of methanol and recrystallized from the same solvent to yield pure ester, (+)-VIa as colorless, rods, mp 240—241°C, IR: 2830 (ν_{C-H}, -OCH_3), 1714 ($\nu_{C=O}$, -$COOCH_3$) cm^{-1}, CD: $\lambda_{max}^{dioxane}$ ($\Delta\varepsilon$) 325—288 (+0.4), 280 (+2.6), 265 (−2.5), 242* (+8.3), 232 (+12.2), 220 (−56.8) nm.

Found: C, 80.81; H, 5.34%. Calcd for $C_{23}H_{18}O_3$: C, 80.68; H, 5.30%.

Optical Resolution of 5-Methoxy-7-carboxytriptycene (VIIb).

To a hot solution of VIIb (170 mg, 0.518 mmol) in acetone (5 ml) was added brucine dihydrate (111 mg, 0.258 mmol). After refluxing for 15 min, crystals deposited (84 mg) were recrystallized from acetone (6 ml) to give brucine salt, 31 mg, $[\alpha]_{350}^{15}$ −206° (*c* 0.34, chloroform). (+)-VIIb obtained from an acetic acid solution of the brucine salt on dilution with water was sublimed *in vacuo* to give pure (+)-VIIb, mp 310—313°C, $[\alpha]_{600}$ +21.1°, $[\alpha]_D$ +23.7°, $[\alpha]_{400}$ +55.3°.

Found: C, 80.00; H, 4.85%. Calcd for $C_{22}H_{16}O_3$: C, 80.47; H, 4.91%.

The residue obtained on concentrating the mother liquor of recrystallization of brucine salt was decomposed to yield (−)-VIIb with unknown optical purity (negative rotation in the visible wavelength region).

The experiments were repeated under the same and different conditions, but no optical resolution could be achieved except for the above described run. The cause of the poor reproducibility is not clear.

(+)-2-Hydroxy-7-carboxytriptycene (VIIIa). A mixture of (+)-VIIa (467 mg), acetic acid (10 ml), 48% hydrobromic acid (10 ml) and 52% hydriodic acid (1 ml) was refluxed for 15 hr. The resulting red reaction mixture was poured onto water (80 ml) containing sodium hydrogen sulfite, and extracted with chloroform (20 ml×4). The extract was washed with water and dried (sodium sulfate). The residue (426 mg, 95.3%) obtained by evaporation of the solvent was recrystallized from petroleum ether–methyl acetate to yield pure (+)-VIIIa, mp 269—271°C (*dl*-VIIIa, mp 263.0—264.0°C), IR: 3020, 3200 (ν_{C-H}), 1683 ($\nu_{C=O}$, -COOH) cm^{-1}, UV: $\lambda_{max}^{95\%EtOH}$ (ε) 300* (3400), 286 (4350), 269 (3410), 214* (46200) nm.

Found: C, 80.05; H, 4.36%. Calcd for $C_{21}H_{14}O_3$: C, 80.24; H, 4.39%.

(+)-2-Hydroxy-7-methoxycarbonyltriptycene (IXa). The reaction mixture obtained on refluxing a mixture of (+)-VIIIa (393 mg), anhydrous methanol (7 ml) and concentrated sulfuric acid (0.4 ml) for 8 hr was poured onto water (40 ml). The crude ester (404 mg, 98.5%) obtained as a white precipitate was recrystallized from cyclohexane–methyl acetate to give pure (+)-IXa, mp 217—225°C (*dl*-IXa, mp 231—234°C), IR: 3400 (ν_{O-H}), 1697 ($\nu_{C=O}$) cm^{-1}.

Found: C, 80.20; H, 4.76%. Calcd for $C_{22}H_{16}O_3$: C, 80.47; H, 4.91%.

(+)-2,5-Dimethoxy-7-methoxycarbonyltriptycene (Xa). A mixture of concentrated hydrochloric acid (0.14 ml) and ice-water (5 ml) was added to an ice-cooled solution of sulfanilic acid (185 mg, 0.97 mmol), sodium carbonate (57 mg) and sodium nitrite (82 mg) in water (5 ml), and the mixture was stirred for 30 min at 0°C. To the resulting solution of diazotized sulfanilic acid was added a solution of (+)-IXa (219 mg, 0.667 mmol) in methanol (20 ml) and water (4 ml) containing sodium hydroxide (147 mg). After being stirred for 1 hr at room temperature, the deep red reaction mixture was poured onto water (40 ml). Sodium hydrosulfite was added in small portions at 40—50°C until the color of the mixture turned light yellow, and then extracted with ethyl acetate (20 ml×4). The extract was washed with a saturated sodium chloride solution (20 ml×2) and dried (sodium sulfate). Aminophenol derivative (195 mg) obtained by evaporating the solvent was mixed with 2N sulfuric acid (35 ml). Ethanol was then added to result in a homogeneous solution. Ferric sulfate (3.3 g) was added to the solution and the mixture was kept for 2 hr on a boiling water-bath. After cooling, the reaction mixture containing yellow precipitate was extracted with chloroform (20 ml×4). The extract was worked up in the usual way to yield crude quinone derivative. The crude quinone in ethanol (10 ml) was reduced with a saturated aqueous solution of sodium hydrosulfite. Water was added to the resulting pale yellow mixture and extracted with ether. The dried extract was concentrated to yield crude hydroquinone derivative (116 mg). A mixture of the hydroquinone, acetone (5 ml), anhydrous potassium carbonate (1.0 g) and dimethyl sulfate (0.4 ml) was refluxed for 5 hr. The reaction mixture was mixed with water (50 ml) and extracted with benzene (20 ml×4). After washing and drying, the extract was concentrated to *ca.* 20 ml and chromatographed on alumina (5 g) to yield (+)-Xa (83 mg). Pure (+)-Xa was obtained by recrystallization from benzene, mp 261.5—262.5°C. (+)-Xa thus obtained showed no depression of melting point [mixed mp 261.5—262.3°C] on admixture with (+)-2,5-dimethoxy-7-methoxycarbonyltriptycene [(+)-X, mp 261.5—262.5°C] prepared by a different route.[3] Both compounds showed identical IR spectra. The optical purity of (+)-Xa was confirmed by comparison of $\Delta\varepsilon$ value at 267 nm in dioxane [(+)-Xa: $\Delta\varepsilon$=−3.15, (+)-X: $\Delta\varepsilon$=−3.06[3]].

Found: C, 77.55; H, 5.46%. Calcd for $C_{24}H_{20}O_4$: C, 77.40; H, 5.41%.

(+)-2-Acetoxy-7-methoxycarbonyltriptycene (XIa). A mixture of (+)-IXa (70 mg), acetic anhydride (3 ml) and a small amount of anhydrous sodium acetate was heated on a boiling water-bath for 3 hr. After cooling, water was added to the reaction mixture. Crystals deposited were recrystallized from methanol to yield (+)-XIa, colorless rods, mp 175.5—176.5°C, IR: 1767 ($\nu_{C=O}$, -$OCOCH_3$), 1723 ($\nu_{C=O}$, -$COOCH_3$) cm^{-1}, UV: $\lambda_{max}^{dioxane}$ (ε) 294 (3830), 276.5 (2170),

215 (53300) nm, CD: $\lambda_{max}^{dioxane}$ ($\Delta\varepsilon$) 285 (−0.6), 272.5 (+1.5), 260 (−1.16) nm.

Found: C, 78.43; H, 4.77%. Calcd for $C_{24}H_{18}O_4$: C, 77.82; H, 4.90%.

dl-XIa: mp 189.0—191.5°C, IR: 1755 ($\nu_{C=O}$, -$OCOCH_3$), 1708 ($\nu_{C=O}$, -$COOCH_3$) cm^{-1}.

(+)-2-Hydroxy-5-phenylazo-7-carboxytriptycene (XIIa). To a solution of (+)-VIIIa (93 mg, 0.30 mmol) in methanol (5 ml) and 10% aqueous potassium hydroxide solution (1.5 ml) was added a solution of benzenediazonium chloride prepared from aniline (46 mg, 0.49 mmol), concentrated hydrochloric acid (0.15 ml), water (0.5 ml) and sodium nitrite (36 ml). After the mixture had been stirred for 10 min at 0°C, water (20 ml) was added to the resulting red solution and extracted with dichloromethane. The residue obtained by working up the extract was dissolved in ether–benzene (1: 1) and chromatographed on silica gel. Pure (+)-XIIa, red crystals, mp 279—280°C, was obtained by recrystallization from benzene–cyclohexane (1: 1), IR: 3100—3600 (broad), 3040, 1685 ($\nu_{C=O}$, -COOH) cm^{-1}, UV: $\lambda_{max}^{95\%EtOH}$ (ε) 466 (3700), 359 (17700), 269 (10200) nm, CD: $\lambda_{max}^{dioxane}$ ($\Delta\varepsilon$) 450 (−2.9), 319 (−0.9), 277 (+6.1) nm.

The azotriptycene (XIIa) gave no satisfactory elemental analysis presumably owing to its incomplete combustion.

Found: C, 78.11; H, 4.73; N, 5.91%. Calcd for $C_{27}H_{18}O_3N_2$: C, 77.50; H, 4.34; N, 6.69%.

5-Chloroanthraquinone-1-carboxylic Acid (XIVa) and 8-Chloroanthraquinone-1-carboxylic Acid (XIVb). Anthraquinone-1-sulfonic acid was converted into XIVa and XIVb according to the reported method.[11]

5-Chloroanthracene-1-carboxylic Acid (XVa). A mixture of crude XIVa (6 g), 14% aqueous ammonia (350 ml) and zinc dust (10.5 g) was stirred on a water-bath at 90°C. Zinc dust and aqueous ammonia were further added in small portions during the course of reaction until the deep red color of the reaction mixture turned greenish grey. Excess zinc dust was removed by filtration. The filtrate was treated with active charcoal and the hot filtrate was made acidic to Congo red with concentrated hydrochloric acid to precipitate crude XVa as yellowish brown solid, 4.5 g, mp >300°C.

8-Chloroanthracene-1-carboxylic Acid (XVb). Crude XIVb (9.9 g) was converted into XVb (6.9 g, 78%) according to the procedure given above.

Methyl 5-Chloroanthracene-1-carboxylate (XVIa). A mixture of crude XVa (21.7 g), anhydrous methanol (680 ml) and concentrated sulfuric acid (10.8 ml) was refluxed. The reaction mixture was worked up in the usual way and extracted with benzene. The benzene solution was chromatographed on alumina to yield XVIa (11.0 g, 48%) which was recrystallized from methanol to give pure XVIa, light yellow needles, mp 131.5—132.5°C, IR: 1690 ($\nu_{C=O}$, -CO_2CH_3) cm^{-1}, NMR: τ 0.40 (C^9-H), 1.70 (C^{10}-H), 5.95 (-CO_2CH_3).

Found: C, 71.24; H, 4.16; Cl, 13.26%. Calcd for $C_{16}H_{11}O_2Cl$: C, 70.99; H, 4.10; Cl, 13.10%.

Methyl 8-Chloroanthracene-1-carboxylate (XVIb). Crude XVb was converted into XVIb according to the method used for the 5-chloro isomer. Pure XVIb was obtained by repeated recrystallization from methanol and petroleum ether–methyl acetate, light yellow leaflets, mp 126.0—126.8°C, IR: 1700 ($\nu_{C=O}$, -CO_2CH_3) cm^{-1}, NMR: τ 0.00 (C^9-H), 1.58 (C^{10}-H), 5.93 (-CO_2CH_3).

Found: C, 70.75; H, 4.07; Cl, 13.23%. Calcd for $C_{16}H_{11}O_2Cl$: C, 70.99; H, 4.10; Cl, 13.10%.

2-Chloro-7-methoxycarbonyltriptycene (XVIIa). To a mixture of XVIa (4.7 g, 17 mmol), dichloromethane (94 ml) and isoamyl nitrite (2.9 ml, 22 mmol), stirred vigorously under gentle reflux, was added a solution of anthranilic acid (2.72 g, 20 mmol) in tetrahydrofuran (62 ml) over a period of 5 hr. After being refluxed for further 1 hr, the solvent was removed under reduced pressure. Maleic anhydride (3.6 g, 37 mmol) and xylene (55 ml) were added to the residue and refluxed for 3.5 hr. The reaction mixture was mixed with dichloromethane (100 ml) and water (100 ml). The organic layer was washed with 5% aqueous potassium hydroxide solution (30 ml × 5) and water, successively, and dried. The dichloromethane was removed by distillation and the residue was chromatographed on alumina. Slightly crude XVIIa (1.75 g, 29.1%) obtained from benzene eluate was recrystallized from cyclohexane to yield pure XVIIa, mp 164—165°C, IR: 1710 ($\nu_{C=O}$, -$COOCH_3$) cm^{-1}, UV: λ_{max}^{EtOH} (ε) 216 (56600), 263 (1550), 280* (2710), 295 (3990) nm, NMR: τ 3.00 (C^6-H), 4.04 (C^1-H), 6.03 (-$COOCH_3$).

Found: C, 76.30; H, 4.30; Cl, 10.02%. Calcd for $C_{22}H_{15}O_2Cl$: C, 76.19; H, 4.36; Cl, 10.22%.

5-Chloro-7-methoxycarbonyltriptycene (XVIIb). The product obtained by the reaction of XVIb (3.0 g) with benzyne generated by the above method was chromatographed on alumina, yielding slightly crude XVIIb (1.2 g, 31.2%). Pure XVIIb was obtained by recrystallization from cyclohexane, mp 248—249°C, IR: 1710 ($\nu_{C=O}$, -$COOCH_3$) cm^{-1}, UV: λ_{max}^{EtOH} (ε) 216 (55000), 263 (1550), 280* (2590), 295 (3740) nm, NMR: τ 2.57 (C^6-H), 4.57 (C^1-H), 6.00 (-$COOCH_3$).

Found: C, 76.16: H, 4.12; Cl, 10.54%. Calcd for $C_{22}H_{15}O_2Cl$: C, 76.19; H, 4.36; Cl, 10.22%.

2-Chloro-7-carboxytriptycene (XVIIIa). A mixture of XVIIa (979 mg), acetic acid (100 ml) and 10% aqueous sulfuric acid (30 ml) was refluxed for 10 hr. The crystals deposited on cooling the reaction mixture were combined with the second crop obtained from the concentrated filtrate. The combined crystals (quantitative yield) were recrystallized from benzene–cyclohexane to give pure XVIIIa, mp 295—296°C, IR: 1680 ($\nu_{C=O}$, -COOH) cm^{-1}.

Found: C, 75.80; H, 3.79; Cl, 10.39%. Calcd for $C_{21}H_{13}O_2Cl$: C, 75.79; H, 3.94; Cl, 10.66%.

5-Chloro-7-carboxytriptycene (XVIIIb). XVIIb was converted into XVIIIb according to the method given above, mp 217°C (from methanol), IR: 1680 ($\nu_{C=O}$, -CO_2CH_3) cm^{-1}.

Found: C, 75.76; H, 4.24; Cl, 10.86%. Calcd for $C_{21}H_{13}O_2Cl$: C, 75.79; H, 3.94; Cl, 10.66%.

Optical Resolution of 2-Chloro-7-carboxytriptycene (XVIIIa). Brucine dihydrate (1034 mg, 2.40 mmol) was added to a solution of XVIIIa (796 mg, 2.40 mmol) in 99% ethanol (30 ml). After the mixture had been refluxed for 10 min, the solvent was removed under reduced pressure. The residue was recrystallized twice from acetone to yield pure brucine salt, mp 195—199°C, $[\alpha]_{350}$ −154°, $[\alpha]_{400}$ −54.0°, $[\alpha]_{500}$ −6.00°, $[\alpha]_D$ +4.00° (*c* 0.50, $CHCl_3$).

Found: C, 72.76; H, 5.32; N, 3.85; Cl, 4.62%. Calcd for $C_{44}H_{39}O_6N_2Cl$: C, 72.66; H, 5.41; N, 3.85; Cl, 4.88%.

The brucine salt was dissolved in hot acetic acid and diluted with water to precipitate (+)-XVIIIa, mp 289—291°C (decomp.), $[\alpha]_{350}^{15}$ +103°, $[\alpha]_D^{15}$ +19.4° (*c* 0.515, dioxane), CD: $\lambda_{max}^{dioxane}$ ($\Delta\varepsilon$) 287 (−1.2), 275 (+3.2), 259 (−1.3) nm.

Found: C, 75.30; H, 3.75%. Calcd for $C_{21}H_{13}O_2Cl$: C, 75.79; H, 3.94%.

Optical Resolution of 5-Chloro-7-carboxytriptycene (XVIIIb). To a solution of XVIIIb (128 mg, 0.4 mmol) in ethanol (6 ml) was added brucine dihydrate (172 mg, 0.4 mmol) and the mixture was refluxed for 30 min. The mixture was allowed to stand overnight. The crystals deposited were recrystallized from methyl acetate to afford pure brucine salt, mp 225—231°C.

Found: C, 72.56; H, 5.43; N, 3.83; Cl, 4.62%. Calcd for $C_{44}H_{39}O_6N_2Cl$: C, 72.66; H, 5.41; N, 3.85; Cl, 4.88%.

A hot acetic acid solution of the brucine salt was diluted with water to result in the precipitation of (+)-XVIIIb, mp 285—277°C, CD: $\lambda_{max}^{dioxane}$ ($\Delta\varepsilon$) 285 (−0.8), 275 (+1.3) nm.

Found: C, 75.64; H, 3.75%. Calcd for $C_{21}H_{13}O_2Cl$: C, 75.79; H, 3.94%.

(+)-2-Chloro-7-methoxytriptycene (XIX). A mixture of (+)-2-chloro-7-carboxytriptycene (XVIIIa, 0.330 g), thionyl chloride (0.4 ml) and tetrahydrofuran (10 ml) was refluxed for 2 hr. The volatile material was removed under reduced pressure to give crude acid chloride (0.350 g). To an ice-cooled solution of the crude acid chloride in tetrahydrofuran (15 ml) was added a solution of sodium azide (130 mg, 2.0 mmol) in water (1 ml). After the mixture had been stirred for 2 hr, the reaction mixture was poured onto water (100 ml). The solid deposited was washed thoroughly with water and dried *in vacuo*. The well-dried acid azide (0.304 g) was spread on the bottom of a 100 ml Erlenmeyer flask in a thin layer and gradually heated to 120°C avoiding the atmospheric moisture. After being kept at the same temperature for 2 hr, 99% ethanol (30 ml) containing potassium hydroxide (2.0 g) was added to the resulting isocyanate. After being refluxed for 6 hr, the ethanol was removed under reduced pressure. The residue was mixed with water (100 ml) and extracted with benzene. The extract, after being washed with a saturated sodium chloride solution and dried, was concentrated under reduced pressure to give amino derivative (0.250 g). The chloro-aminotriptycene thus obtained was dissolved in acetic acid (10 ml) and a solution of sodium nitrite (0.058 g) in water (2 ml) was added to the solution in small portions over 20 min period under stirring at 10—15°C. After being stirred for further 30 min, the resulting red solution of diazonium salt was added dropwise to boiling 6N sulfuric acid (30 ml). After further boiling for 10 min, water was added to the reaction mixture to make 100 ml of mixture and extracted with benzene. After being washed and dried, the extract was concentrated under reduced pressure to give phenolic derivative (0.263 g). A mixture of the crude phenol, acetone (15 ml), anhydrous potassium carbonate (1.2 g) and dimethyl sulfate (0.3 ml) was refluxed for 8 hr under stirring. The residue obtained by evaporation of the solvent under reduced pressure was mixed with water (40 ml) and extracted with benzene. The extract was worked up in the usual way. A benzene solution of the crude methyl ether was passed through a column of alumina (10 g). The crystals (186 mg) obtained from the initial filtrate (110 ml) were chromatographed on alumina (30 g). Elution with ligroin–benzene (2: 3) afforded colorless crystals (58 mg) which were recrystallized from methanol and then sublimed *in vacuo* to give pure (+)-XIX, mp 235—236.0°C, UV: $\lambda_{max}^{dioxane}$ (ε) 280 (2500), 276 (2620), 273* (2600), 268* (2580), 264 (2600), 217 (60500) nm, CD: $\lambda_{max}^{dioxane}$ ($\Delta\varepsilon$) 280 (+3.74), 275* (+2.28), 262 (−4.71), 242 (−4.31), 224 (+36.8), 216 (−31.0) nm.

Found: C, 78.93; H, 4.74; Cl, 11.00%. Calcd for $C_{21}H_{15}OCl$: C, 79.12; H, 4.74; Cl, 11.12%.

(+)-XIX thus prepared was admixed with approximately the same amount of (−)-XIX. The mixed melting point was found to be 240.5—241.4°C indicating the formation of a racemic compound.

(−)-2-Chloro-7-methoxytriptycene (XIX). Thionyl chloride (0.8 ml) was added to a solution of (−)-2-methoxy-7-carboxytriptycene (VIIa, 604 mg) with *ca.* 60% optical purity, obtained from the mother liquor of optical resolution of *dl*-VIIa with brucine, in tetrahydrofuran (20 ml). After the mixture had been refluxed for 2 hr, the volatile material was removed under reduced pressure to give crude acid chloride [659 mg, IR: 1750 ($\nu_{C=O}$, -COCl) cm^{-1}]. To an ice-cooled solution of the acid chloride in tetrahydrofuran (30 ml) was added a solution of sodium azide (254 mg) in water (2 ml). After being stirred for further 2 hr at the same temperature, the reaction mixture was poured onto ice-water (200 ml). Thoroughly dried acid azide [88 mg, IR: 2130 ($\nu_{N=N^+=N^-}$), 1680 ($\nu_{C=O}$) cm^{-1}] was heated to 180°C as previously to give isocyanate [66 mg, IR: 2250 ($\nu_{N=C=O}$) cm^{-1}]. A mixture of the crude isocyanate (343 mg), potassium hydroxide (2.0 g), water (10 ml) and 99% ethanol (50 ml) was refluxed for 6 hr. After the solvent had been removed under reduced pressure, the residue was mixed with water (200 ml) and extracted with benzene. Concentration of the extract, after washing and drying, under reduced pressure afforded amino derivative [338 mg, IR: 3480, 3390 (ν_{N-H}) cm^{-1}]. A solution of sodium nitrite (925 mg) in water (2 ml) was added to an ice-cooled mixture of the amine (402 mg) in concentrated hydrochloric acid (5 ml). Freshly prepared cuprous salt [from cupric sulfate pentahydrate (500 mg), sodium chloride (130 mg), sodium hydrogen sulfite (106 mg), sodium hydroxide (70 mg) and water (24 ml)] was dissolved in concentrated hydrochloric acid (5 ml). To the solution of cuprous chloride in hydrochloric acid was added the diazotized amine in the same acid, and the mixture was kept at 80°C for 1 hr. Crude crystals (377 mg) obtained by diluting the reaction mixture with water were dissolved in *n*-hexane–benzene (1: 1) and percolated through a column of alumina. Crystals (260 mg) obtained from the initial filtrate (100 ml) were recrystallized from methanol and then sublimed *in vacuo* (bath temp. 200°C/2 mmHg) to give (−)-XIX, mp 234.0—235.0°C, UV: $\lambda_{max}^{dioxane}$ (ε) 280 (2530), 276 (2770), 273* (2670), 268* (2570), 264 (2750), 217 (60000) nm, CD: $\lambda_{max}^{dioxane}$ ($\Delta\varepsilon$) 281 (−2.23), 275* (−1.39), 269 (+3.00), 242 (+3.42), 225 (−22.0), 215 (+13.0) nm.

The optical purity of (−)-XIX thus obtained was found to be 60%.

Found: C, 78.99; H, 4.59; Cl, 11.10%. Calcd for $C_{21}H_{15}OCl$: C, 79.12; H, 4.74; Cl, 11.12%.

Tubercidin. Its Conversion into 5′-Deoxytubercidin

Kentaro ANZAI and Masanao MATSUI

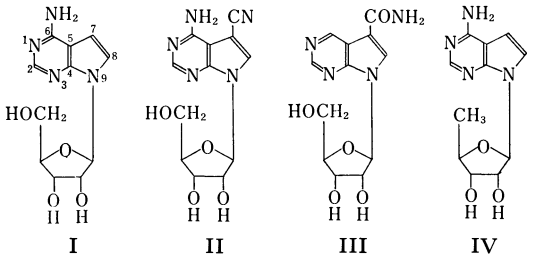
The Institute of Physical and Chemical Research, Wako-shi, Saitama

(Received January 24, 1972)

Tubercidin (I) was converted into 5′-deoxytubercidin (IV). Mesylation of 2′,3′-*O*-isopropylidenetubercidin (IX) afforded-2′,3′-*O*-isopropylidene-5′-*O*-mesyltubercidin (XVIII), which *in situ* was treated with benzoyl chloride. The product, N^6,N^6-dibenzoyl-2′,3′-*O*-isopropylidene-5′-*O*-mesyltubercidin (XXII), was converted into N^6,N^6-dibenzoyl-5′-deoxy-5′-iodo-2′,3′-*O*-isopropylidenetubercidin (XXIV). Catalytic hydrogenation of XXIV afforded N^6-benzoyl-5′-deoxy-2′,3′-*O*-isopropylidenetubercidin (XXVII). 5′-Deoxytubercidin (IV) was obtained on debenzoylation and deacetonation of XXVII.

Tubercidin (4-amino-7-(D-ribofuranosyl)-7*H*-pyrrolo-[2,3-*d*]pyrimidine)[1,2] (I)[3] was first isolated by Anzai *et al.*[4] from the fermentation broth of *Streptomyces tubercidicus*[5] in 1957. It has selective bactericidal activities against *Mycobacterium tuberculosis* of human and bovine types[4] as well as high activities against NF mouse sarcoma[4] and some experimental tumors.[6] Its clinical use was examined for cancer patients, and was shown to be highly toxic.

Several works[7] were directed to the total synthesis of I and related antibiotics including toyocamycin (II)[8] and sangivamycin (III),[9] both of which were also reported to have high activities against experimental tumors.



I II III IV

In 1969 Tolman *et al.* succeeded in the synthesis of these three compounds.[10] They as well as others synthesized derivatives of tubercidin whose pyrro[2,3-*d*]-pyrimidine moiety was subjected to various substitution.[11] Phosphorylated derivatives of tubercidin, *i.e.* tubercidin-5′-phosphate,[12,15] dan tubercidin-3′,5′-cyclophosphate,[13] and the oligonucleotide analogues[14] were also synthesized, and their biological activities were investigated.[15] However, the modification of the ribose moiety has never been reported, and our investigation has been undertaken along this line. In this paper the conversion of I to 5′-deoxytubercidin (IV) will be described.

5′-Deoxyadenosine has been synthesized from adenosine[16] through a route involving catalytic reduction of N^6-acetyl-5′-deoxy-5′-iodo-2′,3′-*O*-isopropylidene-adenosine (V) which was synthesized from 2′,3′-*O*-isopropylidene-5′-*O*-tosyladenosine (VI)[17] by treatment with sodium iodide in acetic anhydride.

We followed this experiment and found that the yield of V was moderate (58%), but that of VI was good (90%). The iodide substitution reaction of VI yielding V is likely to compete with the formation of the cyclonucleoside VII.

Synthesis of the tubercidin analogue of V was attempted. Under the same conditions as applied to

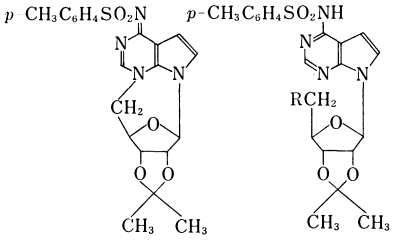
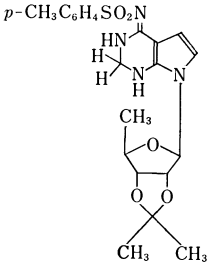
V VI VII

the synthesis of VI 2',3'-*O*-isopropylidenetubercidin (IX)[18] was converted into 2',3'-*O*-isopropylidene-5'-*O*-tosyltubercidin (VIII) in a 76% yield.[20] However, contrary to expectation, the following treatment of VIII with sodium iodide and acetic anhydride afforded cyclonucleoside X[21] as the main product and the tosyl iodo compound XVII as a minor one. None of the acetyl iodo compound corresponding to V was obtained.

With excess tosyl chloride and at a higher temperature, cyclonucleoside XI, N^6-tosylate XII and N^6,5'-*O*-ditosylate XIII were obtained in low yields, X being still the predominant product.



XI XII R=OH
XIII R=*p*-$CH_3C_6H_4SO_3$



XV

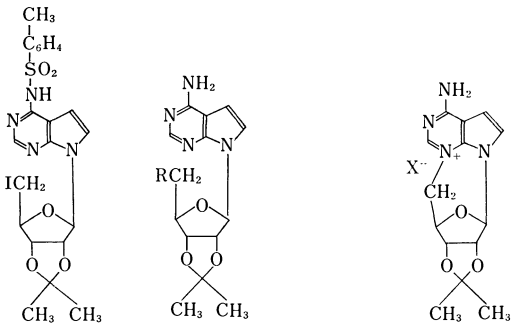
Facile transformation of VIII into X was confirmed by storing VIII in a desiccator at room temperature for 2 days to give a mixture of VIII and X (28: 72), *i.e.*, VIII is transformed easily into X even in the solid state. This is in contrast with the fact that 38% of VI is transformed into VII under the same conditions.

18) W. J. Wechter and A. R. Hanze, U. S. 3336289 (1967).
19) J. Zemlicka and A. Holy, *Collect. Czech. Chem. Commun.*, **32**, 3159 (1967).
20) Tosylation was carried out at −15°C to −20°C as reported[17] for the synthesis of VI, though Mizuno *et al.* obtained VIII at a higher temperature (0°C) in a 30% yield.
21) Though the reported UV spectrum, λ_{max}^{EtOH} 281 mμ (ε 11.7×10³), and that measured by the authors, λ_{max}^{EtOH} 293 (ε 11.2×10³), 275 (shoulder, ε 10.0×10³) and 214 mμ (ε 22.7×10³) differ, analytical data and other properties show that both samples are the same.

Thus, another route to IV should be explored on account of the lability of VIII.

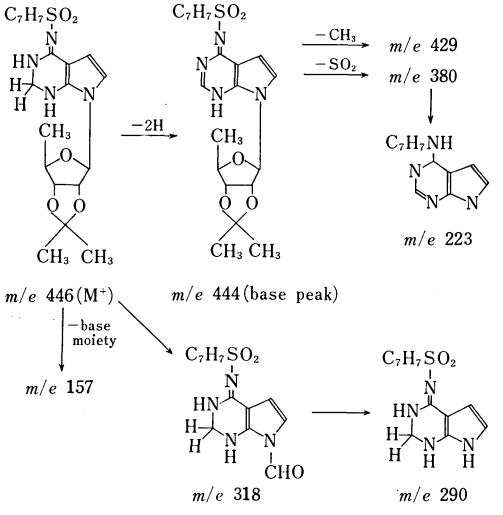
Tosylate XIII was reduced with lithium aluminium hydride in tetrahydrofuran, XIV being expected to be produced in one step. However, the main product was a deoxydihydro derivative XV, XIV being obtained only as a minor one.

The dihydro compound XV lacks a NMR signal corresponding to the hydrogen at C-2 of tubercidin and shows a doublet at δ 1.30 assignable to the methyl group.



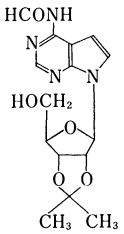
XVII VIII R=*p*-$CH_3C_6H_4SO_3$ X X=*p*-$CH_3C_6H_4SO_3$
IX R=OH XIX X=CH_3SO_3
XIV R=H
XVI R=CH_3CO_2
XVIII R=CH_3SO_3

In the mass spectrum the molecular ion was observed at *m/e* 446 and the base peak at M^+-2. Further fragmentations schematically shown in Chart 1 are also consistent in structure with that proposed for XV.



Treatment of XIV with dilute hydrochloric acid afforded IV, the NMR spectrum of which exhibited a three proton doublet at δ 1.28 assignable to the methyl group. The low yield of IV (1% from IX) in this procedure is, as mentioned above, attributable to the susceptibility of VIII to form X.

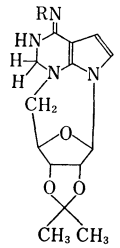
To prevent cyclonucleoside formation an attempt was made to protect the amino group of IX prior to *O*-tosylation. Ketal IX was treated with acetic anhydride in methanol. The reaction could not be brought to completion, and the product which was, unexpectedly, 5'-*O*-acetyl-2',3'-*O*-isopropylidenetubercidin (XVI) was obtained in a low yield.



XXVIII

An attempt to prepare the N^6-dimethylaminomethylene derivative[19] using dimethylformamide dimethyl acetal as a reagent was also unsuccessful, and N^6-formyl-2′,3′-*O*-isopropylidenetubercidin (XXVIII) was obtained in a low yield.

2′,3′-*O*-Isopropylidene-5′-*O*-mesyltubercidin (XVIII) was treated with sodium iodide and acetic anhydride. Here again the formation of the cyclonucleoside XIX was predominant and XVIII was also converted into XIX easily on being left in a desiccator. Excess mesyl chloride afforded no N^6-mesyl compound.



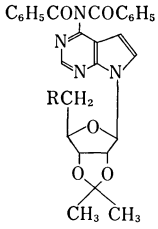
XX R=CH_3SO_2
XXI R=*p*-$CH_3C_6H_4SO_2$

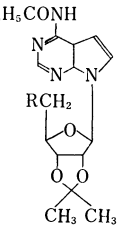
Reduction of XIX with sodium borohydride in an aqueous solution was investigated, the nucleophilic attack at C-5′ of hydride anion being expected to afford the deoxy compound XIV. However, the product was intractable gummy material, and the dihydro cyclonucleoside XX was isolated from the reaction mixture in a low yield. The NMR spectrum of XX shows that two protons at C-5′ as well as those at C-2 are unequivalent. The mass spectrum is also consistent with the proposed structure, and the fragmentations are characterized by the cleavage of 2H, CH_3, CHO, $-NH-CH_2-$, $-CH_2CHO-$, and CH_3SO_2 from the molecular ion.

Similarly, X was reduced with sodium borohydride to give N^6-tosyl cyclonucleoside XXI. The close similarity of the UV spectrum of XXI to that of XV also supports the structural assignment.

Finally the conversion of tubercidin into 5′-deoxytubercidin was accomplished in the following manner. After mesylation of IX was carried out in pyridine at 0°C, excess benzoyl chloride was added to the reaction mixture without isolation of XVIII. N^6,N^6-Dibenzoyl-2′,3′-*O*-isopropylidene-5′-*O*-methanesulfonyltubercidin (XXII) was obtained along with a small amount of the tribenzoyl compound XXIII.

Compound XXII was treated with sodium iodide in methyl ethyl ketone to give three products. The main product was N^6,N^6-dibenzoyl-5′-deoxy-5′-iodo-2′,3′-*O*-isopropylidenetubercidin (XXIV), the monobenzoyl iodo compound XXV being obtained as a minor





XXII R=CH_3SO
XXIII R=$C_6H_5CO_2$
XXIV R=I
XXVI R=H

XXV R=I
XXVII R=H

one. Another crystalline product was proved to have the molecular formula $C_{21}H_{21}N_3O_6$.[22]

Catalytic hydrogenation of XXIV afforded N^6,N^6-dibenzoyl-5′-deoxy-2′,3′-*O*-isopropylidenetubercidin (XXVI) and N^6-benzoyl-5′-deoxy-2′,3′-*O*-isopropylidenetubercidin (XXVII), the latter being the predominant product. Treatment of XXVII with dilute sodium hydroxide afforded 5′-deoxy-2′,3′-*O*-isopropylidenetubercidin (XIV), and the isopropylidene group of XIV was removed by heating in 80% aqueous acetic acid. Thus, tubercidin was converted into 5′-deoxytubercidin.

Experimental

2′,3′-O-Isopropylidene-5′-O-p-toluenesulfonyltubercidin (VIII) and its Cyclonucleoside Formation. The reaction was carried out under the same conditions as reported by Kuhn and Jahn.[17] Tosyl chloride (500 mg) was added at once to a solution of 2′,3′-*O*-isopropylidenetubercidin (IX) (500 mg) in pyridine (3 ml) cooled at −20°C. The solution was stirred for 2 hrs and was allowed to stand overnight at −15°C to −20°C. Ice-cooled water was added to the solution and the product was extracted with chloroform. The organic layer was washed with cold 2N H_2SO_4 and then with water. The solvent was evaporated to dryness below 30°C, affording 598 mg of the residue (yield, 76%). Though the maximum of the UV absorption was initially found at 270 mμ which is characteristic for the pyrrolo[2,3-*d*]pyrimidine chromophore of tubercidin, it gradually shifted to a higher wavelength on prolonged standing.

The residue was kept in a desiccator for 2 days at room temperature (15—25°C) and was distributed again between chloroform and water. The organic layer was evaporated to dryness below 30°C yielding 157 mg of syrup. Evaporation of the aqueous layer to dryness afforded 433 mg of crystalline solid, which was identical with a sample of the cyclonucleoside X obtained by the method reported by Mizuno *et al.*[2]

These results show that 72% of VIII was converted into X under the above-mentioned conditions.

For comparison 2′,3′-*O*-isopropylideneadenosine (500 mg) was tosylated under the same conditions affording 706 mg of a crude sample of 2′,3′-*O*-isopropylidene-5′-*O*-*p*-toluenesulfonyladenosine (VI) (yield, 90%). The product was kept in a desiccator at room temperature for 2 days and was distributed between chloroform and water. Evaporation of the organic layer as well as the aqueous layer to dryness afforded 430 mg and 266 mg of the residue, respectively, showing that

22) The loss of one nitrogen atom seems to be unusual. The NMR spectrum suggests that it is a cyclonucleoside showing characteristic signals of ABX type corresponding to two unequivalent methylene protons at C-5′.

38% of VI was converted into VII.

N^6-p-*Toluenesulfonyl-5'-deoxy-5'-iodo-2',3'-O-isopropylidenetubercidin (XVII).* A crude sample of VIII obtained from 2 g of IX was heated at 100°C in acetic anhydride (60 ml) in which sodium iodide (4 g) had been dissolved. After evaporation of acetic anhydride the residue was distributed between chloroform and an aqueous solution of sodium sulfite, and the organic layer was washed repeatedly with water. Column chromatography on silicic acid (benzene: ethyl acetate=1: 1) afforded 41 mg of XVII which was crystallized from ethyl acetate and ligroin. It decomposed gradually at 100—115°C; $\lambda_{max}^{methanol}$ 290 mμ (ε 19400).

Found: C, 44.77; H, 4.18; N, 9.83, S, 5.62%. Calcd for $C_{21}H_{23}N_4O_5SI$: C, 44.21; H, 4.06; N, 9.62; S, 5.71%.

Tosylation of 2',3'-O-Isopropylidenetubercidin (IX) at Room Temperature. Isolation of N-Tosylated Products. Tosyl chloride (4.9 g) was added at once to a solution of IX (2.2 g, 0.75 mmol) in pyridine (20 ml). After the solution was left standing at room temperature for 3 days, the products were distributed between an ice-cooled aqueous solution of sodium bicarbonate and ethyl acetate. The organic layer was concentrated to dryness, and the residue was extracted with hot methanol. The methanol insoluble substance was crystallized from dimethylformamide and methanol, and was assigned as 3,5'-cyclonucleoside (XI) of N^6-*p*-toluenesulfonyl-2',3'-*O*-isopropylidenetubercidin; yield, 110 mg; mp >300°C; $\lambda_{max}^{methanol}$ (ε) 313 (13800) and 220 mμ (33500); NMR (100 MHz, DMSO-*d*): 1.17, 1.42 (two isopropylidene methyls), 2.32 (s-3H, C<u>H</u>$_3$C$_6$H$_4$SO$_2$-), 4.13, 4.83 (a pair of doublet, 2H, H-2' and H-3', $J_{2',3'}$=6 Hz), 4.32 (broad d, 1H, H_a-5', J_{gem}=15 Hz), 4.6—5.0 (complex, 2H, H-4' and H_b-5'), 6.33 (s, 1H, H-1'), 6.62, 7.34 (a pair of doublet, 2H, -C<u>H</u>=C<u>H</u>-N<, $J_{7,8}$=4 Hz), 7.26, 7.80 (a pair of doublet, 4H, CH$_3$C$_6$<u>H</u>$_4$SO$_2$-, J_{orth}=8 Hz) and 8.24 ppm (s, 1H, -N=C<u>H</u>-N=).

Found: C, 56.95; H, 4.99; N, 12.77; S, 7.17%. Calcd for $C_{21}H_{22}N_4O_5S$: C, 57.00; H, 5.01; N, 12.67; S, 7.25%.

The methanol extract was fractionated with column chromatography on silicic acid, developed with a mixture of benzene and ethyl acetate (1: 1). Two compounds were obtained. One, moving faster and assigned as N^6-*p*-toluenesulfonyl-2',3'-*O*-isopropylidenetubercidin (XII), was crystallized from benzene; yield, 275 mg; mp 106—109°C: $\lambda_{max}^{methanol}$ (ε) 291 (16200) and 220 mμ (18600); $[\alpha]_D^{23}$ −77.5 (*c* 0.48, chloroform).

Found: C, 52.84; H, 5.45; N, 11.72; S, 7.55%. Calcd for $C_{21}H_{24}N_4O_6S\cdot H_2O$: C, 52.70; H, 5.48; N, 11.71; S, 6.70%.

The other compound, assigned as N^6,5'-*O*-di-*p*-toluenesulfonyl-2',3'-*O*-isopropylidenetubercidin (XIII), could hardly be separated from XII, and to obtain an analytical sample chromatography was repeated. It crystallized from benzene; yield, 300 mg; mp 106—109°C; $\lambda_{max}^{methanol}$ (ε) 291 (19600) and 223 mμ (35900).

Found: C, 54.73; H, 4.92; N, 9.30; S, 9.72%. Calcd for $C_{28}H_{30}N_4O_8S_2$: C, 54.71; H, 4.92; N, 9.12; S, 10.43%.

Similarity of the UV spectrum of XII with that of XIII shows that XIII is not a *N,N*-ditosyl compound.

Reduction of N^6,5'-O-*di*-p-*toluenesulfonyl-2',3'-O-isopropylidenetubercidin (XIII) with $LiAlH_4$.* A solution of XIII (300 mg) in tetrahydrofuran (20 ml) was refluxed with $LiAlH_4$ (300 mg) for 20 hr, and excess of the reagent was decomposed in the usual manner. The products were extracted with ethyl acetate and developed on a column of silicic acid. Two compounds were obtained. The less polar one assigned as 1,2-dihydro-N^6-*p*-toluenesulfonyl-5'-*O*-deoxy-2',3'-*O*-isopropylidenetubercidin (XV) was eluted from the column with a mixture of benzene and ethyl acetate (1: 1) and was obtained as a glass melting at 75—85°C; yield, 90 mg; $\lambda_{max}^{methanol}$ (ε) 308 (6900), 252 (14200) and 222 mμ (19800); NMR (60 MHz, $CDCl_3$): 1.30 ppm (d, 3H, $J_{4',5'}$=6 MHz).

Found: C, 56.81; H, 5.74; N, 12.29; S, 6.90%. Calcd for $C_{21}H_{26}N_4O_5S$: C, 56.48; H, 5.87; N, 12.25; S, 7.18%.

The other compound, assigned as 5'-deoxy-2',3'-*O*-isopropylidenetubercidin (XIV), was eluted from the column with a mixture of ethyl acetate and methanol (19: 1). The spectral data were identical with those of a sample obtained by alkaline hydrolysis of N^6-benzoyl-2',3'-*O*-isopropylidenetubercidin (XXVII).

Acetylation of 2',3'-O-Isopropylidenetubercidin (IX) in Methanol. Acetic anhydride was added (2 ml, each time) at 8 hr intervals (three times) at room temperature to a methanolic solution of IX (1 g/10 ml). After 24 hr the solution was poured on an ice-cooled aqueous solution of sodium bicarbonate. The product was extracted with ethyl acetate and separated from the starting material by silicic acid chromatography using a solvent system of ethyl acetate and methanol gradually increasing the content of the latter.

It was assigned as 5'-*O*-acetyl-2',3'-*O*-isopropylidenetubercidin (XVI), the UV spectrum being similar to that of tubercidin; $\lambda_{max}^{methanol}$ 270 mμ (ε 11000); M^+ 348 ($C_{16}H_{20}N_4O_5$); ν_{max}^{KBr} 1745 cm^{-1} (ester).

Found: C, 55.15; H, 5.93; N, 15.55%. Calcd for $C_{16}H_{20}N_4O_5$: C, 55.16; H, 5.93; N, 16.08%.

Reaction of 2',3'-O-Isopropylidenetubercidin (IX) with Dimethylformamide Dimethylacetal. Dimethylformamide dimethyl acetal (0.5 ml) was added at once to a solution of IX (200 mg) in dimethylformamide (5 ml). The solution was heated at 70°C for 60 hr and then left standing at room temperature for 14 hr. After the solvent was removed, the residue, which showed two distinct spots on tlc, was applied to column chromatography on silicic acid. The less polar compound, assigned as N^6-formyl-2',3'-*O*-isopropylidenetubercidin (XXVIII), was eluted from the column with ethyl acetate and obtained as a syrup; yield, 40 mg: Mass: M^+ 334.1292 (Calcd for $C_{15}H_{18}N_4O_5$ 334.1278), M^+ +CO 362.1196 (Calcd for $C_{16}H_{18}N_4O_6$ 362.1226).

To obtain an analytical sample, fractional precipitation from ethyl acetate and ligroin was effective.

Found: C, 53.54; H, 5.23; N, 15.92%. Calcd for $C_{15}H_{18}N_4O_5$: C, 53.88; H, 5.43; N, 16.76%.

The other compound, eluted with a mixture of ethyl acetate and methanol (9: 1), was found to be the starting material.

3,5'-Cyclonucleoside Methanesulfonate (XIX) of 2',3'-O-Isopropylidenetubercidin. Mesyl chloride (1.432 g, 13.2 mmol) was added dropwise to an ice-cooled and stirred solution of IX (1.224 g, 4 mmol) in pyridine (30 ml). After the solution was kept at 0°C overnight, it was poured on an ice-cooled aqueous solution of sodium bicarbonate. The product, 2',3'-*O*-isopropylidene-5'-*O*-methanesulfonyltubercidin (XVIII), was extracted with ice-cooled chloroform and the organic layer was heated under reflux for 1 hr. The product XIX was hardly soluble in solvents and could be easily separated from XVIII by extraction with water; yield, 1.2 g. To prepare an analytical sample, fractional precipitation from methanol and benzene was effective: mp 188°C; $\lambda_{max}^{methanol}$ (ε) 293 (11200), 275 (10000) and 214 mμ (22700).

Found: C, 45.97; H, 5.23; N, 14.24; S, 8.27%. Calcd for $C_{15}H_{20}N_4O_6S\cdot 1/2H_2O$: C, 45.79; H, 5.38; N, 14.24; S, 8.15%.

Reduction of the Cyclonucleoside XIX with Sodium Borohydride. $NaBH_4$ (800 mg) was added at once to an aqueous solution of XIX (800 mg/10 ml), and the solution was stirred at room temperature for 6 hr. Extraction with chloroform and evaporation of the solvent afforded 400 mg of the residue, which was then purified with silicic acid chromatography. A compound showing a distinct spot on tlc was obtained. It was

assigned as 3,5′-cyclonucleoside (XX) of N^6-methanesulfonyl-1,2-dihydro-2′,3′-*O*-isopropylidenetubercidin; syrup; yield, 35 mg; $\lambda_{max}^{methanol}$ (ε) 308 (7000), 240 (15600) and 222 mμ (18200); Mass: M$^+$ 368 ($C_{15}H_{20}N_4O_5S$), M$^+$ −2H 366, M$^+$ −CH_2NH 260; NMR (100 MHz, $CDCl_3$): 1.34, 1.52 (two isopropylidene methyls), 3.02 (s, 3H, CH_3SO_2N=), 3.29 (q, 1H, H_a-5′, J_{gem}=24 Hz, $J_{5'a,4'}$=3 Hz), 4.70, 4.96 (a pair of doublet, 2H, –NH–CH_2–N=, J_{gem}=6 Hz), 5.62 (s, 1H, H-1′), 6.36 and 6.44 ppm (a pair of doublet, 2H, –CH=CH–N=, $J_{7,8}$=4 Hz).

With increase of methanol content in the developing solvent, gummy materials which tailed on tlc were eluted, and an attempt to obtain another compound failed.

Reaction of the Cyclonucleoside X with Sodium Borohydride. $NaBH_4$ (10 mg) was added to an aqueous solution of X (10 mg/ml), and the solution was stirred at room temperature for 1 hr. The product, 3,5′-cyclonucleoside (XXI) of 1,2-dihydro-N^6-*p*-toluenesulfonyl-2′,3′-*O*-isopropylidenetubercidin, was extracted with ethyl acetate, and was fractionally precipitated with ethyl acetate and ligroin to give a syrup; yield, 3 mg; $\lambda_{max}^{methanol}$ (ε) 312 (5700), 245 (shoulder, 8400) and 220 mμ (17500); Mass: M$^+$ 444.1455 (Calcd for $C_{21}H_{24}N_4O_5S$ 444.1468), M$^+$−H−SO_2 379.1724 ($C_{21}H_{23}N_4O_3$ 379.1770), M$^+$−$C_7H_7SO_2$ 289.1289 ($C_{14}H_{17}N_4O_3$ 289.1301), M$^+$−$C_7H_7SO_2$−CH_2N 261.1126 ($C_{13}H_{15}N_3O_3$ 261.1113).

N^6,N^6-Dibenzoyl-2′,3′-O-isopropylidene-5′-O-methanesulfonyltubercidin (XXII). Mesyl chloride (1.37 g, 12 mmol) was added dropwise to a stirred and ice-cooled solution of IX (3.06 g, 10 mmol) in pyridine (10 ml), and the solution was kept at 0°C overnight. Benzoyl chloride (4.2 g, 30 mmol) was added, and after the solution was left overnight in a refrigerator it was poured on an ice-cooled aqueous solution of sodium bicarbonate. The products were extracted with chloroform and separated with column chromatography on silicic acid. The less polar product, eluted with a mixture of benzene and ethyl acetate (4: 1), was crystallized from ethyl acetate and ligroin, and was assigned as N^6,N^6,5′-*O*-tribenzoyl-2′,3′-*O*-isopropylidenetubercidin (XXIII); yield, 170 mg; mp 110—113°C; $\lambda_{max}^{methanol}$ (ε) 281 (11600), 273 (12000) and 226 mμ (43000); $[\alpha]_D^{25}$ −38.1° (*c* 17.0, chloroform).

Found: C, 67.37; H, 4.87; N, 8.99%. Calcd for $C_{35}N_{30}N_4O_7$: C, 67.95; H, 4.89; N, 9.06%.

The main product, N^6,N^6-dibenzoyl-2′,3′-*O*-isopropylidene-5′-*O*-methanesulfonyltubercidin (XXII), was eluted from the column with a mixture of benzene and ethyl acetate (1: 1). After being crystallized from ethyl acetate and ligroin, the yield was 3.38 g; mp 110—113°C; $\lambda_{max}^{methanol}$ (ε) 280 (shoulder, 11100), 240 (shoulder, 27200) and 222 mμ (33400); NMR (60 MHz, $CDCl_3$): 1.38, 1.63 (two isopropylidene methyls), 2.86 (s, 3H, $C\underline{H}_3SO_2$-) and 7.3—7.9 ppm (complex, 10H, $C_6\underline{H}_5CONCOC_6\underline{H}_5$); $[\alpha]_D^{25}$ −13.4° (*c* 1.61, chloroform).

Found: C, 58.66; H, 4.69; N, 9.33; S, 5.39%. Calcd for $C_{29}H_{28}N_4O_8S$: C, 58.77; H, 4.76; N, 9.46; S, 5.41%.

Reaction of N^6,N^6-Dibenzoyl-2′,3′-O-isopropylidene-5′-O-methanesulfonyltubercidin (XXII) with Sodium Iodide. A solution of XXII (1.284 g, 2 mmol) and sodium iodide (1.3 g, 8 mmol) in methyl ethyl ketone (20 ml) was refluxed for 30 min. After sodium mesylate which rapidly precipitated was removed by filtration, the products were distributed between an aqueous solution of sodium sulfite and chloroform. The organic layer was taken, washed with water and concentrated to dryness. The residue (1.18 g) was applied to column chromatography on silicic acid, developed with a mixture of benzene and ethyl acetate increasing ethyl acetate content gradually. The main product, N^6,N^6-dibenzoyl-5′-deoxy-5′-iodo-2′,3′-*O*-isopropylidenetubercidin (XXIV), was eluted first and was crystallized from ethyl acetate and ligroin; yield, 784 mg; mp 105—112°C; $\lambda_{max}^{methanol}$ (ε) 280 (12000) and 223 mμ (21000); $[\alpha]_D^{23}$ −51.2° (*c* 0.91, chloroform).

Found: C, 53.90; H, 3.99; N, 8.83; I, 20.42%. Calcd for $C_{28}H_{25}N_4O_5I$: C, 53.85; H, 4.04; N, 8.97; I, 20.32%.

N^6-Benzoyl-5′-deoxy-5′-iodo-2′,3′-*O*-isopropylidenetubercidin (XXV) was eluted next, and was purified with fractional precipitation from ethyl acetate and ligroin; syrup; yield, 77 mg; $\lambda_{max}^{methanol}$ (ε) 299 (9800), 235 (shoulder, 22000) and 223 mμ (27000); M$^+$ 520.0583 (Calcd for $C_{21}H_{21}N_4O_4I$ 520.0607).

The starting material, which moved slightly more slowly than XXV, was also isolated; yield, 48 mg. It was also found by other experiments that attempts to complete the reaction by prolonged reaction time resulted in the decrease of the yield of XXIV.

The most polar substance, eluted from the column with a mixture of benzene and ethyl acetate (1: 1) was obtained as crystals; yield, 100 mg; mp 191—193°C. The structure is still undetermined.

N^6,N^6-Dibenzoyl-5′-deoxy-2′,3′-O-isopropylidenetubercidin (XXVI) and N^6-Benzoyl-5′-deoxy-2′,3′-O-isopropylidenetubercidin (XXVII). The iodo compound XXIV (784 mg) was catalytically hydrogenated at room temperature for 3 hr in 95% ethanol (20 ml) containing sodium acetate (1 g) in the presence of 10% Pd-C (200 mg). Ethanol was removed by evaporation and the residue was extracted with chloroform. Tlc showed the presence of two compounds which were separated with column chromatography on silicic acid developed with a mixture of benzene and ethyl acetate (2: 1). The less polar compound, assigned as N^6,N^6-dibenzoyl-5′-deoxy-2′,3′-*O*-isopropylidenetubercidin (XXVI), was crystallized from ethyl acetate and ligroin; yield, 58 mg; mp 192—194.5°C; $\lambda_{max}^{methanol}$ (ε) 280 (shoulder, 11500) and 223 mμ (33500); $[\alpha]_D^{23}$ −60.8° (*c* 0.45, chloroform); M$^+$ 498.1882 ($C_{28}H_{26}N_4O_5$ 498.1903); NMR (60 MHz, $CDCl_3$): 1.37, 1.62 (two isopropylidene methyls) and 1.39 ppm (d, 3H, $C\underline{H}_3$-ÇH–, $J_{4',5'}$=7 Hz).

Found: C, 66.93; H, 5.05; N, 11.16%. Calcd for $C_{28}H_{26}N_4O_5$: C, 67.46; H, 5.26; N, 11.24%.

The main product, N^6-benzoyl-5′-deoxy-2′,3′-*O*-isopropylidenetubercidin (XXVII), was eluted later and crystallized from ethyl acetate and ligroin; yield, 430 mg; mp 128.5—129.0°C; $\lambda_{max}^{methanol}$ (ε) 300 (9400) and 224 mμ (26400); $[\alpha]_D^{23}$ −43.2° (*c* 0.84, chloroform); M$^+$ 394.1675 (Calcd for $C_{21}H_{22}N_4O_4$ 394.1641); NMR (60 MHz, $CDCl_3$): 1.37, 1.63 (two isopropylidene methyls) and 1.38 ppm (d, 3H, $C\underline{H}_3$–ÇH–, $J_{4',5'}$=6 Hz).

Found: C, 63.98; H, 5.48; N, 14.88%. Calcd for $C_{21}H_{22}N_4O_4$: C, 63.94; H, 5.62; N, 14.21%.

5′-Deoxy-2′,3′-O-isopropylidenetubercidin (XIV). A solution of XXVII (100 mg) in 50% ethanol (10 ml) containing 0.05N NaOH was refluxed. Tlc monitoring showed that the reaction was complete after 1 hr, and the product was homogeneous. Extraction with chloroform and concentration to dryness afforded 70 mg of syrup: $\lambda_{max}^{methanol}$ 268 mμ (ε 11900); M$^+$ 290.1422 (Calcd for $C_{14}H_{18}N_4O_3$ 290.1379).

5′-Deoxytubercidin (IV). A solution of XIV (150 mg) in 80% acetic acid (20 ml) was refluxed for 5 hr and concentrated to dryness. The residue, which was homogeneous on tlc, was crystallized from ethanol and benzene, and assigned as 5′-deoxytubercidin (IV) containing one mole of acetic acid; yield, 110 mg; mp 203—207°C; $\lambda_{max}^{methanol}$ 270 mμ (ε 12700); NMR (100 MHz, DMSO-*d*): 1.28 (d, 3H, $C\underline{H}_3$–ÇH–, $J_{4',5'}$=6 Hz), 1.92 (s, 3H, $C\underline{H}_3COOH$), 6.03 (s, H-1′, $J_{1',2'}$=5 Hz), 6.63, 7.27 (a pair of doublet, 2H, –C$\underline{H}$=C$\underline{H}$–N=, $J_{7,8}$=3 Hz) and 8.04 ppm (s, 1H, –N=C$\underline{H}$–N=).

Found: C, 50.03; H, 5.70; N, 18.19%. Calcd for $C_{13}H_{18}$-

N_4O_5: C, 50.31; H, 5.85; N, 18.06%. $[\alpha]_D^{23}$ −70.3° (*c* 0.48, DMSO).

Acetic acid was lost on heating at 100°C for 4 hr *in vacuo*. M^+ 250.1078 ($C_{11}H_{14}N_4O_3$ 250.1066).

Found: C, 52.28; H, 5.54; N, 22.29%. Calcd for $C_{11}H_{14}N_4O_3$: C, 52.79; H, 5.64; N, 22.39%.

The authors express their hearty thanks to Kaken Kagaku Co. Ltd. for the supply of tubercidin.

Structural Effects on the Properties of Nonionic Surfactants. II. Acetal Type Homogeneous Nonionics Having Polyoxyethylene Chains Terminated with Methoxyl Group[1]

Hideo TAKAHASHI and Tsunehiko KUWAMURA

Department of Synthetic Chemistry, Faculty of Engineering, Gunma University, Tenjincho, Kiryu

(Received July 8, 1972)

A series of homogeneous acetal nonionics (AGM types) with the general formula $RCH[O(C_2H_4O)_mCH_3]_2$ were prepared from higher alkanals (C_8–C_{14}) and several pure polyoxyethylene (POE) glycol monomethylethers (m: 3—6), and purified by repeated distillation *in vacuo*. Cloud point, critical micelle concentration (CMC) and molecular area on adsorbed film were determined for AGM types. The results were compared with data on homogeneous acetals (AG types) having terminal hydroxyl in POE chains. The result confirms the suggestion that two POE chains in AG strongly interact with each other owing to intramolecular hydrogen-bonding and intertwisting. AGM are extremely low foaming nonionics although their ability to lower surface tension is comparable to that of the usual nonionics.

The object of this study is to clarify the effect of multi-chain hydrophile in polyether type nonionics on surfactant properties. It is well-known that molecular area (A) of polyether type nonionics is determined by the chain length of POE. Van Voorst Vader[2] theoretically interpreted the fact that $A/m^{1/2}$, where m is a unit number of POE chain, is constant, on the basis of a random coil configuration of POE chain. However, A of AG types with the general formula $RCH[O(C_2H_4O)_mH]_2$ is only slightly greater than that of simple type nonionics $RCH_2O(C_2H_4O)_mH$ (S types).[3] Thus, we have assumed that two POE chains are closely situated by acetal linkage and by mutual interaction owing to hydrogen-bonding of terminal hydroxyl groups, holding an intertwisted configuration rather than random coil. We have also suggested that the configurational characteristics of AG types should be related to the fact that their cloud point is unexpectedly low and CMC decreases with increasing m.

We measured cloud point, surface tension and foaming power for a series of AGM having terminal methoxyl in place of hydroxyl in POE chains in order to confirm the interaction between two geminal POE chains. Discussion is given on surface film state and the configuration of acetal type nonionics in aqueous solution.

Experimental

Materials. Straight alkanals purified as described previously were used.[3] POE monomethylethers were obtained by the fractional distillation of polyaddition products of ethylene oxide to methyl cellosolve. They were determined to be 99% pure by glc on Carbowax 20 W. Unit number m was evaluated from integrated NMR spectra, where signals of terminal methyl and methylene protons of POE chains appeared at 3.30 and 3.55 ppm, respectively.

Preparation of AGM Acetals. In a reaction flask, were placed 0.75 mol of POE monomethylether, a catalytic amount of concentrated hydrochloric acid and 0.15 mol of alkanal which were heated at 60°C for 4 hr. The reaction mixture was then treated in the same way as described in the preparation of AG[3] and finally distilled under reduced pressure in a stream of nitrogen to give a colorless AGM acetal. Purity and structure of the products were confirmed by elementary analysis, thin layer chromatography, IR and NMR spectra.

Measurements. Cloud point was measured on a 1.0% aqueous solution. Equilibrium surface tension γ at 20 ± 1°C and foaming power at 25 ± 1°C were measured by the methods described previously.[3] In addition to the surface tension method, iodine solubilization method[4] was used for the determination of CMC. In the latter the minimum transmittance at 390 mμ (T_{390}) referring to iodine-surfactant micelle complex was measured with a Hitachi spectrophotometer ES-20 and plotted against concentration.

Results and Discussion

Preparation of pure acetal nonionics was insured by use of pure starting materials and careful final purification. Physical constants, properties and analytical data to assess the purity of POE monomethylethers and AGM products are shown in Tables 1 and 2.

Table 1. Properties and hydroxyl content of polyoxyethylene glycol monomethylethers $CH_3O(C_2H_4O)_mH$

m	Bp, °C/mmHg	n_D^{25}	OH%	
			Found	Calcd
3	86— 89/1	1.4355	10.7	10.4
4	123—125/1	1.4439	8.3	8.2
5	145—147/1	1.4489	6.5	6.7
6	160—167/1	1.4513	5.6	5.7

The IR spectra of AGM showed no carbonyl and hydroxyl absorption but a strong absorption at 1000—1100 cm^{-1}. In the NMR spectra (in CCl_4), five signals at δ=0.88, 1.27, 3.30, 3.55, and 4.50 ppm due to the protons of methyl, methylene in the alkyl chain, methoxyl, methylene in POE chains and methine in acetal linkage respectively, were observed with reasonable intensity (Fig. 1). Plotting of refractive index of AGM against m gave a smooth curve suggesting no contamination with impurity (Fig. 2). In all cases of preparation, purity rather than yield was emphasized. The yields given in Table 2, however, represent practical values as compared with those in the conventional method which consists of several steps to build up a homogeneous nonionics containing such a large number of m.

Cloud point was plotted against m giving characteristic smooth curve (Fig. 2). In order to clarify the structural effect of hydrophile on hydration, cloud point is represented as a function of Davies's HLB value in Fig. 3. If the "group numbers" proposed by Davies[5]

have a universality for various types of nonionics, the curve of AGM would be superimposable on those of S and AG types.[3] However, they are situated separately in the following order: S, AGM, and AG from left to right in Fig. 3. The result suggests a discount of Davies "group number" for acetal type nonionics. Such a hindrance to hydration for AG could be discussed on the basis of the following three structural factors. (1) The interaction between two POE chains

in a molecule due to hydrogen-bonding of terminal hydroxyl groups. (2) Very close situation of two POE chains by acetal linkage. (3) The presence of two oxyethylene units adjacent to the hydrophobe. The hindrance related to (2) and (3) can be observed in some multi-chain type nonionics derived from α,α'-glyceryl diethers[7] and alkyl ethers of pentaerythritol.[8] On the basis of (1), the fact that the replacement of two terminal hydroxyl with methoxyl causes the shift of the cloud point-HLB curve to the left side can be explained (Fig. 3), but the curve for AGM cannot be superimposed on that for S type. We see that, in the region of cloud point 50—60°C, 40—60% of the hindrance for AG is due to (1) and the rest to (2) and (3). In the region of high cloud point, however, the interaction in (1) may be significantly released and the cloud point markedly rises up by regaining of hydration capacity, so that the curve for AG is somewhat concave in contrast to the typical convex curves for AGM and S types.

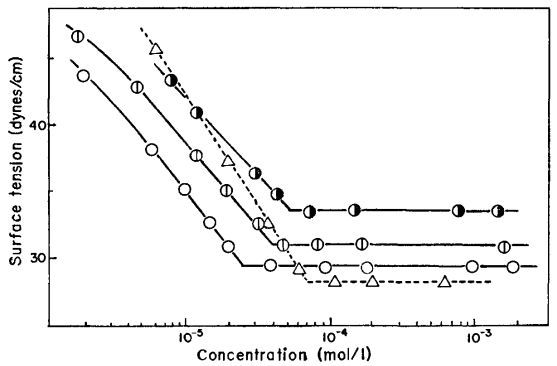

Fig. 5. Plots of γ *vs.* concentration. ○; AGM-14(6), ◐; AGM-14(8), ◑; AGM-14(10), △; AG-14(6).

On the measurement of aqueous surface tension, considerably long periods of ageing (2—4 hr) were observed for AGM as well as AG. Plots of the obtained γ *vs.* logarithm of the concentration for AGM are shown in Figs. 4 and 5. From the slope of the curves, surface excess Γ and molecular area A at CMC were determined by applying the simple form of Gibbs' adsorption equation. They are listed together with the related data for AG and S in Table 3.

The magnitude of A apparently increases in the order S<AG<AGM. However, A of AGM does not yet attain twice as large as that of the corresponding S[9,10] (*e.g.*, it is appropriate to compare among AGM-12(10), AG-12(10), and S-12(5)). Plots of $A/m^{1/2}$ for S and of $A/(2m^{1/2})$ for AG and AGM against m gave three straight lines which increase the negative slope in the order S<AGM<AG (Fig. 6). This indicates that A of S expectedly increases in proportion to $m^{1/2}$ and that the increment of A per one POE chain for AGM with increasing m is smaller than that for S and greater than that for AG.

The results could be discussed on the basis of structural factors as regards the hindrance of hydration for acetal nonionics. For AG containing factors (1) and (2), the interaction between two POE chains in a molecule is so pronounced that POE chains in surface film might take a significantly stretched and intertwisted configuration. Although the interaction is considerably released for AGM lacking factor (1), the POE chains still do not take such free random coils as those of S but undergo a sort of configurational restriction. All acetal nonionics we studied contain the shorter POE chains ($m<6$), for which van Voorst Vader's theory might virtually not be applicable. Thus, the characteristic film state of acetal nonionics might be due to shortness of POE chains attached. As for homogeneous S types ranging in m 1—10, however, the data obtained by Lange[11] with the use of film balance method gave no evidence for configurational transformation in surface film with variation in m.

a) Ethylene oxide condensate of *n*-dodecanol prepared by the base-catalyzed method. The average number of ethylene oxide added is shown in parentheses.

Interesting information was obtained from plots of *A vs. m* for acetal nonionics. In Fig. 7, is shown the extrapolation of the linear *A vs. m* plots for AG and AGM varying in hydrophobe chain length. All the extrapolations converge at $m=0$ and give a limiting area, 45—47 Å², which seems to be equivalent to molecular area of hydrated higher alkanal, $RCH(OH)_2$, in a closely packed film.

The CMC values determined by two methods are listed in Table 3. We found that[3] CMC of AG decreases with an increase in m contrary to m dependence of CMC for the conventional nonionics[12] and suggested that this phenomenon is closely related to a configurational feature of hydrophile in AG. Plots of logarithm of CMC *vs.* *m* gave a straight line with positive slope for AGM in contrast to negative one for AG (Fig. 8). We also see that CMC of acetal nonionics increases by the replacement of terminal hydroxyl groups with more hydrophobic methoxyl groups.

It is concluded that the relatively low CMC and the abnormal trend on micellization of AG is caused by factor (1), which significantly affects hydration and configuration of POE chains.

The foaming property of AGM is markedly low as compared with those of S and AG (Table 4). It is likely that the greater cross section of the hydrophile and the hydrophobic terminal groups in AGM are unfavorable to closely packed alignment as regards the strength of foam film.

The authors wish to thank Miss Y. Umezu and the late Mr. M. Gotoh for their assistance in the experiment, and Givaudan Co. Ltd. for the supply of alkanal. Acknowledgement is made to the Ministry of Education for financial aid.

Topochemical Studies. II. The Crystal and Molecular Structure of the Second Polymorph of Chalcone, Ph-CH=CH-CO-Ph

Kenji OHKURA,* Setsuo KASHINO, and Masao HAISA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received June 13, 1972)

Crystals of chalcone are polymorphic and exist in many forms with different melting points.[1] Photochemistry of chalcone in solid state is of interest from a topochemical point of view because polymorphic modifications of this compound show significant differences in chemical behavior against ultraviolet light. Crystal structure of form I (mp 59°C) has been determined by Rabinovich,[2] the molecules are arranged in alternating layers related by the two-fold screw-axis along [001] and the shortest contact between C=C group is 5.2 Å so that crystals of this modification are light-stable. We have obtained crystals of form II and determined the crystal and molecular structure of this modification.

Experimental

The material was prepared by the condensation of benzaldehyde and acetophenone in alcoholic sodium hydroxide.[3] Crystals obtained by slow evaporation from ether solution were orthorhombic parallelepipeds elongated along the *b*-axis.

Crystal data: $C_{15}H_{12}O$; $M=208.2$; mp=56°C, orthorhombic, $a=10.90(2)$, $b=11.90(1)$, $c=17.93(1)$ Å, $V=2324.6$ Å^3, $Dm=1.179$, $Dc=1.178$ g·cm^{-3}, $Z=8$. Absorption coefficient for Cu $K\alpha$; $\mu=6.88$ cm^{-1}. $F(000)=880$.

Systematically absent spectra: $h0l$ when l odd, $0kl$ when k odd, $hk0$ when $h+k$ odd. Space group *Pbcn*.

Reflections were recorded with Cu$K\alpha$ radiation for the layers $h0l$ to $h8l$ and $0kl$ to $1kl$ by means of the equi-inclination Weissenberg technique. A total of 726 independent non-zero reflections were measured visually. Corrections for the Lorentz and polarization factors and for the spot-shape were applied.

Structure Determination and Refinement

Approximate positional parameters y and z of all the non-hydrogen atoms were obtained from a Harker section for the two-fold screw-axis along the *a*-axis. Approximate positional parameters x were estimated from a three-dimensional sharpened Patterson map.

Refinement was carried out by means of the block-diagonal least-squares method,[4] with anisotropic temperature factor for all the non-hydrogen atoms. The R index became 0.143 for all the observed reflections. A difference Fourier synthesis at this stage revealed all the hydrogen atoms. Further refinement including the hydrogen atoms with isotropic temperature factors reduced the R index to 0.110 for 726 observed reflections. The following weight system was adopted:

TABLE 1. ATOMIC PARAMETERS AND THEIR E.S.D.'S ($\times 10^4$) FOR NON-HYDROGEN ATOMS

Anisotropic thermal parameters are expressed as $\exp(-B_{11}h^2-B_{22}k^2-B_{33}l^2-B_{12}hk-B_{13}hl-B_{23}kl)$.

$\sqrt{w} = 14.0/F_o$ when $F_o > 14.0$,
$\sqrt{w} = 1.0$ when $14.0 \geq F_o \geq 2.0$
and
$\sqrt{w} = 0.0$ when $2.0 > F_o$.

The final atomic parameters for non-hydrogen atoms and their estimated standard deviations are given in Table 1 and those for hydrogen atoms in Table 2.

The atomic scattering factors used were those of Hanson, Herman, Lea, and Skillman.[5] Computations were performed on the HITAC 5020E computer of the Computer Center of the University of Tokyo.

Results and Discussion

The average bond length of the C–C bonds in the two benzene rings is 1.386 Å. The bond lengths of the C–C single bonds between trigonal carbon atoms are 1.486, 1.511, and 1.486 Å for the C(6)–C(7), C(8)–C(9), and C(9)–C(10) bonds, respectively. They are slightly larger than the expected value 1.466 Å[6] for sp^2-sp^2 single bond. The C=C and C=O bond lengths are 1.325 and 1.208 Å respectively, which are comparable to the corresponding values, 1.319 and 1.206 Å, in form I of chalcone.[2] The average length of the C–H bonds is 1.07 Å.

The C(6)–C(7)–C(8) angle, 126.5°, is significantly greater than 120°. Similar results have been reported for several disubstituted ethylenes:[7] 127.6° for form I of chalcone[2] and 127.2° for *p*-methoxychalcone.[8] The C(1)–C(6)–C(5) angle, 120.1°, seems to be normal, although it has been pointed out[7] that a decrease in the corresponding angle is observed in the benzene ring with the -CH=CHR substituent: 118.2° in the form I of chalcone,[2] 117° in *p*-methoxychalcone[8] and 117.7° in 2,5-distyrylpyrazine.[7] In Table 3 the pertinent conformational details of form II are compared with those of form I[2] of chalcone.

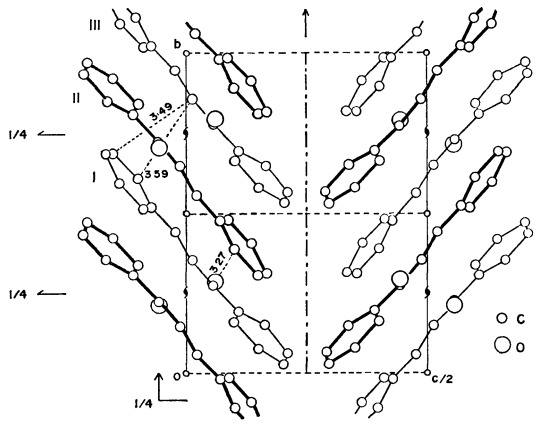

Fig. 1. Projection of the crystal structure along the *a*-axis. Short intermolecular contacts are shown by broken lines. Key for molecules I: x, y, z II: $1-x, 1-y, 1-z$ III: $1/2-x, 1/2+y, z$.

The projection of the crystal structure along the *a*-axis is shown in Fig. 1 together with short intermolecular contacts. The long axis of the molecule declines by about 50° from the *a*-*c* plane and is nearly parallel to [021]. The pairs of molecules related by the *b*-glide plane are stacked along the *b*-axis. This mode of packing allows loose intermolecular contacts around the atoms C(6), C(9), and C(10); for which the C–H distances are 3.4, 3.4, and 3.6 Å, respectively. This is consistent with the fact that the density of the crystals of form II is smaller than that of form I.

The distances between neighboring ethylenic double-bonds are greater than 4.76 Å; thus the crystals of the second polymorph of chalcone might be light-stable.

Table 3. Comparison of the conformational details of the two forms of chalcone

	Form II[a]	Form I[b]
Maximum deviations of the non-hydrogen atoms	+0.375 Å (C(12))	+0.25 Å (C(8))
from the mean molecular plane	−0.354 Å (O(16))	−0.20 Å (C(3))
Dihedral angle between two benzene rings	13.7°	11.1°
Rotation of the benzene ring		
C(1)—C(6) about C(6)—C(7) bond	0.6°	9.3°
C(10)—C(15) about C(9)—C(10) bond	21.6°	4.1°
Twist about C(8)—C(9) bond	9.7°	16.9°

The Charge-transfer Complexes of Metal Chelates of 8-Quinolinol with 7,7,8,8-Tetracyanoquinodimethane

Shigeo KOIZUMI and Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received June 15, 1972)

Although there have been a large number of charge-transfer complexes made of electron donors and acceptors,[1] there are few donor molecules that are known to be composed of organic metal chelates. In 1962 Melby *et al.* prepared an unusual (1 : 1) complex between the copper chelate of 8-quinolinol, Cu(Ox)$_2$, and 7,7,8,8-tetracyanoquinodimethane, TCNQ.[2] Williams and Wallwork investigated the crystal and molecular structure of this complex in order to see whether or not the predominant factor influencing the orientation and packing of the molecules was the charge-transfer interaction between the donor of Cu(Ox)$_2$ and the acceptor of TCNQ.[3]

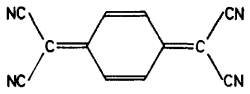

Fig. 1. 7,7,8,8-Tetracyanoquinodimethane (TCNQ).

The present paper will describe the (1 : 1) complexes of the copper and palladium metal chelates of 8-quinolinol with TCNQ.[4] The measurements of the diffuse reflection spectra of these solid complexes were attempted in order to ascertain the charge-transfer transitions in the solid-state spectra. We will show that these complexes are essentially charge-transfer complexes, in which the metal chelates of 8-quinolinol act as electron donors, and TCNQ, as an acceptor. On the other hand, we reported earlier on the charge-transfer complexes of Cu(Ox)$_2$ and Pd(Ox)$_2$ with various halogen-substituted *p*-benzoquinones.[5,6] Therefore, the complexes of Cu(Ox)$_2$–TCNQ and Pd(Ox)$_2$–TCNQ are interesting in comparison with these charge-transfer complexes.

Experimental

The crystals of Cu(Ox)$_2$–TCNQ were prepared according to the method of Melby *et al.*[2] They were deposited when boiling solutions of the components in chloroform were mixed and allowed to cool very slowly. The Pd(Ox)$_2$–TCNQ complex was prepared in a way similar to that used for Cu(Ox)$_2$–TCNQ.

These complexes were pulverized and diluted with potassium bromide. The diffuse reflection spectra of the solid complexes were recorded as the difference in the reflectance between the mixture and pure potassium bromide by means of a Beckman DK-2A spectroreflectometer. The solid-state spectra were then obtained by plotting the diffuse reflection spectra using the Kubelka-Munk equation, $f(R)=(1-R)^2/2R$, in which R is the reflectance.

The Cu(Ox)$_2$-TCNQ Complex

According to Williams and Wallwork,[3] this complex crystallizes as black triclinic crystals (space group $P\bar{1}$), with one molecule of the complex in the unit cell. The component molecules are stacked in a plane-to-plane manner, so that the double bond adjacent to one dicyanomethylene group of TCNQ lies over the 5 : 8 positions of one donor molecule, while the other double bond is similarly oriented with respect to the benzenoid ring of the centrosymmetrically-related donor molecule. The perpendicular separation of the molecules, in the region of overlap, is approximately 3.2 Å. These crystallographic features, although there appears to be a specific interaction between the dicyanomethylene group of TCNQ and the benzenoid group of the oxinate, are common in structures of the π-π charge-transfer type.

The solid-state spectrum of this complex (Fig. 2, Curve (a)) shows intense band peaks at 12.1 kK and 23.9 kK and a shoulder around 29.6 kK. The high-energy band at 23.9 kK and the shoulder around 29.6 kK arise mostly from the absorptions due to the component molecules, while the broad band at 12.1 kK appears in the low-energy region, where neither of the component molecules absorb. This low-energy band at 12.1 kK seems to be attributable to the charge-transfer transition from the donor of Cu(Ox)$_2$ to the acceptor of TCNQ for the following reasons. In the Cu(Ox)$_2$–*p*-chloranil charge-transfer complex, the corresponding band is located at 15.9 kK.[6,7] The electron

affinities of TCNQ and *p*-chloranil have been reported to be $E_A(\text{TCNQ})=1.7$ eV and $E_A(p\text{-chloranil})=1.3_7$ eV respectively.[8] If one assigns the band at 12.1 kK of the $Cu(Ox)_2$–TCNQ complex to the charge-transfer transition, the difference in the charge-transfer energies between these two complexes, $h\nu_{CT}(Cu(Ox)_2\text{–}p\text{-chloranil})-h\nu_{CT}(Cu(Ox)_2\text{–TCNQ})$, should be caused mostly by the difference in the electron affinities between TCNQ and *p*-chloranil. In accordance with this view, the observed value of $h\nu_{CT}(Cu(Ox)_2\text{–}p\text{-chloranil})-h\nu_{CT}(Cu(Ox)_2\text{–TCNQ})=0.47$ eV was found to agree almost exactly with $E_A(\text{TCNQ})-E_A(p\text{-chloranil})=0.3_3$ eV.

The $Pd(Ox)_2$-TCNQ Complex

The assignment of the band at 12.1 kK of the $Cu(Ox)_2$–TCNQ complex to the charge-transfer transition was confirmed by replacing the donor of $Cu(Ox)_2$ by $Pd(Ox)_2$. The ionization potential of $Pd(Ox)_2$ has been reported to be lower than that of $Cu(Ox)_2$ by 0.16 eV.[6,7] For the common acceptor of TCNQ, the difference in the ionization potentials of the donor molecules mainly causes the variation in the charge-transfer energies. Therefore, one can expect that the charge-transfer energy of $Pd(Ox)_2$–TCNQ will be lower than that of $Cu(Ox)_2$–TCNQ by that amount.

Figure 2, Curve (b), shows the observed solid-state spectrum of the $Pd(Ox)_2$–TCNQ complex. It has strong absorption band peaks at 11.6 kK and 22.8 kK and a slight shoulder around 32.0 kK. The high-energy band at 22.8 kK and the shoulder around 32.0 kK are attributable to the absorptions due to the component molecules. The energy value of the low-energy band at 11.6 kK of $Pd(Ox)_2$–TCNQ was found to be lower than that of $Cu(Ox)_2$–TCNQ by 0.06 eV. Therefore, although this energy difference is not sufficient, as is to be expected from the ionization potential difference between $Cu(Ox)_2$ and $Pd(Ox)_2$, one can also assign the low-energy band at 11.6 kK of the $Pd(Ox)_2$–TCNQ complex to the charge-transfer transition from the donor of $Pd(Ox)_2$ to the acceptor of TCNQ. On the other hand, the charge-transfer band of the $Pd(Ox)_2$–*p*-chloranil complex has been reported to be located at 14.8 kK.[6,7] Thus, the difference in the charge-transfer energies, $h\nu_{CT}(Pd(Ox)_2\text{–}p\text{-chloranil})-h\nu_{CT}(Pd(Ox)_2\text{–TCNQ})=0.40$ eV, was again found to agree well with $E_A(\text{TCNQ})-E_A(p\text{-chloranil})=0.3_3$ eV.

Discussion

The crystallographic features and also the marked appearance of the strong charge-transfer absorptions clearly show that the $Cu(Ox)_2$–TCNQ and $Pd(Ox)_2$–TCNQ complexes behave as usual π-π charge-transfer-type complexes. Bailey *et al.* have reported the virtual ionization potentials of the donors of $Cu(Ox)_2$ and $Pd(Ox)_2$ to be 7.3 eV and 7.1 eV respectively.[7] Their electron-donor strengths are of the order of pyrene or perylene in the series of aromatic hydrocarbons.[9] It is interesting to note that the electron-donor strengths of these metal chelates of 8-quinolinol are much influenced by the species of the central metal ions.

Ionization of Aromatic Molecules *via* σ-Complex with Aluminum Chloride in Solid Phase

Hiroyasu SATO and Yoshifumi AOYAMA
College of Liberal Arts, Kagoshima University, Kagoshima
(Received July 19, 1972)

While Perkampus and Kranz[1] observed the formation of σ-complex of aromatic molecules on an evaporated film of aluminum chloride, Terenin *et al.*[2] observed that of aromatic cation radical on it. The condition of formation of these two species does not seem to have been clarified. We would like to show that the formation of tetracene cation radical takes place by way of a σ-copmlex. For anthracene, an additional intermediate was found between the σ-complex and the cation radical.

Procedure. Aluminum chloride was prepared from aluminum and silver chloride by the procedure described in an earlier report.[3] The cell assembly used in this study was similar to that shown in it. A break-off seal containing aluminum chloride was fused to the cell assembly. After evacuation (10^{-3} mmHg), the sublimed film of aromatic molecule was prepared on the inside wall of the cell. The break-off seal was then broken and aluminum chloride vapor was brought into contact with the sublimed film of aromatics.

Primary Step: σ-Complex Formation. The absorption spectra of colored products given by the contact of aromatics and aluminum chloride vapor were essentially in accordance with those of Perkampus and Kranz,[1] and can be interpreted in terms of σ-complex formation, as discussed by them (π-v complex in their notation).

– – – anthracene in excess (before heating)
– – – – anthracene in excess (after heating)
(b): tetracene–aluminum chloride
—— before heating, – – – – after heating.

Table 1. Absorption spectra of tetracene- and anthracene–aluminum chloride system
(Positions of Bands, nm)

Aromatic Molecule	Before Heating	After Heating
Tetracene	354	355, 385
	450	395, 670
	650	760, 850
Anthracene		
Aluminum chloride in excess	420	420
Anthracene in excess	420	730
	665	

Cation Radical Formation on Heating. The colored σ-complex was heated over a free flame. In the cases of anthracene and tetracene, the spectra changed into those which have the characteristics of cation radical. These spectra are shown in Fig. 1. The positions of bands are shown in Table 1. The spectra of cation radicals of these molecules are well-established.[4,5] Anthracene cation has absorption maximum at 735 nm, and tetracene cation at 348, 397, 667, 752, 833 nm.[5] The spectra of the heated products are quite similar to those of the cation radical. The samples gave ESR signals which were structureless and broad. The values of ΔH_{msl} were 7.2 G for anthracene, 5.6 G for tetracene. These findings seem to support the formation of aromatic cation radical in these systems.

In producing tetracene cation radical, no excess aromatics was necessary (in contrast with anthracene, *vide infra*). An approximate isosbestic point was obtained in its reaction from σ-complex into cation. Thus, this cation seems to arise from the σ-complex. In the case of anthracene the reaction was more complex.

Cation Radical Formation in Anthracene. The yellow σ-complex of anthracene did not change into its cation radical on heating, without the presence of an excess of anthracene. When the σ-complex was brought into contact with an excess of anthracene (supplied from another break-off seal), the yellow color changed into deep green. No heating was necessary, but a little warming accelerated the reaction. The deep green material (hereafter called species 665) showed an absorption maximum at 665 nm, and when it was heated over a free flame the color changed to

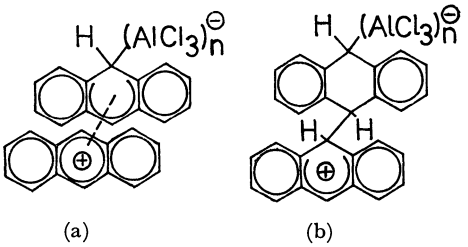
dark brown. This dark brown material has an absorption maximum at 730 nm, and gave the ESR signal mentioned above. 9,10-Dimethylanthracene and 9,10-diphenylanthracene gave corresponding σ-complexes (λ_{max} at 425 and 430 nm, respectively). However, addition of excess aromatics did not give any species corresponding to species 665, and no cation radical was given on heating. When an excess of 9,10-disubstituted anthracene was added to anthracene σ-complex (with $AlCl_3$ in excess), neither species 665 nor cation formation was observed. When an excess of anthracene was added to 9,10-disubstituted anthracene σ-complex (with $AlCl_3$ in excess), species 665 was formed and anthracene cation was obtained on heating. These findings seem to show that cation radical is formed only *via* species 665, the latter not being obtained for 9,10-disubstituted anthracene. Thus, cation radical is not derived directly from a σ-complex, but from an additional intermediate, species 665. The presence of this species is reported. Actually it almost always appears when ionization of anthracene is found on solid Lewis acid.[2,6] However, its true nature has not been assigned, neither has its relation to ionization been noted. Hall[6] once assigned it tentatively to the dication but without any reasoning at all. On the other hand, Aalversberg *et al.*[4] remarked that anthracene is peculiar in the point that it is more liable than expected from its ionization potential to form cation radical on contact with Lewis acid in solution. The presence of species 665 as an ionizing intermediate may clarify these points.



(a) (b)

Fig. 2. Expected structures for the "665 species."
(a): a π-complex, (b): a σ-complex.

In order to determine the structure of species 665, an attempt was made to measure its NMR spectrum in solution. However, the attempt failed, because it decomposed on contact with the solvent used (dry chloroform, dimethyl sulfoxide, benzene, *etc.*). Thus we cannot give any definite molecular structure to this species, but we might say that it is either a π-complex or a σ-complex as shown in Fig. 2, considering that anthracene can dimerize at 9,10-position and that steric hindrance of 9,10-substituents prevents its formation.

Effect of Substituents on the Keto-Enol Equilibrium of Alkyl-substituted β-Diketones

Hideo KOSHIMURA, Jun SAITO,* and Teiji OKUBO**

Tokyo Metropolitan Industrial Technology Center, Kita-ku, Tokyo
**Mitsui Toatsu Chemicals, Inc., Totsuka-ku, Yokohama*
***National Chemical Laboratory for Industry, Shibuya-ku, Tokyo*

(Received January 26, 1972)

β-Diketones are commonly used as extractants in the solvent extraction of many metals. In the elucidation of the mechanism of the extraction process, it is necessary to know the nature of the extractant. It is well known that β-diketones possess keto-enol tautomerism. Burdett and Rogers[1] have determined the percentages of enol tautomers for acetylacetone and several β-diketones containing the trifluoromethyl group.

In a previous paper of this series,[2] the separation of various metals with the alkyl-substituted β-diketones was reported. In the present investigation, twenty-six alkyl-substituted β-diketones were used in order to establish the effects of substituents on the keto-enol equilibria.

Experimental

Materials. The alkyl-substituted β-diketones used in the present study were synthesized by the method of Hauser and Adams.[3] The compositions were confirmed by elemental analysis. Acetylacetone, trifluoroacetylacetone, and hexafluoroacetylacetone were purchased from the Dojindo Co. and were redistilled before use.

Nuclear Magnetic Resonance Measurements. All the spectra of NMR were recorded at 60MHz with a Japan Electron Optics Model JNM C-60 spectrometer. During the measurements, the temperature was held at 24°C. The chemical shifts of the signal were measured with respect to the tetramethylsilane used as the internal standard, the peak positions are given in parts per million downfield from the internal TMS (δ). The accuracy of the measurement was within

about ±0.03 ppm. Equilibrium constants were obtained by the integration of the keto and enol resonance peaks. At least six integrations were performed; the percentage of the enol tautomer was accurate to within ±2%. The spectra of these β-diketones were measured in the pure liquid state.

Results and Discussion

The identification of the resonance signal for the proton of the α-position in the enol and keto forms in β-diketone from the chemical shift has been possible. The percentages of the enol and keto tautomers have been determined by the integration of the relative intensities of these resonances for a given compound. While two possible enol structures can be postulated for unsymmetrically-substituted β-diketones, as, for example, by thenoyltrifluoroacetylacetone,[4] these peaks for two enol forms can not be observed independently within the limits of this experiment.

The proton chemical shifts of the α-proton in the enol and keto tautomers, their percentages, and the corresponding equilibrium constants are summarized in Table 1 for each of the β-diketones.

From Table 1, it can be seen that the enolic content of these β-diketones increases considerably with an increase in the branching of the alkyl chain near the donating oxygen atom. The enolic content of the alkyl group increases, to a certain extent, with the increase in chain length. However, the enolic contents of β-diketones containing methyl groups are slightly higher than those of β-diketones containing ethyl groups. The enolic contents of β-diketones containing a two-ethyl-group system are lower than would be expected from the effect of the ethyl group in this series. No explanation for the difference will be offered. However, a similar relation was observed with β-diketones containing the alkoxy group. Ness and McElvain[5] have pointed out that the enolic content of β-diketones containing the ethoxy group was lower than that for methoxy and other alkoxy-group systems. In the presence of phenyl groups there is a greater tendency for an increase in enolization. Burdett and Rogers[1] have pointed out that the substitution of electron-withdrawing groups, such as the trifluoromethyl groups, and the aromatic ring in β-diketones results in an increase in enolization. Park *et al.*[6] have

also suggested the stabilization of the enol tautomer in trifluoroacetylacetone by an F–HO intermolecular bond.

It would appear that the high enol content for a given compound is a result of electron release in the region of the oxygen atom in the carbonyl group. The correlation between the substitution group and the enolic contents of the β-diketones in this study suggests that the keto-enol ratio is probably dependent on the difference in the electron density of the alkyl groups.

It is known that the enol OH protons show a considerable variation in chemical shift, particularly among the β-diketones. Lintvedt and Holtzclaw[7] have pointed out that the chemical shift of the enol OH proton is shifted downfield on an increase in the basicity of the substituent with the β-diketones. The chemical shifts of the OH proton are given in Table 2 for β-diketones whose acid-dissociation constant is known from the literature.[2,8,9] The results from the present study are plotted in Fig. 1; a linear relationship exists between the chemical shift of the enol OH proton and the acid-dissociation constant. A higher acid-dissociation constant corresponds to a lower chemical shift of the enol OH proton and, presumably, to a stronger intermolecular hydrogen bond. A similar relation was observed with thiazolylazophenol derivatives.[10]

The authors are deeply indebted to Mr. Kenzo Fujii and Mr. Tamotsu Minami of Mitsui Toatsu Chemicals, Inc., for their considerable assistance with the NMR spectra. They also gratefully acknowledge the valuable help of Dr. Totaro Goto in discussions relating to this work.

Infrared Analysis of Copolymers. II. The Sequence Distribution of Methyl Acrylate Units in Methyl Acrylate–Styrene Copolymers

Naobumi Ōi, Koichi Moriguchi, Hiro-o Shimada, and Fusako Hashimoto
Central Research Laboratory, Sumitomo Chemical Co., Ltd., Tsukahara, Takatsuki, Osaka

(Received July 6, 1972)

In the infrared spectra of copolymers, the characteristic stretching vibrations such as the C=O stretching mode in acrylate copolymers, have generally been considered to be independent of the sequence environment. In fact, in methylacrylate (MA)–styrene(ST) copolymers Kamiyama *et al.* noted that no shift of the peak position of the carbonyl absorption band is observed with changes in the composition, although the half-band width decreases regularly with a decrease in the MA content.[1)]

However, we recently found that the C≡N stretching mode in acrylonitrile(AN)–styrene(ST) copolymers is sensitive to sequence environment and, hence, useful in determining the sequence distribution in AN–ST copolymers.[2)] In order to ascertain whether this is a phenomenon characteristic of all copolymers with polar groups, the infrared spectra of MA–ST copolymers were studied.

Experimental

The random copolymers were prepared by copolymerizing MA and ST monomers, with benzoyl peroxide as the initiator, at 60°C. The low-conversion copolymers thus obtained were used for the infrared measurement. The MA–ST copolymer prepared with ethylalminum sesquichloride[3)] was also used. These samples are listed in Table 1. The MA contents of copolymers were determined by NMR spectrometry.

The infrared spectra were recorded in a benzene solution with a Hitachi-Perkin Elmer 125 grating infrared spectro-

meter which was calibrated against the absorption bands of atmospheric H_2O in 1800—1700 cm^{-1}.

Results and Discussion

The observed $\nu_{C=O}$ frequencies are summarized in Table 1. It is apparent that the C=O stretching mode of MA units regularly shifts to lower frequencies as the MA content decreases, and attains to a constant frequency in copolymers with low MA contents. This fact suggests that the peak positions of the carbonyl absorption bands are correlated to the sequence distributions of MA units in copolymers. Thus, the $\nu_{C=O}$ frequencies were plotted against P_{MM} and P_{MMM}, which are the probabilities for finding the MA–MA and MA–MA–MA linkages respectively in a chain. These probabilities were calculated for low-conversion copolymers from the feed compositions and the reactivity ratios for MA and ST, $r_{MA}=0.20$ and $r_{ST}=0.75$,[4] according to the equations in Ref. 5.

Figure 1 shows that $\nu_{C=O}$ is linearly proportional to P_{MM}. Thus, the following equation was used to calculate P_{MM} values in copolymers:

$$\nu C{=}O = aP_{MM} + bP_{MS}$$

In this equation, P_{MS} is the probability of finding the MA–ST linkage in a copolymer chain and the coefficients, a and b, represent the frequencies of the carbonyl bands for MA units in the MA–MA and MA–ST diads respectively. The a coefficient was evaluated from the spectrum of the MA homopolymer, and b, from the spectra of the copolymers with low MA contents, because the MA units are essentially isolated. As $P_{MM}+P_{MS}=1$, $a=1739.6$, and $b=1734.9$ in a benzene solution, the P_{MM} values of random copolymers can be

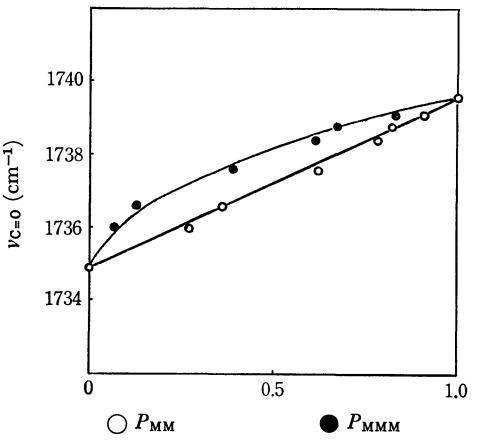

Fig. 1. The C=O stretching frequencies related to the probabilities of MA–MA and MA–MA–MA linkages in methyl acrylate(MA)–styrene copolymers.

determined by measuring the $\nu_{C=O}$ frequencies in a benzene solution and by using the following equation:

$$P_{MM}=(\nu C{=}O-b)/(a-b)=(\nu C{=}O-1734.9)/4.7$$

The measured P_{MM} values are in reasonably good agreement with the calculated values, as is shown in Table 1. Moreover, noteworthy that the measured P_{MM} value of the copolymer prepared with ethylaluminum sesquichloride is nearly zero; this fact supports the idea that such a copolymer has a highly alternating sequence.[3]

In conclusion, the carbonyl stretching mode in MA–ST copolymers is sensitive to the sequence environment and is, hence, useful for determining the sequence distribution of MA units.

The authors are grateful to Dr. Masaaki Hirooka and Mr. Yoshiki Komiyama for providing samples of the copolymers.

Magnetic Circular Dichroism of $Cu(acac)_2$, $Fe(acac)_3$, and $Co(acac)_3$

Hajime KATÔ and Junichi GOHDA
Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe

(Received May 9, 1972)

The magnetic circular dichroism (MCD) spectra of $Cu(acac)_2$, $Fe(acac)_3$, and $Co(acac)_3$ have been measured; they are shown in Fig. 1.

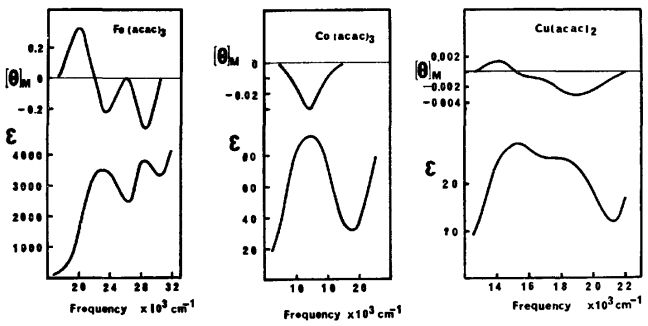

Fig. 1. The experimental MCD and absorption spectra of $Fe(acac)_3$, $Co(acac)_3$, and $Cu(acac)_2$. $[\theta]_M$ is the molar ellipticity per unit magnetic field. ε is the molar extinction coefficient. MCD has been measured by the techniques described in detail in an earlier paper.[5,8]

There has been considerable discussion concerning the assignment of bands appearing in the visible region of the spectrum of bis(acetylacetonato)copper(II), $Cu(acac)_2$, but no final solution to the problem has yet appeared.[1-4] One of the present authors (H.K) has studied the MCD of some Cu^{2+} complexes and found that the B-term of the MCD parameters is dominant in the MCD of the Cu^{2+} complexes at room temperature.[5] According to the analysis, the MCD line shape of $Cu(acac)_2$ suggests two possible assignments: the order of the energy levels is $|xz, yz \gg |x^2\text{-}y^2 \gg |z^2 \gg |xy>$ or $|z^2 \gg |x^2\text{-}y^2 \gg |xz, yz \gg |xy>$, where the locations of the x and y axes are in the plane and along the C_2 axes. However, in order to understand the high-frequency shift of the peak with a large negative MCD band from the maximum point of the absorption band, it is reasonable to assume a positive MCD band in the 16500 cm^{-1} region. Therefore, we propose this order of energy levels; $|xz, yz \gg |x^2\text{-}y^2 \gg |z^2 \gg |xy>$ on the basis of the MCD analysis.[5] Assuming the transition energies to be 14500, 16500, and 18500 cm^{-1} for the $^2B_{1g} \rightarrow {}^2A_{1g}$, $^2B_{1g} \rightarrow {}^2B_{2g}$, and $^2B_{1g} \rightarrow {}^2E_g$ transitions respectively, we have calculated the oscillator strengths and the Faraday parameter B (Table 1). The zeroth moment of the MCD satisfies the relation:[6]

$$\int_{band}([\theta]_M/\nu)d\nu = -33.53(B + C/kT)$$

The values of $(B+C/kT)$ are extracted by simple numerical integrations of the experimental data. By estimating the line shape, we have obtained the experimental values shown in Table 1. The estimated values of B for the lower two bands depend on the estimation of the line shape. However, the order of magnitude is in very good agreement with the calculated ones; these results support the present assignment.

The MCD spectra of $Co(en)_3^{3+}$ and $Co(ox)_3^{3+}$, which are of a D_3 symmetry, were studied by McCaffery and his co-workers.[7] The MCD of $Co(acac)_3$ (Fig. 1) is very similar in appearance to the MCD of the 17000 cm^{-1} band of $Co(ox)_3^{3+}$. $[\theta]_{M_{max}}/\varepsilon_{max}$ is 2×10^{-4}, which is of the same order of magnitude as the value for the $^1A_1 \rightarrow {}^1E_a$ band of $Co(ox)_3^{3+}$. The resemblance to $Co(ox)_3^{3+}$ shows that the static distortion is the major factor governing the d-d intensities. Since the ground state, $^1A_1$, is nondegenerate, the MCD of the 16800 cm^{-1} band of $Co(acac)_3$ shows that the Faraday B-term is absolutely dominant. However, the maximum contribution of an A-term to MCD, $[\theta^A]_{M_{max}}$, is given by $3\sqrt{3}\omega_{ja}{}^{(0)}A/4\Gamma_{ja}{}^2\hbar$. The magnitude of A/D for the $^1A_1 \rightarrow {}^1E$ transition in a D_3 symmetry in solution is theoretically given as $1/2\beta k$, where $k(>0)$ is the orbital angular momentum reduction factor. The value of D is obtained from $\int \varepsilon d\nu$. Then, $A(^1A_1 \rightarrow {}^1E_a)$ is $0.098\beta k$ (in Debye^2 unit). Using the experimental values of $\omega_{ja} \simeq 16800$ cm^{-1} and $\Gamma_{ja} \simeq 4000$ cm^{-1}, we obtain $[\theta^A]_{M_{max}} = 0.0028k$. This value is about 10% of $[\theta]_{M_{max}}$. Therefore, we cannot estimate the magnitude of the quenching of the excited-state angular momentum.

The ground state of $Fe(acac)_3$ is $^6A_1$. In such a case, where the ground state is spin-degenerate and orbitally nondegenerate, the spin-orbit splitting of the orbitally degenerate excited state causes the C terms of the split components of the transition no longer to cancel and gives rise to a MCD changing in sign

through the band.[7,8] However, the bands of moderate intensity at about 23000 and 29000 cm^{-1} can plausibly be assigned to allowed charge-transfer transitions, $^6A_{1g} \rightarrow {}^6T_{1u}$ ($^6A_1 \rightarrow {}^6E + {}^6A_2$). The magnitude of spin-orbit spliting is determined by $\langle {}^6A_{1g}|H_{so}|{}^6T_{1u}\rangle$, which is reduced to one-electron matrix elements, $\langle d|H_{so}|L\rangle$ for the $d^5L^2 \rightarrow d^6L$ transition and $\langle L'|H_{so}|d\rangle$ for the $d^5 \rightarrow L'd^4$ transition. These two-center integrals are small; therefore, the C-term must be negligible. The magnitude of A/D for the $^1A_1 \rightarrow {}^1E$ transition in a D_3 solution is given by $\langle E||\mu||E\rangle i/\sqrt{6} \propto \beta$. Therefore, the expected MCD is of the β-type (which is defined in Ref. 9); this contradicts the observed one. Therefore, the observed MCD must be the B-term; it shows the existence of three bands, at 20000, 24000, and 28500 cm^{-1}. Hanazaki and his co-workers[10] predicted the existence of three bands, a transition to $V_1(E)$, $V_1(A_2)$ at 17000 cm^{-1} with $f=0.007$, a transition to $V_6(E)$ at 24000 cm^{-1} with $f=0.095$, and a transition to $V_8(E)$, $V_4(A_2)$ at 26500 cm^{-1} with $f=0.039$. The present MCD analysis supports their assignments. A much more detailed analysis of the B-term would confirm our assignments. MCD studies of the solvent effects of some copper β-diketonates are now in progress in our laboratory.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 637—639 (1973)

The Design and Performance of a Long-path "Multi-flame" Burner for Atomic Absorption Spectrophotometry

Taketoshi NAKAHARA, Haruyuki DATE, Makoto MUNEMORI, and Sôichirô MUSHA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-umemachi, Sakai

(Received June 26, 1972)

In atomic absorption spectrophotometry, different kinds of burners must be used depending on the nature of the flames employed. For example, a 10-cm slot burner is used for an air-acetylene flame, a 5-cm slot burner for a nitrous oxide-acetylene flame, and a nebulizer-burner of the total-consumption type for air-hydrogen and inert gas-hydrogen flames. Several elements require a specific flame; for example, refractory elements require a nitrous oxide-acetylene flame, and some others prefer low-temperature inert gas-hydrogen flames. Therefore, at least the three kinds of burner mentioned above must be provided when a good number of elements are to be determined under the best conditions.

In this experiment, a long-path slot burner of a new type, one which permits various flames to burn, was designed and constructed. Its performance and use in atomic absorption spectrophotometry will be described below. The authors call this new burner a "multi-flame" burner.

Design and Construction

The production of a stationary flame requires that the stream velocity of the fuel-oxidant mixture through the burner slot is at least equal to the burning velocity. If this condition is not met, the flame is liable to flash back down the burner and cause an explosion in the nebulizer chamber. The problems of designing burners for relatively high-temperature flames particularly arise principally from the fact that gas mixtures with high flame temperatures usually have high burning velocities. This requires a limitation of the size of burner slot, with the attendant disadvantage of easier blockage by deposits of salt or carbon particles. It may be noted also that, for some gas mixtures, the burning velocity increases with the temperature of preheating,[1] so the burner head should be kept sufficiently cool; it must

1) A. G. Gaydon and H. G. Wolhard, "Flames, Their Structure, Radiation and Temperature," Chapman and Hall, London (1960), p. 80.

in any case be kept well below the ignition temperature of the gas mixture.

In view of these requirements, a new-type burner head which can be adapted to any premixed-type burner was designed. The burner head is shown schematically in Fig. 1. It consists of a burner top and a top holder, both of which are made of brass because of its facility of construction, though stainless steel would be preferred. The burner top consists of two pieces of surface-ground plate of the same features; these pieces form a slot and grooves. The slot serves as a nozzle. An outlet area of the nozzle is 1/23 that of the inlet. The length and width of the slot are 11.5 and 0.045 cm respectively. The height of the nozzle is 1.0 cm. To ensure an adequate entrainment of secondary air, the outer surfaces of the nozzle are tapered toward the groove, which is 1.7 cm wide and 0.7 cm deep. The rapid build-up of carbon particles and salt deposition, and the production of water when hydrogen is used as a fuel, were thereby minimized. To maintain the stability of hydrogen flames, which are liable to flash back down the burner and cause an explosion in the nebulizer chamber because of their higher burning velocity, a porous ceramic plate which contains about 50 holes (0.5 mm in diameter) per cm^2 and which is 1.25 cm thick, commonly used for a gas-infrared stove, is placed inside the top holder. Two ducts are provided in the top holder for cooling the burner top with water. The purpose of these ducts is to increase the effectiveness of the quenching action at the burner slot.[2)]

Experimental

In this study the "multi-flame" burner was fitted to a Techtron nebulizer chamber, and its utility was examined on acetylene or hydrogen with air, nitrous oxide, or inert gas (argon or nitrogen) entrained air. The placement of the burner relative to the optical axis of the spectrophotometer (a Nippon Jarrell-Ash Model AA-1 atomic absorption/flame emission spectrophotometer) was effected by means of a compound slide assembly mounted on an optical bench. The single beam-single pass system was arranged in the usual manner. The light beam was modulated at a frequency of 90 Hz by means of a mechanical light-chopper. The flow rates and pressures of the fuels and nebulizing gases were controlled by means of needle valves and were measured by means of calibrated flow meters.

The premixed acetylene or hydrogen flames were formed and extinguished on the burner in much the same manner as that on a welding torch. An acetylene diffusion flame or a hydrogen diffusion flame was first formed at the necessary flow rate (1.0—1.2 l/min for acetylene and 7.2—9.0 l/min for hydrogen). The nebulizing gas (air, nitrous oxide, argon or nitrogen) was then slowly introduced into the nebulizer chamber until the pressure of a nebulizing gas attained 1.5 kg/cm^2, at which point the flow rates of the nebulizing gases were 4.9, 3.8, 4.5, and 5.0 l/min for air, nitrous oxide, argon, and nitrogen respectively. The sample aspiration rates were 8.85, 9.35, 8.90, and 8.95 ml/min with air, nitrous oxide, argon, and nitrogen respectively at the same pressure of 1.5 kg/cm^2. Slight variations in the flow rates and pressures of the nebulizing gases caused only a negligible change in the sample aspiration rates. The flame was extinguished by first terminating the nebulizing gas flow. In particular, a violent flash-back may occur if the acetylene flow is stopped before the nitrous oxide flow. The burner was employed under water-cooling for all the flames. Although the cooling of the burner head promoted salt deposition at the burner slot, the lower temperature of the burner slot markedly reduced the possibility of flash-back.

Performance and Characteristics of a "Multi-flame" Burner

Winefordner *et al.* have used the argon(entrained air)-hydrogen flame[3,4)] and the nitrogen(entrained air)-hydrogen flame[5)] in atomic fluorescence spectrophotometry and in flame emission spectrophotometry[6)] with satisfactory results. On the other hand, Menis and Rains[7)] have described that the argon(entrained air)-hydrogen flame with a premixed-type burner system was unstable and that unsuccessful results were obtained for the atomic absorption spectrophotometry of arsenic. In this study, however, not only an argon (entrained air)-hydrogen flame, but also a nitrogen (entrained air)-hydrogen flame, when used with the "multi-flame" burner, was found to be remarkably stable and useful for atomic absorption spectrophotometry.

With this burner, atomic absorptions were measured for various elements. The elements studied were aluminum, bismuth, cadmium, calcium, copper, iron, lead, magnesium, mercury, strontium, tin, and zinc. These elements were chosen for a variety of reasons: efficiency of atomization, background absorption at the wavelength of atomic absorption measurement, susceptibility to chemical interferences, refractory oxide formation, *etc.* The atomic absorptions were measured for each element at various flame compositions and flame heights. Linear analytical calibration graphs were obtained for all the elements and for all the flames. A comparison of the sensitivities for 1% absorption of the elements studied under the optimum experimental conditions for each flame is shown in Table 1.

Salt deposition occurred along the burner slot after a very long period (about five hours) of operation and resulted in flame distortion. The burner clogging depends on the total concentration of solutes in the solutions sprayed into the flame. To minimize this burner clogging, a pure solvent was sprayed into the flame between each measurement. Any remaining particles on the burner slot could easily be cleaned off by passing a thin board through the slot a few times. Air was run out through the burner during the cleaning of the burner slot.

It may be seen from the results shown in Table 1

A: Air-acetylene flame. B: Nitrous oxide-acetylene flame. C: Air-hydrogen flame. D: Nitrous oxide-hydrogen flame. E: Argon(entrained air)-hydrogen flame. F: Nitrogen (entrained air)-hydrogen flame. G: Results obtained by Slavin.[8]

that the new "multi-flame" burner can be satisfactorily used with several gas mixtures and that it gives some increase in sensitivity for some elements, compared with those values obtained using a commercial burner.[8] Furthermore, the hydrogen flame using argon or nitrogen as a nebulizing gas gives significantly better sensitivities for some elements, but severe chemical interferences are likely to occur, because the flame temperature is much lower. The "multi-flame" burner is completely silent in operation, even when using hydrogen as a fuel.

Hydrogen flames with argon(entrained air) and nitrogen(entrained air) would be useful for the atomic absorption spectrophotometric study of some elements which are easily atomized in a low-temperature flame, such as arsenic, bismuth, cadmium, tin, selenium, and zinc.

The Atomic Absorption Spectrophotometric Determination of Zinc in Premixed Inert Gas(Entrained Air)-Hydrogen Flames and the Measurement of the Flame Temperature

Taketoshi NAKAHARA, Makoto MUNEMORI, and Sôichirô MUSHA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-umemachi, Sakai

(Received June 26, 1972)

Previous studies have indicated that the premixed inert gas(entrained air)-hydrogen flame produced with a "multi-flame" burner[1] can be used as a suitable atom reservoir for the determination of bismuth[2] and tin[3] by atomic absorption spectrophotometry. This paper will describe the application of this flame to the atomic absorption spectrophotometric determination of zinc and, in addition, the measurement of its temperatures using a thermocouple probe.

Whereas the temperatures of most flames can only be measured satisfactorily by such spectroscopic techniques as the Ornstein iron two-line method[4-6] and the sodium line-reversal method,[5,7] the cool inert gas-(entrained air)-hydrogen flame gives a temperature of only a few hundred degrees centigrade,[8] and it can be measured fairly reliably by inserting a thermocouple probe into the flame.[9]

Experimental

Apparatus. All the atomic absorption measurements were made using a Nippon Jarrell-Ash Model AA-1 atomic absorption/flame emission spectrophotometer. A long-path "multi-flame" burner[1] constructed in the authors' laboratory was mounted on a Techtron nebulizer chamber, and a single pass system was used. The height in the flame was taken as zero when the light beam from the hollow-cathode lamp just touched the top of the burner head. The analytical wavelength was 213.9 nm, and the light source was a multi-element (Cu–Fe–Mn–Zn) hollow-cathode lamp (Westinghouse, Type No. 45492), operated at 10 mA. The gas-flow rates were carefull regulated by means of needle valves and were monitored on calibrated flow meters.

Reagents. A standard zinc solution containing 1000 ppm of zinc was prepared by dissolving 1.000 g of high-purity zinc metal in 10 ml of hydrochloric acid and by then diluting this mixture to 1000 ml with distilled water. Various concentrations were made by diluting the stock solution.

Results and Discussion

Flame Parameters. The flames employed in this study produced 5 and 8% absorptions respectively when nitrogen and argon were used as the nebulizing gases. The absorbance values cited in this study were corrected for this background absorption.

The optimum flame parameters for zinc atomic absorption are summarized below. Argon(entrained air)-hydrogen flame: hydrogen flow rate, 3.6 l/min; argon flow rate, 4.5 l/min; argon pressure, 1.5 kg/cm^2; height of the flame, 4 mm above the top of the burner head. Nitrogen(entrained air)-hydrogen flame: hydrogen flow rate, 5.4 l/min; nitrogen flow rate, 5.0 l/min; nitrogen pressure, 1.5 kg/cm^2; height of the flame, 6 mm above the top of the burner head. Under these flame conditions, the hydrogen flames are almost invisible and are very quiet. The sample aspiration rates were 8.90 and 8.95 ml/min with argon and nitrogen respectively.

Calibration Graph for Zinc. Under the optimum conditions outlined above, the straight calibration graphs were obtained over the range of 0—0.5 ppm of zinc in argon(entrained air)-hydrogen and nitrogen-(entrained air)-hydrogen flames. The sensitivities for 1% absorption for zinc were 0.005 and 0.007 ppm in argon(entrained air)-hydrogen and nitrogen(entrained air)-hydrogen flames respectively.

Effects of Acids. The interference effect of acids on the determination of zinc was studied. The concentration of zinc was 0.5 ppm, and the concentration range of acids was from 0.5 to 2.0M. The acids examined were hydrochloric, nitric, perchloric, and sulfuric acids. The results obtained in both inert gas(entrained air)-hydrogen flames are shown in Fig. 1. It can be seen from Fig. 1 that the interference from the acids is greater in the nitrogen(entrained air)-hydrogen flame than in the argon(entrained air)-hydrogen flame. Hydrochloric and nitric acids caused little or no interference with the determination of zinc, but perchloric and sulfuric acids, particularly in the nitrogen(entrained air)-hydrogen flame, had a depressing effect on the zinc atomic absorption. Furthermore, the depressing interference from perchloric and sulfuric acids was considerably dependent upon the flame composition, becoming greater as the flames became reducible.

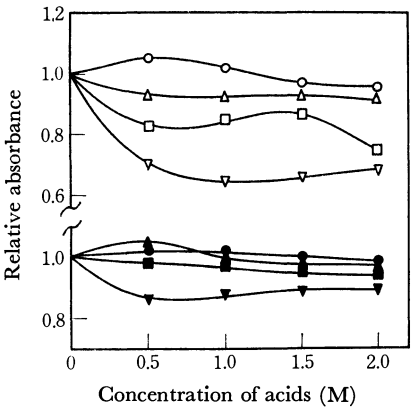

Fig. 1. Effect of acids on zinc atomic absorption. Concentration of zinc: 0.5 ppm. In an argon(entrained air)-hydrogen flame: (●) hydrochloric acid; (▲) nitric acid; (■) sulfuric acid; (▼) perchloric acid. In a nitrogen(entrained air)-hydrogen flame: (○) hydrochloric acid; (△) nitric acid; (□) sulfuric acid; (▽) perchloric acid.

Effects of Various Other Elements. The effects of the presence of 10- and 100-fold weight excesses of various diverse elements on the determination of zinc were studied at the 0.5 ppm level. Some severe chemical interferences were observed to depress the zinc atomic absorption. The refractory compound-formers, such as aluminum, beryllium, boron, silicon, and vanadium, exhibited a greater depressing interference with the zinc atomic absorption.

Because flame composition and flame height have been found to be important parameters in the study of interference,[10] the hydrogen-flow rate and the flame height in the inert gas(entrained air)-hydrogen flames were varied to see what effect, if any, would be produced on the depressing interference; it was found that the depressing interference was dependent on these parameters.

Effect of Lanthanum on the Depressing Interference. In an attempt to eliminate the depressing interference due to aluminum, beryllium, boron, *etc.*, the effects of third elements on the depressing interference were studied. The elements examined were barium, iron, mercury, lanthanum, lithium, magnesium, sodium, lead, antimony, tin, and yttrium. Some elements were found to eliminate the depressing interferences. Lanthanum was the most effective of the elements examined. When solutions were prepared so as to contain 2000 ppm of lanthanum(as chloride) as an interference-releasing agent, all the chemical interferences were completely removed. This phenomenon would be applicable to the determination of zinc in various practical samples.

Measurement of the Flame Temperatures. Dagnall

10) J. A. Dean and T. C. Rains, "Flame Emission and Atomic Absorption Spectrometry," Vol. 1, Marcel Dekker, New York, N. Y. (1969).

et al.[8] have reported that the hydrogen-nitrogen diffusion flame and the shielded air-hydrogen flame give temperatures of only a few hundred degrees centigrade, and that they can be measured fairly reliably by inserting a calibrated thermocouple probe into the flame. Furthermore, Smith *et al.*[9] have described the temperature profiles of turbulent hydrogen diffusion flames, the temperatures of which were measured with the aid of an iridium/60% iridium-40% rhodium thermocouple.

The temperatures of the inert gas(entrained air)-hydrogen flames were measured in this study by inserting a platinum/90% platinum-10% rhodium thermocouple probe into the flames. The thermocouple was made of 0.2 mm diameter platinum and platinum-rhodium (90—10%) wires which were welded to give a bead junction *ca.* 0.4 mm in diameter. The joined wires were mounted in two-bore, ceramic insulators of high-purity alumina. The thermocouple was mounted on a manually-operated horizontal/vertical traverse mechanism. The thermoelectric emf was measured on a millivoltmeter calibrated in units of 0.05 mV, and the temperature was determined by referring to a calibration table.[11]

The variation in the flame temperature with the flame height and the hydrogen-flow rate, at the flame center only, was measured for the argon(entrained air)-hydrogen flame and for the nitrogen(entrained air)-hydrogen flame with the aspiration of distilled water. The results obtained are shown in Fig. 2. For both the flames, the temperatures could be reproduced to $\pm$10 K at any point on the central axis of the flame. As the hydrogen flow rate was increased, the flame became larger and the flame temperature increased, as is shown in Fig. 2. Furthermore, the maximum

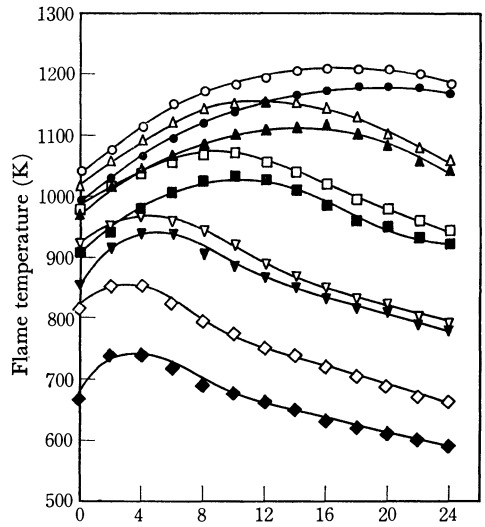

Fig. 2. Flame-temperature variation along central, vertical axis of the inert gas(entrained air)-hydrogen flames.
Hydrogen flow rate in an argon(entrained air)-hydrogen flame: (◇) 3.6 l/min; (▽) 5.4 l/min; (□) 7.2 l/min; (△) 9.0 l/min; (○) 10.8 l/min. Hydrogen flow rate in a nitrogen (entrained air)-hydrogen flame: (◆) 3.6 l/min; (▼) 5.4 l/min; (■) 7.2 l/min; (▲) 9.0 l/min; (●) 10.8 l/min.

temperature shifted toward the higher part in the flame with the increase in the hydrogen flow rate. When distilled water is not sprayed into the flame, the flame temperatures about 4 mm above the top of the burner head increase by only 20 K. It may be noticed in Fig. 2 that the temperature in the argon-(entrained air)-hydrogen flame was higher at any point than that in the nitrogen(entrained air)-hydrogen flame. This is presumably due partially to the differences in interference effects on the zinc atomic absorption described above.

Sesquiterpenoids of *Parabenzoin praecox*

Keiko OHARA, Yoshimoto OHTA, and Yoshio HIROSE
The Institute of Food Chemistry, Dojimanaka, Kita-ku, Osaka

(Received March 13, 1972)

The essential oil of *Parabenzoin praecox* (Sieb. et Zucc.) Nakai, distributed in the southern part of Japan, has been reported to be composed mainly of several monoterpenoids, with *cis*-ocimene the major one, together with a few sesquiterpenoids, such as caryophyllene.[1] In this paper, we wish to report the analysis of the sesquiterpenoid fraction of this oil and the structural determination of two new sesquiterpenoids, α-copaene-11-ol (I) and 8-acetoxy-elemol (III), isolated from this source. In our experiments, unlike as in the previous results,[1] camphor was isolated as the main component of the oil and the following known sesquiterpenoids were isolated, α-copaene, β-elemene, β-caryophyllene, elemophyllene, α-muurolene, β-selinene, δ-cadinene, γ-cadinene, nerolidol, elemol, ledol, epicubenol, spathulenol, γ-eudesmol, T-cadinol, T-muurolol, δ-cadinol, α-eudesmol, β-eudesmol, and α-cadinol.

α-Copaene-11-ol, Compound (I) ($C_{15}H_{24}O$ (M^+ *m/e* 220), needle crystals, mp 99.5—100.5°C, $[\alpha]_D$ +9.2° in $CHCl_3$) was shown to have the following groupings, $-C(CH_3)_2OH$ (ν_{max} 3350 cm^{-1} (hydroxyl group), $\delta^{CCl_4}_{ppm}$

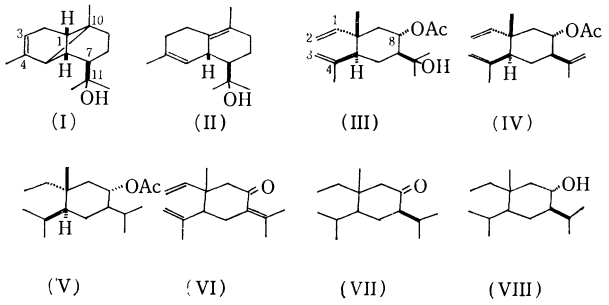
1) H. Shinozaki, *Kogyo Kagaku Zasshi*, **24**, 444 (1921); H. Komae, N. Hayashi, S. Kosela, and T. Aratani, *Flavour Industry*, **2**, 427 (1971).

1.04 (6H s.), *m/e* 59 ($C_3H_7O^+$, 100%)), $>CCH_3$ (δ 0.77 (3H s.)), and $-HC=C(CH_3)-$ (δ 1.62 (3H br.s.), 5.13 (1H br.s.)). The dihydro-derivative of I obtained by catalytic reduction (PtO_2/EtOH) was further hydrogenolyzed with PtO_2 in acetic acid to yield two hydrocarbons (both M^+ *m/e* 206) in a ratio of 3: 1, they were identical with copane and ylangane respectively. The dehydration of I with thionyl chloride in pyridine and the subsequent selective hydrogenation of the resulting terminal double bond with tris(triphenylphosphine) chlororhodium in benzene afforded α-copaene as the main product. From these results, Compound (I) was concluded to have α-copaene skeleton and a hydroxy group at C-11, as is shown by Formula (I). Although the absolute configuration of this compound was not determined, it is presumed that I has the same stereostructure as (−)-α-copaene on the basis of the coexistence of this and α-copaene($[\alpha]_D$ −4.9°) in the same oil. The isomerization of this alcohol, catalyzed by 0.1N hydrochloric acid in 80% aqueous dioxane, yielded a new bicyclic compound (II) ($C_{15}H_{24}O$ (M^+ *m/e* 220) $[\alpha]_D$ +52°). The spectral data of this compound showed the presence of $-C(CH_3)_2OH$ (ν_{max} 3400 cm^{-1}, δ 1.14 and 1.19 (each 3H s.) and *m/e* 59 (100%)), tri- and tetrasubstituted double bonds (δ 1.58 (6H s.) and 5.63 (1H br.s.)). This compound was presumed to be δ-cadinene-11-ol, since the mother hydrocarbon, α-copaene, yields δ-cadinene and α-murolene on acid treatment.[2)]

In another experiment, α-copaene-11-ol was isolated from the wood oil of *Litseae japonica* (Thumb.) Juss. as the major component of the sesquiterpene alcohol fraction.

8-Acetoxyelemol, Compound III ($C_{17}H_{28}O_3$ (M^+ *m/e* 280)), a minor component of the oil, showed the following spectral data, ν_{max} 3350, 1730, 1240, 910, and 890 cm^{-1}, δ 1.08 (3H s.), 1.15 (6H br.s.), 1.69 (3H br.s.), 2.00 (3H s.), 4.60—5.00 (5H m.), and 5.75 (1H d.d.). These spectra are identical with those of elemol except for the additional signals due to an acetoxy group (ν_{max} 1730 and 1240 cm^{-1}, and δ 2.00 (3H s.)). On heating in a sealed tube or on glc separation at 200°C, this compound afforded a dehydrated derivative (IV) ($C_{17}H_{26}O_2$). The NMR spectrum of IV showed the presence of an isopropenyl group instead of a $-C(CH_3)_2OH$ group in III. The NMR spectrum of the hexahydro-derivative (V), obtained by the hydrogenation of IV, exhibited the presence of a proton at δ 4.75, this confirmed the secondary nature of the acetoxy group. The position of this acetoxy group was decided to be at C-8 on the basis of the following experiments. β-Elemenone (VI) was hydrogenated with PtO_2 in acetic acid to yield a saturated ketone (VII). The subsequent lithium aluminium hydride reduction of VII afforded two secondary alcohols, VIII and IX, the minor product (VIII), carrying an equatorial hydroxyl group (H-8 at δ 3.40, $W_1/_2$ 24 Hz), was acetylated with Ac_2O in pyridine to yield an acetate which was identical with V in all respects. From these results, the structure of Compound III can be represented by Formura (III). The coexistence of III and elemol ($[\alpha]_D$ −3.5°) in the same oil also suggests the stereochemistry.

At present, there have been found only a few cadalene-type compounds carrying a hydroxyl group at C-11 as our alcohol (I) does, and since, in the genesis of cadalene-type alcohols a S_N1-like attack of a water molecule on the C-10 carbonium ion from the mediate germacrenoid cation is generally accepted, the hydroxylation at C-11 probably occurs after the cadalene skeleton has been formed. Such *de novo* hydroxylation is quite rare in sesquiterpenoids, and further study of the biogenesis of the compounds of this type should be undertaken.



Experimental

Stems (16.5 kg) and leaves (15.0 kg) of *Parabenzoin praecox* were collected in Osaka Prefecture. Each was extracted with acetone, and the extract, after the evaporation of the solvent, was steam-distilled. After the removal of acidic components from the distillate, neutral oils were obtained in the amounts of 12.9 g and 20.8 g from the stems and the leaves respectively. No significant difference in their constituents could be detected by analytical gas chromatography using a capillary column (HB-2000, 45 m × 0.25 mm), therefore, the two oils were combined for analysis. The combined oil was separated into a hydrocarbon fraction (18.8 g) and a fraction of oxygenated compounds (14.1 g) by column chromatography on neutral alumina. Each component of the hydrocarbon fraction was purified by column chromatography on silica gel, followed by preparative glc (Varian, model 90-P, 20 ft. × 3/8 in. aluminium column packed with 10%-Carbowax 20M on Diasolid L at 180—200°C, using helium as the carrier gas). The oxygenated compound fraction was distilled under reduced pressure (3 mmHg) to separate sesquiterpenoids from monoterpenoids roughly. Each sesquiterpenoid, as well as α-copaene-11-ol (I) and 8-acetoxyelemol (III), was purified by column chromatography on silica gel, this was followed by preparative glc under the same condition as those for used for hydrocarbons except in the case of III. 8-Acetoxyelemol (III) was isolated using a 5ft. × 3/8 in. column of Carbowax 20 M at 175°C. The compounds thus isolated were identified with authentic samples by comparing their RT on glc, and thier IR, NMR, and MS spectra.

α-Copaene-11-ol (I); *m/e* 220 (rel. int. 2%, M^+), 202 (7.5%, M^+-H_2O), 187 (11%, $M^+-H_2O-CH_3^+$), 162 (52%, $M^+-C_3H_6O^+$), 159 (41%), 147 (30%), 132 (38%), 119 (47%), 105 (55%), 91 (43%), 59 (100%, $C_3H_7O^+$).

8-Acetoxyelemol (III); *m/e* 280 (0.05%, M^+), 220 (0.3%, $M^+-CH_3CO_2H$), 202 (0.9%, $M^+-CH_3CO_2H-H_2O$), 162 (22%), 147 (23%), 119 (69%), 117 (71%), 108 (47%), 59 (42%, $C_3H_7O^+$), 43% (100%, $C_3H_7^+$).

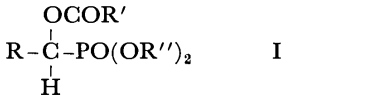
The Pyrolysis of Dialkyl α-Acyloxyphosphonates

Yoshiki OKAMOTO and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Suita-shi, Osaka

(Received March 27, 1972)

Several dialkyl α-acyloxyalkyl (aralkyl) phosphonates (I) were prepared,[1] and their behavior in pyrolysis was investigated.

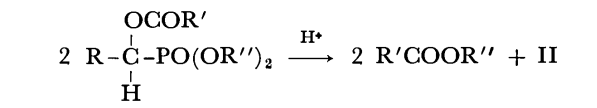


I

I-a,	$R=C_6H_5$,	$R'=CH_3$,	$R''=C_2H_5$
I-b,	C_6H_5,	CH_3,	C_3H_7
I-c,	C_6H_5,	C_3H_7,	C_2H_5
I-d,	C_3H_7,	C_6H_5,	C_2H_5
I-e,	C_3H_7,	CH_3,	C_2H_5
I-f,	C_6H_5,	CH_3,	CH_3
I-g,	C_2H_5,	CH_3,	CH_3
I-h,	C_6H_5,	CH_3,	$CH(CH_3)_2$

In every run, 0.1 mol of I was pyrolyzed in a distillation flask heated by means of a metal bath. I-a, I-b, I-c, I-d, and I-e decomposed rapidly in the range from about 260 to 280°C, and alkyl carboxylates (R'COOR'') were quantitatively obtained as the sole distillable product (>97% pure by glc).

The pyrolysis was over in a few minutes. However, I-f and I-g were stable at this temperature. I-f and I-g began to decompose at 320°C and gave a mixture of methyl acetate, acetic acid, methyl alcohol, and benzaldehyde or propionaldehyde. In the presence of a catalytic amount of phosphoric acid, the temperature of the beginning of decomposition of I-f fell to 260°C and only methyl acetate was obtained. I-h decomposed at 190°C, and propylene, benzaldehyde, and acetic acid were obtained. When the pyrolysis of an equimolar mixture of I-b and I-c was performed, propyl acetate, ethyl acetate, ethyl butyrate, and propyl butyrate were obtained in the mole ratio 1.1: 1.0: 1.2: 1.1, as was determined by glc analysis. When a mixture of propyl acetate and ethyl butyrate was refluxed for 10 min in the presence of a small amount of phosphoric acid, interesterification did not occur. These results indicate that the formation of alkyl carboxylate from I is catalyzed by acid and proceeds by means of an intermolecular mechanism:



The structure of the undistillable product (II-a) obtained by the pyrolysis of I-a was identified from the following findings. II-a was a resin-like and hygroscopic solid, softening at 140—150°C. It was dissolved in water, and a small amount of an insoluble, oily matter was removed. When the solution was acidified with hydrochloric acid, a viscous matter was precipitated; this matter was separated and dried in a vacuum (yield, 98%), (II-a') mp 135—140°C. Found: C, 54.21; H, 5.54; P, 15.52%. Calcd for $C_{18}H_{22}O_6P_2$: C, 53.92; H, 5.59; P, 15.63%. UV λ_{max} 260 mμ, 11400 (in water). II-a' was refluxed with 6N hydrochloric acid for 24 hr. The hydrolyzed product: mp 142—145°C. Found: C, 47.06; H, 5.18; P, 18.08%. Calcd for $C_{14}H_{14}O_6P_2$: C, 49.42; H, 4.18; P, 18.20%. Acid value, 549 (Calcd for $C_{14}H_{14}O_6P_2$, tetrabasic acid 564). When treated with bromine water, II-a' gave a quantitative yield of the bromide, which was then recrystallized from ether; mp 159—160°C. Found: C, 39.75; H, 4.33; Br, 30.82%. Calcd for $C_{18}H_{22}O_6Br_2P_2$: C, 38.87; H, 4.28; Br, 29.93%. The methyl ester of II-a', esterified with diazomethane, MW: 435.5 (Cryscopic in benzene). Calcd for $C_{20}H_{26}O_6P_2$: 424.4. NMR $\tau(CCl_4)$ 8.8 (6H, t), 6.2—6.6 (10H, m), 2.72 (10H, s).

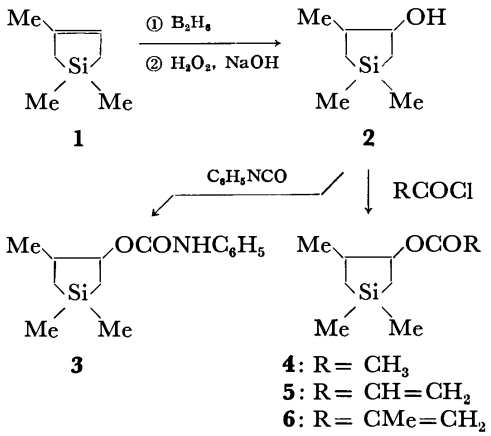
The Synthesis of the Derivatives of Silacyclopentanol and Silacyclopentylamine

Tsunao ARAKI, Daiyo TERUNUMA, Fumio KATO, Hiroshi KANEDA, and Akira IINO

Department of Applied Chemistry, Faculty of Science and Engineering, Saitama University, Urawa

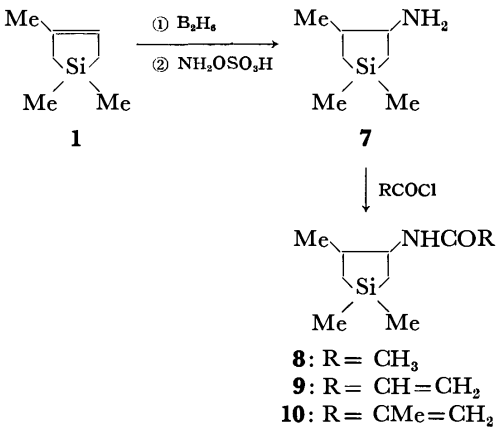
(Received April 22, 1972)

Recently, several papers have been reported on the synthesis and reactions of carbofunctional derivatives of silaheterocyclic compounds.[1] The present authors previously reported the synthesis[2] and polymerization[3] of silacyclo-pentene and -pentane derivatives. In this paper, we wish to report the synthesis of several new derivatives of silacyclopentanol and silacyclopentylamine 3,3,5-trimethyl-3-silacyclopentylphenylurethane (**3**), 1,1,3-trimethyl-4-acetoxy-1-silacyclopentane(**4**), 1,1,3-trimethyl-4-acryloxy-1-silacyclopentane(**5**), 1,1,3-trimethyl-4-methacryloxy-1-silacyclopentane(**6**), 1,1,3-trimethyl-4-amino-1-silacyclopentane(**7**), 1,1,3-trimethyl-4-acetylamino-1-silacyclopentane(**8**), 1,1,3-trimethyl-4-acryloylamino-1-silacyclopentane(**9**), and 1,1,3-trimethyl-4-methacryloylamino-1-silacyclopentane(**10**). The starting material, 1,1,3-trimethyl-1-silacyclopent-3-ene(**1**), was prepared in a 38% yield[2] by a modification of the method of Weyenberg *et al.*[4] The hydroboration and oxidation[5] of **1** with diborane and alkaline hydrogen peroxide gave 1,1,3-trimethyl-1-silacyclopentan-4-ol(**2**).[1b] **2** was reacted readily with phenyl isocyanate, acetyl chloride, acryloyl chloride, and methacryloyl chloride to afford **3**, **4**, **5**, and **6** respectively (Scheme 1).



Scheme 1.

3 was a highly viscous liquid soluble in common organic solvents, such as CCl_4, Et_2O, and EtOH. The esters of silacyclopentanol, **4**, **5**, and **6**, were liquid and stable under ordinary conditions. In the case of compounds **5** and **6**, the addition of a small amount of hydroquinone as a polymerization inhibitor was necessary for obtaining them in better yields. Other new silacyclopentane derivatives were synthesized according to Scheme 2. The amination of chloroalkylsilane with ammonia has been successfully employed in the preparation of aminoalkylsilane.[6] This method, however, cannot be used in the synthesis of silacyclopentylamine because of the instability of the chloro-derivatives of silacyclopentane. *Via* hydroboration in diglyme, Brown and Zweifel[7] succeeded in preparing amines from hidered olefines, such as 1-methylcyclohexene, 1-methylcyclopentene, and α-pinene. By applying this method, hydroboration followed by treatment with NH_2OSO_3H in glyme (bp 82°C) in place of diglyme (bp 160°C), **7** was obtained in a 16.9% yield (Scheme 2). When tetrahydrofuran was used as the solvent, the yield of **7** was decreased to about 5%.



Scheme 2.

7 was a liquid miscible in common organic solvents and was stable under ordinary conditions. **7** was identified by an analysis of the IR and NMR spectra. (IR spectrum: silicon containing a five-membered ring,[8] 1080, 1030, and 1020 cm^{-1}; NMR spectrum: the two singlets at τ=9.91 and 9.88 for Si-$(CH_3)_2$ show that the silacyclopentane ring remains intact.) **7** was found to undergo reaction with acyl chlorides, such as acetyl chloride, acryloyl chloride, and meth-

acryloyl chloride, to yield **8**, **9**, and **10** respectively. Compounds **8**, **9**, and **10** were colorless crystals. Their structural assignment was done by the analysis of the IR and NMR spectra. The acryloyl and methacryloyl derivatives, **5**, **6**, **9**, and **10**, could be polymerized easily by a radical initiator, such as BPO or AIBN. More detailed studies of the polymerization of these compounds are in progress.

Experimental

The NMR spectra were measured by means of a Varian A-60 spectrometer, using tetramethylsilane as the internal standard. The infrared spectra were obtained on a Shimadzu IR-27C spectrophotometer.

Preparation of ***2***. To a tetrahydrofuran (30 ml) solution of 12.6 g (0.1 mol) of **1** cooled at 0°C, we added gaseous diborane generated from 1.9 g of sodium borohydride in diglyme and boron trifluoride etherate over a period of 2 hr. After this mixture had stood for 2 hr at room temperature, small chips of ice were added to hydrolyze the excess diborane. The solution was immersed in an ice bath, and 11 ml of 3M sodium hydroxide was added, followed by 11 ml of 30% hydrogen peroxide over a period of 1 hr. One hour later the organic layer was separated and the aqueous layer was extracted with ether. The combined organic layer was dried over anhydrous sodium sulfate and distilled to yield 9.8 g (68%) of **2**. Bp 82—86°C/30 mmHg, n_D^{20} 1.4553.

Preparation of ***3***. Phenyl isocyanate (0.03 mol) was added to 3.6 g (0.025 mol) of **2** at room temperature. After 15 min at 75°C, a small amount of water was added to the mixture to hydrolyze the excess phenyl isocyanate. The mixture was then diluted with 20 ml of carbon tetrachloride. Filtration and distillation gave 4.0 g (75.3%) of **3**. NMR: τ 9.87 (s, 6H, CH_3–Si), 8.98 (d, 3H, C–CH_3), 8.40—9.50 (m, 4H, CH_2–Si), 7.80—8.30 (m, 1H, CH–Me), 5.41 (sextet, 1H, CH–O), 2.50—3.25 (m, 6H, –NH–Ph). IR: 3400(m), 2950 (m), 1720 (s), 1601 (m), 1550 (m), 1240 (s), 1075 (m), 1050 (m), 1030 (m), 850 (m). Bp 145—147°C/0.15 mmHg n_{20}^D 1.5303. Found: N, 5.47; Si, 10.53%. Calcd for $C_{14}H_{21}O_2NSi$: N, 5.32; Si, 10.62%.

Preparation of ***4***. To a mixture of 4.8 g (0.033 mol) of **2** and 4 g (0.04 mol) of triethylamine in 30 ml of dry ether was added 3.1 g (0.04 mol) of acetyl chloride in 10 ml of dry ether at 0°C with stirring. Then the mixture was refluxed for 1.5 hr. The ether layer was separated from precipitates of triethylamine hydrochloride. The ether layer was washed with five 20 ml portions of water, and then dried over anhydrous sodium sulfate. Distillation gave 3.14 g (68.4%) of **4**. NMR: τ 9.80, 9.83 (two singlets, 6H, CH_3–Si), 9.01 (d, 3H, C–CH_3), 8.50—9.75 (m, 4H, CH_2–Si), 8.05 (s, 3H, CO–CH_3), 5.40 (sextet, 1H, CH–O). IR: 2935 (m), 1740 (s), 1250 (s), 1080 (m), 1050 (s), 1025 (m), 850 (s). Bp 100—104°C/70 mmHg, n_D^{20} 1.4438. Found: Si, 14.34%. Calcd for $C_9H_{18}O_2Si$: Si, 15.08%.

Preparation of ***5***. The synthesis procedure was similar to that described above. To a solution of 4.8 g of **2** and 4 g of triethylamine in 30 ml of dry ether, we added 3.62 g (0.04 mol) of acryloyl chloride in 10 ml of dry ether in the presence of a small amount of hydroquinone as a polymerization inhibitor. NMR: τ 9.82, 9.85 (two singlets, 6H, CH_3–Si), 9.01 (d, 3H, C–CH_3), 8.40—9.70 (m, 4H, CH_2–Si), 7.70—8.30 (m, 1H, CH–Me), 5.35 (sextet, 1H, CH–O), 3.50—4.40 (m, 3H, CH=CH_2). IR: 2950 (m), 1735 (s), 1610 (s), 1210 (m), 1070 (m), 1050 (w), 1020 (w), 850 (m). Yield, 2.24 g (34.1%); Bp 58—61°C/3.5 mmHg, n_D^{20} 1.4580. Found: Si, 13.24%. Calcd for $C_{10}H_{18}O_2Si$: Si, 14.30%.

Preparation of ***6***. The procedure was similar to that used for **4**. To a solution of 4.8 g of **2** and 4 g of triethylamine in 30 ml of dry ether, we added 4.17 g (0.04 mol) of methacryloyl chloride in 10 ml of dry ether in the presence of a small amount of hydroquinone. NMR: τ 9.82, 9.86 (two singlets, 6H, CH_3–Si), 9.05 (d, 3H, C–CH_3), 7.40—8.30 (m, 1H, CH–Me), 5.40 (sextet, 1H, CH–O), 4.56 (m, 1H, C=CH), 4.00 (m, 1H, C=CH). IR: 2980 (m), 1725 (s), 1640 (m), 1300 (m), 1250 (m), 1180 (s), 1070 (m), 1050 (m), 1020 (m), 840 (s). Yield, 1.96 g (37.1%); Bp 77—79°C/2.5 mmHg, n_D^{20} 1.4590. Found: Si, 12.83%. Calcd for $C_{11}H_{20}O_2Si$: Si, 13.36%.

Preparation of ***7***. To a flask containing 12.6 g (0.1 mol) of **1** in 30 ml of glyme at 0°C, we added gaseous diborane generated from 1.9 g of sodium borohydride in diglyme and boron trifluoride etherate over a period of 2 hr. After this mixture had stood 2 hr at room temperature, a solution of 13.6 g (0.12 mol) of hydroxylamine-*O*-sulfonic acid in 25 ml of glyme was added; the solution was then refluxed for 4 hr. The reaction mixture was cooled, treated with 20 ml of concentrated hydrochloric acid, and poured into 200 ml of water. The acidic phase was extracted with ether to remove glyme and the residual boronic acid. The aqueous solution was then made strongly alkaline with sodium hydroxide, and the amine was extracted with ether. The ether extract was dried over potassium hydroxide and distilled. NMR: τ 9.00—9.70 (m, 4H, Si–CH_2), 9.04 (d, 3H, C–CH_3), 8.80 (m, 2H, –NH_2), 7.38 (octet, 1H, CH–N). IR: 3350 (w), 3250 (w), 2940 (s), 1580 (m), 1450 (m), 1400 (m), 1360 (m), 1250 (s), 990 (w), 830 (s). Yield, 2.40 g (16.9%); Bp 74—75°C/42 mmHg, n_D^{20} 1.4535. Found: N, 9.50; Si,18.22%. Calcd for $C_7H_{17}NSi$: N, 9.77; Si, 19.53%.

Preparation of ***8***. Into a mixture of 1.43 g (0.01 mol) of **7** and 1.2 g (0.012 mol) of triethylamine in 20 ml of dry ether, we stirred 0.94 g (0.012 mol) of acetyl chloride in 10 ml of dry ether at 0°C. After the addition was completed, the mixture was stirred at room temperature for 3 hr. The ether layer was separated from precipitates of triethylamine hydrochloride, and then washed with five 15 ml portions of water. The ether solution was dried over anhydrous sodium sulfate. On the evaporation of the solvent, we obtained 1.43 g (77.5%) of a colorless solid product. This product was recrystallized from petroleum ether. NMR: τ 9.86 (s, 6H, CH_3–Si), 9.02 (d, 3H, C–CH_3), 8.50—9.60 (m, 4H, CH_2–Si), 8.07 (s, 3H, O=C–CH_3), 7.40—8.30 (m, 1H, CH–Me), 2.31 (d, 1H, NH). IR: 3300 (m), 3150 (w), 2950 (m), 1650 (s), 1560 (m), 1300 (m), 1250 (m), 1085 (w), 1070 (m), 1040 (w), 850 (s). Yield, 1.04 g (56.3%); Mp 99.5—100°C. Found: N, 7.40; Si, 14.76%. Calcd for $C_9H_{19}OSi$: N, 7.56; Si, 15.10%.

Preparation of ***9***. The synthesis procedure was similar to that described above. Into a mixture of 1.43 g (0.01 mol) of **7** and 1.2 g (0.012 mol) of triethylamine in 20 ml of dry ether, we stirred 1.09 g (0.012 mol) of acryloyl chloride in 10 ml of dry ether at 0°C in the presence of a small amount of hydroquinone. NMR: τ 9.88, 9.91 (two singlets, 6H, CH_3–Si), 9.00 (d, 3H, C–CH_3), 8.40—9.50 (m, 4H, CH_2–Si), 7.80—8.50 (m, 1H, CH–Me), 6.32 (m, 1H, CH–N), 4.50 (q, 1H, CH=C), 3.70 (t, 2H, C=CH_2), 2.32 (d, 1H, CH–N). IR: 3330 (m), 3130 (w), 3080 (m), 1660 (s), 1610 (m), 1550 (m), 1250 (m), 1160 (m), 1070 (m), 1000 (w), 980 (m), 840 (m). Yield, 1.20 g (61.3%); Mp 114—115°C. Found: N, 6.95; Si, 13.01%. Calcd for $C_{10}H_{19}OSi$: N, 7.90; Si, 14.18%.

Prepatation of ***10***. The procedure was similar to that described above. To a solution of 1.43 g (0.01 mol) of **7**

and 1.2 g (0.012 mol) of triethylamine in 20 ml of dry ether, we added 1.25 g (0.012 mol) of methacryloyl chloride in 10 ml of dry ether in the presence of hydroquinone. NMR: τ 9.89, 9.92 (two singlets, 6H, CH_3–Si), 9.00 (d, 3H, C–CH_3), 8.40—9.50 (m, 4H, CH_2–Si), 8.13 (s, 3H, O=C–CH_3), 7.80—8.60 (m, 1H, CH–Me), 6.33 (m, 1H, CH–N), 4.78 (m, 1H, C=CH), 4.40 (m, 1H, C–CH), 3.40 (d, 1H, NH). IR: 3300 (m), 2940 (m), 1660 (m), 1620 (s), 1540 (s), 1250 (m), 1160 (m), 1070 (m), 1005 (m), 980 (w), 840 (s). Yield, 1.37 g (64.8%); Mp 102—103°C. Found: N, 6.49; Si, 12.82%. Calcd for $C_{11}H_{21}NOSi$: N, 6.63; Si, 13.24%.

The authors wish to thank Dr. H. Nohira for his many helpful discussions and the Shinetsu Kagaku Co. for providing the dimethyldichlorosilane.

Results and Discussion

The results of the competitive nitration of toluene and benzene in non-polar or polar solvents are shown in Table 1. The results of previous works mainly related to the nitration in organic solvents are given in Table 2 for comparison. We see that the rate ratios (k_T/k_B) of nitration in the organic solvents studied have a value of about 20 in all cases except for the case of Olah *et al.*[3] and Bonner *et al.*[7] However, the result of the latter differs from that of Coombes,[6] although Coombes suggests that the discrepancy is due to heterogeneity. According to our results in carbon tetrachloride, *n*-hexane, and cyclohexane, the lower values of k_T/k_B were obtained. In the nitration of toluene involving an ideally strong electrophile, in which the π-complex formation is rate-determining, an *ortho* to *para* ratio of 2: 1 and a lower value of k_T/k_B would be obtained.[3] The *ortho*/*para* ratios in the above three solvents are not so high as expected on the basis of the lower values of k_T/k_B in Table 1. All the partial rate factors of the *meta* position (m_f^T) in the above three solvents are below 1. The results are in line with those of Olah *et al.*[3]

Hughes *et al.*[4a] indicated by conductivity measurements that the self-dissociation of nitric acid is represented as follows:

$$2HNO_3 \rightleftharpoons NO_2^+ + NO_3^- + H_2O$$

They showed that according to Raman spectroscopic observations, anhydrous nitric acid contains approximately 1% of nitronium ion and solutions of nitric acid in organic solvents such as nitromethane contain no detectable amount of nitronium ion. On the other hand, in the nitration of aromatics with nitric acid in carbon tetrachloride, the rate dependence on nitric acid concentration was indicated by Coombes,[6] and Bonner *et al.*[7] to be an order of 5 or 6. Thus nitronium ion may not exist as free ion but as aggregate

Table 3. Relationship between dielectric constants and rate ratios

Solvent	ε (20°C)	k_T/k_B
Carbon tetrachloride	2.23	2.15— 2.31
n-Hexane	1.89	2.45— 2.82
Cyclohexane	2.02	1.75— 2.56
Methylene dichloride	9.08	15.8 —17.3
Nitromethane	35[a)]	16.3 —19.7
Acetonitrile	37.5	13.8

a) The value at 30°C.

such as $NO_2^+\cdots NO_3^-$ or $NO_2^+\cdots NO_3^-\cdot HNO_3$. This aggregation might partly correspond to the smaller value of the *ortho*/*para* ratios.

The relationships between dielectric constants and rate ratios are summarized in Table 3. This indicates that the more polar the solvent, the higher the substrate selectivity (k_T/k_B). The activation parameters are shown in Table 4. We see from Tables 1 and 4 that the values of k_T and ΔE_B are larger than those of k_B and ΔE_T, respectively. On the other hand, the values of $\Delta S_B^{\neq}$ are larger than those of $\Delta S_T^{\neq}$. Thus, toluene is nitrated faster with nitric acid than benzene ($k_T > k_B$), primarily depending upon the differences in activation energies with the compensating effects in the entropies of activation. It is concluded that in the competitive nitration of toluene and benzene with nitric acid in organic solvents, the polarity of solvents affects the relative rate constant (k_T/k_B) considerably.

Table 4. Activation parameter

Solvent	$\Delta E_B - \Delta E_T$ (kcal·mol^{-1})	$\Delta S_T^{\neq} - \Delta S_B^{\neq}$ (cal·mol^{-1}·deg^{-1})
Carbon tetrachloride	0.67	−0.56
n-Hexane	1.26	−2.3
Cyclohexane	1.35	−2.68
Nitromethane	1.83	−0.11

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 648—649 (1973)

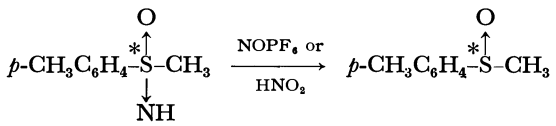
The Reaction of Elemental Sulfur with Organic Compounds. V. Reactions of Optically Active Sulfoximine with Elemental Sulfur and with Diphenyl Disulfide[1]

Shigeru OAE, Yoshiyuki TSUCHIDA, and Naomichi FURUKAWA

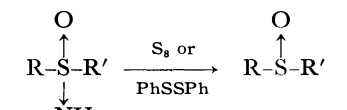
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received June 5, 1972)

The stereochemistry of sulfur compounds having S–N bonds such as sulfilimine and sulfoximine has recently drawn considerable attention.[2-7] Cram and his coworkers reported a stereospecific cleavage of S–N bond of sulfoximine with $NOPF_6$ or HNO_2 to afford the corresponding sulfoxide having the same configuration as that of the original sulfoximine.[2,3]



We reported a convenient method of deimination of sulfoximine by treatment with elemental sulfur or diphenyl disulfide to the corresponding sulfoxide in nearly quantitative yield.[1] In this paper we report on a stereochemical course and plausible mechanism of the reaction.



1: R=*p*-$CH_3C_6H_4$–, R′=CH_3–
2: R=Ph–, R′=CH_3–

The results of the reaction with optically active methyl *p*-tolyl sulfoximine are shown in the table. We see that the reaction proceeds stereospecifically retaining nearly completely the original configuration around the sulfur atom. The reaction with optically active methyl phenyl sulfoximine was found to give a similar result. These stereochemical observations suggest that the hybridization at sulfur atom of sulfoximine is left undisturbed in the course of the reaction.[8] A conceivable mechanistic pathway is shown below.

In view of the basic nature of the imino group of sulfoximine,[9] the initial step of the reaction is considered to involve a nucleophilic attack of the nitrogen atom of sulfoximine on the sulfur atom of S–S bond forming a dipolar intermediate (**3**). In the following step, **3** would decompose through the attack of thiolate anion on the nitrogen atom eventually cleaving off

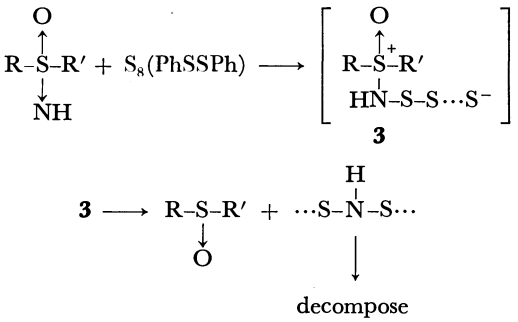
Table 1. Reaction of optically active sulfoximine

Reaction	$[\alpha]_D$ (optical purity)	Condition	Product	$[\alpha]_D$ (Optical purity)
(−)-(*R*)-**1**+S_8	−33.4° (100%)	neat 160°C 10 min	(+)-(*R*)-*p*-TolS(O)CH_3	+147° (98%)
(−)-(*R*)-**1**+PhSSPh	−33.4° (100%)	*o*-$C_6H_4Cl_2$ reflux 18 hr	(+)-(*R*)-*p*-TolS(O)CH_3	+148° (99%)
(+)-(*S*)-**2**+S_8	+33.8°	neat 160°C 10 min	(−)-(*S*)-PhS(O)CH_3	−141° (95%)

p-Tol=*p*-$CH_3C_6H_4$-

sulfoxide.[10] Thus the sulfoxide formed can maintain the same configuration as that of sulfoximine.



Experimental

Materials. Optically pure (−)-(*R*)-methyl *p*-tolyl sulfoximine ((−)-(*R*)-**1**) was prepared from optically pure (+)-(*R*)-methyl *p*-tolyl sulfoxide ($[\alpha]_D$=+150°, *c* 0.67, acetone) according to the method used by Cram *et al.*[2] $[\alpha]_D$=−33.4° (*c* 1.86, acetone); lit, $[\alpha]_D$=−33.4° (*c* 2.275, acetone).

(+)-(*S*)-Methyl phenyl sulfoximine ((+)-(*S*)-**2**) was prepared through resolution of sulfoximine according to the method used by Fusco and Tenconi.[11] To a solution of *d*-camphor-10-sulfonic acid (15 g) in ethanol was added methyl phenyl sulfoximine (6.5 g) and the mixture was refluxed for an hour. Acetone (50 ml) was then added to the reaction mixture and cooled in a refrigerator overnight. The crystals deposited were collected by filtration and recrystallized several times from a mixture of acetone–ethanol: mp 176°C, $[\alpha]_D$=+45.3° (methanol). The salt of sulfoximine-*d*-camphor-10-sulfonic acid was dissolved in a cold dilute sodium hydroxide solution and extracted with chloroform, washed with water and dried over anhydrous magnesium sulfate. After the solvent was evaporated, oily (+)-(*S*)-**2** was obtained and used for the reaction without further purification. $[\alpha]_D$=−33.8° (*c* 3.62, acetone).

Elemental sulfur was purified by recrystallization of commercial sulfur from benzene: mp 114°C.

Diphenyl disulfide was prepared from thiophenol by iodine oxidation in water: mp 61°C.

Reaction of (−)-(R)-1 with Sulfur. A mixture of 0.153 g (1 mmol) of (−)-(*R*)-**1** and 0.032 g (1 mg-atom) of sulfur was placed in a glass tube and heated in an oil bath maintained at *ca.* 160°C for 10 min. The red colored product was chromatographed on silica gel with chloroform as an eluent. Methyl *p*-tolyl sulfoxide was obtained as the main product in an almost quantitative yield. After recrystallization several times from ether–hexane, the optical rotation was measured; $[\alpha]_D$=+147° (*c* 0.54, acetone). The sulfoxide was 98% optically pure. Since the starting sulfoximine was nearly optically pure, the reaction is 98% stereospecific.

Reaction of (−)-(R)-1 with Diphenyl Disulfide. Diphenyl disulfide, 0.218 g (1 mmol), and (−)-(*R*)-**1**, 0.153 g (1 mmol) were dissolved in 5 ml of *o*-dichlorobenzene and refluxed for about 18 hr. The product was treated in a similar manner to that described above and the sulfoxide was obtained in 99% optical purity. $[\alpha]_D$=+148° (*c* 0.63, acetone).

Reaction of (+)-(S)-2 with Sulfur. This reaction was carried out in a similar manner to that described. After chromatography oily sulfoxide was obtained and the optical rotation was measured without further purification. $[\alpha]_D$=141° (*c* 19.3, ethanol) 95% optically pure (optically pure methyl phenyl sulfoxide, $[\alpha]_D$=149°[12]).

10) There is the possibility of substitution on the sulfur atom. If the nucleophilic attack of thiolate anion on the sulfur atom of **3** should occur to form a hypothetical pentacoordinated sulfur intermediate (**4**), the configuration of the resulting sulfoxide would be either retained, inverted or racemized depending on the mode of displacement on the sulfur atom. However, such a valence expanded sulfur intermediate is not necessary for interpreting the results of the stereochemistry of the reaction of optically active sulfoximine with sulfur or diphenyl disulfide.

The Reaction of Elemental Sulfur with Organic Compounds. VI.[1] ^{35}S-Tracer Study of Aromatic Displacement Reaction of Thianthrene, Phenoxathiin, Dibenzothiophene and Their Oxidation Compounds by Sulfur

Shigeru OAE, Shigeo MAKINO, and Yoshiyuki TSUCHIDA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received June 6, 1972)

We reported on aromatic displacement reactions which take place when diphenyl sulfide, diphenyl sulfone,[2] and halobenzenes[3] are heated with elemental sulfur at elevated temperature as follows.

$$Ph^{35}SPh + S \longrightarrow Ph^{35/2}SPh + {}^{35/2}S \quad (1)$$

$$Ph^{35}SO_2Ph + S \longrightarrow PhSPh + {}^{35}SO_2 \quad (2)$$

$$PhX + S \longrightarrow PhS_xPh + S_xX_2 \quad (3)$$

It is of interest that these three reactions essentially involve displacement of aromatic substituents (sulfonyl, sulfide groups and halogen) by a sulfur atom of elemental sulfur without any rearrangement or migration.[4] We have extended the investigation to reactions of elemental sulfur with a few polycyclic aromatic sulfur compounds, *i.e.*, thianthrene (**1**), phenoxathiin (**4**), dibenzothiophene (**7**), and their oxidation compounds (sulfones **2**, **5**, **8** and sulfoxides **3**, **6**, **9**). This paper will describe the reactions in detail.

Sulfur Exchange Reaction of 1, 4, and 7 with Elemental Sulfur. The results of the tracer experiments using ^{35}S-labeled compounds are shown in the table. The sulfur exchange reaction was found to take place when **1**-^{35}S or **4**-^{35}S was heated with elemental sulfur at above 300°C. Under similar reaction condition **7** did not undergo such reaction, while prolonged heating of the reactant resulted in the formation of a polymer-like substance with evolution of H_2S. This is reasonable since the strength of C–S bond of **7** is increased by the intraresonance stabilization of the thiophene ring to retard the cleavage of C–S bond.

Reactions of 2, 5, and 8 with Sulfur. The reduction of **2** by elemental sulfur to **1** was reported earlier.[5] The reactions of **5** and **8** with elemental sulfur were found to proceed under the usual conditions giving the corresponding reduction compounds **4** and **7** respectively. The results of the tracer experiments of these reactions are also shown in the table. We see that

TABLE 1. ^{35}S-TRACER EXPERIMENT

Reactant ($\times 10^5$ cpm/mmol)	Product ($\times 10^5$ cpm/mmol)	Displacement of sulfur (%)	Reaction condition	Yield of product (%)
1 (5.23)[a]	**1** (4.44)	85.2	320°C 2 hr	69

a) Radioactivity of elemental sulfur-35. In these reactions nonactive reactants (**1**, **4**, **7**, **8**, and **9**) were reacted with radio active elemental sulfur.

the sulfonyl group in all the sulfones **2**, **5**, and **8** was replaced by sulfur atom of elemental sulfur in the main path of the reaction. The fact that these three reactions do not proceed *via* a simple reduction, namely the S–O bond cleavage of the sulfonyl group, can be attributed to the large bond strength of S–O bond in these sulfones.[6]

Reactions of 3, 6, and 9 with Sulfur. We carried out the reduction of the sulfoxides **3**, **6**, and **9** which have a weaker S–O bond than that of sulfone.[6] These sulfoxides were found to be reduced to the corresponding sulfides at somewhat lower temperatures than for the sulfones. The tracer experiments (Table) clearly suggest the reaction to be a simple reduction (S–O bond cleavage).

Mechanism of the Reaction. Sulfur is known to undergo homolytic cleavage of S–S bond at an elevated temperature and to exist as a mixture of many allotropes S_2, S_3, S_4, *etc.*[7] In these aromatic displacement reactions these allotropes of sulfur, which are expected to be active radical species, seem to be actually involved in the initial attack on the aromatic carbon atom bearing sulfur atom, although the subsequent steps are still unclarified. A plausible mechanistic pathway is as follows.

Experimental

Materials. Compounds **1**, **4**, and **7** were prepared by the usual method. **1**, mp 155°C (lit,[8] 159°C); **4**, mp 56.5°C (lit,[9] 57.5—58°C); **7**, mp 96°C (lit,[10] 99°C).

Radioactive **1**, **4**, and **7**. A mixture of **1** (3.04 g) and radioactive sulfur (0.90 g) was heated for 2 hr at *ca.* 330°C. The resulting mixture was poured into 10% aqueous NaOH solution and refluxed for 3 hr to remove elemental sulfur. The water insoluble **1**-^{35}S was filtered and recrystallized from methanol. Compound **4**-^{35}S was prepared similarly by the sulfur exchange reaction of **4** with radioactive elemental sulfur.

Radioactive **2**, **3**, **5**, and **6** were prepared by oxidation of **1**-^{35}S or **4**-^{35}S with a required amount of 30% H_2O_2 in acetic acid. **2**-^{35}S, mp above 300°C (lit,[11] 324°C); **3**-^{35}S, mp 137.5°C (lit,[12] 143°C); **5**-^{35}S, mp 143°C (lit,[13] 147—148°C); **6**-^{35}S, mp 150.5—151°C (lit,[13] 158—159°C).

Compounds **8** and **9** were similarly prepared from **7**. **8**, mp 227.5—228°C (lit,[14] 230°C); **9**, mp 185.5°C (lit,[15] 188°C).

Reactions of 1—9 with Elemental Sulfur. The reactions were carried out by the following general procedure. A mixture of 1 mmol of aromatic sulfur compound and 1 matom of sulfur (2 matom in the case of the reactions of **1** and **2**) was placed in a glass tube and heated in a metal bath. The resulting mixture was poured into 10% aqueous NaOH solution and refluxed for several hours. After cooling, the water insoluble precipitate was filtered and passed through a column elution chromatography (silica gel, hexane) and then recrystallized from alcohol for counting of activity.

Counting of Radioactivities. The activities of all the compounds were counted by TEN liquid scintillation counter in toluene solution using POPOP as a scintillator.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 651—653 (1973)

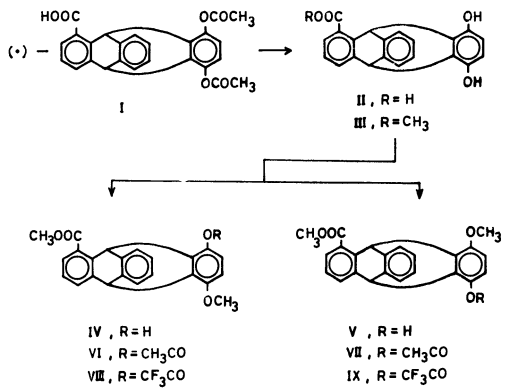
Optically Active Triptycenes. III.* Synthesis of Optically Active 2-Methoxy-5-acyloxy- and 2-Acyloxy-5-methoxy-7-methoxycarbonyltriptycenes

Fumio OGURA and Masazumi NAKAGAWA

Department of Chemistry, Faculty of Science, Osaka University Toyonaka, Osaka 560

(Received June 12, 1972)

A report was given on the synthesis and optical resolution of 2,5-diacetoxy-7-carboxytriptycene (I).[1] The present paper deals with the transformation of (+)-I into the title compounds. As outlined in Scheme 1, (+)-2,5-dihydroxy-7-carboxytriptycene (II) obtained by the hydrolysis of (+)-I was converted into (+)-methyl ester (III). Monomethylation of (+)-III by the Robinson method[2] with some modification afforded (+)-2-methoxy-5-hydroxy-7-methoxycarbonyltriptycene (IV) and 2-hydroxy-5-methoxy-7-methoxycarbonyltriptycene (V) together with a small amount of 2,5-dimethoxy-7-methoxycarbonyltriptycene and 7-methoxycarbonyltriptycene-2,5-quinone. Formation of the quinone seems to be attributable to the presence of a small amount of peroxide in tetrahydrofuran used as a solvent. The isomeric (+)-IV and (+)-V could be separated on column chromatography on alumina. Treatment of (+)-IV and (+)-V with dimethyl sulfate afforded an identical dimethyl ether, 2,5-dimethoxy-7-methoxycarbonyltriptycene. The structures of IV and V could be confirmed by IR spectroscopy, *i.e.*, the IR spectrum in chloroform of



Scheme 1.

* For a preliminary report, see Ref. 6. For part II of this series, see Ref. 7.

1) A. Sonoda, F. Ogura, and M. Nakagawa, This Bulletin, **35**, 853 (1962).

2) R. Robinson and J. C. Smith, *J. Chem. Soc.*, **1926**, 393.

IV exhibits a broad absorption due to hydrogen bonded hydroxyl group even in a dilute solution indicating the proximate spatial positions of hydroxyl and methoxycarbonyl groups. On the other hand, the absorption of associated hydroxyl group observed in the spectrum of V disappeared on dilution indicating the absence of intramolecular hydrogen bonding. The fact that the carbonyl stretching vibration ($\nu_{C=O}$) of IV in chloroform is observed at a lower wave number (1710 cm^{-1}) than that of V (1720 cm^{-1}) is also consistent with the assigned structures.

Acylation of (+)-IV and (+)-V with acetic and trifluoroacetic anhydrides gave two sets of optically active isomers, VI, VII and VIII, IX. The structures of VI and VII were also supported by the measurement of dipole moment using 2-acetoxy-5-methoxytriptycene as a reference substance[3] which was prepared by a similar procedure from 2,5-dihydroxytriptycene.[4]

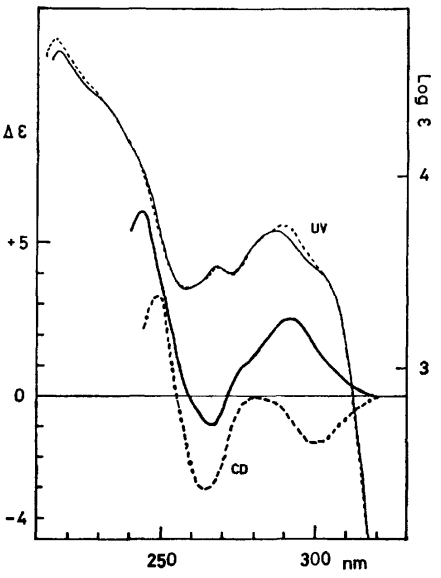


Fig. 1. UV and CD spectra of VI (——) and VII (----) in dioxane.

The absolute configurations of optically active triptycenes described above are evident in relation to I, *i.e.*, all of them have 1*R*,6*S* configuration since the absolute configuration of (+)-2,5-dimethoxy-7-methoxycarbonyltriptycene derived from (+)-I was proved to be 1*R*,6*S* on the basis of X-ray structure analysis by the Bijvoet method.[5] The UV and CD spectra of (+)-VI and (+)-VII are shown in Fig. 1. The sign of the longest wavelength Cotton effect is reversed as suggested by the ORD data.[6] This indicates that the center of transition dipole of $^1B_{2u}$ state in the hydroquinone ring is displaced in opposite direction according to the inversion of the position of electron attractive substituent. However, the CD spectral pattern at shorter wavelength region suggests that the effect is restricted to the $^1B_{2u}$ state.

Experimental

The experimental procedures refer to optically active substances unless otherwise stated. The IR and UV spectra were obtained on Hitachi EPI-2 and Hitachi EPS-2 spectrophotometers, respectively. The optical rotations and CD spectra were measured with a Rudolf Model 200S-80 spectropolarimeter and a Roussel-Jouan Dichrograph B, respectively. The inflections and shoulders are indicated by an asterisk.

2,5-Dihydroxy-7-methoxycarbonyltriptycene (III). A mixture of II[6] (1.0 g), methanol (5 ml) and concentrated sulfuric acid (0.3 ml) was refluxed for 8 hr. After being left standing overnight, the crystals deposited were washed successively with methanol and water to yield pure III, mp 294—297°C [racemate, mp 285—290°C].

Found: C, 76.59; H, 4.74%. Calcd for $C_{22}H_{16}O_4$: C, 76.73; H, 4.68%.

IR (KBr-disk): 3600—3100 (ν_{O-H}), 1680 ($\nu_{C=O}$) [racemate, 1683] cm^{-1}. UV: $\lambda_{max}^{dioxane}$ (ε) 298 (8610), 269.5 (2940), 261.5 (2370), 214.5 (45400) nm. ORD (15°C): $[M]_{5791}$ +95.0°, $[M]_{5461}$ +115.7°, $[M]_{4358}$ +230.4°, $[M]_{4047}$ +318.9°, $[M]_{3650}$ +547.5° (*c* 0.420, dioxane).

2-Methoxy-5-hydroxy-7-methoxycarbonyltriptycene (IV), 2-Hydroxy-5-methoxy-7-methoxycarbonyltriptycene (V), 2-Methoxy-5-acetoxy-7-methoxycarbonyltriptycene (VI), and 2-Acetoxy-5-methoxy-7-methoxycarbonyltriptycene (VII). A solution of III (4.50 g) in tetrahydrofuran (90 ml) was mixed with sodium methoxide in methanol (from sodium, 0.6 g and methanol, 75 ml). To the resulting suspension of sodium salt was added a solution of dimethyl sulfate (1.6 g) in tetrahydrofuran (15 ml) in an atmosphere of nitrogen. After being stirred overnight and left to stand overnight, the product dissolved in benzene–tetrahydrofuran (5: 1) was chromatographed on alumina (130 g) and eluted successively with benzene–tetrahydrofuran (5: 1 and 1: 1), tetrahydrofuran, and tetrahydrofuran–methanol (100: 1 and 10: 1). Dimethyl ether and quinone derivatives were obtained from benzene–tetrahydrofuran eluate and could be separated on re-chromatography on alumina. Tetrahydrofuran and tetrahydrofuran–methanol (100: 1) eluates afforded a mixture of IV and V, the former in abundance. A mixture of the same isomers rich in V was obtained from tetrahydrofuran–methanol (10: 1) eluate.

Acetylation: A mixture containing a larger amount of IV (0.5 g) in tetrahydrofuran (10 ml) was refluxed with acetic anhydride (1.5 g) for 1.5 hr to yield VI, mp 270—271°C (from methyl acetate) [racemate, mp 279—280°C], IR (KBr-disk): 2855 (ν_{C-H}, $-OCH_3$), 1765 ($\nu_{C=O}$, CH_3COO-), 1716 ($\nu_{C=O}$, $-COOCH_3$) cm^{-1}.

Similarly, a mixture rich in V afforded VII, mp 278—279°C (from methanol–methyl acetate) [racemate, mp 269—270°C, from methyl acetate], IR (KBr-disk): 2845 (ν_{C-H}, $-OCH_3$), 1750 ($\nu_{C=O}$, CH_3COO-), 1722 ($\nu_{C=O}$, $-COOCH_3$) cm^{-1}.

Found: VI, C, 74.48; H, 5.01%. VII, C, 74.69; H, 5.06%. Calcd for $C_{25}H_{20}O_5$: C, 74.99; H, 5.03%.

UV: $\lambda_{max}^{dioxane}$ (ε) VI, 217 (45700), 268 (3470), 288 (5290); VII, 216 (52700), 268.5 (3410), 290 (5660) nm. ORD: VI (15°C), $[M]_{5791}$ +402.4°, $[M]_{5461}$ +466.5°, $[M]_{5000}$ +583.0°, $[M]_{4358}$ +873.5°, $[M]_{4047}$ +1104°, $[M]_{3650}$ +1312° (*c* 0.8975, dioxane); VII (16.5°C), $[M]_{5791}$ +3.0°, $[M]_{5000}$ +3.0°, $[M]_{4358}$ −23.6°, $[M]_{4047}$ −51.3°, $[M]_{3650}$ −152.2°

(c 0.7990, dioxane). CD: $\lambda_{max}^{dioxane}$ ($\Delta\varepsilon$) VI, 291 (+2.6), 266.5 (−1.07), 244 (+6.12); VII, 300 (−1.51), 266 (−3.07), 262.5 (−2.92), 249 (+3.31) nm.

Hydrolysis and Esterification: A mixture of *dl*-VI (0.50 g), acetic acid (35 ml) and 3N sulfuric acid (15 ml) was refluxed for 8 hr to yield 2-methoxy-5-hydroxy-7-carboxytriptycene (0.4 g, mp 280—287°C). The crude material in acetone–methanol was treated with an ethereal solution of diazomethane to afford *dl*-IV, mp 279—280°C (from benzene).[7] The same treatment of *dl*-VII gave 2-hydroxy-5-methoxy-7-carboxytriptycene, mp 290—302°C which gave *dl*-V, mp 255—258°C (from benzene) on treatment with diazomethane. Optically active VI and VII were converted into IV, mp 249—251°C and V, mp 256—258°C by the same method.

Found: IV, C, 76.91; H, 5.01%. V, C, 77.73; H, 5.06%. Calcd for $C_{23}H_{18}O_4$: C, 77.08; H, 5.06%.

IR (KBr-disk): IV, 3700—3200 (ν_{O-H}), 2840 (ν_{C-H}, $-OCH_3$), 1707 ($\nu_{C=O}$, $-CO_2CH_3$); V, 3700—3100 (ν_{O-H}), 2840 (ν_{C-H}, $-OCH_3$), 1715, 1695 ($\nu_{C=O}$, $-CO_2CH_3$) cm^{-1}. ORD: IV (14—16°C), $[M]_{5791}$ −120.4°, $[M]_{5461}$ −121.5°, $[M]_{5000}$ −144.1°, $[M]_{4358}$ −210.4°, $[M]_{4047}$ −273.1°, $[M]_{3650}$ −482.4° (c 0.286, dioxane); V (12.5—16°C), $[M]_{5791}$ −76.7°, $[M]_{5461}$ −85.7°, $[M]_{5000}$ −113.2°, $[M]_{4358}$ −179.2°, $[M]_{4047}$ −236.9°, $[M]_{3650}$ −382.0° (c 0.472, dioxane).

2-Methoxy-5-trifluoroacetoxy-7-methoxycarbonyltriptycene (VIII) and 2-Trifluoroacetoxy-5-methoxy-7-methoxycarbonyltriptycene (IX). Trifluoroacetylation of mixtures of IV and V followed by chromatography on silica gel according to the method used for VI and VII afforded VIII, mp 262—263°C (from benzene–benzine) and IX, mp 241—243°C (from benzene–benzine).

Found: VIII, C, 66.30; H, 4.10%. IX, C, 66.50; H, 3.87%. Calcd for $C_{25}H_{17}O_5F_3$: C, 66.08; H, 3.77%.

IR (Nujol mull): VIII, 1805 ($\nu_{C=O}$, CF_3CO_2-), 1722 ($\nu_{C=O}$, $-CO_2CH_3$); IX, 1802 ($\nu_{C=O}$, CF_3CO_2-), 1716 ($\nu_{C=O}$, $-CO_2CH_3$) cm^{-1}. UV: $\lambda_{max}^{dioxane}$ (ε) VIII, 215.5 (48500), 267 (3910), 285 (4910); IX, 215 (49300), 261 (3580), 267.5 (4010), 288 (5420) nm. ORD: VIII (12—14°C), $[M]_{5791}$ +379.1°, $[M]_{5461}$ +441.2°, $[M]_{5000}$ +565.7°, $[M]_{4358}$ +842.0°, $[M]_{4047}$ +1059°, $[M]_{3650}$ +1558° (c 0.2780, dioxane); IX (11—14°C), $[M]_{5791}$ −3.8°, $[M]_{5461}$ −9.1°, $[M]_{4358}$ −42.3°, $[M]_{4047}$ −85.4°, $[M]_{3650}$ −191.3° (c 0.3990, dioxane).

2-Acetoxy-5-methoxytriptycene and 2,5-Dimethoxytriptycene. According to a previously described method, 2,5-dihydroxytriptycene[4] was methylated and the product was chromatographed on alumina. The benzene–tetrahydrofuran (10: 1) eluate afforded the dimethyl derivative, mp 241—243°C (from acetic acid).

Found: C, 84.21; H, 5.80%. Calcd for $C_{22}H_{18}O_2$: C, 84.05; H, 5.77%.

IR (KBr-disk): 2850 (ν_{C-H}, $-OCH_3$) cm^{-1}. UV: $\lambda_{max}^{dioxane}$ (ε) 217 (57300), 262 (2720), 271 (3030), 277.5 (4430), 294 (4,050) nm.

Acetylation of the monomethylated product obtained from the tetrahydrofuran–methanol (100: 1) eluate yielded 2-acetoxy-5-methoxytriptycene, mp 274—275.5°C (from acetic acid).

Found: C, 80.77; H, 5.29%. Calcd for $C_{23}H_{18}O_3$: C, 80.68; H, 5.30%.

IR (KBr-disk): 2850 (ν_{C-H}, $-OCH_3$), 1745 ($\nu_{C=O}$, CH_3CO_2-) cm^{-1}. UV: $\lambda_{max}^{dioxane}$ (ε) 217 (58500), 261 (2990), 270 (3140), 277.5 (3880), 288 (2040) nm.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 653—655 (1973)

The Synthesis of [6.0.6.0]Paracyclophane

Riichiro NAGANO, Joji NISHIKIDO, Takahiko INAZU,* and Tamotsu YOSHINO

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received June 14, 1972)

It has been reported that 1,6,19,24-tetraaza[6.0.6.0]- and 1,6,19,24-tetraoxa[6.0.6.0]paracyclophane form an inclusion compound with benzene or dioxane.[1,2] These cyclophanes have nitrogen or oxygen atoms attached to biphenyl nuclei. To see if the presence of such hetero atoms had any effect on the inclusion of a guest molecule in an empty space of the macro cyclic compounds, [6.0.6.0]paracyclophane, I, constructed with two biphenyl nuclei and two hexamethylene bridges, was synthesized as a reference compound free from hetero atoms. No addition compound of the I cyclophane with benzene has been isolated under similar conditions. [6.0.6.0]Paracyclophane, I, and its open-chain model compound, XI, were synthesized as is shown in Figs. 1 and 2. We adopted the acyloin condensation of the diester, V, in the ring-closing step. In the NMR spectrum of I, the signals for aromatic protons showed an A_2B_2 pattern, and the peaks of I, centered at 7.15 ppm, were found to shift toward an upper field by 0.18 ppm compared with those of the open-chain model, XI.

The electronic spectrum of I (λ_{max} 255 nm, ε_{max} 2.9×10^4 in *n*-hexane) showed a slight blue shift and a hypochromic effect compared with that of the open-chain compound, XI, (λ_{max} 258 nm, ε_{max} 4.46×10^4 in *n*-hexane), the shapes of the curves being virtually the same. The shapes of the electronic spectra of 1:1 electron-donor-acceptor complexes of I and XI with tetracyanoethylene (TCNE) in dichloromethane were virtually the same. However, the λ_{max} at the longest wavelength in the spectra (λ_{max} 398, 418, 578 nm) of the I-TCNE complex showed a blue shift by 10 nm compared with that in the spectra (λ_{max} 400, 417, 588 nm; ε 588 nm 770) of the XI–TCNE complex. Accordingly, the I–TCNE complex appears, unexpect-

Experimental

All the melting and boiling points are uncorrected. The electronic spectra were measured on a Hitachi EPS-3T spectrophotometer. The NMR spectra were recorded on a Hitachi R-20 model at 60 MHz, using tetramethylsilane as the internal standard and $CDCl_3$ as the solvent.

1,6-Bis[4'-(2-ethoxycarbonylethyl)-4-biphenylyl]-1,6-hexanedione, III. Procedure A: Ethyl biphenyl-4-acrylate[4] was reduced to ethyl biphenyl-4-propionate, II, by catalytic hydrogenation with palladium-on-carbon in ethanol at room temperature. Into a mixture of 80.5 g of the ester, II, and 28.9 g of adipyl chloride in 500 ml of tetrachloroethane, we stirred

4) D. H. Hey, *J. Chem. Soc.*, **1931**, 2478.

150 g of anhydrous aluminum chloride, portion by portion, at −10°C. The dark green reaction mixture was kept below 0°C for 7 hr and was then allowed to come to room temperature. The mixture was poured onto crushed ice. The organic layer was separated, and the solvent was removed by steam distillation. A light brown solid was thus obtained.

1,6-Bis[4'-(2-ethoxycarbonylethyl)-4-biphenylyl]hexane, V. Procedure B: A mixture of 6.2 g of the keto ester, III, and 70 g of 80% hydrazine hydrate in 400 ml of ethylene glycol was refluxed for an hour. Then potassium hydroxide was slowly added in small portions. The yellowish-gray mixture was refluxed for 24 hr, while two 50 ml portions of 80% hydrazine hydrate and 100 ml portions of ethylene glycol were added at 10 hr intervals. After the usual treatment, a crude reduction product, IV, was obtained. This reduction product, IV, was esterified by the usual method.

3-Hydroxy-4-oxo[6.0.6.0]paracyclophane, VI. A solution of 4.43 g of the diethyl ester, V, in 1 l of xylene was stirred into 2.90 g of dispersed sodium in 1 l of xylene over 41 hr under a nitrogen atmosphere. The usual work-up of the reaction mixture[5] then gave crude acyloin, 1.136 g (30.1%). A small sample was chromatographed on silica gel with benzene.

[6.0.6.0]Paracyclophane, I. Activated zinc was prepared by swirling 12 g of zinc with a solution of 1.5 g of $HgCl_2$ and 1.5 ml of concentrated HCl in 28.5 ml of water. To the zinc we then added 20 ml of glacial acetic acid, 40 ml of toluene, 20 ml of concentrated HCl, and 251 mg of the acyloin.

The mixture was refluxed for 10 hr, during which time two 30 ml portions of concentrated HCl were added. After the usual treatment, 165 mg of the crude I was obtained (70%). The crude cyclophane, I, was chromatographed on silica gel with benzene; the subsequent evaporation of the column filtrates gave solid residues. In the mass spectrum, the molecular ion peak was found as the base peak at *m/e* 472 (Hitachi RMS-4 model).

The equilibrium constant of the XI–TCNE complex was determined to be $K=1.53$ l/mol by a modified Benesi-Hildebrand plot.[6]

Organic Syntheses by Means of Noble Metal Compounds. XLIX.[1] Oxidation of 3-Hexenedioate to 2,4-Hexadienedioate Catalyzed by Palladium Chloride and Copper(II) Chloride

Tosaku SUSUKI and Jiro TSUJI

Basic Research Laboratories, Toray Industries Inc., Kamakura

(Received June 21, 1972)

Divalent palladium is a unique oxidizing agent and it can abstract hydrogen from various organic compounds.[2] This is exemplified in the nucleophilic substitution of olefins and coupling of aromatic compounds in its presence. This led us to investigate the possibility of liquid phase oxidative dehydrogenation of carbonyl compounds to α,β-unsaturated compounds as shown below.

$$-\overset{\overset{\displaystyle O}{\|}}{C}-CH_2CH_2- \longrightarrow -\overset{\overset{\displaystyle O}{\|}}{C}-CH=CH-$$

An attempted oxidation of cyclohexanone with palladium chloride in acetic acid gave phenol, probably formed through cyclohexenone, but it was impossible to stop the reaction at the stage of cyclohexenone formation.[3] The oxidation of diethyl 3-hexenedioate (I) was then attempted in acetic acid in the presence of sodium acetate. As expected, the ester was dehydrogenated smoothly to give 2,4-hexadienedioate(II) (diethyl *trans,trans*-muconate) in 78% yield.

$$EtO_2C-CH_2CH=CHCH_2-CO_2Et \quad (I)$$

$$\longrightarrow EtO_2C-CH=CH-CH=CH-CO_2Et \quad (II)$$

As is often the case in the oxidation reaction with divalent palladium, addition of cupric chloride made the reaction catalytic with regard to palladium chloride.

The reaction can be explained in the following way. At first, the acidic α hydrogen of I is abstracted with the base to give anion, which attacks palladium chloride to form μ-dichlorobis(1-carbethoxy-3-carbethoxymethyl-π-allyl)dipalladium(III). The formation of π-allylic complexes from β,γ-unsaturated esters is a known reaction.[5] The acidic hydrogen α to the ester group in the complex III is then abstracted, followed by reductive elimination of palladium to give rise to II. Reoxidation of the reduced palladium with cupric

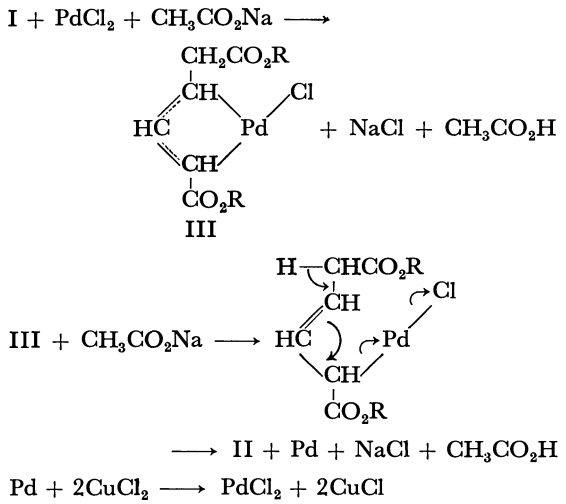
3) Selective oxidation of cyclohexanone and other ketones to α,β-unsaturated ketones using bis(triphenylphosphine)dichloropalladium was recently reported.[4]

4) R. J. Theissen, *J. Org. Chem.*, **36**, 752 (1971).

5) J. Tsuji and S. Imamura, This Bulletin, **40**, 197 (1967).

chloride makes the reaction a catalytic cycle with palladium. As an evidence of this mechanism, complex III was isolated when a part of the reaction mixture was taken out during the course of reaction.



The reaction is another example of the unique oxidation catalyzed by palladium chloride. It is feasible because of two properties of divalent palladium, π-allylic complex formation from β,γ-unsaturated esters and abstraction of active hydrogens.

Experimental

A mixture of palladium chloride (3.6 g, 0.02 mol), sodium acetate (6.0 g), ethyl 3-hexenedioate (8.0 g, 0.04 mol) in acetic acid (60 ml) was stirred at 70° for 50 min, during which period metallic palladium precipitated gradually. After filtration, the solution was diluted with water and extracted with ether. Distillation of the ethereal solution gave an oily mixture (7.0 g, 125—130°C/6 mm) which partly crystal lized on cooling. Filtration and recrystallization from *n*-hexane gave crystals (3.1 g, 78%) which proved to be diethyl *trans*, *trans*-muconate, and were identified by their IR and NMR spectra and mixed mp determination (60—61°C) with an authentic sample.

Catalytic process was carried out in the following way. Diethyl 3-hexenedioate (10 g) was heated with a mixture of palladium chloride (1.8 g), cupric chloride (13 g) and sodium acetate (6 g) in acetic acid (60 ml) at 80° for 7 hr stirring. After the usual work-up, an oily distillate was isolated (8.5 g, 110—120°C/6 mm). Gas chromatographic analysis showed that the distillate contained 6.4 g of ethyl muconate.

Convenient Preparation of Methyl 2-Acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside

Kazuhiko YAMAMOTO and Taku HAYASHI

Department of Chemistry, Osaka University College of Science, Toyonaka, Osaka

(Received June 22, 1972)

The *O*-benzylidene group is a good protective group for preparing several sugar derivatives, but some difficulties in its preparation and the lower yield of product have sometimes been encountered in reactions of sugar with benzaldehyde and a catalyst. The use of freshly-distilled benzaldehyde and anhydrous zinc chloride seems to give a higher yield.[1] In order to eliminate some tedious treatments, the preparation of the *O*-benzylidene group by an acetal exchange reaction was attempted. Its use in the preparation of methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside (II) led to an almost quantitative yield. When methyl 2-acetamido-2-deoxy-α-D-glucopyranoside (I) was treated with benzaldehyde dimethyl acetal and a catalytic amount of *p*-toluenesulfonic acid in dimethylformamide (DMF), the reaction was shown to be completed within 1 hr, judging from the thin-layer chromatogram of the reaction mixture. Moreover, benzaldehyde dimethylacetal was also found to be more suitable for *O*-benzylidenation because the reagent, stored for several months, gave the same yield of the *O*-benzylidenated product.

When the same reaction was performed under reduced pressure, methyl 2-acetamido-3-*O*-(α-methoxybenzyl)-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside (III) was found to be produced in the reaction mixture, but it was not produced under atmospheric conditions. The structure of (III) was confirmed by elemental analysis and NMR spectroscopy, and was also supported by the experimental evidence that (III) was formed by the reaction of (II) with benzaldehyde dimethylacetal under reduced pressure.

No 3-*O*-substitution with the α-methoxybenzyl group in 4,6-*O*-benzylidene sugar has been found so far; therefore, this seems to be the first example of a mixed acetal of benzaldehyde between the hydroxyl of sugar and simple alcohol. The 3-*O*-(α-methoxybenzyl) group was found to be more acid-labile than the 4,6-*O*-benzylidene group, as had been expected; it was removed selectively by treatment with 90% acetic acid at 0°C. The thin-layer chromatographic analysis of 90% acetic acid hydrolysis for (III) is shown in Fig. 1.

Recently, during the preparation of our manuscript, Evans[2] reported the preparation of methyl 4,6-*O*-benzylidene-α- and β-D-glucopyranosides by a similar

manner and noted that the preparation of the *O*-benzylidene group with benzaldehyde dimethyl acetal and *p*-toluenesulfonic acid was a better procedure.

Experimental

The melting points were determined with a micro melting point apparatus (Yanagimoto, MFG) and uncorrected. The optical rotations were measured with a Jasco DIP-SL photoelectric automatic polarimeter at 25.0°C. The NMR spectra were recorded with a Varian T-60 NMR spectrometer. Thin-layer chromatography was performed on Silica gel H (Merck) developed with the solvent (toluene: acetone: pyridine= 2: 1: 1), and spots were detected by spraying with 5% methanol–sulfuric acid.

Benzaldehyde dimethyl acetal was prepared by the method of Claisen,[3] using methyl orthoformate instead of the ethyl derivative, and showed bp 215—218°C/760 mmHg (lit,[4] 207°C).

Reaction of I with Benzaldehyde Dimethyl Acetal under Atmospheric Pressure. To a solution of I[5] (5.0 g) in 50 ml of dimethylformamide, we added 14 ml of benzaldehyde dimethyl acetal and 0.5 g of *p*-toluenesulfonic acid; the reaction was then performed at 40°C for 1 hr. After determining the completion of the reaction by thin-layer chromatography, which indicated a spot (R_f 0.54) corresponding to authentic (II)[6] and the disappearance of (I), the reaction mixture was evaporated *in vacuo* to dryness. The white residue was suspended in a dilute sodium bicarbonate solution and collected by filtration. The crystallization of dried raw product from methanol gave a pure (II) (6.3 g, 91%); mp 255—259°C (lit,[6] 255°C), $[\alpha]_D^{25}$ +75.5° (*c*, 1.04, dimethylformamide), (lit, +19° chloroform,[6] +70° chloroform[7]). Found: C, 56.77; H, 6.68; N, 4.12%. Calcd for $C_{16}H_{21}O_6 \cdot H_2O$: C, 56.29; H, 6.79; N, 4.10%.

The $[\alpha]_D$ value observed by Kasai was referred to because his value was comparable to our value and because he used the α-glycoside purified by column chromatography. (The $[\alpha]_D$ values reported for I were +105° by Neuberger and +131° by Kasai.[7])

Reaction under Reduced Pressure. a): The same reaction mixture as above was kept at 40°C under reduced pressure (15 mmHg) for 8 hr. A similar treatment of the reaction mixture afforded 7.3 g (78%) of a crystalline (III), which showed a mp of 193—196°C and $[\alpha]_D^{25}$ +52.5° (*c*, 1.22, dimethylformamide); NMR spectrum (in deuteriochloroform, with tetramethylsilane as the internal standard). δ 7.43 m; (aromatic, 10H), 5.60 s; (CH of acetal, 2H), 4.80 d; (anomeric, 1H) 3.44 s; (OMe of acetal, 3H), 2.04 s; (OMe of glycoside, 3H) 1.15 s; (NAc, 3H). Found: C, 65.17; H, 6.85; N, 3.18%. Calcd for $C_{24}H_{29}O_7N$: C, 65.00; H, 6.59; N, 3.16%.

b): A solution of 5.0 g of (II), 14 ml of benzaldehyde dimethyl acetal, and 0.5 g of *p*-toluenesulfonic acid in 50 ml of dimethylformamide was allowed to react under reduced pressure (15 mmHg) at 40°C for 8 hr; then, the mixture was treated as has been mentioned above. The crystallization of the crude product gave 6.0 g (92%) of a crystalline III. Mp 192—196°C, $[\alpha]_D^{25}$ +51.7° (*c*, 1.02, dimethylformamide) Found: C, 64.87; H, 6.82; N, 3.16%. Calcd for $C_{24}H_{29}O_7N$: C, 65.00; H, 6.59; N, 3.16%.

The melting point was not depressed by admixture of the specimen prepared in a).

Acid Hydrolysis of III. A 10 mg portion of (III) dissolved in 1 ml of 90% acetic acid (v/v), was kept in an ice bath (0°C). Aliquots of 0.3 ml were removed at 1-, 3- and 6- min intervals and neutralized with 0.5 ml of pyridine. Each sample removed at each interval was applied to a tlc plate, and developed with toluene: acetone: pyridine (2: 1: 1). The thin-layer chromatogram of the hydrolysates is shown in Fig. 1. It can be concluded from the thin-layer chromatogram that the 3-*O*-(α-methoxybenzyl) group of III is completely hydrolysed by 90% acetic acid over 6 min at 0°C, while, on the contrary, the 4,6-*O*-benzylidene group was not affected under these conditions.

The authors are most grateful to Professor Y. Matsushima (Faculty of Science, Osaka University) for his continued interest and support during this work.

The Preparation of *p*-Nitrophenyl 2-Acetamido-3-*O*-methyl-2-deoxy-β-D-glucopyranoside

Kazuhiko YAMAMOTO

Department of Chemistry, Osaka University College of Science, Toyonaka, Osaka

(Received June 30, 1972)

The title compound is required for a mechanistic study on the *N*-acetyl-β-D-glucosaminidase [EC. 3.2.1. 30] hydrolysis. The 3-*O*-substitution of 2-acetamido-2-deoxy-D-glucose is usually achieved by a reaction on the 4,6-*O*-benzylidene derivative as an intermediate.[1] However, in the case of *p*-nitrophenyl glycoside which is very acid-labile, the destruction of glycoside occurs when the 4,6-*O*-benzylidene group is removed. The cleavage of *p*-nitrophenyl glycoside under the conditions which had been used for debenzylidenation (in 66% acetic acid at 100°C for 30 min) was determined. The results (Table 1) indicate that *ca.* 30% of the *p*-nitrophenyl 2-acetamido-2-deoxy-β-D-glucopyranoside is damaged under those conditions. A more easily removable group than *O*-benzylidene was desirable, and *p*-methoxybenzylidene group was selected because it was found to be cleaved by the milder treatment.[2] Moreover, a further application of *O*-(*p*-methoxybenzylidene)-blocking and an improved procedure for *O*-benzylidenation was attempted in connection with the previous studies.[2,3] *O*-Benzylidene formation by acetal exchange reaction was recently reported as a convenient method.[3,4] Although *p*-methoxybenzaldehyde was less reactive than benzaldehyde, the preparation of 4,6-*O*-(*p*-methoxybenzylidene) derivative in good yield by the acetal exchange reaction of *p*-methoxybenzaldehyde dimethyl acetal was also successful.

20 min	22%	1.7%
30 min	29%	2.1%

The treatment of I with *p*-methoxybenzaldehyde dimethyl acetal and a catalytic amount of *p*-toluenesulfonic acid under reduced pressure afforded an almost quantitative yield of II, which was then methylated by Kuhn's method. Then, the removal of 4,6-*O*-(*p*-methoxybenzylidene) group led to the title compound (IV). The conditions for the removal of the blocking group were successfully achieved by the treatment with 90% acetic acid at 100°C for 1 min.

The synthetic scheme and compounds prepared are shown in Fig. 1.

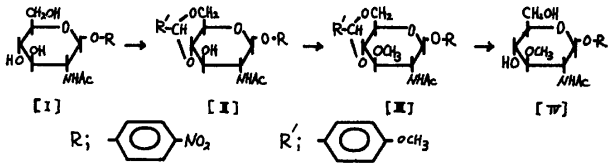

Fig. 1.

Experimental

The melting points were determined by means of the Yanagimoto-micro melting point apparatus and uncorrected. Optical rotations were measured by means of a recording spectropolarimeter (Yanagimoto ORD-185). Thin-layer chromatography was performed on Silica Gel H (Merck), and spots were detected with 5% sulfuric acid in methanol.

p-Methoxybenzaldehyde dimethyl acetal was prepared by the method of Claisen.[5] Methyl orthoformate was used in place of ethyl orthoformate. Bp 95—96°C/1.0 mmHg (lit,[6] bp 261—263°C/760 mmHg). (Found: C, 65.96; H, 7.76%. Calcd for $C_{10}H_{14}O_3$: C, 65.91; H, 7.74%).

p-Nitrophenyl 2-Acetamido-4,6-O-(p-methoxybenzylidene)-2-deoxy, β-D-glucopyranoside (II). *p*-Nitrophenyl 2-acetamido-2-deoxy-β-D-glucopyranoside (I)[7] (3.5 g) dissolved in 150 ml of dimethylformamide (DMF), was treated with 15 ml of *p*-methoxybenzaldehyde dimethyl acetal and 0.50 g of *p*-toluenesulfonic acid at 40°C for 8 hr under reduced pressure (15 mmHg). The reaction mixture was evaporated *in vacuo* to dryness, and then the residue, suspended in a cold saturated sodium bicarbonate solution, was collected by filtration. The precipitate dried *in vacuo* was crystallized from toluene and acetone; 4.5 g (96%) of (II) were thus obtained. Mp 239—240°C (dec.), $[\alpha]_{589}^{25}$ −14.5° (*c*, 0.813, DMF). Found: C, 57.25; H, 5.41; N, 5.93%. Calcd for $C_{22}H_{24}O_9N_2$: C, 57.39; H, 5.25; N, 6.08%.

Unlike as in the case of benzaldehyde dimethyl acetal,[3] the formation of mixed acetal at 3-hydroxyl could not be observed when the experiment was conducted under reduced pressure.

p-Nitrophenyl 2-Acetamido-3-O-methyl-4,6-O-(p-methoxybenzylidene)-2-deoxy-β-D-glucopyranoside (III). To a solution of II (0.50 g) in 20 ml of DMF, we added 30 ml of methyl iodide and 5.0 g of barium oxide. The reaction mixture was then allowed to stand at room temperature for 20 hr. The filtrate, freed from insoluble materials, was evaporated *in vacuo* to dryness. The subsequent crystallization of the residue form toluene and chloroform afforded 0.32 g (62%) of III. Mp 250—251°C (dec), $[\alpha]_{589}^{25}$ −5.59° (*c*, 0.760, DMF). Found C, 58.12; H, 5.51; N, 5.90%. Calcd for $C_{23}H_{26}O_9N_2$: C, 58.22; H, 5.52; N, 5.90%.

A second crop of crystalline III (0.12 g, 23%) was obtained from the evaporation of the mother liquor. Mp 249—251°C (dec.).

p-*Nitrophenyl 2-Acetamido-3-*O*-methyl-2-deoxy-β-*D*-glucopyranoside (IV).* Two hundred mg of (III) in 20 ml of 90% acetic acid (v/v) were heated to 100°C for 1 min, and then the acetic acid solution was evaporated *in vacuo* to dryness. The subsequent crystallization of the residue from ethanol gave 60 mg (40%) of a crystalline IV. Mp 186—187°C (dec.), $[\alpha]_{589}^{25}$ −34.8° (*c*, 0.467, DMF). Found: C, 50.32; H, 5.70; N, 7.71%; Calcd for $C_{15}H_{20}O_8N_2$: C, 50.56; H, 5.56; N, 7.86%.

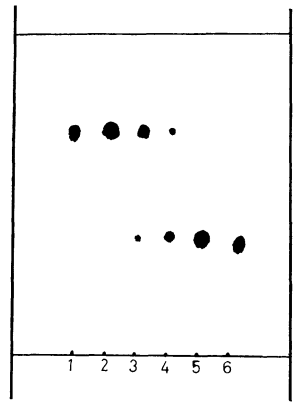

Fig. 2. Thin layer chromatogram of (III) treated with 90% acetic acid at 50°C.
1: Compound (III), 2: Reaction mixture of III, Sampling at 0 min, 3: Reaction mixture of III, Sampling after 2 min, 4: Reaction mixture of III, Sampling after 5 min, 5: Reaction mixture of III, Sampling after 10 min, 6: Compound (IV).

The further crystallization of the mother liquor from ethanol and ether afforded a second crop of IV (70 mg, 47%). Mp 184—187°C (dec.).

Treatment of III with 90% Acetic Acid. The reaction of III (1.0 mg) in 1.0 ml of 90% acetic acid (v/v) was followed by sampling the aliquots of 0.2 ml at 2, 5, and 10 min intervals. Each sample, after it had been neutralized with 0.5 ml of pyridine, was applied to a tlc plate and developed in toluene: pyridine: acetone (2: 1: 1). A thin-layer chromatogram of the reaction mixture is shown in Fig. 2.

The removal of the *O*-(*p*-methoxybenzylidene) group was completed within 10 min at 50°C. Then, the conditions (at 100°C for 1 min) were good enough for the removal because the reaction rate was about 32 (2^5) times faster at 100°C than at 50°C.

Acid Hydrolysis of p-*Nitrophenyl-β-*D*-glucopyranoside and* p-*Nitrophenyl-2-acetamido-2-deoxy-β-*D*-glucopyranoside.* A solution of each *p*-nitrophenyl glycoside (1 mg) in 1.0 ml of 66% acetic acid was heated at 100°C, and 0.2 ml aliquots were removed at 10, 20, and 30 min intervals. Three ml of 0.5M-sodium cabonate were then added to it, and the absorbance was measured at 400 nm. The destruction of glycosides was estimated from the amount of *p*-nitrophenol which was liberated from the glycosides by acid hydrolysis. The results are shown in Table 1.

The author wishes to thank Professor Yoshio Matsushima, Faculty of Science, Osaka University for his continued interest and support during this work and Mrs. Hiroko Kuritani for her kind operation of ORD instrument.

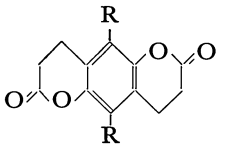
Preparation of Hydroquinone Derivatives

Susumu IWABUCHI, Minoru KOBAYASHI, Kazuo SUZUKI, and Kuniharu KOJIMA
Department of Applied Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba

(Received July 6, 1972)

Nakabayashi and Cassidy prepared hydroquinone-bis-δ-lactone (Ia) by heating 2,5-bis(2′-carbethoxy)-hydroquinone.[1] We previously reported on the preparation of 2,5-dimethylhydroquinone-bis-δ-lactone



Ia: R=H
Ib: R=CH_3

I

(Ib).[2] In the course of our studies on redox polymers containing hydroquinone or benzoquinone units in polymer chains,[3,4] we prepared some hydroquinone derivatives including 2,3,5-trimethylhydroquinone-δ-lactone (II). In this paper, we describe the preparation of the lactone (II), 2-(3′-hydroxypropyl)-3,5,6-trimethylhydroquinone (III), and 2-(3′-hydroxypropyl)-3,5,6-trimethylbenzoquinone (IV).

We attempted to synthesize hydroquinone alcohol (III) from the malonic ester (V) *via* the carboxylic acid (VI) and its ester (VII). When V was heated in hydrobromic acid at 140—160°C for 15 hr, the lactone (II), 6-hydroxy-5,7,8-trimethyl-3*H*,4*H*-dihydrocoumarin, was obtained in a good yield instead of VI. The IR spectrum (KBr disk) of II showed characteristic absorption bands at 3482 and 1740 cm^{-1}, assignable to hydroxyl and lactone carbonyl groups, respectively. The NMR spectrum in acetone-d_6 gave signals at δ (ppm) 2.20 (s, 9H, CH_3) and 2.73 (m, 4H, CH_2). These spectral data and elemental analysis verify the formation of II.

When the bis-malonic ester (VIII) was subjected to the same treatment, the carboxylic acid IXa was formed from VIIIa after 3 hr,[1] while the bis-lactone (Ib) was obtained from VIIIb as in the case of V.

(Suffixes denote a: R=H and b: R=CH_3)

Reduction of II with lithium aluminum hydride yielded 2-(3′-hydroxypropyl)-3,5,6-trimethylhydroquinone (III). The IR spectrum (KBr) showed characteristic bands at 3420 and 3150 cm^{-1}, assignable to hydroxyl groups, but not to carbonyl or ester groups. The NMR spectrum in acetone-d_6 showed signals at δ(ppm) 1.37 (qui, 2H, CH_2), 1.75 (s, 9H, CH_3), 2.40 (tr, 2H, CH_2), 3.16 (tr, 2H, CH_2O), 5.95 (s, 1H, OH), and 6.75 (s, 1H, OH).

Hydroquinone alcohol (III) was oxidized with lead tetracetate to yield 0.95 g (53%) of benzoquinone alcohol (IV); mp 42—43°C. The IR spectrum showed characteristic bands at 3210 cm^{-1} (OH) and 1645 cm^{-1} (quinone C=O). The NMR spectrum in $CDCl_3$ showed signals at δ(ppm) 1.73 (m, 2H, CH_2), 2.05 (s, 9H, CH_3), 2.50 (s, 1H, OH), 2.63 (tr, 2H, CH_2), and 3.63 (tr, 2H, CH_2O).

Experimental

Preparation of II. 22 g (0.063 mol) of V[5] was heated in 440 ml of 48% HBr solution up to 120°C (bath temp.) and for 2 hr to remove ethyl bromide. The tempetature was then raised to 140°C (3 hr) and finally to 160°C (15 hr). The raw product crystallized from the solution upon cooling in an ice bath. It was filtered, washed with water and dried. Recrystallization from *p*-xylene gave 8.7 g of II as pale yellow needles (yield: 68%); mp 172—173°C (lit,[6] 173—174°C). Found: C, 69.73; H, 6.79%. Calcd for $C_{12}H_{14}O_3$: C, 69.88; H, 6.84%.

Preparation of III. The method of Karret and Banerjed for the reduction of coumarin[7] was applied to II with the following modification. To a stirred suspension of 3.0 g (0.08 mol) of $LiAlH_4$ in 150 ml dry THF cooled with ice was added dropwise 100 ml THF containing 10.3 g (0.05 mol) of II. After the vigorous reaction had subsided, the mixture was refluxed for 2 hr. Excess hydride was decomposed by careful addition of water, and the mixture was neutralized with acetic acid. To this was added 50 ml of saturated aq. NH_4Cl soln. The upper, organic layer was decanted and the lower extracted with four 150 ml portions of THF. The combined THF layers were dried over magnesium sulfate. After the solvent was removed by evaporation from the dried mixture, the residue was recrystallized from chloroform to give 6.58 g (64%) of III as white crystals; mp 135—136°C. Found: C, 68.35; H, 8.62%. Calcd for $C_{12}H_{18}O_3$: C, 68.54; H, 8.63%.

Preparation of IV. To a solution of 1.82 g (8.7 mmol) of III in 70 ml THF were added 70 ml of water under stirring and then 4.43 g (10 mmol) of lead tetracetate. The mixture was refluxed for 30 min. After addition of aqueous NaOH, the mixture was extracted with ether. Red-yellow oil obtained on removal of ether was recrystallized from THF–*n*-heptane to yield 0.95 g (53%) of IV as yellow crystals; mp 42—43°C. Found: C, 69.19; H, 7.80%. Calcd for $C_{12}H_{16}O_3$: C, 69.20; H, 7.74%.

Solvents and Reagents. Solvents were purified in the usual way just before use. Commercial $LiAlH_4$ and lead tetracetate were used without further treatment.

Spectral Measurements. IR data were obtained with a Perkin-Elmer Model 421 spectrophotometer and NMR data with a Varian Associates Model A-60 spectrometer.

We wish to thank Professor H. G. Cassidy for his continuous encouragement throughout this research. One of us (S.I.) is indebted to The United States Public Health Service for postdoctoral support at Yale University. Thanks are also due to Dr. Akira Terahara for the measurement and interpretation of the spectral data.

Studies of Saturated Heterocyclic Compounds. Preparations and PMR Spectra of *cis* and *trans* 2,5-Disubstituted 1,3-Dioxolan-4-ones[1]

Yoshihiro ASABE, Shoji TAKITANI, and Yojiro TSUZUKI*

Faculty of Pharmaceutical Sciences, Science University of Tokyo, Ichigayafunagawara-machi, Shinjuku-ku, Tokyo
**Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo*

(Received July 11, 1972)

Although a number of investigations have been made into the chemistry of 1,3-dioxolan-4-ones,[2-5] studies of their geometrical isomers have been left undeveloped, presumably because of the difficulty in the isolation and identification of each isomer. The present work aims at isolating the *cis* and *trans* isomers of some 2,5-disubstituted homologues by means of preparative thin-layer chromatography (tlc) and at assigning these isomers by means of PMR spectroscopy. The product of 2-trichloromethyl-5-phenyl-1,3-dioxolan-4-one(I) was found by PMR spectral studies to be a mixture of *cis* and *trans* isomers. The integrated signal intensities really showed the mixture to be in a ratio of about 1: 1.3(=b: a). Each isomer (a: mp 67—68°C, in the upper band; b: mp 88—89.5°C, in the lower band) was isolated from the mixture by means of tlc; the identification of the 1,3-dioxolan-4-one ring of each isomer was made by studying the stretching vibrations ($\nu_{C=O}$) in their IR spectra.[5,6] In Fig. 1, the PMR spectra of the a-isomer are shown; signals due to 5-H and 2-H appear at τ 4.43 and τ 4.03 respectively, and signals due to the phenyl-ring protons are observed as an almost single peak at τ *ca.* 2.63. On the other hand, as is shown in Fig. 2, the b-isomer gives signals arising from 5-H and 2-H at τ 4.56 and τ 4.13 respectively, and shows signals due to the phenyl-ring protons as complicated multiplets at τ *ca.* 2.56. No detectable change in the spectral pattern was observed at elevated temperatures (to *ca.* 100°C, in $CCl_2=CCl_2$). In the *trans* form, it is expected that the phenyl-ring protons give a spectral pattern similar to those of the 5- or 2-phenyl derivatives. On the other hand, it may be expected for the *cis* form that the phenyl-ring protons will give a complicated spectral pattern because of larger chemical-shift differences among the ring protons due to the predominant anisotropic effect of the Cl atoms in the trichloromethyl group,[5] which is located on the same side as the phenyl group in the five-membered ring. In this regard, the isomer in the lower band (b-isomer) on the tlc, which shows the phenyl-ring proton signals as a complicated spectrum, should be *cis*, and the isomer in the upper band (a-isomer) on the tlc, which gives the phenyl-ring proton signals as a simple pattern, much like those of the 5- and 2-phenyl-1,3-dioxolan-4-ones (III and IV respectively), should be assigned as the *trans* form. Although the spectra of the phenyl-ring protons in $CCl_2=CCl_2$ as well as in $(CD_3)_2CO$ and $CDCl_3$ differ from those in CCl_4 because of the solvent effect, the same conclusion was derived for the same reasons.[7] As is shown in Fig. 1,

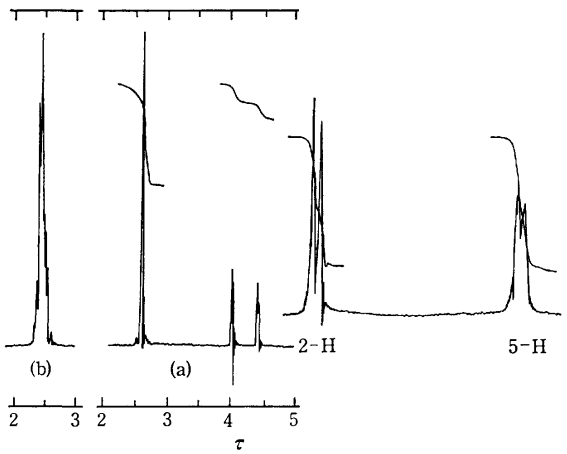

Fig. 1. 100 MHz PMR spectra of the isomer in the upper band (a-isomer, *trans*) (a): in CCl_4 (b): in $(CD_3)_2CO$.

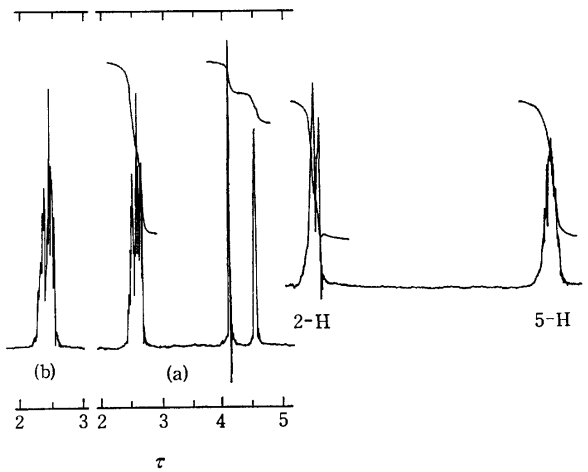

Fig. 2. 100 MHz PMR spectra of the isomer in the lower band (b-isomer, *cis*) (a): in CCl_4 (b): in $(CD_3)_2CO$.

7) In a paper recently published, Cort and Stewart gave the same assignment on the basis of the PMR spectra of the phenyl rings as well as on that of the dipole-moment measurements of Compound (I). Since they obtained an equal value for the *cis* and *trans* coupling of the long-range couplings between 2-H and 5-H, they claimed that the characteristic long-range couplings could not be used for assignment in the stereochemistry of these compounds. However, our results on the long-range couplings are different from theirs. See L. A. Cort and R. A. Stewart, *J. Chem. Soc. C*, **1971**, 1386.

Table 1. The PMR spectral data of the compounds

Compound		Chemical shift (τ)[a] 2-H *cis*[b]	2-H *trans*[c]	5-H *cis*[d]	5-H *trans*[e]	Phenyl protons	Coupling constant, J (Hz) $\lvert J_{2H-5H}\rvert$	$\lvert J_{gem}\rvert$

							0.4	

a) in CCl_4. b) *cis* to the 5-substituent group. c) *trans* to the 5-substituent group. d) *cis* to the 2-substituent group. e) *trans* to the 2-substituent group. s: almost single peak. c: complicated multiplet.

two doublets are observed due to long-range couplings through the oxygen atoms ($|J|=1.4$ Hz) for expanded patterns of the 2-H and 5-H signals in the a-isomer; the 5-H doublet is further broadened because of the long-range couplings with the phenyl-ring protons. Similarly, the 2-H in the b-isomer gives a doublet ($|J|=1.1$ Hz), and the 5-H gives a more broadened signal than that shown in Fig. 1 for the same reason (see Fig. 2). Accordingly, the absolute magnitude of the long-range couplings between the 2-H and the 5-H *via trans*($|J|=1.4$ Hz) was found to be larger than that of the coupling *via cis*($|J|=1.1$ Hz). As is given in Table 1, the *trans* coupling ($|J|=1.6$ Hz) is, in a similar manner, larger than the *cis* coupling ($|J|=1.1$ Hz) in the 2-phenyl-5-trichloromethyl derivative (II), a structural isomer of Compound(I). As is given in Table 1, the 5-H and the 2-H signal in Compound(I) both appear at a slightly higher field in the *cis* than in the *trans* isomer, but the 5-H signals of both isomers of Compound(II) have equal chemical shifts. Therefore, the assignments of the isomers on the basis of the chemical shift seem very difficult. Although the magnitude of the long-range couplings between the 2-H and 5-H signals of these compounds and the differences between the two couplings, are very small, it is possible to distinguish between them, at least, by comparing them with each other in the samples containing both isomers.

This result is in accordance with one of the empirical generalizations for 2,5-dihydrofurans,[8,9] which may be considered to be isoelectronic with 1,3-dioxolan-4-ones. This coupling mechanism is regarded as the same as in 2,5-dihydrofurans in view of the contribution of the $C-\overset{\overset{O}{\|}}{C}-O-C \longleftrightarrow C-\overset{|}{C}=\overset{+}{O}-C$ of the planar lactone function[10,11] in the 1,3-dioxolan-4-one ring.[5] The assignment based on the long-range couplings on the methylene protons of the C-2 and C-5 signals of Compounds-(III) and (IV) was in accordance with that made on the basis of the deshielding effects of their phenyl group. Hardly no solvent effect was observed on the long-range couplings.

Experimental

Preparation of Materials. *2-Trichloromethyl-5-phenyl-1,3-dioxolan-4-one (I)*: This was prepared by the reaction of *dl*-mandelic acid, chloral, and phosphorus pentoxide in tetrachloroethane (at *ca.* 100°C); the *cis*, *trans* mixture was purified by recrystallization from CCl_4–ligroin. Mp 66—67°C. Yield, 51.3%. Each isomer was separated by preparative tlc[12] from the mixture, and was recrystallized from petroleum ether. The upper band (a-band, *trans* isomer) yielded colorless needles; mp 67—68°C. Found: C, 42.77; H, 2.73%. Calcd for $C_{10}H_7O_3Cl_3$: C, 42.67; H, 2.51%. The lower band (b-band, *cis* isomer) gave colorless plates; mp 88—89.5°C. Found: C, 42.16; H, 2.49%.

2-Phenyl-5-trichloromethyl-1,3-dioxolan-4-one (II): This was similarly prepared by the reaction of *dl*-β,β,β-trichlorolactic acid with benzaldehyde; then the excess benzaldehyde was removed by distillation under reduced pressure, and the residue was treated in the same manner as Compound (I). Mp 74—76°C. Yield, 52.8%. The upper band (*trans* isomer) on the tlc gave colorless needles; mp 86—87°C. Found: C, 42.50; H, 2.22%. The lower band (*cis* isomer) gave colorless plates; mp 88—89.5°C. Found: C, 42.75; H, 2.41%. 5-Phenyl-1,3-dioxolan-4-one (III, colorless liquid, bp 124—125 °C/5 mmHg) and 2-phenyl-1,3-dioxolan-4-one (IV, colorless liquid, bp 123—124°C/5 mmHg) were prepared from the corresponding α-hydroxycarboxylic acids and aldehydes by Gerhardt's method[2,3] with a slight modification; they were purified by repeated distillation before use.

Measurements. All the melting points and boiling points are uncorrected. The PMR spectra were measured with a Varian A-60 spectrometer and a JNM-4H-100 spectrometer at room temperature. Carbon tetrachloride, chloroform-*d*, acetone-d_6, and tetrachloroethylene were used as the solvents (the concentrations were about 60—70 mg/0.5 ml), and TMS was used as the internal reference; none of the samples were degassed.

Aromatic Substitution of Olefins. XIX. Reaction of Five-membered Heterocyclic Aromatic Compounds with Styrene

Ryuzo ASANO, Ichiro MORITANI, Yuzo FUJIWARA, and Shiichiro TERANISHI
Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received July 27, 1972)

We reported on substitution reactions of olefins with benzene derivatives in the presence of palladium(II) salts to give aryl-substituted olefins, and demonstrated that a number of olefins undergo the substitution with benzene derivatives.[1] Ferrocene, a nonbenzenoid aromatic compound, undergoes the reaction with vinyl compounds to give alkenylferrocenes *via* direct substitution.[2] If the reaction is of general applicability, heterocyclic aromatic compounds such as furan, thiophene, selenophene, or *N*-methylpyrrole should react with an olefin to give alkenyl-substituted derivatives. We have found that styrene reacts with heterocyclic five-membered aromatic compounds to give styryl-substituted derivatives.

Results and Discussion

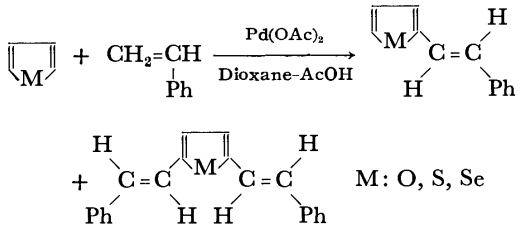
The heterocyclic compounds have greater aromatic reactivity than benzene.[3] Thus it is of interest to determine whether they also react with olefins.

A solution of furan, styrene (equal mole equiv. to furan), palladium(II) acetate (equal mole equiv. to furan) in acetic acid and dioxane was stirred under reflux for 8 hr, to give *trans,trans*-2,5-distyrylfuran (46%, all yields based on palladium(II) acetate) with *trans*-2-styrylfuran (15%). Reactions with other heterocycles such as thiophene, selenophene, or *N*-methylpyrrole were carried out under similar reaction conditions. The results are given in Table 1.

TABLE 1. REACTION OF STYRENE WITH FIVE-MEMBERED HETEROCYCLIC AROMATIC COMPOUNDS BY PALLADIUM(II) ACETATE[a)]

Aromatics	Products and yield, %[b)]	
Furan	*trans*-2-Styrylfuran	15
	trans,trans-2,5-Distyrylfuran	46
Thiophene	*trans*-2-Styrylthiophene	13
	trans,trans-2,5-Distyrylthiophene	36
Selenophene	*trans*-2-Styrylselenophene	9
	trans,trans-2,5-Distyrylselenophene	34
N-Methylpyrrole	*trans*-2-Styryl-*N*-methylpyrrole	11
	trans-3-Styryl-*N*-methylpyrrole	3
trans-2-Styryl-furan	*trans,trans*-2,5-Distyrylfuran	68
	trans,trans,trans-2,3,5-Tristyrylfuran	12

a) Equimolar amounts of aromatics, styrene, and palladium acetate were used, and all the reactions were carried out under reflux for 8 hr. b) Yields are based on palladium acetate.



It was found that these heterocycles can easily react with styrene to give styryl-substituted heterocycles. Distyryl-substituted cyclic compounds are formed as a major product except for the case of *N*-methylpyrrole, suggesting that the mono-substituted derivative derived from a single-step alkenylation of the heterocycle undergoes further alkenylation reaction with styrene. This may be due to the higher reactivity of the mono-styryl-substituted compound in the present reaction. In fact, 2-styrylfuran reacts easily with styrene to afford 2,5-distyrylfuran in a good yield. This double-step alkenylation has not been observed in the reaction of benzenoid aromatic compounds with olefins.[1]

The substitution reaction appears to take place exclusively at positions 2 and 5 of the heterocycles except for *N*-methylpyrrole. This is consistent with the result obtained in electrophilic substitution reactions of these compounds.[4,5] *N*-Methylpyrrole seems to be of low reactivity since the aromatic character of the compound is destroyed by addition of acid.

The results provide a very convenient method for the synthesis of alkenylheterocyclic compounds.

Experimental

IR spectra were recorded on a Japan Spectroscopic Co. IR-E spectrometer. NMR spectra were obtained using a Japan Electron Optics JNM-4H-100 or JEOL C-60HL spectrometer, with tetramethylsilane as an internal standard.

Materials. Palladium (II) acetate was prepared from palladium sponge and acetic acid in the presence of concd. nitric acid. Selenophene (109—110°C) was prepared from butadiene and selenium metal according to the procedure of Yur'ev and Magdesieva.[6,7] Commercial aromatics and styrene were purified before use. Dioxane was refluxed with sodium metal and distilled. Acetic acid was dried over phosphorus pentoxide for 1 week and distilled. Light petroleum refers to a fraction of bp 38—60°C.

General Procedure for the Alkenylation of the Heterocycles. Solutions containing equimolar amounts of palladium(II)

a) Ref. 8.

acetate, styrene, and the heterocycle in acetic acid and dioxane were stirred for 8 hr under reflux. The resulting mixture was filtered to remove palladium metal. The filtrate was poured into water and the mixture was extracted with chloroform. The chloroform extract was washed with aqueous sodium bicarbonate and water, dried (Na_2SO_4) and then the solvent was evaporated. The products were isolated by alumina column or gas chromatography and identified by comparison (mixed mp, IR, and NMR spectra) with authentic samples. Analytical results and the properties of the styrylheterocycles are given in Table 2. A specific example of the reaction follows.

Reaction of Furan with Styrene. A solution of styrene (1.56 g, 15 mmol), furan (1.02 g, 15 mmol) and palladium(II) acetate (3.37 g, 15 mmol) in dioxane (160 ml) and acetic acid (40 ml) was stirred for 8 hr under reflux ($CaCl_2$ guard tube). After the work-up the residue was chromatographed on a column of alumina (130 g). Elution with light petroleum (900 ml) and recrystallization yielded *trans*-2-styrylfuran (0.38 g, 15%), which was identified by comparison with an authentic sample.[8] Further elution with benzene (500 ml) and recrystallization from ethanol gave *trans,trans*-2,5-distyrylfuran (0.92 g, 46%) which was identified by comparison with an authentic sample.[8] Finally elution with with ether (500 ml) and methanol gave tarry material (0.22 g) which was not further examined. Glc of the solvent evaporated off showed the presence of styrene and a trace amount of β-acetoxystyrene (*cis* and *trans* mixture).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 665—666 (1973)

The Ferrocenylation of Styrenes-β,β-d_2 with the Ferrocenylpalladium Compound

Akira KASAHARA and Taeko IZUMI

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa, Yamagata

(Received June 16, 1972)

Recently, the arylation of olefin with arylpalladium compound (I), formed *in situ* by the exchange of arylmercuric compounds (II) with palladium salts, has been shown to be a useful reaction for the synthesis of various olefinic compounds [Eq. (1)].[1] Moreover, Heck[2] has reported that the reaction of olefin with I was stereospecific with internal olefin, giving products consistent with a *cis* addition of the organopalladium reagent to the olefin, followed by a *cis* elimination of a hydridopalladium(II) species. Henry[3] has also reported that the phenylpalladation of cyclohexene-3,3,6,6-d_4 (III) by phenylmercuric acetate and palladium acetate produces products (IV and V) which are consistent with the *cis* phenylpalladation, followed by *cis* palladium(II) hydride elimination and readdition [Eq. (2)]. On the other hand, Moritani *et al.*[4] have reported that, judging from the deuterium analyses of the *trans* stilbene formed, it seems that the phenylation of styrenes-β,β-d_2 (VI) with benzene in the presence of palladium acetate, without using a phenylmercuric compound, proceeds without any hydride shift. We ourselves have also reported that the reaction of benzo[*b*]furan with I results in the formation of 2-arylbenzo[*b*]furan, and that no hydride shift takes place in the reaction.[5]

Previously, we described the ferrocenylation of olefin with chloromercuriferrocene (VII) in the presence of palladium salts to produce alkenylferrocene derivatives.[6] Therefore, in order to study whether or not the hydride shift also occurs in the reaction of VI with VII, the reaction was performed in the presence of lithium chloropalladite. If the hydride shift occurs in the reaction, the reaction of VI with ferrocenylpalladium chloride (VIII), formed *in situ* from VII and palladium salts, will produce styrylferrocenes (IX) containing two and/or one deuterium as is shown by Eq. (3), and the deuterium content of IX will be 150%. Contrary to this, according to the no hydride shift mechanism,[4,5] the deuterium content of the product should be 100% [Eq. (4)]. The results are summarized in Table 1. Styrene-β,β-d_2, *p*-methylstyrene-β,β-d_2, and *p*-methoxystyrene-β,β-d_2 all resulted in the formation of IX, indicating that the deuterium content is *ca.* 150%, unlike the case of no hydride shift. These results clearly show that the hydride shift occurs in this reaction.

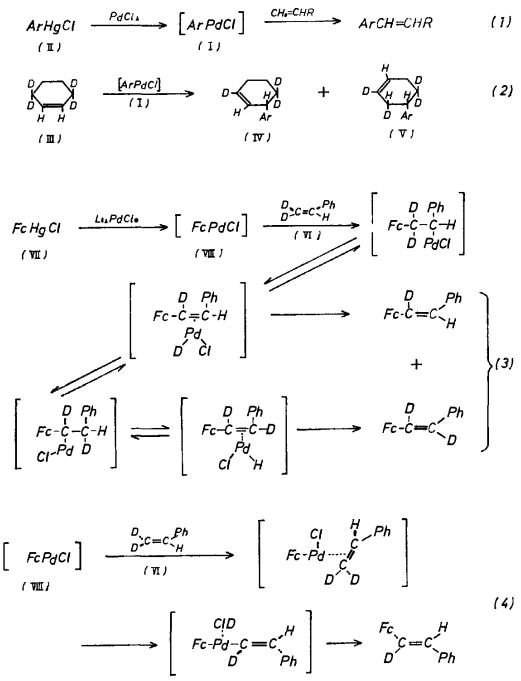

Fig. 1

Experimental

Analysis and Materials. All the melting points are uncorrected. The IR spectra were measured on KBr disks with a Hitachi EPI-S spectrometer, while the NMR spectra were obtained by means of a Hitachi H-60 NMR spectrometer at 60 MHz in $CDCl_3$, using tetramethylsilane as the internal standard. Their chemical shifts are presented in terms of ppm values, together with the splitting pattern and the relative integrated area. The letter designates the multiplicity of the signal: s, singlet; d, doublet; t, triplet; q, quadruplet; *m*, multiplet. The mass spectra were obtained on a Hitachi RMU6E mass spectrometer, using a direct inlet and an ionization energy of 70 eV.

The following compounds were synthesized by the methods described in the literature: chloromercuriferrocene,[7] styrene-β,β-d_2,[8] *p*-methylstyrene-β,β-d_2,[4b] and *p*-methoxystyrene-β,β-d_2.[4b]

General Procedure for the Ferrocenylation of Styrene-β,β-d_2. Lithium chloropalladite solutions were prepared by stirring 0.84 g (20 mmol) of anhydrous lithium chloride and 1.77 g (10 mmol) of palladium chloride overnight at room tempera-

ture in 100 ml of ethanol. To these lithium chloropalladite solutions, mixtures of 4.20 g (10 mmol) of I and twice as much VI were added, after which the mixtures were stirred at room temperature for 12 hr. The products were isolated by filtering to remove a precipitated palladium, and by distilling under reduced pressure to remove the solvent. The residue was dissolved in benzene and chromatographed on alumina. The first elution with benzene and subsequent recrystallization from ethanol afforded deep yellow crystals (mp 228—229°C, 3—9% yields) which were identified as biferrocenyl (X)[9] by a comparison of the IR spectra and by a mixed-melting-point determination with an authentic sample. Further elution with benzene and recrystallization from ethanol afforded the respective ferrocenylation product (IX). The structures of the products were confirmed by the observation of the IR and NMR spectra. The deuterium-content of the products was also calculated from the NMR results (see Table).

The authors would like to express their thanks to Assistant Professor Kaoru Hanaya and Mr. Hideaki Kudo of Yamagata University for the measurements of the NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 667—669 (1973)

The Reaction of Acyl-substituted Sulfonium and Pyridinium Ylides with Diphenylthiirene Dioxide

Yosio HAYASI, Hideo NAKAMURA, and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto

(Received July 28, 1972)

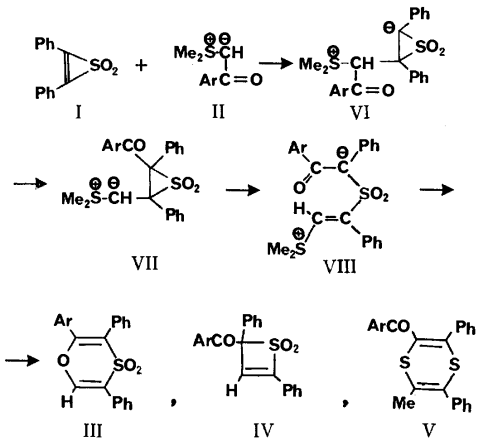
In contrast to the preceding paper,[1] which dealt with the reaction of sulfonium ylides with cyclopropenone, the present paper will report studies of the reactions of diphenylthiirene dioxide (I) as an electrophile with acyl-substituted sulfonium and pyridinium ylides.

Reaction with Sulfonium Phenacylides. The reaction of I with an equimolar quantity of dimethylsulfonium *p*-methylphenacylide (IIa) in benzene at reflux gave four crystalline products; the major one (67%) was a sulfur dioxide-elimination product, tolan, while the three minor products were identified as an oxathiin dioxide, IIIa (15%), a thiete dioxide, IVa (13%), and a dithiin, Va (12%). These products were identified from their spectral properties and from the results of elementary analyses. Thus, in the mass-spectrum fragmentation of IIIa, the elements of SO_2+CHO were lost from the molecular ion (*m/e* 374) to give a significant peak at *m/e* 281, probably because of a cyclopropenium ion. Meanwhile, the mass spectrum of IVa displayed a characteristic toluyl ion (*m/e* 119).

The formation of IIIa and IVa could be formulated by assuming the following sequences: (1) the benzoyl-migration in the VI adduct, giving intermediary ylides, VII;[2] (2) the subsequent isomerization to VIII, and finally (3) the ring closure of VIII with the elimination of dimethyl sulfide (Scheme 1). Remarkably, the carbon-to-carbon bond of the episulfone VII is preferentially broken instead of extruding sulfur dioxide.[3] The reaction pathway leading to Va is open to future research.

Analogously, the reaction of dimethylsulfonium phenacylide IIb with I afforded three crystalline products upon careful chromatography on silica gel. The spectroscopic and elementary analyses of the major product (36%) supported the structure IIIb; the very small amounts of the two minor products could be formulated as IVb (<5%) and Vb (6%) after a comparison of their spectra with those of IVa and Va respectively.

Reaction with Pyridinium and Related N-*Ylides.* 1,3-Dipolar cycloadditions of pyridinium and related heteroaromatic ylides with diethyl acetylenedicarboxylate, ethyl propiolate, and so on have been reported to give indolizine derivatives.[4] Diphenylthiirene dioxide (I) was found to behave similarly to *N*-ylides. Thus, pyridinium phenacylide (IX) reacted with an equimolar amount of I in benzene at room temperature to yield a yellow, crystalline solid, X (46%). The UV spectrum indicated the presence of cyclic conjugation systems.[4] The results of elementary analysis and the mass spectrum were in good accordance with the empirical formula of $C_{27}H_{19}NO$. The IR spectrum showed intense absorption bands at 1595, 1385, and 1210 cm^{-1}, which revealed the contribution of a charge-separated structure, *e.g.*, Xa, to the resonance hybrid. The structure of X was further confirmed by com-



Ar=*p*-MeC_6H_4 (Series a), Ph (Series b)

4) a) T. Sasaki, K. Kanematsu, Y. Yukimoto, and S. Ochiai, *J. Org. Chem.*, **36**, 813 (1971), and references cited therein; b) J. E. Douglass and J. M. Wesolosky, *ibid.*, **36**, 1165 (1971); c) N. Basketter and A. O. Plunkette, *Chem. Commun.*, **1971**, 1578.

parison with an authentic sample, independently prepared from 1,2-diphenylindolizine by reaction with benzoyl chloride following the general method of Borrows.[5] It should be added that the attempted reaction of IX with tolan (1 : 1) at room temperature for 22 hr in benzene failed to afford the adduct X. A similar pattern was repeated using isoquinolinium (XI) and quinolinium (XIII) phenacylides to furnish two 3-benzoylindolizine derivatives XII and XIV respectively.

Experimental

All the melting points are uncorrected. The microanalyses were performed at the Elemental Analyses Center of Kyoto University. The NMR spectra were taken with JEOL C-60H and JNM-MH-60 spectrometers, and the chemical shifts are reported in δ values relative to TMS as the i nternal standard, unless otherwise stated. The abbreviations s and m refer to singlet and multiplet respectively. The UV absorption spectra were measured in 95% EtOH on a Shimadzu MPS-50L spectrometer, and the mass spectra, on a Hitachi RMU-6E instrument by the direct-injection method.

Reaction of Dimethylsulfonium p-*Methylphenacylide (IIa) with Diphenylthiirene Dioxide (I).* A solution of IIa (2.7 g, 13.6 mmol) and I (3.0 g, 12.4 mmol) in benzene (150 ml) was stirred at room temperature for 2 hr. The reaction mixture was then heated at reflux for 9 hr. The chromatographic separation of the crude products on a silica gel column (benzene and chloroform) gave tolan (1.5 g, 67%), IIIa (0.7 g, 15%), IVa (0.6 g, 13%), and Va (0.6 g, 12%).

3,5-Diphenyl-2-*p*-tolyl-1,4-oxathiin dioxide (IIIa): mp 183.5—185°C (PhH); λ_{max}^{EtOH} 233 (log ε 4.30), 238 (4.33) nm; IR (KBr) 1645, 1605, 1290, 1220, 1140 cm^{-1}; NMR ($CDCl_3$) 2.31 (s, 3), 7.2—7.8 (m, 15) ppm; MS *m/e* 376 (9), 375 (27), 374 (100, P), 311 (26), 310 (95), 282 (9), 281 (32), 193 (37), 192 (64), 191 (72), 190 (18), 184 (27), 165 (31), 119 (17), 91 (14), 89 (17), 77 (11).

Found: C, 74.0; H, 4.8%. Calcd for $C_{23}H_{18}O_3S$: C, 73.8; H, 4.9%.

2,4-Diphenyl-2-*p*-toluylthiete dioxide (IVa): mp 230—231°C (PhH); λ_{max}^{EtOH} 218 (4.35), 268 (4.35) nm; IR (KBr) 1680, 1610, 1280, 1150 cm^{-1}; NMR (DMSO-d_6) 2.5 (s, 3), 7.4—8.1 (m, 15) ppm; MS *m/e* 376 (1), 375 (4), 374 (13, P), 342 (5), 236 (6), 311 (22), 310 (77, P-SO_2), 205 (12), 191 (25), 189 (13), 165 (6), 120 (33), 119 (100), 105 (19), 91 (54), 77 (13), 64 (16).

Found: C, 74.0; H, 4.9%. Calcd for $C_{23}H_{18}O_3S$: C, 73.8; H, 4.9%.

2-Methyl-3,5-diphenyl-6-*p*-toluyl-1,4-dithiin (Va): mp 145—145.5°C (PhH); IR (KBr) 1655, 1605, 1280 cm^{-1}; NMR ($CDCl_3$) 2.30 (s, 3), 2.47 (s, 3), 7.2—8.2 (m, 14), ppm; MS *m/e* 402 (7), 401 (31), 400 (100, P), 285 (6), 367 (12), 309 (10), 295 (11), 262 (4), 234 (8), 220 (7), 154 (4), 121 (6), 119 (14), 91 (17).

Found: C, 74.5; H, 5.0; S, 15.5%. Calcd for $C_{25}H_{20}OS_2$: C, 75.0; H, 5.0; S, 16.0%.

Reaction of IIb with I. A solution of IIb (3.3 g, 18.2 mmol) and I (4.0 g, 16.5 mmol) in benzene (200 ml) was stirred at room temperature for 24 hr and then at reflux for 3 hr. After concentration, the residual oil was chromatographed on a silica gel column (benzene) to afford IIIb (2.4 g, 36%), IVb (0.3 g, 5%), and Vb (0.4 g, 6%).

2,3,5-Triphenyl-1,4-oxathiin dioxide (IIIb): mp 206—207°C (PhH); λ_{max}^{EtOH} 228 (4.35), 240 (4.32), 266 (4.12) nm; IR (KBr) 1650, 1283, 1220, 1135 cm^{-1}; NMR ($CDCl_3$) 6.9—7.8 (m) ppm; MS *m/e* 362 (3), 361 (7), 360 (23, P), 296 (40, P-SO_2), 268 (11), 267 (21), 178 (100), 177 (11), 176 (9), 152 (7), 149 (7), 105 (11), 102 (6),

Found: C, 73.2; H, 4.7%. Calcd for $C_{22}H_{16}O_3S$: C, 73.3; H, 4.5%.

4-Benzoyl-2,4-diphenylthiete dioxide (IVb); mp 142—143°C (PhH); IR (KBr) 1665, 1300, 1150 cm^{-1}; NMR ($CDCl_3$) 7.2—7.8 (m) ppm; MS *m/e* 362 (1), 361 (3), 360 (9, P), 297 (8), 296 (24, P-SO_2), 191 (14), 189 (7), 165 (10), 105 (100), 77 (19).

2-Benzoyl-3,5-diphenyl-6-methyl-1,4-dithiin (Vb): mp 111—112°C (PhH); λ_{max}^{EtOH} 244 (4.53), 286 (4.25) nm; IR (KBr) 1638, 1420, 1226, 1012 cm^{-1}; NMR ($CDCl_3$) 2.43 (s, 3), 6.8—7.5 (m, 15) ppm; MS *m/e* 388 (14), 387 (33), 386 (100, P), 372 (11), 371 (19), 353 (11), 309 (16), 295 (6), 262 (7), 234 (14), 221 (6), 193 (8), 154 (6), 145 (5), 121 (13), 105 (32), 77 (38).

Found: C, 74.6: H, 4.6; S, 16.5%. Calcd for $C_{24}H_{18}OS_2$: C, 74.6; H, 4.7; S, 16.5%.

Reaction of IX with I. A solution of IX (2.0 g, 10 mmol) and I (2.4 g, 10 mmol) in benzene (150 ml) was stirred at room temperature for 10 hr. After the solvent had then been removed *in vacuo*, the residual solids were chromatographed on a silica gel column (benzene) to give the unchanged I and yellow crystals (X, 1.7 g, 46%): mp 166—167°C (EtOH); λ_{max}^{EtOH} 251 (4.56), 286 (sh, 4.25), 400 (4.17) nm; IR (KBr) 1595, 1572, 1385, 1210 cm^{-1}; NMR ($CDCl_3$) 6.8—7.8 (m) ppm; MS *m/e* 375 (5), 374 (32), 373 (100, P), 344 (7), 296 (20), 268 (13), 267 (32), 239 (4), 186 (5), 177 (9), 133 (4), 105 (11), 77 (14).

Found: C, 86.6; H, 5.5; N, 3.6%. Calcd for $C_{27}H_{19}NO$: C, 86.8; H, 5.1; N, 3.8%.

1,2-Diphenylindolizine. A solution of 2-benzylpyridine (5.0 g, 30 mmol) and phenacyl bromide (5.9 g, 30 mmol) in ether was stirred at room temperature for 10 days. The resulting precipitates were filtered and then washed with ether to afford 1-phenacyl-2-benzylpyridinium bromide (quantitatively); mp 174—176°C (decomp.). The pyridinium bromide (0.6 g, 1.7 mmol) was dissolved in water (6 ml), $NaHCO_3$ (0.5 g) was added, and the mixture was brought to a boil. The resulting thick magma was recrystallized from ethanol to afford 1,2-diphenylindolizine (0.40 g, 94%); mp 112—113°C (EtOH).

Found: C, 89.0; H, 5.5; N, 5.4%. Calcd for $C_{20}H_{15}N$: C, 89.2; H, 5.6; N, 5.2%.

3-Benzoyl-1,2-diphenylindolizine (X). A mixture of 1,2-diphenylindolizine (0.40 g, 1.6 mmol) and benzoyl chloride (1.2 ml) was heated at 40°C for 24 hr. The cooled reaction mixture was triturated with petroleum ether (bp 30—50°C), and the resulting green solid was filtered off. Recrystallization from ethanol gave X (0.24 g, 35%); mp 166—167°C. Both specimens showed no depression upon a mixed-mp determination, and the IR spectra were completely superimposable.

Found: C, 86.7; H, 4.9; N, 3.9%. Calcd for $C_{27}H_{19}NO$: C, 86.8; H, 5.1; N, 3.8%.

Reaction of Isoquinolinium Phenacylide (XI) with I. A solution of isoquinolinium phenacylide (XI, 1.86 g, 7.5 mmol) and I (1.80 g, 7.4 mmol) in acetonitrile (300 ml) was heated at reflux for 39 hr. Chromatography (silica gel, benzene) afforded yellow crystals of 3-benzoyl-1,2-diphenylpyrrolo-[2,1-*a*]isoquinoline (XII, 1.95 g, 61%); mp 196—199.5°C (PhH); λ_{max}^{EtOH} 270 (4.57), 296 (4.19), 336 (3.94), 398 (4.23)

5) E. T. Borrows, D. O. Holland, and J. Kenyon, *J. Chem. Soc.*, **1946**, 1069.

nm; IR (KBr) 1605, 1592, 1365, 1198 cm^{-1}; NMR ($CDCl_3$) 6.75—7.8 (m) ppm; MS *m/e* 425 (6), 424 (36), 423 (100, P), 394 (4), 346 (19), 318 (10), 317 (20), 211 (9), 105 (10), 77 (7).

Found: C, 88.1; H, 5.1; N, 3.0%. Calcd for $C_{31}H_{21}NO$: C, 87.9; H, 5.0; N, 3.3%.

Reaction of Quinolinium Phenacylide (XIII) with I. A solution of quinolinium phenacylide (XIII, 0.93 g, 3.7 mmol) and I (0.90 g, 3.7 mmol) in benzene (150 ml) was stirred at room temperature for 2 days. Subsequent chromatography (silica gel, benzene) afforded yellow crystals of 1-benzoyl-2,3-diphenylpyrrolo[1,2-a]quinoline (XIV, 0.12 g, 8%): mp 218—219°C (PhH); λ_{max}^{EtOH} 266 (4.59), 292 (sh, 4.15), 332 (3.92), 380 (4.11), 394 (4.18) nm; IR (KBr) 1600, 1350, 1198, 890 cm^{-1}; NMR (CCl_4) 6.6—7.7 (m) ppm; MS *m/e* 424 (35), 423 (100, P), 394 (4), 346 (18), 318 (8), 316 (10), 211 (9), 105 (8), 77 (8).

Found: C, 87.9; H, 5.2; N, 3.0%. Calcd for $C_{31}H_{21}NO$: C, 87.9; H, 5.0; N, 3.3%.

A Convenient Method of Synthesizing Protected α-Amino-γ-butyrolactones

Hiroshi SUGANO and Muneji MIYOSHI

Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., Kashima-cho, Higashiyodogawa-ku, Osaka

(Received July 31, 1972)

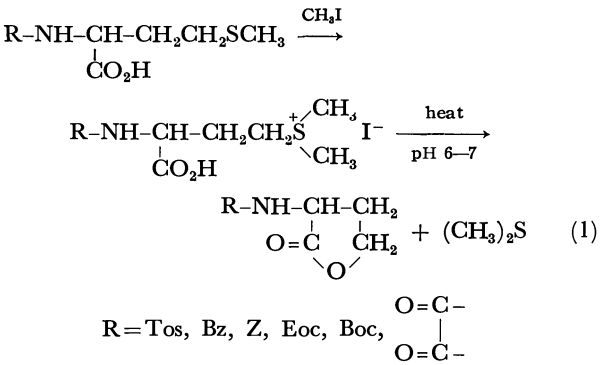
α-Amino-γ-butyrolactone (homoserine lactone) is a key intermediate in the synthesis of amino acids, especially γ-substituted α-amino acids, such as cystathionine,[1,2] homolanthionine,[2] canaline,[3] canavanine,[4] phosphinothricin,[5] and selenium analogs of methionine and homocysteine.[6] Suitable synthetic methods for the preparation of an optically-active α-amino-γ-butyrolactone are, therefore, of importance in connection with the synthesis of such types of amino acids and of peptides containing a homoserine.

The known method for the preparation of an optically-pure *N*-protected α-amino-γ-butyrolactone involves a two-step sequence in which *N*-tosyl-glutamine is converted into *N*-tosyl-α,γ-diaminobutyric acid with potassium hypobromite, followed by diazotization.[1] However, the amino-protecting group in this method is limited to an acid-stable group, such as the tosyl and benzoyl groups.

It was reported previously, in connection with studies of the determination of amino acid sequences in peptides containing methionine, that a methionine residue is transformed into an α-amino-γ-butyrolactone residue by treatment with methyl iodide or cyanogen bromide, followed by hydrolysis.[7]

We will report in this paper the application of the above procedure on a preparative scale to the widely-used, optically-active α-amino-γ-butyrolactones, suitably protected for further elaboration in the synthesis. Thus, readily-available, optically-active *N*-acyl-methionines, such as *N*-benzyloxycarbonyl(Z)-, *N*-tosyl(Tos)-, *N*-benzoyl(Bz)-, and *N*-ethoxycarbonyl(Eoc)-methionine, were treated with methyl iodide in a mixture of acetic acid and formic acid to form sulfonium salts; they were then hydrolyzed under reflux at pH 6—7. The resulting *N*-acyl-α-amino-γ-hydroxybutyric acids were converted into the corresponding lactones with hydrogen chloride. The unreacted *N*-acyl-methionines were extracted out with a sodium bicarbonate solution; optically-pure *N*-acyl-α-amino-γ-butyrolactones are thus obtained in good yields (Eq. (1)).

The *N*-*t*-butyloxycarbonyl (Boc) derivative, in which the Boc-group was cleaved by formic acid, was methylated in acetic acid without the use of formic acid, but the yield was rather low because the cleavage of the Boc-group occurred during the hydrolysis.



(1)

Bis-amide was obtained analogously from oxalyl bis-methionine. No appreciable racemization occurred during the procedure. The specific rotations of the derivatives synthesized above agreed with those of the derivatives which were obtained by the acylation of commercially-available optically-pure homoserine and by subsequent lactonization. The results are shown in Table 1.

a) This was not recrystallized. b) c 1, N NaOH.

(1 mol) in a mixture of acetic acid (300 ml), 80% formic acid (600 ml), and methyl iodide (110 ml) was allowed to stand in a dark place at room temperature for 10 hr. (In the case of Boc-L-methionine, formic acid was not used, and the mixture was allowed to stand for 48 hr). The mixture was then concentrated under reduced pressure below 40°C. The resulting oil was triturated with dry ether and dissolved in a N sodium hydroxide solution (1000 ml). The mixture was heated at 90°C with stirring for 3 hr. During the course of the reaction, the reaction mixture was kept at pH 6—7 by the addition of N sodium hydroxide. After cooling, the crystals which had appeared were collected by filtration, washed well with water, and dried. Recrystallization from ethyl acetate–petroleum ether gave an optically-pure *N*-acyl-α-amino-γ-butyrolactone. The mother liquor was adjusted to pH 2—3 with N hydrochloric acid and then allowed to stand at room temperature for 1 hr. The product was extracted with ethyl acetate, and the extract was washed with 4% sodium bicarbonate, N ammonia, and water, and dried over magnesium sulfate. The solvent was removed *in vacuo* and the crystals thus obtained were recrystallized from ethyl acetate–petroleum ether to afford an optically-pure *N*-acyl-α-amino-γ-butyrolacetone. The oxalyl derivative could not be recrystallized because of its low solubility in various solvents.

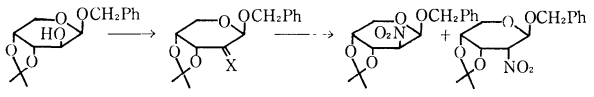
Studies on Nitro Sugars. IV.[1] The Synthesis of Benzyl 2-Deoxy-3,4-*O*-isopropylidene-2-nitro-β-D-arabino- and ribo-pyranoside

Tetsuyoshi TAKAMOTO, Minoru OHKI*, Rokuro SUDOH, and Toshio NAKAGAWA*

Department of Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received August 10, 1972)

Recently, we reported the syntheses of 3- and 2-nitro furanoses[1-3] through the oxidation of sugar oximes with trifluoroperacetic acid. As an extension of our studies to the pyranose series, we have now examined the oxidation of the 2-oximino-pentopyranoside derivative to the corresponding 2-nitro compound by this method.



1 **2**: X=O, **3**: X=NOH **4** **5**

The dimethyl sulfoxide oxidation[4] of benzyl 3,4-*O*-isopropylidene-β-D-arabinopyranoside (**1**),[5] followed by distillation at 155—157°C/3 mmHg, afforded sirupy 2-ulose (**2**), showing 1756 cm^{-1} (neat); this was immediately converted to benzyl 3,4-*O*-isopropylidene-2-oximino-β-D-*erythro*-pentopyranoside (**3**) in the usual manner in a 27% overall yield from **1**. When **3** was treated with trifluoroperacetic acid in the presence of excess dibasic sodium phosphate as a buffer in acetonitrile, the corresponding 2-nito-pentoses, which consisted of benzyl 2-deoxy-3,4-*O*-isopropylidene-2-nitro-β-D-arabinopyranoside (**4**) and its 2-epimer (**5**) in the ratio of *ca.* 1: 1, were obtained in a 75% yield. The separation of both the products, according to the small difference in chromatographical mobility, could

be achieved by using a long silica-gel column.

As is shown in Fig. 1, what was eluted later was identified as the *arabino*-isomer (**4**) on the basis of the coupling constant values, $J_{1,2}=3.7$, $J_{2,3}=8$, and $J_{3,4}=6$ Hz, which would mean a slightly twisted 1C conformation. On the other hand, the first-eluted component, *i.e.*, the *ribo*-isomer (**5**), showed $J_{1,2}=7$, $J_{2,3}=3$, and $J_{3,4}=7$ Hz, which would mean a twisted boat form, as is shown in Fig. 2.

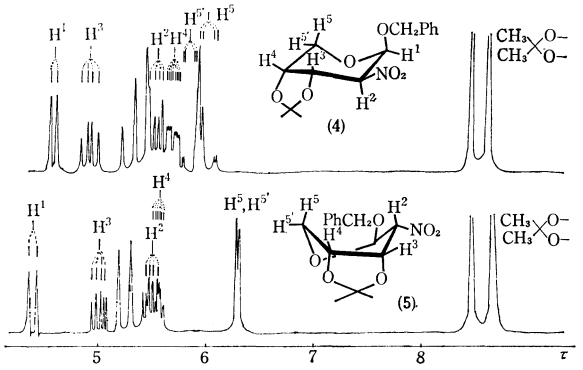

Fig. 1. 100 MHz NMR spectra (in $CDCl_3$).

As an explanation of the stereochemically-interesting results, it appears that an equatorially-oriented nitro group might be effective, but any detailed discussion must await further investigations concerning nitro sugars.

Experimental

The specific rotations were measured with a Carl Zeiss photoelectric polarimeter. The NMR spectra were recorded at 100 MHz with a spectrometer JNM-4H-100 (JEOL), using tetramethylsilane as the internal standard. Column chromatography was carried out on silica gel (100 Mesh, Mallinckrodt, St. Louis). All the evaporations were performed *in vacuo*.

*Benzyl 3,4-O-Isopropylidene-2-oximino-β-*D-erythro-*pentopyranoside (3).* To a solution of benzyl 3,4-*O*-isopropylidene β-D-arabinopyranoside (**1**) (58.6 g) in dimethyl sulfoxide (680 ml), acetic anhydride (452 ml) was added with manual stirring. After standing for 48 hr at room temperature, the mixture was evaporated below 60°C. A solution of the residue in chloroform (1 l) was washed with water four times, dried over calcium chloride, and evaporated. The sirup was distilled at 155—157°C/3 mmHg to give 2-ulose (**2**) contaminated with the starting material (**1**). The distilled sirup (43.8 g), showing an absorption band at 1756 cm^{-1} (C=O), was heated under reflux with hydroxylamine hydrochloride (21.9 g) in a mixture of pyridine (438 ml) and ethanol (438 ml) for 2 hr. The solution was evaporated to give a sirupy residue containing pyridine hydrochloride, which was then washed out with water several times. The sirup was crystallized and recrystallized from ethanol–petroleum ether to give crystalline **3** (16.7 g, 27%); mp 161.5—163.5°C (uncorrected); $[\alpha]_D^{20}$ −232° (*c* 1.02, $CHCl_3$); IR (KBr): 3320 cm^{-1} (OH). Found: C, 61.22; H, 6.27; N, 4.87%. Calcd for $C_{15}H_{19}NO_5$: C, 61.42; H, 6.53; N, 4.78%.

*Benzyl 2-Deoxy-3,4-O-isopropylidene-2-nitro-β-*D-*arabino-(4) and ribopyranoside (5).* Oxime **3** (100 mg) was stirred into an oxidizing agent, prepared by mixing successively 90% hydrogen peroxide (0.05 ml), trifluoroacetic anhydride (0.3 ml), acetonitrile (5 ml), dibasic sodium phosphate (1.15 g), and urea (5 mg), at room temperature. After 2 hr, the mixture was evaporated, then, the residue was dissolved in methylene chloride (100 ml). After it had been filtered, the solution was evaporated and chromatographed on silica gel with benzene to give a sirupy product (79 mg, 75%), which was subsequently rechromatographed on a silica-gel column (14×2.5 cm) developed slowly with benzene. The eluate was collected in 20 ml portions. Fractions No. 9—12 were combined and evaporated to give **5**, which was too hydroscopic and low-melting to be recrystallized; $[\alpha]_D^{20}$ −121° (*c* 1, $CHCl_3$); IR (neat): 1560 cm^{-1} (NO_2); NMR ($CDCl_3$): τ 4.39 (1H-*d*, $J_{1,2}=7$ Hz, H^1), 5.50 (1H-*q*, $J_{2,3}=3.5$ Hz, H^2), 5.01 (1H-*q*, $J_{3,4}=6.5$ Hz, H^3), 5.56 (1H-*sex*, $J_{4,5}=3.5$ Hz, H^4), 6.32 (2H-*d*, H^5, $H^{5'}$). Found: C, 58.21; H, 6.26; N, 4.45%. Calcd for $C_{15}H_{19}NO_6$: C, 58.24; H, 6.19; N, 4.53%.

The evaporation of Fractions No. 20—25 afforded sirupy **4**; $[\alpha]_D^{20}$ −200° (*c* 1, $CHCl_3$); IR (neat): 1560 cm^{-1} (NO_2); NMR ($CDCl_3$): τ 4.61 (1H-*d*, $J_{1,2}=3.7$ Hz, H^1), 5.55 (1H-*q*, $J_{2,3}=8$ Hz, H^2), 4.95 (1H-*q*, $J_{3,4}=6$ Hz, H^3), 5.71 (1H-*oct*, $J_{4,5}=2.5$ Hz, $J_{4,5'}=1.2$ Hz, H^4), 6.04 (1H-*q*, $J_{5,5'}=13.8$ Hz, H^5), 5.87 (1H-*q*, $H^{5'}$). Found: C, 58.20; H, 6.21; N, 4.40%

The Absolute Configulation of Dimethyl (−)-*erythro*-2-Ethyl-3-methylglutarate

Shosuke Ito and Yoshimasa Hirata

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received August 21, 1972)

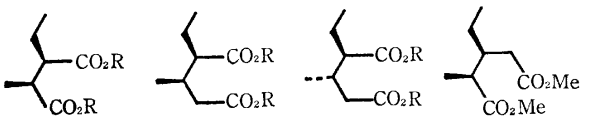
In the course of the structure elucidation of a new antibiotic, ikarugamycin, dimethyl (−)-2-ethyl-3-methylglutarate, $[\alpha]_D^{25}$ −8.6° (*c* 0.64, $CHCl_3$), was obtained as an oxidation product of ikarugamycin.[2)]

The two diastereomeric forms of 2-ethyl-3-methylglutaric acid (IIa and IIIa) have been prepared by Michael and Moss,[3)] but their stereochemistry has yet been determined distinctly. On the other hand, the absolute configuration of 2-ethyl-3-methylsuccinic acid has recently been determined by Brockmann and Müller-Enoch.[4)] Therefore, (+)-*erythro*-2-ethyl-3-methylsuccinic acid (Ia), whose absolute configuration had been proved to be 2*R*, 3*S*,[4)] was converted into optically-active dimethyl *erythro*-2-ethyl-3-methylglutarate (IIb) and dimethyl *erythro*-3-ethyl-2-methylglutarate (IV) as follows:

The *cis*-anhydride derived from Ia by the known method[5)] was heated with methanol to give a mixture of monocarboxy-monomethyl esters. It was homologized by successive treatment with oxalyl chloride, diazomethane, and then silver oxide in methanol. The resulting mixture consisted of three esters, Ib, IIb, and IV, which could be separated by preparative glc.

The structures of (−)-IIb, $[\alpha]_D^{25}$ −14.9°, and IV, $[\alpha]_D^{25}$ +46.3°, were determined on the basis of the following NMR and mass spectral evidence: The NMR spectrum of IIb shows two C-methyl signals in a relatively high field (δ 0.89 and 0.93), and its mass spectrum exhibits a peak due to McLafferty rearrangement at *m/e* 102. These facts indicate the presence of the CH_3–CH_2–CH–COOMe group. On the other hand, the presence of the CH_3–CH–COOMe group in IV is confirmed by the appearance of a C-methyl doublet at δ 1.07 and a peak due to McLafferty rearrangement at *m/e* 88.

The optically-active dicarboxylic acid IIa could not be crystallized, but it formed a crystalline dicyclohexylamine salt. To obtain further proofs for the IIb structure, racemic IIb and IIIb were prepared as authentic samples. A mixture of synthetic IIa and IIIa was converted into a mixture of anhydrides, which could be separated by preparative glc. The hydrolysis of the anhydrides gave (±)-IIa, mp 97—98°C, and (±)-IIIa, mp 99—100°C, respectively. The latter could also be obtained by repeated recrystallizations of the crude mixture of dicarboxylic acids.



Ia: R=H Ib: R=Me IIa: R=H IIb: R=Me IIIa: R=H IIIb: R=Me IV

The IR spectra of the naturally-derived ester, the optically-active synthetic ester ((−)-IIb), and the racemic ester ((±)-IIb) were superimposable on one another. Thus, the absolute configuration of dimethyl (−)-*erythro*-2-ethyl-3-methylglutarate ((−)-IIb) was determined to be 2*R*, 3*R*.

Experimental

All the melting points are uncorrected. The IR spectra were recorded on a JASCO IR-S spectrometer. The NMR spectra were recorded on a Nihondenshi JNM-C60H spectrometer, using TMS as the internal reference. The mass spectra were measured on a Hitachi RMU-6D mass spectrometer operating with an ionization energy of 70 eV. The optical rotations were measured on a JASCO ORD/UV-5 spectrometer and a JASCO DIP-SL spectrometer. The glc were carred out on a Varian Aerograph 1828-4 instrument.

*Syntheses of Dimethyl (−)-*erythro*-2-ethyl-3-methylglutarate (IIb) and Dimethyl (+)-*erythro*-3-ethyl-2-methylglutarate (IV).* (+)-*erythro*-2-Ethyl-3-methylsuccinic acid (Ia)[6)] (290 mg) was converted into the *cis*-anhydride (255 mg) by the known method.[5)] A solution of the anhydride in methanol (5 ml) was refluxed for 4 hr, and then concentrated to give a mixture of half methyl esters ($\nu_{max}^{CCl_4}$ 1748, 1711 cm^{-1}); the NMR spectrum of this mixture showed it to consist of two isomers in the ratio of *ca.* 2:1. Into a solution of the half methyl esters in benzene (2 ml), oxalyl chloride (2 ml) was stirred in one portion at 0°C; the mixture was then stirred at the same temperature for 1 hr and at room temperature for 5 hr. The subsequent concentration of the mixture under reduced pressure gave crude acid chlorides (330 mg), which were then dissolved in benzene (5 ml). Into an ethereal diazomethane (30 ml), the solution was vigorously stirred, drop by drop, at −10°C over a period of 0.5 hr; the mixture was then stirred at −10—0°C for 0.5 hr and at room temperature for 5 hr. The excess diazomethane and the solvent were removed under reduced pressure to give crude diazoketones ($\nu_{xeu}^{CCl_4}$ 2130, 1742, 1649 cm^{-1}). A mixture of the diazoketones and silver oxide (freshly-prepared from 0.2 g of silver nitrate) in methanol (30 ml) was refluxed for 2 hr with stirring. The mixture was then treated with charcoal, filtered through celite, and washed with methanol. The filtrates were concentrated under reduced pressure to give a mixture (215 mg) of dimethyl esters, which was roughly separated by column chromatography on silica gel (10 g) with

6) $[\alpha]_D^{25}$ +8.6° (*c* 2.5, EtOH); mp 179°C (lit,[4)] $[\alpha]_D^{20}$ +8.6° (*c* 2.5, EtOH); mp 180°C).

n-hexane–ether (9: 1) as the eluent. Further purification by repeated preparative glc (10% OV-17 column at 160°C) gave pure (+)-Ib (12 mg), (−)-IIb (35 mg), and (+)-IV (17 mg) as colorless oils. (+)-Ib: $[\alpha]_D^{25}$ +9.7° (*c* 1.0, $CHCl_3$). (−)-IIb: $[\alpha]_D^{25}$ −14.9° (*c* 1.13, $CHCl_3$); δ^{CCl_4} 0.89 (3H, d, J=6.8), 0.93 (3H, d, 6.3), 1.1—2.7 (6H, m), 3.61 (3H, s), 3.62 (3H, s); *m/e* 171 (M^+–OMe), 142, 129, 102, 101 (base peak), 87, 74. (+)-IV: $[\alpha]_D^{25}$ +46.3° (*c* 0.81, $CHCl_3$); δ^{CCl_4} 0.92 (3H, t, J=6.5), 1.07 (3H, d, 7.2), 1.1—1.6 (3H, m), 1.9—2.8 (3H, m), 3.61 (3H, s), 3.62 (3H, s); *m/e* 171 (M^+–OMe), 142, 129, 115, 88 (base peak), 73.

Dicyclohexylamine Salt of (−)-IIa. A solution of (−)-IIb (17 mg) in methanol (0.3 ml) was treated with 10% aqueous potassium hydroxide (0.3 ml) at 50°C for 2 hr. Working up as usual afforded 13 mg of (−)-IIa as an oil which could not be crystallized. Crude crystals of dicyclohexylamine salt of (−)-IIa were recrystallized from ethyl acetate–*n*-hexane to give 13 mg of needles; $[\alpha]_D^{25}$ −16.7° (*c* 0.72, MeOH). It showed no distinct melting point; mp *ca.* 103—108°C. Found: C, 67.59; H, 10.80; N, 3.94%. Calcd for $C_8H_{14}O_4C_{12}H_{23}N$: C, 67.57; H, 10.49; N, 3.94%.

Preparation of (±)-erythro-(IIa) and (±)-threo-2-ethyl-3-methylglutaric acid (IIIa). A mixture of (±)-IIa and (±)-IIIa was prepared according to the procedure of Snyder and Putnan.[7] A mixture of the acids (100 mg) and acetic anhydride (2 ml) was refluxed for 4 hr, and then concentrated under reduced pressure to give 80 mg of a mixture of *trans*- and *cis*-anhydrides. Separation with preparative glc (5% OV-17 column at 160°C) afforded 42 mg of *trans*-anhydride (93% pure) as an earlier fraction and 20 mg of *cis*-anhydride (80% pure) as a later fraction.

trans-Anhydride: $\nu_{max}^{CCl_4}$ 1821, 1772 cm^{-1}; δ^{CCl_4} 0.98 (3H, t, J=7.2), 1.13 (3H, d, 6.0).

cis-Anhydride: $\nu_{max}^{CCl_4}$ 1821, 1773 cm^{-1}; δ^{CCl_4} 0.98 (3H, d, J=6.0), 1.04 (3H, t, 6.6).

Each anhydride was hydrolysed by refluxing it in tetrahydrofuran–water (2: 1) for 2 hr; this gave crude acids. Several recrystallizations from ether–*n*-hexane gave pure (±)-IIIa (37 mg) and (±)-IIa (10 mg) as prisms respectively. The pure (±)-IIIa was also obtained by repeated recrystallization of a mixture of (±)-IIa and IIIa from ether–*n*-hexane.

(±)-IIIa: mp 99—100°C (lit, mp 100—101°C[3]). The dimethyl ester ((±)-IIIb): δ^{CCl_4} 0.89 (3H, t, J=6.8), 0.95 (3H, d, 6.8), 1.1—2.6 (6H, m), 3.62 (3H, s), 3.64 (3H, s).

(±)-IIa: mp 97—98°C (lit, 88°C[3]). The NMR and IR spectra of its dimethyl ester ((±)-IIb) were identical with those of the natural and synthetic (−)-IIb.

The Reaction of 7-Methylenebicyclo[3.3.1]nonan-3-one and Bicyclo-[3.3.1]nonane-3,7-dione with Several Nucleophiles[1)]

Ryohei YAMAGUCHI, Kwan Her YANG, and Mituyosi KAWANISI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

(Received August 14, 1972)

In connection with the current interest in bicyclo-[3.3.1]nonane system,[2-4)] we had occasion to examine the behavior of some nucleophiles towards 7-methylene-bicyclo[3.3.1]nonan-3-one (Ia) as well as bicyclo[3.3.1]-nonane-3,7-dione (Ib), reactions of which led to some novel products.

In the following reactions, transannular cyclization took place giving *adamantane* derivatives. In the reaction of Ia with aniline, Schiff's base (Ic) was not formed, but 3-phenylaminoadamantan-1-ol (IIa) was obtained as the sole isolable product in a 90% yield.

a: X=Ph-NH
b: X=Ph-NMe
c: X=Ph-O
d: X=Ph-S

By the similar treatment of Ia with *N*-methylaniline, 3-*N*-methylphenylaminoadamantan-1-ol (IIb) was obtained in a 56% yield. The Eschweiler-Clarke methylation[5)] of IIa afforded IIb; thus, a structural correlation between IIa and IIb was established. *N,N*-Dimethylaniline did not react with Ia under the reaction conditions. With phenol, Ia afforded 3-phenyloxy-adamantan-1-ol (IIb) in a 38% yield, with thiophenol 3-phenylthioadamantan-1-ol (IId) in a 53% yield. The structures of these compounds were all supported by the spectral data. The transannular reaction described herein did not take place without molecular sieves. Stetter has pointed out that Ia cyclizes under acid

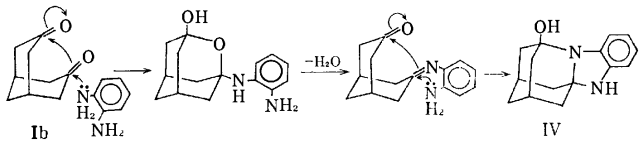
catalysis,[3d] and in the present case the molecular sieves probably act as an acidic catalyst.[6]

In the reaction of Ib with aniline, an *oxaadamantane* derivative, 3-phenylamino-2-oxaadamantan-1-ol (III), was formed as a labile product in a 28% yield. The structure of III was supported by its spectral data. The prolonged heating of Ib under the same conditions produced another product (Id) at the expense of III; this was confirmed by following the progress of the reaction by means of glc. We also observed that III was converted into Id by the reaction with aniline in the presence of molecular sieves. These observations suggest that III, a metastable hemiacetal, is dehydrated by the action of molecular sieves into an intermediate such as Ie, which subsequently condenses with aniline to give Id.

In the similar reaction of Ib with *o*-phenylenediamine, an intriguing cyclization took place to give IV, an *azaadamantane* derivative, in an 81% yield as a considerably unstable compound. The structure of IV could be assigned on the basis of the physical data. The NMR spectra, however, were not reproducible because of the instability of IV in solution. The formation of IV can be tentatively explained by the following scheme:



Experimental

All the melting points are uncorrected. The microanalyses were performed by Mrs. Kiyoko Fujimoto. The IR spectra were obtained on a Shimadzu IR-27 spectrophotometer. The mass spectra were taken using a Hitachi RMS-4 mass spectrometer. The NMR spectra were obtained on a JEOL C-60-H spectrometer in a $CDCl_3$ solution, with TMS as the internal standard.

Reagents. 7-Methylenebicyclo[3.3.1]nonan-3-one (Ia)[3d] and bicyclo[3.3.1]nonan-3,7-dione (Ib)[4b] were prepared according to the reported methods. The aniline, *N*-methylaniline, phenol, thiophenol, and *o*-phenylenediamine were of commercial reagent grade. The molecular sieves was of Type 3A.

Preparation IIa. A mixture of Ia (0.9 g), aniline (0.69 g), and molecular sieves (2 g) in benzene (20 ml) was refluxed for 26 hr, and then the molecular sieves were removed by filtration. The evaporation of the solvent yielded 1.69 g of a brown oil which gradually solidified. Recrystallization from benzene gave 1.43 g (90%) of pure IIa; mp 115—118°C. Found: C, 78.87; H, 8.64; N, 5.92%. Calcd for $C_{16}H_{21}NO$: C, 78.97; H, 8.70; N, 5.76%. IR (KBr): 3300, 3280, 2920, 1600, 1495, 1320, 1125, 1050, 910, 770, 740, 695 cm^{-1}. NMR: δ 1.33—1.93 (m, 12H), 2.27 (br. s, 2H), 2.73 (s, 2H), 6.67—7.33 (m, 5H). MS: *m/e* 243 (M^+), 93 (M^+—150: 100%).

Preparation of IIb. A mixture of Ia (0.9 g) *N*-methylaniline (0.65 g), and molecular sieves (2 g) in benzene (20 ml) was treated similarly; a subsequent work-up as described above gave a white solid (0.86 g; 56%). Recrystallization from petroleum ether (bp 40—60°C) yielded pure IIb; mp 114.5—116.5°C. Found: C, 79.08; H, 8.85; N, 5.45%. Calcd for $C_{17}H_{23}NO$: C, 79.33; H, 9.01; N, 5.44%. IR (KBr): 3240, 2920, 1595, 1490, 1445, 1305, 1260, 1100, 1010, 940, 800, 770, 695 cm^{-1}. NMR: δ 1.35—1.70 (m, 12H), 2.25 (br. s, 3H), 2.76 (s, 3H), 7.27 (s, 5H). MS: *m/e* 257 (M^+), 107 (M^+—150; 100%).

Methylation of IIa. A mixture of IIa (12 mg), formaldehyde (37%; 2 ml), and formic acid (99%; 1.5 ml) was heated under reflux for 24 hr. The base liberated by the addition of potassium hydroxide was extracted with ether and chloroform. The extracts were combined and dried (Na_2SO_4). Evaporation left a white solid, the sublimation of which gave pure IIb (58 mg; 88%); mp 115—117°C.

Reaction Ia with Phenol and Thiophenol. The similar reaction of Ia with phenol and with thiophenol afforded IIc (38%) and IId (53%) respectively. Analytical samples were obtained by preparative glc. The physical data of IIc and IId are as follows.

IIc; IR (KBr): 3370, 2950, 1595, 1495, 1115, 1030, 1010, 995, 675 cm^{-1}. NMR: δ 1.27—2.50 (m, 15H), 6.83—7.43 (m, 5H). MS: *m/e* 244 (M^+), 94 (M^+—150; 100%). mp 94—96°C. Found: C, 77.54; H, 8.27%. Calcd for $C_{16}H_{20}O_2$: C, 77.65; H, 8.25%. IId; IR (KBr): 3300, 2920, 1470, 1350, 1100, 1090, 975, 935, 750, 690 cm^{-1}. NMR: δ 1.43—1.90 (m, 12H), 2.03 (s, 1H), 2.23 (br. s, 2H), 7.40 (br. s, 5H). MS: *m/e* 260 (M^+), 151 (M^+—109; 100%). mp 131—133°C. Found: C, 73.67; H, 7.53%. Calcd for $C_{16}H_{20}OS$: C, 73.80; H, 7.74%.

Preparation of III. A mixture of Ib (618 mg), aniline (1.6 g), and molecular sieves (10 g) in benzene (15 ml) was refluxed for 6 hr. The usual work-up yielded a brown oil which solidified afterward. Recrystallizations from benzene gave a white solid (280 mg; 28%). This compound is exceedingly unstable and did not give satisfactory analysis. Mp 81.5—82.5°C. IR (KBr): 3300, 3260, 1605, 1500, 1340, 1190, 1155, 970, 930, 885, 745, 695, 680 cm^{-1}. NMR: δ 1.96—2.95 (m, 12H), 3.44 (s, 2H), 6.55—7.42 (m, 5H). MS: *m/e* 227 (M^+—18), 152 (M^+—93), 95 (M^+—150). The reaction of III and aniline in the presence of molecular sieves in benzene was effected similarly; the formation of Id described below was confirmed by glc.

Preparation of Id. A mixture of Ib (2 g), aniline (3.7 g), and molecular sieves (50 g) in benzene (30 ml) was refluxed for 28 hr. The usual work-up gave a brown oil, which immediately solidified. The solid was washed with ether and recrystallized from benzene, thus yielding pure Id (2 g; 51%); mp 190—191°C. Found: C, 83.28; H, 7.52; N, 9.11%. Calcd for $C_{21}H_{22}N_2$: C, 83.40; H, 7.33; N, 9.26%. IR (KBr): 3060, 2950, 1660, 1595, 1490, 1245, 1185, 1070, 905, 830, 785, 705 cm^{-1}. NMR: δ 1.80—2.85 (m, 14H), 6.70—7.45 (m, 10H). MS: *m/e* 302 (M^+), 170 (M^+ 132), 77 (M^+—225; 100%).

Preparation of IV. A mixture of Ib (110 mg), *o*-phenylenediamine (80 mg), and molecular sieves (2 g) in benzene (3 ml) was refluxed for 2 hr; the catalysts were then removed by filtration while the solution was hot. On cooling, colorless needles were obtained; these were collected by filtration and washed with chilled benzene. The azaadamantane derivative (IV) (141 mg; 81%) was obtained after drying *in vacuo*; mp 191—193.5°C (in nitrogen-sealed tube). Found: C, 74.67; H, 7.73; N, 11.46%. Calcd for $C_{15}H_{18}N_2O$: C, 74.35; H, 7.49; N, 11.56%. IR (KBr): 3390, 3290, 2930, 1594, 1489, 1295, 1145, 1085, 730 cm^{-1}. MS: *m/e* 242 (M^+), 132 (M^+—110; 100%).

N-Isopropylidene- and *N-sec*-Butylideneanilines. I. Preparation and Characterization

Michiko TSUCHIMOTO, Shigeo NISHIMURA, and Hiizu IWAMURA*

Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Koganei, Tokyo

**Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo*

(Received March 27, 1972)

In marked contrast to the chemistry of *N*-benzylideneanilines,[1] little is known of the ketimines from lower aliphatic ketones and aromatic amines because of the difficulty in preparing pure samples.[2] Recently some ketimines have been prepared from acetone and amines using a molecular sieve as dehydrating agent.[3]

In this paper we report syntheses of twenty-one new ketimines of acetone and ethyl methyl ketone with various anilines by means of a method using a molecular sieve as dehydrating agent. The course of the reaction was effectively monitored by the NMR spectra of the aliquots. It was found important to run the reaction at temperatures not higher than room temperature. Under these conditions, undesirable side reactions were minimized. The structure of the ketimines was confirmed by elemental analyses and IR and NMR spectra (Tables 1 and 2).

All the acetone anils showed two characteristic peaks due to the methyl groups in the NMR spectra as summarized in Table 2. Those from *p*-substituted anilines gave a symmetric NMR pattern characteristic of AA'XX' spin system for ring protons, showing the correct structure for ketimines. This also indicated that, while nitrogen inversion is sufficiently slow to give distinction between methyl groups *syn* and *anti* to the aromatic ring, the rotation around the *N*-Ar bond is fast relative to the time scale of the chemical shifts; otherwise the aromatic protons should give an ABXY pattern.

The assumption that the methyl group *syn* to the aromatic ring is the one with the resonance at higher field was verified by a study of the paramagnetic shifts induced by the addition of tris(dipivalomethanato)-europium(III) ($Eu(DPM)_3$). It was always the methyl signal at lower applied field which underwent a larger paramagnetic shift.

a) 0.25 mmol/0.5ml D-DMSO b) Koga *et al.* previously reported NMR data of some *N*-isopropylideneanilines without obtaining the products in pure states; G. Koga, *et al.*, *5th NMR Symposium*, Abstract p. 28, Sendai (1966). c) H. A. Staab, *et al.*, *Tetrahedron Lett.*, **1965**, 697. d) D. Y. Curtin, *et al.*, *J. Amer. Chem. Soc.*, **88**, 2775 (1966).

The NMR spectra of *N*-*sec*-butylideneanilines are composed of two sets of peaks, one always about 4 times stronger than the other. From numerical comparison of the chemical shifts with those of *N*-isopropylidene derivatives and also from a shift reagent study, it is concluded that the presence of the *E* form is more prevalent than that of the *Z* isomer.

Experimental

Preparation. According to the standard procedure for the synthesis of *N*-isopropylideneaniline, 30 g of molecular sieve 4A (18—20 mesh, Gasukuro Kogyo Co., Ltd.) was added to a solution of 0.1 mol of acetone and 0.05 mol of aniline in anhydrous ether. The mixture was kept at 10°C for 24 hr. About 30% of the starting aniline was still found to remain unchanged. In order to complete the reaction, it was advisable to renew the molecular sieve at this stage of the reaction. It took about 48 hr to attain more than 95% completion of the reaction (the reaction was followed by observing the lower field signals of 3,5 ring protons by NMR spectra with 0.5 ml of aliquots). The reaction of *p*-chloro- and *p*-bromoaniline was sluggish and took 9 to 10 days to practically reach completion. *p*-Nitroaniline reacted exceedingly slowly under these conditions, only 50% conversion being attained after 10 days. It took 25 days to get more than 95% conversion by renewing the molecular sieve 4 times. After removing the molecular sieve by filtration and the solvent on a rotary evaporator, the residue was fractionally distilled, great care being taken to exclude moisture throughout the operation. The anils with the electronegative ring substituents are less stable, a slight decomposition being noted during the course of distillation. *N*-Isopropylidene-*p*-aminophenol was prepared by letting the solution of *p*-aminophenol in warm acetone to stand for about 15 min at room temperature, without using the molecular sieve. Mono acetone anil of *p*-phenylenediamine was prepared from the equimolar diamine and acetone, while the diacetone anil was obtained with the use of excess acetone. These anils were obtained as crystals and purified by recrystallization from ether–DMSO (20: 1).

N-sec-Butylideneanilines were similarly prepared by the reaction of ethyl methyl ketone with aromatic amines.

Nuclear Magnetic Resonance Spectra. NMR spectra were obtained on a JEOL C-60 HL (Japan Electron Optics Lab. Co., Ltd.) (60 MHz), with an internally-locked field-frequency stabilization control system. The samples (0.25 mmol) were dissolved in 0.5 ml of $CDCl_3$ and the chemical shifts were read relative to TMS as an internal reference at 25°C by an electronic-frequency counter in Hz. $Eu(DPM)_3$ was added to the above $CDCl_3$ solutions when required. The shift values for the ring protons (Table II) were obtained by a first order approximation from their peaks.

The authors wish to thank Mr. Shozo Masuda and members of his group, The University of Tokyo, for the elemental analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 677—678 (1973)

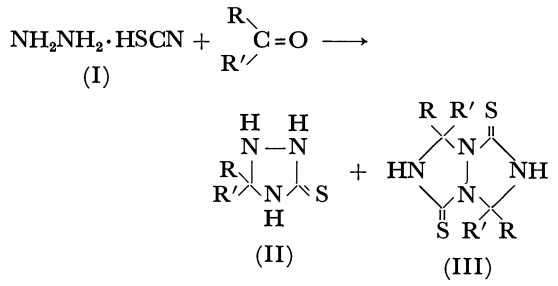
Reactions of Hydrazinium Thiocyanate with Aldehydes and Ketones

Isamu ARAI, Shintaro ABE, and Akira HAGITANI

Department of Chemistry, College of Science, St. Paul's University (Rikkyo Daigaku), Nishi-Ikebukuro, Toshima-ku, Tokyo

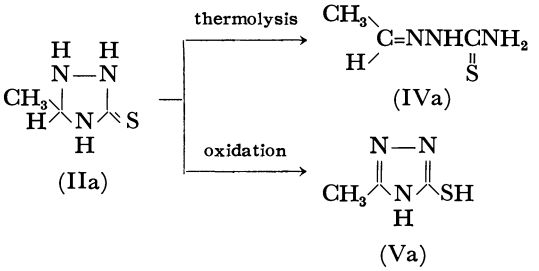
(Received September 4, 1972)

In a previous paper,[1] we reported on the reactions of hydrazinium thiocyanate (I) with alcohols to give 1,2,4-triazolidine-5-thione derivatives (II). These reaction mechanisms were not clear but the structure of II suggested that II can also be prepared from the reactions of I with aldehydes and ketones. Sunner[2] and Futaki and Tosa[3] studied these reactions and obtained triazolo-triazole derivatives III, but they did not isolate II. We have reinvestigated these reactions and have found that fairly large quantity of II is obtained together with III. Formation of II is easily overlooked because II is not stable to heat, light and moisture, and readily hydrolyzes or decomposes by ring opening. In this paper, we report on preparation of II and its structure.



When an aqueous solution of (I) and acetaldehyde was allowed to stand at room temperature, white needles (IIa), mp 122°C (decomp.), were obtained together with 1,5-dimethyl-*s*-triazolidino [1,2-*a*]-*s*-triazolidine-3,7-dithione (triazolo-triazole compound (IIIa)[4]). The elemental analysis (Table 2) and MS spectral data of (IIa) gave a molecular formula $C_3H_7N_3S$. The IR spectrum showed absorption bands for NH, CH_3, and C=S groups; and the NMR spectrum indicated the presence of ethylidene group at τ 8.61 (3H, d, J=6.0 Hz) and 5.00 (1H, q, J=6.0 Hz). Thermolysis of IIa gave acetaldehyde thiosemicarbazone (IVa) and oxidation gave 3-methyl-5-mercapto-1,2,4-triazole (Va).

The following structure was deduced for IIa.



The mass spectrum also supported this structure *viz.*, it showed ions at *m/e* 117 (M), 116 (M−1), and 102 (M−15). The ion of *m/e* 58 generated by the loss of HSCN from the molecular ion indicated the presence of an –NH·CS– group in the molecule.

Other aldehydes and ketones were also treated with I to give 1,2,4-triazolidine-5-thione derivatives (II) in considerable yields (Table 1).

TABLE 1. REACTIONS OF HYDRAZINIUM THIOCYANATE (I) WITH ALDEHYDES AND KETONES[a]

Aldehyde	Yield (%) of II	Ketone	Yield (%) of II
CH_3CHO	34.36	CH_3COCH_3	6.85

		$C_2H_5COC_2H_5$	56.18
			72.18

a) Water (ketone) or 50% aqueous methanol (aldehyde) was used as reaction solvent.

We considered that the 1,2,4-triazolidine-5-thione derivatives (II) was produced by the cycloaddition of thiocyanic acid to the hydrazones formed from aldehydes and ketones with hydrazine.

Experimental

All melting points are uncorrected. The IR spectra were recorded from KBr pellets using a Shimadzu model IR-27B infrared spectrometer, and the NMR spectra were measured in a solution of deuteriomethanol with a Varian A-60 spectrometer. The mass spectra were obtained on a CEC 21-110B spectrometer at 70 eV.

Reaction of Hydrazinium Thiocyanate (I) with Acetaldehyde. Freshly prepared acetaldehyde (4.41 g, 0.1 mol) was added dropwise to a cooled solution of hydrazine monohydrochloride (6.85 g, 0.1 mol) and sodium thiocyanate (8.10 g, 0.1 mol) in 50% aqueous methanol (100 ml) with stirring. The solution was then stirred at room temperature for 24 hr under shield from light. The white precipitate (2.03 g) was filtered and recrystallized from methanol to give 1,5-dimethyl-*s*-triazolidino [1,2-*a*]-*s*-triazolidine-3,7-dithione (IIIa), mp 169°C (decomp.), (lit,[2] 168°C (decomp.)). The filtrate was evaporated to dryness under reduced pressure and the residue was extracted with methylene chloride. This extract was evaporated and the residue (3.87 g) gave 3-methyl-1,2,4-triazolidine-5-thione (IIa), mp 122°C (decomp.), from chloroform.

IR of (IIa): 3175, 2975, 2850, 1510, 1465, 1405, 1375, 1210, 1070, 945, 885 cm^{-1}.

MS of (IIa): *m/e* 117 ($C_3H_7N_3S^+$), 116 ($C_3H_6N_3S^+$), 115 ($C_3H_5N_3S^+$), 102 ($C_2H_4N_3S^+$), 101 ($C_2H_3N_3S^+$), 58 ($C_2H_6N_2^+$).

Thermolysis of 3-Methyl-1,2,4-triazolidine-5-thione (IIa). A solution of 0.5 g of (IIa) in 2-butanol (25 ml) was refluxed for 3 hr and then evaporated. The residue (0.5 g) was recrystallized from ethanol to give acetaldehyde thiosemicarbazone (IVa), mp 140°C, (lit,[5] mp 140°C).

Oxidation of 3-Methyl-1,2,4-triazolidine-5-thione (IIa). Oxygen was passed into a solution of one gram of (IIa) in 1N sodium hydroxide (50 ml) for 5 hr with stirring at room temperature. The solution was then acidified with 1N hydrochloric acid and concentrated under reduced presure. The white precipitate (0.64 g) was filtered and recrystallized from water to give 3-methyl-5-mercapto-1,2,4-triazole (Va), mp 270°C, identified by comparison (mixed mp and IR spectra) with an authentic sample.[6]

Kinetic Studies of the Acid-catalyzed Amination of *p*-Nitrosoanisole with Anilines in Methanol

Yoshiaki FURUYA and Katsumi TERAOKA

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto

(Received November 4, 1971)

The allelotrope of *p*-nitrosophenol[1] and/or another keto-enol tautomers[2,3] are easily etherified with an alcohol in the presence of inorganic acid, even at room temperature. Furthermore, the methoxy group of the methyl ether of the allelotrope, *p*-nitrosoanisole, can readily be replaced by an electro-negative atom with an unshared electron pair, such as the N-atom of amines. Thus, *p*-nitrosodiphenylamines are obtained by the title reaction in a favorable yield.[4]

In the present paper, we should like to propose a new reaction mechanism, though a mechanism has previously been speculated on the basis of the synthetic data.[4]

Experimental

Materials. The *p*-nitrosoanisole (abbreviated as PNA) was prepared by the reaction of the allelotrope of *p*-nitrosophenol (abbreviated as PNP) with methanol in the presence of sulfuric acid.[5] The blue crystals obtained by subsequent steam distillation were recrystallized twice from petroleum ether; yield, 50%; mp 23°C (lit, 23°C[6]). The product was kept at 0°C in a dark place for safe storage. Commercial *p*-nitrosodiphenylamine (abbreviated as PNDA) was recrystallized three times from benzene; mp 143—145°C (lit, 143°C,[7] 144—145°C[4]). The *p*-nitroso-*p'*- or -*m'*-substituted diphenylamines were prepared by the acid-catalyzed amination of *p*-nitrosoanisole with the corresponding *p*- or *m*-substituted anilines and were recrystallized from benzene and/or methanol; *p*-nitroso-*p'*-methoxydiphenylamine, mp 163—165°C (lit, 164—166°C[4]); *p*-nitroso-*p'*-methyldiphenylamine, mp 172—173°C (lit, 172—173°C[4]); *p*-nitroso-*p'*-chlorodiphenylamine, mp 158—159°C (lit, 157—160°C[4]); *p*-nitroso-*m'*-chlorodiphenylamine,[8] mp 148.5—149.5°C. Found: C, 62.04; H, 3.93; N, 12.05%. Calcd for $C_{12}H_9ClN_2O$: C, 61.95; H, 3.93; N, 12.04%. Commercial aniline, *p*-toluidine, *m*-chloroaniline, and *p*-chloroaniline were distilled twice under reduced pressure; aniline, bp 83°C/23 mmHg; *p*-toluidine, bp 95—95.5°C/22 mmHg; *m*-chloroaniline, bp 114—114.5°C/20 mmHg; *p*-chloroaniline, bp 115—116°C/21 mmHg. The *p*-anisidine was recrystallized from water and methanol–water; mp 58°C. Methanol as a medium was rectified; bp 65—65.5°C. The methanolic solution of hydrogen chloride was prepared by bubbling hydrogen chloride well dried with phosphorus pentoxide into the rectified methanol.

Reaction Product Criterion. A mixture (50 ml) of PNA (0.2M), aniline (0.5M), and hydrogen chloride (0.05N) in methanol was kept at 30°C for 11 hr, and then neutralized with methanolic potassium hydroxide. The mixture was filtered after adding water. PNDA was thus obtained; mp and mmp 143—145°C; yield 90%.

Ultraviolet Spectrophotometry and Chemical Analysis. The conversion percentages were calculated from the calibration curve which has been prepared by plotting the difference in extinction at 260, 290, and 340 nm, $(E_{260}-E_{340})$ *vs.* $(E_{290}-E_{340})$, and at 0 and 100% conversions. The difference between the conversion percentage obtained from the curve and that obtained from the composition of the mixture was within 1% at each attempted conversion percentage.

A Typical Run for the Rate Measurements. A two ml portion of methanolic solution of 1M PNA was poured into 8 ml of a methanolic solution containing 0.625M aniline and 0.0625N hydrogen chloride in order to start the reaction after both the solutions had attained the temperature equilibrium at 30°C. Aliquots (0.1 ml, each) were taken out at appropriate intervals of time and then diluted with methanol to a 4×10^{-5}M total concentration of PNA and PNDA. The conversion percentage was calculated graphically.

Results and Discussion

When the reaction product, PNDA, was kept at 30°C for 48 hr in methanol containing 0.01N hydrogen chloride, a slight side reaction tends to occur,[9] but the reverse reaction does not take place at all. There-

fore, the amination reaction follows the irreversible second-order rate equation with PNA and aniline:

$$v = k_{2obs}[PNA][Aniline] \quad (1)$$

The rate was affected by the acidity. The plots of k_{2obs} *vs.* the square root of the concentration of hydrogen chloride gave a straight line passing through the point of origin, as is shown in Fig. 1. Therefore, the rate constant, k_{2obs}, may be expressed as follows:

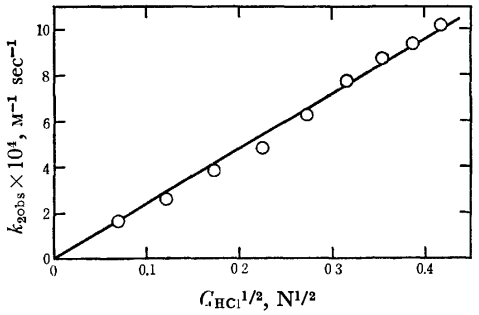

Fig. 1. The plot of k_{2obs} *vs.* square root of the concentration of hydrogen chloride in methanol for the amination of PNA with aniline at 30°C.
Initial concen. of PNA: 0.2M, Initial concen. of aniline: 0.5M

$$k_{2obs} = k_2 C_{HCl}^{1/2} \quad (2)$$

Here, $C_{HCl}^{1/2}$ is expressed as:

$$C_{HCl}^{1/2} = C_{H^+}/K^{1/2} \quad (3)$$

where K is the dissociation constant of hydrogen chloride in methanol. Therefore, the following relationship is obtained:

$$k_{2obs} = k_2 K^{-1/2} C_{H^+} \quad (4)$$

The pK_{BH^+} values of aniline, methanol, and the allelotrope of PNP in water are 4.6,[10] −2.5,[11] and −3.4,[1] respectively. As the σ_p value of the hydroxyl group (−0.357) is smaller than that of the methoxy group (−0.268), the pK_{BH^+} value of PNA may be smaller than that of the allelotrope of PNP. Thus, the order of ease for the protonation may be expressed as: aniline≫methanol>PNA. In other words, the protonated aniline exists in the medium predominantly.

On the other hand, the reaction was accelerated by the introduction of an electron-releasing group into the phenyl group of aniline, and retarded by the introduction of an electron-attracting group, as is shown in Table 2 and Fig. 2. The plot of the logarithm of the rate constant ratio, $\log k_2/k_{20}$, against Deno's σ^+ gives a straight line with a slope of −0.95 (r=0.994), as is

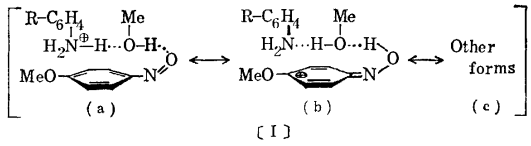
Concen. of HCl: 0.05N.

shown in Fig. 2.[12] These results suggest the participation of the anilinium ion in the formation of transition state of this reaction.

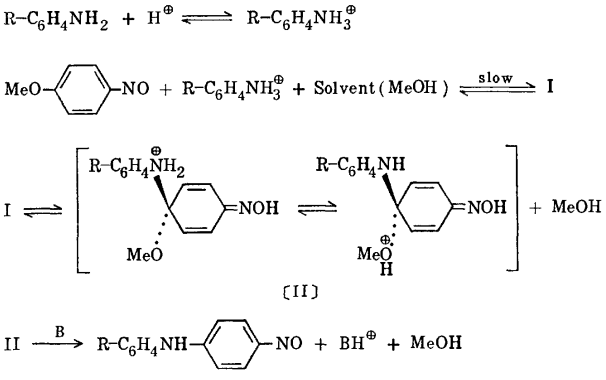
Moreover, the value of the activation entropy of the reaction (−47.01 e.u.) is much smaller than that in the ordinary protonation. Therefore, the transition state having a hydrogen-bonding annular construction of the protonated aniline, PNA, and a solvent molecule such as is illustrated below might be involved.[13] The over-all rate may be controlled by this step.



[I]

It is considered that the contribution of the Ib structure may be important because of the increase in the stability of the positive charge by diffusion into the benzene ring of PNA; hence, the nucleophilic attack of the N-atom of aniline on the positive C-atom of Ib may occur predominantly in the following step.

From these findings and considerations, a probable mechanism may be charted as below:



[II]

12) If the direct nucleophilic attack of aniline on the protonated PNA[4] occurs, σ values should be used in Hammett plot of this reaction.

^{18}O Tracer Studies of Catalytic Oxidations of Olefin over Transition Metal or Metal Oxide Catalysts. II. Oxidation of Propylene to Acrolein over Pd-Carbon Catalyst

Yoshihiko MORO-OKA, Tomohisa OHHATA, Yusaku TAKITA, and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo

(Received June 27, 1972)

In the first paper of this series, we reported a new type oxygen incorporation where oxygen atom in water molecule is incorporated into the oxidized products, *i.e.*,

$$A(olefin) + 1/2O_2 + H_2O^* \rightarrow AO^* + H_2O \quad (1)$$

We demonstrated by use of $H_2{}^{18}O$ tracer that the oxidation of propylene to acetone over SnO_2-MoO_3 catalyst follows Eq. (1) and called it oxyhydration.[1,2] Further study has been carried out to find new oxyhydrations. The route of oxygen incorporation was examined using $H_2{}^{18}O$ tracer in the catalytic oxidation of propylene to acrolein over Pd-carbon catalyst which was independently found by Fujimoto *et al.*[3] and by Seiyama *et al.*[4].

Experimental

Pd-carbon catalyst was prepared from activated charcoal and palladium chloride.[3] 10—20 mesh activated charcoal was boiled for 5 hr in dilute nitric acid solution and then washed with water until pH of the filtrate become higher than 4. This was impregnated with palladium chloride dissolved in 0.5 N HCl solution and allowed to stand for 24 hr. Palladium chloride supported on the activated charcoal (5 wt% $PdCl_2$) was reduced to metallic palladium by hydrogen gas at 250°C for 5 hr and activated by air at 230°C for 12 hr.

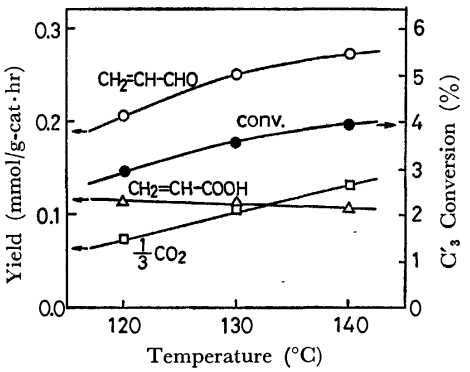

Fig. 1. One pass conversion of propylene and yields of oxidized products in the oxidation of propylene over Pd-carbon catalyst.

All the runs were carried out using a conventional flow system at atmospheric pressure. The reactor was a Pyrex tube of 8 mm diameter. The exit gases were cooled by water to separate gaseous and liquid phases, and analyzed by gas chromatography and mass spectrometry.

The ^{18}O content of the oxidized products was determined by mass spectrometry after separation and purification by gas chromatography. The mass spectra obtained at 80 V of ionization voltage were corrected for natural abundances, no isotope effect being assumed for the ionization efficiency. The ^{18}O content of acrolein was calculated from the peak height ratio, h_{58}/h_{56}, in the corrected mass spectra. The ^{18}O content of the unreacted oxygen was determined by mass spectrometry after it was converted into carbon dioxide by the reaction with the stoichiometric amount of carbon monoxide using a closed circulating reaction system and Pt-asbestos catalyst.

Results and Discussion

Propylene was oxidized at 120—140°C over Pd-carbon catalyst. 1.9 g of the catalyst was used in the fixed catalyst bed. The flow rates of each reactant gas were 10.0, 8.0, and 27.6 ml-STP/min for propylene, oxygen and water, respectively, GHSV being 530 ml-STP/ml-cat hr.

The activity of Pd-carbon catalyst and selectivity for each product changed gradually during the first few hours. They became constant after 10 hr and did not change any more in the subsequent runs. The main products were acrolein, acrylic acid, and carbon dioxide.[3] Although small amounts of acetone and acetaldehyde were produced, their total yield did not exceed 10% of the converted propylene. The values of one pass conversion of propylene and the yields of the main products at three different temperatures are shown in Fig. 1. The selectivity to acrolein was 50—55% of the converted propylene.

Tracer experiment was carried out at 130°C. Propylene was oxidized over Pd-carbon catalyst under the same conditions as mentioned above except that water in the reactant gas was replaced by water enriched with $H_2{}^{18}O$. The results are summarized in Table 1.

The values in the third column of Table 1 give ^{18}O content of the acrolein produced in the presence of 5.48% $H_2{}^{18}O$. In every run, ^{18}O tracer is found in acrolein with reasonably high concentrations. Thus, it is clear that the oxygen atom comes mostly from the water molecule. This suggests that acrolein is produced by an interaction between propylene and some active species derived from water on Pd-carbon cata-

lyst. However, another possibility should be examined, *i.e.*, the incorporation of ^{18}O into the oxidized product results from the following exchange reactions.

$$^{16}O_2 + H_2{}^{18}O \rightleftharpoons {}^{16}O{}^{18}O + H_2{}^{16}O \quad (2)$$

$$CH_2{=}CH{-}CH^{16}O + H_2{}^{18}O \rightleftharpoons CH_2{=}CH{-}CH^{18}O + H_2{}^{16}O \quad (3)$$

These oxygen exchange reactions were also examined using $H_2{}^{18}O$ tracer. The ^{18}O contents of the unreacted oxygen are listed in the last column of Table 1. They suggest that a slight oxygen exchange reaction takes place between molecular oxygen and water under the conditions adopted in the runs. However, the values are too low to explain the ^{18}O contents found in the acrolein produced. Thus, the possibility that ^{18}O in the acrolein was incorporated from the $^{16}O{}^{18}O$ molecule formed by the exchange reaction as expressed in Eq. (2) can be rejected.

Table 1. ^{18}O content of the product in the oxidation of propylene to acrolein over Pd-carbon catalyst[a)]

Reaction	^{18}O content (atomic %)	
	$CH_2{=}CH{-}CHO$	O_2 (unreacted)
Oxidation	3.62	0.20
	4.36	0.22
	3.41	0.14
Exchange[b)]	0.75	—
	1.13	—

a) ^{18}O content of the reactant water is 5.48%.
b) Oxygen exchange reaction between acrolein and water.

Another oxygen exchange reaction between acrolein and water was examined using $H_2{}^{18}O$ tracer. The reaction conditions were the same as adopted in the oxidation runs, except that propylene in the reactant gas was replaced by nitrogen. The contact time of acrolein and its concentration in the reactant gas were adjusted to those produced in the oxidation runs. The results are shown in Table 1. Although some exchange reaction was observed under the conditions, the rate of exchange reaction was smaller than that of oxidation. The ^{18}O contents found in the produced acrolein are not attributable to the exchange reaction as given by Eq. (3). It seems reasonable that acrolein is produced by direct interaction between some active species of propylene and water, and that the oxidation of propylene on Pd-carbon catalyst is at least partly an oxyhydration.

Although the incorporation of ^{18}O into acrolein seems to be due to some direct interaction between the active species of propylene and water, ^{18}O content found in the acrolein was somewhat lower than that of water in the reaction system. The ^{18}O content of the issuing water was not determined because of inaccuracy of the mass spectrometry of water. However, since the conversion of propylene was lower than 4%, the ^{18}O content of the issuing water calculated on the mass balance of ^{18}O is higher than 5.30%. This indicates that the incorporation of oxygen into the acrolein also involves some active species originating from molecular oxygen as well as water. One possible explanation is that the oxidation to form acrolein involves a hydroxyl group which is formed by a reaction between atomic oxygen and propylene or some intermediate derived from propylene. If this is the case, the hydroxyl group formed on the catalyst surface would be indistinguishable from the active species of water, and the oxidation to form acrolein might be a sort of chain reaction.

A number of transition metal oxide catalysts have been developed for the oxidation of propylene to acrolein. Keulks[5)] and Wragg *et al.*[6)] have proved by using ^{18}O tracer that the oxygen ion in the oxide catalyst is incorporated into the oxidized acrolein over MoO_3-Bi_2O_3 catalyst. Our results demonstrate that the mechanism of the oxidation of propylene to acrolein over Pd-carbon catalyst differs from that of the oxidation of propylene to acrolein over the transition metal oxide catalyst such as MoO_3-Bi_2O_3 and strongly supports the mechanism proposed by Fujimoto *et al.*[3)] and Seiyama *et al.*[4)] They found that the rate of oxidation of propylene to form acrolein depends on the partial pressure of water,[3)] and estimated the following mechanism for this oxidation.

$$CH_2{=}CH{-}CH_3 \xrightarrow[-H]{} CH_2{=}CH{=}CH_2 \quad (4)$$

$$CH_2{=}C{=}HCH_2 \xrightarrow[+OH]{} CH_2{=}CH{-}CH_2OH \quad (5)$$

$$CH_2{=}CH{-}CH_2OH \xrightarrow[-2H]{} CH_2{=}CH{-}CHO \quad (6)$$

A hydrogen atom in methyl group of propylene is abstracted on the catalyst surface to form an allylic intermediate. Some active species of water such as hydroxyl group attacks one of the terminal carbon atoms of this intermediate to form allyl alcohol which is easily oxidized to acrolein.

The authors wish to thank Dr. K. Fujimoto and members of Prof. Kunugi's laboratory of the University of Tokyo for many useful suggestions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 683—684 (1973)

The Phase Transitions of the Anion Radical Salts of $[(C_6H_5)_3PCH_3]_{1-x}^+$ $[(C_6H_5)_3AsCH_3]_x^+$ $(TCNQ)_2^-$, $(0 \leq x \leq 1)$, as Studied by the ESR Measurements

Yukio SUZUKI and Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received August 28, 1972)

The prominent magnetic, electrical, and optical properties of the solid anion radical salts of 7,7,8,8-tetracyanoquinodimethane (TCNQ) have been the subject of many theoretical and experimental investigations over the past several years.[1-11] In particular, the anion radical salts containing the mixed cations represented by $[(C_6H_5)_3PCH_3]_{1-x}^+$ $[(C_6H_5)_3AsCH_3]_x^+$ $(TCNQ)_2^-$, $(0 \leq x \leq 1)$, show electron spin resonance (ESR) spectra characteristic of a triplet exciton state lying close to a singlet ground state.[1,3,11]

The salt of $[(C_6H_5)_3PCH_3]^+(TCNQ)^-$, $(x=0.00)$, undergoes a first-order phase transition at 315.7 K, where we earlier found anomalies in the temperature dependences of the ESR absorption and the electrical conductivity,[6,9] while the salt of $[(C_6H_5)_3AsCH_3]^+$ $(TCNQ)_2^-$, $(x=1.00)$, does not undergo such a phase transition.[5,8,10] The phase transitions of the anion radical salts containing the mixed cations have been studied, as a function of the composition parameter, by means of a differential scanning calorimeter (DSC) and by observing the anomalies in the temperature dependences of the magnetic susceptibility and the electrical conductivity.[5,8,10] The purpose of the present paper is to show that the measurements of the ESR absorption and its variation with the temperature are useful for investigating the phase transitions of these mixed crystals.

The six anion radical salts with the compositions of $x=0.00$, 0.20, 0.40, 0.60, 0.80, and 1.00 were prepared according to the method of Melby *et al.*[2] The ESR spectra of single crystals (5 mm × 5 mm × 1 mm) in the temperature range including the transition temperature were measured by means of a JES-ME X-band spectrometer with 100 KHz modulation. The temperature of the specimen was controlled to within ±1°C by its temperature equipment.

The ESR spectra of the triplet excitons in $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$, $(0 \leq x \leq 1)$, have been shown from the anisotropic zero-field splitting at low temperatures.[1,3,11] Until the transition temperature, as the temperature is raised, the doublet components due to the zero-field splitting in the ESR spectra broaden and move together, eventually collapsing into a single line which becomes progressively sharper, while the temperature dependence of the ESR absorption intensity can be understood in terms of an equilibrium between a singlet ground state and a triplet state lying an energy (0.065 eV) above the ground state; this system has been established by Kepler from the temperature dependence of the static magnetic susceptibility.[5] However, striking discontinuities in the temperature dependence of the ESR spectra were found for all the salts except for that with $x=1.00$. At the temperature where the anomaly occurs, the linewidth of the ESR absorption becomes abruptly sharper, while the intensity discontinuously increases, in the higher temperature range. This change was found to be thermally reversible. In the region above this temperature, the linewidth is practically constant, while the intensity gradually decreases, as the temperature is raised.

As an example, the salt of $[(C_6H_5)_3PCH_3]_{0.80}^+$ $[(C_6H_5)_3AsCH_3]_{0.20}^+$ $(TCNQ)_2^-$, $(x=0.20)$, is described in some detail. At 59±1°C where the anomaly occurs, the ESR spectra of a single crystal for an arbitrary orientation were recorded just below and above this temperature, as is shown in Fig. 1. These spectra were obtained with the same spectrometer gain settings. In this salt, the intensity of the ESR absorption increased abruptly by a factor of about 1.2 in the

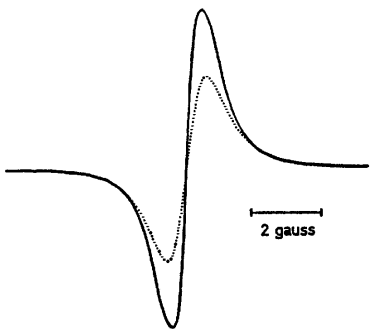

Fig. 1. The ESR spectra of a single crystal of $[(C_6H_5)_3PCH_3]_{0.80}^+[(C_6H_5)_3AsCH_3]_{0.20}^+(TCNQ)_2^-$, $(x=0.20)$, for an arbitrary orientation at 59±1°C, where a discontinuity occurs in the temperature dependence of the ESR absorption. The solid line and the broken line are the ESR spectra recorded just above and below this temperature, respectively, with the same spectrometer gain settings.

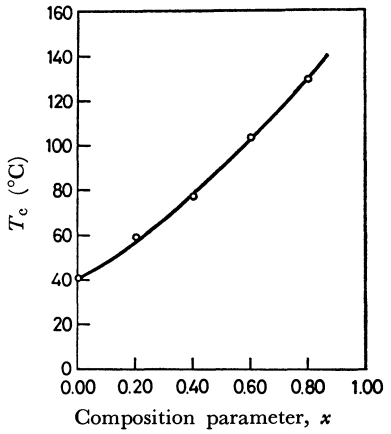

Fig. 2. The relation of the temperature, T_c, where the anomaly occurred in the temperature dependence of the ESR absorption, to the composition parameter, x, in $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$, $(0 \leq x \leq 1)$.

higher-temperature range. Although the linewidth was found to be somewhat anisotropic, for a fixed orientation the linewidth of 1.1_2 gauss in the lower-temperature range abruptly sharpened to 0.8_4 gauss in the higher-temperature range.

In $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$, $(0 \leq x \leq 1)$, the temperature, T_c, at which the anomaly occurred in the ESR spectra shifts progressively to higher temperatures as the value of the composition parameter, x, is increased. The relation of T_c to x was obtained as is illustrated in Fig. 2. This relation was found to be in good accordance with the relation of the phase-transition temperature to the composition parameter, as has been determined previously from the DSC measurements or from the electrical conductivity measurements.[8,10] On the other hand, the magnitude of the discontinuity of the ESR absorption intensity at T_c was found to decrease gradually as the value of x increased. This situation was good agreement with that investigated on the basis of static magnetic susceptibility measurements by Kepler.[5] However, in the salt of $[(C_6H_5)_3AsCH_3]^+$ $(TCNQ)_2^-$, $(x=1.00)$, no discontinuity in the temperature dependence of the ESR absorption was observed up to about 150°C.

At the transition temperature, the increase in the ESR absorption intensity and the decrease in the linewidth in the higher-temperature range can be understood by assuming that the abrupt reduction in the singlet-triplet energy separation is caused by the phase transition in the higher-temperature range.[12] In this case, at the transition temperature the ESR absorption will be markedly intensified in the higher-temperature range because the population of the paramagnetic triplet excitons is abruptly increased by the reduction of the singlet-triplet energy separation. Since the linewidth of the ESR absorption is narrowed by the exchange interaction due to the triplet exciton collisions,[3] the abrupt increase in the exciton population gives rise to a sharper linewidth of the ESR absorption in the higher-temperature range.

In view of these results, the application of the ESR absorption and its variation with the temperature brings valuable knowledge concerning the phase transitions of the $[(C_6H_5)_3PCH_3]_{1-x}^+$ $[(C_6H_5)_3AsCH_3]_x^+$ $(TCNQ)_2^-$, $(0 \leq x \leq 1)$, anion radical salts.

The Molecular Forms of the Rotational Isomers of Ethylmethylsilane

Michiro HAYASHI, Keiichi OHNO, and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received August 31, 1972)

In a previous note[1] on the rotational isomerism of ethylmethylsilane, the existence of two rotational isomers was reported. However, the molecular forms of the isomers could not be conclusively determined. In the gaseous state, one of the present authors has since found by microwave spectroscopy[2] that one of the isomers was in the *trans* form. However, since the microwave spectra of this substance were too weak for them to be assigned to another isomer, he could not find whether or not one of the isomers was in the *gauche* form.

In the present note, we will consider the unknown molecular form of the isomer, using the vibrational spectra of an asymmetrically-deuterated species of ethylmethylsilane.

Experimental

A sample of an asymmetrically-deuterated species of ethylmethylsilane was prepared by the method of reducing $CH_3CH_2SiCl_2CH_3$ with an equimolar mixture of $LiAlH_4$ and $LiAlD_4$ in *n*-butyl ether.[3] A mixture of $CH_3CH_2SiH_2CH_3$, $CH_3CH_2SiD_2CH_3$, and $CH_3CH_2SiHDCH_3$ was thus obtained and was used for the measurements without further attempts at isolation. In order to find the assignments of the spectra, the corresponding mixture of dimethylsilane and $(CH_3)_2SiH_2$ and $(CH_3)_2SiD_2$ were also prepared from dimethyldichlorosilane by a similar method.

1) M. Hayashi, K. Ohno, and H. Murata, This Bulletin, **45**, 298 (1972).

2) M. Hayashi and C. Matsumura, *ibid.*, **45**, 732 (1972).

3) A. E. Finholt, A. C. Bond, Jr., and H. I. Schlesinger, *J. Amer. Chem. Soc.*, **69**, 1199 (1947).

The infrared spectra in the region from 200 to 4000 cm^{-1} were recorded in the gaseous, liquid, and crystalline states with a Perkin-Elmer instrument (model 621), using the same technique as has been described in the previous note.

Results and Discussion

As is shown in Fig. 1, since the two *gauche* forms come not to be equivalent when one of the hydrogens of the SiH_2 group is replaced by a deuterium, the spectra of the *gauche* isomer are expected to be split into doublets, while the spectra of the *trans* isomer are singlets, without regard to the asymmetrical deuteration.

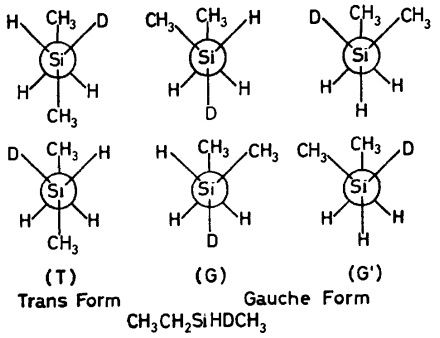

Fig. 1. Rotational isomers of $CH_3CH_2SiHDCH_3$.

In Fig. 2, the observed infrared spectra in the region from 300 to 600 cm^{-1} are shown for the mixture of $CH_3CH_2SiH_2CH_3$, $CH_3CH_2SiD_2CH_3$, and $CH_3CH_2SiHDCH_3$ species, where the solid and the dotted lines indicate the spectra in the liquid and in the crystalline states respectively. Since the pure sample of $CH_3CH_2SiHDCH_3$ can not be prepared at present, the spectra for this species must be found from the spectra of the mixture. For this purpose, the spectra in the liquid state for the corresponding species of dimethylsilane are considered as suitable references; they are also shown in Fig. 2.

The rocking mode of the SiH_2 group is expected around 480 cm^{-1}, which is probably well localized from the other modes; it is expected to be shifted to the region around 390 cm^{-1} for the deuterated species with the SiD_2 group. For dimethylsilane, it is found at 476 cm^{-1} for the SiH_2 species and at 385 cm^{-1} for the SiD_2 species. There are two additional bands at 496 and 415 cm^{-1} for the mixture besides the bands due to the SiH_2 and SiD_2 species. Therefore, they can be assigned to the SiHD deformation vibrations, which originate from the twisting and rocking modes.

For ethylmethylsilane, in the spectra for the mixture four bands are seen, at 422, 438, 486, and 513 cm^{-1},

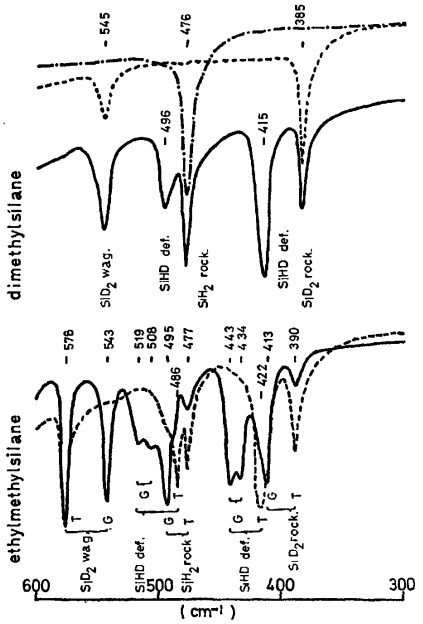

Fig. 2. Observed infrared spectra of dimethylsilane and ethylmethylsilane.
Upper: —— indicates the spectra of the mixture for $(CH_3)_2SiH_2$, $(CH_3)_2SiD_2$, and $(CH_3)_2SiHD$.
—•— indicates the spectra of $(CH_3)_2SiH_2$.
– – – indicates the spectra of $(CH_3)_2SiD_2$.
Lower: Solid and dotted lines indicate the spectra of the mixture for $CH_3CH_2SiH_2CH_3$, $CH_3CH_2SiD_2CH_3$, and $CH_3CH_2SiHDCH_3$ in the liquid and the crystalline states respectively.

attributable to the $CH_3CH_2SiHDCH_3$ species; the bands at 422 and 486 cm^{-1} are shoulders of the strong bands due to the other species. In the crystalline state, the bands at 422 and 486 cm^{-1} persist, while the two other bands at 438 and 513 cm^{-1} vanish. The persisting bands are obviously singlets, while the vanishing bands are doublets with spacings of 9 and 11 cm^{-1} respectively.

Therefore, it can be concluded that the isomer persisting in the crystalline state is definitely the *trans* and that the other isomer vanishing in the crystalline state is not the molecular form with a plane of symmetry such as the *trans* and *cis* forms, but is probably a *gauche* form, in which two hydrogens attached to the Si atom come not to be equivalent for the asymmetrically-deuterated species.

For the other modes, the assignments of the observed spectra seem to be difficult since the spectra due to three different species overlap. Therefore, no obvious evidence is obtained for the molecular form from these modes of vibrations.

The Addition of Nitrosyl Chloride to Nickel(0) Complexes. The Preparation of Nitrosyl Nickel Complexes

Masanobu HIDAI, Makoto KOKURA, and Yasuzo UCHIDA
Department of Industrial Chemistry, The University of Tokyo, Hongo, Tokyo

(Received September 30, 1972)

Several methods for preparing nitrosyl nickel complexes have been established.[1-5] During the course of a study of oxidative-addition reactions of covalent molecules to nickel(0) complexes,[6] we have found that nitrosyl chloride adds to nickel(0) complexes to yield a series of nitrosyl nickel complexes.

The nitrosyl complex, $NiCl(NO)(PPh_3)_2$, prepared by the reaction of $NiCl_2(PPh_3)_2$ with $NaNO_2$,[4] was obtained by the addition reaction of nitrosyl chloride to nickel(0) complexes such as $Ni(PPh_3)_4$ and $Ni(PPh_3)_2(COD)$ (COD=1,5-cyclooctadiene). The use of excess nitrosyl chloride afforded only $NiCl_2(PPh_3)_2$. The $NiCl(NO)(P(OPh)_3)_2$ complex was also prepared from $Ni(COD)_2$, triphenyl phosphite, and nitrosyl chloride. Hieber *et al.*[3] prepared similar nitrosyl complexes, $NiX(NO)(P(OPh)_3)_2$ (X=Br, I), by the reaction of triphenyl phosphite with $[NiX(NO)P(OPh)_3]_2$.

Nitrosyl chloride also added to $Ni(COD)_2$ in the presence of equimolar ditertiary phosphines *in ether* to afford new nitrosyl complexes, $NiCl(NO)(Ph_2P(CH_2)_nPPh_2)$ (n=1, 2, and 3). These nitrosyl complexes are fairly

$$Ni(COD)_2 + Ph_2P(CH_2)_nPPh_2 + NOCl \rightarrow NiCl(NO)(Ph_2P(CH_2)_nPPh_2)$$
$$n=1,\ 2,\ \text{and}\ 3$$

air-stable, but easily decompose in toluene or benzene at an ambient temperature. The nitrosyl complexes were, therefore, not obtained when the above reactions were carried out in benzene or toluene. Table 1 shows that ν_{N-O} shifts to a lower frequency with an increase in the length of the methylene chain of the ditertiary phosphines, as in the case of ν_{N-N} of $Mo(N_2)_2(Ph_2P(CH_2)_nPPh_2)_2$.[7] The reaction of nitrosyl chloride with $Ni(Ph_2P(CH_2)_nPPh_2)_2$ (n=1 and 2) at 90°C did not yield the nitrosyl complexes.

Table 1. Analytical and physical data for $NiCl(NO)(Ph_2P(CH_2)_nPPh_2)$

2	198—199	1735	60.04 (59.76)	4.55 (4.63)	2.43 (2.68)	6.70 (6.78)
3[a]		1725				

a) The complex was not obtained in a pure state.

Experimental

All the reactions were carried out under a nitrogen atmosphere in a small Schlenk-type flask containing a magnetic stirring bar. Tetrakis(triphenylphosphine)nickel(0) $Ni(PPh_3)_4$[8] and bis(1,5-cyclooctadiene)nickel(0) $Ni(COD)_2$[9] were prepared by the published methods. All the operations for preparing nitrosyl nickel complexes are very similar, so only a few typical examples will be described below.

Preparation of $NiCl(NO)(PPh_3)_2$. To a solution of $Ni(PPh_3)_4$ (0.374 g, 0.337 mmol) in benzene (10 ml) was added a solution of nitrosyl chloride (0.337 mmol) in toluene (0.1 ml) at an ambient temperature. The colour of the solution turned dark blue. After stirring the solution for 2 hr at that temperature, hexane (20 ml) was added to the solution and $NiCl(NO)(PPh_3)_2$ was precipitated as blue crystals (0.139 g, 65%).

Found: C, 66.85; H, 4.84; N, 2.02; Cl, 5.84%. Calcd for $C_{36}H_{30}NOClNi$: C, 66.67; H, 4.63; N, 2.16; Cl, 5.47%.

Preparation of $NiCl(NO)(Ph_2PCH_2PPh_2)$. A suspension of $Ni(COD)_2$ (0.155 g, 0.56 mmol) and bis(diphenylphosphino)methane (0.215 g, 0.56 mmol) in ether (20 ml) was stirred at −15——20°C for 2 hr. To this yellow suspension was then added a solution of nitrosyl chloride (0.56 mmol) in toluene (0.17 ml) at that temperature, after which the reaction mixture was stirred for 2 hr. The colour of the mixture thus changed into purple. The purple precipitate was separated by filtration and recrystallized from tetrahydrofuran-hexane, thus affording $NiCl(NO)(Ph_2PCH_2PPh_2)$ as reddish-purple crystals (0.156 g, 53.5%).

Reaction of Sulfenyl Chlorides with Sulfides. IV.[1] The Reaction with 1-Phenylvinyl Sulfides

Michinori Ōki and Keiji Kobayashi*

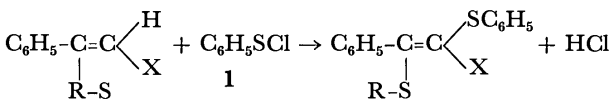
Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Tokyo

** Department of Chemistry, College of General Education, University of Tokyo, Komaba, Meguro, Tokyo*

(Received February 21, 1972)

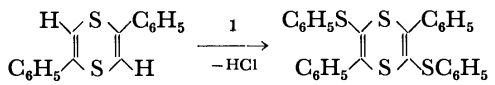
The reaction of benzenesulfenyl chloride (**1**) with α-methylthiostyrene (**2**) gives no adducts but causes the formation of α-methylthio-β-phenylthiostyrene (**3**) in an almost quantitative yield.[2] Since styrene is known to react with sulfenyl chlorides to give the addition products,[3] the presence of a sulfur atom at the alpha-position of styrene appears to be essential for the displacement reaction on β-hydrogen by a phenylthio group to occur. This paper describes the results of an extended investigation on the reaction of 1-phenylvinyl sulfides with **1**.

The reaction of α-phenylthiostyrene (**4**) with one equivalent of **1** was examined at room temperature in carbon tetrachloride. Evolution of hydrogen chloride was observed and an isomeric mixture of *cis*- and *trans*-α,β-bis(phenylthio)styrene (**5**) was obtained in 70% yield.



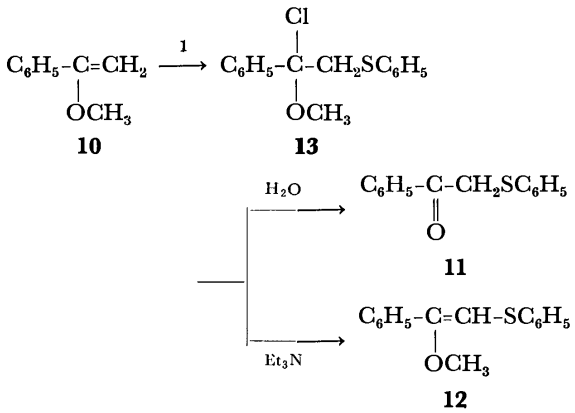
2; R=CH_3, X=H — **3**; R=CH_3, X=H
4; R=C_6H_5, X=H — **5**; R=C_6H_5, X=H
6; R=C_6H_5, X=Cl — **7**; R=C_6H_5, X=Cl

In a similar manner the reaction of α-phenylthio-β-chlorostyrene (**6**) with **1** led to the formation of α,β-bis(phenylthio)-β-chlorostyrene (**7**) in 48% yield. When 2,5-diphenyl-1,4-dithiin (**8**) was treated with two equivalents of **1** in chloroform, 2,5-diphenyl-3,6-bis(phenylthio)-1,4-dithiin (**9**) was obtained in 54% yield.



8 **9**

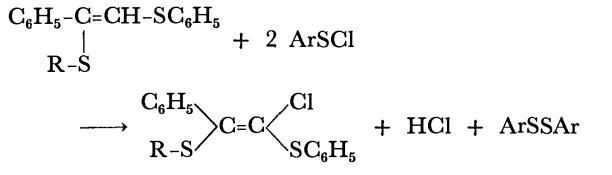
In contrast to the 1-phenylvinyl sulfides, the oxygen analog, α-methoxystyrene (**10**), afforded the Markownikoff-type adduct: the isolated product from the reaction of **10** with **1** was only α-phenylthioacetophenone (**11**), which would be formed by hydrolysis of the adduct **13** during the course of work-up. When the reaction mixture obtained from **10** and **1** was treated with triethylamine, α-methoxy-β-phenylthiostyrene



10 **13** **11** **12**

(**12**) was obtained in 63% yield. The marked difference in behavior between the sulfur analog and the oxygen analog is of interest for more detailed study.

In extending the β-phenylthio displacement reaction to **3**, a new chlorination reaction was found; the treatment of an isomeric mixture of **3** with one equivalent of **1** in carbon tetrachloride at room temperature led to the formation of an unexpected α-methylthio-β-phenylthio-β-chlorostyrene (**14**) in 34% yield. Although hydrogen chloride was evolved, the anticipated α-methylthio-β,β-bis(phenylthio)styrene was missing and *ca.* 40% of **3** was recovered. Diphenyl disulfide was also isolated in 81% yield. When **3** was treated with one equivalent of *p*-toluenesulfenyl chloride, the results were similar to those obtained from **1** except that di-*p*-tolyl disulfide was obtained in 67% yield instead of diphenyl disulfide. The results indicate that **14** arises according to the stoichiometry indicated below.



14; R=CH_3
7; R=C_6H_5

The reaction of **5** with **1** also afforded β-chlorinated product, α,β-bis(phenylthio)-β-chlorostyrene (**7**), in 22% yield. In this case, α,β,β-tris(phenylthio)styrene (**15**) was also isolated in 16% yield.

Treatment of **5** with two equivalents of methanesulfenyl chloride in carbon tetrachloride afforded **14** in 24% yield together with 61% methyl phenyl disulfide as detected by vpc analysis. Thus the chlorination reactions to give **14** may be supposed to involve the anti-Markownikoff addition of benzenesulfenyl

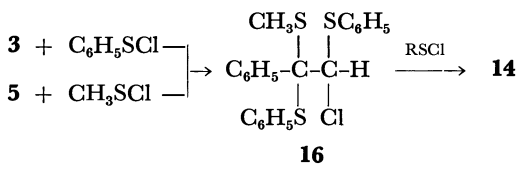
chloride to **3** and methanesulfenyl chloride to **5**, giving rise to the formation of **16** as an intermediate.



16

Experimental

*α,β-Bis(phenylthio)styrene (**5**).* To a mixture of **4**[4] (5.0 g, 0.023 mol) and carbon tetrachloride (100 ml), **1**[5] (3.5 g, 0.024 mol) was added at room temperature and the solution was stirred until it turned pale yellow and no further color change took place. The mixture was washed with saturated sodium bicarbonate, dried over anhydrous sodium sulfate and concentrated. The resulting yellow oil was chromatographed on alumina. Elution with petroleum ether–benzene (2 : 1) gave 5.3 g (70%) of **5** as viscous oil. M^+: 320; IR (cm^{-1}): 1580, 1540, 1025, 820, 760, 740, 690, 680; NMR (τ): 2.3—3.1 (m).

Found: C, 74.67; H, 4.91%. Calcd for $C_{20}H_{16}S_2$: C, 74.96; H, 5.03%.

An analytically pure sample of **5** showed the presence of two components attributed to the geometrical isomer on vpc.

*α,β-Bis(phenylthio)-β-chlorostyrene (**7**).* The reaction of **6**[6] with **1** was carried out as for **5**. The crude product mixture was chromatographed on alumina. Elution with benzene followed by recrystallization from petroleum ether–benzene (2 : 1) gave 48% of pure **7**, mp 89°C. M^+: 354; IR (cm^{-1}): 1580, 1540, 855, 750, 735, 690; NMR (τ): 2.90 (5H, s), 2.6—3.0 (10H, m).

Found: C, 67.93; H, 4.44; S, 17.87%. Calcd for $C_{20}H_{15}ClS_2$: C, 67.68; H, 4.26; S, 18.07%.

*2,5-Diphenyl-3,6-bis(phenylthio)-1,4-dithiin (**9**).* A solution of **8**[7] (1.5 g, 0.0056 mol) in chloroform (15 ml) was allowed to react with **1** (1.7 g, 0.012 mol) at room temperature for 30 min. The reaction mixture was washed, dried and concentrated. The residual oil was chromatographed on alumina. The yellow solid eluted with benzene was recrystallized from ethanol to give 1.4 g (54%) of **9**, mp 150—152°C. M^+: 484; IR (cm^{-1}): 1570, 1525, 1068, 1020 837, 775, 738, 692; NMR (τ): 2.72 (10H, s), 2.60—2.45 (6H, m), 2.32—2.28 (4H, m).

Found: C, 69.34; H, 3.98; S, 26.02%. Calcd for $C_{28}H_{20}S_4$: C, 69.38; H, 4.16; S, 26.46%.

*α-Methoxy-β-phenylthiostyrene (**12**).* To a solution of **10**[8] (13.4 g, 0.1 mol) in carbon tetrachloride (100 ml) was slowly added **1** (14.5 g, 0.1 mol) at 0°C and then triethylamine (18 g, 0.18 mol). Usual work-up and distillation under reduced pressure gave 15.2 g (63%) of **12**, bp 149—152°C/2 mmHg. M^+: 242; IR (cm^{-1}): 2820, 765, 740; 700; NMR (τ): 6.39 (3H, s), 3.99 (1H, s), 2.7 (10H, m) and 6.34 (3H, s), 4.61 (1H, s), 2.7 (10H, m).

Found: C, 74.08; H, 5.80; S, 13.35%. Calcd for $C_{15}H_{14}OS$: C, 74.35: H, 5.82; S, 13.23%.

*α-Methylthio-β-phenylthio-β-chlorostyrene (**14**).* To a solution of **3** (8.0 g, 0.031 mol) in carbon tetrachloride (50 ml) was added **1** (5.0 g, 0.035 mol). After decolorization of **1**, the mixture was washed with saturated sodium bicarbonate, dried and concentrated. The oily residue was chromatographed on alumina. Elution with petroleum ether gave 3.1 g (81%) of diphenyl disulfide and that with benzene afforded 3.1 g (34%) of **14**, mp 98—99°C. M^+: 292; IR (cm^{-1}): 1580, 1540, 858, 750, 735, 700, 692, 622; NMR (τ): 8.15 (3H, s), 2.80 (5H, s), 2.75 (5H, m).

Found: C, 61.57; H, 4.50; S, 22.01%. Calcd for $C_{15}H_{13}ClS_2$: C, 61.54; H, 4.44; S, 21.90%.

A similar treatment of **3** with *p*-toluenesulfenyl chloride gave 43% of **14** and 67% of di-*p*-tolyl disulfide.

*Reaction of **5** with **1**.* The reaction of **5** (5.7 g, 0.018 mol) with **1** (4.1 g, 0.028 mol) in carbon tetrachloride (15 ml) was carried out as described for the reaction of **3** with **1** to give 1.1 g of diphenyl disulfide, 1.4 g (22%) of **7**, and 1.3 g (16%) of α,β,β-tris(phenylthio)styrene, mp 79—80°C (lit,[9] 77—78°C).

On the Cleavage of 2,4-Dibromo-5-methylanisole

Kazuo ADACHI

Osaka Institute of Technology, Omiya, Asahi-ku, Osaka

(Received June 13, 1972)

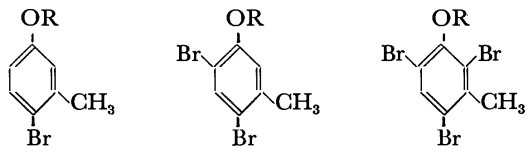
The phenolic hydroxyl group is sensitive to numerous reactions, but it may be protected in the ethers. On the treatment of phenol ethers with hydriodic or hydrobromic acid, the ether bond cleaves to the regenerated original phenols. This important reaction has been employed frequently in synthetic organic chemistry.[1)]

However, the refluxing of 2,4-dibromo-5-methylanisole (**2b**) with hydrobromic acid in acetic acid unexpectedly gave a mixture of 4-bromo-3-methylphenol (**1a**), 2,4-dibromo-5-methylphenol (**2a**), and 2,4,6-tribromo-3-methylphenol (**3a**). These three phenols, **1a**, **2a**, and **3a**, were methylated with dimethyl sulfate to give 4-bromo-3-methylanisole (**1b**), **2b**, and 2,4,6-tribromo-3-methylanisole (**3b**) respectively.

1) R. B. Wagner and H. D. Zook, "Synthetic Organic Chemistry," John Wiley & Sons, New York, N. Y. (1953), p. 171.

These results show that the cleavage of the methoxyl group of **2b** with hydrobromic acid is accompanied by bromination and debromination of **2a**.

In a recent paper, Kamikawa and his collaborators[2] described that the treatment of 2,4-dibromo-3,5-dimethylanisole with hydriodic acid gave 3,5-dimethylphenol. Similarly, the refluxing of **2b** with hydriodic acid in acetic acid gave *m*-cresol.



(**1a, b**) (**2a, b**) (**3a, b**)

a: R=H, **b**: R=CH_3

Experimental

*4-Bromo-3-methylanisole (**1b**) and 2,4-Dibromo-5-methylanisole (**2b**).* *m*-Cresol was brominated[3] to give 4-bromo-3-methylphenol (**1a**) containing 2,4-dibromo-5-methylphenol (**2a**).

*4-Bromo-3-methylphenol (**1a**)*: Needles from petroleum ether; mp 59—60°C (lit,[3] mp 56—57°C).

The crude bromo-*m*-cresol was methylated with dimethyl sulfate and then distilled. 4-Bromo-3-methylanisole (**1b**) and 2,4-dibromo-5-methylanisole (**2b**) were thus obtained.

*4-Bromo-3-methylanisole (**1b**)*: bp 91°C/4 mmHg (lit,[4] bp 81—83°C/4 mmHg).

*2,4-Dibromo-5-methylanisole (**2b**)*: Prisms from petroleum ether; mp 73—74°C (lit,[5] mp 73—74°C).

*Treatment of 2,4-Dibromo-5-methylanisole (**2b**) with Hydriodic Acid.* A mixture of **2b** (25.0 g), hydriodic acid (*d*, 1.7; 50 ml), and glacial acetic acid (50 ml) was refluxed with stirring for 4 hr. The reaction mixture was then diluted with water and extracted with benzene. The benzene layer was washed with aq. $NaHSO_3$ and then water, and extracted with aq. NaOH. The oil obtained by the subsequent acidification of the resulting alkaline solution with HCl was extracted with ether. The distillation of the crude product gave an oil boiling at 93—94°C/13 mmHg (5.7 g; 58.7%) which was identical with *m*-cresol (IR spectrum).

The removal of the solvent from the above benzene solution gave the unchanged **2b** (4.1 g).

*Treatment of **2b** with Hydrobromic Acid.* A mixture of **2b** (39.0 g), hydrobromic acid (*d*, 1.48; 280 ml), and glacial acetic acid (280 ml) was refluxed with stirring for 10 hr. The subsequent distillation of the phenolic components in the reaction mixture gave an oily mixture of bromo-*m*-cresols boiling at 83—130°C/6 mmHg (22.0 g; 57.9%) and 2,4,6-tribromo-3-methylphenol (**3a**) boiling at 130—166°C/6 mmHg (12.1 g; 31.9%), which solidified. The higher-boiling distillate was recrystallized to give **3a**.

*2,4,6-Tribromo-3-methylphenol (**3a**)*: Needles from petroleum ether; mp 81.5—82.5°C(lit,[6] mp 80—81°C).

By redistillation, the lower-boiling distillate was divided into three fractions, A, B, and C. The components in each fraction were confirmed by gas chromatography.

Fraction A (2.8 g), boiling at 85—120°C/7 mmHg, was a mixture of 4-bromo-3-methylphenol (**1a**), 2,4-dibromo-5-methylphenol (**2a**), and a trace of *m*-cresol.

From Fraction B (16.6 g), boiling at 120—127°C/7 mmHg, crystals (4.3 g) of **2a** and an oily mixture (11.9 g) of **1a** and **2a** were obtained. The crude crystals of **2a** were filtered and purified by recrystallization to give *2,4-dibromo-5-methylphenol (**2a**)*; needles from petroleum ether; mp 64—64.5°C (lit,[3] mp 65—66°C).

Fraction C (2.0 g), boiling at 127—136°C/7 mmHg, was a mixture of **1a**, **2a**, and **3a**. Fractions B and C contained two more components, which appeared to be isomers of **1a** and **2a** but which were not identified.

The methylation of **2a** and **3a** with dimethyl sulfate gave **2b** and 2,4,6-tribromo-3-methylanisole (**3b**) respectively. The oily mixture of bromo-*m*-cresols, obtained after the removal of **2a** from Fraction B, was methylated with dimethyl sulfate to give a mixture of **1b**, **2b**, and **3b**.

*2,4,6-Tribromo-3-methylanisole (**3b**)*: Microneedles from petroleum ether; mp 75.5—76.5°C. Found: C, 26.55; H, 1.94%. Calcd. for $C_8H_7Br_3O$: C, 26.77; H, 1.97%. IR: 6.89, 7.08, 7.40, 7.91, 9.56, 10.78, 11.58, and 13.00 μ.

*Treatment of **2b** with the Other Acids.* When **2b** (14.0 g) was refluxed with 20% HCl (140 ml) and also with 63% H_2SO_4 (140 ml) in glacial acetic acid (140 ml) with stirring for 10 hr, only a small amount of **2a** was obtained (0.6 g) in either case.

Synthetic Photochemistry. II.[1] The Cycloaddition Reaction of Dehydroacetic Acid with Olefins

Hitoshi TAKESHITA,* Ryoko KIKUCHI, and Yoshikazu SHOJI
Department of Chemistry, Tohoku University, Sendai 980

(Received September 5, 1972)

As a part of the study of the photochemical cycloaddition reactions of α,β-unsaturated ketones bearing functional substituents, we have recently reported the reaction of methyl acetopyruvate with olefins.[1] According to the results thus obtained, the photoadducts have been directly formed by a reaction with the tautomer which exists in the ground state by means of remarkable regiospecific control. Dehydroacetic acid (I) possesses several tautomeric forms because of different orientations of enolization; this, from the preparative point of view, aroused our interest in examining the cycloaddition reaction with olefins.

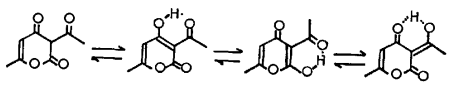

Chart 1.

During the course of our investigations, Kumamoto *et al.*[2] reported their results on the photochemical reactions of I with cyclohexene, acrylonitrile, and trimethylethylene. Our observations contain some novel features which we want to record in this brief paper.

The irradiation of I and cyclohexene in an ethyl acetate solution through a Pyrex glass filter by means of a 450 W high-pressure mercury lamp afforded several products, but the reaction could not be completed because of the production of a resious material. The products isolated by chromatography were II (pale yellow liquid (2%)), III(colorless needles, mp 85.5—87°(20%)), IV(colorless liquid (20%)), and V(colorless crystals, mp 215—216° (2.5%)).

Among these, III and V were identified, by comparisons of their physical data, as the 1 : 1 adduct previously obtained by Kumamoto,[2] and as the dimer formed by the solid-phase irradiation of I by Sugiyama,[3] respectively. The structure of II was deduced to be 3-(2-acetylcyclohexyl)-4-hydroxy-6-methyl-α-pyrone on the basis of NMR and IR spectral analyses, since the disappearance of the tricarbonyl-methane chromophore and the presence of a vinylic-methyl group and an olefinic proton were evident.

The structure of III has already been proposed by Kumamoto to be the *cis-cis-cis* isomer, mainly on the basis of his analysis of the NMR spectrum but his assignment of the stereochemistry seems unconvincing. The IV we obtained revealed physical properties very similar to those of III and was deduced to be a stereoisomer of III; therefore, the inspection of the NMR spectra of the two compounds might provide information on the point. When the NMR spectrum was measured in a benzene solution, the signal attributable to the C-5 methin proton clearly appeared as a doublet (J=9.3 Hz) at δ 2.35 indicating that the vicinal protons in the cyclobutane ring were in a *cis*-relationship. On the other hand, the NMR signal of the corresponding proton of IV had the same magnitude of the coupling constant, with a still-smaller spin-spin splitting (δ 3.09 dd, J=9, 2.5 Hz) in a carbon tetrachloride solution also showing a *cis*-relationship. In addition, the occurrence of only the long range coupling in IV would represent the *W*-letter-type relation for both the protons, and the *cis-cis*-configuration for three hydrogens at the A/B/C ring junctures. Therefore, III must be the *trans-cis* isomer. Moreover, the configuration of the methyl group and the hydrogen at the B/C ring should be a thermodynamically stable *cis*-configuration. Thus, the stereochemistry of III and IV has been deduced.

A few other products were isolated, but because of the limited quantity available for characterization and because of the instability to the isolation conditions, no further work was attempted.

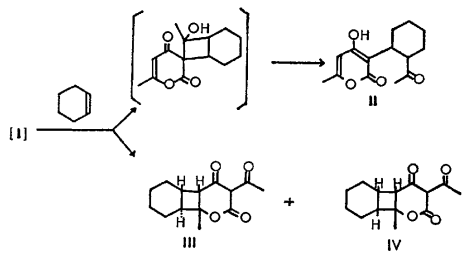

Chart 2.

A similar reaction of I with vinyl acetate also resulted in several products; among those fractionated from a complex mixture were VI (pale yellow liquid (21% as an isomeric mixture)), VII (pale yellow liquid (4.1%)), and VIII (colorless needles, mp 90.5—91°C (5.2%)).

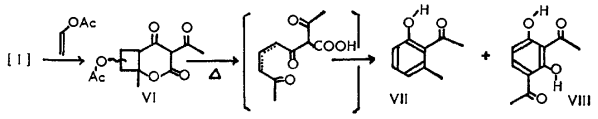

Chart 3.

* Present address: Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka 812.

1) Previous paper; H. Takeshita and S. Tanno, This Bulletin, in press (1973).

2) S. Kumamoto, K. Somekawa, and A. Tsuchida, Abstract Papers of 23rd Annual Meeting of Chemical Society of Japan(Apr., 1070, Tokyo), [III], 1300.

3) N. Sugiyama, T. Sato, H. Kataoka, and C. Kashima, This Bulletin, **44**, 555 (1971). In this paper, the authors described however I did not cause any photochemical change in solutions.

Although VI appeared as a single spot on thin-layer chromatograms, the NMR spectrum indicated it to be a mixture of all four of the possible stereo- and regio-isomers of the 1 : 1 adducts. Intensive efforts to separate them failed, except that the least polar component (VIa) could be obtained in an 80% purity, according to the NMR spectral analysis. VIa has shown a characteristic NMR signal for the tricarbonyl system, like I, indicating that a reaction has taken place at the C-5,6 position. The rest of the isomers also have very similar NMR spectral data for this reason.

The structure of VII was deduced to be 2-acetyl-3-cresol on the basis of the NMR and the other spectral properties. VIII was also identified as 2,4-diacetylresorcine.[4] Obviously, VII and VIII were formed by the aromatization of VI during the work-up. In fact, when a methanolic solution of VI was refluxed for a while, considerable amounts of VII and VIII were obtained.[5]

Thus, our results agree, in general, with those of Kumamoto. However, the formation of II shows a bi-functional nature in the photochemical cycloaddition.[6]

Experimental

Photochemical Reaction of Dehydroacetic Acid (I) and Cyclohexene. I (3.5 g) was dissolved in cyclohexene (70 ml) and ethyl acetate (80 ml), and then the solution was internally irradiated by means of a 450 W high-pressure mercury lamp through a Pyrex glass filter in a nitrogen atmosphere. The solution soon become dark brown and a polymeric material has deposited on the wall; therefore, irradiation was terminated after 5 hr. The reaction mixture was heated under reduced pressure to remove the solvent, and the residue was washed with a small amount of ligroin to recover the unreacted I, which weighed 0.63 g (22%) after collection. Then, the product mixture in ligroin was distilled *in vacuo* to give a yellow, viscous oil (2 g). This was fractionated by silica gel (200 g) column chromatography with benzene. After the elution of unidentified crystals (6 mg), II was isolated as a faintly colored liquid (bp 130°/0.5 mmHg (bath temp.), 80 mg). This sample showed a single spot on thin-layer chromatograms. (Found: C, 67.25; H, 7.40%). λ_{max}^{MeOH} 230 nm(sh.), 281 nm (6300). $\nu_{C=O}$ 1715 cm^{-1}(v. strong). δ_{CCl_4} 1.5(9H, m), 2.05(3H, s), 2.12 (3H, s), 2.86(1H, br.), and 5.50(1H, s).

Next several fractions containing a crystalline material were collected to give III (colorless needles; mp 85.5—87° (from ether-cyclohexane)(lit.[2] 88—89°C); weight, 120 mg). (Found: C, 67.83; H, 7.40%). δ_{CCl_4} 1.43(3H, s), 2.65 (3H, s), and 2.72(1H, d, J=9 Hz); $\delta_{C_6H_6}$ 1.03 (3H, s), 2.55(3H, s), and 2.35(1H, d, J=9.3 Hz).

Further elution with benzene-ethyl acetate gave on oily mixture of III and IV(1.87 g), which additionally yielded some crystalline III; repeated silica-gel chromatography with petroleum ether-benzene and preparative thin-layer chromatography finally yielded an enriched fraction of IV, together with some crystalline III. The NMR assay of the fraction still indicated the presence of III(*ca.* 5—10%), but a further attempt at its purification was not made. This specimen (colorless liquid, bp 120°C/0.5 mmHg(bath temp.)) showed an IR spectrum almost undistinguishable from that of III. (Found: C, 67.41; H, 7.44%). δ_{CCl_4} 1.53(3H, s), 2.67(3H, s), and 3.09(1H, dd, J=9, 2.5 Hz). The estimated yields of III and IV was both about 20% respectively.

Subsequent elution with benzene-ether gave mainly V and some unidentified compounds, from which V was isolated by fractional crystallization with cyclohexane as colorless needles(mp 215—216°C(from cyclohexane)(lit,[3] 214.5—215.5°C); weight, 75 mg).

Photochemical Reaction of I and Vinyl Acetate. I (3.5 g) was dissolved in vinyl acetate (35 ml) and ethyl acetate (250 ml), and the mixture was irradiated much as in the preceding reaction; again, the formation of a polymeric material prevented the completion of the reaction. The reaction mixture was evaporated under reduced pressure to remove most of the solvent and the unreacted vinyl acetate; the residue was washed with cold ligroin to separate the unreacted I (510 mg) and the products, which were distilled *in vacuo* to give a pale yellow liquid(bp 155—165°C/3 mmHg(bath temp.), 2.9 g) and separated by silica gel chromatography. The first fraction, eluted with benzene, contained VII, which was obtained in a pure form through preparative thin-layer chromatography as a pale yellow liquid(110 mg). (Found: C, 71.70; H, 6.87%). δ_{CCl_4} 2.59(3H, s), 2.64(3H, s), 6.72(1H, dd, J=7.5, 1.2 Hz), 6.83(1H, dd, J=7.8, 1.2 Hz), 7.28(1H, dd, J=7.8, 7.5 Hz), and 12.15(1H, OH).

The next fraction yielded VIII (colorless needles; mp 90.5—91°C(from ethyl acetate)(lit.[4] 88—90°C); weight, 189 mg). The following fraction, eluted with benzene-ether, contained VI and unidentified compounds; after repeated chromatography, VI(950 mg) was obtained as a colorless liquid(bp 120—130°C/1.5 mmHg(bath temp.)), whose least polar fraction, VIa, was obtained in a purity of *ca.* 80%. (Found: C, 56.69; H, 5.55%). δ_{CDCl_3} 1.58(3H, s), 2.00 (3H, s), 2.60(3H, s), 2.2—2.9(3H), and 4.87(1H, dd, J= 5.5, 3.5 Hz).

Aromatization of VI in Methanol. VI(30 mg, as a mixture of isomers) was heated in a methanol(10 ml) solution under reflux. The VI disappeared within 30 min, and after the removal of the solvent, VII(9 mg) and VIII(3 mg) were isolated by preparative thin-layer chromatography.

We wish to thank Professor S. Itô for his helpful suggestions, Mrs. H. Arai and Miss M. Suzuki for the elemental analyses, and T. Kondo for the NMR measurements. H. T. is also grateful to The Matsunaga Science Foundation for a research grant, by which a part of the expense has been defrayed.

4) G. Witting, *Ann. Chem.*, **446**, 155 (1926).

5) In this treatment, colorless needles (mp 87.5—87.5°) were obtained, and the structure was considered to be a monomethyl ether of VIII. However, no further characterization was attempted.

6) The formation of II can be regarded as another example of the cycloaddition reaction of α-acyl-β-diketone. The photochemical reaction of such a system has been successfully employed in the total synthesis of loganin; *cf.* G. Büchi, J. A. Carlson, J. F. Powell, Jr., and L. F. Tietze, *J. Amer. Chem. Soc.*, **92**, 2165 (1970).

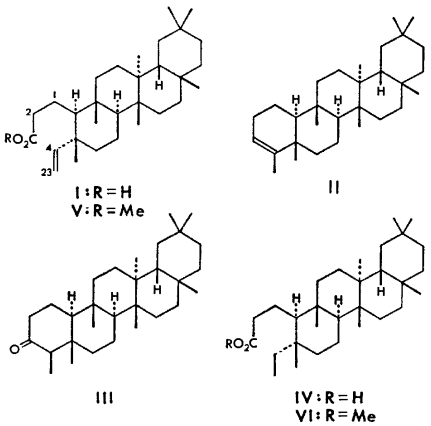
One-step Synthesis of Putranjivic Acid from Friedelin

Reiko AOYAGI, Takahiko TSUYUKI, and Takeyoshi TAKAHASHI
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received September 11, 1972)

A triterpene, putranjivic acid, isolated from leaves of *Putranjiva roxburghii* (Euphorbiacea) has been characterized by spectral and chemical methods to be 10β-(2-carboxy)ethyl-5α-vinyl-des-A-friedelane (3,4-seco-friedel-4(23)-en-3-oic acid) (I) by Seshadri *et al.*[1-3] Very recently Sengupta and Dey[4] have described the synthesis and stereostructure of putranjivic acid (I). These authors have synthesized this acid from friedel-3-ene (II) through seven steps and established the configuration of all asymmetric centers in the acid.



We now wish to report a one-step synthesis of putranjivic acid (I) from friedelin (III) by photochemical oxidation reaction. It is well-known that cyclohexanone derivatives are irradiated in the presence of oxygen to afford an unsaturated seco-acid and that this reaction was applied to syntheses of nyctanthic and roburic acids.[5]

Irradiation of friedelin (III) in benzene under oxygen atmosphere gave a complex mixture, which was subjected to column chromatographic separation. Acidic fractions were treated with diazomethane. The methyl esters were further separated by silver nitrate-impregnated silica gel tlc into unsaturated and saturated esters. The latter was shown to be methyl 3,4-seco-friedelan-3-oate (VI) by comparison with the authentic sample which was prepared by methylation of 3,4-seco-friedelan-3-oic acid (IV).[6] The former was hydrolyzed to an unsaturated acid. The olefinic acid and its methyl ester were identical with putranjivic acid (I) and its methyl ester (V), respectively, in respects to mp, IR, and MS.

The methyl ester (V) was catalytically hydrogenated to give a saturated ester, which was identical with methyl 3,4-seco-friedelan-3-oate (VI) in every respect. Thus the structure of the synthesized putranjivic acid (I) was confirmed.

Experimental

All melting points were determined on a hot block and uncorrected. IR and mass spectra were measured using Hitachi EPI-G2 and Hitachi RMU-6 mass spectrometers. NMR spectra were recorded in $CDCl_3$ on Hitachi Model R-24 NMR spectrometer at 60 MHz, using TMS as an internal standard.

Photo-oxidation of Friedelin (III). Friedelin (500 mg) was dissolved in benzene (700 ml) and irradiated with a high pressure mercury lamp for 11 hr with introduction of oxygen at room temperature. The concentrated solution was passed through a column (SiO_2, 95 g) and elution was continued with benzene (2.6 l) to give acidic fractions, which were combined and treated with diazomethane. After evaporation, the residue was separated by thin layer chromatography using 10% $AgNO_3$-impregnated silica gel, developed with a 3 : 1 mixture of petroleum ether and benzene. The unsaturated ester (V, R_f=0.23) was extracted with ether and recrystallized from methanol to yield 21 mg of V, mp 136.0—136.5°C; ν_{max}(Nujol) 1737, 1630, and 905 cm^{-1}; NMR: δ 3.65(s, $-COOC\underline{H}_3$) and 4.75—6.0($-C\underline{H}=C\underline{H}_2$); M^+ 456 ($C_{31}H_{52}O_2$) [lit,[1] mp 133—135°C, ν_{max}1754 cm^{-1}, $[\alpha]_D$ −8.3° (*c* 1.2, $CHCl_3$)].

V (13 mg) was heated under reflux with potassium hydroxide (10 mg) in methanol (7 ml) for 4 hr and then treated as usual. The unsaturated acid (I) was obtained (12 mg), mp 173.0—173.5°C; ν_{max}(Nujol) 1705, 1660, 990, and 905 cm^{-1}; $[\alpha]_D$ −12° (*c* 0.24, $CHCl_3$); NMR: δ 4.75—5.90($-C\underline{H}=C\underline{H}_2$) and 2.30(m, $-C\underline{H}_2-COOH$); Found: C, 81.45; H, 11.26%. Calcd for $C_{30}H_{50}O_2$: C, 81.39; H, 11.38%. M^+ 442 [lit,[1] mp 177—179°C, ν_{max} 1730 cm^{-1}, $[\alpha]_D$ −15° (*c* 0.4, $CHCl_3$)].

The saturated ester (VI, R_f=0.8) was extracted with ether from the $AgNO_3$-impregnated silica gel and recrystallized from methanol to give 18 mg of VI, whose spectral data [ν_{max}(Nujol) 1740 and 1163 cm^{-1}; NMR: δ 3.66(s, $-COOC\underline{H}_3$), M^+ 458 ($C_{31}H_{54}O_2$)] were identical with those of the authentic methyl 3,4-seco-friedelan-3-oate (VI), prepared by methylation of 3,4-seco-friedelan-3-oic acid (IV)[6] with diazomethane in ether.

The saturated methyl ester (VI) was hydrolyzed with potassium hydroxide in ethanol and recrystallized from methanol to afford 3,4-seco-acid (IV), mp 210.5—211.5°C. Mp, IR, NMR, MS, and tlc were identical with those of the authentic 3,4-seco-friedelan-3-oic acid (IV).[6]

Hydrogenation of Methyl Purtanjivate (V). The unsaturated methyl ester (V, 7 mg) was dissolved in ethanol (7 ml) and hydrogenated in the presence of 10% Pd-C. Recrystallization from methanol gave methyl 3,4-seco-friedelan-3-oate (VI), which was identical with the authentic sample, described above.

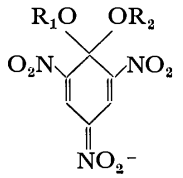
Aromatic Nulceophilic Substitution. I. Preparation of Spiro Meisenheimer Complexes of Arenes

Shizen SEKIGUCHI and Takeo SHIOJIMA

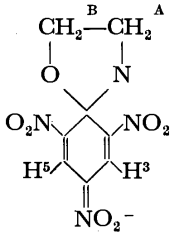
Department of Synthetic Chemistry, Gunma University, Tenjincho, Kiryu, Gunma

(Received September 20, 1972)

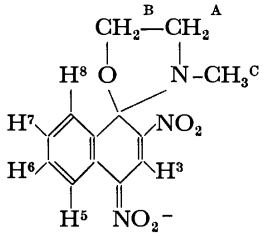
Since Jackson and Gazzolo,[1] and Meisenheimer[2] synthesized the so-called Meisenheimer Complex I (R_1, R_2; alkyl), a large number of the complexes have been prepared.[3] We have recently found that the spiro Meisenheimer complexes (II, III) having the N–C_1–O bond could be isolated at room temperature (*ca.* 20°C) in the reaction of 1-[*N*-methyl-(2′-hydroxy)ethylamino]-2,4,6-trinitrobenzene (IV) or 1-[*N*-methyl-(2′-hydroxy)ethylamino]-2,4-dinitronaphthalene (V) with sodium methoxide.



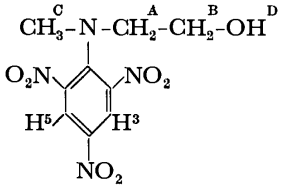
I



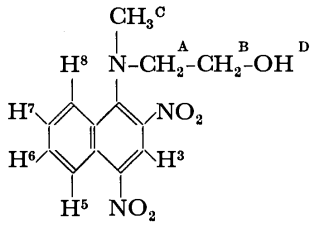
II



III



IV



V

Preparation of II. When IV was treated with sodium methoxide in methanol at room temperature, II was formed. In the IR spectrum of V, the strong broad bands at 1220 and 1516 cm^{-1} could be assignable as the nitro group carrying the increased negative charge,[7] whereas these bands appeared at 1340 and 1516 cm^{-1} in that of IV. In the visible spectrum of II (3.47×10^{-5} mol/l), there are double maxima: λ_{max} 421 nm (ε 26100); λ_{max} 490 nm (sh, ε 16800). Not only the shape, but also the positions and intensities are similar to those of well-characterized Meisenheimer complexes.[3] In the NMR spectrum of II, the proton resonances at τ 1.41 (s, 2H), 5.77 (t, 2H), 6.62 (m, 2H), and 7.82 (s, 3H) are assignable as H^3 and H^5 (ring protons), H^B, H^A, and H^C ones, respectively, whereas H^3 and H^5 ones appeared at τ 1.17 (s, 2H) in that of IV. In the spectrum, a resonance appeared at τ 8.87 as a triplet. This resonance was due to the methyl group of diethyl ether, which was used for purification of II (see Experimental Section). The resonances of the methylene group of diethyl ether and the *N*-methylene one of II (or H_A resonance) overlapped each other at τ 6.62.

Preparation of III. Under the similar reaction condition to II, III was produced from V. In the IR spectrum of III, strong broad bands appeared at 1487 and 1150 cm^{-1}, assignable as the asymmetric and symmetric stretching absorptions of the nitro group,[8] whereas these bands appeared at 1510 and 1300 cm^{-1} in that of V. The visible spectrum of III (4.373×10^{-5} mol/l) has double maxima [λ_{max} 502 nm (ε 19400); λ_{max} 344 nm (ε 14200)], characteristic of 1,1-disubstituted 2,4-dinitronaphthalene σ-complexes.[4] Its shape, positions, and intensities are similar to those of VI, the presence of which was confirmed by Orvik and Bunnett.[9] The postulated structure of III was supported by its NMR spectrum. For III, H^3 and H^8 resonances appeared at τ 0.75 (s, 1H) and 1.18 (d, 1H), respectively, and H^5, H^6, and H^7 resonances overlapped at τ about 2.60 (m, 3H). These chemical shifts are different from those of V, in the NMR spectrum of which H^3 resonance appeared at τ 1.32 (s, 1H), H^5 and H^8 ones centered at τ 1.38 (m, 2H), and H^6 and H^7 ones centered at τ 2.07 (m, 2H).

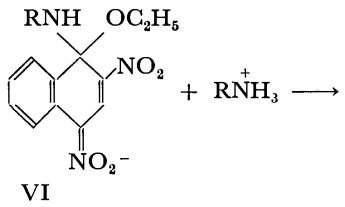
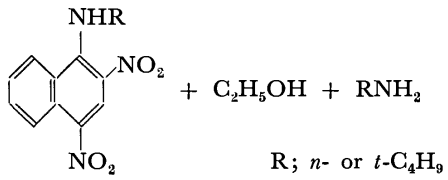
heimer complexes have been reported.[10,11] Bunnett and Zahler[12] stated the formation of an anion by dissociation of a complex to depend upon the stability of the anion. The ease of anion seperation decreases in the order of alkoxide ions>amide ions. The decomposition of II and III with methanolic hydrochloric acid quantitatively gave IV and V, respectively. Our results are very consistent with the above order. Orvik and Bunnett[9] studied the nucleophilic substitution reaction of 2,4-dinitro-1-naphthyl ethyl ether (DNEE) with *n*- and *t*-butylamines in dimethyl sulfoxide solution, during the course of which VI, produced in the initial stage, was acid-catalyzed with butylammonium ion to seperate the alcohol. Our results are similar to those of Orvik and Bunnett.[9]



VI



Experimental

Elemental analyses were performed in the Microanalytical Center of the University of Gunma. NMR spectra were recorded in DMSO-d_6 on a Varian A-60D spectrometer. IR spectra were measured in nujol mull on a Jasco DS-301 spectrophotometer. Visible spectra were recorded in methanol on a Hitachi-124 UV-VIS spectrophotometer. All melting points were uncorrected. The solvents and reagents were purified by the usual methods.

1-[N-*Methyl-(2'-hydroxy)ethylamino*]-*2,4,6-trinitrobenzene (IV)*. To a stirred solution of 3.2 g (0.043 mol) of *N*-methylethanolamine (NMEA) in 100 ml of acetone was added at room temperature 5.0 g (0.020 mol) of picryl chloride in 30 ml of acetone. After an additional 4 hrs' stirring at 40°C, the mixture was poured into 200 ml of ice-water, filtered, and dried. Recrystallization from methanol yielded 5.0 g of IV (86%, based on picryl chloride), mp 138.0—139.0 °C. IR (Nujol): ν_{OH} 3570, 3400 cm^{-1}, ν_{NO_2} 1516, 1332 cm^{-1}, ν_{Ar-N} 1352 cm^{-1}. NMR: τ_{Me_4Si} 5.46 (s, 1H, H^D).

The formation of 1-[2'-(*N*-methylamino)ethoxy]-2,4,6-trinitrobenzene was excluded by the evidence that in the IR spectrum of IV the band attributable to the ether bond [C(sp^2)-O-C(sp^3)] was not found by comparison of the spectrum of picryl ethyl ether.[13]

1-[N-*Methyl-(2'-hydroxy)ethylamino*]-*2,4-dinitronaphthalene (V)*. To a stirred solution of 3.2 g (0.043 mol) of NMEA in 50 ml of acetone was added at room temperature 5.0 g (0.020 mol) of 2,4-dinitro-1-naphthyl chloride (DNC) in 50 ml) of acetone. After the temperature had been raised to 40°C, the mixture was stirred for 8 hr. Then, the mixture was poured into 300 ml of ice-water. The aqueous mixture was extracted with three 50 ml portions of benzene. After drying of the benzene solution over calcium chloride, the distillation of benzene produced crude V. Further, chromatographic separation was carried out on a column of sicila gel. Recrystallization from diethyl ether-petroleum ether yielded 4.0 g (69%, based on DNC), mp 77.0—77.5°C. IR (Nujol): ν_{OH} 3518 cm^{-1}, ν_{NO_2} 1510, 1305 cm^{-1}, ν_{Ar-N} 1305 cm^{-1}. NMR: τ_{Me_4Si} 5.18 (s, 1H, H^D). Found: C, 53.33; H, 4.66%. Calcd for $C_{13}H_{13}N_3O_5$: C, 53.61; H, 4.50%.

The formation of 1-[2'-(*N*-methylamino)ethoxy]-2,4-dinitronaphthalene was excluded by comparison of IR spectra of IV and DNEE.[9]

Preparation of spiro Meisenheimer Complexes (II and III). A typical procedure is noted below in the case of III. When 7 ml (0.0045 mol) of methanolic sodium methoxide (0.638 mol/l) was added to a stirred solution of 1.310 g (0.0045 mol) of V in 30 ml of methanol at room temperature under nitrogen stream, the solution became red immediately. After an additional 30 mins' stirring, the solution was concentrated by evaporation of methanol at 30°C under reduced pressure. Further, the precipitate was filtered, washed with three 20 ml portions of diethyl ether in a dry box. After that, the precipitate was dried. Yield 1.0 g (71%, based on V). The complex (II) was obtained by the same method in a 65% yield. Found: C, 50.22; H, 3.62; N, 13.22%. Calcd for $C_{13}H_{12}N_2O_5Na$ (III): C, 49.84; H, 3.86; N, 13.41%. Found: C, 38.62; H, 4.01; N, 16.46%. Calcd for $C_9H_9O_7N_4Na\cdot\frac{1}{2}(C_4H_{10}O)$ (II): C, 38.26; H, 4.08; N, 16.23%.

Acid decomposition of spiro Meisenheimer Complexes (II and III). When an equimolar amount of hydrochloric acid in 10 ml of methanol was added to a stirred solution of 0.50 g (0.0014 mol) of II in 15 ml of methanol at room temperature, the mixture became immediately yellow. This mixture was poured into 200 ml of ice-water, filtered, and dried. Thin layer chromatography and mixed melting point test proved this compound to be IV. Yield 0.40 g (98%) for crude IV. The same treatment of 0.5 g (0.0016 mol) of III yielded 0.45 g (97%) of crude V.

The Photochemical Reactions of Tetrahydrofuran and Tetrahydrothiophene with Sulfur Dioxide

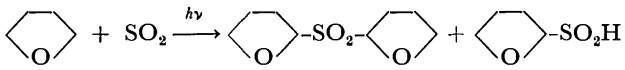
Hiroshi TAKEUCHI*, Toshikazu NAGAI**, and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Yamada-kami, Osaka

(Received May 29, 1972)

The reaction of photochemically-excited sulfur dioxide (SO_2) with paraffins and olefins has been studied by a number of investigators.[1-7] Calvert and his co-workers[6,7] concluded that the excited triplet SO_2 molecule is the most important reactant leading to the product formation in the above systems. Though Dainton and Ivin[1] thought that sulfinic acids are the main products of the above reactions, there was no assurance that the products were thermally-unstable sulfinic acids. Dunken and Winde[8,9] reported the formation of a charge-transfer complex between ether and SO_2. We have initiated studies aimed at the confirmation of the photochemical products in the reaction of tetrahydrofuran (THF) with SO_2.

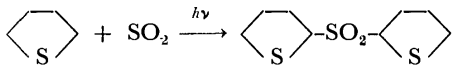
In the dark, no product was formed in the system of THF and SO_2, but a photochemical reaction in the above system yielded two new compounds, di-2-tetrahydrofurylsulfone (I) and 2-tetrahydrofuran-sulfinic acid (II). Since these products were unstable under atmospheric conditions, they were confirmed by the method to be described in the experimental section.



(I) (II)

The results are indicated in Table 1. The formation of I and II was observed in experiments using various irradiation sources under both degassed and aerial conditions.

The experiment using tetrahydrothiophene (THT) in place of THF was carried out to see if sulfone or sulfinic acid could be formed. The new compound, di-2-tetrahydrothiophenylsulfone (IV), was obtained in a low yield. In this reaction, the formation of sulfinic acid could not be observed. The mechanism of this reaction is ambiguous, but one possible explanation of the low reactivity of THT with SO_2 may depend upon the more reactive C–H bond at the transition state in the reaction of THF with SO_2 in comparison with the C–H bond in that of THT with SO_2.



(IV)

Since the products, I, II, and IV, were formed by the selective reactions of SO_2 at the 2-positions of THF and THT, these ractions were interesting synthetically.

Experimental

A solution of THF and SO_2 in a quartz pressure-vessel was irradiated at 0°C under the conditions shown in Table 1. The solvent was distilled under reduced pressure, and the residue was recrystallized from cyclohexane to give di-2-tetrahydrofurylsulfone (I) (mp 68—70°C). Since product I was unstable under atmospheric conditions, it was immediately analyzed after drying under a vacuum. IR (Nujol):

TABLE 1. PHOTOCHEMICAL REACTION OF THF WITH SO_2

THF (g)	SO_2 (g)	Surrounding conditions	Irradiation source[a]	Irradiation time (hr)	Products (g)

Michael Cycloaddition of 2-Phenylethene-1-sulfonamide with Carbon Disulfide[1)]

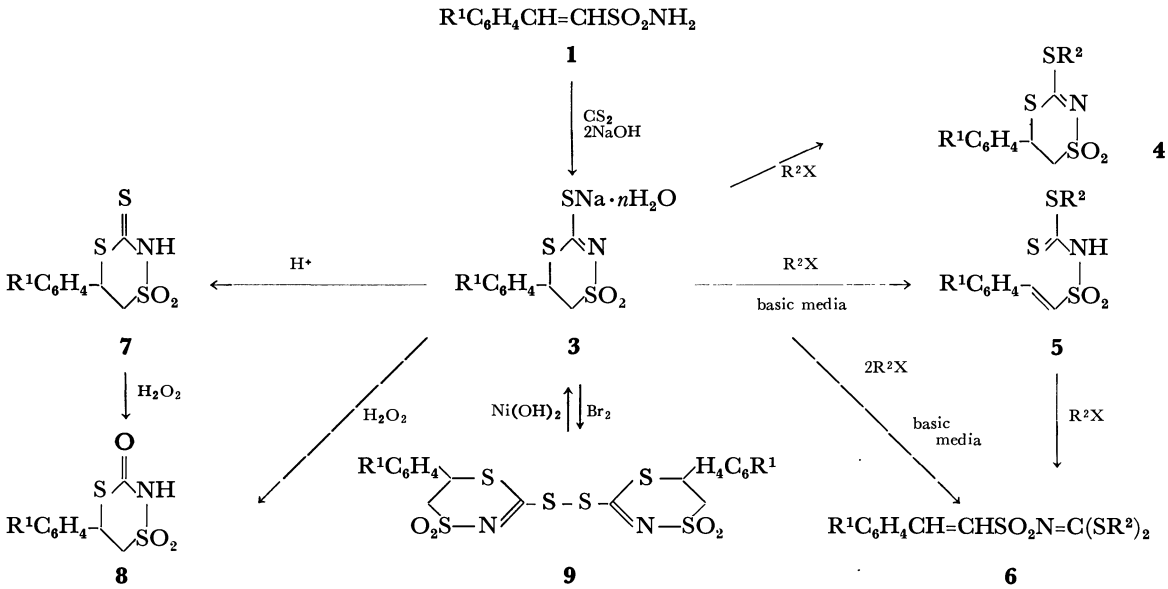
Kiyoshi HASEGAWA, Tadashi SASAKI,* and Syuzi HIROOKA

Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Takaoka-shi

** Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chigusa-ku, Nagoya*

(Received November 1, 1972)

In the preceding paper,[2)] we reported that 2-phenylethene-1-sulfonamide **1** reacts with carbon disulfide and alkyl halide in the presence of base giving 3-alkylthio-5-phenyl-1,1-dioxo-5,6-dihydro-1,4,2-dithiazines **4**. The postulated mechanism for the formation of **4** involves an intermediary sodium salt of

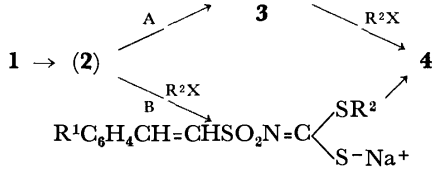


Scheme 1.

1) Presented at the 27th Annual Meeting of the Chemical Society of Japan, Nagoya, 12, October(1972). No. 2NO2.

2) K. Hasegawa and S. Hirooka, This Bulletin, **45**, 1567 (1972).

3-mercapto-5-phenyl-1,1-dioxo-5,6-dihydro-1,4,2-dithiazine **3**, which is intramolecular Michael cycloadduct of 2-phenylethene-1-sulfonyliminodithiocarbonate **2** ($R^1C_6H_4CH{=}CHSO_2N{=}C(S^-Na^+)_2$). This paper describes the isolation of **3** and the syntheses of some new derivatives from **3**. The process is outlined in Scheme 1.



Results

The hydrates of the Michael cycloadducts **3** (n= 1,2) were isolated from the reaction mixture of **1**, sodium hydroxide and carbon disulfide. The results are given in Table 1. As regards the mechanism for the formation of **4**, the following two paths **A** and B are conceivable.

Isolation of **3** supports path **A** in which highly reactive intermediate **2** undergoes rapid ring-closure giving **3** followed by alkylation. The C–S bond in **3** could not be cleaved by strong bases, **3** being recrystallized from a 1 N sodium hydroxide solution. The structure of **3** was determined on the basis of analytical and spectral data. In the NMR pattern of **3a**, ring protons, $H_AH_CH_B$, showed an ABX spin system consisting of three quartets of H_A centered at δ 3.06, H_C 3.39 and H_B 4.79 (J_{AC}=13.5 Hz, J_{AB}=13.0 Hz, J_{BC}=3.6 Hz). Monoalkylation of **3** in 50% ethanol afforded **4** in a yield greater than 89% (R^1=H, p-Cl, p-Br, p-CH_3, R^2=CH_3), but the reverse Michael cycloadducts of **4**, *N*-(2-phenylethene-1-sulfonyl)-dithiocarbamates **5** were obtained in a strong alkali (R^1=H, p-Cl, p-CH_3, R^2=CH_3). Dialkylation of **3** in strongly basic media afforded alkyl 2-phenylethene-1-sulfonyliminodithiocarbonates **6** which were the same

as alkylation products of **5** (Table 2). Acidification of aqueous solution of **3** under cooling gave yellow analytically pure crystals of 3-thio-5-phenyl-2,3,5,6-tetrahydro-1,1-dioxo-1,4,2-dithiazines **7** (Table 3). Cycloadducts **3** and **7** were desulfurized with alkaline hydrogen peroxide to give 5-phenyl-2,3,5,6-tetrahydro-1,1,3-trioxo-1,4,2-dithiazines **8** (Table 3). Oxidation of **3** with bromine afforded 3,3'-bis(5-phenyl-1,1-dioxo-5,6-dihydro-1,4,2-dithiazinyl)disulfides **9** (Table 4) whose S–S bonds were cleaved by reduction with nickel hydroxide[3] in basic media to give **3** again. The structures of the new compounds **6**, **7**, **8**, and **9** were determined on the basis of analytical and spectral data.

Experimental

Sodium Salt of 3-Mercapto-5-phenyl-1,1-dioxo-5,6-dihydro-1,4,2-dithiazine ***3a***. To a stirred solution of **1** (5.50 g, 0.030 mol) in DMF (60 ml) was added a solution of NaOH (2.40 g, 0.060 ml) in water (4.0 ml) and then CS_2 (3.40 g, 0.045 mol) at 20—30°C. The reaction mixture was stirred for 2 hr at room temperature. Evaporation of the DMF *in vacuo* left a dark red residue, into which 1N NaOH solution (100 ml) was added, and the solution was cooled overnight. The crystal was collected to give 6.30 g (67%) of **3a** as dihydrate. Recrystallization from 1N NaOH solution gave a colorless crystal. IR(KBr): 3570 and 3440 (dihydrate), 1385, 1135, and 1110 (SO_2) cm^{-1}. NMR (acetone-d_6): δ 3.06 (q, 1H, H_A), 3.39 (q, 1H, H_C), 4.79 (q, 1H, H_B), J_{AC}=13.5 Hz, J_{AB}=13.0 Hz, J_{BC}=3.6 Hz, 7.35 (s, 5H, phenyl).

Dimethyl N-(2-p-chlorophenylethene-1-sulfonyl)iminodithiocarbonate ***6a***. To a stirred solution of **3b** (0.33 g, 0.0010 mol) in methanol (8 ml) and 0.5 N NaOH solution (4 ml) was added drop by drop two equivalents of dimethyl sulfate (0.28 g, 0.0022 mol) at 0—10°C, after which the reaction mixture was stirred for 2 hr at 0—10°C. The precipitate was collected to give 0.23 g (72%) of **6b**. IR (KBr): 3040 (=CH), 1620 (C=C), 1460 (N=C), 1305 and 1140 (SO_2) cm^{-1}. NMR ($CDCl_3$): δ 2.59 (6H, SCH_3), 6.88 (1H, H_A), 7.52 (1H, H_B), J_{AB}=15.2 Hz, 7.34 (s, 4H, phenyl). When one equivalent of dimethyl sulfate (0.14 g, 0.0011 mol) *vs* **3b** was used, 0.18 g (59%) of the dithiocarbamate was obtained on acidification of the alkaline aqueous layer. mp 113—116°C (lit.[2], 114—117°C).

3-Thio-5-phenyl-1,1-dioxo-2,3,5,6-tetrahydro-1,4,2-dithiazine ***7a***. IR (KBr): 3080 (NH, broad), 1330 and 1140 (SO_2) cm^{-1}. NMR (acetone-d_6): δ 3.81 (q, 1H, H_A), 3.98 (q, 1H, H_C), 5.09 (q, 1H, H_B), J_{AC}=13.8 Hz, J_{AB}=11.0 Hz, J_{BC}=5.8 Hz, 6.62 (1H, NH), 7.43±0.07 (5H, phenyl). MS *m/e*: 258.9783 (M^+, calculated for $C_{10}H_9NO_2S_3$: 258.9765).

5-Phenyl-1,1,3-trioxo-2,3,5,6-tetrahydro-1,4,2-dithiazine ***8a***. To a stirred solution of **3a** (0.48 g, 0.0015 mol) in acetone (2.0 ml) was added drop by drop a 30% hydrogen peroxide solution (0.21 g, 0.0060 mol) at 0—10°C, after which the reaction mixture was stirred for 3 hr at room temperature. The acetone was evaporated *in vacuo*, and the solution was acidified with concentrated hydrochloric acid to afford 0.24 g (67%) of **8a**. Analogously, **8a** was also formed in 59% yield from **7a** (0.26 g, 0.0010 mol), 0.5 N NaOH solution (6.0 ml) and 30% hydrogen peroxide solution (0.47 g, 0.0040 mol). IR (KBr): 2960 (NH), 1630 (C=O), 1330 and 1150 (SO_2) cm^{-1}. NMR (DMSO-d_6): δ 4.06 (q, 1H, H_A), 4.22 (q, 1H, H_C), 4.99 (q, 1H, H_B), J_{AC}=13.0 Hz, J_{AB}=10.8 Hz, J_{BC}=5.8 Hz, 5.77 (1H, NH), 7.46± 1.20 (5H, phenyl). MS *m/e*: 243 (M^+).

3,3'-Bis(5-phenyl-1,1-dioxo-5,6-dihydro-1,4,2-dithiazinyl) disulfide ***9a***. To a stirred solution of **3a** (0.66 g, 0.0021 mol) in DMF (5.0 ml) was added bromine (0.19 g, 0 0012 mol) at 0—10°C. After being stirred for 3 hr at 0—10°C, the reaction mixture was poured into ice water (100 ml) and kept overnight. The precipitate was collected to give 0.53 g (98%) of an analytically pure crystal. IR (KBr): 1520 (N=C), 1320 and 1140 (SO_2) cm^{-1}. NMR (DMSO-d_6): δ 4.09 (q, 2H, H_A), 4.41 (q, 2H, H_C), 5.43 (q, 2H, H_B), J_{AC}=14.0 Hz, J_{AB}=12.0 Hz, J_{BC}=4.1 Hz, 7.54± 0.03 (10H, phenyl).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 699—700 (1973)

The Decomposition Product of Ethyl 2-Cyano-3-mercapto-3-methylthioacrylate

Masataka YOKOYAMA* and Shigeki HONGO

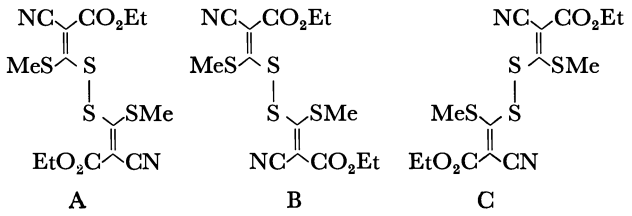
Department of Chemistry, Faculty of Science, Chiba University, Yayoi-cho, Chiba

(Received October 2, 1972)

2-Cyano-3-mercapto-3-methylthioacrylamide is stable but the 2-cyano-3-mercapto-3-methylthioacrylic acid ethyl ester (**1**) obtained as colorless needles has been found to be unstable and to change easily into a stable yellow material after being left standing for several hours at room temperature.[1] The present work was undertaken in order to determine the structure of the yellow material derived from **1**.

It was found that heating solution (in EtOH or CS_2) of **1** gave yellow material (**2**), which was also synthesized by adding hydrogen sulfide to disulfide (**3**) prepared by oxidizing **1** with ammonium persulfate.

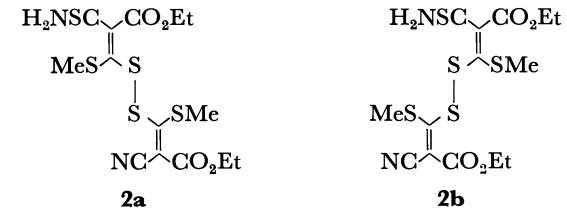
Structural assignments of **2** and **3** were made on the basis of elemental analysis, IR and NMR spectra. The NMR spectrum (DMSO-d_6) of **3** showed two signals due to two methylthio groups at δ 2.77 and δ 2.63, two quartet signals at δ 4.25 and δ 4.23, and two triplet signals at δ 1.27 and δ 1.25 which were assignable to the two ethyl groups. The following three structures can be considered for **3**.



A B C

It was demonstrated by tlc that **3** was not a mixture of geometrical isomers. The above results supported the view that **3** has the structure of B, for only B has nonequivalent methylthio and ethyl groups. Hence, the structure of **3** was determined to be diethyl (1*Z*, 5*E*)-1,6-dicyano-2,5-bis(methylthio)-3,4-dithia-1,5-hexadiene-1,6-dicarboxylate.

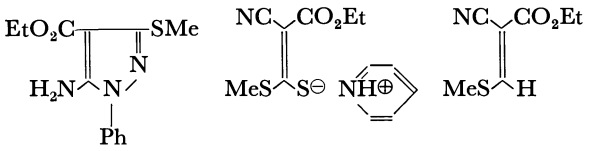
In the IR spectrum (KBr) of **2**, the absorptions of 3305, 3190, 3150, and 2195 cm^{-1} suggested the presence of the amino group and the conjugated cyano group. The NMR spectrum (DMSO-d_6) of **2** showed two broad amino signals (δ 10.70 and 9.68) disappearing on deuterium exchange and two sharp singlet singlas (δ 2.87 and 2.33) due to two methylthio groups. The spectroscopic evidence revealed the presence of the two nonequivalent thiocarbamoyl groups. The result of tlc revealed that **2** existed as two geometrical isomers (see Experimental). Hence, the decomposition products were tentatively assigned to the structures of diethyl (1*E*, 5*E*)-6-cyano-2,5-bis(methylthio)-1-thiocarbamoyl-3,4-dithia-1,5-hexadiene-1,6-dicarboxylate (**2a**) and diethyl (1*Z*, 5*Z*)-6-cyano-2,5-bis(methylthio)-1-thiocarbamoyl-3,4-dithia-1,5-hexadiene-1,6-dicarboxylate (**2b**).



2a **2b**

Compounds **2a** and **2b** were not separated.

Pyridine cleaved both **2** and **3** to give pyridinium salt of **1** (**5**). Compounds **1**, **2**, and **3**, treated with phenylhydrazine, gave 5-amino-4-ethoxycarbonyl-3-methylthio-1-phenyl-1,2-pyrazole (**4**). The chemical reactivities also supported the structure of **2**.



4 **5** **6**

The decomposition reaction of **1** could not be carried out in a sealed tube *in vacuo* without the irradiation of an ultraviolet ray (234 nm). On the other hand, the reaction could be depressed by the addition of hydroquinone as a radical trapping reagent. A small amount of ethyl (*E*)-2-cyano-3-methylthioacrylate (**6**) was isolated as a by-product of the decomposition reaction of **1**. This suggests that **1** is degraded by a radical mechanism.

Experimental

Compound **1** was prepared according to the method of Gompper and Töpfel.[2] The NMR spectra were recorded with a JNM-4H-100 MHz spectrometer, using tetramethylsilane as an internal standard. The IR, UV and mass spectra were recorded with Nihon Densi 403 G, Hitachi EPS-3T, and Hitachi Double Focus RMU-6E, respectively. Microanalyses were carried out at the Institute of Physical and Chemical Research.

*Preparation of **2a** and **2b**.* A mixture of **1** (7.55 g) and carbon disulfide or ethanol (100 ml) was refluxed for 1 hr. The crude material was collected by filtration, washed with ethanol and recrystallized from ethanol to give 1.40 g of yellow needles: yield 17%; mp 136—138°C; UV max (99% EtOH) 224 nm (log ε 4.25), 240 (sh, 4.16), 294 (sh, 4.14), 334 (4.53); NMR (DMSO-d_6) δ 10.70, 9.68 (br, 2, NH_2), 4.40, 4.38, 3.98, 3.96 (q, 2, CH_2, J=7.5 Hz), 2.89, 2.87, 2.33, 2.30 (s, 3, SCH_3), 1.35, 1.32, 1.15, 1.12 (t, 3, CH_3, J=7.5 Hz).

Found: C, 38.02; H, 4.15; N, 6.35; S, 36.52%; mol wt (Rast), 440. Calcd for $C_{14}H_{18}N_2S_5O_4$: C, 38.33; H, 4.15;

1) M. Yokoyama, This Bulletin, **44**, 1610 (1971).

2) R. Gompper and W. Töpfel, *Chem. Ber.*, **95**, 2861 (1962).

N, 6.38; S, 36.55%; mol wt, 438.62.

Compound **2** also was obtained when an ultraviolet light of 234 nm was irradiated on a sealed tube *in vacuo* containing **1** for 16 hr by using a minerallight UVSL-25 (Ultraviolet Products Inc. 13.8 W).

When **2** was examined by tlc with methanol and benzene (1 : 3) as a developing solvent, two spots (R_f: 0.72, 0.70) could be recognized.

*Conversion of **3** into **2**.* Compound **3** was prepared by the method of Gompper and Töpfel[2]: **1** (9.2 g, 45 mmol) was dissolved in 100 ml of 2% sodium hydroxide solution. To the resulting mixture was added aqueous ammonium persulfate solution (10.3 g of ammonium persulfate in 50 ml of water) dropwise under stirring. Stirring was continued for several minutes after the addition was complete. The solid product was collected and recrystallized from ethanol to give 3.5 g of colorless plates: yield 38%; mp 125—126°; UV max (99% EtOH) 255 nm (log ε 4.23), 335 (4.61); NMR (DMSO-d_6) δ 4.25, 4.23 (q, 2, C$\underline{H}_2$, J= 2.5 Hz), 2.77, 2.63 (s, 3, SC$\underline{H}_3$), 1.27, 1.25 (t, 3, C$\underline{H}_3$, J= 2.5 Hz).

Into a 200 ml acetone solution containing **3** (4.75 g) was gently passed hydrogen sulfide for 1 hr with stirring at room temperature. The whole was shaken for an additional 1 hr. The yellow crystals were collected and recrystallized from ethanol to give 2.8 g of yellow needles; yeild 54.2%. The IR spectrum coincided with that of **2**.

*Preparation of **4**.* A mixture of **3** (3.2 g, 8 mmol), phenylhydrazine (1.58 ml, 15.8 mmol), and ethanol (25 ml) was refluxed for 45 min. The colorless product was collected and recrystallized from ethanol-water to give 0.41 g of colorless needles; mp 98°C; UV max (99% EtOH) 248 nm (log ε 4.78); IR (KBr) 3440, 3340 (s), 3050 (w), 2985, 2920 (m), 1668 (vs), 1605 (vs), 1525 cm^{-1} (vs); NMR (DMSO-d_6) δ 7.50 (m, 5, C$_6\underline{H}_5$), 6.30 (br, 2, N$\underline{H}_2$), 4.20 (q, 2, C$\underline{H}_2$, J= 6 Hz), 2.38 (s, 3, SC$\underline{H}_3$), 1.25 (t, 3, C$\underline{H}_3$, J=6 Hz).

Found: C, 56.24; H, 5.44; N, 15.28; S, 11.52%; mol wt (Rast), 276. Calcd for $C_{13}H_{15}N_3SO_2$: C, 56.27; H, 5.49; N, 15.15; S, 11.56%. mol wt, 277.4.

*Preparation of **5**.* 11.35 g of **5** was obtained as yellowish prisms by dissolving **1** (9.75 g, 50 mmol) in pyridine, followed by the addition of ether. Compound **5** decomposed at 120—130°C; UV max (99% EtOH) 223.5 nm (log ε 4.73), 289 (4.57), 343.8 (5.06); IR (KBr) 3240, 3180 (m), 3080 (s), 2200 (vs), 1640 (vs), 1530 cm^{-1} (vs); NMR (DMSO-d_6) δ 8.65 (t, 2, C(2,6)$\underline{H}$, J=8 Hz), 8.10 (t, 3, C(3,4,5)$\underline{H}$, J= 8 Hz), 7.35 (br, 1, N$\underline{H}^{\oplus}$), 4.02 (q, 2, C$\underline{H}_2$, J=6 Hz), 2.38 (s, 3, SC$\underline{H}_3$), 1.18 (t, 3, C$\underline{H}_3$, J=6 Hz). The signal of δ 7.35 disappeared on deuterium exchange. Compound **1** was recovered by adding dilute hydrochloric acid to the aqueous solution of **5**. Compound **5** was also obtained by the above method from **2** and **3** in yields of 98% and 48%, respectively.

*Isolation of Ethyl (E)-2-cyano-3-methylthioacrylate (**6**).* A mixture of **1** (1.36 g) and 50 ml of ethanol was refluxed for 20 min. 0.82 g of **2** was filtered off and the resulting filtrate was evaporated with a vacuum evaporator to give a red oil, which was then extracted by shaking with two 50 ml portions of ether. A small amount of yellow crystal was obtained from the extracted ether and recrystallized from *n*-hexane to give yellowish plates; mp 68—69°C; UV max (99% EtOH) 304 nm (log ε 4.21); IR (KBr) 3005 (m), 2980, 2919 (m), 2210 (s), 1705 (vs), 1538 cm^{-1} (vs).

Found: C, 49.33; H, 5.02; N, 8.06; S, 18.63%; mol wt (mass spectrum) 171. Calcd for $C_7H_9NOS_2$: C, 49.11; H, 5.32; N, 8.18; S, 18.73%; mol wt, 171.23. A vinyl proton at δ 8.87 is just in the range expected for one of the *E*-form.[3]

*Geometrical Structure of **1**.* The NMR spectrum of **6** showed a singlet signal due to methylthio group at δ 2.70. The two singlet signals due to the two methylthio groups of ethyl 2-cyano-3,3-bis(methylthio)acrylate were observed at δ 2.72 and 2.52, which seem assignable to the *cis* methylthio group and the *trans* methylthio group with respect to the cyano group, respectively. This supports the conclusion that **1** in DMSO-d_6 can exist only in **1a** because the NMR spectrum of **1** shows a singlet signal at δ 2.70. The chemical shifts are summarized as follows:

Electron Spin Resonance Study on Photoinduced Changes of the Radicals Produced in Methyl Isocyanate Solid Irradiated with γ-Rays

Masato FUJIWARA, Naoyuki TAMURA,* and Hidefumi HIRAI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo
**Takasaki Radiation Chemistry Research Establishment, Japan Atomic Energy Research Institute, Takasaki*

(Received April 24, 1972)

Free radicals in the γ-irradiated solid of methyl isocyanate at -196°C have been studied by electron spin resonance (ESR) at $-196\sim-100$°C. An oriented solid of methyl isocyanate was prepared by solidification of methyl isocyanate around an aluminum rod under cooling. The original radical and trapped electron produced by γ-irradiation were recorded at -196°C in the dark. The original radical produced in the oriented solid gave a resonance pattern consisting of a triplet of triplets and was assigned to $\cdot CH_2NCO$ radical. This was converted completely into a new radical on irradiation with visible light for 90 min. The new resonance pattern consists of a triplet of triplets whose nitrogen and proton splitting constants are 20.0 and 87.4 gauss, respectively. The nitrogen hyperfine splitting was anisotropic and the proton splitting constant agreed with that of methylene imino radical ($H_2C{=}N\cdot$). The new radical was assigned to methylene imino radical. The resonance pattern of $\cdot CH_2NCO$ radical was restored when the temperature was raised up to -120°C. The mutual conversion between the two radicals by visible light and heat was concluded to be a decomposition of $\cdot CH_2NCO$ into $H_2C{=}N\cdot$ and CO, and a recombination of these two moieties.

Recently, several ESR studies on reversible changes of free radicals on irradiation of light and heating have been reported on allylic radical[1] in γ-irradiated polyethylene, isobutyl radical,[2] ethoxy radical,[3] and deuterated acetonitrile anion radical.[4] The photochemical changes of allylic and isobutyl radicals were attributed to an intramolecular transfer of hydrogen. On the other hand, the changes of ethoxy radical and deuterated acetonitrile anion radical were suggested to be decomposition and recombination reactions of the radicals.

The radical produced by γ-irradiation of methyl isocyanate at -196°C has been reported by Chung and Williams.[5] The electron spin resonance (ESR) spectrum was recorded at -196°C after the subsequent irradiation of visible light for a short period and ascribed to $\cdot CH_2NCO$ radical. They used the irradiation of visible light only for the purpose of obtaining a more symmetrical spectrum than that obtained in the dark. A slight orientation effect of the specimen was also noted by them. The change of the radical on irradiation of light and heating, however, has not so far been reported.

The object of this work is to study both the photochemical and thermal changes of the radical in γ-irradiated methyl isocyanate solid by ESR spectroscopy. The radical produced by γ-irradiation and the subsequent exposure to visible light are identified with the aid of the anisotropy of the spectrum and the deuteration of methyl isocyanate. The anisotropy is also examined by use of the oriented solid method which has been found to be useful for ESR measurement of vinyl acetate[6] and isocyanic acid,[7] whose melting points are too low for the preparation of single crystals.

Experimental

Methyl isocyanate (guaranteed reagent grade, Tokyo Chemical Industry Company Ltd.) was purified by vacuum distillation. Deuterated methyl isocyanate (CD_3NCO) was prepared in the following manner.[8] Deuterated acetyl chloride (CD_3COCl) was obtained by heating deuterated acetic acid (CD_3COOD) (degree of deuteration=99%, 20 g) with thionyl chloride under reflux. Sodium azide (24 g) dissolved in isoamyl ether (150 g) was added dropwise to the deuterated acetyl chloride, resulting in deuterated acetyl azide (CD_3CON_3) which was converted into deuterated methyl isocyanate by heating; Total yield=55.0%. The resulting deuterated methyl isocyanate was purified by gas chromatographic fractionation, using a 1 m column of Carbowax 1500. The degree of deuteration was determined as 98.5% with a Hitachi RMU-6 mass spectrometer.

An oriented solid of methyl isocyanate was prepared according to a procedure similar to that used for the preparation of an oriented solid of vinyl acetate.[6] Methyl isocyanate was solidified around an aluminum rod in a glass tube by cooling with liquid nitrogen and was irradiated with ^{60}Co γ-rays (8×10^5—8×10^6 rad) at -196°C.

After γ-ray irradiation, the solidified methyl isocyanate was cleft radially into several pieces, one of which was inserted in a crack of Teflon tube so as to hold the longitudinal axis of the piece, *i.e.* the axis of the mark of aluminum rod, horizontally. The angle between the longitudinal axis of the piece and the direction of the DC magnetic field is referred to as "orientation-angle." Orientation-angle 0 and 90° indicate the axes parallel and perpendicular, respectively, to the magnetic field. The ESR measurement was carried out using a Varian V-4502 X-band spectrometer with 100 KHz field modulation at several different temperatures between

−196 and −100°C. The method described above is referred to as the oriented solid method.

The γ-irradiated solid of methyl isocyanate was exposed to visible light (wave lengths>4000 Å) from an Ushio Denki HB 500/B high pressure mercury lamp in a transparent quartz Dewar vessel at −196°C, using a Dow Corning CS-3-75 filter.

Results

γ-Irradiated Methyl Isocyanate in the Dark. Figure 1 shows the ESR spectra of methyl isocyanate and deuterated methyl isocyanate irradiated with γ-rays (1×10^6 rad) and recorded at −196°C in the dark in a Spectrosil tube. Spectra 1a and 1b correspond to methyl isocyanate and deuterated methyl isocyanate, respectively. No changes in the pattern occurred when the Spectrosil tube was rotated about its longitudinal tube axis in the dc magnetic field. The spectra were unsymmetrical because of the overlapping of a singlet at the center of the spectra.

γ-Irradiated Methyl Isocyanate Exposed to Visible Light for a Short Period. The γ-irradiated methyl isocyanate and deuterated methyl isocyanate exposed subsequently to visible light for 1 min gave spectra 2a and 2b, respectively. Spectrum 2a consists of a set of nine lines which is grouped into a triplet of triplets. Spectrum 2b consists of seven lines with a relative intensity ratio of about 1: 3: 5: 9: 5: 3: 1, the line splitting being 3.5 gauss. The singlet centered at $g=2.002\pm0.001$ disappeared not only on subsequent exposure to visible light for 1 min but also on the storage in the dark at −196°C for a long period (20 hr). This singlet must be the absorption of trapped electron, since its behavior on irradiation of light and its g-value are analogous to those of the trapped electron.[9]

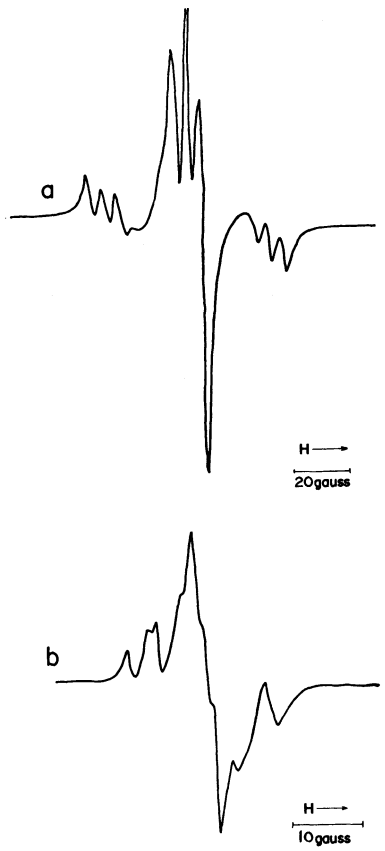

Fig. 1. ESR spectra of methyl isocyanate (a) and deuterated methyl isocyanate (b) irradiated with γ-rays (1×10^6 rad) at −196°C in a Spectrosil tube and measured in the dark.

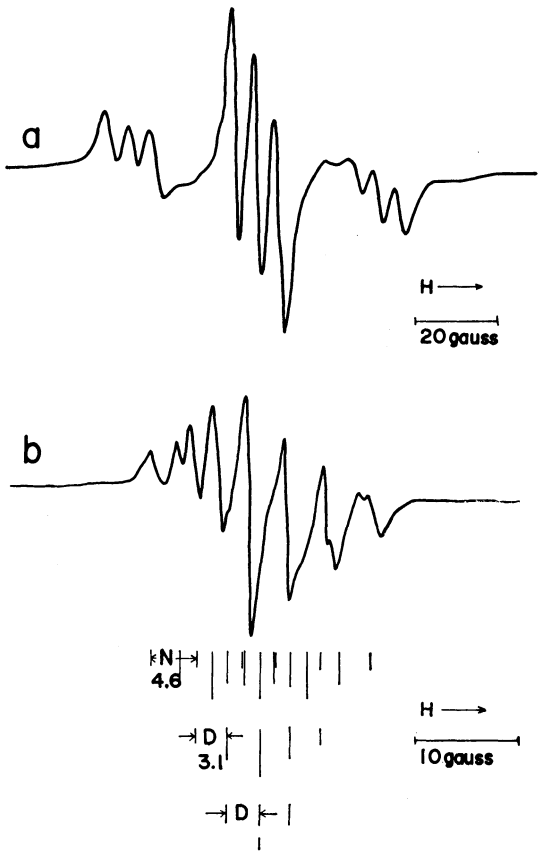

Fig. 2. ESR spectra of methyl isocyanate (a) and deuterated methyl isocyanate (b) irradiated with γ-rays and exposed subsequently to visible light for 1 min.

Theoretical intensity ratios of spectrum 2b whose nitrogen and deuteron splitting constants are 4.6 and 3.1 gauss, respectively, are reconstructed as shown at the bottom of Fig. 2. The line splitting, 3.1 gauss, corresponds to 1/6.65 of the proton splitting at orientation-angle 0°. The intensity ratios of the observed line agrees with theoretical ones.

Figure 3 shows the ESR spectra of the γ-irradiated oriented solid exposed subsequently to visible light for 1 min. The oriented solid method gives the anisotropic spectra when the specimen is rotated in the magnetic field keeping the longitudinal axis horizontal; the outer components of the spectra were anisotropic, while the three central lines were isotropic. The spectrum at orientation-angle 0° (Fig. 3a) consists of a triplet of triplets with a relative integral intensity ratio of 1: 2: 1. The larger triplet and the well-defined 1: 1: 1 triplet splittings were 20.6 and 4.6 gauss, respectively, at orientation-angle 0°. The larger triplet splitting at orientation-angle 45° and 90° could not

be determined because of broadening of the outer components, while the well-defined triplet splitting of the central components was 4.6 gauss. Elevation of temperature to about −100°C gave no changes in shape except that the singlet disappeared above −180°C as shown in Fig. 4. These results indicate that γ-irradiation of methylisocyanate solid gives only one species of radical, which is hereinafter referred to as Radical **1**.

γ-Irradiated Methyl Isocyanate Exposed to Visible Light for a Long Period. On continuing the irradiation of visible light to the γ-irradiation specimen, a new resonance pattern appeared gradually, accompanied by the disappearance of the original pattern, the changes being completed within 90 min (Fig. 5). The new resonance pattern shown in Fig. 5c was found to consist of a triplet of triplets with a relative integral intensity ratio 1:2:1. The main triplet splitting was 87.4 gauss, which agreed with that of the proton splitting constant of methylene imino free radical.[10] Each line of the main triplet was split into a secondary triplet whose splitting constant was 20.0 gauss. It was observed that the outer lines of each secondary triplet were weak and unsymmetrical, indicating that the hyperfine interaction responsible for this splitting is anisotropic. The new radical produced by the irradiation of visible light is referred to as Radical **2**. The concentration of Radical **1** obtained with spectrum 5a was almost equal to that of Radical **2** obtained with spectrum 5c.

Elevation of temperature of the γ-irradiated specimen exposed subsequently to visible light for 90 min showed a remarkable change in which the resonance pattern

Fig. 5. The changes of ESR spectra of methyl isocyanate irradiated with γ-rays and exposed subsequently to visible light for 5 min (a), 30 min (b), and 90 min (c).

10) E. L. Cochran, F. J. Adrian, and V. A. Bowers, *J. Chem. Phys.*, **36**, 1938 (1962).

of Radical **1** was regenerated, accompanied by the decrease of the pattern of Radical **2** (Fig. 6). The change was completed at −120°C. When the γ-irradiated specimen was warmed at about −120°C without the irradiation of visible light and subsequently exposed to visible light at −196°C for 90 min, the resonance pattern of Radical **2** appeared. This indicates that the mutual change between the two radiacls by visible light and heat was a reversible conversion of radical.

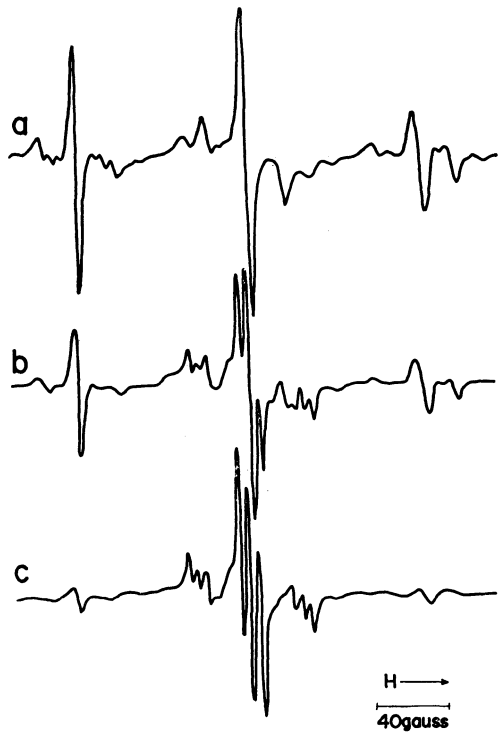

Fig. 6. The changes of ESR spectra of methyl isocyanate irradiated with γ-rays and exposed subsequently to visible light for 90 minutes at various temperatures; −196°C (a), −150°C (b), and −120°C (c).

The resonance pattern of deuterated methyl isocyanate also changes with the irradiation of visible light to the spectrum which consists of a quintuple of triplets (Fig. 7). The splitting of the main quintet with intensity ratio 1: 2: 3: 2: 1 was 13.1 gauss. Each line of the main quintet splits into a secondary triplet whose splitting constant is 20.0 gauss (Fig. 8). The value of this quintet splitting corresponds to 1/6.67 of the main triplet splitting of Radical **2** in methyl isocyanate and is ascribed to deuteron coupling. The secondary triplet splitting remains constant both for methyl isocyanate and for deuterated methyl isocyanate and is assigned to nitrogen coupling. Accordingly, the main triplet and the secondary triplet splitting of Radical **2** can be derived from the two protons and nitrogen coupling, respectively.

Determination of g-values of Radical 2. The shape of the ESR lines of deuterated Radical **2** (Fig. 8) clearly shows unsymmetrical absorption lines in the lower magnetic field and absorption lines separated into three lines in the higher magnetic field. The shape was ascribed to the broadening effect of the magnetic anisotropy similar to the case for DĊO

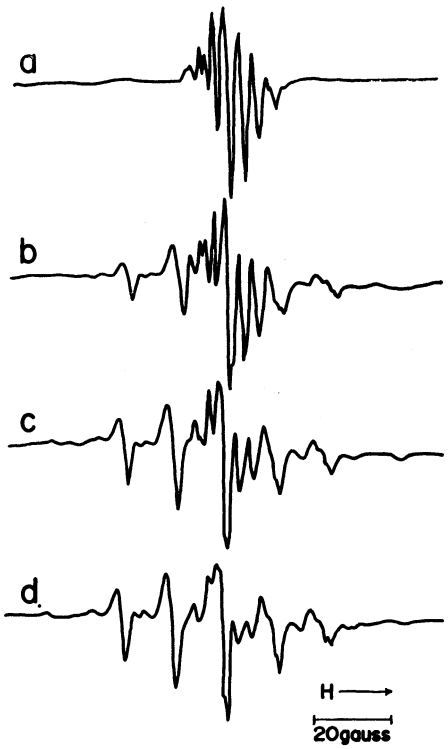

Fig. 7. The changes of ESR spectra of deuterated methyl isocyanate irradiated with γ-rays and exposed subsequently to visible light for 1 min. (a), 5 min (b), 30 min (c), and 90 min (d).

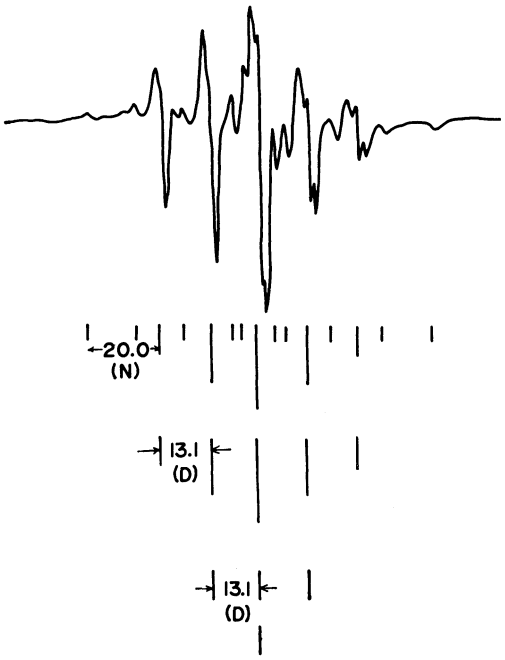

Fig. 8. ESR spectrum of deuterated methyl isocyanate irradiated with γ-rays and exposed to visible light for 90 min.

radical.[11] The line width between the strong five lines of the deuterated Radical **2** shows that the line broadening is due to the combination of anisotropic g-values and hyperfine interactions both with deuteron

11) F. J. Adrian, E. L. Cochran, and V. A. Bowers, *J. Chem. Phys.* **36**, 1661 (1962).

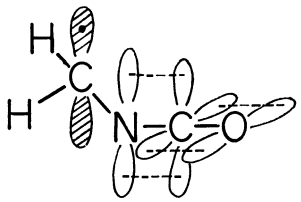
and nitrogen. In the spectra of deuterated Radical **2**, the central line broadening due to the anisotropy of *g*-value is large compared to the line width due to the other sources such as the anisotropic hyperfine interactions, since the magentic quantum numbers, M_I, both of nitrogen and of deuteron are zero. In this case, the principal *g*-values could be determined from the central strong line of the deuterated Radical **2**. The high- and low-field peaks of the derivative of the ESR absorption gave g_x and g_z, respectively, while g_y corresponded to the crossover point where the derivative vanished. The results are given in Table 1.

Table 1. Principal components of the *g*-value for radical **2**

$g_x=2.0038$
$g_y=2.0023$
$g_z=2.0015$

Discussion

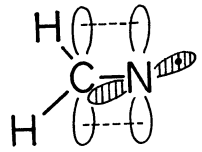
Structure of Radical 1. The resonance pattern of spectrum 3a gives us the assignment of Radical **1**. The well-defined 1:1:1 triplet structure (4.6 gauss) is ascribed to the isotropic nitrogen coupling and the larger triplet structure (20.6 gauss) with a relative intensity ratio 1:2:1 to the coupling of the two equivalent protons. The anisotropy of spectra (Fig. 3) suggests that the protons of Radical **1** are α-protons. The outer components of spectra 3b and 3c consisted of many absorption lines due to the coalescence of the ESR absorption lines with different splitting constants caused by the anisotropic hyperfine interaction of α-protons. Accordingly, the nine-line spectrum can be assigned to $\cdot CH_2NCO$ radical. The two equivalent α-protons, as would be the case for a rotating methylene group,[12] give such characteristic hyperfine structures that the central component remains narrower and the outer components become broader. These characteristic structures which are typical of non-oriented specimen are found in spectrum 2a. Consequently, the methylene group of $\cdot CH_2NCO$ radical is assumed to be rotated around the C–N bond and the radical can be represented by the following formula;



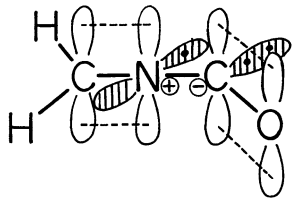
1

The unpaired electron occupies the carbon 2p orbital. The unpaired electron density on carbon atom ($=\rho_C$) which is estimated to be about 0.8 from the proton splitting may be reasonable, since the 2p orbital occupied by the unpaired electron is rotated around the C–N bond. The fact that the proton splitting is 20.6 gauss was confirmed by the result of deuterated methyl isocyanate; the ESR spectrum consists of fifteen-line, a quintuple of triplets (the bottom of Fig. 2b) and the splitting of quintet component of fifteen-line due to the deuteron coupling is 3.1 gauss, corresponding to 1/6.65 of proton splitting at orientation-angle 0°, while the splitting of triplet component due to the nitrogen coupling equals that of undeuterated specimen.

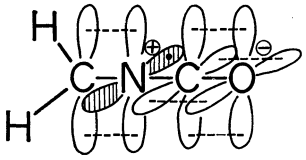
Structure of Radical 2. The proton splitting of Radical **2** gave the same value as that of methylene imino free radical[10] and the nitrogen splitting was anisotropic (Fig. 5). This suggests that the structure of Radical **2** is analogous to that of methylene imino radical. The unpaired electron of methylene imino radical occupies a nitrogen 2p orbital which is perpendicular to the C–N bond lying in the same plane as the C–H bonds.[10] Thus, three types of the structure might be proposed as shown in Structures **3**, **4**, and **5**;



3



4



5

where Structure **3** is methylene imino radical itself and the radicals with Structures **4** and **5** are isomers of Radical **1**. The unpaired electron of Structure **3** occupies the nitrogen 2p orbital. In Structure **4**, it is located at an antibonding σ-molecular orbital (MO) consisting of sp^2 carbon hybrid orbital and nitrogen 2p orbital. In Structure **5**, it occupies a conjugated orbital consisted of nitrogen 2p orbital and π-orbital of carbonyl group.

The experimental values of nitrogen splitting and unpaired electron density on nitrogen atom ($=\rho_N$) are given by Adrian[13] for HCN^- radical. The unpaired electron occupies an antibonding σ-orbital similar to that of Structure **4** which consists of a sp^2 carbon hybrid orbital and a nitrogen 2p orbital. The observed

12) E. L. Cochran, F. J. Adrian, and V. A. Bowers, *ibid.*, **34**, 1161 (1961).

13) F. J. Adrian, E. L. Cochran, V. A. Bowers, and B. C. Weatherley, *Phys. Rev.*, **17**, 129 (1969).

value of nitrogen splitting (20.0 gauss) agrees with A_1 (20.9 gauss) of HCN^- radical. The value of ρ_N (=0.41) in HCN^- radical, however, is much smaller than that of Structure **3** (ρ_N=1). The unpaired electron of Structure **5** may be delocalized in the π-orbital of carbonyl group and ρ_N is estimated to be as large as that of allyl radical.[14] The delocalization of unpaired electron density can not give the large splitting of proton and nitrogen. Thus, Structures **4** and **5** are discarded. On the other hand, Structure **3** is acceptable for the interpretation of the large proton splitting and anisotropic nitrogen splitting. For the methylene imino radical in motion in the hydrogen cyanide matrix at −196°C, the nitrogen splitting has reported to be 11—21 gauss[15] which coincides with the observed value of spectrum 5c. Cochran reported that the nitrogen splitting was 34.4 gauss[10] in rigid argon matrix at 4.2°K. The matrix of methyl isocyanate should not be so rigid as to prohibit the motion of the radical at −196°C. Consequently, Structure **3** is most plausible for the assignment of Radical **2**. The authors had first considered that the mutual conversion between Radicals **1** and **2** was the isomerization between Radical **1** and the radical with Structure **4**, since Radical **1** changed quantitatively into Radical **2** on irradiation with visible light, and Radical **1** was regenerated as the temperature was raised.[16]

The mechanism of mutual conversion between Radicals **1** and **2** may be as follows. The decomposition of Radical **1** into $H_2C{=}N\cdot$ and CO, and the recombination of these two moieties $H_2C{=}N\cdot$ and CO might take place in the neighborhood of each other in the matrix of methyl isocyanate which is so rigid as to stabilize $H_2C{=}N\cdot$ at −120°C. This reaction can be represented by the formula

$$\cdot CH_2NCO \underset{\Delta}{\overset{h\nu}{\rightleftharpoons}} H_2C{=}N\cdot + CO$$

The authors wish to thank Dr. Hiroaki Sawai, the University of Tokyo, for his help in preparing deuterated methyl isocyanate.

16) The referee's suggestion that ρ_N of Structure **4** is too small to give the proton splitting (87.4 gauss), has been carefully investigated and accepted. The authors wish to thank the referee for his valuable suggestion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 706—710 (1973)

The Carbon-13 Chemical Shift of *n*-Butane

Isao ANDO and Atsuo NISHIOKA

Department of Polymer Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 13, 1972)

The temperature dependence of the carbon-13 chemical shift of *n*-butane was calculated using the CNDO/2 method, taking into account the rotational isomers and assuming the Boltzmann distribution among them. The observed results could be well interpreted by assuming *ca.* 11.15 eV as the average excitation energy.

The chemical shifts of carbon-13 nuclei in saturated hydrocarbons have been studied systematically by the experiment of Grant *et al.*[1] Pople[2] has given a theory of the carbon-13 chemical shift, and has caluclated the shifts of ethane and other simple molecules. His approach is not convenient for calculating the carbon-13 chemical shift of a large molecule because of the tedious work involved. Then Sichel *et al.*[3] have reported empirically on an apparent correlation between the carbon-13 chemical shifts and the electron charge densities on the carbon atoms of hydrocarbons, as calculated by the extended Hückel method.[4] Yonezawa *et al.*[5] have interpreted theoretically the carbon-13 chemical shifts of various hydrocarbons by approximating Pople's theory[2] for the paramagnetic shielding of the carbon-13 nucleus, but the agreement between the calculated and observed chemical shifts is not good. This disagreement may be due mainly to the approximation, assuming the constancy of terms containing the bond orders between neighbouring atoms, the ambiguity of the value of the average excitation energy, and the neglect of the rotational isomers.

In this paper we will calculate the paramagnetic shielding constants of carbon atoms in *n*-butane based on Pople's theory, and will interpret the temperature dependence of the carbon-13 chemical shifts by estimating the diamagnetic shielding constant in addition to

its paramagnetic shielding constant, taking the rotational isomers into account also.

Experimental

The proton-decoupled carbon-13 NMR spectra of *n*-butane in neat liquid were measured at temperatures from −60 to 0°C at 25.25 MHz in the external-locked mode, using a Japan Electron Optics Laboratory, JEOL PS-100-type, spectrometer. The sample (purity: 99.9%) was obtained from the Tokyo Kasei Co., Ltd.

Calculation

The magnetic shielding constant of any specified carbon atom, A, in a molecule, σ_A, may be approximated by a sum of the following terms:[2]

$$\sigma_A = \sigma_{AA}^{dia} + \sigma_{AA}^{para} + \sigma' \quad (1)$$

where σ_{AA}^{dia} and σ_{AA}^{para} are the diamagnetic and paramagnetic contributions to the specified carbon atom, A, respectively, and σ', the contribution from the neighbouring atoms bonded to the A atom. Usually the effect of σ' on the carbon-13 chemical shift is known to be very small,[2] contributing less than a few parts per million. With Slater atomic orbitals, σ_{AA}^{dia} increases 14 ppm if a 2p electron is added, only about 10% of the width of the observed range of the carbon-13 chemical shifts. However, in this paper in order to discuss the carbon-13 chemical shift in detail we will take into account the terms of both the diamagnetic and paramagnetic shielding effects.

The value of σ_{AA}^{dia} is given by the formula:[6]

$$\sigma_{AA}^{dia} = (e^2/3mc^2)\sum_i \langle r_i^{-1} \rangle \quad (2)$$

where $\langle r_i^{-1} \rangle$ is the mean inverse distance of an electron from a nucleus; m, its mass; e, its charge and c, the velocity of light; the summation is over all the electrons on the atom being considered. The approximate value of σ_{AA}^{dia} for the carbon atom is given as:

$$\sigma_{AA}^{dia} = 4.45Z^*q \quad (3)$$

where:

$$Z^* = 3.25 - 0.35(q-4) \quad (4)$$

in which q is the total electron density around the carbon atom, and Z^*, the "effective nuclear charge" estimated according to Slater's rules.[7]

According to Pople's theory,[2] σ_{AA}^{para} is given as:

$$\sigma_{AA}^{para} = -(e^2\hbar^2/2m^2c^2\Delta E)\langle r^{-3} \rangle_{2p} \sum_{B(=A)} Q_{AB} \quad (5)$$

where:

$$Q_{AB} = \frac{4}{3}\delta_{AB}(P_{x_Ax_B} + P_{y_Ay_B} + P_{z_Az_B}) - \frac{2}{3}(P_{y_Ay_B}P_{z_Az_B} + P_{z_Az_B}P_{x_Ax_B} + P_{x_Ax_B}P_{y_Ay_B}) + \frac{2}{3}(P_{y_Az_B}P_{z_Ay_B} + P_{z_Ax_B}P_{x_Az_B} + P_{x_Ay_B}P_{y_Ax_B}) \quad (6)$$

$$\langle r^{-3} \rangle_{2p} = \frac{1}{24a_0^3}(3.25 - 0.35(q_{2p} - 3))^3 \quad (7)$$

$$q_{2p} = P_{x_Ax_B} + P_{y_Ay_A} + P_{z_Az_A} \quad (8)$$

In these formulae, ΔE is an averaged electronic excitation energy; $\sum_{B(=A)}$, a summation over all the atoms; $\langle r^{-3} \rangle_{2p}$, the mean inverse cube radius for carbon 2p orbitals; q_{2p}, the electron density of the 2p electrons; δ_{AB}, the Kronecker symbol, and a_0, the Bohr radius. $P_{x_Ax_B}$ is the element of the matrix for the $2p_x$ atom orbitals on the A and B atoms. When A=B, it is the charge density in $2p_x$ on the A atom, and When A≠B, it is the bond order between the two atomic orbitals.

σ_{AA}^{para} and σ_{AA}^{dia} were estimated by the CNDO/2 (Complete Neglect of Differential Overlap) molecular orbital method.[8]

In the *n*-butane molecule, three conformations are possible as the rotational isomerism (*trans*(T) and *gauche* (G or G′) with respect to the central bond). T, G, and G′ are defined as occuring at the rotational angles about 0, 120, and 240° respectively, by the clockwise rotation around the C–C bond, as expressed in the Newman projection. One of the three methyl protons was assumed to take the *trans* position in relation to the third carbon atom from the methyl carbon atom.

Then, obtaining the chemical shift of *n*-butane, we must average the calculated chemical shifts of the three possible isomers. For the averaging of the chemical shifts of the isomers, the following formula was used:[9]

$$\sigma_{AV} = \sum_{i=1}^{3} X_i \sigma_{A_i} \quad (9)$$

where σ_{AV} is the averaged chemical shift; σ_{A_i}, the chemical shift of the i-th isomer, and X_i, its fraction. X_i is expressed as:

$$X_i = e^{-\Delta E_i/RT} / \sum_{i=1}^{3} e^{-\Delta E_i/RT} \quad (10)$$

where R is the gas constant; T, the absolute temperature, and ΔE_i, the energy difference between the reference isomer (*trans*) and the i-th isomer. From the equations presented above, we can calculate the carbon-13 chemical shift and the temperature dependence of *n*-butane.

Here, the C–C and C–H bond lengths are set at 1.54 and 1.10 Å respectively, and both the C–C–C and the C–C–H bond angles are set at 109°28′.[10]

The numerical calculation was carried out by means of the HITAC-5020E computer of the Computer Center of the University of Tokyo.

Results and Discussion

n-Butane can take three rotational isomers, of one *trans* and two *gauche* forms; the total electron densities of the *trans* and *gauche* isomers are shown in Fig. 1. The electron densities and bond orders of the 2p electrons of the carbon atoms in these isomers are shown in Table 1. There is not much differences in the electronic states between the *trans* and *gauche* forms. Therefore, the large temperature dependence of the chemical shift of *n*-butane cannot be explained in terms of these

total densities.

The carbon-13 chemical shifts of the *trans* and *gauche* isomers, and those averaged over these isomers, were calculated using Eqs. (1), (3), (5), and (9); they are shown in Table 2. The calculated and observed chemical-shift differences between the methyl and methylene carbons at 300K are also shown. Since there is no definite value for the average excitation energy (ΔE) published for *n*-butane, we first tried to use 10 eV for ΔE; this value was originally used by Pople[2] in the case of ethane.

As expected, and as Table 2 shows, σ_{AA}^{para} contributes mainly to the chemical-shift difference between the methyl and methylene carbons. The calculated chemical shifts of both methyl carbons in the *trans* and *gauche* isomers are nearly equal to each other, but those of the methylene carbon in the former appear at a slightly higher field than in the latter. This is due to the change in the electronic state of the methylene atom for the rotation around the central bond. Therefore, the chemical shift of the methylene carbon may be expected to depend upon the population of the rotational isomers, which is itself governed by the energy difference (ΔE_g) between the *trans* and *gauche* forms. It is known from spectroscopic studies that extensive results for liquid *n*-hydrocarbons confirm a value of 500 ± 100 cal/mol for ΔE_g.[11] Recently, on the basis of a laser-Raman spectroscopic study,[12] it has been reported that 600 cal/mol is more reasonable as

a) Reference is the signal of the methylene carbon.
b) Calculated using 500 cal/mol as ΔE_g.
c) Calculated using 600 cal/mol as ΔE_g.

the ΔE_g value. Here, we have calculated the chemical shifts of the methyl and methylene carbons for both ΔE_g value, 500 and 600 cal/mol, at 300K. As may be seen from Table 2, the calculated chemical shifts between the methyl and methylene carbons using ΔE_g values of 500 and 600 cal/mol at 300K are 13.23 and 13.17 ppm respectively. There is only a slight difference (about 5%) between them.

The calculated and observed chemical-shift differences between the methyl and methylene carbons are 13.23 and 11.90 ppm respectively at 300 K. The agreement is good; the small difference is considered mainly to be due to the ambiguous estimation of the average excitation energy.

Now let us attempt to estimate an appropriate value of ΔE in order to interpret the observed chemical shift rigorously. As the first approximation, it may be considered that, according to Gutowsky's consideration,[9] the observed temperature dependence of the carbon-13 chemical shift of *n*-butane can be interpreted in terms of the temperature dependence of the fraction of rotational isomers. Therefore, if the ΔE_g and the

TABLE 3. THE OBSERVED CHEMICAL SHIFT DIFFERENCES BETWEEN THE METHYL AND METHYLENE CARBONS ($\Delta\sigma_{CH_3-CH_2}$) AND ΔE IN VARIOUS TEMPERATURES

T(K)	212	252	270	294	300
$\Delta\sigma_{CH_3-CH_2}$ (ppm)	11.75	11.77	11.84	11.86	11.90
ΔE (eV) (a)	11.19	11.23	11.16	11.17	11.10
ΔE (eV) (b)	11.13	11.15	11.12	11.13	11.17

a) ΔE_g=500 cal/mol, b) ΔE_g=600 cal/mol

temperature are determined, all the values of the chemical shifts observed for a wide range of temperatures can be estimated by a single value of ΔE.

The absolute measurement of the temperature dependence of the carbon-13 chemical shifts of the methyl or methylene carbons is very difficult because of some possible temperature drifts of the external or internal reference signal, whereas the temperature dependence of the chemical-shift difference ($\Delta\sigma_{CH_3-CH_2}$) between the methyl and methylene carbons is not affected by the temperature drifts of the reference signal. Thus, the values of $\Delta\sigma_{CH_3-CH_2}$ were measured at temperatures from 212 to 300 K, as is shown in Table 3; the values of ΔE were then calculated to fit the observed $\Delta\sigma$ value (where both 500 and 600 cal/mol were used as ΔE_g values). From the results, it was found that the observed values can be interpreted reasonably using the constant (ΔE) value of 11.16±0.04 and 11.14±0.02 eV in the cases of ΔE_g values of 500 and 600 cal/mol respectively. There is no significant difference between the two cases.

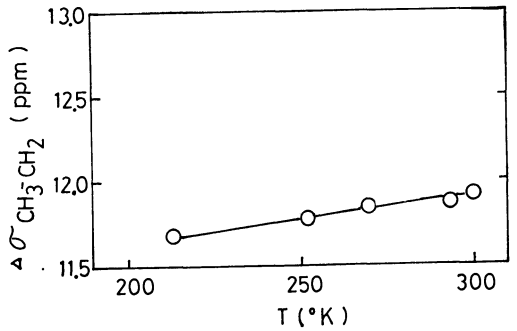

Fig. 2. The calculated and observed temperature dependences of the chemical shift difference between the methyl and methylene carbons of *n*-butane.
Drawn line: calculated using 11.16 eV as ΔE
○: observed

Next, in order to compare clearly the observed and calculated results, they are both shown in Fig. 2; the latter was obtained using 11.16 eV as ΔE and 500 cal/mol as ΔE_g. In this figure the observed data may be found to fit the calculated line better. Therefore, we may conclude that the temperature dependence of the carbon-13 chemical shift of *n*-butane may be interpreted using the rotational isomers and a single value of ΔE

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 710—713 (1973)

Automatic Recording of Liquid Penetration through Filter Paper and Wetting Behavior of Liquids

Akio NAKAMURA, Tsutomu SEIMIYA, and Tsunetaka SASAKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Tokyo

(Received May 16, 1972)

The penetration of liquid through a vertically suspended filter paper was studied by measuring the weight increase with a strain gauge tensiometer for several organic liquids and aqueous solutions. The plot of penetration rate $K=h/t^{1/2}$ (h, height of liquid rise and t, time) against $(\sigma/\eta)^{1/2}$ (σ, surface tension and η, viscosity coefficient of wetting liquids) showed two straight lines, one for organic liquids and the other for aqueous solutions of sodium dodecyl sulfate. Both these lines passed the origin, suggesting Lucas-Washburn formula to hold. The plots for ethyl alcohol–water mixtures showed behaviors intermediate between those two linear relations. The aqueous solutions caused swelling of fibers and reduced the mean capillary radius of the filter paper, resulting in a decrease of the penetration constant $P=K/(\sigma/\eta)^{1/2}$ but with a rather large K value. The plots for penetration of water through an untreated paper fell far below the straight line obtained for aqueous solutions of sodium dodecyl sulfate. The penetration was recovered by removing fatty contaminants from the filter paper using Soxhlet extractor with ether. The results of a simple test of unfolding a folded paper by touching it with liquids are also in line with those mentioned above.

A number of studies have since been made for the wetting of the fibrous and powder materials as a function of the porosity of fiber,[1-3] the degree of dispersion of powder, the surface treatment and the effect of surface-active agent[4] on these substances. The sinking time of solid sample may be used as a simple criterion of

wetting power of surface-active agent,[5] while wettabilities of fibers,[6,7] filter papers[8,9] and powder materials[10,11] are measured by the penetration velocity or pressure of a liquid through the sample strip or the powders packed in a column. The rate of penetration should be a subject worth studying from both theoretical and practical interest. However, the frontal line of the ascending liquid is not easy to find visually because of its irregular and rapid movement, sepecially at the initial stage of penetration. This difficulty has been overcome by measuring the changes of the weight or the electrical capacity of the sample due to the liquid penetration, by torsion balance[6] or capacity meter.[11] In the present study, the weight increase was measured by a self-recording strain gauge tensiometer[12] which enabled a simple and accurate measurement of the kinetic process of penetration, especially at its early stage.

The penetration of filter paper by various liquids and solutions is described in the present paper to elucidate the different wetting and swelling behaviors of the filter paper towards water and organic liquids. Of the numerous studies of a similar nature[8] only little has been reported on these behaviors.[9]

Experimental

Materials. Ethyl alcohol, butyl alcohol, acetone, dioxane, *n*-hexane, and toluene were purified by dehydration and distillation.[13] Sodium dodecyl sulfate (SDS) was prepared by the sulfation of dodecyl alcohol free from its homologues, and was used after repeated purification.[14] Water used was obtained by refluxing ordinary distilled water first with acid permanganate, then distilling from alkaline permanganate solution, and finally distlling twice with a Hysil flask. The filter paper (No. 50 for chromatography, Toyo Filter Paper Co., Japan) was cut into strips 2×7 cm so as to make its total weight after the penetration within the maximum permissible load (300 mg) of the strain gauge. The paper was subjected to extraction with ether to remove fatty contaminants.

Apparatus and Measurement. A cantilever type self-recording strain gauge tensiometer[12] (Fig. 1) was used for the measurement of liquid penetration. A strip of filter paper was hung from the end of the tension arm, and the wetting liquid was introduced from the reservoir into the cell until it just touched the lower end of the filter paper. An increase of weight of the filter paper due to the penetration of liquid was converted into an electrical output by the strain gauge, and recorded with a 1 mV full scale recorder (QPD 33, Hitachi, Japan). The apparatus was kept at 30°C in a thermostat designed so as to keep the cell from outer environment and prevent the evaporation of solutions.[15] The reading of the recorder was calibrated to the height H of penetrating liquid from the electrical output of tensiometer for the liquid rise of unit length. The measurement was started after the saturation of the cell with the vapor of sample liquid. About five minutes of measurement was enough for analysis, since the approximate Eq. (2) was used which is only applicable for the early stage of penetration. A slight change of the surface tension with time and of the depth of paper in a liquid, caused a negligible error in the calculation of H. The viscosity of liquid was measured by an Ostwald viscometer, and the surface tension of liquid was measured by the same tensiometer using Wilhelmy's glass plate.[12] All measurements were made at 30°C.

Results and Discussion

The velocity of liquid ascending through fibrous material like filter paper was given by Peek and McLean[2] as

$$dh/dt = \bar{r}\sigma\cos\theta/4h\eta - \bar{r}^2dg/8\eta \quad (1)$$

where h denotes the height of liquid at time t, $\bar{r}$ the mean capillary radius, σ the surface tension, η the viscosity coefficient, d the density, g the gravity constant and θ the contact angle. At the initial stage of penetration Eq. (1) is approximated by

$$dh/dt = \bar{r}\sigma\cos\theta/4h\eta \quad (2)$$

which, after integration, gives Lucas-Washburn formula[1]

$$h = (\bar{r}\sigma \cos\theta/2\eta)^{1/2} t^{1/2} = Kt^{1/2} \quad (3)$$

Thus a plot of h *vs.* $t^{1/2}$ should give a straight line with a slope K, which is called hereafter the rate of penetration of liquid. If $\bar{r}$ is known, wetting tension $\sigma\cos\theta$ can be calculated from Eq. (3). We see also that in the case of constant $\bar{r}\cos\theta$, plot of K *vs.* $(\sigma/\eta)^{1/2}$ for various liquids should lie on the same straight line passing through the origin with a slope $P=(\bar{r}\cos\theta/2)^{1/2}$, which is called hereafter the penetration constant.

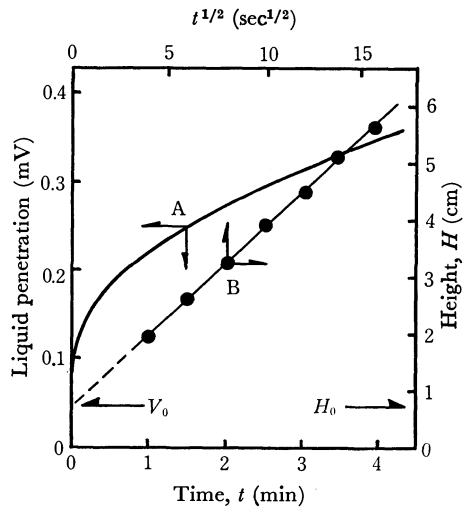

Fig. 2. Typical example of output against time and height against $t^{1/2}$ for water penetration.

Curve A in Fig. 2 shows a typical example of the liquid penetration process. The recorder reading increases along a parabolic curve with time, after an abrupt increase V_0, due to the pull by surface tension of liquid. The reading in terms of the apparent liquid rise H is plotted against $t^{1/2}$ as shown by the straight line B in Fig. 2. The value of H_0 (corresponding to V_0) was obtained by extrapolation as shown in the figure. Since $h=H-H_0$ is the true height of liquid rise, the straight line B with H_0 as zero point is taken as the h *vs.* $t^{1/2}$ plot. The linear relations are seen to hold for all systems so far studied, and show the Lucas-Washburn formula to hlod at least for the initial several minutes of the penetration process. Some typical results are shown in Fig. 3. The fair agreement with Lucas-Washburn formula might also imply the constancy of surface tension, presumably a dynamic one,[6,16] and the absence of chromatographic separation of solute at the ascending front in its initial stage. In the case of aqueous SDS solution, extrapolation to time zero was necessary to obtain the dynamic surface tension.

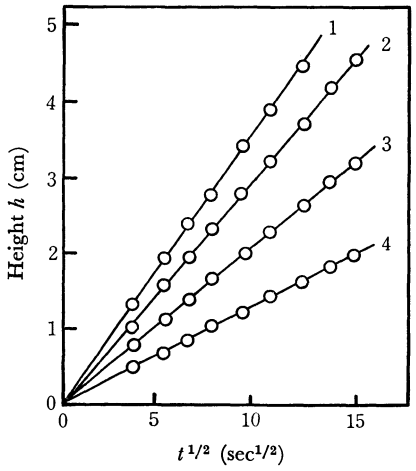

Fig. 3. Some plots of height against $t^{1/2}$.

◑: aqueous ethyl alcohol solutions (vol %), a: 5% b: 10% c: 20% d: 40% e: 60%
⊙: water, ●: water (untreated filter paper)
⊖: aqueous SDS solutions, ⊕: aqueous SDS solutions (untreated filter paper)

The plots of K *vs.* $(\sigma/\eta)^{1/2}$ are shown in Fig. 4. As expected, all plots for organic liquids tested fell on the same straight line passing through the origin with a slope $P=(\bar{r}\cos\theta/2)^{1/2}=4.3\times10^{-3}$ cm$^{1/2}$. Since $\bar{r}$ is considered to be constant for a given filter paper, the constancy of $\bar{r}\cos\theta$ means the constant θ, presumably zero degree, because most organic liquids are known to show zero contact angle against various compact solid surfaces.[2] The fact that Soxhlet extraction of the filter paper was immaterial for the penetration by organic liquids is quite reasonable, since the contact angles are unaffected by contamination and remain zero for these liquids. Figure 4 shows also that the plots for water and aqueous solutions considerably fall off the linear relation for the organic liquids. In the case of water penetration, removal of fatty contamination from the filter paper was seen to cause a remarkable increase of K value. The fact that the wetting of filter paper by aqueous SDS solution or organic liquids was not affected by the removal of fatty contamination of the paper also confirms this view. However, the increase of K due to the removal of contamination still does not bring the plots on the line obtained for the organic liquids. This can not be due to the incomplete removal of the contamination, since even a good wetting SDS solution can not bring the plots on the line of the organic liquids. This might suggest that the contact angle has already attained zero value, and that the decrease of $\bar{r}$ due to the swelling of fiber, for instance, affects the penetration by water or aqueous solutions.

16) H. Lange, *Kolloid-Z.*, **136**, 136 (1954).

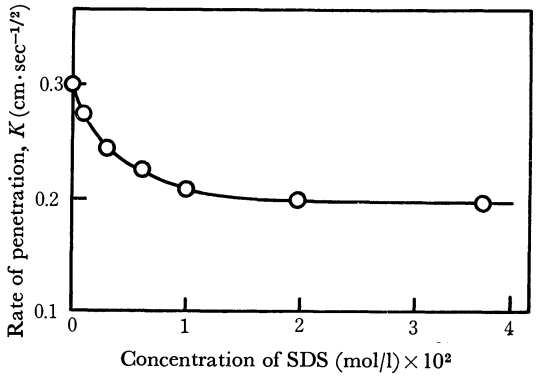

Fig. 5. Concentration dependence of rate of penetration K for aqueous SDS solutions.

The plots for aqueous SDS solutions and pure water lie on a straight line of smaller P than that for organic liquids. This may mean that the value of $\bar{r}$ for these aqueous systems is constant and smaller than that for organic liquids. The values of $\bar{r}$ estimated from the slope of straight lines in Fig. 4 are 3.4×10^{-5} cm for organic liquids, and 2.0×10^{-5} cm for both water and aqueous SDS solutions. The contact angle between pure water and the untreated filter paper is found to be 43°. The change of K with the concentration of SDS for clean filter paper is also shown in Fig. 5. The value of K decreased with increasing SDS concentration in contrast with the increased wetting of fibrous material contaminated with fatty substances.[14]

The penetration experiment of the filter paper by ethyl alcohol–water mixtures of various compositions revealed that the various states of swelling probably depend on the concentratration of ethyl alcohol. As seen in Fig. 4, the plots moved from the linear relation for aqueous solutions to that for organic liquids as the alcohol content increased. This may be caused by the increase of $\bar{r}$ with the decrease of water content and accordingly the decrease of the swelling. Curve A in Fig. 6 shows the regular increase of the P value with the concentration of ethyl alcohol in water, while the K value shows an irregular change with the alcohol concentration. Thus P is reasonably used as a measure of penetration.

As a simple demonstration of swelling, the rate of unfolding of a folded paper strip was measured by

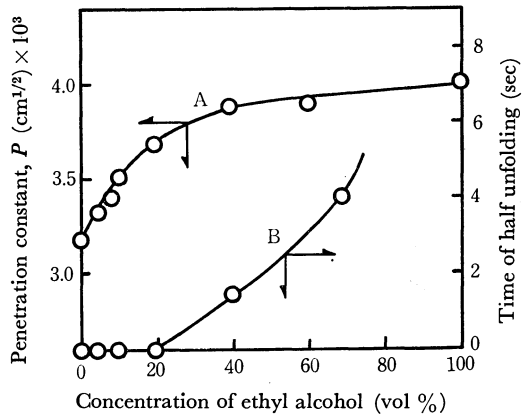

Fig. 6. Plots of penetration constant P and time of half unfolding against ethyl alcohol concentration.

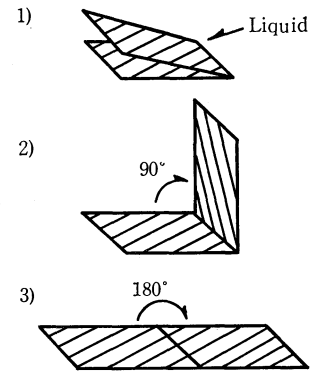

Fig. 7. Unfolding of filter paper strips.
1): no unfolding 2): half unfolding 3): full unfolding

applying a drop of liquid on the folded part of the paper (Fig. 7). No unfolding was observed for organic liquids tested, but for water and aqueous SDS solutions, it was full and instantaneous. The difference in unfolding also explains the difference in penetration shown by two straight lines in Fig. 4. Although the rate of penetration K is larger for n-hexane and acetone than that for water, the organic liquids neither cause swelling nor unfolding. The time for half-unfolding of the paper by aqueous solution of ethyl alcohol is also shown as curve B in Fig. 6. Unfolding and swelling were seen to be instantaneous in water-rich solutions. Half-unfolding angle of 90° was never reached at a concentration of ethyl alcohol higher than 80%. The tendency of non-unfolding presumed from a saturation of P value at higher concentration of ethyl alcohol seen in curve A of Fig. 6, is in line with the increasing tendency of unfolding time.

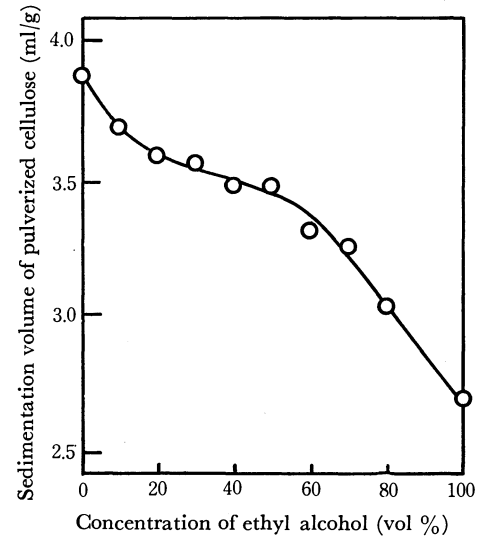

Fig. 8. Sedimentation volumes of *Avicel* in aqueous ethyl alcohol solutions.

The measurement of the sedimentation volume of pulverized cellulose in aqueous ethyl alcohol solution was carried out. The result shows that the tendencies of both swelling and non-swelling of cellulose depend on the concentration of ethyl alcohol. Figure 8 shows a decrease of sedimentation volume of pulverized cellulose (Avicel, Asahi Chemicals Inc., Japan) with increase of concentration of ethyl alcohol. This might also support the above view.

Charge-transfer and Proton-transfer in the Formation of Molecular Complexes. IV.[1] Picric Acid Complexes with Benzidine and Its Derivatives

Gunzi Saito and Yoshio Matsunaga
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo
(Received June 5, 1972)

The preparation of picric acid complexes with benzidine, *o*-tolidine, 3,3′-dichloro-*o*-tolidine, 3,3′-dibromo-*o*-tolidine, *o*-dianisidine, and *N,N,N′,N′*-tetramethylbenzidine was attempted in the following three solvents: benzene, chloroform, and ethanol. From benzene and chloroform, 3,3′-dibromo-*o*-tolidine forms a 1: 1 complex of the charge-transfer type, but the other five diamines give yellow salts formed by means of proton-transfer. Some complexes prepared in ethanol are of an unfamiliar nature. The spectroscopic examination of the 1: 1 complexes with *o*-tolidine, *o*-dianisidine, and tetramethylbenzidine revealed that a half of the diamine molecule acts as a proton-acceptor, while the other half has a charge-transfer interaction with the picrate ion. The simultaneous operation of charge-transfer and proton-transfer interactions was also demonstrated in the black-colored complex with benzidine of a 2: 1 composition.

Our earlier study of the vibrational and electronic spectra of the orange-colored α-naphthylamine-picric acid (2: 1) complex revealed that a proton is transferred from picric acid to α-naphthylamine, and that the interaction between the picrate ion and the second α-naphthylamine molecule is capable of producing a charge-transfer absorption band.[2] For brevity, such a complex may be denoted as a complex of the CPT type because of the simultaneous operation of charge-transfer (CT) and proton-transfer (PT) interactions between the component molecules.

When an aromatic diamine such as benzidine is combined with picric acid in a mole ratio of 1: 1, one may imagine the classification of the resulting complexes into the following three types. If the pK_a value of the diamine is low, a complex of the CT type may be formed.[1,3] On the other hand, the PT interaction may take place when the pK_a value of the diamine is high. In addition, a third possibility may be conceived on the basis of the observation of the above-mentioned naphthylamine complex; that is, a half of the diamine molecule acts as a proton-acceptor, while the other half has a CT interaction with the picrate ion. In this way, the complex of a 1: 1 composition can be of the CPT type (Case 1 of CPT complexes). Of course, the hydroxy group of the acid must be in the proximity of the amino group acting as a proton-acceptor to make the PT interaction feasible, and the molecular stacking must allow the picrate ion to superpose upon the unprotonated half of the adjacent diamine molecule. Two ways of stacking, (a) and (b), may be produced by the orientation of this diamine molecule.

In the *s*-trinitrobenzene (TNB) complexes of *N,N,N′,N′*-tetramethylbenzidine and *o*-dianisidine, the mole ratio of the diamine to TNB has been known to be 1: 2.[4,5] Because of the structural similarity between TNB and picric acid, the picric acid complexes of a 1: 2 composition and of the CT type may exist. It is also highly likely that the diamine molecule accepts two protons. In a situation intermediate between these two, a complex of the CPT type may be obtained; that is, one of the two picric acid molecules may be a proton-donor, and the other, an electron-acceptor (Case 2 of CPT complexes). As has been found with the 2,4-dinitrophenol and picric acid complexes of aromatic monoamines,[1,6] a delicate balance between the pK_a value of picric acid and those of the diamine may be the major factor governing the formation of such a complex.

By analogy to the α-naphthylamine-picric acid (2: 1) complex, the diamine complexes of a 2: 1 composition can also be expected to be of the CPT type (Case 3 of CPT complexes). The three cases imagined above for the picric acid (PiOH) complexes of the CPT type may be schematically shown as follows:

Case 1 (a) $H_2N{-}\phi{-}\phi{-}NH_3^+\cdots{}^-O{-}Pi$
⋮
$H_2N{-}\phi{-}\phi{-}NH_3^+\cdots{}^-O{-}Pi$

(b) $H_2N{-}\phi{-}\phi{-}NH_3^+\cdots{}^-O{-}Pi$
⋮ ⋮
$Pi{-}O^-\cdots{}^+H_3N{-}\phi{-}\phi{-}NH_2$

Case 2 $H_2N{-}\phi{-}\phi{-}NH_3^+\cdots{}^-O{-}Pi$
⋮
PiOH

Case 3 $H_2N{-}\phi{-}\phi{-}NH_3^+\cdots{}^-O{-}Pi$
⋮
$H_2N{-}\phi{-}\phi{-}NH_2$

This theorizing has led us to look into the picric acid complexes of benzidine and its five derivatives. As will be described below, the complexes belonging to most of the cases mentioned above, including Cases 1 and 3, were found by these combinations.

Experimental

Materials. The sources and handling of benzidine, *o*-tolidine, 3,3′-dichloro-*o*-tolidine, 3,3′-dibromo-*o*-tolidine, and *N,N,N′,N′*-tetramethylbenzidine have been described in a

previous paper of ours.[7] In addition to this series, *o*-dianisidine obtained commercially was used in this work. The complexes were prepared in the following three solvents of different polarities: benzene, chloroform, and ethanol. Generally, the complexes were precipitated by mixing equimolar amounts of the component compounds separately dissolved in a hot solvent. However, preparation with an excess of either the diamine or picric acid was also attempted when ethanol was used as the solvent.

Measurements. The vibrational spectra of the solid complexes in the region from 2000 to 4000 cm^{-1} were determined as hexachloro-1,3-butadiene mulls with a JASCO IR-G infrared spectrophotometer, and the electronic spectra in the visible region, with a Beckman DK-2A spectroreflectometer. The procedure in the latter measurements was similar to that described in a previous paper.[8] All the complexes with one exception decompose rather gradually. Therefore, the temperatures recorded as the decomposition points are only approximate.

Results and Discussion

The characteristics of the picric acid complexes obtained in this work are displayed in Table 1. Only the following pK_a values are available in the literature: 4.95 and 3.85 for the first and second pK_a values of benzidine, and 4.5 and 3.3 for those of *o*-tolidine.[9]

Table 1. Composition, color, and melting point of the picric acid complexes with benzidine and its derivatives

Diamine	Solvent		
	Benzene	Chloroform	Ethanol
N,N,N',N'-Tetramethyl-benzidine	2:3 Bright yellow 196°(decomp)	2:5 Yellow 199°(decomp)	2:5 Yellow 195°(decomp) 1:2 Greenish yellow 199°(decomp) 1:1 Tan 198°(decomp)
Benzidine	1:2 Yellow 230°(decomp)	1:2 Yellow 215°(decomp.)	1:2 Dull yellow 225°(decomp) 2:1 Black or brown 124°
o-Dianisidine	1:2 Yellow 230°(decomp)	2:3 Dark yellow 216°(decomp)	1:1 Orange 220°(decomp)
o-Tolidine	2:3 Yellow 215°(decomp)	2:3 Yellow 223°(decomp)	1:1 Brick red 190°(decomp)
3,3'-Dichloro-*o*-tolidine	1:1 Yellow 194°(decomp)	1:1 Yellow 195°(decomp)	1:1 Yellow 195°(decomp)

Therefore, the diamines in this table are arranged in the order in which the pK_a values of the related aniline derivatives decrease.

One may start a search for complexes of the CPT type by a visual examination. If the color is deeper than yellow, which arises from an absorption band due to the picrate ion, the presence of a CT interaction in some form is likely. As has been previously reported by us, the dissociation of picric acid does not much affect its electron affinity, which is close to that of TNB.[2,10] Consequently, the location of the CT absorption band in Case 3 of CPT complexes is expected to be not far from that of the corresponding TNB complex. On the other hand, a complex belonging to Case 1 or 2 cannot be so deep as the TNB complex because one of the two amino groups, which make the molecule a good electron-donor, is protonated.

10) G. Saito and Y. Matsunaga, This Bulletin, **45**, 2214 (1972).

The Benzidine Complexes (Figs. 1 and 2). A yellow-colored powder precipitates from all the three solvents when the component compounds are mixed in equimolar proportions. The mole ratio of the diamine to the acid was found to be 1:2. Found: C, 45.15; H, 2.93% (from benzene); C, 45.32; H, 2.96% (from chloroform); and C, 44.87; H, 3.03% (from ethanol). Calcd for $C_{12}H_{12}N_2 \cdot 2C_6H_3N_3O_7$: C, 44.86; H, 2.80%. Their electronic spectra are all the same. The absorption maximum located at about 25 kK can be assigned to the picrate ion (see Curve a in Fig. 1). Moreover, the vibrational spectra of all the three show the pattern characteristic of the picrates of primary amines, namely, broad bands in the region from 2500 to 3000 cm^{-1} and at about 3250 cm^{-1}.[11] This yellow-colored complex is undoubtedly a salt formed by the transfer of protons from two picric acid molecules to a diamine molecule.

When an excess of the diamine was employed in ethanol, the 2:1 complex was obtained as black needles or occasionally as a brown powder. Found: C, 61.70; H, 5.27%. Calcd for $2C_{12}H_{12}N_2 \cdot C_6H_3N_3O_7$: C, 60.30; H, 4.52%. As is shown in Fig. 1, this complex possesses an additional electronic absorption located below 20 kK. The comparison of this spectrum with that of the corresponding TNB complex clearly indicates that the diamine as a whole acts as an electron-donor. In this complex, the band to be assigned to the picrate ion appears at 23.5 kK. Such a location is not unusual, as we have seen in the cases of the α-naphthylamine- and pyridine-picric acid complexes.[2] The vibrational spectrum exhibits both the bands ascribed to the picrate of primary amine in the region from 2500 to 3250 cm^{-1} and those ascribed to the NH_2 group in the region from 3250 to 3500 cm^{-1}. The latter are well approximated by those in the spectrum of the TNB complex (see Curve c in Fig. 2). However, the assignment of the band appearing around 3500 cm^{-1} could not be settled. A sharp band at 3250 cm^{-1} observed in the 1:2 complex is not seen in the 2:1 complex. It may be added that a similar observation has been made in the α-naphthylamine-picric acid complexes.[2] These pieces of spectroscopic evidence lead to the conclusion that this 2:1 complex is of the CPT type. Moreover, the intensity of the absorption band appearing below 20 kK is consistent with our earlier observation that the weakness of the CT absorption is characteristic of the complexes with picrates.[2,10] The same 2:1 complex was isolated as black-colored plates when prepared in an aqueous solution containing a small amount of pyridine. Found: C, 60.87; H, 5.04%. It must be pointed out that the 2:1 complex melts at a temperature about 110°C lower than the 1:2 complex, reflecting the difference in the nature of intermolecular forces. The formation of the 1:1 and 1:2 complexes has been described by Rascanu.[12] Unfortunately, we could not obtain the former one, the melting point of which was reported to be 200—205°C.

The o-Tolidine Complexes (Figs. 3 and 4). The

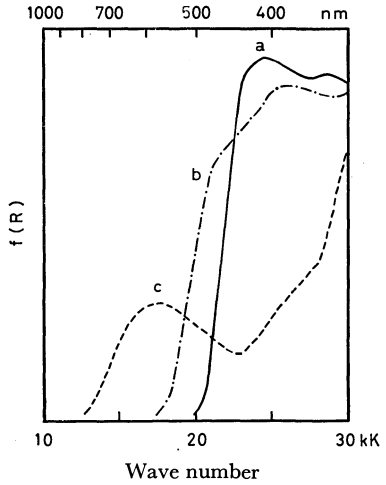

Fig. 3. Diffuse reflection spectra of a) the *o*-tolidine-picric acid (2:3) complex from benzene, b) the 1:1 complex from ethanol, and c) the corresponding TNB complex.

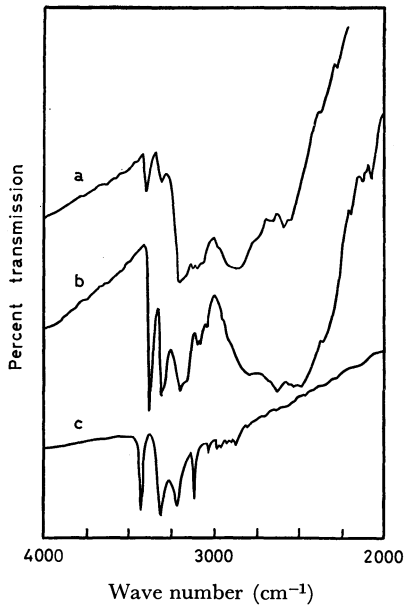

Fig. 4. Vibrational spectra of a) the *o*-tolidine-picric acid (2:3) complex from benzene, b) the 1:1 complex from ethanol, and c) the corresponding TNB complex.

complexes precipitated from benzene and chloroform are in the form of a yellow powder and have a mole ratio of 2:3, whereas the brick red-colored powder precipitated from ethanol is of a 1:1 composition. Found: C, 50.39; H, 3.78% (from benzene); C, 50.29; H, 4.10% (from chloroform), and C, 54.59; H, 4.48% (from ethanol). Calcd for $2C_{14}H_{16}N_2 \cdot 3C_6H_3N_3O_7$ and for $C_{14}H_{16}N_2 \cdot C_6H_3N_3O_7$: C, 49.68; H, 3.69% and C, 54.42; H, 4.31% respectively. As the spectra of the 2:3 complexes are identical, only that of the sample made in benzene is presented in Fig. 3. The bands above 23 kK are common to both 2:3 and 1:1 complexes and can be ascribed to the picrate ion. An extra absorption band at about 21 kK apparently accounts for the deep coloration of the 1:1 complex. A comparison with the spectrum of the corresponding TNB complex shown by Curve c indicates that the

12) R. Rascanu, *Ann. Sci. Univ. Jassy.*, **26**, 3 (1940), through *Chem. Abstr.*, **34**, 4385 (1940).

electron-donor is not a neutral *o*-tolidine molecule. If the electron-donor strength of the monoprotonated *o*-tolidine cation is essentially determined by that of the unprotonated half, the CT absorption is expected to appear near that of the *o*-toluidine-TNB complex, 23.1 kK. The close similarity of the locations strongly suggests that this 1:1 complex belongs to Case 1 of CPT complexes. This speculation is supported by the vibrational spectral analysis. Both the 2:3 and 1:1 complexes show patterns characteristic of the picrates of primary amines and also the NH_2 group. The latter pattern consists of bands appearing at 3300 and 3390 cm^{-1}, as evidenced by the spectrum of the corresponding TNB complex (see Fig. 4). The intensity of this pattern in the 2:3 complex is definitely weaker than that in the 1:1 complex; therefore, all the picric acid molecules in the former complex seem to participate in the PT interaction. Although the free amino group must be left in the 2:3 complex, no CT absorption could be detected.

The melting point observed by us for the 1:1 complex differs considerably from that reported by Rascanu, 110°C. Furthermore, we failed to obtain the 1:2 complex described by her.[12]

The 3,3'-Dichloro-o-tolidine Complexes. All the yellow-colored complexes precipitated from the three solvents were found to be of a 1:1 composition. Found: C, 47.31; H, 3.23% (from benzene); C, 46.67; H, 3.16% (from chloroform); and C, 47.16; H, 3.35% (from ethanol). Calcd for $C_{14}H_{14}N_2Cl_2 \cdot C_6H_3N_3O_7$: C, 47.06; H, 3.33%. Contrary to the case of the *o*-tolidine-picric acid (1:1) complex, no band to be assigned to the CT absorption could be detected. As would be expected from the color and the composition, the coexistence of the NH_3^+ and NH_2 groups is demonstrated by the vibrational spectrum.

By the prolonged heating of an ethanolic solution of the complex on a water-bath, a green powder of a 1:1 composition deposited. On the basis of the spectral behavior, we suppose that the product is a picrate of the 3,3'-dichloro-*o*-tolidine cation-radical.

The 3,3'-Dibromo-o-tolidine Complexes (Fig. 5). Jet black-colored needles were crystallized from benzene and chloroform. Their compositions appear to be 1:1. Found: C, 40.29; H, 2.90% (from benzene); C, 39.98; H, 2.92% (from chloroform). Calcd for $C_{14}H_{14}N_2Br_2 \cdot C_6H_3N_3O_7$: C, 40.08; H, 2.84%. Not only the electronic spectrum, but also the vibrational spectrum, strikingly resemble those of the TNB complex (see Fig. 5 for the reflection spectra). Thus, the complex is certainly of the CT type. In accordance with this conclusion, dibromo-*o*-tolidine is supposedly the poorest proton-acceptor among the diamines studied here.

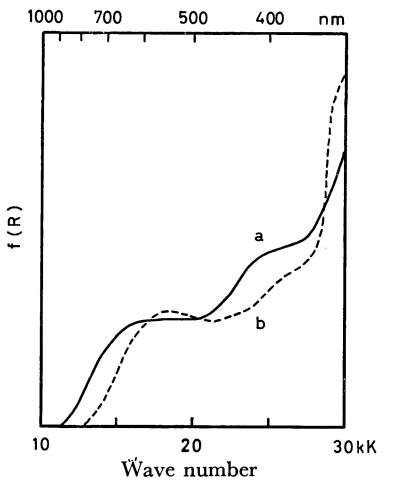

Fig. 5. Diffuse reflection spectra of a) the dibromo-*o*-tolidine-picric acid (1:1) complex and b) the corresponding TNB complex.

Upon storage for months in air, the color turned green. A bright green product was directly obtained if the component compounds were mixed in ethanol. These two samples show spectra similar to each other. The behavior of this and the above-mentioned diamine cation-radical salt will be reported in detail later.

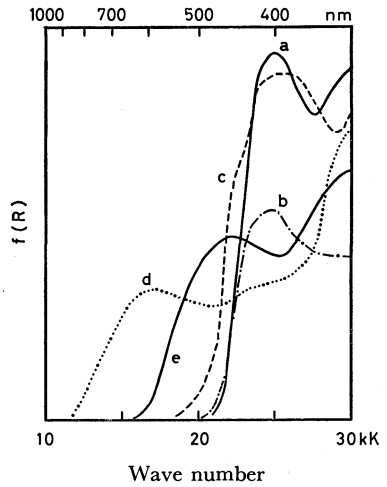

Fig. 6. Diffuse reflection spectra of the *o*-dianisidine-picric acid (1:2) complex from benzene, b) the 2:3 complex from chloroform, c) the 1:1 complex from ethanol, d) the corresponding TNB (1:2) complex, and e) the *o*-anisidine-TNB complex.

The o-Dianisidine Complexes (Fig. 6). The yellow-colored complex crystallized from a benzene solution has a 1:2 composition. Found: C, 44.35; H, 3.27%. Calcd for $C_{14}H_{16}N_2O_2 \cdot 2C_6H_3N_3O_7$: C, 44.44; H, 3.13%. The vibrational spectrum is dominated by the pattern to be ascribed to the NH_3^+ group, indicating that the two amino groups in an *o*-dianisidine molecule are protonated. This complex is undoubtedly of the same nature as the benzidine-picric acid (1:2) described above.

When chloroform is employed as the solvent, a yellow-colored powder was precipitated. The mole ratio is more complicated; namely, 2:3. Found: C, 47.05; H, 3.46%. Calcd for $2C_{14}H_{16}N_2O_2 \cdot 3C_6H_3N_3O_7$: C, 46.97; H, 3.49%. The presence of the NH_2 group is indicated by the appearance of vibrational bands at 3300 and 3380 cm^{-1}. Nevertheless, the electronic spectrum is essentially the same as that of the 1:2 complex. The possibility that this complex is a mixture of the 1:2 and the 1:1 complexes was ruled out by the X-ray diffraction measurements. Presumably this belongs to the same category as the *o*-tolidine complex of a 2:3 composition.

The 1:1 complex prepared in ethanol is orange-

colored. Found: C, 50.69; H, 4.14%. Calcd for $C_{14}H_{16}N_2O_2 \cdot C_6H_3N_3O_7$: C, 50.74; H, 4.02%. The reflection spectrum shown in Fig. 6 has an absorption in addition to those of the above-mentioned 1:2 and 2:3 complexes. This new band is at a location higher than the CT absorption band in the corresponding TNB complex, 17.3 kK, while close to that in the *o*-anisidine-TNB complex, 22.2 kK. Further evidence that the electronic absorption arises from the CT interaction between the monoprotonated *o*-dianisidine cation and the picrate anion comes from the coexistence of the vibrational patterns due to the NH_2 and NH_3^+ groups. This is a second example of Case 1 of CPT complexes.

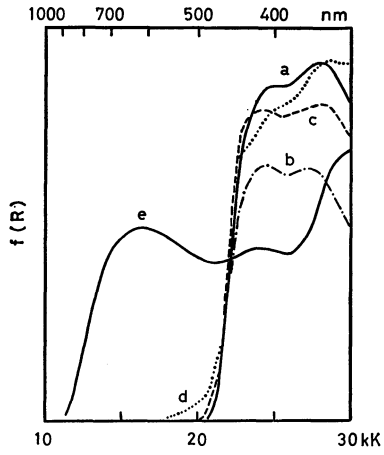

Fig. 7. Diffuse reflection spectra of a) the tetramethylbenzidine-picric acid (2:3) complex from benzene, b) the 2:5 complex from chloroform, c) the 1:2 complex from ethanol, d) the 1:1 complex from ethanol, and e) the corresponding TNB (1:2) complex.

The Tetramethylbenzidine Complexes (Fig. 7). The bright yellow complex deposited from benzene is of a 2:3 composition. Found: C, 51.21; H, 4.15%. Calcd for $2C_{16}H_{20}N_2 \cdot 3C_6H_3N_3O_7$: C, 51.41; H, 4.20%.

From chloroform a yellow-colored complex was precipitated. The mole ratio was found to be 2:5. Found: C, 45.43; H, 3.61%. Calcd for $2C_{16}H_{20}N_2 \cdot 5C_6H_3N_3O_7$: C, 45.78; H, 3.38%.

When ethanol was employed, the following three complexes were isolated, depending upon the ratio of the component compounds mixed. One of them was the 2:5 complex previously obtained from chloroform. Found: C, 45.93; H, 3.53%. The complex of a 1:2 composition is greenish yellow. Found: C, 47.39; H, 3.36%. Calcd for $C_{16}H_{20}N_2 \cdot 2C_6H_3N_3O_7$: C, 48.14; H, 3.72%. The last one has a 1:1 composition and is tan-colored. Found: C, 56.69; H, 5.09%. Calcd for $C_{16}H_{20}N_2 \cdot C_6H_3N_3O_7$: C, 56.29; H, 4.90%. The intensity of the electronic absorption unique to this complex is weak. However, its location is very clearly observable by the original recording in reflectance and can be well compared with that of the CT absorption in the solid *N,N*-dimethylaniline-TNB complex, 19.3 kK. Consequently, this may be considered as the third complex belonging to Case 1 of CPT complexes. Broad bands characteristic of the picrates of the tertiary amines in the region from 2300 to 2750 cm^{-1} are dominant in the vibrational spectra of all the complexes. Of course, the higher the picric acid content, the more dominant these bands are.

The ionization potentials of the diamines estimated by the energies of the CT absorption bands developed by mixing with *p*-chloranil in chloroform increase in this order: tetramethylbenzidine$<$*o*-dianisidine$\sim$*o*-tolidine$<$dibromo-*o*-tolidine$\sim$dichloro-*o*-tolidine$<$benzidine. The location of benzidine is dependent on the particular electron-acceptor chosen and is somewhat ambiguous.[13] The electron-donor strength seems to have no direct correlation with whether or not a diamine forms a solid complex of the CPT type. This is not at all surprising, since the stabilization by the CT interaction is only a minor fraction of the total ground-state binding energy in the complexes where both the CT and PT interactions simultaneously operate. The two which do not form such complexes are 3,3'-dihalo-*o*-tolidines; therefore, the steric effect of the two substituents introduced *ortho* to an amino group may be considered as a primary factor.

It must be noted that all the complexes of the CPT type were prepared in ethanol, the most polar solvent among the three. Even though the association of electron-donor and acceptor is expected to be poor in this solvent, the dissociation of the ion-pair formed by means of the PT interaction may facilitate the CT interaction between the picrate anion and the diamine molecule or the monoprotonated diamine cation.

No example of Case 2 of CPT complexes could be found in the present work. If the difference between the first and second pK_a values is as small as those in benzidine and *o*-tolidine, it may not be easy to find such a complex.

Very recently, Thewalt and Bugg have reported the crystal and molecular structures of red-colored serotonin picrate monohydrate.[14] The protonated serotonin cation and the picrate anion are arranged in alternatingly stacked arrays to form continuous columns. The interaction between these two components has been concluded by them to be of the CT type. This salt may be considered another example of Case 1 of CPT complexes.

The Cation-radical Salts Derived from Benzo- and Dibenzo-phenothiazines

Yoshio MATSUNAGA and Yukio SUZUKI*

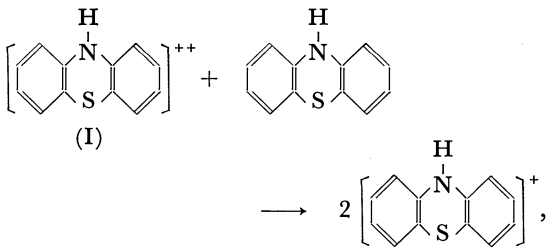
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received August 18, 1972)

The chloride, iodide, and perchlorate of benzo- and dibenzo-phenothiazine cation-radicals have been prepared by the reaction of an equimolar mixture of the thiazine and its *S*-oxide with an appropriate acid. The vibrational spectra of the products have been found to be in close agreement with those of the bromides made by the familiar oxidation of thiazines with bromine. The results of electronic spectral and ESR measurements have furnished further support for our conclusion that the thiazine cation-radical salts can be prepared by the above-mentioned reaction. The electronic spectra of the iodides of benzophenothiazines have been found to differ markedly from those of other salts and to bear a resemblance to those of the low-resistivity iodine complexes.

The cation-radical or semiquinoid salts derived from phenothiazine were described by Pummerer and Gassner and also by Kehrmann and Diserens over half a century ago.[1,2] These authors claimed the preparation of the following salts: bromide, periodide, sulfate, nitrate, perchlorate, and picrate. The first three salts were made by the oxidation of the parent compound with bromine, iodine, and concentrated sulfuric acid respectively. The next two were obtained as precipitates when the desired counter ion in an appropriate form was added to a dilute sulfuric acid solution of the sulfate thus prepared. The oxidation of phenothiazine with ferric chloride in the presence of picric acid resulted in the formation of the picrate. More recently, some new salts have been prepared by the oxidation of phenothiazine and its *N*-methyl derivative with antimony pentachloride.[3,4] Although halogens have been widely used as oxidizing agents in the preparation of cation-radicals, *e.g.*, those derives from aromatic diamines and tetrathiotetracene,[5–8] chlorine is not suited to the oxidation of either phenothiazine or diamines. Consequently, the use of ferric chloride has been proposed by Hatano *et al.* for the preparation of the chlorides of *p*-phenylenediamine and benzidine cation-radicals.[9] Moreover, the addition of iodine to phenothiazine has been known to produce a molecular complex with a 2: 3 mole ratio instead of the monoiodide.[10,11]

Earlier we studied the effects of iodine addition on the electrical resistivity and the electronic and vibrational spectra of the semiquinoid phenothiazine bromide.[12] A marked resistivity minimum was found to lie around the mole ratios from 1: 0.25 to 1: 0.30. The values in this composition range are from 4 to 5 ohm·cm, lower than those exhibited by the above-mentioned iodine complex, 13—20 ohm·cm.[10,12–14] The composition of this adduct corresponds approximately to (phenothiazine)$_2Br_2I$. As the mixed halide ion, Br_2I^-, is a well-known species, the formation of a complex cation-radical salt, (phenothiazine)$^+$(phenothiazine)$^0Br_2I^-$, is very likely. In order to examine systems consisting of iodine and the chloride or iodide, the method of preparing these halides must first be established. In this paper, we wish to present a method based on the following reaction:



(I)

where the charge is proportionated between the protonated holoquinoid cation (I) and the phenothiazine molecule. The former species can be easily obtained when phenothiazine *S*-oxide is dissolved into strong acids.[1,2,15] A preliminary attempt to prepare the chloride and bromide by this reaction has already been reported by one of the present authors;[16] therefore, attention has here been directed towards the cation-radical salts derived from benzo[*a*]-, benzo[*c*]-, and dibenzo[*c,h*]-phenothiazines. As is indicated by the low energies of the charge-transfer absorptions in the *s*-trinitrobenzene and picric acid complexes listed in Table 1, the present compounds are expected to produce cation-radicals more easily than phenothiazine itself. The molecular orbital calculations made by Tyutyulkov *et al.* support this prediction.[17] In light of the size of the conjugated systems, the cation-radicals may be more stable than that of phenothiazine.

a) Taken from Ref. 17.
b) 18.2 kK by Iida, Ref. 18.

Experimental

Materials. The examples cover only dibenzophenothiazine and its derivatives; however, they illustrate all of the preparative procedures which we employed.

Dibenzo[c,h]*phenothiazine*: β,β-Dinaphthylamine and sulfur were fused together in the presence of a small amount of iodine.[19] The product was then recrystallized from benzene.

Dibenzophenothiazine S-*Oxide*: Following the procedure described by Pummerer and Gassner for phenothiazine *S*-oxide,[1] dibenzophenothiazine, potassium hydroxide, and hydrogen peroxide in ethanol were gently heated for two hours. Subsequent recrystallization from ethanol gave yellow fine needles.

Dibenzophenothiazine Chloride and Iodide: An equimolar mixture of dibenzophenothiazine and its *S*-oxide was thoroughly ground in an agate mortar. The fine powder was spread in a beaker and moistened with concentrated hydrochloric acid. The reaction mixture was then dried in a vacuum desiccator containing potassium hydroxide pellets. Found: C, 67.2; H, 3.9; Cl, 10.0%. Calcd for $C_{20}H_{13}NS^+Cl^-\cdot H_2O$: C, 68.0; H, 4.3; Cl, 10.0%.

The iodide was prepared similarly. Found: C, 52.9; H, 2.9; N, 3.1; I, 32.8%. Calcd for $C_{20}H_{13}NS^+I_{1.15}^-$: C, 53.0; H, 2.9; N, 3.2; I, 32.8%.

Dibenzophenothiazine Bromide: The thiazine dissolved in a mixture of acetone and ether was cooled with an ice-salt mixture, and then bromine corresponding to less than one equivalent in cold ether was added, drop by drop. A black precipitate was then filtered out and washed with ether. Found: C, 63.1; H, 3.4; N, 3.2; Br, 21.5%. Calcd for $C_{20}H_{13}NS^+Br^-$: C, 63.3; H, 3.4; N, 3.7; Br, 21.1%.

Dibenzophenothiazine Perchlorates: An equimolar mixture of dibenzophenothiazine and its *S*-oxide was added to perchloric acid cooled with an ice-salt bath. A black precipitate appeared immediately. Found: C, 61.3; H, 3.3; N, 3.0%. Calcd for $C_{20}H_{13}NS^+ClO_4^-$: C, 60.2; H, 3.3; N, 3.5%.

If dibenzophenothiazine *S*-oxide alone is employed in place of the mixture, the holoquinoid perchlorate can be isolated. Found: C, 59.5; H, 3.0; N, 3.2; Cl, 9.2%. Calcd for $C_{20}H_{12}NS^+ClO_4^-$: C, 60.3; H, 3.0; N, 3.5; Cl, 8.9%.

Dibenzophenothiazine Picrate: The thiazine dissolved in ethanol was cooled with an ice-salt mixture and was then oxidized by adding it to an ethanolic solution containing an equimolar amount of ferric chloride and an excess of picric acid. The black picrate precipitated immediately. Found: C, 58.4; H, 2.8; N, 10.5%. Calcd for $C_{20}H_{13}NS^+C_6H_3N_3O_7^-$: C, 59.2; H, 2.9; N, 10.6%.

Measurements. The vibrational and electronic spectra of the solid salts were examined as have been reported elsewhere.[12] The ESR measurements were carried out by means of a JEOL model JES-ME-3X spectrometer in the temperature range from -100 to 100°C. The spin concentrations were estimated at room temperature by comparing the signal intensities due to the sample and the standard material, violanthrone (8.1×10^{19} spins/g) with the aid of a multimode cavity model JES-MCX-1.

Results and Discussion

Syntheses. Although the preparation of phenothiazine chloride by the above-mentioned reaction was not satisfactory,[16] the composition of the dibenzophenothiazine chloride agrees well with the calculated one. With the benzo derivatives the results were less satisfactory; those results were: C, 65.0; H, 4.1; N, 4.5; Cl, 10.9% for benzo[*a*]phenothiazine chloride, and C, 62.6; H, 4.0; N, 4.5; Cl, 10.7% for benzo[*c*]phenothiazine chloride. Calcd for $C_{16}H_{11}NS^+Cl^-\cdot H_2O$: C, 63.5; H, 4.3; N, 4.6; Cl, 11.7%.

A monoiodide hitherto unknown could be prepared by this method. In the case of benzo[*a*]phenothiazine, we obtained the following analytical results: C, 48.8; H, 2.6; N, 3.6; I, 35.3%. Calcd for $C_{16}H_{11}NS^+I_{1.07}^-$: C, 49.9; H, 2.9; N, 3.6; I, 35.3%. As for benzo[*c*]-phenothiazine iodide, C, 49.7; H, 2.8; N, 3.9; I, 34.8%. Calcd for $C_{16}H_{11}NS^+I_{1.05}^-$: C, 50.2; H, 2.9; N, 3.7; I, 34.9%. In all three, the presence of free iodine produced from hydroiodic acid during the preparation accounts for iodine contents higher than those expected for a 1:1 composition.

The reaction was also successfully applied to the preparation of the semiquinoid perchlorate. In addition to the dibenzophenothiazine perchlorate described above, we obtained the salts derived from benzo[*a*]- and benzo[*c*]-phenothiazines by the same technique. Found: C, 53.8; H, 3.0; N, 3.9; Cl, 10.5% for the former salt and C, 54.8; H, 3.1; N, 4.0% for the latter. Calcd for $C_{16}H_{11}NS^+ClO_4^-$: C, 55.1; H, 3.2; N, 4.0; Cl, 10.2%.

In the present work, the dibenzophenothiazine bromide was prepared by a method analogous to that reported by Pummerer and Gassner; however, it has already been shown that phenothiazine bromide can be obtained by the reaction described above.[16]

The present work seems to provide justification for our hypothesis that the addition of an equimolar mixture of a thiazine and its *S*-oxide to a strong acid is a convenient method for preparing the semiquinoid salts, provided that the cation-radical is stable in the acid. As will be discussed in the following sections, the physical properties of the salts so prepared support this conclusion.

Vibrational Spectra. If the chloride and iodide are indeed of the cation-radical, their vibrational spectra must be identical with that of the bromide prepared

18) Y. Iida, This Bulletin, **44**, 663 (1971).

by the authentic oxidation with bromine. The spectra of the three salts of dibenzophenothiazine are compared with each other in Fig. 1. As we noted earlier in the cases of phenothiazine and its benzo derivatives,[12,14] the bromide gives a spectrum distinctly different from that of the parent compound. The bands in the chloride and iodide are overlapped by the electronic absorption to be described later and are not well resolved; however, it is easy to see that their general features are in essential agreement with those of the bromide. The spectrum of the semiquinoid perchlorate is dominated by strong broad absorption bands due to the anion. Nevertheless, this is also in good accordance with that

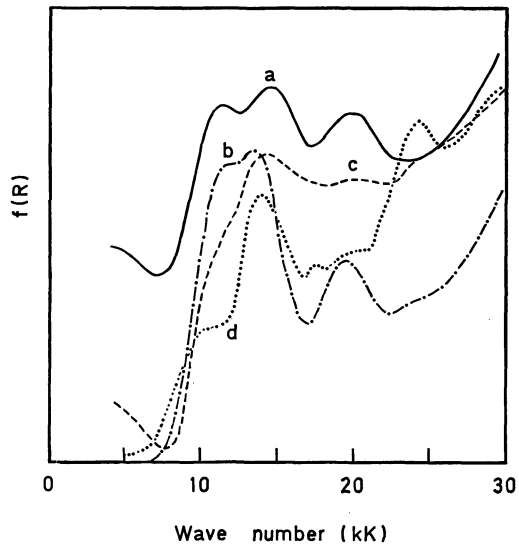

Fig. 2. Diffuse reflection spectra of (a) dibenzophenothiazine chloride, (b) the bromide, (c) the iodide, and (d) the picrate.

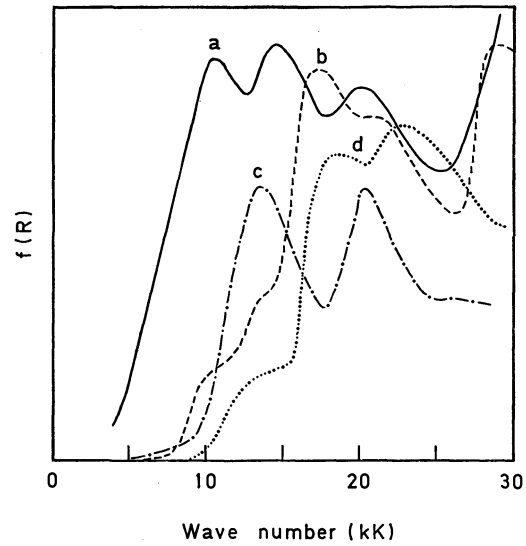

Fig. 3. Diffuse reflection spectra of (a) semiquinoid dibenzophenothiazine perchlorate, (b) the holoquinoid perchlorate, (c) semiquinoid phenothiazine perchlorate, and (d) the holoquinoid perchlorate.

of the bromide, as far as we can compare them. It must be added that the spectrum of the holoquinoid perchlorate differs appreciably from that of the corresponding semiquinoid salt. Thus, the vibrational spectra of the chloride, iodide, and perchlorate prepared by our method are definitely those of the cation-radical. This conclusion is also valid for the salts derived from benzophenothiazines.

Electronic Spectra. The dibenzophenothiazine cation-radical in hydrochloric acid-acetic acid (1: 1 by volume) exhibits absorption maxima at 14.3, 17.9, and 20.4 kK, with an intensity ratio of 1: 0.44: 0.52. The diffuse reflection spectra of the solid chloride, bromide, iodide, and picrate are presented in Fig. 2, and that of the perchlorate, in Fig. 3. The spectrum of the bromide includes bands at 11.6, 13.4, and 19.6 kK. The spectra of the chloride, iodide, and perchlorate prepared by our method also show bands around 11, 14, and 20 kK. Among the five, the picrate gives the most complicated spectrum, consisting of bands located at 10.3, 13.9, 17.4, about 20, and 24.2 kK. The last band can be assigned to the picrate anion. The locations of the second and third are close to those of the two strong ones observed in the solution spectrum; however, the one appearing around 11 kK is undoubtedly characteristic of the solid cation-radical salts. By analogy with the spectra of the phenothiazine cation-radical salts,[18] this band may arise from the pair-by-pair interaction between the cations. In addition to this, the chloride and iodide have bands located below 4 kK, indicating some difference in the mode of interaction. It must be noted that the relative intensities of the bands located at about 11 kK in the iodide and picrate are appreciably weaker than those in the other two. The nature of the extra band appearing at 17.4 kK in the picrate will be speculated on in connection with the ESR data.

In Fig. 3 the spectrum of the perchlorate of dibenzophenothiazine is compared with that of the holoquinoid

perchlorate. Although the holoquinoid salt absorbs also down to 10 kK, the intensities in the region below 15 kK are much diminished and the locations of the absorption maxima above 15 kK differ substantially from those of the cation-radical salt. A similar comparison is made for the semiquinoid and holoquinoid phenothiazine perchlorates in the same figure. The spectrum of this semiquinoid perchlorate is simpler than those of the phenothiazine bromide, bisulfate, and picrate reported earlier;[12,18] that is, a band near 23 kK common to the latter three is not observed here.

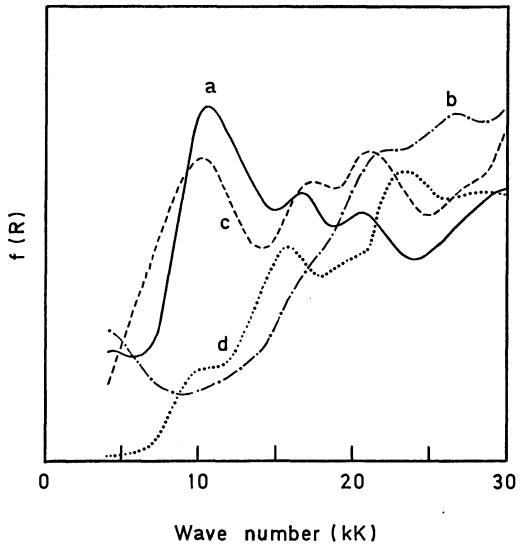

Fig. 4. Diffuse reflection spectra of (a) benzo[*c*]phenothiazine chloride, (b) the iodide, (c) the perchlorate, and (d) the picrate.

The diffuse reflection spectra of the cation-radical salts of benzo[*c*]phenothiazine prepared by our method are shown in Fig. 4, together with that of the picrate shown for the sake of comparison. The iodide was found to give a spectrum quite different from the others. This spectrum resembles that of the low-resistivity iodine complex presented in a previous paper.[14] The pattern of these two may be assigned to the cation-radicals in a more-than-by-pairs interaction. However, the band around 15 kK seen in the iodine complex is much diminished in the iodide. On the other hand, the absorption above 25 kK is intensified, resulting in the appearance of a maximum at 26.4 kK. Here again, bands at 16—17 and about 21 kK common to the chloride, perchlorate, and picrate are located close to the bands observed in the solution spectrum: 16.8 and 21.1 kK, with an intensity ratio of 1 : 0.70. The absorption located at about 10 kK is possibly due to the pair-by-pair interaction between the cation-radicals. A similarity in the spectrum was also noted between the iodide of benzo[*a*]phenothiazine and the iodine complex.

In spite of the coincidence in the locations of the absorption maxima, the whole spectrum of the solid salt varies considerably with the counter ion. Such pronounced variations are not unexpected in the solid-state spectrum of ion-radicals.[20,21]

Spin Concentrations. Electron-spin-resonance absorption was detected in all the salts which were supposed to be of cation-radicals, but not in the holoquinoid perchlorate. The absorptions are all symmetric except in the case of the benzo[*a*]phenothiazine perchlorate, where the *g*-values estimated by the method according to Kneubühl are as follows: $g_{//}=2.0027$ and $g_{\perp}=2.0074$.[22] The distance between the points of the maximum slope measured at room temperature are in the range from 7 to 12 Gauss, and the spin concentrations, in the range from 0.01 to 0.10 spins per molecule. Thus, the major fraction is diamagnetic. This finding is in accordance with the electronic spectral behavior discussed above. Besides, the concentrations were found to be temperature-independent; therefore, the observed spins must be ascribed to some imperfections and impurities in crystals. The dibenzophenothiazine picrate gave an exceptionally wide absorption; that is, a distance of 34 Gauss was observed. Moreover, a spin concentration as high as 0.30 was detected in this salt. One should recall the observation that this solid salt shows an electronic absorption maximum at 17.4 kK, corresponding to the weakest band in the spectrum of the monomeric cation-radical. The high spin concentration may be correlated with the appearance of this band in the solid-state spectrum. However, the weakness of the absorption at 10—11 kK is common in the solid picrates and cannot be correlated with the spin concentration. The benzo[*c*]phenothiazine salt has a spin concentration as low as 0.01.

The authors wish to express their thanks to Professor Minoru Kinoshita of the University of Tokyo for his gift of the sample of violanthrone. The ESR spectrometer was obtained with a grant-in-aid from the Ministry of Education.

The Crystal Structure of Di-π-allyl(dihydropentalenylene)dinickel

Yukishige KITANO, Michio KASHIWAGI, and Yukio KINOSHITA*

Basic Reseach Laboratories, Toray Industries, Inc., Tebiro, Kamakura 248

(Received June 8, 1972)

The crystal structure of di-π-allyl(dihydropentalenylene)dinickel, $(C_8H_6)Ni_2(C_3H_5)_2$, has been determined from three-dimensional single-crystal X-ray photographic data. The crystal of this compound is composed of discrete molecular units in the monoclinic space group $P2_1/a$, with two molecules per unit cell with dimensions of $a=8.451\pm0.004$, $b=12.691\pm0.005$, $c=5.976\pm0.006$ Å, and $\beta=108.81\pm0.05°$. The calculated and observed densities are 1.650 and 1.60 g·cm^{-3} respectively. The structure was deduced from a sharpened Patterson synthesis and was refined by means of the least-squares method to the final R index of 0.121 for 1151 independent non-zero reflections. The molecule has a crystallographic center of symmetry; therefore, two nickel atoms which are complexed in a sandwich fashion between the dihydropentalenylene ring and the π-allyl group take a *trans* configuration. The distances of the nickel atom from the ring carbons range from 2.03 to 2.27 Å, the closest approach being to the three non-bridging atoms of the five-membered ring. The orientation of the π-allyl groups with respect to the nickel atom is similar to those found in other π-allyl complexes.

In the reaction of (dihydropentalenylene)dilithium with allyl metal chlorides, Miyake and Kanai have newly synthesized π-allyl-dihydropentalenylene complexes of nickel, chromium, and zirconium.[1] The NMR spectra of the nickel derivative in C_6D_6 and benzene indicate the presence of the π-allyl group and the dihydropentalenylene ring. In order to confirm the configuration of the complex, the measurement of the dipole moment was attempted; however, because of its small value ($\mu=0.65\pm0.5$ D in benzene at 30°C), no definite conclusion was obtained. Thus, it is not certain whether the complex has a *cis* or a *trans* configuration; therefore, a single-crystal X-ray structure analysis of the complex was carried out in order to determine the molecular configuration and the mode of coordination of the π-allyl groups to the nickel.

Experimental

Di-π-allyl(dihydropentalenylene)dinickel, $(C_8H_6)Ni_2(C_3H_5)_2$, was prepared by the reaction of (dihydropentalenylene)-dilithium and bis π-allyl nickel chloride. The complex was recrystallized from an ether solution as extremely air-sensitive, deep green monoclinic plates elongated in the *b* direction. For the crystallographic analysis, the crystals were sealed into thin-walled glass capillary tubes, under an argon atmosphere; therefore, no serious crystal decomposition was found during the collection of the intensity data. The unit-cell dimensions were obtained by the least-squares procedure from measurements on Weissenberg photographs around the *b* and *c* axes. The density was measured by flotation in an aqueous solution of zinc chloride at 25°C. The crystal data are summarized in Table 1.

TABLE 1. CRYSTAL DATA

Di-π-allyl(dihydropentalenylene)dinickel, $Ni_2C_{14}H_{16}$
Molecular weight: 301.6
Monoclinic
$a=8.451\pm0.004$Å
$b=12.691\pm0.005$
$c=5.976\pm0.006$
$\beta=108.81\pm0.05°$
$V=606.77$ Å^3
$D_m=1.60$ g·cm^{-3}, $D_x=1.650$ g·cm^{-3} for $Z=2$
Systematic absences, $h0l$ with $h=2n+1$
$0k0$ with $k=2n+1$
Space group C_{2h}^5—$P2_1/a$ (No. 14)
Linear absorption coefficient for Cu$K\alpha$: $\mu=48.9$ cm^{-1}

The three-dimensional intensity data were collected from equi-inclination Weissenberg photographs taken with Ni-filtered Cu$K\alpha$ radiation. The multiple-film technique was used, and zero to seventh layers about the *b* axis and zero to fifth layers about the *c* axis were recorded. The intensities were estimated visually by comparison with a calibrated

* Present address: Ehime Laboratory, Toray Industries, Inc., Masaki, Ehime.

1) A. Miyake and A. Kanai, *Angew. Chem.*, **83**, 851 (1971); *Angew. Chem. internat. Edit.*, **10**, 801 (1971).

TABLE 4. OBSERVED AND CALCULATED STRUCTURE FACTORS
The table gives h, k, 10 $|F_0|$, and $10F_c$ in blocks of constant l.

H	K	FO	FC
	L = 0

intensity scale. The usual Lorentz and polarization corrections were applied to 1151 independent intensities. The crystals used for the intensity measurement had dimensions of $0.12\times0.25\times0.15$ and $0.13\times0.15\times0.30$ mm for the *b*-axis and *c*-axis Weissenberg photographs respectively, which were cut out from large crystals. No absorption correction was made.

Structure Determination

Since the unit-cell contains two molecules with the space group of $P2_1/a$, it is necessary for each molecule to lie on a crystallographic center of symmetry. The position of the nickel atom was readily deduced from a three-dimensional sharpened Patterson synthesis. The carbon atoms were found on successive Fourier syntheses phased initially by the nickel atom. The inclusion of these atoms in the structure-factor calculations reduced the conventional agreement index, $R(=\sum||F_o|-|F_c||/\sum|F_o|)$, from 0.36 to 0.28. The structure thus obtained was refined by the isotropic least-squares method; the *R* index fell to 0.20 after a few cycles of this refinement. The structure was further refined by several cycles of positional and anisotropic thermal parameters refinement, which led to the final *R* index of 0.121 for all the non-zero reflections. A difference Fourier synthesis was then computed in an attempt to find the positions of the hydrogen atoms. Some peaks appeared at or near the expected positions, but not all the hydrogen atoms could be located. Thus, contributions from the hydrogen atoms are not included in the structure-factor calculations. Throughout the refinement of the structure, equal weights were employed for all the reflections, and the atomic scattering factors were adopted from the International Tables for X-ray Crystallography.[2] The main part of the calculations was performed on the IBM7040 and 360 computers, with the use of the ERFR2 program for Fourier synthesis[3] and the HBLS program for structure-factor and least-squares refinement calculations.[4] The positional and anisotropic thermal parameters,along with their estimated standard deviations, are listed in Tables 2 and 3 respectively. The final observed and calculated structure factors are given in Table 4.

Results and Discussion

The principal interatomic bond distances and angles, along with their estimated standard deviations, are listed in Tables 5 and 6. A perspective view of the molecule is shown in Fig. 1, along with the atomic levels. Figure 2 represents the front and side views of the asymmetric unit of the molecule in order to show the mode of coordination of carbon atoms to the nickel.

The molecule has a crystallographic center of symmetry; therefore, two nickel atoms take a *trans* configuration, with a nickel-nickel distance of 4.31 Å. The nickel atom is bonded to the carbon atoms of the dihydropentalenylene ring and of the π-allyl group in a sandwich fashion. The nickel-carbon distances for the five-membered ring range from 2.03 Å to 2.27 Å, the closest nickel-carbon approach being to the non-bridging atoms of the ring. The mean Ni–C distance of 2.146 Å and the perpendicular distance from the nickel atom to the best plane of the ring carbons of 1.75 Å can well be compared with the corresponding ones observed in $(\pi\text{-}C_5H_5)Ni(P(C_6H_5)_3)C_6H_5$,[5] $(\pi\text{-}C_5H_5)Ni(P(C_6H_5)_3)C_6F_5$,[6] and other π-cyclopentadienyl nickel

Table 5. Principal interatomic lengths along with their estimated standard deviations in parentheses

Bond	Length	Bond	Length

complexes.[7-11] The dihydropentalenylene ring carbons are nearly coplanar. The best plane through the five-membered carbons of the ring is defined, with respect to the crystallographic axes, by this equation:

$$0.6605x + 1.1647y + 0.4975z = 0.0218.$$

The average displacement of atoms from the mean plane is 0.03 Å, with the maximum deviation of 0.05 Å for C(3). The mean carbon-carbon bond length of 1.424 Å, and the mean bond angle of 107.9° in the dihydropentalenylene ring, are comparable with those expected for the five-membered conjugated ring systems and are similar to the corresponding values found in π-cyclopentadienyl rings.[12]

As far as the allyl group is concerned, the mean distance of 1.99 Å of the carbon atoms of the π-allyl group from the nickel atom resembles those found in other allyl complexes of nickel[13-15] and palladium.[16-20]

The mean carbon-carbon bond length of 1.41 Å is within the range of those previously determined, and the bond angle of 118.5° is comparable with the values of 119.6° for dimeric 2-carboxyethyl-π-allylnickel bromide[13] and 118.9° for bis(1,2-diphenylphosphino)-

ethane-π-metallylnickel bromide.[14] The equation for the best plane containing the π-allyl carbon atoms is:

$$0.7066x + 0.6097y + 0.4419z = 4.2586.$$

The dihedral angle between this plane and that containing the carbon atoms of the dihydropentalenylene ring is 18.2° (Fig. 2), which is comparable with the corresponding value found in bis(cyclopentadienyl)-2,2′-bi-π-allyl-bis(nickel).[21]

The molecular arrangements in the crystal viewed along the *b* and *c* axes are illustrated in Figs. 3 and 4 respectively. The crystal is built up of individual molecules of $(C_8H_6)Ni_2(\pi\text{-}C_3H_5)_2$, with the adjacent molecules held together by van der Waals forces. All interatomic contacts less than 4.0 Å were calculated. There are no abnormally short distances.

The authors are grateful to Dr. Akihisa Miyake and Mr. Atsuo Kanai for their kindness in supplying the compound, and to Mr. Susumu Arai for his aid in the reflection-data collection.

Electron-spin-resonance Studies of the Formation and Properties of the Trimeric Vanadyl Dibutylphosphate Complex

Mitsuo SATO, Teruo TAKAYANAGI, Yuzaburo FUJITA, and Takao KWAN

Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo

(Received June 24, 1972)

The extraction of the vanadyl ion (VO^{2+}) from aqueous solutions by di-*n*-butylphosphoric acid ($(C_4H_9O)_2PO_2H$) in hexane has been studied by ESR. It has been found that monomeric and trimeric vanadyl di-*n*-butylphosphate complexes were present in the organic phase, and the equilibrium constant of the reaction involving monomeric and trimeric forms was determined. The ESR spectrum of the trimeric complex, characterized by 22 hf lines with a separation of 39 gauss, was interpreted as resulting from the magnetic exchange interaction between three vanadyl ions. A crystalline vanadyl complex was isolated from the hexane solution and found to be $(VOX_2)_3$, where X represents $(C_4H_9O)_2PO_2^-$. The properties of the complex were investigated by means of ESR, IR, and the optical absorptions. The mechanism of the extraction of VO^{2+} by $(C_4H_9O)_2PO_2H$ was discussed, and a cyclic model was proposed for the structure of $(VOX_2)_3$.

The extraction of the vanadyl ion (VO^{2+}) dissolved in aqueous solutions by di-(2-ethylhexyl)-phosphoric acid (HDEHP) in kerosene has been studied by several workers.[1,2] Accordingly, the vanadium/HDEHP ratios of the extracts ranged from 0.25 to 0.50, suggesting that at least two species of vanadyl complexes were formed. Moreover, it has been suggested[2] that polymeric vanadyl complexes are formed at lower HDEHP concentrations, while monomeric complexes are formed at higher HDEHP concentrations.

In the present study, the vanadyl complexes extracted from sulfuric acid solutions into the hexane phase by di-*n*-butylphosphoric acid (HDBP) have been investigated, with special interest being taken in the formation of polymeric species. Preliminary observations of extracts by electron spin resonance revealed that trimeric complexes rather than polymeric ones are formed. It was decided, therefore, to investigate first the conditions for the formation of the trimeric complex. Subsequently attempts were made to isolate the complex and to clarify the chemical stoichiometry and properties of the complex. The present paper will report the results of these investigations.

Experimental

Materials. HDBP (E.P. grade, Tokyo Kasei Kogyo Co.,) was used without further purification. The IR spectrum showed few impurities. Hexane (G.R. grade, Wako Junyaku Kogyo Co.,), which has previously been known to be the most effective diluent in the extraction of vanadium by HDEHP,[2] was used as the diluent after distillation. The vanadyl sulfate hydrate ($VOSO_4 \cdot nH_2O$) was obtained from Kishida Kagaku Co.; the colorimetric peroxide method indicated that the $VOSO_4$ content was 55 wt%. All the other reagents used were of a reagent grade and were commercially available.

Extraction of the Vanadyl Ion (VO^{2+}) by HDBP. The extraction of VO^{2+} from acidic aqueous solutions by HDBP in hexane was carried out in a 300 ml separating funnel, generally with equal volumes (100 ml) of the aqueous and organic phases. The two phases were mixed vigorously by shaking for about 10 min at the ambient temperature, and were then allowed to stand until the separation into two layers was complete. Little trouble was experienced with emulsions. The extractions were carried out under the following conditions:

initial HDBP concentrations as monomer in the organic phase: $C_{HX(i)} = 0.12—1.2M$

initial VO^{2+} concentrations in the aqueous phase: $C_{V(i)} = 0.02—1.5M$

final pH values in the aqueous phase: $pH_{(f)} = 0.8—5.5$

The variation in the final pH values in the aqueous phase was accomplished by adding the requisite amounts of H_2SO_4 or NaOH solutions either immediately before or during the mixing. The $pH_{(f)}$ values were determined by means of a Toadempa pH-meter (Model HM-5A) after the separation.

Isolation of the Trimeric Vanadyl Complex. The hexane phase was dehydrated with anhydrous sodium sulfate, and then the solvent was evaporated under a reduced pressure. The resulting blue viscous liquid was then chromatographed over a column packed with SiO_2, using benzene as the eluent; the blue fractions thus obtained were evaporated under a sufficiently reduced pressure (10^{-4} Torr) at 60°C for about 3 hr to give again a blue, oily liquid. After 1—2 weeks' standing in a refrigerator, a light blue crystalline material was obtained (mp 43°C).[3]

Measurements of ESR, IR, and Optical Spectra. The ESR spectra were recorded at room temperature with a JEOL spectrometer, Model JES P-10 (X-band), using 100 KHz field modulation. The magnetic field was calibrated with an ESR marker, MgO:Mn^{2+} powder, supplied by JEOL. Powdered DPPH was used as a reference in the determination of the *g*-values. Samples from the extracted organic phases were subjected to ESR measurements without any pretreatment, while those from isolated crystals were measured, generally *in vacuo*, after dissolving them in various organic solvents.

The IR spectra were recorded on a DS-402G grating spectrophotometer (Japan Spectroscopic Co.,) in Nujol mulls and in thin liquid films. The optical spectra were recorded on a Hitachi spectrophotometer (Model EPS-3T) in the range of 300—1200 nm.

Chemical Analyses. Vanadium was analysed by the colorimetric peroxide method.[4] Samples dissolved in hexane were back-extracted with 2N HCl, and color development was performed by the successive additions of 2N H_2SO_4, 85% phosphoric acid, and 30% hydrogen peroxide. The optical densities of the colorimetric solutions were determined at wavelength of 450 nm with a Shimadzu spectrophotometer (Model QV-50). The analyses of carbon and hydrogen were performed at the Microanalytical Center of our laboratory.

Molecular-weight Measurements and Differential Scanning Calorimetry. The molecular weights were determined in a chloroform solution at 35°C using a Hitachi Model 115 vapor-pressure osmometer calibrated with benzil. Scale readings were made 5 min after a drop of the solution had been placed on the thermistor. The concentrations of the solution were in the range of 10^{-2}—10^{-3}M. The DSC thermograms were recorded on a DSC-1B calorimeter (Perkin-Elmer) in an atmosphere of nitrogen.

Results and Discussion

ESR Spectra of Extracted Vanadyl Complexes. Hexane solutions of the extract were subjected to preliminary ESR measurements at room temperature in order to obtain some information about the states of the extracted vanadyl complexes.

Two types of spectrum were observed, depending upon the extraction conditions. As will be discussed below, one was assigned to a monomeric vanadyl species, and the other, to a trimeric one. Hereafter, the former will be denoted as the "M-spectrum", and the latter, as the "T-spectrum".

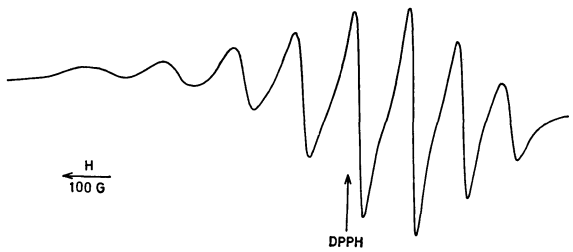

Fig. 1. ESR spectrum of the hexane phase (M-spectrum) obtained under the following extraction condition; $C_{HX(i)}$ = 1.20M, $C_{V(i)}$ = 0.30M, $pH_{(f)}$ = 0.8.

Assignment of M-spectrum: A typical M-spectrum obtained from the hexane solution extracted under the conditions; $C_{HX(i)} = 1.20$ M, $C_{V(i)} = 0.30$ M, and $pH_{(f)} = 0.8$, is shown in Fig. 1. The spectrum was characterized by eight resonance lines with unequal separations and linewidths. It is quite similar to the reported spectra[5] for many monomeric vanadyl complexes in liquid solutions, and can be interpreted by an isotropic spin Hamiltonian as:

$$\mathcal{H} = g_0\beta HS_z + a\boldsymbol{I}\cdot\boldsymbol{S} \qquad (1)$$
$$S=1/2,\ I=7/2$$

where the z axis is defined by the direction of the external magnetic field, where g_0 is the isotropic g value, where a is the isotropic hyperfine constant due to the vanadium nucleus, and where the other symbols have their usual meanings. The solution of the above Hamiltonian up to second order of a leads to the resonance condition described as:[5,6]

$$h\nu = g_0\beta H + am + \frac{a^2}{2g_0\beta H}\left(\frac{63}{4} - m^2\right) \qquad (2)$$
$$m=7/2,\ 5/2,\ 3/2,\ \cdots\cdots,\ -5/2,\ -7/2$$

The M-spectrum shown in Fig. 1 was then fitted to the equation to obtain the following parameters:

$$g_0 = 1.961 \qquad a = 119 \text{ gauss}$$

These values are in good agreement with those reported for monomeric vanadyl complexes coordinated with oxygen ligands, such as $VO(H_2O)_5^{2+}$,[6,7] $VO(Ac)_2$,[8] and VO(phthalic acid)$_2^{2-}$.[9]

On the other hand, it has generally been accepted that dialkylphosphoric acids ($(RO)_2PO_2H$) extract a

3) In some cases the crystallization did not take place even after a much longer period of standing. This was because of the contamination by a small amount of monomeric species in a blue oily liquid; the contamination was obvious from the ESR and molecular-weight measurements. It was necessary in such cases to wash the blue oily liquid after dissolving it in hexane with an appropriate amount of the 0.01N NaOH solution and then to repeat the treatment described above.

number of metal cations by this ion-exchange reaction:[10]

$$M^{n+}_{(a)} + n(HX)_{2(o)} = M(X_2H)_{n(o)} + nH^+_{(a)} \quad (3)$$

in which X represents the anion $(RO)_2PO_2^-$; $(HX)_2$, the dimeric $(RO)_2PO_2H$; and (a) and (o), the aqueous and organic phases respectively. Furthermore, Sato *et al.*[2] have recently shown that the mechanism is applicable also in the case of the extraction of VO^{2+} by excess HDEHP, and they have confirmed the existence of $VO(X_2H)_2$, $X=(C_8H_{17}O)_2PO_2$, in kerosene from an analysis of the partition coefficients. Therefore, it is quite natural in our system also that the monomeric vanadyl complex $VO(X_2H)_2$, $X=(C_4H_9O)_2PO_2$, is formed in hexane *via* the reaction:

$$VO^{2+}_{(a)} + 2(HX)_{2(o)} = VO(X_2H)_{2(o)} + 2H^+_{(a)} \quad (4)$$

Consequently, the M-spectrum can be interpreted as resulting from the monomeric vanadyl complex, $VO(X_2H)_2$. This assignment may be further supported by the spin Hamiltonian parameters, and also by the experimental findings to be described in the later sections.

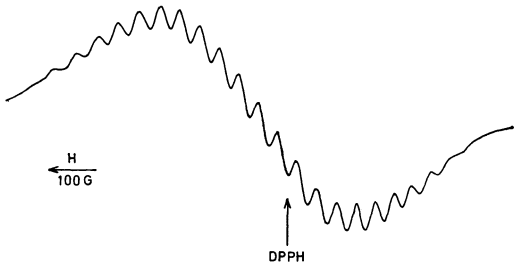

Fig. 2. ESR spectrum of the hexane phase (T-spectrum) obtained under the following extraction condition; $C_{HX(i)}=0.12M$, $C_{V(i)}=1.5M$, $pH_{(f)}=1.6$.

Assignment of T-spectrum: When the extraction was carried out under these conditions; $C_{HX(i)}=0.12$ M, $C_{V(i)}=1.5$ M, and $pH_{(f)}=1.6$, a typical T-spectrum was obtained. As is illustrated in Fig. 2, the T-spectrum has the following characteristics; (I) 22 resonance lines are found to be equally spaced with a separation almost equal to one-third of the average splitting found for the M-spectrum, (II) the resonance intensity for each line decreases with the line position almost symmetrically from the center of the spectrum to the outside. From such characteristics, it can readily be presumed that there are magnetic exchange interactions between three vanadyl ions.

In order to explain the observed T-spectrum qualitatively, we further assume that vanadium atoms of the trimer form equilateral triangular arrangements and that three vanadium ions of $S=1/2$ are exchange-coupled with an isotropic exchange Hamiltonian:

$$\mathcal{H}_{ex} = J(\boldsymbol{S}_1\cdot\boldsymbol{S}_2+\boldsymbol{S}_2\cdot\boldsymbol{S}_3+\boldsymbol{S}_3\cdot\boldsymbol{S}_1) \quad (5)$$

where J denotes the isotropic exchange integral and where $\boldsymbol{S}_1$, $\boldsymbol{S}_2$, and $\boldsymbol{S}_3$ are the spin operators for the respective vanadium ions. Thus, the total spin Hamiltonian describing the system becomes:[11]

$$\mathcal{H} = \mathcal{H}_1 + \mathcal{H}_2 + \mathcal{H}_3 + \mathcal{H}_{ex} \quad (6)$$

in which $\mathcal{H}_1$, $\mathcal{H}_2$, and $\mathcal{H}_3$ are each given by the form (1); it can be rewritten as:

$$\mathcal{H} = g_0\beta H(S_{1z}+S_{2z}+S_{3z}) + a(\boldsymbol{S}_1\cdot\boldsymbol{I}_1+\boldsymbol{S}_2\cdot\boldsymbol{I}_2+\boldsymbol{S}_3\cdot\boldsymbol{I}_3) + J(\boldsymbol{S}_1\cdot\boldsymbol{S}_2+\boldsymbol{S}_2\cdot\boldsymbol{S}_3+\boldsymbol{S}_3\cdot\boldsymbol{S}_1) \quad (7)$$

The eigen values of this Hamiltonian can readily be evaluated[12,13] by solving the secular determinant of the Hamiltonian on the assumption $|J|\gg|a|$; we then obtain the following ESR transitions[14] for the quartet state and for the two doublet states which are degenerate and which lie at a distance $3/2\,|J|$ from the quartet state.

Transitions for the quartet state:

$$h\nu = g_0\beta H + a/3(m_1+m_2+m_3) \quad (8)$$

Transitions for the two doublet states:

$$h\nu = g_0\beta H + a/3(m_1+m_2+m_3) \pm 2/3a(m_1^2+m_2^2+m_3^2-m_1m_2-m_2m_3-m_3m_1)^{1/2} \quad (9)$$

where m_1, m_2, and m_3 are the magnetic quantum numbers for each vanadium nucleus; each takes on the value of 7/2, 5/2, 3/2, ……, −5/2, −7/2.

Thus, it can be shown for the quartet-state spectrum that the 22 hf lines have the equal separation of $a/3$ and the intensity ratio of 1:3:6:10:15:21:28:36:42:46:48:48:46:42: ……, while the predicted spectrum for the doublet states consists of two sets of irregularly-spaced hf lines, both of which are symmetric to each other with respect to the magnetic filed defined by $h\nu=g_0\beta H$.

The characterisic (I) for the observed T-spectrum is quite consistent with the above expectation for the quartet-state spectrum. Furthermore, the observed intensity distribution of hf lines (Characteristic (II)), which is difficult to measure accurately, seems to follow approximately the expected one. One can, then, reasonably state that the T-spectrum results from the quartet-state transitions. On the other hand, it is not obvious at the moment why irregularly-spaced hf lines due to the doublet-state transitions are not observable.

The parameters determined from the T-spectrum on the basis of Eq. (8) are:

14) The second-order correction terms with respect to a must be added to Eqs. (8) and (9). The correction terms evaluated for (8) are as follows:

$$\frac{a^2}{18g_0\beta H}\{3I(I+1)-m_1^2-m_2^2-m_3^2\} + \frac{a^2}{18g_0\beta H}(2m_s-1)(m_1+m_2+m_3)$$

where $I=7/2$ and $m_S=3/2,\ 1/2,\ -1/2$. However, these terms are much smaller than that given in Eq. (2) and do not contribute to the line positions very much. Thus, the terms are ommitted from Eq. (8), although it seems that the terms are more or less related to the linewidth because of the superposition of resonance lines differing in m_S values.

$g_0 = 1.960$ $a/3 = 39$ gauss

These values are in good agreement with those obtained for the monomeric complex $VO(X_2H)_2$, indicating that our interpretation is valid. Moreover, the interpretation is consistent with that reported by Hasegawa *et al.*,[13] who studied the ESR of the trinuclear vanadyl pyrophosphate complex.

As will be described in the later section, a crystalline trimer was in fact isolated from the hexane solution. Thus, it can be concluded with reasonable certainty that the appearance of the T-spectrum results from a trimeric vanadyl complex.

Extraction Conditions for the Formation of the Trimeric Vanadyl Complex. In order to find how extracting conditions affect the selective formation of the trimeric or monomeric complex, the ESR measurements were further applied to hexane solutions obtained under systematically varied conditions. The results are summarized in Table 1.

a) Relative intensities of the M- and T-spectra are given roughly by an inequality.

Effect of $C_{V(i)}$: Extractions were carried out with $C_{V(i)}$ values varying from 0.024 to 1.2 M, while $C_{HX(i)}$ and $pH_{(f)}$ were kept constant as follows: $C_{HX(i)}=0.12$ M, $pH_{(f)}=1.3$—1.4 (Table 1, Exp. No. 1—6).

As is shown in the last column of Table 1, the M- and T-spectra were obtained for $C_{V(i)}=0.024$ and 1.2 M respectively. However, when $C_{V(i)}$ was intermediate between the above two extreme values, superimposed spectra of the M- and T-spectra with varying relative intensities were obtained. Some of the superimposed spectra are illustrated in Fig. 3.

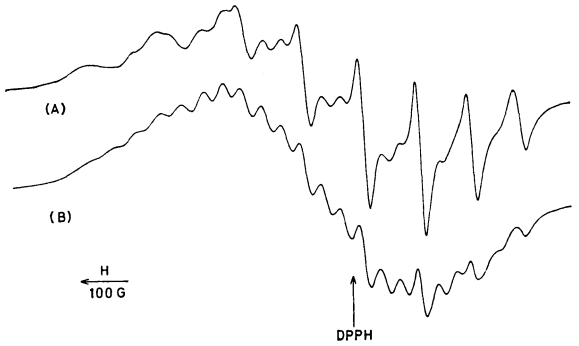

Fig. 3. ESR spectra of the hexane phases obtained under the following extraction conditions; (A) $C_{HX(i)}=0.12$M, $C_{V(i)}=0.096$M, $pH_{(f)}=1.4$; (B) $C_{HX(i)}=0.12$M, $C_{V(i)}=0.24$M, $pH_{(f)}=1.4$.

As can be seen from Table 1 (Exp. No. 1—6), an increase in $C_{V(i)}$ caused a progressive decrease in the ratio of the monomeric to the trimeric vanadyl complex; that is, $C_{V(i)}$ had a significant effect on the selective formation of the respective vanadyl complex.

Effect of $C_{HX(i)}$: As is obvious from Table 1 (Exp. No. 7—11), $C_{HX(i)}$ also had a singificant effect; the increase in $C_{HX(i)}$ favored the formation of the monomeric vanadyl complex. The increase in the ratio of $C_{HX(i)}$ to $C_{V(i)}$ resulted in a greater formation of monomeric vanadyl complex, but the decrease in the ratio resulted in that of trimeric one, as is evident from Table 1 (Exp. No. 1—11).

Such effects of $C_{HX(i)}/C_{V(i)}$ were closely correlated with the pH values of the final aqueous phase ($pH_{(f)}$) and were noted only in the $pH_{(f)}$ range from 1.0 to 2.0. For example, when the $pH_{(f)}$ values were kept constant at 0.9—1.0 (Table 1, Exp. No. 12—16), only the monomeric complex was formed for any value of $C_{HX(i)}/C_{V(i)}$, while the trimeric complex was selectively formed for $pH_{(f)}$ from 3.6 to 4.0 (Table 1, Exp. No. 17—21). Therefore, it appears that the effect of $C_{HX(i)}/C_{V(i)}$ is less significant than that of $pH_{(f)}$.

Effect of $pH_{(f)}$: Extractions were further carried out with $pH_{(f)}$ values varying from 0.8 to 5.7 and with a constant $C_{HX(i)}/C_{V(i)}$ (Table 1, Exp. No. 22—31). As expected, the extracted vanadyl complex was monomeric at $pH_{(f)}$ values below 1.0. The monomeric complex was, however, replaced by the trimeric one when $pH_{(f)}$ reached 1.3—1.8, while the trimeric complex was exclusively formed at higher $pH_{(f)}$ values. It is interesting to note that the coexistence of monmeric and trimeric complexes in the extracted hexane phase is limited to a narrow range of $pH_{(f)}$, where the effect of $C_{HX(i)}/C_{V(i)}$ is significant.

Distribution Ratios for Vanadium: Although we have not measured accurately the distribution ratios for vanadium ($D_V=[V_{(o)}]/[V_{(a)}]$) as functions of $C_{HX(i)}$, $C_{V(i)}$, and $pH_{(f)}$, it has been found that D_V depends rather sensitively upon $pH_{(f)}$. D_V increased markedly with the increase in $pH_{(f)}$ from 1.0 to 2.0. It reached a maximum at $pH_{(f)}$ about 2.0, and then decreased remarkably beyond $pH_{(f)}$ 3—4, accompanied by the

appearance of turbidity or a precipitate of hydrolyzed vanadyl ions in the aqueous phase. On the contrary, D_V was not markedly influenced by $C_{HX(i)}$ and $C_{V(i)}$ except in the $pH_{(i)}$ range below 2, where the increase in $C_{HX(i)}/C_{V(i)}$ brought about an increase in D_V.

Chemical Stoichiometry and Properties of Trimeric Vanadyl Complex. Isolation and Thermal Properties: As has already been described in the Experimental section, a light blue crystalline solid with a somewhat amorphous appearance was isolated from the hexane phase which exhibited the T-spectrum. The crystalline solid was stable to air and light. It melted at about 43°C to a blue, oily liquid, which was also stable in air but which decomposed to a dark brownish mass at higher temperatures (about 260—280°C).

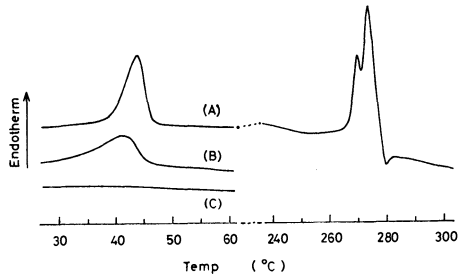

Fig. 4. DSC thermograms of trimeric vanadyl complex (sample S-II) crystallized from the oily state at the ambient temperature for different periods of time; (A) about 60 days, (B) 5 days, (C) 1 day.
(Heating rate and recorder sensitivity are 2°C/min and Range-4 for the low temperature region and 4°C/min and Range-16 for the high temperature region, respectively.)

Such thermal behavior of a crystalline sample is shown diagrammatically in the DSC thermograms (Fig. 4). The thermograms further indicated that the sample crystallizes with considerable difficulty. As is illustrated in Fig. 4, the crystallization took place very slowly when the crystalline sample was once melted to an oily liquid and then allowed to stand at the ambient temperature.

Table 2. Analytical data of the trimeric vanadyl complex

Calcd[b]	10.50	39.60	7.48	1456.1

a) Crystalline solids obtained from three independent preparations.
b) Calculated values for $(VOX_2)_3$

Chemical Stoichiometry: Three crystalline samples obtained from independent preparations were subjected to chemical analyses and molecular-weight measurements; the results are summarized in Table 2. No significant difference was found between the three samples, indicating that all the samples were chemically identical and of a high purity, in spite of the facts that they were obtained without further recrystallization and were somewhat different in the color and crystallinity from each other.

The chemical formulae determined from the results given in Table 2 were in close agreement with the following stoichiometry:

$$(VOX_2)_n;\ n=3$$

where n denotes the association value, and X, the di-*n*-butylphosphate anion $(C_4H_9O)_2PO_2^-$. The association value of 3 is consistent with the appearance of the T-spectrum.

Dissolved States of $(VOX_2)_3$ in Various Solvents: Although the crystalline sample of $(VOX_2)_3$ was insoluble in water and ethyleneglycol, it was highly soluble in most of the organic solvents. However, the dissolved state and stability of $(VOX_2)_3$ were found to be dependent upon the solvents.

As is summarized below, the solvents were classified roughly into two groups according to the type of ESR spectrum of the solution *in vacuo*:[15]

1) Non-polar or weakly polar solvents (hexane, *iso*-pentane, benzene, toluene, chloroform, methylenechloride, carbon disulfide, ethylacetate, acetone, ethylether, tetrahydrofuran, *etc.*): $(VOX_2)_3$ was dissolved in these solvents to give the T-type spectra. This means that, in these solvents, $(VOX_2)_3$ is present as the trimeric state.

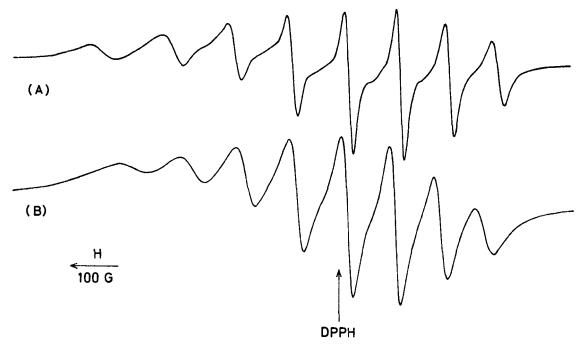

Fig. 5. ESR spectra resulting from methyl alcohol (A) and pyridine (B) solutions of $(VOX_2)_3$.

2) Polar solvents (methyl alcohol, ethyl alcohol, pyridine, picolines, *etc.*): In these solvents, the M-type spectra shown in Fig. 5 were observed with the disappearance of the T-type spectra. The ESR parameters for some of the M-type spectra were determined as follows:

$g_0=1.968$ $a=106$ gauss (for a pyridine solution)

$g_0=1.962$ $a=117$ gauss (for a methyl alcohol solution)

The results imply that $(VOX_2)_3$ reacts with these polar solvents to be converted into monomeric species. The reactions can presumably be expressed as follows:

$$(VOX_2)_3 + 6Py = 3VOX_2Py_2 \quad (10)$$

$$\left.\begin{aligned}(VOX_2)_3 + 6ROH &= 3VOX_2(ROH)_2\\ VOX_2(ROH)_2 + 2ROH &= VO(RO)_2(ROH)_2 + 2HX\end{aligned}\right\} \quad (11)$$

where Py denotes pyridine or picolines, and ROH, methyl or ethyl alcohol. Here, the di-*n*-butylphosphate

15) Although no spectral change with time was observed *in vacuo*, some of the solutions were found to show progressive spectral changes with time when the solutions were exposed to air. Work along this line is now in progress; the details will be reported in the future.

anion, X^-, in monomeric species is assumed to be coordinated as a monodentate ligand. The ESR parameters given above do not seem to be incompatible with these postulated monomeric species, because vanadyl complexes coordinated with nitrogen ligands usually give smaller hf constants than with oxygen ligands.

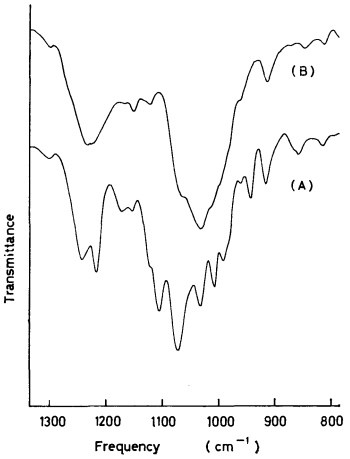

Fig. 6. Infrared spectra of $(VOX_2)_3$ as a Nujol mull (A) and of $(HX)_2$ as a thin liquid film (B).

IR Spectra: The spectrum of $(VOX_2)_3$ as a Nujol mull is given in Fig. 6, where it is compared with that of HDBP as a thin liquid film. As is shown in the literature,[16,17] the spectrum of HDBP shows the P=O stretching band at 1230 cm^{-1}, the superimposed bands due to P–O–(C), P–O–(H), and (P)–O–C stretching modes in the 1000—1070 cm^{-1} region, and three broad bands at *ca.* 2700, 2350, and 1700 cm^{-1} which are assignable to the vibrational modes of hydrogen-bonded hydroxyl groups in the HDBP dimer, $(HX)_2$.

It is seen, however, in the spectrum of $(VOX_2)_3$ that the P=O stretching band splits into two peaks at 1215 and 1240 cm^{-1}, with the complete disappearance of the hydrogen-bonded hydroxyl bands. Furthermore, the spectrum of $(VOX_2)_3$ shows a well-resolved structure in the 940—1100 cm^{-1} region with new bands at 945 and 1105 cm^{-1}, the former of which is presumed to be the V=O stretching vibration.[2,18]

Although an unambiguous assignment of each band is difficult, the above results may indicate that HDBP is coordinated to vanadium through two vacant oxygens as a result of the ionization of hydroxyl hydrogen atom, causing hence the spectral change from HDBP to $(VOX_2)_3$.

Visible Absorption Spectra: The visible absorption spectrum of the trimeric complex $(VOX_2)_3$ dissolved in hexane is presented in Fig. 7, along with that assignable to the monomeric complex $VO(X_2H)_2$. The latter spectrum was obtained from the hexane solution containing $(VOX_2)_3$ and a large excess of HDBP. The details will be described below.

18) J. Selbin, L. H. Holmes, Jr., and S. P. McGlynn, *ibid.* **25**, 1359 (1963).

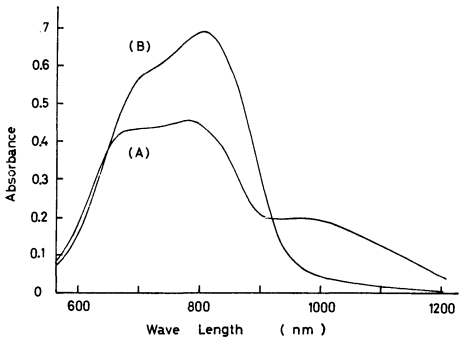

Fig. 7. Visible absorption spectra of $(VOX_2)_3$ (A) and $VO(X_2H)_2$ (B).

The following absorption maxima (with molar extinction coefficients given in parentheses) were derived from Fig. 7:

$(VOX_2)_3$	680 nm (40 $M^{-1}\cdot cm^{-1}$)
	780 nm (45 $M^{-1}\cdot cm^{-1}$)
	980 nm (19 $M^{-1}\cdot cm^{-1}$)
$VO(X_2H)_2$	700 nm (19 $M^{-1}\cdot cm^{-1}$)
	805 nm (23 $M^{-1}\cdot cm^{-1}$)

As will be shown below, $VO(X_2H)_2$ may have a local symmetry of C_{4v} with an unpaired electron in the $3d_{xy}$ orbital. Thus, according to the Ballhausen and Gray energy level scheme,[19] it seems probable that the absorption bands for $VO(X_2H)_2$ at 700 and 805 nm can be identified as $B_2(3d_{xy})\rightarrow B_1^*(3d_{x^2-y^2})$ and $B_2(3d_{xy})\rightarrow E_\pi^*(3d_{xz},3d_{yz})$ transitions respectively.

On the other hand, the situation in $(VOX_2)_3$ is more complicated, because exchange interactions among three vanadium ions exert a perturbing influence on the energy levels derived from the combination of three sets of monomeric energy levels. It is not within the scope of this paper to examine possible assignments for the visible spectra of $(VOX_2)_3$. However, it seems likely that the three absorption bands at 680, 780, and 980 nm originate from the perturbed d—d transitions, since the typical exchange energies for most of the polynuclear metal complexes thus far reported are of the order of a few hundred cm^{-1} or less.[11]

Equilibrium Reaction between $(VOX_2)_3$ and $VO(X_2H)_2$ in Hexane. In order to get information about the extraction mechanisms of $(VOX_2)_3$ and $VO(X_2H)_2$, the reaction of $(VOX_2)_3$ with HDBP in hexane was investigated at the ambient temperature (about 20°C) by both ESR and visible-absorption methods.

ESR Method: When HDBP was added, little by little, to a hexane solution of $(VOX_2)_3$, the ESR spectrum of the solution was found to show gradual changes from the T-spectrum to the M-spectrum with an increasing HDBP through such an intermediary spectrum as is given in Fig. 3. The change was reversed when $(VOX_2)_3$ was added to a HDBP solution. It was thus presumed that $(VOX_2)_3$ reacts reversibly with HDBP to form $VO(X_2H)_2$ according to:

$$(VOX_2)_3 + 3(HX)_2 = 3VO(X_2H)_2 \qquad (12)$$

19) C. J. Ballhausen and H. B. Gray, *Inorg. Chem.*, **1**, 111 (1962).

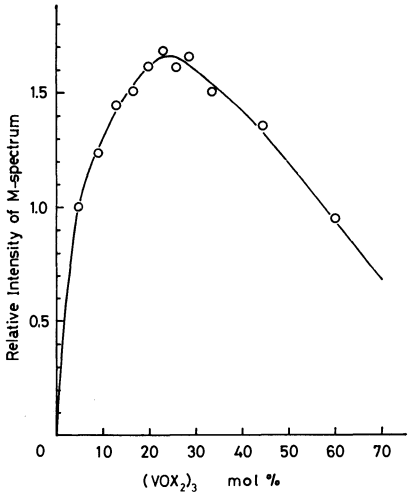

Fig. 8. Continuous variation method as applied to the $(VOX_2)_3$–$(HX)_2$ system by ESR measurements. $[(VOX_2)_3]+[(HX)_2]=2\times10^{-2}$M (const)

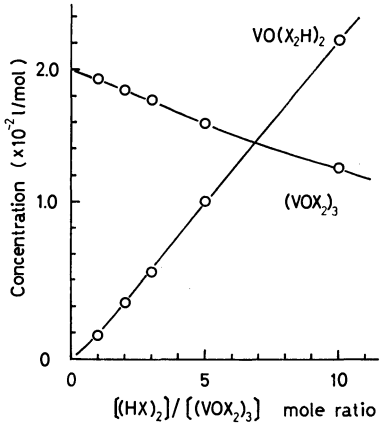

Fig. 9. Mole ratio method as applied to the $(VOX_2)_3$–$(HX)_2$ system by ESR measurements. $[(VOX_2)_3]=2\times10^{-2}$M (const)

where HDBP is assumed to exist as the dimer, $(HX)_2$, in hexane.

Then Job's method of continuous variations and the mole-ratio method[20] were applied to Eq. (12) in order to verify the validity of the assumed reaction and also to determine its equilibrium constant. Both results are presented graphically in Figs. 8 and 9. It is apparent from Fig. 8 that the signal intensity due to the M-spectrum, which is proportional to the concentrations of $VO(X_2H)_2$ formed, reaches a maximum at about 25 mol% of $(VOX_2)_3$, indicating that one mole of $(VOX_2)_3$ reacts with three moles of $(HX)_2$ in accordance with the presumed reaction scheme. On this basis, the equilibrium constant was evaluated directly from Fig. 9, where the equilibrated concentrations of $VO(X_2H)_2$ and $(VOX_2)_3$ are plotted as functions of the mole ratio of $(HX)_2$ to $(VOX_2)_3$. The equilibrium constant thus obtained is given by:

$$K=\frac{[VO(X_2H)_2]^3}{[(VOX_2)_3][(HX)_2]^3}=(1.0\pm0.5)\times10^{-1}\ \text{l/mol}$$

The rather poor accuracy of the value seems to have arisen from the inaccurate determination of the equilibrium concentrations because of the superposition of the M- and T-spectra.

Visible Absorption Method: The continuous-variation method was applied to the visible absorption spectra of the reaction system in a manner similar to that used in the case of the ESR measurements. Unfortunately, however, the method was found to be unusable for this system because the effective variation in the absorbance with a change in the mol% of $(VOX_2)_3$ was too small.

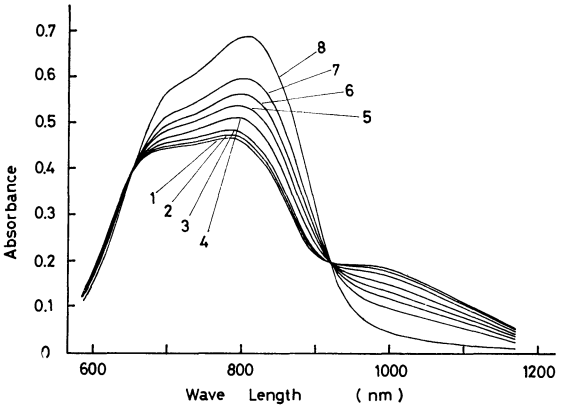

Fig. 10. Mole ratio method as applied to the $(VOX_2)_3$–$(HX)_2$ system by visible absorption measurements. $[(VOX_2)_3]=1\times10^{-2}$M (const.); $[(HX)_2]=2\times10^{-2}$M (1), 3×10^{-2}M (2), 5×10^{-2}M (3), 1×10^{-1}M (4), 1.5×10^{-1}M (5), 2×10^{-1}M (6), 3×10^{-1}M (7), $8\sim12\times10^{-1}$M (8).

On the other hand, the mole-ratio method was found to be successful in the evaluation of the equilibrium constant. A typical set of data is illustrated in Fig. 10, where a sharp isosbestic point is observed at 920 nm; this is consistent with our hypothesis of the presence of two absorbing species, $(VOX_2)_3$ and $VO(X_2H)_2$, in solutions.

The equation used for the calculation of the equilibrium constant was:[21]

$$K=\left\{\frac{3(A-A_0)}{3\varepsilon_M-\varepsilon_T}\right\}^3\Big/\left\{[(VOX_2)_3]_0-\frac{A-A_0}{3\varepsilon_M-\varepsilon_T}\right\}\times\left\{[(HX)_2]_0-\frac{3(A-A_0)}{3\varepsilon_M-\varepsilon_T}\right\}^3$$

where ε_T and ε_M are the molar extinction coefficients at the chosen wavelengths for $(VOX_2)_3$ and $VO(X_2H)_2$ respectively; A, the measured absorption at the wavelength ($A=\varepsilon_T[(VOX_2)_3]+\varepsilon_M[VO(X_2H)_2]$); A_0, the absorption of $(VOX_2)_3$ in the absence of $(HX)_2$ ($A_0=\varepsilon_T[(VOX_2)_3]_0$), and $[(VOX_2)_3]_0$ and $[(HX)_2]_0$, the initial concentrations of the two species.

The resulting K values were then averaged to give the following one, with a much smaller deviation than that determined by the ESR method:

$$K=(1.1\pm0.2)\times10^{-1}\ \text{l/mol}$$

20) A. Nakahara, "Jikken Kagaku Koza," Vol. 6, ed. by The Chemical Society of Japan, (1965), p. 184; H. Hosoya, "Jikken Kagaku Koza," Vol. 11, ed. by The Chemical Society of Japan (1965), p. 523.

21) R. L. Carlin and F. A. Walker, *J. Amer. Chem. Soc.*, **87**, 2128 (1965).

The extinction coefficient, ε_M, used for the calculation was approximated by that obtained from the spectra of the solution containing a large excess of $(HX)_2$, ranging from 80 to 120 times the amount of $(VOX_2)_3$. Under such conditions, the absorbance of the solution showed no significant change in relation to the variation in the $(HX)_2$ concentration, suggesting that $(VOX_2)_3$ is almost completely converted into $VO(X_2H)_2$. Consequently, one can consider the approximation in ε_M fairly good.

Mechanism of the Formation of $VO(X_2H)_2$ and $(VOX_2)_3$. It is well known that dialkyl phosphoric acids show a strong tendency to form dimers[16,22-24] in non-polar solvents similar to carboxylic acids. The proposed structure[16,22-24] of the dimer is illustrated in Fig. 11 (A), where an eight-membered ring structure is formed as the result of hydrogen bonding. If one of the acidic hydrogen atoms of this dimer is removed by ionization, and if the remaining hydrogen bond is not broken, the resulting, singly-charged dimeric anion should have the possibility of a relatively stable chelation with metal ions.

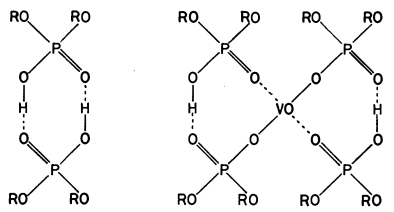

Fig. 11. Proposed structures of $(HX)_2$[16,22-24] and monomeric vanadyl complex $VO(X_2H)_2$[1].

From this point of view, it is well understandable that HDBP dimer extracts the vanadyl ion by the simple hydrogen ion-exchange reaction[10] given in Eq. (4), which then leads to the formation of a monomeric complex, $VO(X_2H)_2$, with the structure[1] shown in Fig. 11(B).

However, it should be noted here that the formation of $VO(X_2H)_2$ by this mechanism is strongly dependent upon the extraction conditions. As was described in the previous section, the monomeric complex $VO(X_2H)_2$ was selectively formed when the $pH_{(f)}$ was below 1. However, as the $pH_{(f)}$ increased from 1 to 2, the selective formation was suppressed by the simultaneous formation of the trimeric complex $(VOX_2)_3$; this was observed in this $pH_{(f)}$ region only when HDBP was present in excess. Furthermore, an increase in $pH_{(f)}$ values above 2 brought about the selective formation of $(VOX_2)_3$ in place of $VO(X_2H)_2$.

It is thus obvious that the simple ion-exchange mechanism is not applicable to all cases, and we are now in a position to take another mechanism into consideration in order to interpret the formation of $(VOX_2)_3$.

According to Rigg *et al.*,[1] who investigated the extraction isotherm for the vanadium-HDEHP system, a monomeric complex with the VOX_2 stoichiometry is formed at higher vanadium concentrations *via* this reaction:

$$VO^{2+}_{(a)} + VO(X_2H)_{2(o)} = 2VOX_{2(o)} + 2H^+_{(a)} \qquad (13)$$

where the formation of polymeric species is discounted on the ground that no increase in viscosity is noticeable in the solvent extracts. On the other hand, it has been postulated more recently by Sato *et al.*[2] that the formation of polymeric species is involved under the condition of a relatively low HDEHP concentration and that all the extraction reactions in the vanadium-HDEHP system can be described by the following general equilibrium reaction:

$$nVO^{2+}_{(a)} + (n+1)(HX)_{2(o)} = (VO)_nX_{2(n+1)}H_{2(o)} + 2nH^+_{(a)} \qquad (14)$$

where $n \geq 1$.

The latter mechanism, leading to the formation of a chain polymer of the $HX_2(VO)X_2(VO)X_2\cdots\cdots(VO)X_2(VO)X_2H$ type, is the most readily acceptable one if one remembers that Equation (14) is only an extension of the simple ion-exchange mechanism and that such a mechanism has already been accepted for the extraction of such metal ions as UO_2^{2+},[25,26] Th^{4+},[27] and Zr^{4+}.[28] In fact, the mechanism can interpret the extraction isotherm, because the $(VO)_nX_{2(n+1)}H_2$ chemical stoichiometry can be approximated to 1:2 for the vanadium-to-HDEHP mole ratio when n is large.

Unfortunately, the previous workers did not isolate the extracted vanadyl species. In view of the extraction conditions employed by the previous workers, it seems very likely that the postulated complex, VOX_2 or $(VO)_nX_{2(n+1)}H_2$, is identical with the trimeric complex, $(VOX_2)_3$, disclosed in the present work.

Equation (14) does not exclude the formation of trimeric species; according to this equation, many sorts of polymeric species, such as dimer, trimer, and tetramer, could be present. In this work we have observed no vanadyl species other than monomer and trimer. Furthermore, the chemical stoichiometry, $(VOX_2)_3$, determined for the isolated species was quite different from the formula, $(VO)_3X_8H_2$, expected from Eq. (14).

It has now become clear that Eqs. (13) and (14), proposed by previous workers, are inadequate for extractions at high $pH_{(f)}$ values and at high vanadium concentrations. Accordingly, the over-all reaction scheme under such conditions must be rewritten as follows:

$$3VO^{2+}_{(a)} + 3(HX)_{2(o)} = (VOX_2)_{3(o)} + 6H^+_{(o)} \qquad (15)$$

At the same time, one can obtain from Eqs. (4) and (15) such additional reactions as:

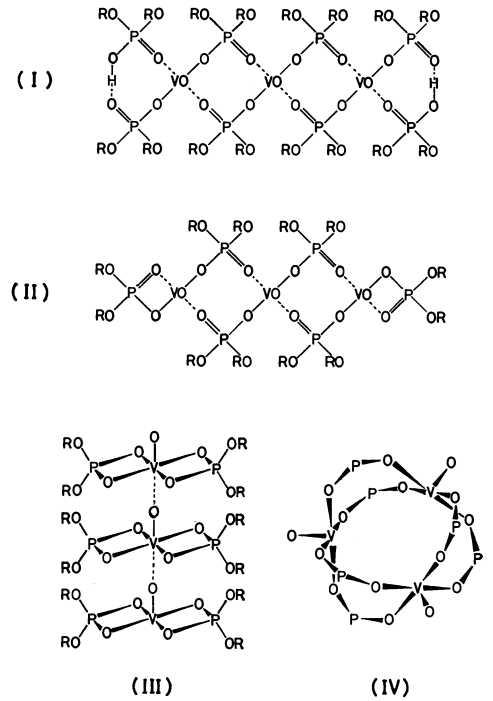

Fig. 12. Possible structures for trimeric vanadyl complex; (I) linear trimer for the stoichiometry $(VO)_3X_3H_2$, (II), (III) linear trimer for the stoichiometry $(VOX_2)_3$, (IV) cyclic trimer for the stoichiometry $(VOX_2)_3$, where each P represents $P(OR)_2$ with the two OR groups toward the outside.

in Fig. 12 (IV), where three vanadium atoms are assumed to be linked by the double-phosphate bridge in an equilateral triangle. A simple geometrical construction using a molecular structure model (HGS, D-type, Maruzen Co.), with the usual bond lengths, showed that this cyclic structure appeared reasonable, with no undue strain nor steric hindrance. Moreover, this cyclic structure can well explain the T-spectrum on the assumption that the magnitude of exchange interaction between vanadium ions satisfies the relation $|J| \gg |a|$.

A similar structural model has recently been proposed by Hasegawa *et al.*[13] for the trimeric vanadyl pyrophosphate complex, $Na_6(VOP_2O_7)_3 \cdot 12H_2O$, on the basis of ESR and magnetic susceptibility measurements, where magnetic electrons on the three vanadium atoms were found to interact antiferromagnetically with the exchange integral of $|J| \fallingdotseq 30\ cm^{-1}$. It can, therefore, be presumed that the exchange integral for $(VOX_2)_3$ does not differ greatly from that determined for $Na_6(VOP_2O_7)_3 \cdot 12H_2O$, and that the relation $|J| \gg |a|$ is valid. Thus, we can consider that the cyclic model (IV) is most probable for the structure of the trimeric vanadyl di-*n*-butylphosphate complex, $(VOX_2)_3$.

It is interesting to note that the proposed structure is closely related to those determined by X-ray single-crystal studies of such trimeric complexes as $Pd_3(CH_3COO)_6 \cdot 1/2H_2O$[31] and $Cr_3(CH_3COO)_6OCl \cdot 5H_2O$.[32] Our complex differs from $Pd_3(CH_3COO)_6 \cdot 1/2H_2O$ only in that the three metal ions are linked together by double-phosphate bridges rather than by double-acetate bridges. Needless to say, the final proof of the structure must await study by X-ray diffraction.

This work was supported in part by a grant of the Ministry of Education, to which the authors' grateful acknowledgements are made. The authors wish to thank Dr. T. Ohama for his kind advices on the molecular-weight measurements and Dr. H. Uchida for his invaluable help in the differential scanning calorimetries.

The Effects of Ion-pair Formation on the ESR Spectra of the Anion Radicals of 4-Nitropyridine *N*-Oxide and 4-Nitropyridine[1]

Yoshiko KAWAMURA(née ŌISHI),[2] Koichi NISHIKIDA, and Tanekazu KUBOTA
Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553
(Received June 26, 1972)

The effect of potassium ion-pair formation on the ESR spectra of the anion radicals of 4-nitropyridine and its *N*-oxide (4NPO) was studied at various temperatures lower than room temperature. The hyperfine splitting constant values due to hydrogen, nitrogen, and potassium nuclei were determined by applying the simulation technique. The above value arising from the potassium nucleus, decreased with a decrease in the temperature. Molecular orbital calculations covering the whole system of the $4NPO^{\cdot-}$–M^+ ion pair and employing the McLachlan modification for the spin-density calculation were carried out in order to discuss the configuration of the ion pairs and the temperature dependence of the hyperfine coupling constants. It was reasonably concluded that an alkali metal cation occupies the C_2 axis of the anion radicals and is in contact with the nitro-group oxygen atoms (the symmetry of the ion pairs is C_{2v}.). The temperature dependence of the hyperfine splitting constants was explained using the vibrational model of Atherton and Weissman.

In the foregoing paper we discussed the hydrogen-bonding effects on the electron spin resonance (ESR) spectra of 4-nitropyridine (4NP), 4-nitropyridine *N*-oxide (4NPO), and related *N*-oxide compounds from the experimental and theoretical viewpoints.[3] As part of a series of intermolecular interaction studies of free radicals, the effect of the alkalimetal ion-pair formation on the ESR spectra of the 4NPO and 4NP anion radicals will be reported in this paper.[4] It would be expected that the charge-transfer (CT) force and the electrostatic force may both play important roles[3] in the hydrogen bonding interaction and in the ion-pair formation of radical anions. Therefore, it seemed that it would be valuable to compare and discuss the effects of these two kinds of molecular interactions on the ESR spectra of 4NPO and 4NP anion radicals.

Experimental

Special-grade dimethoxyethane (DME) was carefully rectified and then dried, first with NaH and later with the Na–K alloy *in vacuo* (10^{-4}—10^{-5} mmHg). The solvent turned dark blue. Just before the use of DME as the solvent, degassing was done in the vacuum system by repeated freeze-thaw cycles at about the temperature of liquid nitrogen. In the present experiment, the ESR spectra due to the ion pair formed with the potassium ion alone were successfully obtained with a good resolution. The potassium was first purified by repeated distillation in a vacuum system, and finally a pure K film was prepared in the usual manner.[5,8] To obtain the high-resolution spectrum, the sample solution should be placed in contact with the above K film *in vacuo* as follows. After being placed in contact at room temperature, the glass apparatus, which had been sealed off from the vacuum system, was immersed overnight in liquid nitrogen. Then spectral observation at various temperatures lower than room temperature was carried out the next day. For 4NP, however, it was not necessary to leave the contact solution at the temperature of liquid nitrogen overnight. In turn, the spectra of electrochemically-generated free radicals in the DME solvent were adopted as an example of those where no ion-pair formation occurs.[6]

The ESR spectra were recorded with a Varian V-4502-15X-band spectrometer with a 100 KHz magnetic field modulation, the magnetic field being monitored with a Varian F-8 nuclear fluxmeter and a Takeda Riken TR-5578 frequency counter. The observed spectra were computer-simulated in order to verify the hyperfine coupling constant values.[6,7]

Results and Discussion

A well-resolved hyperfine splitting (hfs) due to the potassium nucleus was obtained at a temperature lower than 0°C. As an example Fig. 1 shows the ESR spectrum and a simulated one of the $4NPO^{\cdot-}$–K^+ ion pair obtained at −10°C, all the experimental data being collected in Table 1. The numbering of each atom in 4NPO and in 4NP is shown in Figs. 1 and 4 respectively. Here note that the lower the temperature, the smaller the values of a_K (the hfs value due to the potassium nucleus), $a_N^{NO_2}$, and a_{2H} for the $4NPO^{\cdot-}$–K^+ ion pair. However, the values of $a_N^{N\to O}$ and a_{3H} are almost independent of the temperature variation. By comparing the hfs values of the $4NPO^{\cdot-}$–K^+ ion pair with those of the 4NPO anion radical itself (see Table 1),

b) Obtained electrochemically in dimethoxyethane. See Fig. 's 1 and 4 for the numbering of each atom.

we can find that when the ion pair is formed, the values of $a_N^{NO_2}$, a_{3H}, and a_{2H} are increased, but the $a_N^{N\to O}$ value is decreased. Theoretically, these results proceed from the previously-reported MHMO calculation,[3] assuming that the Coulomb integral at the nitro-group oxygen atoms (α_0) comes out deeper[3] as a reslut of the ion-pair formation compared to that of the anion radical itself. Since the charge transfer may occur from the oxygen atoms to the K^+ ion, the deeper α_0 value seems reasonable. Therefore, it appears likely that the active center for the ion-pair formation is the nitro-group oxygen atoms. This result is in agreement with the active site for the 1:1 hydrogen-bonding interaction of $4NPO^{\dot{-}}$ and $4NP^{\dot{-}}$.[3] Next, it should be noticed that the hfs constants of the two *ortho*-protons and the two *meta*-protons in the ion-paired 4NPO and 4NP free radicals all become equivalent, as may be seen in Table 1. This means that the K^+ ion may, as a time average, lie on the σ_v plane, which contains the C_2 axis but which is vertical for the molecular plane (the symmetry of the ion pair may be C_s or C_{2v}). Summarizing the afore-mentioned discussions, the K^+ ion may occupy the position on the σ_v plane (perhaps on the C_2 axis) and near the NO_2-group oxygen atoms. This result can also explain the temperature dependence of the a_K value resonably in terms of the vibrational model of Atherton and Weissman[8] (*vide infra*).

Let us now consider quantitatively the structure of the ion pair and its behaviour. There have been reported several papers describing the theoreticl treatments of the structure of radical-ion pairs by applying the charge-transfer model or the electrostatic model, which more or less uses the perturbation technique.[9-12] Here we have treated the problem using the simple molecular orbital (SMO) method, which covers the whole system of the $4NPO^{\dot{-}}$–K^+ ion pair and which employs the McLachlan modification[13] for the spin density calculation.[14] The calculation procedure is as follows. The perturbation potential, V, due to a metal cation (the effective charge is Ze) on π or lone-pair orbitals is written by $V=-Ze^2/\varepsilon r_{M\mu}$, where $r_{M\mu}$ is the distance from the metal cation to an electron occupying the atomic orbital, ϕ_μ, in the radical anion. The ε is the dielectric constant of solvents, since the ion pair is embedded in the solvents[17] (see below). The mutual interaction of the alkali-metal cation with each $2p\pi$ atomic orbital and with the lone-pair orbitals of the nitro-group or *N*-oxide-group oxygen atoms in the anion radical is taken into account. Because the chemical orbital should be employed for the above mutual interaction, we assumed the lone-pair orbitals to be in the sp^2 hybridization. In addition, the charge transfer is considered to take place from the anion radical to the 2s, 3s, 4s, and 5s atomic orbitals of Li^+, Na^+, K^+, and Rb^+ cations respectively. Therefore, these s orbitals have been used for the present computation.

For the actual calculation, a zero-differential overlap approximation was adopted, so that the potential:[9]

$$V_{\mu\nu} = (-Ze^2/\varepsilon)\langle\phi_\mu|1/r|\phi_\nu\rangle \approx -2Ze^2S_{\mu\nu}/\varepsilon(r_{M\mu}+r_{M\nu})$$

is zero for $\mu \neq \nu$. Here, $S_{\mu\nu}=\langle\phi_\mu|\phi_\nu\rangle$ is the overlap integral. The parameters, k_a, in the form $\alpha+k_a\beta$, for the SMO calculation of the 4NPO anion radical are

14) This technique is convenient for the present case, because our previous calculation data[3,6,7] can extent to this kind of study. After we had presented this paper at the Symposium,[1] Goldberg and Bolton,[15] and Takeshita and Hirota[16] reported the theoretical calculation of several radical ion pairs. Their methods are somewhat similar to ours, but are more simplified than the present treatment.

the same as those in the foregoing papers.[3,6] Here we employed the values[18] of $\alpha=-6.31$ eV and $\beta=-2.93$ eV. The electrostatic energies were expressed in β units, *i.e.*, $k_e\beta$. Thus, the total potential at each atom becomes $\alpha+(k_a+k_e)\beta$. The Coulomb integral due to the s orbital of alkali-metal cations is taken to be equal (as the absolute value) to the ionization potential of the neutral atoms;[19] thus, the values are: α_{Li} $(-5.39\text{ eV})=\alpha-0.314\,\beta$, α_{Na} $(-5.14)=\alpha-0.399\,\beta$, α_K $(-4.34)=\alpha-0.672\,\beta$, and α_{Rb} $(-4.18)=\alpha-0.727\,\beta$. In turn, we assumed that the energy of the lone-pair orbitals at the oxygen atoms of the 4NPO anion radical equals that of the corresponding oxygen π Coulomb integral.[20] The resonance integral between a metal cation s orbital and a π atomic orbital or a lone-pair orbital was estimated according to the $(\beta_{M-X}/\beta_{C=C})=(S_{M-X}/S_{C=C})$ relation at various metal positions (*vide infra*). Here note that the overlap integral, S_{K-X}, was obtained by the intrapolation method from the theoretical values using 1s, 2s, 3s, and 5s atomic Slater's orbitals, because $n-\delta=3.7$ in the atomic orbital parameter $\mu=(Z-\sigma)/(n-\delta)$ for the case of the 4s (potassium) orbital. In the present case the contact-ion pair was assumed, so that we take the sum of the ion radius and the Van der Waals radius for the distance[24] between the metal cation and each atom of the 4NPO anion radical, whose dimensions are put equal to those[21] of the neutral molecule.

Now we will solve the secular Eq. (1), to yield the necessary quantities for the discussion of the ion pairs:

$$|H_{\mu\nu}-E\delta_{\mu\nu}|=0 \tag{1}$$

where

$$H_{\mu\nu}=H^0_{\mu\nu}-Ze^2\langle\phi_\mu|1/r\varepsilon|\phi_\nu\rangle\delta_{\mu\nu} \tag{2}$$

$H^\circ_{\mu\nu}$ is for the SMO parameters of the 4NPO anion radical itself.[3,6] The above-mentioned calculation model represents the adoption of the π electron approximation; *i.e.*, the charge transfer of an odd π electron occurs to the vacant s orbital of alkali metal cations. The value of $\langle\phi_\mu|1/r_{M\mu}|\phi_\mu\rangle$ was theoretically calculated using the Slater orbital. The lone-pair orbitals in sp^2 hybridization are obtained explicitly in the usual manner; *i.e.*, they are first written out under a suitable coordinate at the oxygen atoms, and then these orbitals are transformed to those which are suitable for the coordinate of the whole molecule (see Fig. 2)[22] and are used for the calculation of S_{M-X} and the values of Eq. (2). Some integrals necessary here are given in the footnote.[23] The stabilization energy due to the ion-pair formation can thus be expressed by the equation:

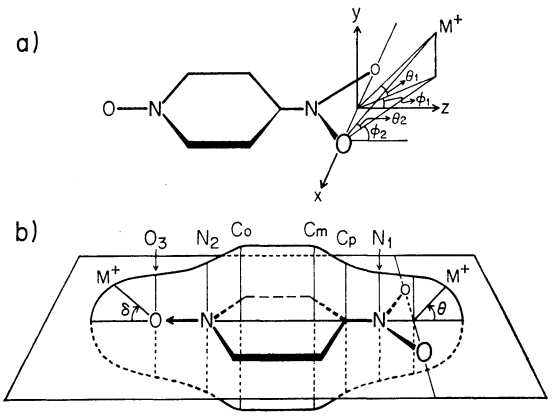

Fig. 2. a) The coordinate which has been used for the molecular orbital calculation of the whole system of the alkali metal ion pairs with 4-nitropyridine *N*-oxide (4NPO) anion radical. b) Each point on the circle, which is in the σ_V plane of 4NPO and drawn by keeping the distance of ion pair contact, is designated by θ, δ, N_1, Cp, *etc.* and employed for the abscissa in Fig. 3A. See text for detailed explanation.

$$\Delta E=\sum_i^{occ}n_i(E_i-E_i^0)+\sum_a\frac{ZZ_ae^2}{\varepsilon r_{Ma}} \tag{3}$$

Here, n_i is the electron number which occupies the i-th molecular orbital, E_i^0 being the i-th molecular orbital energy of the 4NPO anion radical itself. The last term in Eq. (3) stands for the nuclear repulsion energy between the nuclear cores a's (the core charge of the

$$-Ze^2\langle 2p\pi_a|1/r_{Ma}|2p\pi_a\rangle=-\frac{Ze^2}{R\rho^2}\left[-\frac{3}{2}+\rho^2+e^{-2\rho}\left(\frac{3}{2}+3\rho+2\rho^2+\frac{1}{2}\rho^3\right)\right]$$

$$-Ze^2\langle 2p\sigma_a|1/r_{Ma}|2p\sigma_a\rangle=-\frac{Ze^2}{R\rho^2}\left[3+\rho^2-e^{-2\rho}\left(3+6\rho+7\rho^2+\frac{11}{2}\rho^3+3\rho^4+\rho^5\right)\right]$$

$$-Ze^2\langle 2ps_a|1/r_{Ma}|2ps_a\rangle=-\frac{Ze^2}{R}\left[1-e^{-2\rho}\left(1+\frac{3}{2}\rho+\rho^2+\frac{1}{3}\rho^3\right)\right]$$

$$-Ze^2\langle 2p\sigma_a|1/r_{Ma}|2ps_a\rangle=-\frac{5Ze^2}{2\sqrt{3}R\rho}\left[1-e^{-2\rho}\left(1+2\rho+2\rho^2+\frac{6}{5}\rho^3+\frac{2}{5}\rho^4\right)\right]$$

In these equations R is the distance in atomic units between the metal cation and each atomic orbital in 4NPO$^-$, and $\rho=\mu_aR$.

atom a is $Z_a e$) of the conjugated system and the alkali metal cation (core charge: Ze). This term ought to be subtracted from the first electronic stabilization energy term. Here note that $Z_O^{NO_2}$, $Z_N^{NO_2}$, $Z_O^{N\to O}$, $Z_N^{N\to O}$, and Z_C of 4NPO are 5, 2, 5.3, 1.7, and 1 respectively. The calculated results are demonstrated in Fig. 3. In Part A of this figure, each point shown on the abscissa corresponds to that indicated in Fig. 2b. In Part B the ϕ angle is the same as that in Fig. 2a; *i.e.*, the metal cation occupies the $4NPO^{\pm}$ molecular plane and moves between $\phi=90$——$-90°$ by keeping the distance of the ion-pair contact constant.[24] It is now clear that, although the absolute value itself of the stabilization energy is not very accurate,[25] the most stable position of the metal cation is at $\theta=0$ and $\phi=0$; that is, the cation occupies the C_2 axis of the 4NPO anion radical and is in contact with the nitro-group oxygen atoms. In addition, the potential valley arising from the change in the ϕ angle is very narrow and quite deep (see Fig. 3). This may indicate that the metal cation can move more easily along the potential surface derived as a change in the θ angle, *i.e.*, in the direction deviating from the 4NPO molecular plane. These results support the previous qualitative discussions by other authors on the structure of the ion pairs of nitrobenzene, *etc.*[26-29]

Next, the calculated results depicted in Fig. 3 show that the stability of the alkali-metal ion pairs of $4NPO^{\pm}$ is in the order: $Li^+>Na^+>K^+>Rb^+$; the smaller the ion radius, the larger the stability. This conclusion is the same as that reported by Ling and Gendell[26] for the case of the alkali-metal ion pairs of nitrobenzene anion radical. On the other hand, they found a different behaviour in the Li^+ ion pair from the other alkali-metal ion pairs. For example, the hfs value due to the Li^+ nucleus (a_{Li}) has a tenednecy to increase with a decrease in the temperature. This behaviour can not be explained by the present calculations. On the basis of the small size of the Li^+ ion, there occurs more contact complex between Li^+ and the atoms of the nitro group. The terms, such as "spin polarization", other than the assumptions made here for the present calculations should also be taken into account in this kind of calculation.[30]

a) For the actual calculations see text.
b) See text and Fig. 2 for the definition of the angle θ.
c) ρ_M indicates calculated spin density on metal cations.

Table 2 shows the calculated hfs values for hydrogen, nitrogen, and metal cations as a function of the θ angle, but at $\phi=0$. The equations combining the spin densities and the hfs values for the $a_N^{NO_2}$, $a_N^{N\to O}$, and a_H were the same as those reported previously.[3,6] The a_M values due to alkali metal cations were obtained using the equation $a_M=Q_M\rho_M$, where the Q_M values are:[31] $Q(^7Li)=143.3$, $Q(^{23}Na)=316.2$, $Q(^{39}K)=82.4$, $Q(^{87}Rb)=1219$. In Table 2 we can see that the increasing θ causes an increase in a_M and $a_N^{NO_2}$, although the $a_N^{NO_2}$ value again shows a tendency to decrease at $\theta>60°$. Therefore, the decreasing temperature, which corresponds to the decreasing θ, can be expected to bring about the decrease in the a_M and $a_N^{NO_2}$ values, since the metal ion in the ion pair would submerge to the bottom of the potential valley illustrated in Fig. 3.[8] These theoretical results explain well the experimental results previously mentioned, though, in our present treatment, the contributions from the effects of spin polarization, *etc.* to the a_M values were disregarded. Therefore, the spin density on alkali metal cations turns out to be zero when $\theta=0$. Here note that the linear relation is satisfied when the calculated values of $a_N^{NO_2}$ (see Table 2) are plotted against the values of $1/(R_M+C)$, where R_M is the ion radii of Li^+, Na^+, K^+, and Rb^+, and where C is a constant (1.4 Å in the present case). This kind of linear relation for radical-ion pairs was suggested by Nakamura[28] and by McClelland;[9a] the former author found this relation experimentally for

24) The ion and the Van der Waals radii (Å unit) used are shown in parentheses: Li^+ (0.6), Na^+ (1.0), K^+ (1.3), Rb^+ (1.5), 0 atom (1.4), N (1.5), and $2\pi p$ electron cloud of carbon (1.7).

25) One main reason for this may be the ε value, for which we used 3.0 as an average of the dielectric constants of ether-like solvents. After we had finished this work, Takeshita and Hirota[16] discussed the physical meaning of the ε value. They used it as an adjustable parameter in intimate correlation with the $r_{M\mu}$ value.

27) J. M. Gross, J. D. Barnes, and G. N. Pillans, *J. Chem. Soc.*, *A*, **1969**, 109.

28) K. Nakamura, This Bulletin, **40**, 1 (1967).

29) Here note that there are two shallow potential minima at $\phi=50°$ and $-50°$ (see Fig. 3b), especially in the case of small-size alkali-metal ion pairs. These positions correspond to those where the lone-pair orbitals at each oxygen atom of the nitro group interact with an alkali ion. Previously, Nakamura[28] indicated the possibility of those potential minima in his qualitative discussion.

30) G. W. Canters, C. Corvaja, and E. de Boer, *J. Chem. Phys.*, **54**, 3026 (1971). In this paper it was theoretically emphasized that the charge-transfer process from doubly-occupied aromatic π MO's to the atomic orbitals (especially the ns orbital) of an alkali metal cation plays also a very important role in explaining the metal-spin density (particularly the negative spin density) in alkali-radical ion pairs.

the $a_N^{NO_2}$ values of alkali-metal ion pairs of halogen-substituted nitrobenzenes.

Now, let us turn to a discussion of the energy level of lone-pair orbitals. The calculation for the $4NPO^{\cdot-}$—K^+ ion pair indicated that the use of a deeper Coulomb integral for the oxygen lone-pair orbitals (α_l), compared to that of the carbon π orbital resulted in a smaller energy difference between two points, A (σ type ion pair) and B (π type ion pair), in Fig. 3A. The adoption of the deeper α_l value indicates a smaller interaction of lone-pair orbitals with the vacant s orbital of alkali-metal cations. Thus, the charge-transfer effect from the lone-pair orbitals to the s orbital becomes small, resulting in the structure of the above σ-type ion pair becoming unstable.

Last, we would like to add an experimental finding on the K^+ ion pair of the 4-nitropyridine ainon radical ($4NP^{\cdot-}$), the ESR spectrum of which is shown in Fig. 4 (see also Table 1 for the hfs values of each atom) and which was obtained under almost the same conditions as in the case of the $4NPO^{\cdot-}$–K^+ ion pair. The temperature dependence of the a_K and $a_N^{NO_2}$ values is quite similar to that of the $4NPO^{\cdot-}$–K^+ ion pair previously discussed in detail. Therefore, the nature of the $4NP^{\cdot-}$–K^+ ion pair seems to be the same as that of the $4NPO^{\cdot-}$–K^+ ion pair; *i.e.*, the K^+ ion would interact with the nitro-group oxygen atoms in the 4NP anion radical. This conclusion is the same as was derived from the study of the hydrogen-bonding effect on the ESR spectra of the 4NP anion radical,[3] where the active sites participating in the hydrogen-bonding interaction are nitro-group oxygen atoms.

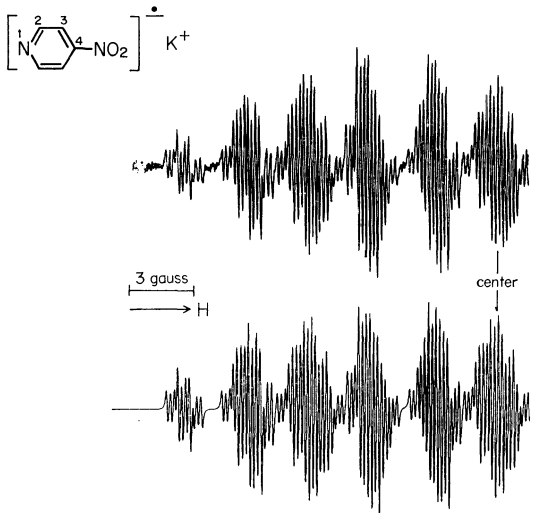

Fig. 4. Recorded (upper) and simulated (lower) ESR spectra of potassium ion pair of 4-nitropyridine anion radical observed at −20°C. See also Table 1 footnote a.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 741—744 (1973)

The Bromine Nuclear Quadrupole Resonance of Two Modifications of Indium Tribromide

Tsutomu OKUDA, Yoshihiro FURUKAWA, Hiroko SHIGEMOTO, and Hisao NEGITA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received June 29, 1972)

The bromine nuclear quadrupole resonance study of indium tribromide has revealed that there are at least two modifications in its solid state. The high-temperature modification shows the two ^{81}Br resonance lines of 85.985 and 86.205 MHz, with the relative intensity of 1 : 2 at 24.5°C. This modification was stable unless the temperature was lowered to ~15°C. The low-temperature modification shows one ^{81}Br resonance line, 86.915 MHz, at −196°C and was stable up to ~30°C. The directions of the z axes of the field gradient were determined by studying the Zeeman effect on each resonance line of the two modifications at room temperature. For the two resonance lines of the high-temperature modification, one and two directions, which had the asymmetry parameters of 0.362 and 0.400 respectively, were observed. The resonance line of the low-temperature modification showed three directions with the asymmetry parameter of 0.387. The crystal structures of the high- and low-temperature modifications were, therefore, concluded to be monoclinic and hexagonal respectively, from the numbers of resonance lines and of the nonequivalent directions of the z axes. The quadrupole coupling constants and asymmetry parameters were analyzed by means of the Townes-Dailey method.

Indium trihalides, InX_3 (X: Cl, Br, I), exist as dimers in the gaseous state,[1] but their crystal structures are not always the same. According to the X-ray diffraction analysis,[2] the crystal of $InCl_3$ has a layer structure in which every indium atom is octahedrally surrounded by chlorine atoms, and its space group is C2/m as in $AlCl_3$.[3] On the other hand, the crystal of InI_3 is made up of dimer molecules joined by iodine bridges,[4]

as in the gaseous state. As for $InBr_3$, the X-ray analysis has not yet been reported, as far as we know.

The results of the nuclear quadrupole resonance (NQR) of bromine in $InBr_3$ were reported previously by Ludwig[5] and Barnes *et al.*,[6] but they are not completely consistent. Barnes *et al.* studied extensively the NQR on the trihalides of Group IIIb elements and found that all the NQR spectra consist of a singlet on the lower-frequency side and a doublet on the higher-frequency side.[6,7] The ^{81}Br NQR spectrum of $InBr_3$ consists of the singlet of 86.912 MHz and the doublet of 106.974 and 107.428 MHz at −196°C. The former is ascribed to the bridging bromine atoms, while the latter is assinged to the terminal ones.

On the other hand, Greenwood *et al.* have reported the infrared and Raman spectra of InX_3.[8] According to their results, the spectra of $InBr_3$ are more similar to those of $InCl_3$ than those of InI_3; that is, the crystal of $InBr_3$ has a layer structure. This is contrary to the NQR results presented above.

We re-examined the ^{81}Br NQR of $InBr_3$ and, furthermore, observed the Zeeman effect on the NQR. We obtained different spectra from those reported previously; our results can be satisfactorily explained by the layer structure suggested by Greenwood *et al.*

Also, the study of the temperature dependences of the NQR frequencies revealed the existence of at least two modifications in $InBr_3$ crystals. The high-temperature modification shows two resonance lines, while the low-temperature modification shows only one resonance line. The measurements of the NQR Zeeman effect were made on these two modifications.

Experimental

The sample of $InBr_3$ was purchased from Katayama Chemical Industries Co., Ltd., and was purified by sublimation. The single crystal necessary for the study of the Zeeman effect was grown by the Bridgman-Stockbarger method.

The NQR spectrometer used in these experiments was a super-regenerative oscillator with frequency modulation; the absorption lines were observed on an oscilloscope. The resonance frequencies were determined with a VHF signal generator and a frequency counter, TR-5578, from the Takeda Riken Industry Co., Ltd. The Zeeman effect was examined by means of the zero-splitting cone method used in a low-magnetic field. The magnetic field of about 200 G was applied by means of a Helmholtz coil, and the patterns of the zero-splitting loci were determined at room temperature. The temperature dependences of the resonance frequencies were measured by using a thermostat from the Takara Kogyo Co. After the sample had been cooled or heated at a fixed temperature for 30—60 min, the resonance frequencies were determined.

Results and Discussion

The ^{81}Br NQR frequencies of $InBr_3$ observed in our experiment are presented in Table 1. Those for ^{79}Br were observed at frequencies corresponding to the frequency ratio (1.197) of $\nu(^{79}Br)/\nu(^{81}Br)$. The crystals of $InBr_3$ commercially obtained or purified by sublimation always show two closely-spaced resonance lines at room temperature. The intensity ratio of the higher line (ν_{β_2}) to the lower (ν_{β_1}) is approximately 2: 1. These results indicate that there are two kinds of non-equivalent bromine atoms in the crystal and that their abundance ratio is 2: 1. On cooling, this modification is apparently transformed to the other one, which shows only one resonance line. Tentatively we will refer to the former as the β-modification and to the latter as the α-modification.

Table 1. ^{81}Br nuclear quadrupole resonance frequencies in the modifications of indium tribromide

Modification		Resonace frequency[a] (MHz)		
		−196°C	24.5°C	49°C
α	ν_α	86.915	85.962	.....
β	ν_{β_1}	.....	85.985 (1)[b]	85.867 (1)
	ν_{β_2}	.....	86.205 (2)	86.074 (2)

a) Experimental error is ±0.01 MHz.
b) The value in parenthesis is the relative intensity.

The resonance frequencies in Table 1 are close to that of the bridging bromine atom reported by Barnes *et al.*[6] Especially, the resonance frequency of the α-modification (ν_α) at −196°C is consistent within the limits of experimental error. We scanned carefully the frequency regions around 105 and 125 MHz, where the resonance frequencies of the terminal ^{81}Br and ^{79}Br atoms in the dimer have been reported by Barnes *et al.*,[6] but we could not detect any resonance line.[9] Therefore, we concluded that neither of the modifications observed here is composed of dimers.

The temperature dependences of the resonance frequencies were measured between −48 and 49°C, as is shown in Fig. 1. The transition point is hard to determine because of the large hysteresis. In the course of cooling the single crystal of the β-modification, an absorption line of the α-modification appeared at ~15°C. On warming, the signal of the α-modification was observed up to ~30°C. Using the powder sample, the region of the hysteresis spread as may be seen in Fig. 1. Furthermore, in the temperature range from −6 to −16°C, the absorption lines of both the α- and β-modifications were observed.

The β-Modification of Indium Tribromide. The single crystal of $InBr_3$ initially obtained had the β-modification, because it was crystallized from the melt. The patterns of zero-splitting were obtained on each resonance line. For the bromine atom (I=3/2), the

9) The sensitivity of the spectrometer was confirmed by the detection of ^{127}I resonance line of InI_3 for 125 MHz region. The ^{79}Br resonance lines of $AlBr_3$ and also, of $InBr_3$ give the enough sensitivity for 105 MHz region.

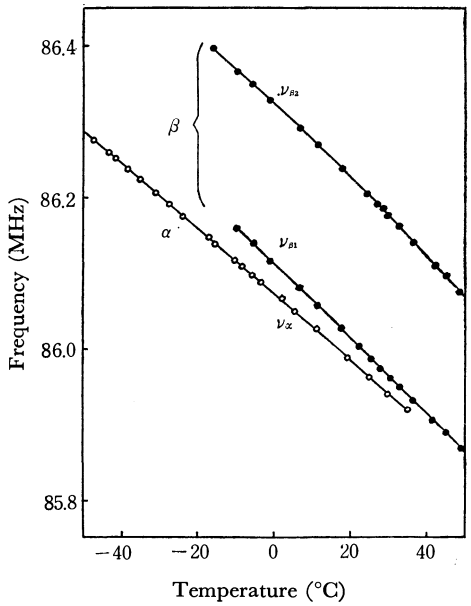

Fig. 1. Temperature dependences of ^{81}Br nuclear quadrupole resonance frequencies in indium tribromide.

zero-splitting occurs under the following conditions:[10]

$$\sin^2\theta = 2/(3-\eta\cos 2\varphi), \qquad (1)$$

where the orientation of the magnetic field is expressed by the polar coordinates (θ,φ) with respect to the coordinates of the principal axes (x, y, and z axes) of the field gradients at the resonant nuclei and where η is an asymmetry parameter of the field gradient. In this way, a cone about the z axis can be drawn by θ and φ which satisfies Eq. (1). The axes corresponding to $\varphi=0$ and $\varphi=\pi/2$ are shown by the x and y axes respectively. Only one zero-splitting pattern was obtained for ν_{β_1}, whereas two patterns were observed for ν_{β_2}. The experimental results are shown in Fig. 2, where Z_1, Z_{2A}, and Z_{2B} are the directions of the z axes at the bromine atoms contributing to ν_{β_1} and ν_{β_2}. From the number of the z axes of ν_{β_1} and ν_{β_2}, the symmetry of the β-modification must be lower than the tetragonal,

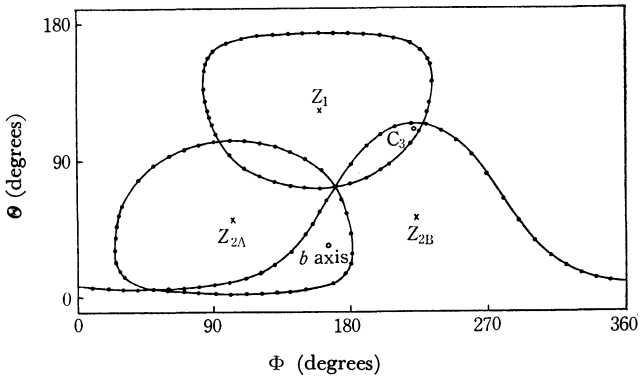

Fig. 2. Zero-splitting patterns of the Zeeman effect of the β-modification of indium tribromide. Θ and Φ are polar and azimuthal angles in the coordinates fixed to the sample respectively.

but not the triclinic.[11] However, as a symmetry higher than the monoclinic is ruled out by the requirement for the angles between the z axes, it can be concluded that the β-modification belongs to the monoclinic space group. The asymmetry parameters of the field gradient were determined from Eq. (1) by the use of the least-squares method. As may be seen in Table 2, large values of η were obtained.

Table 2. Asymmetry parameters and quadrupole coupling constants for ^{81}Br in indium tribromide at room temperature

Modification		η	e^2Qq/h(MHz)	Up
α	(ν_α)	0.387±0.005	167.79	0.2609
β	(ν_{β_1})	0.362±0.002	168.33	0.2618
	(ν_{β_2})	0.400±0.007	167.99	0.2612

Greenwood *et al.* suggested that the crystal structure of $InBr_3$ is similar to that of $InCl_3$ or $AlCl_3$.[8] In the case of the $AlCl_3$-type structure, there are two non-equivalent halogen atoms which form slightly different bridges. Therefore, the low-resonance frequencies and the large asymmetry parameters may be attributed to the bridging bromine atoms in the β-modification. Also, it is reasonable, in view of this structure, that the β-modification shows two resonance lines with the intensity ratio of 1 : 2 and that the zero-splitting patterns observed are one for ν_{β_1} and two for ν_{β_2}. Table 3

Table 3. Angles between the z axes and the b axis in the β-modification of indium tribromide

	Z_1-Z_2	$Z_{2A}-Z_{2B}$	Z_1-b axis	Z_2-b axis
NQR	92°08′	88°16′	90°	44°08′
X-Ray[a]	90°27′	88°26′	90°	44°13′

a) These values were calculated from the atomic positions of $AlCl_3$. (Ref. 3).

shows the angles between the z axes and the b axis of the monoclinic lattice as determined by the Zeeman effect. The values in the second row are calculated from the atomic positions of $AlCl_3$,[3] because the data of X-ray analysis are not available for $InBr_3$. In this calculation, the z axis was assumed to be directed perpendicularly to the plane including M–X–M, as in the case of a bridging halogen atom of the dimer molecule.[12,13] The results of the NQR and those of the X-ray analysis are in good agreement, though the latter are derived for a related compound, $AlCl_3$. Accordingly, it seems most likely that the β-modification is isomorphous with $AlCl_3$. This conclusion is further supported by the fact that Zeeman patterns similar to those in Fig. 2 have been found in $ErCl_3$, which has an $AlCl_3$-type structure, by Carlson and Adams.[14]

The α-Modification of Indium Tribromide. When the single crystal of the β-modification mounted on the apparatus was cooled to about −50°C by means of a cold stream of nitrogen gas from liquid nitrogen, it was transformed to the single crystal of the α-modification. The measurements of the zero-splitting on this modification show three different directions of the z axes, indicating that the crystal of the α-modification has a threefold axis.[15] In Fig. 2, C_3 indicates the orientation of this threefold axis of the α-modification at the same coordinates of the β-modification. The compound that possesses three nonequivalent directions of the z axes belongs, in general, to the hexagonal (point group C_3 or C_{3i}) system or, in special cases, to another hexagonal or cubic system. In this case, however, the cubic system, which has three z axes orthogonal with one another,[11] can be excluded because the observed angle between the z axes is 92°13′.

The zero-splitting patterns of the α-modification are very similar to those of the β-modification. The directions of the z axes of the α-modification deviate from the relevant axes of the β-modification to a small degree. It can, therefore, be expected that the crystal structure of the α-modification is slightly different from that of the β-modification; that is, the crystal of the α-modification may be composed of a polymeric layer lattice like $AlCl_3$. In view of these results, it is likely to be of the BiI_3-type, the structure of which is closely related to the $AlCl_3$-type[16] and which has the space group $R\bar{3}$.[17] The ^{127}I NQR of BiI_3 indicates only a resonance line and a large asymmetry parameter of the field gradient.[18] The transition may occur between monoclinic and hexagonal systems, as in the case of $CrCl_3$ reported by Morosin and Narath.[19]

The crystal of $InBr_3$ is easily cloven along the plane perpendicular to the threefold axis, which may be parallel to the c axis of the hexagonal unit cell. The b axis of the monoclinic lattice of the β-modification was perpendicular to the threefold axis of the α-modification; that is, it was parallel to the cleavage plane.

It is interesting to notice that $InBr_3$ has a higher melting point (436°C) than those of the other Group IIIb trihalides which form dimers in the crystal (*e.g.*, 210°C for InI_3[20]) and that the ratio of the ionic radii for In^{3+}/Br^- is 0.42. This value is slightly larger than the lower limiting ratio, 0.414, for the octahedral coordination of the metal atom. In view of these points, $InBr_3$ can be expected to form an infinite layer lattice, as is proposed by this experiment.

Bond Character. The analyses of the Zeeman effect of $InBr_3$ reveal a close relation between the α- and β-modifications. Such a result as above can also be seen from Tables 1 and 2, *i.e.*, the resonance frequencies and the asymmetry parameters in both modifications are almost the same.

The observed x axis of the field gradient at the bromine atom is directed nearly along the bisector of In–Br–In and the y axis is parallel to the In–In direction. The z axis is perpendicular to the plane including In–Br–In, as has been explained before. From these coordinates of the principal field gradients, we can construct the hybrid orbitals of the bromine atom to bind with two indium atoms. Using the Townes and Dailey theory and appropriate approximations, the following two equations are found to hold for the NQR parameters:[21]

$$\eta = -3\cos\alpha, \tag{2}$$

$$Up(1+\eta/3) = 2 - a, \tag{3}$$

where a is the electron population in the bonding orbital directed to the indium atom and where α is the interbond angle, ∠In–Br–In. Up is the number of unbalanced p electrons and can be determined from the observed quadrupole coupling constant, e^2Qq_{obsd}:

$$h\nu = 1/2e^2Qq_{obsd}(1+\eta^2/3)^{1/2}, \tag{4}$$

$$Up = e^2Qq_{obsd}/e^2Qq_{atom} \tag{5}$$

where e^2Qq_{atom}/h is 643.03 MHz.[22]

Substituting the observed values of η and Up into Eqs. (2) and (3), we obtain $a=1.7$ as the mean value, which gives a negative charge of $0.4e$ on the bromine atom. This ionic character is smaller than the 55% expected from the electronegativity difference between indium and bromine. This discrepancy may be due to the crystal field exerted by the neighboring nuclei. The angles of In–Br–In are deduced to be 96°56′∼97°40′. These values are somewhat larger than the relevant angles, 94°20′ and 95°30′ for $AlCl_3$.

15) The NQR Zeeman analysis always introduces the center of symmetry. It is impossible to distinguish between the threefold rotation axis and the threefold inversion axis on the basis of the Zeeman analysis. (Ref. 11).

Photochemistry of Acridines. XIX. Photoreduction of Acridine in Mixed Solvents

Mikio HOSHINO and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai

(Received March 1, 1972)

The photoreduction of acridine has been investigated in three kinds of mixed solvents, benzene–isopropanol, benzene–methanol and benzene–cyclohexane, all in aerated and deaerated conditions. The following general tendensies have been found for the plot Φ_{rel} *vs.* mole fraction. It is approximately linear or slightly concave upward for molecular mechanism, while convex upward for radical mechanism. This indicates that for molecular mechanism a cage model trapping two radicals (*e.g.* C-radical and alcohol radical) is unsuitable while one act process involving two reactive sites is suitable.

Photoreduction of acridine in H-donating solvents occurs *via* dual mechanisms, molecular and radical. In general, the contribution of excited singlet state and triplet (n-π^*) state to each mechanism depends upon the nature of the solvent. In the case of isopropanol both mechanisms occur only in the singlet excited state, while in methanol both singlet and T(n-π^*) contribute to radical mechanism and molecular mechanism occurs mainly in the singlet excited state.[1] The case is essentially the same with ethanol and *n*-propanol. However, the feature is quite different in cyclohexane, radical mechanism occurring only in singlet excited state and molecular mechanism only in T(n-π^*).[2] The cause of such behavior still remains unclarified.

Concerning the meaning of radical and molecular mechanisms, the former is a mechanism in which half-reduced acridine is produced as an intermediate and is captured by the oridinary flash technique. In the latter no transient intermediate is observed by the flash technique in contrast to radical mechanism. It is still unknown whether it really occurs as one act or occurs *via* a transient intermediate too short-lived to be captured by the flash technique. Even the possibility that an intermediate in this mechanism is two radicals, *e.g.* acridine semiquinone and alcohol radical trapped in one cage is conceivable. In fact, Zanker and Prell[3] distinguished two mechanisms resembling radical and molecular ones and proposed a cage-like model for the photoreduction of 9-CH_3-acridine by ethanol.

To elucidate the problem, we have studied photoreduction in three mixed solvents, *i.e.*, 2-propanol, methanol and cyclohexane containing various amounts of benzene. They are the three H-donors which display distinct features of the reaction as listed below.

	Molecular mech.	Radical mech.
2-Propanol	singlet	singelt
Methanol	singlet, very littleT(n-π^*)	singlet, T(n-π^*)
Cyclohexane	T(n-π^*)	singlet

If the transient intermediate in molecular mechanism are two radicals trapped in a cage, the contribution of molecular and radical mechanisms will change with a certain correlation depending upon the composition of the solvent. Thus the stability of radicals trapped in the cage will depend upon its structure and nature which varies according to the composition of the solvent. Therfore, if the structure changes in such a way as to make it easy for the two radicals to separate from each other, the molecular mechanism will be transformed to radical mechanism by the amount determined by the cage structure. On the other hand, if the two mechanisms occur independent of each other, or if molecular mechanism occurs *via* a path completely different from the path involving semiquinone, they will show different dependencies upon the composition of the solvent, characteristic of each mechanism.

An outline is given on the method to determine the contribution of singlet excited state and T(n-π^*) state to molecular and radical mechanisms. The quantum yields due to radical (Φ_R) and molecular mechanism (Φ_M) can be discriminated in a simple way. Since the half-reduced acridine is oxidized back entirely to acridine in the aerated solution, the quantum yield experimentally obtained in the aerated solution gives Φ_M, and Φ_R can be obtained as the difference between the quantum yields in the aerated and deaerated solutions.

The contribution of singlet excited state and triplet state T(n-π^*) (the lowest T(π-π^*) of acridine is unreactive) to two mechanisms, $\Phi_M{}^S$, $\Phi_M{}^T$ ($\Phi_M=\Phi_M{}^S+\Phi_M{}^T$), $\Phi_R{}^S$ and $\Phi_R{}^T$ ($\Phi_R=\Phi_R{}^S+\Phi_R{}^T$) can be obtained from the quenching experiment using biacetyl as a quencher.[1,2] The triplet state of biacetyl being located a little lower than acridine T(n-π^*), the triplet energy transfer occurs from the latter to the former at fairly low concentrations of biacetyl. It was established[1] that the singlet excited state of acridine which is considered to be much shorter-lived than that of T(n-π^*) is also deactivated at higher concentrations of biacetyl. Thus, the quenching experiment with biacetyl in the aerated solution can, in principle, distinguish $\Phi_M{}^S$ from $\Phi_M{}^T$. Similarly $\Phi_M{}^T+\Phi_R{}^T$ and $\Phi_M{}^S+\Phi_R{}^S$ can be separated experimentally for the deaerated solution. Since $\Phi_{tot}=\Phi_M{}^S+\Phi_M{}^T+\Phi_R{}^S+\Phi_R{}^T$, $\Phi_M{}^S+\Phi_M{}^T$, $\Phi_M{}^S$, $\Phi_M{}^T$, $\Phi_M{}^T+\Phi_R{}^T$ and $\Phi_M{}^S+\Phi_R{}^S$ are determined experimentally, $\Phi_M{}^S$, $\Phi_M{}^T$, $\Phi_R{}^S$, and $\Phi_R{}^T$ can be evaluated in general. The procedures are more simplified in many cases.

Experimental

Acridine was purified by recrystallization twice from

aqueous ethanol. Biacetyl was purified by distillation immediately before use. All the solvents used were purified by standard methods. As a light source of 365 nm, a 100 W high pressure mercury lamp was used with suitable filters. All the measurements were made at 25°C.

Results

Quantum Yields of the Photoreduction of Acridine in Mixtures of 2-Propanol–Benzene and Cyclohexane–Benzene. The quantum yields in the mixed solvents of various composition were measured for aerated and deaerated conditions, the former dealing with molecular mechanism. The quantum yields due to radical mechanism were calculated from the difference of the two. In

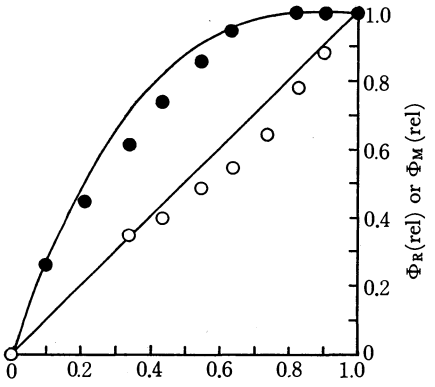

Fig. 1. Plots of Φ_R(rel) (●) and Φ_M(rel) (○) against the mole fraction of 2-propanol. A curve and a straight line are the calculated ones from the following equation by putting $n=3$ and 1 respectively.

$$\Phi_{rel}=1-(1-X)^n$$

Fig. 1, the relative values of Φ_M and Φ_R for a mixture of benzene and 2-propanol are plotted against the mole fraction. Only singlet excited state participates in the reaction and we have $\Phi_M=\Phi_M{}^S$ and $\Phi_R=\Phi_R{}^S$. It is seen that the former is approximately linear or a little concave upward and the latter convex upward. Figure 2 shows the results obtained for a mixture of benzene

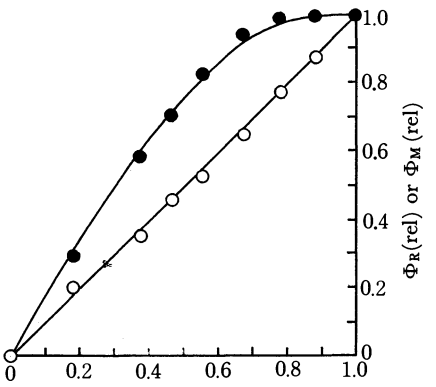

Fig. 2. Plots of Φ_R(rel) (●) and Φ_M(rel) (○) against the mole fraction of cyclohexane. A curve and a straight line are the calculated ones from the following equation by putting $n=3$ and 1 respectively.

and cyclohexane. The curves for Φ_M(rel) and Φ_R(rel) are very similar to the corresponding ones in Fig. 1. In this case we have $\Phi_M=\Phi_M{}^T$ and $\Phi_R=\Phi_R{}^S$. It is interesting that the characteristic feature of Φ_M(rel) is independent of the reactive state.

Quantum Yields of the Photoreduction of Acridine in a Mixture of Benzene and Methanol. The results are shown in Figs. 3 and 4. The plot for molecular mechanism resembles those of the above two systems though the degree of curvature is somewhat larger, but the plot for radical mechanism is quite different. The shape of the plot $(\Phi_R{}^T+\Phi_R{}^S)/\Phi_{tot}(CH_3OH)$ ($\Phi_{tot}(CH_3OH)$ is the value for pure methanol) suggests the superposition of the two components, one resembling the Φ_R plot of the previous systems (convex upward) and the other approximately a straight line.

Anticipating that this is due to the fact that T(n-π^*) in addition to singlet excited state contributes to radical mechanism, we have attempted to discriminate the two contributions $\Phi_R{}^T$ and $\Phi_R{}^S$. This has been done by examining the effect of the addition of biacetyl on the quantum yields of the photoreduction in the mixed solvent of composition, methanol: benzene=4:6, at which a component convex upward appears to approach a limiting value. In Fig. 5 the inverse of the relative quantum yield (in reference to the Φ-value in the absence of biacetyl) is plotted for the aerated and

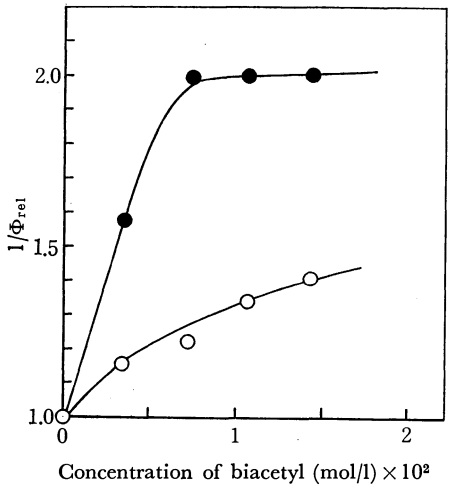

Fig. 5. Plots of $1/\Phi_{rel}$ for the degassed solution (●) and aerated solution (○) against the concentration of biacetyl. Solvent; methanol: benzene=4: 6 (in volume).

deaerated solutions, against biacetyl concentrations. The plot for the aerated solution deals with molecular mechanism to which singlet excited state mainly contributes. It is natural that the curve still increases at about 10^{-2}M. The plot for the deaerated solution apparently consists of two parts, one with a steep slope in the lower concentration region of biacetyl and the other with a very gradual slope in the higher concentration region. It is appropriate to relate the former to T(n-π^*) and the latter to the singlet excited state. We can estimate from the plot for the deaerated solution the value of Φ_R^T for the mixed solvent at methanol: benzene=4: 6, which was found to be 0.025_6. The value of Φ_R^T in pure methanol is 0.057—0.063.[1,2] The values of $\Phi_R^T/\Phi_{tot}(CH_3OH)$ are obtained by dividing the above two values by Φ_{tot} for pure methanol, 0.128.

It is seen that the contribution of T(n-π^*) to radical mechanism is approximately linear with respect to the volume fraction of methanol. Substracting this portion from the $(\Phi_R^R+\Phi_R^T)/\Phi_{tot}(CH_3OH)$, we obtain the Φ_R^S-values. The plots Φ_R^S(rel) *vs.* mole fraction and volume fraction are given in Fig. 6. The curves are convex upward and the limiting value is reached at a mole fraction of methanol of about 0.8.

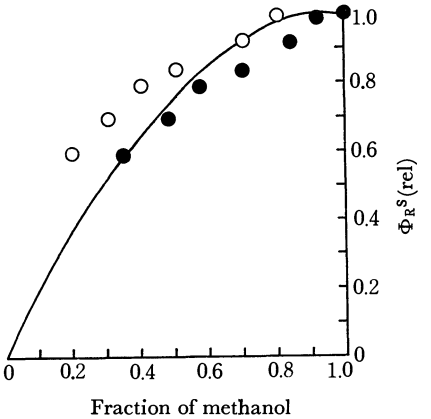

Fig. 6. Plots of Φ_R^S(rel) against the mole fraction (●) and against the volume fraction (○). The curve is a calculated one from the following equation by putting n=2.
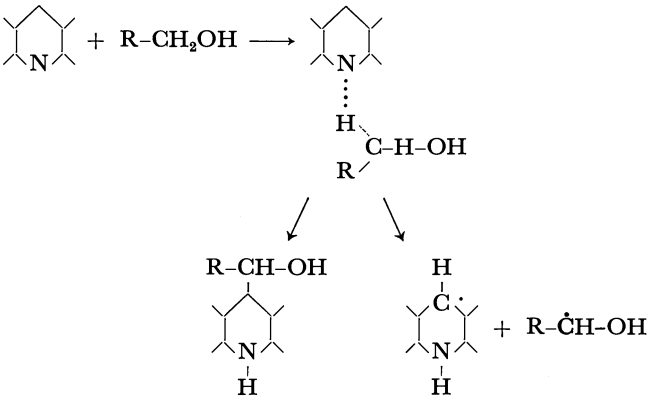
$\Phi_{rel}=1-(1-X)^n$

Discussion

From the present results we can say that the Φ_R(rel) *vs.* X plot and the Φ_M(rel) *vs.* X plot are not related with each other at all and that the two plots show their own characteristic dependency on the mole fraction. Therefore a cage model involving two radicals can not be adopted. Since the concentration of H-donor is high enough under the present conditions (from X= 0.1 to pure solvent), the behavior of semiquinone will not be affected by the composition of the solvent in view of a long lifetime of semiquinone (>msec).[4] Accordingly the present results deal mainly with the characteristics of the primary processes for molecular and radical mechanisms, which essentially depend on the nature of H-donor.

A plausible model for molecular mechanism is either (1) a one act process involving two reactive sites (N and 9-C of acridine) or (2) a consecutive reaction with a very short-lived intermediate (first, N-atom and secondly 9-C atom react).

For the latter, it is likely that the step of intermediate formation is common to radical mechanism as written schematically below,



It is thus expected that M- and R-mechanisms are related to each other in a certain way. If the first step is essential in determining the feature of reaction, the solvent dependence should be common to both mechanisms, whereas if the second step is the key-process, a similar deduction to that for the cage model should hold. Both expectations contradict the experimental results and it is thus most likely that the M- and R-mechanisms occur *via* different paths from the start.

In order to discuss the solvent dependence of Φ_M and Φ_R quantitatively, we should know the lifetime of the excited state. However, acridine is nonfluorescent in nonpolar solvents and the lifetime of the singlet excited state cannot be measured. Still less knwon is the solvent dependence of the lifetime.

We have found that the feature in the solvent dependence of M- and R-mechanisms is not related to the existence of OH group in a H-donor molecule which

4) A. Kira, S. Kato, and M. Koizumi, This Bulletin, **39**, 1221 (1966).

is attached to N of acridine *via* H-bonding. This seems reasonable for M-mechanism for which two site reaction occurs as one step but not so for radical mechanism, since the existence of specific interaction in the form of H-bonding is suspected to favor the reaction in which N of acridine is attacked by H-atom. One is tempted to consider that the upward convex shape of the Φ_R *vs.* X plot is due to this specific interaction which suppresses the dilution effect of benzene. However, this view does not hold because a similar dependence of Φ_R on X has been obtained in the case of cyclohexane for which no such interaction exists. It is therefore inferred that the relative positions of acridine and H-donor together with their configurations necessary for R-mechanism to occur are taken newly after acridine is excited and irrespective of the ground state configuration. This is reasonable because a hydrogen atom to be detached from alcohol is a α-H atom and not one of the OH group. Thus it is considered that for the reaction to occur, a molecule of H-donor must occupy a specific site, orientation and configuration relative to N of acridine. When such an effective encounter is realized, the reaction will occur with certain probability. Assuming the constant lifetime of the excited state, the rate can be determined by the number of occurrences of such an encounter.

If such a view is adopted, the Φ_R *vs.* X relation will be treated approximately by a site-jumping model. Neglecting energy factor and assuming that the probability for H-donor to occupy this effective configuration is merely proportional to mole fraction, the relative quantum yield for radical mechanism can be given by

$$\Phi_{rel} = 1 - (1-X)^n$$

where X is a mole fraction and n is the number of effective encounters (number of jumping) during the excitation.

This model is too crude to treat the present results quantitatively, but it seems suitable as one step in a mathematical approach to the problem. If one applies the formula to the present results, the values of n for radical mechanism are evaluated as follows. The numbers in parentheses are the values of n when volume fractions are used instead of mole fractions.

2-propanol	$n = 3$ (3)
cyclohexane	$n = 2$ (2)
methanol	$n = 2$ (3)

The results appear to be reasonable.

If the same model is applied to molecular mechanism the value of n becomes 1 or less than 1. However, the concave upward curve may partially be due to the excess inhibiting action of benzene. For instance, a larger size of benzene molecule than of methanol will reduce the occurrence of effective encounter.

The results obtained strongly suggest that M- and R-mechanisms are two independent reactions occurring *via* different paths from the start. However, the reasons for the following behaviors still remain unclarified.

1) T(n-π^*) participates in the case of methanol but not isopropanol.

2) Only R-mechanism occurs in S* in the case of cyclohexane while both R- and M-mechanisms occur in S* in the case of methanol.

3) Only M-mechanism occurs in T(n-π^*) in the case of cyclohexane, while R-mechanisms mainly occurs in T(n-π^*) in the case of methanol.

4) Linear relation holds between Φ_R^T and the volume fraction for methanol in contrast to the convex upward curve of Φ_R^{S*} *vs.* volume fraction in general.

Interaction between Excited β-Naphthol and Pyridine. Hydrogen-bond Formation in S* and H-Transfer Reaction in T

Koichi KIKUCHI, Hitoshi WATARAI, and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai

(Received July 10, 1972)

The interaction between the excited β-naphthol and pyridine in cyclohexane has been investigated by an absorption-emission flash technique. The triplet naphthol has been found to be deactivated by pyridine with the rate constant of $1.5—1.9\times10^{9}$ $M^{-1}sec^{-1}$, yielding naphthoxyl radical. With 10^{-4} M pyridine the triplet naphthol is completely transformed into naphthoxyl radical. Above 10^{-1} M pyridine naphthol exists almost exclusively as a H-bonded species in the ground state, which is non-fluorescent and produces no transient species detectable by an ordinary flash apparatus. For $10^{-4}—10^{-1}$ M pyridine, the singlet excited naphthol undergoes collisional deactivation which most likely leads to a H-bonded species (rate constant, $1.2—1.4\times10^{10}$ $M^{-1}sec^{-1}$). At the same time naphthoxyl radical is also produced with about the same rate constant as that for the triplet state. The results strongly suggest that the mechanism for the internal conversion of the singlet excited state *via* H-bonding is a transient H-atom transfer.

An interesting feature of fluorescence of a hydrogen-bonded compound is that two π-electronic systems, fluorescer and quencher combined in conjugation *via* a hydrogen bond, such as naphthol–pyridine,[1c,5] carbazole–pyridine[4] and acridine dye–naphthol[1b] have no emissivity in general. This phenomenon was extensively studied in particular by Mataga and his coworkers,[1-4] and was attributed to the delocalization of π-electrons *via* H-bond, which may naturally involve charge transfer interaction as is expected from the mechanism proposed for hydrogen-bonding.[6] This was exemplified by one of the present authors (M.K.);[5] quinoline acting as an acceptor in C–T interaction quenches the fluorescence of β-naphthylmethylether (donor) in *n*-hexane although the quenching constant is about half that for β-naphthol which forms hydrogen bond with quinoline.

In the case of carbazole–pyridine in methylcyclohexane–isopentane at 77 K, Mataga *et al.* demonstrated that H-bonding significantly enhances internal conversion but not the intersystem crossing.[4] However, it is still unknown whether this conclusion generally holds or not.

On the other hand, Rehm and Weller[7] proposed on theoretical grounds that the mechanism of fluorescence quenching for naphthol–pyridine, benz(*c*)acridine–phenol is due to the transient hydrogen transfer. Thus it is desirable to study the effect of H-bonding on the two nonradiative processes in a more direct way at room temperature, and to study whether hydrogen transfer actually occurs and if so to study the correlation between H-bonding and H-transfer. In order to tackle these problems we have applied the absorption-emission flash technique[8] to the naphthol–pyridine system, measuring the triplet yield and the time-integrated fluorescence intensity of naphthol with one sample.

Experimental

Materials. β-Naphthol (G.R. grade, Wako Junyaku) was recrystallized twice from a mixed solvent of water and ethanol, and then sublimed twice *in vacuo*. β-Naphthylethylether synthesized by a standard method was recrystallized five times from ethanol and sublimed *in vacuo*. Cyclohexane and pyridine were purified by the standard method. Triethylamine (G.R. grade, Wako Junyaku) was used without further purification.

Apparatus and Procedure. Absorption spectra were measured with a Hitachi EPS-3T spectrophotometer. The fluorescence intensity was measured with a specially constructed fluorometer. The flash apparatus was modified so that two or three phenomena could be observed simultaneously. The energy of a flash was usually about 130 Joule and its half duration was about 10 μsec. A Hoya-U2 filter was used for excitation. All the measurements were made in cyclohexane solutions at room temperature; the solutions were degassed by pump and thaw method unless otherwise stated. The peak heights in the fluorescence spectra were used as a measure of fluorescence intensity since fluorescence spectra of β-naphthol were not affected by the addition of pyridine. The methods of measuring transient absorption spectra and the time-integrated fluorescence intensities during flashing were essentially the same as reported.[8]

Outline of Method. In principle, the absorption-emission flash technique is expected to be applicable for studying quantitatively the responsibility of internal conversion and intersystem crossing to the nonradiative process.

The triplet yield $[T]_0$ is related with the total quantity of light absorbed during one flash by

$$[T]_0 = \tilde{\phi}_{ST}\int I_{ab}dt \qquad (1)$$

and the time integrated fluorescence intensity (measured at λ') during a flash is given by

$$\int I_f(\lambda')dt = \alpha(\lambda')\tilde{\phi}_f\int I_{ab}dt \qquad (2)$$

where $\tilde{\phi}_f$ and $\tilde{\phi}_{ST}$ are the eventual fluorescence quantum

yield and intersystem crossing probability, respectively and $\alpha(\lambda')$ is a constant depending upon the setup of the apparatus and experimental conditions. It should be noted that $\tilde{\phi}_f$ and $\tilde{\phi}_{ST}$ are not constant but depend upon the composition of the solution. From (1) and (2) we have

$$[T]_0/\int I_f(\lambda')dt = \tilde{\phi}_{ST}/\alpha(\lambda')\tilde{\phi}_f \quad (3)$$

For the present system, the emitter of fluorescence is only the free naphthol molecule as verified experimentally. Thus, putting a fraction of light absorbed by free naphthol as δ and using the genuine ϕ_f, Eq. (2) can be rewritten as follows, where A is pyridine acting as a proton acceptor and k_q is the overall quenching constant.

$$\begin{aligned} &\int I_f(\lambda')dt = \alpha(\lambda')\delta\phi_f\int I_{ab}dt \\ &\phi_f = k_f/\{(k_d+k_f)+k_q[A]\} \\ &k_d = k_i + k_c \end{aligned} \quad (4)$$

(i, internal conversion; c, intersystem crossing)

The intersystem crossing is in general involved in the collisional quenching for free species, occurring also for the H-bonded species. Thus Eq. (1) is most generally rewritten as follows.

$$[T]_0 = \delta\int I_{ab}dt \times (k_{ST}+k_q^c[A])/(k_d+k_f+k_q[A]) + (1-\delta)\frac{k_c'}{k_i'+k_c'}\int I_{ab}dt \quad (5)$$

where k_q^c is the rate constant for the collision induced intersystem crossing, $k_c=k_{ST}$ and $'$ stands for hydrogen-bonded species. Hence

$$\frac{[T]_0}{\int I_f(\lambda')dt} = \frac{k_{ST}+k_q^c[A]}{k_f\alpha(\lambda')} + \frac{(1-\delta)}{\delta}\frac{k_c'}{\alpha(\lambda')k_f}\gamma \quad (6)$$

or

$$\tilde{\phi}_{ST}/\tilde{\phi}_f = (k_{ST}+k_q^c[A])/k_f + (1-\delta)k_c'\gamma/\delta k_f \quad (7)$$

where

$$\gamma = (k_d+k_f+k_q[A])/(k_i'+k_c')$$

On the basis of the above equation, we may obtain information on the rate constants k_q^c, k_i', and k_c', if we know some fundamental constants for the solution of β-naphthol including ϕ_{ST} and if we measure $[T]_0$ and $\int I_f(\lambda')\,dt$ at various pyridine concentrations.

Results and Discussion

First the ground state hydrogen bonding equilibrium of naphthol-pyridine in cyclohexane was investigated. The spectroscopic procedures and the method of evaluating the equilibrium constant K from them are similar to those in *n*-hexane.[5]

The value of K at 16°C was evaluated as $140M^{-1}$. This is compared with $K=125$, 61 in *n*-hexane at 21 and at 42°C respectively.[5]

Quenching of Fluorescence by Pyridine. The fluorescence behavior of β-naphthol influenced by the addition of pyridine in cyclohexane is also similar to that in *n*-hexane.[5] Thus the significant quenching occurs without any spectral change. Therefore, the same method of analysis can be applied if we assume the non-emissivity of hydrogen-bonded species. The equation[5]

$$\frac{F_0/F-1}{[A]} = \left(k_q\tau_0+\frac{\varepsilon'}{\varepsilon}K\right) + k_q\tau_0\frac{\varepsilon'}{\varepsilon}K[A] \quad (8)$$

can easily be derived from the scheme below. (In practice, the exciting wavelength was chosen so that $\varepsilon(\lambda)$ is equal to $\varepsilon'(\lambda)$. ε and ε' are the molar extinction coefficients of free naphthol and H-bonded species respectively.)

(I)
- i) $D + A \rightleftharpoons DA$ K (equilibrium constant)
- ii) $DA \xrightarrow{h\nu} DA^*$
- iii) $DA^* \longrightarrow DA$ $(k_i'+k_c')$
- iv) $D \xrightarrow{h\nu} D^*$
- v) $D^* \longrightarrow D + h\nu'$
- vi) $D^* \longrightarrow D$ $k_d = k_i + k_c$
- vii) $D^* + A \longrightarrow D + A$ k_q

Thus the collisional quenching vii) is superposed on the static quenching i) and iii). In a previous paper,[5] it was assumed simply that process vii) consists of the formation of hydrogen bond in the excited state followed by a rapid degradation of electronic energy.

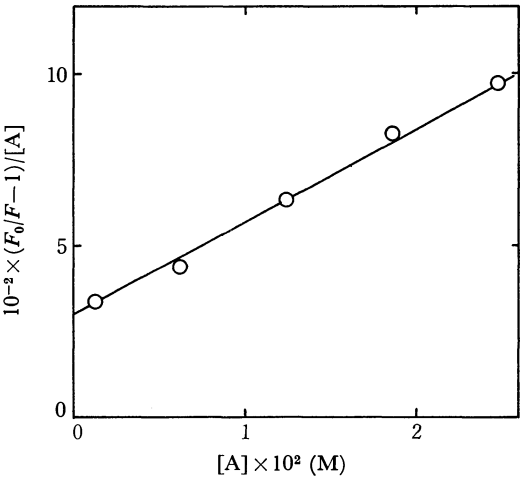

Fig. 1. The plot of $(F_0/F-1)/[A]$ *vs.* [A].

Figure 1 shows the plot of $(F_0/F-1)/[A]$ against [A]. By using $K=140M^{-1}$, we evaluate the value of $k_q\tau_0$ as $160—190M^{-1}$. This is compared with the previous $k_q\tau_0$-value of 120 (21°C) in *n*-hexane. Putting $\tau_0=13.3$ nsec,[9] we obtain $k_q=1.2—1.4\times10^{10}M^{-1}\,sec^{-1}$. Thus the collisional quenching occurs with the diffusion controlled rate constant.

Reaction between Triplet Naphthol and Pyridine. We first investigated the interaction between triplet naphthol and pyridine at low pyridine concentrations. Below $10^{-4}M$ of pyridine, the formation of H-bonded species in the ground state and the dynamic quenching of the singlet excited naphthol can be neglected as judged from the values of K, τ_0, and k_q obtained above.

Figure 2 gives a transient absorption spectrum obtained when the deaerated sloution of β-naphthol in cyclohexane is flashed; it does not appear in the aerated solution. This spectrum is attributed to the triplet-triplet absorption because of its close resemblance to the

9) J. B. Barlman, "Handbook of Fluorescence Spectra of Aromatic Molecules," Academic Press, New York, N.Y. (1965), p. 114.

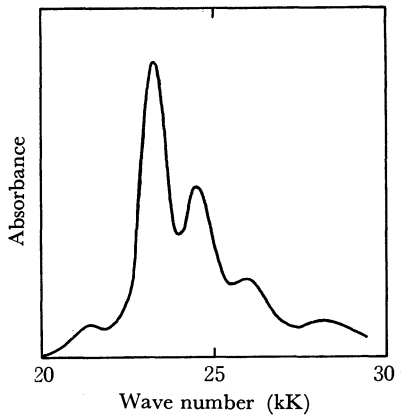

Fig. 2. T–T absorption spectrum of β-naphthol.

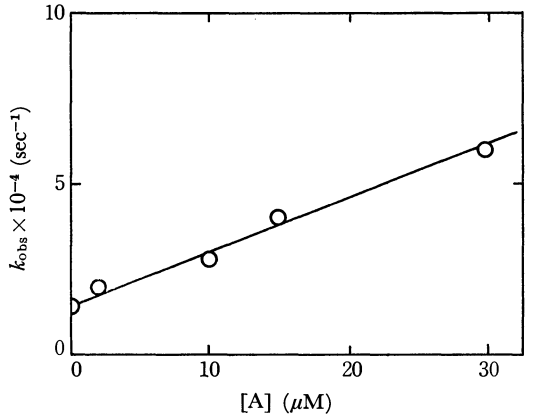

Fig. 3. The relation between the observed first order decay constant of β-naphthol triplet and pyridine concentration.

spectrum in literature.[10,11] For the sake of confirmation, T–T energy-transfer was ascertained to occur from β-naphthol to perylene. The decay was of first order with the rate constant 1.5×10^4 sec^{-1}.

The decay rate of triplet β-naphthol increased with increasing pyridine concentration. As shown in Fig. 3, the observed rate constant is satisfactorily linear with respect to [A].

$$k_{obs} = k_{dt} + k_{qt}[A]$$

where subscript t stands for triplet. From the intercept and inclination of the plot, we obtain

$$k_{qt} = 1.5\times10^9\ M^{-1}\ sec^{-1} \qquad k_{dt} = 1.5\times10^4\ sec^{-1}$$

For pyridine concentrations higher than 10^{-4}M, quite a different spectrum as shown in Fig. 4 completely replaces the T–T absorption spectrum. The spectrum decays as a second order process with the rate constant k/ε—1.9×10^6 cm sec^{-1} (at 470 nm). The yield measured at the end of flashing increases with increasing pyridine concentrations up to 10^{-4}M. Since in this concentration region of pyridine, neither the formation of H-bond species in the ground state nor the collisional quenching of singlet excited naphthol by pyridine scarcely occurs, there is no doubt that this species (R)

10) G. Jackson and G. Porter, *Proc. Roy. Soc. Ser. A.*, **260** 13 (1961).

11) E. J. Land, G. Porter, and E. Strachan, *Trans. Faraday Soc.*, **57**, 1885 (1961).

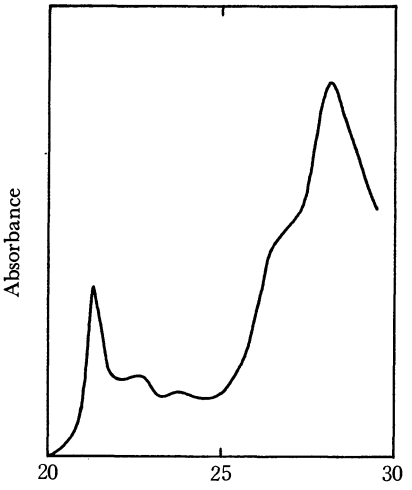

Fig. 4. The absorption spectrum of β-naphthoxyl radical.

is produced by the reaction between triplet naphthol and pyridine. In fact it was confirmed that at 10^{-4}M of pyridine, the decay of triplet is accompanied by the build-up of R. Assuming the scheme

$$\text{(II)}\quad \begin{cases} \left.\begin{array}{ll} \text{v)} & D \xrightarrow{h\nu} D^* \\ \text{viii)} & D^* \longrightarrow D^T \end{array}\right\} \phi_{ST} I_{ab} \\ \text{ix)} \quad D^T \xrightarrow{k_{dt}} D \\ \left.\begin{array}{ll} \text{x)} & D^T \xrightarrow{A} R \quad (k_{qt}^r) \\ & \searrow^{A} D + A \end{array}\right\} k_{qt} \end{cases}$$

the yield of R at the end of a flash is given as follows ($I_{ab}{}^0=\int I_{ab}dt$. $D_R{}^0$, optical density (at 470 nm) at the end of a flash).

$$[R]_0 = \frac{D_R{}^0}{\varepsilon_R d} = I_{ab}^0 \times \phi_{ST}\left(\frac{k_{qt}^r[A]}{k_{qt}[A]+k_{dt}}\right) \tag{9}$$

Hence

$$\frac{1}{D_R{}^0} = \frac{1}{\varepsilon_R d \phi_{ST} I_{ab}^0}\left(\frac{k_{qt}}{k_{qt}^r} + \frac{k_{dt}}{k_{qt}^r[A]}\right) \tag{10}$$

Figure 5 gives the $1/D_R{}^0$ *vs.* $1/[A]$ plot from which we obtain $k_{dt}/k_{qt}=7.9\times10^{-6}$ M. Inserting the value of $k_{dt}=1.5\times10^4$ sec^{-1}, we get $k_{qt}=1.9\times10^9$ M^{-1} sec^{-1} which agrees with the value of k_{qt} obtained from the effect of pyridine concentration on the triplet decay.

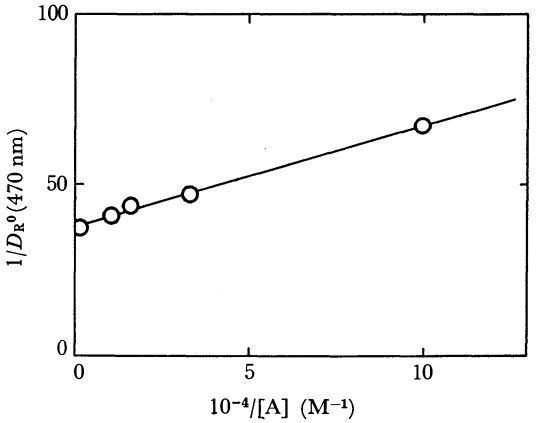

Fig. 5. The plot of $1/D_R{}^0$ *vs.* $1/[A]$.

It might be concluded that the interaction between triplet naphthol and pyridine mainly leads to the formation of R. R was identified to be a neutral naphthoxyl radical for the following reasons. Porter and Jackson reported the formation of this species upon flashing the solution of naphthol in liquid paraffin.[10] The peak position they observed was 465 nm which agrees with the present result. Further it was found that a similar reaction occurs between triplet acridine[12] and β-naphthol in cyclohexane and benzene. In this case the transient spectra are the superposition of that of acridine C-radical and that of β-naphthoxyl radical. Figure 6 shows the plot of the observed decay rate of acridine triplet state against naphthol concentration from which we obtain $k_q=2.9\times10^9M^{-1}sec^{-1}$. An analogous reaction is known to occur between phenol and eosin yielding phenoxy radical and semiquinone of dye.[13]

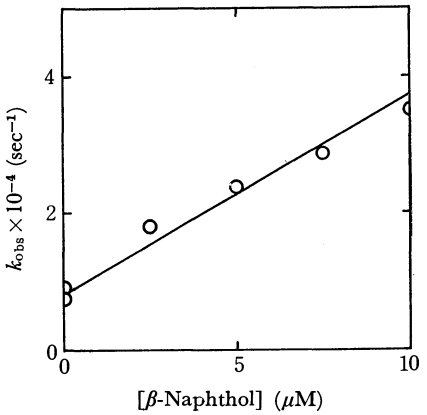

Fig. 6. The relation between the observed first order decay constant of acridine triplet and β-naphthol concentration.

Hence the reaction giving rise to this intermediate may be written as follows,[14]

xi) 
It is interesting that the same reaction occurs even in the aerated solution although the yield of the intermediate is less on account of the quenching action of oxygen upon triplet naphthol. The effect of oxygen concentration on the yield of naphthoxyl radical can be treated by adding the following reaction to shceme (II).

$$\text{xii)}\quad D^T + O_2 \xrightarrow{k_q'} D + O_2$$

However, since the concentration of pyridine is moderately high, we should use Eq. (6) instead of (9),

12) It is interesting that the lowest T(π-π^*) of acridine is involved in this photoreduction.

13) L. I. Grossweiner and E. F. Zwicker, *J. Chem. Phys.*, **34**, 1411 (1961).

14) It should be noted that another peak observed in the near ultraviolet region is also attributed to the same radical, since its decay feature is quite the same as that of the 470 nm peak both in deaerated and aerated solutions.

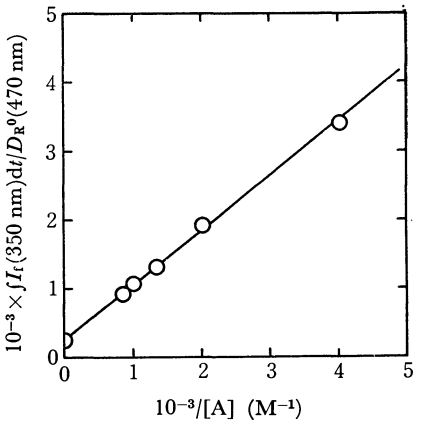

Fig. 7. The plot of $\int I_f(\lambda')dt/D_R^0$ *vs.* 1/[A].

$[T]_0$ being replaced by $[R]_0$. Under the present conditions, the second term and $k_q^c[A]$ on the right hand side of (6) are neglected for the reason described later. Since the condition $k_{dt}\ll k_q^r[A]$ is satisfied, Eq. (10) can be modified as follows.

$$\frac{\int I_f(\lambda')dt}{D_R^0}=\frac{\alpha(\lambda')k_f}{\varepsilon_R dk_{ST}}\left(\frac{k_{qt}}{k_{qt}^r}+\frac{k_q'[O_2]}{k_{qt}^r[A]}\right) \qquad (11)$$

Figure 7 gives the plot of $\int I_f(\lambda')dt/D_R^0$ against 1/[A]. The datum for 1/[A]=0 was taken from the result in the deaerated solution and is exactly on the line drawn through other experimental data for the aerated solution. From the slope and intercept we obtain

$$k_q'[O_2]/k_{qt}=3.3\times10^{-3}M$$

Inserting the value of $k_{qt}=(1.5\text{—}1.9)\times10^9M^{-1}sec^{-1}$ and $[O_2]=2.4\times10^{-3}M$ (from the soubility of oxygen in cyclohexane), we evaluated k'_q to be $2.6\times10^9M^{-1}sec^{-1}$. This is a reasonable value which supports scheme (II).

Table 1. The effect of addition of TEA on the decay rate of triplet naphthol

$[TEA]_M$	$k_{dt}(sec^{-1})$	D_T(432 nm)
0	1.5×10^4	0.212
3×10^{-5}	2.2×10^4	0.189
3×10^{-4}	2.2×10^4	0.189
2×10^{-2}	2.6×10^4	0.072

In contrast to pyridine, triethylamine (TEA) which cannot act as a hydrogen atom acceptor scarcely affects the decay of triplet naphthol below $3\times10^{-4}M$ as shown in Table 1. At $2\times10^{-2}M$ of TEA, the yield of triplet naphthol decreases to some extent. This might be due to the increase in the rate of internal conversion of H-bonded species as in carbazole-TEA.[4] For naphthylmethylether which is incapable of hydrogen bonding with pyridine, the decay rate of triplet state is scarcely affected by the addition of pyridine. To sum up, scheme (II) holds only for the system consisting of H-atom donor and acceptor.

Quenching Action of Pyridine on the Singlet Excited State of Naphthol. Since it has been established that triplet naphthol is converted into neutral radical at pyridine concentrations $\gtrsim10^{-4}M$, D_R^0 should be used instead of D_T^0 in order to investigate the quenching action of pyridine on the fluorescence of naphthol. $\int I_f(350)$

Table 2. Time integrated fluorescence intensity of naphthol and the yield of naphthoxyl radical

dt and D_R^0 (470 nm) were measured at various pyridine concentrations. The results are given in Table 2. It is seen that for $[A]_0 \gtrsim 10^{-1}$M, both $\int I_f(350)\,dt$ and $D_R^0(470)$ become zero. Since more than 90% of naphthol exists as hydrogen-bonded species, the remaining free naphhthol being almost completely quenched by pyridine in this concentration region of pyridine, it could be concluded that β-naphthol hydrogen bonded with pyridine scarcely undergoes intersystem crossing nor the reaction yielding naphthoxyl radical. Therefore the second term on the right hand side of Eqs. (6) and (5) can be neglected. However, there is a possibility of the formation of radical taking part in the collisional quenching of fluorescence, which may be discerned in the region of somewhat smaller pyridine concentrations. For this purpose, an analysis of the data in Table 2 was made by dividing process vii) in scheme (I) into three processes as follows.

$$\text{xv)}\quad D^* + A \xrightarrow{k_q^r} R$$

$$\text{xvi)}\quad D^* + A \xrightarrow{k_q^h} (D\cdots A)^* \text{ (H-bonded species)}$$

$$\text{xvii)}\quad D^* + A \xrightarrow{k_q^c} D^T + A$$

In other words, k_q in scheme (I) was assumed to be composed of three terms, $k_q = k_q^c + k_q^r + k_q^h$. However, since triplet naphthol if formed is quickly converted in to R under the present conditions, k_q^r and k_q^c cannot be discriminated experimentally. Therefore representing $(k_q^c + k_q^r)$ by k_q^r and replacing $[T]_0$ by $[R]_0$, we get from (6)

$$\frac{D_R^0(\lambda)}{\int I_f(\lambda')dt} = \frac{\varepsilon_R(\lambda)d}{\alpha(\lambda')k_f}(k_{ST} + k_q^r[A]) \qquad (12)$$

It is assumed that the triplet naphthol is converted into R completely.

The left hand side of Eq. (12) is plotted against pyridine concentration in Fig. 8. We see that the radical formation reaction takes part in the quenching process. From the plot we obtain $k_q^r/k_{ST} = 5.6\times 10\text{M}^{-1}$. Using the value of (τ_0) of the singlet excited naphthol, we obtain $(\tau_0)^{-1} = k_f + k_d + k_{ST} = 7.5_2\times10^7$ sec^{-1}, our preliminary result for ϕ_{ST} being 0.5—0.7. Therefore k_{ST} is 3.8—5.3×10^7, and k_q^r is evaluated as 2.1—3.0×10^9 $\text{M}^{-1}\,\text{sec}^{-1}$. Thus it is concluded that the formation of naphthoxyl radical occurs through the collisional interaction between singlet excited naphthol and pyridine, its rate constant being about the same as that in the triplet state. It is noteworthy that the value is significantly smaller than that of k_q, 1.2—$1.4\times10^{10}\text{M}^{-1}\text{sec}^{-1}$, which was evaluated from the quenching of naphthol fluorescence by pyridine.

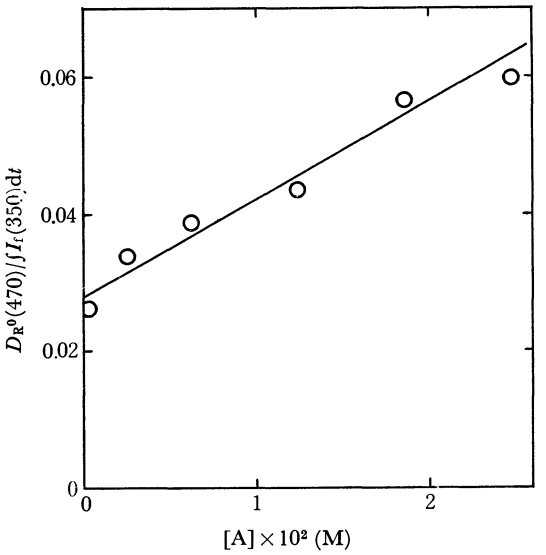

Fig. 8. The plot of $D_R^0(\lambda)/\int I_f(\lambda')dt$ *vs.* [A].

Critical Consideration

The rate constants of various elementary reactions pertaining to the singlet excited and triplet states of naphthol are listed in Table 3. Comments will be given on some of them, in particular k_q^h for excited free naphthol. k_i' and k_c' for the hydrogen-bond species were estimated as follows; k_i' from k_f[15] of free species multiplied by 10^3 on the basis of non-occurrence of fluorescence and intersystem crossing, and k_c' from the non-appearance of naphthoxyl radical.

Table 3. Rate constants of elementary reactions pertaining to the excited naphthol molecule in cyclohexane

	Singlet state		Triplet state
	free species	H-bonded species	
k_d	$k_i < 1.7\times10^7\ \text{sec}^{-1}$	$k_i' \gtrsim 2\times10^{10}\ \text{sec}^{-1}$	$k_{dt}\ 1.5\times10^4\ \text{sec}^{-1}$
	$k_c\ 3.8\text{—}5.3\times10^7\ \text{sec}^{-1}$	$k_c' < 10^7\text{—}10^8\ \text{sec}^{-1}$	
	$k_f\ 2.04\times10^7\ \text{sec}^{-1}$	$k_f' \sim 2\times10^7\ \text{sec}^{-1}$	
	$k_h\ 9\text{—}12\times10^9\ \text{M}^{-1}\,\text{sec}^{-1}$		
	$k_q^r\ 2.1\text{—}3.0\times10^9\ \text{M}^{-1}\,\text{sec}^{-1}$		$k_{qt}^r\ 1.5\text{—}1.9\times10^9$
	$1.2\text{—}1.4\times10^{10}\ \text{M}^{-1}\,\text{sec}^{-1}$		$\text{M}^{-1}\,\text{sec}^{-1}$

The present results demonstrate, that internal conversion is greatly enhanced by the formation of a hydrogen bond in the ground state. This is why the hydrogen-bonded species does not practically undergo intersystem crossing. The conclusion is essentially the same as that made by Mataga *et al.* on the carbazole–pyridine system.[4]

Next will be discussed the nature of k_q^r and k_q^h and the smaller value of k_q^r than that of k_q^h. There is no direct evidence for k_q^h being connected with the forma-

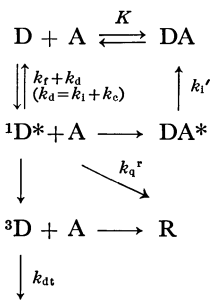
15) The absorption spectrum of the H-species dose not appreciably differ from that of the free species, and thus k_f' is equated to k_f.

tion of a H-bonded species, but this is highly plausible. According to Jackson and Porter,[10] acidity constants of β-naphthol in the ground, singlet excited and triplet states are respectively $pK_G=9.5$, $pK_{S*}=3.1$, and $pK_T=8.1$—8.3 (at 25°C). Since the strength of a hydrogen bond of an acid with a given base increases with the acidity, it is reasonable that hydrogen bond formation occurs much more easily in the singlet excited state[16] than in the ground and triplet states.

As regards k_q^r, it very likely occurs in the singlet excited state, although there is no direct experimental evidence, since if it connected with the reaction in the triplet state produced by the intersystem crossing of the excited H-bonded species, the value of k_q^r should be more than one order less than the observed value, as judged from the values of k_i' and k_c'.

Thus, such a model can be rejected, and we may conclude that the singlet excited and triplet states of naphthol have about equal reactivity toward hydrogen atom transfer, as demonstrated by the same values of k_q^r and k_{qt}. Further we may conclude that the significantly larger quenching constant of pyridine to naphthol fluorescence is mainly due to the formation of a H-bonded species, which does not occur in the triplet state. Perhaps radical formation and hydrogen bonding in the singlet excited state occur as competitive reactions and the latter overwhelms the former.

The above conclusions can be summarized by the scheme



where the reaction between D* and pyridine is mainly the formation of a H-bonded species, whereas that of triplet naphthol is only a radical formation.

Such situations might exist in general, since acidity and basicity for the singlet excited state differ greatly from those for the ground state but not so for the triplet state. As is well-known, acridine in the singlet excited state abstracts a hydrogen atom from alcohol (a poor proton donor), playing a role in the quenching of fluorescence. However, if we use a stronger proton donor such as naphthol or phenol, it might be expected also for acridine that a hydrogen-bond formation participates in the quenching of fluorescence whereas radical formation is dominant in the triplet state.

As regards the mechanism of internal conversion *via* H-bonding, it has been attributed in the past to the delocalization of π electron which usually induces C–T interaction.[1-4] This is true in some systems[5] but in the present case H-atom transfer is more plausible. Since the occurrence of H-transfer has been established both in the singlet excited and triplet states, it seems natural to assume that in the hydrogen-bonded species a transient H-transfer is also occurring *via* charge transfer interaction followed by proton transfer, producing a certain kind of radical pair. The pair, being unstable without doubt, will quickly be reconverted into the initial compound. This is likely to be the cause of internal conversion *via* H-bonding in the present system and similar ones. The results support the theoretical argument of Rehm and Weller[7] who concluded the hydrogen transfer mechanism of quenching for naphtholpyridine, benz(*c*)acridine–phenol *etc.* It is to be noted, however, that the eventual hydrogen transfer occurs not *via* excited hydrogen-bonded species but as a one act bimolecular process which plays only a small role in the quenching action of pyridine on naphthol.

16) When the H-bonded species is fluoroscent as TEA–carbazole, the rate constant for its formation is known to be diffusion controled. (Ref. 4).

The Applicability of the Theory of R. A. Marcus to the Electron-Transfer Reactions between Polycyclic Aromatic Hydrocarbons and Their Anion Radicals

Kosaku SUGA and Shigeru AOYAGUI

Faculty of Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received July 13, 1972)

The rates of electron-transfer from the anthracene-anion radical to anthracene, 1,2-benzanthracene, and pyrene are measured by the electron spin resonance method, with a line-broadening procedure, under experimental conditions in which anion radicals are in a state of free ions or of loose ion pairs. The dependence of the observed rate constants on the standard free energy of reaction, the dielectric constant of the solvent, and the temperature are discussed on the basis of the theory of R. A. Marcus. The free energy of nuclear reorganization, as estimated from the $\Delta G°$-dependence of the rate constants, is much smaller than that predicted theoretically. The observed rate constants are almost independent of the dielectric constants of the solvents; consequently, the reorganization free energy of the solvent must be smaller than the theoretical value. The entropy term contributes to the activation energy to almost the same extent in the solvents with different dielectric constants; this is inconsistent with the theoretical prediction and requires a smaller value for the free energy of solvent reorganization than its theoretical value.

A number of rate constants for electron-transfer reactions between polycyclic aromatic hydrocarbons and their anion radicals have been measured by the electron spin resonance (ESR) method since the pioneering work of Ward and Weissman.[1] It has been revealed that these anion radicals form ion pairs with alkali ions and that the formation of such ion pairs affects the electron-transfer rates.[2] According to Hirota,[3] there can be two kinds of ion pairs, the tight ion pairs whose ESR spectra exhibit hyperfine splittings due to alkaki ions, and the loose ion pairs which yield ESR spectra without such hyperfine splittings. The rate constants of about 10^7 and $10^9 M^{-1}sec^{-1}$ were attributed to the tight and the loose ion pairs respectively. On the other hand, there is no difference between the rate constants of loose ion pairs and free ions;[3b] thus, it is not necessary to distinguish the loose ion pairs from free ions in the following discussion. They will be designated "free ions" in this paper for the sake of simplicity.

The electron-transfer reactions of hydrocarbon free anions can be pure electron-transfer reactions without the formation and/or rupture of chemical bonds; they resemble those of metal-complex ions with an outer-sphere mechanism. Thus, the theory of Marcus[4] is expected to be applicable to the former reactions, which have been scarcely discussed on the basis of the molecular theory. A test applying Marcus' theory to these reactions may be an approach to elucidating their microscopic mechanism. Moreover, such a test will serve to improve and refine the theory itself.

In this paper we will examine the applicabliity of the Marcus' theory to the electron-transfer reactions between hydrocarbon molecules and their radical anions when the latter reactants are in a free-ion state. The following aspects should be emphasized at the outset: first, the theoretical equation for the rate constant contains several parameters which can be specified experimentally; the standard free energy of reaction, the dielectric constant of the solvent, the temperature, and the molecular radii of the reactants; thus, the dependence of the rate constant on these parameters must be examined as a whole, not individually. Secondly, it is preferable that the measurements be made with at least two measuring techniques based on different principles. Such a comparative study as this is not only necessary for an examination of the reliability of the measuring technique itself, but it may inform us of the influence on the observed rate constants of the experimental conditions, which may be inevitably different from method to method.

This paper will deal with the $\Delta G°$, D_s, and T parameters.[5] A comparison between the ESR and the pulse-radiolysis methods will be made with regard to D_s. The $\Delta G°$-dependence obtained by the methods of pulse radiolysis, the quenching of the fluorescence, and ESR has already been discussed comparatively elsewhere.[7]

Experimental

Procedures. The electron-transfer rates were determined from the increase in the linewidth of the central hyperfine line in the ESR spectra of anthracene anion radicals after the addition of a known amount of neutral molecules. The rates of cross-electron-transfer reactions were evaluated with the procedure described in the preceding paper.[8] The con-

5) Spherical molecular shape of the reactants is assumed in the theory of Marcus,[4] but all the reactants in this investigation are planar. Thus the molecular radii of the reactants, a's, appearing in his theoretical expression for the rate constant cannot be well-defined quantities even when the molecular geometry is given. In fact we could not prove the a-dependence of the rate constant predicted theoretically.[6]

centration of the anthracene anion radicals was determined spectroscopically using the value for the extinction coefficient reported by Balk *et al.*[9]

Materials. All the aromatic hydrocarbons as well as the solvents used were commercially obtained. The anthracene (A), 1,2-benzanthracene (B), and pyrene (P) were recrystallized from benzene and ethanol. The solvents were purified to remove all traces of acidic materials, water and oxygene. The tetrahydrofuran (THF) and 1,2-dimethoxyethane (DME) were purified in a way described previously.[8] The *N,N*-dimethylformamide (DMF) was refluxed over calcium hydride, distilled, and then allowed to stand over calcium hydride in a vacuum for about two weeks; it was degassed after the evolution of hydrogen gas had ceased and then distilled into a glass ampoule containing solid sodium anthracenide in order to remove the residual water and oxygen.

Preparation of Radical Solutions. Only the anthracene radical anion was required in this experiment. A DME solution of its sodium salt was prepared by dissolving solid sodium anthracenide into DMF because of the reactivity of this solvent with sodium metals. The sodium anthracenide was prepared by the soidum reduction of anthracene in THF and was then made free from the solvent by distillation. The solutions in the DME–DMF mixed solvent were prepared by mixing the DME solution with DMF.

Measuring Devices. The ESR measurements were carried out on a JEOL Model JES-3BSX spectrometer operated at about 9.5 kMHz, with 100 kHz field modulation. The modulation amplitude was 0.03—0.08 Gauss. The temperature was maintained and controlled with a JEOL Model JES-UCT-2AX variable-temperature adaptor on the ESR cavity. All the measurements were made at 25°C unless otherwise stated.

Results and Discussion

According to the theory of Marcus,[4] the rate constant of the electron-transfer reaction, $R_1^- + R_2 = R_1 + R_2^-$, when the non-coulobmic interaction between reactants and between products can be neglected, is given by the following equation:

$$k = Z \exp(-\Delta G^*/RT), \quad (1)$$

with;

$$\Delta G^* = \lambda/4 + \Delta G^\circ/2 + (\Delta G^\circ)^2/4\lambda, \quad (2)$$

$$\lambda = \lambda_0 + \lambda_i, \quad (3)$$

$$\lambda_0 = e^2(1/2a_1 + 1/2a_2 - 1/r)(1/D_{op} - 1/D_s). \quad (4)$$

In these equations, Z is the bimolecular collission number of the hypothetical uncharged species in solution when they have a unit concentration; ΔG^* and ΔG° are the activation free energy and the standard free energy of the reaction respectively; λ is the free energy needed to reorganize both the solvent molecules and the reactants in forming the activated complex; λ_0 and λ_i are the contributions to λ from the reorganization of the solvent and of the bonds in the reactants respectively; e is the electronic charge; a_1 and a_2 are the radii of the reactants; D_s and D_{op} are the static and optical dielectric constants respectively, and r is the distance between the centers of the reactants in the activated complex.

Equation (1) can be rewritten in the form:

$$k = k_0 \exp(-\Delta G^\circ/2RT) \exp[-(\Delta G^\circ)^2/4RT], \quad (5)$$

with

$$k_0 = Z \exp(-\lambda/4RT), \quad (6)$$

where k_0 is the rate constant of the electron-exchange reaction with $\Delta G^\circ = 0$. In deriving Eq. (5), it is assumed that the values for λ of the cross-electron-transfer reaction and of the electron-exchange reactions, $R_1^- + R_1$ and $R_2^- + R_2$, are the same. The validity of this assumption will be discussed below.

Table 1. Observed rate constants, corrected forward rate constants and corrected backward rate constants for the electron transfer reactions $A^- + A$, $A^- + B$, and $A^- + P$ in DME at 25°C

Reactions	ΔG° (eV)	k_{obs} (M^{-1} sec^{-1})	$\vec{k}_a$ (M^{-1} sec^{-1})	$\overleftarrow{k}_a$ (M^{-1} sec^{-1})
$A^- + A = A + A^-$	0	$(1.8 \pm 0.2) \times 10^9$	2.4×10^9	2.4×10^9
$A^- + B = A + B^-$	0.052	$(5.4 \pm 1.0) \times 10^8$	5.9×10^8	4.5×10^9
$A^- + P = A + P^-$	0.113	$(9.6 \pm 1.5) \times 10^7$	9.7×10^7	7.8×10^9

ΔG°-Dependence of the Electron-transfer Rates. When the ΔG°-dependence of the electron-transfer rates are examined, the reaction rates between different mloecular species must be measured. Measurements were made on the A^-/B and A^-/P couples in the DME solvent. Plots of the increase in the linewidth *vs.* the concentration of added neutral molecules are illustrated in Fig. 1. The linearity of each plot is satisfactory. The rate constants of the cross-electron-transfer reactions calculated from the slopes of the straight lines in Fig. 1 are listed in Table 1, together with the rate constant of electron exchange between A^- and A.

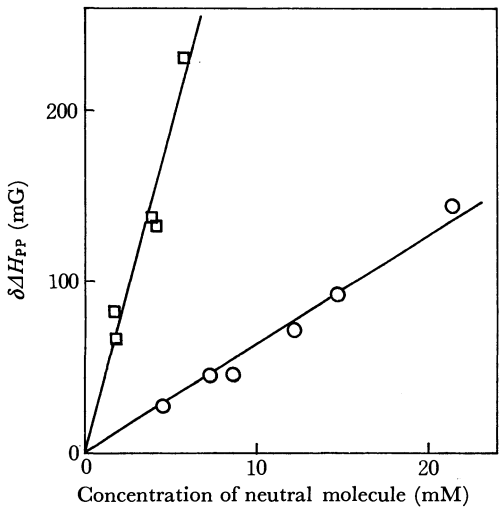

Fig. 1. Linewidth broadening ($\delta\Delta H_{PP}$) *vs.* concentration of neutral molecules in the cross electron transfer reactions in DME: □, $A^- + B = A + B^-$; ○, $A^- + P = A + P^-$.

Equation (2) shows that the rate constants of cross-electron-transfer reactions are dependent only on ΔG° when λ is a constant. According to the theory of Marcus, on the one hand, the λ value of the cross-electron-transfer reaction between A^- and B is approximately equal to the mean value of the λ's for two exchanging couples, A^-/A and B^-/B. On the other

9) P. Balk, G. J. Hoijtink, and J. W. H. Schreurs, *Rec. Trav. Chim.*, **76**, 813 (1957).

hand, the rate constants of the electron-exchange reactions between polycyclic aromatic hydrocarbons and their anion radicals generated by sodium reduction in DME are nearly equal: *e.g.*, $2.0\times10^{9}M^{-1}sec^{-1}$ for P^-/P[6] and $1.8\times10^{9}M^{-1}sec^{-1}$ for A^-/A. Although the electron-exchange rate of P^-/P has never been measured, it is quite probable that its rate constant is almost identical with those for A^-/A and P^-/P. Consequently, it is reasonable to assume that both cross-electron-transfer reactions treated in this paper have an λ value identical with that of the A^-/A couple. The λ value for an exchange reaction is obtainable experimentally with Eq. (6) and the observed k value when Z is given. In the following discussion, Z is taken to be 10^{11} and $10^{10}M^{-1}sec^{-1}$.

The observed k value must be corrected for diffusion. In the case of an activation-diffusion mixed control, the corrected or activation-controlled rate constant, k_a, is given by the equation:

$$1/k_a = 1/k - 1/k_d, \tag{7}$$

where k and k_d are the observed and the diffusion-controlled rate constants respectively. k_d can be estimated with the equation $k_d=4RT/3\eta$.[10] The observed k value for A^-/A, $1.8\times10^{9}M^{-1}sec^{-1}$, is of the same order of k_d, $7.2\times10^{9}M^{-1}sec^{-1}$, in DME at 25°C; this is a rate constant controlled by both the activation and the diffusion processes.

The rate constants for cross-electron-transfer reactions with negative ΔG° values are not obtainable in the present procedure. They are estimated with the ΔG° value of the reaction, the corrected forward rate constant, k_a, and the following equation:

$$\overleftarrow{k}_a = \overrightarrow{k}_a \exp(-\Delta G^\circ/RT) \tag{8}$$

Table 1 compiles the values for $\overleftarrow{k}_a$ and $\overrightarrow{k}_a$ thus obtained.

The λ value for the electron exchange reaction of anthracene, as calculated with the k_a in Table 1, is 8.8 kcal mol^{-1} when Z is assumed to be $10^{11}M^{-1}sec^{-1}$. The rate constants of electron-transfer reactions calculated with this λ value and Eq. (5) are drawn by dotted lines in Fig. 2. An identical plot with $Z=10^{10}M^{-1}sec^{-1}$ and, consequently, with $\lambda=3.4$ kcal mol^{-1} is shown by a dot-dash line. The solid straight line in the same figure shows the relation between k and ΔG° when the third term on the right-hand side of Eq. (2) is neglected; this line embodies the so-called "Linear Free Energy Relationship".[3]

The corrected observed rate constants are plotted with closed circles in Fig. 2. They fit best with the dot-dash line. However, it is rather unlikely that the collision number in solution is $10^{10}M^{-1}sec^{-1}$; according to recent reasoning, this is considered to be two or three times as large as the collision number in the gas phase, which is about $10^{11}M^{-1}sec^{-1}$.

Dependence of the Electron-transfer Rates on the Dielectric Constant of Solvents. The ESR measurements of the electron-transfer rates of aromatic hydrocarbon anion radicals have been made almost exclusively in solvents with low dielectric constants, *e.g.*, in DME

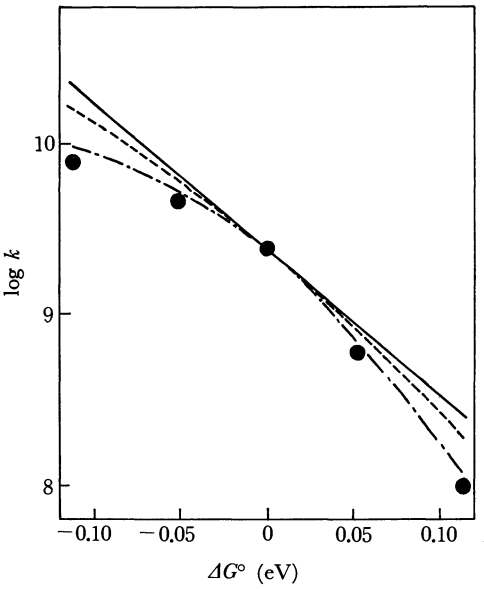

Fig. 2. ΔG°-dependence of electron transfer rates: ●, corrected observed values for rate constants in DME; ——, k *vs.* ΔG° plotted according to Eq. (5), the quadratic term in ΔG° neglected; —— and -·-·-, k *vs.* ΔG° plotted according to Eq. (5) with λ of 8.8 and 3.4 kcal mol^{-1} respectively.

($D_s=7.2$ at 25°C), even when free anion radicals were studied. There is one exception: a measurement in DMF ($D_s=36.7$ at 25°C) with electrolytically-generated radical anions.[11] Because of the large amount of supporting electrolytes indispensably present in the solution, however, it may be meaningless to compare the results with those obtained in solutions which do not contain such electrolytes.

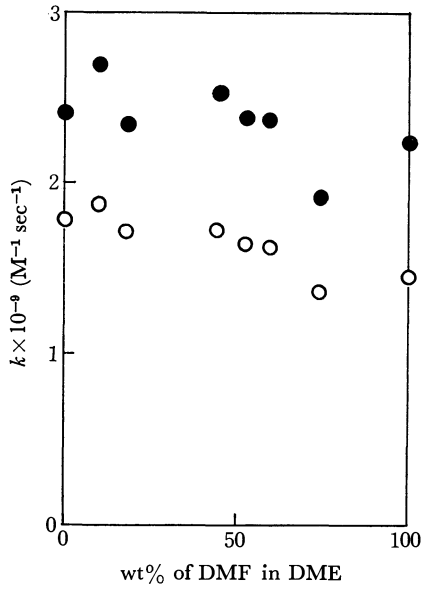

Fig. 4. Rate constants of electron exchange between A^- and A *vs.* weight percent of DMF in the mixture of DME and DMF: ○, observed values; ●, diffusion-corrected values.

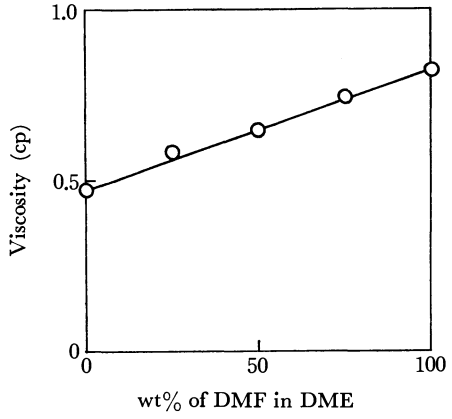

Fig. 5. Viscosities of DME–DMF mixtures.

The electron-exchange rates between anthracene and its anion radical were measured in several mixtures of DME and DMF. The correction of the linewidth for the decrease in the radical concentration was made in the same way as in the measurements of the cross-electron-transfer rates. Figure 3 illustrates the relations between the linewidth increase and the concentration of anthracene added in DMF and in DME respectively. The rate constants thus obtained are plotted in Fig. 4 with open circles against the weight percent of DMF in the mixed solvent. The corrected rate constants are shown with closed circles. The data for the viscosity of the DME–DMF mixture required in the correction are shown in Fig. 5; it is found that they depend almost linearly on the ratio of the composites.

Figure 4 shows that the corrected rate constants are nearly constant within the limits of experimental error. According to Eq. (4), the rate constant depends on D_s through the dependence of λ_0 on D_s. In the electron transfer of aromatic hydrocarbon-anion radicals, the contribution of λ_i to λ can be neglected; λ_0 is then

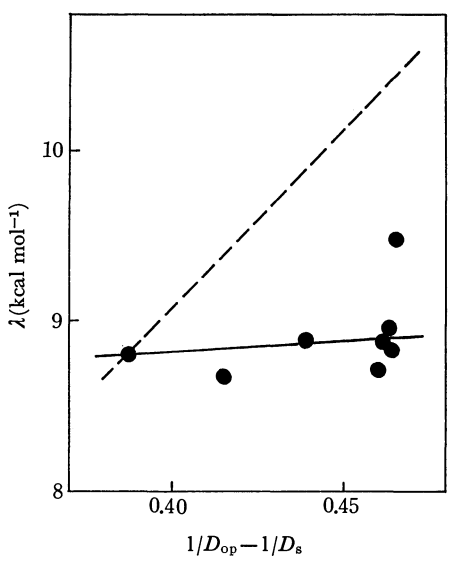

Fig. 6. Dependence of λ on the dielectric constants of solvents: ●, λ values calculated from Eq. (6) with corrected observed values for rate constants; ——, λ *vs.* $1/D_{op}-1/D_s$ plotted according to Eq. (4), the terms in the first parentheses estimated semi-empirically from λ values in DME.

approximately proportional to $(1/D_{op}-1/D_s)$. Since the D_{op} of each solvent is almost fixed, the value for λ, and consequently that for the rate constant also, are both substantially dependent only on D_s. The dotted line in Fig. 6 shows a theoretical plot of λ against $(1/D_{op}-1/D_s)$ drawn semi-empirically with the λ value and the slope calculated from the rate constant obtained in DME. The corrected observed λ values are plotted with closed circles in the same figure. The data for D_s in a DME–DMF mixture were not available. They were estimated from the D_s values of both solvents on the assumption that the D_s for the mixture depends linearly on the mixing ratio. The latter assumption was based on the fact that the viscosity of the mixture behaves in this manner without any molecular association at any specific mixing ratio, as is shown in Fig. 5. Figure 6 shows that λ depends on D_s to a much smaller extent than was predicted theoretically. This might be due to the neglect of the dielectric saturation in estimating the contribution to the activation free energy from solvent reorganization. This point will be discussed further later.

There has been an investigation examining the dependence of the rate constant on the dielectric constant of solvents with the pulse-radiolysis method.[12] Measurements were made on the electron-transfer from the pyrene anion to 9,10-dimethylanthracene; it was found that the results supported the theory of Marcus. However, it must be noticed that, on the one hand, the observed value for k is close to the diffusion-controlled one in this experiment. Consequently, errors in both the k_d and k values would seriously affect the accuracy of the corrected k_a values. On the other hand, the value for k_d was taken as that of the rate constant for

12) a) S. Arai, D. Grev, and L. M. Dorfman, *J. Chem. Phys.*, **46**. 2572 (1967). b) J. R. Brandon and L. M. Dorfman, *ibid.*, **53**, 3849 (1970).

reactions with sufficiently large negative ΔG° values, *e.g.* $6.7\times10^9 M^{-1}sec^{-1}$ in isopropanol. This is about four times the value calculated from $k_d=4RT/3\eta$; the validity of this relation has recently been reexamined in the ESR investigation of the Heisenberg spin-exchange process between tetracyanoethylene mononegative ions.[10] Moreover, the rate constants reported of the reactions with positive ΔG° values, *e.g.*, A^-/P, are as small as about one-tenth of that obtained by the ESR method. It is rather close to the value for an electron transfer from the anthracene$^-$-tetrabuthylammonium$^+$ ion pair to pyrene.[8] This suggests the ion pair (not loose ion pair) formation of the anthracene anion with some organic cationic species generated by electron-beam irradiation.

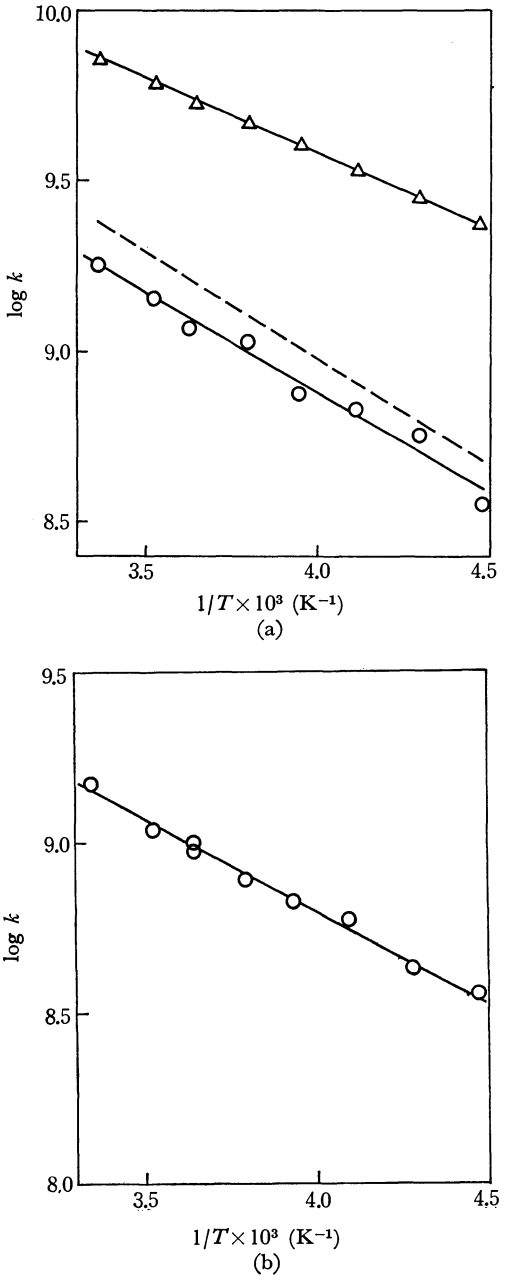

Fig. 7. Temperature dependence of rate constants of electron exchange between A^- and A in (a) DME and (b) DMF: ○, observed values; △, calculated values for k_d; ——, diffusion-corrected rate constants.

Temperature Depencence of the Electron-transfer Rates. Figures 7a and 7b show the temperature dependence of the rate constants of the electron-exchange reactions between anthracene and its anion radical in DME and DMF respectively. The observed rate constants are shown by open circles. The calculated k_d values and the corrected rate constants are shown in Fig. 7a by triangles and a dotted line respectively. The activation energies obtained from Fig. 7 are listed in Table 2.

Table 2. Semi-empirical estimate of activation enthalpy and observed activation energy of the reaction A^-+A in DME and DMF
(energies in kcal mol^{-1})

Solvents	$Z=10^{11}$ M^{-1} sec^{-1}		$Z=10^{10}$ M^{-1} sec^{-1}		E_a
	ΔH^*	ΔG^*	ΔH^*	ΔG^*	
DME	3.34	2.21	1.28	0.84	2.7±0.3
DMF	2.45	2.24	0.94	0.85	2.6±0.2

The corrected activation energy is nearly equal to the apparent one. The activation energy obtained from the calculated diffusion controlled rate constants in DME is 2.25 kcal mol^{-1}. The results in DMF could not be corrected, because the data for the viscosity of DMF at low temperatures were not available. The apparent activation energy in this solvent was assumed to be equal to the corrected one.

The activation energies in DME and in DMF are nearly equal; they are rather smaller than the activation energy obtained by Hirota in DME, 3 kcal mol^{-1}.[13]

Table 3. Non-empirical estimate of λ_0
(λ's in kcal mol^{-1})

Solvents	$(\lambda_0)_{calc}$ $a=5.15$ Å $r=10.3$ Å	$(\lambda_0)_{calc}$ $a=2.85$ Å $r=5.70$ Å	λ_{obs}
DME	12.5	22.5	8.81
DMF	14.9	26.8	8.84

The activation enthalpy of the electron-transfer reactions can be expressed in terms of the activation free energy in the sense of Marcus' theory, ΔG^*, as follows:

$$\Delta H^* = \Delta G^* - T(\partial \Delta G^*/\partial T).$$

It is ΔH^* that should be compared with the experimental activation energy, E_a. When λ_i is assumed to be negligible, ΔH^* is expressed as follows:

$$\Delta H^* = (1/4)[\lambda_0 - T(\partial \lambda_0/\partial T)].$$

In view of the fact that only D_s depends on the temperature in Eq. (4), the above equation can be rewritten in the following form:

$$\Delta H^* = (1/4)\left[\lambda_0 + T\frac{\lambda_0}{1/D_{op}-1/D_s}\frac{\partial}{\partial T}\left(\frac{1}{D_s}\right)\right]. \quad (9)$$

The temperature dependence of the dielectric constant of solvents is expressed by the empirical equations:

13) a) N. Hirota, *J. Phys. Chem.*, **71**, 127 (1967). b) N. Hirota, "Radical Ions," ed. by E. T. Kaiser and L. Kevan, Interscience Publishers, New York (1968), p. 35.

$D_s(\mathrm{DME}) = -2.83 + 2950/T$[14] and $D_s(\mathrm{DMF}) = -24.8 + 18300/T$.[15] The λ_0 values are obtainable from the observed rate constants using an appropriate value for Z. Table 2 shows the values for ΔH^* calculated from Eq. (9) with Z values of 10^{11} and $10^{10}\mathrm{M^{-1}sec^{-1}}$. The values for ΔG^* and E_a are also included in the table.

It may be seen from Table 2 that ΔH^* agrees with E_a fairly well when Z is $10^{11}\mathrm{M^{-1}sec^{-1}}$. Moreover, it may be noticed that the experimental activation energies in the two solvents are nearly equal; this differs from the theoretical prediction that the extent of the contribution to ΔH^* from the entropy term would be different in DME and DMF solutions.

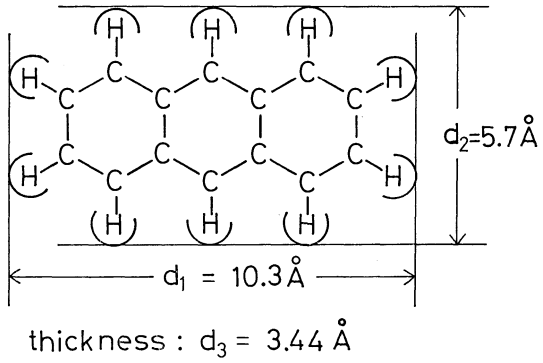

Fig. 8. Molecular geometry and dimensions of anthracene.

Non-empirical Estimate of λ_0. In the above discussion, the λ values were determined semi-empirically from the observed rate constants with an appropriate value for Z. According to Marcus' theory, λ_0 can be estimated non-empirically using Eq. (4) when λ_i is negligible. In deriving Eq. (4) Marcus assumed the reactants to be spherical. The reactants in the present discussion, *i.e.*, anthracene and its anion, however, have planar structures; the molecular radii must be estimated in an arbitrary way from the molecular geometry. Figure 8 shows the molecular geometry and dimensions of anthracene. In estimating d_1 and d_2 in Fig. 8, the van der Waals radii were taken into account besides the bond distances. The thickness, d_3, is rather indefinite. Because of the possible closest approach of reactants which may put the anthracene molecular planes face to face, it is assumed that the thickness is equal to the distance between the molecular layers in graphite, 3.44 Å. The value for λ_0 was calculated on the assumption that $a=a_1=a_2=r/2$. The value of a was tentatively taken as $d_1/2$ and $d_2/2$. Table 3 shows that even with the largest a val ue possible, *i.e.*, 5.16 Å, the calculated λ_0 values do not agree with the observed values. The agreement will be even less satisfactory for smaller a values.

Concluding Discussion. The following aspects were pointed out in the above examination of experimental results made on the basis of the Marcus' theory. First, the observed rate constants depend on ΔG° in such a way as is predicted theoretically when λ takes the value of 3.4 kcal mol^{-1}; this λ value is much smaller than that predicted by Eq. (4) with $Z=10^{11}\mathrm{M^{-1}sec^{-1}}$, 8.8 kcal mol^{-1}. Secondly, the rate constant is almost independent of D_s against the theoretical prediction. Thirdly, there is no difference between the experimental activation energies in DME and in DMF; thi might be a result of the difference in D_s; in other words, the activation entropy contributes to E_a to almost the same extent in solvents with different D_s values. The second and the third points require that the contribution of λ_0 to the activation free energy be smaller than that predicted theoretically. The inclusion of λ_i into λ cannot provide any successful elucidation: the situation that λ_0 is small, while $\lambda=\lambda_0+\lambda_i$ is large, is not probable in view of the first point.

The inconsistency between the theoretical predictions and the experimental results might be removed by reasoning as follows: when the non-coulombic interactions between reactants as well as products, which were neglected in deriving Eq. (2), are taken into consideration, the activation free energy can be expressed by:[4b]

$$\Delta G^* = (w^r + w^p)/2 + \lambda/4 + \Delta G^\circ/2 + (\Delta G^\circ + w^p - w^r)^2/4\lambda, \quad (10)$$

where w^r and w^p are the reversible work to bring two reactants together and two products together respectively, from the bulk of solution to the positions they would occupy in the activated complex. Generally, w's can be coulombic and/or non-coulombic. Here, one of the reactants as well as the products being neutral, they are non-coulombic. If $w^r=w^p=w$ is assumed for the sake of simplicity, Eq. (10) becomes:

$$\Delta G^\circ = w + \lambda/4 + \Delta G^\circ/2 + (\Delta G^\circ)^2/4\lambda. \quad (11)$$

Let $w=1.4$ kcal mol^{-1} and $\lambda=3.4$ kcal mol^{-1}, in view of the following facts: the observed ΔG^* for the A^-/A couple is 2.2 kcal mol^{-1} when Z is $10^{11}\mathrm{M^{-1}sec^{-1}}$, and the ΔG°-dependence of the observed rate constants can be elucidated by taking λ as 3.4 kcal mol^{-1}. Then, λ_0 can be quite small; this is consistent with the requirements of the second and third points.

Such a small λ value, however, cannot agree with that estimated non-empirically from Eq. (4), 12 kcal mol^{-1}. The agreement might be expected if the value of $1/D_{op}-1/D_s$ is one-fourth to one-third smaller than that calculated with the macroscopic D_s value or, consequently, if D_s is as small as 2 or 3. However, it is hardly probable that such a strong dielectric saturation occurs in the vicinity of hydrocarbon anions, which have an extensively-spread charge distribution.

In conclusion, the observed rate constants for the electron-transfer reactions between aromatic hydrocarbons and their anions depend on the parameters, *i.e.*, the standard free energy of reaction, the dielectric constant of the solvent, and the temperature, as a whole in some different way from that predicted by the theory of Marcus. This is inconsistent with the results of the previous investigations, which treated the parameters individually.[12b,16]

16) D. Rehm and A. Weller, *Ber. Bunsenges. Phys. Chem.*, **73**, 834 (1969).

There is some possibility that the most fundamental assumption in the Marcus' theory, *i.e.*, the small overlap of the wave functions of reactants, might not be completely fulfilled in the reactions in which the aromatic hydrocarbons participate.

not observed within the range of experimental scattering. The ξ-function of this system is almost constant over the entire composition range. In view of the small difference in the electronegativity values of sulfur and selenium, the enthalpies seem to be attributable to the transformation of the covalent bonding, that is, to

$$\text{-S-S-} + \text{-Se-Se-} \longrightarrow 2\ \text{-S-Se-}$$

in rings or chains, and to minor effects from the change in the van der Waals interaction among the rings and chains of various chain compositions. Although the equilibria between ring and chain molecules of various lengths will shift on mixing, the heat effects due to this transformation can not be estimated at the present stage of knowledge.

Sulfur+Tellurium. In this system, the enthalpy of mixing is positive on the sulfur- and tellurium-rich sides, but negative in the intermediate composition ranges. The composition at which the minimum appears is about 0.25, by the suflur atomic fraction. The ξ-function of this system was divided conveniently into three straight lines. The least-squares method leads to the following results:

$$0 \leq X_s \lesssim 0.25\text{: } \xi = 2880 - 19890X_s,$$

$$0.25 \lesssim X_s \lesssim 0.30: \quad \xi = -5500 + 16160X_s,$$

and:

$$0.30 \lesssim X_s \lesssim 1.0: \quad \xi = -1620 + 3825X_s,$$

where X_s is the atomic fraction of sulfur.

The above equations are helpful in calculating the partial molar enthalpies of mixing. The forms of the ξ-functions is similar to that of binary systems in which the associated species are formed on mixing, for example, in the $MgCl_2$+KCl system studied by Kleppa.[5] The activity of each component can be calculated from the equilibrium-phase diagram.[6] With the data of the heat of fusion and the melting point of tellurium,[7] and on the assumption that the solid solution of sulfur in tellurium is ideal with respect to the tellurium solvent, the activity of tellurium on the liquidus temperature was derived. Further, the present enthalpy data permitted us to calculate the change in activity with the temperature. The acitivity of tellurium and that of sulfur derived from the former by means of the Gibbs-Duhem relation were combined with the present enthalpy values in order to evaluate the entropy of mixing. The free energy from the activities and the entropy are shown in Fig. 4, together with the enthalpy values. Although the free energy curve is smooth, the entropy value is less than that of the ideal solution and shows a minimum at $X_s=0.25$. These curves are similar to those of mixtures which generate the associated complex on mixing. From the trends of the entropy as well as from the enthalpy, some sorts of orderings can be suspected in the mixture around $X_s=0.25$. In order to interpret this entropy, let us consider for a moment a pseudo-binary mixture consisting of Te_3S and excess tellurium or sulfur, like thallium+tellurium.[8] The configurational entropies of the pseudo-binary mixture can be calculated on the basis of the quasi-crystalline lattice model. When $X_s>0.25$, the mixture consists of Te_3S and S and the entropy of mixing is given by:

$$-\Delta S^M/R = X_s[(1-X_2)\ln\phi_1 + X_2\ln\phi_2]$$

in which

$$X_2 = (1-X_s)/3X_s$$

and

$$\phi_2 = 1-\phi_1 = rX_2/[(1-X_2)+rX_2] \quad (r=4 \text{ in this case})$$

and for Te_3S+Te ($X_s<0.25$) by:

$$-\Delta S^M/R = (1-3X_s)[(1-X_2)\ln\phi_1 + X_2\ln\phi_2]$$

in which

$$X_2 = X_s/(1-X_s).$$

The entropies based upon above model are shown in Fig. 4 as a broken line. The agreement between the experimental and calculated values is satisfactory. One may note, however, that this does not necessarily mean that any molecule like Te_3S is present in the mixture. Considering the small enthalpy of mixing, the idea of the compound formation is far from reality. Rather,

the sulfur atoms seem to be preferably surrounded by three tellurium atoms when $X_S<0.25$. The positive enthalpies of mixing on the two sides of the composition may be attributable to positive heats effects, such as the difference in size between sulfur and tellurium.

Selenium+Tellurium. In this system, the enthalpy is negative throughout the composition range. The minimum of the enthalpies of mixing appears at the composition of 0.4, by the atomic fraction of selenium. The electronegativity difference between selenium and tellurium is the largest among the three combinations. Therefore, the enthalpies of mixing of this system are expected to be the most exothermic, in agreement with the experimental results. The ξ-function of this system can also be divided into two portions. Though there are no thermodynamic functions available except the present enthalpy data, the ordered structure may be constructed in the same manner as in the sulfur+tellurium system.

As has been shown by many authors, liquid sulfur has the so-called transition temperature, above which long chains with various chain lengths are formed in addition to the S_8 ring.[9] Liquid selenium can also be understood similarly, though the transition temperature lies below its melting point.[10] Since the experimental temperatures of the present work are higher than the transition temperatures, we must consider the presence of these species. In contrast to sulfur and selenium, liquid tellurium has only a short chain structure at low temperatures. However, it has recently been shown that liquid tellurium has a three-dimensional network structure. This idea is proposed on the basis of the experimental evidence that the numbers of the nearest neighbors in liquid tellurium are not two but three, even as high as above the temperature of 950 °C, as determined by the neutron diffraction measurement.[11] Therefore, the mixing process of these elements involve ring opening, chain scission, and the formation of co-ring and co-polymer chains.[12] The observed enthalpies of mixing are related to these processes. Therefore, the mixture cannot be simply treated like a usual metallic solution. A further aspect to be noted is the fact that the present enthalpy-composition curves are similar to those of metal+chalcogen systems. In the binary mixture of tellurium with sulfur or selenium, tellurium perhaps functions as a metal-like component. The theoretical evaluation of the thermodynamic functions depends on a certain structural model of the mixture. Unfortunately, such information is not available at the present time and a quantitative discussion was not attempted in this work. At the end of this paper, it may be noted that, in the selenium+tellurium system, the mixture is conventionally divided into two distinct portions, according to recent NMR studies.[13]

In the region in which the compositions of tellurium are higher than 70 at. per cent, the mixture behaves in a metallic manner. On the other hand, in the lower composition range, the valence electrons are localized in the chain molecules. Although the composition of the minimum ΔH observation is slightly different from the above boundary, our opinions that an ordered structure is present and that the system is divided into two portions in the mixture are consistent with this view.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 765—769 (1973)

The Reflection Spectra of Würster's Salts

Yukako Oohashi and Tadayoshi Sakata*

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo

(Received July 17, 1972)

The reflections of *N,N*-dimethyl-*p*-phenylenediamine (WR) perchlorate, bromide, and iodide, and also of *p*-phenylenediamine (PD) perchlorate and bromide were measured over the range from 5000 to 42000 cm^{-1} by Avery's method. The absolute absorption intensity and the refractive index of these solids were obtained by computer analysis. The absorption intensity of the solid was found to be, as a whole, larger than that of the dimer in solution; in particular, the CT band becomes broader and splits in a solid. Further, the anion was found to have a large effect on the electronic structure in the crystal. By taking account of these features of the spectrum and other experimental results, the WR salts were classified into two types according to their way of packing: Type I takes the dimer-unit structure (WRP) and Type II, the equidistantly-overlapped form (WRB and WRI).

It is known that an equilibrium exists between monomer and dimer ions in the solutions of some radical ion salts and that the charge-transfer (abbreviated hereafter to CT) band pertinent to the dimer appears at low temperatures.[1)]

In the crystalline state, *N,N,N',N'*-tetramethyl-*p*-phenylenediamine perchlorate (WBP) shows its phase transition at 186K; below the transition point, the ESR signal due to the triplet exciton[2)] appears, and the CT band intensity is sensitive to the temperature. These observations were found to be consistent with the dimerization mechanism of the phase transition,[3)] and to contradict the disproportionation mechanism presented by Kommandeur and Pott.[4)]

At room temperature, the crystalline spectra of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (WB) radical salts show only weak CT bands and rather resemble the spectra of the corresponding monomers in solution.[1b,5)] The crystals of *N,N*-dimethyl-*p*-phenylenediamine (WR) and *p*-phenylenediamine (PD) radical salts, however, show vivid CT bands, and their spectra are similar to those of the corresponding radical dimers in solution.[6)] This means that the CT interaction is stronger for the WR and PD crystals than for the WB crystal.

In comparison with the solution spectra of radical dimers, the solid-state spectra were found to be broader; in particular, the CT bands become broad and split into two peaks. The absolute intensities of the crystalline absorption bands, however, were difficult to determine because of the difficulty of measuring the thickness of the very thin crystals. This fact prevents us from making a detailed discussion of the interaction between the radical ions, including the effect of the counter anion. In the present investigation, we measured, at various wavelengths, the reflection intensities of the pressed pellets of WR and PD radical salts and determined the refrative index (n) and the extinction coefficient (k). On the basis of the experimental results of the absolute absorption intensities, we will discuss the electronic structures of these radicals in the solid state.

Experimental

Materials. Würster's red perchlorate (WRP), bromide (WRB), *p*-phenylenediamine perchlorate (PDP), and bromide (PDB) were prepared and purified by the method described in the literature.[7)] Würster's red iodide (WRI) was prepared by a method analogous with that used for WRB. (WRI; Calcd: C, 36.52; H, 4.56; N, 10.65; I, 48.27%. Found: C, 36.42; H, 4.59; N, 10.68; I, 48.84%). The radical salts are considerably stable in the air, and the measurements were carried out within a few days after the syntheses.

Measurements. Several methods have been used for the determination of the optical constants of the crystals from the reflection measurements. We constructed the apparatus on the basis of the method of Avery[8)] and measured the

reflections at the incident angles of 50 and 70°. The characteristics of the method are to measure the ratio of the reflecting powers by the use of lights polarized parallel and perpendicular to the incident plane, and to suppress the scattering effect. Kondo[9] showed, taking fuchsine as an example, that this method gives the same refractive index and extinction coefficient for the crystal and the pressed pellet. Therefore, this method is useful for the measurement of Würster's salts, for which it is difficult to obtain a crystal large enough for the reflection measurement.

The light sources were a tungsten lamp for the range of 5000—30000 cm^{-1} and a deuterium-discharged lamp for the range of 25000—42000 cm^{-1}. The polarizers were a Polaroid HR for the range of 5000—11000 cm^{-1} and a Glan-Thompson prism for the visible and ultraviolet regions. A photomultiplier, HTV 7102 or 1P28, was used as a detector. Corrections were made for the polarization of the incident light caused by the optical systems. The samples were ground by means of an agate mortar and were pressed by a KBr disc presser at about 10 kbar.

Analysis. The following relation exists for the isotropic solid with the complex refractive index of $N=n-ik$:

$$I = \frac{r_p}{r_s} = \frac{a^2+b^2-2a\sin\beta\tan\beta+\sin^2\beta\tan^2\beta}{a^2+b^2+2a\sin\beta\tan\beta+\sin^2\beta\tan^2\beta}$$

$$a^2 + b^2 = \{(n^2-k^2-\sin^2\beta)^2+4n^2k^2\}^{1/2}$$

$$a = \left\{\frac{1}{2}(n^2-k^2-\sin^2\beta)+\frac{1}{2}[(n^2-k^2-\sin^2\beta)^2 + 4n^2k^2]^{1/2}\right\}^{1/2}$$

where r_p and r_s are the reflecting power by the incident light polarized, respectively, parallel and perpendicular to the incident plane, and β is the incident angle. We determined n and k from the I's at $\beta=50$ and 70° by means of the Newtonian approximation for two variables using the electronic computer. The larger the absorption intensity, the smaller the experimental error; when the molar extinction coefficient $\kappa(\nu)$ is larger than 3000 $(mol/l)^{-1}cm^{-1}$, the error is estimated from repeated measurements to be less than 10%. The following equation represents the relation between $k(\nu)$ and $\kappa(\nu)$:

$$\kappa(\nu)C = \frac{4\pi k(\nu)\nu}{2.303c}$$

where $I(z)=I(0)10^{-\kappa Cz}$, C is the concentration (mol/l), and c is the light velocity. On the other hand, the oscillator strength is calculated from $n(\nu)$ and $k(\nu)$:[10]

$$f = \frac{m}{e^2 n_0}\int 4n(\nu)k(\nu)\nu d\nu$$

where n_0 is the number of molecules in a unit volume.

In order to discuss the difference in the absorption intensity between the solid and the solution, the oscillator strengths must be compared.[11] Here, the $4\pi n(\nu)k(\nu)\nu/2.303Cc$ value will be plotted to show the wave number dependence of the absorption intensity. For the solution, $n(\nu)$ is reasonably approximated as 1.0. Some other physical constants of the solid can be calculated from $k(\nu)$ and $n(\nu)$. The complex dielectric constant, $\varepsilon(\nu)=\varepsilon'(\nu)+i\varepsilon''(\nu)$, is related to $k(\nu)$ and $n(\nu)$ as follows:

$$\varepsilon'(\nu) = n(\nu)^2 - k(\nu)^2$$

$$\varepsilon''(\nu) = \frac{2\sigma(\nu)}{\nu} = 2n(\nu)k(\nu)$$

$\sigma(\nu)$ is the electric conductivity constant.

Results and Discussion

Figure 1 shows the solid-state spectra of WRP, WRB, and WRI determined from the reflection measurements of pressed pellets, together with the low-temperature spectrum of an ethanol solution of WRP. The low-temperature spectrum of the ethanol solution was assigned to the WR cation dimer.[1b] The band at 15000 cm^{-1} has mainly the character of the CT band between WR cations (CT band), and the bands at 24500, 27500, 35300, and 39000 cm^{-1} are the locally (within the WR cation)-excited (LE) bands (the LEI, LEII, LEIII, and LEIV bands).[1c] The solid-state spectra, which are similar to the solution spectrum of the dimer, have the characteristics that the absorption intensity is, as a whole, stronger than that of the solution dimer, and that the CT band becomes remarkably broad and splits in a solid.[5] Furthermore, the solid-state spectrum is changed by the counter anion, while the solution spectrum is insensitive to it. These characteristics are also seen in PDP and PDB (see Fig. 2).

The Absorption Intensity of the Solid-state Spectrum. The oscillator strengths (f) are listed for the WR and

PD radical salts in Tables 1 and 2 respectively. The value for each CT band was calculated with respect to the broad peak with splittings. The CT band is stronger for the solid radical salts than for the corresponding dimers in solution—4 times for WRP, 1.6 times for WRB and WRI, and 3—4 times for PD salts. Furthermore, the $f_{CT}/\sum_{I}^{III} f_{LE}$ ratios are 1.9, 1.4, 0.7, 1.5, and 1.9 times larger for the solid WRP, WRB, WRI, PDP, and PDB salts respectively than for the corresponding dimers in solution. Thus, the intensity increase in the solid state is more remarkable for the CT band than for the LE bands except for WRI, for which the tail of the strong absorption above 40000 cm^{-1} makes it difficult to calculate f_{LE} accurately.

The crystal structures of Würster's salts have been reported for WBP,[12] WBB,[6] WBI,[13] and WRB;[14] all of them contain a one-dimentional column of equidistantly-overlapped cation radicals. Theoretically, it was concluded that, in the infinite column, the intensity of the CT band is twice as large as that of the isolated dimer, and that the intensity of the LE band shows no increase, as long as the interaction between the LE states and CT states is negligibly small.[15] The observed increase in the intensity of the CT band for the solid WRB and WRI compared with that for their solutions is of a reasonable magnitude and is caused by the influence of the infinite column.

The intensity of the LE band is influenced by the degree of the mixing of the corresponding LE state with the lowest CT state. As WRB has a very short interplanar distance of the cation radicals (3.105 Å),[14] the interaction between the CT state and the LE state is not completely neglected. Moreover, the higher LE and CT states have complicated effects on the intensity in the crystalline state. On the other hand, WRP has a remarkably strong CT band, and its absorption spectrum as a whole resembles that of the dimer in solution. Taking into consideration the reported experimental results that WBP takes the dimer form in the low-temperature phase[12] and that WR salts show a stronger intercationic interaction than the WB salts in the crystalline state,[5] we can safely anticipate that the WRP radical will take the same molecular packing form as the low-temperature phase of WBP. The zeroth and the first-layer Weissenberg photographs of the WRP single crystal show the extinction rule that $h0l$ and $0kl$ (l=0,1) are absent when h and k are odd[16] (a=10.19, b=13.00, c=7.01 Å, Z=4, orthorhombic). This extinction rule supports the dimer form of WRP because, if the radicals were arranged in the unit cell equidistantly, the resulting interradical distance would become too large compared with those previously reported for Würster's salts. Furthermore, the ESR study of the temperature dependency of WRP powder reported of the triplet signal[17] that its intensity increases as the temperautre increases. From the above-mentioned results, it may be concluded that WRP takes the dimer form in the crystalline state and that the large increases in the CT band intensity compared with that of the dimer in solution is mainly attributable

to the increase in the intercationic interaction, accompanied by the change in the molecular configuration. PDP and PDB both show strong CT bands, and the LEIII band is especially strong for PDP. There being no other experimental data, any detailed discussion is now impossible: however, PDP and PDB seem to show the optical properties similar to those of WRP and WRB respectively.

Table 3. The bandwidth and splitting of CT band

	Solid	Solution dimer	Splitting in solid
WRP	6500 cm^{-1}	1800 cm^{-1}	Yes
WRB	6500		Yes
WRI	7500		Yes
PDP	8500	1600	Yes

WBC[18]	3400[a]		No
N-EP[3]	2700[a]	1700	Yes

a) Calculated from the transmission spectra of the quartz plates smeared with the samples at 77 K and 50 K.

The Splitting of the CT Band. Table 3 shows the bandwidths of the CT bands of the solid-state spectra and the low-temperature solution spectra, and the presence of the splitting of the CT band in the solid. The values of the second column show the width of the wave numbers, which correspond to half of the peak-absorption intensity, because a reasonable deconvolution of CT band is impossible. The fact taht the values of PD salts are larger than those of WR salts seems to be due to the larger splitting of the CT band. For comparison, Table 3 also shows the bandwidths of WB salts (P: perchlorate, B: bromide, and C: chloride) and *N*-ethylphenazyl (*N*-EP), which have weak intercationic interaction in the crystalline state. The origin of this splitting has been explained before as being due to the forbidden CT state appearing by means of the intensity borrowing through vibrational or other kinds of perturbations.[6] However, as may be seen in Table 3, WR and PD salts, with strong intercationic interaction, have the splittings, while WB salts, with weak interaction, have not. Thereofre, the explanation can not be denied at present that a new absorption occurs due to the long-range interaction between the cation radicals characteristic of the strong intercationic interaction.

The Effect of the Anion Species. The third characteristic of the solid-state spectra of WR and PD salts is the remarkable difference produced by the change of the anion species. In the case of WR salts, the following classification is possible. The conclusion that a salt of Type I has the dimer unit in the crystal is supported by the ESR and X-ray studies. From the characteristics of the salts of Type II (the extroadinary broadning of the solid-state spectra with strong higher energy absorptions, the large red shift of CT band, and the lack of a triplet signal), it is conceivable that the salts of Type II contain a one-dimensional column of equidistantly-overlapped cation radicals in the crystalline state.

Table 4. Classification of WR salts

	Type I (WRP)	Type II (WRB, WRI)
Red shift of CT band from that of dimer in solution	1200 cm^{-1}	3000cm^{-1}
Splitting of CT band	Less clear	Clear
Absorption higher than 40000 cm^{-1}	No tail	Strong tail
ESR	Triplet signal	No signal[a]

a) Preliminary study by M. Itoh found only the impurity signal.

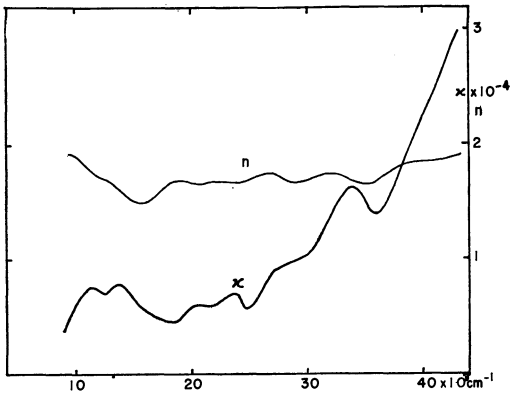

Fig. 5. The molar extinction coefficient and the refractive index of WRI solid determined by the reflection measurement.

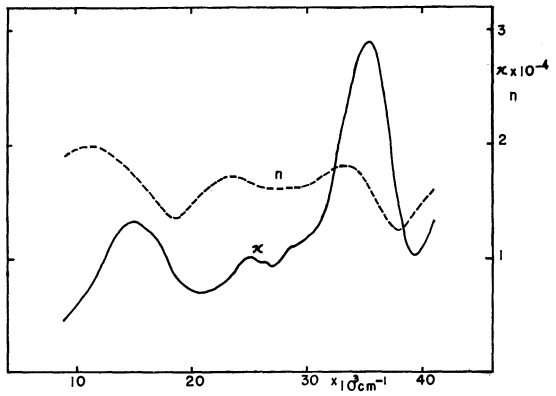

Fig. 6. The molar extinction coefficient and the refractive index of PDP solid determined by the reflection measurement.

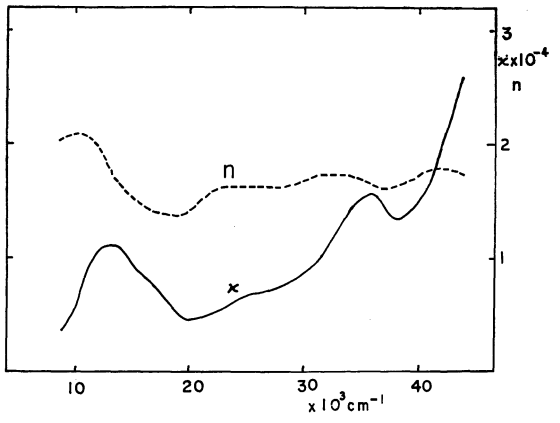

Fig. 7. The molar extinction coefficient and the refractive index of PDB solid determined by the reflection measurement.

The Determinations of the Optical Constants. Figures 3, 4, 5, 6, and 7 show the wave number dependence of the refractive index, $n(\nu)$, together with the molar extinction coefficients of WR and PD salts. At the wave number near the CT band, $k(\nu)$ takes the maximum value, and the wave number dependence of $n(\nu)$ is especially large. This suggests that the absorption maximum determined by the transmission measurement must be modified by taking the reflection effect into account. Figures 8 and 9 show the real and imaginary parts of the dielectric constant. The very small value of the real part of WRP near 17000 cm^{-1} causes the remarkably strong reflection.

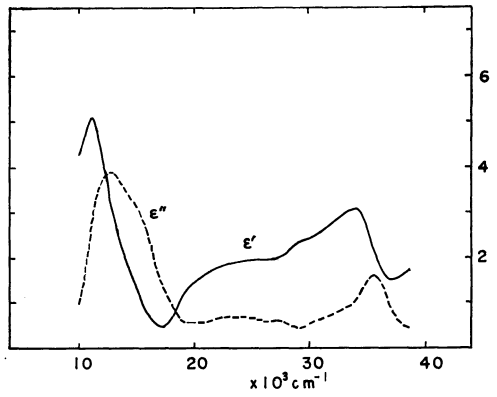

Fig. 8. The real and imaginary parts of the dielectric constant of WRP solid.

The authors would like to express their deep gratitude to Professor Saburo Nagakura of this Institute for giving them the chance to do this work and for his helpful discussions and critical reading of the manuscript. The authors are also grateful to Professor Shogen Nakahara, Rikkyo University, for his kind advice on the measurements of the reflection spectra.

The Preparation and Crystal Structure of Ternary Rare Earth Borides, RCo_3B_2

Koichi NIIHARA and Seishi YAJIMA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received July 24, 1972)

In the ternary system of rare earth-cobalt-boron, RCo_3B_2 compounds (R=rare earth elements) were prepared by arc-melting methods. Their crystal structure was investigated by X-ray diffraction methods. These ternary borides, RCo_3B_2, crystallize in a hexagonal lattice. The lattice parameters are $a=5.020\pm0.002$ Å and $c=3.027\pm0.002$ Å for YCo_3B_2 and $a=5.066\pm0.003$ Å and $c=3.022\pm0.002$ Å for $GdCo_3B_2$. The good agreement between the X-ray diffraction intensities observed and calculated shows that the ternary borides, YCo_3B_2 and $GdCo_3B_2$, crystallize in the $CaZn_5$-type structure. The space group and atomic positions are as follows: P6/mmm (D^1_{6h}), 1R in 1(a), 3Co in 3(g), and 2B in 2(c). It can be seen from these results that the ternary borides, RCo_3B_2, have a superstructure in which two Co atoms in the 2(c) site of intermetallic compounds, RCo_5, with the $CaZn_5$-type structure are replaced by two B atoms. The B atoms in this structure are situated at the center of a trigonal prism formed by six Co atoms. The interatomic distances between B and the six Co atoms are 2.11—2.10 Å and are fairly constant, although the radii of the rare earth atoms are changed according to the lanthanide contraction. We have also found RCo_3B_2 compounds to be isostructural with YCo_3B_2 and $GdCo_3B_2$, where R= Ce, Sm, Tb, Dy, Ho, and Er. Efforts to prepare $LaCo_3B_2$, $PrCo_3B_2$, and $NdCo_3B_2$ by arc-melting were unsuccessful.

Only recently have ternary metal-boron compounds been reported.[1-9] The most interesting borides are the family of the borides with the $Cr_{23}C_6$-type structure, found when the works that led to the perovskite carbides and nitrides were extended to include boron. The composition of the ternary boride varies from system to system and can best be symbolized by the $T_{23-m}M_mB_6$ formula. Here, T represents one of the d-transition metals, cobalt or nickel, M is a nontransitional metal or, a IVth or Vth-group transition metal, and B is boron. Roughly, m ranges from 2 to 3.5. There also exist some other ternary phases, such as Mo_2CoB_2,[10] Mo_2FeB_2,[11] W_2CoB_2,[12] $MoFeB_4$,[13] $ThWB_4$,[14] and $Mo_2Fe_{13}B_5$.[14] However, there have been few investigations concerning any ternary rare earth borides except $YCrB_4$.[15]

Recently we reported[16,17] that, in the system of rare earth-cobalt-boron, there exist two ternary compounds, RCo_2B_2 and $RCo_{12}B_6$, with tetragonal and rhombohedral structures respectively, where R represents a rare earth atom. In the present paper, we will describe the preparation and the crystal structure of another ternary rare earth boride, RCo_3B_2, of a hexagonal $CaZn_5$-type[18] structure in systems of rare earth-cobalt-boron.

Experimental

Materials. The cobalt metal and the crystalline boron were obtained from Wako Pure Chemical Industries, Ltd., Tokyo. The purities were 99.99 and 99.9% respectively. All the rare earth metals[19] except samarium were prepared in our laboratory by the calcium-metal reduction of rare earth trifluorides. The samarium metal was prepared from samarium oxide by lanthanum-metal reduction. These metal rods were refined by arc-melting. The purity of the metals obtained by these methods was 99.8%. The main impurities were oxygen and carbon.

Preparation of Alloys. The alloys were prepared by co-melting mixtures of the rare earth metal, the cobalt metal, and crystalline boron in an arc furnace under an inert gas atmosphere. Each sample was remelted three times to prove its homogeneity. After melting, some of the alloy buttons were analysed by chemical methods; it was found that the rare earth metals lost during the melting process were negligible except for samarium. In the case of samarium, 10—15 wt% of the samarium metals were vaporized during the melting process.

In order to establish the thermal equilibrium, some of the alloy buttons were annealed at 1150°C for 96 hr in tantalum crucibles sealed into quartz tubes under a reduced pressure of purified argon.

The densities of the samples were determined at 24.5°C by the flotation technique using CCl_4.

X-Ray and Chemical Analytical Procedures. The samples

for X-ray and chemical analyses were generally taken from the most homogeneous part of annealed specimens. They were crushed in an agate mortar under toluene in order to avoid unnecessary oxidation and then divided for X-ray and chemical analyses.

After the solution obtained by dissolving the samples into aqua regia was fumed with conc. $HClO_4$, the precipitates of RF_3 obtained by the addition of conc. HF were submitted to a gravimetrical determination of the rare earth content. The analyses of the Co metal were performed by means of X-ray fluorescence analysis. The boron content was determined by a method[20] previously reported.

All the X-ray powder patterns were taken with a Debye-Scherrer camera (114.6 mm in diameter) which corrected using standard silicon powder. Mn-filtered Fe ($K\alpha_1$=1.9360 Å, $K\alpha_2$=1.9399 Å, and $K\bar{\alpha}$=1.9373 Å) radiation was employed. The lattice parameters were determined by the Nelson-Riley extraporation method. The observed X-ray diffraction intensities were obtained by measuring the peak areas which were produced using a diffractometer in combination with an NaI(Tl) scintillation counter and a pulse-height analyser.

Results and Discussion

In investigating the phase equilibria in the system of Y–Co–B, a ternary compound was found by chemical and X-ray analyses. This compound was, at 1150°C, in equilibrium with YCo_2, YCo_5, and the ternary compounds YCo_2B_2[16] and $YCo_{12}B_6$.[17] The chemical analyses of the samples in the single-phase region showed that the new ternary compound existed in the region (at.%): Y(16.5—16.7), Co(50.0—50.4), and B(33.2—33.3). The stoichiometric composition of YCo_3B_2 was proposed on the basis of the results of X-ray and chemical analyses and density measurements. Ternary compounds with a similar composition were also prepared by the arc-melting method in the systems of (Ce, Sm, Gd, Tb, Dy, Ho, and Er)–Co–B. However, efforts to prepare $LaCo_3B_2$, $NdCo_3B_2$, and $PrCo_3B_2$ by arc-melting were unsuccessful.

The Crystal Structure of YCo_3B_2 and $GdCo_3B_2$. The X-ray powder pattern for YCo_3B_2 was indexed on the basis of a hexagonal unit cell. The d-values are shown in Table 1. As is shown in this table, the observed d-values are in good agreement with those calculated. The lattice parameters for YCo_3B_2 were a=5.020±0.002 Å, c=3.027±0.002 Å, and c/a=0.603. The calculated and measured densities were 4.35 g/cm³ and 4.29 g/cm³ respectively. Therefore, the unit cell contains one formula unit of YCo_3B_2.

The crystal structure of the YCo_3B_2 compound was considered to be of a type similar to that of the intermetallic compound $CaZn_5$,[18] because the X-ray diffraction pattern of YCo_3B_2 appeared to be similar. $CaZn_5$ has the following atomic positions, according to the International Table for X-ray Crystallography:[21] space group P6/mmm (D^1_{6h}), 1Ca in 1(a), 3Zn in 3(g), and 2Zn in 2(c). Therefore, it was assumed that the Y, Co, and B atoms of YCo_3B_2 occupy the following positions: 1Y in 1(a), 3Co in 3(g), and 2B in 2(c). The X-ray diffraction intensities were calculated according to the formula;

$$\mathbf{I}_{cal} = A \cdot |\mathbf{F}|^2 \cdot M \cdot Lp \cdot \theta$$

in which A, $\mathbf{F}$, Lp, M, and θ represent the scaling factor, the structure factor, the multiplicity, the Lorentz polarization factor, and the overall temperature factor respectively. In the structure-factor calculation, the atomic scattering factor for the neutral atoms listed in the International Table for X-ray Crystallography and the anomalous dispersion corrections for the Y and Co atoms of Cromer[22] were employed.

In this structure, the positions of all the atoms are fixed by symmetry. Thus, the only variable parameter is the temperature factor.

The temperature factors were found by a least-squares solution of the plot of $\log |I_c/I_0|$ *vs.* $(\sin/\lambda)^2$. Using an overall temperature factor of 0.64, the calculated and observed X-ray diffraction intensities obtained for YCo_3B_2 are given in Table 1. The reliability factor, $R=\sum_{hkl}|I_{cal}-I_{obs}|/\sum_{hkl}I_{obs}$, amounts to 0.122 for this structure. From this result, it can be considered that the Y and Co atoms occupy the 1(a) and 3(g) sites respectively. However, from only the value of the R-factor it cannot be evaluated accurately whether or not the assumption concerning the positions of the B atoms is reasonable because of the small atomic scattering factor of the B atoms. It is impossible, however, that B atoms occupy the 2(d) and 2(e) sites in the P6/mmm space group, considering the atomic sizes of Y, Co, and B, and the coordination of the B atoms. Generally, B atoms of metal-rich borides, such as Re_3B, Pd_3B, Cr_5B_3, and Pd_5B_3,[23] are surrounded by nine metal atoms, situated at the six corners of a trigonal prism and outside the three lateral faces of this prism. Thus, with these simple geometrical arguments it is reasonable to think that the B atoms in YCo_3B_2 occupy the 2(c) site. In the ternary system of Gd–Co–B, a ternary boride $GdCo_3B_2$ with the $CaZn_5$-type structure was synthesized by arc-melting. The lattice parameters and densities are shown in Table 3. In order to calculate the X-ray diffraction intensities for $GdCo_3B_2$, it was assumed that the crystal structure of this compound was the same as that of YCo_3B_2. The final results are compared with the observed intensities in Table 2, using a temperature factor of 0.87. The

reliability factor, R, is 0.130. The crystallographic data for YCo_3B_2 and $GdCo_3B_2$ are summarized in Table 3. Figure 1 indicates the projection of the YCo_3B_2 structure on the (001) plane. The coordination polyhedron of the B atoms was formed by the combination of a trigonal prism and three rectangular pyramids on its lateral faces. In other words, the boron atom is surrounded by six Co atoms and three Y atoms, situated at the corners of a trigonal prism and outside the lateral faces of the prism respectively. Figure 2 shows the polyhedron of the B atom in the 2(c) site of the YCo_3B_2 structure. The ternary boride YCo_3B_2 has a superstructure in which two Co atoms in the 2(c) site of the intermetallic compound YCo_5[24] with the $CaZn_5$-type structure are replaced by two B atoms.

The interatomic distances between the B and the six nearest Co stoms are 2.10 Å for both YCo_3B_2 and $GdCo_3B_2$. This distance is closer to the sum of the Goldschmidt metallic radii[23] for the 12-coordination of B (0.88 Å) and Co (1.16 Å) than to the sum of the Pauling metallic radii[25] for the 12-coordination of B (0.98 Å) and Co (1.25 Å). The distances between the B atom and three rare earth atoms in the next-nearest neighbor are 2.90 and 2.93 Å for YCo_3B_2 and $GdCo_3B_2$ respectively.

The Structure of Ternary Rare Earth Borides, RCo_3B_2 (R=Ce, Sm, Tb, Dy, Ho, and Er). The crystal structure of RCo_3B_2 compounds (R=Ce, Sm, Tb, Dy, Ho, and Er) is isostructural with YCo_3B_2 and $GdCo_3B_2$. The powder X-ray data are shown in Table 4 for $CeCo_3B_2$, $SmCo_3B_2$, $TbCo_3B_2$, $DyCo_3B_2$, $HoCo_3B_2$, and $ErCo_3B_2$. As is shown in this Table, there is a good agreement between the observed and calculated interplanar spacings. The lattice parameters of RCo_3B_2 compounds are summarized in Table 5. The change in the a parameter against the atomic number of the rare earth elements plotted in Fig. 3 is characteristic of the well-known lanthanide contraction. The c para-

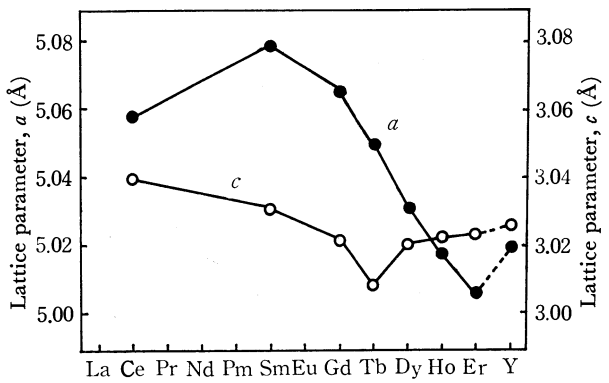

Fig. 3. The lattice parameters of the hexagonal RCo_3B_2 compounds as a function of atomic number of rare earth elements. ○: the c parameter, ●:the a parameter.

24) J. Schweizer and F. Tasset, *Mat. Res. Bull.*, **4**, 369 (1969).
25) L. Pauling, "The Nature of the Chemical Bond," 3rd ed., Cornell University Press, (1960), Chap. 11.

meter is fairly constant, increasing slightly with the atomic number of the rare earth element from the $TbCo_3B_2$ compound onwards.

The parameters of the $CeCo_3B_2$ compound are an exception. They are similar to those of the compound at the second series of lanthanides. It may be seen that the Ce atom has a relatively small radius in this structure. Various authors[26-28] have attributed this contraction of the Ce atom to the loss of the 4f electron to the compound's conduction band.

A similar variation in the *c* parameter has been observed in the case of RCo_5,[29] which has the $CaZn_5$-type structure. The *c* parameters of the RCo_3B_2 compounds do not indicate the lanthanide contraction, probably because of: (a) the effect of the nonstoichiometric composition in RCo_3B_2 compounds and (b) the fairly constant interatomic distances between the B and Co atoms in the trigonal prism. With reference to (b), the interatomic distances, B–6Co, in the trigonal prism of RCo_3B_2 (Fig. 2) are 2.11—2.10 Å and are fairly constant, although one rare earth is replaced by another small rare earth. Figure 4 shows the variation in the interatomic distances in the coordination polyhedron of the B atom in the RCo_3B_2 structure (Fig. 2) against the atomic number of the rare earth elements and the variation in the corresponding distances of RCo_5 compounds. As is shown in Fig. 4, the interatomic distances of B–3R, Co_1–Co_1, and R–4Co indicate an acceptable lanthanide contraction. The Co_1–Co_2 distance has its minimum at $TbCo_3B_2$. From these results, it may be seen that, in the compounds at the end of the second rare earth series, the Co_1–Co_1 distance decreases and the Co_1–Co_2 distance increases in order to preserve the stable Co–B interatomic distance (2.11—2.10) in the trigonal prism of the RCo_3B_2 structure, when one rare earth element is replaced by other small rare earth elements.

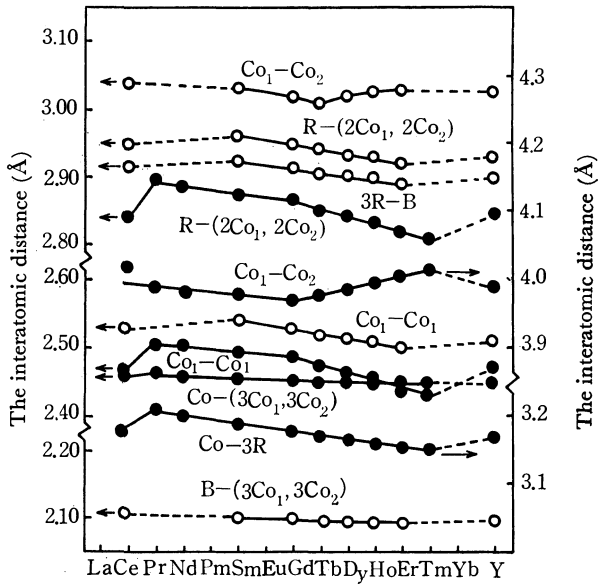

Fig. 4. The interatomic distances in the coorinatidon polyhedron of B and Co atoms situated at the 2(c) sites of RCo_3B_2 and RCo_5 structure, respectively (Ref. Fig. 2).
○: RCo_3B_2; ●: RCo_5.

Similar phenomena were observed in the RCo_5 compounds,[29] as is shown in Fig. 4. The nonstoichiometric and magnetic properties of these borides will provide additional data which may be useful in the interpretation of the nature of bonding. These data will be the subject of a separate paper.

Theoretical Calculations and Assignments of Electronic Absorption Spectra of Cation Radicals of *o*-, *m*-, and *p*-Disubstituted Benzenes Having Amino and Hydroxyl Groups

Shunji KATSUMATA and Katsumi KIMURA

Physical Chemistry Laboratory, Institute of Applied Electricity, Hokkaido University, Sapporo

(Received August 3, 1972)

Calculations have been carried out on the electronic spectra and electronic structures of the cation radicals of *o*-, *m*-, and *p*-disubstituted benzenes having the amino and hydroxyl groups, by an open shell SCF MO CI method involving some doubly excited electron configurations. Assignments of the electronic absorption spectra of these cation radicals have been made on the basis of resulting transition energies and oscillator strengths. The results are in good agreement with experimental data. Effects of methyl-substitution on the cation spectra are discussed. Spin densities of these cation radicals have also been calculated and compared with experimental data.

Kimura *et al.*[1-3] observed the electronic absorption spectra of cation radicals of various disubstituted benzenes, *i.e.*, *p*-aminophenol$^+$, *m*-aminophenol$^+$, and their *N*- and *O*-methyl derivatives, by ultraviolet irradiation in rigid glasses at 77K. The electronic absorption spectra of hydroquinone$^+$ and several of its *O*-methyl derivatives have also been measured in concentrated sulfuric acid by Kimura and Yamada.[4] For EPA glasses containing *m*-aminophenol$^+$, *m*-anisidine$^+$, and *m*-phenylenediamine$^+$, appreciable blue shifts of the electronic absorption bands due to trapped electrons have been observed.[5] It has been pointed out that the mangitudes of such spectral shifts depend largely on electronic structures of the cations.

The open shell SCF MO method involving configuration interaction (CI) is now generally known to be advantageous for calculating electronic spectra and structures of organic free radicals having an odd electron. Using a method which combines the open shell SCF procedure of Longuet-Higgins and Pople[6] with CI, Ishitani and Nagakura[7,8] have extensively studied the electronic structures and spectra of the anion radicals of substituted benzenes having nitro, nitroso, and cyano groups and the anion radical of paracyclophane. Zahradnik and Carsky[9] have employed a similar theoretical method for studying the electronic spectra of the free radicals of various alternant hydrocarbons in more detail. Shida and Iwata[10] have recently carried out CI calculations of nitro-substituted aromatic anion radicals in order to explain experimental absorption spectra, by including some doubly excited electronic configurations.

However, as regards the cation radicals of disubstituted benzenes with electron donating groups such as amino and hydroxyl groups, only a few fragmentary reports have been given on their theoretical assignments; by Monkhorst and Kommandeur[11] for the electronic absorption spectrum of *N*,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine$^+$ and by Kimura and Mataga[12] for that of *p*-phenylenediamine$^+$, with the open shell MO CI calculation.

In connection with our previous works,[1-5] the present authors used the open shell SCF MO CI method to carry out theoretical studies on the cation radicals of a series of substituted benzenes having amino and hydroxyl groups, in order to clarify the electronic absorption bands already known for these cations and to predict those still unknown in experiment. It is especially interesting to compare the electronic transition of isomers of the disubstituted benzenes.

Method of Calculation

The SCF MO CI method was used in the calculation of cation radicals of *o*-, *m*-, and *p*-disubstituted benzenes having OH and NH_2 groups, and also that of monosubstituted benzenes such as phenol$^+$ and aniline$^+$. Numberings of carbon atoms in the cations are illustrated in Fig. 1.

We used a computer program in which a total of 40 configurations was chosen for each symmetry from the first 100 low-energy configurations of one- and two-electron excitations.[13]

The Coulomb repulsion integrals of the type $(pp|qq)$ were calculated by using the Pariser-Parr approximation. The valence state ionization potentials and electron affinities were taken from literature[14] as follows: $I_C=11.22$ eV, $A_C=0.62$ eV, $I_N{}^+=28.88$ eV, $A_N{}^+=12.28$ eV, $I_O{}^+=34.43$ eV, $A_O{}^+=14.97$ eV. Nuclear charge values $Z_C=1$, $Z_N=2$, and $Z_O=2$ were used for carbon, nitrogen, and oxygen atoms, respectively. The penetration integrals were neglected, and core resonance integrals parametrized as $\beta_{\mu\nu}$. Bond lengths r(C–C)= 1.39 Å and r(C–N)=r(C–O)=1.36 Å were used throughout this work. The calculations were carried out with a FACOM 230-60 electronic computer in Hokkaido University using a computer program prepared by Iwata and Katsumata.[13]

Results and Discussion

Calculated results for energies of the ground and lower electronic excited states of aniline$^+$ and *o*-, *m*-, and *p*-phenylenediamine$^+$ are given in Table 1, together with electron configurations contributing to the various states by more than 4% (those of doubly excited configurations are underlined). Electronic configurations having doublet states are distinguished from each other with a prime, configurations $(i\to k)$ and $(i\to k)'$ designating $\sqrt{1/2}(|im\bar{k}|-|i\bar{m}k|)$ and $6^{-1/2}(-2|\bar{i}mk|+|im\bar{k}|+|i\bar{m}k|)$, respectively. The resulting transition energies, oscillator strengths and directions of transition moments are summarized in Table 2 together with experimental data available for comparison.

Cations of o-, m-, *and* p-*Phenylenediamines* (o-, m-, *and* p-*PD*$^+$). Electronic transition energies and oscillator strengths of *m*- and *p*-PD$^+$ were calculated for different β_{CN} values from −2.40 to −3.60 eV with an interval of 0.2 eV. The resulting transition energies were plotted against the β_{CN}'s and compared with experimental data available, as shown in Fig. 2. The electronic transition to the excited state to which the (4→5) configuration mainly contributes is forbidden in *p*-PD$^+$ because of molecular symmetry (D_{2h}), whereas

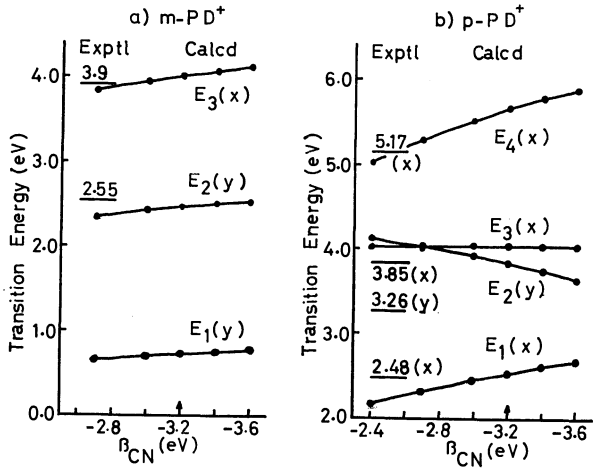

Fig. 2. Transition energies plotted against β_{CN}.

13) The program was prepared by S. Iwata and S. Katsumata, and used in the calculation of Ref. 10.

it is allowed in o- and m-PD$^+$. We see that E_1, E_2, and E_4 in p-PD$^+$ are considerably sensitive to β_{CN}, while E_3 in p-PD$^+$ and E_1 to E_3 in m-PD$^+$ are insensitive. The E_1 transition energy of p-PD$^+$ corresponding to the first visible absorption band was found to be well reproduced at $\beta_{CN}=-3.20$ eV. This value was therefore employed throughout the present work, and the transition energies and oscillator strengths shown in Table 2 are those calculated with it.

Contributions of nitrogen AO's to SCF MO's (ϕ_3–ϕ_7) of o-, m-, and p-PD$^+$ are as follows. In p-PD$^+$, the contributions of (N_1+N_2) to $\phi_3(b_{3u})$ and $\phi_7(b_{3u})$ are 21 and 7%, respectively, and that of (N_1-N_2) to $\phi_5(b_{2g})$ is 16%. There are no nitrogen contributions to $\phi_4(b_{1g})$ and $\phi_6(a_u)$ corresponding to the e_{1g} and e_{2u} MO's of benzene, respectively. In m-PD$^+$, contributions of (N_1+N_2) to ϕ_3, ϕ_4, and ϕ_6 in symmetry b_1 are 10, 14, and 2%, respectively, and those of (N_1-N_2) to ϕ_5 and ϕ_7 in symmetry a_2 are 11 and 6%, respectively. In o-PD$^+$, contributions of (N_1+N_2) to ϕ_3, ϕ_5, and ϕ_6 in symmetry b_1 are 8, 16, and 2%, respectively, and those of (N_1-N_2) to ϕ_4 and ϕ_7 in symmetry a_2 are 6 and 1%, respectively.

The electronic absorption spectrum of p-PD$^+$ was interpreted by Kimura and Mataga[12] with the open shell MO CI method using Hückel MO's. However, in the present work, much better results were obtained for transition energies and oscillator strengths (see Table 2).

In p-PD$^+$, electron configurations with the largest contributions are (3→5), (5→6), (5→7), and (4—6) in Ψ_1 to Ψ_4, respectively (Table 1).

The calculated results of m-PD$^+$ are also in good agreement with the experimental ones (Table 2). For o-PD$^+$, however, there are no experimental values reported. It is interesting to note that the present calculations of o- and m-PD$^+$ predict that the first transitions $\Psi_0\rightarrow\Psi_1$ (f=0.01) should cause weak absorption bands in near infrared region, although no such absorption bands have so far been reported.

Cations of o-, m-, *and* p-*Aminophenols (*o-, m-, *and* p-*AP*$^+$*).* Transition energies of p-AP$^+$ were calculated with various β_{CO} values from −2.40 to −3.60 eV with an interval of 0.20 eV. By plotting the resulting transition energies against β_{CO}, it was found that E_2 corresponding to the visible absorption band is fairly sensitive to β_{CO} and the experimental value of this second transition energy is reproduced at $\beta_{CO}=-3.20$ eV. This β_{CO} value and the β_{CN} value (−3.20 eV) previously determined were used in the calculation of all the isomers (Table 2).

The electronic absorption spectra of p-AP$^+$ and its *N*- and *O*-methyl derivatives are known to consist of three bands in a wavelength region greater than about 250 nm.[2] We see that agreement between the calculated and experimental transition energies is excellent for m- and p-AP$^+$.

Cations of o-, m-, *and* p-*Dihydroxybenzenes (*o-, m-, *and* p-*DHB*$^+$*).* The electronic absorption spectra of cation radicals of several p-dialkoxybenzenes (hydroquinone, p-methoxyphenol, p-dimethoxybenzene, p-ethoxyphenol, p-diethoxybenzene, and 2,3,5-trimethylhydroquinone) were measured in concentrated sulfuric acid by Kimura and Yamada.[4] Our calculation (Table 2) indicates that the first allowed transition of p-DHB$^+$ (hydroquinone$^+$) occurs at E=2.75 eV, in good agreement with the experimental value of 2.95 eV obtained from the 420 nm band.

Phenol$^+$ *and Aniline*$^+$. Electronic spectra of phenol$^+$ and aniline$^+$ were also calculated with the same parameter values as mentioned above. The visible absorp-

tion bands of aniline$^+$,[15] *N*-methylaniline$^+$,[16,17] and *N,N*-dimethylanilinc$^+$ [15-17] have been reported in the region 400—450 nm. According to the present results, such absorption bands may be interpreted as transition $\Psi_0 \rightarrow \Psi_2$ (f=0.06), which is mainly due to configuration (2→4).

No absorption data concerning phenol$^+$ are available. The present calculation predicts that a visible band should be located around 440 nm (2.84 eV) with f= 0.06.

Cations of N,N-*Dimethyl*-p-*Phenylenediamine and* N,N,N′,N′-*Tetramethyl*-p-*Phenylenediamine (DMPD$^+$ and TMPD$^+$).* The electronic absorption spectrum of TMPD$^+$ (so-called Würster's blue cation) has been studied in solution and crystalline state by many workers, this being the only cation whose experimental polarization has been reported.[18] Thus, it is of particular interest to compare the calculated results of TMPD$^+$ with experiment. In the present calculations of DMPD$^+$ and TMPD$^+$, the effect of methyl substitution was taken into account in such a way that the valence state ionization potential of the methyl-substituted nitrogen atom is reduced by 2.0 eV[19] and β_{CN} is made equal to −3.05 eV proportional to $1/2\,(I_N+I_C)$. Very good agreement was obtained between theory and experiment (Table 2).

The first transition of DMPD$^+$ is not symmetry-forbidden, but its intensity is very low. The first visible absorption band can be assigned to the second transition.

Effect of Methyl Substitutions. It was indicated[2] that the experimental shifts of the absorption bands of

a) Spin density on the N atom belonging to the $N(CH_3)_2$ group

15) K. D. Cadogan and A. C. Albrecht, *J. Phys. Chem.*, **73**, 1868 (1969).
16) E. J Land and G Porter, *Trans. Faraday Soc.*, **59**, 2027 (1963).
17) S. Arimitsu, K. Kimura, and H. Tsubomura, This Bulletin, **43**, 1858 (1969).
18) A. C. Albercht and W. T. Simpson, *J. Amer. Chem. Soc.*, **77**, 4454 (1955).
19) Since the first ionization potentials of NH_3, CH_3NH_2, and, $(CH_3)_2NH$ are 10.16, 9.18, and 8.36 eV, respectively (A. D. Baker, D. P. May, and D. W. Turner, *J. Chem. Soc.*, **B 1968**, 22), it is inferred that the change in the valence state ionization potential of the nitrogen atom per one CH_3 group is about −0.9 eV.

p-aminophenols$^+$ from that of *p*-phenylenediamine$^+$ are approximately interpreted in terms of differences in valence-state ionization potentials of the substituents by using the first-order perturbation theory. In the present work, using the SCF MO's for the parent cations as unperturbed systems, we applied this perturbation method in order to explain the experimental band shifts of the various methyl substituted cations. The shifts of the first visible bands for the methyl derivatives of *p*-PD$^+$, *p*-AP$^+$, and *p*-DHB$^+$ (Table 3) may be given by $\{-0.0765(\Delta I_{N_1}+\Delta I_{N_2})\}$, $\{-0.0591\Delta I_N-0.0597\Delta I_o\}$, and $\{-0.0438(\Delta I_{o1}+\Delta I_{o2})\}$, where $\Delta I_N=2.0$ eV and $\Delta I_o=3.0$ eV were used. We see that calculated shifts are in good agreement with the experimental shifts of the longest wavelength absorption bands.

Spin Densities. Spin densities in cation radicals are obtainable from an analysis of hyperfine splittings of ESR spectra. Since hyperfine ESR splittings of *p*-PD$^+$,[20] TMPD$^+$,[11,21] *p*-AP$^+$,[22] and *p*-DHB$^+$ [23] have already been measured, we carried out theoretical calculations of the spin densities of these cation radicals and other related cations, obtained from the McLachlan relationship[24] using the experimental hyperfine splittings and appropriate Q values.[25] The calculated results are shown in Table 4. As far as comparison is possible, the calculated spin densities are in agreement with the experimental ones.

Effect of Doubly Excited Configurations. It should be mentioned that all the singly excited electron configurations are included for all the compounds studied except for aminophenols, in which a few of the singly excited configurations with high energies are excluded because of the low molecular symmetries. Contribution of the doubly excited configurations is less than a few percent in the lower states of the cations as underlined in Table 1.

The Magnetic Properties of Some Iminoxyl Polyradicals. IV. The Paramagnetic Susceptibilities of the Diluted Crystals of the TEMPAD Biradical

Akira NAKAJIMA

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto

(Received August 15, 1972)

The paramagnetic susceptibilities of the diluted crystals of bis(2,2,6,6-tetramethylpiperidine-4)azine-1,1′-dioxyl (the TEMPAD biradical) have been measured from 1.8 to 77.3 K. The χ_M-T curves obey the Curie-Weiss law in the high and low temperature regions, and two kinds of the Weiss constant were found. The Weiss constant in the high-temperature region, which is caused by the strong inter-molecular exchange interaction, varies with the radical concentration from -8.5 to -15 K. The Weiss constant in the low-temperature region is of the order of magnitude of -1 K and reveals the existence of a weak intra-molecular exchange interaction. We can assume that the TEMPAD biradicals are distributed randomly in the matrix of the diamine and that they form either an isolated portion in which the weak intra-molecular exchange interaction exists only, or a clustering portion coupled by a strong inter-molecular exchange interaction besides the intra-molecular one. Then, the concentration dependence of the χ_M-T curves can be explained as the superposition of the contributions from these two portions. The curves caluclated on the assumption of the random distribution agreed with the experimental results.

There are many works concerned with the magnetic properties of organic stable free radical solids, which were introduced in Part II of the present series.[1] In these works some short-range ordering effects caused by exchange interaction among the unpaired electron spins were observed, and the linear chain or the spin-cluster model was applied. These two models are based on the localized spin treatment as in the case of the transition-metal ion salts. In iminoxyl radicals the unpaired electron is localized around the N–O bond, so they can also be treated as localized spin systems.

Previously the present author and his colleagues reported on these magnetic study of bis(2,2,6,6-tetramethylpiperidine-4)azine-1,1′-dioxyl (the TEMPAD biradical) and bis(2,2,6,6-tetramethylpiperidine-4)sulfite-1,1′-dioxyl (the sulfite biradical), and concluded that the strong inter-molecular exchange interaction has a

1) A. Nakajima, H. Ohya-Nishiguchi, and Y. Deguchi, This Bulletin, **44**, 2120 (1971). Please refer the added two works. J. Yamauchi, This Bulletin, **44**, 2301 (1971). W. Duffy, Jr., J. F. Dubach, P. A. Pianneta, J. F. Deck, D. L. Strandburg, and A. R. Miedema, *J. Chem. Phys.*, **56**, 2555 (1972).

short-range ordering effect in both biradicals.[2,3]

In this paper the author will report on the paramagnetic susceptibilities of the diluted crystals of the TEMPAD biradical and will discuss the intra- and inter-molecular exchange interactions in these systems.

Experimental

The TEMPAD biradical and bis(2,2,6,6-tetramethylpiperidine-4)azine (the diamine corresponding to the TEMPAD biradical), shown in Fig. 1, were prepared from 2,2,6,6-tetramethyl-4-piperidone supplied by the Aldrich Chemicals Co.; this substance was introduced in a previous paper.[3]

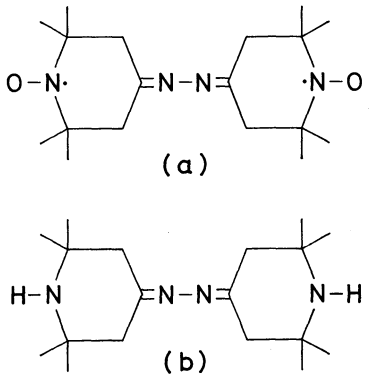

Fig. 1. Molecular structure of the TEMPAD biradical (a) and the corresponding diamine (b).

The space groups and the lattice constants of the TEMPAD biradical and the corresponding diamine listed in Table 1 are nearly equal to each other, so the diluted crystals of the TEMPAD biradical in its diamine can be prepared in various concentration ratios. The diluted crystals with 75, 50, and 25 mol% were crystallized from their ether solutions, and their elementary analyses agreed with the calculations.

TABLE 1. THE SPACE GROUPS AND THE LATTICE CONSTANTS FOR THE DIAMINE AND THE TEMPAD BIRADICAL

Name	Diamine	TEMPAD
Space-group	Monoclinic C_c	Monoclinic C_c or $C_{2/c}$
a	29.0 Å	29.1 Å
b	12.6	12.8
c	10.4	10.5
β	~90°	~90°

The paramagnetic susceptibility measurements were carried out using a torsion balance with powder samples from 77.3 to 1.8 K, the details of which have been described in the previous paper.[3] The diamagnetic contributions of the TEMPAD biradical and the diamine were calculated at -2.37×10^{-4} and -2.33×10^{-4} emu/mol respectively. The diamagnetic contributions of the diluted crystals were estimated as the sum of the aforementioned two values multiplied by each concentration ratio.

Results and Discussion

The inverse paramagnetic susceptibilities of the 100, 75, 50, and 25 mol% TEMPAD biradicals versus the temperature are shown in Fig. 2. Each curve obeys the Curie-Weiss law above 30K and below 4K except for the 100% case. The paramagnetic Curie constants and the Weiss constants of each concentration in these temperature regions are listed in Table 2.

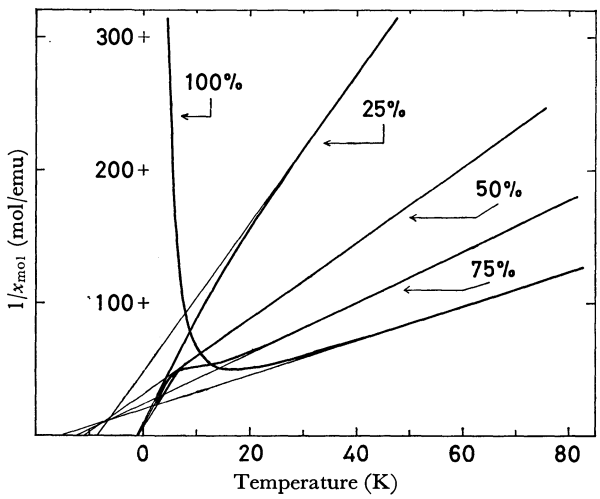

Fig. 2. Temperature dependence of the inverse paramagnetic susceptibilities of the diluted crystals of the TEMPAD biradical for 100, 75, 50, and 25 mol %.

TABLE 2. THE EXPERIMENTAL AND THE THEORETICAL MAGNETIC CONSTANTS FOR EACH CONCENTRATION. THE LATTERS ARE IN THE CASE OF $|J_1|/k=12.8$K AND $\alpha=1/20$.

C_H and C_L: the paramagnetic Curie constants
θ_H and θ_L: the Weiss constants (K).

The Weiss constant generally indicates the magnitude of the exchange interaction among the coupled magnetic spins. In the diluted crystals of the TEMPAD biradical, two kinds of Weiss constant were found, in the high- and in the low-temperature regions. The Weiss constant in the high-temperature region, which is of

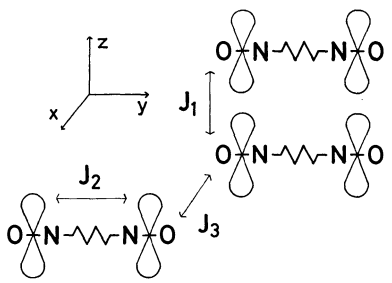

Fig. 3. Simplified molecular stack model for the TEMPAD biradical.

the order of magnitude of -10K, must be caused by the strong exchange interaction. On the other hand, the Weiss constant in the low-temperature region is of the order of magnitude of -1K.

By the dilution of the monoradical the inter-molecular exchange interaction can generally be eliminated, thus leading to the disappearance of the broad maximum in the χ_M-T curve. In the TEMPAD biradical two kinds of exchange interaction exist (see Fig. 3);[4] one is the strong inter-molecular exchange interaction (J_1), which causes the short-range ordering effect in the 100% case.[2] The other is the weak intra-molecular exchange interaction (J_2), which affects the hyperfine structure of the EPR in the dilute solution.[3] In the diluted crystals of the TEMPAD biradical, we can assume that the biradicals are distributed randomly in the matrix of the diamine and that they form two portions magnetically different in microscopical scale; one is the isolated portion in which the weak intra-molecular exchange interaction exists alone, and the other is the clustering portion coupled by the strong inter-molecular exchange interaction besides the intra-molecular one. Then the paramagnetic susceptibility of the diluted crystals may be considered to the superposition of the contributions from these two portions. If we adopt the pair model for the clustering portion and apply the Weiss molecular-field approximation for the weak intra-molecular exchange interaction, the theoretical susceptibility can be calculated on the assumption of the following random distribution:

$$|J_1|\chi_M/N_0(g\beta)^2 = 2[n^2x/(3+e^{2x})+n(1-n)x/4]/(1+\alpha x),$$

where $x=|J_1|/kT$; $\alpha=|J_2/J_1|$; N_0 is the Avogadro number; g, the g-value (2.0060 for the TEMPAD biradical[5]); β, the Bohr magneton, and n, the mole concentration of the biradical. The first term is the susceptibility of the pair model (the clustering portion), and the second term is that of the isolated portion. The theoretical $1/\chi_M-T$ curves for $|J_1|/k\simeq 12.8$K and $\alpha=1/20$ are shown in Fig. 4, while the theoretical paramagnetic Curie constants and the Weiss constants are listed in Table 2. They are in good qualitative agreement with the experimental results.

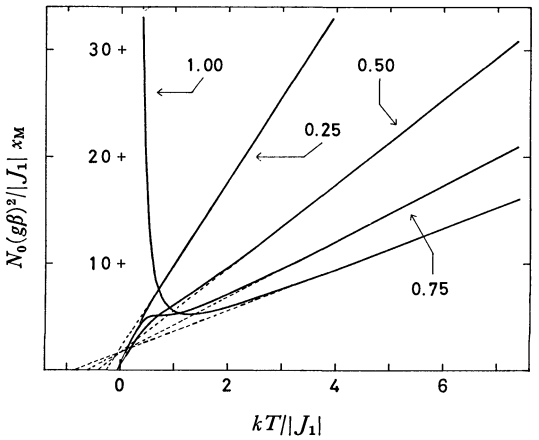

Fig. 4. Theoretical curves of the inverse paramagnetic susceptibility of the diluted systems for $n=1.0$, 0.75, 0.50, and 0.25 in the case of $\alpha=|J_2/J_1|=1/20$.

The exchange energy estimated from the Weiss constants in the low-temperature region is still larger than the value estimated from the EPR spectra in the dilute solution.[3] This is possibly caused by the difference in magnitude of the intra-molecular exchange interaction (J_2 in Fig. 3), which results from the distinction of the molecular conformation between the solid state and the dissolved state, and by the existence of another inter-molecular exchange interaction, *e.g.*, J_3 in Fig. 3.

The pair model was applied to the clustering portion on the basis of the random distribution, but the experimental results are different from those calculated—the value of χ_M deviates from the pair model near T_{max} ($=16.5$K) in the 100% case[2] and the Weiss constants of the high-temperature region are different from the calculated values (Table 2). If the TEMPAD molecules are distributed randomly enough in the diamine host, we must consider the higher-order clusters (trimers, tetramers, and so on) besides the pairs. As the data were explained qualitatively by the pair-model at so high a concentration, it may be suggested that the systems are fairly uniform.

The author wishes to thank Professor Yasuo Deguchi, Dr. Hiroaki Ohya-Nishiguchi, Dr. Jun Yamauchi, and their collaborators for their helpful advice and discussions. He is also indebted to Professors Hideo Takaki and Mamoru Mekata for their continuous guidance and encouragement during this work.

4) From the crystal structure, the distance between unpaired electrons in x-, y-, and z-directions are thought to be nearly equal to each other. Then the overlap integral will be the largest in the z-direction, namely $|J_1|>|J_2|$, $|J_3|$. The study of the dipolar interaction in ESR spectra also support this assumption.[5]

The Infrared Spectra of α-Chlorinated Acetamides

Yoshiyuki MIDO

Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe 657

(Received August 16, 1972)

The polarized infrared spectra of α,α,α-trichloroacetamide (TCA) and its deuterated compound (TCA-*d*) have been measured in the 400—4000 cm^{-1} region, and the infrared spectra of the series, $CCl_nH_{3-n}CONH_2$ (n= 0—3), and their deuterated compounds have been observed in the solid state. On the basis of the results, the vibrational assignments, the orientation of TCA, the intermolecular hydrogen bonds, and the inductive effect of the introduction of the chlorine atom, and the conformation of TCA have been discussed. It has been proposed that TCA in the solid state has two conformations, which are in linear-chain associations through hydrogen bonds.

The infrared spectra and vibrational analyses of acetamide[1-5] and *N*-alkylacetamides[6-8] have been extensively studied, with special interest taken in them as model molecules of polypeptides and proteins. However, the infrared spectra of α-chlorinated acetamides have been less widely studied than those of acetamide and *N*-alkylacetamides. Herman and Bièvre[9] have observed the infrared spectra of α-chlorinated acetamides in the solid state, but their spectra are in the sodium chloride region and the spectra of their *N*-deuterated compounds have not been reported. There is a spectroscopic study of chlorinated acetamides in a carbon tetrachloride solution as a part of the study of primary acid amides,[10] in which their molecular structure has been discussed by analogy with the intramolecularly-bonded structure of *N*-alkyl-α-chlorinated acetamides offered by Nyquist.[11]

As α,α,α-trichloroacetamide (TCA) grows into considerably large plate crystals by recrystallization from an ether solution, we were able to prepare the oriented crystal of TCA between potassium bromide plates.

In this paper, we will describe our findings on the polarized infrared spectra of TCA and TCA-*d* and on the infrared spectra of chlorinated acetamides and their *N*-deuterated compounds in the $CCl_nH_{3-n}CONH_2$ series (n=0—3).

Experimental

Materials. The TCA, DCA (α,α-dichloro-), MCA (α-monochloro-), and NCA (nonchloro-acetamide) were obtained from Nakarai Chemicals, Ltd., and each sample was purified by repeated recrystallization from an aqueous solution. The deuteration of MCA was done by a usual method,[12] while those of DCA and TCA were done by the method for water-insoluble compounds described in a previous paper.[13]

The oriented crystals of TCA and TCA-*d* were obtained by allowing the molten sample to crystallize between potassium bromide plates, with a temperature gradient. We observed through a microscope many long crystals arranged parallel to each other.

Infrared Spectra. The infrared absorption measurements in the 400—4000 cm^{-1} region were made by use of a Hitachi EPI-2G Infrared Grating Spectrophotometer. The spectra in the solid state were measured as potassium bromide discs and Nujol mulls. The spectra in the liquid state of TCA and TCA-*d* were obtained by the use of a cell with an electrically-heated and beam-transparent box, in which the solid sample between the window plates was heated to *ca.* 145°C, which is slightly higher than its melting point (141°C). The dichroic measurements of the oriented crystals were made with a pair of silver chloride polarizers.

Results and Discussion

Vibrational Assignment of TCA. The observed bands in the infrared spectra of TCA and TCA-*d* were assigned by observing the changes in the spectra according to the state of aggregation (Table 1) and by comparing them with the spectra of NCA, MCA, and DCA (Fig. 1).

As expected,[6,14] with the change in state from the solid to the liquid, the frequencies of a few $\nu(NH_2)$ bands in the 3μ region and the ν(C=O) band around 1700 cm^{-1} increase, but the frequencies of the other amide bands decrease more or less.

On deuteration, the two bands at 1379 and 1351 cm^{-1} are replaced by a band at 1395 cm^{-1} and a shoulder band at 1370 cm^{-1} assignable to the ν(C–N) modes, while, instead of a sharp $\delta(NH_2)$ band at 1616 cm^{-1} in TCA, a new band appears at 1159 cm^{-1} assignable to the $\delta(ND_2)$ mode. The upward frequency-shift of the ν(C–N) bands by deuteration may be due to the decoupling of the contribution of the $\delta(NH_2)$ mode, just as in NCA.[2] The bands at 1105, 922, and 437 cm^{-1} correspond to the bands at 1155, 875, and 464 cm^{-1} in NCA, which have been assigned by Suzuki[2] to the $\delta r(NH_2)$, ν(C–C′), and δ(C′–C=O) modes respectively. The strong bands near 825 cm^{-1}

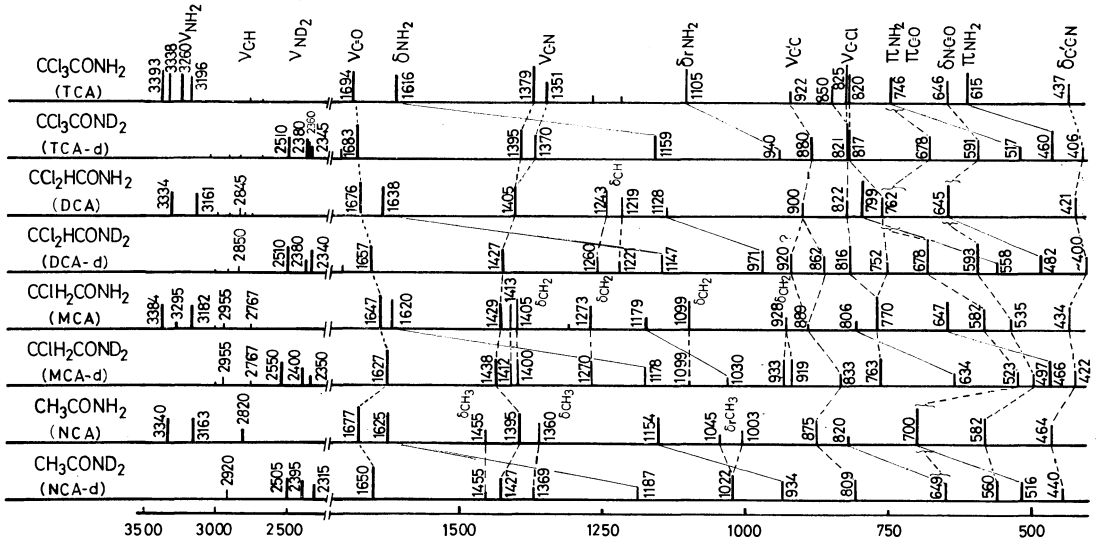

Fig. 1. Observed frequencies and relative intensities of $CCl_nH_{3-n}CONH_2$ ($n=0-3$) and these *N*-deuterated compounds. Bands combined with a solid line between an undeuterated and its deuterated compounds are related to a vibration due to NH_2 or ND_2 group, and among their compounds these bands are not combined with any lines. Data for NCA-*d* are by Suzuki (Ref. 2).

which are unshifted on deuteration and on the change in state are associated with the ν (C–Cl) vibrations.

In the 500—800 cm^{-1} region, four amide bands are predicted; a δ(N–C=O), a π(C=O), and two $\pi(NH_2)$ bands. In the observed spectra, only three bands are observed for TCA, whereas four bands are observed for TCA-*d*. The bands at 746 and 615 cm^{-1}, which disappear on deuteration, are assigned to the two $\pi(NH_2)$ modes, since these bands are very broad and the most sensitive to the change in state (see Table 1), just like the amide V band (mainly the π(N–H) vibration) of secondary amides[6] and dialkylureas.[12,13] The band at 646 cm^{-1} and an undetectable band probably covered by the higher $\pi(NH_2)$ band[12,13,15] may be associated with the δ(N–C=O) and π(C=O) modes respectively.

The observed frequencies and the vibrational assignment obtained are in agreement with those obtained by Herman and Bièvre[9] except for the assignment of the band at 746 cm^{-1}, which we assigned to the $\pi(NH_2)$ mode since this band disappears on deuteration.

Polarized Infrared Spectra of TCA and TCA-d.

The polarized infrared spectra of TCA and TCA-*d* are shown in Fig. 2. The ν(C=O) band exhibits a definitely parallel dichroism in both samples. This means that the direction of the C=O bond is parallel to the long direction of the oriented crystal and that the association of TCA shown below is acceptable. The parallel ν(C=O) band is contrasted with the ν(C=O) band of benzamide[16] at 1656 cm^{-1}, having an indistinguishable dichroism. The structure of the associated molecules of benzamide[17] has a chain association of dimer units, with a center of symmetry, in which the C=O bonds are placed in an inclined position to the

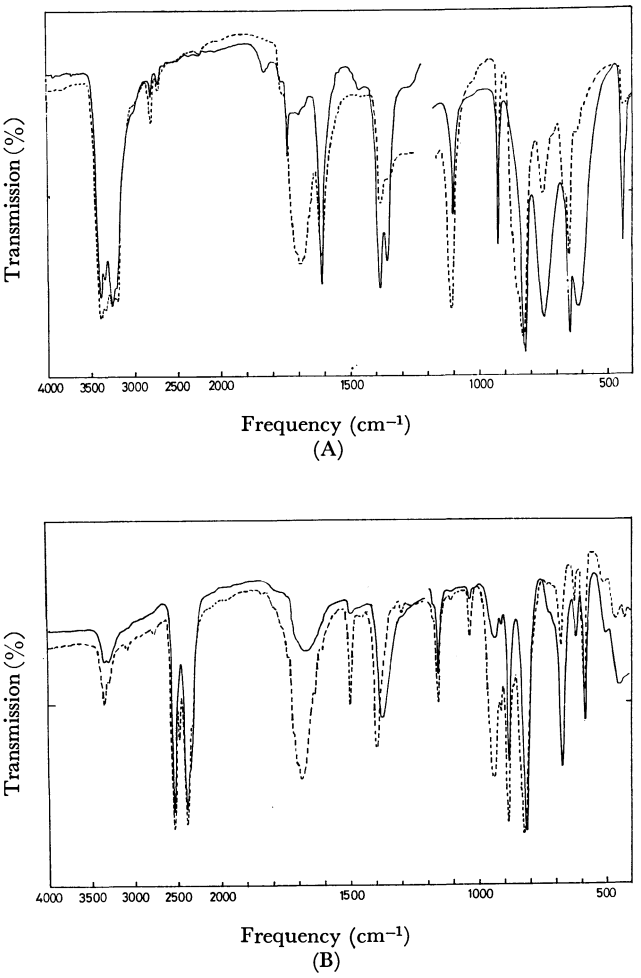

Fig. 2. The polarized infrared spectra of TCA (A) and TCA-*d* (B) with the electric vector of the incident infrared beam being parallel (broken line) or perpendicular (solid line) to the long direction of the oriented crystal.

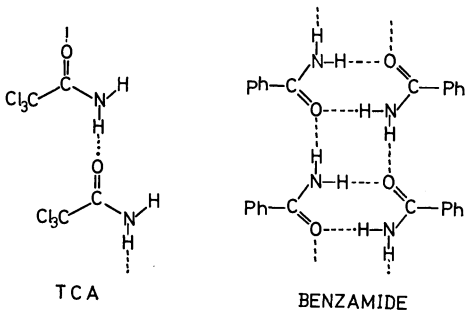
oriented axis;



From the above figure, one can understand the indistinguishable dichroic property of ν(C=O) band of benzamide, and can see that the structure of TCA is not like that in benzamide. If such a chain association of TCA is assumed, it may be expected that $\nu a(NH_2)$ and $\delta r(NH_2)$ bands will exhibit a rather parallel dichroism, whereas $\nu s(NH_2)$, $\delta(NH_2)$, ν(C–N), and ν(C–C′) bands will exhibit a rather perpendicular dichroism. The polarized spectra of TCA almost satisfy the above expectation. This indicates that the assumed chain association model of TCA is reasonable. The dichroic properties of some bands of TCA-*d* do not satisfy the expectation. The unsatisfactory dichroism may be due to the insufficient deuteration and/or orientation. All bands related to out-of-plane vibrations exhibit a perpendicular dichroism in both samples, as expected. This indicates that the assignment of these bands is correct, and that the chain association suggested is also reasonable.

Amide Bands and Their Frequency Changes in $CCl_nH_{3-n}CONH_2$. The correlation among the observed frequencies for $CCl_nH_{3-n}CONH_2$ (n=0—3) and their *N*-deuterated compounds are graphically summarized in Fig. 1. With the successive introduction of a chlorine atom into the methyl group of NCA, the frequencies of the ν(C=O) and ν(C–N) bands sensitively and regularly move upwards and downwards respectively, and the frequencies of three NH_2 deformation bands (but not the $\delta(NH_2)$ band) also move downwards. These frequency changes may be explained as being due to the changes in the electronic state of the amide structure and the intermolecular hydrogen bonds.

The difference in the free ν(C=O) frequency (in nonpolar solvent) among the α-chlorinated acetamides may be due to the inductive effect of the α-substituent, which tends to raise its frequency.[14] The frequency-difference between the free ν(C=O) band and the associated ν(C=O) band (solid state) may be considered to be a qualitative measure of the strength of the hydrogen bonds. In Table 2, it can be understood that, with the α-successive introduction of a chlorine atom, the inductive effect regularly becomes larger; the more chlorine atoms are introduced to the methyl group, the larger the double bond character of the C=O bond becomes, at the expense of that of the C–N bond. Table 2 also indicates that α-chlorinated acetamides have stronger intermolecular hydrogen bonds than acetamide and that the frequency lowering of 37 cm^{-1} (1677—1640) from NCA to MCA in the solid state may be due mainly to the stronger hydrogen bonds of α-chlorinated acetamides.

The two $\pi(NH_2)$ bands seem to receive the inductive effect of chlorine atoms regularly. The behavior of the π(C=O) and δ(N–C=O) bands, on the other hand, is rather complicated.

Conformation of TCA. Contrary to our expectations for two ν(N–H) bands, four ν(N–H) bands appear definitely in TCA in the solid state. Also, two ν(C–N) bands are observed. These facts suggest that TCA has two different conformations in the solid state, just as

a) Bands named by Krueger and Smith in Ref. 10 and their data for NCA.
b) Concentration-dependent band.
c) The data obtained by King in Ref. 5; $\nu as(NH_2)$ and $\nu s(NH_2)$ bands alike are a doublet.

in *N*-methyl-α-monochloroacetamide.[18] This suggestion is supported by the chlorine NQR studies[19] of chlorinated acetamides from 77K to the melting point. In those studies, six lines in TCA, two lines in DCA, and one line in MCA are observed. They can be classified into two types on the basis of the different temperature coefficients of the NQR frequency (the slope); the two lines of DCA and the one line of MCA belong to the different types, while of the six lines of TCA, three lines belong to one type and remaining three lines to the other type. These NQR data indicate that TCA has two crystallographically-inequivalent CCl_3 groups.

In the infrared spectra of TCA in a dilute carbon tetrachloride solution, we observed two additional bands on the lower-frequency side of the $\nu as(NH_2)$ band at 3530 cm^{-1}, as is shown in Fig. 3. With an increase in the concentration, the intensity of the lower band at 3488 cm^{-1} increases more sensitively than the higher band at 3506 cm^{-1} and the typical associated N–H bands in the 3150—3350 cm^{-1} region. Also, the other chlorinated acetamides show similar spectral behavior, as is shown in Table 3. The lower band corresponds to the C band of three additional bands, at 3518 (named the A band), 3504 (B), and 3486 cm^{-1} (C), in the solution spectra of NCA, interpreted as being due to a cyclic dimer, a trimer, and a higher polymer of NCA with a free N–H bond and a bridged N–H bond respectively.[10]

In the solution spectra of NCA, we observed a concentration-dependent band at 3504 cm^{-1}, porbably corresponding to the B band. In the infrared spectra of NCA in the argon matrix, King[5] has observed only two bands in the 3500—3600 cm^{-1} region and assigned the lower band at 3515 cm^{-1} to the ν(N–H) mode due to a dimer species of the associated polymers. With due consideration of the frequency-differences (*ca.* 15 cm^{-1}) between the free $\nu as(NH_2)$ or $\nu s(NH_2)$ band in the matrix and in the solution, the 3515 cm^{-1} band in the matrix may be said to correspond to the B band. The lower frequency of the concentration-dependent band of chlorinated acetamides (the C band) than that of NCA (the B band) indicates that chlorinated acetamides may be in a higher polymer than in a dimer in the carbon tetrachloride solution.

With the change in state from the solution, through the liquid, to the solid state, the frequency of the corresponding C band of TCA is lowered and reaches 3393 cm^{-1} in the solid state, as is listed in Tables 1 and 3. The highest band at 3393 cm^{-1} in the solid state may be also characterized by the higher polymer of TCA with a weakly hydrogen-bonded N–H bond and a bridged N–H bond, but not by the associated polymer of dimer units, such as in benzamide. Considering the results of the previous NQR studies, two of the remaining three ν(N–H) bands of TCA in the solid state may be due to another higher polymer with two bridged N–H bonds.

The author wishes to express his deep gratitude to Dr. Katsunosuke Machida of Kyoto University, Dr. Hiroatsu Matsuura of Osaka University, and Mr. Masao Hashimoto of Kobe University for their very helpful discussions and suggestions.

The Coupled Perturbed Hartree-Fock Calculations of the Magnetic Susceptibility for Some Nonbenzenoid Aromatic Hydrocarbons

Yasushi MIKAMI, Seiko MIYAI, and Takeshi NAKAJIMA
Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Sendai
(Received August 24, 1972)

The semi-empirical SCF MO method is applied to the calcutations of the magnetic susceptibility of the π-electron systems of several nonbenzenoid aromatic hydrocarbons. To avoid origin-dependent results, a method actually equivalent to Hall and Hardisson's one which is currently called the coupled perturbed Hartree-Fock method is used. With the best-fit parameters, the calculated results are in good agreement with the available experimental values except for the case of aceheptylene.

The diamagnetic susceptibilities of aromatic hydrocarbons are so anisotropic that they do not follow Pascal's sum rule. The first quantitative explanation of this anisotropy was given by Pauling,[1] who introduced the idea of the ring current in π-electron systems. The concept of the ring current, which should be replaced by the more suitable term "*delocalization susceptibility*,"[2] has survived in spite of corrections from the quantum-mechanical point of view.[3] The first attempt to treat the delocalization susceptibility quantum-mechanically was made by London.[4] In his method, the Hückel molecular orbital theory was generalized to include the gauge-invariant atomic orbitals, and the variation method was used to obtain the orbital energies in a magnetic field.

The semi-empirical aspect of the molecular orbital theory for conjugated molecules has been developed by Pariser and Parr[5] and by Pople.[6] They included the electron repulsion explicitly and used the zero-differential overlap approximation. All of the atomic integrals concerned were reduced to empirical parameters or were neglected completely. This semi-empirical scheme is quite simple, but it yields quantitative results which are in good agreement with the experimental values.

Advanced methods of the calculation of the anisotropy corresponding to the development of the molecular orbital theory should obtain more satisfactory results. However, it is well known that the self-consistent version of the molecular orbital theory leads to results which show an obvious origin-dependence[7] resulting from the approximate nature of wavefunctions. To overcome this diffrculty, two methods have been suggested. One is the coupled perturbed Hartree-Fock method which was first employed for aromatic hydrocarbons by Hall and Hardisson.[8] The other, simpler one is the uncoupled Hartree-Fock method,[7] in which the geometric approximation[9] is used instead of the complicated coupling procedure. These methods have given satisfactory results, mainly for benzenoid aromatic hydrocarbons.

The purpose of this paper is to show that, taking several examples, one can apply the above method to calculations of the delocalization susceptibility of nonbenzenoid aromatic hydrocarbons. It has been known that some of these molecules exhibit unusual magnetic properties, that is, a paramagnetic delocalization susceptibility. For actual calculations, the coupled perturbed Hartree-Fock method is adopted, though it is rather more tedious than the uncoupled one. The semi-empirical SCF MO method[10] combined with the variable bondlength technique, which is a variation of the Pariser-Parr-Pople theory, is adopted. The molecules examined are azulene, fulvene, heptafulvene, pentalene, heptalene, aceazulylene, and aceheptylene.

Theory

The Hamiltonian of a π-electron system in a magnetic field can be written as:

$$\mathcal{H} = \sum_a \left\{ -\frac{1}{2}(\nabla_a + i\alpha \mathbf{A}_a)^2 + \sum_\eta V_\eta(\mathbf{r}_a) \right\} + \sum_{a>b} \frac{1}{r_{ab}} \qquad (1)$$

where $\mathbf{A}_a$ is the vector potential of the magnetic field at the point occupied by the a-th electron, α, the fine structure constant, V_η $(\mathbf{r}_a)$, the potential due to the σ-core associated with the atom, η, and the last term, the interaction energy between π-electrons. Atomic units will be used throughout this paper.

We assume that the wavefunction for the ground state of a molecule with $2n$ π-electrons is the Hartree-Fock single determinant:

$$\Psi = \frac{1}{\sqrt{2n!}} |\tilde{\phi}_1(\mathbf{r}_1)\alpha\tilde{\phi}_2(\mathbf{r}_2)\beta \cdots \tilde{\phi}_{2n-1}(\mathbf{r}_{2n-1})\alpha\tilde{\phi}_{2n}(\mathbf{r}_{2n})\beta| \qquad (2)$$

in which $\tilde{\phi}_i$ is the i-th molecular orbital with spin functions of α or β in the presence of the magnetic field. Following London, $\tilde{\phi}_i$ is written as a linear combination of the gauge-invariant atomic orbitals:

$$\tilde{\phi}_i = \sum_\mu \tilde{C}_{i\mu}\omega_\mu, \qquad (3)$$

where:

$$\omega_\mu = \chi_\mu \exp(-i\alpha \mathbf{A}_\mu \cdot \mathbf{r}), \qquad (4)$$

where $\mathbf{A}_\mu$ is the vector potential at the μ-th atomic site. The equations for the coefficients, $\tilde{C}_{i\mu}$, are:

$$\sum_\mu \tilde{F}_{\mu\nu}\tilde{C}_{i\mu} = E_i \sum_\mu \tilde{S}_{\mu\nu}\tilde{C}_{i\mu}, \tag{5}$$

Following the Pariser-Parr-Pople approximation, we neglect the overlap integrals, $\tilde{S}_{\mu\nu}$, and the matrix elements, $\tilde{\mathscr{H}}_{\mu\nu}$, except for those between the nearest neighbours, unless $\mu=\nu$. Thus, the Fock element, $\tilde{F}_{\mu\mu}$, is expressed as:

$$\tilde{F}_{\mu\mu} = \tilde{\mathscr{H}}_{\mu\mu} + \frac{1}{2}\tilde{P}_{\mu\mu}\gamma_{\mu\mu} + \sum_{\eta(\neq\mu)}(\tilde{P}_{\eta\eta}-\zeta_\eta)\gamma_{\mu\eta}, \tag{6}$$

$$\tilde{F}_{\mu\nu} = \tilde{\mathscr{H}}_{\mu\nu} - \frac{1}{2}\tilde{P}_{\mu\nu}\gamma_{\mu\nu}, \qquad (\mu\neq\nu), \tag{7}$$

where:

$$\tilde{\mathscr{H}}_{\mu\nu} = \int w_\mu^*(\mathbf{r})\left\{-\frac{1}{2}(\nabla+i\alpha\mathbf{A})^2+\sum_\eta V_\eta(\mathbf{r})\right\}w_\nu(\mathbf{r})d\mathbf{r}, \tag{8}$$

$$\gamma_{\mu\nu} = \int w_\mu^*(\mathbf{r}_1)w_\nu^*(\mathbf{r}_2)\frac{1}{r_{12}}w_\mu(\mathbf{r}_1)w_\nu(\mathbf{r}_2)d\mathbf{r}_1d\mathbf{r}_2$$
$$= \int \chi_\mu^*(\mathbf{r}_1)\chi_\nu^*(\mathbf{r}_2)\frac{1}{r_{12}}\chi_\mu(\mathbf{r}_1)\chi_\nu(\mathbf{r}_2)d\mathbf{r}_1d\mathbf{r}_2, \tag{9}$$

$$\tilde{P}_{\mu\nu} = \sum_i^{occu} 2\tilde{C}_\mu\tilde{C}_{i\nu} \tag{10}$$

and where ζ_η is the effective charge of the σ-core of the ζ atom. For hydrocarbons, $\zeta_\eta=1$. According to London,[4] the matrix element, $\tilde{\mathscr{H}}_{\mu\nu}$, is simplified as follows. The $(\mathbf{A}-\mathbf{A}_\mu)^2$ term is neglected and $\exp[(i\alpha(\mathbf{A}_\mu-\mathbf{A}_\nu)\cdot\mathbf{r}]$ is replaced by $\exp[i\alpha(\mathbf{A}_\mu-\mathbf{A}_\nu)-(\mathbf{r}_\mu+\mathbf{r}_\nu)/2]$, where $\mathbf{r}_\mu$ and $\mathbf{r}_\nu$ are the position vectors at the μ-th and ν-th atomic sites respectively. One thus obtains:

$$\tilde{\mathscr{H}}_{\mu\nu} = \exp\{i\alpha(\mathbf{A}_\mu-\mathbf{A}_\nu)\cdot(\mathbf{r}_\mu+\mathbf{r}_\nu)/2\}\beta_{\mu\nu}$$
$$= \exp(i\alpha HL_{\mu\nu})\beta_{\mu\nu}, \tag{11}$$

where $\beta_{\mu\nu}$ is the usual resonance integral:

$$\beta_{\mu\nu} = \int \chi_\mu^*(\mathbf{r})\left\{-\frac{\nabla^2}{2}+\sum_\eta V_\eta(\mathbf{r})\right\}\chi_\nu(\mathbf{r})d\mathbf{r}, \tag{12}$$

and where $L_{\mu\nu}$ is the signed area of the triangle formed by the point of origin and the nuclei, μ, ν. The diagonal matrix element, $\mathscr{H}_{\mu\mu}$, is also simplified by a similar approximation:

$$\tilde{\mathscr{H}}_{\mu\mu} = \int \chi_\mu^*(\mathbf{r})\left\{-\frac{\nabla^2}{2}+V_\mu(\mathbf{r})\right\}\chi_\mu(\mathbf{r})d\mathbf{r} = \alpha_\mu, \tag{13}$$

where α_μ is the Coulomb integral.

Following Hall and Hardisson, each term related to the magnetic field is expanded into a series in the descending order of the field strength, H:

$$\tilde{F}_{\mu\nu} = F_{\mu\nu} + iHF_{\mu\nu}^{(1)} - H^2F_{\mu\nu}^{(2)} - \cdots, \tag{14}$$
$$\tilde{C}_{i\mu} = C_{i\mu} + iHC_{i\mu}^{(1)} - H^2C_{i\mu}^{(2)} - \cdots, \tag{15}$$
$$\tilde{E}_i = E_i + iHE_i^{(1)} - H^2E_i^{(2)} - \cdots, \tag{16}$$
$$\tilde{\mathscr{H}}_{\mu\nu} = \beta_{\mu\nu}\left\{1+i\alpha L_{\mu\nu}-\frac{1}{2}\alpha^2H^2L_{\mu\nu}{}^2+\cdots\right\}, \tag{17}$$
$$\tilde{P}_{\mu\nu} = P_{\mu\nu} + iHP_{\mu\nu}^{(1)} - H^2P_{\mu\nu}^{(2)} - \cdots, \tag{18}$$

The actual expressions, say $F_{\mu\nu}$[1], *etc.*, are shown in Table 1. The self-consistent Eq. (5) become, to the zeroth order:

Table 1. Expressions for quantities in matrix elements

$$F_{\mu\nu} = \beta_{\mu\nu} - \frac{1}{2}P_{\mu\nu}\gamma_{\mu\nu} + \delta_{\mu\nu}\left(\sum_\eta P_{\eta\eta}\gamma_{\eta\mu} - \sum_{\eta(\neq\mu)}\gamma_{\eta\mu}\right)$$
$$F_{\mu\nu}^{(1)} = \alpha L_{\mu\nu}\beta_{\mu\nu} - \frac{1}{2}P_{\mu\nu}^{(1)}\gamma_{\mu\nu}$$
$$F_{\mu\nu}^{(2)} = \frac{1}{2}\alpha^2L_{\mu\nu}\beta_{\mu\nu} - \frac{1}{2}P_{\mu\nu}^{(2)}\gamma_{\mu\nu} + \delta_{\mu\nu}P_{\eta\eta}^{(2)}\gamma_{\eta\mu}$$
$$P_{\mu\nu} = 2\sum_i^{occu} C_{i\mu}C_{i\nu}$$
$$P_{\mu\nu}^{(1)} = 2\sum_i^{occu}(C_{i\mu}^{(1)}C_{i\nu} - C_{i\mu}C_{i\nu}^{(1)})$$
$$P_{\mu\nu}^{(2)} = 2\sum_i^{occu}(C_{i\mu}^{(2)}C_{i\nu} - C_{i\mu}^{(1)}C_{i\nu}^{(1)} + C_{i\mu}C_{i\nu}^{(2)})$$

$$\sum_\mu (F_{\mu\nu}-\delta_{\mu\nu}E_i)C_{i\mu} = 0 \qquad (\nu = 1, 2, \cdots, 2n), \tag{19}$$

to the first order:

$$\sum_\mu (F_{\mu\nu}-\delta_{\mu\nu}E_i)C_{i\mu}^{(1)} = \sum_\mu (E_i^{(1)}\delta_{\mu\nu} - F_{\mu\nu}^{(1)})C_{i\mu}$$
$$(\nu = 1, 2, \cdots, 2n), \tag{20}$$

and to the second order:

$$\sum_\mu (F_{\mu\nu}-\delta_{\mu\nu}E_i)C_{i\mu}^{(2)} = \sum_\mu (E_i^{(1)}\delta_{\mu\nu} - F_{\mu\nu}^{(1)})C_{i\mu}^{(1)}$$
$$+ \sum_\mu (E_i^{(2)}\delta_{\mu\nu} - F_{\mu\nu}^{(2)})C_{i\mu}$$
$$(\nu = 1, 2, \cdots, 2n). \tag{21}$$

The expression of the π-electron energy, E_π, is:

$$\tilde{E}_\pi = \frac{1}{2}\sum_{\mu\nu}\tilde{P}_{\mu\nu}\{\tilde{\mathscr{H}}_{\mu\nu}+\tilde{F}_{\mu\nu}\}$$
$$= \sum_i \tilde{E}_i + \frac{1}{2}\sum_{\mu\nu}\{\tilde{\mathscr{H}}_{\mu\nu} - \sum_{\eta(\neq\mu)}\gamma_{\mu\nu}\delta_{\mu\nu}\} \tag{22}$$

where the relation:

$$\sum_i^{occu}\tilde{E}_i = \frac{1}{2}\sum_{\mu\nu}\tilde{P}_{\mu\nu}\tilde{F}_{\mu\nu} \tag{23}$$

is used. As E_i is an eigenvalue of $F_{\mu\nu}$, Eq. (20) can be solvend only if:

$$\sum_{\mu\nu} C_{i\nu}(E_i^{(1)}\delta_{\mu\nu} - F_{\mu\nu}^{(1)})C_{i\mu} = 0, \tag{24}$$

but since $F_{\mu\nu}$[1] is skew, this implies that

$$E_i^{(1)} = 0. \tag{25}$$

The corresponding relation for Eq. (21) is:

$$E_i^{(2)} = \sum_{\mu\nu} F_{\mu\nu}^{(2)}C_{\mu i}C_{\nu i} + \sum_{\mu\nu} F_{\mu\nu}^{(1)}C_{\mu i}^{(1)}C_{\nu i}, \tag{26}$$

so that:

$$\sum_i^{occu} E_i^{(2)} = \frac{1}{2}\sum_{\mu\nu}F_{\mu\nu}^{(2)}P_{\mu\nu} + \frac{1}{4}\sum_{\mu\nu}F_{\mu\nu}^{(1)}P_{\mu\nu}^{(1)}. \tag{27}$$

On the other hand, from Eq. (23), we obtain:

$$\sum_i^{occu} E_i^{(2)} = \frac{1}{2}\sum_{\mu\nu}F_{\mu\nu}^{(2)}P_{\mu\nu} + \frac{1}{2}\sum_{\mu\nu}F_{\mu\nu}^{(1)}P_{\mu\nu}^{(1)}$$
$$+ \frac{1}{2}\sum_{\mu\nu}F_{\mu\nu}P_{\mu\nu}^{(2)}, \tag{28}$$

therefore:

$$\sum_{\mu\nu}F_{\mu\nu}^{(1)}P_{\mu\nu}^{(1)} = -2\sum_{\mu\nu}F_{\mu\nu}P_{\mu\nu}^{(2)}. \tag{29}$$

Since the magnetic susceptibility is of the second order in H, we need the energy expression of this order. From Eq. (22), we may express it as:

$$E_\pi^{(2)} = \sum_i^{occu} E_i^{(2)} + \frac{1}{2}\sum_{\mu\nu}[\{\beta_{\mu\nu} - \sum_{\eta(\neq\mu)} \gamma_{\eta\nu}\delta_{\mu\nu}\}P_{\mu\nu}^{(2)} + L_{\mu\nu}\beta_{\mu\nu}P_{\mu\nu}^{(1)} + \frac{1}{2}L_{\mu\nu}^2\beta_{\mu\nu}P_{\mu\nu}. \quad (30)$$

This expression can be simplified by the use of Eqs. (27) and (29) to:

$$E_\pi^{(2)} = \frac{1}{2}\alpha^2\sum_{\mu\nu}L_{\mu\nu}^2H_{\mu\nu}P_{\mu\nu} + \frac{1}{2}\alpha^2\sum_{\mu\nu}L_{\mu\nu}H_{\mu\nu}P_{\mu\nu}^{(1)}. \quad (31)$$

Therefore, in the presence of the magnetic field, the total π-electron energy of the molecule is:

$$E_\pi = E_\pi - H^2E_\pi^{(2)} + \cdots\cdots, \quad (32)$$

since the linear term in H vanishes for a normal molecule with doubly-occupied orbitals. The magnetic susceptibility of a π-electron system is:

$$K_z^\pi = -\partial^2E_\pi/\partial H^2 = 2E_\pi^{(2)} = 2\alpha^2\sum_{\mu\nu}L_{\mu\nu}^2\beta_{\mu\nu}P_{\mu\nu} + 2\alpha\sum_{\mu\nu}L_{\mu\nu}\beta_{\mu\nu}P_{\mu\nu}^{(1)}. \quad (33)$$

This gives the delocalization susceptibility required.

Method of Calculation

The first step of our calculations is to solve the zeroth-order Eq. (19). The method used here is a modification of the Pariser-Parr-Pople method, in which the bond lengths and, consequently, the resonance and Coulomb repulsion integrals are allowed to vary with the bond order at each iteration until self-consistency is reached. The bond length is calculated from the bond order by the relationship:[10]

$$r_{\mu\nu}(\text{Å}) = 1.520 - 0.186P_{\mu\nu} \quad (34)$$

The Coulomb repulsion integrals are calculated using the Nishimoto-Mataga formula. The resonance integrals are evaluated by the relation:

$$\beta_{\mu\nu} = \beta_0 \exp\{a(r_0 - r_{\mu\nu})\} \quad (35)$$

where β_0 and r_0 are the resonance integral and the C–C bond distance for benzene respectively. The a=2.5 value has been adopted, because it reproduces well the experimental C–C bond distances and dipole moments of a number of aromatic hydrocarbons.[10]

The second step is to solve the first-order perturbation, Eq. (20). We must consider the additional condition that the perturbed eigenfunction is orthogonal to the unperturbed one, *i.e.*:

$$\sum_\mu C_{\mu i}^{(1)}C_{\mu i} = 0 \quad (36)$$

If the matrix, $F_{\mu\nu}^{1)}$, is assumed to be known, the set of Eqs. (20) and (36) can be solved as linear equations for various $C_{i\mu}$ values. These $C_{i\mu}$ values are then used to produce a new $F_{\mu\nu}^{1)}$ and the linear equations are iteratively solved until this matrix element becomes self-consistent.

The computations were done on the NEAC-2200 computer at Tohoku University.

Results and Discussion

The calculations following the method given in the previous sections have been carried out by varying the positions of the point of origin. These positions, shown in Fig. 1, are various H-atomic sites, C-atomic sites, the midpoint of the C–C bond, and the center of an odd-membered ring. The calculated delocalization susceptibilities, K_z^π, are given in Table 2 in units of the K_z^π of benzene. It turns out that, for all of the molecules concerned, K_z^π is actually origin-independent. The small variation in the values with the displacement

of the point of origin seems to be within the limits of unavoidable error arising from the termination of higher-order terms in the calculating processes. Azulene, aceheptylene, and aceazulylene are predicted to be diamagnetic, while heptalene and pentalene, classified as the $4n$-electron system, are predicted to be paramagnetic so far as the delocalization susceptibility is concerned. There exists an uncertainty about the sign of K_z^{π} of fulvene. However, this does not indicate a serious defect of the method, because the variation in the sign may be due to unavoidable errors since the absolute value of K_z^{π} is approximately zero. Contrary to the predictions of earlier works,[11,12] heptafulvene has a paramagnetic K_z^{π}. For azulene, the value (2.30) is in good agreement with the result (2.28) obtained by Hall and Hardisson. The discrepancy may be due to slightly different integral values in the two calculations.

In order to compare the calculated results with the experimental ones, we should add the local contributions to K_z^{π}. The most direct result obtained from the experiment on gaseous molecules is the mean susceptibility, K^{m}, which can be written as:

$$K^{\mathrm{m}} = \frac{1}{3}(K_x + K_y + K_z + K_z^{\pi}), \tag{37}$$

where we assume that:

$$K_x = K_y = N_C K_C^{\mathrm{m}} + N_H K_H^{\mathrm{m}}, \tag{38}$$

and that:

$$K_z = N_C K_C^{\perp} + N_H K_H^{\perp}. \tag{39}$$

In these expressions, N_H and N_C are the numbers of hydrogen and carbon atoms in a molecule respectively. For the Pascal constants of carbon and hydrogen atoms for the field perpendicular to the plane, we have used the Amos[7] values, $K_C^{\perp} = -8.5$, $K_H^{\perp} = -2.1$ (in units of 10^{-6} cgs emu), which are obtained from the original Hoarau[13] values by slight modifications. For the local values of the in-plane susceptibility, we take the values of $K_C^{\mathrm{m}} = -3.23$, and $K_H^{\mathrm{m}} = -2.69$. These values have been successfully used elsewhere.[7] The mean susceptibilities thus obtained are given in Table 3, together with the experimental results. For aceazulylene and aceheptylene, experimental values are available only for their derivatives. The calculations of the mean susceptibilities of these molecules were carried out on the assumptions that the methyl group contributes only to local effects and that the phenyl group gives one-half of the mean susceptibility of biphenyl. We have no experimental values for heptafulvene and pentalene.

TABLE 3. MEAN SUSCEPTIBILITY χ_{m}
(cgs emu 10^{-6}cm^3 mol^{-1})

Molecule	Theoretical	Experimental[a]
Benzene	54.94	54.8
Azulene	93.10	91.0
Fulvene	42.40	43.0
Heptafulvene	56.69	
Pentalene	41.93	
Heptalene	65.93	72±7
Aceazulylene	102.48	
its derivative[b]	(170.44)	179±4
Aceheptylene	113.10	
its derivative[c]	(131.35)	112±3

a) H. J. Dauben *et al.*, *J. Amer. Chem. Soc.*, **91**, 1991 (1969).
b) 2-phenyl-5,7-demethylaceazulylene.
c) 3, 5-dimethylaceheptylene.

A comparison of the theoretical and experimental values shows a good agreement in general, except for the case of aceheptylene. As for aceheptylene, no accurate comparison is possible unless the delocalization susceptibility of the derivative can be calculated on a reasonable basis. Moreover, there still remains an ambiguity in the allocated values of the local effects. Subtracting their own local effects, Dauben *et al.*[14] obtained 0.0 as the exaltation value (corresponding to the delocalization susceptibility) of aceheptylene. However, our calculation does not support this conclusion, because no choice of parameters could lead to the vanishing of the exaltation. It is, therefore, hoped that the experimental value of aceheptylene will be reexamined.

Finally, we may conclude that the coupled perturbed Hartree-Fock method gives satisfactory and gauge-invariant results on the delocalization susceptibility, K_z^{π}, for nonbenzenoid aromatic hydrocarbons as well as benzenoid ones.

Light Scattering Studies on the Thermal Denaturation of Bovine Serum Albumin[1]

Masayuki NAKAGAKI and Yoh SANO

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto

(Received September 4, 1972)

Thermal denaturation of bovine serum albumin (BSA) was studied by means of light scattering and viscosity measurements. The degree of denaturation ($w_D°$) was measured by using HABA, an anionic dye. The values of intrinsic viscosity, weight-average molecular weight and radius of gyration showed no appreciable changes when $w_D°$ was within 85 percent, but increased remarkably when $w_D°$ exceeded 85 percent. Thus, it has been concluded that the thermal denaturation proceeds in two steps, *i.e.*, intramolecular denaturation in the earlier stage and intermolecular association in the later stage. Analysis of the light-scattering data showed that the aggregated molecule was in a rod-like shape, whose length increased almost linearly with the weight fraction of the aggregated molecule w_n, the latter being obtained by analysis of the refractive index increment. On the other hand, the diameter did not change with the degree of denaturation, and its value was about 140 Å, which is almost equal to the largest dimension of the native BSA molecule. It has been concluded that the BSA molecules form aggregates by side-by-side association, whose length is about 2910 Å and diameter about 140 Å.

The thermal denaturation of proteins has been studied by many investigators with the use of the solubility method,[2] Tiselius electrophoresis,[3] ultracentrifugation,[3] optical density difference,[4] and acrylamide gel electrophoresis.[5] From the results of these investigations, it was concluded that the polar groups of the inner parts of BSA are exposed to the surface of the molecule and the mechanism of the thermal denaturation of BSA differs at the initial stage from that at the later stage, some fractions of BSA aggregating while some remain undenatured. However, such points as the percentage of the aggregates in the solution and its variation with heating time and the dimension of the aggregated molecules, have not been clarified. With particular attention to these points, we have studied the mechanism of thermal denaturation of BSA by means of light scattering and viscosity measurements.

Experimental

Materials. The bovine serum albumin (here after called BSA) used was made by Armour Co., Ltd., (Fraction V, No. G5715, D. 1092), as in the previous paper.[6] A solution containing about 0.25 percent BSA in 0.05M phosphate buffer (pH 7.2) was heated at the desired temperature between 25 and 90°C for the desired length of time in test tube fitted with a lid. It was dipped, into cold water in order to stop thermal denaturation.[2-5] Under these conditions, turbidity did not increase very much. Phosphate buffer solution (pH regions 6.2—7.4) is said to be more suitable than acetate buffer solution, because the BSA in it shows less turbidity. The concentration of BSA was determined by measuring the optical density at 278 mμ. Water used was distilled, refined by ion-exchange resin, and distilled again with an all-glass still.[6]

Degree of Denaturation. It is well-known[7] that an anionic dye, 2-(4′-hydroxyphenylazo) benzoic acid (abbreviated HABA) is specifically bound to the native BSA and causes a remarkable optical change giving a new absorption band at 482 mμ at pH=7.2. The degree of denaturation was therefore determined with HABA by using the difference of optical density at 482 mμ from a blank solution of the same dye concentration as a reference, with a Shimadzu photoelectric photometer QR-50 with quartz cells 1 cm thick. A stock solution of 10^{-3}M HABA, stable for at least 10 months, was diluted to 5×10^{-4}M with a phosphate buffer. The dilute solution was stable for at least two weeks. Protein and dye reacted immediately and the colour of the complex was stable for several hours. Concentration of HABA used was 5×10^{-4}M and that of BSA about 0.1 percent or below. In these concentration regions, Beer's rule was satisfied. The degree of denaturation, $w_D°$, was obtained experimentally by the relation

$$w_D° = 1 - \Delta E/\Delta E_N \quad (1)$$

where ΔE is the optical density difference between the heat-denatured solution and the reference solution and ΔE_N is that of the native BSA.

Intrinsic Viscosity. Viscosity of BSA solution denatured at various temperatures and at various times was measured by the Ostwald type viscometer, the flow time of the clean water being about 120 sec at 25°C. The viscometer was cleaned immediately before use by chromate mixture, rinsed with distilled water many times to remove all traces of the acid, and then dried with acetone which had been distilled three times. Measurements were carried out in a thermostat kept at 25°C. The intrinsic viscosity, $[\eta]$ (ml/g), was determined according to the Huggins equation

$$\eta_{sp}/c = [\eta] + k[\eta]^2c \quad (2)$$

where η_{sp} is the specific viscosity of the solution, c the concentration of the BSA in g/ml, and k the Huggins constant.

Light Scattering Measurements. The method of measurements was the same as that given in a previous paper.[8] A

Shimadzu electrophotometric light scattering photometer PG-21 was used at 436 mμ and at 25°C. The reduced scattering intensity for unpolarized incident light was obtained and examined by the Zimm plot method. The solutions and solvent were made optically clean by ultrafiltration with Membrane Filter No. 15 from Sartorious Co. Ltd. It has been ascertained that the concentration of the thermally denatured BSA does not change by ultrafiltration.

Refractive Index Increment. Measurements were carried out with a Shimadzu photoelectric differential refractometer DR-3 (Brice type) at 436 mμ and at 25°C.

Density. A picnometer of about 35 ml was used at 25°C.

Results

Degree of Denaturation. The weight fraction of denatured BSA, $w_D°$, was obtained by using HABA for the solutions heated at various temperatures for various lengths of time. The results are shown in Figs. 1 and 2. We see from Fig. 1 that the value of $w_D°$ increases with time and seems to reach a final value determined by the temperature. When the temperature was below 53°C, the $w_D°$ value reaches, at most 25 percent, while at or above 80°C it reaches 90 percent in about 20 min. At 56—60°C, it increases gradually with time.

The $w_D°$ values obtained at various temperatures at the constant heating time of 100 min are plotted in Fig. 2. The value was less than 10 percent below 50°C but increased remarkably in the temperature range 50—60°C. Thus, $w_D°$ reached about 80 or 85 percent when the BSA solution was heated at 60°C for 100 min.

Intrinsic Viscosity. Two samples obtained by heating (A) at various temperatures for 100 min, and (B) at 60°C for various lengths of time, were studied, the values of the intrinsic viscosity [η] being obtained for the BSA of various degrees of denaturation, $w_D°$. The results are shown in Fig. 3, where open circles denote

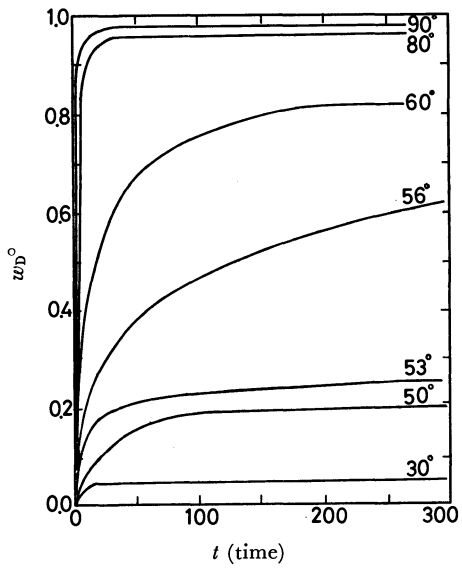

Fig. 1. Degree of denaturation, $w_D°$, obtained at various heating temperatures and heating times, with HABA (at 482 mμ) in 0.05M phosphate buffer at pH 7.2.

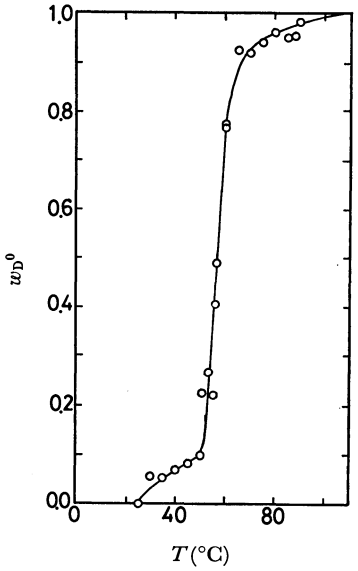

Fig. 2. Degree of denaturation, $w_D°$, obtained at various heating temperatures for 100 min.

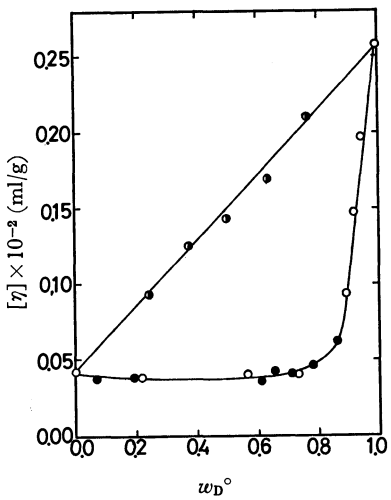

Fig. 3. Intrinsic viscosities, $10^{-2}[\eta]$, (ml/g) obtained by heating (A) at various temperatures for 100 min. (open circles) and (B) at 60°C for various times (closed circles) and (C) for the mixed solution of the native BSA and the denatured BSA, the latter having been heated at 90°C for 100 min. (half-open circles).

the BSA heated at various temperatures for 100 min (case A), and closed circles that heated at 60°C for various lengths of time (case B). Both plots lie on the same curve when plotted against w_D^0. This suggests that the state of BSA molecules and therefore the mechanism of the thermal denaturation in heated solutions does not depend on the method of heating but only on the degree of denaturation $w_D°$.

Half-open circles in Fig. 3 show the values of intrinsic viscosity obtained for the mixture of the solutions of untreated native BSA and of the almost fully denatured BSA, the latter being obtained by heating at 90°C for 100 min. It is seen that the additivity of the intrinsic viscosity against $w_D°$ holds for the mixed solution, and that the value of [η] of the mixture is entirely different from that of the partially denatured solutions. It is thus concluded that the actual solution is not a simple

mixture of fully denatured BSA and native BSA.

The curve $[\eta]$ *vs.* $w_D°$ is bent at about $w_D°=0.85$. When $w_D°$ was below 85 percent, the intrinsic viscosity showed no appreciable change but it increased remarkably when $w_D°$ exceeded 85 percent. The data indicate that the mechanism of thermal denaturation differs for below and above 85 percent of $w_D°$. In the initial stage of heating, intramolecular denaturation which does not affect the value of $[\eta]$ would mainly occur, while in the later stage, intermolecular aggregation which gives rise to an increase of $[\eta]$ would mainly occur. Light scattering measurements were carried out in order to clarify the results.

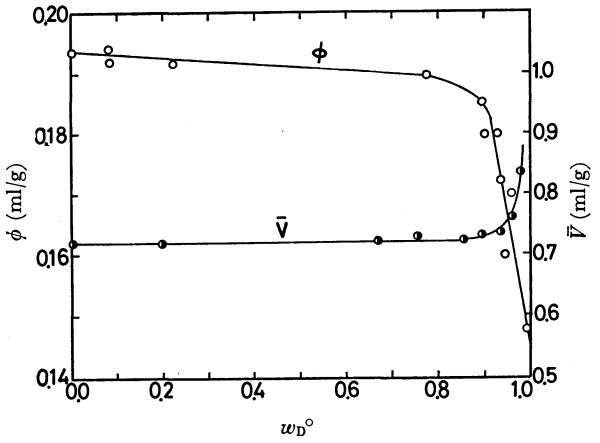

Fig. 4. Refractive index increment, ϕ, (ml/g) and the partial specific volume, $\bar{V}$, (ml/g) at various degree of denaturation.

Refractive Index Increment. The refractive index of the thermally denatured solution n was found to be linear with respect to BSA concentration c (g/ml). As the inclination of the straight lines, the value of the refractive index increment ϕ (ml/g) was determined for each thermally denatured solution and the result is given in Fig. 4. The quantity ϕ is the apparent refractive increment defined as follows.

$$\phi = (\mathrm{d}n/\mathrm{d}c)$$

We see that ϕ does not change appreciably for $w_D°$ values less than 85 percent but decreases remarkably at values exceeding 85 percent. This is in line with the variation of intrinsic viscosity.

Light Scattering. The reduced scattering intensity for unpolarized incident light, R_θ, was measured as a function of the scattering angle θ at various BSA concentration c (g/ml), in 0.05M phosphate buffer as a solvent. According to the Zimm plot method, apparent values of the weight-averaged molecular weight M, the radius of gyration R_g and the second virial coefficient A_2 are obtained on the basis of the following equation:

$$\frac{K'\phi^2 c}{R_\theta} = \frac{1}{M}\left(1+\frac{16\pi^2 n_0^2}{3\lambda_0^2}R_g^2 \sin^2\frac{\theta}{2}\right) + 2A_2 c \qquad (3a)$$

where

$$K' = 2\pi^2 n_0^2/N_0\lambda_0^4 \qquad (3b)$$

Here, N_0 is Avogadro's number, λ_0 is the wavelength in a vacuum, the value used in this experiment being 4360 Å.

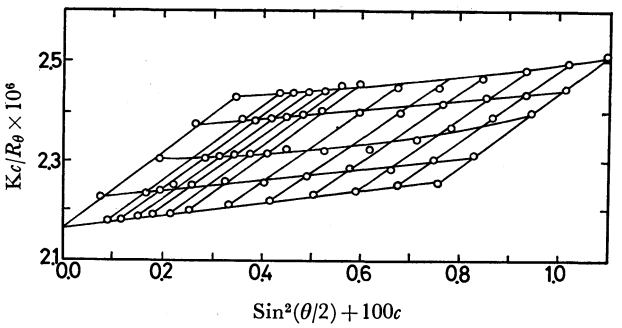

Fig. 5. Zimm plot for the thermally-denatured BSA at 60°C for 100 min.

It has been reported[8] that the Zimm plot of native BSA in 0.01M sodium chloride solution (pH=5.40) is narrow because the value of the second virial coefficient A_2 is nearly equal to zero, and that the value of the molecular weight M is 71900, which is in good agreement with the value reported.[9] The Zimm plot of the BSA thermally denatured by heating at 60°C for 100 min is shown in Fig. 5 as an example. The plots obtained by the extrapolation to zero of θ are linear against c. From the straight line, the apparent molecular weight M and the second virial coefficient A_2 can be calculated according to Eq. (3). The curves of the reduced scattering intensity against $\sin^2(\theta/2)$ at finite concentration are slightly concave upwards, but the curve obtained by the extrapolation to zero of c is almost linear against $\sin^2(\theta/2)$. The apparent radius of gyration R_g can therefore be obtained from the inclination of the straight line. The values of M, R_g, and A_2 thus obtained are given in Tables 1 and 2, which give the results obtained by the methods of heat treatment A and B, respectively, and Fig. 6 which gives the results of M and R_g plotted as a function of the degree of denaturation $w_D°$. We see that the increase of M is relatively small when $w_D°$ exceeds this value. Similarly, the value of R_g is nearly constant when $w_D°$

is below 85 percent, and increases remarkably when w_D° exceeds this value.

Discussion

Mechanism of Denaturation. It is thought that the mechanism of denaturation changes at about 85 percent of the degree of denaturation. No appreciable change in $[\eta]$, ϕ, and R_g and relatively small increase of M, observed at the earlier stage of heating, would suggest intramolecular denaturation in the range where w_D° is less than 85 percent. When w_D° exceeds 85 percent, the values of M, R_g, and $[\eta]$ increased and ϕ decreased remarkably, from which the intermolecular aggregation of denatured molecules could be suggested. There will, therefore, be at least three components in the solutions, that is, native (N), intramolecularly denatured (D), and intermolecularly aggregated (D_n) components. The following reaction would occur between them:

$$n\mathrm{N} \longrightarrow n\mathrm{D} \longrightarrow \mathrm{D}_n \qquad (4)$$

Component D is mainly formed in the stage where w_D° is less than 85 percent. The value of $[\eta]$, R_g, ϕ, M, and $\bar{V}$ of this component are nearly the same as those of the native BSA, although the component differs from that of native BSA in conformation. Component D_n is formed by the intermolecular aggregation of the intramolecularly denatured BSA mainly in the stage where $w_D{}^0$ exceeds 85 percent. Many papers have dealt with qualitative studies of aggregation of denatured proteins,[2-5] but not much with quantitative studies.

Weight Fraction of Denatured Components. The following equation is derived for the refractive index increment of a solution containing z macromolecular components at constant temperature T, and at constant pressure P.

$$\left(\frac{\partial n}{\partial c}\right)_{T,P} = \sum_{i=1}^{i=z}\left(\frac{\partial n}{\partial c_i}\right)_{T,P,c_{j\neq i}} \cdot \left(\frac{\partial c_i}{\partial c}\right)_{T,P} \qquad (5)$$

where

$$c = \sum_{i=1}^{i=z} c_i \quad \text{and} \quad w_i = c_i/c, \qquad (6)$$

n being the refractive index of the solution and c the concentration for the total solutes g/ml, related to the concentration of i-th component according to Eq. (6) where w_i is the weight fraction of the i-th component. If the refractive index increment by the i-th component $(\partial n/\partial c_i)_{P,T,c_j}$ is expressed by ϕ_i, Eq. (5) can be written as follows.

$$\phi = \sum_{i=1}^{i=z} \phi_i w_i \qquad (7)$$

where ϕ is the apparent refractive index increment obtained for the total solutes in the mixed solution. The following equations can be obtained for a mixed solution of three macromolecular solutes N, D, and D_n mentioned above:

$$1 - w_D{}^{\circ} = w_N \qquad (8a)$$

$$w_D{}^{\circ} = w_D + w_n \qquad (8b)$$

$$\phi = \phi_N w_N + \phi_D w_D + \phi_n w_n \qquad (8c)$$

where the subscripts N, D, and n represent N, D, and D_n, and w_D° is the degree of denaturation obtained experimentally by using HABA according to Eq. (2).

Since the value of ϕ in Fig. 4 showed no appreciable change when w_D° was within 85 percent, it may be proper to assume that the value of the refractive increment of component D is nearly equal to that of native BSA, *viz.*, $\phi_N \fallingdotseq \phi_D$. Thus, according to Eq. (8):

$$w_n = (\phi - \phi_N)/(\phi_n - \phi_N) \qquad (9a)$$

$$w_D = w_D{}^{\circ} - w_n \qquad (9b)$$

The results obtained are shown in Fig. 7 by using the values ϕ_n=0.1422(ml/g) and ϕ_N=0.1935(ml/g). The curve of w_D has a maximum point as expected for the intermediate component of a successive reaction as Eq. (4). The maximum point is for w_D°=85 percent. On the other hand, w_n showed no appreciable increase when w_D° is less than 85 percent. When w_D° exceeds this value, w_D increased remarkably as a result of the intermolecular aggregation.

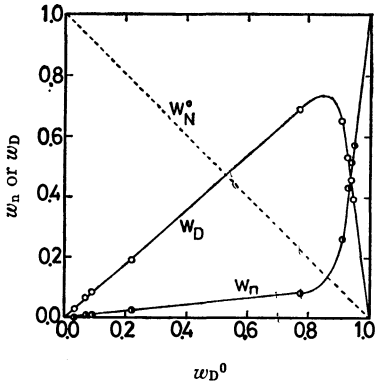

Fig. 7. Weight fraction of the monomeric, denatured BSA, W_D, and of the aggregate, W_n, at various degree of denaturation W_D°.

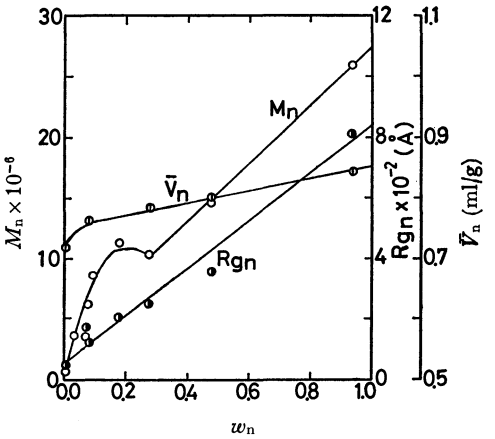

Fig. 8. Molecular weight, M_n, radius of gyration, R_{gn}, and partial specific volume, $\bar{V}_n$, of the aggregate at various degree of denaturation.

Physico-chemical Properties of Aggregated Molecules. For the light scattering of a solution containing z macromolecular components, the following equation derived by the theory of fluctuation of the chemical potential was used in the previous paper,[8]

$$\frac{K'c}{R_\theta} = \frac{1}{\sum_{i=1}^{i=z} M_i w_i \phi_i^2}\left\{1 + \frac{16\pi^2 n_0^2}{3\lambda_0}\left(\frac{\sum_{i=1}^{i=z} M_i w_i \phi_i^2 R_{gi}^2}{\sum_{i=1}^{i=z} M_i w_i \phi_i^2}\right)\sin^2\frac{\theta}{2}\right\} + 2c\frac{\sum_{i=1}^{i=z}\sum_{j=1}^{j=z} A_2^{(ij)} M_i M_j P_i(\theta) P_j(\theta) w_i w_j \phi_i \phi_j}{\left(\sum_{i=1}^{i=z} M_i P_i(\theta) w_i \phi_i^2\right)^2} \quad (10)$$

where R_θ is the reduced scattering intensity of the solution containing z macromolecular components, $P_i(\theta)$ the interference factor of the i-th macromolecular component, $A_2^{(ij)}$ the second virial coefficient describing the interaction between the i-th and j-th components, w_i the weight fraction of the i-th component in the total solute, M_i the weight-average molecular weight of the i-th component, ϕ_i the refractive increment of the i-th component, n_0 is the refractive index of the solvent and λ_0 the wavelength in a vaccum (the value 4360 Å was used). From this equation the following equations can be obtained for a mixed solution of three macromolecular species, N, D, and D_n,

$$M\phi^2 = M_N w_N \phi_N^2 + N_D w_D \phi_D^2 + M_n w_n \phi_n^2 \quad (11a)$$

$$R_g^2 M\phi^2 = R_{gN}^2 \phi_N^2 M_N w_N + R_{gD}^2 \phi_D^2 M_D w_D + R_{gn}^2 \phi_n^2 M_n w_n \quad (11b)$$

where M, ϕ, and R_g are experimental values.

From Eq. (11a) and the relations $M_D \fallingdotseq M_N$, and $\phi_D \fallingdotseq \phi_N$, the value of M_n can be obtained:

$$M_n = \{M\phi^2 - (1-w_n)M_N\phi_N^2\}/(w_n\phi_n^2) \quad (12)$$

The results are given in Fig. 8 and Table 3. The degree of association n can be obtained as (M_n/M_N).

It is seen that the value of M_n increases remarkably with the increase of w_n, the increase being almost linear when w_n exceeds 0.3. The last column of Table 3 shows values obtained by the extrapolation of w_n to 1, according to the data shown in Fig. 8. We see that the weight-average molecular weight of the aggregate is 27.2×10^6 at the maximum, and the aggregate is composed of 378 molecules of denatured BSA.

The conformation of the intramolecularly denatured BSA, D, is expected to differ more or less from that of the native BSA. The result given in Fig. 6, however, shows that the radius of gyration remains constant in the initial stage of thermal denaturation where w_D° is less than 85 percent. The radius of gyration of the component D, R_{gD}, is therefore assumed to be nearly equal to that of native BSA, R_{gN}. The value of the radius of gyration of the aggregate, R_{gn}, can then be obtained according to the equation easily derived from Eq. (11b):

$$R_{gn}^2 = \{R_g^2 M\phi^2 - R_{gN}^2 M_N \phi_N^2 (1-w_n)\}/(w_n M_n \phi_n^2) \quad (13)$$

The results are shown in Fig. 8 and Table 3. We see that R_{gn} increases almost linearly with the increase of w_n. The value of the radius of gyration of the aggregate itself was about 841 Å at the maximum, as obtained by extrapolation of w_n to 1. This value is about 19 times larger than that of the native BSA.

For the partial specific volume of polymer mixtures, the additivity rule is usually assumed. In the present case of three solutes,

$$\bar{V} = \bar{V}_N w_N + \bar{V}_D w_D + \bar{V}_n w_n \quad (14)$$

The value of $\bar{V}$ remains almost constant in the region of w_D° less than 85 percent, where the intramolecular denaturation mainly takes place. The partial specific volume of the denatured, monomeric BSA, $\bar{V}_D$, is therefore assumed to be nearly equal to that of the

Table 3. Results of light scattering and specific volume of the aggregates

w_n	0.0791	0.1724	0.2759	0.4726	0.9331	1.000
$M_n \times 10^{-6}$	6.42	7.73	10.3	14.7	25.8	27.2
R_{gn} (Å)	126	206	249	355	816	841
n	89.3	108	143	205	359	378
$\bar{V}_n$ (ml/g)	0.7607	0.7710	0.7847	0.8037	0.8448	0.8990

native BSA, $\bar{V}_N$. If $\bar{V}_D \fallingdotseq \bar{V}_N$ in Eq. (14), the value of the partial volume of the aggregate $\bar{V}_n$, can be obtained. The results are shown in Table 3 and Fig. 8. We see from Fig. 8 that values of $\bar{V}_n$ increase almost linearly with increase of w_n and that the value of $\bar{V}_n$ is 0.8990 ml/g at the maximum association state where w_n is equal to 1.

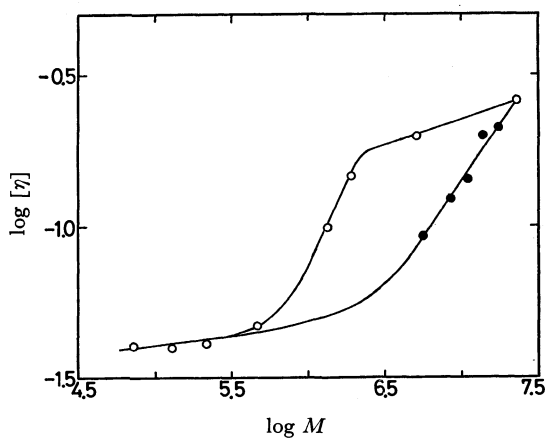

Fig. 9. Log-log plots of intrinsic viscosity against apparent molecular weight.

Dependence of $[\eta]$ *and* R_g *on* M. The log-log plots showing the dependency of the intrinsic viscosity on weight average molecular weight are given in Fig. 9. Open circles denote the experimental values obtained for variously denatured solutions and closed circles those obtained for the mixed solutions of the native BSA and completely denatured BSA. The latter was obtained heating at 90°C for 100 min, its molecular weight being 2.30×10^7. The exponent a in the Kuhn-Mark equation $[\eta]=KM^a$ was obtained from the slope of curves in Fig. 9. In the former, three values of the exponent a 0.054, 1.1, and 0.166 are obtained for lower, intermediate and higher M values, respectively. In the latter mixed solutions, the values of a are 0.055 and 0.75 for lower and higher M-values, respectively.

Log-log plots of R_g *vs.* M for the results from thermally treated solutions (open circles) and for calculated values of the aggregated molecules themselves (closed circles) are shown in Fig. 10. The relations are linear and expressed by the empirical equation: $R_g=K'M^b$. The value of the constants, $K'=0.185 \times 10^{-8}$ and $b=0.496$, were obtained for the solutions, and $K'=1.68 \times 10^{-17}$ and $b=1.578$ for the aggregates.

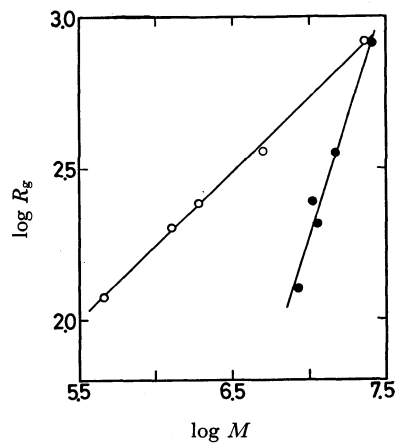

Fig. 10. Log-log plots showing dependence of radius of gyration on molecular weight for the mixture solutes (open-circles) and for the aggregate (closed circles).

The results indicate that native and intramolecularly denatured species are approximated with a compact, comparatively spherical shape because of the low a and b values, while the intermolecularly aggregated species is approximated with rigid, cylindrical rod molecules because of the relatively large a and b values.

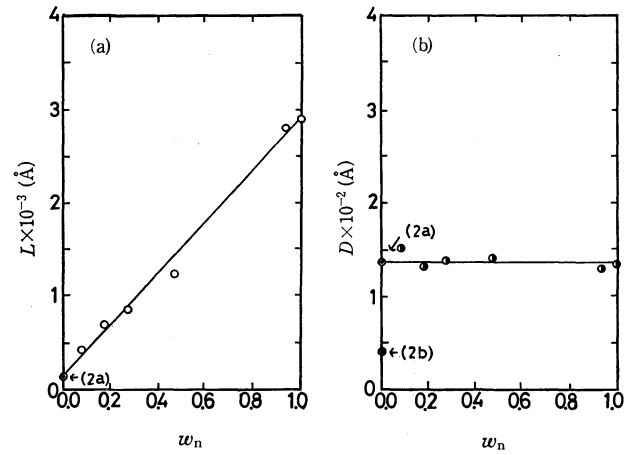

Fig. 11. Variation of molecular length L and diameter D by association.

TABLE 4. MOLECULAR DIMENSIONS OF THE AGGREGATES AS CYLINDRICAL RODS

Size and Shape of Aggregated Molecules. If the aggregate is assumed to be rigid and the mass is distributed uniformly all over the volume of the aggregate, the size and shape of the aggregate can be calculated from the above data of M_n, $\bar{V}_n$, and R_{gn}. The dimensions and axial ratio of the aggregates as cylindrical rod molecules are given in Fig. 11 and Table 4, where L and D are the length and diameter, respectively, of the rod molecule, and p is the axial ratio ($=L/D$). The diameters of the native BSA as a rigid prolate spheroid with major axis a and minor axis b are $2a=$ 140 Å and $2b=70$ Å as shown in Fig. 11 by double circles at $w_n=$zero. We see from Fig. 11a that the length L increases almost linearly with the increase of the weight fraction of the aggregate w_n. The value of the length of the aggregate obtained by extrapolation of w_n to zero agreed with the length of the native BSA: $2a=140$ Å. The length per one BSA in an aggregate

L/n (n is the degree of association) is about 6.41 Å, irrespective of the value of w_n (Table 4).

On the other hand, the diameter of the aggregated molecule D was almost constant irrespective of w_n (Fig. 11b). The average value of diameter D thus obtained was 140 Å, which is equal to the length of the native BSA, $2a$, instead of the diameter $2b$. This would indicate that the aggregate is formed by side-by-side association, so that the diameter of the aggregate is almost constant, but the length of the aggregate increases linearly with the degree of aggregation. At $w_n=1$, the length and diameter of the aggregate are 2910 and 140 Å, respectively, and one aggregate consists of 378 molecules.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 797—804 (1973)

The Molecular Vibrations and the Rotational Isomerism of (Chloromethyl)methylsilane

Michiro HAYASHI, Keiichi OHNO, and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received September 6, 1972)

The infrared spectra of (chloromethyl)methylsilane and its deuterated species have been measured in the gaseous, liquid, and crystalline states. The normal vibration calculation has been carried out using a modified Urey-Bradley force field. It has been concluded that, in the gaseous and liquid states, there exist both the *trans* and *gauche* isomers, while only the former persists in the crystalline state. For $ClCH_2SiD_2CH_3$, a different spectral pattern has sometimes been recorded in the crystalline state before the sample has been annealed enough. It has been concluded that the persisting isomer is in the *gauche* form in this metastable crystalline state. The *trans* and *gauche* isomers have been found, from the temperature dependence of the relative intensities of the spectra, to have nearly the same energy in the liquid state. From the solvent effects of the spectra, the *trans* isomer has been found to be more polar than the *gauche* isomer. Therefore, if the C–Cl bond moment is assumed to have the direction of C^+–Cl^-, the group moment of the C_2SiH_2 part of the molecule must be in the direction of

on the bisector of the C–Si–C angle. The vibrational assignments have been worked out taking into account the results of the normal vibration calculations and the reported assignments for chloromethylsilane, dimethylsilane, and ethylmethylsilane.

Recently, we have worked out the vibrational assignments and the rotational isomerism for alkylsilane. The vibrational assignments and the normal vibration calculations for halogenomethylsilane,[1] methylsilane,[2] dimethylsilane,[2] ethylsilane,[2] and ethylmethylsilane[3] have already been reported. In this paper, the vibrational assignments of (chloromethyl)methylsilane will be dealt with in relation to the rotational isomerism around the C–Si bond as an axis.

The normal vibrations of this molecule have been calculated using modified Urey-Bradley force constants transferred from those of chloromethylsilane and dimethylsilane.

The direction of the group moment of the C_2SiH_2 part of the molecule will be discussed using the results of the solvent effects of the spectra.

Experimental

The samples of (chloromethyl)methylsilane and its deuterated species were prepared by the reduction of a commercial product of $ClCH_2SiCl_2CH_3$ (Pierce Chem. Co. U.S.A.) with $LiAlH_4$, $LiAlD_4$, or an equimolar mixture of $LiAlH_4$ and $LiAlD_4$ in *n*-butyl ether.[4] The purities of the samples of $ClCH_2SiH_2CH_3$ and $ClCH_2SiD_2CH_3$ were checked by means of the infrared spectra and gas chromatography.

The infrared spectra in the region from 200 to 4000 cm^{-1} were recorded on a Perkin-Elmer instrument (model 621). For the measurements in the crystalline state, the vapors of the samples were directly condensed on a CsI plate in a cell cooled with liquid nitrogen in a vacuum and were then annealed several times in order to keep the samples from being in a supercooled state. The spectra in the gaseous state were measured with one-meter and 10 cm gas cells with CsI windows.

In order to measure the relative intensity changes in the infrared spectra, the solution spectra were also measured using a sealed KRS-5 cell (0.2 mm thick), with carbon disulfide and acetonitrile as the solvents.

Rotational Isomerism

In this substance, two rotational isomers are expected around the C–Si bond, as is shown in Fig. 1.

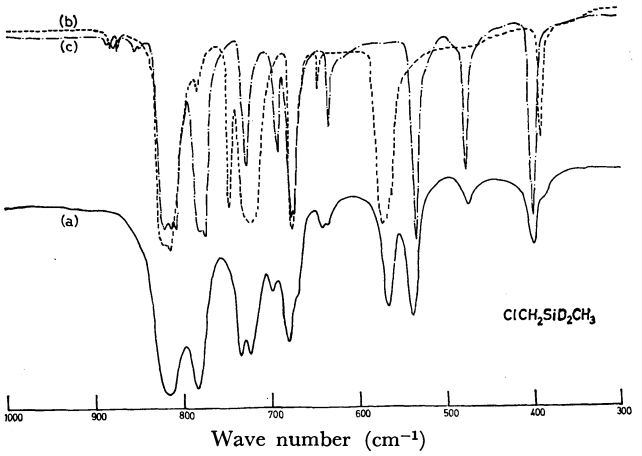

Fig. 3. Infrared spectra of $ClCH_2SiD_2CH_3$.
(a): in the liquid state,
(b): in the stable crystalline state,
(c): in the metastable crystalline state.

A comparison of the observed spectra in the liquid state with those in the crystalline state reveals the existence of rotational isomers in this substance, since some of the infrared bands vanish in the crystalline state.

Especially, it is to be noted that, for $ClCH_2SiD_2CH_3$, a different spectral pattern is sometimes obtained in the crystalline state before annealing the sample enough, as is shown in (c) of Fig. 3; furthermore, the superposition of these two kinds of spectral patterns, (b) and (c), coincides with the spectral pattern in the liquid state.

This is understandable if the persisting isomer has different molecular forms for $ClCH_2SiD_2CH_3$ in the metastable and stable crystalline states.

In the cases of ethylmethylsilane and its deuterated species, the existence of the rotational isomers has been proved from the lower-frequency mode of two Si–C stretchings and the SiH_2 rocking, SiD_2 rocking, and SiD_2 wagging modes appearing in the region from 300 to 650 cm^{-1}.[3] The spectra assigned to these modes have been observed for ethylmethylsilane as pairs which consist of two bands attributable to the *trans* and *gauche* isomers respectively.

These modes are also expected for (chloromethyl)-methylsilane in the same region as those for ethylmethylsilane; that is, for $ClCH_2SiH_2CH_3$, the lower-frequency mode of the two C–Si stretchings and the SiH_2 rocking mode are expected around 620 and 490 cm^{-1} respectively, and for $ClCH_2SiD_2CH_3$, the C–Si stretching, the SiD_2 wagging, and the SiD_2 rocking modes are expected around 640, 560, and 400 cm^{-1} respectively. In this region, for $ClCH_2SiH_2CH_3$ three bands are seen in the liquid state; one of them accompanies a shoulder on the higher-frequency side, while two bands persist in the crystalline state.

For $ClCH_2SiD_2CH_3$ five bands are seen in the liquid state; two of them accompany a shoulder on the lower-frequency side, while there are four and three bands persisting in the metastable and stable crystalline states respectively.

Although some of these bands can be regarded as pairs, only single bands can be found for the other

modes. However, these single bands can be regarded as unresolved pairs of two bands, since these bands are reduced in their relative intensities in the crystalline state; this fact can be understood if one of two unresolved bands vanishes in the crystalline state. The possibility of the unresolved bands in a pair is also supported by the fact that even the resolved bands in a pair actually have much smaller spacings than those for ethylmethylsilane.[3]

Because of the smallness of the spacing of the bands in the pair, the existence of the rotational isomers cannot be concluded from the SiH_2 rocking mode for $ClCH_2SiH_2CH_3$. However, for $ClCH_2SiD_2CH_3$, definite evidence is obtained from the SiD_2 wagging and the SiD_2 rocking modes. The pair at 567 and 537 cm^{-1} assigned to the SiD_2 wagging mode, and that at 401 and 389 cm^{-1} assigned to the SiD_2 rocking mode, are seen in the liquid state, where the bands at 537 and 401 cm^{-1} disappear in the stable crystalline state. This is the same as in the case of ethylmethylsilane.

Therefore, if the bands in the pair appear in the same order as in the case of ethylmethylsilane, the bands disappearing in the stable crystalline state are attributable to the *gauche* isomer and the bands persisting in the stable crystalline state are attributable to the *trans* isomer.

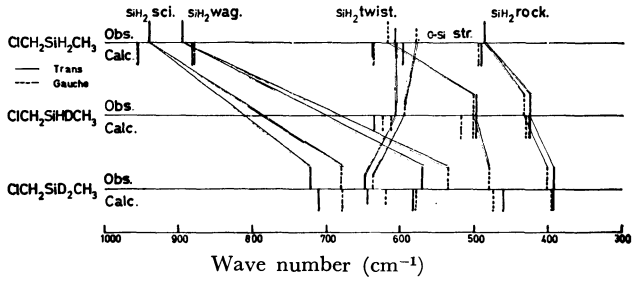

Fig. 4. Observed and calculated frequencies of the SiH_2, SiD_2, and SiHD deformation modes and the lower frequency C–Si stretching mode.

As is shown in Fig. 4, this conclusion is also confirmed by the normal vibration calculation, as will be described later.

The pair at 608 and 579 cm^{-1} for $ClCH_2SiH_2CH_3$ and that at 644 and 637 cm^{-1} for $ClCH_2SiD_2CH_3$ are seen in the liquid state, where one of two bands in each pair (579 and 637 cm^{-1}) disappears in the crystalline state. These are assigned to the lower-frequency mode of C–Si stretching from the results of the calculations.

Usually, the spectra of an asymmetrically deuterated species such as $ClCH_2SiHDCH_3$ give difinite experimental evidence on the molecular forms of the rotational isomers. For $ClCH_2SiHDCH_3$ and $CH_3CH_2SiHDCH_3$, since the two *gauche* forms come to be not equivalent, the spectra of the *gauche* isomer are expected to be split into doublets, while the spectra of the *trans* isomer remain singlets.

This is actually the case with ethylmethylsilane.[3] For the present case of $ClCH_2SiHDCH_3$, however, this is not actually the case.

As is shown in Fig. 5 although the doublet at 433

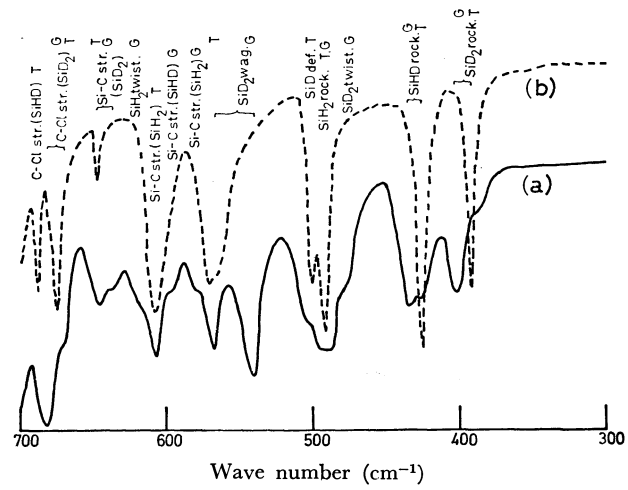

Fig. 5. Infrared spectra of the mixture of $ClCH_2SiHDCH_3$, $ClCH_2SiH_2CH_3$, and $ClCH_2SiD_2CH_3$.
(a): in the liquid state,
(b): in the crystalline state.

and 425 cm^{-1} assigned to the SiHD rocking mode is seen in the liquid state, one of the components, that at 433 cm^{-1}, disappears in the crystalline state. This component can be regarded as two unsplit bands due to two different pairs of *gauche* forms.

The existence of the rotational isomers in the gaseous state can also be proved from a comparison of the spectra in the gaseous and liquid states.

In the case of $ClCH_2SiD_2CH_3$, in the crystalline state it is concluded from the above discussions of the molecular forms of the isomers that the *gauche* isomer persists alone in the metastable state, while the *trans* isomer persists alone in the stable state.

As no appreciable changes in the relative absorption intensities between the spectra at low temperatures (*ca.* −100°C) and those at room temperature (*ca.* 23°C) were observed, the energy difference between the isomers can be disregarded in the liquid state. In the gaseous state, the larger overlapping of the key bands prevents the measurement of the relative intensities of the bands.

The Solvent Effects of the Spectra

The solvent effects of the spectra were measured using the pair of Si–C stretching bands at 608 and 579 cm^{-1} for $ClCH_2SiH_2CH_3$ and the pair of SiD_2 wagging bands at 567 and 537 cm^{-1} for $ClCH_2SiD_2CH_3$, where the higher-frequency bands of each pair are due to the *trans* isomer and the lower bands are due to the *gauche* isomer.

The bands for the *trans* isomer increase in their relative intensities when a mixture is made with a polar solvent such as acetonitrile, while the bands for the *gauche* isomer increase in their relative intensities in a mixture with a non-polar solvent such as carbon disulfide, as is shown in Fig. 6. Therefore, it can be concluded that the *trans* isomer is more polar than the *gauche* isomer.

From these results, if the C–Cl bond moment is assumed to have the direction of $C^+–Cl^-$, the group

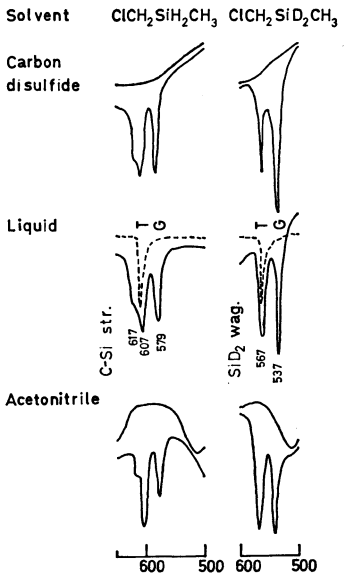

Fig. 6. Solvent effects of the infrared spectra for (chloromethyl)-methylsilane.

moment of the C_2SiH_2 group should be in the direction of $+\begin{smallmatrix} C\diagdown & \diagup H \\ & Si \\ C\diagup & \diagdown H \end{smallmatrix}-$ on the bisector of the C–Si–C angle.

The Normal Vibration Calculation and the Vibrational Assignments

In order to confirm the molecular forms of the rotational isomers and the assignments of the observed spectra, the normal vibration calculation for (chloromethyl)methylsilane was carried out using a modified Urey-Bradley force field.

The force constants used were transferred from those for chloromethylsilane[1] and dimethylsilane[2] except for the two force constants of H(Cl–C–Si) and F(Cl···C···Si), which were adjusted in order to predict the observed Cl–C–Si bending vibration, which had not been observed for chloromethylsilane.

The modified Urey-Bradley force field used in the calculation was the same type as in the cases of chloromethylsilane and dimethylsilane, where the internal rotation force constants for the CH_3–Si and CH_2–Si groups were taken so as to predict the observed barrier height of 1.65 kcal/mol for dimethylsilane[5] by microwave spectroscopy.

The structural parameters were transferred from those of chloromethylsilane[6] and dimethylsilane[5] determined by microwave studies. However, the valency angles were assumed to be tetrahedral without regard to the reported values.

The force constants used in the calculation are listed in Table 4. The observed and calculated frequencies of (chloromethyl)methylsilane and its deuterated species are given in Tables 5—7, together with their predominant symmetry coordinates in the potential energy

a) The chlorine atom occupies the *trans* position to the deuterium of the SiHD group.
b) The chlorine atom occupies the *trans* position to the hydrogen of the SiHD group.
c) Only the predominant symmetry coordinates are shown.
d) These four frequencies have the complicated mixing modes of the four symmetry coordinates of the CH_2 rocking, C–Si stretching, Si–H deformation, and C–Cl stretching. However, the correspondence of the observed frequencies to these symmetry coordinates can be found as is shown in the table from the comparison with those for the other species.

distribution.

A fair agreement is obtained between the observed and calculated frequencies. The deviation is within 3% for almost all of the modes. However, a little larger deviations (~5%) are seen for the C–Si and C–Cl stretching modes for $ClCH_2SiH_2CH_3$ and $ClCH_2SiHDCH_3$ and for the SiD_2 wagging mode for $ClCH_2SiD_2CH_3$. Although these larger deviations indicate the limitation of the transferability of the force constants, further adjustments of the force constants were not attempted.

From the calculated potential energy distribution, the mixings of the modes were found to be complicated among the C–Si and C–Cl stretchings and some of the hydrogen deformation modes of the CH_3, CH_2, and SiH_2 groups.

As is shown in Tables 1 and 2, according to the present assignments the frequency differences between the CH_3 rocking modes belonging to the A′ and A″ species are found to be more than 100 cm^{-1} for $ClCH_2SiH_2CH_3$ in both the *trans* and *gauche* forms, while those for $ClCH_2SiD_2CH_3$ are less than 10 cm^{-1}. The situation is the same with the CH_3 rocking modes for dimethylsilane[2] and ethylmethylsilane,[3] as has been reported in previous papers.

This is understandable for the following reasons. For $ClCH_2SiH_2CH_3$, as the SiH_2 wagging mode is found at a frequency close to the expected frequency for the CH_3 rocking mode belonging to the A′ species, the CH_3 rocking mode receives a strong coupling from the SiH_2 wagging mode and is pushed down to the lower-frequency side. On the other hand, for $ClCH_2SiD_2CH_3$, as the SiD_2 wagging mode is far from the frequency for the CH_3 rocking mode, the coupling becomes negligible.

This is also supported by the calculated potential energy distribution for these modes.

As has been already pointed out in the cases of dichlorosilane,[7] dimethylsilane,[2] and ethylmethylsilane,[3] for $ClCH_2SiHDCH_3$ the calculated potential energy distribution also shows that the SiHD rocking mode keeps its original mode, while the SiHD twisting mode should be more properly called the SiD deformation mode.

The vibrational assignments for the other modes can be obtained by taking into account the results of the normal vibration calculations and by comparing the observed spectra with those of similar molecules, such as dimethylsilane,[8–10] chloromethylsilane,[1] and ethylmethylsilane.[3] The results are shown in Tables 1—3.

The Crystal and Molecular Structure of *p*-Hydroxybenzoic Acid Monohydrate

Keiichi FUKUYAMA, Kenji OHKURA*, Setsuo KASHINO, and Masao HAISA
Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received September 25, 1972)

The crystal and molecular structure of *p*-hydroxybenzoic acid monohydrate has been determined by a single crystal X-ray analysis. The crystals are monoclinic, space group $P2_1/a$, $Z=4$, with $a=17.79$, $b=6.39$, $c=6.79$ Å, and $\beta=105.6°$. The structure was solved by the Patterson and Fourier methods, and refined by the block-diagonal least-squares method to a final R value of 0.086 for 806 non-zero reflections. Pairs of acid molecules form dimers by the hydrogen bonds between carboxyl groups (2.678 Å). The dimers are held together by the hydrogen bonds between phenolic hydroxyl groups and water molecules (2.595 and 2.823 Å); these hydrogen bonds extend around two-fold screw axes to make up layers of the dimers parallel to the (401). The layers are linked by the additional hydrogen bonds between carbonyl oxygens and water molecules (2.823 Å).

As a part of the investigation of the addition compounds of amines with carboxylic acids,[1] determination of the crystal and molecular structure of the title compound has been undertaken. This compound is of interest not only in hydrogen bonding scheme in the crystal, but also in molecular geometry of benzoic acids.

* Present address: Kyowa Carbon Co. Ltd., Ushimado, Okayama.

Experimental

Crystals prepared by slow evaporation from acetone solution were transparent plates elongated along the c axis. Cell constants were obtained from the oscillation and Weissenberg photographs taken with Cu$K\alpha$ radiation ($\lambda=1.5418$ Å). Space group was uniquely determined to be $P2_1/a$ from systematic absences; $h0l$ when h is odd, $0k0$ when k is odd. Elementary analysis and density measurement showed that the crystals contained four water molecules per unit cell.

TABLE 1. CRYSTAL DATA

p-HO-$C_6H_4COOH \cdot H_2O$ $FW=156.1$
Monoclinic $P2_1/a$
$a=17.79\pm0.05$ Å $b=6.39\pm0.02$ Å $c=6.79\pm0.01$ Å
$\beta=105.6\pm0.2°$
$D_m=1.38_6$ g cm^{-3} (by flotation)
$D_x=1.395$ g cm^{-3} (for $Z=4$)
$\mu=10.0$ cm^{-1} for Cu $K\alpha$ radiation
$F(000)=328$

The crystal data are listed in Table 1. Intensities were collected with Cu$K\alpha$ radiation by means of the multiple-film equi-inclination Weissenberg techniques for the layers $hk0$ to $hk5$. A total of 807 non-zero independent reflections were measured visually. The intensities were corrected for the Lorentz and polarization factors, and for spot shape.

Structure Determination and Refinement

The approximate positional parameters of p-hydroxybenzoic acid molecule were determined by the interpretation of a three-dimensional sharpened Patterson map and Harker section. The Fourier map based on the positional parameters of the acid molecule revealed the oxygen atom of water molecule. The structure thus obtained was refined by the block-diagonal least-squares calculations with isotropic temperature factors. For a time reflections 211, 311, 401, and $\bar{4}03$ were rejected because of strong extinction effect. A difference map revealed all peaks corresponding to eight hydrogen atoms. The least-squares refinement was made with anisotropic temperature factors for carbon and oxygen atoms including the hydrogen atoms with fixed parameters, which are shown in Table 2. The positional parameters of the hydrogen atoms were calculated by assuming suitable geometries, and their temperature factors were assumed to be equal to those of the heavy atoms to which they are attached. This refinement reduced an R value to 0.096. An extinction correction, $I_{corr}=I_o/(1-gI_o)$, was applied for strong reflections including 211, 311, and $\bar{4}03$, but inaccurate 401 was omitted. Further least-squares refinement for the non-hydrogen atoms gave the final R value of 0.086 for 806 non-zero reflections. The following weighting scheme was applied;

$$\sqrt{w} = 0.0 \text{ for } F_o = 0,$$
$$\sqrt{w} = 0.5 \text{ for } 0 < F_o < F_{min} \ (2.5),$$
$$\sqrt{w} = 1.0 \text{ for } F_{min} \leqq F_o \leqq F_{max} \ (22.6)$$

and

$$\sqrt{w} = F_{max}/F_o \text{ for } F_{max} < F_o.$$

The final atomic parameters are listed in Table 3. The final electron density map is shown in Fig. 1(a).

TABLE 2. THE ASSUMED ATOMIC PARAMETERS OF HYDROGEN ATOMS

a) The reflection 401 ($F_o \times 10 = 832$, $F_c \times 10 = 1703$) is omitted.

Difference electron density map, for which the contributions of the hydrogen atoms were excluded from the calculated structure factors, is shown in Fig. 1(b). A list of the observed and calculated structure factors is given in Table 4.

The atomic scattering factors were taken from International Tables for X-ray Crystallography.[2] The computations were performed on a HITAC 5020E computer at the Computer Center of the University of Tokyo using the UNICS program system,[3] and on a NEAC 2200-N700 computer at the Computation Center of Osaka University using the program for block-diagonal least-squares calculation (HBLS–IV) written by Okaya

2) "International Tables for X-ray Crystallography," Vol. III, The Kynoch Press, Birmingham, (1962), p. 201.

3) "The Universal Crystallographic Computing System," The Crystallographic Society of Japan, Tokyo, (1967).

and Ashida[4] and that for Lorentz and polarization factors and spot shape corrections written by Yasuoka.

Description of the Structure and Discussion

The bond lengths and angles are listed in Table 5. Unlike terephthalic acid[5] or *p*-toluic acid,[6] *p*-hydroxybenzoic acid shows significant difference in the two C–O bond lengths of the carboxyl group, 1.214 and 1.310 Å, as found in *p*-nitrobenzoic acid,[7] 1.222 and 1.319 Å, in *p*-bromobenzoic acid,[8] 1.225 and 1.307 Å, and in anisic acid,[9] 1.233 and 1.290 Å. The difference is more significant than that in potassium hydrogen di-*p*-hydroxybenzoate,[10] 1.232 and 1.284 Å. The bond length of C(1)–C(7) is 1.486 Å, which agrees with the corresponding bond length in terephthalic acid,[5] 1.483 Å and in *p*-toluic aicd,[6] 1.476 Å, but is somewhat shorter than that found in potassium hydrogen di-*p*-hydroxybenzoate,[10] 1.504 Å, and in *p*-nitrobenzoic acid,[7] 1.501 Å. The C(4)–O(3) bond length is 1.359 Å. This value agrees with phenolic C–O bond length in α- and β-modifications of *p*-nitrophenol,[11,12] 1.351 and 1.361 Å respectively, but is smaller than that in potassium hydrogen di-*p*-hydroxybenzoate,[10] 1.385 Å and in *p*-cresol,[13] 1.395 and 1.387 Å. Although the bond lengths of both C(1)–C(7) and C(4)–O(3) agree with those in the compounds reported to have quinoid character, no significant deviations of any bond lengths in the benzene ring from the mean value of 1.387 Å could be observed except for C(4)–C(5) bond length. The angle of C(5)–C(4)–O(3), 117.8°, is smaller than that of C(3)–C(4)–O(3), 121.8°. Such an inequality of the two C–C–O angles has been observed in many phenols, such as catechol,[14] α- and β-modifications of *p*-nitrophenol[11,12] and *p*-cresol.[13]

The least-squares plane of the benzene ring is

Table 5. Bond lengths (Å) and angles (°) along with their e.s.d.'s within parentheses

represented by the equation:

$$-0.7077X - 0.2327Y - 0.6671Z + 3.3222 = 0,$$

where X, Y, and Z are the lengths (in Å) along the a, b, and c^* axes, respectively. The deviations of the atoms of the acid molecule from the plane are given in Table 6. The least-squares plane of the carboxyl group and C(1) is represented by the equation:

$$-0.6590X - 0.2726Y - 0.7010Z + 3.4743 = 0.$$

The deviation of the atoms of the carboxyl group and C(1) from the plane are also given in Table 6. The dihedral angle between the two planes is 4.1°, while the corresponding angle in potassium hydrogen di-*p*-hydroxybenzoate[10] is 9.5°. The C(1)–C(7) and C(4)–O(3) bonds bend to the same side out of the benzene ring plane.

The crystal structure is shown in Fig. 2. Pairs of acid molecules are linked through the hydrogen bonds (2.678 Å) between carboxyl groups to form dimers. The dimers in the crystal are held together by the hydrogen bonds between phenolic hydroxyl groups and water molecules (2.595 and 2.823 Å); these hydrogen bonds extend around two-fold screw axes to make up layers of the dimers parallel to the (401). The layers are linked by the additional hydrogen bonds between carbonyl oxygens and water molecules (2.823 Å). The two hydrogen atoms, H(7) and H(8), of the water molecule are accepted by the carbonyl oxygen, $O(1^{IV})$, and the phenolic oxygen,O (3^{III}), respectively, and the hydrogen atom of the phenolic hydroxyl group, H(6), is accepted by the oxygen atom of the water molecule $O(4^{I})$. The $O(4^{I})$ deviates only by 0.35 Å from the plane through $O(3^{I})$, $O(1^{IV})$, and $O(3^{III})$. The angle, $O(3^{III})$–$O(4^{I})$–$O(1^{IV})$, is 108.5° and is close to the H–O–H angle in a water molecule.

The intermolecular distances shorter than 3.6 Å are shown in Fig. 2(b), indicating no abnormal short contact.

The authors thank to Dr. Tamaichi Ashida of the Institute for Protein Research of Osaka University and Dr. Noritake Yasuoka of Faculty of Engineering of Osaka University for permission of using their programs.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 808—812 (1973)

The Dependence of the Electron-transfer Rates of Aromatic Hydrocarbon Anion Radicals upon the Molecular Radii of the Reactants

Kosaku SUGA, Shin-ichi ISHIKAWA, and Shigeru AOYAGUI

Faculty of Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 22, 1972)

The applicability of the theory of R. A. Marcus is tested, the behavior of the rate constant being examined as a function of the molecular radii of the reactants. The rate constants of the electron-transfer reactions from the anion radicals of pyrene, perylene, and tetracene to their respective parent molecules are measured under experimental conditions in which the anion radicals are in a free ion or loose ion-pair state. The rate constants thus obtained and subsequently corrected for diffusion are 2.8×10^9, 3.0×10^9, and 2.6×10^9 $M^{-1}sec^{-1}$ respectively, in 1,2-dimethoxyethane at 25°C. These rate constants, as well as others obtained elsewhere for naphthalene and anthracene, are compared with those predicted theoretically, assuming a spherical and an oblate spheroidal molecular shape. The consistence between the theoretical and experimental results is not satisfactory; the variation in the observed rate constants with the molecular radii of the reactants is much smaller than that expected theoretically. The spin-exchange rate constants for anion radicals of pyrene, perylene, and tetracene are also determined to be 7.0×10^9, 5.1×10^9, and 4.8×10^9 $M^{-1}sec^{-1}$ respectively, in the same solvent at 25°C.

The theoretical expression of R. A. Marcus for the rate constants of electron-transfer reactions contains the following parameters, adjustable experimentally: the standard free energy of reaction, the dielectric constant of the solvent, the temperature, and the molecular radii of the reactants.[1] In the preceding paper,[2] we have discussed the applicability of this theory to the electron transfer from polycyclic aromatic hydrocarbon anion radicals to their respective parent molecules by examining the dependence of the rate constants on the following three parameters: the standard free energy of reaction, the dielectric constant of the solvent, and the temperature. It has been revealed that the contribution to the activation free energy from the nuclear reorganization energy, especially from the reorganization energy of the solvent, is smaller than that predicted theoretically.

This paper will deal with the dependence of the rate constants of the last parameter mentioned above, *i.e.*, the molecular radii of the reactants, in the homogeneous electron-transfer reactions; the rate constants of elec-

tron-transfer reactions from the pyrene, perylene, and tetracene anion radicals to their respective parent molecules are measured in 1,2-dimethoxyethane (DME) under experimental conditions in which the anion radicals are in a free ion or loose ion-pair state. A theoretical estimate of the rate constants is made on the assumption of spherical and non-spherical molecular shapes.

Experimental

The pyrene was purified in a way similar to that described previously.[2] G.R.-grade perylene and tetracene were obtained from the Tokyo Kasei Kogyo Co. and were used without further purification. The hydrocarbons were reduced with sodium metals in DME. The purification of the solvent and the preparation of radical solutions as well as the determination of their concentrations were performed in the same way as in the preceding paper.[2]

The rates of the electron-exchange reactions were determined ESR-spectroscopically by the conventional line-broadening method. Since the hyperfine lines in the ESR spectra of the anion radicals of perylene and tetracene were not perfectly resolved, their linewidth was determined by a computer-simulation method described elsewhere.[3] The linewidth parameter, l_2/l_1, was taken in this case in the way shown in Fig. 1. Figure 1(a) typically illustrates the central portion of the ESR spectra of the perylene anion radical, while (b) illustrates that with added perylene. In Fig. 2 the calculated l_2/l_1 values of the simulated spectra are plotted by triangles *versus* ΔH^t_{pp}, the given width of the hypothetical, unoverlapped hyperfine lines. The apparent linewidths of

the overlapped hyperfine lines obtained from the simulated spectra are designated as ΔH^a_{pp} and are shown by circles in the same figure. The latter plot shows that the direct measurement of the linewidth is not practicable when the observed or apparent linewidth is larger than 0.15 Gauss in the case of perylene. Simulation was performed on a JEOL JRA-5 spectrum computer. As for the pyrene anion, on the other hand, its linewidth was determined according to a procedure described previously.[2]

All the measurements were carried out at 25°C.

Results

Figures 3, 4, and 5 illustrate the increase in linewidth due to electron exchange plotted against the concentrations of perylene, pyrene, and tetracene respec-

tively. The rate constants with and without correction for diffusion were determined from these figures according to the procedure described previously. They are presented in Table 1, designated as k_a and k_{obs} respectively. The values for the linewidth determined from the l_2/l_1 values of the observed spectra are typically plotted by circles *versus* the concentration of the perylene anion radicals in Fig. 6. The linearity of the plot was satisfactory; it supports this procedure in linewidth determination. The plot shown by triangles in the same figure is the linewidth from which the contribution due to electron exchange is eliminated; it corresponds to pure electron exchange. The second-order rate constant of a spin-exchange process between anion radicals can be determined from the slope of the latter plot.[4,5] The rate constants of the spin-exchange process thus determined are listed in Table 2. The diffusion-con-

trolled rate constant calculated theoretically is $7.2\times 10^9 M^{-1}sec^{-1}$.[4,5] The agreement between the experimental and theoretical values was satisfactory. This may be another support of the present procedure of linewidth determination.

Discussion

According to the theory of Marcus,[1,6] the rate constant of an electron-exchange reaction, whose standard free energy is zero, is dependent on the molecular radii of the reactants. When the contribution to the activation free energy from the reorganization free energy of the inner-coordination shell can be neglected, the rate constant is expressed by the following equation:

$$k = Z\exp(-\Delta G^*/RT) \quad (1)$$

with:

$$\Delta G^* = (e^2/4)(1/2a_1+1/2a_2-1/r)(1/D_{op}-1/D_s) \quad (2)$$

where Z is the bimolecular collision number of the hypothetical uncharged reactants in solution at a unit concentration (it is assumed to be $10^{11}M^{-1}sec^{-1}$ in this paper); ΔG^* is the activation free energy; a_1 and a_2 are the molecular radii of the reactants; r is the distance between the centers of the reactants within the activated complex, and D_{op} and D_s are the static and the optical dielectric constants of the solvent respectively.

In deriving the equations above, Marcus assumed the reactants to be spherical. However, in the electron-transfre reactions discussed here the reactants, *i.e.*, the aromatic hydrocarbons and their anion radicals, are not spherical but planar. Hence, we shall examine the dependence of the electron-transfer rates on the molecular radii of reactants using two models, the spherical and the non-spherical models. In each case, a knowledge of the geometry and dimensions of the reactant molecules is required. Table 1 shows the molecular dimensions of several polycyclic aromatic hydrocarbons. The d_1, d_2, and d_3 dimensions have been defined previously.[2]

Spherical Model. In this model, the reactants are assumed to be spherical. If $a_1=a_2=r/2=a$ is assumed as usual, the activation free energy is given by the following equation:

$$\Delta G^* = (1/8)(1/D_{op}-1/D_s)(e^2/a) \quad (3)$$

Consequently, the activation free energy can be expected to be inversely proportional to a, the molecular radius of the reactants.

The values for the rate constant, k_{calc}, calculated from Eqs. (3) and (1) with $a=\sqrt{d_1d_2/2}$ and $Z=10^{11}$ $M^{-1}sec^{-1}$ assumed, are shown in Table 3. They are considerably smaller than the corresponding values for the corrected observed rate constants. Furthermore, the variation in the calculated rate constants with the molecular radii of the reactants is larger than that in the observed values.

The behavior of the observed rate constants might agree with that of the calculated ones, when it is assumed that the solvent around the reactants is dielectrically saturated to have a dielectric constant of about 3. Such a strong saturation, however, probably cannot be realized in the present reactions, in which the reactants have a π-electron distribution spread extensively. The idea of a spherical model for a planar molecule must be discarded.

Non-spherical Model. In this model each reactant is assumed to be an oblate spheroid. In the theoretical estimate of ΔG^* according to Marcus, the free energy of the non-equilibrium polarization of a solvent must be calculated.[1] Such a calculation is quite difficult when the shape of reactants is not spherical. Hush[7] has derived an expression for ΔG^* almost identical with that of Marcus. His theory, however, is based on an assumption of an equilibrium polarization of the solvent. His reasoning is: the electron-transfer occurs through the activated complex, in which the probability of the electron being on one of the reactants is intermediate between the probabilities it has in the initial and final states; the solvent around the reactants stays in thermal equilibrium with the ionic charge. Consequently, if the non-spherical ions are in thermal equilibrium with the solvent and if their free energy of solvation can be calculated, the ΔG^* value for non-spherical reactants can be obtained.

According to Soma and Yamagishi,[8] the solvation free energy of an oblate spheroid, with a major axis of length of $2a$ and a minor axis of length of $2c$, is given by;

$$\Delta G_{solv} = -(q^2/2\sqrt{a^2-c^2})(1-1/D_s)\tan^{-1}\sqrt{(a^2-c^2)/c^2} \quad (4)$$

where q is the charge of the spheroid. If an aromatic hydrocarbon is considered as an oblate spheroid with

Table 3. Comparison of corrected observed rate constants with calculated rate constants based on two models

Hydrocarbon	$\sqrt{d_1d_2/2}$ (Å)	a^* (Å)	k_{calc} (M^{-1} sec^{-1}) Spherical model $a=\sqrt{d_1d_2/2}$	Non-spherical model $r=d_3$	Non-spherical model $r=2d_3$	k_a (M^{-1} sec^{-1})
Naphthalene	3.35	2.70	2.55×10^7	1.45×10^9	5.37×10^5	2.1×10^9
Anthracene	3.88	3.05	6.90×10^7	1.34×10^9	6.50×10^6	2.4×10^9

6) R. A. Marcus, *J. Chem. Phys.*, **43**, 679 (1965).
7) N. S. Hush, *Trans. Faraday Soc.*, **57**, 557 (1967).
8) M. Soma and H. Yamagishi, presented at the 23rd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1970.

$a=\sqrt{d_1 d_2/2}$ and $c=d_3/2$, ΔG^* can be calculated from the following equation:

$$\Delta G^* = (e^2/4)(1/2a_1^* + 1/2a_2^* - 1/r)(1/D_{op} - 1/D_s) \quad (5)$$

with:

$$1/a^* = (1/\sqrt{a^2-c^2}) \tan^{-1} \sqrt{(a^2-c^2)/c^2} \quad (6)$$

The a^* values of each reactant have been calculated from the values of d_1, d_2, and d_3 in Table 1 and are listed in Table 3. Considering that r is fixed rather indefinetely in this case, this quatity is just an adjustable parameter even in the non-empirical calculations. The values for k_{calc} calculated from Eqs. (5), (6), and (1) with $r=d_3$ or $r=2d_3$ are tabulated in Table 3. When r is assumed to be d_3, on the other hand, the values for k_{calc} are much smaller than those for k_a. In either case, the variation in the calculated values with the molecular radii of the reactants is larger than that in the observed values. Consequently, even if r takes an appropriate value between d_3 and $2d_3$, k_{calc} does not agree with k_a.

Thus, the theory of Marcus, in both its original form (spherical model treatment) and its modified form (non-spherical model treatment), has failed to predict the experimental behavior of the rate constant as a function of the molecular radius. This suggests that the contribution to the activation free energy from the reorganization free energy of the solvent is again smaller than that predicted theoretically, as was seen in the previous paper concerning other parameters.

Isothermal Decay of Trapped Electron in Irradiated 2-Methyltetrahydrofuran Glass

Tsuneki ICHIKAWA, HIROSHI YOSHIDA, and Koichiro HAYASHI
Faculty of Engineering, Hokkaido Universtiy, Kita-ku, Sapporo

(Received October 3, 1972)

The isothermal decay of the electron trapped in gamma-irradiated 2-methyltetrahydrofuran glass was studied by electron spin resonance measurements at 92—95 K. Shape of the decay curves was found to be independent not only of radiation dose but also of temperature if they were plotted on the time scale in unit of half-life at each temperature studied. Although the decay follows neither a first order nor a second order reaction, the activation energy is able to be determined uniquely to be 0.8 eV. These results indicate that the mobilization of trapped electron is caused by repeated sequences of detrap-retrap due to thermal distortion or destruction of traps and that the evolution of decay is determined by the initial distribution of the electron-cation separation. On the basis of Nernst-Einstein assumption, the normalized distribution of the separation distance is numerically obtained and found to be close to a Gaussian function, though the absolute value of distance is unable to be determined because of the lack of knowledge of diffusion coefficient for the migration of electron in the glass. The effect of partial photobleaching of the trapped electron on the isothermal decay for the rest of electron was also studied and found to be the same as that of partial thermal bleaching.

2-Methyltetrahydrofuran (MTHF) glass is one of the glassy matrices where the nature of radiation-formed trapped electron has been most extensively studied by a number of techniques such as electron spin resonance (ESR) and optical absorption measurements.[1-4] The radiation-formed intermediates observed in this glass are mostly trapped electron and free radical. The former is characterized by an ESR sharp single line spectrum and a broad optical absorption spectrum with the maximum at about 1200 nm. The latter shows a seven line ESR spectrum, which is interpretable as due to the free radical formed by the cleavage of a hydrogen atom attached to tertiary carbon atom of MTHF molecule[5] or alternatively due to radical cation formed by the intramolecular hydrogen transfer reaction in the primary cation.[6] Although further studies seem needed to distinguish between these two possible interpretations, the present authors suggested that the decay of the trapped electron (at least, a considerable part of it) is caused by the charge neutralization process between the electron and the radical

cation, by measuring the recombination luminescence.[7]

The isothermal decay of the trapped electron in this glass was studied by optical absorption[5] and ESR measurements.[6] The decay is now known to be independent of radiation dose and to be a composite first order reaction, which suggests that electron is trapped in close proximity of its partner positive charge to recombine with. However, the decay at about 77K was too slow to determine the exact shape of the decay curve.[6] Recently, Ogasawara *et al.* studied the decay at temperatures higher than 95.6K.[8] They found also, that the decay was independent of the radiation dose. In this study it was difficult to observe the whole shape of decay curves because the decay was very rapid.

Photobleaching of the trapped electron and photo-induced conductivity were also studied by Baverstock and Dyne,[3a] and Huang *et al.*[2d] These investigations gave an insight into the nature of electron traps in the glass. The electron is released from its trap to the conduction level by the absorption of light and then migrate to cationic entities to recombine with. The low quantum efficiency for the photobleaching suggested that electron undergoes detrap-retrap sequences repeatedly until it disappears. However, the migration of electron has not been studied well when it is thermally mobilized.

Smith and Pieroni studied the paramagnetic relaxation of the trapped electron in this glass, and estimated the separation distance between paramagnetic species at 77K.[6a] This result gave an evidence of the non-uniform spatial distribution of the radiation-formed intermediates, though it was not known which is important between the distance between trapped electrons or the distance between trapped electron and other paramagnetic intermediates in determining the relaxation process studied. Kevan *et al.* presumed the relaxation depending upon the interdistance between the trapped electrons and estimated the radius of spur (probably assumed that a spur contains more than one electron) to be 63 Å.[2a] Recent study of electron-electron double resonance of the irradiated MTHF glass showed that the cross relaxation between the trapped electron and the entity giving the seven line ESR spectrum played an important role in the paramagnetic relaxation process in the glass.[9] This suggests that the trapped electron is closely correlated with the free radical (or the radical cation).

If one assumes that the composite first order decay of the trapped electron is dependent upon the time required for it to migrate to its partner cation, precise determination of the decay curve may give another approach to study the distribution of electron-cation separation. On the basis of differential equation of diffusion under the influence of Coulombic attraction between oppositely charged ions, Ludwig showed a mathematical way to correlate the evolution of decay with the distribution of separation distance of isolated ion pairs in liquids.[10] Hamill and his co-workers studied the recombination luminescence in viscous liquids after pulse irradiation and examined it in terms of the initial distribution of ion pair separations.[11] Such an approach seems essentially applicable to the thermal decay of the trapped electron in the glassy matrices.

With this respect, it will be worth determining the shape of the isothermal decay of trapped electron at the temperature where the decay is appropriately fast to be studied precisely and conveniently. In the present investigation, the MTHF glass was chosen, because the nature of trapped electron has been well elucidated and the trapped electron decays at temperatures controlled rather easily.

Experimental

MTHF was purified as described elsewhere.[7] It was dried with sodium-potassium alloy under vacuum and sealed in ESR sample tubes of pure quartz (inner diameter: 0.3 cm) also under vacuum. Irradiation was carried out with ^{60}Co gamma-rays at the dose rate of 7×10^{17} eV/g min at 77K in dark.

The irradiated sample was quickly transferred into a variable temperature Dewar insert attached to the ESR resonant cavity, of which temperature was adjusted beforehand by flowing cold nitrogen gas from liquid. The intensity of the trapped electron ESR spectra were repeatedly recorded at constant temperature with a conventional X-band ESR spectrometer (JEOL JES-ME-2X) using a modulation width of 0.8 G and a microwave power level of 0.1 mW. The temperature was monitorred with a thermocouple positioned at the bottom of the sample tube with the accuracy of ±0.1 K. The temperature monitor was calibrated by comparing with the temperature measured by another thermocouple burried in the sample.

Photobleaching of the trapped electron was carried out with light of an incandescent lamp through a cut-off filter ($\lambda>660$ nm). During the photobleaching, the sample was rotated to avoid a spatially inhomogeneous bleaching.

The absorption spectrum of the trapped electron was recorded with a conventional recording spectrophotometer (Hitachi, EPS-3) for the sample in a rectangular quartz cell of 1.0×1.0 cm^2 immersed in liquid nitrogen.

Results

ESR spectral shape observed from irradiated MTHF glass is composed of a sharp single line spectrum due to trapped electron and a seven line spectrum due to free radical superposing each other. Although both spectra are stable at 77K, the former spectrum decays rapidly at temperatures higher than 90K accompanying a partial decay of the latter.[3b,4c,6a,8] Isothermal decays of the trapped electron were obtained at several temperatures between 92.2 and 95.0K by observing the change in intensity of the single line spectrum (correction was made for the free radical spectrum superposing on the trapped electron spectrum.)

Dependence of the decay upon radiation dose was studied in the range of $0.7—2.0\times10^{19}$ eV/g, as shown in Fig. 1. Immediately after warming the samples from 77K to a proper temperature, the intensity of the

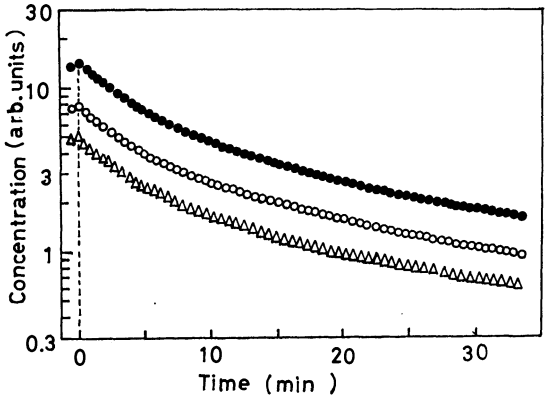

Fig. 1. Isothermal decay of trapped electron in MTHF glass irradiated to (●) 2×10^{19}, (○) 1×10^{19} and (△) 0.7×10^{19} eV/g at 77K and measured at 93.4K.

spectrum shows a slight increase. It may be caused by shorter paramagnetic relaxation times (especially spin-lattice relaxation time) at higher temperature. Under the present condition of ESR measurements, the microwave power level is a little too high to avoid a partial saturation of the trapped electron spectrum. Therefore, the intensity increases more or less when the relaxation times becomes shorter. It was assumed that the temperatures where the isothermal decay should be studied were reached when the observed decay curves reached the maximum. So the zero time for the isothermal bleaching was arbitrarily selected as shown in Fig. 1.

Depending on the radiation dose, the initial concentration of the trapped electron changes. However, the semilogarithmic plots of the decays can be completely superimposed if normalized at the initial concentration, which indicates that the rate of decay is independent of the radiation dose or the concentration of trapped electron. The decay does not follow an exponential curve nor is resolved into a few exponential curves.

Figure 2 shows the dependence of the isothermal decay upon temperature. The zero time was chosen as was done in Fig. 1. The scale of abscissas was chosen, so that the half-life ($t_{1/2}$, the time for the decay to 50% of the initial concentration), of the trapped electron has a fixed length for all temperatures examined.

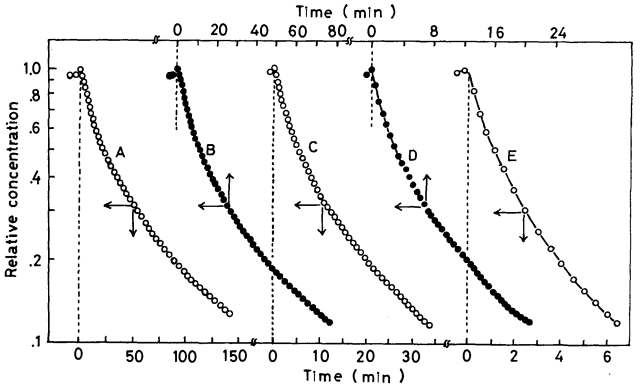

Fig. 2. Isothermal decay of trapped electron in MTHF glass irradiated to 1×10^{19} eV/g at 77K and measured at (A) 92.2, (B) 92.8, (C) 93.4, (D) 94.0, and (E) 95.0K.

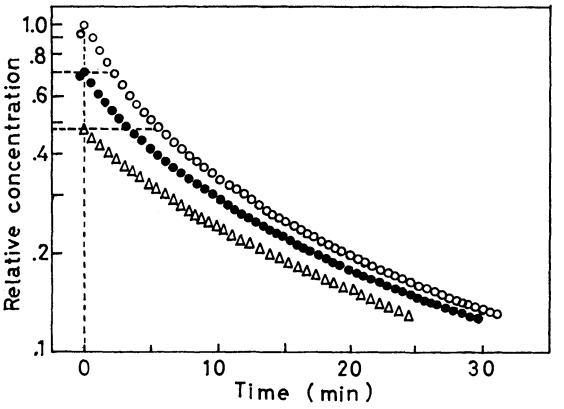

Fig. 3. Isothermal decay of trapped electron in MTFH glass irradiated to 1×10^{19} eV/g and measured at 93.4K after a partial photobleaching of trapped electron with light of $\lambda>660$ nm to (●) 70% and (△) 47% of its initial concentration. The decay without the photobleaching (○) is shown for comparison.

The concentration of trapped electron was also normalized to be unity at $t=0$. The decay becomes much faster with increasing temperature. However, the observed decay curves are again superimposed on each other, except a slight deviation observed for the curve at 95.0K, the highest temperature examined.

The decay curves were examined also after a partial photobleaching of the trapped electron with light of wavelength longer than 660 nm. They are shown in Fig. 3 as well as the decay curve obtained without the photobleaching. Evidently, the decay behavior after the partial photobleaching is the same as that after partial thermal bleaching. The curves A and B, obtained after the partial photobleaching, can be superposed on the curve C without photobleaching when they are horizontally shifted. Partial bleaching either thermally or by light affects equally on the decay behavior of the rest of trapped electron.

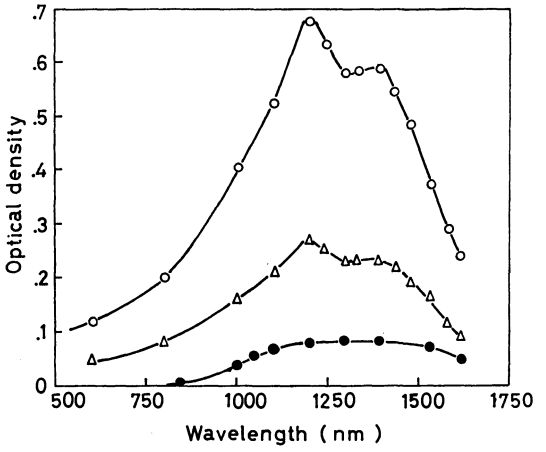

Fig. 4. Optical absorption spectra of trapped electron in MTHF glass irradiated to 7×10^{17} eV/g and measured at 77K (○) before and (△) after a partial photobleaching to 40% of its initial concentration. The spectra shown were obtained by subtracting the spectrum of the glass completely photobleached from those of the glasses containing the trapped electron. The residual spectrum (●) was determined as the difference in absorption between the glass irradiated and completely photobleached and the unirradiated glass.

Optical absorption spectrum of the trapped electron was studied immediately after the irradiation and after subsequent partial photobleaching of the trapped electron to 40% of its initial concentration both at 77 K. The results shown in Fig. 4 was obtained by subtracting the absorption of the sample irradiated and completely photobleached from that of the sample with trapped electron. It should be noted that a broad absorption was found at the wavelength region of 800—1600 nm, even after the complete photobleaching of trapped electron. This unidentified absorption disappeared when the irradiated glass was melted. The results clearly indicate that the absorption spectrum of trapped electron does not change in its shape during its decay.

Discussion

Activation Energy for the Decay of Trapped Electron. Since the decay curves show the same shape independent of the radiation dose and temperature, they can be characterized by a single parameter, for example, half-life. This implies that the apparent activation energy can be defined uniquely for the whole decay cruves. In other words, the activation energy remains unchanged during the decay.

The Arrhenius plot of the half-life is shown in Fig. 5, where the half-life appeared in the previous literatures are included for comparison. A good linear relationship is found in the temperature range studied in the present investigation. The present results seem consistent with the previous ones cited, though the activation energy tends to decrease with decreasing temperature.

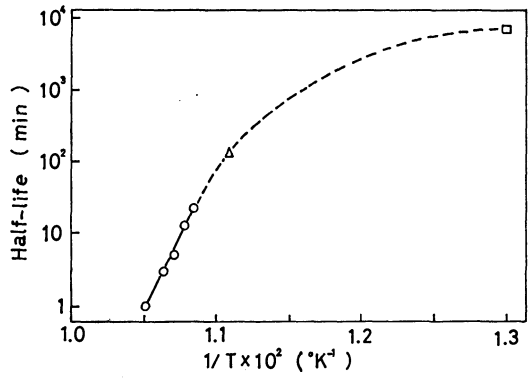

Fig. 5. Arrhenius plot of the half-life of trapped electron in irradiated MTHF glass when isothermally bleached. Half-lives estimated from the previous literatures (△) by Dainton and Salmon and (□) by Smith and Pieroni are also shown for comparison.

The activation energy is determined to be 0.8 eV (19 kcal/mol) from Fig. 5 in the temperature range of 92—95 K. The value is compared with the activation energy 14 kcal/mol determined in the same temperature range by Dainton *et al.* from the optical absorption measurements. They used the sample in a optical absorption cell of the cross section of 0.5×1.5 cm^2 and they mentioned that it took about 2.5 min to attain thermal equilibrium.[5a] In addition, the sample temperature is thought to have been inhomogeneous during rapid warming of a big sample. These factors may fortuitously cause a smaller activation energy. It should be noted also that the time 0.5 min of the transient rise of the sample temperature in the present investigation may have been a little too long to study the fast isothermal decay at 95 K and caused the slight distortion of the decay curve.

Ogasawara *et al.* studied previously the isothermal decay of the trapped electron in irradiated MTHF glass at temperatures higher than 95.6 K and obtained the activation energy of 6.1 kcal/mol.[8] The reason why the activation energy suddenly changes at around 95 K is not known well, though it may be attributed to the glass transition point of the MTHF glass.[12]

Decay Process of Trapped Electron. A unique value of activation energy for the whole decay process indicates that a single kind of migration process as well as a single kind of trap is responsible for the decay of trapped electron. In the MTHF glass, the primary cationic entity is believed to be stabilized by the intermolecular protonation or the intramolecular hydrogen transfer reaction.[5,6] The free radicals in this glass disappear in recombining with each other at about 100K somewhat higher than the temperature where the trapped electron decays very rapidly.[6a,8] This indicates that the stabilized cationic entity with the same size as MTHF molecule cannot migrate in the temperature range studied in the present investigation. Accordingly, the moving entity during the isothermal decay of trapped electron is the electron itself released from its trap.

The activation energy of 0.8 eV is considerably higher than that for the decay of trapped electron in irradiated 3-methylhexane glass caused by the migration of electron, 0.13 eV.[13] However, it is apparently less than the energies corresponding the absorption maximum of trapped electron and the threshold wavelength for its photobleaching.[2d,3a] Release of electron from its trap is very probably caused by the thermal distortion or destruction of the trap but not by the vertical transition up through the conduction level. Among the three possbile models for the mechanism of thermal mobilization of the trapped electron proposed by Kevan,[1] (1) diffusion of the matrix solvated electron as an entity, (2) tunneling between matrix traps due to matrix diploe reorientation, or (3) diffusion of a quasi-free electron, the present results support the second possibility. The strong temperature dependence does not indicate quantum tunneling of electron[3d,14] from electron trap to cation. With this respect, it may be interesting to compare the activation energy for the electron decay with that obtained from the temperature dependence of the viscosity of MTHF glass, 0.88 eV, in the temperature range of 92.0—101.5 K.[15]

Irrespective of the radiation dose and the temperature, all observed isothermal decay curves are superimposed on each other. A non-exponential decay indicates that the decay is not determined by a single thermally activated process of releasing electron from its original trap but by a sequence of detrap-retrap processes which the electron undergoes until it reaches at the predestined cation to recombine with. Therefore, the distribution of the life time of trapped electron is determined by the distribution of the number of detrap-retrap processes required for the electron to encounter the cation. An alternative interpretation may be that the decay was determined by the distribution of trap depth and the charge neutralization process involved a single thermally activated process of detrapping from the original trap. However, this is excluded by the observed constancy of the activation energy throughout the whole evolution of decay.

It was well established by the study of low temperature pulse radiolysis measurements[16] and by the study of irradiation at 4 K[4a,17] that the electorn formed in the MTHF glass is trapped primarily in a shallow trap and then the trap depth is deepened by the orientation of the matrix molecules at 77 K. However, the absorption spectrum of trapped electron stable at 77 K exhibits a structure attributable to two different depth of trap, and the shallow trap transforms to the deep one by warming the glass up to 85 K.[18] In the present measurements at higher temperature, the decay of deeply trapped electron may have been observed after the complete transformation of the shallow trap to the deep one, so that only one value of the activation energy may have been determined. After the partial photobleaching at 77 K, no change was found in the shape of the absorption spectrum. Therefore, the trapped electrons both in the shallow and deep traps are equally bleached by light of continuous spectrum ($\lambda>660$ nm). After that, the shallow trap may have been deepened by warming to the temperature of subsequent isothermal decay.

Electron-Cation Separation. On the basis of the assumption of isolated electron-cation pair and the neutralization time proportional to migration path length of electron or the number of detrap-retrap cycles before encountering with its partner cation, the evolution of electron decay can be correlated with the separation distance between the electron and the cation by the well known Smoluchowski equation.[10,19] However, if we assume that the migration of electron is to a large extent determined by the Coulombic interaction only, it is described simply by the Nernst-Einstein relationship,[20]

$$-\frac{dr}{dt} = \frac{Dr_c}{r^2} \tag{1}$$

where r is the distance between electron and cation, D is the diffusion coefficient of electron, and r_c is Onsager length defined as

$$r_c = \frac{e^2}{\varepsilon kT} \tag{2}$$

By integrating Eq. (1) under the initial condition $r=r_i$ at $t=0$, the following relationship is obtained between r and t:

$$r_i^3 - r^3 = 3Dr_c t \tag{3}$$

This gives the recombination time t_r for the electorn initially at r_i as

$$t_r = \frac{r_i^3}{3Dr_c} \tag{4}$$

which turns out to be $dr_i/dt_r = Dr_c/r_i^2$. Consequently, the survival probability of electron, P, is defined by the probability density of finding electron at r_i at $t=0$, $W(r_i)$, which is the initial distribution of separation distance between trapped electron and cation:

$$-\frac{dP}{dt_r} = W(r_i)\cdot\frac{dr_i}{dt_r} = \frac{Dr_c}{r_i^2}\cdot W(r_i) \tag{5}$$

The left-hand side of the above equation is the decay rate obtained from the normalized decay curve of the trapped electron. If one transforms t_r and r_i to dimensionless parameters $\tau=t_r/t_{1/2}$ and $x_i=(Dt_{1/2}r_i)^{-1/3}$. r_i, the following relation is obtained:

$$-x_i^2\cdot\frac{dP(\tau)}{d\tau} = W(x_i) \tag{6}$$

Equation (6) gives straightforwards the initial distribution of separation $W(x_i)$ from the observed decay curve by using the relationship $3\tau=x_i^3$. The distribution is temperature independent because not only the product $Dt_{1/2}$ but also r_c remains unchanged in a small range of temperature studied.

The initial distribution is numerically obtained from the whole evolution of the electron decay. In the same way, the probability of finding electron at reduced distance x at reduced time $\tau=\tau_1$ during the isothermal decay can be obtained from the evolution of decay in the region of τ larger than τ_1, using the relationship

$$-x^2\cdot\frac{dP(\tau+\tau_1)}{d\tau} = W(x,\tau_1) \tag{7}$$

Thus obtained distribution of the initial separation distance as well as those during the isothermal decay[21] is shown in Fig. 6.

The initial distribution qualitatively agrees with the Gaussian distribution, $W(x_i)=x_i^2\exp(-\alpha x_i^2)$, which was used to estimate the average separation between ion pair in irradiated liquid hydrocarbon.[22] The disagreement at large x_i values is much improved if the Smoluchowski equation is rigorously applied in the present analysis.[23] It should be noted that the maximum of distribution function and the average separation increase during the isothermal decay. This is

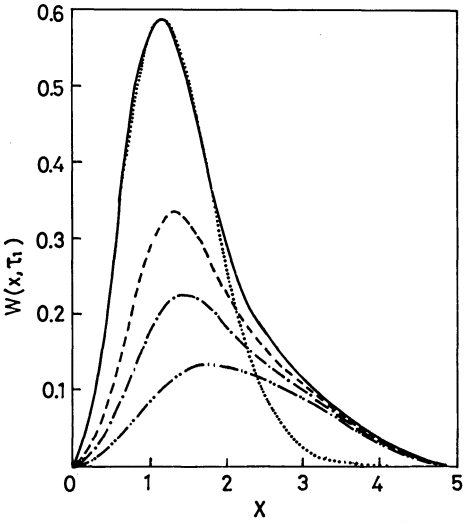

Fig. 6. Distribution of electron-cation separation distance in irradiated MTHF glass before and during the thermal decay of trapped electron determined from its isothermal decay curves. $W(x,\tau_1)$ is the probability density of finding electron at the reduced distance x at the reduced time τ_1. The distribution is shown for $\tau_1=0$ (——), 1/2 (– – –), 1 (–·–), and 2 (–··–). The definition of x and τ is given in the text. Gaussian distribution (·····) is also shown for comparison.

due to relatively short life time of electron at short distance from cation (see equation 3). This trend is more pronounced when the diffusion term in the Smoluchowski equation is taken into account in deriving the distribution.[23]

The quantum efficiency for the photobleaching of trapped electron in the MTHF glass was found to be much smaller than unity.[2d,3a,24] This implies that the electron undergoes several detrap-retrap cycles until it recombines with cation when photobleached. The present results of the effect of partial photobleaching on the subsequent isothermal decay (see Fig. 3) gives another evidence of the detrap-retrap cycles under the bleaching light. It indicates that the change in $W(x, \tau_1)$ during the photobleaching is the same as that during the isothermal decay of electron which is characterized by the migration of electron described by equation (1) but not by the single thermal activation process of detrapping from the original trap.

The decrease in the quantum efficiency of photobleaching with bleaching time was attributed to two class of trapped electron: one is electron trapped in proximity with cation and another is that trapped homogeneously in the glass.[24] However, such a classification of trapped electron seems unnecessary. The average distance between unbleached electron and cation increases longer and longer during the photobleaching, so that the number of detrap-retrap cycles required for the electron to recombine with the cation increases with photobleaching time, which results in a smaller quantum efficiency.

Lin and Kevan observed the increase in the paramagnetic relaxation times of trapped electron in the MTHF glass by a partial photobleaching, if the glass was irradiated to the dose at which the spurs did not overlap with each other.[2c] They thought that this result gave an evidence that a spur contains more than one trapped electron. However, if one presumes that the stabilized cationic entity is still paramagnetic (radical cation),[6,7] the observed change in the paramagnetic relaxation times during the photobleaching is interpreted by the increase in average distance between electron and the cation as shown in Fig. 6. Although the change in the separation distance seems to be slight, the spin-spin dipolar interaction depends on the inverse cube of the distance and very sensitive to the change in the distance.

Kinetics and Mechanism of the Reaction of Iodine Mono Chloride with Some Alcohols

C. R. Das and A. N. Bose*

Department of Chemistry, Ravenshaw College, Cuttack-3, India
**Department of Chemistry, R.C.E, Ajmer, Rajsthan, India*

(Received December 14, 1971)

Kinetics of the reaction of ICl with some aliphatic alcohols, methanol to *n*-butanol and isobutyl alcohol and isopropyl alcohol, have been studied by the conductance method at five different temperatures. Arrhenius parameters have been determined. Plot of log *k* against the reciprocal of dielectric constant has been drawn to test the applicability of the Amis and Jaffé equation. Energy of activation has been correlated with polarity of alcohols. The IR analysis of the product shows a sharp peak at 1620 cm^{-1}, which confirms a (O–I) bond stretching in the product. From these results a reasonable mechanism has been suggested as follows:

$$ICl \xrightarrow{\text{fast}} I^+ + Cl^- \quad (1)$$

$$R\text{–}O\text{–}H + I^+ \xrightarrow{\text{slow}} R\text{–}O\text{–}I + H^+ \quad (2)$$

Iodination reactions by ICl have been studied by various workers.[1–6] Lambourne and Robertson[7] studied the kinetics of iodination of various aromatic compounds using glacial acetic acid or chloro benzene as solvents. Kinetics of iodination of *p*-Cl $C_6H_4NH_2$ with ICl in water containing excess of chloride and H^+ ions has been studied by Berliner.[8] He suggested that the reaction involves free amine and hypo-iodous acidium ion (H_2OI^+). Irent'ev and Yanovskaya[9] have found that iodo derivatives are formed in the case of reactions of acids and resorcinol with ICl.

In the present investigation kinetics of the reaction of ICl with aliphatic alcohols, methanol to *n*-butyl alcohol, isobutyl alcohol, and 2-propanol has been studied systematically. It has been found that the reaction takes place according to the equation, provided

$$R\text{–}O\text{–}H + ICl = R\text{–}O\text{–}I + H^+ + Cl^-$$

no other complexities arise due to the impurities present either in alcohols or ICl. This has been confirmed in several ways. Infrared analysis confirms the presence of a (O–I) bond in the product. Gravimetric estimation of Cl^- ions confirms that Cl^- ions are not consumed during the course of the reaction. The aim of the present work is (a) to find out Arrhenius parameters, (b) to correlate rate constants with dielectric constant of the medium, (c) to find out the relationship between energy of activation (E) and polarity (μ) of the substance and (d) to suggest a reasonable mechanism for such reactions.

Experimental

(a) Materials. Iodine monochloride, E. Merck, E. P., was used for the experiment. It was kept in a vacuum desiccator to avoid moisture contamination.

The alcohols were of B. D. H. Analar quality. All the substances were dried with anhydrous calcium chloride and then distilled several times. Adequate precautions were taken to keep the sample dry.

Since ions were formed during the course of the reaction, kinetics was studied by conductance measurements most accurately with the help of a Beckman model RC 16 B 1 conductivity bridge and a cathod ray oscilloscope as a null point detector. This method was used in preference to the usual titriometric methods since it involves minimum number of operations and can be conveniently followed with the help of a small amount samples.

Fresh solutions were prepared every time before the experiment. First anhydrous alcohols were kept in glass stoppered tubes in a thermostat for one hour to attain the temperature of the bath. Calculated quantity of ICl was then taken by means of a perfectly dry syringe and accurately weighed inside the coloured glass conductivity cell as quickly as possible. 10 m*l* of the alcohol that had previously been kept in the thermostat was added to the cell. Thus a solution of ICl in alcohol of exactly 0.099M was immediately obtained in the cell. Rate of the reaction was then followed by measuring the resistance at different time intervals. Pseudo unimolecular rate constants were determined[10] at five different temperatures ranging from 15 to 35°C by applying the least square method from which Arrhenius parameters were determined.

Test for I^+ Ion. The presence of I^+ in the reaction mixture after completion of the reaction was tested by the method adopted by Arotsu *et al.*[11] When a drop of the reaction mixture was added to oleum, no blue colouration was observed, which proved the absence of I^+.

Effect of HCl. In order to find out if HCl has any catalytic effect, 0.05 ml of M/10 HCl was added to the reaction mixture of ICl and methanol, and then the rate of the reaction was followed by the conductance method. The rate constant was calculated. It was found that at 25°C

$k=35.97\times10^{-4}$ min^{-1} with HCl and $k=36.02\times10^{-4}$ min^{-1} at 25°C without HCl. The little difference was within experimental error.

Effect of Water. To find out whether water has any effect on the rate of the reaction, 0.05 ml of water was added to the reaction mixture at the beginning and then the rate was followed. It was found that a small amount of water had no effect.

Estimation of Cl$^-$ Ion. The amount of Cl$^-$ was estimated gravimetrically[12] as AgCl before and after the reaction. It was found that the amount of Cl$^-$ after the reaction was the same as at the beginning. This proved that Cl$^-$ was not consumed during the course of the reaction.

Results and Discussion

It is of interest that in all cases the reaction was completed when a reactant (*i.e.* -alcohol) was present in a large excess.

This was further verified by the method given by Arotsu *et al.* (loc. cit.), from the fact that no free I$^+$ (iodonium ion) remained after the reaction was over.

Table 1. Values of μ, E, and log PZ

Alcohol	μ	E (kcal/g mol)	log PZ (min)
Methanol	1.70	11060	5.61
n-Butanol	1.69	13200	7.65
Ethanol	1.68	14700	8.45
Propanol	1.67	16400	9.82
2-Propanol	1.60	26700	16.98
Isobutyl alcohol	—	20300	12.92

From the results given in Table 1, it is observed that the frequency factor (log PZ) and energy of activation (E) both vary in the case of reactions of methanol to *n*-butyl alcohol, 2-propanol, and isobutyl alcohol. The variation of frequency factor A can be explained in terms of collision theory. A is made up of two factors probability factor P and collision number Z. They may be identified in the following form as has been described by Stern and Eyring.[13]

$$P \approx (f_v/f_r)^5$$

$$\text{and } Z \approx kT/h(f_r^2/f_t^3)$$

where f_v, f_r, and f_t are the partition functions for vibrational, rotational, and translational degrees of freedom, respectively. At ordinary temperature f_v is of the order of unity while f_r may vary from 10 to 100 in case of complex molecules. If the molecules are less complex, the smaller will be the value of f_r and so the factor P will be high, which will help raise the values of 'PZ'. In the present case it can be seen from Table 1 that the higher values of PZ may be due to the increase in the probability factor P. But if the complexity of the molecules increases with solvation, P will have lower values and consequently factor A will be low. According to collision theory we have

$$Z = N^2\sigma_{AB}^2[8\pi RT(1/M_A+1/M_B)]^{1/2}C_AC_B \quad (1)$$

In the present case, M_B the molecular weight of ICl is constant and M_A, the molecular weight of alcohols, does not vary much from methanol to *n*-butanol; so the factor 'Z' is constant.

Effect of Dielectric Constant on Reaction Velocity. Many equations[14] have been derived to correlate the dielectric constant of the medium with reaction velocity. Amis and Jaffé[15] gave the following equation for the ion-dipole interaction:

$$\ln k' = \ln k'_{r=0} + \frac{\xi Z_B \cos\theta_0}{DkTr_0^2}\left(\mu_0+\frac{\mu^*(1+Xr_0)}{e^{Xr_0}}\right) \quad (2)$$

In the limiting case of the direct approach of an ion to a dipolar molecule, Eq. (2) was modified by Amis[16] as follows:

$$\ln k'_{D=D} = \ln k'_{D=\infty} + \frac{Zc\mu}{DkTr^2} \quad (3)$$

According to this equation, the rate decreases with the increase of dielectric constant for a positive ionic reaction. Recently Laidler and Landskroener[17] developed the following general equation incorporating the corrections due to non-electrostatic forces.

$$\ln k = \ln k_0 + \frac{\xi^2}{2kT}\left(\frac{1}{D}-1\right)\left[\frac{Z_A^2}{b_A}+\frac{Z_B^2}{b_B}-\frac{(Z_A+Z_B)^2}{b_*}\right] + \frac{3\xi^2}{8kT}\left(\frac{2}{D}-1\right)\left[\frac{G_A}{b_A^3}+\frac{G_B}{b_B^3}-\frac{G_*}{b_*^3}\right] \quad (4)$$

This also, predicts a linearity between log k and the reciprocal of the dielectric constant.

Table 2. Values of $k_{25°C}$ and $100/D$ for the reaction of ICl with alcohols

Alcohol	$k_{25°C}\times10^4$ (min^{-1})	$100/D$
Methanol	36.02	3.062
Ethanol	54.81	4.110
Propanol	76.11	4.975
2-Propanol	92.12	5.464
n-Butanol	109.85	5.848
Isobutyl alcohol	132.10	6.330

In the present case of the reaction between ICl and alcohols, it has been found that log k increases with the decrease of the dielectric constant (Table 2) and the plot of log k against $100/D$ is a straight line (Fig. 1). This is in agreement with the Amis equation (2).

It can therefore be concluded that it is an ion-dipolar reaction.

Correlation of Polarity and Energy of Activation. Many equations have been derived by Amis,[16] Ingold and Nathan[18] and Evans, Gordon and Watson[19] connecting energy of activation and polarity of the solvents. Moelwyn-Hughes[20] has explained similar rela-
